A straight incision is made on the midline until the sternum is encountered. The hyaline cartilage is split longitudinally with the scalpel, and with the help of a periosteal elevator, the sternebrae are identified. The cancellous bone graft is harvested from each sternebra that is isolated. Care is taken not to incorporate hyaline cartilage within the bone chips. If more cancellous bone is needed than is contained within one of the sternebrae, the next nucleus may also be excavated and used as a graft. There are six or seven usable nuclei within the sternum, allowing an adequate amount of high-quality cancellous bone graft to be harvested for any type of fracture.

Closure consists of an initial simple-continuous layer along the border of the cartilage, through which the two cartilage flaps are united, followed by routine closure of the subcutaneous tissues and skin. It may be advisable to install a suction or Penrose drain for 24 hours. Additionally, the skin incision should be protected with a stent bandage, because otherwise this region is very difficult to protect.

PROXIMAL TIBIA

A straight incision is made over the medial aspect of the proximal tibia through skin, subcutaneous tissues, and periosteum (see Figure 77-2, *C*).[24] Using a 5.5-mm drill bit, the cortex is penetrated in one or two places, depending on the amount of cancellous bone graft needed. In one reported technique, two holes were drilled next to each other so that they became one hole 8 to 9 mm (¼ to ⅓ inch) long.[25] This allowed access of a rather large curet, and a large amount of high quality cancellous bone graft could be harvested. Closure of the incision is routine. Again, a stent bandage is applied over the incision to stabilize the skin edges.

PROXIMAL HUMERUS

The quantity of cancellous bone collected from the proximal humerus with traditional harvesting instruments is comparable to that collected from other sites in horses. The procedure is associated with minimal postoperative incisional complications or lameness. However, because one horse suffered a catastrophic humerus fracture following graft harvesting from this site, further research is required to assess the effects of this procedure on humeral breaking strength. On the basis of the risk of catastrophic fracture, this technique cannot be recommended for use in clinical cases, especially if an unassisted recovery from general anesthesia is planned.[26]

BONE REPLACEMENTS

Healing of fractures with concomitant bone loss is still one of the most challenging features in trauma surgery in all species, but especially in horses. Because of their slow bone metabolism, and therefore slow callus formation and fragment bridging, the mechanical load is resting mainly on the metallic implants for the first 2 months. Hence, promotion of fracture healing using synthetic bone replacements alone or in combination with active bone-forming agents *(biomimetics)* is an attractive alternative to the gold standard of autologous cancellous or cortical bone grafts (see earlier). The main reasons to use bone replacements instead of autografts are to reduce donor bed morbidity, including pain, and to decrease surgery and anesthesia time for the patient. With the increasing role of nanotechnology, polymers, and molecular biology in modern medicine, bone replacements using a combination of three-dimensional (3-D) scaffolds or matrices in combination with biomimetics may in the future well exceed the results expected with traditional bone-grafting procedures.

Bone replacements based on natural materials (allografts or demineralized bone matrices [DBMs]) have been applied in human and animal surgery with good success. DBMs, previously produced as a human product, are now available commercially in the equine form (COLLOS E).[29] Earlier products (e.g., Bio-Oss) consisted of bovine (demineralized) bone sources with the potential for causing weak allergenic effects, although pretreatment with hydrochloric acid was supposed to destroy antigenic matrix properties.[30]

Bone banks are common in human medicine for use of allografts, especially to replace joint structures,[31] but never became routine in equine surgery because of the risk of infections, slow incorporation of full (cortical) grafts, and the overall low turnover for such a product in clinical practice.

Many new synthetic bone replacements are on the market that either replace autologous bone grafts alone (ceramics, bone cements) or that are used in combination with other biomaterials (e.g., hydrogels, polymers), biomimetics (e.g., growth factors), and/or primary mesenchymal stem cells. Although these products are available, they are still rarely used in equine patients in a clinical setting and are more often applied in research, mostly as cartilage replacement in combination with microfracturing procedures[32] or osteochondral grafting.[30,33,34] Additionally, bone cements[35] and composites[36] have been successfully used to treat subchondral cystic lesions in young horses. However, none of these materials have been used to supplement fracture repair in the horse. On the other hand, this may change in the future, and therefore possible materials or composites to be used in horses are outlined in the following sections.

Ceramic Bone Substitutes

Marc Bohner

Chemistry

There are two main classes of ceramic bone substitutes (CBSs): *calcium sulfates (CaSs)* and *calcium phosphates (CaPs)*. Both families consist of several chemical compounds representing more than a dozen compositions (Table 77-1).

The first CBS that was used *in vivo* was α-CaS-hemihydrate (β-$CaSO_4 \bullet \frac{1}{2}H_2O$; also known as "plaster of Paris").[37] Addition of water to this material elicits an exothermic reaction, with the end products being a set form of gypsum ($CaSO_4 \bullet 2H_2O$) and heat.[38,39] Besides β-$CaSO_4 \bullet \frac{1}{2}H_2O$ and gypsum, there is another clinically relevant CaS, which is α-$CaSO_4 \bullet \frac{1}{2}H_2O$. α-$CaSO_4 \bullet \frac{1}{2}H_2O$ and β-$CaSO_4 \bullet \frac{1}{2}H_2O$ have the same crystallographic structure and composition, but the former compound is produced in an aqueous solution, whereas the latter

TABLE 77-1. Main Ceramic Bone Substitutes

Name	Formula	Ca/P	Mineral Name	Symbol
Monocalcium phosphate monohydrate	$Ca(H_2PO_4)_2•H_2O$	0.50	*	MCPM
Dicalcium phosphate	$CaHPO_4$	1.00	Monetite	DCP
Dicalcium phosphate dihydrate	$CaHPO_4•2H_2O$	1.00	Brushite	DCPD
Octocalcium phosphate	$Ca_8H_2(PO_4)_6•5H_2O$	1.33	*	OCP
Precipitated hydroxyapatite ("tricalcium phosphate")	$Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}$	1.50-1.67	*	PHA
Amorphous calcium phosphate	$Ca_3(PO_4)_2•nH_2O$ n = 3-4.5; 15%-20% H_2O	1.50	*	ACP
Monocalcium phosphate	$Ca(H_2PO_4)_2$	0.50	*	MCP
α-Tricalcium phosphate	$α\text{-}Ca_3(PO_4)_2$	1.50	*	α-TCP
β-Tricalcium phosphate	$β\text{-}Ca_3(PO_4)_2$	1.50	*	β-TCP
Sintered hydroxyapatite	$Ca_5(PO_4)_3OH$	1.67	Hydroxyapatite	HA
Oxyapatite	$Ca_{10}(PO_4)_6O$	1.67	*	OXA
Tetracalcium phosphate	$Ca_4(PO_4)_2O$	2.00	Hilgenstockite	TetCP
Calcium sulfate	$CaSO_4$	—	*	CS
Calcium sulfate hemihydrate a	$CaSO_4 • ½H_2O$	—	*	a-CSH
Calcium sulfate hemihydrate b	$CaSO_4 • ½H_2O$	—	Bassanite	b-CSH
Calcium sulfate dihydrate	$CaSO_4•2H_2O$	—	Gypsum	CSD

Note: The first six calcium phosphate compounds precipitate at room temperature in aqueous systems. The last six calcium phosphate compounds are obtained by thermal decomposition or thermal synthesis.
*Not known or not indicated.

compound is obtained in dry conditions.[39] This provides $α\text{-}CaSO_4 • ½H_2O$ crystals with a more compact shape, which is of relevance when trying to produce strong and dense gypsum cements or gypsum-based drug carriers with a slow release rate.

Hydroxyapatite ($Ca_5[PO_4]_3OH$), β-tricalcium phosphate ($β\text{-}Ca_3[PO_4]_2$), and their composites (commonly called biphasic calcium phosphate) are the most common CaP bone substitutes. However, apatites can be synthesized with various structures and compositions. Moreover, many other CaPs, such as dicalcium phosphate dihydrate and octocalcium phosphate, are available and have been used *in vivo*.

To simplify, there are presently two classes of CaP: low-temperature and high-temperature CaPs. Low-temperature CaPs are obtained at room temperature, either through a setting (i.e., hardening) or a conversion reaction. These CaPs can be found *in vivo* and typically have a small average crystal size and a large specific surface area (up to 200 m^2/g for apatites). High-temperature CaPs are generally obtained by sintering reactions, which are above 700° C to 800° C. Because high-temperature CaPs are easier to synthesize than low-temperature CaPs, most commercial products are obtained via sintering reactions, an example of which is chronOS, the AO standard. However, low-temperature CaPs, such as dicalcium phosphate dihydrate (= brushite)[40] or precipitated apatite,[41] are likely to become more important in the future, because these compounds are very similar in physical structure to the CaPs present in the body.

Hydraulic cements set or harden via dissolution-precipitation reactions in an aqueous solution. For example, $α\text{-}CaSO_4 • ½H_2O$ and $β\text{-}CaSO_4 • ½H_2O$ dissolve in water, then gypsum crystals nucleate and grow. If the powder-to-liquid ratio is large enough (typically more than 2 g/mL), gypsum crystals grow close enough to entangle and hence provide mechanical stability to the resulting hardened compound. The setting reaction is generally exothermic, but the rate of heat release is too low to cause biocompatibility problems. Hardened cement blocks are nanoporous or microporous, and their porosity is typically on the order of 40% to 50% of the volume.

Whereas plaster of Paris (also a CaP compound) has been used for over 100 years, the discovery of CaP cements is recent.[42] The first products were introduced in the mid 1990s. Interestingly, many compositions have been proposed, but the end product of the reaction consists generally of brushite (e.g., chronOS Inject) or an apatite (e.g., Norian SRS). As a result, one talks about brushite or apatite cements. Because of their higher solubility, brushite cements tend to biodegrade much faster than apatite cements (see later).

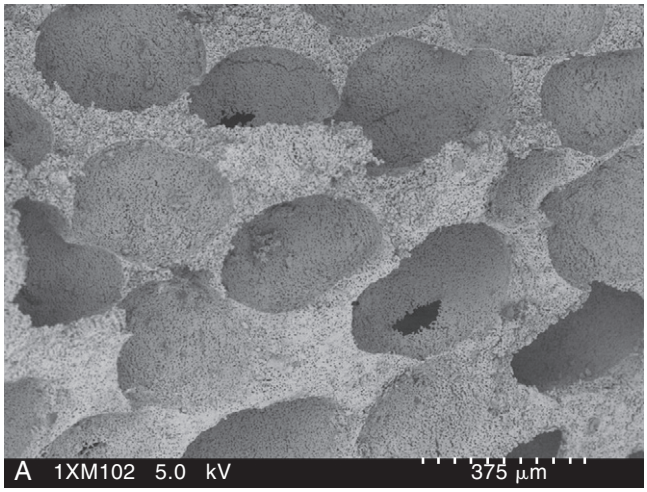
Porosity

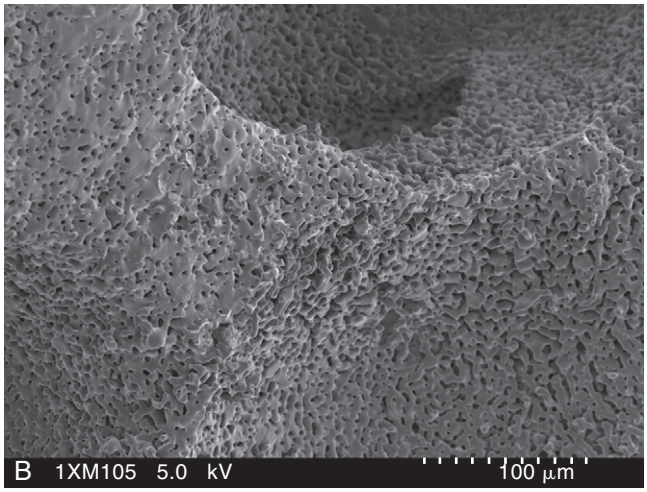
The porosity strongly influences the mechanical and biological properties of CBSs. Generally, two types of pores are discussed: micropores and macropores (Figure 77-5). Micropores typically have a diameter in the size range of 0.1 to 10 μm. Micropores have been considered to promote ceramic biodegradation,[43-46] but the scientific data are very scarce. It is, therefore, not possible to define an optimum micropore size or volume fraction. However, micropores are essential to prevent crack propagation[47] and hence should be a standard feature of CBSs. A practical advantage for the clinician is that a microporous CBS can be shaped with a blade. Presently, only a few products contain a significant fraction of micropores, one of them being chronOS.

Macropores typically have a diameter in the size range of 50 to 2000 μm. Macropores enable blood vessel and cell ingrowth; hence they promote bone ingrowth and have short biodegradation times.

Mechanical Properties

Compressive strengths as high as 150 megapascals (MPa) (i.e., almost as high as bone) have been reported for some CBSs. Unfortunately, CBSs are ceramics and therefore they are inherently brittle. As a result, tensile strengths are typically 5 to 20 times lower than compressive strengths, and shear properties are very poor. Therefore CBSs can break at very small loads (much





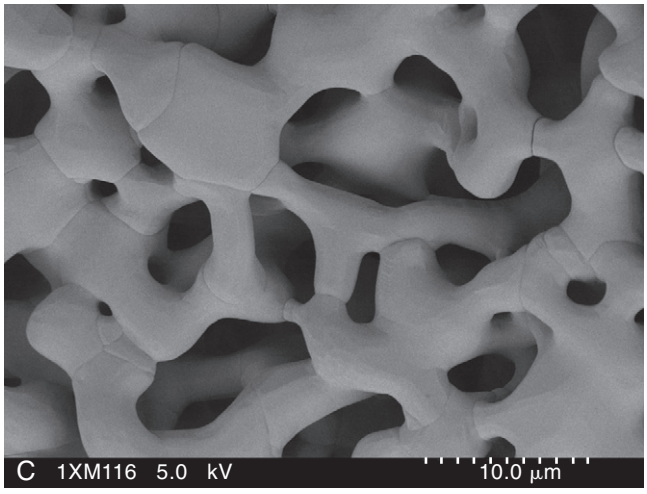


Figure 77-5. Microporosity and macroporosity in a β-TCP bone substitute as seen by scanning electron microscopy. **A,** Overall view of a macroporous bone substitute. **B,** Closer view of the macroporosity. The micropores are visible in the walls of the macropores. **C,** Microporosity. (Size of the bar: 500, 100, and 10 µm.)

lower than the listed average mechanical strength) and hence should be used in combination with internal or external fixation.

Many factors such as porosity, chemistry, and crystal and grain sizes influence the mechanical properties of CBS. Typically, an increase of porosity decreases the mechanical properties of a material exponentially. Moreover, and as previously mentioned, micropores decrease the brittleness of a CBS.[47] Furthermore, the least soluble CBSs, such as hydroxyapetite, tend to have the best mechanical properties. Finally, a small crystal or grain size favors better mechanical properties.

Forms

CBSs are available in various forms: granules, macroporous blocks, hydraulic cements, and putties (pastes). Each of these forms has specific advantages and disadvantages. *Granules* can be used to fill in any defect, but this procedure is often cumbersome and granules may migrate. Bone formation and ceramic biodegradation are both optimal because blood vessels and cells can invade the space between the granules. *Blocks*, such as cylinders, wedges, and prisms, are difficult to place in complicated defect geometries. However, blocks are mechanically stable and often have an optimal porous structure facilitating fast blood vessel and cell ingrowth. *Hydraulic cements* are generally injectable. As a result, cements are easy to apply into any defect and can be shaped. Moreover, cements harden with time, hence providing a stable (but not load-bearing) defect site. However, commercial cements are not (yet) macroporous. Therefore biodegradation occurs slowly, layer by layer.

The latest form of CBS is the putty, which is a thick paste.[48] The nature of putties varies from one producer to another. Some putties are simultaneously a hydraulic cement, and hence harden shortly after mixing. But traditionally, putties consist of a mixture of a gel and granules and do not harden. The advantage of puttiescompared to granules is that it is easier to apply a putty than granules. Moreover, the granules in the putty do not move out of the defect as easily as granules alone.

Biological Behavior

The mechanisms of biodegradation of CBSs vary widely depending on their solubility. CaS dissolves *in vivo* because body fluids are undersaturated in CaS. As a result, a change of blood supply or sample volume is expected to modify the dissolution time. A large gap occurs between implant and bone.[49] Typically, the amount and quality of the bone formed in the defect filled with CaS is poor: it consists of very narrow and small trabeculae, which tend to biodegrade with time. On the other hand, traditional CaPs such as β-tricalcium phosphate, hydroxyapatite, and their composites are insoluble in body fluid (e.g., serum).[50] This low solubility leads to an osteoclast-mediated biodegradation,[51] the rate of which depends on the composition. Whereas β-TCP is typically biodegraded within a year,[51] hydroxyapatite can be considered to be inert.[52] However, for all traditional CaPs, a direct apposition of bone on the ceramic surface is observed. Other CaPs, such as dicalcium phosphate dihydrate, have an intermediate solubility and hence an intermediate biodegradation rate (Figure 77-6). In that case, biodegradation mostly occurs via dissolution or the action of macrophages.[53] Moreover, often a small gap between bone and implant develops. This gap is typically filled with osteoid tissue.

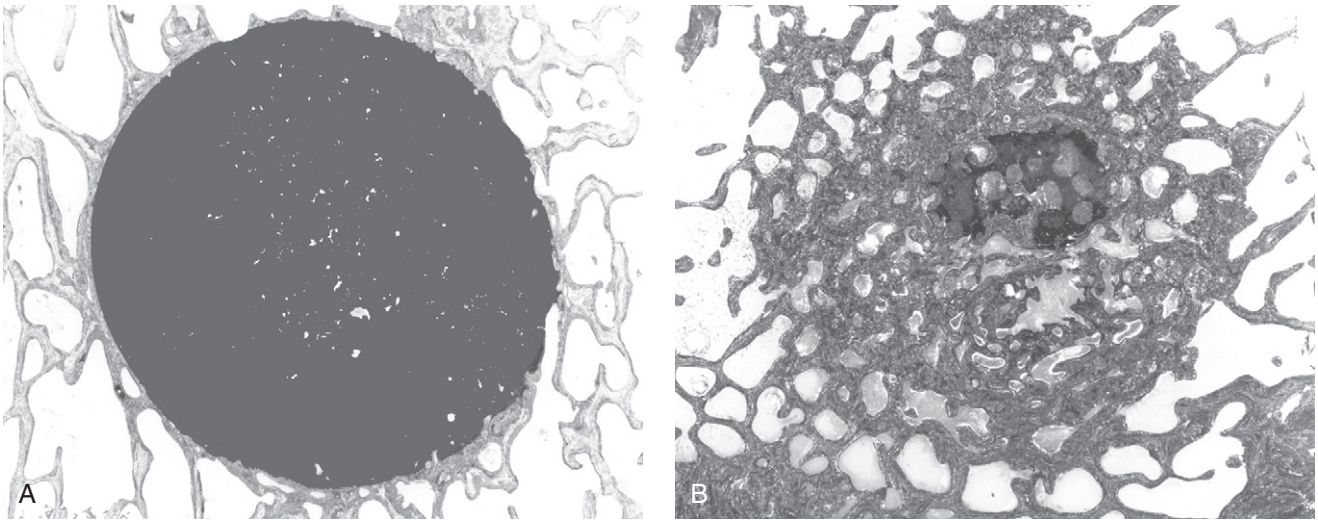

Figure 77-6. General appearance of an 8-mm cylindrical defect filled with **(A)** apatite and **(B)** brushite cement after 6 months of implantation in a sheep.[53] **A,** Only very small amounts of bone can be seen within the apatite cement (lighter areas within the cement). **B,** Brushite cement is almost completely biodegraded and replaced by new bone.

Apatite cements are slowly biodegraded (see Figure 77-6),[51,53,54] whereas hydroxyapetite is practically nonbiodegradable.[52] This apparently peculiar difference is caused by a variation of crystal size: apatites obtained from hydraulic cements are nanosized, whereas sintered hydroxyapetite is microsized. Actually, apatite cements have a biodegradation rate similar to that of β-TCP.

Many studies have been conducted to determine an optimal macropore size for bone ingrowth and biodegradation rate.[55-63] However, the results are not conclusive for two main reasons: it is difficult to synthesize ceramics with perfectly controlled geometries, and most *in vivo* studies have considered only a few geometries (e.g., one or two) at a few implantation times (e.g., one or two). Nevertheless, it was shown that a pore diameter in the range of 100 to 1000 μm is adequate,[55-63] macropores should be interconnected, and the size of the interconnections should be larger than about 50 μm.[62] A study applied a theoretical approach to determine an adequate pore structure to minimize the biodegradation time; it revealed that a pore diameter in the range of 200 to 800 μm is optimal but that this depends on the size of the bone substitute, with larger volumes requiring larger pores.[64]

Polymers

Margarethe Hofmann

Classes of Polymers

Polymer-based biomaterials were developed to replace metals or natural polymers because their properties could be tailored according to the requirements of the patient, for example, specific mechanical, chemical, or cell biology–related properties. These materials had to be adapted from the industrial application for which they were developed to fulfill the requirements in medicine. They have to be biocompatible, which means that they must be nontoxic, nonantigenic, and noncarcinogenic,[65] and they must have "the ability of a material to perform with an appropriate host response in a specific application."[66]

Polymers have a structure that in its simplest form is a linear chain. To these chains, branches can be added and combined into networks. Such polymers can be classified as:

- Natural or biopolymers, which are produced by living organisms. This group includes cellulose, starch, chitin, proteins, peptides, and DNA- and RNA-based materials. The monomeric units of the polymers are built of sugars, amino acids, and/or nucleotides. These natural polymers are all biodegradable.
- Synthetic polymers are produced by polymerization, a process by which small molecules called monomers are bonded together covalently. The synthetic polymers can be classified into three main categories: thermoplastics, thermosets, and elastomers. Synthetic polymers can be biodegradable, biodegradable-like, or nonbiodegradable.

When going back in the history of orthopedic implants, the polymeric biomaterials can be grouped into three generations.

FIRST-GENERATION

First-generation polymers include nonbiodegradable materials like silicone rubber, polyethylene (PE), acrylic resins, polyurethanes (PUs), polypropylene (PP), and polymethyl methacrylate (PMMA). One of the most prominent materials is bone cement based on PMMA and is intended for use in arthroplastic procedures of the hip, knee, and other joints when polymeric or metallic prosthetic implants are fixed to living bone. PMMA has excellent properties as a fixation medium for implants and is still in clinical use with a good rate of success. In equine clinics, it is used for plate luting and as antibiotic-impregnated beads that are prophylactically applied near the bone plates for local infection control. PMMA has significant drawbacks because of its toxic degradation products, which may provoke fat embolism. In addition, heat is produced during polymerization, which may cause necrosis in the tissues surrounding the implant. The continuous improvement in the synthesis of PMMA bone cements has altered their microstructure and mechanical properties. Nevertheless, the U.S. Food and Drug

Administration (FDA) reclassified the material in 2002 from a class III to a class II (special controls) device.[67] Today PMMA is also used in vertebroplasty and kyphoplasty where the vertebral body is augmented to increase stability.[68]

Other polymers of the first generation are of the family of PEs, to which belong ultrahigh-molecular-weight polyethylene (UHMWPE), a thermoplastic PE with extremely long chains and molecular weights of some million daltons. Such long chains are of interest in applications exposed to high load bearing, such as the liner of acetabular cups in total hip arthroplasties, in the tibial insert and patellar component in total knee arthroplasties, and as a spacer in intervertebral artificial disc replacement. This material exhibits special physical properties, such as high abrasion resistance and low friction coefficient. Despite these properties, wear is still a problem and needs to be improved. The high impact strength and the excellent toughness combined with a low density make this material a good candidate, relative to metals, for use in implants. Easy fabrication and desirable biological properties (good biocompatibility and biostability) make this material a good selection for surgeons.[68]

Another material that has been increasingly used in orthopedic, trauma, and spinal applications since its commercialization in the 1980s is the group of polyaryletherketones (PAEKs), which can be reinforced with fibers like carbon or glass to improve stiffness and long-term stability.[68] The group of PAEKs (including the most important representatives used in spine and orthopedic applications consisting of poly[aryl-ether-ether-ketone] [PEEK] and poly[aryl-ether-ketone-ether-ketone-ketone] [PEKEKK]) represents high-temperature thermoplastic polymers consisting of an aromatic backbone molecular chain interconnected by ketone and functional ether groups. PEEK-OPTIMA, carbon fiber reinforced PEEK-OPTIMA compounds, and composites produced by Victrex meet the criteria for FDA Master Files.[69]

SECOND AND THIRD GENERATION

The polymers in these two generations are variably biodegradable. Their interaction with the biological environment and their degradation properties define the crucial factors for their use, such as in tissue engineering. The important group of polymers called bioelastomers is part of this new generation of polymers having the following characteristics: good biocompatibility with surrounding tissues, glass transition temperatures* (Tg) lower than body temperature (35° C to 40° C), and good elastic properties (e.g., the ability to return to at least 1.25-fold the original length after 1 minute of release if stretched to 1.5-fold its original length for 1 minute maintaining the stretch stress in the range of 0.1 to 20 MPa). These bioelastomers can be classified into two categories: (1) elastomers suitable for long-term physiological contact or implantation and (2) biodegradable elastomers for a determined time of physiological contact or implantation.[70]

A perfect biodegradable implant can be described as follows: "Once implanted, it should maintain its mechanical properties until it is no longer needed and then be absorbed and excreted by the body, leaving no trace."[71] The ideal polymer for such an application needs to fulfill the following criteria[72]: (1) the polymer does not evoke an inflammatory or toxic response disproportionate to its beneficial effect; (2) it is metabolized in the body after fulfilling its purpose, leaving no trace; (3) it is easily processed into the final product form; (4) it has an acceptable shelf life; and (5) it is easily sterilized. Polymers fulfilling these demands can be used to manufacture scaffolds, which can be loaded with specific drugs or growth factors and implanted into the target tissue. The initial time, duration, and quantity of drug released from the scaffolds can be tailored, and once the drug is released, the scaffold disintegrates and does not have to be removed through a second surgical intervention. Examples of constructs that could be used in fracture repair are a scaffold impregnated with osteoblasts, chondrocytes, mesenchymal stem cells, various tissue and growth factors to improve bone defect healing, and/or antibiotics to control or prevent infection. Such constructs may help to reduce or even eliminate problems of donor site scarcity, immune rejection, and pathogen transfer.[73,74] The scaffold also could be applied in the clinical fields of tissue replacement and tissue function enhancement. In the latter, the form and structure of the polymeric scaffold would resemble the structure and form of the tissue or organ that it replaces. Examples include scaffolds used as artificial skin, artificial pericardium, or periosteum that would be manufactured as a flat microporous membrane. Tubular scaffolds could be used for blood vessels or nerve regeneration, and solid block scaffolds for bone substitutes and repair of articular cartilage would be contoured to the proper shape in surgery.[75]

Degradable polymers used in load-bearing orthopedic implants are of interest as skeletal fixation devices. Ideally they would only stay in the body to fulfill a temporary function and prevent the necessity of retrieval surgeries. The advantage compared to metallic devices is that these implants would lose their mechanical properties gradually during degradation, whereas in the best-case scenario, the healing tissue would gain strength, so that at the end of the healing process the implant would be fully degraded and the damaged tissue would be completely remodeled. To achieve this mechanical balance, the stiffness (E-modulus) of the implant would need to be comparable to that of the tissue it substitutes, such as bone. Another advantage of polymeric implants is their radiopacity, which would allow radiographic assessment of bone healing without implant superimposition.

Polylactides and their combinations have been chosen as scaffolds because of their excellent biocompatibility and their relatively high mechanical strength. However, they have a relatively poor long-term performance under prolonged mechanical loading because these implants, produced by poly(L/DL-lactides) (PLDLLAs), develop severe plastic deformation after about 6 months. This behavior may be related to the intrinsic properties of amorphous polylactides rather than degradation of the polymer.[76]

Polyurethane (PU) elastomers belong to another very important and popular group of polymers. They were developed more than 50 years ago as biostable implant materials. PUs show a greater versatility in physical and mechanical properties than other polymers. They can be tailored, which also influences their biological properties, like biodegradation and biocompatibility. The incorporation of soft components may enhance degradation, which depends on the crystallinity or amorphous behavior of the soft components. Hydrolysis is likely the main degradation pathway.

*"The liquid-glass transition (or glass transition for short) is the reversible transition in amorphous materials (or in amorphous regions within semicrystalline materials) from a hard and relatively brittle state into a molten or rubber-like state. An amorphous solid that exhibits a glass transition is called a glass."[71a]

TABLE 77-2. Important Biodegradable Polymers of Synthetic and Natural Origin

Abbreviation	Polymer	Properties
PGA	Poly(glycolide)	Biodegradable, thermoplastic polymer, and simplest linear aliphatic polyester
PLA	Poly(lactide) acid	Has softer amorphous regions and can exist in two different isomeric configurations: poly-L-lactic acid (PLLA) or poly-DL-lactic acid (PDLLA)
LPLA; also called PLLA	Poly(L-lactide)	Biodegradable, thermoplastic aliphatic polyester derived from renewable resources such as corn, starch, or sugarcane
DLPLA; also called PDLLA	Poly(DL-lactide)	Amorphous poly-DL-lactide (PDLLA) by polymerization of a racemic mixture of L- and D-lactides Used for sutures, stents, dialysis media, drug delivery devices, and tissue engineering
LDLPLA	Poly(DL-lactide-*co*-L-lactide)	Poly(D,L-lactide) homopolymers polymerized either from meso-lactide or from equimolar (racemic) combinations of D-lactide and L-lactide They are considered to be amorphous and typically possess nominal mole fractions that equal or exceed 50% lactide.[134]
DLPLG	Poly(DL-lactide-*co*-glycolide)	Poly(D,L-lactide-coglycolide) copolymers are copolymerized from a combination of glycolide and either meso-lactide or racemic quantities of D-lactide and L-lactide (amorphous and mole fractions similar to LDLPLA).
LPLG	Poly(L-lactide-*co*-glycolide)	See DLPLG.
PGA-TMC	Poly(glycolide-*co*-trimethylene carbonate)	Biodegradable, thermoplastic polymer and simplest linear aliphatic polyester; it can be prepared starting from glycolic acid by means of polycondensation or ring-opening polymerization
PDO or PDS	Poly(dioxanone)	Colorless, crystalline, biodegradable synthetic polymer
PCL	Poly(e-caprolactone)	Biodegradable polyester with low melting point; degrades by hydrolysis of its ester linkages in physiological conditions
PHB	Polyhydroxybutyrate	Polyhydroxyalkanoate (PHA) produced by microorganisms; water insoluble and relatively resistant to hydrolytic degradation
POE	Polyorthoester	Bone filler material
PHEMA	Poly(2-hydroxyethyl-methacrylate)	Shows physical properties similar to natural gel-like extracellular matrices; used with hyaluronic acid (HA) for orthopedic application
—	Chitosan	Prepared from chitin by partial deacetylation; is nontoxic, biocompatible, and biodegradable[135]

Because of their special mechanical properties, biodegradable elastomers can be used in the repair or replacement of tissues of a similar structure (tissue engineering). As mentioned earlier, this group of materials can sustain and recover from multiple deformations without irritating the surrounding tissue.[70]

Biodegradable polymers of both synthetic and natural origin, most of which appear in Table 77-2, are used for surgical sutures, orthopedic implants, plastic surgery, drug delivery, cardiovascular applications, and tissue engineering. In orthopedics, many different polymers and combination products with polymers using hydroxyapetite, fibers, or growth factors are used to fill osteochondral defects, to facilitate bone regeneration of mandibular defects, and to fill cartilage defects. Screws are manufactured from polylactides (PLAs) or by combining polyglycolic acid (PGA) and variations of PLAs. Meniscus staples are produced from polyglycolide or polyglycolic acid (PGLA), a copolymer of PLA and PGA, and pins and rods are made out of PGLA, a combination of poly-L-lactide (PLLA) with poly-DL-lactide (PDLLA) and PLA. Bone plates and meshes can be manufactured out of PLLA-PDLLA, PGA-PLLA, and PLLA-PDLLA; the combination is also used for spinal cages.[77]

Mechanism of Polymer Degradation

There are different names to describe the degradation of a polymer during its lifetime, including bioabsorbable, biodegradable, and bioresorbable, all of which mean that the material degrades over a certain time through hydrolysis into fragments and water. If this process does not provoke any harm or negative side effects (inflammation or toxic response) to the patient, the material is biocompatible. Hydrolysis can be influenced by several factors, including (1) the production process, which influences the microstructure, and (2) the sterilization techniques, which strongly influence the surface of the material or implant.

The initial aim of polymeric implant development was to replace metallic implants. Therefore materials were selected that resist degradation within the human body. However, the polymers did not always meet the requirement of clinicians; some materials failed because it was difficult to achieve sufficient inertness and because problems with cracks, oxidation, or degradation occurred.[78,79] This balance between degradation of synthetic or biopolymers and the regeneration of new animal or human tissue without any negative side effects is one of the big challenges in polymer development. Thus it is critical to understand the mechanisms of polymer biodegradation in relation to the surrounding tissue.

For biodegradable elastomers, the *rate of degradation* is one of the most important properties. All biodegradable polymers contain hydrolyzable bonds. For this reason, the most important mechanism of degradation for tissue engineered scaffolds is chemical degradation through hydrolysis or enzyme-catalyzed hydrolysis.

Passive hydrolysis is the determining mechanism of degradation for many bioelastomers. The chemical bonds determine the rate of hydrolysis, but other factors may influence the type, time, and intensity of degradation. These factors include the crystallinity and hydrophilicity of polymers, the polymers' composition, and the pH and temperature of the surrounding tissue. Anhydrides and orthoesters are the most hydrolyzable components, followed by esters and amides. The degradation rate is mostly determined by the time dependent molecular weight and is much higher for hydrophilic polymers than for hydrophobic ones.[70]

The molecular weight of the polymer begins to decrease immediately (PGA, PLA) or a few weeks (PLLA) after placement in an aqueous medium. PGA biodegrades rapidly and loses its strength within 1 month. In both the semicrystalline structured PLA and PGA, degradation occurs in two phases: (1) the *hydrolysis phase*, in which water molecules inserted into the long macromolecule cleave long chains into shorter ones, and (2) the *metabolic phase*, where macrophages phagocytize the small polymer fragments. The liver eventually metabolizes the breakdown products of glycolic and lactic acids.[80]

During the hydrolysis phase, acid degradation products may be liberated and released into the surrounding tissues, provoking inflammatory cellular reactions involving macrophages and giant cells. After the polymer has been depleted, these cell reactions decrease, and the space occupied by the former implant is filled with connective tissue or bone. Although the mechanism of degradation is often well known, it is difficult to predict the rate of degradation and the reaction with the surrounding tissue. Depending on the size, the material, and the target tissue, the time it takes to completely degrade can vary between days and years.[81]

Outlook

Vast improvements have been made in the materials recently developed, including improved biocompatibility, better adaptation of mechanical properties compared to the surrounding tissue, and new functions (smart or intelligent materials). Materials scientists and biologists have worked together to develop polymeric materials that respond better to cell–matrix interactions and improve repair, regeneration, and recovery of a tissue to its functional state. Designing new biomaterials is a combination of modeling, materials science, biotechnology, advanced cell biology, and eventually animal testing. It becomes increasingly important to expand our knowledge about cellular signaling processes and to learn more about how biomaterials affect bioadhesion. Soon, the surface and interfaces of biomaterials will have the potential to deliver complex molecules such as drugs, genes, or mesenchymal stem cells to stimulate the biological environment. Polymeric nanoparticles alone or applied to surfaces may serve as a source for such molecules, and smart gels will respond to temperature changes and pH, triggering the release of molecules. Therefore implants will not only serve as replacements of tissue but also may become valuable components in the treatment of diseases.[82]

Because implants do fail (implant loosening), modifying the implant design to mimic the surface of bone (cell–biomaterial interaction) may improve osseous integration and overcome such problems in orthopedic and dental applications. There is increasing interest in placing an osteoconductive protein in an osteoconductive carrier medium to facilitate timed-release delivery and/or to provide a material scaffold for bone formation.[83]

Gels

Brigitte von Rechenberg

Hydrogels consist of a network of polymer chains that have the capacity to hold water (up to 99% volume) with their hydrophilic groups and therefore remain flexible, similar to tissue.[84] Their 3-D structure mimics the *in vivo* tissue environment and enhances the interaction between cells and the customized macromolecules of the gels. Because chemical cross-linking of hydrogels disrupts the delicate structure of impregnated pharmaceuticals, growth factors, or cells, they have been replaced by gels that spontaneously assemble under physiologic conditions.[85] However, swelling of hydrogels after polymerization may be an advantage if a "press fit" of implants is attempted and micromotion must be prevented.[86] The porous structure of hydrogels may be changed by cross-linking density, which may influence cell behavior or survival[87] as well as degradation and overall biocompatibility, such as inflammatory reactions within the environment.[88]

Natural hydrogels are based on fibrin,[89] which allows the incorporation of bioactive substances via heparin-binding delivery systems in a 3-D matrix.[90] Synthetic hydrogels such as agarose or alginate are often used for *in vitro* systems to study cell interactions and proliferation, such as with chondrocytes,[91] but new technology has resulted in the synthesis of mechanically stronger materials based on polyethylene glycols. Therefore smart hydrogels, either protein or DNA based and hybrid hydrogels,[92] have a promising future for medical use in the surgical patient.[93,94] A combination of natural and synthetic hydrogels resulted in successful repair of tibial defects in rabbits,[95] and a synthetic polymer alone was successful to bridge a tibia defect in sheep.[96]

Hydrogels are normally degraded through hydrolysis, and depending on their composition, their degradation can be fast or slow. Modern chemistry facilitates controlled degradation as well as incorporation and release of biomimetic substances.[97] Histologically, hydrogel remnants commonly can be visualized in the cytoplasm of macrophages.

In the equine literature, the use of hydrogels is reported for research in cartilage cell cultures[98] and wound healing.[99] Reports of hydrogels used in fracture or bone defect healing as the sole substitute are absent.

Composite Materials

Composite materials, often abbreviated to "composites," are engineered or naturally occurring materials made from two or more constituent materials with significantly different physical or chemical properties (that remain separate and distinct at the macroscopic or microscopic scale within the finished structure). Modern polymer technology makes it possible to synthesize biocompatible, mostly porous structures that can be further enriched with appropriate coatings and gelling fluids to improve cell adhesion, proliferation, and differentiation. Often, advantage is taken of the different constituent mechanical properties, such that two-layer grafts are created, such as in osteochondral grafts.[100,101] As with all biomaterials, biocompatibility of composites depends not only on the finished product but also on the byproducts generated during degradation, and in the case of composites it depends on the interaction of the different constituents.

Biomimetics

Brigitte von Rechenberg

The term *biomimetics* originally referred to the "study of the structure and function of biological systems as models for the design and engineering of materials and machines," whereas the roots come from the Greek words *bios* (meaning "life") and *mimesis* (meaning "to imitate"). Although *bionics* and *biognosis* are often also used as synonyms, the term *biomimetics* is preferred when "chemical reactions, in nature, involve biological macromolecules (e.g., enzymes or nucleic acids) whose chemistry can be replicated using much smaller molecules *in vitro*." Today, the term is used broadly in biotechnology to designate molecules that are known to enhance new tissue formation.

Biomimetics are normally applied locally as proteins, peptides, or plasmids, although they are seldom used alone but rather in combination with scaffolds or other biomaterials as carriers. If these molecules are applied alone, elimination is normally so fast that their biomimetic effect is ablated. The combinations allow a constant and often protracted release of the molecules; therefore, effective concentrations are maintained over an ensured time period. Most of the biomimetics are dose and time dependent, and therefore their use has to be carefully orchestrated in the desired environment.

Growth factors were the first molecules detected to enhance tissue formation *in vitro* and *in vivo*. Among those, bone morphogenetic protein played a major role in the history of bone research leading to the so-called bone induction principle[102] and the discovery of its related molecule, bone morphogenetic protein, which is now commonly referred to as BMP.[103] Today up to 20 different BMP molecules are known, of which BMP-2 through BMP-7 were later found to be part of the transforming growth factor-β (TGF-β) superfamily. Though BMP-2 and BMP-4 were shown to be important molecules for bone induction, BMP-7 (or osteogenin [OP1]) seemed to enhance cartilage formation.[104] At the time of this writing, BMP-2 and BMP-7 are the only members of the family that are approved by the FDA for human application. For veterinary use, the commercially available products are cost-prohibitive, and therefore most of the BMPs applied in veterinary medicine were either in experimental animals[105] or a select few clinical patients.[106] Because the BMP patent will expire within the next few years, costs may come down considerably and products may be developed for veterinary use.

Apart from BMP, other growth factors, such as PDGF, FGF a and b, IGF-1, and TGF-β were demonstrated to play a role in fracture healing.[107] Whereas PDGF and FGF are released mainly soon after the fracture and are responsible for cell recruitment and proliferation, IGF and TGF are responsible for callus formation (TGF), angiogenesis (IGF), and finally, fracture healing. PDGF is mainly released by platelets in the initial fracture hematoma; FGF is synthesized by cells of the soft callus; and IGF-1, TGF-β, and BMP-2 are liberated from the bone matrix during initial bone biodegradation of the fracture ends and later are produced by osteoblasts building up the new bone matrix. Additionally, BMP plays a major role in pushing osteoprogenitor cells toward differentiation into osteoblasts.

Because of their prominent role in physiologic fracture healing, PDGF, FGF, IGF, and TGF were also tested in research situations to enhance bone healing in fractures or bone defects. PDGF has gained some attention in clinics by the introduction of platelet-rich concentrates applied in trauma cases in the operating room.[108] Because this concentrate can be easily prepared by medical personnel and its autologous source does not evoke immunologic responses, this has become an attractive form of therapy. The concentrate contains high levels of PDFG, VEGF (vascular endothelial growth factor), and TGF, which are released by the platelets and are thought to increase migration of cells into the fracture hematoma; their proliferation enhances callus formation and angiogenesis. Nevertheless, the efficacy of platelet-rich concentrates is still debated and awaits clinical proof. IGF encapsulated in microspheres showed significant dose-dependent enhancement of bone-forming properties in a tibial defect model in sheep,[109] whereas TGF that was exogenously applied in tibia osteotomies in rabbits increased callus size but not osseous bridging of the fracture line.[110] Nevertheless, the combination of IGF and TGF enhanced cervical spine fusion when titanium cages coated with a polymer layer (PDLLA) were enriched with both.[111]

The local use of biomimetics other than growth factors is still rare, but one of the more promising molecules is based on parathyroid hormone (PTH). Although PTH is known to cause bone biodegradation to maintain systemic calcium homeostasis, in low and intermittent dosages it increases bone formation and is now clinically used to treat osteoporosis in menopausal women.[112] $PTH_{1\text{-}34}$ also has been studied as a local biomimetic to enhance fracture and bone defect healing[113] in combination with carriers, such as fibrin-based hydrogels alone or mixed with calcium phosphate granules ($PTH_{1\text{-}34}$ + hydrogel) vs. ($PTH_{1\text{-}34}$ + hydrogel + CaP granules). $PTH_{1\text{-}34}$ has been used successfully to bridge 1- to 2-cm tibial defects in experimental sheep (Figure 77-7), and a first clinical trial in humans confirmed its safety as well as its beneficial effects in healing human distal radius fractures.[114] Systemic application of low intermittent dosages of PTH during fracture healing also increased bone formation in laboratory rodents.[115] However,

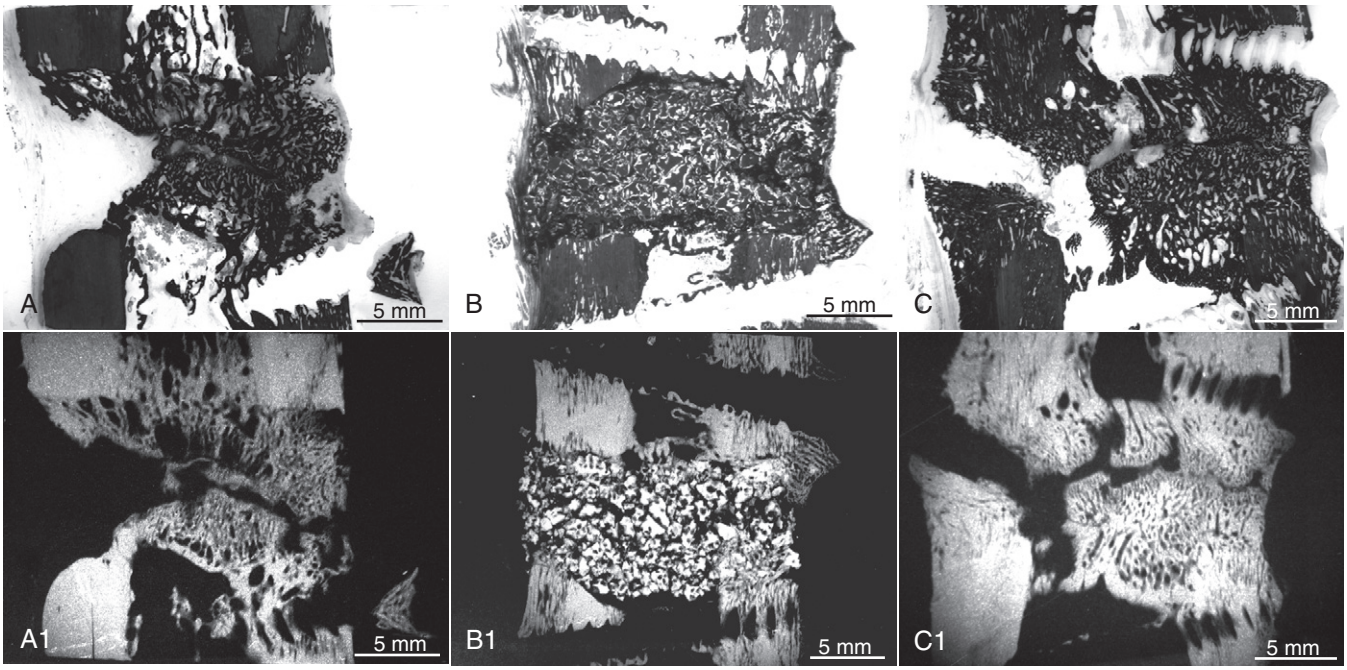

Figure 77-7. Hydrogel and composite bone replacements in a 1-cm tibia defect in sheep at 3 months after surgery. **A,** Fibrin hydrogel + biomimetic alone. **B,** Fibrin hydrogel + tricalcium phosphate and hydroxyapatite granules + biomimetic. **C,** Synthetic hydrogel based on polyethylene glycol (PEG) alone. *Top row:* Ground sections. *Bottom row:* microradiographs. **B** shows the best results for bone healing.

successful clinical use in horses is limited to a report of healing of a subchondral cystic lesion.[8]

Because the delivery of these growth factors as native proteins is costly and difficult (see earlier), alternative routes are to use gene delivery in the form of DNA plasmids in carrier systems[116,117] or to transfect cells *in vitro* and introduce the transfected cells into the desired area. Transfection of cells *in situ* can be achieved by either virus-mediated plasmid incorporation, often associated with adenoviruses,[118] or nonviral methods; the most promising of the latter include liposomes,[119] superparamagnetic iron oxide nanoparticles,[120] and CaP-based delivery systems.[121]

Tissue Engineering and Regenerative Medicine

Brigitte von Rechenberg

Tissue engineering emerged from materials science, and because of its increasing importance it has become a field of its own right. In a larger sense, the term *regenerative medicine* is used almost as a synonym. However, the difference is that tissue engineering is an effort to replace organ tissues with a combination of biomaterials, cells as well as biochemical and biomechanical factors; regenerative medicine concentrates more on methods using mesenchymal stem cells. Both involve classic interdisciplinary or translational approaches to improve functions of a diseased organ system in the body. In equine medicine and surgery, tissue engineering and regenerative medicine are still mostly exploratory[122] but are gradually finding their way into clinical applications involving, for example, tendons[123,124] and cartilage[125,126] and, less frequently, bone.[127]

Cells used for these applications are mostly either autologous primary cells, taken from the target organ itself (e.g., cartilage, bone), or stem cells. Although primary cells must be assessed for their ability to maintain phenotype and function through several passages during cell culture expansion, harvesting of stem cells from bone marrow or blood may prove difficult because of their limited availability in adults. Therefore, alternative sources, including adipose and umbilical tissues, are being characterized and may prove to be richer sources of stem cells. The use of embryonic or fetal tissue is an ethical issue in human medicine, but is less so in the veterinary field. The advantages of using fetal tissue are that they lack immunogenic properties[128] and it may be possible to establish cell banks for tissue engineering or regenerative medicine with veterinary applications. Because allographic tissues are used, this path is therefore highly attractive. Conversely, if autologous cells were the only source for cell expansion, the technical and financial difficulties encountered when trying to prepare tissue-engineered products or suitable cell constructs for clinical applications would severely limit their use in the veterinary field. Cell banks with fetal tissue could circumvent this problem to a large extent. Fetal cells were used successfully to engineer bone tissue constructs[129,130] *in vitro* and new bone formation *in vivo* using experimental sheep.[131]

Tissue engineering, especially in bone defect healing, normally involves 3-D scaffolds or matrices. Collagen, fibrin, and hyaluronic acid–based matrices (Hyaff), flexible polymer scaffolds enriched with CaP layers, and other composites were proved suitable for cell seeding. Modern technology (nanoconstructs) provides almost unlimited possibilities for creating porous structures as effective bone substitutes. However, independent of the scaffold type used, effective cell seeding is difficult to accomplish in the center of the grafts, where it is difficult to supply sufficient nutrients if only traditional cell culture conditions are used. Therefore bioreactors have been developed that maintain steady flow dynamics of the culture media and promote access of cell nutrients to the center of grafts.[132,133] Bioreactors also can be used to induce biomechanical loading of grafts, which stimulates cell differentiation. In combination with appropriate cell culture media, a permissive biochemical and physical environment is created for cells to

differentiate into bone or cartilage constructs that can be implanted in patients. Types of bioreactors may vary, such that compressive cylinders, spinner flasks, and rotating or stirring suspension bioreactors have been proposed to facilitate tissue engineering of bone substitutes.

With all of these exciting prospects for tissue engineering and regenerative medicine, it is important to realize that none of these technologies had yet to be routinely used in equine bone surgery at the time this chapter was written, but rather were still in their embryonic stages.

CHAPTER
78 Synovial Joint Biology and Pathobiology

David D. Frisbie

The function of synovial joints depends on the integrity of normal anatomy and proper cellular function of each of its components. Bone, articular cartilage, synovial fluid, synovial membrane, fibrous joint capsule, and ligamentous structures make up these components (Figure 78-1). On either side of a synovial joint, subchondral bone is covered by articular cartilage, providing the nearly frictionless contact surfaces of the joint. Synovial membrane and ligamentous joint capsule surround the cartilage and attach to bone on either side of the joint, providing stability and a reservoir for the synovial fluid. The synovial joint is further stabilized by ligamentous and muscular structures that surround the joint; these structures are extracapsular in most instances. Three different *classifications of joints* exist: synarthroses (immovable), amphiarthroses (slightly movable), and diarthroses (movable). Diarthrodial joints account for the greatest number in the body and are the focus of this chapter. The articulations of diarthrodial joints facilitate movement of the rigid skeleton. A healthy joint provides a frictionless system with efficiency that is an order of magnitude superior to the best bearing surfaces known to modern engineering.[1] When pathologic states arise, it is usually because of dysfunction of one or more components. Because the health of the synovial joint depends on the sum of its parts working in unison, it is often referred to as an organ system, as all components must be functional for the health of the "organ." This chapter explores each component of the synovial joint both in health and disease in more detail.

ANATOMY OF SYNOVIAL JOINTS

Synovial Membrane and Synovial Fluid

The synovial membrane, or synovium, lines the joint cavity and is made up of two layers: intimal and subintimal. The *intimal layer* is largely responsible for the content of the synovial fluid, is typically one to four cell layers thick and does not have a basement membrane. The lack of basement membrane is relevant with respect to the role the synovium plays in determining the content of the synovial fluid in the joint and is covered in more detail later. The *subintimal layer* is made up of fibrous, areolar, and fatty tissues. A very good blood supply is present in the subintimal tissue, as well as innervation originating from both peripheral and muscular nerve branches (Figure 78-2).[2,3] In fact, using an arthroscope close up and focused directly on normal synovial membrane, one can see individual red blood

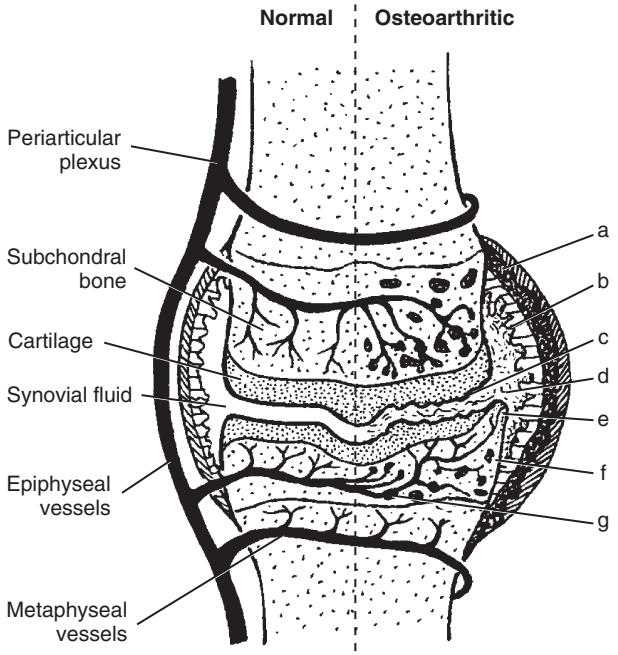

Figure 78-1. A normal synovial joint *(left),* including articular cartilage, synovial fluid, and synovial membranes, together with changes seen in a joint with osteoarthritis *(right).* In an osteoarthritic joint, the following abnormalities can be present: *a,* capsular fibrosis; *b,* synovitis; *c,* cartilage failure; *d,* depolymerized hyaluronic acid; *e,* osteophytes; *f,* subchondral cysts; *g,* vascular engorgement. (Modified from March L: Articular Cartilage in Health and Disease. p. 86. In Sambrook P [ed]: The Musculoskeletal System. Churchill Livingstone, New York, 2001.)

cells coursing through the capillary network of the villi. When viewed both grossly and arthroscopically, the synovium has areas that are flat intermixed with areas of loose collections of villi. These areas of villi are often described as "seaweed-like" when viewed arthroscopically in a fluid medium. The two appearances of the synovium are thought to be related to biomechanical characteristics of the joint area, since they remain relatively unchanged throughout the life of healthy joints.

The cellular population of the intimal layer is based on two basic functions: *phagocytosis* and *protein secretion*. The cell types have historically been classified as type A or B synoviocytes on the basis of ultrastructure and immunohistologic characteristics. Cells engaged in phagocytosis or pinocytosis are termed type A synoviocytes, whereas those responsible for protein secretion have been referred to as type B synoviocytes.[4] More recently, the description of type C cells has been reported, and these cells are thought to represent a cell type between type A and B. Because type A and B cells have demonstrated functions assigned to the other cell type, and because synoviocytes have been shown to be dynamic, it is likely that type C cells represent synoviocytes in a transition from type A to B, or vice versa.[5,6]

When the focus is on the function of the intimal layer of synoviocytes, the importance of its role in both health and disease of the joint becomes apparent. One function is phagocytosis—the mechanism whereby unwanted particles can be cleared from the joint. However, a central role of the synoviocytes is the secretion of proteins that contribute to both the anabolic and the catabolic metabolism of the joint as a whole. Like many other metabolic processes, when checks and balances are in place, these metabolic processes are part of normal turnover, but when unregulated or aberrant regulation occurs, these same processes can lead to the development of disease. The synoviocytes are responsible for the secretion of a diverse array of proteins that contribute to the synovial membrane proper, as well as to the composition of the synovial fluid, and they include hyaluronan, collagen, lubricin, pro-matrix metalloproteinases (pro-MMPs), interleukins, and eicosanoids (e.g., prostaglandin E_2).[7,8] The breadth of these proteins in the pathophysiology of the joint underscores the importance of this tissue.

Another important role of the synovial membrane is to *regulate the composition of synovial fluid.* Synovial fluid is often referred to as an ultrafiltrate of the plasma. This term implies a more passive process, but it is actually very dynamic and inter-related with many factors, including the molecules composing synovial fluid (e.g., hyaluronan size and concentration), degree of inflammation, and lymphatic drainage. Components of the plasma, such as glucose, oxygen, carbon dioxide, and proteins, typically less than 10 kDa in size, are allowed through the endothelium of the subintima and contribute to the composition of the synovial fluid, whereas large molecules are excluded. Routine cytologic examination techniques, as well as normal and disease-state levels of the constituents, are reported later. Most laboratories consider levels of less than 500 cells per deciliter of synovial fluid normal.

Molecules such as hyaluronan and lubricin are contributed to the synovial fluid directly by the synoviocytes. These molecules are thought to be important in the *steric exclusion* (i.e., steric hindrance: a process of separation of molecules by size) of larger molecules from the synovial cavity, thus regulating synovial fluid composition (Figure 78-3), and as *boundary lubricants* of the joint surfaces. The regulation of size and concentration of hyaluronan within the synovial fluid is unknown, but these two factors do affect the functional properties assigned to the molecule. A variety of methods have been used to determine both the concentration and the molecular weight (or size) of hyaluronan. The diversity of methods has provided a

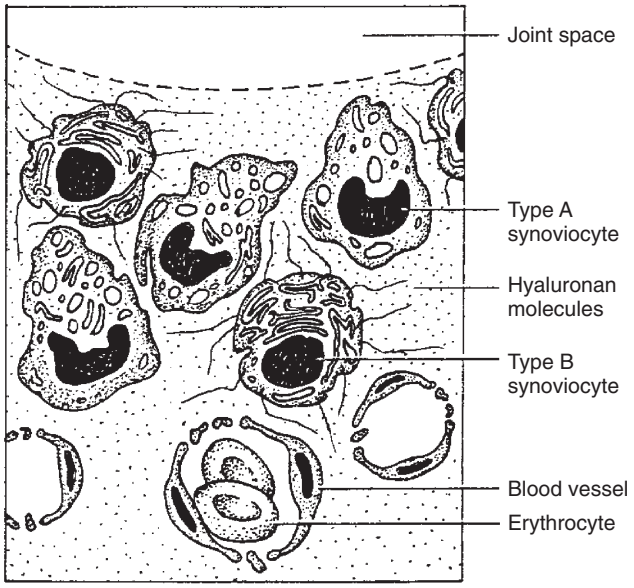

Figure 78-3. Hyaluronan secretion from type B synoviocytes, and its close association with the synovium, where it is thought to aid in excluding leukocytes and other solutes from the joint space through steric hindrance. (Adapted from Howard RD, McIlwraith CW: Hyaluronan and Its Use in the Treatment of Equine Joint Disease. p. 257. In McIlwraith CW, Trotter GW [eds]: Joint Disease in the Horse. Saunders, Philadelphia, 1996.)

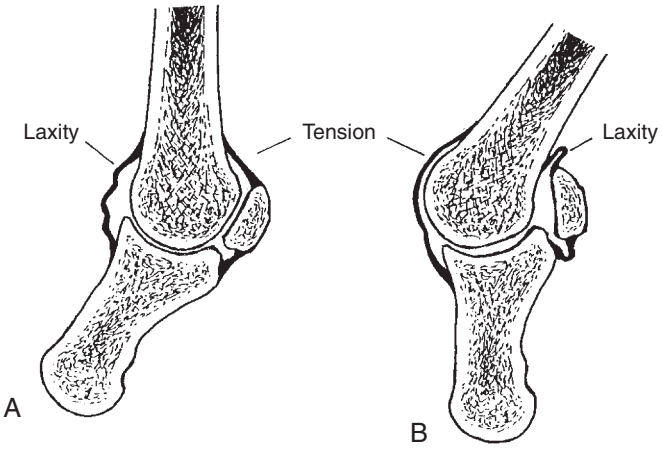

Figure 78-4. Synovial and joint capsule laxity or tension based on the anatomic position of the joint. The dorsal aspect of the joint capsule is lax in fetlock extension **(A)** and under tension in flexion **(B).** This figure also illustrates the change in joint congruity thought to occur during loading. In an unloaded position **(B),** it is thought that joints are not completely congruous, but as load is applied, a more congruous joint is formed. (Adapted from McIlwraith CW: Diseases of Joints, Tendons, Ligaments, and Related Structures. p. 459. In Stashak TS [ed]: Adams' Lameness in Horses. 5th Ed. Williams & Wilkins, Philadelphia, 2002.)

wide range of normal values, 0.33 to 1.5 mg/mL and several thousand kilodaltons, respectively.[7,9] The half-life of endogenous hyaluronan has been estimated by injecting radiolabeled hyaluronan into the joint and tracking both its degradation and its clearance. It appears that the majority of exogenous hyaluronan is cleared within 48 hours through the synovium and lymphatics, with degradation occurring in both the synovium and the liver.[7]

Periarticular Ligaments and Joint Capsule

Periarticular ligaments, the fibrous joint capsule, and surrounding muscles provide stability to synovial joints. The contribution to stability afforded by each of these structures differs according to its anatomic location. Joints higher in the limb obtain more stability from muscle than those lower in the limb, so the contour of the joint surface and stability from the joint capsule are more important in the lower limb, although muscular stabilization is a factor. The role of muscular stabilization cannot be overemphasized. For example, even with all periarticular ligaments and the joint capsule intact, desensitization of the suprascapular nerve results in subluxation of the shoulder joint.

The ligamentous and capsular configurations within a joint are different depending on the specific joint and the location within the joint, presumably based on range of motion and other biomechanical considerations. For example, in extension, the dorsal aspect of the metacarpophalangeal joint has capsular redundancy, but in flexion, the same region of the capsule is under tension (Figure 78-4).[10,11] It is easy to see how a decrease in compliance of the joint capsule because of increased fibrous tissue deposition could limit the range of motion within a particular joint.

The ligaments and fibrous joint capsule are composed mainly of type I collagen with some elastin fibers, accounting for 75% of the organic solids, with 23% being proteoglycan.[12] The organization is mainly in parallel fascicles with occasional fibrocytes and blood vessels. Most of the innervation of a joint is seen in association with perivascular structures.[10] The attachment of these structures to bone has been compared to Sharpey fibers, because the collagen fibers course through both fibrocartilage and calcified cartilage before their insertion in bone. This type of transition is credited with the biomechanical pullout properties (the amount of force needed to pull a ligament from the bone attachment) of the ligaments and joint capsule.[13] It is important to note that these tissues are metabolically active and undergo hypertrophy with activity and atrophy with immobilization. Immobilization has been shown to affect the microscopic, enzymatic, and biomechanical properties of ligaments, suggesting that immobilization should be used temporarily to maintain joint stability during a controlled return to use after injury, as is used in human medicine in the form of function splints (knee braces).[14]

Subchondral Bone

The subchondral bone plate, along with epiphyseal bone, provides contour and stability to the articular cartilage. The subchondral bone plate consists of *cortical bone with the haversian system running parallel to the joint surface*, unlike the diaphyseal cortical bone, where the haversian system runs perpendicular to the joint surface. The biochemical and histologic appearance of subchondral bone is similar to bone in other locations. In humans, the subchondral bone plate has been shown to be approximately 10 times more deformable than the cortical shaft.[10] Remodeling or stiffening of the subchondral bone plate

has been noted to occur with osteoarthritis in humans and is considered deleterious to the joint function.[15] This has sparked similar exploration in horses, and although remodeling and subchondral bone sclerosis is easily documented, especially in areas such as the third carpal bone, deleterious changes in proteoglycan content in this location have not been documented to date.[16] However, subchondral bone microcracks and other forms of bone remodeling have been demonstrated in this area in response to exercise, although their relationship to pathophysiology is not well defined.[17] The subchondral bone plate is integral to joint function as a whole; research in this area is quite active and may provide insights into its role in disease.

Articular Cartilage

Articular cartilage is the central structure that constitutes the joint surface and ultimately its function. In conjunction with the synovial fluid, articular cartilage is credited with providing the nearly frictionless movement of the synovial joint. Although other components of the joint, such as the subchondral bone, synovial membrane, joint capsule, and ligamentous structures, are integral for proper function and continued health of the joint, it is the state of the articular cartilage that is typically used to define joint health. Furthermore, although it is likely that disease may start in components of the joint other than the articular cartilage (e.g., subchondral bone or ligamentous structures), the degeneration and slow or poor healing response of the cartilage usually defines the level and progression of the joint disease.

On gross appearance, the articular cartilage appears smooth or glasslike (hence the term hyaline). In most areas, the articular cartilage has an opaque white color, with areas of thin articular cartilage appearing slightly pink because of the underlying subchondral bone color showing through. Although grossly the surface of articular cartilage appears flawless, a scanning electron microscope reveals it to be gently undulating with depressions that appear to correlate with interchondrocyte spaces immediately under the articular cartilage surface. These depressions have been estimated to be 20 to 40 μm in diameter and have a density of about 430/mm^2.[10] The thickness of articular cartilage varies by joint, location (related to the degree of weight bearing), and age, but it is in the 1- to 4-mm range.

The lack of vascular, lymphatic, and neural supply makes cartilage a unique tissue and dictates a *dependency on diffusion for nutrient supply and waste removal.* The nutritional supply is provided via the synovial fluid. The nutritional solutes diffuse from subintimal vessels through the intimal layer of the synovium to the synovial fluid, then through the articular cartilage matrix, until they finally reach the chondrocytes. The ultrastructure of the chondrocytes supports a diffusion gradient; for example, a decrease in the number of mitochondria in deeper chondrocytes suggests that they are less dependent on oxygen than more superficial chondrocytes.

The chondrocyte content of articular cartilage typically accounts for 1% to 12% of the volume of the cartilage, with the remaining component being termed extracellular matrix.[7] The *extracellular matrix* is somewhat complex but can be broken down into three main components: collagens, proteoglycans, and water. Water is the most abundant molecule of the extracellular matrix, making up about 70% of the wet weight in adults and closer to 80% in young and immature animals. On a dry weight basis, the extracellular matrix is composed of approximately 50% collagen, 35% proteoglycan, 10% glycoprotein (e.g., growth factors, cartilage oligomeric protein [COMP], proteinases), 3% minerals, 1% lipids, and 1% miscellaneous substances.[7]

Microscopic Appearance

On the basis of the microscopic appearance of both the chondrocytes and collagen orientation, articular cartilage has been historically divided into four contiguous zones (Figure 78-5):

1. The *superficial (tangential) zone* has the highest density of chondrocytes. These chondrocytes appear flattened and are oriented with the long axis of the cell parallel with the joint surface. The collagen here is more densely packed than in deeper layers, and the orientation of the fibers is also parallel

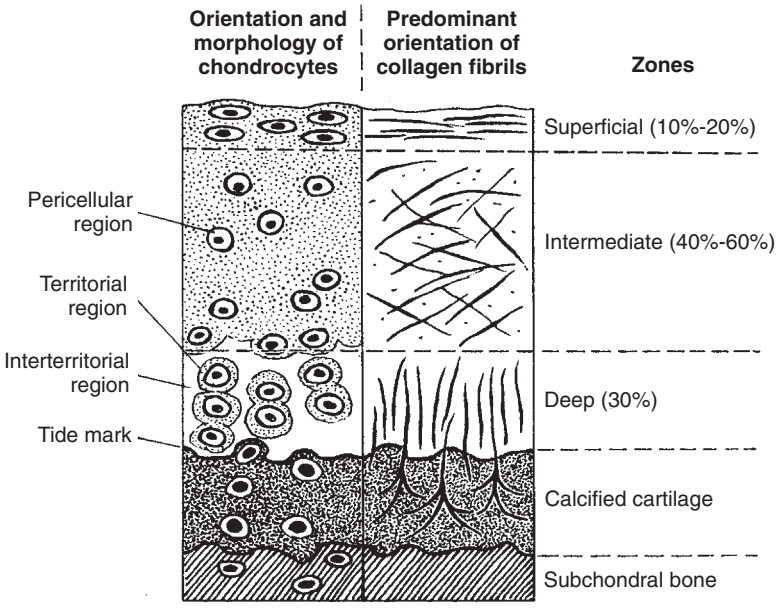

Figure 78-5. Normal articular cartilage with orientation and morphology of the chondrocytes, orientation of the collagen fibrils, and the relative contribution of the zone or layer. (Adapted from March L: Articular Cartilage in Health and Disease. p. 86. In Sambrook P [ed]: The Musculoskeletal System. Churchill Livingstone, New York, 2001.)

with the joint surface. There now is acceptance of a previously described but refuted acellular layer of collagen called the *lamina splendens.* This layer has fibril diameters that are distinctly different from those of the traditional cellular portion of the superficial zone and that can be consistently separated from the cellular portion of the superficial zone without damage to the collagen network. The lamina splendens is only loosely connected to the fibrous structure in the adjacent layer beneath. It is, however, firmly connected to the deeper cartilage matrix in the vicinity of the synovium, where it undergoes transition to synovial tissue.[18]

2. The *intermediate (transitional) zone* is characterized by larger, more ovoid to round chondrocytes.
3. The *deep (radiate) zone* has the largest chondrocytes, and the long axis of the cell is oriented perpendicular to the joint surface.
4. The *calcified zone* consists of mineralized cells and matrix. The *tidemark* refers to the junction of the noncalcified and calcified cartilage, which is a distinct transition seen on histologic sections. More recently, the tidemark has also been described arthroscopically.[19]

Cartilage Collagens

Collagen is considered the component of articular cartilage that provides the framework or lattice in which all other matrix molecules are constrained. It is also the component attributed to the counteraction of tensile stresses seen at the joint surface. As described earlier, the architecture of the collagen differs depending on its zone or depth within the cartilage. In 1925, Benninghoff described an arcade configuration of articular cartilage collagen, which is helpful in understanding the function of the cartilage. Although the overall accuracy of his model has been challenged, it is useful for demonstration purposes (Figure 78-6).[1] The superficial pattern of the collagen framework was described as "armor plating," referring to the tough, resilient, skinlike cartilage surface. The collagen content in this area is higher and the fibrils have a smaller diameter (about 31 nm) and an orientation parallel with the joint surface, which is different from collagen in deeper zones. Based on this configuration, minute openings exist in the superficial layer of cartilage, which have been calculated to be around 6 nm in diameter. This pore size would preclude large proteins such as hyaluronan from entering the cartilage from the synovial fluid in any significant quantities. However, small ions and molecules such as glucose could readily pass through an opening of this size.[20] As previously mentioned, the collagen fibrils of the intermediate zone are oriented in a more random pattern and are between 40 and 100 nm in diameter. The collagen fibrils of the deep zone have the largest diameter, are oriented perpendicular to the joint surface, and cross the calcified zone before attaching within the subchondral bone. This pattern of collagen orientation is supported by light and electron microscopy, with further confirmation by an interesting phenomenon called the *Hultkrantz line,* which appears when the articular surface is penetrated with a pin and stained with India ink.[21] The round hole made by the pin appears as an elongated slit, and the axis of the slit has been found to run perpendicular to the collagen fibril orientation and to the maximal surface tensile strains.[22] This method is currently the preferred test to determine the orientation of collagen in articular cartilage (Figure 78-7).

At least 16 different collagens have been described in mammalian species, and they are divided into two main categories on the basis of their primary structure and supramolecular assembly: *fibril-forming collagens* (including types I, II, III, V, and XI) and *non–fibril-forming collagens.*[23] Collagen turnover is much like that of other fibrous connective tissues, but it tends to be slower than that of other matrix components of the articular cartilage. It has been shown that significant collagen synthesis occurs in adult cartilage, although not much is understood about the process by which orientation is controlled in response to remodeling.

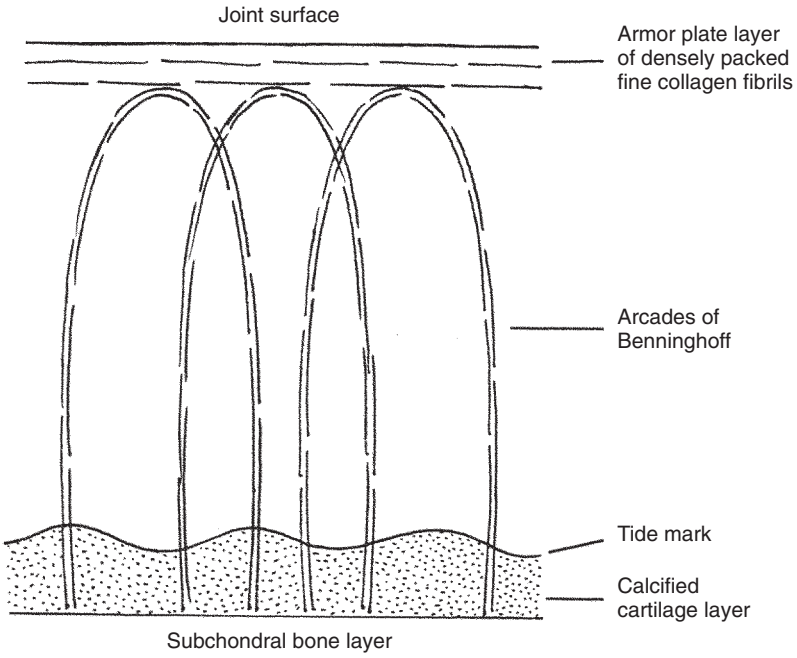

Figure 78-6. Simplistic illustration of the biomechanical function of the collagen fibrils in the different areas of articular cartilage. The tightly packed, smaller-diameter collagen fibrils are near the surface in the superficial layer (armor plate layer), notably in the lamina splendens. The larger-diameter, more loosely spaced fibrils of the deep layer (forming the arcades of Benninghoff) traverse the calcified layer and are anchored in the subchondral bone. (Adapted from Daniel DM, Pedowitz RA, O'Connor JJ, et al [eds]: Daniel's Knee Injuries: Ligament and Cartilage Structure, Function, Injury, and Repair. 2nd Ed. Lippincott Williams & Wilkins, Philadelphia, 2003.)

TYPE II COLLAGEN

The primary collagen of articular cartilage is type II and is produced by the chondrocytes. It constitutes 90% to 95% of the total collagen content.[24] The principal differences between type II and type I collagen (the latter found in the majority of other musculoskeletal tissues) are the number of hydroxylysine molecules and an increase in glycosylation. Type II collagen is a homotrimer composed of three identical collagen molecules that are constructed in such a manner that the start of each molecule is offset from the next by 25%, or by a "quarter stagger" (see Figure 80-3). Of the other types of collagen found in articular cartilage, types IX and XI are thought to be integral in the organization and mechanical stability of the type II collagen fibrillar network (Figure 78-8) and are intimately associated with type II collagen.

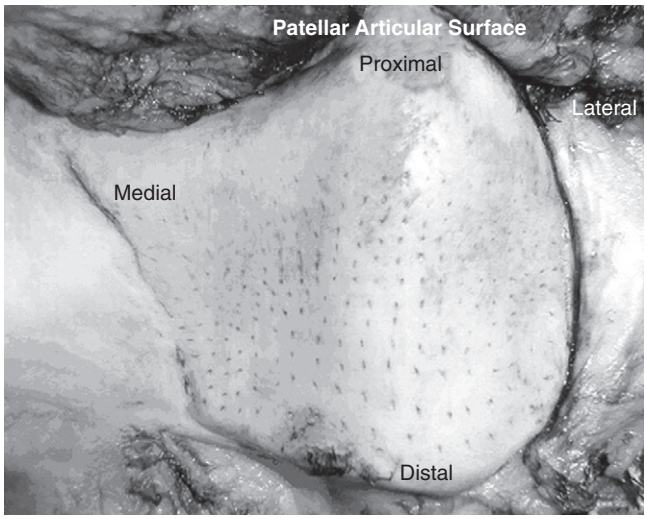

Figure 78-7. Gross photo demonstrating Hultkrantz lines in an equine patella following round perforations of the articular cartilage. The orientation of the slits after pin prick of the surface runs perpendicular to the orientation of collagen fibril. (Courtesy Dr. Chris E. Kawcak and Dr. Chad Lewis.)

MINOR COLLAGENS

The content of *type IX* collagen in articular cartilage decreases from being around 10% of the collagen protein in fetal tissue to being about 1% in the adult. This molecule is found on the outer surface of the type I triple helix and is thought to provide a covalent interface between the surface of the type II collagen fibril and other type II fibrils as well as the interfibrillar proteoglycan domain, thus providing mechanical stability of the fibrillar network.[1] Types VI, XII, and XIV collagen also are thought to have roles in the association between fibrillar collagen and other matrix components.[25,26] *Type XI collagen*, on the other hand, is found within the type II triple helix and acts as a core filament on which the type II molecules are deposited during formation.[27] Type XI collagen accounts for about 3% of mature collagen protein. Type VI collagen binds both hyaluronan and fibronectin and has been identified in the perilacunar area.[1]

Proteoglycans

Proteoglycans make up the other major component of the articular cartilage extracellular matrix, about 35% of the dry weight. As the name implies, these molecules are a combination of protein (*proteo* for the core protein to which glycosaminoglycans are attached) and glycosaminoglycan (*glycan* for the repeating disaccharide or polysaccharide). At first glance, the nomenclature of proteoglycans appears somewhat complex, but when broken down into its components it is relatively straightforward, and it is important to understand its evolution. The proteoglycan molecule aggrecan makes up about 85% of the proteoglycans that in turn make up the extracellular matrix, and it is mainly responsible for providing the resistance to compressive forces within the articular cartilage. The other proteoglycans are less studied but function in interactions with collagens and in various metabolic roles in cartilage.

AGGRECAN

A single (monomer) aggrecan molecule is made up of two main components: the core protein, which acts as the backbone of aggrecan, and the glycosaminoglycans (GAGs) that attach

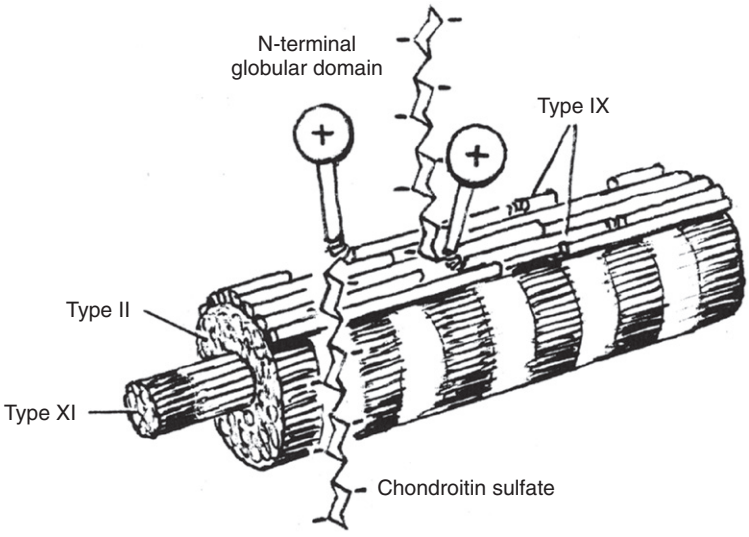

Figure 78-8. Arrangement of types II, XI, and IX collagen in articular cartilage. (Adapted from Eikenberry EF, Mendler M, Burgin R, et al: In Kuettner KE, Schleyerbach R, Peyron JG, et al [eds]: Articular Cartilage and Osteoarthritis. Raven Press, New York, 1992.)

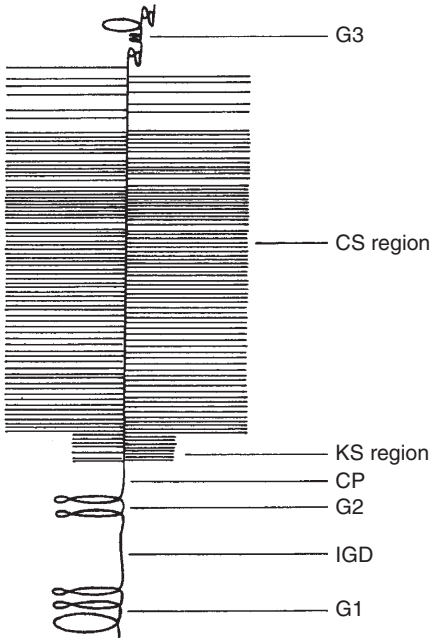

Figure 78-9. An aggrecan monomer consisting of a central core protein *(CP)* interrupted by three globular domains *(G1, G2,* and *G3).* Peripherally on the molecule are the keratan sulfate *(KS)* and chondroitin sulfate *(CS)* regions. Proteolytic cleavage of the molecule *in vivo* first occurs in the interglobular domain *(IGD).* (From Koopman WJ [ed]: Arthritis and Allied Conditions: A Textbook of Rheumatology. Vol 1, 13th Ed. Williams & Wilkins, Baltimore, 1997.)

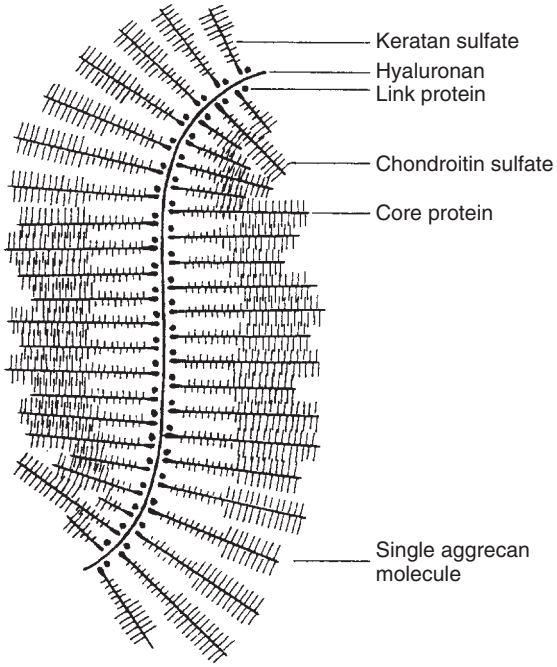

Figure 78-10. An aggregate containing many aggrecan molecules that are linked to hyaluronan via a noncovalent bond associated with the link protein. (From Rosenberg L: Structure of Cartilage Proteoglycan. In Simon WH [ed]: The Human Joint in Health and Disease. University of Pennsylvania Press, Philadelphia, 1978.)

radially to the core protein. The three main GAG molecules (Figure 78-9) that make up aggrecan are chondroitin-4-sulfate, chondroitin-6-sulfate, and keratan sulfate. Their ratio in cartilage differs with age. Of note is an increase in chondroitin-6-sulfate over chondroitin-4-sulfate as the cartilage becomes more mature. The GAGs covalently attach to the core protein, and about 100 chondroitin sulfate molecules preferentially attach at the carboxy end of the molecule. Likewise, approximately 100 keratan sulfate molecules are preferentially found closer to the N-terminal (amino-terminus) region of the aggrecan monomer.[11] These regions are sometimes described as chondroitin- or keratan-rich regions. Because of the high negative charge associated with the GAGs, they tend to repel each other (chemical expansive stresses) and attract water, creating positive pressure (Donnan osmotic pressure). The combination of these two forces has been termed *cartilage swelling pressure* and is roughly the equivalent of tire pressure.[28]

Current research has focused on delineating various functional and structural domains along the core protein. These regions or domains have been shown to help define the breakdown of various catabolic enzymes involved in normal and pathologic processes—for example, the cleavage site of *aggrecanase* is different from that of *stromelysin*, two important molecules associated with aggrecan turnover. Three main domains have been defined: G1, G2, and G3. The G1 region of the core protein interacts with hyaluronan, and this interaction is involved in arranging about 100 aggrecan monomers along a hyaluronan backbone. The G2 region is located on the N-terminal side of the keratan sulfate–rich region and is a key target of enzymes that break down aggrecan.[29] The G3 region is on the "end" or carboxy side of the aggrecan molecule and in fact is present in only some aggrecan molecules, suggesting a less-important role.[30]

AGGRECAN (PROTEOGLYCAN) AGGREGATES

Aggrecan monomers are further organized into large aggregates around a hyaluronan molecule. These aggregates can be in the range of 200 million daltons in size and comprise over 100 aggrecan monomers.[31] The noncovalent bond between the aggrecan monomers and hyaluronan is stabilized by a small group of link proteins in conjunction with the G1 domain of the core protein (Figure 78-10).[1]

SMALL PROTEOGLYCANS

About 5% of the articular cartilage proteoglycans are termed *small proteoglycans* or *nonaggregating proteoglycans.* Like aggrecan, they consist of a protein core and attached GAG chains. As the name implies, these molecules are smaller than aggrecan—in fact, the core protein is about 25% of that found in an aggrecan molecule. Examples are biglycan, decorin, and fibromodulin. Decorin and fibromodulin are found associated with collagen molecules in the superficial zones of the articular cartilage. *Decorin* has been shown to inhibit type I and II collagen formation, and *fibromodulin* inhibits fibrillogenesis. Biglycan and decorin have been shown to bind transforming growth factor-beta (TGF-β), thus making it unavailable to perform its biologic function. This may play an important role in the healing process of articular cartilage and needs to be better understood to improve intervention in cartilage healing.[1] The overall organization of the extracellular matrix is presented graphically in Figure 78-11.

Chondrocytes

The chondrocytes, as previously mentioned, represent a small proportion of the total volume of the articular cartilage. The morphology and metabolism of the chondrocytes vary

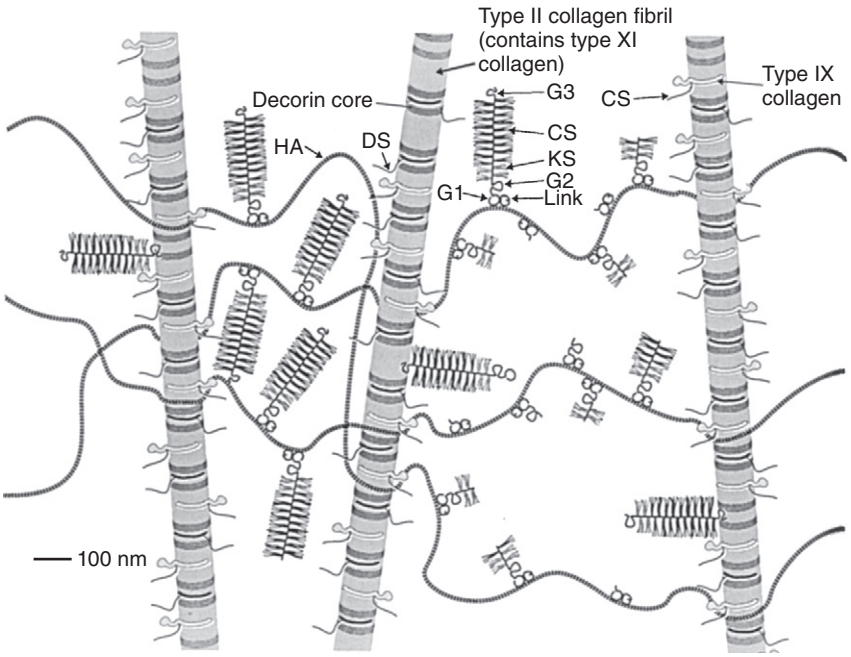

Figure 78-11. Organization of the major extracellular matrix components in articular cartilage. The principal collagen of cartilage is type II, and a network of these fibrils provides much of the tensile strength of the tissue. Aggrecan consists of a linear protein with three globular domains *(G1* to *G3),* to which are attached numerous glycosaminoglycan chains of chondroitin sulfate *(CS)* and keratan sulfate *(KS).* Supramolecular aggregates are formed by the noncovalent interaction of aggrecan with hyaluronan *(HA)* and stabilized by a link protein *(Link).* The negatively charged glycosaminoglycans *(CS* and *KS)* attract several times their weight in water, and this proteoglycan–water composite is responsible for the compressive stiffness of cartilage. Cartilage also has a number of minor proteoglycans and collagens (e.g., decorin and dermatan sulfate [DS]) whose functions are not fully characterized. Fragments of aggrecan, remaining bound to HA, are shown to illustrate the effects of proteolytic activity in cartilage. (From Koopman WJ [ed]: Arthritis and Allied Conditions: A Textbook of Rheumatology. Vol 1, 13th Ed. Williams & Wilkins, Baltimore, 1997.)

according to their depth within the cartilage, and the presence of lacunae represents a microenvironment around the chondrocytes that is more prevalent in the deeper layers. Chondrocytes have cytoplasmic processes that extend into the interterritorial region and appear to sense the biochemical and biomechanical environment, but, unlike the cytoplasmic processes of osteocytes, they do not make contact with cellular processes of other chondrocytes. These cytoplasmic processes may represent one mechanism through which the chondrocytes respond to *articular cartilage loading.* It appears that at a low level of mechanical stress, chondrocyte metabolism favors the catabolic processes, whereas at normal physiologic levels, anabolic processes are favored, and a balance of metabolism is possible. In contrast, at superphysiologic levels, the metabolism favors catabolism, potentially as a result of an overwhelmed anabolic pathway.[32] Alterations in extracellular matrix pressure caused by biochemical changes may also direct chondrocyte metabolism.

Turnover of the proteoglycan portion of the extracellular matrix occurs faster than in the collagen component. Specifically, proteoglycan turnover has been estimated at about 300 days in dogs and rabbits, versus an estimated 350 days for total turnover of the collagen in humans and 120 days in dogs.[11] These rates can be upregulated in disease states—in fact, upregulation of anabolism of both aggrecan and collagen synthesis appears to be one of the earliest changes detected in osteoarthritic processes.[33] More detail on cytokines and regulation of articular cartilage metabolism are covered later.

PHYSIOLOGY OF SYNOVIAL JOINTS

Intra-articular Volume and Pressure

The volume of the synovial space or joint cavity varies with its anatomic location, and, because of the elasticity of the joint capsule, it can change depending on various factors (e.g., disease, level of exercise). As an example, horses exercising at an increased level are often noted to have synovial effusion, notably in the fetlock and tarsocrural joints, without pathology being present. Some data on the "normal" synovial volume have been published, but, as previously noted, this can be somewhat subjective depending on the degree of joint capsule distention that is perceived as typical.[34] The mechanisms by which intra-articular volume and pressure are regulated are poorly understood. Most synovial joints are reported as having negative pressure in a neutral position, whereas at the extremes of flexion and extension the intra-articular pressure increases up to 30 psi in the human knee. These pressures are also sensitive to synovial effusion; increased pressures can be translated to the innervation of the joint capsule and subsequently to joint pain during range-of-motion activities.

Joint Mechanics

Joint mechanics are unique and very complex, largely because of the articular cartilage and its response to loading. The study of the loading properties of synovial joints is a very active field whose scope is beyond the reach of this chapter, but it is summarized here. Joint mechanics depend on three aspects: kinematics, kinetics, and joint lubrication. *Kinematics* involves the study of the motion of the articulating surfaces in relation to each other. *Kinetics* relates to the forces that are created during the motion of the joint and the loads that are created across the articular surface. *Joint lubrication* provides a nearly frictionless movement of the soft tissues and articular cartilage.

Kinematics

The kinematics of a particular joint are a function of the geometry of the joint surface—specifically, of the articular cartilage and the underlying subchondral bone, as well as the periarticular supporting structures such as ligaments and muscles. The types of motion that occur in joints fall into three categories: translational, rolling, and sliding motions. *Translational motion* refers to movement without rotation, where two surfaces move past each other. This type of motion somewhat describes the movement in the spine and shoulder. Both rolling and sliding

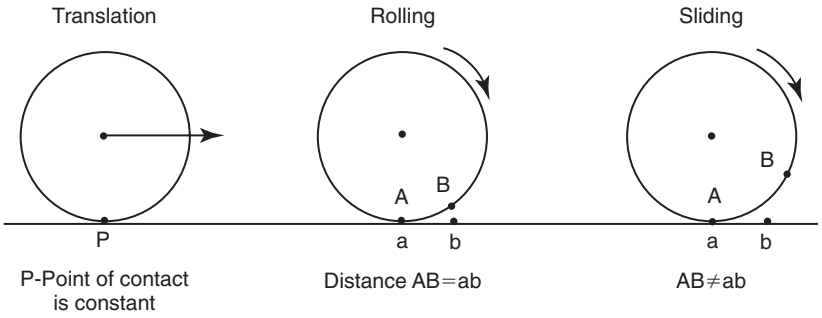

Figure 78-12. The three types of joint motion. (Adapted from Delahay JN: In Wiesel SW, Delahay JN [eds]: Principles of Orthopaedic Medicine and Surgery. Saunders, Philadelphia, 2001.)

imply some degree of rotational component, which adds another dimension and makes the mathematical models and understanding of these motions complex. Pure *rolling motion* implies that the instant center of rotation is always at the point of contact between the two surfaces and that the distance over which contact occurs is similar on both opposing surfaces. In *sliding motion*, the point of contact is not the instant center of rotation, and the areas of contact during the motion are not equal on both surfaces (Figure 78-12). Most synovial joints have some component of sliding and translational motion, and pure rolling motion is just theoretical.

Another factor that affects the kinematics of synovial joints is the observation that joint surfaces that are relatively congruent possess thinner articular cartilage than those with incongruent surfaces. Furthermore, in some joints, overall joint congruity appears less when they are unloaded than when they are under load. This is thought to allow better distribution of forces over a larger surface with increasing loads (see Figure 78-4).[10] It becomes quickly apparent that loss of any component of the synovial joint will alter the normal motion of a joint and its ultimate function.

Kinetics

The analysis of joint forces is even more complex, because it depends on the kinematics of the joint as well as on any change of normal position, which then alters the forces as they are applied to the joint. Kinetics takes into account the muscle forces pulling across a joint, the superimposed body weight, the force of the floor or surface pushing back against the joint in question, and the force felt by the cartilage in any given load-bearing situation (termed the J-force).[35] Joint modeling has been a focus in human research for some years and is currently being conducted in the equine carpus. This may provide valuable insight into the joint as a whole organ in the years to come.

Lubrication

Lubrication of the synovial joint can be broken down into two main components, that of the soft tissue and that of the articular cartilage. From a pure point of view, two types of lubrication function in the synovial joint: boundary and fluid-film lubrication. *Boundary lubrication* prevents adhesion and abrasions of two surfaces and is independent of the physical properties of the lubricant or contacting surfaces. Hyaluronan and lubricin (secreted by the synovial membrane) are believed to be the main boundary lubricants of the diarthrodial joint. Boundary lubrication is the main way of decreasing friction between soft tissue and bone, but it is believed to be relatively ineffective at providing a frictionless surface between articular cartilage surfaces at physiologic loads.[35]

Fluid-film mechanisms are believed to provide the low friction environment for the articular cartilage at physiologic loads, accomplished by creating a wedge of fluid between the two bearing surfaces. Several models have been proposed, including squeeze film, hydrodynamic, and elastohydrodynamic models (Figure 78-13). The *elastohydrodynamic model*, which is accepted as best representing lubrication of the articular cartilage, is based on the attraction of water by aggrecan molecules at the porous articular surface. In this model, when load or pressure is applied to the surface, water is squeezed from the articular surface and interposed between the bearing surfaces. With joint movement, a wedge of fluid is created, the leading edge of which is wider and exudes fluid, and at the thinner trailing edge, fluid is thought to be resorbed. Stated another way, as load is applied to the bearing surface of the articular cartilage, fluid is squeezed from the cartilage, separating the surfaces, and is resorbed as the load decreases on the back side of the motion.[35] The material properties responsible for the fluid flow in the articular cartilage have been studied in detail.

An air tent (like those used to cover tennis courts) has been used as an analogy to understand the biomechanical function of the articular cartilage as it relates to the components of the cartilage matrix and fluid flow.[1] The components required for the proper function of the air tent are a pump (intake portal and fan), an inflation medium (air), and some form of fabric enabling containment of the inflation medium, thus creating a pressurized system. These tents are engineered to have small openings in the fabric, which require the pump to move more air inward than is escaping to keep the tent inflated. In articular cartilage, the pump corresponds to the proteoglycans; their ability to attract solutes based on their strong negative charge is the driving force of the pump. The inflation medium is solutes from the synovial fluid made up mainly of water, and the containment material, or fabric, is the network of collagen. Instead of entering through a single intake port of a mechanical pump, solutes gain access to the articular cartilage through the fine network of pores formed in the superficial layer of collagen, and likewise these molecules exit via these pores. Both systems (air tent and articular cartilage) depend on all components functioning appropriately and in unison. For example, if a tear in the containment material is too large, the pump cannot continue to pressurize the tent and the system collapses; likewise, if the pump fails, the normal egress of inflation media ultimately ends in a collapse of the tent.

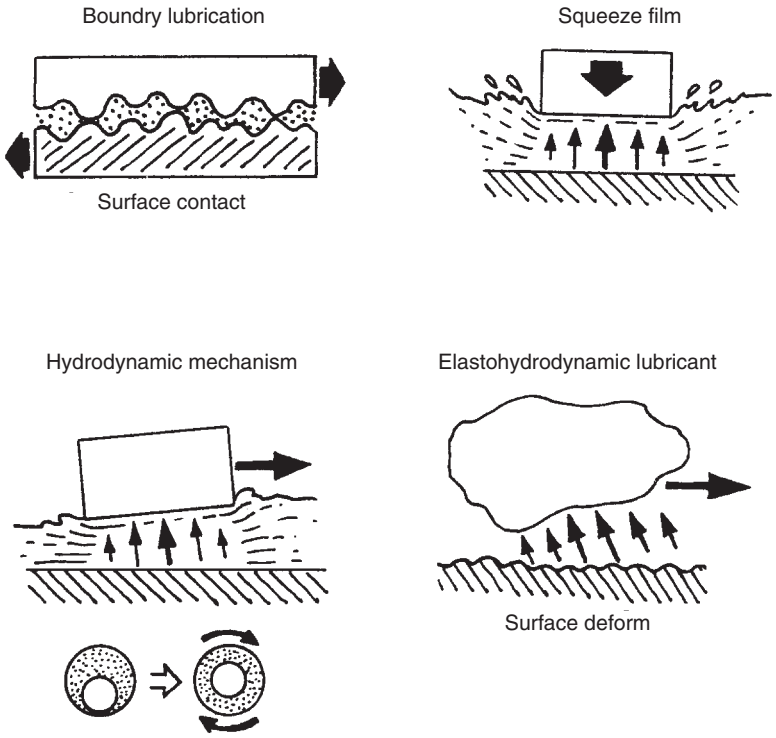

Figure 78-13. Models of lubrication: boundary, squeeze film, hydrodynamic, and elastohydrodynamic (a combination of squeeze film and hydrodynamic). (Adapted from Delahay JN: Basic Science. p. 1. In Wiesel SW, Delahay JN [eds]: Principles of Orthopaedic Medicine and Surgery. Saunders, Philadelphia, 2001.)

In a state of equilibrium, the articular cartilage maintains a balance of pressure created by the interaction of aggrecan and water that is counteracted by the constraints of the collagen network. When an external load is applied to the articular surface, water flows out of the surface pores until a new equilibrium is reached. This process is relatively complex and not linear in nature. For example, as water egresses out of the articular cartilage as a result of increased surface load, the proteoglycans are forced closer together and generate greater repulsive pressures as they come closer to each other, much like similar poles of magnets repel each other with increasing proximity. Such fluid movement in and out of the articular cartilage is of great interest, because it is integral to the lubrication of the joint surface, load-bearing functions of the articular surface, and nutrition of the chondrocytes.

The nutritional supply of the articular cartilage is thought to be provided through the exchange of solutes present in the synovial fluid during loading and unloading of the articular surface. It has been calculated that based on this type of supply, the articular cartilage was limited to 6 mm of thickness for chondrocyte viability to be maintained, a calculation that appears to be accurate in terms of synovial joints.[35]

The term *viscoelastic* is used to describe the biomechanical properties of articular cartilage, and as the name implies, it is a combination of viscous, or fluid, and elastic biomechanical properties. When a static load is applied in a laboratory setting, there is an initial rapid movement of water out of the cartilage in the fluid phase, followed by a slower loss of water and compression of the collagen known as the *creep phase*. A time–deformation curve is used to graphically represent the response of the cartilage to loading after the static application of a load (Figure 78-14). The loss of water and compression of the tissue, forcing the proteoglycans or aggrecans into closer proximity and repelling the forces of the proteoglycans from one another, also contributes to opposing the loading force in the creep phase. It has been estimated that 2- to 4-mm-thick cartilage can take 4 to 16 hours to reach creep equilibrium.[36]

PATHOPHYSIOLOGY OF OSTEOARTHROPATHY

Osteoarthropathy is a general term defined as any disease of the joints and bones. It is derived from the Greek words *osteo* ("bone") and *arthron* ("joint"). A more-specific term that relates to disease of the articular cartilage is osteoarthritis, defined as a disorder of movable joints characterized by degeneration and loss of articular cartilage. The suffix *itis* is somewhat misleading because it suggests a central inflammatory role, which is not present in many joint diseases of horses and humans. Human rheumatoid arthritis is a notable exception and does have a central inflammatory role. Some definitions of osteoarthritis even state that it is a noninflammatory disease process, which is also somewhat misleading because inflammatory factors do play a part in most arthropathies (defined as any joint disease). Because of these discrepancies, several terms are used to describe similar disease processes. Other common terms are degenerative joint disease (DJD), which circumvents these issues but is often not favored as a scientific term. *Osteoarthrosis* is also sometimes used, correctly not emphasizing the inflammatory component, but this is defined as a chronic condition, which is not always accurate. *Osteoarthritis* is, in my experience, the currently accepted term describing degeneration of the equine articular cartilage. Therefore this term is used in this chapter.

Many texts define specific mechanisms as being responsible for the pathogenesis of osteoarthritis. For example, one author describes three proposed mechanisms for osteoarthritis, the first being fundamentally defective cartilage with abnormal biomechanical properties. Thus the cartilage fails under normal

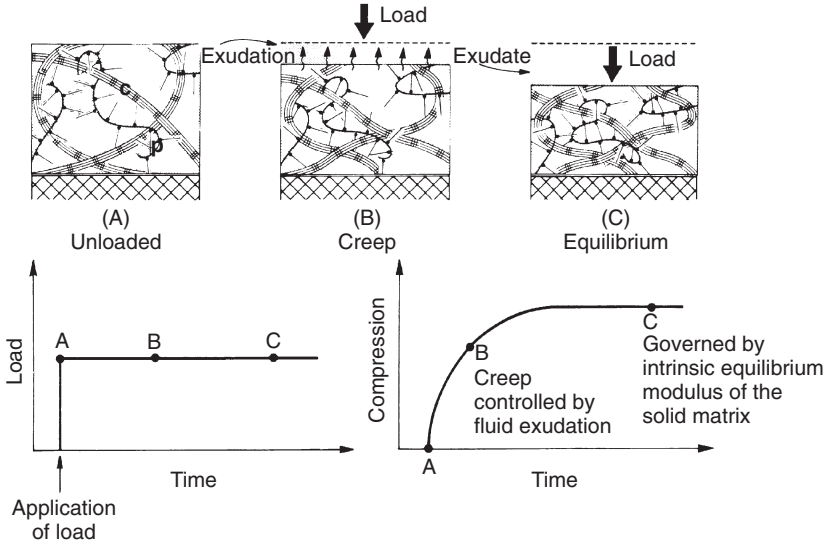

Figure 78-14. Schematic representation of time-dependent deformation of cartilage. The steep portion of the curve *(A* to *B)* represents initial loading. Subsequently, in the creep phase, there is further deformation of the matrix, which is a result of a slower flow of water through the matrix, until the equilibrium stage *(C)* is reached. (From Myers ER, Mow VC: Biomechanics of Cartilage and its Response to Biomechanical Stimuli. p. 313. In Hall BK [ed]: Cartilage. Vol 1. Academic Press, New York, 1983.)

loading conditions.[37] An example of *abnormal biomechanical properties* is the genetic defect described in humans that results in a type II collagen that is unable to withstand normal joint loading.[38] The second mechanism involves *abnormal change in the subchondral bone.* It is accepted that subchondral bone typically undergoes remodeling in response to exercise or to changes in load. It is thought that in some cases, the bone increases its density to a pathologic level, which in turn results in a stiffer or less compliant bone–cartilage unit that is prone to failure. The third proposed mechanism revolves around *normal cartilage that is exposed to abnormal forces*—for example, those that may be seen with abnormal joint congruity resulting from a collateral ligament strain. In this mechanism, abnormal forces overwhelm the normal metabolic repair mechanisms in the articular cartilage and ultimately lead to its failure.

Another author has also outlined discrete mechanisms whereby osteoarthritis may ensue, and many similarities exist.[8] More recently, he gave an example of a scenario that could lead to osteoarthritis and described how the different joint tissues may be involved, but he did not elaborate on previously defined mechanisms.[11] This trend for more general pathogenic descriptions is favored by the author. It is probable that most cases of equine joint disease have some involvement of most joint tissues: subchondral bone, articular cartilage, synovial fluid, synovium, ligamentous joint capsule, and external stabilizers of the joint, such as ligaments, tendons, and muscles. This is not to say that specific components do not play a leading role, and initial failure of a single component or tissue is not often the case, but rather each component has some capacity for repair, and clinical disease usually is characterized by involvement of multiple joint tissues in some degree of pathology.

Metabolism of Arthritic Cartilage

It is widely accepted that all joint tissues have normal metabolic turnover, and the turnover is a balance of anabolic and catabolic pathways. Osteoarthritis at its origin may be defined by the predominance of the catabolic pathway, which leads to the ultimate failure of the tissue. Two interrelated factors should be considered in the pathogenesis of osteoarthritis: abnormal mechanical loads and metabolic tissue failure. *Abnormal mechanical loads* may be in the form of mechanical instability that can overwhelm the normal repair process of the tissues it is acting on. It may range from microdamage because of slight imperfections in conformation, to a single traumatic event leading to immediate failure, often a catastrophic one. *Microdamage* is believed to accumulate over time, leading to failure of the tissue after a failed reparative effort, and it may be likened to microcracks in an airplane wing that ultimately lead to failure if not repaired in time. On the other end of the spectrum, immediate damage to the cartilage could occur with a single impact without chance for repair, such as an articular fracture caused by a traumatic event. *Metabolic tissue failure* revolves around normal tissue metabolism and the fact that all the tissues of the joint have some capability for normal turnover and thus repair. However, some tissues, such as bone, are very adept at repair, whereas others, such as articular cartilage, are less adept. Thus osteoarthritis could be defined as the point at which the anabolic repair processes are overwhelmed by the catabolic processes. As described earlier, the imbalance and failure can be initiated by mechanical forces or by an inherent defect caused by a genetic imperfection, such as a type II collagen defect. A continuum of disease severity and involvement of multiple joint tissues is often the case in osteoarthritis; the etiology is most likely multifactorial, and at some stage, it includes some degree of both abnormal mechanical loads and metabolic tissue failure. The current understanding for normal metabolism and, in the case of osteoarthritis, response to injury for each joint tissue is described next.

Mechanisms of Articular Cartilage Matrix Depletion

Synovial Membrane and Ligamentous Joint Capsule

The involvement of the synovial membrane and joint capsule in the pathogenesis of osteoarthritis is often not emphasized, with more focus being on the articular cartilage and bone. The synovium is a very dynamic tissue that has an integral role in influencing the joint environment, especially through the constituents of the synovial fluid, and thus it can have an especially

significant effect on the articular cartilage. The highly vascular nature of the synovium allows it to act as the conduit and regulator for inflammatory cells and peripheral mediators that influence metabolic processes, especially in the release of catabolic substances affecting the joint. Likewise, the synoviocytes themselves, much like the chondrocytes, are capable of producing a wide variety of anabolic and catabolic enzymes, including prostaglandins, cytokines, and MMPs.[8] *In vitro* experiments have shown the importance of mediators released specifically from the synovial membrane in regard to the degradation of articular cartilage. A limitation in determining the relative quantitative and temporal contributions of the synovial membrane to disease *in vivo* is our inability to identify the origin of the mediators *in situ* as being synovial or chondrocytic. To avoid redundancy, a more-detailed description of the mediators and their role in osteoarthritis is presented later, under "Chondrocytes."

Primary synovitis or *capsulitis* is thought to result from biomechanical damage, which may be on a continuum of repetitive trauma from discrete incidents. Severe trauma can lead to an effect on the joint capsule's role in joint stability and thus joint-wide abnormal biomechanical forces. The response of the joint capsule to injury is to form a fibrous repair tissue that is not biomechanically equivalent to the original tissue and can often result in a decreased range of motion for the particular joint. It is conceivable that this may have long-term ramifications of altered use of the joint and overall abnormal biomechanical forces to the joint tissues. Although the synovium is not thought to have any biomechanical stabilizing properties, it does respond to injury through cellular and enzymatic pathways. It is worth noting that synovitis and capsulitis can be secondary to other abnormalities in the joint. Synovitis may be secondary to other damage within the joint such as occurs with an osteochondral fragment in the carpus. In this example, physical damage to the tissues as well as liberation of debris and mediators from the damaged cartilage and bone will affect the synovial membrane and capsule. In concert with the lymphatic drainage of the joint, the synovial membrane is responsible for clearing debris from the synovial space. Neutrophils, macrophages, and mononuclear cells can also be routinely found in inflamed synovial membrane, contributing to both the phagocytic role of the membrane and the production of enzymatic mediators.

Histologic abnormalities seen in the synovial membrane can be characterized by edema, hyperplasia of the intimal cell lining, hypervascularity, cellular infiltration of inflammatory cells, and fibrosis of the subintima. The order in which these events appear loosely corresponds to the appearance of the abnormalities in a equine model of osteoarthritis and presumably in naturally occurring disease.[39] Changes documented histologically support alterations seen in other areas of the joint. For example, an increase in vascularity is typically associated with some degree of synovial effusion and an increased protein concentration in the synovial fluid. The increase in protein and fluid is thought to be associated with "gaps or leakiness" of the endothelial cell layer. Although ill defined, alterations in the lymphatic drainage of the synovial space is most likely a component of synovial effusion, with one proposed mechanism being an increased fluid pressure allowing less egress via the lymphatics. Intimal cell hyperplasia is also seen in cases of synovitis and is believed to be associated with a substantial metabolic response by the synoviocytes and most likely contributes to the central pathophysiologic events in osteoarthritis.

Chondrocytes

The joint chondrocytes are responsible for maintaining their surrounding environment through a complex interaction of anabolic and catabolic mediators as well as mechanical stimuli. In osteoarthritis, the net outcome favors the catabolic pathways, and degeneration of the articular cartilage ensues with *loss of the key matrix components, including aggrecan and type II collagen*. There has been a long-raging debate over the definition of the earliest sign of osteoarthritis as it relates to aggrecan or type II collagen loss (reminiscent of the chicken-or-egg argument). Both *in vitro* and *in vivo* studies have documented loss of aggrecan as an initial biochemical event.[33,40-42] Furthermore, it appears that upregulation of the synthetic pathways is one of the earliest metabolic manifestations, although the net loss of aggrecan and collagen prevail. The quality and quantity of both matrix components are affected, with an increase in water content and surface fibrillation also being early events in articular cartilage degeneration. This in turn affects the mechanical properties of the cartilage, making it less able to withstand normal loads, perpetuating the disease process, and inciting changes in other tissues such as bone and synovial membrane as the cartilage loses its functionality.

The proteolytic enzymes synthesized by the chondrocytes and synoviocytes, and their role in cartilage breakdown, have been extensively studied. They are described by their catalytic mechanisms and include MMPs, aspartic proteinases, cysteine proteinases, and serine proteinases, with the MMPs thought to be most involved in the pathogenesis of osteoarthritis.[8,43]

Matrix Metalloproteinases

The MMPs are grouped together by a requirement for zinc in their active binding site and are typically identified either by a descriptive name or by a numerical MMP assignment. To date, 25 different MMPs have been described.[44] The descriptive name is often based on the substrate the MMP was first observed to degrade, such as *collagenases*, *stromelysins*, and *gelatinases*. The MMPs are secreted in an inactive "pro" form and collectively possess the ability to degrade all of the major components in the articular cartilage; thus they play a major role in both health and disease of the articular cartilage. The synoviocytes and chondrocytes as well as other cell types are capable of MMP production. Increasing concentrations of MMPs have been correlated to areas of histologic abnormalities, signifying their active role in cartilage degradation.[45,46] The major MMPs that have been incriminated in osteoarthritis include collagenase 1 (MMP-1), collagenase 2 (MMP-8), collagenase 3 (MMP-13), stromelysin 1 (MMP-3), and two gelatinases (MMP-2 and MMP-9). A family of enzymes called "a disintegrin and metalloproteinase" (ADAM) is structurally and functionally related to the MMPs and is also a major factor in aggrecan cleavage. A summary of the nomenclature and function of the MMPs and related proteinases can be found in Table 78-1.

Interstitial or *tissue collagenase* (MMP-1) is able to break intact type II collagen molecules by cleaving all three collagen α-chains of the triple helix at a specific amino acid sequence (residues 775-776).[8] Collagenase 2 or human neutrophil collagenase (MMP-8) is released from polymorphonuclear leukocytes (PMNs) and was first shown to be active in human osteoarthritis and has been identified as having activity in equine cartilage.[47,48] Collagenase 3 (MMP-13) has been shown to be more

TABLE 78-1. Matrix Metalloproteinases (MMPs) Implicated in Cartilage Matrix Degradation

Enzyme	MMP Number	Function	TIMP Number
COLLAGENASES			
Interstitial collagenase (collagenase 1)*	MMP-1†	Collagens II and X (not IX and XI), denatured type II, aggrecan, link protein	TIMP-1 > TIMP-2
Neutrophil collagenase*	MMP-8	Collagen II, aggrecan, link protein	TIMP-1, TIMP-2
Collagenase 3*‡	MMP-13†	Collagens II, IV, IX, X; aggrecan; fibronectin	TIMP-3
STROMELYSINS			
Stromelysin 1*	MMP-3†	Aggrecan, fibronectin; denatured collagen II	TIMP-1 > TIMP-2
Stromelysin 2*	MMP-10	Collagens IV, IX, X, XI; procollagens; link protein; decorin; elastin; laminin and the function of stromelysin 1	TIMP-3
GELATINASES			
Gelatinase A (72 kD)*	MMP-2†	Denatured collagen II, collagens X and XI, elastin	TIMP-2 > TIMP-1
Gelatinase B (92 kD)*	MMP-9†	Aggrecan, fibroconectin, collagens IX and XI, procollagens, link protein, decorin, elastin	—

TIMP, Tissue inhibitor of metalloproteinase.

aggressive in type II collagen degradation, cleaving it 10 times faster than MMP-1. Also found in higher concentrations in diseased cartilage of horses and humans, MMP-13 synthesis is upregulated by interleukin-1 (IL-1) and tumor necrosis factor (TNF), key enzymes at the top of the articular cartilage catabolic pathway.[46,49] *Stromelysins* have been studied most notably for their ability to break down proteoglycans, but partially degraded collagen and other minor cartilage proteins can be substrates. Much of the credit for breaking down aggrecan in osteoarthritic cartilage has recently been given to members in the ADAM family of enzymes, specifically *aggrecanases*.[43] It is currently thought that aggrecanases play a pivotal role in proteoglycan depletion in diseased cartilage. The *gelatinases* also have a diverse range of substrates, including partially degraded collagens and elastins.[8]

Cytokines

Historically, the term *cytokine* denoted small regulatory proteins that were associated with catabolic pathways. More recently, the term has been broadened and is now considered to define catabolic, modulatory, and anabolic proteins that are produced by one cell while acting on another. Cytokine pathways are relatively complex, and more in-depth knowledge of these pathways, as well as their interactions with other molecules, is being published. These mediators play a pivotal role in the metabolism of the synovial membrane and articular cartilage in health and disease.

Most notable of the *catabolic cytokines* are IL-1 and TNF-α, which can be secreted from chondrocytes and synoviocytes. Both have been demonstrated to be upregulated beyond a normal level in osteoarthritis, promoting production of MMP, nitric oxide, and prostaglandin E_2 (PGE_2), as well as inhibiting aggrecan and type II collagen synthesis.[8] Although IL-1 and TNF-α have relatively similar actions, it is thought that IL-1 is the most important of the proinflammatory cytokines.[50] *In vitro*, the two molecules do appear to potentiate each other, and TNF-α has been shown to stimulate IL-1 activity.[51] In addition to having these effects, IL-1 has been shown to inhibit the production of natural antiarthritic molecules such as the MMP inhibitors (tissue inhibitor of matrix metalloproteinase, or TIMP) and interleukin-1 receptor antagonist (IL-1Ra), which utimately potentiates the catabolic cascade.

The *modulatory* or *regulatory cytokines*, such as IL-4, IL-10, and IL-13, have actions that balance or modulate the proinflammatory cytokines, namely IL-1 and TNF-α. They have been shown to inhibit the synthesis of IL-1 as well as to promote the synthesis of the natural inhibitors, specifically the TIMPs and IL-1Ra. IL-6 has a mixed mode of action that includes magnifying the effects of IL-1 while promoting synthesis of the TIMPs.[52]

Cytokines that promote the *anabolic* cascade of cartilage metabolism, such as insulin-like growth factor (IGF) and transforming growth factor (TGF), play a role in osteoarthritis. These molecules have been shown to promote chondrocyte production of matrix molecules such as proteoglycans and type II collagen. Thus anabolic cytokines can be helpful in reparative attempts in diseased joints. The use of anabolic cytokines in treatment protocols of osteoarthritis is an area of current research.[53,54]

Although not classified as cytokines, levels of *nitric oxide* (as well as other oxygen-derived free radicals) and *prostaglandins* are increased in joints with osteoarthritis. Free radicals play a role in the degradation of hyaluronan and collagen. Cells have been shown to produce nitric oxide in response to IL-1, and its production has been related to inhibition of chondrocyte anabolic activities. Association with activation of MMPs and the reduction in the natural inhibitors has also been observed with nitric oxide, although this molecule's specific role in osteoarthritis is still somewhat controversial.[55,56] Also associated with decrease in anabolic synthesis is the E series of prostaglandins. PGE_2 has been shown to be increased in the synovial fluid of horses with osteoarthritis and has been correlated with both synovitis and clinical lameness as well as being produced after stimulation with IL-1 and TNF-α *in vitro*.[8]

Natural Inhibitors of MMPs and Cytokines

The biological response to IL-1 and TNF-α occurs after the molecules bind to a specific receptor. Both molecules have at least one mechanism by which their activity is blocked by a natural inhibitor. One example of a natural inhibitor of IL-1 is *IL-1Ra*, which has affinity for the IL-1 receptor, but when it binds to the receptor, it does not elicit a biological response, and thus it acts as a natural inhibitor of IL-1. In the case of TNF-α, the membrane-bound receptors can be secreted or solubilized (in this form, there is no way to signal a biological response once they are bound to TNF-α). They maintain the affinity for the TNF-α molecule and, in thus binding the molecule, prevent it from binding a membrane bound receptor. Numerous *in vitro* and *in vivo* studies have been carried out using natural inhibitors of the cytokines with very promising results (see Chapter 79).[57,58]

Like the cytokines, natural inhibitors of the MMPs also exist, termed *TIMPs*. Four different TIMPs have been described, three of which (TIMP-1, TIMP-2, and TIMP-3) are thought to be active in inhibiting joint-related functions. Synthesized by numerous cells that include chondrocytes and synoviocytes, these inhibitors bind one-to-one with MMPs to form an inactive complex.[59,60] Believed to play an important role in the normal regulatory mechanism of the joint environment, these inhibitors have been shown to be present in abnormal levels in human osteoarthritic cartilage.[61,62] Therapeutic intervention using TIMPs has not appeared to advance as rapidly as cytokine inhibitor therapy, which may suggest a less-global role in osteoarthritis, although more research is needed.[63]

In summary, a vast number of mediators are involved in joint metabolism in both health and disease. This chapter has only outlined the major molecules and the current level of understanding. Given the discovery of new mediators and common pathways, substantial changes in our understanding of osteoarthritis should be expected in the next decade. Additional information on this subject can be found in Chapter 79.

Clinical Manifestations of Osteoarthritis

Sources of Pain

Joint-related problems account for the greatest single economic loss to the horse industry, much of which can be related to osteoarthritic pain. Although the articular cartilage is devoid of innervation, the surrounding tissues are rich in unmyelinated C fibers. The capsule, synovium, tendons, ligaments, periosteum, and bone have all been defined as sources of pain in osteoarthritis cases. Sensory nerves are known to respond both to *mechanical stimuli*, such as stretching, and to *chemical mediators.* Mediators such as kinins and the neuropeptides (e.g., substance P) have been shown to stimulate pain fibers directly. These mediators, along with others, such as PGE_2 and IL-1, sensitize fibers to be more reactive after mechanical stimulation. Upregulation of pain receptors and involvement of the central nervous system (i.e., the spinal nerves) has also been demonstrated in osteoarthritis.[64] Elevated levels of substance P have been observed in both equine and human patients with osteoarthritis, and they can stimulate monocytes to release other proinflammatory cytokines such as IL-1 and TNF-α.[65-67]

In both horses and humans, correlation between clinical signs and disease severity is poor. In humans, there is an increased chance of reporting pain with increasing radiographic changes consistent with osteoarthritis, but a significant number of people report pain despite normal radiographs, and many individuals with unequivocal knee osteoarthritis deny having pain. Similar parallels can be drawn from equine patients, although anatomic location in both horses and humans appears to play a part in the correlation between clinical pain and the objective parameters. One explanation for the lack of association between pain and structural damage is the lack of sensitivity of outcome parameters, such as radiographs. Many of the soft tissue structures responsible for the pain, such as joint capsule, ligaments, and menisci, are poorly imaged using radiographs. In fact, the importance of soft tissue in joint health is underscored by the fact that quadriceps weakness is a risk factor for human knee osteoarthritis. Multiple studies have shown that strengthening exercises are an effective method of reducing pain and improving function in people with osteoarthritis.[68-70]

It is also believed that the periosteum and bone can play a significant role in osteoarthritic pain. People report focal pain in the area of osteophyte growth, and it is believed that growth of the osteophyte may result in elevation and stretching of the richly innervated periosteum.[64] In some cases, the subchondral bone plate appears to be a source of pain, although not all horses with subchondral cystic lesions demonstrate clinical lameness.[71] Increases in intraosseous pressure have been demonstrated in osteoarthritis, and there is evidence to link this with pain in people, especially following reduction of symptoms after cortical fenestration.[64] Similar mechanisms have been proposed for horses, and decompression of cystic lesions has led to improved lameness scores.

Clinical Parameters

An increase in synovial fluid or synovial pressure is a common finding, especially in joints with excessive joint distention. Thought to be initiated by inflammatory events occurring in the joint, synovial effusion is in part a result of increased vascular permeability (ingress) and a decrease in lymphatic drainage (egress). This net increase in fluid results in an abnormal use of the joint for both mechanical and pain-related reasons. If not controlled, the inflammatory process may lead to changes in the synovium and the joint capsule, which are often observed as a decreased range of motion. Although an increase in synovial fluid can be solely responsible for decreases in range of motion, edema and a decreased pain threshold most likely also contribute. More chronic changes, such as fibrosis in the synovial membrane and joint capsule, can also be observed histologically.

Changes in the content of the synovial fluid are also observed in most cases of osteoarthritis, and *reduction in viscosity* is one of the oldest measures of a diseased joint. An evaluator can roughly determine viscosity by handling a tenacious string of synovial fluid between his or her fingers. The loss in viscosity is typically attributed to a decease in hyaluronan concentration as well as to depolymerization or shortening of the molecule.[72] The large variation in scientific methods and the time-consuming nature of measuring synovial fluid viscosity often make this measurement clinically impractical. The addition of acetic acid leading to precipitation of mucin or a "mucin clot" is a quick and easier but less-specific or sensitive way to measure synovial fluid quality. This, in combination with gross observation of the synovial fluid, which is usually pale yellow to clear and free of flocculent material, has been used in the field to assess quality. In a laboratory setting, the determination of synovial fluid total

protein is often useful in relation to the degree of synovitis and also has been correlated to articular cartilage damage arthroscopically.[73] Cytologic examination of the synovial fluid also is routinely performed in the laboratory. Although synovial fluid total protein and cytology is not diagnostically very specific or sensitive, it can be useful in some cases, especially those with extreme values (Table 78-2).

More-sophisticated methods of measuring cartilage-specific (aggrecan and type II collagen) synthetic and degradation molecules for use on synovial fluid and serum of horses with osteoarthritis involve biomarkers. These biomarkers show promise in early detection and staging of equine joint disease, although more clinical research is needed.[33,73]

As previously mentioned, the usefulness of radiographs is somewhat limited in osteoarthritis, but, because of their ease, they have historically been a method for evaluating joint disease. Although often not correlated to the severity of clinical signs, periarticular enthesiophytes, joint-space narrowing, subchondral bone sclerosis or lysis, and the presence of osteochondral fragments are typical features that can be present radiographically in an osteoarthritic joint (Table 78-3).

Other imaging modalities such as ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) have more recently gained acceptance in veterinary medicine. The ability of ultrasonography to image soft tissues, including articular cartilage, makes it an especially useful adjunctive diagnostic tool in osteoarthritis. The level of sophistication and general knowledge in equine ultrasonographic joint anatomy has greatly increased in the last decade, making joint ultrasonography a standard tool.[74] Likewise, with increased knowledge of normal anatomy and increased availability of equine-dedicated MRI units, this modality will surely gain greater acceptance. The use of MRI in the human orthopedic field is commonplace, largely because of the ability to image all of the joint tissues in a three-dimensional space.

Cartilage Repair

An observation made in 1743 that "cartilage once destroyed never heals" is still accurate today.[75] Modern nomenclature defines healing as the restoration of structural and functional integrity, whereas regeneration suggests the tissue will be identical to that of the original. Repair, on the other hand, has a more limited meaning and suggests that cells and tissue structures replace the damaged tissue, but that the tissue does not necessarily return to its original structure or function. The degree of damage to normal articular cartilage is typically described by the dimensions of the lesion and its depth into the tissue; both of these factors, as well as anatomic location and weight-bearing, play a significant role in the degree of healing and return to normal function.

It is important to note discrepancies in the cartilage repair literature regarding the definition of *full-thickness defects.* This term has been used by some to describe lesions including only the noncalcified cartilage (superficial, intermediate, and deep, but not the calcified cartilage layers) all the way to lesions that extend past the subchondral bone plate. Until recently the true depth was known only if histologic confirmation was performed. However, after studies using arthroscopic visualization of experimental cartilage defects were correlated directly to histologic sections, some degree of confidence about the depth of defects can be made. Today, most authors use "full-thickness articular cartilage defects" to describe a lesion through the calcified cartilage layer but not involving the subchondral bone plate (Figure 78-15).

Figure 78-15. A 15-mm-diameter full-thickness articular cartilage defect on the medial trochlea of the femur depicted through an arthrotomy.

It is believed that full-thickness defects greater than 3 to 5 mm^2 in surface area have a poor capacity for repair. In general, defects of this size range are difficult to identify grossly 1 year after they are created, whereas larger defects show good initial healing but degenerate within a year's time.[76,77] *Partial-thickness defects* are believed to have some minor capacity for healing, but typically they appear neither to be progressive nor to compromise joint function, and they are therefore not the focus of most cartilage repair procedures. Clinically, partial-thickness lesions are débrided of any surface fibrillation without débriding deeper. This is because currently used cartilage-repair processes do not provide a repair tissue that is clearly better than the tissue in a partial-thickness defect.

Historically, two different repair mechanisms are described for articular cartilage: intrinsic and extrinsic. Intrinsic, as the name implies, occurs from within the cartilage. Thus *intrinsic repair* relies on the limited capacity of the chondrocytes to divide and repair the damage. A type of intrinsic repair termed *matrix flow* describes healing lesions that have chondrocytes and surrounding matrix that appear to flow from the peripheral cartilage edges into the defect in an attempt to fill the lesion. Small defects appear to repair via this process. *Extrinsic repair* derives cells and other factors contributing to the repair process from sources other than the chondrocytes. One example is repair following surgical perforation of the subchondral bone plate, which is believed to allow stem or progenitor cells as well as growth factors access to the defect, thus enhancing the repair of large defects, which would otherwise exhibit poor healing.[19] The currently accepted method of subchondral perforation is called subchondral bone *microfracture.* Contrary to historic beliefs, mounting evidence suggests that progenitor cells may exist in the surface layer of articular cartilage, thereby challenging the distinction of intrinsic and extrinsic healing, although it is still accepted that large lesions most likely derive most of

TABLE 78-2. Synovial Fluid Cytology Corresponding to Various Clinical Conditions and Diagnostic or Therapeutic Manipulations

Parameter	Normal	Mild Synovitis (e.g., OCD)	Osteoarthritis	Septic Arthritis*	Arthrocentesis	Balanced Electrolyte Solution	Local Anesthetics†‡	Gentamicin†	DMSO† (10% Solution)
Total leukocytes (/μL)	50-500	20-250	≤1 × 10?	20-200 × 10^3	1-4 × 10^3	6-45 × 10^3 (typically 20 × 10^3)	2-10 × 10^3	8-40 × 10^3	6-20 × 10^3
Neutrophils (%)	<10	<10	<15	>90 (variable toxic changes)	50	80	60	50	>50
Mononuclear cells (%)	>90	>90	>85	<10	50	20	40	50	<50
Total proteins (g/dL)	0.8-2.5	0.8-3	0.8-3.5	4.0-8+	1.5-2.5	3-4	2.5-4	4.5-6	2.5-4

Listed ranges are approximate. Considerable variability exists in published reports.
*Significant elevations in leukocyte counts and total protein concentration occur within the first 12 hours in experimentally inoculated joints. Values shown represent those observed at 24 hours.
†Leukocyte counts and total protein concentrations correspond to the maximum values that typically occur within the first 24 hours.
‡Synovial response to lidocaine and mepivacaine are comparable.
DMSO, Dimethyl sulfoxide; *OCD,* osteochondrosis dissecans.

TABLE 78-3. Radiographic Features of Osteoarthritis

Radiographic Feature	Pathogenic Mechanism*
Periarticular osteophytosis	Endochondral ossification occurring at bony margins of unknown cause. Possible repair attempt modulated by altered cytokine milieu.
(Asymmetrical) joint space thinning	Cartilage degeneration and loss.† Usually at areas of weight bearing or high stress. May be absent when focal cartilage loss occurs.
Subchondral sclerosis	Deposition of new bone as a response to changes in force transmission and from healing of trabecular microfractures. Corresponds to areas of maximum stress. Significant sclerosis often corresponds to full-thickness cartilage loss.
Subchondral lysis	Less-common change of uncertain pathogenesis. Possibly pressure necrosis from synovial fluid gaining access to subchondral plate via fissures, or related to pressure necrosis from trauma to bone.
Osteochondral bodies	Disintegration of joint surfaces or fractured osteophytes. May represent inciting lesions (e.g., osteochondral fracture).
Advanced remodeling/ ankylosis	Articular response to advanced degeneration. Environment more consistent with fracture than synovial joint.

*Specific pathophysiologic mechanisms and reasons for disproportionate representation of changes among and between joints remain unclear.
†Seldom used as a marker of disease progression because of problems with technical aspects of radiographic positioning and focal-film distance.

their reparative capacity from extrinsic sources.[78] Another example of extrinsic repair is through the implantation of chondrocytes obtained from an external source, which are typically suspended in some form of scaffold and secured into the defect. Greater detail on specific cartilage repair procedures can be found in Chapter 80.

Repair of clinically significant lesions (i.e., greater than 5 mm in diameter), which requires extrinsic repair methods, appears to be hampered by a less-than-optimal aggrecan and type II collagen content and by a lack of re-formation of normal subchondral bone and calcified cartilage layers. As was previously described, all of these components are integral to the normal function of articular cartilage and hence the joint. Significant improvements in reestablishment of the type II collagen content and to some degree aggrecan have been made recently, but little has been done to improve, enhance, or even control the re-formation of the subchondral bone plate or calcified cartilage layer. Experimental defects have been shown to heal through an influx of granulation tissue, which is characterized by types I and III collagen, and by little proteoglycan or aggrecan in the first 6 weeks. The granulation tissue is then slowly replaced with increasing amounts of type II collagen and aggrecan by chondrocyte-like cells.[79] At best, a hyaline-like tissue is formed, but the biomechanical and biochemical properties of this tissue leave much to be desired. Although modern science has made great leaps in improving the *in vitro* character of tissue-engineered cartilage, the absence of normal physiologic mechanical stimuli appears to be a rate-limiting step *in vivo*, given the critical role it plays in tissue integration and long-term survival of these creations. Interestingly, it has been observed in humans that the quality of the repair tissue is not always directly correlated to the functional outcome of the patient. Thus less emphasis is now being placed on the regeneration of the articular cartilage and more on long-term improvement in function. In some older human patients, 5 years of dramatic pain relief, thus delaying joint replacement, is considered a success.[80]

CHAPTER
79 Medical Treatment of Joint Disease

David D. Frisbie

There are two main goals for medical treatment of osteoarthritis (OA) in the horse: reducing pain (lameness) and minimizing progression of joint deterioration. When formulating a treatment plan, the optimization of these goals is influenced by an accurate and specific diagnosis, the stage of disease, severity, available treatment modalities, and rehabilitation time. Clinicians realize that treating joint disease is an art and does not follow any specific recipe.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The use of nonsteroidal anti-inflammatory drugs (NSAIDs) for inhibiting the arachidonic acid cascade has been a mainstay for the treatment of joint disease for many decades. NSAIDs are typically used in cases of acute injury and are often accompanied by other treatment modalities. The renal and gastrointestinal side effects associated with NSAID administration limit their long-term use for treatment of joint disease. NSAIDs inhibit the production of prostaglandins and thromboxanes, especially the prostaglandin E (PGE) series, which is thought to be intimately involved in pain, altered cartilage metabolism, and ongoing inflammation in damaged joints (Figure 79-1).

Traditionally, inhibition of PGEs and the resulting symptomatic pain relief has been viewed as a beneficial goal in treating OA (Figure 79-2). Although relatively recent research has offered some suggestion that this inhibition may have long-term unfavorable effects on cartilage metabolism and does warrant further investigation, the current level of knowledge of these unfavorable effects most likely will not alter the use of NSAIDs in clinical practice.[1] Research has also suggested that NSAIDs may have a role in mediating joint pain at the level of the spinal cord as well as locally, although specific research in this area has not yet been conducted in the horse.[2] In the early 1990s, a major advancement in NSAIDs for treatment of OA occurred with the identification of isoenzymes for the cyclooxygenase (COX) pathway (COX-1 and COX-2), and this does have implications for current treatments in horses.

COX-1 has been associated with the housekeeping functions of the cyclooxygenase pathway. It is known to be constitutively produced and important in the balance of normal physiologic function of the gastrointestinal and renal systems, although it has a lesser role in the inflammatory cascade. COX-2 has mainly been associated with inflammatory events, especially those driven by macrophages and synovial cells, and has only minor roles in normal physiology, thus its "bad" or inducible role (Figure 79-3). These findings have led to a paradigm that the anti-inflammatory properties of NSAIDs are mediated through the inhibition of the COX-2 enzyme, whereas the untoward effects occur as a result of their action on COX-1.

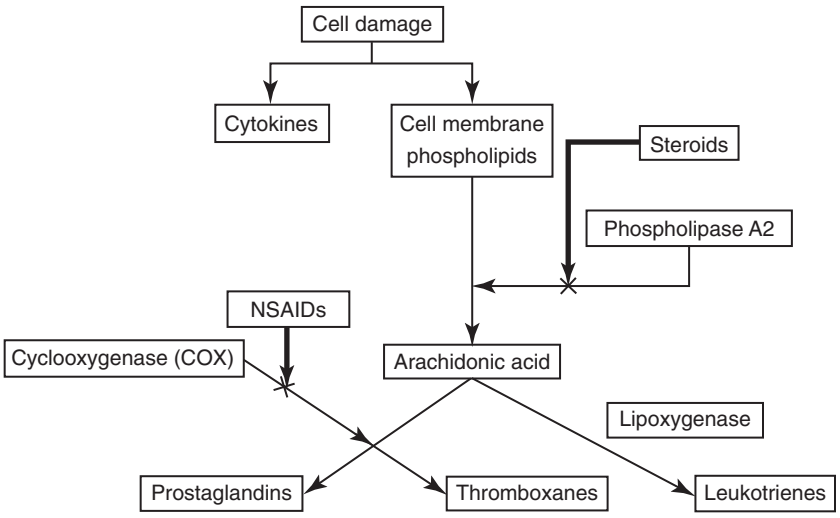

Figure 79-1. Schematic representation of inhibition of the inflammatory cascade by nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids.

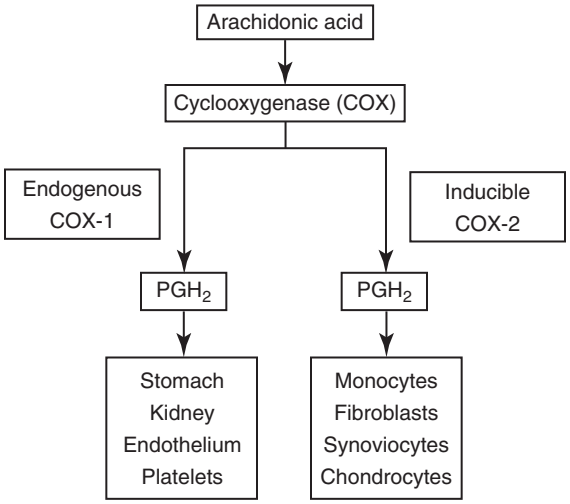

Figure 79-3. Schematic representation of the cyclooxygenase isoenzymes and target tissues. *PGH,* Prostaglandin H.

The protective role of COX-1 for the gastroduodenal mucosa has been shown both experimentally in laboratory animals and in human clinical trials. Furthermore, studies have shown that the greatest degree of damage to the gastroduodenal mucosa is generally caused by NSAIDs that preferentially inhibit COX-1.[3] In fact, the preferential COX-2 inhibitor rofecoxib (Vioxx) was shown in human patients to induce ulceration at a lower incidence than that produced in a randomized placebo group.[4]

As with most biological systems, complete inhibition of COX-2 may not be optimal; some value, albeit minimal, has been shown from expression of COX-2 as well as some demonstrable negative effects of COX-1 expression. More specifically, a low level of COX-1 expression is inducible during stress or inflammatory periods. Likewise, some constitutive expression of COX-2 has been demonstrated by the brain, kidney, and pancreatic islet cells, and it has a function in bone resorption. Furthermore, COX-2 suppression has been shown to delay gastric ulcer healing in rats. Thus, as Oscar Wilde said, "The pure and simple truth is rarely pure and never simple."

To summarize: COX-1 is mainly responsible for the protective prostaglandins, but COX-2 plays some accessory role that is more important than previously thought. However, these facts still might not outweigh the beneficial effects of selective COX-2 inhibition in joint disease.

Research in humans has indicated that topical NSAID application can be clinically beneficial and may reduce systemic side effects.[5] The effect of topical application of diclofenac liposomal suspension has been evaluated in both an equine clinical trial and a model of OA with promising results.[6,7] This product is indicated for horses with a finite number of affected joints, especially if prolonged treatment is not necessary.

Of products currently on the market, phenylbutazone remains one of the most popular NSAIDs for musculoskeletal pain in horses. Its cost, ease of administration, and relatively few side effects during short-term administration make it a good therapeutic choice. It should be noted that when phenylbutazone was compared to diclofenac cream during a 56-day treatment period in horses with OA, phenylbutazone was associated with significantly more pathology.[7] Thus the use of phenylbutazone to treat OA should most likely be limited to the acute period. Flunixin meglumine and ketoprofen both have uses in treatment of equine OA, especially with some reports of fewer side effects; however, the cost-to-benefit ratio often limits their use. Also the use of the first-generation COX-2 inhibitor carprofen (not U.S. Food and Drug Administration [FDA] approved for use in horses) had historically been indicated in horses experiencing side effects from NSAIDs or when extended treatment periods of these medications were expected, but now a selective COX-2 inhibitor (firocoxib) has been approved by the FDA and would be recommended.

Continued use of NSAIDs for treating acute inflammation associated with joint disease is likely for the foreseeable future. Selective COX-2 inhibitors such as firocoxib are being used more often for clinical applications. The NSAIDs currently prescribed in the horse are summarized in Table 79-1.

CORTICOSTEROIDS

More equine-specific research has been published on intra-articular (IA) administration of corticosteroids than any other equine joint medication. Since the introduction of IA corticosteroid use in the mid 1950s, controversy has existed over the risk-to-benefit ratio of this class of medication. Much of this controversy has been fueled from unsubstantiated statements in both the scientific and lay press. Studies showing potentially detrimental effects of corticosteroids on articular cartilage have been conducted using normal cartilage.[8] Current research suggests that inflamed or abnormal joints do not exhibit the

TABLE 79-1. Partial Listing of Currently Available NSAIDs*

Generic Name	Product Name	Formulations	Recommended Dosage (mg/kg)	Standard Availability	Cost
Phenylbutazone	Equi-Phar Phenylbutazone	1 g tablet	4.4 bid for 1 day, 2.2 bid for 4 days, 2.2 sid	Bottle 100 tabs	$9.98
	Equi-Phar Phenylbutazone injection 20%	Injectable 20%	2.2-4.4 bid (5 days)	100 mL	$8.89
	Phenylzone Paste	200 mg/g (20% paste), 12 g Rx	1-2.2 bid (4 days)	60 g	$8.95
	Phenylzone Paste	200 mg/g (20% paste), 6 g Rx	1-2.2 bid (4 days)	30 g	$4.78
Carprofen	Rimadyl	Injectable or tablets	0.7 daily (IV, PO)	Bottle of 180 tablets	$0.84/tablet
Flunixin meglumine	Flu-Nix D Rx (Flunixamine)	Injectable	1.1 daily (5 days) (IV, IM)	100 mL	$18.75
				250 mL	$38.50
	Banamine Paste	Paste	1.1 daily (5 days)	30-g tube	$21.17
Ketoprofen	Ketofen	Injectable	2.2 daily (5 days) (IV)	100 mL	$135.25
				50 mL	$80.76
Firocoxib	EQUIOXX	Paste	0.1 mg/kg daily (up to 14 days)	6.93 g syringe	$5.50

bid, Twice daily; *IM*, intramuscular; *IV*, intravenous; *NSAID*, nonsteroidal anti-inflammatory drug; *PO*, by mouth.

TABLE 79-2. Corticosteroids Commonly Used for Intra-articular Administration

Corticosteroid	Product Name	Manufacturer	Concentration (mg/mL)	Dose (mg)	Potency Relative to Hydrocortisone
Betamethasone sulfate	Celestone Soluspan	Schering-Plough	6	3-18	30
Triamcinolone acetonide	Vetalog	Solvay	6	6-18	5
Flumethasone	Flucort	Syntex	0.5	1.25-2.5	120
Isoflupredone acetate	Predef 2X	Pharmacia and Upjohn	2	5-20	50
Methylprednisolone acetate	Depo-Medrol	Pharmacia and Upjohn	40	40-120	5

detrimental effects seen in normal joints when corticosteroid is administered, potentially explaining some discrepancies seen in experimental studies conducted on normal tissues compared to clinical impressions.[8]

It is well documented that corticosteroids inhibit the arachidonic acid cascade by blocking phospholipase A_2 and that they are selective COX-2 inhibitors.[9] The selective COX-2 inhibition and low incidence of side effects may be reasons why this class of medication is so useful in the horse. The use of corticosteroids for joint disease often brings up questions about three issues in particular: which preparation to use, what dose to prescribe, and what length of rest period to recommend.

Currently, three main corticosteroid preparations are available to the equine clinician: methylprednisolone acetate (Depo-Medrol), triamcinolone acetonide (Vetalog), and compounded betamethasone sodium phosphate and betamethasone acetate (Celestone Soluspan, formerly Betavet) (Table 79-2). Compounded betamethasone has been difficult to obtain commercially in the United States, but it remains available in other countries. As a result, it has been compounded by various pharmacies; however, significant problems have resulted from the use of some of these formulations.

Experimental studies have provided a relatively good comparison of these three products and found that they are not equivalent.[10-12] The three preparations were tested using a relatively similar osteochondral fragment model. Results of this work indicated that the most beneficial effects were seen with triamcinolone, and some protective effects were associated with this preparation. Methylprednisolone did have beneficial effects, but detrimental effects on the articular cartilage were also demonstrated. Compounded betamethasone had no measured effects, which suggests that this preparation has a less-potent effect on joint tissues compared to triamcinolone and methylprednisolone. Compounded betamethasone might not have caused significant improvement because the newly developed experimental model might not have elicited sufficient lameness to evaluate a difference. These *in vivo* studies coupled with *in vitro* work have fueled the recommendation to use triamcinolone, especially in high-motion joints. A recent survey of American Association of Equine Practitioners (AAEP) members[13] suggests that practitioners are in fact using triamcinolone in high-motion joints. Further, this study suggests that when used, methylprednisolone is applied predominantly in low-motion joints.

Recent research has also focused on low-dose corticosteroid administration for the treatment of equine joint disease. It appears to take about a tenfold change in concentration to alter *in vitro* effects of corticosteroids. As an example, joint dose between 1 and 10 mg of triamcinolone or between 20 and 200 mg of methylprednisolone would respond in a relatively similar manner. However, *in vitro* studies have indicated that lower concentrations of these corticosteroids might not inhibit the catabolic pathways driving joint disease.[14] The currently recommended doses appear to be within an acceptable range given in published information (see Table 79-2).

Corticosteroids combined with hyaluronan are very commonly administered. This combination is based on limited scientific evidence but good clinical responses. Combination treatment was supported by 60% of recently polled equine practitioners, reinforcing the favorable clinical response.[13]

The exercise or rest period following treatment with IA corticosteroids is also somewhat controversial. The controversy is based on the ability of some corticosteroids to transiently decrease the anabolic metabolism of chondrocytes and potentially blunt the normal metabolic responses to exercise. Although this is a concern, it is most likely overstated. A decrease in chondrocyte anabolic rate has not been proved to be detrimental. Furthermore, studies have not identified gross or histologic lesions subsequent to IA corticosteroid administration and exercise; however, changes in biochemical and biomechanical parameters have been identified.[15,16] Changes induced by methylprednisolone have been noted to last for more than 21 days, and this information has influenced exercise recommendations for all other corticosteroids. Anecdotal recommendations for rest periods after IA corticosteroid injection vary widely from immediate return to work to more than 30 days of rest. Even a relatively aggressive protocol, involving a high dose of corticosteroids repeated at 14 days along with concurrent strenuous exercise, has failed to demonstrate definitive detrimental effects.[10-12] Thus a rest period might not be absolutely necessary. Anecdotal clinical impression does suggest that confinement to a box stall or paddock for 7 to 10 days, with a slow return to full work in the subsequent week, can prolong the duration of action following injection, but it does not appear to alter the effect of the treatment.

Some consideration should be given to the reported incidence of corticosteroid-induced laminitis; however, no direct association has been proved. It has been suggested that the total body dose of triamcinolone should not exceed 18 mg, methylprednisolone should not exceed 200 mg, and compounded betamethasone should not exceed 30 mg. These numbers are based on some facts and some fiction, but one of the main goals is to eliminate corticosteroid-induced laminitis. Two publications have challenged this doctrine. The first study with long-term follow-up on 205 clinical cases of joint injections using either 40 mg or 80 mg of triamcinolone acetonide found that the incidence of laminitis was effectively 0.5%.[17] The second 2000 cases were treated with 20 to 45 mg of triamcinolone, resulting in 0.15% of the cases having reported laminitis, and all but one were ponies.[18] Because it is not possible to have a consistent model of laminitis following corticosteroid injection, we must rely on clinical reports and anecdotal suggestions for dosing regimens. Based on published literature and clinical experience, I routinely use 20 to 40 mg total body dose of triamcinolone in a healthy athletic horse. The frequency of treatment should be considered, and these higher total body doses should not be repeated frequently, especially in unfit or overweight horses.

HYALURONAN

Hyaluronan (HA) (disaccharide composed of D-glucuronic acid and *N*-acetyl-D-glucosamine) is a normal and necessary component of synovial fluid and proteoglycan aggregates (aggrecan) (see Figure 78-10). Based mainly on *in vitro* work, both the concentration and molecular weight (degree of polymerization) appear to be important in the normal function of HA. Although the exact mechanism through which endogenous or exogenous HA exhibits an effect is not known, additional effects of exogenous HA administration have been documented to include anti-inflammatory activity, such as inhibition of chemotaxis, inhibition of phagocytosis of granulocytes and macrophages, and reduction in the stimulation, proliferation, and migration of lymphocytes. Hyaluronan has also been shown to decrease the formation and release of prostaglandins from macrophages and to scavenge oxygen-derived free radicals in a dose-dependent manner.[19] Researchers also hypothesize that exogenous administration of HA increases the synthesis of high-molecular-weight hyaluronate by the synoviocytes, a theory that is yet to be definitively proved. In addition, some questions exist about the molecular weight requirement for effectiveness of exogenous HA.

Assessing the literature suggests that molecular mass less than 500 kDa has little effect, whereas HA with a larger molecular mass demonstrates a dose-dependent response. Other studies have failed to correlate molecular mass to outcome parameters. Summarizing the current literature, it appears that some basal molecular mass is needed for effectiveness.[20] I therefore use products with molecular mass greater than 500 kDa and selects products with yet higher molecular mass based more on economic consideration of the client (Table 79-3).

Cross-linked exogenous HA has been introduced in an attempt to improve viscosupplementation of joints. Briefly, viscosupplementation refers to the injection of HA or its derivative in an attempt to return the elasticity and viscosity of the synovial fluid to normal or higher levels. Cross-linked HA has been developed as an improvement to other synthetic HA. Because its rheologic properties are increased, it has a longer retention time in the synovial space and appears to be more resistant to free radicals. Hylan G-F 20 (Synvisc-One), a cross-linked HA with a molecular mass on average greater than 6 MDa, has demonstrated favorable results in large multicenter human clinical studies, showing effectiveness as a nonsteroidal medication.[21-23] An experimental study conducted in the horse failed to show beneficial effects of hylan G-F 20, but it does cite the difference in acute experimental synovitis compared to the more chronic OA (in the human trial) as one possible explanation for the study outcome.[24] The authors also mention that the severity of the model may have been too harsh to observe a significant treatment effect. Further work on case selection for viscosupplementation (cross-linked HAs) is needed.

The dosage of conventional HA (0, 1, 10, 20, and 40 mg per joint) has been tested using an equine OA model.[25] This study demonstrated that a dosage of 20 mg per joint was needed to demonstrate improvement in degree of lameness measured using a force plate. Dose–frequency studies are based on work in human clinical patients, suggesting that at least three doses

TABLE 79-3. Partial Listing of Available Hyaluron Products*

Product Name	Manufacturer	Concentration	Molecular Weight (daltons)	How Supplied	Recommended Dose (for Small- to Medium-Size Joints)	Standard Availability	Cost
Hylartin V	Pfizer	10 mg/mL	3.5×10^6	2-mL syringe 20 mg	20 mg	Each	$54.16
MAP-5 (used intra-articularly at this dose)	Bioniche	10.3 mg/mL (2 mL) 5 mg/mL (10 mL)	7.5×10^5	2-mL vial 10-mL vial	20 mg	10 mL 2 mL	$37.93 $17.78
Legend (Hyonate) Intravenous/ intra-articular use	Bayer Corporation	10 mg/mL	3×10^5	4-mL vial	40 mg (IV)	Box of 6	$388.08
Hyalovet (Hyalovet 20)	Boehringer	10 mg/mL	$4\text{-}7 \times 10^5$	2-mL syringe	20 mg	2 mL	$42.79
HyCoat (used intra-articularly)	Neogen	5 mg/mL	$>1.0 \times 10^6$	10-mL vial	30 mg	10 mL	$37.17
Hyvisc	Boehringer	11 mg/mL	2.1×10^6	2-mL syringe	20 mg	each	$53.04
HY-50	Bexco Pharma	17 mg/mL	—	3-mL syringe	51 mg	each	$35.00

*Availability and costs are as of 2010.

are required (administered 1 week apart) to see significant effects in clinical parameters of pain and effusion. A recent blinded, randomized, placebo study evaluated a high-molecular-weight product (Hyvisc), in which horses with experimental OA were dosed three times, 1 week apart. Though no symptom-modifying effects were seen, a decrease in gross articular cartilage fibrillation as well as improvements in synovial membrane parameters were noted.[26] Thus the currently recommended equine HA treatment protocol is 20 mg of HA once a week for 3 weeks. It appears that HA may be more effective when used in cases of mild synovitis or capsulitis and not as effective in severe synovitis or capsulitis and chronic OA.[26,27]

The use of intravenous (IV) HA in the treatment of joint disease is very common. An experimental study documented improvement in clinical lameness and synovial membrane histology, as well as better synovial fluid parameters, such as lower PGE_2 and total protein levels in a carpal chip model.[28] These improvements were seen 42 days following the last of three treatments (40 mg) that were given 1 week apart.

Research to elucidate the mechanism of action for IV HA has been conducted, although relatively few answers have been found. A recent survey of 20 equine practitioners did not reflect an overwhelming usefulness of IV HA; however, case selection or objective outcome parameters were not clearly defined.[13] From both scientific and anecdotal reports, it appears that the use of IV HA in cases of acute synovitis could yield a better chance for success than in cases of chronic OA, where significant cartilage loss is present.

The prophylactic use of IV HA has also been studied in both Quarter Horse and Thoroughbred racehorses. The Quarter Horse study enrolled 140 horses; subjects received either IV saline or HA every 2 weeks for the duration of the 9-month study.[29] HA-treated horses tended to race longer before requiring the first joint injection and to have a better speed index, higher average number of starts, and more money earned compared to placebo-treated horses. Anecdotal reports from trainers in various equine disciplines have been positive regarding the prophylactic use of IV HA.

POLYSULFATED POLYSACCHARIDES

Polysulfated polysaccharides include polysulfated glycosaminoglycan (PSGAG; Adequan), GAG peptide complex (Rumalon), and pentosan polysulfate (Cartrophen Vet; Pentequin). These drugs have been referred to as exhibiting chondroprotective effects or, by more recent definitions, are slow-acting, disease-modifying osteoarthritic drugs (SAMOADs). Such agents are meant to prevent, retard, or reverse the morphologic cartilaginous lesion of OA.

PSGAGs are manufactured from bovine lung and trachea extracts containing mainly chondroitin sulfate. Numerous equine studies have been carried out *in vitro* and *in vivo* using PSGAGs and have had contradictory results.[30,31] Some studies have shown PSGAGs to inhibit many of the key enzymes or cytokines involved in OA, including interleukin 1 (IL-1), matrix metalloproteinases (MMPs), and PGE_2, and to affect proteoglycan synthesis and degradation.[31] Because the testing systems, duration of experiments, and dosages varied from study to study, direct comparisons are difficult. The precise mechanisms of action of PSGAGs are uncertain, and the interaction of PSGAGs with cytokines involved in joint disease has not been well defined.[20]

Some of the earliest work involving IA PSGAGs in the horse investigated the effects of administering 250 mg biweekly for 3 weeks in clinical cases. This study and others using models of acute synovitis have shown improvements in clinical disease parameters following PSGAG treatment.[32-35] One study also looked at cartilage histology, observing improvement in chondrocyte morphology. The same authors, using a similar model, also tested PSGAG via an intramuscular (IM) route with less

impressive results.[20] In a group of ponies with experimentally induced osteochondral lesions, IA PSGAGs (250 mg once a week for 5 weeks) significantly improved clinical lameness, radiographic progression of OA, and joint capsule parameters, compared with untreated ponies. However, PSGAGs also reduced the endogenous repair of the cartilaginous lesions.[28] Therefore, care should be taken when using PSGAGs in cases where significant cartilage lesions exist on weight-bearing surfaces.

In an experimental study, IM PSGAGs administered every fourth day for 28 days, starting 14 days following OA induction, demonstrated some improvement in clinical lameness 56 days after initiation of treatment.[36] Although PSGAG-treated horses did show biochemical improvements compared to placebo-treated horses, overall more impressive improvements were observed with shock wave treatment of the affected joint (see "Extracorporeal Shock Wave Therapy," later). The study was repeated using an IA route of administration once a week for 3 weeks and did in fact show significant improvement in reducing synovial effusion and improvement of synovial membrane parameters when compared to placebo.[37] This further suggests a more potent response when used IA versus IM.

A survey to assess the perceived efficacy of PSGAGs by 1522 equine practitioners was published in 1996.[27] Practitioners treating Thoroughbred racehorses gave the highest efficacy scores, and practitioners treating pleasure horses gave the lowest efficacy scores. PSGAGs were considered more effective than hyaluronan for the treatment of subacute OA and less effective for idiopathic joint effusion and acute synovitis. The authors of the survey concluded that the efficacy of PSGAGs for incipient and chronic forms of OA is comparable to that of hyaluronan.

Important information has been published indicating that a lower bacterial inoculation is needed to establish septic arthritis when PSGAGs are administered IA.[38,39] This result is abolished with the addition of 125 mg amikacin to the PSGAG treatment. Therefore, administration of amikacin with PSGAGs administered IA is strongly recommended.

Like PSGAGs, pentosan polysulfate (PPS) is a heparinoid compound, but it is unique in that it is derived from beech wood hemicellulose instead of the animal or bacterial sources used for PSGAGs. These products have been administered mainly in horses in Australia, although efficacy reports have been anecdotal. To my knowledge, sodium pentosan polysulfate has been used only parenterally in horses. Although a form has been complexed with a calcium salt and tested in other species, the results indicate that pentosan appears to be bioavailable following oral administration. Clinical studies in dogs and people with OA have shown convincing evidence of clinical efficacy.[40] In the horse, an unpublished study using an experimental model of OA has shown favorable results.[41] In this model, parenteral PPS showed significant improvement in reducing articular cartilage fibrillation and a strong trend for overall improvement in the histologic appearance of cartilage. Furthermore, most parameters showed numerical improvements (lameness, joint flexion, synovial fluid total protein, synovial fluid collagen degradation products, and aggrecan synthesis), although statistical significance of greater than 95% was not obtained.

Clinically, PPS could be used to treat horses with mild or early-stage OA, particularly with multiple joint involvement, because it is a systemic therapy. At this time, a dosage of 3 mg/kg IM once weekly for 4 weeks is recommended for treatment of equine OA.

ORAL JOINT SUPPLEMENTS

A vast number of oral supplements are available for the horse. Many of these work on the premise of providing building blocks of molecules that are integral in the articular cartilage or joint fluid. Although the formulation, concentration, and source of the products differ widely, most contain chondroitin sulfate, glucosamine, or hyaluronan, or some combination thereof. Chondroitin sulfate has been assessed using radioisotope tracking and shown to be absorbed through the gastrointestinal tract, but it is thought to be in a smaller monomeric form compared to the ingested molecule. Glucosamine is even more bioavailable than chondroitin sulfate.[41-45]

A study was conducted to document absorption specifically in the horse, but how these levels relate to clinically therapeutic levels is yet to be determined.[42] Double-blinded controlled studies in humans have indicated that these substances are efficacious in the treatment of joint disease.[46-49] Unfortunately, only limited, poorly controlled equine clinical studies have been performed to date, but anecdotal reports and *in vitro* tests are favorable for the use of glucosamine and chondroitin sulfate.[50]

Oral hyaluronan products are relatively new on the market and have been tested less compared to chondroitin sulfate or glucosamine. However, a controlled experimental *in vivo* trial comparing IV Legend and Conquer, an oral hyaluronan, is under way. An interesting report in the human literature compared the label ingredient with the independent testing of the products and found little correlation to label claim and content or price and content. This potentially emphasizes the use of trusted brands that have at least undergone some testing.

Laboratory and live animal work as well as a human clinical trial have shown beneficial effects of oral avocado and soya unsaponifiables (ASU) on joint disease.[51] Likewise an equine-specific study showed significant improvement in the gross joint and cartilage health in response to oral ASU administration in horses with OA.[51] Platinum and Cosequin ASU are currently commercially available but provide 2 and 1 g/day respectively, compared to the 6 g/day administered in the experimental study showing efficacy.[51]

EXTRACORPOREAL SHOCK WAVE THERAPY

Recent experimental evidence and anecdotal clinical impressions of extracorporeal shock wave therapy (ESWT) for the treatment of OA have been reported.[52-54] Unpublished clinical studies in the dog have shown promising results, as have anecdotal reports of treating shoulder, pastern, and coffin joint OA in horses.[36] An equine-specific, controlled experimental OA study has been completed comparing ESWT to PSGAGs and sham treatments.[55] The study used an established short-term (70 days) OA model where an osteochondral fragment was created at time zero and treatments were initiated 14 days later.[12] IM PSGAG treatment was administered every 4 days for 28 days. ESWT was administered on days 14 and 28 using a VersaTron 12-mm probe, and a sham shock wave procedure was performed on the control horses on days 14 and 28. In the ESWT group, 2000 shock waves at the E4 energy level were administered on study day 14 and 1500 shock waves at the E6

level on study day 28. The energy was delivered mainly to the middle carpal joint capsule attachment, but some energy (approximately 20%) was delivered to the area of fragmentation. Significant improvement in clinical lameness, decreased synovial fluid total protein (as a marker of synovitis), and reduced GAG release into the bloodstream were observed with ESWT compared to both control and PSGAG-treated horses. These results appear to show promise for this type of therapy for use in localized joint disease in horses, although clinical studies are still needed.

BIOLOGICAL THERAPIES

Since the 1990s, research has led to a greater understanding of joint pathophysiology and identification of major mediators driving the disease process. Also, the identification of naturally occurring antagonists or synthetic analogs with the ability to block these degenerative mediators has been realized. Numerous novel medical treatments are being tested *in vivo* after successful *in vitro* trials.[56,57]

Treatment of generalized OA using novel methods of administering antiarthritic therapeutic proteins is one of the most rapidly expanding areas in treating equine joint disease. Given that the inhibition of IL-1 and tumor necrosis factors (TNFs) has been shown to be clinically beneficial, practical methods of administering these therapeutics *in vivo* are being explored. Specific examples that have shown clinical success in people with either rheumatoid arthritis or OA are the administration of IL-1 receptor antagonist (IL-1Ra, a natural antagonist of interleukin-1), soluble receptors to TNF (receptors that bind the parent molecule but have no further biological action), and antibodies directed at TNF.

In one study conducted in the horse, the administration of *autologous conditioned serum* (ACS), or interleukin-1 receptor antagonist protein (IRAP) (another abbreviation of IL-1Ra) as it is commercially known, resulted in demonstration of both beneficial symptom- and disease-modifying effects.[58] Though ACS has been shown to increase IL-1Ra levels, many other proteins are also upregulated during the 24-hour culture period. The specifics of this process are currently under investigation. Clinically, anecdotal reports of significant improvement in horses following treatment with ACS have been seen even in joints that are or have become unresponsive to corticosteroids. In some horses ACS is being used as a primary treatment of OA.

Platelet-rich plasma (PRP) has also recently been used to treat joint disease. However, little proof from basic science is currently available to support its use over a biological treatment such as ACS. It is most likely because of the decreased time (does not require a 24-hour culture period) and increased convenience (can be done in the stall with home commercial products) of PRP that this treatment is being used clinically. Further research on the beneficial effect of PRP in the equine joint is needed.

Stem cells are also now being used to treat equine joint disease. Early work using labeled *mesenchymal stem cells* (MSCs) has shown they do have an affinity for damaged joint tissues, and more recent *in vivo* studies have confirmed their ability to localize and participate in repair of damaged joint structures, including cruciate ligaments, menisci, and cartilage lesions.[59] Most of the *in vivo* studies using MSCs have focused on meniscal repair. In some cases, MSCs are delivered on a carrier or scaffold, whereas in others, they are directly injected into the joint.[60-62] These studies have shown positive outcomes when bone marrow–derived cells are used to treat meniscal damage. The degree of damage has ranged from experimental meniscal lacerations treated with bone marrow aspirates, separating and using only the nucleated cells,[63] to total medial meniscectomy treated with injection of bone marrow–derived and culture-expanded MSCs.[61] Early work indicated that MSCs deposited in a fibrin matrix would be useful in improving cartilage healing. Although a recent equine study demonstrated early benefit, no significant differences were noted when treatment using MSCs and fibrin was compared to fibrin alone at 8 months.[64] Based on this work, it appears likely that the matrix or cells will need to be modified to achieve long-term benefit of MSCs for cartilage repair.

Although a goat study demonstrated regeneration of the meniscus, it was aimed at evaluating the *in vivo* effects of IA stem cell injection on decreasing the progression of OA.[61] This study used medial meniscectomy and cranial cruciate transection to induce OA. The investigators concluded that the decrease in OA seen in the study appeared to be secondary to the regeneration of the medial meniscal tissues, which was dramatic in seven of nine cases. However, the design of the study did not lend itself to determining if the stem cells had a direct effect on the articular cartilage and progression of OA. Thus the authors completed an equine study that used an osteochondral fragment with bone and cartilage debris to induce OA,[65] unlike the study mentioned earlier, which relied on joint instability (medial meniscal model) to create secondary OA. The results of this study indicated significant improvement in synovial fluid PGE_2 levels in response to treatment with bone-derived cells. Also demonstrated was a negative response via an increase in synovial fluid TNF concentrations in response to adipose-derived cells. The beneficial response seen with bone-derived cells overall was interpreted as a nominal improvement in symptom or disease-modifying effects.[65] The results of this study combined with the meniscectomy study[61] suggest that the regeneration of the medial meniscus in the goat study may have been the reason for slower OA progression. These studies also suggest that MSCs by themselves do little to counteract the progression of acute OA mediated by enzymatic degradation and joint debris. It would appear that modification of the MSCs is needed if they are to be useful in treating OA. Treatment timing relative to the degree of pathology could also contribute to the insignificant results of the equine study. Specifically, because MSCs appear to have a tropism for damaged cells, including fibrillated articular cartilage, it may be that at day 14 (day of treatment) the degree of fibrillation was not great enough for an effect of MSC treatment to be realized. Evaluation in cases with more-advanced fibrillation would need to be conducted to answer this question. Because significant improvement in acute OA could not be demonstrated following IA treatment, I have a dampened enthusiasm for the use of MSCs in clinical cases of acute OA. I did conclude that the use of MSCs appears to be indicated with loss of soft tissue structures leading to instability, such as with meniscal damage, and have pursued this treatment modality specifically in a multicenter clinical trial.

The results of this prospective multicenter trial are promising.[66,67] Currently 39 cases have been treated with IA administration of autologous bone marrow–derived MSCs with a mean follow-up time after treatment of 21 months. Cases selected for this trial were meant to have failed routine treatments, be moderate to severely affected, and have surgical confirmation of the

diagnosis. Seventy-seven percent returned to some level of work. Thirty-six percent (14/39) returned to or exceeded their prior level of work, 36% (14/39) returned to work at a lesser level or required some level of additional medical treatment in the affected joint, and 28% (11/39) did not achieve the work status held before follow-up.[67] Stifle injuries accounted for 29 of the 39 of the cases. This work is an extension of the study previously presented in 2007 where there were 15 cases with 6-month follow-up and a 67% return to work.[67,68] These data suggest further exploration of MSCs for the treatment of joint-related soft tissue pathology. For additional information on biological therapies please review Chapter 8.

CHALLENGES OF MEDICAL MANAGEMENT IN EQUINE JOINT DISEASE

Some of the considerations in treating equine joint disease have been presented in this chapter. Challenges that equine clinicians face are numerous, but the rapid evolving knowledge of joint disease pathophysiology, the relative lack of specific equine research, economic considerations of the owner, and rules imposed by governing bodies of sanctioned equine events pose a unique set of challenges. More specifically, the pathophysiology of joint disease is extremely complex; the multifactorial nature of the disease presents additional experimental complications, and at best it is only partly understood in any species.[69,70] Even with the greatest understanding of the disease being in people, human physicians do not agree upon a course of treatment based on the joint affected, stage of disease progression, or age of the patient. Further removed is the equine practitioner, who is often making therapeutic decisions based on extrapolations from human studies and therapies, comparisons that are not always justifiable.

The lack of specific equine research often drives the need to extrapolate from other species on the class of substance to use, specific compound within a class (e.g., a specific corticosteroid), dose, and frequency of administration, and in some cases, a combination of medications are recommended. The equine clinician is often left to make a plan based on anecdotal information rather than substantial evidence showing safety or efficacy of a specific regimen. Advances in equine-specific studies are occurring, thus confirming or refuting many anecdotal or uncontrolled published studies, although as expected, much work is left to be completed.

Other factors do play a role in arriving at a therapeutic plan, but some of them have little to do with the defined treatment goals. Economic consideration and medication rules governing many sanctioned equine events are two such examples. The coordination of all of the presented factors and issues into a sound, effective therapeutic plan are what makes treatment of equine joint disease challenging. Through an understanding of the historic and current literature, anecdotal information, and up-to-date rules pertinent to equine events, advancements can be realized in the treatment of equine joint disease.

CHAPTER 80

Surgical Treatment of Joint Disease

David D. Frisbie

Over the last decade, significant advancements have been made in the understanding of medical and surgical treatment of equine joint disease. Many of these advances originally were aimed at helping humans, but the principles have been adapted for use in the horse. Advances in understanding pathophysiology, novel surgical techniques, improved surgical equipment, and more-sophisticated imaging modalities have led to improved treatment of joint disease.

It is important to focus on the two main treatments for joint disease: the relief of pain to regain functional use of the diseased joint and the arrest of disease progression. In many cases, generalized osteoarthritis (OA) is treated using medical management and exercise protocols, whereas full-thickness articular cartilage damage usually involves some surgical intervention.

SURGICAL TREATMENT

Diagnostic and Surgical Arthroscopy

Equine arthroscopy was first described as a diagnostic tool to visualize lesions that were undetectable using radiography or other routine imaging procedures, but it was soon employed for therapeutic purposes, such as surgical removal of osteochondral fragments. Arthroscopy is now considered part of routine equine surgery and has, for the most part, replaced arthrotomy. It allows better visualization of the joint anatomy and inflicts less damage to the joint capsule and surrounding tissues, leading to quicker return to use and a more favorable outcome for the horse.[1] Since the 1980s, various publications have described arthroscopy in the horse; many of the early publications only described various techniques and approaches to joints, with more detailed outcomes and prognoses for specific pathologies following in subsequent publications. Most of the published work has been compiled in equine-specific texts.[1,2] The equipment used for arthroscopy and the surgical technique is discussed in Chapter 13.

Arthroscopy has a diagnostic and a therapeutic function in joint disease. Even with modern imaging modalities, it is still considered the gold standard for diagnosing equine joint problems. The cost and availability of arthroscopic equipment, along with arthroscopy's specificity and sensitivity when compared to more-complex imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI), and the expertise needed to perform definitive joint ultrasonography, will likely keep arthroscopy in the forefront of diagnostics for equine joint disease for many years. This is especially true in cases that show no demonstrable or questionable joint lesions using traditional imaging modalities, even though the horse has localized clinical pain based on diagnostic analgesia.

In recent years, additional joint pathology, such as meniscal and cruciate lesions, has been described. This may be because diagnostic arthroscopy, especially in the stifle joint, has become more accepted. Therefore, these types of lesions, which are not detectable using radiography, are being recognized more often. With an increased awareness of how often these types of lesions occur, further work is being focused on therapeutic treatments. This is especially true in the field of cartilage resurfacing and meniscal pathology, with many of the therapeutic avenues pursued in equine practice representing the current state of the art in human medicine.

Another advantage of the use of arthroscopy is the potential benefit of lavage. Arthroscopy is often performed using fluid to distend the joint for better visualization. The accompanying egress of joint fluid, which potentially contains cytokines and cartilage wear particles, may be therapeutically beneficial, even when lavage is performed as a sole treatment in cases of osteoarthritis. However, the benefit of lavage is controversial, and it does not work in cases with significant definable disease such as meniscal tears. Research also has shown that when lavage is performed with large-gauge needles (14 gauge), it is not as effective as using arthroscopic cannulas.[3-5] Distention of the joint can be accomplished using inert gas, which can be especially helpful if bleeding of intrasynovial tissues impairs visualization when a fluid medium is being used.

In general, arthroscopy is of more therapeutic benefit in acute than in chronic cases. For example, removing a freshly detached osteochondral fragment before OA can develop typically produces a better outcome than waiting until after OA has developed to remove an osteochondral fragment that has been present for some time. However, there are some indications that specific chronic pathologies, such as osteonecrosis and cartilage fibrillation of the third carpal bone, can be successfully managed using arthroscopy.

Another consideration regarding arthroscopic surgery is the documentation of the surgical procedure. Since the 1990s, reduction in cost and increase in availability of video and still-capture devices have allowed real-time documentation of arthroscopic surgery to be made and kept as part of the medical record. This real-time information is embraced by trainers and owners as a means of understanding the pathology and treatment procedures, as well as providing more specific information about the surgery.

Removal of Osteochondral Fragments

In most instances, osteochondral fragments are removed when they are diagnosed in conjunction with clinical lameness. Some fragments are considered relatively benign, and removal is not indicated without clinical lameness.[1,6,7] The routine use of arthroscopy has improved the outcome of osteochondral fragment removal as compared to removal using arthrotomy. Outcomes related to osteochondral fragment removal are presented in Table 80-1, and specific anatomic landmarks relating to arthroscopic approaches to the different joints can be found detailed in this text and in published references.[1]

In general, diagnostic visualization of the entire joint cavity is performed before fragment removal (Figure 80-1). When multiple fragments are present, typically the smaller fragments are removed first. This postpones the need to increase the size of the instrument portal and delays the potential for subsequent

TABLE 80-1. Prognosis* for Racing or Athletic Soundness Given by Various Authors for Intra-Articular Osteochondral (Chip) Fractures† in Various Locations and Joints

*The prognoses have been graded as excellent (80% to 90% chance of athletic soundness), good (60% to 80%), guarded (40% to 60%), and poor (<40%) and usually refer to the ability to race after injury. These are approximate percentages extrapolated from the literature because these categories are not always used by each author and a definition of these categories is not usually given. "Favorable" has been graded with "good." In general, the prognosis given is for horses with no radiographic signs of osteoarthritis (i.e., the horse is given its best chance of recovery).

†These fractures do not cause major joint instability.

‡*a,* Arthrotomy; *b,* arthroscopy.

§Guarded to good used when the percentages spanned 2 ranges.

¶HR, Hazard ratio was used to compare the racing performance of the treated with that of a control group, taken from the race horse registry for the same period. A hazard ratio of approximately 1 means that the same number of treated horses dropped out of racing as the controls. A hazard ratio of 2 means that twice as many treated horses were lost as the controls.

C3, Third carpal bone; *DIP,* distal interphalangeal; *HR,* hazard ratio; *IC,* intermediate carpal bone; *M,* medical; *P,* phalanx; *RC,* radial carpal bone; *S,* surgical.

reduced visualization until the end of the surgery. Very large fragments can be broken into smaller pieces using a rongeur or osteotome to prevent the need for excessive portal size. Hand curettes are typically used to débride the parent bone down to the appropriate level as well as to smooth any edges that might traumatize opposing joint surfaces postoperatively. Before finishing arthroscopic surgery, typically the joints are lavaged with fluids while a final inspection of the joint is completed to ensure all debris has been removed. Debris often accumulates in certain locations within a specific joint, and knowledge of these locations often aids in finding debris that has inadvertently escaped removal by lavage alone.

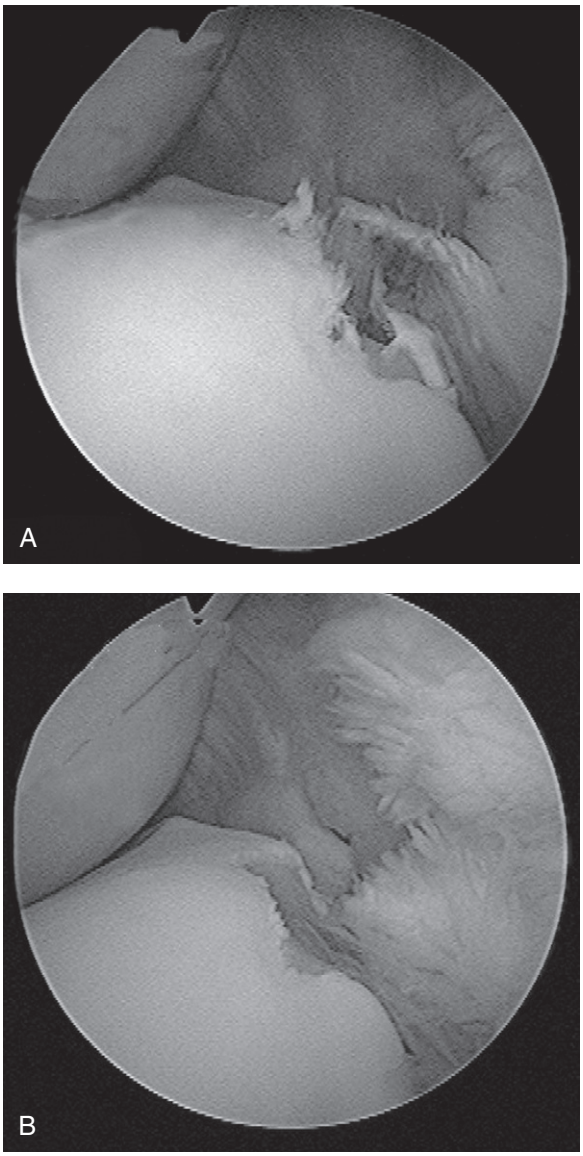

Figure 80-1. Arthroscopic image of a chip fragment off the distal radial carpal bone before **(A)** and after removal **(B).**

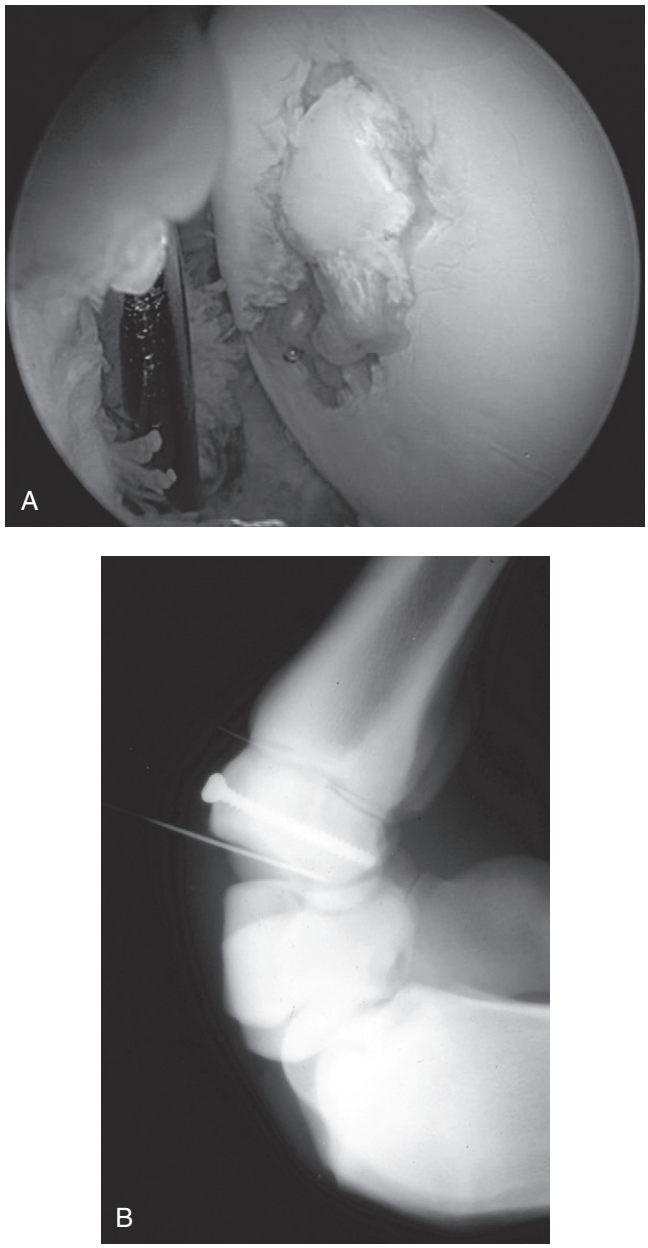

Figure 80-2. A, Arthroscopic image of a slab fracture of the third carpal bone before reduction. **B,** Lateromedial radiographic view of the slab fracture seen in **A** after reduction and fixation using a 4.5-mm cortex screw in lag fashion.

Reconstruction of Intra-Articular Fractures

Once damaged, bone can be repaired so that it is indistinguishable from the original tissue. However, articular cartilage does not have the same ability to heal. Therefore correct anatomic alignment and reconstruction of the fracture gap, especially the articular component, is integral to the repair process and determines the long-term resolution of intra-articular fractures.

Arthroscopic visualization during the reconstruction of the articular component of the fracture is recommended to ensure the best possible outcome in a high-motion joint. In many cases, loose debris is removed and flushed from around and in the fracture gap, allowing more anatomically correct reduction and better stabilization of the fracture. In some cases, such as with slab fractures of the third carpal bone, assessment of the articular component dictates the surgical procedure, namely repair or removal of the fracture fragment (Figure 80-2).

Common intra-articular fractures encountered in equine athletes are condylar fractures of the third metacarpus (MCIII) and third metatarsus (MTIII), third carpal bone slab fractures, and sagittal fractures involving the proximal phalanx. Most cases of intra-articular fractures are repaired using internal fixation with screws inserted using lag technique (see Chapter 76). These fracture repairs are covered in other chapters of the text, but some treatments and outcomes are listed in Table 80-2.

Synovectomy

Equine synovium is occasionally removed locally (partial synovectomy) to help arthroscopic visualization, but synovectomy can also be performed as a therapeutic treatment, most often in cases of septic arthritis. With sepsis, the synovial membrane can be laden with fibrin. Fibrin is thought to harbor bacteria; thus removal of the involved synovium is thought to aid in the treatment and potentially prevent recurrence of the septic process.

TABLE 80-2. Prognosis* for Racing or Athletic Soundness Given by Various Authors for Intra-Articular Fractures

Fracture Location and Type	Treatment†	Prognosis	Reference

*The prognoses have been graded as excellent (80% to 90% chance of athletic soundness), good (60% to 80%), guarded (40% to 60%), and poor (<40%) and usually refer to the ability to race after injury. These are approximate percentages extrapolated from the literature because these categories are not always used by each author and a definition of these categories is not usually given. Favorable has been graded with good. In general, the prognosis given is for horses with no radiographic signs of osteoarthritis (i.e., the horse is given its best chance of recovery).

†Articular fractures of long bones (except for the metacarpus and metatarsus) have not been included because of insufficient numbers from which to derive prognoses or other complicating factors, or both.

‡All fractures repaired surgically with stab incisions or arthrotomies, or both, except C3 slabs, in which repair was guided by arthroscopic visualization. Two grades are given when percentages spanned two categories.

Adapted from Caron JP: Principles of Treatment of Joint Disease. p. 678. In Auer JA, Stick J (eds): Equine Surgery. 2nd Ed. Saunders, Philadelphia, 1999.

Some septic equine joints appear to produce more fibrin than others (tarsocrural, distal interphalangeal, and elbow joints are among the most prolific), which requires visualization of the joint space and synovectomy rather than ingress–egress flushing using large-gauge needles. In some cases of chronic osteoarthritis, marked hypertrophy of the synovium can be encountered, and current practice is to perform a subtotal or complete synovectomy of the affected membrane to reduce cytokine production as well as physical impingement. The carpal joints and the metacarpophalangeal and metatarsophalangeal joints appear to benefit clinically from this type of treatment.[8]

The role that the synovial membrane plays in equine joint disease is not as well characterized as it is in humans. In human osteoarthritis, the synovial membrane is thought to play a secondary role to the cartilage lesion in the pathogenesis. Conversely, in rheumatoid arthritis, the synovial membrane is thought to be the primary instigator and to propagate the ongoing degeneration of the cartilage. Thus an effective method of controlling rheumatoid arthritis in people is through synovectomy, although it has a limited duration of clinical effectiveness.[9-12] A rheumatoid condition has not been identified in the horse.

Different methodologies have been used to accomplish synovectomy, including use of surgery, chemicals, and radioisotopes. Typically, surgical methods in horses use motorized synovial resection. Experimentally, synovectomy has been performed in normal horses and has shown no ill effects, but the regeneration of the synovial membrane was slower than expected when compared to other species.[8,13,14]

Joint Resurfacing

Partial-thickness lesions and full-thickness articular cartilage lesions greater than 5 mm in diameter do not heal spontaneously in the horse. In spite of the recent interest in assessing treatments for chondral defects, efforts have been under way for more than 250 years to heal articular cartilage with only moderate progress.[15] The reason is related to the highly specialized nature of articular cartilage and the need for an intact structure to perform its biochemical and physiologic functions.

Damage to articular cartilage is common in horses and typically is described in two forms: chronic degenerative lesions and acute damage. Chronic lesions are often considered OA, and whereas these lesions would benefit from joint resurfacing, this

type of lesion is the most challenging in which to achieve long-term repair because of generalized joint pathology that is not addressed with most current joint-resurfacing techniques. Conversely, acute lesions typically comprise a discrete or focal area of cartilage loss without other chronic manifestations of joint degeneration. Such lesions are currently best treated with equine joint resurfacing techniques.

The outcome of cartilage repair is typically assessed on biochemical content (including type II collagen and aggrecan), histologic appearance (resemblance to hyaline cartilage), biomechanical properties, and functional outcome of the joint and patient. As a general rule, it appears that cartilage in younger patients has a better capacity for repair compared to that of older patients.

When intra-articular osteochondral fragmentation occurs in the horse, surgical treatment involves removal of the fragment and débridement of the damaged cartilage and subchondral bone. In general, because of a generalized poor regenerative response, articular cartilage is usually minimally débrided, doing no more than is necessary to remove damaged cartilage. Partial-thickness cartilage lesions are typically not converted into full-thickness lesions, but rather the fibrillated cartilage is removed, leaving the intact cartilage below the fibrillated cartilage in place. In the case of a full-thickness lesion, the edges of the damaged articular cartilage are débrided until cartilage that is firmly attached to the subchondral bone plate is reached. The edges of the cartilage are débrided so that they have a sharp vertical border. The bone is always débrided down to a level of the subchondral bone plate so as to fully remove the calcified cartilage, which has been shown to impede the repair process. When necrotic bone is encountered, it is débrided aggressively to ensure that healthy bleeding bone is being left in the lesion.

Chapter 79 covered general concepts regarding treatment based on the lesion depth, size, and basic repair or treatment options. Two basic approaches are historically considered in joint resurfacing: stimulated endogenous repair and transplantation or grafting of tissues. Although these techniques are covered as separate entities, many cutting-edge approaches are combining the techniques as well as augmenting either or both techniques with growth factors.

Stimulated Endogenous Cartilage Repair

Because bone marrow has a good supply of both stem cells and growth factors thought to be integral to cartilage health and repair, direct communication of articular lesions to these elements beneath the subchondral bone plate has been a cornerstone of stimulated cartilage repair. Growth factors believed to be important in cartilage repair include insulin-like growth factor-1 (IGF-1), transforming growth factor-β (TGF-β), and bone morphogenetic proteins (BMPs) 2 and 7. Access to these marrow elements has been facilitated by various surgical techniques, including *abrasion arthroplasty*, which involves débridement to the level of the subchondral bone plate; *spongialization*, which is débridement past the subchondral plate into cancellous bone; focal drilling to the depth of cancellous bone in discrete locations throughout the cartilage lesion (*osteostixis*); and subchondral bone *microfracture*, which also penetrates to the level of the subchondral bone in discrete locations. Current literature and clinical practice do not favor spongialization, in part because it is thought to destabilize the subchondral bone plate.[16,17]

Based on the human and equine literature, the current recommendations for stimulated endogenous repair of an articular lesion are débridement of lesions to the level of the subchondral bone plate (abrasion arthroplasty) alone or in conjunction with subchondral bone microfracture.[17] If the lesion crosses the subchondral bone plate into the cancellous bone, the addition of subchondral bone microfracture is probably not necessary. In the presence of sclerotic bone, the lesion is débrided to a depth that produces petechial bleeding (in the absence of fluid pressure) but does not enter the cancellous bone. In this case, subchondral bone microfracture is also used.

Currently, subchondral bone plate drilling is not widely used based on subsequent formation of subchondral bone cysts and poor histologic appearance of repair tissue, especially when compared to other, more recently developed techniques such as subchondral bone microfracture.[18,19] The greater depth of penetration, smooth penetration through the bone, and heat generated with the drilling process probably contribute to the less-than-optimal tissue repair. Bone cyst formation associated with the drilling technique is probably a result of synovial fluid movement into the bone through the drill holes (see Chapter 89).

Subchondral bone microfracture allows access to the cells and growth factors beneath the subchondral plate, without disrupting the subchondral plate's biomechanical stability (Figure 80-3). In addition, the penetration of the stainless steel bone awl causes cracks in the bone as well as spicules of bone that protrude from the penetration site, both of which are believed to aid in the attachment of the repair tissue. Experimental studies have demonstrated that large articular cartilage defects (1 to 2 cm in diameter) débrided to the level of the subchondral bone have significantly greater volume of healing tissue following subchondral bone microfracture compared to defects that were débrided to the level of the subchondral bone plate but did not undergo microfracture. Biochemical analysis of the repair tissues also has shown a greater type II collagen content in repair tissue of microfractured defects in two experimental

Figure 80-3. Arthroscopic image of microfracture spacing on the medial femoral condyle.

studies, although histologic appearance of the repair tissues was similar.[20,21]

Further improvement in the repair tissue obtained following subchondral bone microfracture has been achieved by supplementing IGF-1 and interleukin-1 (IL-1) receptor antagonist using gene transfer.[22] Experimental work assessing subchondral bone microfracture has also confirmed the poor attachment of repair tissue in areas where the calcified cartilage layer had been incompletely removed. Confirmation of the level of débridement can be achieved using a microarthroscope or focusing close to the defect margins with a standard arthroscope. A granular appearance of the defect should be evident, differentiating the subchondral bone plate from the glasslike appearance of the calcified cartilage layer. Following débridement of the lesion, microfracture holes are spaced 2 to 3 mm apart, avoiding communication between sites and penetrating approximately 2 mm into the bone (see Figure 80-3).

To date, no long-term follow-up on clinical results after resurfacing therapy have been published relating specifically to horses, although anecdotal reports have been promising. However, human data compared long-term follow-up of the most commonly used cartilage resurfacing techniques: autologous cartilage implantation (ACI) as described by Brittberg,[23] and subchondral bone microfracture first described by Steadman.[24,25] The short-term and long-term results of this study show minor significant improvement with subchondral bone microfracture over ACI but no significant differences in histologic appearance of repair tissue or patient outcome between the two techniques. Both of these techniques are considered better than débridement alone for most human and equine patients. Because subchondral bone microfracture does not require a second surgery and is less technically challenging compared to ACI, it is favored by most equine surgeons.

Articular Cartilage Grafting

Many different tissues have been transplanted or grafted into cartilage defects; they include periosteal and perichondrial autografts, osteochondral, chondral, or isolated chondrocyte autografts or allografts, and stem cell transplants from bone marrow or fat. Periosteal and perichondrial grafts have been performed in laboratory animals with some success, but results in the horse have been very disappointing and are no longer a focus of ongoing research.[26,27]

Osteochondral grafting procedures have been well developed for use in people, but they have had limited success in the horse. Early work in the horse demonstrated short-term success but resulted in long-term failures.[28-30] Many of the failures with osteochondral grafting have been attributed to lack of congruity of the recipient and donor tissues as well as difficulties with surgical technique. Some concern also revolves around morbidity in the donor graft site. Typically, in people, a non–weight-bearing region is used for donor harvest, reducing morbidity, but lack of suitable non–weight-bearing donor tissue has been a limitation in horses. More recently, with the advent of specialized surgical tools designed for human osteochondral grafting, studies are under way using this technique in the horse. Surgical technique and donor site selection are the main hurdles yet to be overcome before this technique reaches mainstream practice.[31-34]

Chondrocyte transplantation has been a very active area of equine research since the 1990s. Techniques using both allografts and autografts have been reported, but most work, especially in humans, has focused on autografts. The technique described by Brittberg and marketed by Genzyme is the most well studied grafting technique.[23] This technique uses autologous chondrocytes harvested from a non–weight-bearing region, usually the trochlea of the distal femur, followed by a 4-week *in vitro* expansion of chondrocytes. The expanded cell population is then implanted during a second surgical procedure and held in the defect beneath autologous periosteum, which is sutured to the cartilage bordering the defect to create a watertight seal. Although this technique has been performed in horses with outcomes similar to those seen in people, the cost, laboratory facilities, need for multiple surgeries, and technical challenges of the procedure have limited its usefulness in clinical cases.

Techniques using frozen chondrocytes harvested from neonatal foals, which are implanted in a fibrin glue to help retain the cells in the chondral defect, have had some success in a limited number of chondral defects. The technique is being used more commonly in cystic defects to date.[35] Other materials used to fill cystic lesions are discussed in Chapter 89.

Techniques using autologous chondrocytes harvested from the non–weight-bearing region of the lateral trochlea of the distal femur, implanted into 15-mm-diameter defects, have been successful in experimental equine trials. One of the tested procedures uses fibrin glue holding minced cartilage to a bioresorbable scaffold, which is subsequently stapled to the subchondral bone of the defect in a one-step surgical procedure.[36,37] In comparable equine experimental trials this technique has been superior to the ACI technique. This technique is now undergoing human clinical trials, and because of the ease, cost, and promising results in equine experimental trials, it is likely to be used in equine clinical cases in the near future.

Considerable research is being directed toward the use of *mesenchymal stem cells* for implantation in cartilage defects. This cell population has been shown to improve healing in experimental animals, but gaining access to a sufficient number of stem cells without *in vitro* expansion is a hurdle yet to be resolved in horses.[35]

Arthrodesis

Assisted fusion of a joint is sometimes indicated when destruction to the joint is beyond any other treatment. Although most commonly achieved through surgical methods typically involving internal fixation, arthrodesis can be carried out using chemical or laser-based methods as well.[2,38-40]

In high-motion joints, such as the antebrachiocarpal, midcarpal, metacarpophalangeal, and distal interphalangeal joints, surgical fusion using internal fixation is required (see Chapter 81). The expectation of this procedure is to alleviate the pain associated with movement of the joint and to salvage the animal for nonathletic function. Conversely, arthrodesis of low-motion joints often carries a reasonable prognosis for athletic soundness and can be accomplished using surgical, chemical, or laser-based techniques. This is especially true for the proximal interphalangeal, tarsometatarsal, carpometacarpal, and distal intertarsal joints. Some risks have been identified with chemical fusion of joints because unexpected anatomic communications with other synovial and nonsynovial structures can be encountered. Thus contrast studies outlining the structure and extent of the communication should be performed before chemical fusion, and caution should be used not to create further injury by overdistending the joint capsule.

In the distal tarsal joints, some initial studies have been performed comparing surgical drilling to ablation of the joint space using a laser in both clinical and experimental cases.[41] Early results indicate that some decrease in time to resolution of clinical lameness may be seen for the laser-based procedure, but actual bony union of the joint space appears to occur more quickly with drilling. Further research comparing these techniques is needed, but the morbidity associated with the early reports using the laser favors the continued use of surgical arthrodesis in the distal tarsal joints, using the modified drilling technique. Further discussion of the principles of arthrodesis can be found in more detail in Chapter 81.

Joint Replacement

When reparative surgical procedures have failed, and the patient is unresponsive to medical management, many end-stage cases of osteoarthritis in people are treated using joint replacements, especially in the knee and hip. Joint replacement procedures are typically postponed until the patient is old enough that the implant will not fail during the expected remaining lifetime. Implant wear is improving, but it is still in the 10- to 20-year range, depending on the location and type of implant. Even in humans, where a large number of joint replacements are carried out annually, and to a lesser extent in dogs, relatively high morbidity is associated with such procedures, especially related to implant loosening. With respect to equine joint replacement, cost of implant design and manufacturing, difficulties with prolonged non–weight-bearing, and surgical morbidity continue to keep equine joint replacement out of mainstream clinical practice.

Aftercare

The aftercare for surgical joint treatment is often as important as the central treatment itself. Treatment goals and pathophysiology of healing tissue should be kept in mind when the aftercare protocol is being designed. Each aftercare protocol varies depending on the procedure, but a common focus is to minimize the duration to full return to function without compromising the athletic soundness of the patient. Following surgery, the goals are to provide support to the weakened areas, often through bandaging, casts, and controlled exercise, which can range from strict stall rest to specific graded exercise programs.

It is also well accepted that decreasing postoperative inflammation is beneficial in the healing process, as is controlling postoperative pain. Given that maximal inflammation in a surgical wound typically occurs 3 to 5 days postoperatively, nonsteroidal anti-inflammatory medication is administered systemically for at least this time period. The postoperative use of corticosteroids, although providing potent anti-inflammatory activities, is often contraindicated in the first 4 weeks because of their role in decreased cell metabolism, which affects healing time, as well as the decreased ability of the immune system to combat infection.

Other medications believed to have chondro-enhancing or chondroprotective qualities, such as hyaluronan or polysulfated glycosaminoglycans (Adequan), have also been studied in an attempt to demonstrate enhanced postoperative healing. However, they have not shown significant benefit in most studies, with the exception of decreasing adhesions in tendon sheaths.[42-44]

CHAPTER
81 Arthrodesis Techniques

Christoph J. Lischer and Jörg A. Auer

Arthrodesis is a salvage procedure that is used for relief of pain associated with severe degenerative joint disease, stabilization of a limb after loss of supporting soft tissue structures, and/or treatment of complicated fractures involving a joint.

By definition, ankylosis involves fusion of bones of a joint damaged by disease or injury, or it may be performed intentionally through a surgical procedure.[1] A genetic predisposition for natural or spontaneous ankylosis in horses has been suggested.[2,3] Procedures that aim to accelerate bony fusion in a particular joint by removing the articular cartilage or destroying chondrocytes without providing additional fixation to the joint may be categorized as facilitated ankylosis techniques. The most commonly used technique is mechanical removal of cartilage, which can be achieved by drilling across the joint space or removing the cartilage with a curet or a motorized burr. Other techniques to induce ankylosis include the intra-articular injection of chemical substances (e.g., monoiodoacetate, ethyl alcohol), the direct application of laser[4] or electrosurgical energy to the cartilage or, as recently investigated *in vitro*, a hydrothermal intra-articular lavage procedure.[5] Arthrodesis, which is another type of iatrogenically induced ankylosis, typically involves cartilage removal and surgical stabilization of the joint to promote fusion of the joint surfaces.

In selected high-motion joints, surgical arthrodesis is carried out to salvage valuable breeding stock or pet horses. However, certain low-motion joints can be fused without unduly compromising an athlete's performance.[6]

GENERAL GUIDELINES

Arthrodesis is most successful when two cancellous bone surfaces are aligned, compressed, and stabilized to faciltate fracture healing.[7] For any arthrodesis, as much cartilage as possible should be removed, allowing maximum bone-on-bone contact, because articular cartilage inhibits vascular invasion and ossification.[7-11] Immobility of a joint with persistent articular cartilage results in malnutrition of the cartilage and its eventual degeneration. However, this is a very slow process, and islands of articular cartilage can persist between bone bridges across a joint for several years. Therefore, in low-motion joints, such as

in the small tarsal joints[11] or the carpometacarpal joint,[12] partial removal of cartilage by drilling along the joint surface produces a functional ankylosis with relief of pain symptoms, although the convalesence time and the radiographic fusion of the joint is highly variable. This technique involves drilling several 2.5- to 3-mm-diameter holes across the dense subchondral bone plate of each of the opposing bone ends. This type of osteostixis promotes ingrowth of blood vessels across the bone plate and accelerates fusion.

A cancellous bone graft or an alternative osteoinductive material (see Chapter 77) may be used to improve bone fusion. However, if a cancellous bone graft is used, it should be loosely packed around the arthrodesis site and not squeezed between opposing bone ends, because this will mechanically damage viable cells.

Joint immobility and compression are best accomplished by placing a combination of multiple transarticular screws in lag fashion and applying bone plates. Generally, it is believed that increased stability of the fixation may improve postoperative comfort and minimize patient morbidity. Newer locking implants seem to be considerably more stable, which may facilitate the use of less-invasive arthrodesis techniques and therefore further improve the success rate of these procedures.[13,14]

DISTAL INTERPHALANGEAL JOINT

Indications

Indications for arthrodesis of the distal interphalangeal joint (DIP) are rare. This surgical intervention represents a salvage procedure and does not permit the patient to assume any form of athletic competition. The indications include severe osteoarthritis, injuries to the collateral ligaments that result in joint instability, luxation of the DIP joint after rupture of the deep digital flexor tendon at the level of the distal sesamoid bone, chronic intra-articular fractures, and septic arthritis.

Surgical Techniques

Arthrodesis of the DIP joint in adult horses has been reported using three transarticular 5.5-mm cortex screws[15,16] or stainless steel baskets with transarticular 4.5-mm cortex screws.[17] Facilitated ankylosis and immobilization in a half-limb cast for 50 days (initially for 4 weeks in a transfixation cast) resulted in complete ankylosis in a 3-month-old foal with septic arthritis.[18]

The two recommended techniques are described later.

Dorsal Hoof Wall Approach

We prefer a lag technique through a dorsal hoof wall approach.[15] For this arthrodesis, the hoof capsule is thoroughly cleaned the day before the procedure, including removing the superficial layer of horn with a rasp. The hoof is subsequently scrubbed using antiseptic products and covered with a sterile bandage.

The surgery is performed the following day with the horse in lateral recumbency with the affected limb positioned uppermost. The articular cartilage is removed arthroscopically using a 5.5-mm spherical burr through both a dorsal and a palmar/plantar approach. It is a difficult and time-consuming procedure to remove the cartilage from the palmar/plantar aspects of the joint, but 80% of cartilage could be removed using both arthroscopic approaches.[15] A 10-mm drill bit is used to create three parallel holes in the dorsal aspect of the hoof wall under fluoroscopic guidance, one axially, one dorsomedially, and one dorsolaterally. With the 5.5-mm drill bit, a glide hole is prepared across the distal phalanx in a dorsodistal to palmaro/plantaroproximal direction through each of these hoof wall openings. The beginning of the glide hole is at the junction of the proximal to the middle third of the distance from the extensor process to the tip of the distal phalanx. The glide hole is aimed toward the center of the distal articular surface of the middle phalanx. Accuracy of the depth and location of the glide holes can be observed arthroscopically through the dorsal pouch of the DIP joint.

Subsequently the 4.0-mm drill sleeve is inserted into the center glide hole and used to align the distal and middle phalanx in a normal weight-bearing position, then the thread hole is drilled across the middle phalanx. Threads are hand tapped and the three 5.5-mm cortex screws inserted and firmly tightened (Figure 81-1). Autogenous cancellous bone grafts may be placed through the dorsal and palmar/plantar arthroscopic portals into the joint space. The hoof wall defects are filled with polymethyl methacrylate impregnated with 1 g gentamycin sulfate, and the surface edges are sealed with cyanoacrylate. Perioperative intravenous regional perfusion with antimicrobials (with the horse still on the surgery table) is recommended to reduce the risk of postoperative infection. The horse is recovered in a half-limb cast, which should be maintained for approximately 2 months. Radiographic evidence of complete fusion of the joint was observed 8 months postoperatively in one horse.[15] At that time the horse was sound at walk.

Palmar/Plantar Approach

An alternative, but more invasive technique has been described using two surgical approaches.[16] Through a dorsal approach to the DIP joint, as much articular cartilage as possible is removed. An 8-cm (3-inch) semicircumferential horizontal skin incision is made 1 cm proximal and parallel to the coronary band, centered over the midline of the foot. The incision is extended through the common digital extensor tendon into the dorsal pouch of the DIP joint. The incision is further extended through the joint capsule, transecting the collateral ligaments, allowing subluxation of the joint. Approximately 70% of the articular cartilage can be removed with a curet through this approach, but the distal sesamoid bone and the palmar aspect of the middle phalanx cannot be accessed for cartilage removal.

Then the implants are inserted through a palmar approach to the proximal and palmar/plantar aspect of the middle phalanx, entering the tendon sheeth of the deep digtal flexor tendon. The initial 8-cm skin incision parallel to the long axis of the limb in the median plane centered over the proximal interphalangeal (PIP) joint is extended into the digital tendon sheath, where the deep digital flexor tendon is transected and reflected. Three stab incisions are made through the distal sesamoidean ligament and the insertion of the superficial digital flexor tendon, respectively, to provide access to the proximal palmar/plantar rim of the middle phalanx.

While maintaining the DIP joint in reduction, the first thread hole is prepared under fluoroscopic control across the middle phalanx and DIP joint in a distodorsal direction into the distal phalanx. The thread hole across the middle phalanx is enlarged into a glide hole, with the joint opened to prevent inadvertent

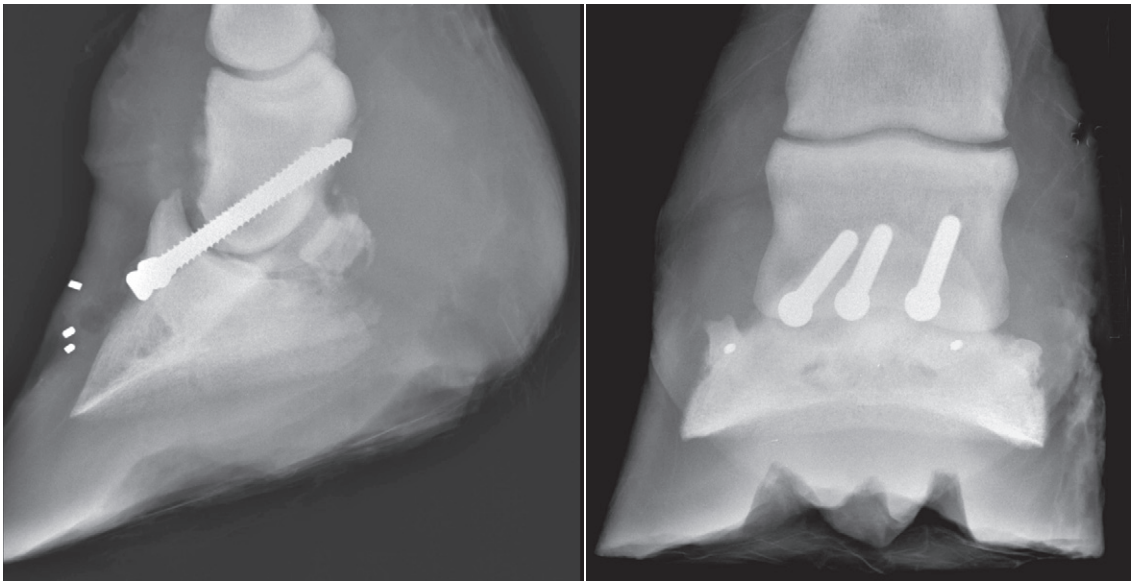

Figure 81-1. Arthrodesis of the distal interphalangeal (DIP) joint using three parallel 5.5-mm cortex screws placed in lag fashion through a dorsal hoof wall approach. Note the metallic markers in the hoof wall that served as landmarks for screw placement.

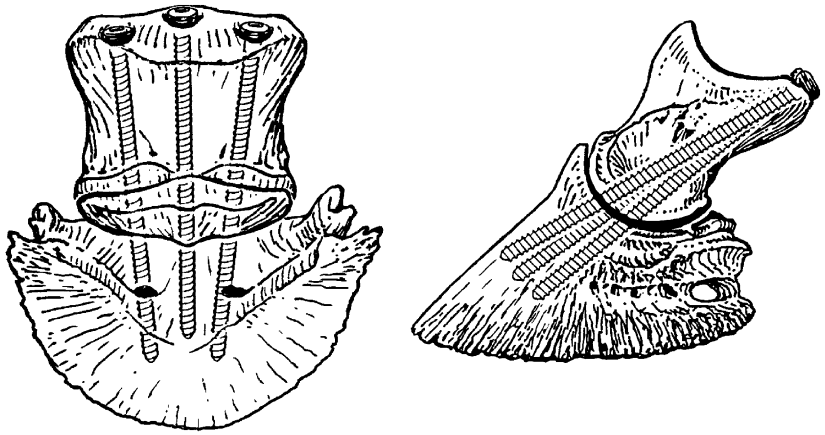

Figure 81-2. Graphic illustration of an arthrodesis of the DIP joint using three parallel 5.5-mm cortex screws placed between the proximal and palmar aspect of the middle phalanx and the distal phalanx.

enlargement of part of the thread hole in the distal phalanx. Two more glide holes are drilled parallel to the first one across the middle phalanx. The center hole is finished using lag technique, and a 5.5-mm cortex screw of correct length is inserted and solidly tightened. The other two 5.5-mm cortex screws are implanted using lag technique (Figure 81-2). A cancellous bone graft or an alternative osteoinductive material may be placed in the dorsal and the palmar/plantar aspect of the joint before closing the joint.

The dorsal incision is closed in three layers: extensor tendon and joint capsule, subcutaneous tissue, and skin. Although an attempt should be made to suture the ends of the deep digital flexor tendon with interrupted sutures of 0 polydioxanone, the tendon ends often retract, making accurate anatomic reconstruction impossible. The palmar incision is closed in two layers: tendon sheath and subcutaneous tissues in one layer, followed by the skin layer. The limb is placed into a half-limb (transfixation) cast for 3 months, ideally with only one cast change. Routine anti-inflammatory therapy and antibiotic prophylaxis are used.

In one horse that suffered from nonresponsive progressive arthritis of the DIP joint, this technique resulted in solid fusion. The horse was able to ambulate with a mechanical lameness but was pain free for more than a year at the time of reevaluation.[16]

The advantages of the dorsal hoof wall approach over the two-incision technique are the minimal soft tissue damage and the greater purchase of the screws, because the thread hole in the middle phalanx is much longer compared to the short thread hole in the distal phalanx, when screws are placed in proximal-palmar/plantar to distal-dorsal direction. The disadvantage of the dorsal hoof wall technique is associated with the hoof wall holes that have to be prepared and may lead to infection. With a more widespread use of this technique, this potential danger can be better assessed.

PROXIMAL INTERPHALANGEAL JOINT

Indications

Indications for arthrodesis of the PIP joint include osteoarthritis (high ring-bone), comminuted fractures of the proximal or middle phalanx, and luxation or subluxation of the PIP joint.[6,19-21]

Because of the low-motion[22] and high-load nature of this joint and the lack of interdigitation, attempts to manage the majority of common conditions of the PIP joint by methods

other than arthrodesis usually fail to provide long-term success. Unlike arthrodesis of high-motion joints, the goal of PIP joint arthrodesis is to return the horse to athletic performance.

Fractures entering the PIP joint through either the proximal or the middle phalanx often result in osteoarthritis or subluxation. Therefore arthrodesis is often performed as part of the definitive treatment of the fracture. In comminuted fractures of the proximal phalanx, the middle phalanx serves as the distal fragment, achieving additional stability for the fixation. Conversely, the proximal phalanx can serve as the proximal fragment in comminuted middle phalanx fractures.

Lag Technique

Over the years, a variety of techniques have been advocated for PIP joint arthrodesis.[16-19] The first technique routinely applied since the 1980s used two or three transarticular cortex screws placed in lag fashion in a parallel or diverging pattern.[16-18]

A *cadaveric* study compared interfragmentary cortex screws applied in lag fashion in forelimbs and hindlimbs.[23] Three parallel 4.5-mm cortex screws were compared to two parallel 5.5-mm cortex screws in three-point bending to failure. The bending moments were greater in the forelimbs than in the hindlimbs. The difference between the two techniques was not statistically significant. However, more 4.5-mm cortex screws failed than 5.5-mm counterparts. Further cadaveric studies revealed that two parallel 5.5-mm cortex screws provided an equally strong PIP joint arthrodesis compared with three 5.5-mm cortex screws inserted in a similar manner, when tested in three-point bending to failure[24] and in cyclic loading.[25] In these studies, no discernible mechanical difference between forelimb and hindlimb constructs was observed. Insertion of two parallel headless, tapered, varible-pitched titanium compression screws were biomechanically comparable with two parallel 5.5-mm stainless steel cortex screws inserted in lag fashion across the PIP joint.[26] In contrast to previous studies, forelimb constructs were significantly stiffer than hindlimb constructs in this testing series using 8 forelimbs and 12 hindlimbs.

The lag technique may be the fixation technique of choice for PIP joint arthrodesis in young foals.[27] Recent clinical case series suggest that the lag screw technique remains a viable option for arthrodesis[28-31] of adult horses with severe osteoarthritis and significant periarticular new bone formation. This is especially true when the procedure is performed through a minimally invasive approach, such as inserting the screws through stab incisions[29a,30] and in combination with laser-facilitated, minimally invasive cartilage destruction.[31]

However, insertion of three transarticular screws in lag fashion using the conventional open approach increases the need for cast support when compared with plating techniques for PIP joint arthrodesis.[31] The almost linear alignment of the screws in the frontal plane provide minimal stability, especially at the dorsal aspect of the joint. This results in patient discomfort because of excessive new bone formation impinging on the extensor tendon or the coffin joint, or both.[32] This presumably reflects decreased stability.[33]

Combination of a Plate and Lag Technique

An arthrodesis technique using an axial plate with two abaxial transarticular cortex screws inserted in lag fashion was tested *in vitro* and compared to a method using three transarticular screws. There was a substantial increase in stability across the dorsal aspect of the PIP joint in addition to a significantly longer fatigue life compared to the three-transarticular screw method.[33,34]

The combination of transarticular screws and dorsal plate has a biomechanical advantage over a single plate: it provides compression across the entire joint because the tensile forces at the palmar aspect of the joint induced by the plate are neutralized by the two oblique transarticular screws inserted in lag fashion. It has a similar advantage over the three-screw technique because the dorsal joint instability seen with that technique is obviated by the plate.

Positive clinical results achieved on horses suffering from osteoarthritis, subluxations, and some stable middle phalanx fractures support the *in vitro* results.[31] Postoperatively, the patients were more comfortable on the limb, and the cast was removed earlier compared to patients treated with the three parallel 5.5-mm cortex screws.[31]

Other attempts to improve stability induded the use of two plates,[35] a T-plate,[36] a Y-plate,[37] and most recently a spoon plate,[38] but currently the best clinical results have been reported by using a dorsal three-hole narrow dynamic compression plate (DCP)[39] or locking compression plate (LCP)[14] combined with two transarticular abaxial 5.5-mm cortex screws inserted in lag fashion. Therefore we recommend this technique for arthrodesis of the PIP joint with an open approach. The potential increase in stability achieved in a clinical case has to be weighed against the cost of the implants and the surgical trauma. If these aspects are considered, the recently developed PIP arthrodesis plate is the implant of coice.

Surgical Techniques

APPROACH

The joint is approached through an inverted-T skin incision that begins just distal to the level of the metacarpophalangeal (MCP) or the metatarsophalangeal (MTP) joint and ends at a horizontal skin incision made 2 cm proximal to the coronary band. The horizontal incision extends 4 cm (1½ inches) on either side of the midline. The subcutaneous tissues are separated sharply down to the common digital extensor tendon. The two triangular skin flaps are dissected free from the common digital extensor tendon with the help of scissors and sutured to the intact skin on either side of the incision.

The common digital extensor tendon is transected with an inverted V-shaped tenotomy at the level of the insertion of the extensor branches of the suspensory apparatus (Figure 81-3).[40] The proximal tendon stump is reflected proximad using scissors, taking care to spare the attachments of the extensor branches of the suspensory ligament. The distal tendon stump is sharply incised along its lateral and medial sides and reflected distad, exposing the dorsal pastern region. If necessary, bony proliferations on the dorsal aspect of the pastern are removed with a chisel and a mallet.

The dorsal attachments of the PIP joint capsule are sharply incised parallel to the joint surface, the medial and the lateral collateral ligaments are transected, and the joint is disarticulated. As much cartilage as possible is removed from both articular surfaces with a curet. By removing the articular cartilage layers, the radii of the two opposing bones are altered (Figure 81-4, *A*); the radius of the proximal phalanx is reduced, whereas that of the middle phalanx is increased. Theoretically, this results in reduced contact between opposing bones (see Figure

81-4, *B*). By rasping the subchondral bone of the distal articular surface of the proximal phalanx, the contact area can be increased (see Figure 81-4, *C*). Osteostixis of both subchondral bone plates is performed at 0.5-cm intervals using a 2.5-mm diameter drill bit.

ARTHRODESIS

The preferred technique for arthrodesis of the proximal interphalangeal joint involves the application of a 3-hole narrow plate with two additional transarticular cortex screws. Although the technique was originaly described with a DCP (Figures 81-5 and 81-6),[33] the introduction of the LCP concept led to the development of a PIP arthodesis LCP.[14] For more information on the LCP technology, please review Chapter 76. This plate has a wider space between the stacked combi-hole (most distal hole), usually placed over the proximal aspect of the middle phalanx, and the remaining two regular combi-holes. The principles and steps for implant application are the same for either plate and are described later with particular details for the LCP.

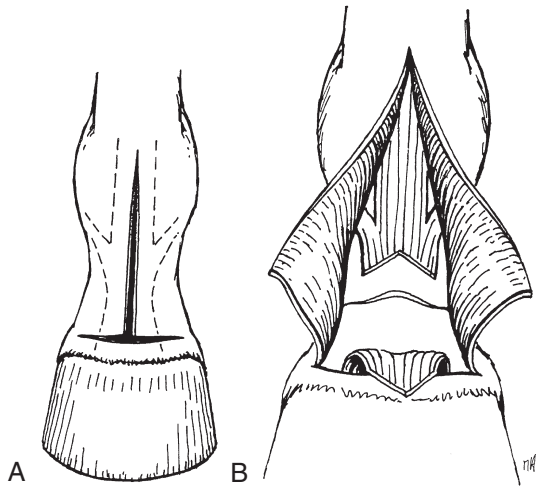

Figure 81-3. A, The surgical approach for arthrodesis of the proximal interphalangeal joint involves an inverted-T skin incision with the horizontal portion located 1.5 cm proximal to the coronary band. A sagittal vertical incision is extended to the level of the metacarpophalangeal joint. **B,** An inverted-V tenotomy of the common digital extensor tendon, just distal to the insertion of the extensor branches of the suspensory ligament, allows access to the joint. The distal part of the tendon (shaded vertically) is reflected distally, whereas the proximal part (also shaded vertically) is still in its original position.

The drill sleeve for the 5.0-mm locking head screw is fastened to the stacked combi-hole and the previously contoured 3-hole LCP is placed axially over the joint, with the stacked combi-hole positioned at the proximal and dorsal aspect of the middle phalanx. By positioning the plate as far proximad as possible, interference between the extensor process of the distal phalanx and the distal end of the plate is prevented. Additionally, the risk of inadvertent injury to the distal sesamoid bone at the palmar or plantar aspect of the middle phalanx is reduced. With the joint opened, allowing a good view along the axial ridge of the proximal articulation of the midddle phalanx, the 4.3-mm thread hole is drilled across the bone and followed by insertion of the 5.0-mm locking screw using the power-tapping technique. The screw is not completely tightened.

With the phalanges maintained in neutral position, the location of the two transarticular screws are marked on either side of the plate on the distal aspect of the proximal phalanx, making sure to leave enough space for countersinking the bed for the screw heads.

With the joint opened, drilling of the 5.5-mm glide hole for the first transarticular screw to be inserted on one side of the plate is started perpendicular to the bone surface of the proximal phalanx, followed by a gradual redirection of the drill bit to the desired oblique orientation. Because the middle phalanx is wider than the proximal phalanx, the drill holes are prepared in slightly diverging directions (dorsoaxial to palmaro/plantaroabaxial). Drilling is continued until the drill bit enters the joint to ensure an ideal lag effect without drilling into the palmar and proximal aspect of the middle phalanx. The hole should enter the joint midway between the dorsal and palmar/plantar cortices. The same procedure is repeated on the other side of the plate for the second lag screw.

The countersink is used to prepare depressions in the bone for the heads of the transarticular screws. Care is taken to work predominantly on the proximal rim. The joint is closed to its normal anatomic position and the plate is aligned axially between the glide holes. The load drill guide is placed in the dynamic compression unit (DCU) portion of either the middle or proximal combi-hole of the plate, and then a perpendicular 4-mm thread hole is prepared across the proximal phalanx. The selected 5.5-mm cortex screw is inserted following final preparation of the thread hole, but it is not fully tightened.

The thread hole for one of the transarticular screws is drilled, the hole is tapped, and the screw is inserted and tightened. The second transarticular screw is implanted in the same manner

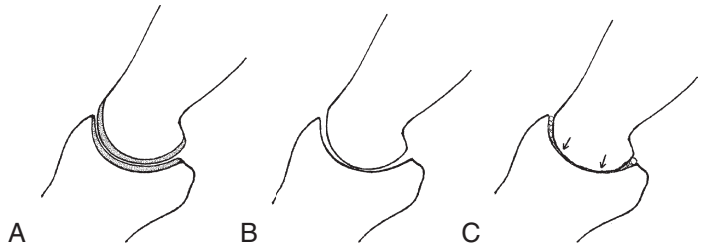

Figure 81-4. A, The articular cartilage covering the two opposing bones normally allows congruency of the surfaces during joint loading and maximum contact surface. **B,** Removal of the articular cartilage from the bone ends results in an incongruity between the two surfaces. Insertion of three lag screws after this type of preparation results in an inadequate fixation because of cyclic screw failure. **C,** Rasping of the distal subchondral surface of the proximal phalanx *(between the two arrows)* substantially enlarges the contact surface. Cancellous bone may be placed between the two bone ends.

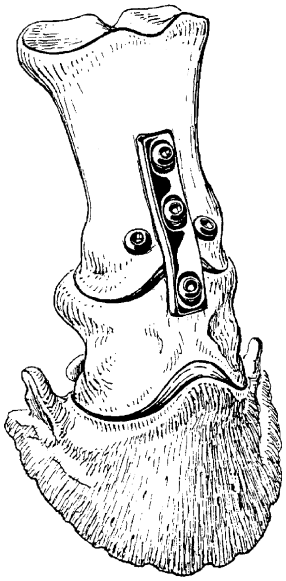

Figure 81-5. Graphic illustration of an arthrodesis of the proximal interphalangeal joint, using a 3-hole narrow dynamic compression plate (DCP) and one 5.5-mm cortex screw applied in lag fashion across the joint on either side of the plate. The plate is applied axially over the dorsal aspect of the joint with the most distal screw inserted into the proximal aspect of the middle phalanx.

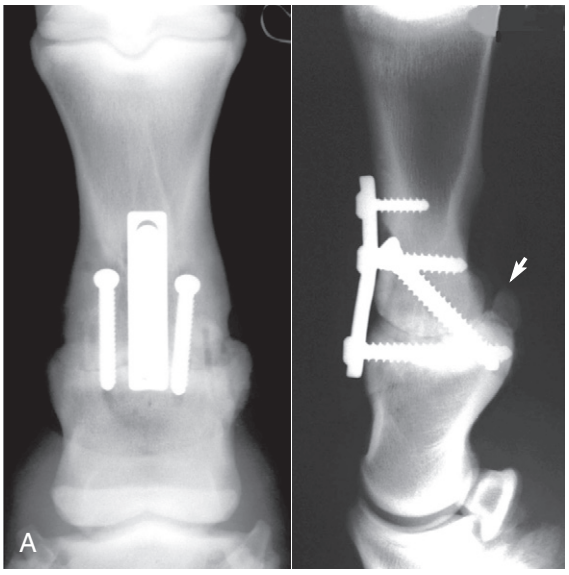
on the other side of the plate. The two plate screws are now tightened as well, bringing about transarticular compression. Finally, a second 5-mm locking head screw is inserted orthogonally across the bone through the threaded part of the remaining empty combi-hole and tightened (Figure 81-7).

CLOSURE AND AFTERCARE

Closure of the V-plasty of the tendon is accomplished with size 1 polydioxanone suture material using a simple-continuous pattern, and the skin is apposed using a combination of size 0 polypropylene (Prolene) and skin staples. A standard distal limb cast is applied for the immediate postoperative period to protect the fixation during recovery and, most importantly, to support healing of the soft tissues. The cast is removed at about 2 weeks, and every other skin suture is taken out at that time, with the patient standing. The limb is protected with a three-layer Robert Jones half-limb bandage, and the remaining sutures are removed at the next bandage change. In the absence of complications, the horse can be discharged from the clinic about 3 weeks postoperatively with instructions to maintain the bandage for another 3 weeks. The owner is advised to confine the horse for 3 months in the box stall. During the first 6 weeks, grazing in hand is allowed. A progressive program of hand-walking exercise is instituted during the second 6 weeks of confinement. A minimum of 3 additional months of paddock exercise is recommended before retintroducing the horse to riding activities.

Proximal Interphalangeal Joint Arthrodesis for Fracture Repair

When treating fractures of the middle or proximal phalanx with a PIP joint arthrodesis technique, it may be advisable to apply two plates, one dorsomedially and one dorsolaterally, once the



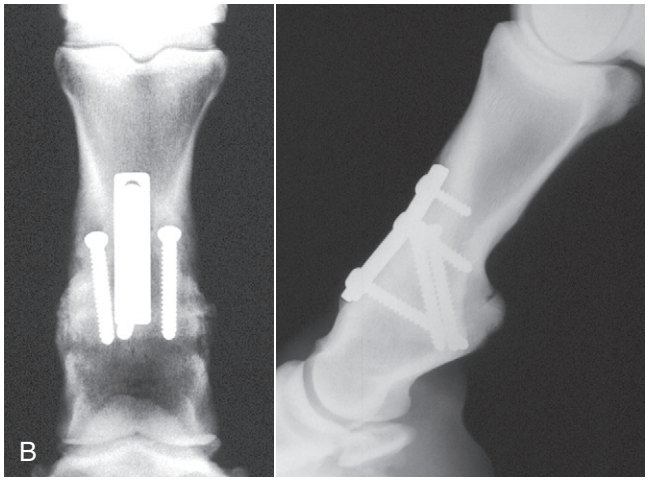


Figure 81-6. A, Immediate postoperative dorsopalmar and lateromedial radiographs of a PIP joint arthrodesis in a 2-year-old Thoroughbred filly with a proximal palmar fracture of the middle phalanx. The arthrodesis was accomplished with a 3-hole narrow DCP and two 5.5-mm cortex screws. The plate used two loaded bicortical 5.5-mm screws and a single unicortical 4.5-mm screw in the proximal hole. The two transarticular 5.5-mm cortex screws were inserted in lag fashion to provide plantar compression. The *arrow* points to the palmar fragment of the middle phalanx. Note the slightly radiolucent osteostixis holes in the distal aspect of the proximal phalanx. **B,** The 11-month follow-up dorsopalmar and lateromedial radiographs show complete fusion of the joint, with negligible periarticular new bone formation. (Courtesy J. Watkins, Texas A&M University.)

bone has been reconstructed with strategically placed screws using lag technique.[41,42] Care is taken to prevent interference of the interfragmentary screw heads with the plates. Therefore, 3.5-mm cortex screws are often used because they permit the screw heads to be buried within the cortex.

A biomechanical *in vitro* study compared two seven-hole, 3.5-mm broad DCPs with two 5-hole 4.5-mm narrow DCPs. The DCPs were placed dorsomedially and dorsolaterally, respectively. No significant difference was detected either in composite stiffness or maximal bending moment between the two fixation

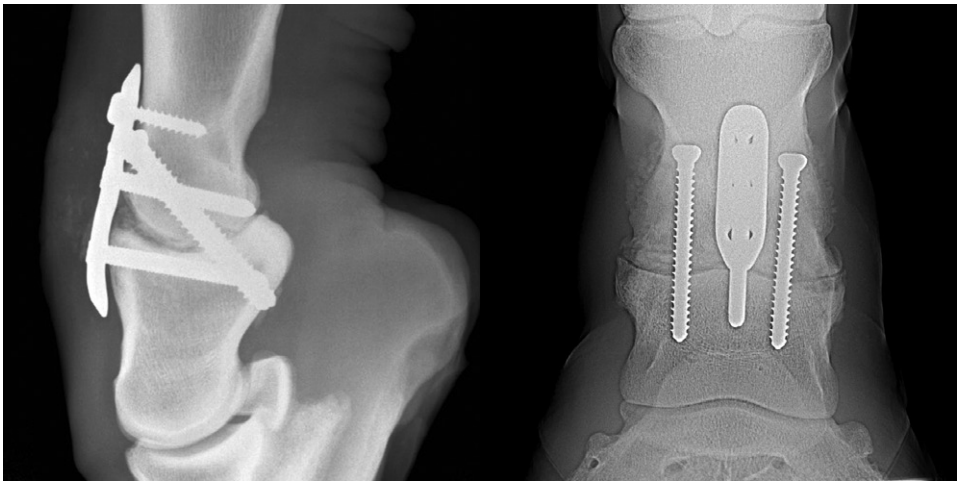

Figure 81-7. Postoperative lateromedial and dorsopalmar radiographic views of a 3-hole PIP arthrodesis LCP application combined with two transarticular 5.5-mm cortex screws. This represents the present state-of-the-art surgical technique.

techniques.[35] Therefore either plate size could be used for arthrodesis of the PIP after fractures to the pastern.

The closure of soft tissues is routine. The type of external coaptation is dictated by the complexity of the fracture and the quality of repair. For complex fractures, a transfixation cast might be necessary. The time period will vary depending on stability of the repair and progress of healing.

Minimally Invasive Appliction of LCPs

Horses with fairly advanced osteoarthritis with significant cartilage loss are candidates for minimally invasive plate application using an LCP technique.[13] This technique is more difficult and requires good intraoperative imaging facilities for cartilage removal and implant placement. Although in the PIP joint it is difficult to remove a large amount of cartilage with drill bits, a combination of lateromedial and dorsopalmar/plantar passes with a 5.5-mm drill bit seems to result in adequate cartilage destruction.

The two 5.5-mm transarticular screws are first placed in lag fashion through stab incisions abaxially using intraoperative imaging in lateromedial and dorsopalmar/plantar direction to ensure that there is enough room centrally for the plate. After preparing a subtendinous tunnel along the dorsal midline through a small axial incision down to the bone, the previously described PIP arthrodesis LCP is placed using a plate-passing tool. The most distal locking screw is inserted in the proximal aspect of the middle phalanx through a stab incision across the stacked combi-hole and firmly tightened. Subsequently, a 5.5-mm cortex screw is placed through the middle or the proximal combi-hole in a load position to achieve maximal axial compression over the dorsal aspect of the PIP joint. Finally a 5.0-mm locking head screw is placed in the remaining empty plate hole. The small incisions are closed with skin sutures (Figure 81-8), and a half-limb cast is applied. It has been reported that osseous fusion of the joint with this type of arthrodesis progresses more slowly than that seen with the traditional open technique, and lameness remains for several weeks, requiring cast coaptation for more than 6 weeks.[43]

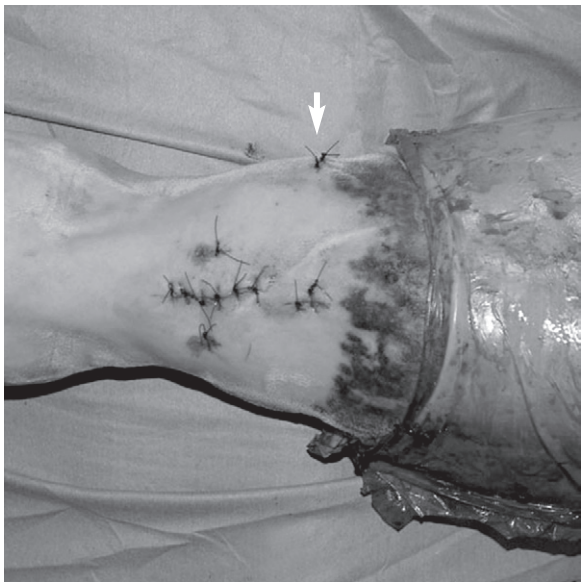

Figure 81-8. Immediate postoperative appearence of the PIP region following minimally invasive application of a 3-hole LCP. The plate was applied through the small axial incision and the transarticular screws through the stab incision on either side of the central incision. The *arrow* points to the incision on the lateral side that was used to remove cartilage with a drill.

Arthrodesis for Septic PIP Joints

PIP joint sepis secondary to wounds that penetrate the PIP joint are fairly common. In the case of joint instability, the use of implants for surgical arthrodesis is not recommended in the acute stage because of increased risk of a generalized infection of the implants.[6,44] These cases are best immobilized with a cast or transfixation cast in combination with aggressive débridement of the joint, cancellous bone graft, and systemic and local antimicrobial treatment.[6] Once the infection has resolved, surgical arthrodesis might be considered to treat the persistent lameness caused by the osteoarthritis of the joint.[39]

Prognosis

Early postoperative complications related to surgical arthrodesis include cast sores, incisional infection, implant infection, and construct failure.[31,39] Reported long-term complications are persistent postoperative lameness, cast-related morbidity, and excessive new bone formation.[32] Some horses develeop pathology of the distal interphalangeal joint after successful fusion of the PIP joint; therefore good case selection is important, which means that early signs of concurrent arthritis of the DIP joint must be recognized before surgery.[6]

The period from surgery to return to intended use r anges from 6 to 12 months and is related to indication for arthrodesis, arthrodesis technique, and the intended use of the horse.[30,31,39]

Long-term follow-up results after arthrodesis of the PIP joint using transarticular screws placed using lag technique revealed a range of success rates from 50% to 85% in the forelimbs and from 80% to 89% in the hindlimb.[28,31,32,45,46] Combining all four studies, arthrodesis was considered successful in 76 of 97 (78%) cases (28 of 41 [68%] forelimbs, and 48 of 56 [86%] hindlimbs). In a study on PIP joint arthrodesis using a combination of plates and transarticular screws, long-term outcome was evaluated in 53 horses.[39] Eighty-seven percent returned to intended use with a success rate of 81% for forelimb arthrodesis and 95% for hindlimb arthrodesis. Horses in this study consisted of American Quarter Horses (43%), Arabians (13%), Peruvian Pasos (11%), and similar types of working horses (33%). Their intended use was predominantly for pleasure riding (23%), showing (21%), and breeding (19%). This illustrates that direct comparsion of outcomes is not always feasible, because criteria for success, type of horse, and use may be different. However, there is a lack of information on the long-term outcome for PIP arthrodesis in larger Warmblood horses or Thoroughbreds used for show jumping, dressage, racing, or similar athletic activities. We assume that the success rates in those horses might not be as favorable as the ones presented in the studies discussed earlier.

METACARPOPHALANGEAL OR METATARSOPHALANGEAL JOINT

Indications

MCP or MTP joint arthrodesis is performed predominantly in the management of breakdown injuries of the suspensory apparatus. This injury occurs almost exclusively in the forelimbs of Thoroughbred racehorses, although it can be acquired by any horse running at high speed.[9,47] Fatigue of the digital accessory ligaments and flexor muscles supporting the MCP/MTP joint and digit leads to higher stresses in all components of the suspensory apparatus and permits development of the injury. Comminuted proximal phalanx fractures, advanced osteoarthritis, and severe flexural deformities of that region represent other indications for the arthrodesis.[6] In flexural deformities, an osteotomy might be needed to achieve an acceptable joint angle before arthrodesis.

The major physical finding after breakdown injuries of the suspensory apparatus is dorsiflexion or hyperextension (dropping) of the MCP/MTP joint as the horse attempts to bear weight. Many horses become anxious or even frantic as they attempt to control the injured limb. The disruption can occur as a result of fracture of both proximal sesamoid bones in the injured limb or, less often, rupture of the distal sesamoidean ligaments or the two suspensory ligament branches.

Breakdown of the suspensory apparatus should always be considered a career-ending injury. Because of the massive trauma that occurs with this injury, a myriad of complications are expected. It is therefore important to explain the situation to the owner so that an informed decision can be made concerning treatment. Horses can be saved as pasture-sound or breeding animals, but treatment is often prolonged and expensive, regardless of the therapeutic approach selected.

Surgical Techniques

The most frequently used technique for MCP/MTP arthrodesis involves the use of a 10- to 14-hole, 4.5-mm or 5.5-mm broad plate with an approximately 10-degree angle applied to the dorsal aspect of the limb and the creation of a tension band on the palmar/plantar aspect of the joint (Figure 81-9).[47] Dorsal plating without a tension band on the palmar/plantar aspect of the MCP/MTP joint usually results in failure, because the plate cycles in bending on the joint's dorsal surface and eventually breaks. The different techniques used to create the tension band depend on the type of injury and are discussed later.

Reports of experimental use of a dynamic hip screw,[48] a dynamic condylar screw,[48] or a prototype intramedullary pin

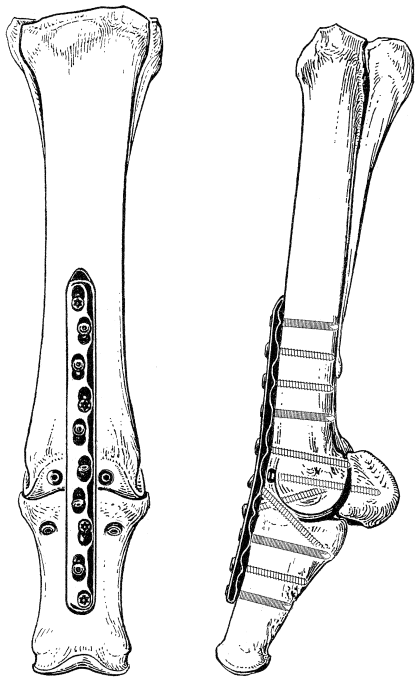

Figure 81-9. Graphic illustration of an arthrodesis of the MCP joint using a dorsally applied 10-hole 5.5-mm LCP. Note the stacked combihole at the distal end of the plate allowing insertion of either a cortex screw or a locking head screw. (This hole is filled with the latter in this illustration.) Two locking head screws are applied in MCIII and in the proximal phalanx. The remaining plate screws are of the cortex screw type. Two cortex screws are implanted transarticularly through the plate, and an additional cortex screw is inserted from the dorsal aspect of the MCIII into each proximal sesamoid bone. An additional cortex screw on either side of the plate (not shown) may be implanted transarticularly from the proximodorsal aspect of the proximal phalanx into the palmar or plantar aspect of the MCIII to improve stability.

plate[49] have been published, but reports on clinical use are currently not available. LCP is currently the treatment of choice for arthrodesis of the MCP/MTP joint.[14,50,51] The recently developed 5.5-mm LCP is more rigid than the standard 4.5-mm plate and represents a good option for an arthrodesis of the MCP/MTP joint. The price difference between locking compression technology and conventional internal fixation implants is found in the locking head screws. The plate itself is only slightly more expensive than a limited contact DCP (LC-DCP) or DCP. However, it is not necessary to use only locking head screws with the LCP; two such screws on either side of the MCP/MTP joint are adequate to provide the stability desired. The rest of the screws can be of the 4.5- or 5.5-mm cortex type. However, if exclusively locking head screws are used, except for the transarticular screws applied in lag fashion, the cost is about three times that of a conventional construct.[51]

Surgical Approach

A straight skin incision is made over the lateral digital extensor tendon, extending from the proximal aspect of the third metacarpal or third metatarsal (MCIII/MTIII) bone to the proximal interphalangeal joint. The incision is continued through the lateral digital extensor tendon, splitting it longitudinally, and extended, splitting the lateral extensor branch of the suspensory ligament.

The joint capsule of the MCP or MTP joint is transected parallel to the articular surface. Transection of the lateral collateral ligament and the lateral metacarposesamoidean or metatarsosesamoidean ligament allows disarticulation of the joint and removal of all articular cartilage from the proximal phalanx, the distal MCIII/MTIII, and the proximal sesamoid bones.

The cartilage is removed with a curet or an oscillating saw, and multiple osteostixis holes are drilled across the subchondral bone plates of all of the bones. The proximal dorsal end of the proximal phalanx and the intermediate ridge of the distal MCIII or MTIII are contoured with the help of an osteotome to improve the contact area and reduce the need to excessively contour the plate.

Plate Application

The 10- to 14-hole, 5.5-mm LCP (see Figure 76-17) is slightly bent between the fourth and fifth holes from the rounded end of the plate to an angle of about 10 degrees. One experienced equine surgeon uses a broad 10-hole LCP for this procedure with good success.[52] The plate is aligned to the dorsal surface of the proximal phalanx and MCIII/MTIII so that the bend is located directly over the dorsal aspect of the articulation, allowing four holes to be positioned over the proximal phalanx. One cortex screw is inserted through the DCU portion of the combi-hole next to the stacked combi-hole and solidly tightened. This presses the plate onto the bone surface. The two adjacent plate holes are filled with locking head screws. These three screws attach the plate firmly onto the proximal phalanx. The hole adjacent to the joint should be left without a screw.

Application of the Tension Band

For both procedures described later, the joint is maintained in a neutral or slightly flexed position (5 degrees).

LAG TECHNIQUE THROUGH THE PROXIMAL SESAMOID BONES

When a suspensory apparatus is intact or when the suspensory apparatus disruption is associated with suspensory ligament disruption proximal to the sesamoid bones, one 5.5-mm cortex screw is placed in lag fashion from the dorsal aspect of the distal MCIII or MTIII into each proximal sesamoid bone.

CERCLAGE WIRE

With comminuted fractures of proximal sesamoid bones, screw insertion is not effective. Also, in cases where the distal sesamoidean ligaments are ruptured, inserting the screws into the proximal sesamoid bone using lag technique does not produce a tension band across the palmar/plantar joint surface. In such cases, a double strand of 1.25-mm-diameter cerclage wire is placed in figure-of-eight fashion across the palmar/plantar aspect of the joint. A 3.2-mm hole is drilled in a frontal plane parallel to the joint surface about 4 to 6 cm (1½ to 2½ inches) proximal and distal to the joint surface across the MCIII/MTIII and the proximal phalanx, respectively. Care is taken not to interfere with the screws placed in the proximal phalanx and the ones inserted into MCIII/MTIII.

The wire is guided through these holes and directed toward the palmar or plantar joint surface using the large wire passer to place the wires between the bone and the suspensory apparatus in a figure-of-eight pattern. It is important to not induce acute bends in the wire, because these resist effective tightening of the wire. The wires ends are tightened with the joint maintained in a neutral or slightly flexed position. One set of wire ends is tightened on the lateral side of the MCIII/MTIII and the other set on the medial side of the bone. Before final tightening, all the slack has to be taken out of the wire to ensure the development of an effective tension band function. Alternatively, one 1-mm diameter stainless steel cable with crimping sleeve has been used successfully for tension band application.[51]

Completion of Plate Application

Once the tension band is created using either screws or cerclage wire, the angulated tension device is applied to the most proximal hole of the plate and attached to MCIII/MTIII with a unicortical cortex screw. With the help of the socket wrench, the device pulls the plate proximad, and in doing so the palmar/plantar tension band is further tightened. If the tension band is accomplished with screws in the proximal sesamoid bones, tension is transferred via the distal sesamoidean ligaments to the suspensory ligament. The second plate hole from the top and the sixth plate hole from the bottom are filled with 5.5-mm cortex screws, allowing the plate to be firmly pressed onto the bone surface. At least two locking head screws are inserted into MCIII/MTIII. The tension device is removed, and the remainder of the screws can be either of the cortex or the locking head type. Across the two juxta-articular empty plate holes, cortex screws are implanted transarticularly using lag technique. Additionally, two or three transarticular screws are inserted next to the plate to increase stability across the joint to be fused.

A longer plate may be used when an arthrodesis of the MCP/MTP joint and the PIP joint is desired. Indications include fixation of severely comminuted proximal phalanx fracture, or breakdown injuries with suspected damage to soft

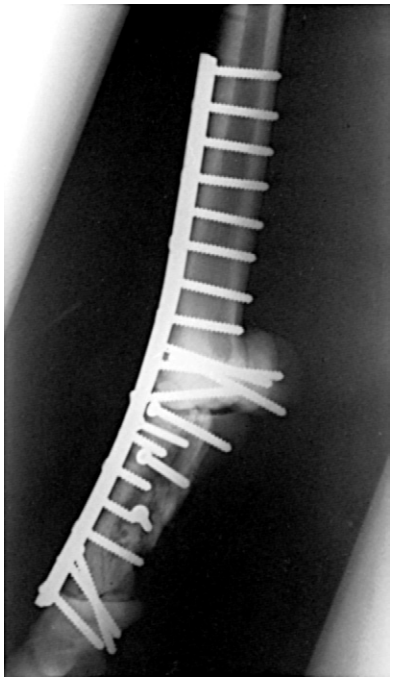

Figure 81-10. Radiograph of a comminuted proximal phalanx fracture repaired with an 18-hole DCP. The plate was applied to the dorsal aspect and spanned the PIP and MCP joints. This repair is used as a salvage procedure.

tissue support structures of the PIP joint to prevent its luxation (Figure 81-10).

Minimally Invasive Technique

With the introduction of the LCP to equine orthopedics, minimally invasive techniques[50] or less-invasive techniques[13] have been described for MCP/MTP joint arthrodesis. The prebent plates are introduced through a small incision after a tunnel is prepared for the future plate bed with the help of a sharp chisel-like instrument. The screws are inserted across the plate hole through stab incisions. These incisions are best prepared through an identical plate applied over the inserted one. The authors reported shorter surgery time, lower infection rates, and higher survival rates when compared to the open-approach technique.[50] However, none of the differences were statistically significant.

Prognosis

The major risks of the procedures are deep infection[53] and subsequent instability of the construct, controlateral limb laminitis, and PIP joint luxation. Survival rates are 25% (open approach, DCP),[50] 33% (minimally invasive technique, DCP),[50] 65% (open approach, DCP),[54] 67% (open approach, LCP),[51] and 75% (open and minimally invasive approach, LCP).[51] The prognosis is better for horses that were treated with MCP/MTP arthrodesis as a primary treatment than in situations where nonoperative treatment was tried initially and the MCP/MTP arthrodesis was elected as a last resort.[54] The prognosis was also better for horses treated for osteoarthritis than for horses treated for rupture of the suspensory apparatus, because the former have less trauma to the limb before surgery.[54]

CARPUS

Indications

In the carpal region, two types of arthrodeses are performed: the pancarpal arthrodesis, where all the joints in the carpal region are fused, and the subtotal or partial arthrodesis, involving only one or two of the joints.[6,55,56] Carpal arthrodeses are indicated for treatment of comminuted carpal fractures as well as luxations and subluxations of this region. In most animals, these operations should be viewed as salvage procedures, with the exception of animals with carpometacarpal luxations and carpometacarpal osteoarthritis. Partial carpal arthrodeses are recommended for severe osteoarthritis of the carpometacarpal joint, in cases in which the distal or proximal row of carpal bones has comminuted fractures and accurate anatomic reconstruction is impossible,[57,58] or in luxations of the carpometacarpal and the antebrachiocarpal joints.

Surgical Techniques

Facilitated Ankylosis for Osteoarthritis of the Carpometacarpal Joint

Carpometacarpal osteoarthritis (CMC-OA) is characterized by progressive lameness that responds poorly to medical treatment. With conservative management, prognosis for use is poor and prognosis for life is unfavorable.[59,60] In a recent report, 12 horses with CMC-OA in 15 joints were treated with a drilling technique that produced a bony ankylosis in 6 of 9 joints that were available for follow-up radiographs 10 months (range, 6 to 14 months) after surgery.[61] Long-term follow-up by owner interview (mean, 28.6 months after surgery) revealed that 10 of 12 horses (83%) were considered sound, and 8 of 12 horses (67%) returned to their original activity. In an *in vitro* study, three drilling techniques to remove cartilage from the CMC joint were evaluated using 4.5-mm or 5.5-mm drill bits in different drilling patterns. The mean percentage of damage caused by the three drilling techniques to the articular surface and calcified cartilage ranged from 16% to 33% and 14% to 23%, respectively.[62]

Partial Carpal Arthrodesis

Depending on the injury, partial carpal arthrodesis involves either fixing the proximal row of carpal bones to the distal row and MCIII or fixing the distal row of carpal bones to the MCIII (Figure 81-11). Additionally, partial carpal arthrodesis can be used for antebrachiocarpal luxations, where the proximal row of carpal bones is fastened to the distal radius (epiphysis and/or metaphysis). For these arthrodesis techniques, a variety of plates may be used. Currently the preferred plate is the locking compression type. Selection depends on size of the animal, availability of the plates, and preference of the surgeon. Generally 6- to 8-hole plates are used.[6,58] The horse is positioned in dorsal or lateral recumbency. General surgical and specific anatomic considerations guide the surgeon in selecting the proper approach.

Typically, the carpus is approached through two vertical skin and subcutaneous incisions, one on either side of the extensor

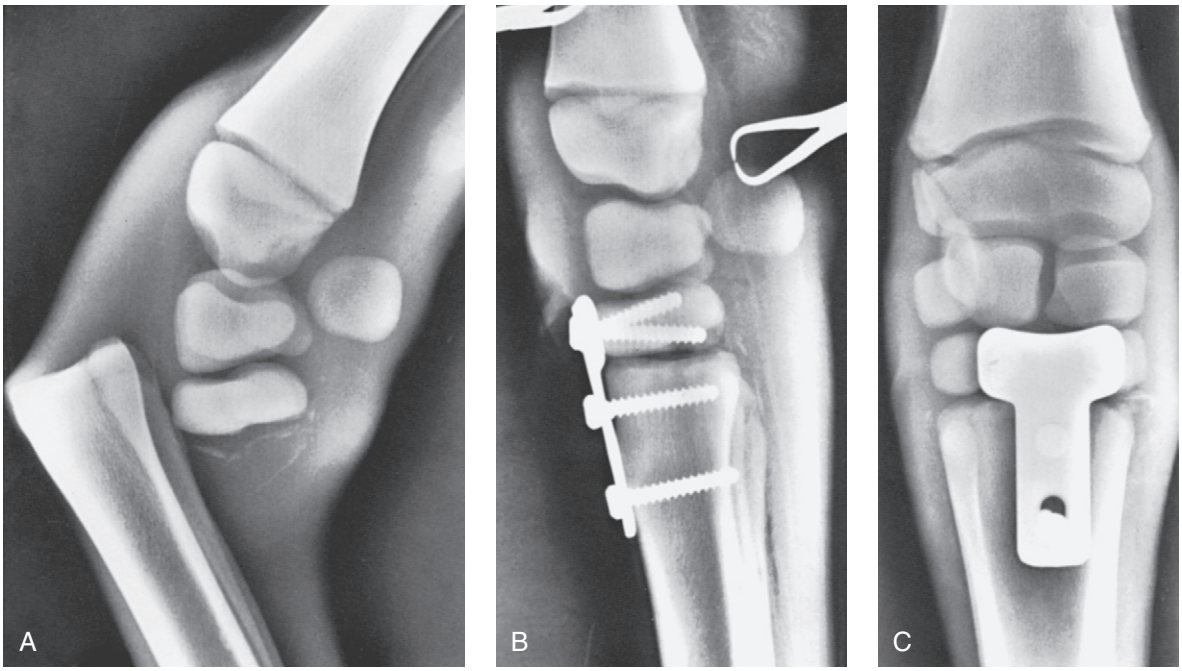

Figure 81-11. A, Lateromedial radiograph shows a carpometacarpal luxation in a 2-week-old foal. Lateromedial **(B)** and dorsopalmar **(C)** radiographs of the repair depict a 2-hole T-plate applied to the dorsal aspect of the distal row of carpal bones and the proximal aspect of MCIII. (From Auer JA, Taylor JR, Watkins JP, et al: Partial carpal arthrodesis in the horse. Vet Comp Orthop Traumatol 3:51, 1990.)

carpi radialis tendon. The incisions are extended through the joint capsule of the affected joints.Whenever possible, articular cartilage should be removed to facilitate fusion of the joint surfaces. Osteostixis as well as application of a cancellous bone graft or an alternative osteoinductive material are indicated to enhance fusion. In comminuted carpal bone fractures, strategically placed interfragmentary screws inserted in lag fashion across large bony fragments contribute considerably to the stability of the construct. In most cases, it is prudent to maintain alignment by applying one or two bone plates across the joint(s) involved. The same holds true for selected subluxations with signs of avulsion fractures and displacement of specific bones (Figure 81-12).

In a mare with severely comminuted fractures, all the fragments of the distal row of carpal bones were removed, with subsequent fixation of the proximal row of carpal bones to the MCIII. After 3 months in a tube cast, the mare developed fusion at the arthrodesis site and served for several years as a successful brood mare.[56]

One of the problems in carpal arthrodesis is the closure of the skin over the two plates that are routinely used. The placement of tension sutures in the skin over the distal carpus and the proximal metacarpus 24 hours before the surgical procedure has been effective in creating more available skin to cover the dorsal carpus. This should partially relieve the tension on the skin incision during closure over the plates.[6] If needed, relief skin incision(s) distant to the surgical approach in the carpal region facilitates skin closure.

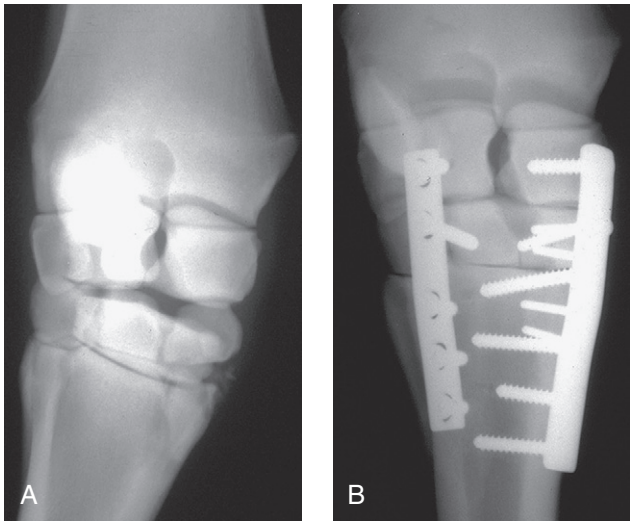

Figure 81-12. A, Dorsopalmar radiographic view of subluxation of the middle carpal joint in a 6-year-old brood mare. Note the avulsion fracture at the medial aspect of the carpometacarpal joint. The second carpal bone is also partially luxated. **B,** Postoperative dorsopalmar radiographic view showing a broad 6-hole 4.5-mm DCP applied to the dorsomedial aspect and a narrow 5-hole 4.5-mm DCP applied to the dorsal aspect of the carpal region to achieve a partial carpal arthrodesis.

Pancarpal Arthrodesis

Pancarpal arthrodesis using two long, broad DCPs or LCPs[63] is advocated for comminuted fractures involving both rows of carpal bones (Figure 81-13) and for severe degenerative carpal joint disease in older horses that develop a carpus valgus or varus deformity.[56] In severely comminuted fractures, the purpose of the plates is to buttress the unstable limb and maintain a straight axis. The 5.5-mm LCP and DHS or DCS plates are excellent options for those cases, because they are stronger than the DCP. Plate luting is recommended in pancarpal arthrodeses (see

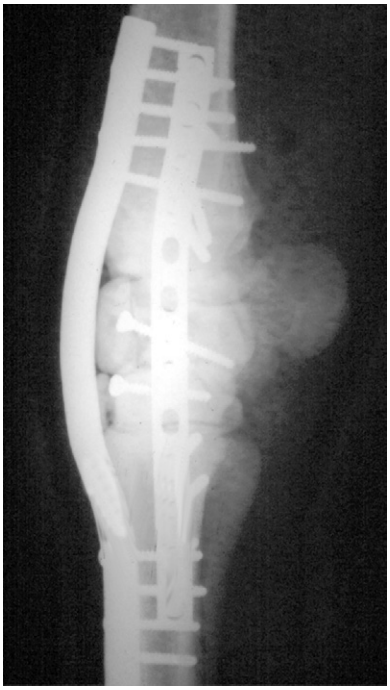

Figure 81-13. Lateromedial radiograph depicting pancarpal arthrodesis used to repair a comminuted carpal fracture. A 12-hole broad DCP bone-lengthening plate was applied to the dorsocranial aspect of the limb, and a narrow 12-hole DCP was applied laterally. Cortex screws were used to provide interfragmentary compression across slab fractures.

Chapter 76).[64] Simple cast application is not effective in supporting collapsed comminuted intercarpal fractures.[56]

The approach to the carpus can be achieved by a single, 40-cm (16-inch) vertical skin incision on the dorsal aspect of the limb and centered over the carpus. Because a long incision is used, both plates are placed through this incision along the dorsomedial and dorsolateral aspect of the limb, on either side of the extensor carpi radialis tendon, and centered over the carpus.[63] To facilitate skin closure, several towel clamps can be used to fatigue the skin edges. In extreme cases, a relief skin incision is made at a location distant to the main skin incision, avoiding an area where pressure necrosis may develop under the splint or cast (see later).

Postoperative Management

Splints, casts, or transfixation casts may be necessary, depending on the injury that led to the partial or pancarpal arthrodeses.

Complications are common with carpal arthrodeses, including supporting limb lameness, incisional infections, and implant infection. Approximately 67% of horses survive and achieve comfortable weight bearing.[65] Timing of surgery is important: a prolonged period of non–weight bearing because of conservative management of severe osteoarthritis or comminuted carpal fractures reduces the prognosis for successful outcome of the arthrodesis.[6]

SCAPULOHUMERAL JOINT

Indications

Advanced osteoarthritis and persistent luxations and subluxations of the scapulohumeral (SH) joint (Figure 81-14, *A*) in Miniature or small horses may be treated by arthrodesis with

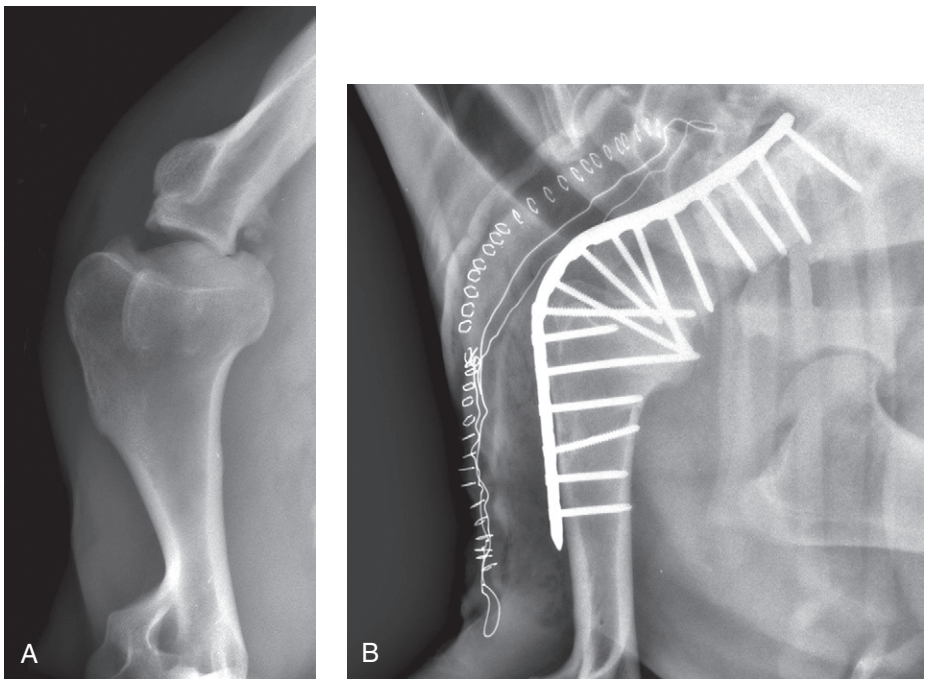

Figure 81-14. A, Craniocaudal radiographic view of a scapulohumeral subluxation in a Miniature Horse stallion. **B,** Lateromedial radiographic view of the scapulohumeral arthrodesis performed in the Miniature Horse stallion. A 16-hole 3.5-mm LCP was applied to the cranial aspect of the joint region. Over the joint, transarticular screws were implanted through the plate, providing additional stability to the fixation.

the goal of rendering the animal free from painful lameness.[66-68] This technique is not well suited for horses, because the quality of bone in this region is inadequate to withstand the tremendous mechanical forces that would be exerted on the implants. There is a report of a successful SH arthrodsis in a Paint Horse treated with two LCPs.[69]

Surgical Technique

A 10- or 11-hole, 4.5-mm narrow DCP or LCP and 4.5-mm cortex screws are applied to the cranial surface of the scapula and cranial surface of the humerus after osteotomy of the intermediate tubercle. An alternative technique involves the use of a 16-hole broad LCP (or reinforced 3.5-mm DCP) applied to the cranial aspect of the proximal humerus and the scapula following transection of the biceps tendon at the level of the shoulder joint.[70] The broad 3.5-mm plates have the same cross-sectional area as the 4.5-mm narrow plates, but more screws can be inserted through these plates, which provides a biomechanically superior fixation. Additionally, because the plate holes are smaller, there is more metal surrounding the DCP holes. In most patients, one or two plate holes located over the joint should be filled with transarticular screws inserted in lag fashion.

A report of four Miniature Horses suffering from SH osteoarthritis, some with concurrent shoulder luxation or subluxation, described SH arthrodesis as a successful technique, despite some complications.[68] The animals developed a mechanical lameness but were able to ambulate well after surgery. A recent report on a Miniature Horse suffering from persistent shoulder subluxation associated with severe osteoarthorsis resulted in the horse's becoming sound and able to gallop around the pasture without any gait anomaly following application of a 3.5-mm broad LCP (see Figure 81-14, *B*).[70]

TARSUS

Indications

The primary indication for arthrodesis in the tarsus is osteoarthritis of the tarsometatarsal (TMT) and the distal intertarsal (DIT) joint that is unresponsive to medical therapy.[8,71-73] Occasionally, luxations of the tarsus, especially involving the TMT and DIT joints, necessitate an arthrodesis.[74] Talocalcaneal arthrodesis has been described as a promising treatment for talocalcaneal osteoarthritis.[75,76]

Facilitated Ankylosis Techniques

Chemically Induced Ankylosis

Chemically induced ankylosis of the TMT and DIT joint involves the injection of a chemical agent that with time destroys the articular cartilage and facilitates ankylosis of the joints. Before such an agent can be injected into a joint, it has to be ascertained that no communications with other joints exist, such as between the DIT and the proximal intertarsal (PIT) joint. This can be established by a contrast arthrography. Two agents have been used to induce ankylosis in the tarsal region as treatment for bone spavin: monoiodoacetate (MIA) and ethyl alcohol.

Intra-articular injection of 100 to 250 mg of MIA, a chemical compound that causes cartilage death and stimulates fusion, was introduced as a treatment for osteoarthritis of the TMT and DIT joints.[77,78] Attributes of this treatment that limit its acceptance as a method for treatment of bone spavin include the severity of discomfort of the horse immediately after treatment, postinjection soft tissue swelling, progression of osteoarthritis in the PIT joints, severe soft tissue necrosis that can occur with extra-articular injection, variable length of convalescence, and inconsistent outcome.[4,77-79]

Two reports recommend the use of intra-articular administration of ethyl alcohol for treatment of bone spavin in horses.[80,81] The mechanism of action of ethyl alcohol is through nonselective protein denaturation and cell protoplasm precipitation and dehydration.[80] Ethyl alcohol also functions as a neurolytic agent that results in a sensory innervation blockade at the intra-articular level. The neurolytic properties and nonselective destruction of proteins contribute to its success at disrupting the cartilaginous matrix, causing necrosis of the chondrocytes and facilitating arthrodesis.[79] Ethyl alcohol is inexpensive and readily available to most practitioners. This newer method of faciltated ankylosis of the TMT joint has been invesigated in eight healthy horses.[80] In each horse, one TMT joint was injected with 4 mL of 70% ethyl alcohol, and the opposite joint was treated with 4 mL of 95% ethyl alcohol. A mild swelling at the injection site persisted for 24 hours in all horses, but no obvious signs of discomfort were observed. Mild lameness was detected in 2 of 16 limbs during the first week of the study. Postmortem examination 12 months after treatment revealed that there was gross and histopathologic evidence of local bony fusion in all but 1 of the 16 TMT joints. However, complete obliteration of the TMT joint was not detected in any of the joints investigated. A second study reported radiographic evidence of ankylosis 4 to 6 months following injection of 3 mL of 70% ethyl alcohol in 16 horses.[81]

Laser-Facilitated Ankylosis

Laser-facilitated ankylosis using a neodymium:yttrium-aluminum-garnet (Nd:YAG)[81] or diode[4,82] laser to destroy articular cartilage by superheating and vaporizing synovial fluid, which should result in chondrocyte death, has also been performed. Clinical studies are currently not available, but experimental studies in sound horses demonstrated that laser application promotes partial ankylosis of the DIT joint within 5 to 12 months.[4,82] However, diode laser–facilitated ankylosis resulted in significantly less fusion of the distal tarsal joints compared to MIA injection or transarticular drilling (see next).[4]

Transarticular Drilling Technique

Transarticular drilling of the distal tarsal joints to facilitate ankylosis is a commonly performed surgical treatment.[83] The animal is positioned in lateral recumbency, providing access to the dorsomedial aspect of the tarsus involved. If the procedure is performed in both hindlimbs at the same time, the horse is positioned in dorsal recumbency. After routine preparation of the surgical site for aseptic surgery, a 3-cm (1¼-inch) vertical skin incision is made on the dorsomedial aspect and centered over the TMT and DIT joints. The sites for drill bit entry are midway between a line extending from the groove between the proximal MTII and MTIII and the most dorsal aspect of the distal tarsus (at the level of the TMT and DIT joints) (Figure 81-15). This is adjacent to the plantar margin of the saphenous vein, which has to be displaced dorsally to avoid iatrogenic

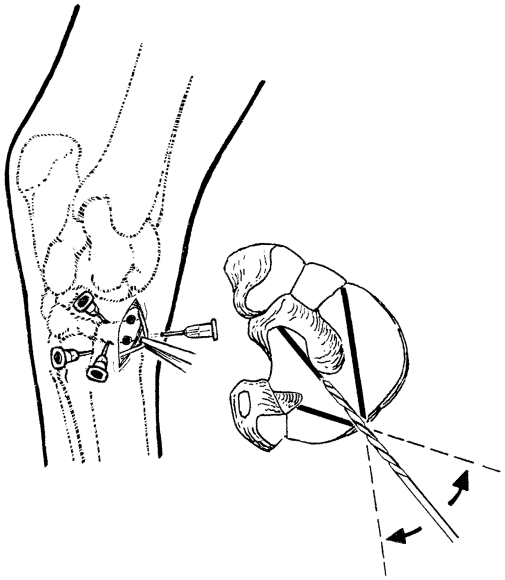

Figure 81-15. Graphic illustration of the drilling technique for tarsal arthrodesis. The sites for drill bit entry are midway between a line extending from the groove between the proximal MTII and MTIII and the most dorsal aspect of the distal tarsus (at the level of the TMT joint and DIT joint). Three diverging drill holes are made along the articular surfaces of the distal tarsal joints using intraoperative imaging.

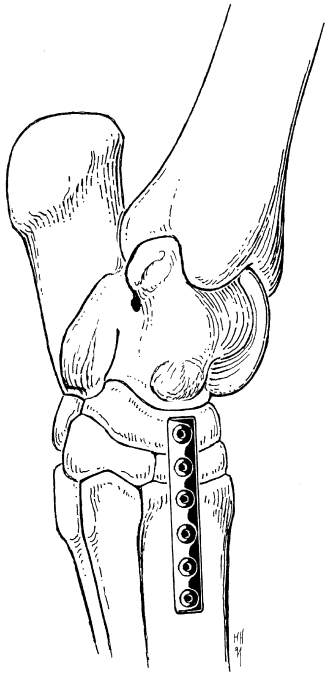

Figure 81-16. Graphic illustration of a tarsal arthrodesis with a six-hole narrow DCP applied medially. One screw penetrates both the central and third tarsal bones. The remaining screws are placed into the proximal MTIII.

trauma. Placement of a Penrose drain around the vein facilitates its manipulation during the surgical procedure. The TMT and DIT joints are identified with hypodermic needles using intraoperative radiographs or fluoroscopy.

A 4.5-mm drill bit is passed into the joint space in three directions from a single entry point on the dorsomedial aspect of the tarsus, creating a fanlike pattern of holes.[11] The tracts are best drilled in pairs (TMT and DIT): first, a 20-mm long tract directed toward the most lateral palpable extremity of MTIV; second, a 20-mm tract angled 30 degrees to the first in a plantar direction; and third, a 35-mm tract angled 30 degrees to the first in a dorsal direction. For intraoperative imaging, it is important to orient the x-ray beam perpendicular to the drill tract and to angle as necessary in a distal to proximal direction to bring the joint margins into convergence. The number of images can be reduced if two drill bits are used and tracts in the TMT and DIT joints are imaged simultaneously. The procedure described resulted in consistent destruction of articular surface of the TMT and DIT joint.[84] The average destruction of joint surface was 18.0% (14.5% to 23.8%) for the proximal MTIII and 21.7% (15.1% to 30.4%) for the proximal third tarsal bone, respectively.[84]

Drilling too deeply may lead to penetration of the tarsal canal, resulting in unnecessary periosteal reaction or profuse hemorrhage from disruption of the perforating branch of the cranial tibial artery. Excessive side-to-side drilling causes instability, severe pain, and prolonged recumbency and is associated with excessive periosteal new bone formation.[85] Most of the horses in which excessive drilling has been performed never regain complete soundness.[85]

The estimates of outcome following transarticular drilling suggest that this treatment may be successful in 47% to 85%, depending on the technique and study design.[71,86-88]

Fixation Techniques

Plate Application for Arthrodesis

One technique consists of applying a narrow DCP or LCP over the medial aspect of the tarsal region (Figure 81-16). Fibrous covering of the dorsomedial aspects of the joints together with any exuberant exostoses are partially removed with an osteotome and mallet. This facilitates identification of the joint spaces involved, provides a greater plate–bone contact area, and reduces the amount of plate contouring needed. The PIT joint space is identified through placement of two hypodermic needles or two 2-mm drill bits using intraoperative imaging technique.

As an optional procedure, two drill holes, 4.0-mm in diameter are prepared along each of the joints as previously described.[85] These holes may be filled with a bone graft plug harvested from the proximal tibia or the tuber coxae. Placement of such a plug, hydroxyapatite granules, or biodegradable bone cement will enhance osseous union of the two articulations by means of spot welds.

The selected 5-hole narrow 4.5-mm DCP is applied to the arthrodesis site.[89] The thread hole for the most proximal plate screw is drilled with the 4.0-mm drill bit protected by the corresponding drill guide within the body of the central tarsal bone, parallel to the joint surfaces. In smaller horses, 4.5-mm screws may be used instead of 5.5-mm screws. In that case, a 3.2-mm thread hole is prepared. (It is important to use 5.5-mm cortex screws whenever possible, because they resist cyclic loading better than 4.5-mm screws. Screws 4.5 mm in diameter often fail in an adult horse.)

After tapping the thread hole, a 30- to 40-mm-long cortex screw is inserted through the most proximal plate hole and tightened. Care is taken to select screws shorter than the

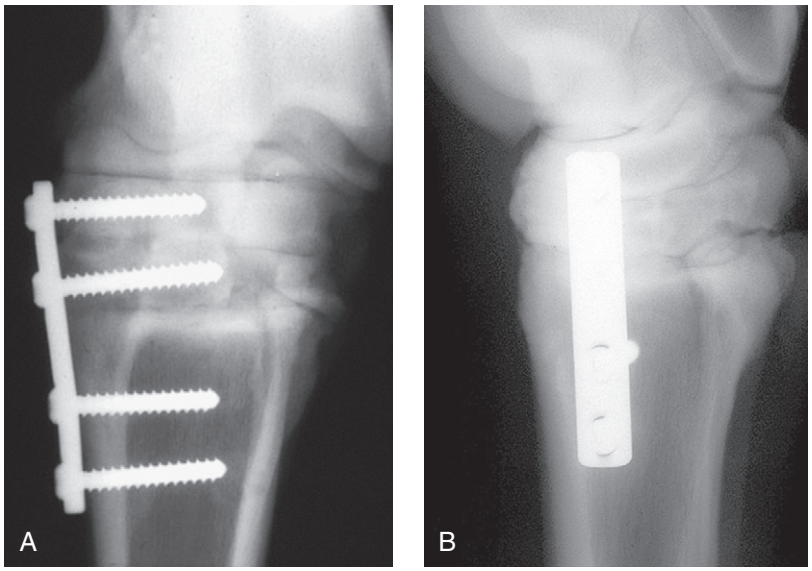

Figure 81-17. Dorsoplantar **(A)** and lateromedial **(B)** 4-week postoperative radiographic views of a tarsal arthrodesis using a four-hole narrow DCP in a 9-year-old Andalusian gelding. One 5.5-mm cortex screw is inserted into both the central and the third tarsal bones. Two identical screws are placed into the proximal MTIII. Note that the drill holes into the two distal joints are already filling in with new bone and becoming less obvious on these radiographs.

measured blind-ending hole in the bone to prevent impacting upon the dead-end hole, which prevents the screw from compressing the plate onto the bone. The tension device is applied subsequently at the distal end of the plate, secured to MTIII, and tightened. One or two plate screws are subsequently inserted into MTIII. After the tension device is removed, the remaining plate holes are filled with screws. If the DIT and TMT joints are to be fused, one screw is inserted into the central tarsal bone and one into the third tarsal bone (Figure 81-17).

After flushing the surgical site, the subcutaneous tissues and the skin are closed in routine fashion. The surgical site is covered by a bandage.

Postoperatively, the limb is kept under a bandage for 2 to 3 weeks. The skin sutures or staples are removed 10 days after the surgery. Lameness can persist for several months. Rehabilitation must be conducted gradually over several months.

The disadvantage of this techniques is that the only implant bridging the different joints is the plate at one loaction. It can be argued that this fixation technique does not sufficiently counteract rotational forces acting parallel to the joint surfaces. Therefore the insertion of oblique transarticular screws through the plate and adjacent to the plate should result in a greater area of fixation throughout the tarsal region. Up to now, no *in vitro* studies have been conducted to prove this theory.

The use of LCPs is presently encouraged for this procedure. A prototype of an LCP (Figure 81-18) that includes seven fixed-angle locking screws that cross the joint spaces of the DIT and the TMT joint is currently under investigation. The plate is applied to the dorsomedial aspect of the central and third tarsal bone as well as to the proximal aspect of MTIII. The second hole from the bottom is an elongated combi-hole and it allows dynamic axial compression. The remaining three plate holes over MTIII are filled with locking head screws. The placement of the screw holes within the head of the plate and their orientation in proximodistal as well as in lateromedial direction was tested in several cadaveric bones to ensure correct arrangement. No clinical case has yet been treated with this plate.

An alternative technique involves implanting perforated stainless steel cylinders filled with autogenous cancellous bone in the distal tarsal joints.[53] This technique was applied in four horses. Graft cell survival was poor 2 weeks after surgery in one horse. In two horses at 10 months, there was partial arthrodesis of the joints, with incorporation of the implants into the osseous union. The implants were filled with vascularized bone. These two horses were sound 9 months after surgery, but one horse fractured its third tarsal bone and still had a positive response to a hock flexion test 12 months after surgery.

A more involved technique that is occasionally used in tarsal luxations involves the application of a 12- to 14-hole broad DCP or 5.5-mm LCP to the plantarolateral aspect of the calcaneus and proximal metatarsal region (Figure 81-19). This technique allows extension of the plate farther proximad, resulting in a stronger arthrodesis. In selected cases, MTIV is removed before plate application. However, care must be taken to avoid damage to the greater metatarsal artery coursing between MTIII and MTIV. The surgical approach is more extensive than that for the technique described earlier, and the surgery itself is more demanding. Care must be taken to avoid penetrating the tarsocrural joint with a screw. Selected screws can be placed in lag fashion across the more distally located joints, facilitating interfragmentary fixation.

Talocalcaneal Arthrodesis

For talocalcaneal arthrodesis, the horse is placed under general anesthesia in lateral recumbency, with the affected limb positioned uppermost.[75] Application of a tourniquet proximal to the tarsus is optional. A slightly curved incision is made over the distal half of the calcaneus, and the tissues are sharply divided down to the bone.

Needle markers are used to determine the correct angulation of the future screws under fluoroscopic guidance. Computer-assisted guidance greatly facilitates preparation of the drill holes (see Chapter 13). The drill bit is aimed toward the plantaromedial aspect of the medial trochlear ridge of the talus, avoiding penetration of the tarsocrural joint at the intertrochlear groove.

Two or three 5.5-mm cortex screws are inserted in lag fashion across the lateral facet, using routine technique (Figure 81-20).

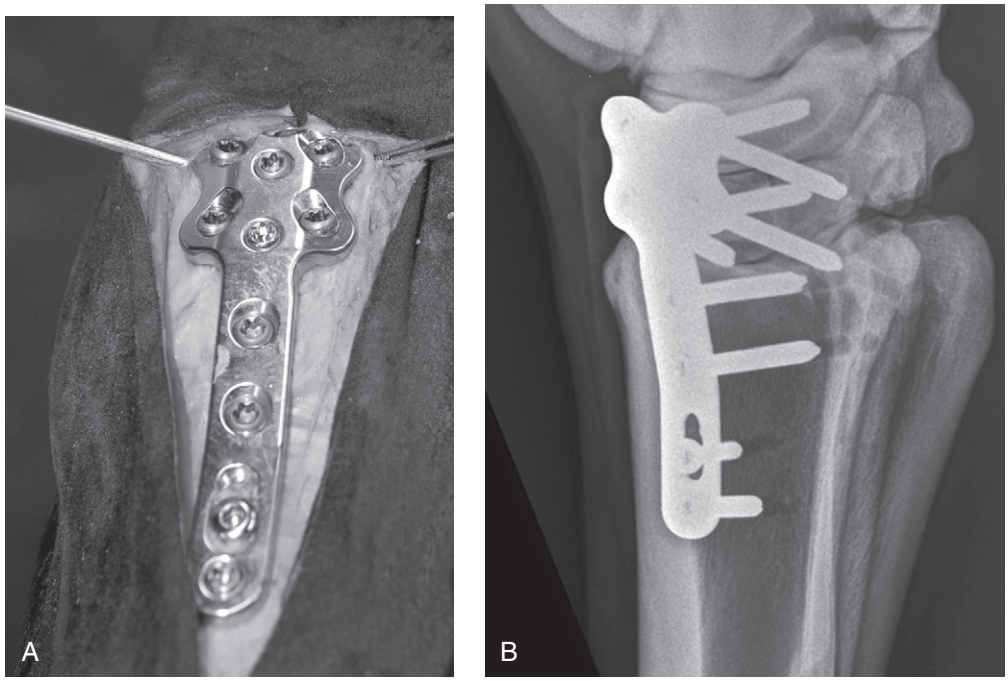

Figure 81-18. A, The new tarsal arthrodesis plate applied to the tarsal region. Seven locking screws are applied into the small tarsal bones at different angles. The second hole from the bottom is oblong and allows dynamic axial compression. The remaining three plate holes over the MTIII are filled with locking head screws. **B,** Oblique radiographic view of the tarsal region depicting the orientation of the screws.

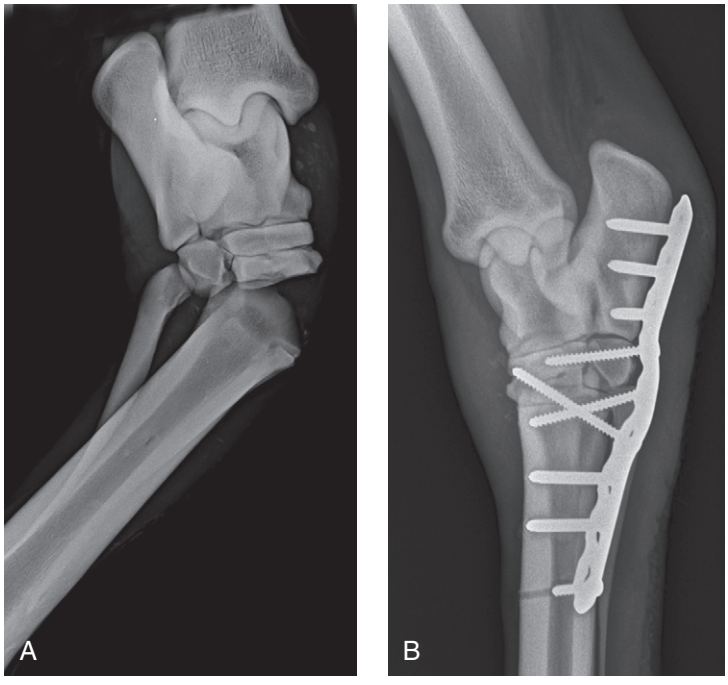

Figure 81-19. A, Craniocaudal radiographic view of a tarsometatarsal luxation in a pony. **B,** Oblique postoperative radiographic view of the tarsal region after application of 9-hole narrow 4.5/5.0-mm LCP to the palmarolateral aspect of the calcaneus and proximal MTIII region.

There is an adequate amount of solid bone present to achieve stable transarticular compression. By slightly altering the direction of the screws, an increased compressive effect can be achieved. To prevent weakening of the calcaneal bone, washers may be applied, which negate the need for countersinking.[75] Alternatively, the screws may be inserted through a plate contoured to the calcaneal surface. Once the screws are in place and solidly tightened, the incision is closed using routine technique.[75]

A slightly different technique was presented in another report, where two clinical cases were also treated with 5.5-mm cortex screws applied in lag fashion.[76] In a pony, three parallel screws were inserted through a dorsomedial arthrotomy to the talus. The screws were placed across the medial facet into the

Figure 81-20. Oblique postoperative radiographic view of a talocalcaneal arthrodesis performed through three converging 5.5-mm cortex screws inserted in lag fashion across the lateral facet of the talocalcaneal joint. Washers were used in the two proximal screws to increase the contact area of the implants and reduce stress concentration at the bone–screw head junction. (Courtesy R. Smith, Royal Veterinary College, London.)

calcaneus; in a horse, identical screws were augmented with two additional screws similarly inserted as described in the first technique.[76] Both techniques resulted in successful fusion.[6,89] Talocalcaneal arthrodesis could develop into an effective treatment for local talocalcaneal osteoarthritis. Early results are encouraging.

COMPLICATIONS

Complications of arthrodesis include postoperative infection,[90] implant failure, laminitis in the opposite limb, long-term lameness, and development of angular limb deformities. Accidental insertion of bone screws into a joint space can provide a continuous source of pain and should be avoided. This can be done by meticulous surgical technique and careful intraoperative radiographic control.

CHAPTER
82 Management of Bursitis

Gary M. Baxter

STRUCTURE AND FUNCTION OF BURSAE

A bursa is a closed sac lined with a cellular, synovial-like membrane, interposed between two moving parts or at points of unusual pressure such as between bony prominences and tendons.[1] This synovial sac can be completely enclosed beneath the skin or tendon, or it can partially surround the tendon in the form of a synovial sheath (Figure 82-1). Bursae differ from tendon sheaths because they do not completely surround the tendinous structure and are located on one side of the tendon only, between it and a bony prominence.

Bursae in horses are often classified as to when they form (congenital versus acquired) and their anatomic location (subcutaneous versus subtendinous versus subligamentous). *Congenital* bursae are those that are part of the normal anatomic structure and develop before birth. They are in a constant position, are often associated with deep structures, such as fascia, muscles, and tendons; and are viewed as "true" synovial bursae. Examples are the navicular bursa, bicipital bursa, and calcaneal bursa. *Acquired* bursae are those that occur after birth, usually from trauma. They develop over bony prominences, are usually located subcutaneously, and are viewed as "false" bursae. Examples are carpal hygroma, elbow hygroma, and capped hock. A subcutaneous bursa is nearly always acquired and has also been termed "reactive" or "functional" since they usually develop from mechanical effects after birth.[1] Movement of the skin after some form of trauma contributes to tearing of the subcutaneous connective tissue, gap formation under the skin, and fluid accumulation. The fluid exudate accumulates in the subcutaneous space and becomes encapsulated by fibrous tissue, forming a false bursa.[1] Ultimately, a synovial-like membrane develops and produces jointlike fluid, although it differs in viscosity and mucin clot formation.[1] Subtendinous bursae are congenital or true bursae associated with origins and insertions of muscles and tendons and are critical in normal movement of the limbs. They are considered synovial structures similar to tendon sheaths and joints and have the most significant clinical implications in the horse. Subligamentous bursae are the least problematic type of bursa and have few clinical implications in horses. The most notable examples are the atlantal and supraspinous bursae associated with the ligamentum nuchae.[1]

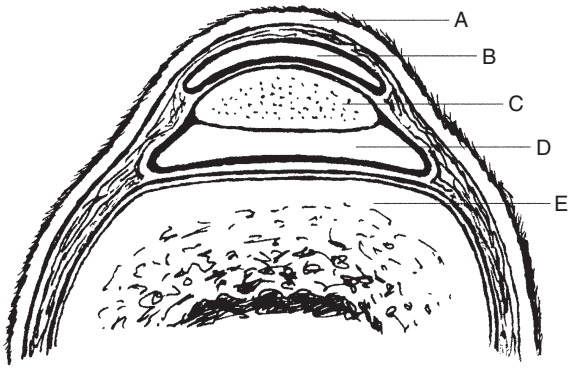

Figure 82-1. Diagram illustrating the anatomic location of a subcutaneous bursa and a subtendinous bursa as they occur at the tuber calcanei. *A,* Skin; *B,* subcutaneous bursa; *C,* tendon (SDFT); *D,* subtendinous or calcaneal bursa; *E,* bone (calcaneus).

Chronic bursitis is characterized by the accumulation of bursal fluid and thickening of the bursal wall by fibrous tissue; fibrous bands and septa may develop in the bursal cavity, and the subcutaneous tissues around the bursa may continue to thicken. Bursal enlargement usually develops as a painless swelling that does not typically interfere with function unless it becomes greatly enlarged. In most cases, the acquired bursa is only a cosmetic blemish unless it becomes infected. The bursae may become infected by a puncture or iatrogenic incident.[2] An infected bursa is usually painful, which contributes to lameness, and it may break open to drain, resulting in a fistula (see Chapter 28).

ETIOLOGY OF BURSA-RELATED CONDITIONS

Bursitis is defined as an inflammatory reaction within a bursa and may range in severity from a cosmetic blemish associated with a capped hock to a non–weight-bearing lameness secondary to infectious bursitis. Trauma is the most common cause, and in general, horses with noninfectious bursitis are much less symptomatic than those with infectious bursitis. Trauma may occur in the form of repetitive use injury as seen with navicular disease or syndrome, repetitive external injury such as occurs with elbow hygroma, single event external blows often seen with carpal hygroma, and external wounds causing infection commonly seen in the navicular and calcaneal bursae.[1,3-6] Infection within a bursa, however, may also occur from hematogenous spread of bacteria similar to other synovial cavities.[7-10]

Repetitive Use Trauma

This type of problem is most commonly identified in the navicular bursa associated with navicular disease or syndrome, the cunean bursa associated with distal tarsal osteoarthritis, and the trochanteric bursa secondary to other lameness conditions in the hindlimb. Bursitis in these horses is usually a secondary manifestation of the primary problem and not the only cause of the lameness. For instance, navicular bursitis in horses with navicular disease may result from pathology of the navicular bone, the deep digital flexor tendon, or the podotrochlear apparatus. It is rarely the only pathologic process (see Chapter 90).

Repetitive External Trauma

This form of trauma causes problems at bony prominences such as the point of the ulna (elbow hygroma; shoe boil) and tuber calcanei (capped hock) and contributes to the development of a subcutaneous or false bursa in these locations. For instance, the shoe of the affected limb constantly hitting the point of the elbow when the horse is lying down contributes to elbow

hygromas. The repetitive nature of the trauma also worsens the problem and makes treatment difficult unless the predisposing cause is eliminated.

Single Event External Trauma

This tends to occur most commonly over the cranial aspect of the carpus (horse falling to its knees) contributing a carpal hygroma, the cranial aspect of the shoulder (kick injury or running into a solid object) causing bicipital bursitis, and the tuber calcanei (hit a stall door or wall) contributing to a capped hock.

Wounds or Penetrating Injuries

Any type of wound that enters a bursal sac may contribute to infection. This can occur with both congenital and acquired bursae, and in any location. Infectious bursitis secondary to wounds most commonly involves the navicular bursa, calcaneal bursa, and bicipital bursa. Iatrogenic infection of subcutaneous bursae may occur following medical (drainage and injection of corticosteroids) or surgical (Penrose drain placement) treatments. Hematogenous spread of infection has been reported most commonly in the bicipital bursa and the supraspinous bursa. I have seen several foals suffering from infectious bicipital bursitis consistent with the "joint ill" syndrome. *Brucella abortus* infection of the supraspinous bursa can be associated with fistulous withers.[11]

DIAGNOSIS OF BURSA-RELATED CONDITIONS

The diagnosis of bursitis depends on the specific bursa that is affected and the initiating cause. For instance, the diagnosis of subcutaneous bursitis can often be made based on the history and physical findings of a soft, fluctuant swelling in specific anatomic locations where they tend to occur. Acute and chronic bursitis of true bursae, such as the navicular, calcaneal, bicipital, and trochanteric bursae, usually cause lameness in horses. Local swelling, heat, and pain may be evident in horses with bicipital and calcaneal bursitis but are often not present with navicular and trochanteric bursitis. In addition, bursitis at any of these locations is often secondary to other musculoskeletal problems that usually require additional imaging modalities, including radiology, ultrasonography, and magnetic resonance imaging (MRI). (See the discussion of specific bursal problems next.)

In general, most bursal problems can be diagnosed with a combination of radiology (including contrast radiology) and ultrasonography. The exception to this is the navicular bursa, where MRI is often needed to document the extent of the damage within the bursa (Figure 82-2). With subcutaneous bursae, ultrasonography can document fluid accumulation beneath the skin and rule out involvement of deeper structures. Ultrasonography is also helpful to determine primary tendon or ligament pathology, especially with bicipital, infraspinatus, and calcaneal bursitis, and to identify involvement of the bursa from wounds and penetrating injuries. Injection of sterile contrast media combined with radiographs can also be used to determine the extent of a subcutaneous bursa but is especially beneficial to document bursal involvement from penetrating injuries. This is especially true for injuries involving the navicular and calcaneal bursae (Figure 82-3).

Horses with infectious bursitis from wounds are typically much more lame than those with noninfectious bursitis, and they often present with clinical signs consistent with any synovial infection.[10] Their lameness grade is often 4 to 5 out of 5, and they often have significant heat, pain, swelling, and drainage associated with the infected bursa. Although any bursa can become infected, those involved most frequently include the navicular, calcaneal, and bicipital bursae. The diagnosis,

Figure 82-2. Lateral **(A)** and dorsopalmar **(B)** MRIs of an 8-year-old Quarter Horse gelding showing obliteration of the navicular bursa with scar tissue *(arrows)* secondary to chronic navicular disease and deep digital flexor tendinitis.

treatment, and prognosis of infectious bursitis are similar to those of any other synovial cavity in the horse.

GENERAL TREATMENT OF BURSA-RELATED CONDITIONS

Treatment of bursitis varies considerably depending on the location, duration, and presence of infection or other primary musculoskeletal problems. In general, conservative treatments are usually attempted first unless synovial infection is present. Acute *subcutaneous bursae* of the elbow, tarsus, and carpus usually respond to topical and systemic anti-inflammatories, pressure bandaging, and removal of the inciting cause. More chronic hygromas may be treated with drainage, injection of corticosteroids or iodine-containing compound and bandaging. Surgical drainage using Penrose drains may also be used, although I do not advocate it, and surgical extirpation of the entire subcutaneous bursal sac is recommended if other treatments fail.[1,2] Treatment of *subligamentous bursae* primarily involves the supraspinous bursa (fistulous withers), which is usually infected and usually requires surgical extirpation of the bursa and fistulas together with systemic treatment with antimicrobials.[12,13]

Treatment of nonseptic and septic bursitis affecting true or synovial bursae is similar to that for synovitis of joints and tendon sheaths. *Acute nonseptic bursitis* can be treated with systemic, topical, and/or intrasynovial anti-inflammatories, such as corticosteroids and hyaluronan, combined with rest and pressure bandaging. *Infected bursae* should be treated with wound débridement, synovial lavage and drainage, and systemic, intrabursal, and regional antimicrobials.[10] Approaches for bursoscopy of the navicular, calcaneal, and bicipital bursae have been described and are preferred over open techniques in most cases.[4,14-16] In addition, bursoscopy is recommended as both a diagnostic and treatment tool in many cases of chronic bursitis where a definitive cause cannot be determined.

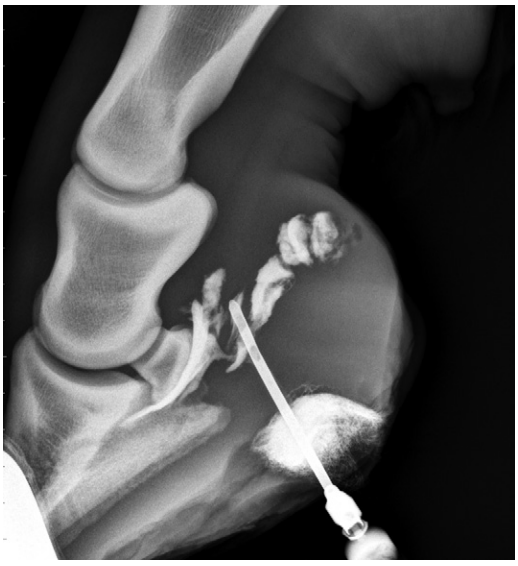

Figure 82-3. Lateral contrast radiograph of the foot of a horse with drainage from the lateral sulcus of the frog of 6 weeks' duration. Placement of a teat cannula into the defect and injection of contrast media confirmed communication with the navicular bursa.

PROGNOSIS OF BURSA-RELATED CONDITIONS

In general, bursitis in small subcutaneous and subligamentous bursae usually responds well to treatment and has an excellent prognosis for complete resolution. More chronically problematic subcutaneous bursae or those that become infected can present a greater clinical challenge, but most can be successfully resolved without causing lameness. Recurrence of infection tends to arise most commonly in horses with supraspinous bursitis, and leads to redevelopment of draining tracts in the withers area.[12,13] The prognosis for horses with infectious bursitis is nearly always more serious than those with noninfectious bursitis, regardless of the location. Infection within bony structures nearly always worsens the prognosis, especially within the navicular, calcaneal, and bicipital bursae.

MANAGEMENT OF CLINICALLY SIGNIFICANT BURSAE

Subcutaneous Bursae

Olecranon Tuberosity (Olecranon Bursitis)

Shoe boil or capped elbows are two common names for olecranon bursitis.[17] It has been regarded as a problem in draft breeds, but a recent report detailed 10 cases in Quarter Horses.[2] It is usually seen as a movable swelling over the point of the olecranon tuberosity that is usually trauma-induced from the shoe of the affected limb hitting the point of the elbow during motion or more commonly when the horse is lying down. The swelling may contain fluid, primarily fibrous tissue, or both, in the chronic stages (Figure 82-4). Lameness is usually not present unless the bursa is greatly enlarged or infected. The diagnosis can usually be made on physical findings alone. However, if the bursa appears infected, radiographs should be

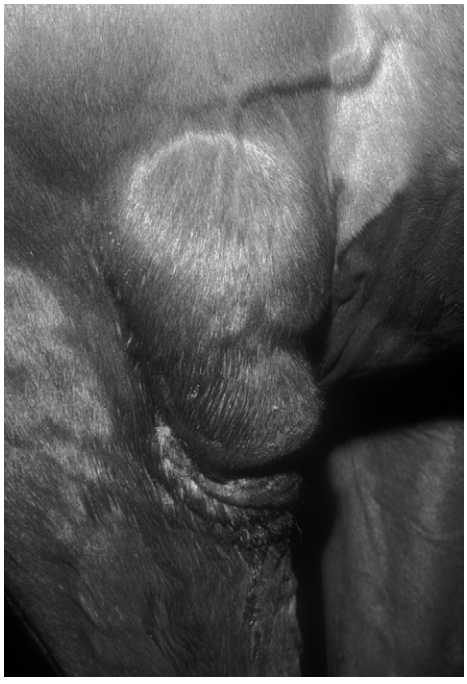

Figure 82-4. Large "shoe boil" on the olecranon process that was soft, fluctuant, and nonpainful.

taken to rule out trauma or infection involving the olecranon process.

In the acute stage, the condition may resolve by preventing further trauma to the region, with the use of a shoe boil roll or boot. The fluid can be drained aseptically and corticosteroids injected, and this can be repeated multiple times.[2] However, in one report, bursitis in 7 of 10 horses treated with intrabursal steroids did not resolve.[2] Anecdotally, injecting 7% iodine or iodine-based radiographic contrast material into the lesion or packing the incised bursa with iodine-soaked gauze have also been recommended with variable success.

Surgical intervention either by drain placement or *en bloc* resection appears to have the greatest success.[2,18] *En bloc* resection is the treatment of choice for large and mature acquired olecranon bursae. Preferentially the procedure is performed standing. Local anesthesia is administered and a curved skin incision over the lateral aspect is made. A plane of dissection is made to remove the mass in its entirety. Excess skin is removed as needed, and the deep and subcutaneous layers are closed with absorbable sutures. The skin is then closed in a tension-reducing manner, such as widely placed vertical mattress sutures. A stent bandage is placed to protect the suture line and provide some compression. The horse can be maintained in cross ties or an overhead wire until satisfactory healing is attained, usually for 2 to 3 weeks.[2] *En bloc* resection is regarded as a superior way to manage the lesion with good cosmesis.[2]

Tuber Calcanei (Capped Hock)

The subcutaneous bursa on the tuber calcanei is located between the skin and the superficial digital flexor tendon and is analogous to the bursa at the point of the olecranon. However, the subcutaneous bursa may communicate with the subtendinous bursa at the point of the hock in about one-third of horses.[19] Direct trauma to the point of the hock from a kick or the horse hitting a hard object such as a stall wall (this may be a bad habit and occur repeatedly) or fence is the most common cause of a capped hock.[20] These injuries may or may not be associated with a wound.

A nonseptic capped hock is usually characterized by a soft, fluctuant swelling located directly at the point of the hock. Subcutaneous edema in acute cases and thickening and fibrosis of surrounding tissues in chronic cases may make the diagnosis more difficult. Lameness may or may not be present, depending on the time since injury, but it is usually minimal after a few days. In general, signs of lameness are much less for nonseptic injuries of the subcutaneous bursa than the calcaneal bursa. Penetrating injuries to the tuber calcanei may involve the subcutaneous bursa, the calcaneal bursa, or both, and close evaluation of these injuries is important to determine the ideal treatment protocol.

Treatment of horses with a capped hock can be variable depending on the severity. Small swellings may merely be a cosmetic concern and not require treatment. However, measures to eliminate further trauma to the tuber calcanei are suggested to prevent the capped hock from worsening.[1] Larger swellings are treated in a manner similar to olecranon bursitis and carpal hygromas. Topical application of anti-inflammatories such as ice, dimethyl sulfoxide (DMSO), or diclofenac liposomal cream (Surpass) combined with bandaging may be beneficial in the acute stage. Other options include aseptic drainage and injection of corticosteroids or iodinated contrast agents.[1] Counterpressure with bandaging is recommended for at least 2 weeks but can be difficult in this high motion area. A compressive sleeve type of bandage can be beneficial in these cases. Surgical drainage using Penrose drains or complete removal of the bursa is rarely recommended because of the problems with wound healing in this location. The prognosis for acute swellings is usually very good with appropriate treatment. Superficial wounds to the subcutaneous bursa usually resolve with routine wound care and have an excellent prognosis.[6] Chronic swellings at the tuber calcanei can be problematic but are more of a cosmetic than functional problem in most horses. However, puncture wounds to the tuber calcanei can contribute to infection within the subcutaneous and calcaneal bursae and subsequent osteitis or osteomyelitis of the calcaneus. Treatment of severe infection in this location can be problematic and may greatly limit future performance.

Carpal Hygroma

A hygroma is an acquired bursa on the dorsum of the carpus caused by trauma from falling, getting up and down, or hitting a fence or by chronically pawing and hitting the dorsum of the carpus, such as on a feeder or water trough.[18,21] A nonpainful fluctuant, uniform soft tissue swelling develops on the dorsal aspect of the carpus that is not associated with joints or tendon sheaths (Figure 82-5). Range of motion of the carpus may be mechanically reduced, but lameness is unusual. However, if the hygroma is infected, then lameness can be moderate to severe. Injection of a radiopaque contrast agent into the hygroma usually confirms its extra-articular position, although ultrasonography can be used. If a hygroma is suspected of being infected, a fluid sample should be submitted for cytologic evaluation and culture, similar to the procedures performed for septic arthritis.

Some hygromas resolve on their own, but in most cases drainage and injection of anti-inflammatory agents are used,

Figure 82-5. A hygroma on the cranial aspect of the carpus that developed from trauma to the area.

and in many horses repeated injections are necessary.[18,21] I have seen spontaneous resolution of carpal hygromas after injection of iodine-containing contrast agent. Injection of atropine (7 mg total dose) may also help to resolve the swelling. Owners should be warned that bandaging and possibly splinting is an essential component of treatment and that long-term chronic thickening may occur. Draining the mass with a Penrose drain and bandaging have also been used successfully for recurrent hygromas. In recalcitrant cases, surgical excision is best accomplished if the fluid sac is left intact (complete extirpation) and is dissected free *in toto* from the other tissues. Soft tissue and skin closure are routine, and a splint or sleeve cast should be used to prevent carpal flexion for at least 10 days or until the sutures are removed. The limb is subsequently kept under a bandage for 2 more weeks.

Subtendinous Bursae

Navicular Bursa

The navicular bursa (bursa podotrochlearis) is a true synovial bursa interposed between the deep digital flexor tendon (DDFT) and the fibrocartilaginous distal scutum covering the flexor surface of the navicular bone. It has a large outpouching that extends proximally almost to the distal aspect of the digital flexor tendon sheath (see Figure 82-3). The volume of the navicular bursa is small (2 to 3 mL), and although no direct communication exists between it and the distal interphalangeal joint, both medication and local anesthesia can diffuse into the bursa from the joint.

The cause of *nonseptic navicular bursitis* is repetitive-use trauma in horses with navicular disease or syndrome. Pathology of the flexor surface of the navicular bone and the DDFT at the level of the navicular bone is common with navicular disease or syndrome, and both can contribute to acute or chronic navicular bursitis (see Chapter 90).[22,23] Adhesions between the navicular bone and the DDFT, thickening of the bursal lining, and collapse of the bursal space are not uncommon in horses with chronic navicular disease or syndrome (see Figure 82-2). A definitive diagnosis of navicular bursitis and pathology secondary to navicular problems is best determined with MRI,[22] but is often assumed to be present in most horses with the disease. Treatment of nonseptic navicular bursitis is usually aimed at the primary navicular syndrome but often includes injections of anti-inflammatories into the navicular bursa.[22,24] Corrective trimming and shoeing to alleviate the pressure of the DDFT on the navicular bone (and therefore the bursa) is often performed concurrently.

The causes of *septic navicular bursitis* include penetrating injuries of the foot (see Chapter 90) or iatrogenic infection following intrabursal injections. The classic example is puncture of the central third of the frog with a nail that enters the navicular bursa. Bacteria and possibly other debris are deposited within the bursa, which contributes to synovial infection and severe lameness. If possible the location, direction, and depth of a nail or other metallic object are best determined with radiographs before removal. Additional diagnostics that can be performed to confirm involvement of the navicular bursa include distention of the bursa with saline to detect leakage from the wound, plain radiographs (presence of gas), radiographs with a metallic probe inserted in the previously thoroughly débrided wound, or contrast radiography (fistulogram; see Figure 82-3).[10] Concurrent fractures and osteolysis as a result of infection should also be assessed with radiography. Treatment should be aggressive and is similar to any infection within a synovial cavity. Less-invasive approaches to treat septic navicular bursitis, such as endoscopy or bursoscopy, is recommended and is usually effective.[3,4] Débridement of a large defect within the DDFT ("street nail" procedure) to provide drainage should be avoided whenever possible.[10] There are, however, still clinics that perform that surgery with good success (see Chapter 90)

Bicipital Bursa

The bicipital bursa is located between the bilobed tendon of origin of biceps brachii muscle and the M-shaped tubercles at the cranioproximal aspect of the humerus (Figure 82-6). Although uncommon, communication can exist between the shoulder joint and the bicipital bursa. Trauma to the cranial surface of the shoulder region is believed to be the most common cause of a primary bursitis.[9,25-27] Other suggested causes include a stretch or tear of the bursa or biceps tendon during the cranial phase of the stride with the limb in full extension, or by a fall or slip that results in flexion of the shoulder with extension of the elbow. Dislocation of the biceps brachii tendon possibly associated with congenital hypoplasia of the minor tubercle has also been reported to cause bicipital bursitis.[28,29]

Reported causes of infection and inflammation of the bicipital bursa include an open or penetrating wound or hematogenous spread to the bursa.[8,9,26] Other reported and associated causes include *Brucella abortus,* in very old reports[7]; influenza or other viral respiratory disease outbreaks, in one case following a long trailer ride[9]; septic tendinitis and arthritis of the scapulohumeral joint; and tendinitis and humeral osteitis.[30,31]

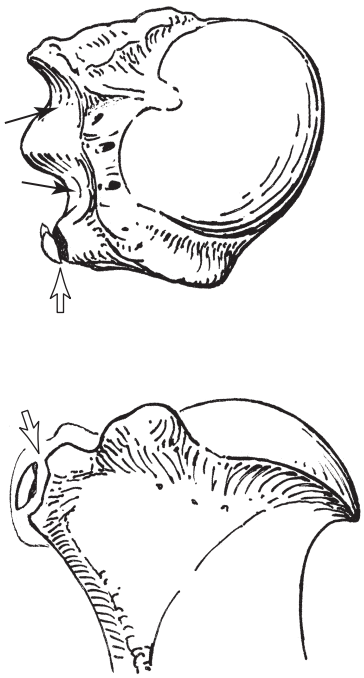

Figure 82-6. Diagram illustrating the location of the bicipital bursa between the M-shaped humeral tubercles *(black thin arrows).* Fractures of the lateral tubercle may contribute to bicipital bursitis *(fat white arrows).*

The signs of lameness usually have an acute onset, and swelling over the cranial aspect of the shoulder region may be evident with or without a wound being present. Pressure applied over the biceps tendon and bursal region and manipulation of the elbow into hyperextension may stress the biceps brachii tendon, which helps localize the lesion.[32] The lameness grade is often 3 to 4 out of 5 (greater if septic) and is often characterized by a shortened cranial phase of the stride, decreased height of the foot flight arc, reduced carpal flexion, and a fixed shoulder appearance during movement. If the localizing signs are not obvious, bursitis can be confirmed by centesis and local anesthesia of the bursa. A proximal approach to the bursa is considered the most successful for bursal centesis (Figure 82-7).[33]

Radiographs of the shoulder are recommended to identify any osseous changes in the tubercles, bicipital groove, or bursa; to rule out the possibility of fractures of the supraglenoid tuberosity or proximal humerus; and to rule out ossification of the biceps tendon.[9,25,26] Radiographic changes associated with bursitis include mottled changes in the tubercle, demineralization of the greater tubercle, osseous densities in the periarticular region, osseous cysts in the cranioproximal humerus, osteitis in the bicipital groove, ossification of the tendon, and calcification of the bursa (see Figure 82-6).[25,27] Radiographs may appear normal if the disease involves the bursa only. An ultrasonographic examination of the biceps tendon, bursa, and bicipital groove can be very informative, even when radiographs appear normal.[34-36] Ultrasonographic changes associated with bursitis include edema or hemorrhage in the biceps tendon or bursa, disruption of the tendon architecture with peritendinous thickening, an irregular surface of the bicipital groove, and hyperechoic material in the bicipital bursa.[9,37]

Noninfectious bursitis without radiographic abnormalities of the humerus may respond favorably to rest, parenteral administration of nonsteroidal anti-inflammatory drugs (NSAIDs), and in some cases intrasynovial injection of the bursa with corticoids and hyaluronan.[26,38] Application of topical NSAIDs may also help alleviate the inflammatory response. Manipulating the limb passively through a range of motion may also be helpful.[26,27,38] In cases where the tendon has been injured, rest periods up to 3 months followed by paddock rest for another 3 months may be required to allow healing of the tendon.

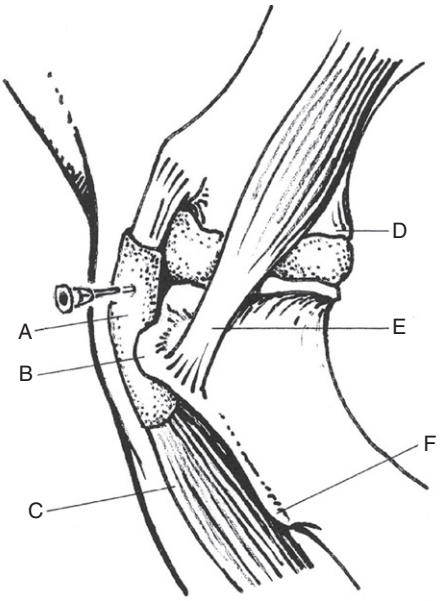

Figure 82-7. Centesis of the bicipital bursa can be difficult, but the proximal approach adjacent to the lateral tubercle is recommended. *A,* Bicipital bursa; *B,* lateral tuberosity of the humerus; *C,* biceps brachii muscle; *D,* glenoid; *E,* tendon of the infraspinatus muscle; *F,* deltoid tuberosity.

Bursitis from either a displaced fracture, osseous changes associated with the proximocranial aspect of the humerus, or sepsis generally requires surgery to resolve the problem. Incisional as well as arthroscopic approaches to the intertubercular bursa have been used and described.[15,16,25,26] If a fracture is present the fragment should be removed and the bed débrided and smoothed (see Figure 82-6). With septic bicipital bursitis, bursoscopy is recommended to permit débridement, lavage, and drainage followed by instillation of a broad-spectrum antimicrobial drug into the synovial cavity.[15]

Though acute cases of nonseptic bursitis in the absence of a fracture usually respond favorably to conservative treatment, this approach appears less satisfactory for more chronic cases of nonseptic or septic bursitis.[9,25] In one report, all three horses that were suffering from chronic nonseptic bicipital bursitis and were treated surgically became pasture sound.[27] Surgical intervention with débridement, lavage, and appropriate antimicrobial therapy usually results in a favorable prognosis in horses with septic bicipital bursitis.[8,9,30,31]

Infraspinatus Bursa

The infraspinatus bursa is located between the tendon of the infraspinatus muscle and the caudal eminence of the greater tubercle of the proximal humerus. The bursa is not visible in most horses except when inflamed or septic, and it is a rare cause of lameness.[39] Severe adduction of the forelimb and direct trauma to the region are considered the most likely causes.[39,40] The involved forelimb in affected horses may be held abducted, presumably in an attempt to reduce the pressure on the infraspinatus bursa. During exercise, a moderate lameness is usually present with an obvious decreased cranial stride.[39,40] Adduction of the limb reportedly elicits a painful response and results in increased signs of lameness at exercise.[40] If the bursa is septic, the lameness exhibited is severe.[39] Ultrasonographic evaluation and comparison with the opposite limb may be required along with ultrasound-guided centesis and local analgesia for a definitive diagnosis.[39]

In the acute stage, synoviocentesis and administration of corticosteroids into the bursa is recommended. With sufficient stall rest (6 weeks or more) and parenteral administration of NSAIDs, a good end result can be expected. With chronic cases, varying degrees of lameness may remain.[40] Septic involvement of this bursa will require endoscopic débridement and flushing. The initial distention of the bursa may require ultrasonographically guided needle placement followed by fluid instillation. The bursa is small and movement of instruments is restricted by the overlying muscle and infraspinatus tendon.[39] In one report, three horses returned to soundness after surgical treatment of septic infraspinatus bursitis.[39]

Calcaneal Bursa

Swelling at the point of the hock (calcaneus) is usually attributable to damage to the subcutaneous calcaneal bursa (capped hock) or to problems within the subtendinous calcaneal bursa

Figure 82-8. Horse with significant swelling and effusion within the right calcaneal bursa from lateral luxation of the superficial digital flexor tendon.

located beneath the superficial digital flexor tendon (SDFT). The subtendinous calcaneal bursa may be further divided into the gastrocnemius calcaneal bursa and the intertendinous calcaneal bursa, but in most horses these two bursae communicate and should be considered as one synovial structure.[19] The subcutaneous bursa at the tarsus is analogous to the bursa at the point of the olecranon but communicates with the subtendinous bursa in about 30% of horses.[19] The subtendinous calcaneal bursa is a true synovial cavity analogous to the bicipital bursa and navicular bursa, and problems within this anatomic structure are much more problematic than those within the subcutaneous bursa. The subtendinous calcaneal bursa extends approximately 7 cm (3 inches) distad and 9.6 cm (4 inches) proximad, relative to the tuber calcanei (point of the hock).[19] An acquired subcutaneous calcaneal bursa is usually located over a much smaller area. Therefore it is very important to determine the location of the swelling over the point of the hock to best address treatment and prognosis. This is especially true for traumatic wounds in this location.

Subtendinous Calcaneal Bursitis

True calcaneal bursitis (subtendinous) may be secondary to trauma such as that seen with luxation of the SDFT from the tuber calcanei and damage to the attachment of the gastrocnemius tendon to the tuber calcanei (Figure 82-8)[41,42] Nonseptic osteolytic lesions within the calcaneus at the insertion sites of the gastrocnemius tendon and the plantar ligament have also been reported to cause calcaneal bursitis.[14,42] Horses with nonseptic subtendinous calcaneal bursitis can be a diagnostic challenge because fluid distention of the bursa is often not readily apparent. However, the area above and below the retinaculum that keeps the SDFT on top of the tuber calcanei is usually enlarged compared to the opposite calcaneus, and fluid distention is usually palpable either above or below the retinaculum on the medial or lateral aspects of the tuber calcanei. In affected horses, direct palpation of the bursa often elicits a pain response. They are lame at the trot, and they hyperreact to tarsal flexion. Intrasynovial anesthesia directly into the subtendinous calcaneal bursa is usually the best approach to confirm the location of the lameness (Figure 82-9).

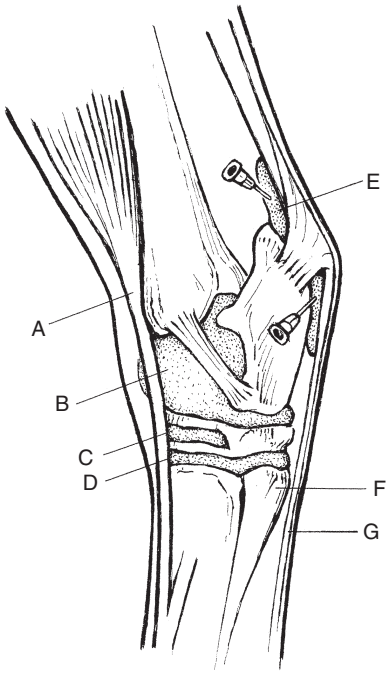

Figure 82-9. Diagram illustrating the injection sites for centesis and blocking the subtendinous calcaneal bursa above or below the retinaculum. *A,* Long digital extensor tendon; *B,* tarsocrural joint; *C,* distal intertarsal joint; *D,* tarsometatarsal joint; *E,* calcaneal bursa; *F,* head of fourth metatarsal bone; *G,* superficial digital flexor tendon.

A definitive diagnosis of the cause of nonseptic subtendinous calcaneal bursitis usually requires a combination of radiography and ultrasonography. However, endoscopy of the bursa is recommended as a diagnostic tool if other imaging results are negative.[14] Scintigraphy and MRI may also be beneficial but are not necessary in most cases. The cause of nonseptic subtendinous calcaneal bursitis may not be determined in all cases. Treatment of nonseptic subtendinous calcaneal bursitis depends on the initiating cause, but it is similar to that for other types of synovial inflammation. Acute bursitis without a defined cause can be treated with intrasynovial triamcinolone and hyaluronan combined with a short period of rest. Known causes of subtendinous calcaneal bursitis, such as osteolytic lesions within the calcaneus, should be débrided endoscopically.[14,42] In some chronic cases, endoscopy should be used as both a diagnostic and treatment tool for lesions within the gastrocnemius tendon, SDFT, and other soft tissue injuries within the bursa. Based on a very limited number of cases, horses with osteolytic lesions of the calcaneus and chronic wounds involving the bursa have a guarded prognosis for athletic activity.

Penetrating wounds that enter the subtendinous calcaneal bursa appear to be the most common cause for swelling and lameness referable to this structure.[6] These injuries often involve small puncture wounds that do not seem to be very important initially but subsequently result in infection within the bursa (Figure 82-10). Secondary osteitis or osteomyelitis of the tuber calcanei is not uncommon. The lameness may be mild initially but becomes severe with the onset of synovial infection. The point of the hock is usually swollen and painful to palpation, and purulent exudate often exits the wound. The diagnosis of infection is determined similarly to other sites of synovial

Figure 82-10. Small wound just distal to the tuber calcanei that entered the distal aspect of the calcaneal bursa. The horse presented with severe lameness and swelling and pain associated with the calcaneal bursa.

infection and includes a combination of plain and contrast radiography, ultrasonography, aspiration of synovial fluid, and culture.

Horses with septic calcaneal bursitis should be treated with a combination of synovial lavage (endoscopy), local and parenteral antibiotics, including IV regional perfusion, and NSAIDs.[10,14] Secondary osteomyelitis of the calcaneus should be débrided as part of the treatment protocol. In one study, 75% of horses with wounds involving the calcaneal bursa survived, but only 44% of horses with secondary osteomyelitis of the tuber calcanei survived.[6] Horses with septic calcaneal bursitis tend to have a fair to guarded prognosis for athletic use because of the high motion required in this area during limb flexion.

Subcutaneous calcaneal bursitis was discussed earlier.

Trochanteric Bursa (Trochanteric Lameness, Whirlbone Lameness)

The trochanteric bursa is located beneath the strong, flat tendon of the middle gluteus muscle as it passes over the convexity of greater trochanter of the femur.[43] The inflammatory response may involve the tendon of the middle gluteus muscle as well as the cartilage over the trochanter. In many cases, there is a concurrent source of chronic lameness in the same limb, or chronic forelimb lameness may cause the horse to place more strain on the hindlimbs.[43,44] A bruise resulting from the horse falling on the affected side, or strain of the tendon during racing or training, may also contribute to the bursitis.[44]

Lameness is usually mild, but pain may be evident when pressure is applied over the greater trochanter.[43] At rest, the limb may remain flexed, and the inside wall of the foot may be worn more than the outside wall.[43] The horse tends to travel "dog fashion," with the hindquarters moving toward the sound side, because the stride of the affected limb is shorter than that of the sound side. The gluteal muscles can atrophy with chronicity. The condition is difficult to differentiate from inflammation of the coxofemoral joint and may be confused with spavin lameness. Injection of a local anesthetic into the bursa may be helpful in confirming the location of the lameness. Addressing other concurrent sources of lameness is an important aspect of treatment. However, injection of the bursa with corticosteroids appears to be the most effective method to treat the bursitis. The prognosis is variable and often influenced by the second source of lameness.

Cunean Bursa

The cunean bursa is located on the medial surface of the distal tarsus between the medial collateral ligament of the tarsus and the medial branch of the tibialis cranialis (cunean) tendon. The bursa is relatively small and is not routinely anesthetized or treated alone, because it often communicates with the distal intertarsal (DIT) joint.[45] Cunean bursitis infrequently occurs as a separate clinical entity but is often considered part of the distal tarsal osteoarthritis complex. However, some clinicians treat the cunean bursa concurrently when medicating the DIT joint in horses with distal tarsal osteoarthritis.

Bursa of the Long Digital Extensor Tendon

The bursa of the long digital extensor is beneath the common origin of the long digital extensor and peroneus tertius muscles over the lateral surface of the tibia.[1] It communicates with the lateral femorotibial joint and can be seen during arthroscopy of the joint. Problems within this bursa are rare in horses.

Bursa of Common Digital Extensor Tendon

The bursa of the common digital extensor tendon is beneath the common digital extensor tendon at the level of the fetlock and pastern joints. Intersynovial fistulas between this bursa and the fetlock and pastern joints have been reported to occur[1] but are extremely rare.

Bursa of Extensor Carpi Radialis Tendon

The bursa of the extensor carpi radialis tendon is beneath the extensor carpi radialis tendon and the third carpal bone. It has been recommended to avoid this bursa when performing a carpal arthrotomy.[1]

Subligamentous Bursae

Supraspinous Bursa

The supraspinous bursa is located beneath the nuchal ligament over the third and fourth thoracic vertebrae at the withers. Fistula development secondary to infection is the most common clinical entity associated with this bursa and is referred to as *fistulous withers* (see Figure 28-8). The cause of the infection is not always readily apparent as a wound or penetrating injury and therefore often not part of the history. Infection with *Brucella abortus* was found in 9 of 24 horses with fistulous withers in one study, and seropositive horses were more likely to be pastured with cattle and have vertebral osteomyelitis than seronegative horses.[11] In another study, beta-hemolytic *Streptococcus* spp. were the most common bacterial isolates found.[12]

Most horses with supraspinous bursitis present with either swelling alone or a draining fistula over the withers. Direct palpation of the area usually elicits a pain response, but the horse is usually not lame or systemically ill. Septic bursitis alone or septic bursitis with osteomyelitis of the dorsal thoracic vertebral processes are possible; therefore, radiographs of the withers are recommended. Treatment with systemic antimicrobials alone is usually unsuccessful, and surgical débridement of the bursa and draining tracts is recommended.[11-13] The surgery can be performed in the standing or recumbent horse, multiple surgeries may be required, and the most common complication is recurrence of the fistulas.[12,13] Preoperative injection of a diluted vital dye, such as Evans or methylene blue, facilitates intraoperative recognition of the associated cavities within the infected tissue. The goal of the surgical intervention is to remove all the discolored membranes and to facilitate drainage.

Atlantal or Nuchal Bursa

The atlantal bursa is located between the nuchal ligament and the rectus capitis dorsalis muscle at the level of the first cervical vertebra (poll).[1] The layman's term for bursitis in the atlantal bursa is "poll evil." It has also been called the "nuchal bursa" and is thought to be secondary to pathology of the nuchal ligament at the level of the first or second cervical vertebrae.[46] Nuchal bursitis is considered to be a rare condition, but veterinarians in the field of equine sports medicine diagnose bursitis of the nuchal ligament quite frequently.[46] It is difficult to confirm the diagnosis on clinical signs and ultrasonographic examination alone. A common treatment for nonseptic nuchal or atlantal bursitis is ultrasound-guided injection of corticosteroids into the bursa. Calcification in the bursa region may be observed on radiographs of the poll and may be associated with recurrent injections of the bursa.[46] Surgical débridement may follow the same path as described earlier for supraspinous bursitis.

CHAPTER
83

Diagnosis and Management of Tendon and Ligament Disorders

Charlotte S. Avella and Roger K. W. Smith

TENDON BIOLOGY

Structure of Tendons and Ligaments: From Molecule to Organ

Tendons and ligaments are complex organs built up in a hierarchical arrangement of increasingly smaller subunits (Figure 83-1). Tendon is highly hydrated, having a water content of around 70%, and the remaining 30% (the dry weight) is composed predominantly of type I collagen. Collagen is synthesized as procollagen molecules consisting of an α-helical chain and amino-terminal and carboxy-terminal extensions that are cleaved by procollagenases immediately before three α-chains are combined to confer a single collagen fibril. This process appears to take place postnatally outside the cell, but recent evidence has suggested that the original structural template for tendon formation is laid down by cells in the embryo that secrete formed fibrils into the extracellular space.[1] Thereafter, growth of the tendon occurs via a "seed-and-feed" mechanism, whereby collagen fibrils form extracellularly and accrete onto the sides of the template fibrils.

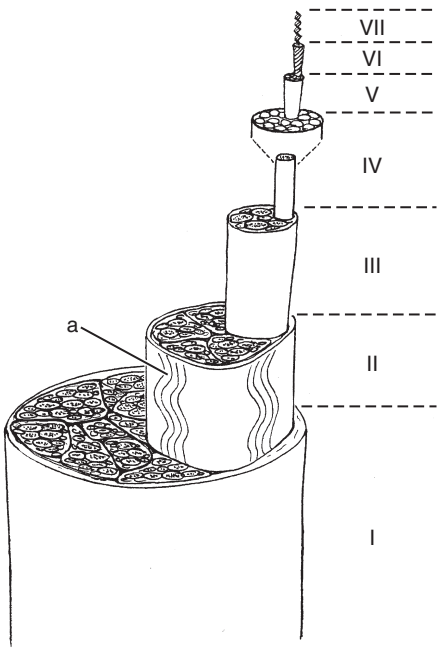

Figure 83-1. The structural hierarchy of tendon. The tendon is composed of increasingly smaller subunits, from fascicles visible to the naked eye (see Figure 83-3), to fibers seen under light microscopy, to individual collagen fibrils seen by electron microscopy. *I,* Tendon unit surrounded by paratenon in extrasynovial locations and epitenon in synovial locations; *II,* third-degree fascicle (1 to 3 mm diameter); *III,* second-degree fascicle (400 to 1000 μm diameter); *IV,* first degree fascicle (15 to 400 μm diameter; *V,* collagen fiber (1 to 20 μm diameter); *VI,* collagen fibril (20 to 150 nm diameter); *VII,* collagen triple helix (1 nm diameter); *a,* crimp.

The structural and material properties of tendon depend on a large number of factors, including the spatial organization of the collagen fibrils and their cross-linking. The determination of collagen fibril size, organization, and cross-linking is provided by an array of noncollagenous proteins, many of which are yet to be characterized fully. The next most abundant protein in young tendon is cartilage oligomeric matrix protein (COMP),[2] which is believed to be involved in the organization of the collagen fibril framework during formation and growth. In support of this proposed action, experimental data have shown that COMP accelerated collagen fibril formation *in vitro*.[3] From these data, it was proposed that COMP molecules bring together five separate collagen molecules in the "quarter-stagger" that is characteristic of collagen fibrils. Once these collagen molecules have formed a fibril, COMP no longer functions in binding and is displaced from the collagen fibril. In keeping with this role, levels of COMP in tensional regions of equine digital flexor tendons increase dramatically during growth and peak at around 2 years of age.[2] The importance and relevance of this protein during growth is suggested by a correlation between ultimate tensile strength of the tendon and the level of COMP at skeletal maturity.[4]

The extracellular composition varies along the length of the tendon, reflecting different biomechanical environments. Hence, the small proteoglycans (decorin, fibromodulin, lumican, and mimecan) predominate in the tensional regions, whereas the large proteoglycans (aggrecan and versican) are mainly, but not exclusively, located in the regions of the tendon that are subjected to compression as the tendon changes direction over a bony prominence, reflecting the fibrocartilagenous nature of the tendon in these regions (e.g., the deep digital

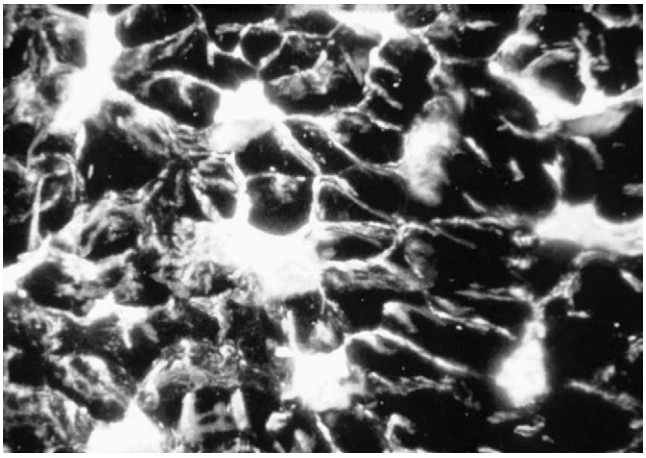

Figure 83-2. Transverse section of tendon stained to show the cytoplasmic membrane of the tenocytes. Note the large cell bodies and the extensive network of cytoplasmic extensions, which connect adjacent cells via gap junctions to produce a syncytium capable of orchestrating coordinated responses to loading. (Courtesy of Dr. Jim Ralphs, Cardiff University, UK.)

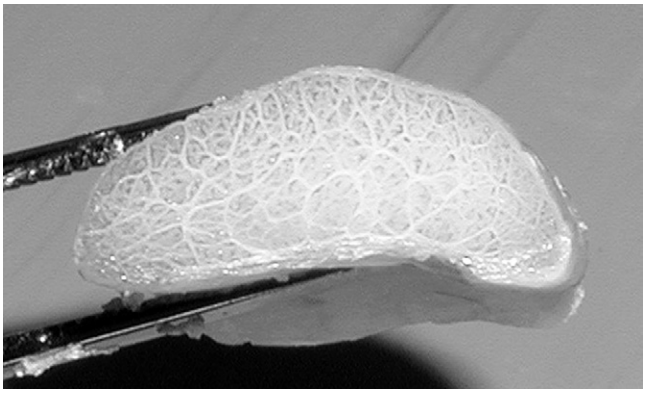

Figure 83-3. Cut surface of a frozen piece of superficial digital flexor tendon revealing the extensive interfascicular tissue, the endotenon, which contains the internal vascular and nervous supply to the tendon and is responsible for interfascicular gliding movements (where most of the tendon's stretch occurs). (From Smith RKW, Goodship AE: Tendon and Ligament Physiology. p. 130. In Hinchcliff KW, Kaneps AJ, Geor RJ (eds): Equine Sports Medicine and Surgery. Saunders, Philadelphia, 2004.)

flexor tendon [DDFT] at the level of the metacarpophalangeal joint).[5,6]

Bundles of collagen fibrils are grouped together into fibers that are separated by cytoplasmic extensions of the cellular components of tendon, e.g., tenocytes[7] (Figure 83-2). Little is known about these cells, although several different types are identified on light microscopy on the basis of their nuclear morphology.[8,9] These different nuclear shapes may represent stages of activation or differently differentiated cells. Type I cells, which have thin, spindle-shaped nuclei characteristic of adult tendon, are most likely to be relatively inactive forms of the type II cells, whose nuclei are more oval and are abundant in young, growing tendon. The fibrocartilagenous regions of adult digital flexor tendon, subjected to external compression, contain type III cells, which have round nuclei characteristic of chondrocytes. Other cell types are found within the endotenon (see later) and are associated with aging changes (e.g., chondroid metaplasia).

On a large scale, collagen fibers are grouped together in increasingly larger subunits divided by looser connective tissue known as the *endotenon.* It is these subunits, known as *fascicles,* that are visible to the naked eye on a cut section of tendon (Figure 83-3). In relaxed tendon, the fascicles have a waveform known as *crimp,* which is best seen under polarized light and which is partly responsible for tendon elasticity. However, the majority of tendon elongation comes from the sliding of the fascicles over one another rather than stretching of the fascicles themselves, and so the endotenon is believed to be critically important for this role.[10] The endotenon carries blood vessels and nerves and contains a different type of cell, one that is more rounded; these cells are believed to be the source of mesenchymal stem cells within the tendon. The endotenon contains higher levels of certain growth factors, such as transforming growth factor-β (TGF-β), than the content of the fascicles.[11]

The endotenon is continuous with the layer of connective tissue surrounding the outside of the tendon, known as the *epitenon.* Outside this layer, around tendons that are not contained within a tendon sheath, a thicker layer known as the *paratenon* is found. The paratenon is able to stretch considerably and is therefore rarely ruptured when a tendon suffers a strain injury. This layer is believed to play particularly important roles, both in reducing frictional forces between the tendon and the surrounding soft tissues and as a supplier of new blood vessels and cellular elements for repair. It is hypothesized that the lack of this layer intrathecally and within the synovial fluid environment results in slower healing of these regions.

Where tendon changes direction over a joint, the tendon is usually enclosed within a tendon sheath (Figure 83-4). This structure provides a synovial environment for the smooth gliding of tendon over a bony prominence. Associated with this sheath, there is usually a smooth fibrocartilaginous pad covering the bony prominences, best exemplified by the scuta of the distal limb—the proximal scutum or intersesamoidean ligament at the level of the metacarpophalangeal or metatarsophalangeal (MCP/MTP) joint, the middle scutum attached to the middle phalanx, and the distal scutum attached to the distal sesamoid (navicular) bone. The tendon sheath, like a joint, consists of an outer fibrous wall and an inner synovial membrane, which also surrounds the tendons within the tendon sheath. Dividing the sheath into complete or incomplete compartments are a number of mesotenons that are composed of two layers of synovium and frequently, but not always, carry the blood supply to the tendon.

Blood Supply

The blood supply to the tendon comes from its muscular origin and osseous insertion and variably from accessory ligaments, the paratenon, and mesotenon attachments. However, work on equine digital flexor tendons showed that stripping the paratenon failed to cause any ischemic damage to the tendon,[12,13] indicating the importance of the intratendinous supply for this tendon. Based on the microvascular anatomy determined by microradiographs,[14] this intratendinous blood supply is most abundant around the periphery of the tendon, which has led to the hypothesis that the central region of the tendon is relatively

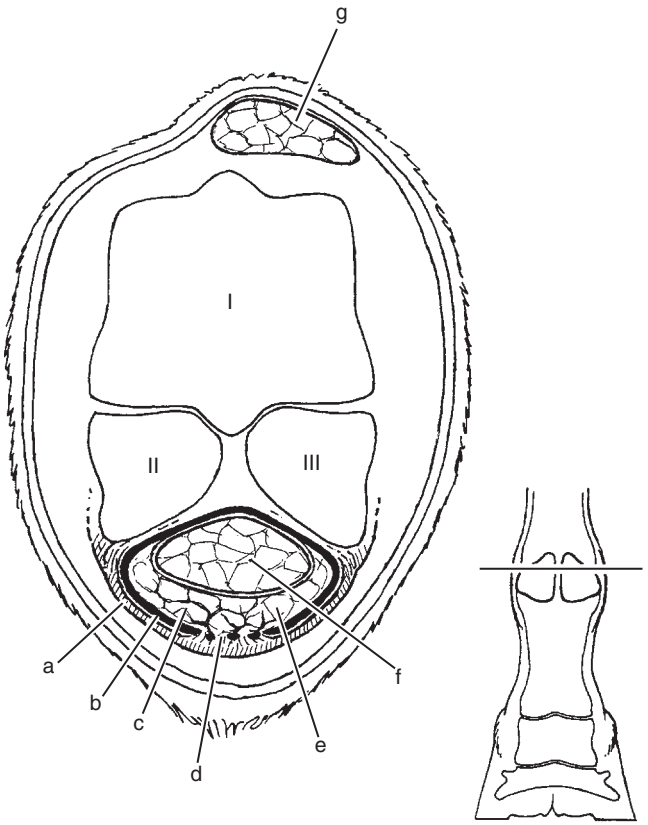

Figure 83-4. The anatomy of a tendon within a tendon sheath. Note the absence of a paratenon and the presence of mesotenon attachments, which are incomplete along the length of a sheath and through which blood supply gains access to the tendon. *a,* Palmar annular ligament; *b,* digital flexor tendon sheath wall; *c,* superficial digital flexor tendon (SDFT) endotenon; *d,* mesotenon attachment; *e,* SDFT fascicle; *f,* deep digital flexor tendon; *g,* common digital extensor tendon; *I,* MCIII; *II* and *III,* proximal sesamoid bones.

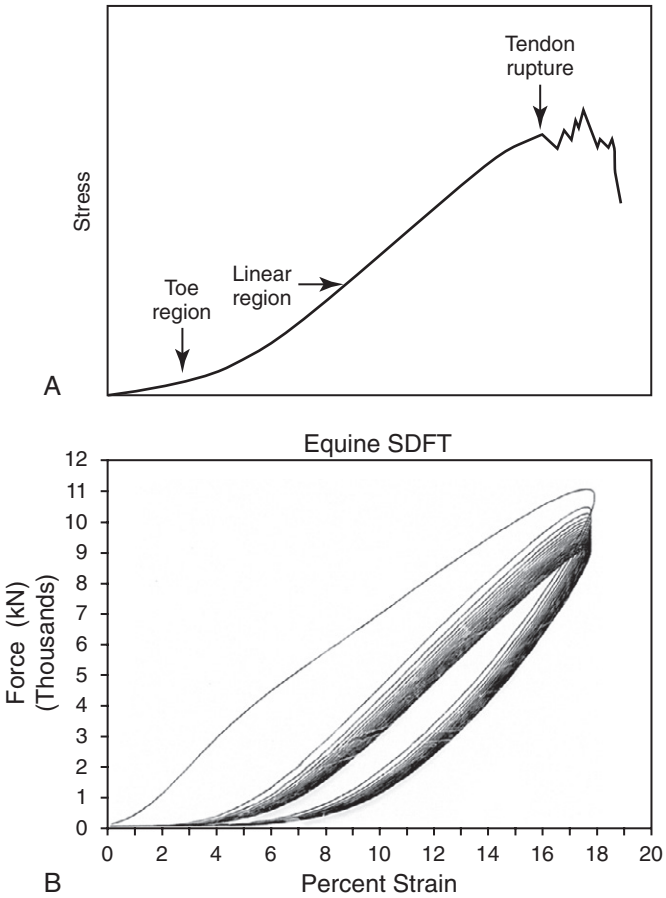

Figure 83-5. A, The stress–strain curve for tendon showing its viscoelastic properties. The toe region is associated with elimination of "crimp," and the linear region is where the tendon is operating in an elastic fashion. At the end of the linear region, the yield point is reached, where irreversible damage starts to occur before the tendon ruptures completely. **B,** Hysteresis and conditioning. The loading and unloading curves are not the same, resulting in an energy loss, which is represented by the area between the two curves (hysteresis loop). If the tendon continues to be loaded repeatedly, the curve moves to the right until it reaches a steady state, when the tendon is more elastic. *SDFT,* Superficial digital flexor tendon. (From Smith RKW, Goodship AE: Tendon and Ligament Physiology. p. 130. In Hinchcliff KW, Kaneps AJ, Geor RJ (eds): Equine Sports Medicine and Surgery. Saunders, Philadelphia, 2004.)

hypoxic, and that this is one of the reasons for the common manifestation of tendon disease as a central core lesion. However, there is little supporting evidence for this hypothesis, and, in fact, the superficial digital flexor tendon has a blood supply, as determined by xenon clearance, similar to that of resting skeletal muscle and is capable of increasing flow during exercise and after injury.[15]

Functional Characteristics of Tendons and Ligaments

Tendons and ligaments have a variety of functions: they transmit forces to move the equine skeleton, they provide support of the distal limb in the case of the digital flexor tendons, or, as ligaments, they maintain joint alignment and integrity. Their structure is optimized to perform these mechanical roles.

Tendons and ligaments have viscoelastic properties, which means that their mechanical properties vary as they are stretched. A typical force–elongation curve for tendon is shown in Figure 83-5. Initially, the tendon stretches under relatively little load, which is associated with the elimination of crimp in the fascicles. Thereafter, the curve is almost linear. It is from this area of the curve that the *structural property* of stiffness is determined (load divided by deformation). As the load increases further, there is a change in the gradient such that the tendon becomes less stiff. This is known as the *yield point,* and it is thought to arise from covalent crosslink rupture and irreversible slippage of collagen fibrils. If the tendon is stretched past this point, irreversible damage occurs. In other words, if loading is continued past this point, the tendon ruptures, which for the equine superficial digital flexor tendons (SDFT) is approximately 12 kilonewtons (kN) or 1.2 tons (ultimate tensile strength).[16,17]

If the cross-sectional area and length of the tendon is known, the stress (force per unit area) can be plotted against strain (change in length over original length), from which the *material properties* of ultimate tensile stress (N/mm^2) and Young's modulus of elasticity (E [MPa]) can be calculated. The approximate *ultimate tensile stress* of 100 MPa for the equine SDFT is similar to previously documented figures in other species (20 to 144 MPa).[18,19]

In vitro, equine flexor tendons can extend 10% to 12% of their length before they rupture (*ultimate tensile strain*), and values of up to 20% have been reported.[8] However, the ultimate

tensile strain reflects only the final strain before rupture and includes the yield portion of the stress–strain curve, which represents irreversible damage to the tendon tissue. The normal strains in the digital flexor tendons, recorded *in vivo*, are in the region of 3% to 8% at the walk, 7% to 10% at the trot, and 12% to 16% at the gallop.[20] Such strains, far greater than usually expected in tendons from most other species, may reflect the importance of the digital flexor tendon as an elastic energy store, where maximal deformation stores the most energy but also makes them operate close to their functional limit.

In addition to these basic functional characteristics, tendon has other mechanical properties of potentially important biological relevance. There is a difference between the stress–strain relationship when the tendon is loaded and the relationship when it is unloaded, which is known as hysteresis (see Figure 83-5). The area between these two curves represents the energy lost during the loading cycle. This is usually about 5% in equine tendons. Much of this energy is lost as heat and is responsible for the rise in temperature in the tendon core when the horse exercises. These temperatures can rise to as high as 44° C, which is potentially damaging to both tendon matrix and tenocytes. However, tenocytes recovered from the center of equine SDFT remain viable when subjected to rises in temperature of this magnitude, whereas those recovered from the periphery of the tendon do not.[21] This property is also present in fetal tenocytes, which suggests that the tendon has an inherent genetic adaptation to this physical process.

The loading rate has only a minimal effect on tendon biomechanics: a rapid loading rate results in a stiffer tendon, whereas repeated loading results in a less-stiff tendon, a process known as *conditioning* (see Figure 83-5). This effect appears to occur *in vivo* in humans,[22] although it is not clear whether this is also the case in horses. Because they are rarely recumbent, they usually constantly load their flexor tendons. The change is recoverable, but significant resting time is necessary.[8]

The Relationship of Structure to Function

It would appear that all tendons are formed *in utero* in a similar fashion and with a similar composition, analogous to the "blank joint" concept for articular cartilage.[6,23,24] However, as soon as the animal is born and stands, tendons and ligaments receive very different mechanical loading. It is believed that different mechanical environments drive growth and differentiation of tendons, so that at skeletal maturity, different tendons have different compositional and structural properties that relate to their function. Thus mature tendons are not all composed of the same material and hence do not all have the same functional characteristics. Furthermore, different loading patterns induce anisotropy within certain tendons. Thus, as mentioned earlier, where the digital flexor tendons change direction across the palmar/plantar aspect of the MCP/MTP joint and are subjected to external compression, they develop a cartilage-like matrix.[25]

The horse's distal limb is designed like a spring to store energy from weight-bearing for the subsequent stride.[26] The horse essentially bounces up and down on its forelimbs, whereas its hindlimbs provide propulsive force. This system is optimized by having a hyperextended MCP joint and by the energy being stored in the palmar soft tissue structures, principally the SDFT and suspensory ligaments (Figure 83-6). The superficial digital flexor muscle contains a high proportion of fibrous tissue, and data have indicated that its maximal contraction shortens the muscular unit by only 2 mm.[26] Hence, the muscle acts not to flex the MCP joint but rather to fix the origin of the SDFT and dampen high-frequency damaging oscillations. Although the muscle within the suspensory ligament is considered vestigial, it may also have a similar role in dampening the damaging oscillation during high-speed exercise.

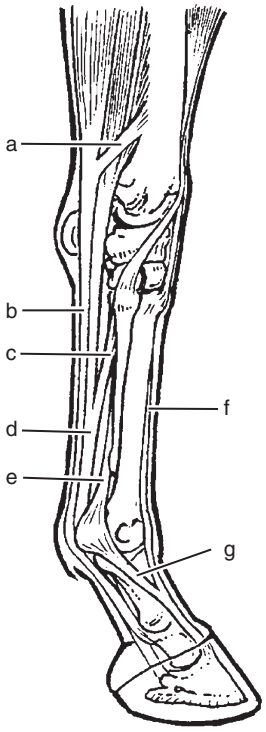

Figure 83-6. The anatomy of the equine distal limb showing the important weight-bearing tendons and ligaments on the palmar aspect of the limb. It is these structures that most frequently suffer strain-induced injury. *a,* Acessory ligament of the SDFT; *b,* SDFT; *c,* accessory ligament of the DDFT; *d,* DDFT; *e,* suspensory ligament; *f,* common digital extensor tendon (CDET); *g,* extensor branch of the suspensory ligament.

Consequently, these two structures have very similar matrix compositions and configurations: both contain high COMP levels and a combination of small and large collagen fibrils. In contrast, the common digital extensor tendon (CDET), a low-load tendon, and the deep digital flexor tendon (DDFT), which also has a different role, have lower levels of COMP and predominantly large collagen fibrils. These compositional differences are reflected in their mechanical properties. Tendons can be divided into weight-bearing tendons that function like springs (and are less stiff, or more elastic) and those that position the skeleton (which requires greater stiffness). Thus the CDET is almost twice as stiff as the SDFT.

Etiopathogenesis of Tendon Injury

Tendons and ligaments can be injured in one of two ways: from overstrain or percutaneous trauma. Overstrain injuries are believed to occur by one of two mechanisms. They can result from a sudden overloading of the structure, which overwhelms its resistive strength. This type of injury is probably the

Figure 83-7. Superficial digital flexor tendinopathy. Note the bowing, or swelling, of the palmar border of the right limb. Careful attention must also be given to the contralateral limb, which may exhibit a smaller swelling that can be easily missed *(arrow)*.

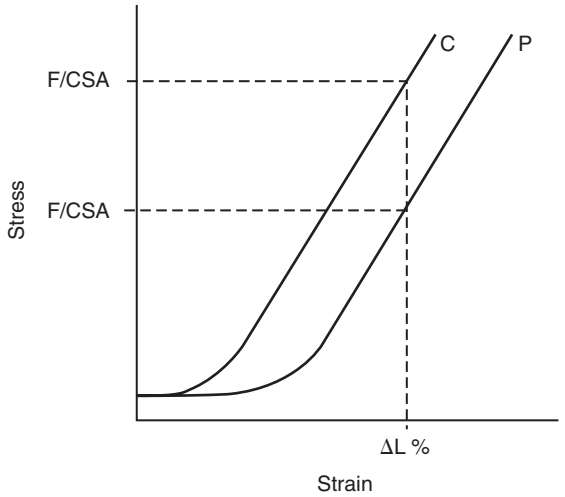

Figure 83-8. One possible explanation for the occurrence of a core lesion in the superficial digital flexor tendon. With aging and exercise, the central *(C)* crimp pattern, which is responsible for the toe region on a stress–strain curve (see Figure 83-5), is reduced more than that in the periphery *(P)*. Consequently, as the tendon is loaded, the central fibers are loaded first and take the most load for a given strain. Hence, it would be expected that they would rupture first, giving rise to a core lesion. ΔL%, Percent change in length; *F/CSA*, force per cross-sectional area. (From Wilmink J, et al: Functional significance of the morphology and micromechanics of collagen fibres in relation to partial rupture of the superficial digital flexor tendon in racehorses. Res Vet Sci 53:355, 1992.)

mechanism for most ligament and some DDFT injuries in the horse. However, for the most common strain-induced injuries in the horse, involving the palmar soft tissue structures of the metacarpal region, the clinical injury is believed to be preceded by a phase of molecular degeneration ("molecular inflammation"[27]), which induces neither a clinically evident inflammatory reaction nor any reparative response, but instead progressively weakens the tendon.[28] The evidence for this degeneration is based on four observations:

- "Asymptomatic" lesions are present both grossly and microscopically in postmortem studies of normal horses.[29] However, analysis of these lesions suggests that they are the result of healing of low-grade clinical injuries rather than true degeneration.[30]
- Many clinical strain-induced tendinopathies are bilateral, but one limb is more severely affected than the other (Figure 83-7). Careful ultrasonographic examination often reveals changes in the contralateral limb. Furthermore, in seemingly unilateral cases, blood flow studies have demonstrated increases in the "normal" contralateral tendon, which would suggest that it is not totally unaffected.
- Epidemiologic studies in both horses and humans have shown strong associations between injury rates and age.[31-33]
- A number of experimental exercise studies and postmortem analyses of normal tendons have indicated that increasing age and amounts of exercise induce tendon matrix degeneration rather than adaptation in the adult horse.[28]

Response of Tendons to Aging and Exercise

When evaluating the gross mechanical properties of the SDFT in a large group of normal horses, there is a reduction in tendon strength with age, but this is statistically insignificant because of the high variance. Therefore, in a population of normal horses, there is more than a twofold variation in ultimate tensile strength of the SDFT. This high variance arises from inaccuracies in measuring ultimate tensile strength *in vitro* and the true variation in tendon strength, which is influenced by genetic components,[34] but probably most importantly by environmental factors of aging and exercise.

The collagen crimp angle and length showed a regional reduction in the central core with exercise and age, both acting synergistically.[35,36] This results in the central fibers being straightened first under loading, and hence they are the most likely to rupture first, giving rise to a possible mechanism for the generation of the "core lesion" frequently seen clinically (Figure 83-8).

Within the tendon matrix, regional differences in collagen fibril diameter were seen in mature horses that trained for 18 months on a high-speed treadmill compared to age- and sex-matched controls that were only walked.[37] The higher proportion of small fibrils in the central region of long-term exercised horses does not appear to be associated with increased collagen content, and the collagen-related fluorescence (a measure of collagen age) is unaltered, suggesting that this change results from disassembly of the larger-diameter fibrils.

Collagen content varies little with age and exercise. The collagen in the equine SDFT has recently been shown (using aspartate racemization) to have a half-life of 198 years, whereas the noncollagenous matrix has a much shorter half-life of 2.2 years.[38] Thus, in longer-term exercised and older horses, the noncollagenous component of tendon shows changes in the

center of the tendon where clinical injury is seen and where there is an accelerated loss of glycosaminoglycans (GAGs) and COMP. This is in contrast to the central discolored regions seen as an occasional coincidental finding at postmortem examination, which contain higher hydration and increased GAG levels more consistent of reparative (scar) tissue formation.[27]

In contrast, exercise in immature horses appears to stimulate tendon formation and adaptation, and experimental long-term exercise studies have failed to induce any degenerative change.[39]

From the results of these studies, it is hypothesized that the midmetacarpal region of the equine SDFT can adapt to exercise during skeletal development, but it has little or no ability to do so after skeletal maturity[23,33] when the synergistic effect of aging and exercise causes an inevitable accumulation of microdamage (degeneration). In support of this hypothesis, analysis of matrix gene expression in bovine digital flexor tendons has shown prominent matrix gene expression at birth and during growth, but a dramatic reduction in the tensile (but not compressed) regions after skeletal maturity.[40]

Mechanisms for Tendon Degeneration

Cumulative tendon microdamage arises from the induction of tendon matrix damage and the failure of the resident cell population to repair this damage. The mechanism for the failure of tenocytes to repair or adapt to exercise-induced microdamage in the adult is unclear, but it possibly involves a combination of factors including reduced cell numbers and gap junctions that enable a coordinated anabolic response,[41] an absence of appropriate growth factor stimulus, and a degree of cellular senescence. Investigations into the synthetic response by equine tenocytes to mechanical load (biaxial stretch) and growth factors (e.g., TGF-β) *in vitro* have demonstrated that tenocytes recovered from aged flexor tendons do demonstrate a significantly reduced response.[42] Interestingly, this age effect is not apparent in tenocytes recovered from digital extensor tendons, which appear to continue to remodel and adapt during maturity.

The mechanism of degeneration of the tendon is currently unknown, but there are several possibilities. The close association between age and exercise suggests that the number of loading cycles is important, and it is logical to presume that the highest loading rates are likely to be the most damaging, so the amount of time spent at the fastest gaits (canter and gallop) is likely to contribute the most to degeneration. The actual mechanisms can be either physical or metabolic. The physical energy imparted to the tendon under weight-bearing load can directly damage the matrix by disrupting fibers, cross-links, or actual matrix proteins.[43,44] An indirect physical effect of weight bearing occurs via the energy lost through hysteresis.[45] The previously described increase in temperature (see earlier, "Functional Characteristics of Tendons and Ligaments") within the core of the SDFT up to 44° C during galloping could be damaging to matrix proteins or cell metabolism (Figure 83-9). Cyclical loading of tendon explants *in vitro* induces the upregulation of both synthesis and activity of proteolytic enzymes, potentially inducing a reduction in strength.[46] Furthermore, cleaved matrix proteins, generated either from direct physical forces or from enzymatic cleavage, also can provoke further matrix degradation, giving rise to an exercise-induced cycle of matrix degeneration.[47] Further work is necessary to elucidate the mechanisms of soft tissue degeneration so that preventive strategies can be developed.

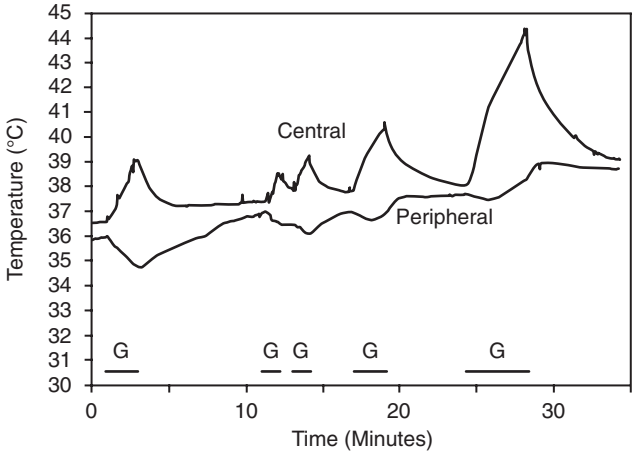

Figure 83-9. The hyperthermia theory of tendinopathy. When the horse is galloped *(G),* the temperature in the superficial digital flexor tendon rises as high as 44° C, which could damage the tendon matrix and be responsible for tendon degeneration. (Courtesy Dr. Alan Wilson.)

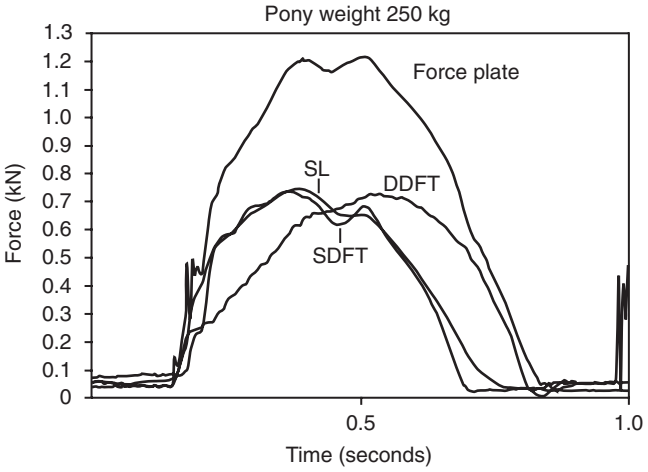

Figure 83-10. The force of individual tendons and ligaments of the equine distal limb during stance. Note the rapid rise in loading in the superficial digital flexor tendon (SDFT) and suspensory ligament (SL) (including what is thought to be damaging high-frequency "transients" at foot placement), whereas loading rises more slowly in the deep digital flexor tendon (DDFT). This may help explain why injuries are much more common in the SDFT and SL than in the DDFT. (Courtesy Dr. Alan Wilson.)

Mechanisms of Clinical Injury

STRAIN-INDUCED INJURY

Degeneration is usually the first phase of a tendinopathy. Any change in the structural properties of the tendon does not have to be large, because the tendon is already operating close to its tolerance limit. Clinical injury occurs when the highest stresses encountered by the tendon overwhelm its structural integrity, resulting in irreversible damage. At heel strike, the loads rise most quickly in the soft tissue structures that support primarily the metacarpophalangeal joint: the SDFT and the suspensory ligament (SL)[8] (Figure 83-10). The load in the DDFT rises later during stance, which may help to explain why the SDFT and the SL are the most prone to injury.

Once the peak load on the tendon overcomes its structural strength, there is physical disruption to the tendon matrix. The clinical injury varies in degree from fibrillar slippage, with

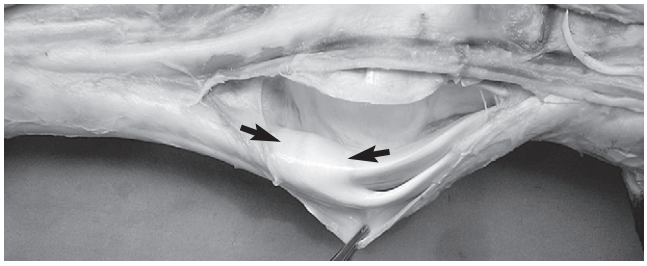

Figure 83-11. The manica flexoria *(between arrows).*

breakage of cross-linking elements, to fibrillar rupture and, in some cases, complete separation of tendon tissue. Once this occurs, the damage induces a repair process similar to that found in other soft tissues, such as skin, characterized by inflammation followed by fibroplasia (scar tissue formation).

This process allows the incorporation of risk factors that have been identified for inducing tendinopathy. These risk factors act to increase the peak loads on the SDFT, thereby increasing the risk of structural disruption. One of the most important factors is the speed of the horse. The faster the horse is going, the greater the risk of developing tendinopathy. Thus a hard track surface is associated with tendinopathy, because it increases the speed of the horse and also increases the peak impact loading.[31] Slower surfaces (including soft track surfaces) tend to be protective. Other factors, such as the weight the horse is carrying, fatigue, and the shoeing, can all influence peak tendon loads in this way. Heel elevation has been shown to decrease the load on the DDFT and cause a variable increase in the degree of extension in the MCP joint,[48,49] with toe elevation having the opposite effect. It may be thought, therefore, that low heels would be protective of tendinopathy. However, epidemiologic studies have shown an association between low heel and long toe conformation and musculoskeletal injury, of which the most common were tendon and ligament injuries.[50]

TENDON TEARS

The mechanism for generating tendon or ligament tears within synovial cavities is much less clear. The most common site is the DDFT (mainly in the forelimb) and the manica flexoria of the SDFT (predominantly in the hindlimb) in the proximal digital flexor tendon sheath (Figure 83-11). For the former, higher pressures within the compressed portion of the DDFT as it passes over the palmar aspect of the MCP joint may cause "bursting" of the lateral (or, less commonly, of the medial) borders of the tendon. Manica tears may develop when the structure gets caught as it passes into the fetlock canal. Because many of these tears have been seen after a period of tenosynovitis, they may be exacerbated by synovial hypertrophy or plantar/palmar annular ligament constriction within the sheath (making this passage even more restricted) or, less commonly, by the presence of adhesions.

PERCUTANEOUS TENDON INJURY

Percutaneous tendon injuries arise most frequently from trauma to the distal limb because of the minimal soft tissue cover. These injuries are usually associated with considerable contusion. Traumatic injuries involving overreaching, wires, jumping injuries, and kicking injuries are the most frequent causes. Tendon laceration usually requires the tendon to be taut, so tendons are most frequently partially or fully severed when under weight-bearing load. The exception to this is the lacerations caused when limbs are caught (e.g., in wire), and repeated attempts to free the limb can saw through any associated tendon or ligament.

The most serious consequences follow trauma to the palmar aspect of the metacarpus or pastern. Up to 50% of the tendon can be lacerated and still provide full tendon function at the walk. In contrast, extensor tendon lacerations on the dorsal aspect of the distal limb, although common (especially in hindlimbs caught in wire), rarely have long-term functional consequences.

Pathophysiology of Tendon Repair

All tendon injuries result in disruption of the tendon matrix, with initial intratendinous hemorrhage, usually followed rapidly by a pronounced inflammatory reaction (Figure 83-12). This inflammatory reaction results in an increase in blood flow; the development of edema; the infiltration of neutrophils, macrophages, and monocytes; and the release of proteolytic enzymes. Although this is the earliest stage of repair, designed to remove damaged tendon tissue, the response is thought to be excessive, further damaging the tendon. The inflammatory phase is usually short, and it overlaps the reparative phase, which begins within a few days and lasts several months. This phase is associated with a pronounced angiogenic response and fibroblastic cellular infiltration (extrinsic repair). It is believed that intrinsic repair mechanisms (i.e., from the tendon itself) are limited. The result is the synthesis of scar tissue with a composition that is different from that of tendon, with a higher ratio of collagen III to collagen I (about 50% compared with 10% for normal tendon), a higher hydration, and higher levels of GAGs[27] (see Figure 83-12).

The reparative phase of tendon healing merges with the remodeling phase, during which there is a gradual but incomplete transformation to a higher proportion of type I collagen as the scar tissue matures (see Figure 83-12).[51] The new collagen fibrils become thicker and cross-links increase in number and mature. Although mature scar tissue tends to be less stiff than tendon, because large amounts are formed, the scarred tendon is often stiffer than the original. As a result, the healed tendon becomes strong but it is functionally inferior to normal tendon, which predisposes it to reinjury, often at sites adjacent to the original injury, and potentially reduces performance.

This process is less efficient when injuries occur to an intrathecal tendon, which is thought to be the consequence of the absence of a paratenon and reduced extrinsic repair. In addition, any surface defect within a tendon sheath will be bathed in synovial fluid, which will slow or even halt repair.

DIAGNOSIS

Clinical Evaluation

Diagnosis of strain-induced tendon injury is usually based on history (frequently a preceding period of exercise) and the development of the signs of inflammation (pain, heat, swelling, and lameness) over the affected structure. Lameness, which is often severe in the early stages, is not always evident when a patient is presented to a clinician, and it tends to be related to the degree of inflammation rather than to the degree of damage.

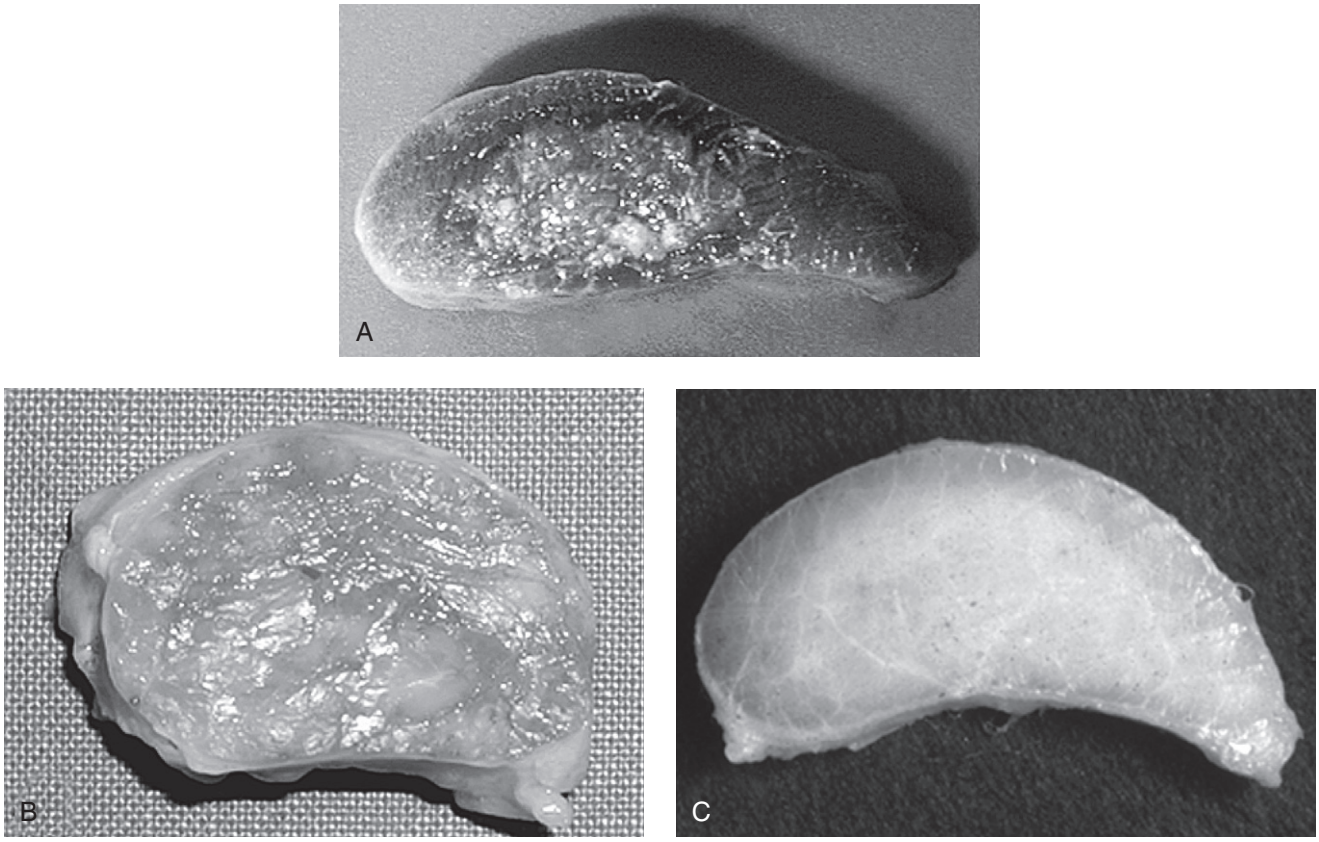

Figure 83-12. The different stages of superficial digital flexor tendinopathy. **A,** Acute. **B,** Subacute. **C,** Chronic. Note the replacement of tendon tissue with white fibrous tissue in **C.**

Similarly, once the inflammatory phase has passed (within 1 or 2 weeks), lameness usually resolves rapidly.

The posture and function of the limb may be altered depending on the structure damaged and on the severity of the injury. In the case of severe superficial digital flexor tendinopathy, resting MCP joint angle may be normal because of the action of the other supporters of this joint (SL and DDFT). However, when loading on the limb increases (e.g., when the contralateral limb is raised off the ground), the affected limb shows greater than normal overextension of the MCP joint (Figure 83-13). Severe damage to the SL has a greater effect on MCP joint extension. Complete disruption of the peroneus tertius produces a characteristic mechanical lameness because of disruption of the reciprocal apparatus. This allows tarsal extension when the stifle is flexed. Similarly, complete rupture of the extensor carpi radialis tendon results in hyperflexion of the carpus during limb protraction.

For subtle cases, careful palpation of the tendons and ligaments in the limb should be made both when the limb is bearing weight and when it is raised. Careful attention should be given to pain response, subtle enlargement, and consistency of the structure (soft after recent injury; firm after healing). The horse must be relaxed so that muscle activity does not tense the tendons and make them appear artificially firm. Careful visual assessment of bowing of the palmar contour of the metacarpal region can help to identify subtle superficial digital flexor tendinopathy. This assessment also should include the contralateral limb, because many strain-induced injuries are bilateral but with one limb more severely affected than the other.

Percutaneous tendon injuries are usually associated with moderate to severe lameness and may or may not have a concurrent wound. If a wound is present, it should be initially cleaned and explored digitally with sterile gloves to ascertain which structures are damaged. Small wounds may hinder full evaluation, because the site of the tendon laceration, sustained under full weight-bearing load, is unlikely to be visible in the wound when the horse is severely lame. In such cases, concurrent ultrasonographic examination is very useful. Penetration injuries or partial severance of a tendon does not alter the function of the tendon, so, other than lameness, there are few alterations of limb conformation. Complete transection, however, is associated with significant alterations in limb conformation under loading (see later). If the laceration is complete, the proximal part of a lacerated tendon often recoils as a result of the action of the associated muscle. It is necessary to assess whether any synovial structures have been penetrated, because this is a common complication of trauma to the distal limbs.

Ultrasonography

Clinical examination may not detect the most subtle injuries of strain-induced tendinopathies, and it provides a poor objective assessment of severity. Because prognosis is most dependent on the severity of the initial injury,[52] it is prudent to evaluate the damaged tendon ultrasonographically. This can be performed any time after the injury, but the optimal baseline scan for severity is best performed approximately 1 week after the onset of

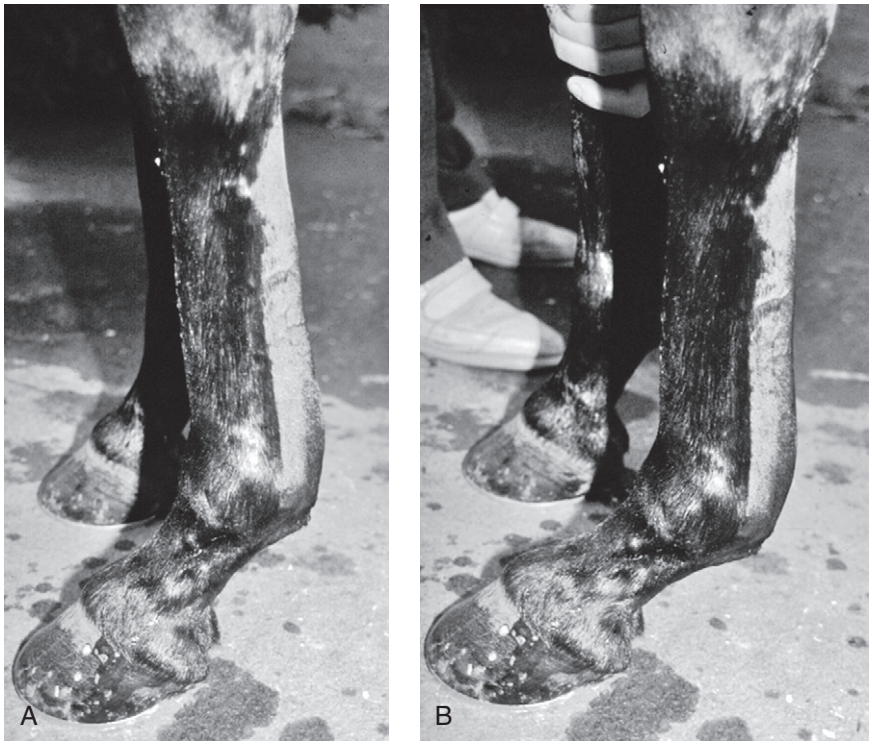

Figure 83-13. Demonstration of significant damage to the superficial digital flexor tendon (and/or suspensory ligament). **A,** Weight is evenly distributed over both limbs. **B,** Increasing the load on the affected limb by lifting the contralateral limb causes an abnormal increase in metacarpophalangeal joint extension.

the injury, because many lesions expand during the initial few days. Modern ultrasound machines with a 7.5- to 14-MHz linear transducer produce excellent-quality images of the flexor tendons and SL. Although the metacarpal region can be evaluated ultrasonographically without clipping the hair, it is best to prepare the limb by clipping and washing (with a surgical scrub and alcohol) to obtain the best-quality images. The horse should stand square, and both transverse and longitudinal images should be obtained methodically throughout the length of the region containing the injured tendon. For the metacarpal region, the area is divided into seven zones, each with characteristic anatomy. Alternatively, the distance between the transducer and the accessory carpal bone can be recorded. The palmar soft tissue structures of the metacarpus can be evaluated satisfactorily from the palmar aspect of the limb, except for the SL branches, which should be evaluated from the medial and lateral aspects of the limb, respectively. Both limbs should *always* be examined, because approximately one third of cases of strain-induced tendon injury have bilateral components but with one limb more severely affected.[53] Detailed information on ultrasonography of tendons and ligaments can be found in Chapter 68.

Acute tendon pathology is manifest ultrasonographically by enlargement, hypoechogenicity (focal or generalized), reduced striated pattern in the longitudinal images, and changes in shape, margin, or position (Figure 83-14). Chronic tendinopathy is associated with variable enlargement and echogenicity (often heterogeneous), and an irregular striated pattern indicates fibrosis (see Figure 83-14).

Ultrasonography is particularly useful for the assessment of tendon lacerations, which are associated with small wounds that limit digital exploration. However, ultrasonographic assessment may be impeded because of air artifacts and skin contusions.

Molecular Markers

Molecular markers have the potential to contribute useful parameters to the evaluation of equine tendon disease. They may be used to provide a diagnosis when other tests are negative (rarely needed for first-time injuries of the SDFT, but they may be useful for detecting reinjury). Additionally, molecular markers offer the following benefits:

- They may be useful for screening as part of a preventive strategy; early detection may enable introduction of measures (e.g., altered training) to minimize the risk of a career-ending injury.
- They may allow a more objective assessment of the severity of the pathology and therefore help to determine prognosis.
- They may provide information about the stage of the disease process, optimizing rehabilitation protocols.
- They may assist in the choice of treatment and provide an objective assessment of its efficacy.

To date, the diagnosis and assessment of stage, severity, and prognosis of equine tendinopathy have been correlated to semiquantitative ultrasonographic changes,[52] but this procedure is time consuming and has a relatively low sensitivity. In contrast, molecular markers have the potential to reflect specific processes, anabolic or catabolic, within the tissue of interest. Initial investigations assessed markers of both collagen I synthesis (carboxy-terminal propeptide of type I collagen [PICP]) and degradation (cross-linked carboxy-terminal telopeptide of type I collagen [ICTP]) after tendon injury.[54] Tendinopathy resulted in a significant rise in PICP concentrations, whereas ICTP concentrations were not different from those in the control group. These results indicated that serum concentrations of PICP are able to reflect changes in type I collagen formation in healing

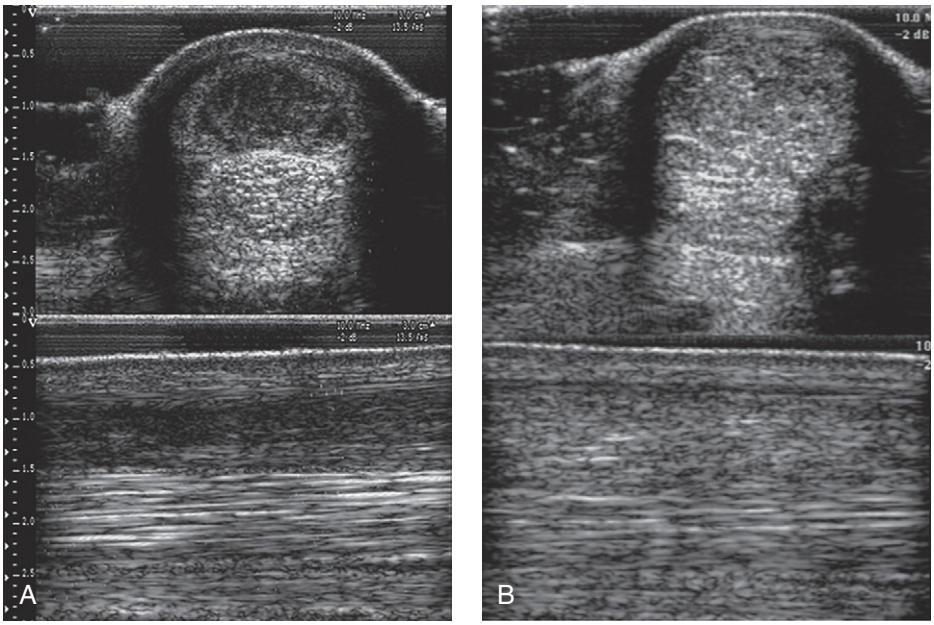

Figure 83-14. Ultrasonographic appearance of superficial digital flexor tendinopathy. **A,** Acute injury is manifested by enlargement, a reduction in echogenicity (especially centrally), and a disrupted striated pattern on longitudinal views. **B,** Chronic injury. The tendon is variably echogenic (usually heterogeneous), is enlarged, and has a poorer striated pattern than normal tendon, which is thought to represent the quality of the healed tendon.

connective tissue in one area of the body. The results also suggest that PICP is not an entirely bone-specific marker, if repair in tissues other than bone can contribute to concentrations in serum.

Another candidate, COMP, which as mentioned earlier is abundant in young tendon, also has been assessed.[55] Synovial fluid levels were more than tenfold higher than serum levels and have been shown to be significantly elevated in the synovial fluid from the digital flexor tendon sheath in cases of intrathecal tendon and ligament tears.[56] In older horses, increased levels of COMP within the DFTS synovial fluid appeared to be strongly suggestive of the presence of a tear even when there is no evidence of this ultrasonographically. In contrast, serum COMP levels were not significantly elevated with tendon disease, which is related to high natural levels of COMP in blood. Longitudinal studies with this marker have shown variable results, but rather than reflecting specific tendon pathology, serum COMP levels might be more useful for detecting joint disease or for determining whether training levels are too excessive and are damaging multiple soft tissues.

Clinical Characteristics of Specific Strain-Induced Injuries

For the SDFT, the clinical injury may be focal or generalized, one of the more common manifestations being a central region of injury (the so-called core lesion seen ultrasonographically). Usually, the most severe level is just below the midmetacarpal region, but it can extend throughout most of the length of the metacarpal extrasynovial tendon and give rise to swelling on the palmar aspect of the metacarpal region (the "bowed" limb). Regions of the SDFT enclosed within a tendon sheath (carpal sheath proximally, digital sheath distally) are much less often affected, although this can be more common when the metacarpal region was previously injured.

Desmopathy of the accessory ligament of the DDFT may occur as an isolated injury or in conjunction with superficial digital flexor tendinopathy. Although ponies rarely suffer strain-induced tendinopathies, they do have a relatively high incidence of desmopathy of the accessory ligament of the DDFT. Lameness is often mild, or even absent, in this injury. Swelling is restricted to the proximal half of the palmar metacarpal region, immediately dorsal to the SDFT and surrounding the DDFT.

The SL can fail at any site along its length. Injury to its proximal region at its origin at the palmar/plantar aspect of the third metacarpal/metatarsal bone (MCIII/MTIII) is often restricted to this area, whereas injuries to the branches usually occur separate from proximal suspensory desmopathy and may extend into the body of the ligament. Some branch injuries may also "tear" into the MCP/MTP joint and result in persistent joint effusion and lameness (Figure 83-15). The synovial fluid environment dramatically slows down healing processes.

In contrast to the SDFT and the SL, the DDFT is most frequently injured within the digital flexor tendon sheath (DFTS) or distal sesamoidean bursa. MRI has facilitated diagnosis of DDFT lesions within the foot.[57] Two manifestations within the DFTS are seen clinically. The first arises within the substance of the tendon (although it may extend to the borders of the tendon) and is similar to other clinical manifestations of tendinopathy.[58] The second arises at the medial or lateral borders of the tendon, usually in the region of the MCP joint.[59] Both lesions are invariably associated with a distended digital sheath, but the latter can be difficult to identify ultrasonographically if the tear does not extend into the body of the tendon (Figure 83-16). In a study of 264 horses with lameness localized to the foot, 82.6% had DDFT lesions identified on MRI examination.[60] These lesions within the DDFT were most commonly located at the level of the collateral sesamoidean ligament and the distal sesamoid bone.

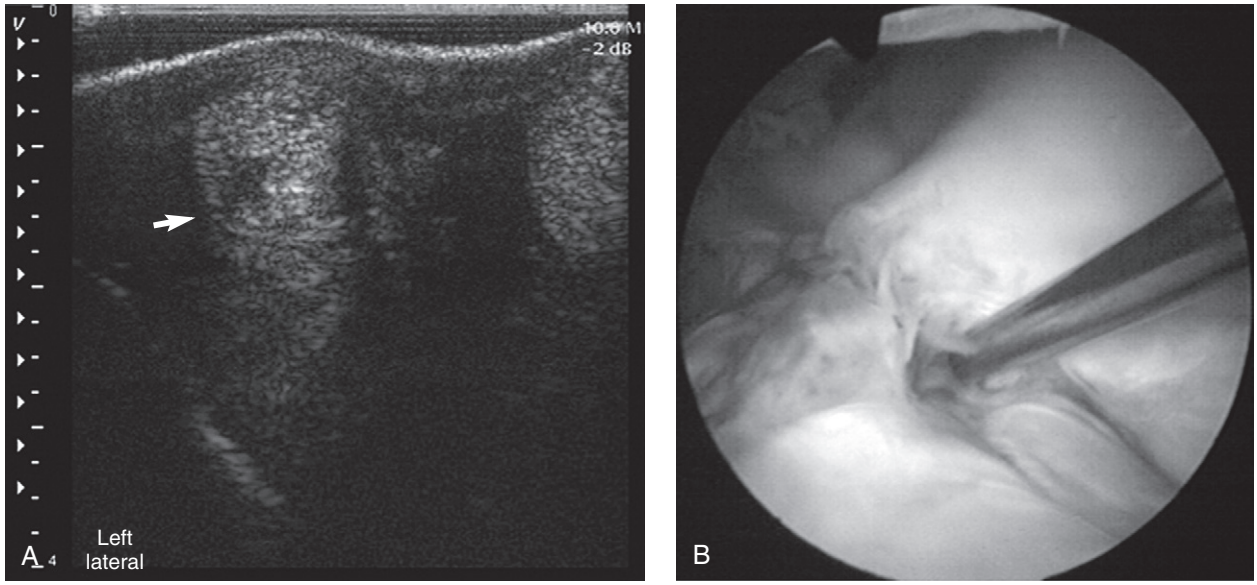

Figure 83-15. A, A hypoechoic defect *(arrow)* in the lateral suspensory ligament branch, which communicates with the metacarpophalangeal joint, causing joint distention, persistent lameness, and slow healing. **B,** This communication was confirmed by arthroscopy.

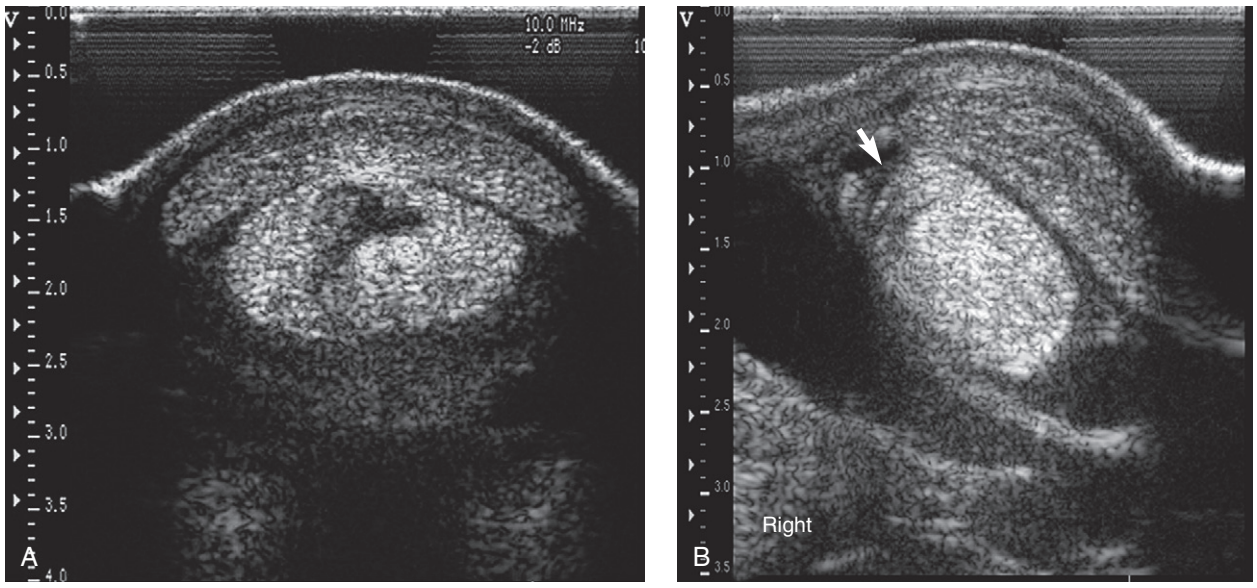

Figure 83-16. Deep digital flexor tendon injury. **A,** Mid-substance strain injury, **B,** Surface tear *(arrow).* The surface tear can be easily missed using ultrasonography and requires tenoscopy for confirmation and débridement.

Other tendons can suffer from strain-induced injury, although much less commonly than that affecting the palmar soft tissue structures of the metacarpal region. Ligament injuries tend to occur when the joint they span is loaded inappropriately, resulting in a degree of subluxation or even complete luxation. Collateral ligament injuries are most commonly diagnosed in the distal interphalangeal, MCP/MTP, and tarsocrural joints. The consequences of these injuries vary from an isolated desmopathy to more severe injury resulting in significant instability of the associated joint. Alternatively, because of their subsynovial location, there can be partial ligament rupture into the adjacent synovial cavity. Both of these consequences may result in secondary osteoarthritis.

Clinical Characteristics of Specific Tendon Lacerations

Complete transection of specific palmar metacarpal tendons and ligaments produces characteristic alterations in limb conformation, which may indicate the tendon or ligament that has been lacerated (Figure 83-17). With SDFT laceration, the MCP/MTP joint is hyperextended (dropped) relative to the normal limb when the limb is loaded, but in the standing horse no difference compared to the joint in the contralateral limb can be detected. If the SDFT and DDFT are lacerated concurrently, in addition to the signs described for SDFT laceration, the toe is raised from the ground. If the SL is completely transected in

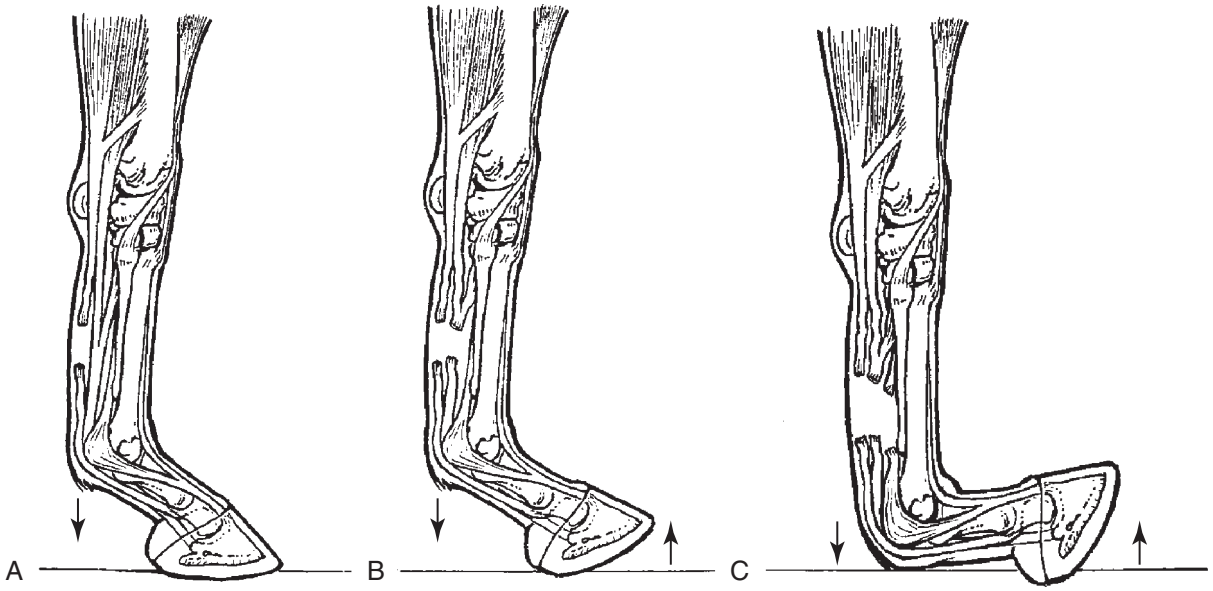

Figure 83-17. A, There is a degree of hyperextension of the metacarpophalangeal joint when the superficial digital flexor tendon has been transected proximal to the joint. **B,** Relative hyperextension of the joint and elevation of the toe off the ground when both the superficial and the deep digital flexor tendons are transected. **C,** Complete loss of metacarpophalangeal joint support when both digital flexor tendons and the suspensory ligament have been disrupted.

addition to the SDFT and the DDFT, there is complete loss of support of the MCP/MTP joint, which is hyperextended to the extent that the MCP/MTP joint contacts the ground during the stance phase. Complete loss of MTP/MCP joint support often causes the horse to be severely distressed.

Extensor tendon lacerations frequently involve the metacarpal and metatarsal regions, although lacerations proximal to the dorsal aspect of the carpus involving the extensor carpi radialis or common digital extensor tendons are not uncommon. Lacerations proximal to the tarsus may involve the cranialis tibialis tendon, the long digital extensor tendon, or the peroneus tertius tendon. Lacerations of the extensor tendons generally do not result in significant gait abnormalities or lameness, although they may cause the horse to stumble onto the dorsal aspect of the MTP/MCP joint region at a walk and to be unable to protract the limb completely.

TREATMENT OF TENDON AND LIGAMENT INJURIES

Strain-Induced Tendinitis (Tendinopathy)

In 1964, Asheim described the common treatment of tendon and ligament injuries as "phlebotomy, local cooling, plaster bandaging and rest."[61] Over the last four decades, many treatments have been proposed for the management of tendon injury, although few, if any, have convincing supporting evidence of efficacy, and some can even be considered deleterious or detrimental to healing. However, the basic principles described by Asheim of cooling, support, and rest remain integral parts of the management protocol. Acute tendon and ligament injuries are medical emergencies requiring prompt and appropriate treatment to reduce inflammation rapidly, because persistent inflammation may be responsible for further damage to the tendon.

Nonsurgical Therapies

PHYSICAL THERAPIES

Cold therapy

In the acute inflammatory phase of tendon injury, cold therapy is an important aspect of treatment as it is both anti-inflammatory and analgesic, largely through its ability to increase vasoconstriction, decrease enzymatic activity, reduce the formation of inflammatory mediators, and slow down nerve conduction.[62] The optimal frequency and duration of cold treatment for musculoskeletal disorders in horses has not been determined. The authors recommend 20 minutes of cold hosing several times daily during the acute phase of tendon and ligament injuries.

Research data have indicated that cold hydrotherapy is superior to the use of ice packs because of the increased contact and evaporation.[63] It is also less likely to cause adverse effects such as superficial tissue damage and cold-induced nerve palsy. Prolonged exposure to cold temperatures can cause a reflex vasodilatation, which can accentuate tissue swelling and edema. For this reason, it is recommended not to apply cold therapy for longer than 30 minutes. One highly effective way of providing cold hydrotherapy is the use of equine spas, which are currently gaining popularity. They provide both cold and compression using hypertonic saline at 5° to 9° C.[64] In addition to equine spas, underwater treadmills, used as part of controlled exercise programs in tendon and ligament injury rehabilitation, allow conditioning of the musculoskeletal system with minimal concussive forces.

Compression and coaptation

In the acute phase of injury, pressure applied to the affected limb reduces inflammation and edema by increasing interstitial hydrostatic pressure. A modified Robert Jones bandage is suitable in most cases of acute tendon and ligament injury.

Figure 83-18. The use of a palmar splint to protect overloading of the superficial digital flexor tendon or suspensory ligament. **A,** The splint is fashioned out of casting tape on the back of a bandaged limb with normal conformation (either the contralateral limb or a "dummy," as shown here). **B,** It is then cut from the limb, the edges are smoothed off, and it is taped to the palmar aspect of the bandaged affected limb. **C,** This limb has also been fitted with a heel extension shoe to protect the deep digital flexor tendon, because this was damaged concurrently.

With severe injuries when there is hyperextension of the MCP joint, a palmar/plantar splint or cast may be applied to the bandaged limb to support the MCP joint (Figure 83-18). A palmar splint can be fashioned from two rolls of 7.5-cm (5-inch) casting tape. One roll is layered on top of itself over a length that matches the length of the limb from the carpus to the bulbs of the foot. This is placed on the palmar aspect of a 2.5-cm-thick support bandage on the contralateral limb. The contralateral limb can be used as a template for making the splint, as it has the optimal degree of extension of the MCP joint. A second roll of cast tape is wrapped around the palmar splint and bandage and left to set. The palmar splint is then cut away from the bandage using a cast saw and applied to the palmar aspect of the bandaged affected limb. A similar effect can be achieved more easily with a specially designed support boot.[65] A full distal limb cast may be used as an alternative in the most severe cases, such as suspensory ligament rupture, when all MCP joint support has been lost.

External coaptation is important in cases of joint instability resulting from collateral ligament injury. In cases where collateral ligament desmopathy of the distal interphalangeal joint that has not significantly destabilized the joint, corrective farriery has been advocated to reduce strain on the injured ligament. Fitting a shoe with increased width on the side of the affected ligament has been proposed to reduce strain on the damaged ligament by impeding downward vertical movement of the wider side of the shoe when the horse is exercised on a soft surface.

Controlled exercise

Controlled exercise is an intrinsic part of the rehabilitation of tendon and ligament injuries, helping to resolve residual inflammation, maintain gliding function, and promote optimal collagen remodeling.[66] Most SDFT injuries require at least 8 to 9 months of rehabilitation before resumption of full athletic function, although some require up to 18 months. It is rarely necessary to prolong rehabilitation longer than this, because healing appears to be complete by this stage.

A suitable exercise rehabilitation program should be created on the basis of the severity of the ultrasonographic appearance of the lesion. The aim of the program is to provide a controlled and ascending exercise regimen that optimizes scar tissue function without causing further injury. Because variability between animals makes this difficult to predict, the program should be adapted on the basis of serial ultrasonographic monitoring and clinical signs such as lameness, heat, and swelling.

Ultrasonographic monitoring of tendon or ligament injuries should include measurements of tendon cross-sectional area (CSA). An increase in CSA of greater than 10% between examinations suggests a degree of reinjury, and in such cases the level of exercise should be reduced. Because there is a sudden increase in strain levels in the SDFT and SL with an upward transition in gait from walk to trot, trot to canter, and canter to gallop, ultrasonographic examinations before and after these transitions can help to determine if the injured tendon or ligament can withstand the increased strain levels.

The importance of a controlled exercise program was illustrated by Gillis, who demonstrated that of 28 Thoroughbred racehorses with SDFT tendinopathy placed in a controlled exercise program, 71% returned to racing, compared with only 25% of 8 horses managed with uncontrolled turnout.[66] An example of rehabilitation programs for racehorses and sports horses is shown in Table 83-1.

Extracorporeal shock wave therapy

Extracorporeal shock wave therapy (ECSWT) has been established for a number of years for the treatment of human orthopedic conditions, especially insertional desmopathies. In this

TABLE 83-1. Typical Exercise Program* after Tendon Injury

Exercise Level	Weeks	Duration and Nature of Exercise
0	0-2	Stall rest
1	3	10 minutes walking
1	4	15 minutes walking
1	5	20 minutes walking
1	6	25 minutes walking
1	7	30 minutes walking
1	8	35 minutes walking
1	9	40 minutes walking
1	10-12	45 minutes walking
WEEK 12: REPEAT ULTRASOUND EXAMINATION		
2	13-16	40 minutes walking and 5 minutes trotting daily
2	17-20	35 minutes walking and 10 minutes trotting daily
2	21-24	30 minutes walking and 15 minutes trotting daily
WEEK 24: REPEAT ULTRASOUND EXAMINATION		
2	25-28	25 minutes walking and 20 minutes trotting daily
2	29-32	20 minutes walking and 25 minutes trotting daily
WEEK 32: REPEAT ULTRASOUND EXAMINATION		
3	33-40	45 minutes exercise daily with slow canter, gradually increasing in amount
3	41-48	45 minutes exercise daily with fast work three times a week
WEEK 48: REPEAT ULTRASOUND EXAMINATION		
4	48+	Return to full competition/race training

*This program is shortened or lengthened depending on the severity of the lesion and the progress of the patient.

therapy, shock or pressure waves are transmitted into the tissues where the handpiece is applied. Both focused and nonfocused units have been used, although the data that compare these machines are too limited to indicate a significant difference. The mechanism of action of ECSWT on tissues is unclear, but it is most likely related to induction of analgesia through an effect on sensory nerves.[67] The most frequently reported use of ECSWT in horses has been for the treatment of proximal SL desmopathy, and a significant improvement in prognosis over conservative treatment for chronic hindlimb proximal SL desmopathy has been reported. Investigation into ECSWT as a treatment for chronic SL desmopathy resulted in 41% of hindlimb patients returning to full work within 6 months of diagnosis,[68] compared with the previously reported 13% for conservatively managed cases.[69] There is evidence that ECSWT can be deleterious to normal tendons and ligaments, resulting in matrix disorganization; however, it was acknowledged that this initial disorganization could be a stimulus for repair in chronically injured tissue.[70]

Therapeutic ultrasound, laser, and magnetic fields

The effect of ultrasound, laser, and magnetic fields on tissues is not completely understood. It is thought that the main effect of ultrasound is the conversion of sound energy into thermal energy. Although there is a paucity of scientifically convincing research into the effects of ultrasound for the treatment of equine musculoskeletal disorders, a study by Morcos and Aswad showed that in experimentally split equine tendons, therapeutic ultrasound resulted in increased vascularization and fibroblastic proliferation compared with controls.[71]

Low-level laser (light amplification by stimulated emission of radiation) therapy has been shown to stimulate cellular metabolism and to enhance fibroblast proliferation and collagen synthesis *in vitro*.[72] However, there are no clinical trials demonstrating a significant difference between laser-treated and control cases of tendinopathy or desmopathy.

Magnetic therapy has not been demonstrated in any clinical trials to enhance tendon or ligament healing, despite its widespread use by horse owners and anecdotal reports of its efficacy.

Counter-irritation

Counter-irritation, in the form of chemical or thermal cauterization, has long been used in equine practice for the treatment of tendon and ligament injuries. Topical iodine and mercury-based compounds have been used for chemical cauterization or "blistering" of tendon injuries. Thermal cauterization (or "firing") is performed under general anesthesia or standing sedation with local analgesia, using heated bars or pins, which are applied to the skin over the injured tendon or ligament. In some cases, the tendon is penetrated with the heated pins. Studies have shown that there is no histologic difference between the collagen arrangement in the scar in cases of tendinopathy treated with firing and that of the controls.[73] It has been postulated that any benefits from firing result from the enforced rest, the local release of inflammatory cytokines, or a protective "bandage" of fibrous tissue or skin that supports the tendon. However, it has been demonstrated that firing causes thinner and weaker skin in the region that was cauterized.[73] The limited controlled studies that have been performed on firing have concluded that it is not an effective treatment for tendon and ligament injuries.

PHARMACOLOGIC MANAGEMENT

Systemic medication

Both systemic corticosteroids and nonsteroidal anti-inflammatory drugs can be considered for the management of tendon or ligament inflammation during the acute stages. Phenylbutazone is commonly used at a dose of 2.2 mg/kg twice daily, but the clinical effects of this drug appear to be more analgesic than anti-inflammatory.[74] Systemic corticosteroids can be administered within the first 24 to 48 hours after injury, but they should be avoided after this time because they also inhibit fibroplasia and hence repair of the tendon. The most commonly used systemic steroid is dexamethasone at 0.1 mg/kg as a single dose. The induction of laminitis with systemic steroids represents a small, but nevertheless real, risk. Topical or intravenous dimethyl sulfoxide (DMSO) may reduce the inflammation, but a study has shown that 40% to 90% topical medical grade DMSO may weaken normal tendon tissue.[75]

Intralesional medication

Various intralesional treatments have been advocated for the management of tendinopathy. These treatments include polysulfated glycosaminoglycans (PSGAGs), hyaluronan (HA), and beta-aminopropionitrile fumarate, with recent interest being focused on novel growth factor and cell-based therapies. Intralesional tendon and ligament treatment can be performed under standing sedation and local analgesia or under general anesthesia. Weight-bearing potentially assists injection, as the tendons are then taut. Although the technique is frequently performed blindly, by injecting where the least resistance in the tendon is detected, accurate placement of the needle in the center of the lesion is best achieved using ultrasonographic guidance. The skin overlying the tendon or ligament to be injected should be clipped and aseptically prepared, and if ultrasonographic guidance is used, a sterile sleeve should be placed over the probe. A 2.5-cm, 22-gauge hypodermic needle can be used for most intratendinous treatments, but this depends on the viscosity of the agent. Intralesional treatment should not be administered until 3 days after the injury, because there is the potential to increase hemorrhage. The volume injected into the tendon or ligament depends on the extent of the lesion. Large volumes can be damaging to the healing tendon.[76]

PSGAGs have been shown to inhibit collagenases and metalloproteinases and to inhibit macrophage activation,[5] but they were shown to have no effect on fibroblasts.[77] Hence, this drug can be viewed as a soft tissue anti-inflammatory agent. PSGAGs have been widely used for the treatment of tendinopathy and desmopathy, both intralesionally and intramuscularly. In one study of 73 horses, treatment with PSGAG either intramuscularly or intralesionally resulted in 76% of horses returning to work versus 46% of the control animals, although these results were not statistically significant.[78] Another study demonstrated improved echogenicity of collagenase-induced superficial digital flexor tendinopathy treated with intralesional PSGAGs, with faster resolution of core lesions.[79] However, another study demonstrated no significant difference in reinjury rates between horses treated with PSGAGs and those treated with controlled exercise alone.[80]

HA consists of repeating units of D-glucuronic acid and repeating units of *N*-acetyl-D-glucosamine and is a component of the tendon matrix. HA has been administered peritendinously, intralesionally, intrathecally, and systemically to treat tendinopathy. A study showed no significant difference between the reinjury rates of horses with SDFT tendinopathy treated with intralesional HA and those treated conservatively.[80] In a study of collagenase-induced digital flexor tendinopathy, HA was found to minimize tendon enlargement compared with controls, although histopathologic examination of the tendons failed to demonstrate a significant difference in the degree of inflammation.[81] Peritendinous HA has been shown to have no effect on ultrasonographic or histologic appearance, biomechanical properties, or molecular composition of tendons in collagenase-induced tendinopathy compared with controls, although it did appear to reduce lameness.[82]

HA has been shown to decrease the extent of adhesions when administered intrathecally to treat collagenase-induced deep digital flexor tendinopathy within the digital sheath.[83] Horses treated with intrathecal HA showed decreased inflammatory cell infiltrate and less intratendinous hemorrhage than controls.[83]

Methylprednisolone injected into and around normal equine tendons has been shown to cause dystrophic tissue mineralization and tissue necrosis, most likely a consequence of the carrier.[84] Hence, the local use of this steroid should be avoided. Nondepot preparations may be used peritendinously with caution.

New advances: Tissue engineering approaches

The use of *growth factors* is a relatively recent approach. Insulin-like growth factor-1 (IGF-1) has been investigated to assess its effect on tendon healing both *in vitro* and in collagenase-induced models of tendinopathy.[85] IGF-1 stimulates extracellular tendon matrix synthesis, and it is also a potent mitogen.[85] In collagenase-induced models of tendinopathy, initial swelling was decreased after intralesional injections of IGF-1 compared with controls, although no differences were found at later time points and there was no difference between the quantities of type I and type III collagen synthesized.[85] There are no published long-term follow-up data regarding reinjury rates of tendinopathy treated with IGF-1.

Recombinant equine growth hormone administered intramuscularly has demonstrated a negative effect on some of the biomechanical properties (decreased yield point and ultimate tensile strength) of the SDFT during the early phases of healing in collagenase-induced tendinopathy, although elasticity was maintained.[86] However, these properties were assessed at 6 weeks after treatment, which may have been too soon to detect any beneficial effects.

TGF-β has been considered another appropriate growth factor treatment, but clinical experience has been limited. Horses treated with TGF-β_1 (a proscaring isoform of TGF-β) showed significant enlargement of the tendon and, although reinjury rates were similar to those in conservatively managed horses, these reinjuries were all on contralateral, untreated limbs.[87]

Platelet-rich plasma (PRP) is defined as plasma with at least twice the platelet concentration of normal plasma[88] and can be created using centrifugation or gravity filtration of autologous blood. PRP is a rich source of certain growth factors (in particular, platelet-derived growth factor [PDGF], TGF-β, and vascular endothelial growth factor [VEGF]), which can stimulate cell proliferation and matrix synthesis. In an experimental model, modulation of composition, organization, and biomechanical properties of PRP-treated tendon was demonstrated in a surgically induced model of tendinopathy.[89] These preparations have become popular for the intralesional treatment of mainly suspensory ligament injuries, but long-term clinical data on a sufficient number of cases have yet to be published, although reports on small case series suggest efficacy.[90]

ACell Vet is a novel intralesional treatment for tendinopathy using acellular tissue components derived from porcine urinary bladder submucosa. This preparation has been suggested to deliver appropriate growth factors to the injured tissue and to attract mesenchymal stem cells. There is only anecdotal evidence that this treatment improves tendon and ligament healing, and controlled clinical trials are required to further assess efficacy.

Treatment with intralesional *bone marrow* has been investigated for SL desmopathy.[91] The aim was to stimulate ligament regeneration rather than scar tissue formation by the delivery of stem cells to the damaged tendon or ligament. Bone marrow is a rich source of growth factors[92] but contains very few

mesenchymal stem cells (1 in 10^4 nucleated cells). Hence, this treatment more closely resembles a growth factor treatment.

The use of intralesional bone marrow as a source of *mesenchymal stem cells* (MSCs) led to the development of culturing MSCs from bone marrow before implantation. The use of autologous MSCs for intralesional treatment of SDFT and SL lesions offers the prospect of tissue regeneration rather than repair. MSCs have the potential to differentiate into tenocytes and to regenerate tendon matrix, thereby creating a repair that is functionally superior to fibrous scar tissue. Initial studies have included the isolation of MSCs from either bone marrow or fat, followed by either direct implantation or expansion *in vitro* before implantation.[93] A recent study evaluated the efficacy of cultured bone marrow–derived stem cells for the treatment of superficial digital flexor tendinopathy in racehorses in the United Kingdom. The reinjury rate was 26%[94] in 113 National Hunt racehorses with 3 years of follow-up after treatment, which was significantly better than data previously reported for a similar population of National Hunt horses treated conventionally and analyzed in the same way.[80,95]

Surgical Therapies

TENDON SPLITTING

Tendon splitting was first performed in the 1940s and the technique was published in 1967.[96] It was initially advocated as a treatment for chronic tendinopathy to improve blood flow to damaged tendon tissue that is relatively avascular. The technique fell out of favor when subsequent research demonstrated extensive granulation tissue formation, and increased trauma to the tendon tissue and persistent lameness after treatment.[97] Tendon splitting is therefore no longer recommended for the treatment of chronic tendinopathy, but it is now thought to be more relevant to the management of acute cases when there is an anechoic core lesion evident on ultrasonographic examination, indicating the presence of a seroma or hematoma. It has been hypothesized that the presence of a core lesion within a tendon produces a compartment syndrome, resulting in decreased perfusion and ischemia of the region.[98] The aim of tendon splitting in acute cases is therefore to decompress the core lesion by evacuating the serum or hemorrhage and to facilitate vascular ingrowth.[98] Removal of the fluid in the core lesion may also reduce proximodistal propagation of the lesion. In a collagenase-induced model of tendinopathy in six horses, tendon splitting using the knife technique resulted in a faster resolution of the core lesion, quicker revascularization of the lesion, and increased collagen deposition than in controls.[99]

Tendon splitting may be performed under standing sedation or under general anesthesia. It can be done blindly or using ultrasonographic guidance, which minimizes damage to normal tendon tissue by enabling the needle or knife to be inserted at a point where the core lesion is closest to the periphery of the tendon. A No. 11 scalpel blade or double-edged blade is inserted into the tendon and "fanned" proximad and distad (Figure 83-19). Alternatively, the procedure can be achieved with multiple insertions of a 23-gauge needle, possibly with less damage to the remaining, relatively intact tendon tissue. Needle splitting may also be combined with various intralesional treatments.

After tendon splitting has been performed, a modified Robert Jones bandage should be applied and the horse rested in a stall for 10 to 14 days, after which a controlled exercise program should be initiated.

DESMOTOMY OF THE ACCESSORY LIGAMENT OF THE SUPERFICIAL DIGITAL FLEXOR TENDON

Superior check ligament desmotomy was first described as a treatment for SDFT tendinopathy by Bramlage in 1986.[100] The aim of the surgery is to produce a functionally longer musculotendinous unit to reduce strain on the SDFT. However, it has been shown in equine cadaver models that desmotomy of the accessory ligament of the SDFT (DALSDFT) actually increases the strain on the SDFT during loading because of increased extension of the MCP joint.[101] The biomechanical alterations of

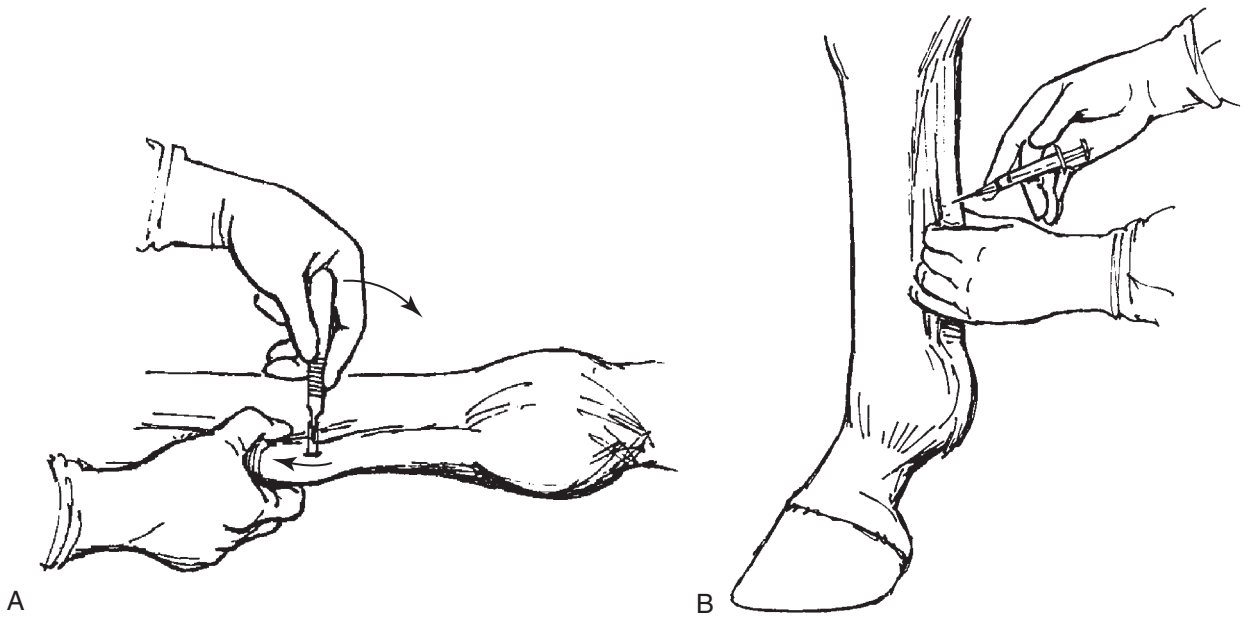

Figure 83-19. Tendon splitting can be performed with a blade **(A)** or with needles **(B).** With needles, the splitting procedure can be combined with an intratendinous treatment, if appropriate.

DALSDFT therefore are complex, and studies using cadaver limbs may not represent the biomechanical events in a fatigued galloping racehorse. However, increased risk of injury of the suspensory ligament after DALSDFT has also been demonstrated *in vivo*.[102] Initial results from Bramlage demonstrated that 79% of horses suffering from superficial digital flexor tendinopathy treated with DALSDFT competed in two races without recurrent tendinopathy.[100]

DALSDFT can be performed with the horse in lateral or dorsal recumbency. A 10-cm skin incision is made between the cephalic vein and the caudal radius on the medial aspect of the limb. The incision should extend from the level of the medial malleolus of the radius to midchestnut proximally. A transverse branch of the cephalic vein may require ligation to improve access. The cephalic vein is retracted caudad to expose the flexor carpi radialis (FCR) sheath, which is incised to reveal the FCR tendon. The FCR tendon is retracted caudad to expose the accessory ligament of the SDFT, which is located adherent to and deep to the lateral aspect of the FCR sheath. Both the transverse and the deeper oblique fibers of the accessory ligament of the SDFT are transected sharply, with or without the assistance of forceps to elevate the latter. Ideally the artery and vein of the proximal SDFT are identified on the proximal border of the accessory ligament and preserved.[103]

The FCR sheath and the fascia should be closed in two layers using a simple-interrupted or simple-continuous pattern and with 2-0 or 0 (3 or 3.5 M) synthetic absorbable suture material for each layer (e.g., polyglactin 910). The skin is then closed with a simple-interrupted or vertical mattress suture pattern using 2-0 or 0 (3 or 3.5 M) nonabsorbable material (e.g., monofilament nylon).

A well-padded bandage capable of providing compression is applied over a sterile dressing for 10 to 14 days to reduce the risk of seroma formation at the surgical site, which is a common complication of this procedure. The initial rehabilitation period involves 2 weeks of stall rest, followed by a controlled exercise program as previously described.

More recently, this procedure has been carried out tenoscopically through the carpal sheath.[104] With the affected limb uppermost and partially flexed, an arthroscopic portal is created into the carpal sheath 2 cm proximal to the distal radial physis on the lateral side of the limb. An instrument portal is made immediately proximal to the distal radial physis. With the limb in 90 degrees of flexion, the accessory ligament is visualized on the medial aspect of the sheath and cut using a No. 10 scalpel blade on a long handle or a meniscectomy knife. The very proximal portion of the ligament cannot be visualized directly but is transected by careful dissection using punch biopsy forceps, taking care to avoid the perforating blood vessel at the proximal limit of the accessory ligament. Experience is needed to perform this aspect of the surgery, and the operator may not sever all of the attachments of the accessory ligament of the SDFT, resulting in a poor outcome.

TENOSCOPY

The increasingly widespread use of tenoscopy has demonstrated a high frequency of intrathecal tendon tears that are associated with tenosynovitis and lameness. Hence, horses presenting with tenosynovitis with pain on palpation of the proximal digital sheath and lameness should always be considered candidates for tenoscopic evaluation. Based on a recent survey of cases, tears in the DDFT are more commonly found in forelimb digital sheaths, whereas tears to the manica flexoria are more commonly found in hindlimbs (Figure 83-20). Ultrasonographic evaluation usually reveals nonspecific changes of synovial hypertrophy, and it is frequently not possible to identify tears on ultrasonographic examination with confidence. However, when a tendon tear extends into the center of the tendon, it can be identified as an anechoic lesion (as it is filled with synovial fluid). Manica tears are particularly difficult to identify ultrasonographically, but occasionally disruption of the attachment of the manica to the SDFT can be demonstrated. In addition, tears can also be found and débrided tenoscopically in the SDFT and in the distal sesamoidean ligaments within the digital sheath.

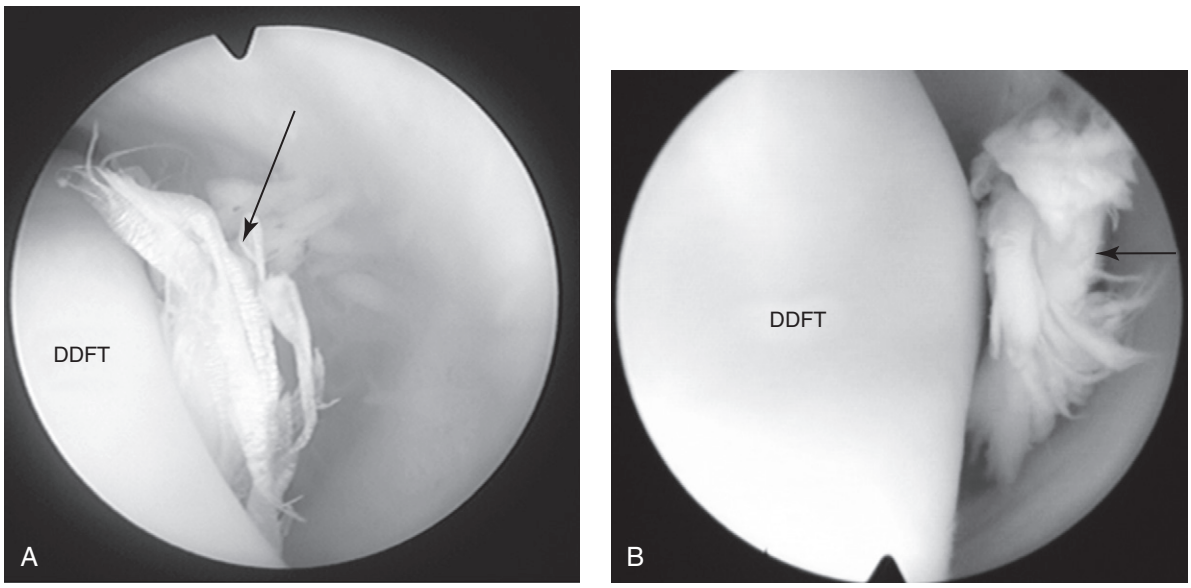

Figure 83-20. Commonly detected abnormalities that cause tenosynovitis of the digital sheath. **A,** Surface tear *(arrow)* of the deep digital flexor tendon *(DDFT),* most commonly found in forelimb tenosynovitis. **B,** Rupture *(arrow)* of the attachments of the manica flexoria, most frequently seen in hindlimb tenosynovitis.

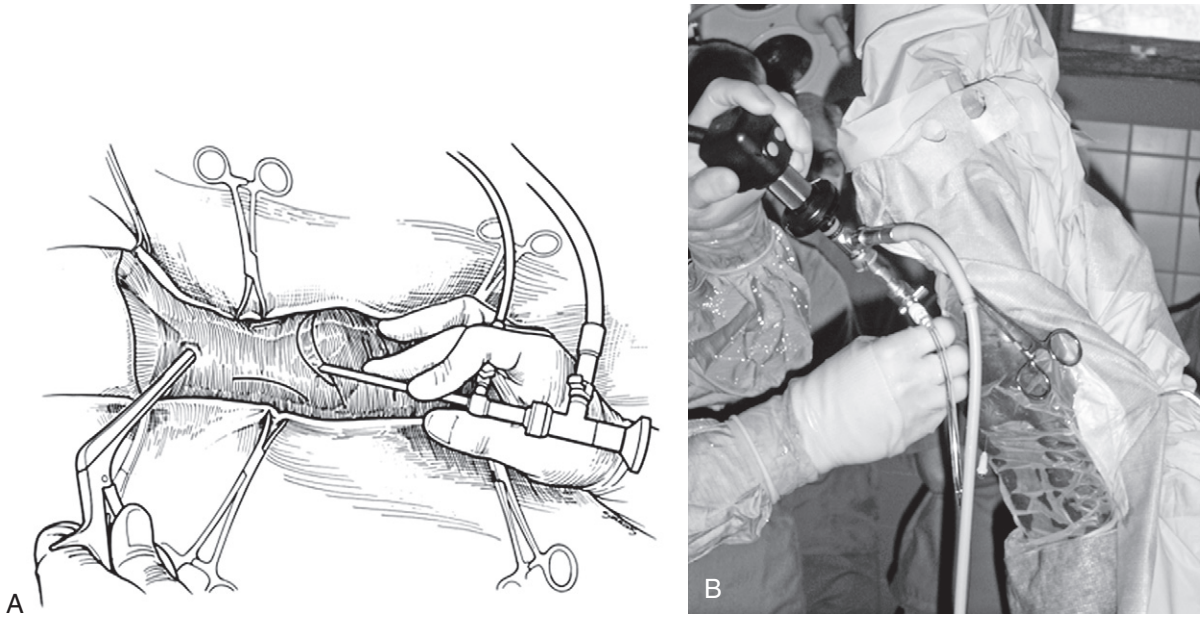

Figure 83-21. Tenoscopy of the digital sheath, which is now a routine procedure. **A,** The original description was in lateral recumbency, and the arthroscope was introduced into the digital sheath immediately distal to the palmar annular ligament, 1 to 2 cm palmar to the neurovascular bundle. **B,** However, dorsal recumbency allows more flexibility to evaluate both sides of the digital sheath and an easier bilateral approach for surgical removal of the manica flexoria. (From Nixon AJ: Endoscopy of the digital flexor tendon sheath in horses. Vet Surg 19:267, 1990.)

Tears of other tendons and ligaments communicating with a synovial cavity have been seen to be associated with synovial distention and lameness (e.g., in the suspensory ligament branches into the MCP/MTP joint) (see Figure 86-15).

Tenoscopy of the digital sheath requires general anesthesia and can be performed in lateral or dorsal recumbency. However, dorsal recumbency allows easier access to both sides of the digital sheath and is recommended. Arthroscopic portals are created immediately distal to the proximal sesamoid and 1 to 2 cm palmar/plantar to the neurovascular bundle[105] (Figure 83-21). This allows evaluation of the proximal and distal parts of the digital sheath, although distal visualization is sometimes easier with the arthroscope inserted through a portal in the proximal digital sheath (e.g., as for a proximal instrument portal). Instrument portals are created where appropriate to allow débridement of any tendon tears with a mechanical resector. This may require the instrument portals to be extended through the synovial reflection that attaches to the proximal border of the manica flexoria to allow access to DDFT tears located within or proximal to the manica. Although manica tears can also be débrided as is done for DDFT tears, this has been associated with poorer outcome than complete removal. Because no adverse effects have been observed with complete removal, this is recommended for all but the most minor manica tears. Removal requires transection of both medial and lateral attachments to the SDFT, as well as transection of the synovial attachment to the proximal border of the manica. This is facilitated by an assistant who maintains tension on the manica with rongeurs through the contra-axial proximal instrument portal. Transection can be achieved with arthroscopic scissors, bistoury, or a hook knife.

Chronic tenosynovitis can be associated with synovial masses attached to the synovial plicae in the proximal digital sheath. These, together with isolated adhesions, can also be resected during tenoscopic evaluation, and the palmar or plantar annular ligament can be transected if it is believed to be involved in the pathology. Postoperatively, the horse should be strictly rested for at least 2 weeks, after which hand-walking can be started and gradually increased over a period of at least 6 weeks. Thereafter, the duration of rehabilitation depends on the severity of the injury. The prognosis for simple DDFT tears (about 40%) is worse than for simple manica tears (about 80%).[106]

BURSOCOPY

Intrabursal lesions of the DDFT identified on postmortem examination most commonly consisted of tears and fibrillation of the dorsal surface of the tendon, followed by torn DDFT fibers adhered to the distal sesamoid bone, and DDFT core lesions.[107] A 2005 study[108] demonstrated that the prognosis for return to full athletic function without recurrence of lameness was 28%. DDFT lesions associated with distal sesamoid bone pathology had a poor prognosis. Treatment consisted of corrective farriery, controlled exercise, and in some cases medication of the distal sesamoidian bursa with hyaluronan, with or without corticosteroids. The technique for distal sesamoidian bursoscopy has been described using a transthecal approach[109] and has been associated with an improved prognosis.[110]

ANNULAR LIGAMENT DESMOTOMY

Annular ligament desmotomy has been advocated for the management of DDFT and SDFT lesions in the region of the MCP and MTP joints. The procedure is indicated if the annular ligament is impeding the normal gliding function of the flexor tendons. Annular ligament desmotomy is performed under general anesthesia and is ideally performed tenoscopically using a hook knife, with or without a slotted cannula (Figure 83-22), rather than via closed or open techniques, because it is less traumatic, ensures accurate transection of only the palmar or plantar annular ligament, and allows evaluation of the tendons to identify any primary causes. For a more detailed

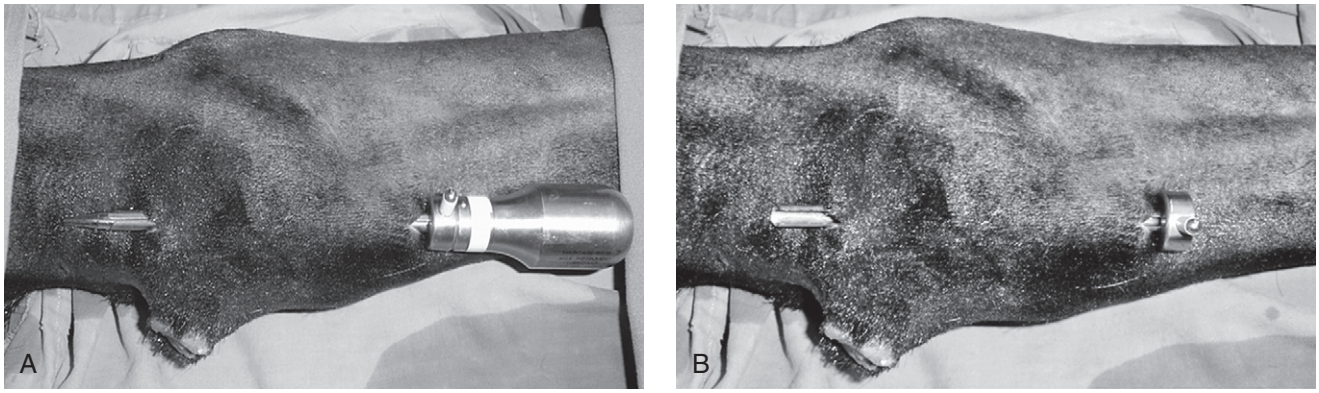

Figure 83-22. The use of the slotted cannula for transection of the palmar annular ligament. **A,** The cannula is guided through the sheath from proximal to distal under arthroscopic control to ensure that it does not lie inside the manica flexoria. **B,** The central obturator is removed and a hook knife is introduced (knife not shown) to cut the palmar annular ligament via the slot in the cannula. This can be introduced from either a proximal or a distal direction, with the arthroscope (without its sleeve) in the opposite end to view the procedure. This technique allows closed and accurate transection of the ligament without damaging other structures.

discussion of annular ligament desmotomy and its indication, please review Chapter 91.

FASCIOTOMY AND NEURECTOMY OF THE DEEP BRANCH OF THE LATERAL PLANTAR NERVE FOR THE TREATMENT OF PROXIMAL SUSPENSORY LIGAMENT DESMOPATHY

Surgery has been advocated in cases of proximal suspensory ligament desmopathy (PSLD) of the hindlimb that are unresponsive to conservative management. It has been reported that horses have returned to high-level competition after tibial neurectomy to treat PSLD.[111] However, a more specific neurectomy of the deep branch of the plantar nerve has been described.[112] This is performed under general anesthesia with the horse in dorsal recumbency. A 4- to 6-cm incision is made adjacent to the lateral border of the SDFT, originating proximally from the level of the chestnut (Figure 83-23). The plantar metatarsal fascia is incised and the incision is extended deep to the SDFT by blunt dissection, facilitated by retraction of the SDFT. The lateral plantar nerve is located in connective tissue, the deep branch is identified and transected using a scalpel, and a 3-cm section is removed. The connective tissue fascia covering the suspensory ligament is cut (fasciotomy) adjacent to the lateral splint bone to decompress the origin of the suspensory ligament, because hindlimb proximal suspensory desmopathy is believed to be associated with a compressive compartment syndrome involving the plantar metatarsal nerves.

Postoperatively, only a short period of strict rest is needed (about 2 weeks) to allow the surgical incisions to heal. Thereafter, the horse can gradually begin a controlled ascending exercise program. Nonpublished reports have suggested that this technique is associated with a high level of success in returning affected animals to full work with minimal risk of exacerbating the desmopathy.

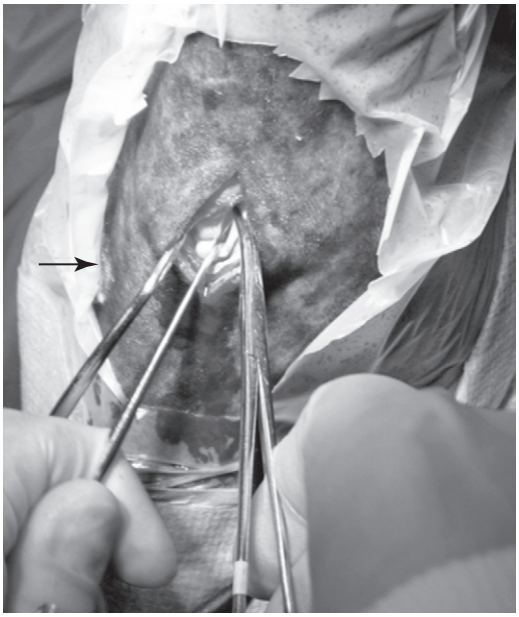

Figure 83-23. Cadaver specimen showing surgical approach for neurectomy of the deep branch of the lateral plantar nerve. Note the level of the incision compared to the location of the chestnut *(arrow)*. The nerve is held in a spay hook, and after bathing in local aesthetic, gentle traction is used to retract the nerve to allow removal of up to 5 cm.

DESMOTOMY OR DESMECTOMY OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON

Conservative management of accessory ligament of the DDFT (ALDDFT) desmopathy is usually successful. However, in some cases, desmopathy recurs or causes adhesions between the ALDDFT and the SDFT or a flexural deformity. In such cases desmotomy, or preferably desmectomy, of the accessory ligament of the DDFT may be considered.[113]

ALDDFT desmotomy is performed under general anesthesia in lateral recumbency. The ALDDFT can be approached medially or laterally. A medial approach results in improved cosmesis but an increased risk of vascular damage to the medial palmar artery, and the lateral technique has the opposite effect. After aseptic preparation of the surgical site, a skin incision is made in the proximal half of the metacarpus adjacent to the palmar border of the DDFT (see Figure 87-20. The incision is continued deeper by blunt dissection to expose the ALDDFT. The ALDDFT is elevated using forceps and is transected with a scalpel. Greater exposure can allow complete removal of the accessory ligament if necessary. The wound is closed in two layers—first the fascia with a simple-continuous pattern using an absorbable suture

Figure 83-24. Loss of digital extensor function secondary to extensor tendon laceration, resulting in weight-bearing on the dorsum of the hoof and phalangeal region.

material, and then the skin. A modified Robert Jones bandage should be applied to the distal limb postoperatively for 3 to 4 days.

Tendon Lacerations

Lacerations of the digital extensor tendons can result in the partial or complete loss of protraction of the distal limb or the animal may place the limb in an abnormal position (Figure 83-24). However, many cases show minimal signs. In contrast, horses suffering from flexor tendon lacerations are usually in severe pain and need immediate attention.

Emergency Treatment of Tendon Lacerations

The limb should be stabilized before the horse is moved to an appropriate place for treatment. It is important that the limb be supported to ensure the comfort of the horse by restoring some biomechanical function to the limb to prevent further tissue damage. It is particularly important to avoid further trauma to the neurovascular structures of the distal limb. For flexor tendon lacerations, a palmar or dorsal splint or a commercial splint (e.g., a Kimsey splint [see Figure 73-6]) should be applied. Any difficulty in limb protraction with an extensor tendon laceration can be managed with a simple splint bandage. For more information on the first aid of traumatized horses, review Chapter 73.

Surgical Repair

FLEXOR TENDONS

Surgical repair of flexor tendon lacerations involves débridement, suturing of the tendon, and closure of the wound and is usually performed under general anesthesia with the horse in lateral or dorsal recumbency. The aims of tenorrhaphy are to restore tendon gliding function, minimize gap formation between the tendon ends, minimize adhesion formation, and preserve functional vasculature. If the laceration is complete, the tendon may have recoiled, requiring proximal and distal extension of the skin wound in an elongated S shape to locate both tendon ends (Figure 83-25). Flexing of the MCP/MTP joint may facilitate locating the distal tendon end. The wound and tendon ends should be débrided and lavaged. If the tendon ends can be apposed, tenorrhaphy can be performed using a monofilament absorbable suture (e.g., polydioxanone or polyglyconate). Nonabsorbable materials should be avoided, as they can result in shearing between the healed tissue and the suture material and may be responsible for persistent lameness. Two suture patterns are commonly used, the three-loop pulley and the interlocking loop. The three-loop pulley prevents distraction of the ends of the tendon under loading (i.e., gapping), whereas the interlocking loop has little suture material outside the tendon and is therefore the recommended technique for repair of intrathecal lacerations. The interlocking-loop pattern can be supplemented with simple-continuous sutures to reduce gap formation between the tendon ends. A single locking-loop suture is not as strong as a double- or triple-locking loop or a three-loop pulley pattern.[114]

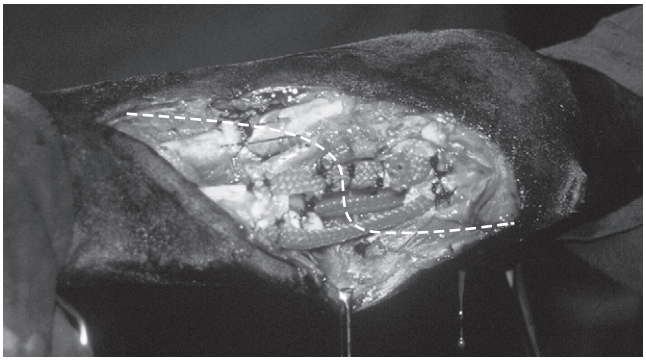

Figure 83-25. The use of poly-L-lactic acid (PLLA) to repair extensive defects in the digital flexor tendons. This horse suffered a transverse wound to the plantar aspect of the mid-metatarsal region, which transected both the superficial and deep digital flexor tendons and the lateral branch of the suspensory ligament. The wound margins were resected and the area exposed by using an S-shaped incision *(dotted line)*. After débridement of the tendons, a 5-cm defect was present in both tendons, which was bridged with two PLLA implants sutured to each end of the tendons. The lateral branch of the suspensory ligament was apposed using a three-loop pulley suture.

Frequently the injury is associated with significant blunt trauma to the tendon ends, which precludes direct apposition of the tendon ends. In this situation, the tendons ends can be left after débridement, the wound closed, and the limb cast, or an implant can be used to maintain the alignment of the tendon ends. The ideal tendon implant material would have biomechanical properties similar to those of normal tendon. Various implant materials have been used to repair lacerated flexor tendons, including carbon fiber, terylene (polyester), autologous extensor tendon grafts, and poly-L-lactic acid (PLLA).[115] Carbon fiber implants were associated with persistent lameness postoperatively, which may have been caused by tenalgia resulting from shear forces between inelastic carbon fibers and the healed tendon tissue. The use of autologous grafts using extensor tendons to bridge the deficit between two ends of a lacerated tendon has never gained popularity. The advantage of PLLA is

that it supports fibroblast growth on its surface and loses its strength over several months, thereby being able to match its mechanical properties with the tendon. Implants are anchored in each end of the lacerated tendon by fixing the ends in V-shaped incisions created in the tendon ends with sutures of monofilament absorbable sutures. Implants are not recommended as a treatment for strain-induced tendinopathy.

Partial lacerations involving less than 50% of the tendon may need only local débridement. Lacerations involving greater than 50% are probably best sutured, as this can prevent the generation of longitudinal splits between loaded and unloaded parts of the tendon.

Flexor tendon lacerations require a protracted rehabilitation period. A distal limb cast should be placed with forelimb lacerations postoperatively. In the hindlimb, a full-limb cast is required after flexor tendon laceration to immobilize the forces of the reciprocal apparatus. However, distal limb casts can be used in the hindlimb to avoid the increased risk of complications of full-limb casts, unless an implant has been placed, in which case the result is usually that one end is pulled out of the tendon. Casting is required for a minimum of 6 to 8 weeks and no more than 12 weeks, thereby often necessitating one cast change under general anesthesia, as studies have shown that the breaking strength of the tendon repair at 6 weeks approximates the body weight of the horse.[116]

Adequate support to the MCP/MTP joint in an adult horse cannot be provided by a bandage alone. A palmar/plantar splint applied over a modified Robert Jones bandage and caudal shoe extensions (for DDFT lacerations) provide protection of the repair after cast removal. Alternatively, a specifically designed boot has been shown to provide sufficient support.[65] This device has the advantage that it can be used during exercise because it is jointed. Continued stall rest is necessary for a further 2 to 3 months, after which walking exercise followed by an ascending exercise regimen can be initiated. Ultrasonographic monitoring of tendon healing is useful to assess the integrity of the tendon repair. A minimum of 8 to 12 months is usually required before full athletic function can be resumed.

The prognosis for flexor tendon injuries is guarded, with approximately 45% of horses returning to athletic function in one study[116]; in another study, the prognosis was 59% for flexor tendon lacerations.[117] In the second study, the prognosis for return to soundness was not increased if the DDFT and SDFT were simultaneously lacerated compared with involvement of only a single structure.[117] Complications of tendon lacerations include necrotic tendinopathy (which occurs as a result of infection or damage to the vascular supply), concurrent synovial sepsis, cast complications, adhesions resulting in continued pain and lameness, exuberant granulation tissue formation, flexural deformity, and reinjury.

EXTENSOR TENDONS

Extensor tendon lacerations heal remarkably well without tenorrhaphy and respond well to conservative management. The wound should be débrided and the primary wound closed if appropriate. If the extensor tendon has been lacerated within the confines of a tendon sheath (e.g., for extensor lacerations over the dorsal aspect of the carpus), the area should be lavaged, and elimination of sepsis from the tendon sheath will need to be addressed. Fibrous scar tissue gradually forms an attachment between the two tendon ends. A period of 4 to 6 weeks of stall rest until the wound has healed is usually all that is required. A cast can be used to assist soft tissue healing if contusion has been extensive. The prognosis for extensor tendon lacerations is good (with 72% to 80% of horses returning to athletic function).[117,118] The prognosis for extensor tendon lacerations is better than for flexor tendon lacerations, because the extensor tendon bears considerably less load and has a minimal effect on the gait, with most protraction of the limb and digit arising from the upper limb and momentum of the foot. Indeed, a publication reported the successful management of septic common digital extensor tenosynovitis by complete resection of the tendon.[119] Stumbling may be evident at the walk until the tendon has healed, but this can be reduced by shortening the toe of the hoof and rolling the toe of the shoe or by fitting a Natural Balance type of shoe. If extension cannot be maintained spontaneously, a toe extension can be fitted to the shoe to prevent secondary contracture, although this may make stumbling more severe.

The most common complications associated with extensor tendon lacerations include exuberant granulation tissue and sequestrum formation associated with underlying damage to the bone, although acquired flexural deformities can occur.

CHAPTER

84 Biology and Management of Muscle Disorders and Diseases

John G. Peloso

STRUCTURE AND FUNCTION OF MUSCLES

Of the three types of muscle in the body—skeletal, smooth, and cardiac—skeletal muscle makes up about 40% of the body weight.[1,2] All movement is the result of contraction of skeletal muscles, and most patients with neuromuscular disease exhibit abnormal movement. *Skeletal muscle* consists of a central fleshy muscle belly and a tendon at each end. The tendon at one end of the muscle originates on one bone, and the tendon at the other end inserts on a different bone, with at least one movable joint interposed. When activated by a motor neuron, a skeletal muscle can only contract (or shorten). Movement occurs when the central muscle belly shortens, causing the two tendons and their bones of attachment to move with respect to each other around a central joint. A muscle returns to its original longer length by the pull of its antagonistic counterpart, a muscle that traverses the joint on the opposite side. In some locations, it may be more than one muscle. Some muscles increase joint angle (extensors), and some muscles decrease joint angles (flexors).

Anatomy

Skeletal muscle has several levels of organization (Figure 84-1). Each muscle belly is made up of thousands of muscle cells (also called muscle fibers). Each muscle fiber contains thousands of myofibrils that are arranged in parallel along its length, and each myofibril is made up of a series of repeating sarcomeres. The *sarcomere* is the basic contractile unit of the muscle fiber.[1,2]

Myofibrils have an arrangement of alternating thick and thin filaments. The thick filaments are composed of the protein *myosin*, and the thin filaments are composed of the proteins *actin*, *tropomyosin*, and *troponin*.[1,2] Myofibrils are surrounded by membranes in the form of tubules. These tubules are composed of a transverse tubular system and the sarcoplasmic reticulum, and collectively they are called the *sarcotubular system*. Each muscle fiber is innervated by a terminal branch of a motor nerve fiber. The junction between the nerve and the muscle fiber is the neuromuscular junction. All muscle fibers that are innervated by a single nerve fiber are called a *motor unit* because all of the muscle fibers within a unit are excited simultaneously and contract in unison.

Physiology of Contraction

It is at the neuromuscular junction that action potentials are generated. The resting membrane potential of the sarcolemma is excited by a synaptic transmission at the neuromuscular junction. Via transverse tubules, the action potential reaches the sarcoplasmic reticulum throughout the muscle fiber.

Skeletal muscle cells (muscle fibers) convert chemical energy into mechanical energy. At rest, calcium ions are maintained within the sarcoplasmic reticulum of the muscle cell. The arrival of an action potential to the sarcoplasmic reticulum causes the release of calcium ions. These calcium ions perfuse the sarcomere and bind with troponin. This alters the actin filament, allowing it to react with the myosin filament. Although a detailed molecular explanation of the sliding filament mechanism is not known, the altered actin molecule is now able to slide along the myosin molecule, causing a physical shortening of the sarcomere (Figure 84-2). As the action potential passes, calcium ions are returned to the sarcoplasmic reticulum, allowing the sarcomere to relax. Therefore, in the presence of calcium ions and adenosine triphospate (ATP), actin and myosin molecules slide over one another. This results in a physical shortening of the sarcomere and ultimately of the myofibril and the muscle belly. The cumulative effect of a shortened sarcomere is a reduction in the distance between the two tendon ends, and their bones of attachment move with respect to each other around a central joint.

ATP is needed for this contraction, and creatinine phosphate can be used to replenish ATP stores from adenosine diphosphate (ADP). The enzyme creatine phosphokinase (CPK) catalyzes this conversion and is found in high concentrations within muscle cells. During muscle cell damage, the CPK that

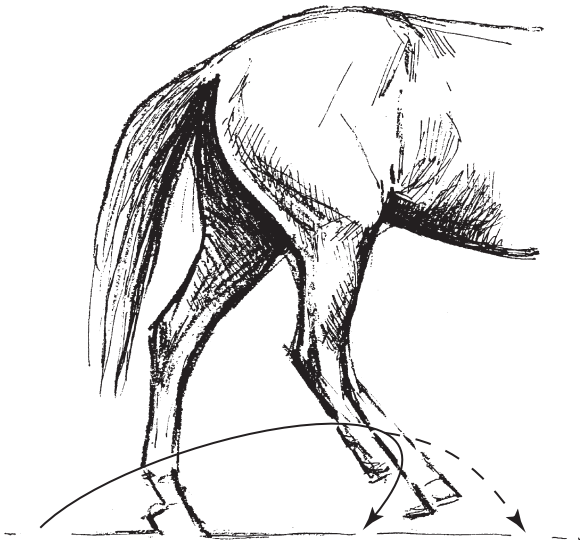

Figure 84-3. Motion of the rear limb of a horse affected with fibrotic or ossifying myopathy. The limb is jerked backward just before hitting the ground.

is normally contained within intact muscle cells can leak into the bloodstream. Therefore identification of an abnormally high concentration of serum CPK is used routinely to assess skeletal muscle necrosis. Muscle contraction is only about 40% efficient in converting chemical energy to mechanical energy, and most of the energy is lost as heat. This phenomenon is exploited during shivering to raise core body temperatures. During shivering, antagonistic muscle groups are activated so that they produce no useful work. The chemical energy lost as heat is transferred to the body core to increase temperature.

Muscle Repair

Muscle has a very limited capacity for regeneration. In some muscles, stellate cells have been identified that can form new muscle fibers. For practical purposes, however, new muscle fibers are not formed after birth. Enlargement and growth of muscle occur via enlargement of fibers caused by formation of additional myofibrils. Repair of damaged muscle occurs by replacement with connective tissue. Muscle has a good blood supply and a ready source of fibroblasts. Healing of damaged muscle with scar tissue is usually rapid, but replacement of damaged muscle with large amounts of scar tissue can restrict muscle length and function.

SPECIFIC MUSCLE DISORDERS

Fibrotic Myopathy

The classic description of fibrotic myopathy is that of a unilateral hindlimb gait abnormality, in which the cranial phase of the stride is shortened and there is a rapid caudal movement of the limb during the caudal phase of the stride as the foot slaps the ground (Figure 84-3). This condition is most evident when the horse is observed at the walk from a lateral perspective.[2-12] The overall prevalence of the disease is low: of the 167,132 horses examined by 22 university veterinary hospitals in North America over the 10 years from 1979 to 1988, 102 horses (0.06%) were diagnosed with fibrotic myopathy.[2]

Pathophysiology

In most horses, traumatic injuries that cause adhesions and fibrosis of the *semitendinosus muscle* are responsible for the condition. Less commonly, injury to the semimembranosus, biceps femoris, and gracilis muscles has been identified.[7,8] Trauma may result from lacerations, slipping while exercising, and entrapment of a foot in halters, lead shanks, or fences. In one study, 5 of 18 horses with fibrotic myopathy developed the condition secondary to intramuscular injections.[6] Tearing the insertion of the semitendinosus muscle during activities that create extreme tension on the caudal aspect of the hindlimb (barrel racing, the slide of a reining horse) has also been incriminated.[8] The characteristic gait of horses with fibrotic myopathy can occur temporarily after transportation in a trailer; in this case, it is caused by a localized myositis of the semitendinosus muscle because of prolonged pressure by the rear rope or bar on the muscle. Fibrotic myopathy in the neonate is speculated to be caused by trauma at or soon after birth, although the exact etiology is unknown in congenital cases.[9] Horses born with the gait characteristic of fibrotic myopathy have a taut semitendinosus muscle and tendon, but they do not have palpable fibrosis of the muscle. In a small series of horses, traumatic or degenerative neuropathy causing denervation of the distal semitendinous muscle resulted in fibrotic myopathy.[13] The underlying neuropathy is the most likely cause in horses when the condition progresses to involve both limbs. If bone forms in the affected tissue, the condition is termed *ossifying myopathy.*

Diagnosis

The diagnosis of fibrotic myopathy is made by observing the abnormal gait and by palpating the fibrotic or ossified muscle areas. Lameness is usually most apparent at the walk and is characterized by an abrupt cessation of the cranial phase of the

stride of the affected limb, with the foot suddenly jerked caudad just before it hits the ground (see Figure 84-3). This gait abnormality is not painful and is caused by mechanical restriction (either fibrous or osseous) of the affected thigh muscles. The gait abnormality is evident on every stride, is nonresponsive to analgesics, and is not altered by manipulative tests.

The fibrotic or ossified areas of the affected muscles may be palpated on the caudal aspect of the thigh at the level of the stifle joint or immediately above it. Ultrasonography may be helpful in defining areas of fibrosis, whereas radiography is more useful to demonstrate areas of ossification.

Treatment

Several surgical procedures for the correction of this disorder have been described. These techniques include semitendinosus myotomy, semitendinosus myotenectomy, or semitendinosus tenotomy at the tibial insertion of the muscle.[3,5,6,9-12] Earlier treatments described for these conditions include resection of the fibrous or ossified part of the semitendinosus muscle and removal of adhesions to surrounding muscles.[3,6] Myotomy and myotenectomy are no longer recommended because of the relatively high rate of postoperative complications, including protracted hemorrhage, wound dehiscence, high recurrence rate, and noncosmetic outcomes.

Semitendinosus tenotomy is presently the treatment of choice for fibrotic myopathy of the semitendinosus muscle.[9,11] This procedure is performed under general anesthesia in lateral recumbency with the affected limb down, providing access to the medial aspect of the tibia. Landmarks for surgery include the tibial insertion of the muscle on the caudomedial aspect of the tibia just distal to the medial femorotibial joint and caudal to the saphenous vein overlying the gastrocnemius muscle. An 8-cm vertical skin incision is made directly over the palpable tendon and through the subcutaneous and crural fascia until the tendon is exposed. A large forceps, such as a curved Kelly or Crile, is passed under the tendon to isolate it from the muscle, and the tendon is transected (Figure 84-4). Resection of a 3-cm segment of the tendon obviates or delays recurrence of the gait abnormality. Fascial layers are closed with interrupted or continuous synthetic absorbable sutures, and the skin is closed with interrupted or continuous nonabsorbable suture material.

When the affected limb is pulled forward during surgery, the tendon of insertion of the semitendinosus muscle onto the calcaneal tuber may become very taut in some horses.[2] An additional 3- to 4-cm-long incision has been recommended directly over the taut tendon, which is then isolated and transected. This incision is caudal and slightly distal to the first incision. Tenotomy is technically easier than the other myotomy procedures and eliminates an incision into diseased muscle.

Prognosis

With myectomy and myotomy, improvement is usually noticed immediately, but it may take up to 7 days for maximal improvement. Standing myotomy resulted in partial recurrence of the gait abnormality after surgery in approximately one third of 39 horses treated.[12] The tenotomy procedure alone results in fewer complications than the other techniques, including less predisposition for re-formation of the fibrous band, but it may not result in complete resolution of the gait abnormality.[9] If a degenerative neuropathy is the cause of the condition, recurrence of clinical signs is likely, regardless of the surgical technique employed.

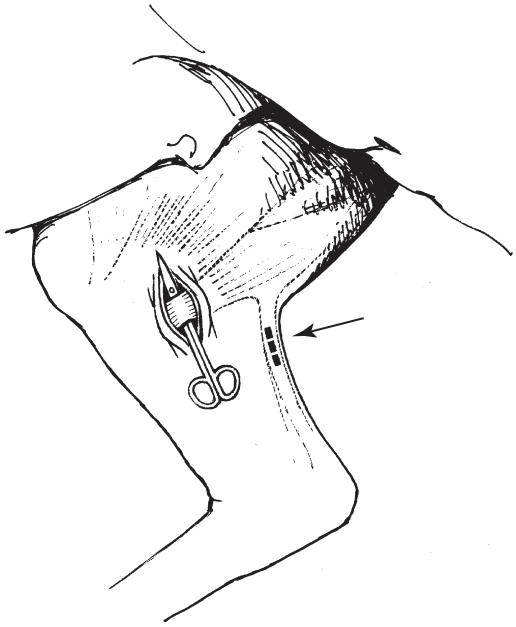

Figure 84-4. Semitendinosus tenotomy. The tendon of the tibial insertion has been isolated on the medial side of the proximal tibia and is ready to be severed. The *dashed line (arrow)* indicates the location for the second incision, which is performed if the insertion of the tendon on the tuber calcis is taut.

Stringhalt (Equine Reflex Hypertonia)

Stringhalt, recently renamed *equine reflex hypertonia*,[14] is a hindlimb gait abnormality characterized by involuntary and exaggerated flexion of one or both limbs.[14-26] During the cranial phase of the stride, the limb is jerked toward the abdomen (Figure 84-5). There may be a wide variation in the severity of the signs that occur during every walk stride. The gait abnormality has a classic appearance, but it should be differentiated from mild forms of intermittent upward fixation of the patella. The patella catches on the medial trochlea of the distal femur in intermittent upward fixation of the patella, and when it releases it gives the appearance of a horse with stringhalt.

Pathophysiology

Two clinical presentations of stringhalt have been described: an idiopathic (sporadic or conventional) form and an acquired (Australian or outbreak) form. The *idiopathic form* has been reported worldwide; it usually involves a single hindlimb, and clinical signs can progress over years.[16,20,26,27] Idiopathic stringhalt is rarely seen as a bilateral condition. The cause has been attributed to an overextension injury of the tarsus and metatarsus; metatarsal, tarsal, and stifle injuries; foot pain; spinal cord disease; and tendon adhesions.[16,20,26,27]Although the true etiology for the condition is unknown, idiopathic stringhalt is suggested to be caused by an underlying neuropathy.[19]

Figure 84-5. Exaggerated flexion of the rear limb is a characteristic sign in horses with stringhalt.

One author reports that all muscle or peripheral nerve isolates from horses with idiopathic stringhalt had histologic evidence of neuropathy or degenerative myopathy.[19] Idiopathic stringhalt has not been associated with the spontaneous recovery that is seen in the acquired form.

The *acquired form* is usually observed in both hindlimbs and occurs epidemically.[14-26] Presenting as outbreaks during the late summer or fall in horses on pasture, it often follows drier-than-normal months and is related to the presence of toxic plants. Outbreaks are usually related to one of the following plants: *Hypochaeris radicata* (Australian dandelion), *Taraxacum officinale* (European dandelion), or *Malva* (mallow), with outbreaks being reported in Australia, New Zealand, North America, Brazil, Italy, Chile, and Japan.[21-25] Its etiology has been clearly shown to involve an underlying neuropathy.[19,25] A definitive diagnosis of distal axonopathy has been obtained after postmortem examination of selected muscles and nerves[15,16] and antemortem by histologic examination of nerve and muscle biopsy specimens.[25] Evaluation of limb nerve samples from horses with acquired stringhalt has demonstrated widespread neuropathy. Lesions also occur in the left recurrent laryngeal nerve in approximately 60% of these horses.[17] The lameness in acquired stringhalt is caused by a peripheral neuropathy and neurogenic muscle atrophy of the long digital extensor, lateral digital extensor, and gastrocnemius muscles. Many horses recover without treatment.[14-19,21-26]

Diagnosis

The diagnosis is based on observation of the characteristic gait caused by exaggerated flexion of one or both hindlimbs. The abnormalities are usually bilateral in acquired stringhalt. The onset is often sudden. Some horses show a very mild flexion of the hock during walking, and others show a marked jerking of the foot toward the abdomen, with the foot actually hitting the abdomen in severe cases (see Figure 84-5). The abnormal gait is usually evident with each step. Rest and cold weather tend to accentuate the gait, and in some horses, the gait may return to normal with exercise. All breeds can be affected.

Treatment

Horses with *acquired stringhalt* often recover spontaneously. Removal from the incriminated pasture may be curative, although recovery can take from months to years and may not be complete. In one study, 78% of the horses recovered over a period ranging from a few days to more than 18 months.[17] Although surgical treatment is not recommended for horses with acquired stringhalt, good results were recently reported in 13 horses.[18] Five horses were able to walk normally immediately after the surgery (described later) in both hindlimbs, whereas only partial improvement was noted immediately postoperatively in the remaining six horses. Five of them resumed a normal gait in 4 to 12 weeks postoperatively. The last horse suffered a relapse several weeks postoperatively and eventually recovered spontaneously 9 months after surgery.[18]

Because *idiopathic stringhalt* is rarely associated with spontaneous recovery, lateral digital extensor tenectomy and partial myectomy is the treatment option for these horses.[20,28]

The objective of *lateral digital extensor (LDE) tenectomy and partial myectomy* is to remove the distal 2 to 10 cm of the LDE muscle, and the entire tendon, from the muscle to its attachment to the long digital extensor tendon. The procedure may be performed using local anesthesia when removing small portions of muscle belly, or under general anesthesia when removing large portions of the muscle belly. For the standing procedure, a 2-cm line of local anesthetic is injected over the LDE tendon just proximal to its junction with the long digital extensor tendon on the lateral aspect of the metatarsus. This site is easily palpable just below the tarsometatarsal joint. Local anesthetic also is infiltrated directly into the muscle belly of the LDE, about 2 cm above the lateral malleolus of the tibia.

The distal incision is made directly over the tendon just proximal to its junction with the long digital extensor tendon (Figure 84-6). The tendon is subsequently exposed by bluntly dissecting beneath the tendon with a curved Kelly or Ochsner forceps. The proximal incision is located on the lateral aspect of the limb approximately 6 cm above the lateral malleolus of the tibia. It extends through the skin, subcutaneous tissue, and fascia directly over the lateral digital muscle in a vertical direction, parallel with the muscle fibers. The muscle belly is exposed using blunt dissection, and a heavy curved instrument is placed underneath it (see Figure 84-6). Before severing the tendon, the surgeon should ensure that the tendon in the distal incision corresponds to the muscle belly in the proximal incision. The tendon is severed in the distal incision and is pulled through the tendon sheath by traction on the proximal portion with a curved Ochsner forceps or Mayo scissors. Removing the tendon from its sheath is a maneuver that requires substantial force, particularly if adhesions are present. After the entire length of the tendon has been exteriorized, the muscle is severed at the proximal aspect of the incision, thereby ensuring that at least 2 cm of the muscle is removed.

The heavy fascia of the proximal incision is closed with a simple-interrupted or continuous pattern of No. 0 synthetic absorbable suture material. The subcutaneous tissue is closed with 2-0 synthetic absorbable suture using a simple-continuous pattern, and the skin is closed with nonabsorbable suture material in a simple-continuous pattern. The distal incision is closed with skin sutures only. The wounds are covered with a sterile dressing, and the entire limb is bandaged for 10 to 14 days to

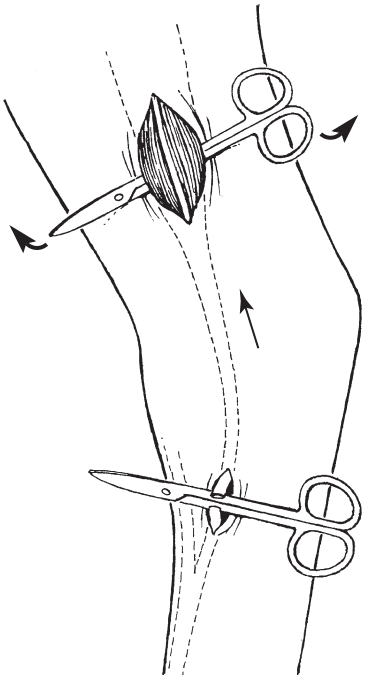

Figure 84-6. Lateral digital extensor tenectomy and partial myectomy. The muscle belly and tendon of the lateral digital extensor muscle have been isolated through two separate incisions. The distal part of the muscle and adjacent tendon are removed between these two incisions by transecting the tendon at the distal incision and pulling it out through the proximal incision *(arrows)*. The distal 2 cm of the muscle with the attached tendon are subsequently severed, and the incisions are closed.

control seroma formation. The horse is confined to a stall for this time, after which the sutures can be removed. The horse is then given 1 week of controlled hand-walking, and normal exercise can resume 3 to 4 weeks after surgery.

Complications of surgery include dehiscence; infection, which may enter the open tendon sheath of the LDE tendon; and failure of the lameness to improve.

Prognosis

The prognosis for acquired stringhalt is fair. Many horses recover spontaneously, although a few have stringhalt of such severity that they are euthanized. The prognosis for idiopathic stringhalt is guarded to favorable, because surgery is unpredictable and can result in partial to complete recovery. Many horses show improvement after surgery, but the degree of improvement varies from slight to a complete remission.[16,20,26] Improvement may occur immediately or take several months.

Peroneus Tertius Disorders

The peroneus tertius (PT) is an entirely tendinous muscle. It has a common tendon proximally with the long digital extensor muscle and originates in the extensor fossa on the cranial lateral aspect of the distal femur. Then it courses distad over the cranial aspect of the tibia and ultimately attaches to the distal tarsus and proximal metatarsus.[29,30] At the level of the proximal lateral aspect of the trochlear ridge of the talus the PT forms a sleeve through which the tibialis cranialis muscle passes.[29,30] At the dorsal aspect of the tarsus and just distal to this sleeve, the tibialis cranialis tendon divides into medial and dorsal branches and the peroneus tertius tendon divides into four portions (dorsal, medial, deep and superficial lateral). The dorsal portion attaches with the tibialis cranialis tendon on the central and third tarsal bone and the third metatarsal bone. The medial portion attaches medially on the central and third tarsal bones and the proximal aspect of the third metatarsal bone. The superficial lateral portion attaches to the calcaneal and fourth metatarsal bones, and the deep lateral portion attaches to the middle extensor retinaculum.[29,30]

The PT tendon is an important part of the reciprocal apparatus that coordinates flexion and extension of the stifle and hock (see Figures 97-2 and 97-3). The tarsocrural joint is flexed by the active contraction of the tibialis cranialis muscle and the passive pull of the tendinous peroneus tertius muscle.

Injury to the PT tendon is a relatively rare condition and has been reported to occur in three locations.[29-35] In a retrospective of 27 cases of rupture of the peronius tertius, the location of the rupture was identified in 24 cases: the origin (within 5 cm of its attachment to the distal femur; 2 cases), the insertion (just proximal to the sleeve formed by the peroneus tertius; 11 cases), and midbody (located between the origin and the insertion; 11 cases).[29]

Rupture at the origion of the PT tendon is typically associated with an avulsion fracture of the distal femur. Given their anatomic relationship, the long digital extensor muscle must also be involved. Ruptures at the origin of the PT are usually seen in foals,[29,31-33] but they have also been reported in adult horses.[29] It has been speculated that foals may be more likely to suffer avulsion injuries as a result of inherent weakness in their bones.[31]

Pathophysiology

Trauma was the most common cause for rupture to the PT.[29,31,34] In a retrospective of 27 cases,[29] blunt trauma resulting in a closed injury was caused by falling down (10 cases), followed by slipping (4 cases), caught in bars (3 cases), or running into a solid object (2 cases). In this same report, the PT was also disrupted in 6 of 27 cases because of a laceration resulting in an open injury.

By virtue of the anatomy described earlier, flexion and extension of the tarsus and stifle must occur simultaneously if the PT is intact. Therefore, rupture of the PT has also been surmised to be caused by an overextension of the hock while the stifle is held in flexion. This may occur when the horse slips with a hindlimb extended backward, during the exertion of a rapid start, or when the limb is trapped and the horse struggles to free it.[29,34] A full-limb cast extending to the proximal tibia may cause rupture if the horse slips with the leg extended behind or struggles against the cast.[34]

Diagnosis

Although the PT tendon may rupture anywhere along its length, it does so most commonly at the midbody of the tendon and the site of insertion. The classic sign of a complete rupture is the ability to extend the hock while the stifle is flexed.[29] A characteristic dimple forms in the common calcaneal tendon on the caudal lateral aspect of the crus, just proximal to the calcaneal tuber (Figure 84-7). When standing, the horse may bear weight

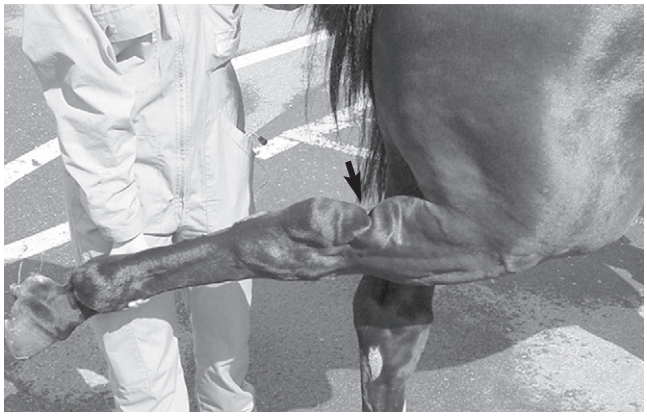

Figure 84-7. A horse with rupture of the peroneus tertius. The hock is extended while the stifle is flexed. Note the characteristic dimple in the contour of the caudal distal aspect of the crus *(arrow).*

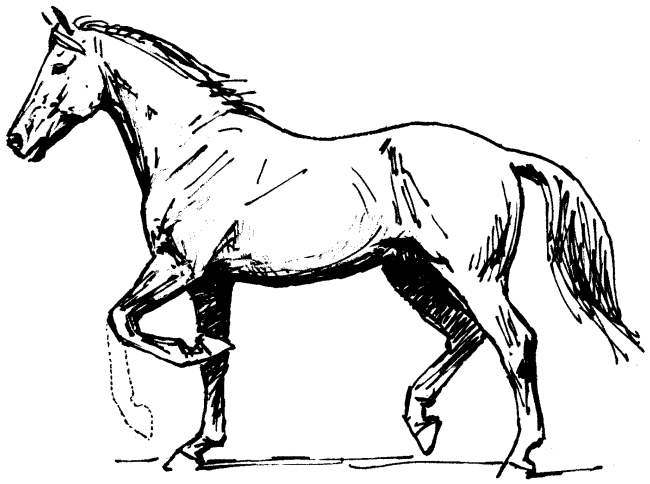

Figure 84-8. Drawing of a horse demonstrating the exaggerated flexion and forward movement of the left forelimb as a result of a traumatic rupture of the extensor carpi radialis tendon. The dotted outline of normal forelimb flexion is shown for comparison.

normally, but during the caudal phase of the stride during the walk or trot, the distal limb appears abnormally flaccid. With avulsion injuries, horses can be severely lame initially, and there may be accompanying distention of the femorotibial and femoropatellar joints.[31-33] In the acute phases of a rupture, digital palpation may reveal some swelling and pain in the craniolateral aspect of the tibia, but typically there is little evidence of pain on physical examination.

When the horse is walked, the tarsus may be noted to extend more than usual, and at the trot lameness was reported as a grade 1 out of 5 (3 horses), grade 2 (6 horses), grade 3 (10 horses), and grade 4 (2 horses).[29] A delay in the cranial phase of the stride can be easily identified because of an inappropriate degree of extension in the tarsus. Recognizing that the PT tendon is the most echogenic structure on the craniolateral aspect of the crus, it is readily identified by ultrasonography initially during the diagnosis and serially during the recovery period.[29] Radiography is necessary for diagnosing avulsion fractures.

Treatment

Horses with avulsion injuries of the origin of the PT tendon are best evaluated arthroscopically.[31-33] Small bone fragments can be removed, but large bone fragments that are encapsulated by the joint capsule are better left in place. Six weeks of stall rest followed by controlled exercise for 3 months is recommended. Ruptures of the midbody and insertion are treated conservatively using stall rest and a controlled return to exercise.

In a retrospective of 27 cases,[29] rupture of the PT was treated with stall rest for a median time of 16 weeks (range, 0 to 52 weeks), with or without hand-walking. After stall rest, horses were turned out to pasture for a median of 12 weeks (range, 4 to 48 weeks). Twenty-two of 27 horses were gradually returned to their previous level of exercise over a median time period of 8 weeks (range, 4 to 12 weeks). Overall, 18 of 23 horses (78%) returned to their previous level of exercise, and 5 of 23 (21.7%) horses were euthanized because of persistent lameness.[29] Premature return to exercise was implicated as the cause for reinjury. The value of serial ultrasonographic examinations to monitor the healing of the PT tendon before returning a horse to exercise was emphasized.[29]

Prognosis

Horses with avulsion injuries have a guarded prognosis for full soundness, but successful outcomes have been reported.[29,31-34] Age, an open or closed injury, lameness at presentation, ultrasonographic size at presentation, location of the rupture, and duration of rehabilitation had no significant influence on a horse's return to exercise.[29] A horse was significantly less likely to return to its intended use if the horse was racing at the time of injury (13 times less likely) or if a structure in addition to the PT tendon was damaged at the time of injury (8 times less likely).[29]

Rupture of the Extensor Carpi Radialis Tendon

Rupture of the extensor carpi radialis tendon is usually the result of a traumatic insult, such as a kick or laceration at the distal cranial aspect of the radius, stumbling and falling on a road (coronation), or contact between a forelimb and a sharp object.

Diagnosis

Horses suffering from a rupture of the extensor carpi radialis tendon have a peculiar gait. Protraction of the involved forelimb results in hypermetric elevation, because the flexor muscles are not opposed by their main antagonist, the extensor carpi radialis muscle (Figure 84-8). Palpation of the cranial aspect of the carpal and distal radial region reveals a defect in the area of the missing tendon. In cases with a laceration, the distal tendon stump is often seen in the injury site.

Treatment

Lacerations should be carefully débrided and closed, and a drain should be placed for the initial few days. If possible, the tendon should be repaired with a three-loop pulley or a locking-loop technique. The laceration should be sutured using routine wound repair techniques and the limb placed in a splint bandage that prohibits carpal flexion for 6 weeks. The bandage should be changed after 3 days and the drain removed. The

horse is restricted to a box stall and the splint bandage is changed at regular intervals. If no open wound is present or the wound does not involve the sheath of the extensor carpi radialis tendon, the tendon is not sutured, but the limb is kept in a splint bandage for 6 weeks, followed by bandaging the limb for an additional 3 weeks. Hand-walking is initially the only exercise, and it is gradually increased. Local wound management should be applied to superficial wounds.

Prognosis

Generally, a good prognosis for return to a successful athletic career is given for rupture of the extensor carpi radialis tendon. Complications include infection of the tendon sheath and dehiscence of the sutured tendon or sutured laceration. In such cases, conservative management involving daily wound care and bandage changes is required. The prognosis in complicated cases is guarded for return to an athletic career.

Cribbing and Aerophagia

Etiology

Cribbing or crib biting in the horse is a vice characterized by the placement of the upper incisors on a solid object, arching the neck, depressing the tongue, elevating the larynx, and pulling backward.[36-52] If the horse swallows air, the process is called *aerophagia* or *wind sucking,* and an audible grunt can be heard. The sequelae to this habit are poor performance, weight loss, erosion of the incisors, and chronic colic. It has been demonstrated that cribbing and aerophagia significantly increased the risk for simple colonic obstruction and distention in horses,[36] significantly more ulcers and inflammation of the stomach of foals,[37] and epiploic foramen entrapment colic.[38,39] The principal reason that horses with this vice are presented to a veterinarian is because the behavior is objectionable and irritating to owners, and it results in an unacceptable level of property destruction.[40] Studies suggest that limiting this behavior would reduce the incidence of certain types of gastrointestinal distress.[36-39] The habit is learned or acquired and is usually associated with stabled horses, although once learned it can continue in the pasture. Another reason patients are presented is that pressure is exerted on the horse's owner by owners of horses stabled in the same barn, who are afraid their horses will acquire the vice as well. It is not known what causes horses to initiate this activity, but a common explanation is boredom, stress, frustration, and habit or addiction.[40] In a 4-year prospective study of 225 young Thoroughbreds, abnormal behavior affected 34.7% of the population.[41] Foals of dominant mares versus low-ranking mares, weaning by confinement in a stable or barn versus paddock-weaning, housing in barns versus grass after weaning, and feeding concentrates after weaning were significantly associated with an increased rate of development of abnormal behavior.[41] The results of this study suggest that simple changes in feeding, housing, and weaning practices could substantially lower the incidence of abnormal behavior in young horses.[41] The results of a postal survey on 2341 Swiss horses from 622 stables led to the hypothesis that preventing sterotypic disorders like crib biting should be based on housing and management pratices that allow tactile contact with other horses, daily free movement (paddock exercise), and high amounts of roughage with little or no concentrates.[42] Aerophagia may also be a pleasurable sensation to horses experiencing gastrointestinal discomfort.[27] Cribbing and wind sucking may be acquired vices or may be learned from other horses, although learning the vice has not been proved.[27,40] It has also been associated with genetic factors.[46]

Treatment

NONSURGICAL MANAGEMENT

Horses that are stalled continuously may limit or discontinue the behavior when they are moved to pasture.[41-44] Removing fixed objects that are grasped while cribbing may deter horses that have just learned the vice. Management changes rarely deter horses with established habits; some horses are capable of aerophagia without grasping a fixed object. Cribbing straps are perhaps the most common nonsurgical means used to control cribbing or windsucking. Leather straps with or without a ventrally located piece of articulating metal are placed snugly around the throatlatch of the horse to discourage contraction of the ventral neck muscles and arching of the neck. More severe straps have metal prongs that pierce the skin when the neck is flexed. Cribbing straps are adjusted to allow the horse to eat and breathe normally and are worn at all times except during exercise. Acupuncture may be useful for eliminating or decreasing cribbing and aerophagia.[47] Aversion (shock) therapy has also been used to treat horses that crib.[48]

SURGICAL MANAGEMENT

Three surgical procedures are described for the control of cribbing and aerophagia: the Forssell procedure, a modified Forssell procedure, and bilateral neurectomy of the ventral branch of the spinal accessory nerve.[43-45,49-53] The original procedure was developed by Dr. Forssell in 1920 and involves the surgical removal of portions of the sternomandibularis, sternothyrohyoideus, and omohyoideus muscles.[43-45,49-53] A modification of Dr. Forssell's original surgery, developed to produce a better cosmetic appearance, is the treatment of choice for wind sucking when used in combination with neurectomy.[43-45,49-53] The technique of bilateral neurectomy of the ventral branches of the spinal accessory nerves (eleventh cranial nerves) is modified from the technique described by Hamm.[51-55] The ventral branches provide motor innervation to the sternomandibularis muscles, which are the major muscles used by the horse to flex its neck. Because of the poor results achieved with this procedure alone, it is now described as a part of the modified Forssell procedure.[51-53]

Modified Forssell procedure

The horse under general anesthesia is placed in dorsal recumbency with the head tilted at a 30-degree angle to the horizon.[45,50-53] After surgical preparation, a 30-cm incision is made on the ventral midline of the neck through the skin, the edges of which are retracted laterally, exposing the ventral surface of the paired bellies of the omohyoideus and the sternothyrohyoideus and the cranial aspect of the sternomandibularis muscle. Careful attention to hemostasis minimizes staining of the areolar tissue and thus simplifies identification of the nerve. A plane of dissection is created on the medial aspect of the sternomandibularis muscle about 5 cm caudal to the musculotendinous junction. The ventral branch of the spinal accessory nerve is located on the dorsomedial aspect of this muscle

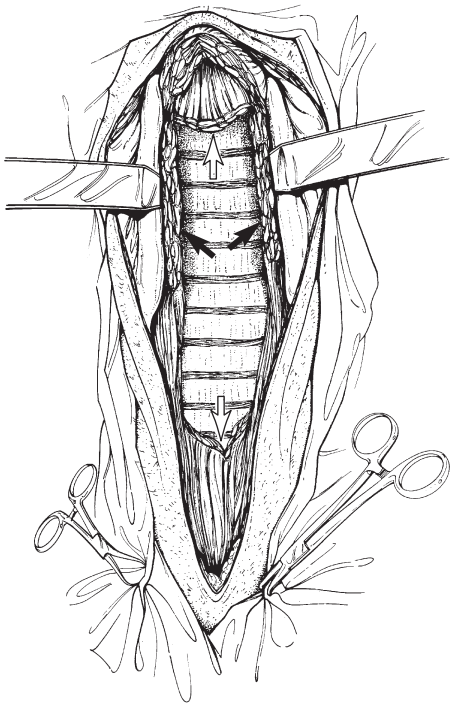

Figure 84-9. The modified Forssell procedure for cribbing is performed by a myectomy of the omohyoideus and sternothyrohyoideus muscles and by a neurectomy of the ventral branch of the spinal accessory nerve. *Black arrows,* Omohyoideus muscle stumps; *white arrows,* stumps of the sternothyrohyoideus muscles.

by carefully rolling the muscle belly laterally. Curved hemostatic forceps are placed under the nerve, which is elevated until a sizable portion of it can be exteriorized. Contraction of the sternomandibularis muscle after the nerve is pinched with hemostat forceps confirms isolation of the correct nerve. A large portion (6 to 12 cm) of nerve is removed. This same procedure is then repeated on the opposite side of the neck.

After the bilateral neurectomy, the myectomy is performed. A 30-cm (12-inch) section of the combined bellies of the omohyoideus and sternothyrohyoid muscles is removed (Figure 84-9). These muscles are identified in the cranial aspect of the incision, just ventral to the larynx, and they are freed from the larynx and fascial attachments to the linguofacial vein and thyroid gland. Curved scissors or other curved instruments are passed under the muscles to ensure inclusion of all parts of the muscle bellies, which are then transected. These muscles bellies are then grasped and "peeled" caudad. The areolar connective tissue connecting them to the trachea is sharply dissected. The omohyoideus muscles are sectioned obliquely and the sternohyoid bands transversely at the caudal aspect of the incision using scissors. The sternothyroid bands of the sternothyrohyoideus muscles are elevated from the trachea and removed. Special attention is given to hemostasis of the muscle stumps to prevent hematoma formation.

A Penrose drain is inserted in the wound and brought out through separate stab incisions on both ends of the incision. The subcutaneous tissues are closed with a simple-continuous suture pattern using No. 0 synthetic absorbable suture material, and the skin is closed with any suitable pattern and material. To help eliminate dead space, a stent bandage is sutured over the incision to provide constant pressure to the wound and to protect it during the initial phase of healing.

After surgery, the horse is confined to a stall or small paddock for 2 weeks. Unless it is soiled earlier, the stent bandage is removed 2 or 3 days postoperatively. The Penrose drain is removed 4 to 6 days later, followed by the skin sutures 10 to 14 days postoperatively. Exercise can be resumed after 21 days. Hematomas or seromas, although rarely encountered, can be managed conservatively or by drainage. Antibiotic therapy initiated preoperatively can be applied until the drain is removed. In a retrospective on 10 horses, there were slight modifications in the technique just described.[53] The sternothyrohyoideus and the omohyoideus muscles were transected rostral to the ventral aspect of the larynx at the basihyoid bone, and an Nd:YAG laser was used to perform the neurectomy.[53]

Prognosis

The modified Forssell procedure produces a good cosmetic appearance after surgery and rapid healing of the wound.[45] A review of 35 horses that underwent the modified Forssell procedure revealed that 57% had complete remission, 31% had improvement, and 12% had no improvement.[45] In a retrospective of 10 horses that had cribbing behavior and received surgery, none of the horses had cribbing behavior after surgery, and all horses had returned to their previous use with long-term outcome of 7 to 72 months.[53]

Calcinosis Circumscripta

Pathophysiology

Calcinosis circumscripta (tumoral calcinosis) is an uncommon condition that is identified more commonly in the young horse.[54-59] In a retrospective study on cutaneous nodular and proliferative lesions submitted to a veterinary diagnostic lab on horses, donkeys, and mules over a 3½-year period, 116 non-neoplastic nodular and proliferative lesions were identified and comprised 18% of all lesions submitted. Calcinosis circumscripta was identified as the most common non-neoplastic nodular lesion in horses up to 10 years of age.[59] Although the etiology of these lesions is unknown, it has been suggested that prolonged repeated trauma may be the cause.[55] These horses have normal serum calcium and phosphorus concentrations.[58] Histologically, these masses are calcified granular amorphous material that induces a fibrous reaction.[54-59] They are surrounded by a thick fibrous capsule that contains deposits of gritty material. They are typically located in the subcutaneous tissue close to joints or tendon sheaths. The lateral aspect of the stifle adjacent to the fibula is an area of predilection, although they also can be found on the dorsolateral aspect of the tarsus and around the neck and shoulder.[54-56] In 14 affected horses, the characteristic feature was a 3- to 12-cm dense subcutaneous mass located at the lateral aspect of the gaskin, adjacent to the stifle.[54-56]

Diagnosis

Rarely is lameness or pain associated with the condition. Typically, these horses present for cosmetic reasons and do not have any lameness.[58] Owners notice an unsightly lesion that may be increasing in size. Lesions are usually hard, are occasionally bilateral, are well circumscribed, do not involve the overlying

skin, and are tightly adherent to the underlying tissue. Radiographs demonstrate a circumscribed mineralized tissue lying close to the lateral aspect of the femorotibial joint with a density that is similar to that of cortical bone.

Treatment

Treatment is indicated only if the cosmetic appearance is unacceptable to the owner, or if there is lameness caused by the mass. When required, surgical excision is the recommended treatment option. Attention to aseptic technique is imperative, since some masses attach to the femorotibial joint capsule, which may be accidentally entered during surgery. Closing dead space during surgery and applying snug limb bandages or stent bandages will prevent postoperative seroma formation, because wound dehiscence and septic arthritis are potential complications.

Prognosis

For horses that are not treated, the mass remains and may not cause complications. A good result can be expected after surgical excision, and regrowth has not been reported. Wound healing is important if the joint capsule is entered during surgery.

CHAPTER 85

Synovial and Osseous Infections

Dean W. Richardson and Benjamin J. Ahern

Musculoskeletal system infection remains one of the most challenging, frustrating, and expensive orthopedic problems commonly seen in the horse. Infections can involve bone and synovial structures such as joints, tendon sheaths, and bursae. Orthopedic infections can be separated into those that are acquired "naturally," such as from hematogenous or traumatic causes, and those that are induced iatrogenically, such as from surgical infections and therapeutic or diagnostic injections. Traumatic injuries of the lower limb in horses lead to infection of synovial structures and bones because there is so little protective soft tissue (muscle) over them. Fracture fixation in horses has a high incidence of infection because of the poor soft tissue coverage, meager vascularity of the lower limb, and the size and number of metal implants needed for stable fixation. Infections secondary to injections of synovial structures are common not only because of the frequency of the procedure performed but also because of the agents that are injected. For example, glucocorticoids are often administered and they impair the host's immune response.

The major change in therapy for musculoskeletal infection in the last 20 years or so has been the widespread acceptance of the principle that intensive local treatment is the key to success. This includes vigorous lavage, various means of delivering antimicrobials locally, and effective drainage.

SEPTIC ARTHRITIS/OSTEOMYELITIS IN FOALS

Neonatal foals with a failure of passive transfer of immunity are at high risk of bacteremia that can lead to localization of pathogens in a bone or synovial structure.[1-5] The anatomic locations where these infections are most likely to occur have been established.[6]

Types of Infections

S-Type Infections

The synovial membrane and fluid are the only structures involved in S-type infections. Foals with S-type arthritis tend to be the very young (less than 1 week old). The larger joints, such as the stifle or tarsocrural joints, tend to be affected most frequently, but any articular structure can be involved and multiple joints are commonly affected. The interphalangeal joints, distal tarsal joints, and axial skeleton joints are underrepresented.

Because these foals are neonates, the acute lameness exhibited is frequently presumed to be because they were stepped on by the mare. However, rarely is this a direct observation, and education of the owner and manager is essential to avoid delays in treatment.

E-Type Infections

The bone subjacent to the articular cartilage, technically the articular epiphyseal complex, which is a source of growth for the expanding epiphysis in the growing animal, is involved in E-type infections. These foals are weeks old and may have multiple joints involved. However, monoarticular E-type infections are common. These foals usually have a history of failure of passive transfer of immunity or development of some other disease, such as pneumonia or diarrhea.

These foals frequently have a history of very mild or intermittent lameness, with or without a fever, before an acute exacerbation coupled with noticeable joint effusion. Any joint can be infected, but the distal femur, talus, radius (proximal and distal), and tibia (proximal and distal) are commonly affected.

P-Type Infections

Primary infection of a long bone physis is termed a P-type infection. It may occur without joint involvement, but the infection can extend into the nearest joint. In most cases, this extension occurs at the attachment of the joint capsule. The peripheral portions of the physis are usually involved and at much more risk of dissecting into the adjacent joint. Foals with P-type osteomyelitis range in age from weeks to a few months. They may be seemingly healthy foals without a history of previous disease.

Clinical Signs

The clinical signs of S- and E-type infections are similar; lameness and effusion are consistent and fever is common. Radiographs of foals with E-type infection will reveal subchondral lysis, although lesions may be difficult to detect in some locations. Ultrasonographic evaluation may confirm both hypercellular synovial fluid and possibly an area of subchondral irregularity, but the combination of plain radiographs and synovial fluid analysis is usually adequate. Nucleated cell counts in

synovial fluid may be extremely high (greater than 50,000/μL), but lower cell counts in the single thousands do not preclude infection. Protein is less than 2 g/dL in the normal joint. In the septic joint, the total protein is elevated and may equal or even exceed serum values. The viscosity of synovial fluid from septic joints is usually reduced. The color of the fluid may vary from nearly normal to dark orange to red, or occasionally opaque pink or yellow. Cytology of septic joint fluid reveals more than 90%[7-9] neutrophils, the majority being degenerated. Fluid should be examined for the presence of intracellular bacteria, but they are only present in a minority of cases.[8]

Foals may have a neutrophilic leukocytosis, but the only consistent clinical laboratory abnormality is a hyperfibrinogenemia in E- and P-type infections. With bone involvement, the plasma fibrinogen is usually at least 900 mg/dL.[10]

Unlike in S- and E-type infections, foals with P-type infections present without synovial effusion but with periarticular edematous swelling. They are usually point sensitive to palpation over the affected area. These foals nearly always have a history of premonitory lameness, followed by acute severe lameness with a noticeable swelling if it involves the extremity. Although any growth plate in the body, including the vertebrae and ribs, may be involved, the distal physes of the third metacarpal/metatarsal bone (MCIII/MTIII), radius, and tibia are common sites. The P-type infection commonly involves only one site in an individual. The bacterial isolates from P-type osteomyelitis can include nearly any pathogen, but common organisms include *Streptococcus, Rhodococcus, Actinobacillus,* and Enterobacteriaceae (e.g., *Escherichia coli, Salmonella*).

SEPTIC ARTHRITIS/TENOSYNOVITIS/BURSITIS IN ADULT HORSES

The large majority of synovial infections in adult horses develop following an injection or a penetrating traumatic injury. Post–joint injection sepsis is predominantly caused by *Staphylococcus* spp. Penetrating wounds may have an enormous range of potential infecting organisms, including *Staphylococcus, Pseudomonas,* members of the Enterobacteriaceae family, and yeast and other fungi. The clinical signs are similar to those in foals, but early bone involvement is much less common. Exceptions to this are palmar/plantar and axial sesamoid osteitis in which hematogenous localization may lead to a bone abscess that eventually opens into the adjacent synovial structure, such as a joint or digital sheath.[11-14] Apparently because of hematogenous extension, septic bursitis has also been recognized in many sites, including the bicipital, calcaneal, atlanto-occipital, supraspinatus, olecranon, and other bursae.[15-22] In many of these septic bursae, the subsynovial bone appears to be the site of bacterial localization because radiographs often reveal bone lysis.

Diagnosis

Microbiology

Microbial culture is the gold standard for the diagnosis of sepsis. All synovial structures that are suspected of having an infection should have a culture and sensitivity performed before treatment with antimicrobials. It is important to emphasize, however, that valuable positive culture information is still commonly obtained when samples are taken after initiation of antimicrobials.[9] Culture of synovial fluid is more effective than a biopsy of the synovial lining.[23] Results of bacterial culture can be significantly improved when enrichment media or blood culture media are used.[7-9] In typical blood culture vials (Septi-Chek) an effort should be made to retrieve and culture 8 to 10 mL of fluid to maximize the chances of a positive culture. It is important to submit samples for fungal culture, especially if there is a history of intrasynovial injections or wounds, and to repeat culture submissions if results from the initial sample are negative. In foals with cases of hematogenous spread of infection it can be useful to culture a sample from the primary site of infection, or directly aspirate a suspected physis, because the synovial infection will likely result from the same pathogen and can guide antimicrobial choice.

The most common isolate from a retrospective study of 206 adult horses (older than 6 months) with synovial infection was *Staphylococcus aureus* (34.3%).[9] Earlier studies recognized that *S. aureus* is more common in cases of sepsis that develop after intra-articular injection or after surgery, and Enterobacteriaceae species are more common after traumatic wounds.[8]

Diagnostic Imaging

In S-type infections, the only radiographic evidence of infection will be soft tissue density associated with the marked effusion. In E-type infections, a subchondral lytic defect is generally apparent, although this may be subtle, especially in very young foals with incomplete endochondral ossification (Figure 85-1) P-type osteomyelitis is readily apparent through diagnostic imaging once the adjacent joint becomes septic, because there is generally a large lytic lesion extending to the outer cortex (Figure 85-2). Ultrasonographic guidance allows the accurate aspiration of a suspected site or evaluation of difficult to palpate articulations, such as the coxofemoral or scapulohumeral joints. In foals, the umbilical structures also should be examined. Scintigraphy may be useful for localization of a lesion, especially in the axial skeleton and proximal parts of the appendicular skeleton. It is important to remember that decreased rather than increased radiopharmaceutical uptake (photopenia) may be an indicator of a septic osteitis.[24] Labeled leukocytes[25] or other inflammation-seeking radiopharmaceuticals may prove to be of value.

Treatment

Initial Management

An essential component common to the successful treatment of any synovial infection is rapid recognition and aggressive therapy. It is imperative that articular cartilage be returned to a normal environment or there will be loss of matrix and irreversible loss of cartilage structure. If a significant amount of cartilage is lost, the chances of returning the horse to full athletic soundness drops drastically. Once a synovial sample has been obtained to confirm the diagnosis and for culture and sensitivity testing, treatment should be initiated. In a study of foals with osteomyelitis, positive results from synovial fluid cultures had 57.2% gram-positive and 42.8% gram-negative infectious agents.[26] Therefore, until culture results are available, suspected synovial infections should be treated with broad-spectrum antibiotics, such as a combination of penicillin and an aminoglycoside. In adult horses with postinjection sepsis, the probability of *Staphylococcus* infection is high, but even knowing that, broad-spectrum initial therapy is justified before culture results are available.

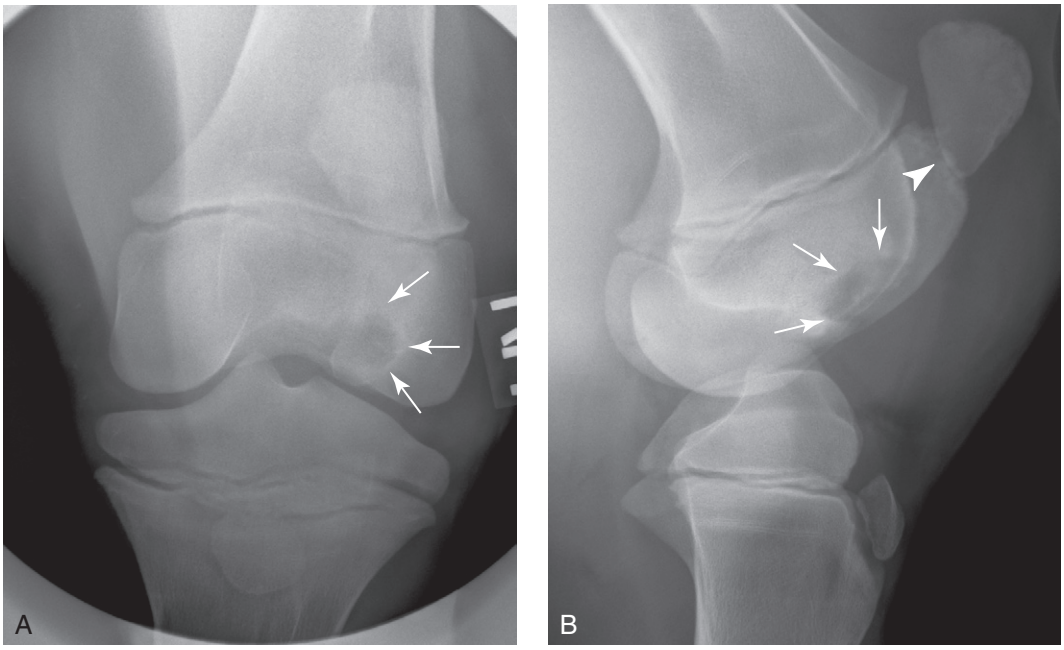

Figure 85-1. Craniocaudal **(A)** and lateromedial **(B)** projections of the stifle showing a large E-type osteomyelitis in the axial articular margin of the lateral femoral condyle *(arrows).* Note the normal irregular radiographic appearance of endochondral ossification of the femoral trochlear ridge *(arrowhead).*

Synovial Lavage

There is now widespread acceptance of the principle that septic synovial structures should be aggressively lavaged, early and often.[3,27-31] The physical removal of bacteria and inflammatory cells and mediators is still considered a mainstay of therapy, especially in the acute phase. There are many techniques in use by clinicians and little available proof that one technique or another is truly superior. The only likely truth is that early lavage is most valuable, and large volumes are superior. Probably the ideal technique for effective large-volume lavage is under anesthesia with the help of an arthroscope.[32] This allows not only rapid, accurate delivery of fluids but also the opportunity to remove fibrin clots, débride any unstable cartilage or bone, and evaluate the condition of the joint surfaces. If an arthroscopic examination is not possible for practical or economic reasons, a thorough lavage can still be performed under local or general anesthesia. If done standing, which is usually the case, sedation and local anesthesia facilitate the procedure. Local anesthesia can be achieved either by a regional

nerve block applied proximal to the joint, easy in a metacarpophalangeal (MCP) or interphalangeal joints, or by distending the joint with 2% mepivacaine and allowing it to sit for 5 to 10 minutes, followed by local infiltration of skin and subcutaneous tissues at the sites of needle insertion and drainage. Dean Richardson's preference is to use a large (18 to 16 gauge) needle for an ingress and a stab incision equivalent to an arthroscopic instrument portal for an egress. Another advantage of this approach is that an experienced arthroscopist can blindly remove fibrin clots through the stab incision with Schlesinger forceps or a similar instrument. Being able to unclog the egress site allows a much larger volume of fluid to be effectively flushed through the synovial cavity. With egress needles, synovial villi or fibrin obstruction can be a big annoyance. The stab incision can be left open and covered by a sterile bandage, or the skin can be closed with simple skin sutures if bandaging is difficult, such as in the stifle or shoulder.

Lavage should be performed with a balanced electrolyte solution. The addition of antiseptics such as povidone-iodine and chlorhexidine causes inflammatory changes at known bactericidal concentrations and has not been shown to have additional benefit for septic synovitis.[33-35]

Dimethyl sulfoxide (DMSO) scavenges free radicals and suppresses prostaglandin activity; it appears to be safe when added to lavage solutions.[36,37] However, there is no clear evidence of any advantage from using DMSO. Antibiotics should be injected into the synovial cavity following lavage to ensure maximum concentration.

Lavage of an infected synovial structure is initially performed daily in cases that do not fully respond immediately. One of most difficult decisions in the management of a septic synovial structure is when to discontinue lavage. Cell counts are of little value because the numbers are often unreliable in the frequently lavaged joint, and the lavage itself is moderately irritating, so cell numbers will not be normal. Improvement of lameness and swelling coupled with discontinuation of analgesic and anti-inflammatory drugs are the best indicators of when to discontinue regular lavage.

Antimicrobials

Antimicrobial therapy is ideally directed by culture and susceptibility results, but antibiotics with the broadest range of activity should be selected before sensitivity results are available. The route of administration of the antibiotics has evolved considerably and has shifted to focus on methods of local drug delivery. Systemic antibiotics are still commonly used, especially where there is a concurrent systemic infectious process or when local treatment is not possible. The systemic administration of a β-lactam and an aminoglycoside provide a broad spectrum of activity. Metronidazole can be added if an anerobic infection is suspected (e.g., *Bacteroides*). Local administration of antibiotics can achieve extremely high concentrations at the site of the infection and are a vital component of modern treatment of synovial sepsis.

LOCAL ANTIBIOTIC DELIVERY

Various techniques involving pumps have been used to deliver constant (or intermittent) infusion of antibiotics into joints.[38,39] The results of using constant infusion techniques seem to be similar to traditional intermittent dosing regimens using other techniques.

The choice of local antibiotic delivery method also may be influenced by the culture and susceptibility results. If an organism is susceptible to an aminoglycoside, the use of a technique yielding intermittent enormously high peak concentrations (i.e., perfusions or injections distal to a tourniquet) should be selected because the aminoglycosides are a clear example of a concentration-dependent antibiotic. A need to deliver time-dependent drugs suggests that the best methods to use would be indwelling pumps and other local infusion techniques.

The delivery of locally administered antimicrobials by intraosseous (IO), regional limb perfusion (RLP), intra-articular (IA), or antimicrobial infused biomaterials (e.g., collagen sponges, polymethyl methacrylate [PMMA], plaster of Paris, hydrogels, dextran gels) results in high concentrations of the antimicrobial at the site of infection. Intra-articular administration results in higher synovial concentrations than RLP, but there is no difference in the two techniques with regard to bone concentration of gentamicin.[40]

Regional limb perfusion

RLP with antimicrobials is possible in situations where a peripheral vessel is accessible and an effective tourniquet can be applied to isolate the infected region. The major disadvantage of regional perfusion in postoperative cases is the condition of the tissues and the need to prevent vascular damage near the surgical site. Some antibiotics, notably enrofloxacin, will induce significant vasculitis when used for regional perfusions.[41] Under heavy sedation, a tourniquet is placed above and, if feasible, below the area to be treated. The key is to have an accessible peripheral vein distal to the proximal tourniquet. If necessary, regional analgesia is used but many horses will stand with sedation alone. Although there are reports of success with indwelling catheters, the use of 25- to 27-gauge butterfly catheters seems to cause the least vascular trauma (Figure 85-3). Because treatments are usually repeated, it is imperative to keep the vessel in the best possible condition. The application of topical anti-inflammatories (e.g., liposomal encapsulated diclofenac) has been shown to decrease postinjection swelling and makes repeated treatments easier to perform.[42] Dosage varies, but around one third of a systemic dose diluted to about 30 mL is typical for the distal limb, 60 mL if the tourniquet is above the carpus or tarsus. With aminoglycosides, it is possible to use the entire daily systemic dose for regional perfusions. The injection is performed slowly over a period of about 5 to 10 minutes and the tourniquet is left in place for approximately 30 minutes, if possible. Subjectively, these very high doses given regionally seem to result in the best clinical responses, but more vascular irritation can be a complication with the more-concentrated doses of antimicrobials. The efficacy of RLP depends upon the function of the tourniquet, so it is essential to use a tough broad rubber tourniquet (see Figure 85-3) or a pneumatic tourniquet.[43] It is equally important to have the horse well sedated, and occasionally locally anesthetized, to prevent motion of the treated limb.[43] Care must be taken to ensure that the systemic dose of antibiotic is not exceeded in cases of polysynovial infections, especially in foals.

Intraosseous and intra-articular administration

Intraosseous and intra-articular antibiotic administration are used to maximize antibiotic levels at the desired site of action. Commercial intraosseous catheters as well as

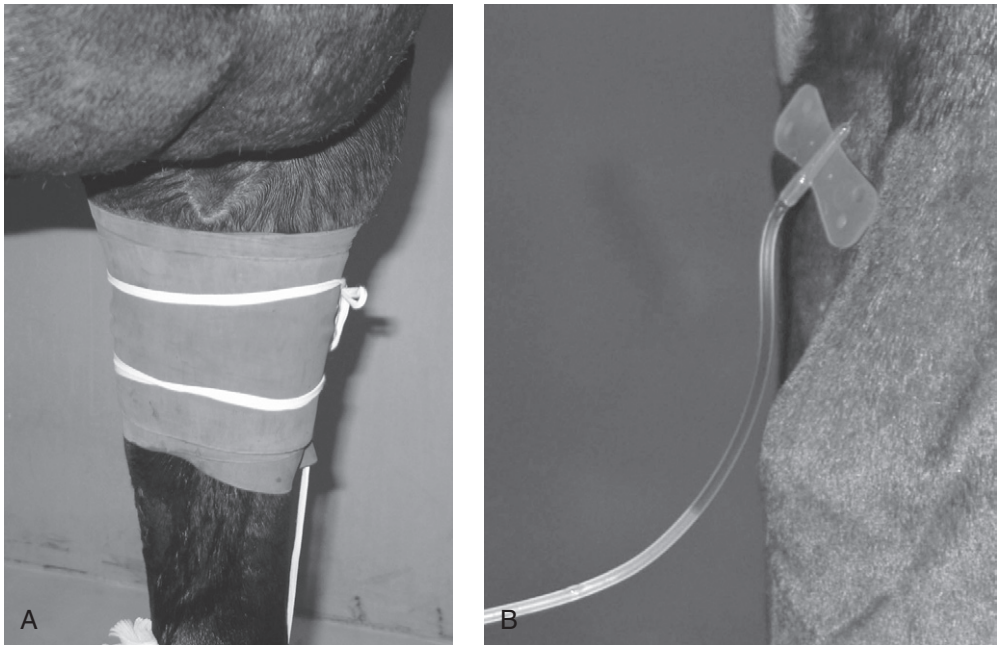

Figure 85-3. Two important technique tips for successful repeated regional limb perfusions are to use a wide rubber tourniquet **(A)** and a small-gauge butterfly catheter in a large vessel **(B).**

homemade cannulated screws can be inserted for repeated intraosseous treatments. A simple technique is to drill a 4-mm hole into the medullary cavity at the desired location. The male end of a Luer-tipped extension set will fit snugly into the hole, allowing direct injection. Recently, a severe complication was reported, where intraosseous perfusions of gentamicin caused toxic osteonecrosis and resulted in pathologic fracture of the perfused proximal phalanx.[44] Both intraosseous and intra-articular perfusions should ideally be performed with the region under tourniquet for 30 minutes to maximize tissue levels.

Antibiotic-impregnated biomaterials

Antibiotic-impregnated biomaterials (collagen sponges, PMMA, plaster of Paris, hydrogels) have not been used as commonly in septic synovial structures as they are in orthopedic infections, because synovial structures generally have motion and there is the risk of the implant moving and damaging adjacent structures such as cartilage. Collagen sponges have been successfully used in the tarsocrural joint in healthy horses without eliciting mechanical trauma or an inflammatory response[45] and have been used clinically with some success.[46] One potential disadvantage of collagen sponges is that they release the antibiotic very rapidly.[45] For P-type osteomyelitis or septic arthritis in foals, antibiotic plaster of Paris beads can deliver antibiotics efficiently[47,48] and have the distinct advantage of being absorbable, unlike PMMA beads (see Figure 85-2).

Débridement and Drainage

Débridement of infected synovial structures is often essential for the complete resolution of an infection. This is especially evident in cases with subchondral bone involvement or chronically infected structures. In these cases, mechanical débridement either arthroscopically or via open incision is used to reduce bacterial numbers to a point that antibiotics can be effective. Endoscopic procedures allow synovial débridement with motorized resectors, but it should be emphasized that motorized equipment must be used prudently. It is possible to damage the joint capsule with overly aggressive resection. Even severely thickened synovial tissue is usually soft and easily resected. If the surgeon is having to apply a lot of pressure to the handpiece, the resection may be too extensive. Open drainage can be achieved by performing multiple arthrotomies and subsequent daily lavage. However, experimentally, the success of arthroscopic lavage or arthrotomy with lavage were both similarly high.[49] Open drainage is probably best reserved for chronically infected structures that are resistant to initial vigorous attempts to treat with closed techniques. Endoscopic débridement would have to be considered the most appropriate technique for the great majority of infected synovial structures that require it.[32]

Analgesia

Septic synovial structures in horses can cause excruciating pain, which in turn can lead to contralateral limb laminitis or prolonged recumbency with attendant potential for decubital sores, weight loss, and respiratory and gastrointestinal problems. The response of individual horses to typical nonsteroidal anti-inflammatory drugs (NSAIDs), such as phenylbutazone and flunixin, can be remarkably variable. Adverse responses to NSAIDs seem equally inconsistent, but the clinician must always be looking for signs of NSAID toxicity in these patients. Oral ulcers, soft manure, and low plasma protein may be early signs. Increasing creatinine due to renal toxicity and colic because of gastric ulcers or right dorsal colitis are even more serious problems that can arise in horses receiving high doses of NSAIDs for extended periods. Horses that are debilitated by pain and that are neither drinking nor eating normally also are probably more vulnerable to NSAID-related problems. Omeprazole and sucralfate are usually both given in stressed, high-risk horses receiving long-term NSAIDs.

In horses that need more analgesia, opiates can be used judiciously. In a hospital setting, constant infusions of lidocaine or ketamine can be helpful. If the septic process is in the hind limbs, an epidural catheter for administration of opiates or detomidine, or both, can be extremely effective and reasonably economical.

Because clinical lameness and pain are the most reliable (and *important*) measures clinicians can use to assess the response of an individual horse to treatment, it is absolutely critical to remember that NSAIDs and other treatments could be masking that pain and giving a false impression of clinical success. A clinician should never discontinue any antimicrobials or efforts at drainage until the status of the horse is more fairly evaluated after use of analgesics and anti-inflammatories has been sharply reduced or discontinued.

Other Intrasynovial Treatments

Restoration of the synovial lining back to normalcy is the secondary goal after eradication of infection. Injections with hyaluronan, autologous conditioned serum, or platelet-rich plasma are all reasonable adjuncts to consider, even though there is little information regarding their efficacy. Hyaluronan is arguably the most plausible candidate since it is an essential moiety in normal synovial fluid and has few potential deleterious effects on host resistance and healing. The most difficult decision would be to inject a glucocorticoid to help resolve a persistent post-septic synovitis because of concern that a subdued, but not eradicated, infection might recrudesce under the potent anti-inflammatory actions of the steroid.

OSSEOUS INFECTIONS

Sequestrum

The equine limb is vulnerable to trauma because of its anatomy and how it is used. Kicks, lacerations, punctures, and any other penetrating wounds that infect bone are quite common, especially in horses at pasture. The poor soft tissue coverage over most of their limbs allows easy, direct contamination of bone, and the lack of muscle tissue eliminates a source of healthy blood supply. The consequence is often sequestrum formation. The stripping of periosteum and loss of blood supply leads to necrosis of a segment of bone that in turn is gradually walled off (i.e., sequestered) from the healthy intact bone. Reactive bone forms around the necrotic portion (the sequestrum) in a somewhat conical form termed the *involucrum*. The draining tract to the skin that is usually present connects with an opening to the sequestrum that is termed the *cloaca* (Figure 85-4).

The diagnosis of a sequestrum is usually only made after a wound over a bone has failed to heal normally or when it opens and drains following sutured closure. Radiographs may be unremarkable until the lysis around the sequestrum becomes advanced (Figure 85-5).

Treatment of bone sequestra does not always require surgical intervention. If there is minimal tissue reaction, minor discomfort, and a relatively small piece of sequestered bone, patience and several weeks of appropriate antimicrobials may result in complete resolution. However, it is always prudent to discuss with the owner or trainer that earlier surgical intervention might actually be less expensive. A sequestrectomy with accurate débridement can completely eliminate the infection quickly with minimal supportive therapy with antimicrobials. If possible, an Esmarch bandage or tourniquet should be placed proximal to the surgical site because it will make it much easier to identify normal and abnormal tissues during débridement. If the sequestrum and the tract leading to it are not obvious, it may be helpful to inject the tract with diluted methylene blue dye. This will make is easier to follow the tract and to completely excise the dyed tissues. It is not necessary to remove the entire involucrum unless cosmetic "debulking" of the area is an issue. It is necessary, however, to fully open the cloaca to expose the sequestrum and thoroughly scrape out all infected and reactive bone and exudate. Local antimicrobial delivery in conjunction with a cancellous bone graft, plaster of Paris, or other

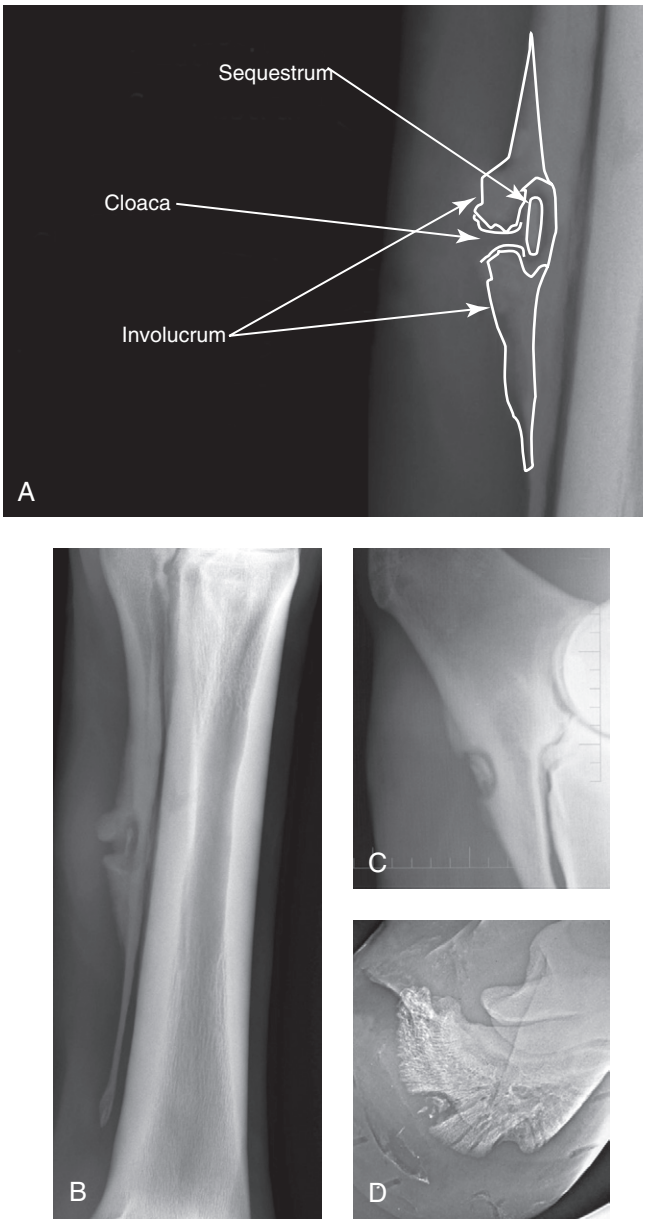

Figure 85-4. A-C, Infected sequestra have typical radiographic appearances including surrounding reactive bone (involucrum) and an opening that typically forms a tract to the skin surface (cloaca). **D,** In some anatomic locations like the distal phalanx, the reactive bone is less likely to be evident.

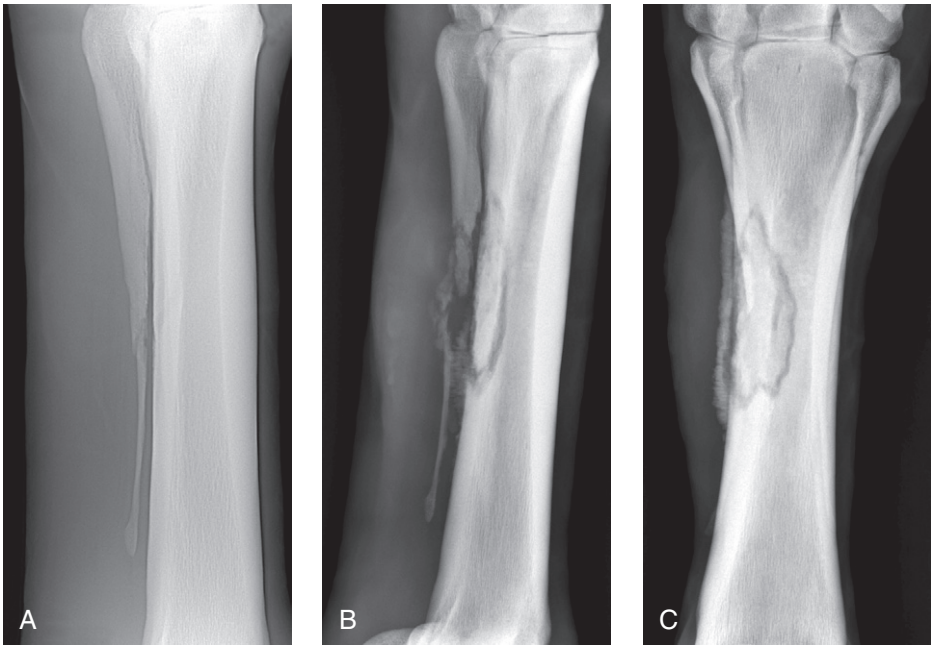

Figure 85-5. A, Radiograph taken 1 day after a kick wound to the metacarpus. There is clearly a minimally displaced small metacarpal fracture, but nothing more is evident. **B** and **C,** Approximately 2 weeks later the sequestrum of MCIII is evident.

degradable delivery device may all be used in cases where there is a large postdébridement defect. With large sequestra of the small metacarpal or metatarsal bones, an antibiotic-soaked collagen sponge is placed axially to separate the bone defect from the suspensory ligament and flexor tendons before filling the defect created by the débridement (Figure 85-6). Simple drainage with a Penrose drain also should be strongly considered if a significant dead space is present. With proper débridement, neither intensive local nor long-term antimicrobials are usually necessary.

Postoperative Infection

With the advent of arthroscopy completely replacing traditional open arthrotomies, infections following joint surgery are rare. Unfortunately, the same cannot be said of major orthopedic surgical interventions in horses, where infection has proved to be the most important and disappointingly common complication following internal fixation.[50]

Etiology

A surgical infection occurs when bacteria (or much more rarely, fungi) overwhelm the host's immune response. It has long been established that any foreign material in a surgical wound greatly increases the risk for a clinical infection, primarily because the bacteria can form biofilms on their surfaces that protect them from host defense. In equine fracture repair, surgeons are often forced to use numerous and large implants for mechanical reasons, enhancing the chances of infection considerably. The number of bacteria that enter the wound also affect the probability of surgical infection. In horses, plating procedures usually involve extensive open surgical approaches that expose the site and implants to the ambient air for long periods. Efforts have been made to develop minimally invasive plate fixation techniques in horses,[51] but not all fractures are amenable to these types of repair. There is no doubt that the risks of common joint surgeries have been diminished by the ubiquitous use of arthroscopy. Presumably this is because of the minimally invasive nature of arthroscopy combined with the constant mechanical cleaning (fluid delivery) during the procedure. It still remains to be proved if minimally invasive bone plating techniques reduce the incidence of surgical infection.

Prevention

Optimal aseptic technique should be the standard for major orthopedic procedures in any species because of the inherent risks. Even with excellent aseptic technique, however, the risks are high enough that antimicrobial prophylaxis is justified, usually using multiple delivery methods in the same patient. Preoperative antimicrobials ideally should be administered intravenously shortly before (or during) the beginning of the procedure to maximize plasma concentrations. The choice for most surgeons is a broad-spectrum combination of a penicillin and an aminoglycoside. During the procedure, tissues should regularly be rinsed with antibiotic-containing sterile fluids. Because of the volume used, a relatively inexpensive selection of drugs that are not commonly used systemically (e.g., bacitracin, polymyxin B, neomycin) are often chosen for lavage solutions. The use of hyperimmune plasma for intraoperative lavage has also been proposed.[45] In plating procedures, the voids in the surface of the plate next to the screw heads can be filled with antibiotic-impregnated PMMA (AIPMMA) as can the voids in the undercuts of specific plates—limited-contact dynamic compression plate (LC-DCP), locking compression plate (LCP)—if open reduction and internal fixation is performed. A half-dose (20 g) of a sterile prepackaged PMMA (e.g., Surgical Simplex P) can be mixed with 5 mL of 250 mg/mL amikacin sulfate solution. The components should be mixed quickly in a sterile

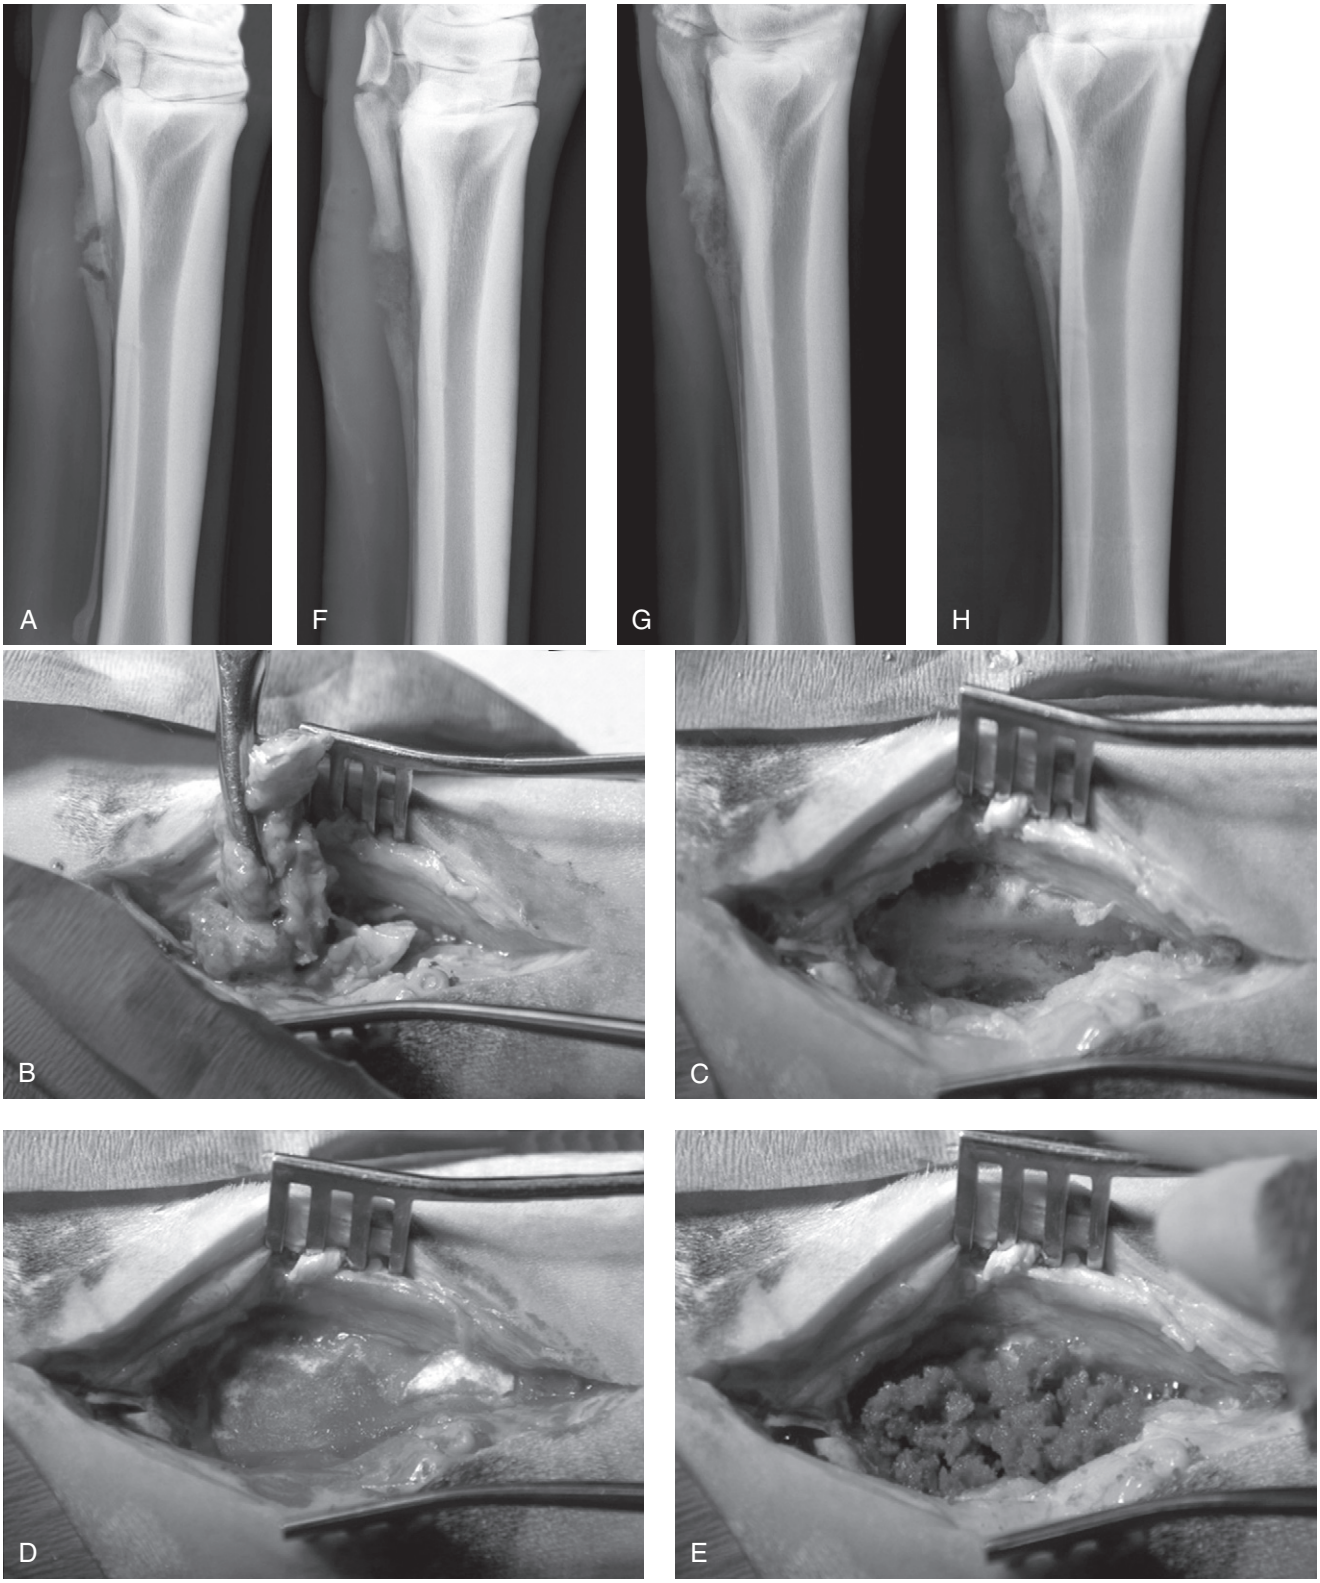

Figure 85-6. A, An infected large sequestrum of the proximal MTII. **B,** A simple linear incision made over the lesion allows débridement of the infected tissue to the point where it is visibly clean **(C). D,** An antibiotic-soaked collagen sponge is placed axially. **E,** A combination of cancellous bone and small chips of antibiotic soaked plaster of Paris fill the defect. **F,** Follow-up radiographs at 1 month. **G,** Follow-up radiographs at 3 months. **H,** Follow-up radiographs at 6 months.

container and aspirated into a 60 mL dose syringe while it is still very liquid. As soon as the mass becomes slightly doughy, it can be squeezed out of the dose syringe into the screw hole voids and around the edges of the plate (Figure 85-7). Again, this must be done quickly, especially if the ambient temperature is high, because the AIPMMA will harden rapidly. An injection needle or a small pin is used to remove any cement that gets into the screw head recesses. Meticulous attention should be given to avoid getting AIPMMA into any fracture gaps. A premade AIPMMA with tobramycin is also available. Additional useful antibiotics that have been used include gentamicin, imipenem, vancomycin, ceftiofur, cefazolin, daptomycin, teicoplanin, enrofloxacin, ticarcillin/clavulanic acid, and metronidazole. Heat-sensitive drugs such as chloramphenicol should not be used, and most penicillins are not ideal. A large range of antibiotic concentrations have been used, but clinical success has been seen with weight/weight ratios of 1:10 to 1:5 (antimicrobial/substrate) (Table 85-1). A larger proportion of antimicrobial placed in the cement presumably has more effect

Figure 85-7. Antibiotic-impregnated PMMA can be mixed, placed in a 60-mL dose syringe, and injected while still soft and doughy into any "open" spaces in a bone plate.

TABLE 85-1. A Partial Listing of Commonly Used Biomaterials for Local Antimicrobial Delivery

Biomaterial	Brand Name	Antibiotic	Concentration	Notes
BIODEGRADABLE				
Collagen sponge	Ultrafoam Collagen Sponge; Davol Inc., Warwick, RI	Gentamicin	130 mg/joint[43,44]	Short elution profile, quickly resorbed. Commercially available. Easy to use.
Plaster of Paris (calcium sulfate hemihydrate)		Gentamicin Tobramycin	25-60 mg/g[46] 100 mg/g	*Very* inexpensive. Beads are best made before surgery; slow to harden. No reasonably priced commercial product ("homemade," requires sterilization)
Hydroxyapatite	BoneSource; Stryker Corp., Kalamazoo, MI	Gentamicin	50 mg/g[52]	Expensive commercial bone replacement product.
		Amikacin Vancomycin	62.5-125 mg/g[52] 100 mg/g[53]	
		Ceftiofur	50-100 mg/g[52]	Poor kinetics for cefazolin.
Dextran gel	R-Gel; Royer Animal Health, Frederick, MD	Amikacin Amikacin + clindamycin Vancomycin	60 mg/mL 50 mg/mL + 25 mg/mL 25 mg/mL	Easy to use gel formulation. Elution 7-10 days. Gel degraded in 3-4 weeks. Commercial product.
NONBIODEGRADABLE				
Polymethyl methacrylate	Simplex P; Stryker Corp., Kalamazoo MI Palacos R, Zimmer Inc., Warsaw IN	Gentamicin	50-100 mg/g[54]	Easy to use sterile commercial product. Very exothermic curing so only heat stable antimicrobials can be used. Decades of successful clinical use.
		Ceftiofur Vancomycin Amikacin Cefazolin Tobramycin	50 mg/g 25 mg/g 50-125 mg/g 50-200 mg/g 100-250 mg/g	

on the mechanical properties of the resulting cement, but that is not a concern when it is used for drug delivery.

Finally, during or following wound closure of major internal fixation in the distal limb, a regional limb perfusion with amikacin should be considered. The "extra" 20 to 30 minutes is a minimal concern, because the perfusion can be done while a lower limb cast is being applied. Time is also often spent applying a special shoe to the contralateral foot.

The postoperative duration of prophylactic antimicrobial therapy depends on multiple factors, including the presence of drains, difficulty encountered in closing the incision, concerns about incisional integrity, and the condition of the adjacent skin or nearby wounds. In closed fractures without complicating factors, however, there is little evidence to support antimicrobials being given for more than 48 to 72 hours.

Meticulous management of the incision, especially in the first few days following surgery should include changing bandages in clean areas and keeping the wound covered with sterile dressings. Skin sutures should be removed at the appropriate time (usually 10 to 14 days postoperatively) after carefully cleaning the sutures and skin surface. It is particularly important in incisions with little underlying soft tissues covering a plate that sutures be correctly removed, not leaving fragments of potentially contaminated material beneath the skin. If a cast is going to be left in place over an incision for more than 2 weeks, a monofilament absorbable material for skin closure should be strongly considered, especially if skin sutures are being placed under tension or in complex patterns (mattress, near-far-far-near) that will be very difficult to remove when they pull through the skin surface.

Diagnosis

Early subtle signs are invariably present on every orthopedic case that develops an infection. Early recognition of the clinical signs of a developing septic process can prove essential to successful management. Experience with the degree of postoperative comfort to be expected from each orthopedic procedure is useful because an early sign of a developing infection is lameness not in line with case expectations. An adequately stabilized fracture or arthrodesis without infection is nearly always fully weight bearing and comfortable to palpation within 36 to 48 hours. Any prolonged discomfort that is resistant to reasonable analgesic efforts should raise the suspicion of infection. The noninfected surgical site should heal evenly, rapidly, and cleanly. If expected postsurgical swelling persists or increases, it should be further investigated, as should any type of drainage or a fluid pocket palpable at the surgical site. Although a cast precludes direct palpation of a surgical incision, careful assessment of the cast can detect heat, and drainage can be seen or possibly smelled if there is a problem. A regular inspection routine of any horse wearing a cast should include picking up the contralateral limb and walking the horse a short distance each day. Any early decrease in comfort is a reason to consider early removal of the cast and inspection of the incision.

During the postoperative period an easy and reliable indicator of potential infection is pyrexia. Any elevated temperature (higher than 38.6° C [101.5° F]) that cannot be readily and clearly attributed to another cause should be assumed to be a surgical site infection until proved otherwise (see Chapter 7). Even minor fevers should be considered important in a horse receiving substantial NSAID therapy. All clinical signs inconsistent with expectations should be investigated aggressively. It is vastly more cost-effective to aggressively investigate and treat a suspected case of infection than it is to wait for overwhelming proof and commence treatment at that stage. Monitoring of plasma fibrinogen is a useful means of monitoring case progression. The absolute number is often not conclusive; however, serial monitoring can be very useful in the early detection of infection. Leukocytosis is generally an unreliable indicator of infection in horses because they can have normal white cell counts. Diagnostic aids are very useful in detecting orthopedic infections. Ultrasonography performed by an experienced operator is a sensitive means of detecting infection. The accumulation of exudate adjacent to a bone or implant can be identified and early accurate aspirates obtained for culture and sensitivity testing. Radiography can be useful; however, the information gained from the images in the acute stages is often limited to increased soft tissue swelling and separation of tissue planes. Later signs are bony lysis developing adjacent to metallic implants and periosteal proliferation unassociated with fracture healing (Figure 85-8). A major benefit of early radiographic evaluation of the operated site is to ensure the structural stability of the construct. Culture and sensitivity testing of any subcutaneous fluid pocket or a draining tract is mandatory for directed treatment of an orthopedic infection. All sampling should be performed aseptically and using ultrasound guidance if necessary. Aspirates collected into culture media or swabs of draining tracts should be performed using previously outlined techniques to maximize culture efficiency. Culturing the deeper portions of the infected region may prevent erroneous culture results. If any implants are removed, they should also be submitted for culture.

Treatment

A major factor in the improved handling of orthopedic cases over recent years has been a shift to concentrated local delivery of antibiotics to the surgical site. Obvious benefits of these local techniques over systemic administration include extremely high levels of antimicrobials at the site of infection, avoidance of potential side effects, and significant financial savings. Many of these techniques are the same as those used for prophylaxis, including local antibiotic elution devices and regional vascular perfusions. Once an infection has become established, in addition to the use of local antibiotics, basic principles of treating infection must still be followed. If possible, drainage of the infected tissues should always be considered. This may involve an ultrasound-guided incision into a fluid pocket or opening of the most dependent portion of the incision.

Local techniques to treat an established infection can be used to control an infection until there is sufficient healing of the fracture/arthrodesis that implants can be safely removed. Removal of an infected implant will help resolve even the most persistent infections.

If there is the unfortunate combination of an inadequately stable internal fixation and infection, the best options, if finances allow, is usually to either replace the implants or remove them and manage the fracture/arthrodesis with a transfixation cast (or external fixator). It is feasible to remove an infected plate and vigorously débride the underlying bone, adjacent tissues, and fracture site. While the débridement is being performed, the plate(s) can be cleaned and autoclaved and reimplanted with fresh screws in new holes. If the situation

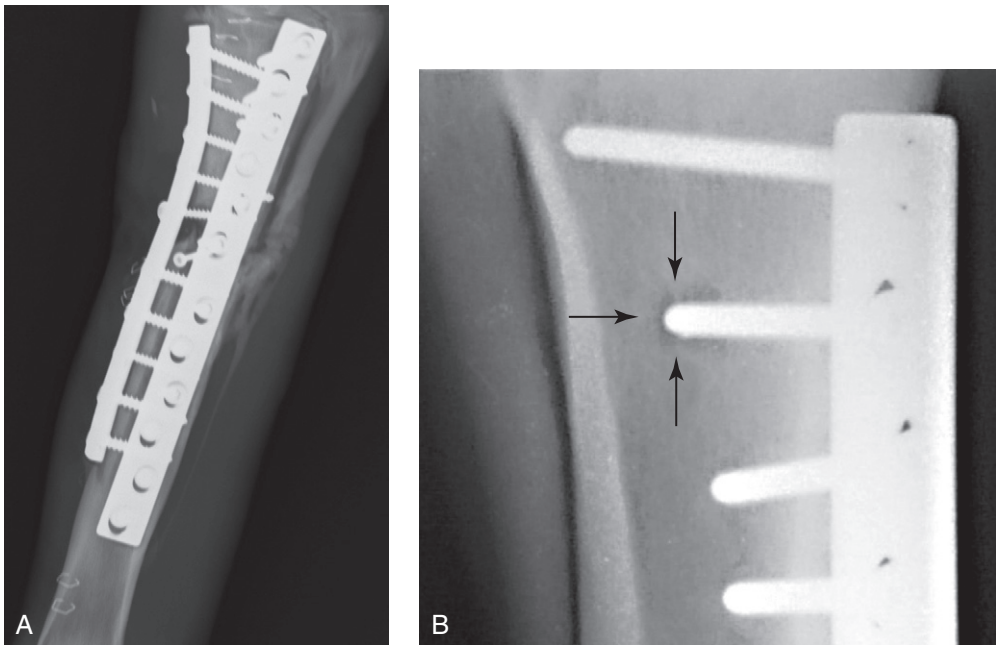

Figure 85-8. A, Typical radiographic signs of infected implants include lysis and proliferation at the fracture site; **B,** or more subtle signs such as lysis along a single screw *(arrows)*.

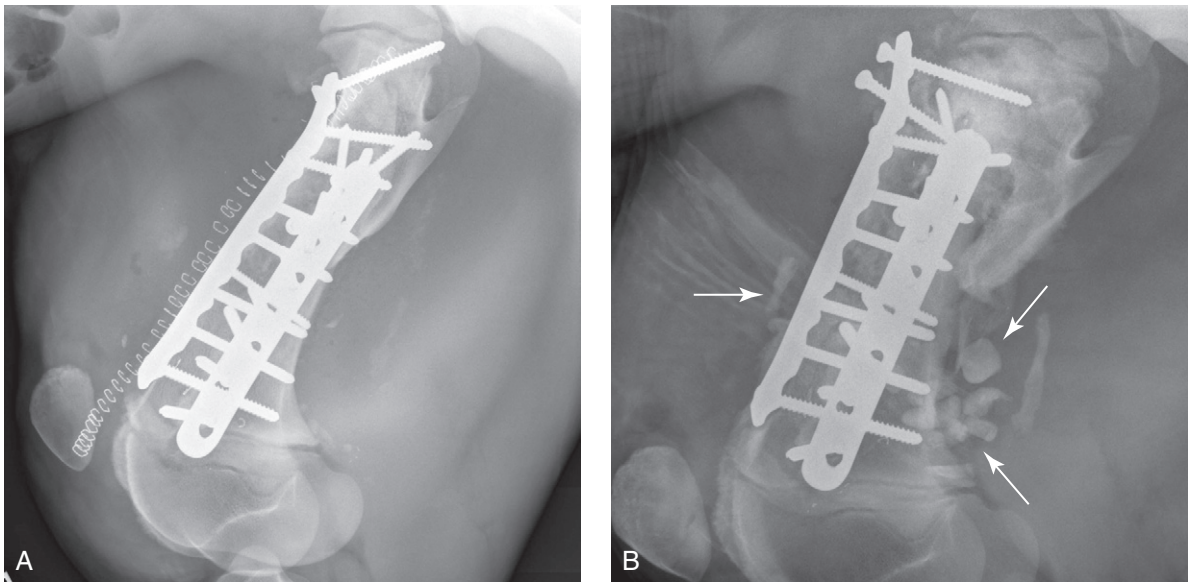

Figure 85-9. A, A severely contaminated open 4-day-old fracture of the femur repaired with two locking plates and abundant antibiotic-impregnated polymethyl methacrylate (AIPMMA) along the plates. As expected, some infection did develop. **B,** The wound was drained and packed multiple times with AIPMMA beads *(arrows)*. The fracture healed. Normal femoral longitudinal growth followed, and the implants are still in place 4 years later.

allows it, dynamic compression or a tension device can be used to restabilize the site. The empty screw holes can be filled with antibiotic-impregnated collagen, antibiotic-impregnated dextran gel (R-gel), antibiotic-impregnated plaster of Paris or other absorbable antibiotic-eluting materials. Drainage should always be considered; leaving a few centimeters open at the bottom of an incision or even using surgical drains may help.

Parenteral antimicrobial therapy alone nearly always fails in seriously infected internal fixation cases. If the internal fixation is stable, the treatment strategy involves drainage, local instillation of correctly selected antimicrobial beads if feasible (Figure 85-9), and repeated regional limb perfusions. The implantation of eluting materials can usually be performed in the standing horse under local anesthesia. Although AIPMMA has the disadvantage of being nonabsorbable, PMMA has very good elution properties and excellent biocompatibility, and it is very easy to form beads of appropriate shape for insertion. AIPMMA beads have widely been used on a "string" to facilitate later removal, but individually placed fusiform beads are easier to insert in a standing patient alongside an infected plate or in pockets surrounding an infected implant. The beads can usually be removed without too much difficulty when the plate is removed later.

Although it is possible for the depleted beads themselves to later serve as a nidus for an infection, many horses have lived for a decade or more with depleted AIPMMA beads inertly in place.

The regional limb perfusions ideally should be performed daily for as long as possible, using the highest possible dose, which is the systemic daily dose. Using very small gauge (25- to 27-gauge) butterfly needles for injection, large vessels (e.g., accessory cephalic and saphenous veins), immediate compression of the injection site to minimize bleeding and extravasation, application of topical NSAIDs and bandaging, it may be practical to treat with maximum vigor for weeks. Regional limb perfusions can be safely and repeatedly performed in a horse wearing a lower limb cast. As emphasized earlier in this chapter, an appropriate tourniquet and heavy sedation to prevent movement of the perfused limb both improve efficacy.

Prognosis

The prognosis for horses with orthopedic infections has substantially improved with the routine use of intensive local therapy. But the cost of treatment is enormous, and there may still be significant long-term adverse consequences for a horse, even with successful clinical resolution of the infection.

CHAPTER 86

Angular Limb Deformities

Jörg A. Auer

The surgical techniques used for the management of angular limb deformities (ALDs) in foals are well established.[1-10] However, which technique to use and when remains controversial. At one time, most foals showing some degree of angular deviation were surgically corrected, but a more differentiated approach is presently applied.[11]

DEFINITION

Animals with ALD present with either a valgus deformity (lateral deviation of the limb distal to the location of the deformity) or a varus deformity (medial deviation of the limb distal to the location of the problem) (Figure 86-1). Either type of deviation is usually associated with a certain degree of axial rotation. In foals with valgus deformity, this is displayed as an outward rotation (splay foot), and in cases of varus deformity, as a medial rotation of the feet (pigeon toes). In most cases, these deformities are initially merely postural, through a rotation of the limb axis toward either the outside or the inside, respectively. With time, however, the bone adapts to abnormal loading, according to Wolff's law, and differential metaphyseal growth results in the development of a permanent rotational deformity.[8,12]

ANATOMY

Maturation of the skeleton from the primordial or precursor cartilage to bone is a very complicated process and occurs mainly during the later stages of gestation. Radiographs taken of the carpal and tarsal regions of aborted fetuses at 230 days of gestation reveal only partial ossification of the diaphyses and metaphyses of the long bones as well as of the calcaneus.[10] Other bones are not ossified at all at that time. For instance, intra-articular injections of contrast medium provide outlines of the bone templates in their normal shapes, although they consist of precursor cartilage only. Ossification of these structures begins in the center and expands spherically in all directions to the periphery.[10,13] At about 260 days of gestation, ossification centers are noticed in the distal radial epiphysis, distal tibial epiphysis, talus, and accessory carpal bone. Later,

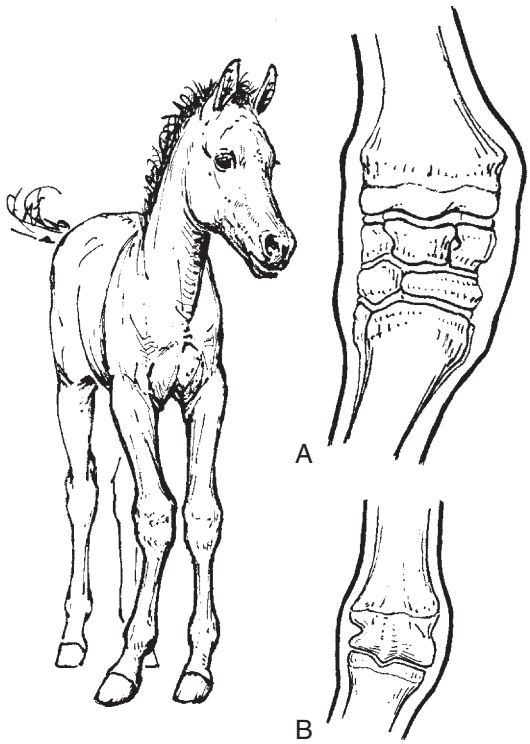

Figure 86-1. Drawing of a foal with a valgus deformity in the right carpal region **(A)** and a varus deformity in the left metacarpophalangeal region **(B).**

ossification centers in the intermediate, radial, and third carpal bones, and the central, third, and fourth tarsal bones develop. At around 290 days, the proximal epiphyses of the third metacarpus/third metatarsus (MCIII/MTIII) appear, and they unite shortly thereafter with the metaphyses of these bones (Figure 86-2). At about 300 days of gestation, all bones of the carpus and tarsus are visible radiographically. The ulnar styloid process, which is the last ossification center to appear, is still not seen at this time. During the remaining days of gestation, ossification progresses toward the periphery, and the bones acquire their final shape. At birth, the edges of these bones are still somewhat rounded, but the "radiographic joint spaces" are within normal limits (Figure 86-3). These spaces consist of two layers of cartilage in addition to the actual joint space.[6,14,15]

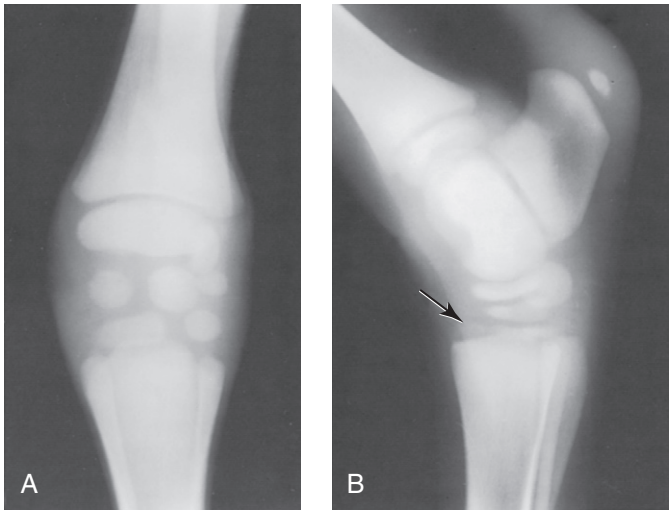

Figure 86-2. Dorsopalmar (DP) radiograph of a carpal region and lateromedial (LM) radiograph of a tarsal region of a premature foal. **A,** The DP view of the carpal region at 2 days of age shows incomplete ossification of the carpal bones. **B,** The LM view of the tarsal region shows inadequate ossification of the tarsal bones, especially the third and the central tarsal bones. Note the ununited proximal epiphysis of MTIII *(arrow)*.

Longitudinal Bone Growth

The vast majority of longitudinal growth in the long bones occurs at the level of the physis. Some growth is attributed to the epiphysis, growing toward both the articular cartilage and the physis. However, the vast majority of growth occurs in the metaphyseal region of the physis. The exact mechanisms responsible for this bone growth are not completely understood, but strides toward solving this mystery are being made with the help of molecular biology techniques.[16,17] In mice, it was found that a feedback loop exists in the growth plate centered on the following molecules: parathyroid hormone–related protein (PTHrP), PTH/PTHrP receptors (PTHrPR) and Indian hedgehog (Ihh).[18] The feedback loop is regulated via the periosteum/perichondrium through the signaling molecules Patched1 (Ptc1), Gli, and Smoothend (Smo). If Ihh secretion is increased, PTHrP molecules are upregulated and inhibit differentiation of proliferating chondrocytes into hypertrophic chondrocytes, thus promoting longitudinal growth. Since Ihh and PTHrP are not expressed in the same vicinity, and molecule diffusion through the extracellular matrix is limited, intermediates, such as Ptc1, transforming growth factor-β_2 (TGF-β_2), bone morphogenetic proteins (BMPs), and fibroblast growth factor (FGF), that are located in the perichondrium participate in this regulatory process.[18] Once these mechanisms are understood in the horse, an explanation for the disproportionate long bone growth across a physis may become clear and specific molecular therapy may be developed.

The following is clear. Ideally, bone growth should occur evenly across the entire physis; immediately after birth, growth is most active; and each physeal region has an approximate time span during which new bone growth occurs. Closure of the physes of the different long bones occurs at predictable time points. Therefore, if manipulations to correct growth are to be effective, the closure time of the physes has to be considered.

ETIOLOGY

A variety of etiologies are responsible for the development of ALD and can be grouped into two main categories: perinatal factors, which include conditions that are present either during

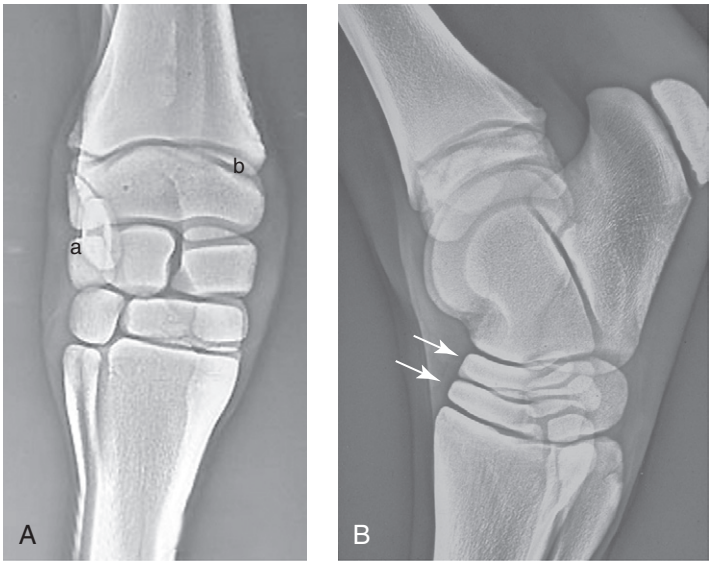

Figure 86-3. Normal ossification of the carpal and tarsal regions at the time of birth. **A,** Dorsopalmar radiograph of the carpal region. All the bones are ossified adequately, and the ulnar styloid process *(a)* is visible. The rough surface at the medial distal metaphysis of the radius *(b)* represents active endochondral ossification and is normal at that age. **B,** Lateromedial radiograph of the tarsal region showing adequate ossification of the central and third tarsal bones *(arrows)*. It is important that the ossification process proceed to the level of the proximal aspect of MTIII. These two radiographic views are the most relevant to evaluate ossification at the time of birth.

the later phases of gestation or in the immediate perinatal period, and developmental factors, which influence limb axes at a later stage.

ALD may originate at different locations of the appendicular skeleton: within the cuboidal bones of the carpus or tarsus, in the epiphyseal region of the long bones (epiphyses, physes, and metaphyses), and occasionally in diaphyses of the long bones. Most frequently, the deviation develops through disproportionate growth at the level of the metaphyseal growth plates. Physeal trauma, such as Salter-Harris type V or VI fractures, can cause local retardation of growth at the medial or lateral aspect of the bone and result in the development of ALD.[18,19] Compensatory ALD can occur in remote sites such as the proximal phalanx of the affected limb because of prolonged disproportionate loading of a growth plate distad to the deviation. Such compensatory deviations may straighten the limb axis, but when the foal ambulates, the joint involved rotates, because the joint is not oriented at a right angle to the long axis of the limb and the ground.

Perinatal Factors

Incomplete Ossification

After a normal gestation period, a foal should be born with adequate ossification of the carpal and tarsal bones (see Figure 86-3). A variety of events affecting the mare, including placentitis during pregnancy, severe metabolic disease over a prolonged period, heavy parasite infestation, and colic, may jeopardize the intrauterine environment of the foal and result in incomplete ossification at the time of birth.[10] Premature birth is usually associated with the same problem. Because the placenta of a mare does not provide as intricate a blood exchange between the fetus and the mare as it does in humans and dogs, normal intrauterine development of more than one fetus at the same time is not possible. Twin foals always exhibit incomplete ossification at birth. These immature foals do not mature properly and have a poor prognosis as athletes. Therefore abortion of one of the twins during the early embryonic stages is standard.

Because most foals are born with a certain degree of angular limb deformity, they initially load their joints unevenly. The uneven pressure on the relatively thick layer of articular and precursor cartilage may deform these soft structures, especially in a dysmature foal. Incomplete ossification per se does not represent an ALD, but the uneven loading of the dysmature skeleton leads to it. Once ossification reaches the periphery, the precursor cartilage ossifies in an abnormal configuration, resulting in a permanent ALD. In severely dysmature foals, osteochondral fractures may occur, which render the foal permanently lame because of osteoarthritis (Figure 86-4).[8] This is especially true in the rear limb, where weight-bearing forces must change direction in the tarsal region from a cranioproximal-caudodistal direction to a vertical one. The most affected region is the dorsal aspect of the small tarsal bones. If these bones are incompletely ossified, loading causes thinning of the soft precursor cartilage and eventually leads to a pathologic fracture and dislocation of a dorsal fragment.[6,8] This problem results in a partial collapse of the dorsal aspect of the tarsus and tilting of the proximal limb in a cranial direction (Figure 86-5). Affected foals do not trot but rather "bunny hop" with their rear limbs. In chronic cases, a secondary flexural deformity of the forelimbs may result because of chronic overload.

If collapse of the cartilage template of cuboidal bones in dysmature foals is left untreated, the deformations worsen and

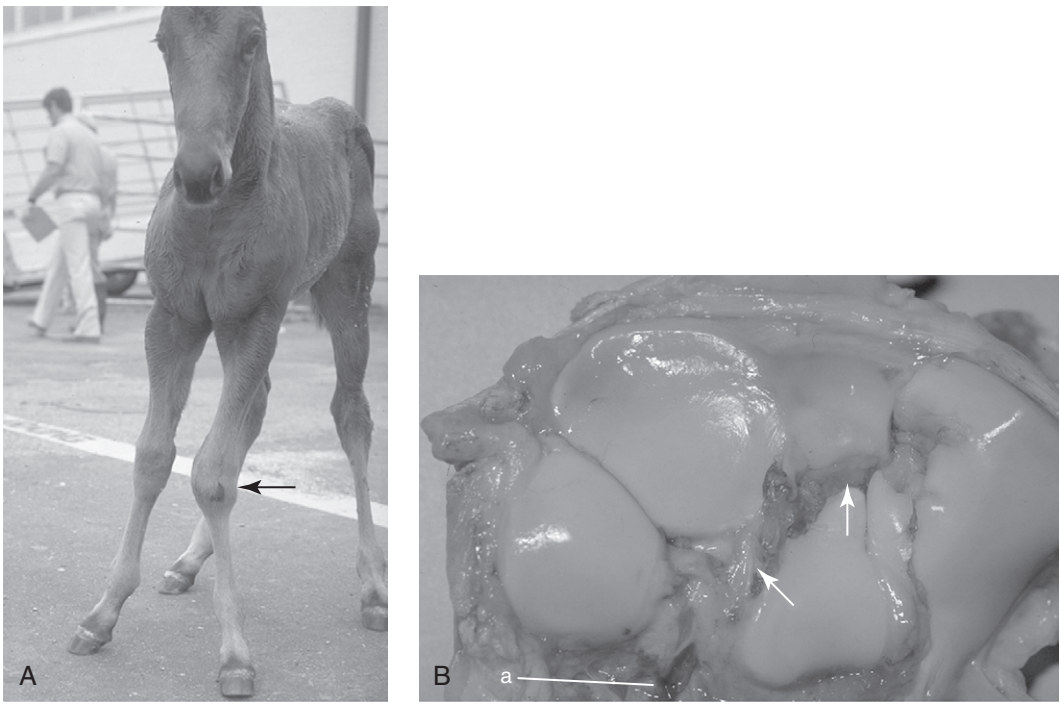

Figure 86-4. A, A 6-week-old foal with a marked carpal valgus deformity in the left limb. There is swelling *(arrow)* and the animal is lame. **B,** Postmortem picture of the articular surface of the third carpal bone, showing an osteochondral fracture *(arrows).* There is also marked discoloration of the synovial membrane caused by intra-articular hemorrhage.

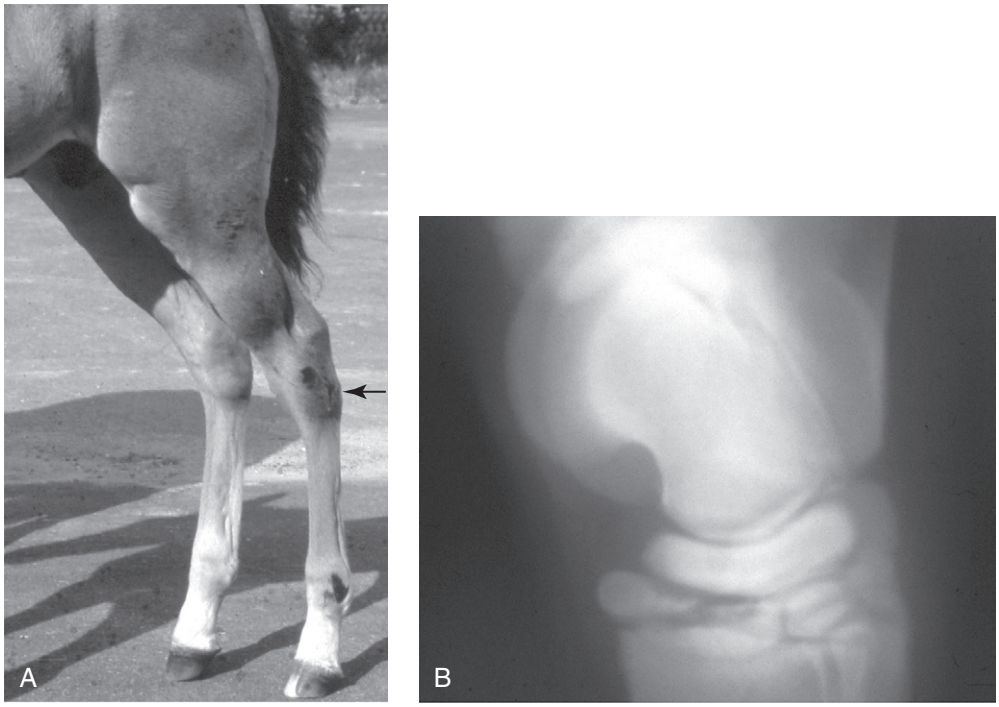

Figure 86-5. A, The hind limbs of a 1-month-old foal with a marked dorsal angulation at the level of the tarsus *(arrow)*. The foal showed the typical gait of a foal with collapsed third tarsal bones: it trotted with the forelimbs and "bunny-hopped" with the hindlimbs. **B,** Lateromedial radiograph showing the collapsed third tarsal bone, which is displaced dorsad.

eventually the small tarsal bones fuse to a single irregularly-shaped, uncorrectable bone. Therefore, early intervention and aggressive treatment are necessary to ensure normal development.

Laxity of Periarticular Structures

Some foals are born with severe ALDs in several regions, allowing oscillation between valgus and varus deviations depending on limb position during weight-bearing. Rotational deformities of various degrees also are encountered during the first few days after birth (Figure 86-6). These foals probably suffer from laxity of the periarticular supporting structures or from soft tissue trauma, both of which result in unstable joints. In most cases, several joints are involved at the same time. These deformities lead to abnormal loading of the articular surfaces and may, in the presence of incompletely ossified cuboidal bones, induce a severe ALD. It is unknown exactly how these problems develop. In some cases, the aberrant development of the long bones relative to the soft tissue structures may be caused by a hormonal imbalance or by intrauterine positioning.[19]

Aberrant Intrauterine Ossification

Occasionally a foal is born with a deformed long bone. The etiology is unknown. Ossification of the third metatarsal bone starts at approximally 150 days of gestation.[20] The influence of a mechanical factor, leading to passive deformation of the precursor cartilage of the bone involved during this gestation period, represents the most likely explanation of the presence of this deformation. A teratogenic factor influencing intrauterine ossification abnormally can be dismissed because in most cases only one bone is involved.

In the majority of these cases, the distal physeal region of the third metatarsal bone is involved and forms a triangular epiphysis. Interestingly, a varus deformity is most frequently diagnosed (Figure 86-7, *A* and *B*). Because there is aberrant ossification, the deformity cannot be manually corrected. On rare occasions a multiplanar deformity is encountered in the diaphyseal region of the third metatarsal bone (Figure 86-7, *C*).

Developmental Factors

Unbalanced Nutrition

The common practice of "crib feeding" often leads to excessive grain intake. It is important that the nutrition be balanced, especially with regard to trace minerals.[21] If the diet is not balanced, developmental orthopedic disease may occur and jeopardize future athletic potential.[22,23] Intake of trace minerals is further compromised by the exhaustion of grasslands and a lack of appropriate fertilization. A soil analysis of the local pasture may not be relevant, because forage (hay) is usually brought in from a distant source. Problems associated with unbalanced nutrition include osteochondrosis, flexural deformities, and ALD, the latter being represented mainly by disproportionate growth at the level of the physes.[22,23] Severe generalized osteochondrosis resulting from zinc toxicity or copper deficiency may cause ALD. On farms with a high occurrence of ALD, feeding practices should be evaluated through a complete feed and water analysis. If abnormalities are encountered, they should be corrected at once.[21]

Excessive Exercise and Trauma

Excessive exercise and trauma cause ALD. This trauma induces microfractures in and actual crushing of the proliferative zone

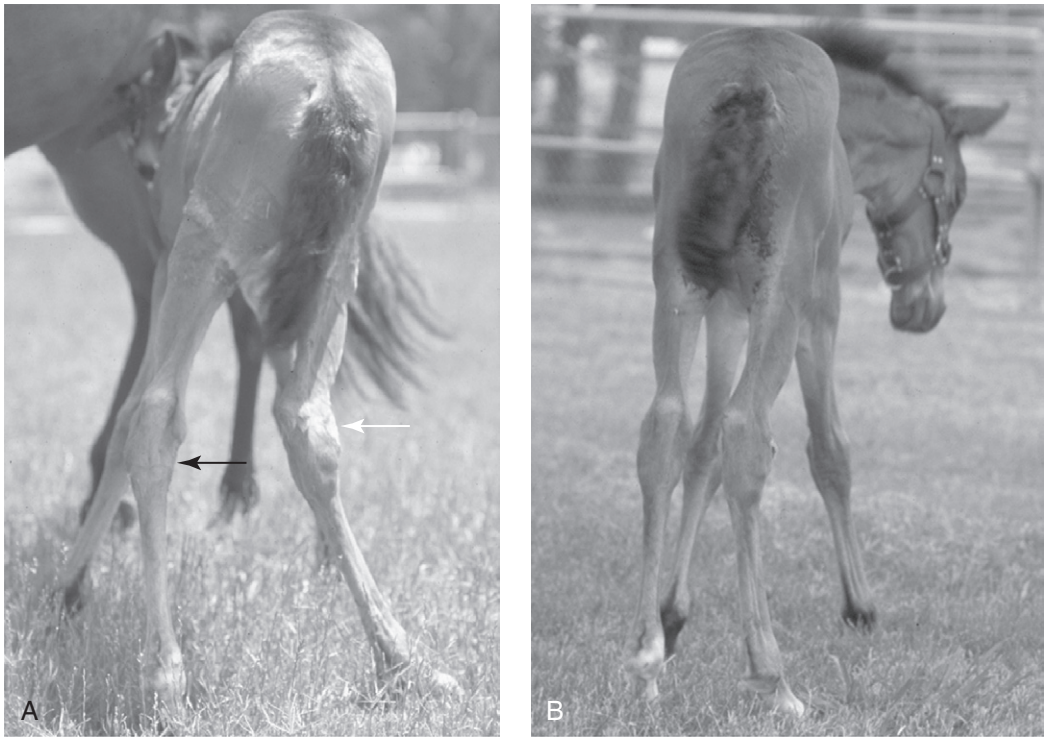

Figure 86-6. A, Photograph of a 1-week-old foal with a marked valgus deformity of the right tarsus *(white arrow)* and a varus deformity of the left tarsal region *(black arrow).* The degree of ossification was normal. **B,** After 2 weeks of light hand-walking and no treatment, the deviations had corrected.

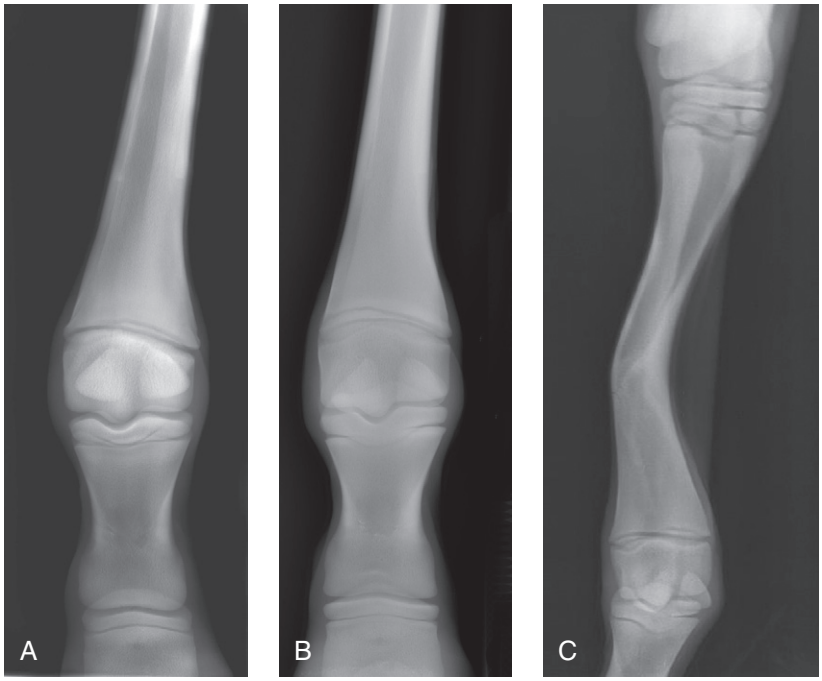

Figure 86-7. A, Dorsoplantar radiographic view of the distal limb in a 2-day-old Warmblood foal suffering from a marked varus deformity in the fetlock region. Note the triangular shape of the epiphysis. **B,** The same foal after 2 weeks of stall rest. The deformity is partially corrected because of the development of a compensatory deformity in the proximal phalanx. **C,** Dorsoplantar radiographic view of severely deformed MTIII in a 1-week-old Thoroughbredd foal. at the base of the physis, altering cell proliferation and maturation, and in severe cases it leads to early local closure. This type of injury has been classified as a Salter-Harris type V fracture.[24] Additionally, epiphyseal fractures caused by external trauma such as kicks from another mare may cause ALD.[24] Most physeal fractures heal with residual ALD because it is almost impossible to maintain viability of the entire physeal plate.[25]

DIAGNOSIS

Diagnosis is based on inspection, manipulation, and diagnostic imaging techniques. The foal is observed from several angles, most importantly from the front and back. To evaluate the limb, the clinician should be positioned perpendicular to the frontal plane of the examined limb. Splay-footed foals, with or without

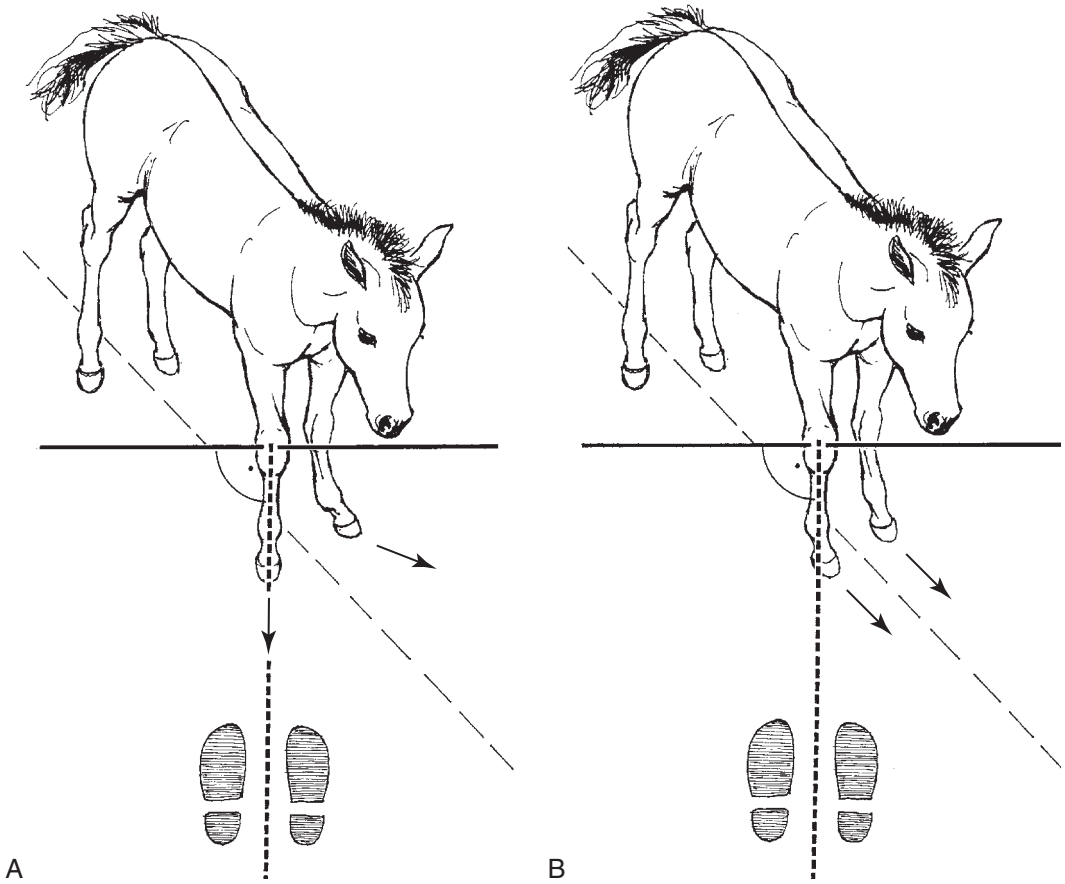

Figure 86-8. A, A valgus deformity of the carpal region is evaluated perpendicular to the frontal plane of the outward-rotated carpus. If the toe points in the same direction, the entire limb is rotated out and surgery can possibly be postponed. **B,** If the toes point forward and the carpus points outward, surgical intervention is indicated to prevent the development of a varus deformity in the fetlock region.

ALD, are therefore evaluated from a craniolateral position, allowing observation for proper alignment of the toe and carpus or tarsus, respectively (Figure 86-8, *A*). It is very important that the toe point in the same direction as the carpus. Newly born foals are weak, thin-chested, and, in relation to their size, long-legged. To provide some support to the forelimbs, which are connected to the chest by only seven muscles, the elbow region is pressed to the side of the chest. This results in an outward rotation of the entire limb and a toed-out posture. With increasing strength and age, the chest fills out and the connecting muscles become stronger, resulting in an inward rotation of the limb and correction of the toed-out posture. However, if the carpus points outward but the toes point straight forward (Figure 86-8, *B*), a varus deformity of the distal limb is present, which may go unnoticed for a few months. Once the limb rotates into a normal position, the feet attain a toed-in posture. Unfortunately, the distal MCIII/MTIII experiences longitudinal growth only for 3 to 4 months,[26] after which the physis closes. Frequently, this is when the problem is noticed.

Palpation and manipulation of the limb help differentiate between most perinatal and developmental deformities. If application of manual pressure to the medial aspect of the carpal region straightens out a valgus deformity (Figure 86-9), the cause of the deformity is either incomplete ossification or flaccidity of the periarticular supporting structures. If the limb cannot be straightened with manipulation, changes of the osseous structures of the region are involved.

Observation of the foal as it walks toward and away from the clinician also provides valuable information. If the joints are aligned parallel to the ground, all the joint movements occur in the same planes and no outward or inward rotation of a joint is noticed. However, pigeon-toed foals frequently rotate their metacarpophalangeal/metatarsophalangeal (MCP/MTP) joints outward while advancing the limb. This is caused by the joints not being oriented orthogonally relative to the long axis of the long bones in the frontal plane or parallel to the ground.

The only diagnostic aid that allows exact determination of the location and degree of the deformity is radiography. It is important to use long, narrow cassettes for the radiographs and to include as much of the bones proximal and distal to the deformity as possible. The dorsopalmar/dorsoplantar views are most important, except in the tarsus, where the lateromedial view is preferred. The radiographs should be taken at a right angle to the frontal plane of the limb (the sagittal plane of the tarsus). The bones constituting the distal MCIII/MTIII and phalangeal region should be aligned in one plane for the radiographs, allowing interpretation of the articular orientation and differentiation of deformities.

The need for early diagnosis cannot be overemphasized, especially in foals with incomplete ossification. The soft precursor cartilage is deformed through the uneven axial loads and, combined with the rapid progression of endochondral ossification, may result in a permanent deformity within 2 weeks after birth.

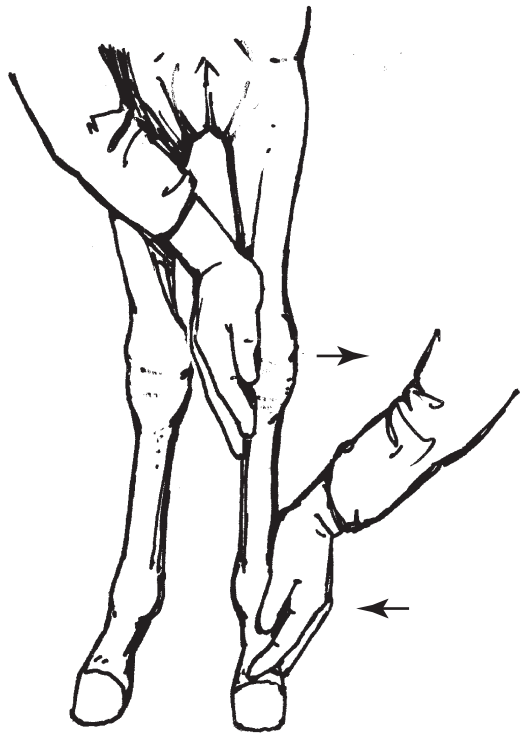

Figure 86-9. Manual pressure to the medial aspect of the carpal region of a foal suffering from bilateral valgus deformity corrects the deformity temporarily, indicating that conservative treatment is possible. Counterpressure is applied to the fetlock region of the same limb.

Compound and noncorrectable deformities present an added challenge. It is sometimes important to accept a compensatory deformity, if it aids the overall athletic soundness of the animal. A foal with a varus deformity in the metacarpophalangeal region would profit from a slight valgus deformity in the carpal region to balance the horse's weight-bearing axis over the foot. This necessitates the visual evaluation of the entire limb at the time of the diagnosis and caution in using radiographs as the sole diagnostic aid.

TREATMENT

Two studies conducted in Thoroughbred horses have significantly changed the philosophy of the management of ALDs.[27,28] One study documented conformational changes with age.[27] The changes occurring from weanling age to 3 years in a population of racing Thoroughbreds were determined by recording specific body measurements. There was a strong relationship between long bone lengths and wither height in all age groups, supporting the theory that horses grow proportionally. Longitudinal bone growth in the distal limb increased only 5% to 7% from weanling age to 3 years and was presumably completed before the yearling year. This study provided objective information regarding conformation and skeletal growth in the Thoroughbred, which can be used for selection and recognition of significant conformational abnormalities.[27]

The other study investigated the relationship of conformation to injury.[28] It found that offset carpi (offset ratio) contributed to MCP joint problems. Long pasterns increased the odds of a fracture in the front limb. A certain degree of carpal valgus deformity exhibited a protective mechanism, because the odds for a carpal fracture and carpal effusion decreased with an increase in the carpal angle.[28]

Based on these studies, the goals of effective management of ALD have changed. Severe deformities that do not correct on their own (see Figure 86-4) need to be distinguished from deviations that are a variation of the normal.[11] The art of management of ALD involves deciding which conditions require immediate aggressive management and which can tolerate a wait-and-see approach.

The following treatment methods are divided into nonsurgical and surgical procedures, according to the appearance and severity of the problem.

Nonsurgical Techniques

Stall Rest

Stall rest is an effective treatment in newborn foals with the following types of ALD:

- *Foals with incomplete ossification and straight limbs at the time of birth.* Under no circumstances should these animals be turned out in a field.[6,8,9,10] Exercise on the weakened, partially ossified carpal and tarsal bones may result in abnormal ossification of the bones with subsequent development of osteoarthritis.[6,8,9] The foals (and mares) should be restricted to stall rest for a maximum of 1 month. During this period, radiographs should be repeated at 2-week intervals to evaluate the progress of ossification. Longer restriction of activity is undesirable because of the normal development of the foal as a potential athlete.
- *Foals with adequate ossification and ALD because of disproportionate growth at the level of the physis (greater than 10 degrees) and foals with diaphyseal deformities.* Stall rest may be continued for 4 to 6 weeks. If correction does not occur during that time, surgical treatment should be implemented.
- *Foals with laxity of the periarticular supporting structures and a normal degree of ossification.* Such animals should be exercised daily for 10 to 20 minutes through walking the mare, to stimulate muscle work and strengthening of the involved soft tissue structures. Three to 5 minutes of swimming daily is the best exercise if facilities are available (see Chapter 87). Growth of the foal usually resolves the problem.

Predicting whether the problem will resolve with stall rest alone is not possible, and valuable time can be lost by waiting too long. This is the main reason for not prolonging stall rest treatment beyond 4 to 6 weeks. It is important to critically observe the foal continually during the stall rest period.

Splints and Casts

Foals with incomplete ossification of the carpal and tarsal bones may be treated effectively with splints or casts (Figure 86-10, *A*).[6,8] The purpose of these devices is to maintain the limb in proper alignment and to allow the inadequately ossified cartilage template to ossify sufficiently and facilitate weight-bearing without detrimental consequences.[9] It is of paramount importance that the cast or splint end at the fetlock. If the foot is incorporated in the splint, the musculotendinous flexor and extensor units weaken, resulting in a dropped fetlock and osteopenia. In most cases, this problem is temporary, but it should

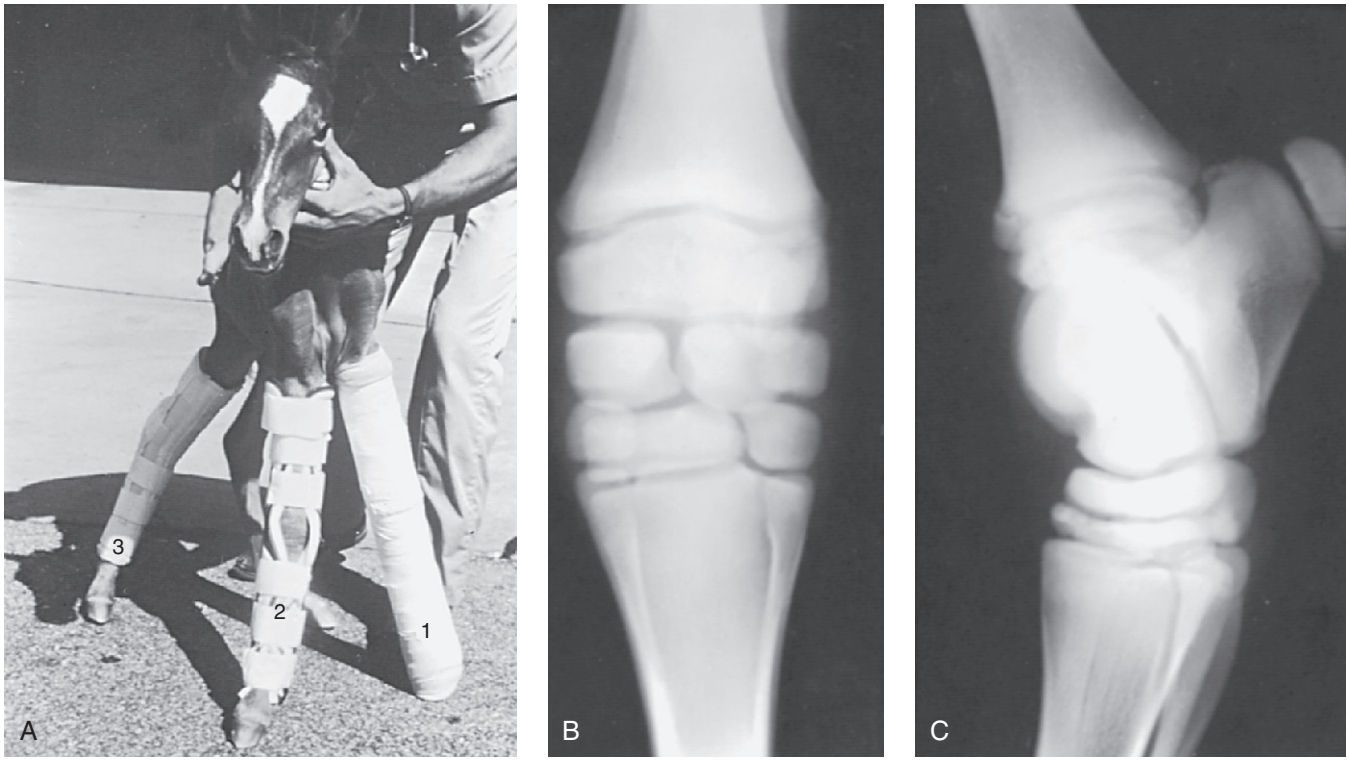

Figure 86-10. The foal mentioned in Figure 86-2 at 2 days of age. **A,** Splints are applied to three limbs. A polyvinylchloride (PVC) pipe splint is applied to the left forelimb (*1*). The PVC pipe is centered over the carpal region and reaches distad to the hoof because the animal also suffered from a ruptured common digital extensor tendon in that limb. The total limb is incorporated in the bandage. A commercial splint (*2*) is applied to the right forelimb. The splint is fastened with Velcro straps and contains medial and lateral metal strips for support. The right tarsal region is also splinted with a commercial splint (*3*). This splint is of the same material as the forelimb splint (*2*). Note that the commercial splints do not incorporate the phalanges. **B** and **C,** Radiographs carried out 30 days after the original radiographs. The dorsopalmar view of the carpal **(B)** and lateromedial view of the tarsal **(C)** regions show increased ossification compared with the previous radiographs. Ossification was sufficient to allow the foal to go without splints. The foal was maintained in bandages, kept in a stall for an additional week, and then turned out.

be prevented because it may lead to additional orthopedic problems. The limb should be well padded before splint or cast application. The splint is changed every 3 to 4 days, and dry padding is placed next to the limb. Casts should be changed between 10 and 14 days after application. Leaving the cast on for too long results in skin damage because of the rapid growth of young foals. The radiographic evaluation is repeated at 2-week intervals and the change in degree of ossification is determined.

Casts and splints should be maintained as long as incomplete ossification is present. Depending on the degree of ossification at the time of birth, this may take 2 to 4 weeks (Figure 86-10, *B* and *C*). In twin foals, it may be continued for up to 2 months of age.

While the limb is under a cast or splint, the flexor carpi ulnaris and the ulnaris lateralis muscles are immobilized and become flaccid. This results in a temporary calf-kneed conformation immediately after the cast is removed (see Chapter 87). However, with time, these defects correct as strength returns to the muscles. Daily swim therapy is beneficial and helps in rapidly overcoming this condition. It is important to keep the limb bandaged for an additional 4 to 5 days after the cast or splints are removed. Care must be taken to prevent development of pressure necrosis of the skin over the accessory carpal bone.

If radiographs demonstrate that the deformity is located within the distal radius or tibia and is not caused by laxity of the periarticular supporting structures or incomplete ossification, splints and casts are ineffective and, in fact, contraindicated. Application of such devices almost invariably results in pressure sores without correction of the deformity.

Aside from somewhat labor-intensive management with the help of polyvinyl chloride (PVC) half-shell splints, custom-fitted snap-on splints made of padded fiberglass (EnduraSplint 2) can be used.[29] These splints have enough strength for foals younger than 6 weeks of age. The foal is sedated and placed in lateral recumbency, and a rectal sleeve is placed over the limb to protect it from contact with water and polyurethane resin. The splint material is immersed in warm water (21° C to 23° C [69.8° F to 73.4° F]) until it is soft and pliable. Excess water is squeezed out and the splint is swiftly applied to the limb with the felt positioned against the skin and covering half of the circumference of the limb. It is secured to the limb with gauze and allowed to dry, with care taken not to flex the limb during the setting time. The splint is removed and allowed to set for 5 to 7 minutes before reapplying it to the limb. Because the splint is padded and molded to the contour of the limb, it is easy to place, and only a single roll of self-adhesive elastic tape is needed to secure it, making it convenient for daily use. In a hospital setting, it is recommended that the splint be left on for

Figure 86-11. A, A 1-day old foal with a slight varus deformity in the fetlock region. **B,** The same foal after application of a lateral toe plate.

12 hours at a time to prevent pressure sores; it should be applied at night while the foal is less active.[10] This is especially important if all four limbs are splinted, making it cumbersome for the foal to lie down and get up. Splinting two limbs for 12 hours at a time and alternating limbs during the following 12 hours may help the foal to cope with this situation. Assisting the foal manually in lying down and getting up several times a day is another option.

One study showed that foals with incomplete ossification of the tarsal bones and greater than 30% collapse of the third and central tarsal bones had a poorer outcome than did similar foals with less than 30% collapse, thereby stressing the importance of early recognition and treatment.[30]

Special custom-fitted hinged braces, which allow the foal to move the carpal and tarsal regions while maintaining correct axial alignment, have been introduced to the market (Farley brace, Redden brace).[31] Foals with incomplete ossification or laxity of the periarticular supporting structures can be successfully treated with these devices. Because these braces allow movement of the joints, this type of treatment is theoretically preferred over stiff splints or casts but is considerably more expensive. However, this is the only application of such braces in foals with ALD.

Hoof Manipulation

Corrective hoof trimming is a frequent conservative treatment of ALD. In valgus deformities, the outside half of the hoof wall is slightly shortened. This causes the inside half of the foot to contact the ground first, and during the process of placing weight on the entire foot, it rotates medially. This type of hoof trimming is carried out with a rasp in young foals. In contrast, for varus deformities and pigeon-toe conformation, the inside wall is slightly lowered. In young foals, this type of treatment may be beneficial as an adjunct therapy to a surgical technique and should be maintained for only a few weeks because of the danger of the development of an abnormal hoof shape and of interphalangeal joint osteoarthritis.

The application of foot plates or shoes with an extension to the inside or outside may assist in correcting the deformity (Figure 86-11). Additionally, these devices prevent excessive wear-down at certain areas of the foot. For valgus deformities, extensions are placed on the medial side of the foot, and for varus deformities, on the lateral side. It is important to fill the extensions placed on the medial aspect of the hoof with acrylic to prevent the foal from stepping onto the plate with the other foot.

Corrective hoof trimming should not be used as the sole treatment for significant ALD distant from the phalangeal region in older foals. By forcing the foot into an uncomfortable, abnormal position, torsional and stress forces are created that cause early degenerative changes of cartilage and periarticular structures. Therefore it is better to opt for surgical procedures at the location of the deformity than to try to bring about correction through altering the loading conditions of the entire limb up to the location of the deformity.

Surgical Techniques

The surgical techniques for correcting ALD are reviewed for the carpal region. As the various techniques are discussed, consideration is given to the other anatomic regions where these surgical procedures may be used.

Growth Acceleration

Since its introduction into equine surgery, periosteal transection and elevation (stripping) has gained universal acceptance.[5,7,8,9,32-34] Periosteal manipulation is performed on the concave aspect of the limb (e.g., in an animal with a valgus deformity in the carpal region, on the lateral side). The original technique described a 3-cm vertical skin incision between the common and lateral digital extensor tendons, starting from a point 4 to 5 cm proximal to the distal physis of the radius and continuing in a proximal direction (Figure 86-12, *A*). The incision is carried down to the periosteum. With a curved hemostatic forceps, the subcutaneous tissues and tendons are separated from the periosteum parallel to the physis and perpendicular to the skin incision at its distal border. The forceps is abducted, with its slightly spread tips pressing onto the bone. Under this protection, a curved scalpel blade (No. 12) is inserted craniad between the tips of the hemostatic forceps. Using moderate pressure, the scalpel blade is pulled back toward the level of the skin incision, transecting the periosteum. Once the blade has reached the lateral aspect of the bone, the incision is stopped. The same procedures are repeated on the caudal aspect of the distal radius. The hemostat is first advanced to separate the lateral digital extensor tendon from the rudimentary ulna and then is redirected to a frontal plane to reach the caudal aspect of the distal radius. The scalpel blade is inserted under the protection of the forceps, and the periosteum, including the rudimentary ulna, is transected as described earlier. The cranial and caudal incisions are connected. Because this transection severs the rete carpi volaris, marked bleeding occurs. The periosteum is then incised parallel to the skin incision in a proximal direction over a length of 2 cm, starting at the horizontal periosteal incision, to create an inverted T. The periosteal elevator is advanced at a 45-degree angle to the periosteal incisions underneath the periosteum to elevate two triangular flaps (Figure 86-12, *B*). Once elevated, the periosteum is gently laid back onto the bone to prevent the ends from curling, which could result in abnormal new bone formation. The subcutaneous tissues are closed in a simple-continuous suture pattern, using 2-0 absorbable suture material, followed by a simple-continuous intradermal suture line. This results in an acceptable cosmetic appearance of the surgical site.

In about 20% of all cases, the rudimentary ulna is ossified and therefore has to be removed with rongeurs. It is important that the rudimentary ulna be transected, because it can act as a tethering mechanism and slow down growth at the concave aspect of the radius.

Postoperatively, a bandage, consisting of a nonadherent dressing (Telfa) and unfolded 4 × 4 gauze sponges, covered by an adhesive elastic bandage (Elastikon), is applied. The elastic tape is attached directly to the skin for a width of 2 cm proximal and distal to the gauze sponges. The bandage is replaced 3 days postoperatively. The second bandage may stay in place for an additional week before it is removed. Because the skin sutures are placed below the surface (intradermally), they do not have to be removed. It is advisable to keep the animal in a stall for 2 to 3 weeks and to allow minimal exercise during that time.

Postoperatively, the outside of the feet (in a valgus deformity) are rasped slightly every 2 weeks to assist in correction of the outward rotation of the feet and straightening of the limbs.

The surgery can be carried out in a foal as young as 2 weeks of age. The earlier the surgery is performed, the faster the correction occurs (Figure 86-13). However, opting for surgical intervention at such an early age may include foals in which the deformity would have corrected spontaneously if the animal was allowed stall rest. Therefore foals should be selected for this surgery after 4 weeks of age, unless the ALD is severe (greater than 10 degrees).

The landmarks for periosteal transection at the distal MCIII/MTIII are the distalmost aspect of the metaphysis of MCIII/MTIII or MCIV/MTIV and, depending on the location of the concavity of the deformed bone, the medial or lateral aspect of the bone (see Figure 86-12, *B*). Care should be taken not to enter the palmar or plantar outpouching of the MCP/MTP joint. These surgical interventions must be performed before 3 months of age, because after that there is only limited growth at the distal physis of MCIII/MTIII.[26] The periosteum at the surgical site of MCIII/MTIII is markedly thinner than that of the distal radius or tibia.[8]

Surgery at the proximal phalanx should be carried out at the level where the extensor branch of the suspensory ligament curves over the lateral or medial aspect of the bone (see Figure 86-12, *B*).[34] On this bone, the periosteal incisions are T-shaped, with the horizontal incision about 1 cm distal to the physis and the vertical incision in a distal direction. At the palmar or plantar aspect of the horizontal incision, some attachments of the oblique distal sesamoidean ligaments will be transected. This appears to present no serious consequences but can result in minor new bone formation that resolves with time.

The surgical approach for the distal tibia is either cranial or caudal to the lateral digital extensor tendon (see Figure 86-12, *C*). The rest of the procedure is carried out in a fashion analogous to that described for the distal radius. It is interesting to note that the periosteum in that area is thicker than that at any other surgical site discussed earlier.

"Bench knees" are a frequently encountered conformational defect that may continue to develop after 1 year of age.[31,35,36] These conformational defects are the result of two opposing ALDs—a valgus deformity at the distal radius and a varus deformity of the proximal third of MCIII (Figure 86-14, *A*).[8,31,36] The limb has a straight appearance in the presence of bench-kneed (off-set) conformation. If this conformational defect is diagnosed within the first 2 months of life, the deformities can be successfully treated with periosteal transection at the distal lateral aspect of the radius and the medial aspect of the distal metaphysis of MCIII (Figure 86-14, *B*).[31,36] Periosteal stripping over the total length of MCIII/MTIII using an I-shaped incision (see Figure 86-12, *D*) is also effective in correcting diaphyseal or metaphyseal deformities of that bone in foals younger than 2 months.[32]

Periosteal transection has its effect for approximately 2 months, which corresponds to the time needed to fill in the defect between the transected ends of the periosteum.[31,36] A prolonged effect is achieved through surgical excision of the elevated triangular flaps. Periosteal transection can be repeated if complete correction is not achieved. Overcorrection of the deformity does not occur.

It has been shown that periosteal transection carried out when the ALD is located within the carpus also corrects malformation of these bones to some degree.[37,38] Nevertheless, such problems should be recognized earlier and the incomplete ossification treated during the immediate postnatal period, as described previously. However, surgery accelerates correction even in these cases, allowing the foals pasture exercise at an

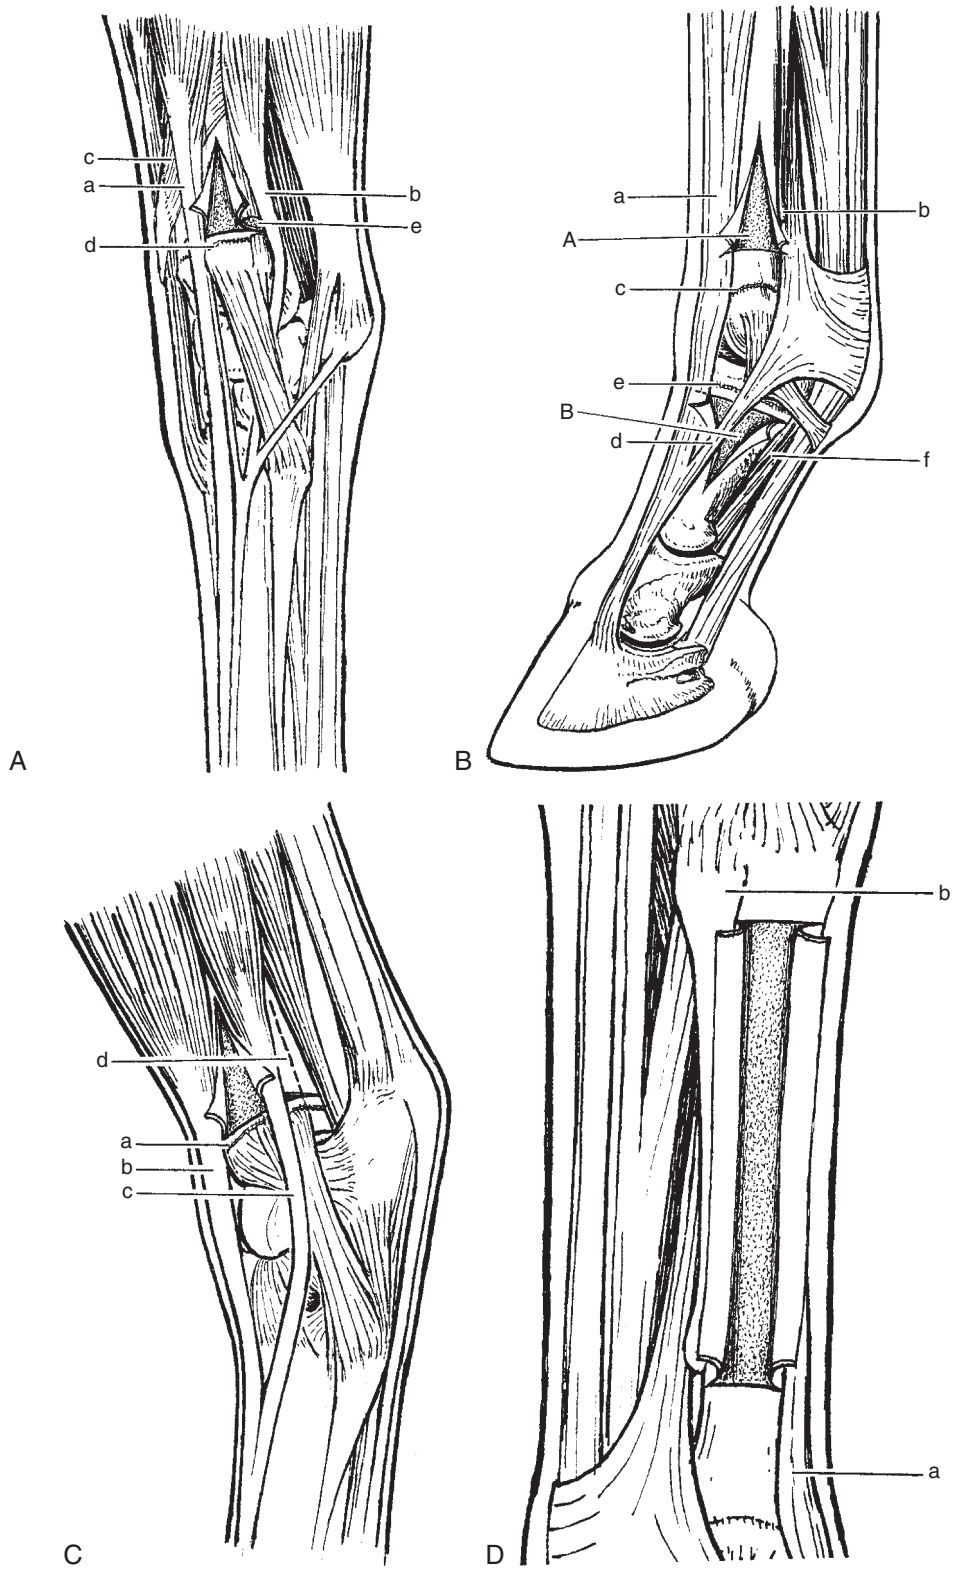

Figure 86-12. Locations at which growth acceleration may be carried out. earlier age while preventing the development of additional deformities farther distad (e.g., digit, hoof).

Periosteal transection and elevation are routinely carried out on an outpatient basis, with the mare and foal returning home immediately after recovery from surgery. The most critical location for early diagnosis and surgery is the distal MCIII/MTIII, because longitudinal growth of MCIII/MTIII occurs mainly during the first 3 months after birth.[26] Later on, growth occurs at a very slow pace, and delaying surgery leads to incomplete correction. Additionally, the prolonged abnormal loading of the metacarpophalangeal joints leads to the development of compensatory deformities in the proximal phalanx.[31,32] Thus the limb may appear to be straight, but when the foal walks, an outward rotation is noted. This is caused by the orientation of the articular surfaces, which are not parallel to the ground (Figure 86-15).

During the first weeks of life, affected foals show an outward rotation of the carpal region while their feet point straight forward (see Figure 86-8, *B*). At that point, an actual varus deformity is hard to detect, especially for an inexperienced clinician. With time, the deformity is aggravated, making diagnosis easy but surgery difficult.

The effectiveness of hemi-circumferential periosteal transection and elevation in treating ALD was questioned after reviewing the results of a controlled study, where temporary transphyseal bridging was performed on the lateral aspect of the distal radius to induce a carpal valgus ALD of 15 degrees in normal young foals.[39,40] At the time of implant removal, the foals were divided into two groups. One group was subjected to an immediate hemi-circumferential periosteal transection and elevation on the same lateral aspect of the distal radius, whereas the other group underwent a sham surgical procedure at the same site to mimic the hemi-circumferential periosteal transection and elevation procedure. In both groups, the deformity corrected, leading to the erroneous conclusion that periosteal transection and elevation was ineffective. Three facts might explain the results: (1) the deformity was induced artificially through manipulation of the physis, (2) a clinical case with a carpal valgus deformity of 15 degrees does not correct without surgery, and (3) physeal growth is influenced by mechanical load, which in turn triggers signal molecules in a feedback loop between the cells of the different cartilage zones and the perichondrium or periosteum of the limb involved.[41] This regulatory mechanism of signaling molecules was triggered at the time of initial surgery, when the periosteum was disturbed, and it was accentuated by the second surgery, performed to remove the implants. Periosteal transection could not be expected to further trigger this cascade. Therefore the assumption that differences should be seen between groups was wrong.

The results of a recent study indicate that periosteal stripping caused an upregulation of Ihh in the early prehypertrophic and hypertrophic zone of the growth plate, followed by an increase of PTHrP, mainly in the perichondrium. In contrast, an increase of parathyroid hormone receptors (PTHR) was noticed in all zones, although it was highest in the perichondrium and the hypertrophic zones.[16,38] FGF and TGFs were upregulated in all zones, but FGF in response to periosteal stripping was more intensely expressed in the proliferatve zone, and the highest peak of TGF was found in the perichondrium. Length measurements of the various zones revealed significant negative correlations between the proliferative and prehypertrophic and hypertrophic zones, an indication that indeed a negative

feedback loop after periosteal stripping exists, coupled with the Ihh/PTHrP/PTHR cascade. The hypothesis that periosteal stripping had an effect on the Ihh/PTHrP/PTHR–related feedback loop in epiphyseal growth was confirmed in this experimental study in lambs.[16] Since these mechanisms are very basic and similar in most species, it can be safely assumed that the effects in foals are similar. In fact, the asymmetric mechanical load in animals suffering from axial limb deformities may even increase the enhancing effect of length correction.[16] Additional work is needed on foals to lay to rest the discussion on effectiveness once and for all.

Modifications of the technique have been described.[42-44] One modification involves minimization of the surgical approach at the same location described originally.[42] The skin incision is performed horizontally down to the bone over 1 cm, followed by a vertical 1-cm incision. This reduction in incision size improves the cosmetic appearance of the surgical intervention. In one study, different approaches to periosteal manipulations in addition to hoof manipulations were evaluated in young foals on a large beeding farm. Ten foals with up to three deformities, mainly of the distal MCIII/MTIII, were randomly assigned to one of eight groups.[42] Each group was treated with a different technique, varying from the technique described earlier,[42] to a transcutaneous horizontal incision conducted by rolling the skin from the dorsomedial aspect of the bone to the palmarolateral/plantarolateral aspect while simultaneously cutting the periosteum with a No. 12 scalpel blade (Figure 86-16), to ligation of an afferent epiphyseal vessel, and juxtaepiphyseal injection of PTH-containing hydrogel. All deformities corrected clinically within 2 months.[43] Another study revealed that multiple insertions of a hypodermic needle into the physis at the concave side lead to correction of the deformity.[44]

These results further verify that periosteal manipulations are effective in correcting angular limb deformities and that a less-traumatic approach leads to good correction as well.[43] I currently use the transcutaneous approach exclusively in young foals. PTH gel may also have interesting applications in human surgery. It represents the least-invasive technique but has two drawbacks: high expense and limited shelf life of the PTH gel.[43]

Growth Retardation

Growth retardation is performed either in young foals (less than 3 months of age) with severe ALD or in foals with significant ALD in a bone after the rapid growth phase is over (MCIII/MTIII and proximal phalanx after 2 months, tibia after 4 months, radius after 6 months).[8,26] Most of the techniques described for growth retardation use the same principle. Implants, applied on the convex aspect of the bone, bridge the physis temporarily,

Figure 86-16. Transcutaneous periosteal transection technique. The skin over the distal medial MCIII/MTIII is rolled with the thumb palmarly. The pointed scalpel blade is inserted through the skin down onto the bone surface, and both the scalpel and skin are pulled in a dorsal direction. This technique allows horizintal transection of the metaphyseal periosteum and afferent physeal vessel through a 1- to 2-mm skin incision that does not have to be sutured.

allowing the shorter aspect of the bone to continue to grow, eventually correcting the deformity.

Stapling was the first technique of growth retardation described in the foal.[45] The surgery is performed in some clinics with favorable results but is not discussed here because it has fallen into disfavor. Complications include implant and correction failures. Despite these drawbacks, a report on how to prepare, place, and remove self-made staples was published.[46]

Screws and cerclage wires are the most frequently applied implants.* Implants are inserted through two stab incisions, one in the center of the epiphysis and the other proximal to the physis (Figure 86-17, *A*). The soft tissues between these incisions are elevated with a hemostat (Figure 86-17, *B*). A 4.5-mm cortex screw is inserted through each incision but not completely tightened (Figure 86-17, *C*). A wire loop is inserted through the proximal incision and hooked over the distal screw head (Figure 86-17, *D*). The two wire ends are twisted together and tightened over the proximal screw head (Figure 86-17, *E*). Twisting the wire ends over the proximal screw rather than the distal screw results in less irritation of the surrounding soft tissues and produces a better cosmetic result. If deemed necessary, a second figure-of-eight wire loop can be applied. The screws are tightened completely, which increases wire tension as the wires ride up on the shoulder of the screw heads. The stab incisions are then closed with two simple-interrupted skin sutures, and the area is protected with a light bandage for approximately 10 days. Sutures can be removed by the referring veterinarian. In foals with minor ALDs and laterally rotated forelimbs, surgery may be delayed for some time. However, foals

with carpal valgus deformity and feet pointing straight forward (fetlock varus deformity) should be treated immediately by applying a growth retardation procedure to the lateral aspect of the distal MCIII/MTIII to prevent development of a toed-in conformation. Implant insertion through two stab incisions improves the overall cosmetic result considerably, compared with the large incision initially used.

Implantation of a transphyseal screw has been described as a method of retarding growth (Figure 86-18).[47] The cortex screw is inserted using a position screw technique from the metaphysis across the physis into the epiphysis to arrest growth in that region. The major application is the distal MCIII/MTIII. The screws are removed when the desired conformation is reached. Some caution is indicated when the screw is applied in the distal radius and tibia, because of the potential development of a physitis. The reason the distal MCIII/MTIII is not affected by the potential development of physitis is attributed to the early closure of their physis (approximately 4 months). The advantages of the single transphyseal screw technique are ease of insertion and the improved cosmesis. A study comparing the results of transphyseal bridging using screws and wires (253 foals in 2003) to the use of a single transphyseal screw (315 foals in 2005) revealed that both techniques represent viable options. However, foals treated with a single transphyseal screw had a significantly higher risk of developing physitis or metaphyseal collapse compared to the ones treated with screws and wire.[48] Another study revealed no deleterious effects on sales or racing performance of 2- and 3-year-old Throroughbreds after the use of a single transarticular screw in the lateral aspect of the distal radius for the treatment of carpal varus deformities.[49] Varus deformities are usually recognized later in life, when the growth potential is already reduced, decreasing the risk for developing a physitis. I still prefer the screw and wire technique for growth retardation of a carpal valgus deformity.

The use of an absorbable screw has been described for MCIII/MTIII.[50] Because this screw was meant to stay in place, a slightly different implantation technique was applied. The periosteum was elevated at 15 mm proximad to the lateral physis. A 5.5-mm drill bit was used to create a glide hole of 5-mm depth. A 3.5-mm drill bit was subsequently seated in the glide hole at a 70-degree angle relative to the physis to prepare the thread hole of 40- to 45-mm depth. A countersink was used to ensure that the screw could be placed without bending forces developing during insertion of the screw head. After the length of the hole was determined and the prepared hole was tapped, a slightly shorter screw than measured (Smart Screw) was inserted and carefully tightened. The periosteum, subcutaneous tissues, and skin were closed in routine manner. ALD was corrected in all six foals treated and none developed complications, such as foreign body reaction or infection. The fact that the screw does not need to be removed is viewed as an advantage.[50] The price for the single screw is considerably higher than for a cortex screw, but because screw removal is not necessary, it adds up to approximately the same overall cost.

A small, 2.7-mm bone plate can be used to correct ALD in older foals. The last hole on each side of the plate is enlarged to accept a 3.5-mm cortex screw.[8,9] This technique provides an excellent cosmetic appearance of the limb. The surgical approach consists of either a slightly curved incision centered over the physis or a stab incision on either side of the physis. The distal stab incision is carried out parallel to the fibers of the collateral ligament. A 2.5-mm hole is drilled and tapped into the physis parallel to the joint surface, which is readily palpable. A 2.7-mm bone plate of adequate length is manually contoured to the shape of the bone and slid through the proximal stab incision distad, where the 3.5-mm screw of about 26 mm in length is inserted through the distal hole of the plate. An additional hole of the same diameter is drilled about 1 mm proximal to the last hole of the plate into the radial metaphysis. The hole is tapped, and the second screw is inserted into the hole. Both screws are tightened alternately until they are completely inserted into the bone (Figure 86-19). It is important that the distal screw be tightened completely to prevent it from protruding into the collateral ligament. The skin incisions are closed with simple-interrupted sutures. Radiographic evaluations should be carried out at monthly intervals to determine the correct time of implant removal and to prevent overcorrection of the deformity.

Growth retardation procedures also may be performed in the distal MCIII/MTIII, the proximal phalanx, and the distal tibia.[5,8,9] It is important to evaluate the anatomic situation at each location. This is especially important for the distal tibia, where the epiphysis has an undulating configuration and the distal screw has to be inserted in a mediodistal to lateroproximal direction to avoid penetration of the joint.[5,8,9] A short screw is used to prevent penetration of the physis. However, the screw is at such a favorable angle, relative to the direction of the tension, that a short screw (22 mm) has adequate holding power. The proximal screw is easily inserted as previously described. A retrospective study on 39 foals evaluating the response to various

Figure 86-19. A, A 2-week-old Warmblood foal with a severe bilateral carpus valgus deformity. **B,** Preoperative craniocaudal radiographic view of the carpal region. Note the physeal ectasia located at the medial aspect of the distal radial metaphysis *(arrows).* **C,** Ten-week follow-up craniocaudal radiographic views of both carpal regions showing correction of the deformity. Note the severe bending of the cancellous 3.5-mm screws in the epiphysis. The implants were removed, and the animal was discharged. The lateral aspect of the distal radius shows some degenerative changes.

treatments and long-term outcome of foals with tarsal valgus deformities revealed that 22 foals (56%) had concomitant incomplete ossification of the tarsal bones.[51] Eight of 19 foals with tarsal valgus deformities that were treated with periosteal stripping responded favorably. Younger foals (60 days or younger) were significantly more likely to respond to periosteal stripping than older foals. Eleven of 21 foals with long-term follow-up performed as intended. Because foals with more-severe incomplete ossification of the tarsal bones respond poorly to periosteal stripping alone, treatment by growth retardation was recommended.[51]

Once the correction is complete and verified radiographically, the implants must be removed through stab incisions over the screw heads, with the horse under short-term anesthesia.[8,9] The exact location of the screw heads is easily determined radiographically. It is important to be sure that the screwdriver is correctly seated in the hexagonal indentation in the screw head. Otherwise, the screw head can be stripped, making removal with a screwdriver difficult or impossible.[8,9] In that case, a screw-removal device (see Figure 76-16) should be used to remove the screws. The plate or wire is then removed through the proximal stab incision by introducing a curved hemostatic forceps into

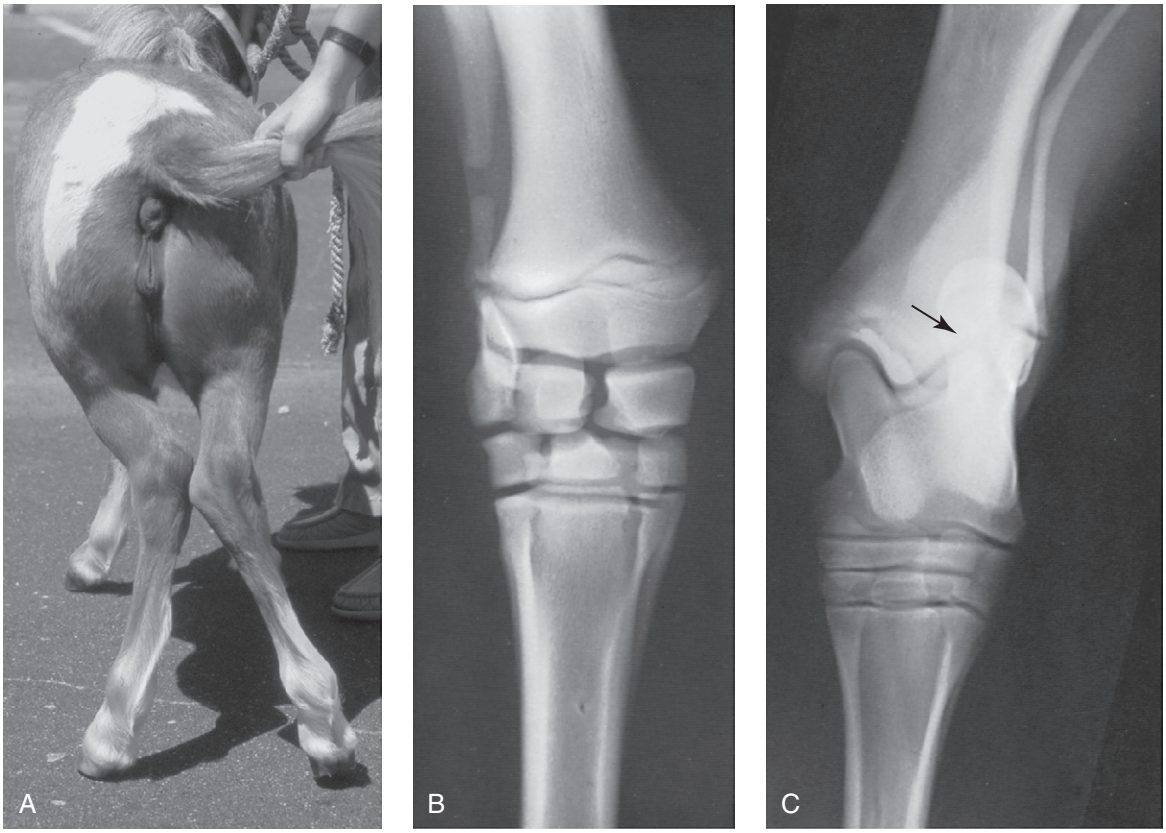

Figure 86-20. A, A 5-month-old Miniature Horse with severe tarsal valgus deformities in both rear limbs. the hole and walking it off the edge of the hole in the bone, engaging the implant and pulling it through the incision. The stab incisions are closed using 2-0 absorbable suture material in a simple-interrupted pattern.

If implants are inserted in both forelimbs, it is important to remove the implants when each limb is straight. Waiting until both limbs are straight invariably results in overcorrection of one or undercorrection of the other limb. Implant removal can be carried out on an outpatient basis. Antibiotics are not routinely used.

As with growth acceleration, signal molecules from the proliferating and prehypertrophic zone in combination with the perichondrium are involved in retardation of the growth plate. It was shown in rats that compressing the growth plate using surgical staples changed the feedback loop of PTHrP and Ihh, so that the prehypertrophic chondrocytes were pushed toward the osteogenic lineage, enhancing osteochondral ossification.[52] After stapling, the Ihh and Ptc1 molecules were modestly upregulated at 3 days, whereas BMP-2 and BMP-6 were inhibited.

An alternative nonsurgical approach of local growth retardation has been proposed.[53] Using a radial shock wave generator at 3 bar, 15 Hz, and 2000 cycles with a 15-mm applicator, weekly treatment sessions were conducted at the convex aspect of the deformed bone on the sedated foals. Straightening of the limbs occurred between 15 and 76 days with a median of 25 days.[53] No explanation of mechanism of action has been offered.

Combination of Growth Acceleration and Retardation

In severe ALD, growth acceleration and growth retardation procedures are combined for a faster and more complete correction.[8,9] By combining the two techniques, there is a possibility that the deformity can be completely corrected. The advantage of using implants is that they can stay in place as long as they are needed, in contrast to periosteal transection, which has a time-limited effect.

In Miniature Horses, ALD is frequently diagnosed (Figure 86-20, *A*). The presence of complete ulnas and fibulas is the predominant cause of ALD in this species and can be judged as an atavism (Figure 86-20, *B* and *C*). Early recognition of the problem is important in these animals. Miniature Horses have less growth potential than regular horses; therefore, a 5-month-old foal with a moderate ALD will not achieve correction, even if growth acceleration and retardation procedures are combined. It is important to remove a portion of both the ulna and the fibula at the time of periosteal transection. However, the distal epiphyses of the complete fibula and the tibia are not united, and the continuous movement at their junction may result in abnormal development of the lateral trochlear ridge of the talus and associated osteoarthritis (see Figure 86-20).[54] This problem is not as severe in the carpal region because of the architecture of the distal radius. In selected cases, transfixation of the distal fibular styloid process to the distal tibial epiphysis or metaphysis, or both, is needed to stop movement at the level of the joint. To insert the screws through the distal fibular

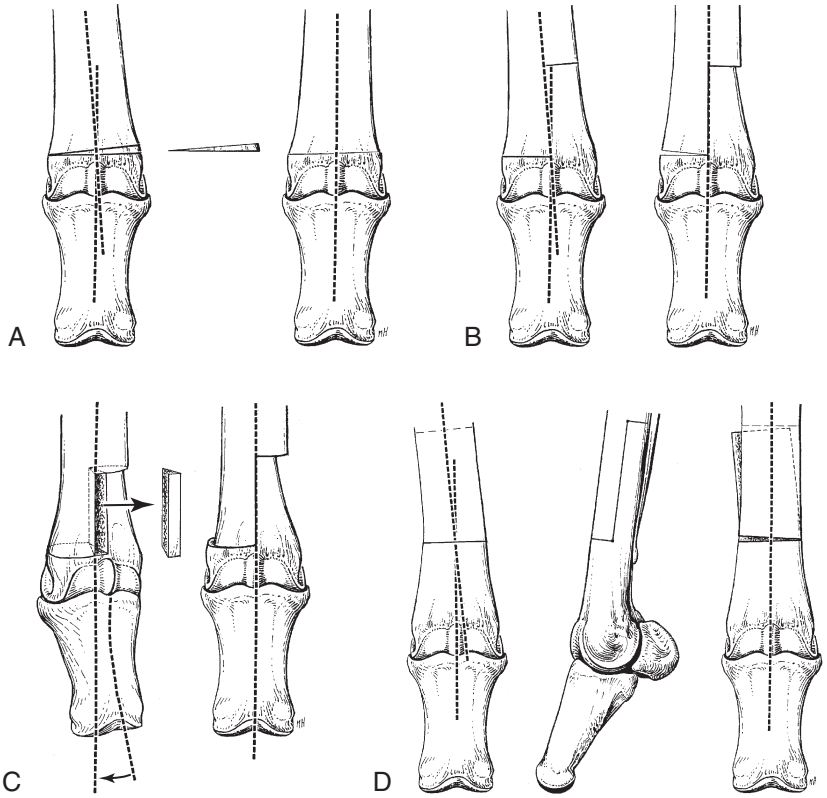

Figure 86-21. A, Closing wedge ostectomy. The bone wedge is removed from the horizontal plane near the physeal region. **B,** Step ostectomy. The wedge is removed from the center of MCIII in the sagittal plane. **C,** Derotational step ostectomy. By removing a vertical wedge with its wide aspect located either dorsally or in a palmar direction, a rotational deformity can be corrected. **D,** Step osteotomy. The Z-plasty is performed in the frontal plane, and the fragments are rotated into alignment.

metaphysis into the tibia, position screw technique (not lag technique) (see Chapter 76) should be applied to prevent alteration of the articular geometry.

Corrective Osteotomy/Ostectomy

Two types of ostectomy have been described in the literature: the closing wedge and the step. Closing wedge ostectomies (Figure 86-21, *A*) have been used for correction of diaphyseal and metaphyseal/epiphyseal ALD in foals with closed growth plates.[55,56] However, the step ostectomy carried out in the sagittal plane and the step osteotomy carried out in the frontal plane are presently the preferred techniques and are discussed here.[57,58]

The skin incision is carried out over the lateral digital extensor tendon from the top of the MCIII/MTIII to the distal physis. At that point, the incision is continued medially (in a varus deformity) or laterally (in a valgus deformity) toward the MCP joint. The lateral digital extensor tendon together with the periosteum is split longitudinally. Subperiosteal dissection is carried out to gain access to the dorsal aspect of MCIII/MTIII. At the level of the proposed Z-shaped osteotomy, the periosteum is elevated circumferentially around the bone.

The step ostectomy in the sagittal plane removes a vertical wedge from the center of the bone (Figure 86-21, B).[57,58]

The pivot point, which was previously established on radiographs (Figure 86-22, *A*) by drawing the longitudinal bisecting lines through MCIII/MTIII and the phalanges, respectively, is identified relative to proper landmarks, and a 3.2-mm hole is drilled across the bone. A second hole is prepared parallel to the first one, approximately 4 cm farther proximad. The oscillating saw is used to cut between the two drill holes across the bone. The previously prepared and sterilized aluminum template with the appropriate angle of the wedge to be removed is laid with one limb parallel to the saw cut and compared with the bisecting lines on the radiograph. A second saw cut is then made along the second limb of the template and parallel to the first one in the sagittal plane. The Z-shaped osteotomy is completed with the proximal cut through the thinner portion of MCIII/ MTIII (lateral in a varus deformity) and the distal cut across the opposite side of the bone in a horizontal plane, parallel to the physis. The wedge is removed, and the two bone fragments are rotated into alignment. Final adjustments are made to ensure complete correction of the deformity and bone-on-bone contact at the palmar/plantar aspect of the bone. If an additional rotational deformity is present, it can be corrected at that point by removing an additional bone wedge from the palmar or dorsal aspect of the bone (see Figure 86-21, *C*). Cortex screws are applied in lag fashion across the vertical section of the cut to reunite the two fragments of the bone. A bone plate is subsequently applied medially (in a varus deformity) or laterally (in a valgus deformity) to the bone, and along the vertical cut the screws are inserted in lag fashion (see Figure 86-22, *B* and *C*). The gap at the distal aspect of the osteotomy may be filled with some bone from the removed wedge as a cortical bone graft. The first row of sutures is placed into the split lateral digital extensor tendon using 2-0 absorbable suture material in a simple-continuous pattern. The subcutaneous tissues are closed, followed by intradermal closure of the skin, as previously described. In selected cases, skin sutures are applied.

Postoperatively, the limb is bandaged and supported by a splint or a cast for a few weeks. A cast would be applied in an adult horse, an excitable horse, or a foal whose step osteotomy

A, Dorsopalmar radiograph and diagram of the distal MCIII region with a varus deformity in an Arabian foal. **A1,** The preoperative drawing shows the 10-degree wedge to be removed from the center of MCIII. **B,** Intraoperative radiograph of the corrected deviation showing a 7-hole dynamic compression plate applied to MCIII with five screws inserted. The second and third screws from the bottom were inserted in lag fashion across the vertical aspect of the step osteotomy. The gap underneath the plate was filled with bone obtained from the wedge that was removed. The remaining screws were inserted through the plate, and an additional lag screw was placed across the vertical saw cut. **C,** Six-month follow-up radiograph of the corrected deformity. Note the excellent cosmetic result. The implants were subsequently removed. (From Auer JA: Step Osteotomy/Ostectomy for Angular Limb Deformities. p. 329. In White NA II, Moore JN (eds): Current Practice of Equine Surgery. Saunders, Philadelphia, 1990.)

was carried out near the physis, allowing only a limited number of screws in the distal fragment.

The holes drilled at the proximal and distal ends of the vertical saw cut reduce the concentration of stress at these locations and prevent postoperative fracture development.

The step osteotomy in the frontal plane is carried out similarly (see Figure 86-21, *D*).[57,58] Again, a Z-shaped osteotomy is performed across the bone, but this time the vertical cut is placed in the frontal plane. In this type of osteotomy, no bone wedge is actually removed. Once the Z-shaped osteotomy is completed, the two fragments are rotated in alignment. At that point, lag screws are inserted and a plate is applied to the bone's dorsal surface. Performing the saw cuts is somewhat more difficult with this technique; nevertheless, careful handling of the periosteum ensures no inadvertent damage to other structures.

Step osteotomies are most frequently carried out in MCIII and MTIII. However, in selected cases, they can be performed in the proximal phalanx or the radius.[56,57] The major advantages of a step ostectomy over a closing wedge ostectomy are maintenance of the bone length and the ability to create a lag effect across the vertical aspect of the saw cut and achieve good interfragmentary compression.[56,57] This cannot be accomplished in a closing wedge ostectomy. Also, the easy correction of rotational deformities is an advantage.

Step ostectomies are gaining in popularity, and a good prognosis can be given in many cases. The use of 5.5-mm bone screws is encouraged for these procedures.[57,58]

PROGNOSIS

Several studies have reported the response to both nonsurgical and surgical treatment of foals with angular limb deformities. One study reported that in 81.5% of foals treated with hemicircumferential periosteal transection and elevation (HCPTE) to correct angular deformities, total limb straightening was achieved and 60% of foals went on to be used at their intended performance level.[37,38] In a study that reported the results of transphyseal bridging, 80% of foals with carpal deformities and 27.3% of foals with metacarpophalangeal or metatarsophalangeal deformities went on to a form of athletic use.[26] The poor results obtained in the foals treated for metacarpophalangeal or metatarsophalangeal deformities were attributed to the fact that several of these foals were operated on near or after the end of the rapid growth phase of the distal third metacarpal or metatarsal growth plate. Racing performance after HCPTE in Thoroughbreds has been reported; treated foals had fewer starts at 2 years of age and lower start percentile ranks.[59] However, it is difficult to rely heavily on these comparison numbers, because many foals that have undergone surgery for ALDs are not declared as such in yearling sales. A study reporting the results of treatment in foals with tarsal valgus demonstrated that only 52.4% met the expectations of their intended use, and these authors concluded that foals with tarsal valgus have a poorer prognosis for future athletic use than do foals with carpal deformities.[34] Another study showed that foals with incomplete ossification of the tarsal bones and greater than 30% collapse of the third and central tarsal bones had a poorer outcome than did similar foals with less than 30% collapse, thereby stressing the importance of early recognition and treatment.[30]

Conflicting results regarding the significance of the location of the pivot point and the presence of radiographic abnormalities in cases of carpal deformities have been published.

According to one study, the more radiographic abnormalities that are seen distal to the distal radial physis and the more distal the location of the pivot point is, the poorer is the prognosis.[37] In another study, no such correlation could be made.[38] Also, it has been demonstrated that surgical manipulation of distal radial physeal growth can cause changes in the angles of all the carpal joints.[38] Thus surgical manipulation of physeal growth may be successful in correcting ALDs originating distal to the growth plate (e.g., epiphyseal deformities).

CHAPTER 87

Flexural Limb Deformities

Jessica A. Kidd

The complex problem of flexural limb deformities appears often in the equine veterinary literature,[1-5] and its treatment was documented as early as the fifth century AD in the *Mulomedicina* by Vegetius.[6] Flexural deformities are a common condition of growing horses in which a joint is held in an abnormally flexed or extended position. They affect soft tissue structures and occur in the sagittal plane, as opposed to angular limb deformities, which primarily affect osseous structures and occur in the frontal plane. Persistent hyperflexion has been termed *contracted tendons*, even though in most cases the tendon units are not actually contracted but are just functionally too short relative to the associated osseous structures.[7] *Contracted tendons* implies a defect in the tendon itself and is incorrect in light of the proposed pathogeneses; this term should consequently be avoided. Tendon contractions can occur as a result of scarring secondary to tendon injury; this is sometimes seen in adult horses but is rare in foals.[8] More broadly, hyperextension deformities are considered as part of the flexural deformity complex in this chapter.

By convention, a deformity is named according to the joint involved and not the tendon. Most often an animal suffers from one type of deformity only, but several areas can be affected in severe congenital flexural deformities. The forelimbs are more commonly affected, and the problem can be encountered in more than one limb at the same time. Flexural deformities present at birth are referred to as congenital deformities. Acquired flexural deformities develop during the remainder of the animal's life, although in typical age groups. Congenital flexural deformities most commonly affect the metacarpophalangeal (MCP) joint[9] or the carpal region. Much less commonly the tarsal region, metatarsophalangeal (MTP) joint, and distal and proximal interphalangeal (PIP) joints are affected. Congenital lateral luxation of the patella can also create a functional flexural deformity of the stifle (Figure 87-1).[10] Acquired flexural deformities affect the distal interphalangeal (DIP) joint and MCP joints most frequently, with the MTP and PIP joints less frequently affected.

CONGENITAL FLEXURAL DEFORMITIES

Pathogenesis

Factors responsible for the development of congenital flexural deformities are shown in Figure 87-2. Some causes mentioned are speculative and lack scientific evidence of their existence. Work is needed to understand the intricate details that lead to the development of such deformities.

Intrauterine malpositioning is a commonly mentioned cause of the problem.[11-13] This could actually be the case in an abnormally large foal relative to the size of the mare, where intrauterine crowding leads to development of the problem. This, however, is the exception to the rule. More likely, congenital flexural deformities are multifactorial in their origin and therefore difficult to explain.

Diseases acquired by the mare during pregnancy can lead to the development of flexural deformities in the foal *in utero*.[1] A multitude of agents and causes have been associated with the problem, including ingestion of locoweed and hybrid Sudan grass during pregnancy, a dominant gene mutation in a sire, equine goiter, an influenza outbreak, neuromuscular disorders, and defects in cross-linking of elastin and collagen caused by lathyrism.[1,14-20] A glycogen branching enzyme deficiency was recently documented in Quarter Horse foals, which caused transient flexural deformities.[21] The evidence in these cases may be only circumstantial, accentuating the need for further investigations into the development of congenital deformities.

Figure 87-1. A congenital flexural deformity of the stifle caused by luxation of the patella secondary to hypoplasia of the trochlear groove.

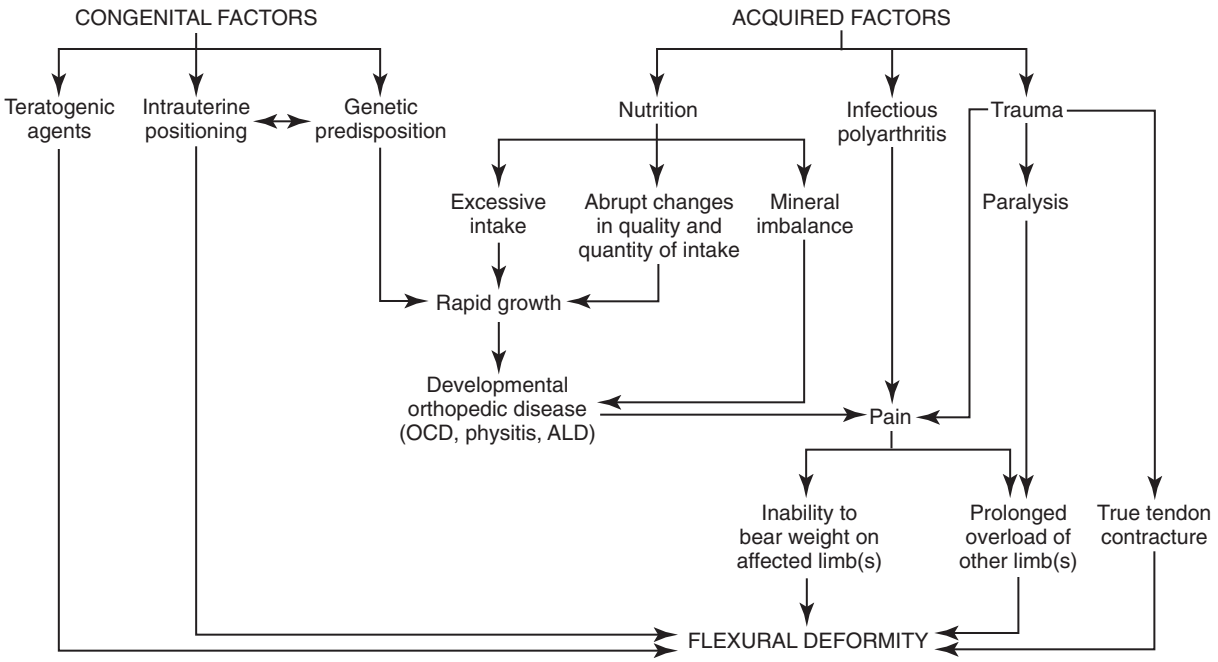

Figure 87-2. Interrelationship among the various congenital and acquired factors and their involvement in the development of flexural deformities. *ALD,* Angular limb deformities; *OCD,* osteochondrosis.

An early report stated that 20% of 608 fetuses and newborn foals submitted for necropsy suffered from miscellaneous limb contractures, which underscores the trend noted by clinicians that the incidence of flexural limb deformities is increasing.[22-24]

Diagnosis

A flexural limb deformity, whether a flexural or digital hyperextension deformity, is considered congenital when it is present at birth. The problem is easily recognized in most cases and should be evaluated by a veterinarian at that time.

Digital Hyperextension Deformities

Newborn foals can be presented with a mild degree of digital hyperextension (Figure 87-3). Such foals might be unable to maintain their toes on the ground; while standing, their MCP or MTP joints are angled more acutely than normal, and the animals are reluctant to ambulate. The problem is caused by flaccidity of the flexor muscles and usually corrects itself within a few weeks because of negative allometric growth of the tendons relative to the bones and increased muscle tone. In more severe cases, the foal walks on the palmar or plantar aspect of the phalangeal region (Figure 87-4), where skin lesions rapidly develop as a result of abnormal loading. These severe hyperextension deformities have to be distinguished from the milder forms, and the skin must be protected accordingly. Radiographic and ultrasonographic evaluations should not be necessary to diagnose the deformity because in most cases, no abnormalities will be found.

Flexural Deformities

Congenital flexural deformities may cause dystocia if they are severe enough[25] or the owner may report that the foal is unable to stand. Some flexural deformities may be overlooked in recumbent foals if the joints can be manually straightened, but they should become apparent once the foal is assisted to stand. Joints should be manipulated to see if manual straightening is possible.

Figure 87-3. A newborn foal with digital hyperextension in all four feet. Additionally a mild flexural deformity is present in both carpi.

DISTAL INTERPHALANGEAL REGION

Flexural deformities of the DIP joint are more common as an acquired deformity. A flexural deformity of the DIP joint seen at birth is usually associated with a flexural deformity of the fetlock.[10]

Figure 87-4. A premature foal showing severe digital hyperextension. The foal responded quickly to exercise restriction.

METACARPOPHALANGEAL/METATARSOPHALANGEAL REGION

Mild cases of MCP/MTP flexural deformities can be overlooked if the foal is examined in grass or deep bedding, whereas patients with more severe deformities may be unable to stand unassisted. Mild flexural deformities usually resolve spontaneously in 4 to 5 days with limited exercise. Patients that do not respond to conservative therapy can be splinted, treated medically, or both (Figure 87-5). One author reports that if there are no osseous changes to the joint or the joint can be manually straightened, the prognosis is good for all degrees of severity of MCP/MTP flexural deformities.[26,27] If the deformity is very severe, radiographs should be taken first to rule out abnormally formed bones, which decreases the prognosis to poor.[26]

CARPAL REGION

Carpal flexural deformities are usually bilateral, and in mild cases, the foal can stand but cannot completely straighten the carpi (Figure 87-6). Mild cases are usually self-correcting in 4 to 5 days with limited exercise, but if the deformity does not resolve spontaneously, other treatments may be instituted (see later). More severely affected patients may be unable to stand, and the common digital extensor tendon may rupture secondary to the flexural deformity (see later). If the limbs can be manually straightened (which may require sedation), the chance of resolution using splints or casts is good, but the prognosis is guarded if the carpus cannot be manually straightened.[26,28]

PROXIMAL INTERPHALANGEAL REGION

Congenital PIP joint flexural deformities are rarely reported and often involve both osseous and soft tissue abnormalities.[26] Cases may show subluxation of the PIP joint or ankylosis of the PIP joint in more severe cases.

TARSAL REGION

Congenital flexural deformities of the tarsal region are rare and are most often the result of incomplete ossification of the tarsal bones, resulting in a secondary flexural deformity. Cases must be identified before the bones are irretrievably damaged, after which time there is no effective treatment (see Chapter 86).

Figure 87-5. A congenital flexural deformity of the metatarsophalangeal joint. The foal responded to splinting, oxytetracycline administration, and analgesics.

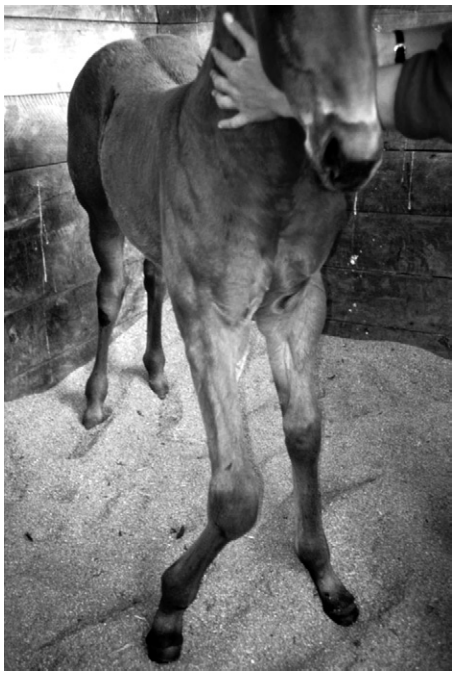

Figure 87-6. A flexural deformity of the carpus. The foal is unable to completely straighten the limb.

Radiography is indicated in these cases for this reason (Figure 87-7).

RUPTURED COMMON DIGITAL EXTENSOR TENDON

This relatively common congenital disorder has some pathognomonic features that simplify the diagnosis.[4,5,29] Affected foals display a characteristic swelling in the tendon sheath at the

Figure 87-7. A lateromedial radiographic view of a newborn foal with an anomaly of the tarsometatarsal joint. The small tarsal bones have collapsed through the subchondral bone plate of the proximal third metatarsal bone. Surgical correction in such a case is not possible or at least not feasible.

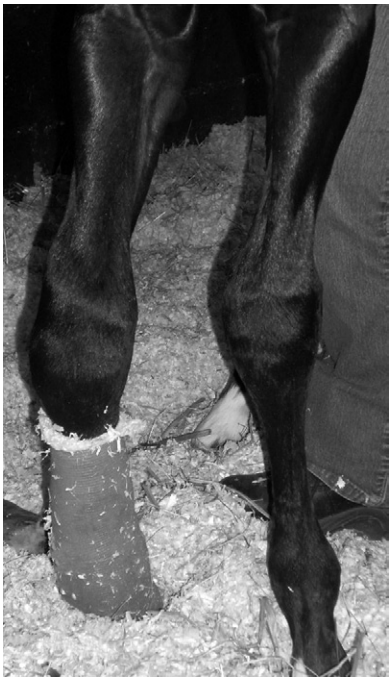

Figure 87-8. Rupture of the common digital extensor tendon in the right forelimb of a young foal, which can create the appearance of a flexural deformity. Note the characteristic bulge over the dorsolateral aspect of the carpus. The foal also has a moderate carpal valgus deformity in the left forelimb.

dorsolateral aspect of the carpus (Figure 87-8), which is recognized soon after birth, but in rare cases it is not evident for up to 3 weeks. Rupture of the common digital extensor tendon is often seen secondary to a flexural deformity and less commonly can lead to a flexural deformity.[30] The foal often has a slightly bowlegged and an over-at-the-knees stance. This stance is caused by the lack of support at the dorsolateral aspect of the carpus, which is normally conferred by the intact common digital extensor tendon. Therefore it is not truly a flexural deformity, but it clinically appears as one. The two ends of the partially or completely ruptured tendon can be palpated in the tendon sheath. With time, these ends proliferate, making their detection during palpation even easier.

During walking, affected animals throw their forelimbs forward, extend them completely, and retract them slightly before contacting the ground. A foal with a ruptured common digital extensor tendon often knuckles at the MCP joint during walking and might buckle in the carpal region while standing. In severe cases the foal may not be able to stand straight without knuckling forward (Figure 87-9).

Radiography for the Diagnosis

Flexural deformities, which can be diagnosed on the basis of clinical signs, do not need to be radiographed, but is useful to identify abnormalities that may alter the prognosis for correction of the deformity. Radiographs of carpal flexural deformities that cannot be manually straightened may reveal incomplete ossification or wedging of the carpal bones, decreasing the prognosis for correction. The same applies for the less common tarsal flexural deformities.

Figure 87-9. The same foal as in Figure 87-8. Because of a lack of extensor support, the foal was unable to walk without stumbling. Application of a distal limb splint improved the foal's ability to walk and support weight on the limb.

Treatment

Digital Hyperextension Deformities

Most foals with mild digital hyperextension do not need treatment other than minimal attention and trimming of the feet; the condition is self correcting.[31] Moderate exercise is indicated to strengthen the musculotendinous unit; therefore access to pasture is allowed. Excessive exercise is contraindicated because fatigue often aggravates the problem. The animals should be carefully observed, and if the problem worsens, further treatment should be promptly initiated. Severe digital hyperextension problems must be treated immediately, because neglect soon leads to necrosis and traumatization of the skin in the palmar or plantar phalangeal region and jeopardizes treatment.

SWIMMING

Swimming has been advocated as excellent controlled physiotherapy.[4] The animal is supported in a swimming pool or pond by one or two helpers or a rescue net (Figure 87-10). The paddling action of the foal in the water is carried out against the resistance of the water and without placing weight on the limbs. The resultant increase in muscle tone brings about rapid amelioration of symptoms.

FARRIERY

Trimming is often unnecessary, but the toe can be shortened with rasping and the palmar/plantar half of the foot also lightly rasped for increased contact with the ground.[31] In more severely affected foals in which the toe is lifted off the ground and the foal is ambulating on the palmar/plantar pastern, application of glue-on shoes or similar devices with palmar or plantar extensions helps maintain the hoof sole on the ground (Figure 87-11).[32] Ready-made or custom-made extensions are used; a cuff type of shoe is available (Dallmer cuff shoes), or the extension can be made from light aluminum, which is cut to shape, curved over the toe for contact, and attached with acrylic adhesive (Equilox) (Figure 87-12). Some farriers feel that any shoe should be attached with adhesive tape only in foals younger than 3 weeks to avoid heat trauma to the delicate foot and contracture of the heels.[31] Extensions are changed at 10 day intervals, although some foals dislodge the extensions before this. These devices constrict the foot and can deform the foot if left in place too long.

BANDAGING

Light bandaging of the phalangeal region is indicated to minimize skin trauma in foals that walk on the back of their pasterns, but the bandages should not be substantial enough to

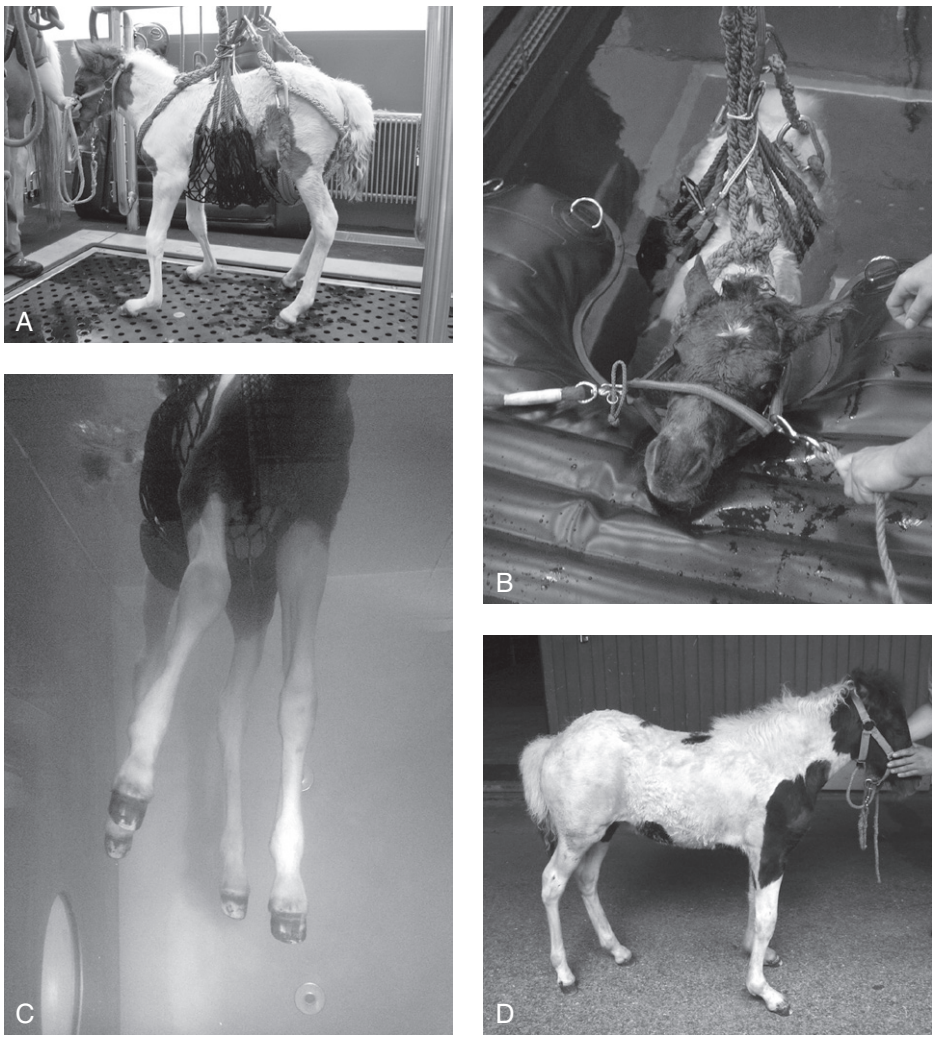

Figure 87-10. A, A 2-week-old Icelandic pony is shown with marked digital hyperextension in both forelimbs. The foal wears a rescue net and stands on a scissor table. **B,** The table was lowered into warm water so that the foal was immersed in it, protected by the rescue net, which was attached to a hoist. **C,** The foal is shown swimming and in doing so, effectively exercises its weak limb muscles. **D,** The same foal 4 weeks later. There is some improvement, but the fetlock angle is still hyperextended. (Courtesy J. Auer, Zurich, Switzerland.)

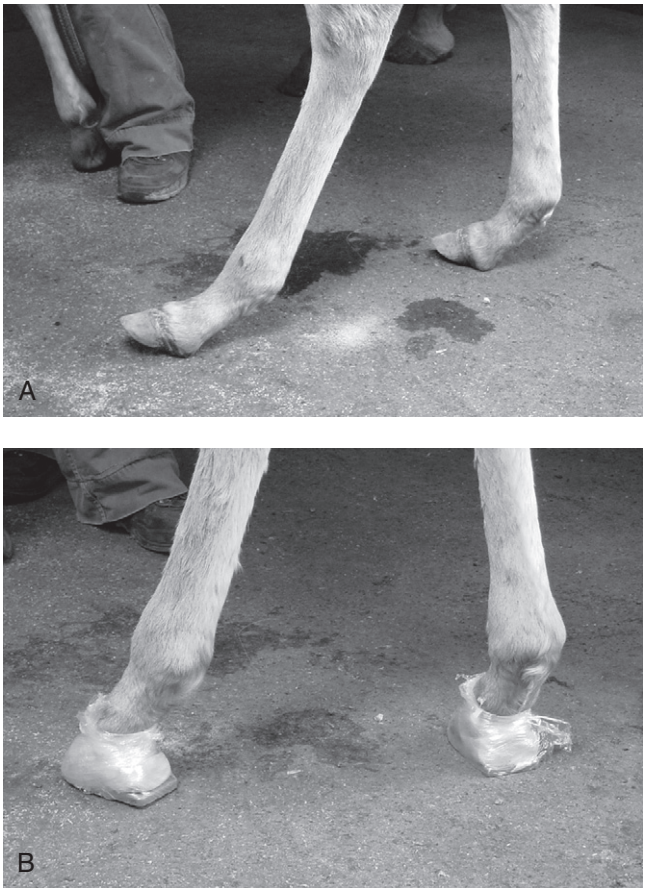

Figure 87-11. A, A newborn foal with marked digital hyperextension in the rear limbs. **B,** The same foal immediately after application of a pair of Dalric glue-on shoes with the clear plastic wrap ensuring good contact between the shoe and the hoof wall during the hardening process of the polymethyl methacrylate (PMMA) still in place. completely support the distal limb. Splint bandages and casts incorporating the foot are contraindicated because they totally support the distal limb, leading to a further loss of tone of the already hypotonic flexor tendon units. Additionally, development of pressure sores on the delicate skin is a common untoward sequela.

Application of some padding over the elongated braces attached to the foot will protect the palmar or plantar aspect of the phalangeal region, decrease the excessive hyperextension angle, and decrease the likelihood that the extensions will be dislodged by the mare or the foal (Figure 87-13). In addition to benefiting the cardiopulmonary system, daily swimming would strengthen the muscles, tendons, and ligaments, and in doing so they help to correct the deformity. Carefully dosed anti-inflammatory drugs are indicated to keep the foal comfortable.

SURGICAL MANAGEMENT

Tenoplasty has been described as a possible surgical management technique for severe digital hyperextension problems in small or miniature foal patients, but it is currently not recommended.[33]

Figure 87-12. Application of metal palmar extensions in a standing sedated foal with a severe digital hyperextension in the hind feet. The metal strips are curved over the toe and secured to the foot with acrylic.

Figure 87-13. A foal with marked digital hyperextension shod with metal palmar extensions, which have been covered with padding and elastic bandage to provide additional protection to the palmar pasterns and to prevent injury to the mare and foal from the metal extensions.

Flexural Deformities

NONSURGICAL MANAGEMENT

There are many available treatment modalities for the treatment of congenital flexural deformities and they can all be used in conjunction with one another. It is important to ascertain

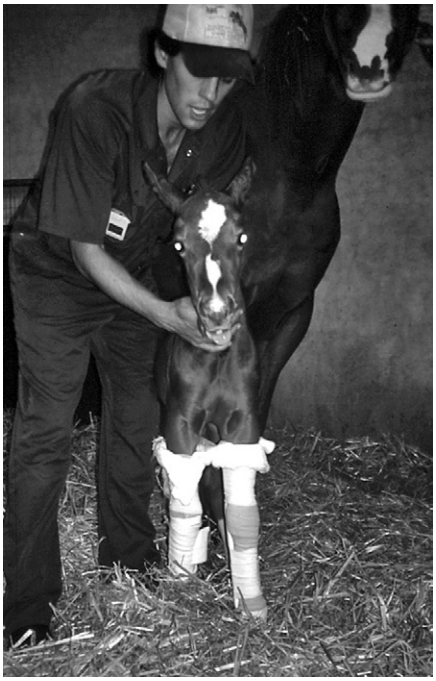

Figure 87-14. A foal with flexural deformities of both carpi, which were treated with application of splints, oxytetracycline, and analgesics. Because both forelimbs were splinted, the foal required assistance to stand but could walk in the splints unaided once it was upright.

whether the foal can stand without assistance, because in these cases, specific treatment is often not required.[30]

EXERCISE

Congenital flexural deformities are best treated with moderate exercise. In many cases, the foal is unwilling to stand and walk and needs regular encouragement to do so, especially if a cast or a splint is applied (Figure 87-14). The treatments discussed later can then be used singly or in combination.

ANALGESICS

Both the primary cause and the effects of treatment of flexural deformities may be painful, and affected foals should be treated with nonsteroidal anti-inflammatory drugs (NSAIDs). However, these drugs should be given judiciously because of the potentially detrimental side effects, including gastric ulceration and nephrotoxicity. Phenylbutazone at 1.1 mg/kg body weight IV or orally once a day or flunixin meglumine at 1.1 mg/kg IV or orally once daily are typically prescribed. Concurrent treatment with omeprazole (4 mg/kg orally once daily) or ranitidine (6.6 mg/kg orally three times a day, or 1.5 mg/kg IV three times a day) has been proposed as gastric protectants.[34] Ideally, biochemical monitoring of the foal's renal parameters (blood urea nitrogen, creatinine, and total protein) should be performed in these cases.

INTRAVENOUS OXYTETRACYCLINE

Administration of oxytetracycline has become popular as an initial treatment for congenital flexural deformities.[35] A single dose of 3 g oxytetracycline in 250 to 500 mL of physiologic saline is administered slowly by the intravenous route. The treatment may be repeated once or twice within the first weeks of life if necessary. Previously, it was thought to act by chelation of calcium and inhibition of muscle contraction, although intuitively, if this were the mechanism of action a more widespread effect on the body would be noted. A more recent *in vitro* study showed that oxytetracycline induced a dose-dependent inhibition of collagen gel contraction by equine myofibroblasts. Oxytetracycline also induced a dose-dependent decrease in matrix metalloproteinase 1 (MMP-1) mRNA expression by equine myofibroblasts.[36] Results of this study indicate that oxytetracycline inhibits tractional structuring of collagen fibrils by equine myofibroblasts through an MMP-1–mediated mechanism.[36]

In young foals, oxytetracycline administration can make the developing ligaments and tendons more susceptible to elongation during normal weight bearing, resulting in correction of the deformity within 24 to 48 hours. In a comparative study, the clinical effect of a single 44 mg/kg dose of intravenous oxytetracycline in normal foals and foals with flexural deformities was examined.[37] Treatment with oxytetracycline resulted in a significant decrease in the MCP joint angle as measured radiographically in both affected and unaffected foals. Joints returned to their pretreatment angles by 4 days after treatment. Oxytetracycline therapy had no significant effect on the DIP joint angle and therefore is unlikely to be of use for flexural deformities of the DIP joint based on these data. No alterations in renal biochemical parameters were detected after a single dose. However, oxytetracycline induced acute renal failure in a foal, which was successfully treated by hemodialysis.[38] This underscores the importance of biochemical monitoring in these cases, particularly in systemically ill foals.

Mild cases of flexural deformities can respond to this treatment with complete correction. In more severe cases, the response is minimal and other treatment modalities must be used.

FARRIERY

Toe extensions

Application of a dorsal hoof extension using acrylic alone or in combination with a lightweight foot plate protects the toe from excessive wear and increases the tensile forces in the deep digital flexor tendons during ambulation (Figure 87-15). This facilitates a delay in breakover in foals suffering from flexural deformities of the DIP and MCP/MTP joints. In severe deformities, however, toe extensions that are not braced back along the dorsal hoof wall can exert significant forces at the toe, leading to distraction and separation of the dorsal hoof wall, infection of the white line, and pain.

To help maintain these devices on the feet, numerous holes of approximately 2 mm in diameter and depth can be drilled into the dorsal hoof wall. The hoof acrylic used to achieve the dorsal extension is spread over the dorsal hoof wall and worked into the holes to add stability to the device. The acrylic, interdigitating with the dorsal hoof wall, serves as an anchoring device and prolongs the life of the extensions. Filling in the space between the extension and the dorsal hoof wall decreases the risk of the foal's stepping on the extensions or stumbling over them.

These devices may be successfully applied in newborn foals with mild flexural deformities of the DIP or MCP joints, when the foal cannot bear weight without knuckling over. Extending the dorsal hoof wall adds the necessary elongation to compensate for the lack of extension in the phalangeal region and allows the foal to stand without knuckling. Once the foal is able

to ambulate, correction of the deformity is usually achieved within 2 weeks, at which time the extensions are removed or typically become detached.

The toes must be protected from excessive wear as the foal is allowed free exercise. A special half-round glue-on shoe has been developed for this purpose, with a toe extension built into its design (Figure 87-16).[39]

SPLINTS AND CASTS

Splints and casts are effective for treating flexural deformities. Splints and casts are useful in cases of MCP/MTP, carpal, and some tarsal flexural deformities. The PIP and DIP joints are difficult to immobilize without casting. Foals suffering from flexural deformities of the DIP joint that are unresponsive to hoof extensions can be treated with half-limb casts, incorporating the feet. This treatment relaxes the muscle–tendon units and corrects the problem.[3,4,40]

Figure 87-15. A polymethyl methacrylate toe extension applied to a foal following a desmotomy of the accessory ligament of the deep digital flexural deformity for treatment of a flexural deformity of the distal interphalangeal joint. The toe extension stretched the deep digital flexor musculotendinous unit, and by filling the gap between the toe extension and the dorsal hoof wall with acrylic, the distraction forces between the hoof wall and the underlying laminae are neutralized.

Splints have several advantages over casts in that they can be removed regularly, are easily reapplied, can be applied under sedation, and are more cost-effective than repeated casting. Casts cannot be reset regularly (unless they have been bivalved) without added expense, often require general anesthesia to apply, and do not allow inspection of the flexural deformity and the skin under the cast. Because the forced extension of the affected limb in a cast or a splint is painful and requires analgesia, some clinicians avoid the use of casts, preferring instead to use splints, which can be placed on the leg for 12 hours and then left off for 12 hours.[34] Splints however, can move out of position on the limb, creating pressure sores. Some clinicians favor the use of casts for these reasons.[41] Casts have to be changed at least every 2 weeks to keep pace with the growth of the foal.

Splints can be made from a variety of materials, including PVC pipe, wood, and fiberglass, and can be custom-made to the limb.[42] Splints made from PVC pipe or wood have the disadvantage of a lack of conformation to the limb and the potential to cause pressure sores. More severe problems such as distal limb necrosis as a result of improperly applied splints have been reported.[43] Splints should be placed over enough padding that the skin is protected from excoriation, but little enough that the splints do not shift out of position. The splints often rotate around the leg, and it is often quite difficult to keep them in the desired position.

Splints that have been custom fit to the contour of the limb are very useful and decrease the likelihood of complications because of their custom-made nature. In foals with a single limb affected, the custom splint can be made from the contralateral unaffected leg. The splint is made from a splinting material consisting of a double layer of seven strips of fiberglass encased in a synthetic padding (Dynacast Prelude) using the unaffected limb as a template. The same construct can be made from strips

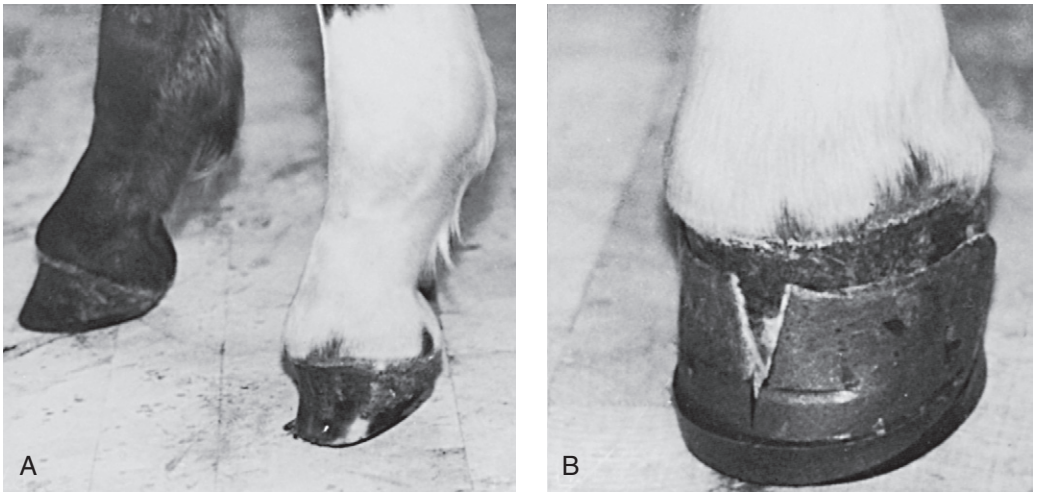

Figure 87-16. A, A 4-month-old foal with a stage I flexural deformity in the distal interphalangeal joint of the left forelimb. Note the dished appearance of the dorsal hoof wall. Allowing the foal to walk around like this would result in excessive wear at the toe and possible development of a painful condition or infection. **B,** A Dalric glue-on shoe was applied to protect the toe and to extend the footing surface dorsad, facilitating delayed breakover during walking. Note the spread cut in the region of the dorsal hoof wall. This allows better fit of the shoe to the foot because of the limited sizes available. (Courtesy H. Dallmer, Salzhausen-Putensen, Germany.)

of 10-cm casting material stacked and encased in padding. The technique is detailed in Chapter 17. The disparity between the affected limb and the splint created from the unaffected limb can be substantial (Figure 87-17). The affected leg is then padded with the same amount of padding used when preparing the splint. The splint is placed on the affected limb and forced into the splint configuration under bandage pressure. The splint is reset daily, and the leg is examined for any evidence that the splint is rubbing. Each day the limb should be able to be pulled further into the splint.

Figure 87-17. A custom-made splint for a foal with a flexural deformity of the metacarpophalangeal region. The splint has been made using the normal metacarpophalangeal region as a template and is now ready to be placed on the limb with a flexural deformity. The extent of the deformity can be seen as the disparity between the splint and the affected limb.

Some foals require sedation to apply the splints to facilitate maximal extension of the affected joint and to allow the splint to be placed on the limb properly. α_2-Adrenoreceptor agonists such as xylazine or detomidine are useful for this purpose and have the added benefit of providing analgesia.

Splints are preferably used in flexural deformities of the MCP and carpal region, especially in mild carpal flexural deformities. Foals that buckle forward on their MCP/MTP joints have lax flexor tendons and tight extensor tendons; these foals should be splinted to allow loading of the flexor tendons.[30] In these cases, the phalangeal region should not be incorporated into the splint.[40] Splints have to be well padded and changed regularly. It is important to use new, dry padding at each bandage change to minimize development of pressure sores (Figure 87-18).

Foals that are unable to rise and nurse must be assisted many times daily. Stretching of tendons and associated contracted soft-tissue structures (e.g., joint capsules) is painful; therefore administration of low doses of anti-inflammatory drugs is necessary (see "Analgesics," earlier).

SURGICAL MANAGEMENT

Surgical intervention is seldom necessary with congenital flexural deformities and is used in severe cases or those that do not respond to medical therapy. Surgical treatment is most commonly carried out for carpal flexural deformities, and transection of the flexor carpi ulnaris and the ulnaris lateralis tendons 2 cm proximal to the accessory carpal bone can correct mild carpal deformities.[44] A recent report of 135 procedures on 72

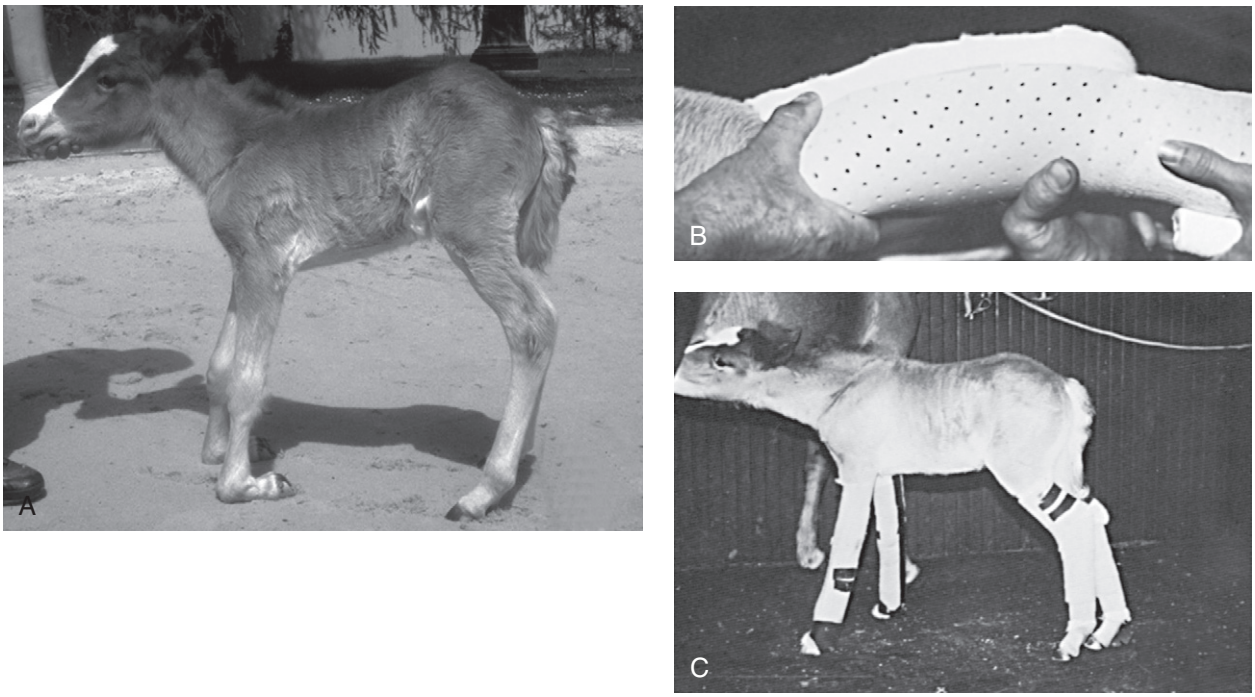

Figure 87-18. Splint application to a foal suffering from rupture of the common digital extensor tendon and incomplete ossification of the carpal and tarsal bones. **A,** The foal knuckling over on both front feet. **B,** A piece of Plastazote is applied to the dorsal and cranial aspect of MTIII and distal tibia, respectively, to manage incomplete ossification. This padding material is suited to application to the tarsal region. **C,** The foal with all four splints applied. Note that the splints were applied without incorporating the feet. In the forelimbs the splints are located palmarly and caudally, and in the hindlimbs they are located dorsally and cranially.

Figure 87-19. A foal with a severe flexural deformity in the carpal region, which was unresponsive to treatment.

horses documented a successful outcome, defined as a straight palmar carpal angle, in 82% of the cases.[27] Cases were graded as 1, 2, or 3, in order of increasing severity. Lower grades with less than 40 degrees of flexion carried the best prognosis, and the success rate in grade 3 cases fell to 57%. The surgery is performed under general anesthesia; a vertical incision is made over the lateral aspect of the accessory carpal bone and the tendons identified deep to the fascia. It is advisable to manipulate the limb immediately before surgery, while the foal is under anesthesia, to ascertain if these tendons tighten when forceful carpal extension is applied. If these tendons are the structures preventing extension of the carpus, once they have been transected surgically, the limb can be manually straightened. After surgery, box confinement is recommended for a few days, and then access to a small paddock or yard is allowed. The limb is kept bandaged until the sutures are removed.

Occasionally, surgical transection of the flexor tendons and palmar capsule of the middle carpal and antebrachiocarpal joint is required to allow the limb to be straightened, but these cases carry a worse prognosis (Figure 87-19).[45] The carpal canal is opened through a medial approach; the joints are identified and subsequently opened through a horizontal incision.

Flexural deformities of the MCP/MTP joint that do not respond to medical treatment can be treated surgically by transection of the flexor tendons or suspensory ligament, but these salvage procedures are not recommended for animals intended for an athletic future.[30] Severe MCP/MTP flexural deformities secondary to abnormally formed bones have been treated using an arthrodesis and resulted in pasture-sound horses.[46]

PIP joint flexural deformities resulting in subluxation may be treated by means of an arthrodesis (see Chapter 81).

Ruptured Common Digital Extensor Tendon

NONSURGICAL MANAGEMENT

Foals with ruptured common digital extensor tendons are best confined to a box stall, because they tend to stumble frequently. Within a few weeks, locomotion normalizes without any other treatment, and more exercise can be allowed.

Application of a well-padded splint bandage to stabilize the MCP joint and allow the foal to walk without stumbling is the treatment of choice when treatment is required.[29] The use of a thermoplastic splinting material (Plastazote) or a custom-made fiberglass splint has had excellent results (see "Splints and Casts," earlier). The splints must be monitored carefully for slipping or causing sores, and they are usually required for several weeks until the ruptured ends have fibrosed and allow a return to a normal ambulation. The prognosis for recovery is excellent, but some foals have a persistent thickening over the dorsal carpus for 6 to 12 months.[47] Aspiration of the synovial fluid from the tendon sheath is discouraged because of the risk of infection.

SURGICAL MANAGEMENT

It is generally accepted that ruptured common digital extensor tendons should not be treated surgically because of the favorable prognosis with conservative management.[29] The risk of complications secondary to surgery outweighs any improvement of the prognosis. However, thorough removal of all fibrin clots from the tendon sheath through a surgical incision, followed by installation of a suction drain and cast immobilization, has resulted in excellent cosmetic appearance of the limbs.[44]

ACQUIRED FLEXURAL DEFORMITIES

Pathogenesis

There are several pathways for the development of acquired deformities (see Figure 87-2). It has been suggested that acquired flexural deformities are part of the developmental orthopedic disease (DOD) complex, which also includes angular limb deformities, osteochondrosis, physitis, and cervical vertebral malarticulations or malformations.[24] Although they are a condition of the developing horse, the DOD complex initially was defined as conditions resulting from a failure of the conversion of cartilage to bone and in the context of this definition, acquired flexural deformities were not included.[24] However, it is likely that acquired flexural deformities occur as a result of pain and may therefore be a sequela to the conditions listed earlier. It is likely that the etiopathogenesis of acquired flexural deformities is multifactorial and complex, but several theories have been proposed for its occurrence. The two main theories are a mismatch in bone and tendon/ligament growth and contraction of the musculotendinous unit in response to pain.

It has been postulated that in rapidly growing foals, the longitudinal growth of the bone is greater than the potential of the tendon unit to elongate passively at a corresponding rate.[8] Most acquired flexural deformities are encountered between 4 weeks and 4 months of age and again at the yearling age, an observation that supports the theory.[3-5,7] Rapid bone growth occurring between 4 weeks and 4 months can induce a flexural deformity in the distal interphalangeal joint. Passive elongation of the tendon might be limited because of the relatively unyielding accessory ligament of the deep digital flexor tendon, which originates at the proximal and palmar aspects of the third metacarpal bone (MCIII) and joins the tendon in the midmetacarpal region. Passive elongation proximal to that region, therefore, has little influence on preventing the problem. Because of the

functional shortening of the deep digital flexor tendon unit, excessive tension is exerted on the distal phalanx, which results in palmar rotation of the entire foot and the development of the typical clubfooted stance.

The rate of bone growth is determined by genetics and nutrition. Foals can be overfed either by heavily lactating mares or by excessive supplementation with concentrates.[48] An abrupt change from inadequate—both in quality and quantity—nutrition to abundant nutrition also can induce the problem in yearlings.[49]

At 3 months of age, growth at the distal MCIII has ceased but continues to occur at the distal radius. The accessory ligament of the superficial digital flexor tendon originates just proximal to the distal radial growth plate from the caudal aspect of that bone. Rapid growth of the radius around 1 year of age can result in a functional shortening of the superficial flexor tendon unit and development of a flexural MCP deformity.[50] This theory was validated experimentally when foals previously kept on a poor ration were fed free-choice high-quality feed at the yearling age and subsequently developed flexural deformity.[51] However, the development of the problem might be more related to nutritional imbalances than excessive high-energy intake.[49,52]

Other authors have theorized that longitudinal bone growth is insufficient at any age to create a relative shortening of the flexor tendons.[34] They postulated that rapid growth increased tension within the flexor tendons and that this could induce pain, ultimately leading to the development of flexural deformities. Flexural deformities often have an acute onset of 24 to 48 hours, which also supports this theory; though muscle contractions can develop in such a short period, bone lengthening would take longer.

A study of skeletally normal foals revealed that most of the cells in the deep digital flexor tendon and its accessory ligament are myofibroblasts.[53] These cells have contractile ability and therefore might play a role in the development of flexural deformities.

This leads to pain as the primary inciting factor associated with acquired flexural deformities.[12,31] Any painful condition could be responsible for the *flexion withdrawal reflex* and the resultant muscle contraction, leading to an altered stance, and it is common for lameness in the affected limb to precede development of an acquired flexural deformity.[30] Osteochondrosis, osteoarthritis, infectious joint disease, acute severe trauma to osseous and soft-tissue structures, bruised feet as a result of prolonged exercise on hard ground,[54] or overzealous foot trimming leading to solar bruising[31] and hoof problems are just a few conditions that may precipitate an acquired flexural deformity.[5,54-56] Such painful processes can induce muscle contractions, leading to the development of flexural deformities. Although pain can be the inciting factor in acute-onset flexural deformities, more permanent states of flexion of the musculotendinous unit can occur with contracture of the flexor aspect of the joint capsule and maintain the deformity, underscoring the need for early diagnosis and effective management.[55,56]

Diagnosis

Acquired flexural deformities are seen more often than acquired hyperextension deformities. Continuous overload of certain limbs can, in selected cases, induce hyperextension deformities. Acquired flexural deformities can also be encountered after ruptures of flexor tendons. The onset of acquired deformities can be divided into two periods of the foal's growth (Table 87-1). Early diagnosis is important to increase the chance of complete resolution, but diagnosis may be made difficult by the foal's being out at pasture with the mare, especially for DIP joint deformities, which may be hidden by the grass. Regular examination on a hard, level surface will aid early detection of acquired deformities. The MCP and DIP joints are most commonly affected.

TABLE 87-1. Age of Onset of the Most Commonly Encountered Flexural Deformities

Age of Onset	Deformity
CONGENITAL DEFORMITIES	
Birth up to 1 month	Carpus
	Metacarpophalangeal region
Less commonly	Metatarsophalangeal region
	Proximal interphalangeal region
	Distal interphalangeal region
Rarely	Tarsal region
ACQUIRED DEFORMITIES	
1 to 4 months	Distal interphalangeal region
1 to 6 months	Metacarpophalangeal region
	Proximal interphalangeal region
Less commonly	Metatarsophalangeal region

Distal Interphalangeal Region

Flexural deformities of the DIP joint occur primarily in foals between 1 and 4 months of age and almost always affect the forelimbs. The condition is usually bilateral, although one limb may be more severely affected. Deformities of the DIP joint involve the deep digital flexor tendon, because this tendon inserts on the solar surface of the distal phalanx and is responsible for flexion of the DIP joint. Initially, the dorsal hoof wall assumes a more vertical angle and the heels may not contact the ground if the condition has occurred acutely. Two sequelae are associated with a foot in this conformation. First, the heels overgrow because of the lack of ground contact, and the foot appears "boxy" as the heels approach the length of the toe. Second, the toe is under greater stress and wear, which can widen the white line and lead to flaring of the distal hoof wall. In more slowly developing cases, the heels may maintain contact with the ground and overgrow.[30] These changes in the conformation of the foot are the result of the deformity and not a cause.

The deformities are divided into stages I and II. Stage I deformities (Figure 87-20) have a more upright dorsal hoof wall where the angle described by the dorsal hoof wall and sole is greater then 60 degrees but less than 90 degrees, and the wall has not passed the vertical plane. In stage II deformities (Figure 87-21), the dorsal hoof wall has passed 90 degrees and is beyond the vertical plane. Stage II deformities have a worse prognosis for resolution than stage I deformities,[57] and the prognosis declines with increased time before treatment.[28] This classification scheme is useful for description of the deformity and formulation of a prognosis, but it does not always dictate the preferred method of treatment.

Figure 87-20. A stage I flexural deformity of the distal interphalangeal joint. Note that the dorsal hoof wall has not passed the vertical and that the distodorsal tip of the hoof wall has flared from the abnormal forces caused by the abnormal foot position.

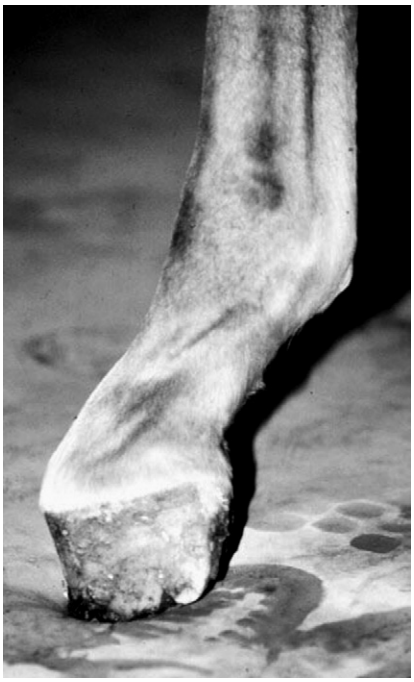

Figure 87-21. A stage II flexural deformity of the distal interphalangeal joint in which the dorsal hoof wall has passed vertical. (Courtesy Alistair Barr, University of Bristol, UK.)

The longer the condition is neglected, the worse the deformity becomes. Permanent changes of the associated soft-tissue structures occur, and the abnormally loaded bones remodel according to Wolff's law.[5] The deformation and distraction of the dorsal hoof wall can lead to seedy toe or subsolar abscesses, in turn causing more pain.

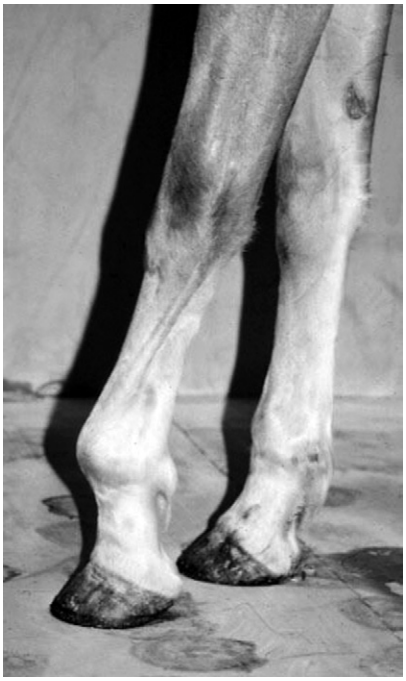

Figure 87-22. An acquired flexural deformity of the metacarpophalangeal joint in which the fetlock joint knuckles forward. The animal is bearing full weight, but the metacarpophalangeal region does not extend fully and there is no loading on the flexor tendons. (Courtesy Alistair Barr, University of Bristol, UK.)

Metacarpophalangeal/Metatarsophalangeal Region

These flexural deformities can be congenital but are also an acquired flexural deformity in animals from 10 to 18 months of age. Both front and back limbs can be affected, but acquired MTP joint flexural deformities are much less common than those affecting the MCP joint.[58] Acquired flexural deformities of the MCP joint are initially characterized by a straighter MCP angle. The foot usually appears normal and is in contact with the ground, but the pastern assumes a more upright position, and if the deformity is left untreated, the MCP joint knuckles forward. Knuckling over in the MCP region is seen in more severe cases (Figure 87-22) and in cases in which treatment has been neglected for a long time.

Three grades of severity of acquired MCP/MTP flexural deformities have been described.[59] *Mild deformities* show a straight MCP/MTP region and rarely flex to greater than 180 degrees; in other words the joint remains caudal to the foot at all times, albeit with a straighter angle than normal. *Moderate deformities* have greater than 180 degrees of flexion, which causes the MCP/MTP joint to be dorsal to the foot, but when walking, these horses can extend their joints to a position caudal to the foot. *Severe deformities* have greater than 180 degrees of flexion at all times, and in these cases, the flexor tendons and suspensory ligament are lax and the extensor tendons prevent further flexion of the joint. In these cases, the extensor tendons are prominent on the dorsal aspect of the leg. The speed at which such a deformity develops greatly depends on the degree of pain present, the pain threshold of the patient, the growth rate, the amount of exercise allowed, and possibly the foot-trimming techniques employed. It is important to diagnose a flexural

deformity as early as possible, and promoting client awareness can be helpful in this regard.

Deformities of the MCP/MTP joint can involve one or both of the deep and superficial digital flexor tendons (and less frequently the suspensory ligament), because these structures all support the palmar/plantar surface of the joint. The choice of surgical treatment, should surgery be required, is affected by which tendon is considered to be involved in the deformity. Identification of the primarily affected tendon is not always straightforward. Palpation of the flexor tendons should allow determination of which structure is tightest: the deep digital flexor tendon unit, the superficial digital flexor tendon unit, or the suspensory ligament. Application of pressure to the dorsal joint region in a palmar direction causes tension in the tendons,[30] and the structure with the most tension is the first released at surgery. Palpation and passive manipulation of the involved region should be carried out with the limb in a non–weight-bearing position to recognize potential adhesions between the tendinous structures.

Flexural deformities also develop after prolonged periods of not bearing weight, such as that occasioned by radial paralysis or following conservative fracture treatment (classically olecranon fractures). Depending on their management, deformities can become permanent and debilitating despite healing of the original ailment. The joint region involved with the flexural deformity can be fixed by the contracture, without osseous ankylosis present (fibrodesis).

Acquired flexural deformities of the MCP joint have also been reported in mature horses secondary to desmitis of the accessory ligament of the deep digital flexor tendon[60] and in a case of nonresponsive digital sheath sepsis, which led to rupture of the flexor tendons within the sheath.[61]

Cases detected and treated early carry a good prognosis for correction with conservative treatment.[14,58] One author reported that mild cases requiring corrective shoeing only had a good prognosis for resolution.[62] Cases requiring surgical intervention carried a guarded[62] to poor[28] prognosis.

Proximal Interphalangeal Region

Acquired flexural deformities of the PIP joint have been primarily diagnosed bilaterally in the hindlimbs of rapidly growing weanlings.[58] It occurs in foals with straight hindlimb conformation in the same time period as acquired flexural deformities of the MCP joint. The biomechanical basis of the condition has been postulated as shortening of the deep digital flexor musculotendinous unit and a concurrent laxity in the superficial digital flexor tendon, which inserts adjacent to the PIP joint.[63] Usually a dorsal subluxation is diagnosed and is accompanied by an audible click as the foal walks. Radiographs might show osteoarthritis in chronic cases.

Radiography for the Diagnosis

Radiography is not required for the diagnosis of congenital flexural deformities, which can be made on the basis of clinical signs. However, radiography is useful to identify abnormalities that may alter the prognosis for correction of the deformity. Secondary radiographic changes can occur as a consequence of the deformity; in relation to the DIP joint, these include modeling of the dorsodistal aspect of the distal phalanx, rotation of the distal phalanx in the hoof capsule, or osteoarthritis of the DIP joint, and all of these worsen the prognosis.[28] MCP/MTP joint flexural deformities may show evidence of osteoarthritis in the MCP/MTP or PIP joints secondary to chronic subluxation.[64]

Treatment

Early recognition and treatment of flexural deformities improves the prognosis, especially if pain-mediated flexion is involved, because these will become worse with time if left untreated. If an underlying cause of the pain can be identified, it should be addressed first. Medical or nonsurgical treatment is indicated initially for all but severe cases. If nonsurgical treatment does not improve the flexural deformity, surgery should be considered. Surgery should be considered as the initial treatment of severely affected patients.

Common Treatment Principles

NUTRITION

Nutrition and genetics control the growth rate of the foal. Overfeeding of foals can occur either by heavily lactating mares or excessive supplementation with concentrates. Alterations in the growth rate may also occur when the nutritional plane increases suddenly, especially after a period of relative deficiency, such as after weaning or after a change of ownership. When a flexural deformity occurs in an unweaned foal, the energy content of the diet should be reduced either by early weaning of the foal or a decrease in the mare's concentrate ration. Weaning at 10 weeks of age did not usually affect the foal's size as a yearling in one hospital.[41] The mineral balance of the ration for both the mare and the foal should also be balanced, primarily with respect to calcium and phosphorus, because research has shown that calcium/phosphorus imbalances are also implicated in developmental diseases.[23]

Older foals and yearlings should have the concentrate portion of the diet reduced to a minimum and be fed hay and a balanced mineral supplement. Presumably, if contraction of the musculotendinous unit in response to pain is the more accepted etiopathogenesis for acquired flexural deformities, then prevention should be aimed at monitoring growth and weight and adjustment of the diet accordingly.

Additionally, it is advisable to evaluate soil and drinking water samples for their mineral and trace mineral composition; adjustments should be implemented immediately after identifying inadequate levels.

PHYSIOTHERAPY AND EXERCISE

Opinions differ on the role of exercise in the treatment of flexural deformities. If the deformity is secondary to a painful condition, then exercise limitation and analgesics would be beneficial. Uncontrolled exercise may exacerbate the painful stimuli and the deleterious loading of the contralateral limb.

ANALGESICS

Both the inciting cause and treatment of acquired flexural deformities is a painful process. To aid the foal in standing and ambulating, NSAIDs are given at low doses as for congenital flexural deformities. Foals with painful limbs tend to lie down for longer periods, which can aggravate the flexural problem

and underscores the need for analgesics. (See "Analgesics," earlier, for a fuller discussion.)

Distal Interphalangeal Region

NONSURGICAL MANAGEMENT

DIP joint flexural deformities in which the foal is bearing weight on the toe generally benefit from controlled exercise on a firm surface to allow stretching of the deep digital flexor musculotendinous unit combined with analgesics; however, it is important that the toe region is protected to prevent excessive wear and possible development of a septic process. Turnout in a small yard that is sufficiently small to prevent uncontrolled exercise is probably a reasonable choice.

FARRIERY

The overgrown heels of DIP flexural deformities giving the typical "boxy" conformation to the foot may prevent proper realignment of the hoof–pastern axis if the heel contacts the ground. The heels should be rasped back gradually. Radical trimming of the heel only serves to increase strain forces on the dorsal toe because of the smaller sole surface making contact with the ground. Similarly, if the heel has been lifted off the ground by the deformity, the heels should not be rasped because this only applies greater forces and leverage to the dorsal laminae and the distodorsal aspect of the distal phalanx. However, judicious trimming of the heel combined with application of a toe extension and protection can be an effective treatment (see Figures 87-15 and 87-16).

Application of a toe extension or a glue-on rubber shoe is effective for many flexural deformities of the DIP joint by increasing tension in the deep digital flexor tendon,[39,47] although some clinicians and farriers do not agree that their use is always beneficial.[30,41] Another useful purpose of toe extensions is protection of the toe and prevention of excessive wear in that region. Simple application of a shoe with a toe extension, without filling or bracing the extension against the dorsal hoof wall with hoof acrylic, can cause frequent stumbling and abnormal flaring of the dorsal hoof wall.

The argument against toe extensions is that if the flexural deformity is secondary to a painful stimulus, further tension on the deep digital flexor tendon (DDFT) will exacerbate this painful element and some clinicians support elevation of the heel to reduce pain, encourage relaxation in the DDFT, and change the weight-bearing surface of the foot from the toe to the entire sole; however, other clinicians feel that elevating the heel leads to a worsening of the deformity. There are likely a subset of cases of DIP flexural deformities that respond to a toe extension and another subset that respond to heel elevation. (See also "Toe Extensions," earlier.)

CAST APPLICATION

Cast application in foals causes temporary weakening of the tendons. The distal limbs of affected foals may be covered with a fiberglass cast that incorporates the feet for 10 days to a maximum of 14 days. After cast removal, the weakened tendons allow correction of the problem. Despite the fact that the weakening persists for only a few days, one author has achieved permanent correction of the problem with this technique.[65] However, because of the potential complications associated with this type of treatment, cast application is rarely used.

SURGICAL MANAGEMENT

Surgical intervention is indicated in foals unresponsive to conservative treatment and in severely affected foals. Corrective trimming can be carried out when the foal is anesthetized.

Desmotomy of the accessory (check) ligament of the deep digital flexor tendon

The treatment of choice for stage I flexural deformities is desmotomy of the accessory ligament of the deep digital flexor tendon (ALDDFT) (inferior check ligament) (Figure 87-23).[4,5,57,66-68] The ligament may be approached from the lateral or medial aspect of the limb. If both limbs require surgery, they can both be approached with the horse in dorsal recumbency, the horse can be turned halfway through surgery from left to right lateral recumbency, or one limb can be approached medially and one laterally with the horse in lateral recumbency. The advantages of a lateral approach are that the major neurovascular bundle, located medially at this level, can be avoided, and the ligament is in a more lateral position. The major advantage to the medial approach is cosmetic, although the procedure is more difficult.

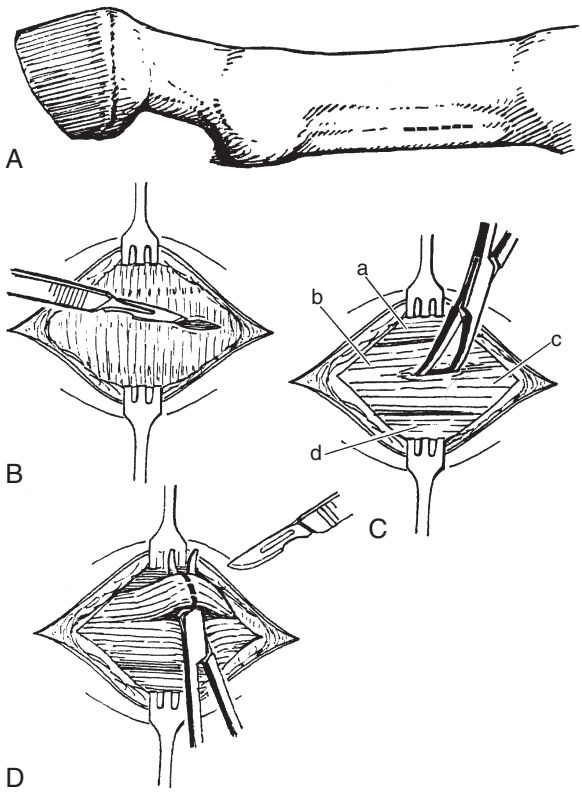

Figure 87-23. Surgical technique of desmotomy of the accessory ligament of the deep digital flexor tendon (inferior check ligament desmotomy). **A,** Location of the surgical site on the medial, or in most cases the lateral, side of the limb *(dotted line).* **B,** The paratenon enclosing the deep flexor tendon and the accessory ligament is incised. **C,** The accessory ligament is isolated along its division plane with the deep digital flexor tendon. *a,* Musculus interosseus (suspensory ligament); *b,* accessory ligament of the deep digital flexor tendon; *c,* deep digital flexor tendon; *d,* superficial digital flexor tendon. **D,** The isolated and elevated accessory ligament is transected along the dotted line. (From Turner AS, McIlwraith CW: Techniques in Large Animal Surgery. 2nd Ed. Blackwell, Oxford, UK, 1989.)

A 5-cm skin incision, centered at the junction between the proximal and middle third of the MCIII, is made over the deep digital flexor tendon. The subcutaneous tissues are bluntly separated and the tendinous structures are identified. With the medial approach, the neurovascular bundle overlying the deep digital flexor tendon and its accessory ligament are identified and reflected away from deeper structures. Palpation of the paratenon surrounding the deep digital flexor tendon and its accessory ligament allows separation between the two structures.

A curved hemostatic forceps is introduced and advanced following the slightly curved surface of the tendon to the opposite side, where the forceps is spread and turned. The ALDDFT lying dorsal to the tendon is elevated to the level of the skin incision. Manipulation of the foot in a dorsal direction tightens the ligament and ensures the isolation of the correct structure. Once the ligament is positively identified, it is sharply transected with a scalpel blade. Dorsal rotation of the DIP joint produces at least a 1-cm gap between the transected ends of the ligament. The gap is inspected and palpated, and any remaining fiber strands of the ALDDFT are transected. The paratenon, subcutaneous tissues, and skin are closed using 2-0 or 3-0 absorbable suture materials in a continuous pattern. Intradermal placement of the skin suture is advised for a better cosmetic result. Postoperatively, a pressure bandage is applied and maintained for 2 to 3 weeks and changed every 3 to 4 days.

Correction or improvement of the deformity is usually observed immediately. In some cases, however, it takes a few days until it is complete. Occasionally, application of a toe protection or extension is needed. Young foals and those without long-standing contracture are allowed controlled exercise within 3 to 6 days after the surgery. Free pasture exercise is encouraged after 2 weeks. In older foals and those with chronic or severe contracture, limiting exercise for a period of months might prevent excessive fibroplasia at the surgery site. To relieve potential pain, NSAIDs may be administered at low doses.

An ultrasound-guided tenotomy of the ALDDFT has been described in standing horses.[69] The surgery applying this technique was more successful in restoring a normal hoof conformation in the younger horses treated (median age, 6 months) compared to the older group of horses (median age, 12 months). The age of surgery did not affect the cosmetic outcome.

Postoperative fibroplasia occurring at the surgery site reunites the transected ends of the ligament with time. In selected cases, fibroplasia in that region is excessive and results in a cosmetically undesirable appearance. Bandaging for 3 weeks after surgery improves the cosmetic outcome and lessens scarring at the surgical site.

Cosmetically unacceptable results can also occur from tendinitis that can be induced from exercise when the tendon has been protected by the contracted accessory ligament for a long time. Tendinitis can be avoided with longer periods of controlled exercise. Daily massage of the swelling can reduce the size.

In horses intended for showing or pleasure riding, the prognosis for athletic function is good; in one study 86% of horses treated before 1 year of age were subsequently used for their intended purpose.[67] Horses treated after 1 year of age had a lower success rate of 78%. One author reported a good prognosis for surgical correction of mild cases but a poor response of severely affected cases to an desmotomy of the ALDDFT.[9] Other authors reported that Standardbred foals treated for DIP joint flexural deformities could reach their athletic potential but that the prognosis was better if the foal was treated at a younger age.[70] In this series, no foals treated after 8 months of age had a favorable outcome.

Tenotomy of the deep digital flexor tendon

Stage II flexural deformities might not correct after desmotomy of the ALDDFT, although this intervention is commonly used as the first surgical approach. Tenotomy of the deep digital flexor tendon can then be used successfully for correction,[71,72] but the deformity is reported to reappear in many cases within months of surgery.[10] Some clinicians feel that cases with a hoof–ground angle of greater than 115 degrees usually require a deep digital flexor tenotomy.[30] Initially, such a tenotomy had been viewed at as a salvage procedure; however, many animals have developed into sound riding horses, although the prognosis for return to function is usually guarded.[30]

Two main sites for the surgical procedure have been proposed: midmetacarpus or midpastern. The distal approach centers at the palmar and median aspect of the pastern region and enters through the digital flexor tendon sheath just distal to the bifurcation of the superficial digital flexor tendon.[72] The deep digital flexor tendon is identified, exteriorized, and transected with a scalpel blade. Immediate retraction of the proximal stump into the tendon sheath is noted. The tendon sheath may or may not be sutured using routine technique in addition to the subcutaneous tissue and the skin.[68,72] While the animal is under anesthesia, the feet are trimmed to a shape that is as normal as possible.

Postoperative correction is often immediate but can be associated with substantial pain. Administration of NSAIDs is therefore routine. Because of the time it takes for some stage II flexural deformities to develop, the soft-tissue structures, such as the joint capsule, ligaments, and periarticular tissues at the palmar aspect of the phalanges, may be significantly contracted. Transection of the deep digital flexor tendon at the level of the PIP joint does not often result in a marked elevation of the toe during weight-bearing, which it does after rupture of this tendon in the region of the navicular bone. Nevertheless, in selected cases, application of a shoe with a heel extension is necessary.

Transection of the deep digital flexor tendon at the midmetacarpal level is also advocated.[73] The procedure is carried out through a medial or lateral approach. The advantage of this approach is the greater distance from the feet and the fact that a tendon sheath is not invaded. Additionally, the procedure is easier to perform at the midmetacarpal level and can be performed as a standing procedure. However, scarring associated with marked disfigurement of the tenotomy site can be an undesirable sequela. Postoperative management is identical to that used with the other technique. Recurrence of the deformity is a potential problem following this technique, because the tendon ends may reunite, initially with scar tissue; this is followed by its contracture.

Metacarpophalangeal Region

NONSURGICAL MANAGEMENT

Nonsurgical management includes proper nutrition, physiotherapy, analgesics, corrective shoeing, and application of splints.

PHYSIOTHERAPY

Hopping an animal is a further attempt to bring about correction of the deformity without surgery.[4] One limb of a foal is elevated and held in that position while a helper leads the animal at a walk. During the support phase of the elevated limb, most of the weight is transmitted to the person holding the limb. The opposite limb is quickly advanced and all the weight brought to bear on it. By repeating this type of physiotherapy several times daily, a potential stretching of the musculotendinous unit can be achieved. Exercise is an important type of therapy, but it should be carried out in a controlled manner.[74] Excessive exercise leads to fatigue, which should be avoided.

FARRIERY

Corrective shoeing can successfully eliminate flexural deformities of the MCP joint. Raising the heel with wedge pads results in a more acute angle of the MCP joint from partial relaxation of the deep digital flexor tendon.[4,50,73] Raising the heels by the use of a wedge pad or shoe has been suggested to decrease the strain in the deep digital flexor tendon while increasing the strain on the superficial digital flexor tendon and the palmar joint structures.[9,75] Some authors have questioned the effectiveness of such treatment, but clinically, an improvement is possible.[5] Conversely, some clinicians[48] recommend lowering the heel to invoke a reverse myotactic reflex. Toe extensions have been advocated and have proved very effective, especially when the condition was diagnosed early (Figure 87-24).[3,5,74] As the animal walks, breakover occurs later, and through this, greater tensile stress is exerted on the flexor tendons.

SPLINTS

Splint application can bring about some correction, especially in cases recognized early. Care must be taken to prevent development of pressure sores. Splints that position the MCP joint caudal to the foot, loading the horse's weight onto the flexor tendons during weight-bearing, can be useful.[30]

Figure 87-24. A toe extension incorporated into a shoe for treatment of an acquired flexural deformity of the metacarpophalangeal joint.

SURGICAL MANAGEMENT

Horses that are unresponsive to conservative management are candidates for surgical correction. Some clinicians feel that any horse with an MCP angle of greater than 180 degrees (forward of the hoof) are immediate surgical candidates.[30]

Because both the superficial and deep digital flexor tendons cross the palmar/plantar surface of the MCP/MTP joint, either or both can contribute to flexural deformities of this region. Distinguishing which tendon is primarily affected through palpation is not necessarily straightforward. Both desmotomies of the ALDDFT and accessory ligament of the superficial digital flexor tendon (ALSDFT) have been used for flexural deformities of this joint and can be used together for the treatment of severe deformities. Using the angle of the MCP region when the joint is in forced extension, guidelines exist for selection of the correct surgical procedure. Flexural deformities with an MCP angle of less than 180 degrees usually respond to desmotomies of the ALDDFT or ALSDFT.[76] For MCP angles of 180 degrees, the surgical procedures mentioned earlier are used in conjunction with a splint. Severe cases with an MCP angle of greater than 180 degrees benefit from both desmotomies plus a tenotomy of the superficial digital flexor tendon. The aim of all surgical procedures for MCP/MTP flexural deformities is to return the regional angle to less than 180 degrees, which facilitates loading of the flexor tendons.[30]

Desmotomy of the accessory (check) ligament of the deep digital flexor tendon

If the deep digital flexor tendon was tighter during palpation and manipulation, its accessory ligament should be transected using the technique described earlier.[76] Application of a preshaped polyvinyl chloride (PVC) half-pipe splint is necessary for 2 to 3 weeks to maintain the metacarpophalangeal angle in the normal range.

Desmotomy of the accessory (check) ligament of the superficial digital flexor tendon

Transection of the ALSDFT should be performed when this tendon is tighter during manipulation.[4,77] Two surgical approaches have been developed. The surgical landmarks for both approaches are the same and consist of the medial distal physis of the radius, the chestnut, and the cephalic vein. An approximately 10-cm skin incision is centered along the chestnut and made craniad to the cephalic vein. The subcutaneous tissue is bluntly separated, and communicating branches to the cephalic vein are isolated, double ligated, and transected between ligatures.

One surgical technique approaches the accessory ligament craniad to the flexor carpi radialis muscle.[50,59,78] The oval foramen in the carpal fascia can serve as the distal border of the desmotomy incision.[66] The carpal fascia is transected carefully, and the ensheathed flexor carpi radialis muscle is identified. Both the cephalic vein and the flexor carpi radialis muscle are displaced using a self-retaining retractor. The desmotomy of the fan-shaped accessory ligament is performed, taking care to avoid inadvertent injury to the palmar carpal rete. After transection of the ligament, the radial head of the deep digital flexor muscle appears and the carpal sheath becomes visible. Hemostasis is established, and the carpal fascia, subcutaneous tissues, and skin are closed routinely.

An alternative approach involves invasion of the sheath of the flexor carpi radialis tendon (Figure 87-25).[79,80] After reflecting

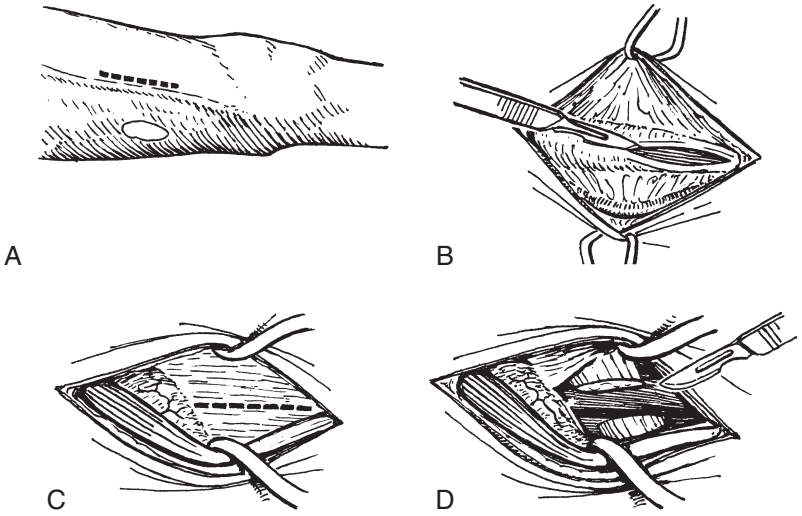

Figure 87-25. Surgical technique of accessory ligament desmotomy of the superficial digital flexor tendon (superior check ligament desmotomy). **A,** Location of the surgical site relative to the anatomic landmarks: cephalic vein, distal radial physis, and chestnut. **B,** The tendon sheath of the flexor carpi radialis muscle is incised. **C,** The flexor carpi radialis tendon is retracted, allowing visualization of the craniolateral tendon sheath wall. The site of the desmotomy incision is marked with a *dotted line* over the accessory ligament, which is at this location part of the craniolateral tendon sheath wall. **D,** The accessory ligament desmotomy is completed, allowing digital access to the radial head of the deep digital flexor muscle. (From Turner AS, McIlwraith CW: Techniques in Large Animal Surgery. 2nd Ed. Blackwell, Oxford, UK, 1989.)

the flexor carpi radialis tendon in the sheath with a self-retaining retractor, the craniolateral wall and accessory ligament are identified. A curved Kelly forceps is placed under the distal border and spread. The ligament is then transected in a distal to proximal direction. Care is taken to avoid injury to the nutrient artery of the superficial flexor tendon, which enters along the proximal border of the accessory ligament. After transection, the same anatomic structures are visible as mentioned with the first technique. Inadvertent incision of the carpal sheath is of no consequence. The tendon sheath is closed using a continuous suture pattern with 2-0 or 3-0 synthetic absorbable material. The rest of the closure is routine.

Additionally, a tenoscopic surgical approach has been developed, which allows a shorter convalescent period and fewer incisional complications.[81]

An *in vitro* study revealed that desmotomy of the ALSDFT was associated with significantly increased strains on the superficial digital flexor tendon and the suspensory ligament and significant alterations in the angles of the MCP and carpal joints.[80] Lengthening of the superficial digital flexor musculotendinous unit after desmotomy of the ALSDFT can be associated with increased strain on the suspensory ligament.[80]

Postoperatively, a sterile pressure bandage is applied and maintained for 2 to 3 weeks. The bandage is changed every 3 to 4 days. A shoe with an elevated heel may be used postoperatively to preferentially load the superficial digital flexor tendon.

In severe cases, the accessory ligaments of both the deep and the superficial digital flexor tendons are transected.[67]

Transection of the suspensory branches

As an additional alternative procedure, desmotomy of the medial and lateral branch of the suspensory ligament may be performed for salvage purposes in persistent cases.[50] However, subluxation of the PIP joint is to be expected.

A stab incision is made directly over the suspensory branch, the subcutaneous tissues are separated with a Kelly forceps, and a curved tenotome is introduced. By applying pressure with a sawing motion, the previously undermined suspensory branch is transected. Care should be taken to prevent inadvertent injury to the palmar artery and vein and the MCP joint capsule. The skin is closed using a few simple interrupted sutures. The same procedure is performed on the other side of the limb.

Horses with chronic or severe flexural deformities respond poorly to any treatment, including surgery, and superior check ligament desmotomies do not carry as good a prognosis as inferior check ligament desmotomies.[9,59] Severe flexural deformities following prolonged non–weight-bearing lameness do not respond to desmotomy of either of the two accessory ligaments. Such cases should be treated either with a tenoplasty as the lengthening procedure in both flexor tendons, followed by long-term cast application, or with an osteotomy plus an MCP arthrodesis (see Chapter 81), although euthanasia is a valid consideration in these cases.

Carpal Region

NONSURGICAL MANAGEMENT

Foals with long-term debilitating injuries that prevent weight-bearing on the limb should be treated with splints early in convalescence to prevent development of a flexural deformity. Passive stretching exercises are indicated. These two therapies are combined with controlled exercise if the original injury allows it. A contracture typically occurs suddenly over a few days after several weeks of not bearing weight on the limb. Therefore, physiotherapy should not be delayed. Care should be taken to prevent development of pressure sores under the splint.

SURGICAL MANAGEMENT

In cases resistant to conservative treatment, tenotomy of the ulnaris lateralis and flexor carpi ulnaris tendons can be performed with good results.[27] The same surgical procedure is performed as described earlier. Passive manipulation of the carpal region at that time demonstrates the greater mobility gained through this procedure.

Postoperatively, a well-padded pressure bandage is applied and a splint centered over the carpal region is incorporated. While the horse is under anesthesia, the limb is forced into a straight position. The splint bandage is changed regularly and maintained for about 2 weeks. Hand-walking exercise is important for the first 3 to 4 weeks. As soon as the animal easily bears weight on the limb, the splint is removed.

Proximal Interphalangeal Region

NONSURGICAL MANAGEMENT

Rest is not usually an effective management tool in these cases. The periarticular tissues may fibrose, and eventually the clicking noise is no longer heard. However, a marked bend at the joint level will be visible. Osteoarthritis could develop, necessitating an arthrodesis of the PIP joint to render the animal pain free again.

The clicking sound associated with dorsal snapping of the PIP and MCP area could also be observed in foals with persistent foal hoof at the tip of the hooves, resulting in an elongated hoof configuration. In one case, trimming of the hoof was successful in eliminating the clicking sound and the snapping of the proximal interphalangeal and metacarpophalangeal area.[65] This approach should be tried before surgical intervention is performed.

SURGICAL MANAGEMENT

Affected horses may respond to exercise restriction and analgesics, but in cases unresponsive to medical treatment, surgical transection of the accessory ligament of the deep digital flexor tendon and the tendon of the medial head of the deep digital flexor tendon at the level of the chestnut has been reported.[63] Three horses treated surgically with this method had resolution of the subluxation, and the one horse for whom follow-up information was available was sound after 10 months.[63]

COMPLICATIONS

Nonsurgical Management

Splint-associated pressure sores are the most often encountered complication and septic arthritis following injudicious use of splints has been reported.[82] To avoid such complications, padding is placed around sites of predilection. Once necrosis is present, local pressure has to be avoided in that area. Application of a donut-shaped pad around the periphery of the lesion can assist in that effort. Alternate application or temporary removal of the splint may be attempted. Daily topical wound care is necessary, especially in the initial period.

Surgical Management

Persistent hematoma formation, especially at the site of transection of the ALSDFT, wound dehiscence, and infections are the most common complications encountered after surgical treatment. Whenever fever, leukocytosis, warmth at the surgery site, or increased pain are noted, the incision should be evaluated and the necessary steps taken immediately. For additional information on wound dehiscence, please review Chapter 26.

Osteochondrosis

P. René van Weeren

The term *osteochondritis dissecans* was coined by König in 1887 and used to describe loose or semiloose bodies in joints of young persons that could have three causes: very severe trauma, lesser trauma and necrosis, or minimal trauma acting on an underlying lesion.[1] Although the name and concept have led to substantial confusion from the onset, this categorization is still valid today.[2]

Osteochondrosis (OC) is the last of König's categories described in the equine veterinary literature, and it is the most difficult to understand. OC represents a disturbance of the

process of endochondral ossification without a clearly understood etiology. This disturbance can eventually lead to the formation of semiloose or even completely loose fragments within a joint.

THE PROCESS OF ENDOCHONDRAL OSSIFICATION

In all mammals, the primordial skeleton is laid down first as a cartilaginous structure that, during the entire period of early development of the animal, is coupled in a process of simultaneous growth and transformation into bone. It is important to note that unlike mature articular cartilage, these fetal cartilaginous structures are well vascularized by vessels running through cartilage canals. Ossification of the primary centers of ossification in the diaphyses of the long bones starts early in fetal life, and at the time of birth, all the diaphyses are bony structures. This does not occur in many secondary centers of ossification located in the epiphyses of the long bones and in other sites such as apophyses and cuboidal bones in complex joints, which remain partly cartilaginous at the time of birth.

After birth, *longitudinal* growth of long bones results from the growth plates or physes where, from a germinal layer of cells (resting cells), chondrocytes proliferate and lay down a scaffold of extracellular matrix. These cells initially hypertrophy and later undergo apoptosis. The scaffold is used for the apposition of primary bone by osteoblasts originating from the metaphysis (Figure 88-1). This primary spongiosa then undergoes continuous remodeling under the influence of biomechanical loading according to Wolff's law during the entire growth period of the foal. This remodeling continues in the adult when biomechanical loading changes, for instance, when the skeleton is exposed to athletic challenges.[3] The entire process of cartilage remodeling, followed by calcification of cartilage, deposition of primary bone, and successive remodeling into bony trabeculae, is known as *endochondral ossification*.[4]

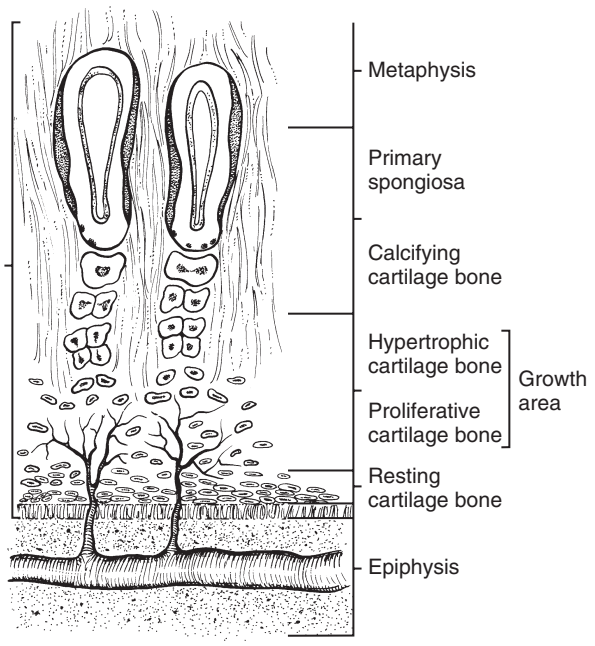

Figure 88-1. The relationship of the cartilage zones of the growth cartilage of a physis. (Redrawn from Watkins JW, Auer JA: Learning Systems 6:S227, 1984.)

The increase in *diameter* of the long bone during growth is the product of a different, but simultaneous and coordinated process, which is by appositional growth from the periosteum. This process results in the formation of compact cortical bone, characterized by the haversian canals.

In the epiphyses of the long bones a growth process similar to that of the physis takes place, but it is not as completely developed as in the diaphyses at birth. This leads to large differences between joints in the times when ossification occurs. In some joints at birth, there is a complete ring of cartilage around the ossification center, connecting articular cartilage with the growth plate. Ossification of this cartilage ring takes place first at the border of the physis and at the perimeter of the epiphysis. The thick cartilage mass at the articular side of the epiphysis functions as a type of growth plate where the simultaneous processes of growth, remodeling, and ossification take place that finally result in a considerably thinner layer of articular cartilage in the mature animal. It is at this level that the characteristic lesions of equine OC develop.

PATHOPHYSIOLOGY

There is little controversy about the gross pathogenetic mechanism of OC. Disturbances of the process of endochondral ossification result in irregularities in thickness of the epiphyseal cartilage. These create areas of focal weakness, which are exacerbated because the cartilage canals regress with increasing age and have disappeared in the horse by the age of 7 months.[5] This affects the nutrition of the deeper layers of the retained cartilage plugs that cannot be sufficiently nourished by diffusion from the articular surface, possibly leading to necrosis. Biomechanical influences, mainly shearing forces, then lead to the formation of fissures and produce cartilage flaps, or detachment of cartilage or fragments of cartilage and subchondral bone. In some locations where biomechanical forces are mainly compressive, infolding of cartilage in these weakened areas can lead to the formation of subchondral bone cysts as another manifestation of OC.[6]

Many caveats concerning this seemingly straightforward mechanism have been made. In an extensive review of pathogenesis and possible etiologic factors of OC, the view that defective ossification lies at the base of all lesions commonly qualified as OC in the horse has been questioned based on clinical and pathologic observations.[4] One of the major arguments was the observation that after injury, bone and cartilage can manifest only a very limited reparative response. This makes it very difficult, if not impossible, to judge the stage of the process (recently originated or already in some phase of repair) and more so the origin of the lesion (delayed ossification or trauma, for example).[7] Things become even more difficult if one realizes that OC is generally assumed to be a multifactorial disease in which the problem is not to single out a specific causative factor but to determine to what extent, and in which order, a variety of factors play a role. These considerations are discussed in more detail later, under "Etiologic Factors."

Along similar lines, comparisons between species should be dealt with cautiously. In the late 1970s, in-depth studies on the phenomenon of OC in a multitude of species (including horses, poultry, dogs, and cattle, but with the emphasis on swine) concluded that because of the striking similarities in manifestation

across the species, including humans, OC should have a common pathogenesis and etiology, the latter being principally growth rate that itself was determined by nutrition and hereditary factors.[8] Ever since, this paradigm of a "seemingly unified hypothesis"[4] has hovered over OC research, and the ease with which conclusions for the horse have been drawn based on research in entirely different species has been remarkable in some instances. It is questionable if this simple explanation of the pathophysiology of OC is justifiable, given many findings from more recent research that are discussed later.

DIAGNOSIS: CLINICAL AND RADIOGRAPHIC SIGNS

The typical OC patient is a yearling that is presented with effusion of the tarsocrural or femoropatellar joint that has been noted recently by the owner. The horse usually is not lame, and radiographic examination shows a fragment at the cranial end of the distal intermediate ridge of the tibia (Figure 88-2) or irregularities at the lateral trochlear ridge of the distal femur (Figure 88-3). However, as with any typical presentation of a disease, many variations on this theme are possible. OC in cervical facet joints has been related to cervical stenotic myelopathy, being a cause of wobbler syndrome in young horses. However, the relationship does not seem to be straightforward, although common pathogenetic pathways may exist.[9]

The age at which OC becomes clinically manifest varies, although in the great majority of cases, OC patients are juvenile animals. In severe cases of OC, which are more common in the femoropatellar (FP) joint than in the tarsus, signs can be seen in foals as young as 6 months. OC can also manifest itself at

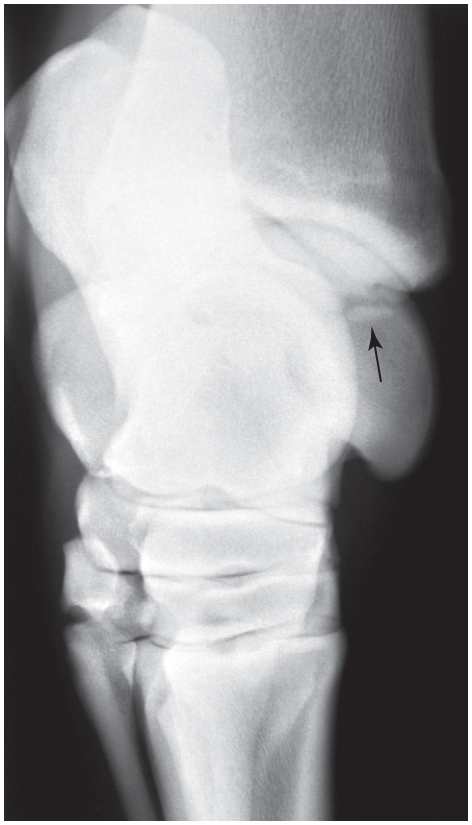

Figure 88-2. Radiograph showing a typical osteochondritic lesion of the dorsal aspect of the distal intermediate ridge of the tibia *(arrow).* (Courtesy Dr. AJM van den Belt, University of Utrecht, Netherlands.)

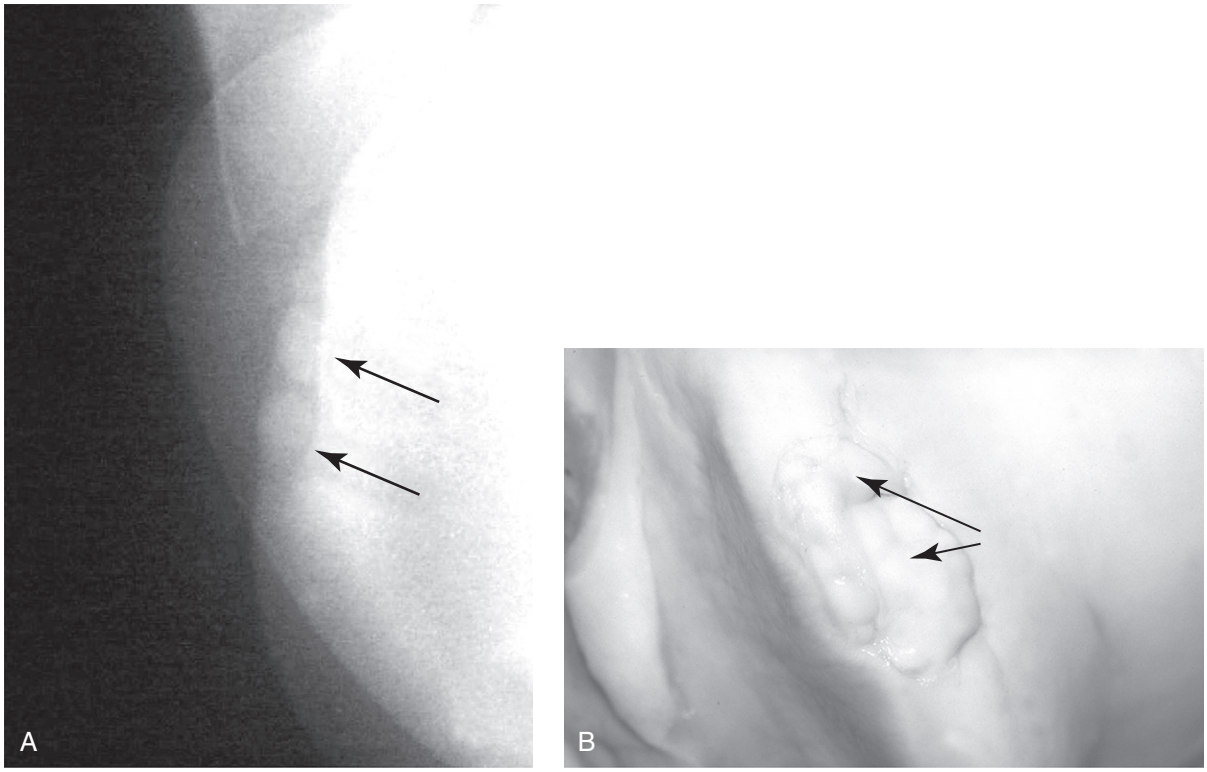

Figure 88-3. A, Radiographic view showing osteochondritic lesions on the lateral trochlear ridge of the distal femur *(arrows).* **B,** Postmortem view of an osteochondritic lesion of the lateral trochlear ridge of the distal femur *(arrows)*.

the age the animals are put into training and the joints become challenged by athletic activity. The age at which this occurs varies with the branch of equestrian industry. For example, Warmblood horses commonly are presented at about 3 years of age or older, whereas racing Thoroughbreds and Standardbreds manifest signs much earlier when they enter training.

Radiography is the gold standard for diagnosing OC but is not capable of detecting very subtle lesions. For this reason, other approaches using a variety of markers (see later) have been tried with varying success. An interesting development is the use of infrared absorption spectral characterization of synovial fluid using Fourier transform infrared (FTIR) spectroscopy that was able to discriminate between samples from OC-affected and normal animals with 50% specificity and 73% sensitivity.[10]

Distribution of Lesions

OC is most commonly diagnosed in tarsal, FP, and metacarpophalangeal/metatarsophalangeal (MCP/MTP) joints, but it has been described in almost every diarthrodial joint. In an experimental study, 43 Warmblood foals were selected out of pairing OC-positive sires and partially OC-positive mares to produce offspring with a high prevalence of OC. Twenty-four foals were sacrificed at 5 months, all joints were inspected at necropsy, and macroscopic lesions were confirmed by microscopy.[11] Lesions were most numerous in the tarsocrural (TC) joint (average of two lesions per animal), followed by the FP and the cervical intervertebral (facet) joints (one lesion per animal), the MTP joint (0.6), the MCP and carpal joints (0.4), humeroradial joint (0.2), and scapulohumeral joint (0.04).[12]

Although the prevalence of OC in this study was artificially high, the relative distribution is in agreement with clinical experience in the Warmblood. Breed differences occur to a certain extent with regard to lesion distribution and relative clinical importance. OC in the FP joint is common in the racing Thoroughbred,[13] but in Warmbloods and Standardbreds, TC OC is seen more often.[14-18]

A hallmark of OC is that lesions almost always occur at certain predilection sites within a joint. In the TC joint, the most common site is the cranial end of the distal intermediate ridge of the tibia (see Figure 88-2), followed by the distal end of the lateral trochlea of the talus and the medial malleolus of the tibia.[19] In the FP joint, the most common predilection site is the lateral trochlear ridge of the femur. Less common sites are the medial trochlear ridge of the femur, the trochlear groove, and the distal end of the patella.[6] Subchondral cysts that occur in the medial femoral condyle are a manifestation of OC as well and are discussed in Chapter 89. The predilection site in the MCP/MTP joints is the dorsal end of the sagittal ridge of the metacarpus and metatarsus. Not all osteochondral fragments are osteochondrotic in origin. Opinions on the nature of the fragments seen at the dorsal margin of the proximal phalanx differ, and the palmar or plantar osteochondral fragments (POFs) that were originally reported as being part of the OC complex[20] are now considered traumatic in origin.[21,22] In a histological study on osteochondral fragments that were harvested from mature (average age 6 years) horses it was shown that even in long-present intra-articular fragments, histology may give an indication about the original etiology with more indications of osteoarthritis (higher Mankin score) in fragments that were not of osteochondrotic nature.[23] Recently, it was shown that POF had a significant linear relationship with grades of wear lines, cartilage ulceration, and dorsal impact injuries in a cohort of Thoroughbred racehorses, and hence could be classified as a manifestation of traumatic overload arthrosis.[24] In the shoulder joint, OC is commonly located on the glenoid and the humeral head.[25]

Lesions are often encountered bilaterally in the TC and FP joints and quadrilaterally in the MCP/MTP joints.[26] Bilateral presence, often with unilateral clinical manifestation only, can occur in the TC and FP joints in more than 50% of clinical cases.[6] Therefore, in horses with unilateral clinical signs it is advisable to radiograph the contralateral joint. In contrast, concomitant occurrence in other joints or joint pairs is much less common. In a study of 225 horses with TC OC, lesions were found in other joints in only eight cases.[26] Therefore, joints other than the contralateral one do not need to be radiographed, except when clinical signs exist.

Joint effusion is by far the most common clinical sign, but lameness can occur, especially when large radiographic lesions exist. Lameness is seen more in FP OC than in TC OC and most likely when a loose or semiloose fragment is observed radiographically, thus when the osteochondritis dissecans (OCD) form is present. Other, less severe radiographic signs include irregularities in the articular contour of the subchondral bone and sometimes only a flattening of this contour.

Minor radiographic aberrations can be reliably classified as OC by an experienced radiologist. In one study, there was a correlation of 0.87 ($P < 0.001$) between radiographic classification of OC of the distal intermediate ridge of the tibia on a 0 to 4 scale[27] and histology.[12]

Nevertheless, the lesion's severity as determined radiographically does not always correspond with arthroscopic or necropsy findings. In many cases, cartilage lesions are more severe than radiographic appearance suggests, or cartilaginous lesions are present without changes in the subchondral bone and hence do not show up on radiographs (Figures 88-4 and 88-5). Severity of lesions can be assessed more accurately with more sophisticated imaging modalities such as magnetic resonance imaging (MRI). However, economic and physical constraints severely limit the wide clinical use of this kind of equipment, especially in the FP joint.

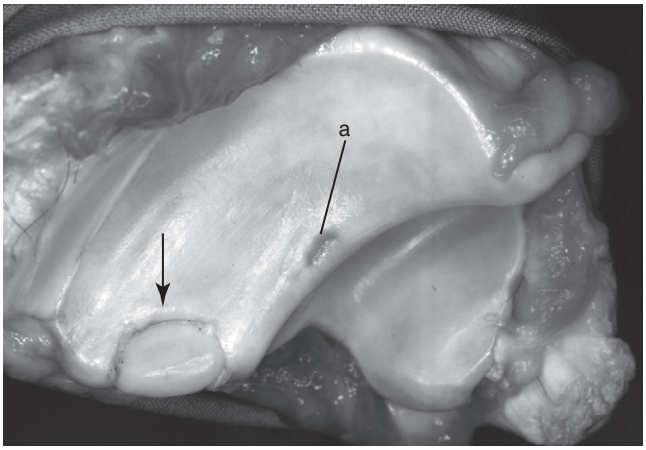

Figure 88-4. Typical osteochondrotic lesion of the distal intermediate ridge of the tibia in a cadaveric specimen *(arrow)*. *a*, Synovial groove.

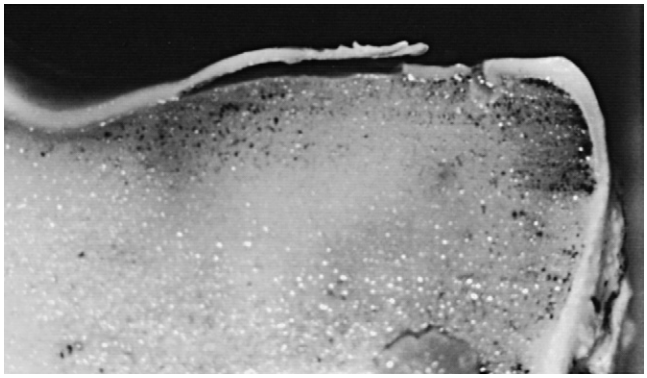

Figure 88-5. Example of an osteochondrotic lesion of the humeral condyle showing the formation of a large cartilage flap but relatively little damage to the subchondral bone.

Breed Predilection

OC is common in many breeds of horses. In Swedish Standardbreds, an incidence of 10.5% was found in the tarsal joints,[17] which was comparable to the 12% found by other authors[15] but less than the 26% found earlier by yet other researchers,[28] also in Standardbreds. One group found an incidence of 35% in the FP and MCP/MTP joints of Standardbreds in a Canadian population.[29] There are fewer studies in Thoroughbreds, but the incidence in that breed is reportedly relatively high as well.[25,30,31] In a study using repository films taken at a yearling sale in New Zealand, relatively low figures of 4% OC in the TC joint and 3% in the FP joint were found, but these figures have limited value because the population at the yearling sale was strongly preselected.[32]

In the Warmblood horse, early Swedish data mentioned an incidence of 15%.[28] More recent figures in the Dutch Warmblood population are higher (25% in the TC joint and 15% in the FP joint).[27] In a large study of 1180 horses in France (mainly Selle Français and Anglo-Arabs, a minority of Thoroughbreds), an incidence of 13.3% was reported in the TC joint.[18] A large-scale field study in Germany in several Warmblood breeds yielded figures of 19.5% for the MCP/MTP joints, 11.1% for the TC joint, and 7.2% for the FP joint.[33] This supports the findings that Warmbloods are at higher risk to develop OC than Thoroughbreds.[34]

Statistics on the prevalence of OC must be considered with utmost caution, given that OC may occur in almost any diarthrodial joint, but above all because the disease is highly dynamic with many lesions disappearing before maturity (see later). Additionally, figures are heavily affected by the number of joints examined and by the age at which examinations are carried out. Further, any form of preselection by breeders (which is common) will affect prevalence figures. and the effects of these factors may be dramatic. In a study on 811 yearlings that had not been preselected, a staggering 67.5% prevalence was reported, when combining results from TC, FP, MCP, and MTP joints in Dutch Warmbloods.[35] When measured conventionally at the age of 3 years, the mean figure for this breed is approximately 30%. A similarly high prevalence for TC and MCP/MTP OC (61.7%) was found in a population of South German Coldbloods that contained many young animals.[36]

Overall, it has been estimated that in northwestern Europe alone, 20,000 to 25,000 foals are born annually that will develop some degree of OC.[11] OC lesions are only rarely encountered in ponies.[37] Further, in a survey of 80 feral horses, extremely low incidences of 2.5% were found in the TC joint and 0% in the FP joint.[38] Because OC is a relatively new disease (see next section), these observations strongly implicate breeding policies and possibly management aspects as key factors in this disease.

OC is a debilitating disease only in exceptional cases, where lesions are so extensive that no repair is possible. Nevertheless, the ailment has a strong impact on the economics of the equine industry, and to a certain extent on animal welfare, because tens of thousands of animals are operated upon each year. Apart from the direct economic loss, there is an even larger indirect cost of the disease, because many studbooks do not approve horses with (major or minor, depending on studbook policy) evidence of OC. It has been estimated that the strict breeding policy the Royal Dutch Warmblood Studbook (KWPN) has adhered to until recently precluded 30% of all potential male breeding stock from participating in the selection procedures for becoming an approved sire. Apart from direct financial loss for the breeders, this also eliminates a large part of the gene pool. A last, but not insignificant, economic impact of OC is the loss in value of animals showing radiographic evidence of OC, regardless of their athletic capacities.

EVOLVING CONCEPTS

The first description of what is retrospectively judged to have been OC appeared in 1947 when fragments in the FP joints of Ardenner horses were noted.[39] Although in the following decades some reports described intra-articular fragments that might have been osteochondrotic,[40] the real history of OC does not start before the classic publication by Birkeland and Haakenstad in 1968.[41] These authors described a series of seven cases of OC of the distal ridge of the tibia, but they did not use the term *osteochondrosis*. In the early 1970s gradually more publications appeared,[42,43] and in the mid-1970s a comprehensive study on OC in a multitude of species was published.[8,44-47]

OC was originally seen as a largely static condition, but this concept gradually changed after a report appeared on changes in the radiographic appearance of FP OC after repeated examinations.[48] Other researchers recognized, after sequentially radiographing a number of foals, that OC lesions of the distal femur could progress until the age of 9 months.[49] In the same year, another group published a study in which they followed a cohort of 77 horses radiographically and found that no major new OC lesions were identified after 8 months of age in the TC joint. Interestingly, the authors noted a regression of a number of minor lesions before the age of 8 months, which had been detected between ages 1 and 3 months.[16]

A group of researchers radiographed the TC and FP joints of 43 foals on a monthly basis from the age of 1 month until age 5 months and of 19 of them until age 11 months. The study showed that not only minor lesions but also radiographically visible larger fragments ceased to exist. The ages at which lesions originated and the ages at which they became undetectable varied for each joint. In the TC joint, lesions at the distal intermediate ridge of the tibia and at the distal aspect of the lateral trochlear ridge of the talus that were seen within the first few

months of life had become undetectable before the age of 5 months. Thereafter no major changes occurred and existing lesions remained visible. In the FP joint where the epiphyseal maturation is known to be late compared to other joints,[50,51] lesions originated later and peaked at approximately 6 months before declining in number until about 8 months, after which the lesions remained stable (Figure 88-6).[27]

In a follow-up study in another group of Warmblood foals that were tracked for 24 months, this general joint-specific pattern was confirmed.[52] In that study, very little change in radiographic appearance was noted from 12 to 24 months. Further confirmation of these patterns resulted from two additional studies. In one study, groups of horses were used to evaluate the relationship between liver copper content and OC,[53] and in the other study the influence of nutrition on OC was examined in the French Saddlebred.[54] The latter study also featured sequential radiographic examinations.

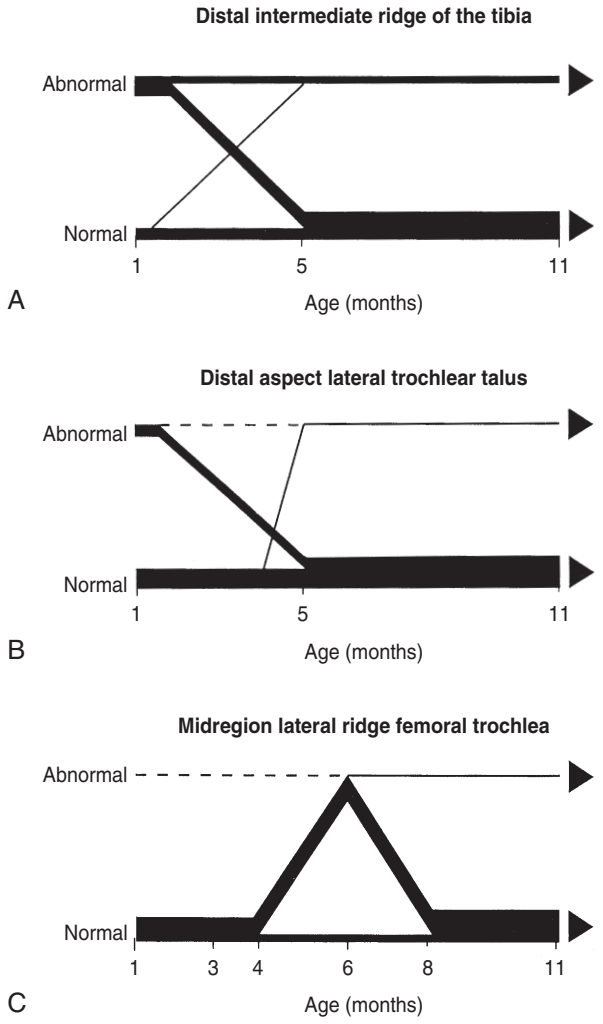

Figure 88-6. A, Schematic diagram of the early development of osteochondral lesions at the distal intermediate ridge of the tibia. At 1 month of age, several lesions can be identified that will heal *(thick line pointing down).* Only a few lesions originate after the age of 1 month *(thin line pointing up)* and, after the age of 5 months, the situation remains stable. **B,** Schematic diagram of the early development of osteochondral lesions at the distal aspect of the lateral trochlear ridge of the talus. The same general pattern as in **A** is seen, but healing potential is better. **C,** Schematic diagram of the early development of osteochondral lesions of the lateral femoral trochlear ridge. The pattern is distinctly different from that of the tarsus. Lesions develop only after the age of 3 months, peak at about 6 months, and have resolved at the age of 8 months, although some lesions will remain. (From Dik KJ, Enzerink EE, van Weeren PR: Radiographic development of osteochondral abnormalities, in the hock and stifle of Dutch Warmblood foals, from age 1 to 11 months. Equine Vet J Suppl 31:9, 1999 with permission from Equine Veterinary Journal Ltd.)

All these observations have led to the conclusion that OC is by no means a static condition, but in contrast is an extremely dynamic one in which lesions appear and apparently heal during the first months of life.[55] The acknowledgment of the dynamic character of OC has led to a profound change in the concept of this disease.

It is well known that the extracellular matrix of the articular cartilage goes through a phase of rapid remodeling in the fetal and neonatal animal. In a benchmark study on the early development of articular cartilage, the research group from Québec investigated very early changes in epiphyseal growth cartilage and articular cartilage (and the relationship between the two) in fetuses (6 to 11 months gestation length) and neonates (0 to 8 days) using histological techniques. They showed that the demarcation of articular cartilage from the much more voluminous growth cartilage occurs by 6 to 8 months of gestation and is followed by subsequent skeletal maturation. Importantly, they also showed areas in the growth cartilage, notably between the proliferative and hypertrophic zones near the ossification front where a dramatic change in collagen fiber organization occurred. These areas were interpreted as regions that were biomechanically very susceptible to induced trauma.[50]

It is in the juvenile period of ongoing endochondral ossification and rapid changes in growth that the topographic heterogeneity in biochemical composition that is necessary to withstand the locally different biomechanical challenges develops through the process of functional adaptation.[56,57] In this process, the collagen network of the articular cartilage is molded under biomechanical influences that induce both compositional and architectural changes[58] in a process not unlike that in bone.[3] However, whereas bone retains its capacity to remodel throughout the life of the horse, cartilage metabolism decreases quickly in the early juvenile period, and turnover times are very long in mature horses.[59,60]

The latter fact precludes any substantial remodeling or repair and makes the formation of the collagen network in the early juvenile phase a once-in-a-lifetime process that can have very important consequences for disease prevention in future life.[61] The sharp drop in collagen metabolism in the early juvenile period determines when the window for repair of lesions closes. Some lesions, either because they originate too late or are too large, do not have enough time for repair. These are the lesions that might eventually become clinically manifest. This means that in OC, a clear distinction should be made between the pathogenesis triggered by a number of etiologic factors, which can be supposed to be specific for OC on the one hand, and the probably largely unspecific repair process on the other.[62,63] A flow chart for the putative mechanism of OC based on this concept is presented in Figure 88-7.

The current concept is that OC is a highly dynamic disturbance of endochondral ossification that is intricately linked with the rapidly changing metabolic status of articular cartilage in the juvenile animal. This concept has led to some hypotheses and statements regarding the origin and implications of the

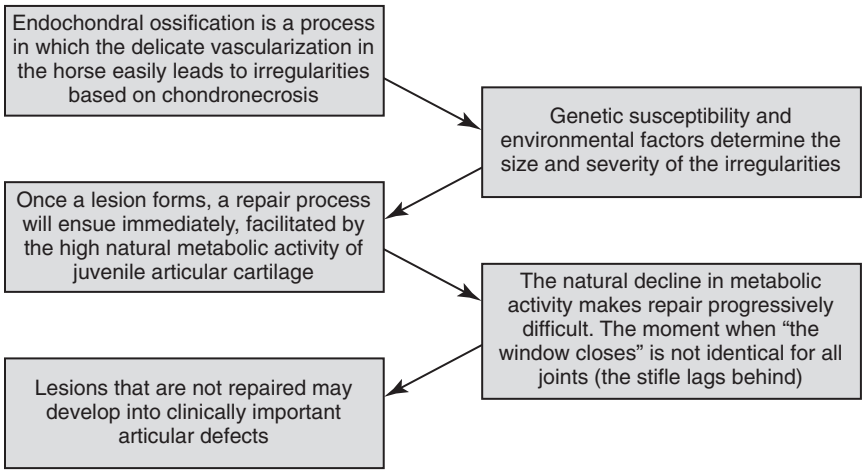

Figure 88-7. Flow chart outlining the supposed pathway along which clinical lesions eventually could become manifest in equine osteochondrosis.

disorder that were expressed at the Third International Workshop on Equine Osteochondrosis that was held in Stockholm in 2008. These assumptions and conclusions include that (1) "OC defined as irregularities in endochondral ossification is inherent to the equine species; modern management and breeding policies have caused the sharp rise in incidence," (2) "differences in collagen metabolism and/or gene expression between OC cartilage and normal cartilage may in many cases reflect the secondary repair process," and (3) "there may be a genetic correlation between susceptibility for OC and desired traits such as mature height, conformation and performance."[64]

ETIOLOGIC FACTORS

OC is a complex disease and multifactorial in origin. Biomechanical influences, exercise, failure of vascularization, nutrition imbalances, and genetic influences have all been incriminated as potential etiologic factors and are probably interrelated. Support for each etiologic factor is presented next.

Biomechanical Influences

Biomechanical loading plays a role in the pathogenesis of OC. This assertion is supported by the consistency of predilection sites within specific joints. It is probable that the dramatic changes in biomechanical loading that take place after birth are an important trigger for initiating lesions. In a pathologic study of the FP and TC joints of 9 fetuses and 10 foals aged 0 to 35 days, an OC lesion was detected in only one 3-day-old foal and none were found in any of the fetuses.[46] Although one group of researchers found many tiny areas of chondronecrosis in all 21 fetuses they studied, which they saw as a feature of normal development, they were not able to find specific changes in the collagen matrix compatible with early OC in any of them.[50] Other attempts to find OC lesions in fetuses have also failed.[65,66] Therefore biomechanical loading most likely plays a role in all proposed mechanisms for OC.

Biomechanical loading can exert an influence late in the process of OC development, where it causes the formation and loosening of cartilage flaps after faulty endochondral ossification, or early where it prematurely disrupts the vascular supply to neonatal cartilage (see next section). Biomechanical influences are strongly correlated with other etiologic factors such as exercise and genetics (through the determination of conformation of the animal). However, apart from direct blunt trauma that will cause an osteochondral fracture, biomechanical forces are considered a necessary additive factor rather than a sole cause of OC.

Failure of Vascularization

One report described the existence of cartilage canals in the epiphyseal cartilage long ago.[67] The author stated that "the primary function of cartilage canals is … the nutrition of cartilage too large to be supplied by diffusion of nutriments through their substance. … Their presence retards rather than hastens the end of ossification." The author also described the process of obliteration of these canals, called *chondrification*, which precedes ossification.

In the pig, extensive studies have been performed on the vascularization of juvenile cartilage, the physiologic process of regression of cartilage canals, and disturbances thereof as possible causes for OC. In this species, areas of chondronecrosis related to obliterated cartilage canals can be found, and they are much larger in commercial pig breeds than in miniature pigs from wild hog ancestry.[68] Artificial devascularization creates islands of cartilage without vascular supply, and these could develop into OC-like lesions.[69] These observations led to the hypothesis that premature interruption of the vascular supply of the growth cartilage of the articular–epiphyseal complex would lead to necrotic areas in the cartilage layer. These would later become engulfed in the ossification front and result in the typical irregularities and cartilage islands seen in OC.[70]

Later in-depth studies in this same area applied a more subtle and natural way of interrupting vascularization, by transecting only a limited number of cartilage canals, leading to the development of OC-like lesions.[71] No relationship between the overall regression pattern of cartilage canals and OC was shown. This led to the conclusion that OC is not the result of a general failure in endochondral ossification, and hence cannot be caused by a systemic factor such as growth rate, but is incited by local biomechanical factors.[72] This finding led, together with additional observations, to the hypothesis that OC was caused by local biomechanical damage to cartilage canals, especially to the anastomosing branches that run through the ossification

front from the bone marrow.[73] Based on their extensive work in pigs, some researchers suggested that a disturbance of the blood supply through cartilage canals to predilected areas of the growth cartilage, with ensuing formation of necrotic areas, was a pivotal element in the early pathogenesis of OC. The authors proposed a refinement of the existing nomenclature by introducing the terms *osteochondrosis latens* for focal areas of necrosis that are not clinically manifest, and *osteochondrosis manifesta* for where the necrotic area had developed into a delay in endochondral ossification. The term *osteochondrosis dissecans* would be retained in cases of cleft formation.[74]

In the horse, cartilage canals are present in the early juvenile period as well, and it could be assumed that a similar early pathogenesis seen in the pig would occur in the young foal. Much work in this area has been done. In the first cross-sectional study in random source foals (ranging from 191 days gestation to 153 days old), it was shown that lesions resembling those in pigs (i.e., characterized by chondrocyte necrosis and apparently caused by cartilage canal failure) were present in 9 out of 100 animals.[75] Interestingly, in all but the two youngest individuals (aged 12 and 18 days) an ongoing repair process was also noted. A highly interesting follow-up experimental study into the development of the vascularization of the tarsus of seven very young foals (0 to 7 days old) followed, showing in an elegant way how the advancing ossification front induces a change in the arterial supply of the cartilage canals in the growth cartilage from perichondral arteries to subchondral sources that are connected to the original cartilage canals through newly formed anastomoses that cross the ossification front (Figure 88-8). The authors found 12 lesions in these seven foals, all located where vessels crossed the ossification front to supply cartilage canals.[76] In a similar study focusing on the distal femur, another predilection site of OC, they could find in principle similar changes in vascularization, but the regression of blood vessels was much less extensive at this early age than in the tarsus, and no lesions could be found.[77] This may have to do with the fact that the FP joint lags behind in its development[50,51] and shows the peak of OC lesion development later than in most other joints.[27] In the MCP/MTP joint, again the pattern of changes in vascularization was similar; in this case one ("*latens*") lesion was found.[78] Of note, microcomputed tomography of the early lesions showed that the secondary repair process follows almost immediately after the formation of the lesion.[79]

As a result of recent studies, there now remains little doubt that, as in the pig, failure of vascularization through occlusion of cartilage canals (and not retention of these, as suggested earlier[80]) plays a crucial role in the early pathogenesis of OC in the horse.[76-79] Many features of equine OC, such as the joint-specific windows in time (related to joint-specific patterns in the progress of the ossification front and subsequent vascular rearrangements), and the frequent bilateral occurrence can be explained in this way. However, it should be realized that these

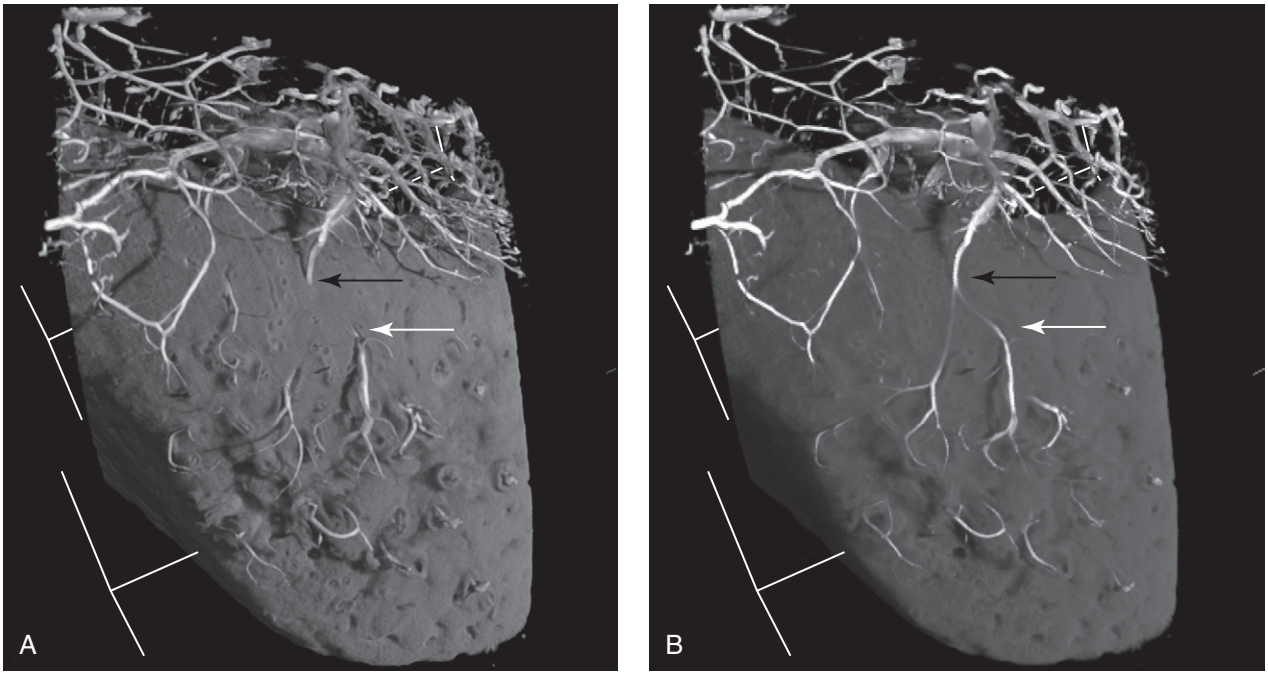

Figure 88-8. Images of three-dimensional volume-rendered models of micro-CT scans of a tissue block from the cranial part of the distal intermediate ridge of the tibia of a 3-week-old Standardbred foal. The block contained a permanent barium angiogram, and only the gray-scale segments representing barium and bone are shown. The block measured approximately 2 cm in all dimensions. **A,** A vessel originating from the perichondrial plexus on the cranial aspect of the distal tibia courses into the subchondral bone toward the cranial apex of the distal intermediate ridge *(black arrow).* Distal and caudal to this, toward the distal articular surface of the intermediate ridge, vessels emerge into the growth cartilage directly from subchondral bone *(white arrow).* **B,** In this model of the same tissue block, the gray-scale segment for bone has been rendered less opaque/more translucent than in model **A.** The vessels emerging from bone into growth cartilage *(white arrow)* are branches of the vessel entering bone on the cranial aspect of the intermediate ridge *(black arrow).* The model illustrates how the midsection of cartilage canal vessels is incorporated into the advancing ossification front during growth. This process, and in particular the requirement for vessels to traverse junctions between tissues of different qualities such as bone and cartilage, is believed to render vessels particularly vulnerable to failure. (Courtesy Dr. K. Olstad, Norwegian School of Veterinary Science.)

vascular events present an early mechanism and not the etiology, as still other factors (like biomechanical loading or even perhaps inferior quality of the cartilage extracellular matrix) are necessary to cause the lesion during the period of vulnerability. These factors will determine in the end why a given horse develops OC and another does not.

Exercise

Exercise is known to be the steering factor in the process of functional adaptation during which the biochemical composition of the extracellular matrix of articular cartilage takes on a topographically heterogeneous character.[57,81,82] This process takes place principally in the first year of life, with emphasis on the first few months. Given the important role of exercise in the juvenile period for cartilage development, it may be hypothesized that this factor would be of importance in the development of OC lesions too, because these originate in the same period that articular cartilage composition is molded.

Preliminary research in which controlled exercise was given to foals from 3 to 24 months of age using a high-speed horse walker yielded promising results. OC incidence was 6% in the high-exercise group and 20% in the low-exercise group, but results were flawed because of a concurrently running nutritional study employing different energy levels that were not consistently applied.[83,84] A study focusing on the effect of exercise alone, given from 10 days until 5 months of age, did not yield conclusive results, although there was a tendency toward a decrease in *severity* of OC lesions in the exercised groups.[12]

In a large field study, one researcher found fewer OC lesions on the distal sagittal ridge of the metacarpus and metatarsus in the MCP and MTP joints of foals that got more exercise during the first months of life. There was, however, no effect on the incidence of OC in the TC joint.[85] Another large field study conducted in Normandy (France) revealed an increased risk of OC in foals with irregular access to pasture, as well as in animals kept in very large plots. These results underline the somewhat ambivalent character of the effect of exercise.[34] Exercise might hence be a factor codetermining the final appearance of OC lesions, but it does not seem to be of primary pathogenetic importance.

Nutrition, Hormonal Factors, and Growth Rate

From the start of research into equine OC, much effort has been dedicated to nutritional factors. The studies can be roughly divided into research on minerals and trace elements, mainly copper and zinc, to a lesser extent calcium and phosphorus, and on dietary energy level. The latter factor is closely related to growth rate, a factor heavily incriminated in OC pathogenesis in a large number of species. However, growth rate is determined not only by energy intake but also by genetic predisposition.

Interest in trace elements was raised by a report on the relationship between low *copper* levels in serum and ceruloplasmin concentrations (a copper-transporting protein present in the blood) and OC.[86] Studies followed on the effect of deliberately feeding low-copper diets[87] and the possible role of zinc in inducing a relative copper deficiency.[88] The mechanism was thought to act via the enzyme lysyl oxidase, a copper-dependent enzyme that is essential for the formation of collagen cross-links. Zinc and cadmium can antagonize copper by displacing it from the sulfhydryl binding sites on metallothionein.[89]

The epidemiologic studies on dietary mineral and trace element levels and the occurrence of developmental orthopedic disease in Ohio and Kentucky seemed to give further evidence for a key role of copper.[90] The original National Research Council (NRC) recommendation[91] of 10 ppm copper in dry matter, which was based on a study with a limited number of horses,[92] was challenged, and supplementation studies were started. These yielded positive results to some extent,[93-95] but they certainly were not conclusive enough to pinpoint copper deficiency as a sole cause of OC.[96] Higher dietary copper levels of 20 to 25 ppm[95] or 50 ppm[97] were recommended, but they were later questioned following studies revealing that copper levels of 4.3 to 8.6 ppm in pasture were sufficient for a healthy development of bone and cartilage.[98] The evidence to support copper supplementation to pregnant mares is equivocal. Although one study showed an increase of liver copper concentration in newborn foals after prenatal supplementation of mares during late pregnancy[99] and noted a (minor) reduction in articular cartilage lesions at age 5 months,[98] another study conducted in the same country (New Zealand) failed to demonstrate both effects.[100] In both studies lesions were minimal, however, and no clinical OC was seen. This means that, if any effect on the initiation of lesions exists, this will be minor. It does not mean, however, that copper supplementation of pregnant mares or newborn foals, which may also raise liver copper content,[101] may have no clinical benefits, because another study showed that there was a relationship between neonatal liver copper concentration and the resolution of lesions, but there was no correlation with the initial occurrence.[53] It was concluded from that study that copper had a positive effect on the repair of OC lesions but not on their pathogenesis. This concept could explain many of the somewhat contradictory and inconclusive earlier findings. Therefore copper retains a clinically important role, because it is the outcome of both the pathogenetic process and the ensuing repair process that determines the eventual and clinically important lesions. Although the proposed mechanism of the effect of copper via lysyl oxidase has been challenged,[102] there is still mechanistic evidence for a role of copper, because *in vitro* research yielded additional information on the role of copper that appeared to have a chondroprotective effect through reduction of the activity of the proteinases cathepsin B and cathepsin D.[103]

High *calcium* levels did not influence the incidence of OC in foals, but high levels (four times the NRC recommendation) of phosphorus resulted in significantly more lesions.[104] The mechanism was supposed to be the induction of secondary hyperparathyroidism, which would lead to increased osteoporosis and subsequent weakening of the subchondral bone. The study is interesting because foals were studied in the period from 2.5 to 6.5 months of age, which is now known to be a period in which the dynamic process of OC is very active.

Dietary *energy levels* have been implicated in the pathogenesis of OC for decades.[105] This was mostly, but not solely, in relation to a high growth rate. In the early Scandinavian studies, it was stated that OC primarily occurred in large-framed, fast-growing animals, be they broilers, bulls, dogs, swine, or horses.[8,48] Later, the literature turned more ambivalent on the subject of growth rate. Several authors found no relation to growth rate,[14,106,107] but others reported a larger prevalence in horses taller at the withers[15,34] or in horses having a higher average daily weight gain.[108] Sometimes this was only true for a limited period of development.[109] In a study where a normal level of nutrition

was compared with an increase of 120% to 150% in all components of the diet, a fast growth rate was associated with a higher amount of OC lesions, regardless of whether the fast growth rate was determined by a higher nutritional level or by genetic predisposition.[54]

Although the data on the effect of growth rate are conflicting and the concept of a high growth rate putting pressure on the process of endochondral ossification and thus leading to irregularities might be too simplistic, there is substantial evidence for other mechanisms. Excessive levels of energy, especially when fed in the form of easily digestible carbohydrates,[110,111] result in a strong postprandial hyperinsulinemia. *Insulin* and its derivatives insulin-like growth factor-1 (IGF-1) and IGF-II have a direct effect on the process of endochondral ossification, acting as mitogens for chondrocytes and stimulating chondrocyte survival or suppressing apoptosis.[112] Many of today's horses are fed excessively and have low activity levels, which may, as in humans, lead to obesity and insulin resistance. The latter condition has been related to many pathological conditions, including laminitis and OC.[113]

Insulin also stimulates a rapid removal from the circulation of the *thyroid hormones* T_3 and T_4,[114] which are involved in the final stages of chondrocyte differentiation and in the metaphyseal invasion of growth cartilage by blood vessels.[115] In fact, OC-positive foals have a significantly lower IGF-1 activity than OC-negative foals.[116] In this way, high carbohydrate levels would induce a transient relative hypothyroidism and hence a retardation of the maturation of growth cartilage. Hypothyroidism in horses has been known to produce skeletal lesions, although they are not equivalent to those seen in OC.[117]

Interestingly, the effect of *carbohydrates* on thyroid hormone levels can be demonstrated in weanlings, but it is not present in yearlings.[118] It has been possible to induce cartilaginous lesions by administering diets with high levels of digestible energy.[104,119] Furthermore, horses with OC have been shown to have higher postprandial glucose and insulin responses to feeding high-grain ratios than did normal horses.[120]

Another indication of the importance of carbohydrate levels in the feed comes from a study in Kentucky on the influence of the season on the occurrence of OC. Early foals appeared to have a significantly higher incidence of OC in the TC joints, but late foals had a higher incidence in the FP joints. This seemingly contradictory effect of the season could be explained by the different windows of vulnerability of these joints, which appeared to coincide with the spring and autumn peaks in the high-energy value of the grass.[31]

There is hardly any doubt that the pathogenetic mechanism outlined here plays a certain role in the development of equine OC. However, it is unlikely that it is the sole mechanism, because many lesions provoked by the administration of high-carbohydrate diets were similar, but they were not always identical to those seen in clinical OC. Besides, many lesions were seen in the growth plate,[107] and in contrast to other species, clinical OC is rarely, if ever, seen in the growth plate in the horse.

Genetics

In many species, the incidence of OC varies considerably with breed. In wild boars, the disease seems to be nonexistent, whereas it is common in many commercial pig breeds.[70] In horses, lesions are rarely found in ponies and have a much lower incidence in feral horses.[37,38] This suggests a considerable genetic influence. Further evidence comes from studies showing large differences in incidence of OC between progeny groups of different stallions.[15,47,121]

There is no doubt that OC is a polygenic trait and that the method of inheritance is complex.[122] Some estimates on heritability have been made, but they differed widely. For the TC joint, heritabilities of 0.24,[123] 0.26,[15] and 0.52[124] have been reported. A large progeny study in the Netherlands succeeded in establishing reliable heritabilities for navicular disease and bone spavin, but it did not give unequivocal results with respect to TC OC, which finally was estimated to be approximately 0.25.[125]

Heritabilities of 0.25 and higher are high enough to warrant selection programs, which indeed have been implemented by many studbooks. However, progress has been disappointing. The Royal Dutch Warmblood Studbook (KWPN) started rejecting any candidate sire with even the slightest radiographic sign of TC OC in 1984 and any sign of FP OC in 1992, but no substantial decrease in incidence had been realized by mid-2010. This is in contrast to the conditions of navicular disease and bone spavin, where a similar selection policy has been followed. The number of potential stallions rejected for these disorders at selection events has fallen dramatically over the past decades.[126]

There are various explanations for this. OC is classically seen as an all-or-none trait with an underlying continuous scale.[122] The genetic background may, however be much more complicated than originally supposed. First, there is mounting evidence that different genes are involved in different joints. This translates to different heritabilities for different joints. In a study where OC was scored on a 5-point categorical scale in 811 yearlings, the h^2* at animal level was estimated at 0.23, which concurs well with the other studies mentioned earlier. However, the figures per joint strongly varied, being high (0.36) for the TC joint, intermediate (0.11) for the MCP/MTP joints, and very low (0.06), for the FP joint.[127] Heritabilities are largely breed dependent. A study on South German Coldbloods revealed heritabilities of 0.16 for the MCP/MTP joints, which is comparable to the figure found by another group, but of not more than 0.04 for the TC joint.[128] A second point complicating the genetic approach of OC is its dynamic nature. This feature allows many animals to be radiographically free of lesions at age 3 or 4 years when they enter the stallion selection procedures, yet they will have had evidence of the disease as a foal. Hence, these foals are genetically predisposed to OC and will pass this trait on. Realization of the complexity of the genetic background of OC has led to adaptations in selection policies in certain studbooks. The KWPN now uses a more differentiated approach in which lesions are classified and stallions with minor lesions still may pass. Approval is temporary, however, because data from offspring are now included in the selection procedure and are used to calculate breeding values. If a provisionally approved sire produces a high prevalence of OC in its offspring, it may still be eliminated.

Recently, studies have been undertaken to identify OC-related genes through modern molecular genetic techniques. The previously mentioned study on South German Coldbloods involved mapping of quantitative trait loci (QTL) for OC and

*h^2 is the broad-sense heritability and reflects all possible genetic contributions to a population's phenotypic variance.

POF in the MCP/MTP and OC in the TC joints. QTL with chromosome-wide significance on was found on 10 chromosomes.[129] The researchers later expanded the data from their whole-genome scan further and found an association of a single nucleotide polymorphism (SNP) located in the acyloxyacyl hydrolase (AOAH) gene on chromosome 4 with OC in the MCP/MTP joint[130] and of other SNPs located in the Xin-actin-binding repeat containing 2 (XIRP2) gene with OC in both MCP/MTP and TC joints on chromosome 18.[131] A similar genome-wide approach in Hanoverian horses identified QTLs with chromosome-wide significance on chromosomes 2, 3, 4, 5, 15, 16, 19, and 21.[132] Further investigations identified a relevant QTL on chromosome 5, indicating collagen type XXIV as a potential functional candidate gene.[133] A later study, in which marker density on chromosome 18 was increased based on the earlier observations by the same group in South German Coldbloods,[131] showed a new QTL on this chromosome that was associated with OC and located very close to the parathyroid hormone 2 receptor gene, qualifying the latter, which had earlier been implicated in familial early-onset osteoarthritis (OA) in humans,[134] as an interesting positional candidate gene.[135]

Another approach was taken by a group, who compared gene expression profiles of leukocytes from horses affected by OC and normal controls, and identified dysregulation of a number of pathways, among others Wnt,* Indian hedgehog (Ihh), and transforming growth factor-β (TGF-β) signaling, in OC-affected animals.[136] The problem with this approach, as with the earlier described genome-wide scans, is that material from horses with established OC is used so that no distinction can be made between primary and secondary processes. This applies to a much lesser extent to work performed on the very young foals from the experimental study[76] on vascular changes in the growth cartilage alluded to earlier, where the Tousler-like kinase 2 gene (TLK2) and an unknown gene were found to be upregulated in foals predisposed to OC.[136]

It is clear from the previous discussion that the genetic background of OC is complex and not very easy to unravel. This may have to do with the fact that most genetic studies try to link the final phenotype, and thus the end product of various processes that have most probably different genetic backgrounds, to certain genes. It is highly unlikely that in the near future OC can be selected against using a simple genetic test that detects one or two culprit genes.

MOLECULAR MECHANISMS

The need for a more fundamental approach to understanding and preventing OC is obvious,[137] and in recent years a large part of research on equine OC has focused on the molecular mechanisms involved. Both *chondrocyte behavior* and composition of the extracellular matrix have been targets of study. A study found that chondrocytes that were freshly harvested from fetal growth cartilage underwent hypertrophy and subsequently apoptosis when cultured in either the commonly used fetal calf serum or horse serum in a situation that strongly resembled the natural processes involved. Chondrocytes from animals older than 5 months did not undergo hypertrophy, and chondrocytes from neonates (7 days) showed intermediate behavior.[138] This research once more stresses the importance of age when studying OC. Failure to undergo hypertrophy as main cause for OC was discarded in a study in which OC was induced in 3- to 6-month-old foals by a high-energy diet and that investigated the expression of hypertrophy-related genes, such as collagen I, II, and X; matrix metalloproteinase (MMP)-13; and the transcription factor Runx2. The higher expression of collagen X and MMP-13 (the main matrix metalloproteinase involved in collagen degradation) indicated that failure of chondrocytes to undergo hypertrophy is not the cause of OC, as had been suggested earlier.[139] Another study found changes in proteoglycan composition of osteochondrotic fragments, but they could not tell whether this was primary or secondary.[140] This is a constant problem, because data from clinical cases and fragments collected at surgery are not representative of the initial phase of the disease.[7]

Studies have focused on normal and abnormal (dyschondroplastic) cartilage, on the expression of various *collagen types* that are represented in the extracellular cartilage matrix (collagen types II, VI, and X), and on the expression of growth factors (TGF-β, IGF-1, IGF-2) that are known to play a role in the development and maturation of cartilage.[112,141-145] There appeared to be distinct differences in expression patterns between normal and abnormal tissues, with notably high levels of activity around the chondrocyte clusters or chondrones in early cases of OC. This increase in activity is in line with the higher level of chondrocyte metabolism demonstrated by one research group[146] and could be the primary cause, but it is more likely a secondary event representing an attempt at repair.[147] The borderline between the OC lesion itself and repair tissue is vague, probably because the onset of repair is almost immediately after formation of a lesion and because events are taking place in juvenile cartilage that still has considerable regenerative capacity. In a study where OC tissue was compared with tissue from healing surgically created osteochondrotic fragments, no discrimination could be made between the two types of tissue. Both resembled an anabolic, reparative process when compared to age-matched controls. However, immunohistochemically, the OC tissue bed stained positive for chondroitin sulfate and collagen type II, which the fracture bed did not.[51]

Little work has been done on the *subchondral bone* underlying the cartilage defects. One group showed changes in bone morphogenic enzymes and in membrane lipid composition of the cellular components of the subchondral bone.[148] There are clear indications that the bone component is involved in lesion formation in OC too, as there is a strong correlation between serum osteocalcin levels as early as at 2 weeks of age with radiographically scored OC at 5.5 and 11 months and postmortem scores at 11 months (i.e., when lesions had become virtually immutable).[149] Osteocalcin might therefore be a potential marker for the susceptibility of individual animals to develop OC. The relationship between OC and osteocalcin may indicate very early events indeed, because in another study where serum from foals aged 1 to 49 days was used, no such correlation was found.[150]

Levels of MMPs were found to be elevated in copper-deficient horses with clinical OC lesions,[95] and there is increasing evidence that changes in collagen metabolism play an important role in the molecular mechanism of OC. The Cambridge group

*The Wnt (pronounced "wint") signaling pathway is an important pathway in intracellular signaling. The name comes from "wingless" (referring to a *Drosophila* mutant where all these basic pathways have been discovered).

performed in-depth studies on the distribution of cathepsins B, D, and L in normal and abnormal cartilage. They found physiologic differences in distribution[151-153] as well as a strong increase in cathepsin B activity in chondrocyte clonal clusters in OC.[154] The latter finding was confirmed in a study on the effect of copper supplementation.[155]

Another study revealed an increase in activity of *gelatinases* (MMP-2 and MMP-9) in osteochondrotic cartilage.[156] However, expression of membrane-type matrix metalloproteinase-3 (MT3-MMP) is not significantly altered in osteochondrotic cartilage.[157] The increased collagen turnover in osteochondrotic cartilage is reflected by an increase in collagen split products that can be detected in the synovial fluid. An increase in the C-propeptide of collagen type II was detected in synovial fluid from OC horses, but a decrease was found for the epitope 846 of aggrecan, demonstrating different alterations in aggrecan and collagen turnover in OC.[158] This finding was confirmed in a later *ex vivo* study where no evidence was found for an increase in proteoglycan metabolism, but an increase in the levels of the $col_{2\text{-}3/4\ short}$ epitope indicated increased collagen breakdown.[159] The different signature of osteochondrotic cartilage with respect to proteoglycan and collagen metabolism was further underlined by a study on expression patterns and chondrogenic potential of osteochondrotic cartilage (from mature animals) versus normal cartilage (from age-matched controls) where OC cartilage showed increased expression of collagen types I, II, III, and X; MMP-13; ADAMTS-4; and TIMP-1; and decreased expression of TIMP-2 and TIMP-3. Furthermore, pellet cultures produced from OC tissues contained significantly less glycosaminoglycans (GAGs).[160] *In vivo* increased collagen degradation has also been shown.[161]

One group was able to predict the presence of OC based on the detection of *collagen markers* in serum.[162] In line with this, a well-controlled experimental study revealed that the ratio of the markers for collagen anabolism and catabolism (CPII/CIIC) at 20 weeks had strong positive correlations to OC, as diagnosed radiographically at 5.5 months.[149] Additional evidence for the crucial role of collagen was provided by studies demonstrating a significant increase in the levels of MMP-1 (but not general MMP activity or specific activity of MMP-3), and in the levels of the collagen degradation product hydroxyproline in synovial fluid from horses with OC compared to OC-free animals.[163-165] Additionally, differences in posttranslational modifications of collagen type II have been demonstrated in samples from early lesions.[166] Serum levels of the collagen degradation marker Coll2-1 were lower in OC-affected horses, and levels of the nitrated form Coll2-1NO_2 were higher. These findings point to some degree at an inflammatory state and at the retention of cartilage, rather than at accelerated breakdown.[167] Also the inflammatory marker myeloperoxidase (MPO) was higher in serum from horses suffering from OC, compared to age-matched controls.[168] However, the subjects of both studies were (young) mature animals in which only secondary processes could be expected to occur. In a study on synovial fluid markers in another group of mature horses, an indication for the existence of low-grade inflammation was also found in the elevated leukotriene B_4 (LTB_4) level, which was putatively associated with the occurrence of joint distention.[169] Overall, there now seems to be conclusive evidence that changes in collagen metabolism play a crucial role in the molecular mechanism of OC. The question of whether this is a secondary or a primary event remains unanswered. There is also low-grade inflammation, which seems to be reactive in nature and is not a primary factor.

Parathyroid hormone related protein (PTHrP) and Ihh have a role in controlling cartilage differentiation and hypertrophy in the growth plate.[170] This influence is mediated by *bone morphogenetic proteins* as signaling peptides. This led to the hypothesis that these molecules would have a similar role in cartilage differentiation in the equine articular–epiphyseal complex and could be implicated in the pathogenesis of OC. There was indeed a significant increase of PTHrP and mRNA expression in chondrocytes from OC-affected cartilage and a trend in Ihh.[171] Expression of bone morphogenetic proteins 6 and 2 was not changed.[172] Also, expression of transcription factors Gli1 and Gli3 was not increased, suggesting either a different transcription factor in osteochondrotic tissue, a dysfunction in local receptor activation, or elevations in Ihh inhibitors. It should be noted that these investigations were performed on samples from horses aged 6 to 18 months, which makes their outcome likely to be representative for early repair rather than for the pathogenesis of lesions.[173] The same applies to the observation that serum IGF-1 levels were higher in a large group of OC-affected horses aged 15 months to 10 years compared to controls.[174]

TREATMENT

Nonsurgical Management

Treatment of small OC lesions might not always be necessary. Single small, radiographically obvious OC lesions in the TC joint without effusion did not influence performance in racing Standardbreds, in contrast to joints where there was significant effusion.[123] There is a negative effect on performance, however, if the lesions are more severe.[175] Trotters with OC lesions in the TC joint had a significantly lower number of starts and somewhat lower earnings compared to controls.[176]

Nonsurgical treatment consists principally of rest and controlled exercise. Systemic NSAIDs and intra-articular medication (corticosteroids to enhance resolution of joint effusion and certain disease-modifying osteoarthritic drugs such as hyaluronan, chondroitin sulfate, or pentosan sulfate) may or may not be administered, but they have not been reported to be of great value in OC.[177] Given the nature of the disease described earlier, nonsurgical management can only be expected to be successful in either very young animals, where there is still good capacity for regeneration, or in very mild cases.

A large study on the natural history of FP OC in three crops of Thoroughbred foals showed improvement and repair of several lesions, which was compatible with the age of the animals studied.[13] One group described a favorable outcome of nonsurgical treatment of TC OC in a group of Standardbreds, half of which were treated nonsurgically and half surgically. The authors mentioned, however, that these results were biased, because the more severe cases tended to be treated surgically.[178]

One study concluded that nonsurgical treatment of TC OC (consisting of simple box rest or a less intense training program with a low-energy diet) was a good option in Warmbloods (80% success rate), but not in Standardbreds (25%). It should be noted that in Warmblood horses, especially those destined for dressage, resolution of joint effusion is often a therapeutic goal in itself. This aspect was not classified as such in this study.[179]

Surgical Management

Surgical management is the treatment of choice in most cases.[180,181] Clinical experience has taught that arthroscopic surgery presents definite advantages over arthrotomy.[182] Soft-tissue trauma is less, the convalescent period is considerably shorter, and functional and cosmetic recovery are better. An additional advantage is that a more comprehensive examination of the joint is possible.[6] A direct comparison of arthroscopic treatment and treatment by arthrotomy demonstrated that hospitalization time was almost five times shorter after arthroscopy than after arthrotomy. Even more importantly, horses returned significantly more often to their intended use.[182]

Arthroscopic surgery is widely used in the FP, TC, MCP, and MTP joints to treat OC. In some other joints where OC is encountered less often but can present a serious clinical problem, such as the scapulohumeral joint, an arthroscopic approach is feasible as well, but the technique is considerably more difficult.[25,183] The surgical techniques applied are discussed in more detail in Chapter 13 and in the relevant chapters discussing the respective joints.

PROGNOSIS

The prognosis after surgical intervention varies among joints and depends on the amount and extent of the lesion. It further depends on the definition of "favorable outcome." In most racing Thoroughbreds and Standardbreds, a favorable outcome means a sound horse that can compete at its maximal athletic capacity. In many show horses, the cosmetic appearance is important as well. In general, prognosis for a return to athletic activity is fair to good for the majority of joints involved.

For the FP joint, a 64% success rate was reported,[184] but this figure might be too pessimistic because the study included many horses operated on at a young age before their first performance. Therefore it included a number of horses that would never have raced despite the OC lesions because attrition rates in Thoroughbred training are high and many young horses will never race. Jockey Club records indicate that only about 60% of all Thoroughbreds intended for racing ever reach the starting gate in the United States.

In another study, 19 of 25 arthroscopically treated horses (76%) were able to perform their intended use.[182] Racing performance in Thoroughbreds treated for FP OC was not different from that in unaffected siblings, but fewer horses raced as 2-year-olds and earnings were less, both at 2 and 3 years of age.[185] Also, 2-year-old Thoroughbreds and Standardbreds that were operated on for OC in the TC joint were less likely to race, compared to unaffected siblings at 2 years of age, but findings were not different between groups at 3 years of age.[186] The differences might be mainly the result of the delay in training caused by the surgery.

One group reported success rates of 73% and 83% for the TC joint in racehorses and non-racehorses, respectively. Synovial effusion resolved in 89% of racehorses and 74% of non-racehorses.[19] Of the other joints, prognosis is least favorable in the shoulder joint, with 46% success reported.[25] In one study a favorable outcome of only 15% was found in racehorses suffering from shoulder OC, regardless of whether treatment was surgical or nonsurgical,[187] emphasizing the poor prognosis of shoulder OC in animals that have to perform strenuous exercise.

In the MCP and MTP joints, there is some confusion about the extent to which radiographically detectable lesions are part of the OC complex. Fragments of the dorsal aspect of the distal metacarpus and metatarsus are commonly accepted to be osteochondrotic, and in these, 57% success has been reported after surgery. This figure is negatively biased because 18% of the cases were classified as unsuccessful for other reasons that made the horse unsuitable for use.[188] A more recent source mentions 90% return to athletic activity if the lesion is located in the more proximal part of the sagittal ridge but an unspecified lower rate for lesions in weight-bearing areas.[189]

Prognosis for arthroscopic removal of osteochondral fragments of the dorsal articular margin of the proximal phalanx, of which the osteochondrotic nature is still contentious, is given as nearly 100%.[188]

CHAPTER
89

Subchondral Bone Cysts

Jörg A. Auer and Brigitte von Rechenberg

DEFINITION

Subchondral cystic lesions (SCLs) are commonly referred to as subchondral bone cysts and are considered by some to be part of the developmental joint disease complex. SCLs in bone were once considered a coincidental finding in horses and not necessarily related to lameness or disease.[1,2] Currently they are recognized as a serious cause of lameness that can be difficult to treat.[3] They are characterized by radiolucent areas of bone (from several millimeters up to and even larger than 3 cm) often accompanied by a thin, but well-demarcated, sclerotic rim (Figure 89-1). The center of the SCL is usually filled with myxomatous tissue, with or without fluid that resembles normal or slightly blood-tinged synovial fluid.[4] The SCL cavity was thought to be lined with a synovial-like membrane that was responsible for fluid production; however, this membrane cannot be verified in all instances.[4]

SCLs can be uniloculated or multiloculated and occur usually in the subchondral bone underlying the articular cartilage in a weight-bearing area of the joint.[3-6] Occasionally they are also found in the metaphysis or close to the growth plate (see Figure 89-1, *B*).[4,7]

ETIOLOGY AND PATHOGENESIS

In the past, SCLs were considered part of the osteochondrosis (OC) complex.[8,9] However, the location of OC lesions is different from that of SCLs. Normally, OC lesions occur at the transition from the weight-bearing to the non–weight-bearing articular surface,[10] whereas SCLs are found underneath the cartilage in a weight-bearing area of the joint.[4] All in all, many pathologic mechanisms leading to the development of SCLs have been proposed.[1,3-14] However, only two hypotheses have been supported experimentally in horses. The first hypothesis is based on a *hydraulic theory* and was supported by an experiment in which a slitlike lesion created in the articular cartilage led to the development of SCLs over a period of several months.[15,16] Other coincidental findings of SCLs in experimental studies using osteochondral grafting procedures support this theory, because SCLs developed at the host–graft interface

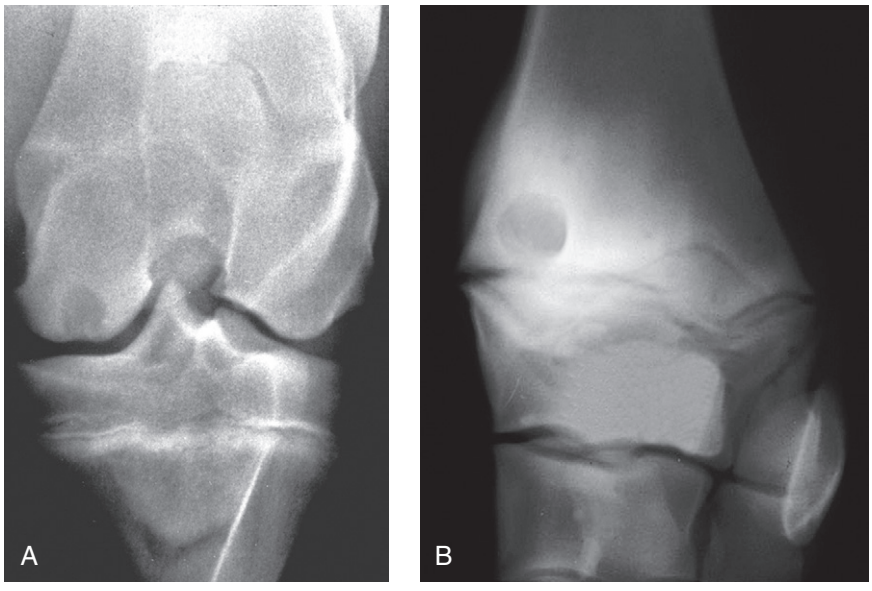

Figure 89-1. A, Radiographic view of a subchondral cystic lesion (SCL) in the medial femoral condyle of the stifle joint of a 3-year-old mare. The lesion is in the center of the weight-bearing area of the condyle and shows as a radiolucency, well demarcated from the surrounding normal bone by a thin sclerotic rim. **B,** Radiographic view of an SCL adjacent to the distal radial physis of a young foal. Note the periosteal new bone formation at the dorsomedial metaphysis.

between the osteochondral transplants and the host bone.[14,17,18] These experiments had a common denominator: there was primary cartilage damage followed by secondary intrusion of synovial fluid. The fluid was thought to place mechanical pressure on the subchondral bone through its hydraulic action during weight-bearing, resulting in necrosis of the subchondral bone plate. The second hypothesis (*inflammatory theory*) evolved around cellular and molecular mechanisms, when inflammation could be demonstrated in tissues and cystic fluid harvested from SCLs in horses.[7] The fibrous tissue harvested from the center of surgically managed lesions contained elevated concentrations of the local proinflammatory mediator prostaglandin E_2 (PGE_2), which also was found in high concentrations in the cystic fluid.[19] In addition, an upregulation of interleukin 1 (IL-1) and IL-6 was documented in the SCL. Using quantitative real-time polymerase chain reaction (qRT-PCR), an upregulation of IL-1 could be demonstrated at the periphery and upregulation of IL-6 at the center of the lesion.[20] Lastly, increased recruitment and activation of osteoclasts could be elicited *in vitro* when media of cultured fibrous, cystic tissue, and cystic fluid was incubated with osteoclasts isolated from 1-day-old rats (the pit resorption assay).[19] This was attributed to the combined effect of the cytokines IL-1 and IL-6 and the mediator PGE_2, which are normally elevated in clinical cases of pathologic bone resorption and inflammation.[21-23]

Other mechanisms have been suggested in the development of SCL in horses. These include primary subchondral bone damage and secondary collapse of overlying cartilage, disturbances of endochondral ossification, primary intraosseous fibroplasias or metaplasia, herniation or protrusion of synovial membrane through a small fissure in the articular surface, and vascular disturbances.[1,4,6,24] In contrast to the two theories presented earlier, none of these have been supported experimentally.

EPIDEMIOLOGY

An extensive literature review[4] involving 703 lesions in 619 horses (84 bilateral) revealed that SCLs occur mainly in the medial femoral condyle (MFC) (45.8%), followed by the phalanges (26.2%) (which included the navicular bone—18.5% of all phalanges), carpal bones (7.1%), metacarpal and metatarsal bones (6%), tibia, radius, talus, proximal sesamoid bones, humerus, patella, scapula, distal tarsal bones, and hemimandible (all less than 5%).[4] Sex distribution revealed that 62% of SCLs occur in males (41% stallions and 21% geldings). Thoroughbreds represented the majority of affected animals (39.5%), followed by Quarter Horses (14.1%), Crossbreds (12.2%), Standardbreds (9.9%), Arabian horses (8.5%), and Warmbloods (7.3%), with less than 5% in various other breeds. It seems that Warmbloods were overrepresented with cysts that occurred in the phalanges,[25] often accompanied by osteoarthritis.[3,26] Other sources report locations where lesions were encountered rarely, such as the proximal tibia and the patella.[12,27]

CLINICAL SYMPTOMS

Horses are often presented with lameness in the affected limb with or without joint effusion.[1] For example, when SCLs are located in the MFC, joint distention may be difficult to appreciate. Lameness is attributed to increased intracystic or intraosseous pressure, or both.[15] SCLs occur mostly in young horses between the ages of 1 and 3 years, when lameness commonly appears at the onset of training.[4] If SCLs are seen in older horses (Warmbloods), they often are accompanied by osteoarthritis (Figure 89-2) and associated with a poor prognosis.[1] Although the onset of lameness can be acute, the lesions are usually longstanding, having formed over time.

Figure 89-2. Radiographic view of a subchondral cystic lesion in the distal aspect of the proximal phalanx of a 9-year-old Warmblood gelding. The lesion is accompanied by osteoarthritis of the proximal interphalangeal joint.

SCLs usually can be localized using routine lameness examinations followed by standard radiographic views of the affected joints. In rare cases, when SCLs cannot be visualized radiographically,[1,5] computed tomography CT) has been of great value (Figure 89-3). Obviously, CT is applicable only from the carpus and tarsus distally, whereas scintigraphy can be used for other regions proximally. In one report, a variety of occult lesions in various bones of the tarsus, which were not radiographically visible, were localized using scintigraphy and confirmed with computed tomography.[28] SCLs also can be found unexpectedly during exploratory arthroscopic examination.

Communication between the SCL and the joint only occurs in 30% of affected animals[4] and often can only be localized during arthroscopic surgery (Figure 89-4) after insertion of an instrument across the overlying cartilage. The cartilage overlying an SCL is generally normal looking except close to the canal, where signs of matrix degradation can be detected (Figure 89-5). When SCLs are associated with osteoarthritis, signs pertinent to osteoarthritic cartilage lesions are present (see Chapter 78).

Tissues harvested from SCLs at the time of surgery or necropsy (Figure 89-6) reveal dense fibrous or myxomatous tissue containing necrotic bone, calcified or mineralized areas, or in some instances fibrocartilage.[4,8,24] The cystic wall consists of elongated fibroblasts aligned parallel to collagen bundles, scattered macrophages, and polymorphonuclear cells. Hypervascularity and thickened bone trabeculae can be noticed in the adjacent bone.[4]

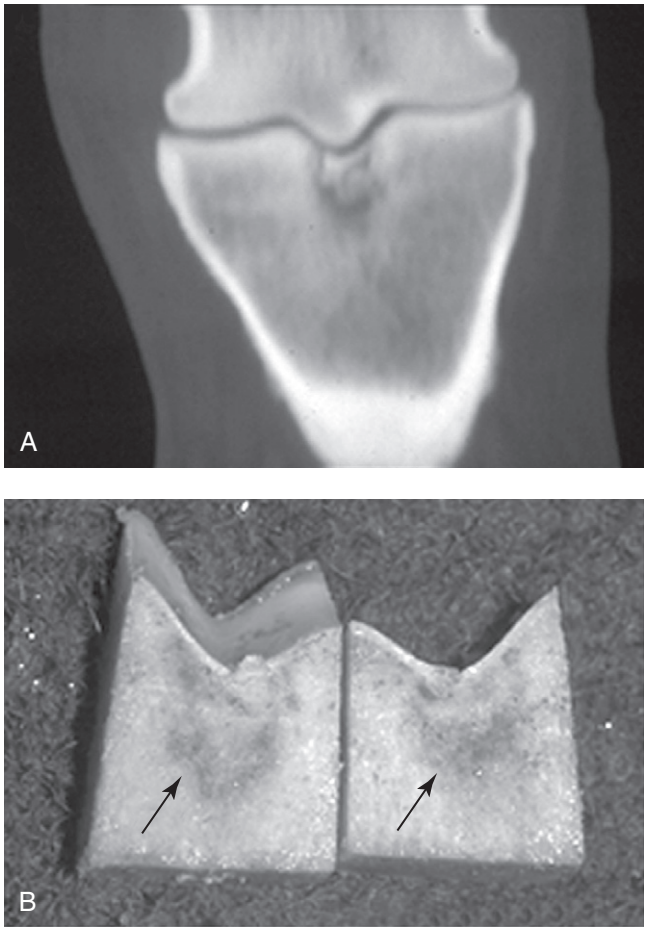

Figure 89-3. A, Computed tomographic image of a subchondral cystic lesion (SCL) in the metacarpophalangeal joint of a 4-year-old Warmblood mare, which was not apparent on radiographs. **B,** The postmortem specimens demonstrate that the SCL is not completely formed and that bone was still present within the SCL cavity *(arrows)*.

DIAGNOSIS

The diagnosis is made through a routine lameness examination. Flexion tests usually aggravate the lameness. Synovial distention is commonly seen, apart from joints proximal to the carpus and tarsus. One exception is in the stifle: when the medial femorotibial joint (with an SCL) communicates with the femoropatellar joint, it becomes effusive. Lameness usually improves with intra-articular anesthesia, and radiographic examination provides a definitive diagnosis in most instances.[5] The same joint in the contralateral limb should be evaluated radiographically to detect bilateral lesions. Other joints should be radiographed if effusion is present, because of the potentially multifocal nature of the disease. The size of the lesions on the radiographs can vary from a flattened condyle to a slight indentation in the subchondral bone surface to a round or oval lesion a few centimeters in height and width.

SCLs are graded using the following classification system[1,16]:

- Grade 1: Lesion less than 10 mm (4 inches) and usually dome shaped
- Grade 2a: Lesion more than 10 mm in depth with a narrow cloaca

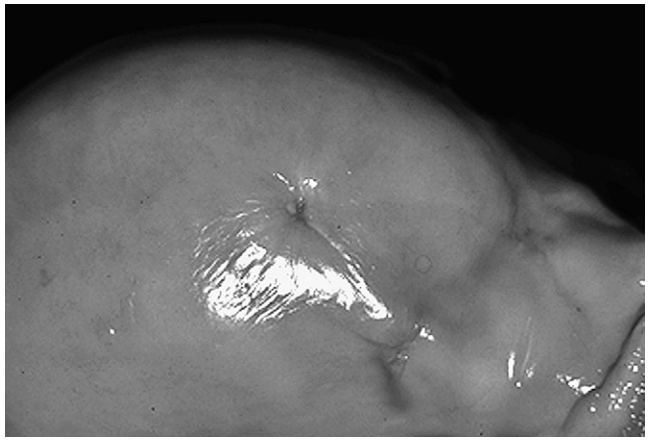

Figure 89-4. Postmortem specimen of a femoral condyle demonstrating a communication of a subchondral cystic lesion with the joint, which occurs in only 30% of the cases.

- Grade 2b: Lesion more than 10 mm in depth with a wide cloaca
- Grade 3: Condylar flattening or small defects in the subchondral bone
- Grade 4: Lucency in condyle seen with no radiographic evidence of a cloaca

The size of the lesion and the amount of articular cartilage involved has been correlated with clinical signs and prognosis in one study (70% returned to racing with less than 15 mm surface involvement after débridement versus 30% with more than 15 mm[29]), but this finding has not been confirmed in others.[1,16]

MANAGEMENT

Nonsurgical Management

Nonsurgical management of SCLs involves rest and the use of nonsteroidal anti-inflammatory drugs (NSAIDs), vitamin supplements, and anabolic drugs. This type of treatment is not very successful, because one study reported a failure rate of 66%.[4] Other reports on conservative management of this condition, with or without the use of nonsteroidal anti-inflammatory medication, listed success rates of 45% to 64%.[11,30] Interestingly, in one study, no significant differences were found in racing results between yearlings with radiographically diagnosed SBCs in the MFC and the unaffected horses, which led to the prediction that some lesions spontaneously resolve without treatment.[30] Nonsurgical management of older horses also suffering from osteoarthritis has a worse prognosis.[31] One author reported that horses resuming athletic activity following conservative management redevelop lesions.[32]

Intralesional corticosteroid injections do have a better success rate than NSAIDs and rest but are usually performed under arthroscopic guidance. This technique is described in the next section.

Surgical Management

SCL enucleation is the treatment of choice. The animal is anesthetized and, depending upon the location of the SCL, the preference of the surgeon, and the approach selected, the patient is

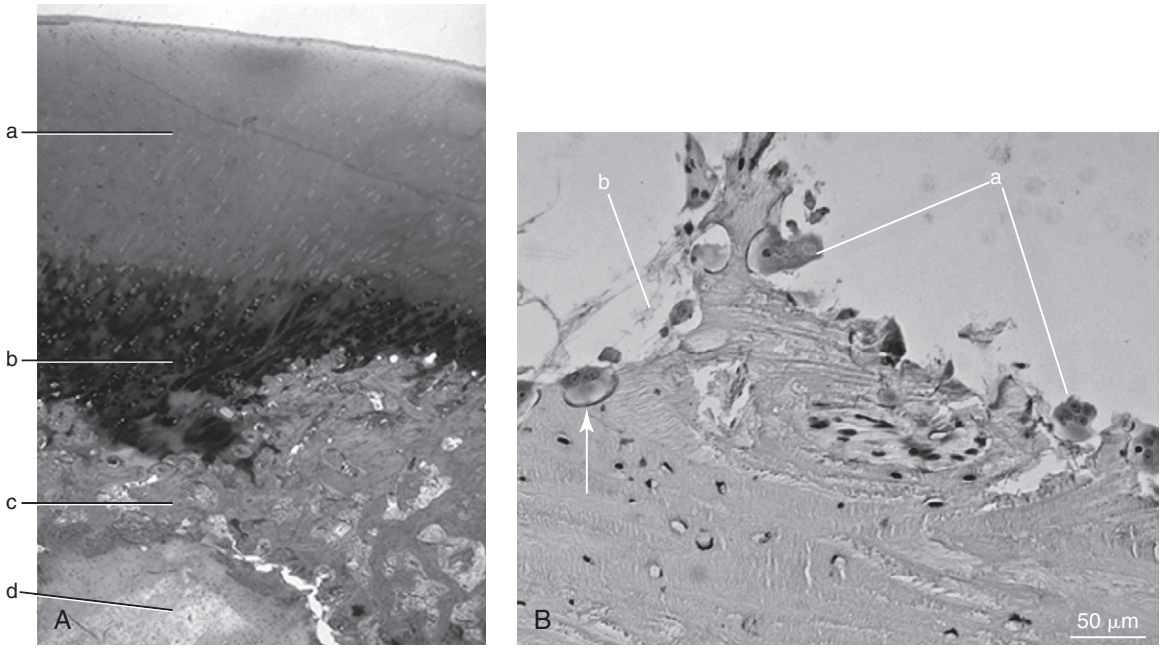

Figure 89-5. Histology specimen of a typical subchondral cystic lesion (SCL) of a horse. **A,** The cartilage overlying the SCL is normal except where it communicates with the joint. *a*, Normal articular cartilage; *b*, calcified cartilage layer; *c*, subchondral bone, *d*, cyst cavity. (Undecalcified 5-μm section, embedded in acrylic resin, stained with toluidine blue.) **B,** Osteoclasts *(a)* are lining the calcified bone *(b)* at the periphery of the SCL. The lacunae are easily recognizable. (Undecalcified 5-μm section, embedded in acrylic resin, Pentachrom Movat stain.)

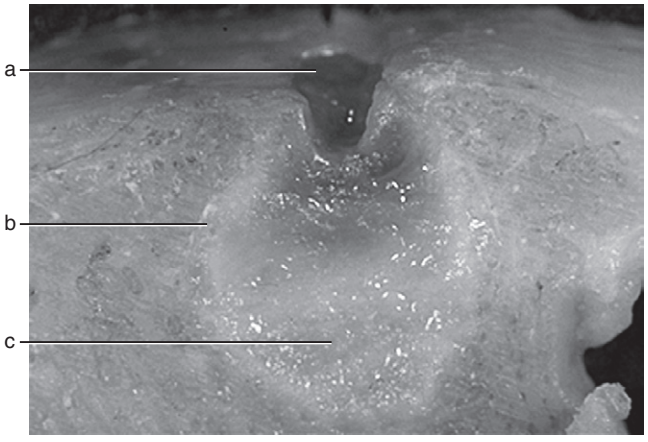

Figure 89-6. Postmortem specimen of a distal sesamoid bone showing a subchondral cystic lesion (SCL) in cross section. *a*, Communication into the joint; *b*, sclerotic border of the SCL; *c*, the contents of the SCL consist of a mixture of fibrous tissue, fibrocartilage, and necrotic bone and can be filled with synovial-like fluid.

positioned in lateral or dorsal recumbency on the surgery table. The surgical site is prepared for aseptic surgery and draped. Surgical débridement is performed using either an intra-articular approach[5] by arthroscopy or a transcortical approach.[33-35]

Approach

ARTHROSCOPIC APPROACH

Early studies used an arthrotomy approach for curettage with excellent results[36] (42 of 51 horses, 82% success rate), but this high rate of success could not be repeated. Despite this, with the rise in popularity of arthroscopy, arthrotomy approaches to joints with their accompanying high morbidity rates, have been abandoned. The arthroscope is introduced into the affected joint using routine technique. The lesion is identified either through the presence of a canal when the SCL has a communication into the joint or by a slight indentation or a "Mercedes star" irregularity. With the help of a hypodermic needle, the location for the instrument portal is identified. A No. 11 scalpel is used to make a small incision through the skin and into the joint along the needle. A blunt obturator or right angled probe is used to identify the cyst either by advancing it through the small articular cartilage opening or by pushing it through the soft, slightly movable cartilage into the cyst.

TRANSOSSEOUS APPROACH

Some SCLs are not accessible through an articular approach and have to be débrided transosseously. Careful preplanning of the surgery is necessary. The skin incision over the selected location is advanced down to the bone. Under fluoroscopic control, a 2.5-mm pilot hole is drilled through the bone into the cyst. If no fluoroscope is available, frequent radiographic images using multiple projections are needed to verify the correct drill direction. If the SCL communicates with the joint, distending it with saline solution may allow backflow through the drill hole when the drill penetrates the SCL. Once placement of the drill tip into the SCL has been verified, the drill hole is enlarged with a 5.5-mm drill bit so that it will accept a curet.

Surgical Curettage and Débridement

Surgical débridement of the lesion with a thorough curettage of the cystic tissue and lining has been considered the treatment of choice for several years because of early reports of postoperative soundness of up to 74%.[1,4]

Once the cyst has been identified, a rongeur can be used to remove the articular cartilage overlying the SCL. A motorized cartilage resector also may be used to remove the cartilage, but it is often cumbersome and time-consuming, because the cartilage is often too thick and pliable to be easily removed this way. Once all the cartilage not supported by underlying bone is removed, the contents of the cyst are evacuated with the help of a curet (Figure 89-7). Osteostixis of the adjacent bone is not recommended, because it can lead to expansion of the cyst.[1,37]

While the contents of the cyst are evacuated, care is taken not to traumatize the articular cartilage adjacent to the rim of the cyst. Although this is easy to accomplish when using the articular approach, it must be verified using fluoroscopy or radiography during a transosseous approach.

Varied success rates for return to previous function after surgical débridement of SCLs of the MFC have been reported, ranging from 56% to 74%.[1,29,38] One study reported on a series of 85 horses with SCL managed with surgical débridement under arthroscopic supervision. In that study, 64% of horses younger than 3 years returned to soundness, compared to 35% of horses older than 3 years.[38]

Following surgical débridement, 64% of Thoroughbreds raced, compared to 77% of siblings.[29] Of this population, 28% of the horses raced as 2-year-olds, 61% as 3-year-olds, and 51% as 4-year-olds. There was a difference in racing percentage based on the width of the surface defect: 60.6% of horses with surface débridement of 15 mm or less, and 39.3% of horses with surface débridement of at least 15 mm started a race. The authors concluded that the amount of cartilage surface involved seemed to be a better predictor of success than depth of the lesion. Recently, a report tried to correlate the amount of débrided cartilage surface with kissing lesions on the opposing cranial meniscal horn and meniscal ligamentous injury.[39] No direct conclusions could be drawn, but these observations led to a change in technique, whereby more emphasis is being placed on sparing the cartilage covering the SCL.

Because direct supervision of curettage of cystic lesions using a transosseous approach is impossible, the curet was always directed away from the articular cartilage, concentrating on the deeper aspects of the cyst. The cysts approached transosseously were subsequently filled with different materials (see later) with good results, although in small populations.[34,40]

Intralesional Corticosteriod Injection

The technique of injecting corticosteroids into the lining of the SCL under arthroscopic or ultrasonic guidance is based on earlier work, where inflammatory mediators were detected in the cystic contents leading to bone resorption.[7,41] The initial use of methylprednisolone has given way to triamcinolone according to one study.[41,42] Although the injection can be performed with ultrasonographic or arthroscopic guidance, with the later technique, identification and débridement of any significant cartilage lesions can be achieved. The corticosteroid is deposited throughout the cyst lining, with the most effective technique involving multiple redirections of the needle to distribute the medication. Lameness resolved in 35 of 52 (67%) horses receiving injections. A total of 73 SCLs were treated and 77% were classified as successful based on followup lameness examination. A success rate of 90% for unilateral and 67% for bilateral SCLs was reported.[42]

Grafting Procedures

CANCELLOUS BONE GRAFTS

Multiple grafting techniques have been developed and evaluated for their ability to accelerate and improve healing of the débrided SCL. Packing the lesion with autogenous grafts also has been recommended (Figure 89-8).[43,44] However, a study comparing healing of surgically created subchondral defects filled with compacted cancellous bone grafts compared to empty defects revealed no difference in the healing patterns after 6 months.[45] This type of management is no longer used.

MOSAIC ARTHROPLASTY

Mosaic arthroplasty (autologous osteochondral grafting) has been studied as a potential treatment for SCLs.[46-48] One study evaluated the bone and cartilage quality of donor sites and concluded that material properties of the grafts from the trochlear groove and axial aspect of the lateral trochlear

Figure 89-7. Intraoperative arthroscopic view under CO_2 insufflation of a distal femoral SCL being enucleated using a curet. The cyst has a wide cloaca into the MFC.

ridge were the closest match for those found in the medial condyle, whereas properties of the lateral condyle were most similar to those found in the trochlear groove and axial aspect of the medial trochlear ridge.[47] Differences of graft performance were found between species.[49] Cartilage surface integrity was best for equine grafts, which contained the highest percentage of bone and lowest fibrous tissue, when compared to cystic lesions treated similarly in bovine, ovine, and human patients.

Osteochondral autograft transplantation (mosaic arthroplasty) was performed in a clinical case series, where grafts were harvested from the abaxial border of the medial femoral trochlea of the unaffected limb (Figure 89-9).[46] Graft implantation was achieved through a small arthrotomy or by arthroscopy depending on SBC location. All horses improved postoperatively; 10 horses had successful outcomes with radiographic evidence of successful graft incorporation, and 7 returned to a previous or higher activity level. On follow-up arthroscopy (5 horses), there was successful reconstitution of a functional gliding surface. One horse had delayed incorporation of a graft because of a technical error but became sound. One horse had recurrence after 4 years of work and soundness. One stallion

was used for breeding and light riding because of medial meniscal injuries on the same limb.[46]

TRICALCIUM PHOSPHATE GRANULES

Tricalcium phosphate (TCP) granules can be implanted in SCLs following transosseous curettage.[41,42] Before implantation, granules are placed in a syringe, autologous whole blood is added, and a vacuum is applied for several minutes. This procedure evacuates air from the granules, and the blood fills the spaces between granules. Both the drill hole into the cyst and the cyst cavity are filled with this mixture (Figure 89-10). Good results were reported with this technique; however, the population was small.[41,42] TCP also was used as the base for other techniques (see later).

HYDROGELS AND PARATHORMONE

In a clinical case series of five horses, parathyroid hormone peptide (PTH_{1-34})-enriched fibrin hydrogel was used in transosseously curetted SCLs. All horses responded with osseous healing of cysts and return to soundness.[34] A prospective study is currently being conducted on the application the same product. Data are available in the first 15 cases, involving 16 joints, after a 1-year follow-up (Figure 89-11).[50] The cysts were curetted under arthroscopic supervision or through a transosseous approach followed by injection of the activated hydrogel. In cases where *arthroscopic supervision* was used, the fluid irrigation was stopped and joint expansion was maintained by switching to gas (CO_2). The cystic cavity was dried, and blood and fluid were removed. Finally, PTH_{1-34} in fibrin was injected through a needle into the surgically prepared cystic cavity. Gelation of the hydrogel took place within 1 to 3 minutes. When the transosseous approach was used, after curettage of the cysts, the lesions were flushed and as much liquid as possible was removed from the cyst through suction, followed by injection of the PTH_{1-34} in fibrin through the drill hole into the cystic cavity, using a blunt arthroscopic probe placed through the most proximal part of the drill hole. Of the 15 horses in the recent study, 11 (73%) were sound at 2 to 6 months postoperatively; at 12 months, soundness reached 91% to 100% in 5 cases, 61% to 90% in 5 cases, and 31% to 60% in 1 case. With these encouraging results, it is hoped that this currently experimental composite will soon be available to equine surgeons across the world.

MISCELLANEOUS TECHNIQUES

Autogenous fibrin plugs containing allogenic chondrocytes and insulin-like growth factor-1 placed over cancellous bone grafts or TCP granules and packed into débrided cysts resulted in success rates of approximately 75%.[51,52] Autologous patient-side grafting, using bone marrow aspirate concentrate and platelet-rich plasma with TCP, showed positive results with regard to the rapidity of bone formation and thickness of the resultant subchondral plate.[53] The injection of a hydraulic biodegradable cement led to a remarkable result in restoring a severely undermined distal metacarpals condyle (Figure 89-12).[54]

Aftercare and Prognosis

Postoperative management of the treatment techniques presented is the same as for any arthroscopic surgical intervention. The healing of treated SCL normally is slow and can take several months to years if just surgical débridement is used, but using bone replacements and growth factors seems to enhance bone healing of the curetted lesion and therefore shortens healing time considerably. Younger horses have a better prognosis for complete recovery compared to older horses. This is especially true if SCLs are associated with osteoarthritis in older patients, where a cautious prognosis must be given.

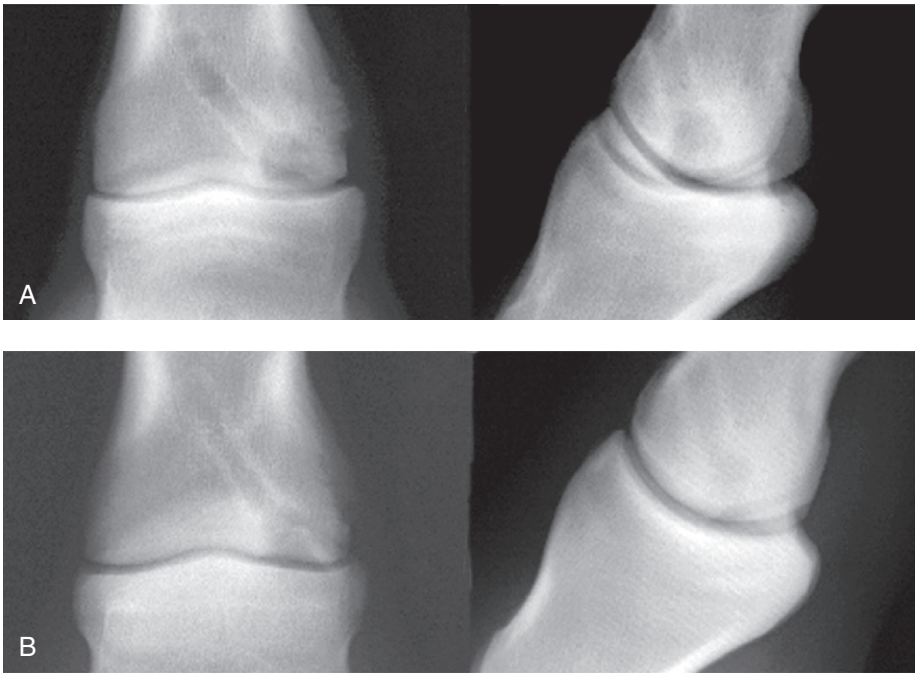

Figure 89-11. A, Immediate postoperative dorsopalmar (*left*) and lateromedial (*right*) radiographic views of a young horse with a subchondral cystic lesion (SCL) in the distal proximal phalanx. The cyst was enucleated through a transcortical approach and was treated with fibrin-based hydrogel and $PTH_{1\text{-}34}$. **B,** Four-month follow-up radiographs of the horse seen in **A.** Note that bone density has increased considerably, and the SCL is hardly visible on radiographs.

CHAPTER
90 Foot

Anton E. Fürst and Christoph J. Lischer

A multitude of disorders affect the equine foot. When the problem is diagnosed, a decision has to be made whether to treat it conservatively or surgically. In some conditions, surgery becomes necessary after conservative management has failed to bring about improvement. For other problems, surgical intervention is the best or even the only treatment option. In this chapter, frequently encountered disorders of the foot managed by surgery are discussed.

DISORDERS OF THE HOOF CAPSULE

Often, changes in the hoof horn quality are noticed that jeopardize the use of the horse for competition or pleasure riding.[1,2] The old saying "no hoof, no horse" holds true even today with all the sophisticated treatment possibilities available in veterinary medicine, which clearly affirms the importance healthy hooves have for the everyday use of horses. Therefore, special attention should be given to the feet not only during lameness evaluations but also during prepurchase examinations, where the clinician is asked to provide the potential new owner of the horse with a statement regarding the future usefulness of the horse for its intended purpose.

Many hoof problems have a number of predisposing causes, such as faulty feeding regimens, including vitamin and mineral deficiencies, as well as excessive and uncontrolled work load, especially on hard and dry ground. Poor hygiene and inadequate hoof care propagate hoof problems because urine and manure weaken or in some cases destroy horn integrity. Trimming and shoeing practices can exacerbate problems with hooves that initially had minimal changes in horn quality. The hoof capsule can be damaged by different external insults. Last but not least, some horses are born with hooves of inferior quality, possibly triggered by genetic factors. These animals may be predisposed to hoof problems despite good stall hygiene, excellent feeding practices, and adequate exercise. Supplementation with biotin improves horn quality over time in some horses.[1,2]

Thrush

Etiology and Diagnosis

Thrush refers to infection that leads to necrotic processes in the frog area, especially in the central and lateral sulci.[3] The sulci become soft and slimy and emit a characteristic foul-smelling odor commonly recognized with this disorder. Horn damage can progress to involve the sensitive lamina; then it is referred to as *pododermatitis*. As a result of the soft nature of the altered horn, foreign body penetration is more likely.

Manure and urine accumulation in the foot dissolve horn in the frog area in association with bacteria and fungi. Therefore, this condition is seen in conjunction with poor stall hygiene and neglected hoof care. However, a contracted hoof and lack of exercise can also predispose a hoof to thrush. Different bacteria and fungi have been shown to colonize the horn of the frog and eventually destroy it.[4-6]

Treatment and Aftercare

Meticulous hoof care and good stall hygiene are important considerations in the management of this condition, along with local treatment of the altered horn in the frog area. Box stalls should be thoroughly cleaned at regular intervals, and all urine-soaked bedding material should be removed. Intially, the sulci of the frog need to be cleaned twice daily to remove any manure packed into the hoof sole.

All damaged horn is removed, which effectively reduces bacteria and fungi colonization and provides better contact of locally applied medications to the affected tissues (Figure 90-1). After removing the diseased horn, the sulci are cleaned with a disinfecting solution.[7] In cases where the sensitive lamina is involved, a protective bandage containing sponges soaked in povidone-iodine (Betadine) should be applied for a few days. Subsequently, the sulci are treated with solutions possessing disinfectant, drying, and hardening properties.[7] In most cases, solutions containing formalin in one form or another are used. These solutions are applied to gauze sponges or small cotton balls and pushed into the affected sulci.

The majority of thrush medication is toxic to epithelium and therefore must be applied with utmost care, especially in the presence of severe horn damage and sensitive lamina. It is better to initiate treatment with povidone-iodine–soaked sponges and then proceed to stronger medications when a thin horn layer has grown over the defect.

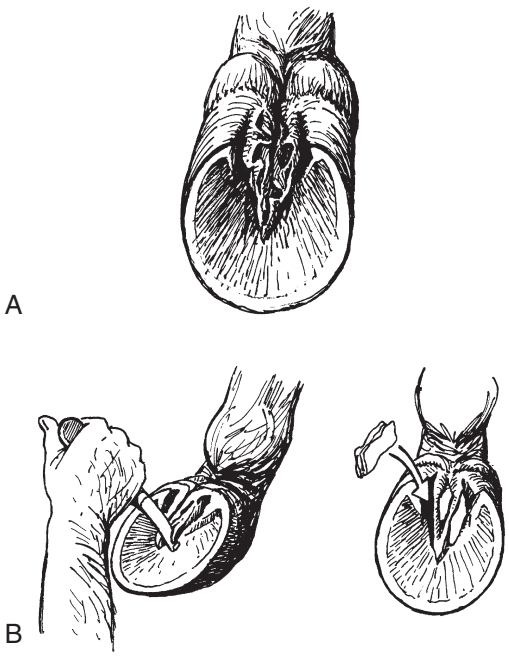

Figure 90-1. A, Graphic illustration of a hoof affected with thrush. **B,** Initially the lateral and middle sulci of the frog are thoroughly cleaned and subsequently medicated.

Figure 90-2. The sole of a hoof of a mule with severe white line disease. Necrotic and dessicated horn has been removed from the white line area.

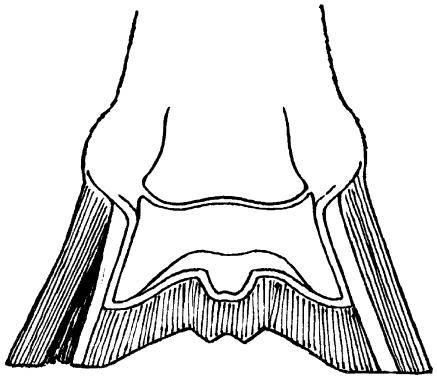

Figure 90-3. Graphic illustration of a hoof with a hollow wall shown on the left *(dark area).*

Prognosis

Horses suffering from thrush are predisposed to acquiring the problem again, mainly when the inciting causes of inadequate stall hygiene and neglect in hoof care and exercise have not been resolved. Therefore, complete resolution of the problem is possible only if good hygiene is maintained for the rest of the horse's life.

White Line Disease

Etiology and Diagnosis

White line disease refers to deterioration of the white line of the hoof capsule, resulting in the loss of the bond between the hoof wall and the sole (Figure 90-2). White line disease is incited through the presence of poor-quality horn, which allows the colonization of different bacteria and fungi.[8] These microorganisms are not able to grow in normal horn of the white line. They are more commonly encountered in geographic regions with a warm and humid climate.

When the hoof wall begins to separate from the sole, the hoof wall is exposed to increased tensional forces, which leads to the development of inflammatory processes in the sensitive lamina and results in lameness. Additionally, the selective placement of hoof nails into the white line is jeopardized, preventing solid attachment of horseshoes to the foot. If the necrotic processes extend farther proximad, entire parts of the hoof wall may become undermined and eventually form a hollow wall.

Treatment and Aftercare

Treatment consists of meticulous stall hygiene and local management of the affected hooves. All the altered and necrotic horn must be removed and the defects treated with solutions to destroy the remaining bacteria and fungi. The solutions used are the same ones used to manage thrush (see earlier). The débridement might need to include hoof wall resection (see later). The horseshoe nails should be placed higher than normal to prolong the duration the shoe is firmly attached to the sole. Additionally, the nail holes and the underside of the cleats should be sealed with bactericidal and fungicidal substances.

Hollow or Loose Hoof Wall

Etiology and Diagnosis

A hollow or loose hoof wall develops when the the most axial layers of the hoof wall, near the sensitive lamina, become separated (Figure 90-3).[9] A loose, hollow wall can develop from an extension of white line disease. In other cases, bleeding into the hoof wall seems to be the inciting cause. Chronic tearing as a result of continuous excessive use can lead to a separation within the hoof wall. As an example, many years ago, hollow walls were commonly diagnosed in pulling horses. Soil, bacteria, and fungi can get access to the dead space between the hoof wall layers and induce a local infection.

As long as no infection is present and the sensitive lamina is not involved, it is possible to apply horseshoes to the foot. However, there is always a risk that the hollow wall will continue to extend proximad, which makes treatment more difficult. Therefore, effective treatment of a hollow wall should be initiated early in the course of events, especially in the presence of an infection.

Treatment and Aftercare

Successful therapy can be achieved only if all diseased, necrotic horn is removed. The remaining hoof defect must be treated with solutions effective against bacteria and fungi, using moist hoof bandages. Depending on the extent of the hollow wall, a considerable amount of horn may have to be removed (Figure 90-4, *A*), which can result in a prolonged convalescent period. Treatment can last several months and the problem must be completely resolved before the horse can be ridden again.

Several artificial hoof products are on the market that allow the lost hoof wall to be effectively replaced. Such products as Keralit, Sigafoos, or Vettec have properties similar to normal hoof wall in respect to stability and flexibility, and they are

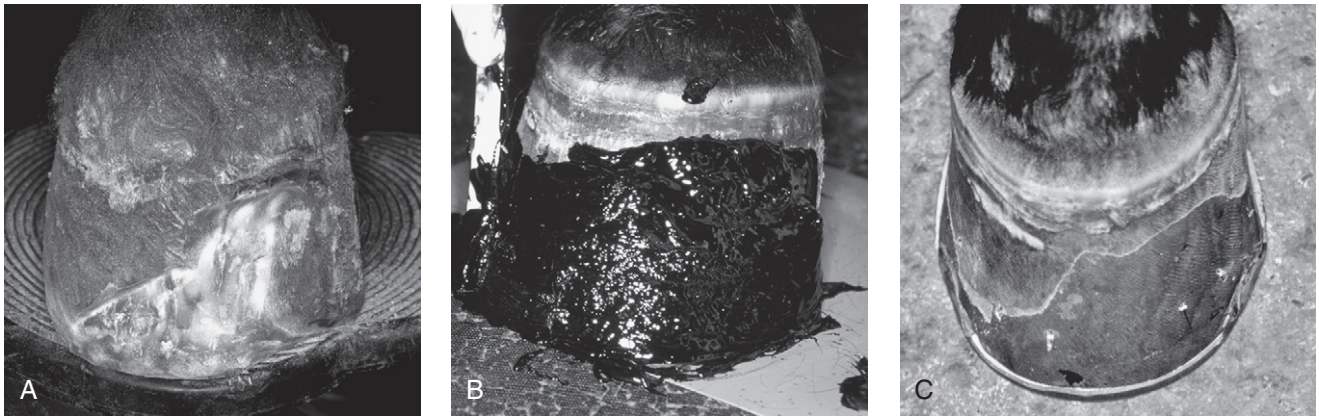

Figure 90-4. A, A hollow hoof wall is removed; **B,** The defect is filled with artificial horn; **C,** A shoe is nailed to the foot, with nails placed into the artificial horn.

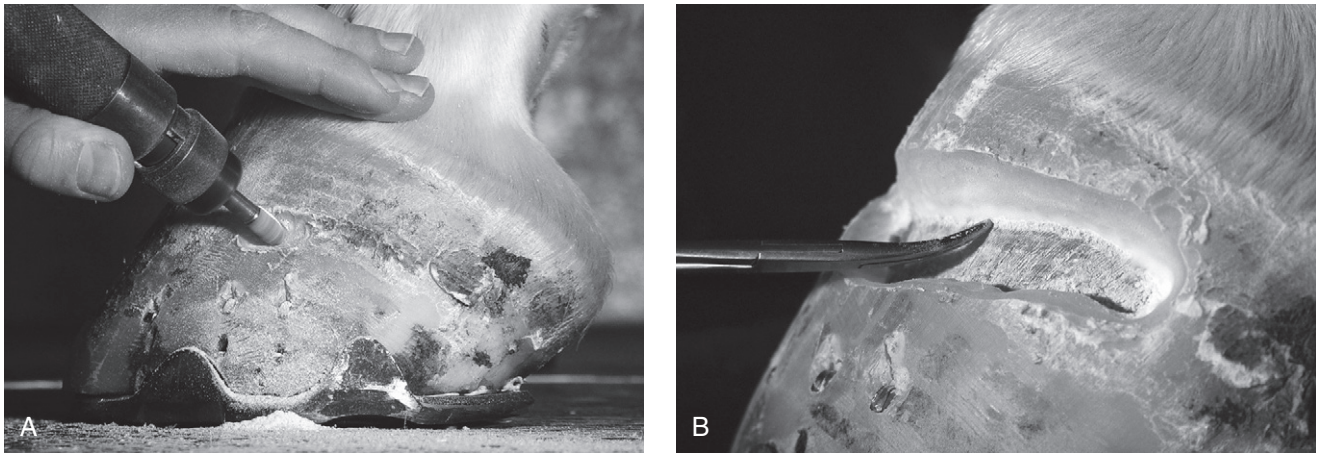

Figure 90-5. A, A loose portion localized only in the proximal part of the hoof wall is removed with a Dremel tool; **B,** The exposed dried laminae are shown.

ideally suited to replace horn defects.[10,11] The artificial horn products contain two components that are mixed together and, when polymerized, develop into a sticky, easily moldable mass. After it is molded into the clean and dry hoof wall defect, artificial horn is shaped to the contours of the hoof wall (see Figure 90-4, *B*). Within a few minutes, the material hardens into horn-like material. The hoof replacement material can be reinforced with fiberglass webbing for additional strength and resistance to wear.

The advantages of these products are that the susceptible laminae are covered with a durable protective layer, which increases the stability of the entire hoof wall. The artificial hoof wall also allows the placement of horseshoe nails (see Figure 90-4, *C*).

There is a potential danger that an infection can develop under the artificial horn, necessitating its immediate removal. Therefore, careful monitoring of the healing process is required until the defect is completely replaced by new hoof wall, which will grow down from the coronary band. In less severely involved hooves, instead of removing the entire wall, just the affected portion of the wall should be eliminated (Figure 90-5).

Hoof Wall Cracks

Etiology

A hoof wall crack occurs as a longitudinal disruption of the hoof wall parallel to the horn tubules and lamellae. It can involve the entire length of the hoof wall, only the proximal hoof wall near the coronary band, or only the distal hoof wall (Figure 90-6). The crack can penetrate the superficial layers only or can extend into the sensitive lamina. The latter cracks are called deep or perforating hoof cracks, which result in inflammation and lameness (Figure 90-7). Horizontally oriented hoof defects parallel to the coronary band are called hoof crevices, but they have the same etiology and treatment as hoof cracks.

The causes of the hoof cracks are diverse. Poor horn quality or a horn wall that is too thin are predisposing factors. Abnormal hoof angles can produce significant tension gradients within the hoof wall, which develop into cracks.[12]

DISTAL HOOF WALL CRACKS

Poor horn quality associated with excessive workload and poor hoof hygiene can lead to development of hoof cracks at the distal hoof wall (see Figure 90-6). Usually, these cracks are

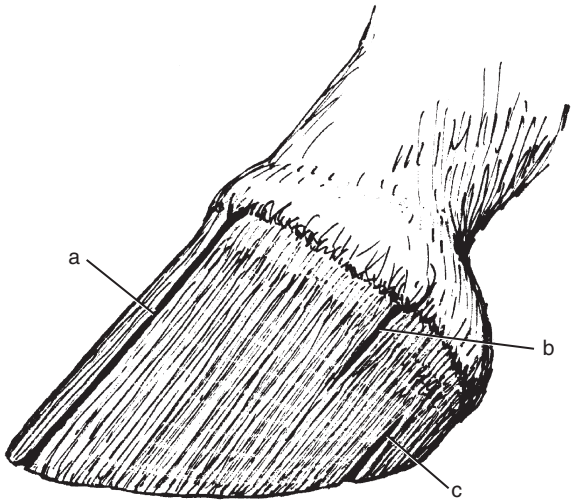

Figure 90-6. Different locations of hoof wall cracks. *a,* Dorsal crack extending over the entire length of the dorsal hoof wall; *b,* proximal lateral hoof wall crack; *c,* distal lateral hoof wall crack.

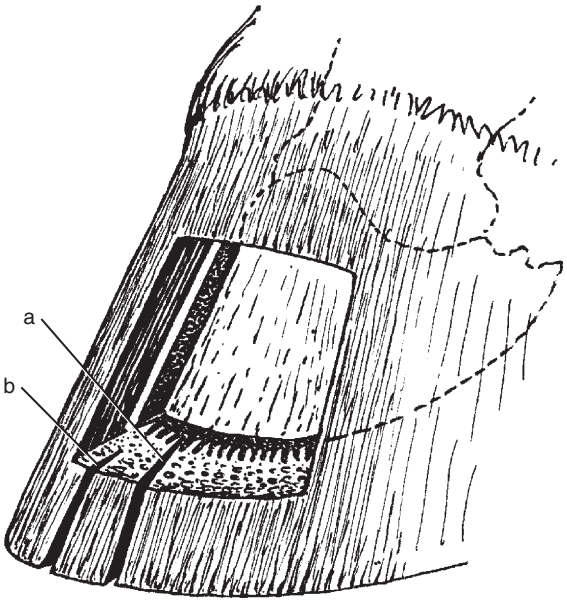

Figure 90-7. Hoof wall with a window, showing cracks penetrating to different depths. *a,* A deep or perforating hoof wall crack involving the sensitive lamina; *b,* superficial hoof wall crack.

superficial initially and do not cause lameness unless they extend and develop into a perforating crack. A horizontal groove may be cut at the most proximal aspect of the crack, and the foot should be trimmed very short to prevent proximal and deep extension of the crack. If these management practices do not stop the progression of the crack, more aggressive surgical techniques will be required (see later).

PROXIMAL HOOF WALL CRACKS

Proximal hoof wall cracks develop as a result of local trauma (Figure 90-8), inflammation, or scar tissue formation near the coronary band. Because of such damage, horn of poor quality is formed, promoting the development of a hoof wall crack.

Figure 90-8. Lateral view of a proximal hoof wall crack after self injury by the contralateral horseshoe.

These cracks slowly extend distad with concomitant horn growth.

HOOF CRACKS INVOLVING THE ENTIRE LENGTH OF THE HOOF WALL

There are many etiologies of hoof cracks along the entire hoof wall, aside from local trauma to the coronary band. Most likely, tension gradients inside the hoof wall combined with extensive use and poor horn quality are major predisposing factors in their development. Often such hoof cracks are found in hooves with excessively long sidewalls (Figure 90-9). Hoof cracks are more commonly seen on the medial hoof wall than on the lateral wall.

Uneven heels and displaced bulbs of the heel are predisposing factors. Hoof wall cracks can also be caused by faulty shoeing practices, such as shoes that are too short, branches that are too narrow or side clips applied too far back, uneven hoof soles, and hoof nails inserted too far caudally. When unphysiologic conditions such as these are present for several months, poor-quality horn can grow, predisposing the hoof wall to form cracks. The combination of long shoeing intervals and excessive work foster hoof crack development.[13]

Diagnosis

Most of the time the diagnosis is made on close visual inspection of the hoof. The deeper layers of the crack often are impacted with dirt and manure. Lameness is a prominent feature of deep or perforating hoof wall cracks. Conversely, superficial horn cracks are not associated with lameness and many do not require treatment. Nevertheless, there is always a risk that a superficial crack will extend into one that eventually initiates an inflammatory process.

Treatment and Aftercare

Because hoof cracks are encountered often and have been a common problem for hundreds of years, many treatment methods are described. However, although many methods and techniques exist, successful management of hoof cracks

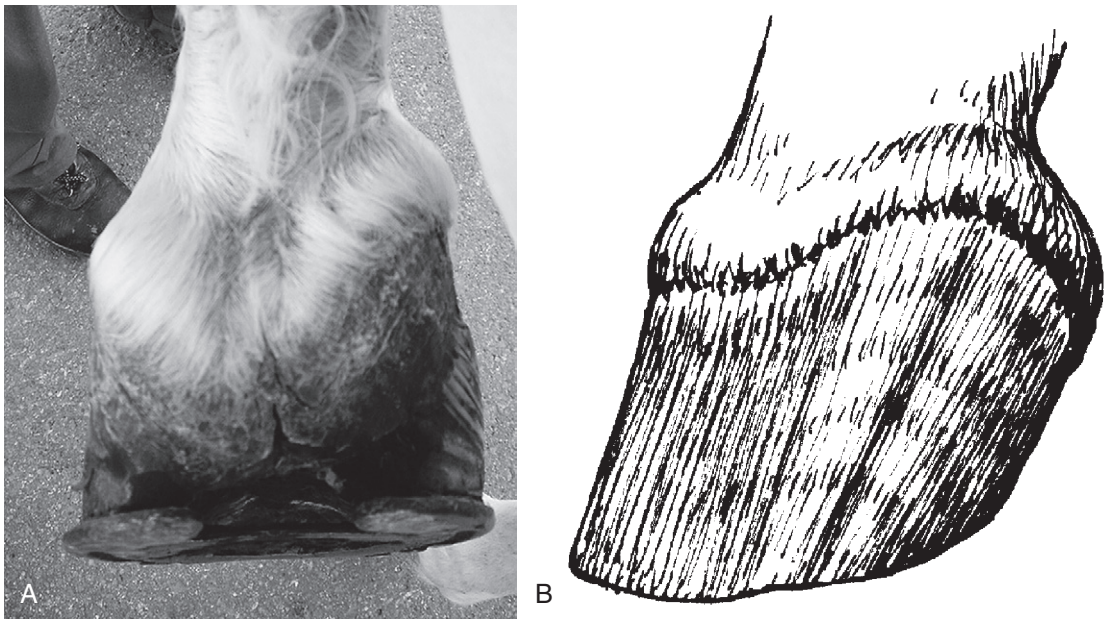

Figure 90-9. A, A hoof with a long and steep inside hoof wall and uneven heels that promoted a hoof crack. **B,** Graphic illustration of a contracted hoof with a distorted coronary band and a hoof crack.

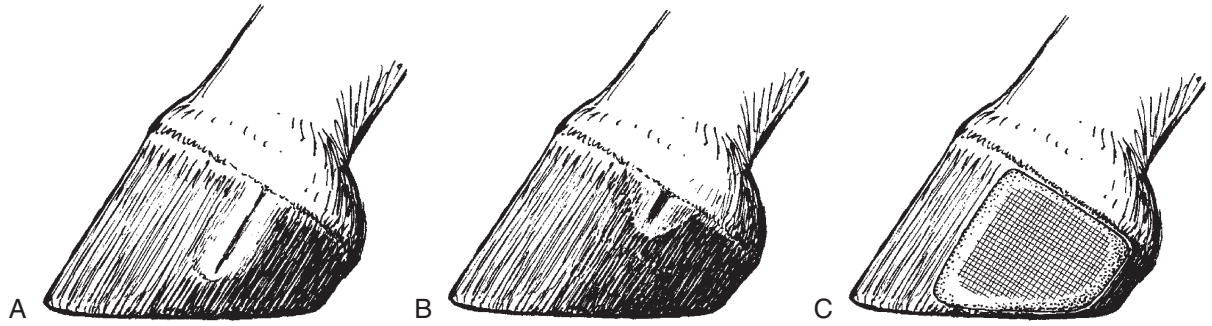

Figure 90-10. A and **B,** The hoof surrounding the two different-sized cracks is carefully removed, taking care to establish smooth transitions before each crack is covered with artificial horn **(C).**

demands close cooperation among the clinician, the farrier, and the owner.

The type of treatment selected depends on the location and depth of the crack, and the length of treatment can be from a few days to several weeks or even months. The first line of attack involves improvement of hoof care and shoeing.[14] The repair of the hoof crack without initial débridement can reduce the movement of the two sides relative to each other, effectively protecting the underlying sensitive laminae. In these instances, lameness will be attenuated. In rare cases, the crack can heal completely, allowing regrowth of normal horn from the coronary band distad.[15] In most cases, however, more-involved techniques are necessary to bring about healing of the defect, especially if the crack is accompanied by infection and lameness.

First, the condition of the shoes has to be assessed, correcting present abnormalities, such as uneven heels and abnormal hoof angles. The old shoe is removed and the hoof is properly trimmed. By cutting the heels on the affected side short, local pressure in the hoof wall can be partially reduced.

Subsequently, the horn adjacent to the crack is carefully removed with a Dremel tool (Figure 90-10).[16] All altered horn down to the sensitive lamina is removed, taking special care to establish smooth transitions toward the sides. When completely cleaned, the defect is covered with gauze sponges, and a hoof bandage is applied.

The foot is shod with a bar shoe, and the sole is filled with silicone and covered with a metal plate. This reduces pressure in the heel region, which is especially beneficial if the crack is located in this area. In some cases, the coronary band immediately proximal to the crack is displaced dorsad. Trimming the hoof wall short just below this crack reduces the continuous movement at the coronary band and leads to the production of better-quality horn.

Last, a fixation device should be applied over the crack. If the crack was débrided down to the sensitive lamina, fixation has to be delayed until a subtle layer of horn covers the defect.

An effective repair unites the two separated hoof parts and reduces individual movements at the transition to the normal horn proximally at the level of the coronary band. There are a

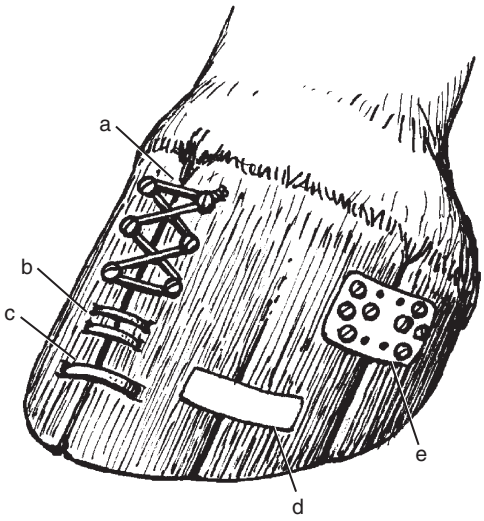

Figure 90-11. Various devices applied to repair hoof cracks. *a,* Umbilical tape laced around small protruding screws in the hoof wall; *b* and *c,* different clamps whose sharp points were tapped into the hoof wall; *d,* a metal plate glued over the crack; *e,* a metal plate spanning the crack fixed to the hoof wall with small screws.

Figure 90-12. Lateral view of a hoof crack covered with artificial horn.

variety of methods that can be used to repair a hoof crack (Figure 90-11). The introduction of the two-component hoof replacement materials mentioned earlier have significantly improved the effectiveness of hoof crack repair.[17] These materials provide a natural covering of the crack with a material having properties similar to the normal hoof wall. These materials cure with an exothermic reaction. Therefore, it is important that at least a thin layer of horn be present to protect the sensitive lamina. It is even possible to install a drainage system underneath the artificial horn. Even so, hoof abscesses can develop after application of the two-component hoof replacement materials.

The hoof wall must be covered with artificial horn material over almost its entire length to prevent a recurrence of a crack (Figure 90-12). Poor horn quality might dictate that a covering

Figure 90-13. An inadequate repair with artificial horn led to recurrence, with the crack extending partially across the artificial horn.

of artificial horn be maintained for several months. New horn growing from the coronary band eventually completely replaces the repaired hoof wall.

Immediately after the repair, the patient should be kept in a stall for a few days before gradually being returned to exercise. Depending on the quantity and quality of new horn production, the patient may go back to light exercise after 4 to 8 weeks.

Prognosis

The prognosis for a successful treatment of a hoof crack is guarded to good. Often, the crack recurs, especially if the predisposing factors are not abolished (Figure 90-13). Because the properties of the horn vary with the location on the hoof, the prognosis varies as well.[18-20]

Keratoma

Etiology

A keratoma represents a columnar thickening of the hoof horn that extends toward the inside of the hoof (Figure 90-14). Because it is rare, the disorder is often overlooked. In addition to the classic keratoma, with its cylindrical appearance and protrusion parallel to the horn tubules, a spherical form of keratoma has been described that can develop anywhere in the hoof capsule.[21]

Most keratomas are found in the dorsal or dorsolateral aspect of the wall. A local inflammation reaction or trauma at the transition of the new horn produced at the coronary band and hoof wall is the most likely inciting cause. This results in the formation of scar tissue in that location, which gradually grows distad as new horn is produced.

A hoof abscess also can lead to the development of a keratoma. Because of the expansiveness of the keratoma,

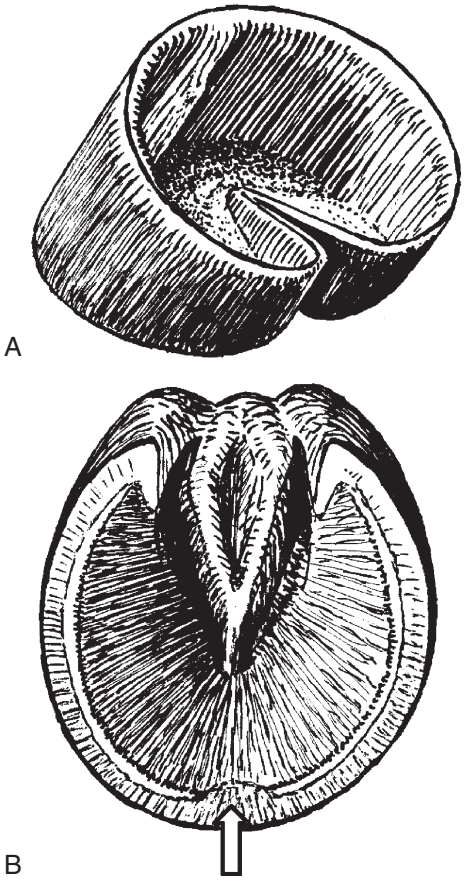

Figure 90-14. Graphic illustration of a keratoma in the hoof shell. **A,** Representation from the inside. Note the horn tissue that has formed at the toe of the hoof. **B,** First manifestation at the median of the white line *(arrow).*

unphysiologic pressures are exerted on the sensitive laminae and the distal phalanx, leading to inflammation and lysis of the underlying distal phalanx. The keratoma consists of poor quality horn (Figure 90-15), which decays early, allowing bacteria and fungi access to the inside of the hoof wall. Therefore, keratomas are often associated with local hoof wall infections and are the reason horses are presented to veterinarians. If a patient is presented with a chronic recurrent hoof abscess, it is prudent to assume a keratoma is the actual cause of the problem.

Diagnosis

Careful inspection of the sole is important for the diagnosis. Trimming and cleaning of the sole surface is necessary to recognize the abnormal configuration of the white line. Typically, the lamellar horn of the white line is replaced by tubular horn and scar tissue (Figure 90-16, *A*). The pathologic tissue displaces the white line toward the sole. In advanced cases, a circular lytic area of the distal phalanx can be recognized radiographically (see Figure 90-16, *B*). This area should not be mistaken for the naturally occurring crena at the dorsal aspect of the distal margin of the distal phalanx. Often, a sclerotic border delineates the lytic area (see Figure 90-16, *B*). If the diagnosis is unclear, a computed tomographic (CT) examination will show the defect in the distal phalanx very clearly (Figure 90-17).

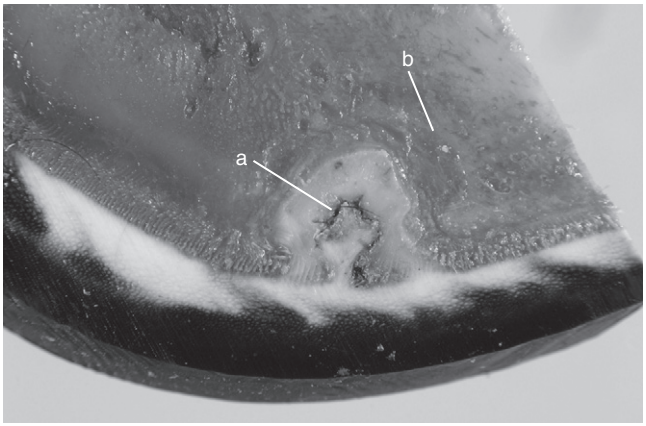

Figure 90-15. Photograph of a sagittal section of the hoof that has keratoma formation. *a,* Keratoma; *b,* the bone surrounding it.

Treatment and Aftercare

In selected cases, it is possible to temporarily abolish the signs of a keratoma with the help of conservative management. However, even with meticulous hoof care and good hygiene it is not always possible to prevent the formation of a hoof abscess. Therefore, an early surgical approach toward solving the problem is advised. For successful resolution, two main principles must be observed[21,22]: the keratoma must be completely removed up to its origin, and support has to be given to the hoof wall.

The timing of the surgery depends to a certain extent on the condition of the patient and the intentions of the owner. The main dilemma is whether to first manage the inflammatory processes medically and remove the keratoma after it has resolved, or to immediately enucleate the structure. The choice should be based on the amount of pain shown by the patient; early intervention may be indicated in very lame patients to avoid the development of laminitis in the contralateral foot. Aside from the altered horn, the altered sensitive laminae also must be removed. The hoof wall defect may be filled with artificial horn as soon as the sensitive lamina is healed. Additionally, a special shoe with large clips placed on either side of the defect should be applied to the foot.

The surgery is performed in two steps, with a tourniquet applied above the foot. First, as much horn as possible is removed with the horse standing until the Dremel tool has to be exchanged for the scalpel and curettes. The second stage of the procedure is carried out under aseptic conditions, and the altered lamina and the entire keratoma are removed *in toto* (Figure 90-18). This procedure also may be carried out on the standing horse if a ring block at the level of the metacarpophalangeal joint is used. The advantages of performing the removal under general anesthesia include the more comfortable position for the surgeon and immobility of the patient. It is of utmost importance to remove all pathologically altered tissue in addition to the altered hoof horn. The keratoma usually has a characteristically round appearance at its origin.

At the end of the procedure, an antiseptic pressure bandage is applied to the phalangeal region, and the tourniquet is removed. The bandage is changed at 3- to 4-day intervals under aseptic conditions. As soon as the bone is covered by granulation tissue, a medication plate shoe is applied. The horse remains confined to a box stall for 4 to 6 weeks, during which

Figure 90-18. Partial hoof wall resection for keratoma removal. The portion of hoof wall left near the ground surface provides stability.

the wound is treated routinely with dressings. After this time, a new shoe is applied. Depending on the healing process, different avenues may be taken. If healing progresses normally, the defect may be filled with artificial horn and the patient subjected to light walking exercise and, after approximately 2 to 4 months, light riding work. If signs of infection recur, all affected tissues have to be removed and the process of postoperative management started again.

Prognosis

With surgical treatment, a significantly better prognosis can be given, with an 83% success rate, compared to conservative management, where an approximate success rate of 43% has been published.[23] The complication rates vary with surgical techniques. Complete hoof wall resection from the coronary band to the sole has a greater complication rate than partial wall resection directly over the mass.[24] Therefore, the hoof wall should be preserved to provide stability to the hoof capsule. Overall prognosis for return to soundness and the previous level of performance is very good for surgical treatment of keratomas.[24]

SEPTIC AND ASEPTIC DISORDERS OF THE SOFT TISSUES

Acute Hoof Abscesses

Etiology

"Hoof abscesses have 1000 faces." Hoof abscesses are among the most frequently diagnosed causes of lameness seen in equine practice. It is interesting to realize how many symptoms

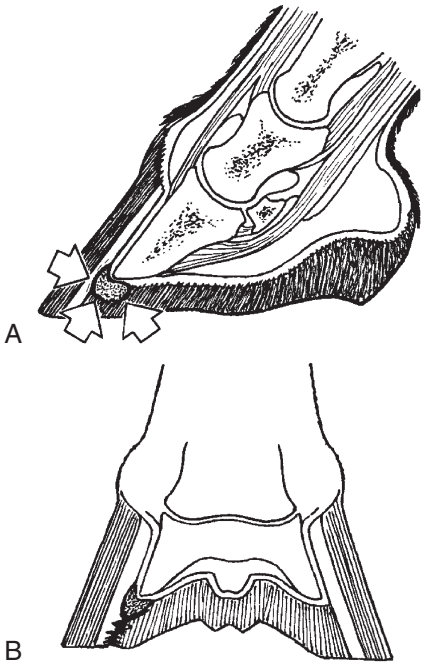

Figure 90-19. Location of a typical hoof abscess at the tip of the foot (**A,** *arrows*) and at the side **(B).**

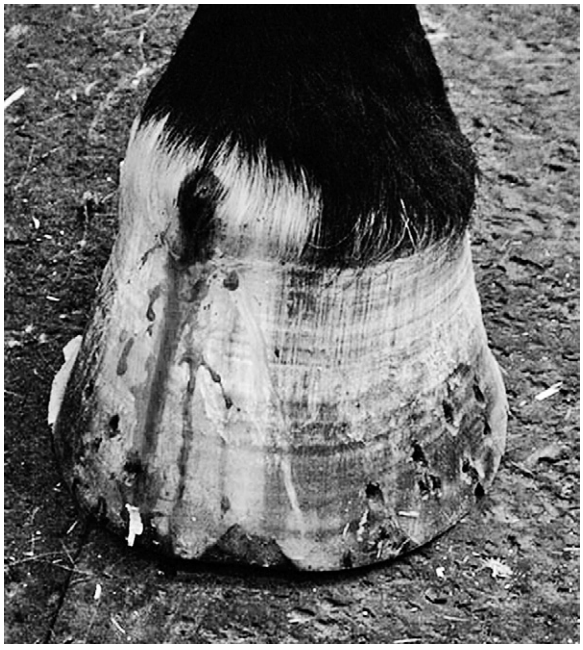

Figure 90-20. Delayed diagnosis or delayed treatment can lead to the abscess breaking out at the coronary band.

Box 90-1. Possible Etiologies for a Hoof Abscess

- Placement of hoof nail too close to the sensitive lamina, allowing bacteria along the nail to induce an infection in close proximity to the sensitive lamina
- Insertion of a hoof nail into the sensitive lamina, resulting in an infection
- Small pointed rocks penetrating the solar horn
- Any penetrating foreign object, such as a street nail[22]
- Any sole bruise, which creates a blood culture medium for the growth of bacteria that enter the tubules in the horn normally

a hoof abscess may generate. It is therefore not surprising that this problem is occasionally misdiagnosed.

Hoof abscesses develop in the unshod horse—often foals—as well as in shod horses. No breed or age predispositions are known. After penetration of bacteria across the hoof wall, infection develops in the region of the sensitive lamina, which includes the accumulation of purulent material inside the hoof capsule (Figure 90-19). Because the hoof capsule provides a solid external shield, increased pressure builds up inside, leading to severe, non–weight-bearing pain. Box 90-1 lists some possible etiologies for the development of a hoof abscess. A sole bruise is the most likely inciting factor.

Diagnosis

The cardinal symptom is a sudden severe lameness, which might be described as "fracture lameness," sometimes resulting in the horse being admitted to a clinic as a fracture patient. The horse might be febrile and have increased warmth of the foot, with strongly pulsating distal palmar and plantar arteries. A generalized swelling of the distal limb might be noticed, which can lead to the erroneous diagnosis of septic tenosynovitis or other similar conditions. Local application of pressure through the hoof tester generally elicits a marked localized positive response. Local perineural anesthetic blocks (deep palmar anesthesia, middle palmar/plantar anesthesia) aid in localizing the problem, allowing subsequent pain-free treatment. Complete blood count (CBC) and blood chemistry analyses are usually unrewarding, but in some cases radiography supports the tentative diagnosis of hoof abscess.

Treatment and Aftercare

If a hoof abscess is suspected, the horseshoe should be removed and each nail closely examined for wetness and odor. Subsequently, the exact location of the abscess is established with the help of the hoof testers. Location with the hoof tester can be difficult in the presence of thick and hard sole horn. In such a case, it might be necessary to apply a povidone-iodine or creosote bandage for overnight, which results in softening of the hoof horn, permitting localization of the abscess and subsequent drainage.

All the undermined and necrotic horn is carefully removed, piece by piece, until a smooth transition is achieved toward the surrounding normal sole. Subsequently, the infected area is cleaned with iodine solution or H_2O_2 and covered with a povidone-iodine–soaked gauze sponge and a hoof bandage. The bandage is changed after 2 to 3 days under aseptic conditions. At that time, the defect is closely examined and any additional undermined sole is carefully removed. As soon as the site is dry, the horse can be reshod. It is prudent to cover the site with a leather or synthetic pad.

If the abscess is not managed properly or in a timely fashion, it can break through at the coronary band (Figure 90-20) or extend deeper into the foot and involve the distal phalanx. In

Figure 90-21. The abscess is flushed daily from the coronary band toward the sole with diluted povidone-iodine (Betadine) solution.

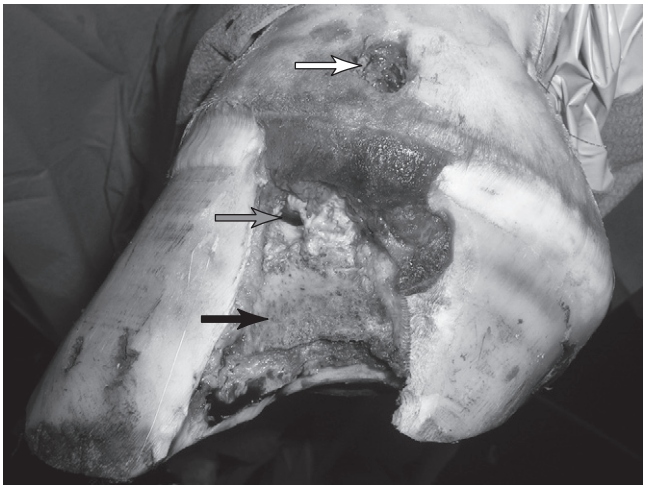

Figure 90-22. Delayed diagnosis or delayed treatment can lead to a septic arthritis of the DIP joint. The opening into the DIP joint is clearly visible *(gray arrow).* The diseased bone was curetted *(black arrow).* The abscess had to be opened proximal to the coronary band to allow effective flushing *(white arrow).*

these cases, the draining tract has to be flushed daily with diluted povidone-iodine solution from the coronary band distad (Figure 90-21). It is important that the flushing solution exits at the sole of the foot to establish ventral drainage. The foot must be kept in a bandage until drainage has stopped. Under extraordinary circumstances, extension of the abscess into the distal interphalangeal (DIP or coffin) joint can occur (Figure 90-22). The management of these cases is described later.

Administration of nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., phenylbutazone) is indicated. Antimicrobial therapy is also indicated, when involvement of other deeper structures is suspected. Generally a good prognosis can be given, even though advanced abscesses can take weeks to heal completely.[25]

Chronic Hoof Abscesses and Septic Pedal Osteitis

Etiology

On rare occasions, a hoof abscess might not be diagnosed right away, especially if the horse has been treated with pain-relieving medications for a period of time. The clinical symptoms are more or less effectively masked, preventing recognition of the problem and its treatment. Also, administration of NSAIDs prevents the abscess from maturing and can permit the microorganisms to invade other tissues within the foot. The abscess can extend into the foot along three avenues: along the dorsal and lateral hoof wall in a proximal direction, eventually breaking out at the coronary band (see Figure 90-20) or invading the coffin joint (see Figure 90-22); or along the sole, potentially undermining it completely or along the distal phalanx, resulting in septic pedal osteitis.[26,27]

Diagnosis

Physical examination of the foot might reveal a draining tract. A thorough radiographic evaluation, with or without a probe positioned in the draining tract, often helps make the diagnosis, because at this point radiographic changes usually are visible on the distal phalanx. Lytic changes can develop as a result of a chronic abscess as well as after aseptic local inflammation.

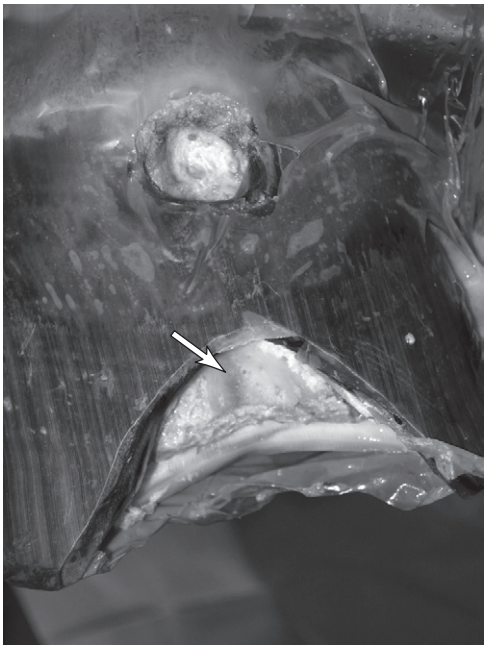

Figure 90-23. A chronic abscess had to be opened up near the coronary band and the distal phalanx had to be curetted as well *(arrow).*

Treatment and Aftercare

As described earlier, the abscess needs to be opened and all the undermined sole removed until normal horn is encountered.[26,27] If the infection spreads out along the side wall, all the undermined wall must be carefully removed, again until normal wall is encountered. If the distal phalanx is involved, all the affected bone must be curetted (Figure 90-23). The

Figure 90-24. Marked reddening of the sole near the frog in a case of aseptic pododermatitis (severe bruising).

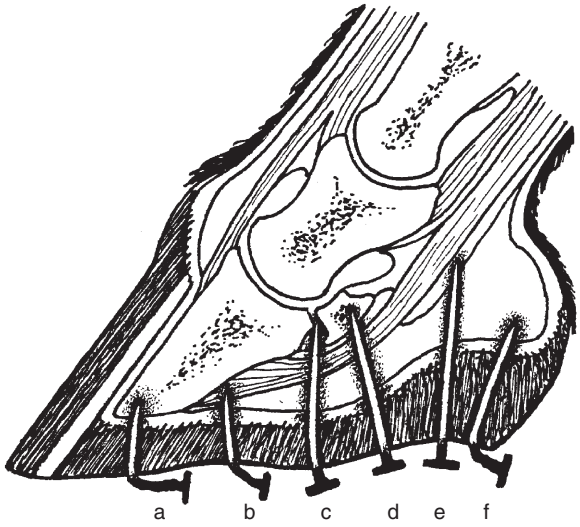

Figure 90-25. Potential puncture wound sites, resulting in the penetration of different anatomic structures. *a,* Tip of the sole, involving the distal phalanx; *b,* dorsal third of the frog, involving the insertion of the deep digital flexor tendon; *c,* middle of the frog, involving the deep digital flexor tendon, the impar ligament, and possibly the distal interphalangeal joint; *d,* palmar third of the frog, involving the deep digital flexor tendon, distal phalanx, and navicular bursa; *e,* palmar aspect of the frog, involving the hoof cushion, deep digital flexor tendon, and tendon sheath; *f,* most palmar frog, involving the hoof cushion.

treatment of a chronic abscess can take several weeks to months, especially if a substantial amount of hoof wall needs to be resected.

Aseptic Pododermatitis

Etiology

Aseptic pododermatitis refers to a severe bruising of the laminae and horn tissues of the foot and is a common cause of lameness in horses. Often this problem is not recognized immediately, and the concomitant lameness is attributed to navicular disease or osteoarthritis of the DIP joint. There are many possible causes for this problem: poor shoeing techniques, excessive use of the horse under difficult conditions, such as hard, uneven ground, and frequent kicking against the stall wall.

Diagnosis

The symptoms are typical but not very specific, leading occasionally to a misdiagnosis (Figure 90-24). The hoof is slightly warmer than normal and a positive pain reaction can be elicited with the hoof testers. Pulsation of the palmar arteries is usually increased. Palmar digital nerve anesthesia usually relieves the lameness. Radiography helps to differentiate the problem from a fracture in this region. Keratoma is part of the differential diagnosis in cases of chronic persistent pododermatitis.

Treatment and Aftercare

Management of this disorder is directed at removing the actual cause. In most cases, the shoe must be removed. Application of creosote bandages for three or more days is very effective. These bandages are followed by dry bandages for several weeks. Some patients require NSAIDs because of persistent pain. Some handwalking on soft ground is optional, and after 7 to 10 days the horse is reshod.

TRAUMATIC INJURIES

Puncture Wounds

Etiology

Nail prick refers to an injury caused by inadvertently driving a nail through the sole and sensitive laminae during shoeing. *Street nail* refers to puncture of the solar surface of the hoof by nails or other sharp objects, such as screws. A hoof is *nail bound* when a horseshoe nail is driven too deep into the horn, causing excessive pressure on the corium. All three types of injuries usually result in pain, inflammation, and infection.

Although puncture wounds of the sole can appear small, they are often deep and can have disastrous effects when such structures as the distal phalanx, distal sesamoid bone, DIP joint, navicular bursa, deep digital flexor (DDF) tendon, or tendon sheath are penetrated (Figure 90-25). The penetrating object is usually contaminated with soil, rust, or manure, which can lead to serious infection. The superficial wound in the sole usually seals quickly, leaving no area for drainage. The anaerobic environment created favors the growth of *Clostridium tetani*, the microorganism causing tetanus.

Depending on the location and depth of the puncture wound, various structures can be affected (see Figure 90-25).[28,29] Deep puncture wounds are extremely serious and difficult to treat. Affected horses are often referred to specialized clinics for surgical therapy. For these reasons, deep puncture wounds must be treated as an emergency to prevent the infection of bones, joints, and tendon sheaths.

Diagnosis

Horses usually have a moderate to severe supporting-leg lameness, often pointing the affected toe. The hoof is warmer than normal, and there is increased pulsation of the digital arteries.

The horse might have a fever. Examination with hoof testers usually elicits severe pain. In horses with severe acute lameness, the hoof must be thoroughly cleaned and examined for a foreign body or puncture wound (see Figure 90-25).

Treatment and Aftercare

The nail or foreign body should be promptly removed. However, it is imperative that the depth and direction of the tract be noted and the point of entry marked on the sole or recorded on paper, because it will rapidly become inapparent. The point of entry is cleaned, and the entire hoof is bandaged.

Based on the location, direction, and depth of the injury, the horse may be treated on site or referred to a clinic. When there is suspicion of injury to deeper structures, such as the navicular bursa, DIP joint, or the DDF tendon sheath, the horse must be referred immediately for surgical treatment. Broad-spectrum antibiotics are started, and tetanus antitoxin and toxoid are administered.

Treatment in a Clinic

A thorough clinical examination is carried out, after which local anesthesia is administered. The shoe is removed and the entire hoof is trimmed. The decision to pursue further treatment is based on the results of the clinical examination and radiography. The puncture tract is carefully cleaned and disinfected. A sterile metal probe is inserted into the puncture tract, and the hoof is radiographed in two planes (Figure 90-26, *A*). Placing a needle into the navicular bursa using aseptic technique and injecting a contrast medium can enhance the diagnosis (see Figure 90-26, *B*). Alternatively, a 20-gauge needle is placed in the DIP joint and synovial fluid is collected into an EDTA tube. Approximately 10 mL of contrast medium is injected into the joint. After a few minutes, the hoof is radiographed again to determine whether the contrast medium is exiting through the puncture tract.[28] The same procedure is repeated for the DDF tendon sheath.

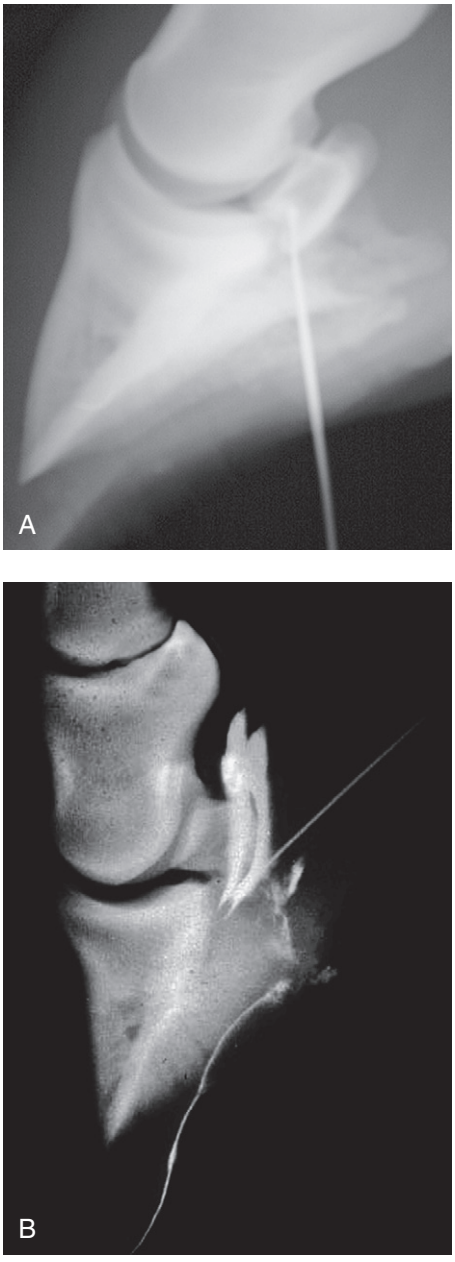

Figure 90-26. A, Lateromedial radiographic view showing a probe inserted through a puncture wound, which penetrated the navicular bursa and distal sesamoid bone. **B,** Lateromedial radiographic contrast study of the navicular bursa, showing contrast media exiting through the puncture wound.

SURGICAL DÉBRIDEMENT AND TREATMENT OF PUNCTURE WOUNDS

Surgical débridement of puncture wounds is usually performed with the horse under general anesthesia. This procedure entails two parts: initial débridement of the sole in the standing and sedated horse followed by aseptic treatment of the puncture wound and the involved deeper structures (Figure 90-27).[30] With the horse sedated and standing, the hoof is cleaned and the horn around the puncture tract is carefully removed down to a thin layer of horn that can be cut with a scalpel blade. The hair from the hoof to the fetlock joint is clipped. The prepared area is cleaned with chlorhexidine scrub (Hibiscrub) and covered with a bandage.

The horse is positioned in lateral recumbency under general anesthesia and a tourniquet is applied. Occasionally, it is necessary to remove additional horn at this time. All affected tissues around the puncture tract are excised. The horn around the tract is removed in an area measuring approximately 3 × 3 cm. The corium and subcutis are then removed and the underlying structures are exposed. If the foreign body has penetrated the DDF tendon, a 1.5 × 1.5 cm area of the tendon is resected. Curettage is necessary if the foreign body penetrates the distal phalanx or the distal sesamoid bone (Figure 90-28). With perforation of the impar ligament and penetration of the DIP joint, the ligament must be resected and the joint as well as the navicular bursa must be lavaged. Involvement of the digital tendon sheath requires thorough lavage.

The affected synovial structures are lavaged with copious amounts (several liters) of lactated Ringer's solution to which antibiotics have been added. A pressure bandage is applied, followed by a hoof bandage and a wedge under the heel. Repeated regional intravenous perfusion with an antibiotic is recommended.[31]

An arthroscopic technique has been developed to lavage and treat a deep puncture wound that penetrates the navicular bursa or DIP joint (Figure 90-29). This technique has a good outcome because it permits a less-invasive approach to the penetrated

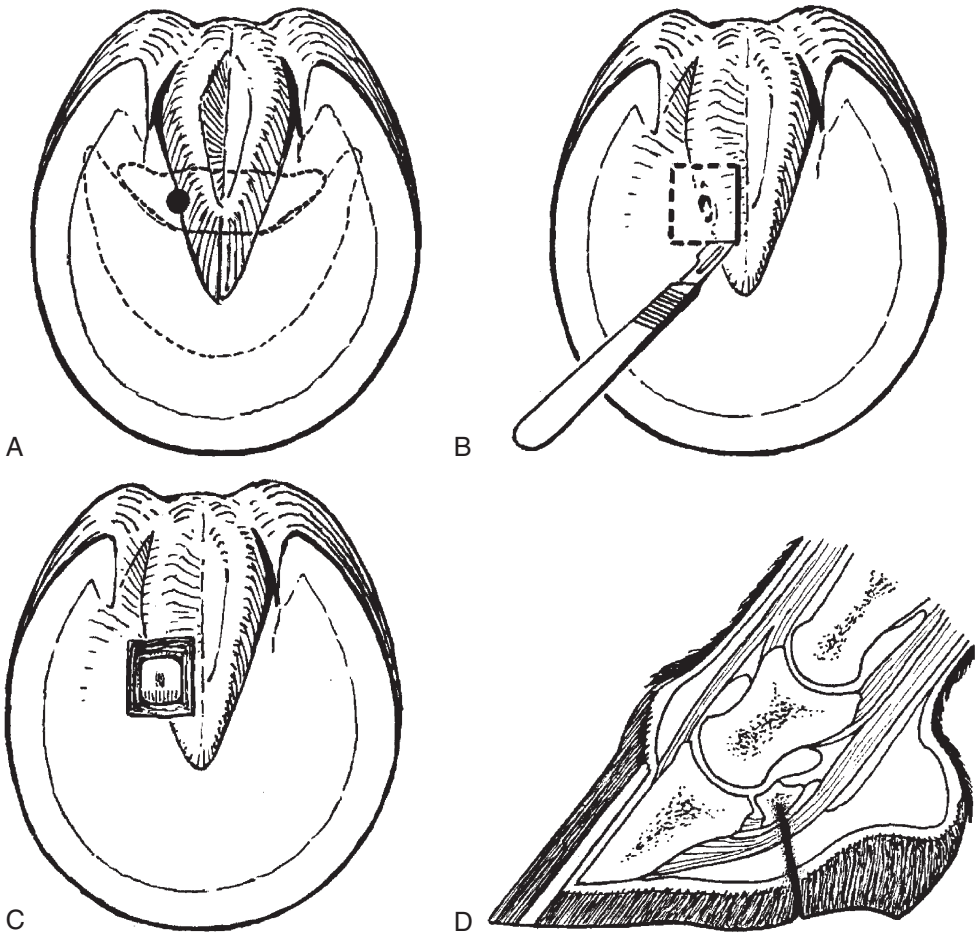

Figure 90-27. Street nail procedure. **A,** Localization of the entry point. **B,** Subcutis and sensitive lamina is removed. **C,** The deep digital flexor tendon is fenestrated. **D,** Representation of the puncture wound in a parasagittal plane.

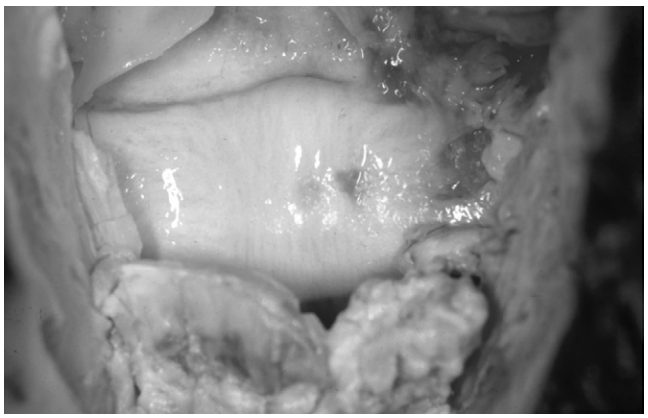

Figure 90-28. Ten-day postoperative appearance after a street nail procedure for a foreign body penetrating the distal sesamoid bone.

structures, allowing débridement to be carried out under endoscopic guidance.[32,33] Also, the area is under constant lavage during treatment, decreasing surgery time.

Depending on the severity of the injury, lavage may be repeated once or twice with the horse under general anesthesia. Soon thereafter, the bandage is changed under aseptic conditions on the standing and sedated horse. Systemic antibiotics and anti-inflammatory drugs are administered for at least 2 weeks and regional intravenous perfusion should be repeated several times. After horn tissue begins to cover the soft tissues, a medication-plate shoe can be applied (Figure 90-30).

Prognosis

The prognosis for puncture wounds of the sole is generally guarded. Horses that receive prompt surgical treatment and have few deep structures affected have the best prognosis.[30] Injury to the distal sesamoid bone can eventually result in adhesions between the bone and the DDF tendon, necessitating neurectomy. Bursoscopic treatment can lessen the development of morbidity.

Scalping Injuries

Etiology

Coronary band and heel injuries occur at the transition between the skin and hoof capsule. They are usually caused by overreaching, where one foot treads on the coronary band or heel of another foot. Heel calks on shoes can result in very deep injuries as well.

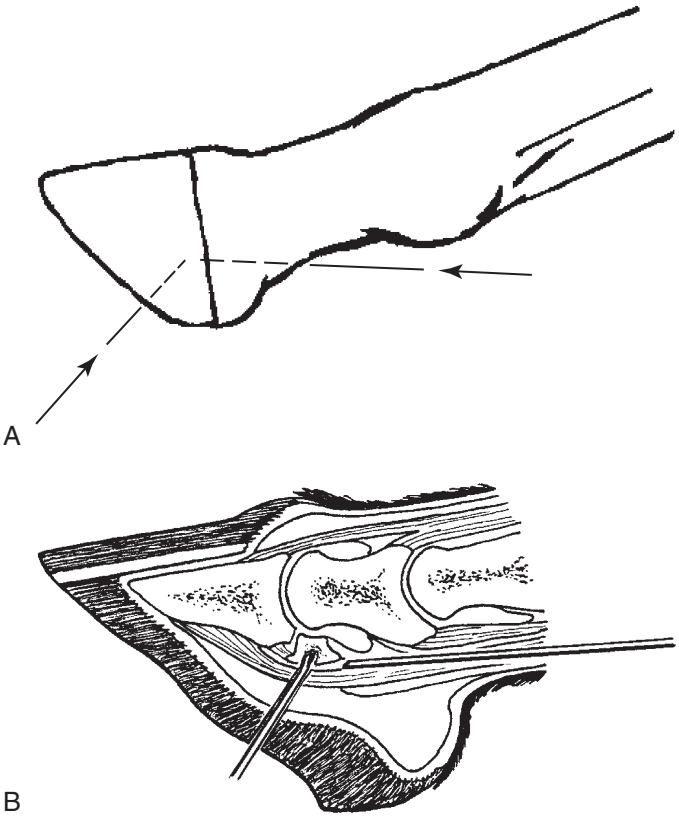

Figure 90-29. Bursoscopy in lateral recumbency. **A,** Overview of the surgical portals. **B,** Close-up view showing the anatomic structures involved.

Figure 90-30. A medication-plate shoe used for postoperative protection of a foot after surgery. The wound may be dressed daily by removing the plate.

Figure 90-31. Canker in a horse showing a flaky, hypertrophic frog.

Diagnosis

These injuries are usually quite painful in the acute stages and can cause severe lameness. Inadequate treatment can lead to infection within the hoof capsule. There is also a risk of permanent damage to the horn-producing cells, resulting in abnormalities of hoof growth, such as cracks and ridges.

Treatment and Aftercare

The damaged horn should be removed to allow drainage of wound secretions. Heavy scissors, ronguers or a hoof knife are ideal for this. The wound is subsequently cleaned with a mild disinfectant solution and bandaged.

Other Hoof Lacerations

Injuries to the hoof capsule are relatively common. Trauma to the corium usually results in marked hemorrhage and severe pain. This type of injury is particularly problematic when the coronary corium is involved; damage to the horn-producing cells results in the production of poor-quality horn. A pressure bandage is applied to injuries that are bleeding severely. The bandage is changed daily until a stable and healthy layer of horn is formed.

DEGENERATIVE AND NEOPLASTIC DISEASES OF THE FOOT

Canker

Etiology

Canker used to be a common disease in working draft horses. Therefore, detailed descriptions can be found in older textbooks. Canker of the frog represents abnormal horn proliferation in the frog region and is rarely seen in other areas of the hoof (Figure 90-31). It is not a true neoplasm, but rather a chronic inflammatory reaction characterized by massive parakeratosis.[34] The sensitive lamina hypertrophies and the

superficial horn and corium degenerates. Canker can spread from the frog to the adjacent sole and even involve the hoof wall.

This disease is slowly progressive and spreads to adjacent structures over the course of months. In some horses, the skin adjacent to the hoof capsule is affected. The skin near the coronary band is reddened, the hair grows in all directions, and the area is painful when palpated. In rare cases, the horn of the chestnuts is affected.

The cause of canker is not known, although unsanitary stall conditions appear to be a predisposing factor. Long-standing thrush is thought to result in canker formation, because it causes the original degeneration of the horn cells. Horses that are kept in moist and warm stalls with urine-soaked bedding often suffer from canker. Also, there seems to be a breed predilection; draft horses are most commonly affected, but the disease is also seen in Thoroughbreds, Standardbreds, ponies, and even donkeys. Young horses rarely have canker. Spirochetes have been identified histologically in canker lesions in several horses but not in healthy hoof tissues.[35,36]

The hind hooves are more often affected than front hooves, and one or more hooves may be involved. Bacteriologic examination of affected tissue usually reveals gram-negative anaerobic bacteria. Although many microorganisms can be isolated, anaerobic bacteria seem to be most important in this disease.

A differential diagnosis must include advanced thrush and fungal infection of the coronary band.

Diagnosis

Horn of rubber-like consistency that breaks easily on the surface is characteristic of canker. The horn produced by the epidermal cells affected by canker is soft, greasy, and friable. Cauliflower-like growths that are not cornified at the surface but covered with a greasy, grayish-white material are typical. These hypertrophic horn growths have a foul odor somewhat reminiscent of an abscessed tooth. The area is painful to pressure and horses are usually lame. When traumatized, the area bleeds profusely. The poor horn quality can result in injury and infection of the underlying structures.

Treatment and Aftercare

Treatment of canker is very difficult and time consuming, and it does not always result in a cure. All damaged cells must be removed to allow the growth of healthy horn tissue. Treatment must be as hygienic as possible and involves a number of steps.[37,38]

SURGERY

The first step is surgical débridement under local anesthesia. All necrotic and abnormal horn is removed with the horse standing or, in severe cases, with the horse under general anesthesia. A tourniquet is applied to the limb in the middle metacarpal or metatarsal region. All abnormal horn is removed so that the area can be thoroughly cleaned and cut with a scalpel blade (Figure 90-32).

The transition between abnormal and healthy horn is determined during paring with a hoof knife. A cut is made around the frog to define the surgical field. Then, beginning from the palmar or plantar surface, the entire frog is removed (Figure 90-33). It is important not to cut too deeply in or near the apex of the frog. Alternatively, cryotherapy can be used.[39] Normal epithelium is then able to grow from the remaining healthy tissue.

In most cases, removing the abnormal horn while sparing the stratum germinativum is adequate. A new frog grows within a few months (Figure 90-34). The foot is bandaged during this time, so this treatment is labor intensive and time consuming for the owner.

LOCAL TREATMENT

The second step involves local treatment consisting of disinfection, drying, and hardening of the horn. The hoof is cleaned and disinfected with povidone-iodine scrub and treated with

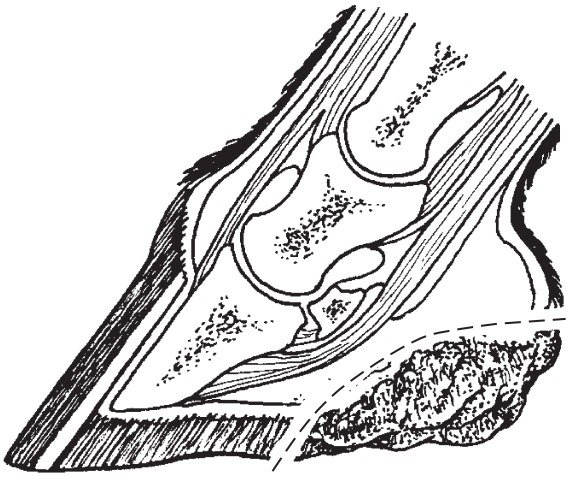

Figure 90-32. Sagittal view of a graphic illustration of a hoof with canker. The *dotted line* represents the level of the surgical cut needed for removing the frog.

Figure 90-33. Postoperative picture following removal of the entire frog in a horse affected with canker.

Figure 90-34. Four-month follow-up picture showing progressive healing after removal of the entire frog.

povidone-iodine–soaked bandages for 2 to 3 days. Daily bandage changes are required thereafter.

When healing is observed, a shoe with a pad is applied. The pad must be removable so that the area can be cleaned daily with povidone-iodine scrub and rinsed with povidone-iodine solution. The defect is covered daily with a mixture of 20 g iodoform iodine, 20 g zinc oxide, 20 g tannic acid, and 40 g metronidazole; this mixture acts as a disinfectant, astringent, and drying agent. The wound is subsequently bandaged or covered with gauze and protected with the pad.

Administration of local or systemic antibiotics might be necessary; chloramphenicol and metronidazole are particularly effective.[40] Systemic antibiotics should be administered when more than one hoof is affected. Recently the local and systemic treatment with doxycycline and oxytetracycline has been recommended.[41] Biotin and zinc supplements should be added to the nutritional regimen.

The horn defect becomes smaller as it heals (see Figure 90-34). The persistence of soft greasy horn usually indicates recurrence of the disease. Repeated surgical débridement is required in some cases. Treatment entails many months and requires good owner compliance. Sanitary stall conditions also are important.

DISORDERS OF THE COLLATERAL CARTILAGES

Mineralization

Etiology

Mineralization of the collateral cartilages of the distal phalanx (side bone) is a common radiographic finding in the front feet of heavy horses.[42,43] Ossification of the collateral cartilages has been considered as a part of the normal aging process, and such factors as heavy body weight, working on hard surfaces, repetitive concussion, poor conformation, improper shoeing or trimming, and other foot problems, such as collateral ligament or distal phalangeal injuries,[44] are often mentioned as possible causes.

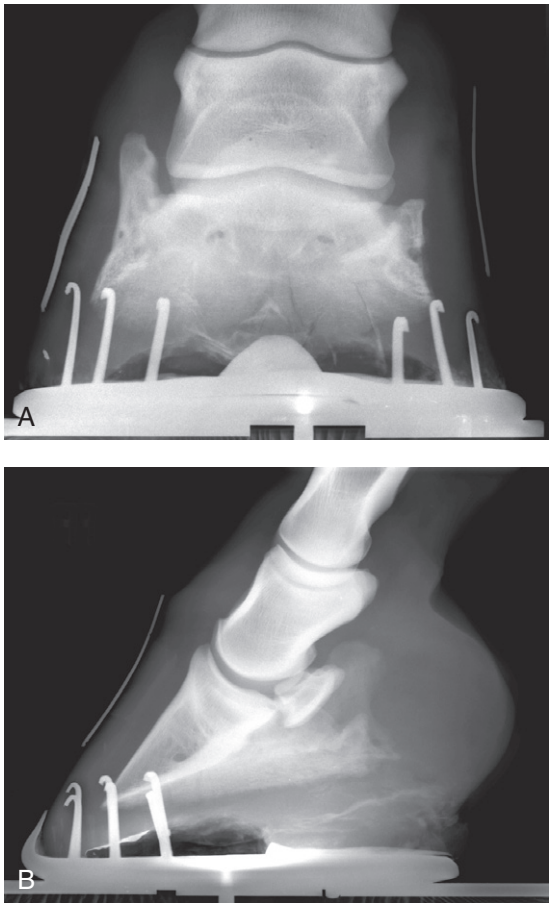

Figure 90-35. Dorsopalmar **(A)** and lateromedial **(B)** radiographic views of a hoof with mild ossification of the lateral collateral cartilage at the palmar process of the distal phalanx. A wire was taped to the hoof wall to identify its exact orientation.

However, large side bones have also been found in young horses that have not yet started working; therefore an inherited tendency to develop side bones has been suspected. Side bones are more common in mares than in stallions and geldings.[45,46] Extensive ossification is more commonly found in the lateral than the medial cartilage.

Diagnosis

Ossification of the collateral cartilages is most often an incidental finding. Lameness associated with side bone is difficult to confirm. It is important to correlate radiographic findings with signs of pain. Radiographs reveal ectopic ossification emanating from the proximal aspects of the palmar or plantar eminences of the distal phalanx in the area of the collateral cartilages (Figure 90-35). Because separate centers of ossification exist in these cartilages, these findings should not be confused with fractured side bones (Figure 90-36), although in rare cases the side bone can fracture (Figure 90-37).

Digital manipulation of the collateral cartilages can reveal loss of pliability and elicit a pain response. Lameness is most marked when the horse is turned at a trot on a hard surface. A palmar

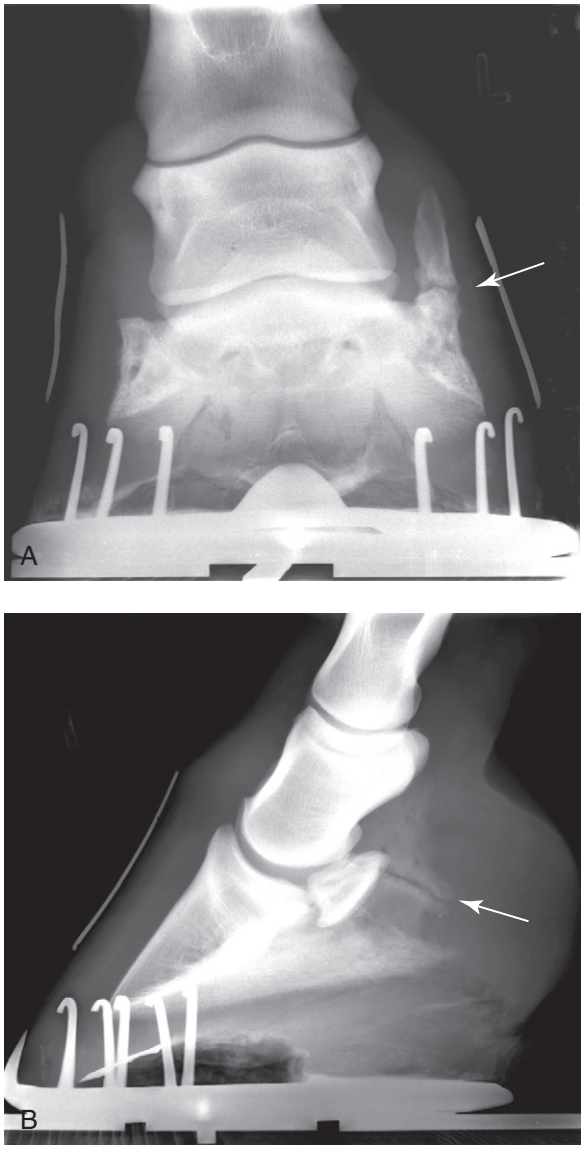

Figure 90-36. Dorsopalmar **(A)** and lateromedial **(B)** radiographic projections of a horse suffering from ossification of the lateral collateral cartilage in a left forelimb. Note the radiolucent line *(arrow).* This separate ossification center should not be confused with a fractured side bone. Dorsally and on each side of the foot, small wires were taped along the hoof wall to identify its surface.

digital nerve block on the suspected side of the hoof should improve the painful gait. Scintigraphy may provide information on the potential clinical significance of ossification of the cartilages of the foot.[47] Increased radiopharmaceutical uptake associated with a different radiographic appearance from that of other ossifications of the front feet was a conclusive sign of clinical significance in a report of 21 Finnish horses.[48] Although ossification of the cartilages is commonly associated with obscure lameness problems, most often ossification is not the cause.

Treatment

When ossification of the collateral cartilage has started, it cannot be stopped, and specific treatment is not available. However, if the side bones are suspected as the cause of lameness, rest and administration of NSAIDs would be the logical initial treatment. Any foot imbalances should be corrected, and breakover should be moved caudad on the foot by rolling or rockering of the toe. The heels should have as much opportunity for expansion as possible, which is especially important for unbalanced or sheared heels.

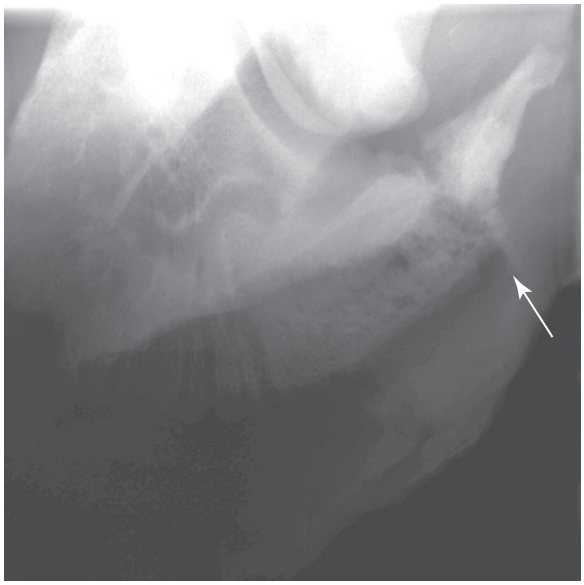

Figure 90-37. Oblique radiographic projection of the distal phalanx of an Arabian horse with a 6-month-old fracture of the medial side bone. Healing is in progress, but the fracture line *(arrow)* is still visible.

A fracture of an ossified cartilage is treated conservatively with NSAIDs and an extended period of stall rest or small paddock turnout (8 to 12 weeks) followed by controlled exercise on level surfaces for 6 to 8 months. It is most likely that after this period of time, the fracture line will still be visible on radiographs but surrounded by proliferative exostosis (see Figure 90-37). In refractory cases, unilateral palmar digital neurectomy can be performed.

Small fragments can be removed eventually if any signs of sequestrum formation are observed. An incision 1 to 2 cm parallel to the palmar or plantar aspect of the coronary band provides access to the proximal part of the collateral cartilage. No attempts should be made to remove large proximal fragments.[49]

Necrosis

Necrosis of the collateral cartilage (colloquially termed *quittor*) is characterized by an intermittent purulent discharge and sinus tract formation at or proximal to the coronary band in proximity to the collateral cartilage. These lesions are chronic and do not heal. Lameness occurs in the acute stages but might show remission when the lesion appears to be healing. Usually a mixed bacterial infection is present, associated with subsequent necrosis of the cartilage, as the result of injury to the cartilage itself or to the adjacent soft tissue.[50] The quittor condition can develop secondary to a penetrating wound through the sole where infection has gained access to the collateral cartilage.

Diagnosis

Clinical signs of quittor include enlargement over the affected collateral cartilage with one or more chronic sinus tracts that continue to drain. The most important differential diagnosis is a chronic ascending infection of the white line that breaks and drains at or slightly proximal to the coronary band. With quittor, the swelling is usually more diffuse and is located more proximally over the collateral cartilage.

Radiography can be helpful to detect foreign bodies or to rule out involvement of the middle or distal phalanx. The depth and direction of the draining tracts are determined radiographically after injection of a contrast medium or insertion of a flexible metal probe into the tract.[51]

Treatment

The treatment of choice is surgical débridement. Prior to surgery the region is clipped and the hoof is trimmed and rasped, scrubbed, and placed in a povidone-iodine–soaked bandage for 24 hours. After the horse is anesthetized, a tourniquet is applied. The foot is held in maximal extension during dissection to tighten the joint capsule and retract it from the area of dissection, minimizing the risk of accidental penetration into the DIP joint.[50] A slightly curved incision beginning just dorsal to the coronary band over the diseased collateral cartilage is made (Figure 90-38). The flap is dissected distad to expose the collateral cartilage, and a probe is used to identify the draining tract. Alternatively, diluted methylene blue can be injected into the tract to identify it during dissection.

Necrotic cartilage is recognized by its dark blue or reddish blue appearance. All of the necrotic tissue and cartilage is removed until healthy margins remain. Subsequently, arthrocentesis of the DIP joint is performed and the joint is distended with polyionic fluid to assess the integrity of the joint capsule axial to the removed portions of the collateral cartilages. In case of accidental laceration of the joint capsule, the joint must be flushed with large amounts of fluid through a needle placed in the dorsal aspect of the joint capsule.

After débridement, the defect is closed with 2-0 monofilament absorbable suture material in a simple interrupted pattern. An injection of 2 mL of amikacin into the joint protects it from developing an infection. If necrotic cartilage extends distal to or below the coronary band, a hole is drilled in the hoof wall over the ventral-most limits of the excised cartilage to provide drainage (see Figure 90-38). After extensive flushing, the proximal skin incision is closed with nonabsorbable tension sutures, and the wound is packed through the hole in the hoof wall using antiseptic-soaked gauze sponges. The surgical site is protected with a sterile bandage.

The following day the bandage is removed and the wound is flushed. Bandages are changed every other day until all evidence of infection has subsided and a healthy bed of granulation tissue is present. When this occurs, a short limb cast can be applied to the limb for 8 to 10 days to minimize movement at the suture line and to encourage primary healing. After removal of the sutures, bandaging is continued until granulation tissue fills the defect and epithelium begins to cornify.

FRACTURES OF THE HOOF REGION

Fractures occurring in the hoof region are separated into distal phalanx fractures and fractures of the distal sesamoid bone.

Fracture of the Distal Phalanx

Fractures of the distal phalanx are diagnosed in horses of all ages, even very young foals.[52,53]

Etiology and Classification

Fractures of the distal phalanx are caused by acute trauma, such as a kick toward a hard, nonmovable object. Most often fast or excessive work induces fractures of the distal phalanx.[54]

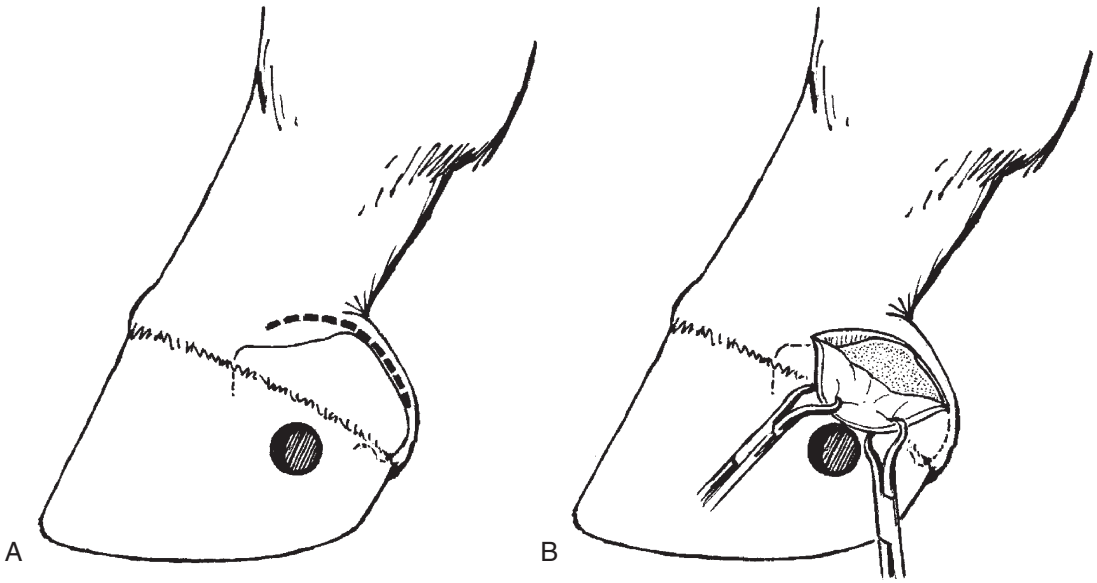

Figure 90-38. Graphic illustration of the surgical treatment for quittor, or necrosis of the collateral cartilage. A hole drilled in the hoof wall is required for adequate drainage if infection and necrosis extend distal to the coronary band. **A,** The *dotted line* represents the surgical incision line. **B,** A slightly curved incision beginning just dorsal to the coronary band over the diseased collateral cartilage produces a skin flap, which allows removal of the proximal part of the necrotic cartilage.

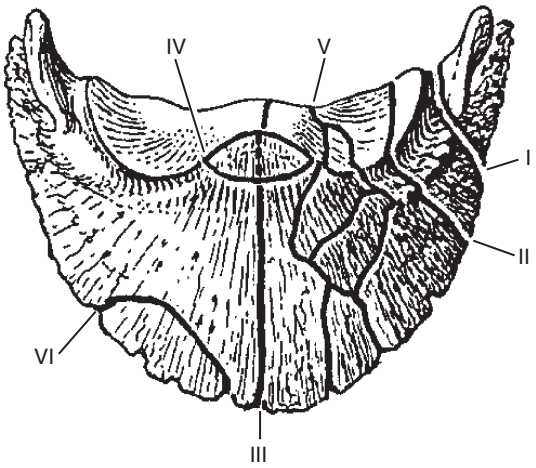

Figure 90-39. Classification of distal phalangeal fractures: *I*, Abaxial nonarticular fracture; *II*, abaxial articular fracture; *III*, axial and periaxial articular fracture; *IV*, extensor process fracture; *V*, multifragment articular fracture; *VI*, solar margin fracture.

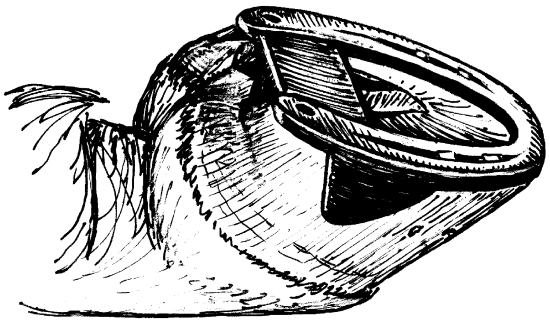

Figure 90-40. Bar shoe with large side clips to limit hoof expansion laterally during weight bearing. This shoe is often used after hoof wall resection is performed to access the interior of the hoof capsule, as well as for pedal bone fractures.

Laceration of the hoof capsule may result in fractures as well. The forelimb is more commonly involved than the hindlimb.[55]

Fractures of the distal phalanx are classified into the following types (Figure 90-39)[55]:

I. Abaxial/paramedian fractures without joint involvement
II. Abaxial/paramedian fractures with joint involvement
III. Axial/sagittal and perisagittal fractures with joint involvement
IV. Fractures of the extensor process
V. Multifragment (comminuted) fractures with joint involvement
VI. Solar margin fractures

Some complicated fractures involve several fracture types and therefore they cannot be assigned to one of these classifications alone.[54,56]

Clinical Symptoms and Diagnosis

The patient usually shows an acute, moderate to severe lameness accentuated during turns. The hoof and distal phalangeal region are warm to the touch, and an increased pulse can be palpated over the palmar or plantar arteries.[52] Pressure exerted with the hoof testers might elicit a positive response. Arthrocentesis of the DIP joint results in a blood-tinged synovial sample when there is articular involvement. Signs are relieved by regional anesthesia of the distal phalangeal region. In the differential diagnosis, a hoof abscess should be considered.

Radiography confirms the diagnosis in most cases. However, occasionally it is difficult to detect a fracture line because of minimal displacement. Additionally, the irregular border of the distal phalanx and debris on the hoof capsule can make recognition of the fracture difficult. It is important to take several radiographs from different angles.[55] Abaxial nonarticular fractures are usually difficult to recognize because they are normally only minimally displaced.

It is important to distinguish vascular channels from potential fractures. The presence of thin lines crossing vascular channels at different angles indicates a fracture. If no fractures can be recognized, the animal should be placed in a box stall and the radiographs repeated after 7 to 10 days.[57] Because of displacement of the fracture or osteolysis occurring at the fracture margins, the radiographic fracture gap enlarges with time, aiding in recognition of the fracture. Scintigraphy, CT, and magnetic resonance imaging (MRI) are often successful in delineating an obscure fracture (see Chapters 69 to 71).[57,58] CT and MRI are especially useful to assess articular fractures and to identify displacement of the fragments, which, if they result in a step in the articular surface, have a poor prognosis.

Treatment

Fractures of the distal phalanx can be managed with fragment removal, cast application and special shoeing, compression screw fixation, and neurectomy.[59-61] Foals are best treated with stall rest.[53,60]

ABAXIAL FRACTURES (TYPES I AND II)

These fractures are supported for 2 months by application of a fiberglass cast around the hoof capsule. The sole must be filled with silicone or polyurethane to impede any movement of the hoof capsule. Alternatively, a bar shoe with large side clips is applied to the hoof, providing support to the heels to limit hoof expansion during loading (Figure 90-40). NSAIDs are administered to reduce the pain level and allow the horse to bear weight on the foot. Stall rest for 2 to 4 months is required. Follow-up radiographs are taken to evaluate fracture healing.

Usually after 4 months, the horse can be ridden at a walk on even terrain. Depending on the reaction, the workload is slowly increased.

A reasonable prognosis can be given for future use.[59,62] It usually takes 4 to 6 months for the fracture to heal. However, radiographically the fracture line is visible much longer. Initially a fibrous union develops, which ossifies at 6 to 12 months. In some cases, a nonunion develops (Figure 90-41).

Abaxial articular fractures with substantial displacement may also be treated surgically using lag screw technique as described later (Figure 90-42). There is room for one screw, but insertion in this location is technically difficult and good intraoperative imaging is mandatory for this procedure. Computer-assisted surgery is recommended (see Chapter 13).[63]

Figure 90-41. Dorsolateral-palmaromedial oblique radiographic view of a slightly displaced abaxial fracture of the distal phalanx with joint involvement, 6 weeks after the injury. The displacement of the fracture is easily recognized at the palmar articular edge *(arrow)*.

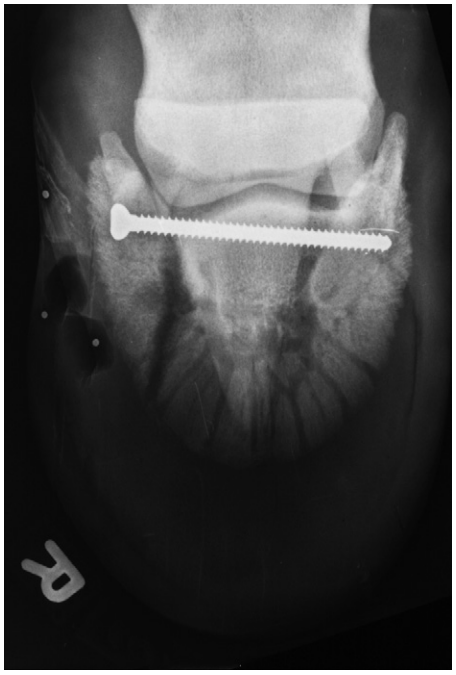

Figure 90-42. Dorsopalmar radiographic view of a displaced articular abaxial fracture repaired with a 4.5-mm cortex screw inserted in lag fashion from plantarolateral to dorsomedial.

AXIAL AND PERIAXIAL FRACTURES (TYPE III)

Axial fractures may be managed conservatively or surgically.

Nonsurgical management

The same type of treatment is used as that for abaxial fractures (see earlier). However, it is important to prolong the rest period: 4 months of stall rest followed by 4 months of hand-walking exercise. Additionally, the horse should be shod for 6 to 8 months with a bar shoe. A guarded prognosis is given for horses older than 3 years that are to be used as future riding animals, whereas horses younger than 2 years have a good prognosis.[61,64]

Surgical management

On the day prior to surgery, the entire hoof is thoroughly cleaned, the sole is trimmed, and all crevices are removed.[64] The entire hoof wall surface is rasped and the foot is placed overnight in a bandage soaked with an antiseptic (Betadine). A preoperative CT technique to determine landmarks for screw insertion has been established in the standing horse.[65]

For surgery, the animal is anesthetized and positioned in lateral recumbency on the surgery table. The use of a fluoroscope during the surgery aids in achieving correct positioning of the screw. With the aid of an arthroscope in the dorsal pouch of the DIP joint, anatomical reduction of the fragments can be observed and if necessary adjusted (Figure 90-43). The entry point through the hoof capsule is determined by taping a radiodense object to the lateral hoof wall and taking a lateromedial radiograph. By comparing the radiographic image with the objects on the hoof wall, the entry point is determined and marked on the hoof wall with an awl. The final preparation of the hoof and phalangeal region for aseptic surgery is then completed.

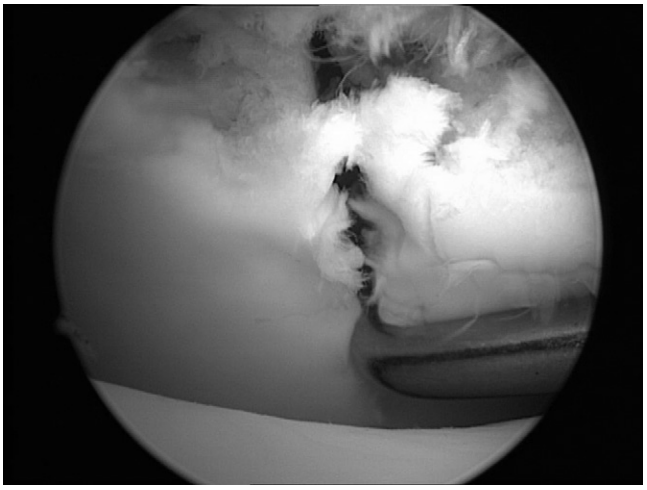

Figure 90-43. Arthroscopic view of a displaced axial fracture of the distal phalanx using a dorsal approach.

Using an 8- to 10-mm diameter drill bit, a hole is prepared through the hoof capsule parallel to the sole surface and aligned with the bulb of the heel. The hole is continued until the drill bit reaches the distal phalanx. A pilot hole is drilled into the distal phalanx with a small drill bit until it crosses the fracture. This depth cannot usually be determined without the help of fluoroscopy or intraoperative radiography. When the desired location and direction of the drill bit is determined, the glide hole is prepared (Figure 90-44). Frequent fluoroscopic views will help identify the moment when the fracture plane is crossed with the drill bit. At this point, the drill bit is removed, the drill sleeve is inserted into the glide hole, and the thread hole is

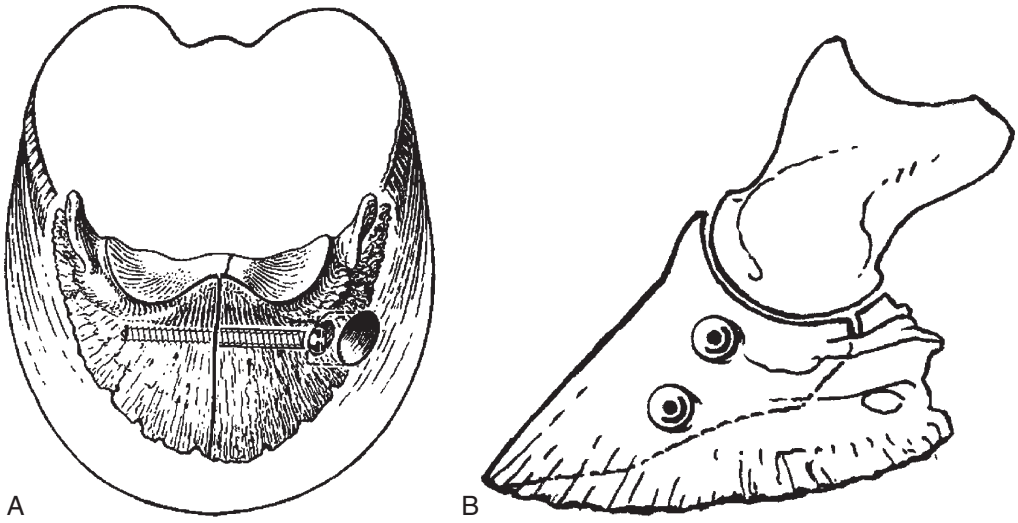

Figure 90-44. A, Graphic illustration of a dorsopalmar view of a fixation of a type III fracture with one cortex screw inserted in lag fashion. **B,** Graphic lateromedial illustration of a fixation of a type III fracture with two cortex screws inserted in lag fashion.

prepared concentrically across the bone. Care is taken to identify the exit point through the opposite fragment to prevent inadvertent trauma to the sensitive lamina. After countersinking and tapping, a 4.5-mm or a 5.5-mm cortex screw of predetermined length is inserted and solidly tightened.

Tangential radiographs are taken directed at the exit point of the screw tip to ensure correct length. Screws that are too long are exchanged for shorter ones. Conventionally, one screw is inserted without taking too big a risk of entering vital structures. With the help of computer-assisted navigation (see Chapter 13), two screws can safely be implanted.[66,67] The hole in the hoof capsule may be filled with an antibiotic-soaked sponge and placed under an aseptic pressure bandage or closed with antibiotic-impregnated polymethyl methacrylate (PMMA). When the horn defect is dry (if it is not immediately filled with PMMA), it is filled with artificial horn.

Postoperatively the horse is kept in a box stall for 4 months followed by hand-walking exercise for an additional 4 months. Barring any complications, the screw may be left in place; otherwise it is removed if problems develop. The prognosis for a pleasure horse to return to athletic use is guarded to good. Complications include postoperative infection and abscess formation.

EXTENSOR PROCESS FRAGMENTS (TYPE IV)

Etiology

These fragments have three known etiologies: hyperextension injury, avulsion by the extensor tendon, and a separate center of ossification (osteochondrosis, which may be bilateral).

Clinical symptoms and diagnosis

Some horses show no clinical signs, and the presence of a fragment of the extensor process is found incidentally. Often the clinical signs are similar to those exhibited with other articular disorders of the DIP joint. A routine lameness examination including perineural and intra-articular anesthesia and a radiographic examination permit a definitive diagnosis (Figure 90-45).

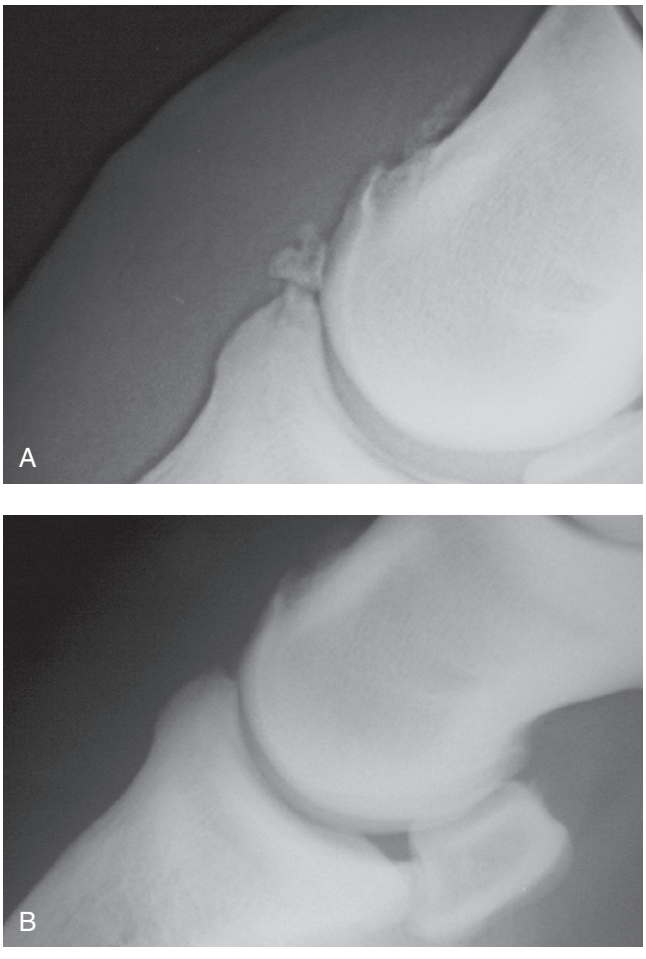

Figure 90-45. A, Preoperative lateromedial radiographic view of an extensor process fracture. **B,** Postoperative lateromedial radiographic view of the same horse after removing the fragment.

Treatment

Small fragments (see Figure 90-45) should always be removed because they are mobile and have contact with the articular surfaces.[68] Fragment removal is accomplished by routine arthroscopy (Figure 90-46). Adjunctive therapy with intra-articular hyaluronan is encouraged. Postoperatively, the phalangeal region is kept under a bandage for 3 weeks and the horse is rested for 6 to 8 weeks.

There is no ideal treatment for large fragments (Figure 90-47). Therefore, conservative therapy is usually tried first. Insertion of one or two screws in lag fashion has been described, but only rarely is a rigid fixation achieved.[69-71] Therefore, if lameness persists after conservative management, surgical removal of the fragment is recommended.[71] The fragment is divided into smaller pieces and these smaller pieces are removed under arthroscopic supervision. Generally, a good prognosis can be given.[72] Postoperatively, a fiberglass cast or a compression bandage should be applied over the surgery site.

MULTIFRAGMENT FRACTURES (TYPE V)

Multifragment fractures are always associated with severe lameness. Radiographically, several fracture lines can be appreciated (Figure 90-48). Application of a fiberglass cast may be tried; however, these fractures have a poor prognosis for future soundness. Therefore, euthanasia has to be considered. Alternatively, a neurectomy can be performed if euthanasia is not an option for the owner.

SOLAR MARGIN FRACTURES (TYPE VI)

Solar margin fractures do occur often and are underdiagnosed.[55,73] Direct or blunt trauma, possibly caused when the horse kicks a hard, immobile object, are common causes of solar margin fractures. In the spring of the year in some climates, when freezing and thawing produces hard uneven ground in the mornings, these fractures are prone to occur. These fractures can also develop as a result of chronic laminitis.[55] Most solar margin fractures heal by bony union; rarely,

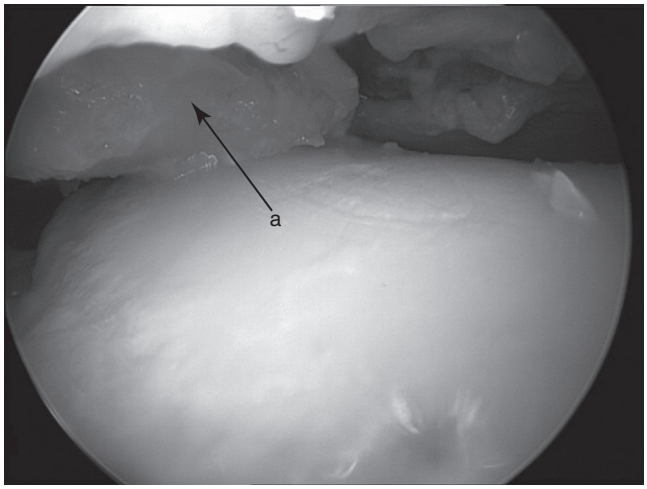

Figure 90-46. Arthroscopic view of the fractured extensor process *(a)*. The *arrow* points toward the fragment.

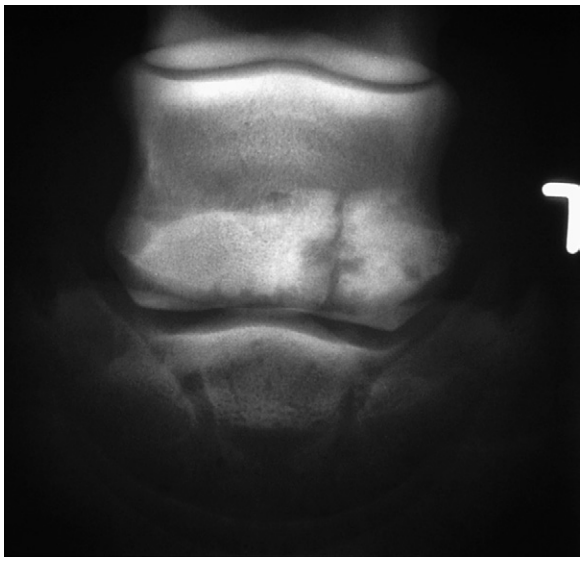

Figure 90-51. Dorsopalmar radiographic view of a pathologic fracture of the distal sesamoid bone. Note the large radiolucent area in the center of the fracture and the proliferative new bone formation on the proximal rim.

resorption of small fragments can occur.[55] Surgical removal of fragments has been reported in individual cases, especially if sepsis develops.

Fractures of the Distal Sesamoid Bone

Fractures of the distal sesamoid bone (DSB) occur rarely. They are diagnosed more often in the forelimbs. Four different types are distinguished: avulsion fractures, simple fractures of the body, comminuted fractures, and frontal fractures.

Avulsion fractures of the distal margin are often found in conjunction with navicular disease. Therefore, these fractures are considered part of an osteoarthritic syndrome (see later in this chapter).

Most of the simple fractures occur abaxially in a vertical or slightly oblique direction (Figure 90-49). Some displacement is possible.

Multifragment fractures are rare and in most cases carry a poor prognosis. Fractures in the frontal plane are highly unusual (Figure 90-50).

Etiology

Most fractures of the DSB have a traumatic origin and are the result of excessive or repetitive loading through the middle and distal phalanges and the DDF tendon.[74] Occasionally, a preexisting pathologic condition in the DSB predisposes it to fracture (Figure 90-51). In these cases, chronic navicular disease is usually implicated.[75]

Clinical Signs and Diagnosis

Clinical signs include an acute moderate to severe weight-bearing lameness associated with an intense pain reaction to turning, increased pulsation of the palmar or plantar arteries, and positive reaction to the application of hoof testers. The low palmar or plantar nerve block is usually diagnostic. All standard radiographic views of the DSB should be taken (lateromedial, tangential, and oblique) to rule out the potential presence of a bipartite or tripartate DSB (two or three ossification centers) or other disorders. Air shadows of the sulci of the frog will project over the DSB and can be mistaken for fracture lines. Therefore, it is important to fill them with a suitable modeling compound before taking the radiographs.

Treatment

Management options for fractures of the DSB include conservative and surgical techniques. Callus formation is rare, and often syndesmoses are formed (fibrous tissue union).[74]

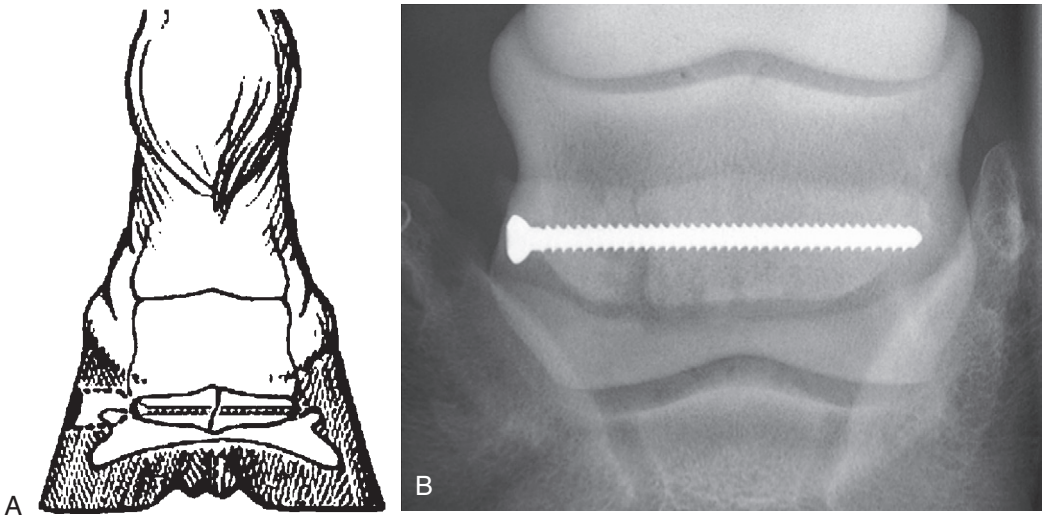

Figure 90-52. A, Graphic illustration of a screw inserted through the hoof wall into the distal sesamoid bone, stabilizing the fracture. Note the large hole drilled through the hoof wall to get access to the distal sesamoid bone. **B,** Dorsopalmar radiographic view showing a 3.5-mm cortex screw inserted across the fracture.

NONSURGICAL MANAGEMENT

Corrective shoes are recommended to protect the DSB. Therefore, nonsurgical management involves stall rest and an elevated heel and bar shoe for 4 months, followed by small paddock exercise and a shoe with thickened branches.[76] Even if the patient improves clinically during the first few months, an osseous union cannot be detected radiographically. Healing requires 10 to 12 months. The prognosis for future athletic activity is unfavorable.[77]

One option involves fixation of the distal limb in an extremely flexed position using a fiberglass cast, which relieves excessive stresses on the DSB. Acceptance of the cast takes a special patient, and healing requires about 6 months. Despite these measures, the prognosis for a future pleasure horse is guarded.

SURGICAL MANAGEMENT

The surgical options include screw fixation and neurectomy. Insertion of a cortex screw in lag fashion provides stability and promotes bone union.[78] The difficulty lies in correct placement of the screw, avoiding penetration of the DIP joint and the palmar tendon sheath (Figure 90-52). Close intraoperative monitoring through fluoroscopy or multiple radiographic images is of utmost importance. The application of a specially developed radiolucent aiming device (Figure 90-53) is mandatory for a correct screw placement. Computer-assisted navigation is an alternative technique (see Chapter 13).

Effective preoperative preparation of the hoof is initiated the day before surgery, as described earlier. The entry point through the hoof wall is determined and marked with the help of fluoroscopy. The horse is placed under general anesthesia and positioned in lateral recumbency on the surgery table. The lateral hoof wall and the pastern region is prepared for aseptic surgery.

After preparing an 8-mm drill hole across the hoof wall at the previously marked location, the aiming device is applied to the hoof and adjusted with the help of fluoroscopy. There is considerable variation among horses in relation to the structures that have to be navigated to get access to the lateral aspect of the DSB. In some horses, only the collateral cartilage has to be traversed, whereas in others part of the distal phalanx and/or the ossified collateral cartilage has to be traversed. It is important to prepare a large enough opening to allow the screw head to pass easily down to the DSB. The 3.5-mm glide hole is prepared, just crossing the fracture plane. The insert drill guide is inserted into the glide hole, and a 2.5-mm thread hole is drilled into the opposite fragment. After tapping, a 3.5-mm cortex screw of estimated length is inserted and tightened. With the help of a dorsopalmar radiograph, correct positioning and length are verified.

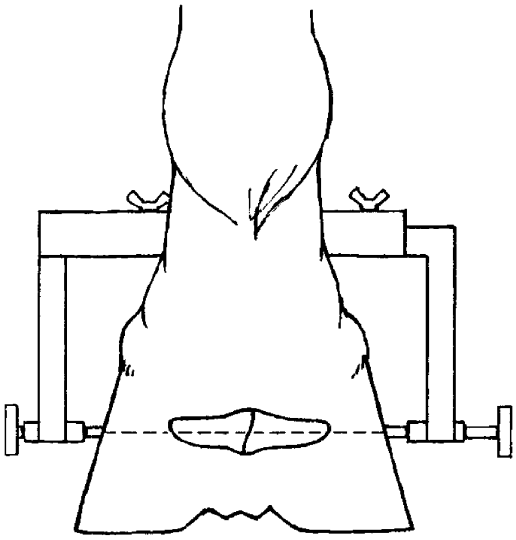

Figure 90-53. Graphic illustration of the aiming device used to ensure intraosseous placement of a screw into the distal sesamoid bone.

Computer-assisted surgery has significant advantages over screw insertion via an aiming device.[79] Using a computer-assisted surgery system, 3.5-mm and 4.5-mm screws were implanted into normal DSBs.[80] The glide hole was drilled from the surface of the hoof wall down to the lateral aspect of the

DSB. Subsequently, the drill bit was exchanged with a new one of the same size, with which the glide hole was created across the DSB just beyond the imaginary fracture plane. Finally, the thread hole was drilled using routine technique. This was followed by expanding the hole in the hoof wall across the distal phalanx/collateral cartilage to an 8 mm diameter. The lateral aspect of the DSB was countersunk and the thread hole was tapped. The screw length was determined with computer-assisted navigation. Using this technique, it was possible to insert all 3.5-mm and 4.5-mm cortex screws without penetrating the DIP joint or flexor surface of the DSB. The problem with the 4.5-mm cortex screw was their relatively large screw head relative to the depth of the DSB.[80] In 8 out of 10 cases, the screw head modified either the articular rim or the rim of the flexure surface.[80] The use of the 4.5-mm cortex screws would be preferred but the screw head is too large. The screw head was machined to a 5-mm diameter, which solved the problem. The use of the 4-mm cortex screws could be considered to improve the stability of the fixation and reduce the risk of screw breakage through cyclic loading.

Healing of the fracture takes 6 to 8 months, during which stall rest and hand-walking exercise are implemented. Barring any complications, the screw is left in place.[81] The prognosis for athletic competition is guarded, but for pleasure riding it is favorable.[77] To allow the horse to return to competitive work, it is often necessary to perform a neurectomy.[78]

ARTICULAR SURGERY

Arthroscopy

Arthroscopy of the DIP joint (Figure 90-54) has replaced arthrotomy, as it has in other joints. The advantages include the small approach portals, the small risk of postoperative infection, and the shortened convalescent period.[68] Indications for arthroscopic interventions include fragment removal from the extensor process, lavage in cases of infection, and curettage of subchondral cystic lesions.[82]

Preparation

The hoof should be thoroughly cleaned the day before surgery, and the coronary band and the phalangeal region should be clipped. The entire area is scrubbed and placed overnight under an antiseptic bandage. The shoe may be left in place.

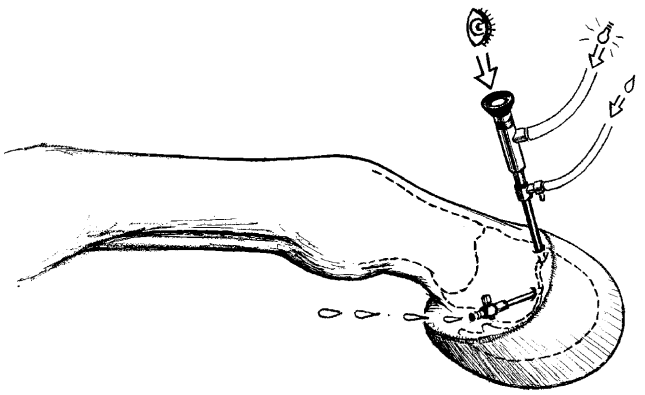

Figure 90-54. Typical location of the arthroscopic and instrument portals (or egress needle shown here) used for arthroscopy of the distal interphalangeal joint.

For arthroscopic interventions in the forelimb, the animal is positioned in dorsal recumbency. Lateral recumbency is usually selected in the hind limb because the reciprocal apparatus makes manipulation easier in this position. An Esmarch bandage is applied to prevent intraoperative bleeding. Because of the location of the surgery site, meticulous attention is paid to the draping procedure. The use of a sterile incise drape is advisable.

Surgical Technique

DORSAL APPROACH

With the DIP joint in an extended position, a needle is advanced in a dorsolateral to distomedial direction from 2 cm proximal to the coronary band and 1.5 cm abaxial. Withdrawal of synovial fluid ensures the correct placement of the needle. The joint is distended with gas or with 20 mL Ringer's lactate solution.

The arthroscope portal is prepared with a No. 11 scalpel blade introduced into the joint along the needle, and the needle is withdrawn. Immediately after the incision is prepared, the sleeve and the blunt obturator are carefully advanced together into the joint with a rotating movement. The obturator is subsequently replaced by the arthroscope.

Working with a dorsolateral arthroscope portal allows inspection of a medial fragment and its removal through an instrument portal positioned directly over the fragment (see Figure 90-54). The joint is very small, providing little room for recognition of the anatomic landmarks. The middle phalanx is recognized by its articular cartilage surface and the proximal prominent ridge, which provides access to the dorsal outpouching of the joint. The synovial membrane, located at the dorsal aspect of the joint cavity, is covered with synovial villi, which partially obstruct the view. Often the osteochondral fragment of the extensor process is hidden behind the villi. The surface of the fragment is usually rough and irregular.

The key to identifying the fragment is to recognize the separation between the fragment and the parent portion of the bone. The abaxial aspect of the joint should be inspected initially to provide an overview of the condition of the joint. It is possible that displaced small fragments can be found in these locations.

Most fragments are well attached to the soft tissues. Insertion of an elevator between the fragment and the distal phalanx and careful manipulation loosens most fragments. It is important to disrupt a significant portion of the attachments of the extensor tendon and surrounding tissues from the fragment before attempting to remove the fragment with rongeurs. When good purchase of the fragment is achieved, rotating movements are performed to disrupt the remaining attachments. Because of the softness of the fragment, it is usually removed in pieces.

The fracture bed is inspected and curetted if deemed necessary. Introduction of the arthroscope through the instrument portal allows inspection of the fragment bed from a different view and occasionally the detection of other small fragments. The joint is then flushed and the portals closed with two simple-interrupted sutures of an absorbable monofilament material.

A postoperative pressure bandage is maintained for 2 weeks.[83] The portals for the surgery heal slower than similar portals in other joint regions. Therefore, there is an increased risk of infection. Additionally, intra-articular injections (such as hyaluronan) are delayed for about a week. The horse is kept in a box stall for 4 weeks and can then slowly return to work.

The prognosis depends on the nature of the problem, the age of the patient, and the arthroscopic findings during surgery. In young horses, a good prognosis can usually be given, whereas in older horses with concomitant osteoarthritis, the prognosis for successful return to work decreases.

PALMAR APPROACH

An arthroscopic approach to the palmar aspect of the DIP joint has been described.[82] The horse is positioned in lateral recumbency and the joint is distended through a dorsally placed needle. Observation of the process of joint distention allows identification of the best palmar location to access the joint. A needle is placed into the site to facilitate correct scope positioning. A 5-mm skin incision is made over the lateral/medial aspect of the palmaro/plantaroproximal pouch, axial to the collateral cartilage and the neurovascular bundle and abaxial to the deep digital flexor tendon, and the blunt obturator is directed toward the apex of the frog. The midsagittal ridge of the dorsal articular border of the navicular bone, the entire proximal border of the navicular bone, the medial and lateral aspect of the joint, parts of the collateral sesamoidean ligaments can be evaluated. Osteochondral fragments and navicular cysts can be found.

PALMAR OR PLANTAR DIGITAL NEURECTOMY

General Considerations

Neurectomy is one of the oldest surgical procedures described in horses.[84] Palmar or plantar digital neurectomy is a viable option for alleviating pain in horses with certain kinds of chronic lameness, particularly navicular disease. A thorough clinical examination and proper case selection are critical. For example, digital neurectomy is contraindicated in horses with laminitis or infection of the DIP joint.

Various techniques for digital neurectomy have been described. The operation may be performed with the horse standing or in lateral or dorsal recumbency under general anesthesia.[85,86] With the horse standing, the procedure is carried out quickly, avoiding the risks of general anesthesia. With the horse in dorsal recumbency, repositioning the horse to access both sides of the limb is not required, and a tourniquet is not necessary because minimal bleeding occurs.[86] A nonsteroidal anti-inflammatory drug should be administered postoperatively and the horse should be kept in a box stall for 4 weeks. The horse is then slowly reconditioned by walking for another 4 weeks.

Re-innervation can occur when the severed nerve endings re-establish contact with each other (Figure 90-55). This can happen as early as 6 months postoperatively, depending on the technique used. However, ideally this does not happen for many years.[82,87] Neuritis and neuroma formation are common complications, particularly in the proximal nerve stump; depending on the study, up to 20% of patients are affected. These lesions are very painful, and in selected cases they must be treated with local injections of triamcinolone acetate (5 to 10 mg for each neuroma), sarrapin, or alcohol blocks. Rupture of the DDF tendon and subluxation of the coffin joint can occur after neurectomy, especially if it was compromised before surgery (Figure 90-56). Another sequela is laminitis, which can develop after a second operation or with injury of the blood vessels.

Figure 90-55. Specimens of neuromas excised following re-innervation of a neurectomized digit.

Figure 90-56. Lateromedial radiographic view of a subluxation of the distal interphalangeal joint, which occurred after palmar digital neurectomy.

Special techniques are used to prevent or at least delay regrowth of the severed nerve ends as well as to reduce the risk of neuroma formation. Various methods have been described for cutting the nerve and treating the severed nerve ends. However, the "guillotine technique," meaning simple scalpel transection of the nerve, does not use any form of nerve end treatment and is the most commonly used method.[82,87] This technique can be applied through one large or two small incisions, as described later.

For the sake of completeness, discussion of the methods that have been used to treat severed nerve ends is presented here. Electrocoagulation is a rarely used method. Other methods include epineural capping, inserting the nerve in a hole drilled into the proximal phalanx, or ligating the nerve.[88,89] A valid alternative to digital neurectomy is cryoneurectomy, in which

the nerve is frozen to as low as −30° C transcutaneously.[90] Other alternatives include topical application of chemicals and injection of neurotoxins, such as cobra venom.[91] Carbon dioxide laser treatment of the proximal nerve stump has reduced the development of neuromas.[92]

In certain countries, animal welfare legislation and equine sports associations (e.g., the International Equestrian Federation [FEI]) prohibit horses that have had a digital neurectomy from competing in official events. As a consequence, various methods of detecting a neurectomy have been developed.[93,94]

Palmar Digital Neurectomy in the Pastern Region Using One Skin Incision

The horse is positioned in dorsal recumbency, and the limbs are extended and tied to restraints attached to the ceiling.[86] The surgical field is clipped, prepared for aseptic surgery, and draped. The nerve is palpated, and an approximately 4-cm incision is made in the pastern skin directly over the nerve (Figure 90-57, *A* and *B*).[82] Usually the skin incision is made along the dorsal edge of the DDF tendon, which directly exposes the nerve.

The ligament of the ergot is identified and split longitudinally (see Figure 90-57, *C* and *D*), allowing access to the neurovascular bundle located beneath it. Splitting the ligament provides an extra layer to be closed over the severed nerve and potentially reduces postoperative irritation and subsequent neuroma formation. Additionally, mistakenly transecting the ligament instead of the nerve can be prevented with this technique. The nerve is isolated within the neurovascular bundle and isolated from the artery (see Figure 90-57, *E* and *F*). The neurotomy is initially performed proximally and then distally, followed by removal of the loose piece of nerve (see Figure 90-57, *G*).

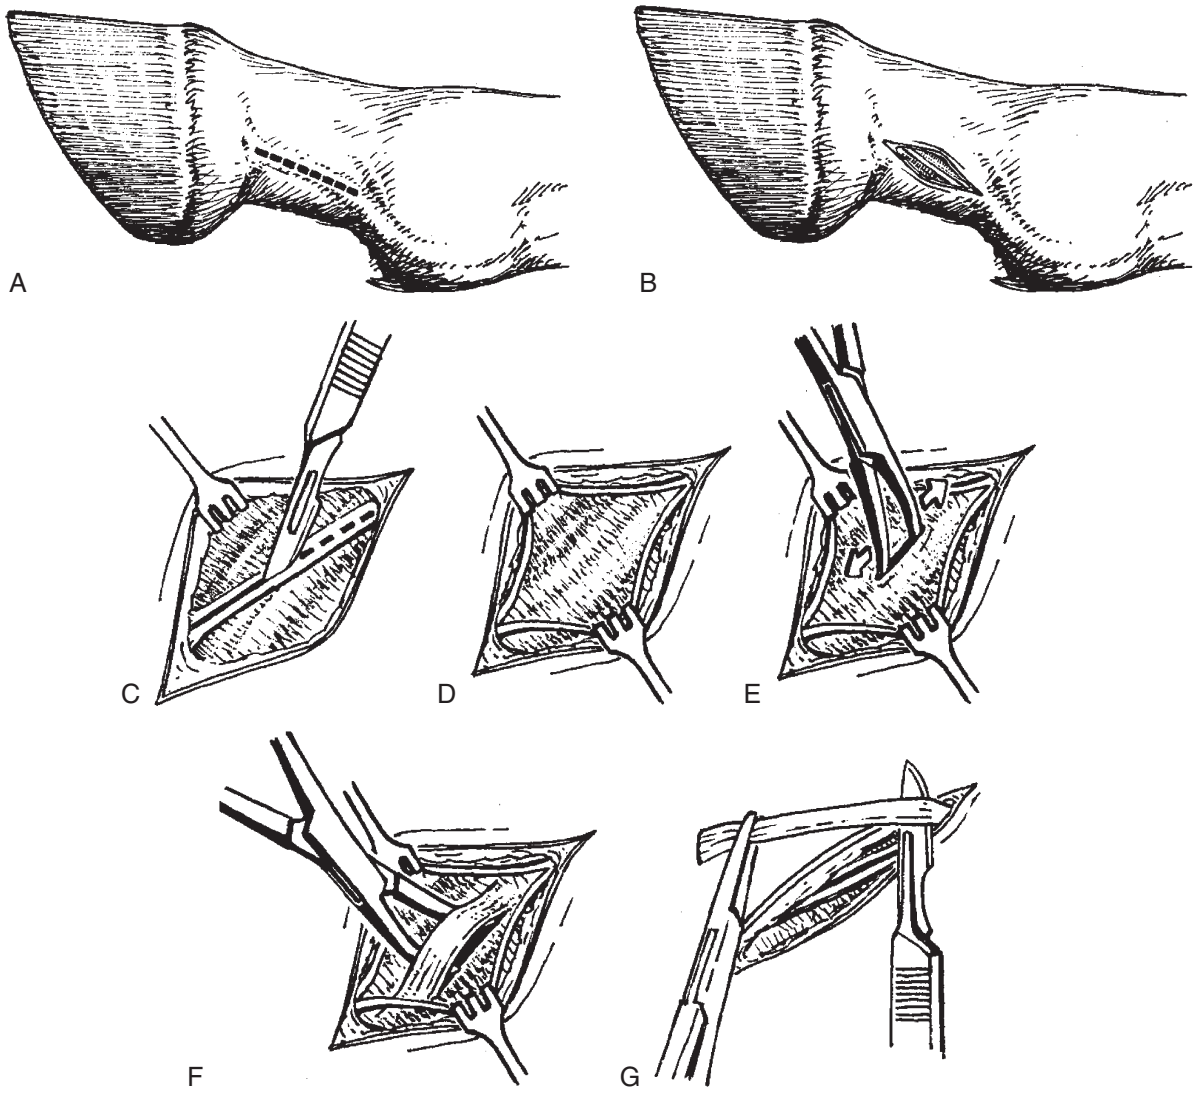

Figure 90-57. Graphic illustration of the palmar digital neurectomy procedure performed in the phalangeal region through one incision. **A,** Location of the skin incision. **B,** The skin incision has been made. The ligament of the ergot is split longitudinally **(C)** and separated **(D),** giving access to the underlying tissues and the neurovascular bundle. The structures of the neurovascular bundle are separated **(E),** and the nerve is isolated **(F). G,** A 2-cm piece of nerve is excised.

The ligament of the ergot is closed in a continuous pattern, and the skin is closed with simple interrupted sutures. Aftercare is the same as that for the method using a small incision, described under "General Considerations."

An alternative and simpler technique involves a small stab incision about 1 to 1.5 cm in length at the mid pastern region. The nerve is isolated palmar to the artery and elevated up to the skin, applying some tension. Subsequently the nerve is transected at the proximal aspect of the incision and, applying considerable tension, the distal transection is performed as far distal as possible. Skin closure is routine in two layers. This technique allows the removal of 2 to 3 cm of nerve.

Palmar Digital Neurectomy in the Pastern Region Using Two Small Incisions—Pull-Through Technique

The location of the nerve is palpated and two approximately 1.5-cm skin incisions are made directly over the nerve (Figure 90-58, *A* and *B*). The distal skin incision is located at the distal end of the pastern region at the transition to the bulb of the heel. The proximal skin incision is selected at the proximal end of the pastern region at the transition to the metacarpophalangeal joint.

The tissue is bluntly dissected longitudinally with a mosquito forceps so that the dorsal and palmar aspects of the nerve are isolated (see Figure 90-58, *C*). It is important that the nerve and artery are well separated. Proximally the nerve might be obscured by the ligament of the ergot, which runs superficial to the nerve at a slightly different angle. The nerve is always covered by fascia, and it can be surprising how deep a dissection is required for its isolation.

When the nerve has been freed proximally and distally, it is alternately pulled at either end to ensure that the correct structure has been exposed. The nerve is pulled up with a mosquito forceps, held with tissue forceps, and cut sharply as far distally and proximally as possible with a No. 15 scalpel blade (see Figure 90-58, *D* and *E*). One clamp is applied to the proximal end and another one to the distal end of the severed nerve segment, and tension is applied to ensure that all attachments are eliminated and the nerve segment can be completely removed (see Figure 90-58, *F* and *G*). The skin incisions are closed with 2-0 nonabsorbable suture material.

The advantages of this technique are the small size of the skin incisions, short time of surgery, and low incidence of neuroma formation.[95]

Repeated Palmar Digital Neurectomy

A second neurectomy might be necessary when re-innervation occurs and the horse becomes lame again. For this procedure, a long incision is usually made so that the nerve can be adequately isolated. This procedure is often more difficult than the initial operation because the nerve is generally very closely attached to the artery.

Small neuromas are always seen in the proximal aspect of the previous surgical field. These nodules can be easily palpated in horses that have had a neurectomy. Sometimes the regrown nerve is surrounded by a large amount of scar tissue, which renders its isolation more difficult. Only the neuroma and part of the distal nerve should be removed. Skin closure and aftercare are the same as for the other neurectomy procedures.

High Lateral and Medial Palmar Neurectomy

The goal of high lateral and medial palmar neurectomy is to disrupt afferent and efferent nerve tracts proximal to the division into palmar and dorsal branches to prevent pain sensation from chronic disease processes innervated by the dorsal branches of the lateral and medial palmar nerve. This is usually performed proximal to the flexor tendon sheath, because locating and removing the nerve is easy in this location (Figure 90-59). Also, there is little relative movement in this area, so that the nerve endings are less traumatized. The operation is carried out with the horse in dorsal recumbency. The skin is incised immediately proximal to the flexor tendon sheath on the lateral and medial aspects of the metacarpus. The nerve is located, isolated, and removed. Aftercare is the same as for the other techniques.

SURGICAL MANAGEMENT OF NAVICULAR SYNDROME

Navicular disease is a degenerative disorder that involves the DSB and its surrounding structures. The etiopathogenesis of the condition is multifactorial, and many theories have been proposed.[96-99] Vascular and mechanical theories continue to be debated as to the primary cause of the disease.

Treatment

There is no actual cure for navicular disease. Its management concentrates on abolishing the symptoms and clinical signs.

Nonsurgical Management

Management strategies include corrective shoeing, NSAIDs, and vasodilators (such as isoxsuprine or metrenperone).[100] Intra-articular administration of hyaluronan with or without corticosteroids into the DIP joint or in the navicular bursa can provide transient relief of clinical signs. The bisphosphonate tiludronate (Sanofi-Aventis, Paris), a drug designed to inactivate osteoclast activity, has demonstrated positive results in the treatment of navicular after disease in horses with lameness of less than 6 months duration.[101,102]

Another novel medical treatment is based on the pathophysiologic mechanism that podotrochlosis is associated with an increase of the intraosseous pressure in the navicular bone. The increase of pressure might be caused by an accumulation of osmotically active substances in the interstitium, as has been described in cases of compartment syndrome. Therapy with benzopyrone is proposed.[103] This drug is used successfully in humans to reduce high-protein edema.[104]

Surgical Management

Surgery is usually reserved for cases of navicular syndrome that have not responded to such conservative treatments as corrective shoeing and medical management. Three surgical procedures are currently available: navicular suspensory desmotomy, palmar digital neurectomy, and periarterial sympathectomy. These surgical procedures should be combined with balancing the feet and applying corrective shoes.

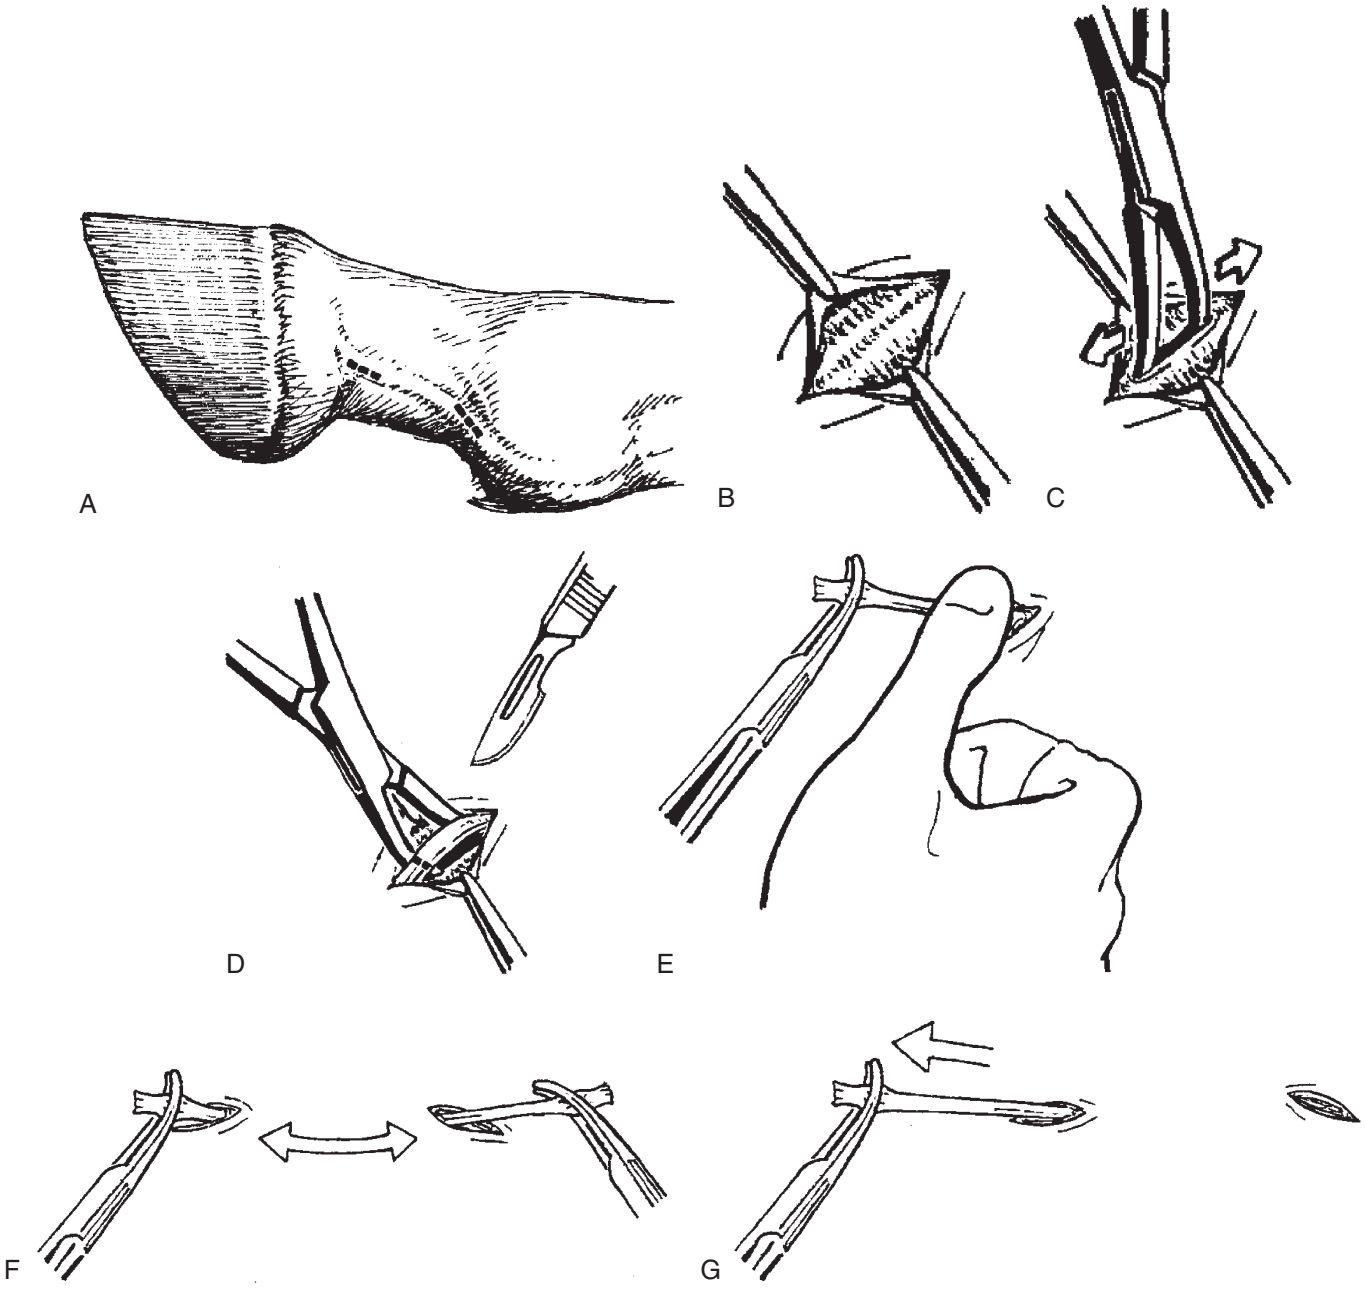

Figure 90-58. Graphic illustration of a palmar digital neurectomy performed through two small incisions. **A,** Location of the two incisions. **B,** The neurovascular bundle is visible through an incision. The nerve is isolated **(C)** and elevated above the incision **(D).** The proximal end is transected **(E),** followed by the distal end **(F),** and the piece of nerve is pulled out of the distal incision **(G).** The incisions are subsequently sutured.

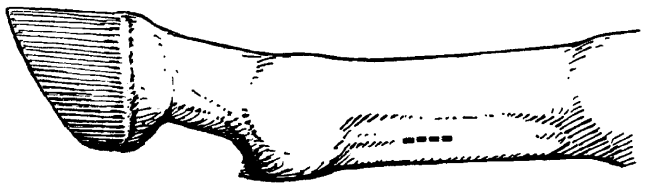

Figure 90-59. Graphic illustration of the location of the surgical site for the high palmar neurectomy.

DESMOTOMY OF THE SUSPENSORY LIGAMENTS

Desmotomy of the suspensory ligaments (DSL) of the DSB has been proposed on the assumption that the syndrome has a mechanical basis. The proposed mechanism of action of the surgery reduces the forces on the navicular bone and perinavicular structures associated with the caudal weight-bearing phase of the stride (the portion of the stride where the suspensory ligaments are loaded).[105-107]

The DSB has its own supporting ligaments: proximally, the collateral sesamoidean ligaments (CSLs) and distally, the impar ligament and the chondrosesamoidean ligaments (Figure 90-60). The suspensory ligaments of the DSB are broad, elastic

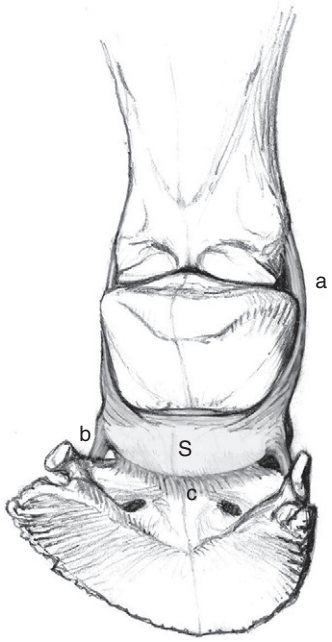

Figure 90-60. Graphic illustration of the supporting ligaments of the distal sesamoid bone (palmaromedial view). *a,* Collateral distal sesamoidean ligament; *b,* chondrosesamoidean ligament; *c,* impar ligament; *S,* distal sesamoid bone.

structures containing an abundance of nerve fibers. They originate at the dorsodistal aspect of the proximal phalanx and insert primarily on the proximal border of the DSB (Figure 90-61, *A*). A branch of each ligament, the chondrosesamoidean ligament, also inserts on the axial surface of the adjacent collateral cartilage and the palmar process of the distal phalanx.

The biomechanics of the DSB and its suspensory apparatus are not completely understood and are explained mainly with the help of theoretical models. It is generally accepted that the CSLs anchor the DSB and prevent its descent during weight bearing.[106] However, the exact biomechanical implications of the CSL during loading are difficult to explain because the ligament passes over two joints, and time and maximum amount of tension depend on the foot or pastern axis and hoof conformation, as well as on the phase of the stride. Nevertheless, it is argued that under maximal extension of the CSL, third-order acceleration (vibratory) forces between the DSB and the deep flexor tendon can develop.[107] Desmotomy of the CSL would remove these vibratory forces, which could potentially damage the DSB and impar ligament with all the associated vasculature.

Surgical transection of the CSL is performed as described in the literature.[97,105] The horse is anesthetized and positioned in dorsal recumbency. An Esmarch bandage is applied as a tourniquet proximal to the metacarpophalangeal joint. A 4-cm vertical incision is made midway between the common digital extensor tendon and the distal eminence of the proximal phalanx, from the level of this eminence to the coronary band (see Figure 90-61, *B*). The incision continues deeper through the subcutaneous fascia to permit identification and isolation of the coronary plexus (see Figure 90-61, *C*) on the proximal margin of the collateral cartilage. Dissection axial to the cartilage allows identification of the dorsal margin of the CSL. A mosquito forceps is passed in the dorsopalmar direction under the CSL to elevate the ligament, and a No. 11 scalpel blade is used to transect it (see Figure 90-61, *D*). The subcutaneous tissues are closed with a simple-continuous suture pattern using 2-0 absorbable suture material. Skin closure is routine. The opposite CSL in the same limb and the ligaments of the opposite limb are transected applying identical technique.

Postoperative care includes protective bandages for 10 days until the sutures or staples are removed. Hand-walking exercise should be initiated soon after surgery and is continued for 3 weeks. Thereafter, a gradually increasing exercise program is implemented with the goal of achieving full work levels by 3 months after surgery.[97] Postoperative complications are rare but include wound dehiscence, infection, local swelling, and postoperative scarring. Recently, an arthroscopic approach for transecting the CSL has been evaluated in an experimental study.[108]

Preliminary results from the United Kingdom were encouraging: 13 of 16 horses treated with CSL desmotomy were able to work without lameness.[105] In the same year, another study revealed clinical improvement in 50% of 57 horses.[109] Two additional studies reported success rates of 15 of 21 horses and 12 of 17 horses, with the horses in the second group being sound at least 6 months after surgery.[110,111] In a review of 118 horses that had navicular syndrome and that were treated with CSL desmotomy, 76% were sound at 6 months, and 43% were sound after 36 months.[112]

All of the following conditions were associated with a diminished response: flexor cortex defects, proximal border enthesiophytes, mineralization of the DDF tendon, and medullary sclerosis of the DSB. Horses with more than 1 year's duration of clinical signs had a poor prognosis. The procedure is not recommended in horses with inflammatory disease of the DIP joint and the navicular bursa, but horses with new bone growth at the site of insertion of the CSLs (enthesiophytes) are considered excellent candidates for this surgery. The procedure should be attempted early in the course of the syndrome.[113]

It was originally stated that desmotomy of the CSL should modify the biomechanical forces acting on the DSB, but clinical improvement could also be the result of transection of the sensory fibers that course within the suspensory ligaments. It seems that the procedure is more effective in improving clinical signs on a short-term basis (6 to 12 months), and the lameness can recur later on because of re-innervation of the sensory fibers in the CSL.

PALMAR DIGITAL NEURECTOMY

The most commonly performed surgical technique to abolish lameness associated with the navicular syndrome is palmar digital neurectomy (see earlier).

PERIVASCULAR SYMPATHECTOMY AND FASCIOLYSIS

Perivascular sympathectomy and fasciolysis around the lateral and medial digital artery and vein have been described for the treatment of navicular syndrome.[114] A 10-cm skin incision is centered over the lateral and medial proximal sesamoid bones. The subcutaneous tissues and fascia are carefully transected as well and the neurovascular bundle is identified. The artery and vein are isolated from their perivascular tissues and adventitia over the entire length of the surgical site. The nerve is isolated from its surroundings as well. Inadvertent trauma to the vessels

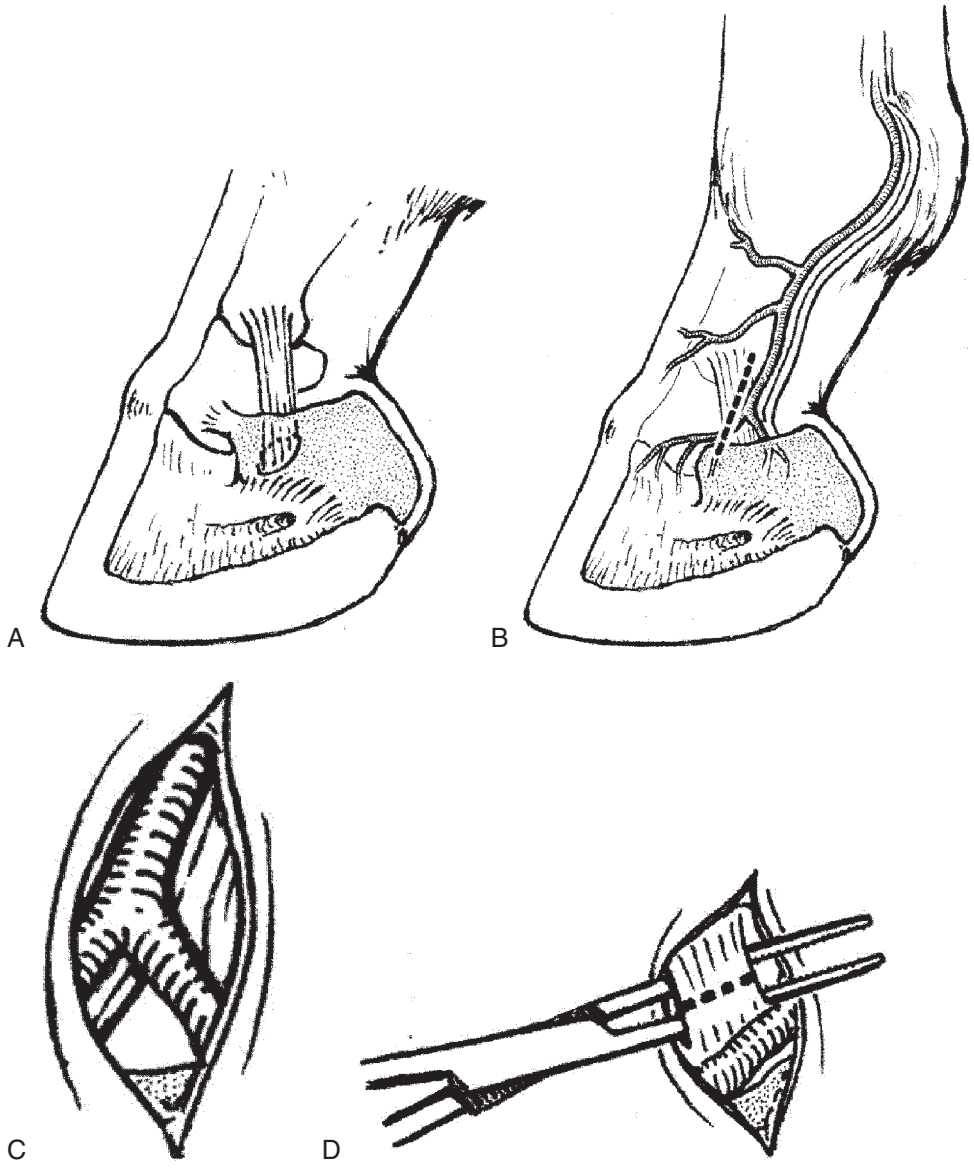

Figure 90-61. Graphic illustration of the desmotomy of the collateral distal sesamoidean ligament. **A,** Overview of the anatomic structures. **B,** Location of the skin incision over the ligament. **C,** After the skin is incised, the ligament can be seen underneath the superficial vessel. **D,** The ligament is isolated, elevated above the skin incision, and transected.

and the nerve should be avoided at all costs. Through this dissection the sympathetic nerve supply of the vessels is stripped, which results in a prolonged vasodilation. The subcutaneous tissues and the skin are closed in routine fashion.[115]

A significant increase in skin temperature caused by increased blood circulation in the region could be demonstrated at 8 and 20 weeks postoperatively with the help of thermography in 30 horses.[114] In each horse, one forelimb was operated on, whereas the other served as a control. A significant increase in hoof horn growth could be seen in the experimental limb compared to the control limb. In a review of 79 horses that had navicular syndrome and that were treated with perivascular sympathectomy and fasciolysis, 73% were sound and returned to the intended use. The mean duration of follow-up was 23.6 months (range, 3 to 72 months).[114]

SURGICAL MANAGEMENT OF LAMINITIS

Laminitis is characterized by a breakdown of the connective tissue suspensory apparatus of the distal phalanx inside the hoof wall. As a result of lamellar pathology, the distal phalanx is no longer supported by the laminar attachment and starts to displace. As soon as the first signs of displacement are recognized, the disease becomes chronic.

There is a direct relationship between the degree and speed of movement of the distal phalanx away from the hoof capsule and the severity of damage to the laminae at the initial insult. Therefore, the most useful diagnostic and monitoring aids in the course of the disease are high-quality radiographs in both lateromedial and dorsopalmar (horizontal) projections.

Clinical Signs

Clinical signs, severity of damage, and response to therapy vary among individual horses, but it is widely accepted that the single most important factor influencing the final outcome of equine laminitis is the severity and extent of the initial damage to the internal anatomy of the foot.

Diagnosis

Clinical signs are very typical, and the radiographic examination further helps to diagnose this condition.

Treatment

Treatment of laminitis consists of dietary management, medical treatment, soft bedding, and hoof care. In all phases of the hoof care, corrective shoeing and trimming should aim at reducing stress to the damaged lamellae by minimizing the distracting forces affecting the displacement of the distal phalanx (rotation or sinking). DDF tenotomy is a salvage procedure for horses with chronic refractory laminitis accompanied by rotation of the distal phalanx and persistent pain. However, it is reported that even foundered horses with persistent draining tracts caused by osteomyelitis and excessive heel growth respond favorably to the procedure.[116]

Tenotomy of the Deep Digital Flexor Tendon

The rationale for tenotomy of the DDF tendon is based on the biomechanical forces in the foot. The procedure is performed to reduce the palmarly directed pulling forces of the DDF tendon on the distal phalanx and subsequently decrease the shearing stresses on the lamellae of the dorsal aspect of the hoof capsule. It also serves to reduce the pressure of the apex of the distal phalanx on the corium of the sole. Tenotomy of the DDF tendon permits lowering the heels to allow a more normal alignment (derotation) of the distal phalanx using orthopedic shoeing.[115]

DDF tenotomy can be performed at the midmetacarpal or the pastern area of the limb. Both procedures are equally effective, but tenotomy at the level of the midmetacarpus is preferred for various reasons. It is easier to perform and can be performed in a standing horse, the digital tendon sheath is not invaded, it bears less risk of postsurgical infection, and it leaves some support to the DIP joint through fascial attachments. Pastern region DDF tenotomy must be performed under general anesthesia and should be reserved for cases that require a second tenotomy.

Before either surgery, horses should be shod with a heel extension to stabilize the foot and help prevent postoperative hyperextension or subluxation of the DIP joint.

MIDMETACARPAL APPROACH

The hair is clipped circumferentially from the level of the metacarpophalangeal joint to the carpus. The horse is sedated, and local anesthesia is achieved through a high palmar ring block.

After aseptic preparation of the limb and appropriate draping, a vertical incision through the skin, subcutaneous tissue, and paratenon is made directly over the lateral aspect of the DDF tendon, centered at the junction of the proximal and middle third of the MCIII (Figure 90-62, *A*). With the help of curved Kelly forceps, the DDF tendon is separated from the neurovascular bundle (see Figure 90-62, *B*), the accessory ligament, and the superficial digital flexor (SDF) tendon. The DDF tendon is elevated out of the incision (see Figure 90-62, *B*). During this part of the procedure, an assistant should lift the limb off the ground to relieve the tension on the DDF tendon. Care must be taken to avoid elevating the neurovascular bundle located medially to prevent its inadvertent transection together with the tendon. The elevated tendon is subsequently transected with the scalpel blade. An immediate separation of the ends of 1 to 3 cm is usually noted after complete transection of the tendon.

An alternative tenotomy technique involves the blind transection of the DDF tendon with the help of a blunt bistoury while the animal is weight bearing.[117] Concomitant transection of the medially located neurovascular bundle can occur with this technique.

The subcutaneous tissue is closed with an absorbable monofilament suture material in a simple-continuous pattern. The skin is closed with stainless steel staples.

PASTERN APPROACH

DDF tenotomy is performed with the horse in lateral recumbency under general anesthesia.[118] A 3-cm vertical skin incision is made along the palmar midline of the pastern region, 1 cm proximal to the bulb of the heel (Figure 90-63, *A*). The skin, subcutaneous tissue, and sheath of the DDF tendon are incised, and the DDF tendon is exposed, elevated, and transected (see Figure 90-63, *B* and *C*). The amount of separation of the tendon ends is greater after tenotomy at this level (6 to 10 cm) because there are no attachments to the distal tendon other than the insertion site to the distal phalanx.[117] Closure of the tendon sheath, subcutaneous tissue, and skin is routine.

Postoperative Management

Bandages should be maintained for a minimum of 6 weeks to minimize swelling and prevent contamination of the surgery site. The horse is administered phenylbutazone for pain as needed and confined to the stall, wearing a heel extension shoe for 6 to 8 weeks. For midmetacarpal tenotomy, this type of shoe seems to be less necessary.[116]

A mild degree of hyperextension of the DIP joint occurs, but it is usually self-limiting.[113] Most horses show an initial improvement within 2 to 3 days of surgery. After tenotomy in either location, flexor support for the distal phalanx should develop through attachments of the distal tendon end by 6 to 8 weeks after surgery, and maintenance of a normal hoof–pastern axis without extended heels should be possible.[118] Tension relief after tenotomy appears to last for several months.[117]

Complications directly related to the surgery are rare but can include incision infection and postoperative pain. Chronic pain can result from overloading the SDF tendon before healing, osteoarthritis of the DIP joint, or chronic infection of the digit.[117] A flexural deformity of the metacarpophalangeal joint (dorsiflexion) can develop from chronic pain, resulting in an inability to bear weight on the limb and contracture of scar tissue at the tenotomy site.

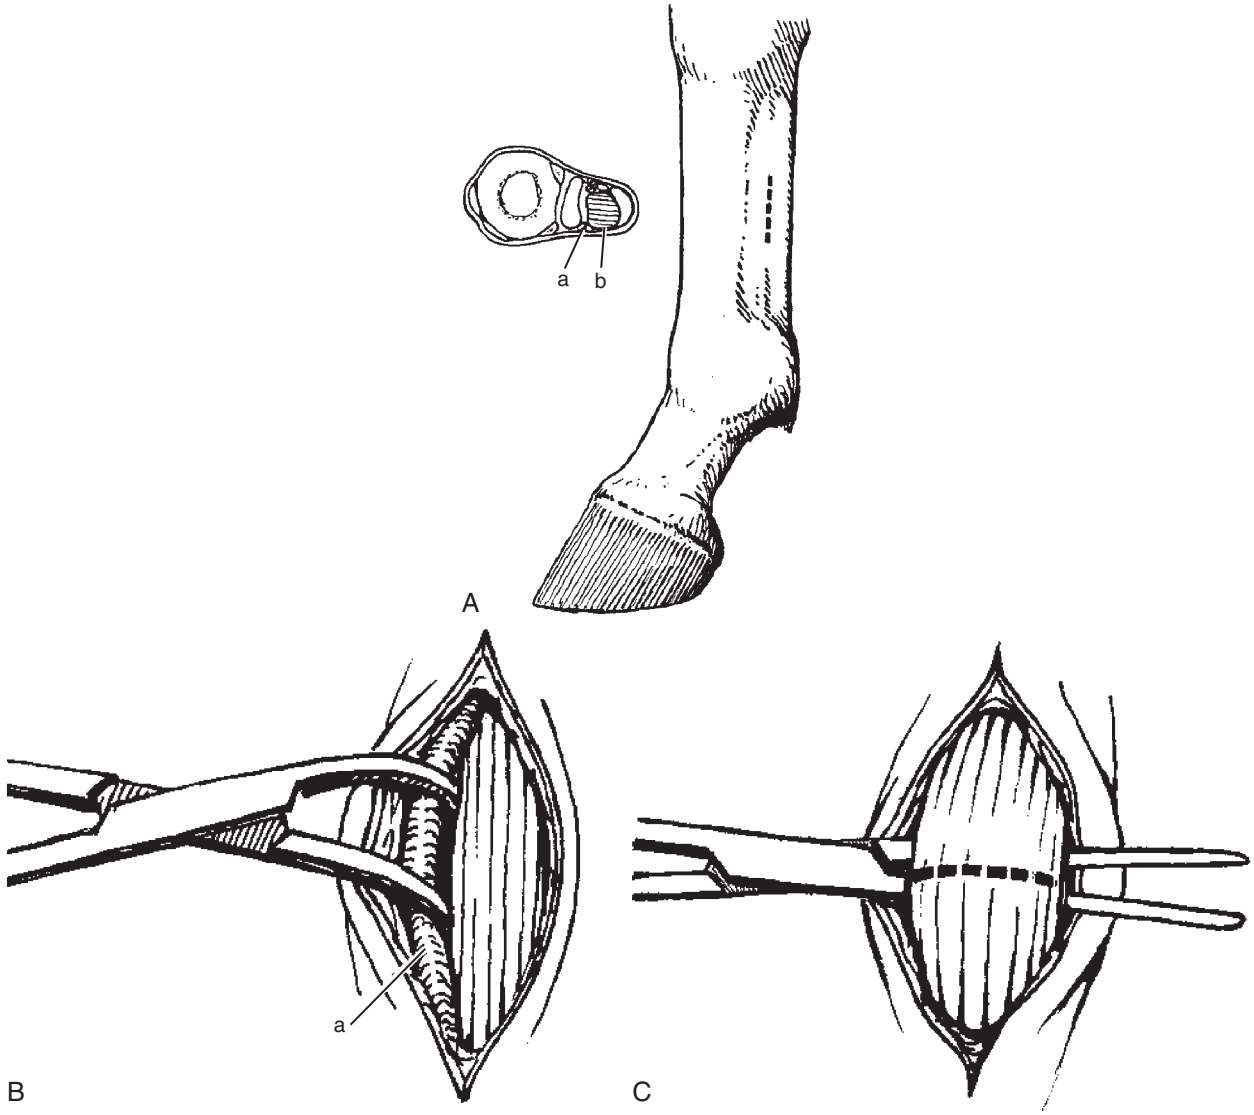

Figure 90-62. Graphic illustration of the deep digital flexor tenotomy in the mid-metacarpal region. **A,** Location of the surgical site on the lateral aspect of the limb. **B,** The deep digital flexor tendon is separated from the neurovascular bundle. **C,** The isolated deep digital flexor tendon is elevated above the incision and transected. *a,* Neurovascular bundle; *b,* deep digital flexor tendon.

Prognosis

In a study of 13 horses with chronic laminitis and 12 to 36 degrees of rotation of the distal phalanx from the dorsal hoof wall, the first clinical improvement was noted by the third or fourth day after midpastern tenotomy of the DDF tendon.[118] At the end of 2 weeks after surgery, the horses continued to improve and were willing to walk without the benefit of nerve blocks. Eventually, five horses could be lightly ridden, seven horses were pasture sound, and one horse was euthanized.[118] In another report of DDF tendon transection at the midmetacarpal level in 20 horses with severe acute or chronic laminitis unresponsive to conventional treatment, 11 patients survived less than 1 month after surgery, and six horses survived longer than 6 months. Three horses remained lame, and no horse returned to athletic performance.[119]

One study evaluating the effect of DDF tenotomy as a treatment for chronic laminitis in 35 horses (midmetacarpal, 30 horses; midpastern, 5 horses) found that 27 horses (77%) were alive 6 months after surgery, and 19 of 32 (59%) horses were alive for at least 2 years.[120] Body weight at the time of surgery and the degree of distal phalangeal rotation had no effect on the 2-year survival. Of the horses in this study, 10 became sound enough for light riding, and there was no correlation between the Obel grade of lameness, the degree of rotation, and the ability to be ridden.[119]

Another study evaluating the effect of DDF tenotomy in the midcarpal region of nine horses with severe laminitis associated with complications, such as intense pain, rotation more than 15 degrees, perforation of the sole, or evidence of infection of the sole or distal phalanx found an initial survival rate of 100%.[121] Six of the nine horses survived more than 21 months, and the other three were convalescing at the time the report was published. Four of the nine horses could be used for pleasure riding.

Although the recent studies report surprisingly good results, it should not be forgotten that these horses require prolonged

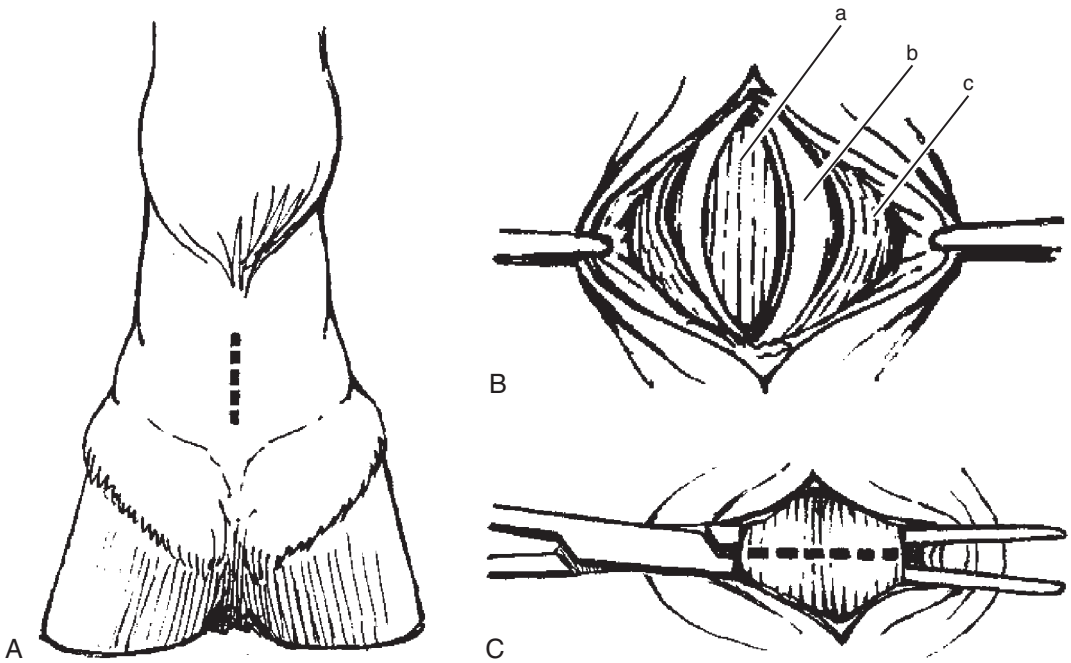

Figure 90-63. Graphic illustration of the deep digital flexor tenotomy in the mid-pastern region. **A,** Location of the surgical site. **B,** The skin, subcutaneous tissues *(c),* and tendon sheath *(b)* are sharply transected. **C,** The deep digital flexor tendon *(a)* is elevated above the incision and sharply transected.

and expensive supportive care and often additional surgical interventions. They suffer months of crippling foot pain and recumbency, and everyone involved must be dedicated to the patient.

CHAPTER
91

Phalanges and the Metacarpophalangeal and Metatarsophalangeal Joints

Alan J. Nixon

MIDDLE PHALANX

Anatomy

The middle phalanx is a relatively compact bone that is loaded predominantly in axial and torsional planes during athletic activity. It articulates with the distal phalanx through a high-motion joint and proximally with the proximal phalanx through a relatively low-motion joint. The middle phalanx is enclosed distally within the confines of the hoof and coronary band, but it is more exposed proximally, particularly over the palmar and plantar eminences.

The middle phalanx is bounded by multiple ligaments and tendons. The common (or long) digital extensor tendons dorsally and the digital flexor tendons palmarly (or plantarly) contribute to motion of the proximal and distal interphalangeal (PIP and DIP) joints and provide resistance to overextension of the distal limb. In addition, the middle phalanx is stabilized by strong lateral and medial collateral ligaments of the proximal and distal interphalangeal joints and the suspensory ligament of the distal sesamoid bone. Additional perimeter support to the distal aspect of the middle phalanx is derived from the surrounding hoof capsule.

Etiology of Fractures

Fractures of the middle phalanx are most common in Quarter Horses and Arabians but occur in all breeds.[1-3] Horses that turn predominantly on their hindlimbs, such as cutting and reining horses, incur comminuted fractures of the middle phalanx almost exclusively in the hindlimbs. More than 70% of middle phalanx fractures in one report involved the hindlimb.[1] Similarly, distraction fractures of the plantar eminences occur primarily in the hindlimbs because of the forces incurred during sudden stops and turns, most likely as an avulsion of the bony insertion of the superficial digital flexor (SDF) tendons.

Clinical Signs and Diagnosis

Lameness is acute and severe. Comminuted fractures generally result in non–weight-bearing-lameness and attempts to bear weight often result in hyperextension of the digits and sinking of the metacarpophalangeal (MCP) joint. More inherently stable fractures, such as palmar/plantar process fractures, and axial fractures improve within 24 hours and allow weight bearing. Diagnosis is confirmed by radiographic examination. Computed tomography (CT) is often used to better define fracture planes in comminuted fractures.

Fracture Configurations

Middle phalangeal fractures are classified as simple or comminuted and fall into one of four categories: 1) dorsal or palmar/plantar intra-articular osteochondral chip fractures, 2) palmar or plantar eminence fractures, 3) axial fractures, or 4) comminuted fractures.[1]

Osteochondral Fractures

Dorsal or palmar/plantar osteochondral fractures are rare.[2-5] Most osteochondral fractures occur on the palmar or plantar aspect of the middle phalanx, either immediately lateral or medial to the axial midline (Figure 91-1). These fractures do not involve the insertion of the SDF tendon or distal sesamoidean ligaments and therefore do not distract. The fragments do tend to grow *in situ*, which increases the likelihood of lameness. Despite the size and intra-articular location of these fragments, development of osteoarthritis is relatively slow. Nevertheless, they have been reported as a cause of lameness, and surgical removal is recommended if a lameness examination confirms the mid-phalangeal region as the site of pain. They can be incidental findings.

Surgical removal of palmar or plantar fragments using arthroscopy is recommended,[6] although open approaches through the digital sheath are described. The arthroscopic portal is made into the proximal aspect of the voluminous palmar pouch of the PIP joint (Figure 91-2). Access for instruments is provided by a second portal 2 cm distad to the arthroscope, and often an additional portal on the contralateral side of the palmar region of the pastern, especially when removing large

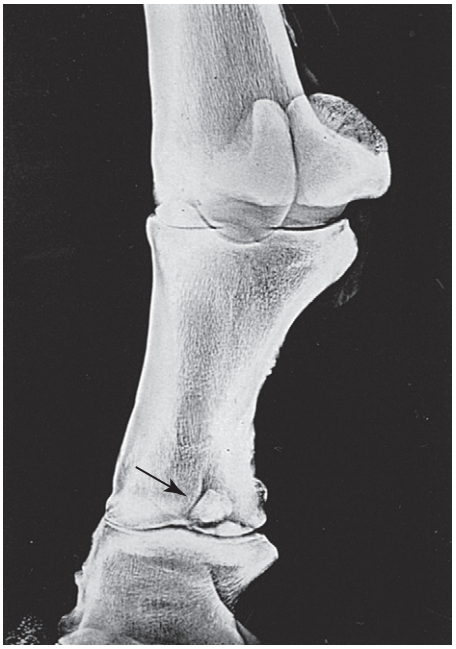

Figure 91-1. Oblique radiographic view of a plantar osteochondral fracture of the proximal margin of the middle phalanx *(arrow)*. Arthroscopic access can be used to remove the fragments that cause lameness.

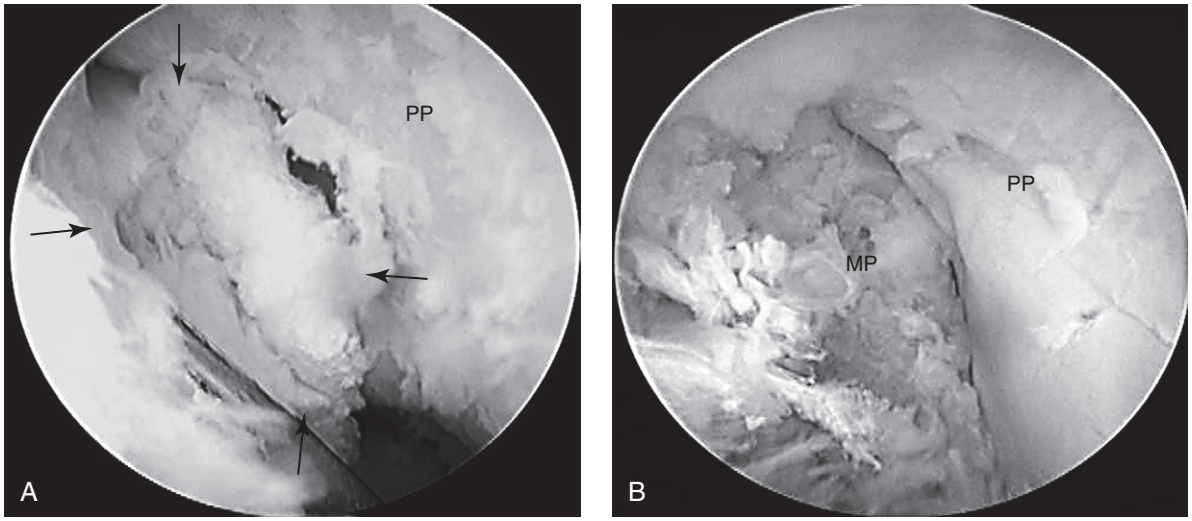

Figure 91-2. A, Arthroscopic appearance of a middle phalangeal palmar fragment *(arrows).* Rongeurs have been introduced through an ipsilateral portal adjacent to the palmar condylar surface of the proximal phalanx (PP). **B,** After removal of the fracture fragment, the fracture bed on the proximal aspect of the middle phalanx (MP) is evident.

palmar fragments. Fragment dissection and removal can be difficult. Fragments located more abaxial to the midline are obscured by the middle scutum and may need removal by open approaches.

Dorsal fragments also can be removed arthroscopically with an approach over the dorsal joint pouch.[5,7] Most fragments develop lateral or medial to the midline and tend to be small and in close proximity to the dorsal rim of the middle phalanx (Figure 91-3). Limited maneuverability results from the attachment of the extensor tendon immediately distal to the joint. Arthroscope entry is usually abaxial to the extensor tendon. Instrument access is adjacent to the fragment, and careful dissection is required in the tight dorsal recess of the PIP joint.

The prognosis after surgical removal of dorsal and palmar fragments is favorable, unless the fragmentation is associated with early joint degeneration, which can develop relatively quickly after the initial chip fracture.

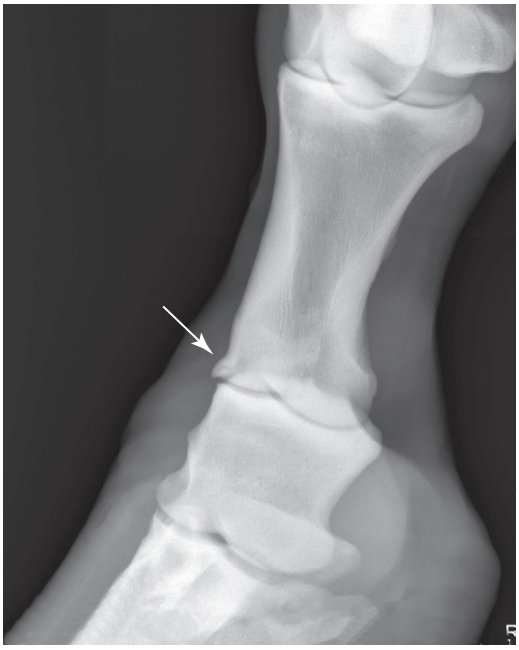

Figure 91-3. Oblique radiographic view of a dorsal osteochondral fragment in the PIP joint *(arrow).*

Palmar or Plantar Eminence Fractures

Fractures of the palmar or plantar eminence of the middle phalanx can be uniaxial or biaxial.[3] The treatment and prognosis vary considerably depending on this configuration. These fractures result from hyperextension of the pastern joint, with tension on the palmar or plantar attachments of the SDF tendon, or the palmar/plantar middle scutum and distal sesamoidean ligaments. Uniaxial fracture does not result in pastern subluxation or the considerable lameness associated with biaxial fracture. Occasionally, fracture fragments do not involve the entire eminence. Rarely, the palmar soft-tissue structures are disrupted without fracture of the bony insertion (Figure 91-4).[8] Radiographs verify the type and extent of the fracture.

UNIAXIAL FRACTURES OF THE PALMER OR PLANTAR EMINENCES

Uniaxial palmar or plantar eminence fractures (Figure 91-5, *A*) can be treated with selective screw fixation or pastern arthrodesis, depending on the duration and configuration of the fracture.[9] Screw fixation in lag fashion can be performed through stab incisions over the proximal extremity of the fractured eminence, with the screws inserted under radiographic control (see Figure 91-5, *B* and *C*).

Fracture reduction can be difficult depending on the duration of the fracture. The interfragmentary screw is inserted in a distal axial direction, with the primary access to the eminence gained by splitting the insertion of the SDF tendon longitudinally. A delay in presentation or the presence of biaxial palmar eminence fractures necessitates pastern arthrodesis. Even with stable articulations and uniaxial eminence fracture, arthrodesis can be preferable and is best performed using a combination of plates and screws (see Chapter 81).[10-13] Cortex screws that are 5.5 mm in diameter provide more rigid fixation than 4.5-mm screws. bone graft is not usually necessary, although forage of the subchondral bone of the proximal and the middle phalanx is used to promote vascular invasion and access to bone-forming cells.

A postoperative cast is usually maintained for 10 days to 2 weeks. The prognosis after arthrodesis for uniaxial fractures is fair to favorable.[1,11,14] The outlook for return to active work is improved with fractures of hindlimb versus forelimb eminences. Recuperative periods of up to 12 months are required, which can be shortened by the use of plate fixation for pastern arthrodesis.

BIAXIAL FRACTURES OF THE PALMER OR PLANTAR EMINENCES

Biaxial fractures of the palmar or plantar eminences result in considerable lameness and instability of the PIP joint. Pastern arthrodesis is preferred by dorsal application of a locking compression plate (LCP) or, if one is not available, a dynamic compression plate (DCP) application.[15,16] Plate configurations include a single broad LCP or two narrow LCPs placed on the dorsal aspect of the proximal and middle phalanges.[14,17] The palmar or plantar eminence fractures are stabilized by screw fixation placed in lag fashion through the distal plate screw holes. This will require additionally bending an LCP if it is used in this repair. If space is available (in larger fragments), individual interfragmentary screws unassociated with the plate should be added to strengthen the repair. Pastern arthrodesis by plate fixation without attempted perfect reduction of the individual eminence fractures is satisfactory; however, callus production and induced secondary lameness are minimized if the eminence fragments can be incorporated into the repair.

Prognosis after biaxial eminence fracture repair by arthrodesis is fair, particularly for fractures involving the hindlimbs.[1,11] For additional information on pastern arthrodesis, see Chapter 81.

Axial Fractures

Simple axial fractures of the middle phalanx occur rarely (Figure 91-6). These fractures can be repaired with cortex screws applied in lag fashion. The fracture configuration dictates the approach. Adequate reduction is confirmed radiographically before placement of the first screw. Cast fixation during the initial 4 postoperative weeks is important. The prognosis for soundness is guarded because some proliferative new bone formation, especially at the articular margins, is expected as a result of the initial trauma.

Comminuted Middle Phalanx Fractures

Comminuted fractures are the most common configuration encountered in the middle phalanx.[1,3] Clinical appearance includes severe non–weight-bearing lameness with palpable instability and, occasionally, crepitus of the distal limb. The configuration of the fracture is confirmed with radiography, and the treatment is selected based on the extent of the fracture and possibility of adequate repair. The initial and most important decision to be made is whether to pursue treatment or elect euthanasia. Treatment options include screw fixation in lag fashion of minimally comminuted fractures, application of a single broad LCP or DCP with additional screws, use of two narrow LCPs or DCPs for fracture fixation and pastern arthrodesis, or application of strategic cortex screws applied in lag fashion in combination with a transfixation cast.

An extensive series of preoperative radiographs is required to establish the extent of comminution. Most comminuted fractures involve proximal portions of the phalanx, and many extend into the DIP joint, reducing the prognosis. A CT scan is particularly helpful in defining multiple fracture planes entering

the DIP joint. Most are more complex than suggested by plain radiographs.

The aim of surgical repair is reconstruction of the distal, and to some extent the proximal, articular surfaces of the middle phalanx. If reconstruction of the DIP joint is inadequate or the bone is severely comminuted and unlikely to be adequately repaired with a plate and screws, humane destruction should be considered.

The most frequent configuration of comminuted fractures involves fractures in both a sagittal and frontal (transverse) plane, often with added comminution on the palmar or plantar proximal aspect. Marked instability because of connection of the attachments of the palmar or plantar ligaments and tendinous structures is common. Rarely, the distal sesamoid bone is also fractured. Treatment for most comminuted middle phalanx fractures involves application of two narrow LCPs or DCPs, although use of a single broad DCP and a T-plate have been described.[1,3,15,16] The use of a T-plate is discouraged because of the biomechanical weakness of this thin plate combined with the fact that the plates are applied on the compression side of the phalanges. Use of LCPs for comminuted fractures tends to limit screw insertion angle when using a locking screw in the distal plate hole, and DCPs are often preferred. However, the LCP can be used with cortex screws only, where it will act as a limited-contact DCP (LC-DCP).

Plate fixation in combination with independent screws placed in lag fashion to achieve pastern arthrodesis optimizes the chances for adequate reconstruction of the distal articular surface of the middle phalanx. This region is poorly visualized at surgery and accurate reconstruction, to avoid later osteoarthritis of the DIP joint, relies on precise alignment of the proximal portion and fixation as far distally as practically possible. An extensive dorsal approach to the proximal and middle phalanx is used. The application of two narrow LCPs or DCPs allows greater versatility in screw placement than a single plate.

The proximal articular surface of the middle phalanx is exposed to allow initial reduction and stabilization of the palmar or plantar portions of the fracture to the dorsal struts of bone.[3] The sagittal fractures are reduced later with individual screws inserted in lag fashion. Intraoperative radiographs or fluoroscopy ensure reconstruction of the articular surface within the DIP joint. Three-dimensional fluoroscopy and portable CT units provide a more precise method to assess alignment, and they may be used during reduction and fixation to assess screw trajectory and fracture reduction.

The cartilage of the PIP joint is removed, and the plate screws in the proximal phalanx are inserted. If possible, one or two plate screws should be placed transarticularly. Postoperative cast fixation for 4 to 8 weeks is used, particularly where fracture stability is tenuous. Follow-up radiographs at the time of cast removal dictate the period of stall confinement, which is generally an additional 6 to 12 weeks. Postfixation callus development can be extensive, depending on the extent of fracture line reduction and rigidity of the stabilization. The union of the proximal and middle phalanges usually progresses quickly. The most common cause of persisting lameness is osteoarthritis of the DIP joint.

Repair of severely comminuted fractures with cast or transfixation cast techniques is reserved for fractures that cannot be adequately reduced and stabilized by implants and when humane destruction is not an option for the owner. Fractures entering the DIP joint usually result in some osteoarthritis, and the degree of residual lameness varies accordingly. The prognosis is partly determined by the development of weight-bearing laminitis on the opposite limb. The selection of fixation should provide the earliest return of comfortable weight bearing on the fracture to minimize this complication.

Complete resolution of lameness with implant fixation can occur; however, residual lameness is anticipated if there is inadequate reduction of the fracture fragments entering the DIP joint.[1,3,15-17] Concurrent fractures of the distal sesamoid bone reduce the prognosis further. The vascular supply to the distal limb and the soft tissue integrity can occasionally be compromised through the initial fracture or during attempts at repair. Preoperative immobilization in a supporting splint is important for the long-term outcome of these cases (see Chapter 73). Infection can also be a serious complication, and local and systemic antibiotics are used to minimize bacterial growth.

PROXIMAL INTERPHALANGEAL JOINT

Osteoarthritis

Osteoarthritis of the PIP joint (high ringbone) is a relatively common condition affecting multiple breeds, particularly those with a tendency for short upright pastern conformation. In addition, horses that make quick stops and hard turns with rapid twisting, such as Western performance horses and show jumpers, have a high incidence of pastern osteoarthritis. In young horses, there is also the possibility of arthritic change induced by osteochondrosis (OC).[18]

Osteoarthritis can occur in the PIP joints of the forelimbs and hindlimbs and often results in grade II to III/IV lameness. Palpable enlargements of the PIP joints are a feature after the development of periarticular new bone. Confirmation of the PIP joint as a site of lameness usually requires perineural anesthesia and radiographs to confirm the involvement of the joint. Nonarticular new bone production can be misdiagnosed clinically as true intra-articular osteoarthritic change and should be assessed with radiography before any discussion of surgical therapy. Pain on manipulation of the PIP region is occasionally elicited, and the horse can have a positive response to flexion tests of the distal limb. Heat and swelling over the PIP joint are indicators of pastern arthritis. The lameness is usually chronic and exacerbated by increased work. Radiographic evidence of osteoarthritis can be confined to one limb but occasionally occurs in both, if the problem is conformational in origin.

Treatment of true intra-articular PIP osteoarthritis is usually surgical fusion of the involved joint.[11,14] The response to intra-articular medication with corticosteroid preparations is usually short term. Horses improve considerably with phenylbutazone therapy. Recalcitrant lameness is treated with surgical fusion of the PIP joint. For simple arthritic conditions, this can be accomplished by dorsal exposure of the affected joint, removal of articular cartilage, and application of two 5.5-mm cortex screws in lag fashion to provide transarticular compression, as previously described (see also Chapter 81). Additionally, a three-hole LCP or DCP is applied to the dorsal midline of the two phalanges involved. The use of the LCP in combination with two abaxial 5.5-mm lag screws has been shown to be as strong as the 4.5-mm DCP applied with two adjacent 5.5-mm screws.[19] However, better *in vivo* performance of the LCP could be anticipated based on other studies of the cycles to failure of the locked screw design. Further, the single 4.5-mm DCP and two abaxial 5.5-mm screws have been shown to be biomechanically

superior to the three 5.5-mm lag screw arthrodesis technique.[20] For horses more than 500 kg, application of two LCPs or DCPs is preferred for additional fixation, using the distal screw in each to engage the palmar/plantar process of the middle phalanx and the second most distal plate screw to lag obliquely across the PIP joint and engage the more axial regions of the middle phalanx (see Figure 91-4). Postoperative cast fixation is needed for up to 2 weeks after arthrodesis. Cast bandage combinations may be substituted for the cast in the second week of the 2-week coaptation period and may be continued for an additional 4 weeks.

Minimally invasive techniques for arthrodesis of the PIP joint have been described, using percutaneous insertion of two LCPs and independent stab wounds for plate screw insertion.[12] Additionally in cases with advanced osteoarthritis, laser facilitated cartilage débridement of the PIP joint, and application of three 5.5-mm parallel lag screws through stab incisions, reduces surgical exposure and time, minimizes the need for postoperative casts, and provides early pain relief.[21] Two 5.5-mm screws may be adequate depending on the horse's size, given *in vitro* studies that show similar biomechanical performance of two and three 5.5-mm lag screw configurations for PIP arthrodesis.[22] Laser-facilitated arthrodesis is not suitable for horses with extensive residual cartilage in the arthritic PIP joint, which develop instability and extensive callus as the cartilage undergoes necrosis and reduces the initial compression provided by the screws. Use of ethyl alcohol for eliminating cartilage before applying compression with the screws as an alternative to laser-facilitated arthrodesis has also been described.[23]

Application of LCPs by percutaneous insertion, in combination with multiple passes of a 4.5-mm or 5.5-mm drill to remove residual cartilage, is a better choice for less-advanced osteoarthritis. Physical removal of cartilage may provide improved bone-to-bone contact, but more importantly, two LCPs enhace the rigidity of the repair and minimize postoperative callus formation. Additionally, contouring of the LCPs is lessened because direct cortical contact of the plate is not a prerequisite, allowing flexibility in plate positioning. For large horses, insertion of an independent 5.5-mm screw across the PIP joint in lag fashion, or angling the second plate screw across the PIP joint by using a 4.5-mm or 5.5-mm cortex screw inserted using lag technique, provides three or four stabilizing screws in the middle phalanx. Minimally invasive collateral ligament sparing techniques also allow considerable PIP cartilage to be removed by multiple passes of a 4.5-mm or 5.5-mm drill bit and provide better acute resistance to lateral bending in cadaver specimens.[24]

The rate at which bone union is achieved depends on the degree of stability afforded by internal stabilization. Most horses continue to form periarticular callus for 6 months after surgical repair. Unstable repairs result in exuberant callus, which can interfere with the action of the flexor tendons on the palmar or plantar surface of the pastern and occasionally with the extensor tendons over the dorsal middle phalanx region. Digital extensor tendons can adhere to exostoses on the dorsal aspect of the middle phalanx,pulling on the insertion to the extensor process of the distal phalanx, resulting in residual lameness.[11,25] Excessively long screws that penetrate the palmar or plantar surface of the middle phalanx and interfere with the action of the distal sesamoid bone are also causes of residual lameness.

The prognosis for riding soundness is fair to favorable, particularly for conditions involving the hind limb. The outcome in one report indicated 16 of 22 horses returned to full function.[10] A second study indicated 16 of 21 clinical cases became sound after arthrodesis, with a better response in the hind limbs.[11]

Figure 91-7. Subchondral cystic lesion of the distal aspect of the proximal phalanx. If conservative therapy fails, transcortical approaches either laterally or through the palmar cortex allow access to the cyst.

Osteochondritis Dissecans and Subchondral Cystic Lesions

Osteochondritis dissecans (OCD) can occasionally develop in the PIP joint. Subchondral cystic lesions (SCLs) are diagnosed more often than dissecting cartilage flap lesions and involve the distal articular surface of the proximal phalanx (Figure 91-7), or rarely the proximal articular surface of the middle phalanx. Late stages of OCD with secondary osteoarthritis have been diagnosed in young horses unilaterally and bilaterally. Solitary SCLs are readily apparent on radiographs, whereas multiple SCLs are associated with a persistent lameness leading eventually to osteoarthritis.

Intra-articular hyaluronan injections provide temporary pain relief in solitary SCLs. Surgical curettage of solitary SCLs of the proximal phalanx has been performed in five horses (three foals and two adults).[26] Because the lesion is often not approachable arthroscopically, transosseous drilling is used. Initially, a small drill bit is advanced under fluoroscopic control into the cyst, which is confirmed by the drainage of saline previously injected into the PIP joint. Proper alignment of the drill is verified radiographically, and the drill hole is enlarged with a 5.5-mm drill bit, allowing access with a curette to evacuate the cyst. After copious flushing from the joint, the cyst and drill hole are filled with tricalcium phosphate granules.[26] Long-term follow-up revealed that four of the five horses treated were serviceable and could engage in their intended athletic function. More recently, a similar cyst has been successfully packed with fibrous gel containing $PTH_{1\text{-}34}$.[27] Additional information about these treatments is found in Chapter 89.

Multiple cystic lesions show a poor response to medical treatment, leaving elective arthrodesis of the joint as the only

Figure 91-8. Lateromedial radiographic view of a dorsal subluxation of the proximal interphalangeal joint caused by loss of support from the extensor branches of the suspensory ligament. Note the distal location of the proximal sesamoid bones as a result of failure of the suspensory ligament.

treatment (see Chapter 81). Simultaneous bilateral arthrodesis can be performed in foals, whereas staged fusion is elected in adult horses.

Luxation and Subluxation

Luxation and subluxation of the PIP joint are usually treated with arthrodesis. Subluxation is more common and occurs in either a dorsal or a palmar direction. Dorsal subluxation is the result of damage to the suspensory ligament and its terminal extensor branches (Figure 91-8); it is occasionally caused by contracture of the distal sesamoidean ligaments. Palmar subluxation results from failure of the palmar supporting connective tissues such as the distal sesamoidean ligaments, the middle scutum, and the SDF tendon insertions (see Figure 91-4). This condition is manifest by marked hyperextension of the PIP joint and considerable swelling associated with the soft tissue disruption.

The clinical signs associated with dorsal and palmar subluxation include acute lameness initially, with the dorsal subluxations resulting in an obvious dorsal swelling over the PIP joint. Palmar subluxation, because of disruption of the support structures, usually results in hyperextension of the pastern and sinking of the MCP joint. Radiographic examination is used to confirm the diagnosis of subluxation and to differentiate lesions associated with osteoarthritis or bony disruption of the middle phalanx. The lameness associated with PIP joint subluxation is less severe than that associated with fracture disruption.

Dorsal subluxation occurs bilaterally in the hind limbs of some horses with upright conformation. When this occurs, it can be managed with anti-inflammatory medication and a controlled exercise program. As the horse gains condition, the subluxations often resolve.

Pastern arthrodesis is used to treat recalcitrant dorsal and palmar subluxations. Surgical arthrodesis is performed using either the slightly diverging three lag screw technique or, preferably, the application of a single bone plate or a pair of bone plates (see Figure 91-4), as previously described for larger horses. Some acquired dorsal subluxations are caused by excessive tension in the deep digital flexor (DDF) tendon, and successful resolution in three hindlimb cases resulted from release of the medial head of the DDF tendon.[28]

The prognosis after repair of subluxation is fair to favorable. With adequate surgical reduction and stabilization of the subluxation, the pastern can be fused without excessive callus formation. Few cases are described in the equine literature that provide information on long-term follow-up, but horses can return to athletic activity, particularly if a hindlimb is involved. Rarely, bilateral subluxations develop, and a staged pastern arthrodesis can provide a return to soundness.

PROXIMAL PHALANX

Clinical Signs and Diagnosis

Comminuted fractures of the proximal phalanx result in severe lameness, whereas stable sagittal or intraarticular dorsal and palmar/plantar fractures improve rapidly to mild or moderate weight-bearing lameness. The clinical diagnosis is confirmed by radiography. Additional information on complex fracture configuration can often be derived from CT evaluation.

Fracture Configurations

Fractures of the proximal phalanx can be divided into two categories: 1) proximal intra-articular osteochondral fractures and 2) fractures involving the shaft or diaphyseal region of the proximal phalanx. The cause of most of these fractures is trauma, with hyperextension being particularly important for osteochondral fractures, and torsion with axial weight bearing being more important for fractures of the shaft of the proximal phalanx.

Proximal Osteochondral Fractures

PROXIMODORSAL OSTEOCHONDRAL FRACTURES

Osteochondral fractures of the proximal dorsal margin of the proximal phalanx within the MCP joint are common in racehorses.[29-31] They also frequently occur in non-racing breeds.[32] They arise from hyperextension of the MCP joint with impact of the proximal and dorsal aspect of the proximal phalanx onto the dorsal region of the third metacarpal bone (MCIII). Proximodorsal fragments in immature horses have been described as OC, but it is uncommon to find histologic evidence to support these claims.[33] Initial clinical symptoms include several days of moderate lameness associated with obvious synovial effusion and pain on flexion of the affected joint. Depending on the size of the fragment, lameness dissipates quickly. Radiography with four views, including horizontal beam oblique views, demonstrates the lesion adequately. The most prevalent site for proximodorsal fragments is the dorsomedial eminence of the proximal phalanx. Occasionally, both lateral and medial eminences of the phalanx are involved.

The treatment of choice is surgical removal using arthroscopy.[7,30,31] However, small chip fractures (less than 2 mm in diameter) can be rapidly covered by synovial tissues, and many heal without causing clinical symptoms. Moderate to large dorsal fragments should be removed to prevent synovitis, cartilage degeneration, and chronic proliferative (villonodular) synovitis mass development. Large chip fractures result in erosion of the opposing metacarpal condyle and often result in persistent lameness.

The arthroscope is placed into the joint just proximal to the middle of the visibly distended dorsal joint pouch, adjacent to the extensor tendon, because this facilitates examination of both lateral and medial portions of the joint without damage to the dorsal aspect of the sagittal ridge. A second entry portal is then made for instrument entry and fragment retrieval.

Postoperative convalescence includes 6 to 12 weeks' rest from training, depending on the damage to the third metacarpal cartilage. Results of arthroscopic surgery for the treatment of osteochondral fractures of the proximal phalanx in 336 horses revealed a return-to-use rate of 86% for racehorses.[29] Additionally, 68% of horses returned at the same or higher level of racing performance. Removal of osteochondral fractures also may be useful even when moderate levels of osteoarthritis are present. Seventy-five percent of horses with other MCP lesions, including arthritis, were able to return to previous use. Other studies indicate similar excellent results after chip fracture removal, with 89% of 461 Thoroughbreds returning to racing, and 82% racing at a similar or better class.[31]

Figure 91-9. Elevated oblique radiographic projection (D15Pr20L-PlDiMO) of the rear MTP region of a Standardbred pacer with a type I (axial) osteochondral fracture *(arrow)* in the plantar pouch. These fragments need to be differentiated from type II fractures on the abaxial corner of the proximal phalanx, many of which do not need surgery.

PROXIMOPALMAR AND PROXIMOPLANTAR OSTEOCHONDRAL FRACTURES

Bone fragments associated with the plantar or palmar portions of the proximal phalanx within the metatarsophalangeal (MTP) or MCP joint have been recognized for many years.[34,35] The cause of fragmentation is controversial; one suggestion being that they are OCD lesions. Recent data support a fracture etiology.[33,36]

The osteochondral fragments have been categorized as *type I fractures* when they are avulsed from the axial, proximal, plantar or palmar rim of the proximal phalanx and are mostly articular. Most have extensive regions of short sesamoidean ligament insertion still attached to the avulsed fragment. Larger, abaxially located, partly articular osteochondral fragments have been categorized as *type II fractures*. Type II fractures extend distad 2 to 3 cm and contain minimal articular cartilage. Lameness associated with type I fractures is minimal and usually only evident at higher speeds.[37,38] Type II fractures do not appear to produce persistent lameness.

Affected MTP or MCP joints often exhibit synovial effusion, moderate pain on flexion, and a mild to moderate response to flexion tests. Intra-articular anesthesia is often required to confirm the diagnosis. The fragments are less common in the forelimb, possibly as a result of a more angled shape to the equine palmar aspect of the proximal phalanx compared with the plantar counterpart. Fragments have occurred in weanlings and yearlings, presumably the result of hyperextension of the MCP or MTP region with avulsion of one or both short sesamoidean ligament insertions, but at this age it has been common to consider them a form of OCD.[37,39] Because most occur in younger animals, they are often covered by synovial tissue at the time of surgical removal. They are most prevalent in Standardbreds; in surveys, 11.8% of all Standardbred yearlings in Norway and 28.8% of yearlings in Sweden were affected.[40,41] In Warmblood horses, these lesions are often overlooked until they are diagnosed in 3- to 6-year-olds, when the training level for show jumping is increased.

Radiography is used to confirm the diagnosis. Routine oblique views are not particularly satisfactory for delineating type I fractures. A better projection results from raising the radiographic beam 20 degrees above horizontal and taking the oblique projections only 15 to 20 degrees dorsal to a standard lateromedial projection (Figure 91-9).[42] These projections, the proximo(20)dorso(15)lateral—distal palmaromedial or the opposite view, the proximo(20)dorso(15)medial—distal palmarolateral projection, highlight the plantar rim of the phalanx and the associated base of the proximal sesamoid bone. These projections allow differentiation of type I axial fractures from the type II abaxial fractures (nonunited proximal plantar tuberosity of the proximal phalanx).[43,44] Type II fractures are quite evident on standard oblique radiographs. Both types of fragments are common in the MTP joints.

Type I plantar fracture fragments are often removed in yearlings to prevent the development of lameness during training and racing. Lameness in yearlings is rare, and the prediction of later lameness induced by these plantar fragments is difficult. An arthroscopic approach through the plantar pouch of the MTP joint provides access to the intra-articular type I fractures.[7,38] The instrument portal is prepared at the base of the proximal sesamoid bone; the exact location of the portal is identified with a hypodermic needle. The fragments are dissected from the covering of synovial membrane and remnants of the attached short sesamoidean ligaments and removed with sturdy rongeurs. The use of motorized resectors, radio-frequency cutting loupes, or diode or CO_2 laser for removing excessive soft

tissue proliferations and resection of the fragment reduces intraoperative bleeding and improves visualization.[38,45]

Surgery is rarely indicated for type II abaxial osteochondral fractures. Additionally the incidence of these fragments is lower (2.4% of 753 Standardbred yearlings), and they might not be fractures but rather constitute a form of delayed ossification.[44] Lesions in 11 of 18 horses had radiographically united to the parent proximal phalanx after 12 months. Occasionally nonhealing abaxial "fractures" and true traumatic fractures with fresh margins and associated lameness require screw fixation in lag fashion to achieve radiographic union. This type of fixation is only warranted when lameness is present, and simple absence of progressive bony fusion is not a reason for surgical fixation.

Convalescent care for type I fracture patients includes 6 to 12 weeks' rest from training, depending on the damage to the distal sesamoidean ligaments at the time of surgery. In a review of 119 surgery cases, follow-up race performance information was available on 87.[38] Fifty-five horses (63%) returned to racing at or above their preoperative level. Abnormal arthroscopic findings, including articular cartilage loss over the palmar condyles and extensive synovial proliferation, had a negative impact on successful outcome.

DORSAL FRONTAL FRACTURES OF THE PROXIMAL PHALANX

Dorsal frontal fractures entering the MCP or MTP joints are relatively rare; in a case series, they represented only 9 of 123 (7%) fractures involving the shaft of the proximal phalanx.[46] These fractures occur predominantly in Thoroughbreds and are prevalent in the hindlimbs. Dorsal frontal fractures tend to be short, extending from the articular surface 2 to 5 cm distad in the dorsolateral cortex of the proximal phalanx. Fractures are generally complete and minimally displaced. Fracture configuration and degree of displacement dictate the need for surgical repair.

Complete fractures are better repaired using screw fixation in lag fashion, although nondisplaced fractures heal with conservative therapy.[46] Complete displaced fractures should be repaired with interfragmentary screws. The surgical repair can be supplemented by arthroscopic examination of the dorsal intra-articular region of the affected joint and débridement of associated cartilage damage. Insertion of one or two 3.5-mm cortex screws using lag technique under arthroscopic guidance is recommended (Figure 91-10). Other screws such as the 4.0-mm cancellous screw also suffice, although the shaft on these screws is fragile.

Most horses recover in a soft bandage. Two weeks of complete stall rest is followed by 6 weeks of limited daily handwalking. The implants are removed only where lysis or reaction has developed beneath the screw heads. If conservative therapy is selected, adequate radiographic healing of the fracture occurs in 4 to 6 months.[46] The prognosis for a return to racing is favorable, with 6 to 9 horses reported to have returned to satisfactory performance with nonsurgical therapy.

Diaphyseal Fractures

Most axial fractures of the proximal phalanx occur in the sagittal plane and propagate distad from the articular surface of the MCP or MTP joint. The mid-sagittal groove is mechanically predisposed to the initiation of the fracture, possibly as a result of torsion applied to the sagittal groove from the opposing

Figure 91-10. Oblique radiographic view of a dorsal frontal fracture of the dorsolateral cortex of the proximal phalanx in the rear limb. Repair using two 4-mm cancellous screws has resulted in improved joint congruity.

articular surface of the sagittal ridge of MCIII or MTIII. Fractures of the proximal phalanx are more common in the forelimbs and are particularly prevalent in racehorses, although proximal phalanx fractures are recorded in most breeds of horses.

The clinical signs associated with an axial fracture of the proximal phalanx depend on the extent of fracture propagation. Affected horses with incomplete sagittal fractures show moderate pain of relatively short duration. Fractures extending the full length of the proximal phalanx and those that tend to comminute result in non–weight-bearing lameness and moderate swelling of the pastern. Short, incomplete proximal fractures of the phalanx are sometimes difficult to isolate through a routine lameness examination, and perineural anesthesia is necessary to localize the site of lameness. The use of desensitizing nerve blocks in this situation increases the risk of propagation of the fracture lines during the lameness examination.

Radiographs define the extent of the fracture; most fractures commence in the sagittal groove and extend distad. Complete fractures exit on either the lateral or, rarely, medial cortex of the proximal phalanx or enter the proximal interphalangeal joint (Figure 91-11, *A*). Short sagittal fractures can be difficult to localize on routine dorsopalmar radiographs. Several different dorsopalmar projections, using proximodistal and distoproximal dorsopalmar projections, better demonstrate the fracture. Short sagittal fractures are often detected using nuclear scintigraphy, with radiographs performed to verify the extent of the fracture. Computed tomography or MRI scans are also exquisitely sensitive at detecting these fractures, but many are identified using scintigraphy in the standing horse without the need for more elaborate equipment.

Most short sagittal fractures are initially treated conservatively because the fracture is incomplete and stable. Screw fixation applying lag technique is reserved for fractures that do not heal after 3 months of conservative therapy. Screw stabilization

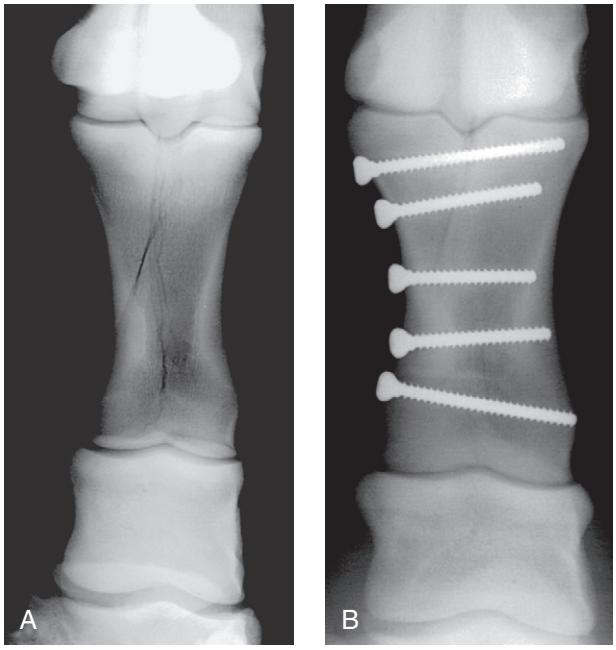

Figure 91-11. A, Dorsopalmar radiographic view of a complete nondisplaced fracture of the proximal phalanx commencing at the sagittal groove within the MCP joint and spiraling distally to enter the PIP joint. **B,** Repair using 4.5-mm cortex screws placed in lag fashion through stab incisions.

induces primary bone union and reduces the chance for further propagation of the fracture in the convalescent period.[47,48] Because of this, interfragmentary screw fixation may be considered as the initial treatment, especially in Warmblood horses.[49] Complete nondisplaced and displaced fractures require surgical repair.[48,50-52] The extent of comminution varies considerably, and as a result, the inherent stability of the fracture configuration varies accordingly. Use of CT imaging can increase the success of surgical reconstruction by improved definition of the fracture planes for screw insertion. The prerequisite for selecting screw reconstruction of proximal phalanx fractures over transfixation casts or external fixator devices is the presence of an intact strut of bone spanning from the MCP to the PIP joint. Disruption of weight-bearing support without an intact bony column is generally a contraindication to screw repair alone. Occasionally, the articular surface of the MCP and PIP joints can be reconstructed with interfragmentary screws, but without an intact strut axial stabilization must be provided with a transfixation device.

SURGICAL TECHNIQUES

Nondisplaced fractures

For routine nondisplaced fractures, the proximal phalanx can be stabilized by inserting screws in lag fashion through stab incisions (see Figure 91-11, *B*). The most proximal screw in the series preferably should be a 5.5-mm cortex screw for additional compression of the articular surface, although 4.5-mm screws usually suffice. Intraoperative radiographic and arthroscopic monitoring is recommended to ensure that the proximal screw does not penetrate the MCP joint and the fracture planes are being adequately compressed.

Ideally, the proximal screw should pass within 5 mm of the most distal point of the sagittal groove of the proximal phalanx to provide maximum compression to the articular surface. This screw should penetrate the transcortex, and the screw head should be adequately countersunk to avoid torque on the screw shaft from the oblique angle of the cortex beneath the head. Additional screws are placed at intervals of 20 to 22 mm until the entire fracture line has been stabilized.

A less common configuration involves fractures in a frontal plane. These fractures are often uniplanar and can be repaired similarly, placing screws in a dorsal-to-palmar direction (Figure 91-12). More comminuted frontal plane fracture configurations can result in trauma to the distal sesamoidean ligaments either by sharp fragments or instruments during repair. This can result in subluxation of the proximal interphalangeal joint after fracture healing. This potential complication should be discussed with the owner of the horse prior to fracture repair.

Postoperative support is provided using a fiberglass cast if the fracture is extensive. Simple fractures that are repaired with several screws can be safely recovered in a firm bandage or a splint. Follow-up radiography is used to assess bone union, and most horses can return to light training 4 months after repair. Proximal phalanx fractures of the hindlimb are more likely to require cast support for the recovery phase because of increased torsional loads on the hindlimbs during recovery.[50] Implant removal is not necessary for fractures of the proximal phalanx. Rarely, lysis beneath the screw head, drainage from an incision, or excessively long screws are identified, and all are indications for screw removal.

Mildly to moderately displaced fractures

Complete fractures that involve sagittal and oblique fracture planes with mild to moderate displacement can generally be better reduced with open approaches to the proximal phalanx followed by screw stabilization using lag technique.[50,51] Access for fracture débridement and reduction is provided by an incision over the dorsal aspect of the sagittal fracture. The incision usually enters the MCP or MTP joint for direct inspection of the articular surface, particularly to ensure accurate realignment of the subchondral bone plate and overlying cartilage. More complicated fractures require a more extensive longitudinal incision and occasionally use of an "I" incision or curvilinear flap for extensive fracture plane manipulation. Separate stab incisions can be used for placing the screws in lag fashion in a lateral plane to stabilize the sagittal fracture and reduce the extent of soft tissue dissection.

Extensive fractures that involve multiple sagittal and frontal planes require an extensive open approach either using an I-shaped incision that exposes the entire dorsal and abaxial cortices of the proximal phalanx or an S-shaped incision.[51] The latter approach involves severing a collateral ligament of the MCP or MTP joint to expose the proximal articular surface of the proximal phalanx. The exposure of the fracture planes and the proximal articular surface allows placement of interfragmentary screws in lag fashion in multiple directions to anatomically reconstruct the bone around the residual intact strut. Most screws are placed in a lateromedial or dorsopalmar direction to provide stabilization of sagittal and frontal fracture planes, respectively. Alternatively, using the dorsal I-shaped incision, the dorsal articular margin of the proximal phalanx can be evaluated during screw insertion, and intraoperative radiographic control is used to ensure the remaining fracture planes are adequately aligned during reduction and stabilization (Figure 91-13). This preserves the collateral ligaments and the

Figure 91-12. metacarposesamoidean ligaments, and it provides some opportunity for a return to competition.

The limb is cast to the proximal aspect of MCIII or MTIII for recovery from anesthesia and for the next 3 to 6 weeks. Radiographic evaluation is used to determine the appropriate cast time required. Preoperative antibiotics are continued for 3 to 5 days after surgery to minimize the risk of sepsis. Intraoperative culture during extensive and prolonged procedures might also be useful before closing the soft-tissue structures.

Severely fragmented (comminuted) fractures

Fractures without an intact strut of bone are poor candidates for internal fixation. They are generally high-energy fractures and the bone is extensively fragmented (Figure 91-14). Lameness is marked, and considerable swelling can develop if the limb is left unbandaged for any length of time. Extensively fragmented fractures need to be stabilized within a cast before transfer of the horse for evaluation and surgery (see Chapter 73). Radiographs can often be taken through the cast to define the fracture configuration and determine if surgical repair is possible or humane destruction is indicated. For cases where repair is desired, transfixation casts usually provide a reasonable possibility of salvaging the horse. Return to athletic activity is not possible.

Simple cast fixation does not provide resistance to axial collapse of the fracture within the cast. The complications of collapse include continued lameness, a high risk for development of pressure necrosis of the skin leading to an open fracture, and laminitis of the unaffected weight-bearing limb. Transfixation techniques reduce the collapse of the fracture within the cast by using transcortical pins in the distal and mid portion of the MCIII or MTIII.[53] Pins with positive threads located in the center are preferable, and slow sequential drilling followed by preparation of the threads in the hole with a suitably sized tap are generally required before the pin is inserted (see Chapter 76).

An alternative to a transfixation cast is the external skeletal fxaton device, which uses a series of transfixation pins through the MCIII or MTIII joined to side-connecting tapered bars attached to a foot plate (see Chapter 76).[54,55] The most significant complications of transfixation casts and the external skeletal fixator is ring sequestrum formation around the pin tracts, especially in heavy horses, and subsequent fracture through a pin hole (see Figure 76-9).[56] Despite these complications, this fixator is a good choice for salvaging horses with extremely comminuted fractures.

THE METACARPOPHALANGEAL JOINT

Palmar Metacarpal Fragmentation

Palmar fragmentation of the metacarpal condyles is a trauma-induced disorder that results from the accumulated stress and sclerosis that develops during racing. This syndrome has also been referred to as *palmar osteochondral disease* during more detailed studies of the pathogenesis.[57] Previously, this disease was thought to belong to the osteochondrosis complex, in this joint located at the palmar or plantar surface of the MCIII condyles.[58,59] However, there are no histologic data to verify this etiology, and classification as an OCD lesion has been abandoned. Most patients are Thoroughbred racehorses that are 3 years old or older and have moderate to severe MCP lameness.

The palmar lesions are identified on standard lateromedial and flexed lateromedial projections (Figure 91-15). Additional information can occasionally be derived from 125-degree dorsopalmar projections.[60] The radiographic lesions appear on the lateral projection as differently shaped palmar defects, including crescent, flattened, concave, oval, or circular lesions.

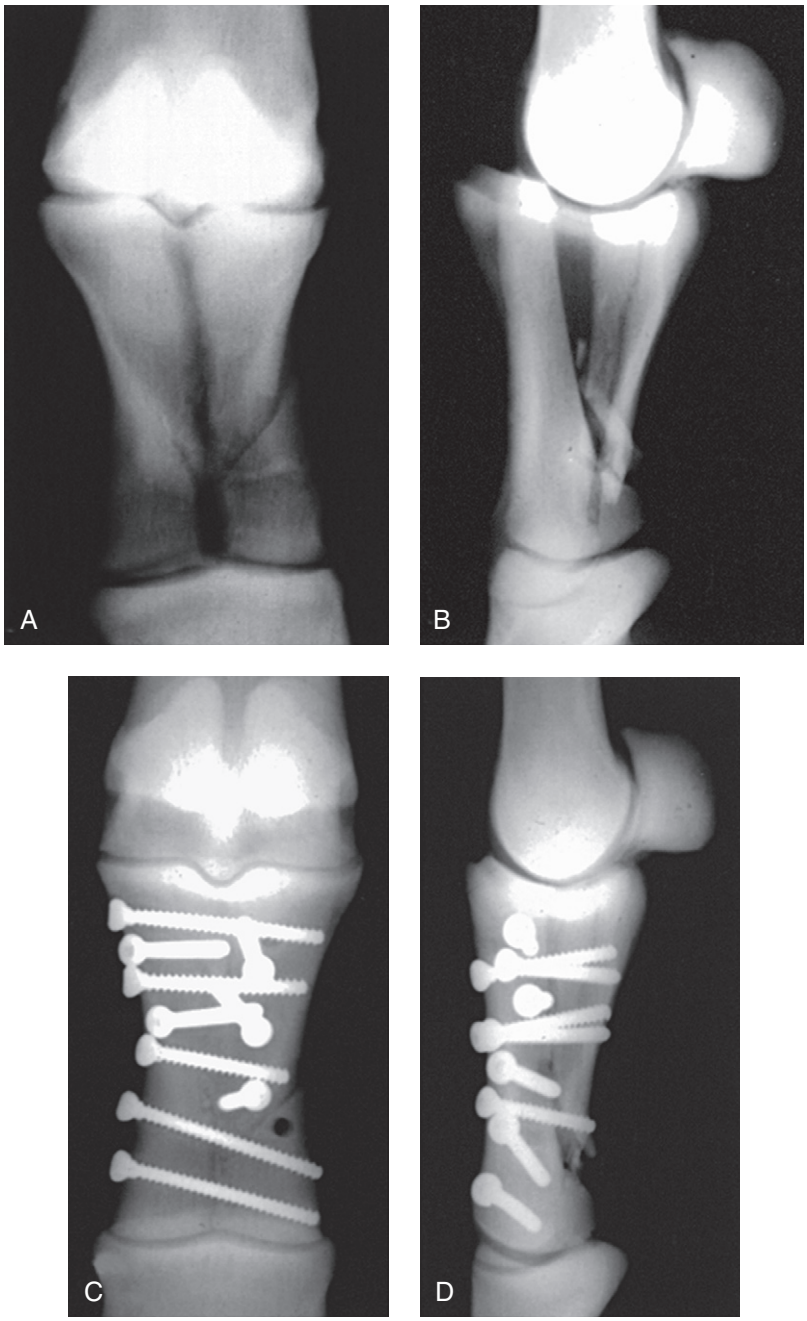

Figure 91-13. Dorsopalmar **(A)** and lateromedial **(B)** preoperative radiographic projections of a multifragment fracture of the proximal phalanx showing sagittal and frontal plane components. There is an intact medial strut of bone that is to be used in reconstructing the fragmented portions. Dorsopalmar **(C)** and lateromedial **(D)** postoperative radiographic projections show the repaired fracture.

Secondary arthritic changes are common, with periarticular osteophytes or enthesiophytes, narrowing of the joint space, and supracondylar lysis. A prominent secondary feature is intense sclerosis of the palmar region of the condyle, deep to the lytic region. Morphologic assessment of these degenerate metacarpal condyles indicates an area of acellular and apparently necrotic bone over the entire distal palmar region of the affected metacarpus.[61] Deep to the necrotic area is a zone of new bone formation producing a sclerotic barrier that compensates for the biomechanical dysfunction of the palmar fracture. These remodeling and fracture changes are the result of accumulated stress fractures in the palmar region of the condyle, largely as a result of hyperextension of the MCP joint. Early lesions may have little overlying cartilage damage; however, eventual fracture and displacement of the subchondral bone result in complete bone and cartilage loss (Figure 91-16). Lameness, although initially mild or moderate, then becomes severe.

Scintigraphy is sensitive in detecting the early stress fracture and bony deposition forming the sclerotic zone within the palmar region of the condyle. Early recognition is particularly helpful because the sclerosis can be reduced or allowed to remodel rather than progress to palmar fracture with prominent symptoms. CT imaging and MRI also are both important diagnostic modalities to define early lesions and track progress. This condition is difficult to treat, and efforts at prevention are important. Access to the palmar region of the distal metacarpus is very limited and is made more difficult because most of these lesions are close to the sagittal ridge.

Figure 91-14. Dorsopalmar radiographic projection of a severely fragmented fracture of the proximal phalanx, without an intact strut and lacking inherent stability. Screw repair is generally inadequate, and transfixation casting or external fixators are required for salvage.

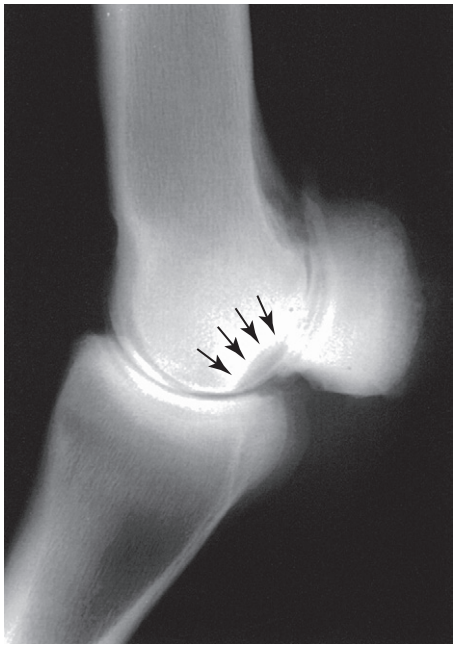

Figure 91-15. Lateromedial radiographic projection of a 5-year-old Thoroughbred with marked palmar fragmentation, bone loss, and extensive subchondral sclerosis of the metacarpal condyles *(arrows).* Enthesiophyte formation is noted at the proximal and distal ends of the proximal sesamoid bones, indicating chronic arthritis.

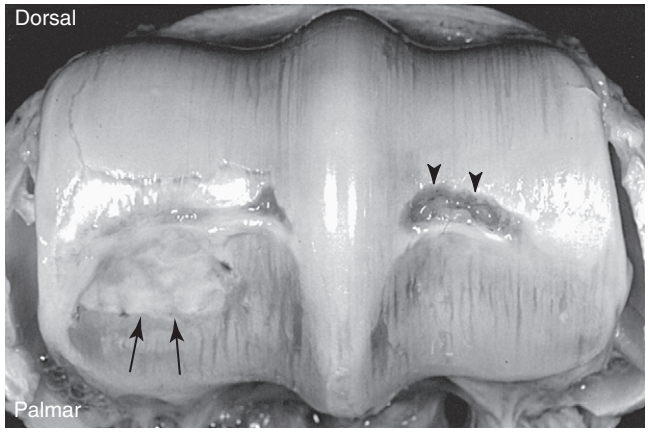

Figure 91-16. A cadaveric specimen of palmar metacarpal fragmentation of the condyles in a 4-year-old Thoroughbred racehorse. Extensive score lines have developed over the entire cartilage surface, with fragmentation and granulation laterally (*arrowheads*) and fibrous healing tissue in the defect medially *(arrows).*

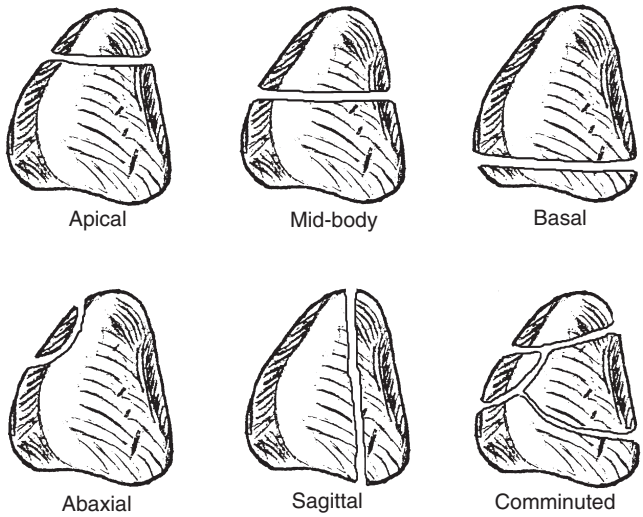

Figure 91-17. Proximal sesamoid fracture configurations.

Proximal Sesamoid Bone Fractures

Fractures of the proximal sesamoid bones are relatively common, particularly those involving the apical portion.[62-75] Other configurations include basal, midbody, abaxial, sagittal, and comminuted fractures (Figure 91-17). Most proximal sesamoid fractures occur because of excessive tension from the suspensory apparatus.

Apical Fractures

Apical fractures are particularly common in the hindlimbs of Standardbreds, and the resultant prognosis often is dictated by the extent of loss of suspensory ligament insertion and preexisting suspensory desmitis.[62] All fracture configurations, except abaxial, nonarticular fractures, result in MCP effusion and moderate to severe lameness of short duration.

Apical fractures involving the proximal one fourth to one third of the proximal sesamoid bone always contain an articular

component. However, they do not result in extensive suspensory derangement, and lameness diminishes rapidly. Removal of apical fragments up to one third of the proximodistal dimension of the proximal sesamoid bone is recommended. Better results are evident with smaller apical fractures, where there is less disruption of suspensory ligament insertion[62,64] because removal of the proximal third of the proximal sesamoid bone results in delay of return to racing and a considerably reduced likelihood of a successful postinjury career. Large apical fractures with obliquity to the fracture plane may be better candidates for internal fixation.[75]

Arthroscopic removal of apical fractures results in less-extensive dissection and secondary fibrosis. The arthroscope is inserted in the proximal aspect of the palmar or plantar pouch, and the instrument portal is made at the level of the fracture, allowing dissection of the fragment from the suspensory attachment. Use of the contralateral palmar pouch for arthroscope entry often provides better visualization of the apical fracture and an unfettered region for instrument access.[75]

Midbody Fractures

Midbody and basal fractures present special problems for surgical fixation. Both of these injuries are slightly more prevalent in Thoroughbreds, and internal fixation is required for adequate fracture union. Midbody proximal sesamoid fractures should be repaired with either circumferential cerclage wire or screw fixation using lag technique.[67,68] Recent publications suggest screw fixation may be the only option for Thoroughbreds to return to athletic capacity.[76] Previous therapy, including cerclage wire fixation accompanied by insertion of a bone graft into the separated fracture line, combined with extended periods of cast fixation, are unreliable in returning horses to work.

Screw fixation in lag fashion is performed from the base or the apex of the bone, depending on the orientation of the fracture plane. An oblique fracture with the fracture plane declining from medial to lateral is best treated with interfragmentary screws placed from the apex, whereas a fracture declining from lateral to medial is best approached from the base or from a contralateral approach allowing insertion of oblique proximal to distal oriented screws.[75] Interfragmentary compression and reduction during screw insertion is maintained with large pointed reduction forceps. Frequent intraoperative radiographs and/or arthroscopic supervision are essential for a high-quality repair. For screw insertion from the base, the screw head should come to lie between the oblique and straight distal sesamoidean ligaments in a natural fossa in the base of the proximal sesamoid bone. Proximal to distal oriented screws are inserted proximolaterally at the apex of the bone, embedded in the insertion of the lateral suspensory branch. Insertion technique for the screws is routine after the correct screw position has been verified radiographically (see Chapter 76). Interfragmentary screw fixation in lag fashion returns up to 60% of Thoroughbred horses to active racing,[67,68] whereas circumferential wiring has largely been reserved for Standardbreds.[68,76]

Basal Fractures

Basal slab fractures involve the origin of all the distal sesamoidean ligaments, and the prognosis is certainly unfavorable. Lag screw fixation is more challenging because of the thin fragment profile (Figure 91-18). There is an inverse relationship between dorsopalmar fragment length and the likelihood of return to racing.[72] Basal osteochondral fragments that do not extend to the palmar surface have a much better prognosis, with 59% returning to racing in a study of 57 horses.[66] Many of these fractures can be removed arthroscopically. Similarly, in a second study, 57% of horses with fragments involving less than 25% of the base successfully returned to racing after fragment removal, compared to 40% with fragments involving more than 25% but not the entire base.[72]

Abaxial Fractures

Abaxial fractures must be assessed by a 60-degree skyline projection of the abaxial surface of the proximal sesamoid, which demonstrates whether the abaxial fracture enters the joint or is located palmarly/plantarly and is extraarticular (Figure 91-19).[69] Intra-articular fractures can be removed under arthroscopic visualization, whereas the nonarticular fractures are best treated conservatively.[70,71] Return to function is fair to good (61%), depending on the length of the intra-articular fracture.[71]

Sagittal Fractures

Sagittal fractures are rare and tend to occur on the axial margin of the sesamoid bone in conjunction with other MCP injuries such as condylar fractures (see Figure 92-7).[73] Very rarely, they can develop as isolated fractures, but they occasionally can be repaired using several 3.5-mm cortex screws placed in lag fashion in a lateral-to-medial orientation. Postoperatively, application of a cast is recommended for the initial 2 to 3 weeks. At that time, if everything looks satisfactory, the cast is exchanged for a heavy support bandage. The remainder of the postoperative management is routine. Because the fractures usually occur in conjunction with displaced lateral condylar fractures, return to athletic activities is unlikely and retirement from racing is inevitable. Rarely, MCP arthrodesis is necessary, including fractures compounded by injury to the intersesamoidean ligaments or fractures of the proximal phalanx. For additional information see Chapter 92.

Biaxial Fractures

Multifragment and biaxial fractures are severe breakdown injuries involving the MCP joint. In most cases, these horses require MCP arthrodesis for a return to comfortable weight bearing (see Chapter 81) (Figure 91-20).[77,78]

Prognosis

Follow-up on 109 horses with apical sesamoid fractures indicated that 64% of the horses treated surgically raced afterward, whereas only 37% of those treated conservatively raced again.[62] Another outcome study of 84 Thoroughbreds indicated 77% of horses returned to racing after removal of apical fractures, with a slightly better outcome when hindlimbs were involved.[74] For midbody fractures repaired with cortex screws inserted in lag fashion, 9 of 12 horses were able to race after surgery.[62,67] Similarly, in Standardbred horses with midbody fractures repaired by wiring, 11 of 15 were able to resume an athletic career; none of the Thoroughbreds, however, returned to racing.[68,76]

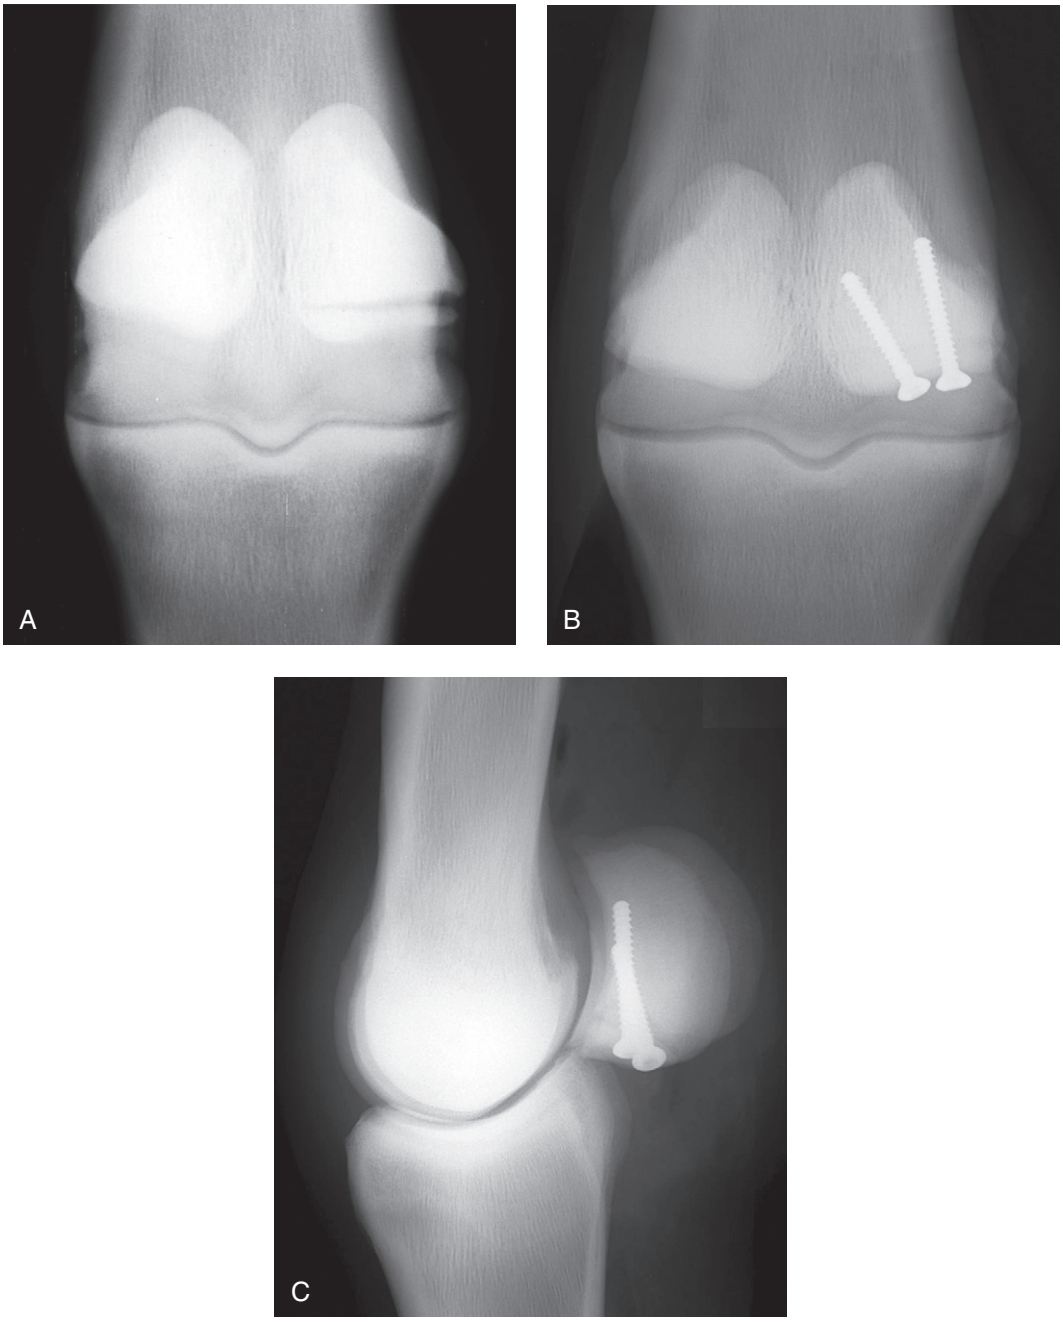

Figure 91-18. A, Dorsopalmar preoperative radiographic projection of a basal fracture of the lateral proximal sesamoid bone. Dorsopalmar **(B)** and lateromedial **(C)** postoperative radiographic projections following repair of the fracture by means of two 3.5-mm cortex screws inserted in lag fashion. Because of the small size of the basal fracture fragment, 3.5-mm screws were selected.

Chronic Proliferative (Villonodular) Synovitis

Development of soft-tissue masses in the dorsal aspect of the MCP joint is common secondary to chronic fibrosing synovitis.[79-83] The most frequent cause is proximodorsal osteochondral fractures of the proximal phalanx that are not immediately treated by fragment removal. In addition, chronic proliferative masses commonly develop with advancing osteoarthritic changes within the joint. Horses with long pasterns are predisposed to this problem. A visible and palpable mass is evident at the proximal dorsal aspect of the affected MCP region. Lameness is usually grade II to III/V depending on the underlying disease. Radiographs occasionally show cortical lysis on the dorsal region of MCIII, under the enlarging mass. Involvement of the hindlimbs in chronic proliferative synovitis is rare. Definitive diagnosis requires either arthrography or ultrasonographic examination.[30] Ultrasonography is more convenient.

Most masses are 7 to 10 mm in diameter. The minimum thickness that warrants surgery is 4 mm; smaller masses can be treated with intra-articular atropine and steroids. The enlarged medial portion of the chronic proliferative plica is usually thicker than the lateral portion.

A critical factor in the decision for surgery is the extent of osteoarthritis present in the joint. Osteochondral fragments and

other fracture diseases in the MCP joint result in secondary fibrous mass development, and these fibrous masses can be removed without difficulty and with reasonably favorable prognoses.[30,82] Masses secondary to osteoarthritis are generally larger and more chronic, and the associated arthritis dictates the likelihood of successful return to work after the mass is removed. A critical evaluation of the joint space on preoperative radiographs and the use of ultrasonography to measure the dorsal articular cartilage thickness prevent inadvertent operation in these cases. Increasing use of MRI has helped define the extent of concurrent cartilage loss and the value of surgical débridement.

Figure 91-19. Elevated 60-degree lateromedial radiographic projection (Pr60L-DiMO) of the proximal sesamoid bones to evaluate the intra-articular component of an abaxial sesamoid fracture *(arrow)*. This fragment enters the joint.

Primary chronic proliferative masses can develop without an obvious initiating factor, and these most likely result from hyperextension of the MCP joint and impact trauma on the normal synovial plica. which primarily cushions and lessens the impact of the dorsal margin of the proximal phalanx onto the metacarpal cortex.[79,82] Hemorrhage and fibrosis in this plica eventually result in significant enlargement, which is then more easily and repeatably injured during exercise. This is quite painful, but the horses do very well after surgery to remove the mass.

Arthroscopic approaches are suitable for removing chronic proliferative masses (Figure 91-21), although some masses are so large that they may be easier to remove by arthrotomy.[30,82] Arthroscopic visualization allows mass removal using synovectomy instrumentation, guarded scalpels, or the biopsy suction punch rongeur for smaller masses (Dyonics). Large masses can also be efficiently removed using larger biopsy punch rongeurs (Sontec Instruments), or CO_2 or diode laser where this equipment is available.[83] Radiofrequency probes are increasingly used to excise these masses, often using a second instrument portal to stabilize the mass during excision.

Postoperative therapy includes intra-articular injections of 20 to 40 mg of hyaluronan. Repeat doses in 3 to 4 weeks are recommended. The use of polysulfated glycosaminoglycan (Adequan) is another option depending on the state of the articular cartilage. Return to race training depends on concurrent arthritis.

Osteoarthritis

Deterioration of articular cartilage is common in mature racehorses and can lead to moderate to severe unrelenting lameness, with the development of periarticular osteophytes, enthesiophytes, and joint space collapse, particularly medially. These horses respond poorly to intra-articular medication and require

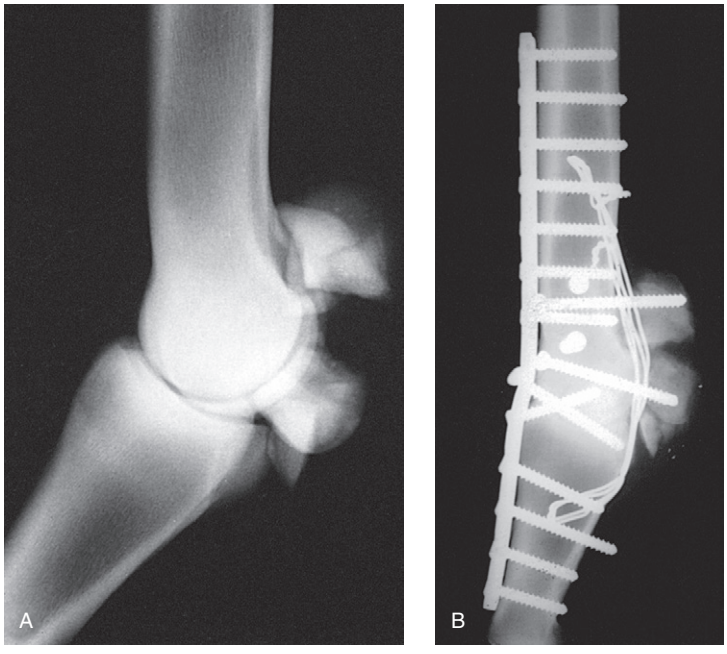

Figure 91-20. A, Lateromedial radiographic projection of the MCP region depicting bilateral transverse mid-body fractures of the proximal sesamoid bones resulting in a breakdown of the suspensory apparatus. **B,** Repair was achieved through an MCP arthrodesis using a dynamic compression plate (DCP) applied to the dorsal surface of the limb and a tension band wire for palmar support.

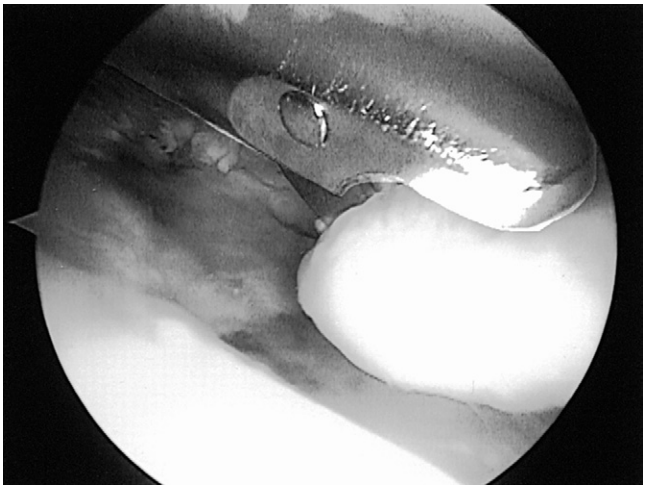

Figure 91-21. Arthroscopic removal of an 8-mm chronic proliferative (villonodular) mass from the MCP joint using a biopsy punch rongeur.

frequent injections to remain comfortable. Collapse of the medial compartment of the MCP joint is more prevalent than the lateral and often indicates the likelihood of a career-ending lameness.

Therapeutic options are limited. Pain relief can be effected by intra-articular steroid administration, but continued cartilage degradation is inevitable. Injection or surgical implantation of cultured bone marrow stromal stem cells (MSCs) may provide generalized improvement in joint function. Some cells may adhere to fibrillated cartilage, although the broader impact seems to be anti-inflammatory, antiapoptotic, and trophic effects of the stem cells at the synovial membrane boundary. In the final stages of joint deterioration, some improvement in the level of lameness has resulted from the administration of silicone oils to the joint. Ultimately, some horses need MCP arthrodesis to become comfortable (see Chapter 81).

Osteochondritis Dissecans and Subchondral Cystic Lesions

OCD can develop as palmar dissecting flaps on MCIII or MTIII, or more frequently in the form of dissecting cartilage flaps[84] that appear as mineralizing lesions on the dorsal sagittal ridge of the MCIII or MTIII, and these are common in young horses 8 to 24 months old.[85] Dorsal OCD lesions can affect all four MCP joints. Palmar metacarpal OCD lesions, which result in a debilitating lameness, often progress to osteoarthritis and represent the most serious form of MCP OCD. Palmar lesions occur in horses as young as 10 months but are more common in young racing-age horses. (Distopalmar metacarpal fragmentation in 3- to 4-year-old racehorses was originally described as OCD but is a different disease from that described here as OCD.) For more information on this disease complex see Chapter 88.

Subchondral cystic lesions (SCLs) of the distal MCIII or MTIII condyle occur most commonly in weanlings and yearlings but can be first diagnosed in 2-year-olds in training. The resulting lameness is variable, and occasionally severe, but osteoarthritis is a rare initial sequela. Most subchondral cysts open to the joint just dorsal to the transverse ridge by a narrow communicating channel. Occasionally, multiple cysts are present in the same bone, and the cysts can be bilateral. Cysts of the proximal articular surface of the proximal phalanx also can be seen, often opening in or near the sagittal groove.

The degree of lameness largely depends on the type of MCP OC. Dorsal sagittal ridge lesions result in mild to minimal lameness, although flexion tests of the involved joints are often positive. The other forms of OCD and SCL result in more significant lameness. Lameness and pain on flexion are most pronounced with palmar OCD lesions in yearlings. Regardless of the site, MCP effusion is a prominent feature. Most horses have sufficient lameness, synovial effusion, and exacerbation of the lameness with flexion tests that a tentative diagnosis can be reached without regional or intra-articular anesthesia. Radiographs are necessary to determine the exact cause of MCP disease and to provide prognostic guidelines. Dorsal sagittal ridge lesions often manifest as mineralized densities adjacent to the sagittal ridge (Figure 91-22, *A*). They often arise from the proximal condylar cartilage and are more correctly termed dorsal parasagittal or dorsal condylar OCD lesions.

Treatment options vary according to the site of involvement. Palmar MCIII and plantar MTIII lesions are relatively inaccessible, and surgical therapy is not possible unless the lesion is located unusually far caudad on the condyles or sagittal ridge. Occasionally, part of these lesions can be débrided under arthroscopic guidance with a palmar or plantar pouch approach. On most occasions, however, the lesions are inaccessible, and osteoarthritis with permanent lameness is the usual sequela. These young horses rarely enter and sustain an athletic career.

Dorsal sagittal ridge and parasagittal condylar lesions should be surgically removed under arthroscopic guidance (see Figure 91-22, *B*). The technique as described previously should be applied.[30] These lesions can achieve considerable size, and removal can leave a substantial subchondral defect. However, in this location, joint stability is unaffected, and the outlook remains favorable. Subchondral cystic lesions of MCIII or MTIII that have narrow openings to the joint can be treated successfully with several injections of hyaluronan (Figure 91-23, *A*). Most yearlings do well, and the lameness quickly resolves. The cystic cavity generally fills in but may take 1 to 2 years. Occasionally, lameness persists despite intra-articular medication and limited exercise, and surgery should then be considered.

Cystic lesions with wide channels to the articular surface do not respond to conservative therapy nearly as well as cysts with narrow openings, and débridement is often recommended at the initial diagnosis (see Figure 91-23, *B*). Surgical débridement of the cysts can be accomplished via dorsal arthroscopy with the MCP joint flexed. Most cysts can be curetted; bone grafts are not usually necessary. In mature horses, chondrocyte or stem cell grafts have been used to assist in repair of the subchondral architecture and overlying cartilage.[86,87] A recent study on the long-term effect of filling of the defect with a $PTH_{1\text{-}34}$–enriched hydrogel following débridement via an articular or transosseous approach revealed good results in cystic lesions in the proximal sesamoid bone (3 out of 3 became sound and radiographically filled), and distal MCIII/MTIII (2 out of 2 became sound and radiographically improved), whereas one lesion each in the proximal aspect of the middle and proximal phalanx remained lame and became larger.[88]

Arthroscopic techniques can be used only with cysts opening on or dorsal to the transverse ridge of MCIII. More palmar cysts are rare and best approached transosseously through drilling. Cysts of the proximal phalanx can be débrided with difficulty

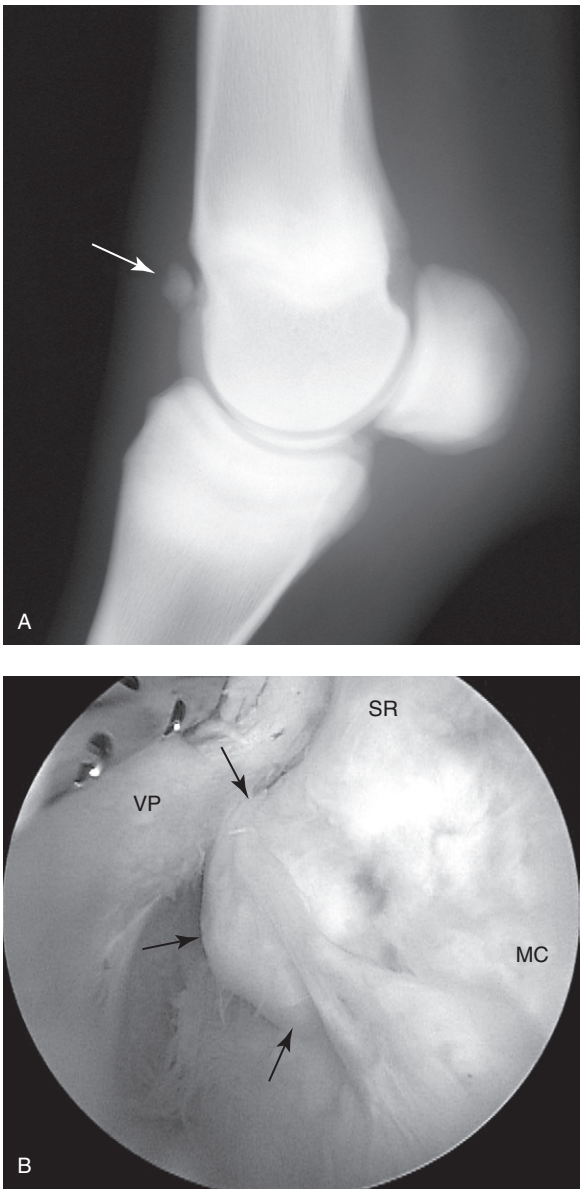

Figure 91-22. A, Lateromedial radiographic view showing dorsal sagittal ridge OCD *(arrow)* that involved the adjacent condyle. **B,** Arthroscopic examination shows the sagittal ridge *(SR)* distal to the fragment *(arrows)*, the metacarpal condyle *(MC)*, and villonodular pad *(VP)*.

from the articular surface, particularly in MTP joints where the joint separates with flexion.

The outlook for a sustained athletic career is favorable for subchondral cystic lesions of the distal MCIII or MTIII, reasonably favorable for dorsal sagittal ridge and parasagittal OCD, and poor for palmar metacarpal OCD flaps.[89]

Luxation

Lateral or medial complete luxation of the MCP and MTP joints occurs after rupture of either the medial or lateral collateral ligament.[90,91] Occasionally, there is an avulsion of the origin or insertion of one of these ligaments, resulting in marked instability. The condition is relatively rare and results primarily from entrapment of the distal limb in holes in the ground or cattle grates. The diagnosis is obvious when an angular deviation can be easily induced on manipulation (Figure 91-24). Radiography with a dorsopalmar projection with the limb under lateral or medial bending stress usually provides clear evidence of the extent of the luxation. Ultrasonographic examination may add additional information when radiographs are inconclusive, but stressed radiographs are a vital source of information regarding the extent of physical disruption.[91] Ultrasonographic studies have identified cases that are stable but have rupture of portions of the collateral ligament. Some injuries associated with trailer accidents result in an open luxation with disruption of the collateral ligament and some loss of bone structure because of pavement injury.

The treatment of closed luxations is simple and involves cast fixation for 6 weeks.[90] Imbrication or repair of the collateral ligament is not usually necessary. The cast is applied with the horse anesthetized, maintaining the lateral–medial stability as the cast cures. Surgery for open luxations is necessary for adequate wound débridement and soft-tissue closure. Extensive antibiotic lavage and removal of all foreign matter are essential. Treatment of the luxation initially in a splint is an option for the acute inflammatory phase, until the infection has been controlled. Later, a cast can be applied for increased stabilization, or arthrodesis by application of a DCP or LCP and screws can be used if the joint surface is extensively damaged (see Chapter 81).

Two case series of MCP luxation have been published.[90,91] One series, involving 10 horses, included five horses that had open luxation and five with closed luxation.[90] The open luxations were treated with joint lavage and cast immobilization, and the majority were sound at follow-up, including one horse that was being actively ridden. A more recent series of 17 horses, combined cases with stable and unstable rupture of the collateral ligaments based on ultrasonographic detail, also concluded the prognosis was favorable for return to function after conservative therapy.[91]

The development of obvious sepsis within the MCP joint can be minimized by aggressive early therapy and the placement of lavage drains and ingress antibiotic portals. Later application of antibiotic-laden bone cement assists in bringing the infection under control. Overall, the prognosis after the development of infection is guarded, and chronic lameness can be expected. Some of these cases can be salvaged with aggressive débridement and elective arthrodesis later.

ANGULAR LIMB DEFORMITY OF THE METACARPOPHALANGEAL REGION

Angular limb deformities originating at the distal physis of the MCIII or MTIII develop relatively often in foals; most are varus deformities. Concurrent valgus of the carpus or tarsus and a varus deformity of the MCP region are common. Many varus deformities are congenital and improve during the early postnatal period. A detailed discussion of angular limb deformity is found in Chapter 86.

FLEXURAL DEFORMITY OF THE METACARPOPHALANGEAL JOINT

Flexural deformities of the MCP joint can be classified as congenital or acquired.

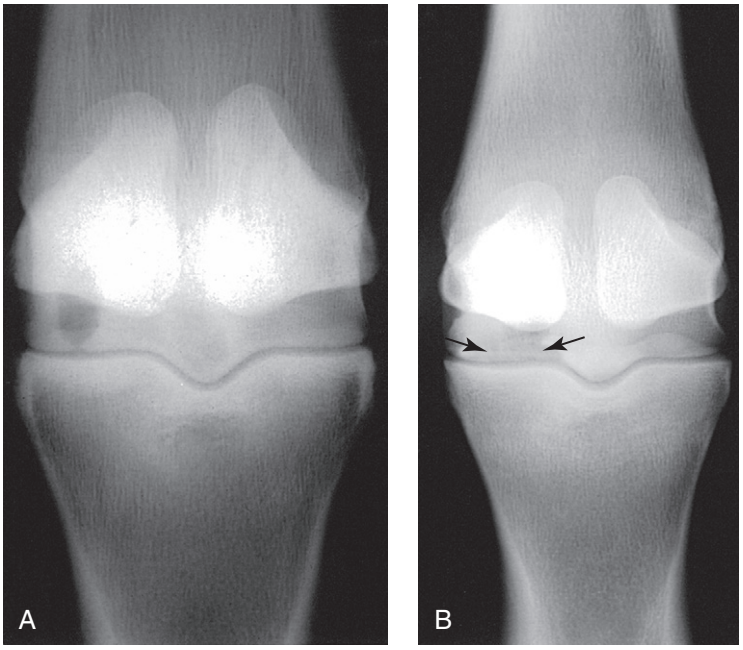

Figure 91-23. Dorsopalmar radiographic views of the MCP joint. **A,** Subchondral cystic lesion with small communication into the joint generally respond well to conservative therapy, such as intraarticular hyaluronan or intralesional corticosteroid injections. **B,** SCLs with wide canals *(arrows)* often need surgical débridement.

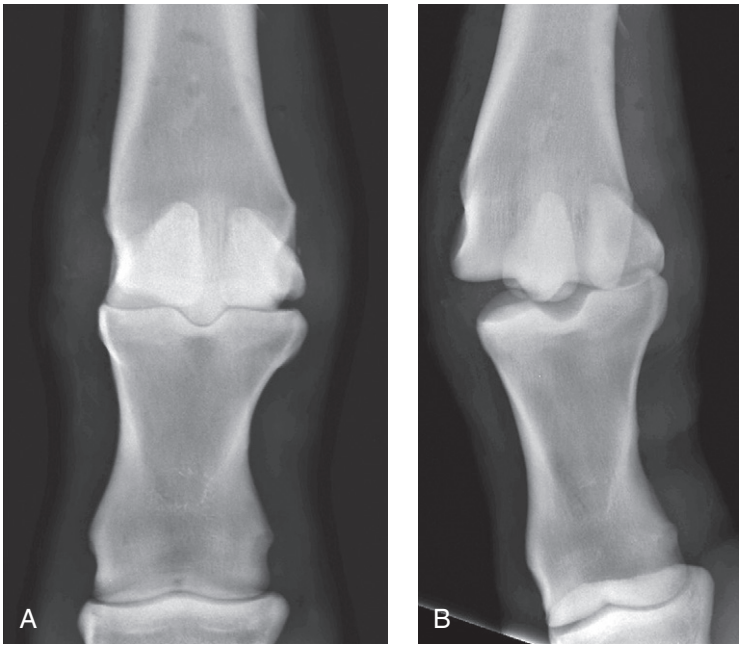

Figure 91-24. Luxation of the metacarpophalangeal joint. **A,** Standing dorsopalmar radiographic projection shows normal MCP alignment. **B,** Bending stress luxates the joint, confirming complete medial collateral ligament rupture.

Congenital Deformities

Congenital deformities are often relatively severe. If they are bilateral, the foal can have difficulty rising or, if it does stand, it tends to knuckle over at the MCP joint. In some congenital cases, tension is apparent in both the deep and superficial digital flexor tendons; in others, the common digital extensor tendon is ruptured. Occasionally, even the suspensory ligament is taut on palpation. The diagnosis and management of these deformities are discussed in detail in Chapter 87.

Acquired Deformities

Acquired flexural deformities can be unilateral or bilateral. Both forelimbs are commonly affected, one generally more severely than the other. The pathogenesis of the acquired form of flexural deformity is thought to involve pain-induced reflex loops in the ipsilateral limb, often precipitated by other skeletal disease. The diagnosis and management of these deformities are discussed in detail in Chapter 87.

ANNULAR LIGAMENT CONSTRICTION

Chronic tenosynovitis is the most common condition of the digital sheaths of horses, developing mostly in the hindlimbs as an insidious reaction to increased workloads. Most cases of tenosynovitis are successfully treated by changing exercise intensity with or without intrasynovial medication. Untreated tenosynovitis or tenosynovitis associated with more serious disruption of the tendon sheath, the various mesotenons and manica flexoria, the annular ligament, or the flexor tendons themselves can result in lameness and a self-perpetuating cycle of tendon sheath fibrosis, repeat tearing, and annular ligament thickening referred to as *complex tenosynovitis*.[92-94] Tenosynovial masses and adhesions can develop as a consequence of this chronic inflammatory action. These latter types of cases do not respond particularly well to medical therapy and not only require surgical intervention but also generally have a reduced prognosis for a cosmetic outcome and a return to complete soundness.

In animals in which the annular ligament causes constriction, chronic lameness (exacerbated by flexion of the fetlock), and tendon sheath effusion and thickening with a notching of the sheath over the width of the palmar/plantar annular ligament are common (Figure 91-25). Ultrasonographic evaluation of the tendons within the digital sheath and fetlock canal is useful to determine the extent of tendon lesions and the thickness of the synovial tendon sheath and annular ligament and to define the number and attachments of tenosynovial masses. Several reports suggest that annular ligament desmitis can be the sole initiator of annular ligament constriction, and ultrasonographic evaluation is critical in making the diagnosis.[95,96] Tears within the DDF tendon also are recognized as a cause of chronic severe tenosynovitis.[97,98]

Figure 91-25. Lateral view of a horse suffering from constriction of the annular ligament, demonstrated by the synovial effusion in the tendon sheath and the characteristic notching of the tendons proximal to the annular ligament *(arrow)*.

Medical treatment is required in chronic cases when a noticeable lameness has developed in conjunction with persistent swelling. Where ultrasonographic examination reveals obvious tendon or digital sheath pathology such as tendon sheath masses and adhesions, tears in the digital flexors, rupture of the manica flexoria, or annular ligament thickening, surgical therapy is preferred for definitive resolution of symptoms.

Treatment

Mass Removal

Open tendon sheath approaches to mass and adhesion removal or resection have been successful. The disadvantage to extensive open approaches is the delay in the initiation of exercise postoperatively and adhesion formation or reformation. However, early postoperative walking increases the risk of wound dehiscence with the attendant risk of sepsis. For these reasons, endoscopic examination of the sheath (tenoscopy), using a standard rigid arthroscope, is preferred.[7,92,94,99]

The entry portal for routine tenoscopy of the digital sheath is on the palmarolateral or plantarolateral surface immediately distal to the annular ligament.[99] This entrance allows examination of most regions of the sheath, and instrument portals can be made proximal to the annular ligament under tenoscopic guidance. Tenosynovial masses can be resected either with motorized synovial resectors or by division at their attachments with biopsy-cutting forceps or retractable blades and subsequent removal with grasping forceps using an additional instrument portal (Figure 91-26). For extensive synovial resection, hemorrhage control is required, and a tourniquet is applied proximal to the digital sheath. If annular ligament transection is also needed, it can be accomplished initially to open further access for manipulation within the sheath, or it can be done at the end of the procedure, using the slotted cannula (Dyonics) available for carpal tunnel release in humans. Where space for surgical manipulation permits, the annular ligament can be transected free-hand with a variety of right-angled blades under arthroscopic visualization.

Figure 91-26. Tenoscopic removal of digital sheath masses from the dorsolateral recess of the sheath cavity using motorized equipment.

Annular Ligament Transection

The only effective treatment for the annular ligament constriction syndrome is division of the ligament. This can be done by limited open incision or, in more complex cases, by using tenoscopic access, which provides more complete assessment and access to other lesions. Preoperative planning is important for determining the degree of exposure of the tendons required to optimize treatment. Where only the annular ligament is involved, the ligament can be severed in the standing animal with a curved bistoury introduced through a 1-cm incision proximal to the ligament. In original descriptions of surgical division of the annular ligament, the horse was anesthetized and the skin was incised over the entire proximodistal length of the annular ligament. This incision provided access to allow sectioning of the annular ligament and subsequent division of adhesions under direct view. Where the annular ligament is the only involved structure, the exposure required for division of the ligament can be reduced to a 2-cm skin incision over the proximal border of the annular ligament.[100] Another surgical approach that can be performed open with less risk of dehiscence uses a paramedian skin incision over the entire length of the annular ligament, followed by palmar or plantar transection of the ligament over the mesotenon. This technique, if performed correctly, prevents opening of the tendon sheath. It can be applied if only the annular ligament is involved. Depending on the presence of tendon core lesions or peripheral adhesions, other surgical procedures such as tendon injection, mass removal, or adhesiolysis are performed as indicated. Currently, minimally invasive techniques are superior for these extensively affected cases and allow earlier initiation of exercise and physiotherpay. This translates into improved outcome.[92,94,101,102]

Tenoscopic examination of the digital sheath with an arthroscope entering distal to the annular ligament allows visual inspection of the entire sheath cavity and division of the annular ligament (Figure 91-27). Second entry portals allow adhesion resection and mass removal, as previously described, and endoscopic release of the annular ligament can be accomplished.[93] The obvious advantages of tenoscopic annular ligament release include the extensive dissection that can be performed through limited entry wounds, allowing better wound healing with less risk of dehiscence and earlier postoperative exercise.

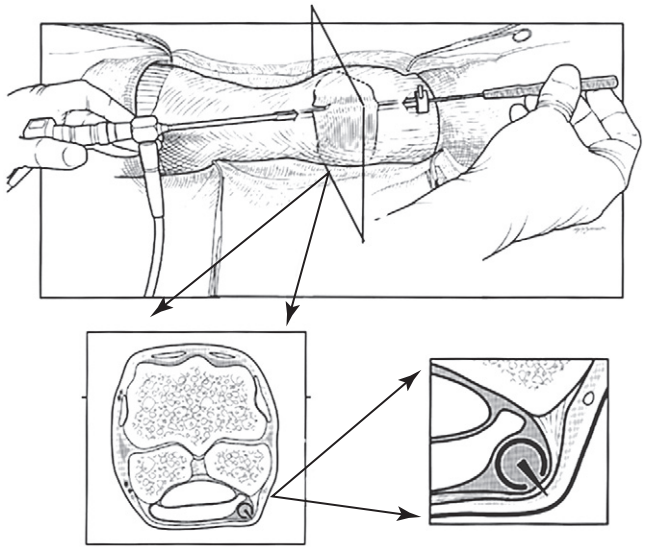

Figure 91-27. Illustration of tenoscopic annular ligament release, using a slotted cannula inserted from proximal, and an arthroscope inserted from distal to the base of the sesamoid to visualize a 90-degree–angled blade used to sever the fibers of the annular ligament. *Inset* shows the position of the blade adjacent to the sesamoid abaxial perimeter.

The entry and angle of the slotted cannula are critical to facilitate insertion of the arthroscope and 90-degree angled blade. The proximal entry portal should be dorsal in the digital sheath and the distal exit point should be plantar or palmar to allow the arthroscope or blades to clear the bulbs of the heel. The cannula with obturator in place is inserted under direct arthroscopic visualization as it traverses from proximal to distal. The insertion path must be external to the manica flexoria, or this ring of the SDF will be divided along with the annular ligament. As the obturator nears the distal portal, the arthroscope is removed, and the obturator and cannula are exteriorized through the vacant portal.

The obturator is removed, and the unsheathed arthroscope is inserted to view and verify the flexor tendons, sesamoid surface, and annular ligament. The slot is oriented to open directly toward the annular ligament, and the 90-degree-angle sharp blade is drawn across the fibers of the annular ligament to sever the full thickness of this structure. Arthroscopic guided free-hand division of the annular ligament using right-angled blades, radio-frequency probes, or bistoury can also be used (Figure 91-28). Hemorrhage is flushed from the cannula, which is then removed, and the tendon sheath is flushed before the skin incision is closed. When additional flexor tendon or sheath lesions need to be addressed, transecting the annular ligament before débriding other lesions improves maneuverability.

Tendon Débridement

Linear tears or clefts within the DDF tendon, and occasionally the SDF tendon, present special problems in repair, with most requiring débridement and some requiring suture.[97,98,102] Ultrasonographic examination is not sensitive in detecting linear clefts in the tendon structure. Any ultrasonographic suggestion of echolucencies within the palmar or plantar third of the surface of the flexor tendons is highly suspicious, and this region should be carefully assessed during tenoscopic exploration. The linear clefts can penetrate a variable distance into the substance of the tendon.

The treatment of choice is tenoscopic débridement (Figure 91-29). Débridement has proved superior to suture repair following open surgical approaches.[94] Tears in the DDF tendon can extend 4 to 10 cm in length. They often involve the DDF tendon from the level of the apex of the proximal sesamoid bones and extend distal to the mid-portion of the proximal phalanx. The depth of the linear cleft varies from penetration to the center of the DDF tendon to more superficial fiber erosion. Trimming of exposed tendon fibers can be accomplished using a combination of biopsy punch rongeurs and motorized resectors with both side and forward aperture, which are also effective in trimming epitenal and tendon fiber damage. The aim should be a relatively smooth tendon surface. Short linear tears in the DDF tendon generally have a good prognosis, however, long tears (more than 4 cm) are more difficult to return to function by débridement.

Tears of the manica flexoria of the SDF tendon can develop acutely and result in lameness and severe digital sheath

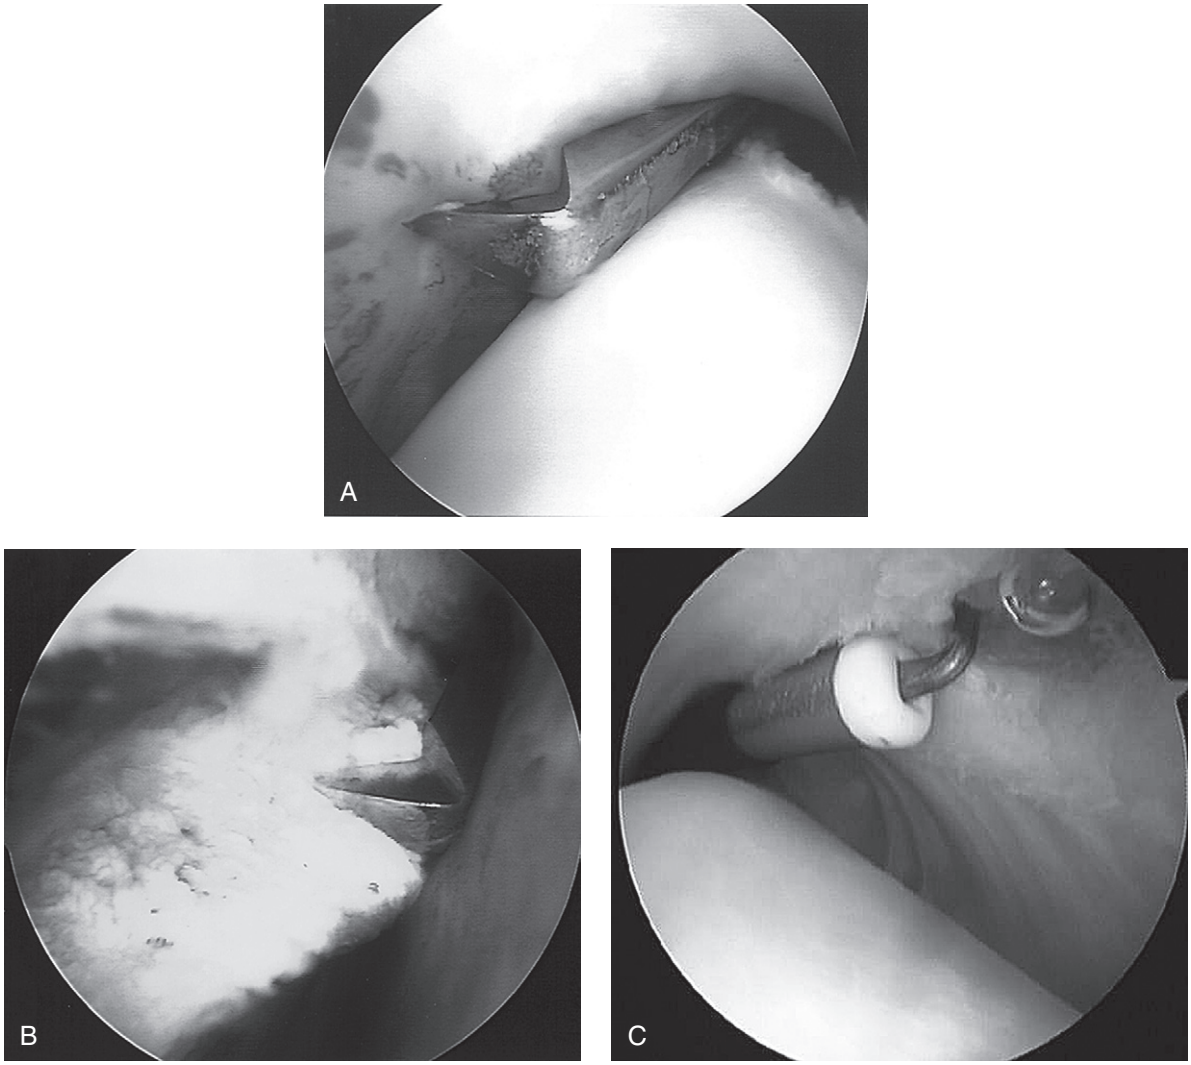

Figure 91-28. Tenoscopically guided free-hand transection of the annular ligament. **A** and **B,** The right-angled blade from the slotted cannula kit can be used free-hand if the MCP canal is not excessively tight. **C,** The 90-degree hook radiofrequency probe provides a clean and more precise cut.

swelling. Incidence varies among countries and sports activity; however, treatment by tenoscopic débridement is often curative. Most manica tears develop along the medial attachment of the SDF tendon and the manica recoils laterally (Figure 91-30). Resection of the torn portion is required. This can be accomplished by biopsy rongeur resection of the torn portion or by using an additional instrument portal to allow retraction of the mobile end of the torn portion of the manica and resection along the lateral attachment to the SDF tendon. Occasionally a thin band of the manica persists intact, and this should be converted to a complete tear and resected.

Postoperative Management

Hyaluronan (20 to 40 mg) can be injected into the tendon sheath at the time of wound closure or later at suture removal. Research in horses and experimental animals indicates hyaluronan can reduce the formation and re-formation of tendon adhesions in the sheath area and can enhance intrinsic tendon healing.[103] The incidence of synovial fistulas associated with the extensive skin incision in the original description of annular ligament transection makes the smaller exposure and the use of tenoscopy attractive alternatives. Nevertheless, the maintenance of a firm bandage with careful changes and sterile nonadhesive padding is important when walking exercise is initiated before suture removal. The limb is usually bandaged for 3 to 4 weeks after surgery. Although extensive tendon synovial mass and adhesion resection can be painful postoperatively, the majority of horses with simple annular ligament section do not require extensive analgesia.

Stall confinement without exercise is recommended initially, but hand-walking should be instituted after 5 days and the time period should be increased rapidly. Long periods of walking exercise are particularly helpful if tendon adhesions were present at surgery. If adhesiolysis was performed at surgery, follow-up injections of hyaluronan are recommended 2 and 5 weeks postoperatively.

Prognosis

Tenoscopic mass removal and annular ligament division in 25 horses followed for 6 to 68 months revealed cosmetically acceptable results in 22 of the horses. Lameness resolved in 18 of the 25 horses (72%).[92] The poorest response was evident in

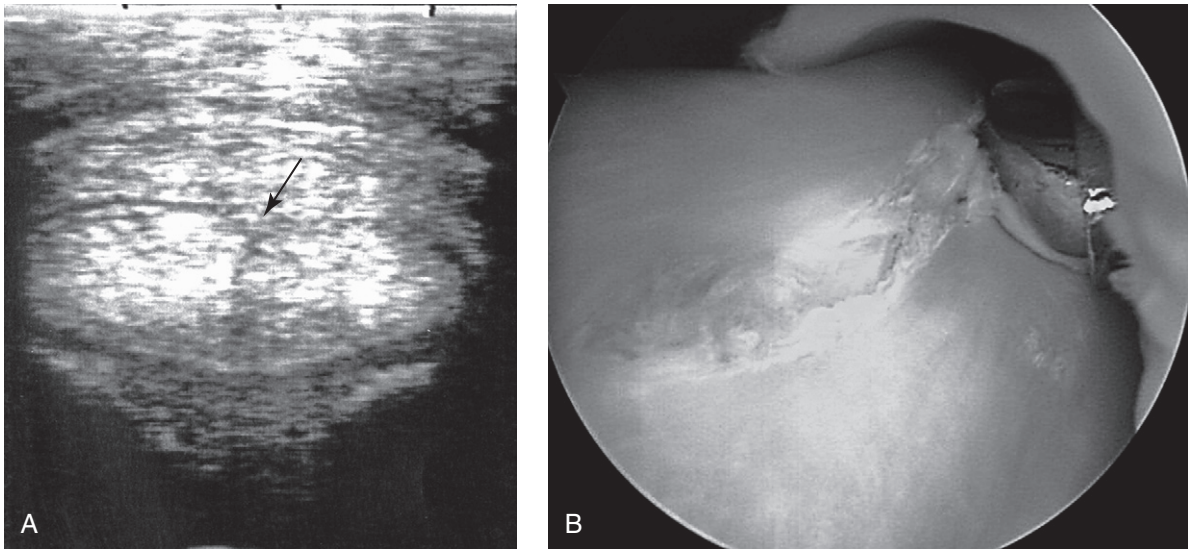

Figure 91-29. Deep digital flexor (DDF) tendon linear tears. **A,** Ultrasonographic image of the DDF tendon with a suspicious echolucency on the palmar surface of the tendon *(arrow)*. **B,** Tenoscopic trimming of the linear cleft in the deep digital flexor.

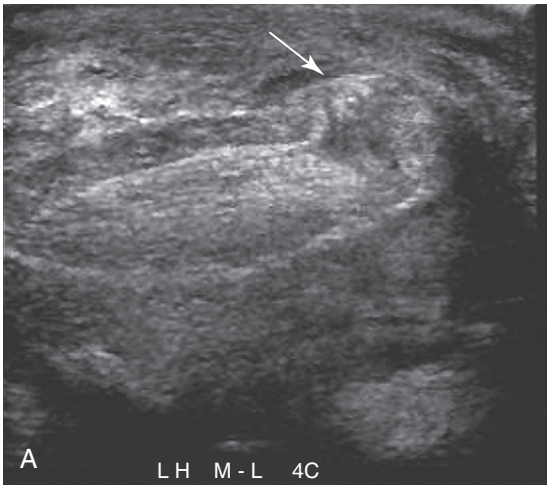

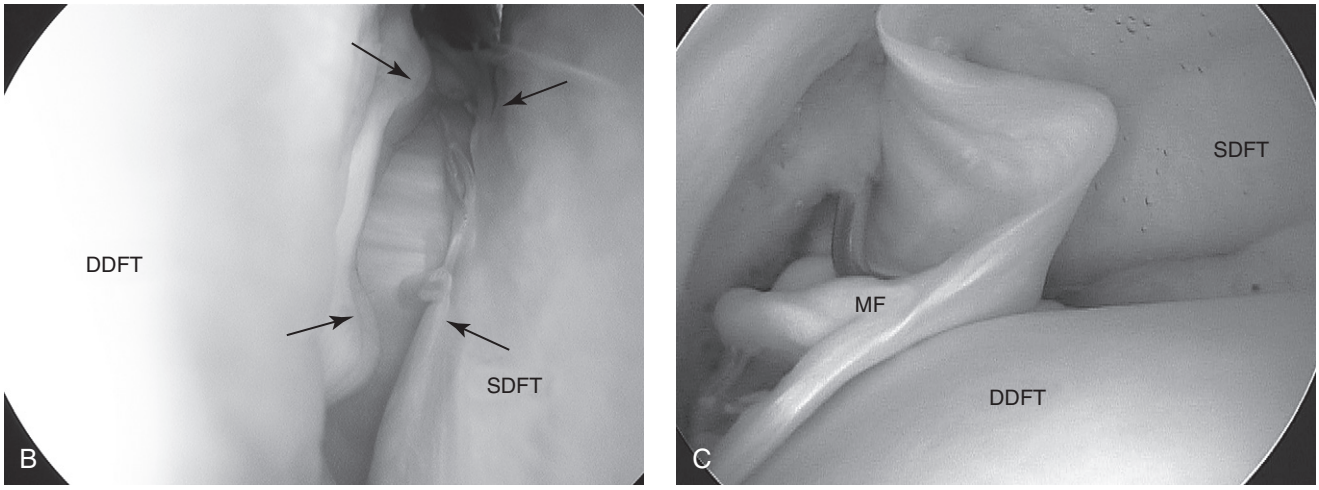

Figure 91-30. Torn manica flexoria of the SDF tendon *(SDFT)*. **A,** Ultrasonographic appearance showing the retracted mass *(arrow)* alongside the DDF tendon *(DDFT)*. **B,** Tear along the medial side of the manica *(arrows)*. **C,** Free portion of manica *(MF)* tear.

two horses with concurrent tendinitis in the region of the digital sheath. The cosmetic outcome was inversely related to the preoperative duration of signs and the thickness of the annular ligament. In addition, a longer history of symptoms led to a thicker annular ligament on preoperative ultrasonography. In a larger series of 76 cases having tenoscopy for nonseptic conditions of the digital sheath, tears of the manica flexoria were found in 23, and most had a favorable outcome.[102] Marginal tears of the DDF tendon, marked preoperative distention, and open surgical repair of deep digital flexor lesions were associated with reduced levels of postoperative performance. Marginal tears were associated with postoperative lameness, and long tears were associated with a reduced performance level compared with short tears.[102]

Simple constrictive syndromes as a result of a wound, desmitis of the annular ligament, or chronic fibrosing synovitis of the tendon sheath have a good prognosis for return to work after sectioning of the annular ligament. The outlook is guarded where extensive tendon adhesions are resected, because these cases often have residual obliteration of the tendon sheath cavity with tendon tie-down in the proximal and distal limits of the sheath. Additionally, long linear tears of the DDFT have a guarded prognosis for recovery of function.[98,102]

Constriction caused by tendinitis of the flexors in the MCP canal is readily relieved by annular ligament division; however, return to work is governed by the poorly healing bowed tendon. A guarded prognosis is common, and extended periods of measured increases in activity are recommended. Follow-up ultrasonograms are useful to evaluate the repair of tendon lesions, particularly where core lesions were injected at the time of annular ligament transection.

CHAPTER 92

Third Metacarpal and Metatarsal Bones

Dean W. Richardson

ANATOMY

The third metacarpal (MTIII) and third metatarsal (MTIII) bones are important and vulnerable elements of the forelimbs and hindlimbs, respectively. The small metacarpal and metarsal bones (splint bones, MC/MT II and IV) are often termed *vestigial*, but both MCII and MTII have major weight-bearing functions, and MCIV and MTIV serve as sites for important carpal and tarsal ligamentous insertions (see Chapter 93). MTIII is slightly longer and typically more round in cross section than MCIII. The cross section of MCIII changes dramatically in response to increased loading as the horse ages and trains.

There is little soft tissue coverage of MCIII/MTIII except for their palmar/plantar aspects where the superficial and deep digital flexor tendons, accessory (check) ligament of the deep digital flexor and the suspensory (interosseous) ligament are located. The suspensory ligament originates in a broad attachment on the proximal palmar/plantar aspect of the bones. The soft tissues in the proximal palmar/plantar metacarpal and metatarsal regions also are invested in a retinacular sheath.

In the forelimb, the major neurovascular structures course along the length of the metacarpus both medially and laterally just dorsal to the flexor tendons. In the hindlimb, the great metatarsal (dorsal metatarsal III) artery's location between MTIII and MTIV make it particularly vulnerable to accidental or surgical injury.

FRACTURES OF THE THIRD METACARPAL AND METATARSAL BONE

Fractures of the MCIII/MTIII are common long bone injuries of athletic horses. These are the most intensely loaded bones of the appendicular skeleton and therefore vulnerable to single-event catastrophic failures, as well as repetitive cyclic fatigue injuries. The most common site of major fracture of MCIII/MTIII is in the distal articulation. Repetitive loading during intensive exercise leads to focal accumulated injury in the parasagittal groove region that eventually results in complete fracture.[1,2] MCIII/MTIII also are common sites of injury because of external trauma, such as kicks.

Lateral Condylar Fractures

Vertical fractures in the sagittal plane occur in the distal condyle of MCIII/MTIII, predominantly in young racehorses either during fast work or a race (Figure 92-1). In Thoroughbreds, MCIII fractures are at least twice as common as MTIII fractures, but in Standardbreds, the ratio of forelimb to hindlimb fractures is nearly equal.[3-5] There is not a large difference in prevalence between left and right forelimb fractures, but fractures

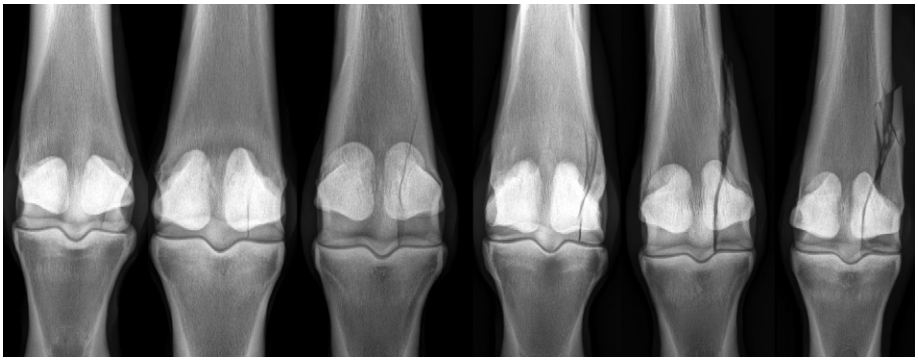

Figure 92-1. Lateral condylar fractures are vertical, occur in the sagittal plane, and range from faint, short linear cracks to complete displaced fractures with extensive comminution.

involving the right MCIII are more likely to be displaced than those in the left.

Clinical Signs

Clinical signs of lateral condylar fractures are typically straightforward, but incomplete fractures involving only the distal few centimeters of the condyle may present a diagnostic challenge. Horses may have a history of metacarpo/metatarsophalangeal (MCP/MTP) lameness preceding the onset of a more severe lameness; however, the most typical presentation is an acute onset of severe lameness after intense exercise or a race. The MCP/MTP joint almost always develops effusion, and there is overt pain on manipulation of this region. The degree of lameness is not well correlated with the amount of fracture displacement; many horses with nondisplaced fractures are extremely lame, whereas some horses with large, displaced fractures walk fairly well on the fractured limb.

Approximately 85% of all condylar fractures involve the lateral condyle.[3,4,6] In the forelimbs, lateral fractures are 7 times more common than medial fractures, and in the hindlimbs, lateral fractures are about 3 to 4 times more common.

Nearly all lateral condylar fractures propagate from the mid to midaxial portion of the lateral condyle for a few centimeters in a sagittal plane and then proximolaterally toward the lateral cortex. There is variation of their height, but the typical fracture breaks out 1 to 3 cm above the physeal scar. Unlike medial condylar fractures, lateral condylar fractures only rarely propagate in a spiral plane or course centrally through the diaphysis.

Diagnosis

Radiographic diagnosis is not difficult, provided good-quality radiographs are obtained. An underexposed dorsopalmar/dorsoplantar (DP) projection or a radiograph in which the distal margins of the proximal sesamoid bones are superimposed over the MCP/MTP joint surface may not be diagnostic. This is avoided by taking the routine DP view in a slightly proximal to distal direction. Many horses have pre-existing degenerative disease involving the distal palmar/plantar condyle adjacent to the base of the ipsilateral proximal sesamoid bone, so an additional radiographic projection further defining this region should be taken. A silhouetting of the distal palmar/plantar condyle can be obtained in slight flexion with the beam angled proximally[7] or by putting the joint in more flexion with the limb pulled forward and using a horizontal beam. Such a radiographic projection should be used in all displaced condylar fractures because comminution along the fracture line is commonly identified in this location (Figure 92-2). As newer imaging modalities are used, such as computed tomography (CT) and magnetic resonance (MRI), earlier recognition of the repetitive stress injury in this location that predisposes to condylar fractures should be feasible. Scintigraphy is probably the best means of early identification of condylar injuries.

First Aid

First aid for a lateral condylar fracture includes compression bandaging, nonsteroidal anti-inflammatories, and absolute rest until definitive therapy is undertaken. The expense of cast coaptation is not justified because very few lateral condylar fractures propagate if the horse is kept quiet in a heavy bandage. Manufactured splints and boots also are not indicated.

Surgical Management

Surgical management of lateral condylar fractures involves compression of the fracture with cortex screws applied in lag fashion. The screws prevent proximal propagation of the fracture and enhance articular healing, therefore minimizing the potential

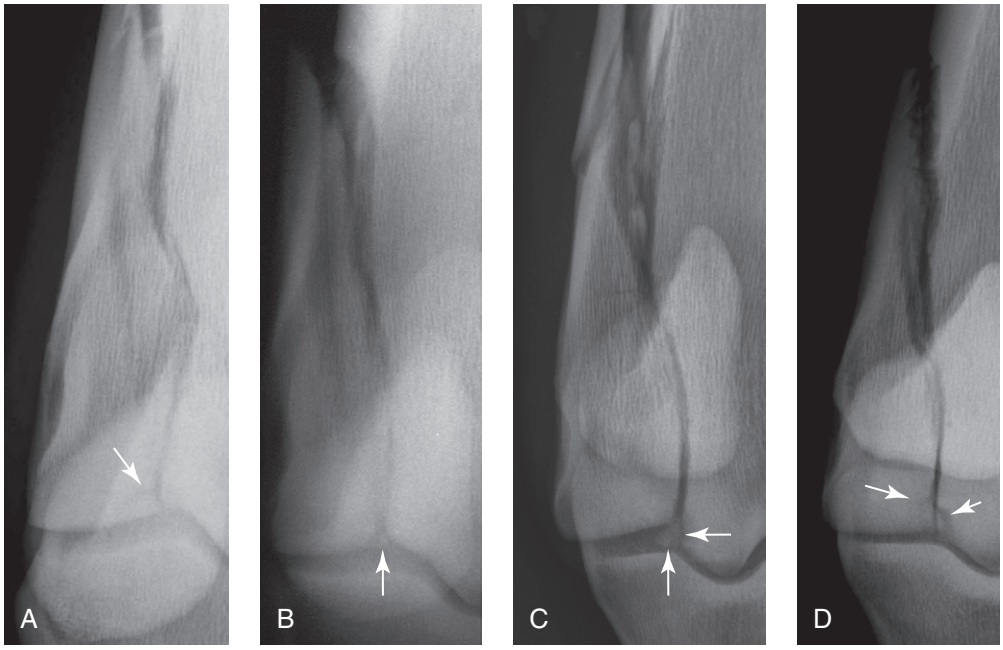

Figure 92-2. For preoperative evaluation of the distal palmar/plantar surface of the MCIII/MTIII, a 120-degree tangential view **(A, B)** or a flexed horizontal beam DP view **(C, D)** should be taken. *Arrows* indicate typical appearance of comminution along that margin that may be very difficult to see on a standard DP projection.

for developing degenerative joint disease. Surgical treatment is essential for displaced fractures because it provides anatomic reduction of the articular surface. Internal fixation renders the horse immediately more comfortable on the limb, thereby avoiding laminitis in the contralateral limb. The disadvantages of surgery are those attendant on all general anesthetic procedures as well as the risk of infection and surgical error. However, condylar fractures can heal successfully without internal fixation, and a conservative approach is a reasonable consideration in nondisplaced fractures where there are economic limitations.

NONDISPLACED FRACTURES

Nondisplaced fractures are repaired with screws applied in lag fashion using minimal soft tissue dissection. The site of screw insertion is determined by topographic landmarks and intraoperative radiography or fluoroscopy. Radiopaque skin markers, such as sterile skin staples, can be used preoperatively to select the sites for screw insertion. Alternatively, needles or other markers can be used intraoperatively. The distal screw is placed as centrally as possible in the lateral condylar fossa. This site can be accurately estimated by taking the midpoint of an imaginary line drawn between the proximal palmar prominence of P1 and the most dorsal aspect of the lateral condyle, both readily palpable landmarks. A stab incision is made down to the surface of the bone in this location and parallel with the collateral ligament fibers to minimize injury to them. The surgeon can feel the scalpel slide into the fossa, confirming accurate placement of the incision. Standard lag technique is used (see Chapter 76). As many additional screws as needed are placed at 15- to 20-mm intervals more proximad. Blindly placing a screw too close (less than 20 mm) to the proximal end of the fracture increases of the risk of splitting the narrow end or entering a fracture line. Correct positioning of the drill during the procedure is ensured through intraoperative radiography/fluoroscopy (Figure 92-3). Some surgeons prefer to place small-diameter (2 mm) marker bits prior to placing screws; the position and direction of the drill bit allows the surgeon to adjust drill/screw position. With either technique, two perpendicular views should be taken to check positioning in the dorsopalmar and lateromedial planes. Either 4.5- or 5.5-mm cortex screws can be used. It remains to be proved whether the larger screws yield improved results. Screw failure is rarely a problem in nondisplaced, noncomminuted fractures. The 4.5-mm screws have the advantage of being replaceable with a larger cortex screw if the bone threads are inadvertently stripped.

The majority of lateral condylar fractures can be treated with two screws. A few propagate proximad enough to justify more screws but usually the more proximal portion of the fragment is quite narrow in its dorsopalmar thickness, and accurate positioning of the screw in the center of that part of the fragment is difficult. There is little evidence to suggest that placing a third or fourth screw in the longer fractures results in a better outcome, particularly in nondisplaced fractures.

The most common technical errors in lag screw fixation of nondisplaced condylar fractures include inadequate compression and incorrect drill/screw placement. The former can be avoided by drilling the thread hole fully through the far cortex and being certain to completely tap the far cortex. The chances of incorrect proximal to distal aiming of the drill can be minimized by predraping positioning of the fractured bone parallel to the ground. Most horses have some degree of external rotation of the limb (especially hind limbs) when they are in lateral recumbency. The surgeon must account for this or the drill will be directed toward the palmar/plantar articular surfaces. Palpation of the medial and lateral wings of the proximal phalanx provides a good topographical key for the surgeon to direct the drill in a true lateral to medial direction.

Headless, variable-taper screws have been used successfully,[8] but their only advantage is the absence of the head and problems with a screw head in this location have never been documented. The headless screws provide less compression than standard cortex screws, have variable compression according to fragment thickness, and lack the versatility of standard lag technique, especially in displaced fractures.[9,10]

Unless there is a strong economic reason not to do so, arthroscopic examination of the dorsal and palmar/plantar

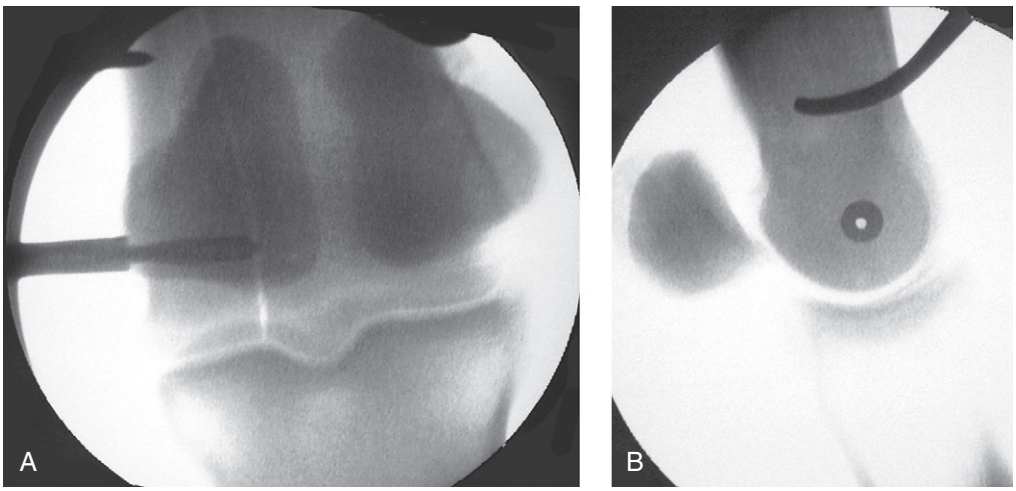

Figure 92-3. Intraoperative imaging is an essential element of consistently successful lag screw repair of condylar fractures. Imaging should *always* be done in two planes. A fluoroscopic DP view **(A)** showing the correct length of the glide hole and the lateral view **(B)** taken with the insert sleeve in place confirms that the hole's dorsopalmar orientation is correct. The distal screw is usually positioned in the condylar fossa to maximize compression at the articular surface.

joint should be done to confirm fracture reduction and characterize pre-existing or fracture-associated cartilage damage at the time of surgery.

DISPLACED FRACTURES

Similar lag technique and positioning of the screws is used for treatment of a displaced fracture. Unlike nondisplaced fractures, displaced fractures demand accurate anatomic reduction and often exhibit more severe injury to the joint surfaces. There is little room for error in the reduction of a displaced fracture in an athletic horse. Complete radiographic obliteration of the entire fracture line does not always occur, even with accurate reduction and screw placement and correct technique. This is caused by fibrin lodged within the fracture plane or bone loss along its margins. However, if the articular surfaces are aligned, the horse has a good chance to heal with minimal arthritic change. If there is a step on the major weight-bearing surface of the condyle after reduction, degenerative joint disease is likely. A significant malalignment of the condyle also puts very high bending and shear loads on the screws that may lead to bending or breaking of these implants.

The best technique for reduction of displaced lateral condylar fractures in most cases is by arthroscopic guidance.[11] To tentatively hold the reduction, the involved joint is dorsiflexed, and large pointed bone-reduction forceps are applied through the intact skin at about the level of the physeal scar.

The 4.5 mm glide hole is subsequently drilled through the fracture fragment using radiographic/fluoroscopic guidance. The glide hole should be drilled exactly to the fracture plane; this may be facilitated by temporarily removing the clamp so that it is possible to feel the drill enter the fracture plane. The insert drill sleeve and a 3-mm pin are placed in the fragment to use as a "handle." The arthroscope is then introduced into the proximal dorsolateral joint pouch. The fetlock can be flexed, extended, rotated and valgus/varus stresses can be applied until articular alignment is perfect. The pin inside the centering drill sleeve can be used for additional manipulation (Figure 92-4). When reduction is judged perfect, the reduction forceps are firmly reset and the remainder of the lag screw procedure is performed. The screw is inserted but not tightened. The arthroscope is repositioned and the articular compression and alignment are checked as the screw is firmly tightened. The palmar/plantar aspect of the joint is then examined arthroscopically through a second stab incision. Many comminuted fragments at the distal margin of the MCIII/MTIII are immobilized by the compression of the major fragment. If there are loose fragments, they can be removed under arthroscopic guidance. This is a difficult arthroscopic maneuver in some horses suffering from chronic arthritis and capsular fibrosis. The instrument portal must be carefully positioned at the base of the lateral proximal sesamoid bone and instruments (curettes/picks/probes) with angled ends are invaluable aids.

Occasionally, the fragment cannot be aligned properly because of interposed comminuted fragments. The pin and insert sleeve can be used to displace the main fragment laterally, allowing insertion of the arthroscope and cannula into the fracture plane. A dorsal instrument portal is positioned exactly over the fracture plane and the palmar fragments are retrieved. Obviously, this is done only in a displaced fracture.

If arthroscopic reduction is not feasible for some reason, displaced fractures should have enough of the fracture line exposed through an open approach to allow the surgeon to verify that reduction is accurate. In some cases this means a 2- to 3-cm incision over the proximal tip of the condylar fragment. In rare instances, it might mean a longitudinal arthrotomy along the dorsal fracture plane extending nearly to the proximal phalanx, but this should be a very unusual occurrence. It is worth noting that in many horses accurate reduction seems to get more difficult as the exposure is increased, presumably because more attachments are disrupted. It is always worthwhile trying to achieve accurate reduction using minimal exposure.

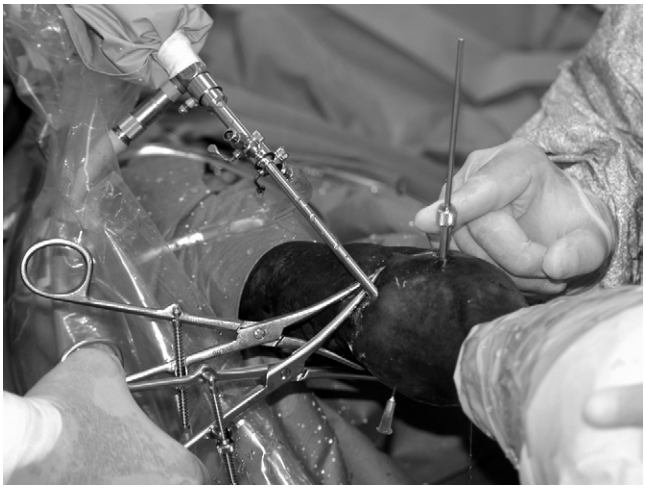

Figure 92-4. Arthroscopically assisted repair of a displaced lateral condylar fracture can be performed by drilling the glide hole and placing the insert sleeve before placing the scope. Fracture reduction is checked with the scope as the fragment is manipulated by flexion/extension/rotation of the hoof and manipulation of the fragment using the insert sleeve. Pointed reduction clamps are used to hold the fragment after reduction is achieved.

The majority of displaced lateral condylar fractures can be successfully treated with two distal screws, one in the epicondylar fossa and another 18 to 20 mm proximal to it (Figure 92-5). The fracture narrows quickly as it propagates proximad and comminution, sometimes occult, is common proximal to the physeal scar. More severe and displaced condylar fractures require more stability, so 5.5 mm screws should be considered. Placing three screws in a triangular pattern within the condyle also can increase the strength of the repair (Figure 92-6).

Since arthroscopic examination of the entire joint has become common, it has been recognized that injury of the proximal sesamoid bones is often associated with condylar fractures. Most proximal sesamoid bones damage involves varying degrees of erosions of articular cartilage, but more serious injuries also occur. Axial proximal sesamoid fractures are complications of displaced condylar fractures that should be identified preoperatively, because they are associated with a very unfavorable prognosis. If an axial sesamoid fracture is present, the condylar fracture should be repaired with the understanding that the horse has virtually no chance of becoming an athlete or resuming athletic activities. Axial proximal sesamoid fractures are crescent shaped and represent an avulsion of the axial margin of the lateral proximal sesamoid bone by the intersesamoidean ligament (Figure 92-7). With large displaced fractures, the fragment can be fixed with one or two 3.5-mm cortex screws, but primary fetlock arthrodesis is probably a better option. Most axial proximal sesamoid fractures have a slender rim of

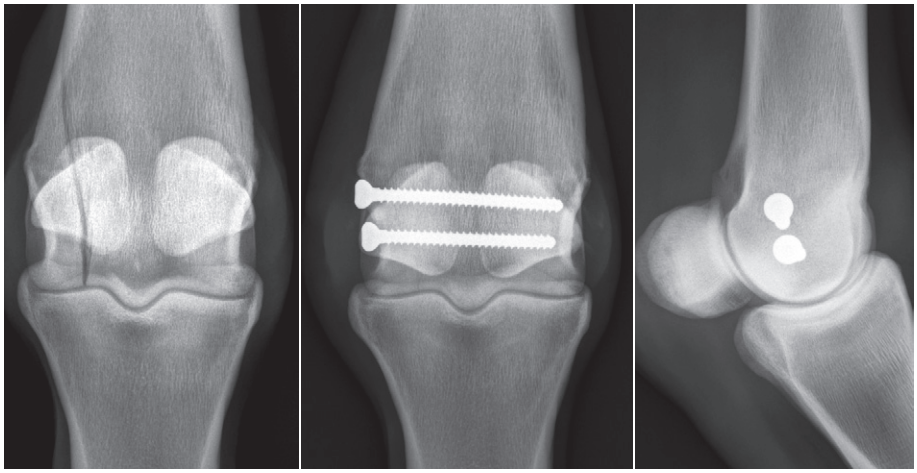

Figure 92-5. Nearly all lateral condylar fractures can be repaired with two cortex screws placed in lag fashion, one in the epicondylar fossa and the other near the physeal scar.

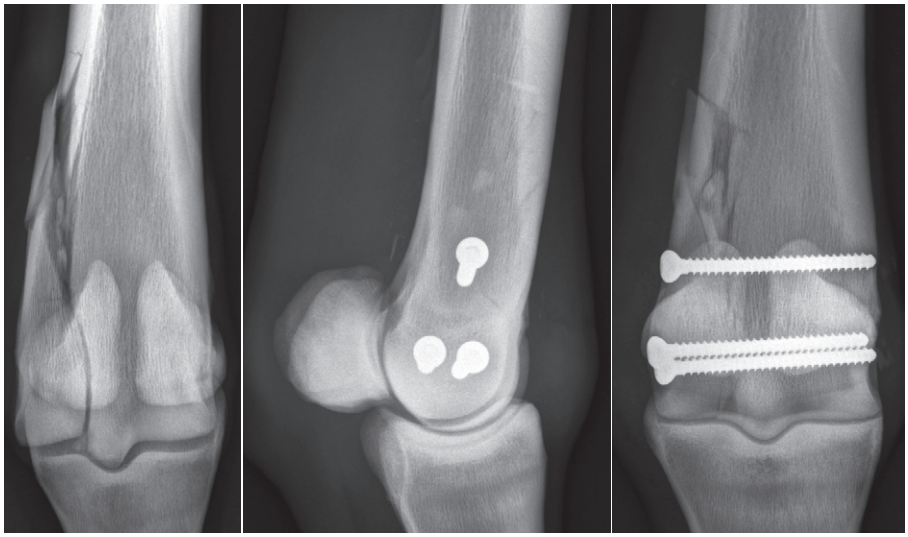

Figure 92-6. Badly damaged and displaced lateral fractures are inherently less stable and the screws are subjected to more bending loads. Both 5.5-mm screws and extra screws in the distal condyle should be considered to enhance stability. No effort is made to reconstruct the comminuted fragments at the proximal end of lateral condylar fractures.

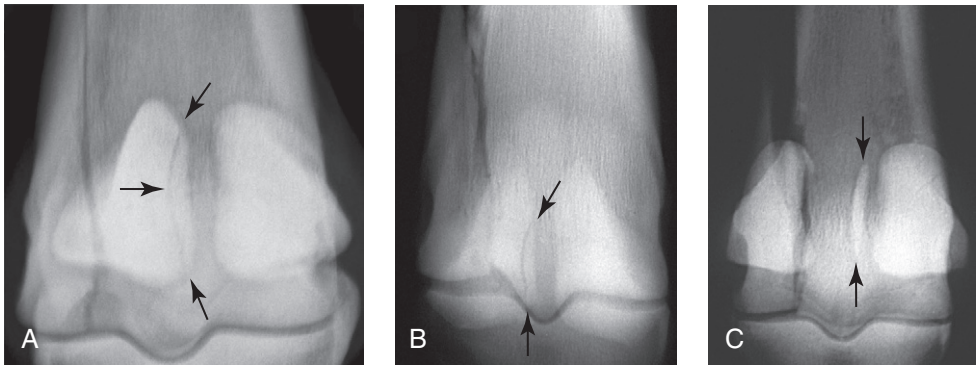

Figure 92-7. Axial sesamoid fractures associated with displaced lateral condylar fractures are a strong indication of major damage to the MCP joint. They can be seen on standard DP **(A)** and flexed DP **(B)** projections. **C,** If the fragment is completely separated *(arrowheads),* the best option is probably MCP arthrodesis.

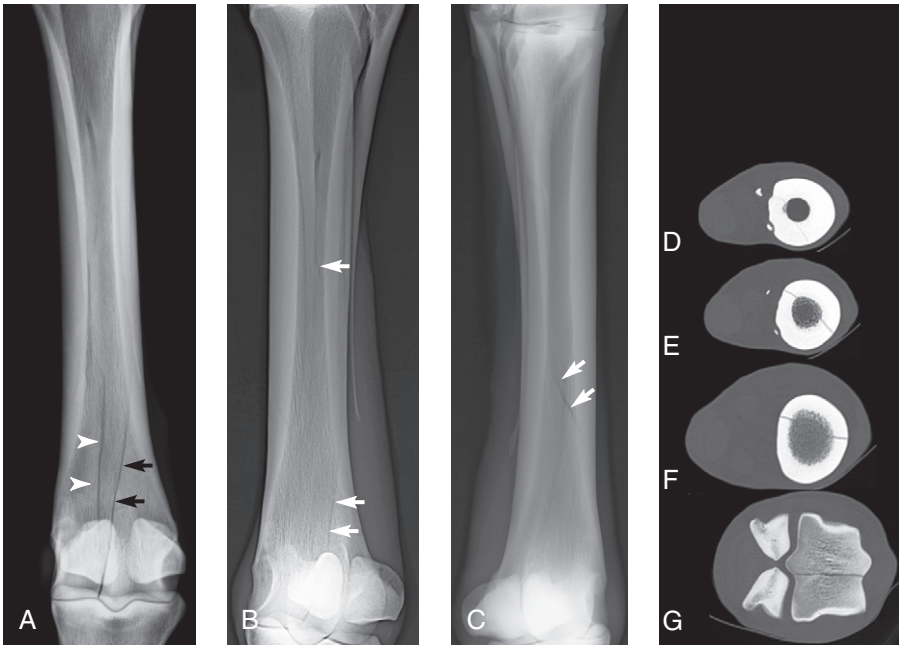

Figure 92-8. Dorsopalmar **(A),** DLPMO **(B),** and DMPLO **(C)** projections of a spiraling medial condylar fracture. Although the standard views can provide an adequate assessment of the fracture configuration, transverse CT images (proximal **[D]** to distal **[G]**) are even more helpful to the surgeon.

articular surface involved, but some fractures occur behind the articular surface and can be localized only with intraoperative radiographs or advanced imaging techniques, such as CT or MRI. Additional information on the management of proximal sesamoid fractures can be found in Chapter 91.

Nearly all lateral condylar fractures can be successfully treated with screws alone, but on occasion, lateral condylar fractures of MCIII also have diaphyseal spiral or oblique components that demand they be treated with more extensive fixation, as described later for medial condylar fractures.

Aftercare

Aftercare is discussed for all condylar fractures later.

Medial Condylar Fractures

Medial condylar fractures are seen in both the forelimb and hind limb of racehorses. Horses typically develop severe lameness immediately after exercise or are lame a few hours afterward. There is rarely significant soft-tissue swelling unless there is displacement of the fracture. In most cases, the site of the lameness is readily identified by manipulation of the MCP/MTP joint, and dorsopalmar/plantar radiographs clearly reveal the medial condylar fracture. Preoperative radiographs of any medial condylar fracture should include a full series of projections over the entire length of MCIII/MTIII. Medial fractures are quite different in terms of configuration, treatment, and complications. They are *not* the mirror image of a lateral fracture. Medial fractures nearly always propagate toward the axial aspect of the MCIII/MTIII, either spiraling up the diaphysis (Figure 92-8) or remaining nearly sagittal to the mid-diaphysis, where oblique fractures can later develop (Figure 92-9). Medial condylar fractures of MTIII are particularly prone to catastrophic failure with or without screw fixation, especially when the horse stands following general anesthesia. The risk extends for several weeks after repair.[12]

Figure 92-9. Medial condylar fractures of the third metatarsal that have an oblique diaphyseal component *(arrow)* are extremely dangerous fractures, prone to catastrophic dehiscence.

Treatment

Although internal fixation with multiple screws applied in lag fashion has been used successfully to treat many medial condylar fractures,[13] plating techniques are probably the most consistently successful technique. Screws alone are not optimal for any fracture with a known oblique diaphyseal component. If an oblique or transverse diaphyseal fracture is identified in the preoperative radiographs, a plating technique should definitely

Figure 92-10. Open exposure of a spiraling metatarsal fracture with the fracture line *(arrows)* "disappearing" in the mid diaphysis. The simplest method of defining the configuration of a medial condylar fracture in the diaphyseal region is to make an open approach with periosteal elevation. Implants can subsequently be placed accurately more easily.

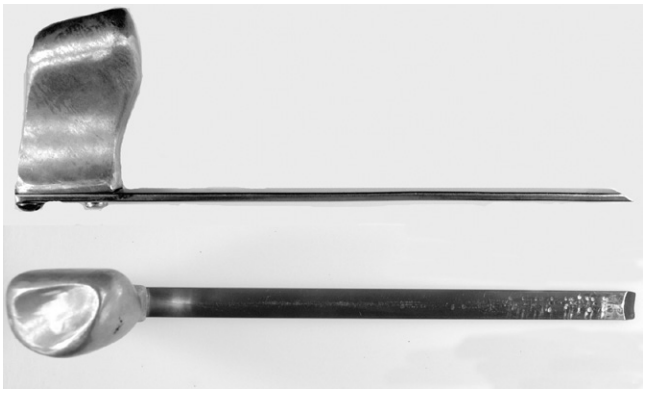

Figure 92-11. A custom-made plate passing device manufactured by sharpening the end of an old plate or by using a piece of steel stock of similar dimension. A solid handle is necessary to force it through the subcutaneous tissues.

be used. In hospitals (or horses) without options for controlled anesthetic recovery (e.g., pool or sling), *standing* screw fixation of the distal portion of the fracture has been shown to be surprisingly successful.[14] Preoperative CT imaging to evaluate fracture configuration and help optimize internal fixation may improve outcome, but a diaphyseal MTIII fracture of any configuration always poses a very serious risk.

OPEN APPROACH

The plate and screws can be placed from either the medial or lateral side, but the lateral approach has advanatages. The fragments are equal enough in size and the bone is so dense that adequate fixation can be obtained with lag screws even if the threads are in the smaller fragment. The advantages of a dorsolateral approach are that the operated limb is uppermost and a lateral plate is easier to remove under local anesthesia in the standing horse after the fracture has healed. The incision is made in one layer down to the level of the bone surface. The periosteum is elevated, and the skin and underlying subcutaneous tissues are retracted together. When the surface of the bone is exposed, the fracture line or lines are clearly identifed (Figure 92-10). The incision is continued distad to the level of the joint capsule, but the capsule is not incised. The distal two screws are placed through stab incisions using radiographic control similar to nondisplaced lateral condylar fractures. If the limb is positioned uppermost, the glide hole must traverse fracture plane and the thread holes engage the medial condylar fragment. This is ensured with intraoperative radiographs or fluoroscopy. A broad dynamic compression plate (DCP) or locking compression plate (LCP) is then positioned on the lateral aspect of the bone extending from just above the second screw to the most proximal portion of the bone. Typically 10- to 12-hole plates are used in MCIII and 12- to 14-hole in MTIII. It is possible to spirally contour the plate if the specific configuration of the fracture is evident, but a straight plate can usually be safely applied in these nondisplaced fractures. Exposure of the diaphyseal bone surface allows accurate placement of additional screws across the fracture plane and centrally within the fracture fragment. Either 4.5- or 5.5-mm cortex screws are used. Although anatomic placement of screws through the plate is straightforward, inadvertent injury to the suspensory ligament, splint bones, or both can occur. Obliquely directed screws or dorsopalmarly directed screws are drilled with care to avoid penetrating these structures, especially when using the 4-mm drill bit needed for the thread hole with 5.5-mm screws. Closure of the incision is routine if initially it was made in one plane. A simple-interrupted, cruciate, or simple-continuous pattern of synthetic absorbable suture material followed by routine skin closure is adequate. If special recovery systems (pool, sling) are not available, a full-length hindlimb cast should be considered for metatarsal fractures. Half-limb casts should not be used for metatarsal fractures. Forelimb medial condylar fractures are usually recovered in a full-limb Robert Jones bandage.

LESS-INVASIVE APPROACH

An alternative technique is to place the bone plate through a minimally invasive technique. This is particularly straightforward if there is no obvious proximal spiraling of the fracture. A 2-cm incision is made adjacent to the common digital extensor tendon at the level of the proximal MCIII/MTIII. A (previously used) broad DCP with a sharpened end attached to a handle (Figure 92-11) can be used to prepare a subcutaneous tunnel for the plate. After the subcutaneous (*not* subperiosteal) tunnel is made, a roughly contoured 10- or 12-hole broad 4.5-mm LCP is slid down along the bone (Figure 92-12). The "fit" of the plate is assessed palpably and with fluoroscopy. The plate is recontoured as needed and replaced. The holes in the plate can be easily palpated distally. Stab incisions are made over holes and screws are inserted routinely. After two screws are inserted, a plate of the same length is placed on the surface of the skin and incisions are made through that plate's holes. The remaining screws are inserted in routine fashion (Figure 92-13). The distal few screws in the plate may be placed in lag fashion if the fracture plane is radiographically visible at that level. Fluoroscopy or intraoperative radiography is used to check implant positioning. One or two skin sutures are used to close each stab incision.

Specific cautions with this technique include the need to avoid the contralateral MCIV/MTIV with the drill bits and screws, the difficulty in accurately measuring the depth of holes, and the need to check carefully that each screw is fully inserted into the plate. Although there is a possibility of inadvertently

placing a screw in a fracture line, the overall stability that the plate provides over the length of the bone appears to be adequate to prevent catastrophic dehiscence of the fracture. All possible precautions should be taken during recovery from anesthesia, especially in metatarsal fractures.

As mentioned earlier, another option for the treatment of high-risk condylar fractures is to place screws (typically two) to repair the distal portion of the fracture in the standing horse under sedation and local anesthesia. Although this still has a risk of catastrophic failure after fixation, the higher risk of fracture during recovery from general anesthesia can be avoided.

Aftercare

Convalescence of horses with condylar fractures involves stall rest with strictly controlled exercise for at least 2 months. Some turnout in a small paddock is allowed in the third month, and the patients usually returned to regular exercise in the fourth to fifth month. Displaced fractures or those with articular comminution are rested longer. The average time from surgery to first racing start is approximately 11 months. Although there is no uniform agreement on the need to remove screws from condylar fractures, many horses have returned to racing without screw removal, and most horses do not have screws removed after repair of typical fractures. When fractures extend into the mid-diaphyseal region, the screws are more likely to cause pain when horses return to intensive exercise. Therefore, diaphyseal screws are removed 3 to 4 months after surgery, usually with the horse under sedation and local anesthesia. The limb is clipped and scrubbed for routine aseptic surgery, and a number of sterile skin staples are placed over the heads of the screws to be removed. Radiographs are taken to facilitate exact placement of the stab incisions over the screws if they cannot be clearly palpated. Closure of the stab incisions is routine. After screw removal, the horse is continued in a walking and jogging program for 60 to 90 days before returning to galloping exercise.

Plates should be removed in horses expected to return to athletic pursuits. Removal of plates used to treat medial condylar fractures is performed with the horse standing under detomidine sedation and local anesthesia. These plates are typically removed about 70 to 80 days following surgery. Local anesthesia with direct infiltration over the implant or by means of a regional nerve block is applied and a short incision is made over the proximal 2 cm of the plate (Figure 92-14). The most proximal screw is partially removed. A matching bone plate is placed on the skin along the plate and stab incisions made through its holes. Each screw is backed out above the skin edge but not removed. After the screws are all counted, they are removed. This helps avoid groping for a screw that has already been removed as well as to avoid trying to remove a plate that still is secured with a screw. A battery-powered drill with the screwdriver attachment is quieter and easier to use in a standing horse. A 12-mm osteotome is used to pry the plate up at its proximal end. The osteotome is left under the end of the plate and then the plate is grasped with sterile vise grips and extracted proximally. A single skin suture per screw is placed and the

Figure 92-12. The plate passer creates a subcutaneous tunnel for the plate outside of the periosteum.

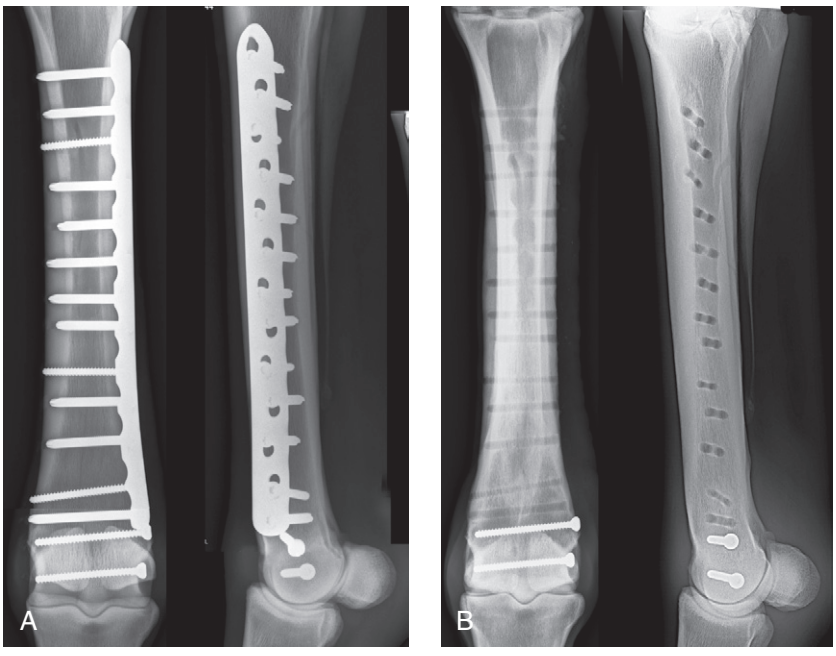

Figure 92-13. A, A medial condylar fracture repaired with distal lag screws and a subcutaneously positioned dorsolateral LCP. **B,** The plate was removed at 90 days. The lag screws are left in place.

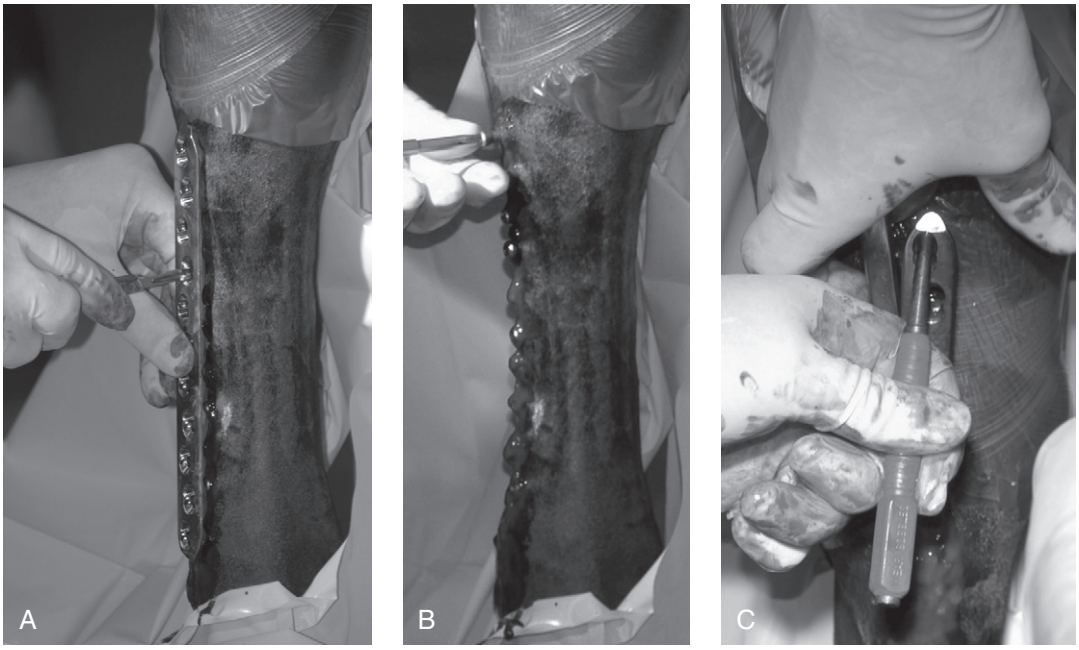

Figure 92-14. Plate removal is performed with the horse standing, using local anesthesia. **A,** A matching plate facilitates accurate stabs over the screw heads. **B,** All of the screws are partially removed. After all are loosened and counted, they are removed. **C,** A nail set and a mallet can be used to loosen the plate. If necessary, the proximal end is grasped with vise grips for removal.

larger proximal incision is closed in two layers. The horse is hand-walked for 60 days, receives paddock turnout for another month, then returns gradually to training.

Prognosis

Prognosis for condylar fractures is favorable (70% to 80% return to full function) if there is minimal pre-existing degenerative joint disease and the fracture is not displaced.[3-5] Displacement requiring open reduction of the fracture lessens the prognosis considerably, both because of the surgical trauma and because there typically is more injury to the joint surfaces (comminution, degenerative changes, proximal sesamoid bone injury, etc.). The prognosis for displaced lateral condylar fractures of MCIII is about 50% for return to racing, less if there is serious comminution or sesamoid injury. Lateral condylar fractures of MTIII have a better prognosis than those of MCIII. The prognosis for medial fractures is more variable and depends on the development of catastrophic complications. Because complications of medial condylar fractures can occur before surgery, during recovery, or even weeks afterward, by far the most important aspect of managing medial condylar fractures is to appropriately advise the owner of complications that can occur.

Diaphyseal Fractures

The most common major long bone fractured in horses is MCIII/MTIII, and diaphyseal fractures are encountered most frequently. They occur at any age and during any type of activity. Many occur as pasture accidents. There are favorable and unfavorable aspects to repairing fractures of MCIII/MTIII. Factors favoring successful repair are: (1) access and exposure of the entire diaphysis, making reduction and internal fixation feasible; (2) strong bone to which screws and plates can be affixed; and (3) the possibility of immobilization by external coaptation. Factors that do not favor repair are quite significant and include: (1) minimal soft tissue coverage, leading to many open fractures; (2) no muscles adjacent to the fracture, resulting in poor extraosseous blood supply to the fracture site; (3) sparse vascularity of the distal limb; and (4) frequent comminution, especially in older horses. Although the approach and treatment of MCIII/MTIII fractures is similar in all age horses, the chances of success are significantly greater in the younger, smaller patients.[15-17]

The diagnosis of diaphyseal MCIII/MTIII fractures is straightforward. In a frantic horse, radiography should be delayed until first aid has been administered and at least a preliminary decision has been made concerning treatment. It is particularly important not to risk a closed fracture becoming open by prolonged attempts to obtain radiographs. If the horse is unequivocally going to have definitive treatment, radiographs of an extremely unstable fracture can be taken through the external coaptation for preliminary assessment and can be repeated after the horse is anesthetized. Diaphyseal MCIII/MTIII fractures probably represent the single most important indication for appropriate external coaptation (see Chapter 17). Success or failure often hinges upon the immediate management.

Nonsurgical Management

Cast or splint coaptation as the sole treatment of displaced diaphyseal MCIII/MTIII fractures is rarely an acceptable approach. These fractures are unstable, horses almost never become comfortable with simple external coaptation, and problems in the contralateral limb develop quickly. Furthermore, the lack of soft tissue coverage over unstable cannon bone fractures may result in the fractures becoming open, even in a well-fitted cast. In young animals, even though fracture healing occurs

more quickly, cast coaptation is not the treatment of choice because permanent deformities develop rapidly in the contralateral limb and serious flexor/suspensory weakness occurs in the cast limb. Even if the fracture heals when treated in this manner, the problems associated with cast immobilization usually result in a less-than-optimal outcome.

Surgical Management

Internal fixation is the treatment of choice for diaphyseal MCIII/MTIII fractures. Although external skeletal fixation and intramedullary interlocking nails have been used, the optimal treatment remains double-plate fixation. Double plating is usually necessary in foals and always indicated in larger horses. A dorsolateral surgical approach is selected, splitting the common digital extensor tendon along its course down the bone. The skin incision is carried directly to the underlying bone down to the periosteum. The periosteum is elevated just enough along the fracture edges to allow visual control of reduction and reconstruction. Unlike in heavily muscled parts of the limb, reduction of MCIII/MTIII fractures is not usually difficult. Reduction of simple oblique or spiral fractures is maintained with large pointed reduction forceps or by insertion of strategically placed compression screws. The sites for screw insertion are selected after planning plate application. If the only practical sites for the screws will be under a plate, 3.5-mm screws that are deeply countersunk are placed to hold the reduction while the plates are applied. After reduction is secure with clamps, lag screws, or both, an aluminum template is used to help shape the two plates. Locking plates have major advantages in nearly all types of diaphyseal fractures. The plates are placed dorsolaterally and dorsomedially at 90 degrees to each other unless fracture configuration dictates otherwise. In a large adult horse, two broad plates with 5.5-mm cortex and 5-mm locking head screws are used, but in a foal, one broad and one narrow plate are adequate. The plates are staggered so screws placed perpendicularly through one plate will not interfere with those from the other. All screw holes in the plates should be used; even if a hole is directly over a fracture line. A screw can nearly always be inserted that will engage at least one cortex. Both plates should be as long as possible without involving the joints or physis. An autologous cancellous bone graft should always be used if there are any cortical defects. It is best to perform the surgery as soon as possible after the injury, because eburnation of the fragment ends occurs with delays and makes reduction difficult and the repaired fracture less stable. The tendon edges are apposed with interrupted synthetic absorbable sutures. Subcuticular and skin closure are routine.

A minimally invasive approach can also be used to repair selected diaphyseal metacarpal or metatarsal fractures.[18] For example, a severely comminuted fracture in a foal and a mildly comminuted fracture in an adult MCIII (Figure 92-15) may be spanned with two locking plates placed through stab incisions with screws inserted under fluoroscopic guidance.

The decision to place a cast versus use of a bandage on the limb depends on the horse's age, postoperative care, apparent stability of the repair, and available special recovery systems. A cast is used for protection of the repair during anesthetic recovery, but long-term protection of the repair with a cast is often undesirable because of the inevitable flexor weakness that develops. In general, foals younger than 1 year are not cast except for recovery. Casts are used in adult horses when the fixation is considered less than secure. The major complication of MCIII/MTIII fractures is infection because of the relatively poor vascularity of the region, poor soft-tissue coverage, a large metal-to-bone ratio, and the frequency of open injury. Implant failure (loosening or breakage) is possible but less of a concern if correctly sized and positioned implants are used.

Figure 92-15. Postoperative radiographic views taken at right angles to one another of a multifragment MTIII fracture in an adult horse treated with two distal cortex screws applied in lag fashion, a lateral 12-hole LCP and a dorsal 14-hole LCP. In each plate, two 4.5-mm cortex screws were used with the remainder being of the locking head type. Note the proximal single screw was placed somewhat too far plantarad.

Aftercare

The same management as described earlier is applied. In any age horse, it is safest to stage the removal of the two plates. In foals, the first plate (usually the larger/longer of the two) can often be removed at around 3 months after implantation, and the second plate can be removed 45 to 60 days later. In neonates, these times can probably be safely shortened even more. An extraperiosteally positioned plate is usually still fairly easy to remove at 4 to 5 months, but overgrowth of bone can make the removal difficult. In most cases, the plate can be removed in a minimally invasive manner, but if bone overgrows the plate, a direct incision will be needed to remove the bone with an osteotome and mallet. In adult horses, staging also is recommended, although the earliest plate removal is likely to be around 4 months or so after implantation. As described earlier, standing removal should be strongly considered in adult horses. If general anesthesia is elected, great care should be taken during recovery from anesthesia.

Distal Physeal Fractures

Distal physeal fractures of MCIII/MTIII are common injuries in suckling and weanling foals. Nearly all are Salter-Harris type II fractures with a variable length of metaphyseal involvement

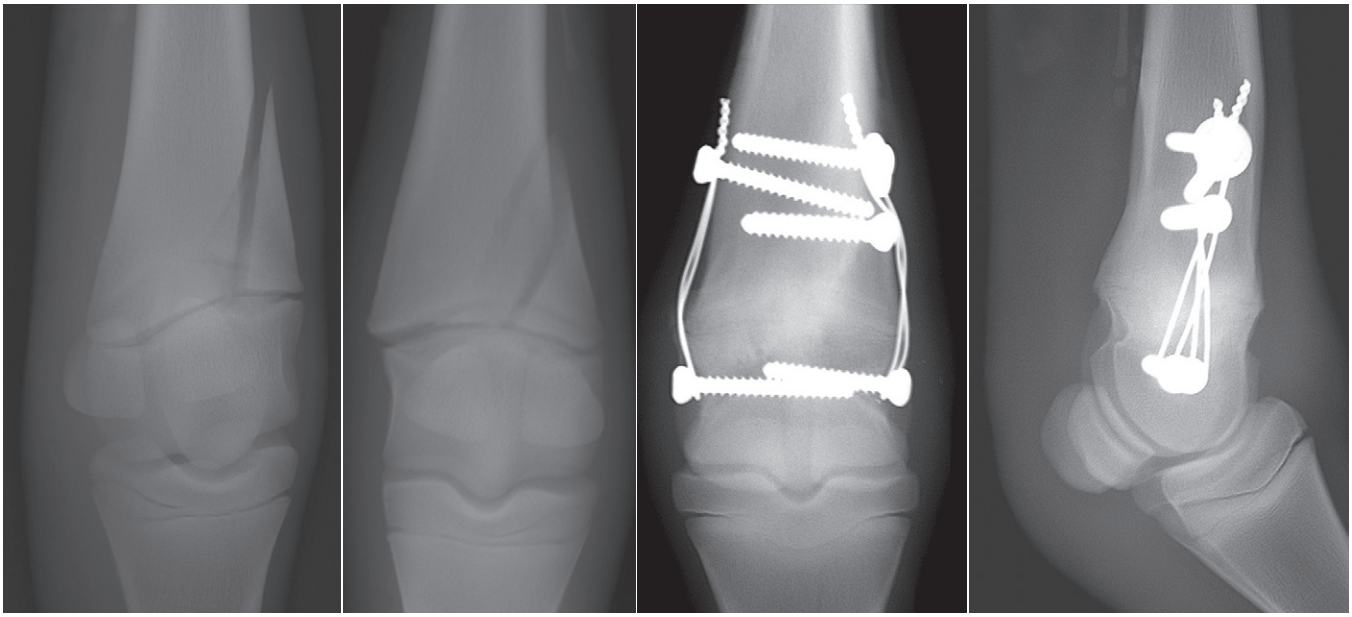

Figure 92-16. Although many methods can be successful for treatment of distal Salter-Harris II MC/MTIII fractures, a very reliable technique is to combine simple lag technique of the metaphyseal spike with a screw and wire transphyseal bridge. (Courtesy Dr. Alan J. Ruggles.)

(Figure 92-16). Such injuries usually heal relatively quickly with minimal surgical management. Young foals (less than 6 weeks old) with these fractures can be treated with cast coaptation alone for 2 to 3 weeks followed by 2 to 3 additional weeks in a splinted bandage. If the fracture appears reasonably stable and the foal is comfortable, even less coaptation may be adequate. In older, heavier foals or those with marked instability, the fracture can be repaired with compression screws through the metaphyseal component with or without a transphyseal bridge in addition to external coaptation. Although such minimal internal fixation is not inherently stable, it is adequate if combined with external coaptation in young foals because physeal injuries heal quite rapidly. It is preferable not to cross this growth plate with any implants in animals intended for athletic function. Regardless of the technique used to treat the fracture, the foal's return to exercise is carefully graduated over several weeks while the ligamentous and musculotendinous tissues regain strength.

The timing for implant removal depends on the age of the foal. If the foal is a neonate with significant remaining potential growth, the implants should be removed as early as possible in order to minimize the risk of a shortened bone. This could mean removal as early as 3 to 4 weeks in a neonate. In an older foal with negligible growth remaining, the implants can be removed at 2 to 3 months.

Proximal Articular Fractures

Proximal articular fractures of MCIII/MTIII occur sporadically in racehorses and can be confusing because the lameness associated with them is typically eliminated by local anesthetic injected into the middle carpal or tarsometatarsal joint. *Sagittal* fractures can be seen in any breed; most occur medial to the midline and are best diagnosed by nuclear scintigraphy and excellent-quality dorsopalmar/plantar radiographs. Occasionally, the fracture can be identified ultrasonographically as linear discontinuity in the proximal palmar/plantar cortex. *Frontal/dorsal* plane fractures occur in MCIII or MTIII. In Standardbreds, the fracture is most common in young pacers on the dorsomedial aspect of MCIII.[18] Proximal articular fractures have been treated conservatively with good success, but displaced frontal plane fractures are best repaired with internal fixation through compression screws (Figure 92-17). The sagittal plane fractures are rarely displaced and usually heal with stall rest alone (Figure 92-18). Implant removal is generally not necessary.

Dorsal Cortical Fractures

A large percentage of young Thoroughbred horses in race training develop pain and lameness associated with the dorsal cortex of MCIII; this is called *bucked shins.* In the majority of horses, no specific fracture line is identified, but some develop one or more oblique radiolucent lines in the dorsal cortex accompanied with focal pain and swelling. These so-called stress fractures occur most commonly in 3-year-old Thoroughbreds after they experience bucked shin problems in their 2-year-old season. The most common configuration of such fractures is a line coursing proximally at a 30- to 40-degree angle from the surface of the mid-distal dorsolateral cortex of the left MCIII (Figure 92-19). Typically, the fissure extends approximately 60% to 70% through the dorsal cortex and disappears, but in some cases, the crack curves proximad and courses back to the dorsal cortex, forming a true saucer fracture (Figure 92-20). Fractures may occur in the opposite configuration (proximodorsal to distopalmar, see Figure 92-19, *B*) as well as anywhere along the length of MCIII.

Nonsurgical Management

Treatment of dorsal cortical fractures can be conservative with anti-inflammatory agents and rest (stall and paddock) until the fracture is radiographically healed. Some trainers return the horse to a diminished exercise program as soon as the overt lameness abates and then simply follow the progress of healing

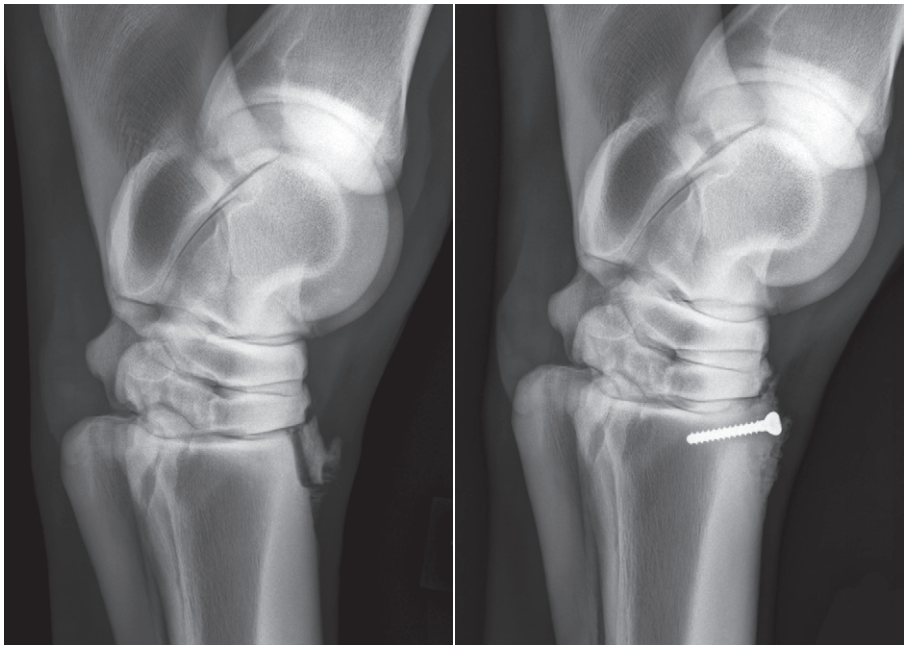

Figure 92-17. Displaced dorsal plane proximal metatarsal fracture treated with a cortex screw placed in lag fashion. This horse won two Eclipse awards after surgery.

Figure 92-18. Proximal sagittal plane fracture of MCIII *(arrows),* which was treated conservatively.

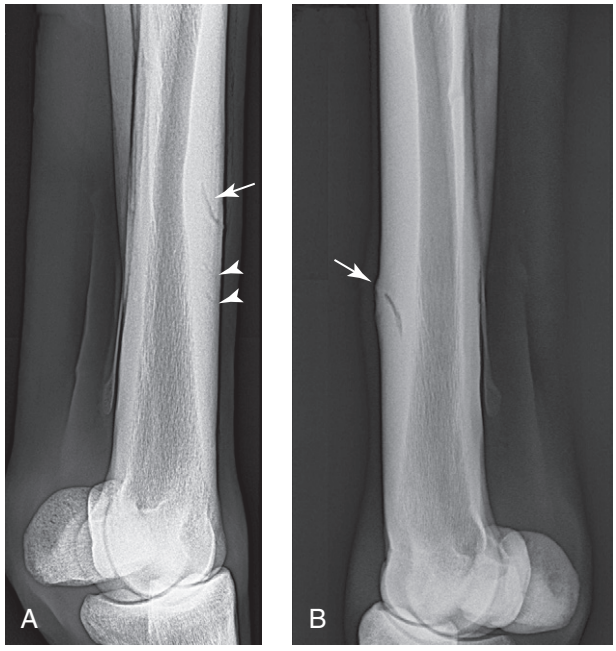

Figure 92-19. A, The most common configuration of dorsal cortical stress fractures of MCIII is shown with the *arrow*. Less distinct lucencies *(arrowheads)* can be seen separately or in combination with larger fractures. **B,** Occasionally, the opposite ("upside down") configuration is seen. The quality of digital imaging has made identification of these fractures more reliable.

with sequential radiographs. Many horses heal without surgical intervention, but a significant percentage has no signs of radiographic healing even after several months. The best candidates for conservative treatment are fractures in the distal or proximal metaphyseal regions of MCIII because they develop periosteal bridging callus much more rapidly than the typical intracortical fracture in the diaphysis.

Extracorporeal shock wave therapy has also been extensively used in the management of bucked shins and dorsal cortical fractures. There is little evidence that it has beneficial effects on healing and it is more likely that its primary effect is local analgesia.

Surgical Management

Surgical treatment of dorsal cortical fractures of MCIII is osteostixis alone or in combination with an intracortically placed screw.[19,20] The advantage of osteostixis alone is that it avoids a second operation to remove the screw. More consistent results have been achieved with the combination followed by routine screw removal at 60 days.

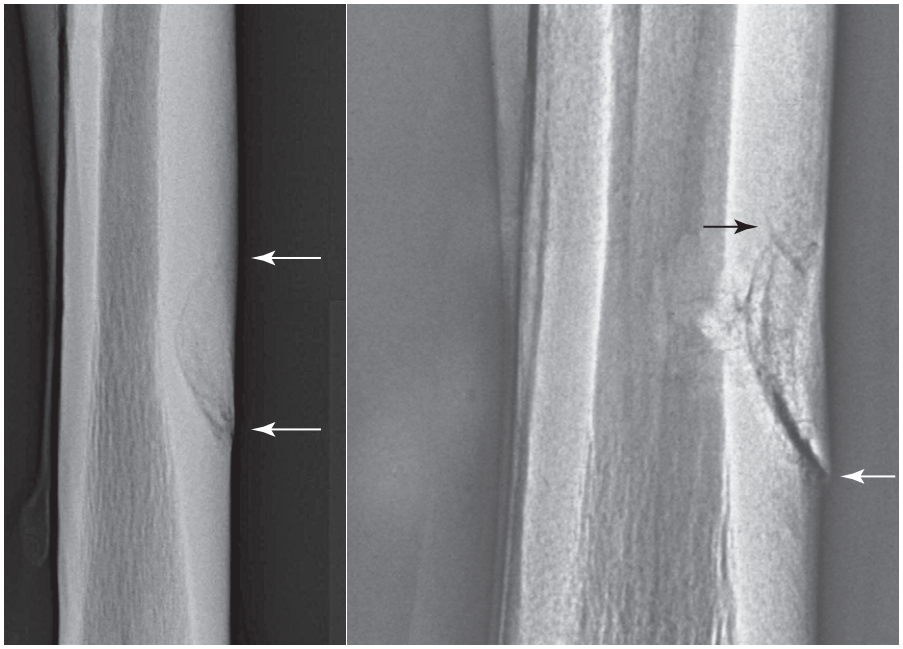

Figure 92-20. The term *saucer fracture,* originally derived from this uncommon configuration. This type of fracture is probably more prone to catastrophic dehiscence. *Arrows* depict the proximal and distal aspects of the fractures.

The surgery can be carried out either under general anesthesia or under sedation and local anesthesia. Local anesthesia has the obvious advantage of avoiding the risks of general anesthesia and recovery but the possible disadvantage of unexpected movement during drilling, leading to broken drill bits/taps. It is important to accurately locate the exact site of the fracture preoperatively because it can often be very difficult to identify it visually at surgery. A useful technique is to take a radiograph of the limb after surgically preparing the skin and place multiple skin staples in a grid over the affected region, varying the orientation of the staples so they can be easily identified. This allows precise positioning of the incision over the fracture.

A 4- to 6-cm incision is made over the fracture site. In the typical dorsolateral fracture, the incision is between the common digital and lateral digital extensor tendons. The incision is made boldly directly to the level of the periosteum to minimize dissection. The periosteum is elevated, and self-retaining retractors are placed to expose the bone surface. Although some surgeons use lag technique, typical dorsal cortical metacarpal stress fractures have no displacement and the effect of compression would be trivial. Because compression of the fracture is not necessary for successful treatment,[20] a position screw (without a glide hole) within the dorsal cortex is frequently placed. Because of the bending that occurs in the mid-diaphysis of MCIII, a screw across both cortices is not recommended. Drilling with a small bit in dorsal MCIII must be done with irrigation and frequent cleaning of the bit to avoid breaking it or causing thermal injury. The fractures can be difficult to identify even with open exposure of the dorsal cortex. An oblique drill hole is made into the medullary cavity and an intraoperative radiograph taken (Figure 92-21). If the hole is correctly placed, it can be used for the screw; if is too proximal or distal, an adjustment is made and the first hole serves as another osteostixis hole. Because the screw is inserted at an acute angle (perpendicular to the fracture line), countersinking is necessary to avoid bending at the head as it is tightened. The amount of countersinking should be minimal, however, because excessive depth of the head will make screw removal much more difficult. Most dorsal cortices accommodate a 22-mm screw. Six to eight 2.5-mm holes are made through the dorsal cortex around the screw. All holes must be drilled toward the medullary cavity (Figure 92-22) and separated at least 10 mm. Closure and bandaging of the area are routine.

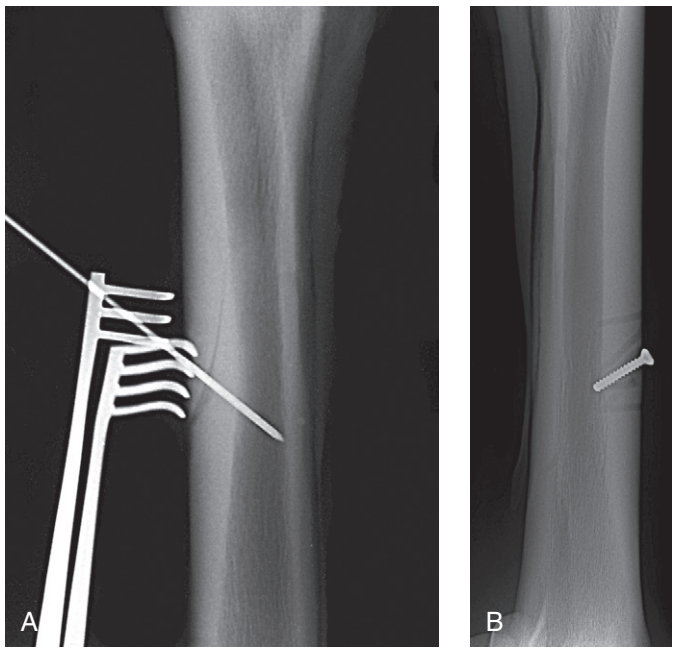

Figure 92-21. A, A single intraoperative image with a pin in the drill hole allows accurate repositioning if needed. **B,** Postoperative image showing the screw inserted and the surrounding osteostixis holes.

Postoperative care includes stall rest and hand-walking for 2 to 4 weeks followed by 4 to 6 weeks of stall rest and paddock exercise. At 60 days postoperatively, the horse is returned for screw removal, which is easily performed in the standing animal

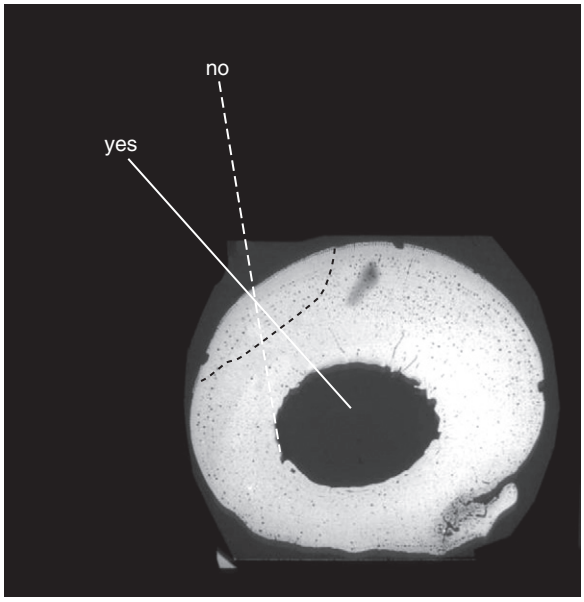

Figure 92-22. When drilling dorsal cortical stress fractures, it is important to aim toward the medullary cavity.

under sedation and local anesthesia. If the screw head cannot be palpated, a grid of sterile skin staples over the area can be placed and a radiograph taken to facilitate localization of the ideal site for a small incision. Local infiltration at the site of the screw head is adequate. Because the hexagonal recess of the 3.5-mm screw head is quite shallow, it is easily stripped; therefore, the screw head recess should be completely cleaned with a needle, sharp hook, or small pin before inserting the screwdriver tip to avoid this complication. If it does strip, the head is grasped with locking pliers and removed. After screw removal, the horse is hand walked for another month then begun in a jogging program for about 6 to 8 weeks before returning to regular race training.

CHAPTER 93

Vestigial Metacarpal and Metatarsal Bones

Michelle A. Jackson and Jörg A. Auer

Although vestigial in nature, the small metacarpal and metatarsal bones (splint bones) are integral parts of the supporting and stabilizing structures of the equine limb and serve as a site for important carpal and tarsal ligament insertions. Traumatic injuries of these bones are predisposed by their relative anatomic exposure, the nature of the horse, and equine management practices.[1] The most common conditions affecting these bones are fractures and splint exostosis. Congenital defects like polydactyly occurs occasionally. Tumor-like lesions are very rare.[2]

ANATOMY

The proximal aspect of the small metacarpal or metatarsal bones articulates with the carpal and tarsal bones, respectively, and provides axial support to these structures. Unlike the other vestigial metacarpal/metatarsal bones, the fourth metatarsal bone (MTIV) has only a small articulation with the fourth tarsal bone, providing minimal weight transfer through this articulation.[3] The metacarpal/metatarsal interosseous ligament is very variable among horses, ranging from a pure ligamentous structure to osseous union (Figure 93-1, *A*). A firm fascia covers the tendons in the proximal region of the third metacarpus (MCIII) and metatarsus (MTIII) and runs from the medial to the lateral splint bone (see Figure 93-1, *B*). A bandlike structure extends distad from the distal end of the splint bone toward the proximal sesamoid bone (see Figure 93-1, *C*).[4] In the hindlimb, the lateral dorsal metatarsal artery's location between MTIII and MTIV make it particularly vulnerable to accidental or surgical injury.

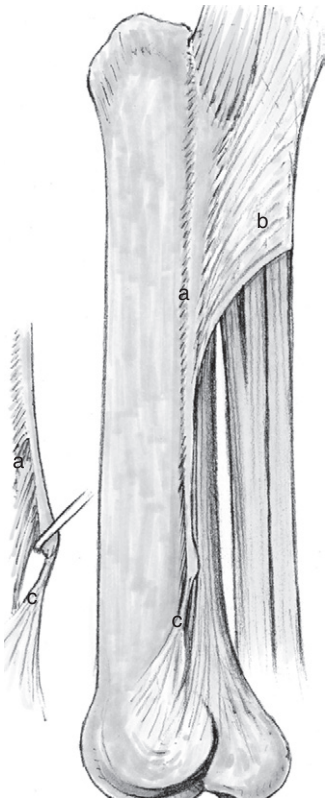

Figure 93-1. Important soft tissue structures surrounding the splint bone.[4] *a,* Metacarpal/metatarsal interosseous ligament; *b,* fascia metacarpi/metatarsi palmaris/plantaris; *c,* ligament-like structure originating from the distal end of the splint bone.

CONDITIONS

Fractures

Fractures of the small metacarpal or metatarsal bones are relatively common in horses of any age. Kicks from other horses are probably the most important cause of injuries to this bone,[5] but fractures may also occur spontaneously during exercise. Splint bone fractures can be open or closed, simple or comminuted, and localized in the proximal, middle or distal part of the bone (Figure 93-2). The horse presents with different grades of lameness, but it is usually severe in open, proximal fractures and moderate in distal fractures. The interval between the occurrence of the injury and the time of admittance at the clinic also has a significant influence on the lameness. The presence of swelling, pain, and heat is directly related to the extent of soft tissue damage. The definitive diagnosis can be obtained through a number of diagnostic imaging techniques; however, radiography is the most frequently applied modality. It is very important to take several radiographic projections and to

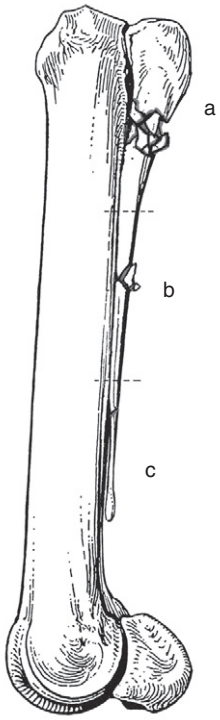

Figure 93-2. Classification of splint bone fractures: The bones can be divided into three equal parts: *a,* proximal; *b,* mid-body; and *c,* distal.

include the proximal articulation. Ultrasonography should be performed to assess concurrent injury to the suspensory ligament. Computed tomography, if available, can be very helpful for a definitive diagnosis in difficult cases (Figure 93-3). Involvement of the MCIII/MTIII affects the prognosis negatively. Complications like nonunion, osteomyelitis, and sequestrum or excessive callus formation are common when the fracture is not treated properly.[1]

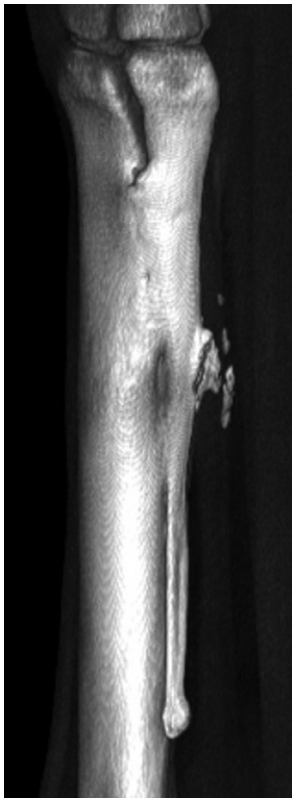

Figure 93-3. Longitudinal CT view of MCII and MCIII, demonstrating calcification near the splint bone.

Proximal Fractures

Proximal splint bone fractures are usually the result of a kick from another horse and therefore are frequently open and may be comminuted. They may become complicated by the development of osteitis, osteomyelitis, and/or bone sequestra. According to some studies, MTIV is the most commonly involved bone. MCIII/MTIII and the articulation between the splint bone and the carpal and tarsal bones should be examined carefully for fractures or fissures.

TREATMENT

Proximal splint bone fractures are the most difficult to treat and a variety of management techniques including surgical interventions have been described.[3,6-10]

Standing surgical intervention

Open multifragment proximal splint bone fractures are candidates for standing surgery, consisting of a thorough wound débridement under sedation and local anesthesia, with removal of loose fracture fragments and temporary installation of a drain.[1,11,12] Postoperative management includes antimicrobial and anti-inflammatory treatment in conjunction with support bandaging. Follow-up radiographs are taken 2 and 4 weeks later. If the wound has healed and the radiographs show that the splint bone is stable and the fracture is healing, no further treatment is necessary (Figure 93-4).[1] The patient should be maintained in a box stall for 1 month followed by 2 months of hand-walking exercise or small paddock.

In one report, 12 of 14 horses with open multifragment splint bone fractures returned to athletic function after conservative therapy.[11] Other authors reported that healing occurred in the majority of horses that were treated with only wound débridement and no additional stabilization or splint bone removal.[1] Another study compared conservative and surgical treatment of open multifragment fractures of MTIV and yielded comparable results with respect to return to full work and cosmesis, with conservative therapy being significantly less expensive and associated with less morbidity.[12]

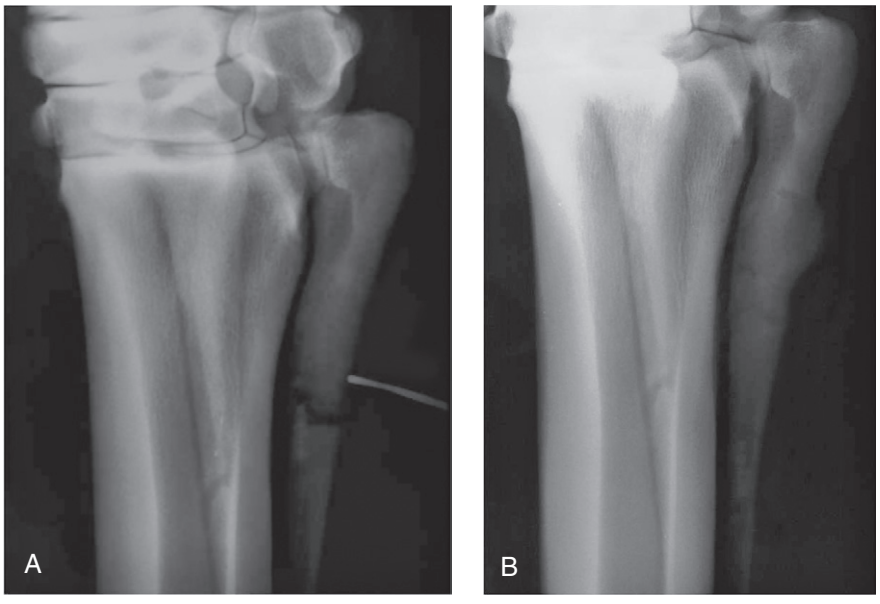

Figure 93-4. A, Proximal, multifragment, open splint bone fracture treated with standing wound débridement. **B,** Healing after 7 weeks.

Internal fixation

Removal of fracture fragments plus the residual distal splint bone is thought to provide a rapid return to function.[7] It is generally accepted that no more than the distal two thirds of the splint bone should be removed, with the exception of MTIV. In cases where more than two thirds of the splint bone has to be removed, internal fixation of the proximal fragment to MCIII/MTIII with the help of a small plate is suggested to maintain axial support.[9]

Because implantation of metallic implants bears a high risk of postoperative infection, particularly if the original injury was caused by external trauma, their use should be reserved for cases in which there is a high probability of luxation or subluxation of the proximal splint bone fragment. The other option and preferred technique for internal fixation is plate application in which the screws only engage the splint bone, providing the most ideal anatomic repair (Figure 93-5).[9] If the screws inserted through the plate holes cross the splint bone and penetrate MCIII/MTIII, horses often remain lame, so that the plate will need to be removed about 3 to 4 months postoperatively (Figure 93-6). Appropriate implants include 3.5 mm (narrow) dynamic compression plates (DCPs) or locking compression plates (LCPs), semitubular plates or reconstruction plates (Synthes Inc., Solothurn, CH). Principles of plate application do not differ from those of other fractures (see Chapter 76). The ligamentous attachments on the abaxial surfaces of the proximal splint bones make the palmar or plantar abaxial aspect a tension surface, making it the ideal location for plate application.[14] Screw fixation alone can be useful in selected cases, such as simple fractures with minimal displacement (Figure 93-7). However, this is generally associated with a relatively high rate of technical failure.[9]

Postoperatively no cast is needed. Horses should be kept in a box stall for 1 month, followed by walking exercise for an additional 2 months or turnout in a small paddock.

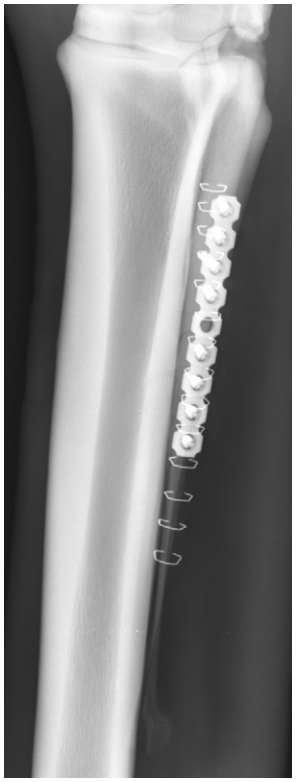

Figure 93-5. Radiographic image showing fixation of a proximal splint bone fracture using a 2.7-mm Unilock plate, with screws engaging only the splint bone.

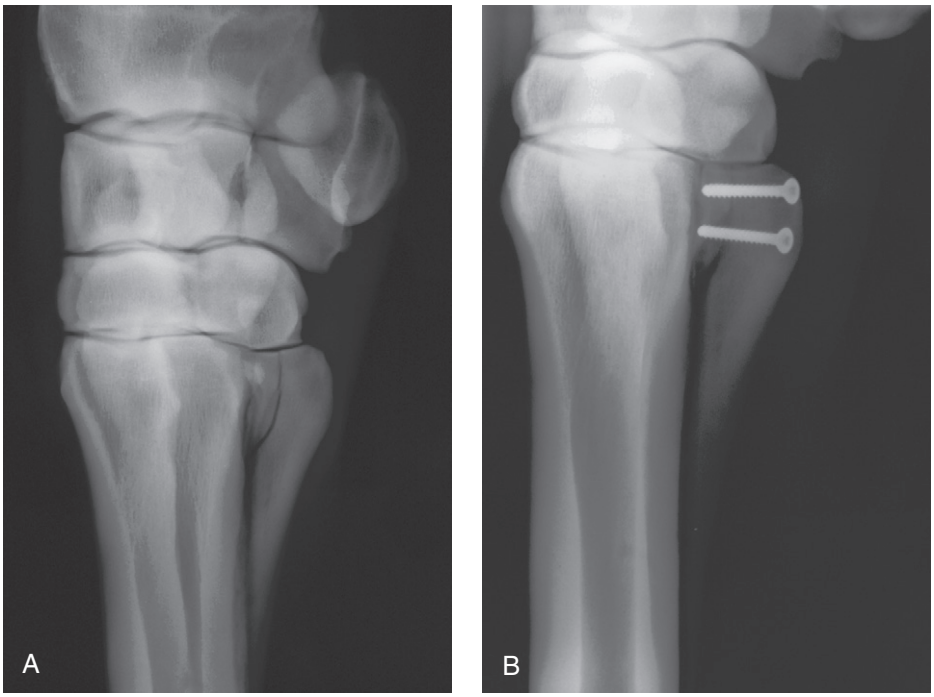

Figure 93-7. APLMO radiographic view. **A,** Proximal, articular, closed splint bone fracture; **B,** Fixation with two 3.5 mm screws.

Segmental ostectomy

A segmental ostectomy with removal of the injured sections of the splint bones can be performed in some complicated fractures composed of multiple small fragments.[10] The horse is usually anesthetized and placed in lateral recumbency; however, a standing procedure with the horse under sedation has also been described.[10] A linear skin incision is made immediately over the affected portion of the splint bone. Contaminated and necrotic tissues are débrided and any loose bone fragments, osseous callus, and sequestra are removed. The remaining proximal and distal portions of the splint bone are subsequently obliquely ostectomized with an osteotome or an oscillating saw. After flushing of the wound, subcutaneous tissue and skin are closed in two layers. In open fractures, a drain is placed in the wound for 2 to 3 days.

Firm pressure bandages are maintained for 2 weeks and horses are rested in a stall for 1 month followed by 2 months of hand-walking or small paddock exercise. Follow up radiographs are recommended to evaluate healing and stability of the proximal fragment.

In one study, three horses with open, proximal multifragment fractures treated with segmental ostectomy returned to normal activity within 8 weeks after surgery with excellent cosmetic results.[10]

Removal of the entire fourth metatarsal bone

Complete removal of the entire MTIV to treat open multifragment fractures of the proximal portion of this bone has been successfully performed.[3] In one report, five of eight horses returned to their intended use and two more were pasture sound.[3] Because of possible subsequent instability or luxation of the tarsometatarsal joint, a full-length hindlimb cast should be considered for recovery and for the first 4 weeks postoperatively (Figure 93-8).

Figure 93-8. Radiographic image showing luxation of the tarsometatarsal joint that occurred during recovery after complete removal of MTIV.

PROGNOSIS

Prognosis for return to athletic function after treatment of proximal splint bone fractures depends on type and age of the fracture as well as additional involvement of soft tissues and MCIII/MTIII. Complicated fractures including open, comminuted, and

articular fractures have a good prognosis after standing surgical intervention without removal of the distal part of the bone or fixation of the fracture.[1,11] Plate fixation is recommended only when the proximal part of the splint bone has become unstable relative to MCIII/MTIII.[1] The prognosis after internal fixation of closed fractures is excellent.

COMPLICATIONS

Possible complications of standing surgical intervention are excessive callus formation, which can interfere with the suspensory ligament, nonunion, and instability of the proximal fragment.[7,13]

The major complication after internal fixation is infection, particularly if the original injury was caused by external trauma. Plate removal may be necessary after healing of the fracture if infection occurs. However, because the splint bones are exposed to limited load bearing, most fractures heal, even in the presence of infection.[14]

Possible complications after segmental ostectomy include instability of the proximal fragment, sequestration of the distal fragment, and excessive exostosis formation at the splint bone ends.[10]

Midbody Fractures

TREATMENT

Surgical management

Midbody fractures should be managed surgically with removal of the distal fragment of the splint bone, removal of the callus, and excision of the distal-most aspect (1 cm) of the remaining proximal fragment (Figure 93-9).[7] Alternatively, a segmental ostectomy can be performed (Figure 93-10).[10] Before closure of the wound, all fragments should be removed and the wound flushed thoroughly. In open fractures, a drain is placed in the wound for 2 to 3 days. This treatment ensures quick recovery of the horse and return to previous use.

Nonsurgical management

Conservative treatment is often chosen for financial reasons. Good candidates are horses that have chronic fractures with minimal callus formation and patients with nondisplaced fresh fractures.

PROGNOSIS

The prognosis for midbody splint bone fractures after surgical treatment is very good.[1] Thirteen horses with mid-body splint bone fractures treated with a segmental ostectomy returned to normal activity within 8 weeks after surgery with excellent cosmetic results.[10]

The outcome after conservative treatment is favorable, but the convalescent time is usually longer.

COMPLICATIONS

Complications after surgical treatment are rare and include exostosis formation at the splint bone and/or MCIII/MTIII, which leads to a longer convalescence. A rare complication, which can occur during removal of the distal splint bone, has been reported.[15] A horse treated by partial ostectomy of a splint bone fracture with an oscillating saw suffered an avulsion fracture of the plantar MTIII cortex during a fall 1 month postoperatively (Figure 93-11, *A*). The fracture originated at the horizontal saw cut that extended into the cortex of the MTIII, which occurred accidentally during the osteotomy.[15] A bone plate was applied to the plantarolateral aspect of the remaining splint bone with the screws extending into MTIII (see Figure 93-11, *B*). The fracture healed uneventfully.

Figure 93-9. Postoperative image showing appearance after surgical removal of the distal half of the splint bone for treatment of a mid-body MTIV fracture.

A possible complication after conservative treatment is excessive callus formation, which can lead to secondary suspensory desmitis. Some cases require surgical removal of the fragment at a later time. Another possible complication is non-union, which most likely is the result of continuous intermittent traction exerted by the collateral ligaments.

Distal Fractures

Fractures of the distal third of the splint bone are usually simple in nature and occur most frequently at the narrowest part of the bone or immediately distal to the attachment of the interosseus ligament.[16] Distal fractures are very common and can result from external or internal trauma. Internal trauma, especially in the forelimb, occurs secondary to excessive stress with extension of the carpus during exercise or secondary to suspensory desmitis with loss of pliability of the suspensory ligament.

TREATMENT

Surgical management

Although distal splint bone fractures can be treated conservatively, surgical excision of the distal fragment improves the prognosis (Figure 93-12).[17] The surgery is technically simple and can be successfully performed under general anesthesia or with the horse standing under local anesthesia.[14] An incision is made directly over the bone, cutting down to the bone surface over the length of the fragment. The distal tip of the fragment is grasped with towel clamps or tissue forceps and elevated. The

attachments between the distal fragment and MCIII as well as the bandlike structure that extends distad from the distal end of the splint bone to the suspensory apparatus are severed with heavy curved scissors or a with a scalpel. As upward traction is applied on the fragment's extremity, sharp dissection is continued proximad to approximately 8 to 16 mm proximad to the fracture site. After the distal fragment and the fracture callus are separated from MCIII/MTIII, the splint bone with its periosteum is transected obliquely with an osteotome or oscillating saw approximately 1 cm proximal to the fracture. Before closure

of the wound, all fragments should be removed and the wound flushed thoroughly. Meticulous hemostasis is indicated to reduce the risk of postoperative excessive new bone formation at the distal stump of the bone. In open fractures, a drain is placed in the wound for 2 to 3 days.

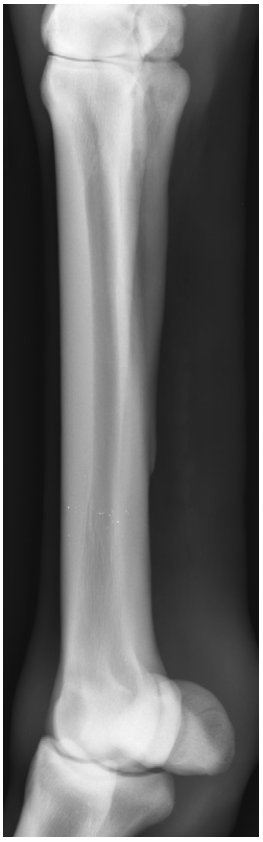

Figure 93-12. Postoperative image of a simple distal splint bone fracture after removal of the distal fragment.

PROGNOSIS

Prognosis depends to a great extent on the coexistence and degree of suspensory desmitis,[18] sesamoiditis, and/or metacarpophalangeal joint disease.[14] Thus, it is essential to preoperatively evaluate adjacent tissues by means of physical examination, radiographs, and ultrasonography. If no other structures are involved, prognosis after surgical removal of the distal splint bone is excellent.

COMPLICATIONS

A possible complication after conservative treatment is excessive callus formation, which could interfere with the suspensory ligament and lead to persistent lameness.[19]

Exostoses

Exostoses (splints) occur mostly in young, immature horses and develop between MCIII and the splint bones. Splints may occur at any level but most commonly develop 6 to 7 cm distal to the carpometacarpal joint and involve MCII (Figure 93-13, *A*). Possible causes for splints are direct trauma leading to subperiosteal hemorrhage and elevation of the periosteum, instability between MCIII and MCII, MCII fractures, or inflammation of the intercarpal ligament.[20] The last can result from too much work on hard surfaces or on a circle, especially in immature horses, or from conformation abnormalities (such as bench knees) or carpus varus deformities. Lameness is usually present in the acute stage, especially if the patient is lunged on hard surfaces, and tends to deteriorate with work. Horses develop a firm swelling at the level of the exostoses, which is warm and painful on palpation.

DIAGNOSIS

Radiography can be useful to determine the size and the activity of the exostosis. Oblique radiographic projections of the affected splint bone should be taken using soft exposures (see Figure 93-13, *B*). It is important to assess the axial part of the exostosis

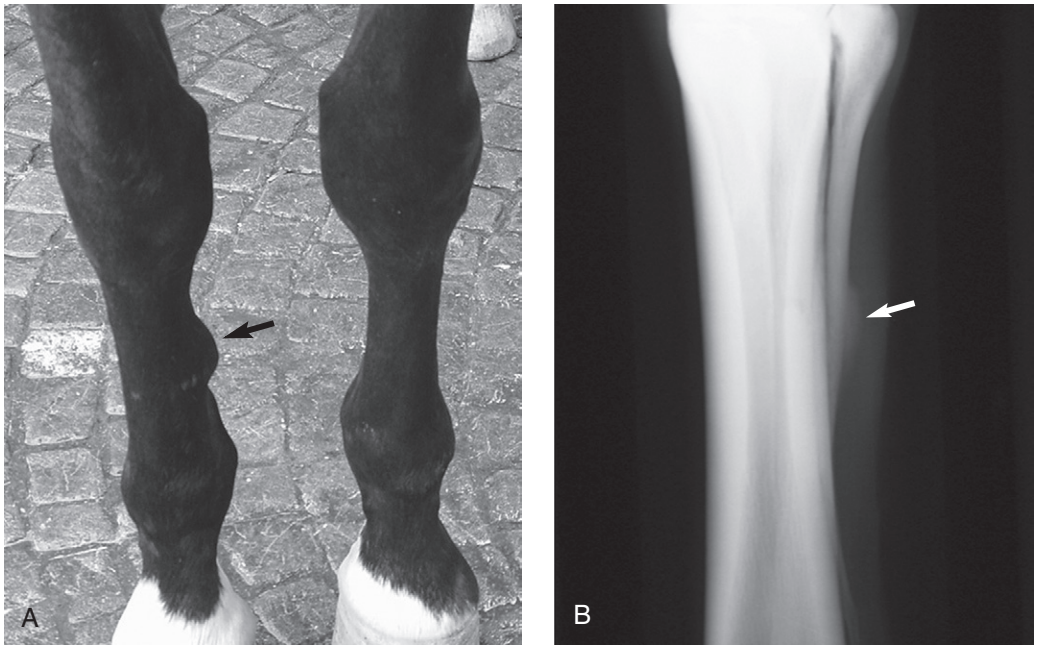

Figure 93-13. A, Photograph of a horse with splint exostosis between MCIII and MCII about 6 to 7 cm distal to the carpometacarpal joint *(arrow)*. **B,** Oblique radiographic projection of MCII with soft exposure showing the size of the exostosis *(arrow)*.

to determine if there is impingement on the suspensory ligament. These cases (hidden splints) are best diagnosed with dorsopalmar radiographs; in difficult cases computed tomography can be very helpful.

TREATMENT

Nonsurgical management

Lameness associated with a clinically active exostosis usually resolves with rest, ranging from 2 to 3 weeks to 2 to 3 months. Local application of dimethylsulfoxide may facilitate reduction of the swelling; infiltration of the exostosis with corticosteroids has a similar effect. In horses with severe exostoses, surgical removal of the exostosis and the distal part of MCII should be considered.

Surgical management

If the axial exostoses are impinging the suspensory ligament and the lameness does not resolve with rest, surgical removal of the exostosis should be attempted. The best technique is a simple linear incision over the exostosis and *en bloc* excision of the entire bone mass along the cleavage line between the new bone and MCIII.[14] This excision should include the overlying periosteum. An oscillating saw or a sharp-bladed osteotome is used to cut the excessive bone and return it to a normal contour. After hemostasis is achieved, the loose subcutaneous tissues are closed over the exposed bone surface, and the skin edges are apposed in routine fashion. In very large exostoses, a portion of the skin margin is excised to reduce dead space and the associated tendency for hematoma or seroma formation. The most critical aspect of managing cosmetic splint removals is postoperative bandaging. A tight bandage applying direct pressure over the surgery site followed by an outer padded compression bandage should be kept in place for 2 to 3 weeks to minimize the accumulation of blood or serum at the surgical site.[14]

Polydactyly

Polydactyly of the metacarpal or metatarsal region occurs occasionally and is the most frequently described congenital phalangeal malformation in the horse (Figure 93-14, *A*).[21] In 80% of the cases the supernumerary digit occurs at the medial aspect of the forelimb.[21] The etiology of polydactyly is unknown in the horse. Usually the digit represents an atavistic form of a regular small metacarpal/metatarsal bone. Other described forms are the teratogenic form, where the supernumerary digit evolved from a teratogenic splitting of the basipodial elements and all the phalangeal bones are affected, but the splint bones are often normal. The bilateral symmetric-inherited form represents yet another hereditary condition in poultry and dogs.[21] The diagnosis is based on clinical examination. A complete radiological examination of the involved metacarpal and metatarsal region and adjacent joints is required to evaluate the osseous abnomalities (see Figure 93-14, *B*). The supernumerary metacarpus or metatarsus and digit should be removed to improve cosmetic appearance and to prevent injury to the digit (see Figure 93-14, *C*).[21] The surgery should be performed under general anesthesia. An incision is made directly over the supernumerary digit starting at mid cannon bone and continuing distad up to the supplementary hoof. The supernumerary digit has extensor and flexor tendons, a suspensory ligament, and sesamoid bones like the other digits, as well as nerves and vessels. The vessels are ligated and transected together with the tendons as far proximad as possible. An osteotomy of the digit (usually MCII) is performed at its middle part with an osteotome or oscillating saw.

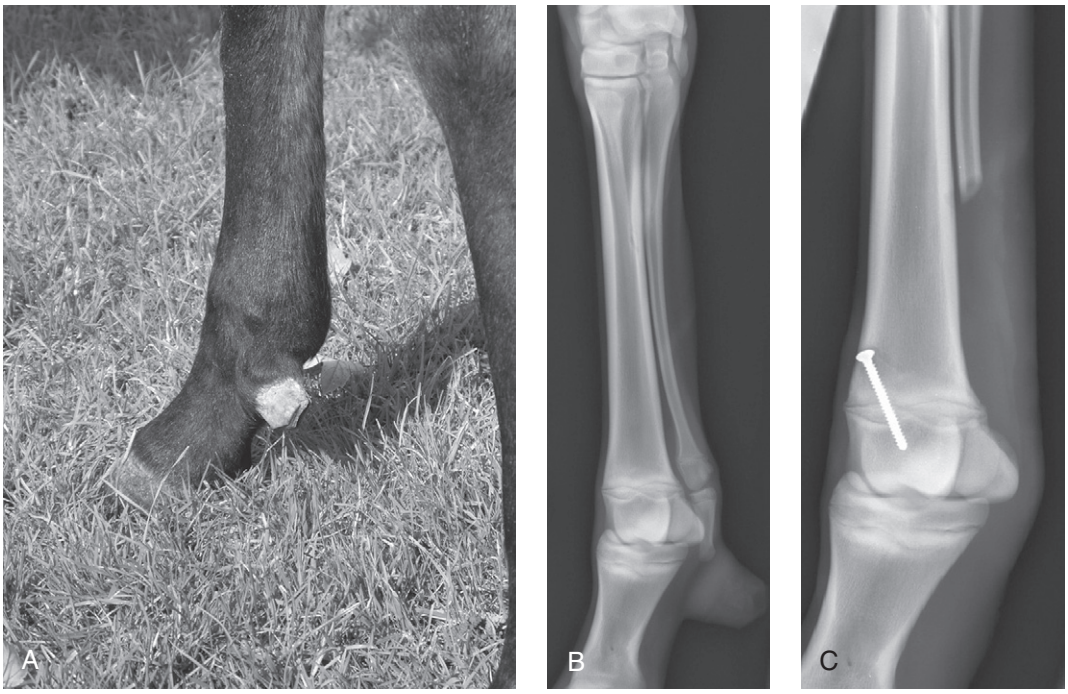

Figure 93-14. Polydactyly in a foal. **A,** The rudimentary medial (second) digit shown on the limb from the side. **B,** Oblique radiographic view depicting the rudimentary digit. **C,** Postoperative oblique radiographic view showing the resected distal half of MCII. Note the placement of a transphyseal screw on the lateral side of the distal MCIII for retarding growth, because the rudimentary digit led to a varus deformity of this bone.

Neoplasia

Fibro-osseous tumors of the appendicular skeleton are very rare in horses.[2] An ossifying fibroma, usually found primarily in the jaw of young animals, has been described in the distal part of the fourth metacarpal bone of a 13-year-old horse.[2] The horse showed neither lameness nor pain on palpation; after surgical removal of the distal third of the splint bone, including the tumor, wound healing occurred without complications. Eighteen months after surgery radiographs showed no recurrence of the mass.[2]

CHAPTER 94

Carpus

Alan J. Ruggles

Carpal injuries in the horse occurs in all breeds but most often in racing breeds. Types of injuries include trauma from direct blows or kicks, fractures or subchondral bone injury from stress adaptive response, lacerations and septic conditions, and soft tissue injury to ligaments or tendons. Diagnostic procedures should be aimed at specifically identifying the site of the injury in the carpal region. The complicated anatomy of synovial structures in this region occasionally jeopardizes this goal. This chapter summarizes anatomy, diagnositic procedures, surgical considerations, and outcomes associated with carpal injury in the horse.

ANATOMY

The carpal region contains three joints: the antebrachiocarpal joint, middle carpal joint, and carpometacarpal joint. The middle carpal and carpometacarpal joints always communicate with each other. This fact is important when evaluating regional anesthesia of the proximal palmar metacarpal region. The palmar outpouchings of the carpometacarpal joint extend distad. Inadvertent puncture to this joint, and subsequent anesthesia of this joint and the middle carpal joint, may occur when performing regional anesthesia of the proximal metacarpal region.[1]

Injury of the carpometacarpal joint is mostly desensitized by intra-articular anesthesia of the middle carpal joint. However, it has been demonstrated that analgesia of the antebrachiocarpal and middle carpal joints is not specific. In one study, diffusion of mepivacaine between the antebrachiocarpal and middle carpal joints occurred in 84% of the tested limbs, and diffusion between the middle and antebrachiocarpal joints occurred in 96% of tested limbs.[2] Therefore, a positive response to intrasynovial anesthesia of one portion of the carpus might not specifically implicate that particular joint as the source of lameness. This information confirms clinical experiences in horses that block out variably in the carpal and proximal metacarpal region. In practical terms, consider evalaution of the whole region (carpus, carpal canal, and proximal metcarpus) when lameness is alleviated by regional or intra-articular anesthesia of the carpal region.

The bones that compose the carpus include the radius; the proximal row of carpal bones (radial carpal, intermediate carpal, and ulnar carpal bones); the distal row of carpal bones (second, third, and fourth carpal bones); the metacarpal (MC) bones II, III, and IV; the accessory carpal bone; and occasionally a first carpal bone (but rarely a fifth). The orientation of the carpal bones relative to themselves is maintained by their soft-tissue attachments, including the intercarpal ligaments,

collateral ligaments, fibrous joint capsule, and the palmar carpal ligaments. The extensor carpi radialis and common digital extensor tendons as well as their sheaths span the carpus dorsally and dorsolaterally, respectively. They are maintained in their position over the dorsal surface of the carpus by the extensor retinaculum located at the distal radius approximately at the level of the physeal scar. The lateral digital extensor tendon courses over the lateral side of the carpus, as does the tendon of the ulnaris lateralis. Palmar and medial to the palmar carpal ligaments is the carpal canal, a synovial structure in which the superficial and deep digital flexor tendons, median artery, and nerve are located as well as the accessory ligament of the superficial digital flexor tendon (ALSDFT). Immediately medial to the carpal canal is the tendon and tendon sheath of the flexor carpi radialis, which is an important surgical landmark for desmotomy of the ALSDFT.

Effusion of carpal joints at the dorsal aspect of the carpus is easily recognized if these structures harbor an inflammatory process. The lateral recesses of the antebrachial and middle carpal joints will also be distended and the effusion can be more easily found by applying pressure over the dorsum of the carpus to distend these recesses. The anatomic borders and clinical significance of these structures has been documented.[3-5]

Arthroscopic evaluation of the palmar aspect of the antebrachial and middle carpal joints can be accomplished for diagnostic procedures and for removal of osteochondral fragments. Areas that can be accessed via palmar approaches to the antebrachial and middle carpal joints include the caudal medial and lateral radius; the palmar aspects of the radial, ulnar, second, third, and fourth carpal bones; and the dorsal aspect of the accessory carpal bones. The palmar bundles of the medial palmar ligaments are easily recognized, but the palmar bundles of the lateral palmar intercarpal ligament are not accessible.[5]

The function of the bony and ligamentous structures of the carpus is to dissipate axial loading during weight bearing. The anatomic position of the carpal bones and the resultant transmission of forces to the intercarpal ligaments protect the weight-bearing surfaces of the carpal bones during exercise to prevent injury.[6] Loss of interosseous fibrous connections promotes instability, lameness, and osteoarthritis. The support of the cuboidal bones and the compressive stiffness of the hyaline cartilage are key to carpal function.

PATHOPHYSIOLOGY

Injury to the carpus most commonly occurs within the antebrachiocarpal and middle carpal joints. Injuries of the proximal metacarpus, which can involve the carpometacarpal joint, are discussed in Chapter 92. Osteochondral fragments develop at both the dorsolateral and dorsomedial aspects of the antebrachiocarpal joint. Injury of the middle carpal joint nearly always involves the medial aspect of the joint—that is, the radial facet of the third carpal bone, the distal aspect of the radial carpal bone, and occasionally the medial aspect of the distal intermediate carpal bone.

High-energy injuries, such as falls or kicks, to the carpus cause acute single load failure. The resultant injury often causes open or comminuted fractures and carpal instability. Additional details on stabilizing luxations of the carpus are found in Chapter 81. Single load injuries including luxations of one or more carpal joints are less common than those developing as a result of repetitive loading. Axial, cyclic loading of the carpus during training induces stress-adaptive remodeling of the carpal bones. Alterations in bone porosity, sclerosis, and associated stiffness can predispose the bone to fracture.[7]

Exercise induces regional changes in bone density, which can be associated with the characteristic location of carpal injury. In one study, Thoroughbred horses exercised on a treadmill had increased trabecular thickening and increased bone mineral density in the third and radial carpal bones, in areas where cartilage degeneration and fractures commonly occur.[8] Previous work had identified increased areas of bone stiffness in the radial facet of the third carpal bone.[7] Loss of compressive stiffness of the subchondral bone plate as a result of exercise, which is radiographically manifested by sclerosis, likely contributes to fractures of the carpus.

Likewise, cartilage injury has been correlated with underlying bone sclerosis.[9] One study demonstrated significant increases in the mean tissue density in the distal, dorsal aspect of the radius, the radial carpal bone, and the third carpal bone in response to exercise.[10] This correlates with areas of increased sclerosis seen on radiographs of trained horses and with predilection sites for carpal injuries in racing breeds. In addition, severity of sclerosis of the third carpal bone has been correlated with lameness in trained Standardbred horses.[11] Training has been shown to increase the thickness of the calcified cartilage zone. The effect of this thickening is unknown, but it might represent a protective reaction to reduce an abrupt stiffness gradient between hyaline cartilage and subchondral bone. Conversely, the thickening of the calcified cartilage zone relative to hyaline cartilage thickness, represented by tidemark advancement toward the periphery, could represent a pathologic process and predispose these areas of bone to failure.[12]

In some horses, the loss of compressive stiffness of the subchondral bone plate and thickening of the calcified cartilage zone can lead to cartilage injury and fracture. Osteochondral fragmentation of the distal radial carpal and proximal third carpal bones is associated with subchondral bone damage caused by repetitive loading. These locations are prone to reinjury following arthroscopic fragment removal and débridement, leading to a poor prognosis because of subsequent joint deterioration from cartilage debris and subchondral bone failure.

Injury to the intercarpal ligaments can occur and usually involves the palmar medial intercarpal ligament within the middle carpal joint. Injury to the collateral ligaments is usually associated with avulsion fractures of the proximal aspect of the vestigial metacarpal bones or distal radius. Injury to the extensor tendons usually develops in association with severe flexural deformities or lacerations. Injuries to the palmar aspect of the carpus do occur, but they are less common than dorsal injuries and have been associated with hyperextension or hyperflexion of the carpus during recovery from anesthesia. Pathology of the deep and superficial digital flexor tendons, fractures of the palmar aspect of the cuboidal bones or accessory carpal bone, and exostoses of the caudal aspect of the distal radius all can cause lameness. Lameness caused by structures within the carpal canal can be difficult to differentiate from lameness originating from other structures of the carpal region.

The role of conformation in carpal injury is complex and subject to personal opinion and anecdotal information. It is an area of intense concern in prepurchase examinations. One study found an association between offset carpi and lameness associated with the metacarpophalangeal joint.[13] The same study demonstrated a protective effect of carpal valgus on carpal injury.[13] These observations are consistent with my clinical

experience. Additionally, severe conformational abnormalities of foals can lead to malformation of the cuboidal bones and early osteoarthritis (see Chapter 86).

OSTEOCHONDRAL FRAGMENTS

Occurrence

Osteochondral fractures of the carpal bones, or carpal chips, are a common cause of lameness in horses. Racing breeds are particularly prone to carpal chip fractures, and the fractures are most likely to be a performance-limiting problem.

The occurrence of osteochondral fragmentation is a consequence of training and racing. In support of this, in Thoroughbred yearlings radiographed prior to sale, only 9 of 1121 horses (0.8%) had an osteochondral fragment in the carpus.[14] In racing Thoroughbreds and Quarter Horses, the distal aspect of the radial carpal bone is most often affected.[15] In another survey of osteochondral fragmentation in racing Thoroughbreds in Japan, 60% of the fractures occured in the antebrachiocarpal joint and 40% in the middle carpal joint.[16]

Additional articular damage associated with osteochondral fragments tended to be greatest in the middle carpal joint.[15] If the injury is located within the antebrachiocarpal joint, the distal lateral aspects of the radius and the proximal intermediate carpal bone are usually involved. If the middle carpal joint is involved, the trauma typically occurs at the distal radial carpal and proximal third carpal bones.[15]

Racing Standardbreds typically injure the carpal bones in the middle carpal joint. In a survey of 176 Standardbred horses undergoing carpal arthroscopy, only two antebrachial carpal joints had osteochondral fragments.[17]

Etiopathogenesis

Osteochondral fragments of the carpus are induced by trauma. The history usually includes a sudden onset of carpal swelling. Certainly, some carpal chips with sharp areas of demarcation and healthy subchondral bone represent acute single-event failures; however, degenerative bone and cartilage, compatible with chronic injury, most often are found both on radiographs and at surgery. Palmar carpal osteochondral fragments can be the result of hyperflexion injuries and may develop during recovery from general anesthesia.

In the third carpal bone, reduction in vascular channels can lead to ischemic necrosis of the subchondral bone.[7] At surgery, degenerative bone appears discolored and brittle relative to the surrounding healthy bone. In racing Standardbreds, the prevalence of lameness was lower, 6.7% in horses with mild versus 45.4%, in horses with severe sclerosis of the third carpal bone.[11] Resorption of the diseased bone predisposes to development of a fracture at the junction of the compliant and noncompliant bone.[18]

Diagnosis

Diagnosis is based on clinical signs, including lameness, painful response to carpal flexion, joint effusion, response to intra-articular anesthesia, and reduced performance. A complete set of well-exposed radiographs, including the tangential view of the distal row of carpal bones and flexed lateral projections, is needed. Occasionally, the tangential view of the proximal row of carpal bones is required for diagnosis. If a carpal chip is detected, radiographs of the contralateral carpus are recommended, because it is common for fragments to be present bilaterally (Figure 94-1).[15]

Figure 94-1. Dorsolateral to palmaromedial 45-degree oblique projection of a Thoroughbred with an osteochondral fragment of the distal medial aspectof the radial carpal bone.

When a carpal chip is identified radiographically, it is important to document it as the cause of lameness, particularly in nonracing breeds, because it can represent an incidental finding. Intra-articular anesthesia in most cases confirms the associated joint as the source of lameness. Some horses become lame in the contralateral forelimb after anesthesia because of the presence of bilateral carpal chips or another secondary lameness.

As mentioned before, local anesthesia of the proximal suspensory region may accidentally involve also the palmar recesses of the carpometacarpal joint, anesthetizing both the carpometacarpal and middle carpal joints. Therefore, the relationship between the palmar recesses of the carpometacarpal joint and the proximal suspensory ligament must be considered when applying local anesthesia in this area. Because of this, anesthesia of the middle carpal joint should be performed before the high palmar block if carpal lameness is suspected. Alternatively, the two-point high palmar block (see Chapter 72) is recommended for regional anesthesia of the proximal metacarpal region, because it prevents the anesthetic agent from entering the carpus.[1]

Using the high palmar block there is a risk of entering the carpal canal and desenstizing structures within the canal. Therefore caution is indicated in the interpretation of a positive local nerve block at the palmar/plantar aspect of the proximal MCIII/MTIII.

Case Selection

Most carpal chips are of clinical importance in racing breeds, and their removal under arthroscopic guidance is the treatment of choice. Factors that should be considered before chips are removed are the degree of lameness, the amount of degenerative change seen on the radiographs or lack thereof, previous intra-articular therapy (especially corticosteroids), racing or training history, and economic concerns. Horses with carpal

Figure 94-2. Dorsomedial to palmarolateral oblique radiograph of the carpus of a Thoroughbred with an osteochondral fragment of the distal lateral aspect of the radius. Note the enthesiophyte formation and subchondral lysis consistent with osteoarthritis.

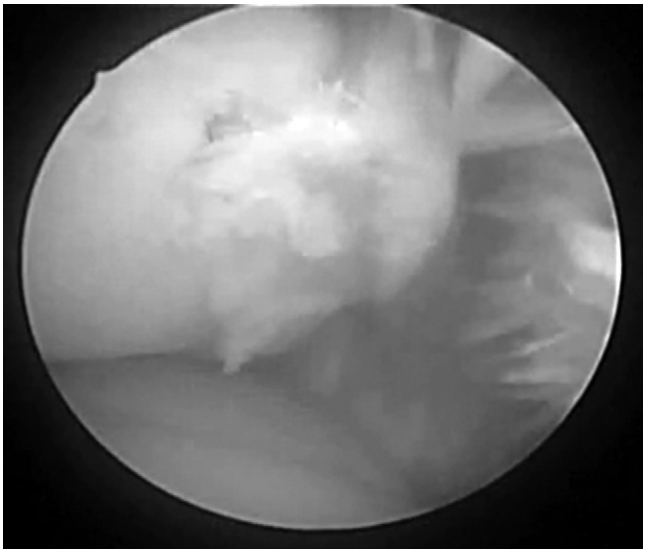

Figure 94-3. Arthroscopic view of the distal aspect of the radial carpal bone with moderate cartilage damage (grade II) and an osteochondral fragment. A greater than 30% loss of cartilage is associated with reduced postoperative performance.

chip fractures are usually sound or mildly lame when jogged in hand, if examined a few days after the injury. If moderate or severe lameness is present, other conditions are suspected, such as a carpal slab fracture, moderate-to-severe cartilage damage, intercarpal ligament injury, or sepsis.

The radiographic findings of enthesiophytosis and subchondral bone lysis are associated with cartilage and subchondral bone damage at surgery (Figure 94-2). In one study, subchondral lysis of the radial carpal bone was associated with both osteochondral fragmentation and additional cartilage injury.[19] In another study, horses with cartilage degeneration involving more than 30% of the articular surface of the affected bone (Figure 94-3) had reduced postoperative performance.[15]

Factors associated with reduced racing prognosis postoperatively include repeated joint injection, reduced response to joint injection, injury early in training, poor preoperative racing record, or previous carpal surgery. These factors, coupled with economic considerations, are important in the surgeon's case selection and the owner's willingness to have surgery performed.

Treatment

The horse is positioned in dorsal or lateral recumbency based on the site of the lesion and the surgeon's preference. If unilateral carpal arthroscopy is to be performed, I choose lateral recumbency with the limb containing the lesion(s) down. If bilateral carpal arthroscopy is planned, or if both sides of a joint are to be examined, I prefer to place the horse in dorsal recumbency with the limbs suspended from a rack or a ceiling mount. Antebrachiocarpal joint injury often occurs on both the lateral and medial side simultaneously, and thus dorsal recumbency is usually selected. Some surgeons always prefer either dorsal or lateral recumbency for all carpal surgeries.

The standard arthroscopy portals for the antebrachiocarpal and middle carpal joints are located between the common digital and extensor carpi radialis tendons (lateral portal) and medial to the extensor carpi radialis tendon (medial portal). Portal locations for instruments and the arthroscope are determined by the location of the lesion, with the arthroscope portal placed distant to the lesion.[20] The portals are made large enough to allow egress of fluid without its accumulation in the subcutaneous space (approximately 6 to 8 mm). Large portals should be avoided because adequate joint distention will be difficult to maintain. If gas is used as the arthroscopic medium, the portals should be very small and only allow access of the arthroscope and instruments. The versatility of arthroscopy allows additional nonstandard portals to be made depending on the site of the lesion.

When the osteochondral fragment is identified, it is partially loosened with an elevator if needed, grasped with Ferris-Smith rongeurs, and removed through the instrument portal by twisting the forceps back and forth while applying traction. Undermined cartilage flaps and diseased subchondral bone are removed with a curette. The lesion is débrided, minimizing the amount of cartilage removed, especially in weight-bearing areas of the joint. Débridement of partial-thickness cartilage lesions adjacent to the fragment is avoided unless the cartilage is detached from the underlying subchondral bone. An exception to this is partial-thickness cartilage injury overlying diseased subchondral bone (e.g., radial facet of the third carpal bone), which is typically débrided. Additional information on arthroscopy is found in Chapter 13.

Aftercare

The postoperative use of intra-articular or intravenous hyaluronan and intramuscular or intra-articular polysulfated glycosaminoglycan (Adequan) varies among surgeons. My standard postoperative instructions for routine osteochondral carpal arthroscopy consists of 2 weeks of stall rest, 2 weeks of stall rest

with hand-walking, and 2 weeks of pasture exercise, continued hand-walking, swimming physiotherapy, or a combination thereof. On occasion, a longer period of rest is given if substantial lameness or marked cartilage injury was present at the time of surgery. Bandaging is carried out until sutures are removed at approximately 12 days after the surgery.

Prognosis

A scale has been developed to grade cartilage injury observed at surgery. Grade I represents minimal articular cartilage fibrillation or fragmentation extending no more than 5 mm from the fracture site. Grade II represents articular degeneration, including up to 30% of the articular surface of the bone. Grade III indicates loss of 30% to 50% of the articular surface. Grade IV represents severe loss of bone and cartilage associated with the fracture.[15]

Postoperative results of carpal arthroscopy for osteochondral fragments depend on the degree of cartilage injury and the horse's previous racing success. Horses with minimal to no cartilage injury (grades I or II) have a 72.8% chance of returning to racing at a level equal to or better than that before injury.[15] If cartilage damage is greater than 30% of the visible surface of the affected bone (grades III or IV), only a 53.5% chance of return to racing at a level equal to or better than that before injury was found.[15] In a survey of carpal arthroscopy in racing Standardbreds, 74% returned to racing after surgery and 61% raced at or above their previous level.[17] In another survey from Japan, 82.6% of racing Thoroughbreds returned to racing after carpal surgery, which is better than results in North America. A likely reason for the discrepancy is the higher percentage of antebrachiocarpal joint injuries with little additional cartilage injury in the Japanese study.[16] It is my experience that cartilage injury is greater and the prognosis worse with chip fractures of the middle carpal versus the antebrachiocarpal joint.

SUBCHONDRAL LUCENCY OF THE THIRD CARPAL BONE

Etiopathogenesis

Subchondral lucency or crush fracture of the third carpal bone is a common injury in racing breeds. It might be a prelude to slab fracture of the third carpal bone. Repetitive loading of the third carpal bone during training and racing leads to increased sclerosis of the radial facet, degeneration of the articular cartilage, and in some cases, loss of support from the subchondral bone. Subchondral lucency significantly influences the degree of carpal lameness in Standardbreds.[21]

Diagnosis

Clinical signs include lameness, reduced performance, and mild-to-moderate effusion of the middle carpal joint. Affected horses improve with intra-articular anesthesia of the middle carpal joint. A well-exposed tangential (skyline) projection of the third carpal bone is required for diagnosis (Figure 94-4). Radiographic signs include both sclerosis and lysis of the radial facet of the third carpal bone. In one study of racing Standardbreds and Thoroughbreds that improved after intra-articular anesthesia of the middle carpal joint and showed minimal to no degenerative changes on radiographs, 80% had cartilage damage, an incomplete fracture, or a crush fracture of the radial facet of the third carpal bone.[22] Lameness has been associated with increased sclerosis of the third carpal bone in racing breeds.[11] Radiographs of the contralateral carpus should be taken because disease affecting both carpi is common.

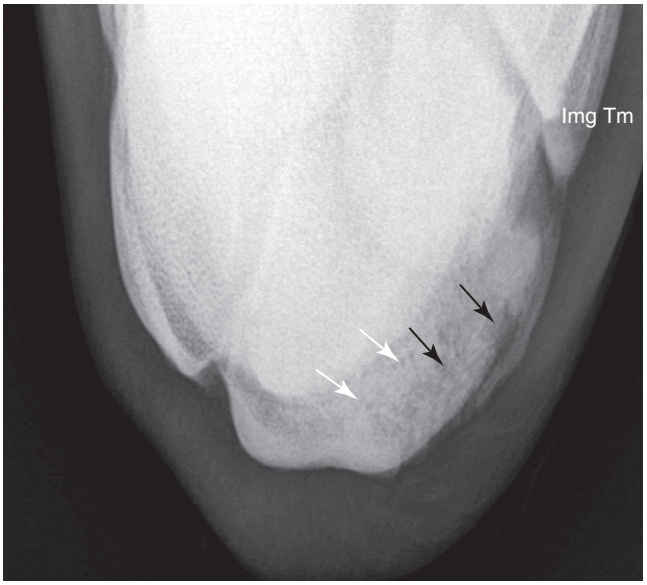

Figure 94-4. Tangential (skyline) projection of the left carpus of a 4–year-old Standardbred demonstrating sclerosis *(white arrows)* and lucency *(black arrows)* of the third carpal bone consistent with third carpal bone degeneration.

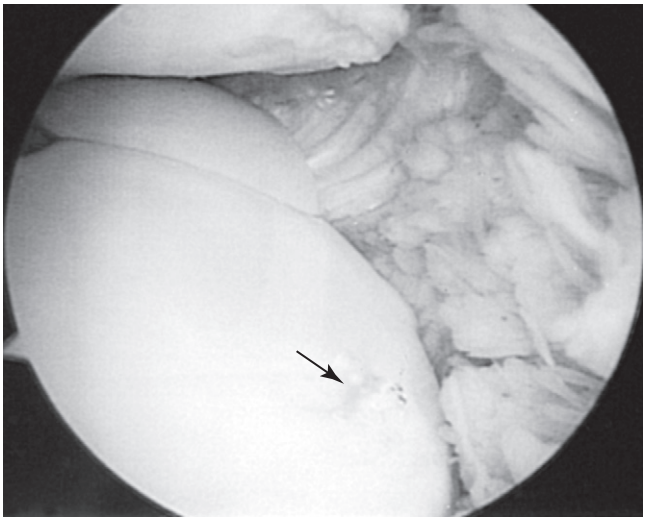

Figure 94-5. Arthroscopic view of the middle carpal joint of a 3-year-old racing Standardbred with a focal defect *(arrow)* in the weight-bearing surface of the radial facet of the third carpal bone. On a tangential radiographic projection, subchondral lucency of the radial facet was seen.

Treatment

Some horses respond to intra-articular therapy but many do not; therefore, arthroscopic débridement is the treatment of choice.[23] The articular cartilage often acquires partial- to full-thickness injury (Figure 94-5). Removal of the abnormal cartilage reveals brittle, yellow, diseased subchondral bone and

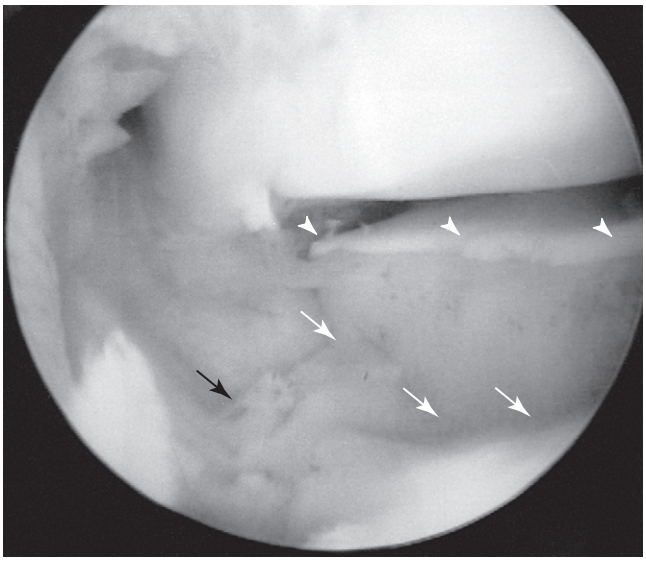

Figure 94-6. Postoperative appearance of the third carpal bone after débridement of degenerative cartilage and subchondral bone in a racing Standardbred. The diseased portion of the third carpal bone was resected until it was no longer in a weight-bearing position. *White arrowheads,* Line where the cartilage and bone were resected vertically. The normal cartilage and its thickness is seen. *White arrows,* Bottom of the verical resection of bone; *black arrow,* dorsal end of the resected cartilage.

occasional fractures. In some cases, the mechanical strength of the cartilage and bone is very poor, and the arthroscopic probe sinks into the subchondral plate. The abnormal cartilage and bone are completely removed. If a dorsal rim remains on the third carpal bone, it is typically removed (Figure 94-6). Postoperative management is identical to that of osteochondral fragments. Prognosis for return to racing for horses after arthroscopic débridement of such lesions is 89%.[24]

MEDIAL PALMAR INTERCARPAL LIGAMENT INJURY

Etiopathogenesis

Diagnosis of partial or complete disruption of the medial palmar intercarpal ligament (MPICL) has become possible because of the use of arthroscopy in equine surgery. The medial and lateral palmar intercarpal ligaments prevent dorsal displacement of the middle carpal joint.[23] The frequency of injury to this ligament ranges between 8.7% and 70%.[25,26] MPICL injury can occur alone or in conjunction with other types of carpal injury, including osteochondral fragments and cartilage damage.[25] One report found no association between intercarpal ligament injury (ICL) and cartilage injury.[27]

Injury to the lateral palmar intercarpal ligament (LPICL) has been described. It is important to differentiate this from lucencies in the ulnar carpal bone, which are generally viewed as incidental finidings. LPICL injuries are characterized by a small avulsion fragment at the origin of the ligament at the ulnar carpal bone.[28] A good prognosis for return to athletic soundness after arthroscopic removal has been reported.[29]

Diagnosis

Clinical signs of MPICL injury include moderate lameness and joint effusion. In acute cases, no radiographic signs specific to this injury are seen. In chronic cases, new bone formation on the distal dorsal aspect of the proximal row of carpal bones can be seen, which is related to a degree of joint instability. Acute ICL injury is suspected by observation of the clinical signs listed earlier, absence of radiographic abnormalities, and response to middle carpal joint anesthesia. Large avulsion fractures of the origin of the MPICL at the distal radial carpal bone are sometimes seen in displaced third carpal bone slab fractures. For this reason, dorsal to palmar radiographic projections should be included in cases of third carpal slab fractures. Ultrasonographic evaluation of the MPICL has been described in the standing horse.[30] Magnetic resonace imaging offers an advanced method of imaging soft tissue structures of the carpus and should be considered in horses with mild to moderate lameness that improves with desentization of the carpal region in the absence of a definite lesion on radiographic, ultrasonographic, and/or nuclear scintigraphy imaging.

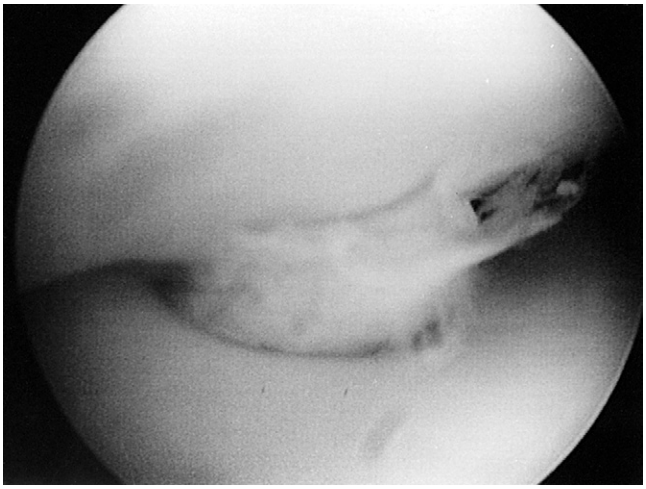

Figure 94-7. Arthroscopic view of the middle carpal joint of a racing Standardbred with a complete tear of the medial palmar intercarpal ligament. The lameness in this horse was isolated by intra-articular anesthesia of the middle carpal joint. The radiographs were normal.

Confirmation of the diagnosis is achieved through arthroscopic evaluation. Most lesions can be diagnosed through examination of the dorsal pouch but visual examination of the palmar pouch of the middle carpal joint may allow specific examination of the palmar bundle of the MPICL. Ligament disruption can be partial or complete (Figure 94-7). A grading scale of injury has been suggested, where grade I indicates rupture or fraying of a small number of fibers; grade II, rupture of up to one third of the ligament fibers; grade III, rupture of two thirds; and grade IV, complete rupture of the ligament. Mild (grade I) tears can be incidental findings at surgery and might not be associated with lameness.[27]

Treatment

No method of ligament repair is available, and the surgical procedure is limited to diagnosis, débridement of free strands of the ligament, removal of any associated avulsion fractures, and débridement of other lesions within the joint. Three months of stall confinement followed by 3 months of pasture turnout is recommended following surgery.

The prognosis is considered fair for partial tears (grades II and III) and guarded for complete tears (grade IV). In one study,

injury to the MPICL combined with subchondral bone damage was the best indicator of postoperative performance.[31] The presence of a complete MPICL tear or a mild tear with large subchondral bone defects was associated with a poor outcome.[32]

CARPAL SLAB FRACTURES

Etiopathogenesis

The third carpal bone is a common site for injury. Fracture types include osteochondral fragments, corner fractures, small and large frontal plane slab fractures, sagittal slab fractures, and comminuted fractures. Carpal slab fractures occur most often in the frontal plane of the radial facet of the third carpal bone.[32] Frontal plane slab fractures also can occur in the radial, fourth, and intermediate carpal bones.[33] Because the radial facet of the third carpal bone undergoes stress-adaptive remodeling during race training, repetitive loading consistently leads to fractures in this location.[32] Additionally, subchondral lucency, cartilage injury, and incomplete fractures are often diagnosed in this area.[15,18,20,22,23] Sagittal slab fractures can be displaced or nondisplaced. These fractures can go undetected unless a properly positioned and exposed skylne projection of the distal row of carpal bones is made. In addition, dorsopalmar and 45-degree oblique dorsomedial to palmarolateral projections are helpful when evaluating sagittal slab fractures of the third carpal bone.

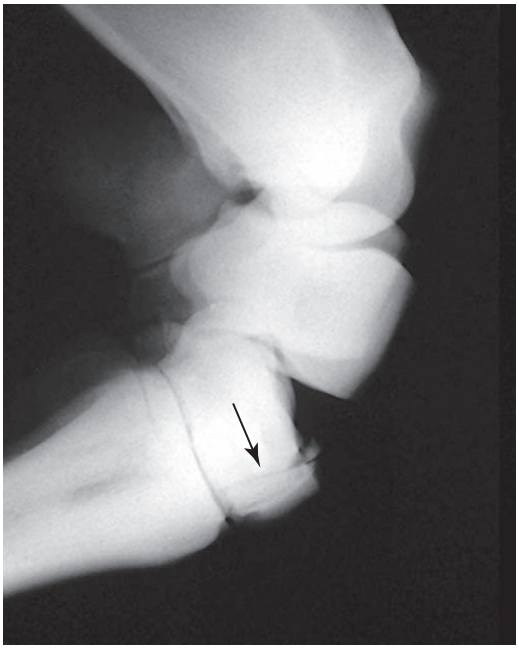

Figure 94-8. Lateral radiographic view of the carpus of a Thoroughbred with a minimally displaced, complete frontal plane slab fracture of the third carpal bone *(arrow)*. Notice the osteochondral fragment (trough lesion) at the proximal articular surface.

Diagnosis

Horses with complete slab fractures of the third carpal bone have moderate to severe lameness, are reluctant to flex the carpus, and exhibit joint effusion. The right forelimb is more often affected in Thoroughbreds, whereas both forelimbs are equally affected in Standardbreds.[34,35] Horses with incomplete slab fractures show a variable degree of lameness and usually exhibit little joint effusion.

Radiographs, including the skyline projection, confirm the diagnosis and aid in the choice of treatment. Fragmentation at the articular margin of the middle carpal joint, third carpal bone sclerosis, and lysis can be present, which usually indicate advanced disease. Diagnosis of incomplete fractures is more difficult because localizing signs can be absent. Careful lameness examination, diagnostic anesthesia, well-positioned and well-exposed radiographs, and occasionally nuclear scintigraphy are necessary for a diagnosis. After a diagnosis is established, radiographs of the other carpus are obtained because bilateral slab fractures or other carpal disease can be present. Bilateral slab fractures occur most commonly in Standardbreds.

Treatment

Treatment options for complete slab fractures include their surgical removal or surgical repair of the fracture with interfragmentary bone screws placed in lag fashion. Surgery is recommended for all horses, even those to be retired from racing. Conservative management of complete slab fractures often results in moderate to severe osteoarthritis. Removal of slab fractures is recommended when thin fragments (less than 10 mm thick) are present or if there is significant loss of articular cartilage associated with the fracture.

In many complete slab fractures, a loose wedge-shaped piece of bone and articular cartilage is found at the parent portion of the bone immediately behind the fracture plane (Figure 94-8). This fragment might not be obvious on the preoperative radiographs. The consequence of this pathology is that curettage of this diseased bone and cartilage results in a significant loss of cartilage and subchondral bone, forming a trough behind the fragment. In such cases, removal of the entire slab fracture may be elected. Alternatively, just the removal of the articular component of the slab combined with screw fixation of the remainder of the slab may be elected. If cartilage loss is minimal or if the slab fracture is more than 10 mm thick or incomplete, compression of the fracture fragments with one or more bone screws is preferred.

Successful management of incomplete fractures is possible with rest alone; however, some horses refracture when they return to racing and eventually require surgery. For this reason, compression of the fracture by placement of a cortex screw in lag fashion under arthroscopic guidance is the treatment of choice for most incomplete third carpal bone slab fractures in racing breeds.

Surgical Technique

FRAGMENT REMOVAL

Fragment removal is best accomplished through an arthrotomy approach. The extent of the fragment is assessed and the joint capsule attachment of the middle carpal and carpometacarpal joints are severed with a scalpel. The fragment is pared loose from its bed with a periosteal elevator and subsequently grabbed with a rongeur. Any remaining fibrous attachments are severed through rotating movements with the rongeur. Persistent tags are sharply transected with the scalpel. When loose, the fragment is removed and the arthrotomy is closed in three layers using routine technique.

Fragment removal under arthroscopic supervision is a time-consuming procedure and only encouraged for small slab fractures. Severing of the joint capsule attachments can be accomplished with a sharp periosteal elevator or an osteotome.

The difficulty in this procedure is the visualization and transection of the carpometacarpal joint capsule.

The postoperative management is identical to that of screw fixation (see later).

SCREW FIXATION

Internal fixation of frontal or sagittal slab fractures can be accomplished using arthroscopic or arthrotomy techniques. However, arthroscopy has considerable advantages over arthrotomy and is considered the treatment of choice. Arthroscopy provides a more complete examination of the joint and facilitates débridement of the fracture gap, but it is technically more difficult to properly orient the implant(s), and requires experience.[20,36]

In arthroscopic repair, the horse is positioned in dorsal recumbency or in lateral recumbency with the affected limb uppermost. The lateral portal is used to position the arthroscope for examination of the medial aspect of the middle carpal joint. Placing the arthroscope in the most lateral aspect of the dorsolateral arthoscopic portal aids in examination, reduction, and fracture fixation of frontal plane slab fractures. The medial portal is used to débride the fracture and should be made along the frontal plane fracture to aid in placing instruments within the fracture plane. The joint is held in extension because this position opens the fracture gap, which aids débridement.

The fracture hematoma and fragments of bone are removed via placement of instruments through the medial portal. Subsequent flexion of the joint reduces the fracture and allows assessment of anatomic reduction. Hypodermic needles are placed at the lateral and medial border of the fracture and along the articular surface of the third carpal bone in the middle carpal joint. An additional needle is placed into the carpometacarpal joint to allow assessment of the width of the third carpal bone. The locations of the hypodermic needles and the reduction of the fracture are confirmed arthroscopically (Figure 94-9). Care should be taken to confirm anatomic reduction of the slab fracture along its entire fracture plane. A 2.5-mm drill bit, oriented perpendicular to the dorsal surface of MCIII, is placed through a separate incision in the center of the fracture fragment. Its location is assessed radiographically or via image intensification (Figure 94-10). Standard AO technique is used to place a 3.5- or 4.5-mm cortex screw in lag fashion. During the placement of the marker bit and screw, it is important to maintain the carpus in flexion to provide adequate reduction.[20,36]

If the fracture is repaired through an arthrotomy, an incision is made into the middle carpal joint over the radial facet of the third carpal bone just medial to the extensor carpi radialis tendon.[37] The fracture line is identified and débrided. Orientation of the drill bit is easier with an arthrotomy compared with the arthroscopic technique. The drill bit should be positioned perpendicular to MCIII and in the center of the fracture fragment (if only one screw is required).

For most fractures 3.5-mm screws are used (Figure 94-11). The 3.5-mm screws have the advantage of easier placement of single or multiple screws because of their smaller size (Figure 94-12). There is reduced risk of splitting the fracture fragment compared with the 4.5-mm screws. The 3.5-mm screw also has a smaller head, which interferes less with the soft tissues over the carpus and is helpful when it is necessary to cross the screws in multiplane fractures (Figure 94-13). Because of these features, 3.5-mm screws are used in thinner slabs. The 4.5-mm screws are used for fractures that are large, typically involving both the radial and intermediate facets of the third carpal bone

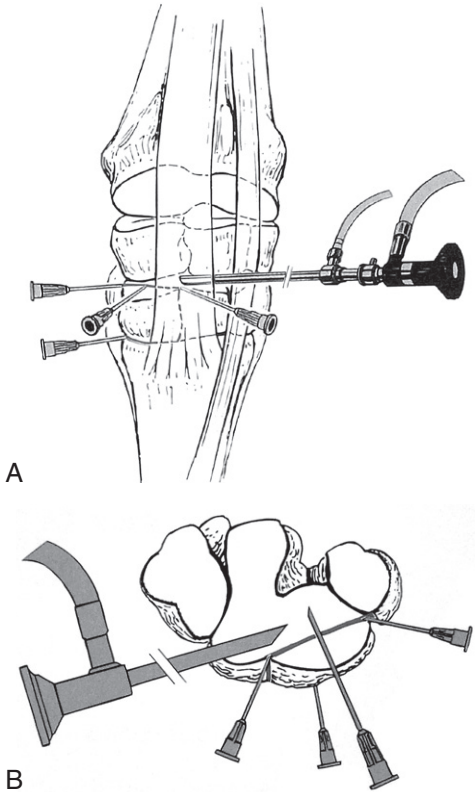

Figure 94-9. Dorsopalmar **(A)** and skyline **(B)** view of a schematic drawing of arthroscope and needle placement for the surgical repair for a third carpal bone slab fracture under arthroscopic guidance. One needle is placed on each end of the fracture, one in the carpometacarpal joint and one centered over the middle of the slab fracture in the middle carpal joint to serve as guides for the location and direction of screw placement.

Figure 94-10. Intraoperative radiographic view of the carpus of a Thoroughbred during surgery for repair of a third carpal bone slab fracture. Notice the placement of the needles to identify the borders of the fracture and the marker drill bits to confirm proper placement and orientation of the implants.

or other carpal bones (Figure 94-14) or radial facet slab fractures that are greater than 15 mm in thickness. Alternatively the use of a headless, tapered screw (Acutrak) has been described for repair of slab fractures, although I have no experience with using this screw system.[38]

Careful intraoperative monitoring with radiographs or image intensification is required regardless of whether the repair was achieved through an arthrotomy approach or under arthroscopic supervision.

Sagittal slab fractures should be repaired with 3.5- or 4.5-mm screws, although 3.5-mm screws are preferred because of their small head size and reduced risk of interference of the screw head with the second carpal bone. These fractures are usually located on the medial aspect of the third carpal bone. Both arthroscopy and arthrotomy approaches can be applied with intraoperative monitoring to guide placement of the implant(s). The surgical approach depends on location of the fracture. Screw placement should avoid contact of the screw head with the second carpal bone, which can cause lameness (Figure 94-15).

The presence of additional carpal pathology is typical for cases of third carpal slab fracture. Aside from the previously mentioned trough behind the slab fragment, distal radial carpal bone chips, cartilage damage at different locations, and MPICL injury may be present.

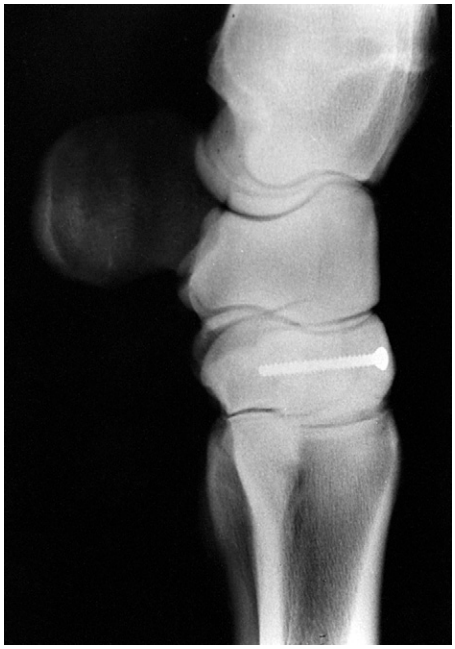

Figure 94-11. Lateral radiographic view after repair of a third carpal bone frontal plane slab fracture with a single 3.5-mm cortex screw placed in lag fashion.

Aftercare

Aftercare is routine, with bandaging for several weeks and a slow, gradual return to work. Most horses require approximately 4 months of recovery before returning to race training; however,

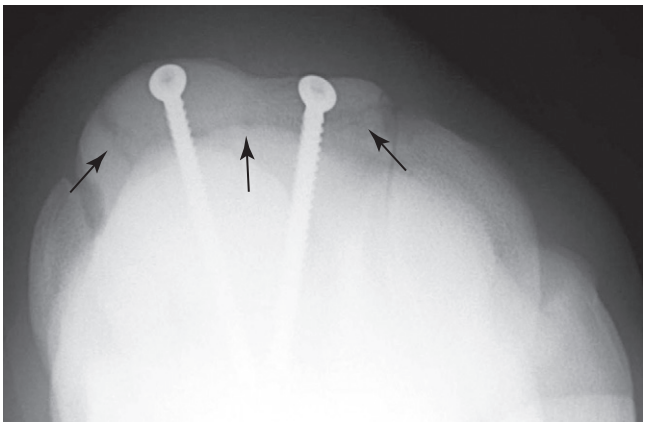

Figure 94-12. Tangential radiographic view of a third carpal bone of a Thoroughbred after repair of a frontal plane fracture *(arrows)* with two 3.5-mm cortex screws placed in lag fashion.

A, Dorsopalmar projection of a 3-year-old racing Thoroughbred with a sagittal plane slab fracture of the medial aspect of the third carpal bone *(arrow)*. **B,** Skyline projection of the third carpal bone after repair with a 3.5-mm cortex screw placed in lag fashion to compress the fracture.

additional time may be required depending on fracture healing. Prognosis differs among breeds, with 77% of Standardbreds and 65% of Thoroughbreds returning to racing after surgery.[34,35] Nondisplaced frontal plane slab fractures repaired with cortex screws placed in lag fashion have a good prognosis for return to function at or above the previous level.[39] Compression of the fracture by the screw coupled with minimal to no significant cartilage injury is significant in the outcome of such cases. Compression of sagittal slab fractures of the third carpal bone with bone screws is associated with an improved prognosis for return to racing soundness when compared to those treated nonsurgically.[40]

MULTIFRAGMENT FRACTURES

Etiopathogenesis

Multifragment fractures typically occur after kicks, falls, or collisions. Such injuries can also occur during racing. Non–weight-bearing lameness and carpal swelling are typical. These horses exhibit angular limb deformity and carpal hyperextension because of carpal collapse.

Diagnosis

Radiographs confirm the presence of multiple fracture lines involving several bones. Most of these fractures involve the medial aspect of the carpus and can include the radial, intermediate, second, and third carpal bones; the proximal vestigial metacarpal/metatarsal (splint) bones; or a combination thereof. The loss of support of the bone column on the medial aspect of the carpus typically causes a carpal varus deformity (Figure 94-16).

Treatment

First aid is aimed at reconstructing the bone column by placing palmar and lateral splints over a heavily padded bandage. The inherent instability and articular nature of the fractures usually makes external coaptation with casts or splints inadequate as the sole treatment, and often results in severe lameness in most horses, the development of pressure necrosis of the skin, and a high risk for developing laminitis or angular limb deformity in the supporting limb.

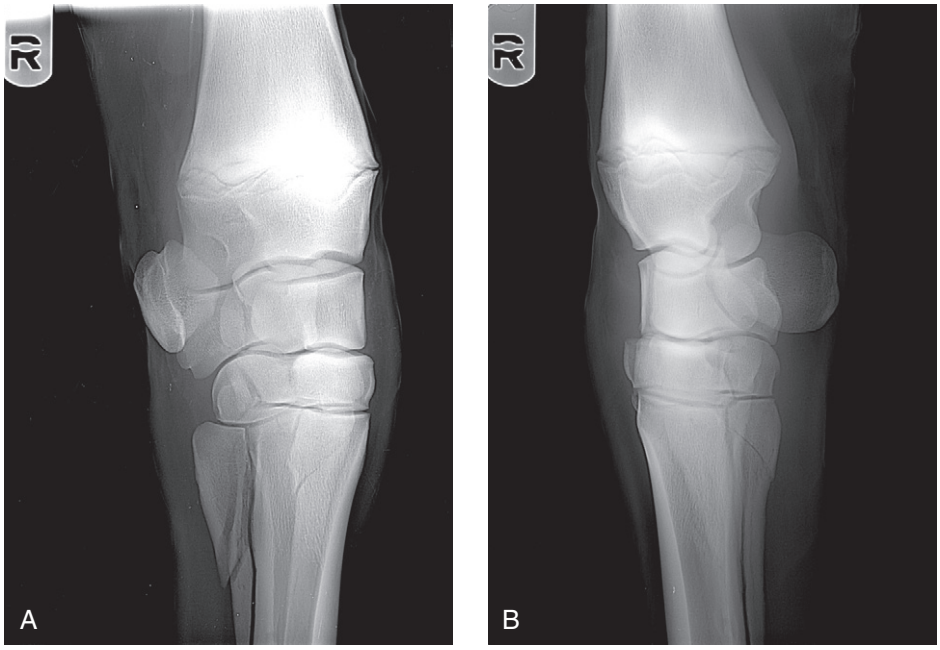

Figure 94-16. Dorsolateral to palmaromedial **(A)** and dorsomedial to palmarolateral oblilque **(B)** radiographic views of a Thoroughbred weanling with a comminuted fracture of the fourth carpal bone and fractures of the proximal aspect of the lateral and medial splint bones.

Realignment of the bone column by reconstruction of the carpal bones with screws is recommended. If the bone column cannot be re-established, carpal arthrodesis with bone plates should be considered (see Chapter 81). Any attempt to treat such an injury is a salvage procedure. For carpal reconstruction, an arthrotomy over the appropriate joint space is performed, and the carpal bones are reconstructed using 5.5-mm, 4.5-mm, and 3.5-mm screws. In some cases, arthroscopic reconstruction is possible but can be quite difficult in comminuted fractures.

Proper reduction of the fracture fragments is of paramount importance during the reconstruction of the bone column for weight-bearing and load sharing with the implants. Additionally, a reduction in the development of osteoarthritis is achieved. At surgery, additional fracture lines and fragments are often found, which complicate the procedure. Coaptation using a sleeve cast for 4 to 6 weeks is recommended postoperatively.

In cases of multicarpal bone fracture, the surgeon and owner should recognize that carpal arthrodesis may be necessary if articular damage is severe or the bony column cannot be reconstructed anatomically. Partial or pancarpal arthrodesis can be performed as needed, although partial carpal arthordesis is preferrred when possible because of the improved mobility and comfort. A variety of implants have been used for partial or pancarpal arthrodesis.[41-43] For a more in-depth description of different arthrodesis procedures, please review Chapter 81.

ACCESSORY CARPAL BONE FRACTURES

Etiopathogenesis

Fracture of the accessory carpal bone occurs in Thoroughbred horses that race over fences, but it can be seen after collisions or falls in any breed. Relative to other carpal injuries, accessory carpal bone fractures are rare, representing 2% of all carpal fractures.[44] In a survey of Thoroughbred yearlings radiographed prior to sale, accessory carpal bone fractures were found in 0.4% of the horses.[14] Because of its location on the palmar aspect of the carpus and its multiple ligamentous attachments, the accessory carpal bone undergoes intense loading during extension of the carpus.

The preponderance of frontal plane fractures is likely caused by avulsion of the bone by its palmar attachments during carpal loading. Other suspected causes of accessory carpal bone fractures include compression between the radius and MCIII and direct trauma. It is typical for a small degree of comminution to be present at the fracture site in frontal plane fractures.[44] Nonarticular chip fractures and comminuted fractures are occasionally diagnosed.[45,46]

Diagnosis

Acute, severe lameness is typical. The carpus can be held in a somewhat flexed position to reduce loading. Carpal canal effusion might be present, but carpal joint effusion might be absent unless there is an articular component to the fracture.

Diagnosis is confirmed through radiographic examination. In acute fractures, displacement is usually present, although nondisplaced fractures do occur. In nondisplaced fractures, another set of radiographs should be taken 10 to 14 days after injury. Nuclear scintigraphy and, if available, computed tomography are helpful in defining the fracture configuration in detail. In chronic fractures, fragment edges are indistinct and rounded off.

Treatment

Treatment options include conservative management or surgical reconstruction and compression with bone screws or plates.

Nonsurgical Management

Nonsurgical management has been successful. Stall rest for 3 months followed by turnout at pasture for 3 to 9 months is recommended. Of 19 horses with accessory carpal bone

fractures, 17 were treated conservatively with rest for 3 to 6 months and two had internal fixation. All 11 horses available for follow-up treated conservatively were sound, and 7 had returned to racing.[44] A recent study evaluationg racing performance of horses suffering from articular fragments revealed that the number of starts was not affected compared to maternal siblings but the earnings in 2- and 3-year-old racehorses were significantly lower.[47]

Surgical Management

Surgical repair with bone screws has been most often attempted in simple vertical fractures. Because of the location, the concave shape of the accessory carpal bone, and the narrow space for error in screw placement, attempts at surgical repair are infrequent. These difficulties, coupled with the low incidence of the injury, make the decision between conservative and surgical management difficult. In one study, vertical fractures were created experimentally, followed by treatment with immediate or delayed repair with bone screws or conservative management.[48] Three horses treated conservatively were still lame 6 months later, whereas all horses that had been surgically treated were sound at 6 months. However, wound infection and screw breakage were reported complications. Another clinical study reports success with surgical management of vertical fractures with bone screws.[46]

In a case report, the application of two four-hole 2.7-mm dynamic compression plates (DCPs) perpendicular to the vertical fracture plane resulted in solid bone union within 3 months and return of the horse to full athletic use.[49] The plate counteracts the tensile forces that displace the fracture, and the compression exerted across the fracture plane aids healing. The same result was achieved with a cervical fusion plate (Synthes Inc.) applied to the lateral surface of the fractured accessory carpal bone in another case (Figure 94-17).[49] The use of LCP technology or of the Unilock system (Synthes Inc.) would have application to this fracture repair as well.

Figure 94-17. Lateral radiographic view of a 5-year-old Thoroughbred with a vertical fracture of the accessory carpal bone that was repaired with a cervical fusion plate. (Courtesy J. Auer, Zurich, Switzerland.)

Prognosis

Although conservative management of accessory carpal bone fractures can result in complete return to athletic soundness in fractures, complete bone union is usually not present. In chronic fractures, the potential for carpal canal syndrome exists and should be evaluated during the examination.[50] Because surgical management of simple vertical fractures has the potential for returning the horse to athletic soundness with minimal callus formation and good bone union, it is the currently recommended treatment.

CARPAL HYGROMA

Etiopathogenesis

Carpal hygroma is characterized by a subcutaneous swelling over the dorsum of the carpus. It is usually associated with a history of trauma to the region. Although the swelling is usually not infected, the potential for sepsis exists after drainage or injection, or both. The management of hygroma is discussed in detail in Chapter 82.

DISTAL RADIAL EXOSTOSIS

Clinical Signs

Exostosis of the distal radius is a rare cause of lameness in horses. The development of exostosis on the caudal border of the distal radial physis induces a tenosynovitis of the carpal canal and irritation and trauma of the deep digital flexor tendon. Exostosis is differentiated from osteochondroma by its location and by histologic examination. Osteochondromas are present on the caudal border of the distal radial metaphysis typically 2 to 4 cm proximal to the distal radial physis. Exostoses are devoid of hyaline cartilage remnants, which are present in osteochondromas.[51] Despite their histologic and location differences, osteochondromas result in the same clinical signs described later for distal radial exostoses and are treated the same. Some exostoses are radiographically inapparent and diagnosis is aided by ultrasonography, which may reveal tendon injury as well.

Regardless of the origin of the mass, the resultant tenosynovitis caused by both conditions results in both a weight-bearing and a swinging-limb lameness. The horse often carries the affected limb slightly abducted at the trot, and the lameness generally worsens with carpal flexion. Occasionally, the gait can appear somehwhat bizarre and almost dysmetric in the affected limb. Effusion of the carpal canal can be difficult to detect without careful inspection of the lateral aspect of the limb in the distal third of the forearm. Lameness is improved after intrasynovial anesthesia of the carpal canal. Consideration of the relationship of the proximal metacarpal structures and the carpal canal should be taken into acount as entry into the carpal canal while performing high palmar anesthesia is possible (see earlier).[1] Nuclear scintigraphy of the distal caudal radius may reveal focal intense uptake of radiopharmaceutical.

Radiography confirms the presence of the exostosis on the caudal aspect of the distal radial physis (Figure 94-18). Exostoses are occasionally seen as an incidental finding on survey radiography. Clinically significant exostoses generally have a

Figure 94-18. Flexed lateral radiographic view of the carpus of a 7-year-old Thoroughbred with an exostosis of the caudal aspect of the distal radial physis *(arrows)*. When these lesions extend more than 1 cm into the canal, they frequently are a cause of lameness.

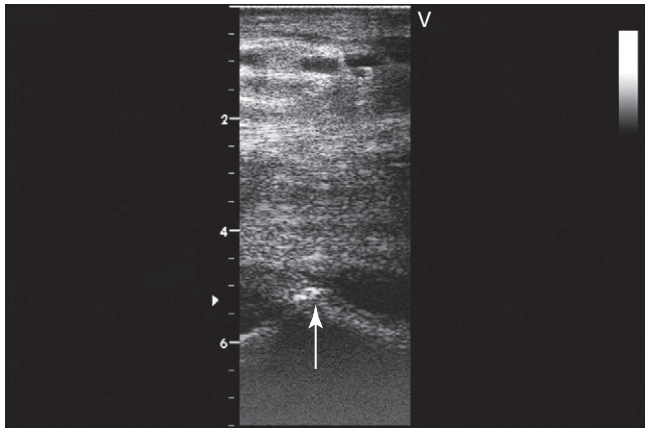

Figure 94-19. Transverse, caudal ultrasonic image of the distal radius of a 10-year-old Warmblood mare revealing fluid within the carpal canal and a caudally projecting exostosis *(arrow)* from the distal radius. This exostosis was not radiographically apparent.

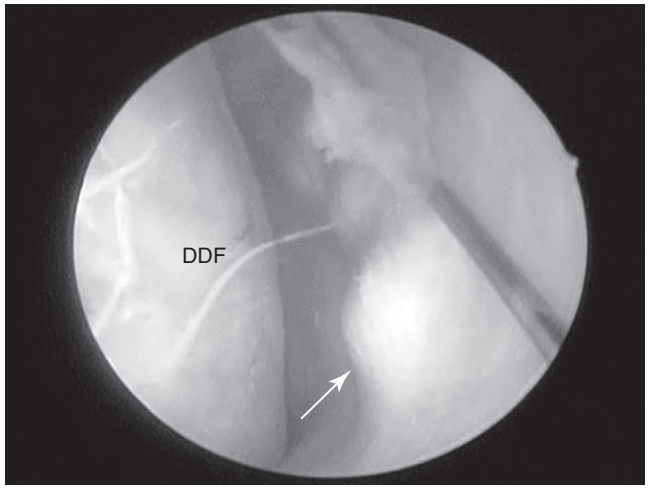

Figure 94-20. Endoscopic view of the mare in Figure 94-19, revealing the exostosis *(arrow)* (just below the hypodermic needle), dorsal to the deep digital flexor tendon *(DDF)*. There is evidence of tendon fibrillation and fibrin within the joint.

protrusion of at least 10 mm from the caudal aspect of the radius into the carpal canal, although potential "radiographically silent" exostoses can cause lameness as well. Ultrasonagraphic examination of the caudal radius and carpal canal may demonstrate radiographically inapparent exostosis, tendon injury, or carpal canal inflammation. It is important to confirm the exostosis as the cause of lameness by intrasynovial anesthesia prior to medical or surgical management (Figure 94-19).

Treatment

Nonsurgical Management

Nonsurgical management of carpal canal tenosynovitis involves intrasynovial injection of hyaluronan and corticosteroids. In my experience, if the response to therapy is incomplete or short-lived, surgical removal of the exostosis is the treatment of choice to remove the underlying cause of the tenosynovitis.

Surgical Management

Distal radial exostoses can be removed via carpal canal endoscopy, which is the method of choice.[52,53] The horse is positioned with the affected limb positioned uppermost or in dorsal recumbency and the forelimb and carpus prepared for aseptic surgery. The carpal canal is distended with lactated Ringer's solution and the arthroscopic cannula is placed between the lateral digital extensor and the ulnaris lateralis tendons through a stab incision at a level of the the distal radial physis.

The carpal canal is entered and a standard 4-mm 25-degree arthroscope is used for the examination. There is ample room within the carpal canal, and the arthroscope is usually positioned to examine the exostosis and any associated deep digital flexor tendon injury without difficulty. A needle is used to ascertain the proper location for the instrument portal distal to the arthroscopic portal (Figure 94-20). A 5-mm osteotome is used to loosen the exostosis from its bed. Care should be taken to separate the exostosis from the radius as close to its base as possible and not to completely dislodge it. The mass is grasped with a Ferris-Smith rongeur and removed. Large proliferations are best removed by extending the stab incision longitudinally. Alternatively the exostosis can be removed piecemeal through the stab incision using Ferris Smith ronguers. The associated bed can be further débrided with a rongeur, curette, or osteotome. On occasion the bony prominence must be detected by probing through the fibrous lining of the carpal canal onto the distal radius. Examination of the soft tissue structures and evaluation for adhesion formation is important during the endoscopy to determine prognosis. Release of the carpal flexor retinaculum can also be accomplished via endoscopic guidance if constriction of the carpal canal is suspected.[54]

The canal is lavaged and the fibrous layer of the tendon sheath or subcutaneous tissue and skin is closed in separate layers. Intraoperative radiographs are recommended to confirm the complete removal of the exostosis. Two-layer closure of the endoscopy and instrument portals is recommended in tendon sheaths to prevent leakage of synovial fluid, which occurs more commonly than after arthroscopic procedures. A full limb bandage is used for recovery from general anesthesia. Postoperative recommendations include box stall confinement for 4 weeks and pasture turnout for 4 to 8 weeks thereafter.

For additional information on this condition, please review Chapter 95.*

Prognosis

Prognosis after removal of distal radial exostoses is good; however, prognosis depends on concurrent flexor tendon injury or adhesion formation, which may be present. In a clinical report, 9 of 10 horses returned to full athletic function after endoscopic removal of the exostosis. The remaining horse became sound after further intrasynovial medication with hyaluronan.[45]

ANGULAR LIMB DEFORMITIES

Angular limb deformities of the carpus occur commonly in foals. Valgus deformity is more common than varus deformity. Angular limb deformities of the carpal region can be caused by physeal dysplasia, joint laxity, and cuboidal bone hypoplasia or malformation.

Methods of treating angular limb deformities of the carpal region include splints, bandages, casts, growth retardation, and, most commonly, periosteal elevation and transection. Treatment varies depending on the age of the horse and the cause of the deformity. Treatment options are discussed in detail in Chapter 86.

LUXATION (SUBLUXATION)

Etiopathogenesis

Carpal luxations are traumatic events caused by falling with one limb wedged in a fixed position, as a result of a being kicked or hit by a vehicle. Other causes are speculative because often the animal is found in the pasture with an obvious luxation whose origin was not observed.

Diagnosis

The animal might be presented with an obvious deformity in the carpus resulting in an abnormal position of the limb distal to the carpal region. In this instance, the diagnosis is obvious from radiographs (Figure 94-21). Alternatively, the animal might bear weight on the limb but show a marked lameness. Standard radiographs might show some small bone chips in the periarticular region as the only abnormality. If the luxation is in association with skin trauma, crepitus is recognized in the periarticular soft tissues. A definitive diagnosis of joint involvement with the wound is made through arthrocentesis and stress radiographs under general anesthesia.

Figure 94-21. Craniocaudal radiographic view of the distal radius of a horse with complete luxation of the middle carpal joint. Note that the proximal and distal rows of carpal bones overlap and are rotated, resulting in a lateral view of the distal limb. A bone fragment is recognized below the intermediate carpal bone, indicating that an avulsion fracture of the palmar aspect of the intermediate carpal bone has occurred. (Courtesy J. Auer, Zurich, Switzerland.)

Treatment

Luxations may be managed conservatively or through surgical intervention.

Nonsurgical Management

Conservative treatment involves cast application for 3 months with two or three cast changes. During this time, the ruptured periarticular soft tissues heal by fibrosis. Depending on which joint is involved, decreased carpal flexion is the result. Careful management of the convalescent period helps in restoring a useful animal. Coaptation should only be considered if the bone column is intact and the bone column does not collapse when the horse is bearing weight.

Surgical Management

Surgical management through partial or pancarpal arthrodesis is an option and is discussed in Chapter 81. Proximal fractures of the second or fourth metacarpal bone may cause subluxation of the carpometacarpal joint. Small plates to repair these fractures are recommended to overcome the tension forces of the collateral ligaments, even in small foals. My experiences with coaptation or screw fixation alone have been disappointing. Plate fixation of proximal fractures of the small metacarpal bones is discussed in detail in Chapter 93.

*An editorial decision was made to discuss this condition in both chapters because slightly different aspects are elucidated in addition to good pictorial material.

Figure 94-22. A Warmblood horse admitted for treatment of coronation, which occurred during a riding accident. (Courtesy J. Auer, Zurich, Switzerland.)

CORONATION (COURONNEMENT)

Etiopathogenesis

Coronation refers to a severe soft-tissue injury of the dorsum of the carpus that occurs after a fall. It is characterized by the loss of skin over the carpus, and in more severe cases, the wound involves the synovial sheaths of the extensor carpi radialis, common digital extensor tendons, or one of the carpal joints.

Diagnosis

Physical signs of injury are obvious, with a flap or degloving wound present over the dorsum of the carpus (Figure 94-22). Entry into the tendon sheaths or joints might be obvious, but puncture wounds might go unnoticed.

If synovial involvement is suspected, a needle should be placed into the carpal joint or tendon sheath at a site distant from the wound after aseptic preparation and the structure distended with sterile saline to detect any leakage through a skin defect. Care must be taken to avoid entry through

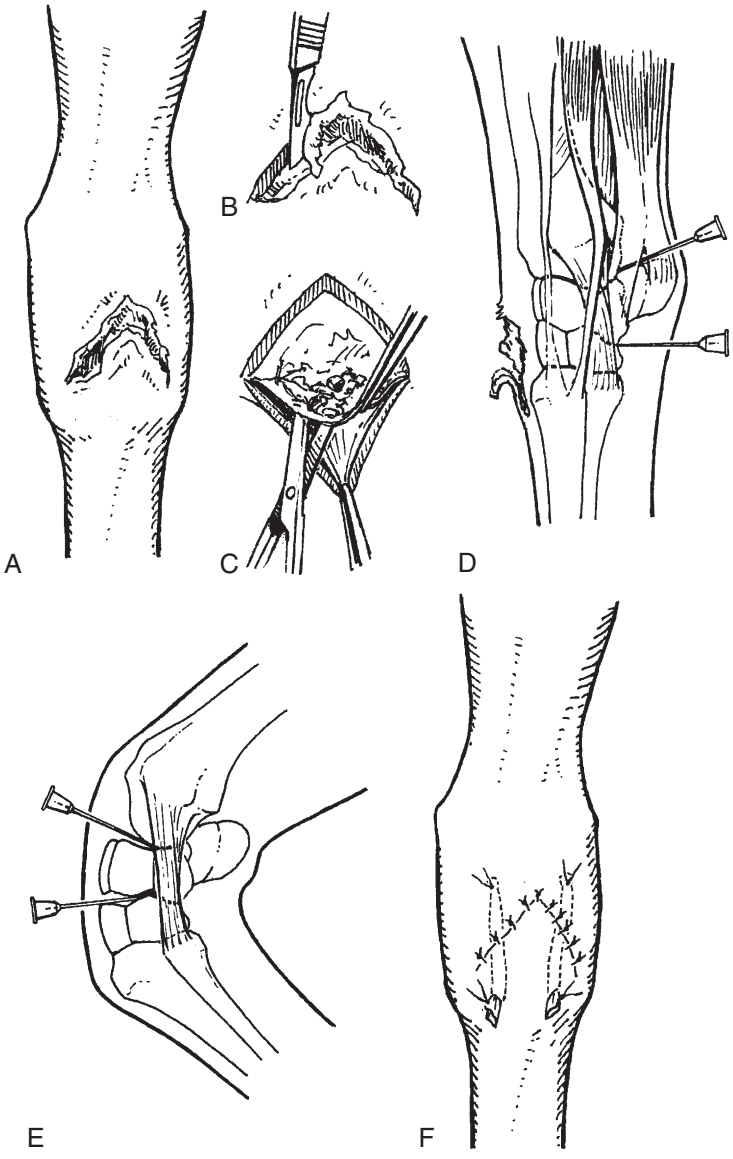

Figure 94-23. Treatment of a coronation injury. **A,** Appearance of the injury. **B,** A 1- to 2-mm rim is sharply removed around the skin defect. **C,** Careful débridement of the subcutaneous tissues aids in determining if the joint is involved as well. **D,** Needles placed from the palmar aspect of the carpus into the joints for joint lavage allows verification of any potential joint involvement. **E,** Alternatively, the needles may also be inserted from the dorsolateral or dorsomedial aspect of the carpus. **F,** After installing one or two drains, the skin is closed in routine fashion.

traumatized or infected tissue to prevent inoculation of the synovial structure with bacteria. For the tendon sheath, a proximal location is chosen, and for the carpal joints, the palmar recesses may be used. Any draining fluid obtained is collected and submitted for cytologic examination and culture and susceptibility testing. Occasionally, the extensor carpi radialis or common digital extensor tendon is ruptured as well.

Radiographs should be obtained after cleaning the wound to assess bone injury and identify additional debris, especially gravel. Contrast radiography can be used to identify communications between the synovial structures and the wound. The use of ultrasonography is limited because of subcutaneous emphysema from the wound.

Treatment

Treatment consists of management of the wounds and any involved synovial structure. Wound management and management of synovial infections are discussed in Chapters 26, 27, and 85, respectively. Some specific issues of management of these wounds deserve mentioning here.

I prefer to close acute wounds into synovial structures after lavage and intrasynovial antimicrobial therapy unless severe contamination exists. A 1- to 2-mm rim of skin is sharply dissected along the skin defect, followed by careful sharp surgical débridement of the deeper tissues (Figure 94-23, *A*, *B*, and *C*). In cases where the joint capsule is opened as well, intra-articular lavage is mandatory. This can be accomplished through needles placed from the palmar aspect of the carpus (see Figure 94-23, *D*) or from the dorsolateral or dorsomedial aspect of the carpus (see Figure 94-23, *E*). The joint capsule is subsequently closed using simple interrupted sutures of a size 0 or 2-0 absorbable suture material.

After implantation of one or two drains the skin is closed in routine fashion (see Figure 94-23, F). Delayed wound closure is sometimes necessary to identify the extent of injury and allow débridement. The use of splints, cast bandages, and casts is usually necessary to provide immobilization for wound healing. Supportive therapy (such as repeated joint lavage), anti-inflammatory agents, and systemic, regional, and/or intrasynovial antimicrobial agents varies with the type and severity of the wound.

Horses can return to full athletic activity after injuries that involve superficial structures. Wounds that involve the tendon sheaths, joints, or carpal bones have a reduced prognosis, which is determined by the extent of the wound and use of the horse. Prognosis is improved with prompt (less than 24 hours) treatment of the open joint. Even wounds that have had significant loss of tissue over the dorsum of the carpus can heal and provide a satisfactory outcome if the synovial structures respond appropriately.

CHAPTER 95

Radius and Ulna

Jeffrey P. Watkins

The equine antebrachium consists of the radius and ulna in conjunction with the muscles that flex and extend the carpus and digit. The radius is the major weight-supporting bone in the antebrachium. The olecranon, by serving as the insertion site of the triceps muscle, acts as the lever arm during elbow and carpal extension. The primary indications for surgical intervention in this area are caused by traumatic events that result in fracture of either the ulna or the radius.

FRACTURES OF THE ULNA

Fractures of the ulna are relatively common in foals and adult horses. A wide variety of fracture configurations occur, and most are amenable to open reduction and internal fixation. The treatment of choice is fracture fixation using a bone plate applied as a tension band. Provided complications are not encountered, the prognosis is favorable for a return to full function.

Anatomy

The ulna has two components, the body and the olecranon process (or more simply, the olecranon). The body of the ulna extends distad from the level of the proximal radial physis. It is triangular in cross section and tapers distally, essentially ending in the mid-diaphyseal region of the radius. It is closely adherent to the radius, and in adult horses, it is fused to the caudal cortex of the radius distal to the interosseous space. Functionally, it serves as the distal attachment of the lever arm through which the triceps muscle functions.

The olecranon is found proximal to the body of the ulna. It is concave medially and has a proximal tuberosity for muscle attachment. Tendinous insertions on the olecranon tuberosity, principally by the triceps brachii muscle, provide elbow extension during locomotion and in doing so, impart weight bearing. Equally important, by extending the elbow during standing, the triceps apparatus allows extension of the carpus through engagement of the stay apparatus of the forelimb. The olecranon is also an important component of the cubital joint, with articular cartilage present in the proximal aspect of the trochlear notch. In the distal aspect of the trochlear notch there is a synovial fossa, which is devoid of articular cartilage.

Foals have a physis in the proximal olecranon. Because the separate center of ossification of the physis is not involved in formation of a joint, it is termed an *apophysis*. Although growth at the olecranon physis is responsible for the ultimate size of the olecranon tuberosity, disturbances of physeal growth

following injury or fracture repair are well tolerated and do not result in disability. However, because growth occurs at the proximal radial physis, the ulna must be able to elongate during rapid growth of the foal along with the radius to maintain congruency between the humeral condyle and the trochlear notch of the olecranon.

Pathogenesis

A direct blow from a kick or a fall causes most fractures of the ulna. A common history includes injury during halter training of weanling foals. Often the fracture occurs when the foal rears up and falls onto its side. The body of the ulna, or more commonly the olecranon, fractures, and fragments are displaced during contraction of the triceps muscle when the foal jumps to its feet.

Several classification systems for ulnar fractures have been published, but to prevent confusion, only the one that I use is listed here (Figure 95-1).[1] The most common configuration in horses younger than 1-year of age is the type 1b fracture, where the caudal one third to one half of the physis is disrupted, propagating the fracture into the metaphysis, and finally exiting into the proximal aspect of the trochlear notch near the anconeal process (Figure 95-2).[2] Less commonly, the fracture breaks out the cranial cortex of the olecranon proximal to the anconeal process and remains nonarticular (also type 1b). Occasionally, comminution occurs at the anconeal process.

Other configurations include physeal separations (type 1a), most common in neonates; transverse fractures entering the trochlear notch near its midpoint (type 2); distal olecranon–proximal ulnar body fractures, which usually have an oblique configuration traversing the bone in a proximal and cranial direction to enter the distal aspect of the trochlear notch (type 5) and are most commonly encountered in horses older than 1 year of age[3]; and comminuted fractures (type 4). Type 3 fractures—nonarticular, nonphyseal fractures of the olecranon extending from the caudal cortex to the cranial cortex proximal to the anconeal process—are rare.

The degree of soft tissue injury varies greatly. Contusions resulting from a kick are often accompanied by a skin wound at the site of impact. These wounds might communicate directly with the fracture, and if the fracture contains an articular

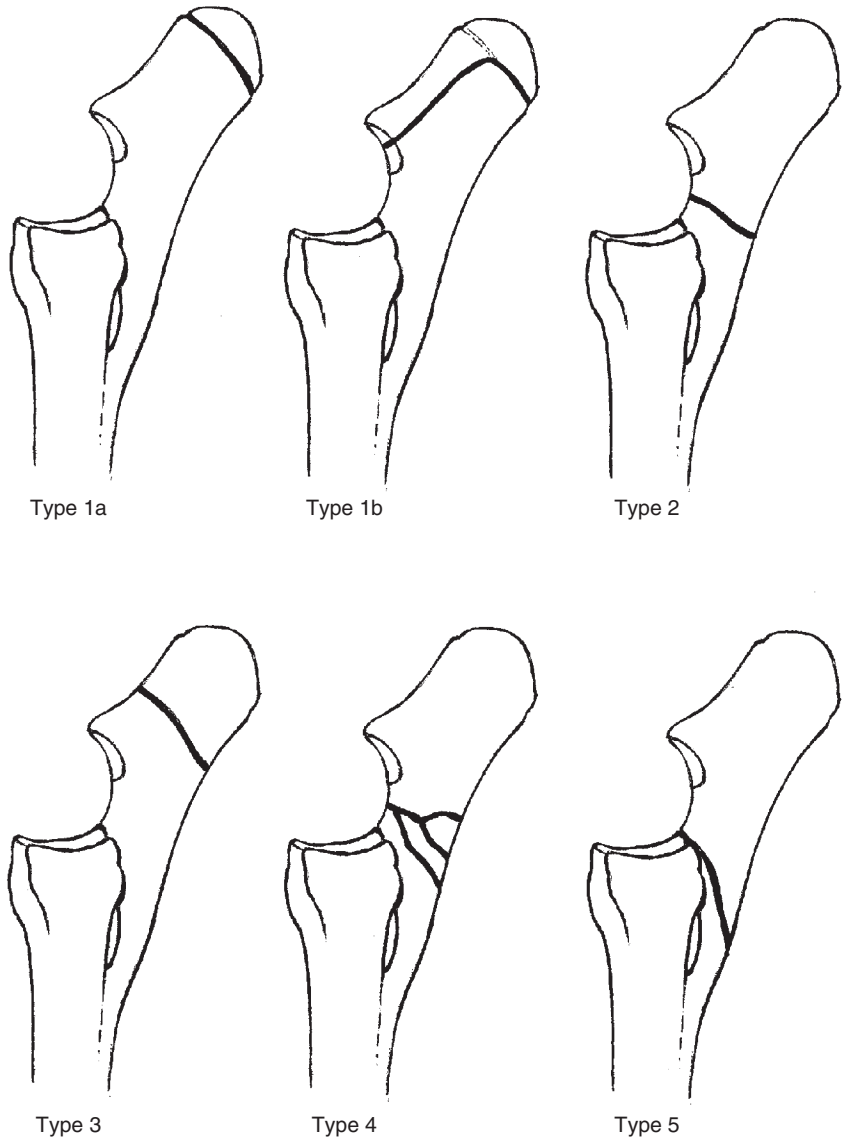

Figure 95-1. Classification scheme for ulnar fractures: *Type 1a,* Fracture along the apophyseal physis; *Type 1b;* fracture staring out along the apophyseal physis and then breaking into the metaphyseal part of the olecranon process and finally entering the joint; *Type 2,* simple fracture through the body of the olecranon process with articular involvement; *Type 3,* simple fracture through the body of the olecranon process without articular involvement; *Type 4,* multifragment fracture of the olecranon process with or without articular involvement; *Type 5,* distal oblique ulnar fracture with marginal articular involvement.

Figure 95-2. Mediolateral radiographic view of a displaced type 1b, articular olecranon fracture.

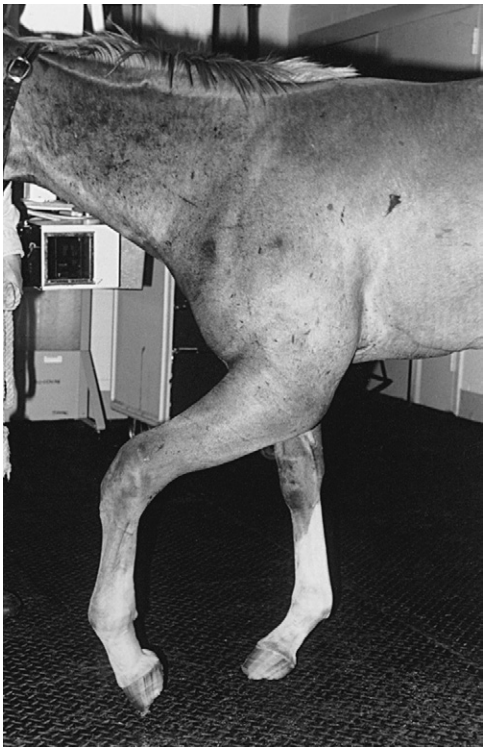

Figure 95-3. Photograph demonstrating the typical dropped elbow stance in a foal with a displaced olecranon fracture.

component, joint sepsis can develop secondary to bacterial colonization of the fracture and subsequent extension into the joint cavity. Displacement of the fracture is another indicator of the degree of soft tissue damage. Marked displacement indicates disruption of the aponeurosis of the ulnar head of the deep digital flexor muscle laterally and the ulnar head of the flexor carpi ulnaris muscle medially.

Diagnosis

Lameness, accompanied by a dropped elbow, is typical on presentation. However, with nondisplaced fractures typical of type 5 fractures, lameness may be the primary presenting complaint. When the fracture becomes displaced, the affected limb will have a dropped-elbow appearance, because the carpus cannot be fixed in extension. Depending on the amount of displacement, the elbow might appear only slightly dropped, with the carpus held in flexion, the limb placed slightly craniad, and the toe touching the ground. With severe displacement, marked dropping of the elbow along with carpal flexion is evident (Figure 95-3). The differential diagnosis for a dropped elbow stance includes ulnar fracture, humeral fracture, and radial neuropathy.

Soft tissue swelling is usually not severe in most ulnar fractures and is localized to the caudolateral aspect of the proximal antebrachium. This is distinct from humeral fractures, in which the swelling is typically much greater and best visualized by standing in front of the horse and comparing the relative thickness of the humeral regions on affected and unaffected sides. Pain on deep palpation and manipulation of the olecranon aids in localizing the fracture.

Definitive diagnosis is based on radiographic documentation of the fracture. Best detail of the area is obtained with a medial to lateral projection and the beam obliqued slightly cranial to caudal. When the affected limb is extended craniad, complete visualization of the cubital joint and olecranon is possible, and the fracture configuration and location can be determined. With type 1b and type 4 fractures, it is important to visualize the anconeal process to delineate comminuted fragments. A cranial to caudal radiograph is necessary to detect concurrent injury to the proximal radius (Figure 95-4). A contrast arthrogram determines the extent of communication between a soft tissue wound and an articular fracture.

Treatment

First Aid

Initial care for horses with fracture of the ulna accompanied by a wound should include appropriate wound therapy consisting of removal of hair at the wound margins and careful cleansing and débridement, followed by application of a sterile bandage to prevent further contamination before surgery. Systemic broad-spectrum bactericidal therapy should be initiated immediately.

It is important to ascertain the extent of soft tissue trauma. Fortunately, many wounds encountered with olecranon fractures are superficial and do not markedly affect therapy or prognosis. However, deep wounds that communicate with the fracture, particularly articular fractures, dictate immediate and aggressive therapy. Therapy for open articular fractures includes administration of intra-articular antimicrobial drugs. In addition, antimicrobial-impregnated polymethyl methacrylate (PMMA) beads placed into the depths of extensive soft tissue wounds may reduce bacterial numbers in the wound prior to open reduction and internal fixation of the fracture.

Many horses with displaced fractures cannot engage their stay apparatus and therefore are unable to support weight on

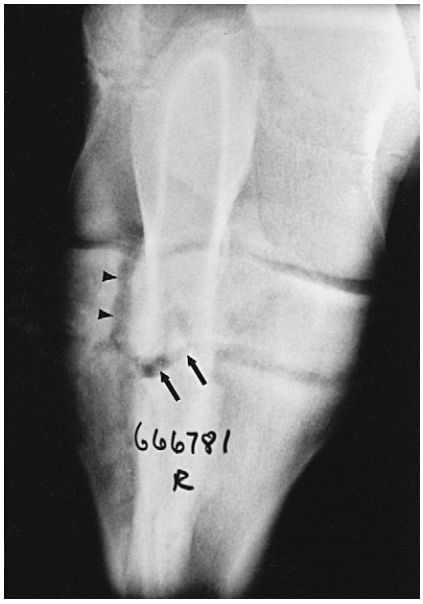

Figure 95-4. Craniocaudal radiographic view demonstrating a Salter-Harris type III fracture of the proximal radius *(arrowheads),* which occurred in conjunction with a fracture of the ulna *(arrows).*

the affected limb. If so, a splint is applied when wound therapy is complete. Although it is not possible to splint the fracture per se, splinting the carpus in extension allows weight to be supported on the affected limb. In horses with a droppped elbow secondary to a displaced olecranon fracature, splinting the limb in extension markedly reduces anxiety and minimizes fatigue of the contralateral limb before internal fixation.

The splint should consist of rigid material applied over a well-padded full-limb bandage. Splints are fashioned from schedule 40 polyvinylchloride (PVC) pipe; an appropriate length is cut from a 15-cm (6-in) diameter pipe and split longitudinally, using one third of the pipe's circumference. The splint should extend from the ground to the proximal antebrachium and is affixed to the bandage with nonelastic adhesive tape. Additional padding at the proximal aspect of the splint prevents soft tissue damage near the fracture site. Futher information on first aid is found in Chapter 73.

Nonsurgical Management

Conservative therapy consisting of strict stall confinement has been advocated for nondisplaced, nonarticular fractures of the olecranon, especially type 5 fractures.[1,4] If the patient does not bear full weight on the limb, a full-limb splint is applied. Functional soundness was reported in 7 of 10 horses with type 5 fractures managed conservatively.[4] Poor results are achieved following conservative therapy for other fracture configurations.[1]

Horses with nondisplaced, nonarticular fractures that are managed conservatively have a prolonged convalescent period because of the instability of the fracture. Healing is slow, and lameness is protracted. Although type 5 fractures do not violate the articular surface of the cubital joint, they communicate with the synovial cavity. Inflammatory mediators released into the joint from the fracture may have detrimental effects on the articular cartilage and lead to degenerative articular changes. More importantly, synovial fluid entering the fracture line may disrupt healing, leading to development of a pseudarthrosis. Despite the inherent risk of surgery and anesthesia, surgical treatment is preferable, and the primary determinant for choosing conservative therapy over surgical therapy is economics.

Surgical Management

Open reduction and internal fixation is the treatment of choice for articular or displaced fractures of the ulna. By using the tension-band principle, stable fixation of nearly all fracture configurations can be achieved with minimal complications and a favorable prognosis. Tension-band fixation can be accomplished using a plate applied to the caudal aspect of the ulna or by using tension-band wire or cable fixation.

The surgical approach to ulnar fractures has been described.[5] It is advisable to curve the skin incision proximad to avoid the point of the elbow. When possible, wounds should also be avoided when approaching the fracture. After the skin and subcutaneous fascia have been incised, deep dissection between the ulnaris lateralis muscle and ulnar head of the deep digital flexor tendon exposes the caudal and lateral aspects of the ulna.

Distally, the ulna is exposed for plate application by subperiosteal dissection. Proximally, the caudal and lateral aspects of the olecranon are closely invested in the dense fibrous connective tissue aponeuroses of the ulnar head of the deep digital flexor and flexor carpi ulnaris muscles. Sharp dissection of the fibrous connective tissue attachments from the olecranon is necessary for plate application. Additional dissection exposes the proximal aspect of the olecranon tuberosity for fixation of type 1 and 3 fractures. In these cases, the insertion of the triceps is sharply divided in the sagittal plane parallel to the longitudinal fiber bundles and dissected abaxially at their insertion on the olecranon far enough to accommodate the width of the plate.

After the bone is exposed, the fracture hematoma is evacuated and the fracture line débrided of all fibrin or, in chronic cases, fibrous tissue. Assessment of the bone at this time might reveal hairline cracks in the ulna that might not have been evident radiographically. If the anconeal process is comminuted, the fracture is opened and the fragment is removed through the fracture gap. An alternative technique involves cranial dissection along the lateral aspect of the ulna until the joint can be palpated and penetrated with a short stab using closed blunt scissors. Finger palpation allows identification of the anconeal fragment and its subsequent removal. In displaced fractures, reduction is accomplished by grasping the olecranon process medially and laterally with a large pointed reduction forceps and applying caudal and distal traction with the limb held in extension and pulled caudad.

A soft aluminum template can be used to provide a model for plate contouring. The plate is positioned to allow screw engagement of a minimum of five cortices on either side of the fracture. Usually a narrow limited-contact dynamic compression plate (LC-DCP), a dynamic compression plate (DCP), or a locking compression plate (LCP) is used for fixation. In large patients or for more comminuted fractures, a broad LC-DCP, DCP, or LCP may be chosen. In adult horses with comminuted fractures, double plate fixation with a caudal and a lateral plate may be necessary. A study evaluating 18 ulna fractures in 16 patients treated with one or two LCPs, revealed results similar to those with the use of DCPs.[6] Infection was still the main factor influencing the outcome and complete healing.

The appropriately contoured plate is applied by positioning one screw proximal and another screw distal to the fracture with the fracture held in reduction. It is important to apply the plate to the caudal border and not err to the caudolateral aspect to prevent the screws from exiting through the medial aspect of the olecranon tuberosity proximally and penetrating the medial cortex of the radius distally. The first cortex screw is placed in the proximal fragment using the neutral drill guide through a compression hole. This screw is not tightened completely, and the plate is displaced distad before placing the second cortex screw in the distal fragment using the load drill guide. Tightening these two screws compresses the fracture and brings the plate into contact with the underlying bone. Overcompression of minimally displaced fractures with comminution at the articular surface can result in fragment displacement. Therefore, screws should be applied in the neutral position with comminuted fractures.

At this point in the repair, an intraoperative lateromedial radiograph should be obtained to assess the fixation (Figure 95-5). The intraoperative radiograph can be used to evaluate the adequacy of reduction and screw position and as a guide for directing and gauging the approximate length of the remaining screws.

If further compression is needed, an additional cortex screw on either side of the fracture can be placed in the load configuration. Before tightening these additional load screws, the previously placed screw in the same fragment should be loosened slightly. The remainder of the cortex screws are placed in the neutral position. If an LCP is used, one or two locking screws are placed on either side of the fracture with another locking screw positioned at either end of the plate. If needed, all but two screws (to achieve axial compression) can be locking head type (Figure 95-6).

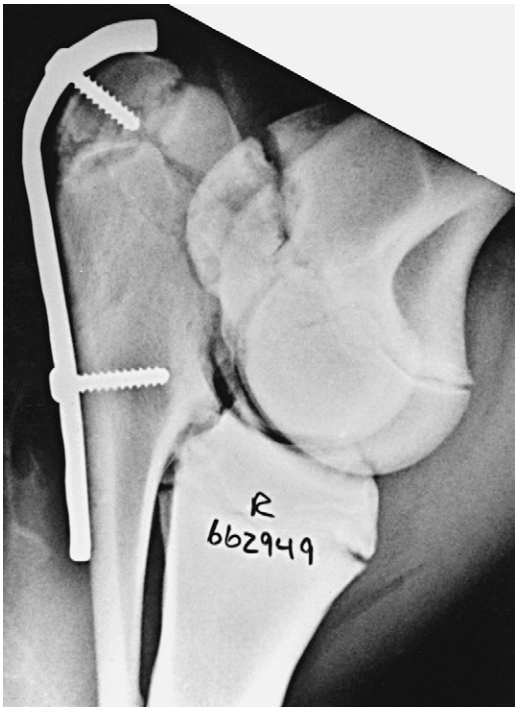

Figure 95-5. Intraoperative lateromedial radiographic view documenting fracture reduction and plate application by means of a proximal and distal cortex screw. The remaining cortex screws are placed in lag fashion through the plate into the cranial cortex of the olecranon in a type 1b fracture.

Screw placement in the proximal fragment must avoid penetrating the concave medial cortex. By aligning the drill bit parallel to a Steinman pin inserted along the medial aspect of the olecranon process in a cranial direction, the surgeon is assured that the drill hole will exit at the cranial border of the bone, ensuring solid fixation. Screws at the level of the trochlear notch should not penetrate into the joint.

Distally, screws should not engage the caudal cortex of the radius in foals. If the body of the ulna is transfixed to the radius, growth of the proximal radial epiphysis forces the anconeal process into the humeral condylar notch, and subluxation of the cubital joint develops, resulting in elbow dysplasia. The age at which it is safe to engage the caudal cortex is not well defined. In one study, there was growth at the proximal radial physis with relative displacement of the ulna until 18 months of age.[7] However, in another study in which the radius and ulna were transfixed, it appeared that subluxation was not a clinical problem in foals that were 7 months old or older at the time of surgery, even though subluxation was evident radiographically and at necropsy.[7]

Therefore, I recommend that engagement of the caudal cortex of the radius be avoided in foals younger than 1 year of age. If not, careful monitoring is necessary, and either the implants or the screws engaging the radius should be removed as soon as the fracture has healed (although subluxation can occur even after the implants are removed).[8] If subluxation occurs, it can be managed with an osteotomy of the body of the ulna at a level distal to the joint (Figure 95-7).[9] By not stabilizing the osteotomy, the ulna can adjust into a normal position during the postoperative period. Another alternative is active proximal displacement of the proximal fragment through flexion and extension of the joint and subsequent bridging of the osteotomy gap with a narrow plate.

The proximal location of types 1 and 3 fractures challenges the fixation, because the small size of the proximal fragment limits the number of screws available for purchase. With a type 1b fracture, the plate is contoured over the dorsal aspect of the apophysis to allow purchase with three short screws. The fourth and usually the fifth screw in the plate are placed in lag fashion across the metaphyseal portion of the fracture to engage the cranial cortex of the olecranon (Figure 95-8). Purchase in the cranial cortex of the olecranon adds substantial strength to the fixation.

Compression at the fracture line improves fracture reduction; this is particularly important for type 1b fractures that enter the articulation. Care is taken with type 1b fractures to avoid overcompressing the caudal aspect of the fracture using a DCP, because the cranial aspect of the fracture can become displaced. In these fractures, the initial screw is placed in the apophysis through the second plate hole, and another screw is placed in the sixth or seventh hole of the plate. These screws are not completely tightened, allowing the fracture to be held in reduction while the lag screws are placed across the metaphyseal fracture. When the lag screws are tight, the remainder of the fixation is routine.

Prognosis

The prognosis following plate fixation of ulnar fractures is favorable. Success, defined as fracture union, occurred in 13 of 19

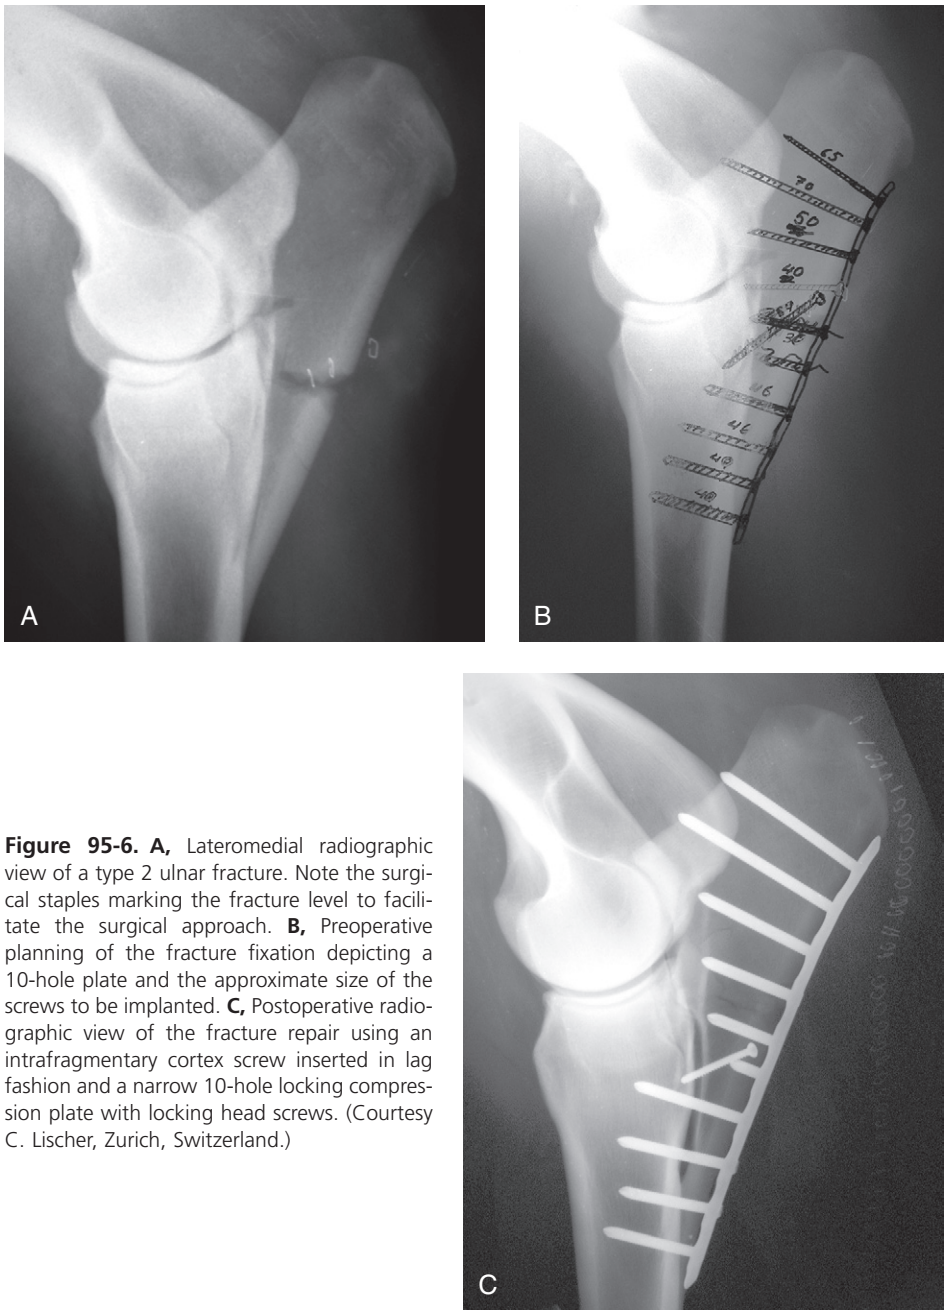

Figure 95-6. A, Lateromedial radiographic view of a type 2 ulnar fracture. patients (68%), with a return to full function in 11 of the 13 cases.[1] Another study reported return to full function in 16 of 21 patients (76%).[10] Type 2 fractures were the most common configuration encountered in both studies. When both patient populations were combined, full function returned in 27 of 34 patients (79%). Type 4 fractures were the second most common configuration in these reports, but only two of seven patients returned to full function. In a retrospective analysis of 17 adult horses with comminuted articular fractures (type 4), long-term follow-up was available for eight, and five were sound enough for riding or training.[11]

In another retrospective study of 77 olecranon fractures, type 1b fractures were the most common configuration in horses younger than 1 year of age.[2] Twenty horses underwent plate fixation as previously described (see Figure 95-8). Fracture healing occurred in 19 of the 20 repaired fractures. Sixteen horses were available for long-term follow-up, and 13 (81%) were reported to be sound. Twelve horses were older than 2 years of age at the time of follow-up, and nine of these were performing their intended purpose. The remaining four horses, which were not yet 2 years of age, were all reported to be in training for their intended use without evidence of complications related to their fracture. In this case series, there were no catastrophic fixation failures, and other complications were minimal. Furthermore, four horses with comminution at the anconeal process did not appear to be negatively effected by removal of the anconeal process fragment. Type 5 fractures were the most common fracture in horses older than 1 year of age, and in those cases, 19 of 20 patients that were repaired by plate fixation had a successful outcome. Follow-up was

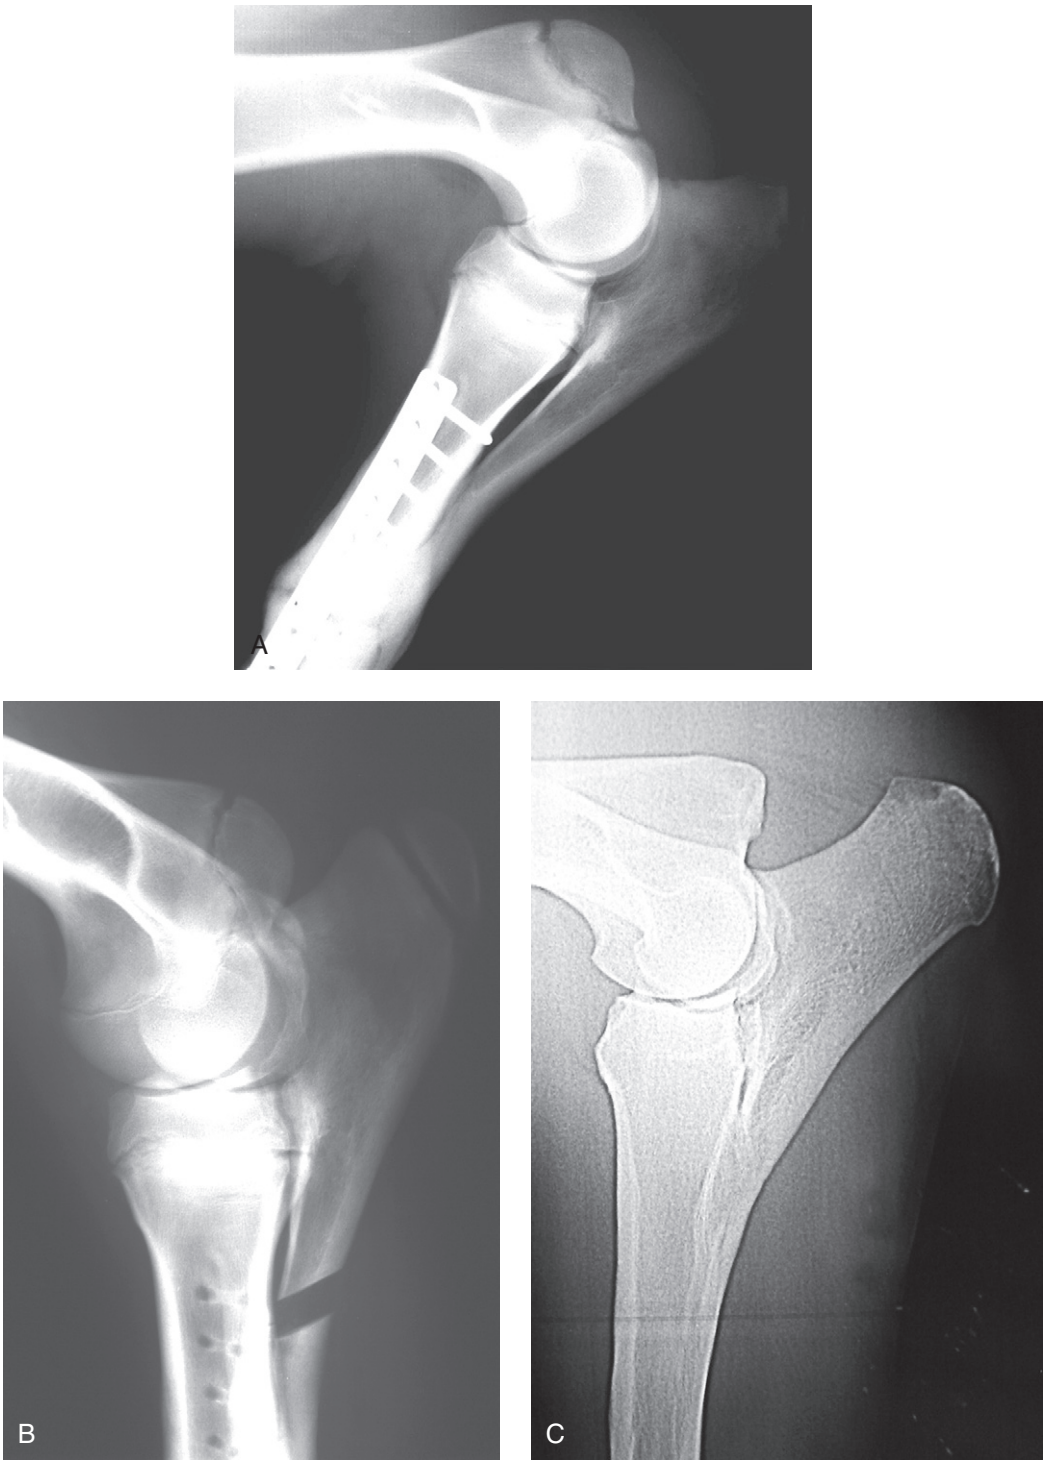

Figure 95-7. A, Follow-up radiographic views of a mid-diaphyseal radius fracture in a foal treated with bone plates. The fracture shows progressive healing; however, there is a subluxation of the elbow joint. **B,** An ulnar osteotomy was performed 10 days prior to taking this radiograph, which resulted in correction of the subluxation and restoration of the normal joint anatomy. An osteotomy gap of 10 mm developed. **C,** The 6-year follow-up of the same animal included a radiographically normal configuration of the joint without osteoarthritis and a sound animal. (Courtesy G. Bodo, Budapest.)

unavailable for 5 horses. Time since surgery in 13 horses was at least 2 years in 13 patients, with 11 of these horses performing their intended use.[3]

Tension-band wire fixation has been used to manage olecranon fractures in horses. In 22 horses managed with tension-band wiring, fracture union was achieved in 18 cases, and 13 of 17 horses returned to athletic function.[12] Patients are candidates for tension-band wiring if they weigh 250 kg or less. When fractures are in close proximity to the physis, either pins or screws are positioned cranial to the apophysis and directed

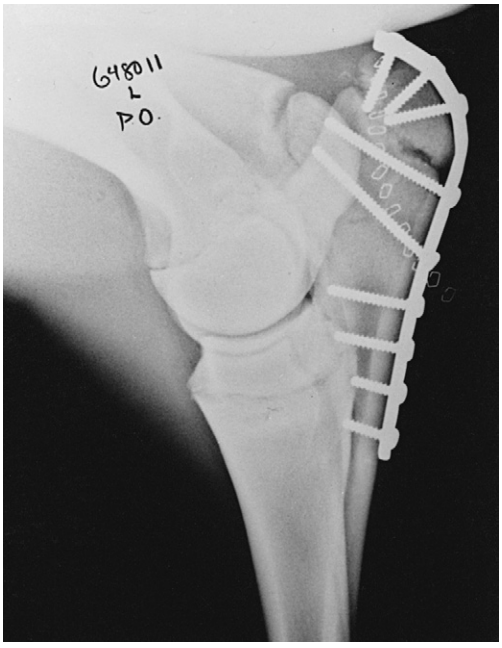

Figure 95-8. Postoperative mediolateral oblique radiographic view of a repaired type 1b articular ulnar fracture. Note the two long interfragmentary screws reaching to the cranial edge of the olecranon process.

distad into the ulnar body. Distal fractures are repaired with wires alone or in conjunction with lag screws. Fractures in foals and weanlings are repaired with at least two or three 1.2-mm diameter wires, whereas four to six 1.5-mm diameter wires are used in older horses.

The advantages of tension-band wiring compared to plate fixation are less-expensive equipment, less risk of screws entering the joint space or engaging the caudal cortex of the radius, less risk of fracture of the apophysis because screw holes in the proximal fragment are not necessary for fixation, and, with more distal fractures, less tissue dissection required.

Complications

Complications of repair of ulnar fractures are infection, fixation failure, tendon contracture, support limb varus deformity, suspensory apparatus fatigue, and support limb laminitis.

Infection is most likely following repair of open, contaminated fractures. However, fractures with substantial soft tissue trauma also have an increased risk. Methods of reducing the infection potential include the use of perioperative systemic antimicrobial agents and, in high-risk patients, local application of antimicrobial-impregnated PMMA, usually as beads or in some cases as plate-luting material. If the fracture becomes infected, but the fixation is stable, a successful outcome is likely. However, the convalescent period is substantially prolonged, and lameness often persists until the infection is resolved. Resolution of infection requires implant removal after the fracture has healed. Infection in the presence of instability at the fracture invariably results in failure. Articular fractures that become infected have the additional risk of joint sepsis, which substantially worsens the prognosis.

Fixation failure can occur secondary to fracture of the apophysis in proximal olecranon fractures, especially with type 1a fractures in neonates, in which the apophysis consists of an ossified nucleus surrounded by a relatively wide rim of hyaline cartilage. Following plate fixation of proximal fractures in older foals and adults, failure can result from fracture of the proximal fragment through the screw holes.[12] However, this complication did not occur following plate fixation of 20 patients with type 1b fractures.[2] Implant failure also can occur from using wire techniques, especially in large foals and adults.[12] Therefore, fractures in large foals and especially in adults deemed at risk for implant failure are candidates for plate fixation. It is important to note, that the proximal end of the plate should extend to the level of the physeal scar of the olecranon to minimize the risk to failure at the proximal aspect of the plate.

At the distal aspect of the plate, where the ulna is positioned along the caudal aspect of the lateral cortex of the radius, screws should be angled toward the midline to avoid the lateral cortex of the radius. Use of locking head screws in the distal aspect of the plate may not be indicated as they have to be inserted perpendicular to the plate, which could weaken the bone and result in a fracture of the radius, especially if the large 5-mm screw is used (Figure 95-9).[6]

Prolonged lameness for any reason results in a number of compensatory complications. Persistent lameness or increasing lameness in the postoperative period indicates fracture instability, infection, or both. With articular fractures, osteoarthritis secondary to incongruent joint surfaces or prolonged, severe synovitis causes persistent lameness. In foals, persistent lameness often results in varus deformities of both the carpus and the metacarpophalangeal (MCP) region, as well as fatigue of the suspensory apparatus with hyperextension of the MCP joint in the contralateral limb. The ipsilateral limb can develop a flexural deformity of the carpus or MCP region, or both. In adult horses, ipsilateral flexor contracture may develop, but support limb laminitis is the most likely and potentially devastating complication in the contralateral limb.

FRACTURES OF THE RADIUS

In horses, radial fractures are not as common as ulnar fractures. When they occur, a wide variety of fracture configurations is possible. For simple, displaced radial fractures, open reduction and internal fixation can be expected to produce a good to excellent outcome in horses weighing less than 250 kg. Fixation of radial fractures in adult horses, however, poses a substantial challenge. Although success has been reported, the prognosis for an adult horse with a completely displaced radial fracture is unfavorable.[13]

Anatomy

The radius is the major weight-supporting bone of the antebrachium. Proximally, it articulates with the humerus and the ulna and forms the cubital joint. Distally, along with the proximal row of carpal bones, it forms the antebrachiocarpal joint. Proximally, the biceps brachii inserts on its cranial surface, and distally, the tendons of the digital extensor muscles pass through their respective tendon sheaths as they traverse the carpus en route to the digit. Medially, the radius lacks overlying muscle and is covered only by skin and subcutaneous fascia. The bone is strongly curved in the sagittal plane and has a distinct cranial bow. Biomechanically, this places the caudal cortex under

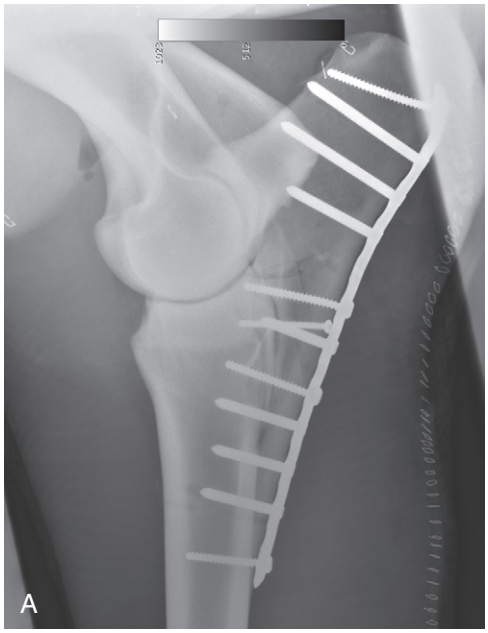

Figure 95-9. A, Immediate postoperative radiographic view of an ulnar fracture repaired with a 3.5-mm cortex screw applied in lag fashion and a 12-hole narrow LCP. Note immediately distal to the most distal locking head screw a drillhole crossing the entire radius is visible. **B,** Specimen of the fractured radius from the horse shown in **A** 7 days after surgery. The most distally located 5-mm locking head screw was positioned in the medial cortex of the radius. The drill hole prepared through the DCU portion of the same combihole (which was abandoned because the locking head screw) is visible *(arrow)*. The locking head screws must be inserted perpendicular to the plate, leading to the introduction into the medial cortex. The combination of the empty drill hole next to the locking head screw served as a stress riser, leading to a radius fracture. (Courtesy A. Fürst, Zurich, Switzerland.)

substantial compression. The cranial and craniolateral aspects of the radius are loaded in tension.

In foals, a proximal and a distal physis are present. These physes, along with their respective epiphyses, are subjected to compressive forces. Therefore, fractures involving these physes are classified according to the Salter-Harris scheme. Growth at these physes is responsible for the ultimate length of the bone and thereby affects limb length and conformation. Disproportionate growth at the distal radial physis is a common cause of carpus valgus limb deformity.

Pathogenesis

Most radial fractures result from external trauma. In foals, entrapment of the limb proximal to the carpus can result in proximal radial physeal fractures. However, direct blows to the antebrachium are the most common cause of fracture in both foals and adults. Often, the cause of the fracture is a kick from another horse.

Commonly, the fracture is comminuted, regardless of the patient's age. In adults, comminution almost always accompanies either a spiral or an oblique fracture of the diaphysis. The degree of comminution varies from single or multiple large butterfly fragments to multiple small fragments. Incomplete or complete nondisplaced fractures of the radius often occur in adult horses that have been kicked. These injuries may be witnessed as a solid blow to the distal medial aspect of the antebrachium. A skin wound may be evident.

Because the fracture is not displaced and an instability is not readily apparent, radiographs are occasionally omitted from the initial evaluation. Because the horse remains noticeably lame, the fracture is detected later, when it becomes unstable or radiographs are taken because the lameness fails to resolve. Therefore, radiographic examination is recommended in all cases in which there is evidence of a kick injury to the antebrachium.

Occasionally, if the initial radiographs are taken immediately after the incident, the fracture cannot be detected. In these cases stall confinement until a suspected fracture is confirmed or eliminated is recommended (see "Treatment," later). Follow-up radiographs taken 5 to 7 days after the injury allow identification of the fracture lines. The degree of fragmentation accompanying comminuted fractures in foals is less than that of comminuted fractures in adults. Fracture configurations in foals vary. Mid-diaphyseal transverse fractures result from a cranial blow to the antebrachium. A lateral blow results in an oblique fracture of the proximal metaphysis. Physeal fractures occur at both the proximal and the distal radial physes. Displacement with Salter-Harris type I and type II fractures of the proximal physis is accompanied by fracture of the ulna. If the radial metaphysis displaces craniad, injury to the radial nerve is possible. Occasionally, Salter-Harris type III fractures are encountered in the proximal epiphysis.

Diaphyseal fractures of the radius are at high risk of becoming open secondary to skin penetration by the sharp fracture fragments on the medial aspect of the antebrachium. Abduction of the distal limb displaces the fracture into the relatively sparse covering of soft tissues medially and predisposes to skin penetration. In addition, there is often substantial injury to the musculature covering the dorsal and lateral aspects of the antebrachium, accompanied by severe soft tissue swelling and hematoma. The degree of soft tissue injury accompanying radial fractures makes them highly susceptible to infection at the fracture site.

Diagnosis

Complete displaced radial fractures are easily identified on physical examination. Non–weight-bearing lameness accompanied by instability and crepitation in the antebrachial region is pathognomonic for these injuries. The patient usually holds the limb with the carpus and MCP joint flexed and drags the toe. Attempts at weight bearing result in valgus angulation at the fracture. Soft tissue swelling is usually evident. Wounds

or secondary penetration of the soft tissues at the medial aspect are often present. Horses with incomplete fractures or with nondisplaced complete fractures do not demonstrate instability or crepitation. However, they are usually lame, and in many cases a wound is evident at the site of traumatic impact.

Radiographic evaluation confirms the presence of a fracture. Multiple views, including oblique projections, are advisable to delineate the severity of the fracture and to assist in determining a course of action and rendering a prognosis. It is important to delineate the extent and location of fragmentation in comminuted, completely displaced fractures. Nondisplaced fracture lines usually emanate proximad and distad from the displaced fracture. Occasionally, these are evident only after the fracture is surgically exposed, but complete radiographic evaluation before attempting internal fixation determines the feasibility of repair and the best method for managing the fracture.

Fractures with multiple small fragments that are likely to preclude anatomic reconstruction should be identified. This is especially important when these fragments are located along the caudal cortex, which must be reconstructed for repair to be successful.

Treatment

First Aid

As with ulnar fractures, wounds associated with a displaced fracture of the radius require immediate attention. There is a high probability that wounds at the medial aspect of the antebrachium communicate directly with the fracture. Initial management should include appropriate hair removal, cleansing, and topical and systemic antimicrobial therapy.

Immediate immobilization of a displaced fracture is of paramount importance. With closed fractures, appropriate external coaptation can prevent fragments from displacing and the fracture from opening. Sedation is necessary for applying a bandage and splint with an unstable radius fracture. When the patient is controlled, and after appropriate wound therapy in open fractures, a Robert Jones bandage is applied extending from the hoof to as far proximal on the antebrachium as possible.

The bandage should be applied in layers to increase rigidity. A caudal splint is applied that extends from the ground to the level of the olecranon process. A second lateral splint extends from the ground to the level of the mid-scapula. The portion of the splint extending proximal to the bandage should contact the brachium when the limb is directly beneath the body (Figure 95-10). This provides counterpressure to prevent the limb from abducting with weight bearing. Nonelastic adhesive tape or fiberglass casting tape is used to affix the splints to the bandage. More information on bandaging and first aid for fracture patients can be found in Chapters 17 and 73.

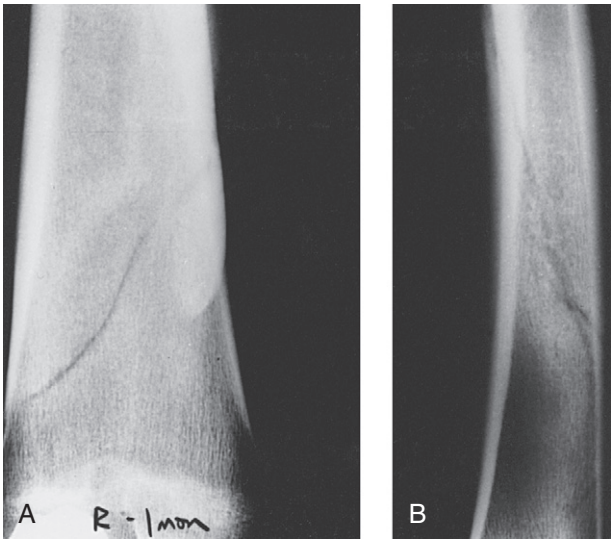

Figure 95-11. Craniocaudal **(A)** and lateromedial **(B)** radiographic views of a nondisplaced fracture of the radius in an adult horse secondary to a kick injury.

Nonsurgical Management

Incomplete and nondisplaced complete fractures are candidates for conservative therapy (Figure 95-11).[14-16] In one report, incomplete radial fractures became complete, displaced fractures in only 3 of 10 horses managed conservatively.[16] Predicting success based on the radiographic appearance of the fracture was not possible. An important aspect of therapy was preventing recumbency to reduce the likelihood of displacement secondary to forces experienced during standing up (see Figure 76-1).

Phenylbutazone should be used judiciously to reduce inflammation and encourage limited weight bearing on the fractured limb. However, care should be taken to avoid providing substantial pain relief, which could result in overuse of the fractured limb.

The horse is confined until there is evidence of advanced fracture healing. This usually requires a minimum of 3 to 4

months. During the last 30 days of confinement, a program of gradually increasing hand-walking is recommended. Access to free paddock exercise is allowed thereafter. An additional 30 days of paddock exercise is recommended before the horse is gradually returned to its intended function.

Surgical Management

ADULT HORSES

Open reduction and internal fixation of displaced radial fractures in adult horses is a monumental task that provides only a limited chance of survival.[13] In many cases, the fracture configuration and degree of soft tissue trauma preclude any reasonable likelihood of success. Even with fractures amenable to fixation, the biomechanical forces acting on the bone–implant construct place the fixation at risk for failure. Even the strongest, most stable construct has a high potential either to fail catastrophically during recovery or to fatigue and fail before fracture union.

Fixation with two plates is necessary; one plate is positioned cranially and the second plate is applied to either the medial or the lateral cortex. One of the plates should be a dynamic condylar plate, with the condylar screw placed in the smaller fracture segment. The second plate should be a broad 4.5-mm LC-DCP, DCP, or ideally a 5.5-mm LCP. As many 5.5-mm cortex and 5-mm locking head screws as possible are implanted, and every opportunity to provide compression across fracture lines is used (Figure 95-12). The entire length of the radius is spanned by the plates, and the plates should be offset to avoid ending at the same level in the transverse plane. The second plate is placed lateral distally and twisted proximad to end on the craniolateral aspect of the proximal metaphysis, lateral to the insertion of the biceps brachii tendon on the radial tuberosity. The use of the human, slightly curved, 4.5-mm LCP allows application over the entire lateral side of the radius without twisting the proximal aspect of the plate (see Figure 76-39). Plate luting with antimicrobial-impregnated PMMA is recommended if LC-DCPs and DCPs are used. Cancellous bone grafts should be incorporated into the fixation to promote healing. Information on the implantation techniques of plates can be found in Chapter 76.

FOALS

Diaphyseal fractures in foals, other than simple transverse middiaphyseal fractures, are double plated as well. Implant selection depends upon the size of the foal, the fracture configuration, and the location. A broad LC-DCP, DCP, or LCP is usually applied to the cranial cortex, and in most cases, 5.5-mm cortex screws and 5-mm locking head screws are used throughout its length. The second plate may be either a broad or narrow LC-DCP, DCP, or LCP, fixed with a majority of 4.5-mm cortex screws. However, nearest the fracture and at the ends of the plate, 5.5-mm cortex or 5-mm locking screws should be inserted. The lateral plate is applied as described for the adult horse earlier (Figure 95-13). The use of the slightly curved human LCP can be used as an alternative in the foal as in the adult.

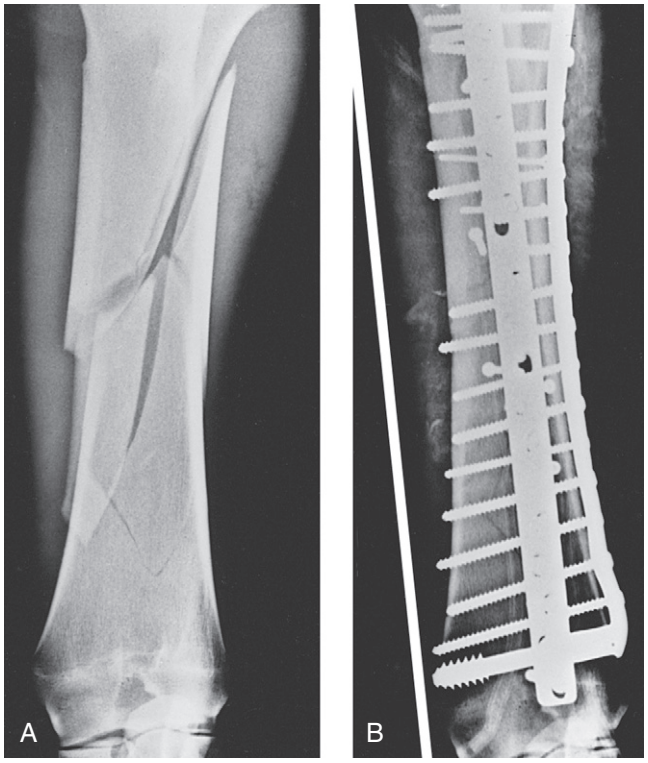

Figure 95-12. Craniocaudal radiographic view of a comminuted radial fracture in an adult horse before internal fixation **(A)** and after application of a dynamic condylar screw plate applied to the lateral cortex and a broad dynamic compression plate applied to the cranial cortex **(B).** Most screws are 5.5-mm cortex screws. Note that the plates span the length of the radius.

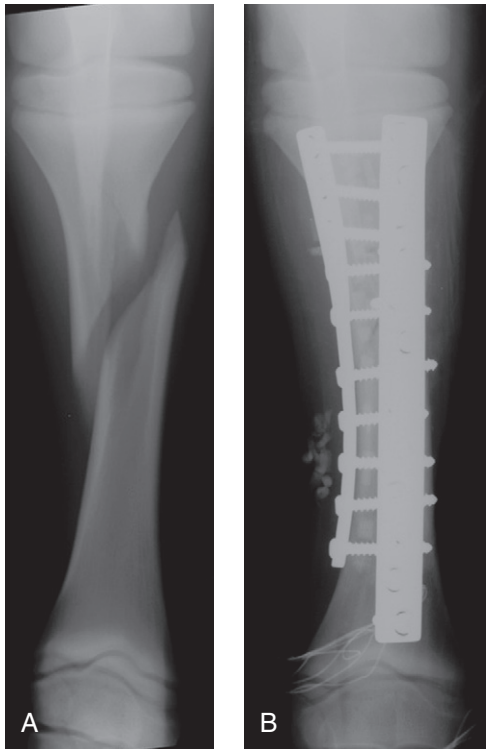

Figure 95-13. Craniocaudal radiographic view of a proximal metaphyseal radial fracture in a foal before internal fixation **(A)** and after application of a broad dynamic compression plate (DCP) to the cranial cortex and a narrow DCP applied to the lateral cortex distally and spiraled cranially at its proximal aspect **(B).**

Multifragment (comminuted) fractures

In foals with multifragment fractures, the repair is as described for adults, with the exception of implant selection. A second broad LC-DCP, DCP, or LCP is used in place of the dynamic condylar screw plate. I prefer to place the second plate laterally, unless the configuration of the fracture dictates medial placement. Lateral placement, although technically more demanding, avoids positioning the implant subcutaneously and, particularly in fractures that are open medially, avoids direct communication with the wound. In most cases, both implants can be placed using a lateral approach between the extensor carpi radialis and common digital extensor muscles. If the lateral plate is extended to the distal end of the radius, placement of the distal screws may require separate stab incisions lateral to the common digital extensor tendon, especially if an LCP is used.

Mid-diaphyseal fractures

Mid-diaphyseal transverse fractures in small foals can be repaired with a single broad LC-DCP, DCP, or LCP applied to the cranial cortex, provided the caudal cortex can be anatomically reconstructed. The strong cranial-to-caudal bending moment of the radius makes this a stable fixation in foals weighing less than 250 kg. With single-plate fixation, it is advisable to use 5.5-mm cortex screws throughout the entire length of the plate. An LCP is preferred , and 5-mm locking head screws should be placed on either side of the fracture and at the ends of the plates. Compression of the LCP onto the bone surface must be accomplished with cortex screws or the push-pull device (see Chapter 76). Although precise bone-plate contact is less important when using an LCP, close apposition to the bone surface improves the plate's mechanical performance, which is very important in management of this fracture.

Proximal physeal fractures

Fractures involving the proximal physis are less common than diaphyseal or metaphyseal fractures. They are candidates for internal fixation, with special considerations.

Type III fractures are rare, and conservative therapy is successful when they are nondisplaced. However, anatomic reconstruction of the articular surface and compression across the fracture is the treatment of choice for displaced fractures. This is accomplished with screw fixation using lag technique alone or in combination with tension band wire fixation.

Salter-Harris types I and II fractures of the proximal physis are accompanied by ulnar fractures (Figure 95-14, *A*). Plate fixation of the ulnar fracture, with screws engaging both cortices of the radius where possible, combined with a laterally applied narrow plate with the most proximal screw in the radial epiphysis, is recommended (see Figure 95-14, *B*). In small foals, transphyseal screw and wire fixation in place of the plate on the lateral aspect of the radius can be used.

As mentioned before, transfixation of the ulna to the radius can result in elbow subluxation, but growth at the radial physis is minimal when the germinal layers of the growth plate are injured and the implants bridge the physis, restraining growth. The apparent disparity in bone length between limbs does not appear to have an adverse effect on gait.

If the metaphyseal portion of the fracture displaces craniad (Figure 95-15), the radial nerve can be traumatized, resulting in low radial nerve paresis. Difficulty in active extension of the digit is the result. Most foals learn to place the foot on the ground appropriately, and the paresis usually resolves, but in the immediate postoperative period a splint may be needed to keep the digit in extension.

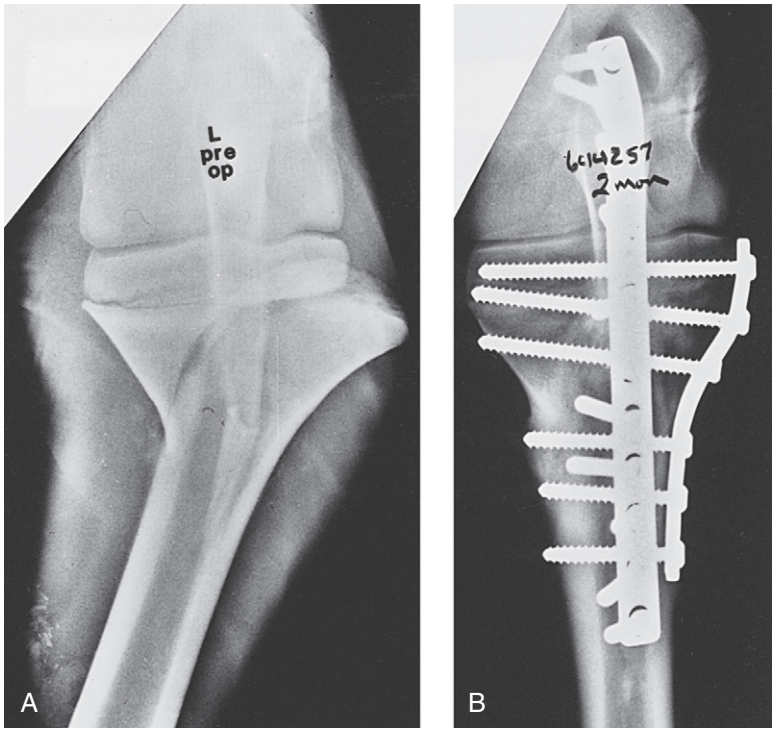

Figure 95-14. Craniocaudal radiographic view of a Salter-Harris type II fracture of the proximal radius prior to repair **(A)** and after the application of a narrow dynamic compression plate (DCP) to the lateral aspect of the proximal radius and a narrow DCP applied to the ulna with screws transfixing the ulna to the radius **(B).**

Figure 95-15. Lateromedial radiographic view of a Salter-Harris type II fracture of the proximal radius accompanied by an ulnar fracture with cranial displacement of the distal fragment, resulting in temporary radial nerve paresis.

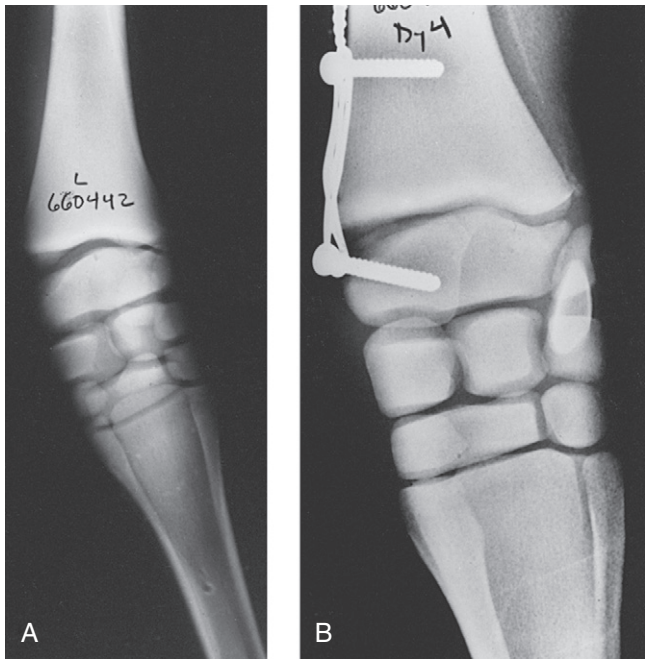

Figure 95-16. Craniocaudal radiographic view of a foal with a Salter-Harris type I fracture of the distal radius, before repair **(A)** and after repair with a transphyseal bridge using screws and wires **(B).**

Distal physeal fractures

Fractures of the distal physis are less common than fractures of the proximal physis. Salter-Harris type I physeal fractures result in displacement at the medial aspect of the physis (Figure 95-16, *A*). The fractures occur in neonates and are treated by transphyseal bridging across the medial aspect of the physis. A T-plate or screws and wires can be used (see Figure 95-16, *B*). The implants are removed when the fractures are healed at approximately 4 to 6 weeks.

Prognosis

Adult horses with displaced radial fractures have an unfavorable prognosis. In rare instances, successful internal fixation can be achieved.[13,15,17,18] In one report, internal fixation was attempted in six adult horses, none of which survived.[19] In another case series, nine of 15 horses that were presented for radial fracture had attempted internal fixation, and only two were discharged from the hospital.[13] However, with careful case selection and improved methods that increase the strength and stability of the bone–implant construct, the success rate can be improved. The substantial expense associated with fixation, combined with the high risk of failure, often dissuades owners from pursuing repair.

However, displaced radial fractures in foals, particularly if there is no comminution and when the fracture is closed, have a favorable prognosis. Physeal fractures and transverse fractures of the mid-diaphysis have an excellent prognosis.[19] In six of seven foals with mid-diaphyseal transverse fractures, and in two other foals, one with Salter-Harris type I and another with a type II proximal physeal fracture, the fractures healed. Similarly, fixation of proximal oblique fractures in 3 of 4 foals had an excellent outcome.

Complications

Complications following repair of radial fractures are the same as for any equine long bone fracture repair. Infection, instability, failure of fixation, and support limb complications are the most common. The propensity for radial fractures to be open medially substantially increases the risk of infection. Even in closed fractures, the degree of soft tissue trauma and the lack of muscle covering of the medial aspect of the radius increase the potential for infection. The technical difficulty of the repair often prolongs surgery time. The quantity of implants used for repair significantly contributes to postoperative infection.

Fixation failure is the most common fatal complication. Catastrophic failure is a major risk during recovery from anesthesia, particularly in adult horses. Long surgery time and the condition of the patient at the time of anesthesia play major roles. Attention to the patient's physiologic status before and during anesthesia, along with a controlled recovery, can reduce the incidence of failure (see Chapter 21). The technical difficulty of the fixation dictates that an experienced surgical team be assembled. Every effort is made to minimize surgery time.

Fatigue failure of the implants is not uncommon. This is especially a problem in adult horses, where the high loads experienced by the bone–implant construct cause micromotion and cycle the implants. The greater the instability, the greater the probability of fatigue failure. Bone-to-bone contact is imperative at the caudal cortex. If that is not achieved, cyclic loading fatigue failure is inevitable (Figure 95-17). Methods to reduce the likelihood of fatigue failure include using the strongest implants available and plate luting except when LCPs are used.

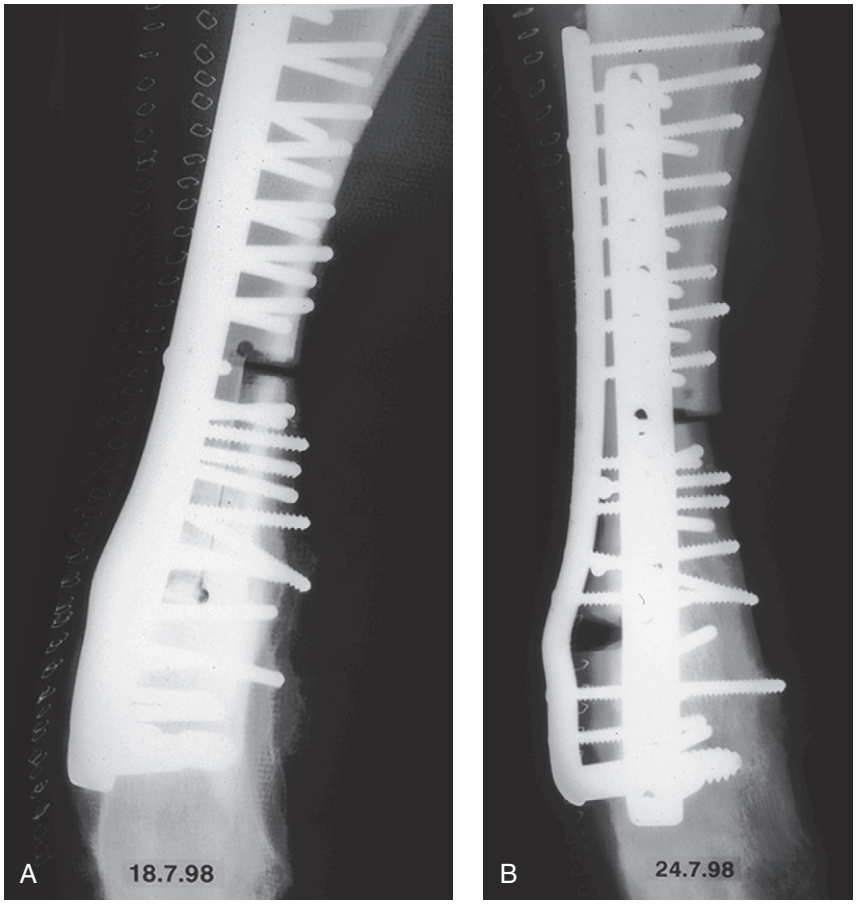

Figure 95-17. A, Lateromedial radiographic view of corrective step osteotomy performed in the frontal plane of an adult Warmblood suffering from a severe varus deformity of the radius following abnormal healing of a radial fracture. Note the gap at the caudal osteotomy site. **B,** A 1-week follow-up radiograph showing narrowing of the gap at the caudal cortex and widening of the gap cranially. Screw loosening can be seen at the level of the proximal osteotomy in the lateral plate. Two days later, the dynamic condylar screw (DCS) plate broke at the level of the osteotomy, resulting in humane destruction of the animal. (Courtesy J. Auer, University of Zurich.)

Anatomic reconstruction of the fracture, especially at the caudal cortex, is an absolute necessity.

To prevent support limb complications, an early return to some weight bearing on the fractured limb is imperative and best accomplished by restoring stability to the fracture site and preventing infection. In foals, the primary concern is for varus limb deformity and fatigue of the suspensory apparatus, resulting in MCP joint hyperextension. To reduce these complications, a foot plate with an extended heel and lateral bearing surface is applied. Support bandages are not advocated in foals because they tend to promote MCP joint hyperextension rather than prevent it. In adult horses, support limb laminitis is a major risk. Appropriate foot support, such as a heart bar shoe, may aid in reducing the frequency of support limb laminitis. Support wraps and judicious use of phenylbutazone are recommended in adults during the postoperative period.

OSTEOCHONDROMA

Osteochondromas originate from the dysplastic growth of aberrant growth cartilage. They are located adjacent to a physis and occur most commonly in adult horses at the caudal aspect of the distal radius.[20-22] Solitary osteochondromas have been reported in two foals: in one, the calcaneus was affected, and in the other, the distal palmar aspect of the middle phalanx was affected.[23,24]

Osteochondromas are exostoses composed of trabecular bone contiguous with cancellous bone of the adjacent medullary cavity. There is a characteristic cartilage cap composed of hyaline cartilage undergoing endochondral ossification. The histologic characteristics are identical to those of multiple cartilaginous exostoses of horses. However, the genesis of the lesion in the latter condition is hereditary. To date, a hereditary basis for solitary osteochondroma has not been identified.[25]

Pathogenesis

Causes of solitary osteochondroma include displacement of a growth cartilage fragment that rotates and grows transverse to the longitudinal axis of the bone, an aberrant nest of subperiosteal growth cartilage, and herniation of growth cartilage through a perichondral defect. With continued growth, the expansile nature of the lesion impinges on adjacent structures and results in lameness. Osteochondromas of the caudal distal radial physeal region are located in the carpal canal and cause tenosynovitis. They also impinge on the deep digital flexor tendon as it passes through the area.[20-22] Bony projections that are not true osteochondromas, referred to as *physeal remnant spikes,* have been noted to cause the same clinical syndrome (see Chapter 94).[25,26]

Diagnosis

Horses with distal radial osteochondromas or physeal spikes are presented with effusion in the carpal canal. Lameness is mild

Figure 95-18. Lateromedial radiographic view demonstrating a solitary osteochondroma of the caudal aspect of the radius proximal to the physeal scar.

and intermittent. Pain is evident on direct palpation and is induced by carpal flexion. In some cases, the bony projection can be identified by deep palpation. Radiography reveals the characteristic bone growth on the palmar aspect of the radius adjacent to the physis (Figure 95-18). There is a wide variation in the size and degree of ossification of the lesion. Ultrasonography can aid in determining the presence of deep digital flexor tendinitis. However, the absence of ultrasonographic changes does not preclude the presence of superficial injury to the tendon due to impingement by the osteochondroma or physeal spike.

Treatment

Instillation of corticosteroids into the tendon sheath temporarily resolves tenosynovitis in most instances. However, clinical signs usually recur. Surgical excision of the bony projection is curative and is the treatment of choice. Although excision via an open approach to the lateral aspect of the carpal canal was originally reported, removal under arthroscopic guidance is currently advocated.[18,21,22]

With the affected limb positioned uppermost, the arthroscope is placed into the proximal aspect of the carpal canal through a stab incision located 3.5 cm proximal to the level of the physeal scar between the lateral digital extensor and ulnaris lateralis muscles.[22] Although a medial approach has been described, the surgeon is less likely to injure the median artery and vein from a lateral approach. Furthermore, the lateral approach makes it technically easier to manipulate the scope and instruments without interference from the opposite limb.

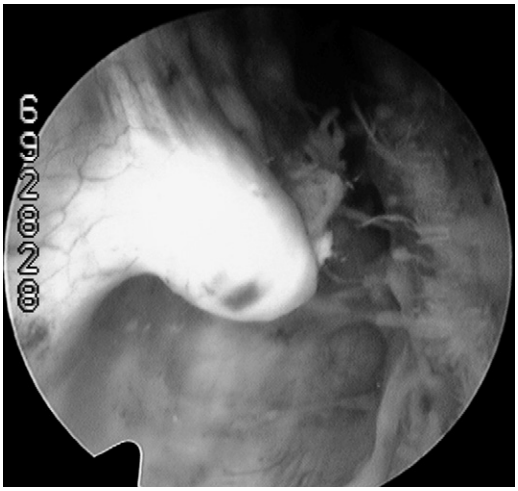

Figure 95-19. Endoscopic view of caudal radial osteochondroma before its removal. Note the injury to the deep digital flexor tendon on the right side of the photograph caused by the osteoochroma.

When the arthroscope is in the carpal canal, the sheath is distended and the osteochondroma or physeal spike is readily identified (Figure 95-19). The bony projection's attachment to the underlying bone is severed with a small osteotome positioned through a separate stab incision distal to the scope portal, and the bony projection is removed. Release of the carpal flexor retinaculum can also be accomplished via endoscopic guidance if chronic distention of the carpal canal is diagnosed as a complicating problem. The bone bed is curetted and the sheath is lavaged before closure of the skin incisions. Postoperative care is routine.

For additional information on this condition, please review "Distal Radial Exostosis" in Chapter 94.*

Prognosis

Horses are reported by their owners to be sound for their intended purpose following removal of the osteochondroma or physeal spike.[20-22,25,26] Distention of the carpal canal resolves with time. With chronic carpal canal distention, resolution of the effusion following osteochondroma removal can require additional medical therapy, including repeat local corticosteroid injection.

SUBCHONDRAL CYSTIC LESIONS

Subchondral cystic lesions have been reported in the proximal epiphysis of the radius. Although they are infrequent, they have been noted as a cause of lameness.[27,28] Like subchondral cysts in other locations, the definitive pathogenesis remains elusive, with developmental and traumatic causes proposed. Affected horses vary in age but are most commonly young individuals that are in athletic training or competition. The degree of lameness is variable, but it can be acute and relatively severe. With rest, lameness usually dissipates, only to return after activity is resumed.

*An editorial decision was made to discuss this condition in both chapters because each describes slightly different aspects aside from the common parts.

Figure 95-20. Craniocaudal radiographic view demonstrating a subchondral cystic lesion in the medial aspect of the proximal epiphysis of the radius.

Clinical findings that aid in localizing the lameness to the cubital joint are lacking. However, intra-articular anesthesia of the affected joint significiantly reduces or eliminates the lameness. Radiographic examination delineates the lesion, most typically in the medial aspect of the epiphysis (Figure 95-20). Options for treatment include intra-articular therapy and rest.[27,28] If lameness persists, an extra-articular surgical approach can be performed, allowing either débridement, intralesional corticosteroid injection of the cyst, or filling of the defect with an osteoinductive material. A potential complication of débridement via the extra-articular approach is fracture through the cyst.[27] Additional information on subchondral cystic lesion is found in Chapter 89. At the time of this writing, too few cases have been treated in a consistent fashion to reliably predict the outcome of management.

CHAPTER 96

Shoulder

Lisa A. Fortier

Orthopedic abnormalities of the scapulohumeral (shoulder) joint are rare. Because shoulder pathologies are uncommon and relatively difficult to diagnose, treatment can be delayed, leading to an increase in secondary osteoarthritis. Further, there are very few large studies documenting treatment and outcome following specific injuries or treatments to guide the surgeon.

DIAGNOSIS OF SHOULDER LAMENESS

Localization of lameness to the shoulder region can be straightforward in cases when there is associated swelling or pain on palpation, but in many patients intra-articular or bursal anesthesia is necessary to confirm clinical examination findings. Horses with fractures of the shoulder region or luxation of the scapulohumeral joint are acutely, and initially, severely lame and have localized swelling. When the scapulohumeral joint is less severely affected, joint effusion cannot be palpated because of the overlying musculature, but a painful response can often be elicited following deep palpation of the notch between the cranial and caudal prominences of the greater tubercle of the humerus. Less-specific signs of shoulder lameness include shoulder muscle atrophy, pain on extension or flexion of the shoulder joint, a narrow ipsilateral hoof with a long heel, and, typical of forelimb lameness, signs of a shortened anterior phase of the stride. Nuclear scintigraphy can help localize the cause of lameness to the shoulder joint.

When the lameness is localized to the shoulder region, radiographs should be obtained. If bicipital bursitis or biceps tendinitis is suspected, an ultrasonographic examination should be performed.[1] Although not currently available for imaging equine shoulders, magnetic resonance imaging (MRI) is considered the method of choice for evaluating shoulder pain in people because it provides detailed information on all bone and soft-tissue components of the shoulder.[2]

Radiographs of the shoulder joint can usually be obtained in the standing horse, although higher-quality images are achieved when the horse is under general anesthesia because of the absence of motion artifact. The horse's leg is extended forward to center the shoulder joint over the trachea for a standard mediolateral or a more specific cranioproximal-craniodistal oblique view of the proximal portion of the humerus projection to diagnose long oblique fractures of the greater tubercle.[3] Normal survey radiographs do not exclude the shoulder as a cause of lameness, particularly in cases of osteochondrosis (OC) or other pathologies of the humeral head or glenoid cavity.[4-6] In cases where survey radiographs are normal and OC is suspected, positive-contrast radiography using 7 to 10 mL of a sterile water-soluble iodinated contrast medium should be performed.[7] Double-contrast radiography more clearly delineates the glenoid notch than positive-contrast radiography. To obtain a double-contrast image, 30 mL of air is injected following positive-contrast radiography.

INTRASYNOVIAL ANESTHESIA OR SYNOVIAL CENTESIS

When clinical examination findings do not definitively localize the lameness to the shoulder joint or bicipital bursa, diagnostic intrasynovial anesthesia can be useful. Local anesthetic (20 mL) is injected into the shoulder joint using an 18-gauge, 8.9-cm spinal needle inserted in the notch between the cranial and caudal prominences of the greater tubercle of the humerus. The needle is directed toward the elbow of the opposite limb, parallel to the ground, and is advanced until bone or cartilage is contacted. Extrasynovial deposition or leakage of local anesthetic solution out of the shoulder joint can block the suprascapular nerve, resulting in lateral subluxation of the scapulohumeral joint, thereby producing the clinical appearance of sweeney.[8] If the suprascapular nerve is inadvertently blocked, the horse should be placed in a box stall until the anesthetic wears off to prevent injury. In horses with intact cartilage that covers subchondral bone abnormalities, there might be minimal or no improvement in lameness following intra-articular anesthesia.

The bicipital bursa is entered approximately 4 cm proximal to the distal aspect of the deltoid tuberosity. An 18-gauge, 8.9-cm spinal needle is inserted between the biceps brachii muscle and the humerus and directed proximomedial to approximately 4 cm in depth, where 5 to 10 mL of local anesthetic is injected. Synovial fluid can usually be aspirated from both the shoulder joint and bicipital bursa to confirm intrasynovial needle placement and therefore deposition of local anesthetic or for synovial fluid analysis and culture in cases where infection is suspected.

DISORDERS OF THE SHOULDER REGION

Osteochondrosis

Osteochondrosis (OC) is reported in the shoulder joint less often than in other sites such as the tarsocrural or femoropatellar joint. Clinical signs usually appear in horses 4 to 12 months old, and the lesions can be bilateral. Clinical examination in combination with conventional or contrast radiography reveals that the majority of shoulder OC lesions in horses are of the osteochondritis dissecans (OCD) type (cartilage flaps). Typical radiographic signs include irregular areas of subchondral bone with radiolucent areas surrounded by sclerosis. Contrast radiography more clearly delineates the presence and extent of undermined cartilage flaps and aids in determining a more accurate preoperative prognosis than one based on plain radiographs alone (Figure 96-1). Subtle cartilage lesions might not be detected using current imaging modalities, and diagnostic arthroscopy should be used if clinical examination, intra-articular anesthesia, or nuclear scintigraphy implicates the shoulder joint as the source of lameness.[4]

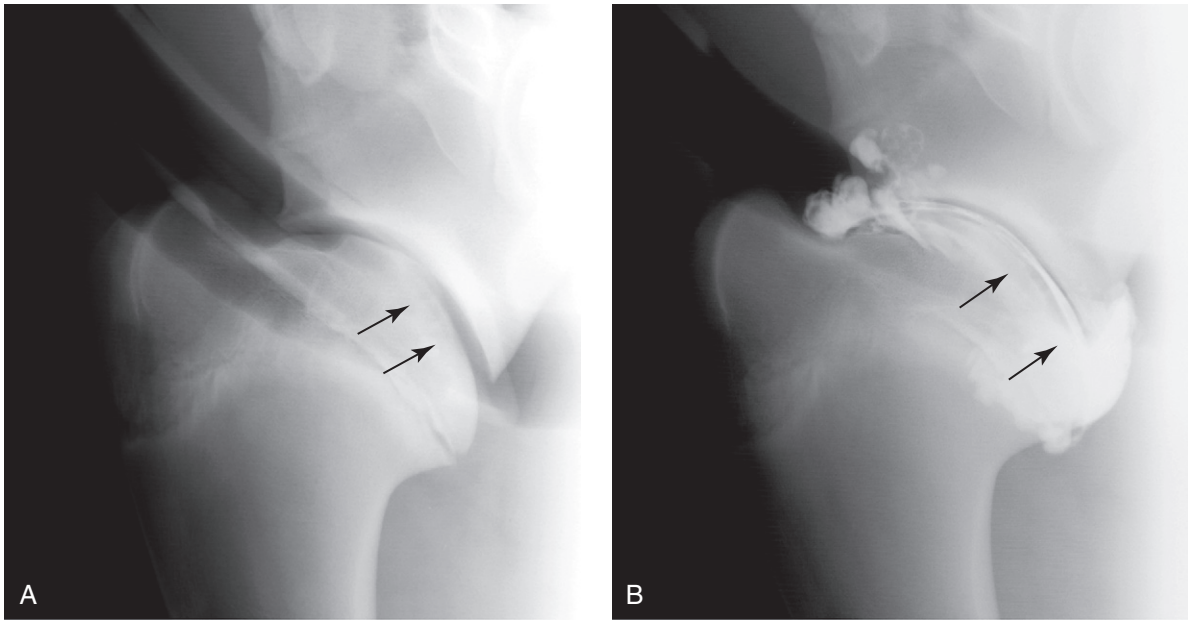

Figure 96-1. A, Mediolateral radiograph of the shoulder joint. A subchondral lucent region is present in the caudal humeral head *(arrows).* The humeral head in this region also appears flattened. **B,** A positive contrast arthrogram of the same shoulder joint depicted in **A.** Contrast material outlines the shoulder joint and further delineates the extent of subchondral bone lysis *(arrows).*

Secondary osteoarthritis (OA) develops rapidly in cases of shoulder OCD, and radiographs should be carefully scrutinized preoperatively for signs of OA, because the prognosis for future athletic function is poor in affected horses. Radiographic signs of shoulder OA include flattening of the humeral head and glenoid cavity, remodeling of the caudal rim of the glenoid, and subchondral bone sclerosis of the humeral head or glenoid cavity.[5]

Treatment

Arthroscopic surgery with débridement of loose cartilage flaps and curettage of abnormal underlying subchondral bone is the treatment of choice for shoulder OCD lesions. Repair of cartilage flaps using polydioxanone pins has been successful in select cases of OCD involving the femoropatellar and metacarpophalangeal joints and should be considered for cases of shoulder OCD.[9] Only cases with smooth, partially attached, unmineralized cartilage flaps should be considered for repair with polydioxanone pins.

Arthroscopy of the shoulder joint is technically more challenging than other joints. Lateral and craniolateral approaches have been reported.[10-12] The lateral approach is described here because it provides maximal visualization of the medial aspect of the humeral head and leaves the cranial portal (cranial to the infraspinatus tendon and proximal to the notch between the cranial and caudal prominences of the greater tubercle of the humerus) open for insertion of an egress cannula. The open cranial portal can also be used to introduce a large curved forceps, which can be engaged in the glenoid notch to distract the humeral head and gain access with the arthroscope to the medial side of the joint.

To perform shoulder arthroscopy, the horse is placed in lateral recumbency with the affected limb uppermost. The leg should be draped to allow adduction and traction during surgery to increase surgical exposure. The joint is distended with 60 mL lactated Ringer's solution using an 18-gauge, spinal needle inserted in the notch between the cranial and caudal prominences of the greater tubercle of the humerus (this site becomes the cranial portal). The arthroscope is inserted 1 to 2 cm caudal to the infraspinatus tendon and cranial to the teres minor muscles. A third site 2 to 4 cm caudal to the arthroscope portal can be used as an instrument portal. The optimal site for instrument portal entry is determined using an 18-gauge, spinal needle. If the lesions are extensive, or if they occur on the humeral head and glenoid cavity, more than one instrument portal might be required to complete the surgical débridement.

Cartilage flaps are removed and subchondral bone is débrided using several instruments including Ferris-Smith rongeurs, motorized resectors, periosteal elevators, and curettes (Figure 96-2). Lesions on the most medial aspect of the humeral head might be inaccessible. When débridement is complete, the joint is lavaged to remove cartilage and bone debris and the skin incisions are closed routinely.

Antimicrobials and phenylbutazone are administered perioperatively, and phenylbutazone is continued for the next 5 to 10 days. Horses are restricted to stall rest for 14 days, at which time hand-walking begins for 5 minutes per day. After 30 days of stall rest with hand-walking, horses are turned out for 4 to 6 months before exercise is resumed.

Prognosis

There are few reports on outcome of surgical or conservative treatment for shoulder OCD in horses, and all of them have limited case numbers so they should be interpreted with some caution. The most recent report indicates that the prognosis for return to soundness with or without surgery is poor with 25% (8/32) of horses returning to their intended use.[13] Of the 32 horses in the study, 18 were operated and 14 were treated con-

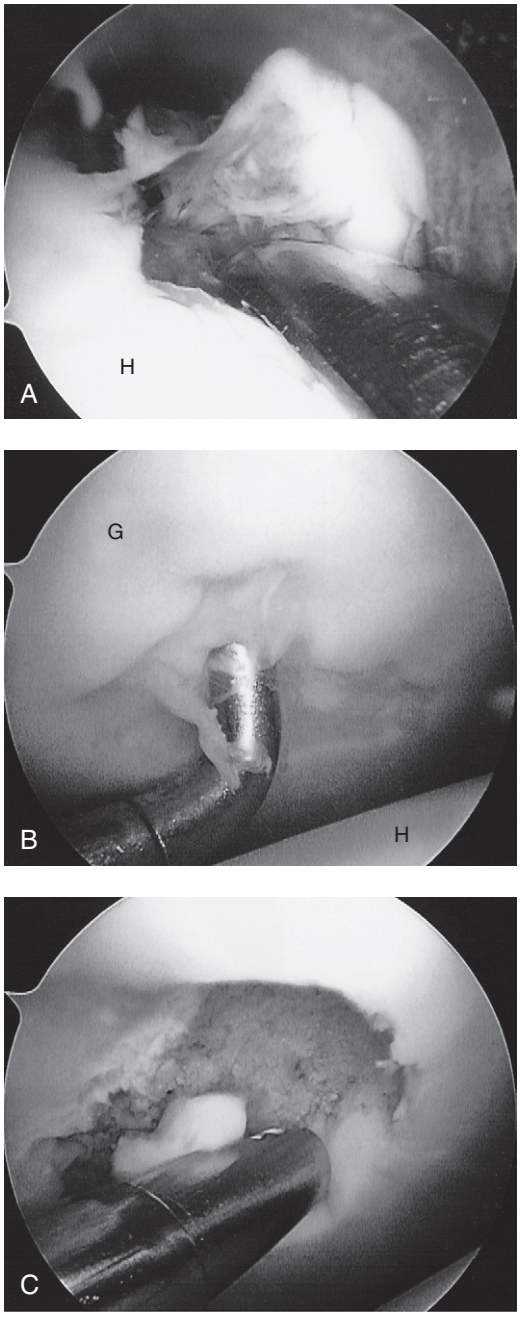

Figure 96-2. A, An arthroscopic image demonstrating elevation of an osteochondritis dissecans lesion of the humeral head *(H).* **B,** A probe is inserted into a cystic defect in the glenoid cavity *(G);* humeral head. **C,** Use of a motorized burr to débride a lesion in the glenoid cavity.

servatively. Only 15% of potential racehorses became sound for the intended use, and 67% of non-racehorses achieved their intended purpose. This study also suggested that there is no significant interaction between unilateral versus bilateral involvement or lesion severity. In two earlier studies enlisting a smaller number of horses intended for racing, the prognosis for return to athletic function following arthroscopic débridement was considered good, even for middle-aged horses with approximately 80% of horses achieving soundness.[4,14] The prognosis is considered to be poor when OA is detected on preoperative radiographs, although this has not been evaluated in a clinical series because most of these horses are not operated because of the poor prognosis. It should be noted that lesions identified during arthroscopy are often more extensive than suggested by radiography.[4,11,13]

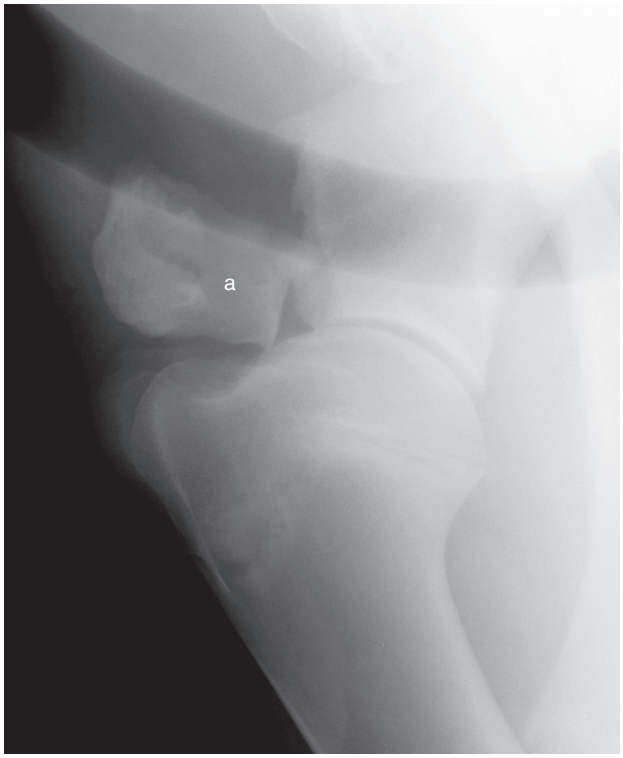

Figure 96-3. Mediolateral radiograph of the shoulder joint. A displaced fracture of the supraglenoid tubercle *(a)* is seen. The fracture fragment is displaced craniad and ventrad.

Fractures

Supraglenoid Tubercle

Supraglenoid tubercle fractures are usually simple, intra-articular epiphyseal fractures. These fractures occur most commonly in horses younger than 2 years of age and are either the result of direct trauma or are avulsion fractures caused by tension from the biceps tendon, which originates on the supraglenoid tubercle. Horses with supraglenoid tubercle fractures are able to bear weight, but they are variably lame and reluctant to fully extend the affected limb.

Careful visual inspection and palpation of the cranial aspect of the shoulder suggests a supraglenoid tubercle fracture. In chronic cases, shoulder muscle atrophy is present. Radiography of the shoulder is diagnostic. On a mediolateral radiographic projection, the fracture fragment is typically displaced in a cranioventral direction as a result of tension from the biceps brachii and coracobrachialis muscles, which originate on the supraglenoid tubercle (Figure 96-3). More recently, a cranioproximal-craniodistal oblique view of the proximal portion of the humerus has been suggested as a more reliable radiographic projection to diagnose long oblique fractures of the greater tubercle and should be included in a thorough radiographic series.[3] The radiographs should be carefully evaluated for signs of OA (described previously), which will decrease the prognosis for athletic function.

TREATMENT

Several treatment options are available, and the therapy chosen depends on the duration of the fracture and the intended use of the horse. Conservative management for all but the smallest fractures typically results in residual lameness and OA of the shoulder joint. Surgical options include repair of the fracture or removal of the fracture fragment. The goal of surgical repair should focus on restoring articular congruity of the glenoid cavity to prevent the development of OA. Therefore, if the fracture is chronic (longer than 1 week), enough bone remodeling will have occurred to preclude accurate reduction of the fracture, and the fragment should be removed. In acute fractures with involvement of a substantial (one third or greater) portion of the glenoid cavity, internal fixation should be considered to reconstruct the glenoid articular surface and provide maximal opportunity for future athletic performance. Acute fracture fragments that involve only a small portion of the glenoid cavity can be removed with no apparent impact on future athletic performance.

Fragment removal

The horse is placed in lateral recumbency with the affected limb uppermost. A 20-cm (8-inch) skin incision is made, beginning at the distal extent of the scapular spine, centering over the cranial aspect of the point of the shoulder, and extending distad over the deltoid tuberosity. The brachiocephalicus and supraspinatus muscles are separated and retracted; the brachiocephalicus muscle is retracted craniad and ventrad, the supraspinatus muscle is incised in the direction of its fibers directly over the tubercle, and the muscle is split and separated with self-retaining retractors to expose the fracture.[15]

At this point, repeated palpation will guide the surgeon to the shoulder joint and fracture fragment. Care should be taken to identify and preserve the suprascapular nerve, artery, and vein as they course across the neck of the scapula. The articular surface of the humeral head and glenoid cavity should be inspected for signs of cartilage damage, which, if present, will diminish the prognosis for athletic function. The fracture fragment is grasped with a large bone-holding forceps and excised using a combination of blunt and sharp dissection to detach the muscular and tendinous attachments. The dissection can be challenging, particularly on the medial aspect of the fragment because of lack of visualization.

Following removal of the fragment, the area is lavaged and closed in several layers to diminish dead space. If substantial dead space remains, a closed suction device should be used to prevent development of a postoperative seroma. Assisted recovery from anesthesia is recommended. Antimicrobials and phenylbutazone are administered perioperatively and continued until the there are no clinical signs of seroma formation.

Horses are restricted to stall rest for 60 days to allow time for the dead space to fill with fibrous tissue and the biceps to reattach. A carefully controlled rehabilitation program is important for these horses to regain strength and coordination in their shoulder joints. Percutaneous stimulation of the shoulder muscles during rehabilitation to minimize muscle atrophy should be considered. In humans, percutaneous muscle stimulation has been shown to minimize muscle atrophy after stroke or spinal cord injury. Typically, physical therapy begins with range-of-motion exercises and hand-walking for 5 minutes per day, followed by walking over ground poles and gradual increases in duration of exercise each day. Horses are not usually ready to return to training or to be turned out into a paddock for 6 to 12 months after surgery.

Fracture fixation

A variety of techniques have been described for internal fixation of supraglenoid tubercle fractures.[3,16-19] Tension from the biceps tendon is the primary force that needs to be neutralized when performing internal fixation. Partial or full transection of the biceps tendon to prevent tension on the fracture repair and facilitate internal fixation has been described, but it is not routinely recommended.[18]

The fracture site is approached as described previously for fragment removal. The fractured bone ends are débrided and the fracture is reduced using large bone-reduction forceps. The fracture is repaired using two or three 5.5-mm cortex bone screws placed in lag fashion. Care is taken to implant the screws in a somewhat diverging pattern to increase resistance against the axial tension on the implants. Additional support is provided by applying a figure-of-eight tension band between the supraglenoid tubercle and the cranial edge of the scapula using large-diameter (1.5-mm) wire (Figure 96-4) or a 1-mm cable.[3,16,17] Wound closure and immediate postoperative care are similar to that described for fracture fragment removal.

Following internal fixation, horses are confined to a box stall for at least 8 weeks, until postoperative radiographs indicate sufficient fracture healing. An intense rehabilitation program involving physical therapy and a controlled exercise protocol should be prescribed until shoulder musculature returns to normal, at which time training may be resumed.

PROGNOSIS

Fractures of the supraglenoid tubercle are rare and therefore there are few reports regarding surgical outcome. Return to athletic function depends on the amount of cartilage damage

Figure 96-4. Internal fixation of a supraglenoid tubercle fracture using three 5.5-mm cortex bone screws and a tension band wire. (Courtesy Alan J. Nixon, Cornell University.)

Figure 96-5. The position for obtaining a caudal proximolateral to cranial distomedial oblique (skyline) view of the lateral tuberosity of the proximal humerus is shown. The x-ray beam is directed from a caudal to a cranial direction.

present at the time of surgery and, in cases where the fracture fragment is removed, the amount of glenoid cavity removed with the fracture fragment. Both of these factors are assumed to be directly related to development of shoulder OA. The few reports that are available regarding supraglenoid tubercle fractures in the horse suggest that the prognosis for athletic function is fair to good following either fracture removal or internal fixation but poor with conservative treatment.[3,18,19] The most recent study indicates that 9 of 10 horses treated surgically and only 2 of 5 treated conservatively returned to athletic function.[3]

Miscellaneous Other Fractures

Fractures of the neck or body of the scapula or proximal humerus are rare but have been described.[20-22] These fractures are usually the result of trauma, and horses are variably lame.

The cranial and caudal aspects of the greater tubercle of the proximal humerus can fracture in different configurations. If the entire greater tubercle fractures transversely, the scapulohumeral joint can luxate. When clinical examination or nuclear scintigraphy suggests involvement of the greater tubercle, a caudal proximolateral to cranial distomedial oblique (skyline) radiograph of the proximal humerus should be obtained to diagnose the fracture (Figure 96-5). Depending on the size of the fracture fragment and the muscular attachments involved, the fragment may be treated conservatively, removed, or repaired using cortex screws placed in lag fashion.

Horses with complete fractures of the body of the scapula or scapular neck are unable to bear weight. A standing mediolateral radiograph with the affected limb pulled forward will reveal the fracture site. If the neck of the scapula is involved, function of the suprascapular nerve should be evaluated (see later). Internal fixation of complete or longitudinal fractures of the scapula has been described using internal fixation with multiple plates.[20,22,23] Application of a locking compression plate (LCP) cranial and caudal to the spine is the preferred technique (Figures 96-6 and 96-7). Incomplete fractures can be managed conservatively.[24]

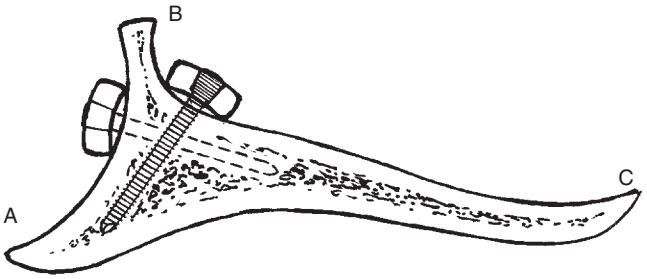

Figure 96-6. Crossectionoal view across the body of the scapula distant to the fracture. One LCP is applied to the cranial and caudal angle between the scapula and its spine. *A,* Cranial edge; *B,* spine; *C,* caudal edge.

Scapulohumeral Joint Luxation

Scapulohumeral joint luxations are rare in horses and are traumatic in origin. Because of their traumatic nature, concurrent fractures of the scapula or proximal humerus can occur.[25] The horses are non-weight-bearing and might have shoulder atrophy if the luxation is chronic. The humeral head can be palpated lateral, or less commonly cranial, to the scapula. Standing caudolateral to craniomedial oblique-view radiographs best demonstrate the luxation (Figure 96-8). The radiographs should be carefully evaluated for fractures of the humeral head or scapula, particularly involving the lateral rim of the glenoid.

Treatment

Closed reduction followed by scapulohumeral joint arthroscopy to evaluate the articular surfaces and remove cartilage debris resulted in return to sound performance in one case.[26] Closed reduction should be attempted whithin 24 hours and before an open approach is performed to preserve intact lateral musculature of the shoulder joint and minimize the potential for re-luxation of the shoulder joint postoperatively. Open reduction should be combined with some form of internal fixation such as scapulohumeral tension wires, although most types of internal fixation eventually fail.

The ultimate outcome for most horses with scapulohumeral luxation is shoulder OA and severe lameness, resulting in euthanasia. Arthrodesis of the scapulohumeral joint has been successful in one small (250 kg) horse and in Miniature Horses.[27-29] Arthrodesis is currently accomplished using a narrow LCP contoured to the cranial surface of the scapula and cranial aspect of the humerus.[29] For more information, review Chapter 81.

Prognosis

There are very few reports detailing repair of scapulohumeral joint luxation, but the prognosis for soundness following repair appears to be poor because of resultant crippling shoulder OA.

Pathologies of the Biceps Brachii and Infraspinatus Tendons and Their Associated Bursae

The biceps brachii muscle originates on the supraglenoid tubercle as a bilobed tendinous structure, and it inserts on the medial radial tuberosity. It passes over the proximal cranial aspect of

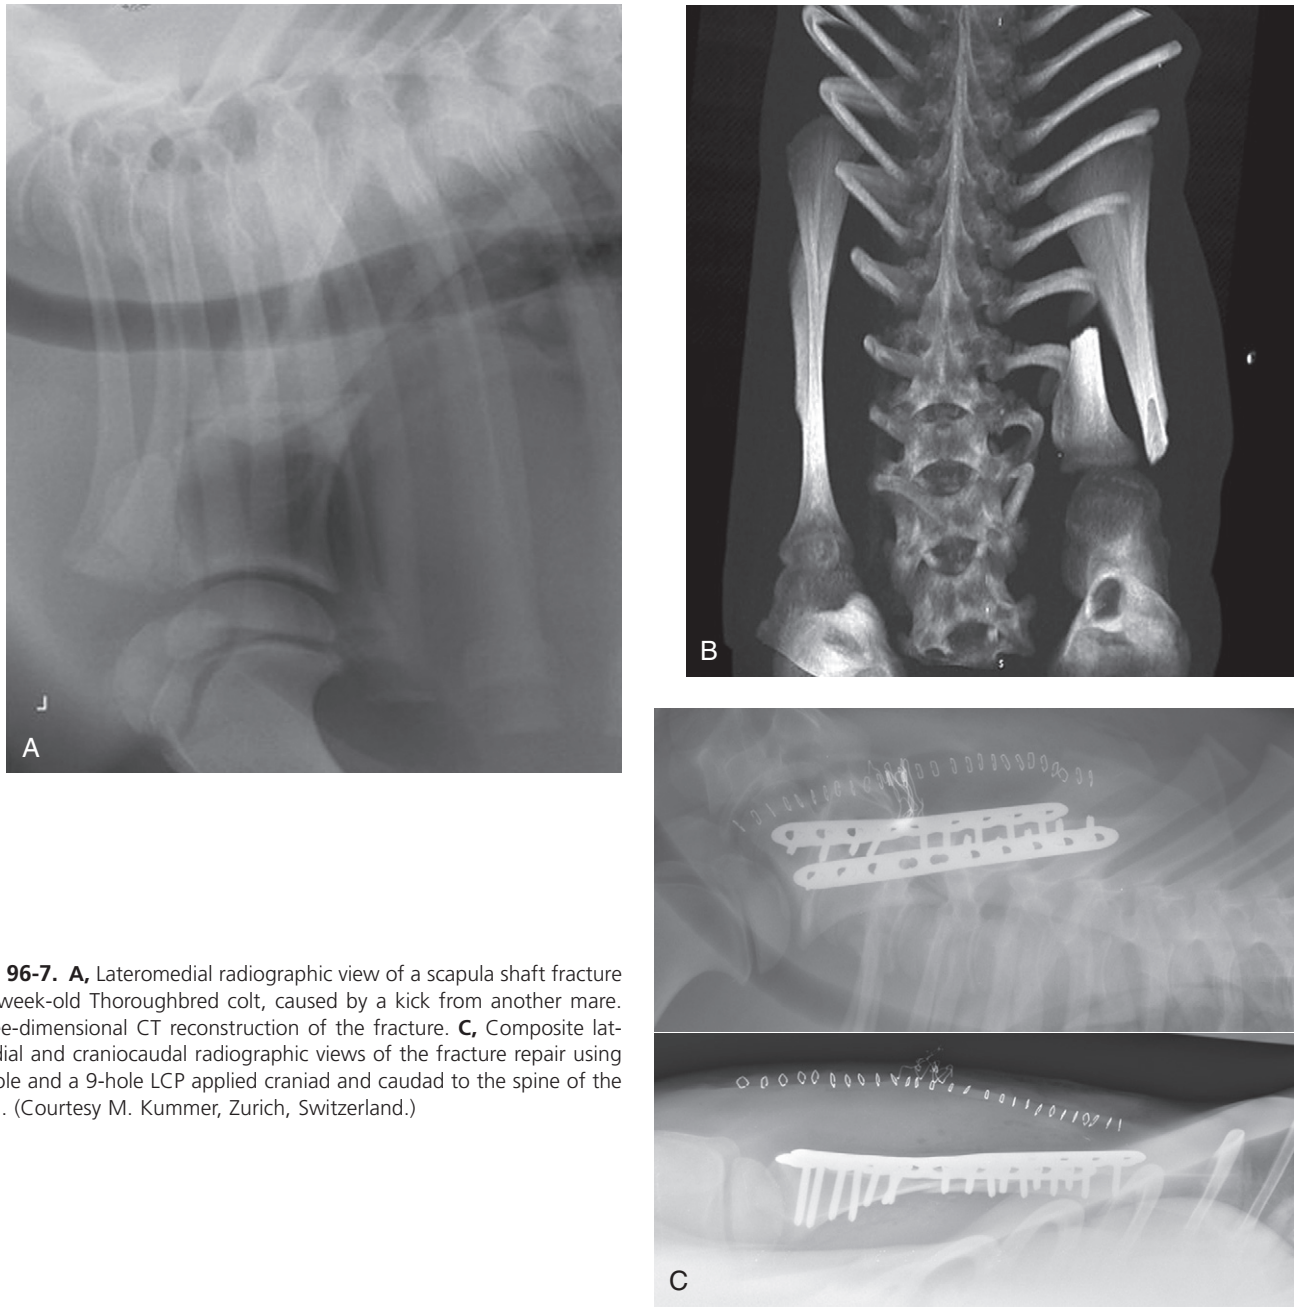

Figure 96-7. A, Lateromedial radiographic view of a scapula shaft fracture in a 3-week-old Thoroughbred colt, caused by a kick from another mare. **B,** Three-dimensional CT reconstruction of the fracture. **C,** Composite lateromedial and craniocaudal radiographic views of the fracture repair using a 10-hole and a 9-hole LCP applied craniad and caudad to the spine of the scapula. (Courtesy M. Kummer, Zurich, Switzerland.)

the humerus, where it is bound to the intertubercular groove by a tendinous part of the superficial pectoral muscle. It acts to flex the elbow joint and provides some stability to the shoulder. Passively, it limits elbow joint extension when the shoulder joint is in flexion, and it limits joint flexion when the elbow joint is extended.[30] The intertubercular (bicipital) bursa lies between the proximal biceps tendon and the humerus.[31]

Horses with bicipital bursitis or biceps tendinitis exhibit pain when the biceps is grasped and pulled laterally. Nuclear scintigraphy can be helpful in any of the vascular, soft tissue, or bone phases, but a definitive diagnosis requires intrasynovial anesthesia. After localizing the lameness to the biceps region, ultrasonographic and radiographic examinations of the biceps region should be obtained. Normal ultrasonographic morphology of the biceps tendon and bicipital bursa have been reported.[32] Caudolateral to craniomedial oblique radiographs of the proximal humerus are required to identify concurrent lesions involving the humeral tubercles (Figure 96-9).

Various pathologies have been reported in association with the biceps tendon or bicipital bursa including bursitis, tendinitis, ossifying tendinitis, medial displacement of the biceps tendon, and infectious bursitis.[33-39] Congenital hypoplasia of the minor tubercle of the humerus with subsequent medial luxation of the proximal tendon of the biceps brachii has also been reported in four mature horses.[40] Simple biceps tendinitis is managed conservatively, but surgical intervention should be considered for horses with idiopathic or infectious bursitis or with chronic bicipital bursitis.

The infraspinatus tendon extends from the infraspinatus muscle and courses over the lateral side of the shoulder joint

Figure 96-8. A caudolateral to craniomedial oblique view of the shoulder joint. A scapulohumeral luxation is present, with the humeral head located lateral to the glenoid cavity. A concurrent fracture, presumably originating from the glenoid, is present *(arrow)*.

and the caudal eminence of the greater tubercle to its insertion on the dorsolateral humerus. The infraspinatus bursa is located between the infraspinatus tendon and the caudal eminence of the greater tubercle. The normal ultrasonographic appearance of the infraspinatus tendon and bursa have been reported.[1] Injury to the greatere tubercle of the humerus and infraspinatus tendon with sepsis of the infraspinatus bursa has been reported in three horses.[41] In all cases, ultrasonography was more sensitive than radiographs for detecting osseous and soft tissue injuries. All three horses became sound following lavage of the bursa, removal of fracture fragments when present, and adminsitration of intrasynovial and systemic antimicrobials.

Treatment

ENDOSCOPY

Infection of the bicipital or infraspinatus bursa should be addressed using endoscopy and systemic antimicrobials. Endoscopy permits a thorough exploration of the infected bursa as well as a means of copious lavage and removal of adhesions. Synovial resection should be considered; however, it is controversial in cases of septic arthritis.

Endoscopy of the bicipital bursa in normal and infected bursae has been described.[38,42] The horse is positioned in lateral recumbency, with the affected limb uppermost. The bursa is distended with 100 mL lactated Ringer's solution as described earlier. The arthroscope is inserted into the distal aspect of the bursa through a skin incision placed 2 to 3 cm proximal to the deltoid tuberosity on the dorsolateral aspect of the humerus. The arthroscope is advanced proximomedially through the brachiocephalicus muscle, beneath the biceps brachii muscle, and along the cranial surface of the humerus. When the distended bursa is entered, and fluid escapes from the cannula, the obturator is removed and replaced with the arthroscope. The instrument portal site is predetermined by placement of a spinal needle in the proximal aspect of the bursa, lateral to the biceps tendon. The bursa is explored and any foreign debris and adhesions are removed.

Endoscopy of the infraspinatus bursa has also been described.[41] The horse is placed in lateral recumbency and ultrasonography is used to identify the cranial aspect of the bursa, where needles are inserted cranial to the infraspinatus tendon and 1 cm distal to the greater tubercles. The bursa is distended and an arthroscope is inserted into this region. Following placement of the arthroscope and further distention of the bursa, an instrument portal is identified with needle placement and established in the caudal bursa. Minimal manipulations, other than thorough exploration and extensive lavage, are possible in the bursa, and the incisions may need to be converted to an open approach for removal of fragments of the greater tubercle.

The type and duration of antimicrobial and anti-inflammatory medications administered depend on the presence or absence of sepsis. Similarly, postoperative rehabilitation and return to training or performance are related to the degree of tendinitis or bursitis.

BICEPS TENDON TRANSECTION

A combination of bicipital bursitis, biceps tendinitis, and humeral osteitis has been reported in horses.[33,35] This disease complex is thought to be a manifestation of chronic bursitis or tendinitis and can be infectious or traumatic in origin. Affected horses are severely lame and unresponsive to conservative therapy. Ultrasonography of the biceps bursa is consistent with bursitis; radiographs of the proximal humerus reveal osteolytic changes associated with the lateral tuberosity.

Complete transection of the biceps tendon results in a fair prognosis for return to soundness.[35] If purulent material is found within the biceps brachii tendon, then a tenectomy should be considered. The approach to the biceps tendon is the same as that described for removal of supraglenoid tubercle fractures. Postoperative management is also similar to that for removal of supraglenoid tubercle fractures because biceps tendon support is lost in both instances. There is, however, less dead space to be filled in by fibrous tissue.

Prognosis

There are too few reports of the various tendon or bursa problems to provide an accurate prognosis. As with most synovial structures, the prognosis for return to sound function ranges from guarded to good depending on the structures involved and the duration of clinical signs.

Suprascapular Nerve Injury (Sweeney)

The suprascapular nerve is typically damaged as the result of trauma to the cranial shoulder where the nerve courses across the neck of the scapula. The suprascapular nerve innervates the

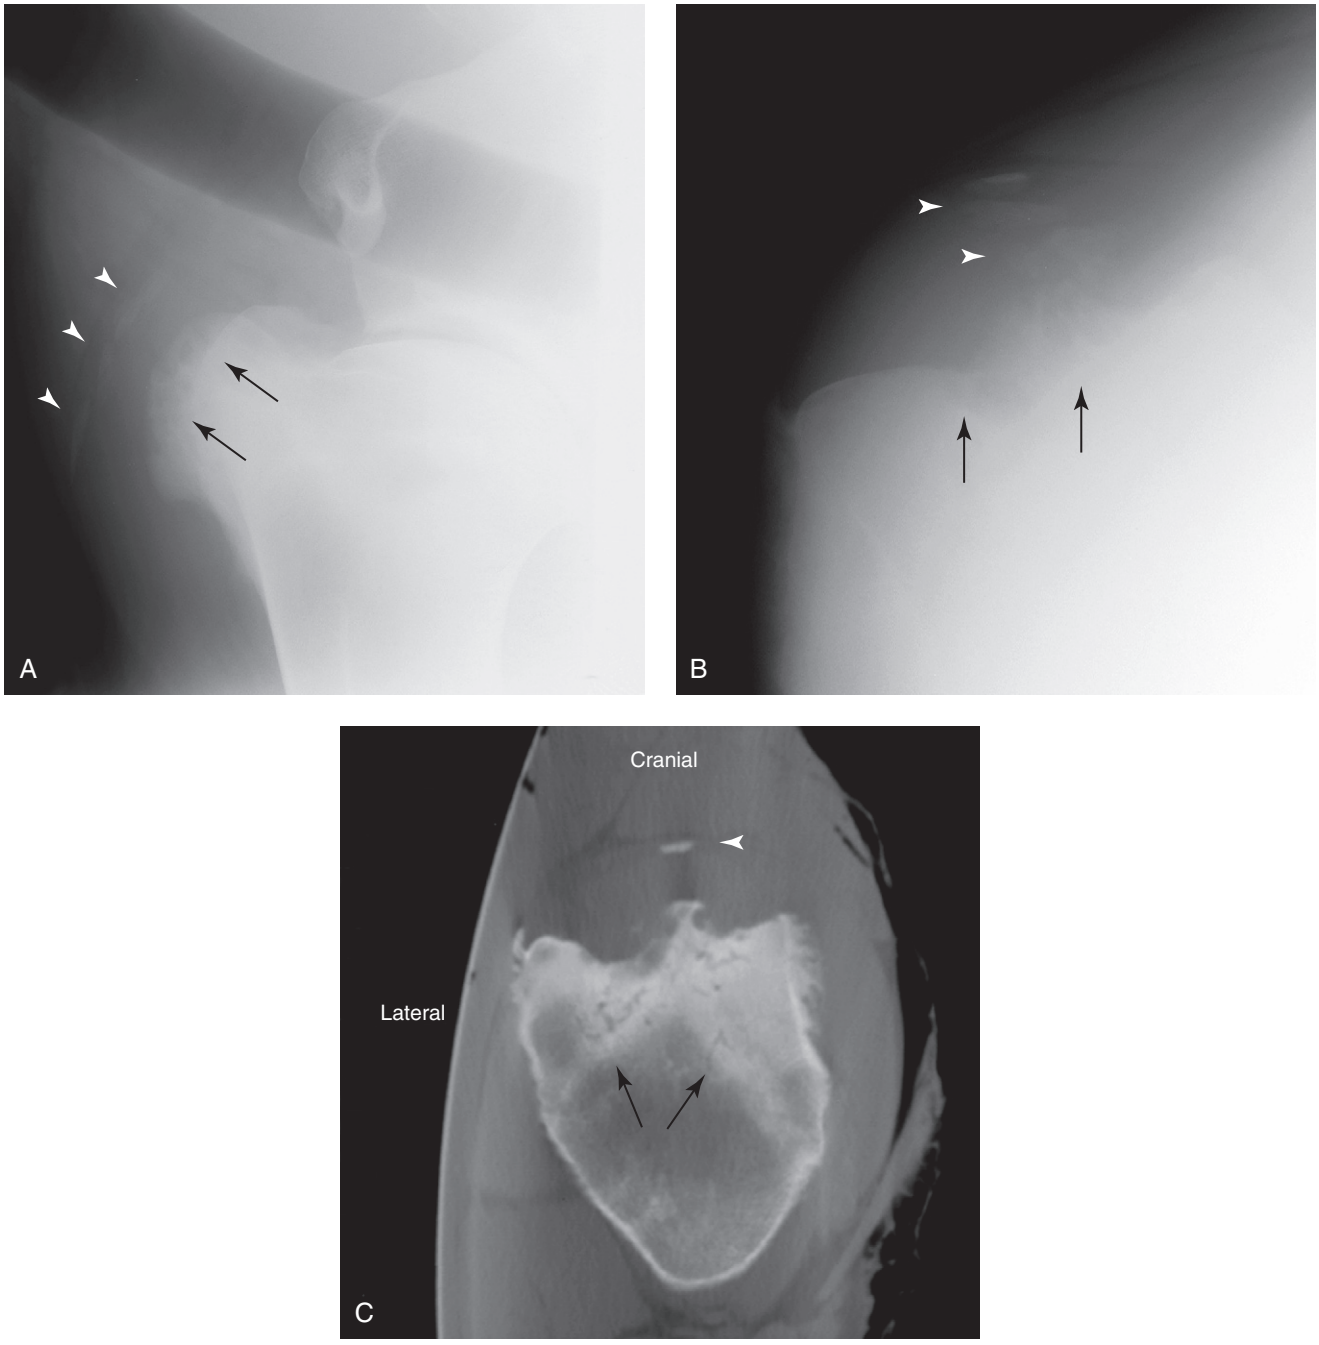

Figure 96-9. A, Mediolateral radiograph of the shoulder region in the intermediate tubercle of the humerus. Multifocal areas of irregular bone lysis *(black arrows)* can be seen. Cranial to the tubercles, there are linear foci of mineralization in the tendon of the biceps brachii *(white arrowheads).* **B,** Radiographic projection of the cranial proximal humerus. The lysis of the intermediate tubercle and mineralization of the bicipital tendon are confirmed and further defined in this radiographic projection. **C,** Postmortem transverse computed tomography evaluation of the affected shoulder region. The tubercles and medullary cavity of the cranial humerus are sclerotic *(black arrows).* There is a focal mineral density in the tendon of the biceps *(white arrowhead).*

infraspinatus muscle, which provides the majority of lateral support to the shoulder. As a result, horses with suprascapular nerve injury have a lateral motion or shoulder slip when bearing weight on the affected limb. This gait can be replicated by selective anesthesia of the suprascapular nerve, which suports the role of the suprascapular nerve in joint stability.[8]

If damage to the nerve is severe, the characteristic gait can be apparent immediately following injury, but more typically, a shoulder slip is not apparent for a few days to weeks after injury. Clinical signs do not indicate the degree of nerve damage, and there is no diagnostic method to determine the degree of recovery each horse will achieve.

Electromyography should be used to confirm that the suprascapular nerve, and not the brachial plexus, is the site of injury. Electromyography is only useful to evaluate nerve function from 7 days after injury on.

Treatment

NONSURGICAL MANAGEMENT

Nonsurgical management consisting of box stall rest alone results in a good return to function.[43] However, shoulder stability takes an average of 7 months to return. Surgical decompression of the suprascapular nerve can hasten the return of shoulder stability, diminish the amount of shoulder muscle atrophy, and return the horse to function sooner than that accomplished with nonsurgical therapy alone.[43,44]

The potential for a modestly decreased time to function needs to be weighed against the costs and risks associated with surgery, especially given the potential for postoperative supraglenoid tubercle or scapular neck fractures in horses following surgery.[45] A balance between the cost and benefit of each treatment is present in a staged approach consisting of nonsurgical management for 3 months, and if little improvement is noted, then surgical nerve decompression.

SCAPULAR NERVE DECOMPRESSION

The horse is positioned in lateral recumbency with the affected limb uppermost. A 25-cm (10-inch) skin incision is made over the spine of the scapula and through the cutaneus trunci muscle. The fascia covering the spine of the scapula is incised, and the brachiocephalicus muscle is elevated from the spine of the scapula while preserving the fascia deep to the supraspinatus muscle to protect the suprascapular neurovascular bundle. The nerve is elevated from the scapula, and a small amount of bone is rasped off the cranial margin of the scapula. Care is taken to maintain smooth edges of the bone to decrease potential postoperative nerve injury. A tendinous band that limits the movement of the suprascapular nerve can be palpated on the medial side of the scapula and covering the nerve. This band should be incised to maximize nerve decompression from scar tissue. Incisional closure is routine, with attention to obliteration of dead space.

Assisted recovery from anesthesia is recommended given the shoulder instability and potential for fracture of the supraglenoid tubercle. The potential for postoperative fracture through the notch created in the scapula exists for 6 weeks postoperatively. Antimicrobials and phenylbutazone are administered perioperatively, and low-dose phenylbutazone is continued for 3 to 5 days. The horse is confined to a box stall until shoulder stability is returned, typically 2 to 3 months. During stall confinement, muscle stimulation should be considered to minimize muscle atrophy. An intensive rehabilitation program then ensues to build shoulder strength prior to return to riding.

Prognosis

The prognosis for return to sound riding following conservative management or scapular nerve decompression is good.[44,45] Atrophy of the supraspinatus and infraspinatus muscles might not completely resolve in all cases.

CHAPTER
97 Tarsus

Jörg A. Auer

ANATOMY

The bones that make up the tarsus include the tibia, the talus and calcaneus, the central tarsal bone, the fused first and second tarsal bone, the third and fourth tarsal bones, and the metatarsal bones (MTII, III, and IV) (Figure 97-1). The tarsal bones are maintained in intimate contact through their soft-tissue attachments, including the intertarsal ligaments, collateral ligaments, fibrous joint capsule, and plantar tarsal ligament. The medial and lateral collateral ligaments of the tarsus each consist of two ligaments: a long and a short ligament. The long collateral ligaments connect the distal tibia to the proximal metatarsal region, but they also have attachements to the talus and small tarsal bones. The short collateral ligaments originate from the medial or lateral malleolus, respectively, cranial to the origin of the long collateral ligaments, and attach to the talus and calcaneus. Although the long collateral ligaments of the tarsus are taut during tarsal extension, the short collateral ligaments are tense in flexion and loose in extension.[1,2]

The tarsus is composed of five joints: the tarsocrural (TC), proximal intertarsal (PIT), distal intertarsal (DIT), tarsometatarsal (TMT), and talocalcaneal (TCa) joints. Four of these five joints are almost immobile. Although micromovements do occur during ambulation and weight bearing, most of the movement of the tarsus is achieved in the tarsocrural joint.

The two distal joints are often injected for diagnostic and therapeutic purposes. In one study, therapeutic concentrations of methylprednisolone were measured in the DIT joint 6 hours after injection into the TMT joint, confirming that communication between the TMT and DIT joints existed in 10 of 10 sampled joints (100%).[3] In an earlier study, communication was found between the TMT and DIT joints in four of 57 tarsi (7%); in one horse (2%), communication between the DIT and PIT was established.[4] In seven horses (14%), communication between the DIT joint and the tarsal canal existed, pointing out the potentially inconsistent results that can be found after intraarticular anethesia.[4] Other studies in the literature cite the communication between the TMT and DIT joints at 7%[5] and 38%.[6] Based on these data, medications injected into the TMT joint can exert effects in the DIT joint, and this seems to be a common phenomenon after corticosteroid injections. However, for diagnostic purposes and to avoid a lack of response to therapeutic medications, the DIT joint should be injected at the same time. The TCa joint in horses is composed of three facets between the two bones: a facet at the medial aspect of the calcaneus and talus, an angulated coracoid facet at the lateral aspect of the calcaneus and talus, and a facet at the lateral aspect of the calcaneus (facing medially) and medial aspect of the talus (facing laterally).[7] A strong interosseus ligament in the central tarsal sinus maintains the two bones in close proximity. The special relationship of the three facets relative to each other prevents motion in the joint.[7]

Dorsally, the long digital extensor tendon spans the entire tarsal region and is maintained in position by the retinaculi. Just distal to the tarsal region, the lateral digital extensor tendon unites with the long digital extensor tendon. The strong fibularis tertius (peroneus tertius) and the tendon of the tibialis cranialis muscle course parallel to the long digital extensor tendon (Figure 97-2). The fibularis tertius tendon is penetrated by the tendon of the tibialis cranialis muscle, which then divides into three branches, the medial, middle, and lateral branches, before inserting on the central, third, and fourth tarsal bones as well as the proximal metatarsal region. The medial branch is better known as the cunean tendon, which at one time was thought to be responsible for the development of spavin. The fibularis tertius forms the cranial part of the reciprocal apparatus (Figure 97-3). The gastrocnemius muscle and tendon form the caudal part. The intact reciprocal apparatus ensures that when one of the major joints of the rear limb is flexed, all others flex.

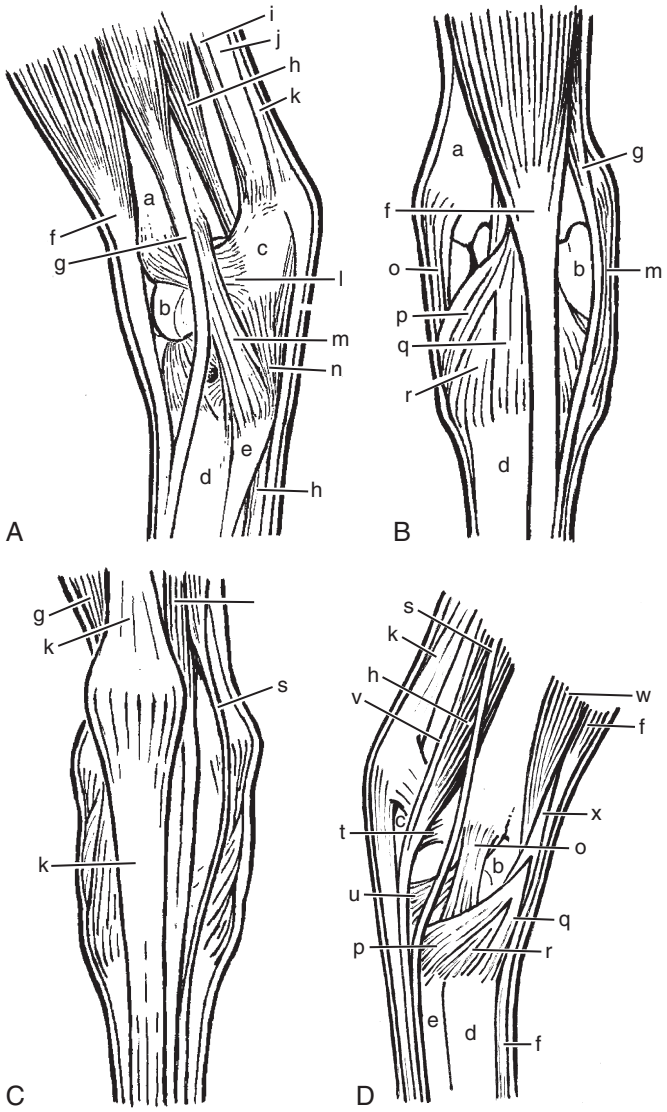

Figure 97-1. Graphic illustration of a lateral **(A),** dorsoplantar **(B),** plantarodorsal **(C),** and medial **(D)** view showing the anatomic structures associated with the tarsal region. *a,* Distal tibia; *b,* talus; *c,* calcaneus; *d,* third metatarsus (MTIII); *e,* MTIV; *f,* long digital extensor muscle and tendon; *g,* lateral digital extensor tendon; *h,* lateral digital flexor muscle (together with "v" form the deep digital flexor tendon); *i,* soleus tendon; *j,* Achilles tendon; *k,* superficial digital flexor tendon; *l,* short lateral collateral ligament; *m,* long lateral collateral ligament; *n,* plantar ligament; *o,* long part of the medial collateral ligament; *p,* medial part of the tibialis anterior tendon (cunean tendon); *q,* middle part of the tibialis cranialis tendon; *r,* branch of the fibularis tertius tendon; *s,* medial digital flexor tendon; *t,* medial plantar ligament between the talus and calcaneus; *u,* short part of the medial collateral ligament; *v,* tendon of the tibialis caudalis muscle; *w,* fibularis tertius muscle; *x,* main branch of the fibularis tertius tendon.

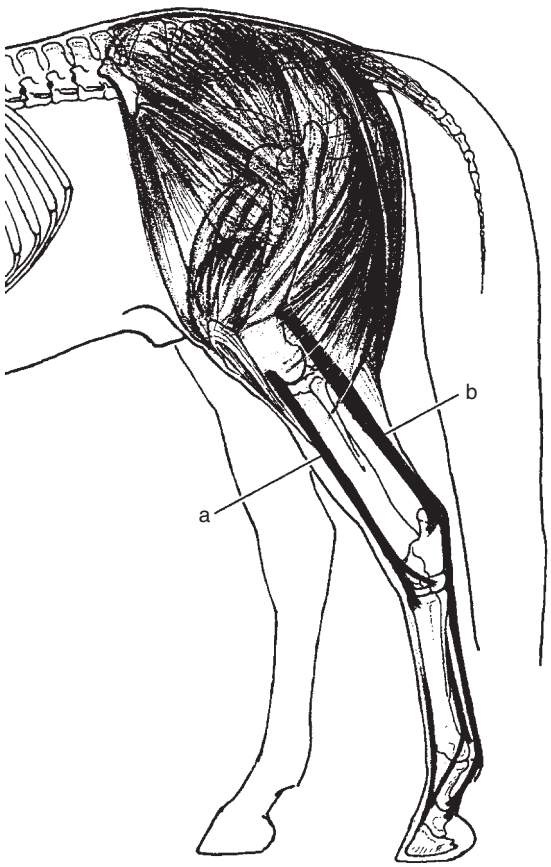

Figure 97-2. Correlation of the anatomic structures composing the reciprocal apparatus of the horse. *a,* The fibularis tertius tendon originates on the muscular fossa of the distal femur and inserts at the small tarsal bones as well as the third metatarsus (MTIII), whereas the lateral part courses toward the fourth tarsal bone; *b,* the gastrocnemius muscle originates from the plantar fossa of the distal aspect of the femur and with the Achilles tendon and unites with the soleus and accessory tendons before it inserts on the tuber calcanei.

Plantarly, the tendon of the superficial digital flexor muscle passes around the medial aspect of the gastrocnemius tendon and continues distad as the most plantar tendinous structure at the level of the tuber calcanei. The superficial digital flexor tendon is attached to the abaxial aspects of the calcaneus via the medial and lateral retinacula and continues distad to the digit. The voluminous intertendinous calcaneal bursa is located between the superficial digital flexor and the gastrocnemius tendon proximally and between the superficial digital flexor tendon and the long plantar ligament distally. A smaller bursa, the gastrocnemius calcaneal bursa, lies dorsal to the insertion of the gastrocnemius tendon on the tuber calcanei. These two bursae usually communicate, most commonly on their medial aspect. Another bursa is located between the subcutaneous tissue and the gastrocnemius tendon and is termed the *subcutaneous calcaneal bursa*. This bursa is usually a separate structure but can communicate with the intertendinous calcaneal bursa in some horses.[8] The tibialis caudalis and lateral digital flexor muscle both contribute to the deep digital flexor tendon that runs over the sustentaculum tali, embedded in the tarsal sheath. The tendon of the medial digital flexor muscle traverses the tarsal region medially and joins the deep digital flexor tendon in the proximal metatarsal region. All tendons pass over the tarsal region within a tendon sheath. The function of the tarsus is to transform axial loading during weight bearing from the cranioproximal to caudodistal oblique forces exerted along the tibia into vertically and distally oriented forces through the metatarsal area.

Figure 97-3. Illustration of the hind limb reciprocal apparatus demonstating that flexion of the tarsus or stifle results in flexion of all remaining joints in the hind limb.

ACQUIRED DISORDERS OF THE TARSAL REGION

Acquired disorders include fractures, osteoarthritis (OA), luxations, and tendon and ligament disorders. There is a large variability in presenting signs and diagnostic modalites needed to diagnose these disorders and subsequently manage them properly.

Osteoarthritis

Osteoarthritis is the most diagnosed acquired tarsal disorder causing lameness.[6] It is seen in three forms: one involves the distal tarsal joints (referred to as *bone spavin*), one is located at the talocalcaneal joint, and the other involves the tarsocrural joint (referred to as *high spavin* or *bog spavin* when joint distention is present).

Etiology

OA of the distal tarsal joints is the most common cause of hindlimb lameness in the horse.[9] The DIT and TMT joints are most often involved, but occasionally the PIT joint also is affected. A study in foals showed that bone density of the compact bone of the subchondral bone plate in the third tarsal bone reacts to variations in exercise at a very young age.[10] Low bone density resulting from a lack of exercise was reversed when exercise was introduced. Osteoarthritic radiographic signs (enthesiophytes) in the distal intertarsal joints were common at 5 months of age and increased in severity until 11 months of age. Although the clinical relevance of these abnormalities in foals is uncertain, they might be related to the development of osteoarthritis in this region later in life.[9]

Although the exact pathogenesis of distal tarsal OA is still unknown, compression and rotation of the distal tarsal bones, which occurs most forcefully at the gallop, can contribute to its development.[11] Dressage horses, western horses, pulling horses, and Standardbreds are prone to the disorder, which is associated with their type of athletic activity. Icelandic horses are often affected, which is possibly related to the mismatch of the horse and the rider and the gaits at which these animals are used. The rack is a fast four-beat gait during which the horses place their hind limbs extremely far forward, and this extreme type of gait can be responsible for the development of bone spavin in these horses. Poor conformation also is a contributing factor to this disorder: bowlegged and sickle-hocked conformation results in abnormal loading of the small tarsal bones and leads to the development of OA.

Crushing of the central or third tarsal bones in dysmature neonates because of incomplete ossification may eventually lead to the development of juvenile OA of the tarsus.

Other inciting causes of distal tarsal OA are septic arthritis, tarsal bone fractures, osteochondrosis, and excessive exercise.[9,12-14] OA also has been associated with increased intramedullary pressure within the cuboidal bones of the tarsal region.[15] Inciting causes for this rarely encountered tarsocrural and sometimes talocalcaneal joint OA include intra-articular fracture, osteochondrosis, septic arthritis, and collateral ligament damage.[16]

For most other tarsal disorders, external trauma, such as a kick from another horse or being hit by or running into an object, is the inciting cause. Repetitive trauma as it occurs during racing or competitive events in general can lead to the development of lameness.

Clinical Signs

The cardinal sign of a tarsal problem is lameness, which can vary depending on the severity, location, and acuteness of the disorder. Toe dragging is a common early sign that occurs because of a reluctance to flex the tarsus. Horses with OA often have a reduced foot flight arc, shortened cranial phase of the stride, gradual axial deviation in the flight path of the foot during the cranial phase of the stride, and a rapid abaxial deviation at ground contact.[17] Affected horses often show pain to back palpation, and many horses are presented for a primary complaint of back pain. However, in most cases, a weight-bearing lameness is noted.

Joint distention is not a typical sign of OA of the distal tarsal joints, because the tarsal retinaculum over these small joints prevents its detection. However, new bone proliferation at the dorsomedial aspect of the limb might be noticeable in chronic cases (Figure 97-4). A typical sign of a tarsocrural disorder is joint distention (bog spavin). However, as often noted in OCD, the swelling does not have to be painful to palpation.

An acute onset of a marked to severe weight-bearing lameness is a clear sign of trauma and is often associated with joint distention or swelling of the neighboring tissues, or both. Penetrating articular wounds often can lead to septic arthritis

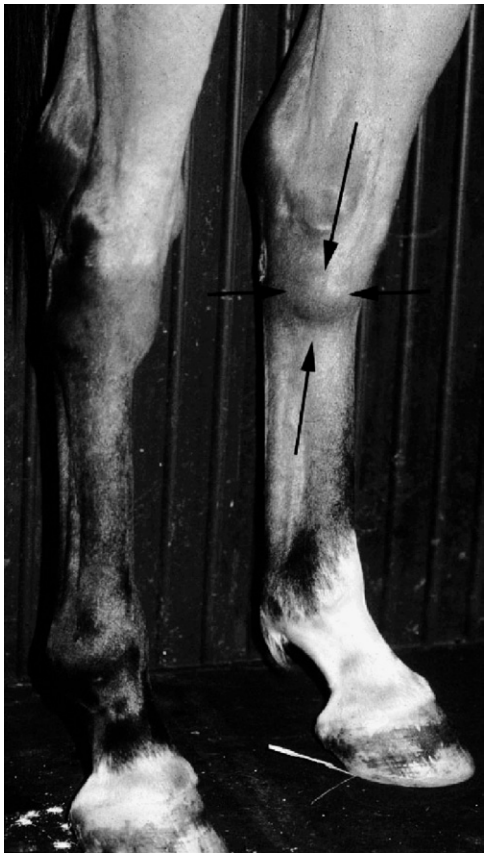

Figure 97-4. Marked enlargement at the dorsomedial aspect of the distal tarsal region *(arrows)* in a horse suffering from osteoarthritis of the distal two tarsal joints (bone spavin). Excessive new bone formation is responsible for this appearance.

with all the accompanying signs including heat, swelling, and pain.

Significant periosteal new bone formation and enthesiophytosis associated with a hopping gait in the rear legs are the distinctive clinical signs of juvenile OA. In severe cases of tarsal bone collapse, foals may show a "curblike" appearance in the distal tarsal region, which is associated with pain. For additional information on this condition, see Chapter 86.

Diagnosis

The diagnosis of tarsal disorders involves a routine lameness examination. In the presence of fractures and joint infections, the origin of which is often easy to localize, immediate attention should be given to the inciting cause, sidestepping the lameness examination.

Leading the horse in tight circles at walk in both directions can exacerbate the lameness on the inside limb. Some horses initially show a marked lameness, but with time they warm out of it. Often the horse exhibits a barely detectable unevenness at the time of presentation or no evidence of lameness at all because of bilateral pain. A history that includes deterioration in the horse's attitude suggests subtle hock pain, which does not produce overt lameness. Evaluation of the shoes and looking for uneven wear can lead the clinician toward the diagnosis. Palpation of the tarsal region can allow detection of enlargement over the dorsomedial aspect of the tarsus; however, most lesions do not cause pain upon digital pressure. Cunean bursitis and effusion of the cunean bursa are rare, but they can be detected by palpation. Flexion tests often exacerbate the lameness.

Intra-articular anesthesia is a valuable aid in localizing the problem. Because there is controversy in the literature regarding communication between the TMT and DIT joints, both joints should be anesthetized.[4,5,18-20] Significant improvement in lameness 10 minutes after intra-articular injection of 2 to 4 mL mepivacaine hydrochloride is diagnostic, but complete resolution of lameness might not occur because of intraosseous pain in the tarsal bones.[15] Larger volumes of anesthetic should not be used because of the potential for periarticular extravasation and contact with nonarticular tissues, including the sensory nerve supply from the distal limb as it passes through the tarsus.[18] In young racing Standardbreds, it might be advantageous to anesthetize the cunean bursa, because cunean bursitis is diagnosed in these animals.

The joint region to be injected is clipped and prepared as for aseptic surgery. Meticulous cleansing of the area without clipping of the hair (application of the antiseptic of choice, scrubbing for 5 minutes followed by removal of the antiseptic soap, repeated twice) has no higher risk of iatrogenic joint infection following arthrocentesis than clipping the hair prior to preparation and needle placement (see Chapter 72).[21,22]

The TMT joint is the easiest of the distal tarsal joints to inject (see Figure 72-13). The needle is inserted laterally, 0.5 cm proximal to the head of MTIV, in a dorsomediodistal direction at a 45-degree angle to both the sagittal plane and the ground until it makes contact with bone, usually at a depth of approximately 2 cm.[15] This technique results in the needle tip's passing deep, medial, and slightly distal to the palpable lateral aspect of the head of MTIV, positioning it near the articulation between MTIV and the fourth tarsal bone. The steep angle is necessary to position the needle tip sufficiently distal to avoid penetrating the DIT joint, which is located only slightly proximal to the head of the MTIV.

The DIT joint is injected medially in the space between the central tarsal bone, the third tarsal bone, and the fused first and second tarsal bones (Figure 97-5). The location for needle placement is found by palpation of the distal border of the cunean tendon, approximately 2 cm caudal to a vertical line extended distad from the medial malleolus.[13] Ideally, the needle is inserted to the hub at a 45-degree angle in a plantarolateral direction and parallel to the ground.

A dorsolateral approach to the DIT has been described (see Figure 72-13).[23] The injection site is located 2 to 3 mm lateral to the long digital extensor tendon and 6 to 8 mm proximal to a line drawn perpendicular to the axis of the third metatarsal bone through the proximal end of the fourth metatarsal bone. The needle is directed at an angle of approximately 70 degrees from the sagittal plane in a plantaromedial direction. In this report, the number of needle repositionings required to complete DIT joint centesis via the dorsolateral and medial approaches was not significantly different. I prefer this location because, in addition to having the same success rate as the medial approach, palpation of the landmarks is easy and the clinician is less vulnerable to getting kicked by the horse.[23]

When using the medial approach, full penetration of a 3-cm (1 inch) needle in small horses can result in the needle's passing completely through the DIT joint and into connective tissue deep to the joint capsule.[9] Also, the TMT joint can be entered

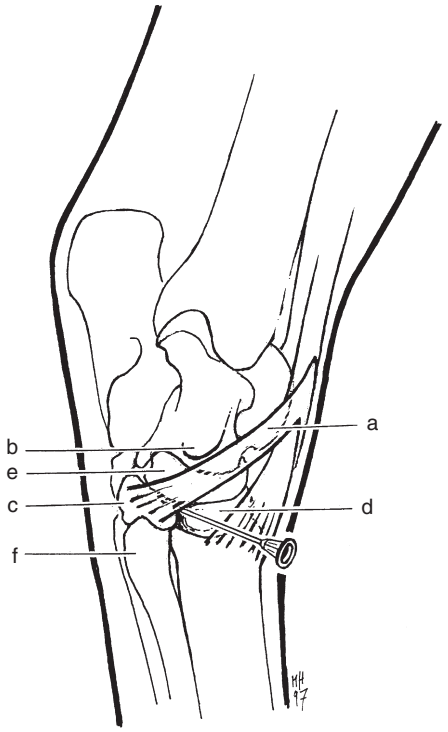

Figure 97-5. Graphic illustration of the injection site for the distal intertarsal (DIT) joint. The DIT joint is injected medially in the proximal aspect of the space that exists between the central tarsal bone *(e)*, third tarsal bone *(d)*, and fused first and second tarsal bone *(c)*. The entrance to this space can often be felt with firm palpation and is found at the distal border of the cunean tendon *(a)*, approximately 2 cm caudal to a vertical line extending distad from the medial malleolus. The location for needle entry can also be located along a line between the distal tubercle of the talus *(b)* and the palpable space between the second metatarsus (MTII) *(f)* and MTIII, where it intersects the cunean tendon.

Figure 97-6. Lateromedial radiographic view of the tarsal region of a 4-month-old foal that was born with incomplete ossification. The central tarsal bone is partially collapsed dorsally. This foal is a good candidate to develop juvenile osteoarthritis.

inadvertently on the medial aspect of the tarsus while attempting to enter the DIT joint, because the TMT joint capsule is located just slightly distal to the DIT joint capsule.[7] The PIT joint is rarely injected alone, because it communicates with the tarsocrural joint, and this injection is not discussed here.

The tarsocrural joint, of all joints composing the tarsus, is the easiest to inject, especially when it is distended. The dorsomedial pouch of the joint can be easily palpated (see Figure 72-12). Taking care to avoid the saphenous vein, the needle is then inserted in a dorsocaudolateral direction, and depending on the degree of joint distention, 10 to 20 mL of synovial fluid is withdrawn prior to injecting 8 mL of mepivacaine hydrochloride.

Diagnosis is confirmed using standard radiographic views, including oblique projections. OA is commonly a bilateral condition; therefore, radiographs of both tarsal regions are recommended. Because some changes might be subtle, it is important to take good-quality radiographs. Lameness associated with the distal tarsal joints can exist with little or no radiographic abnormalities. Conversely, extensive radiographic changes might be present that are not associated with pain or lameness. Therefore, it is important to locate the site of lameness before obtaining radiographs. Fractures are best confirmed with good-quality radiographs. In rare cases, such as fractures of the central or third tarsal bones, this imaging technique may not afford a diagnosis.

Juvenile OA is easily diagnosed with the help of radiography (Figure 97-6). Dorsopalmar and lateromedial views are adequate for the diagnosis. Despite the fact that this problem is usually encounterd bilaterally, taking radiographs of one tarsus is usually enough to confirm the diagnosis.

Ultrasonography also can be used to arrive at a diagnosis as long as the lesions are peripheral. In-depth knowledge of the tarsal anatomy is a prerequisite if this imaging technique is used. Scintigraphy has been used to localize lesions not visible on radiographs, especially in early cases where radiographic changes are not yet apparent.[24,25] A recent study showed that ultrasonography can be a valuable asset in diagnosing dorsal tarsal soft tissue lesions, such as tendon pathology or distended distal tarsal joints.[26] Computed tomography can be applied in the tarsus and provides valuable details for an exact diagnosis, especially in cases of hidden new bone formations and fractures. This technique is gaining in popularity. A comparison of radiography, nuclear scintigraphy, and magnetic resonance imaging (MRI) for diagnosing specific conditions of the equine distal tarsal joints revealed a low sensitivity for radiography because a high percentage of horses had normal or inconclusive radiographs despite pathologic changes that were identified with MRI.[27] Conversely, nuclear scintigraphy correlated well with the location of lesions found with MRI in all horses in this study.

Treatment

OSTEOARTHRITIS OF THE DISTAL INTERTARSAL JOINTS (BONE SPAVIN)

Management of OA includes corrective shoeing, systemic and intra-articular anti-inflammatory medications, shock wave therapy, chemical and surgical arthrodesis, and cunean tenectomy.

Corrective shoeing

Horses with bowlegged conformation profit from corrective shoeing in which the medial hoof wall is shortened and a special horseshoe with a wider, thicker outside branch is applied. The application of lateral wedges between shoes and hoof wall decreases tension on the medial patellar ligament and pressure on the medial side of the tarsal joint. However, the metacarpophalangeal joint experiences considerably more stress.[28] A shoe with a lateral extension is used to unload the medial aspect of the tarsal region by altering the foot-ground weight distribution and foot orientation during stance.[29] A study revealed that proper conditioning also can have a protective effect against bone spavin and lateral luxation of the patella.[28]

Extracorporal shock wave therapy

The systems used to apply extracorporal shock wave therapy in equine medicine are of the middle-energetic (0.2 mJ/mm^2) to high-energetic (0.4 mJ/mm^2) form. Therapy is generally applied in two or three sessions at approximately 3-week intervals. For treatment of soft-tissue calcifications, intervals between 3 and 6 weeks are used. The skin overlying the target tissue is clipped or shaved. During application of the shock waves, the horse is sedated. Depending upon the system used, a session takes 10 to 25 minutes.

Some promising results have been achieved in the management of OA of the distal intertarsal joints.[30] Originally it was thought that the focused shock waves would stimulate bone remodeling, increase blood flow to bone-tendon interfaces, stimulate cellular metabolism, and provide short-term analgesia.[31] Several studies have been conducted to evaluate these effects , especially after some studies indicated a rapid decrease in lameness following treatment.[32] An experimental study comparing the effects of shock wave therapy on cutaneous nerve function to the effects of a local nerve block and sedation discovered that there were no effects on cutaneous sensation distal to the treated region for at least 3 days after shock wave application.[33] Another study conducted on horses suffering from proximal palmar metacarpal/plantar metatarsal pain and using an instrumented treadmill to determine the effect of shock wave therapy showed a slight but not significant gait improvement.[34] However, there was improvement in the forelimb parameters, indicating a certain degree of analgesia. Taking into account the results of the different studies, the ban imposed on the use of extracorporeal shock wave therapy in the days immediately preceding a competition seems justified, even if they are difficult to enforce.

Medical management

Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used as adjunctive medication during the convalescent period after surgery, but as a sole treatment for distal tarsal OA, they are only palliative. As long the medication is administered, the lameness might be reduced or even absent, but as soon as administration is stopped, the lameness returns.

Steroid treatment of OA involves intra-articular injection of long-acting corticosteroids into the involved joints (indicated only after diagnostic intra-articular anesthesia renders the animal free of pain or convincingly reduces the lameness). The TMT and DIT joints of both limbs can be treated simultaneously. With simultaneous treatment, the dose per joint should be reduced, because the total dose per horse should not exceed toxic levels (see Chapter 79 for specific drug dosages).

After injection, horses are rested for 2 or 3 days, following which work can be resumed. Most horses respond favorably to injection and are free of pain for several months. Aseptic technique is very important to avoid inducing a postinjection flare or septic arthritis. A sudden onset of lameness within a few days after the injections should be managed immediately with joint lavage under general anesthesia. Oral anti-inflammatory and systemic antimicrobial therapy is indicated to maintain a reasonably comfortable patient during management of this complication.

Lameness usually recurs after a few weeks to months and can be managed by additional corticosteroid injections. The pain-free interval shortens with repeated injections. In such patients, surgical or chemical fusion should be considered to maintain a useful horse.

A recent survy among equine paractitioners revealed that 70% included corticosteroids in their treatment regimen of tarsal OA. Most respondents combined cortiocosteroids with another medication, such as high molecular weight hyaluronan (59%) or amikacin (57%) (see below).[35] Triamcinolone acetate was the most frequently used drug in high-motion joints, whereas methylprednisolone acetate was most commonly used in low-motion joints.[35] Of the respondents, 44% used 18 to 40 mg of triamcinolone acetate as the total body dosage.

Hyaluronan and polysulfated glycosaminoglycan (PSGAG; Adequan) are used to improve the joint environment and reduce inflammation in high-motion joints (see Chapter 79). The above-mentioned survey also revealed that hyaluronan and PSGAGs were the most commonly used noncorticosteroid therapeutics, and they were primarily used prophylactically.[35] Although hyaluronan was frequently combined with corticosteroids (see earlier), PSGAGs were primarily injected IV.[35] It is my opinion that these drugs can provide temporary relief for distal tarsal OA. However, if the patient is to be used in athletic competition, return of lameness is inevitable. Therefore, these drugs do not have a place in the management of OA of the distal tarsal joints, especially if costs are considered.

A recent study showed that the combination of hyaluronan, chondroitin sulfate, and *N*-acetyl-D-glucosamine (Polyglycan) produced significant improvement in lameness and disease progression after intraarticular injection in an experimental carpal OA model in horses.[36] These results can also be applied to the tarsus.

Chemical fusion of the DIT and TMT joints by intra-articular injection of sodium monoiodoacetate (MIA) was introduced as an alternative to surgical arthrodesis for horses clinically affected with distal tarsal OA. MIA blocks a specific enzyme pathway in chondrocyte metabolism, resulting in chondrocyte death, cartilage necrosis, joint collapse, and fusion of the distal tarsal joints.[37-40]

Horses receiving MIA should be premedicated with phenylbutazone (4.4 mg/kg IV every 12 hours), beginning 12 hours before treatment. Injection with MIA should be preceded by contrast arthrography of each joint, because communication between the DIT and PIT joints and communication between the TMT and PIT joints has been documented (Figure 97-7).[21]

For a detailed description of the technique please review Chapter 81. Because of the inherent danger associated with communication with other joints, this technique has never gained widespread acceptance.

The use of intraarticular injections of ethyl alcohol has also been studied.[41,42] Ethyl alcohol functions as a neurolytic agent

Figure 97-7. Positive contrast arthrogram after injection into the TMT joint, showing communication of the tarsometatarsal joint with the proximal intertarsal and tarsocrural joints and the extensor digital sheath.

that leads to sensory innervation blockade at the intraarticular level.[41] The same potential complications accompany this technique as with MIA injections.. This technique is described in detail in Chapter 81.

Although both techniques of chemical fusion are economical, it must be kept in mind that chemical fusion is a time-consuming procedure that bears the risk of inducing undesired effects in other structures not intended to be involved, such as the talocrural joint. The experimental data are promising; however, these techniques have failed to achieve consistently favorable clinical results.

Surgical management

Cunean tenectomy is a relatively simple procedure performed with sedation and local anesthesia. Cunean tenectomy can improve lameness by decreasing rotational forces on the tarsus that occur when the obliquely oriented cunean tendon tightens.[31] This surgical treatment for acute OA is controversial. In instances when distal tarsal OA is chronic and bone proliferation under the tendon is excessive, this technique can provide some pain relief. The procedure is usually performed bilaterally.

The surgical site is anesthetized by an inverted V-shaped line block spanning from the chestnut to the dorsal aspect of the saphenous vein. A 4-cm vertical skin incision is made over the cunean tendon approximately 5 cm dorsal to the chestnut, where the tendon is easily palpable. A 4-cm section of tendon is removed with a No. 15 scalpel blade, and the skin is sutured. A compression bandage is applied and changed as needed until the sutures are removed at 14 days after surgery.

The Wamberg technique complements cunean tenectomy with gridlike incisions over the medial aspect of the tarsus down to the bone. The purpose of these incisions, performed at 3.5 mm intervals, is to complete neurectomy of the region. This procedure has been abandoned.

Aftercare of cunean tenectomy consists of stall rest for 12 days with limited daily hand-walking. After the sutures are removed, the amount of hand-walking is increased gradually through the twenty-first postoperative day and includes walking over poles. Three weeks after surgery, riding starts over poles, and full work resumes at 6 weeks. This exercise regimen is important for preventing formation of restrictive scar tissue between the severed tendon ends and the cunean bursa.

The efficacy of cunean tenectomy has been debated, but there are no controlled clinical studies or experimental evidence in the literature to either support or refute the validity of the procedure. An owner survey of 285 cases of bone spavin treated by cunean tenectomy showed that most owners (83%) believed that lameness and performance improved after cunean tenectomy and that they would have the procedure performed again.[43] Today, cunean tenectomy as a sole procedure is rarely performed. It is, however, performed together with an arthrodesis using bone plates (see below and Chapter 81).

Laser facilitated ankylosis using neodymium: yittrium aluminum garnet (Nd:YAG) or diode[44,45] laser to destroy articular cartilage has also been performed. The theory behind this technique is that by superheating and vaporizing synovial fluid, chondrocyte death should follow. Clinical studies are currently not available, but experimental studies in sound horses demonstrated that laser application promotes partial ankylosis of the DIT joint within 5 [44] to 12 months.[45] However, in an experiemental study, diode laser–facilitated ankylosis resulted in significantly less fusion of the distal tarsal joints when compared to MIA injection or transarticular drilling (see below).[45]

Arthrodesis of the distal tarsal joints can be achieved using different techniques.[17,46-51] Most procedures involve radiographically guided removal of cartilage by local drilling across part of the joint space. Bone plates, intra-articular stainless steel cylinders, transarticular screws placed in lag fashion, and cancellous bone grafts have been used to improve stability and hasten fusion after drill removal of cartilage and subchondral bone, but none of these treatments appears to offer a substantial advantage over drilling alone.

Joint stability and pain relief can be obtained after bony bridging across only a small portion of the involved articular surface, which act as "spot welds." Techniques have to be developed to provide better stabilization over a larger articular area, similar to the technique used for proximal interphalangeal arthrodesis (see Chapter 81), where a dorsal plate is supplemented by two screws that provide transarticular compression in the palmar region. However, in most of the currently used techniques, only the plate bridges the joints to be arthrodesed, and transarticular screws are not used. For more information on screw fixation for OA, please review Chapter 81. However, I favor parallel transarticular drilling to promote fusion of the distal tarsal joints without internal fixation.

Articular drilling is performed bilaterally on both the DIT and TMT joints as a single procedure. The technique is described in detail in Chapter 81. Drilling too deeply can cause penetration of the tarsal canal, resulting in unnecessary periosteal reactions or profuse hemorrhage if the perforating branch of the cranial tibial artery is inadvertently traumatized. Avoiding these complications is preferable, but they appear to have no effect on the success of the procedure.

Aftercare

Horses can be lightly ridden 3 to 4 weeks after surgery. Administration of anti-inflammatory drugs maintains a reasonable level of comfort during the process of fusion. Most animals are free of lameness within 4 or 5 months of the procedure, but others show persistent lameness. Judgment on the outcome of the procedure is reserved until 12 months after surgery.

Prognosis

The prognosis for horses with distal tarsal OA treated with surgical arthrodesis is favorable, because most horses return to full function when the affected tarsal joints fuse.[17] Return to soundness over a 3- to 12-month period is reported in 66.7% to 85% of horses undergoing arthrodesis of the DIT and TMT joints.[47,49] Involvement of the PIT joint carries a less-favorable prognosis because of its consistent communication with and concurrent involvement of the TC joint.[49]

The prognosis following chemical fusion of the distal tarsal joints with MIA is favorable. Most horses show dramatic improvement in the original level of lameness within 1 week after treatment, even though fusion might not be apparent radiographically for 3 to 6 months (Figure 97-8).

Thirty-nine horses that had OA and were treated with intra-articular MIA were evaluated.[38] Treatment was considered a short-term success when there was simultaneous documentation of radiographic fusion and soundness. At 1, 3, 6, and 12 months, success was achieved in 4 of 26 (8%), 15 of 27 (56%), 21 of 26 (81%), and 27 of 29 (93%) horses, respectively. Long-term evaluation showed that 16 of 16 (100%) horses had radiographic fusion of the treated distal tarsal joints, and 12 of 16 (75%) were free of lameness and the treatment was considered successful. OA of the PIT and TC joints was encountered in 4 of 39 horses (10%) and was diagnosed between 1 and 4 years after MIA treatment as acute severe lameness and swelling of the TC joint.[38] Each horse was treated with MIA before the potential for communication between the DIT and PIT joints was recognized, and none received contrast arthrograms. It is presumed that such a communication resulted in contact of MIA with cartilage of the PIT and TC joints.

Another study revealed that in 50% of normal horses injected with 70% ethanol were radiographically fused at 4 months post injection and in 15 of 16 horses (94%) were fused after 12 months.[37]

OSTEOARTHRITIS OF THE TALOCALCANEAL JOINT

The TCa joint has a curved contour, which is best recognized on lateromedial radiographs. The medial, lateral, proximal, and interosseous talocalcaneal ligaments support it.[1]

Osteoarthritis of the TCa is rarely described (Figure 97-9).[16,52] However, two reports have renewed the interest in this disorder.[7,53] The clinical signs are not specific and resemble those of distal tarsal OA. Radiography and scintigraphy have been very beneficial in diagnosing the problem.[7,54]

Conservative therapy is usually unrewarding.[53] Stall rest, pasture exercise, and intra-articular corticosteroids with or without hyaluronan or PSGAG did not bring about consistent improvement of the lameness.

Surgical treatment involving partial tibial and fibular neurectomy cannot be recommended because of the poor results.[53] Osteostixis also did not result in improvement of the lameness.[54] The best results were achieved with arthrodesis of the TCa joint (see Figure 81-22).

Three techniques are described, all applying cortex screws across the joint.[7,53] One technique involves implanting three 5.5-mm cortex screws across the joint from the plantarolateral aspect of the calcaneus into the talus.[53] Lameness improved in

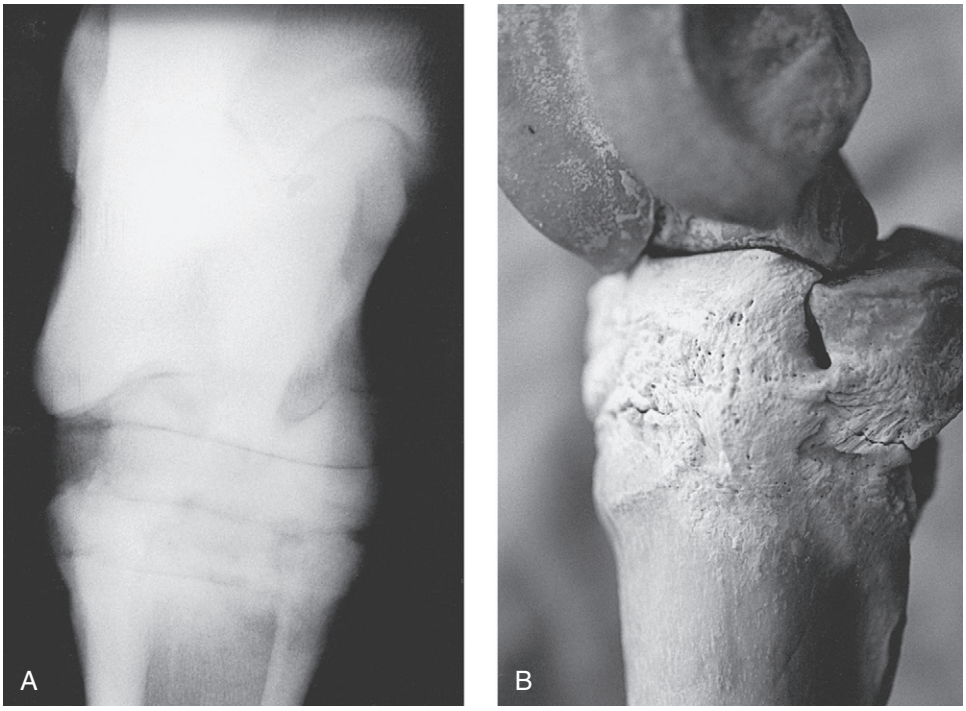

Figure 97-8. A, Dorsoplantar radiographic view demonstrating fusion of the tarsometatarsal and distal intertarsal joints 6 months after injection with sodium monoiodoacetate. **B,** Gross anatomic specimen of the same horse after it was euthanized 1 month later for an unrelated reason. Solid bone bridging is obvious in certain areas.

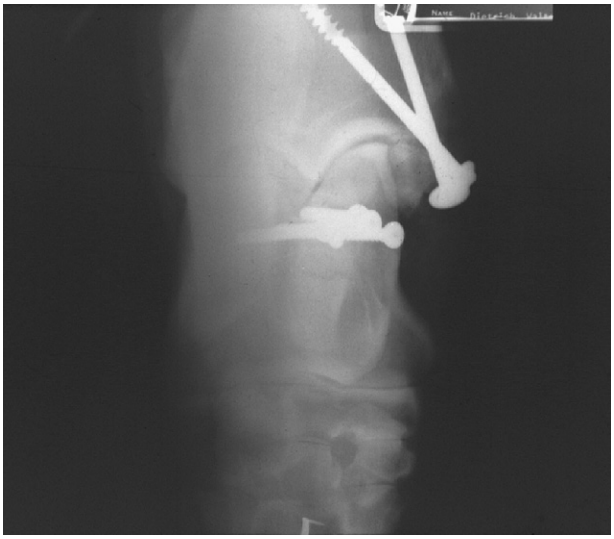

Figure 97-10. Dorsoplantar radiographic view of fixation of a medial malleolar fracture with two long cancellous screws and washers. Additionally, large fragments off the lateral trochlear ridge of the talus were reattached through three cortex screws, which were countersunk below the articular surface.

all six horses subjected to this treatment. The other report described two techniques.[7] In a pony, three parallel 5.5-mm cortex screws were implanted in lag fashion from a dorsomedial arthrotomy approach to the talus across the medial talocalcaneal articular facet into the calcaneus. Successful fusion was achieved. In the other horse, two 5.5-mm cortex screws were implanted as described and two additional identical screws were inserted from the plantarolateral aspect of the calcaneus into the talus.[7] Successful fusion was achieved, allowing the horse to return to full daily work 1 year later. Additional information is found in Chapter 81.

Fractures

Fractures of the tarsus, although rare because of the dense supporting structures that cover the bones in this area, occur when a significant external impact, such as a kick from another horse, is sustained in the tarsal region. Twisting and shearing of the tarsus while the lower limb is fixed can result in disruption of collateral and periarticular ligaments and subsequently lead to fractures. Twisting of the tarsus while the lower limb is flexed can lead to lateral maleolar fractures, which occur as avulsions because of the action of the short part of the collateral ligament.

Distal Tibia

Fractures of the distal tibia often involve the medial malleolus, and these arise from external trauma, which results in avulsion of the medial malleolus from the tibia that is rarely accompanied by rupture of the medial short collateral ligament.[55,56] Fractures of the lateral malleolus can occur as avulsions and usually involve the short lateral collateral ligaments.[25,55] Avulsion fractures of the lateral malleolus are often comminuted. Arthroscopy can be used to remove fragments involving the medial malleolus; however, because of the soft-tissue coverage and intimate association with the joint capsule or lateral collateral ligaments, or both, lateral malleolar fragments can be removed more easily through an arthrotomy into the dorsolateral pouch of the TC joint or through a direct approach over the fracture through the short lateral collateral ligament, or a combination of these techniques under arthroscopic guidance. If arthroscopy is attempted alone, the portals need to be placed into both the dorsoateral and plantolateral pouches and the fragment might have to be divided into smaller pieces for removal using rongeur or an osteotome and mallet.

Fragments larger than 3 cm are best reattached to the parent bone using 3.5-mm cortex screws placed in lag fashion.[12,57] Large avulsion fractures of the medial malleolus can be repaired with one or two 4.5- or 5.5-mm cortex or cancellous screws placed in lag fashion (Figure 97-10). The incisions are closed using routine technique. A full-limb cast is applied for recovery from anesthesia and maintained during the initial postoperative period, if fixation rather than removal has been elected.

Conservative management of nondisplaced distal tibial malleolar fractures is possible. Surgical management, either by removal of the fragment or by repair of the fracture in correct anatomic position, has a favorable prognosis for return to previous performance levels in one report.[30] However, an unfavorable to guarded prognosis was given in another report.[11] A total of 4 to 6 months of rest is needed after surgery, particularly if fracture fixation was used as the surgical treatment.

Trochlear Ridges of the Talus

Fractures of the talus are acute injuries and are almost exclusively the result of external trauma, such as a kick from another horse. The clinical signs vary considerably, depending on comminution, size, and displacement of the fracture. Significant effusion of the TC joint is seen with most fractures of the talus, and response to tarsal flexion is moderate to severe. Standard

radiographic projections should be supplemented with flexed lateromedial and flexed lateromedial oblique projections and skyline views of the trochlear ridges.[13] The distal aspect of the lateral trochlear ridge and the proximal aspect of the medial trochlear ridge (see Figure 97-7) are most often affected.[29,58,59]

Arthroscopic removal of small trochlear ridge fractures is generally the preferred treatment.[60,61] The arthroscope portal for removing trochlear ridge lesions can be either dorsomedial or dorsolateral. The dorsolateral portal offers better visualization of the distal aspect of the lateral trochlear ridge, but the standard dorsomedial portal is preferred because triangulation is better and the surgeon can carry out a more thorough exploratory examination of the joint from a medial approach. The instrument portal is always dorsolateral and is usually slightly distal to that used for distal tibial lesions. Osteochondral defects or cartilage flaps might extend proximad along the lateral trochlear ridge, necessitating extension of the limb during surgery. Some surgeons prefer an arthrotomy approach directly over the lesion.[12,60]

Large trochlear ridge fractures can be repaired with interfragmentary compression using several screws (Figure 97-11).[57] The fracture can be approached either through arthroscopy or an arthrotomy performed lateral to the ridge. After the fragment is identified and reduced, a glide hole is drilled perpendicular to the fracture plane from the dorsal aspect of the ridge. After preparing the thread hole, a deep countersink depression is prepared in the articular surface to accept the entire screw head. Therefore, it is better to use multiple 3.5-mm cortex screws, which have smaller heads, than to use 4.5- or 5.5-mm cortex screws. In large fragments, an adequate amount of solid bone is present to permit fixation. Anatomic reconstruction is a must if fixation is attempted. If this cannot be achieved, it is best to remove the fragment immediately to prevent the development of OA. Alternative fixation techniques include absorbable polydioxanone pins and cannulated screws.[57]

Spurs or fragments associated with the distal end of the medial trochlear ridge of the talus (dewdrop lesions) are usually incidental findings and are not an indication for surgery, because they are usually extra-articular (Figure 97-12).[13,55] Arthroscopic removal has been described in the literature, although the technique is difficult because of extensive soft-tissue covering.[62] For removal of these fragments, both the arthroscope and instrument portals are made in the dorsomedial pouch of the tarsocrural joint, with the instrument portal placed distal and slightly medial to the arthroscope.

Fragments that originate from the proximal aspect of the TC joint are best removed arthroscopically (Figure 97-13). With the horse in dorsal recumbency, the limb is positioned in flexion. With the joint distended, the arthroscope portal is made in the center of the caudolateral pouch of the TC joint. This approach provides good visualization of the most proximal aspect of the talocalcaneal articulation,[60] the proximocaudal aspect of the lateral trochlear ridge, the caudal aspect of the intermediate ridge of the tibia, and the medial trochlear ridge. Access to affected portions of the trochlear ridge can be accomplished as the degree of flexion is modified. The instrument portal is made in the caudomedial joint pouch using needle and visual arthroscopic guidance.

Fractures of the distal lateral or medial aspect of the body of the talus occur rarely. Extreme angular forces need to be involved to cause such a fracture (Figure 97-14, *A*). The animals are almost always non–weight-bearing lame and the tarsus is diffusely swollen. Radiography confirms the diagnosis. Conservative therapy in most cases is unrewarding. The horse shown in Figure 97-14 was readmitted for treatment after a year of limited pasture exercise because of continued lameness and pronounced joint distention of the tarsocrural and proximal intertarsal joint (Figure 97-14, *B*). The fracture was subsequently repaired with 3.5-mm cortex screws in lag fashion through an approach directly over the fragment. The lameness and joint

distention resolved 4 months postoperatively and the horse was returned to show jumping.

Recovery after surgery of the trochlear ridges of the talus takes 8 to 10 weeks after arthroscopic removal of small fragments and 6 to 8 months or more if fracture repair is undertaken. Prognosis after fracture removal is favorable if soft-tissue damage at the time of injury is mild, secondary changes in the joint are minimal, and the fragment is shorter than 3 cm.[57]

Sagittal Fractures of the Talus

Sagittal fractures of the talus are rare.[55,63] The biggest challenge is correct assessment because radiographically they are difficult to evaluate , especially with complicated fracture configurations (Figure 97-15). Computed tomography is the imaging technology best suited for a detailed diagnosis, which is a prerequisite for proper screw placement. The intraoperative use of three-dimensional fluoroscopy (Arcadis orbic 3D) is a good alternative (Figure 97-15, *B*). The medial fragment is usually smaller, and fractures can be repaired with two or three 4.5- or 5.5-mm cortex screws placed in lag fashion. In special configurations, the screws may have to be inserted from the articular surface, making deep countersinking necessary to bury the entire screw head in the trochlear ridge (Figure 97-15, *C*). The fracture can be approached from either the medial or lateral side.[57,63] Arthroscopic visualization during the procedure is useful in assisting anatomic reduction of the fracture. Prognosis is favorable if anatomic reduction can be achieved.[57] Severely comminuted fractures of the talus are associated with severe soft-tissue trauma and destabilization of the TC joint and are inoperable in most cases.[57]

Calcaneus

Calcaneal fractures are often open and can be complicated by osteomyelitis, septic calcaneal bursitis, sequestration, and chronic drainage. Major fractures of the calcaneus can result in displacement of the superficial flexor tendon or can involve the sustentaculum tali (Figure 97-16). An open wound and local infection can eventually extend into the tarsal sheath. Lameness is usually severe with calcaneus fractures, and diagnosis is straightforward. In addition to standard projections, stressed radiographs can provide important information for diagnosis and management. Skyline views are useful for evaluating the tuber calcis and sustentaculum tali.

Small fragments distant from the calcaneal bursa can be removed through a direct approach or left to heal conservatively if they are not infected, but larger fragments should be repaired by screw fixation using lag technique. Transverse fractures of the shaft of the calcaneus require application of one or two narrow 4.5-mm plates or one broad plate placed on the plantarolateral aspect of the bone.[20] The selection of dynamic compression plates (DCPs), limited-contact dynamic compression plates (LC-DCPs), or locking compression plates (LCPs) depends upon availability and financial considerations. The superficial digital flexor tendon is reflected medially to allow placement of the plate, and the horse is recovered and maintained for 2 to 4 weeks in a full-limb cast that is removed with the horse standing. Removal of the implants after fracture healing can be helpful, but the overall prognosis to return to full performance for this type of fracture is guarded.[57,64,65]

Fractures involving the calcaneal bursa in the presence of an open wound from a kick usually have a poor prognosis for

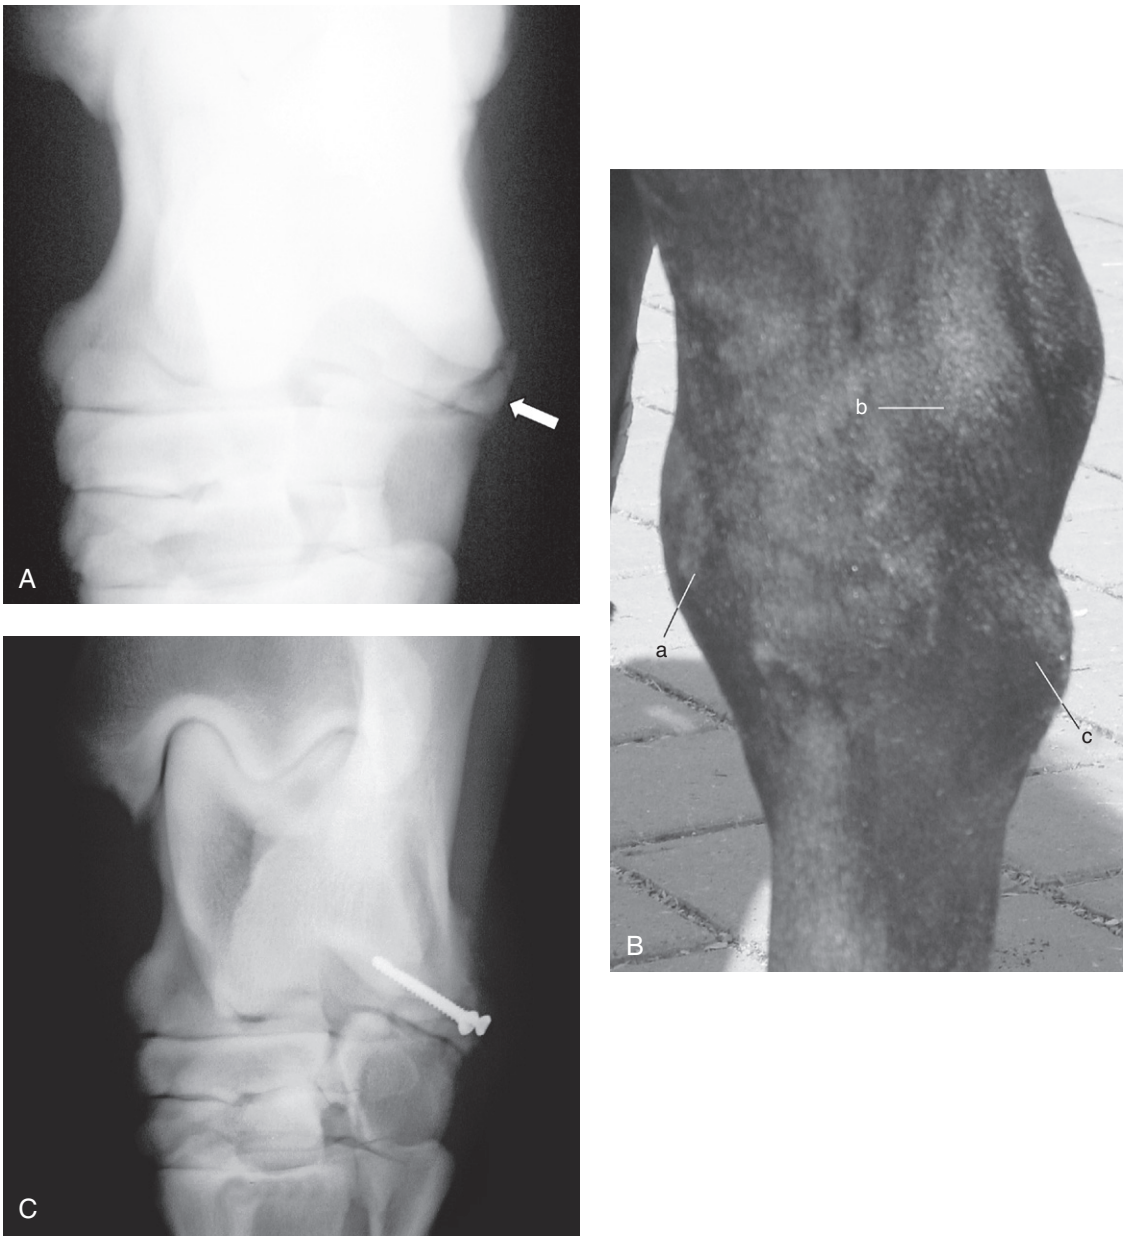

Figure 97-14. A, Avulsion fracture of the lateral aspect of the distal talus with proximal intertarsal (PIT) articular involvement. The horse was managed conservatively with rest for 1 year. **B,** Marked joint distention visible in the tarsocrural and proximal intertarsal joints. *a,* Dorsomedial pouch; *b,* plantarolateral pouch; *c,* lateral aspect of the proximal intertarsal joint. **C,** Postoperative radiographic view showing the fixation of the fracture with two 3.5-mm cortex screws. Six months later, the horse competed successfully in show jumping events.

future soundness. Invariably the bursa gets infected, and eventually the patient has to be destroyed for humane reasons. Aggressive treatment including bursoscopy should be implemented as soon as possible after the injury has occurred and includes meticulous débridement of the wound, removal of fragments, curettage of the fracture bed, lavage of the bursa, broad-spectrum antibiotics for 3 weeks, and placement of the limb in a cast for 3 weeks. Subsequently, a half-shell cast should be applied for an additional 3 weeks, followed by a Robert Jones dressing, provided the horse shows no signs of infection. Infection of the calcaneal bursa is the limiting factor when determining the prognosis in most cases. One study listed a prognosis for survival of 44%,[66] which is rather optimistic in my experience. If signs of infection are present, the wound needs to be evaluated immediately and the owner should be informed of the complication and the potentially grave prognosis. If a decision is made at that time to euthanize the patient, massive costs can be avoided.

Chip Fractures of the Sustentaculum Tali

Fractures of the sustentaculum tali occur rarely. These injuries are caused by acute trauma, mainly in the form of kicking injuries. The skin can be perforated, resulting in communication with the tarsal sheath of the deep digital flexor tendon. The animals are acutely lame and, depending on the duration of the

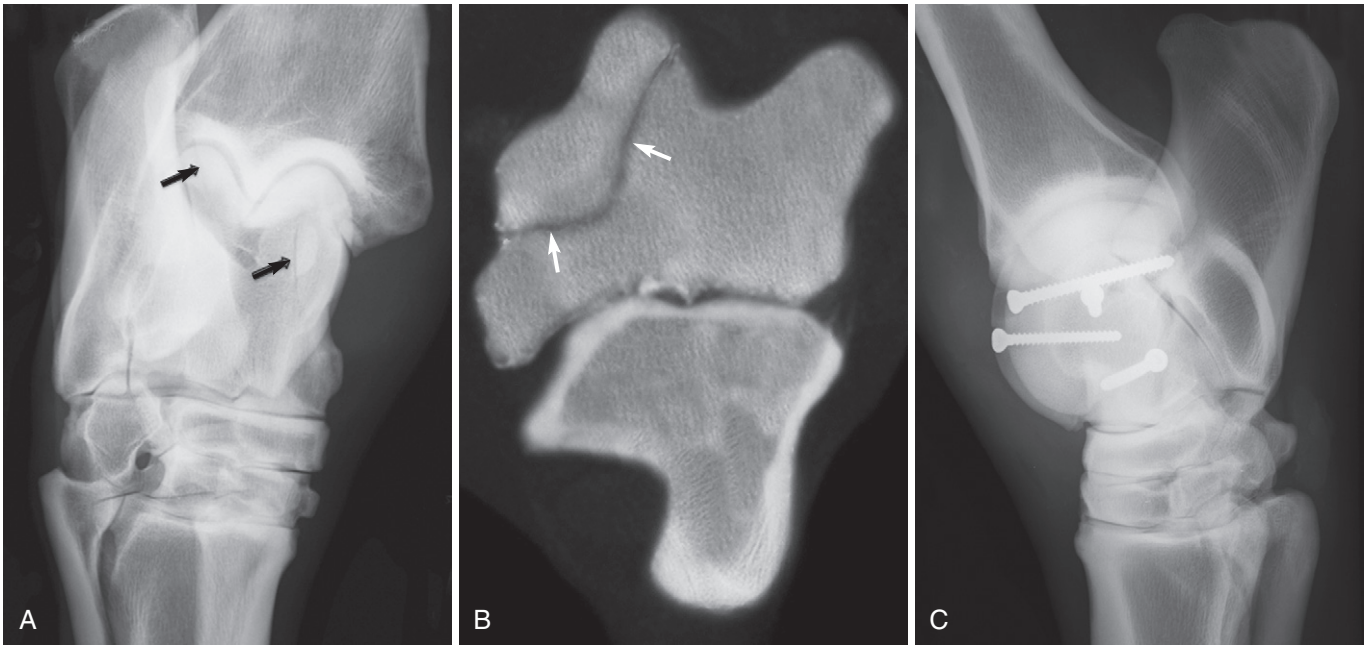

Figure 97-15. A, Dorsolateral-plantaromedial oblique radiographic view of the tarsus of a horse that sustained a sagittal talus fracture. Only two faint fracture lines are visible *(black arrows)* and this does not allow assessment of fracture configuration. The other standard radiographic views were inconclusive. **B,** Transverse intraoperative view generated with the Arcadis orbic three-dimensional C-arm depicting the configuration of the fracture (picture enhanced for better representation *[white arrows]*). **C,** Postoperative lateromedial radiographic view of the tarsus showing the four cortex screws inserted at right angles to each other. injury and possibly associated tendon sheath infection, a grade IV lameness may be present.

Diagnosis is by a radiographic examination using multiple views. The proximodistal flexed view (skyline) best delineates the sustentaculum tali (Figure 97-17). Analysis and culture of the tendon sheath fluid is indicated. Treatment should be initiated immediately, especially when the tendon sheath is penetrated. Chip fracture removal can be achieved with tenovaginoscopic technique, although one study suggests that many of the bony lesions might be outside of the tendon sheath and are best approached directly.[67] Flushing of the tendon sheath with copious amounts of fluids is indicated after chip removal and careful curettage of the fracture bed. The open technique of tendovaginotomy and fragment removal represent another surgical approach.

Conservative management is contraindicated, especially in open injuries. Involvement of the sustentaculum is a key parameter in the decision for surgery. If the fracture involves a significant amount of the flexor surface, reattachment with cortex screws may be considered, especially if the tendon sheath was not penetrated at the time of injury. If treatment is delayed, proliferative changes can develop, leading to chronic lameness with a poor prognosis for future usefulness of the horse.

With immediate, effective treatment, a guarded prognosis for return to athletic use can be given. Neglected cases have a grave prognosis. Chip fracture removal can result in postoperative displacement of the deep digital flexor tendon, but this is rare.

Fractures of the Small Tarsal Bones

Slab fractures of the central or third tarsal bones occur after racing or other high-speed events. Fractures of the third tarsal bone are more common. Lameness is severe initially, but it diminishes over several weeks. Marked response to hock flexion persists over time, and persistent effusion of the TC joint is noted if the central tarsal bone is involved. When the central

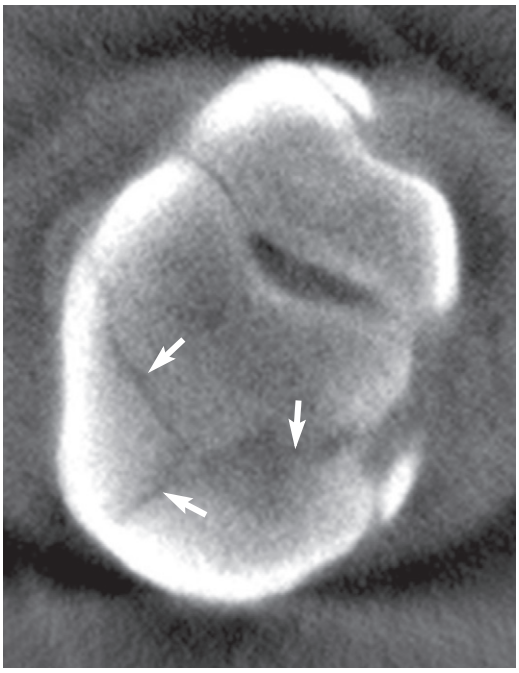

Figure 97-18. Computed tomographic cross section of the central tarsal bone showing a Y-fracture *(arrows)*. (Courtesy A. Fürst, Zurich, Switzerland.)

tarsal bone is fractured, intra-articular anesthesia of the TC joint partially alleviates lameness, but it can take 30 to 45 minutes for maximal effect. Diagnosis of central and third tarsal bone fractures is confirmed with standard radiographic views, but can require multiple oblique projections because central tarsal bone fractures are often complex and comminuted.[68] Radiographic confirmation of these fractures can be difficult. Nuclear scintigraphy and computed tomography are helpful when available (Figure 97-18).[63,69]

Screw fixation of slab fractures of the central and third tarsal bones is the treatment of choice (Figure 97-19). The horse is placed in dorsal or lateral recumbency, and the fracture is compressed using one or two 3.5- or 4.5-mm cortex screws placed in lag fashion through stab incisions using intraoperative radiographic or fluoroscopic control. Conservative treatment (prolonged stall rest) has been successful, and some horses return to athletic use. However, treatment by screw fixation offers the best prognosis, because conservative management usually results in OA.[54,68,70,71] Horses are rested for 4 to 6 months after surgery.

Residual lameness can persist after either surgical or conservative management and eventually requires intra-articular medication, chemical or surgical arthrodesis (see Chapter 81), or screw removal after fracture healing.

Luxations

Luxations usually occur at either the TMT joint or the PIT joint, but they can occur in any of the three distal joints and occasionally involve the TC joint. Lameness is severe, with significant soft-tissue swelling, palpable instability, and crepitus. Luxations and subluxations of the tarsus might reduce spontaneously, but they can still be demonstrated with stressed dorsoplantar radiographs.

Luxations of the tarsus can be associated with fractures. The presence of fractures generally decreases the chances for a successful treatment. Open reduction and internal fixation is mandatory if fractures are present.

Luxations of the distal tarsal joints are best treated primarily with surgical arthrodesis, including débridement of the articular cartilage through an incision (if open, then on the open side of the joint), cancellous bone grafting, and joint stabilization with either transarticular cortex screws placed in lag fashion or bone plates (see Chapter 81).[19] Horses with good temperaments and subluxations can recover for breeding purposes with only stall rest if they are kept tied on an overhead wire or in a rescue net to prevent them from lying down. Horses with luxations of the distal tarsal joints might return to soundness after joint fusion or arthrodesis, but luxation of the TC joint has a poor prognosis for athletic soundness because of joint and ligament damage.[11,72]

Tarsal luxation is diagnosed as an acute traumatic event. The animal is grade IV lame and might show an angular limb deformity in the tarsal region. However, lack of angular limb deformity does not rule out a luxation, because some luxations spontaneously reduce. Diagnosis is derived from palpation and a radiographic examination depicting the exact location of the injury. In cases of reduced luxation, stress views should be taken either standing or under general anesthesia.

Tarsal luxation in the absence of major fractures can be treated with a full-limb cast for 3 months, with several cast changes during that time. This treatment is associated with the usual complications of prolonged cast applications, including pressure sores and cast disease.

Surgical arthrodesis of the TMT, DIT, and PIT joints has achieved superior results. The skin incision extends from the top of the calcaneus to the mid-MTIII on the plantarolateral aspect. The subcutaneous tissues are separated to expose the bone. The head of MTIV is trimmed with a chisel. An alternative

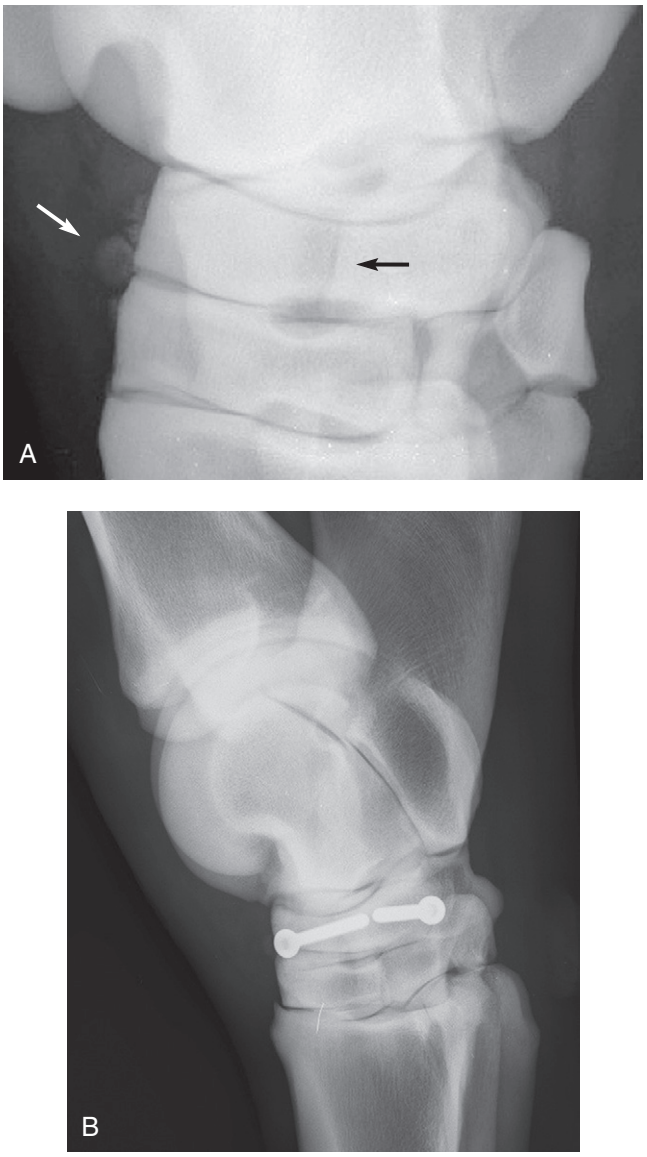

Figure 97-19. A, Preoperative lateromeial radiographic projection of the tarsal region of the same horse shown in Figure 97-15. One clear fracture line can be seen in the central tarsal bone *(black arrow).* Additionally, some small fragments are visible dorsal to the central tarsal bone *(white arrow).* The actual fracture configuration as shown in Figure 97-15 could not be appreciated radiographically. **B,** Postoperative lateromedial radiographic view showing the cortex screws inserted across the main fractures. (Courtesy A. Fürst, Zurich, Switzerland.)

approach involves removing the entire MTIV (see Chapter 81). A 12-hole broad plate is contoured to the bones and applied with 5.5-mm cortex screws (see Figure 97-17). The 5.5 mm LCP, which has superior rigidity to other plates and the added benefit of locking technology, is the recommended plate of choice. Solid purchase of each screw in healthy bone is of great importance with this fixation. Therefore, the direction of each screw through the corresponding plate hole has to be carefully selected using radiographic control. It is important to insert several oblique transarticular screws across the luxated joint to provide additional stability.

After the subcutaneous tissues and skin are closed, a full-limb cast is applied for the initial 2-week period, after which a Robert Jones bandage is applied for 2 to 3 additional weeks. Hand-walking can be started after 2 months, and light riding can be resumed after 3 months. Full recovery is expected, barring no postoperative complications, such as infection or implant breakdown.

Tendon Disorders

Luxation of the Superficial Digital Flexor Tendon

Superficial digital flexor (SDF) tendon luxations are seen in three forms in decreasing frequency: lateral displacement with disruption of the medial retinaculum, medial displacement with disruption of the lateral attachment, or splitting of the SDF tendon with a portion lying on either side of the tuber calcis.[6,33,73,74] The luxations can be partial or complete, with partial luxations causing more discomfort. The etiology can be direct trauma or excessive strain during partial flexion.[72]

Diagnosis of acute SDF tendon luxation can be difficult because of swelling, but palpation and observation during flexion and extension usually allow a diagnosis. Ultrasonography is the diagnostic imaging technique of choice. Sometimes dislocation occurs only during motion, and the tendons maintain appropriate alignment when the limb is at rest. In more chronic cases of permanent luxation, the metacarpophalangeal joint can be hyperextended during weight bearing compared to the other limb. This occurs when the SDF tendon bypasses the tuber calcis in a course that is in a straighter line, which makes it functionally too long.

Partial or intermittent dislocations can heal with stall rest, with or without the benefit of a bandage or full-limb cast. Rest for 4 to 6 months is necessary.[74] Despite a clinical report claiming that conservative management allows a successful return to athletic competition, the general thought is that surgical repair is mandatory for return to athletic function.[36,66,75-77]

The horse is placed in dorsal or lateral recumbency to allow exposure of the damaged side of the tarsal retinaculum. After débridement of the edges, horizontal mattress sutures are preplaced on both sides of the defect well back from the defect margin. The ruptured ends are subsequently apposed and closed with interrupted horizontal mattress sutures of size 0 monofilament absorbable material. A synthetic mesh graft is sutured over the defect using the pre-placed sutures.

Securing the retinaculum to the calcaneus at the original site may be problematic in cases where only a minimal amount of retinaculum is attached to the calcaneus. The use of anchor or suture screws ensures solid fixation (Figure 97-20).

Support of the repair can be provided by placement of bone screws into the calcaneus opposite the tear to provide a buttress against repeated dislocation.[73]

After the incision is closed, the limb is placed in a full-length cast for recovery. Confinement for 4 to 6 months is necessary to allow sufficient fibrosis.

Prognosis with surgical management diminishes as the anticipated level of performance increases. Prognosis for athletic soundness with conservative management is guarded for complete displacement, but it is favorable for cases involving partial rupture of the retinaculum. Medial dislocations have a better prognosis than do lateral displacements.[76]

Displacement of the Deep Digital Flexor Tendon

Luxation or displacement of the deep digital flexor (DDF) tendon is a rare congenital anomaly.[11] In this condition, the DDF tendon is located axial to its normal position and not

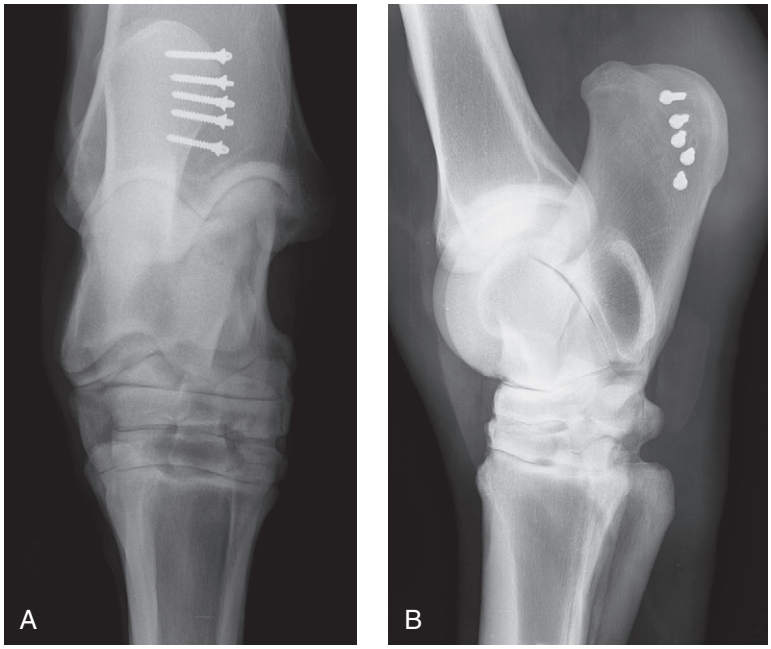

Figure 97-20. Dorsoplantar **(A)** and lateromedial **(B)** radiographic views of the tarsal region showing suture screws inserted into the lateral and proximal aspect of the calcaneus to facilitate the repair of the ruptured retinaculum. (Courtesy A. Fürst, Zurich, Switzerland.)

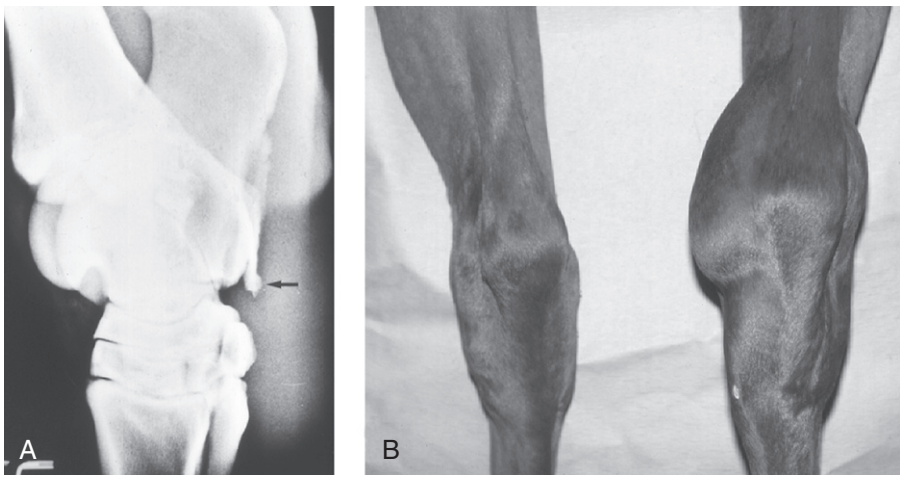

Figure 97-21. A, Lateromedial radiographic view showing osseous proliferation of the distal aspect of the sustentaculum tali. These lesions are associated with chronic irritation and inflammation of the sheath of the deep digital flexor tendon. **B,** Massive distention of the sheath of the deep digital flexor tendon medially in the tarsal region of a 6-year-old gelding. (**A,** Courtesy R. Welch.)

within the groove formed by the sustentaculum tali. The malpositioned DDF tendon exerts a medial pull on the distal limb, and the first recognizable clinical sign is a varus deviation of the tarsus noted at 2 to 4 weeks after birth. Diagnosis is based on palpation, ultrasonography, and skyline radiography of the tarsus that demonstrates hypoplasia of the sustentaculum tali. Surgery to replace the DDFT in its normal position and augment the sustentaculum tali has been recommended[11] but does not seem feasible, because it is very unlikely that the foal will grow up to be a functional athlete.

Tenosynovitis of the Deep Digital Flexor Tendon

Chronic irritation and tenosynovitis of the DDF tendon can be a sequela to sustentaculum tali injury. Radiographically, new bone proliferation (Figure 97-21, *A*) can be seen in the region, leading to tendon sheath distention (Figure 97-21, *B*) and possible ossification. Contrast tenography can provide valuable information on the pathology present within the sheath.

Treatment of these problems involves tenoscopic exploration of the pathology and removal of any proliferative changes. Tendovaginotomy represents an alternative approach. However, chronic degenerative changes of the sustentaculum tali and overlying DDF tendon have a guarded prognosis for resuming normal work. After the skin incision is closed in routine fashion, a pressure bandage is applied and maintained for 3 weeks. Intratendovaginal hyaluronan 1 week postoperatively is indicated.

Avulsion of the Gastrocnemius

Rupture of the gastrocnemius muscle occurs occasionally in foals and young horses. The disorder can be caused by external trauma or excessive exercise in the field, possibly associated with slipping or sudden unexpected turns. The diagnosis is straightforward, because the reciprocal apparatus is not

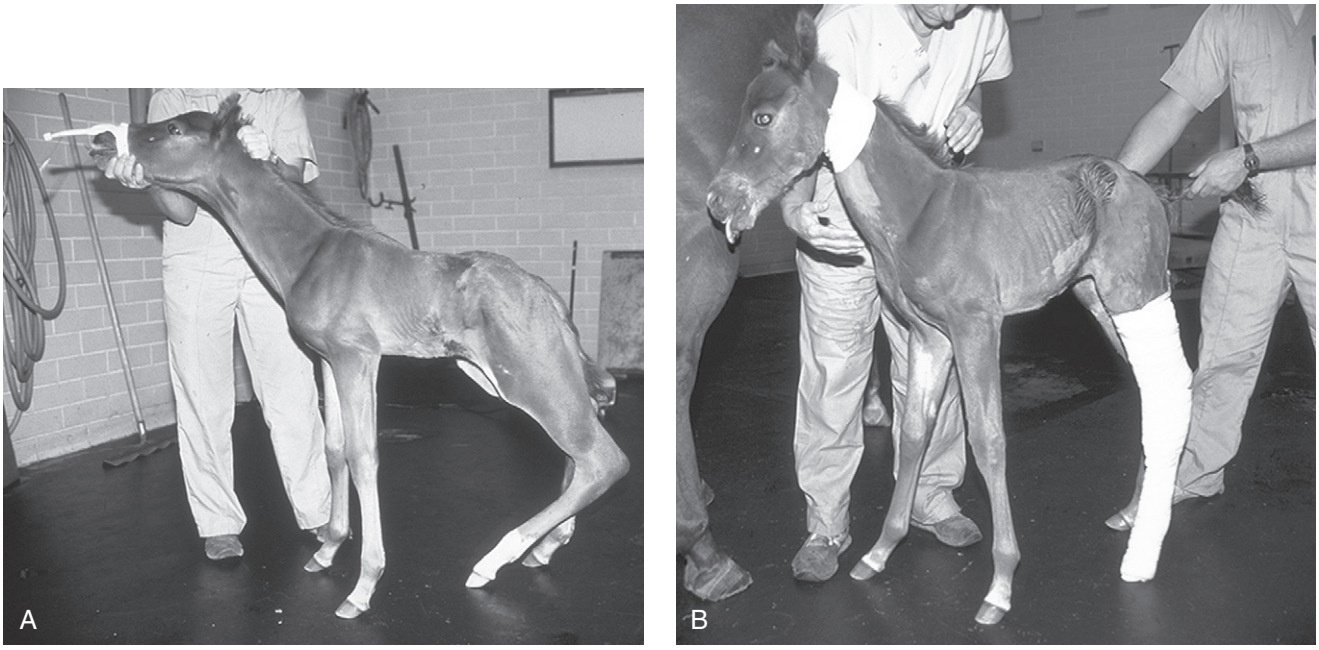

Figure 97-22. Three-week-old Quarter Horse foal with an avulsion of the gastrocnemius muscle. **A,** Weight bearing results in marked flexion of the tarsus and hyperextension of the stifle. **B,** Application of a tube cast over the tarsal region allows the foal to bear weight.

functional. As the animal places weight on the limb, the tarsus collapses distad, and the stifle joint becomes hyperextended (Figure 97-22, *A*).

Ultrasonography usually finds the gastrocnemius tendon intact but the origin of the muscle avulsed from the distal and caudal aspect of the femur. The avulsion can be complete or partial. Partial avulsion causes only slight dropping of the tarsus during weight bearing.

Management involves maintenance of a full-limb Robert Jones bandage with an incorporated splint for several weeks. An alternative treatment is application of a tube cast over the tarsal region (Figure 97-22, *B*) for 3 weeks, followed by a Robert Jones bandage for an additional 3 to 5 weeks.

Both partial and complete avulsions have a favorable prognosis for a competitive future. Complications include all problems encountered with long-term casting and bandaging of the tarsal region.

In a retrospective study, the medical records of 28 foals admitted because of disruption of the gastrocnemius tendon were reviewed.[78] Seventeen of these foals (61%) presented with a concomitant illness. Foals without a concomitant illness were more likely to achieve race training or to start a race ($p = 0.04$). Twenty-three of 28 foals were short-term survivors (discharged from the clinic). Of this population, 82% of the foals were able to achieve race training or start a race.[78]

DEVELOPMENTAL DISORDERS OF THE TARSAL REGION

Osteochondrosis

Etiology

Osteochondrosis (OC) in the equine tarsus occurs most commonly in the distal intermediate ridge of the tibia (Figure 97-23, *A*), followed by the lateral trochlear ridge of the talus (Figure 97-23, *B*), the medial malleolus of the distal tibia, the medial trochlear ridge of the talus, and the lateral malleolus of the distal tibia.[79-81] Subchondral cystic lesions (see Chapter 89) have been identified in the distal tibia and talus, but they are considered unusual.[82] These lesions also have been identified in the cuboidal bones of the distal tarsus and are associated with an inflammatory reaction.[12,83]

Osteochondrosis results from failure of endochondral ossification or loss of blood supply to immature cartilage and subchondral bone and can be influenced by various factors, including exercise, hormone imbalances, nutrition, heredity, and conformation (see Chapter 88).[75,84-89] Heritability estimates suggest that 25% to 52% of the variation in occurrence of OC in the hock can be attributed to genetic factors.[90-94] Others conclude that distal tibial lesions arise from biomechanical trauma early in life or represent supernumerary ossification centers that are not part of the OC complex.[80,95] One study documented 11 of 77 foals with obvious distal tibial fragments that were radiographically normal by 8 months of age.[96]

Diagnosis

Signs of tarsocrural OC are usually associated with the onset of training.[93,97] Synovial distention is the most common manifestation of the condition, sometimes followed by mild lameness (identified in 66 of 144 affected limbs).[91] Pain on flexion of the tarsus is usually mild, and synovial fluid analysis is rarely indicated. Four standard radiographic views of the tarsus should be taken, but flexed views may also be useful to demonstrate loose fragments or osteochondral defects in the caudal aspect of the joint. Bilateral lesions involve the distal tibia 20% to 45% of the time.[88,98] Distal lesions of the tibia vary dramatically in size, ranging from small fragments less than 5 mm in diameter to involvement of the entire intermediate ridge. OC lesions can be identified arthroscopically without radiographic evidence of

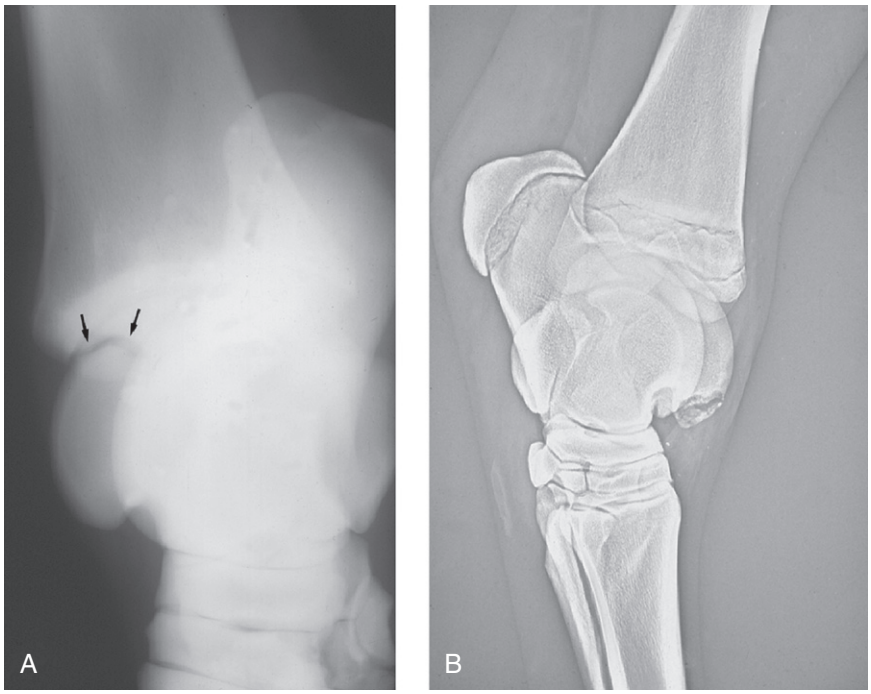

Figure 97-23. A, Dorsomedial-plantarolateral oblique (DMPLO) radiographic view of the tarsus showing a distal intermediate ridge of the tibia osteochondral (OC) lesion *(arrows).* **B,** DMPLO xeroradiographic view of the tarsus showing a lateral trochlear ridge OC lesion. (Courtesy C. W. McIlwraith, Colorado State University.)

their presence. These horses might or might not be presented with synovial effusion.[79]

Treatment

Arthroscopic removal of tarsocrural OC fragments is the treatment of choice, particularly if clinical signs of effusion or lameness are noted. Horses without clinical signs associated with radiographic evidence of OC can develop osteoarthritis of the TC and PIT joints and linear erosions along the side walls of the trochlear groove of the talus later in life.[4] Arthroscopic examination of the TC joint in mature horses with OC often reveals fibrillation of articular cartilage. These findings suggest that early surgical intervention is warranted to minimize secondary joint changes.[12]

DISTAL INTERMEDIATE RIDGE OF THE TIBIA

The horse is placed in dorsal recumbency with the limb in slight flexion. The arthroscope portal is made on the dorsal aspect of the dorsomedial pouch of the tarsocrural joint, centered over the pouch (Figure 97-24). Placement of the arthroscopic portal too far medial makes it difficult to pass over the medial trochlear ridge, and placement too proximal or too distal also will jeopardize visualization. It is best to identify the saphenous vein before or after synovial distention and avoid it.

After the joint is distended, a stab incision is made through the synovial membrane, and the arthroscopic sleeve is inserted into the joint with a conical obturator. The limb is placed in 90 degrees of flexion, the arthroscope is inserted, and the joint is explored (Figure 97-25).

The location of the instrument portal can be identified by passing the arthroscope laterally over the proximal aspect of the exposed lateral trochlear ridge into the dorsolateral pouch and palpating the tip through the skin. This procedure is also useful to demonstrate a vessel in the area by backlighting it with the

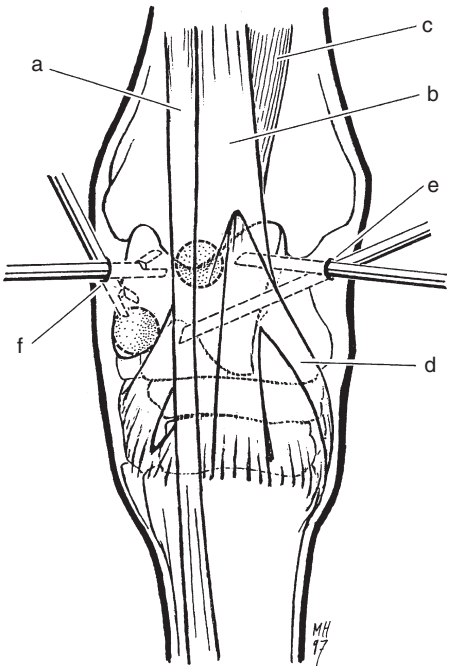

Figure 97-24. Graphic illustration of arthroscope and instrument portals for removing distal intermediate ridge OC lesions and lateral trochlear ridge OC lesions. These portals are also useful for diagnostic arthroscopy of the dorsal aspect of the tarsocrural joint and for removing fragments from the proximal intertarsal joint. *a,* Long digital extensor tendon; *b,* fibularis tertius; *c,* tibialis cranialis; *d,* medial branch of the tibialis cranials or cunean tendon; *e,* dorsomedial arthroscopic portal; *f,* dorsolateral instrument portal.

arthroscope when the surgery room lights are dimmed. Alternatively, a needle can be inserted through the dorsolateral pouch and advanced until it makes contact with the lesion.[16] Insertion of a hypodermic needle at the intended site allows the exploration of the range of motion possible with the instrument.

When the ideal location is determined, a skin incision is made along the needle. A No. 11 scalpel blade is advanced into the joint along the needle, and a small incision is made into the synovial membrane. The needle and scalpel are removed and immediately exchanged with the arthroscopic probe. Intermediate ridge fragments may be loosely attached and elevated with the probe or may be firmly attached to the distal tibia, requiring partial separation with a periosteal elevator (Figure 97-25, *B*) or an osteotome and mallet. Care should be taken not to damage the articular cartilage on the lateral trochlear ridge with the elevator or osteotome. After elevation, fragments are grasped with rongeurs, rotated to divide any remaining attachments, and removed. The surgeon should grasp fragments so that the minimum diameter is presented at the instrument portal. Increasing the size of the instrument portal is often necessary for removal. After the fragments are removed, the OC bed is examined for remaining tissue and curetted until firm subchondral bone remains in the site.

Occasionally, fragments of the intermediate ridge detach from the parent portion of the bone and become located in the distal end of the joint on preoperative radiographs (Figure 97-26). Because these fragments can be free within the joint cavity or can pass into the PIT, removal can be problematic. If the fragments are free, they fall to the most distal aspect of the joint (which is into the dorsal aspect of the pouch [proximal] when the horse is in dorsal recumbency), especially if fluids are used to distend the joint. If fragments are located in the PIT, they can be left alone with minimal consequences or removed using a probe (see later). (The arthroscope can be passed into this joint through the normal communication just axial to the medial trochlear ridge.) Gas distention of the joint can aid in locating the fragment; however, if it cannot be localized intraoperatively, radiographs or fluoroscopy should be used to localize it. The instrument portal is selected in a place where the fragment can be accessed, and the fragment is removed.

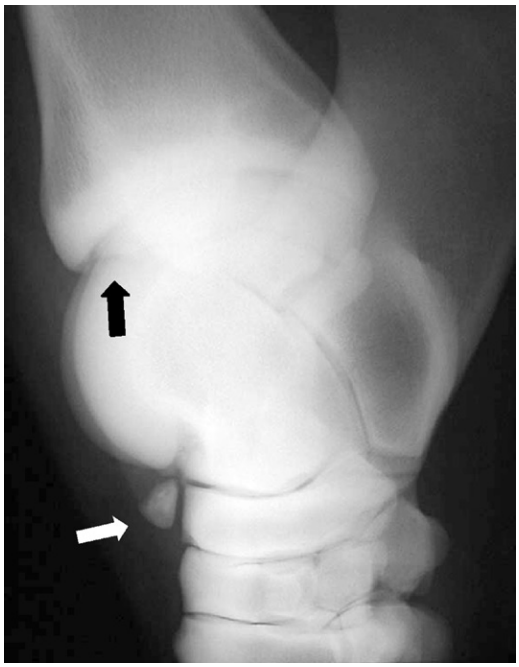

Figure 97-26. Lateromedial radiographic view of a tarsal region showing a loose fragment at the distal aspect of the joint cavity *(white arrow).* It is most likely located in the PIT. The origin of the fragment is the distal intermediate ridge of the tibia *(black arrow).*

MEDIAL MALLEOLUS

The arthroscope portal for medial malleolus lesions is made more ventrad (more distad on the limb) than for intermediate ridge lesions to minimize the risk of accidentally pulling the arthroscope out of the joint during visualization.[16] The instrument portal (also ventromedial) is identified by prior insertion of a needle. Techniques for removing fragments are similar to those used for other lesions in the TC joint.

LATERAL TROCHLEAR RIDGE

The arthroscope portal for removing lateral trochlear ridge lesions can be either medial or lateral. The lateral portal offers better visualization of the distal aspect of the lateral trochlear ridge, but the standard medial portal is preferred because triangulation is better and the surgeon can carry out a more thorough exploration of the joint from a medial approach.[16] The instrument portal is always lateral and is usually slightly distal to that used for distal tibial lesions. Both distal intermediate ridge and lateral trochlear ridge lesions can be treated with a single instrument portal when found concurrently within a single joint (see Figure 97-24). Osteochondral defects or cartilage flaps can extend proximad along the lateral trochlear ridge, necessitating extension of the limb during surgery. Some surgeons prefer an arthrotomy approach directly over the lesion, but it is not the recommended approach.[11,32]

PROXIMAL INTERTARSAL JOINT

Loose fragments, usually shed from the intermediate ridge of the distal tibia, can lodge in the dorsal pouch or dorsal joint capsule of the PIT joint (see Figure 97-26).[33] Although rarely of clinical significance, these fragments can be removed, if they are loose, by arthroscopically inserting an instrument into the pouch to blindly grasp the fragment or manipulate it into the TC joint for removal. Because of their limited clinical significance and the relative difficulty of finding and removing the fragments, it has been recommended that they be removed only if this can be easily accomplished during surgery for the primary lesion of the TC joint.[99]

Aftercare

Stab incisions are closed with skin sutures only. Bandages are applied and maintained for 14 days after surgery and are changed as necessary. Sutures are removed 10 days after surgery. Exercise is restricted to hand-walking for 4 to 8 weeks, and training can be resumed in 8 to 16 weeks, depending on the severity of the lesion and the amount of synovial distention before and after surgery. Postsurgical administration of phenylbutazone, hyaluronan, or PSGAG is useful to help resolve effusion, particularly in horses with prolonged synovial distention before surgery. Synovial effusion of the tarsocrural joint can recur within a few days after turnout, and this can be resolved by returning the horse to stall rest under bandage and administering NSAIDs for 10 days.

Prognosis

It is generally accepted that the prognosis for athletic soundness is improved with surgery compared to conservative management.[75,80,87,100,101] Seventy-seven percent of horses with OC of the tarsus raced successfully or performed their intended function following arthroscopy.[79] However, the prognosis decreases when articular cartilage degeneration or erosion is noted at the time of surgery. In one study, resolution of synovial effusion after arthroscopy was higher in racehorses (83%) compared to nonracehorses (74%), and it was more likely with lesions of the distal tibia compared with other locations.[79] There was no significant relationship between resolution of the effusion and successful performance outcome.[79]

Reports on the effects of OC on racing performance are contradictory. Although one study found no difference in the racing performance of Standardbreds demonstrating OC lesions compared with a radiographically normal control population,[102] another study reported that horses with OC of the TC joint had significantly fewer starts and lower earnings compared with horses without radiographic changes.[103] A third study found that the number of racing starts and race earnings for horses with surgically treated tarsocrural OC was reported to be lower than for age-matched siblings,[104] but a fourth study found that horses treated arthroscopically for OC of the distal tibia performed no worse than did their matched controls.[105] Despite these reports, I recommend surgical treatment of this condition in all types of horses to prevent the development of OA in the TC joint.

Angular Limb Deformities

Angular limb deformities of the tarsus are seen less often than in the carpus or forelimb fetlocks, but they are diagnosed and treated in a similar fashion. Tarsus valgus is by far the most common presentation and can be caused by ligamentous laxity, malformation or incomplete ossification of the cuboidal bones of the tarsus, physeal dysplasia, or uneven growth of the distal tibial physis. A complete discussion of the etiology, diagnosis, and treatment of angular limb deformities can be found in Chapter 86.

CHAPTER 98

Tibia

Lawrence R. Bramlage

ANATOMIC CONSIDERATIONS

The osseous structures of the gaskin region of the horse include the tibia and fibula. The tibia is a strong tubular bone that has a triangular-shaped cross section proximally that changes to an oval shape oriented lateromedially as it courses distad.[1] The tibia is the major weight-bearing bone of the gaskin and transfers forces from the femur to the talus. The tibial crest, located at the proximal cranial end of the bone, contains a deep muscular sulcus, which is filled by the cranial tibial and long digital extensor muscles. The proximal articular surface of the tibia has a flat table surface with a centrally located intercondylar eminence. The distal articular surface has an undulating shape and contains two deep sulci oriented in caudomedial-to-craniolateral direction, which articulate with the trochlear ridges of the talus. For details on the complex soft tissue attachments between the tibia and both the femur and the tarsus, see Chapters 97 and 99.[1]

The fibula is a rudimentary bone of variable shape and completeness. In most cases the fibula is incomplete and consists of several centers of ossification that can be mistaken for fibular fractures.[1] Rarely, an atavistic complete fibula is identified radiographically in a pony or Miniature Horse foal (see Figure 86-21). The pathology associated with this condition creates limb deformities and tarsal osteoarthritis (see Chapter 86). Other than traumatic injury, this is the only condition in which lameness is associated with the fibula.

Other than lacerations, the most common injuries of the tibial region are fractures. Stress fractures in the tibia in training horses are the most common. In addition, traumatic fractures of the tibia in the horse occasionally occur. Two common types

of unstable tibial fractures are seen: the proximal physeal fracture and the diaphyseal fracture.

CLINICAL DISORDERS OF THE TIBIAL REGION

Tibial Stress Fractures

Etiology and Diagnosis

Tibial stress fractures are most frequently diagnosed in unraced Thoroughbreds in training.[2] Horses with stress fractures of the tibia have acute marked lameness that often resolves quickly between exercise periods and then reappears with the next strenuous exercise.[2] Pain can rarely be elicited with palpation and it is not practical to use diagnostic local anesthesia, other than to eliminate other causes of lameness. The diagnosis is made radiographically or with nuclear scintigraphy.[2] A discrete fracture is rarely seen in tibial stress fractures. Most often there is endosteal and periosteal callus, if the stress fracture is of sufficient duration.[2] The lack of significant callus in the presence of severe reoccurring lameness is an indication for nuclear scintigraphy. Nuclear scintigraphy is diagnostic if marked focal disphyseal or metaphyseal uptake is identified. Stress fractures only occur in heavily trained athletes. They are most commonly diagnosed in the distal metaphysis (Figure 98-1) or the caudal diaphysis (Figure 98-2), but proximal posterior lateral stress fractures are not unusual (Figure 98-3).[2]

Treatment

Treatment is cession of exercise. Stall rest with hand walking is allowed until the horse can trot sound in hand.[2] At that point, it is safe to allow paddock exercise. Occasionally acute stress fractures become complete fractures, even in the absence of significant radiographically identifyable fractures. The use of anti-inflammatory medication greatly increases the chances of complete fracture and so should be avoided. If horses are restricted and the lameness is not mitigated with medication, most horses protect the limb sufficiently to allow healing. Healing takes a minimum of 2 months. Follow-up radiographs are taken 60 to 90 days after diagnosis. Soundness

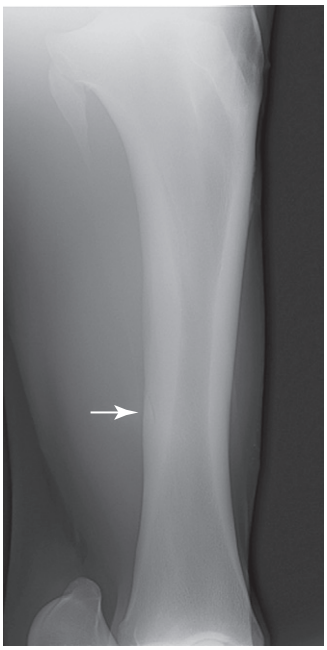

Figure 98-2. An APLMO radiographic view of a tibia with a mid-tibial stress fracture. The stress fracture can actually be seen in this horse *(arrow)*, which is unusual because callus normally obscures the fracture.

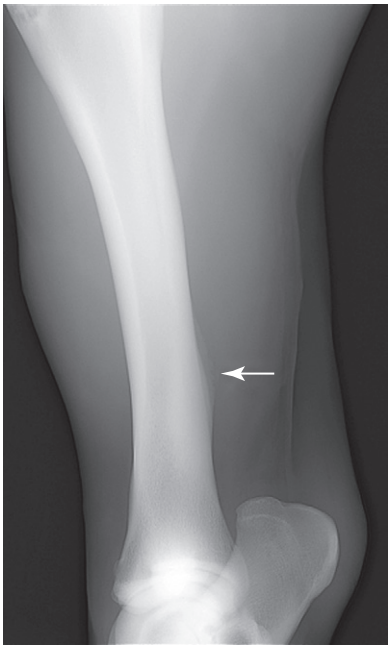

Figure 98-1. An anteroposterior lateromedial oblique (APLMO) radiographic view of the tibia showing the periosteal and endosteal callus *(arrow)* that accompanies a caudolateral tibial stress fracture.

and radiographic healing/remodeling of the callus indicate the horse can resume training.

Fissure Fractures of the Tibia

Clinical Signs and Diagnosis

In most cases, fissure or incomplete fractures result from a kick from another horse or blunt impact from a solid object. Horses with incomplete fractures or with nondisplaced complete fractures do not demonstrate instability or crepitation. However, they are usually lame, and in many cases, a wound is evident at the site of traumatic impact.[3]

Usually, radiographic evaluation confirms the presence of a fracture (Figure 98-4). Multiple views, including oblique projections, are advisable to delineate the severity of the fracture and to assist in determining a course of action.

Figure 98-4. A, Lateromedial radiographic view of a traumatic fissure fracture in the distal tibia *(lower white arrow).* Some small fragments are visible at the caudal aspect of the bone *(black arrow).* There are air pockets in the soft tissues *(upper white arrow).* **B,** Thirty-day follow-up lateromedial radiographic view. The limb was placed in a fiberglass cast. The horse was discharged from the hospital at this time and made a full recovery. (Courtesy M. Kummer, University of Zurich.)

Treatment

Incomplete and nondisplaced complete fractures are candidates for conservative therapy.[3] In one report, incomplete tibial fractures became complete displaced fractures in four of 10 horses using conservative management.[3] One of these fractures resulted from a kick to the stifle region. Therefore, only this region was radiographed and no lesions were detected. The horse was found 16 days later with a fractured tibia.[3] Because an important aspect of therapy is preventing recumbency to reduce the likelihood of displacement secondary to forces experienced during standing up, detection of incomplete fractures is necessary for successful outcome (see Figure 76-1).

Phenylbutazone should be used judiciously to reduce inflammation and encourage limited weight bearing on the fractured limb. However, care should be taken to avoid providing substantial pain relief, which could result in overuse of the fractured limb.

If a wound is present, it should be explored and treated using routine wound care. The indication for bandages is dictated by the configuration of the fracture and the extent of the wound. Parenteral antimicrobial treatment is indicated in horses presenting with a wound. Incomplete and fissure fractures of the distal metaphysis of the tiba may profit from a cast, which is best applied in the sedated standing horse in a weight-bearing position.

The horse should be confined until there is evidence of advanced fracture healing (see Figure 98-4, *B* through *E*). This usually requires a minimum of 3 to 4 months. During the last 30 days of confinement, a program of gradually increasing hand-walking is recommended. Access to free paddock exercise is allowed thereafter. An additional 30 days of paddock exercise is recommended before the horse is gradually returned to its intended function.

Proximal Physeal Fractures

The Salter-Harris type II proximal physeal fracture of the tibia is the most common tibial fracture diagnosed in foals (Figure 98-5, *A*). It most often occurs when the foal is kicked from the lateral aspect on a weight-bearing rear limb. The soft tissue of the medial proximal tibial physis ruptures because of the tension created on the medial aspect of the limb when the traumatic bending force occurs. The fracture propagates across the tibial physis from medial to lateral approximately two thirds the width of the bone, at which point the medial bending force on the distal limb distracts the physis, changing the fracture plane orientation from transverse to vertical, leaving the lateral physis intact and a triangular metaphyseal fragment attached to the epiphysis (see Figure 98-5, *A*).

With this fracture, the periosteal soft tissue is normally intact laterally but disrupted medially. Occasionally, complete disruption of the soft tissue surrounding the physis occurs, rendering the fracture more unstable and creating more displacement.

Preoperative Considerations

The biomechanical force that creates the fracture is a tension force medially; therefore, fracture instability is best neutralized by re-establishing support on the medial aspect of the limb. This requires an implant that maintains the proximal tibial epiphysis in a stable position on the metaphysis. Because normal bone formation, as part of bone growth, is already active in the growing physis, development of the vascular support system for fracture healing is unnecessary. Therefore, the fracture heals rapidly if it is stable, normally in 3 to 4 weeks.

Screw fixation, pinning, and external fixation have been described for treating these fractures, and plate fixation has been used on the lateral aspect of the tibia.[4-8] The biomechanically most stable fixation re-establishes the tension support on the medial aspect of the limb, a function that was previously provided by the soft tissue of the physis. If the lateral soft tissue is intact, stability is relatively easy to obtain. If the epiphysis is completely disrupted from the metaphysis, more elaborate fixation with more implants is required. The most helpful adjunct to the medial plate is the addition of a tension band to stabilize the tibial crest. It will neutralize the distracting forces of the quadriceps muscle that is transmitted across the stifle joint to the tibial crest via the patella and the patellar ligaments' attachment to the tibial crest.

Although this fracture is usually closed, soft tissue damage occurs medially at the site where implants must be inserted. The close implant-to-skin location makes sepsis more difficult to avoid. Broad-spectrum antimicrobial agents and anti-inflammatory medications are administered preoperatively.

Treatment

The treatment of choice for proximal physeal fractures of the tibia in foals is medial plate fixation.[7] The foal is positioned in either dorsal or lateral recumbency. When it is placed in lateral recumbency with the injured limb down, downward pressure on the proximal tibial metaphysis facilitates reduction. The opposite rear limb is flexed, abducted, and tied vertically to prevent it from interfering with surgery on the medial aspect of the injured limb.

The approach to the proximal aspect of the tibia for medial plate application is along the caudal margin of the tibia. The soft tissues are elevated craniad, and the plate is placed on the medial aspect of the tibia. The close apposition of the tibia to the surface of the skin with no interposed muscle on the medial aspect of the limb complicates wound healing if the skin incision lies directly over the implant. Therefore, a slightly curved incision is initiated distally on the caudomedial aspect of the limb and extended proximad across the proximal medial tibia. The proximal tibial physis is thin, and screws must be inserted sufficiently proximal to the growth plate to allow purchase in the bone but without endangering the articular surface. Placement of long needles in the plane of the proximal tibial physis permits orientation to the plane of the physis during drilling for screw placement.

Gentle traction on the physis and elevation of the metaphyseal fragment separates the fracture plane and allows careful débridement. Removal of small fragments and blood clots permits accurate reduction of the physis. Damage to the growth cartilage of the physis is normally induced by the metaphysis near where the fracture plane changes from transverse to vertical. Evaluation of the physeal cartilage provides information on the likelihood of survival of proximal tibial growth plate function. The amount of damage depends on the time from injury to surgery and the adequacy of preoperative immobilization.

After the debris is removed from the fracture, the soft tissue must be elevated along the medial aspect of the proximal tibial physis. If this soft tissue is not elevated, it becomes trapped between the metaphyseal fragment and the physis, preventing

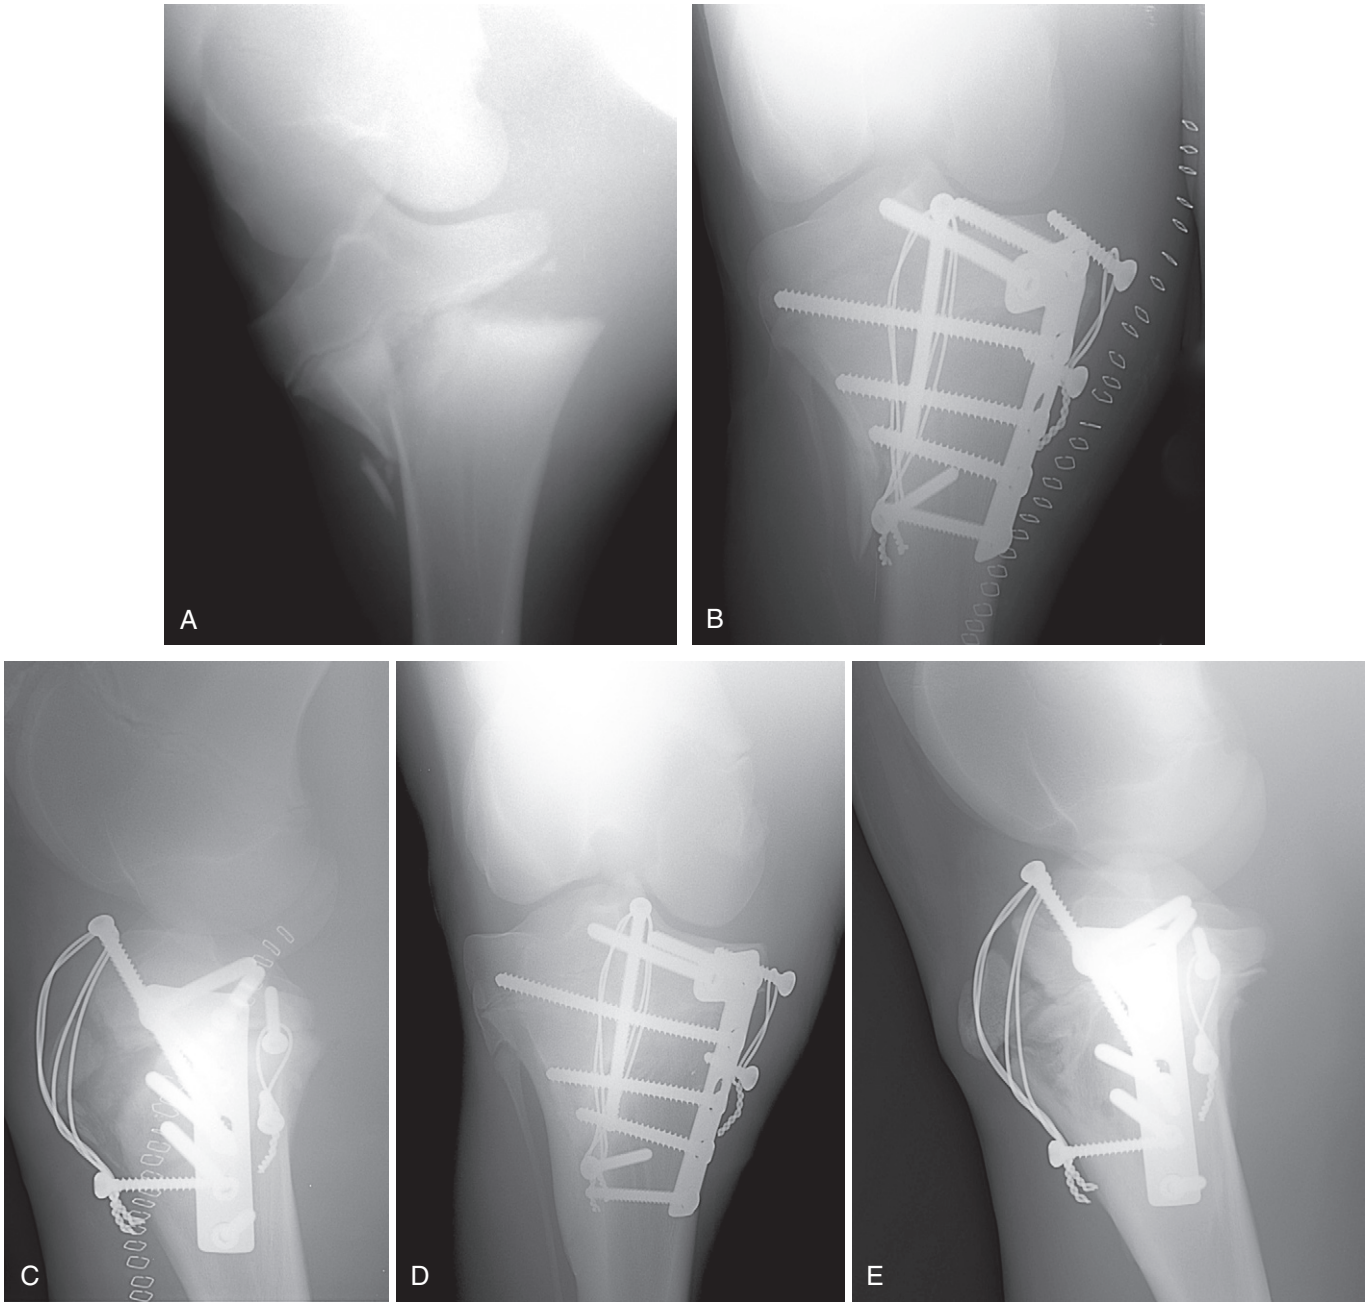

Figure 98-5. A, Craniocaudal radiographic view of a typical Salter Harris type II fracture of the proximal tibia. Craniocaudal **(B)** and lateromedial **(C)** postoperative radiographic views show the repair using a medially placed screw and wire tension band and a four-hole right angle "L" plate. A cranially placed screw and wire tension band was used to stabilize the tibial crest. Craniocaudal **(D)** and lateromedial **(E)** radiographic views of the healed fracture 8 weeks postoperatively. Note that the physis has closed.

complete reduction. Manual downward pressure on the medial aspect of the proximal tibial metaphysis places the intact soft tissue on the lateral aspect of the limb under tension and reduces the fracture. Reduction can be maintained by the placement of one 4.5-mm cortex screw in the epiphysis and one in the metaphysis. A figure-of-eight tension band wire is tightened between the two screws, maintaining reduction during placement of the primary implants if the stability is tenuous (Figure 98-5, *B* and *C*).

Soft tissue dissection is carried to the bone surface on the metaphysis, but the soft tissue on the epiphysis should not be disturbed. A four-hole T-plate, right angle "L" plate, five-hole broad limited-contact dynamic compression plate (LC-DCP) or locking compression plate (LCP), is used for fixation. (T-plates and right-angle "L" plates are named according to the number of vertical holes in the shaft; for example, a four-hole T-plate contains two horizontal holes and four additional holes in the vertical shaft.[7]) The two transverse holes are positioned over the epiphysis closer to the caudal aspect of the proximal tibia, halfway between the femorotibial joint surface and the physis. A right-angle "L" plate with the proximal (short) limb of the plate facing craniad and the long limb of the plate distal along the tibia gives the most diaphyseal contact without the plate overhanging the metaphyseal cortex (see Figure 98-5, *B* and *C*). The

two proximal screws are inserted across the width of the epiphysis. The screws should be oriented as much as possible parallel to the caudal cortex in a transverse plane, not perpendicular to the plate. The use of 5.5-mm cortex screws is ideal in the epiphysis. The distal screws in the T-plate are inserted into the metaphysis after using the tension device or are placed in the load position to achieve axial compression. If an LCP is used, two locking-head screws are placed in the epiphysis first, followed by axial compression of the fracture using a 5.5-mm cortex screw in the load position and finally implantation of the remaining locking head screws in the metaphysis. It is desirable to pass at least one of the plate screws across the proximal metaphysis into the lateral metaphyseal fragment that remains attached to the epiphysis. This increases the stability of the lateral aspect of the fracture (see Figure 98-5, *B* and *C*).

After the plate is in place, a second screw and wire construct can be applied to increase stability on the medial aspect of the bone, but the most stable fixation is achieved with a tension band wire used to stabilize the tibial crest, which always remains attached to the epiphysis. A 5.5-mm cortex screw is placed from proximal to distal through the epiphysis and into the metaphysis to act as the proximal anchor for the tension-band wire. A distal screw in the metaphysis or a hole through the cranial aspect of the metaphysis is used for the distal anchor of the tension band. One or two strands of 1.5-mm wire are subsequently placed in figure-of-eight fashion and twisted to tighten the construct (see Figure 98-5, *B* and *C*). Alternatively, a 1-mm cable can be substituted for the wire. The proximal screw is left above the bone surface under the patellar ligaments and not tightened down to the surface of the bone to allow removal at a later date.

When fixation is complete, the soft tissues are closed in two layers using routine technique. Closed suction drainage is optional. A stent bandage is sutured over the incision to reduce tension on and protect the incision. The area is difficult to bandage, but some compression of the soft tissue to reduce the hematoma can be obtained if elastic tape is used.

Aftercare

External coaptation is not used.[7] The foal is assisted to its feet during recovery from anesthesia. Broad-spectrum antibiotic therapy along with anti-inflammatory treatment is continued until the swelling has subsided. The condition of the soft tissues postoperatively determines the length of antibiotic treatment. Foals are confined to the stall for 4 weeks, after which time radiographs are taken. If there is any indication of postoperative complications, radiographs are taken earlier. The foal should be bearing weight on the limb within 1 or 2 days and should begin walking soundly within 7 to 10 days. Absence of soundness indicates developing complications.

If the 4-week follow-up radiographs indicate healing, exercise is increased over the next month to unrestricted exercise by 8 weeks. If no complications are encountered and the physis has not closed, the implants can then be removed by 8 weeks to allow the physis to resume growth if growth potential remains (Figure 98-5, *D* and *E*).

Complications

Three major complications are commonly encountered with this fracture: failure of the fixation, sepsis, and wound dehiscence. Failure of the fixation most commonly occurs by loss of purchase within the epiphysis. Failure seldom occurs from implant loosening in the metaphysis or by disruption of the implants themselves. In the rare case that a fissure fracture is not diagnosed initially, it may lead to a shaft fracture distal to the implants (Figure 98-6). Postoperative sepsis is possible, as with any equine fracture. A third complication that indirectly results in sepsis is dehiscence of the wound. The skin and subcutaneous tissue on the medial aspect of the limb are often traumatized by the sharp edge of the proximal tibial metaphysis if the duration from fracture to treatment was prolonged or if postinjury first aid was not adequate.[7] Sepsis does not necessarily mean failure if stability is maintained and as long as the infection is appropriately treated with drainage and antibiotics.

Prognosis

The prognosis after repair of proximal physeal fractures is favorable, but the smaller the foal, the better the prognosis.[4-7] The preoperative condition of the soft tissues, the amount of soft tissue stability on the lateral aspect of the limb, the ability to reduce the fracture, and the security of the proximal epiphyseal implants all determine the outcome. Sufficient healing of the fracture and resolution of the injury to allow athletic activity are anticipated in a majority of cases. Closure of the proximal tibial physis usually occurs, but it is not a major complication (see Figure 98-5, *D* and *E*). The proximal tibial physis of the horse does not close as readily as the physes of other animals or other sites, and the horse compensates for decreased limb length in spite of considerable damage if closure does occur.

Diaphyseal Fractures

Diaphyseal fractures are the second most common fracture of the tibia.[9] Most diaphyseal fractures have a spiral configuration and many are comminuted (Figure 98-7, *A* and *B*). The fracture is created when the forces of loading, which in the tibia create considerable torque, are combined with an excessive external force. Diaphyseal fractures can occur in animals of any age. Appropriate first-aid therapy is necessary to minimize secondary soft tissue damage, as with any fracture (see Chapter 73). The trauma required to fracture a tibia often creates an open fracture, which greatly decreases the chances of successful repair.

Preoperative Considerations

Usually, diaphyseal fractures of the adult tibia are high-energy, catastrophic injuries accompanied by extensive comminution and skin penetration.[9] For these reasons, attempts at repair are seldom practical, because of the very poor prognosis. However, tibial fractures in foals usually have less comminution and have a better chance of remaining closed, and repair has a greater chance of success.

Because traction on the distal limb does not reduce a tibial fracture—in fact, it causes overriding because of the reciprocal apparatus—hanging the limb in tension is not helpful. Placing the injured tibia down with the horse in lateral recumbency impedes surgical manipulation of the diaphyseal fracture and necessitates a medial surgical approach, where little soft tissue covers the bone and implant. Therefore, the horse is best positioned in dorsal recumbency with minimal traction on

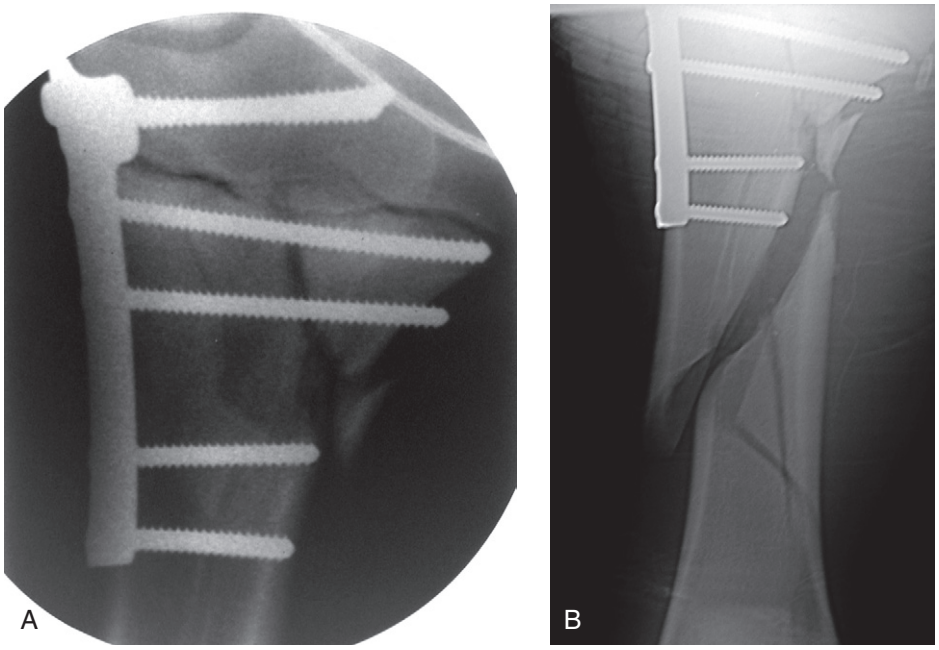

Figure 98-6. A, A craniocaudal intraoperative fluoroscopic view of a proximal tibial physeal fracture repaired with a four-hole T-plate. This fracture was more severe than a routine proximal tibial physeal fracture and required a more involved fixation. The metaphyseal component is comminuted and extends more than half the width of the bone. In addition, there is only one screw that is anchored in healthy bone distal to the comminuted fracture. This fracture probably required two implants and more distal fixation to resist the biomechanical instability the comminution created. **B,** The craniocaudal follow-up radiograph taken the next day because the foal was non–weight-bearing on the limb. A catastrophic bone failure occurred during the night. The fracture initiated at the distal end of the original fracture and spiraled distally, leading to catastrophic failure of the bone. The owner did not want proceed with treatment and the foal was humanely destroyed. (Courtesy J. Auer, University of Zurich.)

the limb or in lateral recumbency with the injured tibia uppermost.

Approaches to the tibia for diaphyseal fracture repair must take the anatomy into consideration. The cranial tibial artery is located on the cranial lateral aspect of the tibia. The lateral outpouching (sulcus muscularis) of the lateral femorotibial joint compartment extends distad, surrounding the long digital extensor tendon on the proximolateral aspect of the tibia. The tenuous soft tissue on the medial aspect of the tibia must be protected and the closely attached digital extensor tendons distally near the tarsocrural joint must be avoided.

Three surgical approaches are available: the medial approach directly over the tibia without muscle cover, the lateral approach between the long digital extensor and the cranial tibial muscles, and the cranial approach, in which the incision is made over the cranial tibial muscle.[9] The cranial approach over the muscle is the most versatile.

Deep dissection is extended slightly mediad allowing the muscle and soft tissue to be retracted as one unit laterad, permitting a cranial approach to the proximal tibial shaft. The cranial approach eliminates the necessity of dealing with any blood vessels, because all the vasculature is elevated with the cranial tibial muscle. Some surgeons prefer to place the implants on the surface of the periosteum. If this approach is elected, the vessels need to be protected if extra-periosteal dissection is used. Implants can be placed on the medial and lateral aspects of the bone through this incision, eliminating the need for two incisions, as are required with the medial and lateral approaches. The biomechanics of weight bearing of the tibia dictate that two plates be used and that one plate is best placed craniolaterally on the tension surface of the bone, spiraling distad to the cranial tibia (Figure 98-7, *C* and *D*).[10]

Broad-spectrum antimicrobial agents and anti-inflammatory medications are administered preoperatively.

Treatment

The incision is initiated craniolaterally along the lateral patellar ligament, extended to the tibial crest, directed craniad over the cranial tibial muscle to the distal aspect of the limb, and curved slightly mediad as the tarsocrural joint is approached. The incision is carried through the skin and subcutaneous fascia until the cranial tibial muscle is encountered. The cranial tibial muscle is elevated laterad, exposing the lateral surface of the bone.

Positioning of the implant at the most proximal aspect of the tibia in proximal metaphyseal and mid-diaphyseal fractures necessitates entering the femorotibial joint through the sulcus muscularis, which surrounds the long digital extensor muscle. Normally, the long digital extensor and cranial tibial attachments are avoided by separating them, which allows placement of the implant near the proximal physis or physeal scar. Working on both sides of the cranial tibial muscle allows placement of the plate without damaging the muscle.

Fracture reduction is accomplished by traction on the distal tibia and appropriate reconstruction of the bone. The repair begins by reattaching comminuted fragments to the parent bone with cortex screws placed in lag fashion to create a two-fragment fracture. The fracture is reduced to a proximal and distal fragment, and the plate is contoured to mimic the curve

Craniocaudal **(C)** and lateromedial **(D)** radiographic views of the repaired fracture using two interfragmentary 4.5-mm cortex screws inserted in lag fashion and two staggered broad 4.5 mm DCPs, 3 weeks after surgery.

of the tibia from craniolateral proximally to cranial distally (see Figure 98-7, *C* and *D*). The use of dynamic condylar screw (DCS) plates or 5.5-mm LCP constructs is desireable, especially in older foals and the rare adult horse undergoing treatment. The screws are inserted in the order dictated by the individual fracture, which differs from case to case. Care must be taken to cross any fracture plane with screws placed in lag fashion and to create interfragmentary as well as axial compression during application of the plate for the most stable fixation.

When the craniolateral plate is in place, the craniomedial plate is applied. It is contoured from craniomedial to medial and positioned in an envelope under the skin and subcutaneous tissue with or without elevation of the periosteum medially. It is occasionally necessary to flex and abduct the limb to gain access to the medial aspect of the tibia. The medial plate is positioned to avoid the screws of the lateral plate. Interfragmentary and axial compression is created as needed. Both plates can be loaded to distribute the axial compression circumferentially around the bone. Plate luting has been advocated for repair of this fracture to increase stability and fatigue life of the implant construct and should be considered for tenuous fixations.[9] After placement of the plates, a suction

drain is inserted, exiting proximolaterad, and attached to a suction reservoir.

Closure involves the fascia of the cranial tibial muscle, subcutaneous tissue, and skin. Release incisions can be made in the skin over the cranial tibial muscle to relieve tension on the closure if swelling has increased the diameter of the limb and endangered the closure.

Postoperatively, no cast is used. Cast immobilization increases the load on the implants because the cast cannot extend proximal to the stifle in the horse and the stifle joint cannot be immobilized. Stent bandages are sewn over the incision. The horse is allowed to recover from anesthesia unimpeded by bandages; bandages are placed after the horse is standing. The horse is always assisted in recovery; it should be helped to regain the standing position in one attempt, if possible. Bandaging is used as indicated during the postoperative period.

Aftercare

Antibiotics and anti-inflammatory drugs are continued for a prolonged period because tibial fractures are accompanied by considerable soft tissue damage. The health of the soft tissue

and the postoperative use of the limb by the patient dictate the length of antibiotic and anti-inflammatory therapy.

Stall rest is maintained, with no exercise allowed for 6 to 8 weeks, depending on the age of the horse. Foals are often radiographed at 6 weeks, whereas follow-up radiographs are taken at 8 weeks in adults to ascertain whether bridging of the fracture has occurred. Postoperative use of the limb is the most accurate assessment of stability of the fracture. If use of the limb is not attained or diminishes, radiographs are taken.

Complications

The most common complication with tibial fractures is breakdown of the fixation because of bone or implant failure. Tibial fractures are most often comminuted, and the torsional force applied to a fractured bone that contains multiple drill holes often causes propagation of the fracture into additional sites. A single acute overload generally causes the bone to fail; cyclic loading in an unstable construct will cause the implants to fail. Complications also include postoperative sepsis because of primary infection or breakdown of the incision. If the fixation remains stable, the fracture will heal even when contaminated and infected (Figure 98-8, *A* through *F*). With any major long bone fracture, all complications that preclude comfortable weight bearing eventually result in failure of the contralateral limb, which results in euthanasia.

Prognosis

Simple fractures in adult horses can be repaired successfully with internal fixation (see Figure 98-7, *A* through *D*); however, this fracture configuration is the exception rather than the rule. Most diaphyseal tibial fractures are comminuted and accompanied by massive soft tissue damage. Therefore, the prognosis for tibial fractures is unfavorable in adults. In foals, however, internal fixation of tibial fractures can be successful when the fracture is immobilized and the implants protect the bone enough to allow healing (see Figure 98-8, *A* through *D*).[11] The prognosis is guarded even in foals, but success in healing of the fracture and dismissal of the horse postoperatively is attainable in selected fractures (see Figure 98-8, *E* and *F*). Athletic activity is undertaken if the surgical procedure and stabilization proceed without complications.

Distal Physeal Fractures

Fractures of the distal epiphysis occur rarely. Diagnosis is routine, and treatment involves external coaptation with a

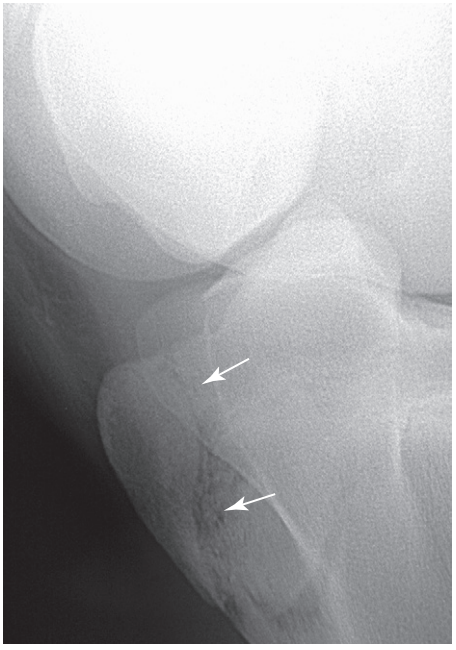

Figure 98-9. Lateromedial radiographic view of the most commonly encountered nondisplaced, nonarticular tibial crest fracture *(arrows).* This fracture was treated conservatively with stall rest.

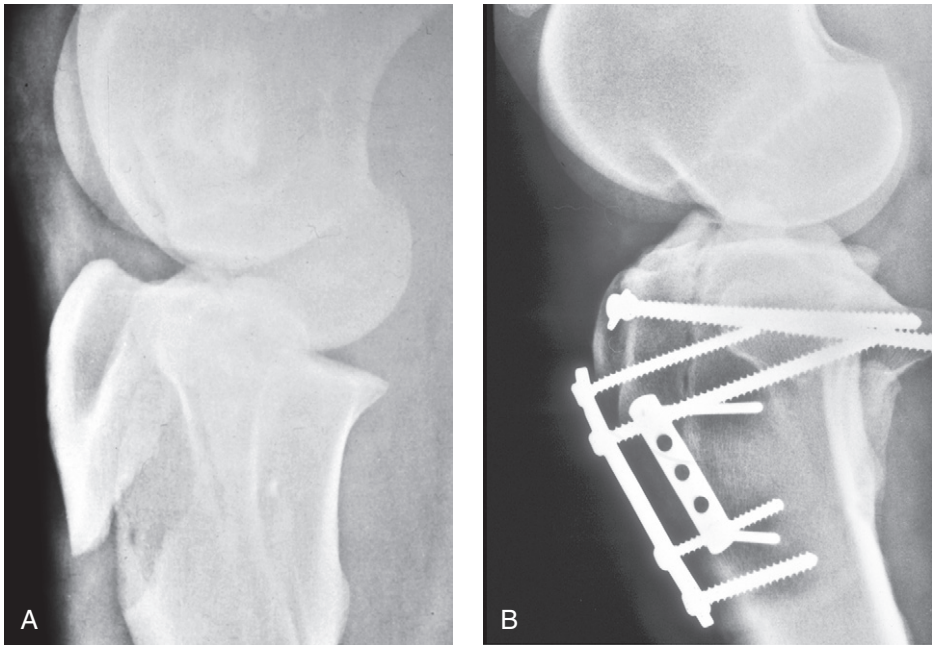

Figure 98-10. A, Lateromedial radiographic view of a displaced tibial crest fracture. **B,** The fracture was repaired proximally with two 5.5-mm cortex screws applied in lag fashion perpendicular to the fracture plane. A washer was used with one screw to avoid countersinking the head and weakening the bone. Additionally, a 5-hole narrow dynamic compression plate (DCP) was applied over the medial ridge as a tension band, and a 5-hole 2.7-mm cuttable small animal plate with two 3.5-mm cortex screws was applied over the lateral aspect of the fracture to provide additional stability. The fracture healed without complications. (Courtesy J. Auer, University of Zurich.)

fiberglass cast alone or in conjunction with selective screw placement. The architecture of the undulating articular surface of the distal tibia and the corresponding physis makes implant placement into the epiphysis especially difficult.

Tibial Crest Fractures

Tibial crest fractures are generally the result of direct trauma, often during attempts to jump a fence or from contact with other solid objects.[12] The most common tibial crest fracture is the nondisplaced nonarticular fracture (Figure 98-9). These fractures require no fixation because the patellar ligaments provide adequate stability for healing. Stall confinement for 60 days with follow-up radiographs at that time usually show healing adequate for gradual re-introduction to exercise.

If the tibial crest fracture is displaced or has an articular component (Figure 98-10), the fracture is stabilized in much the same fashion as a proximal tibial physeal fracture with fixation and stabilization employing a tension band cranially and implants sufficient to stabilize the fracture and reconstruct the joint surface.[12] Because of the anatomic configuration of the tibial crest, it is best to orient the plate obliquely along the tibial crest. The screws should be directed mediad and laterad in an alternating pattern to avoid aligning them in a straight line, which may predispose the underlying bone to fracture.

CHAPTER 99

Stifle

Jennifer G. Fowlie, John A. Stick, and Frank A. Nickels

The stifle joint represents an important source of hindlimb lameness for equine athletes because it is the largest and most complex joint in the horse.[1] The clinical presentation of stifle disorders is highly variable, and the degree of stifle joint effusion, peri-articular swelling, and lameness differs depending on the underlying disorder. The degree of lameness may vary from virtually occult to non–weight-bearing, and when viewed from the rear, asymmetry of the gait is similar to hindlimb lameness from other causes.

The equine stifle consists of three compartments; the medial compartment of the femorotibial joint (MFT), the lateral compartment of the femorotibial joint (LFT) and the femoropatellar joint (FPT). There is a complex arrangement of soft tissues in the stifle (12 ligaments, 2 menisci, and numerous musculotendinous support structures) that provide functional stability, force transduction, and locomotion. Historically bony lesions (particularly osteochondrosis) have been cited to have a higher incidence than soft tissue lesions[2]; however, recognition of soft tissue injuries is increasing with recent access to large-bore magentic resonance imaging, improved ultrasonographic imaging, and more extensive application of traditional and novel arthroscopic techniques.

This chapter reviews the functional anatomy, general diagnostic techniques, and the diagnosis, treatment, and prognosis of specific disorders of the equine stifle joint.

FUNCTIONAL ANATOMY

The stifle consists of two articulations: the FPT and the femorotibial joints (MFT and LFT) (Figures 99-1 and 99-2).[3] The FPT has a large suprapatellar pouch, and the joint capsule inserts abaxially on the trochlear ridges, forming a lateral and a large medial cul-de-sac on each side. Communication between the MFT and LFT is not present under normal conditions,[3-6] and the femorotibial compartments are divided into a cranial pouch and a caudal pouch by the femoral condyles. The volume in the medial and lateral compartments of the femorotibial joint is 41.67 ± 5.77 mL and 61.67 ± 2.89 mL, respectively. The standing femorotibial joint angle has been reported as approximately 150 degrees, with flexion limited only by the contact of the

caudal leg musculature.[3] The "screw home mechanism," as reported in other species, is also seen in the equine stifle, such that the tibia undergoes slight external rotation on full extension and inward rotation on full flexion.[3] This occurs as a result of the interactions of the cruciate ligaments, the collateral ligaments, and the disparate size of the femoral condyles.

Experimental studies show a communication between the FPT and the MFT in 60% to 65% of horses, with communication between the FPT and the LFT occuring in only 1% to 25% of horses.[3,4,7] Variation in communication rates is seen with different materials (i.e., latex vs. contrast arthrography). Diffusion of mepivacaine anesthetic in cadaveric stifles from the FPT to the MFT, from the FPT to the LFT, and between the MFT and LFT (in both directions) occurred in 100% of limbs.[8] As well, mepivacane diffusion occurred from the LFT to the FPT in 90% of the limbs and the MFT to the FPT in 85%. Interestingly, communication between the FPT and the MFT was only noted in 3 of 16 (19%) clinical cases using computed tomographic contrast arthrography,[9] indicating that disease may obstruct these communications.

DIAGNOSTIC TECHNIQUES

Inspection

Lameness evaluation of the stifle includes observation of the horse at rest and during locomotion, palpation of the synovial compartments and the patellar ligaments, and additional diagnostic aids, such as manipulative tests and intra-articular anesthesia. Clinical signs depend on the severity and chronicity of the injury. Severe injuries, such as fractures, sepsis, or instability of the joint (cruciate or collateral ligament damage), generally produce the most severe lameness. Chronic lameness of a rear limb results in atrophy of the gluteal muscles, causing an asymmetric appearance of the croup when viewed from the rear. The lame horse frequently bears weight on the affected limb for a shorter time during movement, resulting in a shortened anterior phase of the stride when viewed from the side. When viewed from the rear at the trot, there is a greater excursion (vertical displacement) of the tuber coxae on the affected side compared to the contralateral side[10], which is typical of most sources of hindlimb lamenesses. Wearing of the toe on the affected side may be seen because of decreased flexion of the hock/stifle during the swing phase of the gait. There are no pathognomonic gait abnormalities that can be used to definitively localize hind limb lameness to the stifle.

Synovial distention of the FPT may be visually obvious (Figure 99-3) or quite subtle. Subtle changes can be detected by careful palpation between the patellar ligaments and cranial to the distal patella and by comparing the two stifle joints. Synovial distention of the femorotibial compartments (particularly the lateral) can be difficult to detect but can be palpated immediately cranial or caudal to the collateral ligaments. Palpation of swelling or crepitation of the patella may indicate a patellar fracture. Upward fixation of the patella should be suspected if delayed unlocking of the patella is palpated as the horse is walking, or if manipulation of the patella proximad and laterad results in pain or the inability to flex the stifle.

Manipulation

Manipulative tests may exacerbate the lameness, aiding in localizing the lesion to the stifle. These tests include the tarsus/stifle flexion test, the patellar test, the cruciate test, and collateral ligament stress tests.

Figure 99-3. Appearance of bilateral FPT effusion. Note the enlargement over both patellar regions.

Figure 99-4. Cruciate ligament test used to detect rupture. The shoulder is placed against the back of the limb and the tibia is pulled caudad and released.

Tarsus/stifle flexion is performed by grasping the distal metatarsus and holding the tarsus/stifle joints in maximal flexion for 1 to 2 minutes. The metacarpo/metatarsophalangeal and phalangeal joints are only passively flexed by this method. A positive response to this test (an increase in lameness) may indicate tarsal or stifle lameness, thus one must use additional diagnostic aids to further localize the lameness.

Two manipulative tests have been described for evaluating the cruciate ligaments. These tests are designed to elicit pain and lameness because of the abnormal movement created between the femur and the tibia if there is damage to the cruciate ligaments. The first test is only safe in the most cooperative of horses. To perform this test, the examiner stands behind the affected limb and firmly grasps the proximal tibia with both hands (Figure 99-4). If any movement or crepitation is detected when the examiner gives a quick pull backward, the test is said to be positive.[11] The second test is carried out with the examiner standing directly in front of the affected limb, placing the inside hand on the cranial aspect of the proximal tibia, and grasping and pulling the tail to load the limb while rapidly pushing and releasing the force on the tibia 20 to 25 times. The horse is then trotted away to evaluate for increased lameness.

The medial collateral ligaments can be evaluated by elevating the limb off the ground and placing pressure on the lateral aspect of the stifle joint while abducting the distal limb. The lateral collateral ligament can be evaluated by elevating the limb off the ground and pulling the stifle joint laterally while adducting the distal limb.

Intra-Articular Anesthesia

Intra-articular anesthesia is an important diagnostic aid in determining articular involvement. Although local anesthesia diffuses between all stifle compartments about 85% to 100% of the time, anesthetic should be deposited in all three synovial compartments to ensure complete anesthesia of the stifle.[4,5,8]

Injection of the FPT can be performed through either a cranial or a lateral approach. The cranial approach is performed by inserting a 7.5-cm (3-inch) spinal needle between the medial and middle patellar ligaments or between the middle and lateral patellar ligaments and directing it proximad into the trochlear groove under the patella. The lateral approach is performed by inserting a 3.75-cm 18-gauge needle into the lateral cul-de-sac of the FPT just caudal to the lateral patellar ligament and approximately 6 cm proximal to the lateral tibial condyle.[12] This approach is best performed with the limb unloaded and is commonly the best approach for obtaining a fluid sample from the FPT.

The approach to the LFT is performed by inserting a 3.75-cm 18-gauge needle between the lateral patellar ligament and the long digital extensor tendon or between the previous tendon and the lateral collateral ligament above the proximal edge of the meniscus into the joint. The approach to the MFT is performed by inserting a 3.75-cm 18-gauge needle between the medial patellar ligament and the medial collateral ligament above the proximal edge of the meniscus into the joint. The use of an 18-gauge needle and a bleb of local anesthetic in the skin at the insertion point reduces the risk of limb flexion during the procedure, decreasing the chance of needle bending and breakage. An alternative approach to the MFT, which may decrease the risk of iatrogenic damage and increase the chance of fluid retrieval, is needle insertion 1.5 cm proximal to the tibial plateau in the depression between the medial patellar ligament and the tendon of insertion of the sartorius muscle.[13]

Injection of all three joint compartments with only one skin penetration may be achieved with an 8.9-cm 18-gauge spinal needle at a site just caudal to the lateral patellar ligament and approximately 2 cm proximal to the tibial plateau. The needle is directed to gently contact the medial and then lateral femoral condyles and then proximally under the patella, depositing anesthetic in all three joint compartments.

DIAGNOSTIC IMAGING

Radiography

Five radiographic views are necessary for a comprehensive evaluation of the stifle: lateromedial, flexed lateromedial,

Figure 99-5. An avulsion fracture *(arrow)* of the cranial cruciate ligament is evident on this lateromedial stifle radiograph. The avulsed osseous fragment is evident near the distal insertion of the cranial cruciate ligament on the medial intercondylar eminence of the tibia.

caudocranial, caudal 30-degree lateral craniomedial oblique, and flexed cranioproximal craniodistal oblique view (skyline). X-ray machines need a minimum output of 90 kV and 20 mAs to obtain quality films of this large joint.

The lateromedial and flexed lateromedial views highlight osseous irregularities near the insertion of the cranial meniscotibial ligaments and the cranial cruciate ligament (Figure 99-5). A flexed lateromedial view of the stifle, with the limb lifted and retracted caudally, permits patellar and condylar lesions to be seen more easily. The caudal 30-degree lateral craniomedial oblique view decreases superimposition of the trochlear ridges and the condyles of the femur (Figure 99-6). The x-ray beam should be aligned 10 to 15 degrees proximodistally and 30 degrees caudolateral to craniomedial. Lateral trochlear ridge lesions are most clearly seen with this view.

The caudocranial view is best obtained by angling the x-ray beam 10 to 20 degrees proximodistally and centered on a line bisecting the limb between the semimembranosus and semitendinosus muscles at the level of the distal third of these muscles. The horse should be standing squarely with the leg underneath the body. This view is best for demonstrating medial condylar cysts (Figure 99-7) and osteoarthritis of the stifle. Osteophyte formation on the abaxial aspect of the medial tibial plateau is commonly the first radiographic sign of osteoarthritis of the stifle.

The cranioproximal craniodistal oblique view (skyline) (Figure 99-8) is used primarily to evaluate the patella (particularly for fractures), the intertrochanteric groove of the distal femur, and the trochlear ridges. In standing horses, the limb should be held semiflexed, drawn caudad and externally rotated to expose the stifle region. The cassette is held horizontally with its caudal edge against the cranial aspect of the tibia. The x-ray beam should be directed perpendicular to the cassette as much as possible.

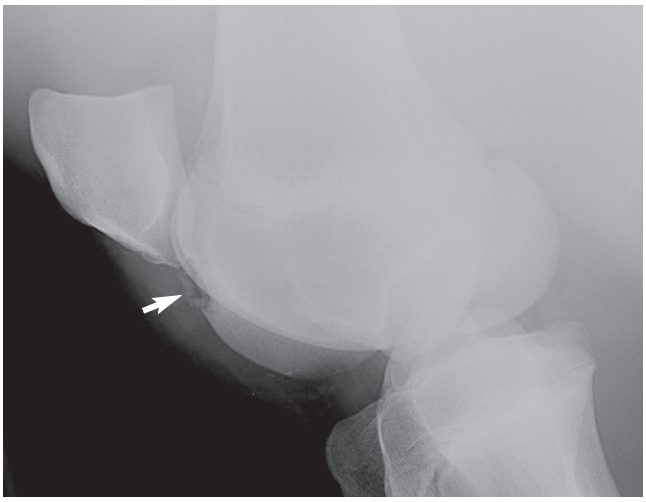

Figure 99-6. A caudal 30-degree lateral craniomedial oblique radiographic view of the stifle highlights an osteochondrosis lesion *(arrow)* of the lateral trochlear ridge of the femur.

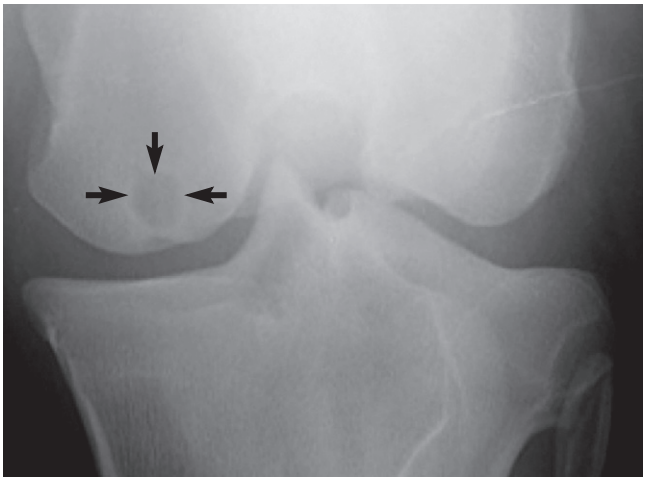

Figure 99-7. A caudocranial view of the stifle demonstrating a large subchondral bone cyst *(arrows)* in the medial femoral condyle.

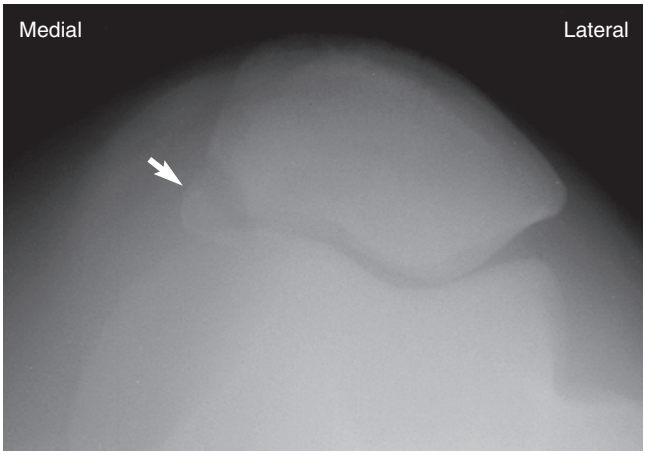

Figure 99-8. Cranioproximal craniodistal oblique radiographic view (skyline) of the equine stifle, which is used to evaluate the patella, intertrochanteric groove of the femur, and trochlear ridges. Note the sagittal fracture of the medial aspect of the patella *(arrow)*.

Radiographic mapping of the origins and insertions of the soft tissues in the stifle region has been completed and is useful in determining potential soft tissue injury if there is an osseous component, such as avulsion fracture or enthesiophyte formation.[14]

The stifle of the horse has six centers of ossification at birth. This makes radiographic assessment of the foal somewhat challenging. A summary of closure of growth plates and ossification sites is as follows. The patella is fully ossified by 4 months of age. The proximal portions of the trochlear ridges show irregular contours and granular subchondral bone opacity, which gradually become a smooth, regular subchondral bone outline between 3 and 5 months of age. The distal femoral physis closes at 24 to 30 months of age. The femoral condyles are smoothly outlined, and any irregularity except in young foals should be interpreted as pathologic. At birth, the center of ossification of the tibial tuberosity (apophysis) is separated from the proximal tibial epiphysis as well as from the proximal tibial metaphysis. The apophyseal epiphyseal physis closes at 9 to 12 months of age, and the apophyseal metaphyseal physis closes at 30 to 36 months. The proximal tibial physis closes at 24 to 30 months of age. The fibula has multiple ossification centers that can remain incomplete throughout the life of the horse.

In adult horses, the trochlear ridges are smoothly curved in outline, but the medial trochlear ridge has a small, flattened area at its junction with the metaphysis of the femur. This creates a plateau at its proximal aspect that articulates with the patella, thus functioning in the passive stay apparatus of the hind limb. On a caudocranial view in the adult horse, the patella is seen superimposed over the lateral cortex of the diaphysis of the femur. The medial femoral condyle is more round than the lateral condyle, and the lateral joint space of the femorotibial joint is narrower than the medial joint space. On the cranioproximal to craniodistal oblique view, the medial trochlear ridge is larger than the lateral ridge and the patella is approximately triangular with its medial angle blunter than the lateral angle.

Ultrasonography

Ultrasonography permits a noninvasive, relatively inexpensive examination of the soft tissue and bony structures of the stifle.[15-20] Ultrasonography is particularly beneficial in evaluating regions of the stifle that are obscured from arthroscopic examination,[21] and techniques for optimal ultrasonographic imaging of the stifle are well documented.[22] A 7- to 14-MHz linear transducer is recommended for evaluating the patellar and collateral ligaments, the menisci, and the femoropatellar and femorotibial joint capsules with the horse bearing weight. A 4- to 6-MHz curvilinear transducer is recommended for the caudal stifle region (during weight bearing) and the cranial aspect of the stifle (with the limb held in 90 degree flexion). The flexed cranial view is used for evaluating the cranial horn of the menisci, cranial meniscotibial ligaments, and tibial and femoral attachments of the cranial and caudal cruciate ligaments. Optimal visualization of the cruciate ligaments is challenging because of their deep position and oblique orientation. Visualization of the caudal aspect of the stifle is also difficult because a lower-frequency transducer is needed to penetrate the thick caudal musculature, resulting in a decreased resolution of the images. Thus, considerable practice is necessary to obtain and interpret diagnostic images.

Because of the complex shape and fiber orientation of the soft tissue structures of the stifle, all lesions should be confirmed in two perpendicular planes. Familiarization with the normal anatomy and comparison with the sound limb is necessary to avoid misdiagnoses. For example, a hypoechoic artifact is frequently created in the cranial medial meniscus and proximal medial collateral ligament with a linear transducer because of a loss of perpendicular alignment of the fibers with the ultrasound beam. These artifacts are not seen with a curvilinear probe, emphasizing that experience and careful interpretation are required for accurate diagnoses.[22]

Multiple lesions can be identified with ultrasonography, such as intra-articular bone fragments, cartilage lesions, thickening of the synovial membrane, joint effusion, desmitis or core ligamentous lesions, and meniscal tears and protrusion. Meniscal lesions may be more apparent when the limb is non–weight-bearing. Lesions that cannot be definitevly diagnosed on radiographs may be more clearly identified ultrasonographically, such as avulsion of the popliteal tendon origin.[23] Ultrasonography has a sensitivity and specificity of 79% and 56%, respectively for identifying meniscal injuries when compared to arthroscopic findings[24]; however, the high false-positive rate in this study may partially be caused by the inability to arthroscopically visualize regions of the joint that can be visualized ultrasonographically. Another study involving 29 cases of meniscal tears identified three horizontal abaxial tears that could not be seen arthroscopically and 10 cases where the tears were only seen arthroscopically,[25] indicating a high rate of false negatives. Horizontal tears of the medial meniscus were the most frequent soft tissue injury identified in another study.[26] Preliminary evaluation indicates that three-dimensional ultrasonography has increased diagnostic capabilities.[27] Ultrasonography will continue to assume a more prominent role in the diagnosis of stifle lesions in the horse, but ultimately multimodal diagnostics will provide the optimal evaluation of the stifle joint.

Nuclear Imaging

Nuclear scintigraphy identifies lesions based on their physiologic characteristics (osteoblastic activity and blood flow). However, nuclear scintigraphy has been inconsistent in imaging and localizing stifle joint pathologies, particularly in cases of subchondral bone cysts.[28,29] The scintigraphic appearance of normal stifles is established,[30] and multiple lesions have been recognized on scintigraphic examinations, such as anterior cruciate ligament avulsion,[31] osteoarthritis, and nonspecific increased radiopharmaceutical uptake (IRU) associated with intra-articular lesions (i.e., a meniscal tear with cartilage and subchondral bone changes).[28] Relatively late growth plate activity in the region of the stifle may mask lesions, and a lack of definitive radionucleotide uptake cannot be used to rule out a stifle lameness.

Computed Tomography

Recent access to advanced imaging such as computed tomography (CT) has permitted more extensive evaluation of the stifle and detection of lesions that would be inaccessible or incompletely identified with more conventional diagnostics (including arthroscopy).[9,32,33] CT arthrography is available at select referral institutes and has identified and further delineated intra-articular stifle lesions. Anatomic studies have used CT and

contrast techniques under fluoroscopic guidance (Figures 99-9 and 99-10).[6] CT arthrography is capable of identifying cruciate ligament pathologies, cartilage lesions, subchondral bone cysts, semitendinosis tendon and deep digital flexor muscle enthesiopathies, and enthesis/subchondral sclerosis of the tibia at the cranial medial meniscotibial ligament attachment that is not evident on radiographs.[9] An ambulatory pQCT (peripheral quantitative computerized tomography) scanner may be used to identify and localize bone fragments in the stifle for surgical removal.[34]

Magnetic Resonance Imaging

Recent access to wide-bore MRI has allowed imaging of clinical cases of equine stifle joint lameness. MRI of the human knee is a well-established diagnostic technique for evaluating soft tissue lesions; however, arthroscopy is still considered the gold standard given that the human knee can be distracted for excellent intra-articular visualization.[35] MRI of equine cadaveric limbs was first completed in 1995 to document the normal anatomy.[36,37] MRI of clinical cases was not possible until recent access to wide/short–bore magnets that can accommodate the average sized equine stifle.[32] Despite the wide (70 cm) and ultra short (125 cm) bore of the Siemens Magnetom Espree (Siemens Medical Solutions USA) 1.5 T magnet, imaging is still limited in adult horses to those with relatively long legs and narrow hips. Stifle MRI is completed under general anesthesia and is generally limited to imaging of one stifle within an anesthetic period because of time constraints and a recumbency change that would be required to complete the contralateral stifle. MRI has been invaluable for idenitifying meniscal and meniscal ligament tears, bone edema, osteochondral fragmentation, cartilage pathologies and cruciate, patellar and collateral ligament desmitis, and many clinical cases of stifle lameness that have multiple pathologies have been identified. MRI may also reveal lesions not identifiable with other diagnostic techniques (Figure 99-11).[32]

ARTHROSCOPY

Diagnostic and therapeutic arthroscopy of the equine stifle is well established. Arthroscopy is most commonly performed to treat osteochondrosis of this joint, and most of the approaches have been developed based on the characteristic locations of this disorder. Arthroscopy is also routinely used to establish a diagnosis and prognosis after traumatic stifle injury or chronic lameness that may involve damage to the menisci, meniscal ligaments, cruciate ligaments, and articular cartilage. Despite

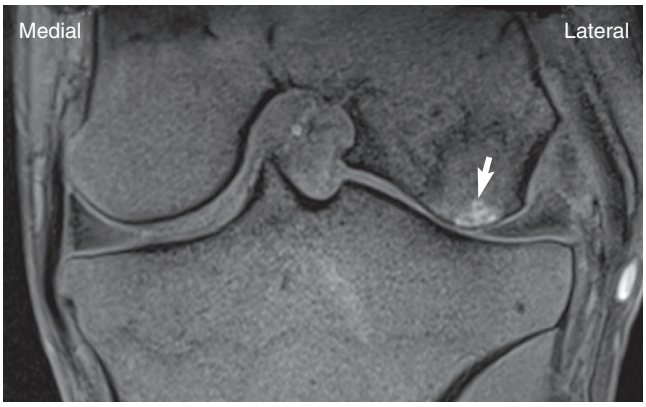

Figure 99-11. A T1-weighted VIBE magnetic resonance image of the stifle in the dorsal plane revealed a large area of bone edema, high signal (with contrast enhancement) in the subchondral bone, and extensive cartilage injury in the lateral femoral condyle *(arrow)* that was not evident on routine radiographs. (Courtesy C.E. Judy, Alamo Pintado Equine Medical Center.)

multiple approaches to the femorotibial joints, regions of the joint (particularly the tibial condyles and abaxial aspect of the menisci) remain inaccessible because distraction of the equine stifle joint is not possible unless collateral ligament injury is present.

Significant postoperative pain is intermittently seen with stifle arthroscopy, particularly if there is extensive débridement of a subchondral cystic lesion of the medial femoral condyle. It can be difficult to predict which cases will have severe postoperative pain. A preoperative epidural with morphine and detomidine has been shown to result in decreased lameness and heart rates after stifle arthroscopy.[38] We also recommend light hand-walking for 5 to 10 minutes three to four times per day beginning 24 hours after surgery to decrease the degree of postoperative discomfort.

Complete arthroscopic examination of the stifle necessitates exploration of six separate synovial compartments. However, this is rarely completed because joint compartments are usually explored based on clinical and radiographic findings that localize lesions to one or more aspects of the stifle. The horse is placed in dorsal recumbency for all approaches, and ideally the distal limb is supported by a hoist, such that flexion of the limb can be adjusted as needed. For all approaches, the stifle is placed at 90 to 100 degrees of flexion, with the exception of the femoropatellar joint, which is best completed at 120 to 130 degrees of flexion.

Each of the two femorotibial joint compartments can be divided into cranial and caudal pouches. The caudal pouch of the LFT is divided into proximal and distal pockets by the popliteal tendon. The following compartments can be explored:

- The FPT
- The cranial pouch of the MFT
- The caudal pouch of the MFT
- The cranial pouch of the LFT
- The proximal pocket of the caudal pouch of the LFT
- The distal pocket of the caudal pouch of the LFT

Femoropatellar Joint

Arthroscopy of the FPT may be performed via a cranial approach (Figure 99-12).[39,40] The horse is anesthetized and placed in dorsal recumbency with the stifle joint maintained at 120 to 130 degrees of flexion. An 8 mm long skin incision is made 2 cm medial to the middle patellar ligament and 2 cm distal to the distal aspect of the patella. The incision is extended through the superficial and deep fascia. Without prior joint distention, an arthroscopic cannula containing a blunt trocar is advanced through the incision distad and caudad, pinning the joint capsule between the trocar and the femur. A rapid but gentle advancement of the trocar with the cannula laterad and distad (or alternatively proximad into the trochlear groove) will advance it through the joint capsule. The trocar is replaced by the arthroscope, and after intra-articular location is verified, the joint is distended through the arthroscopic cannula. Sequential examination of the FPT includes evaluation along the entire length of both the medial and lateral trochlear ridges, the articulating surface of the patella, the attachments of both the medial and lateral patellar ligaments onto the patella, and the suprapatellar pouch. Instrument portal placement is completed with spinal needle guidance to obtain an optimal location for débridement of the specific lesion encountered.

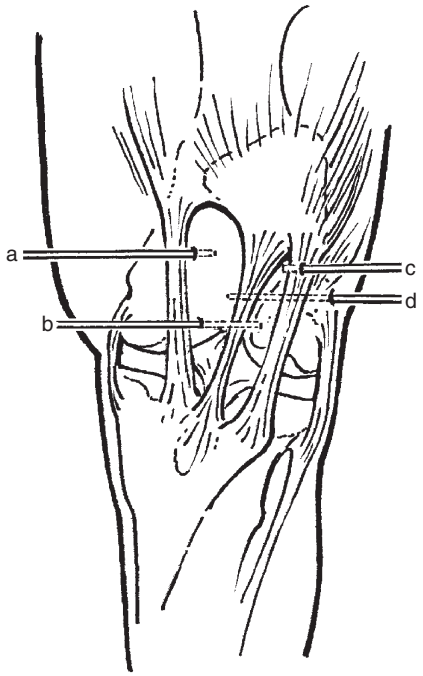

Figure 99-12. A schematic representation of the arthroscope portals used to explore the cranial pouches of the MFT, LFT and the FPT. *a,* The portal used to position the arthroscope in the FPT; *b,* the portal used to position the arthroscope in the LFT (medial approach); *c,* the portal used either to position the arthroscope in the FPT for closer examination of the lateral trochlear ridge, or as an instrument portal to débride the lateral trochlear ridge; *d,* the portal used to position the arthroscope in the MFT (lateral approach).

Arthroscope portal placement 2 cm distal to the patella allows the surgeon to subsequently enter the MFT or LFT via the cranial approach[39-41] and thus is our preferred approach. However, placement of the arthroscope portal in the FPT may be adapted based on the predicted pathology of the joint. For example, placement of the portal further distad—that is, halfway between the tibial crest and patella—facilitates improved access to the distal patella.[42] The most common reason to perform arthroscopy of the FPT is for the treatment of osteochondrosis dissecans of the lateral trochlear ridge, and portal placement is generally best between the medial and middle patellar ligaments, at a level approximately half of the distance between the tibial crest and patella. Portal placement has also been reported through a patellar ligament,[39] although this is likely unnecessary. If the instrument portal is made lateral to the lateral patellar ligament, it may be difficult to manipulate the instrument to operate effectively on lesions in this area.[43]

The suprapatellar pouch can be evaluated by passing the scope between the patella and intertrochlear groove with the limb in maximal extension. In larger horses, a longer scope and instruments are needed to adequately evaluate the suprapatellar pouch and remove debris from this compartment, or alternatively an instrument portal may be placed in the suprapatellar pouch with spinal needle (8.9 cm 18 gauge) guidance. A direct arthroscopic approach to the suprapatellar pouch has been evaluated in cadaveric limbs and clinical cases of sepsis and proximal OCD lesions and for removing debris.[44] Optimal portal placement is 2 cm proximal to the patellar base, and approximately 10 cm lateral to the longitudinal patellar axis in

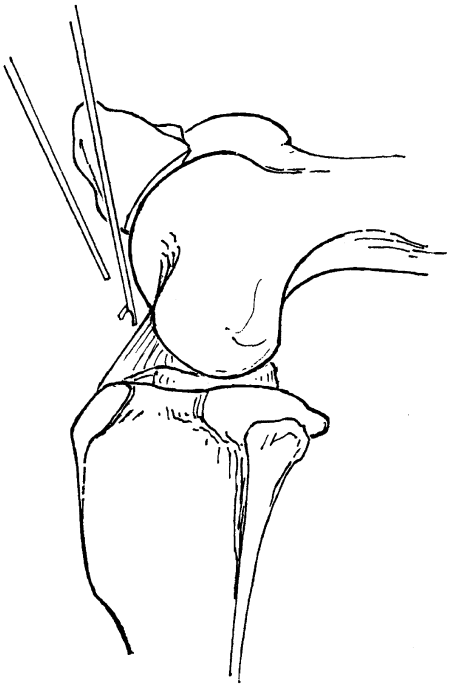

Figure 99-13. The cranial arthroscopic approach to the LFT. The arthroscope and hook scissors are drawn in the appropriate intraoperative positions, with the skin portals placed close to the distal border of the patella.

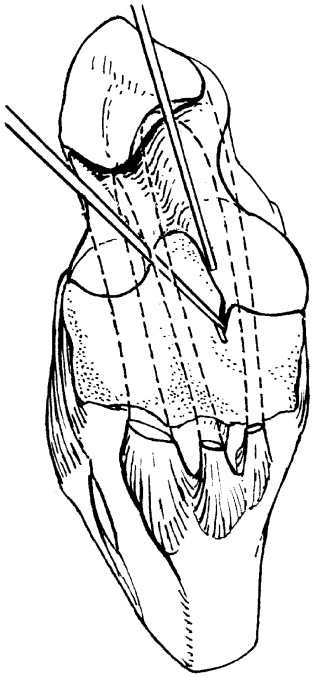

Figure 99-14. The cranial arthroscopic approach to the LFT. The arthroscope and hook scissors bisecting the synovium are drawn in the appropriate intraoperative positions. The *dotted lines* represent the medial, middle, and lateral patellar ligaments.

the intermuscular septum between the biceps femoris and vastus lateralis muscles. A lateral instrument portal can be made cranioproximally to the previous portal or cranially along the longitudinal axis of the patella in the most proximal aspect of the pouch. Medial portals are not recommended because of decreased maneuverability from abdominal interferance and thick musculature at the site and the risk of damage to major nerves and vessels.

Medial Femorotibial Compartment

Arthroscopic approaches to the cranial MFT are well established.[39,45-48] The two most common approaches are the cranial approach[40] and the lateral approach.[47]

The cranial approach involves placing the arthroscope in the FPT, with secondary entry into the cranial pouch of the MFT (and/or LFT), using arthroscopic hook scissors to incise the synovial fold at the distal end of the trochlear ridges (Figures 99-13 and 99-14).[40] Specifically, with the stifle joint at 90 to 100 degrees of flexion, the FPT is entered as described earlier, with the arthroscope portal placed 2 cm distal to the distal aspect of the patella and 2 cm medial to the middle patellar ligament. Following examination of the FPT, an instrument portal is created in the FPT 2 cm lateral to the middle patellar ligament, at the same level as the first arthroscopic portal. Arthroscopic hook scissors (Figure 99-15) are introduced through this portal and are used to elevate and cut (Figure 99-16) the slitlike synovial membrane identified overlying the cranial and distal aspects of the medial femoral trochlear ridge. The arthroscope is then advanced through the slit into the MFT (Figure 99-17). In cases of chronic joint disease, where the synovial membrane is thickened, the hook scissors may not be effective, and in such cases a scalpel blade must be used to transect the fibrous synovial membranes.

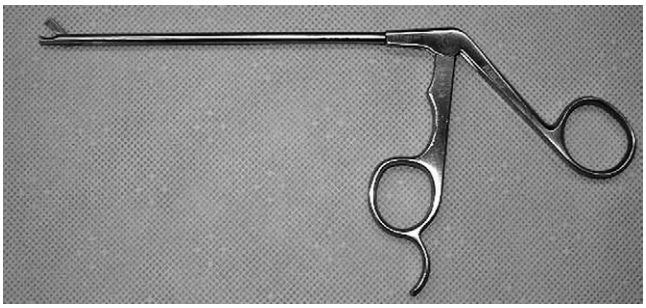

Figure 99-15. Hook scissors used in the cranial arthroscopic approach to the stifle joint.

We have identified multiple benefits to the cranial approach. It permits a controlled and atraumatic entry into the MFT and LFT, thereby decreasing the reported risk of inadvertent meniscal damage from blind trocar insertion. Extravasation of fluid into the periarticular tissues, which renders the surgical approach difficult, appears to be less common with the cranial approach. The cranial approach provides equivalent visualization of the femoral and tibial condyles and the cranial aspects of the menisci relative to the other approaches, and it provides an excellent view of the caudal cruciate ligament, which significantly enhances evaluation and débridement of this structure.

A unique feature of the cranial arthroscopic approach is that a large communication is created between the femoropatellar and femorotibial joints. Thus, when curetting medial femoral condylar cysts using this approach, it is important to

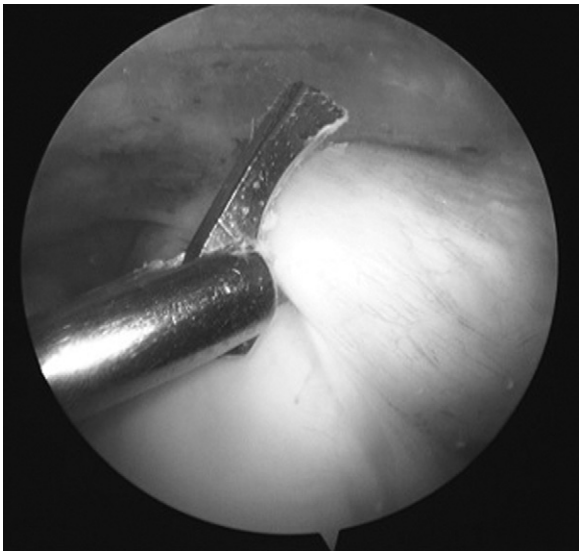

Figure 99-16. Arthroscopic view of the hook scissors engaging the synovium over the cranial and distal aspect of the medial femoral trochlea.

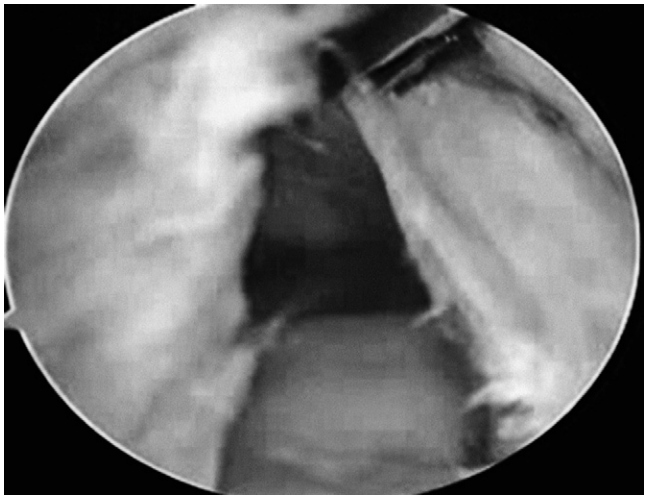

Figure 99-17. Arthroscopic view of the transected synovium located over the cranial and distal aspect of the medial femoral trochlea and the proximal medial femoral condyle. The telescope is advanced through the opening to enter the MFT joint. Limb flexion is also used to enhance the view of the condyle.

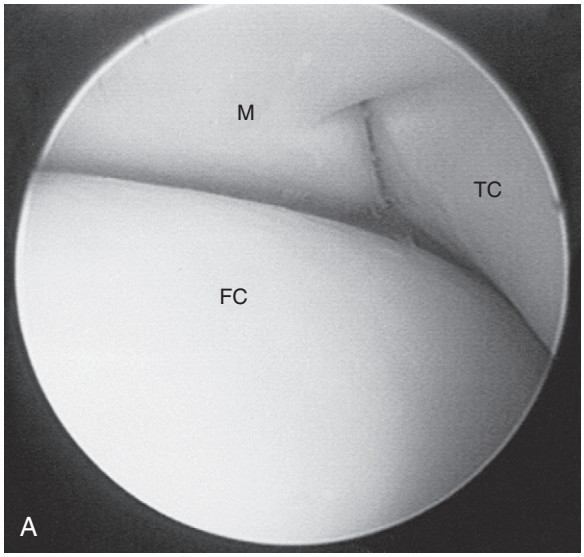

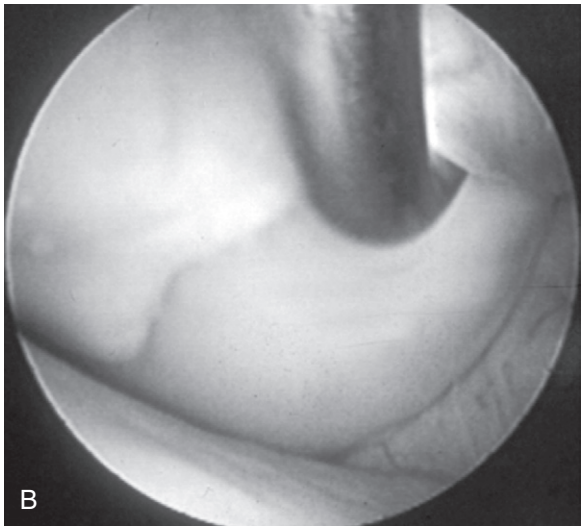

Figure 99-18. A, Arthroscopic view of the cranial pouch of the MFT joint as viewed from the lateral approach showing the medial femoral condyle *(FC)*, the medial meniscus *(M)*, and the tibial condyle *(TC)*. **B,** A probe can be used to elevate the cranial pole of the meniscus and meniscotibial ligament, exposing the medial tibial condyle.

remember to take care to prevent a significant amount of debris from falling into the FPT. It is therefore important to explore the suprapatellar pouch before exiting the joint with the arthroscope.

In cases of synovial sepsis, the cranial approach eliminates the natural synovial barriers between compartments, and care should be taken to avoid contaminating compartments that are not already affected. However, as compartment communication rates are highly variable, each case must be considered individually, and the cranial approach is particularly beneficial for sepsis of the LFT, as access to the sulcus muscularis, a common location of fibrin and debris accumulation, is improved.

The lateral approach is used by many surgeons to evaluate the cranial MFT. The arthroscope portal is located caudal to the lateral patellar ligament, cranial to the long digital extensor tendon, and 2 cm proximal to the tibial crest. With a No. 11 blade, the portal is made through the skin and the deep fascia. Using a blunt trocar, the arthroscopic cannula is directed mediad to penetrate the synovial membrane in the lateral aspect of the MFT (see Figure 99-12). Using this approach, the instrument portal is placed using needle guidance approximately halfway between the tibial crest and the patella and midway between the medial and middle patellar ligaments. This allows examination of the cranial meniscotibial ligament, the cranial aspects of the medial meniscus and tibial condyle, and the weight-bearing surface of the femoral condyle (Figure 99-18). The caudal cruciate ligament can be seen under the synovial membrane (Figure 99-19). Occasionally, the tibial attachment of the cranial cruciate ligament is seen if the synovial membrane of the septum is disrupted.

Figure 99-19. Arthroscopic view of the tibial attachment of the caudal cruciate ligament observed through the synovial membrane *(center).*

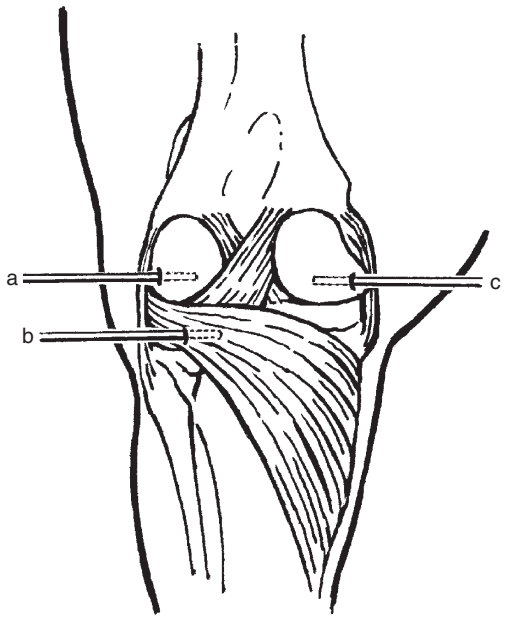

Figure 99-20. Schematic representation of the arthroscopic portals used to explore the caudal pouches of the MFT and LFT. *a,* The portal to the proximal pocket of the lateral caudal pouch is located at the level of the lateral femoral condyle, 2.5 cm proximal to the distal level of the lateral meniscus and 3 cm caudal to the lateral collateral ligaments; *b,* the portal to the distal pocket of the lateral caudal pouch is located at the level of the lateral meniscus, through the popliteal tendon, 1.5 cm caudal to the lateral collateral ligament; *c,* the medial portal is located at the level of the medial femoral condyle, 1 cm proximal to the distal level of the medial meniscus and 3 cm caudal to the medial collateral ligament.

Examination of the caudal pouch of the MFT is best accomplished by locating the arthroscope portal 1 cm proximal and parallel to a line drawn from the tibial crest to the medial condyle of the tibia and 3 cm caudal to the medial collateral ligament[6] (Figure 99-20). Spinal needle placement and distention of the joint to confirm adequate portal location and trajectory for canula/trocar placement is beneficial. The entire caudal aspect of the medial femoral condyle and the proximal aspect of the medial meniscus can be examined (Figure 99-21). The caudal cruciate ligament is located extrasynovially and can be located with a probe through the synovial lining. A similar but more caudal approach, 6 to 8 cm caudal to the medial collateral ligament (1 to 2 cm cranial to the medial saphenous vein, and cranioproximal to the palpable gracilis muscle) allows greater visualization of the axial aspect of the medial meniscus and caudal cruciate ligament.[49]

A cranial intercondylar approach is described for examination of the axial caudal MFT. This approach may be useful when increased visualization of the caudal axial aspect of the medial femoral condyle, the caudal cruciate ligament, and the caudal medial meniscotibial ligament is required.[50,51] With the stifle flexed at 90 to 100 degrees, the scope is inserted with the portal placed between the medial and middle patellar ligaments.[48] The location of the second portal is determined by visualization of a spinal needle advancing into the intercondylar space between the caudal cruciate ligament and medial femoral condyle from just proximal and caudal to the intercondylar eminence. The site of the portal is generally just lateral to the middle patellar ligament, 50% to 60% of the distance from the tibial crest to the patella. A smooth shafted conical obturator is visually guided as described earlier for the spinal needle, and the arthroscope canula is placed over the obturator. Puncture of the caudal joint capsule, scoring of the medial femoral condyle in the intercondylar space, and periarticular fluid accumulation are frequently encountered though of little apparent clincal significance. A caudomedial instrument portal can be created as described earlier for débridement of lesions.

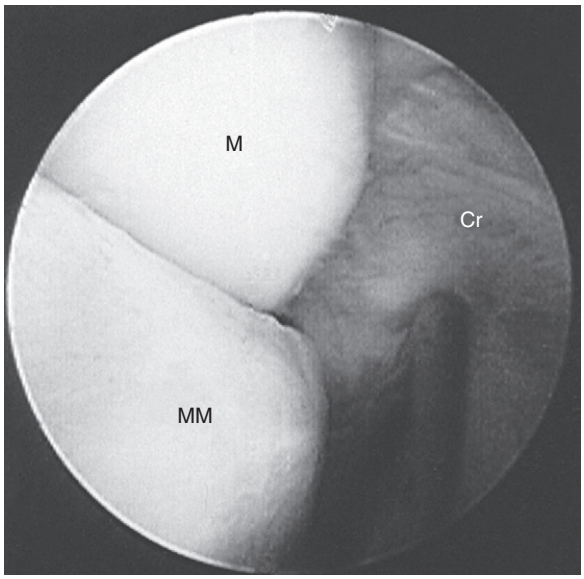

Figure 99-21. Arthroscopic view of the caudal pouch of the MFT joint of the stifle showing the medial femoral condyle *(M),* the medial meniscus *(MM),* and a probe placed on the caudal cruciate ligament *(Cr)* located behind the synovial membrane.

Lateral Femorotibial Compartment

Arthroscopy of the cranial pouch of the LFT is generally performed via a cranial or medial approach. The cranial approach, as described earlier for the MFT, may be used to enter the LFT at the distal end of the lateral trochlear ridge. Arthroscope portals in the FPT may be placed as described earlier, because the arthroscope does not need to be removed from its medial position to be driven into the LFT after the incision is made with the hook scissors at the distal end of the lateral trochlear ridge. Improved exploration of the sulcus muscularis containing the long digital extensor tendon and peroneus tertius is achieved with the cranial approach.

The arthroscope portal for the medial approach to the cranial pouch of the LFT is best located midway between the patella and the tibial crest and halfway between the medial and middle patellar ligaments. The arthroscope is directed caudolaterally to enter the LFT. The cranial cruciate ligament is seen from this approach lying in the medium septum. The lateral femoral condyle, the lateral meniscus, the cranial lateral meniscotibial ligament, and the lateral tibial condyle can be visualized, but this pouch is smaller than the cranial pouch of the MFT, and thus manipulation of the arthroscope is more limited. The opening into the distal synovial diverticulum (the sulcus muscularis) of the long digital extensor tendon and peroneus tertius can be seen; however, exploration of this compartment distad along the tendon is only accomplished through a cranial approach. Collection of fibrin and debris in this diverticulum with synovial sepsis is common, and thus its débridement and lavage is important.

The arthroscope portal that permits the best examination of the proximal pocket of the caudal pouch of the LFT is located 2.5 cm proximal and parallel to a line drawn from the tibial crest to the lateral condyle of the tibia and 3 cm caudal to the lateral collateral ligament (see Figure 99-20, *A*).[6] Spinal needle placement and distention of the joint to confirm adequate portal location and trajectory for canula/trocar placement is beneficial, as for all caudal approaches to the stifle. Most of the caudal aspect of the lateral femoral condyle and tendon of the popliteus muscle can be examined intrasynovially. Rotation of the tarsus laterally (clockwise rotation of the right hindlimb) loosens the popliteal tendon and creates a tunnel. Insertion of the arthroscope into the tunnel still does not permit visualization of the lateral meniscus or of the tibial condyle.

The arthroscope portal that permits examination of the distal pocket of the caudal pouch of the LFT is located on a line drawn from the tibial crest to the lateral condyle of the tibia and 1.5 cm caudal to the lateral collateral ligament (see Figure 99-20, *B*). Entrance at this level is directly through the popliteal tendon, permitting examination of the caudal lateral meniscus, part of the caudal aspects of the lateral femoral and tibial condyles, and the intra-articular portion of the popliteal tendon (Figure 99-22). Care should be taken when approaching the caudal pouch of the LFT to avoid damage to the common peroneal nerve, which is located less than 7 cm caudal to the lateral collateral ligament. Additionally, the popliteal artery and vein are situated directly between the medial and lateral femoral condyles on the caudal aspect of this joint (see Figure 99-9). Therefore, it is not safe to pass from one pouch to the other across the caudal aspect of the joint without risk of injury to this vasculature, which is the major deep blood supply to the stifle.[52]

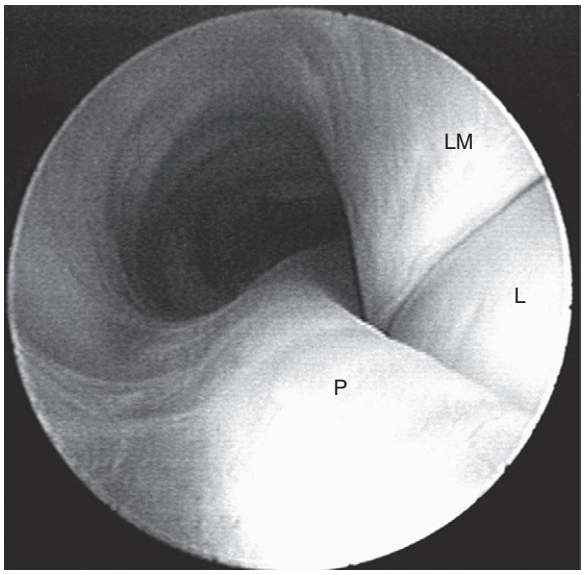

Figure 99-22. Arthroscopic appearance of the distal pocket of the caudal pouch of the LFT, which permits examination of the caudal aspect of the lateral meniscus *(LM)*, part of the caudal aspect of the lateral femoral condyle *(L)*, and the intra-articular portion of the popliteal tendon *(P)*.

DISORDERS OF THE STIFLE

Many stifle disorders present significant sources of acute or chronic lameness for equine athletes. Developmental or traumatic etiologies for these lesions are commonly suspected or identified. The most commonly identified stifle disorder, osteochondrosis, traditionally classified as a developmental condition, is believed to have an element of trauma in its pathogenesis. Soft tissue lesions are a significant source of lameness in other species, and recognition of these lesions in horses is increasing. Osteoarthritis commonly develops secondary to stifle joint pathologies or injuries that lead to joint instability or cartilage trauma and inflammatory mediator release. However, primary development of stifle joint osteoarthritis may be seen without identification of underlying pathologies.

Osteoarthritis

Early signs of osteoarthritis in the equine stifle are most commonly recognized as cartilage damage over the medial femoral condyle, which occurs secondary to joint injury or trauma.[53] These lesions produce lameness in the horse, and diagnostic arthroscopy may be necessary to make an accurate diagnosis.[54] Therefore, horses with lameness localized to the stifle through diagnostic anesthesia or scintigraphy that had no significant radiographic and ultrasonographic findings are good candidates for arthroscopic exploration of the joint. Débridement of focal cartilage lesions allows some horses to successfully resume performance activities.

Numerous small horizontal clefts in the cartilage over the weight-bearing surface of the medial femoral condyle represent pathologic lesions recognized as a source of lameness and poor performance, particularly in Quarter Horses (Figure 99-23). Lesions are generally only identified on arthroscopic examination. Débridement of the lesions would require extensive removal of articular cartilage and thus is generally not

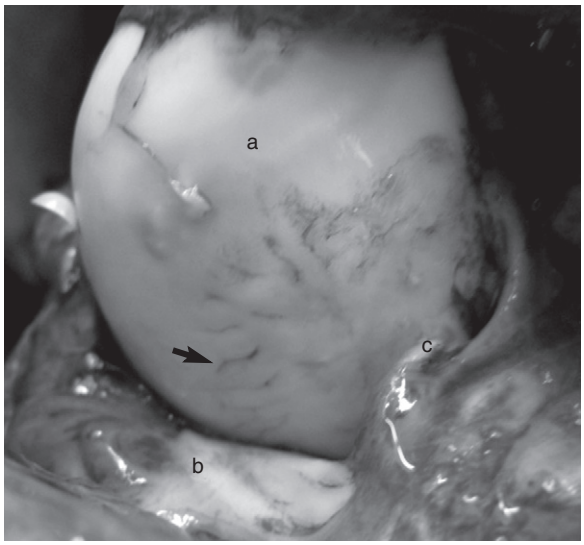

Figure 99-23. Postmortem dissection showing horizontal clefts *(arrow)* in the articular cartilage on the weight-bearing surface of the medial femoral condyle *(a)*. *b,* Cranial horn of the medial meniscus; *c,* medial intercondylar eminence of the tibia.

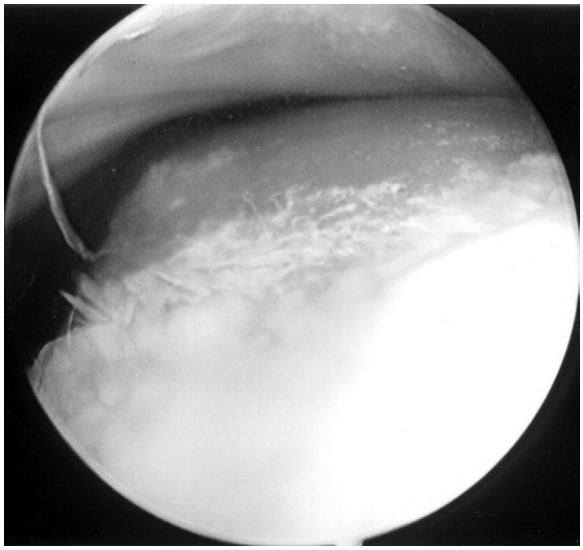

Figure 99-25. Arthroscopic appearance of advanced osteoarthritis of the medial femoral condyle. Articular cartilage débridement was accomplished using a motorized resector.

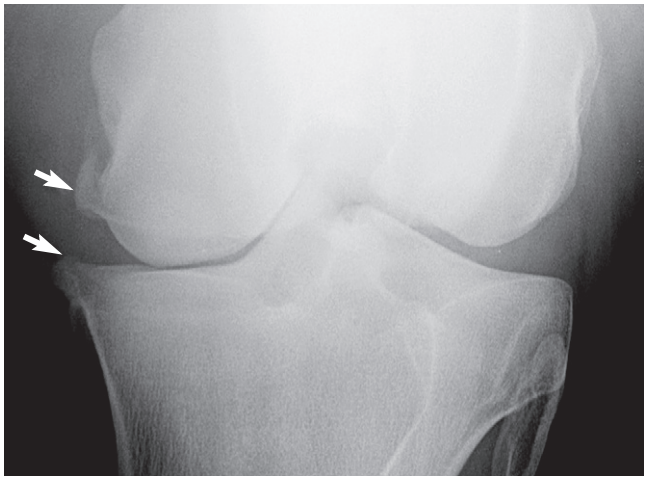

Figure 99-24. A caudocranial radiographic view of a stifle with advanced osteoarthritis showing narrowing of the MFT joint space and large enthesiophytes on the distal femur and proximal tibia *(arrows).*

completed. If recognized early, the lesions may improve with prolonged rest (i.e., 4 to 6 months), although the prognosis for long-term soundness is poor. In our opinion, continued training (with corticosteroid joint injection) is contraindicated because irreversible rapid progression of the cartilage degeneration is likely to occur.

Osteoarthritis of the stifle in the later stages is best detected on a craniocaudal radiograph when the FPT is involved and manifests as articular osteophyte formation, flattening of the articular surfaces, sclerosis of the subchondral bone, or lucent zones in the subchondral bone. Lipping (osteophyte formation) of the medial tibial plateau is most commonly the first recognizable radiographic sign of femorotibial osteoarthritis. Narrowing of the femorotibial joint space is seen in advanced cases (Figure 99-24). Positioning is important when making this determination; the horse should be bearing weight, with the limb centered under the body during this view. The lateromedial view best demonstrates FPT osteoarthritis, which is seen as periarticular osteophyte formation and changes along the distal aspect of the patella. Treatment for osteoarthritis of the stifle involves evaluation for and potentially treatment of any underlying pathologies (i.e., meniscal tears), followed by palliative treatment of the arthritis. As with all other arthritic conditions, treatment is directed at decreasing pain/inflammation and chondroprotection with intra-articular and systemic medications. Because of the size of these synovial compartments (with volumes between 40 and 62 mL), intra-articular medications must be of sufficient quantity to be effective.

Osteoarthritis is commonly established in the femorotibial joint secondary to meniscal or ligamentous injury; however, advanced cases of osteoarthritis with complete erosion of articular cartilage from the medial femoral condyle can be seen (particularly in aged racing Standardbreds) without evidence of other soft tissue injury (Figure 99-25). Treatment of this condition by arthroscopy may include articular cartilage débridement and micropick techniques (Figure 99-26). Microfracture has been shown to improve healing in full-thickness chondral defects of the medial femoral condyles.[55] Significant research into cartilage healing and resurfacing techniques has been completed including evaluation of autologous chondrocyte/cartilage fragment transplantation via a collagen membrane or polydioxanone scaffold,[56,57] interleukin-1 receptor antagonist/insulin-like growth factor-1 gene therapy,[58] and arthroscopic mesenchymal stem cell implantation (see Chapter 80).[59] Positive results from these studies indicate that greater availabilty and application of these techniques may be valuable.

Cartilage lesions on the articular surface of the patella are referred to as *chondromalacia* (Figure 99-27). These changes may be seen as a part of diffuse degenerative joint disease occuring within the stifle. The pathogenesis and significance of this condition in the horse are uncertain, but arthroscopic débridement of cartilage fragmentation using minimally traumatizing motorized cartilaginous débriders generally results in clinical improvement.

Figure 99-26. Arthroscopic appearance of the medial femoral condyle showing micropick technique.

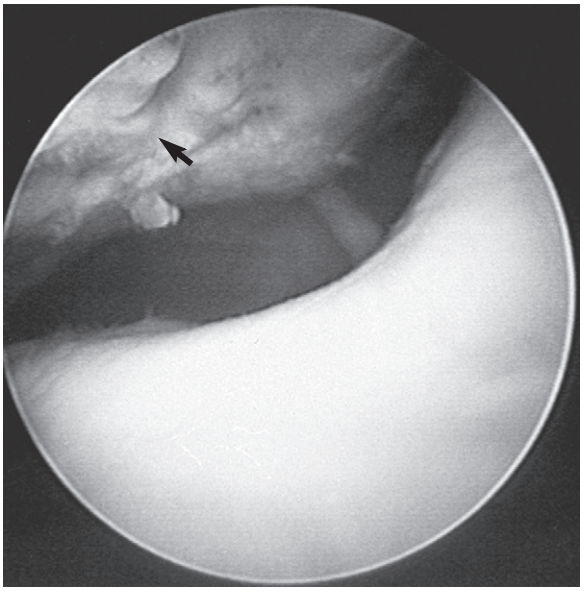

Figure 99-27. Arthroscopic appearance of chondromalacia of the patella *(arrow)*. The intertrochanteric fossa of the femur is seen ventrally.

Soft Tissue Disorders

In addition to collateral ligaments common to most joints, the stifle of the horse includes five ligaments associated with the menisci, cranial and caudal cruciate ligaments, and three patellar ligaments. All the soft tissues of the stifle are subject to sprains and tears.

Collateral Ligament Injury

The femorotibial joint has two large collateral ligaments at its medial and lateral aspect. They orignate on the femoral epicondyles and insert on a roughened area just distal to the margin of the tibial condyle (medial) and the head of the fibula (lateral). Both ligaments consist of a single bundle of fibers, in comparison to a deep and superficial portions as seen in the medial collateral ligament of humans. In my experience, the medial collateral ligament (MCL) has fibers from its cranial aspect insert into the adjacent abaxial aspect of the medial meniscus in approximately 15% of horses, whereas the lateral collateral ligament (LCL) has no attachment to the lateral meniscus. The popliteal tendon runs under the LCL with a bursa interposed between the two. A second bursa is present between the LCL and the tibial plateau.

Collateral ligaments of the femorotibial joint may undergo partial or complete tearing.[60-62] Diagnosis may be evident in acute cases with abnormal range of motion and/or ultrasonographic changes. Radiographs may be obtained with the joint under lateral or medial stress to confirm unilateral widening of the femorotibial space when complete rupture is suspected. Sprain of these ligaments can result in enthesiophyte formation at their attachments on the distal femur and proximal tibia.

Treatment for this condition involves anti-inflammatory medication and rest. Healing should be monitored by periodic ultrasonographic examinations. Surgical repair of a complete MCL rupture has been attempted with unsuccessful long-term results, and thus euthanasia is often recommended.[60,62] The prognosis for horses undergoing partial tearing is guarded to favorable, depending on the degree of tearing and instability of the joint.[63]

Concurrent injury of the menisci or cruciate ligaments commonly occurs in horses with severe injuries or complete rupture of a collateral ligament. The MCL and medial menisci are more commonly involved than the lateral aspect of the stifle. When concurrent structures, such as the cruciate ligaments or menisci, are involved, the prognosis is unfavorable for return to athletic use.

Patellar Ligament Injury

The lateral, middle, and medial patellar ligaments transmit the pull of the quadriceps muscle to the tibia through their origin on the distal patella and insertion on the tibial tuberosity. Patellar ligament disease has been recognized as a primary injury, with jumping horses appearing to be over-represented.[64] Injury to the patellar ligaments should be kept in mind for hindlimb lameness that cannot be blocked out (or shows only mild improvement with intra-articular stifle anesthesia), and the patellar ligaments should be carefully palpated with the limb loaded and unloaded. Ultrasonography is the best diagnostic tool for evaluating the patellar ligaments. Nuclear scintigraphy may localize a lameness to this region; however, false positives with scintigraphy have been recognized.[64] Based on a small number of horses with patellar ligament injury, the prognosis for complete recovery with conservative management is guarded.[64] Evaluation of the patellar ligaments in relation to upward fixation of the patella is discussed later in this chapter.

Cruciate Ligament Injury

The cranial cruciate ligament arises from the lateral wall of the intercondyloid fossa of the femur and runs craniad and distad ending on the central fossa of the tibial spine. The caudal cruciate ligament runs medial to the cranial cruciate ligament, and it arises in the cranial aspect of the femoral intercondyloid fossa, inserting on an eminence at the popliteal notch of the tibia. Both cruciate ligaments are extrasynovial between the MFT and

LFT. The cruciate ligaments may undergo partial or complete tearing and represent a recognized, although relatively uncommon, condition of the equine stifle. The cruciate test may be attempted in cooperative horses, but it is rarely diagnostic because of guarding of the limb. Complete rupture of the cranial cruciate ligament, or less commonly the caudal cruciate ligament, carries an unfavorable prognosis for the horse's return to athletic function.[65-68] Lameness from severe tears may improve over time, but often extensive osteoarthritis prohibits even salvage of the horse as a breeding animal.

Partial tearing of the cranial cruciate ligament occurs most commonly at the mid-body segment, but partial detachment of its insertions can occur. The cranial cruciate ligament is under tension when the stifle joint is in extension, and subsequently hyperextension and/or rotation of the stifle joint are suspected to be involved in its injury. Radiographs may identify enthesiophyte formation or occasionally an avulsion fracture of the medial intercondylar eminence of the tibia (MICET) or, more rarely, the femoral attachment (see Figure 99-5). Fractures of the MICET may be seen with relatively little disruption of the cruciate ligament, and thus some of these fractures may be caused by a traumatic lateral force from the medial femoral condyle as compared to the more typical pathogenesis of avulsion fractures. Proliferative bone changes at the MICET (best seen on a flexed lateromedial radiograph) may be present in chronic cases and was seen in 7% of cruciate injuries in one study.[62] Subchondral cystic lesions can develop at the sites of origin and insertion of the cruciate ligaments over time.

A definitive diagnosis is made after arthroscopic examination of the femorotibial joint. Owners should be warned prior to surgery of the risk that a partial cruciate tear may progress to a complete tear upon recovery from anesthesia, and a smooth, assisted recovery should be executed. A lateral or cranial approach to the MFT may be used, and the septum between the two cranial compartments typically have been ruptured with the traumatic injury, allowing examination of the typically extrasynovial cruciate ligaments through this approach (Figure 99-28). Treatment involves débridement of the damaged ligamentous tissue and bone fragments. Successful repair or replacement of complete tears has not been reported in horses.

Secondary cartilage disease was seen in 61% of cases in one study, and recovery rates for grade I, II, and III lesions were 46%, 59%, and 33%, respectively.[62] With regard to MICET fractures, removal and débridement of a large MICET fragment and sprain of about 25% of the tibial insertion of the cranial cruciate ligament in one horse[69] and internal fixation of a MICET fracture in another horse[70] have been reported with successful outcomes. In our experience, a majority of horses with minor superficial cranial cruciate tearing (Figure 99-29) can return to previous degrees of activity. However, when the damage becomes moderate and approaches disruption of greater than 50% of the ligament, or when there are multiple lesions in the joint (i.e., a meniscal or collateral ligament tear) the prognosis is unfavorable.

Figure 99-28. Endoscopic view of a torn cranial cruciate ligament as viewed from the cranial approach to the MFT. A probe easily separates the fibers of this ligament.

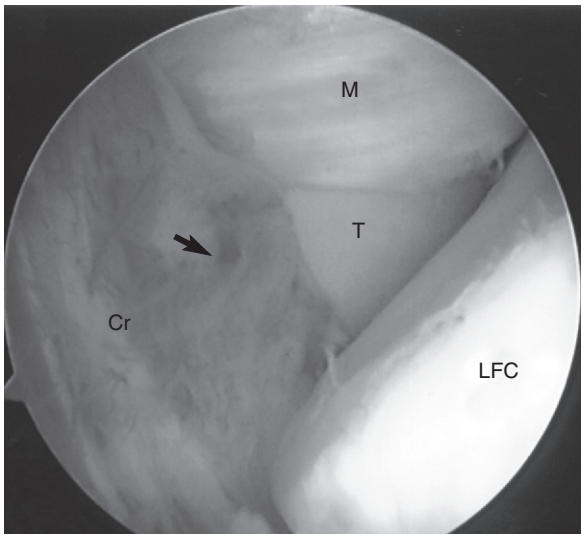

Figure 99-29. Arthroscopic appearance of a minor tear *(arrow)* in the cranial cruciate ligament *(Cr)* as seen in the LFT. The lateral femoral condyle *(LFC)* and the meniscotibial ligament *(M)* and tibial condyle *(T)* are visible.

Meniscal Injury

The menisci are paired semilunar fibrocartilaginous discs interposed between the convex femoral and relatively flat tibial condyles. Four meniscotibial ligaments at the axial aspects of the cranial and caudal horns are the sites of attachment to the tibia and an additional meniscofemoral ligament attaches the caudal horn of the lateral meniscus to the femur. One report documented meniscal tears as the most common soft tissue lesion in the stifle, as they were diagnosed in 68% of soft tissue stifle cases.[24] History may include trauma or a fall, but an insidious onset is common. Lameness is generally more severe initially and mild to moderate on average at the time of presentation.[62] Only about 39% of cases show joint effusion and only 66% show increased lameness with high flexion tests, and thus intra-articular anesthesia is frequently necessary to definitively localize the lameness to the stifle. Severe traumatic injuries may additionally result in injury to other major structures, such as the collateral ligaments and/or the cruciate ligaments, although primary meniscal injuries are more common.[62,68,71] Approximately half of all cases show radiographic changes including new bone at the medial

intercondylar eminence of the tibia (29%), generalized osteoarthritic changes (23%), and mineralization of the meniscus (8%).[72] With severe disruption of the meniscus, collapse of the femorotibial joint space may be evident on caudocranial radiographs. Ultrasonography is beneficial for recognition of meniscal tears, but the specificity and sensitivity of this technique are less than optimal.[24] Large bore MRI's have proven to be valuable in determining the extent of meniscal injury and assessing concurrent lesions.[32] (See "Diagnostic Imaging," earlier.) Arthroscopy (see Figure 99-28) allows direct visualization and assessment of the lesion, but horizontal tears and tears in a large portion of the abaxial menisci cannot be visualized.

Clinically, an isolated lesion of the cranial horn of the medial meniscus and its associated meniscotibial ligament is the most commonly arthroscopically identified site of meniscal lesions in horses.[62,72] The medial meniscus is involved in 79% of cases, and unlike meniscal tears in dogs and humans, only 14% of equine meniscal tears were associated with cranial cruciate ligament injury.[62] Horses with severe trauma and multiple soft tissue structure injury may be more likely to be euthanized prior to arthroscopy and definitive diagnosis, and thus may be underrepresented in case series studies. A grading system for cranial meniscal tears has been established[72]:

Grade I: Tears extending longitudinally down the cranial meniscotibial ligament into the cranial horn of the meniscus with minimal separation of tissues (Figure 99-30).
Grade II: Tears of similar orientation to grade I tears but with further separation of tissue, where the extent of the injury remains fully visible on arthroscopic exam.
Grade III: Severe tears that extend beneath the femoral condyle and cannot be fully visualized arthroscopically (Figures 99-31 and 99-32).

Diffuse degenerative changes to the menisci, particularly the axial aspect of the medial meniscus, have been identified with concurrent osteoarthritis of the femorotibial joint in older horses on postmortem examination and may be more common than currently diagnosed.

Treatment for equine meniscal tears consists of arthroscopic débridement (partial meniscectomy using motorized meniscal resectors) via a lateral, medial or cranial approach. Suturing of meniscal tears has been documented as difficult and

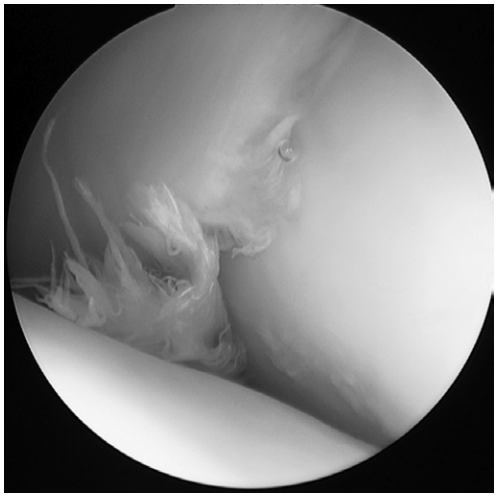

Figure 99-30. Example of a grade I meniscal tear that can be resected.

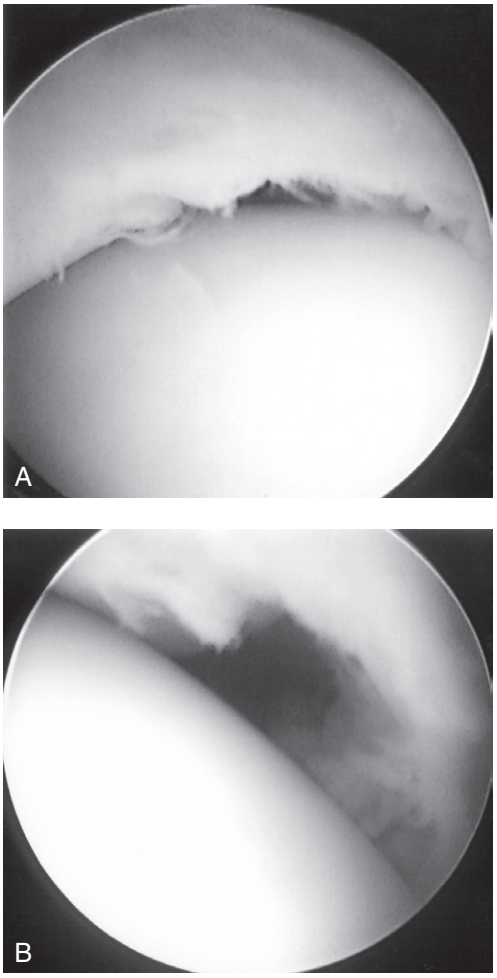

Figure 99-31. The arthroscopic appearance of a chronic medial meniscal tear before **(A)** and after **(B)** meniscal débridement.

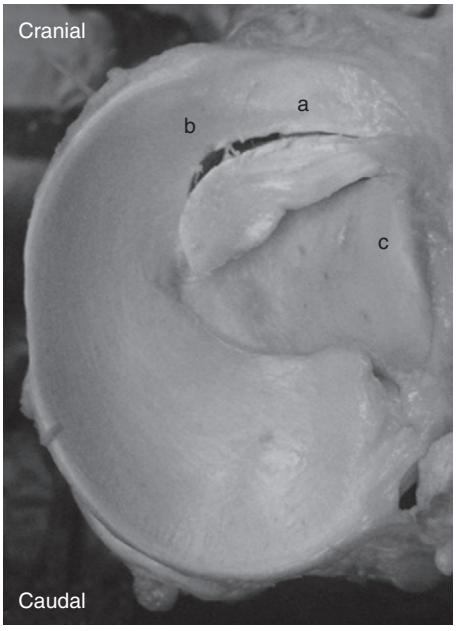

Figure 99-32. Proximal to distal view of the medial meniscus from the right stifle of a cadaveric specimen used to model a grade III meniscal tear. unsuccessful, although successful outcomes have been reported.[48,73] Typical postoperative recovery consists of 6 weeks of stall rest with hand-walking, and at least 6 months of small paddock rest, depending on the severity of injury.

Return to previous athletic function was seen in 63% of horses with grade I tears, 56% with grade II, and 6% with grade III cranial horn meniscal tears.[72] Articular cartilage disease was seen in 71% of cases at the time of diagnosis and had a negative effect on long-term prognosis. Loss of the equitable load transmission function of the meniscus may lead to secondary cartilage injury, particularly in the central portion of the medial femoral condyle. Radiographic changes, such as dystrophic mineralization of the meniscus, also appear to lower the prognosis of return to athletic function. Severe injuries involving multiple structures generally have a poor prognosis. Of 19 horses with meniscal tears and subchondral bone cysts diagnosed concurrently or sequentially, only 4 had a successful outcome.[74]

The pathogenesis of primary meniscal tears has not been clearly delineated, but research indicates that hyperextension leading to significant compression and cranial displacement of the cranial horn of the medial meniscus may place this region at greater risk of injury.[75] Potential etiologies for meniscal injury in association with medial femoral condyle subchondral cystic lesions include a single traumatic incident resulting in both lesions, or alterations in femoral condyle geometry and/or the resultant rim of bone at the débrided defect, resulting in meniscal trauma.[74]

Fractures

Patella

The patella is the largest sesamoid bone in the body and an integral portion of the quadriceps apparatus. Fractures of the patella are most commonly the result of direct trauma to the stifle from jumping over a fixed object or a kick from another horse. Patellar fractures result in variable lameness, soft tissue swelling, and effusion, depending on the amount and configuration of the fracture. Horses with patellar fractures commonly hold the limb in partial flexion, resting the limb with the toe touching the ground, and walk with a careful but weight-bearing gait. Radiographic evaluation should include not only the craniocaudal, lateromedial, flexed lateromedial, and caudal 30-degree lateral craniomedial oblique views but also the craniproximal craniodistal (skyline) view of the patella to thoroughly assess the fracture. Patellar fracture morphology is highly variable; however, sagittal fractures are most common and usually involve the medial aspect of the patella (see Figure 99-8). Fragmentation of the distal aspect of the patella is most commonly associated with medial patellar ligament desmotomy.

Techniques for partial patellectomy and internal fixation have been described; however, fractures located at the base of the patella commonly do not require surgical intervention (Figure 99-33).[76-78] Surgery should be attempted only if there is complete disruption of the quadriceps apparatus (i.e., inability to extend the stifle), the fracture gap is greater than 5 mm on radiographs, there is obvious malalignment of an articular fragment, or the fragments can be palpated under the skin. One should allow the swelling to decrease before surgical intervention is attempted. Medical management of a patella fracture should include administration of nonsteroidal anti-inflammatory drugs for 2 weeks and stall confinement for 2 to 3 months.

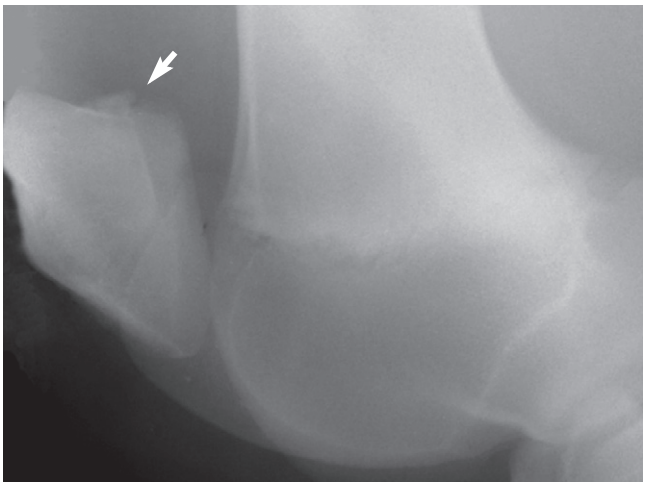

Figure 99-33. Lateromedial radiographic view of the stifle showing a fracture at the base of the patella *(arrow)*.

When there is disruption of the quadriceps apparatus or a very large displaced articular fragment, internal fixation is indicated (Figure 99-34). Screw fixation using lag technique with 5.5 mm cortex screws and/or application of small DCP or LCP plates may be performed via arthrotomy or arthroscopy of the FPT. Partial patellectomy is indicated in sagittal medial articular fractures.[79,80] This can be carried out by removing up to one third of the patella arthroscopically. Portal placement should be about one third to one half of the distance between the distal aspect of the patella and the proximal tibia; portal placement too close to the patella makes it difficult to view fractures on its distal aspect. A mechanical resector and an arthroscopic scalpel are essential tools to separate the fragment from the parent bone. With an osteotome, the fragment is divided into smaller fragments, which subsequently are removed with Ferris-Smith rongeurs. Although it is undesirable, it may be necessary to perform an arthrotomy, to dissect the fragment from its extensive patellar ligament attachments. Concurrent direct trauma to the lateral trochlear ridge is common, and should be evaluated and débrided arthroscopically. The prognosis after partial patellectomy for sagittal transverse fractures is favorable, with reports of an 83% to 100% return to full athletic function in cases with no pre-existing stifle arthritic changes.[80,81] When the quadriceps apparatus has been disrupted, the prognosis is guarded to unfavorable, depending on the success of the repair.

Femoral Trochlear Ridges

Fractures of the femoral trochlear ridges usually result from external trauma to the stifle and resultant fragmentation of the medial or lataral trochlear ridge.[82] They may occur in concert with patellar fractures. Clinical signs include a sudden onset of moderate to severe lameness and effusion of the FPT. Crepitus may be present on flexion of the joint. The fracture site might not be obvious unless a wound is present; however, the potential for joint sepsis must be investigated when a skin wound is present.

Fracture fragments should be removed, which is generally possible with arthroscopy. Trochlear ridge fractures have a good prognosis after fracture removal, if there is no significant damage

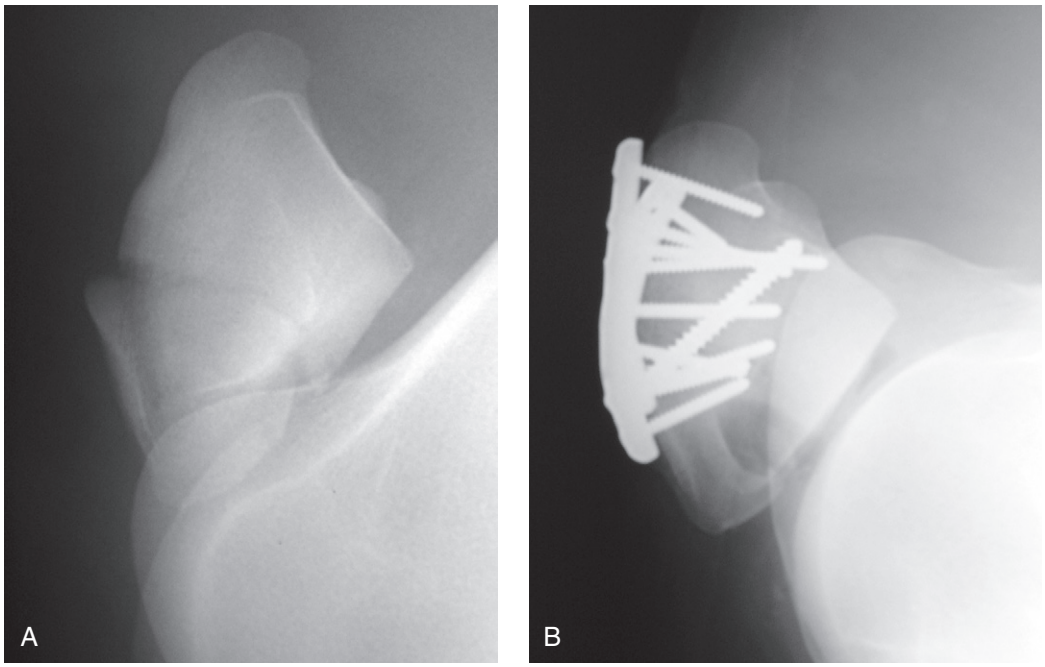

Figure 99-34. A, A lateromedial radiographic view of a patella fracture that resulted in complete disruption of the quadriceps apparatus. **B,** One 5.5-mm cortex screw used in lag fashion and two dynamic compression plates (DCPs) were used in the repair.

to deeper structures or extensive loss of the trochlear ridge. Because it is a non–weight-bearing articular surface where this usually occurs, horses can usually return to complete athletic activity.

Avulsion of the Origin of the Peroneus Tertius and Long Digital Extensor Tendon

The peroneus tertius and long digital extendor tendon arise from a common origin in the extensor sulcus just lateral to the distal aspect of the lateral trochlear ridge. Avulsion of the origin is commonly caused by a sudden forceful hyperextension of the hindlimb, particularly when the distal limb is entrapped. Foals are most likely to suffer avulsion fractures of the peroneus tertius origin, whereas tears of the body or insertion site in the tarsal region is more common in adult horses.[83]

Clinical signs are similar to those found with rupture of the peroneus tertius (see Chapters 83 and 97). However, distention of the femorotibial and femoropatellar joints is a cardinal sign of a proximal avulsion fracture. The condition can be diagnosed radiographically (Figure 99-35).

Treatment is usually initiated by arthroscopic evaluation, which offers the opportunity to examine the stifle for concurrent injury. Arthroscopy of the LFT can be completed via a cranial approach. The subchondral bone in the area of the extensor fossa and origin of the long digital extensor tendon can be débrided and bone fragments removed. Prognosis following this injury is guarded because many horses continue to have some degree of lameness following this injury.[83,84]

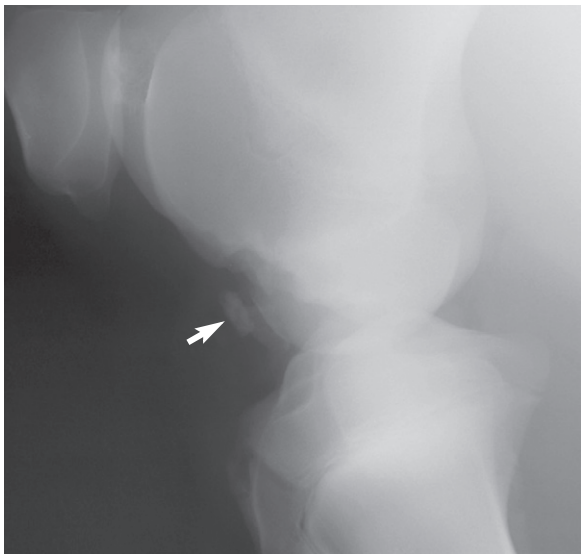

Figure 99-35. Lateromedial view of the stifle in a foal showing avulsion *(arrow)* of the femoral origin of the peroneus tertius and long digital extensor tendon.

Osteochondrosis

Osteochondrosis (OC) is a term used to describe the developmental cartilaginous disease where failure of endochondral ossification results in thickening of the metaphyseal growth plate or the articular cartilage.[85,86] The etiopathogenesis of osteochondrosis and subchondral cystic lesions are discussed in detail in Chapters 88 and 89. For the purpose of discussion in this chapter, OC lesions have been divided into two categories: osteochondritis dissecans (osteochondral fragments) and subchondral cystic lesions (bone cysts).

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is the most common cause of lameness in the stifle, and the FPT is one of the principal sites

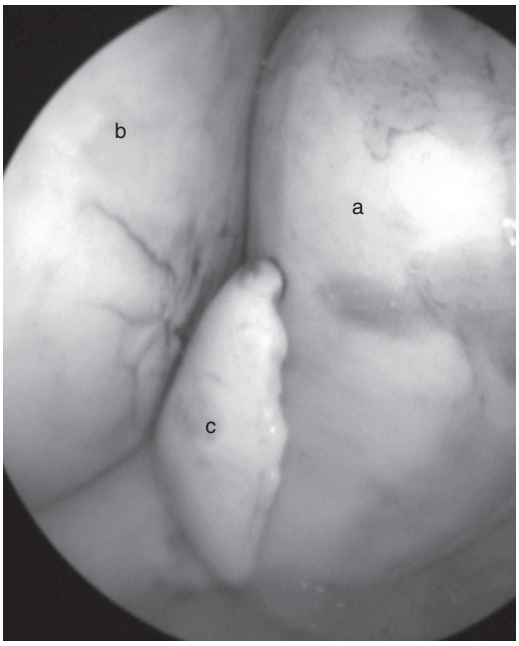

Figure 99-36. Arthroscopic appearance of osteochondritis dissecans of the lateral trochlear ridge *(a)* demonstrating an osteochondral flap *(c)* and an adjacent kissing lesion at the lateral aspect of the patella *(b)*.

of OCD in the horse.[87] The primary area involved is the lateral trochlear ridge of the femur (Figure 99-36). The medial trochlear ridge, the patella, and the trochlear groove are involved less often.[87] Bilateral involvement is common. OCD has been reported in many breeds, but the Thoroughbreds, Quarter Horses, Arabians, and Warmbloods are over-represented. Most cases of OCD are diagnosed in horses between 1 and 2 years of age.

Radiographic examination of Thoroughbreds at yearling sales allowed the prevalence of osteochondrosis of the stifle to be determined in this group.[88] The most common osteochondrosis lesion observed is flattening or fragmentation of the lateral trochlear ridge of the femur (6% of 660 horses).[89] This lesion has a significantly detrimental effect on future performance in racing Thoroughbreds.

Affected horses may present with acute, severe lameness or with a subtle lameness that becomes more obvious with increasing exercise.[85,90] The degree of synovial effusion and lameness varies with the lesion's severity. Young horses and horses that show clinical signs before training usually have more severe lesions from OCD than do those that do not show clinical signs until after training is initiated. In very young horses, the disease can be so severe as to cause difficulty in rising. Flexion test of the stifle usually causes increased lameness.

Radiographs revealing flattening or fragmentation of the trochlear ridge confirm the diagnosis. Foals younger than 5 months of age commonly have irregularity of subchondral ossification of the trochlear ridges that should not be confused with an OCD lesion.[91] Smooth subchondral bone concavities, subchondral bone lysis, and osteochondral flaps and fragments are other lesions that may be seen.[92] Radiographs usually underestimate the severity and the extent of the lesions, especially in foals younger than 9 months of age.[93] Therefore, if signs of stifle OCD are present (FPT distention and lameness), arthroscopic treatment might need to be delayed until radiographic signs are obvious. Generally, lesions are monitored until the foal is older than 9 months of age before surgical intervention is recommended, as many radiographic lesions progress or resolve in this time (see Chapter 88). Ultrasonography of the FPT may identify lesions that cannot be seen radiographically, particularly lesions of the medial trochlear ridge.[94]

The treatment of choice for OCD is arthroscopic removal of osteochondral fragments and undermined cartilage, and débridement of the subchondral bone lesion.[87,90,95] Surgical success rates of 64%[90] to 89%[93] have been reported, without regard to sex, location of the lesions, or bilateral or unilateral involvement. Increased size of the lesion is inversely related to the success rate for return to intended use, as lesions less than 2 cm, 2 to 4 cm, and more than 4 cm had success rates of 78%, 63%, and 54%, respectively.[90] Conservative management of OCD has yielded poor results but might be appropriate under certain circumstances.[96] In one study, early detection and rest allowed lesions to heal and approximately 50% of horses were able to race; however, these animals tended to have less-severe lesions and no joint fragmentation. Arthroscopic reattachment of relatively smooth OCD cartilage flaps in the FPT with resorbable polydioxanone pins has been reported to have a good success rate.[97]

Subchondral Bone Cysts

Subchondral bone cysts (SBCs) of the medial femoral condyle (MFC) are a common cause of hindlimb lameness. SBCs or cystlike lesions are also recognized, although rarely, in the lateral femoral condyle,[98] the proximal tibia,[99] and the patella.[100] There are two commonly proposed etiologies of SBC: developmental orthopedic disease in the form of osteochondrosis and articular cartilage/subchondral bone trauma.[101,102] SBCs have been induced by surgically creating a defect in the subchondral bone of the weight-bearing portion of the MFC.[102] For more information on SBCs, review Chapter 89.

Medial femoral condylar SBCs develop unilaterally in most cases but can be seen bilaterally. Affected horses can be from a few months of age to aged, mature horses, with most cases diagnosed in horses between 1 and 3 years of age. Lameness is the primary clinical sign and flexion tests of the stifle may increase the lameness, but the change is usually not dramatic. The condition is commonly observed as a stiffness in the limb or a reluctance to flex the limb at a walk or trot, and circling the horse in a trot toward the affected limb generally increases the lameness.

Synovial distention may be difficult to detect and the condition generally shows some, although variable, improvement with intra-articular anesthesia; thus radiographic examination provides a definitive diagnosis (see Figure 99-7).[47] Bilateral caudocranial and lateromedial projections are important to assess the nature of the SBC and to evaluate for bilateral lesions.[103] The size of the lesions on the radiographs can vary from a flattened condyle to a slight indentation in the subchondral bone surface to a round or oval lesion a few centimeters in height and width (grading systems are documented[104,105]). There is usually a communication of the cyst with the joint (a cloaca) that can range from being very narrow to quite broad.

The size of the lesion and the amount of articular cartilage involvement has been suggested to correlate with clinical signs and prognosis (70% returned to racing with less than 15 mm

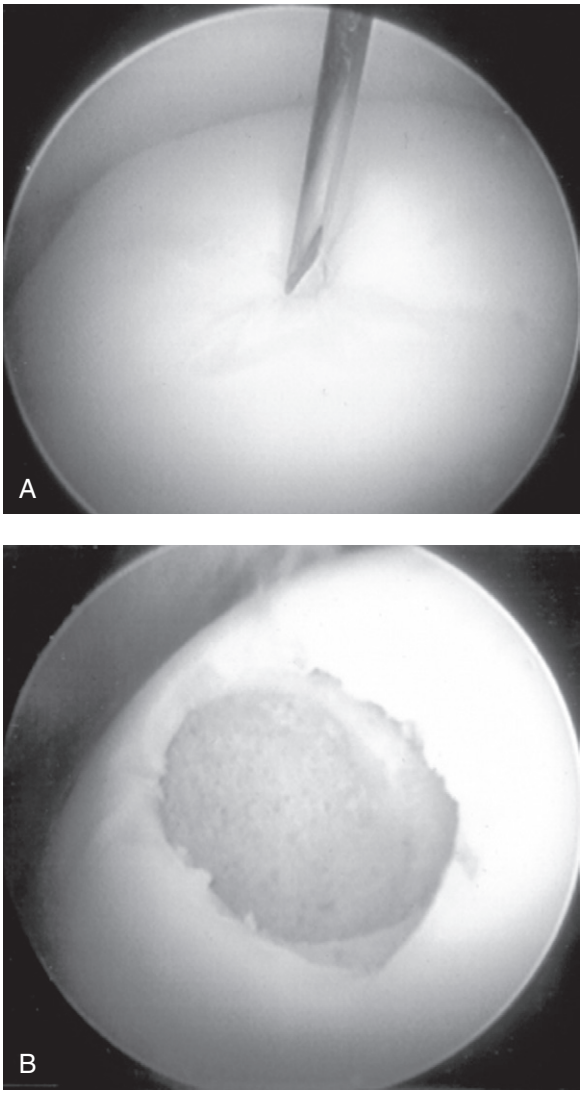

Figure 99-37. A, Arthroscopic appearance of a subchondral bone cyst of the medial femoral condyle showing the typical narrow opening at the articular surface. **B,** Appearance of the medial femoral condyle after débridement of the cyst.

surface débridement versus 30% with more than 15 mm[106]), but this finding has not been confirmed in all studies.[104,106]

Historically, the recommended treatment for this condition has been arthroscopic débridement of the lesion. Débridement of the cyst lining and removal of all debris from the joint is the goal (Figure 99-37). Surgical débridement of small condylar defects that are asymptomatic is contraindicated because it can provoke an enlargement of the cyst; intralesional corticosteroid injection (discussed later) may be beneficial in these cases. Horses with hindlimb lameness localized to the stifle that have subtle MFC radiographic changes (i.e., flattening of the condyle) warrant arthroscopic evaluation because cartilage and subchondral lesions were identified in 24 of 26 such limbs.[107] Subchondral bone drilling of débrided lesions is contraindicated because it may result in enlargement of the lesion.[104]

The success rates reported for return to previous function after surgical débridement of SBC ranges from 64% to 95%.[104,106,108] Following surgical débridement, 64% of Thoroughbreds raced, compared to 77% of siblings.[106] One study reported a 64% return to soundness in horses younger than 3 years of age, compared to 35% in horses older than 3 years of age.[109] More extensive cartilage damage was associated with a decreased odds of return to soundness and was more commonly identified in the group older than 3 years. Concurrent or sequential correlation of SBCs with meniscal tears is associated with a poor prognosis.[74]

Multiple grafting techniques have been developed and evaluated for their ability to accelerate and improve healing of the débrided SBC lesion. Compacted cancellous bone grafting did not result in an improvement in the outcome.[110,111] Mosaic arthroplasty (autologous osetochondral grafting)[112,113] in six horses was shown to result in successful graft incorporation, with 50% of horses returning to an equal or higher level of activity. Autogenous fibrin plugs containing allogeneic chondrocytes and insulin-like growth factor-I placed over cancellous bone grafts or tricalcium phosphate (TCP) granules packed into the débrided cysts resulted in success rates of about 75%.[114,115] Autologous patient-side grafting using bone marrow aspirate concentrate, platelet-rich plasma with TCP, showed positive results with regards to the rapidity of bone formation and thickness of the resultant subchondral plate.[116]

Intralesional or intra-articular injection of corticosteroids (triamcinolone) has been used at various time points perioperatively to depress the inflammatory mediators released into the joint.[117] Intralesional corticosteroid therapy has more recently been advocated as the primary and sole treatment of subchondral bone cysts. Injection can be completed with ultrasonographic or arthroscopic guidance,[105] with the latter technique having the additional benefit of examination and débridement of any significant cartilage lesions. Triamcinolone or methyprednisolone is deposited throughout the cyst lining, with the most effective technique involving multiple redirections of the needle to distribute the medication. Intralesional injection of corticosteroids resulted in success rates of 90% for unilateral cases and 67% for bilateral cases.[105]

Reports on conservative management of this condition, with or without the use of nonsteroidal anti-inflammatory medication, have reported success rates of 45% to 64%.[98,118] Interestingly, one study found no significant differences in racing results between yearlings with radiographically diagnosed SBCs in the MFC and the unaffected horses, leading to the prediction that some lesions spontaneously resolve without treatment.[119]

Postoperative care following surgical débridement of a cyst generally involves 1 to 2 months of stall rest followed by at least 4 months of small paddock rest, and horses should not be returned to work until they are sound at a trot. Postoperative convalescence prior to restoration of soundness may be prolonged (i.e., 4 to 18 months).

SBCs have been identified in the proximal cranial tibia of young and mature horses.[99] Successful arthroscopic débridement and return to athletic performance was achieved in 3 of 4 young horses in which an osteochondrosis etiology was suspected. Pre-exisiting osteoarthritis and other soft tissue injuries in the stifle of mature horses appeared to limit their future performance.

One report has documented an osseous cystlike lesion of the patella seen radiographically.[100] The lesion was seen on the medial articulating surface of the patella, corresponding to the most common location of patellar fractures.

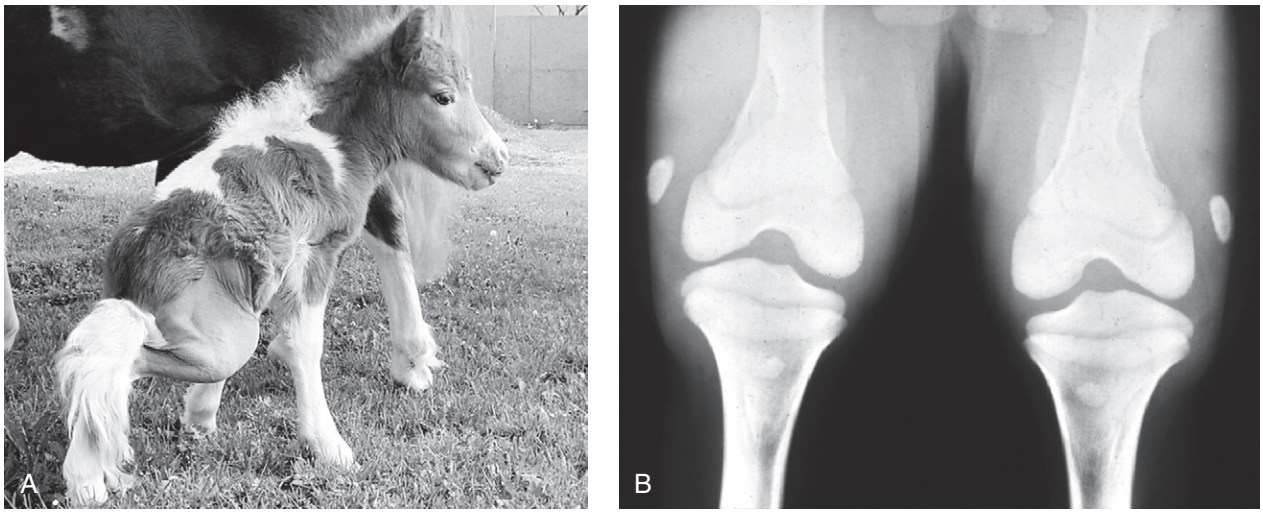

Figure 99-38. A, This 3-month-old Shetland pony foal shows the typical stance of an animal with complete lateral luxation of the patella. **B,** The craniocaudal radiographic views of both stifles show the patella located lateral to the distal femur. (Courtesy J. Auer, University of Zurich.)

Patellar Disorders

Lateral Luxation of the Patella

Lateral luxation of the patella is a rare condition that is most commonly seen congenitally in foals or Miniature Horses. The condition is believed to be heritable.[120-123] Luxation of the patella in mature horses is rare and generally traumatic in origin.

The condition can be unilateral or bilateral, and clinical signs depend on the severity of the displacement of the patella. Foals with complete luxation of the patellas are unable to stand (because the quadriceps acts as a flexor instead of an extensor of the joint), and they assume a classic crouched position (Figure 99-38, *A*). When the patellas are not completely luxated, clinical signs include limb stiffness or lameness at the walk and trot. The patellas can usually be reduced manually. The FPT is generally distended, and there may be crepitation on palpation of the patella.

Radiographic assessment of the stifle should include the degree of degeneration of the joint, the depth of the trochlear groove, the shape of the patella and trochlear ridges, and the amount of ossification of the trochlear ridges and the patella. Irregularity of subchondral ossification of the trochlear ridges in foals up to 5 months of age should not be mistaken for pathology. On craniocaudal radiographic views, the patella is located lateral to the femur (Figure 99-38, *B*); on the lateromedial view, it is projected over the femur or visible just caudal to it.

Surgical correction of patellar luxations includes lateral release incisions combined with reinforcement of the medial patellar support structures. In dorsal recumbency, under general anesthesia, surgical exposure is achieved with one large medially based curved incision extending from 6 cm proximal to the patella distad to the tibial crest. Alternatively, two curved incisions (craniomedial and craniolateral) can be used.

Lateral release of the patella is accomplished by incising the insertion of the biceps femoris, transecting the lateral femoropatellar ligament and the origin of the lateral patellar ligament without invading the joint.[124] Lateral release can sometimes be accomplished by partially transecting the tensor fascia and fibrous joint capsule while preserving the lateral femoropatellar ligament. Removal of excessive FPT synovial fluid with a needle and syringe may be beneficial prior to medial imbrication to decrease tension on the sutures. The medial joint capsule from the base to the apex of the patella is imbricated with No. 5 braided polyester suture. Alternatively, suturing the tendon of the sartorius muscle and the parapatellar fascia to the joint capsule and the medial patellar ligament may be necessary. We have used a mesh implant to reinforce this imbrication in a 370-pound yearling and in cases where the holding capacity of friable tissue is a concern.

A sulcoplasty has been advocated for lateral ridge hypoplasia or instability of the patella in the trochlear groove.[125] In small animals, two different techniques are described.[126] These techniques are performed on young animals that have a thick hyaline cartilage layer covering the ossifying center of the epiphysis. The skin incision as described earlier is used for the approach in both techniques. One technique involves elevation of a U-shaped cartilage flap within the trochlear groove and removal of the subchondral bone (Figure 99-39). The cartilage is incised at an angle (from superficial to deep toward the flap) and is carefully elevated with the help of a periosteal elevator. The soft bone is removed with rongeurs, and the surface is evened out with a curette. The cartilage flap is then repositioned and stabilized with sutures. If an abrupt change in trough angle on either side is noticed, additional cartilage can be removed with a scalpel to provide a smooth articular surface.

The other sulcoplasty technique involves the removal of a wedge from the trochlear groove (Figure 99-40) with a handheld saw. Each saw cut removes some bone, and thus by simply replacing the wedge, some deepening of the groove is achieved. If additional deepening is desired, a parallel saw cut is carried out on one side, and the wedge is replaced. The edges are smoothed out with a scalpel. If the wedge is properly seated, no fixation is required. The soft tissue release and imbrication techniques discussed earlier are also performed.

Both procedures have been used successfully on foals. Postoperative radiographs confirm correct positioning of the patella. Postoperative care includes the use of systemic antibiotics, nonsteroidal anti-inflammatory medication, and good nursing care. Seromas may occur but usually resolve without treatment.

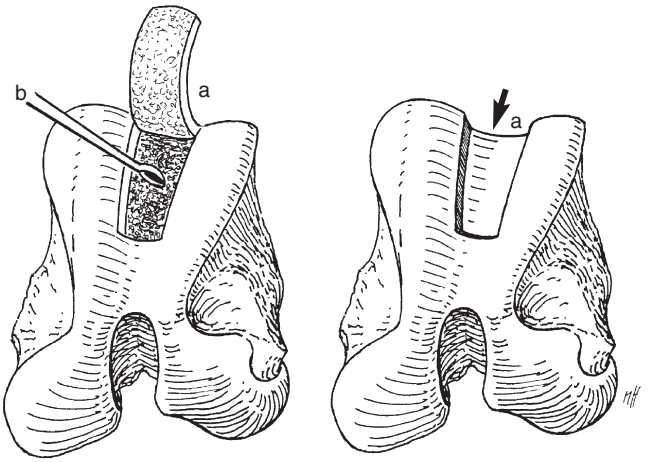

Figure 99-39. Sulcoplasty involving elevation of a U-shaped cartilage flap *(a)* and removal of the subchondral bone with rongeurs and a curet *(b)*. The flap is repositioned *(arrow)* and, if necessary, the edges are smoothed out. The flap can be secured with suture.

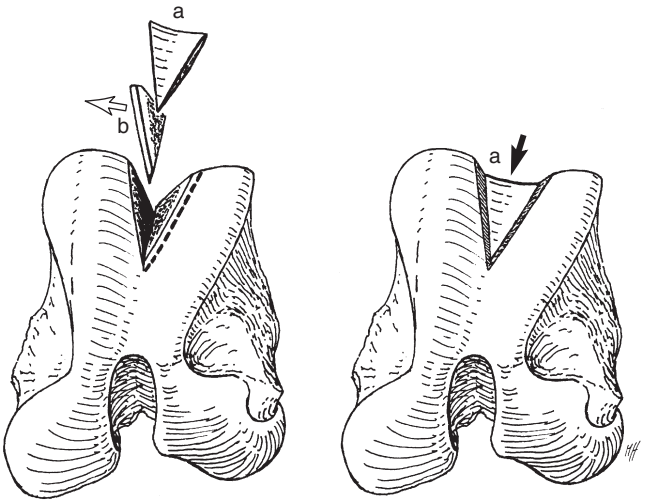

Figure 99-40. Sulcoplasty involving wedge *(a)* osteotomy of the intertrochlear groove. If necessary, an additional piece of bone *(b)* is removed *(arrow)* with an additional saw cut parallel to a previous one. The wedge *(a)* is replaced in the trough and pressed into position *(arrow)*, resulting in a functional intertrochlear groove.

Upward Fixation of the Patella

Upward fixation of the patella is a pathologic condition of the equine stifle that results from a difficulty or inability to release the passive stay apparatus mechanism of the stifle. This condition commonly occurs secondary to the initiation of training in young horses and is related to a straight hindlimb conformation. Severity can vary from a slight delay in flexion of the limb only observed by experienced riders and lameness clinicians to permanent fixation of the patella that cannot be manually corrected. Chronic intermittent upward fixation of the patella may result in excessive trauma to the FPT and secondary effusion and lameness. The treatment for this condition involves alterations in training to increase development of the quadriceps muscle, with surgical treatment reserved for severe cases (complete persistent inability to unlock the stifle) or those refractory to medical management.

Quadriceps development is accomplished by riding at an extended trot up and down hills in deep, sandy, or loamy soil. Working the horse in a circle in an arena (especially at a canter) should be avoided, as this merely contributes to the patella trauma and the horse's continued lack of quadriceps development because of lameness. Rather than box stall confinement, anti-inflammatory medication and turnout for the horse are recommended. Some acute severe cases, which are commonly traumatically induced, resolve with anti-inflammatories and rest, and thus delay of surgical intervention for a few days may be advantageous.

Injection of counterirritants into the middle and medial patellar ligament[127,128] has annecdotally shown some success in treatment of upward fixation of the patella.

MEDIAL PATELLAR LIGAMENT SPLITTING

Medial patellar ligament splitting has been advocated for treating upward fixation of the patella when conservative methods have failed.[129] We have noted numerous advantages over medial patellar desmotomy, particularly with regard to postoperative complications.

The procedure is carried out with standing sedation or under general anesthesia. Using ultrasonographic or palpation guidance, multiple longitudinal splitting incisions are made in the proximal third of the medial patellar ligament. This form of splitting results in a two- to threefold progressive increase in ligament diameter during the first 4 weeks after surgery. No anti-inflammatory medications are used, and hand-walking is initiated the day after surgery. Resolution of all clinical signs was noted in 7 of 7 cases within 12 days of surgery, with no recurrence of upward fixation of the patella.[130]

MEDIAL PATELLAR DESMOTOMY

If the appropriate conditioning and development of the quadriceps muscle tone with training and medial patellar ligament spliting does not resolve the condition, or if persistent inability to unlock the stifle is present, a medial patellar desmotomy (MPD) can be considered as a last resort. MPD has been associated with induction of chondromalacia of the patella, entheseophyte formation, osteolysis, and patellar fragmentation, particularly if horses were returned to work quickly (i.e., 3 weeks) after surgery.[76,131-133] These changes are believed to be induced by alteration in patella positioning and increased biomechanical strain on the remaining patellar ligaments (particularly the middle patellar ligament). These lesions were recognized as causing lameness in normal horses in which experimental MPD was performed. Arthroscopic débridement of these clinically significant lesions is indicated; if fragments develop, they should be removed because they will lead to osteoarthritis.

The surgical procedure of MPD is performed under standing sedation with the tail wrapped to avoid contamination of the surgical site. After preparation of the skin, local anesthetic is injected subcutaneously over the medial border of the distal aspect of the middle patellar ligament and around the distal aspect of the medial patellar ligament. A 1-cm vertical incision is made over the medial border of the middle patellar ligament close to the ligament's attachment to the tibial tuberosity; a subcutaneous fat pad is located in this area and thus the operator is less likely to enter the FPT. Curved Kelly forceps are forced through the fascia and passed behind the medial patellar ligament. A curved bistoury knife is inserted into this channel, the

cutting edge is turned outward, and the ligament is cut. The blade should be fully advanced to the other side of the medial patellar ligament before the ligament is severed. After the ligament has been severed, the tendon of the sartorius muscle feels like a tense band and might lead the inexperienced operator to believe that the medial patellar ligament has not been completely severed. The skin is closed routinely.

To decrease the risk of complications discussed earlier, a prolonged period of rest is recommended before the animal is turned out to allow some scarring to occur at the surgery site to improve realignment and stabilization of the patella in the intertrochanteric groove. However, such changes as new bone production on the tibial tuberosity and the middle patellar ligament attachment to the patella may be seen despite a stall rest period of 120 days after surgery.[134] A retrospective study of clinical cases of upward fixation of the patella found that incidence of gait abnormalities after medial patellar desmotomy may be lower with stall rest more than 3 months (25%) compared to less than 1 month (67%), but the only two horses that showed radiographic changes after MPD had been rested 3 months or more.[135]

CHAPTER
100 Femur and Pelvis

Dean W. Richardson

Disorders of the femur and pelvis of the horse are not uncommon. Injuries ammenable to medical therapy are usually ligamentous in nature or involve the sacroiliac joint. Surgically treatable conditions of the femur and pelvis occur as fractures of either bone or coxofemoral luxations. These latter conditions comprise this chapter.

FRACTURES OF THE FEMUR

Fractures of the femur occur primarily in foals and weanlings, although they can be found in a horse at any age. Most fractures follow a severe traumatic event, such as a fall or a kick. Proximal femoral fractures in adults may occur in horses that fall down with their lower limb extended, such as while wearing a full limb cast or with an upwardly fixed ("locked") patella.

The diagnosis of a distal or diaphyseal fracture is not difficult to make in most cases because of the acute onset as well as the marked lameness and swelling that localize the problem. Although crepitus is usually palpable with manipulation of the limb, hemorrhage and muscle swelling can be severe enough to separate the bone ends and minimize this sign. More severely

comminuted fractures might not have crepitus, because motion between the individual fragments is limited. Less common presentations include shock caused by blood loss into the thigh musculature and dragging of the limb because of upward fixation of the patella.

Diagnostic radiography in larger horses (more than 300 kg) is usually performed under general anesthesia unless the fracture is located distally. There are techniques described for obtaining useful, but not entirely diagnostic, images in standing horses.[1] Ultrasonography can be used to confirm a diagnosis of a displaced fracture in a large horse.[2] It is best to sedate or anesthetize foals so that mediolateral and craniocaudal views can be obtained. For proximal fractures, a ventrodorsal view of the pelvis should be obtained.

Surgical treatment of mid-diaphyseal or proximal femoral fractures has generally been successful in foals and small ponies, although in larger weanlings and even yearlings it may be feasible if fracture configuration is suitable. Distal metaphyseal fractures can also be successfully repaired in yearlings with plates and screws. Locking intramedullary nails are an option for mid-diaphyseal fractures in foals and even larger yearlings,[3] but double plating is probably a superior technique.[4]

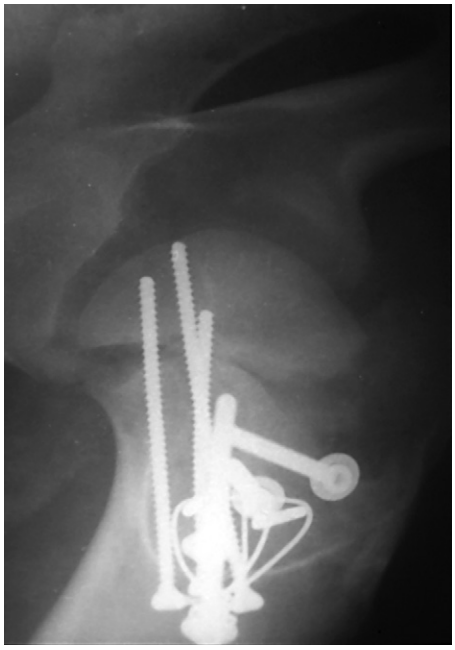

Figure 100-1. Postoperative radiographic view of the femoral head region of a foal. Three 4.5-mm cortex screws were inserted in lag fashion into the capital femoral epiphysis. The trochanteric osteotomy used for the surgical approach to the joint was repaired with screws and tension band wires. There also was radiolucent tension band placed under one washer.

Proximal (Head and Neck) Fractures

Proximal (head and neck) fractures are seen almost exclusively in foals and are the most difficult femoral fractures to diagnose without good-quality radiographs. Conservative treatment of such fractures is unlikely to result in a comfortable horse. Surgical repair is difficult to achieve, and the prognosis is guarded.

The favored surgical approach is craniodorsal, with a curved incision just cranial to the greater trochanter and that parallels the proximal shaft of the femur. Exposure is enhanced by either a tenotomy of the gluteal insertion or a trochanteric osteotomy. If an osteotomy is selected, the drill holes for later tension-band repair should be prepared before transecting the bone.

The bone can be cut with an oscillating saw or Gigli wire. The surgeon should review the anatomy carefully before making the trochanteric osteotomy. It is possible to cut too much and damage the caudal femoral head or too little and leave medial attachments that obscure the intended view. The approach and arthrotomy are extended to allow palpation of the head and neck of the femur. Additional fractures that are not evident radiographically are detected in this manner. It is very difficult to clearly see the fracture site except in small foals, but placing one's finger in the joint allows more accurate reduction of the fracture and alignment of the drill and drill bit.

Although use of multiple pins has been described, techniques involving screws provide more stability[5] (Figure 100-1). These techniques include screws applied in lag fashion, cannulated screws, or a dynamic hip screw plate.[6-8] Regardless of the specific implant selected, alignment is critical to prevent damage to the articular surface. Cannulated screws have a major technical advantage for this particular fracture, because reduction is maintained by the guide wire during the entire procedure and the direction and depth of the drill or screw can be monitored constantly (see Chapter 76). Unfortunately, cannulated screws are significantly weaker in bending than solid screws, so there is a higher risk of screw failure, especially in larger foals.

If a cortex screw and lag technique are used, the glide hole is drilled before reduction. This allows checking for central positioning of the bit before entering the epiphysis with the thread hole. The combination of a minimal length glide hole and a central location will maximize the number of threads engaged in the smaller fragment. If the screw is not centered in the epiphysis or the epiphyseal fragment is penetrated off center with the large bit used for the glide hole, stability of the repair will be significantly compromised.

Ease of reduction is variable and depends mainly on the degree of eburnation of the fracture surfaces. Smooth, eburnated fracture margins can make reduction very difficult. If the femoral shaft is held with forceps, leverage is provided when attempting reduction. However, reduction is maintained digitally because clamps cannot be applied. Predrilling the glide hole across the femoral shaft also minimizes the length of time that the fracture must be digitally maintained in reduction.

It is difficult to accurately estimate the ideal length of the screw from preoperative radiographs; therefore, intraoperative palpation and measurements are essential. To assess the depth and direction of drilling, a pin or drill bit of the same length is placed on the exterior of the bone in a parallel position as drilling is performed. This provides additional visual and tactile help for alignment as holes are drilled into the head of the femur. If at all possible, at least two screws should be used to ensure rotational stability.

Closure of the wound should be in layers with synthetic absorbable suture material. Pre-placing several sutures in the joint capsule before tying is recommended. If a trochanteric osteotomy was performed, it must be repaired with a tension-band technique. Either two screws or two smooth pins can be used to replace the trochanter, but both must be supported distally with 1.25- or 1.5-mm–diameter wire. The wire is passed through a drill hole across the femoral shaft made 5 to 7 mm distal to the osteotomy. In larger foals, two wires are usually

Figure 100-2. A small fragment is visible at the cranial aspect of the bone.

used. If screws are used to replace the trochanter, it might help to feed the screws through washers so that the tension-band wire comes to lie between the washer and the bone, which secures the fixation.

Other types of proximal femur fractures involve the greater trochanter or, more commonly, the third trochanter. These fractures can be diagnosed with physical examination or scintigraphy. Ultrasonography can then be used to more specifically define the injury without general anesthesia. Unless the fractures are associated with a wound or become sequestrated, they should be treated conservatively with stall rest for several months.

Mid-Diaphyseal Fractures

Mid-diaphyseal fractures are the most common type encountered and are the fractures most amenable to successful surgical repair.[9] Most have a spiral or long oblique shape or are comminuted (Figures 100-2 and 100-3).

The skin incision is made laterally over the length of the bone between the greater trochanter and the lateral condyle. After the fascia lata is incised, it is easy to identify the demarcation between the vastus lateralis and biceps femoris. If a small incision is made there in the mid-diaphysis, the fracture hematoma can be digitally identified. The muscle bellies are easiest

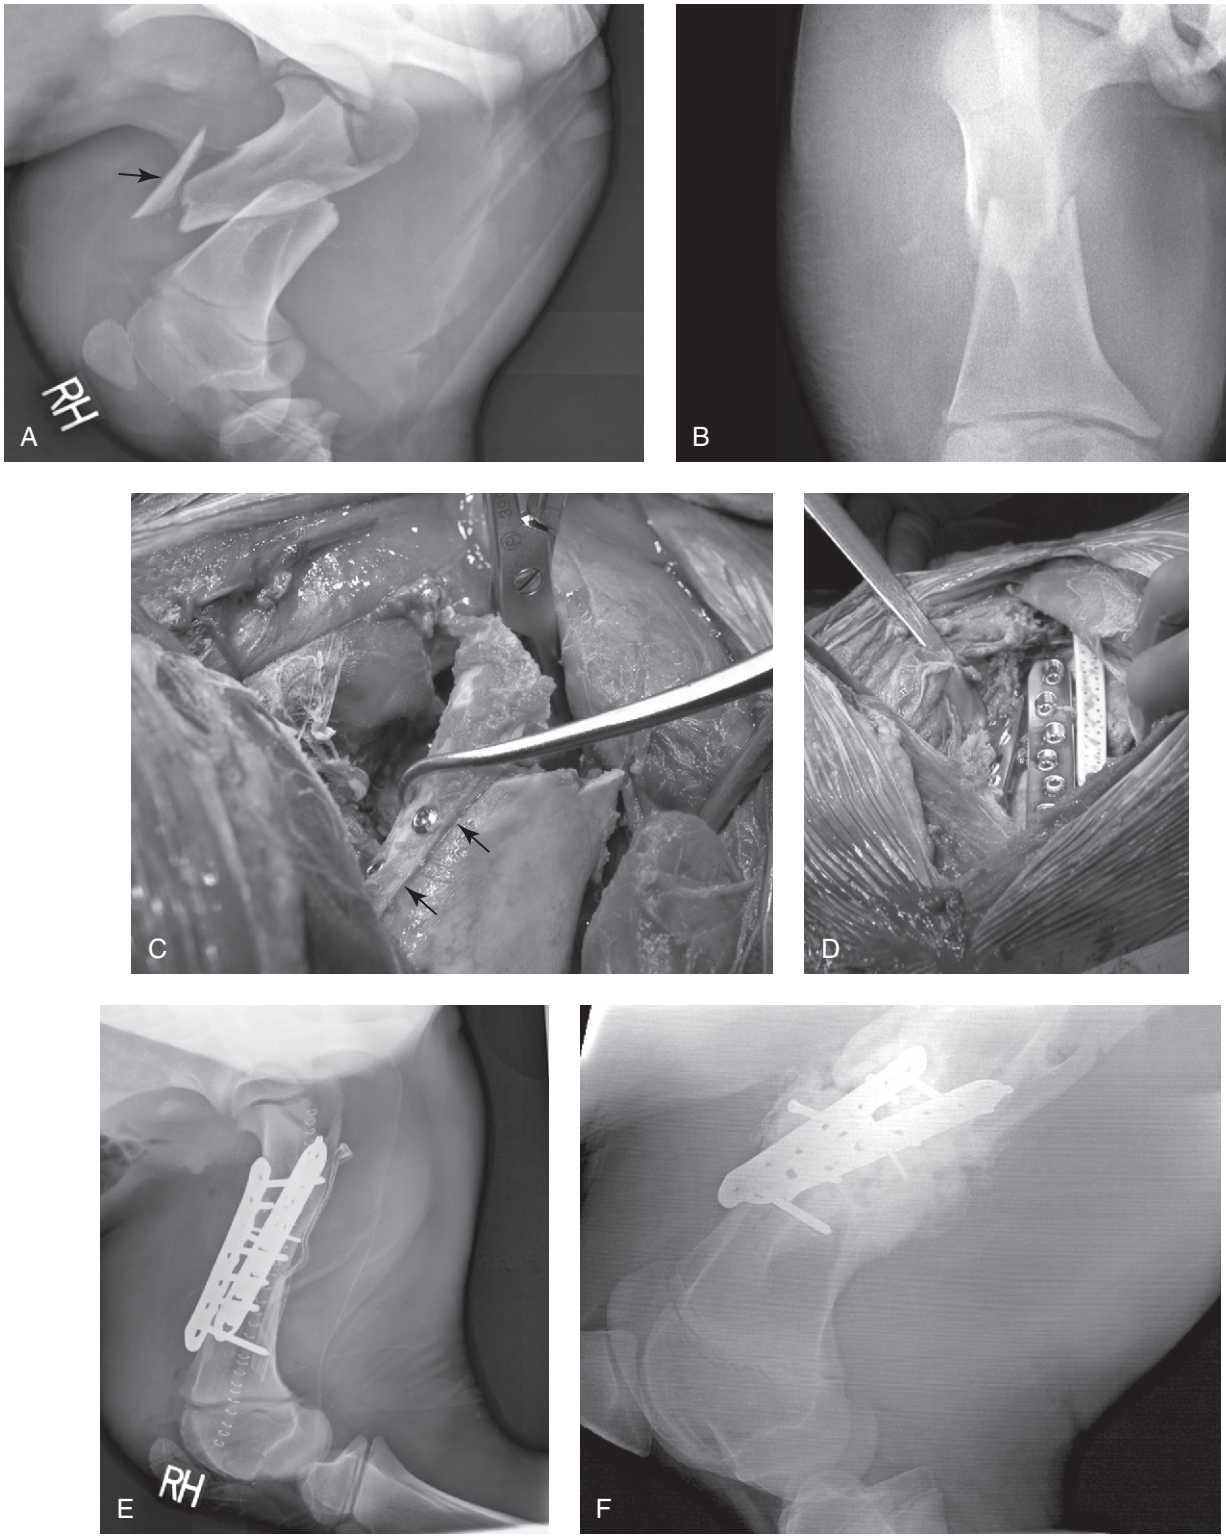

Figure 100-3. Mediolateral **(A)** and craniocaudal **(B)** radiographic views of a typical diaphyseal multifragment femoral fracture in a foal. **C,** A large butterfly fragment (*arrows* in **A** and **C**) was reconstructed with screws using lag technique to make a two-piece fracture. **D,** Intraoperative view of the fracture, repaired with two locking plates. The white suction drain is seen just caudal to the plates. The perpendicular placement of screws into the extremities of the cranial plate can be very difficult, even with vigorous muscle retraction. **E,** Immediate postoperative lateromedial radiographic view of the repaired fracture. **F,** Image at 2.5-month follow-up shows typical femoral fracture healing with large callus formation.

to separate when palpated from inside of the hematoma. The attachments to the third trochanter usually need to be severed to provide exposure at the proximal end of the bone.

Comminuted fragments should be independently reduced with screws inserted in positions outside of the planned locations of the plates until the fracture is reconstructed into two main pieces (see Figure 100-3, *C*). Comminution in some cases is severe and requires extensive reconstruction. It is often useful to place 3.5-mm cortex screws in lag fashion to reduce small fragments, countersinking their relatively small heads deep enough that the plates can be placed over them (see Figure 100-2, *B*). If there is a barrel stave configuration to the fracture extending down the diaphysis, cerclage wires or cables can be used to prevent splitting the bone (see Figure 100-2, *B*).

When the fracture is reconstructed to two pieces, reduction is usually possible by simply elevating the fragment ends out of the incision, aligning them properly, and folding the bone ends back into position. For long oblique fractures, it might be necessary to clamp the bone in an overriding position before sliding it incrementally by direct traction into reduction. Nylon cable ties or heavy cerclage wires can be pre-placed to help hold the reduction as it progresses. Large Lane bone forceps also may be useful. Vigorous traction might be necessary; therefore, it is essential that the foal's or pony's tail and body be tied securely with ropes and girths to the surgery table. It can also be helpful to engage a large (6.35 mm [¼ in]) Steinman pin down the proximal shaft of the femur and another pin across the distal fragments. With Jacobs' chucks attached to each, the pins can be used as "handles" to help manipulate the fragments.

After reduction is obtained, bone clamps are applied to maintain temporary alignment. One or two screws should be placed with lag technique across the oblique fracture in locations where they will not interfere with the lateral plate (see Figure 100-2, *B*). The bone-reduction forceps are removed, allowing application of the longest possible 4.5-mm locking compression plate (LCP) with 5.5-mm cortex screws and 5-mm locking head screws. Alternatively, the plate can be placed with a bone clamp maintaining the reduction, but this is much more difficult.

After applying the lateral plate, a shorter LCP is placed cranially. The LCP has major advantages[10-12] but it is important to note that it will prove quite difficult to place locking screws in all holes of a cranial LCP because of the quadriceps muscle. Hohmann retractors provide adequate exposure to position the plates and insert most screws, but locking screws at the ends of the plate often need to be placed via stab incisions through the musculature (see Figure 100-3, *C*). Lag technique is applied in plate screws crossing any reduced fracture plane for additional compression and stability. Interfragmentary compression increases the overall stability of the repair and helps ensure accurate reduction. The two plates must be staggered a half-hole apart, and the screws must be inserted perpendicular to the long axis of the plates to prevent interference of screws. All cortex defects are filled with autologous cancellous bone and the gaps in the plate holes next to the screws are typically filled with an antibiotic eluting material, such as polymethyl methacrylate.

The incision is closed in at least three layers: the fascial margins of the vastus lateralis and the biceps femoris, subcutaneous tissues, and skin. Interrupted sutures are recommended because wound problems are common and local drainage is sometimes necessary. Because of the considerable muscle trauma (original and surgical), compression bandaging is impossible; closed suction drainage is essential to minimize accumulation of serum (see Figures 100-2 and 100-3).

An alternative technique for simple diaphyseal fractures of the femur is insertion of an interlocking intramedullary nail (see Figure 76-44).[3] The axial position of the nail affords excellent bending stability, and the transfixing screws provide rotational stability. If possible, supplemental fixation in the form of lag screws, cerclage wires, or a locking plate with unicortical screws can be used in oblique or spiral fractures.

A routine incision is made as described earlier to reduce the fracture. A small incision is subsequently made over the medial aspect of the greater trochanter, and a 5.5-mm drill bit is used to prepare a hole across the bone into the medullary cavity. This hole and the medullary cavity are subsequently enlarged with reamers until a uniform-diameter path for the nail is created. The nail length is pre-selected based on measurements taken on radiographs of the contralateral intact bone. The nail is driven into the distal fragment with the targeting jig attached, seating it securely but being careful not to penetrate the distal end of the bone. After the nail is fully inserted, 5.5-mm cortex screws are placed through the bone and the nail. At least two screws are applied at either end of the nail, in most cases more.

One possible major complication of interlocking intramedullary nails is the development of a fracture through the screw holes. The nails are more applicable in mid-diaphyseal fractures than in more distal or proximal injuries, where it is difficult to adequately seat the nail in the shorter fragment.

Because of the massive surrounding muscles, even well-repaired femoral fractures tend to develop large calluses quickly (see Figures 100-2, *E*, and 100-3, *F*). This is valuable because even suboptimal repairs that develop some minor instability can successfully heal as the callus provides adequate stability relatively quickly, especially in younger individuals.

Distal Femoral Fractures

Distal femoral fractures are most commonly encountered in older weanlings and yearlings and are nearly always of the Salter-Harris type II. Most have the metaphyseal fragment positioned caudally. Salter-Harris types III and IV fractures have also been reported but are less common.[13-15] Any distal femoral fracture can be initially misdiagnosed as a stifle lesion because of the location of the swelling (Figure 100-4). Fractures of the distal femur tend to be quite unstable and therefore require surgical repair.

The fracture is approached through a craniolateral incision between the vastus lateralis and biceps femoris muscles. The incision is extended distad to the level of the tibial crest. The lateral femoropatellar ligament must be transected to allow a parapatellar arthrotomy and patellar luxation. Reduction may be quite difficult to achieve. Like many physeal fractures, exact anatomic alignment is difficult to assess. The metaphyseal part of the fracture is not readily visible and is covered by the extensive soft tissues on the distal caudal femur.

After reduction is achieved, a long screw can be placed through the exposed intercondylar notch and into the metaphysis to maintain alignment while the lateral plate is applied. Because the epiphyseal fragment is small, a specialized plate with some type of flared end is usually preferred (Figure 100-5). The strongest plate, which is best suited for larger yearlings, is a dynamic condylar screw (DCS) plate (Figure 100-6). Although the DCS plate is difficult to contour because of its large cross section, it can be bent to fit the distal femur.

Special care must be taken to fit the DCS plate accurately on the horse's curved distal femur, because the plate was designed

for the straight human femur. However, this plate provides superior stability in the distal fragment (see Figure 100-6). In horses weighing less than 175 kg, the condylar buttress plate with a flared end accommodating several screws is easier to apply and is strong enough despite its smaller cross section (see Figure 100-5).[16] LCPs with 5-mm locking screws also have the potential to work well in this location.

Regardless of the plate selected, the largest available screws (5-mm locking head, 5.5-mm cortex or 6.5-mm cancellous screws) should be used. The parapatellar fascial incision is closed with large tension-holding sutures (cruciate, near-far-far-near, or overlap); meticulous skin closure and a closed suction drain are all recommended. An adhesive or sutured stent bandage should be applied to keep the incision clean.

Figure 100-4. The swelling associated with a distal femoral fracture can be misinterpreted as a primary stifle joint problem. Typically, however, crepitus and instability are palpable.

Prognosis

The prognosis for fractures of the femur is guarded because of the high risk of complications.[9] As a result of muscle trauma and because a pressure bandage cannot be used on the area, surgical incisions are susceptible to extensive serum accumulations. Wound dehiscence and sepsis are common problems. If complications are avoided, however, healing of fractures of the femur is remarkably rapid in young animals because of excellent vascularity and muscle coverage. Callus is radiographically visible in foals within a few weeks. Even overtly infected femoral fractures have a reasonable chance to heal if long-term drainage, local antibiotics, and adequate stability are maintained.

Failure of plates and screws in adequately reduced fractures is uncommon, except when there is a bone defect in the caudal cortex. Such a defect leads to excessive cyclic loading of the implants and fatigue failure. If fracture healing is uncomplicated, it is not advisable to remove the implants; removal can be difficult and the repeat incision can still have complications. In distal physeal fractures, the plate might have to be removed if it is interfering with joint function or if there is significant remaining growth potential. Unfortunately, many physeal fractures of the distal femur result in permanent closure of the growth plate and consequently a shortened femur. This is acceptable for breeding soundness, because the animal can compensate somewhat by increasing its joint angles in the stifle and hock.

Although some fractures of the femur have been successfully managed conservatively,[17] younger animals often rapidly develop a serious varus deformity in the contralateral

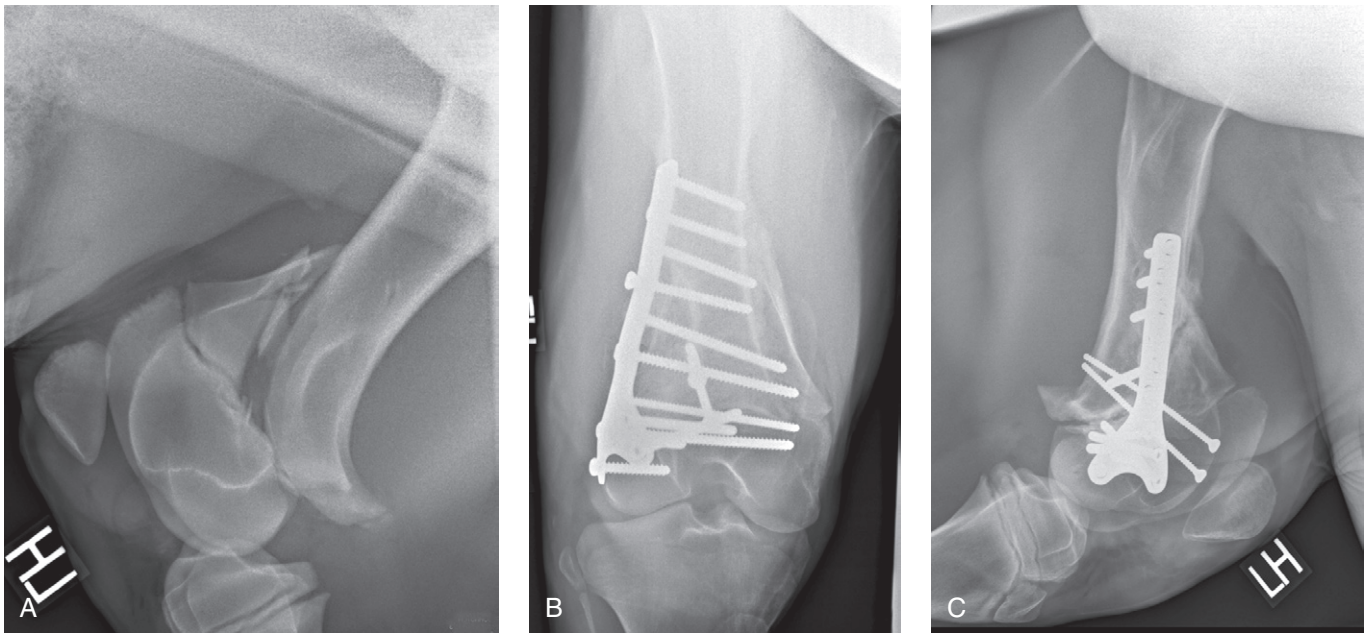

Figure 100-5. A, Salter-Harris type II fracture of the distal femur repaired with a condylar buttress plate having a flared end accommodating multiple screws. Two 5.5-mm screws were placed through the articular surface to help maintain reduction while the plate was applied. Caudocranial **(B)** and lateromedial **(C)** radiographic views of the fracture repair were taken 3 months postoperatively.

Figure 100-6. A, Salter-Harris type II fracture of the distal femur. Lateromedial **(B)** and caudocranial **(C)** radiographic views showing the repaired fracture. A dynamic compression screw (DCS) plate was applied laterally and augmented with a five-hole narrow dynamic compression plate (DCP) containing long screws penetrating the medial condyle. One single screw was buried in the articular surface to provide additional stability to the cranial aspect of the reconstruction. Longitudinally placed screws should augment the plate fixation. (Courtesy C. Lischer, University of Berlin.)

limb (Figure 100-7). Because these fractures can be repaired successfully in foals, the conservative approach should be reserved for older animals in which the surgical approach is too daunting or for cases where comminution is so severe that even locking plate fixation is not feasible.

FRACTURES OF THE PELVIS

Fractures of the pelvis occur in all animals of all ages but are disproportionately common in foals and yearlings.[18,19] Most follow a distinct traumatic event, such as a fall. In adult horses, pelvic fractures can occur during intense exercise without obvious trauma.

The most obvious clinical sign is overt lameness either of the swinging or supporting limb type. External swelling or asymmetry of palpable pelvic landmarks (e.g., the tuber coxae, tuber ischii, tuber sacrale, and greater trochanters) can be present. It is helpful to measure the distances between these landmarks and to compare the two sides. Pain can be elicited by manipulation of the limb or by direct pressure over the trochanter or other prominences. Examination *per rectum* can reveal obvious asymmetry, especially with acetabular fractures in which there is often a rounded, firm swelling over the fractured region.

Crepitus can be difficult to appreciate externally in horses with pelvic fractures, but it is often more obvious if the horse's weight is shifted or if the horse is walked a few steps during a rectal examination. Vigorous manipulation of the limb by an assistant can also be helpful in some cases, although care should be taken to test the horse's pain response to such manipulation before the rectal examination is undertaken. Crepitus is usually appreciated more easily on the first day or two after the injury.

In chronic cases, pelvic musculature is usually atrophied, although this is obviously not specific for a pelvic injury. The

medial thigh region should always be checked for asymmetry, because dependent swelling often develops in this area, especially with displaced acetabular and ileal fractures. The most dramatic presenting signs are seen with a laceration of a major artery (usually the internal iliac artery). This results in bleeding into the abdomen or thigh that is severe enough to cause shock or death.[19,20]

A definitive diagnosis of pelvic fractures is made with radiographs. This usually requires general anesthesia, although standing pelvic radiography has been described.[1,21] Even under general anesthesia, there are significant limitations in the sensitivity of radiographs of the pelvis in adult horses. Consequently, nuclear scintigraphy, either with an imaging or point-counting technique, is often used for screening.[22,23] Scintigraphy is the only technique that can identify subtle injuries, such as ileal stress fractures. If a displaced fracture is suspected, a simpler and less-expensive alternative is ultrasonography; it is possible to clearly identify discontinuities of a cortical surface in accessible locations.[2,24,25] Ultrasonography is particularly useful for diagnosing and defining tuber coxae fractures.

Figure 100-7. A 6-month-old weanling suffering from a femoral shaft fracture of 1 month's duration in the right hindlimb, which was treated conservatively. Note the marked varus deformity in the left hindlimb.

Treatment

Treatment of pelvic fractures is almost always conservative, although displaced iliac shaft fractures in foals can be repaired successfully with internal fixation (Figure 100-8). The ilium is approached by elevating the gluteal musculature sharply along its ventral attachments and forcefully retracting the musculature dorsally with Hohmann elevators. The fragments are reduced and secured with bone plates, preferably locking plates. In non-articular fractures, anatomic reduction is not mandatory for a good result. Surgical repair of pelvic fractures in foals is restricted to those with marked displacement and a need for athletic function.

There are no reported cases of the successful repair of acetabular fractures in horses of any age, although it is feasible to approach the dorsal rim in younger foals or Miniature Horses. Displaced tuber coxae fractures ("knocked-down hips") are usually not treated surgically either, although removal should be considered if they are open and draining.

In adult horses, stall rest for at least 3 to 4 months is combined with adequate analgesia, support bandaging, and frog support on the contralateral limb. Epidural analgesia can be used with caution, especially to manage the more intense pain in the initial period after the injury. Younger horses heal more quickly but also develop limb deformities more readily in the contralateral limb.

Prognosis

The prognosis for pelvic fractures depends primarily on the degree of displacement. Nondisplaced fractures of any portion of the pelvis, even those involving the acetabulum, heal without serious consequences, whereas displaced injuries that cause persistent pain lead to muscle wasting, contralateral limb and foot

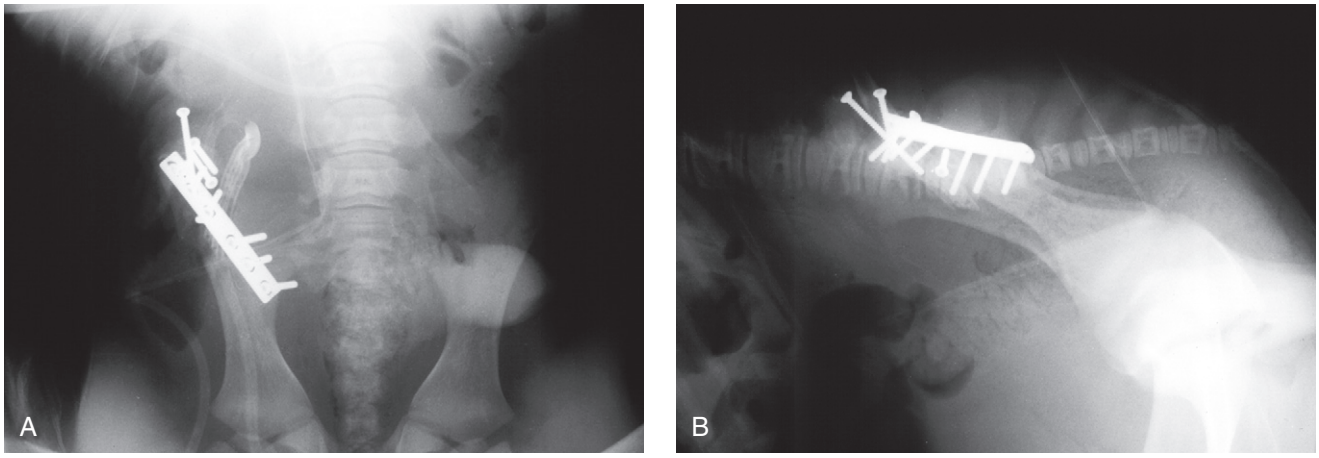

Figure 100-8. Ventrodorsal **(A)** and lateromedial **(B)** radiographic views of a 1-month-old foal with an iliac shaft fracture. The fracture was repaired using open reduction and internal fixation. Adequate exposure and reduction in larger individuals is enormously difficult. In this case, screws were used to hold the fragment in reduction as a single locking plate was applied to the iliac wing down onto the shaft.

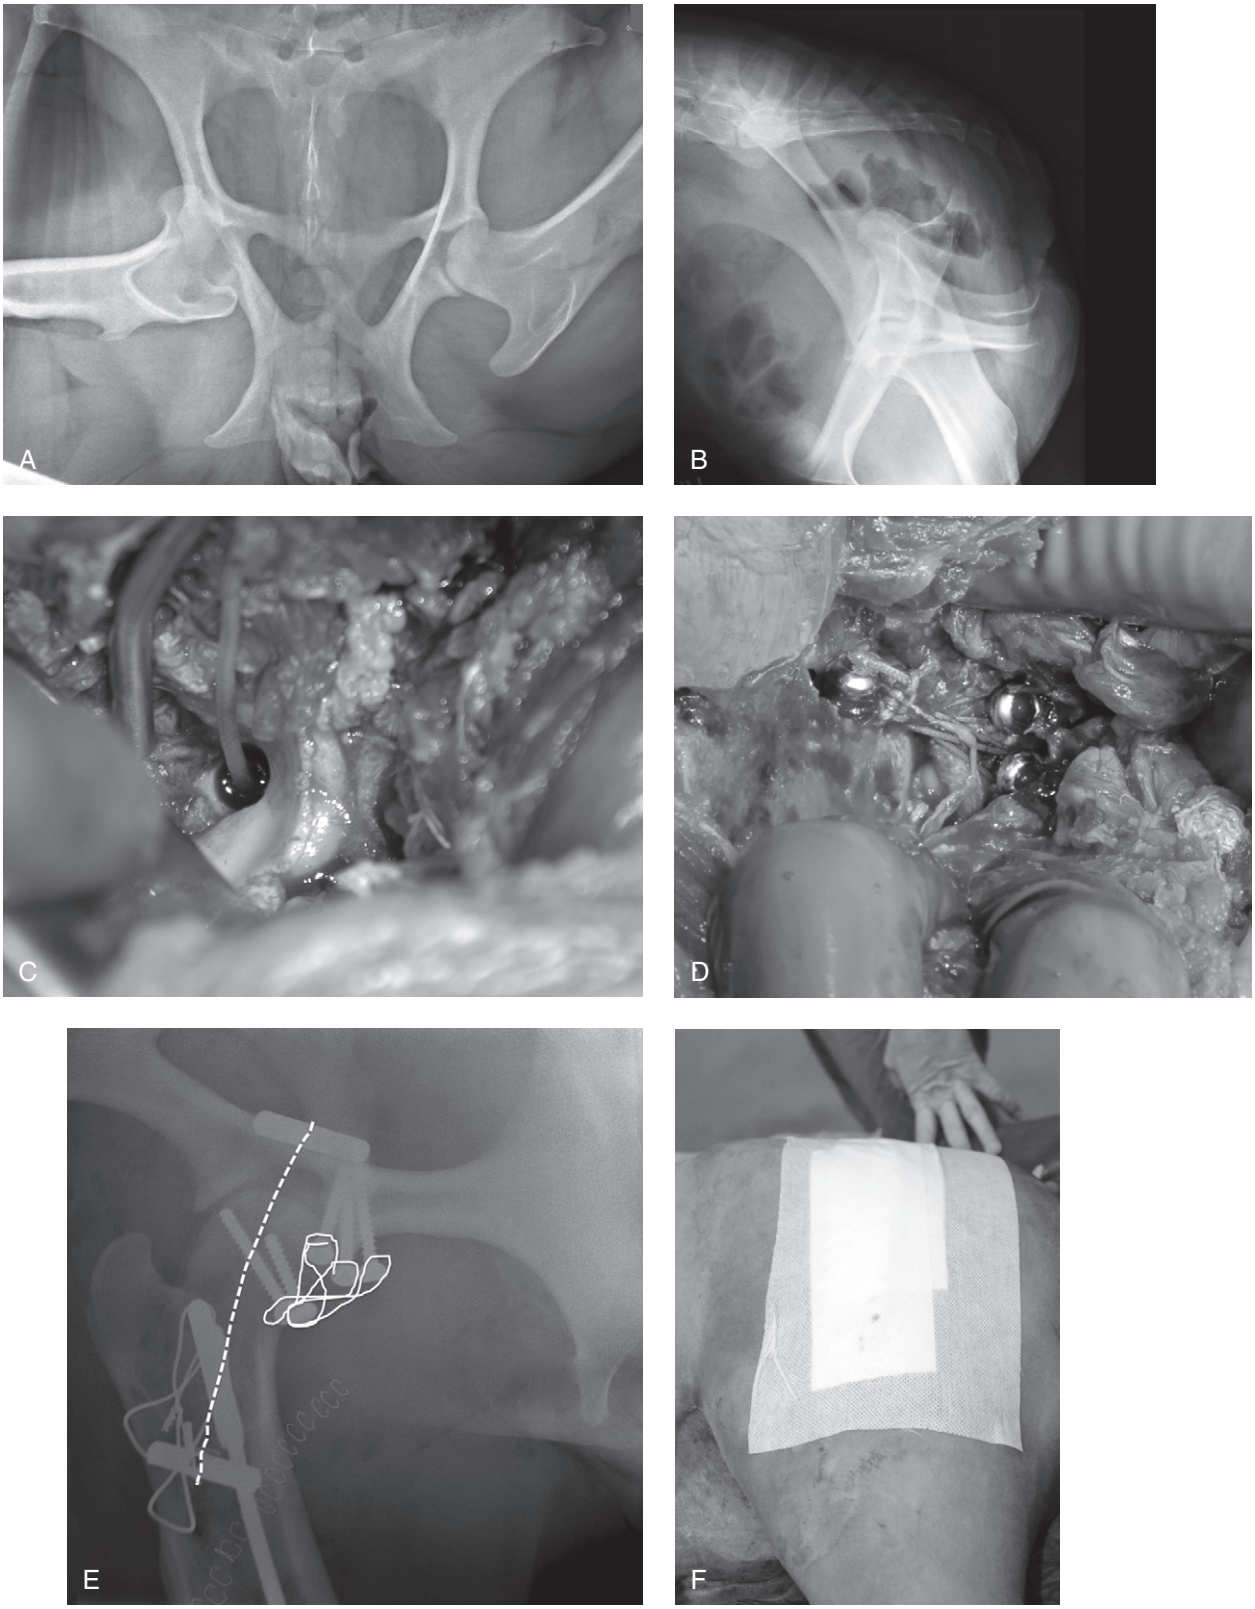

Figure 100-9. Ventrodorsal **(A)** and lateromedial **(B)** radiographic views showing a typical craniodorsal coxofemoral luxation in a Miniature Horse. **C,** Intraoperative view showing a hole made in the central acetabulum through which the toggle-pin is passed. **D,** Intraoperative view of the screws inserted along the acetabular rim and the proximal femur that are connected with multiple interlaced strands of braided suture or cable. **E,** The braided strand of suture or cable is passed through the femoral head and out the side of the femur, where it is secured to another toggle *(dotted line).* The braided wires between the screw heads in the acetabulum and femoral head are shown. **F,** An adhesive bandage is applied over the incision to keep it clean.

problems, and coxofemoral arthritis. In mares, markedly displaced fractures can compromise the birth canal and lead to dystocia. In one study, a successful outcome occurred in 77% of horses that were not euthanized immediately after the pelvic fracture was diagnosed.[19] With ultrasonographic diagnosis becoming more common, characterization of displaced fractures without general anesthesia may allow earlier, more accurate prognosis.[2] However, because surprisingly rapid improvement and healing can occur, precipitous decisions to euthanize horses with pelvic fractures should be avoided, unless it is absolutely clear that recovery is impossible or the economic pressures dictate against continued treatment.

COXOFEMORAL LUXATIONS

Coxofemoral luxations are rare in equids but are more common in ponies and Miniature Horses than in larger animals.[26] Most occur after falls, after attacks by larger horses, or while the animal is struggling to extract an entrapped limb or straighten an upwardly fixed patella.[27] Coxofemoral luxations and femoral head fractures can occur in horses and foals wearing full hindlimb casts.[28]

Clinical diagnosis of coxofemoral luxation is not difficult except to distinguish it from a femoral head fracture, which can be achieved through radiography or ultrasonography. The affected horse is very lame and holds the distal limb externally rotated. Because most luxations occur craniodorsally, the point of the tarsus is higher than the normal side when the horse is viewed from behind. Manipulation of the limb might or might not yield a soft, clicking crepitus. Upward fixation of the patella may be present.

Treatment

Treatment of coxofemoral luxation in Miniature Horses and ponies has been accomplished by reduction and primary repair or by excision arthroplasty.[27,29-31] Although it is possible that a closed reduction may succeed, open reduction and some form of stabilization is nearly always necessary.

Surgical repair involves a craniodorsal approach to the hip with or without greater trochanteric osteotomy. If a trochanteric osteotomy is elected, it is advisable to pre-drill one or two holes to facilitate tension-band repair during closure. Before the femoral head is reduced, the joint is cleaned of fibrin and any debris. Any remnants of the round ligament are removed. An effort should made to avoid any further injury to the dorsal labrum.

Reduction often requires mechanical assistance with either a calf jack or a pulley system rigged up in the operating room. A hip skid, which is a long levering instrument with a curved spoonlike end, can be helpful in reducing the luxation. In most cases, replacement alone is not successful because of continued instability. Therefore, toggle pinning or augmentation of the lateral joint capsule with synthetic sutures attached to screws might be necessary. The latter technique involves placing screws above the cranial acetabular margin and lateral femoral shaft just distal to the neck (Figure 100-9). A large braided suture is tied around the screw heads to help prevent the head from moving proximolaterally. Washers can help to minimize slippage of the suture material from under the screw heads. The success of this procedure is much higher in the smallest, lightest patients, that is Miniature Horses. In heavier Shetland type ponies or any larger individuals, failure of the fixation is fairly common.

The toggle pin technique involves drilling a hole from the lateral proximal femur aiming up through the femoral head precisely where the round ligament inserts. A toggle pin can be made by drilling a hole through the middle of a 2.5 to 3 cm piece of a large-diameter (5 to 6 mm) Steinman pin. The edges of the hole must be smoothed to avoid abrasion of the suture material. A 3- to 5-strand braid of the strongest available nonabsorbable braided suture material (e.g., polyester or, preferably, a polyester/polyethylene composite) is passed through the hole and doubled to a free end. A hole is then drilled in the acetabulum at the site of the round ligament origin. The toggle with braid attached is inserted vertically through the acetabular hole, and then tension is applied to seat it transversely dorsal to the acetabulum. The braid is then passed down the hole made at the round ligament insertion in the femoral head and retrieved from its exit point on the lateral femur. It is usually necessary to use a wire attached to the braid to pass it down the drill tract. The braid is then passed through a second toggle pin. The femur is abducted and the tension on the braid is adjusted until it is taut when the hip is allowed to adduct to a normal position. The braid can be tied over the toggle with routine knotting technique because the knot is tied with the limb abducted. The trochanteric osteotomy is repaired with a tension band technique (screws or pins and wire or cable [see earlier]). The surgeon must be cognizant of the path of the cable through the femoral head and proximal femur so that it is not damaged during the trochanteric repair.

Femoral head and neck excision does not usually result in acceptable long-term comfort except in small ponies and Miniature Horses. The surgical exposure is achieved through a craniolateral approach, and an oscillating saw, Gigli wire, or wide osteotome is used to transect the femoral neck as close to the shaft as possible. Postoperatively, the horse should be kept on optimal footing to prevent the animal from slipping. Use of soft rope hobbles may be helpful to prevent abduction if the horse will tolerate them. A medial patellar desmotomy is usually necessary to avoid persistent upward fixation of the patella.

CHAPTER
101 Temporomandibular Joint Disorders

K. Josef Boening

The detailed anatomy of the temporomandibular joint (TMJ) and its direct relationship to adjacent structures is well documented in the literature.[1-4] This knowledge is a prerequisite for correct diagnosis of TMJ pathologies and enhances the clinician's ability to diagnose temporomandibular disorders.

ANATOMY

The TMJ has an incongruous shape formed ventrally by the mandibular condyle (condylar process) and dorsally by the zygomatic process of the temporal bone (Figure 101-1). Like all joints that are incongruous, a fibrocartilaginous disc (commonly referred to as a *meniscus*) is interposed to level out the incongruity. This meniscus has an elongated, roundish appearance, is approximately 5 mm thick at the border, and divides the joint into two separate compartments (Figure 101-2).[5,6] The dorsal discotemporal compartment is more spacious than the ventral discomandibular compartment. Two ligaments support the joint capsules in maintaining joint alignment (Figure 101-3).

The TMJ is covered by the parotid gland and is in close proximity to the more ventrally located transverse facial artery and vein and the transverse facial branch of the auricular-temporal nerve (Figure 101-4).

CLINICAL SIGNS

Clinical signs are variable and include reluctance to eat and asymmetry of the masseter region. Careful clinical examination

of the entire head, with special attention to the teeth, should be performed.[7-11] Asymmetry of the head can be caused by either muscle atrophy or a swelling on the affected side. It was only recently reported that head shaking, misbehavior, and head tilt were associated with TMJ disorders. Attitude changes, such as a lack of submissiveness, can also be attributed to TMJ disorders.[12]

DIAGNOSIS

In some cases, it is difficult to recognize which joint is affected without the help of diagnostic imaging techniques. Most information can be gained from standard lateral, oblique, and tangential radiographic projections.[13-16] Ultrasonography,[17-21] nuclear scintigraphy,[22] and, more recently, computed tomography (CT)[23-25] and magnetic resonance imaging (MRI) have become the preferred techniques for diagnosing TMJ disease in the horse.

TMJ sepsis[26] is rare in horses and most frequently is related to penetrating wounds.[27-29] However, standard diagnostic aids used to diagnose joint infections can be applied to the TMJ (see Chapter 85).

TREATMENT

As expertise in the diagnosis and management of TMJ disorders increases, invasive techniques are being developed to treat them.[30,31]

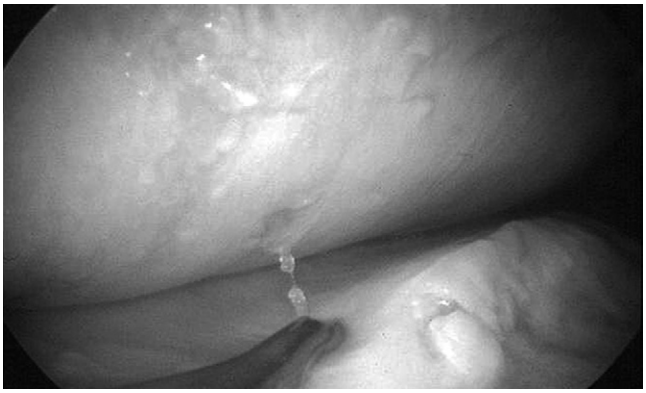

Figure 101-5. Arthroscopic view of the temporomandibular joint showing a focal cartilage defect. The disc is displaced ventrad with the help of a curette.

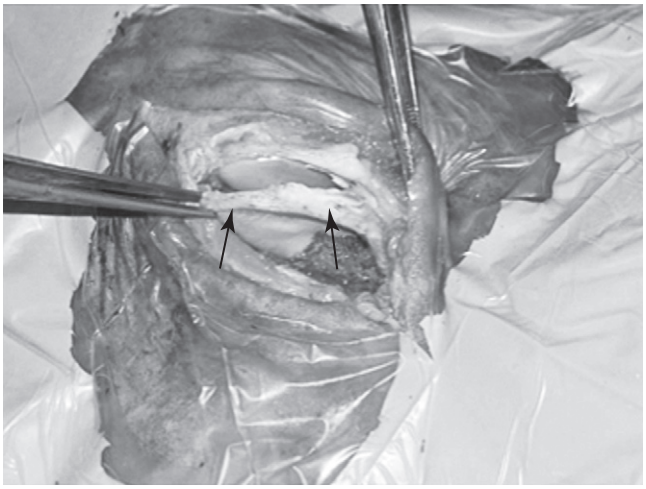

Figure 101-6. Arthrotomy into the TMJ for the purpose of mandibular condylectomy. The meniscus is shown *(arrows)*.

Arthroscopy

A first description of arthroscopic approaches to TMJ compartments was presented in 1986 as part of a clinical case report[12] describing a horse with submissiveness problems and a head tilt, which was associated with a transverse unilateral tear in the TMJ disc. The diagnosis was made after standing nuclear scintigraphy followed by intrasynovial anesthesia.

A cadaveric study revealed that a good portion of the TMJ can be evaluated arthroscopically.[32] The first retrospective clinical study in TMJ arthroscopy has been published and illustrates the advantage of this technique as both a diagnostic and a surgical treatment procedure.[33]

Approach

For unilateral arthroscopy of the TMJ,[34] the horse is anesthetized and placed in lateral recumbency on the surgery table. After routine aseptic preparation of the surgical site, the caudal recess of the proximally located discotemporal joint, which is usually easily palpable, is distended by injecting approximately 15 mL of Ringer's lactate solution through a 20-gauge needle.[35] A 5-mm skin incision is made with a No. 11 scalpel blade next to the needle, followed by penetration of the joint capsule in a rostromedial direction with the blunt trocar of the 4-mm 30-degree arthroscope. Care is taken not to injure the proximal aspect of the parotid gland that may extend into this region. An instrument portal is made adjacent to the arthroscope portal to assist in exploring the joint. Having an assistant performing sideway movements of the mandible facilitates exploration further. The arthroscopic portal to the rostral recess of the discomandibular joint compartment, is located immediately rostral to the mandibular head and ventral to the discotemporal joint space. Because this joint compartment is smaller than the proximal compartment, exploration of the discomandibular joint compartment is more difficult.

Either fluid or gas distention can be used in this joint, but the use of gas prevents the synovial villi from obscuring the surgeon's view.[36] Each arthroscopic procedure is completed by extensive fluid lavage and skin closure.

A clinical case series (Figure 101-5) described five Warmblood horses that underwent arthroscopic débridement of the affected TMJ lavage and in one case removal of a free-floating osteochondral fragment followed by débridement of the meniscal borders. All patients were also treated with intra-articular corticosteroid injections. Three horses became asymptomatic and could resume their athletic careers.[33] One case report described successful management of a septic TMJ with mechanized resection of synovium and fibrinous debris, copious lavage, and intra-articular and systemic antibiotics.[26] Eight months postoperatively, there was no clinical evidence of osteoarthritis or ankylosis of the TMJ.[26]

Condylectomy of the Mandible

Mandibular condylectomy is a radical procedure and is an option for treatment of fractures and chronic septic arthritis involving the TMJ that are not amenable to repair. Other indications include management of luxations and chronic painful osteoarthritis of the TMJ.[37,38] However, this technique should be viewed as a salvage procedure, and additional work is needed to find a practical solution for maintaining TMJs with osteoarthritis.

Surgical Procedure

A condylectomy is performed in lateral recumbency under general anesthesia.[37] An approximately 6-cm horizontal skin incision is made, centered over the TMJ joint and curving somewhat distad caudal to the mandibular condyle. The soft tissues are reflected ventrad to expose the joint capsule. The transverse facial artery/vein and the auricular temporalis nerve should be identified and avoided during the approach (see "Anatomy," earlier).

The TMJ is opened by a horizontal incision of the joint capsule (Figure 101-6). The periosteum on the condyle is incised vertically 2 cm distal from the joint space, and a periosteal elevator is used to reflect it both rostrad and caudad. An oscillating bone saw is used to create a 2-cm deep cut in the mandibular condyle 2.5 cm ventral to the articular surface.

A chisel is inserted into the osteotomy and the lateral portion of the condyle is pried dorsad until it fractures. It is necessary to remove the lateral portion of the condyle before continuing the cut through the rest of the mandible under the condyle in order to to provide room to introduce scissors to sever the

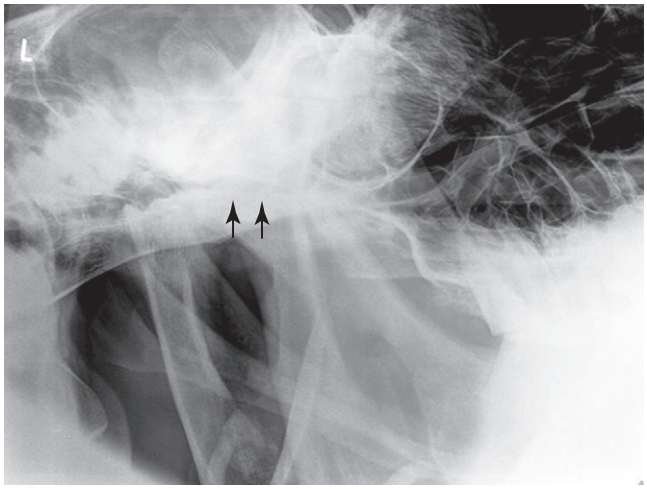

Figure 101-7. Radiographic appearance of the formation of a pseudocondyle after unilateral condylectomy *(arrows)*.

capsular attachments. The oscillating saw is used to continue the osteotomy through the remaining axial portion of the mandible below the condyle. The condyle is grasped with large forceps and removed following scissor transection of any remaining joint capsule attachments. The articular meniscus is removed after severing its attachments with scissors.[37,39] The bone edges are rounded with the help of a curette.

The incision is closed in three layers: the periosteum and joint capsule, the subcutaneous tissues, and the skin. Additional information on TMJ disorders is found in Chapter 30.

Complications and Prognosis

The results of mandibular condylectomy have been summarized for normal horses.[37]

Radiographic, gross, and histological evaluations show that the condylectomy sites undergo remodeling and bony proliferation to develop pseudocondyles (Figure 101-7).[37] Condylectomy has been performed in a case of septic arthritis and end-stage osteoarthritis.[37] Short-term complications in normal horses included masseter atrophy, malocclusion, weight loss, and difficulty in prehension and mastication.

CHAPTER
102 Craniomaxillofacial Disorders

Jörg A. Auer

ANATOMICAL CONSIDERATIONS

The bones of the head consist of the skull, mandible, and hyoid bone (Figure 102-1). The skull can be considered to be composed of the cerebral cranium or neurocranium, which forms a solid shell around the brain, and the visceral- or splanchnocranium, which forms the basis for the face but also includes the mandible and the hyoid bone.[1] Alternatively, the skull can be considered to be made up of only the bones of the upper head (without mandible and hyoid bone).[2] In this chapter, the latter classification has been adopted. In contrast to humans, the visceral cranium of the horse is much larger than the cerebral cranium and lies rostral to rather than below it. The bones of the skull are usually flat and have a compact external and internal lamina separated by a cancellous/spongy layer. The different bones of the skull are joined by serrated suture lines.[1]

The *cerebral cranium* is divided into the roof and base of the skull and consists of the dorsally situated frontal bone, the interparietal bone and parietal bone, the laterally located temporal bone (composed of a petrous part, a tympanic part, which contains the inner and middle ear, and a squamous part attached to the zygomatic process), the ventrally situated sphenoid bone, the occipital bone, and the ethmoid bone.[2]

The bones of the *visceral cranium* form the ocular, nasal, sinus and oral cavities. The visceral cranium consists of the frontal bone and nasal bone dorsally and the lacrimal bone, zygomatic bone, the paired incisive bone, and the premaxilla laterally. The incisive bone consists of the alveolar part, which contains the alveoli of the upper incisors, the palatine process, which forms the rostral part of the hard palate, and the nasal process. Ventrally, the visceral cranium consists of the palatal bone, the vomer and pterygoid bone, and, caudally, the ethmoidal bone.[2]

The *mandible*, as a part of the visceral cranium, consists of the incisive part, interalveolar rim, molar part, mandibular ramus, condylar process and coronoid process. The anatomic terminology describing the mandible is not consistent. In this chapter, the tooth-bearing part is referred to as *body* or *corpus* and the remaining vertical part as *ramus* or *branch* of the mandible. The two mandibular branches are fused to form an intermandibular suture line via a synchondrosis, which ossifies during the second year of life.[2]

FRACTURES OF THE INCISORS, MANDIBLE, AND PREMAXILLA

Trauma to the head often results in fractures of the teeth, incisive bone, mandible, premaxilla, or maxilla. These injuries occur as blunt trauma from kicks, falls, and collisions or from being startled in the stall while cribbing on stall slats or mesh wire. Sudden jerking of the head while chewing on stationary objects may result in avulsion fractures of the incisors.

Whatever the cause, these fractures can be repaired with good cosmetic and functional results. Several factors make this possible. These bones have a good soft tissue covering and have an abundant vascular supply. Because the bones of the head are not subjected to the same loading forces as the bones of the extremities, the demands for fracture fixation are less challenging. The teeth serve as stabilizing aids. Implants of adequate strength are available, and the instrumentation required is in most cases inexpensive and readily available.

Diagnosis

A thorough physical examination is the basis for a correct diagnosis. One of the first signs of a fracture of the jaws is excessive drooling and lack of appetite. Soft tissue swelling, hemorrhage, instability, and malalignment of the teeth and bones are usually noticed on closer inspection. A fetid odor accompanies open fractures that are several days old.

Malocclusion of the incisors can be induced manually even in normal horses because of the normal side-to-side mobility of the temporomandibular joint. However, both mandibles move in the same direction with manipulation unless a fracture is present, in which case one side of the mandible can be manipulated independently of the other. Often, soft tissue

swelling obscures the detection of malalignment, especially if the fracture is located under the masseter muscles. Horses might object to manipulation and examination of the oral cavity because of pain. A protruding tongue should alert the clinician to suspect a bilateral fracture. Drooling occurs as a result of an inability to properly close the mouth.

The diagnosis is in most cases not difficult, but other structures might be injured concurrently; therefore, the nasal passages and cranial nerves should be examined. Horses can become significantly dehydrated after hemorrhage and salivary loss, which can be compounded by the patient's reluctance to drink. This is especially true if the fractures are not detected in a timely manner. The physical examination also should include cardiovascular parameters that would identify potential anesthetic risks. In the majority of the cases, repair is not an emergency procedure, allowing adequate time to arrive at a comprehensive surgical plan.

In most cases, radiographs are difficult to interpret because of the complexity of the bones in the head and the presence of the teeth, which often are superimposed over fracture lines.[3] Nevertheless, radiographs often demonstrate fractures even with minor malalignment and instability. Also, radiographs provide information on the precise location of the tooth roots in relation to the fracture(s), which helps in devising a surgery plan that avoids damage to the permanent teeth. Radiographs often aid in detecting potential sequestrum formation in chronic cases. Computed tomography greatly improves preoperative appreciation of the fracture configuration, especially when three-dimensional reconstruction of the region of the fracture is obtained (Figure 102-2).

Not all fractures require repair. Unilateral fractures of the mandible, maxilla, premaxilla, or incisive bone that are minimally displaced and do not result in significant malocclusion may be treated conservatively. Indications for repair include fractures that are unstable, result in malocclusion of the teeth, or are bilateral.[4] Other considerations that might favor surgical repair include improved cosmesis because of decreased callus formation, more rapid healing in the face of increased stability, and horses that are either unable or reluctant to eat because of pain.[4]

Preoperative Management

Simple fractures involving incisor teeth (when they do not require fixation devices that extend caudad to the canine teeth) can be managed in the standing, sedated horse with regional

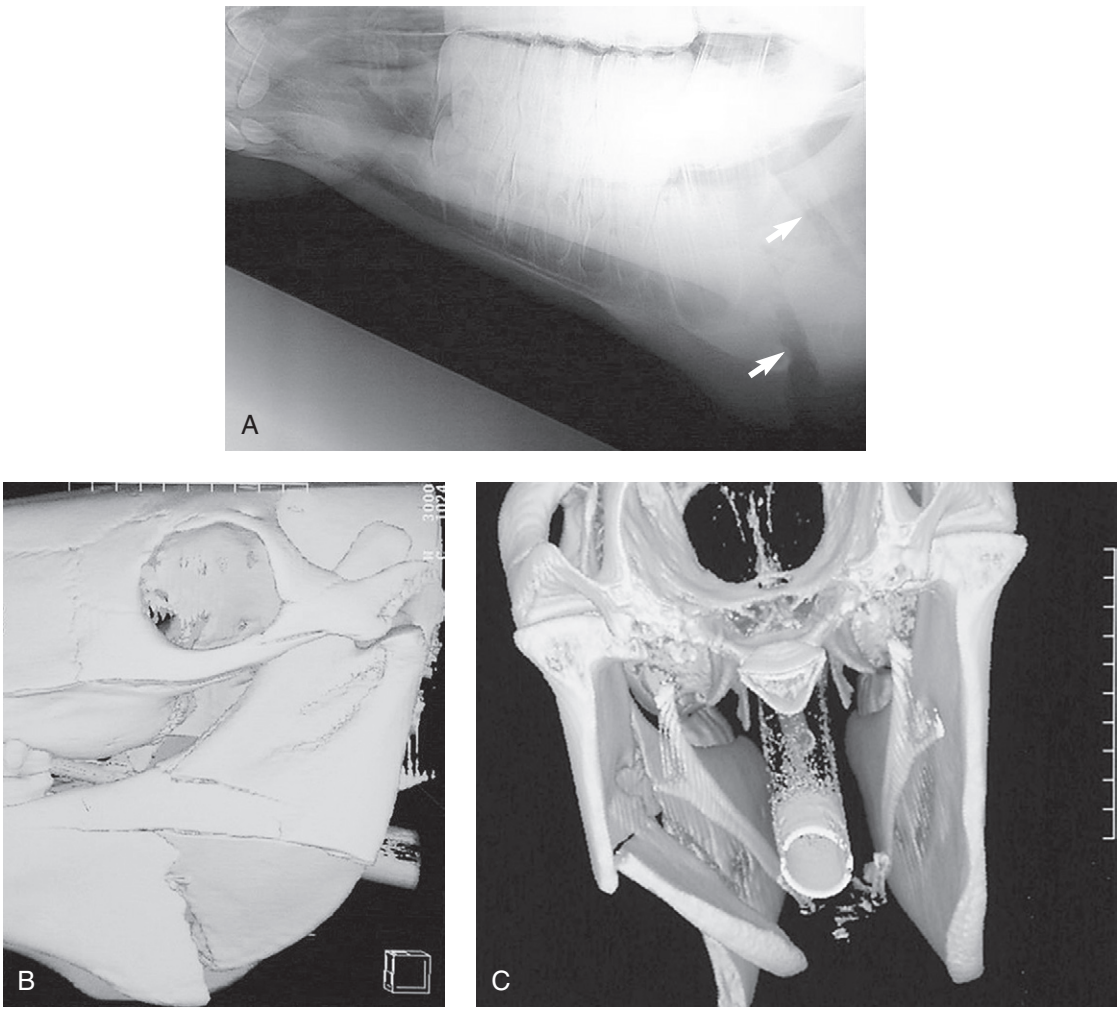

Figure 102-2. A, Lateromedial radiograph of a complicated mandible fracture in a foal. Two fracture lines are visible *(arrows).* Lateral view **(B)** and caudal cross-sectional view **(C)** of the three-dimensional reconstruction of the computed tomography study of this foal. The complexity of the fracture is easily visible.

anesthesia. Local anesthesia is easily accomplished by infiltrating 5 mL of lidocaine or mepivacaine around either the mental or infraorbital nerves at their exit point from their respective foramina.[5] Bilateral infiltration of the nerves is required in most cases.

The standing position facilitates observation of symmetry during surgical repair. However, general anesthesia is preferred because of the potential for injury to the surgeon by the patient in response to painful stimuli. Intravenous anesthetic regimens (see Chapter 19) are appropriate in most of the simple fractures, because patient and surgeon preparation and positioning requirements are minimal, allowing the repair to begin immediately after induction. When inhalation anesthesia is desired or indicated, nasotracheal intubation is preferred to allow unimpeded access to the fracture (see Chapter 18).

The location of the fracture, its complexity, and the personal preferences of the surgeon dictate the patient's positioning on the surgery table. Most uncomplicated unilateral fractures are repaired in lateral recumbency. Access to both sides of the mouth is required for bilateral fractures and is most easily accomplished with the horse in dorsal recumbency, with the poll flexed so that the surgeon can look down into the horse's mouth.[4]

Preoperative planning should include the probability of fracture reduction and determine which implants will provide the best stability. Additionally, any splint that might be required must be pre-shaped, ideally on a cadaveric specimen of approximately the same size as the patient to reduce anesthesia time.

Before repair, the mouth is rinsed with water to remove feed material; a dental pick is used to remove any feed material from fracture lines. The oral cavity is contaminated, and surgical scrubs are of dubious value if intraoral wiring alone is to be used.[4] Repair methods that use internal fixation devices deserve all of the precautions and considerations that internal fixation in other areas require because the implants are usually left in place. Prophylaxis against tetanus is indicated in all cases. Perioperative broad-spectrum antibiotics are strongly encouraged, because the surgery is usually performed in a contaminated field.

Surgical Considerations

The tension side of the jaw is the oral surface of both the mandible and the maxilla, and surgical repair should be directed accordingly when possible. Unilateral fractures of the mandible are partially supported by the intact contralateral side. This aids in the stability of the final repair. Avulsion fractures of the incisors, mandible, and premaxilla are usually simple fractures. The ends of the fractured bone usually interdigitate well and can be repaired using intraoral wiring.

Fractures of the incisors that result from kicks or collisions push the teeth caudad. These fractures are usually associated with a considerable amount of instability and some comminution of the bone caudal to the incisors. The extent of comminution can be assessed during physical examination by the stability of the fracture after it is reduced and by the resistance to collapse with manual manipulation.

Intraoral wiring alone tends to collapse comminuted fractures and results in malocclusion when the wires are tightened. In these cases, it is necessary to provide a buttress to maintain length and prevent collapse. This can be accomplished by intraoral splinting, external fixators, or bone plates applied in buttress fashion.[6]

Closed reduction is desirable to preserve blood supply and to leave soft tissues intact for support. Every effort should be made to prevent contamination of healthy tissues by exposure to the oral cavity.[4] Because accuracy of reduction is in most cases readily determined by visual inspection of the teeth, open reduction is often not necessary to ensure alignment of the fractures. The soft tissue attachments of the gingiva should not be disrupted. Small bone fragments devoid of their soft tissue attachments, and therefore their vascular supply, should be removed when the fracture is open. However, any bone fragment attached to the gingiva or periosteum should be left in place.

Loose teeth should *never* be removed until the fracture has healed and clear evidence is present that they are devitalized. Viability is not always easy to determine at the time of surgery, and many teeth will survive even if they are fractured or loose at the time of repair. More importantly, the teeth often serve a vital function as anchor sites in the thin flat bones of the jaws and quite often support the neighboring teeth when wires are used in the repair.

Intraoral wiring and external fixation methods have some advantages over internal fixation using plates and screws in fractures of the mandible and maxilla for several reasons. Intraoral wiring configurations are inexpensive and almost infinitely variable and adaptable to almost any fracture configuration. Bone in this area is soft, and screws can be easily stripped. The roots of both permanent and deciduous teeth occupy a large part of the mandible and maxilla and make placement of screws for plate fixation difficult to accomplish without damaging the teeth.[4] Radiographic control is usually necessary if internal fixation methods are used. Accuracy of screw placement, screw length, and proper bone engagement of the screws are not easily determined without intraoperative radiographs.

The oral cavity contains a large population of resident microflora. Fractures are usually open and contaminated so that internal fixation often results in infection, therefore necessitating eventual removal of the implant. Instrumentation for internal fixation requires more expertise, and the procedures are more time consuming. It is difficult to place bone plates on the tension surface. This does not preclude their use, and bone plates can result in satisfactory repair when placed on the lateral or ventrolateral aspects of the mandible because in this location the plates are loaded parallel to their width and not their thickness, which provides greater resistance against cyclic loading. The same holds true for the maxilla, where the plates should be applied laterally or slightly dorsolaterally.

When repairing fractures of the teeth, mandible, and premaxilla, the goals are anatomic alignment and stable fixation to restore the ability to masticate. Involved incisors are best ground down to prevent contact with the opposing tooth arcade during mastication, which interrupts fracture healing.

Many successful methods have been reported, and the simplest method of repair that achieves the goal of fracture stability should be applied to any situation. Techniques are often combined as necessary.

Surgical Techniques

Intraoral Wires

WIRING OF THE INCISORS

Fractures involving the incisors, incisive bone, symphysis of the mandible, and premaxilla are amenable to intraoral wiring. The wound is properly cleaned and the potential damage to tooth

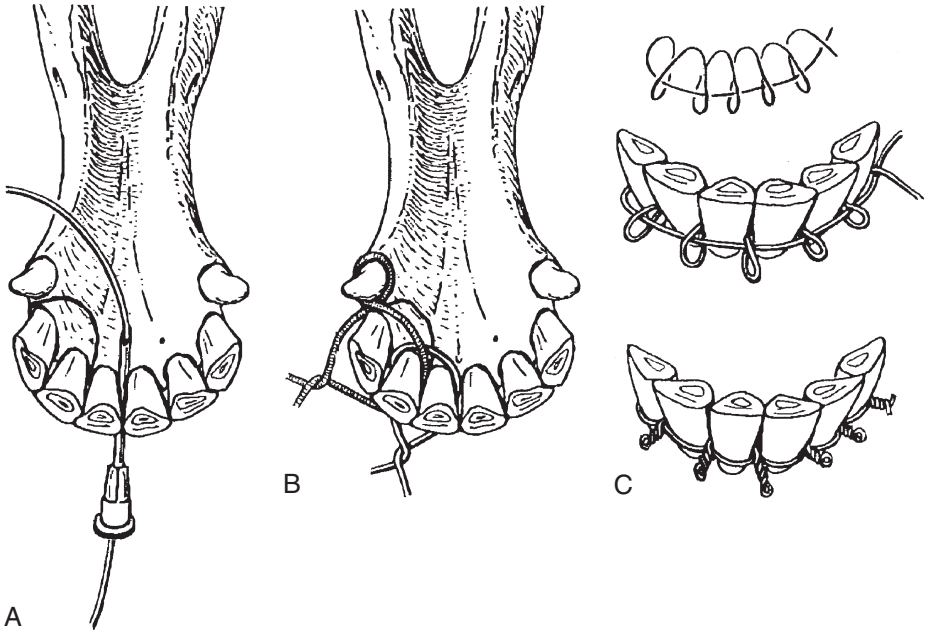

Figure 102-3. Cerclage wiring of a fracture involving 402 and 403. **A,** A 14-gauge needle is inserted between the teeth, and a 1.25-mm stainless steel wire is threaded into the needle as it is withdrawn. **B,** The fracture is treated with two cerclage wire loops, one around 401 and 402 and the other in figure-of-eight fashion around 402 and 403 and the adjacent healthy canine tooth. **C,** An alternate method involves exiting wire loops from the lingual side and the labial side, followed by feeding one end of the wire through each loop. After tightening the two wire ends, each wire loop is tightened as well, resulting in the most stable of all wire fixations. The twisted ends are directed toward the gingiva.

roots or deciduous tooth buds is assessed. Fracture reduction is accomplished by manual manipulation.

A 14-gauge needle is inserted between the teeth at the gum line, and 1.25-mm diameter stainless steel wire is threaded through the needle (Figure 102-3, *A*). Care is taken to prevent sharp bends in the wire from developing while weaving it around the teeth, because these bends prevent effective tightening of the wire. Additionally, cyclic loading of the wire during eating will straighten the wire and in doing so loosen the fixation. Sharp bends also predispose the wire to failure because of local weakening through prestressing. The wires are kept tight during application, and any slack in the wire is removed after each tooth is encircled. Fractured teeth are united to adjacent healthy ones with a figure-of-eight wire passed around all selected teeth and tightened at one end (Figure 102-3, *B*). Another technique involves multiple overlapping cerclage wires placed around the selected teeth in simple loops. Each wire fastens the unstable teeth and associated bone to the normal teeth until alignment and stability are achieved. The selection of the technique to be applied is at the discretion of the surgeon.

Wire fixation is most easily accomplished by simple interrupted wires encircling the teeth. One or two wires are usually sufficient to stabilize most simple fractures of the incisors. After each wire is tightened, the fracture is manipulated to ascertain the alignment and stability. Alternatively, a cable tie can be substituted for each wire, placed with the cut end on the oral side of the teeth to avoid laceration of the lip. Wire repair applying the figure-of-eight technique unites all teeth in one fixation, but because of the relatively long wire arranged in several circles around the involved teeth, tightening the wire is more difficult.[7] Repair is adequate if the incisors cannot be displaced by manual pressure.

A standard wiring technique applied in humans has been proposed.[8] Wire loops are inserted between each tooth from the oral to the labial side (Figure 102-3, *C*). One end of the wire is fed through each loop and is tightened with the other end. Each wire loop is subsequently tightened, resulting in a constricting wire loop around each tooth and therefore increased stability. This technique provides a rigid fixation that allows the patient to eat for months while the fracture heals (Figure 102-4).

Fractures that involve the corner incisors need some sort of anchoring farther caudally. In male horses the canine tooth may serve as such an anchor (Figure 102-5). It is usually necessary to create a notch in the canine tooth at the gum line with a small triangular file to prevent the wire from slipping off of the tooth. Alternatively, a caudal anchor can be created by inserting a 4.5-mm cortex screw into the interdental space and wrapping the wire around the screw head. Loosening of the screw with time is a complication generally encountered with this technique, especially in young horses. Still another technique is to drill a 2.5-mm hole across the lateral edge of the interdental space and feed the wire through it (see later). Tension-band wiring can also be achieved by feeding the wire around the second premolar (i.e., 406, see Chapter 30) and tightening the wire.

In rare cases, cerclage wires may be applied in a circular manner around oblique unilateral fractures of the interdental space (Figure 102-6). The intact opposite side of the mandible ensures maintenance of mandible length and some stability of the fracture ends, and the cerclage wires maintain the fragment ends in approximation and provide some compression across the fracture.

Hemicerclage wires are very useful in fractures of the mandible. Initially a K-wire of 2 to 2.5 mm is introduced across the fracture. The two ends of the pin are united across the surface of the bone in figure-of-eight fashion and solidly tightened,

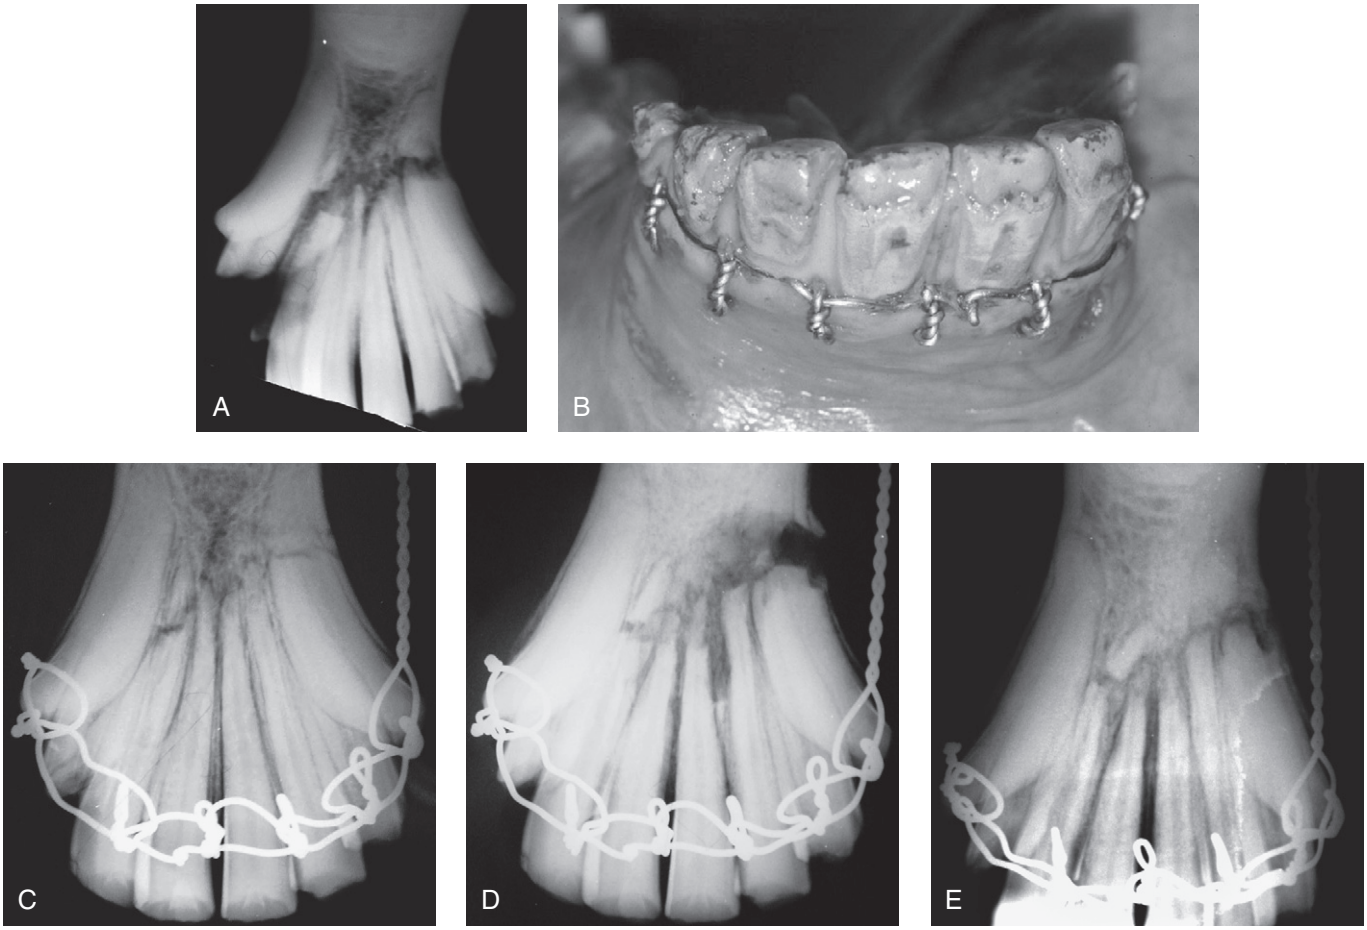

Figure 102-4. Intraoral wiring of a mandible fracture in an 11-year-old Arabian stallion. **A,** Preoperative intraoral radiograph of a fracture involving the base of the incisor teeth. **B,** The technique shown in Figure 102-3, C, was applied. Note the worn-down incisor teeth resulting from continuous crib biting. **C,** Postoperative intraoral radiograph of the fixation. Because the corner incisors were involved in the fracture as well, tension-band wiring was used. **D,** Four-month follow-up intraoral radiograph after curetting of an abscess near the tooth roots. **E,** Seven-month follow-up at the time of wire removal. The fracture has healed and the infection has resolved.

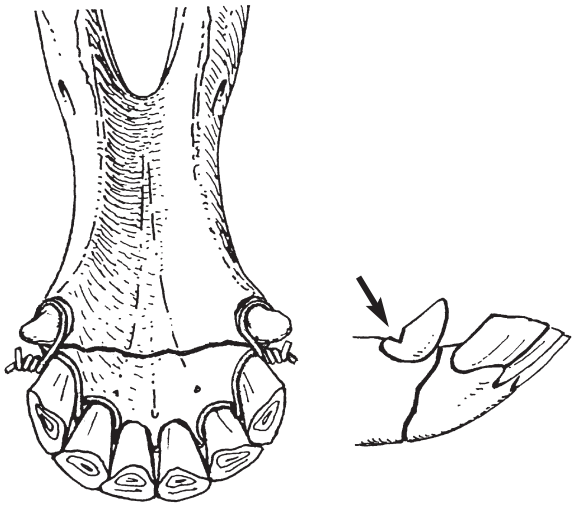

Figure 102-5. Tension-band wiring of incisors to the canine teeth used to repair a fracture involving the incisors. Note that an indentation *(arrow)* was created into the nuchal aspect of the canine teeth with a rasp to anchor the wire.

providing axial compression across the fracture (Figure 102-7). This technique is also very effective in fractures of the symphysis of the mandible in very young foals, where the bone has inadequate strength for screw fixation using lag technique (see later).

Interdental wiring becomes progressively more difficult as fractures happen more caudally on the mandible.[4] It is very difficult to wire one cheek tooth to another one with the limited room to work via an oral approach.

An alternative method of figure-of-eight wiring that does not use bone screws can be performed by anchoring the wire in the bone through holes drilled through the mandible on each side of the fracture (Figure 102-8). The surgical approach is the same. A 2-mm drill bit is used to prepare a hole from a lateral to a medial direction through the mandible near the ventral border approximately 2 cm from the fracture. Figure-of-eight wiring is performed using the drill hole as an anchor site. This technique is adequate for young foals but not for adult horses with fractures of the interdental space.

TENSION-BAND WIRING TO THE CHEEK TEETH

Fractures of the diastema of the mandible are good candidates for repair with intraoral wiring. Unilateral fractures can be realigned and stabilized with a wire placed around the second premolar (306 or 406) and secured to the incisors.

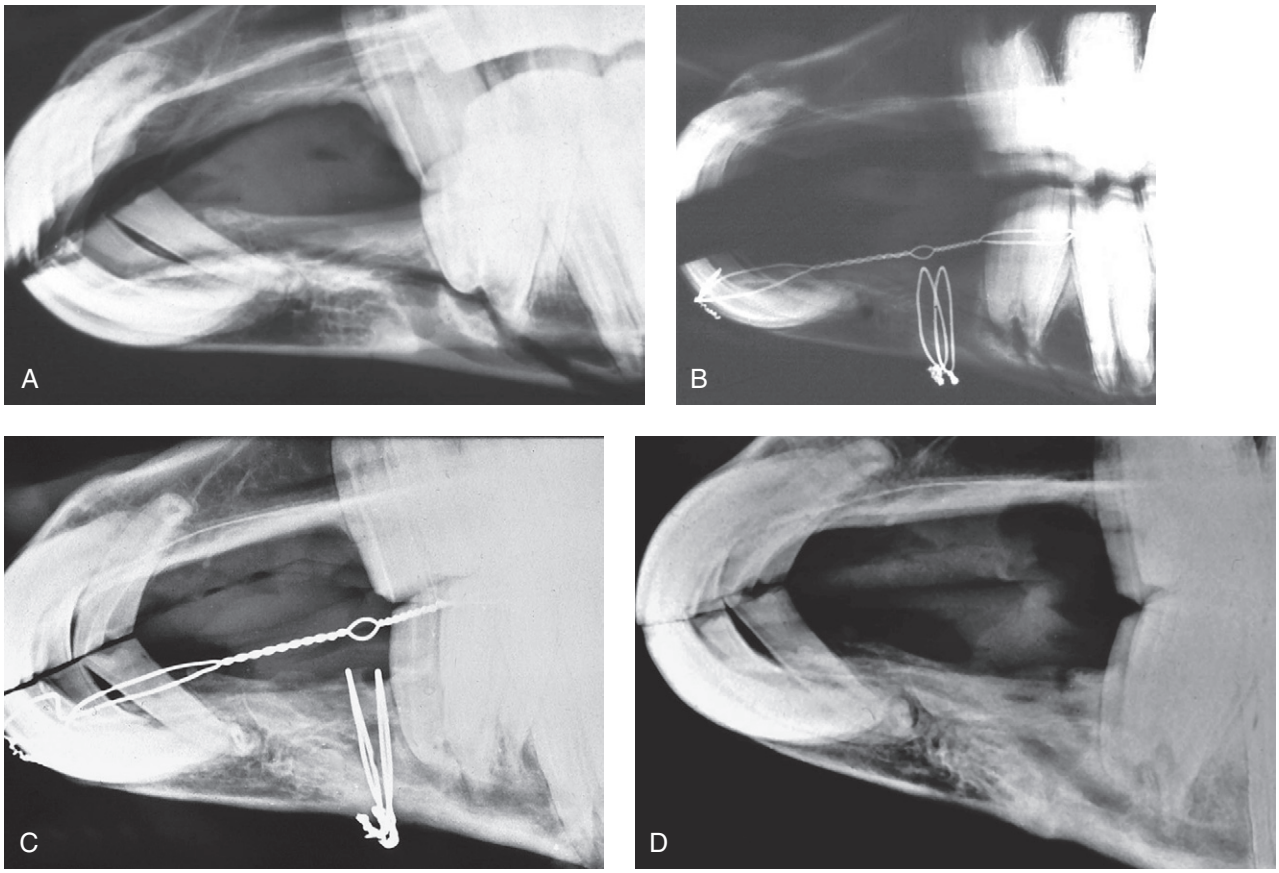

Figure 102-6. A, Preoperative radiograph of a long oblique fracture through the interdental space in a Shetland pony. **B,** Immediate postoperative radiograph showing the two circular wire loops in place, protected by a tension-band wire. **C,** Three-month follow-up radiograph showing the healed fracture. **D,** Radiograph after implant removal.

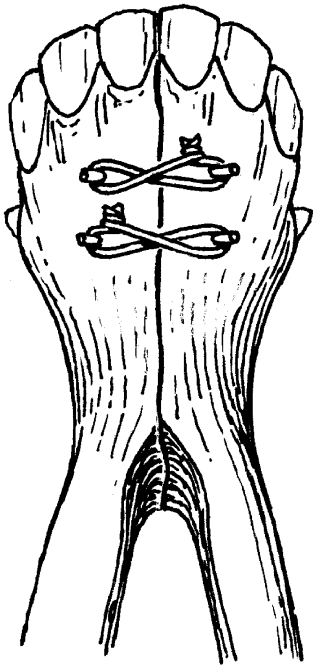

Figure 102-7. Hemicerclage fixation of a symphysis fracture. Two pins are placed across the symphysis. Figure-of-eight wires are placed around the protruding ends and solidly tightened to effectively stabilize the fracture. This type of fixation may also be applied to other locations.

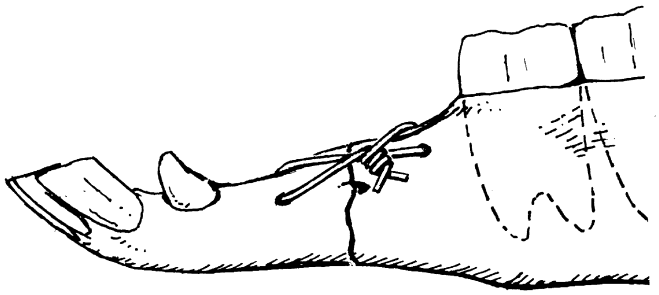

Figure 102-8. Figure-of-eight wiring of a vertical fracture of the mandible through the interdental space. The holes are created with a 2.5-mm drill bit or a Steinmann pin.

Under general anesthesia, the horse is placed in lateral recumbency on the surgery table with the fractured side toward the surgeon. With the help of hypodermic needles, the interdental space at the gingival level between 306 and 307 or 406 and 407 (see Chapter 30) is identified. Occasionally, the interdental space farther back is also used. Digital palpation facilitates identification as well.

When the space is identified, a stab incision is made through the cheek. A 2.5-mm–diameter drill sleeve is introduced through the stab incision and placed over the interdental space, and a 2.5-mm hole is created between the teeth at the level of the gingiva (Figure 102-9). A 1.25-mm diameter stainless steel wire

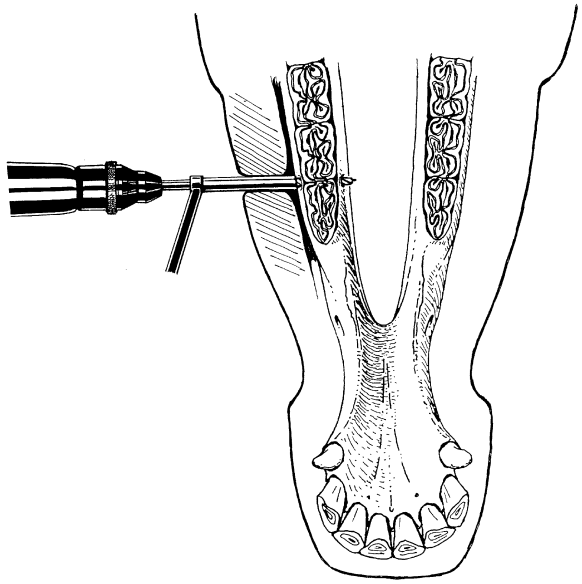

Figure 102-9. The drill guide is used to protect the cheek and gingiva as a drill bit creates a hole for passing the wire between the cheek teeth at the gum line. The wire is used to form a tension band across the interdental space.

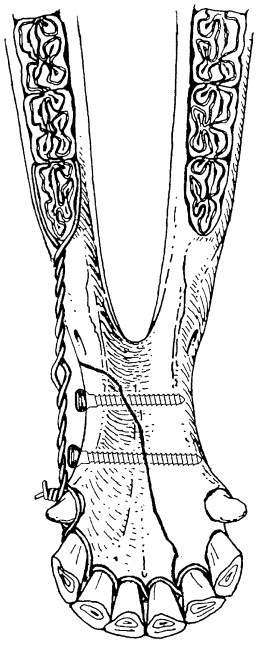

Figure 102-10. Screw repair using lag technique of a unilateral fracture of the mandible containing a large osseous fragment. The fixation is protected with tension-band wiring of the incisors to the first cheek tooth.

is threaded through the cheek and the hole that was drilled between the teeth. Both ends of the wire are pulled into the mouth and drawn rostrad out of the mouth. The wire is crossed and looped around the intermediate and corner incisors by threading the wire through a 14-gauge needle placed between the teeth. In young horses it is advisable to engage the central incisor of the opposite hemimandible to prevent inadvertent separation of the symphysis. The wire is twisted in the interdental space until an adequate tension is achieved (Figure 102-10). This results in a satisfactory repair because the wires compress the fractured bone ends, resulting in stability. Additional stability is provided by the contralateral intact hemimandible. Tension-band wiring to the premolars may be performed bilaterally, if indicated. This technique can be applied to the premaxilla, and in this location the other facial bones, the nasal septum, and the conchae add additional stability to the wiring fixation. This techniques also can serve as an adjunct fixation technique to plate fixation (see later).

Bilateral fractures are often comminuted. With comminution of the bone, tension-band wiring can lead to collapse of the fracture fragments and result in imperfect reduction. In these cases, additional support is required and can be provided by the methods described next.

ACRYLIC REINFORCEMENT OF INTRAORAL WIRING

As mentioned earlier, in comminuted fractures, where wiring causes collapse of the mandible or maxilla, some method of buttressing the bone is required to maintain its length. The simplest method uses acrylic reinforcement of the wires.

After the wires are loosely placed, an intraoral splint is prepared by molding dental acrylic around the interdental wires and contouring it to fit the mouth after anatomic reduction of the fracture (Figure 102-11). The acrylic conforms to either the roof or floor of the mouth from the caudal surface of the incisors to 306 or 406. The acrylic serves as a buttress to maintain length and alignment. Additional wires are placed as deemed necessary across the soft acrylic through drill holes in the bone and are tightened when the acrylic has set.

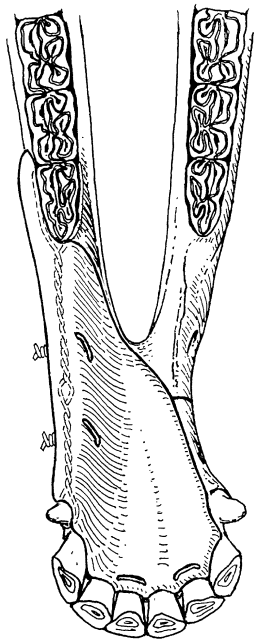

Figure 102-11. Intraoral splinting with dental acrylic (cold-curing type) formed around a tension-band wire between incisors and the first cheek tooth. Several additional wires are used to unite the splint with the mandible.

The surgeon should ensure that the acrylic splint is as form-fitting as possible and uses the least amount of material to serve the desired purpose. Excessive acrylic material in the mouth impedes eating by interfering with the horse's tongue. It is

impotrant to use dental acrylic because it sets with no appreciable exothermic reaction.

A more-precise fit of methyl methacrylate to the oral surface can be obtained by molding methyl methacrylate to the mouth as well as possible and allowing it to harden. The methyl methacrylate is removed after it starts to cure, and the shaping is finished with a rasp or dermal tool to remove excess material and round any sharp edges. After smoothing, holes are drilled in the splint for wiring to the mandible, premolars, and incisors as necessary. Wiring configurations vary with the individual fractures.[9,10]

U-Bar Brace

Bilateral fractures almost always require support in the form of an intraoral brace or external fixator in addition to tension band wiring to maintain axial alignment, limit side-to-side mobility, and prevent collapse (Figure 102-12).[4]

An intraoral splint is made from malleable brass or aluminum rods.[11,12] The pre-bent U-shaped brace is placed on the buccal surface of the incisors and spans the interdental space and the entire length of the dental arcade bilaterally. The brace is adaptable to fixation of fractures of the mandible, incisive bone, and premaxilla. The brace bar is fixed to the incisors and cheek teeth in multiple sites by cerclage wires encircling the teeth and bar. Wiring to the incisors is accomplished using individual cerclage wires, each encircling an incisor and the brace. Wiring to the cheek teeth is accomplished via stab incisions through the cheek and drilling between the teeth at the gum line.

This splint is very stable but is quite time consuming to apply (Figure 102-13). The splint can be aided by application of tension-band wiring as previously described.

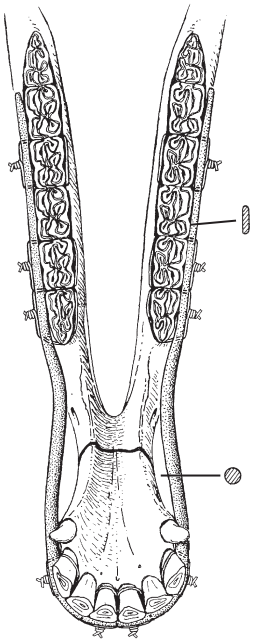

Figure 102-12. Intraoral splint made from an aluminum bar and molded around the contours of the mandible. The bar has a round cross-section in front and a flattened cross-section on each side. The aluminum bar is attached to selected teeth with cerclage wires.

Intramedullary Pins

Intramedullary pins can, in selected cases, be a useful adjunct in the repair of mandibular fractures.[13] Indications for intramedullary pinning are rare, because pin placement options are limited by the tooth roots. Intramedullary pins provide axial alignment, and protruding pin ends can serve as fixation points for wires. When used alone, intramedullary pins are likely to migrate. This type of fixation can be augmented by tension band wiring between the incisor and cheek teeth.

Screws

Interfragmentary screw fixation using lag technique is used to repair selected fractures of the mandible in the region of the diastema and symphysis.[7,14] This type of fixation is useful in this area, especially in adult horses, because the bone is strong enough for purchase of the screw threads, and the screws can be used under biomechanically favorable circumstances (see Figure 102-10). However, symphyseal fractures are rare in adult horses, so the opportunity to use screws is limited.

The fractures are reduced manually and held in reduction by pointed reduction forceps. A stab incision is made through the gingiva, and 3.5-mm, 4.5-mm, or 5.5-mm cortex screws are inserted in lag fashion across the fracture plane using routine technique. At least two screws should be placed to provide rotational stability. Interfragmentary screw fixation using lag technique is appropriate if the fracture configuration allows screw placement without damaging the teeth and there is adequate bone for purchase of the screws. Screws are not removed unless they become infected and are the source of persistent drainage or if they loosen.

A cortex screw may also be placed unicortically on each side of a fracture line so that the screw heads can be used as an anchor for figure-of-eight wiring. This provides a simple, minimally invasive method for tension-band wiring of the body of the mandible. This method also poses little risk to the tooth roots when the screws are placed on the ventral cortex.

A 5- to 7-cm longitudinal incision is made directly over the fracture on the ventral surface of the mandible. The fracture is reduced, and a 4.5- or 5.5-mm cortex screw is placed approximately 2 cm from the fracture line. Figure-of-eight wiring is completed with 1.25-mm stainless steel wire looped under each screw head and twisted until tight. Cortex screws can be inserted on the lateral surface of the mandible if preoperative or intraoperative radiographs are used to plan screw placement.

External Fixators

External fixators are good options for repairing fractures of the ramus or body of the mandible, premaxilla, and maxilla.[15,16] Advantages of external fixators include closed repair, reduced risk of sepsis, easy removal of implants, and good stability. Disadvantages are additional technical expertise and the expense of additional equipment, potential for traumatizing tooth roots, and, frequently, infection of pins associated with loosening. Intraoperative radiographic control is needed.

The indication for using type I external fixators is a unilateral fracture of the horizontal ramus of the mandible. With type I external fixators, the pins engage both cortices of one side of the mandible. A type I fixator may be applied with the horse positioned in either lateral or dorsal recumbency. Ideally, at

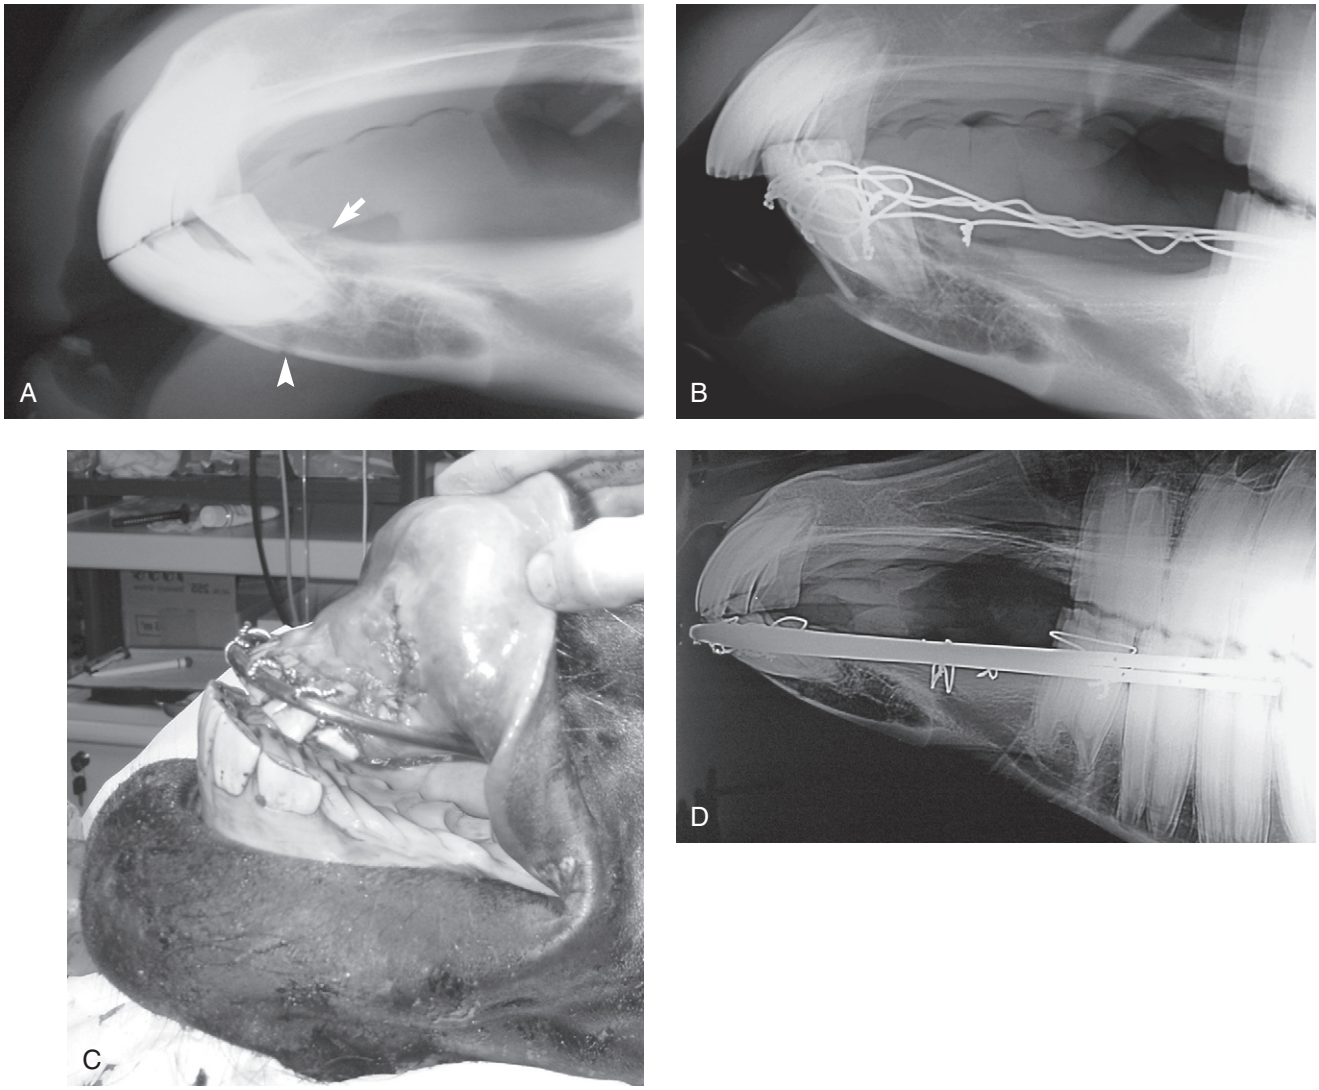

Figure 102-13. A, Preoperative lateromedial radiograph of a mandibular fracture. Good alignment is present and only slight disruptions at the cortex identify the fracture *(arrows).* **B,** Postoperative lateromedial radiograph after intraoral and tension-band wiring. Note the marked caudal displacement and upward rotation of the fragment caused by tightening the wires. **C,** The wires were removed and an intraoral brace was applied to fix the fracture and maintain the length of the mandible. **D,** Lateromedial radiographic view showing the brace in place.

least two pins should be placed rostral and caudal to the fracture.

Indications for a type II external fixator include bilateral fractures of the mandible or premaxilla or a highly unstable unilateral fracture (Figure 102-14). If a type II fixator is selected, Steinmann pins are used to penetrate the medial and lateral cortex of both mandibles, and a connecting bar is placed on each side. Type II fixators are best applied with the horse in dorsal recumbency.

The usual pin size is 4 mm in diameter, and a 6-mm diameter connecting bar is used. In type I fixators, positive profile *end-threaded* pins are preferred to standard smooth pins because of their increased holding power in bone and decreased risk of pin loosening. In type II fixators, positive profile *center-threaded* pins are preferred. The pin holes should be predrilled before inserting the pins. Holes are drilled starting with a 2.5-mm hole and sequentially enlarging it ideally to a size 0.1 mm smaller than the pin size, which provides perfect axial preload to ensure solid fixation within the bone.[17] During drilling, continuous flushing of the drill bit to reduce heat production prevents premature pin loosening caused by thermal necrosis of bone. High-torque, low-speed drills or hand drills are preferred to minimize thermal damage.

Steinmann pins are inserted through both cortices of either one or both mandibles via stab incisions in the skin. Radiographic assistance is used to place the pins either ventral to, or between, tooth roots. Pin placement perpendicular to the sagittal plane prevents the pin from angling in either a rostral or caudal direction and damaging a tooth on the opposite mandible. All pins should be inserted in the same horizontal plane to facilitate placement of the connecting clamps and rod.

An alternative technique that allows more variation in pin placement and is more forgiving of imperfect pin placement is to use an acrylic side bar. This obviates the need for all pins to be in the same plane. An acrylic side bar can be constructed with a piece of flexible rubber hose (25 mm inside diameter). The hose is skewered by the pins. The ends of the hose are occluded, and the lumen is filled with liquid

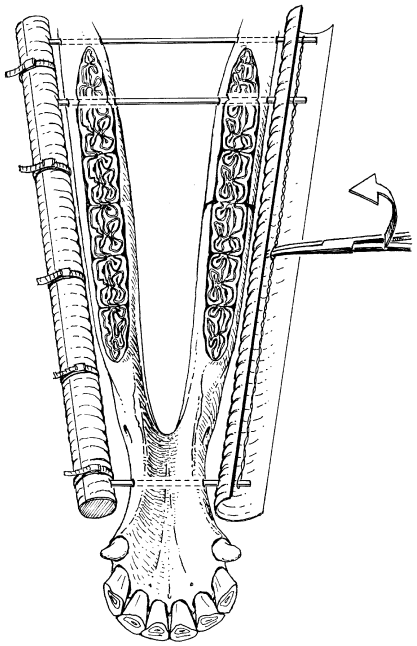

Figure 102-14. Type II external fixator is placed across both rami of the mandible. A tension-band wire is applied around the pins and tightened to achieve interfragmentary compression of the fracture. The open soft tubes are closed with parm bands, and the lumen is filled with epoxy material (e.g., polymethyl methacrylate, hoof acrylic).

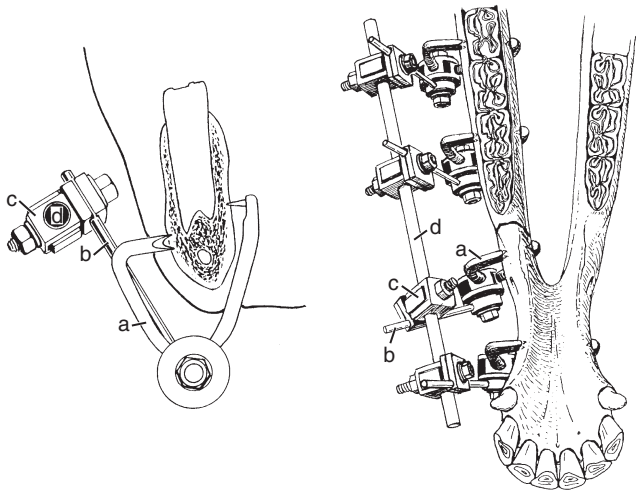

Figure 102-15. Pinless external fixator applied to a mandibular fracture. *a,* Asymmetric clamp attached to the ramus; *b,* small adjustable connecting rod; *c,* single external fixator clamp; d, tubular connecting bar, which fits into the clamp *(c).*

polymethyl methacrylate, which is allowed to harden. An acrylic side bar can be molded to fit closer to the horse's head, which decreases the likelihood of inadvertently catching the fixator on objects in the stall. However, an acrylic side bar cannot be adjusted should the need arise.

A variation of this method involves opening the hose over the whole length (see Figure 102-14). Wire is subsequently looped around the pins and tightened the same way as described for tension wiring of the cheek teeth. This compresses the fracture, resulting in greater stability. The hose is then closed with parm bands, and the hose is filled with acrylic, as described earlier.

PINLESS EXTERNAL FIXATOR

A pinless external fixator attaches to the mandible via clamps instead of conventional transcortical pins (Figure 102-15). Clamps are manufactured in a symmetric configuration with trocar-type points for attaching to the mandibular symphysis and an asymmetric clamp configuration with one trocar point and another bifurcated tip for fastening to the body of the mandible. Stab incisions are made in the soft tissues, and the tips of the bone clamp are embedded in the mandibular cortex by an applicator instrument. Clamp placement avoids soft tissue structures and tooth roots because the clamps attach only to the cortex. Connector rods, clamps, and a rigid side bar complete this type I external fixator configuration.

Use of the pinless external fixator has been described in the horse and in adult cattle.[7,18,19] It may be applied to add stability to a fracture treated with wires and/or a bone plate during the initial postoperative period (Figure 102-16). The benefits of this device include lack of pin tract infections, avoidance of traumatizing tooth roots, flexibility for selecting the application point, and the possibility to adjust the constuct during the healing period should the need arise. If a sequestum develops at the fracture site, it can be removed and the bed can be curetted without disturbing the construct. One disadvantage is the increased cost; however, these clamps can be reused several times, partially offsetting the purchase costs.

With either method of external fixation, daily pin tract care is required to prevent soft tissue infection. The pin–skin interface should be cleaned as necessary and antibiotic ointment and a bandage should be applied.

External fixators can inadvertently catch on objects in the horse's environment. This problem is minimized by fitting the fixator as close to the horse as possible, wrapping the fixator to cover areas prone to snagging, and stabling the horse in an area free of projections.

Plates

Bone plates are used for repair of fractures of the ramus and body of the mandible.[5,7,20] Plating has several disadvantages that limit its usefulness for repair of fractures of the horizontal ramus of the mandible. Plates must be placed on the ventral, ventrolateral, or lateral surface of the mandible. Plate application to the ventral aspect of the horizontal ramus is biomechanically inferior to placing it on the ventrolateral aspect, because the ventral aspect is the compression side of the bone. Exposure of the caudal ventrolateral mandible is complicated by the presence of the parotid salivary duct. Screw placement is difficult because of the tooth roots. There is little soft tissue to cover the plates on the ventrolateral aspect of the mandible. Also, most fractures of the mandible are open, communicate with the oral cavity, and result in contamination of the implants, which necessitates their eventual removal. Plate application to the maxilla also is very difficult except in the region of the interdental space.

Despite these drawbacks, there are indications for bone plates. Fractures of the horizontal ramus of the mandible involving the caudal cheek teeth and body of the mandible are difficult to repair with intraoral wiring procedures because of limited exposure. Severely comminuted fractures might benefit

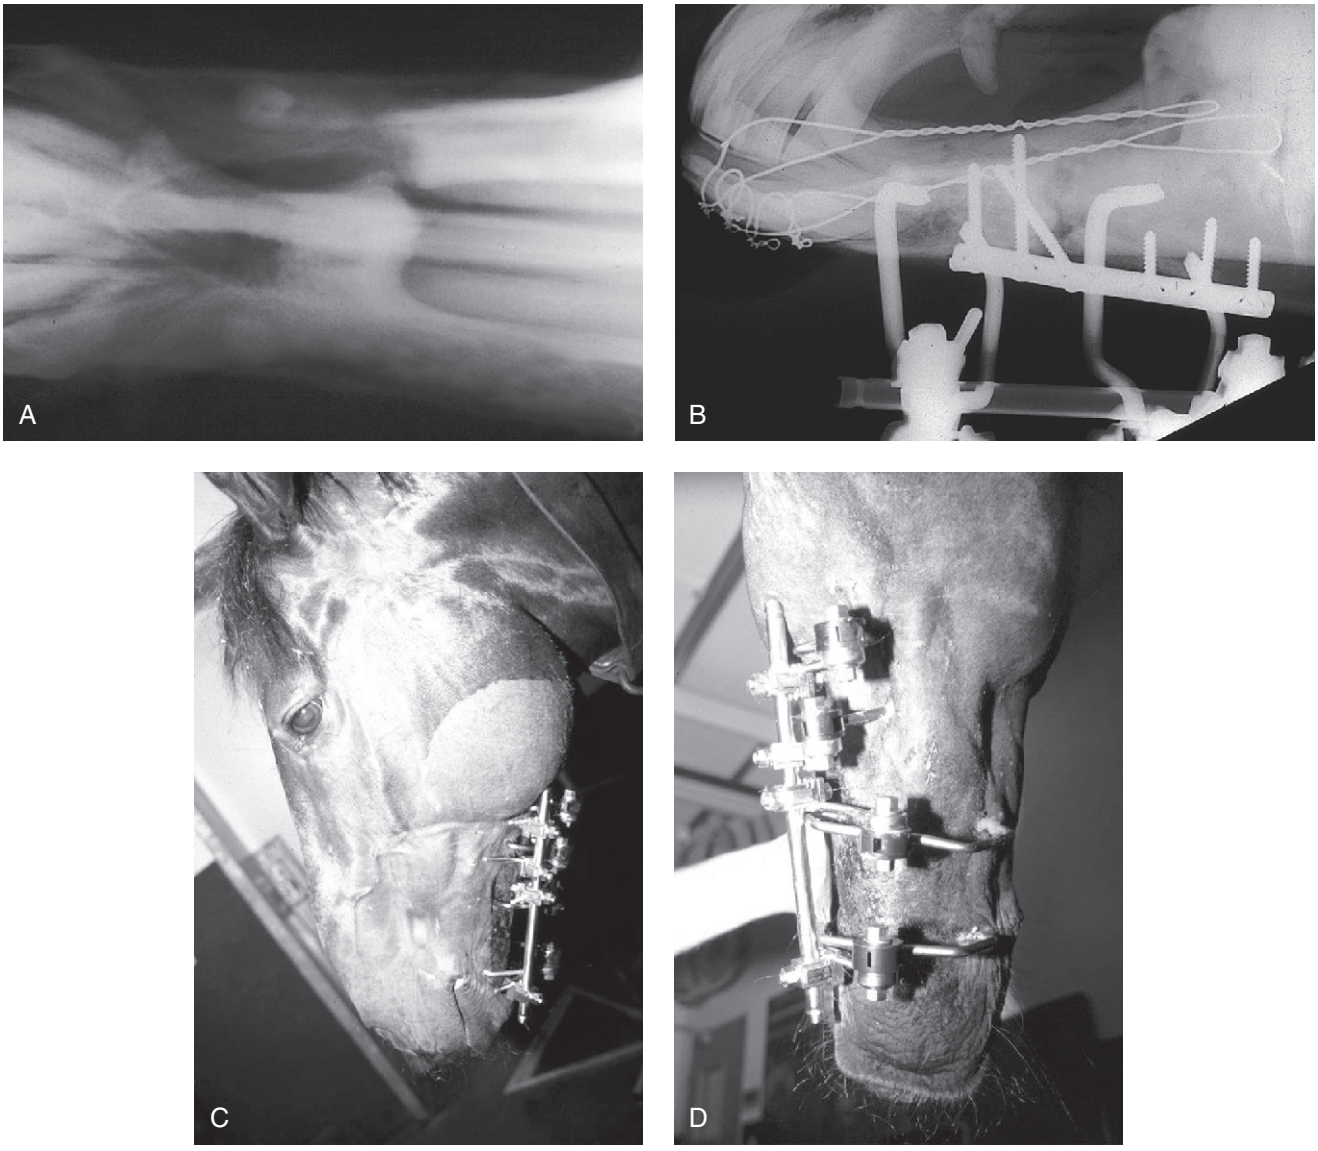

Figure 102-16. A, Ventrodorsal radiograph of a unilateral fracture of the horizontal ramus of the mandible with displacement. **B,** Postoperative oblique radiograph showing the plate implanted across the fracture supported by a tension-band wire. A pinless external fixator was used to provide additional support during the initial postoperative period. Lateral **(C)** and ventrodorsal **(D)** views of the head with the pinless external fixator applied.

from bone plates used in buttress fashion. Broad or narrow 3.5-mm limited-contact dynamic compression plates (LC-DCPs) or reconstruction plates or 4.5-mm LC-DCPs with at least three screws on each side of the fracture have been used. In selected cases, long plates have been used and screws inserted in selected holes along the plate.

As mentioned earlier, compression plating is an option for fractures of the horizontal ramus of the mandible in the interdental space (Figure 102-17). However, the most appropriate indication for the use of bone plates is closed fractures of the body and vertical ramus of the mandible. Horses demonstrate less pain and return to feed quicker when these fractures are stabilized. These fractures are usually closed and have adequate soft tissue covering. The tooth roots do not pose an obstacle to screw placement in this area.

Locking compression plates represent state-of-the-art technology and are currently the preferred choice for repair of craniomaxillofacial fractures.[21] Application technique is as described in Chapter 76. At least two locking-head screws are inserted on either side of the fracture plane to realize the advantage of locking technology. If the plate is applied to the ventral aspect of the mandible, the fixation needs to be augmented with tension-band wires between the incisors and the cheek teeth (Figure 102-18).

Plates are also excellent choices at the caudal aspect of the horizontal ramus. Conversely, the lateral aspect of the vertical ramus is extremely thin and does not accept 4.5-mm screws. Smaller screws may be used, but the implants are not strong enough to withstand the cyclic loading that occurs during chewing. Additionally, the facial nerve and the transverse facial artery and vein are located superficially on the lateral aspect of the ramus.

To place a plate on the caudal aspect of the horizontal ramus, a skin incision is made along the caudal edge of the mandible

that parallels its caudal border. In that location, the masseter muscle can be avoided and there is abundant bone to allow solid insertion of the screws. A large periosteal elevator is used to expose the caudal rim of the vertical ramus.[22] A plate spanning the fracture and providing three to five screw holes on either side is selected (Figure 102-19). Selecting a longer plate allows the surgeon to choose which plate holes to use. In selected cases, wire sutures may be used to appose fracture lines on the lateral surface of the ramus through small incisions (see Figure 102-19). The plate is contoured to the surface of the bone and applied using routine technique. The subcutaneous tissues and skin are reapposed over the plate, with sutures in two separate layers.

A study evaluating multiple fixation techniques of an osteotomy in the diastema of the mandible compared dynamic compression plate (DCP) fixation with an external fixator and

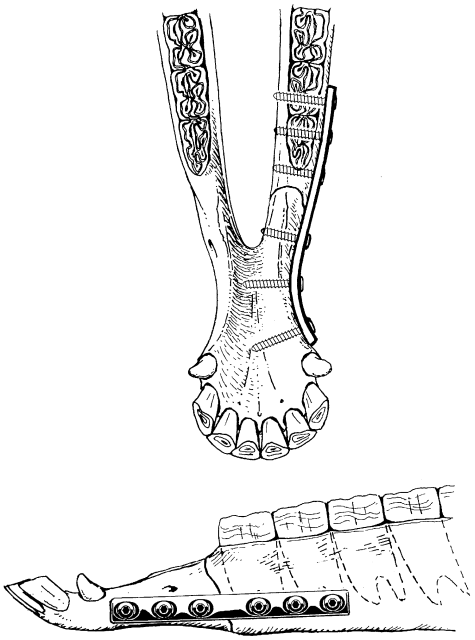

Figure 102-17. A six-hole 4.5-mm narrow dynamic compression plate is applied to the horizontal ramus of the mandible. The screws are inserted between the tooth roots.

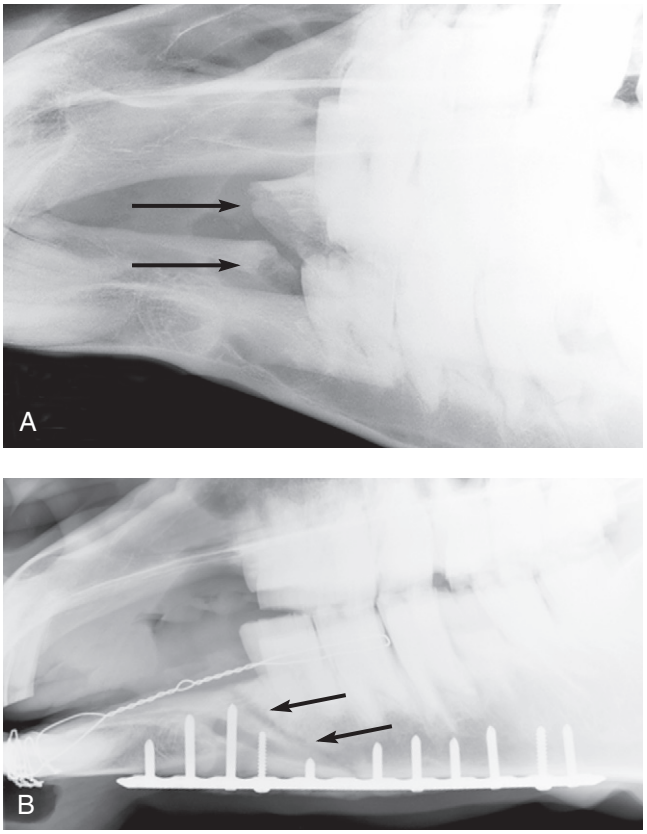

Figure 102-18. A, Oblique radiographic view of unilateral mandibular fracture *(arrows)* in the interdental space of an adult horse. **B,** Postoperative lateromedial radiographic view of the same fracture treated with a 12-hole narrow LCP and an interdental tension wire between the incisor- and cheek teeth. Good fracture reduction was achieved *(arrows)*.

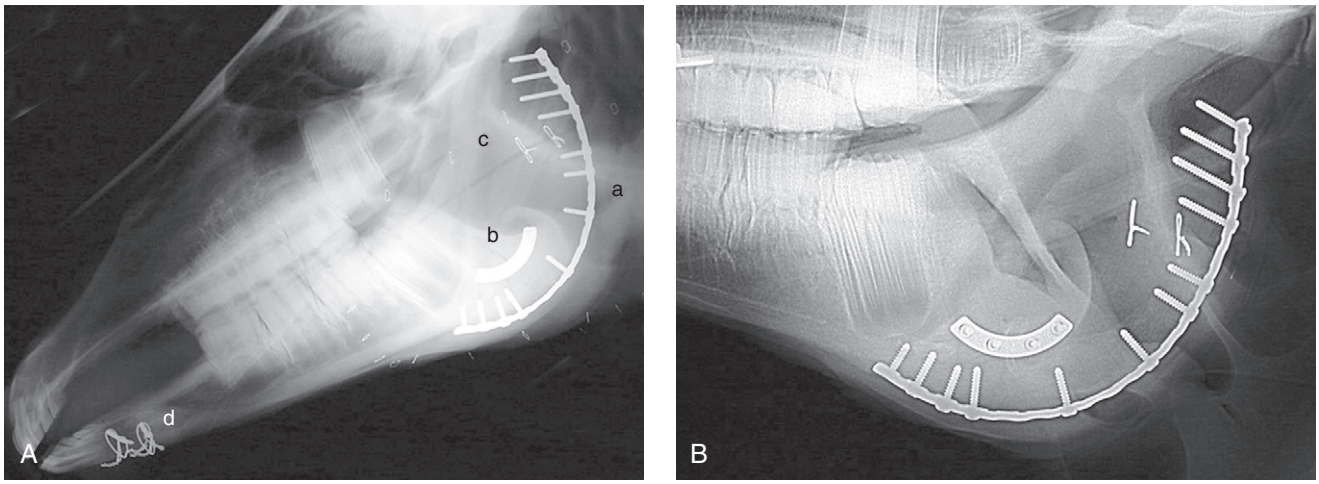

Figure 102-19. A, Immediate postoperative lateromedial radiographic view of the fractured mandible of the same foal as in Figure 102-2. The fractures were repaired with mulitple implants. *a,* A narrow 3.5-mm reconstruction plate was applied to the caudal edge of the ramus with 12 3.5-mm cortex screws placed in selected holes. Four screws were placed at each end; *b,* to provide additional stability to the triangular fragment, a four-hole small-animal 3.5-mm acetabular plate was implanted; *c,* the horizontal fracture was supported with two wire sutures; *d,* the fracture of the symphysis was repaired with two hemicerclage constructs. **B,** Four-month follow-up radiographs before implant removal. All fractures have healed.

interdental wiring and an intraoral splint and interdental wiring. This study revealed that DCP fixation had the greatest stiffness under monotonic bending to failure; however, the relatively low yield value might predispose it to earlier failure in fatigue testing without supplemental fixation.[23] The techniques using tension-band wiring in conjunction with an external fixator or an intraoral splint were similar to DCP constructs in yield, failure, and osteotomy displacement, whereas the external fixator constructs alone were biomechanically inferior to all others.

Therefore, plate fixation is probably the most stable form of fixation for comminuted fractures of interdental spaces.[21,23] However, for simple interdental space fractures, intraoral splinting together with interdental wire fixation should provide adequate stability with minimal invasiveness and decreased expense. Tension-band wiring significantly enhances the strength of type II external skeletal fixators and should be used to augment mandibular fracture repairs.[23]

Chronic mandibular fractures that become non-unions require special management. They usually present with a draining fistula that communicates with the fracture. If surgery is elected, the fracture site should not be disturbed. The skin at the lateral side, proximal to the draining fistula, is opened and the tissues are dissected until the fibrous capsule surrounding the fracture site is identified. The bone on either side of this capsule is exposed and a plate is selected that allows at least three screws to be inserted on either side of the fracture. The plate is contoured to fit over the capsule of the infected fracture. The screws are inserted using routine technique to apply compression across the fracture without inserting screws near the fracture itself (Figure 102-20). Locking compression plates are ideal for this purpose. The goal of this technique is to provide solid bridging fixation of the fracture without spreading the infection to the implants, which could lead to premature loosening of the screws and delayed fracture healing.

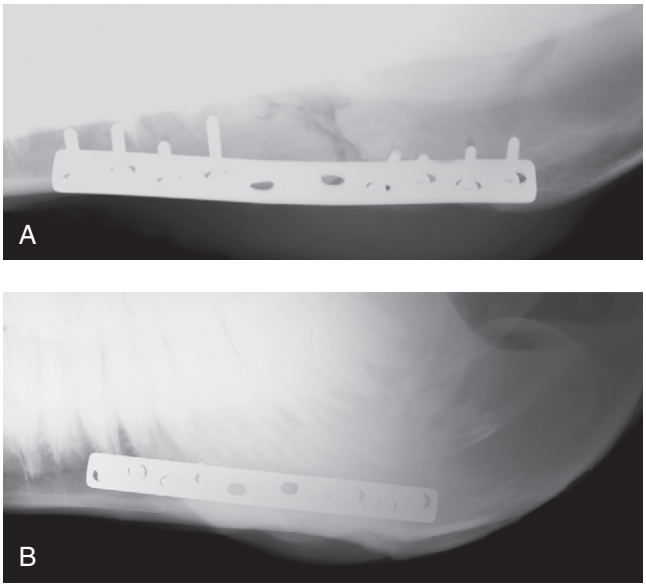

Figure 102-20. A, Immediate postoperative lateromedial radiographic view of a chronically infected mandible fracture in an adult horse repaired with a 10-hole DCP applied to the bone without opening the fracture site. **B,** Three-month postoperative radiographic view of the healed fracture immediately prior to plate removal.

Aftercare

Horses rarely demonstrate a reluctance to eat after mandibular fractures are stabilized, and they quickly return to routine feeding.[4] No attempt to modify the diet is made following repair of incisor fractures. Fractures involving the cheek teeth could give the horse more difficulty during mastication, and some dietary adjustment may be needed. Horses should be provided a palatable diet that can be easily chewed. They usually prefer customary foodstuffs to the gruels and mashes sometimes recommended during convalescence. Therefore, there is little need to modify the diet unless there is a clear indication that the horse is having difficulty in masticating.

All foodstuffs tend to accumulate around the intraoral wires, rods, and acrylic. Frequent garden hose lavage of the mouth to remove accumulated debris is beneficial if the horse will tolerate it.

Phenylbutazone is routinely administered at 4.4 mg/kg *per os* for 7 days. The decision to administer antibiotics is made on an individual basis. Most fractures are open and contaminated and benefit from administration of broad-spectrum antimicrobial agents.

Removal of the implant is usually carried out on the standing patient after healing has occurred, usually in 6 to 8 weeks. Bone plates and buried cerclage wires are not customarily removed unless the implants become infected.

Complications

Implants should be inspected regularly because wires tend to loosen and break (Figure 102-21). Loose wires may be tightened by additional twisting. Undetected loosening of implants can result in malocclusion and delayed healing because of instability. The decision to replace broken implants should be based on the timing of implant failure. The wires can be removed if the fracture is stable at the time of breakage. Failures that occur earlier in the postoperative period require replacement to maintain alignment and stability. Cable ties mentioned earlier serve as alternatives. Even 1 mm cables resist breakage much better than wires, and they should be considered if wires need to be replaced.

Plate breakage is a rare complication but can occur (Figure 102-22). If a plate breaks, it is an indication that there is a considerable amount of instability. The plate should be replaced and additional fixation should be added to the constuct to reduce the cyclic loading of the implants.

Drainage from the fracture is common following repair of open fractures, because infection always develops after exposure to the oral cavity. In most cases, the infection resolves with systemic antimicrobial therapy and effective drainage. Drainage that persists for more than 4 weeks should be investigated.

With closed repair of comminuted fractures, small fragments of avascular bone commonly become sequestra. Radiographs should be taken to ascertain whether there are sequestra if drainage persists. In many cases, the sequestra can be removed by curettage in the standing patient if the fragments are superficial.

Callus formation is to be expected with secondary bone healing of infected fractures and is more prominent with fractures that occur in the horizontal ramus of the mandible, because there is less soft tissue coverage. Factors that increase

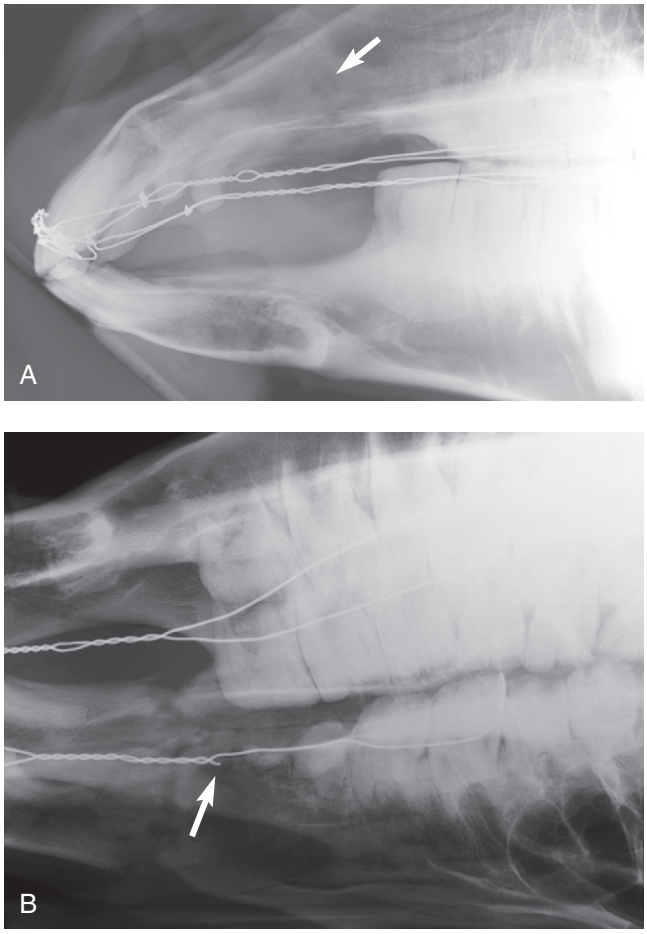

Figure 102-21. A, Lateromedial radiographic view of a unilateral maxilla facture *(arrow)* treated with bilateral tension band wires between the incisor and cheek teeth. **B,** One-month postoperative oblique radiographic view of the treated fracture. One wire is broken *(arrow)* and part of the loop around the cheek teeth is missing. The wire was replaced.

callus formation are comminution, infection, and instability in the repair. Efforts to attenuate these factors are rewarded with a more cosmetic outcome.

Prognosis

The prognosis for a serviceable outcome is favorable in most cases. Imperfect reduction of fractures leads to malocclusion. Fractures of the teeth themselves and fractures involving the alveolus sometimes result in tooth loss. Tooth loss (when it occurs) and irregular tooth wear because of malocclusion are managed effectively by regular dental care.

FRACTURES OF THE SKULL AND SINUSES

Fractures of the skull and sinuses are the result of blunt trauma from being kicked or from collisions. The most commonly injured bones include the nasal, frontal, and maxillary bones and the zygomatic process of the frontal bone. The trauma that produces fractures to these bones can cause damage to the brain, eye, and nasal passages, resulting in severe hemorrhage.[4] Depression fractures are often found.

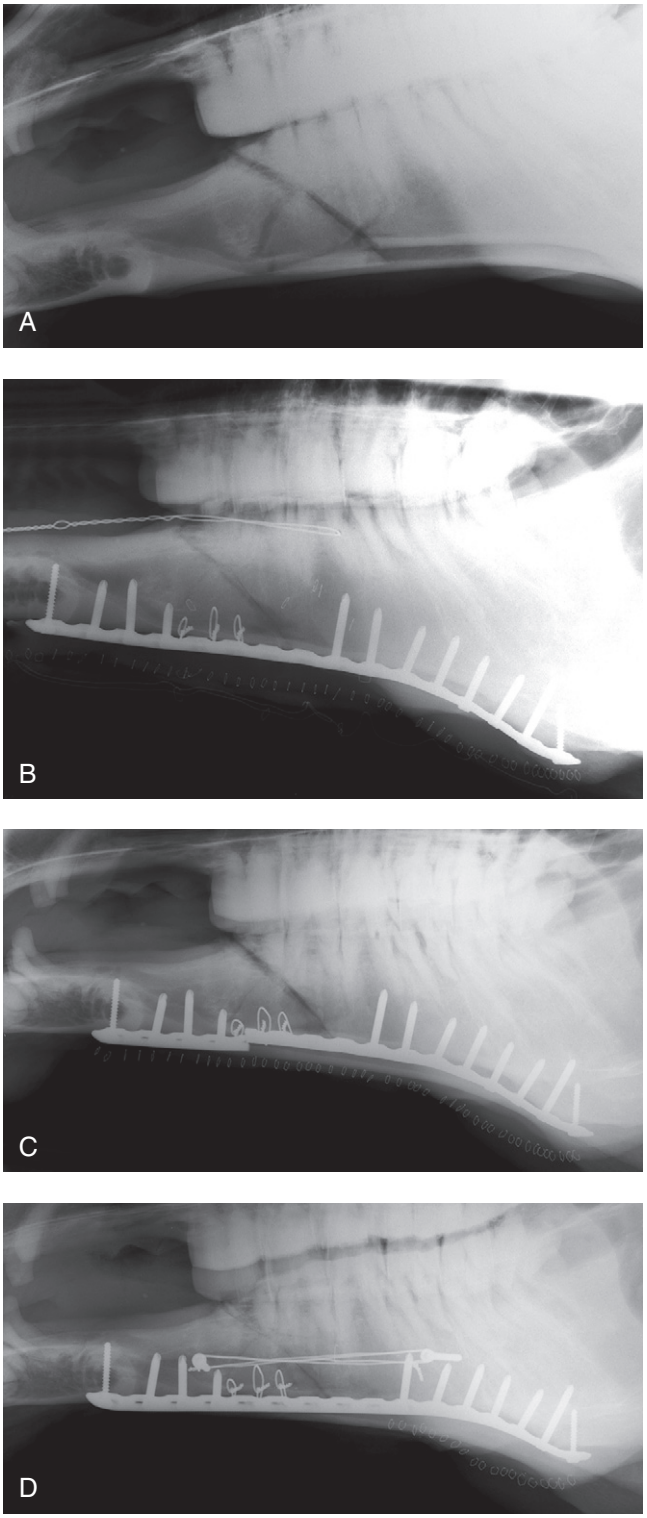

Figure 102-22. A, Lateromedial radiographic view of a multifragment (comminuted) mandibular fracture entering the interdental space. **B,** Postoperative lateromedial radiographic view of the fracture treated with a 16-hole narrow LCP augmented with a tension wire beween the incisor and cheek teeth. Wire sutures were used to unite some fragments. **C,** One-week postoperative lateromedial radiographic view of the fracture showing the broken plate. **D,** Lateromedial radiographic view of the fracture following revision of the repair. The plate was exchanged and the screws were inserted into the same holes. Lateral tension band wires were added to reduce interfragmentary instability.

Diagnosis

Initially, a minimally displaced depression fracture can be difficult to detect on physical examination because of the soft tissue swelling that obscures the depression. Other signs include obvious bone displacement, epistaxis, and skin lacerations. Emphysema can be palpated in the soft tissues as crepitus when fractures communicate with the nasal passages or sinuses. Radiographs with multiple oblique views are necessary to demonstrate the fracture. Computed tomography greatly aids with the final diagnosis and preoperative planning of the repair (Figure 102-23). Physical examination should include endoscopic examination of the upper airways as well as neurologic and ocular examinations to assess for additional undetected trauma.

Treatment

Initial therapy should be directed toward stabilizing the patient, because in most cases there is no urgency in the repair.[4] In fact, fracture repair is often difficult if significant soft tissue swelling has developed, and therefore repair is best delayed until swelling resolves. Skin lacerations should be repaired immediately to prevent infection of the soft tissues, even if fracture repair is delayed. Hyperosmotic wound dressings applied under pressure wraps will dissipate the edema.[4] Phenylbutazone is administered to decrease inflammation, and antimicrobial therapy is indicated for any open fractures or fractures that communicate with the sinuses. Tetanus prophylaxis is indicated in all cases.

Trauma to the facial bones often results in hemorrhage into the sinuses, which shows up on a lateral radiograph as a fluid line within the sinus. Consideration should be given to standing sinus lavage for removal of accumulated blood when present, to prevent the development of empyema within the sinus. Lavage is performed via an ingress portal made with a 6-mm Steinmann pin inserted into the frontal sinus and polyionic fluid lavage with a pressurized fluid delivery system.

Repair should be performed as soon as the soft tissue swelling is resolved. Delay in repair beyond a few days can result in difficulty in achieving reduction. The goals of repair are to maintain a patent airway and nasolacrimal duct, prevent ocular damage, and obtain a cosmetic appearance. Cosmetic

considerations are the main purpose of repairing fractures that do not impact other body systems.

The typical configuration is a segmental depression fracture. Often, the skin and periosteal attachments are intact. Even so, the fractures usually communicate with the nasal passages or sinuses and will be contaminated, so that infection of soft tissues and of implants could develop.[24] Therefore, the surgical approaches should be as minimally invasive as possible. Many fractures can be reduced through stab incisions with no stabilization beyond that provided by the soft tissue attachments.[4]

Adequate reduction can often be achieved by elevating the fragments and wedging them back into place.[25] Whenever possible, closed reduction should be performed. The soft tissue attachments provide vascularity and the means for stabilizing the fractures after they are reduced. Adequacy of fracture reduction can be ascertained by direct inspection or evaluation of the facial contour; this is the reason for allowing the soft tissue swelling to resolve before attempting any repair.[4] Ultrasonography may be used to evaluate anatomic reduction of depression fractures. The depressed fragments can be elevated by drilling holes in the bone and inserting an elevator to pry the fragment back into place.[26] A disadvantage of this approach is that commercially made elevators typically have a broad, flattened shaft that requires large drill holes to insert into the bone.

A better way to elevate the fracture fragment involves drilling a hole into the depressed segment with either a 3.5-mm drill bit or a Steinmann pin on a Jacob chuck. A 3-mm diameter Steinmann pin can be bent and inserted into the hole to elevate and wedge the fragment back into place. The end of the pin is bent at a right angle so that when the pin is inserted into the hole drilled in the fracture segment it has a broad area of contact and added leverage for elevating the fragment (Figure 102-24). The length of the bent end should approximately match the width of the depressed bone segment. Another right angle bend is made in the opposite end of the pin to make a handle.[4] Axial traction is applied to pull the fragment back into place.

The skin over the drill holes is closed with a single suture. If necessary, multiple drill holes can be made with little or no disruption of the soft tissue attachments. In most cases the fragments can be wedged into place with no additional stabilization required because the fractures are not load bearing. If the fractures do require stabilization to maintain reduction, wire sutures can be applied in selected locations around the fragment. A small skin incision is made to expose the fracture line. A Steinmann pin (1.6 mm) and hand chuck or 2-mm drill bit is used to pre-drill holes for 0.8- to 1-mm cerclage wire sutures (see Figure 102-24). Skin closure is routine.

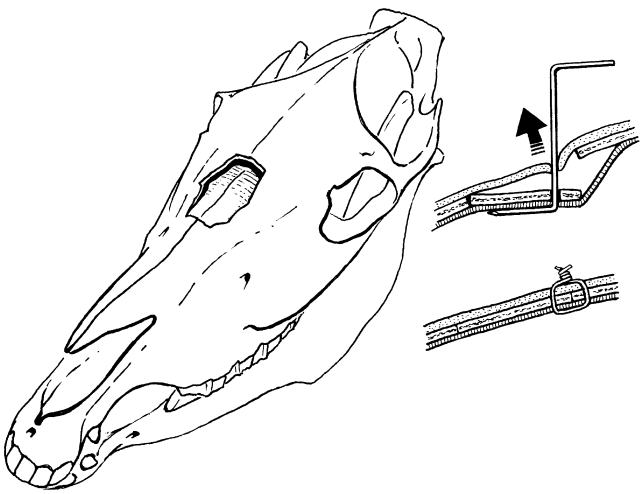

Figure 102-24. Insertion of a Steinmann pin through a small drill hole for elevation of a depressed bone fragment. If necessary, the fragment can be fixed with cerclage wire.

The FlapFix system has been developed for fragment fixation of flat bones. The system is designed for fast, easy, and stable fixation of bone flaps following a craniotomy or the treatment of craniomaxillofacial fractures in humans. The implant consists of a round, smooth, or toothed titanium plate that is centrally connected to a thin orthogonally oriented titanium tube (Figure 102-25, *A*). The plate is slightly cupped to ensure that only the outer rim makes initial contact with the underside of the bone. A smooth, also slightly cupped, cloverleaf-shaped plate is fed over the titanium tube (see Figure 102-25, *A*). The implants are available in three different sizes depending upon the shape and type of fracture or bone flap that needs to be repaired or fixed.

In a clinical case, the round plate with the perpendicular tube is placed underneath the fractured bone and the tube exits through the fracture line or the osteotomy cut (Figure 102-25, *B*). The cloverleaf plate is then fed over the vertical tube and slid down onto the bone. An alternative is to slide the cloverleaf plate over the tube, grab it with the Flap-Fix clamp, and maneuver the lower plate through the osteotomy cut/ fracture line underneath the bones to be united (see Figure 102-25, *B*) The Flap-Fix clamp is then moved down over the tube and pushed up against the second plate. By squeezing the main handles together, the proximal plate is pressed firmly onto the bone surface (Figure 102-25, *C*). When the desired clamping force is reached a second handle is squeezed to cut the tube flush with the upper plate (Figure 102-25, *D* through *F*).

These implants are manufactured from titanium, which renders them tissue-friendly, and no adverse reactions are usually encountered. The limited applications of this implant in horses have all been successful and none of the implants have had to be removed.[27]

The Flap-Fix represents an alternative to wire loops. Its advantages include the rapid speed of application, the increased stability of the fixation, the increased contact area of the implant with the bone, the inertness of the implant material, and the greater resistance to failure.[27] The major disadvantage is the high cost of the implant.

Occasional indications for the use of reconstruction plates arise with severely comminuted or unstable fractures. These plates are made in a variety of shapes and sizes and are easily contoured to fit specific fracture configurations.

Aftercare

Postoperatively, a pressure bandage is applied, and phenylbutazone is administered to decrease postoperative swelling and discomfort. Broad-spectrum antimicrobial agents are administered as necessary to treat soft tissue and sinus infections and prevent implant infections.

Complications

Inadequate reduction results in an inferior cosmetic outcome. Secondary bone healing results in callus formation, which causes an obvious blemish when it occurs over areas with no muscle. This is, however, only of temporary duration, because

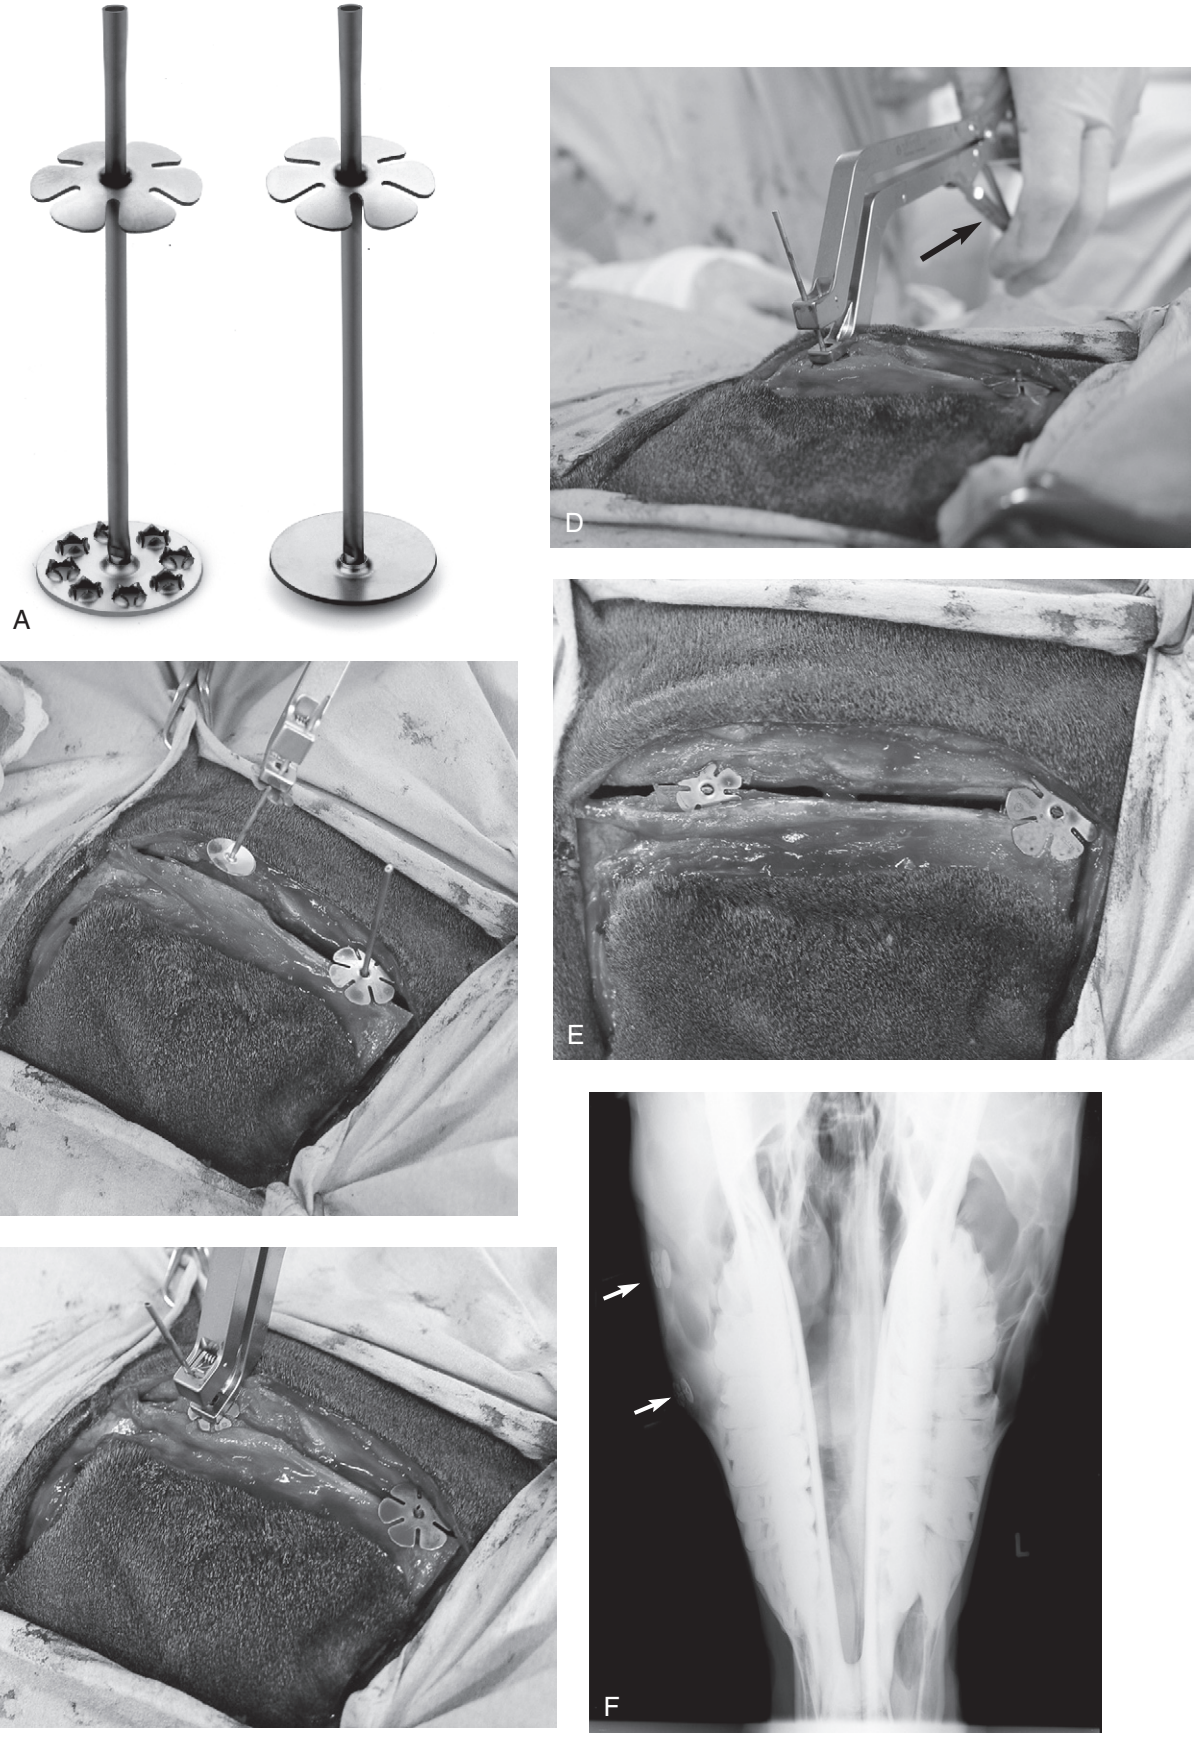

Figure 102-25. A, The two versions of the Flap-Fix assembled but not tightened (toothed type on the *left* and the smooth plate on the *right*). **B,** A large Flap-Fix is in place at one corner of a sinus bone flap, while a second, slightly smaller assembled Flap-Fix is manipulated under the other corner with the help of the Flap-Fix clamp. **C,** The first Flap-Fix has been tightened, while the smaller one is being tightened with the Flap-Fix clamp by squeezing the main handles. **D,** When appropriately tightened, the protruding vertical titanium tube is cut flush with cloverleaf plate by squeezing the secondary handle *(arrow).* **E,** Both Flap-Fix implants are in place and tightened. The vertical tube was cut flush on top of the cloverleaf plate. **F,** Ventrodorsal postoperative radiographic view of the skull of the horse shown in the previous figures. The Flap-Fix implants are easily recognized on the left side of the head *(arrows).*

after the fracture is healed remodeling of the callus occurs, normalizing the contours of the skull. Hemorrhage into the paranasal sinuses can develop into a sinus empyema if untreated. Stenosis of the nasal passages can occur with severe injuries; however, this is rare. If the fragment is denuded of its blood supply through a loss of the periosteum, sequestration can occur, but it is less frequent than with mandibular fractures.

When a sunken appearance is evident after healing because of inadequate reduction of depressed fragments or in cases that were left untreated (Figure 102-26), refracture and proper alignment is not easily accomplished. The facial contour can be restored by implantation of prostheses of either a silicone or a fluorocarbon polymer and carbon fiber combination.[28,29] General anesthesia and strict asepsis are required.

With either technique, a slightly curved incision is made over the defect to expose the sunken bone. The implant material is sculpted to fill the defect and restore the normal facial contour. The silicone prosthetic material is sutured in place between the periosteum and the skin. A subperiosteal dissection is performed for insertion of the fluorocarbon polymer–carbon fiber prosthesis between the bone and periosteum. Skin closure is routine.

Prognosis

The prognosis for return to previous level of performance is usually good. The cosmetic outcome depends on the reduction achieved at surgery and is usually acceptable and often excellent depending on the severity of the injury.

PERIORBITAL FRACTURES

Fractures of the orbit are common in horses. The orbit serves as a protective housing for the eye and associated adnexa.[4] The orbit consists of the lacrimal, frontal, and zygomatic processes of the frontal and temporal bones. Fractures are the result of direct trauma and are usually depression fractures. Concurrent injury can be sustained to the central nervous system, eye, lacrimal duct, other skull bones, and the paranasal sinuses. These structures warrant examination as part of the physical examination prior to repair.

Figure 102-26. An Arabian horse with a depression fracture *(black arrow).* There is some blood at the left nostril *(white arrow).*

Diagnosis

Diagnosis is made by physical examination. Abnormal facial contour, soft tissue swelling, crepitus, and hemorrhage are usually present.[4] Acute soft tissue swelling can obscure the fracture and make detection difficult by physical examination alone. Pain can preclude a thorough physical examination in the unsedated patient.

Radiographs are indicated to identify trauma to the orbit but are also useful to identify concurrent injury and problems such as fluid in the maxillary sinuses. Fractures of the zygomatic arch are visible on the appropriate views; however, trauma to other parts of the orbit are difficult to recognize radiographically.[4] Oblique views at different, sometimes acute, angles are often necessary to highlight the fractures. Ultrasonography might allow diagnosis of fractures and of tissue injuries lying deeper in the orbit. Computed tomography is the best imaging techique to achieve an accurate diagnosis.

The extent of ocular trauma is variable and ranges from chemosis to rupture of the eye. A thorough ocular examination should be performed as soon as possible following the injury, including an assessment of the patency of the lacrimal duct when fractures of the lacrimal bone are present.

Treatment

Fractures will heal without surgery, but in most cases they are associated with a facial deformity. Surgical repair is indicated to relieve impingement on and pressure to the eye. Injury to the eye is treated as circumstances warrant (see Chapter 55). Repair is best attempted as soon as the patient is stabilized. The goal of reconstruction is to relieve impingement on the globe and adnexa and restore the normal anatomic contours to achieve a cosmetic outcome.[4] There are no muscle attachments to the orbit, except the small palpebral muscles that are inconsequential to any repair undertaken. Fractures often need only to be realigned to heal properly.[24] It is important to palpate the inner surface of the orbit to identify and remove any bone fragments that can damage the eye. These fragments are very difficult to identify radiographically.

Fractures of the orbit that involve the zygomatic, lacrimal, or frontal bones are usually depression fractures and may be treated by elevation of the fragments via drill holes in the depressed segment as described in the previous section.

Zygomatic process fractures may be reduced noninvasively by use of a bone hook.[25] The horse is prepared for surgery with the affected side up. A finger is inserted into the orbit in the conjunctival space to palpate the fracture and guide the placement of a bone hook onto the ventral surface of the displaced fragment. Dorsal traction is used to elevate and wedge the fragment back into anatomic alignment (Figure 102-27).[21] Fractures of more than 48 hours in duration are more difficult to reduce.

Most fractures are sufficiently stable so that no other form of fixation is required. Fractures that do not maintain alignment

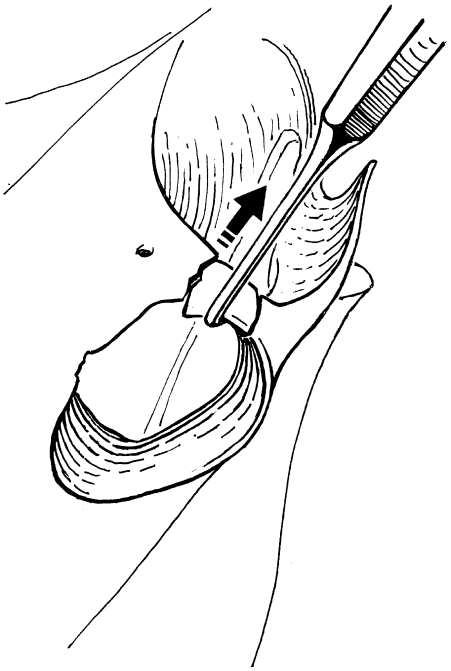

Figure 102-27. Use of a bone hook to reduce a depressed zygomatic arch fracture. The *arrow* shows the direction of the pulling force.

after reduction require some form of stabilization in addition to that provided by the soft tissue attachments. These fractures are usually comminuted or involve portions of the orbital rim other than the zygomatic arch. Open reduction and interfragmentary wiring is the easiest but not the sturdiest method to provide additional stability when needed.

An incision is made directly over the fragments to be wired. Holes are drilled into the bone with a 2-mm drill bit. Cerclage wire of 0.8 mm to 1 mm diameter is pre-placed and twisted to tighten.[25]

Reconstruction plates can be used to repair severely comminuted fractures of the zygomatic arch (Figure 102-28). These plates have the advantage of being easily contoured. Bone plates should be reserved for cases in which easier methods will not achieve a satisfactory result.

Aftercare

Phenylbutazone is administered postoperatively to decrease discomfort and soft tissue swelling. Antimicrobial agents are not required if the fracture is reduced noninvasively. Systemic antibiotic agents should be administered if the fracture is open or communicates with the maxillary sinus, or if implants are used. Pressure bandages are not used because they may cause problems with the eye. Selection of any topical medication, if needed, should be based on safety of the substance for use in the eye.

Complications

Periorbital fractures are often associated with trauma to the eye. Rupture of the eye, proptosis, corneal ulceration and laceration, chemosis, and damage to the nasolacrimal duct are reported complications.[24,29] Empyema of the maxillary sinus can occur secondary to hemorrhage into the sinus.

Prognosis

Healing of the fractures usually proceeds uneventfully. The cosmetic appearance depends on the accuracy of surgical reduction and the amount of callus but is usually favorable. A prognosis for associated ocular trauma depends on the nature and severity of the injury.[4]

CRANIOFACIAL DEFECTS (SINUS FISTULA)

Craniofacial defects can develop as a result of external trauma to the facial bones over the sinuses. If the fragments over a sinus are denuded of their blood supply, they can undergo necrosis, leading to the formation of sinus fistulas of various sizes (Figure 102-29, *A* and *B*).[30] Rarely, congenital anomalies are also associated with bone defects in the skull.

Suturing skin over a bone defect in the skull usually results in failure of the repair. Underneath the skin flap is an air-filled cavity, which dehydrates the skin and results in necrosis. Periosteal and occasionally muscle flaps have been used to correct the problem.[30,31] Periosteal flaps are dissected free from the area adjacent to the bone defect with a base at the edge of the bone defect. The vascularized periosteal flap is flipped over the bone defect and sutured to a similar flap taken from the opposite side (see Figure 102-29, *B*). A cancellous bone graft or biodegradable bone cement is applied over the periosteum. To facilitate closure of the skin over the repaired defect, relief incisions or transportation flaps, or both, might have to be performed.

The surgery site should be protected from trauma during the recovery phase and the immediate postoperative period. Also, the animal should be kept from rubbing the area to prevent destroying the surgical repair. Drainage of the flaps should be aided through insertion of drains, with early removal after drainage has ceased. Anti-inflammatory drugs and antibiotics are indicated to control inflammation and prevent postoperative infection. Sutures should be removed 2 to 3 weeks postoperatively.

Complications include complete or partial breakdown of the repair, usually because of trauma, which can lead to disfigurement. Postoperative infection is always a risk because of the contaminated nature of the surgical site. Complications can require another surgical revision.

RESECTION OF THE ROSTRAL MANDIBLE, PREMAXILLA, AND MAXILLA

Ossifying fibromas of the rostral mandible are the most common indications for a rostral mandibulectomy (Figure 102-30, *A* and *B*).[32] Other neoplasms, such as adamantinomas, and fungal and parasitic diseases can also be indications for the procedure. Inadequate local excision of these lesions results in a recurrence; therefore, block excision with wide nonaffected margins is required. This procedure was developed in an attempt to completely excise the lesions in one surgical intervention.

Surgical Procedure

The animal is anesthetized and placed in dorsal recumbency on the surgery table. The endotracheal tube is placed either through the nasal passages or via a temporary tracheotomy, allowing unimpeded access to the mouth. The oral cavity is washed, making sure that the cuff of the endotracheal tube is tight and

Figure 102-28. The repair was accomplished with the help of a 3.5-mm acetabular plate, a 6-hole 3.5-mm reconstruction plate, and a 2.7-mm L-plate. **D,** View of the horse after healing of the fractures. The eye has a slightly sunken appearance.

prevents fluids from entering the lungs. The jaws are spread and maintained in that position by carefully placing a speculum between the cheek teeth. The dorsal aspect of the oral cavity and the upper lip is draped.

A transverse incision is made in the oral mucosa on the lingual side of the incisors. The gingiva is incised on the labial surface of the incisors ventral to the lesion, and this incision is continued laterally and dorsally on both sides to connect with the initial incision. Both incisions are thus connected and continued down to the bone on the mandibular symphysis.

The soft tissues are elevated and reflected caudad with a periosteal elevator on the mandibular symphysis to expose normal bone. The soft tissues are preserved to allow coverage of the exposed mandibular stump.

The mandibulectomy procedure involves removing the incisive bone and as much of the symphysis of the mandible as needed, taking into account that part of the symphysis should be saved to ensure rostral continuity of the mandible. An oscillating bone saw or Gigli wire is used to transect the mandible at the selected level. After the bone edges are contoured to remove sharp edges, the soft tissue on the lingual surface of the mandible is folded rostrad over the exposed mandible and trimmed to fit the mucosal flap from the labial surface (see Figure 102-30, *B*). A Penrose drain is placed between the bone and the soft tissues.

Closure is performed to prevent the sutures from being subjected to trauma during mastication. An acceptable cosmetic appearance is retained as well as the ability to prehend feed despite significant shortening of the mandible (Figure 102-31).

A similar procedure for excision of the premaxilla and maxilla caudal to the canine teeth has been described.[33]

Complications and Prognosis

For both procedures, a recurrence of the lesions can only be prevented by completely resecting them. The cosmetic outcome is acceptable to many owners.

(Courtesy P. Brink and A. Martensson, Malmö Equine ATG Clinic, Sweden.)

Flaccidity of the lower lip may occur with rostral mandibular resection. Horses have no difficulty with prehension of hay and grain; however, they may have difficulty with prehension of short grass. Protrusion of the tongue may occur.[34]

WRY NOSE (CAMPYLORRHINUS LATERALIS)

Wry nose is present at birth and is assumed to be a congenital disorder. In Arabian horses, it is possibly genetically linked, because of its frequency in this breed.[35] Intrauterine positioning as an etiology of this deformity is highly unlikely.

A computed tomography study of a foal with a wry nose revealed a potential etiology of this deformity. The proximal end of the incisive bone was fused with the nasal bone on the short side (Figure 102-32, *A*) but was not fused on the long side (Figure 102-32, *B*). This observation led to the theory that during the intrauterine development the incisive bone and the nasal bone fused on the short side. This stopped growth on this side, while growth continued on the other side, pushing the premaxilla into a wry position.

Usually a foal is presented within the first few days to weeks after birth because of the cosmetic appearance. Clinically, a varying degree of premaxillar deviation is noticeable upon inspection of the foal's head; the deviation usually results in malocclusion, with no contact between the incisors of the mandible and maxilla (Figure 102-33). Often there is also a certain rotational component in the deviation. Close observation also reveals an enhanced concavity of the hard palate in the interdental space.

An incongruity of the nostrils and nasal septum are additional anomalies. Some foals experience breathing difficulties or have increased respiratory sounds.

This condition will not self-correct, and a decision should be made to treat the foal using reconstructive techniques or to euthanize it to prevent it from suffering.

Surgical Procedure

Surgical correction should be delayed until the foal is 2 to 3 months old to allow the maxilla to gain enough strength to support implants. The foal is anesthetized and positioned in dorsal or sternal recumbency on the surgery table. Special padding is necessary if sternal recumbency is selected. The endotracheal tube is inserted ideally through a tracheostomy

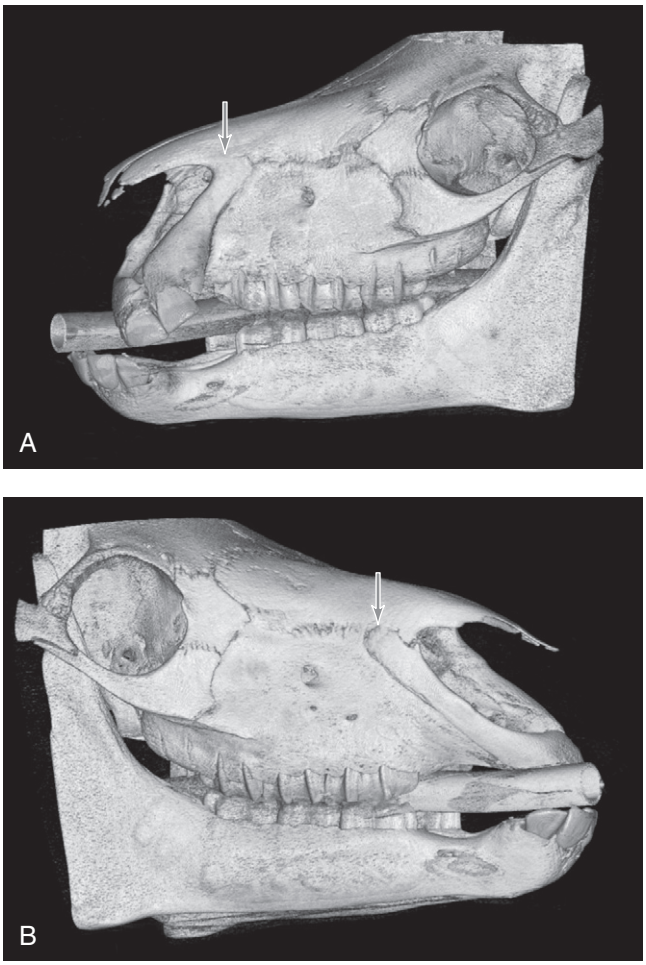

Figure 102-32. A, Three-dimensional CT reconstruction of the left side of a foal head with a wry nose. The incisive bone is fused to the nasal bone at its proximal aspect *(arrow).* **B,** Three-dimensional CT reconstruction of the right side of the same foal showing the open suture line *(arrow)* between the incisive and nasal bones allowing normal growth.

Figure 102-33. A, A photograph of a 1-month-old Warmblood foal with a wry nose. **B,** A ventrodorsal radiographic view showing the mandible and the incisor teeth that are oriented at a 90-degree angle relative to each other.

approach, the cuff is inflated, and the mouth is thoroughly washed.

Because the nasal septum is involved in the deviation, it is best to resect a 6-cm length of the rostral nasal septum at the onset of the surgery. The secion to be removed is centered on the midde of the bend in the nasal septum. The rostalmost aspect of the nasal septum should be left in place to prevent collapse of nares. The partial resection of the septum eliminates resistance to correction after the bilateral osteotomy of the maxilla. The nasal passages are packed with gauze sponges soaked in antiseptic solution to control hemorhage. A surgical approach to the interdental space is made on both sides of the head, and the maxillary periosteum is elevated.

The dorsal aspect of the nose is approached through a curved incision along the midline of the nose. Care is taken not to incise the narrow ligament that connects the nasal bones. The periosteum is left intact. The nasal bones are identified and subsequently transected perpendicular to their long axis, at the point of maximum curvature, with an oscillating saw. Care is taken not to penetrate the underlying parietal cartilage of the nasal septum. The deviation is corrected and stabilized with the help of 2.4-mm Unilock plates. These plates are applied over the periosteum. The gap created at the concave aspect of the nasal bones can be filled with a small portion of a rib graft harvested to fill the gap in the premaxilla.

With an oscillating saw, both rami of the maxilla are transected. The transected rostral portion of the upper jaw is rotated toward the sagittal plane of the head until the premaxillary and mandibular incisors are properly aligned. To achieve symmetry of the upper and lower jaws and normal interdental contact, the incisors of the maxilla and mandible should be temporarily wired shut.[36] An individual wire brace is applied to the incisors of the mandible and maxilla (Figure 102-34). Prior to tightening

Figure 102-34. Interdental wiring of the teeth to align the maxilla and mandible during repair of the osteotomies of the hemimaxillae. The wiring can be accomplished with a circular wire loop around the base of the incisor teeth or through holes drilled through the corresponding incisor teeth as shown here.

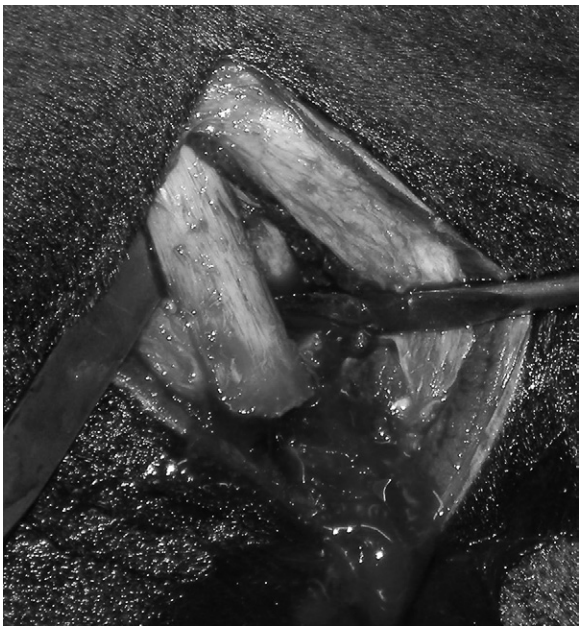

Figure 102-35. The rib graft is dissected free and bluntly separated at the osteochondral junction. The rib is slightly elevated to facilitate separation at the proximal end with an oscillating saw.

of the wire loops around each tooth, a double strand of wires is alternately pulled in a simple continuous fashion between the mandible and maxilla. The individual wires in the mandible are now tightened, followed by the wire loops in the maxilla. Last, the ends of the double-stranded wire suture between the incisors of the mandible and maxilla are connected and solidly tightened, effectively preventing opening of the mouth.

The application of an autogenous cortical bone graft in the form of a rib (Figure 102-35) has been described in the literature.[37-39] The rib graft is cut to fit the gap in the concave side of the premaxilla and wedged between the bone ends. In the next step, 3.2-mm Steinmann pins are inserted from the rostral aspect of the mandible in a caudal direction, crossing the osteotomy sites, providing stability to the maxilla.[35-39] The pin crossing the concave aspect of the mandible also penetrates the medullary cavity of the rib graft before entering the caudal fragment of the mandible.[38]

The wiring of the tooth arcades is left in place to ensure anatomic reconstruction and can be maintained until the osteotomies have partially healed and can provide some stability. During this period, enteral nutrition is provided for the foal, often by milking the mare and administering the milk through a stomach tube.

An alternative technique is to apply bone plates, ideally LCPs (Figure 102-36) to both osteotomies. The rib graft is incorporated into the plate fixation as well. The surgical incisions are closed in two layers using routine technique and covered by a stent bandage consisting of rolled gauze sponges sutured over the skin incisions. When the osteotomies are stabilized, the interdental wiring between the premaxilla and the mandible is removed. The surgical incisions are closed in three layers using routine technique.

Some asymmetry of the rostral part of the nose will persist. Postoperatively the foal is allowed to nurse but should be prevented from eating hay and grain.

Distraction osteogenesis has been described in the literature as a method to treat wry nose.[40] A type II external fixation device was applied to the maxilla and premaxilla with a double connnecting bar on the convex side and a distraction bar on the concave side of the nose. Over the next couple of weeks, the concave side was gradually distracted, eventually ending in a cosmetically acceptable result.[40]

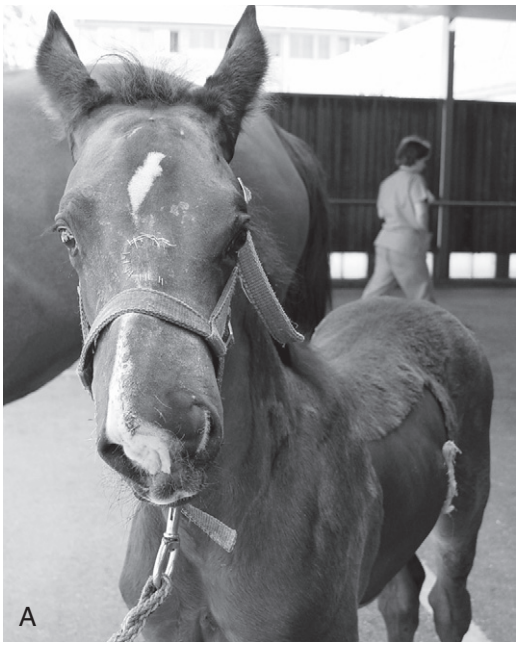
Aftercare

The tracheostomy tube is maintained, changing it with a clean tube every day. Broad-spectrum antimicrobial therapy and nonsteroidal, anti-inflammatory drugs are administered for 5 or more days. Half of the packing of the nasal passages is removed one day postoperatively and the second half one day later. At this time, the tracheostomy tube can be removed. Removing the packing may be difficult if the packing becomes impaled on the point of a pin or wire that inadvertently entered the nasal cavity.[39] The stent bandages are removed at 4 or 5 days, and staples or sutures are removed at 10, 12, or 14 days after surgery. The foal can usually be discharged from the hospital at 2 to 3 weeks after surgery.

Steinmann pins and Kirschner wires used to stabilize the premaxillae/maxillae are removed between 4 and 5 weeks, but most become loosened and are spontaneously shed at about this time. Plates used to stabilize the nasal bones are removed at about 3 months postoperatively.

Complications

Postoperative infection of the surgery sites and breakdown of the fixation are the most serious complications. Depending on the severity and duration of the problem, euthanasia of the patient has to be considered. Partial collapse of the nasal passages as a result of nasal septum removal may lead to respiratory problems. Surgical resection of the alar folds may at least partially correct this problem.[41]



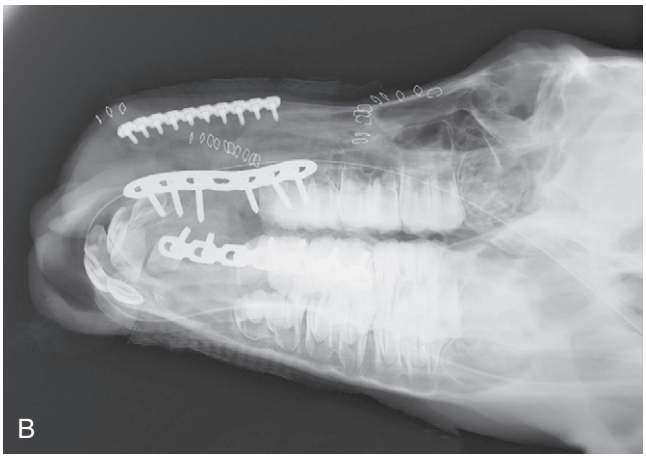


Figure 102-36. A, 1-week postoperative picture of the same foal as Figure 102-33. The sutures are still in place. The C-shaped suture line represents the site where the caudal cut was made for partial removal of the nasal septum. The white marking of the nose accentuates the lopsided appearance of the nose. **B,** Oblique postoperative radiographic view of the head showing the three plates used in the correction of the abnormality.

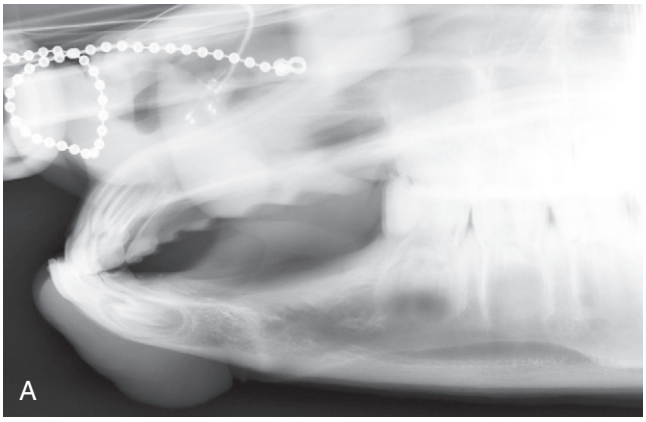

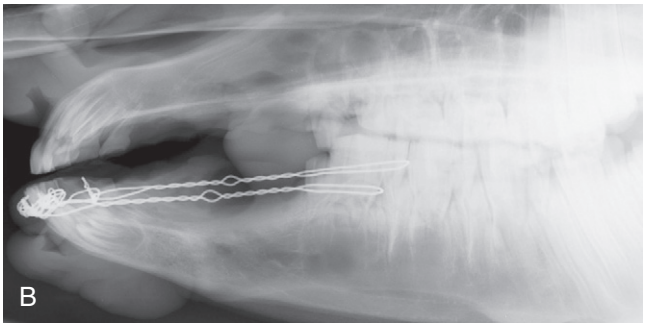

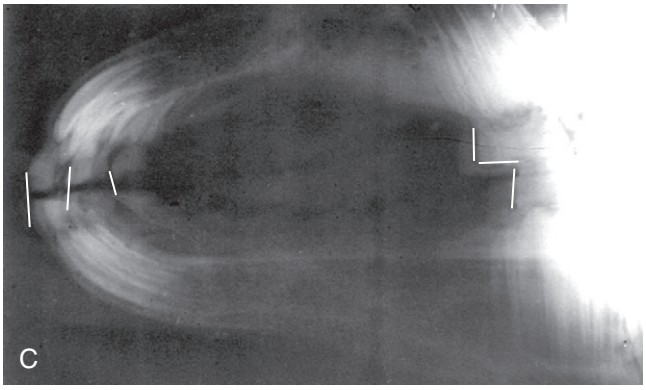

Figure 102-37. A, Lateromedial radiographic view of a 2-year-old Arabian horse suffering from prognathia inferior. The horse is intubated through the nose. **B,** Immediate postoperative lateromadial radiographic view of the horse with the tension wires in place. **C,** Follow-up lateromadial radiographic view of the horse 3 months later. The tension wires have been removed from the mandible and good alignment of the upper and lower arcade is appreciated. Note the mandible shows an increased bend in the region of the incisor arch.

CORRECTION OF PROGNATHIA SUPERIOR (PARROT MOUTH) AND PROGNATHIA INFERIOR

Prognatia superior (or brachygnatia inferior) refers to an assymmetry between the length of the maxilla (and premaxilla) and the mandible, with the mandible being shorter. This condition, called *parrot mouth*, is the most common congenital oral malformation in horses and may be associated with other congenital problems.[41] Varying degrees of parrot mouth may exist, ranging from minor malocclusion to complete lack of contact between the upper and lower incisor teeth. The result is abnormal wear of the incisor teeth, eventually leading to abnormal wear of the premolar and molar teeth. The condition is primarily of cosmetic concern to the horse's owner. On rare occasions, the opposite problem is encountered where mandible is longer than the maxilla and premaxilla, and is called *prognathia inferior* (Figure 102-37, *A*).

Treatment

The teeth should be examined at regular intervals and the teeth floated as necessary to prevent hooks on the rostral and caudal cheek teeth and to keep the incisors from wearing abnormally.

The treatment for both malformations is the same; temporarily slowing down growth is performed on the longer componenet of the malformation, either at the maxilla in prognathia

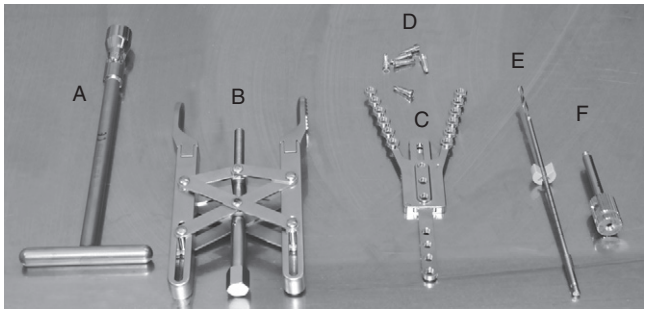

Figure 102-38. RachetDis instrumentation. *A,* Socket wrench for distraction; *B,* distractor placed between the incisors and cheek teeth used to distract the implant 1 mm at a time; *C,* RachetDis implant consisting of a narrow bar containing four round holes for the insertion of 3.5-mm locking head screws, a wider body surrounding the narrow bar and containing three similar holes, and two easily bendable sidearms containing holes for locking head screws to increase stability; *D,* several 3.5-mm locking head screws; *E,* 2.8-mm drill bit; *F,* insert drill sleeve for the drill bit.

superior or at the mandible in proganthia inferior. Extension is performed on the shorter componenet.

In foals with severe malocclusion that impairs their ability to graze and eat, growth of the maxilla or mandible can be temporarily slowed by applying tension wires between the incisor teeth and the cheek teeth (see Figure 102-37, *B*). After the difference in jaw length has evened out, the wires are removed (see Figure 102-37, *C*). In some foals corrected for prognathia superior, the maxilla assumes a dorsal bend over the nose during the time longitudinal growth is halted, rendering a shorter and more stocky head.

An alternative technique involves a surgical implantation of a RachetDis (Figure 102-38) on both hemimandibles or maxillae. The RachetDis allows a distraction of up to 2 cm and is completetly implanted. Distraction is achieved indirectly via distraction of the incisor and the premolar teeth.

Both rami of the mandible are approached through the ventrolateral 12-cm skin incision. The periosteum is separated from the mandible over the entire length. A RachetDis is contoured to each mandible and attached to it through four locking head screws in the rostal part and at least three 3.5-mm locking head screws in the caudal part. The future osteotomy location is marked on the bone and the RachetDis devices are removed. A vertical osteotomy is performed through both interdental spaces followed by reapplication of the RatchetDis implants (Figure 102-39, *A*). If needed, additional screws can be implanted through one or both sidearms of the implant. The periosteum is apposed if possible and the rest of the incision is closed in two layers using routine technique. A stent bandage is applied over the skin incisions.

To improve the conditions for the application of the distractor it is advisable to reinforce the mandibular incisor arcade with polymethyl methacrylate (Technovit). Prior loose application of cerclage wires around the incisors provides additional stability to the construct (Figure 102-39, *B*). While the horse is still under ansethesia, the distraction device is applied between the incisor teeth and the premolar teeth through the interdental space, and with the socket wrench traction is applied until a click is heard, representing a distraction of 1 mm. This action is repeated twice on the same side, followed by a 3-mm distraction on the other side. The horse is allowed to recover from anesthesia.

Figure 102-39. A, The RachetDis implanted to one side of the mandible in a 2-year-old horse with a prognathia superior. The oral cavitiy was not invaded during the approach. The osteotomy is clearly visible. **B,** The prognathia superior shown immediately postoperatively. The cerclage wires were implanted to provide stability to Technovit support of the mandibular incisor arcade needed as a thrust-bearing device for the distractor. **C,** Lateromedial radiographic view of the head of the at the end of the distraction. The RachetDis implants of both hemimandibles are superimposed on each other. The incisor arcades of the maxialla and mandible are evenly aligned and the gap at the osteotomy site is easily recognized. The implants stay in place until the gap is healed in with bone. (Courtesy C. Lischer, Berlin, Germany.)

Aftercare

Routine postoperative management is applied consisting of broad-spectrum antimicrobial and anti-inflammatory therapy for 5 days, stent bandage removal after 5 days, and skin suture or staple removal after 10 to 12 days. Starting on the fifth postoperative day, the RachetDis is distracted daily for 1 mm with the foal under heavy sedation. After perfect occlusion is achieved, distraction is stopped (see Figure 102-39, *C*). The implants are removed 3 months later.

CHAPTER 103

Postoperative Physiotherapy for the Orthopedic Patient

Andris J. Kaneps

Physical treatment and rehabilitation of horses is often a major adjunct to surgical or medical therapy. It may also be the primary therapy under which circumstances a horse may be competing under *Federation Equestre Intrenationale (FEI)* or other competition regulations that prohibit the use of medications. Physical treatment and rehabilitation can be organized into five catagories: thermal therapy, manipulative therapy, exercise, extracorporeal shock wave therapy, and hyperbaric oxygen therapy.

THERMAL THERAPY

One of the most accessible and time-tested methods of physical treatment is thermal therapy. Heat or cold may be administered to horses using many modalities and can range from simply applying water from a garden hose to using deep-heating ultrasound technologies.

Cold Therapy

Physiologic Effects

The major physiologic benefits of cold therapy are decreased local circulation, decreased pain, and reduced tissue swelling.[1-5] These benefits are most effective very early in the period following injury or surgery (Table 103-1).

The primary effect of local cold application is to constrict blood vessels. Local reflexes and central nervous system responses mediate this *vasoconstriction*. The reduced blood flow to tissues may help reduce edema, hemorrhage, and extravasation of inflammatory cells. The consequential *reduced tissue metabolism* may inhibit the effect of inflammatory mediators and slow down enzyme systems.

Cyclical *rebound vasodilatation* is another response to cold therapy.[6] Following a minimum of 15 minutes of cold therapy that results in tissue temperatures that range from 10° to 15° C, cycles of vasoconstriction and vasodilatation occur. An example of this effect is the warm sensation in your fingers after exposure to cold. Rebound vasodilatation associated with cold therapy may help further resolve tissue edema.

Analgesia follows cold therapy. Explanations for the pain relief induced by thermal agents include the following: (1) the stimulus from cold (or heat) receptors closes the neural gate, which modulates the perception of pain via blocking afferent stimuli from peripheral pain receptors (gate-control theory), and (2) cold or heat may act as a counter-stimulus to pain, making the afferent impulses of pain less noticeable centrally.[1-3] Small myelinated nerve fibers are more sensitive to cold therapy and, as they are cooled, conduction is reduced earlier than in similar-sized unmyelinated fibers. For example, application of an ice pack over the ulnar nerve in cats for 20 minutes reduced nerve conduction velocity by 29%.[5]

The viscoelastic properties (i.e., extensibility) of soft tissues are reduced with cold therapy, which is an undesirable effect of this thermal therapy.[1-3]

Indications

Cold therapy is indicated in acute musculoskeletal injuries and following surgical procedures to reduce edema, slow the inflammatory response, and reduce pain. It is particularly effective during the first 24 to 48 hours after injury or surgery.[7] Cold immersion of the distal limbs is also effective in reducing severity of laminitis by decreasing the activity of laminar matrix metalloproteinase (MMP) and causing laminar vasoconstriction when applied during the developmental phase.[8]

Methods of Application

Cold may be applied by ice water immersion, application of ice packs or cold packs, and ice water–charged circulating bandages or boots. The most beneficial therapeutic effects of cold occur at tissue temperatures between 15° and 19° C (59° to 66° F).[1-3] Tissue temperatures of 10° C and less may cause cold thermal damage. Average time of cold application is 15 to 20 minutes. Treatments are best repeated every 2 to 4 hours during the first 24 to 48 hours of injury or surgery if the goal is to reduce tissue inflammation and edema.

TABLE 103-1. Thermal Therapy

Therapy type	Indications	Methods of application	Responses to treatment
Cold	Acute injury (first 24-48 hours) Reduce pain Reduce swelling	Ice water immersion Ice surface application Cold packs	Restricts blood flow Reduces metabolism Reduces activity of inflammatory enzymes Reduces pain
Heat	Chronic injury (after 72 hours) Enhance tissue stretching Enhance healing response	Warm water from hose Hot packs Leg sweat Therapeutic ultrasound	Increases blood flow Increases metabolism Increases activity of tissue enzymes Relaxes muscle spasm Reduces pain Increase tissue extensibility

Cold therapy is effective from the skin to a depth of 1 to 4 cm depending on the amount of adipose tissue present in the area and the local blood supply.[1-3] Cold treatment is rapid and effective in the distal limbs of horses because they lack an adipose layer, and target tissues such as tendons, ligaments, and joint capsules are located superficially.

Direct contact of ice water with the skin is the most effective method of cold therapy. Buckets or turbulator boots may be used depending on the site. If immersion therapy is used immediately following surgery, the wound must be protected with a water-impervious barrier. In human physical therapy, ice baths are maintained at temperatures from 13° to 18° C (55° to 64° F).[1] Ice may be placed in a plastic bag or water may be frozen in a paper cup and applied to the site. To prevent laminitis, *continuous* cold therapy is applied to the distal limbs using plastic bags filled with ice, ice water immersion, or commercial cold therapy boots.

In a study of ice water immersion therapy applied to the metacarpal region in a horse, skin surface temperatures stabilized at 9° to 10° C approximately 10 minutes after therapy was started. Temperature stabilized at 17° to 19° C in subcutaneous tissue and at 20° to 24° C between the flexor tendons approximately 10 minutes after therapy was started. Tissue temperatures did not return to baseline by 10 minutes after therapy was stopped.[5] Ice water immersion of the equine digit for 30 minutes resulted in significant decreases in soft tissue perfusion and laminar temperatures. Vascular perfusion decreased, but not significantly.[9]

Malleable commercial cold packs are an effective means of cold therapy because they readily conform to the anatomic site (First + Ice cold packs. MacKinnon Inc.). Minimizing air gaps between the cold pack and treatment site improves tissue cooling.[10] Commercial products, such as cold leg wraps (Ice Tape cold therapy leg wrap), have the same gel substance as cold packs. The gel is formed as a tape that may be wrapped on a limb and held in place with a wet bandage.

Boots that connect to a cold source and circulate fluid through them are also very effective at chilling tissue. Systems are available with a variety of boot configurations for different portions of the limb, making effective cold therapy logistically very simple. Some of the systems also provide compression and may be used for cold (or heat) therapy (Figure 103-1).

Figure 103-1. Cold and compression therapy using a system that circulates ice water or heated water through site-specific wraps (VitalWear Equine System).

Heat Therapy

Physiologic Effects

The major physiologic benefits of heat therapy are increased local circulation, muscle relaxation (and therefore, reduction of muscle spasms and associated pain), and increased tissue extensibility (see Table 103-1).[1-3]

Increased local blood flow helps mobilize tissue metabolites, increase tissue oxygenation, and increase metabolic rate of cells and enzyme systems. In general, metabolic rate increases two to three times for a tissue temperature increase of 10° C.[1] These responses to heat therapy are especially beneficial for wound healing.

Increased local blood flow may be initiated by three mechanisms: (1) by the axonal reflex, representing a direct response of the blood vessels to local increases in tissue temperature; (2) by local inflammatory mediators, such as histamine, prostaglandins (PGE_2 and prostacyclin), and bradykinin, which may also initiate vasodilatation and increase capillary permeability; and (3) by local spinal reflexes that are stimulated by afferent impulses from the thermoreceptors at the site of heating and result in decreased postganglionic sympathetic adrenergic nerve activity, which decreases smooth muscle tone of vessels, allowing them to dilate.[1]

Increased blood flow and vascular permeability may promote resorption of edema, which is a common reason for heat application in horses. However, vasodilatation of a dependent limb may actually lead to edema by the same mechanisms (increased blood flow and vascular permeability).

Heat application also decreases pain. Pain is relieved via the mechanisms cited earlier for cold therapy.

Muscle spindle firing decreases when muscle temperature increases, resulting in decreased muscle spasms. Decreased spindle firing helps to break the cycle of pain-spasm-pain. The same sort of cycle may be partially responsible for flexural contractures in foals with physitis, where severe physeal pain results in reflex increases in muscle spindle firing. The flexor muscles are the largest group of forelimb muscles in the foal, and continued spasm of the large flexor muscles may lead to flexural contracture (see Chapter 87).

Soft tissues may be stretched more effectively when they are warm. Heat decreases tissue viscosity and increases tissue elasticity. Low-load, prolonged stretching of tissues heated between 40° and 45° C (104° to 113° F) results in increased extensibility of tendons, joint capsules, and muscles.[1-3]

Indications

Heat is best applied after acute inflammation has subsided. It is useful for reducing muscle spasms and pain because of musculoskeletal injuries. Heat therapy can be used to increase joint and tendon mobility, particularly by their application before

active stretching. Heat may benefit recovery of localized soft tissue injuries by accelerating the healing response.

Methods of Application

Superficial and deep heat modalities are available. Superficial heat is most commonly applied using hot packs and hydrotherapy. These modalities provide heat penetration to approximately 1 cm below the level of the skin, which is often sufficient for many veterinary applications on distal limbs because of the lack of an insulating fatty subcutaneous tissue layer. Deep heat may be applied using therapeutic ultrasound.

The most profound physiologic effects of heat occur when tissue temperatures are raised to 40° to 45° C (104° to 113° F).[1,3,4] However, tissue temperatures above 45° C may result in pain and irreversible tissue damage. Skin and subcutaneous tissue temperature increases approximately 5° C after 6 minutes of heat application and maintains that temperature for up to 30 minutes following cessation of treatment.[10] For deeper tissues, such as tendon or muscle, 15 to 30 minutes is required to elevate tissue temperature to the therapeutic range.

Direct contact of the skin to temperatures over 45° C (115° F) may cause thermal injury and tissue damage. When using heat sources warmer than 45° C, the source must be wrapped in several layers of moist towels before application.[4] This is especially important if you are heating the site using hydrocollator packs (Hydrocollator moist heat pack), which are heated to 71° to 79° C or rechargeable hot packs (Sodium acetate rechargeable hot pack), which are heated to 54° C. Heat from these sources is usually applied for 20 to 30 minutes.

Warm water is probably the most accessible method of heat therapy. Methods of application include the use of a hose, wet towels, water immersion in a bucket, turbulator boot, and circulating treatment system. A general rule is that water as hot as your hand can comfortably stand has a temperature of 38° to 41° C (101° to 105° F). However, tissue heated by water at this temperature may only reach the lowest tissue therapeutic range. Therefore, the target temperature should be above this level, but horses commonly experience discomfort with water 45° C and warmer. An electric bucket heater may be used to warm water. To render warm hydrotherapy most effective, a thermometer should be used to determine the water temperature. An inexpensive indoor-outdoor home thermometer with a wire thermocouple is very useful to determine water temperature.

A study of hot water hose therapy applied to the metacarpal region in a horse revealed that water as warm as a human could comfortably stand resulted in skin surface temperatures on the horse of 39.5° to 41° C. Temperature of subcutaneous and deep tissues stabilized at 39° to 40° C approximately 9 minutes after therapy was initiated. Tissue temperatures returned to baseline approximately 15 minutes after therapy was ceased.[10] Heating the equine digit by standing in a 47° C water bath for 30 minutes resulted in significant increases in soft tissue perfusion and laminar temperatures. Vascular perfusion increased, but not significantly.[9]

Therapeutic ultrasound may be used for superficial and/or deep heating of tissues. Ultrasound selectively heats tissue with high protein/collagen content. Tendons, muscles, fibrous connective tissue and bone may be effectively heated to 45° C, but adipose tissue is relatively transparent to the effects of therapeutic ultrasound. The most intense heating occurs at tissue interfaces, much like a diagnostic ultrasound image has sharp delineations between tissue interfaces such as skin, tendon, and fluid. In dog thigh muscles, ultrasound treatment with a 3.3-mHz transducer at 1.5 W/cm^2 resulted in temperature increases of 4.6° C, 3.6° C, and 2.4° C at 1 cm, 2 cm, and 3 cm depths, respectively.[11] Soft tissue temperature has been shown to increase 0.2° C per minute with a 1-mHz transducer set at 1.5 W/cm^2.[12]

An additional benefit of therapeutic ultrasound is the deep massage of tissues caused by the sound waves, referred to as *cavitation* and *streaming*. These nonthermal effects result in compression and expansion of tissues and tissue fluids that may improve tissue healing.[13] Fibrous connective tissue scars may be more effectively stretched following heating with therapeutic ultrasound.[14] Treatment is usually performed once or twice daily for 10 to 14 days. Ultrasound coupling gel must be used to provide good contact between the transducer and the skin. In horses, treatment is usually conducted with a 1-mHz transducer for deepest penetration at 1.5 W/cm^2 for 10 minutes.

MANIPULATIVE THERAPY

Stretching and massage are true physical methods of treatment that may be applied without the need for sophisticated equipment. Stretching is useful for maintaining or increasing the range of motion of an injured or operated site and for increasing a horse's flexibility to improve performance.

To maintain or increase joint mobility, *stretching* should be initiated 24 hours after surgery or after the injury has been accurately evaluated and a diagnosis has been made. Stretching is done by flexing the joint just to the point of discomfort, holding at that level for 10 to 15 seconds, moving the joint to its limit of extension and repeating the sequence 12 times. Joint stretching may be repeated two or three times daily.

Massage therapy may primarily provide some level of warm-up to the muscles and may assist in soothing muscles after exercise. Experience with human athletes has shown that pre- and post-exercise massage makes athletes more comfortable and helps decrease stiffness following competition.[15]

There are variations in massage therapy techniques that focus on specific mechanisms of action. *Trigger point massage* focuses on relaxing tight bands of muscle or fascia that are sensitive to manipulation, thereby reducing sensitivity of the affected areas. This type of massage has been found to reduce heart rate and blood pressure and to significantly relax human patients.[16]

Massage also aims to decrease the sensitivity of active myofascial triggers that may cause discomfort in a distant area.[17] *Acupressure massage* results in stimulation of regions that are connected to Chinese meridians similar to acupuncture points.[18] Massage therapists use friction, vibration, deep friction, and a variety of stroking techniques to achieve the desired outcome.[17]

Massage therapy should be considered palliative, because few of the specific claimed advantages of the techniques have been scientifically tested and verified as being efficacious.[19] Using a trained therapist with a close professional relationship with the attending veterinarian is imperative for safe and effective treatment.

EXERCISE

Controlled exercise and exercise that minimizes concussion may be used during the rehabilitation period after injury or surgery. Controlled exercise protocols have been established

Figure 103-2. The underwater treadmill reduces concussion and encourages full range-of-motion limb use while conditioning muscles and the cardiorespiratory system (AquaPacer equine underwater treadmill). (Courtesy Dr. Steve Adair, University of Tennessee.)

for rehabilitation of tendon and ligament injuries.[20] Gradually increasing the time and intensity level of exercise is beneficial for healing of soft tissues and bone because both tissues become stronger with use than with rest, particularly in growing horses.[20-22] Commonly, the horse is maintained in stall confinement with controlled exercise via hand-walking, ponying, or by use of a mechanical exerciser. Harness race horses may readily enter a controlled exercise program by designating the number of jogging miles at a given pace for each exercise session.

Swimming or underwater treadmill exercise is an excellent method of providing controlled exercise with minimal concussion (Figure 103-2). These methods spare joints and bones from concussion but enhance muscle and cardiorespiratory fitness. Another benefit of swimming and underwater treadmill exercise is that the limbs are used through a full range of motion. Swimming should not replace conditioning for fitness under tack and under circumstances similar to competition. During swimming, the horse will not use the same muscle groups used during weight-bearing exercise and this activity may cause hyperextension of the back muscles.[17,23] Swimming must be combined with regular ring or track work to condition the muscles used in normal work and to strengthen the skeleton and joints.

Treadmill exercise represents a good intermediate step between exercise with minimal concussion (such as walking in hand, riding at a walk, or underwater treadmill exercise) and exercise in the horse's regular tack and training surface. Most treadmills have a rubber belt that reduces concussion during weight bearing. Speed and inclination of the treadmill is adjusted to the level of exercise intensity suited to the horse. The treadmill allows objective control of the exercise program that may be useful during and after rehabilitation is complete.[24] The horses in one study had a substantial amount of their base fitness established with treadmill exercise, followed by the gradual addition of regular track workouts. Eventually treadmill exercise was only 30% to 50% of the total exercise work. Horses trained in this fashion had fewer training and racing injuries and better race times than conventionally trained horses.[24]

Ultimately, horses must work under the same conditions they will encounter in competition. This means that riding or driving with a gradual increase in duration and intensity of exercise will be needed. The key to retraining a horse is to realize that cardiovascular fitness declines significantly after 4 to 6 weeks of rest[25] and that bone strength decreases significantly within 12 weeks of rest.[26] Retraining will result in noticeable improvement of cardiac measurements within 6 weeks, increased bone mineral density within 16½ weeks, and tendon dimensions within 16 weeks.[20,27,28] The studies on bone and tendon do not identify the earliest time that significant strength returns to these tissues so as to allow training or competition without reinjury. I assume that 3 to 4 months is the minimum time required to re-establish musculoskeletal tissue strength following a period of complete rest.

EXTRACORPOREAL SHOCK WAVE THERAPY

Extracorporeal shock wave therapy (ESWT) has few direct indications following surgery, but this modality is very useful for treatment of soft tissue and bone injuries. ESWT consists of short duration (5 μsec) high-pressure shock waves (up to 80 mega pascals) that stimulate tissue.[29]

Focused and non-focused ESWT devices are available for application in horses. Reports of positive treatment effects have been made for both types of ESWT.[29-31] Each treatment usually consists of 2000 pulses. Intensity of shock wave therapy is set in a range of 0.9 to 1.8 mJ/mm^2, or according to the atmospheric pressure at the output probe (2.5 to 4 bar), depending on the manufacturer's recommendations.[29,31] The horse must usually be sedated for treatment. Each treatment lasts 10 to 15 minutes and is repeated at 1- or 2-week intervals. Treatment protocols require one to four separate treatments depending on the nature of the injury and response to initial therapy.

Tissue compression and shear loads occur as the shock wave passes tissue interfaces, resulting in stimulation of bone and soft tissue healing. Bone healing and remodeling have been enhanced and an analgesic effect has been noted for 2 to 4 days following treatment.[29,32,33] ESWT treatment of arthritis of equine distal tarsal joints (bone spavin) resulted in improvement of lameness grade in 59 of 74 horses treated.[30] Chronic suspensory desmitis was successfully treated in 24 of 30 horses after three ESWT treatments.[31]

ESWT is indicated for treatment of insertional desmopathy (such as at the origin or insertion of the suspensory ligament) dorsal cortical stress fractures, incomplete fractures of the proximal sesamoid bone, arthritis, and navicular disease and has also been used for treatment of tendinitis.

HYPERBARIC OXYGEN THERAPY

The use of hyperbaric oxygen therapy in horses has gained some popularity, without much scientific evidence to support its claimed beneficial effects. For example, it has been used in healthy training horses supposedly to achieve quicker recovery after strenuous exercise.

Hyperbaric oxygen is administered in a walk-in pressurized chamber. Horses are treated with pressures of 2 to 3 atmospheres and breathe 100% oxygen for 60 to 90 minutes.[34]

Therapeutic effects of hyperbaric oxygen therapy on complex wounds in humans include reduction of tissue edema, improved tissue oxygenation, and enhanced antibiotic activity.[35] Suggested indications for other uses in horses include severe anemia, fungal pneumonia, thermal burns, cellulitis,

rhabdomyolisis, infected wounds, skin grafts, and nonunion fractures.[34] However, in the only controlled study of this therapy, full-thickness mesh skin grafts did not have an improved tissue response in horses that underwent hyperbaric oxygen therapy, compared to controls.[36]

APPENDIX

A Drugs and Manufacturers

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Acepromazine	acepromazine		Various U.S. manufacturers		19 to 22
		Prequillan		Arovet AG, Zollikon, Switzerland	19, 21, 22
		PromAce	Boehringer Ingelheim Vetmedica Inc, St. Joseph, MO		20
Alfaxalone		Alfaxan 10mg/ml	Not marketed in the U.S.	Vétoquinol GmbH, Ravensburg, Germany	19
Alfentanil		Rapifen, Alfenta	Taylor Pharmaceuticals, Marietta, GA	Janssen-Cilag AG, Baar, Switzerland	18
Atipamezole		Antisedan	Pfizer Animal Health, New York, NY	Pfizer AG, Zurich, Switzerland	20, 22
Atracurium besylate		Tracrium (no longer manufactured under this trade name)	Hospira, Lake Forest, IL	Glaxo Smith Kline, Middlesex, UK	58
Atropine	Atropine SA		Butler Animal Health Holding Company LLC, Dublin, OH; Vedco Inc, St. Joseph, MO		20
	Atropinsulfat 0.1%			Kantonsapotheke Zurich, Zurich, Switzerland	22
Avocado and Soya Unsaponifiables		Cosequin ASU	Nutramax Laboratories, Edgewood, MD		79
		Platinum Performance CJ	Platinum Performance, Inc, Buellton, CA		79
Benztropine mesylate		Cogentin	Merck & Co, Whitehouse Station, NJ		22
Buprenorphine		Temgesic		Essex Chemie AG, Lucerne, Switzerland	22

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Butorphanol tartrate	Alvegesic 1% forte ad us. vet.			Virbac AG, Glattbrugg, Switzerland	18, 19, 22
		Torbugesic	Fort Dodge Animal Health, Fort Dodge, IO		20, 34, 48, 73
		Butrohic	Lloyd Inc, Shenandoah, IA		
		Dolorex	Intervet Inc, Millsboro, DE		
Hyoscine Butylbromide		Buscopan	Boehringer Ingelheim, Ridgefield, CT	Boehringer Ingelheim GmbH, Ingelheim, Germany	38, 59
Carprofen		Rimadyl	Pfizer Animal Health, New York, NY	Pfizer, Kent, UK	23, 79
Chlorpromazine HCl		Thorazine	Baxter Healthcare Corp, Deerfield, IL		22
Climazolam		Climasol ad us. vet.		Dr. E. Graeub AG, Bern, Switzerland	19, 20, 22
Dalteparin		Fragmin	Pfizer Inc, New York, NY	Pfizer is global.	4, 13, 40
Suxibuzone		Danilon Equidos		Janssen Animal Health, Buckinghamshire, UK	23
Dantrolene	Dantrolene i.v. "P & G"	Dantrolen		Vifor SA, Villars-sur-Glâne, Switzerland	21
		Dantrium	JHP Pharmaceuticals, LLC, Rochester, MI		
Desflurane		Suprane	Baxter Healthcare, Deerfield, IL	Baxter AG, Volketswil, Switzerland	18, 20, 21
Detomidine		Domosedan		Domosedan Gel Janssen Pharmaceuticals Beerse, Belgium	20
		Dormosedan	Pfizer Animal Health, New York, NY		20
	Equisedan ad us. vet.			Dr. E. Graeub AG, Bern, Switzerland	18, 19, 21, 22
Dexmedetomidine		Dexdomitor	Pfizer Animal Health, New York, NY	Orion Pharma, Espoo, Finland	20
		Precedex	Hospira Inc, Lake Forest, IL		20
Diazepam		Valium 5mg/mL		Roche Pharma Schweiz AG, Reinach, Switzerland	19, 20, 22
Diazepam injection	Diazepam		Abbott Animal Health, Abbott Park, IL		19, 20, 22
Diclofenac sodium		Surpass Topical Cream	Boehringer Ingelheim, St. Joseph, MO		7, 23, 82

Continued

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Dimethyl sulfoxide (DMSO 20%)	DMSO			Streuli Pharma AG, Uznach, Switzerland	2, 15, 21, 37, 40, 44, 51, 54, 83, 85,
		Domoso	Fort Dodge Animal Health [Pfizer], Fort Dodge, IA		78, 82
Di-tri-octahedral smectite		Biosponge	Platinum Performance, Buellton, CA		2
Dobutamine Hydrochloride		Dobutrex	Eli Lilly and Company, Indianapolis, IN	Abbott Laboratories, Abbott Park, IL Teva Pharma AG, Aesch, Switzerland	20, 21
Dorzolamide hydrochloride		Trusopt	Merck & Co Inc, Whitehouse Station, NJ		58
Droperidol		Inapsine	Hospira Inc, Lake Forest, IL		22
Edrophonium		Enlon	Ohmeda PPD, Liberty Corner, NJ		58
		Reversol	Organon Pharmaceuticals, Allentown, PA		58
		Tensilon	Valeant Pharmaceuticals, Aliso Viejo, CA		58
	Elanone-V	Lenperone	A.H. Robins Co, Richmond, VA		22
Enoxaparin		Lovenox	Sanofi-Aventis U.S. LLC, Bridgewater, NJ		4
Epinephrine	Ephedrine		Akorn Pharmaceuticals Akron, OH		20
	Adrenalin Sintetica			Sintetica S.A., Mendrisio, Switzerland	22
	Adrenaline	Primatene Mist CFC Metered-Dose Inhaler	Cannot be manufactured or sold in the U.S. after December 2011		
		Marcaine	American Regent Inc, New York, NY		20
		Equiplas J	Plasvacc USA Inc, Templeton, CA		2
Etilefrine		Effortil		Boehringer Ingelheim Vetmedica GmbH, Ingelheim, Germany	32
Famotidine		Pepcid AC	Johnson & Johnson, Merck Consumer Pharmaceuticals Co, Fort Washington, PA		20

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Fentanyl (transdermal)		Duragesic	JOM Pharmaceuticals, Raritan, NJ		20
		Durogesic		Janssen Pharmaceuticals, Beerse, Belgium	
Flumazenil		Anexate	Haorui Pharma-Chem Inc, Edison, NJ	Roche Pharma (Schweiz) AG, Reinach, Switzerland	22
		Romazicon	Hoffmann-La Roche Inc, Nutley, NJ; Various generic manufacturers	Roche Laboratories Inc, Basel, Switzerland	20
Flunixin	Flunixin meglumine		Various generic manufacturers		20, 79
		Banamine	Intervet/Schering-Plough Animal Health, Summit, NJ		
		Finadyne		Schering-Plough Animal Health	
Fluphenazine decanoate		pms-Fluphenazine decanoate	Pharmascience Inc, Montréal, Quebec, Canada		22
Guaifenesin		Guailaxin (not currently available)	Fort Dodge Animal Health, Fort Dodge, IO		20
		Gecolate (not currently available)	Summit Hill Laboratories, Navesink, NJ		20, 21
		Myolaxin 15% ad us. vet.		Vétoquinol AG, Ittigen, Switzerland	18, 19, 22
Halothane		Halothane B.P.		Arovet AG, Zollikon, Switzerland	18, 21
Hemoglobin glutamer-200 (bovine)		Oxyglobin	Biopure Corp, Boston, MA		3, 4
Hyaluronic acid		Acrivet Syn 2%		Acrivet, Inc, Hennigsdorf, Germany	58
		Hylartin V	Pfizer Animal Health, New York, NY (previously Pharmacia & Upjohn)		58
		Legend	Bayer Animal Health, Shawnee Mission, KS		79
		Conquer HA	HA Concepts, Inc, Lexington, KY		79
HydroxyEthyl Starch		HAES-steril 10%		Fresenius Kabi AG, Bad Homburg, Germany	21

Continued

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Ibuprofen		Motrin	McNeil Consumer and Speciality Pharmaceuticals, Washington Park, PA		
		Advil	Pfizer Healthcare, Richmond, VA		
		Caldolor	Cumberland Pharmaceuticals, Nashville, TN		20
Isoflurane		Isoflo	Abbott Laboratories, Abbott Park, IL		18, 20
		IsoFlo ad us. vet.		Dr. E. Graeub AG, Bern, Switzerland	21
S (+)-ketamine		Keta-S ad us. vet.		Dr. E. Graeub AG, Bern, Switzerland	18, 19
Ketamine		Narketan 10 ad us. vet.		Vétoquinol AG, Ittingen, Switzerland	18, 19, 21, 22
		VetaKet	Lloyd Inc, Sheneadoah, IA		
		Ketaject	Teva Animal Health, St. Joseph, MO		
		Vetalar	Boehringer Ingelheim Vetmedica Inc, New York, NY		
		Ketaset	Fort Dodge Animal Health, Fort Dodge, IO		20
Ketoprofen		Ketofen	Fort Dodge Animal Health, Fort Dodge, IO		20, 79
Levallorphan		Lorfan	Hoffmann-La Roche Inc, Madison, WI	Hoffmann-La Roche, Inc, Genzach, Switzerland	20
Levomethadone		L-Polamivet ad us. vet.		Veterinaria AG, Pfäffikon, Switzerland	20, 22
Lidocaine	Lidocaine HCl 2% or 5%				18 (5%), 19 (2%), 22 (5%)
	Lidocaine HCl 2% injection		Various generic manufacturers		
		Xylocaine	American Pharmaceutical Partners (APP), Schaumburg, IL	Vedco Ltd, Berkshire, UK	20
		Xylocaine Jelly 2 %	American Pharmaceutical Partners (APP), Schaumburg, IL	Astra Zeneca, Vienna, Austria	20
Lorazepam		Ativan	Baxter Healthcare Corp, Deerfield, IL	Valeant Pharmaceuticals International, Zug, Switzerland	20

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Medetomidine	Dorbene			Dr. E. Graeub AG, Bern, Switzerland	19, 21, 22
		Domitor (no longer sold or marketed in the U.S.; replaced by Dexdomitor)	Pfizer Animal Health, New York, NY		20
Meloxicam		Metacam	Boehringer Ingelheim Vetmedica Inc, St. Joseph, MO	Boehringer Ingelheim Ltd, Berkshire, UK	23
Methadone		Methadon Streuli		Streuli Pharma, AG, Uznach, Switzerland	22
Midazolam		Dormicum		Roche Pharma (Schweiz) AG, Reinach, Switzerland	18, 19, 20
		Versed	Abbott Laboratories, Abbott Park, IL; Numerous generic manufacturers		20
Mitomycin		Mutamycin	Bedford Laboratories, Bedford, OH		57
		MS CONTIN, Astramorph/PF, Avinza, DepoDur, Duramorph, Infumorph, Kadian, MS Contin, Oramorph SR, RMS, Roxanol	Professional Compounding Centers of America (PCCA), Houston, TX		16, 20
Morphine	Morphin HCl sintetica 10 mg			Sintetica S.A., Medrisio, Switzerland	18, 19, 21, 22
Naloxone		Naloxone		Bristol-Myers Squibb GmbH, Baar, Switzerland	18, 20, 22, 40
		Narcan	Various generic manufacturers (no longer marketed under this trade name in the U.S.)	Bristol-Myers Squibb GmbH, Baar, Switzerland	18, 22
Natamycin		Natacyn	Alcon, Fort Worth, TX		57
Norepinephrine		Levophed	Hospira Inc, Lake Forest, IL	Teva Parenteral Medicines, Inc, Lyon, France	20
Omeprazole		GastroGard, Ulcergard		Merial Ltd, Lyon, France	20
Pancuronium bromide		Pavulon	Organon Pharmaceuticals, Allentown, PA		58

Continued

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Phenylbutazone		Butadion ad us. vet.	Not marketed in the U.S.	Streuli Pharma AG, Uznach, Switzerland	21
	Phenylbutazone USP		Various generic manufacturers	Vedco Ltd, Berkshire, UK	20
Phenylephrin		AK-Dilate, Lusonal, Mydfrin 2.5%, Neo-Synephrine, Phenoptic, Rhinall, Sudogest PE, Vicks Sinex, Sudafed PE		Laboratorium Dr. G. Bichsel AG, Interlaken, Switzerland	22
Phenylephrine		Quartuss		G. Streuli & Co AG, Uznach, Switzerland	21, 22
	Phenylephrine Hydrochloride		Baxter Healthcare Corp, Deerfield, IL		20
		Neo-Synephrine HCl, 10mg/mL	Winthrop Pharmaceuticals, New York, NY		37
Hyaluronic acid + chondroitin sulfate + glucosamine		Polyglycan	Arthrodynamic Technologies LLC, Versailles, KY		97
Polymyxin B		Neosporin	X-GEN Pharmaceuticals, Big Flats, NY		2, 4, 36, 37, 40, 57, 58, 85
Promazine HCl		Primazine, Prozine, "acepromazine"	Fort Dodge Animal Health, Fort Dodge, IO		22
		Sparine	Wyeth Laboratories, Philadelphia, PA		22
Propionylpromazine		Combelen		Bayer AG, Leverkusen, Germany	22
		Tranvet Injectable Solution	Fort Dodge Animal Health, Fort Dodge, IO		22
Propofol		PropoFlo, PropfFlo	Abbott Laboratories, Abbott Park, IL		20, 28
	Propofol 1% MCT Fresenius			Fresenius Kabi (Schweiz) AG, Stans, Switzerland	19, 21
Ranitidine		Zantac	GlaxoSmithKline, Research Triangle Park, NC	Boehringer Ingelheim, Ltd, Berkshire, UK	20
Reserpine	Reserpine	No brand name	Wedgewood Pharmacy, Swedesboro, NJ		22
Romifidine		Sedivet		Boehringer Ingelheim Ltd, Berkshire, UK	18, 19, 20, 21, 22, 48
Salmonella typhimurium antiserum		Endoserum	Immvac Inc, Columbia, MO		2
Sarmazenil		Sarmasol		Dr. E. Graeub AG, Bern, Switzerland	18, 19, 20, 22

Drug Name	Generic Drug Names	Trade Names	North American Manufacturer Information	European Manufacturer Information	Chapter(s)
Sevoflurane		Sevoflo	Abbott Laboratories, Abbott Park, IL		20
		Sevorane		Abbott AG, Baar, Switzerland	18, 21
Sodium chloride, Sodium acetate anhydrous, Sodium gluconate, Potassium chloride, and Magnesium chloride		Normosol-R	Abbott Animal Health, Abbott Park, IL		1, 3, 20, 40
Azaperone		Stresnil ad us. vet.	Janssen Pharmaceutials NV, Summit, NJ	Janssen Pharmaceuticals, Beerse, Belgium	22
Thiopental sodium		Pentothal	Hospira [Abbott], Lake Forrest, IL	Ospedalia AG, Hünenberg, Switzerland	22
Timolol maleate		Timoptic	Merck & Co Inc, Whitehouse Station, NJ		58
Tolazolin		Tolazolin HCl 120 mg ml^{-1}		Kantonsapotheke Zurich, Zurich, Switzerland	22
Vasopressin		Pitressin	American Regent Inc, New York, NY		20
Vedaprofen		Quadrisol		Pfizer Ltd, Kent, UK	23
Xylazine		Rompun	Bayer Corporation, Shawnee, MI		20, 48
	Xylazine		Various generic manufacturers		
	Xylazin Streuli ad us. vet.		Glenwood LLC, Englewood, NJ	Streuli Pharma SA, Uznach, Switzerland	18, 19, 21, 22
Yohimbine		Yocon			20
		Yobine Injection	Lloyd Inc, Shenandoah, IA		
	Actibine, Aphrodyne, Baron-X, Dayto Himbin, PMS-Yohimbine, Prohim, Thybine, Yocon, Yohimar, Yohimex, Yoman, Yovital		Sigma Chemicals Co, Saint Louis, MO		22, 40
Zolazepam		Zoletil ad us. vet		Virbac Schweiz AG, Glattbrugg, Switzerland	19, 22
Zolazepma/ Tiletamine		Telazol	Fort Dodge Animal Health [Pfizer], New York, NY		19, 22

APPENDIX

B Products and Manufacturers

Product Name	Manufacturer Information	Chapter(s)
10% povidone iodine solution	Betadine Purdue Pharma, Stamford, CT	5, 7, 9, 12, 56, 57
18-French equine enteral feeding tube	Mila International, Florence, KY	3, 37
2.7-mm reconstruction plate	Synthes, West Chester, PA	48, 93
20% acetylcysteine solution	Ben Venue Inc, Bedford, OH	37
3M Custom Support Foam	3M Animal Care Products, St. Paul, MN	17
4.0-mm cortex screws	Synthes Inc, West Chester, PA	90
45-cm–long Deschamps needle	Eickemeyer, Tuttlingen, Germany	16, 38
5 Dacron	Deknatel Inc, Fall River, MA	38
6 French venous thrombectomy catheter	Fogarty-Edwards Laboratories, distributed by American V. Mueller, Chicago, IL	46
6-F introducer system	Cook Medical Inc, Bloomington, IN	46
6-F single-end-hole nylon angiographic catheter	Cook Medical Inc, Bloomington, IN	46
90-degree hook radiofrequency probe	Stryker Endoscopy, San Jose, CA	91
Abcocide	Abco Dealers Inc, LaVergne, TN	9
Accel HLD 5	ViroxTechnologies, Oakville, Ontario, Canada	9
ACell	ACell Inc, Jessup, MD	27, 83
Acutrack Equine Screw	Acumed Veterinary, Hillsboro, OR	76
Adaptic	Johnson & Johnson Inc, Fort Dodge, IA	25
Adi-Zyme	STERIS Corp, Mentor, OH	9
AMD Foam	Covidien, Mansfield, MA	26
AMSCO Sterilization Container System	STERIS Corporation, Mentor, OH	9
anchor screws	Veterinary Instrumentation, Sheffield, UK, www.vetinst.com	97
Anioxyde 1000	Clinipak Medical Products, Bourne End, UK	9
AquaPacer equine underwater treadmill	Ferno Veterinary Systems, Wilmington, OH	103
Arcadis orbic 3D C-arm	Siemens AG, Munich, Germany	13, 97
Arnold-Bruning intracordal injection syringe, catalog No. 7754	Storz Instrument Company, St. Louis, MO	45
Arrow catheter	Arrow International, Reading, PA	6
Ascal	Dagra Pharma, Ax Diemen, Netherlands	13
Asepti-zyme	Ecolab Healthcare, Mississauga, Ontario, Canada	9
Avagardä	3M Animal Care Products, St. Paul, MN	7, 9, 10
Avitene	Davol Inc, Warwick, RI	4
Bailey-Gibbon rib contractor	Miltex Inc, York, PA	48
Bair Hugger	Arizant Healthcare Inc, Eden Prairie, MN	20
Baktolin Balm	Bode Chemie, Hamburg, Germany	10
Betadine surgical scrub	Purdue Frederick Co, Norwalk, CT	9, 10, 55, 56, 58, 61, 90
Bio-Oss	Geistlich, Wolhusen, Switzerland	77
Biopsy Punch Rongeurs	Sontec Instruments, Centennial, CO	91
Biopsy Suction Punch Rongeur	Dyonics, Smith & Nephew, Memphis, TN	91
Callicrate Bander	No-Bull Enterprises, St. Francis, KS	60
Canevasit	Amsler und Frei, Schinznach Dorf, Switzerland	76
Cardell	Minrad Inc, Orchard Park, NY	20
Cellulose sponges	Weck-Cel Medtronic, Jacksonville, FL	56
cervical fusion plate	Synthes Inc, West Chester, PA	94
ChloraPrep	Medi-Flex Inc, Leawood, KS; Cardinal Health, Dublin, OH, www.cardinal.com	9
Chlorhexidine diacetate 2%	Nolvasan Solution and Surgical Scrub, Fort Dodge Laboratories Inc, Fort Dodge, IA	5, 9

Product Name	Manufacturer Information	Chapter(s)
Chlorhexidine gluconate 4%	Hibiclens, Stuart Pharmaceuticals, Division of ICI America Inc, Wilmington, DE	7, 9, 46
ChronOs Inject	Synthes Inc, Solothurn, Switzerland	77, 89
CicaCare	Smith-Nephew Canada Inc, St-Laurent, Quebec, Canada	5
Cidex	Johnson & Johnson's Advanced Sterilization Products, Fort Dodge, IA	9
Cidex OPA		
CleantopWM-S	CBC Medical Device Group, Duesseldorf, Germany	9
Closed fenestrated drain system	International Win Ltd, Kennett Square, PA, www.internationalwin.com	40
CM Heal	CM Equine Products, Norco, CA, www.cmequineproducts.com	40
Coil sets	International Win Ltd, Kennett, Square, PA, www.internationalwin.com	3
COLLOSs E	OSSACUR AG, Oberstenfeld, Germany	77
Comply EO chemical integrators	3M, St. Paul, MN	9
Conray 400	Mallinckrodt Medical Inc, St. Louis, MO	46
Cosequin ASU	Nutramax Laboratories Inc, Edgewood, MD	79
crimping sleeve	Synthes Inc, West Chester, PA	81
CTFN 135	Yocan Medical, Thornhill, Ontario, Canada	46
Curasalt, 20% hypertonic saline on a Kerlix gauze	Tyco Healthcare/Kendall, Mansfield, MA	26
Dallmer cuff shoes	Nanric Inc, Versailles, KY	87
Davol-Simon skin graft dermatome	Davol Inc, Cranston, RI	25
diathermic snare	Olympus Optical Co, Irving, TX	46
Disposable Skin Stapler	Richard-Allen Medical, Richland, MI	36
Dura-Prep Surgical Solution	3M Health Care, St. Paul, MN	9
Dynacast Prelude	Smith & Nephew, Memphis, TN	87
Dynamap	Critikon, Tampa, FL	20
Dynamic Locking Head Screw (DLS)	Synthes Inc, Solothurn, Switzerland	76
Dynavet	Veterinary Dynamics, Templeton, CA	3
Dyonics	Smith & Nephew, Memphis, TN	91
Elasticon	Johnson & Johnson, Sommerville, NJ	39, 76, 86
electric dermatome	Zimmer, Warsaw, IN	25
electrolyzed weak acid water	Sterilox Technologies Inc, Radnor, PA	9
Embolization coils	Cook Medical Inc, Bloomington, IN	13, 46
Endo-GIA 30	United States Surgical Co, Norwalk, CT	59
Endopath Optiview surgical trocar	Ethicon Endo-Surgery Inc, Cincinnati, OH	34
Endostitch 10-mm Suturing Device	Covidien, Mansfield, MA	62
Endozyme	Ruhof, Mineola, NY, www.ruhof.com	9
Endozyme AW Plus		
Endurasplint 2	Carapace Inc, New Tazewell, TN	86
EnSeal SurgRx	Ethicon Endo-Surgery Inc, Cincinnati, OH	13, 32, 59
Enterotomy table	Kimzey Metal Products, Woodland, CA	37
Enzol	Johnson & Johnson, New Brunswick, NJ	9
Enzygnost	Dade-Behring Inc, Wilmington, DE	4
Equilox	Equilox International, Pine Island, MN	87
Equine Large Fragment Set	Synthes Inc, West Chester, PA	76
Equine laryngeal forceps	Karl Storz, Tuttlingen, Germany	44
ES-10	No-Bull Enterprises, St. Francis, KS	60
Exhalyzer V	Eco Medics, Dürnten, Switzerland	42
EZ Drape Adhesive	Clinipad Corp, Rocky Hill, CT	9
E-Z Pass Foal Enema Kit	Animal Reproduction Systems, Chino, CA, www.arssales.com	37
Fiberwire	Arthrex Inc, Naples, FL	16, 44
fine silica or aluminium powder	Harltons, Elmwood, WI	30
Finochietto retractor with long blades	Sontec Instruments, Centennial, CO	11, 61
First + Ice cold packs	MacKinnon Inc, San Diego, CA, www.mackinnonicehorse.com	103
FlapFix system	Synthes Inc, West Chester, PA	102
