The diagnosis may be confirmed by evaluating clinical signs, manipulating and palpating the head and neck, and taking lateral radiographs of the skull and proximal cervical region. A lateral radiograph should be obtained with the horse standing, with little manipulation of the head and neck. Widening of the space between the dorsal portion of the atlas and the axis, and a rounded cranial end of the axis, indicate of an abnormally shaped or absent dens. A myelogram is normally not required for confirmation of the diagnosis.

The prognosis for AAS is poor. Surgical stabilization of the atlantoaxial joint may be attempted as a salvage procedure. Subtotal dorsal laminectomy of the impinging dorsal arch of the atlas has been described in foals with a developmentally malformed dens.[30,31] In addition, a ventral approach for stabilization of AAS resulting from a Salter-Harris type II fracture of the odontoid process has been described (see Chapter 53).[32,33] Medical therapy (glucocorticoids and hyperosmotic agents) should be administered before surgical correction to reduce spinal cord swelling and edema. Affected foals should be maintained in a quiet environment with minimal handling to avoid additional trauma to the spinal cord.

ATLANTOAXIAL INSTABILITY

Atlantoaxial instability produces clinical signs in older foals and young horses.[30] Subluxation of the atlas relative to the axis occurs during extension of the head and neck because of malalignment of the atlas, resulting in caudal ventral tilting of the atlas relative to the vertebral canal. The subluxation results from ligamentous laxity and malarticulation. A congenital anomaly has been suggested, although trauma may be an important pathophysiologic factor. This syndrome emphasizes the importance of evaluating this area when examining a young horse with clinical signs of spinal ataxia localized to the cervical region. Treatment is not recommended.

The differential diagnosis for OAAM, AAS, and atlantoaxial instability includes cervical trauma, vertebral osteomyelitis after neonatal septicemia, cervical vertebral stenotic myelopathy, and syringomyelia, a congenital malformation of the spinal cord.[2,3,34]

HEMIVERTEBRAE

Hemivertebrae are wedge-shaped vertebral bodies in which the vertebral body apex may point dorsally, ventrally, or medially, resulting in kyphosis, lordosis, or scoliosis.[2,3,35-39] Moderate to severe angulation of the spine may result in animals with hemivertebrae, and the severity of the malalignment typically worsens during growth as a result of compression by adjacent vertebrae. Hemivertebrae can result from a hemimetameric shift of somites during recombination of sclerotomes to form primordial vertebrae or from a defect of the vascular supply at this developmental stage that results in a failure of half of the vertebral body to ossify.[1,3] If metameric shift is abnormal, one right and one left hemivertebra will be adjacent to each other. The vertebrae resulting from an alteration in vascular supply may appear as unilateral, dorsal, or ventral hemivertebrae.

In horses, hemivertebrae have been observed at C5, although in most species T7 and T9 are most commonly affected.[36] Clinical signs of hemivertebrae in foals are observed before 1 year of age. Foals demonstrate progressive vertebral malalignment, leading to kyphosis or scoliosis, with or without neurologic gait deficits. Hemivertebrae are often weaker than normal vertebrae; a sudden jump or fall may result in acute worsening of clinical signs.

THORACIC VERTEBRAL MALFORMATION

Malformation and compression of the thoracic vertebrae has been described in two unrelated horses.[40] Both horses appeared normal for the first year of life, with ages of onset being 13 and 28 months. Clinical signs included acute-onset pelvic limb weakness and ataxia in one horse and severe spinal cord dysfunction and paralysis of the pelvic limbs in the other. Both horses demonstrated Schiff-Sherrington phenomena, characterized by hypertonicity of the thoracic limbs associated with focal thoracic spinal cord compression. This clinical sign has been described in humans and other animals with fracture of the thoracic vertebrae, although it is a rare finding in horses.[41] The malformation of the thoracic vertebrae was similar to malalignment and subluxation observed in horses with cervical stenotic myelopathy.

BLOCK VERTEBRAE

Block vertebrae are examples of improper somite segmentation and appear to be a result of incomplete separation of the vertebral bodies or arches, or both.[1] The length of a block vertebra is equivalent to the number of vertebral segments involved. Block vertebrae are generally stable and do not often result in clinical signs, although the rigid fixation may result in abnormal biomechanical forces on adjacent vertebrae. The sacrum is an example of a normal block vertebra. The most commonly reported location of block vertebrae in humans and animals is C2-3 (Figure 51-5).

BUTTERFLY VERTEBRAE

A butterfly vertebra is a rare anomaly of the equine vertebral column. The embryonic notochord is normally obliterated with the development of the vertebral bodies and remains only as the vestige of the intervertebral disc. If the notochord persists, a dorsal-to-ventral cleft results, which leads to vertebrae that

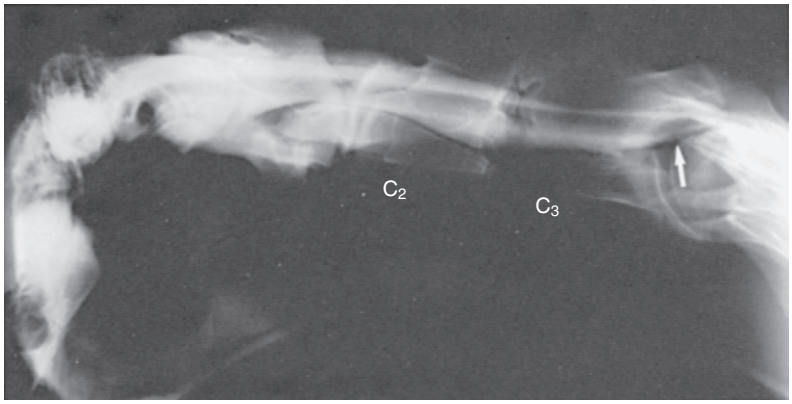

Figure 51-5. Block vertebrae involving C2-3. The block vertebrae are not associated with spinal cord compression, which is present at C3-4.

resemble a butterfly on a dorsoventral radiograph. Butterfly vertebrae typically do not cause spinal cord compression and do not require treatment, except in cases associated with meningeal cysts.[1,3] In one report, the butterfly vertebra was associated with a rare neurenteric cyst, which resulted in hindlimb ataxia, weakness, and frequent "dog-sitting."[42]

VERTEBRAL DEFECTS

Spina bifida results from incomplete fusion of the dorsal components of the vertebrae during the neurulation process. It is often associated with a protrusion of the meninges (meningomyelocele) through the vertebral defect. Spina bifida (C5 through C6) with an accompanying meningomyelocele has been identified in a Miniature Horse foal that was unable to stand at birth.[43] The meningomyelocele appeared as a 5-cm fluctuant mass of the dorsal aspect of the caudal cervical region. The colt also had hydrocephalus, which is present in the vast majority of children with meningomyelocele as part of the Arnold-Chiari malformation (protrusion of caudal cerebellar tissue through the foramen magnum with concomitant caudal displacement and elongation of the medulla oblongata, pons, and fourth ventricle).

Severe posterior ataxia as the result of a congenital cleft in the ventral aspect of a vertebral body (T5) has been described in an Arabian foal.[44] The foal had malformation and fusion of several thoracic vertebrae, with an intraspinal and extraspinal (intrathoracic) cyst. Therefore, a history of posterior paresis and ataxia present at birth should signal a need to perform a careful examination to search for malformation of the vertebral column in the thoracic region.

CHAPTER
52 Surgical Treatment of Developmental Diseases of the Spinal Column

John Walmsley and Barrie D. Grant

Surgical treatment of developmental diseases of the spinal cord is focused on cervical vertebral stenotic myelopathy (CVSM). The goal of treatment is decompression of the spinal cord to allow healing of the compressive lesion and the return to full function. The etiology and diagnostic techniques have been discussed in Chapters 50 and 51, but comments on diagnostic techniques from a surgeon's perspective are appropriate here. Accurate diagnosis of the site of compression is fundamental to successful surgical treatment. A thorough clinical and neurologic examination should be performed, and if cervical spinal cord compression is suspected, survey radiographs of the neck are taken. These are evaluated for abnormalities, and the intervertebral and intravertebral ratios are measured (Figure 52-1).[1]

There are some caveats to note when performing this evaluation. Obvious abnormalities such as angulation or subluxation at C3-4 suggesting cervical spinal cord compression on plain films are not always confirmed as the site of compression on myelography. Osteochondrotic articular facets at C6-7 can be associated with spinal cord compression but they are also a common finding in horses without neurologic problems, and they may be present in horses with ataxia from another cause (e.g., protozoal myelitis) or from compression at another site. A longitudinal postmortem study of osseous changes in the cervical vertebrae of 87 nonataxic horses between 2 and 21 years old was performed by Whitwell.[2] Moderate to severe new bone formation both ventral to the cranial articular processes and on the caudal, lateral aspects of the caudal articular processes of C6-7 was recorded in 18% and 52% of horses, respectively. Equally there may be additional sites of compression not suspected on plain films, which can have a significant bearing on the feasibility of surgical intervention, the prognosis, and the eventual outcome.

The intravertebral and intervertebral ratios are useful (Figure 52-2), but they still require further validation. An intravertebral ratio of less than 0.5 was reported to increase the likelihood that cervical cord compression will be diagnosed by myelography at this site.[3] Hahn and colleagues measuring intervertebral and intravertebral ratios on eight horses with histological evidence of compression reported that these ratios were predictive of the site of compression.[4] Another study evaluating these ratios against myelographic results in 24 horses showed that the ratios were poor predictors of the site of compression but reasonably good predictors that the horse was likely to have

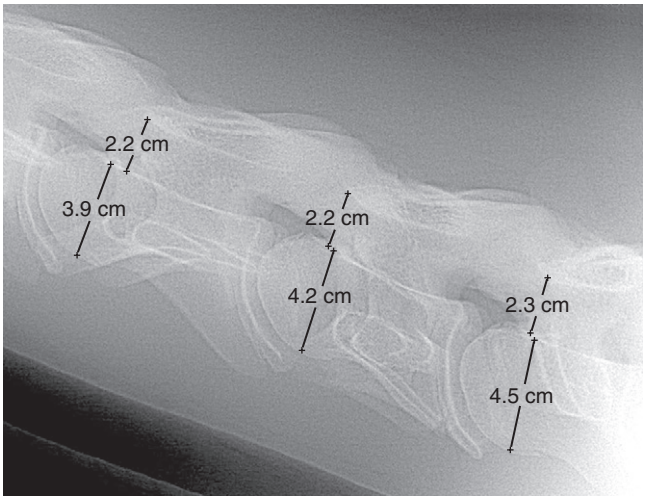

Figure 52-1. Survey radiographs of the cervical spine, showing normal measurements of vertebral body–to–canal ratios.

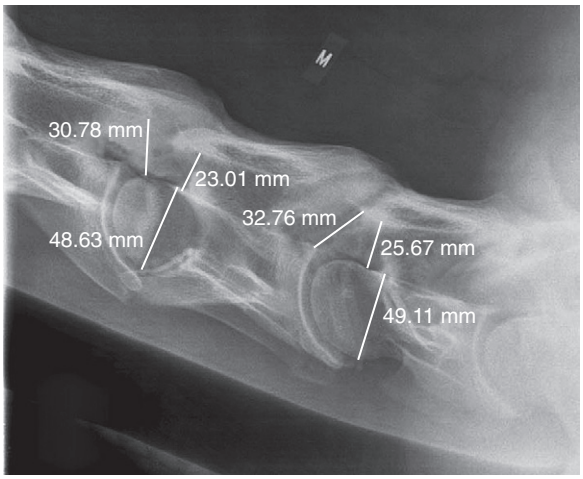

Figure 52-2. Survey radiographs of the cervical spine showing intervertebral and intravertebral measurements at C5-6 and C6-7.

Figure 52-3. Myelogram showing severe cord compression at C6-7 in a 2-year-old Thoroughbred.

a cervical compressive lesion somewhere.[5] Sensitivity for the presence of compression but not specifically the site of compression was 42%, and the specificity was 79%. In six horses the site of compression was predicted but there were multiple false positives in each horse, and three horses had positive results on myelography but had normal ratios. With these comments in mind, it is essential to remember that successful treatment of localized cervical spinal cord compression depends on myelographic confirmation rather than interpretation of survey radiographs.

CASE SELECTION FOR SURGERY

Once cervical cord compression is confirmed, other factors considered important to the successful outcome of the case are (1) number of sites of cord compression, (2) whether the cord compression is static or dynamic, (3) severity of the clinical signs, (4) duration of clinical signs, and (5) the temperament, age, and intended use of the animal.[6] The supporting evidence for these parameters is incomplete but is discussed later.

Anecdotally, horses treated at multiple sites are considered to have a worse prognosis, although one study revealed no statistical difference in outcome between a group of 40 horses treated at one site and 22 at two sites.[7] One group described triple level treatment of 12 horses, out of which 9 improved two grades and 7 returned to ridden work; but all horses had a reduced lateral range of cervical motion postoperatively.[8]

Dynamic lesions (most commonly at C3-4) have been shown to carry a better prognosis after surgical treatment than static lesions at C6-7.[7,9] Another group reported return to use of 69% of horses with dynamic lesions and 59% with static lesions from a series of 45 horses.[10] From another series of 58 horses treated surgically, Walmsley reported that 11 out of 13 horses treated at C3-4 and 14 out of 27 horses treated at C6-7 returned to use, a statistically significant difference ($p = 0.035$, Fisher exact test).[9] The fatal complication rate in horses treated at C6-7 appears to be higher.[7]

The severity of clinical signs is thought to affect outcome because most successful cases improve up to two neurologic grades out of four (using the scale of grades 1 to 4 described by Mayhew and coworkers[11]), though Walmsley reported no statistically significant difference in outcome of surgery between 32 horses with neurologic grade of 1 or 2, and 15 horses with grade 3 or 4.[9] Some severely affected horses with short duration of clinical signs have returned to full use after treatment. Grant and colleagues have shown that the severity of myelographic compression has an impact on the outcome (Figure 52-3).[12] Horses with mild to moderate compression had a more favorable prognosis for future use than horses with severe compression. Only 50% of severely affected horses could be ridden after surgery, whereas 68% with moderate compression and almost 100% with mild myelographic compression were used in various riding disciplines after surgery.[12]

Duration of clinical signs was shorter for successful cases in the series of 63 described by Rush Moore and colleagues,[7] but Walmsley found no statistical effect of duration of signs on postoperative outcome in 58 cases.[9] Long duration of signs alone should not exclude horses from treatment.

The temperament, age, and intended use of the horse are subjective influences on recommendations for surgery. The temperament of the patient is important because there are personality changes associated with cord compression that are probably related to the anxiety of being ataxic. Animals may become intractable and sometimes self-destructive. Young animals that have had little handling (e.g., have never had their feet picked up and trimmed) before the onset of clinical signs are at great risk for traumatic complications resulting from the restraint needed during diagnostic testing, anesthetic induction, recovery, and postoperative treatment. Serious consideration should be given to delaying surgery for 4 or 5 days to accustom an unbroken adolescent horse to handling and restraint.

As for all elective surgery, procedures should not be performed on a patient heavily infested with parasites or suffering from a respiratory condition because these horses are more susceptible to pleuropneumonia from the stress of transportation and anesthesia. A thorough clinical examination, including hematologic tests if appropriate, is essential before embarking on myelography or surgery, and these should be postponed at any stage if adverse signs are noticed.

Because of the association of osteochondrosis with the pathogenesis of developmental cervical cord compression, it is important to ensure that other commonly involved joints (e.g.,

the stifle, tarsus, fetlock, shoulder) are free from significant pathology. If concurrent pathology exists, its significance should be carefully evaluated and its possible effects on the outcome discussed with the owner. Arthroscopic treatment of osteochondrosis lesions in the hock or stifle can be carried out concurrently with interbody fusion.

EXPECTATIONS OF SURGERY

It is important to understand the owner's hopes and expectations for the outcome of surgical intervention and to put them into the context of what is possible. Owner compliance and commitment before surgery is essential, and the owner must be a willing participant if surgery is to be undertaken. Owners must be completely informed of the risks, liabilities, and responsibilities of their decision. Their goals must be tempered with realism. Trainers and owners need to be patient because full recovery may take up to 1 year or more, and they will be required to condition the patient, using a slow, graded training program. In practice, the surgeon should be aware that some owners really hope to have a horse that will be able to compete at a high level, despite initially being emphatic that they will be satisfied with a pleasure horse or breeding animal as an outcome. However a long-term evaluation at 1 to 4 years after surgery did in fact reveal that as many as 90% of clients and referring veterinarians were satisfied with the outcome.[12] Owners should be informed that, if surgery renders an unsuccessful result, they may have a horse that has not recovered sufficiently to be handled safely or cannot be left in a large paddock without supervision. If the horse is to be used for breeding, a mare should be able to stand for service and a stallion should be able to cover a mare naturally with only moderate assistance.

Owners appreciate being informed of the chances of success based on available evidence. An analysis of long-term results of 126 horses that had undergone ventral interbody fusion using the Seattle Slew implant (see later) between 2000 and 2003 showed that 88% of the animals recovered at least one grade, 60% were ridden successfully, and 10% were used for breeding or were retired.[12] Another study revealed that 36 of 61 treated horses showed an improvement by two neurologic grades or a return to athletic use.[7] Sinha and associates documented a positive outcome in 28 of 45 horses (62%),[10] and Walmsley reported a return to full work, measured by return to expected use, in 31 out of 57 horses (53%).[9] Overall, the success rate of most surgeons is approximately 60%. As with any surgical procedure, owners should be warned of the possible complications (see later).

SURGICAL APPROACHES AND TECHNIQUES

Ventral Interbody Fusion

This surgical procedure requires a well-trained team and good facilities. Any delays caused by poor preparation are unacceptable and could increase the complication rate. The most frequently used technique today is a modification of Cloward's procedure developed for use in humans in 1958.[9,13-17] The modification uses a threaded or partially threaded titanium implant, the Kerf Cut cylinder (KCC), which has multiple holes and is open ended. The technique leaves an isthmus of bone in the center of the cylinder, the aim being to encourage faster fusion by increasing the blood supply to the graft material and to reduce the incidence of postoperative fracture and implant migration (Figure 52-4). Another technique using a ventral locking compression plate has been reported and is also described later.[18]

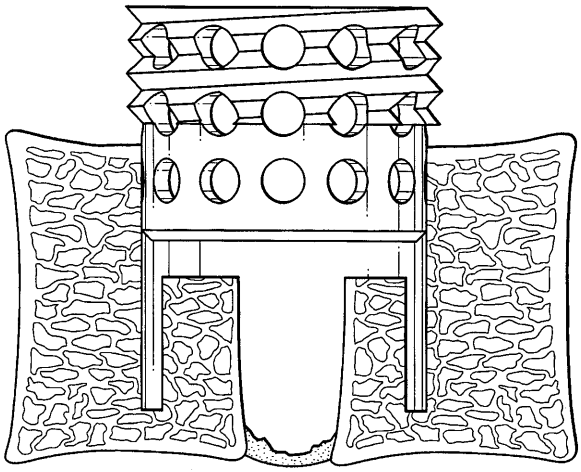

Figure 52-4. Drawing showing the Kerf Cut cylinder advancing into a prepared bone bed. Note the preserved peninsulas of bone, which remain inside the implant.

Preoperative Medication

Preoperative antibiotics consisting of procaine penicillin and gentamicin are administered to the animal before induction of anesthesia, after surgery and for the following 72 hours. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as phenylbutazone or flunixin meglumine are administered at therapeutic levels before induction. They are continued for at least 7 days postoperatively or as long as necessary to reduce postoperative discomfort. Tetanus toxoid is administered to unvaccinated horses.

A preoperative endoscopic examination of the upper airways may be performed to detect laryngeal hemiplegia. The presence of this condition represents a risk for bilateral laryngeal paralysis should the right recurrent laryngeal nerve be damaged during surgery. The surgical approach should be made on the left side of the trachea under these circumstances (see later).

Anesthesia

Positive-pressure-assisted inhalation is the preferred method of maintaining anesthesia because it offers the best control while the surgeon is drilling close to the spinal cord. Common anesthetic problems include hypoxia, hypotension, and, if a facial artery is used, variable blood pressure readings. The latter is associated with the location of the surgical site; the right carotid artery can be compressed with retractors during the procedure, and we recommend using the left facial artery for blood pressure monitoring. Awareness of these possible complications allows early use of inotropic drugs. Frequent arterial blood gas analyses and high oxygen flow rates should enable the anesthetist to react appropriately.

Patient Positioning

The animal is placed in dorsal recumbency, with the neck in extension and the forelimbs tied in a moderately flexed position

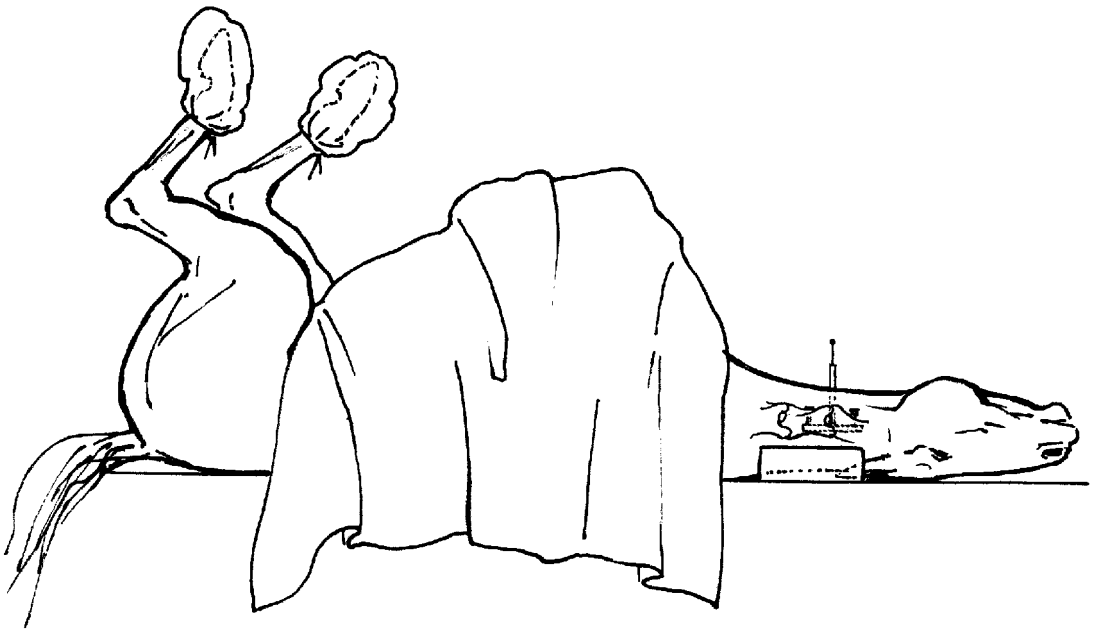

Figure 52-5. Schematic representation of a horse correctly positioned for surgery using a block of wood to extend the cervical articulations.

to allow adequate lateral stability without the excessive tension that could produce radial nerve dysfunction. A 30-cm block of wood or metal, which acts as a crutch for the neck, is placed under the affected area (Figure 52-5). This support assists the extension of the cervical articulations and at the same time stabilizes the neck, reducing excessive movement during drilling. It is very important to ensure that the neck is perfectly straight. At this stage the imaging system to be used (x-ray or image intensifier) should be set up to minimize time wastage during surgery.

Identification of the Surgical Site

Accurate identification of the affected cervical articulation is essential. The site can be determined by measuring one hand width for each vertebra retrograde from the easily palpable wings of the atlas (Figure 52-6). Markers such as 14-gauge needles or skin staples are then placed at the site and lateromedial radiographic projections are taken. The markers should be on the side of the neck closest to the x-ray cassette to prevent excessive distortion as a result of parallax, and they should be placed over the affected articulation as well as ventrally at the level of the incision. Alternatively, since C2 is clearly identifiable radiographically, markers are placed at several sites caudad from C2 and serial radiographs are taken identifying each articulation until the surgical site is reached (see Figure 52-11). Once the markers are verified to be at the correct level, aseptic preparation of the surgical site is completed and the entire horse is draped. The use of suction or electrocautery will reduce intraoperative time. Intraoperative imaging is a key part of the procedure, so the use of an image intensifier is recommended to prevent wasting time developing x-ray cassettes. If the latter are used it is vital to have the most efficient system possible for developing the images and returning them to the surgeon. Digital radiography is a very satisfactory alternative to an image intensifier, although it can be more difficult to identify the correct site because of the small cassette size.

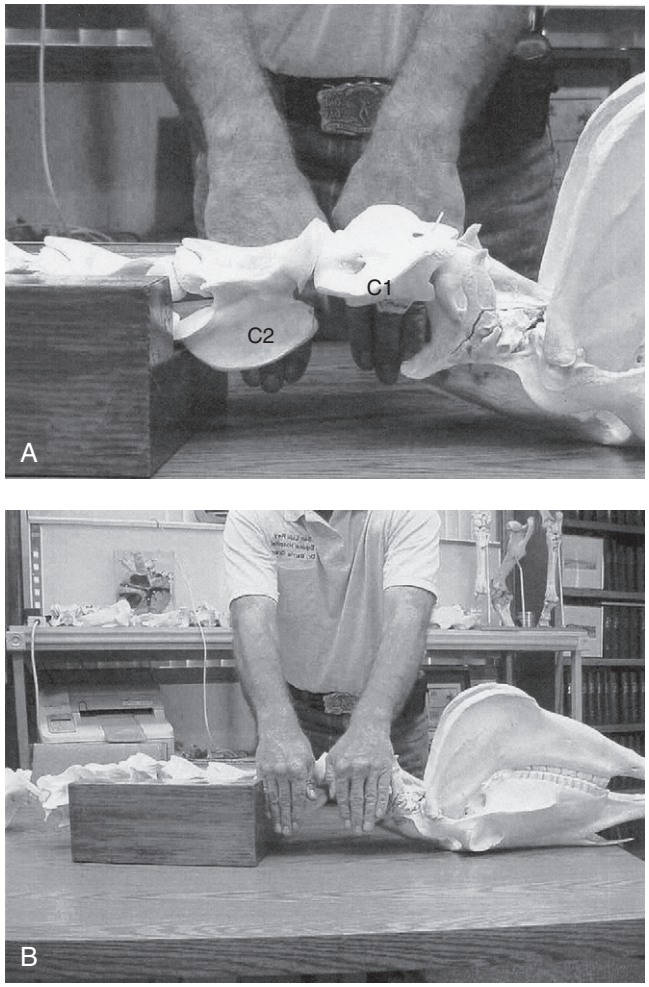

Figure 52-6. Demonstration on a horse skeleton of a technique for identifying the affected articulation. Using the wing of the atlas *(C1)* as a palpable landmark, each vertebral body length is determined to be about one hand-width. **A,** Hands placed behind the vertebrae. **B,** Hands placed in front.

Surgical Technique

THE KERF CUT CYLINDER

Dedicated instrumentation is necessary for implanting the KCC. The right-handed surgeon stands on the horse's left side. For a single-level fusion, a 20-cm longitudinal skin incision is made in the sagittal plane centered over the preplaced markers. A towel clamp placed at this level serves as a landmark and obviates the need for frequent palpation of markers through the drapes. The cutaneous musculature is incised with a scalpel blade or scissors, and hemorrhage is controlled as necessary. The sternothyroideus muscles are separated longitudinally to expose the trachea. Once the trachea has been identified, blunt dissection is continued dorsad down the right side of the trachea, separating it from the carotid artery and vagosympathetic trunk. Hand-held Deaver retractors can be used to retract the trachea to the left to expose the longus colli muscles. To reduce the risk of right-sided laryngeal hemiplegia postoperatively, the carotid artery and vagosympathetic trunk should be protected throughout the surgical procedure and should not be excessively retracted. The ventral spine (only rudimentary at C6-7) of the vertebral body cranial to the articulation to be treated can now be identified and dissected clear of its muscle attachments. Self-retaining Inge retractors are applied to gain access to the ventral spine and adjacent vertebral body for a curved osteotome, with which the ventral spine is removed. This creates a triangular platform on which to place the drill guide at the level of the ventral aspect of the vertebral body of the vertebra. Any hemorrhage is controlled with suction and sponges. The physeal line of the caudal aspect of the vertebra cranial to the articulation can be seen at the caudal edge of the platform in young horses. Since the intervertebral articular surface of the vertebral body is curved cranially, drilling starts just cranial to the ventral margin of the articulation so that the drill will equally bestride the articulation when it reaches a depth of 25 mm.

At this point, Grant proceeds as follows: A 16-mm drill guide is placed on the platform with its caudal surface on the physeal scar. Using a 16-mm drill bit, a test hole is prepared to a depth of 10 mm. For the sake of accuracy, a powered drill is essential. After the drill guide and drill are removed, it is usually easy to see the characteristic drab-white appearance of the intervertebral disc material. Two or three K-wires are gently tapped into the cranial and caudal aspects of the disc on the midline, using the spine of the anterior vertebra as a guide. An intraoperative image is then obtained to establish which K-wire is correctly placed so that the implant will be centered between the two vertebrae and to reconfirm that these are the correct vertebrae. The large centering pin is then placed over the chosen K-wire, and the drill guide is placed over the centering pin and hammered securely into the vertebra as close to perpendicular to the spinal canal as possible (Figure 52-7). This is used to guide subsequent drilling.

Walmsley prefers not to use the K-wires but places the 25-mm drill guide on the platform on the ventral surface of the vertebral body using radiographic control. Lines are drawn on the radiograph to ensure that the drill guide is placed so that the drill bit will equally bestride the articulation at a depth of 25 mm as described earlier (Figure 52-8). The 16-mm drill bit is then advanced to a depth of 10 mm to debulk the bone before using the 25-mm drill.

In both methods the implant site is now prepared by drilling with a series of drills starting with a solid 25-mm drill bit to a depth of 15 mm. If this is not done, the island of bone inside the implant may be too large, rendering it vulnerable to fracturing when reaming is performed with the Kerf Cutter later in the procedure. The drilling is continued with a narrow-core saw followed by a thicker-core saw (Figure 52-9), using radiography and depth measurements to monitor the direction and depth of the drill bit. Drilling should be performed only by one surgeon whose responsibility is to focus on the depth. The drilling depth should be 25 to 30 mm but must not be less than 10 mm from the spinal canal. It has been our experience that this shelf of bone should be left between the bottom of the drill hole and the spinal canal to provide overall strength to the articulation during the recovery process. Once the correct depth has been reached, the drill guide is removed and the implant site is initially widened with a No. 1 Kerf Cutter followed by the slightly larger No. 2 Kerf Cutter (Figure 52-10). The implant site is now tapped with the dedicated tap that matches the threads of the KCC implant. The implant is then inserted until firm resistance is encountered (Figure 52-11). A partially threaded implant is preferred, since this is less likely to cross-thread and drill a separate channel if the leading nonthreaded edge is toggled into place and gently twisted until it engages the already created thread cuts. The fully threaded implant is used in situations where a partially threaded implant fails to tighten. Care must be exercised because the self-tapping design of the fully threaded implant can permit the implant to be twisted into the spinal canal. A Hall drill or spoon curette is used to remove as much intervertebral disc material as possible to provide a bleeding surface of bone and encourage rapid acceptance of the bone graft. During the drilling an assistant collects bone from

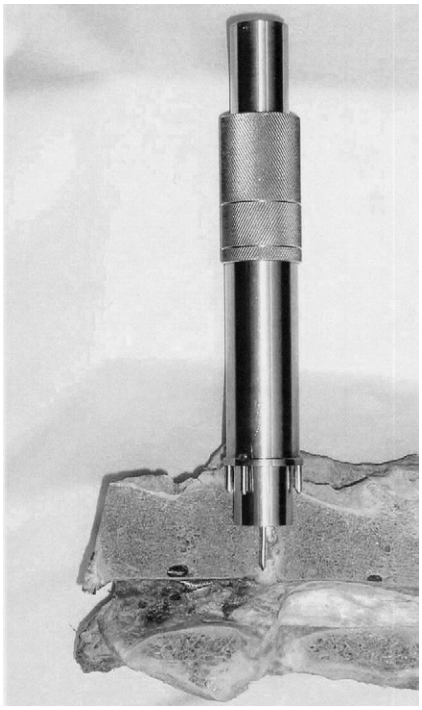

Figure 52-7. A cadaver specimen showing correct positioning of a solid cylinder placed over the guide pin, with a four-pronged drill guide placed over the cylinder. The guide pin and cylinder are removed after the drill guide is tapped into place. From this point the drill guide acts as the guide for the drilling processes.

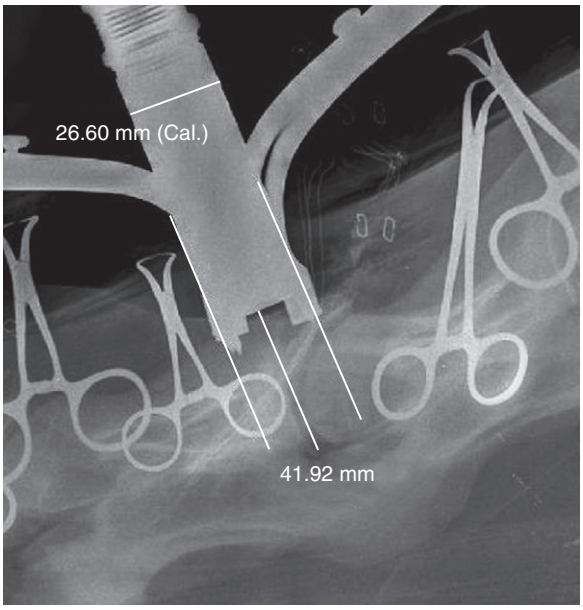

Figure 52-8. Intraoperative radiograph of drill guide in place with lines drawn on radiograph to confirm correct positioning. The distance to the spinal cord is also measured for the surgeon's reference.

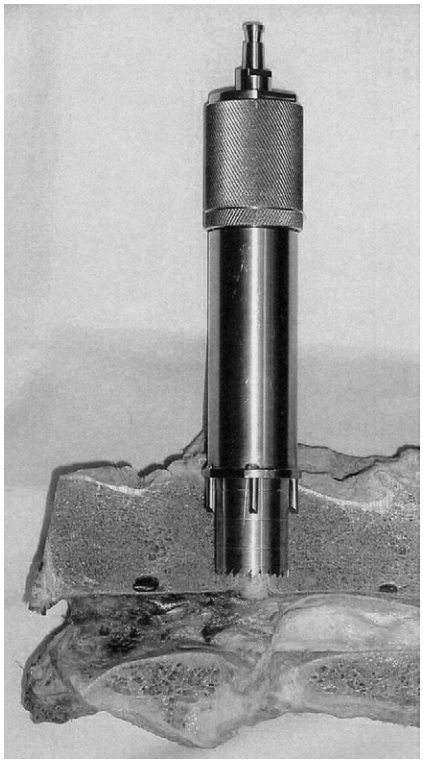

Figure 52-9. A cadaveric specimen showing the thin Kerf Cut saw advanced to the proper depth.

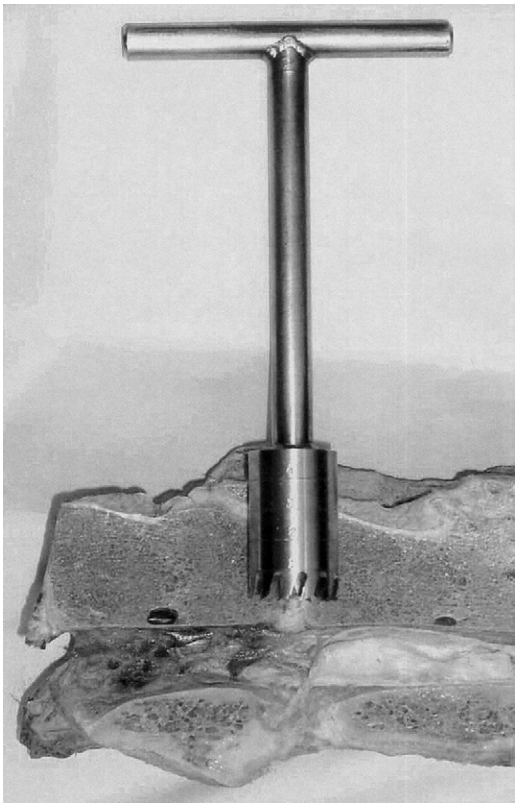

Figure 52-10. A cadaveric specimen showing the manual Kerf Cut widener and cleaner, which is used after the thin- and thick-cut saws.

the ventral spine and the drilling fragments to prepare a bone graft by dividing the dark red cancellous bone into small pieces and removing disc material and periosteum. The graft material should be covered with a blood-soaked sponge for optimal survival of the osteoblasts until it is required (see Chapter 77). Saline should not be used because its osmotic pressure may disrupt the osteoblasts. The graft is placed firmly inside the implant. A final radiograph is taken to confirm correct placement of the implant and for use as a reference before recovery from anesthesia (Figure 52-12). For a multilevel fusion, the whole procedure is repeated at each location.

After liberal flushing of the entire surgical area and a careful check for foreign materials (e.g., surgical sponges), the self-retaining retractors are removed. The longus colli muscle is closed with 0 polydioxanone suture (PDS) in a two-layer mattress pattern to reduce dead space. The remaining ventral cervical muscles are closed with 0 PDS in a simple-continuous or Ford interlocking pattern (the surgeon's choice). 2-0 PDS is used on the subcutaneous tissue and staples are used on the skin. Application of drains is not advised because they increase the risk of postoperative infection. In more than 600 cases, the cosmetic appearance of the surgical area has been very satisfying 4 to 6 weeks after surgery, without the need for aspiration or drainage of any seroma.[19] A sterile stent bandage can be sutured over the incision for recovery and replaced by a sterile dressing when the horse has returned to its stable; or the site can be recovered with an adhesive dressing protecting the incision. The use of a full neck bandage is a matter of the surgeon's choice.

LOCKING COMPRESSION PLATE

The use of a locking compression plate (LCP) for ventral fixation of the affected cervical articulation has been described.[18,20] Although the technique has not been thoroughly evaluated clinically, an *in vitro* study compared fixation using a KCC with fixation using a standard 4.5/5.0 broad 8-hole LCP at C4-5.[20] Testing the construct to failure showed a higher stiffness, moment to yield, and moment to failure with the LCP. Further evaluation is required, but the method may ultimately prove to be a useful alternative that does not require specialist equipment.

The first case reported was a 3-month-old Warmblood filly foal with a grade 3 neurologic deficit of several weeks' duration.[18] The dissection to the ventral aspect of C6-7 was as described for the KCC. The ventral surfaces of the vertebrae were flattened with an osteotome and as much intervertebral disc material as possible was removed using a spoon curette. The LCP was attached with five 5.0-mm self-tapping locking head screws placed under radiographic control. Because three screws pulled out during recovery, the surgery was revised on the following day using the longest possible screws and placing the central cortical screw across the intercentral articulation (Figure 52-13). The filly improved by 2.5 neurologic grades over 30 months. The second case report described fixation of C5-6 in a 2-year-old Standardbred colt showing grade 2 ataxia.[21] A 7-hole broad LCP with 5-mm self-tapping locking screws was used. The horse developed a seroma that was treated and resolved, and there was slight pullout of one screw. Seven months postoperatively the horse was in full training.

Recovery

A smooth recovery is important for a successful outcome in these patients. Some of these ataxic horses are unbroken, have had little handling, and will have difficulty standing up under the best of circumstances. Violent recoveries are associated with migration of the implants and, as with most equine surgeries, anything that anesthetists and surgical personnel can do to promote quiet, prolonged recoveries is beneficial. Hand recovery of cases with a tail and head rope is preferred by many surgeons. The head rope must not be overused because of the possibility that cervical traction will cause cervical fracture at the implant site. The head rope should be handled by an experienced person who has respect for the dynamics of the surgery.

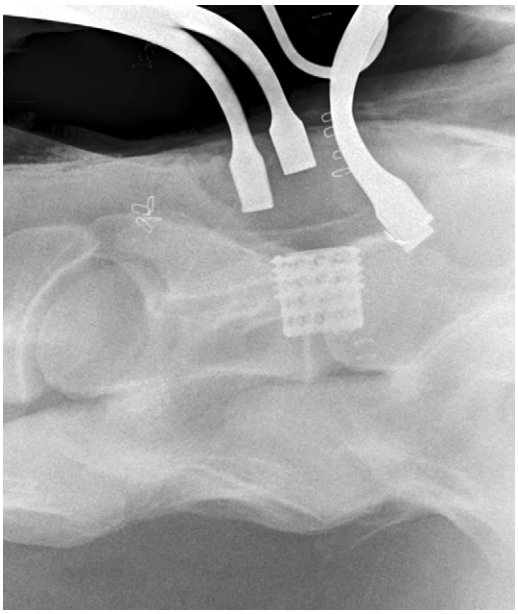

Figure 52-12. Intraoperative radiograph confirming correct placement of implant. Note the rows of skin staples used preoperatively to locate the affected articulation.

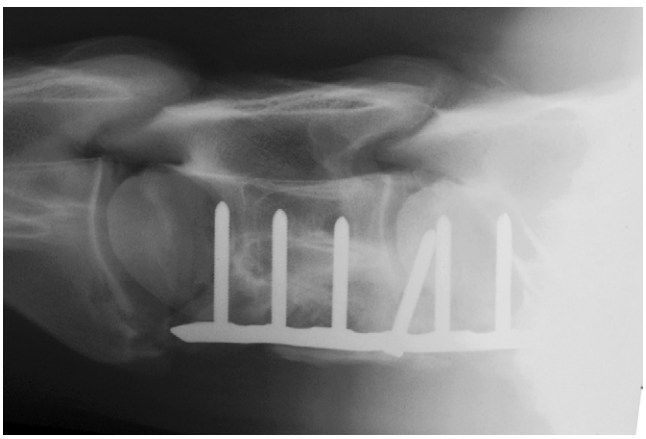

Figure 52-13. An x-ray of a locking compression plate implanted on the ventral surface of C6-7 in a Warmblood yearling taken 10 months after revision surgery.

An extended period of recovery in lateral recumbency (40 to 90 minutes) is usually beneficial. A combination of butorphanol and acepromazine in the early phase of the recovery to keep the horse comfortable and calm has proved to be an effective protocol. The onset of the effect of acepromazine is slow compared with that of xylazine, so early administration is important. It has the advantage of inducing less-severe ataxia than is produced by xylazine, though very small doses of xylazine may be more effective in controlling excessive early movements. Steroids can be useful if the patient's ataxia is greater than grade 3. Sling recoveries are sometimes necessary, especially for the patient with severe ataxia (grade >3.5). Placing these patients in the sling for 15 to 20 minutes a day for 1 to 2 days before surgery greatly facilitates the effectiveness of its use postoperatively. If a sling was required for recovery from the myelogram, it will probably be required after surgery. Pool recovery may be contraindicated since it requires extension of the head to avoid drowning, and this could dislodge the implant.

If there is a problem with stability and ataxia on standing, a second dose of NSAIDs can be administered at this time. The patient should not return to the stall until the surgeon deems the animal to be stable enough to do so. The floor leading to the stable should be dry and not slippery.

Postoperative Management

Penicillin and gentamicin are administered for 3 days postoperatively. Flunixin meglumine is usually given intravenously for 3 days to reduce swelling and postoperative discomfort. Administration of NSAIDs may be continued for a further 4 to 7 days depending on the clinical signs.

Most horses have good mobility and a good appetite postoperatively. Hay and feed should be presented at shoulder level to prevent unnecessary strain on the neck that would be caused by stretching to the floor. The animal should be managed in the stall in a quiet, gentle manner to prevent sudden movements or falls. If the animal objects to intramuscular injections, it can be medicated intravenously through an indwelling catheter or orally depending on the medication. The bandage may be left in place for the first 5 to 6 days postoperatively. It can be completely removed or replaced by a similar bandage if an early good cosmetic appearance is desired. Walmsley prefers not to bandage but to protect the incision with adhesive sterile dressings. The first 7 to 10 days after surgery are the most critical, and during this time the horse should not be walked out.

Postoperative radiographs should be taken 4 to 5 days after surgery to evaluate any change in position of the implant. If at any stage there is an increase in swelling, discomfort, or ataxia, radiographs should be taken immediately and the position of the implant compared with the immediate postoperative image. A change in position may be associated with fracturing of the implant bed, and even though any obvious fracture lines are not appreciated, this is often the cause of the increase in clinical signs. If the horse remains standing, fusion can occur with a satisfactory result; but if the patient is recumbent and cannot achieve sternal recumbency on its own, the prognosis is unfavorable.

At least 45 days of stall confinement is recommended to protect the implant, and the calorie intake is reduced. After 45 days, hand-walking can commence. To assess progress at 60 days, a follow-up radiographic and neurologic examination should be performed, if possible by the same surgeon to maintain continuity. An early study showed that the fusion process is well under way at 60 days, and postoperative myelograms are likely to have normal dye columns by this time, even on patients with static compression at C6-7.[19] Fusion can be substantially completed by 1 year (Figure 52-14). The owner and trainer should be warned that it may take at least 1 year before the clinical signs resolve and that a carefully executed rehabilitation program is of utmost importance for a good result. Exercise will assist in retraining the spinal tracts. After 60 days the horse should be turned out for at least 6 months or until clinical signs resolve. During this time some in-hand exercise may be beneficial for animals with grade 2 or greater ataxia. Horses with grade 1 ataxia can proceed to lunging, depending on progress.

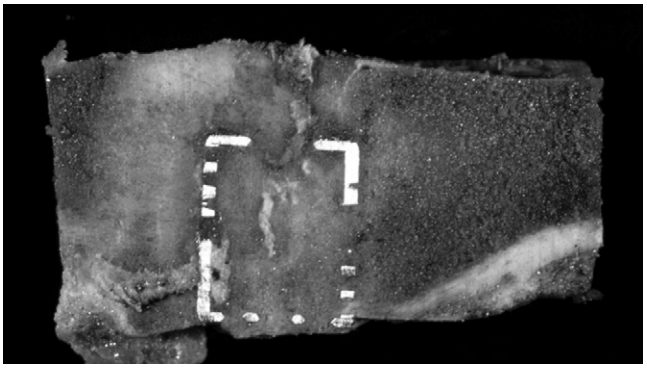

Figure 52-14. Postmortem specimen at 1 year after implantation of a Cloward Bagby Basket at C3-4 showing fusion of the vertebrae.

Complications

SEROMA FORMATION

Seroma formation has been reported in 4 of 126 cases in one study[12] and 9 of 63 cases in another,[3] but excessive seroma formation is rare. In our experience the development of postoperative seroma is usually associated with multiple-level fusions and older patients with heavier ventral cervical muscles that require more extensive dissection and retraction. It is preferable to avoid the use of prophylactic drains, since these could increase the chance of infection and most seromas resolve with time and without treatment. If the seroma develops into an abscess, open drainage will be necessary to avoid seeding the implant with bacteria. Effective control of hemorrhage during surgery, accurate tissue dissection, and closure of tissue layers will reduce the incidence of seroma formation.

INFECTION

Grant reports a relatively low incidence of postoperative infection of the soft tissues or the implant (less than 1%). Soft tissue infection usually induces a febrile response with a firm, painful enlargement at the surgical site, leukocytosis, and hyperfibrinogenemia. Treatment consists of drainage (best guided ultrasonographically), administration of appropriate antibiotics, and hot packing. Infection of the implant produces the same clinical response, but also the patient is noticeably unwilling to move the cervical area and may show worsening neurologic signs. In

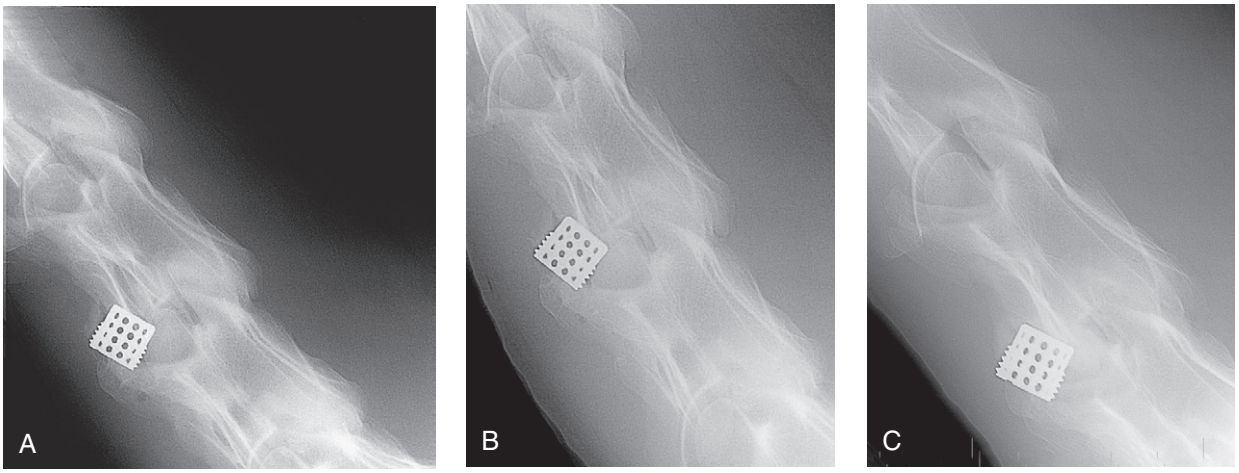

Figure 52-15. A, Cervical radiograph taken 1 day after surgery. This horse experienced a fracture cranial to the implant. **B,** The same fracture 1 week after surgery. **C,** The fracture healed after 8 weeks of stall rest.

one case of suppurative meningitis (from infection with *Klebsiella*), a postoperative myelogram taken when the patient was tetraparetic demonstrated a uniform narrowing of both dye columns of the entire cervical area. The signs resolved after retrieval of the implant and application of methyl methacrylate bone cement impregnated with cephalosporin antibiotic powder.

FRACTURES

Fracture of the adjacent vertebral body is a serious, often fatal complication that in most cases occurs during recovery (Figure 52-15). A fracture should be suspected if the horse shows a worsening of neurologic signs or appears to have excessive neck pain. In these cases radiographs should be taken. Conservative treatment is indicated because revision surgery or surgery to repair the additional fractures carries a high risk. Some horses recover, but if the horse becomes unacceptably ataxic or is unable to stand, euthanasia is usually indicated.

One study reported 3 fatal postoperative fractures in 63 horses.[7] From a series of 17 cases treated at the articulations between C5 and T1, two nonfatal fractures were recorded by Nixon.[22] There is some evidence that surgical treatment at C6-7 carries a higher complication rate.[7,22] In a review of 275 patients, only 3 had catastrophic fractures that resulted in euthanasia.[19] All the fractures occurred at C6-7 and the patients were all older than 15 years and had degenerate discs (narrowed and yellow) at the time of surgery. Two animals had violent recoveries. Walmsley reported 5 fractures in 27 horses treated at C6-7 compared with no fractures in 16 cases treated at C3-4, but the difference was not statistically significant.[9] However, these data showed a statistical trend for a lower chance of fracture when the KCC was used rather than the Cloward Bagby Basket (CBB).[9] Grant compared 69 horses treated with the CBB against 75 horses treated with the KCC and showed a significantly lower incidence of fracture with the KCC.[19]

OTHER COMPLICATIONS

Other complications associated with this procedure include ventral migration of the implant (Figure 52-16), laryngeal hemiplegia (LH), and Horner syndrome. Ventral migration was found on postoperative radiographs of 3.5% of patients and tended to occur within the first 7 days after surgery; but there is evidence that the risk of ventral migration is significantly less when the KCC is used.[17] The incidence of laryngeal hemiplegia appears to lessen with experience and has been variously reported in four studies as 1 out of 63,[7] 6 out of 75,[23] 3 out of 72,[24] and 3 out of 58.[9] Other fatal complications recorded include esophageal rupture and laryngospasm.

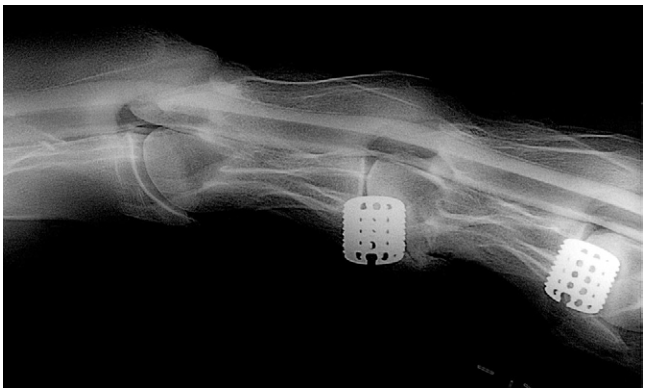

Figure 52-16. Cervical radiograph showing extrusion of the cranial implant, which occurred with a Cloward Bagby Basket implant (same patient as shown in Figure 52-15).

Because the use of the LCP to achieve ventral stabilization has yet to stand the test of clinical experience, the complication rate is unknown. One report of the use of a 9-hole 4.5/5.0 narrow LCP for stabilization of a dynamic stenosis at the C3-4 level demonstrated a serious potential complication.[25] The rostral part of the plate was not in contact with the bone at the completion of the procedure (Figure 52-17, *A*). Several months later the horse showed worsening ataxia; radiographs showed that the rostral plate was now in contact with C3 and the rostral locking head screws had penetrated the spinal cord (Figure 52-17, *B* and *C*). It was presumed that the normal neck movement had gradually forced the plate dorsad and with it the locking head screws. To prevent such complications, accurate contact between the plate and the bone is essential in this procedure.

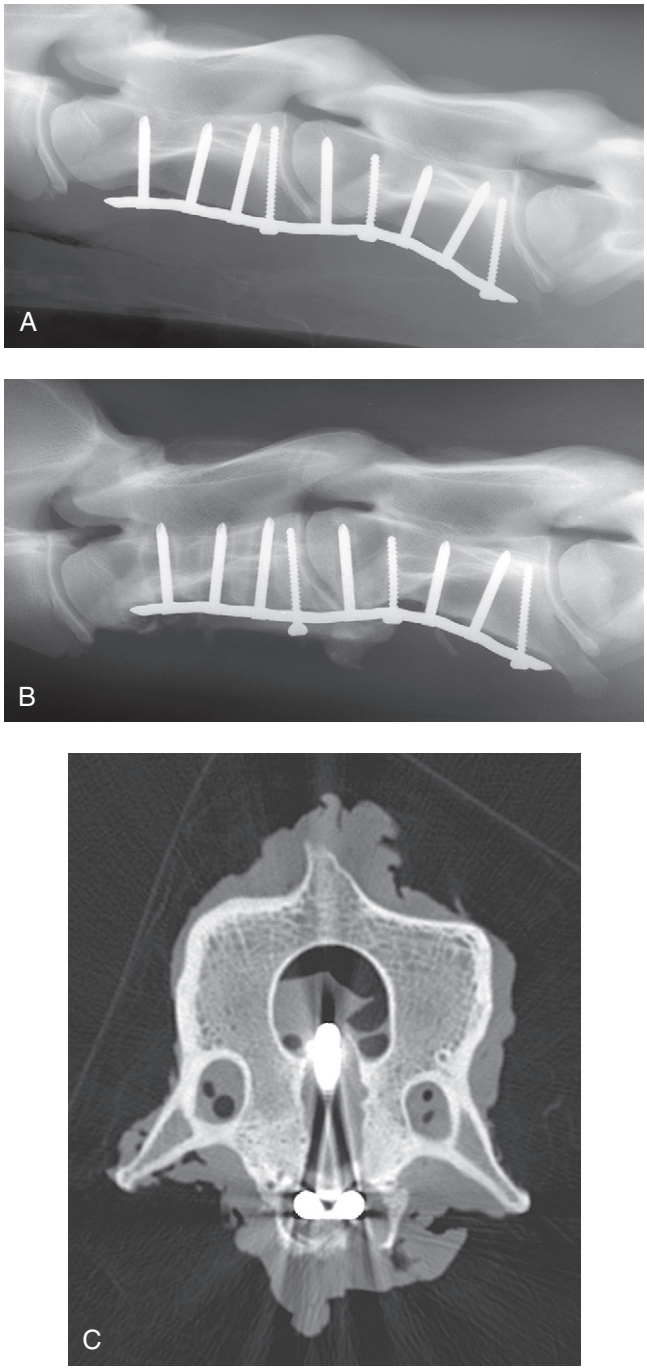

Figure 52-17. A, A 9-hole narrow locking plate was applied to stabilize the two vertebrae in neutral position; note the gap between the rostral aspect of the plate and the vertebra. **B,** A 9-month follow-up radiograph showing penetration of the two most rostral locking head screws into the vertebral canal with traumatization of the spinal cord. The rostral four locking head screws are loose and hold only in the plate hole; a halo can be seen around them. The gap at the rostral end of the plate is closed. **C,** Computed tomography cross-sectional image at the level of the most rostral locking head screw. The screw perforates the vertebral canal and protrudes into the spinal cord. (Courtesy A. Fürst, Zurich, Switzerland.)

Subtotal Dorsal Decompression Laminectomy

Indications

Subtotal dorsal decompression laminectomy, in which the dorsal caudal aspect of the cranial vertebra and the dorsal cranial aspect of the caudal vertebra are removed, is indicated in cases of intramedullary or extramedullary enlargement resulting in cord compression. These include meningeal infiltration of metastatic malignant melanomas, presence of excessive synovial villi from the osteoarthritic facets, and hypertrophic dorsal laminae.[26] Abscesses, parasitic granulomas, and intramedullary neoplasms may also be approached with this method if the diagnosis is reliable (Figure 52-18).

Subtotal dorsal decompression laminectomy is not indicated for the removal of dorsal arches that result from fractures or for the removal of dorsal arches of ankylosed hyperflexed joints that can occur at C2-3. There is even some question as to whether it is indicated for the treatment of a hypertrophic dorsal longitudinal ligament or a disc protrusion into the ventral aspect of the spinal canal.

Surgical Positioning

Once the decision has been made to perform a subtotal dorsal decompression, positioning of the patient is the most important factor contributing to the success or failure of the procedure. A number of surgical positions have been tried, including (1) placing the animal in ventral recumbency with all limbs flexed on a table and extending the head, (2) "hanging" the horse from the vertical surgical table under general anesthesia, and (3) placing the patient in a sling, inducing general anesthesia, and resting the sternum on the operating table. Currently, the third method and a lateral recumbency approach with the neck in full flexion are the most widely used.[27,28] The choice of position usually rests with the surgeon. Only experienced surgeons should attempt this surgery, and cadaver practice is essential before embarking on a clinical case.

Preoperative Preparation

Uneventful induction and recovery is facilitated, especially in younger animals, if 2 or 3 days before surgery the animal can be accustomed to the use of a sling. The usual standard preoperative preventive medicine, including administration of anthelmintic medication and vaccination against upper respiratory infections, is strongly recommended to reduce the incidence of postoperative complications. On the day before surgery the mane is clipped and the animal is given a bath with a medicated shampoo. In addition, scrubbing of the dorsal neck surface with a bacteriostatic detergent is indicated. The perioperative use of NSAIDs and antibiotics is strongly recommended. The use of a depilatory agent 1 or 2 hours before surgery further aids in the removal of small hairs in the many creases of the dorsal aspect of the cervical arch. Some animals show an inflammatory response to the depilatory agents, so the agent should be selected with caution.

Surgical Technique

After the animal is placed in the position favored by the surgeon, a large area on the dorsal surface of the neck extending from T4-5 to C2-3 is disinfected and draped. A long incision (30 to

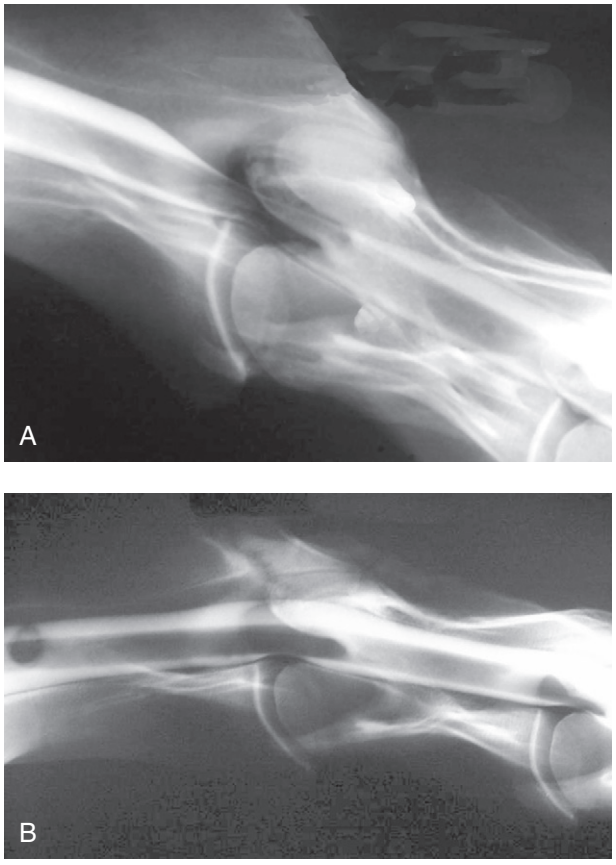

Figure 52-18. A, Myelogram of a 6-year-old Thoroughbred hunter that was falling during competition and was grade 2 (out of 5) ataxic. **B,** A 6-month follow-up myelogram performed after a subtotal dorsal decompression to remove a space-occupying mass later identified as a lymphoma.

40 cm) is made through the thick skin in the dorsal midline. After the initial and often profuse hemorrhage is controlled, the skin edges are draped. Although it is not always necessary, application of the towels and towel clamps helps reduce any further capillary hemorrhage. With a fresh scalpel blade, the subcutaneous tissue and fat overlying the funicular part of the ligamentum nuchae is sharply incised, exposing the dense white fibrous tissue of the ligament. Sometimes three or four small linear incisions are required to find the separation between the lamellar halves of the ligamentum nuchae, but as soon as this division is found the two halves can be separated by blunt manual dissection. The incision needs to be of considerable length because of the depth of the field and the inelastic quality of the ligamentum nuchae. One or two sets of large, self-retaining retractors of the Finochietto or Balfour type facilitate retraction in this area.

At this point it should be possible to palpate the small spinal processes on the dorsal aspect of the vertebra. The location of the dorsal decompression at C6-7 is facilitated by palpating the 3- to 4-cm dorsal spinous process that is often present on the first thoracic vertebra. Radiographic markers (needles) applied before draping in the manner previously described help confirm the proper location. The overlying epaxial muscles and soft tissues are removed from the dorsal arch with the combined use of periosteal elevators, large curettes, and rongeurs. The use of scalpel blades in this area should be avoided because incising the many small blood vessels produces hemorrhage that is often difficult to control, obscures vision, and increases surgical time. After the soft tissue is dissected from the vertebral arches, the white cortical bone is removed using a combination of a Hall drill, cranial drills, and rongeurs.

The original description advocated insertion of Gigli wire between one dorsal foramen and the next foramen. Grant reports that horses with stenotic hypertrophic vertebrae often have no discernible dorsal foramina because of encroachment by the hypertrophic bone, so attempts to pass a Gigli wire as described is not recommended. It is important to remember that the majority of these compressive lesions are the result of proliferation of dorsal bone, which is often much thicker than on normal specimens. Removal of this proliferative bone increases the surgical time, but it is important to be patient and careful. A rapid, forceful puncture through the dorsal arch can result in cord trauma that will exacerbate the already existing neurologic signs. A recommended technique is to identify the remains of any dorsal foramen and work craniad and caudad from this aspect with a Hall or cranial drill. After the inner cortical layer of bone appears, reverse-cutting rongeurs can be used to remove the dorsal arch while protecting the cord. Proliferative or hypertrophic soft tissue arising from osteoarthritic articular facets can be removed with rongeurs and long scissors.

The appearance of epidural fat over the bright, shiny dura indicates that decompression of the spinal cord has been completed. Removal of the bone over the affected site must be adequate, especially on the caudal aspect. If cord compression was caused by a metastatic melanoma, all the discolored tissue should be removed. Following removal of the bone and smoothing with a Hall drill, bone wax is applied to the bleeding edges of bone to reduce the amount of hemorrhage and the risk of clot formation around the spinal cord.

After careful inspection of the surgical site, all sponges and instruments are removed and a drain is secured into the tissues directly overlying the decompression site. The drain should exit through the lateral aspects of the cervical muscles. The drain is secured to the soft tissue surrounding the laminectomy with a 2-0 absorbable suture so that it can be retrieved with gentle traction after 4 to 5 days.

When the self-retaining retractors are removed, the laminar portions of the ligamentum nuchae fall together and need to be apposed only on the most superficial aspect with a continuous Ford interlocking pattern using absorbable monofilament suture material. The funicular portion of the ligamentum nuchae, the subcutaneous tissue, and skin are all apposed using absorbable sutures in a continuous Ford interlocking pattern. Finally, stent bandages are applied to protect the incision from excessive trauma that could occur during a violent recovery. Firmly applying bandages around the entire neck is discouraged because this produces pressure that is directly transmitted to the exposed cord and can result in noticeable discomfort to the patient and increased ataxia.

Postoperative Management and Aftercare

Immediate postoperative management consists of antibiotics for 36 hours or longer, depending on surgical time and the possibility of breaks of aseptic technique during the procedure. Because the procedure destabilizes the dorsal articulation of the vertebrae, fracture is one of the more frequent complications.

The continued use of NSAIDs appears to reduce the chance of a sudden fall, which may cause a fracture. The drain site should be continually bandaged or protected with antiseptic swabs and the drain left in place until there is a noticeable reduction in the amount of fluid obtained, usually 24 to 36 hours postoperatively. Hand-walking and resumption of physical therapy can begin within 10 days; the judgment of the surgeon or neurologist is the most important factor in determining this time.

Subtotal dorsal decompression laminectomy is not widely used because of its degree of difficulty, the amount of surgical time involved, surgical expertise required to perform it efficiently, and the significant incidence of postoperative complications, such as articular facet fractures, compressive hematomas, and suppurative meningitis.[27,29]

CHAPTER 53

Traumatic Disorders of the Spinal Column

James T. Robertson and Valerie F. Samii

Trauma to the vertebral column in horses occurs throughout the cervical and thoracolumbar regions, and the reported incidence varies.[1-3] Vertebral fractures may be present with or without neurologic signs, depending on their location, the portion of the vertebra that sustains the trauma, and the degree and rate of compression of the spinal cord.[4] Confirming a diagnosis of spinal trauma is complicated by the substantial variation in clinical signs. Foals are more susceptible to vertebral fractures than adults, and the cervical vertebrae are more likely to be affected. The most common injuries in foals involve luxations, subluxations, and physeal separations of the cervical vertebrae.[2,3] In adult horses, the injuries tend to involve both the cervical and the thoracolumbar regions.[3,5,6]

Causes of spinal trauma include rearing and falling over backward, collisions with immovable objects, kicks from other horses, hyperflexion or hyperextension of the neck when falling, slipping on wet or muddy footing, and violently sitting backward on the ground or against solid objects.[1-3] Injury to the

spinal cord can occur without radiographic evidence of osseous damage, making the history of possible trauma important for arriving at a diagnosis.

This chapter describes the traumatic spinal injuries that are amenable to surgical correction, although in the horse the number is limited for many reasons. The size of the horse presents unique technical challenges from a diagnostic and surgical standpoint, and it is difficult to maintain vertebral fracture fixation during the anesthetic recovery and rehabilitation period. Innovation is required during the surgical repair to achieve success, and there certainly are not many case reports in the literature from which to draw information when formulating a surgical plan.

TRAUMATIC INJURIES TO THE CERVICAL SPINE

Fractures of the Axial Dens with Atlantoaxial Subluxation

This injury is most commonly seen in foals younger than 6 months, although it can occur in the adult.[3,7-10] The dens or odontoid process originates embryologically from the body of the first cervical vertebra and is attached to the axis by a physis. This physis closes by 8 to 12 months of age. Fracture occurs when a foal falls with the neck in hyperflexion (somersaulting) or when the fall is violent, as in halter-breaking incidents. The fracture most often occurs through the cranial physis of the axis, separating the dens from the body of the vertebrae (Figure 53-1). The dens remains attached by its ligaments to the atlas, and the axis moves ventrally. This results in cord compression at the atlantoaxial joint.

The degree of neurologic deficit depends on the degree and force of the spinal impact at the time of the injury. Neurologic deficits range from a stiff gait and splinted neck to total tetraparesis or even sudden death.[3,7-9] In most cases, the foal becomes ambulatory almost immediately, with signs of neck splinting, ataxia, and tetraparesis developing gradually. Manipulation of the neck produces pain as well as palpable and audible crepitation. There may be an obvious axial malalignment in the atlantoaxial area.[3] Lateral radiographs with the horse under sedation confirm the separation (widening) of the cranial physis of the axis and cranioventral luxation of that vertebra.[3,7-9] If ventrodorsal radiographs can be obtained, asymmetry in the atlantoaxial articulation may be noted.

The prognosis for recovery from this type of injury can be roughly correlated with the severity of the spinal cord damage. If there is motor function of all four limbs, with only paresis rather than paralysis, the prognosis for survival is favorable. If there is paralysis but the foal still shows conscious pain responses in all four limbs, the prognosis is guarded. If there is no conscious pain response, the prognosis is grave.

The method of treatment varies depending on the stability of the fracture and, to some extent, on the intended use of the horse. Nonsurgical management includes stall rest and the judicious use of anti-inflammatory drugs. Worsening of signs may become apparent if the foal falls and further displacement of the axis relative to the atlas results. With time, a fibrous union of the dens to the axis may develop and the neurologic deficits will decrease. However, late-developing neurologic deterioration in a patient that showed initial improvement indicates that a proliferative bony callus or soft tissue hypertrophy is compressing the cord.[3]

Surgical repair is warranted if the foal's clinical signs deteriorate, preferably before the foal becomes recumbent, or if it is a valuable foal intended for athletic competition. Although the prognosis is guarded to poor if the foal is presented in recumbency, it may be improved with surgery. The goal of surgery is to provide decompression at the fracture site by realigning the vertebrae and providing stability with some form of fixation. Surgical techniques for repair of fracture-luxations include external fixation using Steinmann pins, compression plating, ventral atlantoaxial fusion, and dorsal laminectomy of the caudal atlas.[3,7-9]

One report described the placement of two 6-hole, broad dynamic compression plates (DCPs) on the ventral surface of the atlas and axis.[7] The approach and exposure for this technique are the same as those described for ventral interbody fusion (see Chapter 52). After exposing the ventral surfaces of the atlas and axis, the alignment of the vertebrae is corrected and maintained with bone-holding forceps. The ventral spinous processes are removed using rongeurs to create a smooth bed for the two plates. One plate is placed on each side of the midline and anchored using short 4.5-mm cortex screws.

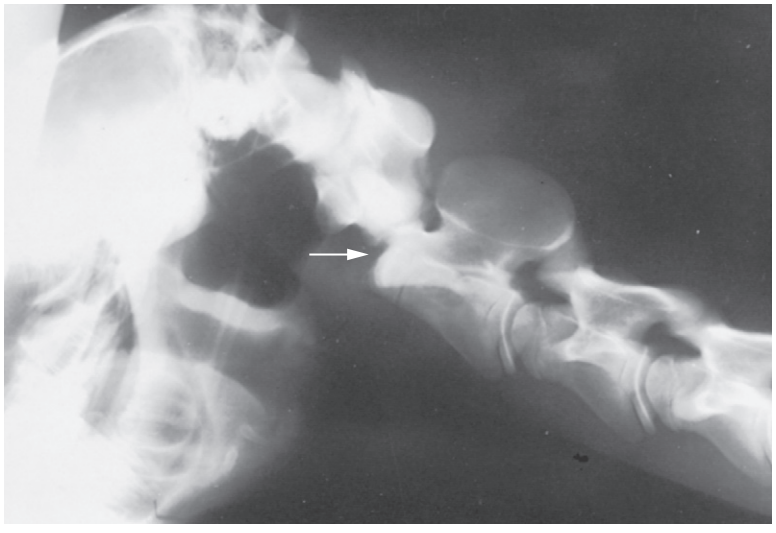

Figure 53-1. Fracture of the dens, which occurs through the cranial physis of C2.

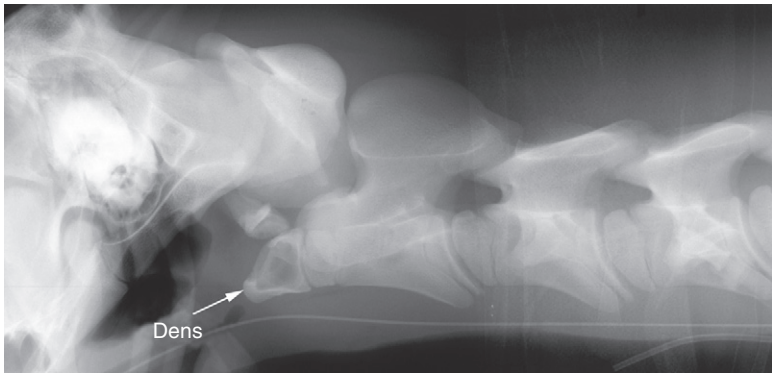

Figure 53-2. Lateral radiograph of the cranial cervical spine in a 1-week-old foal. There is luxation of C2 ventrally, relative to C1. The odontoid process *(dens)* is abnormally angled in a ventral direction. The body of C1 is rotated relative to the caudal cervical spine.

Another report described a ventral stabilization of the atlantoaxial junction by inserting two 6.5-mm cancellous screws across the articulation after removal of cartilage from the articular surfaces. Removal of the fractured dens before stabilization is optional. Care must be taken during drilling of the screw holes in the vertebral arches of the atlas to avoid the spinal canal axially and the vertebral arteries and first cervical nerves abaxially. A bone graft is placed in the articulation to promote fusion, and a polyvinylidine plate is applied to the ventral surface of the atlas and axis to provide additional stability.[3]

In the first of these two reports, ataxia was no longer apparent at 12 months after the surgery and radiography showed fusion of C1 to C2. One complication of surgery was right-sided laryngeal hemiplegia that did not resolve.[7] The author of the second report warns of reduced lateral motion of the cranial portion of the neck after atlantoaxial fusion.[3] Implants need be removed only if there is loosening or lysis of bone.

Various arrangements of Steinmann pins and variations in the application of Kirschner apparatuses in a through-and-through pattern have been reported. Four pins placed through the vertebral bodies of the atlas and axis, anchoring the dens with one pin and securing the pins with plates at the skin surface have been used. Care was taken to avoid the vertebral arteries. The animal recovered completely.[9]

With the introduction of locking plates and screws (see Chapter 76) it is logical that these implants would be preferred in the management of dens fractures. To date, no reports on the use of locking technology in the management of these fractures could be found in the literature.

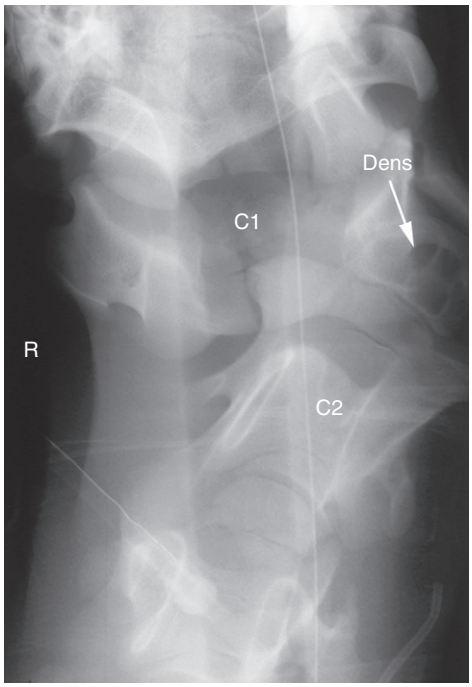

Figure 53-3. Ventrodorsal radiograph of the C1-2 articulation in a 1-week-old foal. There is leftward luxation of C2 relative to C1. The odontoid process *(dens)* is abnormally conformed and contains cystlike cavities.

Atlantoaxial Subluxation and Luxation

Subluxation of the atlantoaxial articulation, without fracture of the dens, is a rare condition seen in young horses up to 3½ years of age.[3,11-13] The condition can be congenital in origin or the result of a traumatic incident. A combination of stretching or tearing of the ligamentous attachments of the dens and the fibrous atlantoaxial joint capsule leads to instability and spinal cord compression that is exacerbated with neck extension and relieved with flexion. The neurologic signs can be acute or chronic, and they vary in severity from mild ataxia to recumbency.[13] The horse may have abnormal head and neck carriage and local swelling if the injury is acute, and it may resent neck manipulation. On plain radiographs, there may be a malalignment of the atlas and axis and, possibly, bony changes of the atlas secondary to trauma. On the extended views, further evidence of subluxation is a lengthening of the space between the articular surfaces of the atlas and the axis ventrally, whereas the space between the dorsal arch of the atlas and the spinous process of the axis is shortened.[3,8] The spinal cord compression is documented with myelography. Computed tomography (CT) scanning of the atlas and axis may help in further defining the nature of the luxation.

Complete luxation of the atlantoaxial articulation resulting in displacement of the dens so that it lies ventral to the atlas is very rare (Figures 53-2 through 53-5). For a complete luxation to develop, there needs to be complete disruption of the ligamentous attachments of the dens. Reportedly, horses with atlantoaxial luxation may have some stiffness of the neck but relatively few neurologic deficits.[3] The diagnosis is confirmed by radiography. With the horse under general anesthesia, efforts can be made to reduce the luxation with head and neck

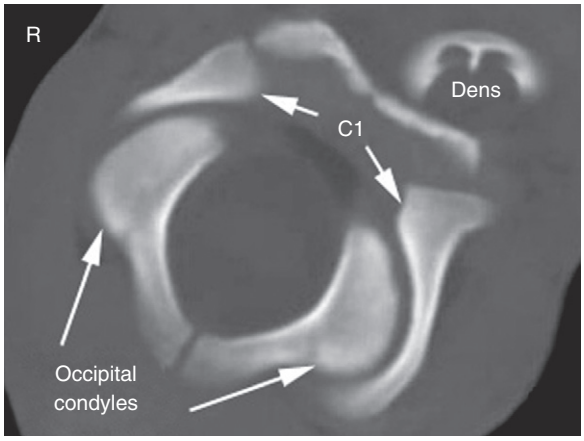

Figure 53-4. Transverse computed tomographic image at the level of the atlantooccipital articulation. The dens is displaced ventral to C1 and to the left, its shape is abnormal, and it contains cystlike cavities.

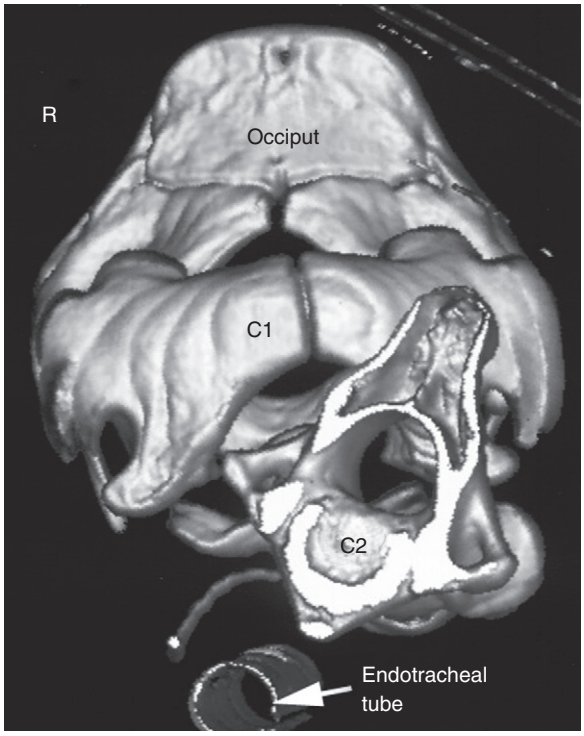

Figure 53-5. Caudodorsal, three-dimensional computed tomographic reconstruction demonstrating the relationship of C2 to C1.

manipulation, but this is likely to be successful only if the injury is acute.[3] In foals, there is also a significant risk of traumatizing the spinal cord during the reduction attempts.

Horses with atlantoaxial subluxation can be successfully treated with subtotal dorsal laminectomy (see "Subtotal Dorsal Decompression Laminectomy," in Chapter 52).[3,13] Surgery is certainly recommended if the horse is showing neurologic deterioration or if neurologic deficits persist despite conservative treatment. Removing the caudal two thirds of the dorsal arch of the atlas relieves the spinal cord compression and allows the range of motion of the atlantoaxial articulation to be maintained. A portion of the dorsal atlantoaxial ligament is left intact. Although the compression may be relieved, persistent instability represents a potential threat for several weeks after surgery. In a report of four horses with atlantoaxial subluxation treated with dorsal laminectomy, two horses recovered completely and a third showed satisfactory improvement. One was lost to follow-up. No surgical treatment has been reported for complete atlantoaxial luxation.

Fractures of the Atlas and the Axis

Fractures involving the atlas and the axis (other than fractures of the dens) occur occasionally. Fractures of the atlas produce neck pain and stiffness, but the degree of ataxia depends on the nature of the fracture and the degree of spinal cord impingement. In some patients, no neurologic deficits are associated with a fracture of the atlas. Standing radiographs, including a dorsoventral view, are used to make a definitive diagnosis. In the foal, the growth plates and their closure times must be taken into consideration when interpreting the films.[14]

Fracture of the ventral arch of the atlas and disruption of the ligaments that secure the dens can lead to the formation of a bony callus that impinges on the vertebral canal and induces ataxia later.[3] Myelography and, if available, CT scanning or an MRI study should subsequently be performed to further document and evaluate the nature of the compression. A dorsal laminectomy of the caudal half to two thirds of the dorsal arch of the atlas can relieve the spinal cord compression created by the fracture callus and may result in a long-term improvement in the neurologic status of the horse.[3] Fractures of the axis (other than those involving the dens) occur, but reports of surgical repair are rare.[2,3] There is a case report of a successful lag screw fixation of an oblique fracture of the body of C2 in a yearling Warmblood stallion that was accomplished with the aid of computed tomography.[15] An additional case report describes the treatment of a horizontal fracture of the body of the axis in a 5-year old French Saddle horse (Selle Français) with the help of a 14-hole DCP in combination with cancellous screws.[16] The horse acquired the fracture during a fall in an international cross-country competition. The partially threaded cancellous screws were used in lag fashion across the fracture and with fully threaded cancellous screws in C3. Part of the intervertebral disc was removed with a 13-mm diameter drill bit. The swath material was reintroduced into the defect. The fracture healed without complications and the horse was subsequently used for pleasure riding.[16] A spectacular vertical fracture occurred in a 7-year-old Swiss Warmblood gelding with history of an acute onset of neck stiffness 3 weeks before admission (Figure 53-6).[17] The owners did not observe a traumatic incident. The horse was anesthetized in sternal recumbency, and by placing a large Steinmann pin into each fragment and applying bone-reduction forceps, the fracture gap could be closed 2 cm. A 7-hole narrow 4.5-mm DCP was applied to the dorsal rim of C2 with three 4.5-mm cortex screws in each fragment (Figure 53-7). The horse made an uneventful recovery from anesthesia and 1 year later returned to athletic competitions.

Cervical Vertebral Fractures (C3 to C7)

Cervical spinal fractures in the adult horse are rare, but of the spinal fractures reported in the horse, approximately 50% involved the cervical vertebrae.[2,5,6,15] Compression fractures of the vertebral body are most frequently diagnosed, followed by

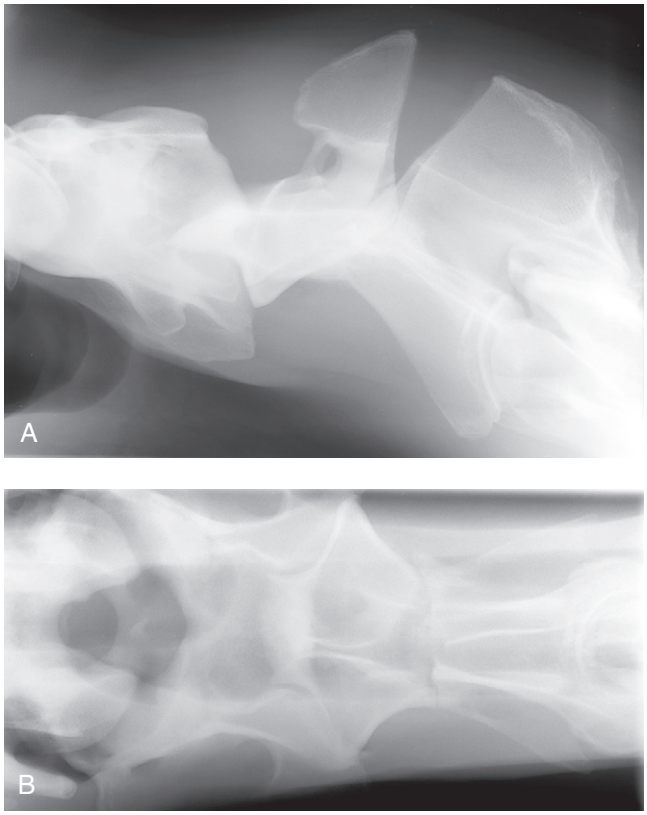

Figure 53-6. Laterolateral **(A)** and dorsoventral **(B)** radiographs of the cranial vertebral column, showing a complete transverse fracture in the cranial third of the axis with a marked deviation of the long axis of the second vertebra at the site of the fracture. (From Gygax D, Fuerst A, Piceck S, et al: Internal fixation of a fractured axis in an adult horse. Vet Surg 40(5):636-640, 2011.)

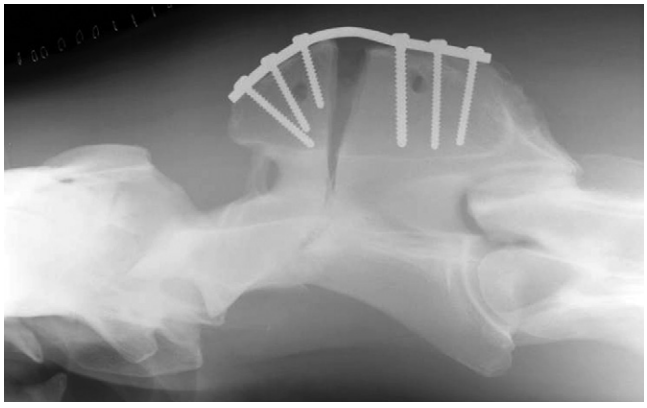

Figure 53-7. Laterolateral radiograph of the axis after fixation of the fracture with a 7-hole 4.5-mm dynamic compression plate (DCP); the hole over the fracture is left empty. Note the nearly normal long axis of the second vertebra when compared with the preoperative radiographs. (From Gygax D, Fuerst A, Piceck S, et al: Internal fixation of a fractured axis in an adult horse. Vet Surg 40(5):636-640, 2011.)

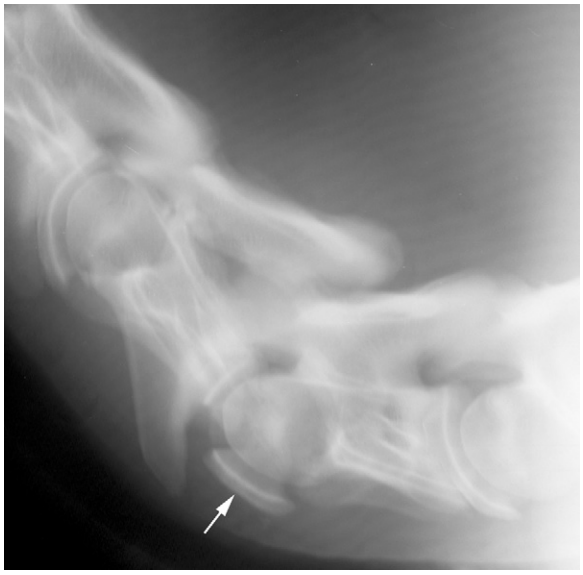

Figure 53-8. Standing lateral radiograph after an acute de-roofing injury at C4-5. The caudal endplate of C4 is fractured and there is fracture-subluxation of the C4-5 articular processes and C4 dorsal lamina, resulting in acute cervical hyperextension at this level. Note that the ventral portion of the caudal epiphysis of C4 remains attached to the C5 vertebra *(arrow).* Motion artifact, secondary to the horse's acute neurologic deficits, is evident on the image. The horse remained standing and subsequently recovered with minimal neurologic deficits.

Figure 53-9. Standing lateral radiograph 40 days after injury. There is periarticular proliferative remodeling at the C4-5 articular processes representing an advanced stage of intervertebral fusion. Proliferative osseous remodeling is also present at the C4 dorsal lamina fracture *(arrows)* summating, and possibly extending into, the vertebral canal. The intervertebral disc space at C4-5 is wedged, and there is static hyperextension of the C4-5 articulation. The fractured ventral portion of the caudal epiphysis of C4 remains attached to the C5 vertebra.

articular process fractures.[2] These injuries result from head-on collisions or falls over jumps or obstacles. Falls in which the neck is severely hyperextended can result in fracture through the ventral half of the caudal end plate of the vertebral body. The ventral portion of the epiphysis remains attached to the caudal vertebra by the strong fibrocartilaginous disc (Figure 53-8). The caudal cervical vertebral body physes in horses are not closed until 4 to 5 years of age, although, practically, the cranial and caudal physes do not separate from the vertebral body in fractures or luxations after the horse is 2 years old.[2,3] If trauma is severe, pedicles of the caudal articular process fracture and elevate, effectively deroofing the spinal canal (Figure 53-9,

and see Figure 53-8). Although the fractures can produce severe angulation of the spine, the neurologic effects are diminished as a result of the deroofing. The dorsal portion of the intervertebral disc that remains intact is quite strong and is capable of providing enough support to maintain stability to the affected joint, despite the deroofing.[4,18]

Cervical vertebral body fractures can also occur after ventral interbody fusion using a Kerf Cut cylinder (KCC), particularly at C5-6 and C6-7.

Clinical signs of cervical vertebral fracture depend on the degree of bony disruption, instability at the fracture site, and the severity of the trauma to the cord. If the fracture is displaced and the spinal cord is compressed, neurologic signs vary from mild ataxia to quadriplegia and, in some cases, sudden death.[2] Because of damage to the central portion of the spinal cord with trauma, the innervation to the forelimbs is severely affected. When compression involves dorsal nerve roots, pain and torticollis are the principal signs. Sympathetic dysfunction, exhibited by Horner syndrome and skin hyperthermia, may be present.

The diagnosis of cervical vertebral fracture is confirmed by radiography. However, in thick-necked horses, even if they are positioned in lateral recumbency, it can be very difficult to get diagnostic radiographs in cases with only minimal disruption of the fracture fragments or with a great deal of swelling in the neck. Fracture lines may be poorly visualized. If the horse is standing, every effort should be made to get diagnostic standing radiographs. This allows a diagnosis without subjecting the horse to anesthesia and subsequent recovery, which may displace the fracture fragments, causing more damage to the spinal cord. In a recent case report, a number of imaging modalities including standard radiography, ultrasonography, nuclear scintigraphy, and fluoroscopy using a novel C-arm were used to diagnose a cervical articular process fracture of 3 weeks' duration in a standing horse.[19] If the horse is already recumbent, or there is progressive neurologic deterioration despite aggressive medical therapy, the horse can be anesthetized to obtain the radiographs. High-quality radiographs, including oblique and ventrodorsal views, and CT scans are necessary to gain an appreciation for the fracture configuration, particularly of vertebral body fractures where there can be multiple fracture lines and minimal displacement. The more distal portion of the neck (C5 to C7) in a large horse may not be accessible by the portal of the CT scanner because of size. If more than one vertebra is fractured, a myelogram may be useful to determine the site or sites of spinal cord compression. When the fracture is amenable to some form of fixation, the surgeon must be prepared to immediately follow the radiographic studies with the surgical repair. The risk of further spinal cord damage is too great if the horse is allowed to recover and undergo repair at a later date.

If the horse remains standing and is not showing progressive deterioration, conservative treatment is preferred. Some horses with pedicle fracture(s) experience further neurologic deterioration, with the formation of a healing callus that impinges on the dorsolateral aspect of the spinal canal causing cord compression (Figures 53-10 and 53-11).[3] Horses with an articular facet fracture can also develop torticollis that becomes permanent as a result of vertebral malalignment. There is a report of coaptation cast application used successfully to immobilize noncomminuted proximal cervical vertebral fractures in foals.[20] These types of casts can be difficult to apply properly and safely.

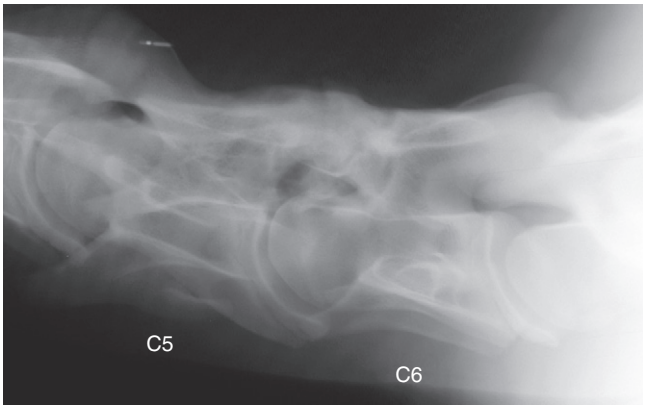

Figure 53-10. Standing oblique lateral radiograph of the C5-6 articulation in a yearling. There is severe proliferative remodeling of the articular processes at C5-6. Lateralization of the observed remodeling could not be determined radiographically.

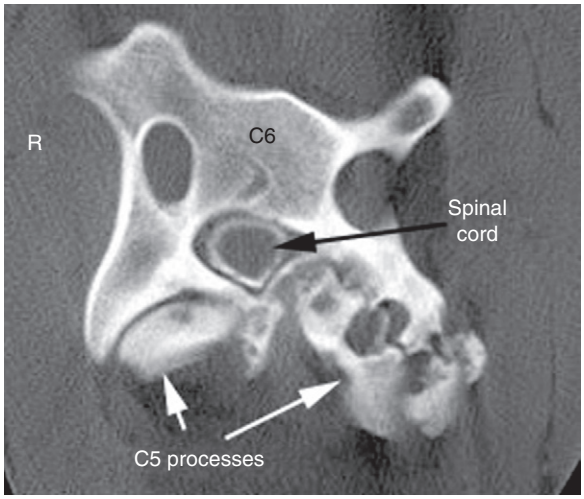

Figure 53-11. Transverse computed tomographic image through the cranial aspect of C6 after myelography. Severe degenerative remodeling and subchondral cystic change of the articular processes of C5-6 is seen on the left. Mild remodeling and subchondral cystic change is also seen at the axial aspect of the C5-6 articulation on the right. The spinal cord is outlined by a contrast-filled subarachnoid space. Note the left-sided, dorsal compression of the spinal cord secondary to the articular process remodeling.

Another problem that can be encountered in horses with cervical fracture and luxation that are managed conservatively is a subsequent worsening of neurologic signs after fusion of the affected intervertebral articulation, a result of the domino effect.[4] Spinal cord compression occurs at intervertebral sites adjacent to the fusion as a result of chronic malalignment and instability. An experienced author suggests that this domino effect occurs more frequently after injury-induced vertebral fusion (no surgery) than after surgical fusion for treatment of cervical vertebral malformation.[4] This should be kept in mind when deciding whether to attempt surgical repair. Successful realignment and stabilization of the affected vertebrae would likely prevent this from occurring.

If enough intact bone exists in the vertebral body to allow secure implant fixation, some types of recent fractures can be

realigned and stabilized with screws or with plate and screw fixation, possibly in combination with ventral intervertebral stabilization.[3] Each case needs to be considered on its own merits with regard to the type of fixation required for a successful repair. The greater the disruption of the vertebrae at the affected site(s), particularly if there is axial instability in conjunction with angular deviation in the sagittal plane, the poorer the prognosis. Intraoperative radiographic control of the drilling depth and screw positioning is critical to prevent penetration of the vertebral canal. It is difficult to get a secure screw purchase in vertebral bone, particularly in foals. There is a report of a successful repair of a cranial articular process and lateral neural arch fracture of C4 using a combination of an intervertebral fusion procedure followed by the ventral application of a broad DCP that spanned the bodies of C3 and C4.[3] In another report a 14-hole DCP was applied ventrally to a horizontal body fracture of C3 with articular involvement.[21] The plate was applied with 10 fully threaded and 3 partially threaded cancellous screws. Seven screws were implanted into C3 and six into C4, and the C4 joint was bridged.[21] A locking compression plate (LCP) can be used in lieu of the DCP for ventral application, without the use of a KCC. In a recent pilot study using the cervical spines of cadavers, the LCP construct was shown to have mechanical properties similar to the KCC fixation.[22] An advantage of the LCP over the DCP for ventral fusion is that the plate does not have to be applied tightly to the bone along the length of the plate, and therefore less bone from the ventral spine needs to be removed in preparation for plate application. An additional advantage is that the head of the locking screw is fixed in the plate and does not move, which results in superior stability. Also, no luting with methyl methacrylate is required to achieve plate contact, as is usually necessary with a DCP (Figures 53-12 and 53-13).

The prognosis for recovery from any form of surgical repair is related directly to the severity of the initial neurologic deficits and the long-term stability of the repair.[3] In horses that have pedicle fractures that develop exuberant bony callus impinging on the spinal canal or the lateral foramen, signs of spinal cord compression or nerve root impingement may develop. One author suggests that surgical intervention is indicated, in the form of either a dorsal laminectomy or a ventral stabilization.[3] Removal of the dorsal lamina and reduction of the bony callus at the compressed site produces immediate decompression, but the procedure is difficult and tedious, and there is a risk of refracture of the affected pedicle and worsening of the neurologic signs as a result of surgical trauma. Ventral intervertebral fusion leads to reduction in the size of the articular facets and the bony callus over a 3-month period after surgery.[3] Although there is not an immediate decompression, as achieved with dorsal laminectomy, there is much less risk associated with the surgery.

TRAUMATIC INJURIES TO THE THORACOLUMBAR SPINE

Thoracolumbar vertebral injuries are more common in adult horses than in foals.[5] Horses that engage in jumping activities are most often affected with life-threatening vertebral fractures.[5,23] The incidence of these types of lesions cannot be accurately assessed because some fractures are never identified. Stress fractures of the caudal portion of the thoracic and lumbar vertebrae in racehorses may go undetected as well.[24] Fracture of the thoracic dorsal spinal processes is often associated with the horse rearing, falling backward, and striking the withers. In a report of 22 cases of thoracolumbar vertebral fractures, 15 involved the vertebral body or neural arch and produced severe neurologic signs that necessitated euthanasia. The remaining seven horses had fractures of the dorsal spinous processes and exhibited no neurologic signs.[23] The more common sites of fracture of vertebral bodies include the first three thoracic vertebrae, around T12 (the area of greatest lateral bending and axial rotation), and the lumbar vertebrae.[25] Dorsal spinous process fractures tend to occur at or near T6. In a foal, a thoracic vertebral body fracture occurred at T11 after an electric shock.[26] Abscess formation in the vertebral body as a result of septicemia in foals can predispose to fracture.

Figure 53-12. A lateral radiograph of a weanling Thoroughbred filly with fractures and angular deviation at C4-5. The filly was originally seen and radiographed 8 days before this examination. In the intervening time, she had deteriorated neurologically and the luxation angle had increased. Surgical repair was recommended. (Courtesy Drs. S. Reed, A. Ruggles, and B. Woodie, Rood and Riddle Equine Hospital, Lexington, KY.)

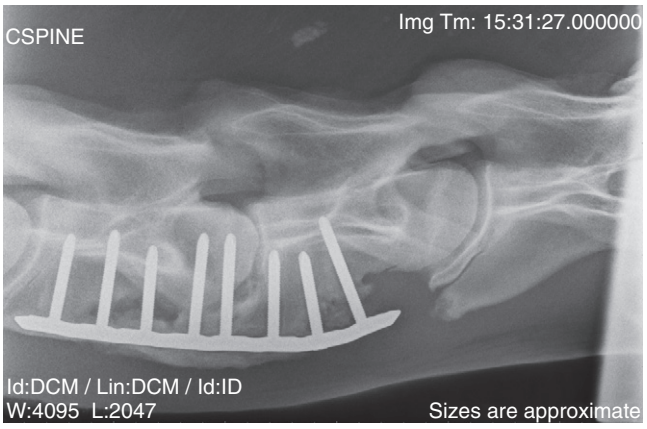

Figure 53-13. At surgery, vertebral realignment and fracture stabilization at C4-5 was achieved with a ventrally applied 8-hole, broad locking compression plate (LCP). Eight 5-mm diameter locking head screws were used, with the longest being 40 mm. This radiograph, taken 4 months after surgery, shows that the fixation has remained stable and vertebral alignment has been maintained. A substantial quantity of new bone formation had developed at the ventral aspect of C4-5 that will lead to bony fusion. (Courtesy Drs. S. Reed, A. Ruggles, and B. Woodie, Rood and Riddle Equine Hospital, Lexington, KY; Dr. Bob Hunt, Hagyard Equine Medical Institute, Lexington, KY.)

The clinical signs associated with a thoracolumbar vertebral fracture depend on the portion of the vertebra that is fractured and the degree of bony disruption. Severe compressive fracture of the vertebral body may result in paraplegia if the fragments displace, in delayed onset of paraplegia if the fragments do not displace immediately but with time through continued movement, and, finally, in no paraplegia if displacement remains minimal. Only the group with little or no displacement of fragments has a chance of total recovery with conservative management.

The diagnosis of a thoracolumbar vertebral body fracture in an adult horse is complicated by the fact that radiography of this area is generally unrewarding because of the massive musculature around the vertebrae. The clinician must often rely on the physical examination and neuroanatomic localization of the lesion to make a presumptive diagnosis. In the horse with a healing fracture, scintigraphy may be useful for localizing the affected vertebra. In foals, CT scanning can be used to assess the thoracolumbar spine, and myelography is used to document the extent of the spinal cord compression—information that is necessary for determining the length of decompression required if a dorsal laminectomy is being considered.[3]

Thoracolumbar laminectomy and fracture stabilization has been described in the foal and should be attempted only if the foal has evidence of deep pain recognition or some voluntary movement of the hind limbs.[3] A dorsal laminectomy of the affected area is performed with the foal in sternal recumbency. Steinmann pins are placed into the adjacent vertebral bodies, the vertebrae are manipulated into alignment, and polyvinylidine plates are applied to the dorsal spinous processes. Polymethyl methacrylate is used to connect the pins and produce rigid fixation. The plates and pin fixation are removed after 3 to 6 months. The author stated that the prognosis for foals with thoracolumbar fractures is generally grave, although surgical treatment may improve the outcome in selected cases.[3] Adult horses that are recumbent and have severe neurologic signs as a result of thoracolumbar spinal fracture are euthanized. In those horses where the signs are limited to back pain and rear limb incoordination, conservative management can be successful.[23]

The diagnosis of fracture of the dorsal spinous processes of thoracic vertebrae is not difficult. The height of the spine is decreased, because the most proximal aspect of the spine fractures and moves laterally. The area becomes swollen and painful to the touch. Radiographs are helpful in confirming fractures of the dorsal spines and the extent of the damage (Figure 53-14). Contrast fistulography is useful in horses with a draining tract to document communication with a dorsal spinous process.[27]

Fractures of the dorsal spine usually do not require surgery unless the bone fragments become sequestered or their position, after fracture, precludes the use of a saddle. A defect in the withers area may necessitate a special saddle pad. If surgery is required or elected, subtotal ostectomy of the dorsal spinous processes can be performed under general anesthesia or in the standing horse.[27-29]

If the procedure is performed under general anesthesia, the horse is placed in lateral recumbency with the displaced processes uppermost. A long, slightly curved incision is centered over the fragments. The incision extends through the skin, the subcutis, and the supraspinous ligament. Bone fragments are identified and removed by freeing them from underlying muscle and ligamentous attachments. If the bone has sequestered or if infection is present, appropriate exits are created to facilitate gravitational drainage. The area will heal enough to resume riding after 8 to 12 weeks; however, special saddle pads may need to be used to prevent abrasion by the saddle.

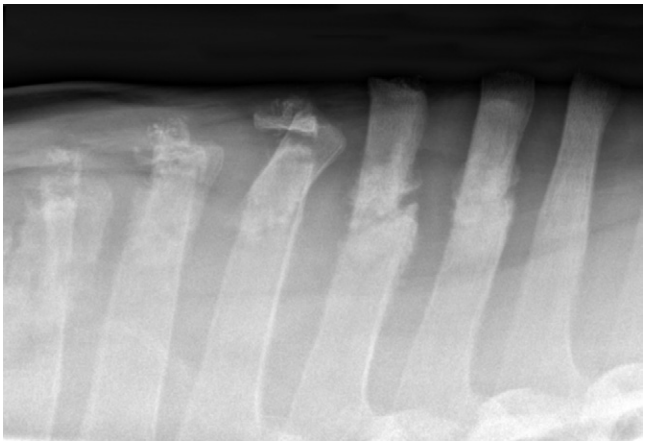

Figure 53-14. Lateromedial radiographic view of an 8-year old Arabian stallion suffering from six fractures of the thoracic dorsal spinous processes (Courtesy J. Auer, Zurich, Switzerland.)

If the procedure is done standing, the risks of general anesthesia are eliminated. In addition, there are other distinct advantages to performing the procedure standing, which include reduced hemorrhage, improved visibility, and better access to both sides of the dorsal spinous process(es), all of which facilitate dissection and separation of the muscular attachments. In a report of nine horses treated standing, thoracic spinous processes were resected for treatment of osteomyelitis, fracture, and impingement. The sites of involvement ranged from T2 to T18 in these horses.[27] With the horse sedated, the tissues surrounding the affected dorsal spinous processes are infiltrated with a local anesthetic. The surgical approach to the affected dorsal spinous process(es) is longitudinal and along the midline. The affected portion of the dorsal spinous process is dissected free, and it is resected using either an oscillating saw or an osteotome.

Endoscopic surgical subtotal resection of the dorsal spinous processes and interspinous ligament has been described.[30] Ten horses were treated for dorsal spinous process impingement in the caudal thoracic region and most were back to work by 8 weeks after this minimally invasive procedure. This technique allows the selective removal of the impinging bone on the spinal process, but it is unlikely that it could be effectively used in a horse with a fractured spinous process, particularly if there is a good deal of fibrosis or the bone is infected. Intraoperative hemorrhage greatly reduces the endoscopic visibility and complicates the procedure.

Fistulous draining tracts from an infected supraspinous bursa necessitate more extensive resection and débridement of infected tissues, including the affected nuchal ligament, the supraspinous bursa, and all infected bone of affected dorsal spinous processes. The supraspinous bursa lies between the funicular part of the nuchal ligament and the dorsal spinous processes of T2 to T5.[29] In one report of surgical treatment of supraspinous bursitis in 10 horses, paramedian incisions, either unilateral or bilateral depending on involvement, were made approximately 8 to 10 cm lateral to the dorsal midline and

dorsal to the scapula. The incisions were 15 to 20 cm in length, dorsal to the scapula, and started 5 cm cranial to the scapula. Ventral drainage was achieved by placing a large gauze seton drain between the ventral edge of the rhomboideus muscle and the dorsoscapular ligament, cranial to the scapula. The authors of that report stressed that the dorsoscapular ligament should not be penetrated. The procedure can be performed with the horse standing or under general anesthesia. There is a significant recurrence rate after surgical treatment of fistulous withers, and multiple surgeries may be required.[30,31] Because of the historical connection between fistulous withers and *Brucella abortus* (Bang disease), and the risk to humans, horses should be serologically tested before surgical treatment is undertaken.

Internal fixation of spinous process fractures with plates and screws has been performed, but the procedure carries the risk of longer time under anesthesia and a difficult recovery from anesthesia.[32]

TRAUMATIC INJURIES TO THE SACRAL SPINE

Trauma to the sacral area occurs when the horse suddenly dog-sits or falls over backward, landing on the croup area.[33] Subluxation where the sacrum articulates with the iliac crests causes chronic pain that may originate with one traumatic event or may be caused by repetitive jarring of the spine in this area during work. Compressive lesions of the sacrum involve the cauda equina with loss of function to the sacral and caudal nerve roots and the pudendal, caudal, and parasympathetic pelvic nerves that originate from these nerve roots.[34] The resultant clinical signs include pain and swelling over the croup and tail head, tail weakness or paralysis, decreased anal tone, retention of feces, bladder distention, and urine dribbling. There may be analgesia of the tail, anus, and perineal region and of the surface of the penis in males. Scintigraphy may be useful for initially localizing an injury to the sacrum. The diagnosis of a sacral compressive lesion is based on the clinical signs, palpation of the sacral area *per rectum*, pelvic ultrasonography, radiography, and, if the horse is small enough, CT scanning.[3,35] A positive contrast epidurogram may show compression in the sacrum.[36] More-extensive injuries that involve the caudal lumbar and sacral regions can produce marked hind limb weakness, ataxia, and neurogenic muscle atrophy of the hindquarters. This may be documented by electromyography and muscle biopsy.

Acute injury should be treated with anti-inflammatory drugs, and up to 10 days should be allowed for signs of recovery. During this time, evacuation of the rectum several times daily and topical treatment of the tail and perineal region to prevent scalding is part of the required management. If there is no improvement within 10 days, the prognosis is unfavorable for recovery, and either surgical intervention or euthanasia should be considered. Surgical decompression of the sacrum can be achieved by removing the spinous processes and dorsal laminae of the sacral vertebrae. Even with surgery, the prognosis is guarded. In acute cases, stabilization after decompression is necessary and can be accomplished by using plates and screws.[3] In foals where stabilization was accomplished using long plates attached to dorsal spinous processes, the plates must be removed within months of the repair to prevent development of lordosis in the lumbosacral region.[3] A recent report discussed the use of LCP fixation in three heifers suffering from fracture of the sacrum, with good results in restoring tail motility and defecation and allowing normal calving.[37]

Robertson examined a 6-week-old foal that had a compressive spinal lesion at L6 and S1 as a result of trauma at birth. The foal underwent a dorsal decompression of L6 and S1 and there was some improvement in clinical signs after surgery. A follow-up CT scan 4 months after surgery showed good decompression at the dorsal laminectomy site, but stenosis of several of the nerve root canals probably contributed to the ongoing muscle weakness. Five years after surgery, the horse had residual ataxia and muscle weakness but had learned to adapt remarkably well as a nonathletic companion animal. In horses with persistent tail paralysis, the tail may need to be amputated.[35]

TRAUMATIC INJURIES TO THE COCCYGEAL VERTEBRAE

Horses have an average of 18 coccygeal vertebrae. Trauma to the more distal vertebrae may well go unnoticed. Coccygeal fractures generally occur as a result of the horse falling back onto the tail or backing into an immovable object. Other causes of tail injury include entrapment in a door, bite wounds by other animals, and improperly placed tail wraps. If the tail distal to the site of trauma loses its blood supply, necrosis occurs, requiring amputation.

Trauma to the base of the tail (Ccy 1 to 3) may cause vertebral fracture, soft tissue injury, and neurapraxia of the motor nerves in this area. In most horses, the fractures are closed, but the fracture may be comminuted with displacement of the fracture fragments.[38] The nerve injury can result in an inability to move the tail and defecate properly. Urine (in females) and fecal scalds can develop. Muscle atrophy over the tail head is consistent with neurogenic atrophy. Manipulation of the tail produces pain, and there is palpable crepitus at the tail base. Distal to the lesion there is loss of motor function. Lateral or oblique lateral radiographs confirm the presence of a vertebral fracture. Nuclear scintigraphy may be useful for identifying concurrent bony trauma, such as a sacral fracture.

Most horses with fractures of the coccygeal vertebrae are managed conservatively with stall rest and the use of anti-inflammatory drugs. The fractures can be relatively slow to heal, and there may be permanent neurologic damage as well as conformational changes as a result of the muscle atrophy and callus formation.[38] In one report of a comminuted fracture of the first coccygeal vertebra with ventral displacement of the remaining coccygeal vertebrae, the fractures were stabilized using a combination of bone plates, wire, and bone cement. The implants were removed 4 months later with the fracture site being stable and pain free.[36] Other forms of stabilization or fixation, such as the placement of Steinmann pins across the fracture or the use of the pinless external fixator (see Chapters 76 and 102), might also hasten healing and reduce the irritation to nerves in the area, thereby allowing a quicker return of tail function.

CHAPTER
54 Peripheral Nerve Injury

Robert J. MacKay

ETIOLOGY AND PATHOGENESIS

Mechanical injuries to peripheral nerves occur because of compression, entrapment, transection, laceration, ischemia, crushing, stretching, and chemical or burn damage.[1,2] These injuries are usually categorized according to the degree of damage to a single axon. However, compound nerves contain numerous fascicles, and each fascicle is made up of many axons within a connective tissue sheath. The functional effect of damage is seldom as straightforward as single-fiber classifications would suggest, and it usually reflects differing degrees of damage across a nerve.

Damage to individual axons fall into two major functional categories. Type 1 injury refers to loss of function *without loss of axonal continuity*. Type 2 injury represents damage to axonal structures such that *Wallerian degeneration of the axon ensues* distal to the site of injury; the proximal axonal segment and the cell body remain intact. Retrograde degeneration of the proximal nerve occurs if connectivity is not reestablished. A well-accepted classification system that divides the spectrum of injury into five categories is shown in Figure 54-1.[3]

Type 1 or *neurapractic lesions* are characterized by a failure of conduction of the action potential across the injured axonal segment.[4] Normal muscle action potentials are evoked by stimulation of the nerve anywhere distal to the lesion, but they are absent when the nerve is stimulated proximal to the injury. The pathologic basis for these *reversible* injuries could be nerve compression, damage to the myelin sheath, or alteration of the functions of the axonal cell membrane or its channel proteins.

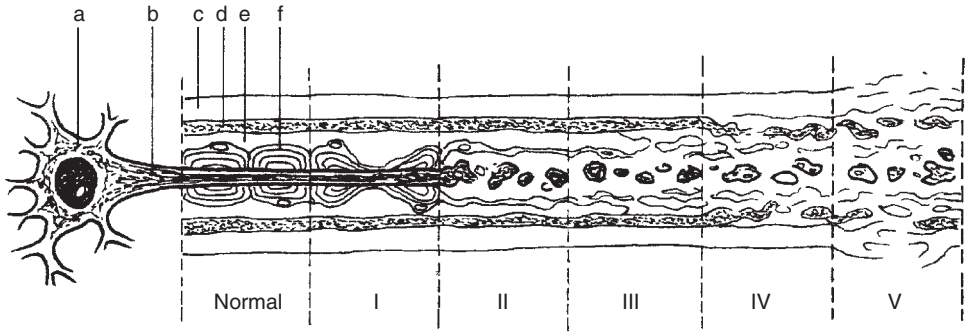

Figure 54-1. Sunderland classification of nerve injury. *a,* Cell body; *b,* axon; *c,* epineurium; *d,* perineurium; *e,* endoneurium; *f,* myelin sheath; *I,* first degree (neurapraxia); *II,* second degree (axonotmesis); *III,* third degree; *IV,* fourth degree; *V,* fifth degree.

Type 2 injuries are characterized by axonal interruption, or *axonotmesis*. This is equivalent to the Sunderland type II injury. If there is disruption of components of the connective tissue sheath and axon, the process is termed *neurotmesis*. According to the Sunderland classification system, there are three grades of neurotmesis (III, IV, and V), reflecting disruption of endoneurium, perineurium, and epineurium. Recovery by axonal regrowth is unlikely after neurotmesis.[5] Immediately after axonotmetic injury, the distal axonal segment is competent to conduct action potentials; however, within 3 to 8 days after injury, the distal segment degenerates and no longer responds to electrical stimulation. In this way, neurapractic (type 1) and axonotmetic (type 2) injuries of greater than 8 days' duration can be theoretically distinguished. Long-standing axonotmetic injuries result in retrograde degeneration of the neuronal cell body and secondary demyelination of the proximal axonal segment. After axonotmesis of motor nerves, muscle reinnervation occurs by two separate mechanisms: collateral sprouting and axonal regrowth.[1] If there is incomplete loss of axons to a muscle, surviving motor axons generate sprouts from their nerve terminals, which can establish competent junctions with adjacent denervated muscle units. Reinnervation of muscle units by this process occurs within days to weeks. However, if the motor axons to a muscle are severed, reinnervation occurs by growth of collateral sprouts from the proximal stump. Axonal sprouts grow at a rate of 1 mm per day (approximately 1 inch per month). Regeneration occurs under the influence of growth factors including neurotrophic growth factor, brain-derived neurotrophic factor, and ciliary neurotrophic factor.[6] Successful reinnervation thus may take many months. Because of progressive fibrous replacement of denervated muscle and retrograde degeneration of the proximal parts of affected motor neurons, it has been suggested that reinnervation may not be possible if more than 12 months have elapsed since the original injury. However, reinnervation surgery has been successful when performed on human patients 20 years or more after denervation.[7]

Large-diameter myelinated fibers are most sensitive to compression forces. The largest axons—sensory axons, including afferent fibers conveying touch-pressure, vibration, and proprioception—are usually damaged first (resulting in ataxia or inappropriate limb placement). The second group to be compromised are the large myelinated motor axons; and the smaller axons, which carry cutaneous and deep mechanoreceptor sensory information, are affected third. The last to be lost are the smallest diameter fibers transmitting pain sensation.

CLINICAL SIGNS

Peripheral nerve injuries are characterized by weakness of the innervated muscle, accompanied within 2 to 4 weeks by appreciable atrophy. When the injured nerve supplies important extensor muscles of the limbs (e.g., as is the case with radial, femoral, sciatic, or peroneal nerve injuries), there is obvious alteration of gait. Areas of cutaneous anesthesia occasionally accompany peripheral nerve injuries. Over the neck and trunk, cutaneous sensory innervation occurs in defined bands corresponding to the territories of the sensory nerves associated with segmental dermatomes. Damage to a peripheral spinal nerve or dorsal nerve root results in cutaneous anesthesia or hypalgesia over the supplied dermatome. With damage to the pudendal nerve or its sacral nerve roots, there is anesthesia or hypalgesia of the perineal area. In contrast, relatively small autonomous zones have been defined for sensory components of the ulnar, musculocutaneous, median, femoral, tibial, and peroneal nerves (Figure 54-2).[8,9] Sympathetic fibers are distributed with peripheral nerves, so denervated skin also may be evident as circumscribed spontaneous sweating. Rarely, pain or other unpleasant sensation (dysesthesia) is a sign of traumatic nerve injury. Neuropathic pain is characterized by exaggerated responses to modest stimuli like pinpricks (hyperalgesia) or painful responses to normally innocuous stimuli such as light touch (allodynia). *Complex regional pain syndrome* is the name given to a neuropathic pain disorder associated with the development of autonomic features, such as changes in skin temperature, color, and sweating and structural changes in soft tissues in and around the nerve's territory. A suspected complex regional pain disorder has been described in horses.[10] Neuropathic pain disorders in horses usually manifest as hypersensitivity to touch or attempted mutilation of a target area over the territory of the affected nerve.

The most common and important syndromes of mechanical injury to peripheral nerves of the limbs are described later.[9,11,12]

Suprascapular Nerve

The suprascapular nerve arises from the 6th and 7th cervical spinal cord nerve roots and passes laterad and ventrad between the supraspinatus and subscapularis muscles before coursing around the cranial edge of the scapula about 7 cm proximal to the scapular tuberosity and ramifying in the supraspinous and infraspinous fossae.

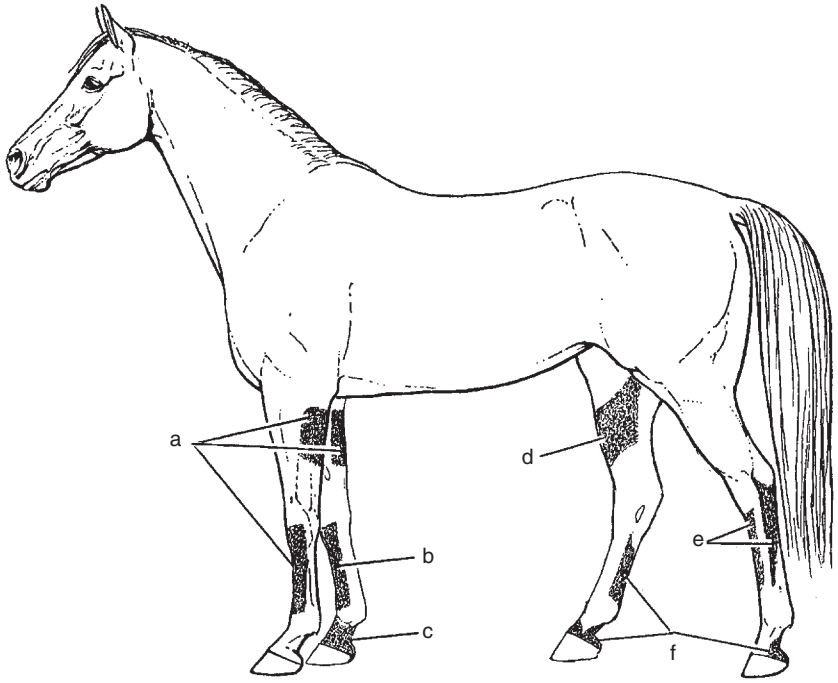

Figure 54-2. Areas of anesthesia/hypalgesia (autonomous zones) associated with injury to the major peripheral nerves of the limbs of the horse. *a,* Ulnar n. dermatomes; *b,* musculocutaneous n. dermatome; *c,* median n. dermatome; *d,* femoral n. dermatome; *e,* peroneal n. dermatomes; *f,* tibial n. dermatomes.

Suprascapular nerve injury occurs most commonly when a horse collides at speed with another horse or with inanimate objects, such as fences, trees, or doorways. It may also occur when a galloping horse stumbles over uneven ground. In each of these situations, there is likely to be stretching or direct compression (or both) of the suprascapular nerve as it curls around the cranial edge of the neck of the scapula under cover of the supraspinatus muscle. The muscles innervated by the suprascapular nerve, the supraspinatus and infraspinatus, normally provide lateral support for the shoulder joint. Consequently, when the nerve is injured, the immediate response is laxity and lateral instability of the shoulder joint, which bows out or "pops" as the affected limb bears weight. Although subluxation of the shoulder joint does occur after the suprascapular nerve is blocked at the scapular neck, it has been suggested that other nerves (e.g., axillary, pectoral, subscapular, brachial plexus roots) and muscles (e.g., pectoral, subclavius, subscapularis) are usually damaged with this type of injury, thus contributing to shoulder instability and subluxation.[11]

Within 2 to 4 weeks of injury, there is obvious atrophy of the supraspinatus and infraspinatus muscles. Wasting of these muscles becomes complete over the ensuing several months. The condition is known as *sweeney.*

Neurapractic damage to the suprascapular nerve should heal within several days to several weeks. After partial nerve damage, sprouts from the neuromuscular terminals of surviving fibers should find denervated muscle and restore function within several weeks. In either of these settings (neurapraxia or partial nerve damage), severe muscle atrophy should not occur before recovery begins. More complete axonal injury results in sweeney, and any recovery depends on regrowth of axonal sprouts from the proximal stump of the suprascapular nerve. Successful reinnervation is evident as recovery of muscle bulk in the ventral part of the supraspinatus muscle beginning within 3 months of injury. Maximal recovery takes an additional 3 to 12 months. Regrowth of the suprascapular nerve can be facilitated by surgery to resect scar tissue (external neurolysis) and reduce tension on the nerve as it crosses the cranial edge of the scapula (see Chapter 96).[13,14] The surgery can be performed either preemptively when soft tissue swelling has subsided or 3 to 6 months after injury when it is clear that spontaneous reinnervation is not occurring.

Radial Nerve

The radial nerve innervates a flexor of the shoulder and the extensors of the elbow, carpal, and digital joints. It arises chiefly from the first thoracic root of the brachial plexus. The nerve travels for a short distance with the ulnar nerve as it passes between the long and medial heads of the triceps. From there, it winds downward and outward around the humerus in the musculospiral groove, crosses the lateral aspect of the elbow joint, and ramifies in the extensor muscles of the digit.

The proximal portion of the nerve is well protected by surrounding muscles and therefore is not normally damaged unless there is severe injury to adjacent tissues. The T1 nerve root may be lacerated by fracture of the C7 or T1 vertebra or the first rib, or it may be compressed by remodeled arthritic intervertebral joints. Likewise, the proximal part of the nerve is commonly damaged as a result of humeral fracture.[15] The radial nerve (or the roots that form it) may be injured with other components of the brachial plexus by trauma to the shoulder region. The plexus or radial nerve, or both, is injured when the thoracic limb is severely hyperextended or abducted, such as, for example, when the upper leg gets wedged (e.g., in a tub or between the rails of a fence) and the horse struggles to release it. Injury may also occur during forceful traction of the forelimbs of a fetus during relief of dystocia. The radial nerve and triceps muscles are vulnerable to damage when horses are positioned in lateral recumbency, usually under general anesthesia. The risk is particularly high in large, muscular horses on poorly padded surfaces, and it increases with the duration of the procedure. Experimental studies have shown that ½ to 1 hour of ischemia produces neurapractic conduction failure, and greater

than 3 hours of ischemia causes permanent changes.[16] The lower part of the nerve is in close proximity to the lateral aspect of the elbow, under cover of the lateral head of the triceps, and it may be damaged by direct trauma to this site (usually by a kick from another horse) or by dislocation or fractures that involve the elbow.

Horses with complete radial paralysis stand with the shoulder extended and the rest of the joints flexed. The elbow is "dropped" (i.e., lower than normal) and the dorsum of the hoof rests on the ground. When forced to walk, the horse may partially protract the limb by exaggerated extension of the shoulder; however, the toe drags and the horse collapses on the limb during the weight-bearing phase of the stride. If the site of damage is distal to the branches to the heads of the triceps (middle third of the humerus), the shoulder is held in normal position and the elbow is not usually dropped. Such horses can bear weight if the hoof is placed flat on the ground. If reflexes can be tested while the horse is recumbent, it is expected that the triceps reflex will be absent but the flexor (withdrawal) reflex will be normal. Although the radial nerve has numerous cutaneous sensory branches, injury to this nerve does not result in any consistent area of cutaneous anesthesia.

Beginning at 2 to 4 weeks, there is progressive atrophy of the extensor muscles of the limb distal to the site of injury. The principles just described for neurapractic and axonotmetic injuries apply. With regrowth of axonal sprouts from the proximal stump of the radial nerve, the triceps muscle is expected to recover function before the digital extensors.

Musculocutaneous Nerve

The musculocutaneous nerve arises near the suprascapular nerve from the part of the brachial plexus supplied by the 7th and 8th cervical roots. It descends on the medial surface of the coracobrachialis muscle and forms a loop with the median nerve directly beneath the brachial artery before terminating in branches to the biceps brachii, pectoral, and brachialis muscles. The musculocutaneous nerve supplies flexors of the elbow.

Injury to the nerve is rare and causes only transient toe-dragging. The shoulder may be held in a flexed position and the elbow in an extended position. The diagnosis can be made by finding hypalgesia or anesthesia over the dorsomedial aspect of the carpal region and proximal metacarpus (see Figure 54-2), beginning immediately after the injury and by appreciating obvious atrophy of the biceps and brachialis muscles beginning 2 to 4 weeks after injury. Injury to the musculocutaneous nerve eliminates the biceps reflex, although this reflex is difficult to obtain even in normal horses. The flexor reflex should be intact, although elbow flexion may be weak.

Median and Ulnar Nerves

The *median nerve* is the largest branch of the brachial plexus and receives input from the 8th cervical and first thoracic nerves. After exchanging fibers with the musculocutaneous nerve, it descends along the medial aspect of the leg in association with major arteries and terminates in palmar and cutaneous branches. The *ulnar nerve* arises from the thoracic part of the brachial plexus, passes downward and backward over the medial epicondyle of the humerus (deep to the medial head of the triceps), and passes along the palmar aspect of the metacarpus under cover of the digital flexors to terminate in branches that contribute to the lateral palmar nerve and cutaneous sensation. These nerves supply muscles that extend the elbow and flex the carpus and digits.

Injury to either or both nerves can be caused by injury at the brachial plexus or along the medial aspect of the upper limb. Experimental section of the nerves causes a "tin soldier" gait, with decreased flexion and dragging of the toe during the protraction phase of the stride. Hypalgesia or analgesia of the skin develops over the caudal forearm, lateral metacarpus, and medial phalangeal areas. When flexor reflexes are tested by pinching the skin of an area with unimpaired sensation (e.g., over the lateral metacarpophalangeal [MCP] joint), there is an intact flexor response, but it is weak compared with the normal side. Even without recovery of nerve function, interference with gait at the walk decreases over time and is minimal by 3 months after the injury. The reason for this adaptation is unclear, although it has been suggested that fibers contributed by the musculocutaneous nerve may take over some of the functions from the median nerve. Atrophy of the carpal and digital flexor muscles is apparent after 2 to 4 weeks.

Femoral Nerve

The femoral nerve arises principally from the 4th and 5th lumbar nerve roots, with contributions also from the 3rd and 6th roots, courses backward and ventrad between the psoas major and minor muscles, and then runs between the sartorius and iliopsoas muscles lateral to the external iliac artery. It terminates as branches to the heads of the quadriceps muscle. The saphenous nerve, a branch with both motor and sensory function, joins the femoral nerve at the point of emergence from the psoas muscles. The femoral nerve innervates muscles that flex the hip and extend the stifle.

The nerve courses too deeply to be directly affected by an external blow to the pelvic limb; however, it can be damaged by ilial, femoral, or vertebral fractures. Ischemic injury caused by prolonged stretch or increased tissue pressure during anesthesia in dorsal recumbency may cause bilateral femoral neurapraxia.[17] A similar presentation, presumably caused by compression of nerve roots by the foal in the birth canal, is seen in mares after severe prolonged dystocia.

With unilateral paralysis of the femoral nerve, the pelvic limb adopts a flexed posture, usually with the foot flat on the ground. When the horse tries to bear weight, the limb buckles. During walking, there is obvious lameness, with a relatively brief and ineffectual weight-bearing phase over the affected limb. This can be quite subtle in horses with partial femoral nerve paralysis. In the case of bilateral involvement, the horse is either unable to rise or gets to its feet with difficulty, and then stands briefly and uncomfortably in a crouched position.

If the nerve injury occurs proximal to the saphenous branch, there is anesthesia or hypalgesia of the skin over the medial surface of the thigh (see Figure 54-2). Atrophy of the quadriceps muscle is evident within 2 to 4 weeks. The flexor reflex should be normal, but the patella reflex is weak or absent.

Sciatic Nerve

The sciatic nerve is the largest nerve in the body. It is derived principally from the 6th lumbar and 1st sacral nerves but also receives a branch from the 5th lumbar nerve. The nerve passes

caudad and ventrad on the sacrosciatic ligament before turning between the greater trochanter and tuber ischii. It courses ventrad in the thigh between the biceps femoris muscle laterally and the adductor, semimembranosus, and semitendinosus muscles medially. It continues as the tibial and peroneal nerves. The sciatic nerve supplies important extensors of the hip and flexors of the stifle.

Sciatic nerve damage is usually a result of deep injections into the caudal thigh ventral to the greater trochanter. Such injections may injure the nerve by direct laceration, by injection of material into the nerve, or through secondary inflammation or compression from scarring induced by previous deposition of the drug close to the nerve.[1] In most cases, the neurologic deficits are apparent within a few minutes. A delayed onset suggests the development of perineural or endoneural inflammation or fibrosis. The nerve may also be injured by fractures of the ilium or ischium or by sacroiliac and coxofemoral dislocations.

The posture of the affected limb is characteristic: it is held slightly caudal with the dorsum of the hoof resting on the ground. The stifle and tarsus are more extended than normal, whereas the distal joints are flexed. During walking, the leg is dragged forward by the actions of the quadriceps and biceps femoris muscles. These muscles, in concert with the reciprocal apparatus, allow the horse to bear some weight on the limb if the foot is first placed in normal position.

There is cutaneous hypalgesia or anesthesia over most of the limb except for the medial thigh. If the flexor reflex is tested by pinching the skin over the medial thigh, the response is intact but weak compared with the normal side.

Peroneal Nerve

The peroneal nerve arises from the sciatic trunk deep to the biceps femoris and descends on the lateral head of the gastrocnemius muscle. It crosses the lateral aspect of the femorotibial joint and terminates in superficial and deep branches, which course ventrally between the long and lateral digital extensors. The nerve provides motor innervation to the flexors of the tarsus and the extensors of the digit.

Paralysis results in extension of the tarsus and flexion of the distal joints of the pelvic limb. At rest, the limb is held slightly caudally, with the distal joints in flexed position and the dorsum of the hoof contacting the ground. During walking, the limb is moved erratically. The toe is dragged along the ground during the weak protraction phase and then pulled caudad as the horse attempts to bear weight. As is the case with sciatic involvement, the limb can support weight if the foot is placed in normal position.

There is progressive atrophy of the cranial tibial muscle and long and lateral digital extensors and immediate cutaneous hypalgesia or anesthesia over the lateral metatarsus. The flexor reflex is intact and usually appears normal.

Tibial Nerve

The tibial nerve represents the direct continuation of the sciatic nerve. It runs between the bellies of the gastrocnemius muscle and passes distad on the medial aspect of the leg immediately dorsal to the superficial flexor tendon before terminating in the medial and lateral plantar nerves. The tibial nerve innervates the gastrocnemius muscle (extensor of the tarsus) and digital flexors.

With tibial neuropathy, the resting limb is held more flexed than is normal, and although the foot contacts the ground in normal position, the MCP joint often partially collapses into a flexed position (i.e., "knuckles"). The foot is moved in stringhalt-like fashion, with exaggerated flexion of the tarsus and stifle during protraction, followed by sudden extension to the weight-bearing phase of the stride.

There is atrophy of the gastrocnemius muscle and cutaneous hypalgesia or anesthesia of the caudal metatarsal region and bulbs of the heels. The flexor reflex is tested by pinching the skin over the dorsal aspect of the metacarpophalangeal joint (MCP) joint. The reflex is present but weaker than on the normal side.

DIAGNOSIS

The diagnosis of peripheral nerve injuries is normally made by careful observation of clinical signs, including testing of reflexes and cutaneous sensation. It may not be possible to discern the effects of nerve damage until fractures are stabilized and soft tissue swelling subsides. The examination must carefully document the location and severity of weakness, atrophy, and sensory and reflex alterations. The findings should be documented thoroughly and recorded at each examination so that progression can be determined.

Beginning 2 to 4 weeks after injury, progressive atrophy becomes apparent in large muscles supplied by the damaged nerve. Beginning about 2 weeks after injury, the distribution of muscular denervation can be determined objectively by needle electromyography in the sedated or anesthetized patient. This is particularly helpful in cases of apparent suprascapular or radial neuropathy to determine whether there is singular involvement of a particular peripheral nerve or injury at the level of the brachial plexus.

Nerve stimulation can be used to assess location, severity, and recovery from nerve injury. With both neurapraxia and axonotmesis, nerve conduction across the lesion is affected. Thus, when the proximal segment of the motor nerve is stimulated electrically, the amplitude of the evoked muscle action potential is reduced in proportion to the severity of the injury. It is technically possible to distinguish signs of neurapraxia from those that are the result of physical interruption of the axons of the nerve. Because axonal injury leads to degeneration of the distal nerve segment, electrical stimulation of the nerve distal to the injury site fails to evoke motor action potentials, or they are of reduced amplitude, when tested at least 9 days after the injury.[1] In contrast, nerves blocked by neurapraxia evoke normal muscle responses after stimulation. It must be remembered that an injured nerve frequently has a mixture of neurapractic and axonotmetic lesions, and the findings may not clearly distinguish between the two types of injury. Sensory nerve conduction studies are performed in humans by electrically stimulating peripheral sensory axons at one point and recording sensory nerve action potentials at a more proximal point. This technique is useful for distinguishing lesions of the dorsal root from those involving peripheral parts of the nerve.

Nerve conduction procedures are not well established in the horse, but "proof-of-principle" studies have been published for selected nerves in normal horses.[8,18-20] High-resolution ultrasonography or magnetic resonance imaging may be used to help pinpoint the location of peripheral nerves and aid in precise stimulation and recording.[21]

MANAGEMENT

Nonsurgical Management

The objectives of medical treatment of peripheral nerve injury are (1) reduction of swelling and inflammation at the site of injury, (2) support and stabilization of the denervated area, and (3) maintenance of the general health of the animal.

In the case of lacerating trauma, the general principles of wound management apply. The wound should be cleaned, irrigated, débrided, and dressed and ventral drainage established. If severed nerve ends are visible, they can be tagged for later identification. Medical therapy for inflammation and swelling should be initiated, especially if there is obvious tissue swelling. This may include any combination of a cyclooxygenase inhibitor (e.g., flunixin meglumine, 1.1 mg/kg IV, IM, or PO once or twice daily), dimethyl sulfoxide (DMSO) (1 g/kg as a 10% solution IV or by nasogastric tube once or twice daily), and a glucocorticoid (e.g., dexamethasone, 0.05 mg/kg IV or IM once daily, or 0.1 mg/kg PO once daily). An additional anti-inflammatory effect can be provided by cold water hydrotherapy or local application of skin-permeant drugs such as DMSO or diclofenac. In the presence of an open wound or other risk for bacterial infection, broad-spectrum antimicrobial therapy should be initiated. This can be directed by culture results, if available.

Fractured or dislocated bones that have the potential to further injure nerves must be reduced and stabilized. Stall rest is essential to prevent further injury. In the case of paralyzed limbs, a protective wrap may be necessary to prevent damage caused by dragging or improperly placing the limb. A support wrap, splint, or light cast should be maintained on a leg affected with radial paralysis so as to prevent limb contracture. A heavy support wrap, possibly with additional fetlock support, should also be placed on the opposite limb to protect against breakdown caused by prolonged increased weight bearing. If the horse has difficulty alternating between recumbency and standing, it should be supported as necessary in an abdominal sling until it is able to rise unassisted. The newly developed Enduro-N.E.S.T. system (NASA equine support technology) (Figure 54-3), although restricted to referral facilities and rehabilitation centers, will obviate many of the problems associated with conventional slings and allow long-term support of valuable patients with multiple-limb or severe single-limb motor neuropathies. Because of the buoyancy provided by water, horses may be able to exercise affected limbs in swimming pools. Skin over bony prominences should be padded to prevent decubital injury; such injuries must be treated aggressively if they occur.

In foals, passive range-of-motion exercises should be performed on paralyzed limbs in an attempt to preserve joint flexibility and prevent contracture. Faradic or galvanic electrical muscle stimulation has been advocated for denervated muscles to help preserve muscle mass, and units designed for use in horses are available. This practice is controversial, however, and may possibly delay nerve regrowth into muscle.[22] Hyperbaric oxygen is an approved adjunctive treatment for acute traumatic ischemic reperfusion injury of humans and theoretically could help horses with postrecumbency neuropathies.

Surgical Management

Because neurosurgery in horses is at a rudimentary stage, it is difficult to provide precise rules for assessment and intervention after mechanical nerve injury. The following guidelines are based on comparable situations in human medicine.[1,2]

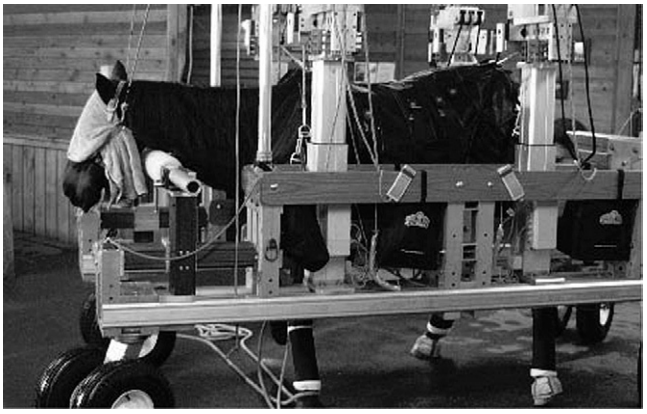

Figure 54-3. Fully anesthetized horse standing in the Enduro-N.E.S.T. sling system. Monoplegic and multiplegic horses can be safely supported indefinitely in this apparatus. The unit safely transduces friction energy to heat and can balance weight individually for each limb.

- In clean lacerating injuries in which the nerve ends are visible or when clinical examination reveals obvious motor and sensory deficits resulting from the injury at the laceration, primary repair may be indicated. In general, results of primary repair (within 3 to 4 days) are better than results of secondary repair (after 2 to 3 weeks).
- In nerve transections resulting from blunt lacerating trauma, secondary repair has a better neurologic result. This allows time for control of infection and resolution of soft tissue swelling.
- Injuries that do not demonstrate evidence of early spontaneous recovery should be explored surgically. This applies especially to traumatic injury of the suprascapular nerve or injection injury of the sciatic nerve. Empirically, the outer time limit for exploration can be estimated from the observations that muscle must be reinnervated within 12 months and that nerve regrows at the rate of 1 inch per month. According to these precepts, the length in inches from the injury site to the muscle supplied plus the time in months since the injury should not exceed 12. For example, if the peroneal nerve is injured 6 inches from its entry into the anterior tibial muscle, no more than 6 months should be allowed for spontaneous recovery of innervation.

Anastomosis

If the nerve is ruptured or severed, the retracted ends should be identified.[23] With the help of an operating microscope, the damaged portions of the nerve should be trimmed and the proximal and distal stumps aligned as accurately as possible by epineurial repair. Coaptation is achieved by simple-interrupted epineurial sutures (8-0 to 10-0 monofilament nylon or silk) around the circumference of the anastomosis. A perfect superficial alignment can be achieved using epineurial vessels as landmarks, but the internal orientation of fascicular bundles and individual fascicles may not be correct (Figure 54-4). The more technically difficult fascicular repair technique involves aligning and attaching individual fascicular groups. Epineurial tissue is resected from around the circumference of the nerve,

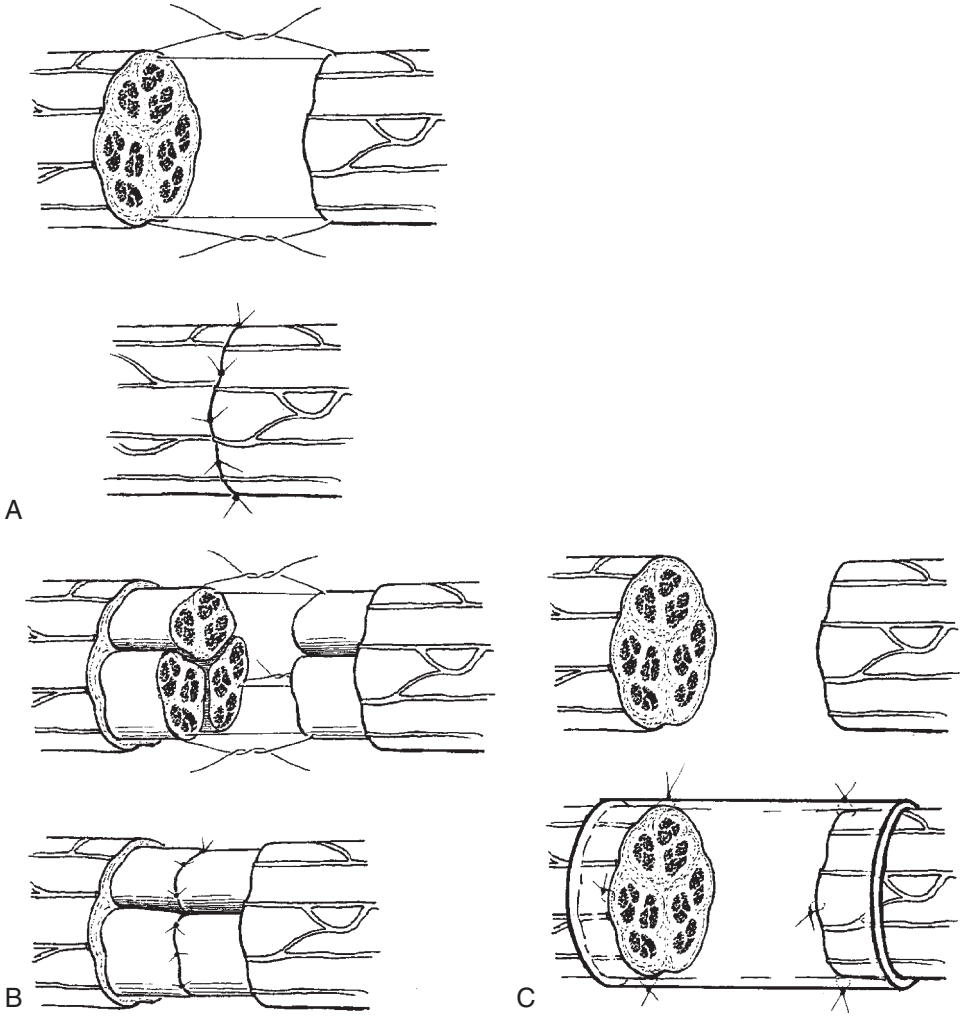

Figure 54-4. End-to-end repair of peripheral nerves. **A,** Epineural suture. Coaptation is achieved by single sutures in the epineurium around the circumference of the nerve. **B,** Group fascicular suture. Epineural tissue has been resected, and fascicular groups are coapted with single sutures in the perineurium or connective tissue surrounding groups of fascicles. **C,** Tubular repair. (Modified from Lundborg GA: 25-year perspective of peripheral nerve surgery: Evolving neuroscientific concepts and clinical significance. J Hand Surg Am 25:391, 2000.)

and fascicular groups are subsequently coapted with single sutures in the perineurium or connective tissue surrounding groups of fascicles. Nonsuture methods have been described and include wrapping the nerve, gluing the ends together with plasma clot or fibrin glue, or using a carbon dioxide laser to weld the nerve ends together.[24]

Tension at the anastomosis site must be minimized by mobilization of the nerve ends and postoperative rest and immobilization of the affected limb. If the gap between the ends is too large to permit anastomosis without tension, a conduit technique may be considered, wherein the defect is bridged in such a way as to support axonal growth toward the distal nerve segment. For this purpose, either a tube or a graft is used. Silicone tubes, freeze-thawed muscle tubes, and collagen-based nerve gap conduits have been used. Nerve autografts from a remote donor site (e.g., sural nerve) could also be used for bridging a long nerve gap. In nerve injuries in which the proximal segment cannot be used for grafting, the distal segment theoretically can be implanted in end-to-side fashion into an epineural window on an adjacent uninjured nerve. Similarly, the technique of direct neurotization of muscle has been validated experimentally in settings where nerve has been traumatically avulsed from muscle. A similar technique has been used in horses with left laryngeal hemiplegia. In this technique, a narrow strip of muscle with an intact nerve supply (the neuromuscular pedicle graft) is removed from the omohyoid muscle and inserted into the paralyzed dorsal cricoarytenoid muscle (see Chapter 45).[25] Over the subsequent months, the dorsal cricoarytenoid muscle becomes reinnervated and is stimulated to contract during exercise.

After surgical exploration of a nonregenerating nerve, the damaged section can be removed and the ends anastomosed using one of the techniques described earlier.

Neurolysis

External neurolysis refers to the dissection of the nerve from a bed of scar tissue.[1] This is indicated if there is obvious compression from fibrous tissue, and it is performed routinely in horses with suprascapular neuropathy (see Chapter 96).[13] Internal neurolysis involves an incision of the epineurium and resection of scar tissue from between nerve fascicles.

COMPLICATIONS

In response to trophic factors produced at the site of nerve injury, misdirected axonal sprouting and Schwann cell proliferation may produce bulblike neuromas, either at the proximal stump of a transected nerve (end-neuroma) or within a partially disrupted nerve (neuroma-in-continuity).[26] End-neuromas are a common complication of palmar digital neurectomy in horses treated this way for navicular syndrome (see Chapter 90).[27,28] Neuroma-in-continuity or fibrous entrapment at the site of injury or surgical repair is associated with a variety of pain syndromes in humans. On the basis of the documented painful local effect of neuromas after palmar digital neurectomy, it is likely that similar syndromes occur in some "nerved" horses. Neuropathic pain cannot be effectively controlled medically. Partial control may be achieved with nonsteroidal anti-inflammatory drugs, narcotic analgesics (morphine, butorphanol), antiepileptic analgesics (carbamazepine, gabapentin), or the tricyclic antidepressant imipramine.

In attempts to reduce neuroma formation in nerved horses, the proximal stumps of sectioned nerves have been exposed to CO_2 laser energy, injected with doxorubicin, heat-coagulated, entubulated with or without silicone, sealed with tissue adhesive or epineural caps, or anchored into the medulla of adjacent bone.[29] The most effective way to avoid postoperative nerve regeneration and associated clinical signs is reported to be guillotine transection of nerves under tension and removal of up to 10 cm of the nerve.[29]

In addition to permanent degenerative changes in muscle, fibrous replacement and contracture may result in reduced range of motion and permanent flexion of involved joints. Such an outcome is particularly likely after radial paralysis in the horse. Proper management by placement in a sling, prolonged stall rest, orthotic support, and passive range-of-motion exercises may help prevent such an outcome. Studies on the use of electrical stimulation of muscles have indicated that the function of denervated muscle can be preserved only if use-specific stimulation paradigms are developed.[22] Previous evidence suggested that electrical stimulation may reduce nerve regrowth into denervated muscle.

PROGNOSIS

With suprascapular neuropathy secondary to confirmed or suspected shoulder trauma, restoration of shoulder stability occurred within 3 to 12 months in seven out of eight horses treated only with stall rest.[30] Atrophy of the infraspinatus and supraspinatus muscles resolved in only two of these horses. Although there is no comparative study to show any additional effect of procedures to relieve entrapment of the suprascapular nerve, it is expected that these procedures should improve recovery of muscle mass.[13,14] Data for outcome of radial nerve neuropathy are not published; however, it is reasonable to assume that the prognosis for complete recovery from signs of radial paralysis induced by positioning in lateral recumbency, soft tissue trauma, and humeral fracture is good (greater than 80%), fair, and poor, respectively. Injection-associated neuropathy (usually sciatic) usually resolves in days.

It is reported that approximately 70% of end-to-end nerve repairs and 50% of graft repairs performed in humans achieve good functional results.[2]

John A. Stick

CHAPTER
55 Surgery of the Globe and Orbit

Kenneth E. Pierce Jr. and Wendy M. Townsend

ANATOMY AND PHYSIOLOGY

The orbits are bony cavities that protect the eye and its associated muscles, blood vessels, and nerves.[1] Because of the myriad structures within and surrounding the orbit, one must clearly understand orbital anatomy to effectively diagnose and treat orbital disease. The equine orbit measures 62 mm in width, 59 mm in height, and 98 mm in depth.[1] The globe itself is 48 mm in width, 47 mm in height, and 44 mm in depth (Table 55-1).[1] The axes of the eyes and orbits are directed laterally 80 degrees off the midline, creating a panoramic field of vision.[1,2]

In horses, the orbital rim is a complete bony perimeter composed of the frontal bone dorsally, the lacrimal bone medially, and the zygomatic bone ventrally. The lateral border is formed by three fused bones—the descending zygomatic process of the frontal bone, the ascending frontal process of the zygomatic bone, and the zygomatic process of the temporal bone (Figure 55-1).[1] The supraorbital foramen, containing the supraorbital vessels and nerve, is located dorsolaterally within the zygomatic process of the frontal bone.[1-4] Along the medial rim of the orbit, the lacrimal sac is positioned within the lacrimal fossa, an indentation in the lacrimal bone.[2,5] The nasolacrimal duct then courses from the lacrimal sac through the lacrimal bone. Therefore, fractures or neoplasia involving the lacrimal bone can disrupt normal tear flow.

Caudal to the orbital rim, the lacrimal, sphenoid, and palatine bones form the medial orbital wall. The zygomatic arch forms the anterior aspect of the orbital floor. Periorbital fascia, orbital fat, and the pterygoid muscle form the remainder of the orbital floor. Multiple vessels and nerves course rostrad along the orbital floor to the pterygopalatine fossa rostroventrally. The fossa contains three foramina. The maxillary vessels and nerve pass through the maxillary foramen into the infraorbital canal. The sphenopalatine vessels and caudal nasal nerve pass through the sphenopalatine foramen toward the nasal cavity. The major palatine artery and nerve pass through the caudal palatine foramen to the palatine canal.[1,2] Therefore caution is required during surgical manipulations involving the orbital floor because of the potential for extensive hemorrhage and nerve damage.

The orbital apex contains four major foramina. The most dorsal is the ethmoidal foramen, through which the ethmoidal artery, vein, and nerve pass. Ventral and slightly caudal lies the optic foramen, through which the optic nerve and internal ophthalmic artery pass. The optic nerve (cranial nerve [CN] II) then travels within the extraocular muscle cone to insert on the globe.[2,3] The oculomotor (CN III), trochlear (CN IV), ophthalmic branch of the trigeminal (CN V), and abducens (CN VI) nerves pass through the orbital fissure, which lies ventral to the optic foramen. The oculomotor nerve innervates the levator

*Extraocular muscle scleral insertion values are from references 2 (values in parentheses) and 3.

palpebrae superioris muscle; dorsal, medial, and ventral rectus muscles; and the ventral oblique muscle. It also provides parasympathetic innervation to the iris sphincter muscle.[2,3,6] The trochlear nerve (CN IV) innervates the dorsal oblique muscle.[2,3] The ophthalmic branch of the trigeminal nerve (CN V) provides sensation to the cornea, conjunctiva, and dorsal eyelid. The abducens nerve (CN VI) innervates the retractor bulbi and lateral rectus muscles. Caudoventral to the orbital fissure lies the rostral alar foramen through which the maxillary artery and nerve pass.[1,2,4,7] The majority of the orbital blood supply is provided by the external ophthalmic artery, a branch of the maxillary artery.[2,3,8]

The orbit contains the extraocular muscles responsible for globe movement. The scleral insertions and innervation of the extraocular muscles are listed in Table 55-2.[2,9] The dorsal, ventral, medial, and lateral rectus muscles originate from the orbital wall medial to the orbital fissure and move the eye as their names suggest.[2] The superior oblique muscle originates from the medial orbital wall, courses rostrad to pass through a trochlea at the medial canthus, and inserts on the dorsolateral sclera. The superior oblique rotates the dorsal aspect of the globe ventrad and mediad. The inferior oblique muscle originates from a shallow fossa close to the lacrimal canal, courses temporad, and inserts inferiorly adjacent to the insertion of the lateral rectus muscle. The inferior oblique muscle rotates the globe superiorly and mediad.[2] The retractor bulbi muscle, as the name indicates, retracts the globe. It originates from the orbital apex and inserts at the globe's equator.

A thin, tough connective tissue envelope (the orbital fascia) is also located within the orbit, which supports the globe, maintains anatomic relationships, and allows precise and coordinated globe movements.[1,3] The orbital fascia is divided into the periorbita, extraocular muscle fascia, and episcleral fascia (Tenon's capsule).[1-3] The periosteum that lines the orbital bones, optic foramen, and orbital foramen contributes to the periorbita and is continuous with the dural sheath of the optic nerve.[1,2,4] A portion of the periorbita separates from the periosteum and extends anteriorly to form the orbital septum, which merges with the tarsal plate at the eyelids.[1,2] The episcleral fascia, or Tenon's capsule, is the connective tissue layer between the bulbar conjunctiva and the sclera. Tenon's capsule is firmly adhered to the sclera at the limbus and extends to blend with the fascia of the extraocular muscles.[1-4] Orbital fat within and external to the extraocular muscle cone cushions the globe and fills dead space.

The lacrimal gland is situated within the periorbita dorsolateral to the globe and encased by orbital fat. The secretions form the aqueous phase of the tear film and are released into the dorsolateral conjunctival fornix via 12 to 16 ducts.[2,3] Caution should be used when incising the dorsolateral conjunctiva to ensure that the ducts are preserved and therefore tear flow is not jeopardized.

The nictitating membrane (third eyelid) is located within the ventromedial orbit. The third eyelid elevates passively as the globe retracts. Within this membrane lies a T-shaped cartilage with the gland of the nictitans surrounding its base.[2] This gland also contributes to the aqueous layer of the tear film. The third eyelid is frequently affected by squamous cell carcinoma.

Finally, numerous sinuses surround the bony orbit. The sphenopalatine sinus is located medial and ventral to the orbit near the optic chiasm.[10] The conchofrontal sinus is located medial to the orbit, extends dorsad and ventrad, and is composed of the frontal and dorsal conchal portions, which communicate.[5,9,11] The two maxillary sinuses are located ventral and axial to the orbit. The bony plate between the orbit and maxillary sinus is very thin.[4] Therefore processes may easily extend from the sinus into the orbit and vice versa. The landmarks for trephination of the maxillary sinus include (1) a vertical line tangential to the medial canthus, (2) the facial crest, (3) an oblique line drawn from the rostral facial crest to the infraorbital foramen, and (4) a line parallel to the facial crest intersecting the infraorbital foramen (see Chapter 43).[11] Trephination dorsal to a line drawn between the infraorbital foramen and the medial canthus may result in nasolacrimal duct damage.

RELEVANT OCULAR EXAMINATION TECHNIQUES AND FINDINGS

Initially a hands-off assessment of the head should be performed, including orbital symmetry, eyelid position, globe size and position, and pupil size. Abnormalities in globe position associated with orbital disease include strabismus (misalignment), exophthalmos (protrusion from the orbit), and enophthalmos (recession within the orbit) (Figure 55-2). The nares should be visually inspected for nasal discharge, air passing equally through both nostrils should be ensured, and the horse's visual status should be determined. Both globes should retain their normal range of motion. If the orbital rim is swollen or disfigured, digital palpation is indicated to identify potential displaced fractures or proliferative lesions. Additional clinical

Figure 55-2. A, Exophthalmos in an aged gelding. Computed tomography revealed a sinus tumor to be the cause of the orbital disease. **B,** Dorsal strabismus caused by an orbital traumatic proptosis in this horse. **C,** Enophthalmos in an adult horse with orbital and adnexal squamous cell carcinoma.

signs may include epiphora, ptosis (drooping of the eyelid), reduced airflow from the ipsilateral nostril, reduced sinus percussion, bone or facial deformation, keratoconjunctivitis sicca, and supraorbital fossa distention.[12] The nictitating membrane may passively protrude with exophthalmos or enophthalmos. Corneal ulceration (exposure keratitis) may occur in severe cases of exophthalmos because the eyelids are unable to completely close over the cornea.

Orbital disease processes can occur within the extraocular muscle cone (intraconal), between the muscle cone and the periorbital sheath, or external to the periorbital sheath (subperiosteal).[13] The degree and direction of globe deviation depends on the size and location of the lesion. Intraconal lesions typically cause exophthalmos, whereas lesions of the medial orbit displace the globe laterally. Retropulsion of the globe through closed eyelids should assist in identifying space-occupying lesions.[14]

In the geriatric horse, orbital fat resorption will cause enophthalmos.[15] Fractures of the walls of the paranasal sinuses and orbit can result in enophthalmos, facial deformity, and orbital emphysema. Tooth root abscesses may cause sinus and orbital disease. It must be remembered that infectious,[16] traumatic,[17-19] inflammatory, parasitic,[20] cystic,[21,22] or neoplastic disease[23-36] processes involving the eyelids, paranasal sinuses, tooth roots, guttural pouches, or nasal cavity may extend into the orbit and produce orbital disease.

The globe size of the exophthalmic eye is normal and should not be confused with the globe enlargement (buphthalmos) noted in advanced equine glaucoma. Comparing the horizontal limbal diameter of the affected and contralateral eyes will aid in identifying buphthalmos. Corneal globosa (abnormal corneal curvature) reported in Rocky Mountain horses affected with anterior segment dysgenesis must also be distinguished from exophthalmos.[37] At the other extreme, one must differentiate phthisis bulbi (globe shrinkage) from enophthalmos (Figure 55-3).

Ocular motility must also be evaluated. Damage to the extraocular muscles, displaced fractures, and space-occupying lesions may entrap the globe within the orbit. The examiner should grasp the horse's halter and move the horse's head in a horizontal plane using gentle sweeping motions. The globes should remain relatively central within the palpebral fissures and move together in a yoked fashion. If the globe does not move normally, a topical ophthalmic anesthetic (0.5% proparacaine or

Figure 55-3. An adult horse with phthisis bulbi.

tetracaine ophthalmic solution) should be applied and the bulbar conjunctiva should be grasped gently with Bishop-Harmon forceps. The globe should be moved in the direction of interest to determine if a mechanical restriction is present. Simultaneously one should feel for globe movement initiated by the patient to confirm that the extraocular muscles are functional.

Sedation

Horses may require sedation, analgesia, and infiltration of a local anesthetic to complete a thorough ophthalmic examination. Typically the α_2-adrenoreceptor agonists detomidine or xylazine are used. Detomidine hydrochloride (10 mg/mL) administered at a dose of 0.02 mg/kg IV provides a steadier head position compared to xylazine and is useful for many minor ocular and periocular surgical procedures.[7,14,38,39] The addition of butorphanol (10 mg/mL) at a dosage of 0.01 to 0.02 mg/kg IV provides additional analgesia.[14,38-40] Confinement within stocks and application of a twitch may also aid in completing the examination.

Regional Anesthesia

Regional anesthesia greatly facilitates the ocular examination, particularly for painful conditions or a severely compromised globe. Lidocaine hydrochloride 1% or 2%, mepivacaine hydrochloride 2%, or bupivacaine hydrochloride 0.75% are typically used. Lidocaine has an intermediate potency and duration (45 to 180 minutes) with a rapid onset of action (5 minutes).[40-42] Mepivacaine is similar but has a slightly longer duration of action (120 to 180 minutes).[41,42] Bupivacaine is highly potent and has a long duration of action (180 to 500 minutes).[41-43]

Akinesia of the eyelids can be achieved by blocking the auriculopalpebral nerve, which innervates the orbicularis oculi muscle. By diminishing the ability to squint, the auriculopalpebral block greatly facilitates examination and is critical for globes in danger of rupture. The auriculopalpebral nerve, the palpebral branch of the facial nerve, can be blocked at three locations (Figure 55-4): (1) at the depression just anterior to the base of the ear, where the nerve emerges from the parotid salivary gland and becomes subcutaneous between the caudal border of the coronoid process of the mandible and the zygomatic process of the temporal bone; (2) lateral to the highest point of the caudal zygomatic arch where the palpebral nerve can be palpated or "strummed" under the skin over the dorsal border of the bone (Figure 55-5); and (3) just caudal to the bony process of the frontal bone where the palpebral nerve lies on the zygomatic arch.[14,44-46] At the location of choice, 1 to 2 mL of anesthetic should be injected using a 25-gauge, 1.58-cm needle, and then the injection site should be massaged to facilitate drug diffusion.[14,44-46]

Analgesia of the central two thirds of the upper eyelid can be achieved by blocking the supraorbital nerve, a branch of the frontal nerve of the ophthalmic branch of the trigeminal nerve (CN V). The nerve should be blocked as it emerges from the supraorbital foramen, which can be easily palpated as a small depression 2.5 cm above the free margin of the supraorbital process (Figure 55-6). A 25-gauge, 1.58-cm needle should be used to inject 1 to 2 mL of anesthetic. The use of a longer needle is discouraged because it could pass through the foramen and penetrate the sclera.

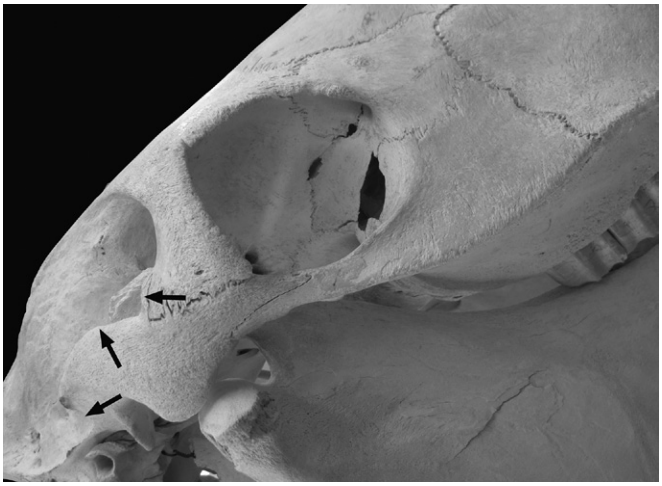

Figure 55-4. The three locations for auriculopalpebral nerve block indicated by the *black arrows*.

Figure 55-5. Auriculopalpebral nerve block anesthetic placement.

DIAGNOSTIC PROCEDURES

Retrobulbar Aspiration

Retrobulbar aspirates and biopsies allow collection of samples for culture, cytology, and histopathology from cases with space-occupying orbital masses. The site of aspiration varies according to the location of the lesion within the orbit. The needle or biopsy punch should be directed through the supraorbital fossa (see the description of retrobulbar nerve blocks in "Anesthetic Considerations," later) or through the conjunctiva. The procedure is often performed while the horse is standing and heavily sedated. Ultrasouznd guidance may facilitate placement of the needle within the mass and reduce the risk of postprocedural complications.[47] Care should be taken to prevent damage to the globe, orbital vessels, and optic nerve. Diagnostic imaging should be performed before collecting retrobulbar aspirates to avoid creating artifacts on the imaging study from the needle passage.

Figure 55-6. Supraorbital nerve block anesthetic placement.

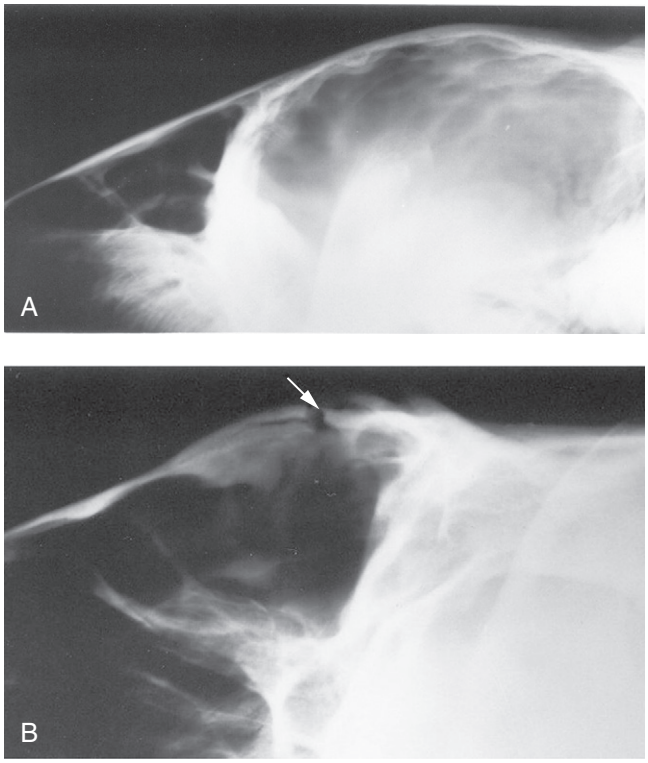

Figure 55-7. A, An orbital fracture is difficult to visualize on a lateral skull radiograph. **B,** The oblique radiographic view shows it well (*arrow*).

Diagnostic Imaging

Radiography

Radiographic examination of the orbit, paranasal sinuses, and nasal cavity can be an effective diagnostic tool (Figure 55-7). However, the superimposition of complex anatomic structures can make accurate diagnoses difficult to obtain.[48] Lesions involving the orbit warranting skull radiography include orbital and facial bone fractures, invasive bone-deforming neoplasia, a gas-forming abscess or cellulitis, exophthalmos, and metallic foreign bodies.[19,49-52] Multiple views, particularly oblique images highlighting the area of interest, should be obtained.[49-53] In the evaluation of unilateral lesions, the involved portion should be placed against the film cassette. Most lateral, dorsoventral, and oblique views of the equine orbit can be obtained with standing sedation. Ventrodorsal views of the orbit will require general anesthesia. A Flieringa ring, which is a stainless steel ring, can be placed at the limbus to help identify the globe within the orbit.

Ultrasonography

Ultrasonography is a useful, noninvasive diagnostic procedure that can usually be performed on the unsedated or sedated standing horse. It can be useful in evaluating exophthalmic globes; suspected retrobulbar or intraocular masses,[25,28,30,54,55] cysts,[22] abscesses,[56] or foreign bodies[57]; and globes obscured by marked eyelid swelling or with opacification of the ocular media (Figure 55-8). Brightness mode (B-scan) is most often used for clinical examination because it creates real-time two-dimensional, cross-sectional images.[58] Ultrasound probes of 6 to 10 MHz provide the best resolution and can penetrate the orbit to a depth of 3 to 7 cm.[57,59,60] The ultrasonic transducer can be placed in contact with the eyelids via a methylcellulose coupling agent to evaluate the globe and anterior orbit, or it can be placed in gentle contact with the cornea after instillation of a topical anesthetic to evaluate the posterior orbit.[61] The orbit can also be imaged through the supraorbital fossa. Abscesses appear as variably hypoechoic areas, whereas neoplasms usually appear more hyperechoic.[61] Both typically cause a markedly abnormal or asymmetric appearance of the affected area.[61] Foreign bodies often hyperechoic.[57] The opposite globe and orbit can provide a normal "control" for comparison.

Computed Tomography

Computed tomography (CT) creates cross-sectional, two-dimensional slices (i.e., tomograms) by measuring the attenuation of x-ray beams as they penetrate the tissue of interest from multiple angles.[48,62] These slices are then reconstructed in sagittal, dorsal, and oblique planes as desired.[48] The normal CT anatomy of the horse has been published,[63,64] and the reader is also referred to Chapter 70 for further information. Three-dimensional reconstructions of a CT study can be created, which are excellent for surgical planning and client education (Figure 55-9).[48] CT is an excellent modality for evaluating bone lesions and is superior to radiographs in evaluating soft tissues.[65] The large amount of orbital fat surrounding the globe, extraocular muscles, and associated nerves aids in identifying orbital soft tissue because it functions as a physiologic contrast agent.[57] Intravenously administered iodinated contrast medium accumulates in areas of increased perfusion and can therefore be used to delineate the margin between normal and abnormal tissues.[48,57,66] The drawbacks associated with CT imaging are its restricted availability and requirement for general anesthesia.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is another viable option for obtaining advanced imaging detail of the equine orbit, sinuses, and brain. MRI provides superior soft tissue detail of orbital

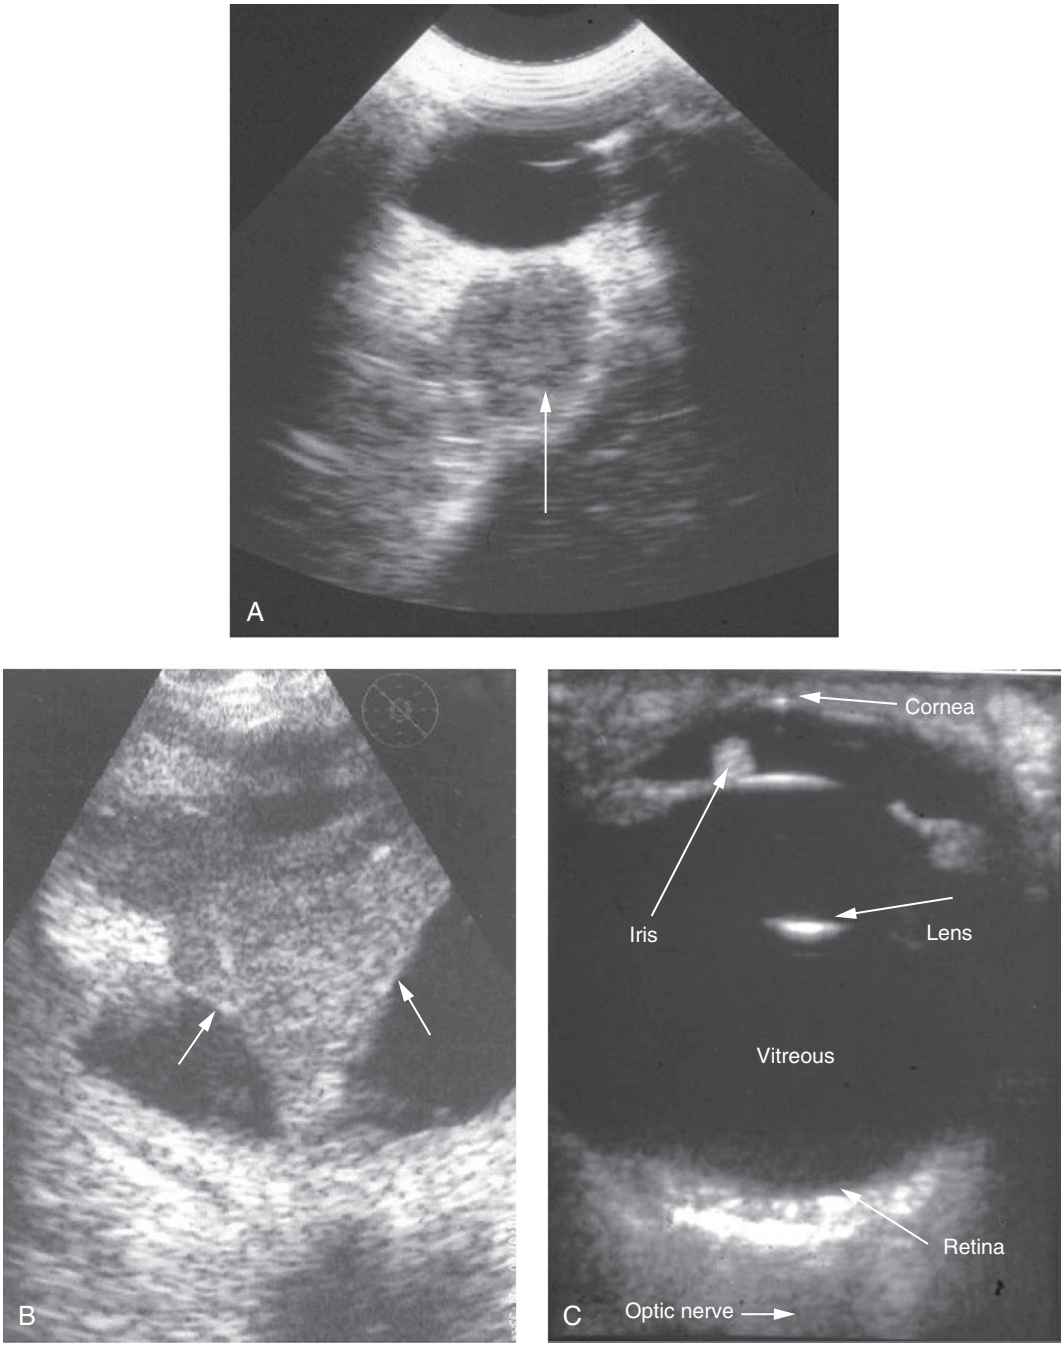

Figure 55-8. A, B-scan ultrasonographic view reveals an orbital optic nerve tumor (*arrow*). **B,** This ultrasonographic scan reveals a retinal detachment that resulted from severe eye trauma (*arrows*). The vitreous is opaque from hemorrhage. **C,** A normal B-scan ultrasonographic image is shown for comparison.

structures (Figure 55-10). MRI images are created by radiowaves emitted from hydrogen protons as they return to an equilibrium orientation within a magnetic field after being stimulated by a radiofrequency pulse.[67] A paramagnetic contrast agent can be used to identify increased vascular permability within the tissue of interest. Please see Chapter 71 for details regarding the various pulse sequences and their use. Similar to CT, MRI requires general anesthesia and has limited availability.[62,67] However, MRI provides better image resolution, anatomic detail, and tissue characterization of the orbital structures when compared to CT and does not rely on ionizing radiation.[67] The disadvantages of MRI include longer acquisition times, increased tissue slice thickness, poorer spatial resolution, and decreased ability to detect cortical bone defects or soft-tissue mineralization.[67] The reader should refer to the listed references for details of interpreting MRI images of the orbit, sinuses, and brain.[62,68-71]

ANESTHETIC CONSIDERATIONS

Equine anesthesia for ocular procedures remains challenging. Anesthesia for ocular surgery has a higher complication rate because of an increased incidence of movement under anesthesia and unsatisfactory recoveries associated with multiple attempts to stand.[72] The use of an anesthetic gas analyzer

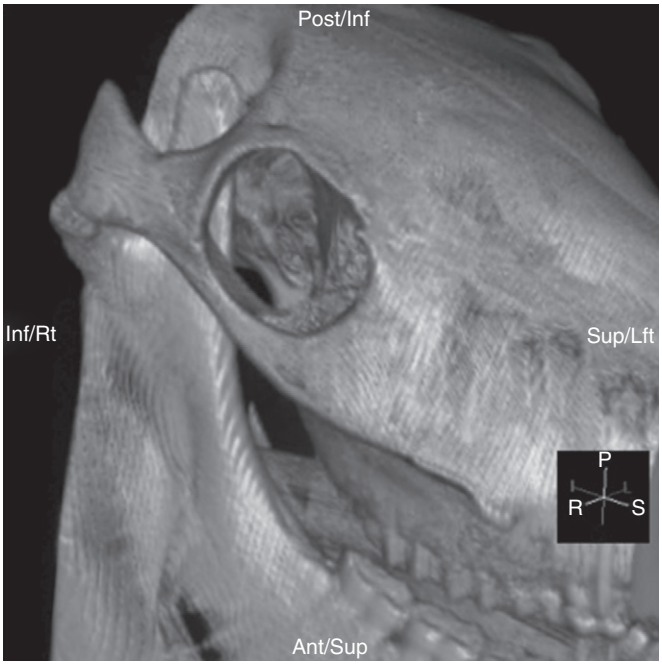

Figure 55-9. 3-D CT reconstruction of an adult equine orbit and skull.

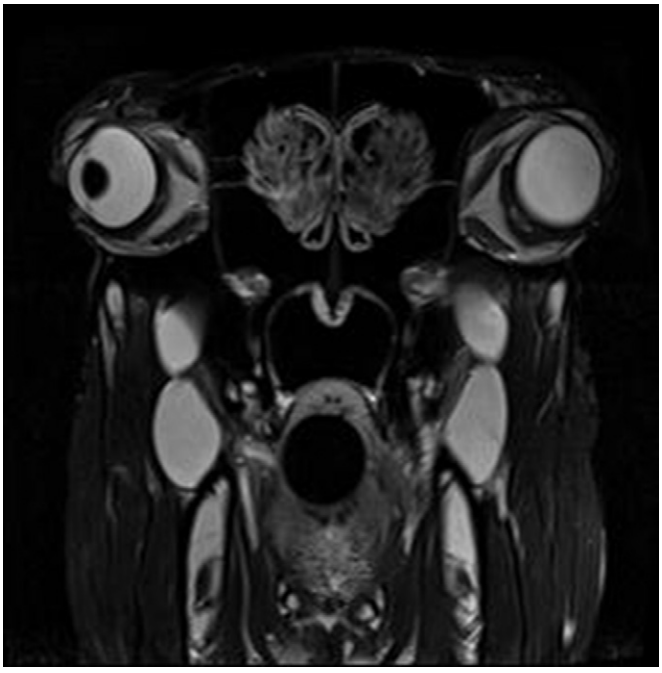

Figure 55-10. T2-weighted MRI image of a normal adult horse.

significantly reduces the incidence of movement.[72] Movement often occurs because of the persistence of palpebral and corneal reflexes and changes in globe position despite a deep plane of anesthesia. Administration of neuromuscular blocking agents can decrease these movements and thereby avoid a deep plane of anesthesia and its associated complications.[73] Retrobulbar nerve blocks can also be used to abolish the unwanted movement.[74] In our experience, even the minimal addition of a topical anesthetic agent (proparacaine or tetracaine ophthalmic solution 0.5%), a supraorbital block, and an auriculopalpebral block can relieve some of the unwanted movement.

Figure 55-11. A retrobulbar nerve block placed in the supraorbital fossa immediately caudal to the posterior aspect of the dorsal orbital rim in a horse with a corneal stromal abscess.

Alternatively, procedures such as enucleation can be performed with standing sedation if the horse's temperament allows it. Flunixin meglumine (1.1 mg/kg IV) should be administered preoperatively.[75] The horse should be placed in stocks and sedated with detomidine (0.01 mg/kg IV) and butorphanol (0.03 mg/kg IV). Sedation should be maintained throughout the procedure with a detomidine constant-rate infusion (0.6 µg/kg/min).[75] The head should be suspended from cross ties after padding the halter or the chin can be rested on a padded table or dental rest. Regional anesthesia is crucial. A topical anesthetic should be applied to the corneal surface. Tetracaine 0.5% ophthalmic gel has been shown to provide superior analgesia for a longer duration when compared to proparacaine ophthalmic solution.[76] Auriculopalpebral, supraorbital, and retrobulbar blocks should be performed. The remainder of the eyelid margin can be desensitized through blocks of the infratrochlear and lacrimal nerves or placement of line blocks.

Several approaches have been described to perform a *retrobulbar nerve block*. For all, the injection site must first be prepared for aseptic surgery. Potential complications associated with retrobulbar blocks include orbital abscess formation; orbital cellulitis; laceration of the extraocular muscles, optic nerve, sclera, or ophthalmic artery; retrobulbar hemorrhage; optic neuritis; and elicitation of the oculocardiac reflex.[77]

In one approach, a 22-gauge, 6.35-cm (2½-inch) spinal needle is inserted into the supraorbital fossa immediately caudal to the posterior aspect of the dorsal orbital rim (Figure 55-11).[78] The needle should be oriented perpendicular to the skull and advanced until it reaches the retrobulbar muscle cone. A slight dorsal movement of the eye and/or a "popping" sensation should occur as the needle passes through the muscle cone. Once the needle is positioned, aspiration should be performed before injecting 10 to 12 mL of local anesthetic. Accurate anesthetic placement results in slight exophthalmia.

In a modification of the Peterson block an 18-gauge, 10.16 cm (4-inch) spinal needle is molded to a curvilinear shape.[74] The needle should then be inserted 1 cm lateral to the lateral canthal margin and directed in a ventromedial path in a line parallel to the contralateral medial canthus. The local anesthetic should be injected after needle placement and negative pressure aspiration.

A four-point nerve block can also be applied.[79] A slightly curved 20-gauge, 7.62 cm (3-inch) spinal needle should be used

to place 5 to 10 mL of local anesthetic in each quadrant of the orbit. The needle should be passed through the conjunctival fornix or eyelid and curved around the globe to the extraocular muscles and retrobulbar space. The ventral injection should be directed slightly nasally to avoid the optic nerve. Because of the large total volume injected, this technique can increase pressure on the globe and increase the risk of corneal perforation in a compromised globe.[79] Marked conjunctival swelling can occur if one inadvertently injects anterior to the orbital septum.[79]

REQUIRED SURGICAL EQUIPMENT

The instruments required for orbital surgeries include many of the standard instruments used for soft tissue surgeries. Magnification via head loupes may aid in visualization of tissues and suture material. The addition of ophthalmic instruments such as Bishop-Harmon tissue forceps, Stevens tenotomy scissors, and Castroviejo needle holders should facilitate manipulation of the conjunctiva and sclera (Figure 55-12). Osteotomes, an oscillating bone saw, and pneumatic drill will be required for resecting the zygomatic arch or other orbital bones (Table 55-3).

SURGICAL TECHNIQUES

For all ocular surgeries, the surgical site should be prepared with a 1:50 dilution of 10% povidone-iodine solution (Betadine), and the ocular surface should be flushed with this solution. The conjunctival fornices should be swabbed with sterile cotton-tipped applicators soaked in povidone-iodine solution. Alcohol, scrubs, and chlorhexidine are toxic to the corneal epithelium and therefore their use should be avoided. The surgical site should be draped routinely.

Evisceration and Intrascleral Prosthesis

An evisceration involves the surgical removal of the uveal tract, lens, vitreous, and retina from the fibrous tunic (cornea and sclera), which remains intact. Evisceration is a cosmetic surgical procedure for blind and painful eyes. It is not appropriate for eyes with septic endophthalmitis, intraocular neoplasia, or marked phthisis bulbi. Globes with preexisting corneal disease have an increased risk of complications postoperatively. A conjunctival advancement graft can be placed concurrently in cases with corneoscleral laceration.[80]

Surgical Procedure

A lateral canthotomy should be performed to improve exposure of the surgical field. Using tenotomy scissors, the conjunctiva should be incised parallel to and 68 mm posterior to the limbus to create a 180-degree peritomy (Figure 55-13).[81] The sclera should be exposed by bluntly undermining the conjunctiva, taking care not to undermine the insertions of the extraocular muscles (Figure 55-14). A No. 15 scalpel blade or No. 64 microsurgical blade should be used to make a 1.5-cm full-thickness incision in the sclera 4 to 5 mm from the limbus. Suction and cautery should be used to control extensive hemorrhage and visualize the incision. An evisceration spoon should then be inserted into the suprachoroidal space to separate the uvea from the sclera. The scleral incision should then be extended to 180

degrees with scissors. The uveal tract should be grasped crosswise with a pair of blunt-tipped forceps and gentle traction applied with a rocking motion to deliver the uvea, retina, and vitreous. The lens can be removed with the evisceration spoon or a lens loop. Care should be taken to avoid scraping the corneal endothelium. The intraocular contents should be submitted for histopathologic examination if neoplasia is suspected. A suitably sized silicone implant (usually 34 to 44 mm in diameter) (Jardon Plastics Research Corporation, Southfield, MI) should be inserted into the sclera. A sphere introducer will facilitate implantation. The scleral incision should be apposed without undue tension. Preoperative ultrasonic measurement of the anterior-posterior dimension of the contralateral eye will aid in the selection of the proper-sized implant.[82] A simple-interrupted pattern of 6-0 absorbable suture should be placed in the sclera. A simple-continuous pattern of 6-0 absorbable suture should be placed in the conjunctiva. The lateral canthotomy should be closed routinely.

Aftercare

Topically applied antibiotics and systemically administered antibiotics and nonsteroidal anti-inflammatories should be used postoperatively. A temporary tarsorrhaphy should protect the cornea from exposure and mechanical abrasion while postoperative eyelid swelling subsides. The typical time for healing is 6 to 8 weeks.

Complications

Postoperative complications include corneal ulceration, endophthalmitis, and sugical site dehiscence.[12,82,83] Corneal perforation or incisional dehiscence can allow extrusion of the implant.[84] Enucleation is the only recourse if this occurs. Protective headgear should help prevent damage from head rubbing. Placement of a too-small implant will result in a cosmetically unacceptable eye. Owners should be warned that corneal opacification and vascularization occur in some animals and create a less-satisfactory cosmetic appearance. Tinted contact lenses can be placed for short periods to mask corneal opacification for show purposes.[83]

Enucleation

Enucleation involves the surgical removal of the palpebral margins, nictitans, conjunctiva, and globe.[85] This is one of the most commonly performed orbital surgeries. Enucleation is indicated for blind painful globes, severe corneal or intraocular infection, intraocular neoplasia, and traumatized globes not amenable to surgical repair. There are two surgical approaches: transpalpebral and subconjunctival.[85] An orbital prosthesis may be placed to improve cosmesis (Figure 55-15). If a visual eye must be removed, an opaque mask or full cup blinker should be placed for a day or two preoperatively to allow the horse to adjust to the vision loss and facilitate a smoother anesthetic recovery.

Transpalpebral Enucleation with Intraorbital Prosthesis

The conjunctiva, globe, and nictitating membrane are removed en masse. This approach prevents contamination of the orbit if neoplasia or severe ocular infection are present. However, it leaves a large orbital soft-tissue defect.[85,86]

The eyelids should be sutured together with 2-0 to 3-0 nonabsorbable suture in a continuous pattern (Figure 55-16, *A* to *D*). An elliptical, full-thickness skin incision should be created around and 5 mm posterior to the eyelid margins using a No. 15 scalpel blade. Using Metzenbaum scissors, blunt and sharp subcutaneous dissection should be performed posteriorly, taking care to avoid incising the conjunctival sac. The firm medial and lateral canthal ligaments should be transected with heavy gauge scissors. Care should be taken to avoid the angularis oculi vein at the medial canthus. Blunt dissection should be continued along the sclera with transection of the extraocular muscles at their tendinous insertions, thus minimizing hemorrhage. The retractor bulbi muscle should be blindly transected using curved, serrated Mayo scissors. Clamping of the optic nerve with either a Rochester-Carmalt forceps or Satinsky vascular clamp is optional. Curved, serrated Mayo scissors should be used to transect the optic nerve while avoiding incising the globe. Also, one should avoid excess tension on the optic nerve, which could traumatize the optic chiasm and result in vision loss in the contralateral eye.

At this point a silicone implant (equine conforming intraorbital implant) (Figure 55-17), polymethyl methacrylate sphere (34 to 40 mm in diameter), or suture meshwork can be placed

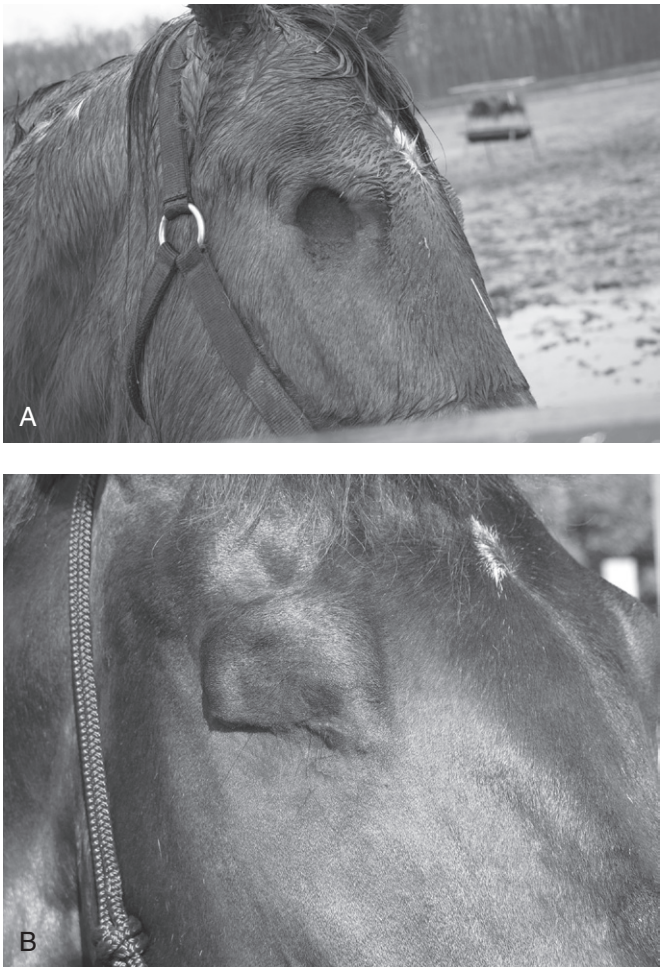

Figure 55-15. Image of two adult horses several years after enucleation. **A,** Without an intraorbital prosthesis. Note the degree of "pitting." **B,** With an intraorbital prosthesis. Note the more cosmetic appearance.

within the orbit to improve postoperative cosmesis.[80,81,87-89] An 8.6% complication rate with intraorbital infection and implant extrusion has been reported for intraorbital prostheses in dogs, cats, and horses.[84] An orbital implant should not be placed in the presence of infection or neoplasia involving the remaining structures within the orbit. The orbital septum should be closed in a simple interrupted pattern with 3-0 absorbable suture, which secures the prosthesis within the orbit and assists with hemostasis. The subcutaneous layer should be closed in a simple continuous pattern with 3-0 or 4-0 absorbable suture. The skin should be closed in a simple interrupted or continuous pattern with 4-0 nonabsorbable suture material.

Subconjunctival Enucleation

The subconjunctival approach is quicker, is associated with less hemorrhage, and removes less orbital tissue.[85] The subconjunctival technique maintains the eyelid margins and therefore must be used when placing a cosmetic shell. Patients with ocular disease confined within the globe should be excellent candidates for this approach.

An eyelid speculum should be placed and a lateral canthotomy performed to improve surgical exposure. The bulbar conjunctiva should be incised 5 mm posterior to the limbus using blunt-tipped Stevens tenotomy scissors and a 360-degree peritomy should be performed (see Figure 55-16, *E* and *F*). All four quadrants should be undermined posteriorly between Tenon's capsule and the sclera with tenotomy scissors and Bishop-Harmon forceps. The extraocular muscles should be isolated and transected at their tendinous insertions on the globe. The retractor bulbi muscle and optic nerve should be transected as described earlier (Figure 55-18). The orbit can be temporarily packed with sterile gauze to provide hemostasis. The third eyelid, gland, and associated conjunctiva should be completely excised with scissors, along with 3 to 5 mm of the lid margin and associated meibomian glands. The remaining conjunctiva should be excised to prevent mucocele formation. Placement of an intraorbital prosthesis and closure of the surgical site should be performed as described previously.[12,82,83,90]

Aftercare

All enucleated globes should be submitted for histologic evaluation. A pressure bandage should be placed immediately postoperatively to assist with hemostasis and reduce postoperative swelling. Slight epistaxis may occur postoperatively. Systemically administered antibiotics and nonsteroidal anti-inflammatory drugs should be beneficial. Most horses should be able to return to their original occupation after unilateral enucleation.[91]

Complications

Complications include intraoperative globe rupture, severe intraoperative and postoperative hemorrhage, orbital cyst formation resulting from incomplete removal of secretory orbital tissue (i.e., lacrimal glands and conjunctiva), and contralateral blindness. Rupture of an infected globe may result in orbital infection. In such cases, the orbit should be extensively irrigated, intraoperative cultures obtained, and broad-spectrum systemic antibiotics administered and modified in accordance with culture results. A drain should be placed if contamination is severe.

Surgical transection of the optic nerve may result in severe intraoperative hemorrhage. Wet-field cautery, application of hemoclips, or careful ligation should restore hemostasis. The surgical closure will tamponade blood within the orbit. Application of a pressure bandage should also assist with hemostasis and diminish trauma to the surgical site during recovery.

Scleral Shell Prosthesis

If exceptional cosmesis is required, a scleral shell or conformer of hydroxyapatite (HA), porcelain, or methyl methacrylate can be placed to cover a disfigured or phthisic globe.[87] If the globe must be enucleated, an HA orbital implant can be secured within the orbit and the scleral shell placed over or pegged to it. The surface of the shell is painted by an ocularist and the prothesis is placed into the conjunctival sac. Daily cleaning and high costs are the main limitations, but the results are quite extraordinary (Figure 55-19).[87] The owner should be aware of the long recovery period (3 to 5 months), frequent treatments, and repeated visits to the ophthalmologist and ocularists for examination and prosthetic fitting.[82] Contraindications to placement of a corneoscleral prosthesis include poorly developed conjunctival fornices, intraorbital infection, intraorbital

Figure 55-16. Figure 55-17. The top hat orbital prosthesis is designed to reduce "pitting" after enucleation.

neoplasia, and a horse that is difficult to treat.[82,88] If a globe will be enucleated with the intention of placing an HA orbital implant, the conjunctival fornices, extraocular muscles, and other orbital tissues must be meticulously preserved. The steps required to prepare the implant and place it within the orbit have been described.[87] Ocular conformers are available from Jardon Eye Prosthetics or can be custom made for horses by Dallas Eye Prosthetics (Dallas, TX).

Exenteration

Exenteration involves removing all orbital tissues (Figure 55-20). Indications for performing an exenteration include orbital and/or extensive adnexal neoplasia, medically nonresponsive orbital infections, or aggressive intraocular neoplasia with orbital extension. An exenteration is smilar to a transpalpebral enucleation. However, the posterior dissection and transection of the extraocular muscles and optic nerve should be performed along the orbital wall. A periosteal elevator may be used to strip the periosteal lining of the orbital wall if the disease extends to the periosteum. In the case of disease involving the bony margins, a curette should be used to remove diseased bone. If needed, rongeurs and an osteotome may be used to excise the diseased tissue, although this will be more traumatic and may damage adjacent healthy bone. The disease process may also extend through the orbital wall into adjoining sinuses. Adjunctive treatment via cryotherapy, radiotherapy implants, or chemotherapeutic agents may be warranted depending on the type of the neoplastic process.[12,85] Increased hemorrhage should be expected when performing an exenteration. Vessel ligation, electrocautery, manual tamponade, hemoclips, Gelfoam, and a LigaSure[92] device can all be used to aid hemostasis. Often, minimal periorbital fascia remain for closure. Orbital implants typically are contraindicated following exenteration. Partial dorsal orbital rim resection, mesh skin expansion, extensive undermining of

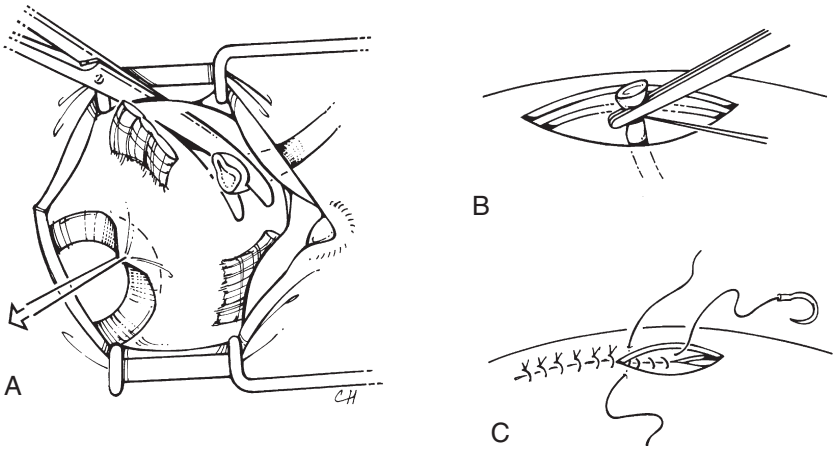

Figure 55-18. In both methods of enucleation (see Figure 55-16), the extraocular muscles are transected and the optic nerve is subsequently clamped **(A** and **B).** A three-layer closure is performed **(C).**

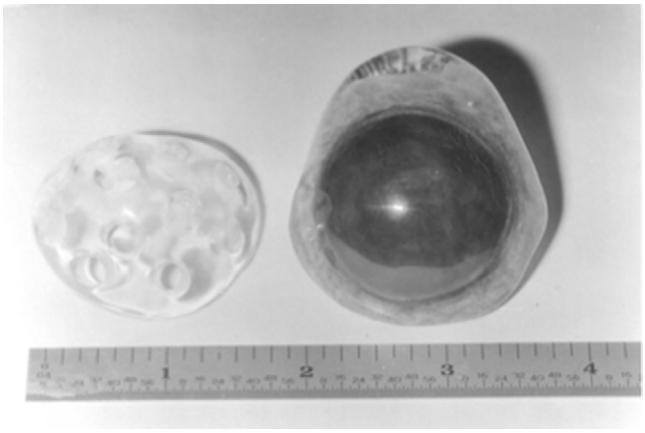

Figure 55-19. This methyl methacrylate cosmetic shell (*right*) was custom made to fit anterior to an orbital silicone implant in a horse. The impression tray (*left*) was used to make the initial mold for the shell.

surrounding skin, tension sutures, and/or second-intention healing may be required to close large orbital defects[93] (Figure 55-21). Placement of an active drain should help to evacuate the large potential dead space. The suction bulb should be secured to the halter after the bandage is placed. Broad-spectrum systemic antibiotics and anti-inflammatories are indicated perioperatively and postoperatively. Complications may include incomplete excision of neoplastic tissue, excessive swelling, and hemorrhage.[12,83]

Orbitotomy

Lesions necessitating orbital exploration include parasitic cysts or granulomas, encapsulated orbital abscesses, foreign bodies, circumscribed neoplasia, repair of some orbital fractures, and cystic dilation of the nasolacrimal or salivary system.[12,19,94] Advanced diagnostic imaging (CT, MRI, or both) should aid in selecting the best approach to the orbit by defining the lesion's location and extent.

A dorsal orbitotomy should be used for lesions in the dorsal orbit and supraorbital fossa.[23] A curvilinear skin incision should be made over the dorsal orbital region just lateral to the external sagittal crest of the parietal and frontal bones, curving laterally caudal to the zygomatic process of the frontal bone.[95] Lateral

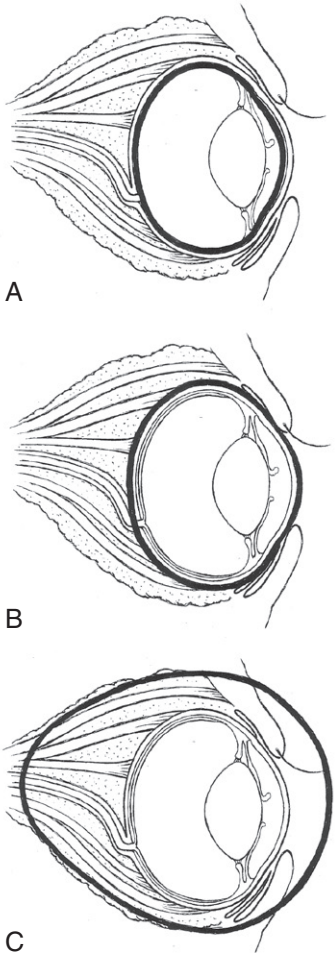

Figure 55-20. The surgical techniques for evisceration **(A),** enucleation **(B),** and exenteration **(C).**

retraction of the frontoscutularis, interscutularis, and temporal muscles exposes the extraocular muscle cone deep within the orbit.[12,23]

In an alternative dorsal approach, an S-shaped skin incision can be made parallel to the zygomatic process of the frontal bone.[94] The surgeon must avoid transecting the neurovascular bundle within the supraorbital foramen and nerve fibers

Figure 55-21. An adult horse after exenteration, dorsal orbital rim resection, meshed skin expansion, and placement of an active suction drain.

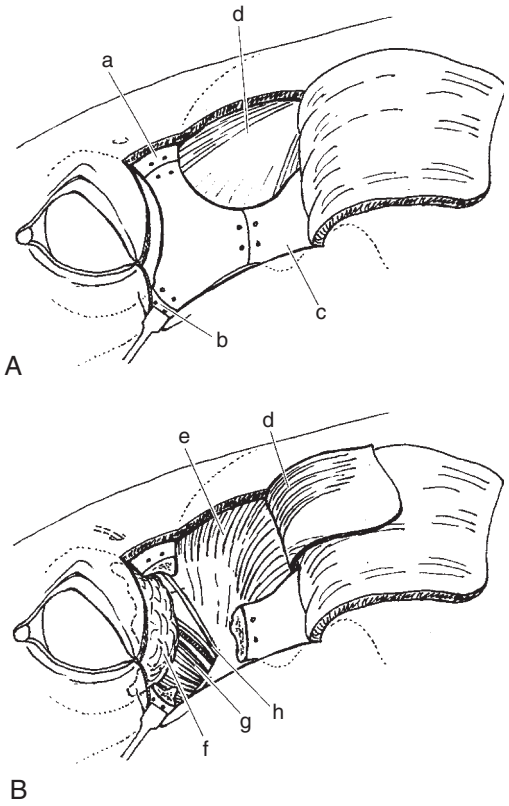

Figure 55-22. Diagrammatic orbitotomy technique involving zygomatic arch transection to remove orbital masses. **A,** The positions where the zygomatic arch and zygomatic process of the frontal bone are drilled before transection of the arch. **B,** The extraocular muscle cone is exposed after removal of the zygomatic arch and temporal muscle. *a*, Zygomatic process of frontal bone; *b*, zygomatic arch; *c*, zygomatic process of temporal bone; *d*, scutular muscles; *e*, temporal muscle; *f*, retrobulbar muscle cone; *g*, lacrimal gland; *h*, supraorbital nerve. (Technique modified from Goodhead AD, Vener IJ, Nesbit JW: Vet Comp Ophthalmol 7:96, 1997.)

entering the orbicularis oculi laterally. The periosteum should be incised anteriorly, reflected off the bone, and preserved for later closure. The zygomatic process of the frontal bone should be resected in section after predrilling 20-gauge holes within the bone for reattachment (Figure 55-22). Performing a lateral canthotomy may increase exposure. At closure, the zygomatic process should be replaced and fixed with 20-gauge stainless steel surgical wire. The periosteum should be closed in a simple interrupted pattern with 4-0 or 5-0 absorbable suture material. The subcutaneous tissue and skin should be subsequently closed.

A lateral approach has also been described.[22,24] A horizontal lateral canthal incision should be extended caudally 5 mm through the skin, followed by dissection through the levator anguli oculi muscle. Two centimeters of the zygomatic process of the temporal bone and its ventrolateral aspect should be resected after predrilling.[24] Closure should be performed as described earlier.

Orbital Fractures

Orbital fractures can threaten the globe's integrity through displacement, impingement, restriction, or laceration.[12] Orbital fractures may produce facial asymmetry, epistaxis, exophthalmos, proptosis, eyelid and conjunctival swelling, depression of the periorbital region, crepitus, and pain on periorbital palpation (Figure 55-23). Damage to the intraosseous nasolacrimal duct, globe, optic nerve, or paranasal sinuses can occur.[18,19] Damage to the poll after rearing or falling over backwards may cause blindness because of fractures of the basioccipital bone and the basisphenoid bone with involvement of the sphenoid foramina.[12] Although orbital fractures may be diagnosed through observation and palpation,[18,19] diagnostic imaging should be recommended.

Periorbital fractures should be repaired quickly before callus forms at 10 to 14 days, which makes manipulation difficult.[18,19] Nondisplaced or minimally displaced fractures of the orbital rim seldom require surgical intervention. Small displaced bone fragments, denuded of periosteum, should be removed surgically to avoid sequestrum formation.[96] Large bone fragments of the zygomatic process or dorsal orbital rim may be amenable to closed reduction.[19] Open fractures should be lavaged and débrided to remove necrotic tissues. Failure to repair large fractures may result in permanent facial deformity.[18,19] Fracture sites should be approached by slightly curved skin incisions adjacent to the fracture site.[18,19] Monofilament stainless steel wire suture (20- to 22-gauge), cerclage wire, small pins, orthopedic bone plates (Figure 55-24), and cancellous bone grafts should be used to stabilize bone fragments and immobilize and repair extensive orbital fractures.[18,19,94] Fractures that are

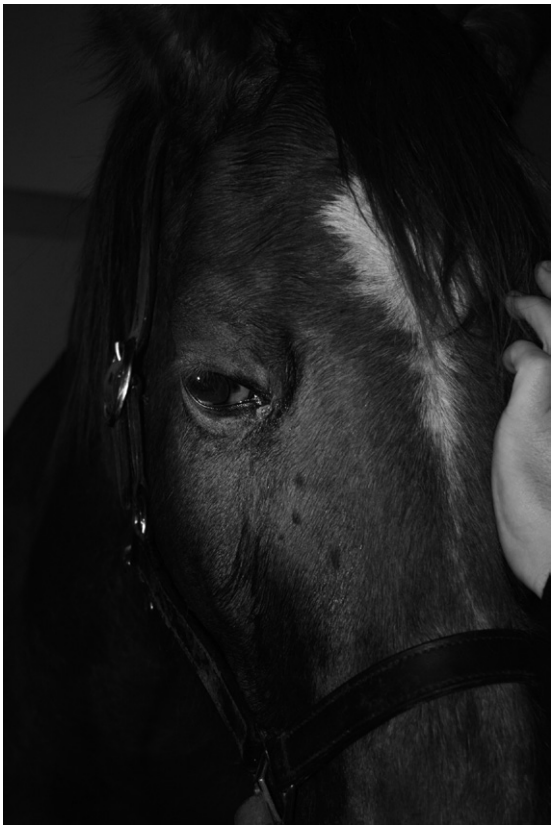

Figure 55-23. Medial orbital rim fractures of the frontal and lacrimal bones in a horse.

Figure 55-24. A 2.7-mm diameter 5-hole bone plate was used to repair this supraorbital process fracture.

difficult to elevate may be reduced by drilling trephine holes at the fracture periphery and using angled probes to elevate the fragment. Sinus fractures often cause epistaxis and emphysema. They should be considered open wounds and treated accordingly. The reader is referred to Chapter 102 for additional information on skull fractures. Broad-spectrum antibiotics and anti-inflammatories are indicated. Tetanus antitoxin or toxoid should be administered if appropriate.[12] Concurrent corneal ulcers, uveitis, lid lacerations, and other associated ocular problems should be treated at the same time.

CHAPTER
56 Adnexal Surgery

Freya Mowat and Joshua T. Bartoe

Adnexa of the eye include the eyelids and conjunctiva, nictitating membrane, and nasolacrimal system. Each of these adnexa contributes to health of the eye by maintaining a normal physiologic environment. Disorders of each of these adnexa can have deleterious effects on health of the globe and vision, and so each is addressed separately in this chapter.

EYELIDS

Anatomy and Physiology

The different eyelid functions include protection of the globe, optimization of light transmission and refraction through the cornea, maintenance of globe position within the orbit, and musculature and motor control. These functions are discussed in detail later.

Protection of the Globe

The upper eyelid cilia (eyelashes; Figure 56-1) provide protection from light and foreign material. Reflex blinking is initiated by tactile sensation from the cornea, eyelid skin, cilia, or tactile hairs (vibrissae; see Figure 56-1, *A* and *B*). Blinking completely closes the palpebral fissure except at the medial canthus where the caruncle protrudes. The glandular secretions of the eyelids include those from the cilia-associated glands of Zeis (sebaceous) and Moll (apocrine), and the tarsal or meibomian glands (the meibomian gland orifices are visible clinically as the "gray line;" see Figure 56-1, *D*). These secretions provide components to the preocular tear film that is important for protecting the eye.

Optimization of Light Transmission and Refraction through the Cornea

The eyelids maintain optical clarity by distributing tears uniformly across the ocular surface. Loss of blinking immediately impairs corneal clarity. The physical action of blinking pumps tears down the nasolacrimal duct via the upper and lower lacrimal punctae (see Figure 56-1, *C*), promoting a uniform preocular tear film.[1]

Maintenance of Globe Position within the Orbit

The fibrous tissues and periocular muscles aid in globe retraction in combination with the extraocular muscles.

The eyelids consist mainly of skin, striated muscle, fibrous supportive tissue, and conjunctiva (Figure 56-2). The skin is thin and is covered with fine dermal hair, which is absent

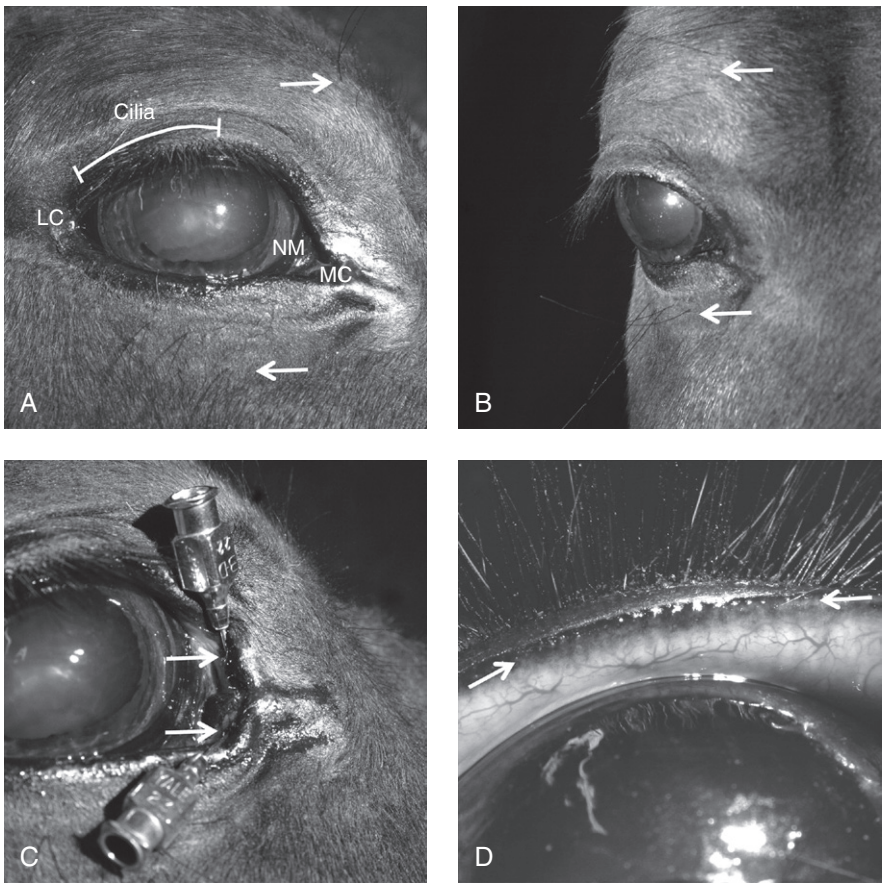

Figure 56-1. Overview of anatomy of the equine ocular adnexa. **A,** Equine eye, lateral view. Cilia (eyelashes) are present in the lateral two thirds of the upper eyelid. Lower eyelid cilia are poorly developed.[92] Upper and lower eyelid skin contains tactile vibrissae *(white arrows).* The palpebral fissures meet at the medial and lateral canthi, and the leading edge of the nictitating membrane is visible at the medial canthus. **B,** Equine eye, anterior view. *White arrows* delineate the position of the tactile vibrissae. **C,** Cannulation of the upper and lower nasolacrimal puncta to highlight their location. *White arrows* identify the puncta. **D,** Magnified view of the upper eyelid mucocutaneous junction. *Arrows* delineate the openings of the meibomian gland orifices (*the gray line*). *LC*, Lateral canthus; *MC*, medial canthus; *NM*, nictitating membrane.

adjacent to the eyelid margin. Sebaceous and apocrine glands are present within the skin. There is sparse subcutaneous loose connective tissue between the skin and the eyelid muscles, and this tissue does not contain any fat.[2] Connective tissue surrounds the muscles of the eyelid and blends with the fascial sheaths and orbital septum. Deep to the eyelid musculature is a region of dense connective tissue known as the tarsal plate. The tarsal plate is most pronounced close to the eyelid margins, blends with the fibers of the palpebral ligaments, and provides structural integrity to the eyelids. The tarsal plate is more extensive in the upper eyelid than the lower. The meibomian (i.e., tarsal) glands are embedded within the tarsal plate and provide the outer lipid component to the tear film, which is important in the maintenance of tear film stability.

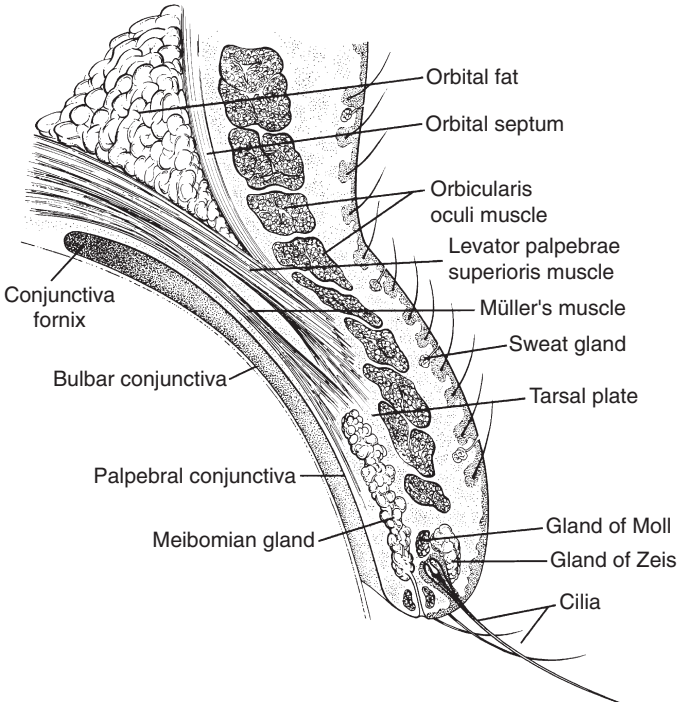

Figure 56-2. Cross-sectional anatomy of the normal upper eyelid.

Musculature and Motor Control

The eyelids are maintained in a roughly elliptical shape by the presence of the lateral and medial palpebral ligaments that restrict movement at the lateral and medial canthi (Figure 56-3). The ligaments originate at the bony orbital rim and insert on the orbicularis oculi muscle. The medial palpebral ligament is a defined fibrous band that overlies the lacrimal sac; the lateral ligament is a wider band containing muscle fibers.[3] The eyelids close in a lateral to medial direction by the contraction of the encircling orbicularis oculi muscle, (see Figure 56-3).[2,3] Opening the eyelids requires the combined action of multiple muscles that insert onto and antagonize the action of the orbicularis oculi muscle. The upper eyelid is larger and more mobile than the lower, and it has greater muscular control. The levator anguli oculi medialis (or corrugator supercilii) muscle inserts a third of the way from the medial canthus and contributes to the asymmetric ellipse of the eyelid aperture.[2] This asymmetry is enhanced during excitement by contraction of the levator palpebrae superioris muscle and levator anguli oculi medialis muscle of the upper lid and the malaris muscle of the lower lid (see Figure 56-3). Müller's muscle in the upper eyelid (in close association with the levator palpebrae superioris muscle) contains smooth muscle innervated by the sympathetic nervous system. The facial nerve (cranial nerve [CN] VII), via the auriculopalpebral and dorsal buccal branches, provides the majority of motor innervation to the eyelid musculature. Exceptions include the levator palpebrae superioris, which is innervated by the oculomotor nerve (CN III), and Müller's muscle, innervated by the sympathetic nervous system.

Sensory Innervation

The trigeminal nerve (CN V) provides sensory innervation to the eyelid skin. The upper eyelid and canthi are innervated by three branches of the ophthalmic division of CN V.[4] The *supraorbital nerve* (a branch of the frontal nerve) emerges from the palpable supraorbital foramen in the zygomatic process of the frontal bone. The *lacrimal nerve* emerges at the dorsolateral aspect of the orbital rim. The *infratrochlear nerve* emerges at a notch in the dorsomedial part of the orbital rim. This nerve also serves the lacrimal caruncle, third eyelid, nasolacrimal puncta, and ducts and areas of the conjunctiva.[3] The lower eyelid is

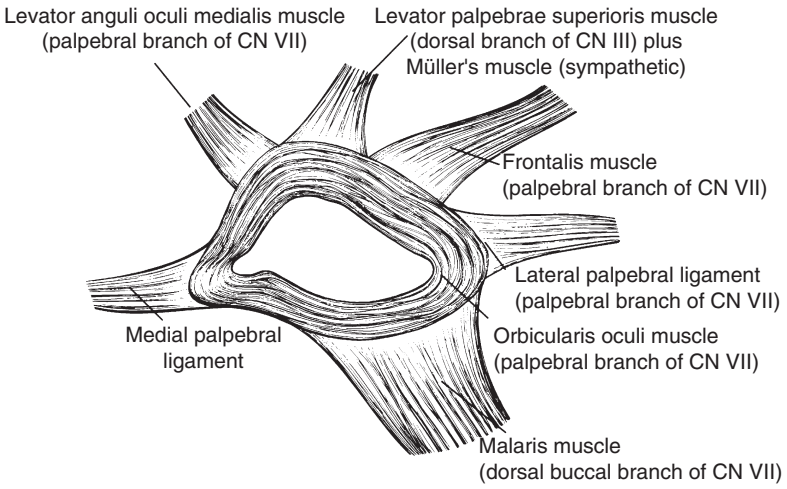

Figure 56-3. Muscles and motor innervation of the equine eyelids.

innervated by the zygomaticofacial branch of the maxillary division of CN V and emerges at the ventral orbital rim.

Vasculature and Lymphatics

The eyelids are well vascularized, which facilitates rapid healing of eyelid injuries. The major arterial supply is derived from the *angularis oculi artery* (a branch of the facial artery) and enters the region at the medial border of the medial palpebral ligament. Accessory arterial supply is provided by the rostral deep temporal artery and branches of the external ophthalmic arteries, including the supraorbital and lacrimal arteries and the malar artery.[2] The major venous drainage occurs via the *infratrochlear vein* (upper eyelids) and the *reflex vein* (lower eyelids and medial canthi), all joining the ophthalmic vein to drain into the internal maxillary vein.[3] The eyelids have significant lymphatic drainage, predominantly to the ipsilateral submandibular and parotid lymph nodes.

Ophthalmic Examination Techniques and Findings

In the investigation of eyelid abnormalities, a systematic approach to diagnosis should always be adopted, including a full bilateral ophthalmic examination and, where indicated, a systemic physical examination. This is particularly important when assessing trauma cases, because significant intraocular disease may be present, which may affect the choice of treatment. Initially a "hands-off" examination to evaluate comfort (epiphora, evidence of self-trauma, blepharospasm, etc.) should be performed. Subtle ocular discomfort or eyelid deformity can be noted by examining the angle of the upper eyelid cilia relative to the surface of the cornea; in an uncomfortable eye with blepharospasm, the angle formed between the cilia and the cornea is more acute.[5] Any asymmetry of eyelid position, swelling or depressions of eyelid or periorbital tissues and should be noted and examined further as necessary. Ptosis in combination with sweating is a consistent symptom of Horner syndrome in horses; enophthalmos and third eyelid protrusion may be less-consistent findings.[6] Vision, eyelid innervation, and eyelid function should be evaluated using the menace response. Both the palpebral and corneal reflexes can be evaluated; it should be noted whether the blink in each test is complete or incomplete. A complete ophthalmic examination should be performed using focal illumination and magnification; a bright light source (Finhoff transilluminator) and magnifying loupes, a direct ophthalmoscope, or a slit lamp biomicroscope are all appropriate choices.

Assuming good general health of the horse, standing sedation can assist with restraint for examination and can be an alternative to general anesthesia for minor surgical procedures. The patient is usually placed in restraint stocks, and cross ties or headrests can be used to achieve greater head stability for surgical procedures. Thoracic auscultation is recommended before sedation because of the cardiovascular suppression induced by sedative agents.[7] Short-duration sedation can be given via intravenous bolus. The α_2-adrenoreceptor agonists detomidine hydrochloride (0.01 to 0.02 mg/kg IV) and xylazine hydrochloride (0.4 to 1.1 mg/kg) each provide analgesia and sedation. Onset of peak activity of xylazine is within 3 to 5 minutes and lasts 30 to 40 minutes at the high end of the dosage range.[7] In fractious animals, a combination of detomidine hydrochloride (0.01 to 0.015 mg/kg IV) and the opioid butorphanol (0.02 to 0.03 mg/kg IV) may provide a deeper plane of sedation with minimal cardiopulmonary depression.[7] Sudden head jerking may occur with the use of opioids in horses, which can be minimized by using them in combination with α_2-adrenoreceptor agonists.[8] A longer duration of sedation may be achieved using detomidine infusions with a loading dose of 7.5 µg/kg followed by a constant-rate infusion of 0.6 µg/kg/minute (infusion rate halved every 15 minutes), providing sedation for up to 135 minutes.[9]

Topical anesthetic may be applied to the eye to facilitate examination and as an adjunct to minor procedures. Proparacaine hydrochloride 0.5% solution has an onset time of 5 minutes and effect duration of 25 minutes following instillation of 0.2 mL of solution.[10] However, even at maximal effect, some corneal sensation remains. Complete corneal anesthesia can be achieved using 0.5% tetracaine ophthalmic preparations (Tetra-Visc, viscous ophthalmic drops, 0.5%) when applied as 2 drops, 1 minute apart.[11] It has an onset time of 5 minutes and effect duration of 60 minutes. In addition to instillation into the conjunctival sac, local anesthetic eye drops can be first applied to cotton-tipped applicator swabs and held in apposition to areas where biopsies or surgical manipulation will be performed.

Regional nerve blocks can be used to provide both motor akinesia and sensory analgesia. Lidocaine hydrochloride 1% or 2% without epinephrine (1 to 2 mL per site[12]) has an onset time of 2 to 5 minutes and effect duration of 1 to 2 hours.[13,14] Mepivacaine hydrochloride has similar onset time but has slightly longer effect duration of 2 to 3 hours.[13,14] Bupivacaine hydrochloride without epinephrine is available in 0.25% to 0.75% concentrations and has an effect duration up to 10 hours.[13,15] After ocular examination, topical lubricants are indicated following instillation of local anesthetic drops and motor or sensory nerve blockade, because tear production and distribution will be impaired.

Motor Blockade

The *upper eyelid akinesis* provided by local blockade of the *auriculopalpebral nerve* facilitates ophthalmic examination and minor adnexal procedures by limiting the palpebral reflex (Figure 56-4). For additional details refer to Chapter 55.

Sensory Blockade

A number of local sensory nerve blocks can be used to anesthetize specific regions of the eyelids (see Figure 56-4).[5,12,14,16] The *central portion of the upper eyelid* is anesthetized using the *supraorbital* block. The supraorbital foramen is palpable clinically as a small depression within the supraorbital process of the frontal bone. The *lateral upper eyelid and lateral canthus* are anesthetized using the *lacrimal* block. A line of local anesthetic is injected along the lateral third of the dorsal orbital rim. The *medial canthus* is anesthetized using the *infratrochlear* block. Local anesthetic is injected through the bony trochlear notch on the dorsal rim of the orbit near the medial canthus.[12] The *lower eyelid* is anesthetized using the *zygomatic* block. A line of local anesthetic is injected along the ventrolateral orbital rim.

Diagnostic Procedures

Radiography, computed topography (CT), or magnetic resonance imaging (MRI) should be considered in cases of eyelid trauma when concurrent orbital fractures or draining tracts are suspected.[17] Further details on imaging techniques are provided

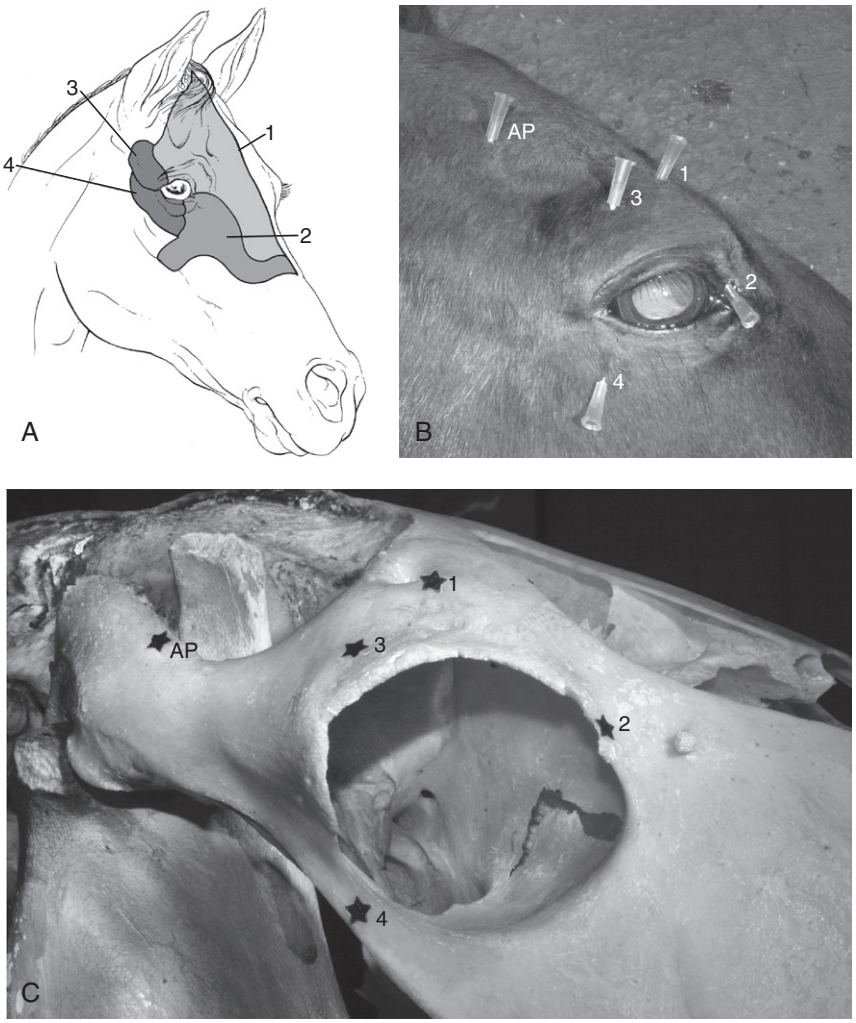

Figure 56-4. An overview of motor and sensory nerve block sites. **A,** Distribution of the sensory innervation of the periocular skin of the horse. **B,** The sites for sensory nerve blockade *(numbers)* and upper eyelid akinesia. **C,** The same sites superimposed onto the equine skull. *AP*, Auriculopalpebral nerve block: motor, upper eyelid; *1*, supraorbital nerve: sensory, central upper eyelid; *2*, infratrochlear nerve: sensory, medial canthus; *3*, lacrimal nerve (line block): sensory, lateral eyelid; *4*, zygomatic nerve (line block): sensory, lower eyelid.

in Chapters 67 to 71. When eyelid neoplasia is suspected, fine needle aspiration or surgical biopsy of masses, suspicious erosions, and regional lymph nodes should be considered to obtain a cell type diagnosis. Eyelid biopsy specimens are commonly fixed in 10% formalin (minimum 10 times the volume of the sample) before submission for histopathology. Suspected infectious eyelid diseases can be thoroughly investigated with impression smears or exfoliative cytology specimens and bacterial or fungal culture with antibiotic sensitivity assessment.

Neoplasia

The differential diagnosis for adnexal neoplasia in the horse commonly includes squamous cell carcinoma, sarcoid, and melanoma[18,19]; less commonly reported connective tissue tumors are fibroma, fibrosarcoma,[20-22] and lymphosarcoma.[23] Other reported tumor types include adenocarcinoma,[22] schwannoma,[24] neurofibroma,[25] plasmacytoma, mast cell tumor, papilloma,[26] and hemangiopericytoma.[27] Neoplasia should be differentiated from blepharitis induced by bacterial, fungal, or parasitic disease including ocular habronemiasis.[28]

Infiltrative periorbital neoplasms may require radical excision, potentially necessitating enucleation or exenteration, periorbital ostectomy, and skin grafting.[29] Although surgical therapy is the principal method of treatment for smaller eyelid masses, *adjunctive therapy* has been widely described in the treatment of periocular squamous cell carcinoma and sarcoids, and it can provide a better clinical response than surgery alone. The choice of adjunctive therapy depends on tumor size and location, availability of equipment, financial considerations, and the clinician's expertise. The choice of therapy should be made in conjunction with a histopathologic diagnosis.

Squamous Cell Carcinoma

The eyelid is a common site for development of adnexal squamous cell carcinoma (SCC) in horses,[24,30,31] and approximately 16% of cases have bilateral lesions.[30] The periorbital location carries a poorer prognosis than other locations on the body, and the eyelid location carries a poorer prognosis for recurrence than the nictitating membrane, nasal canthus, or limbal conjunctival locations.[30] SCC can spread locally, and a 6% to 10.2% rate of metastasis to local lymph nodes is reported.[24,32,33] Metastasis to the thorax and salivary glands has also been reported, although the frequency of this has not been indicated.[34]

Published studies have identified a predilection for draft breeds, Appaloosas, and Paints.[32,35-37] Incidence rises in middle-aged to old animals, with the ocular and skin forms occurring at a mean age of 13 years and 15 years, respectively, which is significantly earlier than penile, vulval, and perianal forms.[37]

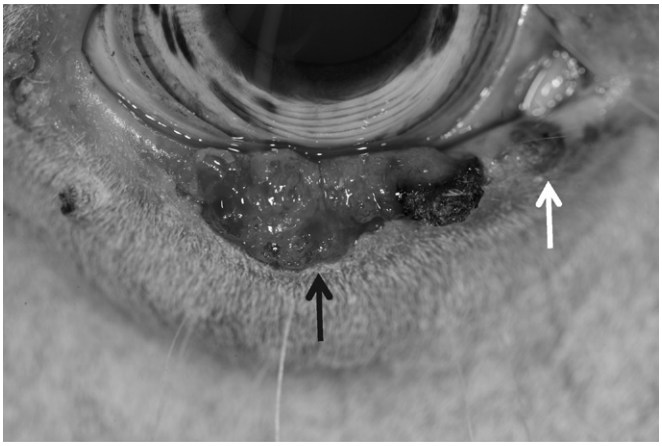

Figure 56-5. A squamous cell carcinoma (*black arrow*) and melanoma (*white arrow*) affecting the lower palpebrum in a horse with no eyelid pigmentation. (Courtesy Dr. Derek Knottenbelt.)

Exposure to ultraviolet light is a risk factor for the development of SCC, with greater incidence in sunny locations and higher altitudes.[35] Animals with minimal or no periocular pigmentation are at increased risk (Figure 56-5).[26,35] Solar-induced epithelial hyperplasia and squamous metaplasia often precede the development of carcinoma *in situ* (where the tumor has not yet invaded through the lamina propria of the epithelium) and overt SCC.[38] Tattooing of the equine eyelids and third eyelid to prevent the development of SCC has been described, lasting 2 to 3 years.[39] There has been no prospective study in horses to show the extent of protection that tattooing provides against solar radiation damage, although there are reports in humans of SCC forming within tattooed skin.[40,41]

Recurrence is a concern following surgical excision, and one study determined a recurrence rate of 68.2% with excision alone.[31] A large study conservatively estimated a survival time of 47 months for animals affected with adnexal SCC.[30] The prognosis is markedly reduced following one or more recurrences.[30] Lesions smaller than 1 cm in diameter and 0.2 cm in depth can be managed successfully using cryotherapy, radiofrequency hyperthermia, beta radiation, or laser ablation treatment, whereas lesions with a surface area of 1 to 2 cm and depth greater than 0.2 cm require cryosurgery, laser ablation, interstitial radiotherapy, or serial cisplatin injections.[19] Enucleation or exenteration should be considered for large, infiltrative lesions. Studies evaluating adjunctive therapies are detailed in Table 56-1. For information of SCC in other areas, please see Chapter 29.

Sarcoids

Although not classified as malignant, sarcoids are common, locally invasive fibroblastic neoplasms that frequently recur following therapy. Periocular sarcoids can cause ocular irritation and swelling of the eyelids, impairing function and abrading the cornea.[42] A previous study found that 14% of sarcoids occur exclusively in the periocular region, and of these, 78% are unilateral and 67% affect the upper eyelid.[42] Sarcoids can be divided into five broad categories: occult, verrucose, nodular (types a and b), fibroblastic (types a and b), and mixed.[42,43] Specific clinical features may indicate which type of sarcoid is present,[44] as outlined in Table 56-2. Biopsy or injury of sarcoids can result in the development of a more-aggressive tumor type.[44] Sarcoids usually develop in young horses between 3 and 6 years of age.[42] Quarterhorses, Appaloosas, Arabians, and Thoroughbreds may be at increased risk, and Standardbreds and Lipizzaner have a reduced risk.[45,46] Bovine papillomavirus infection has been associated with sarcoid development.[43,47-49] The prognosis for periocular sarcoid should be considered guarded because recurrence despite aggressive therapy is common.[5]

Summaries of the *adjunctive therapy* options are outlined in Table 56-3. Surgical debulking has been recommended before many of the adjunctive therapies described. Connective tissue tumors such as fibromas, fibrosarcomas, and neurofibromas should be treated in similar manner to sarcoids, because the success of surgical excision alone is poor.[19] For information on sarcoids located in other areas, see Chapter 29.

Anesthetic Considerations

In cases of trauma where eyelid lacerations have occurred, evaluation should be made regarding the presence and extent of orbital fractures that in extreme cases may involve the cranial cavity. This may affect the animal's demeanor and level of awareness, the timing of which can lag behind the initial injury.[50] Therefore sedation should be used with caution in cases where severe head trauma is suspected (to avoid iatrogenic cerebral edema). Trauma could also involve paranasal sinuses, and in these cases, airway inflammation, hemorrhage, or both could increase the potential for anesthetic complications. Anesthetic recovery should be as smooth as possible, and padded helmets can protect surgical sites during recovery.[51]

Required Surgical Equipment

Standard equipment useful for eyelid surgery is outlined in Table 56-4 and shown in Figure 56-6. Ophthalmic instruments should be kept in a protective container with plastic or foam compartments to protect the fine tips of these instruments. Instruments should be cleaned carefully using fine brushes.

Recommended suture materials are listed in the later descriptions of individual procedures. Most eyelid procedures can be performed using reverse cutting needles, and swaged suture materials minimize tissue drag. Firm monofilament sutures such as nylon should be used with caution close to the cornea to prevent abrasions.

Additionally, cellulose sponges (Weck-Cel, Medtronic, Jacksonville, FL) or cellulose sticks can be used to absorb fluids without damaging the ocular structures. Throughout surgery, regular application of balanced salt solution to the corneal surface is recommended to prevent corneal desiccation. Cautery is often beneficial because the eyelids are highly vascularized. Cryotherapy units used in general surgery can be used for ophthalmic interventions. Liquid nitrogen, carbon dioxide, or nitrous oxide units can be used. Magnifying loupes with or without a light source are useful, and are available with magnifications from ×1.5 to ×5. Loupes should have a comfortable working distance between 20 and 30 cm.

Relevant Pharmacology

Tetanus vaccination status should be established in all cases of trauma, and vaccine or tetanus antitoxin should be administered where the status is unknown or a booster is overdue. If

TABLE 56-1. Summary of Adjunctive Therapies Published for the Treatment of Periocular Squamous Cell Carcinoma

Treatment	Number of Periocular Cases	Stage of Disease	Protocol	Outcome	Reference
Surgical excision alone	22	Not specified	Not specified	68.2% recurrence over mean follow-up time of 313.9 days	31
Cryotherapy	1	2 cm × 2 cm	Not well specified, likely circulating freeze tip with liquid nitrogen. Double freeze-thaw to −20° C to −40° C	No recurrence in 6 months	93
	2	Not specified	Surgical debulking performed	100% recurrence	36
	1	Large tumor in multiple locations	Liquid nitrogen solid probe, 2 freeze-thaw cycles to −20° C, extending 2 to 5 mm beyond margin	Marked improvement within 4 weeks, no comment on resolution	94
	25	Not specified	Double freeze-thaw cycle	40% recurrence over mean follow-up time of 313.9 days	31
Hyperthermia	1	Large, extending into orbit from medial canthus	Initial hyperthermia (1.5-cm, 2-pronged probe in 3 sites for 30 sec) followed by implantation of 12 evenly spaced ^{198}Au seeds; entire treatment repeated after 9 weeks. Hyperthermia repeated 6 weeks later	No recurrence 3 years after treatment	95
	15 ocular or periocular	Not specified	6 surgically debulked	75% nonrecurrence 8 weeks in small tumors not excised, 33% regression in group that had surgery and hyperthermia	32
	8 including ocular, third eyelid, and eyelid	Not specified	Debulked tumors more than 3 mm depth; piercing probe or combination of piercing and surface probes for eyelid masses, using radiofrequency probe with a tissue temperature of 50° C	75% nonrecurrence for minimum 8 weeks	96

TABLE 56-1. Summary of Adjunctive Therapies Published for the Treatment of Periocular Squamous Cell Carcinoma—cont'd

Treatment	Number of Periocular Cases	Stage of Disease	Protocol	Outcome	Reference
Chemotherapy-intralesional	3	Not specified	Cisplatin 1 mg/cm^3 in an oil/water suspension every 2 weeks for 4 treatments	Mean nonrecurrence of 14 months, 1 year nonrecurrence of 65%	97
	13	Stage T2 (2 to 3 cm diameter involving full eyelid thickness)	4 times at 2-week intervals with slow release formulation of 1 mg/cm^3 cisplatin in oil/water emulsion	1 year nonrecurrence of 93%	33
	13	Stage T2 (2 to 3 cm diameter involving full eyelid thickness)	4 times at 2-week intervals with slow release formulation of 1 IU/cm^3 bleomycin in oil/water emulsion	1 year nonrecurrence of 78% (no significant difference in recurrence compared with cisplatin in same study)	33
	3	Not specified	Debulking of larger tumors and implantation of 3-mm degradable beads containing 7% cisplatin at 1.5-cm intervals, mean of 2 treatments	Two thirds had no recurrence for at least 2 years	22
	103	Not specified	Surgical debulking for larger tumors followed by cisplatin 1 mg/cm^3 in an oil/water suspension every 2 weeks for 4 treatments	Periocular cases not examined separately; **cisplatin alone:** 2-year nonrecurrence = 95%, 5-year nonrecurrence = 85%; **with surgery:** 2-year nonrecurrence = 79% to 100%, 5-year nonrecurrence = 78.5% to 100% (depending on timing of treatment and extent of residual disease); prior cryotherapy negatively affected prognosis	98
Immunotherapy	1	Highly invasive involving upper and lower eyelids	Intralesional injection of BCG cell wall fraction 6 weeks following unsuccessful cryotherapy, repeated 1, 3, 7, 14, 19 weeks later	Evidence of lymph node metastasis at final examination	99
Gamma radiation	52	15 = T1 (<2 cm diameter), 29 = T2 (2 to 5 cm diameter), 8 = T3 (>5 cm diameter)	Mean radiation dose of 62.7 Gy administered over 4.8 to 8.9 days using ribbons containing 1-cm spaced ^{192}Ir seeds placed at 0.8 to 1.2-cm intervals in a single or double plane	Mean nonrecurrence 46 months; 1-year nonrecurrence 81.8%, 5-year nonrecurrence 63.5%	100
	1	2 cm × 0.5 cm	Debulking of large tumors, implantation of 0.8-mm diameter ^{198}Au grains delivering total dose of 70 Gy	Lymph node metastasis evident 4 months following treatment	21
	20	Not specified	Surgical debulking followed by ^{90}Sr application 250 Gy extending at least 2 mm beyond edge of margin, repeated until no growth is seen	89% nonrecurrence at 1 year	101
Photodynamic therapy	10	Size range of 0.25 to 20 cm^2	Surgical resection, infiltration with HPPH, irradiation with 665-nm diode laser	Nonrecurrence interval of 25 to 68 months	102

BCG, Bacille Calmette-Guérin; *HPPH*, 2-[1-hexyloxyethyl]-2-devinyl pyropheophorbide-a.

TABLE 56-2. Clinical Characteristics of Different Types of Equine Sarcoids

Type of Sarcoid	Predilection Sites	Clinical Appearance
Occult	Head, neck, hairless skin	Circular, alopecic with small cutaneous nodules and/or mild hyperkeratosis
Verrucose	Face, axilla, groin	Hyperkeratosis, prominent scaling, resemble papillomas or fibropapillomas
Nodular type A	Not described	Firm, well-defined subcutaneous spherical nodules, **no** dermal involvement
Nodular type B	Not described	Firm, well-defined subcutaneous spherical nodules, **clear** dermal involvement
Fibroblastic type 1 (pedunculate)	Groin, eyelid, lower limbs, coronet, site of previous skin trauma or other sarcoid	1a: narrow neck with only superficial involvement 1b: narrow neck with deep and superficial involvement
Fibroblastic type 2 (sessile)	Groin, eyelid, lower limbs, coronet, site of previous skin trauma or other sarcoid	Broad, locally invasive base
Mixed (progressive state between verrucose/occult and fibroblastic/nodular)	Not described	Very variable appearance
Malignant/malevolent	Jaw, face, elbows, medial thighs	Often follows biopsy or trauma of fibroblastic mass. Invasive, metastasize readily to lymph nodes

TABLE 56-3. Summary of Adjunctive Therapies Published for the Treatment of Periocular Sarcoid—cont'd

Treatment	Number of Periocular Cases	Type of Sarcoid	Protocol	Outcome	Ref.
Intralesional chemotherapy	12	Not specified	Cisplatin 1 mg/cm^3 in an oil/water suspension every 2 weeks for 4 treatments	Mean nonrecurrence, 21.6 months; 1 year nonrecurrence of 87%	97
	18	Fibroblastic, extensive nodular	Cisplatin 1 mg/cm^3 at 5- to 7-day intervals for up to 6 treatments	33% resolved (all nodular)	42
	4	Not specified	Debulking of larger tumors and implantation of 3 mm degradable beads containing 7% cisplatin at 1.5 cm intervals, mean of 2.4 treatments	75% had nonrecurrence for at least 2 years	22
	5 on head	Not specified	5-fluorouracil 50 mg/cm^3, 2 to 7 treatments	60% resolved	106
	103	Not specified	Surgical debulking for larger tumors followed by cisplatin 1 mg/cm^3 in an oil/water suspension every 2 weeks for 4 treatments	Periocular cases not examined separately; **cisplatin alone:** 2-year nonrecurrence = 97%, 5-year nonrecurrence = 93.7%; **with surgery:** 2-year nonrecurrence = 89% to 100%, 5-year nonrecurrence = 87.5% to 100% (depending on timing of treatment and extent of residual disease); prior cryotherapy negatively affected prognosis	98
Bacille Calmette-Guérin vaccine	26	Not specified	Surgical debulking for large tumors, 1 mL/cm^3 of 0.75 mg/mL BCG cell-wall fraction, 1 to 6 treatments	No recurrence in 24 months	107
	1 head, 1 eye	Not specified	BCG cell-wall fraction, 3 to 4 treatments	No recurrence in 20 months in eye case, 50% reduction in size in 11 months in head case	105
	3 on head	Not specified	Live BCG vaccine, 5 to 6 treatments	No recurrence in 66% cases in 12 and 18 months, respectively; 90% "remission" in 18 months in 1 case	105
	7, 3 with histological confirmation	Not specified	2 to 7 treatments of intralesional 0.75 mg/mL BCG cell wall fraction 1 to 10 mL	Nonrecurrence of 53 to 260 days	108
	1	Nodular type B	5 treatments of 10 mL intralesional every 2 weeks	No recurrence 2 years	109
	309	Occult, verrucose (26) Nodular, fibroblastic, mixed (283)	Intralesional 1 mL/cm^2 of tumor surface every 2 to 4 weeks	Verrucose, occult, mixed: 58% worsened, 39% static, remainder improved not resolved. Nodular/fibroblastic: 69% complete resolution	42

TABLE 56-3. Summary of Adjunctive Therapies Published for the Treatment of Periocular Sarcoid—cont'd

Treatment	Number of Periocular Cases	Type of Sarcoid	Protocol	Outcome	Ref.
Autologous tumor vaccine	6 on head	3 verrucose, 1 fibroblastic, 2 mixed	Surgical debulking, autologous vaccine made from minimum 10 g tumor tissue with tuberculin adjuvant, injected intradermally in both sides of neck 1 to 2 weeks following tumor excision, minimum 3 treatments, 4 weeks apart until healing is complete	No recurrence in 12 to 30 months in 3 horses treated for the first time, 9 to 48 months nonrecurrence in 3 animals treated with already-recurrent disease	110
Gamma radiation	2	Not specified	Debulking of large tumors, implantation of 0.8-mm diameter ^{198}Au grains delivering total dose of 70 Gy	No recurrence in 18 months and 3 years	21
	14 periorbital	Not well defined; 6 defined as T2 = 2 to 5 cm diameter or minimal invasion, 8 defined as T3 = >5 cm diameter or subcutaneous invasion	Large tumors debulked 52 to 76 Gy total dose administered over 4 to 14 days using ribbons containing 1-cm spaced ^{192}Ir seeds placed at 0.75 to 1.25 cm intervals in a single or double plane	No recurrence in 6 to 41 months, 1 year nonrecurrence 94%	111
	63 (27 recurrent)	Not well defined: 12 = T1 (<2 cm diameter), 27 = T2 (2 to 5 cm diameter), 24 = T3 (>5 cm diameter)	Mean radiation dose of 62.7 Gy administered over 4.8 to 8.9 days using ribbons containing 1 cm spaced ^{192}Ir seeds placed at 0.8 to 1.2 cm intervals in a single or double plane	Mean nonrecurrence of 49 months, 1 year nonrecurrence 86.6%, 5 year nonrecurrence 74%	100
	66	Nodular, fibroblastic, mixed	^{192}Ir rods delivering 70 to 90 Gy, *in situ* for 10 to 14 days	1 year follow-up: 100% no recurrence Long-term follow-up (3 to 14 years): 98% no recurrence	42
	8	Nodular, fibroblastic, mixed, verrucose	Implanted ^{192}Ir rods delivering 45 to 70 Gy	Median nonrecurrence rate of 14.5 months	112
Beta radiation	3	Single/superficial verrucose, occult	Strontium plaque wand delivering 100 Gy over 5 days (5 minutes twice daily)	1 to 4 year follow-up: no recurrence at treated site	42

AW4-LUDES, A Derek Knottenbelt homemade cocktail; *BCG*, Bacille Calmette-Guérin.

eyelid function is compromised, topical artificial tear supplement ointment should be applied regularly to the corneal surface to prevent corneal desiccation.[5] Antibiotics may be required as prophylaxis in the perioperative period or to address active or suspected infection. The hospitalization status and demeanor of the horse along with the results of cytological examination, cultures, and sensitivity testing, if available, will factor into selection of antibiotic class and route of administration. A subpalpebral lavage device is frequently used to deliver liquid topical medications and is particularly helpful in fractious patients. Further discussion of antibiotic selection is provided in Chapter 7 and in current ophthalmology texts.

Systemic anti-inflammatory medications should be considered in the treatment of adnexal disease, particularly following trauma and surgery. Perioperative flunixin meglumine can be administered intravenously, intramuscularly, or orally (maximum dosage 1.1 mg/kg every 12 to 24 hours for approximately 24 to 48 hours, followed by 0.5 mg/kg for up to 5 days).[52] Phenylbutazone can be administered intravenously or orally (maximum dosage 4.4 mg/kg every 12 hours for 24 to 48 hours, followed by 2.2 mg/kg every 12 hours for up to 5 days). Systemic nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with renal and gastrointestinal damage;[53] therefore, maximum doses should be used for a short duration, and

the doses should be reduced as soon as clinically indicated. Particular caution should be used in patients with systemic illnesses such as dehydration.

Surgical Techniques

For most adnexal procedures performed under general anesthesia, the horse is placed in lateral recumbency with the nose elevated using foam wedges or sandbags to maintain the palpebral fissure in a horizontal position. The periocular area is clipped and cleaned using a 1 : 50 dilution of 10% povidone-iodine solution (Betadine, Purdue Pharma, Stamford, CT). The conjunctival sac should also be rinsed with similarly diluted povidone-iodine solution and the area subsequently irrigated with sterile physiologic saline. Cotton or paper quarter drapes should be used surrounding the eye, and their size should be sufficient to prevent contamination from the surrounding surgically unprepared skin of the head and neck. A second paper or plastic adhesive fenestrated drape is placed over the quarter drapes.

Temporary and Permanent Tarsorrhaphy

A tarsorrhaphy is indicated to protect the cornea in cases of facial nerve paralysis or in other situations where blinking is impaired (e.g., severe eyelid trauma). Tarsorrhaphy may provide additional support to the cornea following intraocular surgery.

Temporary tarsorrhaphy is the most frequently used technique and can be performed under general anesthesia or using standing sedation and local anesthesia. The eyelids should be surgically prepared. Three or four horizontal mattress sutures using 2-0 or 3-0 monofilament nylon are usually placed, starting the sutures in the upper eyelid (Figure 56-7). The eyelid sutures should emerge at the meibomian gland orifices (the "gray line") so that neither eversion nor inversion of the eyelids occurs, both of which can predispose to corneal abrasion. The medial canthus can be left slightly open to facilitate the application of topical ophthalmic ointments. Plastic tubing or buttons should be used as stents to prevent the sutures from tearing through the eyelid.

Partial *permanent tarsorrhaphy* may be indicated in cases of prolonged facial nerve paralysis. In this procedure, a limited length of the eyelid margins is excised and sutured together, resulting in surgical apposition (Figure 56-8). The procedure otherwise is similar to performing a temporary tarsorrhaphy, although sutures can be removed after 10 to 14 days. If the underlying disease process resolves and the tarsorrhaphy is no longer required, the site of apposition is incised using scissors to restore a normal palpebral fissure.

Entropion

Entropion is an inward turning of the eyelid. It is uncommon in horses relative to other affected species, but is most frequently seen in foals.[54,55] Entropion can be *congenital* (secondary to microphthalmia or atypical development[5]) or *acquired* (secondary to trauma, scarring, dehydration or wasting, phthisis bulbi, or prolonged blepharospasm) and can affect one or both eyelids. The lateral margin of the lower eyelid is most commonly affected. Entropion can result in contact between the haired skin or cilia and the cornea or conjunctiva, causing irritation (trichiasis). The most common presenting signs include ocular discomfort (blepharospasm, lacrimation), keratitis, or conjunctivitis. Topical lubricants, used as a protective barrier for the cornea, may be sufficient to manage mild transient cases of entropion in foals,[54] although some require the placement of temporary everting sutures.

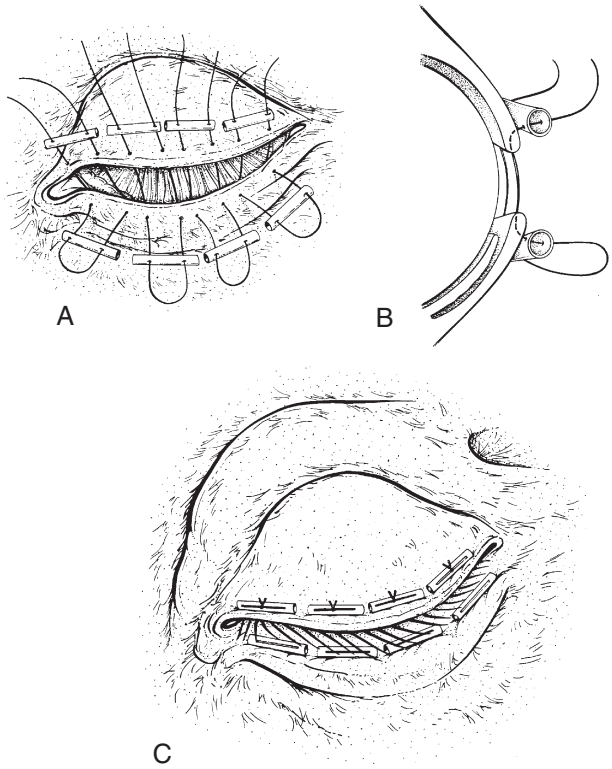

Figure 56-7. Temporary tarsorrhaphy. **A,** Sutures should be preplaced to distribute tension. **B,** Sutures should be placed at partial thickness, crossing the eyelid margin at the level of the meibomian gland openings. **C,** Sutures are tied. The use of stents reduces the risk of sutures cutting into the eyelids.

EVERTING SUTURES

This procedure will *temporarily* limit corneal irritation secondary to the entropion. If the entropion is persistent, permanent surgical correction may be warranted. Vertical mattress sutures are placed using monofilament nonabsorbable suture (e.g., 2-0 to 4-0 monofilament nylon). To accurately place the sutures, the entropion is everted to a normal position and a single vertical bite of eyelid skin is taken approximately 1 to 2 mm from the eyelid margin (Figure 56-9). A similar vertical bite of distal eyelid skin is taken. The distance between the bites determines the extent of eversion of the eyelid, so this bite should be positioned with care, and the suture must be replaced if insufficient or excessive eversion is achieved once the suture is tied. Sutures should be placed at approximately 0.5-cm intervals along the area of entropion. Care should be taken to ensure that the cut ends of the sutures are not at risk of irritating the cornea, and cyanoacrylate glue can be applied to the knots to ensure they remain in place.[52] Sutures are typically removed after 2 to 4 weeks.[52]

MODIFIED HOTZ-CELSUS PROCEDURE

This procedure should be performed when *permanent* correction is required. In foals, this procedure should be performed as late in life as possible because of the risk of overcorrection resulting

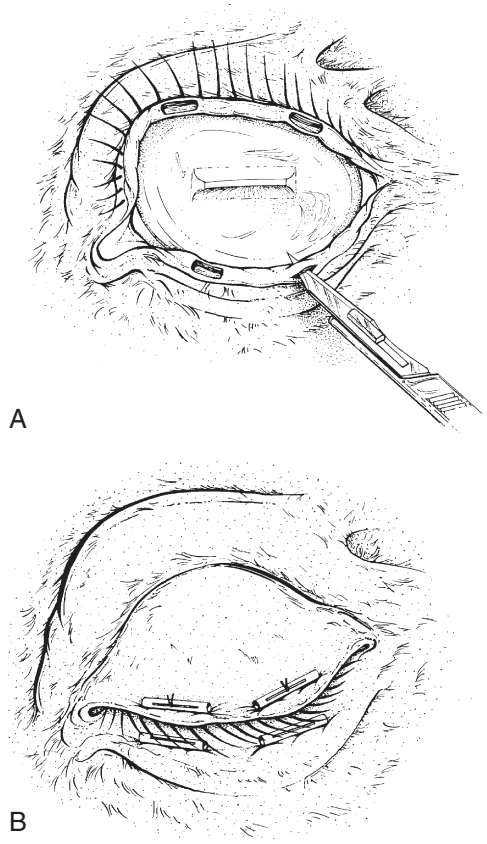

Figure 56-8. Permanent tarsorrhaphy. **A,** Opposing areas of eyelid margin (approximately 3 mm long) are excised with a No. 11 Bard-Parker scalpel blade. **B,** Sutures are placed in the areas of excised margin. Sutures should be left in place for 3 weeks to allow eyelid adhesion.

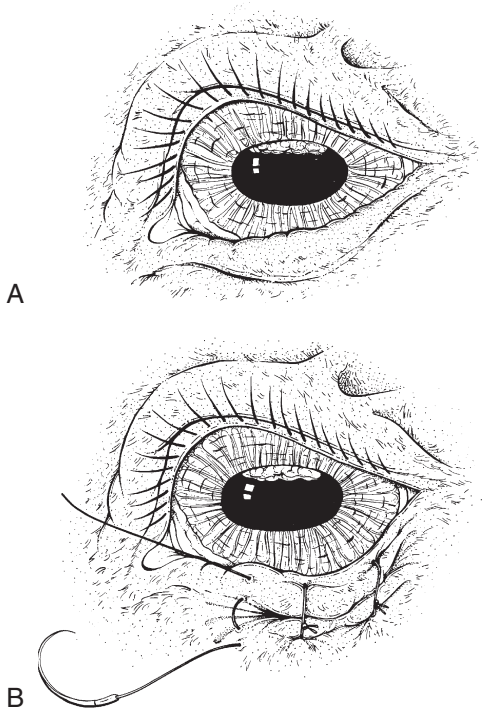

Figure 56-9. A, Entropion of the lower eyelid. **B,** Temporary stay sutures for correction of entropion. Vertical mattress sutures are placed perpendicular to the eyelid margin. The initial bite is taken close (2 to 3 mm) to the eyelid margin. Sutures should be preplaced to distribute tension equally. Knots should be placed away from the eyelid margin to avoid contact with the cornea.

from subsequent growth of the head and face. To effectively plan the extent of surgical correction required, topical anesthetic should be applied and a motor nerve block should be performed to eliminate any spastic entropion related to ocular pain and determine the true extent of the anatomic abnormality.[5,56]

A Jaeger lid plate can be used to support the eyelid, and helps to improve the accuracy of the incision. An incision is made through the skin and orbicularis oculi muscle, parallel to and approximately 2 to 3 mm from the eyelid margin (Figure 56-10). A second elliptical incision is made proximal to the initial incision, and the skin and orbicularis oculi muscle between the incisions is excised. The distance between the two incisions determines the extent of correction of the entropion. Care should be taken not to remove excessive skin initially, because further skin can be subsequently removed. A slight undercorrection is usually appropriate because scarring will increase correction.[5,56] Closure is performed using 4-0 to 6-0 polyglactin 910 suture in a simple-interrupted pattern, with sutures oriented radially away from the cornea. Sutures are placed initially at the widest central portion of the incision to determine the degree of correction. Suture tags should be oriented to prevent contact with the corneal surface. If too little tissue is removed, undercorrection will result in persistent entropion. Ectropion caused by overcorrection can cause exposure keratitis and ulceration.[56] Significant eyelid swelling is

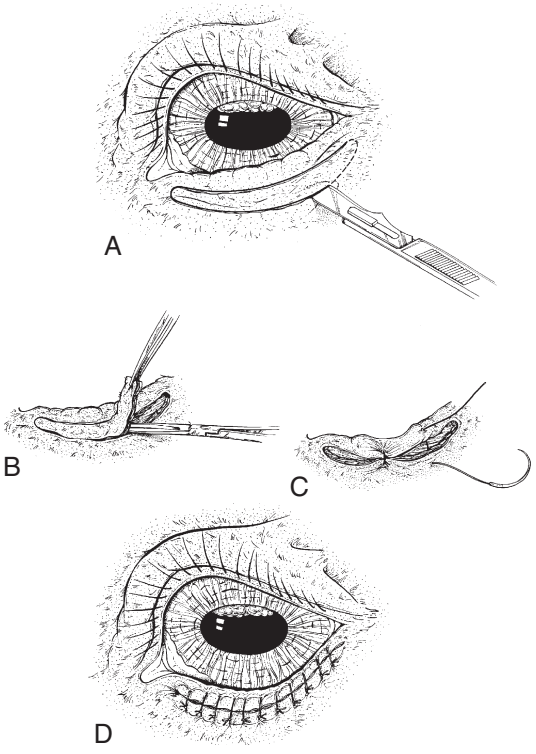

Figure 56-10. Modified Hotz-Celsus procedure for entropion repair. **A,** The initial incisions of the skin and orbicularis oculi muscle are made with a scalpel. **B,** The skin and superficial orbicularis oculi muscle are excised with scissors. **C,** A single-layer closure, starting at the center, incorporates both skin and orbicularis oculi muscle. **D,** Postoperative appearance.

common after surgery and generally resolves within the first 2 weeks postoperatively.

Ectropion

Ectropion is an out-turning of the eyelid. This results in increased exposure of the cornea and conjunctival surfaces that may result in corneal desiccation and inadequate distribution of tears. Ectropion is most commonly associated with scar formation secondary to trauma or previous surgery. The V-to-Y–plasty is useful to correct ectropion (Figure 56-11). A V-shaped incision is made in the eyelid skin, proximal to the eyelid margin, and underlying scar tissue is removed. The incision is then closed as a Y, causing the eyelid margin to roll in immediately adjacent to the surgical site, correcting the ectropion.

Distichia

Distichia are rare in horses and result from aberrant eyelid cilia that emerge from the eyelid margin, usually from the meibomian gland orifices.[57] They can cause corneal trauma and ulceration if untreated. Cilia can be removed under general anesthesia using an operating microscope. The cilia follicle is destroyed, preventing further regrowth using electroepilation or cryotherapy. If cryotherapy is used, a 4-mm probe is placed on the palpebral conjunctival surface, approximately 3 to 4 mm from the eyelid margin (at the base of the meibomian glands). Two freeze-thaw cycles should be completed to maximize destruction of the follicles. Cilia should not be resistant to epilation if effective follicular destruction has been achieved. Cilia too short to be visualized at the time of surgery cannot be treated; therefore the potential for repeated surgeries should be discussed with the owner. Other treatment options include partial tarsal plate excision[58] (although significant eyelid scarring can ensue) and for focal areas, wedge excision.

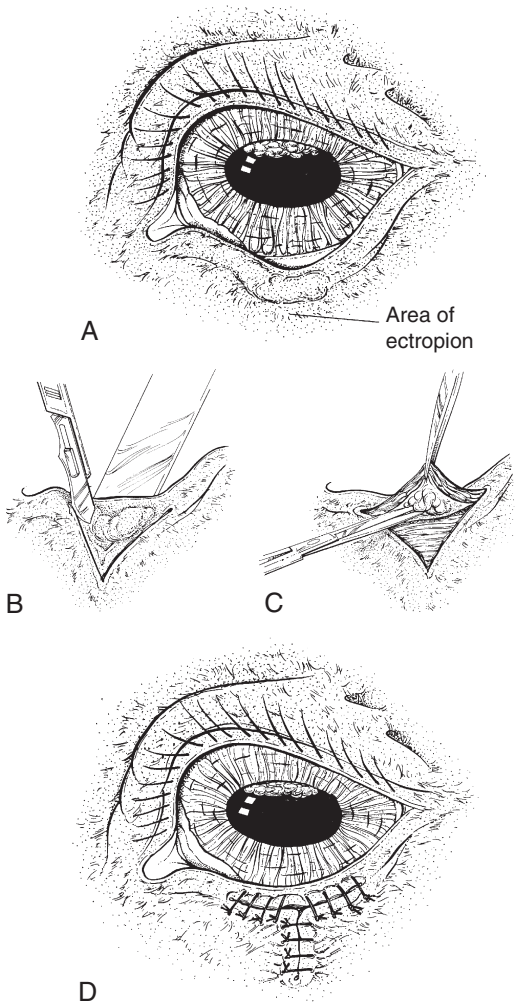

Figure 56-11. V-to-Y correction for ectropion. **A,** The area of ectropion is identified. **B,** The V-incision is made with a scalpel. **C,** The skin flap is elevated, and underlying cicatricial tissue is excised using scissors. **D,** The skin flap is advanced to relieve skin tension. Closure is performed in a Y pattern.

Ectopic Cilia

Ectopic cilia are also rare in horses and result from aberrant eyelid cilia emerging through the palpebral conjunctiva, causing considerable corneal irritation. In one series of seven cases, ectopic cilia were most common in the upper eyelid between the 10 o'clock and 2 o'clock positions.[59] For ectopic cilia, the treatment of choice is surgical excision.[59] The eyelids are immobilized using a Desmarres chalazion clamp, followed by sharp excision of the surrounding conjunctiva, meibomian gland, and cilia follicle *en bloc* using a Beaver blade (No. 6500). Other treatment options include cryotherapy and electroepilation.

Repair of Eyelid Lacerations

Eyelid trauma is relatively common because of the exposure of the wide-set equine eye and hazards of confinement management. It should be established whether lacerations are full or partial thickness. The eyelids are highly vascular and will bleed extensively and become edematous following trauma. Cold packs applied to the eye for 10 minutes, four to six times a day can help to reduce swelling if tolerated. Anti-inflammatory and prophylactic antibiotic drugs are frequently indicated. The globe should be carefully examined for other trauma, and careful palpation should be performed to evaluate any orbital or facial fractures. Radiography and other imaging methods (MRI, CT) should be considered for confirmation if fractures are suspected. A thorough evaluation for potential foreign bodies should be performed. Lacerations affecting the medial eyelids may involve the nasolacrimal apparatus. Nasolacrimal patency should be confirmed before closure, and nasolacrimal lacerations should be treated as described later.

Lacerations should be thoroughly flushed with a 1 : 50 dilution of 10% povidone-iodine solution followed by sterile physiologic saline before closure. All lacerations should be surgically managed using a two-layer closure, because healing by second intention can create eyelid abnormalities resulting from significant proud flesh and scar formation. Fresh lacerations can be closed immediately but long-standing, potentially infected lacerations should be treated with topical and systemic antibiotics for several days before débridement and closure. Closure can be performed using general anesthesia or with standing sedation and local anesthesia. Débridement of necrotic tissue or extensive granulation tissue is necessary, but excessive débridement should be avoided because of the limited tissue available for closure. Tissue-loss defects affecting less than one third of the eyelid margin can be closed using direct apposition, whereas

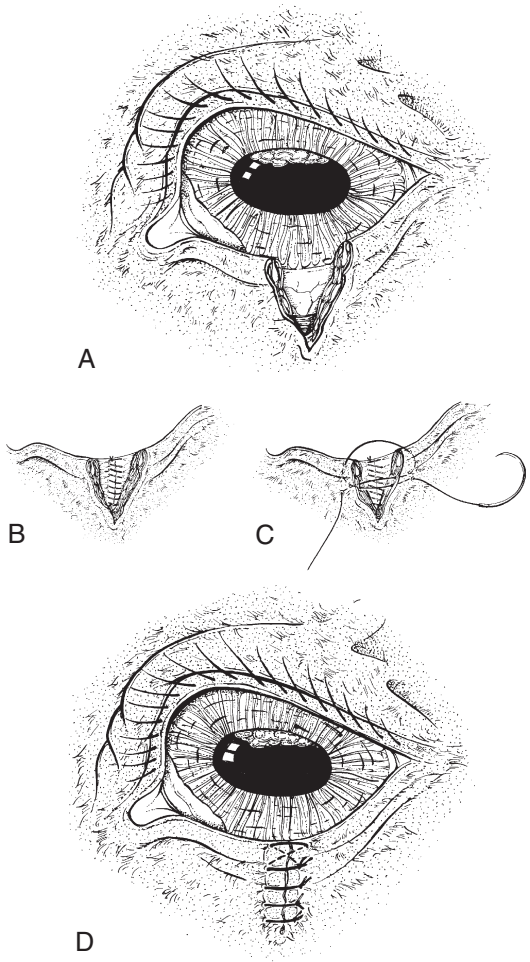

Figure 56-12. Repair of eyelid laceration. **A,** Minimal débridement is performed. **B,** Closure is performed in two layers, starting at the eyelid margin to ensure optimal alignment. **C** and **D,** Skin closure is accomplished with simple-interrupted sutures (4-0 or 5-0). A figure-of-eight suture pattern is useful for closure of the eyelid margin, because it allows suture placement on the eyelid margin, with placement of the knot away from the globe.

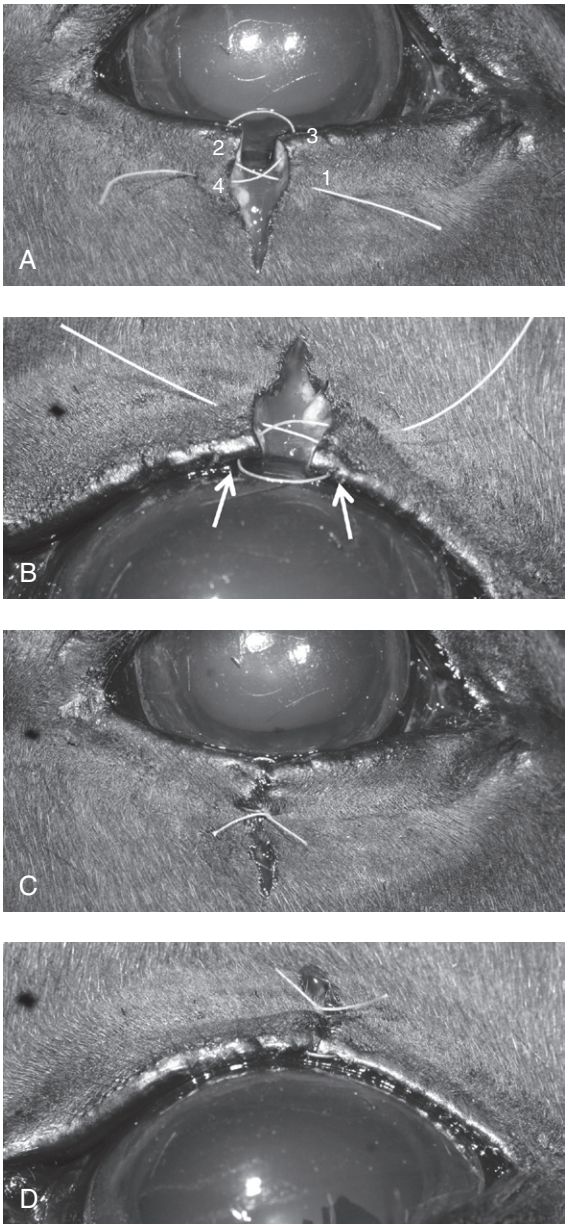

Figure 56-13. The figure-of-eight suture pattern for optimal eyelid margin apposition. **A,** Lateral view. The suture is placed in the numerical order shown, maintaining equal distances with each suture bite. **B,** View from above, illustrating the placement of the suture at the gray line in the eyelid margin (*white arrows*). **C,** Lateral view. The suture is tied and suture tags are positioned away from the corneal surface. The rest of the laceration can be closed using simple interrupted skin sutures. **D,** Shown from above, demonstrating apposition of the eyelid margin.

tissue-loss defects affecting more than one third of the eyelid margin or those close to the lateral or medial canthi may require more complex blepharoplasty procedures (see later). Closure should be performed in two layers, by closing the palpebral conjunctiva first, using a simple-interrupted or simple-continuous suture pattern with 4-0 to 6-0 absorbable suture material, such as polyglactin 910 (Figure 56-12). If the site is infected, nonabsorbable suture material should be used and sutures should be removed after 10 to 14 days. Knots should be positioned away from the palpebral surface of the conjunctiva. The eyelid skin is closed in a simple-interrupted pattern, starting at the eyelid margin to ensure appropriate margin apposition and healing. A figure-of-eight suture pattern (see Figure 56-12 and Figure 56-13) is useful to prevent the suture tags from abrading the cornea. The rest of the eyelid skin is sutured in a simple-interrupted pattern.

AFTERCARE

A protective eye mask with a hard cup may be necessary to prevent rubbing postoperatively. If an eye mask is not adopted, a fly mask should be used until healing is complete. Alternatively, fly repellent ointment can be applied to the skin adjacent to the surgical site.[5] Significant eyelid swelling is common after surgery (Figure 56-14) and generally resolves within the first 2 weeks postoperatively.

Reconstructive Blepharoplasty Techniques

More extensive eyelid lacerations or closure of large defects following removal of neoplasia (removal or loss of greater than one third of the eyelid margin) warrant reconstructive

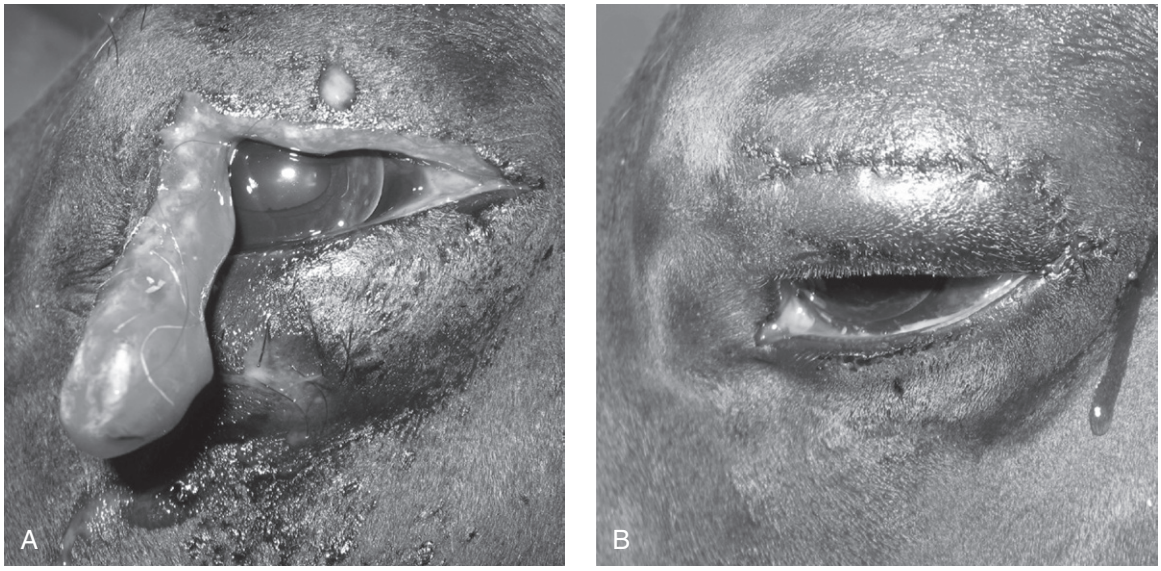

Figure 56-14. A, Example of an eyelid laceration before repair in a horse. **B,** A two-layer closure was performed in the upper palpebral conjunctiva and palpebral skin using absorbable suture material. Wound dehiscence is a risk because of extensive vascular injury.

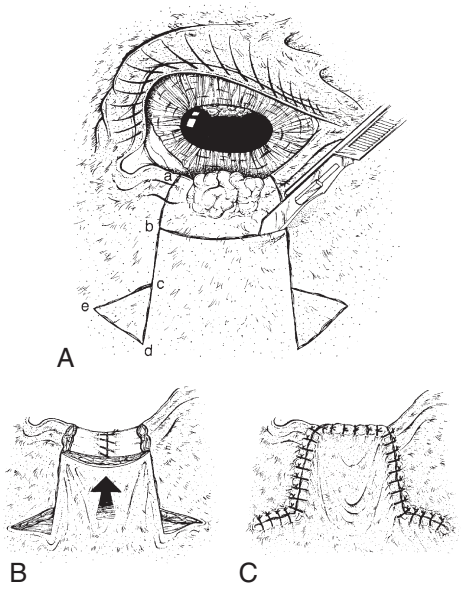

Figure 56-15. Sliding skin flap to repair eyelid defects. **A,** Proportions of incisions should be *ab* = *bc* = *cd* = *de*. **B,** Equilateral triangles of skin are excised, as is the affected portion of eyelid. The skin flap and adjacent skin are undermined with scissors. Adjacent conjunctiva is mobilized and closed with absorbable suture (polyglactin 910 [6-0 Vicryl]). **C,** The skin flap is advanced, and the leading edge of the flap is sutured to the conjunctiva and skin.

blepharoplasty to approximate normal eyelid conformation. This type of surgery frequently warrants general anesthesia.

SLIDING SKIN FLAP

A frequently used blepharoplasty technique is the sliding skin flap (Figure 56-15). Following neoplasia excision or débridement of lacerations, vertical incisions are made in the eyelid skin that extend in height approximately twice the width of the eyelid defect. Slightly diverging incisions compensate for some expected wound contracture. Small triangular portions of skin (Burow's triangles) are excised at the base of the vertical incisions (see Figure 56-15, *A*). These triangles allow closure without skin folds (dog-ears) and help to distribute tension; they should approximate half to the full height of the vertical incision. The surrounding skin, skin flap, and conjunctiva are undermined using blunt dissection, and the skin flap is advanced to the eyelid margin (see Figure 56-15, *B*). Wound contracture should be anticipated, and a slight initial advancement and fixation of the flap past the eyelid margin may provide a better ultimate cosmetic result. The flap is sutured to the conjunctiva at the eyelid margin and to the adjacent skin in a simple continuous pattern using 4-0 to 6-0 absorbable suture (polyglactin 910) (see Figure 56-15, *C*). A temporary tarsorrhaphy may provide additional support during healing.

CONJUNCTIVAL ADVANCEMENT FLAP

In cases of neoplasia or trauma with extensive conjunctival involvement, a conjunctival advancement flap from the opposing eyelid may be required (Figure 56-16). A sliding skin flap is created as detailed previously (see Figure 56-16, *A*). Palpebral conjunctiva from the opposing eyelid is incised approximately 2 to 3 mm from the eyelid margin, measuring the same width as the eyelid defect, and vertical incisions are made toward the conjunctival fornix (see Figure 56-16, *B*). The conjunctival flap is sutured to the remaining conjunctiva in the eyelid defect (see Figure 56-16, *C*). Closure of the sliding skin flap is as previously described. A temporary tarsorrhaphy is required to alleviate tension on the conjunctiva. A second procedure is performed to transect the base of the conjunctival flap and remove the tarsorrhaphy, approximately 1 month following the initial surgery (see Figure 56-16, *F*). This procedure can generally be performed on the standing, sedated horse using local anesthesia.

FULL-THICKNESS EYELID GRAFT

A full-thickness eyelid graft may be required for extensive lesions of the eyelid skin, where sufficient skin cannot be elevated using a sliding skin flap (Figure 56-17). This technique is

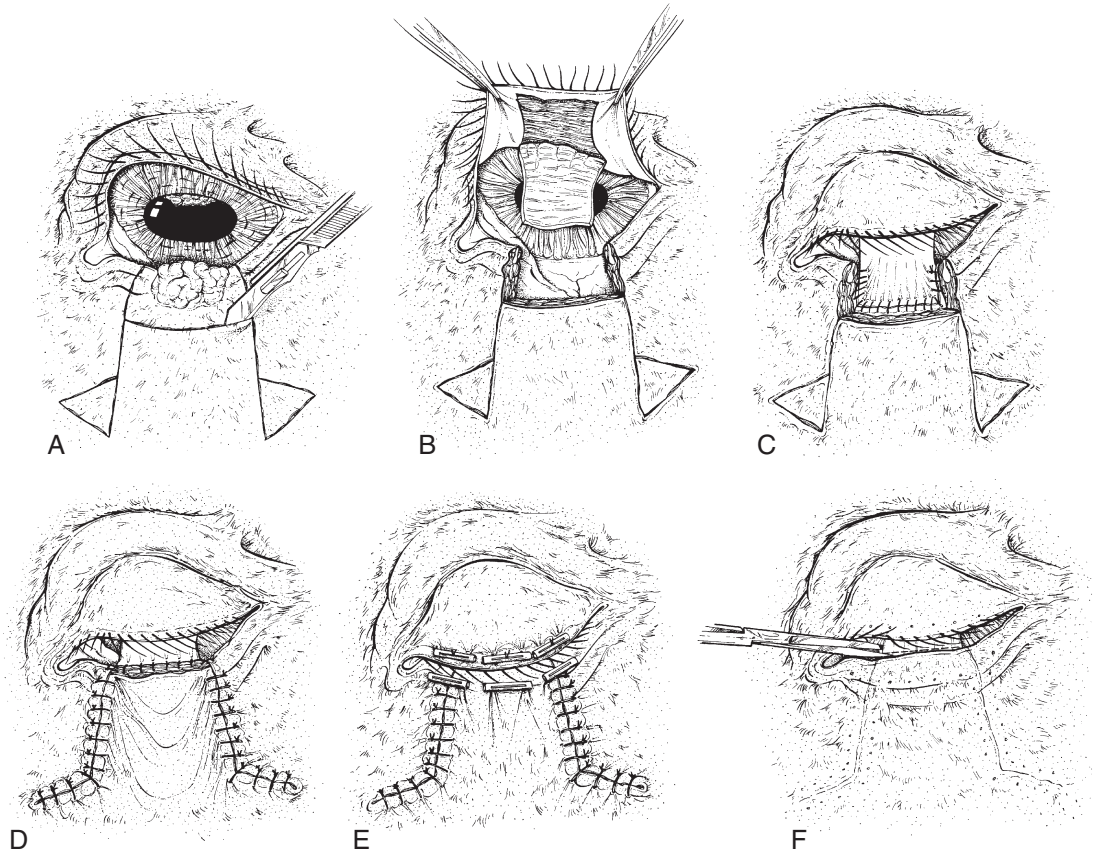

Figure 56-16. Tarsoconjunctival advancement flap. **A,** A skin advancement flap is prepared as in Figure 56-15. **B,** Conjunctiva of the upper eyelid opposite the defect is incised 3 to 4 mm from the eyelid margin and is undermined to create a flap. **C,** The conjunctival flap is advanced and sutured into the defect. **D,** The skin flap is advanced and sutured in place. **E,** A temporary tarsorrhaphy relieves tension on the flaps. The use of stents helps to distribute tension. **F,** After 4 weeks, the tarsorrhaphy is removed and the conjunctival flap is severed at the level of the eyelid margin. The conjunctiva and skin are apposed with a continuous pattern of 6-0 or 7-0 absorbable suture.

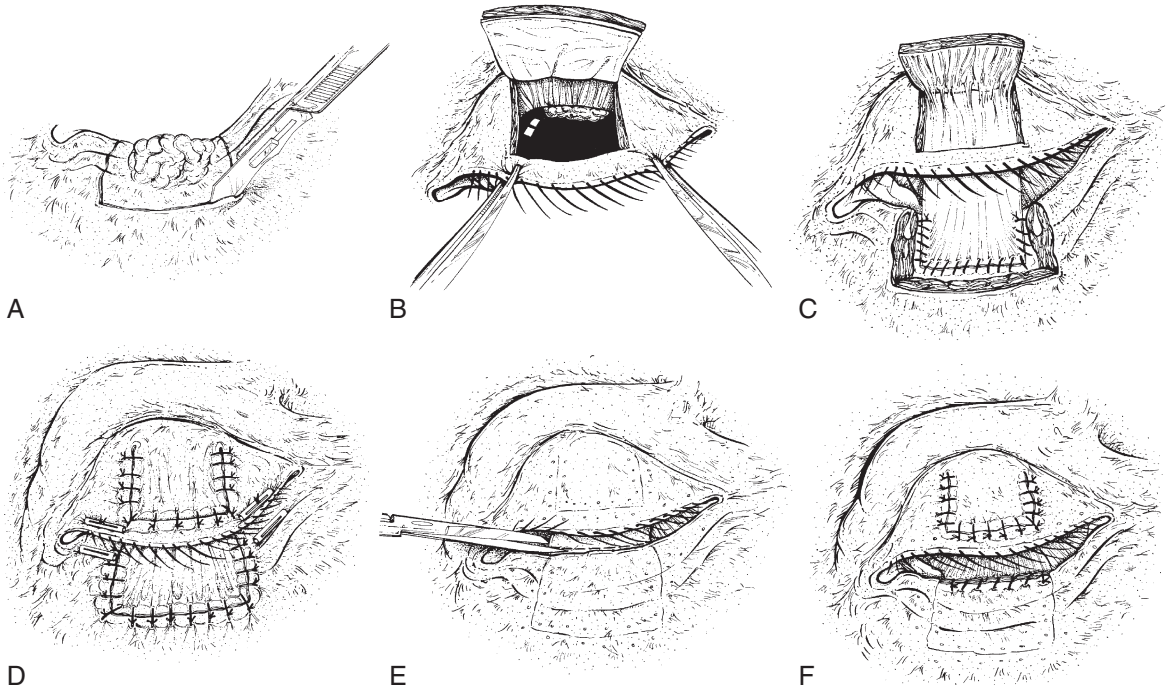

Figure 56-17. Full-thickness eyelid graft. **A,** The area of affected lower eyelid is excised. **B,** The upper eyelid is excised 5 mm above the eyelid margin opposite the defect. **C,** The graft is split into skin and tarsoconjunctival layers. The graft is advanced under the eyelid margin and sutured in place. **D,** The bridging eyelid margin is sutured to the graft. A temporary tarsorrhaphy alleviates tension on the graft. **E,** After adequate healing has occurred, the graft is severed along the intended eyelid margin. **F,** The conjunctiva and skin are apposed along the eyelid margin with a continuous suture pattern. The skin flap is sutured to the bridge to complete the closure.

easier to perform on a lower eyelid defect using the more mobile and extensive upper eyelid as the donor tissue. A sliding skin flap of the lower eyelid can provide partial closure of the defect to be grafted. The width of the graft should be 1 to 2 mm larger than the width of the defect in the opposing eyelid margin. The donor eyelid is incised approximately 5 mm from the eyelid margin (to spare the meibomian glands) (see Figure 56-17, *B*). The flap should be split into skin and muscle, and tarsoconjunctival portions to aid mobility of the tissue. The tarsoconjunctival portion of the graft is sutured to the conjunctival defect in the lower eyelid using a simple-continuous suture of 6-0 polyglactin 910 (see Figure 56-17, *C*). The skin portion of the graft is sutured to the lower eyelid skin defect using 4-0 nonabsorbable suture (e.g., monofilament nylon) (see Figure 56-17, *D*). The bridge in the upper eyelid is sutured to the graft to prevent retraction, and a temporary tarsorrhaphy is placed. In a second procedure, the flap is transected along the new eyelid margin (see Figure 56-17, *E*), and the lower eyelid conjunctiva and skin are sutured using 6-0 absorbable suture material (polyglactin 910) in a simple-continuous pattern (see Figure 56-17, *F*). The donor flap is sutured back within the upper eyelid.

RHOMBOID GRAFT FLAP

Rhomboid and modified rhomboid flaps are used to treat large periocular skin defects in human patients.[60] A large periocular or eyelid margin defect can be grafted by generating a rhombus, or equal-sided parallelogram, which can be rotated to cover the eyelid defect (Figure 56-18). The rhombus can be constructed as a square, or with sides at approximately 60 and 120 degrees. Once the defect is created, two incisions are made in the distal eyelid skin to form two additional sides of the rhombus (see Figure 56-18, *B*). The skin is undermined using blunt dissection and the rhombus is rotated 90 degrees to fill the defect (see Figure 56-18, *C*). Conjunctiva from the distal palpebral or bulbar surfaces should be advanced to the new eyelid margin. Simple interrupted or simple continuous sutures of 4-0 to 6-0 absorbable suture material are used to suture the conjunctiva to the new eyelid margin and to suture the graft in place (see Figure 56-18, *D*).

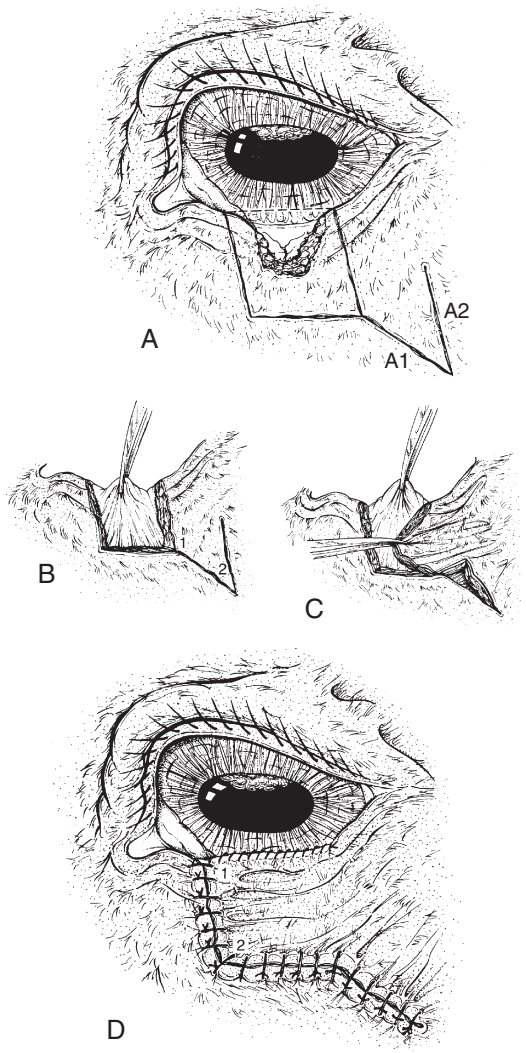

Figure 56-18. Rhomboid graft flap. **A,** The rhomboid is aligned with one side along the position of the eyelid margin. Sides of the rhomboid are equal. The replacement flap is incised on a line *(A1)* continuous with the diagonal of the rhomboid, for a distance equal to the sides of the rhomboid. The second incision *(A2)* is also equal in length and is placed parallel to the side of the rhomboid. **B,** The lesion is excised and conjunctiva is mobilized to cover the replacement flap. **C,** The flap is dissected free from underlying tissue and rotated into position. **D,** The flap is sutured in position with the leading edge forming the new eyelid margin. (Angles 1 and 2 are indicated on **B** and **D** to aid in orientation.)

SLIDING *Z* FLAP

Mass excision or tissue loss at the lateral canthus can be reconstructed using a sliding Z flap (Figure 56-19). The lesion should be fully excised or débrided, and the surrounding skin and tarsoconjunctiva should be separated using blunt dissection (see Figure 56-19, *B*). Triangles of skin are excised superior and inferior to the defect (see Figure 56-19, *C*). The skin is advanced to cover the defect. The new portion of eyelid margin is created by suturing skin and conjunctiva together using 4-0 to 6-0 absorbable suture material (polyglactin 910). The remaining skin is sutured in a similar manner (see Figure 56-19, *D*).

OTHER RECONSTRUCTIVE PROCEDURES

Numerous alternative blepharoplasty procedures with potential application to equine cases can be found in ophthalmology textbooks.[52,61-64]

NICTITATING MEMBRANE

Anatomy and Physiology

The third eyelid (i.e., nictitating membrane, membrana nictitans) is a mobile protective structure covered by conjunctiva located in the inferomedial orbit between the lower eyelid and the globe. This structure is well developed in the horse and moves passively in a temporal and superior direction to cover the anterior surface of the eye with the contraction of retrobulbar muscle (abducens nerve, CN VI) and retrograde movement of the globe. The third eyelid can protrude to cover the majority of the corneal surface.[65]

The third eyelid has a number of functions including the production of a portion of the aqueous layer of the tear film via the nictitans gland and the distribution of tears via passive movement across the globe following globe retraction. Others have suggested that the equine third eyelid provides globe protection, particularly while grazing,[3,63] and has a role in

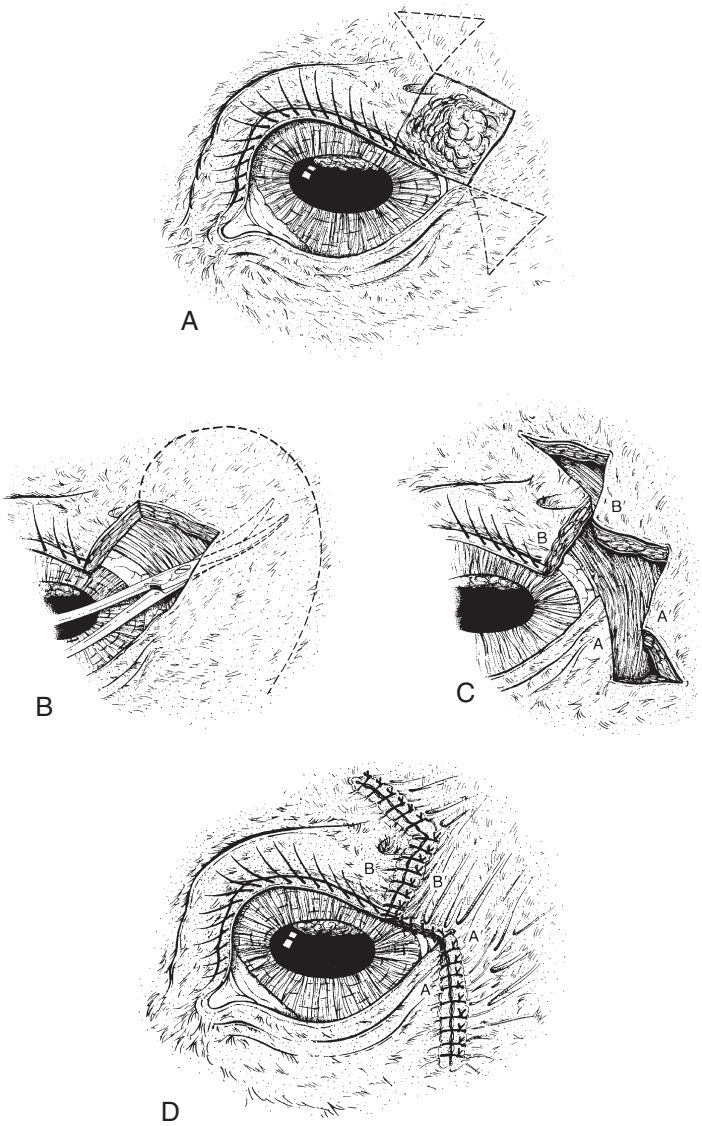

Figure 56-19. Sliding Z flap. **A,** Growths of the lateral eyelid can be removed *en bloc*. The triangular areas of skin to be removed adjacent to the defect are marked. Excision of these flaps facilitates skin mobilization. (The bases of the triangles align with the diagonal of the defect.) **B,** Adjacent skin is undermined. **C,** Equivalent triangles of skin are excised. (Cut edges *A, A′, B*, and *B′* are shown to aid in orientation for advancement of the flap.) **D,** The flap is advanced and sutured in place.

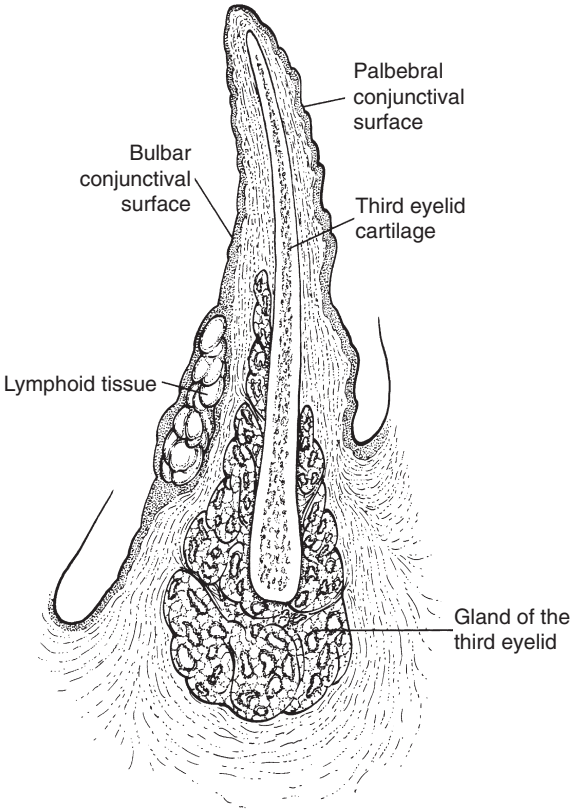

Figure 56-20. A schematic diagram of the histologic features of the third eyelid.

immunologic protection including the secretion of immunoglobulin A.[66]

Structural support of the third eyelid is provided by a T-shaped cartilage, in which the horizontal margin of the T is positioned close to the leading edge of the third eyelid (Figure 56-20), and both ends have a characteristic hook shape.[67] The cartilage contains a substantial elastic component[67] and its shape closely matches the curvature of the globe. The vertical base of the cartilage is surrounded by a large amount of fat and the seromucoid gland of the nictitans. The surfaces of the third eyelid are covered with conjunctiva, containing mucus-secreting goblet cells and intraepithelial glands at the base. The bulbar substantia propria of the third eyelid contains lymphoid tissue.

Sensory innervation is provided by the infratrochlear nerve, a branch of the ophthalmic division of the trigeminal nerve (CN V).[3,67] Retraction of the third eyelid is partially controlled by sympathetic tone in the orbital smooth muscles; loss of tone results in the protrusion that accompanies Horner's syndrome and associated enophthalmos. Vasculature is supplied by the malar artery, a branch of the internal maxillary artery.[3]

Ophthalmic Examination Techniques and Diagnostic Procedures

In the investigation of third eyelid abnormalities, a systematic approach to diagnosis should always be adopted, including a full bilateral ophthalmic and systemic examination. Particularly important is the palpation of regional lymph nodes if third eyelid masses are noted. In cases of corneal or conjunctival disease, the third eyelid should be carefully examined to rule out any contributing lesions. Manual retropulsion of the globe through the superior eyelid causes protrusion of the nictitating membrane, allowing examination of the palpebral surface and leading edge. Topical anesthetic drops and sedation restraint may be required to examine the bulbar surface closest to the globe (see "Eyelids," earlier). Forceps that cause minimal tissue trauma (such as Von Graefe fixation forceps) can be used to retract the third eyelid and examine the deep conjunctival fornices and the bulbar surface. The bulbar surface should be examined if a foreign body is suspected or in suspected cases of conjunctival parasites (e.g., *Thelazia* spp.). Digital palpation may also be necessary to fully evaluate the extent of any observed masses.

Diagnostic procedures such as cytology, fine needle aspiration, biopsy, and bacterial culture and sensitivity testing should be considered as necessary.

Anesthetic Considerations

Most third eyelid procedures can be performed on the standing, sedated horse, although general anesthesia can be performed if deemed necessary. The sensory infratrochlear nerve block provides anaesthesia to the third eyelid and can be used in combination with topical anesthesia. However, topical and local anesthesia will not desensitize the deep portions of the third eyelid; therefore, an additional retrobulbar block should be considered (see Chapter 55) when removing the third eyelid or making deep incisions or crushing tissues. A line block of local anaesthetic at the base of the third eyelid can provide additional anesthesia when performing removal or biopsy.

Required Surgical Equipment

Table 56-5 outlines some additional equipment that may be useful when performing third eyelid surgery.

Surgical Techniques

Third Eyelid Flap

There are limited indications for the use of a third eyelid flap. Unlike conjunctival pedicle grafts, third eyelid flaps cannot replace or support damaged corneal stroma and do not provide any serum-derived factors that assist in corneal healing. Corneal bullae can develop secondary to extensive corneal edema, and a third eyelid flap can provide tamponade of the cornea while facilitating treatment application to the conjunctival sac. Other indications include physically supporting a weakened cornea following a conjunctival graft, reducing contamination of an injured cornea, or reducing evaporative tear film loss secondary to exophthalmos or facial nerve paralysis.[56] Flaps are typically contraindicated in cases of deep ulceration or corneal melting, because they may prevent appropriate penetration of topical medications and promote the retention of inflammatory cells and bacteria adjacent to the corneal surface.[68] The flap also obscures visual examination of the cornea and prevents evaluation of progression or healing, unless sutures are placed to facilitate sporadic lowering of the flap.

A flap is placed either under general anesthesia or standing sedation and local anesthesia. A single suture of 2-0 to 3-0 nonabsorbable material is inserted from the haired skin of the upper eyelid into the upper conjunctival fornix. A bite is taken from the palpebral surface of the third eyelid, approximately 4 to 5 mm from the leading edge, taking care not to penetrate the full thickness of the bulbar surface. Because sutures can tear through conjunctiva, encircling the T-cartilage of the third eyelid helps to retain sutures. The final bite of suture enters the upper conjunctival fornix and exits the haired skin of the superior eyelid. Alternatively, three or four horizontal mattress sutures may be used. Stents of buttons or polyethylene tubing should be used to prevent damage to the eyelid skin. The suture tags can be tied and left long to allow the flap to be sporadically lowered. A subpalpebral lavage device can be placed at the same time the third eyelid flap is constructed.

TABLE 56-5. Additional Instruments Particularly Useful for Equine Third Eyelid Procedures

Instruments	Use	Quantity
Large curved hemostat forceps	Crushing of edges of third eyelid before removal	4
Allis tissue forceps	Third eyelid retraction	2-4
Sterilized buttons/ sections of plastic tubing	Stents for third eyelid flap	4

COMPLICATIONS

The cartilage of the third eyelid can become permanently deformed, causing corneal abrasion, and in severe cases this warrants third eyelid removal.[56] If stents are not used, ulceration of the skin around the sutures can be severe. If inappropriately placed, the suture can cause additional damage to the cornea.

Excision of the Third Eyelid

The third eyelid is a common site of adnexal neoplasia, and it is particularly susceptible to the development of squamous cell carcinoma.[24,30,31,36] Squamous cell carcinoma often initially appears as an area of hyperemia, becoming raised and in some cases developing a papillomatous appearance (Figure 56-21). Tumors of vascular origin, including hemangioma, hemangiosarcoma[69-71] and lymphangiosarcoma[72] have also been described. Hemangiomas and hemangiosarcomas often result in a hemorrhagic ocular discharge.[70,71] Other neoplasms reported include basal cell tumor[73] and lymphsarcoma.[23,74]

Excision is the treatment of choice for confirmed or suspected neoplasms affecting the third eyelid. A success rate of

Figure 56-21. Typical verrucose appearance of a squamous cell carcinoma affecting the leading edge of the nictitating membrane.

approximately 90% has been previously reported using surgical excision alone,[30,36,75] although adjunctive therapies such as gamma- or beta-irradiation have been described in a small number of cases with limited effects on recurrence rates.[30] A recent study has shown that topical mitomycin C (0.2 mL of 0.04% formulation every 6 hours in 1-week cycles) can be effective alone or in combination with surgical excision.[76] Cryotherapy alone or as an adjunct to surgical excision should be avoided in cases of squamous cell carcinoma, because it has been shown to increase the risk of local tumor recurrence by 2.5 times.[30] If the tumor extends beyond the third eyelid, alternative or additional surgical and adjunctive therapies may be necessary. Partial excision is not recommended because of the recurrence risk[75] and the cut edge of the third eyelid cartilage can abrade the cornea. Excision can be performed under general anesthesia but is more commonly performed on the standing, sedated horse with local anesthesia.[75] A combination of auriculopalpebral, infratrochlear, and zygomatic nerve blocks; local infiltration; and topical analgesics usually provide adequate analgesia (Figure 56-22), although a retrobulbar block may be required to provide additional analgesia (see Chapter 55).

The third eyelid is grasped on the T-cartilage using Allis tissue forceps and elevated. Large hemostatic forceps are advanced from the medial and lateral edge along the base of the third eyelid until the tips are apposed proximal to the gland of the nictitans. All tissue superficial to the hemostatic forceps including the T-cartilage and gland are removed *en bloc* using scissors or a scalpel blade. The hemostats are removed after 1 to 2 minutes. The cut edges of conjunctiva can be sutured together using 5-0 or 6-0 polyglactin 910 in a simple-continuous pattern to reduce the risk of orbital fat prolapse.[56] All tissue removed should be submitted for histopathologic examination for determination of tumor type and surgical margins.

AFTERCARE

Topical antibiotic (with or without a steroid) ointment should be applied to the eye for 5 to 7 days following surgery. Flunixin meglumine administration for the first 3 to 5 days will reduce inflammation and discomfort. Although the nictitans gland is removed when excising the third eyelid, very few equine eyes develop tear production deficits,[75] and long-term lubricants are not usually required.

COMPLICATIONS

Complications are rare but include orbital fat prolapse, keratoconjunctivitis sicca, and superficial keratitis.[56] The absence of a third eyelid can impair globe protection and result in mild chronic ocular irritation and discharge.[56]

Lacerations

Lacerations affecting the third eyelid should be treated surgically to reappose the edges of conjunctiva and restore the margin of the third eyelid. Apposition of the margin should precede proximal sutures, because inappropriate apposition may result in scarring and corneal trauma. Sutures of 6-0 or 7-0 polyglactin 910 should be placed emerging from the palpebral surface. Sutures of the bulbar conjunctiva should be placed

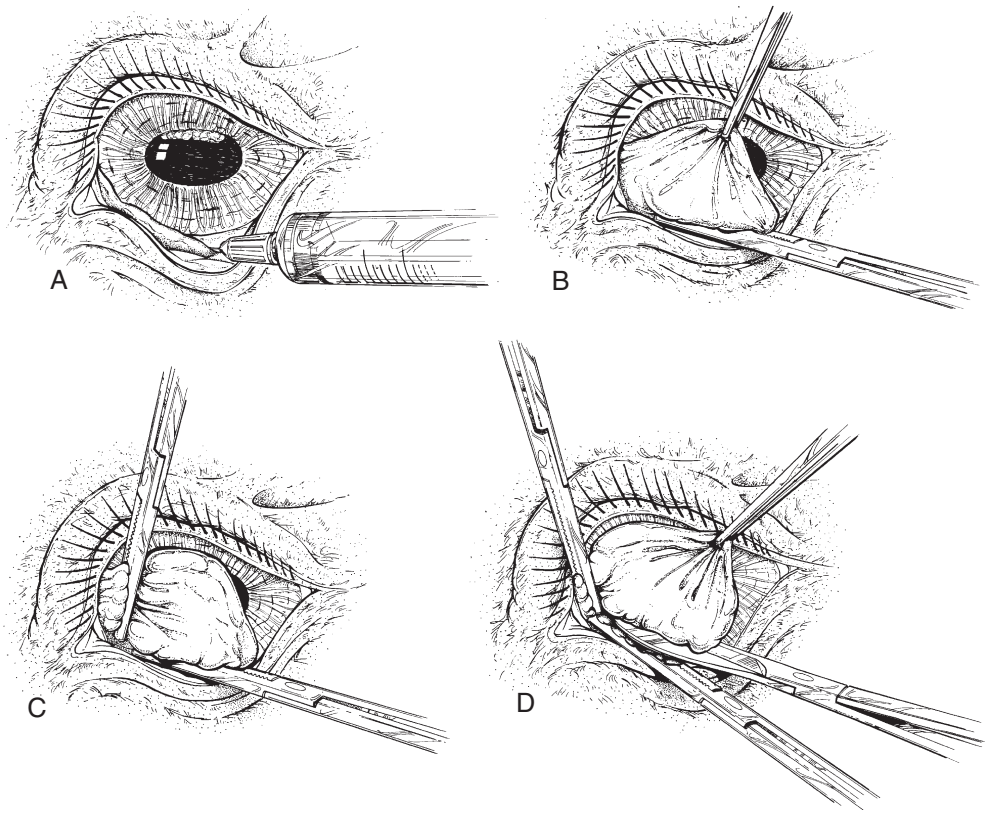

Figure 56-22. Surgical removal of the third eyelid. **A,** Local anesthetic is injected at the base of the third eyelid. **B,** The nictitating membrane is lifted from the fornix with forceps. **C,** Two hemostats are placed across the base of the third eyelid. **D,** The third eyelid is excised along the two hemostatic forceps.

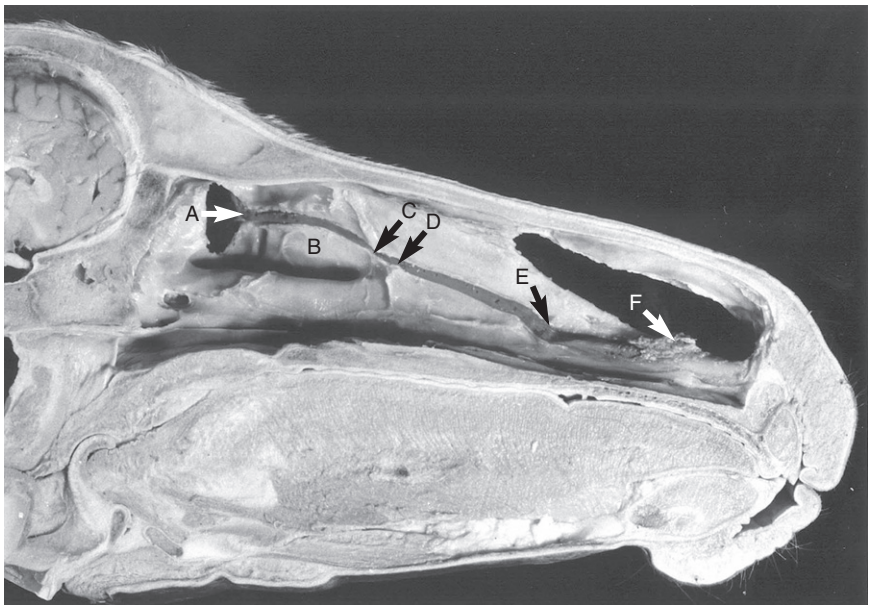

Figure 56-23. Methyl methacrylate cast of the left nasolacrimal duct of a horse. carefully to avoid contact of suture material with the cornea. Any exposed cartilage should be covered by conjunctiva, particularly on the bulbar surface of the third eyelid.

NASOLACRIMAL SYSTEM

Anatomy and Physiology

Preocular Tear Film

The preocular tear film covers the cornea and conjunctiva and has three components. The *outer lipid* component is derived from the meibomian (i.e., tarsal) glands and the sebaceous glands of Zeis within the eyelids. The *middle aqueous* layer is predominantly derived from the lacrimal gland situated in the dorsolateral orbit (between the zygomatic process of the frontal bone and the eye). The secretions from the lacrimal gland enter the lateral part of the superior conjunctival fornix. Smaller contributions to this layer are produced by the gland of the third eyelid (i.e., nictitans gland) and the accessory lacrimal glands of the eyelids. The *inner mucinous* layer is derived from the conjunctival goblet cells and intraepithelial glands within the conjunctiva.

The tear film has many functions including flushing foreign material, lubricating the eye to facilitate the movement of the eyelids and third eyelid, maintaining a refractive corneal surface, delivering nutrients to the cornea and conjunctiva, and facilitating immune protection. In the normal equine eye, a complete recycling of tear volume occurs approximately every 7 minutes.[77] The lacrimal lake results from flow of tears across the cornea following blinking and forms along the leading edge of the lower eyelid and adjacent to the inferior edge of the lacrimal caruncle and third eyelid.

Nasolacrimal Drainage System

Horses possess both superior and inferior lacrimal puncta (see Figure 56-1, *C*). Each punctum is a horizontal slit in the palpebral conjunctiva approximately 2 mm in length. The lower punctum is generally larger, closer to the medial canthus, and farther from the eyelid margin.[78] Tear drainage into the puncta occurs via capillary action and blinking.

The nasolacrimal system begins with a pair of nasolacrimal canaliculi connecting the puncta with the nasolacrimal sac. The sac is often poorly defined in horses and lies within the lacrimal fossa of the lacrimal bone. The nasolacrimal duct measures approximately 29 to 33 cm long[79] and passes through the lacrimal canal within the lacrimal bone and maxilla. The duct is narrowest as it exits the lacrimal canal (Figure 56-23).[78,79] When performing maxillary trephination or evaluating trauma to this region, the course of the nasolacrimal duct may be predicted by drawing a line from the medial canthus to the infraorbital foramen.[78] After exiting the lacrimal canal, the duct continues within the lacrimal groove of the maxilla beneath the mucous membrane of the middle nasal meatus.[2] It continues within the basal fold of the ventral nasal concha, where the duct wall becomes irregular as it passes through the vascular plexus of the basal fold. It courses over the nasal process of the incisive bone to end near the mucocutaneous junction in the ventral nasal meatus at the nasal ostium, which is 3 to 4 mm in diameter and visible clinically (Figure 56-24). The nasolacrimal duct may contain blind-ending branches into channels that may not reach the nasal ostium.

Examination Techniques

In the investigation of nasolacrimal system abnormalities, a systematic approach to diagnosis should always be adopted, including a full ophthalmic and systemic examination. Keratoconjunctivitis sicca is rare in the horse. When it is present, the neurogenic form is most common and is often seen in combination with facial and/or trigeminal nerve paralysis.[80] A complete description of the investigation of dry eye conditions is beyond the scope of this text. However, when investigating corneal surface abnormalities, a Schirmer tear test (Schirmer tear test strips, Schering-Plough Animal Health, Kenilworth, NJ), fluorescein staining, and rose bengal staining should

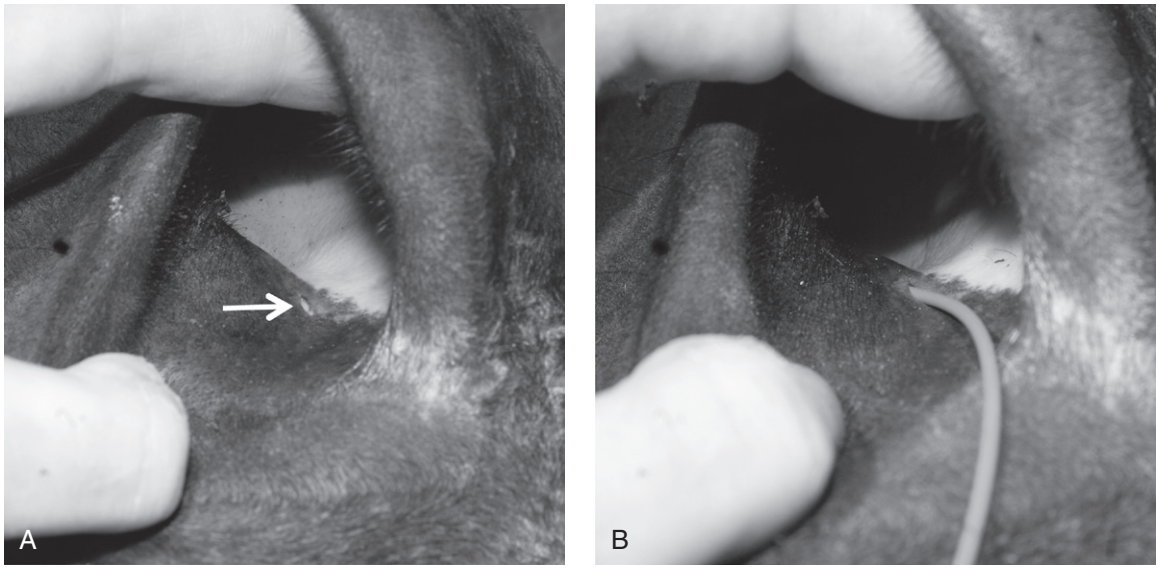

Figure 56-24. Identification and catheterization of the nasal ostium. **A,** The nasal ostium is visible in the ventral nasal meatus close to the mucocutaneous junction (*white arrow*). **B,** Distal catheterization using a 5-French rubber urinary catheter facilitates retrograde flushing of the nasolacrimal system.

be considered part of the ophthalmic diagnostic workup. A Schirmer tear test value of less than 10 mm/min is considered abnormal in horses and ponies.[81] The administration of any topical drops such as tropicamide affect Schirmer tear test values.[82] Cytology and bacterial culture and sensitivity testing should be considered in suspected cases of dacryocystitis.

The most straightforward method to evaluate nasolacrimal system patency is to assess the passive drainage of fluorescein to the nasal ostium by instilling fluorescein stain (wet fluorescein strips or single-use vials containing 2% fluorescein) into the conjunctival sac.[54] Positive drainage confirms nasolacrimal patency. A more-invasive method is to perform nasolacrimal cannulation via the upper and lower puncta (see Figure 56-1, *C*). Sterile disposable cannulas or reusable autoclavable cannulas can be used for cannulation, which can be performed under topical anesthesia on the standing, sedated horse if necessary. Minimal force should be required to achieve drainage through the nasal ostium. The use of fluorescein solution as the flushing medium aids in the positive diagnosis of patency. Retrograde flushing techniques can also be performed using a 5- to 6-French pliable urinary catheter (see Figure 56-24, *B*).

Diagnostic Procedures

Dacryocystorhinography

Radiographic methods of dacryocystorhinography have been described that involve cannulating the upper lacrimal punctum and injecting viscous contrast medium before radiography (Figure 56-25).[78,83] This technique has been described in the standing horse. Even in unilateral disease, it is advantageous to perform the technique on both nasolacrimal ducts to provide an internal control. Recent work has demonstrated that the nasolacrimal duct of the horse can be evaluated using CT dacryocystorhinography (Figure 56-26).[84] This technique requires general anesthesia and positioning the horse in dorsal or sternal recumbency. About 5 mL of iodinated contrast medium is injected retrogradely through the nasal ostium.

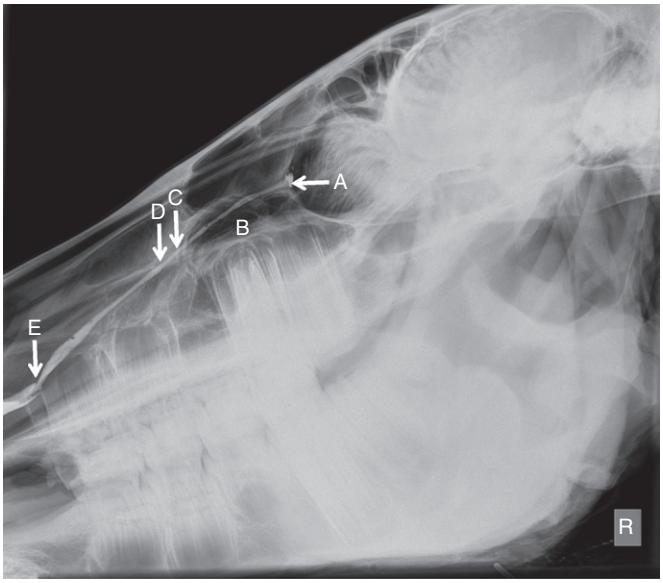

Figure 56-25. Normal right lateral equine dacryocystorhinogram illustrating the anatomical features shown in Figure 56-23. **A,** Lacrimal sac. **B,** Course of the duct within the lacrimal bone. **C,** Mild narrowing of duct lumen before exiting lacrimal bone. **D,** Exit of duct from lacrimal bone. **E,** Compression of duct by cartilage within alar fold. (Courtesy Dr. Anthony Pease.)

Endoscopy

Endoscopic evaluation of the nasolacrimal duct has been described in adult horses.[79] The portion of the duct within the lacrimal bone is difficult to examine using this method. This procedure may be useful for collecting samples in cases of dacryocystitis or aiding the diagnosis and removal of foreign bodies or dacryoliths.

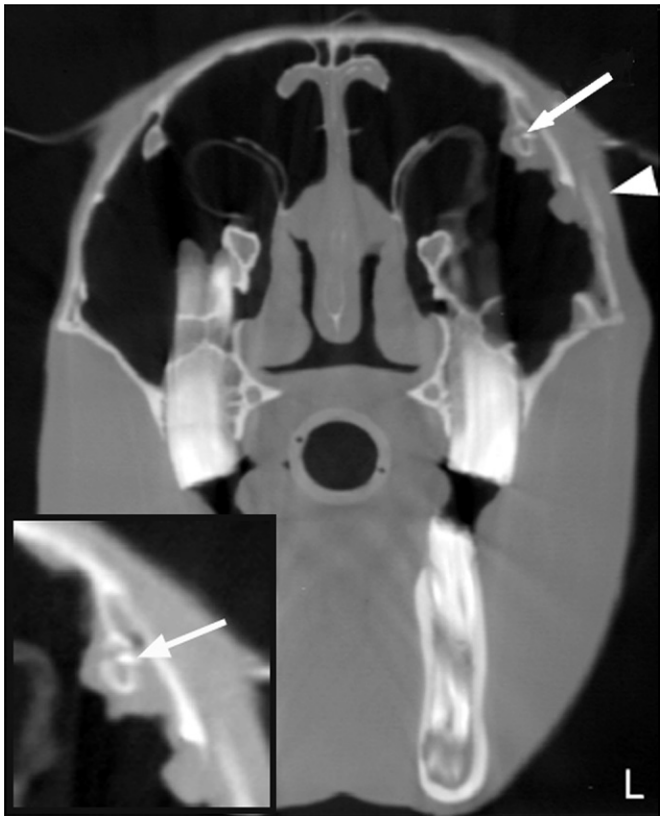

Figure 56-26. Transverse computed tomography dacryocystography scan of an equine skull at the level of the caudal maxillary sinus. There is a fracture of the left maxilla with adjacent soft tissue swelling (*arrowhead*). No disruption of the nasolacrimal duct is evident (*arrow*). The inset is a close-up of the nasolacrimal canal and duct. (Reproduced with permission from Nykamp SG, Scrivani PV, Pease AP: Computed tomography dacryocystography evaluation of the nasolacrimal apparatus. Vet Radiol Ultrasound 45:23, 2004.)

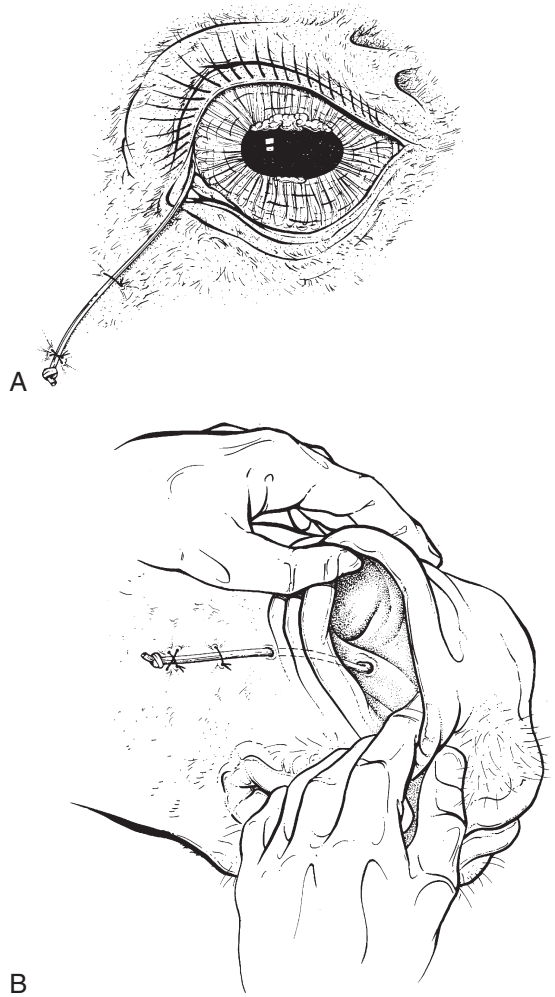

Figure 56-27. A catheter is sutured to the periorbital skin **(A),** and skin of the nostril **(B)** after cannulating and surgically opening an imperforate nasolacrimal duct.

Anesthetic Considerations

Topical anesthesia and standing sedation is useful as described earlier. For additional analgesia, a cotton-tipped applicator soaked in proparacaine can be applied directly onto the nasolacrimal puncta for 2 to 5 minutes before proceeding to its cannulation.

Required Surgical Equipment

Cannulas and catheters for cannulation of the nasolacrimal duct are useful. Standard single-use plastic cannulas and autoclavable steel cannulas are available. For cannulation of the nasolacrimal system to correct nasolacrimal punctal atresia, cardiac catheters of various sizes are useful (No. 4 to 6). A round-tipped, eyed pigtail probe (modified Worst probe) is effective in facilitating the placement of a silicone-tubing stent to treat lacerated nasolacrimal canaliculi.[85]

Surgical Techniques

Imperforate Puncta

The most common defect of the nasolacrimal system in the horse is an imperforate distal nasal punctum.[86] Other abnormalities include imperforate proximal lacrimal puncta within the eyelids and atresia or agenesis of the duct,[87] which should be ruled out by clinical examination, cannulation and flushing of the nasolacrimal system, and/or diagnostic imaging techniques. Clinical signs of epiphora or mucopurulent ocular discharge are typically first reported by owners in animals ranging from birth to 1 year of age.[54,86] Anomalous supernumerary openings of the nasolacrimal system have also been reported.[88]

Treatment of imperforate nasal puncta can usually be performed on the standing, sedated horse. The nasolacrimal duct can be filled with sterile physiologic saline with the addition of dilute fluorescein dye to aid visualization. The mucosa overlying the bleb of fluid within the nasal passage can be incised using a scalpel blade. Alternatively, a catheter (5- to 6-French silicone male urinary catheter[86]) can be inserted into the upper lacrimal puncta and passed down the duct, and the incision can be made over the palpable end of the catheter. The portion of catheter emerging from the lacrimal puncta should be sutured to the skin of the face (Figure 56-27). The distal portion of catheter can be sutured to the nose or lip or passed through the lateral wall of the nostril[86] (see Figure 56-27, *B*). The catheter is typically maintained in place for 2 to 4 weeks.

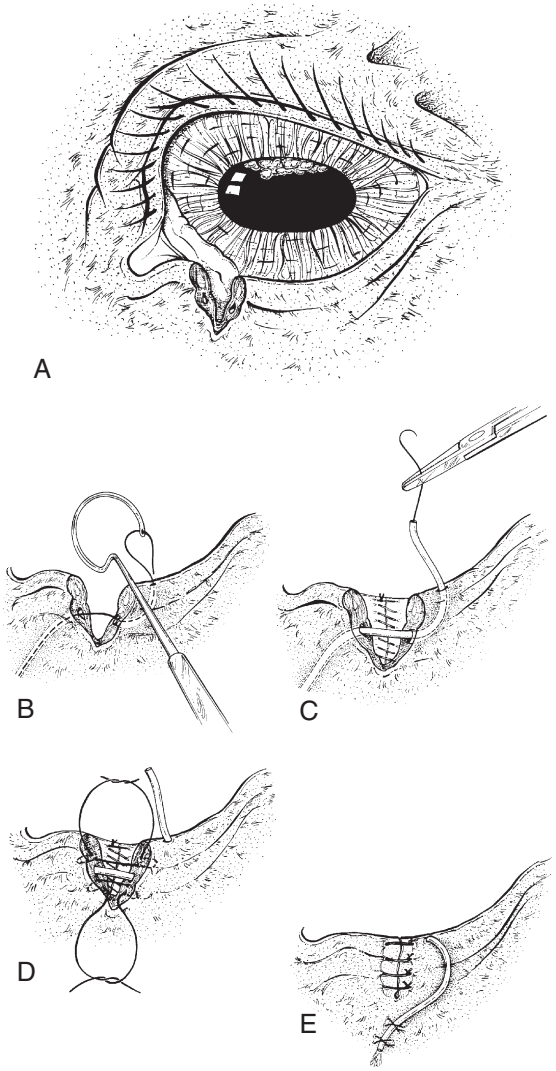

Figure 56-28. Repair of the severed lacrimal canaliculus. **A,** Laceration of the lower eyelid, severing the lacrimal canaliculus. **B,** A 2-0 nylon suture is passed through the nasolacrimal duct and exits through the wound. A Worst probe is passed through the ventral punctum and draws the suture through the distal portion of the severed canaliculus. **C,** A fine silicone tube is cut to a taper, tied to the suture, and pulled through the canaliculi. **D,** The canaliculus and wound are sutured with 6-0 nylon silk. **E,** The tubing is sutured to the skin of the eyelid and at the nasal end. It is left in place for 3 weeks.

Atresia of either the upper or lower lacrimal punctum can be treated by cannulation of the patent lacrimal punctum and using a scalpel blade to incise tissue over the bleb created. A silicone stent can be placed to aid healing.

Canaliculorhinostomy may be a surgical alternative for atresia or agenesis of substantial portions of the distal nasolacrimal duct.[89] An 18-gauge, 1.5-inch needle is used to drill into the rostral maxillary sinus, using the lower eyelid canaliculus as a guide; 60-gauge fishing line is used to create a retention stylette that remains in place for at least 1 month. Another method of conjunctivorhinostomy is to create a stoma between the inferior conjunctival fornix and the maxillary sinus.[90] With both of these procedures, there is a risk of strictures forming in the artificial stoma over time.

Lacerations

Lacerations of the nasolacrimal system occur most commonly at or near the eyelid margin. Surgical correction is indicated to prevent inappropriate healing or scarring, resulting in blockage of the canaliculus or punctum and resultant epiphora. The repair of nasolacrimal punctal lacerations have been well described in human texts, although no reports for equine nasolacrimal lacerations were found. A blunt-tipped, eyed pigtail probe is inserted into the unaffected punctum and fed until it exits from the severed end of the canaliculus (Figure 56-28).[85] A 6-0 polypropylene suture is placed in the eye of the probe, which is then retracted to draw the suture through to the unaffected punctum. The probe is passed through the punctum of the lacerated canaliculus and the suture is again drawn through to exit from this punctum. A silicone stent tube is passed over the suture (the tube cannulates both nasolacrimal canaliculi and puncta) from the unaffected side. The suture material can be tied, maintaining the silicone tubing in place, or it can be removed and the ends of the tube can be sutured together. The canaliculus and eyelid skin are sutured using 6-0 polypropylene. The tube is sutured in place and left for 4 to 6 weeks to maintain patency as the canaliculus heals.[91] Topical and/or systemic antibiotics should be administered in the postoperative period.

CHAPTER
57 Surgery of the Ocular Surface

Matthew J. Annear and Simon M. Petersen-Jones

ANATOMY AND PHYSIOLOGY

The ocular surface consists of the cornea and conjunctiva. The clear cornea allows light to enter the eye and is continuous with the sclera, forming the outermost fibrous wall of the globe. The junction between the cornea and the sclera is termed the *limbus,* and at this site the epithelium of the cornea transitions into conjunctival epithelium. The bulbar conjunctiva overlies the sclera of the globe, over which it is relatively mobile. The conjunctiva is reflected at the fornices to line the third eyelid and the inner aspect of the eyelids where it is termed the palpebral conjunctiva (Figure 57-1). Beneath the bulbar conjunctiva lies loose connective tissue, Tenon's capsule (a thin fascia enveloping the eyeball), and the episclera.

Conjunctiva

Structure and Function

The conjunctiva is a thin mucous membrane, the bulbar component of which is typically pigmented because of the presence of melanin. It has a nonkeratinized stratified columnar to

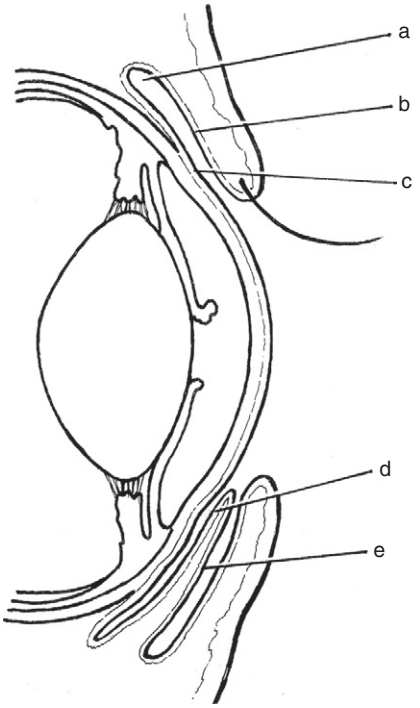

Figure 57-1. Areas of the conjunctiva. *a,* Fornix; *b,* palpebral conjunctiva; *c,* bulbar conjunctiva; *d,* bulbar conjunctiva of the third eyelid; *e,* palpebral conjunctiva of the third eyelid.

cuboidal epithelium, which is interspersed with goblet cells and surrounded on the palpebral and bulbar margins by a stratified squamous epithelium.[1] The substantia propria of the conjunctiva consists of two layers: the superficial adenoid layer that contains the lymphoid tissue and a deeper fibrous layer that contains the nerves and blood vessels. The conjunctiva plays three important roles. It facilitates movements of the globe and eyelids by the relatively loose attachments of its substantia propria to the underlying tissues. It provides an important line of defense through its role as a physical barrier, and more specifically by the presence of conjunctiva-associated lymphoid tissue that plays a significant role in the immune response to environmental antigens.[2] This conjunctiva-associated lymphoid tissue has also been shown to contribute to corneal immune protection.[3] Finally, goblet cells within the conjunctival epithelium produce mucus that is a principal component of the precorneal tear film, essential for maintenance of a clear cornea.

Lymphatics, Vasculature, and Innervation

The conjunctiva contains aggregates of lymphoid follicles, most numerous in the conjunctival fornices and on the bulbar aspect of the third eyelid. The lymphatics drain toward the commissures of the eyelids, with the lateral commissures draining to the parotid lymph nodes and the medial regions draining to the submandibular lymph nodes.

The conjunctival arterial supply is derived from the anterior ciliary arteries, which are branches of the ophthalmic artery, and the vascular arcades of the eyelids are derived from the ophthalmic artery medially and the lacrimal artery laterally. These vessels terminate as small radiating superficial conjunctival vessels. Venous drainage is via the palpebral veins and superior and inferior ophthalmic veins.

The bulbar conjunctiva is innervated by the long ciliary branches of the ophthalmic division of the trigeminal nerve. The superior palpebral conjunctiva is innervated by the frontal and lacrimal branches of the ophthalmic division of the trigeminal nerve, whereas the inferior palpebral conjunctiva is innervated by the both the lacrimal branch of the ophthalmic nerve and the infraorbital branch of the maxillary division of the trigeminal nerve.[4]

Response to Injury

Because of its dense vasculature and prominent lymphatics, the conjunctiva responds rapidly to ocular surface injury or disease by becoming hyperemic and edematous. Swelling of the conjunctiva can be so extensive that it causes the conjunctiva to balloon between the eyelids. This response to injury is nonspecific, consistent for surface irritation, infection, and neoplastic disease. Additionally, hyperemia of the conjunctiva frequently accompanies corneal lesions. With chronicity, the conjunctival epithelium can hypertrophy and lymphoid follicular hyperplasia may be observed. Most importantly for the surgeon, the conjunctival epithelium heals rapidly after injury, and often sutures are not needed if the defect is small.

Sclera

The sclera is the main protective wall of the eye. Along with the cornea, it encloses the intraocular structures to protect them from injury and is important for maintaining the structure of the globe and the intraocular pressure. It is composed almost entirely of collagen with a small amount of elastin and proteoglycans. Unlike in the cornea, the collagen fibers are irregularly arranged, so they scatter light and give the sclera its white color. The well-vascularized episclera is the outermost layer of the sclera, attaching to the fibrous Tenon's capsule that envelops the globe, and is adherent to the conjunctiva. The arterial blood supply is derived from the anterior and posterior ciliary arteries, arising from the ophthalmic artery. Anteriorly the intrascleral venous plexus receives aqueous humor via drainage through the iridocorneal angle. Sensory innervation to the anterior sclera is provided by the long posterior ciliary nerves, derived from the ophthalmic nerve. The posterior sclera is innervated by the short posterior ciliary nerves that branch from the ciliary ganglion to enter the sclera close to the optic nerve.

Limbus

The limbus represents the junction between the corneal stroma and the sclera, with the sclera obliquely overlying the cornea superficially. This scleral "shelf" obscures direct observation of the iridocorneal drainage angle dorsally and ventrally. Temporally and nasally the insertion of the pectinate ligaments, the thin fibers that span from the iris base to the peripheral cornea, can be viewed directly through the cornea (Figure 57-2). Superficially at the limbus the conjunctiva continues over the cornea as the corneal epithelium. At this junctional zone, limbal stem cells are present, located in the basal epithelium. These are important for healing extensive corneal lesions as well as for maintaining a healthy corneal epithelium under normal conditions.[5]

Figure 57-3. Photomicrograph demonstrating the four layers of the equine cornea. *a,* Epithelium; *b,* stroma; *c,* Descemet's membrane; *d,* endothelium *(arrow)* (hematoxylin and eosin, ×170).

Cornea

Structure and Function

The cornea is a transparent, highly specialized structure that transmits light and contributes to the anterior portion of the fibrous tunic of the globe. It is also the major refractive structure of the eye, so maintenance of corneal clarity is therefore essential. To this end, the cornea lacks blood vessels, has a nonkeratinized surface epithelium, and has regularly arranged parallel bundles of collagen fibrils organized into lamellae.

The shape of the cornea is a horizontal ellipse, measuring 29.7 to 34.0 mm horizontally and 23.0 to 26.5 mm vertically in the adult horse.[6] In the Miniature Horse, the cornea approximates 25.8 mm horizontally and 19.4 mm vertically.[7] Measurements of corneal thickness vary with the technique used for assessment but range from 0.77 mm to 0.89 mm centrally, with thickness increasing toward the periphery.[6-9] The cornea can be divided into four layers: epithelium, stroma, Descemet's membrane, and endothelium (Figure 57-3).

The most superficial layer is the *epithelium,* which is 8 to 10 cell layers thick[10] and serves two main functions. It provides a physical barrier to injury, and it is a smooth optical surface, aided in part by the overlying precorneal tear film. The most superficial layer is a nonkeratinized stratified squamous epithelium, and the middle layer consists of polyhedral wing cells. The basal layer of the epithelium is anchored to the underlying basement membrane and thus the corneal stroma by hemidesmosomes. The basal cells are columnar and are continually dividing. This activity is important for the healing of epithelial defects and the constant renewal of the surface epithelium, an important component of the ocular defenses.

The *corneal stroma,* located beneath the epithelium, makes up approximately 90% of the corneal thickness. It maintains transparency by the lack of vasculature and the narrow diameter collagen fibrils, predominantly type I and type V, that are uniformly spaced and organized into parallel sheets.[11] This natural arrangement facilitates separation of the corneal stroma along a plane parallel to the corneal surface, relevant for the surgeon performing a keratectomy. The stroma is relatively acellular but has keratocytes distributed throughout its structure that play an important role in wound healing. Following injury and formation of new reparative collagen fibers, the resulting irregular arrangement can scatter light and is appreciated as a corneal opacity or scar. The corneal stroma is hydrophilic and is maintained in a relative state of dehydration by the presence of an intact corneal epithelium and the action of the corneal endothelial pump mechanism (see later).

Descemet's membrane, lying beneath the stroma, is an exaggerated basement membrane that is produced continually by the corneal endothelium and thickens with age. This is often the last line of defense before perforation of a deep corneal ulcer and does not take up fluorescein stain.

Underneath Descemet's membrane is the *corneal endothelium.* This is a monolayer of roughly hexagonal cells that have tight cellular junctions that limit passage of fluid from the anterior chamber into the stroma. Additionally they have an active Na^+/K^+–ATPase pump that results in a net movement of Na^+ out of the cornea, with water following because of the osmotic gradient effect. Unlike other corneal tissues, the endothelial cells have little or no capacity for regeneration in the adult and their density decreases with age.[9,12-14] Following trauma or damage to the corneal endothelium, the remaining cells spread in an attempt to recreate a complete coverage of the posterior corneal surface.

Vasculature and Innervation

Since the cornea is normally avascular, nutrition is provided by the precorneal tear film and the aqueous humor. Normal corneal health therefore requires functional eyelids and a nictitating membrane for protection and distribution of the preocular tear film, as well as normal circulation of aqueous humor. The cornea is richly innervated by the long ciliary nerves, derived from the ophthalmic branch of the trigeminal nerve. These fibers are myelinated only at the corneal periphery,

and arborization density is greatest superficially. Those entering the epithelium terminate in naked nerve endings among the wing cells.

Response to Injury

The prominent position of the equine globe, along with the environment horses reside in, means that injuries to the ocular surface are common. Corneal responses to injury include development of edema, and with persistence of the insult, vascularization and pigmentation; in some instances, scar forms as the lesion resolves.

Corneal *edema* results in a blue-gray cloudlike haze to the cornea because of the accumulation of fluid separating the regularly arranged stromal collagen fibers. Fluid may enter the cornea from the tear film with loss of the corneal epithelium, or it can enter from the aqueous humor as a result of damage or dysfunction of the corneal endothelial cells. Corneal *neovascularization* develops in response to inflammation, the presence of polymorphonuclear (PMN) leukocytes, and cytokines such as fibroblast growth factor.[15] In disease states, this limbal ingrowth of vessels provides additional leukocytes and antibodies and helps combat infection and speed healing. Occasionally, persistent and prolonged irritation results in an exuberant vascular response. Drugs such as flunixin meglumine have been shown to delay corneal neovascularization. Despite this, they are often used because they play an important role in combating anterior uveitis and improving ocular comfort.[16] Fungi have also been proposed to produce metabolites that inhibit neovascularization, contributing to their persistence in the cornea.[17] Superficial corneal pigmentation can result from chronic corneal inflammation, where there is recruitment of epithelial cells from the limbus with migration of melanocytes from limbal and perilimbal tissue.

Wound Healing

Since the cornea is normally avascular, it requires growth factors, cytokines, and neuropeptides from the aqueous humor, tear film, and limbal vessels to coordinate wound healing. Factors such as epidermal growth factor increase mitosis and protein synthesis in the corneal basal epithelial cells and the stromal keratocytes.[18,19] Cytokines such as transforming growth factor-β (TGF-β) induce differentiation and infiltration of inflammatory cells.[20]

After damage to the corneal epithelium, the epithelial cells at the edge of the defect retract, losing their hemidesmosmal attachments (rivet-like structures that attach the basal epithelial cells to the corneal stroma); they then become thinner and migrate toward the center of the lesion in an amoeboid fashion. This occurs very soon after the initial insult, with basal epithelial cells sending out cytoplasmic processes within 1 hour of injury and PMN leukocytes arriving within several hours.[10,21] In the absence of infection, normal healing of a corneal defect is rapid and linear for 5 to 7 days before slowing.[19]

If the stroma is involved, the defect is filled with a fibrin clot and adjacent keratocytes are transformed by TGF-β into a myofibroblast-like phenotype that facilitates wound contraction. Depending on the chronicity, corneal vascularization occurs and can promote healing of more serious defects. Fibroblastic collagen is deposited in the defect, resulting in corneal scarring, which slowly remodels and becomes smaller with time. The mean healing time of an uninfected corneal wound of 30% stromal depth is reported to be 11 days.[10] However, normal strength of the injured tissue may not return for a considerable time. Preventing and controlling infection is essential to achieve healing with minimal scar formation. Following trauma to the conjunctival epithelium, with or without stromal involvement, the normal bacterial and fungal flora or contaminating organisms can colonize and then infect the wound.[22,23]

Full-thickness wounds resulting in aqueous leakage can seal as a fibrin clot forms. Larger defects that result in collapse of the anterior chamber may be occluded by the iris, forming an anterior synechia, which is an adhesion between the iris and cornea. With larger defects, there may be iris prolapse resulting in protuberance of the iris from the corneal surface, typically with a coating of clotted fibrin. In full-thickness defects that seal without iris involvement, corneal endothelial cells spread to fill the defect. The new layer of endothelial cells produce a new Descemet's membrane in that region. As already stated, endothelial cells in adults do not replicate so the cells adjacent to a defect spread to completely cover the inner corneal surface.

Corneal wounding stimulates the sensory fibers of the cornea and can result in a neurogenic anterior uveitis thought to be mediated by substance P.[24-26] Hence, painful conditions of the cornea can cause miosis, ocular hypotension, increased protein levels, and even hypopyon within the aqueous humor. Infected corneal wounds and ulcers can also cause an anterior uveitis and hypopyon, probably at least partly the result of the liberation of toxins.

Ocular Surface Microflora

The normal equine ocular surface microflora shows geographic variations, likely influenced by ambient temperature and humidity. Gram-positive bacteria are most commonly isolated from the normal equine ocular surface and include *Corynebacterium*, *Streptomyces*, *Staphylococcus*, and *Bacillus* species.[27-31] In disease states, gram-negative and gram-positive bacteria may be involved, with *Pseudomonas* and β-hemolytic *Streptococcus* resulting in more serious infections.[29,32-36] Fungi are also commonly isolated from the ocular surface of normal horses.[37] Most commonly recovered are *Aspergillus*, *Penicillium*, and *Cladosporium*.[30,31,38] In diseased corneas, the fungal species most commonly isolated are *Aspergillus*, *Fusarium*, *Candida*, and *Penicillium*.[39-43]

OPHTHALMIC EXAMINATION TECHNIQUES AND DIAGNOSTIC PROCEDURES

Examination of the Ocular Surface

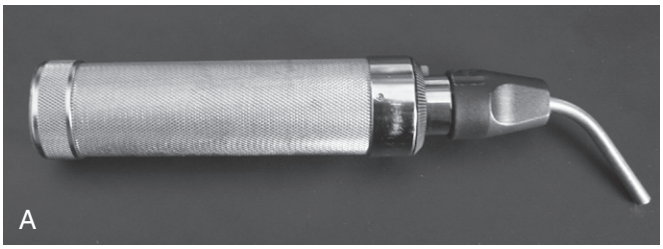
Causes of ocular surface disease can be broadly classified as infectious (bacterial, fungal, viral),[40,44-46] inflammatory (parasitic granulomas, pseudotumors, immune-mediated keratopathies),[47-50] anatomic,[51] traumatic,[52-54] and neoplastic (squamous cell carcinoma, melanoma, lymphosarcoma, mastocytosis, and vascular neoplasms).[55-65] The approach to the investigation of these conditions should begin with collecting data pertaining to signalment and history, followed by a preliminary evaluation of the eyes from a distance, before any manipulation of the globe or adnexal structures. The symmetry and position of the adnexal structures and the globe should be assessed,

with particular attention paid to any evidence of discomfort, appreciated as blepharospasm, epiphora, or photophobia. Variations in conjunctival or corneal coloration, such as red conjunctival hyperemia (engorgement of conjunctival vessels) or blue-gray corneal edema, and the presence of focal opacities or masses should be noted before further examination with illumination and magnification.

Cranial nerve function may be briefly assessed before sedating the horse. Of particular importance is assessment of the *palpebral reflex* and the corneal reflex. Ensuring that the palpebral blink reflex is present and that complete closure of the eyelid is possible is important, because this is required for the normal distribution of the precorneal tear film and thus maintenance of corneal health. The palpebral reflex can be assessed by lightly touching the medial or lateral canthus. In a normal horse, this may not result in complete lid closure; nevertheless, it is important to check that complete closure can be induced.[66] An abnormal palpebral blink reflex can result from deficits of the trigeminal (CN V) or facial (CN VII) nerves. Incomplete lid closure may also occur because of lid abnormalities, including congenital defects and scarring, or abnormalities of the globe's position or size, such as exophthalmos, proptosis, or buphthalmos. Assessment of the *corneal reflex* for any deficits in the ophthalmic branch of the trigeminal nerve will confirm corneal sensation. This test can be performed by lightly touching wisped cotton wool to the cornea and determining whether the response includes eyelid closure and retraction of the globe, mediated by the facial nerve. In performing this test, it is important to ensure that a menace response is not being induced and that contact with the long vibrissae is avoided.

For safe completion of the eye examination, it is necessary to restrain the horse, with the degree of restraint depending on the temperament of the horse and the diagnostic procedures being performed. Use of stocks and sedation may be helpful. When sedation is required, intravenous xylazine (0.5 to 1.0 mg/kg) is adequate for most examinations, though detomidine (0.02 to 0.04 mg/kg IV) will facilitate longer examination and maintenance of a steady head position.[67] Butorphanol (0.01 to 0.02 mg/kg IV) may be used if additional analgesia is required, but as with xylazine, this has been associated with small head jerking motions.[67] Additional information on chemical restraint can be found in Chapter 22. Horses have strong palpebral muscles that can make examination of the ocular surface difficult. Sedation may reduce the strength of the blink but an auriculopalpebral nerve block is often performed, particularly when painful lesions are present. The reader should consult Chapter 55 for details on performing an auriculopalpebral nerve block.

A complete and detailed examination of the ocular surface requires that the exam be performed in a dimly lit environment. Suitable lighting conditions can be achieved by darkening the stall or moving the horse to an area with low light. If this is not possible, many horses tolerate a blanket or towel draped partly over the head of both subject and examiner. Once the light level is reduced, a bright focal light source such as a Finoff transilluminator (Figure 57-4, *A*) can be used to facilitate much of the examination of the anterior segment of the eye. If available, magnification greatly improves the viewer's appreciation of a lesion; this can be via a slit lamp biomicroscope (Figure 57-4, *B*), a simple head loupe (Figure 57-4, *C*), or a direct ophthalmoscope with selection of a high positive diopter lens (+20D). A systematic examination should be performed so that all structures are evaluated and lesions are not missed; this includes an assessment of the adnexa and eyelids, abnormalities of which can contribute to ocular surface disease. The conjunctiva and the ocular surface should subsequently be examined, paying particular attention to the presence and location of corneal neovascularization, edema, stromal infiltrates, and proliferative lesions. It is equally important to assess intraocular structures; for instance, the presence of hypopyon in cases of ulcerative keratitis suggests a poor prognosis and may necessitate therapy with systemic antimicrobials. In instances of fungal



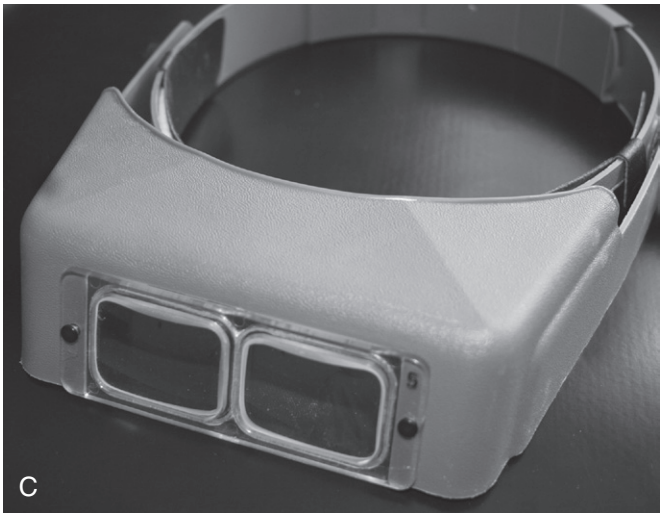


Figure 57-4. A, Finoff transilluminator. **B,** Slit lamp biomicroscope (SL-15, Kowa). **C,** Head loupe (Hongguang Optics).

keratitis, the organisms can traverse Descemet's membrane and persist in the anterior chamber, again indicating a poorer prognosis and altering the therapeutic plan.

Diagnostic Procedures

Ocular surface disease often manifests as a painful red eye. In this case, distinguishing engorged bulbar conjunctival vessels from injected episcleral vessels is important, because the former corresponds to surface ocular disease, whereas the latter is typically seen with intraocular disease. Conjunctival vessels branch extensively, can be moved relative to the underlying globe, and can be blanched by topical application of 2.5% phenylephrine. Other nonspecific signs of ocular discomfort include blepharospasm, photophobia, epiphora, and conjunctival hyperemia, which may indicate adnexal, ocular surface, or intraocular disease. However, approaching such an eye in a logical, systematic fashion yields a diagnosis in the majority of cases. To this end, the order in which diagnostic tests are performed is important. For example, if corneal sensation is to be evaluated, it must be performed before the application of topical anesthetics to the eye. It is also often recommended that samples for culture be taken before topical anesthetics and topical fluorescein are applied, because these agents may reduce the isolation rate of organisms in culture.[68,69] However, in practice the application of a topical anesthetic may be required to facilitate accurate and safe sampling of a lesion. Additionally, the clinician may need to apply fluorescein dye to confirm the presence of an ulcer before sampling for culture is considered.

Ophthalmic Stains

Fluorescein staining is primarily used to detect corneal defects, and this procedure should be performed on any inflamed or painful eye. In areas devoid of epithelium, the dye is able to pass into the hydrophilic corneal stroma, but it does not bind to Descemet's membrane. Hence, an ulcer extending to the depth of Descemet's membrane may be fluorescein negative over the deepest portion, surrounded by a doughnut-shaped area of fluorescein uptake. The dye is available as a single-use 0.5% solution or impregnated paper strips. A portion of the paper strip can be torn off and placed into a syringe containing a commercial eyewash solution to create a fluorescein solution to apply to the eye. This solution can be gently squirted directly onto the cornea from a hubbed syringe with the needle removed (Figure 57-5). Alternatively, the paper strip can be moistened with commercial eyewash and directly applied to the lower conjunctival fornix. Fluorescein peak excitation occurs under blue light, so addition of a cobalt blue filter to a Finoff transilluminator can make it easier to see areas of fluorescein uptake (Figure 57-6). Fluorescein can also be used to assess corneal integrity, for instance, after primary suture closure of a full-thickness corneal laceration. This is known as the *Seidel test*. The dry paper strip is applied directly to the site of injury, which is then monitored for the development of fluorescence, indicating leakage of fluid from the anterior chamber.

Rose bengal is a vital stain that adheres to dead and devitalized epithelial cells. As such, it is useful for detecting the punctate and dendritic patterned lesions seen with equine herpes viral corneal disease and early fungal keratitis.[36] If applied excessively, rose bengal can also stain healthy corneal epithelial cells and has a dose-dependent toxic effect on these cells.[70,71]

Figure 57-5. Application of fluorescein stain to the cornea using a hubbed syringe with the needle removed.

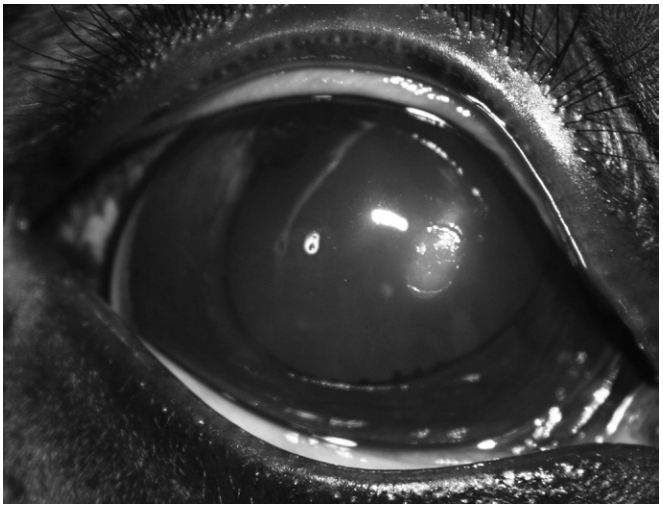

Figure 57-6. Superficial corneal ulcer stained positive with fluorescein.

Culture and Sensitivity

Pathogen culture and sensitivity testing provide useful information for guiding antimicrobial therapy and are important in the management of conditions such as corneal ulcers.[72] Indications for corneal or conjunctival culture include any corneal ulcerative disease, corneal stromal infiltrate, purulent ocular discharge, and proliferative masses. In cases of bacterial or fungal stromal abscesses, the pathogens may be located too deep within the cornea to allow collection of a diagnostic sample. In these cases the removal of epithelium overlying such a region may facilitate a diagnosis. Although topical anesthetics have been shown to inhibit the growth of microorganisms,[69] in many instances their administration is necessary to safely and accurately obtain a sample. To obtain a culture, the eyelids should be retracted and sterile Dacron-tipped culture swabs applied gently to the area (Figure 57-7). Collection of samples for aerobic bacterial and fungal cultures should be performed. In cases of deep or rapidly progressive ulcers, extreme care should be used and the edges rather than the center of the lesion should be sampled. Collection of samples for viral culture may also be

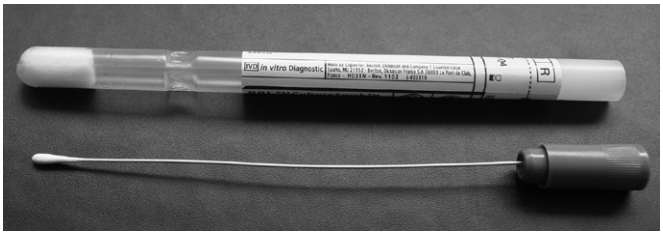

Figure 57-7. Dacron-tipped culture swab (Becton Dickinson).

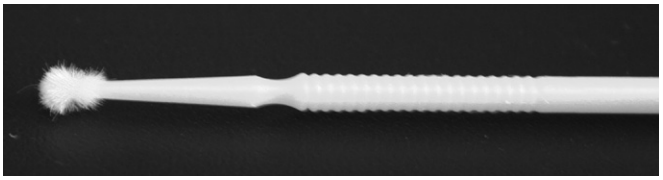

Figure 57-8. Cytobrush for cytology sampling (Microbrush).

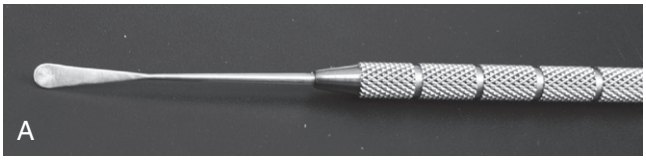
indicated if equine herpesvirus 2 (EHV-2) infection is suspected.[45,73] In these cases, specific instructions for collecting and handling the sample should be obtained from the testing laboratory before sampling the lesion. Treatment should commence before receiving the results of culture and sensitivity testing, and for this reason, performing cytology (see next) at the time of the initial examination can be a very valuable guide to initial treatment options.

Cytology

The evaluation of cytology samples collected from the conjunctival or corneal surface can provide immediate characterization of the nature and severity of an inflammatory response, and it can confirm the presence of bacteria or fungal hyphae, thus guiding the initial therapy. Cytology is particularly recommended for corneal ulcers, corneal abscesses, and proliferative masses of the cornea or conjunctiva. In cases with suspected infection, samples are collected to attempt to identify causal organisms while waiting for more definitive results from culture and sensitivity testing. Samples can be collected using a cytobrush (Figure 57-8), a Kimura spatula (Figure 57-9), or the blunt end of a scalpel blade.[74] Of these implements, the cytobrush has been shown to yield superior diagnostic samples.[75,76] A possible exception is when a deep sample is needed for culture of a fungal abscess, in which case a Kimura spatula may prove superior. For deep ulcers, descemetoceles, and perforations, cytology samples should be collected with extreme care. With corneal perforations or other lesions that require treatment under general anesthesia, cytology sampling may be more safely performed while the horse is anesthetized. Usually smears are made on several slides, which can be stained with different techniques or submitted to a clinical pathologist.

After collection, the sample should be immediately subjected to a Romanowsky type of stain, such as Diff-Quik, and evaluated for the presence of inflammatory cells and infectious organisms. If bacteria are seen, another smear should be stained with Gram stain (Figure 57-10). Failure to identify fungal hyphae does not rule out a fungal keratitis because they can be difficult to identify on routine staining (Figure 57-11). Their identification can be facilitated by use of special stains such as Gomori methenamine silver (GMS), periodic acid–Schiff (PAS), and new methylene blue.



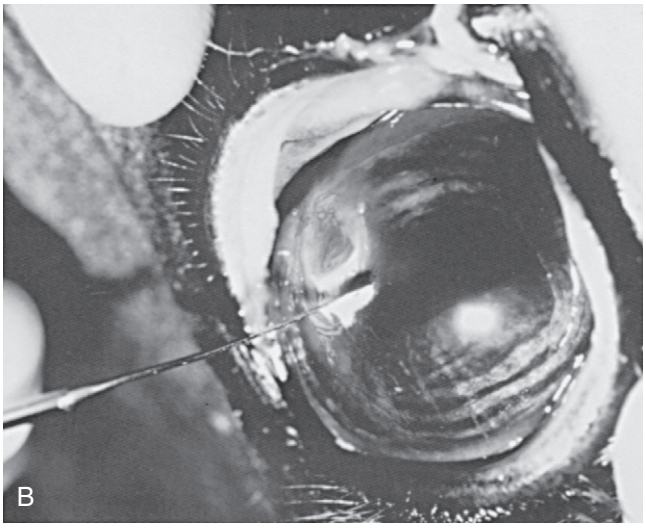


Figure 57-9. A, Kimura spatula. **B,** Technique for acquiring corneal samples for cytology and culture. The corneal surface is aggressively scraped with a Kimura platinum spatula.

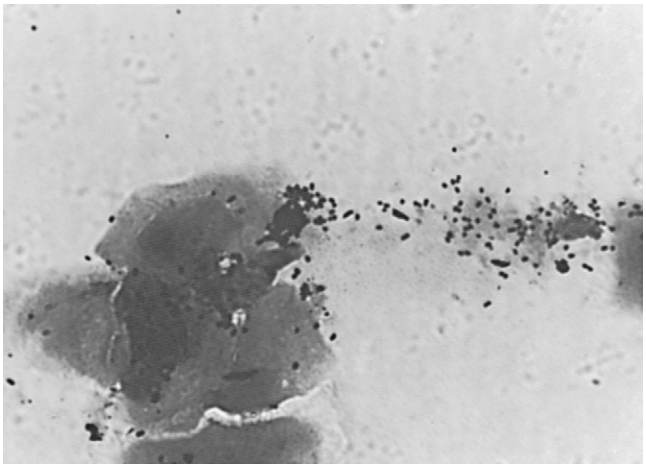

Figure 57-10. Cytologic appearance of corneal scraping from an eye with a bacterial ulcer. Numerous gram-positive organisms are visible (Gram stain, ×1100.).

RELEVANT PHARMACOLOGY

Application of Medication

Topical application of ophthalmic drugs provides a high concentration at the desired site of action for the treatment of ocular surface conditions, often negating the need for systemic dosing. Anti-inflammatories are a common exception to this,

Figure 57-11. Cytologic appearance of corneal scrapings from an eye with a fungal ulcer. Branching hyphae are visible (modified Wright-Giemsa stain, ×700).

and drugs such as flunixin meglumine are often administered systemically in addition to or in place of topical application, both preoperatively and postoperatively, control to ocular inflammation. The retention and absorption of topical ophthalmic mediations depends on precorneal factors, such as lacrimation and nasolacrimal drainage, and characteristics of the drug formulation, which may be solutions, suspensions, or ointments. Topical ophthalmic ointments are often chosen because of their prolonged retention time and relative ease of administration to the equine eye, as compared to ophthalmic solutions. However, if the anterior chamber has been penetrated or is to be entered surgically, ointments should be avoided and an ophthalmic solution should be used. If a solution is used it is common practice to wait 5 minutes between applications of different medications to prevent diluting the previously applied drug. To achieve a persistent high concentration at the site of action, frequent administration may be necessary. This may be facilitated by placing a subpalpebral lavage line.

Subpalpebral Lavage Placement

Placement of a subpalpebral lavage line can be particularly valuable when frequent administration of topical medications is required and painful conditions are being treated. This can reduce the risk of trauma to the surgical site, because the horse often becomes refractory to frequent topical medication for painful conditions. Placement of a subpalpebral lavage may be performed immediately postoperatively before recovery from general anesthesia, or under standing sedation. If placed under sedation, an auriculopalpebral nerve block, topical anesthesia, and infiltration of local anesthetic into the upper eyelid can be performed. Subpalpebral lavage kits are available, comprising a silicone tube plus a circular baseplate with a hubless hypodermic needle for passage through the eyelid (Figure 57-12). Both superior and inferomedial placement have been described,[77] and the choice of site depends on the location of the injury; the goal is to maximize the distance from the tubing and baseplate to the lesion (Figure 57-13). In either instance, the planned entry site at the eyelid should be prepared with 1 : 50 povidone-iodine solution, which is also directly applied with cotton-tipped applicators to the conjunctival fornix at this same

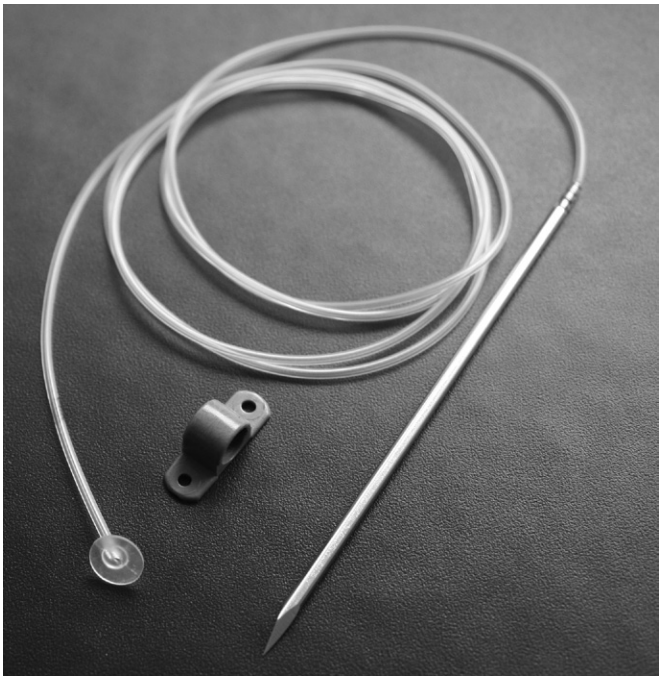

Figure 57-12. Subpalpebral lavage kit (Mila International).

Figure 57-13. Subpalpebral lavage line placed superiorly with silicone tubing secured to the head with tape tabs.

site. Surgical scrubs containing detergents and alcohol preparations should not be used because they may result in epithelial loss and ulceration. The region of the eyelid through which the tube is to pass is anesthetized with subcutaneous 2% lidocaine, and 0.5% proparacaine is applied to the conjunctival surface

Figure 57-14. Subpalpebral lavage line threaded through braided mane, terminating in an injection port for medication administration.

topically. Alternatively, cotton-tipped applicators soaked in proparacaine can be held against the conjunctiva to ensure analgesia. The 12-gauge hubless needle is introduced into the deepest point of the conjunctival fornix and driven through the eyelid. This ensures placement of the baseplate deep in the conjunctival fornix and reduces the risk of corneal irritation and damage to the surgical site. The globe itself should be protected by keeping a finger between the needle and the eyelid. The lavage tube can then be sutured immediately adjacent to the exit site, via tape tabs secured to the line, and similarly secured at two other sites away from the eye, directing the lavage line into the mane. The line can then be threaded through the braided mane and an injection port placed to facilitate administration of medications (Figure 57-14).

Topical Antibiotics

The choice of topical antibiotics for the treatment of ocular surface infections should be based on the results of pathogen culture and sensitivity testing, with initial therapy based on the results of cytology while awaiting the culture results. The desired mode of administration, whether by topical application or via subpalpebral lavage line, also affects the choice of agent because many drugs are available as either an ointment or solution, but not both. Details of commonly used topical antibiotics are provided later.

Topical aminoglycoside antibiotics are often used in "triple-antibiotic" combinations, where neomycin is typically combined with polymyxin B and bacitracin or with polymyxin B and gramicidin. Triple-antibiotic preparations are a good choice for postoperative prophylaxis or treatment of minor ocular surface bacterial infections. They are available as solutions or ointments and are usually applied three or four times daily. For more serious confirmed bacterial infections, other drugs may be chosen and used in combination at an increased frequency. Gentamicin and tobramycin are bactericidal drugs and broad-spectrum aminoglycosides with an enhanced gram-negative spectrum, and they are available alone in solution. Allergic or irritant reactions have been reported with prolonged use of topical aminoglycosides.[78]

Other topical antibiotic preparations commonly used are the second-generation fluoroquinolones, ciprofloxacin and ofloxacin. They possess bactericidal, broad-spectrum activity and are available as ointments or solutions. Chloramphenicol, a bacteriostatic drug with a broad spectrum of action and good penetration, is also widely used. Because this drug has been reported to cause aplastic anemia in humans, it is prudent to warn owners regarding its potential toxicity and recommend the use of gloves when applying it.[78,79]

Topical Antifungal Medications

Because of the propensity of the horse to develop fungal keratitis, topical antifungals are often used prophylactically in cases of corneal injury. When fungal keratitis is suspected or confirmed with cytology or culture, aggressive medical management may be pursued before surgical intervention, as discussed later in this chapter. Briefly, medical therapy should target both the fungus and the reflex anterior uveitis that often increases in severity as the fungal organisms are killed. Of the available antifungal medications, natamycin ophthalmic suspension (Natacyn) is currently the only commercially available drug formulated for topical ophthalmic application. It is recommended for use four to six times daily and may be delivered via subpalpebral lavage. Other commonly used preparations include fluconazole and silver sulfadiazine.[44] For deeper fungal keratitis and corneal abscesses, access of the drug to the deeper cornea can be improved by débriding the corneal epithelium over the area of the lesion or adding DMSO to the preparation.[80,81]

Anti-Inflammatory Drugs

Topical corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs) can be used to control inflammation of the ocular surface. Since topical corticosteroids delay wound healing and potentiate some infections, they are contraindicated in horses with corneal ulceration or overt infection. In other situations, for instance after routine surgery to the ocular surface, the use of a topical corticosteroid preparation has significant merit because of the potentially deleterious effects of ocular inflammation on vision. Topical prednisolone acetate 1% or dexamethasone 0.1%, with or without neomycin and polymixin B, are good choices. Topical NSAIDs can be used alone or in combination with topical corticosteroids. They do not have the potentially dramatic negative side effects of a topical corticosteroid but are best avoided in instances of corneal ulceration. Delayed wound healing and slowed corneal neovascularization should be weighed against their beneficial effects.[78] However, except in cases of overt infection, the benefits of their use generally outweigh these concerns. Flurbiprofen 0.03% solution and diclofenac 0.1% solution are commonly used examples. As already mentioned, systemic anti-inflammatories are often used to help control postoperative ocular inflammation.

ANESTHETIC CONSIDERATIONS

Topical Anesthesia

A topical anesthetic facilitates corneal and conjunctival manipulation for examination of the ocular surface and sample collection. Topical anesthetics can also be used in addition to sedation

or general anesthesia to provide corneal and conjunctival analgesia for procedures such as suturing and foreign body removal. Proparacaine hydrochloride 0.5% solution and tetracaine 0.5% solution are most commonly employed. They can be administered to the cornea via a 1-mL hubbed syringe with the needle snapped off, or they can be instilled directly into the lower conjunctival fornix. The duration of corneal anesthesia achieved by a single administration of either 0.2 mL of proparacaine 0.5% or 1 drop of tetracaine 0.5% is 25 to 30 minutes with maximal anesthetic effect occurring within 5 minutes of application.[82,83] For both agents, the application of multiple drops may increase the duration and intensity of the anesthetic effect.[83,84] Epitheliotoxicity and destabilization of the precorneal tear film are described side effects, and for this reason repeated application for therapeutic purposes should be avoided.[85,86] The antimicrobial activity of these agents also means that swabs for corneoconjunctival cultures should be collected before instillation of a topical anesthetic.[87,88] However, topical anesthetics are often applied first, because subsequent sample collection is safer and the desired site can be targeted more accurately.

Sedation

Sedation is often required for complete examination of the ocular surface. Additionally, minor procedures such as biopsies and cytologic sampling can readily be performed under sedation, topical anesthesia, and nerve blocks. For precision surgery of the ocular surface, general anesthesia is usually required. In addition to the agents described in, "Ophthalmic Examination Techniques and Diagnostic Procedures," a continuous intravenous infusion of detomidine has been successfully used for standing procedures anticipated to be of long duration.

General Anesthesia

General anesthesia is typically required for most surgical manipulations of the cornea; however, it should be borne in mind that the effects of general anesthetics on the eye are not insignificant. For surgery of the ocular surface, the cornea should be centrally positioned, all eye movements such as nystagmus should be eliminated, and the eye should have a normal intraocular pressure.

The effect of anesthetic agents on intraocular pressure is particularly important if the anterior chamber has been penetrated or is to be entered as part of the surgical procedure, such as for penetrating wounds and deep corneal abscesses. In such situations, any increase in intraocular pressure can be detrimental to ocular health and the success of the procedure. Sudden decreases in intraocular pressure have similar consequences and should be avoided by ensuring the globe remains inflated by the use of viscoelastic agents. Most anesthetic agents that are injected or inhaled will lower intraocular pressure. Ketamine is a notable exception; it elevates intraocular pressure, which is thought to be mediated by increased extraocular muscle tone.[89] Additionally, any prolonged respiratory depression or acidosis can elevate intraocular pressure.[90] Positioning of the globe is also important for maintaining intraocular pressure, ensuring that inadvertent pressure is not placed on the eye by the lid speculum or the surgeon's manipulations.

Achieving and maintaining a centrally positioned cornea will best facilitate surgery of the ocular surface, affording the surgeon maximal access to the cornea for surgical procedures. This must be actively addressed by the surgeon because the effect of most injectable and inhalational agents used for general anesthesia produce ventral and medial rotation of the globe. Strategies to overcome this problem include placement of stay sutures through the conjunctiva adjacent to the limbus with 4-0 silk. Alternatively, a neuromuscular blocking agent such as atracurium (0.2 mg/kg IV) can be combined with positive pressure ventilation to improve the position of the cornea. These agents typically relax the extraocular muscles within 1 minute of administration, causing the eye to return to a normal "primary gaze" position. These agents are also valuable to use in cases where the cornea is perforated, or surgical entry into the anterior chamber is planned, as for a penetrating keratoplasty. Neuromuscular blockade also relieves the tension exerted on the posterior globe by the extraocular muscles, which can increase the likelihood that the vitreous will push anteriorly and collapse the anterior chamber when the cornea is entered. Nystagmus may also be encountered and is clearly problematic for the surgeon. This can be rapid movements or a slow drift, and it is best controlled by achieving an appropriate depth of anesthesia and by using neuromuscular blocking agents.

Corneal drying during anesthesia should be prevented to minimize the risk of postoperative complications such as corneal ulceration.[32] To this end, the unoperated eye should be lubricated with an artificial tear ophthalmic ointment. Similarly, the operated eye should be frequently irrigated with a sterile saline solution such as balanced salt solution to prevent damage to the corneal and conjunctival epithelium.

For information on performing general anesthesia, please review Chapters 18 and 19.

SURGICAL EQUIPMENT AND SURGICAL PRINCIPLES

Performing surgical procedures on the ocular surface requires not only specialized techniques but also specialized instrumentation, smaller suture materials, and magnification where available. Magnification is strongly recommended to minimize damage to the delicate structures of the cornea and facilitate accurate placement of sutures. An operating microscope or head loupe can be used and affords an improved surgical outcome, but they also require some practice for the surgeon to adapt to the smaller field of view. Loupes providing ×2.5 or ×4 magnification are commonly used. For more advanced procedures, such as keratoplasty, an operating microscope is desired (Figure 57-15).

Instrumentation

The surgeon should have access to instruments suitable for handling the eyelids, for example to perform lateral canthotomies when indicated. More-delicate instruments for conjunctival manipulations and microsurgical instruments suitable for corneal surgery should also be available. For manipulation of the conjunctiva and sclera, Bishop-Harmon forceps are ideal, and conjunctival tissue is best incised with tenotomy scissors such as the Stevens or Westcott (Figure 57-16). To facilitate exposure, a lid speculum suitable for the equine eyelids is required. Several types are available. Heavy-duty models such as the Guyton-Park eyelid speculum provide good exposure of the ocular surface (Figure 57-17). For surgical procedures involving the cornea, microsurgical instrumentation should be

Figure 57-15. Operating microscope (Zeiss).

used, with correspondingly smaller gauge needles and suture materials. The investment in such equipment is dictated by predicted frequency of use. Considered most important are Colibri or Castroviejo forceps; Castroviejo needle holders; Castroviejo universal scissors, curved with blunt tips; and a Beaver scalpel handle and blades (No. 64, 65, and 69) (Figures 57-18 and 57-19). For advanced procedures, such as a penetrating lamellar keratoplasty, a Martinez corneal dissector and corneal trephines may be used. Additional equipment that may be required includes fine-tipped disposable cautery units and cryotherapy units (liquid nitrogen or nitrous oxide). The investment in fine ophthalmic instruments should be protected by careful use, cleaning, and storage. A microsurgical instrument tray should be used for storing and sterilizing the instruments.

Suture Materials, Needles, and Suture Patterns

Fine suture materials with swaged needles are required for the ocular surface. Both absorbable and nonabsorbable suture materials have been described for corneal and conjunctival surgery. However, when operating on the cornea, absorbable 6-0 to 8-0 suture material, such as polyglactin 910, is recommended. For conjunctival and scleral procedures, 4-0 to 6-0 absorbable suture materials are most suitable. Reverse cutting or spatulated needles are typically chosen for reduced iatrogenic damage to the tissues.

The choice of suture pattern depends on the tissue being apposed and the nature of the surgical procedure. For instance,

if performing a penetrating keratoplasty or conjunctival pedicle graft, a simple-interrupted pattern using 7-0 or 8-0 absorbable sutures on a spatulated needle may be chosen. For closing a partial or full-thickness corneal laceration or surgical wound, a simple-continuous or bootlace pattern using the same suture material and needle just mentioned may be preferred. Apposition of bulbar conjunctiva may dictate the use of 6-0 absorbable sutures on a reverse cutting needle applying a simple-continuous pattern, whereas scleral defects may be best apposed with simple-interrupted pattern of 4-0 absorbable sutures on a reverse cutting needle.

Preparation for Surgery

Preparation for ophthalmic surgery is somewhat different from that for other surgical procedures. The head should be positioned for good access to the ocular surface. If an operating microscope is to be used, the head should be positioned securely with foam wedges so that the eyelids of the surgical eye are as close to horizontal as possible. The lashes and long vibrissae may be clipped before conjunctival or corneal surgery. The adnexa should be prepared for aseptic surgery with 1:50 povidone-iodine solution (diluted with sterile 0.9% saline solution). Surgical scrubs and alcohol should not be used because they are harmful to the corneal and conjunctival epithelium. After preparing the eyelids, the conjunctival fornices should be similarly prepared with povidone-iodine applied with cotton-tipped applicators, and the cornea should be flushed with the same solution. Cotton or paper drapes or aperture drapes are applied around the eye. Alternatively, a specialized disposable eye drape with an adhesive clear plastic center can be used. These drapes can be applied to the periocular tissue and an ellipse then cut out to expose the ocular surface (Figure 57-20).

Additional Exposure of the Globe

Before initiating surgery involving the ocular surface, additional exposure may be desired by the surgeon. In these instances, a lateral canthotomy may be performed. The procedure involves making a full-thickness incision 5 mm to 10 mm in length, extending laterally from the lateral canthus. Standard Mayo scissors are typically used for a full-thickness separation of the thick tissue at this site. Hemorrhage is typically minor and easily controlled with cellulose ocular sticks. After completion of surgery, the canthotomy should be closed in two layers. A simple-continuous pattern is used to close the subconjunctival layer, and the skin is apposed with a simple-interrupted pattern using 4-0 absorbable suture. Most important for achieving secure apposition of the lid margin, without risk of the suture tags causing corneal trauma, is the careful placement of a figure-of-eight suture at the lid margin. See Chapter 56 for more detail on the accurate placement of figure-of-eight sutures.

Intraoperative Hemostasis

For any surgery involving the ocular surface, hemostasis and removal of excess fluid should be performed with sterile cellulose ocular sticks rather than standard 4 × 4 swabs, because cotton swabs shed small cotton fibers and may be abrasive to the corneal epithelium. For full-thickness lacerations or in any procedure where the anterior chamber will be entered, such as a penetrating keratoplasty, Weck-Cel cellulose sponge spears should be used (Figure 57-21). If necessary, additional hemostasis can be achieved by direct application of 2.5% phenylephrine or 1:10,000 epinephrine, applied with moistened sterile cotton-tipped applicators.

Entering the Anterior Chamber

If the anterior chamber is penetrated, which may occur with a perforating corneal foreign body or penetrating keratoplasty, a viscoelastic agent should be administered directly into the anterior chamber to help maintain anterior chamber depth and protect the corneal endothelium. Commonly used agents are hyaluronan and 2% hydoxypropyl methylcellulose. If viscoelastic agents are to be used, an understanding of their properties within the eye and the potential complications associated with their use, such as postoperative ocular hypertension, is essential (described further in Chapter 58).

Postoperative Care

Before moving the horse into the recovery stall, a protective eye mask may be placed over the operated eye to prevent damage to the surgical site during recovery from anesthesia. The eye mask is then typically left in place for several days

Figure 57-20. Disposable ophthalmic drape with clear adherent window (Alcon).

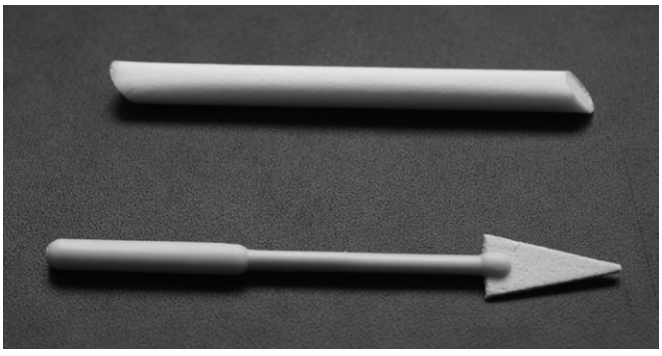

Figure 57-21. Cellulose ocular stick *(top),* and Weck-Cel cellulose sponge spear *(bottom).*

postoperatively to prevent self-trauma. An alternative is closing the eyelid following application of an ophthalmic ointment and covering the area with several 4 × 4 gauze swabs. The head is then wrapped with an Elastikon bandage, ensuring that vision from the unoperated eye remains unobstructed. After any surgical procedure, medical therapy is typically reinstated. This may consist of prophylactic antimicrobial therapy or therapy directed specifically at any organisms previously identified. If anterior uveitis is present or anticipated, topical atropine may be applied two to four times daily on a tapering course, and systemic NSAIDs may be administered twice daily.

ROUTINE SURGICAL TECHNIQUES

Conjunctivectomy and Conjunctival Biopsy

Conjunctivectomy has been described for removing foreign bodies such as burdock bristles embedded in the conjunctiva. Most foreign bodies can be removed without too much difficulty. However, burdock bristles migrate into and become embedded in the conjunctiva, causing chronic ocular irritation and corneal ulceration. They can be difficult to visualize and careful examination of the conjunctiva with magnification is necessary to locate them. Conjunctivectomy to excise the affected conjunctiva and foreign material can be performed under standing sedation and topical anesthesia. The affected region of conjunctiva is elevated with Bishop-Harmon forceps and excised with tenotomy scissors. Hemorrhage can be controlled with pressure, and if necessary, topical 2.5% phenylephrine can be applied directly to the site using a cotton-tipped applicator. A similar procedure is used to obtain a biopsy of conjunctival tissue for histopathologic examination. The conjunctiva heals rapidly, so unless the area of conjunctiva excised is large, the resulting defect can be left to heal by second intention. If sutures are used, care should be taken to ensure that they will not rub on the cornea and potentially cause ulceration.

Repair of Conjunctival Lacerations

Small lacerations can be left to heal by second intention after careful examination and possibly exploration of the wound. This is important since foreign bodies may be present and the underlying structures may also have been damaged. Stick injuries are common, and penetrating sticks can break off, leaving only a small amount or even none of the stick visible. If the foreign body has penetrated the periocular tissues or the globe itself, a complete ophthalmic examination will detect signs of penetration of the globe or laceration of the sclera. It is also possible for severe blunt trauma to the globe to result in scleral splits, the extent of which may not be immediately apparent but are usually accompanied by serious intraocular changes. In some instances, it may be necessary to surgically reflect the conjunctiva to reveal the full extent of underlying scleral lacerations. Scleral defects can be closed with 4-0 to 6-0 absorbable suture, such as polyglactin 910. When conjunctival defects require closure, a simple-continuous pattern of 4-0 to 6-0 absorbable sutures can be used.

Excision of Conjunctival Tumors

The primary approach to a conjunctival mass should be to obtain a histologic diagnosis. With small masses, this can be combined with an excisional biopsy. Larger masses can be sampled by impression smears or a small "snip" biopsy. The extent of the mass and its histologic diagnosis will influence the subsequent choice of therapy. Limbal squamous cell carcinomas (SCCs) are common and typically require a keratectomy to remove the corneal portion and additional excision to eliminate the conjunctival extension of the tumor. Areas of bulbar conjunctiva can be removed using tenotomy scissors to excise and undermine the mass. When excising a conjunctival mass, the inclusion of the underlying substantia propria and Tenon's capsule will help ensure complete excision. Small defects can be left to heal by second intention. If the lesion is larger, partial or complete closure of the resulting defect can usually be achieved by undermining the surrounding remaining conjunctiva to mobilize it and stretch it over the defect. For limbal and bulbar conjunctival SCC, where the recurrence rate has been reported to be particularly high, excision combined with adjunctive therapy has been shown to significantly lower the rate of recurrence.[91]

Superficial Keratectomy

Superficial keratectomy represents the surgical excision of a superficial layer of corneal tissue including epithelium and anterior stroma. Indications for keratectomy include presence of dermoids, typically hairy, skinlike tissue located on the cornea adjacent to the limbus,[92] and development of infection, particularly associated with superficial fungal keratitis, corneal malacia, or superficial corneal stroma abscesses.[44,93] Superficial keratectomy is also commonly performed to remove corneal neoplastic masses, the most common being limbal-based SCC.[94]

Superficial keratectomy is best performed under general anesthesia, with good magnification and illumination. An initial incision is made into the anterior stroma through normal cornea adjacent to the lesion to be removed. This is made using a No. 64 or No. 69 Beaver blade to the depth needed to remove the mass. Corneal forceps are used to grasp the incised edge of the cornea, and the corneal stroma can subsequently be separated along a lamellar plane to undermine the lesion. A blunt instrument can be used for this dissection, ideally a Martinez corneal dissector, which is specifically designed as a lamellar separator. Alternatively, the original blade can also be used for the purpose, taking care to only use it to separate the corneal lamellae rather than change the depth of the dissection. The resulting bed of cornea achieved by stromal dissection should be carefully inspected. If necessary, additional tissue can be removed by dissection along a deeper lamellar plane to ensure removal of all diseased tissue (Figure 57-22). The resulting corneal defect can be left to epithelialize. However, if the lesion is deep or the base of the lesion has been treated with an adjunctive therapy, a conjunctival hood graft or amniotic membrane graft can be used to cover the defect. These procedures are described later. They have the advantages of protecting the cornea and facilitating healing, but they have the disadvantage of potentially masking any tumor regrowth. Other than tumor regrowth, complications associated with superficial keratectomy are rare but include an excessive neovascular response, scarring, infection, and corneal perforation.

Adjunctive or Alternative Therapies for Ocular Surface Tumors

Several adjunctive therapies have been used to manage ocular surface tumors, such as conjunctival, limbal, and corneal

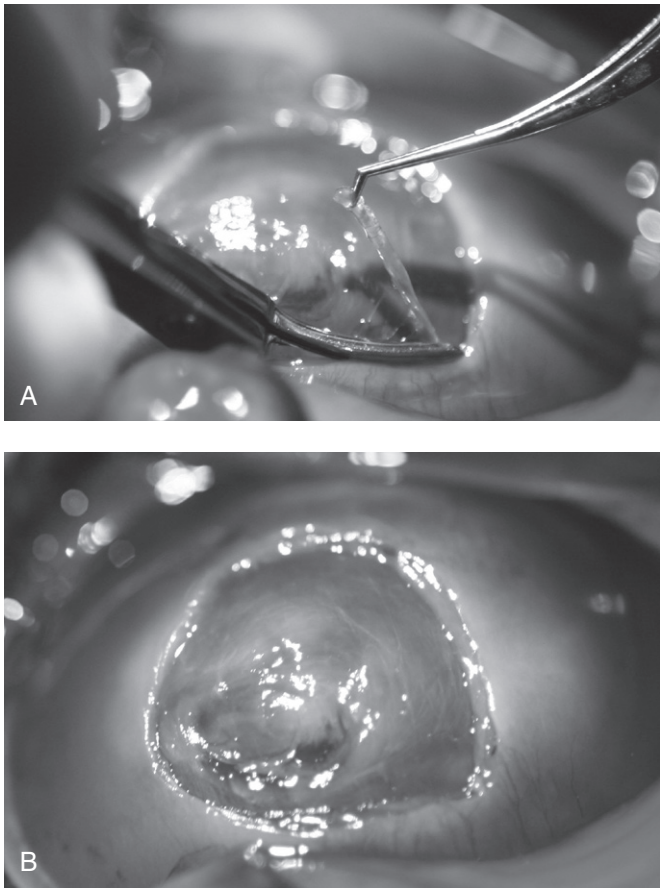

Figure 57-22. Intraoperative images of a superficial keratectomy. **A,** Following dissection along a lamellar plane with a Martinez dissector, the edge of the keratectomy is trimmed with Castroviejo universal corneal scissors. **B,** Final appearance of the completed keratectomy.

masses. These include beta irradiation, cryotherapy, radiofrequency hyperthermia, and CO_2 laser ablation. Most of these procedures can be performed on a horse under standing sedation with topical anesthesia and local nerve blocks. General anesthesia is typically reserved for cases where these therapies are used as an adjunct to more aggressive surgical intervention such as keratectomy.

Beta irradiation may be used as an adjunctive procedure for surface ocular lesions, such as SCC and epibulbar melanoma, by direct application of strontium-90 (^{90}Sr) to the surface ocular tissues. Because tissue penetration is 1 to 2 mm, this therapy is ideal for corneal lesions. A dose of 75 to 100 Gy can be delivered to multiple lesions, ensuring that a total dose of 500 Gy is not exceeded; at doses higher than this, there is a risk of permanent corneal endothelial damage and deep corneal necrosis.[56] Progressive corneal edema and bullous keratopathy are also reported complications.[95] When beta irradiation is combined with superficial keratectomy and permanent bulbar conjunctival grafts to treat corneal SCC, a recurrence rate of only 17% has been reported.[96] Beta irradiation can similarly be used for limbal and conjunctival masses.

Cryoablation may be used alone or adjunctively, in a fast freeze to −20° C to −40° C followed by a slow thaw for two cycles to achieve optimal cryonecrosis of malignant epithelial cells.[97] A nitrous oxide or closed liquid nitrogen probe can be used. Limbal and conjunctival masses are best suited to this treatment, and side effects are uncommon.

Radiofrequency hyperthermia and *CO_2 laser ablation* are additional modalities that have been described for the destruction of surface ocular lesions in the horse.[98,99] Intratumoral treatment with *cisplatin* has also been described for conjunctival lesions.[100] Most recently a report described treatment of ocular SCC that consisted of multiple topical applications of *mitomycin C* (Mutamycin), with or without surgical excision. Complete resolution occurred in 77% and 75% of cases, respectively, with no reported complications.[101]

Repair of Corneal Lacerations

Animals presenting with corneal lacerations should be examined carefully. It is important to ascertain if the injury is full-thickness, if the iris is involved in the wound, and if other intraocular structures such as the lens have been damaged. Involvement of the iris will complicate the repair. If the lens has been damaged, a cataract may ensue; if a large tear in the lens capsule is present, a severe inflammatory reaction to the liberated lens proteins may develop, significantly lowering the prognosis for achieving a comfortable, visual eye.[102]

Corneal lacerations typically require surgical repair using magnification with the horse anesthetized. Deep, uncomplicated corneal lacerations may be repaired by primary closure using simple-interrupted absorbable 6-0 to 8-0 sutures placed 1 to 2 mm apart. Small partial-thickness lacerations may be medically managed similar to a corneal ulcer, after ensuring that there is no foreign material lodged in the wound. If a foreign body is detected, its depth in the cornea must be accurately confirmed, because removal of a foreign body penetrating the entire thickness of the cornea may result in collapse of the anterior chamber. If a foreign body has penetrated the anterior chamber, or if its depth in the cornea cannot be assessed, it should be managed as a full-thickness laceration with the horse anesthetized and a viscoelastic agent available. Full-thickness lacerations may similarly result in collapse of the anterior chamber. If the wound is small it may seal with a fibrin clot, whereas larger wounds often show incarceration of the iris. In both situations, surgical repair is indicated. Typically, during the repair there is further leakage of aqueous humor, necessitating reinflation of the globe with a viscoelastic agent to maintain the shape of the anterior chamber during corneal suturing. Usually minimal débridement of the cornea is required, but the fibrin clot should be removed as the wound is prepared for suturing. A prolapsed iris is irrigated and, where possible, gently manipulated back into the anterior chamber using a blunt spatula or muscle hook. Any adhesions that have formed between the iris and the cornea are separated. This step should be done carefully because the iris is very vascular and hemorrhage may result, necessitating the use of topical epinephrine (1:1000 to 1:10,000). In instances where the laceration has been long-standing and the iris is incarcerated, it may be difficult to break down adhesions between the iris and cornea, and excision of the prolapsed iris may be necessary. In these cases, electrocautery may be useful to avoid excessive iridal hemorrhage (Figure 57-23).

In all cases where the anterior chamber has been penetrated, medical therapy should be prolonged and significantly more aggressive, including administering systemic antibiotics in addition to systemic anti-inflammatories and topical antibiotic solutions. Prognosis for healing with minimal scarring is good for

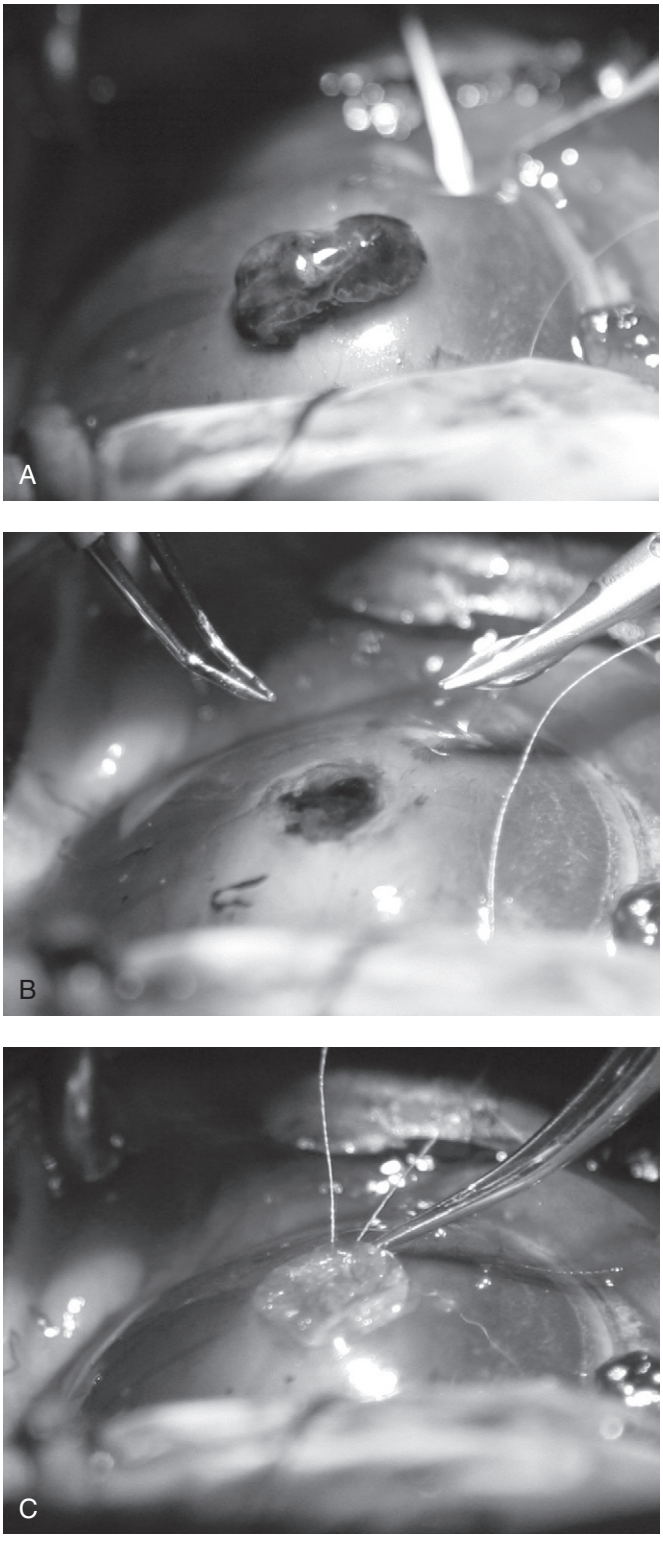

Figure 57-23. A, Preoperative appearance of a corneal laceration with prolapsed iris. **B,** Appearance of the corneal laceration after electrocautery of the prolapsed iridal tissue. **C,** Placement of porcine small intestine submucosa (SIS) in the corneal defect before placement of a conjunctival pedicle graft over the lesion.

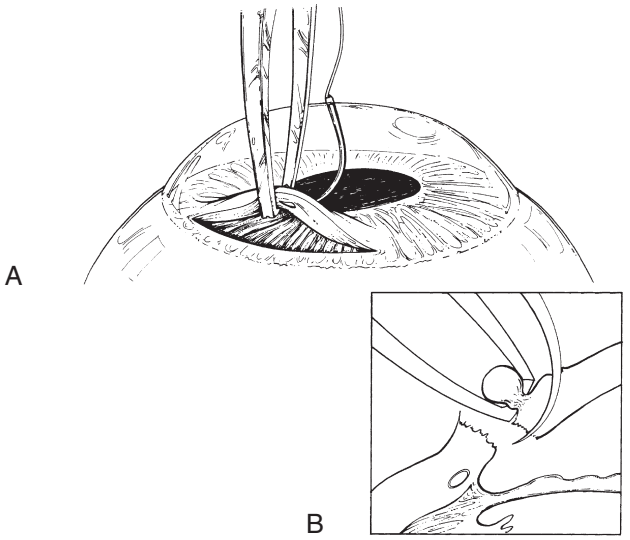

Figure 57-24. A, Correct placement of sutures to a depth of 80% to 90% of the cornea. **B,** Close-up view.

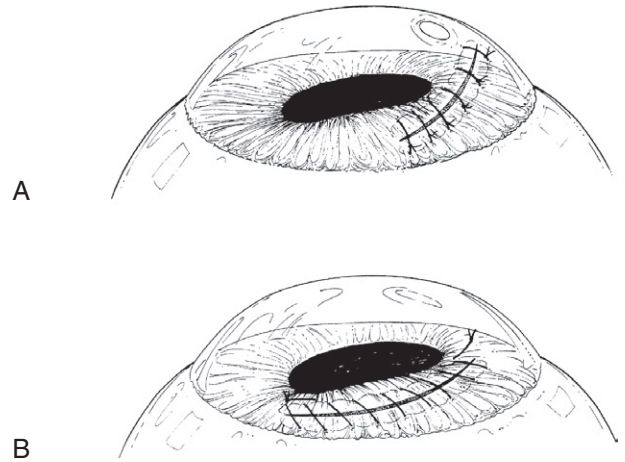

Figure 57-25. A, Closure of corneal defects using a simple-interrupted pattern. **B,** Closure using a simple-continuous pattern.

uncomplicated cases, but when grafting material is included, scarring will be more significant. Potential complications that can arise postoperatively include infection, excessive scarring, astigmatism, and suture dehiscence leading to aqueous humor leakage, iris prolapse, or globe collapse.

Considerations for Suturing the Cornea

Corneal sutures are best placed under magnification using 6-0 to 8-0 absorbable sutures, placed to a depth of approximately 80% to 90% of the cornea (Figure 57-24). Simple-interrupted, simple-continuous, and double bootlace suture patterns (Figure 57-25) are suitable. If sutures are placed too superficially, the posterior aspect of the wound will gape, jeopardizing wound integrity and increasing scarring. If sutures are placed full thickness through the cornea, the suture tracts may allow leakage of aqueous humor and increase the risk of contaminating material reaching the anterior chamber via the suture tracts. Suture

needle entry and exit sites should be at the same distance from the wound edges and be placed to the same corneal depth to avoid "steps" between the wound edges. If an arrowhead-shaped wound is present, a suture can be placed at the tip of the arrowhead first to prevent gaping at this part of the wound. Following the repair, a Seidel test should be performed with fluorescein dye to check that the wound is not leaking aqueous humor (see "Diagnostic Procedures," earlier). If corneal tissue is missing or a satisfactory repair is not possible, the surgeon should consider using a conjunctival graft. This may just be a temporary hood flap that is tacked to the cornea over the defect to give it some protection while healing, with the intention that it will retract unless it heals to the defect. If a larger defect is present, placement of a conjunctival pedicle graft or inclusion of material such as transplanted cornea, amniotic membrane, or porcine small intestine submucosa could be considered. These procedures are described in the following section.

ADVANCED SURGICAL TECHNIQUES

The procedures described here typically require general anesthesia, magnification, good illumination, appropriate instrumentation, and some practice to master. They are most commonly used for deep and perforating corneal ulcers or defects and deep focal corneal abscesses, although procedures such as conjunctival grafts and flaps can also be used to support and protect corneal repairs.

General Principles for Conjunctival Grafting

Conjunctival grafting procedures involve transposing a portion of conjunctival tissue to cover a corneal defect. This provides structural support and a vascular supply to the lesion and hence anticollagenases, fibroblasts, and growth factors that facilitate healing. Their main use is in cases of deep corneal ulceration, melting ulcers, descemetoceles, and corneal lacerations.[103] For the procedure, the conjunctiva should be incised and undermined with tenotomy scissors, and once mobilized it is sutured into position on the cornea, ensuring the needle passes first through the graft and then the cornea. Suturing should begin with placement of cardinal sutures at the tips or end of the graft.[104] A simple-interrupted, simple-continuous, or a combination of both suture pattern can then be used, ensuring that the sutures are placed to a depth of 50% to 65% of the cornea for adequate anchorage of the graft.

There are several types of grafts and flaps to choose from, and the selection largely depends on the position and size of the lesion. Defects close to the limbus can be covered by advancement or hood grafts, whereas more centrally placed lesions may be best covered with a pedicle graft. In some instances, a conjunctival graft may not sufficiently support a corneal defect; this is particularly the case for perforated ulcers but can also be true for larger, very deep ulcers and descemetoceles. In such situations, additional tectonic support for the cornea may be necessary and can be provided by scaffolding materials that can be sutured into the defect before graft placement. Materials that can be used for this purpose include transplanted cornea, either fresh or frozen; amniotic membrane; or commercially available products such as porcine small intestinal submucosa (SIS). The scaffolding material should be shaped to fit the defect and then sutured into the cornea, with the conjunctival graft sutured over the top of the site. Conjunctiva does not adhere well to porcine SIS, so removing a rim of epithelium from the cornea around the defect and suturing the conjunctival graft to the exposed corneal stroma helps the graft to heal into place. Additionally, if porcine SIS is used, a thicker four-ply preparation is preferred over the thin discs that are marketed for corneal use.

Some general principles to consider that may improve the outcome of conjunctival grafting procedures are described later. To reduce the risk of graft dehiscence and improve the cosmetic outcome, the conjunctival dissection should be kept thin, avoiding underlying Tenon's capsule. As a guide, dissection scissors should be visible through the graft as it is being harvested. The risk of dehiscence can also be reduced by ensuring the graft covers the defect without being under tension; if tension is present, additional conjunctiva should be undermined before suture placement. To ensure adequate coverage of the corneal lesion, the graft should ideally be slightly larger (1 to 2 mm) than the defect because it tends to contract. It is particularly important to realize that conjunctiva will not adhere to an epithelialized surface, so in instances where the epithelium has grown down the edges of an ulcer, it should be carefully removed to expose the corneal stroma to which the conjunctiva can adhere. A No. 69 Beaver blade can be used to débride the epithelium, or in some instances it can be peeled off using corneal forceps.

Conjunctival Grafting Techniques

Rotation Pedicle Graft

The rotation conjunctival pedicle graft is best suited for centrally located corneal defects, and it represents the most commonly performed type of conjunctival graft. Since a flap of conjunctiva is to be rotated onto the cornea, the surgery should be carefully planned, considering the site and size of the lesion and paying particular attention to ensure the vascular pedicles are not occluded at the base of the flap when it is rotated. The surgeon will find it is easier to harvest the lateral and dorsal bulbar conjunctiva rather than the medial or ventral conjunctiva because of the presence of the third eyelid. To begin the procedure, the bulbar conjunctiva is incised about 1 mm from the limbus using tenotomy scissors, and a combination of careful, precise blunt and sharp dissection is used to isolate the conjunctiva from Tenon's capsule. A finger-shaped strip of conjunctiva is fashioned, with the length determined by the distance of the lesion from the limbus (Figure 57-26). The recipient bed is prepared by removing necrotic or liquefied cornea and any epithelium that has grown into the defect. The graft can then be sutured into the recipient bed as described earlier, being sure that the conjunctival edges appose the corneal edges of the lesion. Finally, the defect created in the conjunctiva should be sutured closed in a simple-continuous pattern (Figure 57-27).

Advancement Pedicle Graft

An advancement conjunctival pedicle graft represents an alternative to the rotation conjunctival pedicle graft and is used for lesions located closer to the limbus. These grafts are fashioned using tenotomy scissors to create an incision in the bulbar conjunctiva, 1 to 2 mm longer than the width of the defect, adjacent to and parallel to the limbus. Subsequently, the bulbar conjunctiva is carefully undermined and extended up toward

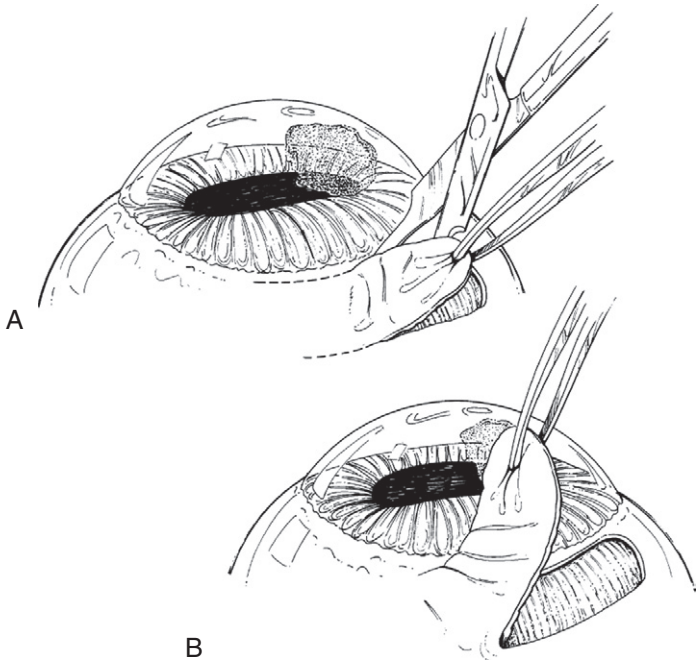

Figure 57-26. A, Conjunctival pedicle graft; the pedicle is dissected from underlying fibrous tissue with tenotomy scissors. **B,** The pedicle should lie over the corneal defect without undue tension.

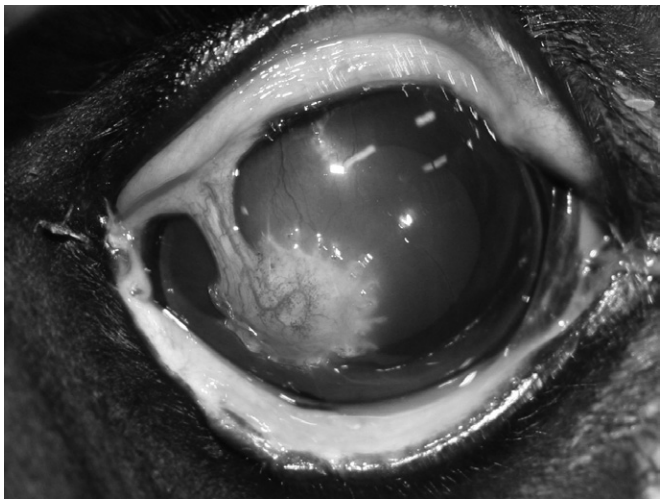

Figure 57-27. Appearance of a conjunctival pedicle graft 3 weeks after surgery showing a healthy, well-vascularized pedicle.

the fornix, again taking care to separate the thin conjunctival flap from Tenon's capsule. Two slightly diverging incisions are then made through the conjunctiva from the edge of the initial incision extending toward the fornix. The resulting strip of conjunctiva is sutured to the cornea after preparation of the recipient bed as described previously.

Tarsoconjunctival Grafts

Conjunctival grafts harvested from the palpebral conjunctiva of the upper eyelid have also been reported. Tarsoconjunctival grafts are created similar to a conjunctival pedicle graft but differ in that their base originates close to the eyelid margin. If this graft is performed, placement of a temporary tarsorraphy to reduce the risk of suture dehiscence has been recommended.[103]

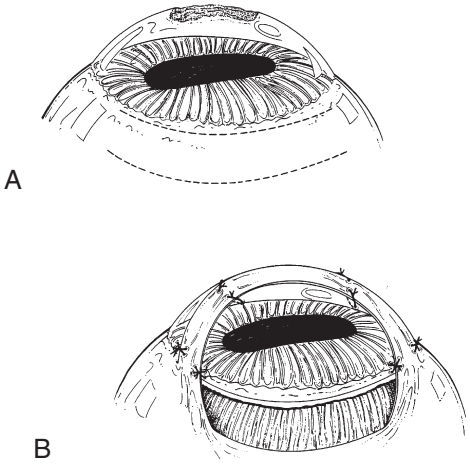

Figure 57-28. Bridge conjunctival graft. **A,** A strip of conjunctiva is incised and dissected from the bulbar conjunctiva. **B,** The bridge of conjunctiva is sutured to the cornea around the edge of the corneal ulcer.

Bipedicle and Bridge Grafts

Bipedicle or bridge conjunctival grafts have been described for linear corneal defects and large axially located lesions, with the advantage of providing additional blood supply. With this technique, the bridge graft carries a reduced risk of ischemia at the graft tip relative to the bipedicle graft.[93] The technique for creating a bipedicle graft involves creating two conjunctival pedicle grafts with their bases located 180 degrees apart, allowing the tips of the graft to meet over the lesion. A bridge graft involves creating two 140- to 180-degree bulbar conjunctival incisions, separated by a distance 1 to 2 mm wider than the lesion (Figure 57-28).

Hood Grafts

A hood conjunctival graft can be used to cover larger lesions close to the limbus. With this technique, a single incision is made 1 mm from the limbus, and the conjunctiva is undermined and advanced axially to cover the lesion (Figure 57-29). A hood graft can also be used to provide temporary additional protection of a peripheral corneal incision made for intraocular procedures.

Free Island and 360-Degree Grafts

Free island grafts have been described but are rarely useful, because their main disadvantage is the absence of a blood supply.[105] Also reported but rarely used are 360-degree grafts, because they preclude vision and prevent visualization of the globe. Their main use is for large lesions that cannot be effectively treated with one of the other grafting procedures. The 360- degree graft involves harvesting circumlimbal bulbar conjunctiva, which is subsequently undermined and advanced to cover the entire cornea (Figure 57-30).

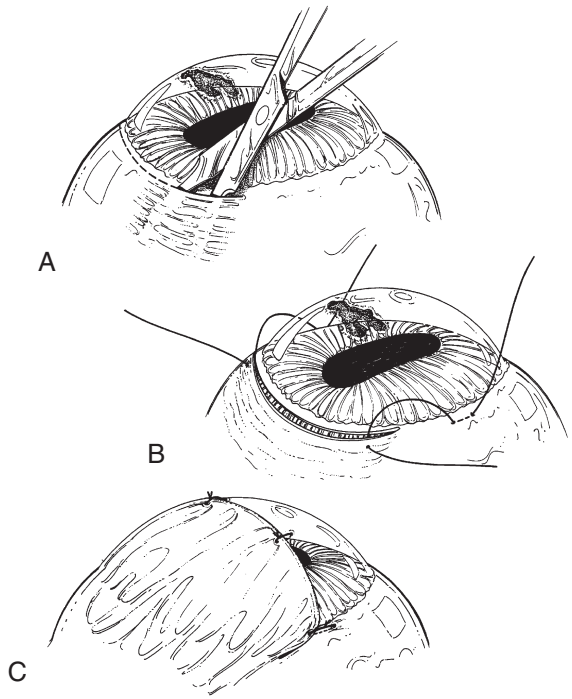

Figure 57-29. Hood conjunctival graft. **A,** An incision is made 1 mm from the limbus, and the bulbar conjunctiva is undermined toward the fornix. **B,** The graft is sutured to the episclera at the edges of the incision. **C,** The graft is sutured to the cornea.

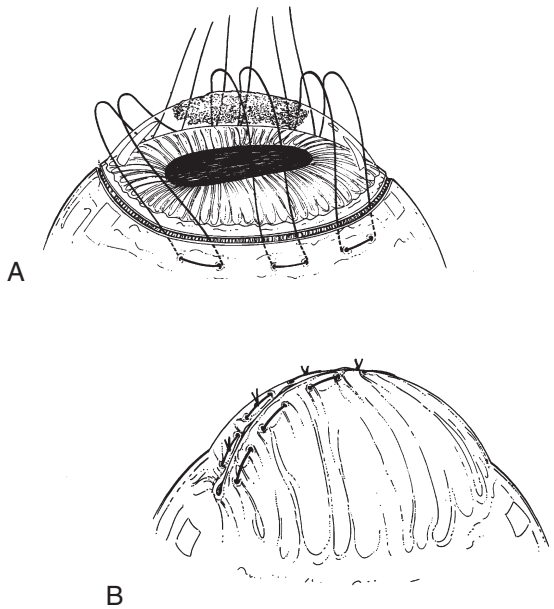

Figure 57-30. 360-degree conjunctival flap. **A,** The bulbar conjunctiva is incised circumferentially around the limbus and is undermined toward the fornix. **B,** The apposing sides of the flap are sutured together with mattress sutures.

Postoperative Management of Conjunctival Grafts

In the postoperative period, topical antibiotics and topical antifungals are typically indicated and may be administered with most ease via a subpalpebral lavage line placed at the time of surgery (see earlier). Systemic NSAIDs may also be indicated. The main complications associated with conjunctival grafting include graft dehiscence and infection. It should also be noted that although graft remodeling will reduce postoperative scarring, there can be a significant effect on vision, particularly if the graft is large or axially located.

Once pedicle grafts have healed in place and the corneal defect has healed, the attachment stalk to the conjunctiva can be cut, thus removing the blood supply. Trimming is typically performed 6 to 8 weeks postoperatively. Light sedation is recommended along with application of a topical anesthetic to the eye. For greatest effect, the topical anesthetic can be placed onto a cotton-tipped applicator that is held directly against the site to be trimmed. The stalk of the pedicle is then grasped with forceps, and one blade of the tenotomy scissors is placed between the cornea and the pedicle, close to the corneal lesion, and the stalk transected. Hemorrhage can be controlled by topical 2.5% phenylephrine if needed. The remaining pedicle will retract and remodel over time if left, or alternatively it can be trimmed close to the limbus. Removal of the blood supply to the graft helps to reduce its size and improves the visual outcome.

Amniotic Membrane Transplantation

Amniotic membrane transplantation can be used as an alternative to a conjunctival pedicle graft.[106-108] Used in cases of corneal ulceration, amnion has been reported to promote wound healing and epithelialization, reduce inflammation, and decrease fibrosis.[109] This may be through reduced expression of matrix metalloproteinases (MMPs) and increased expression of tissue inhibitors of metalloproteinases (TIMPs) in the cornea.[110] Equine amnion can be used fresh or can be stored frozen (Box 57-1). If frozen, the graft should be thawed and subsequently washed for 30 minutes in sterile saline before application. It can be sutured to the cornea with simple-interrupted sutures of 6-0 to 8-0 polyglactin 910, ensuring that the chorion side is oriented toward the cornea. Postoperatively, after reabsorption of the amnion (which may require several months), a new fibrotic stroma forms, which can reduce corneal transparency.[111] However, it has been proposed that amniotic membrane transplantation results in reduced corneal scarring compared to that resulting from a conjunctival pedicle graft.[112] A recent review describes the use of amnion as a graft, a "biologic contact lens," or its use in multiple layers as a "corneal filler." Included in the review is a series of 58 cases describing an excellent cosmetic outcome with corneal scarring classified as mild in 69% of cases.[113]

Box 57-1. Collection and Storage of Equine Amnion[122]

Source: Harvest fresh placenta after routine cesarean section

Harvesting: Separate the amnion from the vascularized chorion by blunt dissection

Cleaning: Rinse with phosphate buffered saline containing 2.5 g/mL amphotericin B, 100 g/mL neomycin, 50 g/mL streptomycin, and 50 g/mL penicillin

Preparation: Place with epithelial side up on 0.45-μm nitrocellulose paper, cut into 4 × 4 cm squares

Storage: Store up to 12 months at –80° C in 1:1 Dulbecco's modified Eagle's medium and glycerol, containing 2.5 g/mL amphotericin B, 100 g/mL neomycin, 50 g/mL streptomycin, and 50 g/mL penicillin

Sliding Lamellar Keratoplasty (Keratoconjunctival Transposition)

A sliding lamellar keratoplasty is suited for the repair of a deep corneal defect where the surrounding cornea is healthy and where achieving a clear axial cornea is desired.[114] Variants of this procedure include corneoscleral transposition and corneoconjunctival transposition.[44,115] The procedure for corneoconjunctival transposition is described here; this procedure is more commonly performed because it preserves the structural integrity of the sclera. Using the technique described for a keratectomy, necrotic corneal stroma is removed from the lesion and a square healthy recipient bed is created. A No. 64 or No. 69 Beaver blade is used to perform two diverging partial-thickness corneal incisions, extending from the site of the lesion 1 mm into the conjunctiva beyond the limbus. Using a Martinez corneal dissector or a Beaver blade, the superficial cornea delineated by the two incisions is separated from the underlying deeper corneal stroma at the required thickness. To facilitate dissection, the leading edge of the cornea can be grasped with corneal forceps, though handling should be minimized. When the dissection has passed the limbus, it is extended into the subconjunctival tissue, leaving the flap of cornea to be advanced attached to the conjunctiva. The conjunctiva is isolated from Tenon's capsule using blunt dissection with tenotomy scissors. The graft can then be advanced into the lesion and sutured in place with 6-0 to 8-0 polyglactin 910 in a simple-interrupted pattern (Figure 57-31). Postoperative care is as described for conjunctival grafting, with the exception of trimming of the conjunctiva, which should not be performed after a corneoconjunctival transposition. Dehiscence and infection are possible complications.

General Principles for Corneal Grafting

Deep corneal stromal abscessation is the main indication for the use of corneal grafting procedures, though these techniques have also been used for corneal endothelial disease and large corneal perforations.[114] The procedures place donor corneal tissue at the site of the excised tissue to facilitate healing and help reduce scar formation. Because they are allografting procedures, they do carry the risk of graft rejection and failure, despite the cornea's status as an immune privileged site.[116] Donor corneal tissue can be harvested fresh or stored frozen. For collection, the donor cornea should be placed epithelial side down on a Teflon block, and a button should be removed with a corneal trephine or disposable punch biopsy. If the tissue is to be used fresh, the epithelium should be completely débrided; otherwise the corneal button can be frozen. Fresh corneal tissue harvested within 48 hours of use is preferable, because freezing damages the corneal endothelial cells.[117] However, whereas fresh tissue is commonly used in human ophthalmology, it is rarely used in horses for practical reasons, so subsequent opacification of the graft is common. Placement of the donor corneal button in the recipient site should be performed with the endothelial side facing the anterior chamber. Cardinal simple-interrupted sutures of 7-0 to 8-0 polyglactin 910 should be placed at the 3, 6, 9 and 12 o'clock positions before securing the donor tissue with a simple-interrupted or simple-continuous pattern. The excised, diseased corneal button may be cultured and submitted for histopathology as indicated.

A number of surgical approaches are available, with the choice of technique depending on both the nature of the lesion and the surgeon's comfort and familiarity with the procedure. For instance, where a focal deep corneal abscess is present, which is typically at the level of deep stroma adjacent to and involving Descemet's membrane, the surgical approach is to excise the lesion. This can be achieved by excising full-thickness cornea with a penetrating keratoplasty (PK) or excising the deeper abscessed region of the cornea, while retaining the superficial corneal layers using procedures such as a posterior lamellar keratoplasty (PLK) or a deep lamellar endothelial keratoplasty (DLEK). All of these procedures use a corneal graft to fill the defect left in the cornea following excision of the abscess. However, the tendency has been to move away from using PK for deep corneal abscesses, because the overlying cornea is

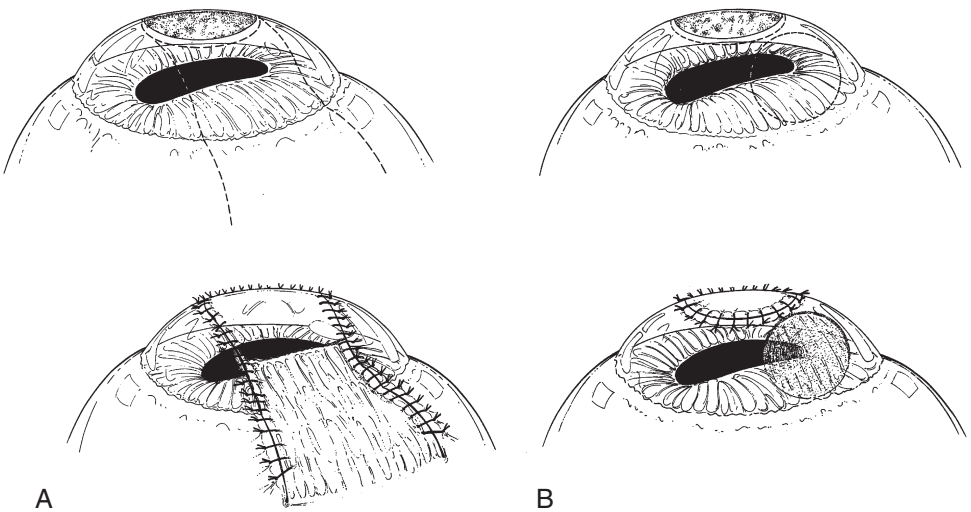

Figure 57-31. Sliding lamellar keratoplasty (corneoconjunctival technique), with diverging corneal incisions extending into the conjunctiva. **A,** A Martinez dissector is used to elevate the flap of cornea, and tenotomy scissors are used to undermine the bulbar conjunctiva. The graft is advanced over the defect and sutured along the edges of the incisions. **B,** Alternatively, the donor corneal tissue may be harvested from a site distant to the defect.

typically not infected and is usually in good condition. PLK and DLEK allow excision of the focal abscess with retention of the overlying cornea. Additionally, we have found that good results can be achieved without placing graft material if a careful dissection of the deep abscess is undertaken while retaining the unaffected overlying portion of the cornea.

Corneal Grafting Techniques

Penetrating Keratoplasty

A penetrating keratoplasty is the surgical placement of a full-thickness donor corneal button into the recipient tissue. Before commencing the procedure, the lesion should be measured with Jameson calipers and the prepared corneal donor button should be 1 to 2 mm larger in diameter than the intended recipient site. The corneal epithelium surrounding the recipient site should subsequently be débrided. A corneal trephine or disposable biopsy punch is used to incise the cornea to a depth of 75% of the stroma. The incision is then continued with a No. 65 or No. 69 Beaver blade to penetrate the anterior chamber. A viscoelastic agent is used to fill and maintain the anterior chamber, facilitating manipulations of the cornea and reducing the risk of hypotony. The incision can be completed with curved universal corneal scissors and the button of diseased cornea removed. The donor button is sutured into position as described earlier (Figure 57-32). Some surgeons choose to suture an amniotic membrane or conjunctival graft over the cornea for additional security. If a corneal graft is chosen, it will also provide a vascular supply and may decrease the risk of dehiscence and secondary infections.[46,118] The downside to their use is that they will increase the resulting scar and hence may limit vision; this may be less of a concern if amniotic membrane is used.[113]

Postoperatively, topical antibiotics and antifungals should be supplemented with a topical mydriatic, and systemic anti-inflammatories should be administered. Vascularization and subsequent scarring at the surgical site are to be anticipated.[119] However the major complication is dehiscence of the graft, and the risk of this is reportedly increased if the graft is larger than 8 mm in diameter or is applied close to the limbus.[115] However, the prognosis can be considered good with a visual outcome reported in 78% of horses with inflammatory keratopathy treated with a PK.[94]

Posterior Lamellar Keratoplasty

An alternative to a PK is a penetrating lamellar keratoplasty. It is suitable for abscesses involving the deep corneal stroma, Descemet's membrane, and underlying endothelium. The advantage of the PLK is that it leaves the healthy anterior corneal stroma and epithelium intact, because only the abscessed region is removed and an allograft applied to replace the diseased tissue.[120] Relative to a PK, a PLK may result in reduced postoperative scarring, it carries a decreased risk of dehiscence, and the surgical time is reportedly shortened.[118] The procedure involves using a No. 64 or No. 69 Beaver blade to create a three-sided corneal incision of approximately 50% corneal thickness over the lesion to be removed. This flap should be slightly larger than the lesion to be removed. A Martinez corneal dissector or Beaver blade is then used to separate the corneal stroma, allowing the created flap to be elevated and reflected to reveal the abscessed region. The diseased tissue is removed with a corneal trephine and curved universal corneal scissors. This excision involves the entire remaining thickness of the cornea and thus penetrates the anterior chamber, necessitating the use of a viscoelastic agent. Donor corneal tissue is subsequently sutured into the site as described earlier. For this procedure, the donor tissue should have the anterior half of the stroma removed by dissection so that only the posterior cornea, including Descemet's membrane, is used. As previously mentioned, we have also achieved excellent results by simply replacing the flap and not placing an allograft. In either instance, the anterior corneal flap should be sutured back into position with simple-interrupted sutures of 7-0 to 8-0 polyglactin 910 (Figure 57-33). Postoperative care is as for PK. Vascularization, scarring, graft dehiscence, and ulceration are among reported complications.[118] However, the prognosis is excellent with a positive visual outcome reported in 98% of cases.[94]

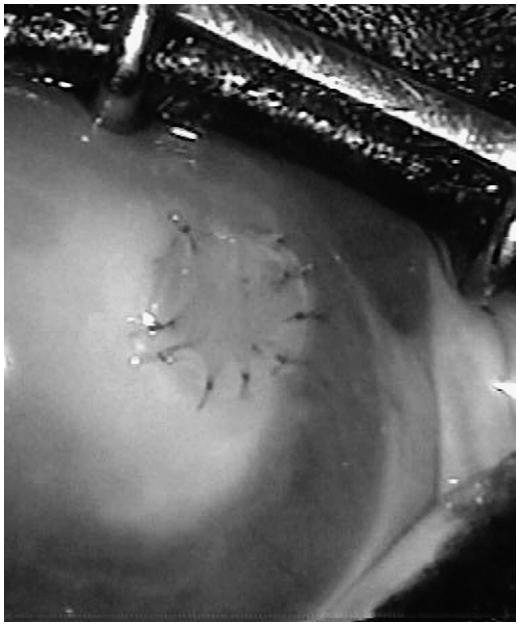

Figure 57-32. Postoperative appearance of a penetrating keratoplasty (PK).

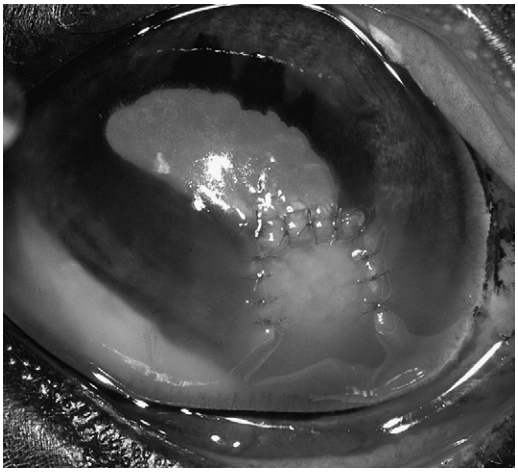

Figure 57-33. Postoperative appearance of a posterior lamellar keratoplasty (PLK).

Deep Lamellar Endothelial Keratoplasty

Deep lamellar endothelial keratoplasty represents an alternative to a PLK, designed to reduce corneal scarring by initiating the corneal incision at the limbus. The procedure is therefore particularly useful for lesions involving the peripheral cornea.[94] The procedure involves creating a pocket over the site of the lesion using a Martinez corneal dissector. This is initiated with a limbal incision using a No. 64 Beaver blade. Once the pocket has been created, a corneal trephine can be introduced, and surgery proceeds as described for a PLK (Figure 57-34). Postoperative care and potential complications are the same as those described for PLK. With this procedure a positive visual outcome was reported in 89% of cases.[94] A separate study has described a positive visual outcome with minimal scarring in 100% of cases.[121]

CHAPTER
58 Intraocular Surgery

Wendy M. Townsend

Equine intraocular surgery is performed primarily to treat equine recurrent uveitis, cataracts, and glaucoma. The relevant diagnostic procedures, anesthetic considerations, and surgical techniques are discussed for each condition within this chapter.

EQUINE RECURRENT UVEITIS

Equine recurrent uveitis (ERU), also known as moon blindness, is one of most common causes of blindness in horses. This immune-mediated condition has a prevalence of approximately 2% in the United States. ERU is characterized by repeated episodes of intraocular inflammation.

Anatomy and Physiology

The uveal tract is composed of the iris, ciliary body, and choroid (Figure 58-1). Damage to the uvea disrupts the ocular blood aqueous barrier (BAB) or the blood retinal barrier.[1] Breakdown of the BAB causes vascular dilation and increased vascular permeability, which leads to increased levels of protein and cells within the aqueous humor and vitreous. The increased protein within the aqueous humor scatters light (the Tyndall effect) when illuminated with a focused beam of light.[2] This so-called *aqueous flare* represents the hallmark of uveitis.

Prostaglandins and leukotrienes are the primary inflammatory mediators.[3] The prostaglandins cause hyperemia and a reduced intraocular pressure (IOP) (hypotony). Prostaglandins, particularly prostaglandin F2-alpha, constrict the iris and ciliary muscles, causing miosis and pain. Prolonged miosis combined with increased aqueous protein levels can create adhesions between the posterior iridal epithelium and the anterior lens capsule, called *posterior synechia*. Extensive posterior synechia can completely obstruct the pupil, causing vision loss. Complete seclusion (blockage) of the pupil can interfere with the

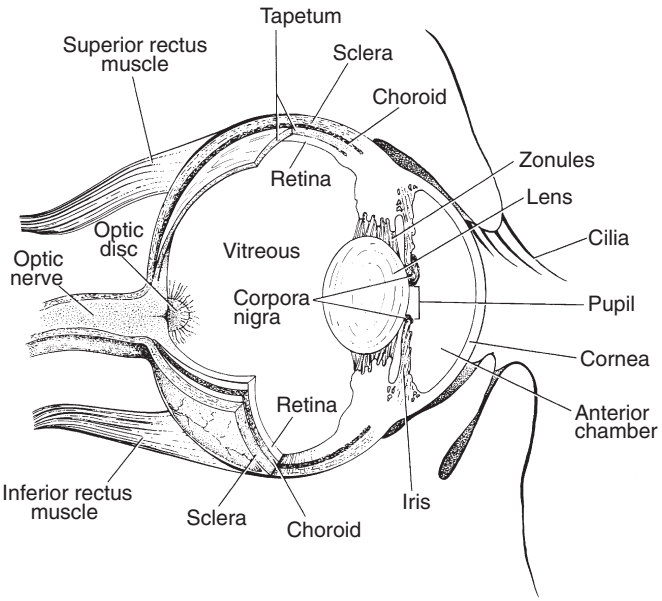

Figure 58-1. A cross-section of an equine eye.

flow of aqueous humor. Fluid can become trapped behind the iris and cause anterior bowing of the iridal face, called *iris bombé*. The altered fluid dynamics can cause *secondary glaucoma*.

Equine recurrent uveitis is characterized by recurrent or persistent bouts of ocular inflammation. ERU cannot be diagnosed after a single bout of uveitis. Immunologic studies have demonstrated the formation of autoantibodies directed at the corneal endothelium and retinal photoreceptors.[4-6] The most frequently implicated inciting cause is infection with *Leptospira interrogans*. In one German study, 75% of vitreous samples from horses with ERU were culture positive for leptospires and 100% were positive by polymerase chain reaction (PCR).[7] However, in chronically affected globes, leptospires were infrequently detected.[8] The association of ERU with leptospires may be based on antigenic homology between microbial peptides and autoantigens.[9]

Relevant Ocular Examination Techniques and Findings

A complete ophthalmic exam is critical for the diagnosis of ERU. Uveitis can be caused by corneal ulceration, stromal abscess, and ocular trauma. These conditions must be definitively excluded to determine the appropriate therapy. Sedation, an auriculopalpebral nerve block, and application of a topical anesthetic agent greatly aid the examination of a painful eye.

The visual status and level of discomfort must be ascertained. Fluorescein stain is then applied to the corneal surface to facilitate detection of corneal ulcers. Because topical application of corticosteroids is absolutely contraindicated in the face of corneal ulceration, this step is critical. The cornea should then be carefully examined, preferably with a slit lamp biomicroscope. A corneal stromal infiltrate suggests of corneal stromal abscess.

The anterior chamber should be examined with a slit lamp biomicroscope to detect aqueous flare. Fibrin can be seen as strands or clots within the anterior chamber. It is possible to see cells suspended within the aqueous humor; they appear as particulate material circulating within the focused beam of light. *Hyphema* (blood in the anterior chamber) and *hypopyon* (purulent material in the anterior chamber) may occur with severe inflammation.

The IOP should be assessed because hypotony is a subtle sign of uveitis.[10] Furthermore, glaucoma can occur secondary to chronic uveitis. Glaucoma may require additional therapy and alter the long-term prognosis. Pupil size and response to light should be noted because inflammation can induce marked miosis. The iris should be closely examined for anterior or posterior synechia. Fibrin may form a web across the corpora nigra, preventing pupillary dilation. A markedly miotic pupil may severely compromise vision.

The lens should be closely examined, preferably after pupillary dilation. Chronic inflammation induces cataract formation, likely because of diffusion of inflammatory mediators across the lens capsule.[11,12] The inflammatory products can also lyse the lens zonules.[13] Extensive zonular destruction allows the lens to luxate from the patellar fossa.

The anterior vitreous is examined with the slit lamp biomicroscope. The posterior vitreous is examined with an indirect ophthalmoscope and condensing lens. Liquefaction or condensation of the vitreous, an inflammatory cell infiltrate, and vitreal hemorrhage have been noted in patients with uveitis. The retina should be examined using indirect and or direct ophthalmoscopy. Areas of retinal detachment, subretinal exudates, retinal scarring, and optic nerve inflammation or atrophy should be identified. Posterior segment involvement influences pharmacologic therapy, potential success as a surgical candidate, and long-term visual prognosis.

Diagnostic Procedures

A full physical examination, complete blood count, and serum biochemical profile can assist in detecting underlying systemic disease. If the horse has received previous systemic nonsteroidal anti-inflammatory drugs (NSAIDs), renal parameters, and serum protein levels, an indicator of gastrointestinal mucosal health, should be established.[14]

Serologic testing for *Leptospirosis* spp. should be strongly considered in endemic areas, but interpretation can be difficult.[9] Serum antibody titers are significantly higher in horses with ERU.[15] However, 19% of normal horses have elevated serum antibody titers.[15] Also, the presence of elevated serum antibody titers does not correlate well with the isolation of *L. interrogans* from vitreous humor.[15] A positive titer for serovars at dilutions of 1:400 or greater is considered clinically significant,[16] and systemic antibiotic therapy (e.g., doxycycline, 10 mg/kg PO twice a day for 30 days) should be administered before considering surgical therapy.

One can perform *aqueous paracentesis* to obtain samples for pathogen culture, cytologic, and/or serologic evaluation. General anesthesia is recommended. The eye is routinely prepared with dilute povidone-iodine (Betadine) solution. An eyelid speculum is placed and a topical anesthetic agent is applied to the cornea and conjunctiva. The conjunctiva is grasped near the limbus with small-toothed forceps. A 25-gauge (or smaller) needle attached to a 1-mL syringe is inserted under the conjunctiva, through the limbus, and into the anterior chamber (Figure 58-2). The needle should be directed parallel to the plane of the iris. No more than 0.5 mL of aqueous should be removed.

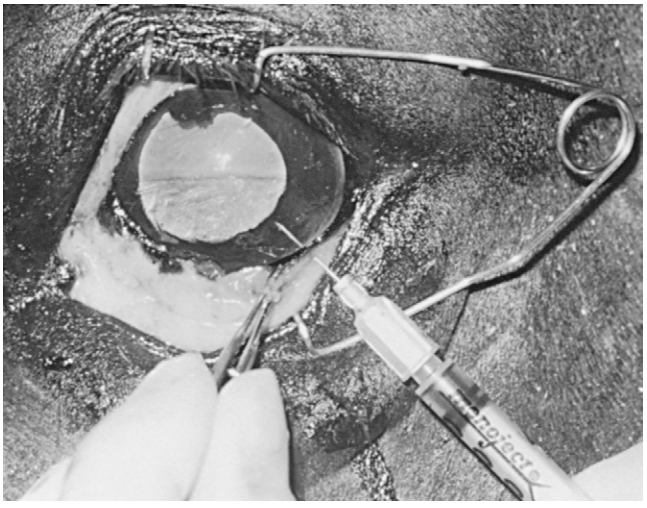

Figure 58-2. Paracentesis of the anterior chamber. A 25-gauge needle attached to a 1-mL syringe is inserted into the anterior chamber at the limbus, and fluid is withdrawn.

Anesthetic Considerations

The surgical techniques described are typically performed under general anesthesia. Retrobulbar anesthesia (see Chapter 55) or neuromuscular blocking agents may assist in globe positioning. For all ocular procedures, a smooth recovery from anesthesia prevents further trauma to the globe and decreases postoperative complications.

Required Surgical Equipment

For intraocular surgery to be successful, the surgeon should be trained in microsurgery and perform enough intraocular procedures to stay competent. Magnification, usually an operating microscope, and microsurgical instruments must be available. The specific instrumentation required for performing intravitreal injections (Table 58-1), suprachoroidal cyclosporine implants (Table 58-2), and pars plana vitrectomy (Table 58-3) are listed later.

Relevant Pharmacology

Corticosteroids, mydriatics, and NSAIDs are used to reduce inflammation and minimize permanent ocular damage at each episode of active uveitis. They do not effectively prevent recurrence of disease. Corticosteroids are applied topically or injected subconjunctivally together with topical 1% atropine sulfate to reduce inflammation and stabilize the BAB. Prednisolone acetate 1% ophthalmic suspension and dexamethasone 0.1% are the only topical corticosteroids that can achieve therapeutic concentrations in the aqueous humor.[17] NSAIDs are administered systemically, particularly if posterior segment inflammation is noted. Intracameral injection of tissue plasminogen activator may be used to dissolve organized fibrinous exudates in the anterior chamber. Aspirin and phenylbutazone may be used by some clinicians to prevent or decrease the severity of recurrent episodes. However, these medications have potentially detrimental side effects when used chronically in the horse.

Surgical Techniques

Intravitreal Injections

For a vitreal injection, a 22- to 23-gauge needle is used. General anesthesia is preferred. The needle is inserted 10 mm behind the limbus at the 12 o'clock position, through conjunctiva, sclera, and the pars plana of the ciliary body. The needle is directed toward the posterior pole of the eye to avoid traumatizing the lens. Because the needle often cannot be observed, intravitreal injections carry a greater risk of injury to the eye.

Intravitreal injections of triamcinolone acetonide are used to control inflammation in human patients with recurrent uveitis.[18] A study performed in normal equine eyes did not note any overt toxicity from intravitreal triamcinolone injections.[19] The ocular triamcinolone levels persisted for up to 21 days.[19] However, 4 out of 12 eyes (3 of which were controls) developed bacterial endophthalmitis. This finding highlighted the need for meticulous aseptic technique and the use of topical and/or systemic antimicrobials at the time of injection.[19]

I have injected 10 mg of filtered triamcinolone acetonide with 20 mg of ampicillin intracamerally in cases with intractable uveitis. Improvement in the uveitis was noted. Endophthalmitis has not been a complication. However, several horses developed persistent superficial corneal ulcers. Because of the complications associated with triamcinolone injections, other

agents such as rapamycin are currently under investigation. In preliminary studies, rapamycin injected subconjunctivally and intravitreally did not produce evidence of ocular irritation or toxicity.[20]

Suprachoroidal Cyclosporine Implantation

A device that allows constant release of cyclosporine A (CsA) was developed for placement in the suprachoroidal space directly adjacent to the ciliary body (Figure 58-3). The best candidates for CsA implantation are horses that have chronic ERU and experience frequent recurrences after stopping medication. The horse must have little or no active inflammation at the time of surgery. Horses whose inflammation cannot be controlled with anti-inflammatory medications are not good candidates for CsA implantation. Inflamed eyes are more prone to surgical and postsurgical complications. Equine patients with significant cataract formation and glaucoma are also considered poor candidates.

The horse is placed under general anesthesia. A 1-cm conjunctival incision is made in the dorsolateral bulbar conjunctiva. A 7-mm-wide scleral flap is prepared, exposing the uveal tract approximately 8 mm posterior to the limbus and just lateral to the insertion of the dorsal rectus muscle (Figure 58-4). The CsA-containing device is placed into the incision, in contact with the uveal tract (Figure 58-5). The scleral flap is closed over the implant using 5-0 to 6-0 polyglactin 910 or similar absorbable suture material in a simple-interrupted pattern (Figure 58-6). Recommended postoperative medications include flunixin meglumine (500 mg PO once a day) for 5 days, topical triple antibiotic ophthalmic ointment twice a day for 10 days, and topical atropine ointment once a day for 7 days. Some horses have a mild flare-up after flunixin meglumine is discontinued. If this occurs additional systemic NSAIDs may be needed.

Figure 58-5. A 7-mm-wide scleral flap is made exposing the uveal tract (the black uvea is just visible through the sclera) approximately 8 mm posterior to the limbus and just lateral to the insertion of the dorsal rectus muscle.

A long-term clinical trial of 133 horses with documented ERU demonstrated retention of vision in 78% of cases.[21] The complications resulting in vision loss were persistent uveitis, glaucoma, mature cataracts, and retinal detachment. The mean frequency of uveitis episodes was 0.09 episodes per month after

Figure 58-6. The cyclosporine-containing device is placed into the incision, in contact with the uveal tract. placement of the CsA implant.[21] Inflammatory episodes increased 48 months after the initial surgery. Therefore, the authors suggest a second CsA implant might be required approximately 48 months following the initial surgery.[21]

Pars Plana Vitrectomy

First described in 1991,* pars plana vitrectomy (PPV) has been increasingly employed in the treatment of ERU, particularly in Europe.[22-24] The beneficial effect of PPV most likely results from the physical removal of resident inflammatory cells from the vitreous.[25] The most common complications are transient hypopyon, vitreal or retinal hemorrhage, retinal detachment, and cataract formation.

The potential complications of PPV necessitate careful patient selection and thorough owner education. Minimal inflammation should be present at the time of surgery. Transpupillary visualization of the vitrectomy probe is required. Therefore the ocular media must be transparent and the pupil must dilate maximally. Preexisting focal cataracts are likely to progress. Patients with secondary glaucoma, phthisis bulbi, or retinal detachment are poor candidates for PPV.

Topical neomycin, polymyxin B, and dexamethasone (NPDex) ophthalmic solution is administered four times a day for 1 week before surgery. Flunixin meglumine is administered beginning 3 days preoperatively. The pupil is dilated with 1% atropine drops on the day of surgery. Postoperatively, topical NPDex is administered 3 times weekly for 2 weeks and then tapered over 4 weeks. Systemic NSAIDs are continued for 1 week.

A standard two-port PPV is performed with the horse in lateral recumbency under general anesthesia. The eye is prepared for intraocular surgery. After draping, an eyelid speculum is inserted. A lateral canthotomy may improve exposure. With a custom-made globe manipulator (Figure 58-7) or limbal stay suture, the globe is rotated to expose the dorsal bulbar conjunctiva. A limbal-based conjunctival flap is prepared and the sclera exposed medial and lateral to the dorsal rectus muscle. Using a CO_2 laser in continuous mode at 50 W, a sclerotomy is performed 10 mm posterior to the limbus. A right-handed surgeon places this first entry to the left of the rectus muscle. The irrigation port is inserted and secured to the sclera with a 4-0 polyglactin 910 suture (Figure 58-8). The irrigation fluid consists of physiologic saline solution with 40 mg of gentamicin added per 500 mL. The fluid bottle is positioned 85 cm higher than the globe to maintain an intraocular pressure (IOP) of 40 mm Hg. The infusion is started at a flow rate of 20 mL/min.

A second sclerotomy is performed 10 mm posterior to the limbus and to the right of the rectus muscle (Figure 58-9). The vitrectomy probe is carefully inserted and advanced toward the central vitreous. A custom-made 55-mm oscillating vitrectomy probe is used at 6.5 Hz with an aspiration vacuum of 240 mm Hg (Figure 58-10). Care is taken to avoid touching the lens (Figure 58-11). The probe is held with the aspiration port facing the surgeon. The port can be visualized through the pupil using an indirect binocular ophthalmoscope (Figure 58-12).

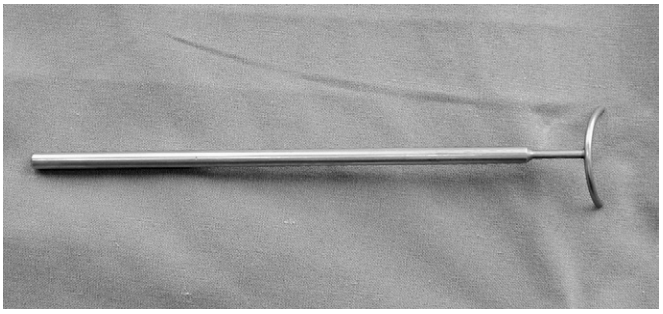

Figure 58-7. Custom-made globe manipulator to facilitate globe rotation during laser sclerotomy.

Figure 58-8. The irrigation port of the two-port vitrectomy unit is anchored to the sclera using 4-0 Vicryl suture.

*Editor's note: The first successful vitrectomy was performed in 1983 in the Equine Clinic in Wahlstedt, Germany, by L. Koehler and his associates.

Figure 58-11. The custom-made vitrectomy handpiece is advanced into the center of the vitreous cavity.

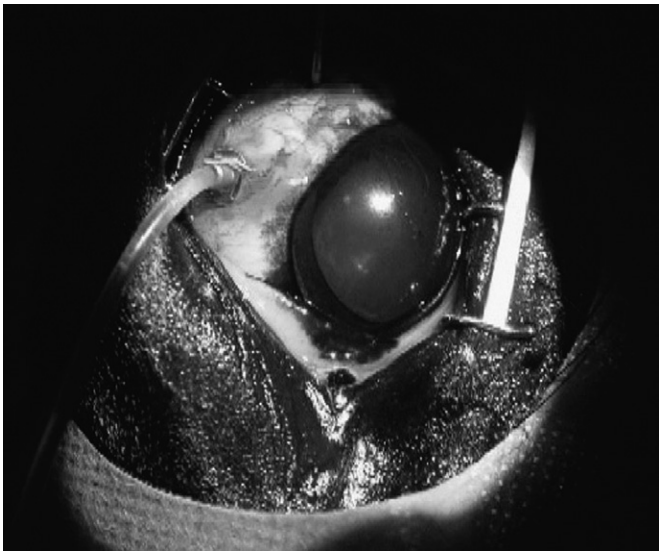

Figure 58-12. Vitrectomy is performed in a darkened operating theater using a binocular indirect ophthalmoscope and a 20D lens. The vitrectomy probe can be visualized through the dilated pupil. (Courtesy Dr. B. Wollanke.)

With a 20 diopter lens in the left hand and the vitrectomy probe in the right, the vitrectomy is started. The shadow cast on the retina by the probe assists the surgeon in estimating the distance between the probe and the retina. The IOP should be maintained at approximately 40 mm Hg. Slight wrinkling of the retina indicates the IOP may be too low. If this is noted, the surgery should be interrupted until a normal IOP is restored. The procedure is continued until all turbid vitreal material has been removed. Under continuous irrigation, the vitrectomy probe is removed and the sclerotomy is closed with one or two preplaced simple-interrupted sutures using 4-0 polyglactin 910. Subsequently, the irrigation port is removed. Remaining vitreous usually prevents fluid from escaping through this sclerotomy, which is closed with 4-0 polyglactin 910. The conjunctiva is closed with polyglactin 910 in a continuous pattern. The canthotomy is closed with a figure-of-eight suture using 4-0 nonabsorbable suture material. At the end of surgery, 20 mg of methylprednisolone is injected subconjunctivally into the inferior bulbar conjunctiva.

In one study of 38 cases, 33 eyes showed no recurrence during a follow-up period of up to 5 years.[24] Five eyes had a recurrence of uveitis between 10 days and 3 years postoperatively; two demonstrated marked loss of vision, and three maintained preoperative vision.[24] Vision remained stable in 28 eyes

and improved in 1 eye. The remaining eyes showed marked vision loss as a result of cataracts (3), phthisis bulbi (1), or unknown causes (1). In an earlier study of 43 eyes, 42 remained free of recurrent uveitis during the 67-month follow-up period, and of these eyes, 70% retained some vision.[26] The most common complication was cataract formation in 19 of 43 eyes, followed by phthisis bulbi in 6 eyes, and retinal detachment in 4 eyes.

CATARACTS

A cataract refers to any opacity of the lens. Cataracts may occur as a congenital lesion. In Morgan, Belgian, Quarter Horse, and Thoroughbred bloodlines, cataracts occur as a dominant trait.[27,28] Therefore breeding of affected individuals is not recommended. Cataracts also occur in Rocky Mountain horses with anterior segment dysgenesis (ASD).[29] In adult horses, cataracts often occur secondary to chronic ERU.[28] Blunt or penetrating ocular trauma can incite cataract formation. Older horses may develop senile cataracts.

Anatomy and Physiology

The crystalline lens is the transparent, biconvex structure that "fine focuses" light on the retina.[30] Zonular fibers suspend the lens behind the iris in the patellar fossa. The zonules extend from the ciliary body and insert onto the lens equator. Breakage of the zonules allows the lens to shift within the patellar fossa (lens subluxation), displace into the anterior chamber (anterior lens luxation), or displace into the posterior segment (posterior lens luxation). Lens luxations occur relatively frequently in horses.[9] Lens luxations may occur secondary to trauma, glaucoma with buphthalmos, resorption of a hypermature cataract, or chronic ERU. Rocky Mountain horses with ASD may suffer lens luxation because of inherited zonular abnormalities.

Relevant Ocular Examination Techniques and Findings

Mydriasis is required to completely examine the lens. Topical application of a rapid-onset mydriatic (1% tropicamide ophthalmic solution) will dilate the pupil within 30 minutes.[31] An opacity may be axial (along the visual axis), equatorial, capsular, subcapsular, cortical, or nuclear. The cataract can be classified based on the extent of lenticular involvement: incipient (less than 15%), immature (15% to 99%), mature (100%), and hypermature (100% with resorption of cortical material) (Figure 58-13). The degree of visual impairment depends upon the size, location, and density of the opacity. The remainder of the eye should be inspected closely for evidence of uveitis and other ocular abnormalities. A fundic examination should be performed if possible.

Congenital and traumatic cataracts typically have the best long-term prognosis for maintaining vision.[32] Rocky Mountain horses with ASD have a poorer prognosis because of the associated retinal dysplasia that predisposes to retinal detachment.[29,32] Horses with cataracts secondary to ERU have a guarded long-term prognosis for vision, because repeated bouts of uveitis often result in keratitis, retinal detachment, synechiae, or phthisis bulbi and blindness.[32] The temperament of the individual also should be carefully considered because restricted activity and the application of topical ocular medications are required for 4 to 6 weeks after surgery. Postoperative trauma incurred while applying medications or suture breakage because of excessive activity can diminish the success of the procedure.

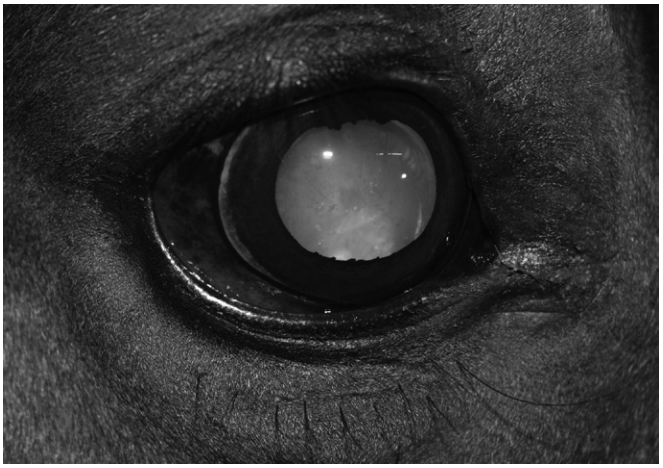

Figure 58-13. A horse with an immature cataract.

Foals with congenital cataracts should undergo surgery early if the cataract completely obscures vision.[32] Human infants with complete cataracts have a better success rate if surgery is performed in the first 6 weeks of life to allow proper development of the visual neural network.[33] Although the definitive age by which cataract surgery must be performed in foals is not known, current recommendations favor surgical intervention before 6 months of age.[32]

Diagnostic Procedures

A complete physical examination should be performed with special emphasis placed on the respiratory system. Occult respiratory infection, especially with *Rhodococcus equi*, can result in postoperative endophthalmitis. A complete blood count with fibrinogen levels should be performed to detect underlying systemic infection or inflammation. A serum biochemistry profile provides baseline renal values and ensures the normal organ function.

If the cataract obscures visualization of the fundus, an electroretinogram (ERG) and ocular ultrasonography should be performed. The latter assists in detecting retinal detachments, vitreal opacities, and remnants of the hyaloid vasculature. Retinal detachments preclude cataract surgery. The ERG evaluates retinal, particularly photoreceptor, function; it can detect diffuse retinal degeneration, especially in patients with evidence of trauma or chronic ERU. The ERG can also be used to rule out congenital stationary night blindness, which occurs in Appaloosas, Thoroughbreds, Paso Finos, and Standardbreds.[34-36]

Anesthetic Considerations

Intraocular surgery is performed under general anesthesia. Either retrobulbar anesthesia or systemic neuromuscular blockade is required to facilitate globe positioning and prevent compression of the globe by the extraocular muscles. Maintaining normal globe shape and IOP decreases the likelihood of posterior capsular tears, iris prolapse, and expulsion of ocular contents through the corneal incision. Retrobulbar anesthesia is performed as described in Chapter 55.

Figure 58-14. A standard phacoemulsification needle is shown in the lower aspect of the photograph. The significantly longer equine phacoemulsification needle is shown in the upper aspect of the photograph.

The neuromuscular blocking agent atracurium besylate (10 mg/mL, currently available only as a generic formulation, formerly available as Tracrium) or pancuronium (1 or 2 mg/mL, generic formulations or Pavulon) are administered at 0.12 to 0.2 mg/kg IV and provide a duration of action of 30 to 60 minutes.[37] Atracurium is preferred because of its reliable duration of action, lack of cumulative effect, lack of cardiovascular effects, and lower costs.[37] The degree of neuromuscular blockade should be monitored with a train of four stimulations from a peripheral nerve stimulator.[37] For ocular procedures, the superficial peroneal nerve is more accessible than the facial nerve.[38] The reversal agent edrophonium chloride (10 mg/mL, Tensilon, Enlon, or Reversol) is administered at 0.5 to 1.0 mg/kg, slowly by IV before recovery to ensure that residual neuromuscular blockade does not compromise the ability of the horse to stand. Recoveries after neuromuscular blockade are generally scored as good to excellent.[37]

Required Surgical Equipment

An operating microscope and phacoemulsification system are required to optimally perform equine cataract surgery. *Phacoemulsification* uses ultrasonic energy to break up lens material, which is removed through an aspiration port. Continuous irrigation maintains adequate pressures within the anterior chamber. Surgery can be performed through a small incision, which reduces the risk of iris prolapse and other operative complications. The degree of postoperative inflammation is significantly reduced. Phacoemulsification systems configured for equine use have longer needles, which greatly facilitate removal of lenticular material (Figure 58-14). The remainder of the required equipment is listed in Table 58-4.

Relevant Pharmacology

There are currently no systemic or topical medications that "dissolve" cataracts. Horses with focal opacities may have improved vision after pharmacologic mydriasis is achieved through application of 1% atropine ophthalmic solution or ointment. The only effective therapy for cataracts causing significant visual impairment is surgical removal.

The day before surgery, topical NPDex ophthalmic solution is applied every 6 hours to the ocular surface. Flunixin meglumine (1.1 mg/kg PO or IV every 12 hours) is administered. Gastric protectants such as omeprazole (2 mg/kg PO daily) are indicated, particularly for foals. Tetanus toxoid is administered if vaccinations are not current.

The day of surgery, topical NPDex and flurbiprofen 0.03% ophthalmic solutions are applied three times each to the ocular surface. Atropine 1% or tropicamide 1% ophthalmic solution is administered to achieve maximal pupillary dilation. Flunixin meglumine is continued. Systemic antibiotics (potassium penicillin 20,000 IU/kg IV every 6 hours, and gentamicin 6.6 mg/kg IV every 24 hours) are administered perioperatively.

Surgical Techniques

Phacoemulsification

After induction of general anesthesia, the horse is placed in lateral recumbency. The head is positioned such that the corneal surface is parallel to the surgery table. The ocular surface is prepared routinely with dilute povidone-iodine solution. The head is draped routinely and an eyelid speculum is placed. A lateral canthotomy is performed if needed to improve exposure. The anterior chamber is entered through a scleral tunnel or a two-step clear corneal incision. A highly cohesive viscoelastic material (hyaluronan; Acrivet Syn 2%, a 2% hyaluronic acid solution) is used to reform and maintain the anterior chamber. A continuous circular capsulorrhexis is performed.

The phacoemulsification needle is introduced and nuclear material is removed via phacoemulsification (Figure 58-15). The remaining cortical material is removed using irrigation and aspiration. After complete removal of lenticular material, a posterior capsulorrhexis may be performed to prevent migration of lens epithelial cells across the visual axis and thereby

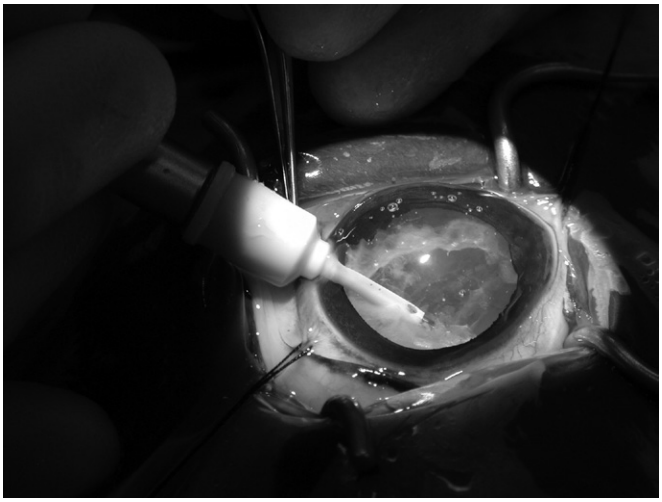

Figure 58-15. An intraoperative photograph demonstrating removal of nuclear material using phacoemulsification.

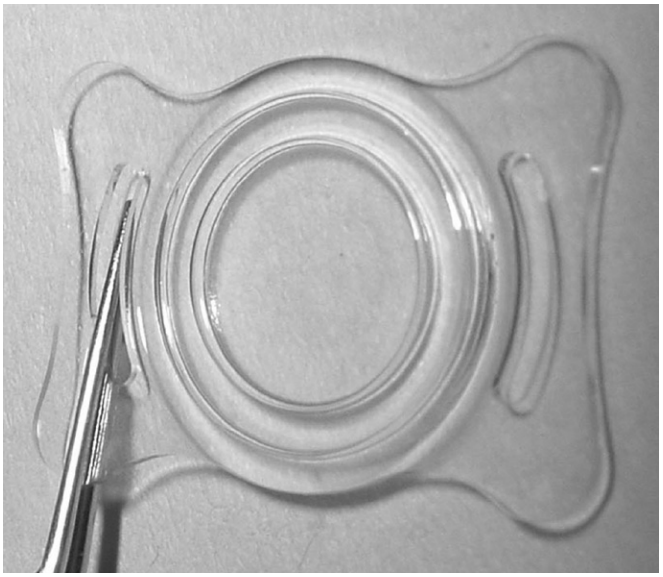

Figure 58-16. An equine intraocular lens with a 12-mm diameter optic and 21-mm overall diameter. This lens is appropriate for use in a foal.

maintaining a clearer visual pathway. If elected, an intraocular lens can then be placed. The cornea is closed with a simple-interrupted or simple-continuous suture pattern of 7-0 absorbable suture. Before the final suture is secured, the surgeon may choose to remove any remaining viscoelastic material (sodium hyaluronate) via irrigation and aspiration.

Unless a corneal ulcer is present, topical antibiotics and corticosteroids are applied every 4 to 6 hours to control postoperative inflammation. Topical atropine is administered as needed to maintain mydriasis. Systemic NSAIDs and gastric protectants are continued. A face mask with a protective eyecup prevents rubbing and suture breakage. Installation of a subpalpebral lavage (SPL) facilitates administration of medications to the globe. However, corneal ulceration is a risk if the SPL should dislodge. Activity is restricted initially to hand-walking only. A recheck examination is performed 7 to 10 days postoperatively. If ocular inflammation is controlled, medications are gradually reduced over 2 to 4 weeks. Once the corneal incision heals, typically 3 to 4 weeks postoperatively, the patient may resume normal activities. Possible postoperative complications include poor anesthetic recovery, systemic infection, suture breakage, endophthalmitis, ocular hypertension, corneal ulceration, inflammation, and retinal detachment.

Intraocular Lens Placement

Equine intraocular lenses (IOLs) are now available (Acrivet, Inc., Jordan UT) (Figure 58-16). They prevent severe hypermetropia (farsightedness), which results when a globe is aphakic (lacks a lens).[39,40] The predicted visual acuity of an aphakic horse would be 20/1200 on the Snellen chart.[41-44] Humans with this degree of uncorrected hypermetropia would be considered legally blind.[45] The lenses are made of foldable acrylic, which minimizes the incision size required for their placement. They are available at strengths of +14D and +18D and 21-, 22-, and 24-mm diameters. The +14D, 21-mm diameter lenses are typically implanted in foals. The lenses are inserted through the corneal incision into the capsular bag using lens forceps or an injecting cartridge. The corneal closure and postoperative management are the same as listed earlier.

Intracapsular Lens Extraction

If the lens luxates, an intracapsular lens extraction is required to remove the lens *en bloc*. This procedure should be reserved for potentially visual eyes. An intracapsular lens extraction requires a 180-degree corneal incision. Therefore, complications such as iris prolapse and marked uveitis are common, and the prognosis for vision is guarded. The postoperative therapy and additional complications are similar to those listed for cataract surgery. In an eye that has been blinded, an eye that has experienced multiple bouts of ERU, or an eye that has sustained marked trauma, enucleation or evisceration with intrascleral prosthesis is the preferred therapeutic option (see Chapter 55).

GLAUCOMA

Glaucoma is characterized by increased IOP resulting in damage to the optic nerve and retina.[46] Glaucoma is relatively rare in horses with an incidence of 0.07%.[28] However, as most equine practitioners lack the instrumentation to measure IOP and are unlikely to suspect the condition, glaucoma is easily missed or misdiagnosed.[47]

Anatomy and Physiology

Aqueous humor is formed by the ciliary processes.[48] Aqueous primarily leaves the eye through the trabecular meshwork within the iridocorneal angle. Aqueous also diffuses through the iris, ciliary body, and vitreous: the uveoscleral outflow pathway. Horses have a greater percentage of uveoscleral outflow than most other species.[49] Obstruction of aqueous outflow results in an increased IOP. The elevated IOP decreases optic nerve axoplasmic flow and eventually causes retinal ganglion cell death.[50] Although congenital and primary cases do occur, equine glaucoma is most often secondary to ERU.[51,52]

Relevant Ocular Examination Techniques and Findings

Horses with glaucoma may not present with overt signs of pain unless concurrent anterior uveitis is present. If the horse has secondary glaucoma with active anterior uveitis, the clinical findings may include chemosis, miosis, synechia, flare, and cataract formation.[47] Elevations in IOP cause corneal edema, mydriasis, and a decreased menace response. The mydriasis may not occur if synechia prevents movement of the pupillary margin. Horses with chronic elevations in IOP develop buphthalmos, corneal striae, corneal vascularization, lens luxation or subluxation, optic nerve degeneration, and retinal degeneration. The corneal striae represent breaks or thinning of Descemet's membrane.[53] However, corneal striae are not pathognomonic for glaucoma and can be present in otherwise normal eyes.[53] Horses with buphthalmos may retain some vision, unlike most other species. Nevertheless, vision is impaired and complete blindness often results.

Diagnostic Procedures

Measuring IOP is critical for diagnosing glaucoma. Use of an applanation (Tono-Pen) or rebound (TonoVet) tonometer is recommended. The normal IOP in unsedated horses is 17 to 28 mm Hg.[54,55] Sedation with xylazine decreases IOP by 23% to 27%.[56] An auriculopalpebral nerve block prevents false elevations in IOP that are due to pressure from the eyelids.[56] Lowering the head below heart level significantly elevates IOP (8 mm Hg).[57] Because many factors influence IOP measurement, a consistent protocol must be followed to allow meaningful interpretation of changes in IOP.

Required Surgical Equipment

Pharmacologic ablation of the ciliary body requires minimal surgical equipment (see Table 58-1). Cyclophototherapy requires a semiconductor diode or neodymium-doped yttrium aluminum garnet (Nd:YAG) laser (Table 58-5).

Relevant Pharmacology

If uveitis is present, medical therapy must address control of inflammation (see "Relevant Pharmacology" earlier). Topical atropine may benefit patients with ERU because it decreases discomfort and stabilizes the BAB.[47] However, the IOP must be closely monitored. In some patients the addition of topical atropine reduces IOP,[58] but in others, atropine may elevate it.[58]

Medical therapy to diminish IOP can be relatively successful early in the course of the disease.[50] However, long-term control of IOP is difficult to maintain with medical therapy alone. A target IOP of less than 20 mm Hg is a reasonable goal for therapy.[50] The most effective pharmacologic agents in horses reduce IOP by *diminishing aqueous humor production*. The topical β-adrenergic receptor blocker timolol maleate (0.5% ophthalmic solution; Timoptic) has been shown to diminish IOP by 17% in normal horses after administration of a single dose.[59] In clinical patients timolol is typically administered two or three times daily. The topical carbonic anhydrase inhibitor dorzolamide (2% ophthalmic solution, Trusopt, and generic formulations) also diminishes IOP through reduction of aqueous humor production.[60] However the reduction occurs through a different mechanism than that of β-adrenergic receptor blockers. Dorzolamide can be used alone or in combination with timolol. The typical frequency of application is two or three times daily.

Prostaglandin analogues are used extensively for glaucoma therapy in humans and small animals. They diminish IOP by *increasing uveoscleral outflow*. However, they have demonstrated little benefit following application to equine globes.[61,62] Adverse effects are frequently noted and include miosis, epiphora, blepharospasm, and blepharedema.[62] Therefore, prostaglandin analogues are not currently recommended for therapy of equine glaucoma.

TABLE 58-5. Surgical Instrumentation Recommended for Cyclophotocoagulation

Instrument	Quantity
Ocular adhesive drape	1
Eyelid speculum	1
Bishop-Harmon forceps (9 cm, 1 × 2 0.5-mm teeth)	1
Tuberculin syringe and 25-gauge needle	1
Sterile cotton-tipped applicators	Package of 10
Tono-Pen or TonoVet	1
Diode laser with glaucoma probe	1

Surgical Techniques

Transscleral Cyclophotocoagulation

Both Nd:YAG and semiconductor diode lasers have been used successfully in horses to reduce IOP.[28,63-65] Laser energy is applied to the ciliary body through the sclera to destroy the ciliary body epithelium and stroma, thereby reducing aqueous production.[50] A recent paper suggests that transscleral cyclophotocoagulation (TSCP) aids in control of IOP and maintenance of vision but does not diminish the need for topical glaucoma medications.[64] Therefore, patients with the potential for vision are the best candidates. Individuals with chronically blind eyes are better candidates for enucleation or evisceration and placement of intraocular silicone prosthesis (see Chapter 55).

When using the Nd:YAG laser, 55 to 60 applications are placed 5 to 6 mm from the limbus with a power of 10 to 11 W for a duration of 0.4 seconds per site.[28,66] For the diode laser, settings are 1500 mW and 1500 msec per site.[64] The number of sites varies from 30 to 80, placed 4 to 6 mm from the limbus.[28,64] The nasal region should be avoided because of the proximity of the retina.[67] Aqueous paracentesis is often performed immediately following TSCP because of rapid elevations in IOP.[64] Hyphema, corneal ulceration, conjunctival hyperemia, increased corneal edema, and aqueous flare have all been reported following TSCP.[50,64,66] Postoperatively, the glaucoma medications are continued. Topical anti-inflammatory therapy is used unless corneal ulceration occurs. In addition, systemic NSAIDs are administered to control the postoperative inflammation. The IOP should be evaluated 24 hours after surgery. The anti-inflammatory therapy is tapered over several weeks. The glaucoma medications often continue indefinitely. A decrease in IOP is typically not seen for 2 to 4 weeks after diode TSCP.[64]

Gonioimplants (Anterior Chamber Shunts)

Gonioimplants are considered experimental in the horse, but they have been used successfully to improve aqueous drainage.[28] The implants provide an alternative outflow pathway for aqueous drainage to the subconjunctival space. The implants typically have a short life span because of fibrosis of the filtration bleb.[50] There are no commercially available equine gonioimplants.

Pharmacologic Ablation of the Ciliary Body

Pharmacologic ablation of the ciliary body is a salvage procedure and should only be performed in eyes that are permanently blind. Owners should be warned that the procedure can induce phthisis bulbi.[50] The procedure is typically performed under a brief episode of general anesthesia or heavy sedation with regional and topical anesthesia. The injection consists of 25 to 40 mg of intravenous gentamicin to ablate the ciliary body and 1 mg of dexamethasone to control inflammation. The injection is performed with a 22-gauge needle attached to a 3-mL syringe. The needle enters the globe 7 to 8 mm posterior to the dorsotemporal limbus at a 45-degree angle toward the optic nerve.[50] The needle must be directed away from the lens. Rupturing the lens capsule with the needle is a catastrophic complication that incites marked inflammation (phacoclastic uveitis). Vitreous can be aspirated before injection or aqueous paracentesis can be performed after injection to reduce the elevation in IOP produced by the increase in volume of globe contents.

CHAPTER
59 Testis

James Schumacher

ANATOMY AND PHYSIOLOGY

Scrotum

The scrotum of the horse is a prepubic diverticulum of skin that contains the testes, their associated ducts, and the distal portion of the spermatic cords.[1] It is divided on the midline by the scrotal raphe, which is continuous with the raphe of the prepuce, penis, and perineum.[1,2] The skin of the scrotum is thin, is sparsely covered with fine hair, and contains an unusually high number of sweat glands.

Intimately adherent to the scrotal skin is a layer of connective tissue and involuntary muscle, the *tunica dartos.*[1,3,4] This muscle relaxes with heat and contracts with cold to regulate testicular temperature, thus varying the size of the scrotum.[1] At the median plane, the tunica dartos sends a sagittal septum into the scrotal sac, dividing the scrotum into right and left pouches, each of which contains a testis.[1,3]

The vascular supply to the scrotum originates from the external pudendal vessels.[1,3,4] The nervous supply descends into the scrotum on the outer surface of the tunica vaginalis via the genitofemoral nerve.[1,3] Lymphatic vessels from the scrotum drain to the superficial inguinal lymph nodes.[4]

Epididymis and Testis

The testes produce spermatozoa and hormones.[5] The hormones govern spermatogenesis, sexual differentiation, secondary sexual characteristics, and libido.[6] The testes are oval and, depending on the age and breed of the horse, weigh between 150 and 300 g each.[1,2] The left testis is usually larger, suspended more ventrad, and situated further caudad than the right testis.[1] The long axis of the testis is nearly horizontal but raised slightly craniad.[1-4] The epididymis attaches to the dorsolateral border of the testis (i.e., the attached or epididymal border) and overlaps the lateral surface slightly (Figure 59-1), forming a testicular bursa between the testis and epididymis. Opposite the attached border is the free border, and opposite the lateral surface is the medial surface.

The epididymis is an elaborately coiled tube consisting of three parts: the head (caput), body (corpus), and tail (cauda).[1] The head lies at the cranial pole of the testis, and the body is positioned on the lateral surface of the testis. The tail projects beyond the caudal border of the testis, wraps around to the medial side, and continues proximally as the ductus deferens.[1,3,4,7] The epididymis receives immature sperm, which enter it through the efferent ducts of the testis. At ejaculation, peristaltic contractions of the epididymis force sperm into the ductus deferens.

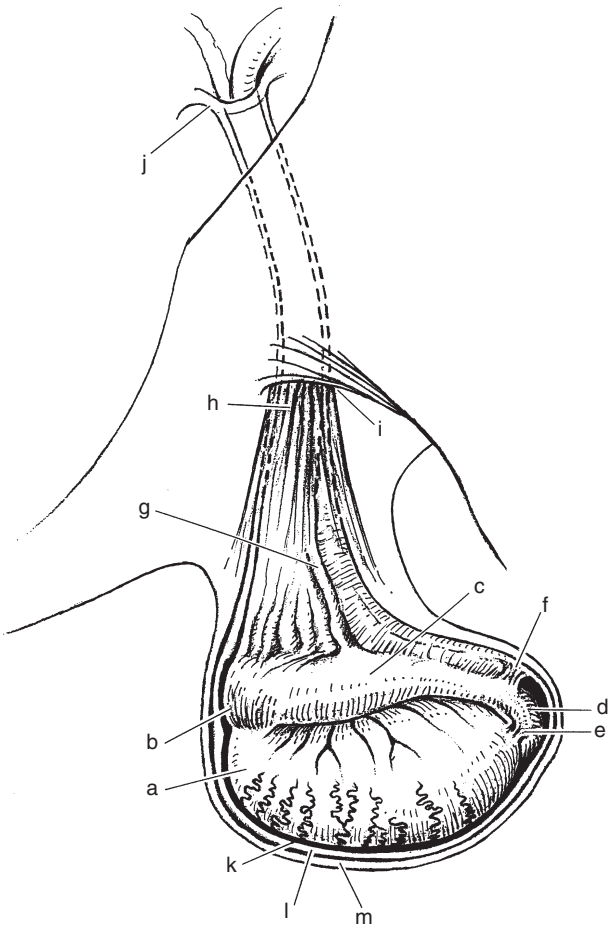

Figure 59-1. Right testis and epididymis of a stallion, lateral aspect. *a,* Testis; *b,* head of epididymis; *c,* body of epididymis; *d,* tail of epididymis; *e,* proper ligamentum testis; *f,* ligament of the tail of the epididymis; *g,* spermatic cord; *h,* cremaster muscle; *i,* external inguinal ring; *j,* vaginal ring; *k,* visceral tunic; *l,* vaginal cavity; *m,* parietal tunic.

The testis is covered by the *tunica albuginea,* a tough, inelastic capsule of dense fibrous tissue.[1,4] Trabeculae and septa of connective tissue from the tunica albuginea penetrate the testis to subdivide the parenchyma into lobules. Each lobule consists of

convoluted seminiferous tubules lined by spermatogonia, from which spermatozoa arise, and *Sertoli cells* (also called sustentacular cells), which supply mechanical and nutritive support for the developing spermatozoa.[1,5] The primary spermatogonia are attached to the basement membrane of the tubule, and the more mature spermatozoa are pushed toward the lumen. Follicle-stimulating hormone (FSH) produced by the hypophysis stimulates spermatogenesis. The seminiferous tubules make up over 70% of the parenchyma of the testis.[8]

Located between the seminiferous tubules are interstitial cells, known as the *cells of Leydig*, which produce androgens in response to interstitial cell–stimulating hormone (which is similar or identical to luteinizing hormone), produced by the hypophysis.[5] The testis of the stallion produces an unusually high concentration of estrogen in comparison to other domestic species, and the source of this estrogen is the Leydig cells.[9]

The seminiferous tubules converge to form the tubules of the rete testis, which pierce the tunica albuginea at the dorsocranial border of the testis to become the efferent ductules.[3] The dozen or more efferent ductules unite in the head of the epididymis to form a single coiled tube, over 70 m long, that continues to become the body and tail of the epididymis and ascends with the testicular vessels as the ductus deferens.[1,2] Spermatozoa mature in the epididymal duct, and the duct's tortuous course allows the storage of a large number of spermatozoa.[5]

Inguinal Canal

The inguinal canal is an oblique passage in the abdominal wall through which traverse the spermatic cord, genitofemoral nerve, external pudendal vasculature, and the efferent lymphatic vessels from the superficial inguinal lymph nodes.[10] The internal opening of the inguinal canal, the deep inguinal ring, is a dilatable slit, about 16 cm long in the average-sized horse, bordered cranially by the caudal edge of the internal abdominal oblique muscle, ventromedially by the rectus abdominis muscle and prepubic tendon, and caudally by the inguinal ligament.[1,3] The external opening of the inguinal canal, the superficial inguinal ring, is a 10- to 12-cm-long slit in the external abdominal oblique muscle.[1,10]

The medial border of the superficial inguinal ring lies directly below the medial border of the deep inguinal ring, making the medial wall of the inguinal canal very short.[3] The superficial inguinal ring is directed craniolaterally, and the deep inguinal ring is directed dorsolaterally, making the lateral angles of the rings widely divergent. The length of the canal in a medium-sized horse is about 15 cm when measured along the spermatic cord.[7] The wall of the inguinal canal is lined by peritoneum, which forms the tunica vaginalis.[10]

Tunics

The *tunica vaginalis,* derived from the abdominal peritoneum, continues through the inguinal canal to line the interior of the scrotum and envelops the testis and its associated ducts and spermatic cord[1,11] (Figure 59-2). The tunica vaginalis consists of a visceral tunic (tunica vaginalis propria) and a parietal tunic (tunica vaginalis communis). The visceral tunic adheres firmly to the tunica albuginea and covers the testis and associated ducts, except at the dorsal border of the testis, where vessels and the epididymis enter or leave the testis.[1,3,4,11] The parietal tunic is continuous with the parietal peritoneum of the abdomen at the deep inguinal ring and forms a sac that lines the scrotal cavity.[1,4,11] This sac is referred to as the *vaginal process* or *vaginal sac,* and its opening at the deep inguinal ring is the *vaginal ring.* The vaginal ring is found, during examination *per rectum* in the average-sized horse, 10 to 12 cm abaxial to the linea alba and 6 to 8 cm cranial to the iliopectineal eminence.[1] The diverticulum of the peritoneal cavity between the parietal and visceral tunics is the vaginal cavity.[1,11] This cavity communicates with the peritoneal cavity and normally contains only a small quantity of serous fluid, which serves as a lubricant to facilitate movement of the testis. The right and left vaginal cavities do not communicate.

Gubernaculum

The gubernaculum testis is a fetal, retroperitoneal, mesenchymal cord that extends between the caudal pole of the fetal testis and the scrotum and guides the fetal testis in its descent from the ventral surface of the kidney to its final position in the scrotum[10] (Figure 59-3). The gubernaculum testis can be divided into three parts: the cranial part, which lies between the testis and the epididymis; the middle part, which lies between the epididymis and the point at which the gubernaculum penetrates the abdominal wall at the inguinal rings; and the caudal or scrotal part, which extends from the abdominal wall at the site of the future inguinal canal to the scrotum. The cranial part becomes the *proper ligament of the testis* and connects the tail of the epididymis to the testis.[3,4,10] The middle part becomes the *ligament of the tail of the epididymis* (also known as the caudal ligament of the epididymis) and connects the tail of the epididymis to the parietal tunic. The caudal part becomes the *scrotal ligament* and connects the parietal tunic to the bottom the scrotum. The scrotal ligament of an abdominally retained testis is sometimes referred to as the inguinal extension of the gubernaculum testis.[12] These ligaments may be abnormally long if the testis fails to descend.[13] Improper function of the gubernaculum may result in abdominal or inguinal retention of a testis.[14,15]

Descent of the Testis

The gonads arise retroperitoneally from the gonadal ridges caudal to the kidney and differentiate into testes or ovaries at 40 days of gestation.[16,17] By gestational day 55, the testis is suspended cranially by the cephalic (suspensory) ligament and dorsally by the mesorchium. The interstitial cells begin multiplying at 6 weeks of gestation, causing the testis to hypertrophy until, at 5 months of gestation, the testis is nearly as large as that of a mature stallion and contacts both the kidney and the deep inguinal ring. This phase of testicular hypertrophy corresponds with a period of high serum concentration of estrogen in the mare.[18]

The gubernaculum extends from the caudal end of the testis to the inguinal canal and ends in a knoblike expansion between the differentiating internal and external oblique abdominal muscles.[15,16] On gestational day 45, the peritoneum invades the subperitoneal tissue around this extra-abdominal expansion of the gubernaculum to form the vaginal process. At about 5 months of gestation, the cephalic ligament atrophies, and the epididymis descends into the vaginal process while the testis remains in the abdomen.[16,17]

At 8½ months of gestation, the gubernaculum begins to shorten. Simultaneously, the testis regresses in size, mainly because of loss of interstitial cells, until during the last month of gestation when it becomes one tenth its former size.[16] The epididymis and subperitoneal gubernaculum expand in diameter, thus dilating the vaginal ring and inguinal canal. This, along with an increase in intra-abdominal pressure, allows the testis to pass into the inguinal canal at between 270 and 300 days of gestation.[7,15-17] The mass of extra-abdominal gubernaculum prevents the testis from moving directly into the scrotum so that, at birth, most testes lie in the inguinal canal. This extra-abdominal portion of gubernaculum can be quite large at birth and easily mistaken for a testis. The vaginal rings contract to approximately 1 cm in diameter during the first few weeks of neonatal life and become so fibrous that the testis cannot be forced through from either direction.[16]

Spermatic Cord

The spermatic cord consists of structures carried ventrad by the testis in its migration through the inguinal canal from the abdomen to the scrotum.[1,10] The spermatic cord begins at the deep inguinal ring, where its constituent parts converge. It extends obliquely and ventrad through the inguinal canal, passes beside the penis, and terminates at the dorsal border of the testis.[1] The structures that make up the cord are the tunica vaginalis; the blood vessels, nerves, and lymphatics of the testis; and the ductus deferens.[1,10,11] Technically, the cremaster muscle is not included as a component of the cord because it lies external to the parietal tunic.[4,14] The neurovascular components of the cord are enclosed in the mesorchium, a fold of serous membrane formed by invagination of the parietal tunic along its caudal wall (Figure 59-4). The mesorchium extends from the origin of the testicular vessels to the testis. The mesoductus deferens is a caudomedially located fold of the parietal tunic containing the ductus deferens and the deferential vessels.[1,3,4] The mesoductus deferens is continuous with the mesorchium. The mesofuniculum is the thin part of the mesorchium between the mesoductus deferens and the parietal tunic.

The *ductus deferens* is a direct continuation of the epididymal duct.[1] It stores spermatozoa, and during ejaculation, it propels spermatozoa from the epididymis to the pelvic urethra.[5] The ductus deferens is somewhat convoluted near the epididymis but straightens as it continues dorsad.[1,2] At the vaginal ring, it separates from other constituents of the spermatic cord and turns caudomedially into the pelvic cavity, where it lies in the genital fold, a horizontal sheet of peritoneum lying between the bladder and the rectum. Dorsal to the bladder, the ductus deferens increases in diameter and forms the ampulla, which in the stallion, is 15 to 20 cm long and about 1 to 2 cm in diameter. The ampulla is not nearly as pronounced in geldings. Beyond the ampulla, the ductus deferens narrows and opens with the ducts of the seminal vesicles at the ejaculatory orifices

Figure 59-4. on the colliculus seminalis, a protuberance on the dorsal wall of the urethra, located about 5 cm caudal to the internal urethral orifice. The ductus deferens is supplied by the deferential artery, a branch of the umbilical artery.[4]

The *testicular artery*, a branch of the abdominal aorta, descends in the cranial part of the cord.[1] As the artery descends in the inguinal canal, it becomes greatly convoluted. At the cranial pole of the testis, it gives off the epididymal artery, then continues caudad with the epididymis, turns ventrad around the caudal pole of the testis, and travels craniad on the free border, sending off branches to the medial and lateral surfaces.[1,19] The testicular artery and its branch, the epididymal artery, constitute most of the vascular supply to the testis.[20] The cremasteric artery and the deferential artery also contribute to the blood supply to the testis. These three arteries are connected by numerous anastomosing vessels.

Testicular veins ascend from the dorsal border of the testis. Small veins coalesce into larger veins about 10 cm proximal to the testis.[21] These larger veins contain valves that prevent retrograde flow of blood. The veins divide and convolute to form the *pampiniform plexus,* which lies around the coiled testicular artery and forms the bulk of the spermatic cord.[1,3,4,7] The veins unite within the abdomen to become the testicular vein. The right testicular vein usually joins the caudal vena cava, and the left testicular vein usually joins the left renal vein.[1] The lymphatic vessels of the testis and epididymis ascend directly to the medial iliac and lumbar lymph nodes.[1,3,4] A plexus of autonomic and visceral sensory nerves accompany the blood vessels to supply the testis and epididymis.

The *cremaster muscle*, a slip of the internal abdominal oblique muscle, lies on the caudolateral surface of the parietal tunic and attaches to this tunic at the caudal pole of the testis.[1,10] Its blood supply derives from the cremasteric artery.[3,4] Contraction of the cremaster muscle retracts the testis.[1]

PATHOPHYSIOLOGY

Congenital Monorchidism

Horses possessing one descended testis and one that has failed to descend are sometimes described incorrectly as being monorchids.[21] The term *monorchidism* should be reserved to describe the rare situation of complete absence of one testis. Horses in possession of only one testis usually reach this state from failure of a surgeon to remove both testes at the time of castration, but the condition can also occur from unilateral testicular agenesis or when a vascular insult, presumably caused by torsion of the spermatic cord, causes an abdominally located testis to degenerate.[22-27]

Monorchidism of an apparently congenital nature is usually caused by testicular degeneration rather than by atresia,[25] and the vascular insult responsible for the degeneration may occur in the undescended testis before birth or in an abdominal testis after birth.[25,27,28] Torsion of the spermatic cord of the abdominal testis may cause the horse to show moderate to severe signs of abdominal pain,[29] but some similarly affected horses do not demonstrate any signs of pain.[28]

Congenital absence of testicular tissue or absence of testicular tissue caused by testicular degeneration is discovered when, during inguinal or abdominal exploration to locate a cryptorchid testis, the tail of the epididymis is found attached to both the ligament of the tail of the epididymis and the ductus deferens, but the testis is absent.[25,27] More rarely, the epididymis or even the ductus deferens may also be missing. Monorchidism can be confirmed with a human chorionic gonadotropin (hCG)-stimulation test after the contralateral testis is removed and the horse has recovered from surgery, but determining whether monorchidism was caused by degeneration, atresia, or surgical excision of a testis may be difficult.[25] The presence of a vaginal process suggests that monorchidism was acquired, and identifying remnants of the cremaster muscle, ductus deferens, and testicular vessels within the inguinal canal suggests that the testis was excised.

Cryptorchidism

Cryptorchidism is an anomaly of testicular position and is the most prevalent, nonlethal developmental defect of the horse.[16,30,31] Abnormal testicular location occurs when one testis or both testes fail to descend completely from the fetal position in the sublumbar area through the inguinal canal into the scrotum.[16] The term *cryptorchid* refers to the nondescended testis (by extension, a horse with this condition is also termed a cryptorchid), and removal of an undescended testis is sometimes referred to as cryptorchidectomy. Colloquial terms for the cryptorchid include *rig, ridgling,* or *original.*[32-34] If a testis and its epididymis are both abdominally retained, the horse is called a complete abdominal cryptorchid. If the epididymis, but not the testis, has descended through the vaginal ring, the horse is called a partial or incomplete abdominal cryptorchid.[33-35] An inguinal cryptorchid or "high flanker" is a horse with a testis retained within the inguinal canal.[32-35]

In boys testes that usually reside in the inguinal region, because of retraction of the cremaster muscle, but that can be manipulated into the scrotum are termed *retractile.*[36] The retractile testis resides in the inguinal region until puberty, when testicular growth causes the testis to reside permanently within the scrotum. The retractile testis of boys is considered to be a

normal variant[36] and is distinguished from a truly inguinal retained testis. Although retractile testes of horses have not been described, at least some inguinally located testes of young horses that can be retracted into the scrotum may warrant being distinguished from truly retained testes and classified as retractile.

Cryptorchidism of stallions is of considerable economic significance, because the seminiferous tubules of the cryptorchid testis are rudimentarily developed and incapable of producing sperm.[16] Unilateral cryptorchids are usually fertile but have reduced production of sperm,[37] and horses affected with bilateral testicular retention are sterile.[16] The androgen-producing cells of Leydig of a cryptorchid testis are functional and produce testosterone, although at reduced concentrations, so that the cryptorchid horse exhibits sexual behavior. Exposure of the testis to the high temperature of the abdomen or inguinal canal appears to be responsible for hypoplasia of the seminiferous tubules and results in a small, soft testis. Location of the testis at sites other than the scrotum complicates removal of the testis. Because malfunction of descent may be inherited, cryptorchid horses are generally considered genetically unsound.[30] For this reason, registration of cryptorchid stallions is disallowed by some breed associations.

Undescended testes of humans may be at risk of developing neoplasia,[38] and the same may be true of undescended testes of horses, although a direct link between equine testicular neoplasia and cryptorchidism has not been proved, perhaps because of the few reports of testicular neoplasia in stallions. Testicular neoplasia of humans may be the result of progressive degeneration of germ cells caused by the abnormal temperature to which the cryptorchid testis is subjected.[39] Factors other than position of the testis may be responsible for the increased incidence of malignancy, raising the question of whether the testis develops neoplasia because it is undescended or whether some abnormality of the testis (resulting in neoplasia) is responsible for failure of the testis to descend.

An epidemiologic survey investigating the prevalence of equine cryptorchidism found that approximately one of six (i.e., about 17%), 2- to 3-year-old colts presented to a veterinary medical teaching hospital was cryptorchid.[30] Of these cryptorchid testicles, only 14 had tumorous derangement, representing 0.3% of the total cryptorchid testes evaluated.[30] Groups most commonly represented were Percherons, American Saddlebreds, American Quarter Horses, ponies, and crossbred horses. Thoroughbreds had the lowest prevalence of cryptorchidism.

Etiology

Improper function of the gubernaculum has been postulated to cause failure of testicular descent.[15,16] Failure of the subperitoneal portion of the gubernaculum to enlarge may result in failure of the vaginal ring to expand sufficiently to allow the testis to pass. Excessive enlargement of the subperitoneal portion of the gubernaculum, followed by its failure to regress adequately, may also inhibit passage of the testis into the inguinal canal.[14]

Events that lead to cryptorchidism in horses have not been determined, but a deficiency in production of gonadotropin by the pituitary gland or the placenta has been shown to result in cryptorchidism in boys, by leading to insufficient production of androgens by the descending testes.[40] These androgens are responsible for development of the vaginal process, testicular vessels, and vas deferens and for changes in the gubernaculum, all of which are necessary for the descent of the testes into the scrotum. Rather than acting directly on the gubernaculum, androgens likely act primarily on the cell body of the genitofemoral nerve in the spinal cord.[41] The genitofemoral nerve, which innervates the gubernaculum, causes the gubernaculum to differentiate, creating a potential space into which the testis descends under the influence of abdominal pressure.[38] Androgens thus act on the gubernaculum indirectly and probably must do so at a specific time during gestation.

The testis may also fail to descend if it does not regress to a sufficiently small size to traverse the vaginal ring.[16,18] A testicular cyst or teratoma or persistence of the suspensory ligament of the testis during gestation may account for failure of testicular descent.[34,42] The complexity of the process of testicular descent suggests that the cause of failure of descent is multifactorial.

Although genetic studies of cryptorchid horses indicate that in many instances the condition is hereditary, no definitive studies have supported a plausible genetic mechanism. The effects of maternal environment and mechanical factors (e.g., dystocia) in the etiology of cryptorchidism have not been examined.[30] The conflicting observations of numerous studies of genetic transmission of equine cryptorchidism suggest that the mechanism of inheritance is complex and most likely involves several genes.[43] One of the most frequently cited investigations is a thesis published in 1943 on the genetic nature of cryptorchidism of several species of domestic animals. The Technical Development Committee of Great Britain (1954), citing this thesis, concluded that equine cryptorchidism is transmitted by a dominant factor.[44] Other researchers, citing the same thesis, reported that the investigation had determined that equine cryptorchidism is caused by a simple autosomal recessive gene.[45] A German study of 21 cryptorchid stallions postulated that at least two genetic factors are involved, one of which is located on the sex chromosomes.[45] Another German study, however, concluded that equine cryptorchidism is transmitted as an autosomal dominant gene.[45]

Researchers at Texas A&M University found that 56 of 58 colts sired by a cryptorchid American Quarter Horse stallion had both scrotal testes.[46] The other two colts were unavailable for assessment of testicular location. This stallion was unlikely to have carried a dominant autosomal gene for cryptorchidism, unless the gene had low penetrance. If equine cryptorchidism is caused by an autosomal recessive gene, the frequency of the recessive gene in the dams of these 56 colts would have to have been nearly zero.

Cryptorchidism is often a feature of intersexuality.[47,48] For example, the testes of the male pseudohermaphrodite are often located within the inguinal canals or the abdomen.[6,47,49] Cryptorchidism may also be a manifestation of an abnormal karyotype.[47,48] Horses that are cryptorchid because of an aberration of genetic sex, however, are usually easily identified by their intersexual phenotypes.[6,47] The prevalence of horses that are cryptorchid because of intersexuality appears to be quite low; in a study of 5018 cryptorchid horses, only 9 were intersexes.[30]

Incidence

Retrospective studies of large numbers of cryptorchid horses indicate that failure of right and left testicular descent occurs with nearly equal frequency.[50-52] Right-sided testicular retention

predominates in young cryptorchid ponies, but the incidence of right-to-left retention decreases as the ponies age.[51] The decrease in incidence of right testicular retention is probably the result of descent of the right testis from an inguinal location.

A study of 350 cryptorchid horses and another of 205 cryptorchid horses found abdominal testicular retention to be more common than inguinal testicular retention.[50,52] Another study of 500 cryptorchid horses, however, found inguinal cryptorchidism to be more common than abdominal cryptorchidism.[51]

The study of 350 cryptorchid horses found that 75% of left undescended testes were located within the abdomen, whereas only 42% of right undescended testes were retained abdominally.[52] The reason for this difference may be that the right testis is smaller than the left during the stage of testicular regression.[17] Consequently, if the gubernaculum fails to expand sufficiently to dilate the vaginal ring, or if the testes incompletely regress in size, the larger left testis is more likely to be incapable of traversing the vaginal ring. Because this difference in testicular size remains after birth, the smaller right testis is more apt to be inguinally retained. Increase in testicular size with the onset of puberty may cause an inguinally retained testis to descend into the scrotum.[50,51]

In one study, 14% of cryptorchid horses were bilaterally affected, and most of these (60%) had abdominal testicular retention.[52] Another study found a 9% incidence of bilateral testicular retention among cryptorchid horses, but in that study, most bilaterally retained testes (67%) were inguinally located.[50] The incidence of cryptorchid horses with one inguinally located testis and one abdominally located testis was quite low in both studies (i.e., when both testes of a horse had failed to descend into the scrotum, the testes were usually either both inguinal or both abdominal).

Inguinal Herniation and Rupture

Inguinal herniation occurs when intestine, usually a portion of the ileum or a loop of the distal portion of jejunum, protrudes through the vaginal ring into the inguinal canal. If the contents extend into the scrotum, the condition is sometimes referred to as scrotal herniation (Figure 59-5), but the terms are used interchangeably.[53,54] Inguinal hernias are sometimes called *indirect hernias,* a term borrowed from descriptions of the comparable condition in humans (for more information on hernias please review Chapter 39).[53]

A *ruptured inguinal hernia* occurs when intestine protrudes through the vaginal ring and then passes through a rent in the parietal tunic and scrotal fascia so that it lies subcutaneously in the inguinal or scrotal region[55] (Figure 59-6). The term *inguinal rupture* describes a similar condition that occurs when intestine protrudes through a rent in the peritoneum and transverse fascia adjacent to the vaginal ring, causing intestine to reside subcutaneously beside the vaginal process[53] (Figure 59-7). Inguinal ruptures have been referred to as *direct hernias,*[56] but this term is derived from descriptions of hernias in humans and inaccurately describes the condition in horses.[53] In humans, the transverse fascia adjacent to the vaginal ring becomes weakened and protrudes, forming a peritoneum-lined sac. In horses, the integrity of the tissue adjacent to the vaginal ring is disturbed, and the intestine passing through the rent is not surrounded by peritoneum. The purported direct hernias of horses are actually ruptures, not hernias.[53,57]

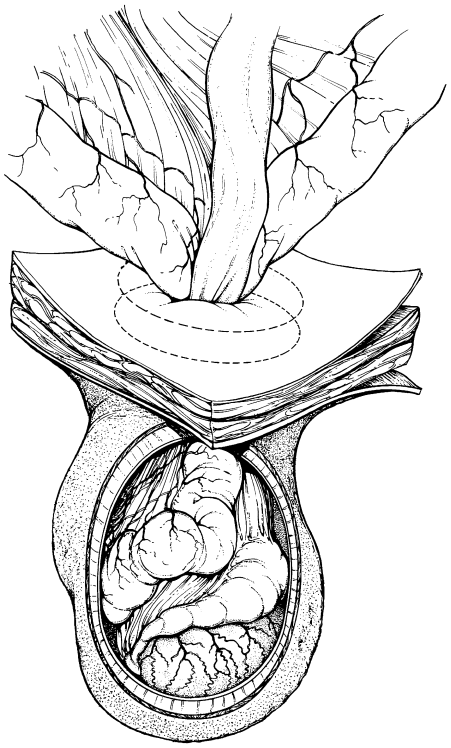

Figure 59-5. Inguinal hernia. Intestine protrudes through the vaginal ring into the inguinal canal or scrotum. The intestine lies within the vaginal cavity.

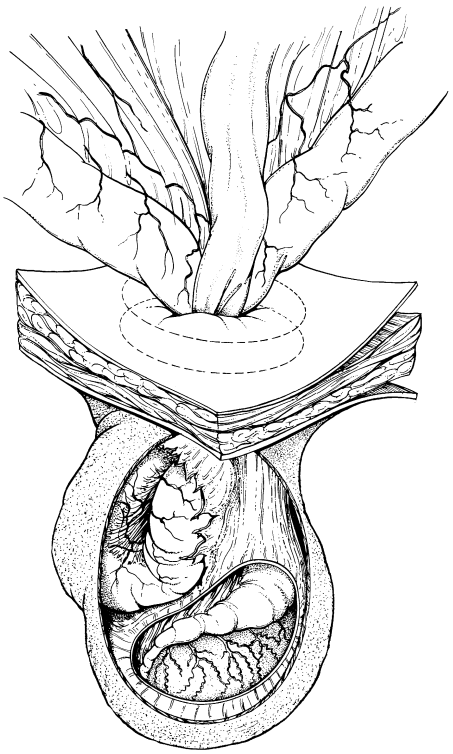

Figure 59-6. Ruptured inguinal hernia. Intestine protrudes through the vaginal ring and passes through a rent in the parietal tunic and scrotal fascia so that it lies subcutaneously in the inguinal or scrotal region.

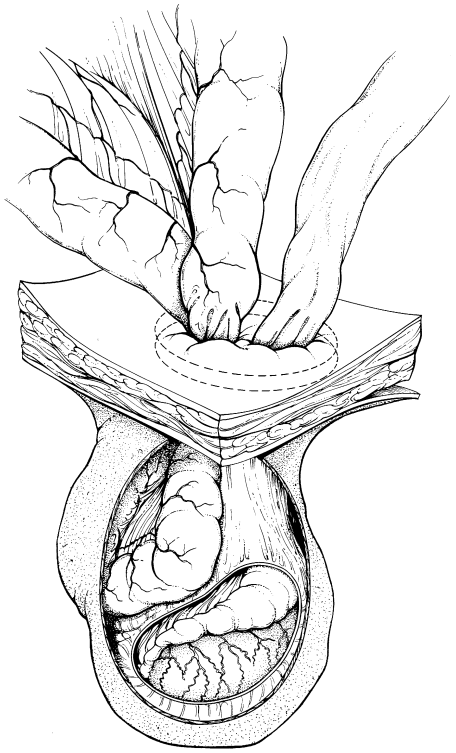

Figure 59-7. Inguinal rupture. Intestine protrudes through a rent in the peritoneum and transverse fascia outside the vaginal sac but adjacent to the vaginal ring.

Etiology

Inguinal herniation and rupture occur almost exclusively in stallions,[54,55,58] but inguinal herniation has been reported to have occurred in a few geldings[54,59,60] and in a mare.[61] Geldings rarely develop an inguinal hernia, because the vaginal rings decrease in size soon after castration.

Inguinal hernias in foals are congenital, and most are hereditary in origin.[6] The left inguinal canal is most often involved.[62] Congenital inguinal herniation may be caused by excessive outgrowth of the extra-abdominal part of the gubernaculum, which results in a vaginal process with an unusually wide neck.[7,15] Congenital inguinal hernias may occur unilaterally or bilaterally, are usually reducible, cause no strangulation, and spontaneously resolve by the time the foal is 3 to 6 months old.[53,60] Longstanding congenital inguinal hernias, however, may lead to testicular atrophy.[60]

Inguinal hernias occurring in adult horses are usually acquired and can occur during exercise or copulation, either of which may contribute to herniation by altering the anatomy of the inguinal canal and increasing abdominal pressure.[54] The incidence of acquired inguinal herniation in Standardbreds, draft breeds, and Andalusian horses is reported to be higher than that of the general equine population.[63-65] Other breeds with anecdotal evidence of increased incidence of inguinal herniation are Tennessee Walking Horses and American Saddlebreds.

An acquired inguinal hernia of an adult horse commonly results in strangulation of intestine and represents a surgical emergency.[54] Small intestine (jejunum and ileum) is the most commonly herniated viscus, but inguinal herniation of small colon, large colon, omentum, and the urinary bladder have been reported.[66-68] Clinical signs are usually referable to obstruction of the small intestine and include recovery of nasogastric reflux after nasogastric intubation and rectally palpable distended small intestine.[54,58] Strangulation of herniated intestine is caused by constriction of the intestine by the vaginal ring.[58] An acquired inguinal hernia usually causes obstruction of the vasculature of the spermatic cord, which leads to edema of the external genitalia and testicular degeneration or necrosis.

Ruptured inguinal herniation appears to occur much more commonly in foals than in adults, and those that occur in foals may be caused by abdominal compression during parturition.[55,69] Inguinal ruptures are probably traumatic in origin, but the traumatic event is not always obvious. With an inguinal rupture or a ruptured inguinal hernia, the intestine that protrudes through the rent may become strangulated or may adhere to subcutaneous tissue, and the separation of the skin from its blood supply may reduce the viability of the skin.

Figure 59-8. Torsion of the spermatic cord has caused necrosis of the testis and the portion of the cord distal to the torsion.

Torsion of the Spermatic Cord

Torsion of the spermatic cord occurs when the attached testis rotates on its vertical axis.[70] The condition is sometimes improperly referred to as testicular torsion. Torsion of the spermatic cord causes the testicular vessels to twist, producing venous and often arterial obstruction, which leads to testicular congestion and edema in mild cases and complete testicular infarction in severe cases.[28,70,71] (Figure 59-8). Clinically significant torsion of the spermatic cord in the horse occurs rarely, and few reports of the condition can be found.[28,72-75] This condition is reported to occur most commonly in trotting Standardbreds.[6]

Torsion of the spermatic cord of 360 degrees or more is accompanied by signs of acute pain, which may resemble signs of colic, and enlargement of the affected testis and cord.[74] The condition represents a surgical emergency that usually requires removal of the affected testis, because the testis is rarely salvageable. Torsion of the spermatic cord of an abdominally located testis may cause the affected horse to show mild signs of colic pain,[29] but acute torsion of the spermatic cord has been recognized during cryptorchidectomy of several apparently normal horses that apparently displayed no signs of colic.[28] The incidence of torsion of the spermatic cord of undescended testes of humans is probably higher than the incidence of torsion of the descended testes,[76] and the same may be true of horses. Because torsion of the spermatic cord of an abdominal testis often goes

unrecognized in horses, the condition may account for some reports of horses with congenital monorchidism.

Evidently, torsion of the spermatic cord of a scrotal testis of the horse less than 180 degrees causes no clinical abnormalities and is considered an incidental finding.[74] Evaluation of testicular blood flow of stallions using color Doppler ultrasonography, however, shows that 180-degree torsion of a spermatic cord may cause retrograde blood flow and suggests that torsion of this degree may have a detrimental effect on testicular function, even in the absence of clinical signs of substantial vascular compromise.[77]

Torsion of the spermatic cord of 180 degrees is relatively easy to diagnose because it causes the tail of the epididymis to reside in the cranial portion of the scrotum, rather than in its normal caudolateral position. Acute torsion of the spermatic cord may be difficult to determine when the spermatic cord is twisted 360 or 720 degrees, because the tail of the epididymis resides in its normal caudolateral position in the scrotum. Torsion of the spermatic cord of 360 degrees or more may be accompanied by so much scrotal, testicular, and epididymal swelling that the epididymis cannot be palpated.

Torsion of the spermatic cord of the descended testis of horses apparently occurs intravaginally (i.e., within the vaginal process).[74,75] Horses may be predisposed to testicular torsion because the testis resides horizontally, rather than vertically, in the scrotum.[75] Torsion may occur because the ligament of the tail of the epididymis (caudal ligament of the epididymis) or the proper ligament of the testis is abnormally long. The ligaments of the contralateral testis may also be abnormally long, making that spermatic cord also prone to torsion.[75] To prevent torsion of the contralateral spermatic cord, the contralateral testis can be fixed permanently in position (orchidopexy or orchiopexy) by placing a nonabsorbable suture through the tunica albuginea and the dartos tissue at the cranial and caudal poles of the testis.

The spermatic cord of an abdominal testis may be more apt to develop torsion than is the spermatic cord of a descended testis, because the proper ligament of the testis and sometimes the ligament of the tail of the epididymis of an abdominal testis are abnormally long.[23,28,37] None of 350 cryptorchid horses in one study, however, developed torsion of the spermatic cord.[52]

Hydrocele (Vaginocele) and Hematocele

A hydrocele, or vaginocele, is an abnormal collection of serous fluid between the visceral and parietal layers of the tunica vaginalis.[78,79] Hydroceles form when fluid normally secreted by the vaginal tunic is produced at a rate greater than that at which it can be absorbed by the lymphatic vessels and veins of the spermatic cord.[80] The cause of the discrepancy between the rate of production and the rate of resorption of the fluid is usually idiopathic.[78] Hydroceles may accompany testicular neoplasia or orchitis, and because the vaginal and peritoneal cavities communicate, some hydroceles could be caused when fluid present in excess in the abdominal cavity enters the vaginal cavity.[81] Migration of parasites through the vaginal cavity, 180-degree torsion of the spermatic cord, trauma, and a hot climate in conjunction with lack of exercise have been implicated as causes of hydroceles.[78,82] Hydroceles may develop acutely or insidiously. A hydrocele is generally considered to cause temperature-induced dysfunction of spermatogenesis by insulating the testis and epididymis, but one investigation found they caused no important effect on semen quality.[78] A hydrocele is occasionally a complication of castration, but only when the parietal tunic is retained (i.e., after an open castration).

Palpation of a hydrocele usually causes no apparent discomfort to the horse, and the involved testis is freely moveable and feels as though it resides within a compressible, fluid-filled bag.[81] Anechoic to semi-echoic fluid surrounding the involved testis and epididymis is seen during ultrasonographic examination of the scrotum, and a yellowish, clear fluid is obtained during aspiration of the vaginal cavity. The involved testis of a chronically affected horse may be abnormally small.

The size of a hydrocele may decrease temporarily with exercise, and some hydroceles spontaneously resolve when the affected horse is moved to a cooler environment.[78,81] Fluid usually reaccumulates quickly after aspiration. Treatment of a horse for hydrocele should be aimed at removing the inciting cause. However, the cause can rarely be identified, so the usual treatment of horses affected with persistent unilateral hydrocele is removal of the affected testis and parietal tunic. The testis and tunic should be removed before spermatogenesis of the contralateral testis becomes affected by increased scrotal temperature. Prognosis for fertility is guarded if bilateral hydroceles persist, but some stallions affected with hydrocele retain normal spermatogenesis.[78]

Sclerotherapy, using a 2.5%, 5%, or 10% solution of tetracycline or using polidocanol injected into the vaginal cavity, has been used successfully to treat men affected with a hydrocele,[83,84] but this treatment may also decrease fertility.[85] Sclerotherapy has not been evaluated as a treatment for stallions with a hydrocele.

A *hematocele* may resemble a hydrocele, but it is characterized by a collection of blood within the vaginal cavity.[86,87] Hematoceles are usually caused by testicular or scrotal trauma, but they may occur as an extension of hemoperitoneum.[37] Ultrasonographic examination of the scrotum and its contents and aseptic aspiration of the vaginal cavity may help differentiate other causes of scrotal enlargement, such as hydrocele, from hematocele.

A horse with a hematocele may be treated successfully by aspiration of blood from the vaginal cavity followed by lavage of the cavity with a balanced electrolyte solution, provided that the tunica albuginea is not ruptured.[86] This treatment may minimize the insulating effect of blood and reduce the formation of adhesions between the visceral and parietal layers of the tunica vaginalis. Ultrasonographic examination of the ipsilateral testis may help determine whether the tunica albuginea has been ruptured. If the integrity of the tunic remains uncertain, the testis should be examined surgically, which allows blood to be evacuated from the vaginal cavity. If torn, the tunica albuginea should be sutured, or the testis should be removed. A horse that has developed a hematocele may have also developed a breach in the blood–testis barrier, which may trigger an immune response to the horse's spermatozoa and, in turn, result in infertility.[88]

Varicocele

A varicocele is an abnormally distended and tortuous pampiniform plexus.[79,89] Valvular incompetence of the testicular vein, where it empties into the vena cava or renal vein, may increase hydrostatic pressure in the pampiniform plexus by causing reflux of caval or renal blood into the testicular vein.[89] Varicoceles in

men are associated with a low total sperm count, but motility and morphology of spermatozoa may remain normal. Varicoceles may disturb countercurrent exchange of heat from the arterial to the venous blood, causing temperature-induced dysfunction of spermatogenesis,[79,89] or they may affect spermatogenesis by impairing drainage of blood from the testis, which results in increased scrotal temperature, testicular hypoxia, and elevated testicular pressure.[90] Although varicoceles are known to cause infertility in men and rams, their effect on fertility of horses has not been evaluated, perhaps because varicoceles of stallions are so rarely encountered. Unilateral varicoceles have been noted in some stallions with normal ejaculates.[91] Varicoceles of stallions usually occur unilaterally and, when palpated, do not cause the horse to display signs of pain. The affected spermatic cord has the texture of a "bag of worms," and the neck of the scrotum on the affected side may be wider than usual.

Humans affected with varicocele have been treated by ligation of the venous loops of the pampiniform plexus,[92] but there is no good evidence that treating subfertile men for varicocele enhances the probability of conception.[90] Treatment of stallions with varicoceles is removal of the affected cord and testis, but treatment is not necessary if the varicocele does not affect seminal quality.

Retraction of a Testis into the Inguinal Canal

Rarely, a stallion retracts one or both scrotal testes into the inguinal area, apparently from persistent contraction of the cremaster muscle caused by pain, either from genital trauma or from musculoskeletal pain of the pelvic limbs. The position of the retracted testis inhibits spermatogenesis from that testis, which may lead to infertility. To reestablish fertility or to improve the quality of semen, the retracted testis can be returned to its normal scrotal position by transecting the cremaster muscle.

To transect the cremaster muscle, the horse is anesthetized and placed in dorsal recumbency, and the ipsilateral inguinal region is prepared for aseptic surgery. To expose the cremaster muscle, a 5- to 7-cm skin incision is created over the long axis of the cord. The incision is extended through fascia until the spermatic cord is encountered. A 3-cm section of cremaster muscle, which is attached to the outer caudolateral surface of the parietal tunic, is isolated from the cord and transected with scissors. The fascia and skin are each closed separately. Descent of the testis into the scrotum can be observed when the horse recovers from anesthesia, and results of improvement in spermatogenesis can be observed in about 3 months.

Testicular Neoplasia

The classification of testicular neoplasms of horses is far less extensive than that of humans. Primary testicular tumors are usually divided into germinal and nongerminal types. Germinal neoplasms arise from germ cells of the spermatic epithelium, and nongerminal neoplasms arise from testicular stromal cells. Reported *germinal testicular tumors* of the horse include the seminoma, teratoma, teratocarcinoma, and embryonic carcinoma. *Nongerminal testicular tumors* of the horse are the Sertoli cell and Leydig cell tumors. Secondary tumors (i.e., tumors that are the result of metastases) of the equine testis are extremely rare.[70,93,94]

The prevalence of primary testicular neoplasia in horses is unknown but is probably low, perhaps because most stallions are castrated while young, before neoplasia has had an opportunity to develop,[93,94] and perhaps because testes removed from apparently normal stallions are seldom examined closely for the presence of neoplasia.[95] Consequently, the few acknowledged characteristics of testicular neoplasms of horses have been established by collecting information gathered from a small number of case reports. Characteristics of equine testicular neoplasms, such as hormonal effects, tendency toward malignancy, and relationship to cryptorchidism, have been inferred from characteristics of testicular neoplasms of other species more commonly affected, such as humans and dogs. Characteristics of testicular neoplasms differ among species, so extrapolating characteristics of testicular neoplasms of other species to horses may result in mistaken assumptions.

Testicular enlargement is the primary presenting sign of testicular neoplasia when the neoplastic testis is located scrotally.[96] Usually, the enlargement is insidious. Signs of tenderness during palpation are uncommon but may be a feature of the neoplastic testis.[93,97] The surface of the neoplastic testis may be characterized by multiple, irregular bumps, and the consistency of the testis may be firmer than normal.[97,98] Horses with neoplastic abdominal testes may be presented for examination because of intermittent signs of colic.[96,99] Metastases may cause weight loss or dyspnea. Identifying a tumor is difficult without histologic examination of either the entire testis or tissue obtained by biopsy.[97] Metastatic spread of testicular tumors is rare, but when it occurs, metastases can sometimes be palpated as an enlargement of the sublumbar lymph nodes.[37]

Seminoma

Seminomas arise from the germinal cells of the seminiferous tubules and are the most common testicular tumors of horses.[93,96] These tumors probably do not produce hormones.[37] As in other species, seminomas of the horse seem to appear with greater frequency in cryptorchid testes and are most commonly found in old horses[96-98,100-102]

Although most equine seminomas behave benignly, they have a higher incidence of malignancy than do some of the other types of testicular neoplasms, and they metastasize more frequently.[93,94,96] The relative risk of a seminoma in a human becoming malignant is highest if the testis is abdominal,[103] but no such correlation has been made between the location of a seminoma in the horse and malignancy. All seminomas of horses should be considered potentially malignant, because clear histologic differentiation between benign and malignant seminomas is almost impossible.[104] Abdominal invasion should be suspected if an enlarged spermatic cord can be palpated externally.[93] Thoracic metastases have been reported.[94,101] The sectional surface of a seminoma is lobulated, homogeneous, and white or grayish white. The tumor is soft to moderately firm, and when squeezed, the surface may exude a milky fluid.[37,101]

Sertoli Cell Tumor

The Sertoli cell or sustentacular cell tumor of the horse arises from the nonspermatogenic cells of the seminiferous tubules.[37] Sertoli cell tumors of horses are less frequently encountered than are other types of testicular tumors.[104-106] Their biological behavior in horses is unknown because of the small number of reports, but in dogs and people, these tumors often cause hyperestrogenism and feminization.[70]

Malignant Sertoli cell tumors in dogs are rare,[70] but of the few Sertoli cell tumors of horses that have been reported, several were malignant.[107,108] A malignant Sertoli cell tumor that had metastasized to many organs was found in a descended testis of a horse,[107] and a malignant Sertoli cell tumor that also had metastasized to many organs was found in an abdominal testis of another horse believed previously to be a gelding.[108] Whether cryptorchidism is a factor predisposing to development of the Sertoli cell tumor cannot be determined from the few reports.[93] The sectional surface of a Sertoli cell tumor is firm, white or tan, and homogeneous.[106,107]

Leydig Cell Tumor

The interstitial or Leydig cell tumor is an infrequently reported equine testicular tumor.[93,104,109,110] Although these tumors arise from the androgen-producing cells of the testis, evidence of production of androgenic hormones by these tumors is lacking in horses and other animals.[37,95,104] Because the Leydig cells of the testes of horses secrete a large amount of estrogen, in addition to androgenic hormones, the hormonal effect of Leydig cell tumors in the horse could vary.[9,111] Cryptorchidism may be associated with this neoplasm on the basis of the observation that, in a study of nine stallions affected unilaterally or bilaterally with Leydig cell tumor, the tumors in all but one horse were found in one or both undescended testes.[95]

Most Leydig cell tumors of horses are benign, and metastases are rare.[37] The sectional surface of the tumor is yellow to brown, which may help grossly to differentiate this tumor from other types of testicular tumors.[93,95,112] The demarcation between the tumor and adjacent normal parenchyma is poor.[95]

Teratoma

Teratomas are tumors of multiple tissues whose embryologic origins are different from that of the tissue in which they arise,[104] and evidence indicates that they develop from pluripotential tumor cells capable of giving rise to any type of tissue found in the body.[113] Most teratomas occur in the gonads.[70] Histologic examination of equine testicular teratomas shows that they are benign, slow growing, and composed of mixed, well-differentiated tissues.[114] Derivatives from all three germinal layers, such as bone, cartilage, brain, and respiratory and glandular epithelium, may be present within the testis.[104,115] Occasionally, teeth are found.[22,104] Teratomas that consist primarily of cysts lined by squamous epithelium and contain hair have incorrectly been referred to as dermoids or dermoid cysts. The term *dermoid*, however, should not be used when referring to a teratoma, because unlike dermoids, teratomas display progressive growth.[22]

The teratoma is the second most common form of equine testicular neoplasia.[93,104] It is found in both descended and cryptorchid testes, but some investigators believe it occurs more frequently in the latter.[105,116-118] Others dispute this claim, stating the opposite.[104,119] Failure of descent of a testis, rather than being a predisposing factor in the formation of a teratoma, may more probably be a result of the teratoma itself.[105,117]

Teratocarcinoma and Embryonal Carcinoma

Teratocarcinomas are similar to teratomas but contain undifferentiated embryonic tissue interspersed among the disarranged mix of differentiated tissues.[120,121] Embryonal carcinomas resemble teratocarcinomas but are composed entirely of undifferentiated embryonic tissue.[121] The undifferentiated embryonic tissue is responsible for the malignant properties of teratocarcinomas and embryonal carcinomas. Teratocarcinomas and embryonic carcinomas of the horse are evidently quite rare but appear to be rapidly fatal.

Intersex

Because male and female reproductive organs arise from the same embryonic structures, errors of development may result in a horse that possesses sexual structures common to both sexes.[70] An individual whose sexual identity is confused because of congenital anatomic abnormalities of the genital organs is called an intersex.[6,48,70] An animal's sexual identity can be defined according to its genetic makeup, the type of its gonads, or the morphology of its accessory genitals. A normal animal is the same sex in all three categories, but the intersex differs in one of the categories.

Intersexes can be divided into three main classes: "true" hermaphrodites, female pseudohermaphrodites, and male pseudohermaphrodites. Hermaphrodites are usually defined on the basis of gonadal sex, with true hermaphrodites having both testicular and ovarian tissue.[6,48,122] Pseudohermaphrodites have gonads of only one sex and are classified as male or female, depending on whether the gonads are testes or ovaries.

The true hermaphrodite is much rarer than the pseudohermaphrodite.[6,48,122,123] One gonad of a hermaphrodite may be a testis and the other an ovary, or one or both gonads may consist of both ovarian and testicular tissue (i.e., ovotestes). The hermaphrodite's external as well as internal genitalia usually represent both sexes, but its external genitalia may tend toward either the male or female. Some cases of equine hermaphroditism have been attributed to chimerism resulting from double fertilization or fusion of blastocysts, but other equine hermaphrodites are one genetic sex.[47,123]

Gonads of the pseudohermaphrodite are of one sex, but the external genitalia resemble those of the opposite sex.[6,48,122] The male pseudohermaphrodite is by far the most common intersex of horses and typically has hypoplastic testes within the abdomen or inguinal canal and a penislike structure, which often resembles a clitoris, emerging from a rudimentary prepuce (Figure 59-9). The rudimentary "penis" and prepuce are positioned anywhere on the midline from the perineum to a scrotal or abdominal location.[6,49] Although the phenotypic appearance of a male pseudohermaphrodite is often that of a female, sexual behavior is that of a male.[122] Most equine male pseudohermaphrodites appear to be masculinized, genetic females (64, XX).[6,48,70,122,124] The contradiction between gonadal and genetic sex has not been fully explained.

DIAGNOSTIC PROCEDURES

History and Physical Examination

History pertaining to problems of the testes and related structures may include such information as infertility, history of unilateral or bilateral testicular retention, enlargement in the inguinal or scrotal areas, testicular pain, and changes in testicular size. Knowledge of events surrounding the onset of testicular pain or increase in testicular size, such as occurrence after exercise or copulation, is sometimes helpful in making a diagnosis.

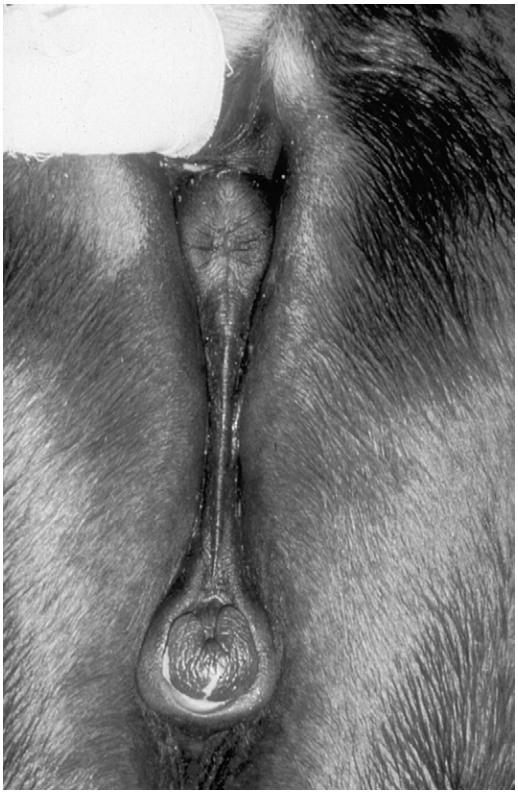

Figure 59-9. Male pseudohermaphrodite. A rudimentary penis and prepuce are positioned in the perineal region. (Courtesy E. Behrens, MV, Ocala, FL.)

Other considerations include previous urogenital surgery, illnesses, and drug therapy.

A physical examination of the testes and associated structures should include inspection and palpation. Notice should be given to the size, shape, texture, and temperature of the testes, and the horse should be observed for evidence of pain when the testes are palpated. Right and left testes should be compared. The scrotum of a normal stallion usually appears asymmetric, because the left testis has a longer spermatic cord and is, therefore, often more pendulous than the right. With cryptorchidism, the scrotum on the involved side is poorly developed. Scrotal scars should be noted, bearing in mind that a scrotal scar may mean only that an orchidectomy was attempted, not that it was accomplished. Occasionally, scrotal edema is noted. This does not usually imply disease related to the genitalia but is more likely a consequence of general retention of fluid associated with disease of other systems.

The testes should feel smooth and elastic. Irregularities in size and texture may indicate trauma, orchitis, torsion of the spermatic cord, thrombosis of the testicular artery, inguinal herniation, or neoplasia. Often, a neoplastic testis is insensitive to digital compression that would cause a normal horse to show signs of pain. Insidious increase in testicular size suggests neoplasia, whereas acute increase in size may suggest torsion of the spermatic cord, inguinal herniation or rupture, or orchitis. As a testicular neoplasm grows, it may seem to replace the entire organ. The neoplastic testis characteristically feels heavier than the normal testis. Because neoplasia may be associated with inguinal or pelvic lymphadenopathy, palpation *per rectum* of internal lymph nodes should, if possible, accompany an examination for testicular enlargement.

The testes of the prepubescent stallion are often quite small and retractile and therefore often difficult to palpate. Before declaring the stallion a cryptorchid, a tranquilizer or sedative should be administered to relax the cremaster muscles and thus facilitate palpation. The medial crus of the superficial inguinal ring is easily palpated if the palm of the hand is turned toward the abdomen.[3] If the palm is turned toward the thigh, the fingers may pass into the inguinal canal without encountering the ring, because the lateral border of the ring is not as readily palpated. Because the average-sized stallion's canal is about 15 cm in depth,[32] only the most ventral part of the inguinal canal can be palpated. An inguinal testis lies with its long axis oriented vertically and is preceded in its descent by the tail of the epididymis. A partial abdominal cryptorchid can be easily mistaken for an inguinal cryptorchid if the epididymis within an everted vaginal process is, by chance, palpated and mistakenly identified as a small testis. The vaginal rings can be palpated only by examination *per rectum*.

The epididymis, located on the dorsolateral surface of the descended testis, should be easily identifiable. The tail of the epididymis should be easily palpated on the caudal pole of the testis. If the tail of the epididymis is located craniad in the scrotum, the spermatic cord has rotated 180 degrees. As mentioned before, torsions of 180 degrees or less probably cause no clinical problems.[74] When palpating the scrotum of a foal to ascertain if testicular descent is complete, the epididymis should be identified so that the remnant of the gubernaculum is not mistaken for a descended testis.

A bulge in the spermatic cord or scrotum may suggest the presence of an inguinal hernia, hydrocele, or hematocele. Because the hernial contents of most acquired inguinal hernias are strangulated, palpation of the scrotum and examination of the vaginal rings *per rectum* should be part of the physical examination of every adult stallion with signs of intestinal obstruction. Unapparent, congenital inguinal hernias may become apparent after castration. Examining the inguinal area of foals before castration for the presence of a congenital inguinal hernia is especially important to avoid evisceration. If a scrotal hernia is present, palpation may elicit a sensation of crepitus. Occasionally, peristalsis may be noted by movement of the skin overlying the bulge.[58] A ruptured inguinal hernia or an inguinal rupture should be suspected if the skin over the inguinal or scrotal swelling is cold, edematous, or macerated. A strangulated inguinal hernia or rupture should be suspected when a stallion develops signs of colic after copulation or exercise, especially if a testis and its spermatic cord are swollen and tender. A varicocele should be suspected if the spermatic cord appears larger than normal and has the texture of a "bag of worms." A hydrocele should be suspected if the scrotum appears to be smooth, nontender, and fluid filled, and the testis is smaller than normal. The presence of a fluid-filled, nontender scrotum weeks after castration also indicates a hydrocele.

Examination *per Rectum*

Per rectum examination of the vaginal rings and structures that traverse them may be helpful in the diagnosis and evaluation of some genital abnormalities, such as cryptorchidism, inguinal or scrotal herniation, scirrhous cord, and testicular neoplasia. The vaginal rings and associated structures are located about

6 or 8 cm cranial to the iliopectineal eminence and 10 to 12 cm abaxial to the linea alba in the average-sized horse.[1] The vaginal ring is palpable in geldings as a slight depression, but in stallions it is large enough to insert a finger.[125]

The risk of rectal injury should be weighed against the value of the diagnostic information to be gained before performing an examination *per rectum*. For example, examination *per rectum* is probably not necessary before removing a cryptorchid testis by an inguinal approach, provided that the owner is confident that orchidectomy has not been attempted previously. If, during surgery, the testis is not encountered in the inguinal canal, it can usually be extracted from the abdomen through the vaginal ring or through a parainguinal incision. Even though mares are more commonly subjected to examination *per rectum*, the incidence of rectal injury in geldings and stallions is higher, perhaps because males are less accustomed to the procedure and resist it more forcibly.[126] Most cryptorchid stallions presented for examination are young, and the small size and fractious nature of young horses predispose them to rectal injury during examination *per rectum*.

To palpate the vaginal rings, the examiner introduces a hand into the rectum until the lateral aspect of the wrist rests on the pubic brim at the pelvic symphysis.[127] The examiner may find it advantageous to palpate the right vaginal ring with the left hand and the left vaginal ring with the right hand. The fingertips are flexed and pressed against the lateral aspect of the abdominal wall, and fingers are extended in a downward and forward direction against the abdominal wall until a finger enters the vaginal ring. If the search is made with a backward flexing motion of the finger, the medial border of the deep inguinal ring tends to close, causing the finger to slide over the vaginal ring. When the vaginal ring is located, the components of the spermatic cord can be felt as a cordlike structure entering the canal. The ductus deferens is more readily palpated at the ring than are the testicular vessels,[3] and it can be palpated on the caudomedial aspect of the ring, if the testis or epididymis has descended.[22]

The vaginal rings should always be examined for evidence of intestinal incarceration when examining a colicky stallion. Palpating distended loops of intestine and a loop descending through the vaginal ring indicates that intestine has become inguinally incarcerated. Traction on the loop usually causes a painful reaction from the horse. For horses with septic funiculitis, thickening of the spermatic cord at the vaginal ring is evidence of ascension of infection into the abdominal cavity. For horses with testicular neoplasia, thickening of the spermatic cord at the vaginal ring suggests that the neoplasm has metastasized. The lymph nodes surrounding the terminal portion of the aorta and its branches should also be palpated for evidence of metastases.

For a horse with an unknown history of castration that displays masculine behavior, or for a stallion known to be cryptorchid, examination *per rectum* may be useful in determining whether a testis has traversed the vaginal ring.[127] Determining the location of a retained testis before orchidectomy is especially important if a flank or paramedian approach is to be used, because an inguinally retained testis is difficult to remove using any approach other than the inguinal one. Palpating an abdominal testis *per rectum* is difficult, because the testis is small and flaccid, and because the proper ligament of the testis is usually elongated, allowing the testis a wide range of movement. Palpation of an abdominal testis *per rectum* by an inexperienced examiner should be regarded as a fortuitous occurrence, and failure to palpate an abdominal testis should not be relied on diagnostically. The vaginal ring cannot be palpated in horses with complete abdominal testicular retention, but palpation of the vaginal ring is evidence that the testis or at least its epididymis has descended through the ring into the inguinal canal. Unfortunately, a partial abdominal cryptorchid cannot be distinguished from a horse whose testes have descended through the vaginal ring by examining the vaginal rings *per rectum*.

Testicular Biopsy

Testicular biopsy is indicated when less-invasive diagnostic methods have failed to provide an etiologic or pathologic diagnosis of testicular disease and when a diagnosis is essential to determine treatment and prognosis.[128] An obviously neoplastic testis should be removed rather than biopsied, because biopsy may disseminate neoplastic cells. Testicular biopsy has been used to a limited extent in the horse, perhaps because of fear of the complications reported after incisional (especially) or needle biopsy of the testes in other species.[129,130] Because horses are usually able to maintain breeding soundness after removal of one testis, obviously diseased testes have often been removed rather than biopsied, even though the testicular disease was not definitively identified.

Biopsy provides the only method for directly assessing stages of spermatogenesis and rates of sperm production and for identifying space-occupying lesions.[113] A biopsy may be helpful in differentiating among causes of testicular enlargement, such as septic orchitis, neoplasia, or trauma. Despite complications reported to occur in other species, aspiration and needle biopsies have been performed successfully in a small number of horses.[130-132]

Aspiration Biopsy

Aspiration biopsy presents little risk to the horse because decreased spermatogenesis is not a likely complication.[128] Although an aspiration biopsy is less damaging to the testis than a needle biopsy, an aspiration biopsy usually does not offer useful information about spermatogenesis.[129] Its main use is to help determine the cause of testicular enlargement. Aspiration biopsy can be performed by inserting a 23- or 25-gauge needle into the testicular parenchyma.[128] Local anesthesia of scrotal skin is unnecessary. A 12-mL syringe is attached to the needle, and the plunger is withdrawn. The needle is retracted without exiting the parenchyma and is reinserted into several areas. The plunger is released, and the needle, still attached to the syringe, is removed from the testis. Although hemorrhage after biopsy is uncommon, digital pressure maintained over the puncture site for several minutes ensures hemostasis. Aspirated material is expelled onto a glass slide, smeared, dried, and stained. Aspirated material should be smeared gently, because cells collected from the testis by aspiration are extremely fragile. The slides should be examined by an experienced cytologist, because normally developing spermatocytes have cytologic characteristics that could lead to a mistaken diagnosis of malignancy.

Needle Biopsy

The needle biopsy provides the most useful information about spermatogenesis, and the technique is unlikely to have

deleterious effects on the testis.[128,130,131] Needle biopsy of a testis can be performed using a 12- or 14-gauge Vim-Silverman needle[130] or a 12- or 14-gauge automated biopsy needle (Monopty Biopsy Instrument).[131] Biopsy can be performed with the horse standing and sedated. The scrotum is prepared as if for aseptic surgery, and a small volume of local anesthetic solution is injected subcutaneously at the proposed site of biopsy using a 25-gauge needle. Unless there is a particular area of interest, the site of biopsy should be the craniolateral quarter of the testis, where the vasculature is the least prominent, and away from the head of the epididymis. The biopsy needle can be guided ultrasonographically to sample a discrete lesion. The testis is held tightly against the scrotal skin, and a small stab incision is created on the lateral surface of the scrotum, down to and through the parietal tunic. The Vim-Silverman needle or automated biopsy needle is inserted through the visceral tunic and tunica albuginea into the testicular parenchyma. Two or three samples are collected through the same skin incision but at slightly different angles. Pressure is maintained over the incision for several minutes, and the cutaneous incision is closed with a single suture. Samples are fixed in Bouin solution for 6 to 12 hours, washed, and stored for about 12 hours in 70% ethanol. They are then shipped to a laboratory in 50% ethanol. The biopsy should be examined by a pathologist trained in reproductive pathology.

Complications associated with needle biopsy of the testis in other species include transient scrotal edema; intratesticular hemorrhage resulting in pressure necrosis; immune reaction to spermatozoa caused by disruption of the blood–testis barrier; dissemination of neoplastic cells if a tumor is biopsied; formation of a hematoma between the testis and the parietal tunic or between the parietal tunic and scrotum, which can result in insulation-induced damage to the seminiferous epithelium; and transient decrease in semen quality.[128] Formation of antisperm antibodies and decrease in semen quality reported to occur in other species after testicular needle biopsy have not been reported to occur in the horse.[128,131]

Hormonal Assays

Occasionally, physical examination is inadequate to determine whether a horse possesses a retained testis, in which case a hormonal assay may be necessary to distinguish between psychic and hormonal causes of persistent masculine behavior. Concentration of testosterone or estrogen in the plasma or serum can be used to distinguish between geldings and horses with extrascrotal testicular tissue.[133-138] Stallions with descended testes (sometimes referred to as "entire stallions") and cryptorchid stallions have significantly higher concentrations of androgens and estrogens in the serum or plasma than do geldings. Concentration of testosterone and estrogen in serum decreases rapidly after castration and stabilizes within about 6 hours.[139]

In several studies, basal concentration of testosterone in castrated horses was generally less than 40 pg/mL of serum, and that of entire stallions was greater than 100 pg/mL.[134,135] The concentration of testosterone of entire stallions was often 1000 to 2000 pg/mL, although the concentration during winter was often as low as 200 pg/mL.[135] In one study, geldings were found to have a testosterone concentration in serum of less than 240 pg/mL, and horses with testicular tissue had a concentration of greater than 440 pg/mL.[133] Another investigation found the concentration of testosterone in the serum of ponies with testicular tissue to be 440 to 1550 pg/mL; 6 weeks after castration, the concentration had decreased to an average of 40 pg/mL.[136] These studies found the concentration of testosterone in the serum of stallions to depend on the age of the horse and the season, with the concentration being lowest in horses younger than 3 years and during the winter.[133-135]

Some investigators noted that cryptorchid stallions generally had a slightly lower concentration of testosterone than did entire stallions.[135-137] In contrast, other investigators observed that mature, bilateral, cryptorchid stallions and hemi-castrated stallions (i.e., unilateral cryptorchid horses whose scrotal testis had been removed) had a similar or higher concentration of testosterone in the serum than did entire stallions.[133] These authors suggested that retained abdominal testes may produce as much testosterone or more than do scrotal testes.

Wide variations in basal concentration of testosterone occasionally lead to confusion.[134-138] Because the concentration of testosterone in some entire stallions is exceptionally low and that in some geldings is exceptionally high, values may overlap, causing erroneous conclusions to be drawn as to whether a horse possesses testicular tissue. One investigator reported 14% error using basal concentration of testosterone to differentiate geldings from horses with testicular tissue.[117] These wide variations in concentration of testosterone were not observed in another study, which found basal concentrations of testosterone to be accurate in predicting the presence of testicular tissue.[133] That study found an error of only 5%.

A rise in the concentration of testosterone in response to stimulation by administration of hCG increases the accuracy of detecting cryptorchidism.[134-138] Investigators reported increased concentration of testosterone in cryptorchid stallions at any time between 30 and 120 minutes after intravenous administration of 6000 or 12,000 units of hCG.[134,135] Horses were classified as cryptorchid if the concentration of testosterone both before and after administration of hCG was greater than 100 pg/mL, or as geldings if the concentration in both samples was less than 40 pg/mL. The hCG-stimulation test was 94.6% accurate in predicting the presence of testicular tissue. Response to hCG was poor in horses less than 18 months old and during the winter.[134] Other investigators found that the response of bilateral cryptorchid stallions and hemi-castrates to hCG was minimal, but that best results were achieved if poststimulation samples were obtained at 24 hours rather than at 1 hour.[133] Other investigators found that administration of hCG to entire stallions induced an increase in concentration of testosterone that lasted about 10 days, and they suggested that for detection of a retained testis, a poststimulation sample should be taken at 2 to 3 days.[138]

In one study, quantification of total free (i.e., unconjugated) estrogen alone was superior to quantification of total androgens, with or without hCG stimulation, for detecting retained testicular tissue.[137] Although other investigators were unable to confirm superiority of free estrogens for detecting testicular tissue, they found a high correlation between the presence of testicular tissue and the concentration of conjugated estrogen (e.g., estrone sulfate) if cryptorchid horses younger than 3 years and cryptorchid donkeys of any age were excluded from the study.[134,135] The investigators found that young cryptorchid horses and cryptorchid donkeys did not consistently produce enough conjugated estrogens to yield reliable results. Quantification of conjugated estrogen was 96% accurate in predicting

the presence of testicular tissue when these animals were excluded from the study. Although cryptorchid horses produced less estrogen than did entire stallions, the lower threshold of conjugated estrogen for a cryptorchid horse was higher than that of testosterone. Horses with a concentration of estrone sulfate less than 50 pg/mL in plasma or serum were determined to be geldings. A concentration in excess of 400 pg/mL indicated cryptorchidism. Another investigation also revealed a high correlation between the concentration of conjugated estrogens and the presence of testicular tissue in horses older than 3 years.[133] In that investigation, geldings had a concentration of estrone sulfate less than 120 pg/mL, and cryptorchid stallions had a concentration greater than 1000 pg/mL.

Knowing the laboratory's standards for normal hormonal concentrations of geldings and horses with testicular tissue is important when evaluating results of hormonal assays. Comparing test results with values from a known gelding may be necessary, if the laboratory cannot furnish standards. False-positive results from hormonal assays to determine the presence of testicular tissue have not been reported.[140] The clinician can be confident that a horse has testicular tissue if the result of a hormonal assay indicates that testicular tissue is present.

Other Diagnostic Tests

Diagnostic tests that can be used to identify or characterize disease of the testes include ultrasonography, semen evaluation, cytological examination of peritoneal fluid, thermography, karyotyping, and possibly measurement of serum biomarkers. Ultrasonographic examination may delineate abnormalities within the testis and associated structures or assist in determining the location of a cryptorchid testis.

To ultrasonographically image an undescended testis, the inguinal area is scanned with a longitudinally placed 3.5-MHz convex probe or a 5-MHz transrectal transducer.[141,142] The testis is recognized as a round structure with a homogeneous granular texture with an anechoic line inside, representing the central vein of the testis. The echotexture of the cryptorchid testis is less dense than that of a normal descended testis.[141] If the testis is not located, the probe is placed more axially to examine the caudal ventral aspect of the abdomen. Most abdominal testes can be visualized lying on the ventral abdominal wall adjacent to the urinary bladder. If the testis is still not detected, the lateral aspect of the flank is scanned.

If the testis cannot be located during transabdominal ultrasonographic examination, transrectal ultrasonography can be performed. To image an abdominal testis, the transducer is inserted rectally, cranial to the pelvic brim, and the abdomen is scanned in a to-and-fro pattern as the transducer is advanced craniad. Transrectal ultrasonography is ineffective in locating an inguinal testis.[141] The sensitivity of transabdominal ultrasonography in detecting an undescended testis is about 98%.[142] Withholding feed from the horse for 24 to 36 hours before examination enhances visualization of an abdominal testis.[142]

Serum concentrations of biochemical markers, such as α-fetoprotein and hCG, are measurable in minute quantities using radioimmunoassay and have been used to monitor the response of humans to treatment for testicular neoplasia.[103] Apparently, no such markers have been used to detect testicular neoplasia of horses or to monitor the presence of metastatic neoplasms after a neoplastic testis has been removed.

Cytologic examination of peritoneal fluid may be valuable in diagnosing certain diseases of the testes and associated structures because the vaginal and peritoneal cavities communicate, so that changes in vaginal cavity fluid can be reflected in the peritoneal fluid. Semen evaluation may be valuable in diagnosing orchitis, epididymitis, or seminal vesiculitis. Thermographic examination of the scrotum may detect a variation in temperature between the testes. A horse with morphologic abnormalities suggestive of intersexuality, such as cryptorchidism accompanied by ambiguous genitalia, can be karyotyped to determine its genetic sexual identity.

SURGICAL PROCEDURES

Castration

Indications

Synonyms for castration include orchidectomy, orchiectomy, emasculation, gelding, and cutting. Castration is one of the most common equine surgical procedures and is usually performed to sterilize horses unsuitable for contributing to the genetic pool and to eliminate masculine behavior. By removing the primary source of androgens, castration renders the horse more docile and manageable.

Although stallions can be safely castrated at any age, managerial convenience usually governs the age at which a horse is castrated. Typically, a horse is castrated simply because facilities are insufficient to safely contain a stallion. Most horses are castrated when they are 1 to 2 years old, when masculine behavior becomes intolerable to the owner. Sometimes castration is delayed until a masculine feature, such as a crest on the neck, has developed or until it becomes apparent that the horse is unsuitable for breeding. Castration may be performed to alter conformation. Bulls castrated before puberty grow to a greater height because castration delays closure of the growth plates of their long bones,[143] and the same may be true of stallions castrated before puberty. The age when colts reach puberty varies greatly between and within breeds. One study found that the mean age at which American Quarter Horse colts reached puberty, defined as the age at which an ejaculate containing a minimum of 100×10^6 sperm with at least 10% progressive motility was first collected, was 68.68 ± 12.7 weeks and ranged between 55 and 101 weeks.[144]

Orchitis, epididymitis, testicular neoplasia, hydrocele, varicocele, testicular damage caused by trauma, torsion of the spermatic cord, or inguinal herniation may necessitate unilateral or sometimes bilateral orchidectomy. Impotent or infertile breeding stallions may be salvaged for other uses by castration.

Preoperative Considerations

A general physical examination of the horse should precede castration, and the scrotum, especially that of very young horses, should be inspected for inguinal herniation and for the presence of both testes. Discovery of inguinal herniation or cryptorchidism may affect the choice of anesthesia and the surgical approach. Preoperative sedation of a fractious horse usually permits safe palpation of the scrotal and inguinal areas and occasionally facilitates palpation of an inguinal testis by causing the cremaster muscles to relax.

Standing Castration

CASE SELECTION

Castration performed with the horse standing can be difficult and dangerous to the surgeon if candidates for the procedure are not selected prudently. Standing castration of horses with poorly developed testes and of ponies is mechanically difficult. Donkeys and mules can be dangerous to castrate while they are standing because of their athletic agility. Stallions that elicit a hostile or evasive response to genital palpation are best castrated while they are anesthetized. Docile stallions with well-developed testes whose genitalia can be palpated without being sedated are usually the safest candidates for standing castration.

PREPARATION OF THE HORSE

Sedating the horse to be castrated while standing is optional but advised. Drugs commonly used, either alone or in combination, are xylazine HCl, detomidine HCl, pentazocine, and butorphanol tartrate. Acetylpromazine, although commonly administered to tranquilize stallions before castration, can result, on rare occasion, in priapism or penile paralysis, and so its use in stallions should be avoided. Additional information about standing restraint of the horse can be found in Chapter 22.

The scrotum must be anesthetized on each side of the scrotal raphe from the cranial to the caudal pole of the testis along the proposed lines of incision. The spermatic cords can be anesthetized by injecting local anesthetic solution, usually 15 to 30 mL, through a 22- to 20-gauge needle directly into each cord. This anesthetic technique ensures good anesthesia of the cord but occasionally causes a hematoma that interferes with application of the emasculator. Alternatively, about 25 mL of local anesthetic solution (without epinephrine) can be injected directly into the parenchyma of each testis through an 18-gauge, 1½-inch needle. The anesthetic solution diffuses proximally into each spermatic cord. The horse's tail should be bandaged to prevent it from contaminating the surgical field, and the scrotum should be scrubbed before and after administering the local anesthetic solution.

RESTRAINT

The horse should be restrained by a competent handler, and to ensure adequate immobilization, application of a lip twitch may be necessary. The standing castration should be performed with both the surgeon and the handler positioned on the same side of the horse, usually the left side for the right-handed surgeon. The surgeon should be positioned at the horse's shoulder well out of kicking range with his or her head and shoulder pressed firmly into the horse's flank.

Standing castration can be performed safely and efficiently if candidates are selected prudently, the horse is adequately sedated, the spermatic cord and scrotum are properly desensitized with a local anesthetic agent, and the surgeon is technically proficient. A standing castration requires less expense and assistance and is often less time-consuming because the surgeon need not wait for the horse to recover from general anesthesia. Risks to the horse that attend general anesthesia are avoided. Because the spermatic cords and scrotum are locally desensitized, measures to rectify immediate postoperative complications, such as hemorrhage, can be accomplished without anesthetizing the horse.

Recumbent Castration

ANESTHESIA

To castrate a horse in the recumbent position, a clean, safe area in which to anesthetize and recover the horse is a prerequisite. A variety of intravenous anesthetics, alone or in combination, can be administered to provide safe and predictable anesthesia of sufficient duration. A thiobarbiturate administered as a bolus produces rapid anesthesia characterized by moderate analgesia and muscular relaxation, particularly if the horse has been sedated with xylazine.[145] Recovery is usually satisfactory if repeated administration of the thiobarbiturate is not necessary. Ketamine, administered after sedating the horse with xylazine, provides 10 to 15 minutes of surgical anesthesia. Muscular relaxation and analgesia are only moderate but can be enhanced if butorphanol tartrate or diazepam is added to the preanesthetic regimen.[145-147] If necessary, anesthesia can be extended by readministering half the dosage of xylazine and ketamine combined in one syringe. Guaifenesin (5% to 10%), in combination with ketamine or a thiobarbiturate, provides smooth induction and recovery and good analgesia with excellent muscular relaxation, but guaifenesin must be administered in large volumes.[148] Succinylcholine, a muscle relaxant, has been widely employed as a chemical restraint for recumbent castration, but because it provides no analgesia, its use alone for castration is inhumane. Additional information on anesthesia can be found in Chapters 18 and 19.

POSITIONING

The horse is anesthetized and positioned in lateral recumbency with its upper pelvic limb pulled forward and secured with a rope. The right-handed surgeon generally finds the recumbent castration most easily performed with the horse positioned in left lateral recumbency, and vice versa.

Approach

SCROTAL INCISION

For the standing castration and most techniques of recumbent castration, the testes are removed through a scrotal incision. If the horse is anesthetized, and if the testes are small and difficult to grasp, as is often the case with prepubescent stallions, the scrotum can be safely incised by pulling the cranial end of the prepuce craniad and upward to tense the scrotal raphe (Figure 59-10). Another method of incising the scrotum is to make two parallel 8- to 10-cm incisions 2 cm distant from the raphe on either side while compressing the testes against the bottom of the scrotum. The incisions should be sufficiently long to provide adequate postoperative drainage. To ensure adequate drainage, many surgeons prefer to partially ablate the scrotum, which can be accomplished by connecting the two parallel incisions craniad and caudad and removing the portion of scrotum between the incisions.

Another method of removing the bottom of the scrotum is to grasp the scrotal raphe between the thumb and forefinger, and while applying traction to the bottom of the scrotum, to excise a portion of the tented tissue with a scalpel (Figure 59-11). When surgery is performed with the horse standing, stab wounds to the horse or surgeon that could result from sudden movement by the horse are prevented by incising the scrotum with a scalpel blade held between the fingers rather than

attached to a handle. A large portion of the scrotum should be excised to ensure adequate drainage. To avoid cutting large vessels, the dissection should remain close to the scrotal skin. After removing a portion of the scrotum, the testes are isolated using digital dissection.

Figure 59-10. Incising the scrotum for castration. If the testes are difficult to grasp, the cranial end of the prepuce can be pulled craniad and upward to tense the scrotal raphae.

INGUINAL INCISION

For the inguinal approach, the horse is anesthetized and positioned in dorsal recumbency. The superficial inguinal ring is exposed through an 8- to 15-cm skin incision (depending on the horse's size) made directly over the superficial inguinal ring.

EMASCULATORS

The emasculator models most commonly used are the improved White's, the Reimer, and the Serra emasculators (Figure 59-12).[149] The Reimer emasculator crushes the cord, and a blade operated by a separate handle severs the cord distally. Because the cord is severed with a separate handle, there is no danger of cutting the cord before it is satisfactorily crushed. The extra handle on the Reimer emasculator makes the instrument somewhat unwieldy for standing castration. The Sand's emasculator is similar to the Reimer emasculator but has no cutting component and only crushes the cord (Figure 59-13). The cord must be severed distal to the crushed segment with scissors or a scalpel blade. This emasculator is used more commonly in Europe than in North America. The jaws of the Serra emasculator are curved, so that the cord is evenly crushed, and the grooves on the crushing blades are oriented parallel to the cord, decreasing the chance of accidentally transecting the cord with the crushing portion of the jaws (Figure 59-14).[21]

The Henderson Equine Castrating Instrument is another tool designed for castration (Figure 59-15). One handle of this pliers-like instrument is attached to a 12 W, or greater, variable-speed drill (slippage is likely to occur with a less-powerful drill) with a $\frac{3}{8}$-inch or larger chuck. With one hand holding the testis, the instrument is clamped across the entire cord, just proximal to the testis. With slight tension on the drill and with the instrument held parallel to the cord, the testis is rotated slowly for about five turns. The speed of the rotations is gradually increased while keeping slight tension on the cord. After 20 to 25 rotations, the cord separates about 8 to 10 cm proximal to the instrument. The twisting of the cord effectively seals the severed

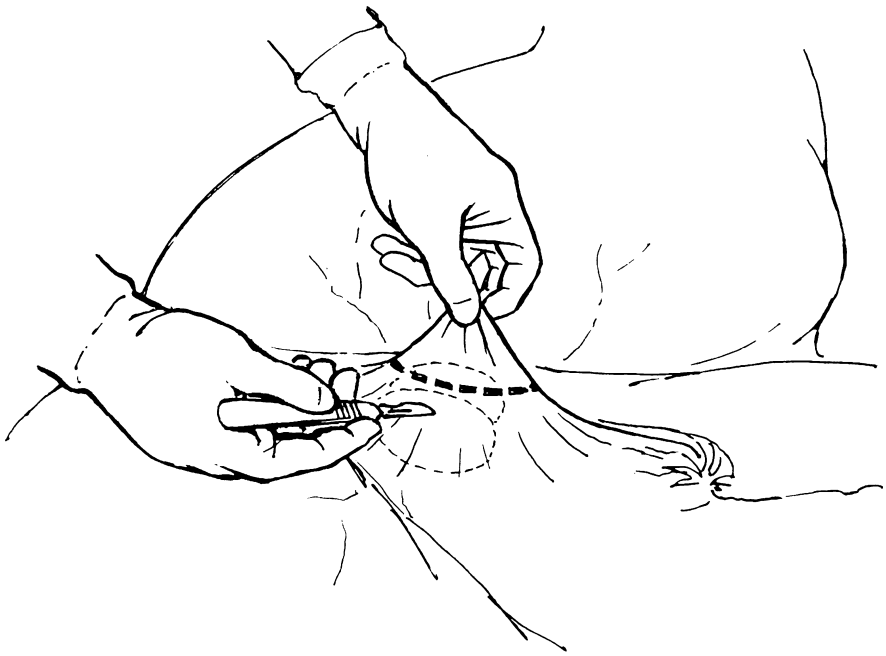

Figure 59-11. The bottom of the scrotum is removed by placing traction on the scrotal raphe with a thumb and forefinger and excising a portion of the tented tissue with a scalpel.

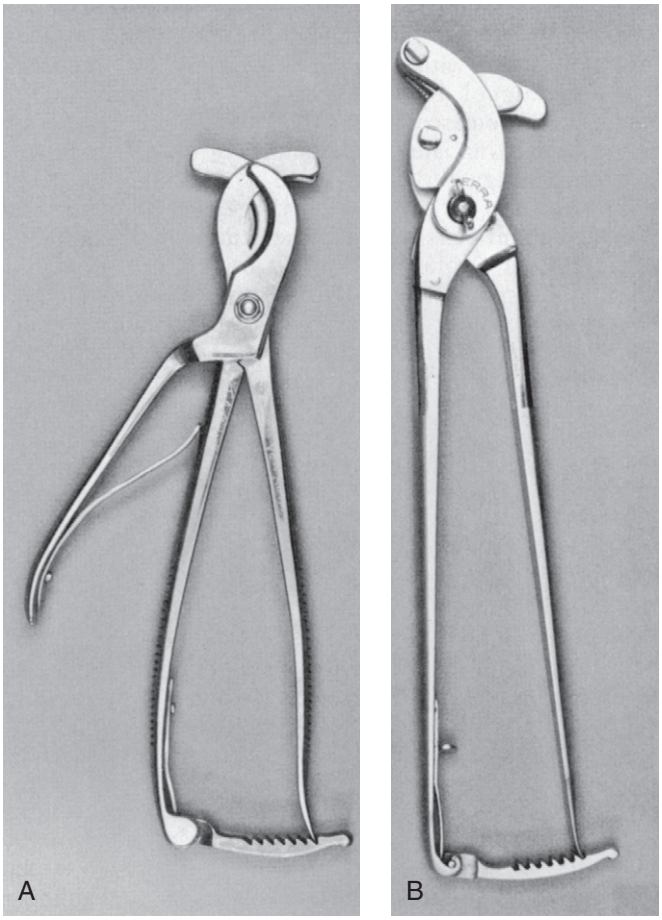

Figure 59-12. Reimer **(A)** and Serra **(B)** emasculators. The Reimer emasculator severs the cord with a blade on a separate handle so that the cord is not accidentally cut before it is satisfactorily crushed.

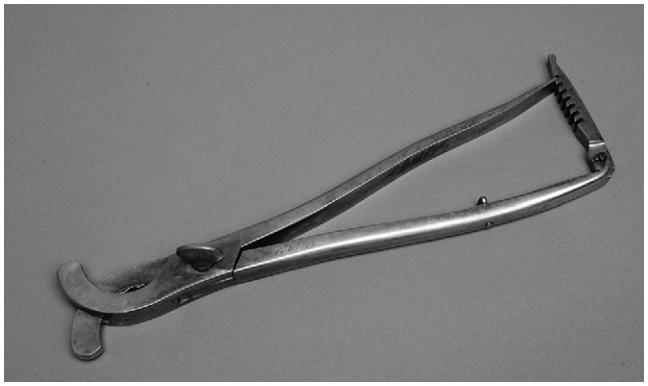

Figure 59-13. The Sand's emasculator is similar to the Reimer emasculator but has no cutting blade. The spermatic cord must be severed distal to the emasculator with a scissors or scalpel blade.

vessels. Because the parietal tunic is sealed using this device, herniation is theoretically less likely than when castration is performed using other instruments. Although castration using this instrument is usually performed with the horse anesthetized, horses can also be castrated with this instrument while they are standing.

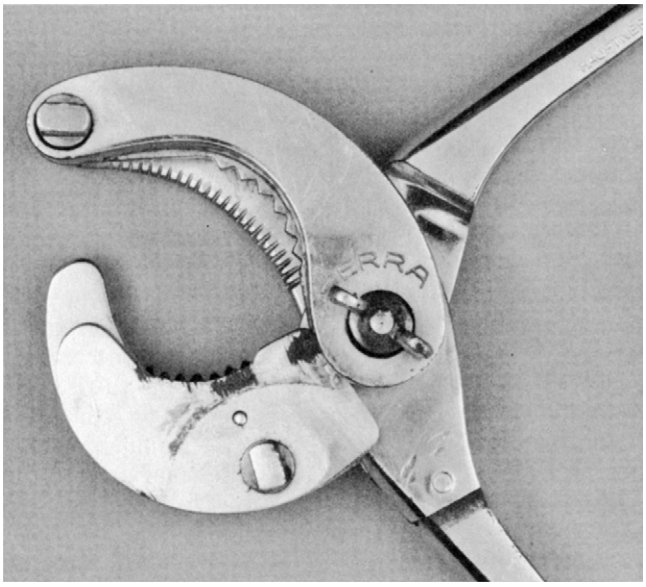

Figure 59-14. Serra emasculator. The grooves of the crushing blade are oriented vertically to prevent the blade from accidentally cutting the cord.

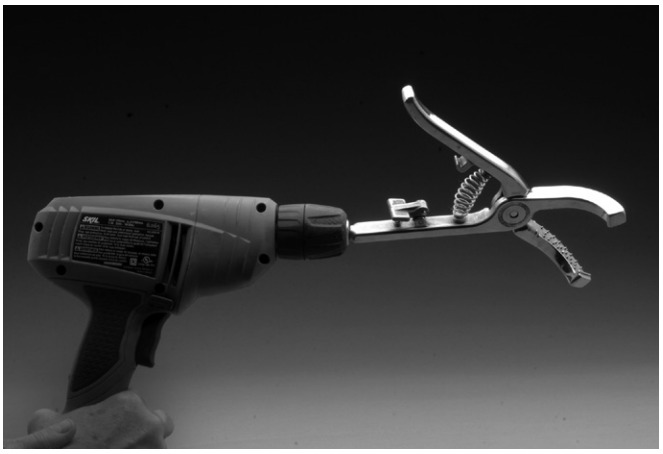

Figure 59-15. A Henderson Equine Castrating Instrument. One handle of this instrument is attached to a variable-speed drill. The instrument is clamped across the spermatic cord and rotated slowly for about five turns before the speed of rotations is increased. The cord is rotated until it separates proximal to the instrument. The twisting of the cord seals the severed vessels.

Surgical Techniques

Techniques of orchidectomy are the open, closed, and half-closed techniques, regardless of whether the horse is castrated while standing or recumbent, or whether the approach is inguinal or scrotal. With the open technique of castration, the parietal (or common vaginal) tunic is retained. With the closed and the half-closed techniques, the portion of the parietal tunic that surrounds the testis and distal portion of the spermatic cord is removed. Regardless of the technique, the scrotal skin is most commonly left unsutured to heal by second intention. When the skin is left unsutured, the castration is sometimes referred to as an open castration, adding confusion to the terminology associated with castration. When the scrotal or inguinal skin is

sutured, the castration is sometimes referred to as a closed castration. To avoid confusion, the terms *open* and *closed* should be used to describe whether the parietal tunic of each testis was removed and should not be used to describe whether the scrotal or inguinal wound was sutured.

OPEN TECHNIQUE

When performing the open technique of castration, the parietal tunic of testis is incised. The ligament of the tail of the epididymis (caudal ligament of the epididymis), which attaches the parietal tunic to the epididymis, is severed or bluntly transected. By transecting the fold of the mesorchium and mesofuniculum, the testis, epididymis, and distal portion of the spermatic cord are completely freed from the parietal tunic and removed using an emasculator. The open technique of castration is probably the most commonly used technique.[149]

CLOSED TECHNIQUE THROUGH A SCROTAL APPROACH

With the closed technique, the parietal tunic is not incised, so it also is removed along with the testis and a portion of the cord. Using digital dissection, the parietal tunic surrounding the testis is freed from the scrotal ligament and scrotal fascia. By placing mild traction on the testis with one hand, the parietal tunic surrounding the cord is then separated from fascia surrounding the spermatic cord with the other hand. After the parietal tunic is separated from the surrounding fascia, it and its contents are removed using an emasculator. Care should be taken, when separating the fascia from the spermatic cord, to include the large pudendal vessels that lie within the fascia, so that these vessels are not included in the jaws of the emasculator.

HALF-CLOSED TECHNIQUE

The closed technique just described can be converted to a half-closed technique by making a 2- to 3-cm vertical incision through the exposed parietal tunic at the cranial end of the testis or the distal end of the spermatic cord. A thumb (the left thumb if the operator is right-handed) is inserted through the incision into the vaginal cavity. The testis and a portion of the spermatic vasculature are prolapsed through the incision by applying downward traction on the tunic with the thumb while simultaneously using the fingers of the same hand to push the testis through the incision. The fundus of the parietal tunic inverts and follows the testis through the incision because of its attachment to the testis by the ligament of the tail of the epididymis. Traction is applied to the parietal tunic with the index and middle fingers, which are placed into the sac formed by the inverted fundus. Traction can also be applied to the parietal tunic and the testis by applying a large Carmalt or Allis forceps to the parietal tunic before prolapsing the testis from the vaginal cavity. The half-closed technique should be considered a closed technique because the parietal tunic is removed along with the testis and the distal portion of the spermatic cord.

CONSIDERATIONS CONCERNING ALL TECHNIQUES

For each technique, the emasculator is applied at a right angle to the spermatic cord, loosely closed to avoid incorporating scrotal skin, and slid farther proximally. The emasculator is applied so that the crushing component is proximal to the cutting blade. When correctly applied, the wing-nut of the emasculator is oriented distad toward the testis, and the emasculator is said to be positioned "nut to nut." This positioning is not critical when using an emasculator that does not have a cutting blade. The scrotal skin is pushed toward the abdomen with one hand (with the spermatic cord positioned between the index and middle fingers) toward the horse's abdomen, and the jaws of the emasculator are inspected to ensure that they do not contain scrotal skin. The tension on the cord is relieved, and the handles of the emasculator are compressed completely to crush and, depending on the emasculator used, to sever the cord. The time that should elapse before the emasculator is removed from the spermatic cord depends on the size of the cord being severed and the dependability of the emasculator used, but applying the emasculator for about 2 minutes is usually sufficient to achieve hemostasis. If the cord is exceptionally large, the emasculator can be applied for a longer time, or the parietal tunic and cremaster muscle can be crushed and severed separately from the testicular vessels and the ductus deferens. The cutting blade of the emasculator should not be so sharp that the cord is completely severed but rather should be slightly dull so that the cord must be torn, although with only slight effort, from the blade. If a noncutting emasculator is used, the cord is severed with a scalpel blade or scissors 2 to 3 cm distal to the emasculator. The emasculator should be directed toward the horse's inguinal area before the cord is released, so that the testicular vessels do not recoil. It is customary, and perhaps prudent, when performing a standing castration to leave the scrotal wound unsutured. Loose scrotal fascia protruding from the scrotal opening is trimmed with scissors.

A technique (i.e., the Zurich technique) frequently used in Europe to ensure adequate scrotal drainage involves suturing a 30-cm-long gauze drain to the stumps of the cords with heavy catgut suture.[150] The drain that exits the scrotal wound is removed 2 days after castration by rupturing the catgut suture with a sharp tug on the drain.

SELECTION OF TECHNIQUE

An advantage of the closed and half-closed techniques of castration is that removal of the parietal tunic decreases the incidence of postoperative complications, such as septic funiculitis and hydrocele[32,35] (see "Postoperative Complications," later). The half-closed technique permits inspection of the components of the cord and allows a greater portion of the ductus deferens and testicular vasculature to be exteriorized. For horses at risk of having an unapparent inguinal hernia, such as Standardbreds, evisceration can be avoided by using a closed technique and placing a ligature proximal to the proposed site of transection.

The closed technique of castration has no advantage over the open technique in preventing evisceration if a ligature is not applied to the cord proximal to the site of transection. The closed and half-closed techniques are indicated for disease conditions that may involve the parietal tunic, such as neoplasia and orchitis. The closed and half-closed techniques require more dissection than does the open method of castration, and this may be a disadvantage when performing a standing castration on a fractious stallion.

Primary Closure of the Incision

By convention, scrotal incisions are usually left unsutured to heal by secondary intention. Primary closure, however, speeds healing and recovery, decreases the possibility of infection, and decreases edema, pain, and muscular stiffness.[151-154] Primary closure may be particularly useful if vigorous exercise cannot be enforced postoperatively.

In one study, 6% of horses castrated under aseptic conditions, while anesthetized, and whose scrotal wound was sutured, suffered from one or more complications, including diarrhea and fracture of limb during recovery from anesthesia, whereas 22% of horses castrated while standing and whose scrotal wound was left open to heal by second intention experienced a complication, which for most was infection at the scrotal wound.[155] The cost of performing a castration with the horse anesthetized and under aseptic conditions was about three times greater than the cost incurred when the horse was castrated while standing. Even considering the cost associated with treatment for complications incurred when castration was performed with the horse standing, however, the overall cost of performing surgery with horses standing was still less than that of performing surgery with horses anesthetized and under aseptic conditions.[155]

Primary closure decreases the time of convalescence but is time-consuming and requires meticulous hemostasis and strict adherence to aseptic technique. In one study in which the scrotal wound was sutured, no complications were encountered when the spermatic cords were simply transected with an emasculator.[151] Hemorrhage from a cord, however, even a small amount, into the sutured scrotum, increases the risk of hematoma formation. Therefore ligation of the cord proximal to the point of division with the emasculator ensures good hemostasis and should be considered an important part of the procedure.

One investigator, pointing out the importance of eliminating dead space, closed the subcutaneous tissue with multiple rows of absorbable suture.[151] Another investigator, however, found multiple-layer closure unnecessary and reported minimal postoperative complications when only the scrotal skin was sutured.[152] The cutaneous incision is best closed with an absorbable 2-0 monofilament suture using a simple-continuous intradermal suture pattern. Because the cutaneous incision is sutured intradermally, removal of cutaneous sutures is not necessary.

The testes can be removed *per primam*, with the horse anesthetized, through an inguinal incision created over each spermatic cord.[156,157] This technique is frequently used in Europe when castrating horses 2 years old or older to avoid evisceration, because the vaginal rings of horses more than 2 years old are thought by some surgeons to be wider than those of younger horses. Using this technique, the testis is pushed craniad from the scrotum so that it lies close to the superficial inguinal ring, and a 5- to 7-cm cutaneous incision is created over the superficial inguinal ring. The inguinal fascia overlying the testis is incised to expose the parietal tunic of the testis. Care is taken to avoid lacerating large branches of the external pudendal blood vessels. The parietal tunic is incised longitudinally for 5 cm in an area not covered by the cremaster muscle.

The ligament of the tail of the epididymis is located with an index finger, and by applying traction on this structure, the testis is pulled from the vaginal cavity. The ligament of the tail of the epididymis, which attaches the testis to the parietal tunic, is transected. Bleeding vessels are cauterized to prevent hemorrhage into the vaginal cavity. Two transfixing ligatures of absorbable heavy monofilament suture are applied 1 cm apart, as far proximad as possible, to the testicular vasculature and ductus deferens. The vasculature and ductus deferens are severed 2 cm distal to the distal ligature, and the stump is replaced into the vaginal cavity. If this technique of *per primam* castration is performed with the expectation of preventing incarceration of intestine into the inguinal canal, a ligature should be applied to each spermatic cord proximal to the site of transection.[64]

The incision in the parietal tunic and the subcutaneous tissue are each sutured with an absorbable 2-0 monofilament suture using a simple-continuous pattern. The cutaneous incision is closed with the same suture using a simple-continuous intradermal suture pattern.

Aftercare

All horses not previously immunized with tetanus toxoid should receive both tetanus antitoxin and toxoid. The previously immunized horse should receive a booster vaccination if more than a year has passed since its last vaccination.[158] The horse's activity should be restricted for the first 24 hours after castration to prevent hemorrhage from the severed testicular and scrotal vessels. After this period, the horse should be exercised to the degree necessary to prevent excessive preputial and scrotal edema. A large, grass-covered field is an ideal environment for postoperative recuperation, but the owner should be cautioned that turning a horse into a field does not ensure that it will receive adequate exercise.

Antimicrobial treatment is probably unnecessary if clean surroundings are provided, but a survey of practitioners, undertaken to determine the type and frequency of complications that occur after castration found that horses may be less likely to develop infection at the castration site if they receive perioperative antimicrobial treatment.[149] The operative site can be hosed vigorously, if the horse permits it, to keep the scrotal wound clean, open, and draining; but this same survey found that horses that receive hydrotherapy after castration may be more prone to develop excessive swelling and infection of the scrotum.

Protecting the wound against flies is usually unnecessary, even during fly season, if the horse's tail-hairs are long enough to reach the scrotal area. The horse should be isolated from mares for at least 2 days after castration. Ejaculates are highly unlikely to contain sufficient spermatozoa to cause impregnation after 2 days.[159] The castration wound should be nearly healed by 3 weeks.

Laparoscopic Castration

Ligating and transecting the blood supply and ductus deferens of scrotal testes laparoscopically with the horse standing or anesthetized results in avascular necrosis of the testicular parenchyma with the testes *in situ*.[160,161]

The standing approach is preferred by most surgeons when the horse is castrated laparoscopically. To ensure safe insertion of a laparoscopic sleeve and cannula into the abdomen, the abdomen can be insufflated through a Verres needle, IV catheter, teat cannula, chest drain, or metal uterine catheter introduced into the abdomen through a stab incision created slightly dorsal to the crus of the internal abdominal oblique muscle, midway between the last rib and the tuber coxae. The abdomen can also be insufflated, using the same devices, through a stab incision created on the linea alba. The abdomen is insufflated using a gas, such as carbon dioxide, nitrous oxide, or helium, until the intra-abdominal pressure rises to 8 to 10 mm Hg. Care should be taken to avoid insufflating the retroperitoneal space. After the abdomen is inflated, the insufflation device is removed, and a laparoscopic sleeve with a trocar is inserted through an incision in the flank. The laparoscopic sleeve and trocar can also be

inserted safely, without insufflating the abdomen, by allowing air to enter the abdomen through a blunt cannula, such as a chest drain, inserted into the abdomen through the flank. Air entering the abdomen causes the viscera to fall away from the body wall, allowing safe introduction of the laparoscopic sleeve and trocar. The trocar is removed, and the laparoscope, which is attached to a fiberoptic light source and a video camera and viewing monitor, is introduced into the abdomen. The laparoscope is directed caudad to view the inguinal area. A 10-mm-diameter instrument portal is created 8 to 10 cm cranioventral to the laparoscopic portal, and another is created 8 to 10 cm caudoventral to the laparoscopic portal. A third 5-mm-diameter instrument portal is created 8 to 10 cm caudodorsal to the laparoscopic portal.

The testicular vessels and ductus deferens are identified in the mesorchium as they course toward the vaginal ring. A ligating loop is placed through the 5-mm instrument portal, and a right-angle dissecting forceps is inserted through the cranioventral portal and the ligating loop. The ductus deferens and testicular vessels are grasped with the forceps. Using a bipolar cautery forceps placed through the caudoventral instrument portal, the ductus deferens and testicular vessels are coagulated distal to the forceps. The cautery instrument is removed and replaced with a laparoscopic scissors, which is used to transect the ductus deferens and spermatic vessel immediately distad to the site of coagulation. The ligating loop is now slid over the right-angle forceps onto the coagulated stump of the ductus deferens and testicular vessels, tightened, and tied, and the ends of the ligature are cut. After releasing the forceps, the stump is inspected for hemorrhage. By elevating the small colon manually *per rectum*, the contralateral testis can be removed using the same portals and technique. Removing the contralateral testis using portals created on the contralateral side, however, may be faster and easier.

The testes, deprived of their blood supply, swell during the first week and then begin to decrease in size. The atrophied testes can be palpated in the scrotum for at least several months,[161] but by 5 months the remnants are no longer palpable.[160] Within 7 days after the testicular vessels are ligated, the concentration of testosterone falls to that expected of a horse with no functional testicular tissue. The body and tail and sometimes the head of the epididymis remain viable, but because the epididymis has no contribution to masculine behavior, the horse behaves as a gelding.[20] Swelling and discomfort observed after laparoscopic castration seem to be less severe than that seen after routine castration.[161]

In one study that evaluated the results of laparoscopic castration, 5.6% of inguinally retained testes and 3.4% of normally descended testes failed to become completely necrotic, as a result of an alternative blood supply from the cremasteric or external pudendal artery, or both, resulting in preservation of stallionlike behavior.[20,162] The owner should be warned of this uncommon complication.

Vasectomy

A stallion used for detecting estrous (i.e., a teaser stallion) can be vasectomized to render it incapable of ejaculating spermatozoa and thus from accidentally impregnating mares. A stallion can be vasectomized through an incision created over each spermatic cord or through a single incision created over one testis.[163] To transect a portion of the ductus deferens through a single incision in the scrotal area, the horse is anesthetized and positioned in dorsal or lateral recumbency, and the scrotum is prepared for surgery. A 2-cm, longitudinal, cutaneous incision is made on the medial aspect of one testis, and the incision is extended through the dartos and parietal tunic. The ductus deferens, which is identified as a white, 2- to 3-mm-diameter, cordlike structure, is exteriorized and separated for a length of several centimeters from its mesorchium, using a curved hemostatic forceps. Two ligatures of 2-0 absorbable or nonabsorbable suture are placed around the most proximal aspect of the exposed portion of the ductus deferens, and a third ligature is placed around the most distal aspect of the exposed portion of the ductus deferens. The segment of ductus deferens between the two proximal ligatures and the distal ligature is removed. Double-ligating the proximal end minimizes the likelihood of spontaneous reanastomosis and formation of a sperm granuloma.

The incision in the parietal tunic is sutured with an absorbable 2-0 suture using a simple-continuous pattern. The ductus deferens on the medial aspect of the other testis is subsequently palpated through the cutaneous incision and exposed by incising the scrotal septum and overlying parietal tunic. A segment of the ductus deferens is exteriorized, ligated, and transected as described. The incision in the parietal tunic and the subcutaneous tissue are each sutured with an absorbable 2-0 suture using a simple-continuous pattern. The cutaneous incision is closed with the same suture using a simple-continuous intradermal suture pattern.

Immunologic Castration

Immunization against luteinizing hormone–releasing hormone (LHRH), a neuropeptide produced by the hypothalamus, was used in a cryptorchid stallion to decrease serum concentration of testosterone,[164] and immunization against gonadotrophin-releasing hormone (GnRH) was used experimentally to suppress testicular function of entire stallions.[165,166] Repeated immunization was necessary to maintain a sufficient binding titer for complete neutralization of LHRH or GnRH and inhibition of the reproductive endocrine axis. Immunization against GnRH caused decreased concentrations of testosterone and estrogen in the serum, diminished sexual behavior, and decreased testicular size, and it had a negative effect on semen quality. Stallions varied in response to immunization, and in one study, libido was not totally suppressed.[165]

If a vaccine against LHRH or GnRH becomes commercially available, unwanted male sexual behavior by cryptorchid or entire stallions can be prevented temporarily. A vaccine against GnRH may enable a stallion to perform at its peak ability at athletic competitions, by decreasing undesirable sexual behavior, until the stallion's genetic potential can be determined, while allowing the stallion to retain its ability to produce progeny. The time required for recovery of libido and semen quality needs to be determined before a vaccine against LHRH or GnRH is used clinically for temporary diminution of male sexual behavior.

Cryptorchid Castration

A retained testis can be removed through an inguinal, parainguinal, suprapubic paramedian, or flank approach. For each of these approaches, except the flank approach, the horse must be anesthetized. The approach is termed noninvasive if the testis

can be removed by introducing only one or two fingers into the abdominal cavity, and an approach that requires insertion of a hand into the abdomen is considered invasive. Only the inguinal and parainguinal approaches allow noninvasive removal of a cryptorchid testis.

Inguinal Approach

For the inguinal approach, the horse is anesthetized and positioned in dorsal recumbency. The superficial inguinal ring is exposed through an elliptical, scrotal incision or through an 8- to 15-cm skin incision (depending on the horse's size) made directly over the superficial inguinal ring. A cryptorchid testis and the contralateral scrotal testis (or two cryptorchid testes) can be removed from one incision if the incision is created over the scrotum rather than over the superficial inguinal ring.

The inguinal fascia is separated digitally to expose the superficial inguinal ring. An inguinal testis is readily encountered when the superficial inguinal ring is exposed. The vaginal sac should always be opened and its contents examined to avoid mistaking the descended tail of the epididymis of a partial abdominal cryptorchid for a small, inguinal testis. If the testis has already been removed, the stump of the spermatic cord is encountered as it exits the canal. Finding a stump of a severed ductus deferens, the remnant of spermatic vessels, and a well-developed cremaster muscle indicates that the horse has been castrated.[25,134]

After the superficial inguinal ring has been exposed, an abdominal testis can be retrieved using one of several noninvasive techniques. One noninvasive technique requires locating the rudimentary common vaginal tunic, or vaginal process. This structure contains a portion the epididymis or sometimes a portion of the gubernaculum testis. The body of the epididymis can be exposed through a small incision in the vaginal process and traced to the tail of the epididymis, which is connected to the testis by the proper ligament of the testis. By placing traction on this ligament, the abdominal testis can usually be exteriorized through the vaginal ring. The key to this technique is locating the vaginal process. The vaginal process of the partial abdominal cryptorchid testis lies everted within the inguinal canal and is readily encountered during inguinal exploration. The vaginal process of the complete abdominal cryptorchid lies inverted within the abdominal cavity, along with the epididymis and testis, and difficulty may be encountered in locating and everting it into the canal.

An inverted vaginal process can be everted into the inguinal canal by exerting traction on the scrotal ligament, which is also known as the inguinal extension of the gubernaculum testis (IEGT)[12] (Figure 59-16). This ligament is a remnant of the gubernaculum testis and attaches the vaginal process to the scrotum. The IEGT is located by carefully examining the margin of the superficial inguinal ring for a fibrous band that descends into the canal. The IEGT can be found on either the medial or lateral aspect of the ring, usually at the junction of the middle

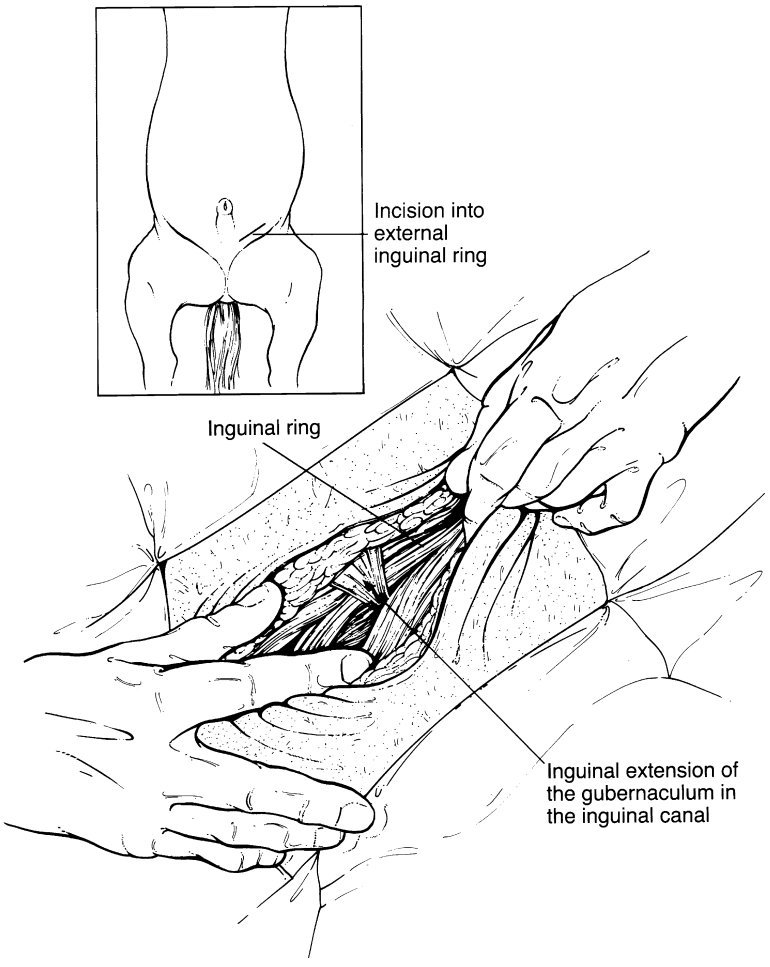

Figure 59-16. An inverted vaginal process can be everted into the inguinal canal by exerting traction on the inguinal extension of the gubernaculum testis. This ligament is a remnant of the gubernaculum and attaches the vaginal process to the scrotum.

and cranial third of the ring. The genitofemoral nerve courses through the canal and can be mistaken for the IEGT. This nerve usually lies farther caudad, in the middle or caudal third of the superficial inguinal ring. The IEGT is most easily located by grasping and retracting loose fascia at the junction of the middle and cranial thirds of the ring with the thumb and index finger of one hand and tracing it into the canal with the index finger and thumb of the other hand. The fascia tears if the IEGT is not contained within the fascia, but if the IEGT lies within this fascia, traction causes the inverted vaginal process to evert into the canal, where it and the epididymis or gubernaculum contained within can be seen and palpated. The everted process is a glistening white structure, usually about the size of a fingertip. A hypoplastic cremaster muscle can be seen attached to the lateral aspect of the vaginal process.

An inverted vaginal process can also be everted using a sponge forceps.[22] A finger is inserted through the vaginal ring into the inverted vaginal process, and a 25-cm curved sponge forceps is introduced beside the finger. The jaws of the forceps are opened and closed to grasp the apex of the vaginal process. Traction applied on the forceps everts the inverted vaginal process. The difficulty of this technique is locating the vaginal ring. The ring can usually be found beneath the third finger when four fingers are inserted into the inguinal canal.

After the vaginal process is everted and stripped of inguinal fascia, it is incised longitudinally (a No. 12 scalpel blade works

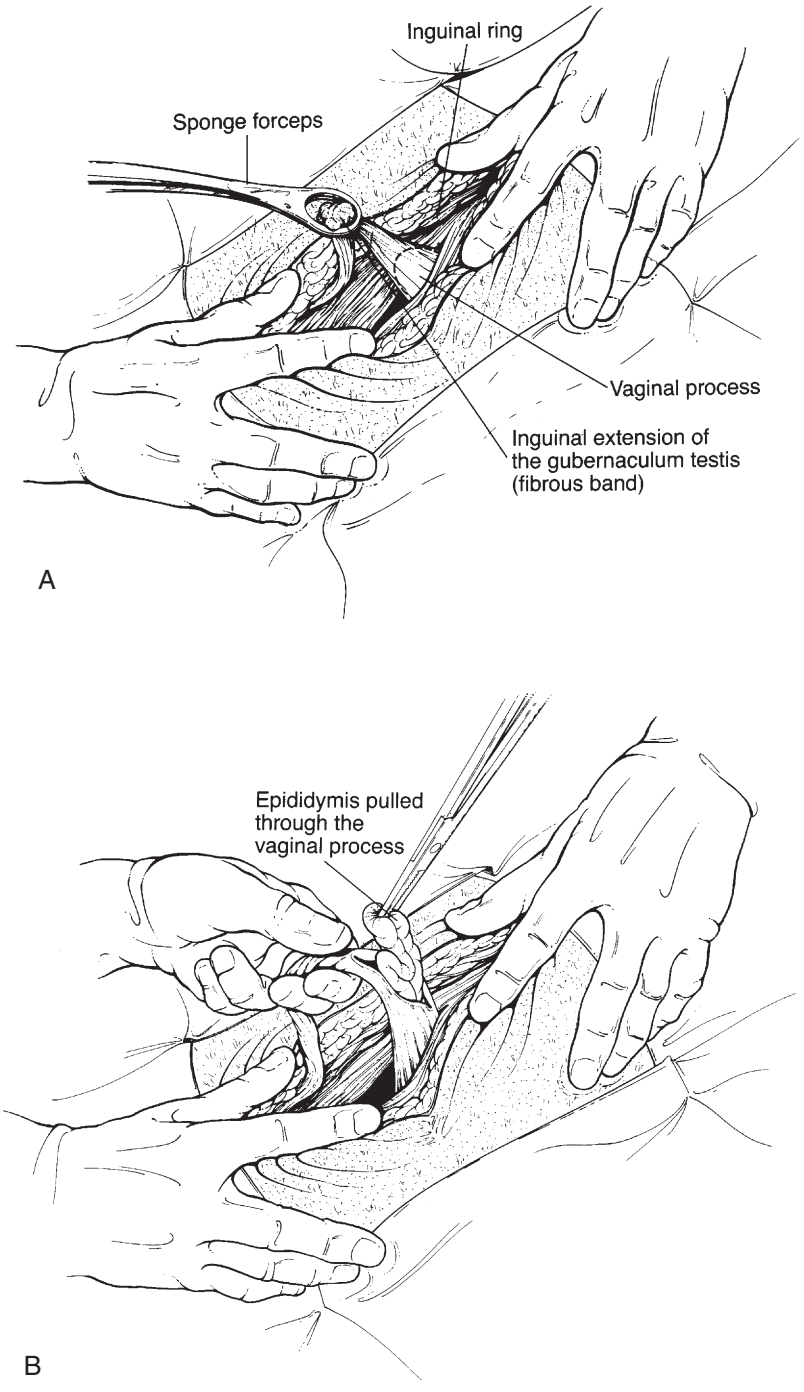

Figure 59-17. A, The everted vaginal process is stripped of inguinal fascia and longitudinally incised. **B,** The epididymis contained within is grasped with a hemostat and exteriorized.

best for this) to expose a portion of the epididymis contained within (Figure 59-17, *A*). The epididymis is grasped with a hemostat and exteriorized until the tail of the epididymis is located (see Figure 59-17, *B*). The proper ligament of the testis connects the tail of the epididymis to the caudal pole of the testis (Figure 59-18), and by applying traction to this structure, the testis can be pulled through the vaginal ring and exteriorized for removal (Figure 59-19). Stretching the vaginal ring to accommodate passage of the testis may not be necessary if the stallion is immature. Usually though, the vaginal ring must be stretched to allow passage of the testis, and this is accomplished by inserting a finger through the incision in the vaginal process and through the vaginal ring. The finger is inserted through the vaginal ring to the level of the second joint, and by flexing the finger, the ring is dilated. The vaginal ring of a mature stallion is usually much more difficult to dilate than that of an immature stallion.

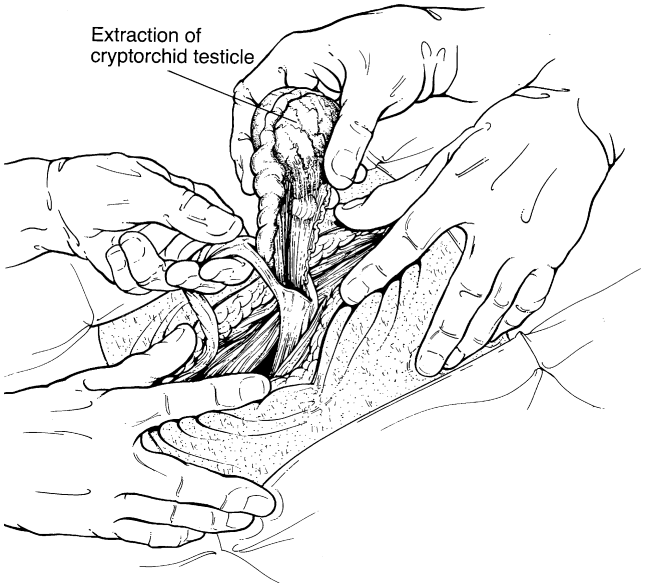

Figure 59-19. With traction on the proper ligament of the testis, the testis is pulled through the vaginal ring.

Rarely, the vascular pedicle of the testis is so short that placing an emasculator proximal to the testis and epididymis is impossible. The cord must then be crushed and transected using an écraseur or severed with scissors after occluding the testicular vasculature with one or two ligatures. The contralateral testis is then removed, and the skin incision is sutured or left to heal by secondary intention.

PREVENTING EVISCERATION

The vaginal ring should be repalpated after the abdominal testis is removed. If the ring accommodates no more than the tips of the index and middle fingers, the horse can be recovered, and unrestricted activity can be safely allowed after several days. If the ring has been dilated beyond this diameter, one of two measures must be taken to prevent evisceration. To prevent evisceration, the inguinal canal can be packed to the level of the vaginal ring with sterile gauze for 24 to 36 hours. The pack is maintained in the canal by partially suturing the skin incision. Evisceration may follow removal of the pack, especially if gauze was inadvertently inserted through the vaginal ring into the abdomen. Not only does gauze in the abdomen prevent the vaginal ring from contracting but it also becomes adhered to viscera. Evisceration can be prevented by palpating the vaginal ring *per rectum* after the pack is inserted and before it is removed to ensure that gauze did not enter the abdomen. After the pack is removed, the horse's activity should be restricted to hand-walking for several days before forced exercise is imposed. Jumping, cantering, and galloping should not be allowed for 3 weeks.

Although the deep inguinal ring is inaccessible for suturing, the superficial inguinal ring can be closed with an interrupted or continuous pattern of heavy, absorbable suture to prevent evisceration. A half-circle, hernia, or kidney needle should be used to suture the inguinal ring. These are heavy, eyed needles with blunt ends, and they are difficult to break. Using a looped suture allows the needle to be pulled through the loop after the first bite, preventing the necessity of tying a knot before proceeding with the continuous suture pattern, and allows the ring to be closed with a doubled strand of suture. Not only does suturing the superficial inguinal ring provide better security against evisceration than does packing the canal with gauze, but it also allows primary closure of the inguinal fascia and skin. Although viscera can enter the inguinal canal, incarceration of intestine by the vaginal ring has not been reported. Inguinal fascia and skin can be sutured after closure of the superficial inguinal ring or allowed to heal by secondary intention. Activity should be restricted to hand-walking for several days before forced exercise is imposed. Heavy exercise should not be allowed for 3 weeks after surgery.

Parainguinal Approach

If the vaginal process cannot be located using the previously described techniques, the testis can be removed noninvasively by converting the inguinal approach to a parainguinal approach.[167] A 4-cm incision is made in the aponeurosis of the external abdominal oblique muscle, 1 to 2 cm medial and parallel to the superficial inguinal ring (Figure 59-20). The incision is centered over the cranial aspect of the ring. The internal

Figure 59-20. Parainguinal approach to cryptorchidectomy. A 4-cm incision is made in the aponeurosis of the external abdominal oblique muscle 1 to 2 cm medial and parallel to the superficial inguinal ring. The incision is centered over the cranial aspect of the ring.

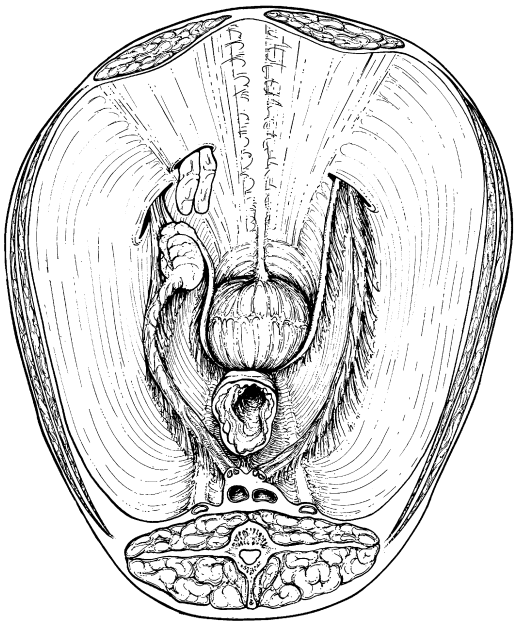

Figure 59-21. Parainguinal approach to cryptorchidectomy. The vaginal ring is palpated caudolateral to the point of entry into the abdomen. Either the epididymis, gubernaculum, or ductus deferens is located at the vaginal ring and exteriorized.

abdominal oblique muscle underlying the aponeurosis is spread in the direction of its fibers, and the peritoneum is penetrated with a sharp thrust of the index and middle fingers. The vaginal ring is palpated caudolateral to the point of entry into the abdomen (Figure 59-21). The epididymis, ductus deferens, and gubernaculum are situated near the ring, and by sweeping the region with index and middle fingers, one of these structures can be grasped between them and exteriorized. The body of the epididymis is followed to the tail. Traction on the proper ligament of testis pulls the testis through the incision.

If difficulty is encountered in locating the epididymis or associated structures, or if exteriorizing the testis is difficult, the incision can be enlarged to accommodate a hand. After excising the testis, the incision in the aponeurosis of the external abdominal oblique muscle is apposed using heavy absorbable sutures in an interrupted or continuous pattern. The subcutaneous tissue and skin can be sutured or left unapposed to heal by secondary intention. The horse can receive exercise after surgery, excluding cantering and galloping, provided that the parainguinal incision was short enough that it could accommodate only several fingers. Unrestricted activity is allowed 3 weeks after surgery.[167]

The parainguinal approach is preferred over the inguinal approach by some surgeons because the vaginal ring is not disrupted.[167] The aponeurosis of the external abdominal oblique muscle is more easily sutured than the superficial inguinal ring.

Suprapubic Paramedian Approach

For the suprapubic paramedian approach, an 8- to 15-cm, longitudinal skin incision is made 5 to 10 cm lateral to the ventral midline.[168-170] The incision begins at the level of the preputial orifice and extends caudally. The large subcutaneous vessels encountered caudally in the incision are ligated. The abdominal tunic and the closely adherent ventral sheath of the rectus abdominis muscle are incised longitudinally, and the underlying fibers of the rectus abdominis muscle are bluntly separated in the same direction. The dorsal rectus sheath, retroperitoneal fat, and peritoneum are penetrated with a finger. The perforation is bluntly enlarged, and a hand is introduced into the abdomen.

The testis is usually encountered near the vaginal ring. If the testis cannot be palpated, accessory structures at the vaginal ring can be located and followed to the testis, or the ductus deferens can be found in the genital fold of the bladder and traced to the testis. Both testes of a bilateral cryptorchid can be removed through one incision, but the contralateral testis is difficult to exteriorize, and its cord usually must be transected with an écraseur. After removing the testis, the abdominal tunic, the subcutis, and skin are each closed separately with interrupted or continuous sutures.

Flank Approach

For the flank approach, a 10- to 15-cm incision is made through the skin and subcutis in the paralumbar fossa of the affected side with the horse standing or recumbent.[171] In a standing horse, the incision site must be anesthetized before the surgery. The external abdominal oblique muscle is transected in the direction of the skin incision, and the peritoneum is exposed by splitting the internal abdominal oblique and transversus abdominis muscles in the direction of their fibers. The peritoneum and retroperitoneal fat are perforated with a finger to enter the abdomen. The testis is located and exteriorized as described for the paramedian approach. If the testis cannot be exteriorized, an écraseur is used to transect the testicular vasculature. After the abdominal testis is removed, the internal and

external abdominal oblique muscles, subcutis, and skin are each closed separately with interrupted or continuous sutures. Closing the peritoneum and transversus abdominis muscle is difficult and not necessary.

Selection of Approach

The paramedian and flank approaches allow removal of only an abdominal testis, because retraction of an inguinal testis into the abdomen can usually be accomplished only with difficulty. Abdominal testicular retention should be confirmed before either of these approaches is used, but often the testicular location cannot be determined reliably. The inguinal approach allows removal of either an abdominal or an inguinal testis. Because an inguinal testis is quickly encountered using an inguinal approach, prior determination of testicular location is not necessary. If the testis is not encountered in the inguinal canal using an inguinal approach, the testis can be removed from the abdomen noninvasively through the vaginal ring or through a small parainguinal incision in the abdominal musculature.

Because the inguinal and parainguinal approaches allow removal of an abdominal testis through a finger-sized abdominal perforation, surgery is rapid, and convalescence is short. The lengthy incision required for the suprapubic paramedian and flank approach prolongs surgery and convalescence. The paramedian approach also increases the risk of postoperative evisceration or herniation. Rarely, an invasive approach is necessary to remove a large, neoplastic, abdominal testis. An abdominal testis can be removed with the horse standing using a flank approach, when general anesthesia is not practical.

Laparoscopic Technique of Cryptorchidectomy

An abdominal testis can be removed laparoscopically with the horse standing or recumbent, but fractious stallions should be anesthetized. Food should be withheld for at least 12 hours before surgery to allow the colon to empty, to decrease the risk of penetrating a viscus when instruments are introduced and to optimize visualization of intra-abdominal structures.[172-174]

To perform laparoscopic removal of an abdominal testis with the horse standing, the horse is restrained in a stock and sedated.[172-175] The flank region is prepared for aseptic surgery, and proposed sites for inserting the laparoscope and grasping forceps are infiltrated subcutaneously and intramuscularly with a local anesthetic agent. The surgical approach is identical to the one described for laparoscopic castration (see "Laparoscopic Castration," earlier).

The testis is located by inspecting the region surrounding the vaginal ring. The vaginal ring and associated structures are easier to see when the horse is standing than when it is anesthetized and recumbent, because the abdominal contents fall away from the inguinal area. The contralateral vaginal ring can be observed by manipulating the laparoscope under the descending colon, or by passing the laparoscope through a small perforation created in the mesocolon of the descending colon, or by elevating the descending colon, either with an instrument placed through an abdominal portal or with a hand *per rectum*.[176] The mesorchium, which contains the testicular vasculature, can be seen coursing caudad from the area of the kidney to the area of the deep inguinal ring. An abdominal testis can be observed to lie anywhere between the kidney and the vaginal ring,[161] but most commonly it is located cranioventral to the ring. The testis is attached to the tail of the epididymis by the proper ligament of the testis, and the epididymis is attached to the vaginal ring and sac by the caudal ligament of the epididymis (ligament of the tail of the epididymis).

The testis and mesorchium are desensitized by injecting a local anesthetic agent into the mesorchium or the testis, using a 30-cm, 18-gauge needle introduced through the flank.[172] Infiltrating the testis with a local anesthetic agent instilled at one site is technically easier than injecting the thin mesorchium in several sites, and the analgesia provided is similar.[177] Desensitizing the testis and mesorchium may not be necessary, especially if caudal epidural anesthesia, using either a combination of 2% mepivacaine (5 mL) and xylazine (0.18 mg/kg), or xylazine (0.18 mg/kg) diluted to 10 to 15 mL with physiologic saline solution, is administered before surgery.[176] An instrument portal close to the vaginal ring is created caudal and ventral to the laparoscopic portal.[172-175] The testis is grasped and exteriorized using grasping forceps inserted through this portal. If triangulation is inadequate, a new portal for the laparoscope can be created between the last two ribs using laparoscopic control.[178] The testicular vessels and ductus deferens are ligated and cut, or crushed and transected using an emasculator, and the stump is returned to the abdomen and inspected through the laparoscope for hemorrhage. If the contralateral testis is also located abdominally, the laparoscopic procedure is repeated on the contralateral side. The abdomen is decompressed by opening the cannula. The abdominal fascia and skin are sutured.

The testicular vessels and ductus deferens of an abdominal testis can also be transected intra-abdominally, with the horse standing, before removing the testis.[176] This technique requires the use of a third portal, created close to the other portals, to introduce instruments used to occlude and transect the testicular vasculature and ductus deferens. Vessel-sealing devices, such as the LigaSure (see Figure 13-13) or SurgRx EnSeal (see Figure 13-14), are ideal for severing and sealing the spermatic cord intra-abdominally. The use of a morcellator to mince the abdominal testis prevents the necessity of enlarging an incision to exteriorize a large testis.[179]

The scrotal testis of a unilateral cryptorchid or an inguinal testis is removed through a scrotal incision, or its ductus deferens and vasculature can be ligated and severed intra-abdominally or severed with a vessel-sealing device (see earlier), which causes the testis to atrophy in the scrotum or inguinal canal.[161] Palpable but nonfunctional remnants of the testis may be detectable in the scrotum several months after the testis is destroyed by ligation of the testicular artery and vein. A scrotal testis of a juvenile stallion or an inguinal testis can be retracted into the abdomen for intra-abdominal transection of the ductus deferens and testicular vessels. The testis is retracted into the abdomen by placing traction on the mesorchium, after enlarging the vaginal ring with scissors. Retracting the testis into the abdomen inverts the vaginal tunic into the abdomen, and the exposed ligament of the tail of the epididymis, which attaches the vaginal tunic to the tail of the epididymis, is severed. The incision in the vaginal ring can be closed with staples or left open.[161,180]

To perform laparoscopic removal of an abdominal testis with the horse anesthetized, the horse is positioned in dorsal recumbency.[172-175,180] After the ventral aspect of the abdomen is prepared for aseptic surgery, a stab incision is made through the umbilicus, and through this incision, the abdomen is insufflated to 10 to 15 mm Hg, as described earlier. A laparoscopic sleeve with a trocar is inserted through the incision into the

abdominal cavity. The trocar is removed and replaced with a laparoscope. The horse is tipped into the Trendelenburg position (i.e., head down approximately 30 degrees) to displace the viscera craniad (see Figure 13-16),[172-175,180] and the laparoscope is directed caudad to view the inguinal areas. Because the hindquarters are elevated, positive-pressure ventilation is necessary. If the testis is not readily visible, it can be located by following the ductus deferens cranially over the lateral ligament of the bladder to the inguinal ring. Traction on the ductus deferens elevates the testis into view.

The testis can be removed before occluding and transecting the testicular vessels and ductus deferens,[172-175] or the testicular vessels and ductus deferens can be occluded and transected intra-abdominally before the testis is removed.[172-175,180] If the testis is to be exteriorized before transecting the testicular vessels and ductus deferens, the instrument portal is created 4 cm cranial and axial to the superficial inguinal ring, on the side of testicular retention. The testis is exteriorized using a grasping forceps introduced into the abdomen through this incision.[172-175] The exteriorized testicular vessels and ductus deferens are ligated and cut or are crushed and transected using an emasculator, and the stump is returned to the abdomen. Both testes of a horse with bilateral, abdominal, testicular retention can be viewed from one portal, but a portal must be created cranial and axial to each inguinal ring to remove each testis. The abdomen is deflated through the laparoscopic cannula, and the portals are closed by suturing the external lamina of the rectus abdominis muscle, the subcutaneous tissue, and skin.

To occlude and transect the testicular vessels and ductus deferens intra-abdominally with the horse anesthetized and positioned in dorsal recumbency, a grasping forceps for manipulating the testis is introduced through a cannula inserted 8 to 10 cm axial and cranial to the superficial inguinal ring.[180] A third instrument portal is created at the cranial, abaxial edge of the sheath to introduce instruments used to occlude and transect the testicular vasculature and ductus deferens.

The testicular vessels and ductus deferens can be occluded using an endoscopic clip or an endoscopic ligating loop and transected using an endoscopic scissor. Ligating the pedicle is generally the most economical method of providing hemostasis, but intra-abdominal ligation requires more experience than does the use of other methods to provide hemostasis. Severing the testicular vessels and ductus deferens with monopolar or bipolar electrocoagulation alone provides adequate control of hemostasis.[181] The risk of accidental thermal injury to adjacent viscera is far greater when using monopolar electrocoagulation than when using bipolar electrocoagulation. Alternatively, vessel-sealing devices, such as LigaSure (see Figure 13-13) or EnSeal SurgRx (see Figure 13-14), can be used to coagulate and sever the testicular vessels and ductus deferens (see Chapter 13). Vessels can also be occluded and transected using an endo-GIA stapler (Endo-GIA 30).[180]

After the attachments to the testis have been transected, the testis is removed from the abdomen by expanding the skin incision over the portal through which the grasping forceps was introduced. Placing the testis in a retrieval bag facilitates exteriorization of the testis and eliminates the risk of dropping it in the abdomen.[181] The testis can also be removed using a morcellator, which minces the tissue, allowing it to be removed by suction through one of the cannulas inserted during the surgery, thus avoiding the necessity of enlarging an incision to exteriorize the testis.[179]

An advantage of intra-abdominal transection over extra-abdominal transection is that with intra-abdominal transection, the severed stump of the vasculature can be inspected before the testis is removed from the abdomen. Exteriorizing a testis causes loss of insufflation, which impairs visibility. A hemorrhaging stump is more easily noted and ligated when the abdomen is still inflated. Insufflation of the abdomen can be preserved during bilateral cryptorchidectomy by occluding and transecting the ductus deferens and vessels of each testis before either testis is removed from the abdomen. In a study in which the abdominal testis of 123 cryptorchid horses was not removed after ligating the spermatic cord at two sites, the entire testis became completely necrotic and incapable of production of testosterone,[20] indicating that removal of the abdominal testis is not necessary after its blood supply has been completely interrupted.

Laparoscopic cryptorchidectomy simplifies locating the cryptorchid testis, prevents disruption of the vaginal ring, which minimizes the likelihood of evisceration, and permits early return to exercise because the incisions are small.[172-175,182] Laparoscopy may be particularly useful in evaluating a horse that displays stallionlike behavior but has the appearance of a gelding, especially when the presence or absence of testicular tissue cannot be determined conclusively by hormonal assay.[174] Laparoscopy is also useful for removing an abdominal testis when the side of the testicular retention is not known.

A disadvantage of laparoscopic cryptorchidectomy is the expense of the equipment.[172-174] A viscus, a large vessel, or the spleen can be penetrated inadvertently if the instruments are not inserted carefully into the abdomen.[183,184] Improper use of electrosurgical coagulation during the procedure may also result in perforation of a viscus.[180] If the procedure is performed with the horse anesthetized, the hindquarters must be elevated to displace the viscera craniad, making positive-pressure ventilation necessary. Familiarity with laparoscopic equipment and experience in laparoscopic techniques are required.

Repair of Inguinal Hernias and Ruptures

Nonsurgical Management

The majority of inguinal hernias are congenital, cause no distress, and spontaneously reduce by the time the foal is 3 to 6 months old.[58,185] Repeated manual repositioning of the herniated viscera may encourage spontaneous reduction, and applying a truss after manually reducing the hernia may speed resolution.[91] To apply a truss, the foal is sedated and positioned in dorsal recumbency. The hernia is reduced, and the superficial inguinal ring is packed with rolled cotton. The cotton is maintained within the ring with elastic gauze and tape wrapped over the back and over both inguinal rings in a figure-of-eight (Figure 59-22). The bandage can be left in place for up to a week. Surgical reduction of a congenital inguinal hernia is not necessary unless contents of the hernia become incarcerated or unless the hernia fails to regress.

Horses with an acquired inguinal hernia, a ruptured inguinal hernia, or an inguinal rupture usually require immediate treatment, because the intestine that has escaped through the vaginal ring or hole in the peritoneum is likely to become strangulated. Nonsurgical reduction of inguinal hernias by external manipulation or rectal traction can be attempted if herniation is diagnosed soon after the onset of signs.[185] Nonsurgical reduction should not be attempted if the viability of the incarcerated

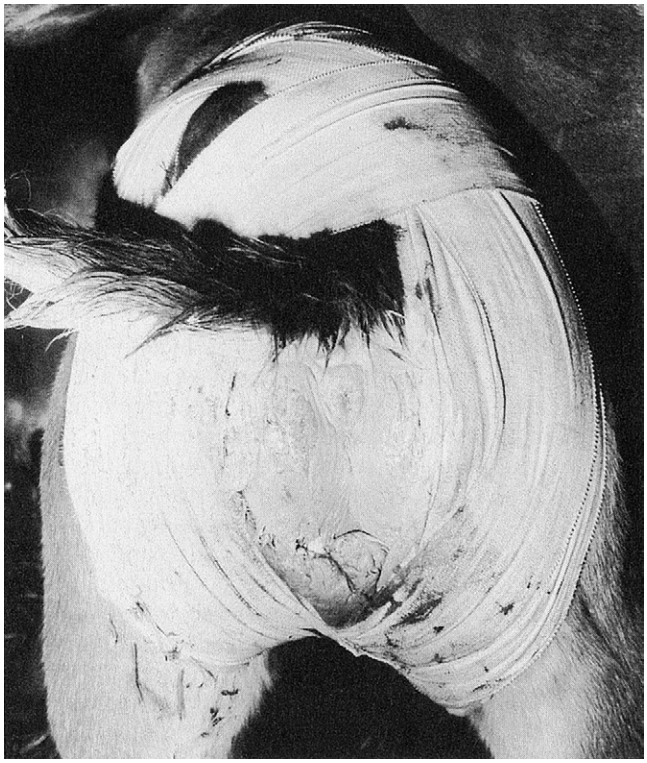

Figure 59-22. Application of a truss after manual reduction of a congenital hernia.

intestine is in doubt or if ruptured inguinal herniation or inguinal rupture is suspected.

To replace hernial contents into the abdomen by external manipulation, the horse is sedated, and the testis of the affected side is grasped and pulled downward so that the vaginal sac is tensed into a rigid, tubelike configuration.[185] With the second hand, the cord is grasped above the testis and slid proximad until herniated intestine is encountered. The second hand maintains traction on the cord and prevents herniated intestine from slipping downward. The first hand releases the testis and grasps and squeezes the cord above the second hand to force the contents of the hernia proximad. The hands are alternated in this manner until the intestine has been returned through the vaginal ring into the abdomen.

If reduction by external manipulation fails, it may be possible to retract the herniated loop of intestine into the abdomen by grasping the loop *per rectum* as it enters the vaginal ring and applying traction.[185,186] The horse should be sedated, and an epidural anesthetic should be administered to minimize the risk of rectal injury or damage to incarcerated intestine. Administering scopolamine butylbromide (Buscopan) to relax the rectum may be helpful. The horse should be observed closely after nonsurgical reduction of an inguinal hernia, because the health of the reduced intestine cannot be assessed directly. Intestinal viability should be monitored periodically by ultrasonographically imaging intestine or by evaluating the horse's peritoneal fluid.

Surgical Management

A congenital inguinal hernia of a foal should be reduced surgically if the hernia cannot be reduced, has escaped into subcutaneous tissue through a rent in the vaginal sac, fails to resolve or enlarges, or is so large that spontaneous resolution is unlikely.[187] To surgically correct inguinal herniation, the foal is anesthetized and positioned in dorsal recumbency. An incision is made directly over the superficial inguinal ring of the affected side, and the vaginal sac is isolated from surrounding fascia using blunt dissection. The scrotal ligament, which attaches the vaginal sac to the scrotum, is transected. While applying traction to the testis, the intestinal contents of the vaginal sac are milked back into the abdomen. Twisting the spermatic cord may facilitate replacement of intestine into the abdomen. The cord is ligated and resected proximal to the superficial inguinal ring. Ligating the cord prevents reherniation, but for added security, the superficial inguinal ring can be closed with absorbable suture placed in a continuous or interrupted pattern. The skin and subcutaneous tissue can be left open to heal by secondary intention or closed primarily.

Nonstrangulating congenital inguinal hernias of foals can be corrected laparoscopically.[187-189] The contents of the hernia are reduced into the abdominal cavity laparoscopically, with the foal anesthetized, and the testis of the affected side is retracted from the vaginal cavity into the abdominal cavity and removed, after ligating and transecting the testicular vessels and ductus deferens. The deep inguinal ring and the vaginal ring are closed using a laparoscopic stapling device or sutures. Closing the deep inguinal ring and the vaginal ring with sutures provides a more secure closure than with staples, because a larger volume of tissue can be incorporated into the closure.[189] The testis of the nonaffected side can also be removed in this manner. Nonstrangulating congenital inguinal hernias can be corrected using a similar laparoscopic technique without removing the testes.[187] Advantages of laparoscopic herniorrhaphy over open herniorrhaphy are the quickness of the procedure, the little postoperative swelling, and the rapid return of the foal to normal activity.

Emergency surgery is usually indicated for horses with an inguinal rupture or a ruptured inguinal hernia and for horses with an acute inguinal hernia that cannot be reduced by nonsurgical manipulation. Surgical correction of inguinal hernias is always indicated if viability of the testis or incarcerated intestine is questionable, because surgery allows these structures to be assessed visually.

Fluids should be administered intravenously in volumes sufficient to combat shock. The horse should be positioned in dorsal recumbency, and the ventral aspect of the abdomen and inguinal area should be prepared for aseptic surgery. The vaginal sac and its contents are exposed and isolated by blunt dissection through an incision created over the superficial inguinal ring. The vaginal sac is opened to expose its hernial contents and the testis. Devitalized intestine may be resected at the inguinal wound, but resection and anastomosis are usually more easily accomplished through a celiotomy. Dilating the vaginal ring and applying traction to the intestine through a ventral midline, paramedian, or parainguinal celiotomy may assist reduction of the herniated intestine. The affected testis should be removed if it appears nonviable or even if its viability is questionable.

If the testis is removed, reherniation through the inguinal canal can be prevented by ligating the spermatic cord and the vaginal tunic as proximally as possible with absorbable suture. For additional security, the inguinal canal can be packed with gauze for 24 to 48 hours, or the superficial inguinal ring can be

closed with heavy absorbable suture. Suturing the superficial inguinal ring gives greater security against reherniation than does packing the inguinal canal. The inguinal fascia and skin can be closed primarily or left unsutured to heal by secondary intention. The celiotomy is closed in routine fashion.

Reherniation through the inguinal canal can be prevented, while at the same time trying to preserve a viable testis, by partially suturing the superficial inguinal ring around the spermatic cord.[190] Suturing starts at the cranial aspect of the ring and ends near the middle of the ring to give a snug, but not tight, closure around the spermatic cord. Difficulty arises in closing the ring adequately to prevent reherniation while still maintaining blood supply to the testis. A more certain method of salvaging the testis is laparoscopic inguinal herniorrhaphy. One method of laparoscopic inguinal herniorrhaphy entails implanting a polypropylene mesh beneath the peritoneum over the deep inguinal ring and the ductus deferens and testicular vessels that enter it, with the horse anesthetized and in the Trendelenburg position.[186] Another laparoscopic technique used to prevent viscera from entering the vaginal ring of a stallion is to cover the vaginal ring with a peritoneal flap using a technique referred to as peritoneal flap hernioplasty.[191] With the horse anesthetized, peritoneum ventrolateral to the vaginal ring is transected on three sides, separated from underlying muscle, inverted, transposed over the vaginal ring, and attached dorsomedially and laterally to the abdominal wall using sutures or staples. A less-sophisticated technique of laparoscopic inguinal herniorrhaphy involves inserting a coiled polypropylene mesh through the enlarged vaginal ring into the inguinal canal.[192] The coiled mesh is pushed into the inguinal canal until the proximal edge of the mesh is distal to the vaginal ring and then allowed to uncoil. The mesh is fixed to the inguinal canal with endoscopic staples. Fibrous reaction to the mesh obliterates the canal, preventing intestine from entering it. The procedure can be performed with the horse standing. Infertility of men, sometimes accompanied by atrophy of the testis, has been reported after inguinal hernioplasty.[193] Infertility is presumably caused by ischemic orchitis because of impaired blood supply, or it may be due to an immunological response.

SPECIAL CONSIDERATIONS

Hemicastration

Fertility is maintained after hemicastration of normal horses. Testes undergo compensatory hypertrophy after hemicastration in response to increased secretion of interstitial cell–stimulating hormone from the hypophysis.[194] A hydrocele, neoplasia, or orchitis of one testis can cause temperature-induced dysfunction of spermatogenesis of the other testis, but removing the diseased testis may allow the remaining testis to regain normal spermatogenesis.[87] Postponing removal of the diseased testis can result in permanent dysfunction of the nondiseased testis.

The descended testis of a cryptorchid should never be removed without first removing the nondescended testis. Failure to find and remove the nondescended testis after the descended testis has been removed enables an unscrupulous owner to fraudulently represent the horse as a gelding and may complicate subsequent surgery, especially if there is no written record of which testis was removed. This significantly increases the cost of cryptorchidectomy.[195] In one study, 8 of 16 unilaterally castrated horses were described as geldings when they were purchased by the owner.[195] Compensatory hypertrophy of the nondescended testis occurs after hemicastration and may complicate removal of an abdominal testis.[18] Removing the descended testis has been advocated to promote descent of the cryptorchid testis,[196] but descent of an abdominal testis becomes impossible within several weeks after birth.[16,197] There is no proof that hemicastration actually results in descent of an inguinal testis. An inguinally retained testis is located easily during inguinal exploration and should be removed along with the descended testis.

Hormonally Induced Testicular Descent

Undescended inguinal testes of boys have been fixed in scrotal position (orchidopexy or orchiopexy) using sutures,[198] but because cryptorchidism of horses may be hereditary, bringing about descent of an inguinal testis by surgical means is considered by most practitioners to be disreputable. There is good evidence that an impaired hypothalamic-pituitary-gonadal axis, which leads to insufficient production of testosterone and dihydrotestosterone, is the main cause of cryptorchidism in boys, and so boys with one or more cryptorchid testes have been successfully treated using GnRH, hCG or LHRH.[40,199] Because testicular descent is hormonally controlled, treatment of a horse for cryptorchidism with hormones would seem to be an attractive mode of therapy, but factors responsible for testicular descent in horses are still obscure, and no specific therapy has been developed to correct the hormonal defect responsible for testicular retention. GnRH and hCG have been administered separately and in combination to horses to bring about testicular descent, but conclusive evidence of efficacy is lacking.[200] Treatment of eight colts, each of which had an inguinally located testis, with 2500 mg hCG twice weekly for 4 weeks, however, was thought to facilitate descent of the inguinal testis of four of the eight colts.[201]

If a cryptorchid testis of a human descends into the scrotum or is surgically placed in the scrotum, degenerative changes within the testis can reverse so that the testis becomes capable of producing sperm; but for degenerative changes to reverse, the cryptorchid testis must enter the scrotum while the child is very young.[202] The optimal time to effect descent of a cryptorchid testis in cryptorchid boys is within 2 years after birth, because after this time, the abnormally warm environment of the undescended testis may irreparably damage the seminiferous tubules.[203] Biopsy of nondescended testes of cryptorchid boys, performed at the time of orchiopexy showed that the concentration of germ cells decreases overtime, beginning as early as 1 year of age.[204] In horses, the age at which a cryptorchid testis must descend into the scrotum to contribute to fertility has not been determined.

After the first few weeks of neonatal life, the vaginal rings contract, reducing the likelihood of descent of an abdominal testis.[16] Hormonal therapy, therefore, is likely to have no effect on descent of an abdominal testis. Testicular growth, brought about by onset of puberty, may bring about descent of an inguinal testis,[18] and this supports the rationale for administration of GnRH or hCG. The effect of exogenous hormones on descent of inguinal testes, however, is unclear. Because genetic studies of equine cryptorchidism indicate that testicular retention is probably hereditary, hormonal therapy to bring about testicular descent is no more ethical than surgically placing the testis in the scrotum.

POSTOPERATIVE COMPLICATIONS

Complications associated with castration are a common cause of malpractice claims against North American equine practitioners.[205] To avoid complications, the practitioner should have a good understanding of male reproductive anatomy and of the various techniques of orchidectomy. The practitioner also should be able to recognize and resolve complications of castration.

Hemorrhage

Excessive hemorrhage is usually the result of an emasculator that is improperly applied or is in imperfect working order. Reversing the emasculator (i.e., placing the cutting edge toward the abdomen) usually results in severe hemorrhage, because the cord is crushed distal to the site of transection. The emasculator should be applied perpendicular to the cord, because transection of the cord other than at a right angle increases the diameter of the severed ends of the testicular vessels. The blade of the emasculator should not be so sharp that the testicular vessels are severed before they are crushed properly. A blade that is too sharp can be dulled by using it several times to cut rope.[190]

The testicular vessels may be insufficiently crushed if scrotal skin is inadvertently included in the emasculator's jaws. The thick cords of a mature stallion may require double application of the emasculator to sufficiently crush the vessels. Using this technique, the parietal tunic and cremaster muscle are crushed and transected separately from the testicular vessels and ductus deferens.

A ligature placed around the entire spermatic cord or around the testicular vessels alone can be used alone, or in conjunction with an emasculator, to prevent hemorrhage. Although a ligature, with or without an emasculator, may be more effective than the emasculator alone in preventing hemorrhage, the use of a ligature may increase the incidence of infection at the surgery site.[149] The increase in risk of infection associated with the use of a ligature is likely the result of reduced resistance of tissue contaminated with bacteria to infection in the presence of foreign material, especially if a nonabsorbable suture is used.

Dripping of blood from the wound for several minutes after emasculation is expected and should cause no concern. Unabated streaming of blood for 15 to 30 minutes is a signal for alarm. The testicular artery is the usual source of severe hemorrhage.[21] Because testicular veins are valved, hemorrhage from these vessels is usually mild. Hemorrhage from scrotal vessels is usually not serious and soon ceases spontaneously. If, after allowing the horse to stand quietly for 15 to 30 minutes, hemorrhage does not diminish, the end of the cord can be grasped, using fingers, and stretched to allow application of a crushing forceps or an emasculator. A crushing forceps with curved jaws, such as a kidney clamp, is easier to apply and maintain in position than a straight forceps. If the horse was castrated while standing, the end of the cord is likely to still be desensitized, and the forceps or emasculator can usually be applied without causing serious discomfort to the horse. The forceps is removed the next day. If the horse was castrated while recumbent, the cord is not desensitized (unless the testes were infiltrated with local anesthetic solution before they were removed), so to safely grasp and crush the end of the cord, the horse may need to be reanesthetized.

If the end of the cord is inaccessible through the scrotal incision, hemorrhage can be stopped by ligating the testicular vessels intra-abdominally using the procedure described for laparoscopic castration.[206,207] Laparoscopic surgery to stop hemorrhage after castration can be performed with the horse standing or anesthetized and positioned in dorsal recumbency. The testicular artery can be coagulated using electrocoagulation or occluded with a laparoscopic suture loop or a vascular clip.

If the end of the cord is inaccessible, and if intra-abdominal ligation of the testicular vessels using laparoscopy is not an option, sterile gauze can be packed tightly into the inguinal canal and scrotum, and the scrotum can be closed with sutures or towel clamps. The pack is removed the next day.

Ten percent formalin (i.e., a 4% aqueous solution of formaldehyde gas created by diluting a 37% to 40% solution of formaldehyde gas with 9 parts of water) has been used with questionable success to stop hemorrhage. In one study, 8 to 16 mL of 4% to 12% formalin administered intravenously to average-sized horses decreased the time of coagulation by 67% for 24 hours.[208] Another study, however, found that 0.37% formaldehyde solution administered intravenously did not appear to enhance primary or secondary hemostasis.[209]

Formaldehyde solution is pyrogenic and accelerates pulse and respiration.[208] Other side effects include restlessness, lacrimation, salivation, elevation of the tail, nasal discharge, increased peristalsis with frequent defecation, sweating, quivering of muscles, signs of severe abdominal pain, and tenesmus. Physical reaction is minimal when 10 mL of 4% formaldehyde solution (i.e., 10% formalin), diluted in a liter or more of isotonic saline solution, is administered intravenously. I have observed dramatic reduction of hemorrhage, with no clinically apparent side effects, within minutes after intravenously administering this amount, but convincing scientific evidence of the safety and efficacy of a formaldehyde solution in reducing hemorrhage is lacking.

Evisceration

An uncommon but potentially fatal complication of castration is evisceration through the vaginal ring and open scrotal incision. A survey of practitioners (performed to determine the type and frequency of complications that occur after castration) reported the incidence of evisceration after castration to be about 0.2%.[149] Horses that eviscerate after castration may have a preexisting, unapparent, congenital, inguinal hernia.[62] Most unapparent inguinal hernias resolve by the time the horse is 3 to 6 months old,[187] so horses castrated before they are 6 months old may be at greater risk of eviscerating after castration than are horses castrated after they are 6 months old. Standardbreds and draft horses may be more frequently affected by postoperative evisceration, because they have a higher incidence of congenital inguinal herniation.[64,149] Based on anecdotal evidence and unpublished data, Tennessee Walking Horses and American Saddlebreds may also have a higher incidence of congenital inguinal herniation and so may be predisposed to evisceration after castration.[210]

To decrease the likelihood of evisceration after castration, the horse's inguinal area should be palpated for the presence of an inguinal hernia before the horse is castrated, and the owner should be questioned as to whether the horse suffered from a congenital inguinal hernia as a foal. If the horse has or has had an inguinal hernia, is less than 6 months old, or is a member

of a breed that has an increased incidence of inguinal herniation, the surgeon should consider taking measures to prevent evisceration. Some clinicians examine the vaginal rings *per rectum* before castrating a horse deemed to be at risk for evisceration because of its breed.[211] The vaginal ring of stallions is normally large enough to accommodate the tip of one finger. According to some clinicians, precautions to prevent evisceration should be taken if a vaginal ring is larger than two fingers. The risk of rectal injury should be weighed against the value of the diagnostic information to be gained before examining the vaginal rings *per rectum*.

For horses that have a higher than normal risk for evisceration, castration should be performed with the horse anesthetized. The testes should be removed using a closed technique, and the spermatic cord should be ligated. The cremaster muscle should be isolated from the cord before the cord is ligated, so that it is not included in the ligature. Including the cremaster muscle in the ligature could cause the ligature to loosen when the cremaster muscle contracts. The closed technique of castration does not diminish the incidence of evisceration unless a ligature is applied to the cord proximal to the site of transection.[64]

Evisceration usually occurs within 4 hours after castration and may be precipitated by attempts to rise from anesthesia.[62,212] Evisceration has occurred up to 6 days after castration,[62] and one horse was reported to have herniated into its sutured scrotum and vaginal cavity 12 days after castration.[213] After intestine enters the canal, peristalsis encourages further protrusion, and intestinal strangulation accompanied by severe signs of colic rapidly ensues. Treatment of a horse that has eviscerated through the inguinal canal is similar to emergency treatment of horses with acquired inguinal herniation.

If evisceration occurs, the protruding intestines should be collected in a clean sheet and tied over the back of the horse to prevent the horse stepping on the intestines. The horse should be transported immediately to a hospital equipped with surgical facilities. The horse should be anesthetized immediately to prevent contamination of and damage to the herniated intestine. Torn mesentery should be repaired, and the intestine should be meticulously cleaned, copiously irrigated, and replaced into the abdomen as rapidly as possible to avoid ischemic damage. Dilating the vaginal ring and applying traction to the intestine through a celiotomy may assist reduction of the intestine. Parenteral antimicrobial therapy should be initiated, and peritoneal fluid should be examined postoperatively if the horse displays signs of septic peritonitis. Factors that negatively influence survival include the amount of intestine that has protruded through the vaginal ring and whether intestinal resection and anastomosis were required.[214]

Protrusion of greater omentum through the scrotal incision after castration causes no immediate distress to the horse and need not be considered a dire emergency (Figure 59-23). The horse should be examined *per rectum* to determine the size of the vaginal ring and to confirm that intestine has not entered the inguinal canal. Exposed omentum is transected as proximally as possible using an emasculator. This can usually be accomplished with the horse standing. To prevent further protrusion of omentum, the horse should be forced to stand in a stall for 48 hours. Suturing the superficial inguinal ring or packing the inguinal canal and scrotum gives additional security against evisceration but is not always necessary, because omentum occupying the vaginal ring prevents intestine from entering the canal. If omentum continues to exit the scrotal incision, the superficial inguinal ring should be sutured.

Figure 59-23. Protrusion of greater omentum through the scrotal incision after castration.

Edema

Preputial and scrotal edema develops after nearly every castration and is generally greatest around the fourth postoperative day.[21] Excessive edema, reported to be the most common complication of castration,[149] can usually be avoided by removing a generous portion of the scrotum during castration and by vigorously exercising the horse for several weeks to promote drainage from the open wound. Without vigorous exercise, the scrotal skin may seal and trap fluid containing bacteria or inflammatory products within the scrotal cavity. Excessive edema can usually be relieved by opening the sealed wound with scrotal massage or by inserting a gloved finger into the scrotal cavity and enforcing vigorous exercise. High-pressure lavage of the scrotal wound with tap water administered using a garden hose may assist in keeping the wound open and clean, but a survey of practitioners (performed to determine the type and frequency of complications that occur after castration) indicated that horses that receive hydrotherapy after castration may be more prone to develop excessive swelling and infection of the scrotum.[149]

Signs of Colic

In one study of 238 horses castrated *per primam*, 8.8% displayed transient signs of colic interpreted to be caused by postoperative pain.[157] Horses older than 10 years were significantly more likely than horses younger than 5 years to display signs of colic. A horse that displays signs of colic after castration and that fails to respond favorably to administration of an analgesic drug should be examined to ensure that signs of pain are the result of castration and are not caused by intestinal pain.

Lameness

Occasionally, a horse is presented for lameness examination with a history of having developed the lameness within several weeks after castration.[215] Palpation of the inguinal region on the side of lameness may reveal abnormally firm tissue in the region of the surgical scar, and examination of the abdomen, performed *per rectum*, may reveal swelling of the abdominal wall in the area of the vaginal ring of the affected side. Resection of the stump of the cord proximal to the abnormal portion of the cord resolves the problem.

Septic Funiculitis

A scrotal wound, like any other wound left unsutured to heal by secondary intention, becomes contaminated and may subsequently become infected. The infection remains confined to the scrotal cavity as long as the scrotal incision remains open and draining, and it resolves as the scrotum heals. Septic funiculitis, or infection of the spermatic cord, can occur from extension of the scrotal infection, especially if the scrotal cavity does not properly drain. Septic funiculitis can also be caused by a contaminated emasculator or ligature. The open method of castration, in which the vaginal tunic and cremaster muscle are not removed, may predispose the horse to septic funiculitis,[34] but the condition can occur if the horse has been castrated using the closed technique of orchidectomy. The condition is characterized by preputial and scrotal edema, pain, pyrexia, and sometimes lameness.[66] Septic funiculitis may resolve with antimicrobial therapy and reestablishment of drainage, but removal of the infected stump is likely to be required, especially if the cord has been ligated.

Champignon (French for "mushroom") is a term used to describe a type of septic funiculitis of the stump of the cord caused by infection with *Streptococcus.*[21] Champignon is characterized by purulent discharge and a mushroom-shaped mound of granulation tissue that protrudes from the scrotal incision.[216] This was a common complication of castration before the invention of the emasculator, when hemorrhage was controlled by ligatures or "clams," but now its importance is mostly historical.[21]

A stump chronically infected with pyogenic bacteria is commonly referred to as a scirrhous cord.[32,70] Scirrhous cord, caused by *Staphylococcus,* is sometimes referred to as botryomycosis.[21,70] The scrotal incision of a horse affected with septic funiculitis may eventually heal, but if the septic funiculitis does not resolve, the cord enlarges with granulation tissue and abscesses, which may eventually discharge through sinus tracts. The cord is hard, often painless, and adhered to scrotal skin. The stump may become so large that it mechanically interferes with locomotion of the rear limb. In extreme cases, infection ascends the cord into the abdomen, where a hard mass can be palpated *per rectum* at the deep inguinal ring.[34] Occasionally, the lesion does not become apparent for several years after castration.[21,217] Treatment is removal of the infected mass. The horse is anesthetized and positioned in dorsal recumbency. An incision is made over the scrotal scar or superficial inguinal ring, and the infected cord is isolated from normal tissue (Figure 59-24). The cord is transected proximal to the mass, using an emasculator or écraseur, and the wound is left unsutured to heal by secondary intention. Removing an infected cord within a few weeks after castration is relatively simple, but a chronically infected cord is difficult to remove because of fibrous adhesions to the parietal tunic and large blood vessels associated with the adhesions. The infected portion of the cord is likely to extend far into the inguinal canal if the horse was castrated using the closed technique of orchidectomy, making dissection difficult.

Figure 59-24. The exteriorized portion of the spermatic cord is thickened and hardened from infection. The demarcation between normal and abnormal portions of the cord is obvious. A thick, hard, infected cord after castration is commonly referred to as a scirrhous cord.

Clostridial Infection

Clostridial infection of the castration wound is particularly severe, because tissue necrosis and toxemia produced by clostridial organisms may lead to death within several days. Specific systemic signs of clostridial infection vary according to the clostridial species involved. *Clostridium tetani* causes general spasms and paralysis of the voluntary muscles. Horses develop a characteristic "saw-horse" stance and protrusion of the third eyelid.[218] *Clostridium botulinum* causes flaccid paralysis, and early signs include decreased tone of the eyelids and tail, weakened gait, muscular tremors, and dysphagia.[219] *Clostridium septicum, Clostridium perfringens, Clostridium chauvoei,* and *Clostridium fallax* have been identified as etiologic agents of malignant edema, a highly lethal disease characterized by fever, depression, toxemia, subcutaneous accumulation of gas, and fulminating cellulitis.[220] Treatment of horses for clostridial infection at the castration site includes administration of high doses of penicillin and nonsteroidal anti-inflammatory and analgesic drugs, supportive therapy, radical débridement of all necrotic scrotal tissue, and establishment of scrotal drainage. Horses infected with *C. botulinum* and *C. tetani* can also be treated with antitoxin.[219,221]

Septic Peritonitis

Subclinical, nonseptic peritonitis occurs in many horses after castration because the peritoneal and vaginal cavities communicate.[222] Postoperative, intra-abdominal hemorrhage may be responsible, at least in part, for nonseptic peritonitis, because free blood in contact with the peritoneum causes inflammation.[223] A concentration of nucleated cells greater than 10,000/μL in the peritoneal fluid indicates peritoneal inflammation. A concentration greater than 10,000/μL can be found routinely in

peritoneal fluid for at least 5 days after uncomplicated castration, and a concentration greater than 100,000/μL is not uncommon.[222]

Septic peritonitis occurs when peritoneal inflammation is accompanied by bacterial infection. Signs of septic peritonitis include colic, pyrexia, tachycardia, diarrhea, weight loss, and reluctance to move.[224] Septic peritonitis should not be diagnosed on the basis of the concentration of nucleated cells in the peritoneal fluid alone, because a concentration greater than 10,000/μL indicates only that the peritoneum is inflamed.[222] The presence of degenerated neutrophils or intracellular bacteria in the peritoneal fluid is more indicative of bacterial peritonitis, especially when accompanied by clinical signs.[225] Treatment of horses for septic peritonitis includes administration of antimicrobial and nonsteroidal anti-inflammatory and analgesic drugs, supportive therapy, and peritoneal lavage. Proper drainage of the scrotum must be established. The occurrence of septic peritonitis after castration is rare, perhaps because the funicular portion of the vaginal process is collapsed as it courses obliquely through the abdominal wall[226] and because mesothelial cells of the vaginal process are phagocytic.[80]

Penile Damage

The surgeon may encounter the shaft of the penis while separating scrotal fascia in search of an inguinal testis and, if inexperienced in orchidectomy, may mistake it for the testis. A portion of the shaft of the penis may be stripped of fascia, partially exteriorized, and amputated before its true identity is recognized (Figure 59-25). Even if the penile shaft is recognized before the penis is damaged, damage to the penile fascia created by dissection can result in excessive edema and even paraphimosis. Damage to the urethra during sharp dissection results in severe necrosis of tissue from extravasation of urine into surrounding tissue.[227,228] Penile damage is easily avoided if the surgeon possesses some familiarity with genital anatomy and proper techniques of castration.

Figure 59-25. Stump of penis emerging from a scrotal incision. Much of the shaft of the penis was inadvertently removed during a standing castration.

Excessive edema after castration can result in protrusion of the penis from the preputial cavity, and if the protruded penis is improperly cared for, its integument can be irreparably damaged. Prolonged penile protrusion can result in permanent penile paralysis.[190] Administering a phenothiazine-derivative tranquilizer as a preanesthetic agent can result in priapism or penile paralysis. Penile paralysis and priapism are described in detail in Chapter 60.

Hydrocele (Vaginocele)

A hydrocele, or vaginocele, is a fluid-filled, painless swelling in the scrotum that may appear months or years after castration and is the result of the accumulation of sterile, amber-colored fluid in the vaginal sac.[21] The fluid can often be reduced into the abdomen. The condition is rare and idiopathic, but open castration predisposes to the condition because the vaginal tunic is not removed. Hydroceles may occur more frequently in mules than in horses after castration.[229] Enlargement of the scrotum with fluid may give the horse the appearance of an entire stallion; or the horse may appear to have an inguinal hernia.

If the hydrocele does not increase in size, is not aesthetically displeasing to the owner, and does not inconvenience the horse, no treatment is necessary; otherwise, the hydrocele should be surgically removed. Drainage only temporarily alleviates the condition. To remove the hydrocele, the horse is anesthetized, placed in dorsal recumbency, and prepared for aseptic surgery. Skin is incised directly over the fluid-filled vaginal sac, the sac is bluntly separated from adherent fascia, and the scrotal ligament, which attaches the vaginal sac to the scrotum, is severed. The sac is transected, using a scissors or an emasculator, as proximad as possible. The wound can be sutured or left open to heal by secondary intention.

Continued Masculine Behavior

Even though the serum concentration of testosterone and estrogen decline precipitously to basal levels within 6 hours after castration, libido is normally lost gradually; in one study, mean scores of libido by horses declined gradually until they stabilized on day 56 after castration.[139] Castration is not always successful in completely eliminating objectionable masculine behavior, and some geldings display sexual behavior, such as genital investigation, erection, mounting, and even copulation. Objectionable masculine behavior of geldings is especially common in spring and early summer. Geldings with objectionable sexual libido and aggressive temperament characteristic of stallions are sometimes referred to as *false rigs.*[230]

Persistent masculine behavior of false rigs has been attributed to failure to remove all epididymal tissue during castration, and geldings that display masculine behavior as a result of retention of epididymal tissue are said to be *proud cut.*[230] Epididymal tissue is unlikely to be inadvertently left with the horse, because the epididymis is intimately attached to the normal descended testis. Regardless, androgens are neither produced

nor released by the epididymis, and therefore, the presence or absence of epididymal tissue should not influence masculine behavior.[136] Because masculine behavior of a false rig cannot be justly attributed to retention of epididymal tissue, there is no such thing as a proud cut horse.[230]

Masculine behavior of a false rig has also been attributed to production of testosterone by the adrenal cortex.[136] The circulating concentration of luteinizing hormone is increased after castration in response to the falling concentration of testosterone, and the rise in luteinizing hormone concentration may produce some adrenal hypertrophy. False rigs, however, have no higher concentration of testosterone or dihydrotestosterone in serum than do normal, quiet geldings, and the presence of significant concentration of any other androgen is unlikely.[230] Moreover, administering hCG to false rigs produces no discernable rise in concentration of testosterone in serum.

Heterotopic testicular tissue has been incriminated as a cause of continued masculine behavior after castration.[231] Failure of embryonic primordial germ cells to migrate caudad and dispersion of the cells of the embryonic germinal epithelium from trauma have been theorized as causes of transplantation of testicular tissue throughout the peritoneal cavity of pigs.[231] The occurrence of heterotopic testicular tissue in horses, however, has not been reported. Administering hCG to a horse with heterotopic testicular tissue would probably produce a rise in concentration of testosterone in the serum.

Objectionable masculine behavior after castration is most likely innate and not caused by extragonadal production of testosterone.[230,232] Masculine behavior of false rigs is probably part of the normal social interaction between horses.[230] About 20% to 30% of castrated horses can be expected to display stallionlike sexual interest in mares and aggression toward other horses, and about 5% can be expected to display stallionlike aggression toward people.[232] Because the prevalence of masculine behavior of horses castrated as juveniles is similar to that of horses castrated as adults, castration before puberty is no more effective in preventing objectionable behavior than castration after puberty. These percentages should be considered the normal prevalence of masculine behavior in geldings.

Amputating the stumps of the spermatic cords was reported to abolish objectionable masculine behavior in 75% of 18 false rigs,[233] but no satisfactory rationale was offered to account for the success of this procedure. Because spermatic cords contain no Leydig cells and are incapable of producing androgens, the efficacy of shortening cords to eliminate libido seems doubtful. Limiting social interaction with other horses or imposing stricter discipline may be more successful in eliminating or diminishing undesirable masculine behavior.[230] Administration of a progestagen (such as altrenogest, 50 to 75 mg daily) may ameliorate sexual and aggressive behavior of geldings.[234,235] Progestagens suppress sexual behavior of stallions by inhibiting production of luteinizing hormone from the anterior pituitary gland, resulting in reduced production of testosterone by Leydig cells. But they also exert a direct calming effect on the central nervous system of horses, and this function may be responsible for the effect of progestagens on geldings that display objectionable, masculine behavior.[235]

Incomplete Cryptorchid Castration

The tail of the epididymis of the partial abdominal cryptorchid lies within the inguinal canal, enclosed within a well-developed vaginal process. Excessive length of the proper ligament of the testis and body of the epididymis may allow the tail of the epididymis to descend through the inguinal canal. A surgeon unfamiliar with testicular anatomy and the mechanism of testicular descent may amputate the tail of the epididymis after mistaking it for a hypoplastic inguinal testis (Figure 59-26). The horse naturally continues to display objectionable, stallionlike behavior.

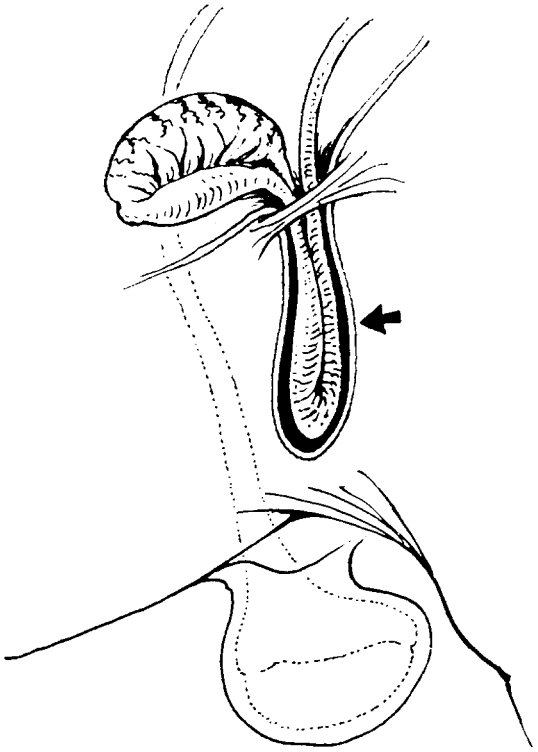

Figure 59-26. The *arrow* points to the epididymis of a partial abdominal cryptorchid. A portion of the epididymis lies within the inguinal canal, enclosed within the vaginal process. This portion of the epididymis could be mistaken for an inguinal testis by an inexperienced surgeon, and amputated.

The vaginal tunic should be opened before removing a structure presumed to be an inguinal testis to ensure that a testis, and not just the epididymis, is contained within. An hCG-stimulation test differentiates a horse with testicular tissue from a false rig. Locating both the end of the epididymis and the stump of the ductus deferens in the inguinal canal at surgery identifies a horse as a partial abdominal cryptorchid whose epididymis has been partially resected.[13]

CHAPTER
60 Penis and Prepuce

James Schumacher

ANATOMY AND PHYSIOLOGY

Penis

The penis is the male organ of copulation and is composed of erectile tissue that encases the extrapelvic portion of the urethra (Figure 60-1).[1-4] The penis of the horse is musculocavernous and can be divided into three parts: the root, the body or shaft, and the glans penis. The penis originates caudally at the root, which is fixed to the lateral aspects of the ischial arch by two crura (leglike parts) that converge to form the shaft of the penis. The shaft constitutes the major portion of the penis and begins at the junction of the crura. It is attached caudally to the symphysis ischii of the pelvis by two short suspensory ligaments that merge with the origin of the gracilis muscles (Figure 60-2). The glans penis is the conical enlargement that caps the shaft. The portion distal to the point of attachment of the prepuce is referred to as the free part of the penis.[5] The urethra passes over the ischial arch between the crura and curves cranioventrad to become incorporated within the erectile tissue of the penis. The ventral surface of the penis is nearest the urethra, and the dorsal surface is farthest from the urethra.[5]

The mobile shaft and glans penis extend cranioventrally to the umbilical region of the abdominal wall.[4] The body is cylindrical but compressed laterally. When quiescent, the penis is soft, compressible, and about 50 cm long[3]; 15 to 20 cm lie free in the prepuce. When maximally erect, the penis is up to three times longer than when it is quiescent.[6]

Erectile Bodies

Two cavernous spaces make up the majority of the penile shaft: the dorsally located corpus cavernosum penis (CCP), which is responsible for erection, and the ventrally located corpus spongiosum penis (CSP), formerly termed the corpus cavernosum urethrae (Figure 60-3).[3,4] The CCP originates below the ischial arch at the union of the crura, which attach to the ischial arch, and makes up the bulk of the shaft.[2,3] It ends distally in one long central and two blunt ventrolateral projections (Figure 60-4).[4] Along the ventral surface of the CCP runs the urethral groove or urethral sulcus.

The CSP lies in the urethral groove of the CCP and surrounds the urethra (see Figure 60-3).[2-4] The bulb of the penis is the proximal enlargement of the CSP. At its distal termination, the CSP expands into the glans penis, which caps the central projection of the CCP (see Figure 60-4). The tunica albuginea of the glans is thinner than that of the rest of the penis, making it softer in the erect state than the CCP.[6] A long dorsal process of the glans penis extends 10 cm proximally on the dorsum of the CCP. The circular edge of the glans penis is termed the corona glandis, and the collum glandis represents the constriction behind it. The convex cranial surface of the glans contains a deep depression, the fossa glandis, into which the urethra protrudes 1.5 to 3 cm as a free tube surrounded only by thin integument (Figure 60-5).[1,3-4,7] This tubular protrusion of the urethra is termed the urethral process. A dorsal diverticulum of the fossa

glandis, the urethral sinus, is often filled with smegma, a caseous mass of sebaceous matter and epithelial debris. A collection of hardened smegma in the urethral sinus is termed a bean. Large beans have been purported to interfere with urination. Two ventrolateral recesses also project from the fossa glandis.[3] The fossa glandis and its recesses can harbor bacteria capable of producing venereal disease.[8]

The erectile bodies are surrounded by the thick, fibroelastic tunica albuginea, which sends fibrous trabeculae inward to form the supporting framework of the cavernous spaces.[1-2,7] The CSP has thinner trabeculae with larger, veinlike cavernous spaces than seen in the CCP. The tunica albuginea of the CSP is thin and elastic and merges distally with the integument of the glans.[3] The cavernous spaces are lined with endothelial cells and longitudinally oriented bundles of smooth muscle. Tonus of these muscular trabeculae and the retractor penis muscles maintains the nonerect penis within the prepuce. Decrease in tonus, as during micturition, causes the nonerect penis to protrude from the prepuce.

Mechanism of Erection

Penile erection is a neurovascular phenomenon, and the primary hemodynamic event leading to erection is increased arterial flow to the cavernous spaces.[3] Sexual excitement stimulates parasympathetic outflow from the sacral portion of the spinal cord and results in dilation and straightening of the helicine arteries (coiled branches of the deep artery of the penis) and relaxation of the sinusoidal smooth muscles, enabling blood to pass into the sinusoidal spaces.[3,9] Engorgement of the cavernous spaces, which is controlled and finally stopped by the unyielding tunica albuginea and trabeculae, lengthens and stiffens the penis.

Obstruction of venous return from the CCP appears to be important during erection in the stallion.[10,11] Circulation to and from the CCP passes between the ischium and the ischiocavernosus muscles. Contraction of the ischiocavernosus muscles from stimulation of the pudendal nerves occludes arterial and venous flow against the ischium, making the CCP a closed system during peak erection. Compression of the crura by the ischiocavernosus muscles forces blood into the CCP to produce high pressures. In one study, the mean pressure within the quiescent CCP measured 13 mm Hg, but it rose to 107 mm Hg

during sexual arousal, and finally to 6530 mm Hg during coitus.[11] Anesthesia of the ischiocavernosus muscles caused diminution of erection by reducing the peak pressure in the CCP to a value close to that of the systemic blood pressure.

During coitus, increased arterial blood flow into the CSP and contraction of the bulbospongiosus muscle lead to increased pressure within the CSP and considerable distention of the glans penis.[12] The glans penis is greatly distensible and may become so large before coitus that the stallion is unable to accomplish intromission. In one study, mean pressure within the CSP was 17 mm Hg during the quiescent state, 76 mm Hg on arousal, and finally, 994 mm Hg during coitus.[12] Contractions of the bulbospongiosus muscles were likely responsible for the high pressure, because anesthesia of this muscle greatly reduced pressure in the CSP during coitus. The CSP remains an open system during erection because vessels entering the bulb of the penis do not pass between an osseous structure and the bulbospongiosus muscles.[12] Blood passes down the CSP to the glans penis and out through the dorsal veins.

Detumescence occurs after ejaculation because parasympathetic impulses diminish and because sympathetic impulses that facilitate emission of semen also cause the helicine arteries to return to their coiled state, thus restricting inflow of arterial blood. Sympathetic impulses also decrease venous compression and allow emissary veins to open, thereby increasing venous outflow.[3,9,13,14]

Muscles

The short, paired, ischiocavernosus muscles that arise from the tuber ischii and the adjacent part of the sacrotuberous ligament attach to the crura and adjacent parts of the body of the penis (see Figure 60-2).[3,4] Contraction of these muscles elevates the erect penis, bringing it into position for intromission. By compressing the penis against the ischium, the ischiocavernosus muscles assist in producing and maintaining erection by impeding venous return from the CCP.

The urethralis muscle surrounds the pelvic urethra and the bulbourethral glands and, by its contractions, forces release of seminal fluid during ejaculation as well as emptying of the last vestiges of urine during urination.[4] The bulbospongiosus muscle, formerly termed the bulbocavernosus muscle, covers

the CSP ventrally and extends nearly the entire length of the penis (see Figure 60-2).[3] It originates near the bulbourethral glands, where it is continuous with the urethralis muscle, and ends at the free part of the penis near the glans penis. It sends transversely directed fibers from the edges of the urethral groove to meet at a median septum. Rhythmic contractions of the bulbospongiosus muscle during ejaculation force blood from the bulb, causing a pressure wave to be sent down the CSP to forcefully expel semen from the urethra.[4]

The ischiourethral muscles extend from the ventral surface of the ischium and crura, pass around the ischial arch into the pelvic cavity, and end at the ventral layer of the urethralis muscle.[3,4] They may assist erection by compressing the dorsal veins of the penis. The paired, longitudinal retractor penis muscles arise on the ventral surface of the first few coccygeal vertebrae and pass ventrad on each side of the rectum to form a loop beneath the terminal end of the rectum and anus (see Figure 60-2).[3,4] From the loop, the muscles pass distad along the bulbospongiosus muscle and end at the glans penis. They retract the penis into the prepuce after erection or protrusion.

Blood Vessels, Nerves, and Lymphatics

Arteries supplying the penis include the terminal branches of the internal pudendal (or internal pudic), obturator, and external pudendal (or external pudic) arteries.[1,2,4] The external pudendal artery supplies the cranial (or dorsal), artery of the penis, a major source of blood for erectile tissue.[2] It supplies a branch to the scrotum and continues as the caudal superficial epigastric artery, which provides branches to the prepuce.[2,3] The deep arteries of the penis originate from the obturator arteries and supply the CCP.[9] The internal pudendal artery supplies the pelvic portion of the urethra and terminates in the CSP as the artery of the bulb of the penis, which supplies the CSP.[2,3] Blood flows from the penis through a venous plexus on the dorsum and sides of the penis.[2,4] The venous plexus is emptied by the external pudendal and obturator veins; blood is carried from the root by the internal pudendal veins.[4]

Nervous supply to the penis is primarily via the pudendal nerves and the pelvic plexus of the sympathetic nervous system.[4] The pudendal nerves branch into the dorsal nerves of the penis, and the sympathetic fibers supply the smooth muscle of the vessels and the erectile tissue. The deep perineal and caudal rectal nerves supply the bulbospongiosus, ischiocavernosus, and retractor penis muscles.[3] Efferent lymphatic vessels of the penis carry lymph to the superficial and deep inguinal lymph nodes.

Accessory Genital Glands

The accessory genital glands of the horse are the paired seminal vesicles, the prostate, the paired bulbourethral glands, and the paired ampullae of the ductus deferens (Figure 60-6).[3,4,15] The accessory genital glands are fully developed in the sexually mature stallion but resume their juvenile size in the gelding.[5] The ducts of these glands empty into the pelvic urethra and provide the major portion of the ejaculate and serve to transport, nourish, and buffer spermatozoa.[9]

The distal 10 to 15 cm of each deferent duct widens to form an ampulla, the wall of which is thickened with secretory glands.[6,16] Each ampulla is evident as an enlargement near the midline of the pelvic floor. The seminal vesicles are two hollow, pear-shaped glands that lie on the dorsal surface of the neck of the bladder lateral to the ampullae.[3,4] They are often difficult to palpate *per rectum*, but identification can be enhanced if the stallion is sexually aroused before palpation.[15] Each vesicle of the stallion is 10 to 15 cm long and 3 to 6 cm wide, but those of geldings are much smaller. The seminal vesicles narrow as they converge toward the midline, and each forms a single excretory duct, which travels beneath the prostate and opens together with or beside the ipsilateral ampulla on the colliculus seminalis. The combined terminal portion of the ampulla and excretory duct of the seminal vesicle is termed the ejaculatory duct. The seminal vesicles are true glandular structures and not just reservoirs for the storage of spermatozoa as was once thought.[9] The secretions of the seminal vesicles are viscous and contribute the major portion of the volume of ejaculate.[3,4,9] Secretions from the seminal vesicles are the last to enter the urethra.[5] Seminal vesiculitis, a rare but important problem in stallions, may be associated with infertility. Surgical removal of chronically infected vesicles has been described.[17]

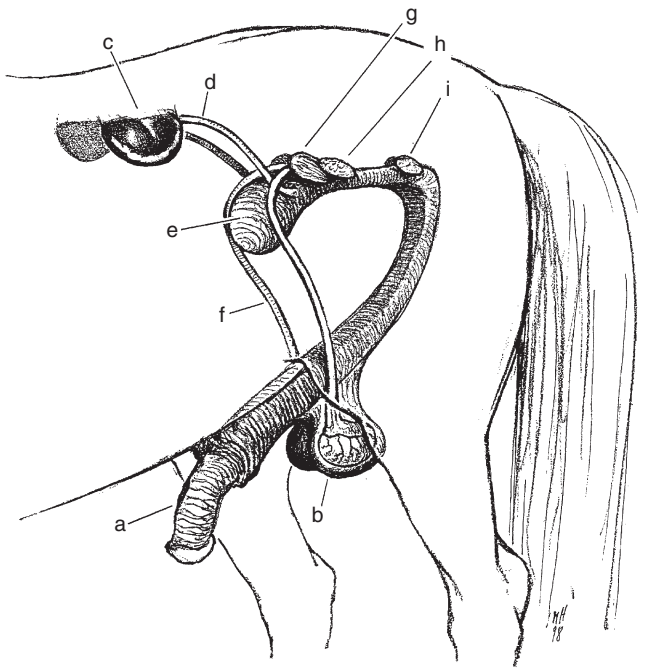

Figure 60-6. Graphic representation of the urogenital tract of the stallion. *a,* Penis; *b,* testes; *c,* kidneys; *d,* ureters; *e,* urinary bladder; *f,* ductus deferens; *g,* seminal vesicles; *h,* prostate gland; *i,* bulbourethral glands.

The prostate is a nodular, bilobed gland that lies dorsal to the neck of the bladder.[3,4] The prostate of a stallion can, with some difficulty, be palpated *per rectum*, especially if the horse is sexually aroused. Each lobe is 5 to 9 cm long, 3 to 6 cm wide, and about 1 cm thick; the lobes are connected across the midline by a 3-cm-long isthmus. Prostatic secretion from each lobe is carried through 15 to 20 prostatic ducts, which open into the urethra through small, slitlike openings located lateral to the colliculus seminalis. The prostate produces a watery, alkaline secretion that neutralizes the acidity of fluid entering the urethra from the ductus deferens.[9]

The two bulbourethral (or Cowper) glands are situated on the dorsolateral surface of the urethra at the ischial arch, 2 to 3 cm caudal to the prostate.[1-4,6] Each is covered by

a bulboglandularis muscle. The bulbourethral glands of the stallion are 4 to 5 cm long and 2.5 cm wide and are difficult to palpate *per rectum*. Six to eight excretory ducts from each gland open in two longitudinal rows of small papillae on the dorsal surface of the pelvic urethra caudal to the openings of the prostatic ducts. The bulbourethral glands produce an alkaline, mucinous secretion that clears the urethra of urine before ejaculation and lubricates the urethra for the passage of seminal fluid.[9]

Prepuce

The prepuce, or sheath, is a voluminous, folded sleeve of integument covering the mobile portion of the quiescent penis.[4] The prepuce consists of the haired external lamina, which is continuous with the skin of the abdominal wall, and an internal lamina, which is in contact with the penis (see Figure 60-5).[3,4,7] The external lamina extends craniad from the scrotum to within 5 to 8 cm of the umbilicus and is continuous with the internal lamina at the opening of the prepuce, the preputial orifice (see Figure 60-1).[3] Close to the cranial extent of the external lamina are two rudimentary teats. The preputial raphe, a cranial continuation of the scrotal raphe, divides the external lamina sagittally on its ventral midline. The prepuce is supported by an elastic suspensory ligament that lies within the external lamina and is derived from the abdominal tunic.[18] When the horse trots or canters, movement of the penis within the prepuce often creates a sucking noise.

The prepuce of the horse differs from that of other species in that it is formed by a double fold of preputial skin, one inside the other.[2-4,7] When the penis is retracted, the internal lamina doubles on itself to form a cylindrical internal fold, the plica preputialis or preputial fold. The preputial cavity is thus divided into external and internal cavities, of which the external is the more spacious.[3] The opening of the plica preputialis is termed the preputial ring. When the plica preputialis unfolds during erection, the preputial ring can be recognized as a thickened band on the extended penis.[1,2]

The penis is not free in the preputial cavity at birth, because epithelium of the internal lamina of the prepuce and epithelium of the free part of the penis are fused into a single lamina. The lamina is split into external and internal laminae by a cytolytic process that forms vesicles that coalesce to form the preputial cavity.[19,20] Separation of the internal and external laminae occurs in the first month after birth and is controlled by androgens.

DIAGNOSTIC PROCEDURES

History

Most preputial and penile abnormalities are easily diagnosed from the horse's history and during physical examination, and further studies are not required. History pertaining to problems of the penis and prepuce may include such information as copulatory performance, drug therapy, behavioral changes, conception rates, duration of disability, and previous injuries, illnesses, or urogenital surgery.

Clinical Examination

Urination

Physical examination of a horse with a penile or preputial disorder should include observation of urination. The horse can sometimes be stimulated to urinate by placing it in a freshly bedded stall; shaking the bedding while whistling may increase the horse's urge to urinate. If this technique fails, intravenously administered furosemide generally results in urination within 15 minutes. If the horse makes painful and unsuccessful attempts to urinate, urethral obstruction should be suspected, and the bladder should be palpated *per rectum*. If the bladder is distended, it should be catheterized to relieve its distention and to determine the location of urethral obstruction. A large accumulation of hardened smegma within the fossa glandis can produce stranguria by distorting the urethral process, but this accumulation is readily identified and easily removed.

Erection and Ejaculation

A breeding stallion that is experiencing difficulty with erection or ejaculation should be observed servicing a mare. Inability of a sexually excited stallion to achieve erection could be caused by a vascular shunt from the CCP to a vessel outside the tunica albuginea or by fibrosis of cavernous tissue from an unresolved episode of priapism. Shunts between the CCP and one or more dorsal veins of the penis could result from a congenital anomaly or from laceration or rupture of the tunica albuginea. Damage to the CCP caused by priapism (persistent erection without sexual excitement) can be assessed by palpating the cavernous tissue. Fibrous, noncompliant cavernous tissue indicates that the CCP has been permanently damaged. A stallion that is reluctant to ejaculate or displays pain during ejaculation may suffer from a urethral rent or seminal vesiculitis. If so, semen and urine should be examined grossly and microscopically for the presence of blood, and the urethra should be endoscopically inspected for evidence of seminal vesiculitis or a urethral abnormality.

Palpation

The penis can be palpated as it lies retracted in the prepuce by inserting a gloved and lubricated hand through the preputial orifice and preputial ring. This may be the only method of physically evaluating the penis and internal preputial lamina of a horse with phimosis (an inability to protrude the penis from the prepuce because of a stricture of the preputial orifice or preputial ring). The external and internal preputial cavities, preputial ring, and free part of the penis, including the urethral sinus and process, can be evaluated by palpation. Beans within the urethral sinus can usually be palpated by compressing the tip of the penis. Dense, brown-black, greasy smegma is normally encountered at the preputial fornix.

Visual Inspection

To ascertain the exact nature and extent of penile or preputial abnormalities, visual inspection of the horse's penis and internal preputial lamina is usually necessary. The horse's penis can be protruded by administering xylazine HCl or preferably by stimulating sexual arousal. Administration of phenothiazine-derivative tranquilizers to stallions should be avoided because of association of these tranquilizers with penile paralysis and priapism. The gelding's penis can be protruded by administering a tranquilizer or sedative or by placing a loop of gauze behind the corona glandis and with steady traction overcoming the pull of the retractor penis muscles. Producing penile

protrusion by chemical means is preferable to pulling the penis from the prepuce, because traction on the penis is resented by the horse and could damage the penis.

The penis can be desensitized and extruded by anesthetizing the pudendal nerves at the level of the ischial arch.[2,21] The point of injection is 2 cm dorsal to the ischial arch and an equal distance lateral to the anus. The needle is inserted at an angle until its point contacts the ischial arch on the midline where the pudendal nerves course around the ischium. The penis usually protrudes within 5 minutes after deposition of 3 to 5 mL of a local anesthetic agent adjacent to each nerve. Unless prolonged penile desensitization is required, a short-acting local anesthetic, such as lidocaine HCl, should be used to avoid prolonged penile protrusion. Desensitization and extrusion of the penis and internal lamina of the prepuce by anesthetizing the right and left pudendal nerves where they are embedded in the sacrotuberous ligament is described, but this pudendal nerve block is difficult.[22]

The urethral process and fossa glandis should be inspected for lesions of cutaneous habronemiasis. With the penis extended, the entire internal preputial lamina is visible and can be evaluated for wounds, scars, hematomas, neoplasia, and granulomas. Penile and preputial wounds should be closely examined to determine if they penetrate the tunica albuginea or invade the urethra. Leakage of urine from a traumatized area may be noted, especially when the horse urinates. A hematoma should be differentiated from an abscess. Physical findings of hematoma include penile swelling and ecchymosis, particularly noticeable in nonpigmented areas. Aspiration of a hematoma confirms the diagnosis. Examination of a horse with paraphimosis (an inability to retract the protruded penis into the prepuce) should include an evaluation of penile sensory innervation, because protrusion accompanied by penile paralysis may be permanent.

If preputial or penile neoplasia is suspected, the entire external genitalia should be examined meticulously for other primary lesions, and the inguinal regions should be palpated to detect enlarged lymph nodes. Superficial inguinal lymph nodes may enlarge initially from inflammation but later from malignant infiltration. Lymph nodes adhered to overlying skin or with fistulous tracts have most likely been infiltrated by malignant emboli. Metastases to internal lymph nodes may be detected by palpation *per rectum*. Recognition of carcinoma of the external genitalia should lead to examination of other structures commonly affected by carcinoma, such as the third eyelids and the perineum.

Other Diagnostic Procedures

Endoscopy

Endoscopy may be useful for identifying the source of hemorrhage noted to occur during urination or ejaculation. Endoscopy of the urethra and bladder is performed with the horse standing and sedated, using a sterile, 100-cm (or longer), flexible endoscope with a diameter no larger than 12 mm. An endoscope with an outside diameter of 9 or 10 mm is suitable for most male horses. The endoscope should be capable of distending the urethra with air, and it should not be so large that it restricts exit of air introduced proximal to it.

To endoscopically examine the urethra, the distal end of the penis is grasped behind the glans by an assistant. The urethra is occluded around the endoscope while the urethra is insufflated as the scope is inserted proximad. The urethral mucosa is normally pale pink and has longitudinal folds, but when the lumen is distended, the mucosa becomes reddened and assumes a smooth, tubular configuration. The blood-filled cavernous spaces of the corpus spongiosum penis that surround the translucent urethra should not be mistaken for an inflamed mucosa.

Two longitudinal rows of six to eight papillae that mark the openings of the excretory ducts of the two bulbourethral glands are seen on the dorsal surface of the pelvic portion of the urethra, and lateral to these papillae lies a longitudinal row of papillae that mark the urethral openings of the excretory ducts of the urethral glands. After advancing the scope beyond the papillae of the bulbourethral glands, the colliculus seminalis, which contains the opening of each of the two ductus deferentes and the opening of the duct of each of the two seminal vesicles, is identified as a round prominence on the dorsal aspect of the urethra. The small orifice of the uterus masculinus, a remnant of the ducts of Müller and the homologue of the uterus and vagina, can sometimes be seen on the center of the colliculus. The openings of the seminal vesicles are crescent-shaped. The lumen of a seminal vesicle can be examined for evidence of infection by passing a 10-mm or smaller diameter endoscope into its duct.[23] The orifices of the 15 to 20 prostatic ducts open into the urethra through small, slitlike openings located lateral and proximal to the colliculus seminalis, but these orifices are difficult to identify.

Ultrasonography

Ultrasonography can be used to assess the physical status of cavernous tissue and to identify urethral lesions, such as calculi or stenosing scars. Ultrasonographic examination of a penile hematoma may identify a rupture of the tunica albuginea. Abnormality of an accessory sex gland can sometimes be detected using transrectal ultrasonography.[15] The glands can be more readily identified if the stallion has been sexually aroused before ultrasonographic examination.

Cavernosography

Cavernosography may be useful for determining the cause of persistent impotence. Contrast medium (100 to 200 mL of iohexol, a 24% water-soluble, organic iodine radiographic contrast medium) is injected into the CCP, and serial radiographs of the penis are obtained. If shunts are present, contrast medium appears in the nutrient vessels of the penis and prepuce. If trabeculae are damaged, the sinusoidal spaces fill incompletely with contrast medium. Cavernosography also may be useful in identifying a rupture or laceration of the tunica albuginea of the CCP.

Miscellaneous Diagnostic Procedures

Urethral and ureteral catheterization may be useful for determining the source of hemorrhage observed to occur during urination or ejaculation or to obtain fluid expressed from the seminal vesicles for cytologic examination and culture.[23] Cytologic or histologic evaluation of penile and preputial lesions may be necessary to distinguish between various diseases, such as cutaneous habronemiasis and squamous cell carcinoma.

PENILE AND PREPUTIAL DISORDERS

Penile and Preputial Injuries

Etiology

Horses can lacerate their penis while jumping barriers, in attempting to breed a mare over a fence, or by falling on sharp objects. During coitus it may be caused by the mare's tail hairs or a loosely tied "breeding stitch." Stallion rings that are too small or improperly cleaned may cause erosions of the shaft.[24] Penile hematomas are usually caused by trauma to the erect penis and can occur when stallions are pastured with other horses or are permitted to breed improperly restrained mares. Severe bending of the penile shaft during coitus or semen collection may cause tearing of a corporeal body or subfascial vessels on the surface of the penis.

Penile lacerations or erosions are usually superficial, but lacerations into the cavernous tissue and urethra have been reported.[25-29] A tear in the urethral sinus leading directly into the CSP caused severe penile hemorrhage in a stallion during coitus,[25] and improper castration of two horses caused urethral damage and necrosis of tissue at the scrotum from escape of urine.[28-29]

Hematomas usually arise from rupture of the extensive vascular plexus located subfascially on the surface of the penis,[30] but occasionally a hematoma originates from a torn corporeal body.[31] Rupture of the CCP is sometimes referred to as fracture of the penis. Rupture of the bulb of the penis, presumably from a blow, eventually led to the death of a stallion by causing urethral stenosis and subsequent rupture of the bladder.[32] A hematoma confined within the intact tunica albuginea of the CCP, apparently caused by a breeding accident, resulted in deviation of a stallion's penis during erection, presumably from disruption of blood flow through the cavernous structure.[33] Aspiration of the hematoma, using ultrasonographic guidance, resulted in straightening of the penis.

Pathophysiology

Unsutured preputial lacerations inevitably become infected, and migration of infection through the loose preputial connective tissue results in cellulitis and generalized swelling. If cellulitis and swelling become severe, the penis and internal lamina of the prepuce protrude through the preputial orifice. Superficial wounds, if properly treated, heal without complication, but large unattended wounds that heal by cicatrization may restrict action of the prepuce. An unsutured wound into cavernous tissue may lead to impotence caused by creation of a shunt between the cavernous tissue and the superficial penile vasculature. Although longitudinal urethral lacerations generally heal without stricture when left to heal by secondary intention, unsutured, transecting urethral lacerations usually heal with obstructing stenosis. An improperly attended urethral injury could result in a cutaneous-urethral or cavernosourethral fistula.

Rupture of superficial penile vessels or corporeal bodies causes extravasation of blood into the loose preputial fascia. Extreme preputial swelling may occur within minutes of injury and may prevent the horse from retracting its penis into the preputial cavity. The penis may rapidly enlarge to several times its normal size. The hematoma may interfere with venous and lymphatic drainage by impinging on undamaged veins and lymphatic vessels, thus exacerbating the swelling,[24] or the hematoma may interfere with urination by impinging on the urethra.[32]

Treatment

OPEN WOUNDS

To avoid infection, fresh penile and preputial wounds should be débrided and sutured. Sutures can be either absorbable or nonabsorbable but should be soft and nonirritating. Infected wounds should be cleansed with a mild antiseptic solution several times daily and covered with an antimicrobial ointment. If the urethra is completely disrupted, it should be reapposed with absorbable sutures; stenting the urethral lumen with a male urinary catheter during surgery simplifies the anastomosis. Stenosis of the urethra caused by cicatrix formation after injury can sometimes be relieved by transendoscopic laser ablation.[34] Often, penile amputation is the most expedient means of treating complete urethral disruption accompanied by severe trauma of surrounding tissue, especially if the injured horse is a gelding.[27]

HEMATOMAS

Treatment of a horse with a penile hematoma should be instituted immediately after injury and aimed at decreasing hemorrhage. Compressing the penis and internal lamina of the prepuce with a pneumatic bandage or tight wrap may relieve edema and minimize hemorrhage. To compress the penis and prepuce, the horse is anesthetized, and starting at the distal end of the penis, the penis and internal lamina of the prepuce are wrapped snugly from the glans to the preputial orifice with an elastic bandage.[35] The wrapped penis and prepuce and the preputial orifice are massaged until the wrap loosens from the decrease in size of the penis and prepuce. The process is repeated until maximal decrease in size is achieved. The penis and internal lamina of the prepuce should then be supported against the abdomen or within the preputial cavity to diminish hemorrhage and edema. Hydrotherapy with cold water may hasten vasoconstriction. If the hematoma continues to expand despite treatment, the area of the hematoma should be examined ultrasonographically for evidence of a rent in the tunica albuginea, or it should be surgically explored. Failure to repair a rupture of the tunica albuginea could result in formation of a shunt between the damaged erectile body and the dorsal veins of the penis.

Aftercare

To avoid erection and more hemorrhage, a horse with a penile or preputial injury should not be subjected to sexual stimuli. Because exercise may exacerbate hemorrhage, the horse should initially be closely confined. After 5 or 6 days, when hemostasis is ensured, the horse should be exercised lightly to decrease the edema. Hot packs applied to the penis at this time stimulate vasodilatation and thus resorption of the hematoma.

Paraphimosis

Etiology

Paraphimosis, or the inability of the horse to retract its protruded penis into the prepuce, occurs most frequently from preputial edema caused by genital trauma, such as preputial laceration, penile hematoma, or castration. Paraphimosis may be a manifestation of disease characterized by extensive edema,

Figure 60-7. Paraphimosis caused by severe debilitation. The preputial ring has become a constricting cuff.

such as dourine and purpura hemorrhagica,[24,36] or it may be caused by damage to penile innervation. The last has been associated with spinal disease, trauma, and infectious diseases, such as equine herpesvirus 1 and rabies.[24,37] Paralysis associated with priapism, debilitation, or exhaustion has been reported (Figure 60-7).[38-40] Penile paralysis has followed administration of phenothiazine-derivative tranquilizers, most notably propiomazine (formerly termed propiopromazine).[41,42]

Pathophysiology

Tonus of the retractor penis muscles and the smooth muscle of the cavernous spaces normally maintains the penis within the prepuce.[40] With penile or preputial injury, edema develops in loose connective tissue between the penis and the internal lamina of the prepuce, and the weight of edema causes muscular fatigue, followed by protrusion of the penis and internal preputial lamina from the preputial cavity. The relationship between debilitation or exhaustion and penile paralysis is obscure, but general debilitation may cause loss of muscular tonus, allowing the penis to protrude and the pudendal nerves to become contused or stretched at the ischial arch.[40,43,44]

Penile paralysis occurring after administration of a phenothiazine-derivative tranquilizer may likewise be caused by mechanical damage to the pudendal nerves from prolonged penile protrusion and not from direct damage to penile innervation by the tranquilizer, as suggested by one investigator.[42] Motor innervation of the retractor penis muscles is probably supplied solely by α-adrenergic fibers, and phenothiazine-derivative tranquilizers block these α-adrenergic fibers.[1] The retractor penis muscles can, however, be transected without causing the penis to protrude. Tranquilization may also block sympathetic impulses to the smooth muscle of the cavernous tissue, allowing the sinusoidal spaces to fill with blood and the penis to drop from the preputial cavity.[37]

Regardless of the reason for penile protrusion, blood within the CCP pools and clots within 2 to 5 hours, making the penis somewhat rigid, rather than flaccid.[45] This rigidity may cause the clinician to conclude erroneously that the penis is protruded because the horse suffers from priapism (see "Priapism," later). Prolonged protrusion itself produces edema of the penis and prepuce by impairing venous and lymphatic drainage. As the penis and internal preputial lamina swell from edema, the preputial ring becomes a constricting cuff that compounds swelling distad. After several days, fluid begins to seep diffusely through the penile and preputial epithelium. Edema increases fragility of tissues, and because the exposed penis is subjected to trauma and effects of temperature, the penile and preputial epithelium soon becomes extensively excoriated.

Bacterial invasion of excoriated epithelium causes inflammation of the penis and prepuce, or balanoposthitis, and bacterial migration through the loose preputial connective tissue causes cellulitis. Eventual invasion of edematous and inflamed tissue by fibroblasts results in fibrosis of the penile integument and fascia, causing permanent impairment of the normal telescoping action of the prepuce.[40] The pendulous weight of the penis may eventually damage the pudendal nerves.[41,44]

The protruded penis becomes curved with the glans penis pointing caudoventrad. Urination is usually unimpeded.[41] Paralysis is usually accompanied by loss of erectile function, but ejaculatory capability is often still preserved.[24]

Treatment

Treatment of a horse affected with paraphimosis should be directed toward controlling edema and preventing further trauma. To preserve normal venous and lymphatic drainage and to protect against injury, the penis should be retained within the external preputial lamina. The penis can be temporarily retained with sutures or towel clamps placed across either the

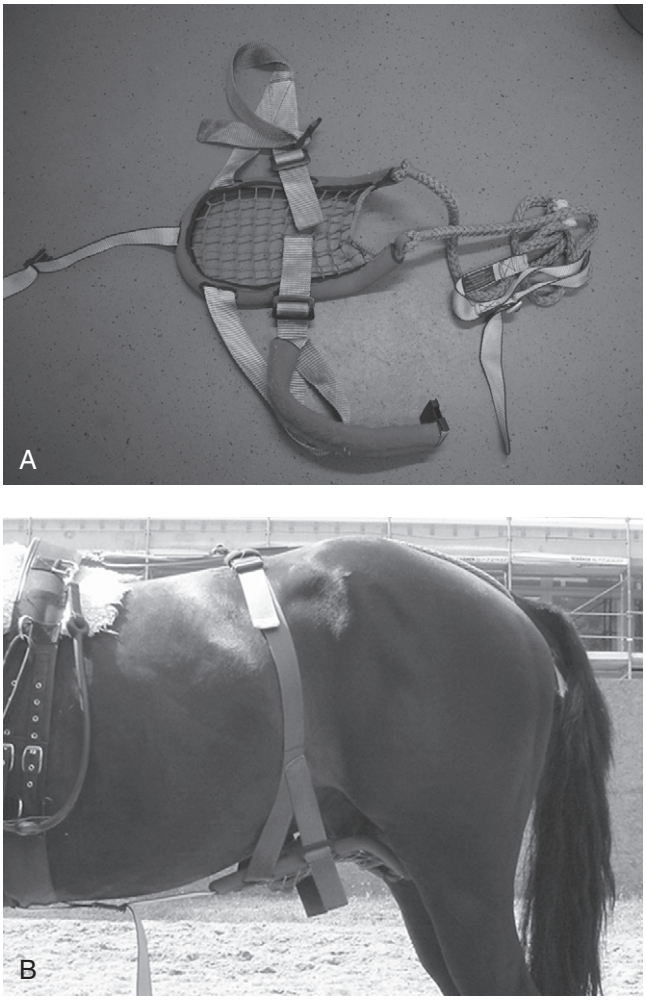

Figure 60-8. A, Suspensory device manufactured from a lightweight aluminum tube and nylon net. **B,** The device fitted to a horse. (Courtesy A. Fürst and R. Keller, University of Zurich.)

preputial orifice or preputial ring, but these devices should not be relied on for more than several days, because they damage the prepuce. Prolonged, atraumatic support can be provided by a nylon net or hosiery suspended at the preputial orifice by a crupper and surcingle made of rubber tubing (Figure 60-8).

If the protruded penis is too edematous to be replaced within the preputial cavity, it should be compressed against the abdomen with a bandage until edema subsides. A pneumatic bandage or a tight bandage applied directly to the penis may also be effective in reducing edema. Applying a nonirritating, hydrophilic agent, such as glycerin, or sulfa-urea to the penis may increase the effectiveness of the compressive bandage. Massaging the penis between bandage changes is helpful for dissipating edema. Applying an antimicrobial ointment to the penis prevents epithelial maceration and infection, and a systemically administered nonsteroidal anti-inflammatory drug reduces inflammation. Daily application of a 2% testosterone cream compounded with an equal amount of an udder cream also helps in maintaining the health of the penile and preputial epithelium.[45] The horse should be lightly exercised to reduce edema.

If the relatively inelastic preputial ring prevents penile retraction or impedes venous and lymphatic drainage, a preputiotomy can be performed. The preputial ring is severed with a longitudinal incision after administration of local, regional, or general anesthesia, and the incision is allowed to heal by secondary intention.[37]

Figure 60-9. Phimosis in a horse caused by a cicatrix at the preputial ring.

With prompt treatment, paraphimosis resulting from acute trauma usually resolves within several days. Even after initial swelling and inflammation subside, preputial cicatrization may restrict normal telescoping action of the prepuce. Excision of restrictive cicatricial tissue by segmental posthetomy (reefing) may be necessary to restore normal preputial function (see "General Surgical Procedures," later). Horses with chronic paraphimosis accompanied by penile paralysis or generalized preputial fibrosis are unlikely to regain the ability to retract the penis. Stallions with penile paralysis generally retain their libido but are unable to achieve erection.[24,42] For some stallions, however, ejaculation is still possible. Penile paralysis need not necessarily end a stallion's breeding career, if the stallion can be trained to ejaculate into an artificial vagina (provided that the horse's breed registry permits artificial insemination). The horse can be salvaged for purposes other than breeding by permanently retracting its penis into the preputial cavity with sutures (i.e., the Bolz procedure) or by extensive posthetomy (i.e., the Adam's procedure) or by partial phallectomy (see "General Surgical Procedures," later, for descriptions of these procedures).

Phimosis

Etiology

Phimosis refers to the inability of the horse to protrude its penis from the prepuce because of a congenital or acquired stricture of the preputial orifice or preputial ring. Discounting the normal fusion of the internal lamina of the prepuce to the free part of the penis present during the first month after birth, congenital phimosis rarely, if ever, occurs in horses.

Acquired phimosis can result from tumors or cicatrizing lesions at the preputial orifice or preputial ring (Figure 60-9) or from impairment of the normal telescoping action of the prepuce. When the horse cannot protrude its penis, urine enters the preputial cavity and produces mucosal inflammation that may eventually lead to more cicatrization and occlusion of the

preputial orifice or preputial ring. An unusual cause of phimosis occurred when a gelding's penis became entrapped in a rent in the suspensory ligament of the prepuce. The ligament had apparently been torn when the horse was castrated.[18]

Treatment

If phimosis is caused by constriction of the preputial orifice, a wedge of external preputial lamina based toward the preputial orifice is removed.[46] The internal and external preputial laminae are joined with a row of closely spaced interrupted sutures. If phimosis is caused by constriction of the preputial ring, a similar wedge can be removed from the internal preputial fold, and after the penis is exposed, the constricting cicatrix can be removed by segmental posthetomy (reefing) (see "General Surgical Procedures," later). Phimosis caused by rupture of the suspensory ligament of the prepuce is corrected by suturing the torn ligament.[18]

Priapism

Priapism, or persistent erection without sexual excitement, occurs when the erect penis fails to detumesce.[47] The condition derives its name from the Greek god Priapus, symbol of fertility, but a frequent outcome of the condition in all species in which it occurs is infertility resulting from impotency.

Etiologic Factors

Etiologic factors in the development of priapism in men include hematologic diseases that cause vascular sludging, such as sickle cell anemia and leukemia; administration of antihypertensive or antidepressant drugs, especially when combined with alcohol; perineal trauma; spinal cord injury; and inflammatory disorders of the urogenital tract.[47] The cause of priapism in about half of all affected men is idiopathic.[48] Priapism of horses usually occurs after administration of a phenothiazine-derivative tranquilizer, usually acetylpromazine.[49] Phenothiazine-derivative tranquilizers may cause failure of detumescence by blocking α-adrenergic impulses that mediate detumescence.[50] Other, less commonly reported causes of priapism of horses include general anesthesia,[51] nematodiasis of the spinal cord,[52] and neoplasia of the pelvic canal.[53] Priapism occurs in both stallions and geldings, but stallions are more commonly affected, perhaps because of a direct influence of androgens on development of the condition, or perhaps because stallions develop erections more frequently.[53,54]

Pathophysiology

During normal erection, the rate of flow of blood into the CCP equals the rate of flow of blood from the structure. The precise mechanisms by which priapism occurs are unknown, but basically, priapism is a result of a disturbance of either the arterial inflow or the venous outflow to the CCP, causing the erect penis to fail to detumesce.[47] Priapism in men is classified as being either high flow or low flow. *High-flow priapism* occurs when arterial blood flow to the cavernosal tissue is increased, usually as a result of a traumatically induced arteriocavernosal shunt, and venous drainage cannot compensate for this increase.[55] High-flow priapism of men almost always results from trauma to the perineum or penis.[55] *Low-flow, or veno-occlusive, priapism* occurs when the neural impulses that mediate detumescence are altered or when vascular or hematologic alterations mechanically interfere with venous drainage. Low-flow priapism occurs in men and horses much more commonly than does high-flow priapism, and in fact, only one stallion has been reported to suffer from high-flow priapism. Priapism of this stallion was classified as the high-flow variety based on the stallion's response to treatment and the content of oxygen and carbon dioxide in blood obtained from the CCP, but the stallion developed priapism after it was administered a phenothiazine-derivative tranquilizer,[56] the most commonly reported cause of low-flow priapism of horses.

Low-flow priapism, regardless of its etiology, is characterized by stasis of blood within the CCP (Figure 60-10). Blood aspirated from the CCP of men affected with low-flow priapism has a low pH (typically, less than 7.25), a low partial pressure of O_2 (typically, less than 30 mm Hg), and a high partial pressure of CO_2 (typically, greater than 60 mm Hg).[57] High partial pressure of CO_2, caused by vascular stasis, causes erythrocytes to sickle and causes endothelial damage to the vessels and trabeculae in the CCP. The sickled erythrocytes occlude the venous outflow from the CCP, eventually irreversibly.[58] Endothelial damage and occlusion cause trabecular edema, which eventually progresses to fibrosis, thereby decreasing the size of the sinusoidal spaces in the CCP and the capacity of the CCP to expand during erection. Arterial flow to the CCP remains patent during early stages of priapism, but ultimately, it too becomes occluded permanently by clots, edema, or fibrosis.[58] Protracted erection in the horse may also damage the pudendal nerves, presumably from tension on the nerves or from compression of the nerves against the ischium, causing paralysis of the penis.[53] The end result of unresolved priapism in the horse is impotence caused by loss of both erectile function and sensitivity of the glans and shaft of the penis.

Clinical Signs

A horse suffering from priapism may not have a full erection, causing the penis to appear to be paralyzed or merely protruded rather than erect. Turgidity of the CCP can be detected when the penis is palpated however, and the engorged penis cannot be reduced manually into the prepuce. Unless properly cared

for, the penis and the internal lamina of the prepuce become edematous soon after the onset of priapism.[54] Although uncommon, dysuria may be a feature of the condition. The CCP of a horse chronically affected by priapism feels fibrous, and during ultrasonographic examination, it appears to be densely echogenic. A chronically affected horse may not respond when a noxious stimulus is applied to the distal portion of the penis or internal lamina of the prepuce.[53]

Treatment

MEDICAL

Horses with priapism have been treated by massaging the penis, by applying an emollient dressing to the penis, and by compressing the penis against the body wall with a sling.[54] These treatments, although important in preventing preputial edema and damage to the penile and preputial integument, have no effect on reestablishing normal circulation in the erectile tissue of the CCP. Affected horses have been treated by administration of benztropine mesylate to reestablish normal venous drainage impaired by drugs that cause α-adrenergic blockade, such as acetylpromazine.[47,51,59-61] Benztropine mesylate, commonly used to treat people for Parkinson disease, is a synthetic drug created by combining the active portions of atropine and diphenhydramine.[51] This drug is most successful in resolving priapism if treatment is initiated soon after the onset of priapism.[51,60] The effects of the drug on horses with priapism are attributed to its anticholinergic effects.[51] The usual dose for a horse of average size is 8 mg, administered by slow intravenous injection. Side effects seen at higher dosages include paralytic ileus, impaction, dysuria, and muscular weakness. Terbutaline, a β_2-adrenergic receptor agonist, has been used successfully to treat men suffering from priapism and may be effective in treating affected horses.[62] Clenbuterol, a β_2-adrenergic receptor agonist commonly used in horses to cause bronchodilation, might also be effective.

α-Adrenergic agents, such as ephedrine, adrenaline, and phenylephrine, are often injected into the CCP of men in the early stages of priapism to achieve detumescence by promoting contractility of cavernous and arterial smooth muscle.[13,47,57,61] Instillation of 10 mg of phenylephrine diluted in 10 mL physiologic saline solution directly into the erect CCP is sometimes effective in resolving priapism of horses, provided that treatment is initiated soon after onset of priapism.[63] Phenylephrine can be injected safely into the cavernous tissue of men every 15 minutes until detumescence occurs,[13] and the same is probably true for horses. Horses chronically affected by priapism experience only temporary detumescence after this treatment.

IRRIGATION OF THE CORPUS CAVERNOSUM PENIS

A horse that does not respond within a few hours to cholinergic blockage or to three or more intracavernosal injections of an α-adrenergic agent, such as phenylephrine, should be treated by irrigation of its CCP with heparinized physiologic saline solution (PSS).[39] Irrigation of the CCP not only removes sickled erythrocytes, it also improves the acidotic environment within the CCP. The CCP can be irrigated with the horse standing, but the procedure is most easily accomplished with the horse anesthetized and in dorsal recumbency. After preparing the penis and perineal area for aseptic surgery, PSS containing 10 IU heparin/mL is introduced into the CCP under pressure through a large-bore needle (e.g., a 12-gauge needle) inserted into the turgid CCP just proximal to the glans penis. The PSS, along with the stagnant blood, is exited 10 to 15 cm caudal to the scrotum, either through one or two large-bore needles inserted into the CCP or through a stab incision into the CCP. The CCP is irrigated until fresh blood appears in the efflux. Phenylephrine (10 mg of 1% solution) instilled into the CCP at the end of irrigation may be useful in evacuating fluid from the CCP. Failure of arterial blood to appear in the efflux after stagnant blood has been evacuated indicates that the arteriolar supply to the CCP is permanently damaged and that the horse is likely to be impotent. The stab incision in the tunica albuginea of the CCP is sutured after irrigation is complete.

CREATION OF A SHUNT

Erection recurs after irrigation if venous outflow remains occluded, provided that arteriolar inflow vessels remain patent. If erection fails to resolve after several irrigations of the CCP, blood trapped in the CCP should be removed by creating a shunt between the CCP and the CSP. The CSP offers a convenient exit for blood trapped in the CCP, because in contrast to the CCP, the CSP does not act as a closed system during erection.[47,48] Shunting should be performed before the cavernous tissue or the pudendal nerves become irreversibly damaged, but the time at which damage to the cavernosal tissue becomes irreversible after the onset of priapism has not been determined for horses.

The shunt is probably best performed in the perineal region of the horse. It could be created farther distally, but creating it in the perineal region allows a more thorough evacuation of the stagnant blood by irrigation and provides drainage of blood from a greater length of the CCP. Because the CSP is thickest in the perineal region, the urethra is less likely to be perforated during the procedure.

To create the shunt, the horse is anesthetized and positioned in dorsal recumbency. The penis and inguinal and perineal regions are prepared for aseptic surgery, and a stallion catheter is inserted into the urethra. A 15-cm incision is created along the perineal raphe, about 4 to 8 cm caudal to the base of the scrotum to expose the penis, and the retractor penis muscle is retracted to expose the bulbospongiosus muscle, which covers the ventral aspect of the CSP. The right or left edge of the bulbospongiosus muscle is elevated from the edge of the urethral groove to expose 4 to 5 cm of the underlying tunica albuginea of the CSP. A 3-cm longitudinal incision is made through the tunica albuginea of the CCP adjacent to the CSP to expose the sinusoidal spaces of the CCP, and stagnant blood is evacuated from the cavernous spaces of the CCP through this incision, using irrigation as described earlier (Figure 60-11).

A matching 3-cm longitudinal incision through the tunica albuginea of the CSP is created adjacent to the 3-cm incision into the CCP. The urethral catheter compresses the sinusoidal spaces of the encircling CSP, so the CSP must be incised carefully to avoid extending this incision into the lumen of the urethra. Bright red blood exits from the incised CSP, and at this point of the procedure, suction is usually required to maintain visibility. The medial edge of the incision in the tunica albuginea of the CCP is sutured to the lateral edge of the incision in the tunica albuginea of the CSP with 3-0 or 2-0 absorbable suture material using a simple-continuous suture pattern. To complete the shunt, the lateral edge of the incision into the CCP is sutured to the medial edge of the incision into the CSP using a simple-continuous suture pattern. The bulbospongiosus

The bulbospongiosus muscle is sutured to the tunica albuginea of the CCP.

muscle is sutured to its origin on the tunica albuginea of the CCP at the edge of the urethral groove, and the subcutaneous tissue and skin are apposed. Horses appear to suffer no discomfort after the surgery, and swelling is minimal.[59] The stallion should receive no sexual stimulation for at least a month after surgery.

Complications of the cavernosal shunt in men include urethrocavernous or urethrocutaneous fistulas, penile gangrene, infection, and a painful CSP during erection.[48] Men receiving a shunt for treatment for priapism may become impotent from failure to achieve or maintain pressure in the CCP required for intromission,[47,48] and this failure can be the result of damaged cavernous tissue or from the shunt itself.[48] The shunt may close as normal blood outflow in the CCP resumes, but whether closure is essential for return of potency is not known. Bulls may become impotent after developing a trauma-induced shunt between the CCP and CSP,[37,64] but a shunt created surgically between the CCP and the CSP of normal stallions does not seem to interfere with subsequent erection and ejaculation, even if the shunt does not close.[59] In one report, a stallion that developed penile paralysis after suffering from priapism for several days regained normal erectile and ejaculatory function within 1 year after resolution of priapism, even though the horse had received two shunts between the CCP and the CSP.[56] Failure of an affected stallion to develop a normal erection after creation of a shunt between the CCP and the CSP is most likely the result of damage to erectile tissue caused by protracted priapism, rather than the result of the shunt.

Erectile function in men with cavernosal tissue damaged by protracted priapism has been enhanced by injecting a vasoactive drug, such as papaverine, phenoxybenzamine, or phentolamine, into the cavernosal tissue.[47,65] Administering a vasoactive drug into the cavernous tissue may likewise be useful for enhancing erectile function of horses with damaged erectile tissue. Some stallions with damaged erectile tissue may regain the ability to achieve intromission if they are assisted in placing their penis into the vagina of the mare, and some may be trained to ejaculate into an artificial vagina. If a stallion has decreased penile sensitivity resulting from damage to the pudendal nerves caused by priapism, an antidepressive drug, imipramine, can be administered before breeding to lower the stallion's ejaculatory threshold.[66]

PARTIAL PHALLECTOMY

Partial phallectomy may be necessary if all other treatments to relieve priapism fail (see "General Surgical Procedures," later).[54,67] Hemorrhage during or after phallectomy may be no worse than that expected during and after amputation of the penis of a horse not affected by priapism, but the remaining portion of the penis may remain erect until the CCP fibroses.

Hypospadias

Hypospadias is a congenital anomaly in which the urethral meatus (opening) is situated on the ventral aspect of the penis proximal to its normal location on the glans penis (Figure 60-12). The condition is sometimes accompanied by chordee, or an abnormal ventral curvature of the penis (Figure 60-13). It can also be accompanied by an incomplete prepuce and by stenosis of the urethral meatus [68] The position of the urethral meatus in affected humans is usually glandular, coronal, or subcoronal, but it may be penile, penoscrotal, or perineal.[69,70] Associated urogenital anomalies that sometimes accompany hypospadias in affected humans include cryptorchidism, inguinal herniation, and hydrocele. Anomalies of other systems include cleft lip and palate, imperforate anus, and cardiac irregularities.[69] The more proximal the urethral defect, the more likely the affected human is to have one or more additional anomalies.

Hypospadias results from arrested development of the penis before the penis and urethra are completely formed[71] and is probably a manifestation of a wide assortment of endocrinopathies. The condition may result from an inadequate production of androgens by the fetal testes, defective conversion of

Figure 60-12. Hypospadias of a stallion. The urethral meatus is located subcoronally and the internal lamina of the prepuce is complete. The stallion also had chordee (see Figure 60-13).

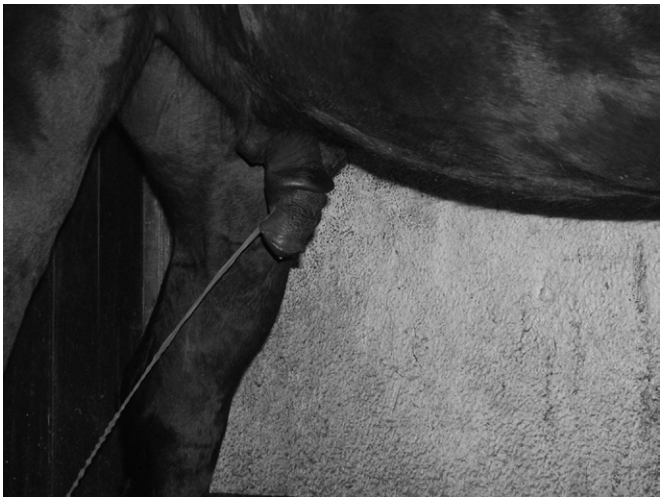

Figure 60-13. Hypospadias of the stallion in Figure 60-12 was accompanied by chordee, or an abnormal ventral curvature of the penis. Chordee caused this stallion to develop urine-induced dermatitis and discomfort during urination.

testosterone to dihydrotestosterone, or poor sensitivity of the target tissues of the developing external genitalia to androgens.[72-74] Hypospadias of men has a familial tendency, but no such tendency for the horse has been reported.[69]

Hypospadias is the most common congenital urogenital anomaly of men,[75,76] but the anomaly is encountered rarely in horses. A Friesian stallion in one report had a 4-cm-long glanular coronal and subcoronal urethral defect,[77] and a horse in another report had a urethral defect that extended from the region of the ischium to the glans penis.[78]

A horse with the anomaly may require no treatment unless the anomaly causes urine-induced dermatitis and discomfort during urination (see Figure 60-13). The most expedient method of resolving the problem may be to amputate the deformed portion of the penis.[79] Correcting hypospadias or chordee of a stallion to permit coitus should be discouraged because the condition may be genetic.

Intersex

Clinical Features

Anomalous development of the external genitalia of intersexes confuses their sexual identification. The most common intersex, the male pseudohermaphrodite, usually has a rudimentary penis, which resembles an enlarged clitoris, and prepuce, which resembles a vulva, situated on the midline somewhere between the ischial arch and the normal ventral abdominal location of the preputial orifice (see Figure 59-10).[46,80-82] Its testes are usually located within the abdomen or inguinal canals or hidden subcutaneously beneath a moderately developed udder (see Chapter 59). Despite its deceptive feminine appearance, the intact male pseudohermaphrodite displays masculine behavior and is even capable of achieving an erection of the rudimentary penis.

Treatment

If the genitalia are located close to the ischium, the pseudohermaphrodite's appearance can be altered to more closely resemble that of a female by amputating the rudimentary penis and constructing a vulva using the prepuce.[46] Alternatively, if the genitalia are less than 15 cm caudal to the inguinal area, the male pseudohermaphrodite's appearance can be altered to more closely resemble that of a male by cranially rotating the genitalia to a more normal position caudal to the umbilicus.[64] The horse should be castrated 4 to 6 weeks before surgery.

Neoplasia

Incidence and Etiology

The incidence of neoplasia of the external genitalia is second only to that of the skin.[83] Neoplasms of the penis and prepuce include squamous papillomas, squamous cell carcinomas, sarcoids, melanomas, mastocytomas, and hemangiomas.[84-87] Melanomas are occasionally found on the prepuce of old gray horses,[24] and squamous papillomas, the benign counterparts of squamous cell carcinoma, are often found on the external genitalia of young horses[88] or adjacent to penile or preputial carcinomas of old horses.[89] Squamous cell carcinoma is by far the most common penile and preputial neoplasm.[84,89] Genital squamous cell carcinoma may arise *de novo* or from malignant transformation of a squamous papilloma.[88,89] Any papillomatous lesion present on the penis or prepuce of a horse should be considered to be premalignant.

Squamous cell carcinoma is usually found on old horses, especially those of breeds with nonpigmented genitalia, such as Appaloosas and American Paint horses.[37,85,90] Lack of preputial or penile pigmentation seems to predispose to carcinoma, even though the external genitalia are unexposed to direct sunlight.[91] One study performed on mice showed that squamous cell carcinoma may be caused by unidentified carcinogenic agents in smegma,[92] but another study, also performed on mice, which used human smegma, was not able to substantiate this finding.[93] Regardless of whether smegma contains a carcinogenic agent, it may stimulate neoplastic changes in penile and preputial integument by causing chronic irritation. Geldings and old horses, therefore, may be predisposed to development of genital squamous cell carcinoma, because they produce a greater amount of smegma than do young horses and stallions.[91,92]

Squamous cell carcinoma occurs most commonly on the glans and internal lamina of the prepuce.[89,90] Penile and

preputial squamous cell carcinomas are locally invasive but have a low grade of malignancy and grow surprisingly slowly for carcinomas.[85,89,90] Metastasis to the superficial and deep inguinal lymph nodes occurs late in the disease. In one study, 12% of 48 horses affected with penile or preputial squamous cell carcinoma had metastatic involvement of the inguinal lymph nodes.[89]

Diagnosis

Most affected horses are presented for examination when the owner observes the lesion, but some may be presented because of a malodorous, purulent, blood-stained preputial discharge.[89,90] The duration of disease is usually unknown but lengthy, because most owners inspect their horse's penis infrequently.[90] Precancerous lesions may appear as a small, heavily keratinized plaque, and cancerous lesions may first appear as a shallow, flat ulceration with an indurated base.[85,90,94] Long-standing carcinomas may attain a cauliflower-like excrescence, containing areas of necrosis, ulceration, and hemorrhage that can interfere with coitus or normal protrusion and retraction of the penis (Figure 60-14).[95] The tumor can cause dysuria by impinging on the urethra. Most affected horses are also affected by balanoposthitis.[87,90]

Metastatic spread of penile and preputial squamous cell carcinoma can sometimes be palpated as an enlargement of the inguinal lymph nodes, but mild, metastatic enlargement of the inguinal lymph nodes may be difficult to differentiate from lymphadenopathy secondary to balanoposthitis.[89] Penile or preputial squamous cell carcinoma can metastasize to internal organs without causing gross enlargement of the inguinal lymph nodes.[96]

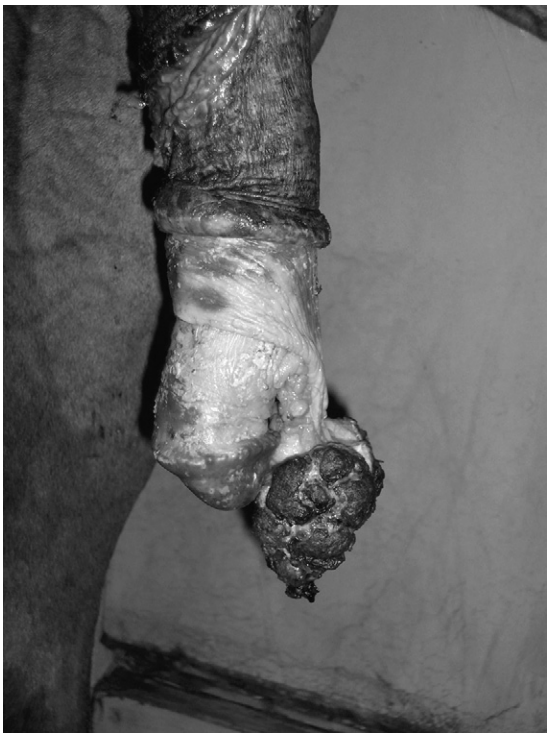

Figure 60-14. Squamous cell carcinoma of the inner lamina of the preputial fold.

Treatment

A variety of treatments for horses affected with squamous cell carcinoma of the penis or prepuce have been described, including surgical excision, cryosurgery, chemotherapy, and hyperthermia.

SURGICAL EXCISION

A small lesion on the prepuce can be excised and the wound sutured. Using a carbon dioxide laser to locally excise squamous cell carcinoma from the external genitalia may decrease the incidence of recurrence of the neoplasm.[97] Using a laser to excise a neoplasm not only decreases postoperative swelling by sealing lymphatic vessels but also has a thermal killing effect on marginal tumor cells.[98] Horses with extensive neoplastic lesions of the external genitalia require preputial reefing or partial phallectomy (see "General Surgical Procedures," later). Occasionally, neoplasms become so extensive that prescrotal urethrostomy combined with *en bloc* resection of the penis, prepuce, and inguinal lymph nodes becomes necessary.[99]

CRYOTHERAPY

Cryotherapy is a useful treatment of horses with early squamous cell carcinoma lesions. Cryotherapy can be performed using liquid nitrogen administered as a spray or through a cryoprobe, or using CO_2 administered through a cryoprobe. Thermocouple needles in a pyrometer (i.e., tissue temperature indicator) are used to monitor the depth and degree of freezing. A double, fast freeze–slow thaw cycle gives the best results.[100] More information on cryosurgery is found in Chapter 14.

CHEMOTHERAPY

Horses with small genital lesions of squamous cell carcinoma have been treated successfully by applying 5% 5-fluorouracil to the lesions at 14-day intervals.[101] Lesions need not be debulked, provided that the lesion is raised no more than to 2 to 3 mm above the surrounding integument. Up to seven treatments may be required to effect resolution of lesions. The drug is also effective in causing regression of preneoplastic lesions to which it is applied.

Horses with squamous cell carcinoma of the external genitalia have been treated by intratumoral injection of cisplatin in sesame oil[102,103] or by intratumoral implantation of cisplatin beads.[104] The drug is administered at a dosage of 1 mg/cm^3 tissue every 2 weeks, usually until the tumor has been injected four times. Intratumoral chemotherapy with cisplatin can be used alone for treatment of horses with small tumors or in combination with surgery for treatment of horses with large tumors. Debulking the tumor increases the efficacy of the cisplatin because antineoplastic drugs are most effective when the tumor burden is low.[105] Tumor cells still present after the tumor has been excised or debulked are stimulated into active proliferation and hence are more susceptible to cisplatin. Administration of cisplatin treatments intraoperatively and at 2-week intervals appears to result in a better outcome, at least for horses with tumors that have a high proliferation index, than does delaying chemotherapy until the wound has healed.[103] Injecting the tumor bed and a margin of normal tissue with cisplatin at the time of surgery and during all phases of wound healing does not have clinically apparent detrimental effects on healing of wounds closed primarily or wounds left open to heal by secondary intention.[102,103] (For more information on skin tumor treatments, and chemotherapy in general, see Chapter 29.) Topical

or intratumoral chemotherapy is impractical for treatment of horses affected with squamous cell carcinoma that has metastasized to internal organs. Horses affected with metastatic squamous cell carcinoma can be treated with a systemically administered chemotherapeutic agent, such as doxorubicin or piroxicam,[106] but little information is available on the efficacy of systemically administered chemotherapy to treat horses for neoplasia.

HYPERTHERMIA

Radiofrequency-induced hyperthermia has been used to treat horses with sarcoids and cattle and horses suffering from ocular neoplasia.[107,108] Although its use to treat horses with genital neoplasia has not been reported, radiofrequency-induced hyperthermia could be useful for treatment of horses with genital neoplasia. Intratumoral hyperthermia is induced by a radiofrequency current of 2 MHz. Using this treatment, the tumor is heated to approximately 50° C for 30 seconds. Large tumors are heated in sections. Multiple treatments are required, but the length of the interval between treatments is determined subjectively.

Prognosis

In one study of 48 male horses with genital carcinoma, 64.5% of horses were alive 18 months after surgical therapy.[89] In another study, about 81% of 45 affected horses survived at least 1 year after surgical therapy with no evidence of recurrence of the disease.[90] Both studies found that prognosis for survival was poor if squamous cell carcinoma had metastasized to the inguinal lymph nodes.[89] Invasion of the cavernous tissue by squamous cell carcinoma is a pejorative prognostic factor for survival in men[109] and is likely to be so in horses as well, because neoplastic invasion into a corporeal body may be more likely to result in hematogenous spread of the neoplasm. In one study, three of four horses that had metastases of penile carcinoma to the abdomen had gross or histologic evidence that the neoplasm had invaded the cavernous tissue.[90] Horses that have corporeal invasion by a carcinoma seem to have a high likelihood of abdominal metastases, and therefore laparoscopic examination of the abdomen of a horse that has neoplastic invasion of a corporeal body may be prudent. Invasion of the CSP by a carcinoma may result in stricture of the urethra.[110] Because lesions of squamous cell carcinoma sometimes recur, horses should be monitored periodically for recurrence of disease after apparently successful treatment.

Habronemiasis

Etiology

Cutaneous habronemiasis, also known as "summer sore" or granular dermatitis, is a granulomatous, mildly pruritic disease caused by cutaneous migration and encystment of the larvae of the equine stomach worm *Habronema*.[94,111] Larvae passed in the feces are ingested by fly maggots, and after the maggot pupates, the larvae are deposited on wounds from the feeding fly. The disease appears in spring and summer, when flies are prevalent, and usually disappears with onset of cold weather. The penis and prepuce are common sites of infestation by these larvae because moisture on these structures attracts flies. Horses that tend to protrude their penis while resting and horses that receive anthelmintic drugs infrequently may be more prone to developing genital habronemiasis.[111]

Pathophysiology

Infestation stimulates an acute granulomatous reaction characterized by exuberant granulation tissue that contains numerous small, yellow, hard, caseous granules composed of eosinophils, nuclear remnants, and larvae. The larvae may excrete a substance lytic to the host's tissue,[94] but a local hypersensitivity reaction to the larvae resulting from repeated reinfestation is probably responsible for the extreme granulomatous response.[111] The presence of mature *Habronema* in the stomach may induce a state of general hypersensitivity, because horses affected by cutaneous habronemiasis are almost always heavily parasitized by adult worms. Some horses appear to be more susceptible and are plagued by yearly recurrence of lesions.

Clinical Signs

The preputial ring and urethral process are the genital sites of predilection. Preputial lesions may appear as ulcerated, red areas demarcated by edges of depigmentation.[94] Lesions may be granulomatous and extensive (Figure 60-15). The infested urethral process may be enlarged from periurethral fibrosis, and hyperemic prolapsed mucous membrane may protrude from the urethral orifice.[112] Preputial lesions may mechanically impede the telescoping action of the preputial laminae, and lesions of the urethral process may partially obstruct the flow of urine.[112] A horse with a distorted urethral process may spray itself or show signs of discomfort during urination. Erosions into the CSP may result in hemorrhage at the end of urination or ejaculation.[113] Horses with a genital lesion of cutaneous habronemiasis may have lesions of cutaneous habronemiasis elsewhere on the body.

Diagnosis

Cutaneous habronemiasis of the external genitalia is usually diagnosed by its typical appearance, but lesions can be confused with squamous cell carcinoma, exuberant granulation tissue, or

Figure 60-15. Massive granuloma on the internal preputial lamina caused by cutaneous habronemiasis. This mass was removed by segmental posthetomy.

phycomycosis.[111] A nonhealing, granulating wound accompanied by marked circulating eosinophilia is suggestive of the disease. Squeezing the lesion may cause granules to extrude, and occasionally a larva is found if exudate is squeezed onto a slide and examined microscopically. Eosinophils, multinucleated giant cells, granules, and, sometimes, cross sections of larvae can be seen by examining affected tissue histologically.[112,114]

Treatment

NONSURGICAL TREATMENT

Lesions are resolved by eliminating the larvae or by reducing the horse's hypersensitivity to them.[111] Ivermectin, administered orally at 200 µg/kg, or organophosphates administered topically, orally, or intravenously have been effective in destroying the larvae.[115] Prednisolone, administered orally at 1.5 mg/kg once a day for 10 to 14 days, or diethylcarbamazine, administered orally at 1.5 mg/kg twice a day for 7 to 14 days, has brought about resolution of lesions by diminishing the body's response to the larvae. Daily topical application of a cream containing an organophosphate, such as trichlorfon, and a corticosteroid, such as dexamethasone, may bring about resolution of small granulomatous lesions caused by cutaneous habronemiasis.

SURGICAL TREATMENT

Elliptical or circumferential resection of fibrotic areas of the internal lamina of the prepuce caused by chronic infestation may be required to restore normal preputial function, and amputation of an affected urethral process may be required to restore normal urination or to prevent hemospermia[112] (see "General Surgical Procedures," later).

Hemospermia

Etiology

Hemospermia, or blood in the ejaculate, is an important cause of infertility of stallions and has been attributed to bacterial urethritis occurring usually at the area of the ejaculatory ducts; habronemiasis or neoplasia of the urethral process; improperly fitted stallion rings; seminal vesiculitis; and trauma to the urethral process or glans penis.[26,116,117] Viral urethritis has been suspected, but not proved, to cause hemospermia.[118] Hemospermia has been reported to occur from urethral rents, the etiology of which is unknown.[119] The source of voluminous hemorrhage in the ejaculate is usually the CSP. Hemorrhage from the CSP typically occurs at the end of ejaculation when contraction of the bulbospongiosus muscle causes pressure within the CSP to increase from 17 to nearly 1000 mm Hg.[12]

Red blood cells in the ejaculate are associated with reduced fertility, even though seminal quality appears otherwise unaffected.[117] Red blood cells affect the integrity of the cellular membrane and the motility of spermatic cells.[120] Seminal quality is proportional to the degree of contamination. The condition may be more common in Quarter Horses,[121] and frequently bred stallions are more often affected.[117]

Diagnosis

Stallions affected by hemospermia may require several mounts to ejaculate and sometimes exhibit pain during erection or ejaculation.[121] Blood in the semen is most easily identified by collecting the stallion's ejaculate with an artificial vagina. Semen of affected horses is usually pink to red, but because blood in amounts too minute to be detected grossly can cause infertility, microscopic examination of the semen may be necessary to detect the condition.[23] Microscopic examination of semen may also reveal a large number of white blood cells if septic seminal vesiculitis is the cause of hemospermia.

Septic seminal vesiculitis, an occasional cause of hemospermia, may be detected by identifying numerous clumps of purulent material in the semen and by finding blood in the gel fraction of the ejaculate.[122] A thickened vesicle filled with echogenic fluid may be seen during transrectal ultrasonographic examination of a septic seminal vesicle. The causative organism of septic seminal vesiculitis can be cultured from fluid obtained directly from the infected seminal vesicle.[122,123]

Rents in the urethra, a common cause of hemospermia, can be detected by examining the urethra with a sterilized flexible endoscope that is at least 100 cm long. A urethral tear into the CSP appears endoscopically as a 5- to 10-mm-long, linear defect on the convex surface of the urethra, distal to the openings of the bulbourethral glands, near the level of the ischial arch.[119,121] The shaft of a hypodermic needle can be introduced percutaneously into the lumen of the urethra at the level of the ischial arch during endoscopic examination to confirm the location of the defect (Figure 60-16). By endoscopically examining the urethra of a horse affected with hemospermia immediately after ejaculation, the examiner may be able to observe blood emanating from an otherwise undetectable rent.[23]

Urethrography to diagnose urethral lesions has been described.[117,118] The penis is radiographed after injecting 180 mL of barium suspension into the urethra. The barium is allowed to drain, 180 mL of air is injected to provide double contrast, and the penis is again radiographed. Bacterial and viral cultures and biopsy and histologic examination of urethral lesions may establish the cause of urethritis.

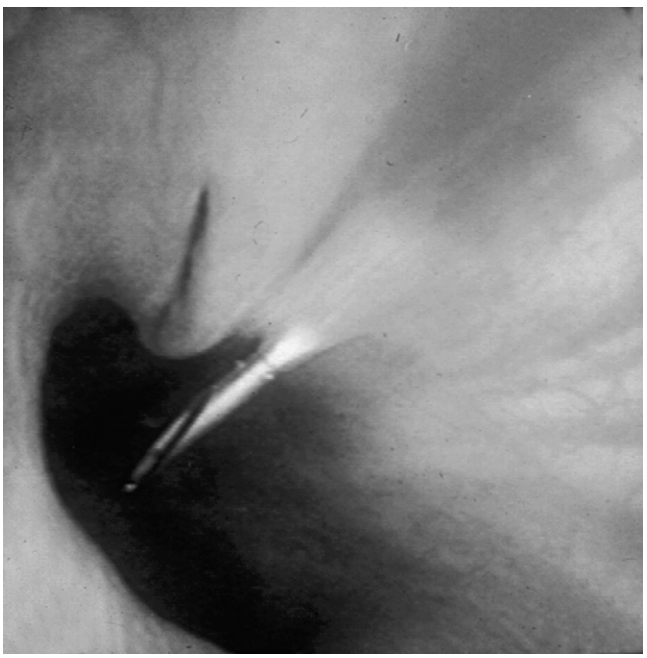

Figure 60-16. Endoscopic view of a urethral rent. The shaft of a hypodermic needle has been inserted percutaneously into the lumen of the urethra at the level of the ischium to pinpoint the location of the defect.

Treatment

NONSURGICAL TREATMENT

Sexual abstinence seems to be important in the treatment of stallions affected with hemospermia, regardless of the origin, because erection and contractions of the bulbospongiosus muscle during ejaculation dilate and further traumatize the urethra.[117,121] Medical treatment of affected horses has included intravenous administration of formaldehyde solution, oral administration of methenamine, and systemic administration of antimicrobial drugs.[118]

Horses affected with hemospermia caused by septic seminal vesiculitis should receive antimicrobial therapy that is effective against the causative organism. Systemic administration of antimicrobial drugs to stallions affected with septic seminal vesiculitis is often ineffective because antimicrobial drugs diffuse poorly into the gland. Infusing the appropriate antimicrobial drug directly into the seminal vesicles after the vesicles have been lavaged may be a more effective treatment.[122] Horses with low-grade hemospermia have been managed by adding an extender to the semen to dilute the effect of the red blood cells on the spermatozoa,[116,124] but adding semen extender is probably ineffective because the deleterious effects occur as soon as blood contacts the spermatozoa.[120]

SURGICAL TREATMENT

Temporary perineal urethrostomy combined with sexual rest has been effective in eliminating hemospermia caused by a urethral lesion.[118,119,121] Eleven of 15 affected horses were successfully treated by temporary subischial urethrostomy and daily installation of suppositories of nitrofurazone and hydrocortisone into the urethra, although two stallions developed a urethral fistula.[121] These investigators offered no sound rationale for the relatively high incidence of success of temporary urethrostomy, but other investigators implied that topical application of antimicrobial drugs to lesions of bacterial urethritis is responsible for resolution of hemospermia.[117] More likely, success of temporary subischial urethrostomy in eliminating hemospermia should be attributed to decreased pressure in the CSP and diversion of blood flow from the urethral lesion. When the bladder has been emptied, the bulbospongiosus muscle contracts to expel urine that remains in the urethra. Incising the CSP at the ischium decreases the pressure gradient between the urethral lumen and the CSP at the end of urination and diverts blood flow from the urethral lesion to the temporary urethrostomy, thus permitting healing of the urethral mucosa and underlying tunica albuginea of the CSP (see "Hematuria," later). Simply incising the convex surface of the tunica albuginea of the CSP at the ischium, without exposing the lumen of the urethra, may be as effective as temporary urethrostomy for eliminating hemospermia, and the risk of the stallion developing a urethral fistula is eliminated. This theory, however, has not been clinically evaluated.

The urethral rent of one stallion, which failed to heal despite subjecting the stallion to prolonged periods of enforced sexual inactivity, healed after it was covered with buccal mucosal graft inserted through a temporary perineal urethrostomy, resolving the hemospermia.[125] The ventral portion of the perineal urethrostomy, below the graft was left unsutured. Whether the graft was accepted at the recipient site on the urethra was not reported.

A simpler method of effecting healing of a urethral rent is to suture the rent.[126] The urethral rent can be sutured through a perineal incision if perineal incision into the CSP or temporary perineal urethrostomy is unsuccessful in allowing the rent to heal by second intention. To prepare for primary closure of a urethral rent, an endoscope is inserted into the urethra so that the rent can be observed. Two 3.81-cm, 20-gauge needles are inserted through the skin of the perineum and advanced so that the shafts of the needles emerge in the urethral lumen at the proximal and distal ends of the rent. The perineum is incised as if a perineal urethrostomy was to be performed, but the incision extends only into the CSP and not through the urethral mucosa. The rent in the urethral mucosa is identified between the shafts of the needle and is closed, using endoscopic guidance, with 3-0 absorbable suture material using a simple-continuous suture pattern. The sutures should incorporate the tunica albuginea of the CSP. The perineal incision can be left open to heal by second intention, or it can be sutured in layers. Sutured layers should include the incisions into the tunica albuginea of the CSP, the bulbospongiosus muscle, subcutaneous tissue, and skin.

Hematuria

Etiology

Hematuria can originate from the kidney, ureter, bladder, urethra, or reproductive organs.[113,116] Causes of hematuria include renal, ureteral, vesicular, or urethral calculi; renal, and vesicular neoplasia; and pyelonephritis. Terminal hematuria (i.e., hematuria that occurs at the end of urination) is associated with a lesion located at the proximal portion of the urethra and the trigone of the bladder. Hematuria associated with a rent of unknown cause at the proximal portion of the urethra has been observed in geldings.[119] The urethral rent appears to be identical to that often seen in stallions with hemospermia (see "Hemospermia," earlier).

The cause of urethral rents is idiopathic, but the reason the rent occurs invariably at the level of the ischial arch may be explained by the anatomy of the urethra. The diameter of the urethral lumen is approximately 1 to 1.5 cm at the origin of the urethra.[4] The lumen dilates to 3.5 to 5 cm in the pelvic portion of the urethra (i.e., at the pars pelvina) and decreases dramatically in diameter to 1 to 1.5 cm where the urethra bends sharply as it crosses the ischial arch. The sharp turn and the narrowing of the urethral lumen in the area of the ischial arch may expose the convex surface of the urethra at the level of the ischial arch to hydrodynamic forces not encountered by other portions of the urethra.

Pathophysiology

Because urethral rents communicate with the CSP, hemorrhage through the rent into the urethral lumen was thought to occur when pressure within this cavernosal space increases at the end of urination when the bulbospongiosus muscle contracts to expel the last vestige of urine.[100] Research, however, showed that the rise in pressure within the CSP associated with contraction of the bulbospongiosus muscle is slight. Investigators theorized that the most likely explanation for terminal hemorrhage in horses with a urethral rent is that the intraluminal urethral pressure suddenly decreases at the end of urination while the pressure in the CSP remains high.[127]

Even though the lesion in stallions is identical in appearance to that responsible for hematuria of geldings, the lesion in

stallions rarely causes macroscopic hematuria.[113,119] The reason for the difference in clinical signs between stallions and geldings is probably that during urination, pressure within the CSP of geldings is nearly double that of stallions.[127] The CSP of geldings is not as well developed as that of stallions, and the difference in volume of the cavernosal space between geldings and stallions results in different pressures in the CSP at the end of urination.

Diagnosis

Blood in urine that results from a urethral rent is characteristically discharged at the end of urination (i.e., terminal hematuria).[119] Occasionally, a horse with a urethral rent shows signs of dysuria, such as tenesmus at the end of urination. Endoscopic examination of the urethra reveals a 5- to 10-mm linear urethral defect on the convex surface of the urethra, distal to the openings of the bulbourethral glands, near the level of the ischial arch. Gross evidence of inflammation around the defect is not observed.

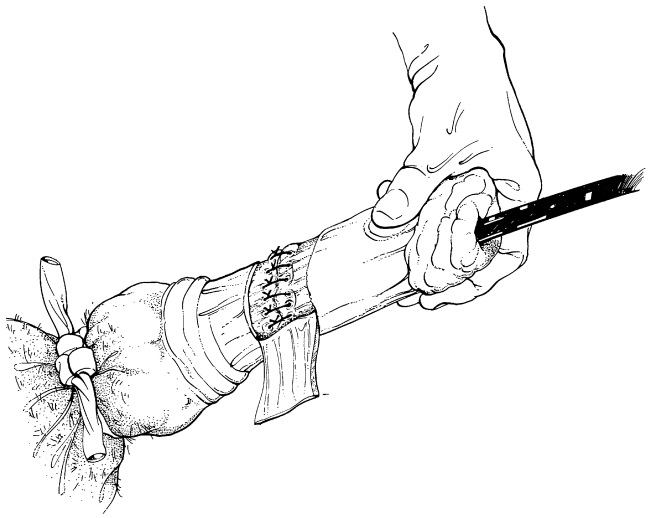

Figure 60-17. Segmental posthetomy. A cuff of epithelium is removed from the shaft of the penis.

Treatment

Some urethral rents heal spontaneously,[128] but horses with hematuria caused by a urethral rent can be treated successfully by temporary perineal urethrostomy (see "Temporary Perineal Urethrostomy," later, for a description of the surgical technique).[113,119,121] Surgery eliminates hematuria, presumably by reducing vascular pressure in the CSP, which prevents escape of blood through a rent at the end of urination, thereby allowing the rent to heal. A perineal incision that extends into the CSP but does not penetrate the urethra seems to be as effective as temporary urethrostomy in eliminating hematuria and may reduce the risk of complications associated with temporary urethrostomy, such as development of a urethral fistula[121] or stricture.[129] Although horses may bleed substantially from the perineal wound, especially at the end of urination, macroscopic hemorrhage from the urethral orifice and evidence of pain during urination are not observed after surgery.

GENERAL SURGICAL PROCEDURES

Segmental Posthetomy

Indications

Segmental posthetomy, or resection of a circumferential segment of the internal preputial lamina, is indicated for removal of preputial neoplasms, granulomas, or scars so extensive that simple excision of the lesion is impossible. Other terms for the procedure include *posthioplasty, circumcision,* and *reefing.*[130] Provided that the preputial lesions do not involve the underlying tunica albuginea, penile amputation can be avoided by segmental posthetomy. By removing most of the internal lamina of the prepuce, a paralyzed penis can be maintained permanently within the preputial cavity.[38]

Surgical Technique

Segmental posthetomy can be performed with the horse standing after anesthetizing the pudendal nerves (see "Diagnostic Procedures," earlier), but the procedure is most easily and safely accomplished with the horse anesthetized and positioned in dorsal or lateral recumbency. The urethra is catheterized, and the penis is extended by traction on gauze looped around the collum glandis. A tourniquet placed proximal to the surgical site may facilitate surgery. Parallel circumferential incisions through the preputial epithelium are created distal and proximal to the lesion, and these incisions are connected by a longitudinal incision (Figure 60-17). Care must be taken to avoid severing the large longitudinal subcutaneous branches of the external pudendal arteries and veins that lie superficial to the tunica albuginea.

When segmental posthetomy is performed to maintain a paralyzed penis within the external lamina of the prepuce (i.e., Adam's procedure), the distal circumferential incision should be made through the penile epithelium at the level where the internal preputial lamina inserts on the free body of the penis. The proximal circumferential incision should be made close to the preputial orifice.[38,131]

The cuff of integument between the incisions is dissected from the penis with scissors, taking care to avoid the large vessels. Normal alignment of tissue is maintained by placing four sutures at equidistant points around the circumference of the penis before the cuff of tissue is removed. The tourniquet is released, and all bleeding vessels are identified and ligated with absorbable sutures or cauterized. Loose adventitia is apposed with interrupted 2-0 absorbable sutures. The epithelium is apposed with interrupted 0 or 2-0 absorbable or nonabsorbable sutures.

When nearly all of the internal lamina is excised to permanently retain a paralyzed penis within the preputial cavity, the surgeon is faced with the difficult task of suturing a small distal circumferential incision to a much larger proximal circumferential incision.[38] To accomplish this, the length of the proximal circumferential incision can be decreased by removing two triangles of epithelium from the internal lamina proximal to the posthetomy, on each side of the penis. The triangles are about 3 cm wide and 4 cm long, and the base of each triangle is the circumferential incision. Suturing the sides of the triangles decreases the circumference of the proximal incision.

Aftercare

Stallions should wear a stallion ring for at least 2 weeks and must be isolated from mares for 2 to 4 weeks.[132] Regular exercise reduces postoperative edema. Nonabsorbable sutures should be removed 10 to 12 days postoperatively.

Bolz Technique of Phallopexy

Indication

The Bolz procedure is a technique used to permanently retract a paralyzed penis into the preputial cavity and is performed to avoid partial phallectomy.[41] This method of permanent retraction cannot be used if the penis or internal lamina of the prepuce is badly damaged or if the horse is still capable of attaining an erection. Damaged sections of prepuce, however, can be removed by segmental posthetomy during the same procedure.

Surgical Technique

The horse is anesthetized and positioned in dorsal recumbency. The urethra should be catheterized for easy identification. A 10-cm longitudinal incision is made on the perineal raphe just caudal to the scrotum (Figure 60-18, *A*), and the penis is bluntly separated from surrounding fascia, taking care to avoid damaging the surrounding large pudendal vessels (see Figure 60-18, *B*). The penis is retracted until the annular ring of the reflection of the internal preputial lamina onto the free body of the penis is visible at the cranial extent of the incision (see Figure 60-18, *C*). The penis is anchored in this position with two heavy, nonabsorbable percutaneous sutures through the annular ring on each side of the penis.

The anchoring sutures should penetrate the skin 2 to 4 cm from the incision at about the level of the middle of the incision. The sutures are inserted through the annular ring on the lateral surface of the penis, taking care to avoid entering the preputial cavity, the urethra, or cavernous tissue. An assistant should palpate the fornix of the preputial cavity during placement of the sutures through the annular ring to ensure that the sutures do not penetrate the preputial epithelium. The sutures exit the skin 2 to 3 cm from their entry points. They are tightened until the glans penis is flush with the preputial orifice and tied over rolls of gauze or large buttons to prevent the suture from cutting through the skin (see Figure 60-18, *D*). The subcutaneous tissue and skin are each closed separately.

The percutaneous anchoring sutures are removed after 10 to 12 days, at which time adhesions of sufficient strength to maintain the penis in its retracted position have formed. Necrosis of skin beneath the rolls of gauze is inevitable, but the technique allows adjustment of tension on the percutaneous sutures and repositioning of the penis. Precise positioning of the penis in the prepuce is important because, if the penis is inadequately retracted, the glans penis may protrude excessively through the preputial orifice, or if the penis is excessively retracted, the horse may develop urine scald from urinating in the preputial cavity. Two heavy absorbable sutures, substituted for the nonabsorbable percutaneous sutures, can be used to anchor the annular ring to the subcutaneous fascia.[133] Necrosis of skin is avoided, but the sutures cannot be adjusted after surgery.

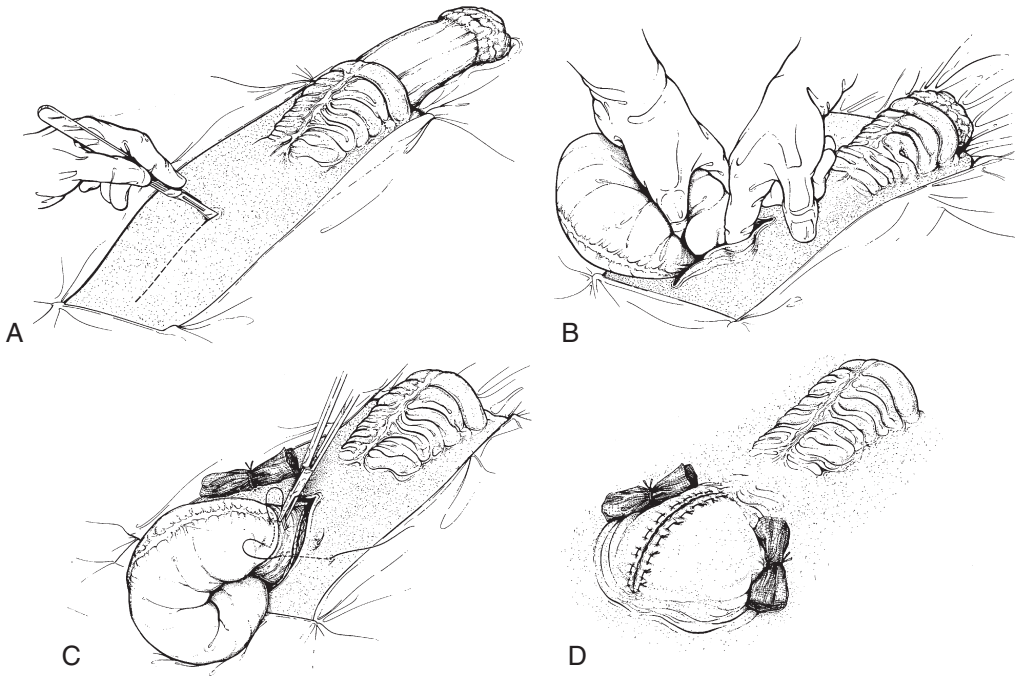

Figure 60-18. A, Bolz technique of phallopexy. A 10-cm incision is made on the perineal raphe just caudal to the scrotum. **B,** The penis is bluntly separated from surrounding fascia, taking care to avoid damaging the surrounding large pudendal vessels. **C,** The penis is retracted until the annular ring of the reflection of the internal preputial lamina onto the free body of the penis is visible at the cranial extent of the incision. The penis is fixed in this position with two heavy nonabsorbable percutaneous sutures through the annular ring on each side of the penis. **D,** The sutures are tightened until the glans penis is flush with the preputial orifice and are tied over rolls of gauze or large buttons to prevent the suture from cutting through the skin. The subcutaneous tissue and skin are closed separately.

Aftercare

The horse should be walked daily to minimize swelling, and heavy exercise can be resumed 2 to 3 weeks after the skin sutures have been removed. Retraction distorts the penis into a sigmoid curvature with acute bends, but penile blood supply and urination remain unaffected. The horse can be castrated during the same procedure, using either an inguinal or a scrotal approach, but the incision should be sutured because an open inguinal or scrotal wound may interfere with healing around the anchoring sutures. If the horse is castrated before the procedure and the scrotal wound is left unsutured to heal by secondary intention, the surgeon is confronted with the tedious task of caring for the protruded penis for several weeks while the scrotal incision heals.

Amputation of the Urethral Process

Indications

The urethral process is most commonly excised to remove a granuloma caused by cutaneous habronemiasis, when the affected horse fails to respond to medical therapy.[112] The urethral process is sometimes excised to remove a neoplastic lesion.[116]

Patient Preparation

The urethral process can be amputated with the horse standing and sedated after infiltrating the base of the urethral process with a local anesthetic agent, but the procedure is most easily and safely accomplished with the horse anesthetized and in dorsal recumbency.[112] The penis is prepared for aseptic surgery, and a urinary catheter is passed into the urethra. After placing traction on the urethral process with one or two Allis tissue forceps, two small-gauge needles (e.g., 23 or 25 gauge) are placed through the urethral process and the catheter at right angles to each other, proximal to the diseased portion of the urethral process (Figure 60-19). These needles anchor the urethral process to the catheter, making the incised margin of the process more stable and accessible for suturing.

Surgical Technique

A circumferential incision extending through the skin, CSP, and urethral mucosa is made around the base of the urethral process proximal to the affected tissue and distal to the anchoring hypodermic needles. The urethral mucosa is apposed to the epithelium of the remaining stump of the process with simple-interrupted or simple-continuous sutures of 4-0 or 5-0 absorbable suture.[116] The sutures should be closely spaced to compress the erectile tissue of the CSP. A simple-continuous suture pattern is probably more effective than a simple-interrupted one in compressing the erectile tissue of the CSP. The entire length of the process can be removed.

Aftercare

Stallions and recently castrated geldings should be isolated from mares for at least 3 weeks. Hemorrhage from the stump of the process, especially at the end of urination, should be expected for at least several days after the urethral process has been amputated. Fibrosis may occur at the site of amputation, and although this fibrous tissue may tear during copulation, it usually heals without complication.

Figure 60-19. This urethral process was amputated to eliminate hemospermia caused by carcinoma of the urethral mucosa. The urethral process was stretched with tissue forceps, and two small-gauge needles were placed through the urethral process and the catheter at right angles to each other, proximal to the diseased portion of the urethral process, to anchor the urethral process to the catheter.

Partial Phallectomy

Indications

Partial phallectomy is indicated when permanent penile paralysis is accompanied by irreparable penile damage, and more commonly, when neoplasia has invaded the tunica albuginea or is so extensive that more conservative treatment by cryosurgery, hyperthermia, local excision, or segmental posthetomy is impossible. For geldings, partial phallectomy may be the most expedient means of treating urethral stenosis distal to the preputial orifice. Partial phallectomy of stallions is generally performed to salvage the horse for purposes other than breeding, but amputation of just the glans penis may not interfere with copulation.[134]

Patient Preparation

If possible, a stallion should be castrated 3 to 4 weeks before partial phallectomy, to avoid postoperative erection, which leads to hemorrhage and suture dehiscence. The procedure can sometimes be performed with the horse standing and sedated after anesthetizing the pudendal nerves or performing a ring block proximal to the site of amputation (see "Diagnostic Procedures," earlier),[27,135] but the procedure is most easily performed with the horse anesthetized and positioned in lateral or, preferably, dorsal recumbency. The urethra is catheterized with an equine male urinary catheter, and the penis is extended with gauze looped around the collum glandis. A tourniquet placed proximal to the proposed site of transection facilitates surgery.

Surgical Techniques

VINSOT TECHNIQUE OF PARTIAL PHALLECTOMY

One of the simplest techniques of phallectomy is the Vinsot procedure.[46,136] A triangular section of tissue that includes

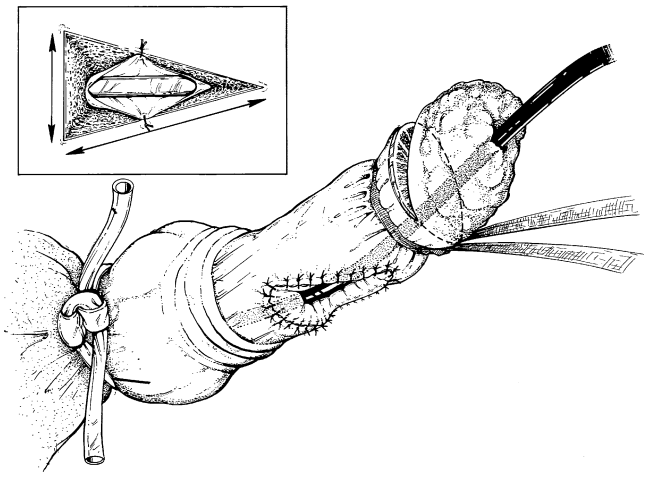

Figure 60-20. Vinsot technique of phallectomy. A triangular section of tissue is removed from the ventrum of the penis proximal to the proposed site of transection, taking care not to enter the urethral lumen. The exposed urethra is incised on its midline from the base to the apex of the triangle, and the incised edges of the urethra and the triangle's epithelial border are apposed with absorbable sutures in a simple-interrupted pattern. A nonabsorbable ligature is placed around the penis distal to the apex of the triangle, and the penis is severed distal to the ligature.

Figure 60-21. A bander castration device (Callicrate Bander) with a latex loop (ES-10) can be applied to the penis slightly proximal to the site of transection to prevent hemorrhage from the penile stump after partial phallectomy.

Figure 60-22. When performing a partial phallectomy using the Vinsot technique, the surgeon can leave the transected end of the penis unsutured to heal by secondary intention. To prevent hemorrhage from the corporeal bodies, a tightly fixed nonabsorbable ligature is placed around the penis 2 to 3 cm distal to the newly created stoma, before the penis is transversely severed 1 to 2 cm distal to the ligature. The ligature used to compress the stump of the penis of this horse was a latex loop applied with a bander castration device, both of which are shown in Figure 60-21.

epithelium, fascia, bulbospongiosus muscle, and CSP is removed from the ventrum of the penis proximal to the proposed site of transection, taking care not to enter the urethral lumen (Figure 60-20). The triangle has a 2.5-cm base and 4-cm sides. Its apex points distad and is located about 4 or 5 cm proximal to the proposed site of transection. The exposed urethra is incised on its midline from the base to the apex of the triangle, and the incised edges of the urethra and the triangle's epithelial border are apposed with simple-interrupted or simple-continuous absorbable sutures. The sutures should include the tunica albuginea of the CSP, and they should be closely spaced to compress the erectile tissue of the CSP. A simple-continuous suture pattern is probably more effective than a simple-interrupted one in compressing the erectile tissue of the CSP. The diseased portion of the penis is removed 4 to 5 cm distal to the urethrostomy using a wedge-shaped incision. Large vessels on the dorsal and lateral aspects of the tunica albuginea are ligated with absorbable suture material, and the corporeal bodies are compressed with absorbable sutures placed through the tunica albuginea in an everting or appositional pattern. The penile or preputial integument is sutured with absorbable or nonabsorbable sutures placed in an everting or appositional pattern.

Instead of suturing the end of the stump, the surgeon can leave it unsutured to heal by secondary intention. To prevent hemorrhage from the corporeal bodies, a tightly fixed, nonabsorbable ligature is placed around the penis 2 to 3 cm distal to the apex of the triangle, before the penis is transversely severed 1 to 2 cm distal to the ligature. A bander castration device (Callicrate Bander) with a latex loop (ES-10) is effective in maintaining continuous, maximal pressure on the stump of the penis to prevent hemorrhage from the corporeal tissue and the vasculature (Figures 60-21 and 60-22).[135]

Rather than removing a triangle of tissue overlying the urethra, the technique can be simplified by making a 4- to 5-cm longitudinal incision into the urethral lumen.[135,137] The incised edges of the urethra and the integument are apposed with simple-interrupted or simple-continuous absorbable sutures. These sutures incorporate and compress the cavernous tissue of the CSP. The Vinsot technique, especially its modification,[135,137] can often be performed with the horse standing. Primary disadvantages of the technique, or its modification, are the tendency of the urethra to stricture and the tendency for some horses to develop urine-induced contact dermatitis.[46,135]

WILLIAMS TECHNIQUE OF PARTIAL PHALLECTOMY

The likelihood of urethral stricture and urine-induced contact dermatitis is decreased when the Williams technique of partial phallectomy is employed.[134] With this technique, a triangle of tissue with similar dimensions to those described in the Vinsot technique is removed from the ventrum of the penis (Figure 60-23, *A*). The triangle's apex is directed proximad, rather than distad, and the base of the triangle is the site of penile transection. The urethra is split on its midline from the base to the apex of the triangle, and the incised edge of the urethra and the triangle's epithelial edge are apposed with 3-0 simple-interrupted or simple-continuous absorbable sutures. These sutures incorporate and compress the cavernous tissue of the CSP. A simple-continuous suture pattern is probably more

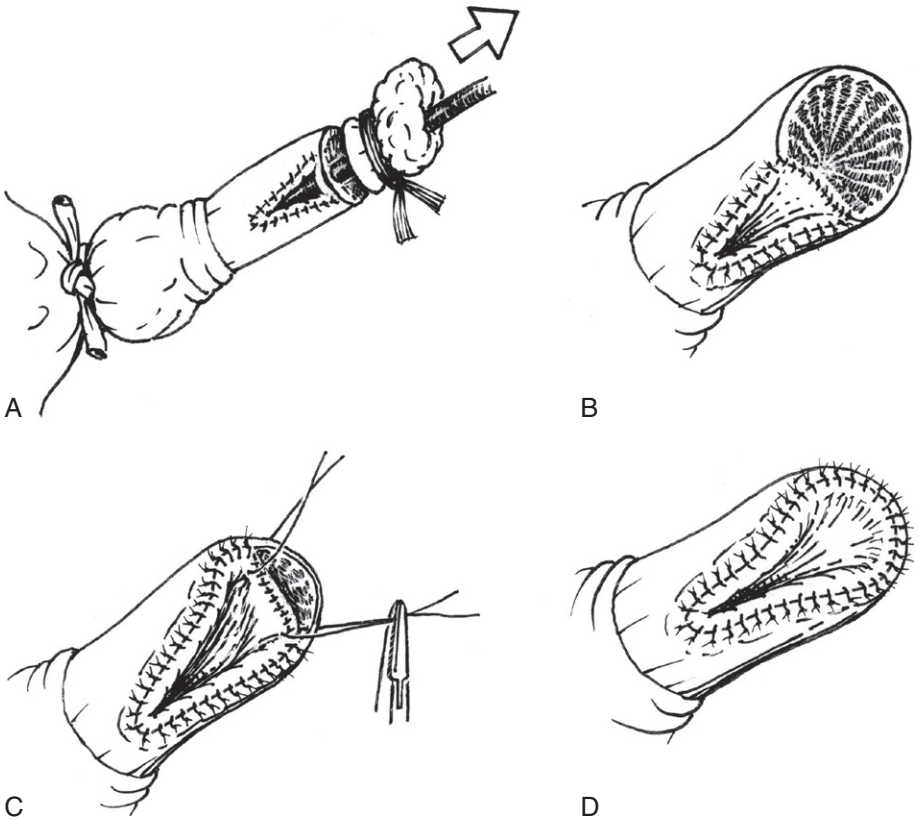

Figure 60-23. A, Williams technique of phallectomy. A triangle is removed from the ventrum of the penis. The triangle's apex is directed proximad. The urethra is split on its midline from the base to the apex of the triangle, and the edges of the urethra and the triangle's epithelial edges are apposed with simple-interrupted absorbable sutures. **B,** Before closing the stump, the transected edge of the CSP at the base of the triangle can be compressed with a simple-continuous absorbable suture line through the urethral mucosa and tunica albuginea. **C,** The stump is closed with interrupted sutures that pass through the urethra, the tunica albuginea of the urethral groove, and the tunica albuginea of the dorsum of the corpus cavernosum penis (CCP) and the penile or preputial epithelium. The sutures should be preplaced at equidistant intervals for an even closure. **D,** The sutures are tightened and tied, compressing the cavernous spaces; and the epithelium is apposed to the urethral mucosa.

effective than a simple-interrupted one in providing compression. The urethral catheter is removed, and the penis is obliquely transected at the base of the triangular urethrostomy in a craniodorsal direction, so that the dorsum of the penile stump is longer than the ventrum (see Figure 60-23, *B*). Large branches of the external pudendal vessels that reside in loose fascia on the dorsal and lateral aspects of the tunica albuginea are ligated with absorbable suture. The transected edge of the CSP at the base of the triangle can be compressed by placing a simple-interrupted or simple-continuous pattern of 3-0 absorbable sutures through the urethral mucosa and tunica albuginea at the base of the triangle.

The rest of the stump, including the CCP, is closed with interrupted absorbable or nonabsorbable sutures that pass through the urethra, the tunica albuginea of the urethral groove, and the tunica albuginea of the dorsum of the CCP and the penile or preputial epithelium (see Figure 60-23, *D*). The sutures should be preplaced at equidistant intervals for an even closure. When these sutures are tightened and tied, the erectile bodies are compressed, and the epithelium is apposed to the urethral mucosa (see Figure 60-23, *E*). Alternatively, after compressing the CSP at the base of the triangle, the stump can be closed by first suturing the urethral mucosa and tunica albuginea of the urethral groove to the tunica albuginea of the dorsum of the CCP with interrupted absorbable sutures placed at bisecting intervals. Then the penile or preputial integument is sutured to the urethral mucosa with interrupted absorbable or nonabsorbable sutures. Suturing the stump in this manner necessitates placing three rows of sutures through the urethral mucosa and CSP but ensures good compression of corporeal tissue.

SCOTT TECHNIQUE OF PARTIAL PHALLECTOMY

With this technique, a circumferential transverse incision through the epithelium of the body of the penis or prepuce is made at the intended site of transection, and branches of the external pudendal vessels are ligated.[95] Dissection is continued through the CCP to the urethral groove. The CSP is circumferentially incised to the urethra, which is easily identified by the urinary catheter in its lumen, and a 4- to 5-cm segment of urethra is dissected free from the amputated section of penis (Figure 60-24, *A*).

The stump of the CCP is closed by apposing the outer perimeter of its tunica albuginea to the tunica albuginea of the urethral groove with interrupted absorbable sutures preplaced at equidistant intervals (see Figure 60-24, *B*). The sinusoidal spaces of the CSP are closed by suturing the tunica albuginea surrounding the CSP to the submucosa of the urethra with interrupted or continuous absorbable sutures (see Figure 60-24, *C*). The urethral stump is divided into three equal triangular segments, with the apex of each triangle pointing distad. These

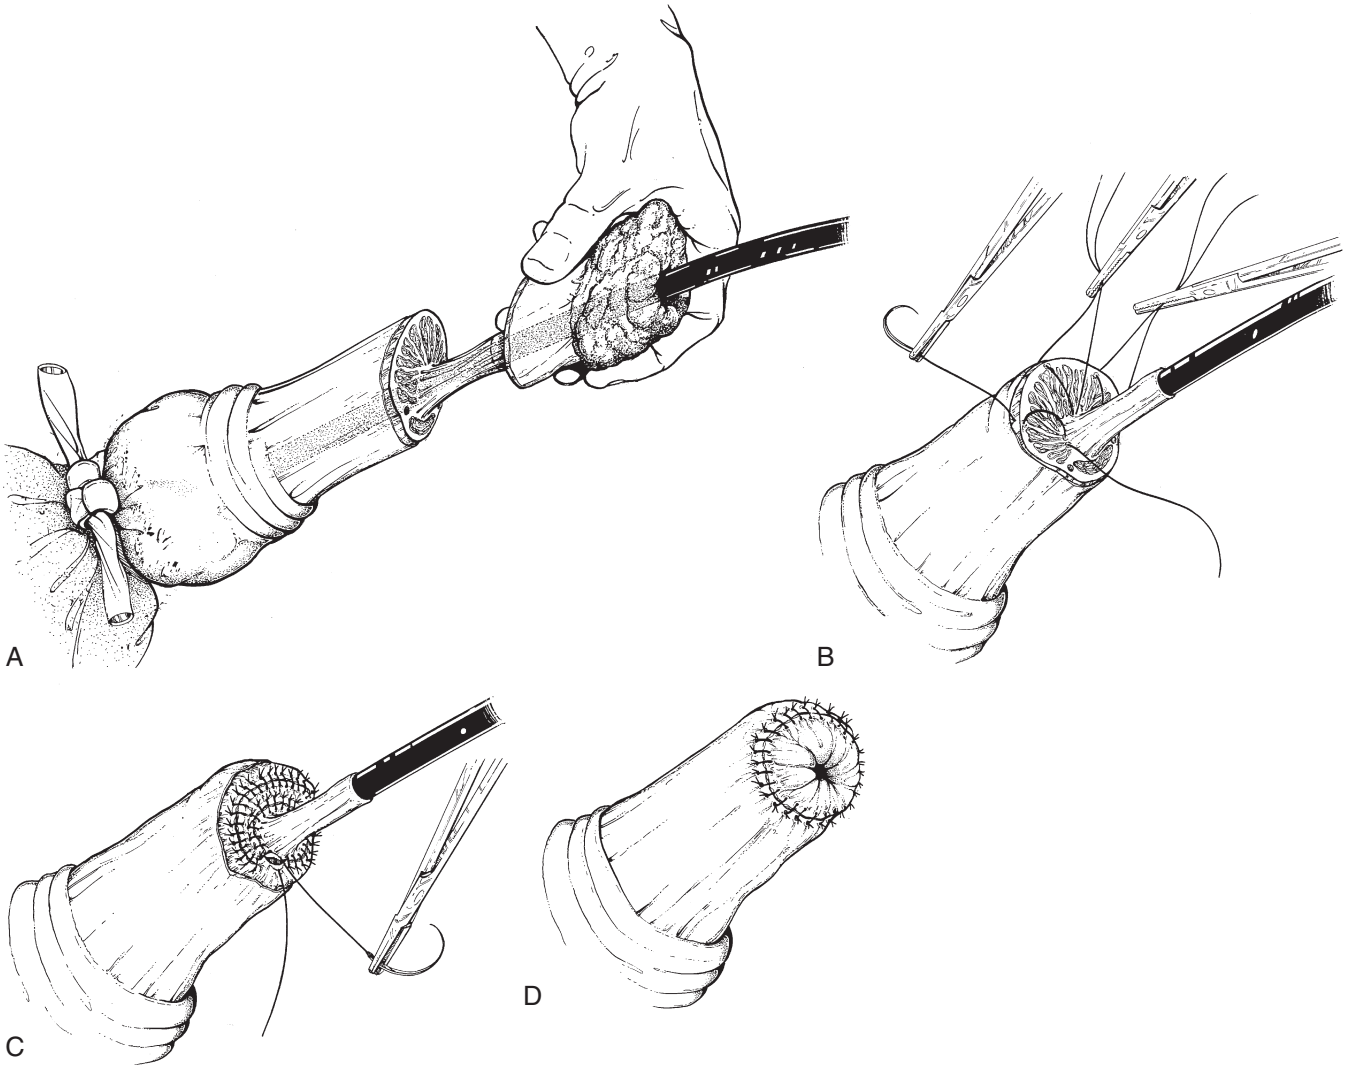

Figure 60-24. Scott technique of phallectomy. **A,** A circumferential transverse incision through the epithelium of the body of the penis or prepuce is made at the intended site of transection. Dissection is continued through the corpus cavernosum penis (CCP) to the urethral groove. The corpus spongiosum penis (CSP) is circumferentially incised to the urethra, and a 4- to 5-cm segment of urethra is dissected free from the amputated section of penis. **B,** The stump of the CCP is closed by apposing the outer perimeter of its tunica albuginea to the tunica albuginea of the urethral groove with interrupted absorbable sutures preplaced at equidistant intervals. **C,** The sinusoidal spaces of the CSP are closed by suturing the tunica albuginea surrounding the CSP to the submucosa of the urethra with interrupted or continuous absorbable sutures. **D,** The urethral stump is stretched and folded back over the end of the penis, where it is sutured to the penile or preputial epithelium and underlying tunica albuginea.

segments are intermeshed with similarly prepared segments of penile or preputial integument and are apposed with simple-interrupted absorbable or nonabsorbable sutures. Sutures should include underlying tunica albuginea. Instead of dividing the urethral stump into three triangles, the urethral stump can be stretched and folded back over the end of the penis, where it is sutured to the penile or preputial epithelium and underlying tunica albuginea (see Figure 60-24, *D*).

PARTIAL PHALLECTOMY BY *EN BLOC* RESECTION WITH PENILE RETROVERSION

Removal of the free portion of the penis, the internal lamina and external lamina of the prepuce, and regional lymph nodes may be indicated when these structures are extensively affected with neoplasia.[99] With this technique of partial phallectomy, a fusiform incision is created around the preputial orifice. The incision begins 6 cm cranial to the orifice and ends 10 cm caudal to it. The incision is carried to the deep fascia of the abdominal tunic, and if neoplasia has metastasized to the superficial lymph nodes, dissection is extended through this plane to both superficial inguinal rings, and the superficial inguinal lymph nodes are removed. The penis is amputated approximately 6 to 8 cm caudal to the fornix of the prepuce, and the amputated portion of the penis and the prepuce are removed *en bloc*. The penile shaft is amputated using a method similar to that described by Scott, so that 4 cm of urethra is left protruding from the penile stump[95] (Figure 60-25, *A*). The technique can be modified by amputating the penis using the Williams or Vinsot technique of partial phallectomy.[138]

By bluntly separating penile fascia, the stump of the penis is retroverted through a 6-cm subischial incision created approximately 20 cm ventral to the anus, so that its distal end points

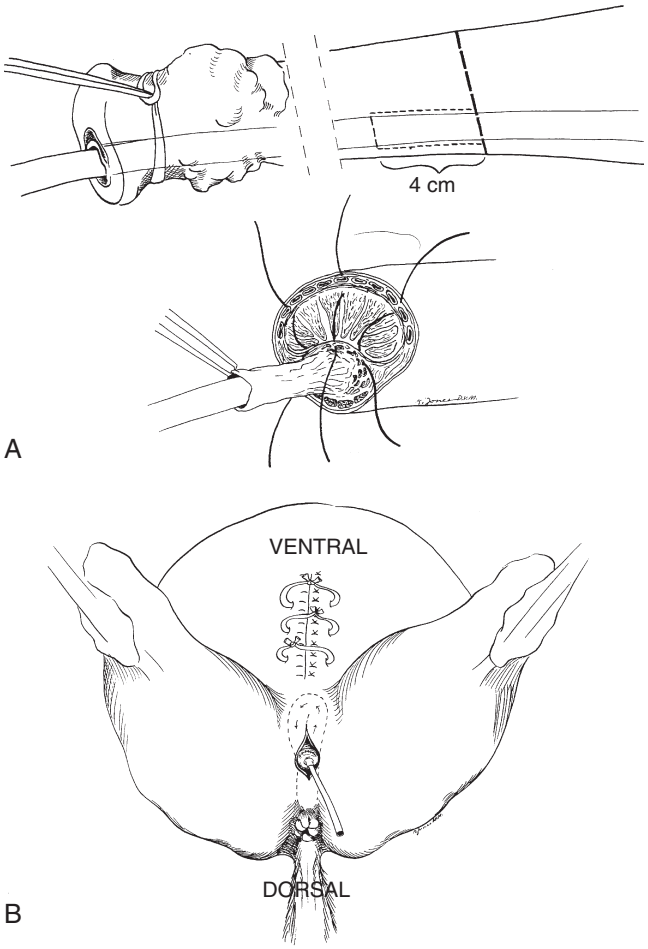

Figure 60-25. *En bloc* resection of the penis. **A,** Four centimeters of urethra is left beyond the penile stump. **B,** The position of the penile stump when retroverted is demonstrated. (From Markel MD, Wheat JD, Jones K: Genital neoplasms treated by *en bloc* resection and penile retroversion in horses: 10 cases 1977-1986. J Am Vet Med Assoc 192:396, 1988)

caudad and extends just beyond the subischial incision (see Figure 60-25, *B*). The tunica albuginea of the CCP and the fascia of the penis are sutured to the subcutaneous tissue of the subischial incision. The ventral aspect of the urethra is incised longitudinally over its 4-cm length, and the edges of the urethra are sutured to the surrounding edges of the incised subischial skin. Penrose drains are placed deeply at the cranial incision, and the subcutaneous tissue and skin are each closed separately.

PARTIAL PHALLECTOMY BY *EN BLOC* RESECTION WITHOUT PENILE RETROVERSION

This technique of phallectomy is similar in many respects to phallectomy by *en bloc* resection with penile retroversion, but with this technique, the stump of the penis is not retroverted but is maintained in its normal ventral position.[139] With this technique, a fusiform incision is created on the midline beginning at the umbilicus. The incision extends caudad on each side of the preputial orifice and continues on the midline to a point 10 cm caudal to the preputial orifice. The caudal portion of the incision is extended and deepened to expose and remove the inguinal lymph nodes, if neoplasia has metastasized to these structures.

Blunt dissection is continued into the loose areolar tissue of the prepuce, ligating large vessels as they are encountered. After the shaft of the penis is exposed, dissection is redirected along the shaft of the penis in a plane superficial to the loose subcutaneous tissue overlying the vasculature of the penis. At least 10 cm of the shaft should be exposed. A tourniquet is applied around the shaft of the penis proximal to the site of amputation. The dorsal arteries and veins of the penis are ligated and transfixed to the tunica albuginea. The penis is transected caudal to the fornix of the prepuce, using the method described by Williams.[134] After the tourniquet is removed, the stump is fixed to the body wall on the midline with heavy absorbable interrupted sutures. The subcutaneous tissue cranial to the penile stump surrounding the exposed penile shaft is apposed. Skin is sutured to the tunica albuginea and the urethral mucosa of the new urethral orifice. The skin cranial and caudal to the urethral orifice is sutured.

This technique of *en bloc* resection requires a smaller incision and results in less alteration to the appearance of the horse than does the retroversion technique, while still allowing the surgeon to remove extensive portions of the penis and extirpate the regional lymph nodes.[139]

Aftercare

Because the procedure is generally performed to salvage the horse for purposes other than breeding, stallions should be castrated several weeks in advance of partial phallectomy. Stallions and recently castrated geldings should be isolated from mares for 2 to 3 weeks and should wear a stallion ring on the penile stump during this time.

Complications

Hemorrhage from the penile stump, especially at the end of urination, should be expected for at least several days after partial phallectomy. Hemorrhage usually emanates from the CSP. Partial phallectomy of geldings is attended by less hemorrhage than partial phallectomy of stallions. Excessive hemorrhage may be caused by minor dehiscence, which is usually of no consequence. Dehiscence of sutured erectile tissue may lead to the formation of a large hematoma. Other complications of partial phallectomy in the immediate postoperative period include pain (which can be severe with *en bloc* resection), infection of the surgical wound, edema of the prepuce, and acute urinary obstruction caused by edema of the urethra.[89,90,99,139] Long-term complications include chronic recurrent cystitis, urine-induced dermatitis, dysuria caused by urethral stricture, recurrence of neoplasia at the site of amputation, and neoplastic metastases to inguinal lymph nodes and internal organs.

Temporary Perineal Urethrostomy

Indications

Temporary urethrostomy at the ischial arch is performed to provide access to small cystic calculi, to treat horses affected with hemospermia or hematuria, and to divert the flow of urine from the penile urethra for such conditions as urethral laceration or urethral urolithiasis.

Surgical Technique

Temporary perineal urethrostomy is best performed with the horse standing and sedated after administering epidural anesthesia or infiltrating the tissue at the proposed site of incision with a local anesthetic agent. A 6- to 8-cm vertical incision is created on the perineal raphe about 2 to 3 cm below the anus. The incision is extended through the skin, the retractor penis and bulbospongiosus muscles, the CSP, and the urethral mucosa (see Figure 60-2).

Preoperative insertion of a large-bore urethral catheter facilitates identification of the urethra. The perineal incision should "funnel" to a short urethral incision as it deepens to avoid postoperative pocketing of urine in the tissues. If the incision strays from the midline, profuse hemorrhage can result from laceration of branches of the external pudendal artery.[36] The urethrostomy is generally allowed to heal by secondary intention; development of clinically apparent urethral stenosis after this procedure is rare. The urethrostomy normally heals within 2 weeks.[127]

CHAPTER
61 Vulva, Vestibule, Vagina, and Cervix

J. Brett Woodie

The caudal aspect of the reproductive tract is composed of the vulva, vestibule, vagina, and cervix. These structures are susceptible to a variety of injuries during breeding and foaling. Conformational abnormalities of the caudal reproductive tract may predispose the mare to pneumovagina, pooling of urine, and other problems. Ultimately problems associated with the caudal reproductive tract can lead to infertility.

ANATOMY

The external genitalia of the mare are the perineum and the vulva. The perineum is defined as the region bound dorsally by the base of the tail, laterally by the semimembranosus muscles and sacrosciatic ligaments, and ventrally by the ventral commissure of the vulva (Figure 61-1).[1] The vulva includes the two labia and the clitoris. The external orifice of the vulva is typically 12 to 15 cm long.[2] The labia of the vulva in their normal position should be vertical and meet dorsally to form the dorsal commissure, which is located just ventral to the anus. The labia should meet ventrally to form the ventral commissure, which should be located caudal and ventral to the ischial arch. Approximately two thirds of the vulvar cleft should be ventral to the ischial arch.[3] Normally, the labia of the vulva are muscular and resist manual separation. The constrictor vulvae muscle lies deep to the skin of the labia. The internal pudendal vessels provide vascular supply to the vulva, its labia, and the clitoris. The pudendal and caudal rectal nerves provide motor innervation to the muscles of the vestibule and vulva.[4] These nerves also supply sensory fibers to the mucous membrane of the vulva and the skin of the labia.[4]

The fibromuscular perineal body lies between the anus and the vulva. The perineal body is formed by the fibers of the external anal sphincter and the constrictor vulvae muscles (Figure 61-2).

The clitoris is the homologue of the penis and is located at the ventral commissure of the vulvar labia. The clitoral glans is approximately 2.5 cm in diameter and contains erectile tissue similar to that of the corpus cavernosum penis. The clitoral fossa that surrounds the glans is located laterally and ventrally. The

body of the clitoris is approximately 5 cm in length and is attached to the ischial arch by two crura.[2]

The vestibule is the terminal part of the genital tract. It is a tubular structure approximately 12 to 15 cm long that connects the vulva to the vagina.[2] The normal configuration of the vestibule is a ventrodorsal slope oriented rostrad.[5] The cranial extent of the vestibule ends at the level of the transverse fold, which is located dorsal to the external urethral orifice. The lateral and ventral surface of the vestibule is covered by the constrictor vestibuli muscle.[1] Dorsally this muscle is incomplete. The constrictor vestibuli muscle blends caudally with the constrictor vulvae muscle. The constrictor vestibuli muscles, the pillars of the hymen, and the floor of the pelvis meet to form the vestibular sphincter.[6]

The vagina is a tubular structure extending craniad from the transverse fold of the external urethral orifice to the vaginal fornix around the cervix. The vagina is related to the rectum dorsally, the bladder and urethra ventrally, and the pelvic wall laterally. The majority of the vagina is located retroperitoneally but a small cranial portion of the ventral aspect and larger portions of the dorsal aspect are always covered with peritoneum.[2] The extent that the cranial part of the vagina is covered with peritoneum is related inversely to the fullness of the rectum and bladder.[4] The vascular supply of the vagina is derived from the internal pudendal vessels. Since there is no skeletal muscle in the vagina, there is no motor innervation. There are multiple sympathetic ganglia in the vaginal wall.[7]

The cervix is an extension of the uterine body with the caudal portion positioned in the cranial aspect (fornix) of the vagina. The caudal portion of the cervix is referred to as the *external cervical os,* which is covered by vaginal mucosa. The cervix is a tubular muscular structure lined with mucosa that forms many longitudinal folds. It functions as a sphincter separating the caudal reproductive tract from the uterus.

There are essentially three protective barriers in the caudal reproductive tract. The constrictor vulvae muscles of the labia form the first barrier, the second is the vestibular sphincter, and the cervix is the third. When any of these barriers becomes incompetent, contamination of the reproductive tract may occur and result in infertility.

PATHOPHYSIOLOGY

Failure of the protective barriers in the caudal reproductive tract can be caused by numerous factors. Conformational abnormalities such as a flat croup, sunken anus, and underdeveloped vulvar labia predispose the mare to pneumovagina.[8] Poor perineal conformation is often found in older multiparous mares that have a thin body condition.

A large percentage of the injuries to the caudal reproductive tract occur secondary to trauma from breeding or foaling. Some of the injuries are readily apparent immediately after delivery, whereas others can go unnoticed until it is time to rebreed the mare. Injuries that occur during foaling include cervical lacerations, cervical contusions, perineal lacerations, rectovestibular fistulas, urinary bladder eversion or prolapse, urinary bladder rupture, vaginal contusions, vaginal lacerations, vestibular lacerations, and uterine prolapse or rupture.[9-11] These injuries range from minor to severe, and not all require intervention. However, extensive surgical repair may be necessary to restore normal anatomic function. Without repair of the injured tissue, infertility is often the result. A thorough examination is necessary to ensure that more than one anatomic structure does not require surgical intervention.

Injuries during breeding do not occur frequently but may require medical and/or surgical treatment.[12] Perforation of the vagina usually occurs during intromission and is typically located at the cranial aspect of the vagina adjacent to the cervix. Predisposing factors for this type of injury have been reported to represent an overly vigorous stallion or a large stallion breeding a small mare.[12] Depending on the location and depth of penetration, the peritoneal cavity may or may not be entered. Semen is not sterile, and peritonitis may develop secondary to ejaculation into the peritoneal cavity.[13,14] Eventration can occur through a tear in the vaginal wall.[15] The development of an abscess in the pelvic cavity may result from an injury that does not involve the peritoneal cavity.[16] Inadvertent entry of the stallion's penis into the mare's rectum during breeding can result in rectal injury or perforation. This type of accident is not common and has been associated with poor vulvar conformation, small vulvar opening after a Caslick procedure, and relaxed anal sphincter following palpation *per rectum.*[12]

DIAGNOSTIC PROCEDURES

Examination of the reproductive tract of the mare should progress from an external to an internal evaluation. A logical starting point is to visually evaluate the conformation of the perineum and vulva and examine the latter for evidence of discharge. The external genitalia should be examined for intersex conditions and diseases such as neoplasia. The conformation of the vulva is very important because this anatomic structure is the first line of defense in protecting the reproductive tract from contamination. The labia should be evaluated for symmetry, position, angle, and tone. Pascoe's Caslick Index is an objective scoring system that can be used to determine

the risk for ascending infection to the reproductive tract.[5] The length of the vulva (in centimeters) is multiplied by the angle of declination of the vulvar lips. Higher pregnancy rates have been reported in mares that had a Caslick Index of less than 150.[3]

The vestibule, vagina, and cervix should be examined digitally as well as visually using a speculum. Samples for endometrial biopsy, culture, and cytology should be taken. The reproductive tract should be assessed by palpation and ultrasonography *per rectum*.

Chemical Restraint

The majority of diagnostic and surgical procedures that are performed on the caudal reproductive tract of the mare are accomplished with chemical restraint of the standing mare. Chemical restraint is usually supplemented with local or regional anesthesia, or both, for surgical procedures. The drugs used for chemical restraint provide variable degrees of sedation and analgesia. A number of sedative-hypnotic, tranquilizing, and opioid agents are available for use in the horse (see Chapter 22). Selection is based on personal preference and the type of surgical procedure that is being performed. The use of drug combinations often optimizes restraint and analgesia as compared to the use of an individual drug.

Acetylpromazine, a phenothiazine tranquilizer, produces sedation without analgesia. The peak onset of sedation following intravenous administration (0.04 mg/kg) is at approximately 30 minutes and may last for 1 to 3 hours depending on dose and route of administration.[17] Because the phenothiazine tranquilizers do not produce analgesia, they should be used in combination with an analgesic agent if a surgical procedure is performed.

Xylazine and detomidine are the most commonly used sedative-hypnotic drugs for standing chemical restraint. These drugs produce varying degrees of sedation, muscle relaxation, analgesia, and ataxia depending on the dose administered. Both drugs induce diuresis, which may warrant placement of a urinary catheter.[18] Detomidine has a longer duration of action and greater potency compared to xylazine.[19] Each of these drugs can be used in combination with an opiate such as butorphanol. This typically produces more profound sedation and analgesia. Reduced doses for chemical restraint should be considered when working on draft breeds because the desired effect can be achieved at lower doses than those used in light breeds such as Thoroughbreds.[20]

Epidural Anesthesia

Epidural anesthesia is achieved by injecting the local anesthetic solution between the dura mater and the periosteum of the spinal canal, which blocks conduction in the caudal nerve roots. Caudal epidural anesthesia implies that sensory innervation is lost without affecting the motor control of the hind limbs. The tail should be tied overhead to support the horse if ataxia develops. The sacrocaudal or first intercaudal vertebral space is selected as the injection site for epidural anesthesia.[21] This location is found by grasping the tail and moving it up and down. The first articulation caudal to the sacrum is the first intercoccygeal space. The site should be clipped and aseptically prepared. The epidural anesthetic agent should be administered using aseptic technique. Various injection techniques and drug combinations can be used. The mare should be sedated and restrained in stocks during administration of epidural anesthesia. A small skin bleb of local anesthetic can be deposited at the proposed injection site to facilitate placement of the spinal needle. A 20-gauge, 7.5-cm (3-inch) spinal needle should be positioned just cranial to the dorsal spinous process of the second coccygeal vertebra. The needle is inserted through the skin at a 30-degree angle relative to the tail and inserted craniad. If bone is encountered, the needle should be redirected. Once the needle is placed, the stylet should be withdrawn and the hub of the needle is filled with the local anesthetic to be injected. If the needle is positioned in the epidural space, the fluid will be aspirated (hanging drop technique). Minimal resistance is encountered during epidural injection. Mares that have had previous epidural injections may develop fibrous scar tissue over the intercoccygeal space, making needle placement more difficult.[21] Following injection, the needle should be removed. Caution should be exercised during placement of the spinal needle because some mares kick during the procedure. An epidural catheter can be placed to facilitate readministration of anesthetic agents if needed during the surgery.[20] Loss of anal sphincter tone is common when epidural anesthesia is achieved.

The type of blockade (motor and/or sensory) and the duration of effect depend on the type of drug(s) and the volume that is administered. Local anesthetics should produce motor and sensory blockade, whereas only sensory innervation is lost with other drugs. A dosage of 5 to 7 mL of 2% lidocaine hydrochloride per 500 kg body weight should produce analgesia within 5 to 15 minutes, and the duration of analgesia should be 60 to 90 minutes.[21] The addition of 2% mepivacaine hydrochloride to the same dosage will produce analgesia in 10 to 30 minutes and last for 90 to 120 minutes.[21] However, ataxia is a complication when using local anesthetics.

Epidural administration of α_2-adrenergic receptor agonists such as xylazine will provide profound analgesia without the complication of ataxia.[22,23] The recommended dosage of xylazine is 0.17 mg/kg. The onset of action is 10 to 30 minutes and the duration of analgesia is 2.5 to 4 hours.[21] The xylazine should be diluted in saline to a total volume of 6 to 10 mL. Epidural administration of detomidine (30 to 60 µg/kg) provides analgesia for 2 to 3 hours but produces sedation and ataxia.[21,22] The combination of lidocaine (0.22 mg/kg) and xylazine (0.17 mg/kg) produces significantly longer analgesia (approximately 5 hours) with only mild ataxia when compared to either agent used alone.[23]

Ataxia and the potential for recumbency must be considered when determining which drug or combination of drugs and the dosage that is to administer.

Preparation of the Surgical Site and the Mare

The rectum should be evacuated before starting any surgical procedure on the caudal reproductive tract. The tail should be wrapped and secured so that it does not interfere during surgery; then the perineum and buttocks should be scrubbed with a nonirritating soap. A dilute antibacterial solution of 1% povidone-iodine (Betadine) can be used to cleanse the vestibule and vagina. All fluid should be removed from the vestibule and vagina before beginning surgery.

Tetanus prophylaxis should be administered if necessary. The use of perioperative antibiotics and anti-inflammatory drugs is

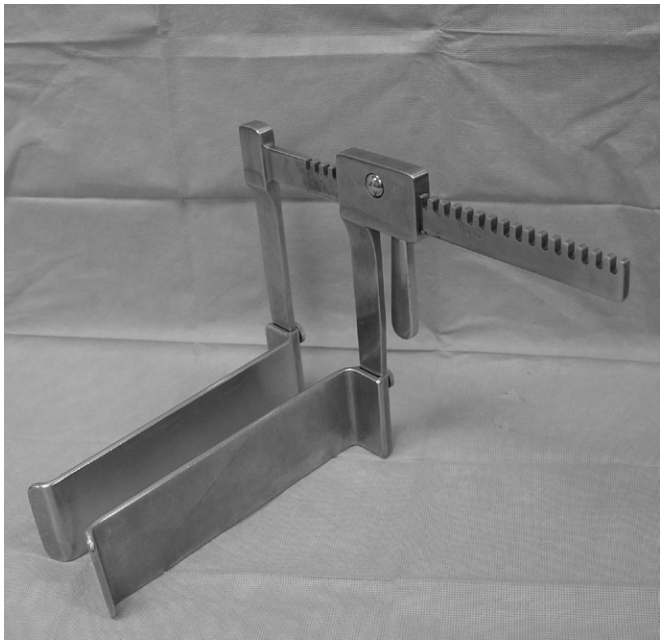

Figure 61-3. Modified Finochietto retractor with long blades. This retractor is very useful for certain surgical procedures of the caudal reproductive tract, such as repair of a cervical laceration.

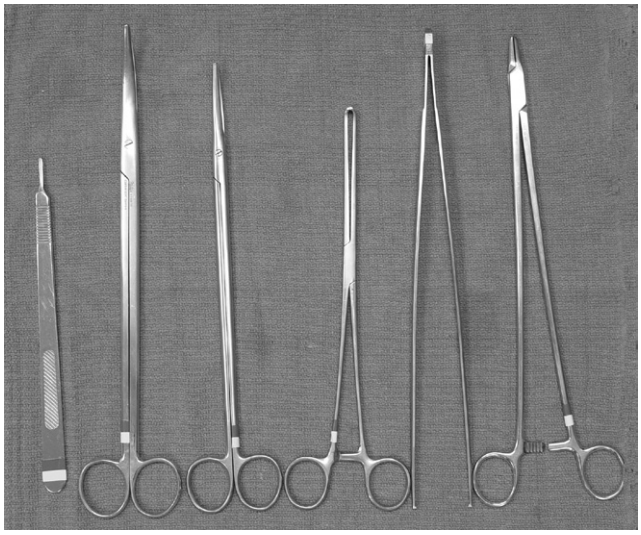

Figure 61-4. Long-handled surgical instruments.

at the discretion of the surgeon. The mare should be restrained in stocks, if available, but some procedures can be performed with the mare backed out of the stall door.

Instrumentation

Special instruments are needed to perform certain surgical procedures on the caudal reproductive tract. Illumination of the surgical field is crucial. Options include a light source that can be attached to the self-retaining retractor, a headlamp, or overhead surgical lights that can be adjusted. Retractors are needed to expose the surgical site. A modified Finochietto retractor with long blades (Figure 61-3) is very helpful in repairing cervical lacerations. Balfour retractors are useful for surgical procedures caudal to the vestibulovaginal junction. Positioning the retractor with the retaining mechanism dorsal to the anus and secured to the tail head using umbilical tape keeps the retractor in place and out of the surgical field. Handheld instruments need to be longer than conventional instruments (Figure 61-4). Scalpel handles, scissors, thumb forceps, Allis tissue forceps, and needle holders should be 25 to 30 cm in length.[24]

DISORDERS REQUIRING SURGERY

Pneumovagina

Pneumovagina leads to chronic inflammation and infection of the vagina and uterus. This is a cause of infertility in the mare. The most common cause of aspiration of air into the vagina is poor perineal conformation. Pneumovagina may develop secondary to foaling trauma with scar tissue formation, excessive stretching of the vulvar tissues from foaling, or poor body condition.[8] Sinking of the anus into the pelvic canal causes the dorsal commissure of the vulva to tip forward so that it is oriented horizontally rather than vertically. This can disrupt the vulvar seal and lead to pneumovagina as well as fecal contamination of the caudal reproductive tract. When manually separating the labia, an inrushing of air indicates a predisposition to pneumovagina. In some mares, pneumovagina only occurs during estrus when perineal tissues are more relaxed.[25] Urovagina can result from the same causes as pneumovagina, and the mare should be evaluated to determine if more than one surgical procedure is necessary.

Episioplasty

CASLICK PROCEDURE

The most common surgical procedure for correction of pneumovagina is the Caslick procedure.[6,16] The intent of the surgical procedure is to form a seal to prevent aspiration of air and fecal material. The original procedure was described by Caslick in 1937.[6] Dr. Caslick felt that introduction of air into the vagina during treatment of uterine infection exacerbated the problem. He observed a dramatic clinical improvement in uterine infections when local treatment was stopped and the dorsal half of the labia was temporarily closed. The procedure subsequently gained acceptance as treatment for pneumovagina.

Pneumovagina can be prevented in most cases by suturing the labia together to the level of the ventral border of the ischial arch. The ventral limit is determined by palpating the ischial arch just lateral to the opening of the vulva.[25] The mare should be sedated and restrained so that the clinician is protected from a kick injury. The perineum is prepared and local anesthetic is infiltrated into the labial margins extending from the ischial arch to the dorsal commissure. A 4- to 8-mm strip of mucosa is excised with scissors along the mucocutaneous junction on each labium (Figure 61-5). It is important to include the dorsal commissure of the vulva in the excision so that a seal at the dorsal aspect is achieved. A scalpel can be used to incise the labia at the mucocutaneous junction rather than excise any tissue. The incision must be of sufficient depth so that a tissue gap of 4 to 8 mm is created.

Closure is achieved using 2-0 absorbable or nonabsorbable suture material in a continuous pattern.[26] Stainless steel skin

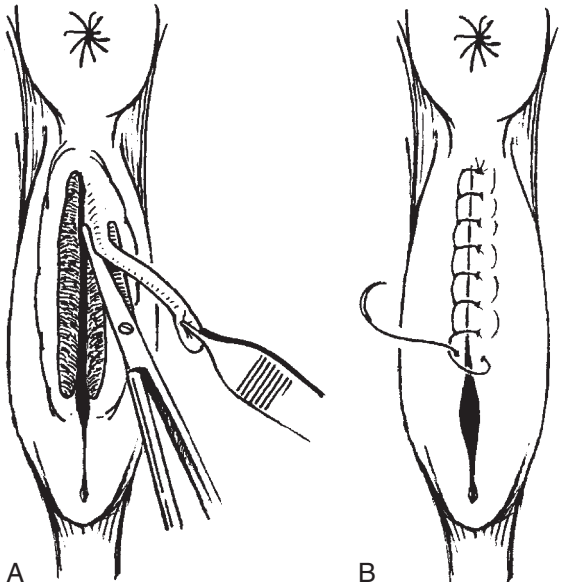

Figure 61-5. Caslick procedure. **A,** Removal of narrow strip of tissue from mucocutaneous junction. **B,** Closure using Ford interlocking pattern.

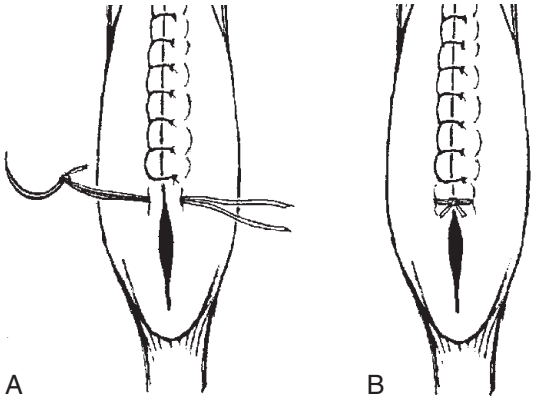

Figure 61-6. Breeding stitch placed ventral to a Caslick suture. **A,** Large suture material or umbilical tape is placed in a simple-interrupted pattern. **B,** The suture is tied and the ends are cut short so that they do not contact the stallion's penis during breeding.

staples can be used for the closure instead of sutures.[27] The sutures or staples should be removed 10 to 12 days later and the surgery site should be evaluated for fistula formation. Fistula formation can lead to aspiration of air and fecal material and negate the effects of the procedure.[28]

A mare requiring a Caslick procedure will likely need one for the rest of her broodmare life, so care should be taken to remove only as much tissue as necessary to achieve a complete seal between the labia.[25] Excessive removal of tissue will make subsequent Caslick procedures more difficult because of fibrosis and loss of tissue. Older mares that have had numerous Caslick procedures occasionally develop enough fibrous tissue or lose enough skin to make closure difficult as a result of tension. This may lead to dehiscence of a routine Caslick procedure. In such cases, a three-layer closure can be used. The inner mucosa of the two labia is apposed using 2-0 absorbable suture material in a continuous horizontal mattress pattern. The constrictor vulvae muscles are apposed using 2-0 absorbable suture material in a similar pattern. Finally the cutaneous layer is apposed using 2-0 or 0 absorbable or nonabsorbable suture material in a continuous pattern.

A breeding stitch is often placed at the ventral limits of the suture line to protect the Caslick procedure at subsequent breeding.[28] This consists of an interrupted suture of small-diameter, umbilical tape, or large-diameter suture material that is placed 2 to 3 cm lateral to both sides of the mucocutaneous border of the labia (Figure 61-6).[26] The suture must be positioned such that it does not interfere with the stallion's penis during intromission. Natural cover of the mare can be achieved with the suture in place by manually elevating the vulvar opening and guiding the stallion's penis. The breeding stitch is removed once the mare is confirmed to be pregnant.

Urovagina may result from excessive closure of the vulvar cleft.[29] Excessive closure is considered if a tube speculum cannot be readily passed.[28] Some mares have such poor perineal conformation that a Caslick procedure predisposes them to urovagina. In such cases, an alternative surgical procedure to correct the pneumovagina or a procedure to correct urovagina is necessary (see later).

In mares having undergone a Caslick procedure, an episiotomy should be performed 2 weeks before foaling to prevent damage to the vulva and perineum during the foaling process.

PERINEAL BODY RECONSTRUCTION

Reconstruction of the perineal body is useful when the vulvar and vestibular constrictor muscles have become ineffective.[25] Damage to the perineal body occurs from repeated stretching of these muscles in older multiparous mares, or from foaling trauma (second-degree rectovestibular injury). The goal of this surgery is restoration of the integrity of the dorsal aspect of the vestibule and vestibular sphincter function. Names of this surgical procedure include episioplasty, the Gadd technique, and perineal body reconstruction.[30] The surgery is performed with the mare sedated and restrained in stocks. Epidural anesthesia or local infiltration is used to desensitize the surgery site. The labia are retracted to the side using towel clamps or stay sutures. An incision is made along the mucocutaneous junction of the labia in a dorsoventral direction and is extended craniad along the dorsal commissure of the vestibule to the level of the vestibulovaginal sphincter. Dissection is continued submucosally from the dorsum and dorsolateral aspects of the vestibule. The triangular tissue flaps of mucosa are dissected so that they approximate the shape of the perineal body. Using caudal dorsal retraction on the stay sutures, the desired position for closure of the tissues is chosen (Figure 61-7). It is important that the procedure results in the vulva being oriented more vertically. Closure of the tissue layers is as follows. The vestibular mucosa is closed using 2-0 or 0 absorbable suture material in a horizontal mattress pattern, inverting the mucosa into the vestibule. The submucosal tissue is closed beginning at the cranial aspect of the vestibule using size 0 or 1 absorbable suture material in an interrupted pattern. The labial skin is apposed as for the Caslick procedure. Four weeks of sexual rest is recommended after surgery. Because the diameter of the vestibule has been decreased by this procedure, some mares require an episiotomy at the time of foaling.[31]

Perineal body reconstruction. **A,** The triangular piece of mucosa to be excised from the dorsal vestibule is outlined. **B,** The dorsal portion of the vulva and vestibule are retracted caudad and the vestibular mucosa is closed. **C,** Submucosal tissues are apposed with a series of interrupted absorbable sutures. **D,** The labial skin is closed with interrupted sutures and the vulva is now oriented in a more vertical position.

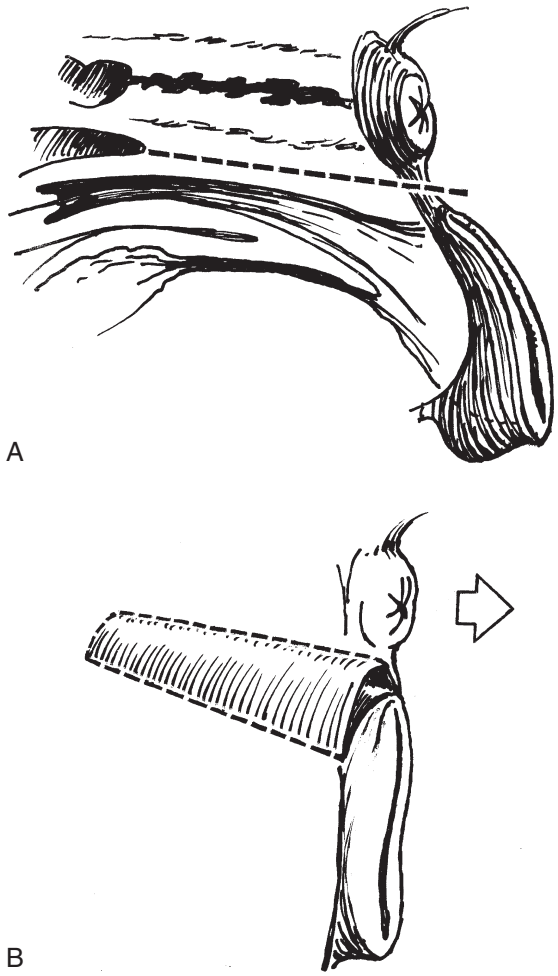

Figure 61-8. Perineal body transection. **A,** The *dotted line* shows the plane of dissection between the rectum and the caudal reproductive tract. **B,** Dissection is performed craniad using a combination of blunt and sharp separation of tissues until the vulva assumes a more vertical orientation.

PERINEAL BODY TRANSECTION

This technique was developed by Pouret and used to treat both pneumovagina and urovagina by the separation of muscular and ligamentous attachments between the rectum and the caudal reproductive tract.[32] The mare is sedated and restrained in stocks and epidural anesthesia or local infiltration of the perineal body is performed. A 4- to 6-cm horizontal skin incision is made midway between the ventral aspect of the anus and the dorsal commissure of the vulva. This incision is continued ventrad for 3 to 4 cm on both sides of the vulva. A combination of blunt and sharp dissection is used to extend the dissection in a cranial direction through the muscles of the perineal body. The dissection is continued craniad for 8 to 14 cm until the connections between the rectum and caudal reproductive tract have been severed.[30] Placing a hand in the vestibule to help guide the dissection is useful to prevent inadvertent entry into the rectum or peritoneal cavity. The dissection should be continued until the vulva has attained a normal vertical position without applying traction (Figure 61-8). No attempt is made to close the resulting dead space between the rectum and reproductive tract. Closure of the skin, either transversely or in a T-shaped configuration, has been suggested.[32,33] An alternative is to allow the wound to heal by second intention, which should occur within 3 weeks.[25] Natural cover should be delayed until the surgery site has healed properly (3 weeks). Mares may be bred by artificial insemination immediately.

Urovagina (Vesicovaginal Reflux of Urine, Urine Pooling)

Vesicovaginal reflux refers to the accumulation or pooling of urine in the vaginal fornix of the mare.[29] Urovagina and urine pooling are terms that have also been used to describe this condition. This abnormality is most often seen in thin, multiparous mares in which the cranial vagina slopes ventrally. Stretching and relaxation of the supporting ligaments of the urogenital tract leads to the excessive cranioventral sloping of the vagina. Mares often have a sunken appearance to their anus and dorsal vulva and frequently have had a Caslick procedure performed.[34] Excessive closure of the dorsal vulva during a Caslick procedure

may contribute to urine reflux by causing urine to splash back into the vagina.[35] In young fillies that are experiencing urovagina, an ectopic ureter may be present and must be ruled out.[29]

The chronic presence of urine in the cranial vagina leads to vaginitis, cervicitis, and endometritis. These inflammatory conditions can interfere with the ability of the mare to conceive and carry a foal to term.[36]

Urovagina is diagnosed by finding an accumulation of urine in the fornix of the vagina during vaginoscopy. It is best to perform a speculum examination of the vagina during estrus because in some mares urine only pools when the reproductive tract is under the influence of higher circulating levels of estrogen.[29] Examination of the mare on several occasions and finding urine in the cranial aspect of the vagina confirms the diagnosis. Differential diagnosis of urine pooling would be uterine infection with accumulation of exudate in the cranial vagina. Differentiation of the accumulated fluid using laboratory tests and cytology is often necessary. A cytologic evaluation of the fluid involves checking for bacteria, white blood cells, or calcium carbonate crystals. Creatinine and urea nitrogen testing can be performed on the fluid. Creatinine levels in accumulated urine will be at least two to three times serum creatinine levels.[29]

Surgical intervention is usually required for treatment of urine pooling.[35,37-39] Mares with poor body condition and the resulting abnormal perineal conformation can benefit from weight gain. Manual evacuation of urine from the cranial aspect of the vagina before breeding may improve conception rates, but this does not address the long-term negative side effects of urovagina. Definitive surgical treatment for vesicovaginal reflux involves modification of the external urethral orifice.

Caudal Relocation of the Transverse Fold

The Monin technique was first described in 1972 and involves caudal translocation of the transverse urethral fold.[39] This procedure has been found to be beneficial only if the reflux and abnormal perineal conformation is minimal.[29] It will not resolve severe vesicovaginal reflux and can make subsequent surgical procedures such as a urethral extension more difficult.

A Balfour retractor or stay sutures are used to access the transverse fold of the external urethral orifice (Figure 61-9). The center of the fold is grasped with Allis tissue forceps and retracted caudad toward the surgeon. The transverse fold is incised horizontally, splitting the fold into dorsal and ventral shelves. Thumb forceps are used to position the transverse fold along the ventrolateral walls of the vestibule. Mucosal incisions are then made in the walls of the vestibule at the proposed site of attachment. The transverse urethral fold is sutured to the vestibular floor in the retracted position, creating the extension. A one- or two-layer closure may be performed using 2-0 absorbable suture material.[39] This technique creates a urethral orifice that opens 2.5 to 5 cm more caudally after completion of the procedure. It is important to position the transverse fold so that it is not under excessive tension. This technique is simple to perform but it has the disadvantage of not being able to extend the urethral opening as far caudad as other urethral extension procedures (see later).[40]

Caudal Urethral Extension

Three urethral extension procedures have been described.[35,37,38] All of these procedures have the advantage of being able to extend the urethral opening as far caudad as necessary, unlike the Monin technique. A common pitfall of urethral extension procedures is fistula formation along the suture line.[40] In most instances, fistulas must be repaired. The surgeon should wait until tissue inflammation has subsided before attempting another repair (Figure 61-10).

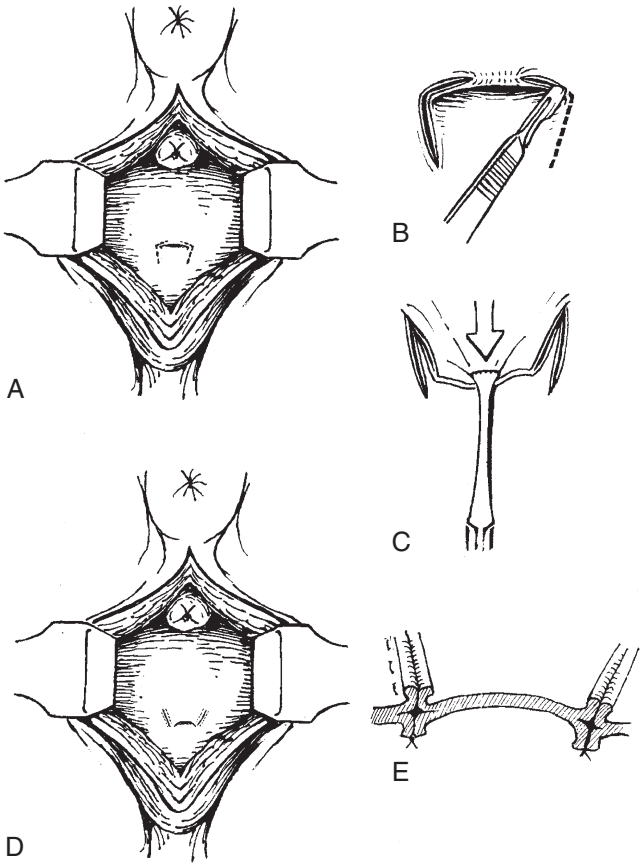

Figure 61-9. Monin urethroplasty. **A,** Incision of the transverse fold of the urethra. **B,** Mucosal incisions in walls of the vestibule. **C,** Caudal retraction of the transverse fold in preparation for suturing. **D,** Completed Monin urethroplasty. **E,** Two-layer closure using horizontal mattress pattern.

The mare should be sedated and restrained in stocks and should have epidural anesthesia to desensitize the perineum. Balfour retractors or stay sutures can be used to provide access to the surgical site. When self-retaining retractors are used, excessive lateral retraction should be avoided because this makes apposition of the vestibular mucosa more difficult. Insertion of a 30-French Foley catheter into the urethra will help ensure an adequate lumen diameter of the urethral extension and helps prevent urine contamination of the surgery site during the procedure.

BROWN TECHNIQUE

The original urethral extension procedure was described by Brown in 1978.[35] This technique involves creating tissue flaps beginning at the level of the transverse urethral fold and continuing to just inside the labia (Figure 61-11).[35] The free edge of the transverse urethral fold is incised horizontally with a scalpel, creating dorsal and ventral tissue flaps of equal thickness. It is important not to create holes in the flaps during the dissection.

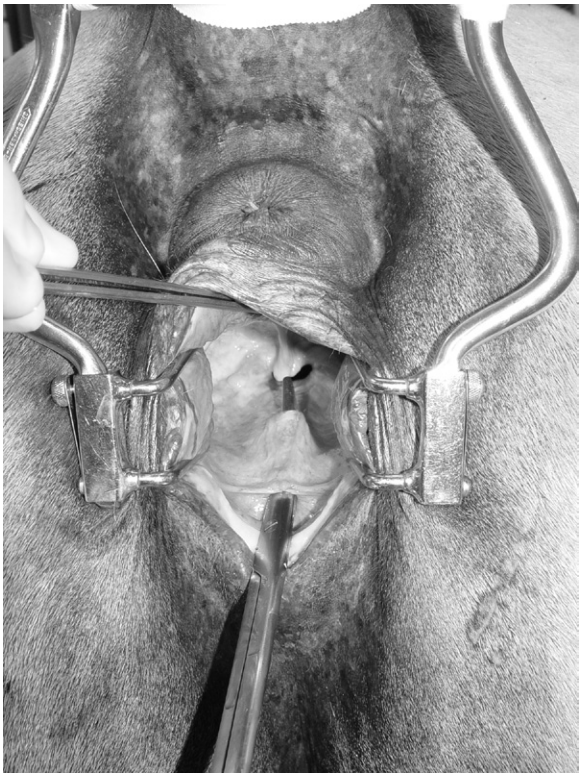

Figure 61-10. One complication of the caudal urethral extension procedures is fistula formation. Tips of scissors are sticking through the fistula.

The transverse incision is continued caudad along the vestibular wall to create a dorsal and ventral shelf of vestibular mucosa and submucosa. Dissection dorsad and ventrad allows the flaps to be apposed on the midline without any tension. It is critical that the dissection generates tissue flaps large enough to result in a urethral tunnel of adequate diameter. The ventral shelves of tissue from opposing sites are sutured using 2-0 absorbable material in continuous horizontal mattress pattern that inverts the mucosa of the ventral shelf into the new urethral lumen. The submucosa is closed using 2-0 absorbable suture material in a continuous pattern. The dorsal shelves are sutured using 2-0 absorbable suture material in a continuous horizontal mattress pattern that everts the mucosa into the vestibule. In the original description, this technique of resolving urine pooling was successful in 16 of 18 mares.[35] Following surgery, 11 mares were bred and 7 of them conceived.[35]

SHIRES TECHNIQUE

The Shires technique creates a urethral tunnel surrounded by loose mucosa from the floor of the vestibule around a Foley catheter placed in the bladder.[38] A 30-French Foley catheter is inserted through the urethral orifice into the bladder, and the balloon is inflated to secure the catheter (Figure 61-12). Interrupted horizontal mattress sutures using 2-0 or 0 absorbable suture material are placed in the ventral vestibular mucosa and tied so that a tunnel is formed over the catheter. The sutures must be positioned so that there is minimal tension on the mucosa over the catheter. The tunnel must begin cranial to the urethral orifice and extend caudad to a point approximately 2 to 3 cm cranial to the vulva. The everted ridges of mucosa dorsal to the horizontal mattress sutures are excised using scissors after

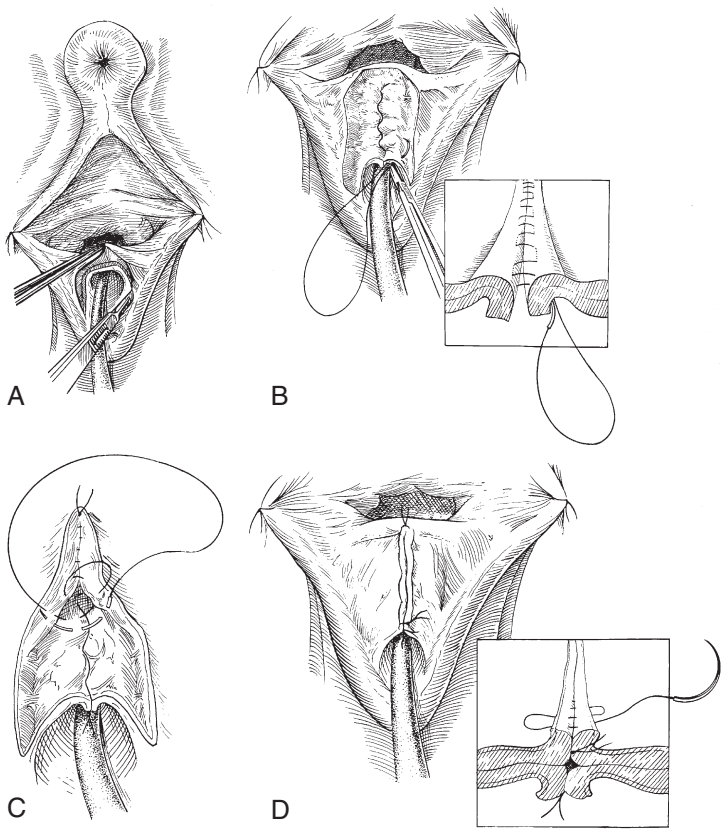

Figure 61-11. Brown technique of caudal urethral extension. **A,** The transverse fold is split into dorsal and ventral shelves, and the incisions are continued caudad along the ventrolateral walls of the vestibule. **B,** The first suture line inverts the vestibular mucosa into the new urethral lumen. **C,** The second suture line apposes the submucosal tissues. **D,** The third suture line everts the vestibular mucosa into the vestibule.

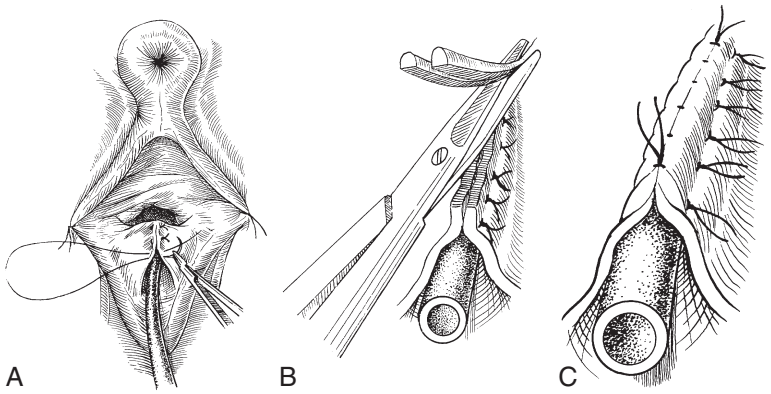

Figure 61-12. Shires technique of caudal urethral extension. **A,** Vestibular mucosa is apposed over a Foley catheter using horizontal mattress sutures. **B,** The everted mucosal ridge is excised. **C,** The exposed submucosa is apposed using a continuous suture pattern.

Figure 61-13. the completion of the tunnel. The cut edges of the mucosa are apposed using 2-0 suture absorbable suture material in a continuous pattern. This procedure is relatively easy to perform and was reported to be successful after a single surgery in 12 of 15 mares.[38]

MCKINNON TECHNIQUE

The McKinnon technique, described in 1988, creates a urethral tunnel that is larger and stronger than the one produced with the Brown and Shires techniques.[37] A horizontal incision is made in the mucosa of the transverse fold of the urethra 2 cm cranial to the caudal free edge (Figure 61-13). Incisions are made in the lateral walls of the vestibule approximately one half the distance from the floor of the vestibule. Dissection of the tissue flaps continues ventrad until the flaps can be apposed on the midline without tension. The tissue flaps are closed using a one-layer technique with 2-0 absorbable suture material in a continuous horizontal mattress pattern, inverting the mucosa into the lumen of the urethral tunnel. The initial dissection over the transverse urethral fold results in the cranial aspect of the closure assuming a Y pattern before the two suture lines meet on midline. Correction of urovagina using this technique was achieved in 32 of 34 mares, with fistula formation occurring in 5 of 34 mares.[37] Fistula formation is most common at the junction of the Y suture pattern. The exposed submucosal tissue heals by second intention. Mares may be bred 1 month postoperatively.

COMBINED BROWN AND MCKINNON TECHNIQUE

Combining the McKinnon and Brown techniques for urethral extension has been reported.[36] The initial dissection is similar to the Brown technique. The caudal free edge of the transverse

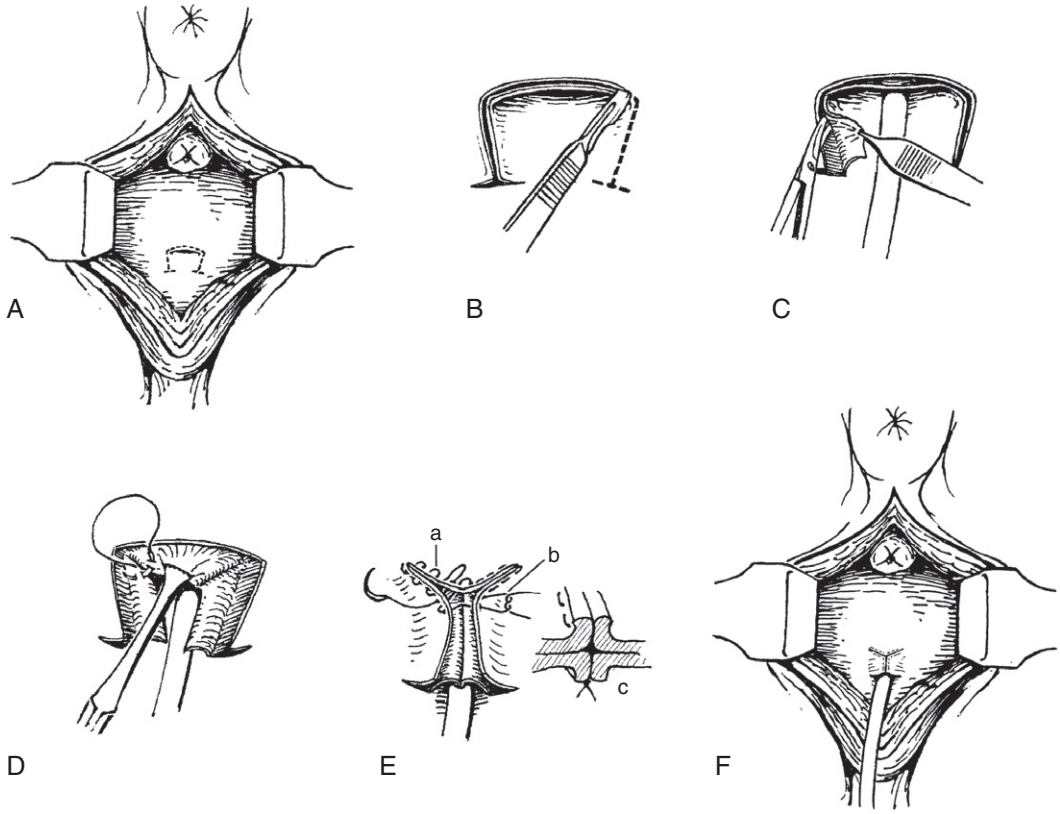

Figure 61-14. Combined Brown and McKinnon technique of caudal urethral extension. **A,** The scalpel is used to split the free edge of the transverse fold into dorsal and ventral shelves. **B** and **C,** Dorsal and ventral mucosal shelves are created by undermining the vestibular mucosa. The dissection should allow the shelves to meet on the midline without tension. **D,** The midpoint of the horizontal shelf is retracted caudad, and the ventral shelf is closed using a continuous horizontal mattress pattern to invert the tissue into the newly created urethral tunnel in a Y pattern. **E,** The dorsal shelves are sutured using a continuous horizontal mattress pattern to evert the tissue into the vestibule *(a)*. An additional continuous everting suture is placed around the three portions of the Y and tied at the end to provide further support to this very vulnerable location *(b)*. Close-up view of the new urethral shelf with the two everting patterns *(c)*. **F,** The completed urethral extension.

fold of the urethral orifice is incised into dorsal and ventral shelves of equal thickness (Figure 61-14). It is important that no holes are created in these tissue layers during dissection. The incisions are continued caudad along the ventrolateral walls of the vestibule to a point approximately 2 cm cranial to the labia. Submucosal dissection is performed to create dorsal and ventral vestibular tissue flaps that can be apposed on midline and create a urethral lumen of adequate diameter. A 30-French Foley catheter can be inserted into the bladder to help determine the location of the incisions and prevent urine contamination of the surgical field. The dissection of the vestibular walls does not reach as far dorsal as described for the McKinnon technique. Closure of the tissue flaps is as follows. The midpoint of the caudal free edge of the transverse urethral fold is grasped with Allis tissue forceps and retracted caudad. Suturing begins at the junction of the right ventral flap of the transverse fold and the right ventral flap of the vestibular wall. A continuous horizontal mattress pattern using 2-0 absorbable suture material is used. The mucosa of the ventral flaps should be inverted into the lumen of the urethral extension. During closure it is important to retract the transverse fold caudad. This suture pattern is continued caudad to the midpoint of the transverse fold, and the suture is tied. The right dorsal flap of the transverse fold and the right dorsal flap of the vestibular wall are sutured next, using a continuous horizontal mattress pattern of 2-0 absorbable suture material that everts the mucosa into the vestibule. The procedure is repeated for the left side. The remainder of the roof of the urethral tunnel is created by first suturing the right and left ventral vestibular tissue flaps, followed by suturing the dorsal flaps. The ventral flaps are apposed using 2-0 absorbable suture material in a continuous horizontal mattress pattern, which inverts the mucosa into the urethral lumen. The dorsal flaps are apposed using 2-0 absorbable suture material in a continuous horizontal mattress pattern, everting the mucosa into the vestibular lumen. The most difficult part of the repair is the junction of the Y of the three tissue layers—the transverse urethral fold and right and left vestibular tissue flaps. This location is most prone to dehiscence and fistula formation. A third layer using 2-0 absorbable sutures placed in a simple continuous pattern can be used starting just cranial to the Y junction and proceeding caudad. Maintaining a urinary catheter postoperatively for some time is based on the surgeon's preference (Figure 61-15).

Foaling Injuries

Numerous types of injuries are associated with parturition in the mare. Injuries caused by foaling and the resulting complications make up a large percentage of injuries to the perineum, rectum, and reproductive tract. Most injuries are obvious after

Figure. 61-15. Completed urethral extension described in Figure 61-15 with a urinary catheter in place.

Figure 61-16. Third-degree perineal laceration with fecal contamination of the vestibule. The vagina and uterus will be contaminated if the vestibulovaginal sphincter is dysfunctional.

foaling, but some are not apparent until it is time to rebreed the mare.

Perineal Lacerations

Perineal lacerations typically occur during unassisted foaling, most commonly in primiparous mares. These types of injuries are most likely caused by the prominence of the vestibulovaginal sphincter and hymen remnants in mares foaling for the first time.[41] It is hypothesized that the forefoot of the foal catches on the dorsal transverse fold of the vestibulovaginal junction, and the mare's abdominal press forces the foal's foot through the roof of the vestibule and into the mare's rectum. A rectovestibular fistula results if a foaling attendant is present to replace the foal's foot back into the vestibule or if the foal retracts its foot. However, if the foot remains in the rectum during foaling, a third-degree perineal laceration can result (see later).

Perineal lacerations have been classified into first, second, and third degree, based on the extent and severity of the injury.[11,42] *First-degree perineal lacerations* involve the mucosa of the vestibule and the skin of the dorsal commissure of the vulva. *Second-degree perineal lacerations* involve vestibular mucosa and submucosa and continue into the muscles of the perineal body, including the constrictor vulvae muscle. These injuries do not involve the anal sphincter or rectum. Second-degree lacerations compromise the closure of the labia, predisposing the mare to pneumovagina. *Third degree perineal lacerations* are complete disruptions of the rectovestibular shelf, penetrating the rectum, perineal body, and anal sphincter. These injuries result in a common opening between the rectum and vestibule (Figure 61-16) and occur in primiparous mares that often have an excitable temperament. Fetal malposition, large fetal size, or aggressive assistance during delivery may play a role in the development of a third-degree perineal laceration.

First-degree injuries typically do not require surgical intervention. If needed, a Caslick procedure can be performed. Repair of second-degree injuries requires a Caslick procedure and reconstruction of the perineal body. The mare will develop a sunken perineum and be predisposed to pneumovagina and urine pooling if the perineal body is not reconstructed.[43] All third-degree perineal lacerations require surgical repair. The management is divided into two categories: immediate treatment and surgical repair. Repair of a third-degree perineal laceration in the acute stage should not be attempted. The tissue is very edematous and contaminated with feces, and some tissues may not be viable. Repair should be delayed at least 3 to 4 weeks or longer if possible to allow healing of the injured tissues (Figure 61-17). Initial therapy involves wound care and cleaning of the contaminated tissues. Third-degree perineal lacerations result in bacterial contamination of the vagina and uterus. Inflammatory uterine changes are reversible after surgical repair. A uterine biopsy is not needed because there are no studies correlating preoperative uterine biopsy grades with conception data after surgery.

Dietary changes may be necessary so that the mare has soft feces without excessive water content. Many methods can be used to soften the feces. Pasturing the mare on lush green grass, administering laxatives such as mineral oil or magnesium sulfate via a nasogastric tube, and feeding wet bran mashes are just a few examples. Dietary changes should be instituted well before surgery so the fecal consistency is soft by the date of surgery. If the mare has firm formed feces, the surgery should be postponed, because dehiscence of the suture repair is likely. Often the surgery is delayed until the foal is weaned so that it does not have to enter the hospital environment; but the timing of the surgery may be dictated by an urgency to repair the injury and rebreed the mare.

Surgery is performed with the mare sedated and restrained in stocks. The use of epidural anesthesia is necessary. Following

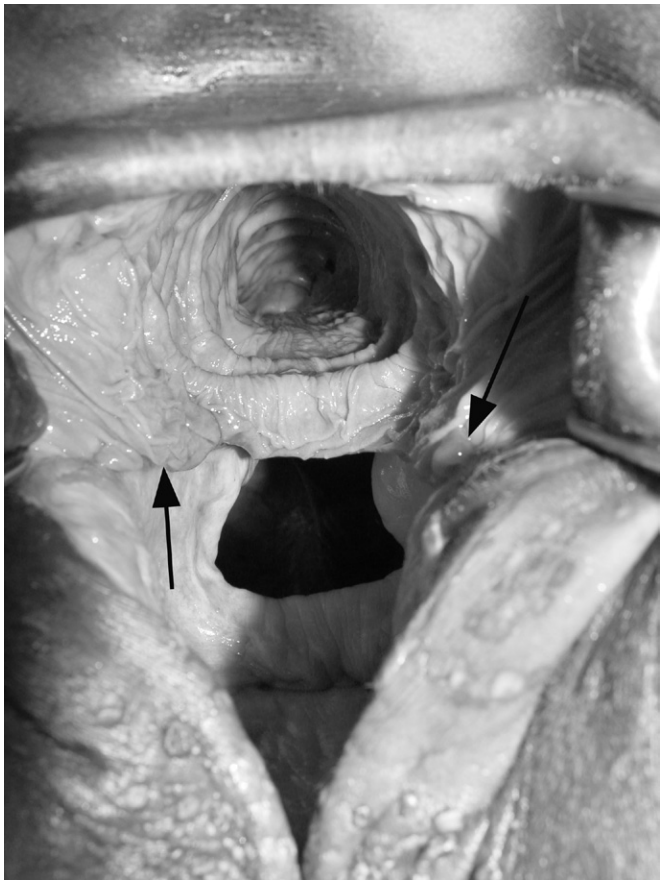

Figure 61-17. Appearance of a third-degree perineal laceration that is ready for repair. The rectal mucosa overhangs the intact shelf at the cranial extent of the laceration. *Arrows* point to the junction of the rectal mucosa and vestibular mucosa.

surgery the mare will need to maintain soft feces for at least 2 to 3 weeks.

TWO-STAGE REPAIR

The Aanes technique or a two-stage repair is designed to minimize obstipation, which can lead to failure of the repair.[42] In the first stage of the repair, the rectovestibular shelf is reconstructed without repair of the perineal body, and 3 to 4 weeks later the second stage or perineal body repair is performed.

Balfour retractors or stay sutures can be used to provide access to the surgical site. Initial dissection begins craniad in a frontal plane at the level of the rectovestibular shelf. Thumb forceps can be used to place tension on the rectovestibular shelf to facilitate dissection. A combination of sharp and blunt dissection is used to divide the tissue into rectal and vestibular shelves (Figure 61-18). The rectal shelf should comprise two thirds of the thickness and the vestibular shelf one third. The plane of dissection is continued craniad for 3 to 5 cm. The cranial dissection is important for relieving tension at the tissue edges. The incisions are continued laterad and caudad along the scar tissue junction of the rectal mucosa and vestibular mucosa. The dissection is continued laterad until the tissue shelves can be apposed on the midline without tension. Hemostasis using electrocautery or ligatures can be performed if necessary. Once sufficient dissection has been achieved, reconstruction of the tissue shelves can commence.

The first suture line apposes the vestibular shelves. A continuous horizontal mattress pattern of 1-0 or 2-0 absorbable suture material is used to invert the vestibular mucosa into the vestibule. This pattern should be interrupted when approximately one quarter to one half of the vestibular defect is closed. This allows easier access for placement of the second set of sutures. The next row of sutures is placed dorsal to the first in an interrupted fashion in the perirectal and perivestibular tissues. Then one or two absorbable sutures are placed in a four-bite purse-string fashion.[41] It is crucial that the rectal mucosa is not penetrated. The four-bite purse-string is placed by taking the first bite in the subrectal mucosal layer on the right; the second, in the subvestibular mucosal tissue on the right; the third, in the subvestibular tissue on the left; and the fourth, in the subrectal mucosal tissue on the left, followed by tying the knot. These two suture patterns are alternated until the level of the dorsal commissure of the vulva is reached. This technique does not repair the anal sphincter or perineal body. The second stage of the repair is performed 3 to 4 weeks later. It consists of removing the epithelium from the triangular surface of the perineal body and apposing these tissues on the midline (Figure 61-19), as described in the section on perineal body reconstruction. The function of the anal sphincter is gained by suturing the tissues of the perineal body. No attempt is made to isolate and suture the muscle fibers of the anal sphincter. A Caslick procedure is performed if necessary.

SINGLE-STAGE REPAIR

The initial dissection is the same in the single-stage and two-stage repair procedures. The Goetze modification of the single-stage repair uses a six-bite suture pattern (Figure 61-20). The suture is typically size 2-0 absorbable material and is placed in an interrupted pattern. The first suture is placed at the cranial edge of the dissected shelf and follows the following sequence. The first bite is deep in the left vestibular flap in a ventral to dorsal direction. The second bite is in the left rectal submucosa, taking care not to penetrate the rectal mucosa. The third bite is in the right rectal submucosa. The fourth bite is through the right vestibular flap in a dorsal to ventral direction. The fifth bite reenters the right vestibular shelf axial to the fourth bite in a ventral to dorsal direction. The sixth bite is in the left vestibular flap from dorsal to ventral and is positioned axial to the first bite. When the suture is tied the rectal edges should be apposed and the vestibular edges should be everted into the lumen of the vestibule. The sutures should be placed approximately 1.5 cm apart. Any sutures that are loose or placed too far apart should be replaced, because failure to do so will compromise the repair. Closure of the rectal mucosa has been proposed but is not necessary.[43] This repair is continued to a point approximately 4 to 6 cm cranial to the cutaneous perineum. At this point, the perineal body is repaired as previously described. A Caslick operation is performed if deemed necessary. The single-stage repair can be performed using the Aanes reconstruction technique as described for the two-stage repair. Another modification of the single-stage repair has been reported by Stickle; it involves a three-layer closure that includes a continuous horizontal mattress suture in the vestibular submucosa and rectal submucosa, inverting the mucosa into the respective lumen.[44] Simple-interrupted sutures are placed in the connective tissue shelf between the rectum and vestibule. All three sutures are started cranially and continue in an alternating fashion toward the vulva.

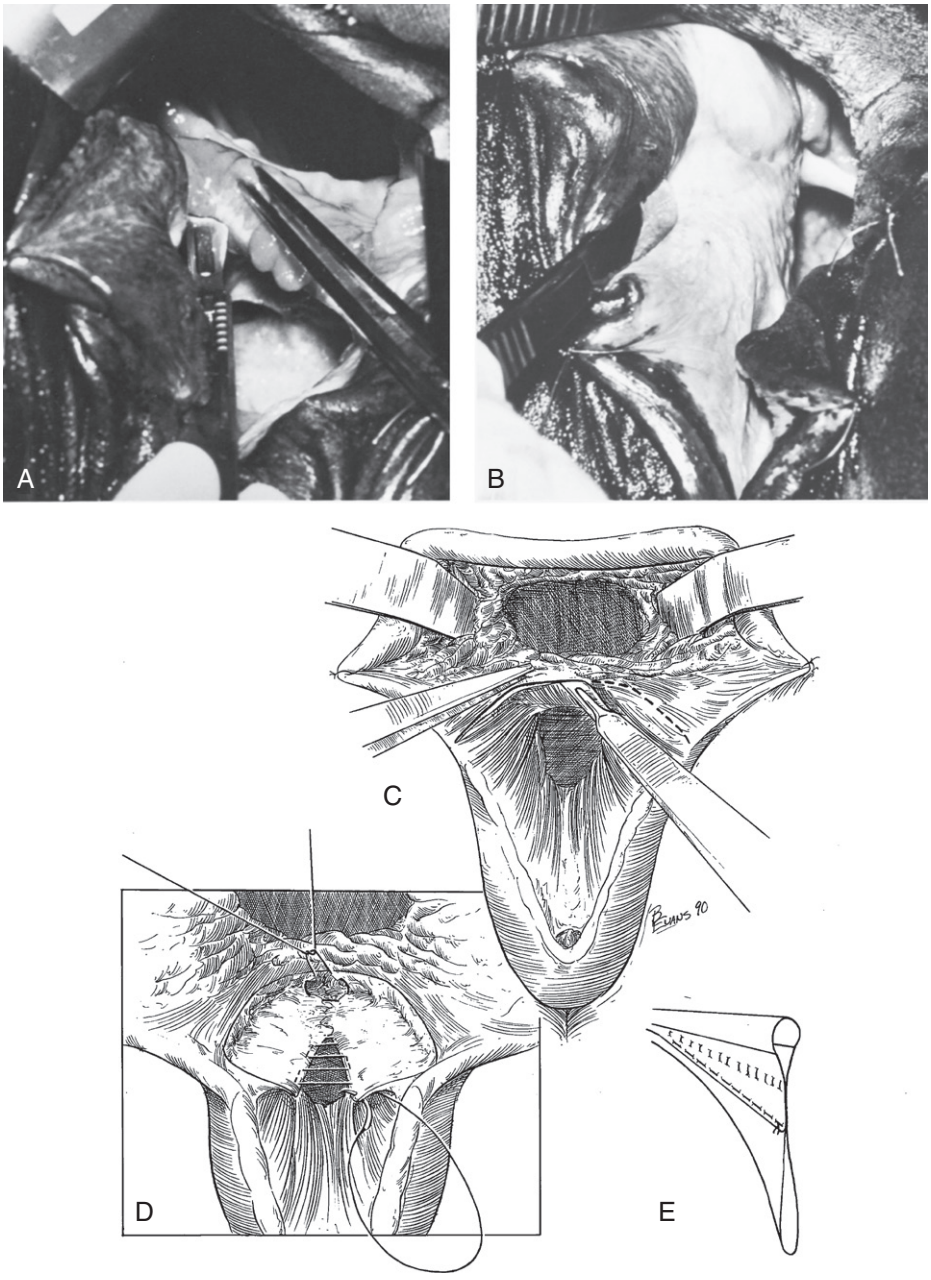

Figure 61-18. First stage of the two-stage repair of a third-degree perineal laceration. **A,** The cranial-most extent of the rectovestibular shelf is incised in a horizontal plane. **B,** The junction between the rectal mucosa and vestibular mucosa is delineated by a thin line of scar tissue. **C,** Vestibular and rectal tissue flaps are created by dissecting along the line of scar tissue. **D,** The vestibular mucosa is inverted into the vestibule using a continuous horizontal mattress pattern. The submucosal tissues are apposed using an interrupted pattern. **E,** Completed first-stage repair.

Rectovestibular Fistula

Rectovestibular fistulas result from a perineal laceration from the dorsum of the vestibule into the rectum, without disruption of the anal sphincter (Figure 61-21). They can form secondary to an unsuccessful repair of a third-degree rectovestibular laceration. Small fistulas sometimes close with conservative therapy, but larger ones require surgical repair.[40] Fistulas are most commonly 3 to 5 cm in diameter and located cranial to the perineal body.[43] Surgical approaches involve converting the fistula into a third degree perineal laceration either by a horizontal approach through the perineal body or a direct suturing technique.

When using the horizontal approach through the perineal body, a horizontal skin incision is made midway between the ventral aspect of the anus and the dorsal commissure of the vulva. A combination of blunt and sharp dissection is used to separate the perineal body. This plane of dissection is continued through the fistula for a distance of 3 cm (Figure 61-22, *A*). Stay sutures or Allis tissue forceps can be used to help retract the tissue during dissection. It is important not to penetrate the rectum or vestibule before reaching the fistula. The dissection should be such that the rectal shelf of tissue is thicker (two thirds of the thickness) than the vestibular shelf (one third of the thickness). The fistula in the rectal tissue is closed transversely using an interrupted Lembert pattern of 0 absorbable suture material (Figure 61-22, *B*). The fistula in the vestibular shelf is closed longitudinally in a continuous horizontal mattress pattern. This results in the suture lines that are at right angles to one another (Figure 61-22, *C* and *D*). The dead space created by the approach is closed using interrupted purse-string sutures. The skin is closed in continuous or interrupted pattern. An alternative is to allow the dead space and skin to heal by second intention.[11]

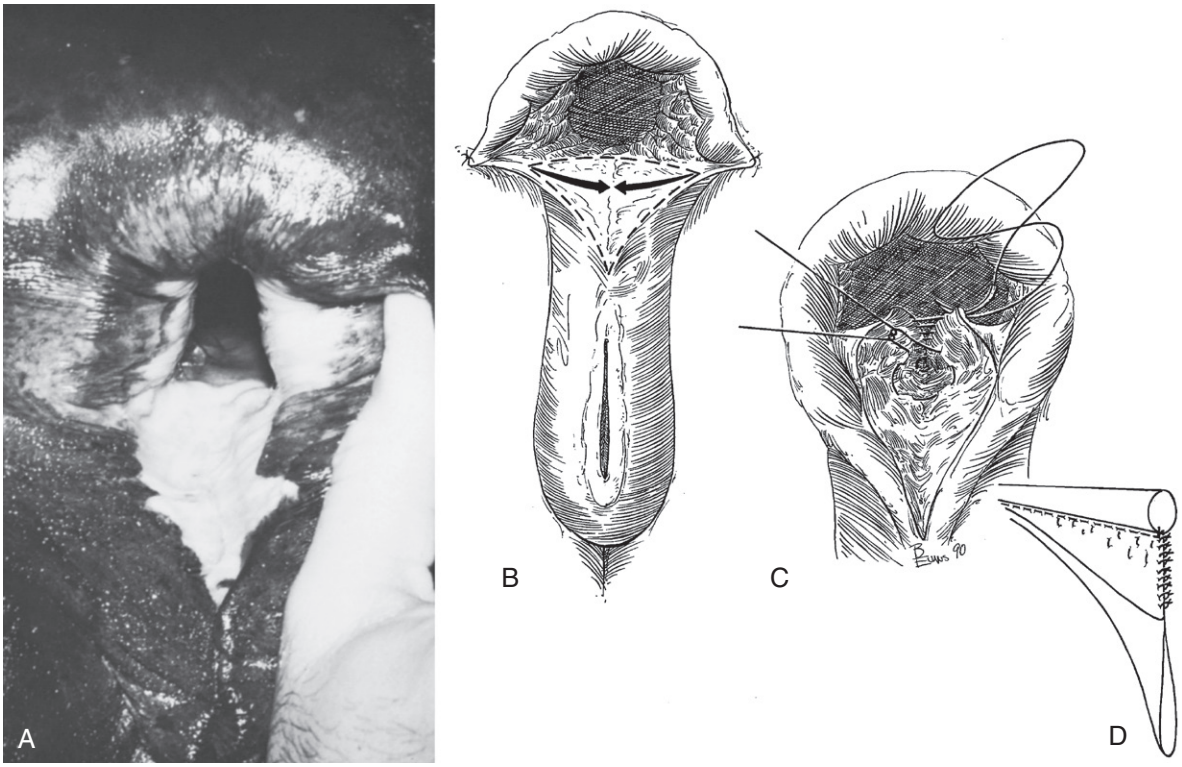

Figure 61-19. Second stage of the two-stage repair of a third-degree perineal laceration. **A,** The first-stage repair has healed and the mare is ready for the second stage of the repair. **B,** The area of epithelialized tissue that is to be excised is outlined. **C,** The submucosal tissues are apposed using interrupted purse-string sutures. This reconstructs the perineal body. **D,** Completed second-stage repair.

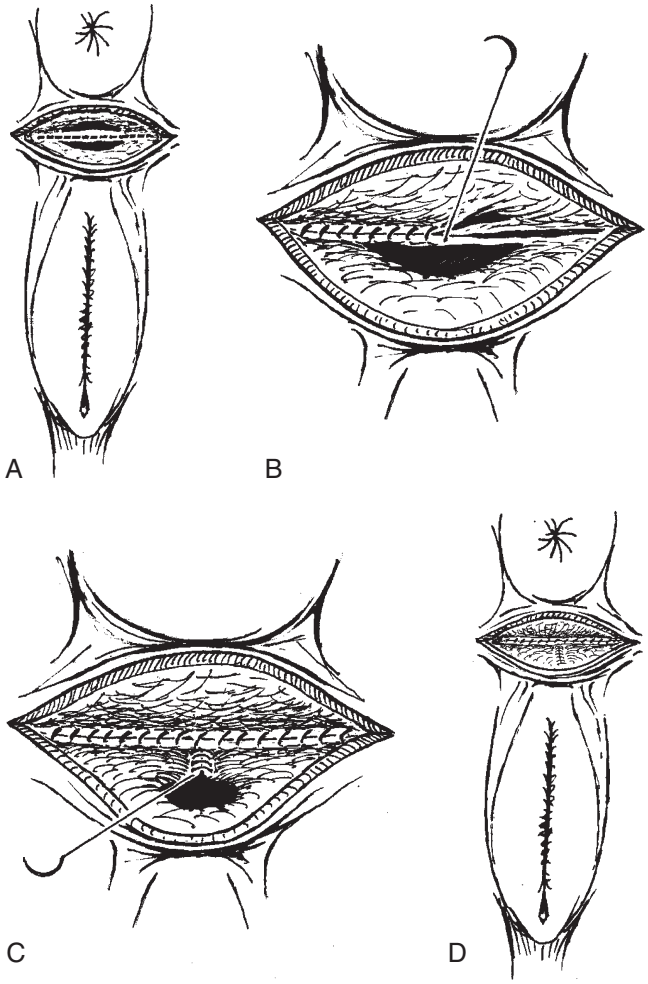

Figure 61-22. Drawing showing dissection and repair of a rectovestibular fistula using the horizontal approach. **A,** Completed dissection for repair of rectovestibular fistula. The fistula is divided into rectal and vestibular shelves. **B,** The rectal shelf is sutured transversely. **C,** The vestibular shelf is sutured longitudinally. **D,** The rectovestibular fistula is repaired. The dead space created by the approach can now be closed.

Direct suturing techniques have been described for successful repair of rectovestibular fistulas.[45,46] A mucosal pedicle flap technique for repair of rectovestibular fistulas in the standing horse has been described.[47] The edges of the fistula are débrided by full-thickness excision of 2 mm of the fistula margin. The fistula dimensions are assessed and a dorsally based U-shaped mucosal and submucosal pedicle flap is dissected from the vestibular wall. The flap is rotated 90 degrees so that the vestibular mucosa is continuous with the rectal mucosa covering the fistula. The flap is held in place by absorbable suture material placed in an interrupted pattern. Two of the three horses treated with this technique healed by first intention. The third horse required additional sutures to repair a partial dehiscence.[47]

Cervical Injuries

Injury to the cervix may lead to significant adverse effects on subsequent fertility. Cervical lacerations, adhesions, and incompetence are the most common disorders encountered.

Figure 61-23. Appearance of laceration at the dorsal aspect of the cervix during a speculum examination.

Lacerations

Lacerations of the cervix usually occur as a result of excessive stretching during foaling. Cervical injury is more likely to develop during dystocia or in association with a fetotomy.[48] Cervical lacerations have been reported to occur during normal parturition or during the abortion of a relatively small fetus. Any injury that disrupts the normal function of the cervix may lead to infertility. The incidence of cervical lacerations is reported to be higher when parturition is induced.[42] This may be the result of the cervix not relaxing adequately before foaling.

The most common clinical signs associated with cervical lacerations are failure to conceive, endometritis, early fetal abortion, and persistent infertility. All mares that have undergone dystocia should have their cervix examined approximately 21 days postpartum (Figure 61-23).[49] Palpation of the cervix is crucial to making a diagnosis of a cervical laceration. Lacerations can be easily missed on visual examination alone. This is especially true if the mare is near estrus with a relaxed cervix. Diestrus is the optimal time to evaluate the cervix. During this stage of her reproductive cycle the cervix should be constricted and allow an accurate determination of cervical competency. The cervix is evaluated in the following manner. The perineum should be washed and prepared for examination. The examiner should wear a sterile glove or sleeve and apply an ample amount of lubricating jelly. The hand is inserted into the vagina of the mare and the cervix is identified at the most cranial aspect of the vaginal fornix. When using the right hand to examine the cervix, the examiner places the thumb in the lumen of the cervix and uses the index finger to palpate the cervix from the most dorsal aspect to the most ventral aspect of the right side of the cervix. To examine the left side of the cervix, the examiner inserts the index finger into the lumen and uses the thumb to palpate the cervix from the most dorsal to the most ventral aspect of the left side of the cervix. If a cervical laceration is present, the severity and extent should be determined. Not all cervical lacerations require surgical repair. It has been reported that surgery is unnecessary if 50% or less of the vaginal cervix

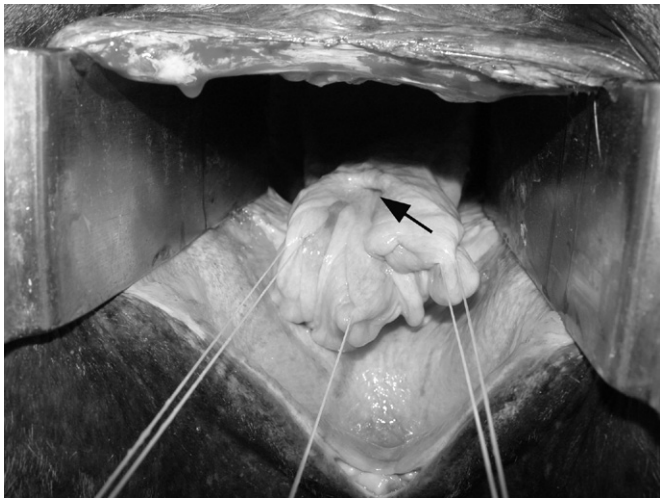

Figure 61-24. Photograph showing stay sutures placed to retract the cervix into the vestibule to facilitate repair. The sutures are placed to accentuate the defect in the cervix. *Arrow* points to the defect.

is involved.[50] However, the economic impact of fetal loss must be considered, and if it is possible to improve the chances that a mare will conceive and carry the foal to term, surgical intervention is warranted.

Surgery should be performed during diestrus and at least 3 weeks postpartum. Alternatively, the repair can be performed during estrus immediately after breeding. The mare is sedated and restrained in stocks, and epidural anesthesia is applied. A modified Finochietto retractor with long blades is very helpful in repairing cervical lacerations. Surgical interventions on the cervix should be performed in a caudally retracted position to bring it closer to the surgeon. Methods for retracting the cervix include Knowles cervical forceps and stay sutures (Figure 61-24). The Knowles cervical forceps are more traumatic than stay sutures and are not necessary. Three stay sutures using large-diameter suture material (No. 2) are placed in the external cervical os by hand or with the aid of long needle holders. The stay sutures must be positioned so they accentuate the cervical defect and do not interfere with the dissection and repair of the defect. The long ends of the stay sutures should be tagged with a hemostat and the needle removed. An assistant should apply gentle, steady caudal traction on the stay sutures so the surgeon has access to the cervix. The cervix can usually be retracted to the level of the vestibulovaginal junction. Allis tissue forceps are used to grasp the caudalmost scar tissue on each side of the cervical laceration. The scar tissue is excised using a scalpel blade or scissors. Following excision of the scar tissue, the three layers of cervical tissue should be evident. Repair of the defect is accomplished in three layers. The first layer, the inner cervical mucosa, is the most difficult to close and probably the most important. This layer is closed using 0 or 1 absorbable suture material in a continuous horizontal mattress pattern to invert the mucosa into the cervical lumen beginning at the most cranial aspect of the defect and working caudad. Following each bite, the surgeon should check whether the cervical lumen was penetrated and ensure that it is still patent. The second layer in the cervical muscle is apposed using 1 absorbable suture material placed in a simple-continuous pattern. The third layer, the outer cervical mucosa, is closed using 1 absorbable suture material placed in a simple-continuous pattern. In a report of 53 mares, a 75% pregnancy rate was achieved following surgical repair of cervical lacerations.[51] The mare should not be bred for at least 30 to 45 days following surgery. It is important to assess the uterus for signs of infection after surgery and before breeding. Uterine infection after surgery is not uncommon and must be addressed if present.

Adhesions

Transluminal adhesions interfere with the normal opening and closing of the cervix.[49] Less-severe adhesions may lead to infertility. More-severe adhesions can result in mucometra or pyometra.[16] Adhesions may form secondary to cervical trauma or cervical laceration repair. The prognosis depends on the severity of the adhesions. Transluminal adhesions can be broken down manually or surgically. Topical application of steroid-based ointment to the cervical lumen has been recommended as a means of preventing the adhesions from reforming.[16] Adhesions from the vaginal wall to the cervical opening can be relieved by sharp and blunt dissection. The surgeon must be careful not to perforate the vaginal wall and enter the peritoneal cavity when working in the cranial aspect of the vagina. Daily topical application of steroid-based ointment can be used as a means of preventing the adhesions from reforming.

Incompetence

Incompetence of the cervix can result from a tear that cannot be effectively repaired, muscle atony from repeated stretching, or a congenital anomaly.[16,52,53] Mares with an incompetent cervix may fail to conceive or experience early fetal abortion. Correction of these cervical problems has been associated with varied success.[16] The use of a buried retention suture or a nonabsorbable suture used in purse-string fashion around the base of the external opening has been described.[54] We recommended that the suture be placed during the first 48 hours following breeding and ovulation, and it must be removed before foaling. The success of this type of procedure is not known.

Clitoral Disorders

Abnormal conditions of the clitoris are rare. Squamous cell carcinoma has been reported to affect the clitoris.[55] Smegma can become impacted in the clitoral sinuses.[56] The sinuses of the clitoris can harbor *Taylorella equigenitalis,* the causative agent of contagious equine metritis.[57] Extirpation of the clitoral sinuses has been recommended as a treatment of affected mares.

Sinusectomy is completed as a standing procedure using local anesthesia. The glans clitoridis is not excised. The frenulum clitoridis, a fold of tissue overlying the clitoral sinuses, is retracted dorsad, and submucosal dissection is used to remove all clitoral sinus mucosa.[57] The resulting surgical wounds are left open to heal by second intention.

Congenital Anomalies

Congenital anomalies do not occur very often. Persistent hymen is the most frequently observed developmental anomaly of the mare's tubular genital system (Figure 61-25).[58] The hymen may be imperforate or may be present in varying

Figure 61-25. Appearance of a persistent hymen after it is exteriorized by an examiner.

degrees because of failure of the caudal sections of the Müllerian duct to fuse with the urogenital sinus. Failure of proper fusion of the Müllerian ducts may result in a dorsovental band in the cranial aspect of the vagina coursing across the external opening of the cervix.[59] Surgical removal easily solves both of these problems.

Developmental anomalies of the cranial vagina, cervix, and uterus are the result of partial or complete inhibition of Müllerian ducts. These anomalies are rare but occur more frequently in the cervix than in the vagina or uterus. Reports of congenital cervical anomalies include cervical aplasia, double cervix, and congenitally incompetent cervix.[52,53] Segmental aplasia of portions of the reproductive tract are rarely seen and may be associated with mucometra.[16] Ovariohysterectomy is recommended as a salvage procedure.

Incomplete separation of the urorectal septum leads to the formation of a rectovestibular fistula.[60] This is often seen in conjunction with atresia ani. In addition to urogenital abnormalities, other anomalies may be present. Atresia ani may be a heritable condition in the horse; therefore salvage of affected foals for breeding purposes is not advised.

Vaginal Varicosities

Vaginal varicosities are dilated veins that are most commonly located around the vestibulovaginal fold.[61] They can be solitary or form in clusters. The walls of the varicose veins are very thin and can rupture, causing recurrent or continued hemorrhage. The volume of blood loss is not life threatening but is concerning to owners and managers. The etiology of vaginal varicosities is unknown. Possible factors include elevated estrogen levels, changes in venous return, and perineal conformation during pregnancy.[62] Treatment options include ligation, cauterization, and laser photocoagulation. A vessel-sealing device such as the LigaSure (see Figures 13-16 and 13-17) can be used. Spontaneous postpartum regression of the varicosities has been reported.[63]

CHAPTER 62

Uterus and Ovaries

Rolf M. Embertson

ANATOMY

The ovaries in the mare are approximately 70 to 80 mm (3 inches) long and 40 to 60 mm (2 inches) wide, but the size varies depending on the season and stage of the estrous cycle.[1] The ovaries are generally kidney shaped with a palpable indentation, the ovulation fossa, present along the ventrally directed free border. The cranial aspect of the broad ligament, the mesovarium, attaches to the dorsal border of the ovary. The mesovarium contains vessels, nerves, and smooth muscle fibers that extend to the ovary. The ovarian branch of the ovarian artery supplies blood to the ovary.[1]

The funnel-shaped infundibulum of the oviduct is loosely attached to the ventral aspect of the ovary around the ovulation fossa. The oviduct continues as the tortuous ampulla and then as the more straight and narrow isthmus, prior to entry into the tip of the uterine horn at the tubal papilla.

The uterine horns extend caudad to the uterine body. The majority of the uterine body is positioned within the peritoneal cavity, with the caudal aspect located retroperitoneally. The uterine body ends caudally as the thick-walled muscular cervix, which projects into the cranial vagina. The uterus is suspended in the caudal abdomen and pelvis by the broad ligament, also known as the mesometrium. The mesometrium contains

vessels, nerves, lymphatics, fat, connective tissue, and smooth muscle. The uterine blood supply, which courses through the mesometrium, originates from the uterine branch of the vaginal artery, the uterine artery, and the uterine branch of the ovarian artery.

DIAGNOSTIC PROCEDURES

A complete history and a thorough physical examination are essential to a comprehensive diagnostic workup. Palpation *per rectum* and *per vagina*, ultrasonography, and hysteroscopy provide additional information important to determining an accurate diagnosis and subsequent appropriate treatment. The results of blood work, hormone assays, culture and sensitivity, cytology, and histology are commonly used diagnostic aids. In addition, the laparoscope has become a frequently used tool for diagnosis of reproductive tract pathology.

PREPARATION FOR SURGERY

Preoperative Concerns

Decreasing the volume of ingesta within the intestinal tract generally facilitates most elective procedures involving the ovaries or uterus. Withholding food for 12 to 36 hours prior to laparotomy or laparoscopy is recommended. However, disruption of a horse's diet, feeding schedule, and environment may increase the risk of developing intestinal abnormalities (i.e., colic).

Perioperative antibiotics and anti-inflammatory drugs are usually indicated for surgery of the cranial reproductive tract. Many surgical interventions on the uterus have to be performed on an emergency basis, requiring well-trained personnel to assist in the management of these conditions.

Analgesia and Anesthesia

Standing surgery of the cranial reproductive tract requires profound sedation, visceral analgesia, and local anesthesia. Detomidine is the most commonly used drug for sedation and analgesia for these procedures. It is commonly used in combination with butorphanol and xylazine. For long procedures, sedation can be effectively maintained with a continuous-rate infusion (CRI) of detomidine. Detomidine also has been administered as an epidural injection for prolonged sedation, although it has not been shown to be more effective than the more easily administered CRI.[2] Epidural anesthesia may help facilitate some procedures.

Many of the cranial reproductive tract procedures require general anesthesia. There is concern about the effects of inhalation anesthetic agents on the fetus in mares with dystocia and those undergoing a cesarean section (C-section). Total IV anesthesia (guaifenesin, ketamine, and detomidine) has been recommended for these mares, at least until the foal is delivered.[3] However, most hospitals use inhalation anesthesia immediately following induction.

For mares encountering dystocia, where resolution requires general anesthesia, I have had consistently good results using xylazine, diazepam, and ketamine for induction and isoflurane in oxygen for maintenance of anesthesia. Anesthesia should be induced promptly and maintained at a light surgical plane, allowing the procedure to proceed as quickly as possible. Rapid delivery of the live foal combined with immediate neonatal care provides the best opportunity for the foal's survival from a difficult dystocia.

Surgery

General surgical concepts are as follows. For standing surgery, positioning the mare in stocks, tying the tail suspended upward, skin preparation, and surgical draping are essentially the same for a standing flank laparotomy or laparoscopy. The site(s) of local anesthetic infiltration for the incision(s) differ.

A modified grid approach is standard procedure used for a flank laparotomy in the mare. Generally, local anesthesia is placed as a 20-cm vertical line block between the last rib and the distal border of the tuber coxae, extending distad from just dorsal to the dorsal margin of the internal abdominal oblique muscle. A vertical incision is made through the skin and subcutaneous tissue, then extended deeper through the external abdominal oblique muscle and aponeurosis. The internal abdominal oblique and transverse abdominal muscles are bluntly separated parallel to the muscle fibers. The peritoneal lining is bluntly penetrated to gain access to the abdomen. This approach is also used by some to assist a laparoscopic ovariectomy.[4]

The ventral approach to the abdomen in the mare, under general anesthesia, is much more commonly used for laparotomy than the flank approach. In part because of staff familiarity with colic surgery, a ventral laparotomy to approach the ovaries or uterus can be performed quickly and efficiently in most hospitals. There are few indications for a ventral laparoscopic approach to the ovaries or uterus.

OVARIES

Neoplastic Conditions

Equine ovarian tumors are classified based on tissue type: surface germinal epithelium, sex cord-stromal tissue, and germ cell origin.[5] In addition, mesenchymal tissue tumors may develop in the ovary and others may gain access through metastases. The sex cord-stromal tumors, generally referred to as *granulosa cell tumors (GCTs)*, usually consist of granulosa cells but may contain granulosa and thecal cells.[5]

The GCT is the most common equine ovarian tumor, comprising approximately 85% of all equine reproductive tract tumors.[4-8] The average age of affected mares is about 11 years.[4,6,8] Affected mares may show anestrus, intermittent or continuous estrus (nymphomania), or stallion-like behavior.[5] Generally, the affected ovary is enlarged, sometimes quite massively, and the contralateral ovary is usually small and inactive. A GCT most commonly develops unilaterally but can occur bilaterally; it is usually benign but may exhibit metastases. Ultrasonographically, GCTs are usually multicystic structures, although the appearance can vary. In one study of mares with confirmed GCT, 54% had elevated testosterone levels and 87% had elevated inhibin levels.[5,9] Therefore, testing for both testosterone and inhibin may be most beneficial. Repeated palpation and ultrasonographic examination of the ovary may be useful to help rule out other causes of enlargement. Juvenile GCT has been reported in a few foals.[5,7,9] Foals with juvenile GCT, although quite rare, usual present with a hemoabdomen.[7,10] Ovariectomy is the treatment of choice to resolve this condition.

Other neoplastic conditions of the ovary are rare. They include teratoma, cystadenoma, adenocarcinoma, lymphosarcoma, melanoma, dysgerminoma, and arrhenoblastoma.[5]

Non-Neoplastic Conditions

An enlarged ovary may have non-neoplastic causes.[9,11] Occasionally, hematomas and cysts become quite large and adversely affect ovarian architecture. Abscessation can cause an enlarged, painful ovary. Ovariectomy is usually needed to resolve these conditions.

Abnormal behavior is occasionally encountered in show mares during estrus. If hormone therapy is unsuccessful, bilateral ovariectomy can be used to correct this behavior.

Ovariectomy

Colpotomy

Ovariectomy via a colpotomy has been used primarily for bilateral ovariectomy, either to improve a mare's behavior or for research applications. The procedure has been used for years and has changed little, except for improvements in sedatives and analgesics.[11-13]

The mare is sedated and placed in stocks, and the tail is wrapped. Epidural anesthesia is generally recommended. The rectum is evacuated, and the bladder is emptied if it is distended. The tail is tied upward and the perineal region is prepared for surgery. A pointed bistoury or guarded scalpel is used to make a small incision through the cranial vaginal wall, 4 to 5 cm caudolateral to the cervix. The incision is made at the 2 or 4 o'clock position if the surgeon is right handed and at the 8 or 10 o'clock position if the surgeon is left handed. These sites avoid inadvertent penetration of the bladder, rectum, and uterine branch of the urogenital artery laterally. The peritoneum is penetrated with a thrust from closed, blunt-pointed scissors. This small incision is enlarged digitally until the entire hand can pass into the peritoneal cavity. Lidocaine-soaked gauze sponges, tethered with a long strand of umbilical tape, are held around the ovarian pedicle for 1 minute. The chain loop of the écraseur is placed around an ovary, with care taken to exclude other tissues, and is slowly (over 3 to 4 minutes) tightened until the ovary falls into the surgeon's hand. The ovary is removed from the abdomen and the procedure is repeated to remove the contralateral ovary.

The vaginal incision is allowed to heal as an open wound and the mare is kept standing for 2 to 3 days to prevent the rare case of eventration. Loose apposition of the wound edges with large absorbable sutures may lessen the anxiety level of the surgeon postoperatively. Broad-spectrum antibiotics and anti-inflammatory drugs are administered for 5 days postoperatively, and the mare is walked daily for 2 weeks before resuming previous activities.

Possible complications include excessive (possibly fatal) bleeding from the ovarian pedicle, eventration through the vaginal surgery site, abscessation or hematoma formation at the incision sites, and adhesions of abdominal contents to the incision sites.[11-13]

Laparotomy

Ovariectomy via a laparotomy allows the ovary to be exteriorized under visual control, which facilitates direct hemostasis. The ovarian pedicle can be short enough that exteriorizing the ovary for resection may be difficult. A flank approach can be used in the standing mare if there is concern about general anesthesia and the ovary is less than 10 cm in diameter. A flank approach may also be used with the mare under general anesthesia. A modified grid approach is used to access the abdomen. The most common complication that occurs at the flank surgery site is development of a postoperative seroma or formation of an abscess.

A ventral approach to the abdomen can be via a midline, paramedian, or diagonal paramedian incision (see Chapter 34). The ventral midline incision may be most ideal for a very large ovarian tumor with a stretched ovarian pedicle. The diagonal paramedian laparotomy approach is the most useful approach for the majority of normal or enlarged ovaries.[11,13-15] Because the incision is positioned directly over the ovary, less tension is applied to the ovarian pedicle during vessel ligation than with the other approaches.

The mare is anesthetized and placed in dorsal recumbency, and the surgery site is prepared for aseptic surgery. A 12- to 15-cm (5- to 6-inches) long incision is made starting approximately 5 cm cranial to the mammary gland and nearly bisecting the angle formed by the ventral midline and the inguinal depression. The site of the incision can be adjusted to avoid large subcutaneous vessels. The incision is continued through the external rectus sheath, and the rectus abdominis muscle fibers are bluntly separated. Ligation and transection of 1 to 2 large neurovascular bundles found coursing perpendicular to the muscle fibers may be required. The internal rectus sheath is opened carefully with scissors. A hand is introduced into the peritoneal cavity, and the ovary is identified and pulled up to the incision. Stay sutures (No. 2 polyglactin 910) are placed through the ovary in a cruciate pattern. These sutures are very helpful for manipulating and removing the ovary. Distended follicles are aspirated to reduce the size of the ovary and to facilitate passage of the enlarged ovary through the incision. Ligatures (No. 1 or 2 absorbable suture) are placed around the cranial and caudal margins of the ovarian pedicle and used as additional stay sutures. A 90-mm thoracoabdominal stapling device (TA 90) is placed across the ovarian pedicle and discharged. The ovarian pedicle is transected between the rows of staples and the ovary. The ovary is then removed from the surgery site (Figure 62-1).

After removal of the stapling device, tension is relieved on the end of the ovarian pedicle while continuing to hold the stay sutures, and the transection site is checked for bleeding. Occassionally, minor bleeding is encountered, requiring additional ligatures. The ovarian pedicle is placed back into the abdomen and the abdomen is closed. The rectus abdominis muscle fibers are reapposed with No. 2 absorbable suture in an interrupted cruciate pattern. The external rectus fascia is closed with No. 2 absorbable suture in a continuous pattern, the subcutaneous tissue with No. 1 absorbable suture in a continuous pattern, and the skin with No. 0 absorbable suture in a continuous pattern. An experienced surgeon is able to perform this procedure bilaterally, if needed, relatively swiftly.[16]

Most mares are hospitalized overnight and discharged the following day. Postoperatively, mares should be hand-walked for 1 week, followed by 2 weeks of small-paddock turn-out prior to returning to routine care. Postoperative complications are rarely encountered but include hemorrhage from the ovarian pedicle, traumatic anesthetic recovery, postoperative abdominal pain, incisional infection, and adhesion of the uterine horn to the surgery site.

Figure 62-1. Ovariectomy, using a commercial stapling unit for hemostasis prior to ovary resection.

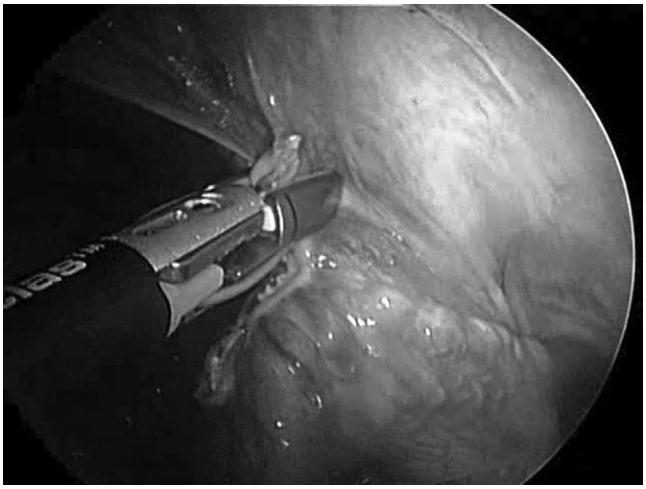

Figure 62-2. Laparoscopic ovariectomy, using the LigaSure Atlas, for hemostasis and transection of the ovarian pedicle.

Laparoscopy

Laparoscopic ovariectomy is generally performed as a standing procedure using an approach made through the flank.[4,6,17,18] The primary advantages of the flank laparoscopy compared to the diagonal paramedian laparotomy for ovariectomy are the enhanced visualization of the surgical site with minimal tension on the ovarian pedicle, the ability to quickly and more confidently address potential hemorrhage, and avoidance of general anesthesia. Complications, although different, can occur with both techniques, with surgical site drainage being more common following the flank approach. Client costs are a function of how equipment, materials, personnel, and facilities are charged. Currently the surgery time may be less with the laparotomy, and the postoperative convalescent period is not dissimilar.

Equipment needed for laparoscopic ovariectomy includes a videoendoscope camera, monitor, light source and cable, insufflator and tubing (not always used), a 0-degree or 30-degree 57-cm (22-inches) rigid endoscope, at least three 10-mm (4-inches) diameter 15- to 20-cm (6- to 8-inches) long cannulas with trocars, laparoscopic forceps, scissors, injection needle, and ligation instrumentation.[17] Ligation of the ovarian pedicle can be done with ligating loop sutures, a stapling instrument, or a bipolar vessel-sealing device. For more information on laparoscopy, please review Chapter 13.

The exact sites of the incisions for the laparoscopic portals vary between surgeons. The hand-assisted laparoscopic ovariectomy technique commences with a modified grid flank approach to the abdomen.[4] The cannulas for the endoscope and instruments then are placed carefully to avoid trauma to bowel or the spleen. The ovary is visualized and the mesovarium is desensitized with lidocaine or mepivicaine. Placing local anesthetic into the mesovarium, rather than the ovary, has been shown to be more effective in reducing pain responses during surgery.[19] The bipolar vessel-sealing device (LigaSure Atlas) (see Chapter 13) has been used effectively in our hospital, and others, for hemostasis and transection of the mesovarium (Figure 62-2).[20] Semm claw laparoscopic forceps provide a relatively secure grasp of the ovary for manipulation and extraction. However, No. 2 polygalactin 910 sutures placed in a cruciate pattern through the ovary provide a more confident purchase of the ovary than the forceps. If the hand-assisted approach was not performed, one of the portals needs to be lengthened to remove an enlarged ovary.

To avoid creating a large flank incision to extract the ovary, an enlarged ovary can be reduced in size prior to removal. Aspirating fluid from some of the enlarged follicles usually results in significant size reduction. Additionally, the ovary can be reduced into smaller pieces by direct sharp dissection or with the use of a morcellator while it is held against the body wall incision within a specimen retrieval bag.[4,6,21] Ovaries up to 30 to 40 cm in diameter have been removed laparoscopically using these techniques. Closure consists of apposing the muscles, followed by subcutaneous tissue and fascia, and finally the skin.

Most mares return to the farm the next day with the same discharge instructions as for diagonal paramedian laparotomy ovariectomy. Complications following laparoscopic surgery through the flank vary.[4,6,17,18] Complications related to sedation and analgesia include inadvertent recumbency and patient noncompliance. Cannula insertion complications include retroperitoneal insufflation, splenic or bowel puncture, and hemorrhage from laceration of the circumflex iliac artery. Loss of the ovary within the abdomen is undesirable. The most common postoperative complications are subcutaneous emphysema, mild colic, and incisional drainage.

UTERUS

Uterine Cysts

Uterine cysts are most commonly found in older mares.[22,23] They can be found on rectal exam but are usually diagnosed ultrasonographically. The presence of multiple uterine cysts may have an adverse affect on fertility. If the cysts are suspected to be the cause of infertility, they should be removed. Methods of cyst removal have included mechanical curettage, cyst rupture manually or with endometrial biopsy forceps, uterine lavage with a hypertonic saline or magnesium sulfate solution, electrocoagulation of the cyst, and laser ablation.[22,23] In our practice,

laser ablation has been the most successful method of cyst resolution and is currently the most accepted technique.

The mare is sedated and placed in stocks, and the perineal region is prepared for hysteroscopy. A 1-m videoendoscope that has been cold-sterilized and rinsed with sterile water is passed through the cervix into the uterus. The uterus is distended with air to allow visualization of the uterine body and both horns. The diode laser fiber is passed through the biopsy channel of the endoscope into the uterus. The uterine cysts are first punctured and drained with the diode laser, set on a power setting of 15 W. Following release of the fluid, lasing is continued until the remaining cystic tissue and its base are shriveled and charred. Smoke and fluid often need to be evacuated from the uterus a few times during the procedure. Immediately after the procedure, the uterus is lavaged or infused with antibiotics. The uterus should be lavaged daily for 2 or 3 days postoperatively to remove the retained cyst fluid and debris created by photoablation. An ultrasonographic examination of the uterus should be performed approximately 30 days postoperatively and prior to breeding. One report of the use of the Nd:YAG laser to ablate endometrial cysts in 55 barren mares demonstrated improved fertility.[23] In my experience, ablation of the lining and base of the cyst should prevent recurrence of the cyst. However, additional cysts may form in other locations.

Pendulous Uterus

Delayed uterine clearance has been recognized as a contributing factor to infertility in the mare.[24] The conformation of the reproductive tract commonly found in older mares, where the cranial aspect is positioned ventral to the caudal aspect, plays a role in delayed uterine clearance. In a mare with poor conformation, a recent report showed that elevating the uterus and fixing it in a more horizontal position would improve her prognosis for conception and carrying a fetus to term.[25]

The surgical technique to elevate the uterus involves creating three laparoscopic portals in the left flank. The mesometrium is infiltrated with local anesthetic solution. The left side of the uterine body and horn are sutured to the mesometrium. The suture line starts at the caudal aspect of the uterus where the mesometrium attaches to the uterus. A suture is passed through the seromuscular layers of the uterus at that level, through the mesometrium approximately 3 cm dorsal to its uterine attachment, and then tied. A continuous suture line is continued in this fashion to near the cranial aspect of the uterine horn. This suture line essentially imbricates the mesometrium. Following placement of this suture, the exact same procedure is performed to elevate the right side of the uterus from the right flank. The original report describes placing the suture line using laparoscopic needle holders.[25] The Endostitch 10-mm Suturing Device has also been used successfully for the uteropexy procedure.[26]

In one report, five mares had been barren for a mean of 3.8 years prior to surgery.[25] Three of these mares became pregnant postoperatively, with one mare having foaled by the time of publication submission. Although the procedure is initially promising, it is too early to determine an accurate success rate and any potential complications that may be encountered.

Uterine Neoplasia and Chronic Pyometra

Uterine neoplasia and chronic pyometra are uncommon conditions.[27-30] Chronic pyometra is generally the result of an obstruction of complete uterine drainage because of severe cervical trauma. If medical therapy is unsuccessful, an ovariohysterectomy is indicated. Drainage of the uterine contents prior to surgery is advisable.

The most commonly encountered uterine tumors are leiomyoma and leiomyosarcoma. Rhabdomyosarcoma, adenocarcinoma, and other types have also been reported.[27,30] Most uterine tumors can be resolved by tumor removal or partial hysterectomy. However, infrequently ovariohysterectomy is indicated.

Total ovariohysterectomy is best approached through a caudal ventral midline incision with the mare under general anesthesia and in dorsal recumbency. The ovarian pedicles are ligated, and dissection continues through the broad ligament, ligating large vessels in the process. The body of the uterus is transected as far caudad as possible, with care taken to avoid contaminating the peritoneal cavity. The uterine stump is closed with a double-inverting suture pattern. The abdomen is closed in routine fashion.[13,27] A recent report describes the laparoscopic dissection and hemostasis of ovarian and uterine structures followed by inversion of the uterus through the cervix and into the vagina, where the uterus was then resected.[30]

Solitary masses, even if quite large, can be successfully removed from the uterine wall with the mare remaining fertile.[31] The affected part of the uterus is approached through a caudal ventral midline or paramedian incision followed by exteriorization and dissection of the mass from the uterine wall. Partial ovariohysterectomy has been used to remove a focal uterine tumor and ovarian masses with adhesions to the uterine horn.[28,32-35] Surgical approaches have included a caudal ventral midline and paramedian laparotomy and a standing flank laparoscopy. Live foals have been produced by mares after partial ovariohysterectomy where various amounts of the uterine horn were removed. It is difficult to determine exactly how much uterine horn is needed to maintain a pregnancy, and this likely varies between horses. Based on a review of several papers, it appears that most mares can maintain a pregnancy with up to 50% of a uterine horn removed, but fertility decreases proportionally to the amount of horn removed beyond that.[36,37]

Uterine Torsion

Mares with uterine torsion generally present with signs of colic. Affected mares usually exhibit mild to moderate, intermittent abdominal pain. The diagnosis is usually made by rectal examination. In most cases, a taut broad ligament is palpable, coursing dorsal to the caudal aspect of the uterus in the direction of the torsion. An ultrasonographic examination may provide useful information about fetal viability, status of the uterus, and other abdominal abnormalities.

Uterine torsion can affect mares of all ages, usually during the last 2 months of gestation, although this varies.[38-40] In the most recent study of 63 mares, 90% were younger than 16 years, 60% had the torsion directed clockwise, and 80% had torsions 180 degrees or less.[40] Overall mare survival was 84%, with a survival rate of 97% if gestation was less than 320 days and 65% if gestation was 320 days or longer. Overall foal survival was 54%, with a survival rate of 72% in foals less than 320 days of gestation and 32% in foals 320 days or more of gestation.[40] These numbers compare favorably to another study involving 26 mares, where 73% of the mares and 46% of the foals survived.[39] Uterine torsion is usually diagnosed

in its acute stage, although chronic uterine torsion has been reported.[41,42]

Surgical and nonsurgical management of uterine torsions have been used successfully. The standing flank approach has been more popular than the ventral midline approach for surgical repair.[38,39] However, in the recent report of 63 mares, 30 were treated through a ventral midline approach, 23 through a flank approach, and 10 by rolling.[40] In this study, there was no statistically significant difference for mare survival regarding method of resolution.

Nonsurgical management usually requires general anesthesia and rolling of the mare 360 degrees in the direction of the torsion. A long wooden plank, firmly placed across the mare's flank, is helpful in keeping the gravid uterus in the same position while the mare is rolled around it. This method of management has been successful. However, uterine rupture in a mare at term has been reported.[43] The few mares that are at term may be successfully corrected while standing by passing a hand into the uterus, grasping the fetus, and gradually rocking it, together with the uterus, in larger and larger arcs until it untwists.[38]

For the standing flank approach, the mare is sedated and placed in stocks. Local anesthesia is administered and routine surgical preparations are made. The flank incision is made on the side toward which the uterus is twisted. A modified grid approach through the body wall is used. An arm is introduced and a hand is placed under the gravid uterine horn. The uterus is gradually rocked back and forth, eventually allowing the uterus to flip back into its normal position. The status of the fetus and of the uterus should be evaluated. Closure is routine.

A ventral midline approach should be used if uterine rupture, tearing, or devitalization is suspected, if the foal is known to be dead and the mare is preterm, and if attempts at standing correction are unsuccessful.[13,39,40] If the mare is in a surgical facility where many abdominal surgeries are performed, the ventral midline approach should be considered instead of the flank approach, since it is more versatile.

Uterine Prolapse

Uterine prolapse occurs rarely in mares.[13,44,45] It tends to occur more frequently after dystocia and when fetal membranes are retained. Tension placed on the placenta and the use of disproportionate amounts of oxytocin have also been implicated with uterine prolapse. Although rare, the condition may be complicated by bladder prolapse, uterine tear, intestinal herniation, or uterine vessel rupture.

Uterine prolapse can be quite painful for the mare, and prompt sedation is indicated. Tocolytic agents, if available, may help decrease straining and discomfort. Prompt treatment is important. The uterus should be cleaned with saline and any placenta not directly attached to the uterus should be resected. Keeping the uterus elevated and protected in a plastic bag until definitive treatment is started reduces swelling, contamination, trauma, and straining.

The uterus can often be replaced in the standing mare if she is heavily sedated. Copious amounts of lubricant are used, and the uterus is gradually pushed back into its normal position. The use of fingertips should be avoided. Epidural anesthesia can be helpful in reducing straining. However, I do not routinely use epidural anesthesia, because it may not eliminate all straining, and its use is contraindicated if general anesthesia is performed. If standing uterine replacement is unsuccessful, the mare is anesthetized and her hind limbs are hoisted. The lack of straining and aid of gravity allow the uterus to be replaced relatively easily into its normal position. Care is taken to ensure that the uterine horns are fully extended. The vulva is sutured closed, except for a small ventral opening, and the mare is recovered. Postoperatively, the mare is treated with antibiotics, anti-inflammatories, and IV fluids if needed. The sutures are removed from the vulva and uterine lavages commence the next day. Although post-reduction oxytocin has been recommended, I avoid its use for 24 to 36 hours, as it may cause discomfort and straining.[13,44,45]

Uterine Tear

A uterine tear (laceration or rupture) usually occurs during a dystocia or normal foaling, but it also rarely occurs with uterine torsion or hydramnios (Figure 62-3).[13,15,46,47] Tears near the tips of the uterine horns are likely the result of acute rapid thrusts of the fetal hind feet during foaling. Most of these injuries occur during a percieved normal foaling. Tears in the uterine body (and vagina) logically result from forceful penetration of a blunt appendage (e.g., foot, muzzle, etc.) through a stretched and relatively unyielding uterine wall. These injuries usually occur during dystocia. Caudal uterine or vaginal tears are infrequently associated with evisceration of bowel during foaling. Presented with this situation, the bowel should be cleansed and replaced in the abdomen prior to delivering the foal. The tear should then be identified and a plan formulated for repair. Very rarely, a fetus gains access to the abdomen through a uterine tear, necessitating abdominal surgery to deliver the foal and repair the uterus.

Tears in the uterine body are sometimes found relatively soon after foaling and prior to development of peritonitis. The cervix and caudal uterus should be palpated during the first postpartum uterine lavage. However, palpation of a tear in the caudal uterus can be difficult after delivery because of the swelling and folding of the uterine lining.

Most uterine tears are diagnosed 1 to 3 days postpartum.[13,15,46-48] The most common presenting signs are depression, fever, mild abdominal discomfort, and tachycardia. This history and clinical signs, ultrasonographically identified excessive, cellular peritoneal fluid, and an elevated peritoneal WBC count

Figure 62-3. Typical appearance of a uterine tear near the apex of the uterine horn.

and total protein point strongly to a diagnosis of uterine tear. Further diagnostics, such as rectal exam, peritoneal fluid cytology, and so on, are needed to rule out intestinal tract trauma as the cause of peritonitis.

Two recent retrospective studies examining uterine tears yielded the following relatively similar results.[47,48] One study compared surgical to medical treatment of uterine tears.[47] The other examined the results of more than 70 mares with surgically treated uterine tears.[48] The most common presenting signs are listed in the previous paragraph. The median age was about 10.5 years. Tears were more common in the uterine horns (about 75%) than the body (about 25%). More tears occurred in the right uterine horn (about 75%) than the left (about 25%). Although there was a broad range, upon admission the median peritoneal fluid WBC count was about 70,000/μL and total protein value about 4.6 g/dL. The overall survival rate was about 76% in both studies.

There were some differences between the studies. In one study, there was no significant difference in survival rate between mares with tears in the uterine horns and those with tears in the uterine body.[47] In the other study, although not statistically analyzed, mares with uterine horn tears had a higher survival rate (84%) than those with uterine body tears (58%).[48] In the former study, there was no significant difference in survival rate, days of hospital stay, treatment costs, or fertility between medical and surgical management of the uterine tears.[47] Of 13 mares bred the same year as the injury, 12 concieved and carried the foal to term. In the other study, medical treatment was not evaluated.[48] All of the uterine tears in the latter study were repaired surgically.[48] All of the uterine horn and some of the uterine body tears were accessed through a caudal ventral midline celiotomy. These defects were closed using a simple-continuous pattern and oversewn with a continuous inverting pattern, both using No. 1 multifilament absorbable suture material. The abdomens were lavaged during surgery and for 2 to 3 days postoperatively. Uterine lavage started 1 day postoperatively and continued for 3 to 4 days. Perforations in the caudal body of the uterus were repaired in the standing mare *per vagina*. Closure usually consisted of a single layer of simple-interrupted or continuous No. 2 absorbable suture.

One paper referenced in this section has shown that medical treatment is a viable option for many uterine tears.[47] However, I am of the opinion that prompt surgical treatment of a uterine tear enables an accurate diagnosis, prevents further contamination of the abdominal cavity, allows the most thorough peritoneal lavage, and therefore hastens recovery.

Periparturient (Broad Ligament) Hemorrhage

Hemorrhage from one of the arteries supplying blood to the reproductive tract in the mare is the most common cause of death of the postpartum mare. A study of 98 mares that died after delivery revealed that 40 died from a rupture of one of these arteries.[49] Recognition of this condition and differentiating it from other causes of acute abdominal pain in the periparturient mare is important, as an exploratory celiotomy is generally contraindicated in these mares.

The actual site of the arterial bleeding was determined in one report of 31 mares that died from periparturient hemorrhage.[50] These sites included the uterine artery (n = 24), internal pudendal artery (n = 5), intenal iliac artery (n = 1), and caudal mesenteric artery (n = 1). The mares in this study had a mean age of 16.9 years, a mean parity of 9.5 times, and a mean time post-foaling to death of 8.5 hours. More than 90% of these mares died within 24 hours after delivery. Histological comparison of the ruptured vessels in these mares to uterine arteries collected from younger, less-multiparous mares revealed that atrophy of the smooth muscle cells with fibrosis of the arterial wall was one of the predisposing factors in aged multiparous mares.[50]

The vast majority of affected mares are aged and multiparous.[13] Often, these mares initially exhibit significant abdominal pain, especially if the blood is contained within the broad ligament. Rectal examination of persistently painful mares generally reveals a fluctuant mass in the broad ligament. If the broad ligament ruptures and the blood gains access to the abdominal cavity, the pain often dissipates and, on rectal examination, the broad ligament has a more edematous feel. On presentation, these mares generally have very pale mucous membranes, a weak pulse, and an elevated heart rate, are anxious, and are often sweating. The condition is diagnosed from the history and physical findings previously stated, identifying a hematoma or free blood on a rectal or abdominal ultrasonographic exam and the presence of blood in a peritoneal fluid sample.

Salient findings from another study of 73 mares with periparturient hemorrhage are as follows.[51] The median age was 14 years and median parity was 8 times. The hemorrhage occurred after delivery in 86% of the mares, and of these mares the median time interval from foaling to the hospital was 12 hours. Only 19% of these mares had a history of dystocia. In this study, 84% of the mares survived to hospital discharge.

Treatment varies depending on the clinician, but it should be aimed at avoiding excitement, restoring cardiovascular volume, controlling pain, enhancing hemostasis, and preventing infection.[51] Attempts to ligate the ruptured artery have met with limited success.

Cesarean Section

Elective Cesarean Section

Candidates for an elective Cesarean section (C-section) include mares that have a compromised birth canal as a result of a previous pelvic fracture or a soft tissue injury within the reproductive tract, and mares that have previously had a difficult dystocia or a severe uterine artery hemorrhage. The surgery must be well timed to yield a viable foal and have minimal adverse effects on the mare. Therefore, it is important to perform the surgery as close as possible to the natural foaling time. The mare should be hospitalized 7 to 10 days prior to her due date. Her physical status is checked frequently to determine udder development, softening of her perineal tissues, and behavior. Concentrations of electrolytes in the mammary secretions are very helpful for timing the surgery.[27] Decreasing sodium and increasing potassium and calcium levels are good indicators of impending parturition. The surgery, when performed, should proceed rapidly, with knowledgeable staff waiting to resuscitate the anesthetized foal on delivery. The fetal survival rate following elective C-section should be higher than 80%.[52-55]

Emergency Cesarean Section

The most common reason to perform a C-section in the mare is to resolve a dystocia.[27,52,54-57] This is truly an emergency situation and when the decision is made, the C-section should

proceed rapidly. The team of people involved should be well organized and prepared for this situation. Other circumstances potentially dictating the need for an emergency C-section include a near-term mare undergoing colic surgery or correction for uterine torsion. Under these circumstances, if the mare appears to have a good prognosis for survival, the fetus should remain in the mare until normal parturition. However, a C-section should be performed if the mare has a guarded prognosis. One study showed only three of eight (38%) term foals delivered during colic surgery survived to discharge.[54] It would be very unusual to encounter significant incisional complications during parturition following a recent abdominal surgery, so this should not be a factor when considering an emergency C-section.

SURGICAL TECHNIQUE

As the obstetrical manipulations for controlled vaginal delivery are being performed, the ventral midline of the mare is being prepared for a possible C-section (Figure 62-4).[56,57] When the decision is made, the surgery room is set up and the mare is positioned on the surgery table and readied for surgery. The time from the decision to perform a C-section to the delivery of the foal should be no more than 20 minutes. If the foal is known to be dead, this time is not as critical.

The most common approach to the uterus used for C-section in the mare is the caudal ventral midline.[15,27,52-58] The mare is positioned in dorsal lateral recumbency with the ventral midline tilted toward the surgeon. A 35- to 40-cm incision is made into the abdomen beginning 10 cm caudal to the umbilicus and extending craniad. The gravid uterine horn, which usually contains the hind limbs of the fetus, is located and exteriorized. One stay suture is placed in a cruciate pattern near the tip of the uterine horn, close to the position of the fetal feet, and another toward the body of the uterus, close to the position of the fetal hocks. An assistant surgeon handles the stay sutures during the procedure to minimize contamination of the abdomen with uterine fluids and to help facilitate closure. An extra impermeable drape is placed over the other drapes on the surgeon's side of the abdomen.

An incision is made through the uterine wall and chorioallantois from the level of the fetal hocks to the feet, creating a straight incision between the stay sutures (Figure 62-5). During extraction of the fetus, it is not uncommon to have the uterine wall tear slightly at the end of the uterotomy. The amniotic membrane, which has collapsed around the foal, is elevated and incised. The surgeon grasps the hind limbs and lifts the fetus up and out of the uterus. The hind limbs are handed to a third assistant, and the surgeon pulls the body up and out of the uterus. In this manner, the fetus is pulled from the mare rapidly. The umbilical cord is clamped and transected and the neonate is quickly transferred to a table set up just outside the surgery room for resuscitation and evaluation. The chorioallantois is separated from the endometrium for 3 to 4 cm along the incised edge of the uterine wall. If the placenta separates easily from the uterus, it may be entirely removed at that time. However, it is usually still well attached.

Infrequently, the hind limbs are not present in a uterine horn, making it extremely difficult to exteriorize any part of the uterus. The uterine incision is then made at the base of a horn and body of the uterus with the uterus in the abdomen. This causes significant concern about the amount of contamination occurring during surgery. After closure of the uterus, the abdomen will be lavaged with copious amounts of saline.

The incised edge of the uterine wall bleeds profusely. A continuous suture line is placed along this edge and large vessels are individually ligated to provide hemostasis. The need for the hemostatic suture line has been questioned.[59] However, I believe that it ensures close examination of the uterine edges and lessens the risk of postoperative bleeding enough to warrant the 10 minutes needed for its placement. The assistant elevates and tenses the stay sutures to facilitate closure of the uterus, which is performed in two layers with No. 1 or 2 absorbable suture material. The suture patterns used depend on the surgeon's preference. An inverting pattern is necessary in the outer layer to provide a serosa-to-serosa seal with exposed deeper tissues. This helps to prevent adhesions. After uterine closure, the uterus is lavaged and 40 units of oxytocin is administered IV. This quickly stimulates contraction of the uterus and aids expulsion of the placenta. The stay sutures are removed and the uterus is replaced into its normal position in the abdomen.

Figure 62-4. Controlled vaginal delivery. The mare's hind limbs are hoisted, the clinician is repositioning the foal, and the technicians are preparing the abdomen in case a C-section is necessary.

Figure 62-5. C-section with the uterine horn containing the hind limbs exteriorized. The amnion is partially incised near the point of the hock.

The extra impermeable drape is removed, the drape surface around the incision is lavaged, and the surgeon's gown and gloves are changed if needed. The abdomen is lavaged with 10 to 15 L of warm saline, which is removed by suction. An abdominal drain for subsequent lavage may be placed if deemed necessary. A crystalline penicillin solution is instilled into the abdomen, which is closed in routine fashion for a ventral midline celiotomy.

Terminal Cesarean Section

Significant concern for a foal in a mare with a terminal illness may require a C-section. Examples include mares recumbent as a result of neurologic abnormalities, severe laminitis, or other potentially fatal or debilitating conditions. If euthanasia is planned for the mare after the surgery, sterility is not a high priority but speed of delivery is. Most of these surgeries can be performed quickly through a low flank approach after induction of anesthesia.

Aftercare

Postoperative care for a C-section mare is very similar to that for any mare after abdominal surgery, with special attention paid to the reproductive tract. Some mares pass their placenta in the recovery stall. If the placenta has not passed, oxytocin is again administered 2 to 3 hours after delivery. The initial dose is 40 U in 1 L of lactated Ringer's solution given IV over 30 to 60 minutes. Since this often causes abdominal pain, the rate of administration is dictated by the response of the mare. In refractory cases, 80 U is used every 4 to 6 hours. Usually, the placenta passes within 8 hours after delivery. Manual rupture of the chorioallantoic membrane and exteriorization of the amniotic membrane *per vagina* may be needed to initiate placental expulsion after an elective C-section. Uterine lavage is started soon after the placenta is passed, or simultaneously if it is retained. The uterus is generally lavaged once daily for 3 to 4 days.

Systemic antibiotics and flunixin meglumine are administered for 3 to 5 days after the delivery, depending on the degree of contamination and tissue trauma encountered. Intravenous fluids are administered as needed to maintain adequate hydration and vascular volume and to correct electrolyte imbalances. Abdominal surgery, even without manipulation of the intestines, combined with possible bruising of the small colon or cecum from the dystocia, can result in transient postoperative ileus. Swollen and painful pelvic tissues may lead to retention of feces. The postpartum diet should reflect concern for these potential problems. Water is offered freely. The mare is walked and allowed to graze on green grass the first postoperative day. A bran mash with mineral oil may be beneficial. Discharge instructions include hand walking 2 to 3 times each day, with or without small-paddock turn-out for 3 to 4 weeks.

DYSTOCIA

Dystocia in the mare is one of the few true emergencies an equine practitioner may encounter. Prompt action increases the probability of survival of the foal and decreases the degree of reproductive trauma to the mare.[56,57,60,61] The four procedures to resolve dystocia are assisted vaginal delivery, in which the mare is awake and is assisted in the vaginal delivery of an intact foal; controlled vaginal delivery (CVD), in which the mare is anesthetized and the clinician is in complete control of the delivery of an intact foal vaginally; fetotomy, in which the dead fetus is divided into more than one part for removal from the uterus *per vagina* in an awake or an anesthetized mare; and C-section, in which the fetus is removed through an incision in the uterus.

The goal of dystocia resolution is to deliver a live foal in a manner resulting in a reproductively sound mare.[57] This is usually accomplished at the farm. However, referral hospitals need to be prepared for difficult cases, and the clinician must be able to perform whatever procedure is necessary to resolve any dystocia. Currently, emergency clinicians, who are usually trained as surgeons or internists, tend to perform C-sections at these hospitals. Thus, these clinicians should also be familiar with CVD and fetotomy techniques. No single procedure is right for every situation.

After the mare is in the hospital, dystocia requires prompt action. The mare is anesthetized shortly after arrival to attempt CVD. The hind limbs are hoisted upward until the pelvis is about 3 feet above the ground. Decreased straining, aided by the effects of gravity, and lubrication usually enable resolution of the dystocia. If the foal cannot be delivered within 15 minutes, a C-section or fetotomy should be considered. C-section techniques were described earlier. Fetotomy techniques are described elsewhere.[62-64]

Results of dystocia resolved in a referral hospital in an area with a high concentration of broodmares were reported in 2002.[56] Of 247 cases of dystocia, 71% were resolved by CVD, 25% by C-section, and 4% by fetotomy. At the same hospital, with now more than 700 cases of dystocia at the time of this writing, the distribution of how dystocias were resolved has stayed essentially the same. The method of dystocia resolution varies between hospitals.[56,58,61]

It is difficult to compare short-term survival rates of dystocia mares between different studies. In studies reporting all the procedures used to resolve dystocia, mare survival rates ranged from 82% to 91%.[54,56,61] The mare survival rate following CVD, in the earlier study was 94%.[56] Mare survival rates following C-section to resolve dystocia have ranged from 82% to 91%.[54,56,58,65] Studies focusing on the results following fetotomy performed in a referral hospital or on a farm yielded mare survival rates of 90% to 96%.[63,64]

Duration of dystocia directly affects foal survival. Two studies have shown significant differences in duration of dystocia (from chorioallantois rupture to delivery) between foals surviving and not surviving to discharge from the hospital.[56,61] In one study, the group of surviving foals had a duration median of 60 minutes and the nonsurvivor foals had a duration median of 79 minutes.[56] In this study, 42% of the foals were born alive and 30% were discharged. In another study, the group of surviving foals had a median duration of 71 minutes and the nonsurvivor foals had a median duration of 249 minutes.[61] In this study, 30% of the foals were born alive and 13% were discharged. The median duration was significantly different. In these studies, no foal survived to discharge following dystocia duration of more than 162 minutes. Interestingly, in another study of 33 Fresian mares, the surviving foals had a dystocia mean of 164 minutes and the nonsurvivor foals had a mean duration of 490 minutes. In this study 42% of the foals were born alive and 31% were discharged. It was surmised that the difference resulted from fewer foals engaging in the pelvic canal prior to resolution of the dystocia in this breed.[58]

Increasing duration of dystocia prior to resolution adversely affects fertility of the mare. Live foaling rates are decreased, but can approach normal. Minimizing trauma to the mare's reproductive tract during resolution of dystocia will improve post-dystocia fertility.[55-58,63,64]

Diagnostic Techniques and Principles of Urinary Tract Surgery

Harold C. Schott II and J. Brett Woodie

PATIENT EVALUATION

Harold C. Schott II

History

Important historical information for horses that may require surgical treatment of the urinary tract includes type and duration of clinical signs, diet, whether other horses may be affected, medications administered, and response to treatment. The most common presenting complaints for horses with urinary tract disease are weight loss, decreased performance, and abnormal urination (stranguria, pigmenturia, pyuria, or incontinence). Other clinical signs vary with the cause and site of the problem and may include fever, anorexia, lethargy, ventral edema, oral ulceration, excessive dental tartar, colic, or scalding or blood staining of the perineum or hind legs (Table 63-1). Although lumbar pain and hind limb lameness have been attributed to urinary tract disease (and may occur with a large renal mass), a musculoskeletal problem is the more common cause of these clinical signs. Decreased performance may be an early presenting complaint for renal disease, possibly a consequence of changes associated with uremia (anemia and lethargy). An occasional horse with urolithiasis or renal neoplasia may have a history of recurrent colic. Prolonged or repeated posturing to urinate and dysuria or hematuria are important findings to implicate the urinary tract as the probable source of abdominal pain in such patients. Obstructive urethrolithiasis in male horses also generally presents as "renal colic," but noteworthy differences from other types of colic are that affected horses typically have the penis dropped and are still willing to eat with this problem.

TABLE 63-1. Historical Factors and Presenting Complaints Associated with Upper and Lower Urinary Tract Disorders

Disorder	Complaints
Upper urinary tract disorders	Decreased performance
	Lethargy
	Partial inappetance
	Weight loss
	Increased thirst
	Polyuria and polydipsia
	Recurrent fever
	Ventral edema
	Oral ulcers
	Excessive dental tartar
Lower urinary tract disorders	Stranguria
	Pollakiuria
	Prolonged or abnormal micturition posture
	Dropped penis
	Distended urethra below anus
	Mass on external genitalia
	Incontinence
	Urine scalding
	Strong urine odor
Upper and/or lower urinary tract disorders	Acute colic
	Recurrent colic
	Abnormal gait
	Hematuria
	Pyuria

When collecting a history, owners should be queried about water intake and urine output as well as changes in frequency, posturing, and appearance of urination. Increased thirst and water intake (polydipsia) may be reported with renal disease, pituitary pars intermedia dysfunction, primary polydipsia, diabetes mellitus, or diabetes insipidus.[1] Astute owners may report increased thirst after exercise or a change in urine appearance, such as a clearer stream, to support polyuria and polydipsia (PU/PD). Owners should also be questioned about any apparent discomfort shown by the horse when posturing to urinate or during actual micturition (i.e., stranguria) as well as abnormal appearance of urine (e.g., pigmenturia, pyuria, or excessive sediment). Pollakiuria (frequent urination) and polyuria (increased urine production) can be confused by an owner and careful questioning is necessary to distinguish between these two problems. Pollakiuria can be seen in normal mares during estrus or with cystic calculi or cystitis in either sex. In contrast, polyuria more often accompanies the previously listed disorders associated with polydipsia. Pollakiuria should also be differentiated from frequent involuntary voiding of urine typical of horses with incontinence. With the latter problem, urine is often passed without the horse posturing to urinate and, in the

early stages of incontinence, may only be observed during exercise. In mares with incontinence, the number of foals delivered should be determined along with any history of dystocia that could have damaged the lower urinary tract. Owners of horses presenting with incontinence should be carefully questioned about possible musculoskeletal or neurologic disorders in the months to years before because incontinence may be a late complication of these primary problems.[2] Further, if excess urine sediment is observed when urine is passed on a flat surface (e.g., when placed in cross ties or a wash stall), accumulation of urine sediment in the bladder should be suspected.

When the presenting complaint is pigmenturia, questions about recent exercise or management changes, as well as when discolored urine is observed, are useful to determine whether the primary problem may be myoglobinuria, hemoglobinuria, or hematuria (Table 63-2).[3] Recent muscle cramping (rhabdomyolysis) during exercise would support myoglobinuria, whereas hemolysis and hemoglobinuria may develop with infectious diseases, exposure to toxins, or as a consequence of immune-mediated hemolysis. Treatment with other medications including rifampin, phenothiazines, nitazoxanide, and phenazopyridine can also cause urine to turn orange, whereas treatment with doxycycline may cause urine to turn dark brown to black. Finally, exposure of equine urine to air typically results in a progressive deepening of color from deep yellow to orange-red to brown. This may be confused with pigmenturia when discolored urine is observed on bedding. This progressive discoloration occurs in some, but not all, urine samples and has been attributed to presence of pyrocatechins in equine urine that change color as they oxidize when exposed to air. In some instances, the urine also turns red after voiding and owners may call when they observe "red urine" on snow.

When pigmenturia is a result of hematuria, passage of red urine throughout urination is consistent with hemorrhage from the kidneys, ureters, or bladder, whereas hematuria at the beginning of urination is often associated with lesions in the distal urethra. Hematuria at the end of urination is usually the result of hemorrhage from the proximal urethra or bladder neck. In fact, the primary rule out for hematuria following exercise is cystolithiasis, whereas passage of several squirts of bright red blood with urethral contractions after the end of urination is nearly pathognomonic for proximal urethral rents in male horses.[4]

TABLE 63-2. Causes of Pigmenturia in Horses

Type of Pigmenturia	Causes
Idiopathic pigmenturia	Oxidation of pyrocatechins in normal urine
	Drug-associated
	rifampin
	Phenothiazine
	Nitazoxanide
	Phenazopyridine
	doxycycline
Myoglobinuria	Exercise-associated rhabdomyolysis
	Complication of anesthesia (crush injury)
	Complication of *Strep. equi* infection
	Clostridial myonecrosis
Hemoglobinuria	Infectious disease
	piroplasmosis
	Equine infectious anemia
	Clostridium spp.
	Intoxication
	Red maple *(Acer rubrum)*
	Onions
	Immunological disorders
	Purpura hemorrhagica
	Neonatal isoerythrolysis
	Adverse drug reactions
	Procaine penicillin G
	Nonsteroidal anti-inflammatory drugs
Hematuria	Urolithiasis
	Urinary tract infection
	Proximal urethral rents
	Neoplasia
	Verminous nephritis *(Halicephalobus gingivalis, Strongylus vulgaris)*
	Idiopathic renal hematuria
	Vascular malformations
	Bladder hematoma (neonates)
	Exercise-associated bladder mucosal trauma
	Intoxication
	Blister beetle (cantharidin) poisoning
	Nonsteroidal anti-inflammatory drugs

Physical Examination

Physical examination findings in horses with upper urinary tract disease may be fairly unremarkable, but subtle changes might be detected. For example, decreased body condition, intermittent decreased appetite, excessive dental tarter, mild ventral edema, and a "fishy" or uremic odor of the oral cavity and skin may be the only outward signs of chronic renal failure (CRF) in uremic horses.[5] Horses with pyelonephritis may have intermittent fevers, lethargy, and decreased appetite, whereas the occasional horse with a renal mass may have altered abdominal conformation (protrusion of the flank on the affected side), mild scoliosis, altered hind limb stance, and hind limb gait abnormalities.[6]

Horses with lower urinary tract disease are often in good body condition with normal vital parameters. Careful examination of the external genitalia may reveal dried blood, a mass, or excessive urine odor. Horses with incontinence typically have urine scalding of the perineum (mares) or of the lower hind limbs (males) in addition to a strong urine odor around the hindquarters. When incontinence is present, it is useful to assess whether the horse appears conscious of bladder distension (becomes restless or uses abdominal muscles to partially empty the bladder) or whether urine appears to be intermittently voided in an unconscious manner. When incontinence is the primary problem, complete lameness and neurologic examinations should be performed to determine whether gait deficits accompany the lower urinary tract disorder. In younger horses with unilateral ectopic ureter, intermittent urine dribbling from the vulva or penis may be observed along with urine scalding. When this problem is unilateral, affected horses are typically reported to also posture and urinate normally.

Part of the initial assessment of horses with suspected renal disease or other disorders causing PU/PD should be to quantify water intake. Daily water intake provided by drinking is normally 45 to 55 mL/kg per day (22.5 to 27.5 L/day for a 500-kg horse) and can be determined by stabling the horse alone and providing a known volume of water.[7] Because water intake can vary with environmental conditions, level of activity, and diet, repeated measurement over several 24-hour periods provides a more accurate assessment of daily water consumption. Quantitative assessment of urine output, which should range between 0.5 and 1 mL/kg per day (6 to 12 L/day for a 500-kg horse), is more challenging to perform. Urine collection harnesses can be applied for 24-hour urine collections, and although horses used for research tolerate these devices fairly well, they have limited application to clinical patients.

Rectal Examination

Rectal palpation should be included as part of a complete physical examination of all horses with suspected urinary tract disease. Initially, the urethra below the anus in male horses should be examined externally as the tail is lifted. Moderate to severe distention often accompanies urethral obstruction, and the offending urolith may be palpated at or below the level of the ischial arch (Figure 63-1). In addition, symmetry of the perineum should be assessed because deformities may be detected in some horses with proximal urethral rents (Figure 63-2). The initial part of the rectal exam involves palpation of the intrapelvic portion of the urethra and urethral sphincter. The latter feels somewhat like the cervix of a mare, only more caudal. Subsequently, the bladder should be palpated to determine size, wall thickness, and presence of cystic calculi, excess sediment, or mural masses. If the bladder is full, palpation should be performed again after bladder catheterization or spontaneous voiding empties the bladder.

If palpating for a suspected cystolith, it is important to remember that dysuria and pollakiuria frequently result in a small bladder that may be entirely within the pelvic canal. In this situation, the bladder and disc-shaped cystolith are best palpated with the hand inserted only wrist deep into the rectum. If the hand is inserted farther forward to search for the bladder in the expected location over the brim of the pelvis, a cystolith can be missed because it may be lying just under the forearm. Most horses presented for incontinence have a large bladder that can easily be made to overflow with pressure placed over the top of the bladder. In contrast, it is nearly impossible to express urine from a horse with a normal urethral sphincter during rectal palpation. Horses with large, atonic bladders often develop sabulous urolithiasis, an accumulation of normal urine sediment in the ventral aspect of the bladder. This sabulous

Figure 63-1. Distention of the urethra below the anus in a gelding with an obstructive urethrolith

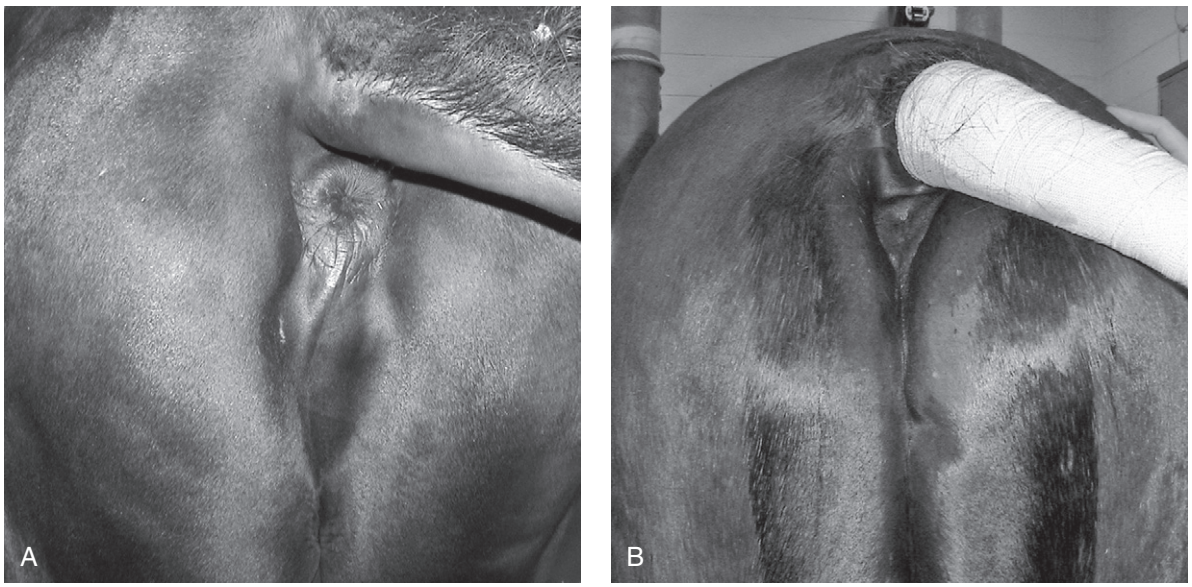

Figure 63-2. Asymmetry of the perineum in two geldings with proximal urethral rents causing hematuria immediately after urination. **A,** Note widening of the perineum. **B,** Note an indentation of the perineum.

sediment can become a large mass and be mistaken for a cystolith.[2] However, two features that can be used to differentiate these problems: (1) the bladder is usually quite large with sabulous urolithiasis when compared to a small bladder with a cystolith and (2) the sabulous sediment can often be indented with firm digital pressure (the bladder may need to be emptied by catheterization to fully appreciate this difference from a cystolith). Last, the apex or cranial portion of the bladder should be palpated to ensure that it is freely movable within the abdomen. Occasionally, the bladder apex remains adhered to the umbilicus, resulting in a bladder that is more tubular and cannot be freely manipulated.

Next, the caudal pole of the left kidney can be palpated for size and texture. The left kidney may be enlarged and/or painful on palpation in horses with acute renal failure (ARF), whereas it may seem smaller, irregularly shaped, and firmer in horses with CRF. It warrants emphasis that these findings are variable and highly subjective. Occasionally, a markedly enlarged kidney, either right or left, may be palpated in cases of polycystic kidney disease or neoplasia. Malposition of one of the kidneys is a rare congenital defect, but I have palpated an apparently normal right kidney immediately above the uterus in a mare. The ureters are generally not palpable unless they are enlarged or obstructed, but the dorsal abdomen (retroperitoneal course of ureters from abaxial to the aorta to the top of the bladder neck) and trigone should be palpated to determine if they can be detected. Dilatation of a ureter (to the size and texture of a garden hose) occurs in some horses with pyelonephritis or ureterolithiasis. In mares, palpation of the distal ureters through the ventral vaginal wall may be more rewarding as they diverge from the bladder neck in a Y-shaped pattern. The distal ureters and ureteral orifices into the bladder can also be palpated in mares at the 2 and 10 o'clock positions between an index or middle finger inserted through the urethra into the bladder and the thumb in the adjacent portion of the vagina. Finally, the reproductive tract in mares and accessory sex glands in stallions should also be palpated to assess whether a reproductive problem could be causing the clinical signs.

Clinical Pathology

Hematology and Serum Chemistry Analysis

A minimum database for a horse with a suspected urinary tract disorder should include a complete blood count (CBC), serum chemistry profile, and urinalysis. An elevated white blood cell (WBC) count and fibrinogen concentration would support an inflammatory or infectious disease process. An elevated globulin concentration further supports chronicity (weeks to months) of an inflammatory response. Mild anemia (packed cell volume 25% to 30%) following decreased erythropoietin production and a shortened red blood cell (RBC) life span with uremia may also be observed in horses with CRF.

On the serum chemistry profile, blood urea nitrogen (BUN) and serum creatinine (Cr) concentrations are the major parameters used to assess renal function, although additional information is provided by electrolyte concentrations. It is important to remember that BUN and Cr are insensitive indicators of decreased renal function because values might not exceed the upper limits of reference ranges until glomerular filtration rate (GFR) is reduced by 75% or more. Although this commonly used percentage is based on studies of subtotal nephrectomy in laboratory animals, it warrants mention that Cr remained normal and body weight was maintained after experimental unilateral nephrectomy in ponies[8] and horses.[9] Therefore, measurement of BUN and Cr is of limited use in evaluating minor changes in GFR. However, when elevated above the upper limit of the reference ranges, small increases in BUN and Cr are sensitive indicators of further deterioration in GFR, because doubling of BUN or Cr can be interpreted as a further 50% decline in remaining renal function (Figure 63-3). Although the term *blood urea nitrogen* concentration is widely accepted, it is important to remember that the actual measurement reported is the urea concentration in serum. Reporting of BUN and Cr also varies among countries. In the United States, BUN and Cr are reported in milligrams per deciliter, whereas in other parts of the world they are reported in standard international units of millimoles per liter and micromoles per liter, respectively. Conversion of BUN from milligrams per deciliter, to millimoles per liter and of Cr from milligrams per deciliter, to micromoles per liter is accomplished by multiplying by 0.357 and 88, respectively.

Azotemia is the term used to describe increases in BUN and Cr detected on a serum chemistry profile; hence, azotemia is a laboratory diagnosis. Azotemia can be prerenal in origin, resulting from decreases in renal blood flow (RBF) and GFR, or it can be the result of primary (intrinsic) renal disease or obstructive disease or disruption of the urinary tract (postrenal failure).[10] The term *prerenal failure* has been used to describe reversible increases in BUN and Cr associated with renal hypoperfusion. Although this term is firmly entrenched in the human and veterinary medical literature, its use likely contributes to a lack of recognition of subclinical renal damage that accompanies a number of medical and surgical conditions. This can be attributed to a large renal functional reserve capacity. In many patients with reversible azotemia and changes in glomerular and tubule function. Integrity can be demonstrated by proteinuria and cast

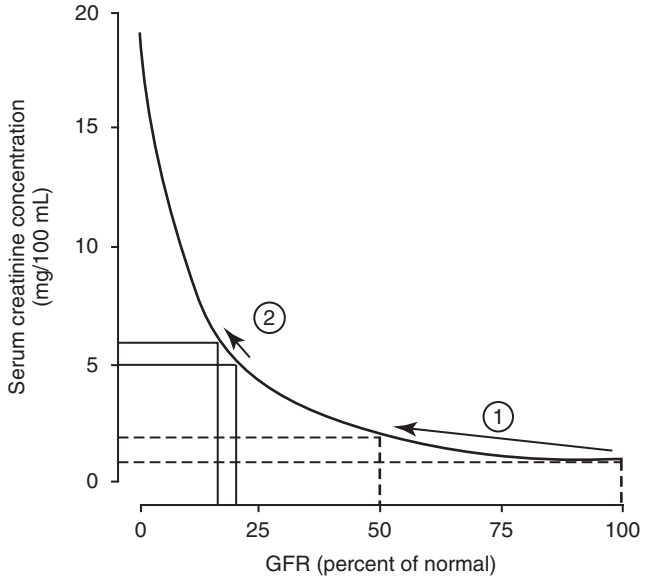

Figure 63-3. Relationship between glomerular filtration rate (GFR) and serum creatinine (Cr) concentration. When renal function is normal, a large decrease in GFR results in a minor increase in Cr *(arrow 1)*. In contrast, when renal function is decreased, as with chronic kidney disease, a much smaller decrease in GFR results in a similar increase in Cr *(arrow 2)*. (From Brenner BM (ed): Brenner and Rector's The Kidney. 8th ed. Saunders, Philadelphia, 2008.)

TABLE 63-3. Incidence of Azotemia (and Associated Mortality) in Horses Presented to a Veterinary Teaching Hospital

	1997		2000	
Examination Data	**Number**	**Percentage**	**Number**	**Percentage**
Horses examined	1902		2289	
Serum chemistry performed at admission*	397	21%	423	18%
Cr ≥ 2.5 mg/dL	82	4.3%	81	3.5%
Cr ≥ 5 mg/dL (mortality rate)	15	0.8% (31%)	19	0.8% (44%)
Cr ≥ 10 mg/dL (mortality rate)	2	0.11% (100%)	3	0.13% (33%)†
Primary renal disease	3	0.16%	2	0.09%

*Assumes that horses that did not have a serum chemistry performed also did not have azotemia.
†The two survivors were neonatal foals with spurious hypercreatininemia.

formation, impaired concentrating ability, and an increase in sodium excretion. Despite the reversible nature of these functional alterations, a degree of permanent nephron loss may occur with prerenal failure and likely explains the finding of microscopic evidence of renal damage in as many as one third of normal equine kidneys.[11] To increase awareness of subclinical renal damage in patients with decreased RBF and GFR, the term *acute kidney injury (AKI)* has been introduced in human and, subsequently, small animal medicine. AKI is defined as an increase in Cr of 0.3 mg/dL or a 50% increase from the baseline value, yet Cr may remain within the reference range.[12] Hemodynamically induced AKI is often associated with oliguria (urine output of less than 0.5 mL/kg for at least 6 hours) whereas urine production with nephrotoxin-associated AKI often remains normal (nonolguric AKI). In addition to changes in Cr and urine output, a number of novel biomarkers of AKI, notably kidney injury molecule-1 in urine, are being investigated as early indicators of renal damage.[13] A similar change in terminology has been adopted in human and small animal medicine for patients with chronic renal disease. Rather than describing patients as suffering from CRF (often an end-stage problem), the term *chronic kidney disease (CKD)* has been introduced to shift attention to the detection of earlier stages of chronic renal disease.[14,15] Although CKD is by nature a progressive disorder, early detection and interventions may slow the rate of progression, thereby prolonging life and, for people, delaying the potential need for renal replacement therapy.

To limit potential nephron damage with renal hypoperfusion, prerenal failure is accompanied by a number of compensatory responses to preserve RBF (autoregulatory response of afferent arterioles) and GFR (increase in filtration fraction due to angiotensin II–mediated efferent arteriolar constriction).[16] However, intrarenal blood flow is not homogeneous with the cortex receiving a substantially greater part of total RBF than the medulla. As a consequence, the medulla, especially the inner medulla, exists in a relatively hypoxic environment even with normal hydration status and RBF.[17] When RBF is reduced, intrarenal production of vasodilative prostaglandins (PGI_2 and PGE_2) is another important response to maintain or even increase medullary blood flow. However, administration of nonsteroidal anti-inflammatory drugs (NSAIDs) nearly abolishes this renoprotective response and can exacerbate the risk of renal damage with renal ischemia. Not surprisingly, the lesion associated with NSAID nephropathy is renal papillary or medullary crest necrosis.[18] Although NSAIDs that preferentially inhibit cyclooxygenase-2 (COX-2) activity (e.g., firocoxib) have been documented to have less adverse effects on the gastrointestinal tract of horses, evidence from other species suggests that the more COX-2 selective NSAIDs offer essentially no protection against NSAID-induced renal injury.[19]

In general, horses with reversible azotemia, covering the spectrum from prerenal failure to mild intrinsic renal damage, tend to have more modest elevations in BUN and Cr than horses with intrinsic ARF or postrenal problems.[20] However, there can be wide ranges of BUN and Cr values for all three categories of azotemia; consequently, specific values do not identify the type of azotemia. The incidence of significant azotemia (defined as Cr ≥ 2.5 mg/dL) in horses that presented to Michigan State University's Veterinary Teaching Hospital during 1997 and 2000 was less than 5% (Table 63-3). Further, the incidence of primary renal disease was less than 0.2%, consistent with azotemia most commonly being a problem secondary to other diseases (e.g., colic, enterocolitis, rhabdomyolysis, intoxications, and others). Of interest, horses with moderate azotemia (Cr 5 to 10 mg/dL) had a mortality rate of 30% to 45%, but the magnitude of Cr elevation did not predict survival in this range of azotemia. Because survival more likely depends on resolution of the primary disease process, it should not be surprising that the magnitude of moderate azotemia did not affect prognosis. In contrast, all adult horses with severe azotemia (Cr > 10 mg/dL) did not survive. In this limited population, only severe azotemia appeared to affect prognosis. In addition to severe azotemia, the change in Cr with treatment also has prognostic value with a reasonable goal being that Cr should decrease by 30% or more during the initial 24 hours of appropriate treatment. As an example, in horses that presented with colic or enterocolitis and a Cr > 3 mg/dL to the University of Georgia Veterinary Teaching Hospital, persistence of azotemia over the initial 3 days of treatment was associated with a greater volume of gastric reflux, abnormal rectal exam findings, and hypochloremia, as compared to horses in which azotemia resolved. Consistent with more severe fluid losses, hypovolemia, and renal damage, horses with persistent azotemia were three times more likely to have a poor outcome.[21]

To further define the type of renal failure in azotemic patients, the BUN:Cr ratio has also been used. In theory, this ratio should be higher for prerenal failure (10 or more using mg/dL units, owing to increased reabsorption of urea with decreased GFR and tubular flow rates) and postrenal failure with uroperitoneum (because of preferential diffusion of urea across the peritoneal membrane) than for azotemia associated with intrinsic renal failure. However, similar to absolute values for BUN

and Cr, BUN:Cr ratios measured in azotemic dogs with naturally occurring diseases were distributed over wide, nondiscriminatory ranges for all three types of renal failure.[22] In horses with acute medical and surgical problems complicated by dehydration and hypovolemia, clinical experience finds that Cr tends to increase (percentage) by a greater magnitude than BUN, leading to a BUN:Cr ratio less than 10:1.[23] In contrast, with CRF the BUN:Cr ratio often exceeds 10:1.[5,24] In addition to differences in excretion and reabsorption of urea and creatinine with decreased RBF and GFR, the preferential increase in Cr with acute disorders may also be related to different chemical properties of urea and creatinine. Urea, a nonpolar molecule, diffuses freely into all body fluids, whereas creatinine, a larger charged molecule, likely requires more time to move out of the extracellular fluid space. The important point is that a sudden decrease in RBF and GFR typically leads to a greater increase in Cr than in BUN, and Cr is the more accurate parameter to follow over time to assess improvement in renal function. As always, exceptions occur and an occasional horse with an acute problem may have a comparatively greater increase in BUN than Cr. In my experience, this is more common in foals and yearlings and may be associated with gastric or upper intestinal bleeding with ulcerative disease. Neonatal foals delivered from mares with placentitis or that experience perinatal asphyxia may have markedly elevated Cr concentrations (occasionally more than 20 mg/dL) after birth with essentially normal renal function. This clinicopathologic finding, termed *spurious hypercreatininemia*, resolves rapidly over the initial 1 to 3 days of life, and normal renal function is supported by adequate urine output and normal serum electrolyte concentrations.[25] With CKD, both BUN and Cr should be monitored over time, and the BUN:Cr ratio may be useful in assessing dietary protein intake because values 15:1 or more suggest excessive protein intake and urea production.[5,24]

Finally, increases in urea and creatinine have different effects on tissues. Specifically, urea is one of the uremic toxins that accumulates with renal failure, and progressive increases in BUN contribute to tissue dysfunction and morbidity, especially at values exceeding 75 mg/dL. In contrast, creatinine has little harmful effect on tissues and should not be considered a toxic compound. Rather, creatinine is simply a marker of renal function that increases when RBF and GFR decline. The reason that Cr is a useful indicator of renal function is that about 1% of muscle creatine is broken down to creatinine daily and the primary route of elimination is in urine (via glomerular filtration with little tubular reabsorption or secretion). Accordingly, as GFR decreases, urinary creatinine excretion also decreases, leading to a progressive rise in Cr.

In addition to screening for azotemia, the chemistry profile yields serum electrolyte, protein (albumin and globulin), and glucose concentrations and muscle enzyme activities. An important difference between prerenal failure and intrinsic renal failure is that electrolyte concentrations should remain normal with prerenal failure, whereas hyponatremia and hypochloremia are characteristic findings in horses with renal disease.[10,20,23] Unfortunately, hyponatremia and especially hypochloremia can also be found in horses with colic or enterocolitis; as a result, these electrolyte changes are not specific for AKI. Serum potassium concentration may be low, normal, or increased with AKI, but significant hyperkalemia (more than 6 mEq/L) is more commonly found with oliguric to anuric ARF or with uroperitoneum. Calcium and phosphorus concentrations vary in horses with renal disease. Hypercalcemia and hypophosphatemia are often found in horses with CKD, especially those fed alfalfa hay, whereas hypocalcemia and hyperphosphatemia may be found with AKI. In fact, the combined findings of azotemia and hypercalcemia are essentially pathognomonic for CKD in horses.[5,24]

Total protein concentration in horses with primary urinary tract disorders is usually normal; however, an occasional horse with a chronic inflammatory lesion (e.g., pyelonephritis, chronic cystitis, neoplasia) has an elevated globulin concentration. With end-stage CRF, intestinal ulceration may lead to hypoproteinemia. Mild hypoalbuminemia may also develop with protein-losing glomerulopathies because albumin tends to pass through the damaged glomerular basement membrane to a greater extent than the higher-molecular-weight globulins. A rare horse with primary glomerular disease may actually develop chronic hypoalbuminemia before onset of azotemia.[26] In horses with AKI secondary to other diseases, total protein concentration is altered more by the primary disease process than AKI. Hyperglycemia secondary to stress, exercise, sepsis, pituitary pars intermedia dysfunction, or diabetes mellitus can result in glucosuria. The renal threshold for glucose in horses has not been well investigated but is likely lower (160 to 180 mg/dL) than in small animals or people. Thus, glucosuria must always be interpreted with knowledge of serum glucose concentration. When pigmenturia is a complaint, measurement of creatine kinase (CK) and aspartate aminotransferase (AST) activities is useful to differentiate myoglobinuria from hematuria or hemoglobinuria.

Acid-Base Balance

Venous blood gas analysis in horses with AKI usually reflects the primary disease process, rather than the secondary renal insult. Thus, horses with colic are often mildly alkalotic because of pain and hyperventilation. With more serious disease and endotoxemia, a variable degree of metabolic and lactic acidosis may be present. With primary renal disease, mild metabolic acidosis may also be detected, but acidosis is usually not severe until marked azotemia (Cr > 10 mg/dL) develops with either oliguric AKI or end-stage CRF.

Urinalysis

SAMPLE COLLECTION

Urine can be collected as a midstream catch during voiding or via urethral catheterization in both sexes. Manual compression of the bladder during rectal palpation may stimulate urination after the rectal examination is completed, especially when a horse is placed in a freshly bedded stall. A fairly practical device to obtain a urine sample from geldings or stallions can be made by cutting off the bottom of a gallon plastic bottle, which is then padded and secured below the sheath (Figure 63-4). The opening of the bottle is covered with a cap that can be unscrewed to collect a urine sample after urine has been voided. In addition, some horses can be trained to void urine on command; often this is most successful following exercise.

Passage of a flexible plastic or rubber catheter via the urethra into the bladder can be easily accomplished in both sexes, although it is generally necessary to sedate male horses for the penis to descend. Bladder catheterization is a clean, but not sterile, procedure because bacteria are present in the vestibule

Figure 63-4. A urine collection device for use in male horses and ponies.

of the mare and the distal urethra of male horses. Thus, clean exam gloves can be used rather than sterile surgical gloves for the procedure, but a sterile catheter should be used. The vulva or end of the penis should be cleaned with soap and water and the accumulation of smega in the urethral sinuses dorsal to the urethra (the "bean") should be removed in male horses. Sterile lubricant is applied to the end of the catheter and it is passed into the urethra. In males, mild resistance to passage may be felt as the catheter is passed over the ischial arch into the intrapelvic portion of the urethra (the catheter should be palpable below the anus). Greater resistance is appreciated as the catheter is passed through the urethral sphincter into the bladder. The end of the catheter outside the horse should be plugged with a 60-mL syringe to prevent air from being aspirated into the bladder, because the weight of urine in a partially full bladder can cause it to fall forward into the abdomen and fill further with air through an open catheter. This is not a major problem when it occurs, but it can make aspiration of a sample more difficult because air may have to be evacuated before urine is recovered. Another potential problem in male horses is that the catheter tip can be advanced into one of the seminal vesicle duct openings on the colliculus seminalis on the dorsal aspect of the urethra immediately caudal to the urethral sphincter. If resistance to catheter passage persists after it has been passed over the ischial arch, this problem can be detected by transrectal palpation of the catheter tip going to either side of the bladder neck. When this occurs, the catheter should be retracted to the intrapelvic portion of the urethra and, with the hand in the rectum, fingers can be placed on either side of the catheter to assist in directing it through the urethral sphincter into the bladder. Mares do not have a urethral diverticulum to complicate catheter passage but it is sometimes challenging to find the urethral sphincter on the pelvic floor at the level of the vestibulovaginal orifice. The most common mistake is to insert the gloved hand too far and enter the vagina, passing over the urethral sphincter. In most mares the urethral sphincter can be found with the hand partly inserted as a cone into the vestibule to the level of the knuckles, followed by moving the index or middle finger back and forth under the urethral papilla in an attempt to insert a finger through the sphincter into the bladder. When a finger has been successfully passed into the bladder, the sterile catheter is inserted under the palm and guided along the finger that is already in the bladder. As the catheter is passed, the finger is withdrawn from the bladder and a sample of urine is then aspirated. Mares generally do not need to be sedated for this procedure, but some will be stimulated to void during catheterization; consequently, an assistant should be ready with a specimen cup to collect a sample if the mare urinates. When collecting urine, it is always advisable to fill two urine specimen cups: one can be used for urinalysis and the other submitted (or temporarily saved) for bacterial culture, when indicated.

In mares, urine can also be collected from each side of the upper urinary tract via ureteral catheterization.[27] Indications for this procedure are rare but include a suspected unilateral kidney problem including pyelonephritis or neoplasia. The vulva is prepared in a similar manner but a stiffer, 8 or 10 French polypropylene catheter with a rounded tip and side opening is used. The ureteral orifices can be palpated at the 2 and 10 o'clock positions in the bladder neck. To pass a catheter into the ureter, the index and middle fingers are inserted through the urethra into the bladder with the catheter tip between the fingers (sedation and/or topical anesthesia of the urethral and bladder mucosa may be necessary if the mare reacts to stretching of the urethra). Use of surgical gloves facilitates palpation of the ureteral orifices, and the catheter is advanced with one finger on either side of the ureteral orifice. When the tip has been inserted, it can be helpful to flex the finger tips caudad and grasp the catheter between the fingers and then extend the fingers to guide the catheter 5 to 10 cm farther into the distal ureter. Because urine is normally passed from the ureter into the bladder in "squirts" every 30 to 60 seconds, patience is required because it may take 3 to 5 minutes to collect an adequate volume (5 to 10 mL) of urine from the ureter. After the sample has been collected from one ureter, a new sterile catheter is passed into the bladder to collect urine from the other ureter. In male horses, the only way to collect urine from each ureter is via endoscopic visualization of the ureteral orifices and passage of sterile polypropylene tubing through the biopsy channel of the endoscope into each ureter. When ureteral catheterization is pursued in an attempt to document unilateral pyelonephritis, urine samples collected from both ureters, as well as a sample initially collected from the bladder, should all be submitted for bacterial culture.

GROSS APPEARANCE

Color, clarity, odor, and viscosity should be evaluated at the time of urine collection. Normal equine urine is pale yellow to deep tan and is often turbid as a result of large amounts of calcium carbonate crystals and mucus.[28] It is not uncommon for urine appearance to change during urination or collection with a catheter, especially toward the end of micturition or collection, when more crystals that have gravitated to the bottom of the bladder tend to be passed, causing urine to appear almost milky white.

ASSESSMENT OF URINE TONICITY

Urine specific gravity is a measure of the number of particles in urine and is a useful estimate of urine tonicity. Although determination of specific gravity with a refractometer is quick and easy (reagent strips should not be used to measure specific gravity in horses),[28] it is important to recognize that urine tonicity is most accurately determined by measurement of urine osmolality (U_{osm}) because larger molecules in urine, such as

glucose or proteins, can lead to overestimation of urine tonicity when assessed by specific gravity. Clinically, this is only a problem in patients with diabetes mellitus or heavy proteinuria. Unfortunately, most refractometers have an upper end of the specific gravity scale of 1.035, making it necessary to estimate specific gravity of more-concentrated samples by extrapolation. As an alternative, refractometers with a wider specific gravity scale (1 to 1.06) are available and may be worthwhile to purchase for equine hospitals.

Urine specific gravity or U_{osm} is used to separate urine tonicity into three categories: (1) urine that is more dilute than serum (hyposthenuria or specific gravity < 1.008 and U_{osm} < 260 mOsm/kg); (2) urine and serum of similar osmolality (isosthenuria or specific gravity of 1.008 to 1.014 and U_{osm} of 260 to 300 mOsm/kg); and (3) urine that is more concentrated than serum (specific gravity > 1.014 and U_{osm} > 300 mOsm/kg).[29] Urine of most normal horses consuming dry forage is usually concentrated (two to four times the tonicity of serum) with specific gravity of 1.025 to 1.04 and a U_{osm} of 600 to 1200 mOsm/kg), whereas horses at pasture may have more dilute urine because of the high water content of grass. When deprived of water for 24 to 72 hours, horses with normal renal function produce urine with a specific gravity > 1.045 and an U_{osm} > 1500 mOsm/kg.[30] In contrast, neonatal foals typically have hyposthenuric urine because their diet consists largely of milk.[31] Because the volume of fluid intake as milk by foals up to 60 days of age is nearly fivefold the fluid intake of an adult horse (on an mL/kg basis), healthy foals are polyuric and their urine appears clear with little yellow color. Another consequence of this high fluid intake and associated diuresis is that BUN and Cr values in foals may be near or below the lower limit of the adult reference ranges. Further, although this fluid intake decreases a foal's ability to generate an osmotic gradient in the medullary interstitium, foals can still produce urine with a specific gravity > 1.03 when dehydrated.

Urine tonicity can be used to differentiate prerenal failure from intrinsic renal failure. With prerenal failure, maintenance of urinary concentrating ability is demonstrated by a specific gravity > 1.02 and a U_{osm} > 500 mOsm/kg, and values are often much higher. In contrast, with intrinsic renal failure urinary concentrating ability is lost: specific gravity and U_{osm} are typically <1.02 and < 500 mOsm/kg, respectively, in the face of dehydration.[32] Assessment of urine tonicity can be problematic, however, because it is only valid when performed on urine collected before initiating fluid therapy or administering medications (e.g., α_2-receptor agonists or furosemide) that can affect urine flow and tonicity.[33]

REAGENT STRIP ANALYSIS

The pH of equine urine is usually alkaline (8 to 9).[34] Strenuous exercise or bacteriuria can result in acidic pH, and bacteriuria can also impart a strong ammonia odor to urine because of breakdown of urea by bacteria with urease activity. Feeding large amounts of concentrate generally decreases urine pH toward the neutral value. Similarly, the more dilute the urine sample is, the closer the pH is to 7. Hyposthenuric urine produced by foals typically has a neutral pH and is relatively free of crystalline material. Occasionally, aciduria is detected in a dehydrated or anorectic horse. Although aciduria can be found with metabolic acidosis, many equine patients have hypochloremic metabolic alkalosis accompanied by aciduria. The mechanism for aciduria is likely similar to that described in ruminants with abomasal outflow obstruction.[35] Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further electroneutral sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus, aciduria is most likely to occur with concomitant hypokalemia or whole-body potassium depletion that develops in horses that have been off feed for several days.

Commercially available urine reagent strips can yield false-positive results for protein when alkaline samples are tested, especially when urine is concentrated.[36] Therefore, proteinuria is better assessed by specific quantification with a colorimetric assay (e.g., assays that are routinely used on cerebrospinal fluid). Urinary protein concentration is less than 100 mg/dL in the majority of normal horses and comparison of the quantitative protein result (mg/dL) to urine Cr concentration (mg/dL) in the form of a urine protein : urine creatinine ratio (UP : UCr) is the recommended test to document proteinuria.[37] Normal horses typically have a UP : UCr < 0.5 whereas significant proteinuria consequent to glomerulonephritis usually results in a UP : UCr > 2. Because proteinuria can also accompany bacteriuria, pyuria, and hematuria or may be found transiently following exercise, an abnormal UP : UCr result must be interpreted in light of these potential confounding factors. Neonatal foals that have acquired good passive transfer of maternal colostral antibodies normally have moderate proteinuria from 24 to 72 hours of life because of excretion of small-molecular-weight proteins in urine.

Normal equine urine should not contain glucose. Although the renal threshold for glucose has not been thoroughly evaluated in horses, early work indicated that it may be lower (160 to 180 mg/dL) than that of small animals and humans.[38] Thus, glucosuria can accompany hyperglycemia associated with the causes described earlier or with administration of dextrose-containing fluids or parenteral nutrition products. In addition, glucosuria may accompany sedation with α_2-agonists or exogenous corticosteroid administration.[39] When glucosuria is detected in the absence of hyperglycemia, primary proximal tubule dysfunction should be suspected. Glucosuria has more often been detected in horses with AKI than in those with CKD.

Unlike in ruminants, ketones are rarely detected in equine urine, even in advanced catabolic states or with diabetes mellitus. A positive result for blood on a urine reagent strip can reflect the presence of hemoglobin, myoglobin, or intact RBCs in the urine sample. Evaluation of serum for hemolysis or elevated CK and AST activities and of urine sediment for RBCs can be rewarding in differentiating between these pigments. Bilirubinuria is occasionally detected on reagent strip analysis of equine urine. Bilirubinuria is associated with intravascular hemolysis, hepatic necrosis, and obstructive hepatopathies. Hepatic disease is further supported by elevated serum bilirubin concentration and increased hepatic enzyme activities.

SEDIMENT EXAMINATION

Sediment examination is an underused diagnostic technique for evaluating urinary tract disorders in horses.[28] Unfortunately, a major limitation is that sediment should be examined within 30 to 60 minutes after collection. To perform sediment examination, 10 mL of fresh urine should be centrifuged (usually in a conical plastic tube) at 1000 rpm for 3 to 5 minutes. The supernatant urine is discarded, and the pellet is resuspended in the few drops of urine remaining in the tube. A drop of sediment is transferred to a glass slide, and a coverslip is applied.

The sediment is first examined at low power to evaluate for casts, and subsequently high-power examination is used to quantify erythrocytes, leukocytes, and epithelial cells and to determine whether or not bacteria are present. Casts are molds of Tamm-Horsfall glycoprotein and cells that form in tubule lumens and subsequently pass into the bladder. They are rare in normal equine urine but are found with acute tubular injury. Casts are relatively unstable in alkaline urine; accordingly, to ensure accurate assessment, urine sediment should be evaluated as soon as possible after collection. Fewer than five RBCs should be seen per high-power field (hpf) in an atraumatically collected urine sample. Pyuria (more than 5 WBCs per hpf) is most often associated with infectious or inflammatory disorders, and normal equine urine should have few bacteria. The absence of bacteria on sediment examination does not rule out their presence, however, and quantitative bacterial culture of urine collected by catheterization should be performed when urinary tract infection is suspected. Equine urine is rich in crystals. The majority of these are calcium carbonate crystals of variable size, but calcium phosphate crystals and occasional calcium oxalate crystals can also be seen in normal equine urine.[40] Addition of a few drops of a 10% acetic acid solution may be necessary to dissolve crystals for more-complete assessment of urine sediment.

URINE ELECTROLYTE CONCENTRATIONS AND CLEARANCES

Urinary electrolyte excretion, reflecting tubular function, can be assessed by measuring urine electrolyte concentrations or can be expressed quantitatively as excretion rates (mEq/min). Horses on an all-forage diet without electrolyte supplementation consume minimal sodium and chloride but large amounts of potassium. As a consequence, their kidneys evolved to conserve more than 99% of filtered sodium and chloride ions. In contrast, potassium ions are not well conserved except during periods of whole-body potassium depletion (i.e., when they are off feed). Normal equine urine typically contains less than 20 mEq/L of sodium, less than 50 mEq/L of chloride, and 200 to 400 mEq/L of potassium, depending on urine tonicity.[41]

Determination of electrolyte excretion rates requires volumetric collection of urine over time, an impractical measurement in most clinical settings. An alternative is to measure fractional electrolyte clearances, comparing the clearance of a specific electrolyte to that of creatinine.[29] A substance that is filtered across the glomerulus but neither reabsorbed nor secreted by renal tubules has a clearance rate similar to that of creatinine and a fractional clearance of 1 (or 100%). In contrast, a substance that is largely reabsorbed by renal tubules after filtration (sodium or chloride) has a lower clearance value than that of creatinine and a fractional clearance less than 1. The fractional clearance of a substance (Cl_A) is calculated by dividing Cl_A by creatinine clearance (Cl_{Cr}):

$$Cl_A/Cl_{Cr} = \frac{\{(\text{urine [A]}/\text{plasma [A]}) \times \text{urine flow}\}}{\{\text{urine [Cr]}/\text{plasma [Cr]}) \times \text{urine flow}\}}$$

which, by rearrangement (cancelling out the urine flow factor) and expressing as a percentage becomes:

$$Cl_A/Cl_{Cr} = \{(\text{plasma [Cr]}/\text{urine [Cr]}) \times (\text{urine [A]}/\text{plasma [A]})\} \times 100\%$$

Although fractional clearance is the appropriate term for this calculation, the term *fractional excretion* is also commonly used. Because urine flow is cancelled out in the equation, only a spot urine sample (not a timed urine collection) needs to be collected. To determine fractional electrolyte clearances, electrolyte and Cr concentrations must be measured in blood and urine samples collected within a few hours of each other. Again, because kidneys conserve more than 99% of filtered sodium and chloride ions, normal fractional clearance values are less than 0.8% for these electrolytes. In contrast, fractional clearance values for potassium are considerably higher (15% to 65%) depending on feed intake.[29] Increases in urine concentration and fractional clearance values of sodium and chloride can be early indicators of renal tubule damage with AKI.[32,42] However, results of these tests must be interpreted in light of diet and treatment because adding salt to the diet or administering polyionic enteral or intravenous (IV) fluids can also increase these values.[33] With CKD, measurement of urine electrolyte concentrations and fractional clearances are of limited diagnostic value because compensatory tubular function with CKD is often accompanied by nearly normal electrolyte excretion.

URINARY DIAGNOSTIC INDICES

In addition to urinary tonicity, diagnostic indices that may also be useful for differentiating prerenal failure from intrinsic renal failure in horses include urine : serum ratios of osmolality, urea nitrogen, and Cr and fractional sodium clearance (Table 63-4). For example, urine : serum Cr ratios in excess of 50 : 1 (reflecting concentrated urine) and fractional sodium clearance values below 0.8% (indicating normal tubular sodium reabsorption) would be expected in horses with prerenal failure, whereas ratios less than 37 : 1 and clearance values greater than 0.8%

TABLE 63-4. Diagnostic Indices that May Be Useful for Differentiating Prerenal Failure from Intrinsic Renal Failure in Horses

Diagnostic Index	Normal Horses	Prerenal Failure	Intrinsic Renal Failure
Urine osmolality (mOsm/kg)	727-1456	458-961	226-495
Urine osmolality : serum osmolality	2.5-5.2	1.7-3.4	0.8-1.7
Urine urea nitrogen : serum urea nitrogen	34-101	15-44	2-14
Urine creatinine : serum creatinine	2-344	52-242	3-37
Urine sodium concentration (mEq/L)	variable*	<20	>20
Fractional sodium clearance (%)	0.01-0.7	0.02-0.5	0.80-10.1

*Urine sodium concentration will vary with the amount of concentrate or supplemental salt added to the diet but is generally less than 20 mEq/L in horses on an all-forage diet.

Modified from Grossman BS, Brobst DF, Kramer JW, et al: Urinary indices for differentiation of prerenal azotemia and renal azotemia in horses. J Am Vet Med Assoc 180:284, 1982, and Seanor JW, Byars TD, Boutcher JK: Renal disease associated with colic in horses. Mod Vet Pract 65:A26, 1984.

were reported in a group of horses determined to have primary renal disease.[32] Although these diagnostic indices can be helpful, the data in Table 63-4 illustrate that renal hypoperfusion is accompanied by a progressive loss of concentrating ability, because ranges for these ratios tend to be lower for horses with prerenal failure than for clinically normal horses. As a consequence, these data also support the concept that progression from prerenal failure to intrinsic renal failure is along a continuum, associated with decompensation of the intrarenal responses to hypoperfusion.[16]

In patients at risk for developing AKI, including horses with serious gastrointestinal disorders and those receiving nephrotoxic medications, additional diagnostic indices such as serial assessment of specific gravity or U_{osm}, reagent strip analysis, sediment examination, urine sodium concentration, and fractional sodium clearance may be useful in identifying significant changes in renal function before the onset of azotemia. Unfortunately, monitoring these parameters is frequently complicated by use of IV fluid support, because a goal of IV fluids is to increase production of less-concentrated urine. Further, IV replacement solutions have a sodium concentration near that of serum (135 to 140 mEq/L) and administration of large volumes (more than 20 L) of IV fluids is associated with a large sodium load that must be eliminated in urine, resulting in urine sodium concentrations that may exceed 50 mEq/L and FCl_{Na} values greater than 1%. In contrast, IV fluid therapy has less effect on reagent strip analysis and changes in urine sediment. Thus, *a practical screening test for documenting tubular damage* is repeated reagent strip analysis for pigmenturia (likely hematuria) and glucosuria. With CKD, the ability to produce either concentrated or dilute urine is lost: affected horses manifest isosthenuria. Administration of IV fluids in an attempt to "diurese" horses with CKD results in a variable increase in urine output, yet specific gravity and U_{osm} remain in the isosthenuric range. The less residual renal function present, the more likely and rapidly IV fluid administration will produce an increase in central venous pressure and, ultimately, edema.

Peritoneal Fluid Analysis

Postrenal azotemia resulting from obstruction or disruption of the urinary tract is usually suspected on the basis of clinical signs, including dysuria and/or renal colic. With bladder rupture, however, some affected foals and adult horses continue to void urine, although progressive abdominal distention usually accompanies development of uroperitoneum. Although the diagnosis is now commonly made via transabdominal ultrasonography, uroperitoneum is best confirmed by measuring a twofold or greater value for peritoneal Cr in comparison to serum Cr.[29]

Imaging Techniques

Numerous imaging techniques are available to examine the urinary tract of the horse. The pros and cons of the various modalities have been well reviewed,[43] and the most rewarding and cost-effective techniques include ultrasonography and endoscopy of the urinary tract. In certain cases, nuclear scintigraphy is a valuable tool because it can provide information on individual kidney function. Textbooks are available with numerous images that provide in-depth review of each of these modalities for investigation of the equine urinary tract,[44-46] so they are only discussed in brief in this chapter. Computed tomography (CT) and magnetic resonance imaging (MRI) are also emerging as useful imaging tools in patients that are small enough (generally less than 200 kg) to fit within the imaging device.

Radiography

Radiography is of limited use to evaluate the urinary tract disease of adult horses because diagnostic radiographs can only be obtained in small foals or Miniature Horses. In smaller patients, intravenous excretory urography can be used to document a nonfunctional kidney or the course of ectopic ureters.[47] However, the procedure may require general anesthesia, and renal elimination of contrast is sometimes difficult to see, leading to inconclusive results.[48] Another approach involves injecting the contrast agent directly into the renal pelvis using a spinal needle under ultrasonographic guidance (pyelography).[49,50] The contrast agent is generally easier to visualize with this approach, and systemic adverse effects of contrast administration are largely eliminated.

Retrograde contrast radiographic studies have also been used in foals with suspected ruptured bladder, ectopic ureter, or urorectal fistula. Radiographic contrast studies can also help to identify strictures or masses in the urethra or bladder, but endoscopy is generally more useful for these problems.

Ultrasonography

Ultrasonographic examination of the urinary tract can be performed transabdominally (kidneys) or transrectally (lower urinary tract).[45,51-55] The right kidney is triangular or horseshoe-shaped and is best imaged transabdominally via the dorsolateral extent of the last two or three intercostal spaces. The left kidney is a bean- to U-shaped organ that lies deep to the spleen. It can be imaged via the last two intercostal spaces or via the paralumbar fossa. Because the left kidney is deeper than the right kidney, it can be difficult to image completely and is best examined with a 2.5- or 3-mHz curvilinear transducer. Occasionally, one or both kidneys cannot be imaged because of gas-filled bowel between the kidney and abdominal wall. Reexamination at a later time is generally required for successful imaging in such cases. The size and shape of the kidneys, intrarenal architecture, and echogenicity of the parenchyma should be assessed systematically. This includes imaging the kidneys in dorsal, sagittal, transverse, and transverse-oblique anatomic planes.[53] With AKI, the kidneys may be normal or enlarged (Figure 63-5, *A*), and abnormalities of parenchymal detail are often not detected. When present, abnormal findings may include perirenal (subcapsular) edema, widening, and subtly increased echogenicity of the renal cortex (see Figure 63-5, *B*). With CKD, especially end-stage renal disease, the kidneys are usually small, have increased echogenicity (the normal left kidney is similar to the spleen), and may have nephroliths or cystic cavities (Figures 63-6 and 63-7). Calculi are often in the area of the renal pelvis and can be differentiated from the normally echogenic renal pelvis because they generally cast an acoustic shadow. In an occasional patient in which the clinical picture is most consistent with AKI, ultrasonography may reveal nephroliths and increased echogenicity in one or both kidneys. These findings support previously unrecognized CKD, with recent exacerbation (so-called "acute on chronic" renal injury), and carry a more guarded

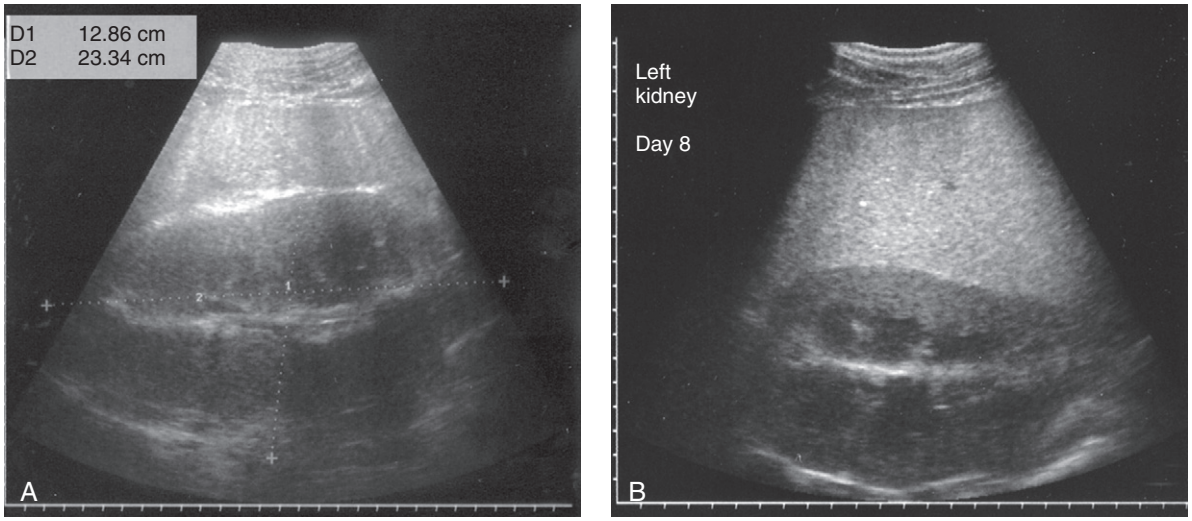

Figure 63-5. Transabdominal ultrasonographic images of the left kidney (deep to spleen) of two horses with acute kidney injury resulting in acute renal failure. **A,** Enlarged left kidney (23.3 cm in length). **B,** Renal cortex is more echogenic than normal.

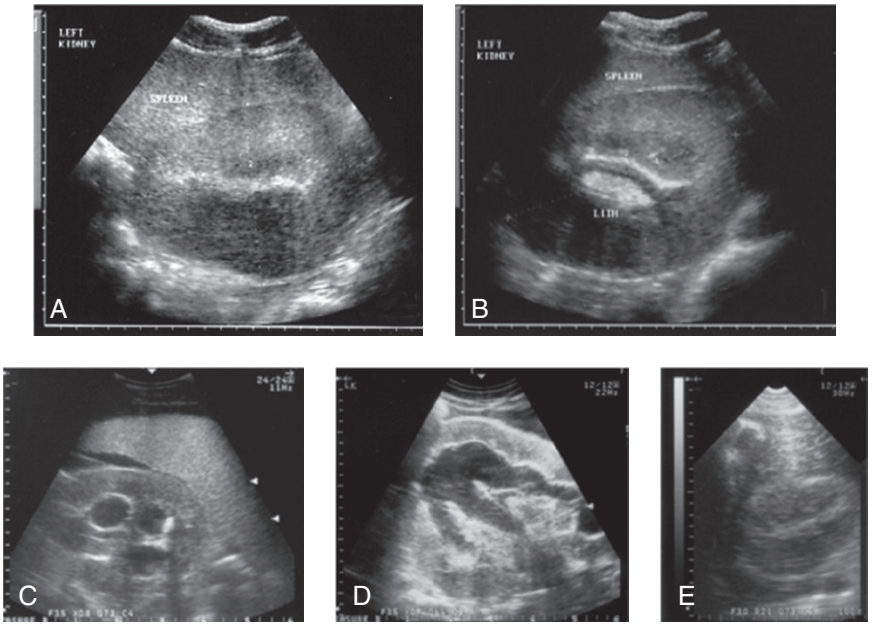

Figure 63-6. Transabdominal ultrasonographic images of the left kidney of two horses with chronic kidney disease. **A,** Left kidney of a yearling with chronic interstitial nephritis that developed 11 months following treatment with an aminoglycoside antibiotic and flunixin meglumine for a leg wound. Note the generalized increase in echogenicity of the renal parenchyma in comparison to the spleen. **B,** Left kidney of the same yearling with the probe directed in a different plane, revealing a large nephrolith adjacent to the renal pelvis. **C,** Left kidney of a stallion with an obstructive ureterolith causing hydronephrosis; note the small nephrolith in the center of the image producing an acoustic shadow. **D,** Left kidney of the same stallion imaged in a plane rotated 90o revealing hydronephrosis consequent to obstructive disease. **E,** Left kidney of the same stallion following relief of ureteral obstruction by electrohydraulic lithotripsy. Note that the kidney is small and the renal parenchyma has a diffuse increase in echogenicity because of renal fibrosis. (From Schott HC: Chronic renal failure in horses. Vet Clin North Am Equine Pract 23:593, 2007.)

prognosis than AKI with normal-appearing kidneys on ultrasonographic imaging.

Imaging of the bladder, urethra, and ureters is best performed transrectally using a 5- to 7.5-mHz linear array transducer commonly used for evaluating the reproductive tract or a 6- to 10-mHz microconvex linear-array transducer. When imaging the bladder, it is important to remember that equine urine, rich in crystals and mucus, is an inhomogeneous, echogenic fluid that can be made to swirl with manipulation of the bladder. Presence of a cystic calculus can typically be confirmed, because calculi have a highly echogenic surface and produce an acoustic shadow; however, ultrasonographic imaging is rarely indicated if the cystolith is suspected on rectal palpation. In contrast, ultrasonography can be a useful tool to evaluate size and echogenicity (homogeneous or heterogeneous) of soft tissue bladder masses. Normal values for bladder wall thickness, distal ureteral, and urethral diameter have been described for normal horses of both sexes.[55] Transrectal ultrasonography can be used

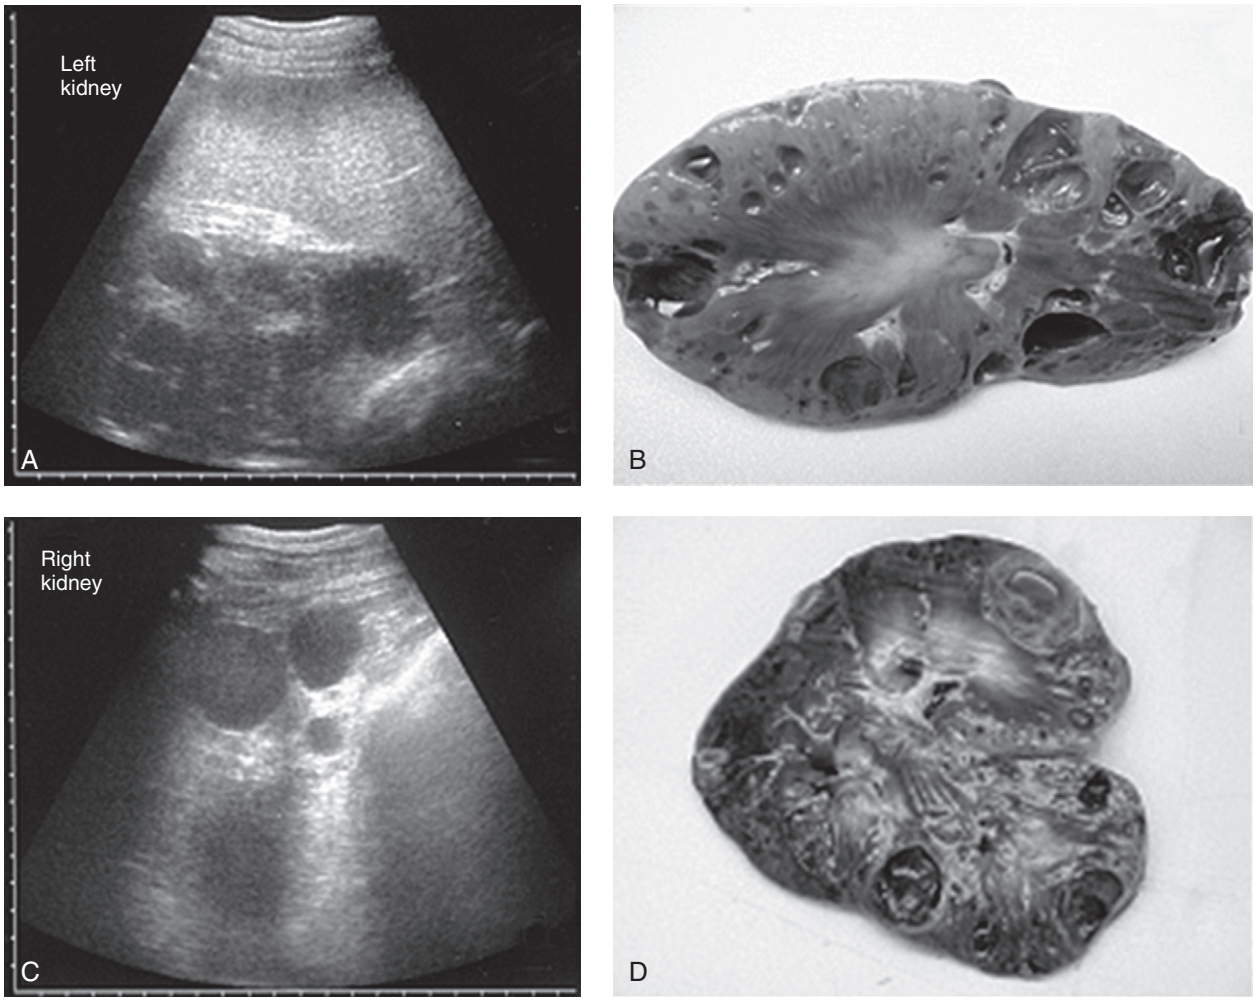

Figure 63-7. Ultrasonographic images of the left **(A)** and right **(C)** kidneys and cross-sectional gross pathology of the left **(B)** and right **(D)** kidneys of a 19-year-old Arabian mare with chronic renal failure consequent to polycystic kidney disease. to image urine passage from the ureters into the bladder and may reveal disruption or distention of a ureter.[56,57]

Endoscopy

Endoscopic examination of the urinary tract is an extremely useful diagnostic aid when the complaint is abnormal urination.[44,58,59] A flexible endoscope with an outer diameter of 12 mm or less and a minimum length of 1 m is adequate for examinating the urethra and bladder of an adult horse of either sex. As for bladder catheterization, lower urinary tract endoscopy is a clean but not completely sterile procedure; nevertheless, the endoscope should be sterilized before use. Tranquilization of the patient is recommended, the rectum should be emptied of feces, and the distal end of the penis or the vulva should be cleansed thoroughly. The bladder should be emptied by catheterization prior to passing the endoscope, and a sample of urine should be retained, if needed. The endoscope is then passed in the same manner as the catheter, using the air control intermittently to inflate the urethra or bladder. Normal distal urethral mucosa in males is pale pink with longitudinal folds. When dilated with air, the mucosa flattens and a prominent submucosal vascular pattern becomes more apparent as the endoscope is advanced up the urethra to the ischial arch. Passage of a bladder catheter before endoscopy can produce mild irritation of the urethral mucosa that may be seen as a reddish line along the urethra (it should not be mistaken as an abnormality). As the endoscope passes over the ischial arch, the urethra begins to widen into the ampullar (pelvic) portion, and paired rows of bulbourethral gland duct openings are seen along the dorsal aspect. In horses with a complaint of hematuria at the end of urination, consistent with a urethral rent, the caudal aspect of the urethra should be closely examined at the level of the ischial arch for fistulous tracts communicating with the corpus spongiosum penis.[3,4] Advancing the endoscope a few more centimeters and distending the pelvic urethra with air allows visualization of the colliculus seminalis protruding from the dorsal aspect of the urethra just before the urethral sphincter. The joint openings of the ductus deferens and seminal vesicle ducts on the colliculus seminalis should be examined closely, because this can be a site of postejaculation hemorrhage in stallions. Subsequent passage of the endoscope through the urethral sphincter and air distention allows evaluation of the bladder for calculi, inflammation, and masses. Viewing the ureteral openings in the dorsal aspect of the trigone can help determine if the source of hematuria or pyuria is

originating from one or both sides of the upper urinary tract. A small volume of urine should pass from each ureteral opening approximately once every 30 to 60 seconds (more frequent with sedation with an α_2-agonist). Ureteral catheterization to obtain urine samples from each kidney can be performed by passing sterile polyethylene tubing via the biopsy channel of the endoscope. Additionally, biopsy of masses in the bladder or urethra can be performed.

Smaller-diameter endoscopic equipment (less than 6 mm outer diameter) has allowed examination of the distal ureter, using a guide wire passed through the biopsy channel as a stylet to enter the ureter. In addition to allowing examination of the ureter, endoscopes of sufficient length (100 cm or longer) have also allowed advancement to visualize the renal pelvis in mares or via a perineal urethrotomy in male horses (Figure 63-8). In an occasional horse with upper tract disease or chronic sabulous urolithiasis, one or both ureteral orifices are damaged to the point that the normal valvelike openings have become permanently open, allowing a larger-diameter endoscope to be advanced up the ureter to allow visualization of nephroliths in the renal pelvis (Figure 63-9).

Nuclear Scintigraphy

Nuclear scintigraphy is an additional modality that can be used to obtain information about renal anatomy and function.[46] In fact, scintigraphy is routinely used for quantitative assessment of GFR in small animals.[60] Several radiopharmaceuticals can be labeled with 99-metastable technetium (^{99m}Tc), depending on the type of scintigraphic examination being pursued. Further,

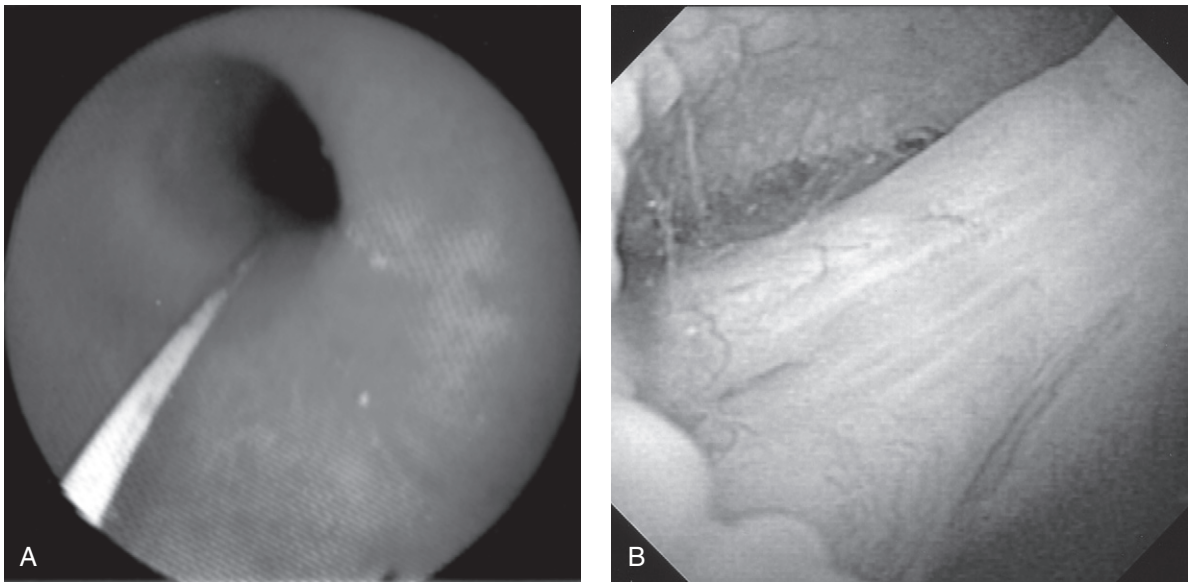

Figure 63-8. Endoscopic images of a normal ureter with a guide wire in place **(A)** and of a normal renal pelvis of a horse **(B).**

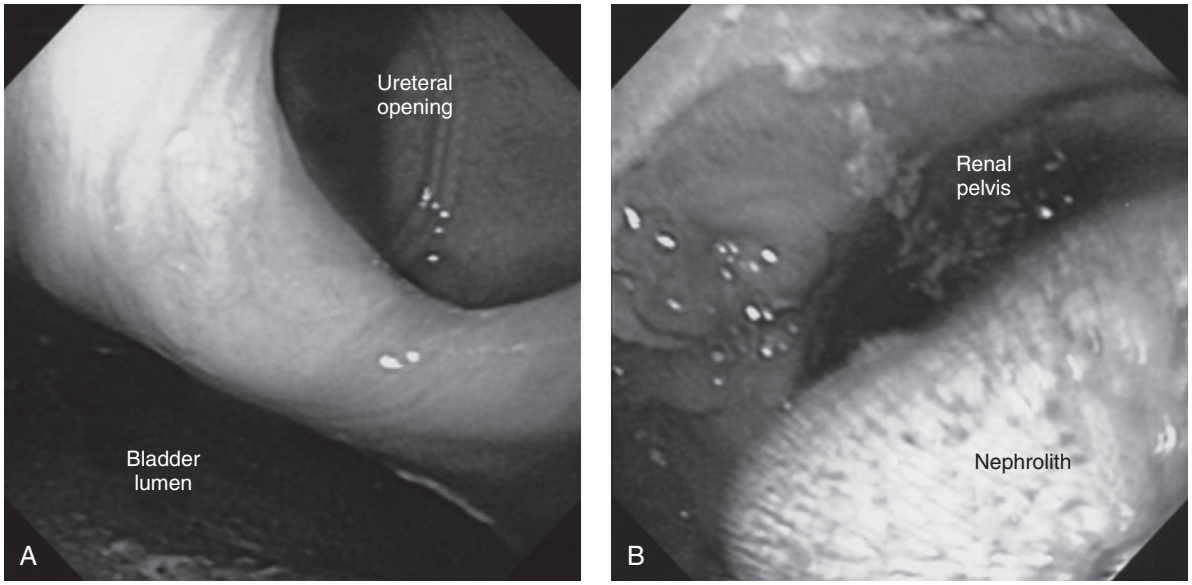

Figure 63-9. Endoscopic images of an abnormal ureteral opening **(A)** and a nephrolith in the renal pelvis **(B)** of a stallion with chronic kidney disease.

labeled radiopharmaceuticals can be used either to generate images or to measure plasma disappearance of radioactivity, to estimate RBF and GFR. In horses, an early study compared measurement of GFR by classic inulin clearance to scintigraphy (using ^{99m}Tc tagged to diethylenetriaminopentaacetic acid [DTPA], similar to inulin in that it is neither secreted nor reabsorbed after filtration). Both plasma disappearance of ^{99m}Tc-DTPA in blood samples collected over time and sequential digital gamma camera images of the kidneys to determine fractional accumulation of the total dose administered were assessed as measures of GFR.[61] Greater variability was found with the gamma camera images, in comparison to GFR values measured by plasma disappearance of inulin or ^{99m}Tc-DTPA, possibly because of the different depths of the two equine kidneys. Renal scintigraphy with gamma camera imaging has also been performed with ^{99m}Tc tagged to glucoheptanate (GH, taken up by the proximal tubule epithelial cells to provide further anatomic detail), and mercaptoacetyltriglycine (MAG_3, nearly completely eliminated during first pass through the kidneys by filtration and tubular secretion) to successfully evaluate renal function in horses with upper urinary tract problems.[48,56,62] With appropriate case selection, renal scintigraphy can provide qualitative information about renal function and is the only method currently available for assessing split renal function (assessing individual kidney function via gamma camera imaging) in horses (Figure 63-10).

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) provide the most detailed images of the urinary tract of all the available imaging modalities. Unfortunately, both imaging modalities are limited by the patient's size (generally less than 200 kg), the need for general anesthesia, and expense. Nevertheless, the modalities have been used in foals and Miniature Horses and, when coupled with use of appropriate contrast agents, provide the surgeon with excellent anatomical detail of the urinary tract problem (Figure 63-11).[63,64]

SURGERY

J. Brett Woodie

Instruments

The instrumentation that is required varies depending on the procedure that is being performed. Therefore it is beneficial to

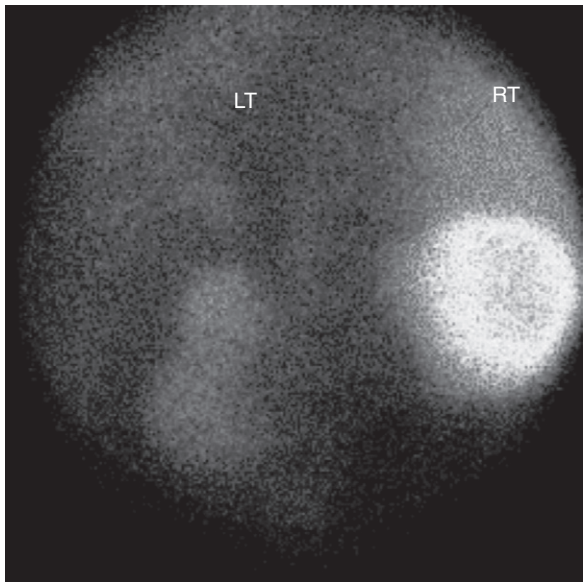

Figure 63-10. Nuclear scintigraphic dorsal image (cranial at *top* and caudal at *bottom*) of the kidneys of a horse with chronic hematuria arising from the left kidney. The study revealed considerably less radiopharmaceutical uptake and elimination by the left kidney and provided support that nephrectomy of the left kidney would not result in a substantial loss of remaining renal function.

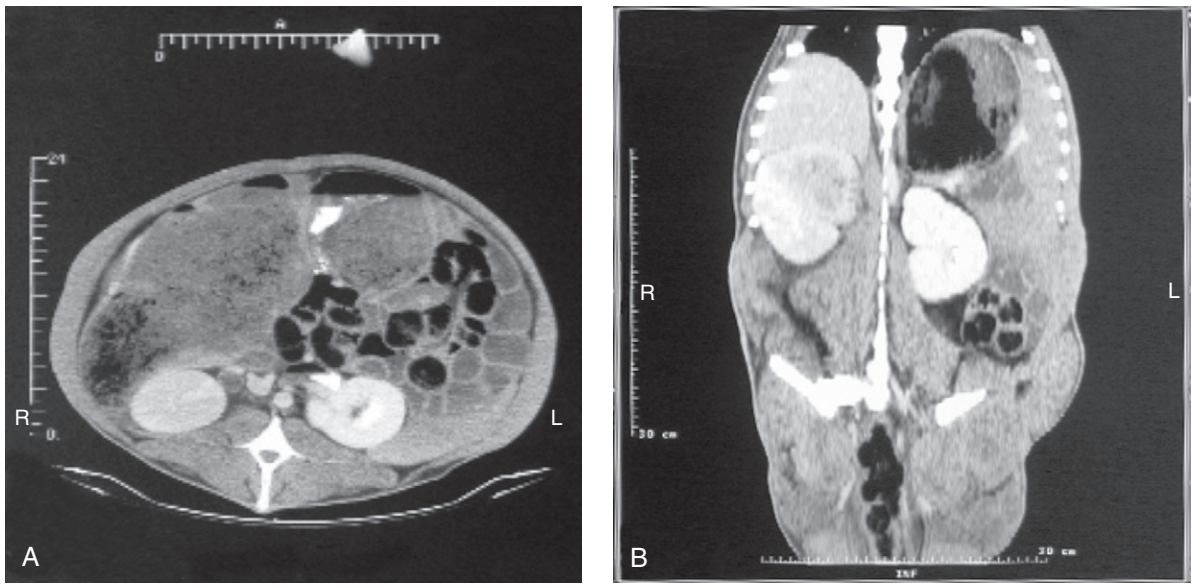

Figure 63-11. Contrast-enhanced computed tomographic images of the kidneys (excretory urography) of a normal Miniature Horse. **A,** The transverse plane image shows nearly homogeneous uptake of the contrast agent in both kidneys. **B,** The reconstructed dorsal plane image provides even greater detail of the intrarenal distribution of the contrast agent within the right kidney *(left side of image).*

have a broad range of long-handled instruments as well as standard-sized instruments. Grasping forceps with delicate teeth and needle holders with fine jaws are necessary to handle the fragile tissues and small-diameter suture needles needed for surgery of the urinary tract.[65] Broad-bladed self-retaining retractors, such as Finnechetto or Balfour retractors, are often essential for effective surgical access to the urinary tract, especially in the adult horse. For electrosurgery, the use of fine-needle electrodes and scalpels is appropriate. Anastomotic procedures and intraoperative stenting of the urethra or ureters can be facilitated by using sterile flexible rubber urethral catheters or silicone or polyethylene cannulas. It has been reported that stents can promote stricture formation in anastomosed ureters. Therefore, if stents are used they should be removed as soon as possible, preferably within 5 to 7 days after surgery.[66,67] Magnifying loupes or an operating microscope and adequate lighting are useful for repairing ureteral defects. Suction with an assortment of suction tips will be required.

Suture Material

The choice of suture material depends on a variety of factors, such as the strength of the tissue, the rate at which the tissue regains strength, the rate at which the suture material loses strength, and the interaction between the tissue and the suture material. Suture materials in a variety of sizes and strengths are required when performing urinary tract surgery. Tissues such as the neonatal bladder are often friable, whereas a bladder that contains a cystic calculus may be thickened. The bladder is considered one of the weakest tissues in the body.[68] Despite this fact, the urinary bladder and ureters have a high regenerative capacity and heal readily.[66,69] These tissues regain nearly 100% of their normal strength within 14 to 21 days.[69] For these reasons, absorbable suture material is an appropriate choice, and the use of nonabsorbable suture material is not indicated.[70]

In fact, nonabsorbable sutures are contraindicated for closure of any structure of the urinary tract. The use of nonabsorbable suture material can serve as a nidus for formation of urinary concretions.[65] As a technical point of urinary tract surgery, no suture material of any type should be placed in such a fashion that it penetrates the urinary epithelium and is exposed to urine.[67,68] Hydrolysis is the mechanism by which synthetic absorbable sutures are absorbed. Hydrolysis may be accelerated if the suture is exposed to alkaline urine, which is commonly found in herbivores or carnivores with urinary tract infections.[71] Absorbable staples provide an alternative method of closure of hollow organs, such as the bladder. To reduce the formation of adhesions, bladders closed with absorbable staples must be oversewn with a continuous-inverting suture pattern.[72] The use of nonabsorbable staples in the bladder is not recommended based on the formation of a urolith in one case report.[73]

A comparative study of bursting strength of rat bladders sutured with 6-0 surgical gut and 7-0 chromic gut suggested that infusion pressures of up to 550 mm Hg are required to induce failure.[74] Voiding pressures of most mammals are considerably lower.[75] The voiding pressures of adult ponies and mares have been determined to be approximately 90 mm Hg.[76] The use of 3-0, 2-0 or 1-0 suture material is adequate to maintain primary closure of incisions in the pressurized portions of the equine distal urinary tract.

Laparoscopy

Laparoscopy offers a minimally invasive method for surgical procedures of the equine urogenital system. Its use has expanded over recent years. Because of the size of the horse and the anatomic location of the urinary tract, traditional surgical approaches may not provide adequate access to complete the surgical procedure. However, a laparoscopic approach may offset these hurdles. Laparoscopy can be performed as a standing procedure or under general anesthesia. The standard laparoscopic equipment and instrumentation (described in Chapter 13) can be used for several surgical procedures of the urinary tract. The list of procedures includes exploratory laparotomy, cystic calculi removal, nephrectomy, renal biopsy, umbilical remnant resection, and urinary bladder repair. Another option is to use hand-assisted laparoscopic techniques. This combines the benefits of laparoscopy with that of an open surgical approach. The hand-assisted techniques offer the advantage of being able to perform manual dissection and retraction. The ability to control hemorrhage is increased as well.

Pharmacologic Considerations

The route of elimation of water-soluble drugs and drug metabolites is through renal clearance. Therefore, the kidneys are exposed to high levels of drugs and drug metabolites. The renal effects of all drugs administered to surgical patients must be considered.[77]

ANESTHESIA

J. Brett Woodie

Anesthetic management of a patient with an impairment of the renal system should be focused on minimizing the time under anesthesia and minimizing hypotension. Renal ischemia can occur during general anesthesia because of systemic hypotension or renal vasoconstriction. It is also important to realize that all anesthetics are likely to decrease GFR. Most decrease GFR by decreasing RBF. Anesthetic agents may indirectly alter renal function through changes in cardiovascular and/or neuroendocrine activity. All fluorinated gas anesthetics are nephrotoxic to some degree.[65] Sevoflurane has cardiopulmonary effects similar to those of isoflurane, and it has the theoretical possibility of creating both hepatic and renal toxicity through the formation of compound A via the interaction between metabolites and CO_2 absorbents.[78,79] Despite the potential for the formation of toxic metabolites, sevoflurane has been used on more than 120 million human patients without one report of induced renal toxicity.[79] However, the effect of compound A formation in the anesthetic breathing circuit of the horse is not known and it would be safest to avoid the use of sevoflurane in patients with kidney disease. Halothane undergoes more hepatic metabolism than other inhalants, but formation of toxic waste products appears to be minimal.[80] Halothane has been a widely used anesthetic agent for horses.[81] Its reduced degree of metabolism renders it relatively less toxic for use in renally impaired horses. Alternatively, isoflurane is useful in critically ill horses and has few renal effects, which are limited to an increase in urine flow and an increase in serum glucose.[82,83]

The kidney is sensitive to hypoperfusion resulting from hypotension. Systemic hypotension while under anesthesia is most likely caused by peripheral vasodilation. Inhalant

anesthetics depress myocardial contractility and cardiac output. Several commonly used anesthetic agents also produce some degree of peripheral vasodilation, which may result in reflex renal vasoconstriction and associated renal hypoperfusion.[84] Renal damage may be avoided by maintaining RBF and minimizing the duration and magnitude of hypotension associated with general anesthesia. Intraoperative administration of balanced fluids enhances perfusion of the kidneys by improving cardiac output. Selective vasopressors, such as dobutamine or dopamine, increase cardiac output and enhance renal perfusion.[85,86] The use of an α-blocker as a premedication reduces the degree of catecholamine-induced vasoconstriction and improves renal perfusion in some anesthetized patients.[87]

Xylazine and detomidine are sedative hypnotic agents commonly administered to horses to facilitate examination. Both of these drugs have a dose-dependent diuretic effect.[88] Horses with uncomplicated obstructive disease of the lower urinary tract that are at risk for acute cystorrhexis could be further compromised by the use of sedatives or tranquilizers with diuretic properties.

ANTIMICROBIAL AGENTS

Harold C. Schott II

Short-term use of perioperative antimicrobial agents is generally indicated for horses undergoing surgery of the urinary tract, and a longer course of treatment is necessary for treatment of urinary tract infection (UTI). The duration of perioperative antimicrobial use may be limited to a single presurgical dose and generally should be discontinued after 24 hours, unless the invasiveness of the surgery warrants a longer treatment course.[89] As a general rule, broad-spectrum coverage against aerobic gram-positive and gram-negative organisms should be provided. Further, potential adverse effects of antibiotics should be considered to determine whether it may be better to avoid use of certain drugs. For example, aminoglycoside antibiotics are best avoided in patients with AKI and CKD, and other drugs may increase the risk of developing enterocolitis in horses that are placed under general anesthesia for urinary tract surgery. Of interest, anecdotes about enterocolitis following general anesthesia and surgery suggest that use of specific perioperative antimicrobial agents may carry differing risks in varying geographical regions; thus, both regional and recent experience should also be used to guide selection of the appropriate perioperative antimicrobial agents.

Selection of an antimicrobial agent for treatment of UTI should be based on culture and susceptibility results of urine or septic tissue débrided at surgery. In addition, practical considerations (e.g., oral versus parenteral medications, frequency of administration, and potential adverse effects) must also be considered when choosing the most appropriate drug to use. It warrants mention that resistance to a particular antimicrobial agent *in vitro* may not preclude successful treatment with the drug *in vivo* as long as high concentrations are achieved in urine. Laboratory reports provide minimum inhibitory concentration (MIC) data for serum, not urine. To determine whether a particular bacterial isolate in urine may be susceptible to urine concentrations of a drug, the actual MIC for some (but not all) organisms can be determined by the laboratory when specifically requested. Similarly, demonstrable susceptibility *in vitro* does not always guarantee a successful response to treatment. For example, *Enterococcus* spp. are often found to be susceptible to the potentiated sulfonamide combinations *in vitro;* however, this pathogen is inherently resistant to these combinations *in vivo*.[90] Recommendations for duration of antimicrobial treatment of UTI in people include 3 days for uncomplicated cystitis (rare in horses) and 1 to 2 weeks for the treatment of upper UTI.[91] Ideally, a voided midstream urine sample should be submitted for bacterial culture 1 to 2 weeks after treatment of an upper UTI has been discontinued.

If the UTI recurs and the same organism is isolated, search for a nidus for persistence of UTI should be pursued (e.g., a urolith or renal abscess) by ultrasonographic examination of the kidneys. Cystoscopy and ureteral catheterization can also be pursued to evaluate whether an upper UTI is unilateral or bilateral. In contrast, isolation of a different pathogen from a recurrent UTI suggests that there may be an anatomical or functional cause of abnormal urine flow predisposing the animal to recurrent infections (e.g., bladder paresis and sabulous urolithiasis). Further, it is not unusual to find highly resistant organisms in the urine of horses with chronic UTIs, especially in those that have bladder paralysis and have been repeatedly catheterized and treated with a variety of antimicrobial agents. In such cases, the antimicrobial agent should be selected based on culture and susceptibility reports of serial quantitative urine cultures. With some problems (bladder paresis and sabulous urolithiasis or pyelonephritis with nephrolithiasis), elimination of UTI is essentially impossible by treatment with antibiotics alone. In these cases, surgical removal of the nidus of infection (i.e., nephrectomy for chronic unilateral pyelonephritis, as long as the contralateral kidney appears normal and azotemia is not present) is the treatment of choice. However, not all persistent infections are amenable to surgical correction (bladder paresis), and long-term (potentially lifelong) antimicrobial treatment may be used with the goal of keeping bacterial numbers "in check" rather than having the goal of eliminating the UTI. For example, I commonly place horses with incontinence, bladder paresis, and persistent UTI on an indefinite course of once-daily treatment with a potentiated sulfonamide because that is the only practical long-term treatment for this type of problem.[2]

Specific Antimicrobial Agents

Penicillins

A single intramuscular (IM) dose (22,000 IU/kg) of procaine penicillin G results in urine concentrations exceeding 60 mg/mL for 48 hours, well above the MIC of many organisms. Thus, frequency of administration of this drug could be decreased to once daily or every other day. Although many of the *Enterobacteriaceae* demonstrate resistance to ampicillin *in vitro*, this drug is concentrated in urine and is often effective against these isolates *in vivo*. The potentiated penicillins (ticarcillin or ticarcillin–clavulanic acid) should be reserved for treatment of horses with UTIs caused by highly resistant organisms (e.g., *Pseudomonas* spp.) and are sometimes selected as an alternative to aminoglycosides in azotemic patients.[92]

Aminoglycosides

The aminoglycosides can be nephrotoxic and should be reserved for the treatment of lower UTIs caused by highly resistant organisms or acute, life-threatening upper UTIs caused by aerobic gram-negative bacteria. It is important to remember that aminoglycoside nephrotoxicity is a cumulative renal insult;

consequently, administration of one or two doses of these drugs is unlikely to precipitate further AKI, even in azotemic patients. However, if azotemia is detected during initial patient work-up, an alternative class of antimicrobials should be selected. Pharmacokinetic and pharmacodynamic studies in adult horses and foals support once-daily administration of both gentamicin (6.6 mg/kg IV) and amikacin (21 mg/kg IV) as the preferred dosage schedule because it improves the bactericidal action (concentration-dependent killing) and lessens the risk of nephrotoxicity.[93,94] Further, there is some evidence that foals may be more susceptible to gentamicin nephrotoxicity than adult horses, providing another reason to consider alternative antimicrobial agents for younger patients.[95]

Potentiated Sulfonamides

Combinations containing the sulfonamide sulfadiazine are preferred for the treatment of UTIs because sulfadiazine is excreted largely unchanged in urine, whereas sulfamethoxazole is largely metabolized to inactive products in the liver prior to urinary excretion.[95] As mentioned earlier, trimethoprim-sulfadiazine combinations (20 mg/kg PO every 12 to 24 hours) are the only practical choice for long-term treatment of horses with persistent UTIs.

Cephalosporins

Cephalosporins are commonly used for treatment of UTIs in other species. However, in horses, the cephalosporins are rarely more advantageous than the penicillins or potentiated sulfonamides. However, ceftiofur has broad-spectrum antimicrobial activity and may be indicated (2.2 mg/kg IM every 12 hours) when urinary pathogens are resistant to other drugs.[92]

Tetracyclines

Intravenous tetracyclines are rarely indicated for the treatment of UTIs in horses. However, there has been a resurgence in use of doxycycline in human and veterinary medicine, and this cost-effective oral antimicrobial agent may be of use for treatment of UTIs caused by susceptible gram-positive isolates. After oral administration (10 mg/kg every 12 hours for 3 days), urinary concentrations reached 145 ± 25 μg/mL 2 hours after the last dose (more than 100 times higher concentrations than in plasma).[96] Bioavailability has not been determined because IV administration of doxycycline causes cardiac toxicity. Caution should be used with this drug because a higher dosage (20 mg/kg PO every 24 hours) resulted in enterocolitis leading to euthanasia in one of six horses in this report.[97]

Fluoroquinolones

Enrofloxacin (5 to 7.5 mg/kg PO every 12 hours) may be a suitable antimicrobial agent for more serious upper or persistent UTIs when the causative organism(s) are resistant to other antibiotics. After oral administration (5 mg/kg every 12 hours), enrofloxacin bioavailability was 60% in horses and the drug was well concentrated in urine.[98] However, fluoroquinolones can damage articular cartilage (particularly in rapidly growing juvenile animals) and their use should, therefore, be limited to adult horses or to foals with urinary pathogens that are not susceptible to other antimicrobial agents.[92]

Other Antimicrobial Agents

The antimicrobial agents discussed earlier should be adequate for prophylaxis for surgery as well as for treatment of most UTIs in the horse. A significant challenge in equine practice is availability of antibiotics that can be orally administered with minimal adverse effects on the gastrointestinal tract and that also have a broad spectrum of activity against many equine pathogens. Although chloramphenicol is not approved for use in the horse, the need for such a drug has also led to a recent increase in chloramphenicol use, and this drug (25 to 50 mg/kg PO every 8 hours) may be indicated for treatment of complicated or persistent UTIs in horses, when supported by culture and susceptibility results. If chloramphenicol is selected, owners and caregivers should be warned about the rare possibility of developing aplastic anemia and should be instructed to wear impenetrable gloves when administering this medication. Further, only formulations that can be dissolved in water or that are prepared as a paste or suspension should be used to limit the risk of inhaling chloramphenicol.

A further challenge in horses undergoing urinary tract surgery in which temporary indwelling urinary catheters or ureteral stents may be used postoperatively is frequent colonization and infection with multidrug resistant organisms, notably *Enterococcus* spp. One antimicrobial agent that may be useful if the UTI persists after catheter or stent removal is vancomycin (7.5 mg/kg IV every 8 hours); however, hospitals should have policies in place to approve and monitor use of this antimicrobial agent, limited to specific cases in which this is the only antibiotic choice on the basis of culture and susceptibility results.[99]

A final medication that is also undergoing a resurgence of use in human medicine and interest in small animal practice for treatment of multidrug resistant UTIs is fosfomycin.[100,101] Pharmacokinetics of this antimicrobial agent after IV, IM, or subcutaneous administration to horses have been reported, and dosages of 10 or 20 mg/kg produced serum and urine concentrations above the MIC for many pathogens.[102] Currently, however, laboratories do not routinely provide a susceptibility report for fosfomycin and I am unaware of the use of this drug in clinical cases of UTI in horses.

ANTI-INFLAMMATORY DRUGS

Harold C. Schott II

Surgical treatment of urinary tract disorders requires short-term treatment with anti-inflammatory drugs to limit postoperative swelling and inflammation and to provide analgesia for the patient. Phenylbutazone and flunixin meglumine, at routine doses, can be used as effective anti-inflammatory drugs and should provide adequate analgesia for most patients. To avoid adverse gastrointestinal and renal effects when using these nonsteroidal anti-inflammatory drugs (NSAIDs), a rule to follow should be to use the lowest effective dosage for the shortest duration that produces the desired clinical result.

The urinary tract presents unique challenges for control of inflammation and pain in the postoperative period. For example, urine may continue to leak through repair sites of disrupted ureters or the bladder. This complication may retard healing of wound margins and result in recurrence of uroabdomen. To minimize this complication, indwelling bladder catheters or ureteral stents may be used in the postoperative period, but their presence may lead to straining. In addition to use of

NSAIDs, administration of phenazopyridine (4 mg/kg PO every 8 to 12 hours) may alleviate lower urinary tract pain in these patients. In people, phenazopyridine relieves burning, irritation, and discomfort, as well as urgent and frequent urination caused by urinary tract infections, surgery, injury, or examination procedures. After renal elimination, the medication acts as a topical local anesthetic on ureteral, bladder, and urethral mucosa. However, phenazopyridine does not have antimicrobial activity and it turns urine an orange color that can stain hands and clothing. Efficacy of the drug should be apparent after the first or second dose, and it is typically administered for only 2 to 3 days. When NSAIDs and phenazopyridine are not effective in providing adequate analgesia, intermittent administration of α_2-receptor agonists or opioids or a continuous-rate infusion of lidocaine (and possibly α_2-receptor agonists and opioids) may need to be considered. In horses in which significant postoperative pain may be anticipated, epidural administration of α_2-receptor agonists or opioids should also be considered to produce prolonged regional analgesia before full recovery from general anesthesia. Refer to recent reviews for further information on these approaches to analgesia.[103-106]

Finally, when a nephrectomy is performed, there is a loss of residual functional nephrons. The reduction in total renal mass should be taken into consideration when formulating an anti-inflammatory and analgesic plan because the risk for nephrotoxicity with NSAIDs may be increased in these patients.

CHAPTER 64

Kidneys and Ureters

Harold C. Schott II and J. Brett Woodie

ANATOMY

Harold C. Schott II

The urinary system of the horse, like that of most mammals, consists of paired kidneys and ureters, the bladder, and the urethra.

Kidney

The kidneys and ureters are located in the retroperitoneal space. In a newborn 50 kg foal, each kidney weighs 150 to 200 g. In the adult horse (400 to 500 kg), the left kidney weighs 800 to 1000 g and the right kidney is usually 25 to 50 g heavier, although this is not a consistent finding and the reverse relation may be observed.[1] The right kidney is located immediately below the dorsal extent of the last two or three ribs and the first lumbar transverse process. It is shaped like a horseshoe and measures about 15 to 18 cm (6 to 7 inches) in length, 15 cm (6 inches) in width, and 5 to 6 cm (2 to 2½ inches) in height (dorsal to ventral). Craniolaterally, it is embedded in the liver, and its more cranial position in comparison to the left kidney prevents it from being accessible on rectal palpation. The left kidney is more elongated than the right kidney, in the shape of a U or inverted J with the longer arm extending caudad. The cranial pole extends to the level of the hilus of the right kidney. The left kidney is about 18 cm (7 inches) long, 10 to 12 cm (4 to 5 inches) wide, and 5 to 6 cm (2 to 2½ inches) in height. Because of its more caudal location, the caudoventral aspect of the left kidney can be palpated routinely during rectal examination. The blood supply to the kidneys comes from one or more renal arteries branching from the aorta. Accessory renal arteries, which generally enter caudally, may also arise from the caudal mesenteric, testicular, ovarian, or deep circumflex iliac arteries.[1]

The surface of each kidney is covered by a fibrous capsule that is easily peeled from the underlying renal parenchyma. The equine kidney consists of an outer cortex that is slightly narrower than the inner medulla. The cortex is dotted with dark spots: renal corpuscles or glomeruli within Bowman's capsules. In horses, the corticomedullary junction is less distinct than in other species and is typically a deep red that contrasts well against the paler medulla and red-brown cortex. This region undulates between regularly spaced interlobar arteries that subdivide the renal parenchyma into somewhat indistinct lobes, consisting of a wedge of cortex overlying a narrower pyramid of medullary tissue. The cortex extends somewhat deeper into the renal parenchyma adjacent to each interlobar artery, and these cortical projections are termed *renal columns* (not well developed in horses). On a three-dimensional view, renal columns surround or cap the convex base of a renal pyramid, the associated medullary portion of each kidney lobe. Renal pyramids narrow as they extend to their apices at the level of the renal pelvis.[2] A commonly cited anatomy text states that equine kidneys contain a total of 40 to 60 lobes arranged in four parallel rows.[1] However, kidney lobation varies among species with cattle having the most obvious separation of the renal parenchyma into lobes; in carnivores, small ruminants, and the horse they are largely fused, thus making histologic separation into distinct lobes somewhat difficult.[2] The renal pyramids are also fused to a large extent in horses; however, at the innermost aspect of the medulla, the apices of the pyramids are partly separated by invaginations of fibrous connective tissue and smooth muscle extending from the renal pelvis that surround the apex of each renal pyramid. In other species, this smooth muscle has been shown to play an important role because contractions squeeze the apices of the pyramids circumferentially, intermittently forcing urine into the renal pelvis and forcing capillary blood, interstitial water, and electrolytes back into the venous circulation.[3]

Deep to the medulla is the renal pelvis, a funnel-shaped proximal extent of the ureter that is flattened in the dorsoventral plane. The renal pelvis consists of three layers: an external fibrous coat, an intermediate smooth muscle layer, and an innermost layer of transitional epithelium. In some areas the fibrous coat can extend into the renal parenchyma to become contiguous with the connecting tissue of the renal columns (incompletely developed in horses). The muscular layer contains smooth muscle fibers that run in assorted directions, attaching near the site where the fibrous coat joins with the renal columns along the pyramids, and continuing without interruption as ureteral smooth muscle.[3] A prominent ridge of tissue with a mildly concave free edge, termed the *renal crest*, protrudes into the renal pelvis along a craniocaudal axis, opposite to the outflow path of the ureter. The renal crest is a fusion of the apices of many pyramids of medullary tissue in the central aspect of the kidney (Figure 64-1).[2] The distal ends of inner medullary collecting ducts (ducts of Bellini) from the middle portion of the kidney open onto the renal crest to allow urine to exit into the pelvis through the area cribosa. In contrast, the collecting ducts draining nephrons in the cranial and caudal parts of the kidney do not open into the pelvis directly but into two narrow tubular structures termed the *terminal recesses*.[2] These tubular structures are only a few millimeters in diameter but extend 5 to 7 cm (2 to 3 inches) into either pole of the kidney.[2] As the pelvis extends into the ureter, beyond the renal crest, transitional epithelium becomes more prominent and consists of numerous folds (to allow distension and contraction). In addition, the renal pelvis and proximal ureter are lined with both compound tubular mucus glands and goblet cells that secrete thick, viscid mucus that is usually found in the renal pelvis and urine of normal horses.[1,4]

Ureters

The ureters are 6 to 8 mm (2½ to 3 inches) in diameter and travel about 70 cm (28 inches) to their insertions in the dorsal bladder neck, or trigone, close to the urethra. The distal 5 to 7 cm of each ureter courses within the bladder wall. This intramural segment of the ureter functions as a one-way valve to prevent vesicoureteral reflux with progressive bladder

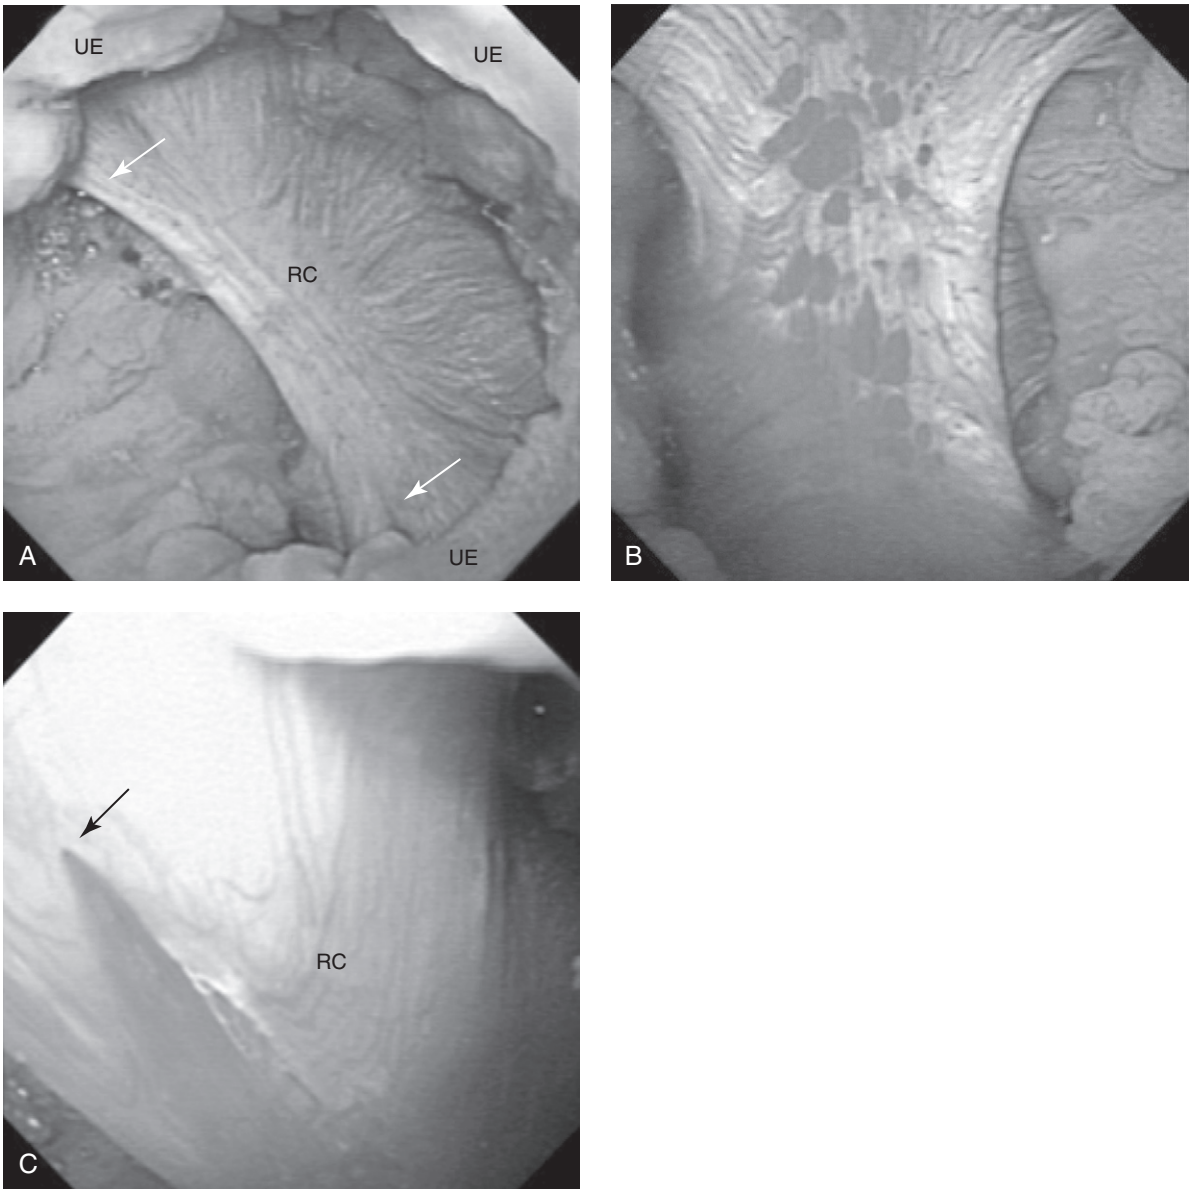

Figure 64-1. Endoscopic appearance of the renal pelvis of the horse. **A,** The renal crest *(RC)* extends from upper right to lower left and uroepithelium *(UE)* of the proximal ureter becomes more prominent toward the periphery of the renal pelvis; entrance of the terminal recesses into the renal pelvis is at the level of the *white arrows*. **B,** Closer view of the renal crest showing phenol red *(dark gray patches)* exiting numerous ducts of Bellini, terminal portions of the innermedullary collecting ducts. **C,** Close-up view over an opening of a terminal recess into the renal pelvis; a gray stream of phenol red–discolored urine is exiting the opening *(black arrow)*.

distention.[1] Ureters are muscular tubes, similar to the esophagus. As a "bolus" of urine accumulates in the renal pelvis, pacemaker activity induces a muscular contraction that propagates the bolus of urine down the ureter to the bladder. With changes in urine flow in other species, the length of the "urine bolus" changes while the rate of transport down the ureter remains the same.[3] Passage of "urine boluses" can be appreciated in horses during either cystoscopy or transrectal ultrasonographic examination. During cystoscopy, streams of urine can be seen to intermittently exit each ureter. These urine streams are asynchronous and vary in volume and frequency with changes in urine flow.[5] During transrectal ultrasonography, forceful passage of urine from the ureters into the bladder can be appreciated by swirling of the echogenic urine in the bladder near the trigone.

Histology

The functional unit of the kidney is the nephron. Each nephron is composed of a renal corpuscle (glomerulus within Bowman's capsule), a proximal tubule (convoluted and straight components), an intermediate tubule (loop of Henle), a distal convoluted tubule, a connecting tubule, and cortical, outer medullary, and inner medullary collecting ducts.[1,2] A study of kidney organogenesis using unbiased stereological techniques found that the equine left kidney contains approximately 10 million glomeruli (for a total of 20 million in both kidneys) and, as in other species, the total number of glomeruli do not increase after birth despite continued growth of the kidney (with increasing glomerular size) until about 1 year of age.[6] Histologically, equine nephrons are similar in most respects to those of other

mammalian species; however, the diameter and epithelial height of the collecting duct segments are comparatively larger. In addition, the equine macula densa (segment of the ascending loop of Henle that lies in close association with the juxtaglomerular apparatus of the afferent arteriole) appears more prominent than that of other mammals.[7] Whether these subtle histologic differences are accompanied by functional differences has not been investigated.

Innervation

Relative to its size, the mammalian kidney has a richer innervation than almost any other organ.[8] Although the neuroanatomy of the equine kidney has not been well studied, autonomic nerves course from the aorticorenal and renal ganglia along the major renal vessels into the kidneys.[1] These nerves are predominantly sympathetic because the kidneys appear to be poorly supplied by cholinergic nerves. Although the best-recognized effect of renal nerves is control of renal vascular resistance (for regulation of renal blood flow over a wide range of perfusion pressures), they also act directly on renal tubules and juxtaglomerular cells. For example, low-frequency stimulation of renal nerves (below the threshold for vasoconstriction) increases proximal tubular sodium reabsorption and renin release by activation of α_1 adrenoceptors.[9] In addition to α- and β-adrenoceptors, renal vasculature is rich in dopaminergic adrenoceptors. Activation of the latter, specifically dopamine type 1 receptors, leads to increased perfusion of the outer renal medulla. Presence of these receptors was the basis for historical use of dopamine (a treatment that is no longer recommended), and recently more specific DA-1 receptor agonists, such as fenoldopam, in an attempt to improve renal blood flow in acute renal failure.[10,11] Renal adrenoceptors can also be activated unintentionally by administration of drugs. A common clinical example is the diuresis induced by administration of the α_2-agonists xylazine and detomidine. Although the diuresis has been attributed to a transient hyperglycemia and glucosuria, the latter is often absent.[12,13] An alternative explanation may be drug binding to α_2-adrenoceptors located on collecting duct epithelium. Activation of these receptors can lead to antagonization of the effects of antidiuretic hormone on cortical collecting ducts, resulting in diuresis.[14]

Autonomic innervation of the ureters is important for ureteral peristalsis. The equine ureteral smooth muscle contains both α_1- and β_2-adrenoceptors, which induce contraction and relaxation, respectively, when activated by norepinephrine.[15] Recent studies of the innervation of the equine ureter demonstrated greater densities of adrenergic neurons in the proximal (renal pelvis) and intravesicular (bladder wall) portions of the ureter.[16] Increased densities in these regions are consistent with the suspected pacemaker activity of the renal pelvis, which initiates ureteral peristalsis, and the sphincter-like function of the distal segment of the ureter.

DISORDERS REQUIRING SURGERY

Harold C. Schott II

Disorders of the kidneys and ureters that may require surgery include congenital anomalies (ectopic ureter and ureteral defects) and acquired disorders. The latter can include nephrolithiasis, ureterolithiasis, pyelonephritis, neoplasia, and ureteral disruption (ureterorrhexis). Rarely, hematuria may be a consequence of vascular malformations for which surgical inteervention may be necessary.

Congenital Anomalies

Ectopic Ureter

Although rare, ectopic ureter is the most commonly described anomaly of the equine urinary tract.[17-34] Ectopic ureters can develop when the ureteric bud (metanephric duct) either fails to be incorporated into the urogenital sinus or fails to migrate craniad to the bladder neck, or when the mesonephric duct fails to regress.[35] In the former instance, ectopic ureters open near the urethral papilla in females or in the pelvic urethra near the colliculus seminalis in males. With the latter, the ureter may open anywhere along the vagina, cervix, or uterus (but only in females because this portion of the mesonephric duct becomes the Wolffian duct system in males).

In horses with ectopic ureters, urinary incontinence is usually apparent from birth. Affected animals are presented for scalding of the hind limbs during the first few weeks to months of life. Horses with unilateral ectopia can also urinate normally, because the other ureter enters the bladder in the appropriate location. Renal function is usually normal, but the affected ureter may be markedly dilated and tortuous (attributed to intermittent obstruction). To determine the site of the ectopic ureteral orifice(s), visual examination of the vestibule and vagina (using a blade speculum) is initially performed to look for intermittent urine flow from the area of the urethral papilla. Endoscopy is helpful in females (while inflating the vestibule and vagina with air and using a hand to form a seal at the vulva) (Figure 64-2) and is required in males to visualize the ectopic ureteral opening. Intravenous administration of a dye (phenolsulfonphthalein [phenol red], 1 mg/kg IV) to discolor urine red may help locate ectopic ureteral openings. As discussed in Chapter 63, intravenous contrast excretory urography has been performed to investigate renal architecture and the course of ectopic ureters; however, detail is often limited and results have frequently been inconclusive. If radiographic imaging is

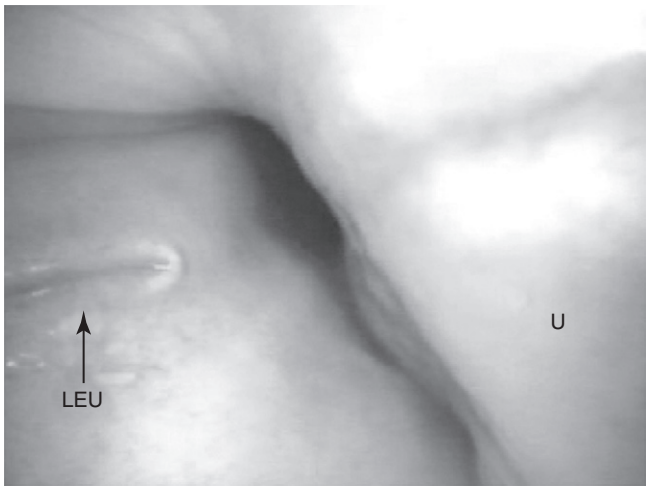

Figure 64-2. Endoscopic image of a left ectopic ureter *(LEU)* opening into the urethral wall *(U)* of a filly. (From Cokelaere SM, Martens A, Vanschandevijl K, et al: Hand-assisted laparoscopic nephrectomy after initial ureterocystostomy in a Shire filly with left ureteral ectopia. Vet Rec 161:424, 2007, with permission.)

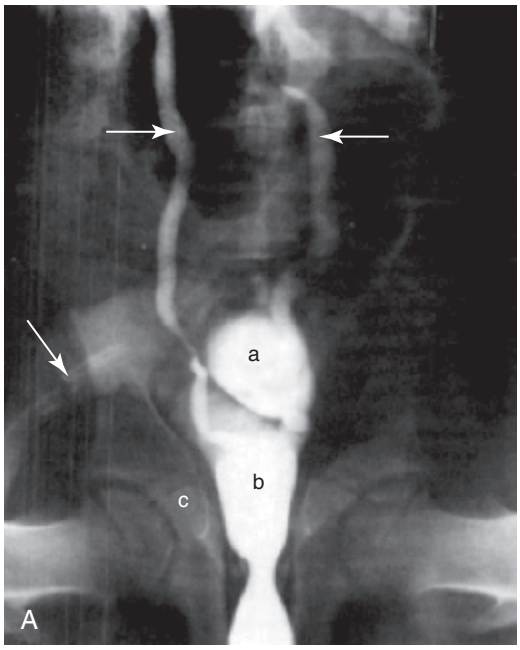
pursued, retrograde contrast studies via catheterization of the bladder and ureters or ultrasound-guided pyelography, in which contrast agent is injected directly into the renal pelvis using a spinal needle (Figure 64-3),[31] are more rewarding contrast radiographic techniques, yet they still may not provide adequate information about the distal end of ectopic ureters. If an abnormal ureteral opening can be documented by direct visualization via endoscopy, further information gleaned from contrast radiographic studies is likely to be of limited value, other than documenting ureteral enlargement or possible hydronephrosis. In fact, a study in dogs with ectopic ureters found that endoscopic evaluation was more successful than contrast radiographic studies for locating the ectopic ureteral opening.[36] Currently, I do not recommend contrast radiographic imaging for evaluation for ectopic ureters; rather, endoscopic and ultrasonographic findings are generally preferred to establish the diagnosis and to formulate a surgical plan. In foals that are small enough to fit into the gantry of computed tomography (CT) or magnetic resonance imaging (MRI) scanners, use of these imaging devices, coupled with IV administration of contrast agents, may provide the best overall detail about the course of ectopic ureters from the kidney to the lower urinary or reproductive tract.[34] In a report of 24 dogs with suspected ectopic ureters, CT imaging was superior to fluoroscopic contrast radiographic studies in identifying ectopic ureters.[37] Of interest, cystoscopic and surgical or necropsy findings were considered gold standards for comparison of results in this study. Drawbacks of CT and MRI are that these imaging procedures require general anesthesia and are costly, and currently there is limited evidence that they provide better information than that obtained via endoscopic examination of the lower urinary tract and ultrasonographic imaging of the kidneys. Nuclear scintigraphy was performed in one case of bilateral ectopic ureter to demonstrate an apparent blind end (atresia) of one ureter and a course of the other ureter beyond the bladder.[32] The scintigraphic findings in this case did not agree with results of intravenous pyelography, and they provided limited anatomical detail about the distal end of the ectopic ureter; however, scintigraphy did provide information about the relative function of each kidney in this patient.

Surgical treatment of ectopic ureter has included ureterocystotomy (surgical reimplantation of the ectopic ureter[s] into the bladder with or without tunneling) or unilateral nephrectomy. Before surgery is pursued, it is imperative to determine whether the condition is unilateral or bilateral, which side is affected if unilateral, and whether urinary tract infection (UTI) is present. Further, attempts should be made to rule out other anomalies, especially of the urethral sphincter and reproductive tract. Because the most significant postoperative problem in dogs with ectopic ureters is persistence of incontinence,[38] it is useful to determine whether detrusor and urethral sphincter function are fairly normal, especially with bilateral ectopia. A simple assessment can be made by infusing saline into the bladder and observing whether incontinence develops (sphincter dysfunction) and if the infused fluid is voided spontaneously (detrusor function). More sophisticated assessment can be performed by cystometrography[39-41] and is worthy of consideration because functional abnormalities of the urethra or bladder were found in eight of nine dogs with ectopic ureter in which urodynamic studies were performed.[42]

In 21 cases of ectopic ureter in horses reported in the literature[17-34] and five further cases I saw, 24 of 26 (92%) have been females; however, this lopsided sex distribution may reflect



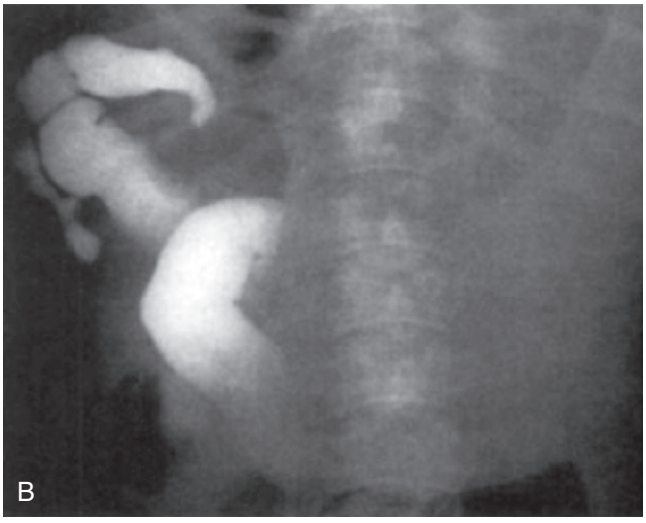


Figure 64-3. A, Ventrodorsal radiographic view of a retrograde contrast-enhanced urethrocystogram in a colt with bilateral ectopic ureters showing the bladder *(a),* pelvic urethra *(b),* and coxofemoral joint *(c).* The *straight white arrow* indicates a catheter within the penile urethra and the *undulating arrows* indicate the ureters. **B,** Ventrodorsal radiographic view of a percutaneous ultrasound-guided pyelogram in a filly with a left ectopic ureter detailing both hydronephrosis and a markedly enlarged and tortuous ureter. Although both approaches provide greater contrast detail than intravenous pyelography, insertion of the distal ends of the ectopic ureters is not well detailed in either study. (**A,** From Modransky PD, Wagner PC, Robinette JD, et al: Surgical correction of bilateral ectopic ureters in two foals. Vet Surg 12:141, 1983. **B,** From Tomlinson JE, Farnsworth K, Sage AM, et al: Percutaneous ultrasound-guided pyelography aided diagnosis of ectopic ureter and hydronephrosis in a 3-week-old filly. Vet Radiol Ultrasound 42:349, 2001, with permission).

that incontinence is easier to recognize in females, because urine entering the pelvic urethra in males may pass retrograde into the bladder. Although a genetic predisposition for ectopic ureter exists for several dog breeds,[43] no breed predilection has been established in horses. However, Quarter Horses and

Standardbreds may be at greater risk: the condition has been found in eight Quarter Horses and six Standardbreds as compared to two Thoroughbreds, two Appaloosas, two Clydesdales, two Shires, one Arabian, one Fresian, one Foxtrotter, and one Warmblood. The condition was unilateral in 17 (left in 11 cases; right in five cases, and not specified in one case) and bilateral in nine. Affected foals should be examined for other anomalies because two foals appeared to have an abnormal urethral sphincter[20,25] and one was a cryptorchid.[19]

Among 20 cases in which surgical correction was pursued, ureterocystotomy was initially successful in establishing a functional ureter in 11 published cases[19,20,24,25,30-33] and two foals seen by me, although four died of postoperative complications.[20,24,31] In contrast, all seven cases treated by unilateral nephrectomy (including two seen by me) had a favorable outcome.[21,22,28,34] Because affected ureters are often dilated and tortuous, surgical reimplantation can be difficult and may not result in a functional ureteral orifice. For example, an attempt to perform a ureterocystotomy in one mare was aborted during the initial surgery because a markedly enlarged ureter was detected; subsequently a nephrectomy was performed several weeks later.[22] A surgically created ureteral opening into the bladder in another case became stenotic and incontinence returned, prompting nephrectomy several weeks after the initial surgery.[32] Consequently, when the problem is unilateral, nephrectomy of the affected side may be the preferred treatment option at present. However, nephrectomy results in a loss of renal functional mass, and with recent improvements in endoscopic equipment, it would seem preferable to pursue endouroscopic laser treatment of ectopic ureters in horses, as is the current treatment of choice in dogs.[44,45] Most reports of ectopic ureter treated by nephrectomy fail to describe what is done with the remnant ureter. In one report, the ureter appeared to continue to pool an exudate that was observed to be passed once or twice daily.[22] Authors of future reports are encouraged to more closely describe whether or not the remaining ureter, which is often dilated and tortuous, is also removed (difficult with a flank approach) or left *in situ*.

Ureteral Defects or Tears (Ureterorrhexis)

Retroperitoneal accumulation of urine and uroperitoneum have been described in seven foals with unilateral or bilateral ureteral defects[46-52] and have been observed in three additional foals by me. These included seven male and three female foals of various breeds (five Standardbreds, two Thoroughbreds, one Belgian, one Oldenberg, and one Appaloosa). Clinical signs including decreased nursing, depression, abdominal distention, diarrhea, and muscle twitching or other signs of neuromuscular irritability, and clinicopathologic abnormalities consisting of hyponatremia, hyperkalemia, hypochloremia, and azotemia, are similar to those seen with bladder rupture but may have a slightly later onset (4 to 16 days of age). Mild protrusion of the vagina may be seen in fillies in which the peritoneum has remained intact. In affected foals, ultrasonographic examination may reveal dilation of the renal pelvis and affected ureter as well as fluid accumulation around the kidneys or farther caudad within the retroperitoneal space. As with ectopic ureters, excretory urography has generally been an unrewarding diagnostic procedure, but contrast pyelography was successfully used to image leakage of contrast agent from a proximal ureteral defect in one report.[52] Contrast radiography has not routinely been pursued because exploratory celiotomy was generally performed shortly after a diagnosis of uroperitoneum was established. Catheterization of the ureters via a cystotomy and retrograde injection of methylene blue allowed localization of the defect(s) during surgery, and four cases, including one seen by me, were successfully treated by suturing the defect around an indwelling catheter.[48,49,52] Although ascending UTI should be an expected complication with a stent, repair of a defect in one foal without use of an indwelling catheter resulted in further urine leakage from the ureter, prompting a nephrectomy 4 days after the initial surgery.[51] Of the five remaining foals, one died consequent to progressive abdominal distention within a few hours after nephrectomy[46] and another foal died after three unsuccessful attempts at surgical repair.[47] Euthanasia was performed in another foal after recurrence of uroabdomen following nephrectomy (because of failure to detect bilateral ureteral defects in one case seen by me) and in two cases in which surgical repair was declined by the owner.[51]

At surgery or necropsy a single defect was found in six foals, bilateral defects were found in four foals, and multiple defects were apparent in one ureter. In most cases the defects were located in the proximal third of the ureter near the kidney. Of interest, distended, tortuous ureters, occasionally accompanied by hydronephrosis, were also described in two affected foals[47,52] and distal obstruction of the ureters at the bladder was suspected in these cases, prompting ureterocystotomy. Although several reports suggest that these ureteral defects may be anomalies of development, the actual cause of these ureteral defects is not known. Traumatic disruption was suggested in the initial report in which histologic examination of the margins of the defect revealed hemorrhage and proliferation of immature connective tissue.[46] A traumatic etiology was further supported by a subsequent report in which histologic examination of the defects revealed absence of transitional epithelium and inflammation in the defect margin in a foal that had been attacked by dogs.[50] Inflammation and granulation tissue also were seen in the apparently obstructed distal ureter in one of the foals with ureteral distention, again suggesting an acquired lesion. Blunt abdominal trauma, as may be sustained during automobile accidents, can cause retroperitoneal accumulation of urine as well as uroperitoneum in humans.[53] Disruption of the ureter is usually near the kidney, and this complication of trauma may not be recognized for several days following injury. In one foal evaluated by me, multiple rib fractures found at necropsy suggested that these ureteral tears could actually be a complication of foaling trauma (Figure 64-4).

Vascular Anomalies

Anomalies of the vascular supply to the equine urinary tract are rare but may result in hematuria, hemoglobinuria, partial ureteral obstruction, or hydronephrosis. Although not described in horses, life-threatening hematuria or hemorrhage into the abdomen could require surgical intervention and possible nephrectomy. A distal aortic aneurysm and associated extrarenal arteriovenous fistula has been described in a 5-month-old colt presented for intermittent hematuria, colic, and lameness.[54] Partial ureteral obstruction and hydronephrosis were observed on the affected side. Intrarenal vascular anomalies, termed *renal arteriovenous malformations,* are similarly rare (reported frequency of 0.04% in humans).[55] Interestingly, these vascular malformations may be silent until later in life, when varying

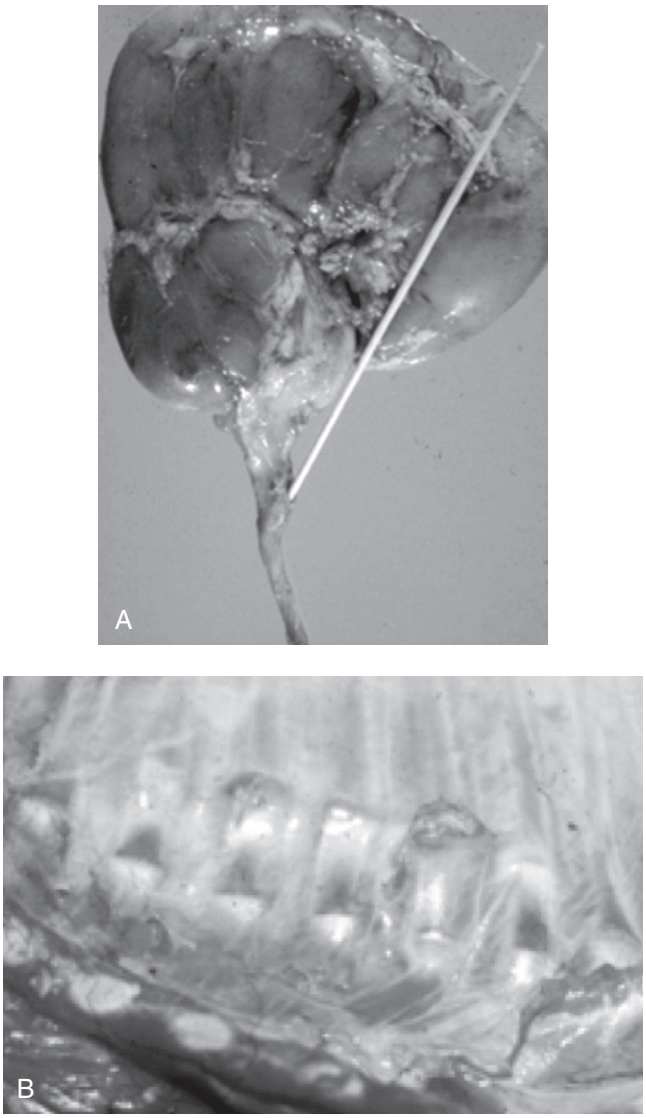

Figure 64-4. A, Kidney and ureter removed from a Standardbred colt with a proximal ureteral defect (or tear) through which a probe is inserted. **B,** Thoracic wall from the same foal showing a series of five fractured ribs, providing support that ureteral defects in foals can be acquired secondary to trauma.

degrees of hematuria and flank pain may ensue. The anomalous vessels are often tortuous and may be focally enlarged and devoid of elastic tissue. Hematuria and hemoglobinuria are thought to arise from areas where the anomalous vessels lie close to the collecting system. With vascular anomalies, an attempt should be made to determine the extent of the defect (unilateral or bilateral) via ultrasonographic examination, contrast radiographic studies, or cystoscopy (visualization that hematuria is coming from only one ureteral orifice). When a unilateral defect is documented in the absence of azotemia, unilateral nephrectomy or selective renal embolization has been recommended to prevent possible fatal exsanguination through the urinary tract[55]; however, conservative treatment may be considered if the urinary tract bleeding is minor and has not resulted in anemia.

A large vascular anomaly resulting in transient hemoglobinuria has been reported in a Quarter Horse colt.[56] Over several weeks, the large anomalous vascular structure spontaneously filled with a thrombus so that specific treatment (a nephrectomy) was not pursued. Occasionally gross hematuria with passage of blood clots can accompany omphalitis or bladder rupture.[57,58] These problems can usually be detected during ultrasonographic examination of the umbilical structures, and tissue echogenicity within the bladder, attributable to a blood clot, can sometimes be imaged.

Acquired Renal and Ureteral Disorders

Renal and Ureteral Calculi

Despite production of urine rich in crystals, urolithiasis is less common in horses than in dogs or cats with reported prevalence ranging from 0.11% to 0.7%.[59,60] In a review of 68 horses with urolithiasis, 15 had uroliths in the kidneys and two had ureteroliths and several horses with cystic calculi also had calculi in the upper urinary tract.[59] Nephroliths develop around a nidus that may be started with a variety of diseases that may damage renal parenchyma.[61] Calcium carbonate and calcium oxalate crystals readily form within collecting ducts and can tightly adhere to damaged renal tissue, forming a nidus for stone enlargement. At present, data on upper urinary tract stones in horses are insufficient to know whether they also develop spontaneously in the absence of tissue damage as in humans and whether they differ significantly in mineral composition from cystic calculi. It has been speculated, but not proved, that prolonged use of nonsteroidal anti-inflammatory drugs can damage renal medullary tissue and increase the risk of nephrolith formation adjacent to or within the pelvis and terminal recesses.[62]

Although nephrolithiasis and ureterolithiasis can be painful conditions in humans, horses often remain asymptomatic, and upper tract stones can be an incidental finding at necropsy.[60] Clinical signs become apparent if obstructive disease develops or bilateral disease leads to chronic kidney disease (CKD).[59,61,62] Nonspecific presenting complaints consistent with CKD including poor performance, lethargy, inappetance, and weight loss are more common than signs of obstructive disease, such as colic, stranguria, and hematuria. In an occasional male horse, a small stone passes down the ureter and leads to urethral obstruction and signs of acute obstructive disease (see Chapter 66). Rectal palpation may reveal an enlarged kidney or ureter (or bladder with urethral obstruction), and ureteral calculi may be palpable in an enlarged ureter.[63] Because normal ureters are generally not palpable on rectal examination, the entire course of the ureters (retroperitoneally along the dorsal abdominal wall to the lateral aspects of the pelvic canal to their insertion at the dorsal bladder neck) should be carefully palpated—an enlarged ureter can be overlooked.

Diagnosis of renal and ureteral calculi is usually made during rectal or ultrasonographic examination (see Figure 63-6). Although ultrasonographic imaging may provide information on the presence, number, and location of calculi, stones smaller than 1 cm diameter can be missed despite complete examination. Other ultrasonographic findings to support upper tract obstructive lithiasis include dilatation of the renal pelvis or proximal ureter and, in longstanding cases, hydronephrosis. Although azotemia generally accompanies bilateral disease, horses with unilateral disease often maintain normal renal function. A quantitative urine culture should be performed in all horses with nephrolithiasis or ureterolithiasis to assess possible concurrent UTI. If stones are available or collected at

surgery, they should also be submitted for culture because they may yield bacterial isolates in the face of a negative urine culture result.[59,61]

Because most horses with nephrolithiasis or ureterolithiasis typically have CKD by the time the diagnosis is established,[59,61,62] few patients are good candidates for surgical treatment. Nevertheless, in a few horses with unilateral disease (without azotemia) or obstructive disease, documented by detection of hydronephrosis on renal ultrasonography or minimal urine production from the ureter on the affected side during cystoscopy, surgery has been effective.[63-67] In one mare, obstructive ureterolithiasis caused apparent lumbar pain, prompting stone removal twice 5 months apart, initially by a ureterolithectomy via a ventral midline approach and subsequently by using a basket retrieval device passed via the urethra into the ureter.[63] However, the mare succumbed to laminitis 3 months later, and bilateral nephrolithiasis was found at necropsy examination. Therefore, further recurrence would have been likely in this case. In a 3-year-old Thoroughbred colt, an obstructive ureterolith was successfully removed via endouroscopically-guided electrohydraulic lithotripsy, and the horse returned to a successful racing career.[64] Unilateral nephrectomy was reported to be a successful treatment for a renal abscess, pyelonephritis, or chronic hematuria associated with a nephrolith in three horses, all of which did not have azotemia and had an apparently normal contralateral kidney.[65-67] Accordingly, with appropriate case selection (lack of azotemia and unilateral disease), nephrectomy can be an effective treatment for nephrolithiasis in horses. In fact, in the absence of azotemia, nephrectomy may be the preferred approach for management of obstructive unilateral renal or ureteral calculi, because removal of the affected kidney should eliminate any associated upper UTI and the potential for recurrence.

Pyelonephritis

Upper UTIs involving the kidneys are rare in horses. The course of the distal segment of the ureters in the dorsal bladder wall creates a physical barrier or valve to prevent vesicoureteral reflux (VUR), a prerequisite for ascending pyelonephritis.[68] Problems that interfere with this barrier and increase the risk for VUR and associated upper UTIs include ectopic ureter or bladder distention, which may occur with bladder paralysis or urethral obstruction. Over time, VUR leads to progressive ureteral dilatation, renal scarring, and infection with commensal organisms. The role of recurrent lower UTI in the development of pyelonephritis is less clear because many cases of recurrent cystitis in other species never proceed to involve the upper urinary tract.[68] Because the kidneys are highly vascular organs, septic nephritis can also develop in association with septicemia in neonatal or adult horses.[69] Unless renal involvement is extensive, the upper UTI may go undetected but could lead to development of nephrolithiasis or CKD months to years later.

Pyelonephritis in horses has been described in association with urolithiasis and chronic cystitis with bladder paresis.[59,68,70] Other causes have included accidental amputation of the penis during castration,[71] foreign bodies in the bladder,[72] and lower urinary tract neoplasia.[73] With pyelonephritis, dysuria is manifested by hematuria or pyuria rather than by stranguria and pollakiuria (as for cystitis). In addition, horses with upper UTIs generally show other clinical signs, including fever, weight loss, anorexia, or depression.[68,74,75] As mentioned in the discussion of renal and ureteral calculi, upper UTIs can accompany nephrolithiasis and ureterolithiasis, and in affected cases it may be unclear which problem developed first.

Diagnostic evaluation includes physical and rectal examinations, urinalysis, and a quantitative urine culture. Careful palpation may allow detection of an enlarged ureter or kidney, although the kidney may also get smaller in long-standing cases. *Actinobacillus equuli*, *Streptococcus equi*, *Rhodococcus equi*, or *Salmonella* spp. are common isolates from horses with hematogenous nephritis.[68,69] In horses with upper UTIs, a complete blood count and serum biochemistry profile should be performed to assess the systemic inflammatory response and renal function. Cystoscopy (to evaluate urine flow from each ureteral orifice) and ultrasonographic imaging of the bladder, ureters, and kidneys are helpful adjunctive diagnostic procedures. Ureteral catheterization (by passing polyethylene tubing via the biopsy channel of the endoscope or by using a No. 8-10 French polypropylene catheter, which can be passed blindly in mares) may allow collection of urine samples from each ureter to distinguish unilateral from bilateral disease.[76]

Treatment for upper UTIs includes a prolonged course of appropriate systemic antibiotics (selected on the basis of susceptibility testing results on isolated pathogens, see Chapter 63). As for upper tract lithiasis, in carefully selected cases with unilateral disease, surgical removal of the affected kidney and ureter may be curative.[65,66] In addition to absence of azotemia, recovery of insignificant numbers of bacteria (fewer than 10,000 CFU/mL) from urine collected from the ureter leading to the unaffected kidney would be valuable information to collect before nephrectomy is pursued

Ureterorrhexis

Ureteral disruption appears to be an extremely rare problem in the adult horse with only three reported cases.[76-78] The cause appeared to be traumatic in a mare following dystocia and in a Thoroughbred gelding after a fall.[77,78] The third case developed iatrogenically during an attempt to enter a ureter transurethrally with a rigid instrument.[76] Unlike in foals, traumatic disruption was more distal toward the bladder and was unilateral in all cases. The postpartum mare presented for abdominal distention because of uroabdomen, and the gelding presented for colic signs with frequent posturing to urinate and uroabdomen was confirmed by a peritoneal fluid to serum creatinine ratio more than 2 in both cases. The diagnosis was made during an exploratory celiotomy in the mare and a ureteral stent was placed without attempting to repair the damaged ureter, because of tissue disruption and fluid (urine) accumulation around the tear. The stent was maintained for 3 weeks and the mare recovered uneventfully. A fluid-filled structure could be palpated dorsolateral to the bladder in the affected gelding, and this case was managed medically (without stenting). He recovered over the next few days with supportive care, and the fluid-filled structure resolved over the subsequent 2 months. In the final case, in which the ureter was traumatically damaged during instrumentation, the tear occurred in the terminal portion of the ureter within the bladder wall and the mare recovered with no specific treatment.

Renal Neoplasia

Renal neoplasms include adenomas, renal cell carcinomas, and nephroblastomas.[79] Renal adenomas are small, well-

circumscribed lesions in the renal cortex that are usually incidental necropsy findings. The most common renal tumor in the horse is renal cell carcinoma or adenocarcinoma.[80-84] These arise from proximal tubular epithelium in most cases. Affected horses usually have nonspecific presenting complaints including poor performance, depression, weight loss, and recurrent colic. Signs that increase suspicion of a primary urinary tract problem include hematuria (94%) and detection of a palpable mass on rectal examination (77%).[84] An occasional horse may have a large enough mass to cause protrusion of the paralumbar fossa or a hind limb gait abnormality and abnormal stance.

Renal cell carcinomas are typically unilateral, and normal renal function is maintained by the contralateral kidney. Although nephrectomy would be the treatment of choice, tumors are typically too large and adherent to surrounding organs by the time they are detected. Accordingly, surgical removal is usually not possible and in one case in which it was attempted, uncontrollable abdominal intraoperative hemorrhage resulted in a decision for euthanasia.[84] Frequent metastases to the lungs and liver are another indication that renal adenocarcinoma is usually not a treatable disease.[84] As an example, in the only other surgical case, a nephrectomy was performed via a flank laparotomy but euthanasia was performed 7 months later because of respiratory difficulty associated with metastases.[83]

In a report of 27 horses with renal adenocarcinoma, only six cases were diagnosed during life (percutaneous biopsy in two and a surgical biopsy in four) but renal ultrasonography was markedly abnormal in all cases in which it was pursued (Figure 64-5).[82,84] Only 2 of 27 horses were discharged from the hospital. The poor prognosis can be attributed to the fact that clinical signs of intra-abdominal neoplasia in horses are often not be apparent until the disease is quite advanced.[85] In one report of renal carcinoma, clinical signs of the tumor were absent until the horse was anesthetized for laryngeal surgery. After an uncomplicated surgery, the horse was repositioned for recovery but died shortly thereafter. Compression of the caudal vena cava by a large renal carcinoma was suspected to lead to a decrease in venous return as the cause of sudden death.[86]

Other neoplastic diseases that may affect the kidneys include nephroblastoma, transitional cell carcinoma, and squamous cell carcinoma.[79,84,85,87] Nephroblastoma (Wilms' tumor) is an embryonal tumor that arises in primitive nephrogenic tissue or in foci of dysplastic renal tissue; the latter tumor types arise from the uroepithelium of the renal pelvis or ureter.[79,87] Neoplastic involvement of the upper urinary tract may also occur with dissemination of lymphosarcoma, hemangiosarcoma, melanoma, or adenocarcinoma arising from other tissues within the abdomen.[88] Although they are not truly cancerous disease processes, mucinous hyperplasia of the renal pelvic and proximal ureteral uroepithelium or ureteropelvic polyp formation can also lead to development of a soft tissue mass in the area of either kidney, ureteral obstruction, and hydronephrosis.[89-91]

SURGICAL PROCEDURES

J. Brett Woodie

Renal Biopsy

Harold C. Schott II

Renal biopsy is a controversial diagnostic procedure but it may provide useful information in select cases.[92-94] Although percutaneous biopsy is considered a reasonably safe procedure when performed with ultrasonographic guidance, it carries risks including perirenal hemorrhage or hematuria and, less commonly, penetration of bowel. In humans, perinephric hematomas are detected by CT imaging in 57% to 85% of patients shortly after biopsy. Microscopic hematuria occurs in virtually all patients for the first couple of days after biopsy, but gross hematuria is observed in less than 10% of patients. Most of these complications are inconsequential, but postbiopsy transfusions have been required in up to 3% of patients, and one death has been reported since 1980.[92] Similarly, in seven normal horses subjected to bilateral renal biopsy, macroscopic (1/7) and microscopic (4/7) hematuria were observed in five and extensive perirenal hemorrhage was found at necropsy examination of four horses subjected to euthanasia 8 hours following biopsy. Evidence of perirenal hemorrhage was still identified at necropsy in a fifth horse euthanatized 9 and 27 days following biopsy (of either side).[94] A recent retrospective study of 151 renal biopsies collected from 146 horses found a complication

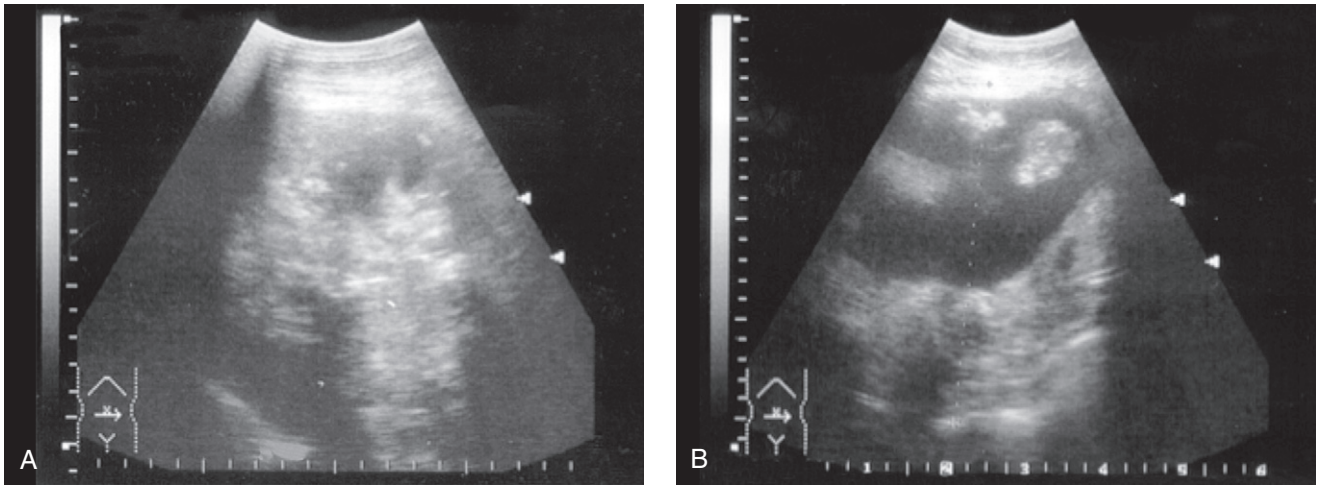

Figure 64-5. Ultrasonographic images of the right kidney of a horse with renal adenocarcinoma. **A,** Little evidence of normal renal architecture remains. **B,** Multiple areas of hypoechoic fluid are apparent within the kidney.

rate of 11.3%: macroscopic hematuria in 3% but a significant decline in packed cell volume in 5%; colic in 4%; one urethral obstruction because of a blood clot in the bladder; one death from hemorrhage; and one abortion of a 60-day fetus in a mare anesthetized for open surgical biopsy.[95] An adequate sample for histopathologic evaluation was collected in 93% of these cases, but the impact of the biopsy results on patient management was not assessed in this report.

Most renal biopsies are collected percutaneously after use of ultrasonography to locate the most appropriate biopsy site (blind biopsy after ultrasonographic localization) and this is the preferred technique in the horse for suspected diffuse renal disease. When a focal abnormality is detected on ultrasonography, laparoscopic-guided or open renal biopsy are more likely to result in collection of the desired abnormal tissue and should be considered. Because renal biopsy is not without risk, the procedure should be approached with caution and pursued only when results could substantially alter the therapeutic plan or prognosis. There is limited information about the impact of renal biopsy results on therapy and outcome of renal disease in humans; however, in one prospective study biopsy results were found to influence physicians' decisions on about half of the cases.[96] In general, renal biopsy is pursued more aggressively in humans with acute renal insufficiency than in those with chronic renal insufficiency, especially when it is difficult to determine the type of renal disease based on results of urinalysis and sediment examination.[92]

In the equine patient, a renal biopsy is performed with the horse sedated and restrained in stocks. With bilateral disease, biopsy of the right kidney is preferred because of its superficial location. After locating the right kidney via ultrasonography, overlying hair is clipped and the site, typically over the 15th to 17th intercostal spaces, is surgically prepared. Local anesthetic is infused subcutaneously followed by a deep stab incision with a No.15 blade to minimize drag of the skin and subcutaneous tissues on the biopsy instrument (a Tru-cut biopsy needle or, preferably, a spring-loaded, triggered biopsy device). Penetration of the needle into the renal parenchyma can often be appreciated by a change in tissue resistance, and the tip of the needle should be advanced about 1 cm deep into the kidney (depth can also be determined via ultrasonographic measurement immediately prior to biopsy). One biopsy sample should be placed in formalin for histopathologic evaluation, and additional samples can be collected for bacterial culture or for specialized microscopic examination, such as by immunohistochemistry or electron microscopy; appropriate sample processing should be determined beforehand by contacting the pathologist who will examine the biopsy samples. Because of the risk of hemorrhage, a minimum number of samples should be collected.

In contrast to humans and small animals, in which the biopsy instrument is angled tangentially in an attempt to collect predominantly cortical tissue, the biopsy needle is generally inserted perpendicular to the equine kidney when the procedure is performed percutaneously. Routine analysis of a renal biopsy in human (and now small animal) medicine typically includes multiple stains of ultrathin sections for light microscopy, immunohistochemistry, and electron microscopy, with an emphasis on evaluation of glomeruli. Unfortunately, no laboratory currently offers detailed evaluation of equine renal biopsies. Additionally, equine renal disease is more often tubulointerstitial in origin than glomerular. When these additional limitations are considered, clinicians should have specific questions in mind before renal biopsies are performed in horses. For example, a biopsy may be useful for establishing a diagnosis of renal dysplasia in a younger horse with CKD or of neoplasia versus infection in a kidney with a focal ultrasonographic abnormality. In the latter instance, a laparoscopically guided or open renal biopsy would have a greater chance of recovering a diagnostic biopsy sample. Specific treatment following a renal biopsy is not required, although patients should be carefully monitored for complications for 1 to 3 days following the procedure.

Nephrectomy

Unilateral right nephrectomy is performed through a right 16th or 17th rib resection or, alternatively, at the 16th and 15th intercostal spaces.[97,98] Depending on the degree of anatomic variation, the most cranial approach can create a plane of dissection across the dorsal aspect of the costophrenic angle and through the diaphragm to the kidney. Although transthoracic approaches have been used successfully, they are more complicated than the right 17th rib resection approach and are not recommended. In the foal, a ventral midline approach can be used for unilateral nephrectomy but in the adult horse this is not feasible.[97]

In the transcostal approach, the horse is placed under general anesthsia, positioned in lateral recumbency, clipped, and prepared for aseptic surgery. Positive pressure ventilation should be available in case the thoracic cavity is entered inadvertently. This complication occurs more commonly on the right side of the horse.[97] A 30- to 40-cm (12- to 16-inch) skin incision is made over the 16th or 17th rib. Dissection is continued through the serratus dorsalis caudalis and the external abdominal oblique muscles to expose the perisoteum of the rib. The periosteum is incised and elevated around the rib, taking care to avoid injury to the intercostal vasculature. A Doyen rib raspatory is helpful for this dissection. The rib is transected 2 to 5 cm distal to the costovertebral articulation using a bone saw or Gigli wire (Figure 64-6). Ventrally, the rib is disarticulated at the costochondral junction. Ronguers and a bone rasp should be used to smooth the end of the bone at the proximal extent of the incision. The medial costal periosteum is longitudinally incised, and the kidney is exposed by blunt dissection through

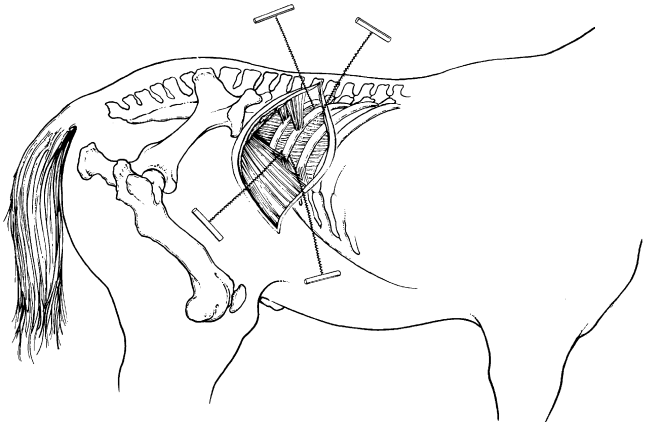

Figure 64-6. Resection of the 17th rib permits surgical access for right nephrectomy or nephrotomy procedure.

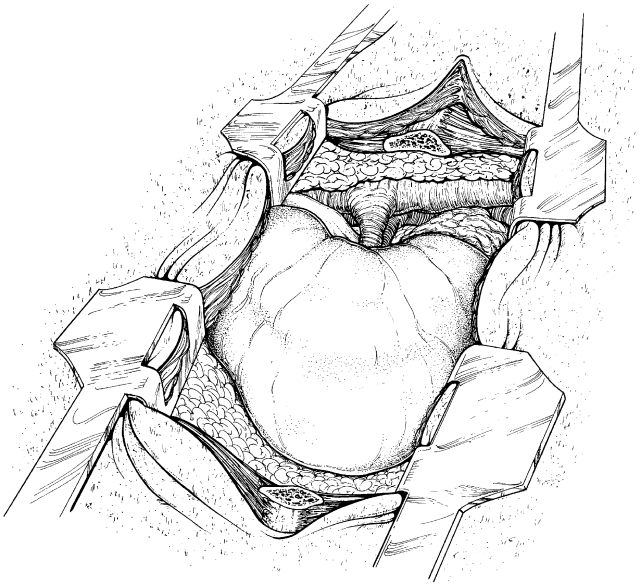

Figure 64-7. All perirenal fat is removed by blunt dissection to permit access to the ureterovascular pedicle.

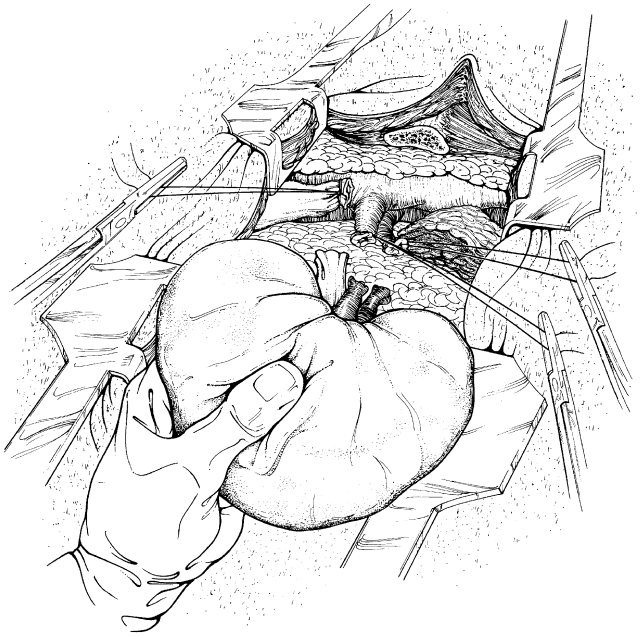

Figure 64-8. The renal artery, vein, and ureter are ligated with transfixing ligatures before resection and removal of the kidney.

the retroperitoneal fat. If additional exposure is required, the incision can be extended ventrad.

The kidney is mobilized by digital circumferential dissection through perinephric fat to expose the ureterovascular pedicle and penetrating capsular vessels (Figure 64-7). A self-retaining retractor is helpful to aid in exposing the kidney. Small capsular vessels and accessory renal arteries should be ligated. Electrocautery can be used if appropriate for the size of the vessel. The ureterovascular pedicle is isolated, and the artery, vein, and ureter are individually double-ligated (Figure 64-8). The use of hemostatic vascular clips or vascular staples facilitates removal of the kidney and provides adequate access for suture ligation of major vascular elements.

After removal of the affected kidney, the renal fossa is lavaged and again evaluated for evidence of hemorrhage. The ureter is mobilized, ligated as far distad as possible, and transected. Resection of the pelvic ureter is not possible when using a flank approach for nephrectomy. Either Penrose or closed suction drains are placed after resection of the kidney to evacuate blood accumulating in the dead space or to manage urine-contaminated tissues.

The periosteum of the rib and deep fascia are closed with a synthetic absorbable suture material placed in a simple-interrupted or simple-continuous pattern. The subcutaneous tissues and skin are closed routinely. Unilateral left nephrectomy of the horse is performed in similar fashion using either a 17th or 18th rib resection or a dorsal flank incision.[21,99,100]

Laparoscopic Nephrectomy by Hand-Assisted Techniques

Laparoscopic nephrectomy in the horse has been described.[101] An ipsilateral flank approach is used to remove the respective kidney. At least three portals are required. The first portal is made between the 17th and 18th ribs at the ventral border of the tuber coxae. The second portal is located midway between the last rib and the dorsocranial border of the tuber coxae. The third portal is prepared approximately 8 cm (3 inches) ventral to the second portal. A 30-cm (12-inch) long, 10-mm (4-inch) diameter, 0-degree laparoscope is used. The procedure for removing the left kidney starts with injection of epinephrine (1 mg in 10 mL of saline) in three or four sites at the dorsal border of the spleen to create splenic contraction. This enlarges the space in which the surgeon has to work. The perirenal fascia is injected dorsally with 20 mL of 2% mepivacaine. A monopolar electrocautery hook blade is used to create a plane of dissection dorsal to the kidney. Perirenal fat is dissected and removed with curved laparoscopic scissors. The hilus of the kidney is carefully dissected free to identify the vessels. Specialized (clockwise and counterclockwise) laparoscopic ligation instruments are used to ligate the renal artery, vein, and ureter, in that order. The area is assessed for hemorrhage prior to making a small flank incision to retrieve the kidney. Complications include pneumothorax and bleeding from accessory renal arteries. This is a technically demanding procedure and requires practice before attempting it on clinical patients.

The first hand-assisted laporoscopic nephrectomy in human medicine was described in 1997.[102] The surgical technique has been described for the left and right kidney in the standing horse.[103,104] Preparation of the horse for this surgery includes withholding feed for at least 12 hours. The administration of perioperative antibiotics and analgesics is at the discretion of the surgeon. The paralumbar fossa corresponding to the kidney that is to be removed is clipped and surgically prepared for aseptic surgery. Administration of a systemic α_2-agonist provides sedation. The paralumbar fossa is desensitized by local infiltration with mepivacaine hydrochloride. Insufflation of the abdominal cavity is not required because of the open approach. A 10- to 12-cm vertical skin incision is made in the paralumbar fossa beginning 5 to 8 cm below the dorsal border of the internal abdominal oblique muscle. The external abdominal oblique

muscle is sharply incised and a modified grid approach is used to gain access to the peritoneal cavity. The peritoneum is sharply incised. A laparoscopic viewing portal is made dorsal to the proximal border of the flank incision. An instrument portal is created 4 to 6 cm cranial and 2 to 3 cm dorsal to the laparoscopic portal.

A 0-degree laparoscope is used for viewing the surgical site, and a hand within the abdomen is used for retraction and blunt dissection. The retroperitoneal space caudoventral to the kidney is infiltrated with 15 to 20 mL of mepivacaine followed by digital massage to facilitate distribution of the local anesthetic throughout the retroperitoneal space. Laparoscopic scissors are used to sharply incise the peritoneum caudal to the kidney. This incision is enlarged by manual dissection to expose the kidney. Careful manual dissection is used to completely identify all of the vascular structures entering and leaving the kidney. The renal artery and vein are double-ligated separately, using size 2 polyglactin 910 with one-handed ties. The vessels are transected using laparoscopic scissors and the kidney is delivered out of the flank incision with the ureter intact. The ureter is double-ligated and transected. The renal vessels are inspected for hemorrhage followed by routine closure of the paralumbar incision in several layers.

The most immediate and severe complication is uncontrollable hemorrhage, which generally originates from a torn accessory branch of the renal artery. Benefits from hand-assisted procedures include: tactile sensation to facilitate dissection, hand retraction, smaller surgical incision, decreased surgical time, and less surgical morbidity, in addition to eliminating the need for general anesthesia.

Nephrotomy

Nephrotomy is not considered a benign or potentially less complicated surgical procedure than nephrectomy. In dogs, it results in a 20% to 50% reduction in renal function.[105,106] In equine patients, nephrotomy is performed less commonly than nephrectomy because indications are fewer and the degree of technical difficulty is substantially greater.

The surgical approach for nephrotomy is similar to that used for nephrectomy. The procedure is technically difficult, given the depth and dimensions of the surgical field and the reduced ability to see the surgical site intraoperatively, complicated by hemorrhage from the penetrating capsular vessels. In canine patients, the approach is through a longitudinal sagittal incision in the convex lateral surface of the kidney.[105,106] To make such an incision, the kidney must be dissected free from the perirenal fat. This disrupts multiple small penetrating capsular vessels that require hemostasis.

After the kidney is mobilized, it may be pivoted about the ureterovascular pedicle to expose the convex surface. Before incising the cortex, major renal vessels are temporarily occluded with noncrushing vascular forceps or Rummel's tourniquets. The renal incision is extended to expose the collecting system and the renal pelvis. Obstructive lesions of the renal pelvis (e.g., renal calculi) are removed, and the collecting system is lavaged. The incision is made just large enough to allow removal of the calculi. Less damage is done to the renal parenchyma if the renal capsule is incised with a blade and forceps are used to bluntly separate the parenchyma.[106] The associated ureter should be cannulated with a size 10 to 15 French polyethylene catheter to ensure patency.

Canine nephrotomy incisions are closed by gently pressing the renal halves together with sustained pressure. The renal capsue is closed with 3-0 or 4-0 synthetic absorbable suture placed in a simple continuous pattern.[106] Although pyelotomy has been suggested as a reasonable approach to the canine renal pelvis, its small size increases the risk of accidental transection of an interlobar artery. Likewise, the close proximity of the renal artery and veins would make pyelotomy a difficult and risky procedure to perform in equine patients.

Ureterotomy

Indications for ureterotomy in the horse are limited principally to obstructive urolithiasis. Presentation of uncomplicated cases of ureteral calculi for surgical treatment is rare. Horses are often chronically affected and have developed some degree of renal pathology. Some horses with sufficient renal mass remain asymptomatic, and the condition is diagnosed as an incidental finding at necropsy.

Horses with identifiable ureteral pathology may be explored through a flank laparotomy, or through caudal ventral midline laparotomy in the mare. Exposure is difficult and extremely limited over the caudal course of the ureter. Typically, lesions are located in the proximal third of the ureter. When lesions can be identified and exposed, the ureter is incised proximal to the obstruction, and the contents are evacuated with surgical suction. The urolith is removed and the ureter is closed in a simple-continuous pattern with small-diameter synthetic absorbable sutures. Silastic tubing may be introduced into the ureter as a stent over which the ureteral repair is performed. When direct surgical intervention is not possible, the use of a grasping basket (Dormia Stone Dislodger) can facilitate closed dislodgment of a ureterolith.[63] The instrument is introduced into the ureteral orifice by direct insertion in mares or under videoendoscopic control using a perineal urethrotomy in males (see Chapter 66). Guidance by rectal palpation is desirable to manipulate the dislodger into a position proximal to the urolith. The dislodger is subsequently opened and retracted to ensnare the urolith and displace it distad using slow, gentle traction.

Repair of ureterorrhexis is approached in similar fashion.[48,77,107] In a case report, successful repair of a traumatic ureteral tear in a postpartum mare was accomplished with an indwelling polyethylene tubing stent (outside diameter, 1.90 mm).[77] The mare had evidence of uroperitoneum and associated electrolyte abnormalities (hyponatremia and hyperkalemia). A ventral midline celiotomy was used; however, because of the accumulation of urine around the ureter and broad ligament, the rent within the ureter could not be identified for primary repair. The surgery was assisted with the use of videoendoscopy of the urinary bladder. This allowed the surgeon to accurately place the stent within the ureter past the presumptive location of the rent. The stent was checked for urine production and subsequently anchored to the vaginal mucosa and perineal skin and kept in place for 21 days. In other reports neonates developed uroperitoneum secondary to a ureteral defect.[48,107] Urine accumulation was also detected in the retroperitneal space. The peritoneum was incised over the swelling and the ureter was exposed. A cystotomy extending from the apex to the neck of the bladder was made. A size 8 French polypropylene catheter was advanced retrograde through the ureteral opening for a short distance and Evans blue dye was injected into the catheter

to locate the defect in the ureter. When the defect was located the catheter was advanced proximal to the defect and the rent was closed using 4-0 or 5-0 suture material. Although a few prosthetic constructs are available for use as ureteral stents in human medicine, the optimal size (7 to 9 French in humans) and material have yet to be determined for the horse and will likely not be determined scientifically because of the rarity of the condition.

Neoureterostomy

Neoureterostomy techniques are used in the horse to manage ectopic ureters. In human and canine patients, vesicoureteral anastomosis has traditionally been the method of choice for treatment of ectopic ureters and selected cases of ureteral avulsion. Complications with these techniques in equine patients prompted treatment of foals by unilateral nephrectomy, assuming that the contralateral kidney was normal.[21,22] Surgical success can be obtained, however, in large horses.

The surgical approach is made through a caudoventral midline incision, extended to the pubis for exposure of the bladder. The viscera are packed off craniad in the abdomen, and the ureter is identified as it traverses the dorsolateral bladder. The ectopic ureter can be identified by retrograde catheterization. If the ectopic ureter is in close proximity to the dorsal bladder, a side-to-side or end-to-side extravesicoureteral anastomosis may be performed to create a new ureteral opening along the dorsolateral cranial base of the bladder. The distal ureter is ligated and dissected free unless it is in an intramural location and surgically inaccessible.

Alternatively, if the ectopic ureter is not in close proximity to the bladder, the ureter may be ligated distad and neoureterostomy achieved by intravesicular anastomosis (Figure 64-9). Tunneling the ureter creates a functional equivalent of a distal ureteral valve, which reduces the likelihood of vesicoureteral reflux.[106] Apposition of the ureteral and vesicular mucosa with 3-0 or 4-0 synthetic absorbable suture material is ideal (Figure 64-10).

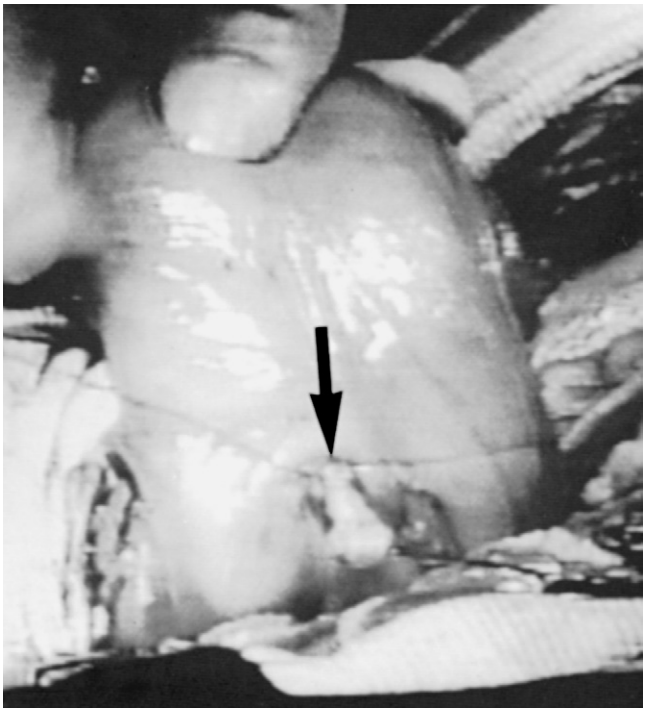

Figure 64-9. Ligatures are placed to secure a ureter *(arrow)* after translocation to the bladder from an ectopic site. The ureter has been tunneled through the seromuscular layer of the bladder to prevent vesicoureteral reflux. (Courtesy Candace Lundin, DVM.)

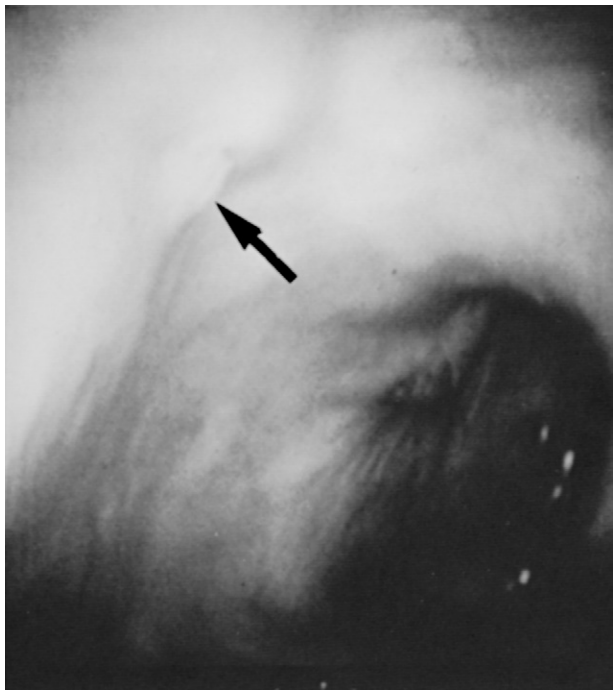

Figure 64-10. Endoscopic appearance of the ureterovesicular anastomosis demonstrated in Figure 64-9. The ureteral stoma can be observed on the dorsolateral wall of the bladder *(arrow)*. (Courtesy Candace Lundin, DVM.)

Aftercare

After all renal surgery, horses should be monitored for adequate water consumption and urine production. The horse should be supported with intravenous fluids. Serum electrolytes and clearance ratios may reveal transient imbalance in electrolyte clearance after nephrectomy, particularly with regard to potassium. Fluid therapy should be adjusted accordingly.

Prophylactic antibiotics are indicated during the perioperative period because this renal intervention is a clean-contaminated surgery. When septic conditions are encountered, antibiotic therapy should be directed by the results of intraoperative culture and sensitivity results. Dosages should be adjusted for the reduction in renal mass when nephrotoxic antibiotics must be used. Depending on the drug, serum levels can be monitored for peak and trough levels to minimize the possibility of renal damage.[108]

Complications

The patient should be monitored for the development of pneumothorax during surgical dissection. Although inherently a part of the transthoracic approach, pneumothorax can develop

when a flank approach using rib resection disrupts the crura of the diaphragm. If this occurs the defect in the diaphragm should be sutured to the adjacent costal musculature to seal the pleural cavity.[97] Access to a mechanical ventilator may be required immediately in the event that the pleural space is opened during the flank approach to the kidney.

Other complications of renal surgery include postoperative hemorrhage and infection. Management of postoperative hemorrhage is based on prevention through application of meticulous surgical technique for isolation and cautery or ligation of contributing and emerging vessels. Assessment of packed cell volume and coagulation defects is appropriate before undertaking renal biopsy or excisional techniques. Surgical drainage is appropriate whenever diffuse hemorrhage, seroma, or bacterial contamination is anticipated.

CHAPTER 65

Bladder

Harold C. Schott II and J. Brett Woodie

ANATOMY AND PHYSIOLOGY

Harold C. Schott II

The bladder is a highly distensible organ capable of holding 4 L or more of urine in a 500-kg horse. When empty, the bladder may lie entirely in the pelvic canal, and when full it drops over the pelvic rim to extend to the level of the umbilicus.[1] When the bladder is full, the lateral ligaments are easily palpated on either side of the bladder on rectal examination. Their cranial free edges, remnants of the umbilical arteries, are called the *round ligaments of the bladder.*[2] The bladder is covered with peritoneum cranially at the apex and with adventitial tissue in the remainder of the retroperitoneal space. The bladder wall contains two smooth muscle layers: (1) an outer layer of longitudinal to obliquely arranged muscle fibers and (2) an inner layer of transversely or circularly arranged muscle fibers.[2] The outer and inner layers are partly interwoven around the bladder; however, at the dorsal aspect the circular layer becomes external to the longitudinal layer. This anatomical arrangement of muscle fibers has been suggested to allow the bladder to distend to a great extent dorsad as it fills, thereby causing less interference with the intestines. However, it also makes the dorsal wall inherently weak and the likely site of rupture with excessive bladder distention.[3] The outer and inner muscle layers are both arranged longitudinally toward the bladder neck and act in concert to close the internal urethral orifice. The musculature of the bladder wall is continuous with an outer longitudinal and an inner circular layer of smooth muscle surrounding the pelvic urethra. Lateral and ventral to the smooth muscle is the striated urethralis muscle. Together these muscles form the urethral sphincter.[2] The bladder is lined with transitional epithelium overlying a thick submucosa that allows considerable stretching.[1]

Sympathetic innervation to the bladder is provided via the hypogastric nerve, with preganglionic fibers arriving from spinal segments L1 to L4 to synapse in the caudal mesenteric ganglion. Postganglionic fibers supply the bladder (β_2-adrenergic receptors) and proximal urethra (primarily α_1-and some α_2-adrenergic receptors).[4,5] In addition to adrenergic innervation, the equine bladder is also innervated by cholinergic and peptidergic nerve fibers.[6] Parasympathetic innervation originates in the sacral segments of the spinal cord with neurons joining to form the pelvic nerve.[4,5] Somatic innervation of the lower urinary tract is primarily to the striated urethralis muscle sphincter via a branch of the pudendal nerve, which originates from the sacral cord segments (S1 to S2).[1] The smooth muscle of the bladder, referred to as the *detrusor muscle,* is innervated by the parasympathetic pelvic nerve and β_2-adrenergic postganglionic fibers.

The bladder has a *filling/storage phase* as well as an elimination phase.[7] During filling there is an increase in tone of the smooth and striated muscles of the urethral sphincter to maintain continence.

Sympathetic nerve activity is dominant during filling/storage and the detrusor muscle relaxes owing to α-receptor–mediated inhibition of pelvic nerve afferents and stimulation of sympathetic β_2-receptors in the smooth muscle of the bladder. The latter is a reflex response that involves sensory input from bladder stretch and pressure receptors via afferent pelvic nerve fibers to the sacral cord, interneurons in the cord, and pre- and post-ganglionic sympathetic axons in the hypogastric nerve. Relaxation of this muscle allows accumulation of a large volume of urine with little increase in intravesicular pressure. As detrusor muscle fibers reach their limit of stretch, intravesicular pressure starts to rise, and stretch receptors transmit signals via the pelvic nerve and ascending spinoreticular tracks to the pons, cerebrum, and cerebellum. Bladder fullness is sensed, and signals for voluntary micturition are initiated in the cerebrum, beginning the *elimination phase*. These signals are transmitted via brainstem upper motor neurons descending in reticulospinal tracts to sacral parasympathetic nuclei, parasympathetic ganglia in the pelvic plexus or bladder wall, and postganglionic fibers, triggering detrusor contraction. Depolarization waves spread throughout the bladder via tight junctions, resulting in a strong, coordinated detrusor contraction. Concurrent inhibition of the pudendal nerve and hypogastric α- and β_2-sympathetic activity leads to relaxation of the urethral sphincter and facilitates detrusor muscle contraction and elimination of urine. Micturition ends when detrusor stretch receptors cease firing and pelvic nerve efferent activity stops. At that time, sympathetic nerve and pudendal nerve activity resumes for the next storage/filling phase.

DISORDERS REQUIRING SURGERY

Harold C. Schott II

Disorders of the bladder that may require surgery include uroperitoneum, in both foals and adult horses, as well as patent urachus and other neonatal bladder problems. In adult horses, cystolithiasis is the most common surgical disorder of the bladder. Other less common problems that may require surgical intervention include prolapse or eversion and neoplasia.

Uroperitoneum

Uroabdomen can develop as a result of leakage from a ureter (see Chapter 64), the bladder, or urachus.

Foals

In foals, uroperitoneum most commonly develops after bladder rupture during parturition in colts, with prevalence ranging from 0.5% to 2.5%.[3,8-10] The commonly accepted explanation is that a high intravesicular pressure that develops during passage through the pelvic canal during parturition, coupled with occlusion of the urethra, leads to bladder rupture in colts that are delivered with a moderately full bladder. However, presence of posterior urethral valves is the most common cause of lower urinary tract obstruction in male infants and can cause bladder rupture, vesicoureteral reflux, and hydronephrosis, but this

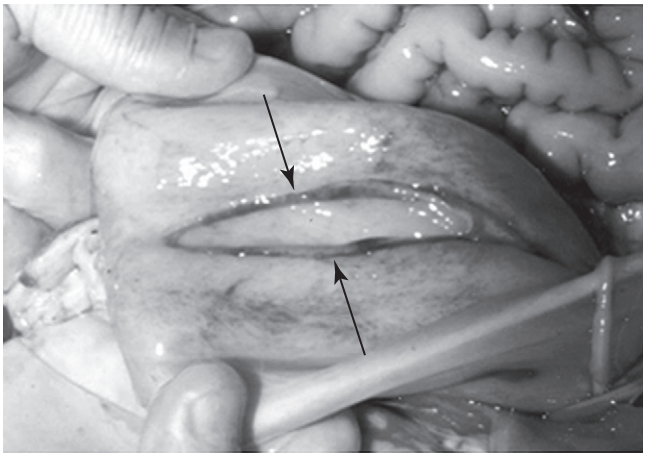

Figure 65-1. Longitudinal bladder tear in the dorsal aspect of a 3-day-old colt *(arrows).* This is the typical surgical finding in a foal that develops uroabdomen consequent to bladder rupture sustained during parturition.

problem has not yet been recognized in horses.[11] Bladder tears are typically 2 to 5 cm in length on the dorsal surface with margins that are hemorrhagic and edematous (Figure 65-1).[3] Surgical exploration also has revealed ventral bladder tears in some foals[8,12] or bladder defects that have smooth margins with no evidence of traumatic disruption,[8,10,13,14] as well as apparent absence of portions of the bladder.[15] Although uncertain, it has been suggested that these latter defects may be developmental anomalies rather than ruptures.

Excessive bladder distention or megavesica has also been described in stillborn[16] and neonatal foals with abdominal distention with or without bladder rupture.[12,17] *In utero* bladder distention suggests lower tract obstruction, but a definite cause of obstruction was not found in these cases. However, an excessively long umbilical cord (more than 85 cm) may lead to intermittent urachal obstruction,[16] but in this instance, urine produced *in utero* should be able to pass into the amniotic cavity via the urethra. Bladder distention causing abdominal distention can be confused with uroabdomen. For example, an enlarged, flaccid bladder was found in a foal undergoing exploratory celiotomy for suspected uroabdomen. Half of the excessively distended bladder was removed and the foal survived.[12] Anomalous fusion of the bladder to the inner umbilical ring, with absence of the urachus, prevented bladder emptying and caused abdominal distention because of megavesica in another report.[18] The bladder was separated from the umbilical ring during surgical exploration to restore normal anatomic and functional integrity of the bladder. Abdominal distention has also been described in an older foal with a markedly distended bladder attributed to an adhesion of the bladder to the urachus.[19] In a colt seen by me, megavesica with uroabdomen was corrected by surgical removal of a large portion of the bladder, but the foal developed recurrent colic after weaning and a narrowing of the distal small colon was found at necropsy. Thus, megavesica remains a poorly understood condition and, when detected, warrants careful evaluation for other congenital anomalies.

Bladder distention is also recognized in foals with perinatal asphyxia syndrome (PAS), especially when recumbent.[12,20,21] Ultrasonographic examination may reveal either an enlarged bladder or incomplete bladder emptying, and both sexes appear to be at similar risk for this problem. Temporary use of an indwelling bladder catheter to keep the bladder empty is useful to decrease the risk of rupture, but ascending urinary tract infection may be a complication. Localized sepsis of the urachus in these patients, as well as foals with septicemia, can lead to urachal urine leakage.[12,20,21] Urine may leak into the abdomen, resulting in uroperitoneum, or externally to cause a patent urachus. Urine can also leak into the subcutaneous tissues and produce a plaque of edema (actually urine) extending from the umbilicus.[8,12,22]

Foals with ruptured bladders sustained during parturition often appear healthy and nurse well for the initial 24 to 48 hours after foaling. Early signs include a decrease in nursing vigor and lethargy followed by progressive abdominal distention and intermittent colic signs.[8-10] Some foals repeatedly posture to urinate, but this behavior can be confused with meconium retention. Subtle differences in straining observed with these two problems may be that colts with uroabdomen have a dropped penis and intermittently pass small amounts of urine, whereas foals with meconium impaction often show more vigorous tail elevation and wagging. The rate at which urine accumulates in the abdomen depends on the size of the defect. Clinical signs with smaller tears, usually in the area of the urachus, may not develop until 3 to 7 days of age.

Clinicopathologic assessment commonly reveals hyponatremia, hypochloremia, and moderate to marked hyperkalemia along with azotemia.[8-10,23,24] These electrolyte alterations may lead to development of fine muscle tremors and neurological deficits.[8,25] Uroabdomen can be confirmed by measuring a ratio of peritoneal fluid to serum creatinine more than 2.[8-10,23,24] More frequently, uroabdomen becomes highly suspect when a large amount of free abdominal fluid is imaged via transabdominal ultrasonography (Figure 65-2), such that confirmatory peritoneal fluid analysis is not consistently pursued.

Because foals with PAS or septicemia are often recumbent, frequency of urination can be difficult to assess, and presence of neurological deficits can be attributed to hypoxic-ischemic encephalopathy or meningitis. Recumbent foals may initially have a dry umbilicus that again starts to leak urine, especially when they are unable to void effectively and have chronic bladder distention. Silent uroabdomen can develop with urachal leakage into the abdomen and may not be detected until abdominal distention becomes apparent. However, this is uncommon because most hospitalized neonates are reassessed once or twice daily with abdominal ultrasonography. As a result, increasing amounts of free peritoneal fluid are often detected before gross abdominal distention develops. In these earlier stages of uroabdomen, alterations in serum electrolyte concentrations and azotemia are less severe, but peritoneal fluid creatinine concentration should still be substantially greater than that of serum.[11,20,21]

Adult Horses

Bladder rupture in adult horses is less common than in foals but has been recognized following parturition[23,26-31] and with obstructive problems including urolithiasis[32-36] and penile hematoma.[37] It has also been observed after blunt abdominal trauma[38] as well as after repair of bladder rupture[39] or treatment of urachal sepsis as a neonate.[40] I also have seen uroabdomen develop following anesthesia for magnetic resonance imaging, and weakness at the bladder apex was a suspected contributing

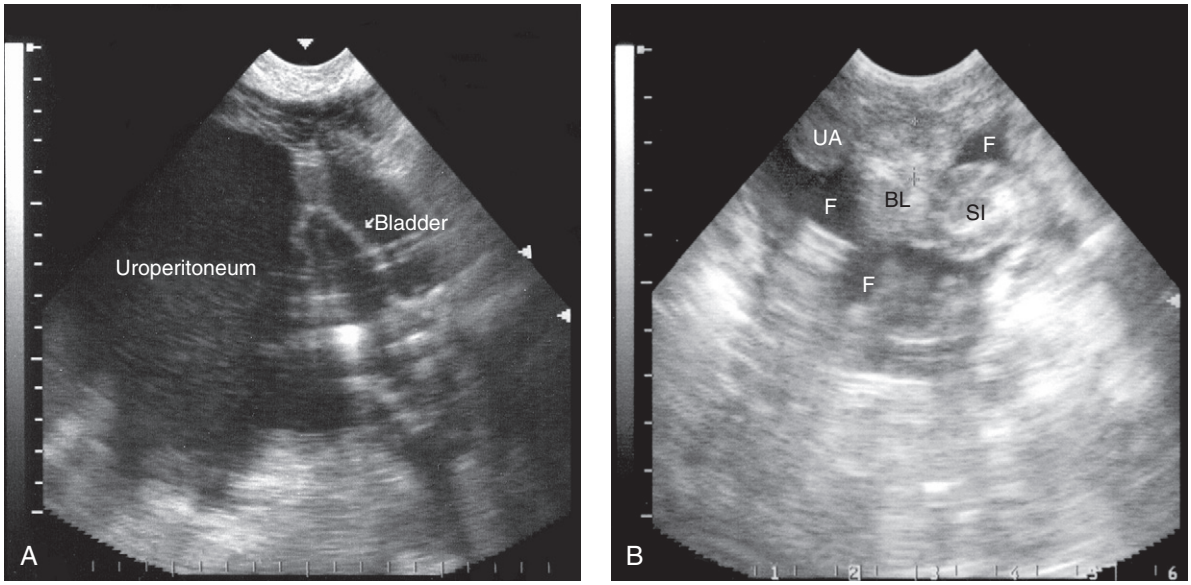

Figure 65-2. Transabdominal ultrasonographic images at the level of the umbilicus in foals. **A,** A large amount of free peritoneal fluid is present in moderate to severe uroabdomen; **B,** Only a modest amount of fluid is visible as would be imaged during the early stages of uroabdomen.

factor. Dystocia or assisted delivery has only been reported in a few mares with postpartum uroabdomen[29,30] and the incidence of this complication of parturition was reported to be 1 in 10,000 births in one large broodmare practice.[31] Clinicopathologic findings of azotemia and alterations in serum electrolyte concentrations in adult horses with bladder rupture are similar to those found in neonates with uroabdomen.

Presurgical Considerations

CORRECTION OF HYPERKALEMIA

Although surgical correction of a bladder tear or resection of the urachus is the preferred treatment for uroabdomen, patients need to be stabilized medically before they are anesthetized for surgical repair. Two main problems that need to be addressed are (1) hyperkalemia, and (2) abdominal distention with urine. Serum potassium concentration is variable with uroabdomen; therefore measurement of electrolyte concentrations is an essential part of case evaluation.[8-10,12,20,21,24] Clinical indicators of significant hyperkalemia ($[K^+]$ > 5.5 mEq/L) can include fine muscle tremors or cardiac arrhythmias.[8,41] When present, hyperkalemia should be addressed by antagonizing the effects of potassium on excitable membranes, redistributing potassium from extracellular fluid to intracellular fluid, and promoting elimination of potassium from the body.[41] Because hyperkalemia raises resting membrane potential, calcium directly and rapidly antagonizes the adverse myocardial effects of hyperkalemia by raising threshold potential, thereby restoring the normal separation between resting membrane potential and threshold potential. In a 50-kg foal with severe hyperkalemia ($[K^+]$ > 6.5 mEq/L), 25 or 50 mL of a 23% calcium borogluconate solution can be added to 500 or 1000 mL of 0.9% NaCl, respectively, and infused over 5 to 10 minutes to rapidly antagonize the effects of hyperkalemia. This should be followed by further administration of potassium-free IV fluids (0.9% NaCl) supplemented with 5% to 10% dextrose. Dextrose administration causes release of insulin that stimulates activation of Na^+/K^+-ATPase pumps to drive potassium back into cells.[41] Dextrose in saline may be all that is needed for treatment of moderate hyperkalemia ($[K^+]$ = 5 to 6.5 mEq/L); however, calcium supplementation would be recommended if a cardiac arrhythmia is detected. Of interest, life-threatening cardiac arrhythmias, including ventricular fibrillation, cardiac arrest, third-degree atrioventricular block, and premature ventricular beats, were reported in nine of 22 foals (41%) with uroabdomen in an early retrospective study.[8] However, arrhythmias have received much less attention in more recent cases series with no mention in one review of 31 cases[20] and description of conduction blocks in only four of 32 foals (12%) in another report.[21] Perhaps this can be attributed to earlier diagnosis of uroabdomen, because ultrasonographic examination has become a routine tool in equine practice. The goal of medical stabilization is to decrease $[K^+]$ to less than 5.5 mEq/L prior to surgical intervention.[8]

DRAINING OF THE ABDOMEN

Drainage of urine from the abdomen also is essential to decrease pressure on the diaphragm to allow adequate ventilation as well as to remove a large amount of potassium from the body. Drainage is most easily accomplished by inserting a large-bore catheter in the ventral aspect of the abdomen (I prefer a 16 French trocar chest tube). However, urine has also been successfully drained via a large-bore tube passed via the urethra and bladder tear into the abdomen in mares.[31] Neonates can be positioned in right lateral recumbency, whereas adult horses are generally drained while standing. In neonates, a stab incision is initially made through the skin and subcutaneous tissue and the chest tube is inserted through the incision, but the tube is used to push the skin about 2 cm to the side before entering the abdomen perpendicularly (not a tunneling procedure). This offsetting of the skin incision and abdominal entry sites limits the risk of omental herniation once the tube is removed. When

a large volume of urine is drained (more than 5 L in a foal or more than 50 L in an adult horse), there is a risk of hemodynamic collapse,[31] and IV fluids (0.9% NaCl) should be concurrently administered during drainage. Foals that have accumulated a large volume of urine in the abdomen may also develop pleural effusion that can complicate ventilation during surgery.[8] Consequently, it is good practice to include an ultrasonographic examination of the thorax at the same time the abdomen is scanned in all cases of uroabdomen. Initiation of broad-spectrum antibiotic therapy to limit the risk of septic peritonitis is also indicated because there is an open conduit from the urethra to the peritoneal cavity. Although accumulation of urine in the abdomen has been incriminated in development of chemical peritonitis,[42] most nonseptic foals and adult horses that undergo successful surgical repair of the bladder have had favorable long-term outcomes without developing abdominal adhesions. Although surgical correction remains the treatment of choice, conservative medical management using an indwelling catheter to keep the bladder small has been a successful treatment in foals with small tears[43] and in an adult horse with uroabdomen in which a distinct bladder tear could not be identified.[44]

Patent Urachus

The urachus is the conduit through which fetal urine passes from the bladder into the allantoic cavity. Normally, the urachus closes at the time of parturition, but incomplete closure is the most common malformation of the equine urinary tract, and a patent urachus occurs more commonly in foals than in other domestic species. Greater than average length or partial torsion of the umbilical cord has been suggested to cause tension on the attachment of the umbilical cord to the body wall. The result can be dilatation of the urachus and subsequent failure to close at birth.[16,19,45] Patent urachus results in a persistently moist umbilicus after birth, from which urine may leak as drips or as a stream. It is important to distinguish a simple or congenital patent urachus, considered a malformation, from sepsis of the urachus, which can also result in urine leakage from the umbilicus within a few hours to days after birth (considered an acquired patent urachus). Local sepsis is often accompanied by more severe illness, including septicemia or other sites of localized infection, particularly of the musculoskeletal system (joints), and may lead to uroabdomen (see "Bladder Rupture," earlier).

Simple patent urachus has been treated with frequent (two to four times daily) chemical cauterization of the urachus with swabs dipped in a concentrated phenol or 7% iodine solution or with silver nitrate applicators. Because the urachus closes spontaneously in many cases, and because these agents desiccate and irritate tissue, predisposing to infection, the rationale for this approach has been questioned.[45] In fact, in a study investigating the effects of various disinfectant solutions on the bacterial flora of the umbilicus of normal foals, the use of a 7% iodine solution was observed to cause rapid desiccation of the umbilical tissue and subsequent development of a patent urachus when the stump fell off a few days later.[46] Consequently, in the absence of apparent infection, no local treatment should be implemented, or it should be limited to a navel dip with 0.5% chlorhexadine solution two to four times a day, but prophylactic antibiotics are commonly administered to affected foals. For acquired patency, likely associated with local infection, broad-spectrum antibiotic therapy is indicated and resolution of the systemic disease may be accompanied by resolution of the umbilical infection and closure of the urachus. Chemical cauterization is contraindicated with local sepsis, as it may increase the risk of urachal rupture and development of uroperitoneum.[47] If no decrease in urine leakage is observed after 5 to 7 days of medical therapy or if ultrasonographic examination reveals abnormalities of multiple structures in the umbilicus,[48] surgical exploration and resection of the urachus and umbilical vessels may be indicated. In a retrospective study of 16 foals treated for sepsis of umbilical cord remnants, six of nine (67%) survived after surgical resection and antibiotic treatment, whereas only three of seven (33%) survived after antibiotic treatment alone.[49] Although this series of 16 foals is often cited in support of surgical intervention, it should be emphasized that this small number of foals were evaluated over a 10-year period (1975 to 1985), during which many aspects of equine neonatal care improved. In a subsequent report of 33 foals with umbilical remnant infections, no difference in survival rate was observed between 23 foals treated with antibiotics in combination with surgical resection or 10 foals treated with antibiotic therapy alone.[48] In the latter report, emphasis was placed on the insensitivity of external examination and palpation of the umbilicus in detecting umbilical remnant infection (normal in 17 foals), in comparison to ultrasonographic examination, and a poorer outcome of cases in which the umbilical vein was involved. As supported by the fact that more than half of the foals in both of these studies were treated surgically, it remains most clinicians' preference to surgically resect infected umbilical remnants, especially with concurrent localized infection of the musculoskeletal system. Although more costly in the short term, surgical treatment allows more-rapid resolution of the problem, decreases the risk that uroabdomen may develop, and usually decreases the overall length of antimicrobial therapy.

Urolithiasis

Bladder stones are the most common type of equine urolith.[50-53] Cystoliths are typically flattened, sphere-shaped stones with a spiculated or smooth surface that cause hematuria, stranguria, pollakiuria, pyuria, or incontinence. In horses there are two basic forms of cystoliths, and both are primarily composed of calcium carbonate crystals.[51,53,54] More than 90% are yellow-green spiculated stones (type 1) that can easily be fragmented (Figure 65-3, *A*). Less commonly, uroliths are gray-white smooth stones (type II) that are more resistant to fragmentation (Figure 65-3, *B*). Type II stones often contain phosphate in addition to calcium carbonate. The crystalline composition of normal equine urine sediment and uroliths is similar: calcium carbonate ($CaCO_3$) in the form of calcite (a hexagonal crystal form of $CaCO_3$) is most common, followed by vaterite (a metastable, hexagonal crystal form in which $CaCO_3$ is partially replaced by magnesium or to a lesser extent by manganese, strontium, and sulfur). Other less common components include aragonite (an orthorhombic crystal form of $CaCO_3$), weddellite (calcium oxalate dihydrate), struvite (magnesium ammonium phosphate hexahydrate), hydroxyapatite, and uric acid.[53-56] Examination of the cut surface of equine cystoliths by scanning electron microscopy reveals a pattern of irregular concentric bands around a core separated by small spherules of crystalline material, suggesting that calculus growth occurs by accretion of crystals already present in normal equine urine on the surface of the growing urolith (Figure 65-4).[54] The gaps between adjacent

spherules result in porosity of the urolith and explain why some stones are relatively easy to fragment.

The role of urinary tract infection (UTI) in the development of cystolithiasis varies with species. Struvite urolithiasis in humans and dogs appears to be almost exclusively a consequence of UTI, whereas the majority of struvite uroliths in cats and sheep are not associated with infection.[57] In 68 horses with urolithiasis, positive urine culture results were found in only 2 of 19 horses in which urine culture was performed; however, culture of material from the center of 30 calculi yielded positive results from 19 stones (63%), and a variety of bacterial species were isolated.[52] Only 1 of 28 calculi examined in this study contained struvite. The significance of finding bacteria in the center of equine calcium carbonate uroliths remains unknown, and culture of an appropriately collected sample of urine is preferred over culture of a calculus.[58]

The classic presenting complaint for cystolithiasis is hematuria after exercise. An affected male horse may also demonstrate stranguria by repeatedly dropping his penis and posturing to urinate but voiding little or no urine. Although cystoliths are less common in mares, stranguria and incontinence are common presenting complaints. Less-common signs include an irritable attitude, recurrent colic, and loss of condition; one burro presented for recurrent rectal prolapse.[59] Diagnosis of a bladder stone is usually made by rectal palpation. It is important to remember that dysuria and pollakiuria frequently result in a

small bladder that may be entirely within the pelvic canal. As a consequence, the bladder and disc-shaped cystolith are often best palpated with the hand inserted only wrist deep into the rectum. If the hand is inserted farther forward to search for the bladder in the expected location over the brim of the pelvis, a cystolith can be missed because it may be lying under the wrist or forearm. If the bladder is distended, it may be necessary to drain it by catheterization to feel a suspected stone. Bladder catheterization also allows collection of samples for urinalysis and quantitative culture. Because bladder distention is not the expected finding with cystic calculi, sabulous urolithiasis or accumulation of urine sediment with bladder paresis should be considered with a distended bladder, especially if incontinence is present or urine is easily expressed during rectal palpation.[60]

Surgical removal is the treatment of choice for equine bladder stones. An early report described excellent long-term results, without recurrence, after cystic calculi were removed by laparocystotomy in four horses.[61] In contrast, in a larger case series, clinical signs of urolithiasis recurred in 12 of 29 horses (41%) with an interval between episodes of 1 to 32 months. Recurrence of cystic calculi was also greater after treatment by perineal urethrotomy as compared to laparocystotomy.[52] Despite success of dietary management (low protein, phosphorous, and magnesium) for medical dissolution of canine[62] and feline[63] uroliths, dietary management is unlikely to replace surgical treatment of cystic urolithiasis in horses. This can be attributed to the fact that dietary management for small animals has been directed at struvite urolithiasis, and these stones are not common in horses. Nevertheless, dietary management should not be overlooked following cystolith removal to decrease the risk of recurrence. At a minimum, legume hays and dietary supplements containing calcium should be avoided. Additional recommendations may include addition of salt to the diet to increase water intake and urine output as well as allowing access to grass at pasture. Unfortunately, acidification of equine urine is not easily accomplished and is not a routine postoperative recommendation.

Figure 65-5. A, An enlarged bladder filled with a sphere of inspissated sabulous urine sediment at postmortem examination. The mass of urine sediment weighed 5 kg. **B,** The sphere of urine sediment could be cut rather easily with a knife. (Reproduced from Schott HC: Urinary incontinence and sabulous urolithiasis: Chicken or egg? Equine Vet Educ 8:17, 2006, with permission.)

Sabulous Urolithiasis

Another form of equine urolithiasis, termed *sabulous urolithiasis,* has been described in a limited number of horses.[60,64] Sabulous (from the Greek word for *sand*) urolithiasis refers to the accumulation of large amounts of crystalloid urine sediment in the ventral aspect of the bladder (Figure 65-5). This condition is a secondary problem, consequent to bladder paralysis or other physical or neurologic disorders interfering with complete bladder emptying. Affected horses usually present for evaluation of urinary incontinence or hind limb weakness and ataxia, and accumulation of urine sediment in a distended bladder can be detected during rectal palpation. These cases can be confused with cystolithiasis, but an important difference is that the bladder is usually enlarged compared to a small bladder, which is typical for a cystolith. Careful rectal palpation, usually after catheterization to empty the bladder of urine, usually allows indentation of the sabulous mass with firm digital pressure, differentiating the concretion from a true cystolith. Most important, horses with sabulous urolithiasis are not surgical candidates. Rather, treatment involves repeated bladder lavage and antimicrobial therapy for concurrent UTI, but the condition carries a poor prognosis unless the primary problem resulting in bladder paralysis can be resolved.[60,64]

Bladder Displacement

Displacement of the urinary bladder is a rare cause of dysuria.[65-73] In mares, two types of bladder displacement can occur: (1) extrusion (or eventration) through a tear in the vagina and (2) true prolapse with eversion of the bladder (Figure 65-6). Urethral obstruction may also occur with vaginal or uterine prolapse. In male horses, scrotal herniation of the bladder has been described, but this type of bladder displacement is extremely rare.[72] Bladder displacements are typically a consequence of repeated abdominal contractions or straining. Therefore, they are most often associated with parturition and, to a lesser extent, with colic. Perineal lacerations, consequent to trauma or foaling, may lead to extrusion, whereas excessive straining without laceration leads to prolapse with eversion. Because the bladder turns inside out with the latter problem, the diagnosis is established by recognizing the appearance of the bladder mucosa and ureteral openings. Eversion occasionally results in obstruction. Umbilical extrusion or eventration of part of the bladder has also been described in a neonatal filly.[73] The problem was suspected to have developed as a consequence of a urachal tear that allowed eversion of the urachus and part of the bladder. Surgical resection of a portion of the bladder corrected the problem.[73]

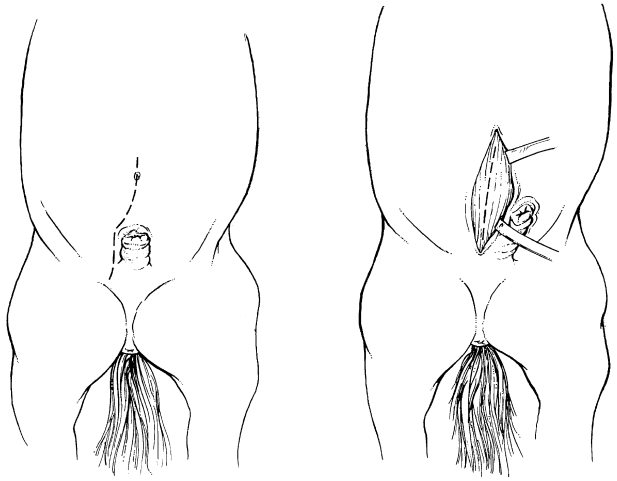

Figure 65-7. A, In male horses or foals, the caudal aspect of the cutaneous midline incision and subcutaneous dissection is directed abaxially to avoid the prepuce and penis. **B,** Then the penis and prepuce are retracted laterally so the body wall can be incised on midline.

Neoplasia

The most common presenting complaint for bladder neoplasia in horses is hematuria; however, straining and urinary obstruction may also occur.[74-79] Unlike dogs, in which transitional cell carcinoma is the most commonly described bladder neoplasm, squamous cell carcinoma has been reported most frequently in horses.[74,77] Other types of bladder neoplasms affecting horses include transitional cell carcinoma, lymphosarcoma, leiomyosarcoma, rhabdomyosarcoma, and fibromatous polyps. Diagnosis of bladder neoplasia can be established by rectal palpation and ultrasonographic imaging of a bladder mass along with endoscopic examination and biopsy. In some instances, masses can also be seen exiting the urethra and vulva in mares. Treatment has included tumor debulking, partial bladder resection, and intravesicular instillation of 5-fluorouracil, but long-term successes have not been reported. The poor prognosis is likely related to extensive bladder involvement by the time clinical signs are initially noted.

Fibroepithelial polyps are another tissue mass that can grow in the bladder or lower urinary tract of the horse. A large polyp mass that developed in the bladder of a pony gelding acted as a ball valve and caused urethral obstruction, bladder distention, and intermittent colic signs.[80] I also have seen vaginal polyps in a neonatal mule that caused confusion with bladder prolapse. Careful examination failed to reveal ureteral openings or urine flow from the abnormal tissue, and passage of an endoscope beyond the polyps revealed a normal urethra and bladder. The polyps were excised and the filly grew without further problems.

SURGICAL PROCEDURES

J. Brett Woodie

Cystorrhaphy

Cystorrhaphy is indicated for disruption of the bladder.[12,19,81-84] The anesthetized patient is positioned in dorsal recumbency. An appropriate-size urinary catheter should be passed through the urethra and secured in the bladder to ensure outflow of urine and to permit intraoperative lavage of the base of the bladder. The prepuce in males is cleansed and closed with sutures or towel clamps to reduce the possibility of incisional contamination. The penis and prepuce can be directed caudad in between the hindlegs so that it is not in the operative field. The abdomen is aseptically prepared for a ventral midline incision. The external umbilicus, if present, should be oversewn with a continuous inverting suture pattern before aseptic preparation of the abdomen.

In the adult female patient, the surgeon should make a 15- to 18-cm (6- to 7-inch) midline incision that extends caudad from a point 2 to 5 cm cranial to the umbilicus. In foals, the incision should be directed abaxially to create a fusiform incision around the external umbilicus for removal. In the male patient, the cranial aspect of the incision is identical; however, the skin and subcutaneous layers of the caudal incision should be directed 2 to 4 cm paramedian to the prepuce (Figure 65-7). The prepuce can be mobilized and retracted to expose the posterior midline for deep incision. If the penis and prepuce has been directed caudad, it may not be necessary to direct the incision lateral to the prepuce.

After the peritoneal cavity has been entered, peritoneal fluid should be cultured and suctioned. The bladder is exposed by maintaining traction on the urachus, if present (Figure 65-8). Balfour or Finochietto self-retaining retractors may be used to facilitate the abdominal exploration. The bladder and urachus should be inspected to identify the site of rupture. The site of rupture in the foal may be in the urachus as well as the dorsal or ventral aspect of the bladder (Figure 65-9).[12] Urachal rupture is often a sequela of urachal infection, especially in septicemic foals (Figure 65-10).[12,84] Tears in the ventral aspect of the bladder tend to run longitudinally toward the neck of the bladder. Accessing the full extent of a ventral defect is often not possible.[84]

If the origin of the uroperitoneum is not evident, the bladder may be distended by retrograde introduction of a sterile solution of fluorescein or methylene blue through the urethral

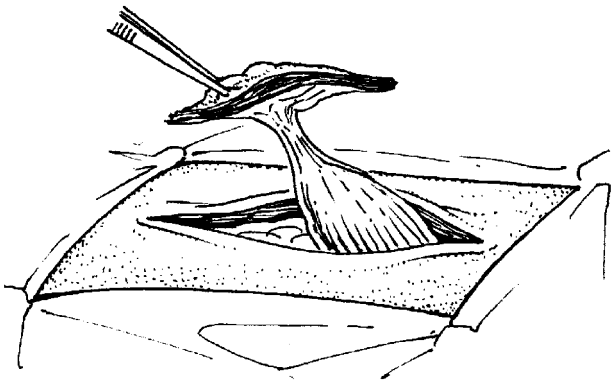

Figure 65-8. After completing the midline incision and mobilizing the umbilicus and urachal remnant from the abdominal wall, the bladder is exposed by careful traction on the umbilicus. When the bladder is exposed, the tissues are retracted caudad.

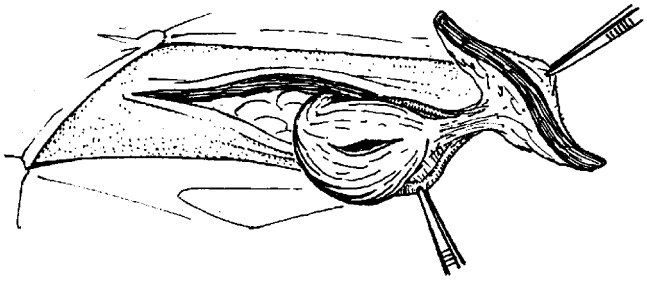

Figure 65-9. The bladder is retroflexed to examine a tear on the dorsocranial border.

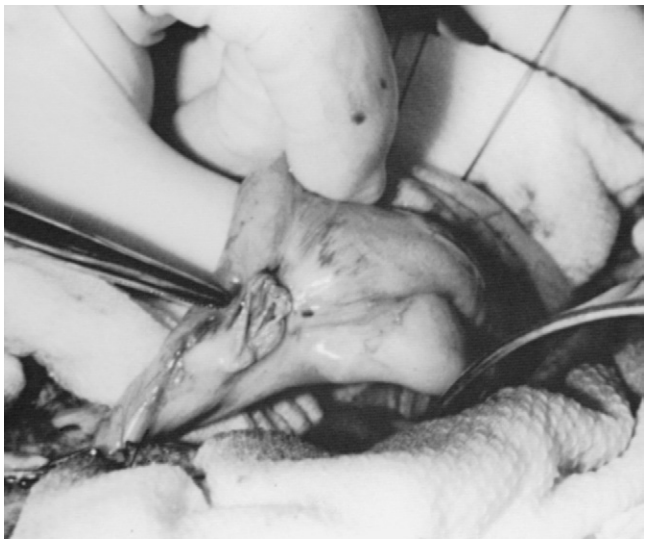

Figure 65-10. A rupture of the urachus (located at the tip of the hemostatic forceps) is readily apparent on inspection of the cranial bladder.

catheter.[12] This method identifies thin areas of the bladder or attenuated areas in the bladder wall that may be leaking, typically on the dorsocranial surface of the bladder.

When the tear is identified, the wound margins are excised (Figure 65-11). Culture and histopathologic evaluation of the

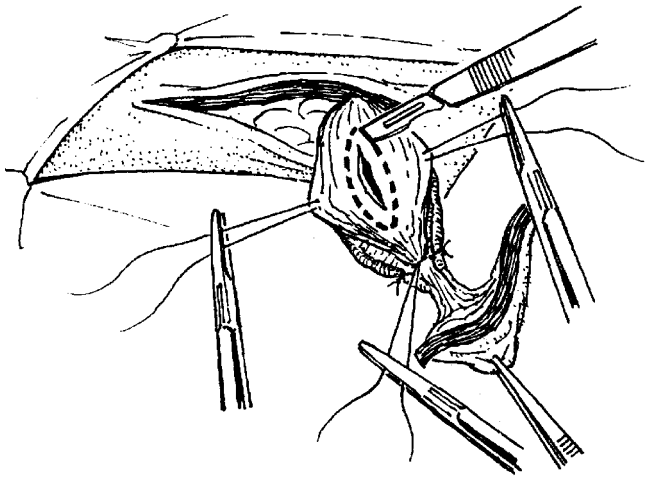

Figure 65-11. Tissues surrounding a tear in the bladder should be excised before primary repair.

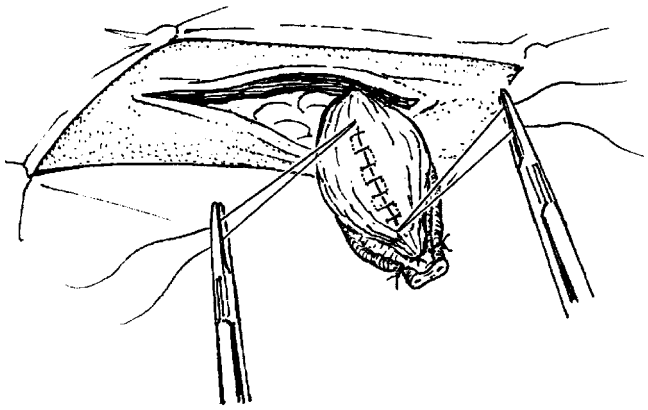

Figure 65-12. A two-layer inverting continuous closure is appropriate for repair of a bladder rupture.

débrided margins of the tear in septic foals should be considered.[12] The use of stay sutures to support the bladder during primary repair is recommended. Surgical closure of the tear should be accomplished in two layers: an interrupted pattern in the first layer, followed by a continuous inverting pattern (Figure 65-12).[83] A double-layer inverting closure is appropriate as well. Small-size (2-0, 3-0) synthetic absorbable suture material on a taper-point atraumatic needle should be used. Care should be taken to avoid suture penetration of the vesicular mucosa, because sutures that penetrate the bladder mucosa perpetuate the formation of cystic calculi in the presence of alkaline urine.[85]

After repair, the bladder should be carefully distended with sterile saline to evaluate potential leakage along the suture line. In a foal in which the urachus is present, the urachus should be resected, cultured, and removed with the umbilicus after primary repair of the tear. Before abdominal closure, the peritoneal cavity is lavaged with warm sterile saline solution. An indwelling abdominal drain may be placed if septic processes are present or anticipated. Despite the irritative nature of urine, clinically significant peritonitis is rare unless concurrent septic disease processes such as omphalophlebitis or neonatal septicemia are present.[12,84] The midline incision is closed with size 1 or 2 synthetic absorbable sutures placed in simple-continuous

fashion. The subcutaneous tissues and skin are closed routinely.

In the foal, it is often advisable to perform a cystoplasty as a means to resolve a tear in the urinary bladder. The viability of the tissue adjacent to the defect is often questionable and does not hold sutures very well, making débridement and closure risky for subsuquent leakage. A cystoplasty procedure would be indicated provided it is possible to resect the apex of the bladder to include the defect.

Urinary bladder repair in the standing mare can also be accomplished by prolapsing the bladder either through a vaginal incision or urethrotomy and sphincterotomy.[30,31] Clinical signs of cystorrhexis are consistent with uroperitoneum, and diagnostic tests should be performed to confirm the presence of a rent. Horses should be stabilized medically and the uroperitoneum should be sterilely drained. Caudal epidural anesthesia is used to desensitize the surgical site. For the vaginal approach, a rigid urinary catheter is placed to identify the location of the urethra and bladder under the vaginal mucosa. A 2-cm incision is made 5 to 10 cm caudal to the cervix. Blunt dissection increases the size of the incision, which facilitates the delivery of the bladder into the vaginal vault. Alternatively, a linear urethrotomy and sphincterotomy can be preformed. A 5-cm incision is made in the urethral sphincter on the dorsal midline. The surgeon places a hand in the bladder and everts the bladder out of the vulva. Care is taken to identify the ureter openings. Rents are closed with a single- or double-layer closure. The bladder is replaced and the vaginal incision or sphincterotomy is closed in a simple-continuous pattern with absorbable 2-0 or 0 suture material.

Cystoplasty

Cystoplasty is the technique of choice for patent or persistent urachus.[12,19,81-84] It can also be used for treatment of bladder rupture. The foal should be anesthetized and positioned in dorsal recumbency. A urinary catheter is placed, and the ventral abdomen is prepared and draped as described earlier (see "Cystorrhaphy," earlier). The external umbilicus should be oversewn with a continuous-inverting suture pattern before aseptic preparation of the abdomen.

A fusiform incision is made around the external umbilicus. This incision can be extended craniad or caudad as needed. The incision is continued as described earlier.

The umbilicus and urachus are dissected free from the body wall. The umbilical vein is double ligated and resected as far craniad as necessary to remove any portion of abnormal umbilical vein. Occasionally, the midline incision must be extended craniad to permit adequate resection of the umbilical vein. The affected urachus may be thickened and distorted. Adhesions may exist between the urachus or its associated vascular structures and the surrounding viscera.[12,84] Care should be taken to identify and transect adhesions that involve the urachus before manipulating the bladder.

Exposure of the bladder is achieved by traction on the urachus. Traction should be applied with caution because of the friable nature of the tissue and the possibility of rupture (Figure 65-13). Exposure of the bladder can be improved by extending the ventral midline incision caudad and/or transecting the ventral ligament of the bladder. Sterile moistened laparotomy sponges can be used to pack off intestines and assist in positioning the bladder. Stay sutures are placed at the ventrolateral

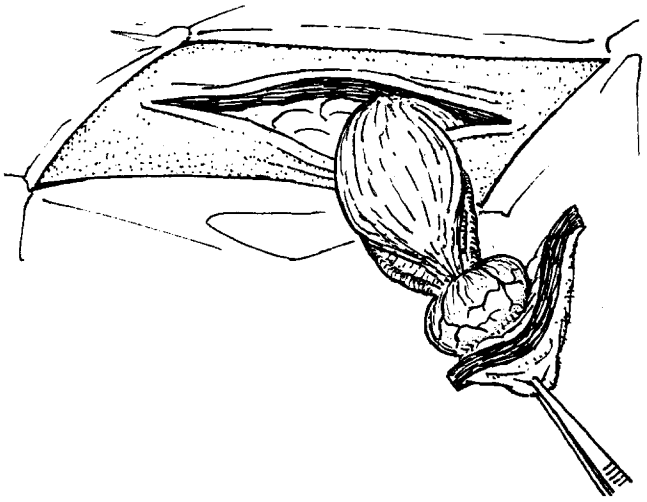

Figure 65-13. After mobilizing and retracting of an umbilical or urachal abscess, the abdomen should be explored for adhesions or additional foci of abscessation.

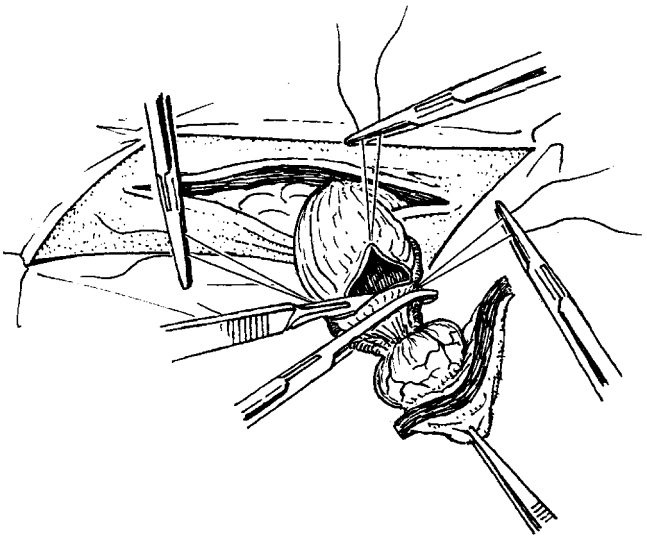

Figure 65-14. Before urachal-umbilical resection, a clamp is applied to prevent spilling urachal contents into the peritoneal cavity. Here, the bladder has been stabilized by stay sutures transfixed as ligatures around the umbilical arteries. The urachus and umbilical tissues are removed by sharp dissection. The bladder is closed by the two-layer inverting continuous suture pattern.

margins of the bladder for additional support and control of the bladder after resection of the urachus. The umbilical arteries should be double ligated with a transfixing suture at the level of urachal resection.

An occluding forceps is used to isolate the urachus and apex of the bladder (Figure 65-14). A transverse incision is made across the apex of the bladder to remove the urachus and vesicular apex (see Figure 65-14). The urachus is removed and submitted for culture and sensitivity testing. Traction is applied to the previously positioned stay sutures to elevate the apex of the bladder and to prevent spillage of urine. Suction is used to remove the residual urine or purulent material from the bladder. Closure is accomplished using a two-layer inverting suture pattern with 2-0 or 3-0 synthetic absorbable suture material,

taking care not to penetrate the lumen. Alternatively, a simple-continuous closure of the first layer may be followed by an inverting suture pattern.[84] The abdomen is lavaged with warm sterile saline before closure. Unless there has been spillage of exudate into the abdominal cavity, an abdominal drain is not necessary. Broad-spectrum antimicrobial drugs are administered routinely for 3 to 5 days because of the potential for abdominal contamination from urachal bacterial contaminants.

Cystotomy

Cystotomy is the surgical treatment of choice for cystic calculi.[50,51,81-83,86] Fasting the horse for 24 to 36 hours reduces the volume of ingesta in the gastrointestinal tract, which can be helpful for this procedure. Positioning of the harse and performing the incision is as described earlier. The large superficial caudal epigastric and external pudendal vessels should be avoided when dissecting deep to the prepuce to expose the caudal midline. In mares, the incision is made on the midline from the umbilicus caudad to the prepubic tendon.

The bladder is identified by palpation in the pelvic canal. Sustained gentle traction is required to exteriorize the bladder (Figure 65-15).[50,51,87] Another method that can be used to facilitate exteriorization of the bladder is allowing the bladder to distend with urine by clamping the urinary catheter while the horse is being prepared for surgery and during the approach to the abdomen. When the surgeon is ready to exteriorize the bladder, the clamp is removed and the bladder is decompressed. The bladder has been stretched by being distended with urine and will be easier to exteriorize. When the bladder is exposed, moistened laparotomy sponges are used to pack off the bowel and elevate the bladder in the surgical field. Large-diameter stay sutures can be positioned at the ventrolateral aspects of the bladder to facilitate control of the cystotomy incision and to reduce urine spillage. A transverse incision is made across the ventral bladder to expose the urolith. Frequently, the urolith is closely adherent to the bladder mucosa, particularly in the case of a type I urolith. The mucosal layer of the bladder must be peeled back from the urolith to permit removal of the calculus (Figure 65-16). The bladder can be lavaged in an effort to remove small fragments of calcular material and blood clots. Irrigation of the bladder by retrograde introduction of sterile saline through the urinary catheter flushes small fragments of the urolith from the neck of the bladder toward the incision, where they can be evacuated by suction.

The cystotomy is sutured with a two-layer closure of synthetic absorbable suture material. Continuous inverting suture patterns such as the Cushing and Lembert patterns are preferred. The sutures should not penetrate the mucosa of the bladder. After closure of the cystotomy, the bladder may be carefully distended with sterile saline to evaluate the closure for leakage. The abdomen is lavaged with sterile balanced saline solution, which is subsequently suctioned off. The midline incision is closed with size 2 or 3 synthetic absorbable suture material in continuous or interrupted fashion. If the caudal limit of the incision was made in a paramedian location, the fascial closure is completed in two layers by suturing the internal and external layers of the rectus abdominis sheath separately. Of the two layers, the external rectus sheath is the more critical to the security of the abdominal closure.[83,84,88,89] The subcutaneous tissues and skin are closed in routine fashion.

Parainguinal Approach

In an adult horse, access to the bladder can be also achieved through a parainguinal approach. This approach has been described in the male horse but can be used in the female patient as well.[90] This approach eliminates the need to reflect the prepuce and reduces the chances of encountering large vessels prior to gaining access to the urinary bladder. The horse is anesthetized and positioned in dorsal recumbency. A urinary catheter should be placed and secured. The inguinal region is clipped and prepared for aseptic surgery. A 12- to 14-cm (5- to 6-inch) skin incision is made parallel and 2-cm axial to the external inguinal ring (see Chapter 34). A combination of sharp and blunt dissection is used to separate the subcutaneous tissues and fat to expose the aponeurosis of the external abdominal oblique muscle. The aponeurosis is sharply incised, parallel to the skin incision for 12 to 14 cm (5 to 6 inches). Retraction is used to gain access to the internal abdominal oblique muscle, which is separated along its fibers. The peritoneum is bluntly entered with the surgeon's finger. The bladder is identified and

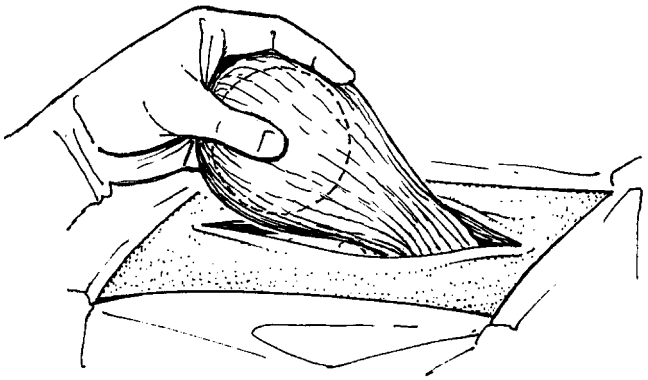

Figure 65-15. The bladder and urolith are delivered into the surgical field by gentle, sustained traction.

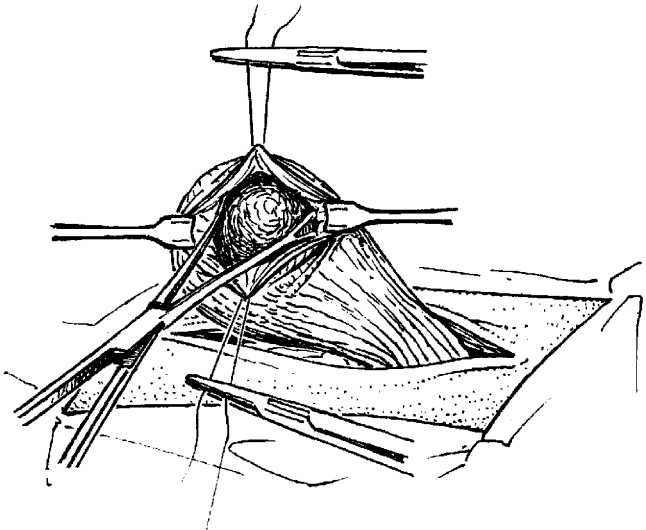

Figure 65-16. The urolith can be grasped with sponge forceps for expedient removal.

exteriorized with steady traction. After the bladder is exteriorized, a moist laparotomy sponge can be wrapped and twisted around the bladder proximal to the urolith. This aids in maintaining exteriorization of the bladder to complete the cystotomy. Following removal of the urolith the bladder is closed in a double layer. Closure of the abdomen is routine, with attention paid to the aponeurosis of the external abdominal oblique muscle. An interrupted cruciate, near-far-far-near, simple-continuous, or a simple-interrupted pattern using No. 2 synthetic absorbable suture material is appropriate for closure.

Laparoscopic Techniques

Laparoscopic techniques have been described for repair of cystorrhexis, persistent urachus, and umbilical infections in the foal.[91,92] Preoperative preparation of the patient including appropriate diagnostic examinations and perioperative therapeutics does not differ from those used for foals undergoing open surgical approaches. The foal is anesthetized and positioned in dorsal recumbency with the pelvic limbs elevated. Intermittent positive-pressure ventilation should be available if needed. The ventral abdomen is prepared for aseptic surgery.

Because the foal's body wall is thin, it is recommended that insufflation be done with a teat cannula or veress needle and that lower (1 to 2 L/minute) insufflation rates be used. The abdominal cavity should be insufflated with CO_2 to a pressure of 10 mm Hg.[92] A 1.5-cm incision is made 5 cm lateral to the ventral midline and 10 to 15 cm cranial to the umbilicus for placement of the laparoscopic cannula. A 30-degree laparoscope is used to explore the abdomen. Additional portals are made 8 to 10 cm lateral and 5 cm cranial to the umbilicus. It is important to avoid damage to the epigastric vessels so that hemorrhage does not obscure visibility.[92] Additional information on laparoscopy can be found in Chapter 13.

For cystorrhexis, urine accumulation needs to be evacuated prior to insufflation. When the laparoscope is placed, the entire bladder should be inspected. Sectioning of the ventral ligament of the bladder using laparoscopic scissors aids in inspecting the bladder. Two working portals are required to resect the edges of the rent and repair the bladder with absorbable sutures using intracorporeal suturing techniques. It is prudent to carefully test the bladder for leaks before deflating the abdomen.

For resection of umbilical remnants, or umbilical remnant infection, the umbilical vein and arteries are isolated with endoscopic scissors and dissected free to facilitate their ligation. A large ligation clip or loop can be used. Several clips may be necessary to ensure proper ligation, especially when structures appear large or pathologically altered. When the umbilical vein and arteries have been transected, a fusiform incision is made around the umbilicus through the body wall under laparoscopic observation. The end of the bladder is exteriorized and resected. A two-layer closure in the bladder is recommended.

Closure of the body wall is routine. Closure of the portals is performed with No. 1 absorbable material in a cruciate pattern in the external fascia of the rectus abdominis or linea alba. The subcutaneous tissues are closed in a continuous pattern. The skin can be closed using a monofilament absorbable material in a continuous pattern, or intradermal sutures can complete the procedure. Overall, good visualization with minimal intervention is obtained with laparoscopic techniques. The use of nonabsorbable linear staples for repair of a tear in the bladder is discouraged, because the staples may serve as nidus for urolith formation.[91]

Laparoscopic techniques for removal of cystic calculi in the adult male horse have also been described.[93] The horse is anesthetized, positioned, and prepared as described earlier. The bladder is lavaged and drained until clear saline irrigation solution is obtained.

A standard umbilical portal is made after insufflation. Five instrument portals are made to complete the procedure. The instrument portals are in a radiant line centered on the sheath. A laparoscopic electrocautery tip is inserted into the cranial right portal and used to make a cystotomy. A suction lavage cannula will be used when the cystotomy is made. A retrieval bag is also placed in the abdomen and positioned below the bladder. The cystotomy must be just long enough to remove the calculus. A retractable metal loop forceps aids in removing the urolith and placing it into the retrieval bag. Suction is used to remove residual debris. The bladder should be closed in two layers using an intracorporal suturing techinque. A double-layer closure is recommended. The bladder is carefully tested for leaks before deflating the abdomen. The umbilical portal is enlarged to retrieve the calculus within the retrieval bag. The linea alba and portal incisions are closed routinely.

Complications of this technique include intraoperative hemorrhage from the instrument portals and obstructed visualization from falciform fat. It should be noted that practice is required to become proficient in using the auto-suturing devices. With proper preparation, cystic calculi can be removed safety and cleanly in the adult male horse.

Lithotripsy

Lithotripsy is a means of fragmenting a urinary calculus into smaller pieces so that the fragments can be removed through a smaller lumen or incision. Lithotripsy can be used to remove cystic calculi through the urethra in mares or through a perineal urethrotomy in male horses.[50] Manual crushing of the calculus has been associated with a high rate of recurrence of urolithiasis.[52] This is most likely because of incomplete fragment removal. Trauma to the urethra is also a potential complication.[52] Based on the high rate of recurrence and potential for urethral injury, other means of fragmenting the calculus should be used if possible.

Laser lithotripsy is an alternative to manually fragmenting a calculus. A pulsed dye laser with a wavelength of 504 nm and a holmium:YAG laser with a wavelength of 2100 nm have been used to fragment uroliths in equine patients.[94,95] The pulsed dye laser causes disruption of the calculus by generating an acoustic wave that is greater than the tensile strength of the crystals in the urolith.[94] The holmium:YAG laser uses photothermal and photoacoustic effects to fragment the urolith.[95] This procedure is performed by using a flexible endoscope that is passed through a perineal urethrotomy to access the bladder in the male patient or through the urethra in the female. Laser energy is applied to the calculus thorough a quartz fiber that has been passed through the biopsy channel of the endoscope. Laser lithotripsy is not a common modality used in cases of equine urolithiasis because of the limited availability of the pulsed dye laser and the high cost associated with renting the appropriate laser equipment. Other drawbacks include long surgery times and the possibility that the laser will not be able to fragment the urolith.[94-96]

Aftercare

Antibiotics are commonly administered after surgery of the bladder. In cases of cystorrhexis or persistent urachus, sepsis represents a risk, so antibiotics are routinely administered to reduce the risk of septic peritonitis and may be continued for several days or weeks postoperatively.[12,49,84] In adult patients with urolithiasis, the risk of urine spillage during removal of cystic calculi is considerable.[51,88] Antibiotics are continued for only 48 to 72 hours unless clinical signs of infection develop.

Postoperative abdominal drainage is indicated if surgical findings suggest the presence of peritonitis or if gross soilage of the peritoneum from an urachal abscess has occurred. Generally, abdominal drainage is not required after cystorrhaphy or cystoplasty. Unless significant spillage with fragments of uroliths has occurred, the need for peritoneal drainage in urolithiasis patients is not necessary. Patients with abdominal drains should remain on prophylactic antibiotic therapy.

Typically, patients are administered low doses of nonsteroidal anti-inflammatory drugs to control postoperative and incisional discomfort. Patients recovering from cystorrhaphy and cystoplasty often require intravenous fluids to correct dehydration and acid–base and electrolyte imbalances. All patients should be routinely monitored for urine output after surgery. Foals that are at risk for sepsis or that are subjected to intensive medical care after surgery are candidates for development of gastric ulceration. Appropriate anti-ulcer and gastroprotectant medications should be given in these cases.

Complications

Clinically significant complications of bladder surgery are rare. The most acute and striking complication is the development of severe ventricular arrhythmias in the anesthetized foal with uroperitoneum.[8,19] Postoperative myositis resulting in death has also been documented.[97] Correction of electrolyte and acid-base status before surgery minimizes the risk of developing these problems.

In foals, contamination of the peritoneal cavity with urine is common and may result in the development of chemical peritonitis.[12] Although most foals with cystorrhexis have a chronic history of uroperitoneum and presumably some degree of chemical peritonitis, the incidence of septic peritonitis is low unless concurrent septic omphalophlebitis or other septic processes are present simultaneously.[12,83,84] In one retrospective study of celiotomy for the treatment of uroperitoneum, several foals had positive culture results for *Mucor* and *Candida* species.[12] All foals with uroperitoneum and concurrent septic disease should be monitored closely for clinical evidence of septicemia or septic arthritis and physitis after surgery.

Adhesions have also been reported as a consequence of abdominal surgery in foals for correction of uroperitoneum.[12] The development of septic peritonitis can result in an increased incidence of adhesion formation, particularly in the caudal abdomen near the bladder.[84]

Contamination of the midline incision with urine or bacteria may lead to the formation of incisional edema and infection. In adult male horses operated on for cystic calculi, preputial edema occurs occasionally,[51] which is generally responsive to anti-inflammatory agents and local wound therapy. Surgical failures of the cystotomy incision after cystoplasty and exploratory cystotomy have been reported, but this complication is rare.[39,98]

CHAPTER
66 Urethra

Harold C. Schott II and J. Brett Woodie

ANATOMY AND PHYSIOLOGY

Harold C. Schott II

Male

The urethra is the conduit for urine to exit the body and is about 75 to 90 cm (30 to 35 inches) long in a male horse. The intrapelvic (ampullar) portion of the urethra, 10 to 12 cm (4 to 5 inches) long, widens in an elliptical pattern to a diameter of 5 cm (2 inches) across and 2 to 3 cm (1 to 1½ inches) from dorsal to ventral.[1] A rounded dorsal prominence, the colliculus seminalis, is located a few centimeters (about an inch) caudal to the urethral orifice. It is the site of the paired ejaculatory ducts, which are the common openings of the ductus deferens and ducts of the seminal vesicles. The openings of the prostatic ducts are arranged as two groups of small papillae on either side of the colliculus seminalis. The bulbourethral glands open in paired dorsal rows of 6 to 8 ducts each, 2 to 3 cm (1 to 1½ inches) farther caudad from the colliculus seminalis (Figure 66-1).[2] The smaller openings of the ducts of the lateral urethral glands open at the same level on the lateral aspects of the urethra. The end of the urethra terminates at the glans penis, where a urethral process protrudes 1 to 2 cm (0.3 to 0.6 inches) under the tip of the glans. Above the urethral process is the urethral sinus (sometimes referred to as the *diverticulum of the glans*), a bilobed, recessed area that can accommodate the finger tip and is the site where the "bean" of smegma accumulates.[1]

The penis encloses the extrapelvic portion of the urethra and is composed of two vascular, erectile bodies: a larger corpus cavernosum penis (CCP) and smaller corpus spongiosum penis (CSP).[1] The CCP forms most of the dorsal aspect of the penis and the CSP forms a vascular tube surrounding the urethra, largely along the ventral aspect of the penis. The CSP is contiguous at its cranial end with the glans penis and forms a slight enlargement, termed the *bulb,* at the root of the penis at the level of the ischial arch. Except at its origin and end, the urethra is surrounded by a continuous layer of striated muscle outside the erectile tissue. The portion of this muscle covering the intrapelvic urethra (as well as the bulbourethral glands) is the urethralis muscle, and its forcible contraction plays an important role in ejaculation. The bulbospongiosus muscle is a continuation of the urethralis muscle around the CSP surrounding the urethra and extends from the ischial arch to the glans penis. The muscle is thickest at the root of the penis (around the bulb of the CSP) and thins out as it extends to the end of the penis. It acts to empty the penis of blood after ejaculation or after the penis is dropped for urination.[1] Several forceful contractions of the bulbospongiosus muscle help expel residual urine from the urethra after urination. Additional information on this subject can be found in Chapter 60.

Mare

The urethra is about 5 cm (2 inches) long in the mare and its lumen easily accommodates a finger. However, it can be dilated to several times this size if needed for access to the bladder. The external opening lies at the anterior end of the vestibule. The urethral muscle surrounds the urethra throughout its length and is contiguous with the constrictor vestibule muscle.

DISORDERS REQUIRING SURGERY

Harold C. Schott II

Disorders of the equine urinary tract that may require surgery of the urethra include congenital anomalies (rectourethral and rectovaginal fistulas) and acquired disorders. The latter include urolithiasis, soft tissue obstructions (neoplasms or strictures), hematomas, and lacerations. Injuries to the distal penis and urethra are the most common traumatic conditions, especially with breeding accidents in stallions. Geldings and stallions with hematuria and hemospermia as a result of urethral rents are also candidates for surgery, because affected individuals may respond favorably to opening the CSP via a perineal urethrotomy approach.

Rectourethral and Rectovaginal Fistulas

During embryonic development, failure of the urorectal fold to completely separate the primitive hindgut from the urogenital sinus results in a rectourethral fistula in a colt or a rectovaginal fistula or a persistent cloaca in a filly.[3] These anomalies are rare in horses and, when present, are usually associated with atresia

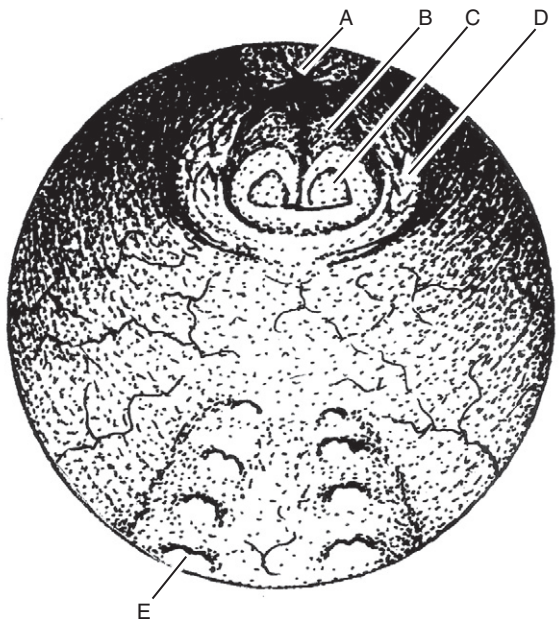

Figure 66-1. Endoscopic illustration of the intrapelvic portion of the urethra of the male horse showing the dorsal surface at the bottom: **A,** Opening to bladder (difficult to see endoscopically). **B,** Colliculus seminalis. **C,** Ejaculatory duct (common opening of the ductus deferens and seminal vessicle duct). **D,** Openings of prostate gland ducts. **E,** Openings of bulbourethral gland ducts.

ani and other anomalies, including agenesis of the coccygeal vertebrae and tail, scoliosis, adherence of the tail to the anal sphincter area, angular limb deformities, and microphthalmia.[4-7] Affected foals are usually presented for atresia ani, although signs of colic and straining may also be observed. Passage of fecal material from the vulva or penis is the sign supporting a fistula. In fillies, rectovaginal fistulas may be detected by digital palpation of the dorsal vestibule and vagina, but in colts a definitive diagnosis usually requires contrast radiographic procedures such as a barium enema or a retrograde urethrogram (Figure 66-2). Surgical correction of atresia ani and fistulas have been performed successfully in several foals, but multiple surgical procedures may be required. Because ascending urinary tract infection (UTI) is common, a sample of urine collected via bladder catheterization (preferably during surgery) should be submitted for bacterial culture. In humans, there is evidence that these anomalies are hereditary; consequently, breeding affected horses is not recommended after surgical correction of the anomalies.

A rectourethral fistula resulting in passage of urine from the anus has also been described in a 3-year-old Thoroughbred gelding.[8] The fistula in this gelding, which was successfully repaired, was thought to be acquired secondary to trauma or straining because no other developmental problems were detected and the edges of the defect were irregular and inflamed when examined with a speculum inserted into the rectum.[8]

Urolithiasis

Surgery may need to be performed on the urethra to divert urine flow in horses with urethroliths that are causing urethral obstruction or to access the bladder for cystolith removal via a perineal urethrotomy (PU). Obstructive urethrolithiasis leads to bladder distention, frequent posturing to urinate, and renal colic.[9-12] It is essentially a male horse problem because mares are generally able to void small stones through the urethra. A persistently dropped penis that may drip urine is also commonly found with obstructive urethrolithiasis. Obstruction can be confirmed by detection of a markedly distended urethra below the anus (see Figure 63-1) and a large, turgid bladder on rectal palpation. Careful palpation of the urethra at the level of the ischial arch may reveal a firm obstructing urolith, although some stones travel more distally into the penis. In horses that have been obstructed for more than 1 to 2 days, bladder leakage or rupture may occur, leading to abdominal distention from uroabdomen. Affected horses typically have a decreased appetite, a large volume of echolucent free peritoneal fluid on transabdominal ultrasonography, and serum electrolyte concentrations typical for uroabdomen (hyponatremia, hypochloremia, and mild to moderate hyperkalemia). Peritoneal fluid creatinine concentration twofold or greater than serum creatinine concentration confirms uroperitoneum.

Figure 66-2. A positive contrast urethrogram in a 3-day-old burro that presented with atresia ani and intermittent passage of fecal material from the urethra. A catheter was passed via the urethra and contrast agent was injected, resulting in accumulation of a large amount of contrast agent in the rectum and a lesser amount in the intrapelvic portion of the urethra. A small amount of contrast agent can be seen in the urethrorectal fistula *(arrow)*. (From Reed WM, Bayly WM, Sellon DC (eds): Equine Internal Medicine. 3rd Ed. Saunders, St. Louis, 2010.)

Obstructive urethrolithiasis is an emergency condition (to prevent bladder rupture) that is generally treated by performing a PU into the distended urethra.[9-12] If the offending urolith is at or just beyond the ischial arch, it can often be removed at the time of surgery; however, if it has traveled more distally, removal is more challenging. Urethral distention with hydropulsion through a catheter passed either from the PU site distad or retrograde from the urethral process to the stone (depending on stone location) may be successful in moving the urolith to one of these openings for removal. Urethroliths are composed primarily of calcium carbonate crystals and are characteristically spiculated, allowing them to become embedded in the surrounding urethral mucosa. As a result, the stone may be firmly lodged at the site of obstruction so that hydropulsion and gentle prodding with a catheter tip are unsuccessful in dislodging the stone. In this situation, an alternative is to snare the stone using a device passed through the biopsy channel of an endoscope followed by gentle traction and removal of the stone. When stones cannot be extracted by these methods, endoscopically guided electrohydraulic or laser lithotripsy is another option that can be pursued to fragment the stone.[13,14] If lithotripsy is unavailable, a linear incision through the ventral aspect of the penis and urethra overlying the stone may ultimately need to be performed to remove the stone. Depending on the extent of mucosal and submucosal damage, this incision may be closed or left to heal by second intention.

Radial extracorporeal shock wave therapy (RSWT), using a device commonly used for therapy of musculoskeletal problems (EMS Dolorcast), was reported to successfully fragment obstructive urethroliths in three equids. Using the large-headed probe placed directly on the urethra over the calculus without contact gel, the pressure was set at 2.5 bar, 7 Hz, and 2500 pulses were administered over a 5-minute period. Initially, sandlike sludge was passed out the end of the urethra followed by fragments of the uroliths.[15] Although this procedure was performed on two animals postmortem and bladder rupture was not prevented in the single live horse treated, this novel approach warrants consideration if it can be performed in a timely manner shortly after the patient is admitted and the stone is found.

When the stone has been removed, a catheter should be placed for 5 to 7 days from the PU site exiting the end of the penis to limit potential development of a urethral stricture. In my experience, second-intention healing of PU incisions typically results in dilation of the urethra above the ischial arch, and urethral strictures are more likely a consequence of the damage and associated inflammation at the site where the urethrolith was lodged (Figure 66-3). Broad-spectrum antibiotics should be administered as long as the catheter remains in place to limit the risk of ascending urinary tract infection, and

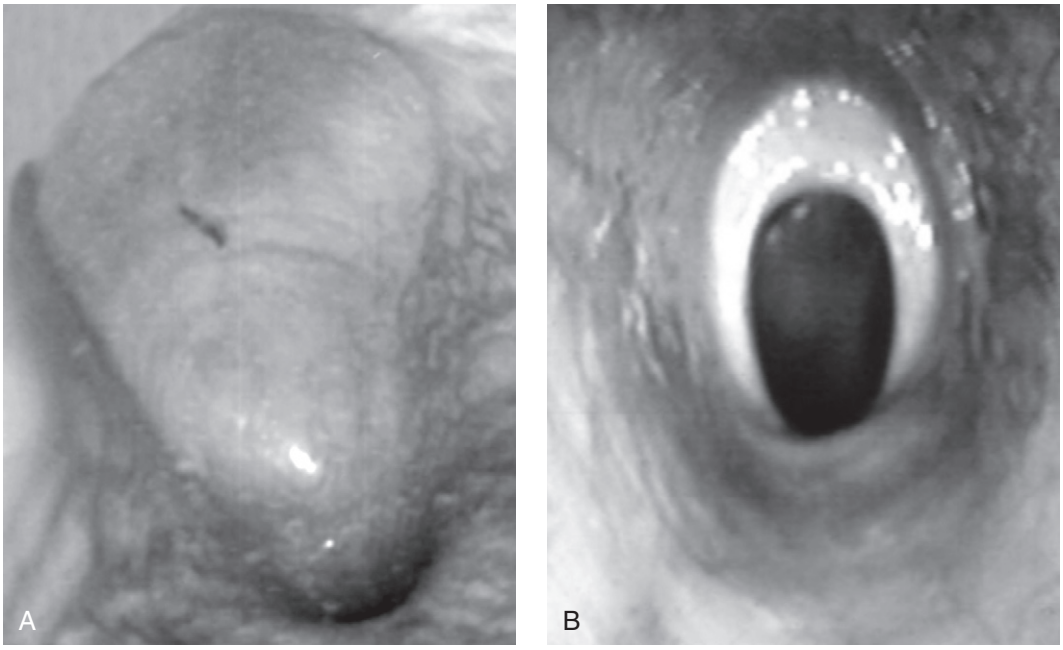

Figure 66-3. Endoscopic images of the urethra revealing distention at the level of the ischial arch **(A)** and a urethral stricture at the site of a previous obstructing urethrolith **(B).** Both images were recorded approximately 1 year following the initial examination.

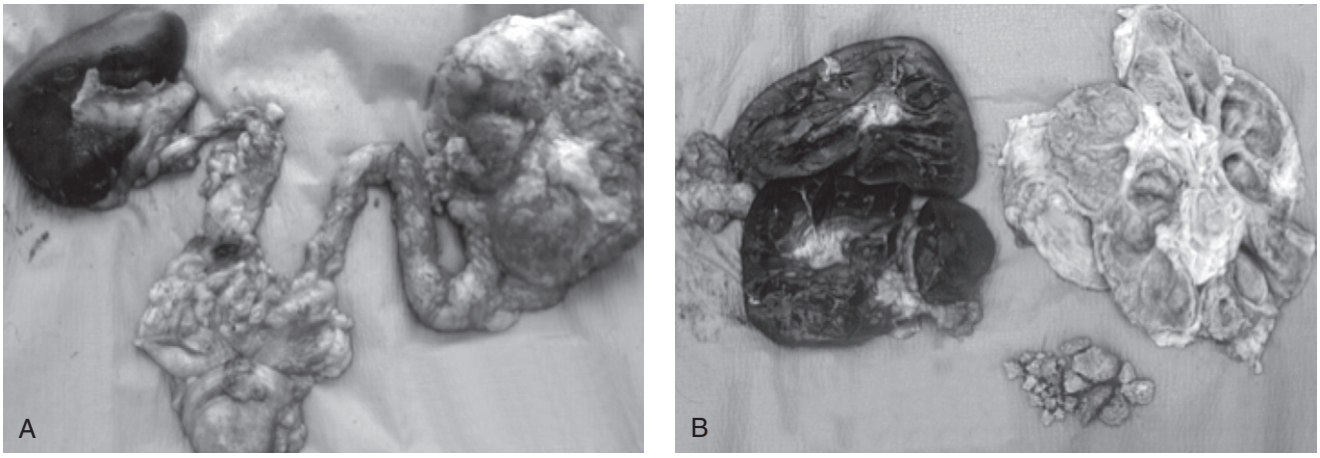

Figure 66-4. Gross pathology photographs of the urinary tract from a 17-year-old Arabian gelding that suffered four bouts of obstructive urethrolithiasis over a 10-year period. The right kidney and ureter were enlarged **(A)** and the kidney parenchyma had been replaced by an abscess containing multiple nephroliths **(B).**

anti-inflammatory drugs are indicated for 3 to 5 days. To limit risk of recurrence, avoidance of forage high in calcium (i.e., alfalfa hay) is typically recommended, although it is important to recognize that all forage provides more calcium than a horse's daily need. Therefore, even when fed grass hay, horses continue to excrete large amounts of calcium carbonate crystals in urine. As described in Chapter 65, use of dietary supplements to acidify equine urine (fewer calcium carbonate crystals form in acidic urine) has not been highly successful.

Over the past decades, I have evaluated several horses with recurrent urethral obstruction due to urethrolithiasis.[16] Further investigation of these cases using transabdominal ultrasonography, cystoscopy, ureteral catheterization, and nuclear scintigraphy has revealed evidence of unilateral upper urinary tract disease including chronic pyelonephritis (to the point of renal abscessation) and nephrolithiasis in many of these patients (Figure 66-4). The most consistent abnormal finding in a series of these cases was an abnormal ureteral opening into the bladder detected with cystoscopy.[16] When affected horses have normal renal function (after acute obstruction and post-renal failure have resolved), unilateral nephrectomy may be the only curative treatment, although I have followed one gelding with a smoldering left-sided pyelonephritis and nephrolithiasis that did not have further problems for over a decade after two episodes of obstructive urethrolithiasis. The important point is that obstructive urethrolithiasis may be a sign of upper urinary tract disease in many horses. Why horses with upper urinary tract disease produce smaller stones that may become lodged in the urethra, as compared to horses with primary cystolithiasis that often have much larger stones, is not known. Nevertheless, in

horses that present with obstructive urethrolithiasis, further investigation for upper urinary tract disease, along with culture of urine and the urolith, may be warranted after the obstruction has been relieved.

Soft Tissue Lesions

Soft tissue lesions involving the urethra include neoplasms, hematomas, and strictures.[17-22] In some parts of the world, parasitic granulomas of the distal urethra also remain a problem.[23-25] However, since the development of avermectin anthelmentics, urethral habronemiasis is rarely observed in well-managed horses. Soft tissue lesions more often result in preputial discharge and dysuria and only rarely cause urethral obstruction. Owners may report a malodorous sheath or diversion of the urine stream and may also observe a growth on the penis when it is dropped for urination. Affected animals may also have urine scalding of the inside of their hindlimbs (males) or perineum (females).

Neoplasia

A recent report of 114 penile and preputial tumors in equids found squamous cell carcinoma (SCC) to be the most common (79%), followed by papilloma (10%) and melanoma (6%).[26] Mean age of affected equids was 19.5 years with no apparent breed predilecton. Common presenting complaints included observation of a penile mass (50%) and malodorous purulent or sanguineous preputial discharge (41%); impaired urination was reported in only 22% of affected animals. The glans penis was the most frequently affected site. In an earlier report of 48 cases of SCC, the glans penis was also the most common site (53% of cases) and the urethral process and urethral sinuses were affected in 28% of cases.[27] Of interest, 75% of affected equids in this earlier report were ponies. Surgical treatment was pursued in 27 animals but recurrence was reported in 9 (33%).[27] In a subsequent report of 45 horses that had surgical resection of penile and preputial SCC, six of 31 (19%) with more than 1 year of follow-up had recurrence, prompting euthanasia in five of these animals.[28] In a more-recent report of 77 horses with penile and preputial SCC, treatment included local excision with or without cryotherapy (15%), partial phallectomy (68%), or penile amputation and preputial resection with retroversion of the penis (17%). Again, recurrence rate approached 30% within 18 months of surgery and was associated with histopathologic score (grade 1 to 3) of the SCC.[29] Taken collectively, these case series clearly demonstrate that SCC is an aggressive, locally invasive neoplasm that warrants a guarded long-term prognosis at initial diagnosis. Larger tumors, evidence of regional lymph node involvement, and a higher histopathologic grade all warrant a poorer prognosis. Because of these high recurrence rates with surgical resection, concurrent treatment with antineoplastic agents is worthy of consideration. Topical application of 5-fluorouracil at 14-day intervals after surgical resection of penile and vulvar SCC resulted in tumor remission (7 to 52 months of follow-up) in eight horses, and another two horses with small penile lesions were succesfully treated with topical application of 5-fluorouracil alone.[30] Similarly, long-term follow up of 573 equids with cutaneous neoplasms treated with a combination of surgical resection and one course of intralesional cisplatin treatment reported a success rate of 88% for SCC, including SCC of the exernal genitalia in 18 males and 15 mares.[31] SCC lesions of the external genitalia of male and female horses were recently shown to contain DNA of a novel equine papilloma virus (*Equus cabillus* papilloma virus-2).[32] Consequently, development of a vaccine to guard against this locally invasive neoplasm may be on the horizon.

Although less common, papillomas (warts) can affect the penis and urethra of younger horses, and melanomas can be problematic in gray horses of all ages.[17,26,33] Infiltration and associated inflammation of preputial tissue may make it difficult for the penis to drop for urination. Urine scalding within the prepuce contributes to further inflammation and development of discharge and a strong urine odor. Papillomas are often self-limiting and regress spontaneously within a few months after appearance; however, some transform into SCC and will need specific treatment.[33]

Melanomas of the prepuce and penis are usually not malignant and are amenable to cryotherapy, surgical removal, or laser ablation.[17,33] However, recurrence may also be a problem with this neoplasm.

Sarcoids can also affect the external genitalia but are more commonly found on the scrotum and prepuce; the penis is rarely affected.[17] Various other neoplasms that may affect the penis and urethra include lymphoma, lipoma, fibroma, basal cell carcinoma, neurofibroma, hemangioma, and adenocarcinoma. For example, a recent report in a mare described a pelvic canal lymphoma that compressed the urethra resulting in dysuria.[18]

Because approach to treatment of preputial and penile neoplasms varies among hospitals and clinicians, comparing treatment outcomes is difficult. As a concequence, a standardized approach to diagnosis and treatment of these lesions has recently been advanced. This approach combines clinical evaluation, including ultrasonography of regional lymph nodes, with histopathology (including grading of SCC) and is worthy of consideration if treatment outcomes are to be improved in the future.[34]

Hematoma

Penile hematomas are an uncommon problem in horses. The diagnosis is made on the basis of history (trauma) and physical examination findings of an enlarged, painful penile shaft. Ultrasonographic evaluation is useful to document size and the characteristic hypoechoic fluid pockets within the hematoma. The injury may cause deviation of the penile shaft and, when severe, may cause urethral obstruction and bladder rupture.[19-21] Trauma to the glans during erection may also cause a rent or rupture of the CSP or CCP into the urethral sinus, leading to penile hemorrhage during breeding.[35] Treatment consists of sexual rest and hydrotherapy, although drainage of the hematoma by needle aspiration can hasten recovery.[21] Temporary placement of an indwelling bladder catheter may be necessary with large hemotomas that can cause partial or complete urethral obstruction. For more information on this condition, see Chapter 60.

Urethral Stricture

Blunt or sharp traumatic injury as well as damage to the urethral mucosa from an obstructive urethrolith can lead to stricture formation, especially following circumferential ulceration of the urethral lumen.[9,22,36] Presence of a stricture may or may not

cause dysuria but likely increases the risk of urethral obstruction. After diagnosis via urethroscopy, phallectomy has been performed, but more recently, laser ablation of the stricture has become the treatment of choice.[22,36]

Urethrorrhexis

Urethrorrhexis, urethral rupture or laceration, is a rare problem in male horses and has not been described in mares, other than iatrogenic sphincterotomy for removal of cystic calculi.[10,37] The problem is most commonly traumatic in origin, either from being kicked or some other form of blunt or sharp trauma. The extrapelvic portion of the urethra is particularly vulnerable to injury at the level of the ischial arch, where it is superficial and relatively unprotected. Urethrorrhexis can also be a complication of urethral obstruction with a urolith and in a recent report in a neonatal colt, the problem was speculated to be a consequence of dystocia.[38] Accidental transection of the urethra during castration has also been described.[39]

Diagnosis of urethrorrhexis can be challenging because horses may have marked soft tissue swelling of the perineum, prepuce, penis, and caudoventral abdomen at the time of presentation. A lack of observed urination should increase suscpicion, as should leakage of serosanguineous fluid from the tip of the urethra. At times, urine may also be observed leaking from the wound. If urine is not detected at presentation, another characteristic finding is rapidly progressive swelling as urine continues to be passed into tissue planes, rather than being eliminated from the body. Rectal palpation is often unrewarding because the bladder will not be distended without obstruction and the intrapelvic portion of the urethra is usually intact.

When open wounds over the urethra are suspected to communicate with the urethral lumen, retrograde infusion of sterile saline through a catheter placed in the distal urethra may result in saline exiting the wound, confirming urethral disruption. Next, urethral mucosal damage can be directly visualized by urethroscopic examination, but it may be difficult to determine whether or not a full-thickness tear of the urethra has occurred. Ultrasonographic examination often reveals fluid accumulation in tissue planes but, again, it may be difficult to confirm actual urethral disruption with this imaging modality, although retrograde distention of the urethra by saline infusion may be helpful during imaging. Retrograde contrast radiography of the penis may be the most definitive imaging modality and also allows determination of the exact site of urethral disruption.

Primary surgical repair of urethrorrhexis is often not possible because urethral margins are irregular and inflamed, unless the disruption was caused by accidental incision. Accordingly, treatment is focused on preventing further tissue damage by urine accumulation (Figure 66-5) by diverting urine flow through a catheter placed into the bladder for 5 to 7 days. Treatment with broad-spectrum antibiotics and anti-inflammatory agents is also indicated to prevent wound sepsis and to limit the risk of a catheter-associated ascending urinary tract infection. Wounds often heal well by second intention, and recovery may be accelerated by partial closure of the urethra.

Hematuria and Hemospermia

Hematuria and hemospermia can be caused by the soft tissue and neoplastic lesions discussed earlier as well as disorders of the accessory sex glands, most notably seminal vesiculitis.[40-42] The latter problem can be challenging to diagnose because there may be no clinical signs other than discoloration of the ejaculate. Catheterization and collection of fluid from each ejaculatory duct for cytology and bacterial culture is required for definite diagnosis.[42] Serosanguineous fluid may also drip from the penis with obstructive urethrolithiasis or urethrorrhexis.

Tears or rents in the proximal urethra at the level of the ischial arch are another cause of hematuria in geldings and hemospermia in stallions.[43] Affected horses generally void a normal volume of urine that is not discolored. At the end of urination, squirts of bright red blood exit the penis, in association with forceful contractions of the bulbospongiosus muscle to empty the urethra of residual urine and to empty the CSP of blood. Occasionally, a smaller amount of darker blood is passed at the start of urination. The condition does not appear painful or result in pollakiuria or dysuria. In actuality, postурination hemorrhage would be a better descriptor for this condition.

Examination of affected horses is generally unremarkable, and laboratory analysis of blood reveals normal renal function

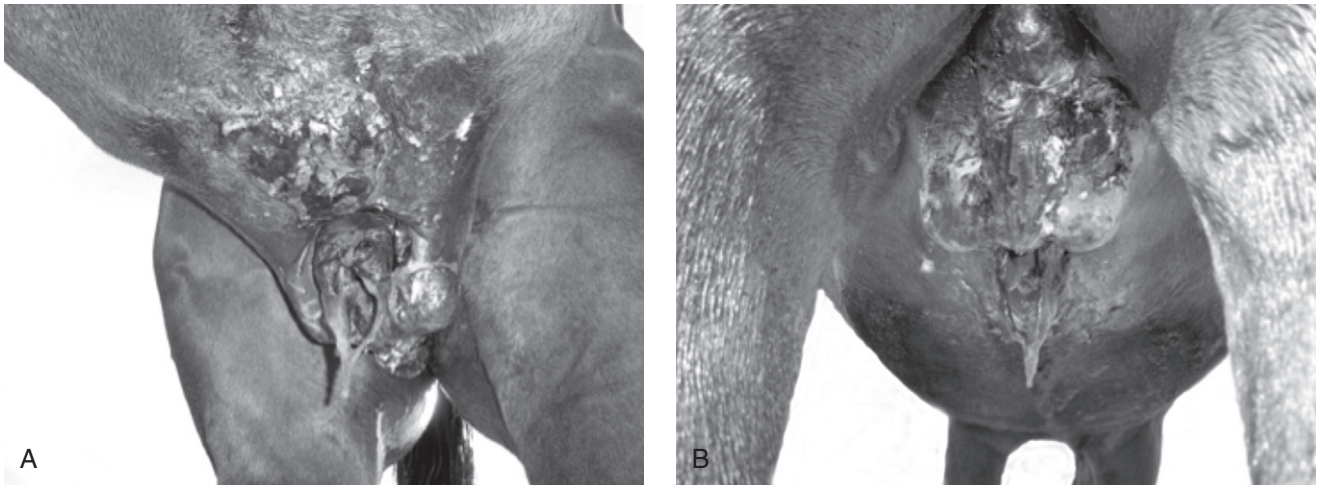

Figure 66-5. Photographs of the front view **(A)** and hind view **(B)** of the prepuce and ventral abdomen of a horse with marked tissue inflammation and necrosis several days following urethral disruption and accumulation of urine in tissues of the perineum, prepuce, and ventral abdomen.

although mild anemia (packed cell volume 25% to 30%) is an occasional finding. Urine samples collected mid-stream or by bladder catheterization appear grossly normal. Urinalysis may have normal results or there may be an increased number of red blood cells on sediment examination, a finding that would also result in a positive reagent strip result for blood. Bacterial culture of urine yields negative results.

Although the pathophysiology of this condition remains unclear, it is likely that the tear or rent develops as a "blowout" of the CSP into the urethral lumen (Figure 66-6). Contraction of the urethralis and bulbospongiosus muscles during ejaculation causes increased pressure in the CSP, which is essentially a closed vascular space during ejaculation. The bulbospongiosus muscle also undergoes a series of contractions to empty the urethra of urine at the end of urination. Hence, the proposed explanation for the bleeding at the end of urination in horses with urethral rents is a sudden decrease in intralumenal urethral pressure after urination while pressure within the CSP remains high.[44] When the lesion has developed, it is maintained by repeated bleeding at the end of urination.

An early report described this syndrome in four Quarter Horse type horses and attributed the post-urination bleeding to ulcers of the proximal urethra that could be seen via urethroscopy.[45] With the introduction of high-resolution videoendoscopic equipment to equine practice, one or more fistulas, rather than ulcers, are typically seen along the dorsocaudal (convex) aspect of the urethra at the level of the ischial arch. Within 1 to 2 weeks after the tear originates (about the time that endoscopy may be pursued), the edges of the urethral mucosal tear have largely healed as one or more fistulas communicating with the vasculature of the CSP (Figure 66-7). External palpation of the urethra in this area is usually unremarkable but can assist in localizing the lesion because external digital palpation can be seen via the endoscope.

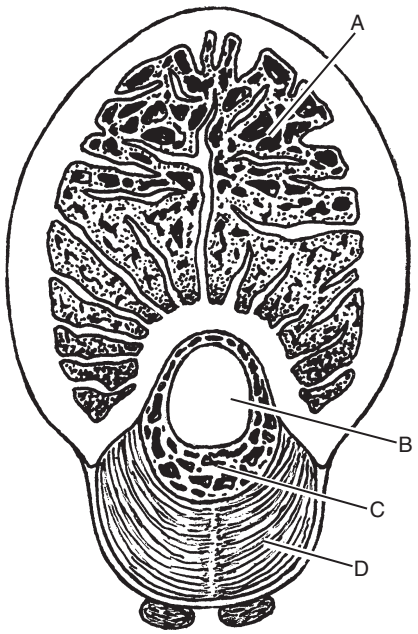

Figure 66-6. A cross section of the equine penis at the level of the ischial arch showing two separate vascular structures: *A,* corpus cavernosum penis; *B,* urethral lumen; *C,* corpus spongiosum penis; *D,* bulbospongiosis muscle.

Interestingly, the majority of geldings with proximal urethral tears have been Quarter Horses or Quarter Horse crosses, which have been free of other complaints. The consistent location of the rents suggests that there may be an inherent weakness of the urethral mucosa adjacent to the CSP at the level of the ischial arch. Some affected horses have unusual perineal conformation (see Figure 63-2), but histologic examination of the penis in a group of normal horses could not demonstrate any anatomical reason for the tears to occur at this specific location.[44]

Because hemorrhage resolves spontaneously in some geldings, no treatment may be initially required. If the problem persists for more than a month or if significant anemia develops (unlikely), a temporary subischial PU approach is made. The incision is extended through the fibrous sheath surrounding the CSP but not into the urethral lumen. The incision creates a "pressure relief valve" or path of lower resistance for blood to exit the CSP after urination. The surgical wound requires a couple of weeks to heal, and moderate hemorrhage from the CSP is apparent for the first few days after surgery. Additional treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for 5 to 7 days. Bleeding should resolve within a week following this procedure.

SURGICAL PROCEDURES

J. Brett Woodie

Perineal Urethrotomy

Perineal urethrotomy (PU) is performed for temporary urine diversion in male patients with obstructive urinary outflow disease or is used to access the bladder to remove small cystic calculi.[9,46-50] In patients requiring chronic urinary diversion, a permanent urethrostomy may be created. It is best to perform a PU or urethrostomy as a standing surgical procedure with the horse sedated and confined in stocks.[9,46,50] The horse should be sedated with detomidine hydrochloride or xylazine hydrochloride. Butorphanol tartrate can be used in combination with either of the α_2-agonists, if necessary. Epidural anesthesia is used to desensitize the perineal region. The rectum should be evacuated prior to starting the surgical procedure and the tail should be tied overhead to the stocks to support the horse if the patient becomes ataxic. The perineal region should be clipped and prepped for surgery. Local anesthetic can be infused to desenstize the skin and superficial tissues if the epidural is not effective. A bladder catheter should be advanced through the urethra to identify the urethra during surgery. Appropriate illumination of the surgical field will be necessary.

A 6- to 8-cm longitudinal midline skin incision is made in the perineum extending from a point 4 to 6 cm ventral to the anus ventrad to just distal to the the ischial arch (Figure 66-8, *A*).[9,46,50] The subcutaneous tissues are divided, and the longitudinal incision is continued deep to divide the paired retractor penis muscles and the bulbospongiosus muscle.[49,50] The incision is continued through the CSP that envelops the urethra. The urethra is exposed by retraction of these muscles. The urethra is identified and stabilized by palpation of the urinary catheter (Figure 66-8, *B*). A longitudinal incision is made along the caudal surface of the urethra, and the mucosa is reflected abaxially. Hemorrhage from the CSP may be copious but subsides spontaneously. It is important that the incision be made

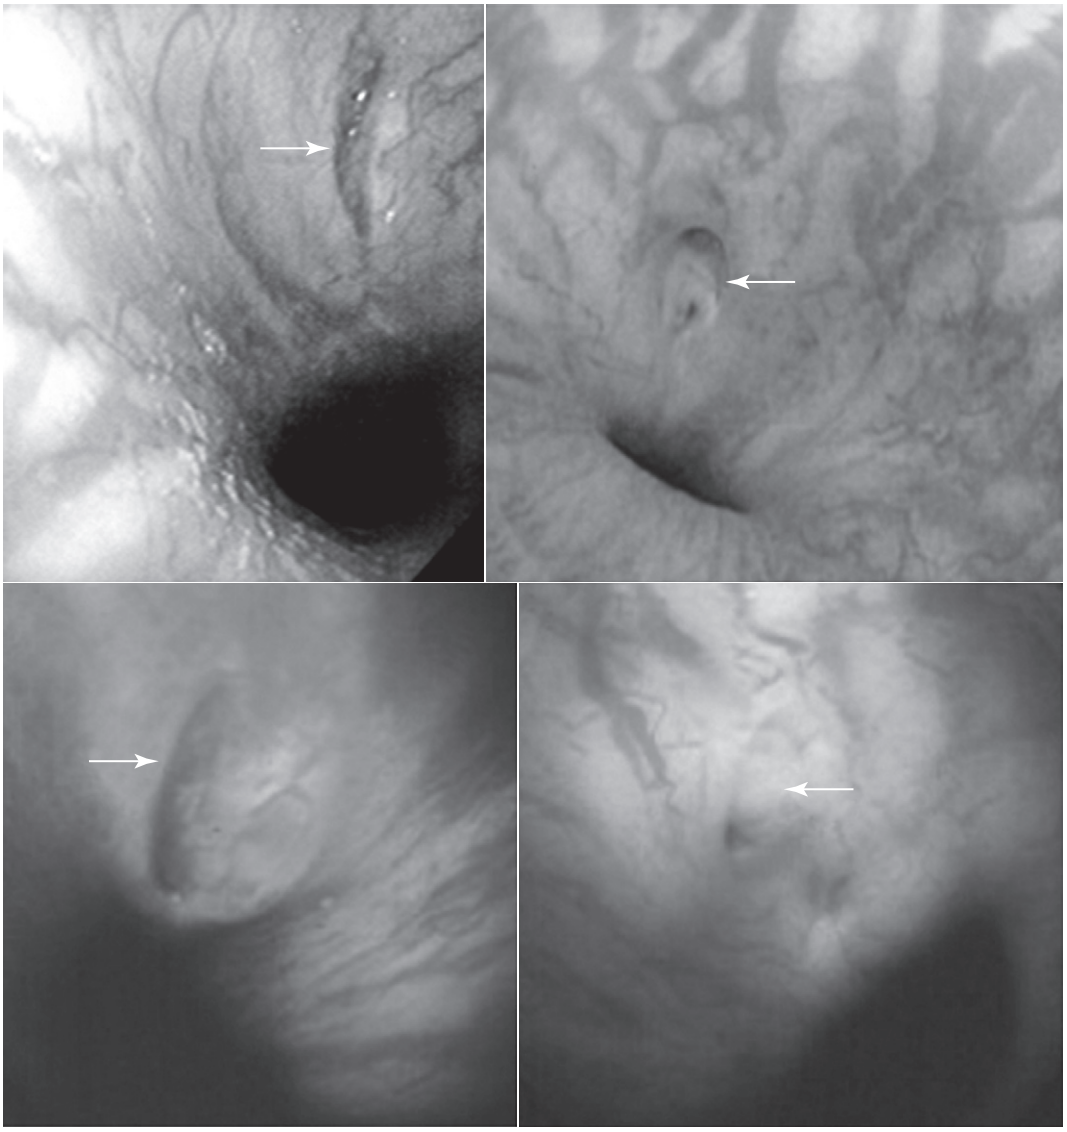

Figure 66-7. Four endoscopic images showing the variable appearance of urethral rents *(arrows)* causing hematuria at the end of urination in geldings or hemospermia in stallions. A consistent finding is that urethral rents are located along the convex aspect of the urethra at the level of the ischial arch.

on the midline and that multiple planes of dissection are not made through the tissues. Edema will form in the tissues if excessive manipulation is required and this will increase the difficulty of the procedure. Intraluminal obstructions such as uroliths may be manipulated and removed by urinary catheters or forceps inserted through the PU incision.[49,50]

For temporary diversion of urine, the wound is managed with local care during the process of secondary-intention wound healing (Figure 66-9). A urinary catheter may be placed through the temporary urethrotomy incision and secured with stay sutures after surgery. Typically, a urethrotomy wound heals within 14 to 21 days with minimal complications.[50] Hemorrhage may occur from the surgical site at the end of urination for up to 2 weeks. The bulbospongiousus muscle contracts at the end of urination, and this increases the pressure in the CSP, causing hemorrhage. If a permanent urethrostomy is desired, the muscles of the ventral penis are sutured along their cut edges with a continuous suture of 3-0 synthetic absorbable suture material to control hemorrhage. The urethral mucosa and skin are approximated using interrupted sutures of 2-0 or 3-0 synthetic monofilament absorbable or nonabsorbable suture material (Figure 66-10). Care must be taken to ensure accurate, tensionless apposition of the perineal skin and urethral mucosa.

Distal Urethrotomy

A distal urethrotomy may be required to remove an obstruction that can not be resolved using endoscopic techniques. Horses should be anesthetized and positioned in dorsal recumbency. Technically, the surgical procedure is similar to that for a PU. If the lesion is sufficiently distal, a tourniquet may be applied to assist with hemostasis and improve intraoperative visualization. Incisions are made over or slightly proximal to the urethral calculus to permit the insertion of grasping forceps. Placement of a catheter to the level of the obstruction can aid in identification of the urethra. Palpation of the calculus may be possible

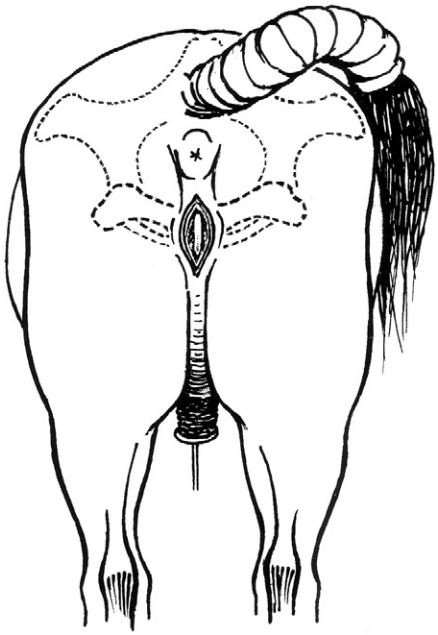

Figure 66-8. The urethral incision is performed immediately dorsal to the ischium to decrease the likelihood of postoperative urine scalding in a horse with a perineal urethrotomy. Preoperative placement of a stallion urinary catheter facilitates intraoperative identification and exposure of the urethra.

Figure 66-9. Perineal urethrotomy for temporary urinary diversion will heal by secondary intention with minimal complications.

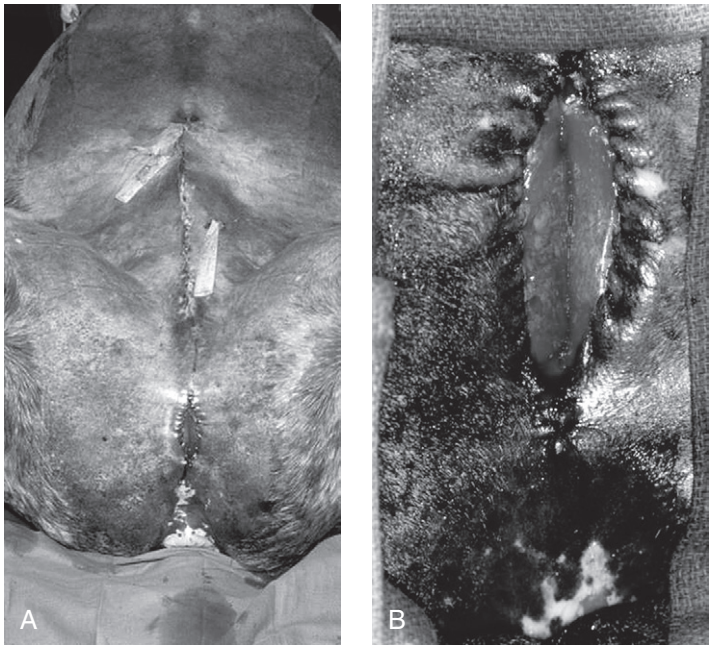

Figure 66-10. A, Perineal urethrostomy for chronic urinary diversion to bypass extensive preputial and penile squamous cell carcinoma. **B,** Accurate apposition of mucosal and cutaneous layers is essential to minimize postoperative complications.

depending on its size. Ultrasonography can assist in localizing the obstruction and guide placement of the incision. After removal of the calculus, the incision is closed in anatomic fashion using 3-0 synthetic absorbable suture material. It is important to accurately reconstruct the CSP and bulbospongiosus muscle to reduce the risk for urine leakage and development of cellulitis. Approximation of the retractor penis muscle provides additional security for the closure.

Urethroplasty

The patient is sedated, restrained, and prepared for standing surgery as described. General anesthesia will be needed if the urethral injury involves the penis distal to the scrotum. Repair of a urethral laceration is consistent with the repair of any other hollow viscus. Careful attention to wound débridement, lavage, and preservation of intrinsic vascular and neural supply is

important. If the urethral laceration is circumferential, an end-to-end anastomosis will be required. Small-diameter (3-0) absorbable suture material such as polyglactin 910 (Vicryl, Ethicon) should be used. The use of an intraluminal stent (urinary catheter) for the repair of a lacerated urethra is considered acceptable.[51]

Aftercare

Postoperatively the patient should be monitored to ensure that urination occurs without difficulty. Antibiotics and nonsteroidal anti-inflammatory drugs should be administered as required. In cases in which urine escaped into the surrounding tissues, the use of surgical drains is required.[39,47]

Traditionally, catheters were left in place after primary repair of a traumatized urethra.[52] However, the literature is unclear whether prolonged maintenance of an intraurethral catheter prevents or promotes stricture formation. More recently, chronic placement of urinary catheters has been discouraged because of locally increased inflammatory response and subsequent stricture formation.[52] Because the value of chronic catheterization is unclear, it is best to remove the catheter as soon as possible.[51-53] Postoperative stricture formation may be minimized by limited duration of catheterization, accurate tissue repair, effective hemostasis, and adequate drainage of the periurethral tissues.[39,47] Foley catheters may be secured in place with stay sutures during the first 48 to 96 hours. The balloon on the Foley catheter should be distended with saline solution rather than air.

Hygiene around the surgical site is imperative. There is a high risk of urine soilage and urine scalding of the hindlimbs and ventral perineum. The urethrotomy and surrounding tissues should be cleaned daily and protective emollients applied. Care should be taken not to disturb the sutures if a urethrostomy procedure was performed. The skin of the ventral perineum, inguinal region, and adductor surfaces of the hindlimbs should be cleansed daily and protective emollients applied.

Complications

Mild tenesmus and discomfort are expected after surgery. The effect of urine contamination of tissues is usually minimal unless tissue trauma is advanced or sepsis is present. Antibiotic and anti-inflammatory therapy is appropriate in such cases. Partial dehiscence of urethrostomy incisions occurs infrequently and may be managed with local tissue therapy, débridement, and delayed closure.[39,47] Stricture of the urethra is a common postoperative finding[8]; stricture is most commonly observed in distal urogenital surgeries such as posthioplasty or subtotal phallectomy.[23] Surgical procedures involving the distal urethra may require spatulation to reduce the likelihood of stricture formation (see Chapter 60).[54] Less commonly, thin veils of urethral mucosa may form in such a fashion as to partially occlude the urethral lumen, requiring further surgical revision.[49]

Diagnostic Imaging

John A. Stick

CHAPTER
67

Radiography

Elizabeth A. Ballegeer and Nathan C. Nelson

Radiography remains the most ubiquitous imaging modality available to the equine practitioner. The importance of radiographs in the evaluation of lameness, as well as areas inaccessible to other modalities because of size or positioning issues, must not be trivialized or forgotten in the age of bigger and better diagnostic modalities.

INDICATIONS

Indications for radiographic examination are multitudinous. The most common reason to obtain equine radiographs is to examine a particular joint or joints following appropriate localization of lameness. Radiographs are also commonly obtained after trauma to a particular body region is witnessed or suspected. Radiographs may be taken after identifying an area of increased bone production on a nuclear scintigraphic study. A swelling seen on a limb or atypical posture may also indicate an area that is appropriate for radiographic examination to either help determine the possible underlying cause or define bony changes. Draining tracts injected with positive contrast material can help define involved structures that may modify therapy or change prognosis. Serial weight-bearing radiographs evaluate and monitor progression of distal phalangeal rotation and/or distal displacement in horses with laminitis. Ataxic horses may have changes seen on cervical spinal radiographs that can suggest spinal cord compression, warranting a more definitive diagnostic imaging technique, myelography. Thoracic radiography is indicated in cases with respiratory or cardiovascular disease. Abdominal radiographs, though rarely performed in the adult equine patient, may be indicated if sand colic or enteroliths are suspected. Neonates with developmentally atretic or mechanically obstructed intestinal loops are more completely evaluated with abdominal radiographs than adults. Radiographs are also the imaging modality of choice for evaluating placement of surgical fixation devices.

X-RAY PRODUCTION AND EQUIPMENT

To better understand the origin of a radiographic image, some underlying principles of x-ray production must be discussed. This begins with the components and function of an x-ray tube.

X-rays are produced when high-energy electrons are accelerated through a vacuum-sealed tube and strike a target called an *anode*. The electrons originate from a small electron cloud surrounding a negative pole *(cathode)*, which is typically a heated tungsten filament (Figure 67-1). The anode is constructed of tungsten alloy to which a positive charge is applied. Because of their negative charge, the accelerating electrons strike the anode, reacting with the nucleus or the shell electrons of the tungsten atoms in the anode. Electromagnetic radiation is released by these interactions, at the wavelength of x-rays (10 to 0.01 nm).

The filament length and anode disc angle may vary, altering the focal spot of the exposure. The focal spot is the area of the anode struck by the electrons generated in the cathode. Some x-ray machines allow selection of a larger or smaller focal spot. Smaller focal spots create better detail in an image, but fewer x-rays can be generated, and the radiographic field coverage may be lessened. Larger focal spots allow higher numbers of x-rays to be generated (which is necessary for thicker areas of the body) but sacrifice radiographic image detail.

As electrons strike the anode, they rapidly decelerate. The lost kinetic energy of the electron beam generates a large amount of heat, which must be removed from the anode. Various mechanisms of heat dissipation exist. Early anodes were stationary tungsten blocks embedded in better-heat-conducting copper; most modern anodes have an anode shaped as a disc. This disc is connected to an induction motor, which rotates the anode, spreading heat along a larger surface. The tube is also housed in an oil bath, which dissipates the radiated heat from the anode. Smaller x-ray tubes (such as portable or dental units) still have a stationary anode. This limits the maximum tube current and number of x-rays that can be generated.

As electrons strike the anode, x-rays are primarily directed at a steep angle away from the anode; however, smaller volumes of x-rays are generated in surrounding directions. The outer layer of the tube housing is lead, which shields the outside environment from stray irradiation produced from the anode. A tube port in this metallic enclosure emits the primary beam in the desired direction. Modifiable ports have movable lead sheets, which collimate the primary beam to a rectangle of variable length and width, though fixed aperture ports are also useful for certain applications, such as dental radiography. A mirror-reflected light within this housing mimics the borders of the primary beam for positioning purposes. The primary beam is also filtered with aluminum, copper, or plastic to remove very-low-energy x-rays that would increase the patient's radiation exposure but are insufficiently energetic to produce a diagnostic image.

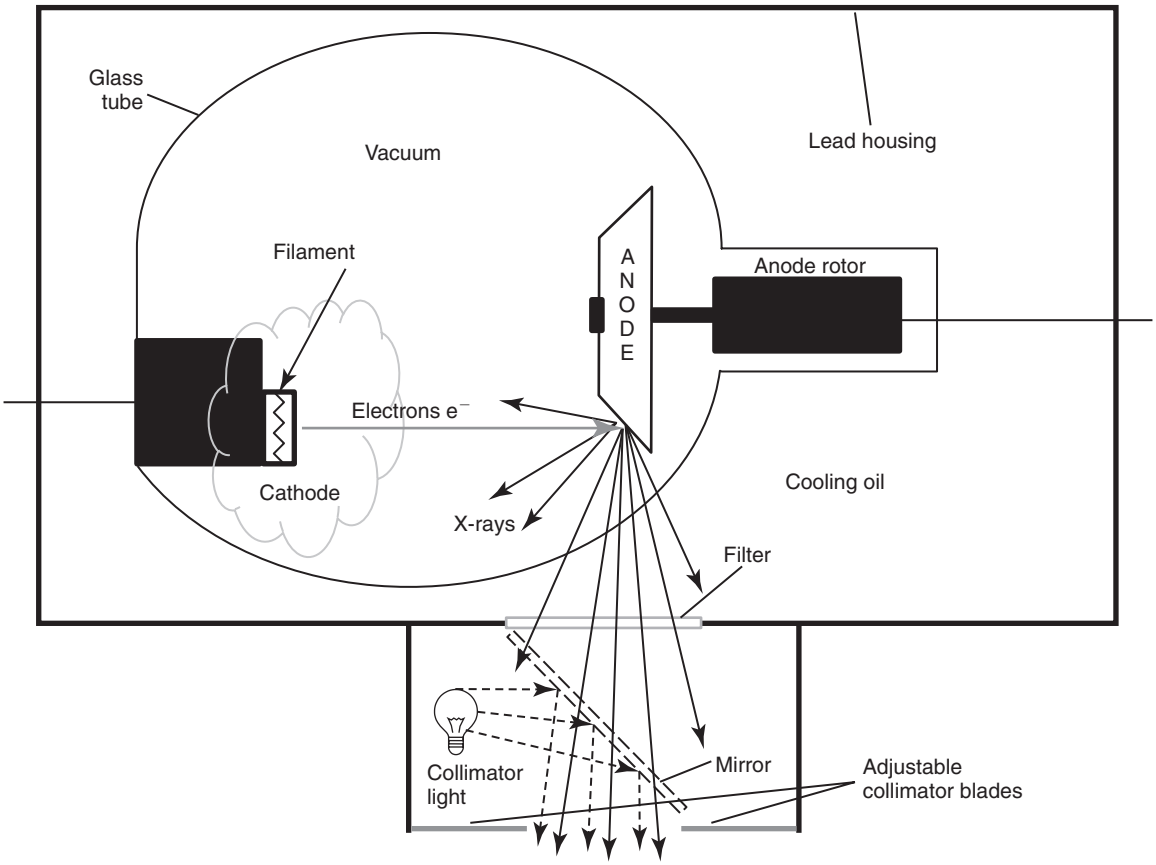

Figure 67-1. Basic x-ray tube configuration; the drawing is not to scale, and the shapes are not strictly accurate.

The energy of x-rays produced is directly related to the modifiable voltage difference between the cathode and anode. This potential difference is usually between 50 and 120 kilovolts (kVp). kVp determines the peak energy of the electron accelerated from cathode to anode, whose energy is then converted into x-ray production. The x-ray beam contains photons of various energies, the mean of which is between one third and one half of the peak energy.

The number of x-rays produced may be increased or decreased by the user depending on imaging needs. A current, measured in milliamperes (mA), is applied through the cathode filament for a selected amount of time, measured in fractions of seconds (s). The product of current and time is mAs and is proportional to the number of x-rays produced.

Both kVp and mAs may be modified to alter the final image quality. Increasing the energy (kVp) of an x-ray beam increases image exposure (resulting in a darker radiographic image) and increases tissue interactions of the x-ray beam. This creates more scatter radiation and more shades of gray on the resulting image, which decreases contrast between different types of tissue (Figure 67-2). Conversely, decreasing kVp reduces overall exposure but enhances image contrast. Increasing the amount of x-rays by increasing the current, exposure time, or both (mAs) will make an image much blacker, but with relatively less tissue interactions than increasing kVp. This creates a very-high-contrast or black-and-white image.

Scatter radiation is always present, both originating directly from the x-ray tube and produced when the beam interacts with matter. Scatter becomes worse with high-kVp techniques, thicker body parts secondary to tissue interactions, or larger fields of view from both the tube and tissue interactions. An increasing amount of scatter degrades the image by adding superfluous radiation that is not related to the imaged anatomy.

The subject of scatter radiation requires brief discussion of grids. Grids improve image contrast by removing some or most of the scatter radiation before it arrives at the image-recording device. Grids are configurations of lead strips divided by radiolucent separators that block radiation that is not oriented parallel to the primary beam. Grids can be focused, which is more common than parallel. *Focused* grid lead strips typically converge slightly on the tube side, and diverge slightly on the film side, in relation to the primary beam x-rays. It is important to note that grids must be centered with the primary beam and be used at a particular distance from the tube, or the angulation of the lead strips will remove primary beam as well as scatter, which is referred to as *grid cutoff*. *Grid ratio* refers to the ratio between the height of the lead strips and the distance between them. The higher the grid ratio, the better the grid functions, although high grid ratio requires a higher technique to create the same exposure of the image. A grid ratio of at least 8 : 1 for techniques with kVp below 90 and at least 12 : 1 for techniques higher than 90 is recommended.[1,2] The *grid frequency* refers to the number of lead strips per unit length; frequencies above 30 lines/cm is recommended.[3] Because grids employ thin linear strips of lead, a normal side effect of use is the appearance of *grid lines* on the final radiographic image.

Typically, grids should be used for body parts that are more than 10 cm (4 inches) thick, because above this thickness,

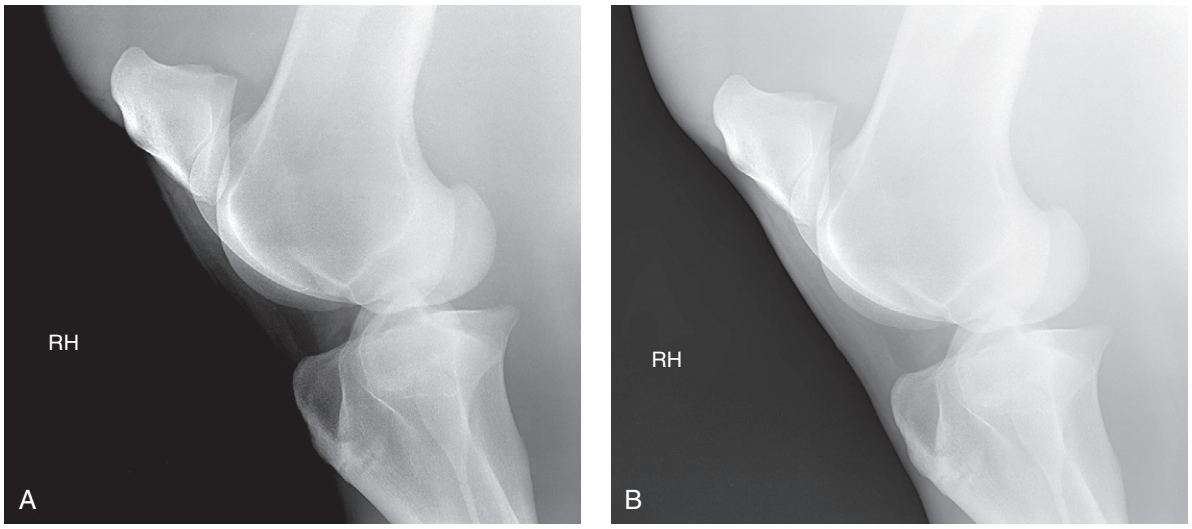

Figure 67-2. A, The lateromedial radiographic view of the stifle of a 3-year-old Thoroughbred gelding simulating high-mAs, low-kVp technique. Note that though the contrast within the bone is great, allowing visualization of trabecular pattern, the large contrast of the image makes soft tissues less visible; **B,** The same radiographic view simulating high-kVp technique. Note the large numbers of grays allowing visualization of soft tissues, differentiation from fat, and the relative lack of contrast within bony structures. Note that the relative brightness of the two images is similar.

significant scatter is produced by tissue interactions. In equine radiography, a grid is often a stationary, separate sheet that must be placed directly against the cassette, but it may be incorporated into the cassette itself. Grids are rarely used for imaging equine distal limbs as the body parts are usually less than 10 cm thick and alignment of the grid with the primary x-ray beam is difficult. Separate grids are somewhat fragile; bending or being stepped on damages the lead strips, resulting in visible white defects on the image.

IMAGE PRODUCTION

After the x-rays have penetrated the patient, carrying with them the differential attenuation that comprises the diagnostic information of the study, it must be transformed into a visible image. This may be accomplished through analog film-screen combinations or through newer digital radiographic techniques.

Film-Screen Combinations

Traditional image formation involves exposing radiographic film to produce an analog picture. The x-ray film is housed within a protective cassette. X-ray film is composed of a plastic base sheet with adherent emulsion on both sides. This emulsion is made of gelatin and contains the silver halide crystals that create the film image.

X-ray film is not particularly sensitive to direct x-ray exposure. To counter this problem, intensifying screens are used. Intensifying screens contain a phosphorescent material that creates either visible or ultraviolet light proportional to the energy and number of x-rays that interact with them. The light emitted by the screens is responsible for the vast majority of x-ray film exposure. This light and the film must be wavelength matched for appropriate exposure. The scintillating crystals in screens were originally calcium tungstate, which has low efficiency of light transformation, and has since been replaced with crystals with higher efficiency in the rare earth group of elements (elements 57 through 71 of the periodic table of the elements).

Screens are described in terms of *fast* or *slow* intensification factors and have numeric values. *Fast* systems (600 to 800 speed) create more light because their phosphor layers are thicker and crystals are bigger and thus more sensitive, but this comes at the cost of resolution. These systems are typically used for thicker body parts, proximal to the carpus or tarsus. *Slow or detail* systems (100 speed) create proportionally less light because of thinner layers with smaller crystals, but they provide much better detail.[1,2] These systems are recommended for detail examinations, such as navicular series or distal phalanx. *Medium speed* systems (400 to 600 speed) are more encompassing for thicker or thinner parts, are more universally used particularly with mobile x-ray units, but may compromise detail in the distal limb.

Image resolution is defined as the ability to discern two adjacent structures on an image; this is limited to more than 0.3 mm in high-speed systems but improves to 0.1 mm with slow/detail systems.[4]

Exposure to light or x-rays reduces some of the silver halide crystals on the film to metallic silver. Not all of the silver is transformed with the light exposure, but it forms small clusters of silver that act as latent image centers, and it catalyzes the reaction to create more metallic silver within the developer. This metallic silver is what creates the blackness on a film.

Full processing of a film begins with (1) the developer step, then (2) fixation, which halts the development and hardens the film emulsion, and (3) washing, which removes the undeveloped silver halide from the film, creating the white portions of the image. The last step in the process is (4) drying, which further hardens the emulsion of the film and allows it to be preserved.[2] All of these steps have precise time requirements, chemical requirements, and, in the case of development, temperature requirements. Automatic processing manages these parameters provided the processor is functioning properly. More room for error and artifact exists with hand development.

Some limitations to film screen systems are inherent to their analog, hard copy acquisition. Radiographic film has a limited

Figure 67-3. Radiographic equipment: **A,** 400-speed film screen equipment with green-based film. **B,** Computed radiography cassette and imaging plate. **C,** AFGA computed radiography processor. **D,** Sound-Eklin Mark IIG direct digital radiography system. Image plate sends the x-ray information transformed into electric signal to a computer for display. (**D,** Courtesy Sound-Eklin Medical Systems, Inc.)

linear response to radiation, which often leads to over- and underexposed areas on the same film.[5] Also, film images cannot be manipulated after exposure. If technique or positioning is incorrect, the study must be performed again, with almost complete duplication of the steps to perform it. The hard copy nature of the film also requires appropriate physical location for storage and physical transportation for another individual to see it. However, benefits include lower initial cost for systems, easy accessibility to previous studies, and usually better quality control on the part of those taking the radiographs.[5,6]

Computed and Digital Radiography

The conversion of x-rays into a visible image may also be completed digitally and viewed on a computer screen. There are multiple ways to achieve this; digital systems are becoming more common in the veterinary medical community and are almost *de rigueur* in the human medical world, and as they are developed by multiple companies for veterinary applications, they have decreased considerably in price. Again, some underlying mechanisms must be understood to help practitioners decide which system is desirable for their circumstances and to understand the tradeoffs between the benefits and costs. Figure 67-3 depicts the different image-formation systems.

Computed Radiography

Computed radiography (CR) applies to systems with photostimulable phosphors (PSP), also known as *storage phosphors*. It was introduced in the 1980s by Fujifilm Medical Systems.[7] The phosphors are usually in the form of barium fluorohalide powders that coat an imaging plate within a light-tight cassette and fluoresce in response to radiation, much as intensifying screens do. However, the image in CR is created through the release of a charge that remains within the phosphors after the initial fluorescence. The imaging plate, placed into an imaging plate reader after exposure and identification, moves from the cassette across a stage with a laser beam, which re-stimulates the phosphor crystals. The crystals then emit visible light that is captured by a photomultiplier tube that transforms the light

energy to an electrical signal. This signal is digitized by an analog-to-digital converter (ADC) and stored. This step is necessary to transform data from a voltage change or pulse into numbers a computer may store and understand.[8] The imaging plate must then be "erased" by exposure to bright white light to release any residual stored charge, before being returned to the cassette.[1,9] Systems may bring the entire cassette into the internal mechanisms of the processor (which may also bring in debris on the surface of the cassette) or just the internal imaging plate. This latent image within the charged crystals is less resilient than that of film-screen systems, and most of it decays within the first hour after exposure.[4,10-12]

Resolution of a CR system is directly related to the scatter of the laser light when it reads the signal from the crystals, which in turn is related to the thickness of the imaging plate.[12] This does not translate into an absolute value similar to film-screen combination, as systems have differing equipment. However, the overall resolution of CR is decreased compared to film-screen combinations (see Figure 67-4 for comparisons). The largest benefit of CR, when compared to film-screen combinations, resides in the linear response of the PSP crystals to exposure, compared to radiographic film, which allows a greater range in technique, resulting in readable images (also known as *exposure lattitude*), especially when coupled with the ability to manipulate the brightness and contrast of images after they are obtained.[1,5]

Indirect and Direct Digital Radiography

Indirect and direct DR systems use digital detectors that translate exposure into digital signals along a panel directly exposed to x-rays and thus are termed *digital radiography*. These systems eliminate the need for a separate image processing unit as used with computed radiography. The difference between indirect and direct DR lies in the presence or lack of an incorporated scintillator, similar to intensifying screens and image plates.

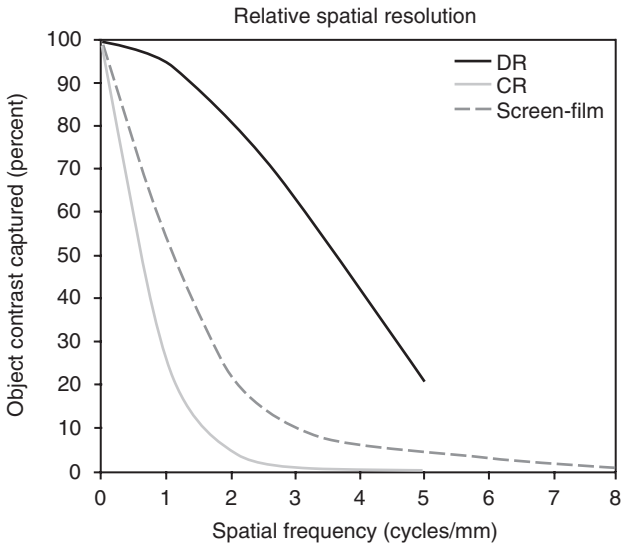

Figure 67-4. Relative resolution capabilities between radiograph modalities, represented as the percentage of an object's contrast recorded by that modality, as a function of size (spatial frequency). Note that discrimination of smaller objects of differing contrast, or increasing spatial frequency, decreases most rapidly with CR system and least rapidly with the DR system. Note this does not take into consideration the resolution of the display system used to view the digital images. *CR*, Computed radiography; *DR*, digital radiography.

Indirect digital radiography (IDR) uses columnar cesium iodide crystals oriented parallel to the primary beam, coupled to a diode layer, which converts light within the differentially stimulated crystals to an electric charge. The charge matrix of the entire array is sensed by an electronic readout system, again converted by an ADC, and stored.[10,13,14] The addition of a scintillating layer adds efficiency to the system, increasing the amount of signal detectable from a measureable amount of radiation,[13] as well as decreasing the blur of signal laterally within the photoconducting layer, though this is also minimized by positively charging the deep side of the layer, attracting electrons.[1]

In contrast, *direct digital radiography (DDR)* omits the scintillation step and uses thin film transistor arrays (TFTs), which directly translate the exposure of an x-ray photoconducting layer (such as amorphous selenium) into a charge, which again undergoes readout, analog-to-digital conversion, and storage.[10,13]

Both of these digital systems make "real-time" images that are displayed within a matter of seconds,[6] unlike CR images, which may take several minutes to be processed. This is a big advantage when retaking radiographs if there are positioning or technique errors. However, digital detectors are expensive, given the number of very small electronic elements that make up a large detector matrix, and are relatively fragile with manipulation. The detectors may be incorporated into positioning tables, or they may be portable and attached to cables. Wireless detector plates are in development, with inherent battery and range challenges. Both IDR and DDR have the similar advantage that CR does over film-screen systems in post-processing manipulation and exposure latitude.

Although the spatial resolution of TFT-based (DDR) systems appears better than film-screen combinations or CR, in reality, the resolution of a digital system is limited by the size of the detector elements and the resulting pixel display (a pixel being one two-dimensional area of data in a digital image), as well as the resolution of the screen upon which they are viewed. Therefore, a very small detector size on a digital system requires more pixels than can be displayed on a monitor, and the advantage over the "lower-resolution" systems is lost.[1]

Charged Coupled Device Cameras

Charged coupled device (CCD) cameras are only mentioned briefly, because they need to be incorporated into a radiographic table and have limited equine application. This system involves a large exposed scintillating layer, which is then minified by an optical lens or fiberoptic coupling devices, a CCD chip that converts the light to electrical charge, and similar analog-to-digital conversion and storage. This system produces a "real-time" image but causes loss of photons in the minification process that leads to increased noise in the image[10,13] and mild distortion of the image at its edges.[6] Despite its shortcomings, this system is much more economical than other digital systems.

Digital System Parameters

A number of parameters are available to assess the performance of a digital radiographic unit, and minimum standards have been established. Each digital system has an inherent spatial resolution, usually expressed as line pairs (lp)/mm, which

directly measures the ability of a system to measure small details. The American College of Veterinary Radiology (ACVR) has recommended that a minimum standard be 2.5 lp/mm; below this, loss of spatial resolution leads to lack of diagnostic information on an image.[15] The American College of Radiology (ACR) has further guidelines for digital systems related to the pixel (length × width of a single element of an image) matrix size. The matrix is the grid of the entire length and width of the image, made of individual pixels. It also has guidelines on the number of gray shades recordable by a device, called *bit depth*. This refers to a binary code used to record digital information, each digit being a *bit*. The ACR recommends a minimum of 2 K matrix and 12-bit depth for digital radiography.[8]

Fluoroscopy

Fluoroscopy is an imaging modality that uses x-rays and differential attenuation to produce a real-time image of anatomy. The image intensifier contains the majority of the electronics used to form the fluoroscopic image, and it receives x-rays emitted by a standard x-ray tube. Within the image intensifier, an input fluorescent screen converts x-ray energy to light, which strikes a photocathode; this creates photoelectrons, which are focused and minimized by a lens as they travel to an accelerating anode. As they travel through this thin anode, they then strike an output phosphorescent layer. This light is then usually imaged by a closed-circuit television camera or converted to a digital signal by an ADC, and the information is stored. The entire image intensifier may be replaced with a system analogous to indirect DR, which presents images in real time and records them as such.[1,2]

The major advantage of fluoroscopy is the ability to watch a dynamic x-ray study in real time. This is essential for the diagnosis of physiological conditions such as dysphagia or airway collapse, and it is a major benefit to watch progress in many contrast studies (see "Image Interpretation," later). Unfortunately, penetration and resolution are limited with fluoroscopy units; very few products are marketed for equine use. One such product offered by GE Healthcare (Figure 67-5) has a capacity of producing 120 kVp/10 mA exposure for fluoroscopy, but this is maximal exposure and may only be carried on for a limited period of time because of tube heat limits.[16]

Digital Image Storage and Display

A fair amount of hardware and software is needed for the digital imaging modalities described earlier. Not only does each imaging device require its own computer but also this computer may be connected via network to a server/archiving device, as well as a diagnostic workstation computer and monitor. This computer must also have the appropriate imaging software to read the archived images. Together, these components form a picture archive and communication system (PACS). Although larger hospitals have a more complicated PACS that communicates with hospital or radiology information systems and may be connected to the Internet, these are not strictly necessary, and a local area network connecting the imaging modality to a server/archiving device represents a PACS in its simplest form.[17]

Typically, the data are stored in digital imaging and communication in medicine (DICOM) format.[18] It should be noted that using this format is voluntary; however, this allows multiple modalities to be stored and accessed in a similar fashion, as well as data compatibility between multiple vendors and hospitals. File size is directly related to pixel size, which in turn is related to the resolution of an image. The smaller the pixel size, the higher the resolution, the larger the matrix (number of pixels high × number of pixels wide) size, the larger the data file. A typical uncompressed radiographic image is 10 to 12 megabytes in size from a high 2048 × 2048 pixel matrix,[8] which can take considerable time to transfer on slower or older networking equipment. The rate at which the network transmits this information is called *bandwidth* and is an important factor to consider.[17] If the network is connected to the Internet, sufficient safety measures to protect security of medical data must be in place, typically in form of a firewall.[19]

Figure 67-5. The large animal fluoroscopy unit from General Electric, at the Michigan State University Teaching Hospital. The x-ray tube is capable of producing high kVp and mA technique and is seen to the *left* of the stocks; the image intensifier, to the *right*, captures the x-ray information and is coupled either to a closed circuit video system or digital detection system for real-time display. The work station seen to the *left* enables the user to see displayed images and capture them as they are taken.

Images may be compressed to save space, though ACR guidelines for these dictate remaining above 20 : 1 ratios to avoid loss of too much diagnostic information.[20,21] Interpretation of images in DICOM format is recommended. Other file formats, such as joint photographic experts group (JPEG), should be interpreted with caution. JPEG compression of an image often exceeds the 20 : 1 ratio, resulting in a loss of detail and image contrast.

A multitude of options exist for data storage and include a variety of discs, solid-state media, and on-site or off-site servers. Each image that is saved must also be backed up to avoid computer error data loss.[22] A full discussion of all of these storage options and computer requirements is beyond the scope of this text but may be found in the referenced articles.[17-20,22]

Typical transfer of images from a PACS occurs on digital storage media, such as CD-ROMs, DVDs, or USB flash drives. Many DICOM PACS include an abbreviated form of DICOM viewing software when the media are transferred. A printer may also be used with digital setup. Most DICOM systems use expensive laser printers that print onto film analogous to radiographic film, although copies may be provided for clients from a standard paper printer.[5] These images are not likely to be of sufficient diagnostic quality for other veterinarians.

Each digital image is also only as good as the monitor used to view it. Lower-quality monitors are employed in exam rooms or in the field, where quality control for positioning and exposure is performed, but higher-quality monitors should be used for primary image interpretation. Medical gray-scale monitors typically have increased brightness, finer pixel matrices, better graphics cards, and are calibrated to a standard gray-scale, over standard color monitors. The major disadvantage to a medical-grade monitor is the significant expense,[23] which can often be $7,000 to $10,000. Color monitors have been shown to have similar diagnostic accuracy to gray-scale monitors, but only if magnification, windowing, and leveling are utilized with software,[24] which can be time consuming and cumbersome. The poor brightness of standard color monitors, which is up to 20 times less than conventional lightboxes and 2 times less than gray-scale monitors, significantly affects diagnostic accuracy.[25-27] A proper darkened environment for interpretation also has considerable effect on length and accuracy of interpretation.[28,29] Clinicians should avoid the tendency to interpret images in the field on small monitors attached to portable digital units suitable only to confirm positioning, or in the hallway on monitors meant for client education.

PERFORMING THE EXAMINATION

The patient should be properly prepared for an examination with adequate sedation in a quiet environment. Dirt should be removed from the haircoat. This is particularly true with preparation of feet for radiographs. Special care must be taken to remove shoes, nails, and debris within the frog or on the hoof wall, and the foot should be packed with petroleum jelly or Play-Doh to remove confusing superimposed gas opacities.

Proper positioning and radiographic technique are the keys to making a radiograph easily interpretable. Standard projections of different body regions are recommended, but special positioning (described later) can be used to highlight a particular area that is normally superimposed over other structures, to visualize fractures tangentially, or to depict soft tissues normally not seen on a radiograph exposed to depict bony structures.

Standardized techniques for specific body parts produce consistent results. Each x-ray machine has specific settings that produce the best diagnostic images, and technique charts made specifically for each machine and imaging capture system are strongly recommended. Having stated this, exposure latitude (or overlap of diagnostic images from differing techniques) of CR or DR systems is much greater than for film-screen systems.

A guide light within the collimator box displays a light field on the patient that represents the area to be exposed by the primary x-ray beam. Superimposed cross hairs are often present to allow the beam to be centered. The collimator light must be recalibrated at regular intervals to make sure the light and primary beam match each other, because the collimator lead sheets and/or mirror reflecting the light may become malaligned with the x-ray beam.

Proper orientation of the x-ray tube to the imaging plate is very important. After the body part being imaged has been centered, the angle of the beam must be carefully observed and adjusted. The tube and x-ray cassette or detector should be parallel to each other, unless a special angled technique is being performed, because this will cause distortion and a lack of tangential imaging of joint spaces. Film focal distance (or distance from the x-ray tube to the film) should be standardized to create consistent images from each chosen technique, with the part of interest directly adjacent to the film. Magnification techniques, which increase patient film distance are possible, and actually decrease scatter radiation reaching the film that may degrade the image, but cause significant unsharpness, or penumbra, of the image, and will not be discussed further here. Lastly, collimation should be adjusted to exclude any areas outside of the primary area of interest.

Study-Specific Positioning

Image projections are named for the path of the x-ray beam. This is confounded by location in the limbs, for which cranial and caudal are used proximal to the carpus and tarsus, but dorsopalmar is used for carpus distally, and dorsoplantar is used for the tarsus distally. Each study should contain at least two orthogonal (90 degrees to each other) projections. This stems from the fact that radiographs are two-dimensional projections of three-dimensional anatomy. To place an object seen on one projection within the third dimension, a second view must be provided. Most commonly, this includes lateromedial and craniocaudal (dorsopalmar or dorsoplantar) projections. This may not always be possible because of anatomical restraints, such as in cervical spine, shoulder, thorax, or abdomen, or it may be performed with great difficulty in an anesthetized horse, such as a ventrodorsal pelvis.

Each projection should have a lead marker placed on the cassette. With distal limbs, this marker indicates which limb (right or left) is being imaged. The marker is usually placed laterally (on craniocaudal and oblique projections) or cranially/dorsally (on lateral projections) with respect to anatomy. Owner's name; horse's age, breed, and sex; exam date; and the hospital name should also be identified clearly.[3] Although digital procedures allow post-processing additions of positional labels, an integrated label used as the image is exposed prevents confusion in labeling a radiograph during the processing step. Labels are particularly important in the limbs distal to the carpus and tarsus, where anatomic differentiation of the lateral and medial surfaces is difficult or impossible.

Many studies require more than two orthogonal projections to provide sufficient information for correct diagnosis. For most studies, this includes oblique projections highlighting the surfaces perpendicular to the path of beam travel. If an angle is included, the degree of angulation refers to the immediately preceding directionality. For example, D45°LPMO means 45% from dorsal toward lateral oblique. See Figure 67-6 for an example of positioning for a dorsolateral, palmaromedial oblique (DLPMO) view of the carpus.

Table 67-1 includes standard radiographic projections for different areas of the equine patient. This is not intended to be an exhaustive reference for all projections that may be needed, but it represents a starting point from which to expand. Particular diseases that occur in each of these areas are covered in their respective chapters elsewhere in this text.

Contrast Studies

Contrast medium adds additional information to radiographic studies involving physiologic processes, or it highlights abnormal communications with the outside environment or between internal structures.

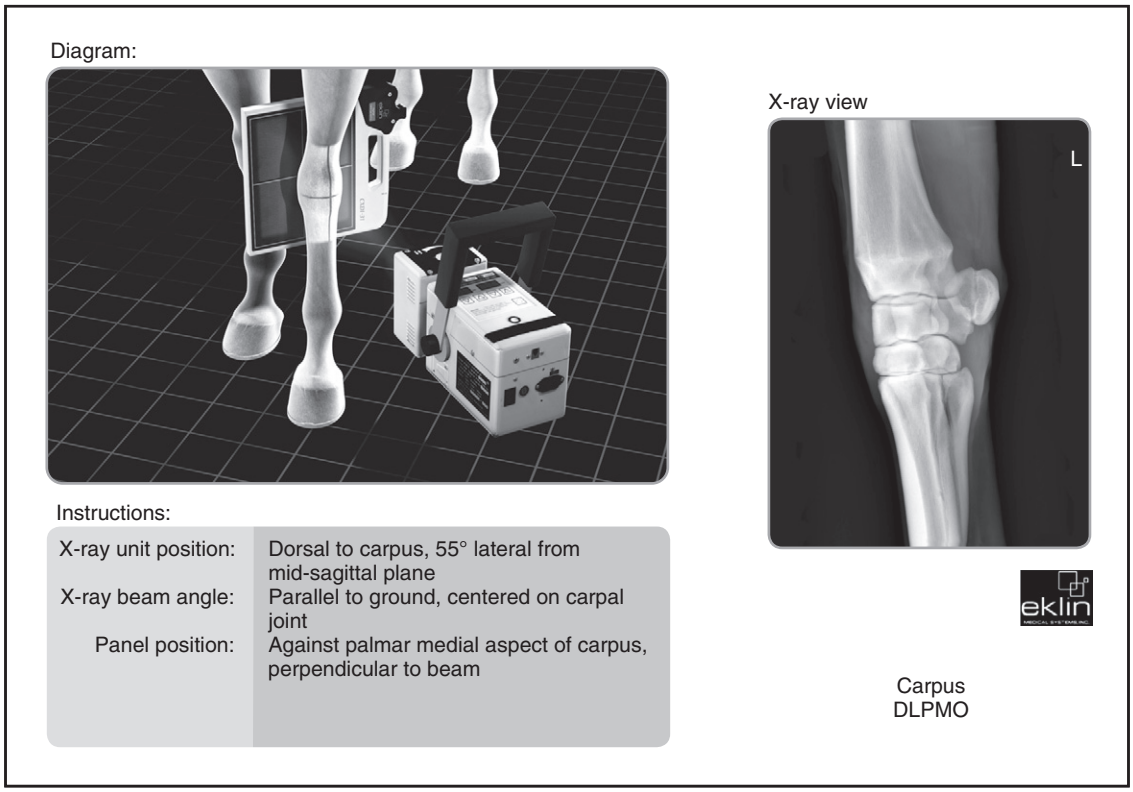

Figure 67-6. Graphic representation of tube and cassette positioning for a carpal 55 degrees dorsolateral palmaromedial oblique *(DLPMO)* projection. Not represented in this image is a holder for the cassette, preferably a metallic frame either supported by a stand or on a long handle that enables the holder to distance himself or herself from both the primary beam and the horse, which will produce scatter radiation. (Courtesy Sound-Eklin Medical Systems, Inc.)

TABLE 67-1. Standard Projections

Imaged Part	Projections	Additional	Considerations
Distal phalanx/ P3	1) Lateromedial 2) Proximal 60° dorsopalmar 3) Flexed proximal 60° D45°MPLO and D45°LPMO	1) Horizontal dorsopalmar 2) Lateromedial with markers placed along dorsal hoof wall or coronary band	Foot placed on radiolucent block, hoof cleaned and packed to remove air from frog, proximal 60-degree views may be taken in upright block (navicular block)
Coffin/DIP joint	See above	Alternate to flexed oblique: proximal 45° D45°LPMO and D45°MPLO	See above
Navicular/distal sesamoid	1) Lateromedial 2) Proximal 65° dorsopalmar 3) Flexed 45-70° (to cassette) palmaroproximal palmarodistal (skyline)		See above; skyline view must be as flexed as possible
Pastern/PIP joint	1) Lateromedial 2) Proximal 30° dorsopalmar	Proximal 30°, D45°LPMO and D45°MPLO	
Fetlock/MCP joint	See above, 3) Proximal 20° D45°LPMO and D45°MPLO	1) Flexed lateromedial, 2) Flexed D45°LPMO and D45°MPLO 3) Flexed dorsoproximal to dorsodistal (skyline)	
Cannon/MCII, III, IV	1) Lateromedial 2) Dorsopalmar 3) D45°LPMO and D45°MPLO	Special angled obliques to highlight a certain surface of MCIII

TABLE 67-1. Standard Projections—cont'd

Imaged Part	Projections	Additional	Considerations
Knee/carpus	1) Lateromedial 2) Dorsopalmar 3) D45°LPMO and D45°MPLO	1) Flexed lateromedial 2) Flexed dorsoproximal to dorsodistal (skyline): 35° distal row of carpal bones, 55° proximal row, and 85° distal radius	Very straight dorsopalmar must be obtained for angular limb deformity
Hock/tarsus	1) Lateromedial 2) Dorsopalmar 3) D35°LPMO and P35°LDMO	1) Flexed lateromedial 2) Flexed 65° proximal palmaroproximal palmarodistal (skyline)	Tube placed plantar is often safer than DMPLO
Stifle	1) Lateromedial 2) Caudolateral 45-60°craniomedial oblique	Flexed proximal 60-70° dorsoproximal dorsodistal (patellar skyline)	Sometimes difficult to position lateromedial, good sedation and effort necessary to place cassette
Elbow	1) Mediolateral 2) Craniocaudal		Leg extended to pull away from the thorax/other limb
Shoulder	1) Mediolateral 2) Cranial 45° medial caudolateral oblique		Leg extended to pull away from the thorax/other shoulder
Spine	Lateral centered on areas in succession	Lateral oblique views only if fracture suspected	Lead markers placed on skin can assist in identifying vertebral number
Pelvis	Ventrodorsal; if standing, 10-25° caudal	Lateral in foals, Miniature Horses only	Recumbent in anesthetized horses; if standing, heavily sedated with as much abduction of pelvic limbs as possible
Skull/teeth/nasal/sinuses	1) Lateral 2) Dorsoventral 3) Dorsal (maxilla) or ventral (mandible) 30° lateral obliques	1) Intraoral dorsoventral (maxilla) or ventrodorsal (mandible) 2) Lateral 45° ventral 30° rostrolateral caudomedial oblique for temporomandibular joint[40]	Intraoral views require excellent mouth gag/sedation
Thorax	Lateral views centered: 1) Cranioventral 2) Caudoventral 3) Caudodorsal (usually × 2) 4) If needed, craniodorsal	Ventrodorsal view in foals only	
Abdomen	Lateral views centered at periphery of abdomen, also centrally if a foal		Penetration centrally only in foals, periphery of abdomen in adults
Pre-purchase exam (AAEP and Keeneland Association[41])	Metacarpophalangeal joint: • Proximal 15° dorsopalmar • D30°LPMO • D30°MPLO • Lateromedial (flexed) Metatarsophalangeal joint: • Proximal 15° dorsoplantar • Proximal 15° D30°LPMO • Proximal 15° D30°MPLO • Lateromedial Carpus: • D35°LPMO • D25°MPLO • Lateromedial (flexed) Tarsus: • D65°MPLO • D10°LPMO • Lateromedial Stifle: • Mediolateral • Caudal 20° lateral craniomedial oblique		

AAEP, American Association of Equine Practitioners; *DIP,* distal interphalangeal; *DMPLO,* dorsomedial-palmarolateral oblique; *LDMO,* lateral dorsomedial oblique; *LPMO,* lateral palmaromedial oblique; *MC,* metacarpal; *MPLO,* medial palmarolateral oblique; *PIP,* proximal interphalangeal.

Three types of contrast agents are used. The simplest of these is gas, also called *negative contrast* medium, consisting of either room air or a specific gas such as carbon dioxide, which is added to spaces to separate them from the soft tissues around them. Carbon dioxide in particular, is used for a negative contrast study when wall integrity of a structure is questionable; its high solubility in the blood stream avoids rare air emboli complications from the high, insoluble nitrogen content of room air. Negative contrast studies involve intubation of the structure in question with insufflation with the desired gas, but they are rarely used in equine patients.

The two other types of contrast are considered types of *positive contrast,* meaning they appear as areas of increased opacity on radiographs. The first is barium sulfate suspension, used in gastrointestinal studies. This is usually prepared as a weight-per-volume (w/v) measurement of a certain gram weight of barium sulfate added to a volume of water. For example, a 60% w/v solution of barium sulfate is 60 g of barium sulfate with enough water added to make a total volume of 100 mL. Commercially prepared suspensions come in this fluid viscosity of 60% to 70% w/v, a more concentrated form as barium paste (typically 70% to 100% w/v), creams with even higher concentration, or tablets. Typically, the 60% suspension is appropriate for esophagram studies. For foals undergoing gastrointestinal contrast study, a full gastric volume of this concentration creates a large enough opacity to be overwhelming, and the suspension should be diluted. Concentration may also be represented as a weight-per-weight (w/w) suspension in which a weight of barium is added to a weight of water to obtain a predetermined total weight (e.g., a 20% w/w solution of barium sulfate would be 20 g of barium added to 80 g of water). See Table 67-2 for typical volumes and concentrations for contrast studies. Each of these studies should have survey films of the area of interest taken before administration of contrast medium for comparison.

Barium sulfate should never be used in areas outside of the gastrointestinal tract. Although it is inert, it causes large fibrotic and granulomatous reactions when it enters body cavities or is injected into fistulas. Its inertness, however, is an advantage when barium is accidentally aspirated into the airways.[30] Barium bronchograms were obtained for diagnostic studies, although they are performed less frequently now. With appropriate treatment for pneumonia, the barium is taken up by macrophages and eventually lymph nodes, which will remain radiopaque.[30,31]

The second type of positive radiographic contrast is *iodinated contrast*, used for the majority of intravenous, fistulogram, arthrogram, or myelogram studies. The contrast medium is provided either in ionic or non-ionic form. The ionic form of contrast dissociates into two osmotically active particles, one iodinated benzene ring anion and the second a cation, either sodium or meglumine, whereas the non-ionic form does not. Most forms of both types are hypertonic to blood, but the ionic form is much more so (approximately seven to eight times the osmolarity of blood). Because of the hypertonicity and dissociation to two charged particles of the ionic form, severe side effects secondary to their use may be seen. Most especially, seizures and death may occur when even a small amount is used in the central nervous system (as with myelograms); seizures are still reported with non-ionic forms in myelograms but are usually focal or self-limiting. Ionic iodinated contrast medium may result in severe pulmonary edema and possibly death when aspirated into the alveolar space, and cardiovascular shock when used intravenously in severely dehydrated patients. Intravenous side effects are less pertinent for equine patients than small animals but should be noted if used in foals. The ionic forms, however, are much cheaper than the non-ionic forms, and are safe for use in areas in which fluid influx or efflux is not a life-threatening issue, such as arthrograms or fistulograms, or in properly hydrated foals for intravenous studies. Other notable side effects that occur in other species but have not been reported in horses are acute renal toxicity or hypersensitivity reactions to intravenous contrast.[30]

Radiation Safety

The easiest way to decrease human handler radiation dose is to distance the handler from the animal and radiograph being taken. This is related to the inverse squares law, which states that dose received by an individual is inversely proportional to the square of the distance from the source. In other words, if a person doubles their distance from the tube, the dose they receive is four times less than the original dose; triple the distance, nine times less dose.[32]

Human dose may also be reduced through passive patient restraint with sedation, stocks and restraint, and devices for holding cassettes or image panels while humans are in another room. If a human is in the same room as the animal, proper dosimeter monitoring must be worn.

Lead aprons, thyroid shields, and gloves decrease scatter doses, but do *not* protect handlers from radiation from the primary beam or block all of the scattered radiation. Gloves containing a 0.5-mm lead equivalent only block 88% of 75 kVp technique and only 75% of 100 kVp technique from the primary beam.[33] Aprons containing a 0.25-mm lead equivalent attenuate only 90% of scatter radiation for tube voltages less than 100 kVp. The shielding efficiency increases to 99% with 0.5-mm thickness.[1] Film badges monitor whole-body, thyroid, or gonadal doses of radiation and should be worn outside of protective lead gear. Distal limbs are among the least radiosensitive tissues, and are monitored separately with ring badges, but dose over time can add up quickly with repeated exposures, and effects, including carcinogenesis, often have a very delayed time to onset.[32]

Collimation is another easy way to decrease exposure. Not only does proper collimation decrease the dose to the patient, it reduces scatter radiation produced by tissues outside the area of interest and dose to the handlers. This is particularly relevant with high-radiation techniques used for very thick body parts such as the thorax, abdomen, or pelvis, but it can also occur with stifle or cervical spine radiographs. Scatter significantly degrades the image and adds to human doses. Cavalier treatment of radiation safety is a potentially dangerous practice to undertake; we urge each individual involved in taking radiographs to take avid interest in decreasing their own and their patients' exposure.

IMAGE INTERPRETATION

Initial evaluation of a radiographic image should focus on technical issues. It should be determined if the image is centered on the area of interest, whether it is exposed properly, and whether projections taken are sufficient for diagnosis or if more-specific projections are needed. Image interpretation should proceed in

TABLE 67-2. Contrast Study Parameters

Study Performed	Indications	Contrast and Dose	Study Specifics
Esophagraphy[30]	Dysphagia; regurgitation; suspected esophageal foreign body, stricture, or diverticulum; recurrent aspiration pneumonia	Barium sulfate suspension 60% w/v, orally, volume dependent upon patient swallowing; *not to be used if esophageal perforation is suspected*, use ionic iodinated contrast	Liquid only first phase, mixed with grain second phase, watch with fluoroscopy or take lateral cervical and thoracic films 5-15 sec after swallowing, respectively
Upper gastrointestinal (foal only)[30]	Lack of defecation, suspected intestinal obstruction, suspected gastric ulceration	5 mL/kg 30% w/v barium sulfate suspension through nasogastric tube; *not to be used if gastrointestinal perforation is suspected*, use iodinated contrast (ionic form not recommended if patient is dehydrated)	4-12 h fast prep, (4 h if <2 weeks old), standing right lateral, recumbent bilateral and ventrodorsal films, survey before contrast, then films at time 0, 30 min, 2 h, then 2-h intervals until contrast reaches small colon
Barium colonogram (foal only)[30]	Suspected rectal stricture, sectional hypoplasia, or mass	20% w/v barium sulfate suspension, volume is patient specific but should begin at approximately 5-10 mL/kg; *not to be used if rectal perforation is suspected*	Clean rectum of as much feces as possible, administer contrast through rubber tube with catheter tip or largest Foley available (up to 26 F available)
Dacryocystorhinography[42]	Chronic epiphora, orbital trauma, chronic nonresponsive conjunctivitis, proptosis of third eyelid	Nondiluted ionic or non-ionic iodinated contrast, approximately 5 mL per injection, or until contrast is seen at the medial canthus of eye	Catheterize nasal puncta, take film as injecting the contrast (or duct may not be uniformly filled), *nasolacrimal duct better resolved with CT, but large abnormalities can be seen on radiographs*
Sialography[30]	Swelling or tubular structure suspected associated with salivary system, abnormal ptyalism or discharge localized to a single salivary duct	Nondiluted ionic or non-ionic iodinated contrast, 20 mL/kg, or until sufficient back pressure is felt or contrast leaks around catheter	Catheterize the salivary duct of interest, preferably watched as injected with fluoroscopy, but orthogonal views taken after injection are an alternative, films repeated if complete filling is not seen, *iatrogenic rupture of duct and/or salivary gland are a potential complication*
Fistulography[43]	Draining tract, suspected sequestrum	Nondiluted ionic or non-ionic iodinated contrast, volume is study specific, injected until contrast begins to leak around catheter or sufficient back pressure	Catheterize fistula with Foley if cavity underneath is large enough (to prevent external leakage of contrast), red rubber tube, or intravenous catheter
Arthrography/ bursography/ tenography[43-45]	Lameness isolated to a joint with suspected cartilage or soft tissue abnormalities, foot lameness (navicular bursography), tendon effusion	Nondiluted non-ionic iodinated contrast for bursa or tendon sheath, diluted 1:1 with saline for arthrogram, volume is joint or bursa specific; distend the structure in question until slightly distended and mild back pressure is felt	Limb must be clipped and aseptically prepped, ensure placement in the proper cavity by aspirating joint or bursal fluid or taking a scout radiograph after small amount of contrast injection, better filling of joints obtained if joint is put through range of motion after injection
Selective angiography[46-49]	Laminitis, lameness isolated to the foot, trauma with suspected vascular disruption to foot	Nondiluted (for radiography) non-ionic iodinated contrast injected into specified artery or vein (see right), continuous infusion with pressure injector or single 20 mL injection, 1:1 diluted for CT	Performed under general anesthesia or heavy sedation with local nerve block, selective common digital artery or medial or lateral palmar digital vein infusion for laminitis, and medial palmar artery infusion reported for CT
Excretory urography (foal only)[50]	Suspected ectopic ureters, suspected uroretroperitoneum or peritoneum, renal azotemia	880 mg I/kg of ionic or non-ionic iodinated contrast given intravenously as a rapid bolus; *this should not be done in dehydrated patients, and may cause contrast-induced nephrotoxicity*	For ectopic ureters, prep bladder with pneumocystogram through urethral catheter, take films at time of injection, 5 min, 15 min, and 30 min post injection, more films may be required if poor renal function

a consistent manner, either in a directional fashion from left to right, top to bottom, skeletal then soft tissue structures, and so on, so that all areas of a radiograph are observed and structures or changes are not overlooked. It is very easy to prematurely terminate radiographic interpretation when an obvious lesion is found, missing more obscure lesions that may change or modify a diagnosis or clinical approach to a patient.

The scales of gray from black to white on a radiograph are based upon differential attenuation of x-rays by different tissues and matter. The five basic radiographic opacities are, in ascending order from black to white: gas, fat, soft tissue/fluid, bone/mineral, and metal. This is also the order of x-ray attenuation from least to greatest. Areas on a radiograph are black because they have been exposed to radiation or light; white because they have not. It is important to note that fluid and soft tissue have the same radiographic opacity and cannot be differentiated on radiographs. If no intervening different-opacity object lies between objects of the same opacity, their margins are lost; this is termed silhouetting or border effacement. Summation causes opacities to occasionally be confusing, such as when gas summates with soft tissue, making it appear similar to fat opacity. Orthogonal or additional oblique projections may help sort out this phenomenon. Inherent large changes in the contrast of adjacent tissue, such as mineral (bone), metallic implants, or gas add the most meaningful and interpretable information to radiographs.

Recognition of normal structures is a highly important step; this may require broad experience in looking at multiple radiographs or referencing a textbook or scientific article. When normal structures and opacities are identified, abnormal ones may be recognized. It is important to note that although a consistent pattern should be followed for each type of study, and recognizing abnormalities is based on pattern recognition by the brain, taking away a pattern may make lesions easier to see. The most obvious but not only example of this occurs with rib lesions (Figure 67-7). The eye is accustomed to looking *through* the ribs on most thoracic radiographs; by turning the image upside down, pattern recognition is changed, and the ribs tend to stand out better. Similar situations may be reproduced with windowing and leveling (or hot-lighting) an image to see soft tissues better on orthopedic films.

Certain unique principles apply to equine radiographic interpretation. The bulk of a patient may not allow penetration or positioning for a view, dictating the use of another modality. The weight-bearing status of most appendicular films allows assessment of joint spaces, most commonly narrowing that indicates loss of articular cartilage. The joint space of non–weight-bearing radiographs should be interpreted with caution because the joint space may be made to appear artificially wide or narrow. Gravity is also responsible for distinct fluid-lines in air-filled cavities. The sheer mass of mineral opacity in most bones causes nondisplaced fractures to be masked unless they are very precisely tangential to the fracture line; this may cause need for a multitude of only slightly differently angled projections through the bone, or a "skyline" view. The precise opposite for nondisplaced condylar fractures exists: a view perpendicular to the fracture line is needed. External debris is often present, mimicking lesions. Therefore extra care must be taken to remove this before the study or to identify it as artifactual.

However, there are certain principles of radiographic changes that apply across species differences. Here are a few important facts:

- Sharp bone margins equals acute disease process; rounded equals subacute to chronic and likely inactive; irregular/indistinct equals active
- Bony lysis equals aggressive processes, typically osteolysis/osteomyelitis, but also neoplasia or necrosis; well-defined rounded lucent regions in bone may represent cysts
- Nondisplaced stress fractures may become more lucent before healing because of bone remodeling. This means some fractures may not be evident on films until 5 to 10 days after the event.[34]
- Enthesiophytes or osteophytes represent at least 3 weeks of disease process.[34]
- A lesion should be seen on more than one projection to increase confidence that it is real and not artifactual.

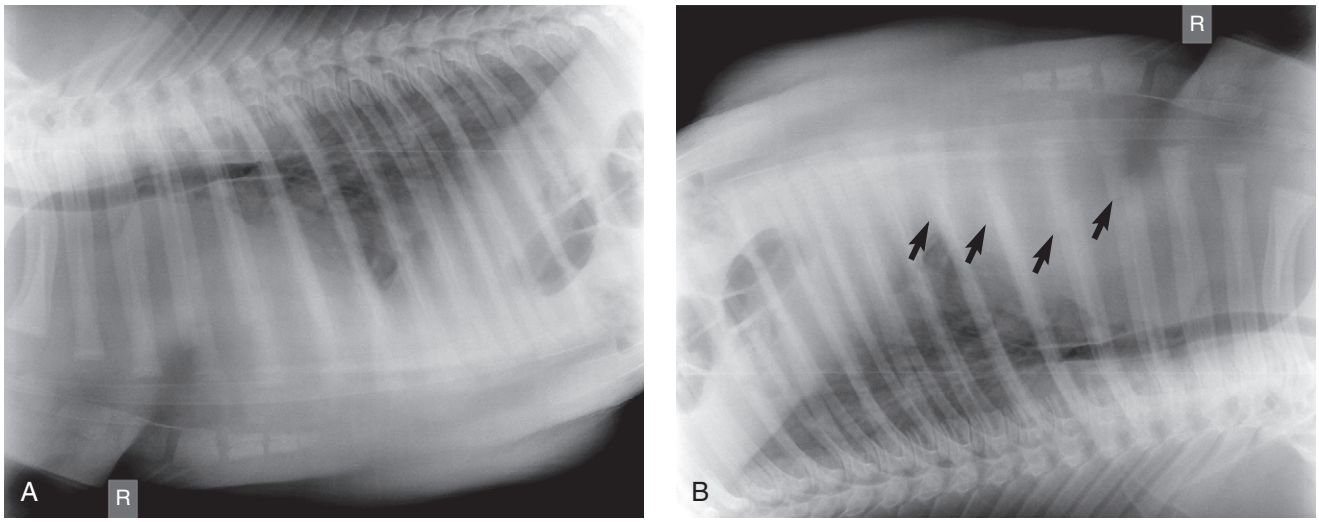

Figure 67-7. A, A traditionally positioned foal thorax view; **B,** The image is flipped upside down, which may depict the ribs more prominent to the viewer after normal positioning pattern is removed. The *black arrows* denote the minimally to nondisplaced rib fractures.

- Radiographs should be interpreted blinded to history or what you *should* find. This will avoid finding "lesions" that fit diagnoses already reached before the examination.

ARTIFACTS

Recognition of radiographic artifacts is important for proper image interpretation, and knowledge of their cause is necessary to facilitate correction and prevent recurrence. Artifacts occur with conventional screen-film radiography and digital radiographic systems. Although some artifacts are common to both modalities, each has unique artifacts as well. A complete review of all radiographic artifacts is beyond the scope of this text, but the most important and common artifacts for screen-film systems and digital radiography systems are discussed later.

Radiographic Screen-Film Systems

Radiographic screen-film systems have a narrow range of appropriate x-ray exposures, with inappropriate technique settings commonly resulting in over- or underexposure. Overexposure occurs when kVp, mAs, or both are too high and results in an image that is generally too dark. This artifact may be corrected by decreasing the mAs by one half or kVp by 10% to 15%. If the resultant image is still overexposed after this correction, the same magnitude correction is applied and imaging is repeated. With underexposure, the resultant image is too light and exposure techniques must be increased (typically by doubling mAs or increasing kVp by 10% to 15%).

The use of grids, though useful to reduce scatter radiation from reaching the film or plate, can also introduce artifact to an image. Particularly the use of focused grids, misplacement from the center of the beam, angling, or using the grid upside-down causes significant artifacts, seen as white lines that travel in a parallel fashion (or grid fashion if the grid is a cross grid) across the image (Figure 67-8).[1,2]

Figure 67-8. *White lines* travel across the image from a decentered grid. If lines occur in a regular, very closely apposed fashion, grids are usually the culprit. Note the *irregular white line* along the upper right side of the image, representing hair in the cassette, as well.

Motion artifact is a common problem that occurs with both film-screen and digital radiography of the equine patient. This artifact is recognized by blurry, indistinct anatomic borders on the resultant radiographic image. The patient's motion during the radiographic exposure is the most common culprit; however, motion of the x-ray tube, particularly if a portable unit is held by hand, can result in identical artifact appearance. Risk of this artifact is greater when examining thicker body parts because mAs is higher and therefore exposure time is longer. Use of appropriate sedation protocols (to minimize patient motion), use of a stand to stabilize the x-ray tube (to minimize tube motion), and using the lowest mAs possible (to reduce exposure time) can all help resolve this artifact.

Radiographic film and intensifying screens are easily damaged with inappropriate handling. Scratches on film remove emulsion and usually result in well-defined white lines. Scratches on an intensifying screen cause insufficient light to be generated, resulting in well-defined white lines on the film where it was not completely exposed.[35] Scratched screen artifact can be differentiated from scratched film by touching the radiographic film. With a film scratch, a divot or physical defect can be felt in the emulsion, whereas with a scratched screen, unexposed emulsion remains on the film (no defect is felt).

Dirt or debris within the radiographic cassette between the intensifying screen and film blocks light emitted from the radiographic screens from exposing the film. This results in abrupt white lines on the radiographic image, which corresponds to the shape of the debris. This can appear similar to scratches on film or a screen, but it may vary in position on subsequent images.[35] Radiographic cassettes and screens should be regularly cleaned using specialized screen-cleaning solution. Harsh cleaning agents may result in iatrogenic removal of screen phosphors.

Inappropriate processing is a common cause of many artifacts, which may occur during the development, fixing, or washing steps. Manufacturer recommendations regarding frequency of chemical replenishment should be strictly followed. Weak chemicals or inappropriate chemical temperatures may result in incomplete development (black areas of film are gray) or fixation (film the cloudiness and color of the emulsion) and cause many problems with image quality. If the wash step is incomplete, fixer material remains on the radiographic film, causing a brown image and characteristic sulfur smell.

Digital Radiography Systems

Digital radiography eliminates problems associated with handling and film processing, but its advent introduces many unique artifacts.[36] Because of their wide dynamic range, digital radiography units can produce high-quality diagnostic images over a larger variation in x-ray exposure techniques than conventional screen-film radiography, but underexposure and overexposure can still occur. With very low exposure settings, the digital image is grainy or pixelated, with low signal-to-background noise ratio. This artifact is properly called *quantum mottle* and can render subtle abnormalities inapparent.[37] Correction requires increasing radiographic exposure settings, typically by doubling mAs or increasing kVp by 10% to 15%.

Digital radiographic systems are more tolerant of inappropriately high exposure settings than screen-film technology, but overexposure artifacts can occur. At very high techniques, areas of the image become completely black and devoid of visible anatomy, a phenomenon called *clipping* (Figure 67-9).[36] This is usually first appreciated at the thinnest or least dense portion

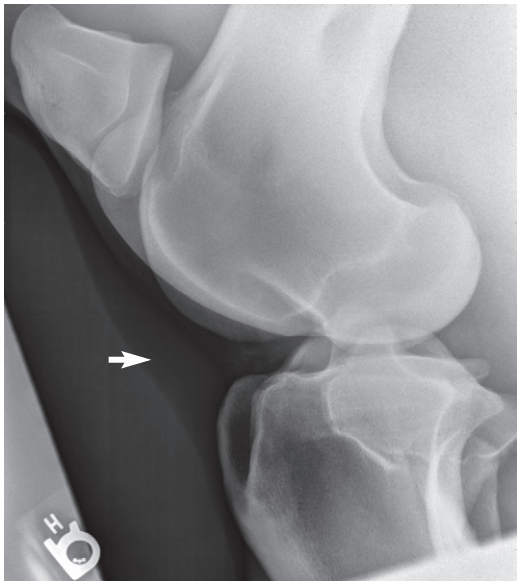

Figure 67-9. Clipping artifact with a digital radiography system. The soft tissues cranial to the stifle joint are rendered black *(indicated by arrows)* from overexposure in this region. Note that the adjacent anatomy is normally displayed and the junction with the clipped area is abrupt.

Figure 67-10. Dirty light guide artifact with a computed radiography (CR) system. Two parallel white lines *(arrow)* seen along the right side of the image are caused by debris on the light guide within the CR image processor.

of the patient, and it encompasses larger areas of the image with higher exposure settings.

Digital image processing algorithms inherent to digital radiography units can introduce imaging errors. A process called *unsharp masking* is frequently employed to maintain well-defined anatomical margins on digital images. The imaging computer may perform this process routinely at the time of initial image display without the clinician's knowledge. This processing step usually enhances the digital image, but at very high contrast margins (such as along the margin of a metallic plate), it may artifactually result in a radiolucent halo around the high-density object, simulating implant loosening or infection.[38] This artifact (called *Uberschwinger, rebound,* or *halation* artifact) may be subtle and visible only on close inspection. The development of newer processing software algorithms has reduced or eliminated this artifact, but it may be especially prominent with older imaging systems. Disabling unsharp masking or using an improved processing algorithm (if one is provided by the particular manufacturer) eliminates this artifact.

Dirt or debris may become adherent to the PSP plate in a CR system. During image readout, light emitted by the plate is not collected by the image processor, resulting in a white defect on the image corresponding to the location of the debris.[39] The appearance of this artifact is similar to that generated when debris is present within the cassette with conventional screen-film radiography. Cleaning the PSP plate (using special CR plate-cleaning solution) and interior of the image processor corrects this artifact. Debris may also become lodged on the light guide, the component that collects light emitted by the PSP plate when it is scanned by the laser within the processor (Figure 67-10). This results in a straight, linear white streak, which usually extends from one end of the image to the other in the direction of light guide movement. This is corrected by cleaning the light guide within the image processor.

After PSP plate readout within the digitizer machine, a faint, latent image remains, which the digitizer machine automatically erases by exposure to very bright light. If the original image is severely overexposed or there is an error in the erasure step, the latent image may not be completely eliminated.[39] When that PSP plate is next exposed during radiography of a patient, the remaining latent image may be superimposed on the current patient's anatomy. This results in a double image, which may be very similar to that produced during a double exposure. This artifact can be very subtle and may mimic pathology. If noted, this artifact can be corrected by processing the PSP plate again within the digitizer machine.

CHAPTER
68

Ultrasonography

Anthony P. Pease and Joana Chaby L.S. Coelho

Diagnostic ultrasonography has revolutionized the quality of medicine for the equine patient. In the last several years, ultrasound machines have become more portable as well as more affordable, and therefore they are more widely available to equine practitioners. The improvements in battery packs and laptop designs have made ultrasonography a convenient modality to use stall-side as well as in the field. Ultrasonography is the only modality that provides real-time evaluation of both soft tissue and, to a limited extent, bone of horses. The purpose of this chapter is to describe how ultrasound produces diagnostic images and explain the indications for equine ultrasonography.

PHYSICS OF ULTRASOUND

Diagnostic ultrasound uses high-frequency sound waves that are outside of the audible range of human hearing to penetrate tissue and reflect back to the transducer, which generates an image. This is accomplished with the use of piezoelectric crystals. These crystals have a unique property that allows them to generate sound when stimulated by an electrical current. Conversely, they produce an electrical current when interacted by sound waves. This electrical current is then converted to a digital image (Figure 68-1).

Various types of ultrasound transducers are available including linear, curvilinear, and phased-array transducers. A common

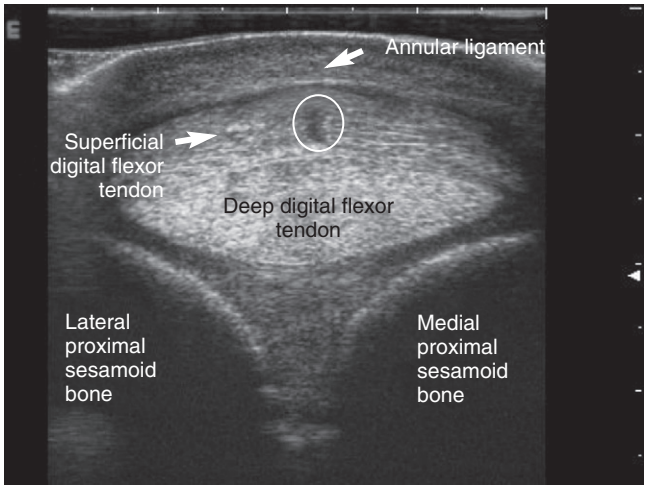

Figure 68-1. Ultrasonography image of the palmar aspect of the metacarpophalangeal joint. Using sound waves, ultrasound provides an image of the ligaments as hyperechoic *(bright)* regions because they reflect sound. Alternatively, bone absorbs sound and therefore only the margin of the bone is seen as a hyperechoic structure with an acoustic shadow seen deep to the bone because of the absorbed sound. A hypoechoic *(dark)* region can be seen within the superficial digital flexor tendon *(circle)*. This loss of the linear fiber pattern represents a tear, where less sound is reflected because of the presence of fluid.

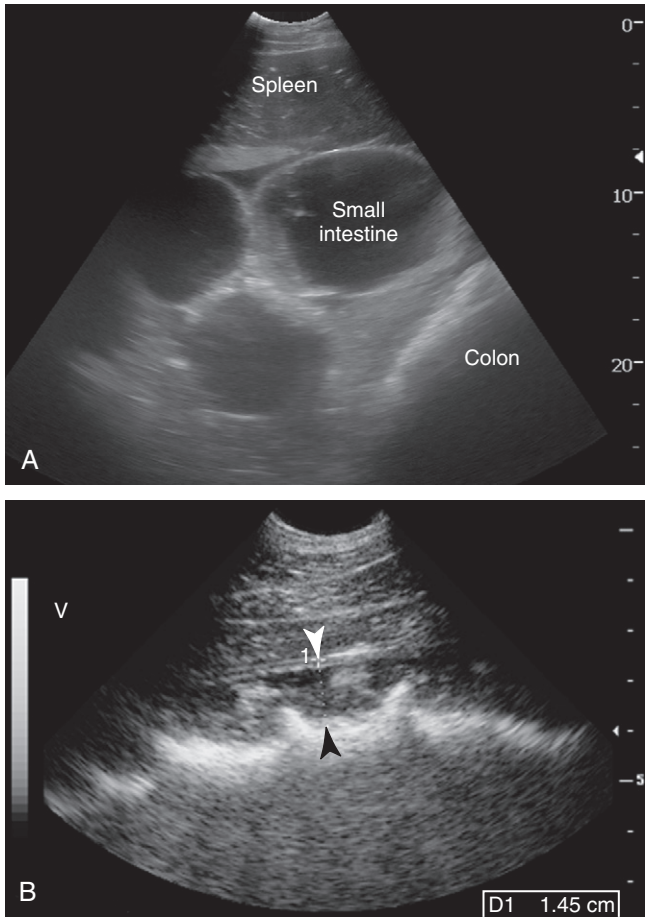

Figure 68-2. A, Image of an obstructed small intestine of a horse using a 4-MHz probe imaging at 20-cm depth. Note the small intestine can be seen in its entirity, but a detailed examination of the wall or evaluation of the spleen seen in the near field is limited. **B,** A colon with a 180-degree volvulus imaged with an 8-MHz probe at 3-cm depth. With the increased resolution and decreased depth, individual wall layers are not seen due to edema rather than poor resolution. The wall has an increased thickness (indicated between the *arrowheads*). However, with the increased resolution, the amount of the abdomen available for review is decreased.

term used to describe a transducer is *sector;* however, this only refers to a transducer that creates a trapezoid shaped image, which all transducers (even the linear transducer with a process called virtual convexing) can do. A *linear transducer* is flat and narrow with approximately 4 cm of scanning surface. The piezoelectric crystals are organized in a linear fashion and emit sound in succession. This characteristic provides the highest resolution, but it makes linear transducers not as useful to image rapidly moving structures (like the heart). Linear transducers are indicated for imaging tendons and ligaments. Specialized linear transducers have the cord attached to the end of the length of the probe to allow transrectal imaging. These transducers can also be used for tendon and ligament imaging as well as imaging the kidneys, left adrenal gland, small intestine, urinary bladder, and uterus. A *curvilinear transducer* is similar to the linear transducer except it is slightly convex, providing a larger field of view. This increased field of view is associated with a slight loss of resolution. A curvilinear transducer is indicated for general abdominal imaging, primarily focusing on the gastrointestinal tract. Because the gastrointestinal tract is superficial, a high-frequency microconvex transducer is used and deeper structures like the liver, spleen, and kidneys are evaluated with the lower-frequency, macroconvex transducers. A *phased-array transducer* has a relatively small rectangular, flat surface. In these transducers, the piezoelectric crystals are arranged in a rectangular shape and send out all the sound waves simultaneously. This allows imaging of rapidly moving structures (like the heart or vessels when using color flow Doppler), and it produces higher-contrast (black and white) images but with less resolution compared to the linear and curvilinear transducers. The flat surface of these probes makes it ideal for imaging between the ribs.

Ultrasound transducers are available in multiple frequencies ranging from 1 MHz to 18 MHz. Image resolution and depth are related to the frequency used. Lower frequencies allow greater sound penetration (deeper structures can be imaged) but offer poorer resolution, whereas higher-frequency sound waves offer greater resolution with decreased image depth. The highest frequency that allows adequate image depth should be chosen to guarantee the best image quality possible. These multifrequency transducers produce the best image at the highest frequency listed and produce a poorer image at the lower frequencies (Figure 68-2).

The high-frequency sound waves used during a diagnostic ultrasound examination are able to penetrate soft tissue and fluid readily but cannot penetrate air and bone. The acoustic impedance of tissues causes these differences in sound penetration. *Acoustic impedance* is the product of a specific tissue's density and the velocity of the sound within that tissue. Sound propagates as a wave based on vibration of the particles in the medium that it is traveling through. This vibration causes compression and rarefaction of the adjacent molecule or cell to propagate the wave over a distance. Because air has molecules that are relatively far apart, sound travels relatively slowly

(approximately 330 m/sec) in air. In soft tissue, the molecules are closer together, which allows sound to travel faster (1540 m/sec). It is this difference in the speed of sound through various tissues that provides a reflective quality to produce an image with ultrasound.

The ultrasound wave travels from the transducer into the tissue and it is reflected from the interfaces between different tissues based on the acoustic impedance of the adjacent tissues. Part of the reflected sound is transmitted through the tissues and received back by the transducers and a portion of the sound is refracted and lost. The strength of the reflective sound is displayed using a gray scale, where black indicates that no sound is reflected and white indicates that a large amount of the sound is reflected. The amount of reflected ultrasound received by the probe depends on the *angle of incidence* (the angle that the sound wave interacts with a structure) of the ultrasound beam transmitted by the probe. Ideally, the transmitted ultrasound beam is oriented perpendicularly to the imaged structure. When the ultrasound beam is not perpendicular to a structure or portion of a structure (such as a tendon), a portion of the reflected ultrasound will be off-angle and will not return to the transducer. As a consequence, a darker (hypoechoic) area will be seen in the image. Thus, during scanning it is essential to maintain the ultrasound beam as perpendicular as possible to the structure being imaged. The appearance of darker (hypoechoic) areas in the image that result from the ultrasound beam not being perpendicular to the structure in question is designated *anisotropism* or *off-normal incidence*. This is especially common when imaging tendons and ligaments. Making sure that the ultrasound beam is perpendicular to these structures can be accomplished by repositioning the probe, moving it closer to the tendon or ligament edges, and by slowly moving the probe in different angles while scanning.

The ultrasound beam that is transmitted by an individual crystal or transducer element has a specific width called *lateral resolution*. *Lateral spatial resolution* is the capacity of the ultrasound to distinguish two points adjacent to each other as separate structures in a direction perpendicular to the beam (along the length of the ultrasound beam). In addition to the beam's inherent width, acoustic principles can be used to narrow the beam further and therefore optimize lateral resolution. The focal point (or focus) controls this optimization of the beam and can be positioned by the operator at any depth level of the image. The ultrasound beam is the narrowest at or immediately above the focal point, which results in optimized lateral resolution at this level. Deeper to the focal point, the ultrasound beam exponentially diverges and therefore the lateral resolution becomes progressively inferior. *Axial spatial resolution* refers to the capability to differentiate two points adjacent to each other as separate structures parallel to the beam (along the width of the ultrasound beam). Axial resolution is determined by the sound wavelength and, hence, by the frequency chosen. Higher sound frequency corresponds to shorter wavelengths and thus better axial resolution. In general, axial resolution is superior to lateral resolution.

After the ultrasound transducer has sent and received a signal, the information needs to be presented on the screen. For any given image, sound can travel through fat, soft tissue, muscle, fluid, blood, and skin. Given that different tissues have different acoustic impedances (the speed that sound travels through the different tissues), the ultrasound image will reflect each tissue type in a different shade of gray on the screen. The depth of a specific structure is then calculated based on the amount of time it takes for the transmitted ultrasound beam to be reflected and received back by the probe. The ultrasound travel time is calculated assuming that sound travels at the same velocity through all tissues. Because soft tissue (versus air or bone) is most abundant in the body, the speed of sound in soft tissues (1540 m/sec) is used as the standard velocity of sound to calculate the depth of ultrasound images.

Knowing how an ultrasound image is produced is the first step to understanding the terminology used in the course of ultrasound: hyperechoic, hypoechoic, isoechoic, and anechoic. All of these terms, except for anechoic (no echoes), are a comparison. Hyperechoic means that the structure is brighter than another structure (preferably on the same image). Hypoechoic means darker than another structure and isoechoic means the structure has the same echogenicity of another structure. This relative echogenicity is important, especially in the abdomen or in tendon lesions to provide a basis for re-evaluation.

Advanced imaging software for ultrasound is also available, such as harmonic imaging, compound imaging, and extended field of view. *Harmonic imaging* can be used to produce a clearer image by reducing artifacts. This requires a specialized probe, but it generates an image from a fundamental frequency that is sent from the transducer. When this frequency interacts with an organ, it creates a resonance frequency that is twice the fundamental frequency. The benefit of this is that the resonance frequency that is used to generate the image is relatively high, giving better resolution, and only travels through the body once, so it is less prone to artifacts. Harmonics can reduce superficial artifacts (e.g., superficial reverberation) as well as side-lobe artifacts, which are produced by weaker sounds that leave the transducer in a direction different from the main beam. *Compound imaging* is the capability to use ultrasound waves sent from multiple angles to evaluate the same region. This is intended to reduce artifacts and give a much more detailed view of a structure, although it is susceptible to blurring with motion. *Extended field of view* allows a complete tendon to be imaged or provides the capability to image a structure or lesion that is larger than the field of view obtained by a given transducer. Three-dimensional imaging and contrast medium ultrasound imaging is also available, but at this time it has very limited use in the equine patient.

ULTRASOUND APPLICATIONS

Because of the noninvasive nature of ultrasound, the transducer can be used on the skin surface, transrectally, intraoperatively, and even endoscopically to evaluate any region of the horse it contacts. Most imaging has been centered on the musculoskeletal system, but abdominal, thoracic, cardiac, and urogenital evaluation are also possible.

To prepare for most musculoskeletal examinations, the hair is clipped with a number 40 clipper blade. Alcohol and/or acoustic coupling gel are applied to establish contact between the skin surface and the probe. Generally, a high-frequency linear probe is used. The use of a stand-off pad is helpful for the evaluation of superficial structures, such as the palmar or plantar annular ligament and the superficial digital flexor tendon in the pastern region (Figure 68-3). A stand-off pad is a gelatin-based pad that is placed between the probe and the skin surface. By increasing the distance between the probe and

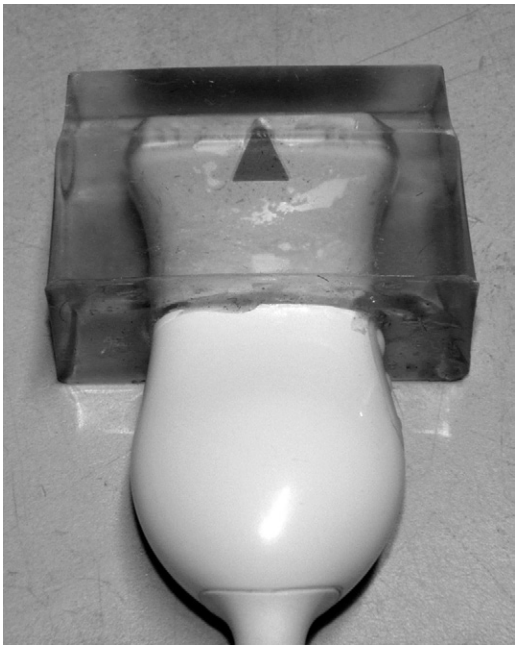

Figure 68-3. A 12-MHz linear ultrasound probe with a stand-off. Note that ultrasound gel is placed within the stand-off to eliminate any air that would be in between the probe and the stand-off. This gelatin pad allows a better contact with a curved surface, such as the equine limb.

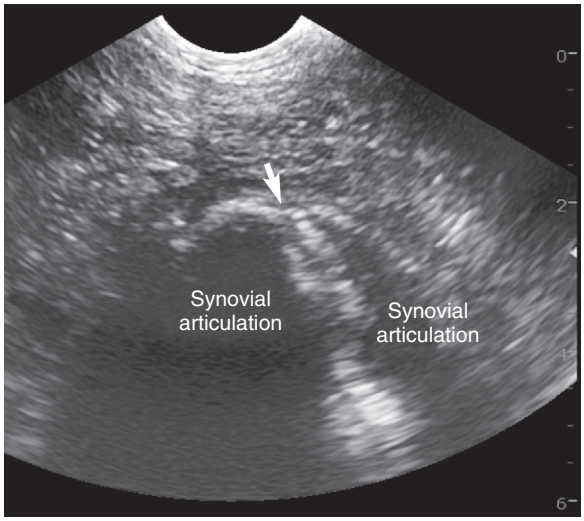

Figure 68-4. Image of the C5-C6 synovial articulation using an 8-MHz curvilinear transducer. The synovial articulations, also called *facets*, are labeled and the *arrow* indicates the joint space.

the skin surface, the near-field artifacts that are seen in the higher portion (near field) of the image are now at the level of the stand-off pad instead of being over the structure of interest.

Cervical Region

Equine cervical degenerative joint disease is a common source of pain and lack of flexibility of the neck in horses. Radiographs can be obtained to assess the proliferation of the synovial articular processes; however, oblique projections are generally needed to determine the side of the proliferation. Additionally, superimposition of the synovial articulations can make radiographic interpretation difficult.[1] High-output x-ray machines with a bucky system and grid are ideal for imaging the neck, although current digital radiographic systems can obtain high-quality images of the cervical regions with portable equipment. Ultrasonography can be used to evaluate the degree of osseous proliferations of the cervical articular facets as well as guide therapeutic injections of corticosteroids and/or hyaluronan into the cervical joint spaces.[2]

The procedure is performed with either a linear or microconvex curvilinear transducer. The cervical articulations from C2-C6 are relatively superficial (approximately 2 cm under the skin) with C6-C7 being slightly deeper (approximately 3 to 5 cm depending on the shoulder musculature). A high-frequency transducer that is greater than 7 MHz provides good resolution with adequate penetration. The transducer can be oriented either craniocaudal[2] or dorsoventral.[3] In my opinion, a dorsoventral approach provides easier landmarks of the cervical articular joint space (Figure 68-4).

In addition to the cervical vertebral bodies, work has been done using ultrasound to evaluate the equine larynx for laryngeal nerve paralysis, dorsal displacement of the soft palate, and inflammatory disease, such as arytenoid condritis.[4,5] Evaluation of the larynx does not require clipping, but a large volume of alcohol is needed to provide adequate contact between the transducer and the skin. During the examination, the hyoid apparatus, vocal folds, arytenoid cartilages, and the cricolateralis, cricopharyngeus and thyropharyngeus muscles can be seen, as well as occasionally the vocalis muscle and saccules of the lateral ventricles.

Shoulder Region

When evaluating the shoulder, one can examine the biceps brachii tendon, bicipital bursa, humeral tubercles, infraspinatus muscle, supraspinatus muscle, and glenohumeral joints. Generally, this examination is performed with the patient in a weight-bearing stance and with the shoulder region clipped as described previously. Ultrasound can be used to guide a needle into the bursal or shoulder joint space for diagnostic or therapeutic purposes.[6]

Evaluating the shoulder joint is generally performed using a microconvex curvilinear transducer. A linear transducer can be used; however, the large footprint of the transducer makes adequate contact with the skin difficult. A high-frequency tranducer should be used (greater than 7 MHz) because the depth that is being imaged is generally between 4 and 6 cm. Application of alcohol followed by acoustic coupling gel provides the best-quality image. As with all body parts, all images should be acquired and evaluated in both the transverse and longitudinal plane. Because of the curvilinear contour of the muscles and tendons in this region, care should be taken to maintain the ultrasound beam perpendicular to the imaged structure to avoid hypoechoic areas in the tendons as a result of anisotropism. Generally, imaging in both planes (transverse and longitudinal) as well as varying the angle of the transducer help to determine if a hypoechoic image persists (representing a lesion) or if it is just an artifact. True lesions should be present in all imaging planes.[7]

Metacarpal and Metatarsal Regions

The palmar metacarpal and plantar metatarsal regions are by far the most commonly examined with ultrasound. Ultrasonography provides valuable information on the tendon and ligaments in these regions. Core lesions can be seen on ultrasound as focal anechoic to hypoechoic regions. The structures normally evaluated in the metacarpal and metatarsal regions are the superficial and deep digital flexor tendons, the suspensory (interosseous) ligament, and the accessory ligament of the deep digital flexor tendon. The proximal suspensory ligament is the most challenging region to examine in the metacarpal and metatarsal regions.[8] Differences in the amount of fat and smooth muscle in the proximal aspect of the suspensory ligament result in normal variations in echogenicity and echotexture of this ligament between horses. Thus, comparison with the contralateral limb is important to confidently differentiate lesions from normal variants of the proximal suspensory ligament. When evaluating any structure in the metacarpal and metatarsal regions, comparison with the contralateral limb is important to evaluate structure size because some normal variation exists between horses. Using magnetic resonance imaging (MRI) as the gold standard for identifying proximal suspensory lesions, one abstract reported that ultrasound had 90% sensitivity and 8% specificity to detect the disease.[8]

Other difficulties of evaluating the metacarpal and metatarsal regions are (1) the narrow width of the palmar or plantar aspect of the limb, which results in difficulty in obtaining a truly perpendicular image of the suspensory ligament at its level of origin (especially in the pelvic limb) and at the level of the proximal sesamoid bones, and (2) a lack of a standard method to determine lesion's location. When imaging the metacarpal and metatarsal regions, ensure that images are obtained as perpendicular to the limb as possible based on the position of the hoof.

Two methods to identify the location of a lesion are (1) a zone method (each zone being about 4 cm in length) (Figure 68-5) or (2) a metric measuring method. In the thoracic limb, the *zone method* starts at the base of the accessory carpal bone or proximal aspect of the calcaneus and extends distad to the level of the ergot. These zones are 1A, 1B, 2A, 2B, 3A, 3B, and 3C. In the pelvic limb, there are nine zones starting at the proximal aspect of the calcaneus. In the pelvic limb, zone 3C is not used but rather zones 3A, 3B, 4A, 4B, and 4C. Zone 1A and 1B are generally used to observe the deep digital flexor tendon and

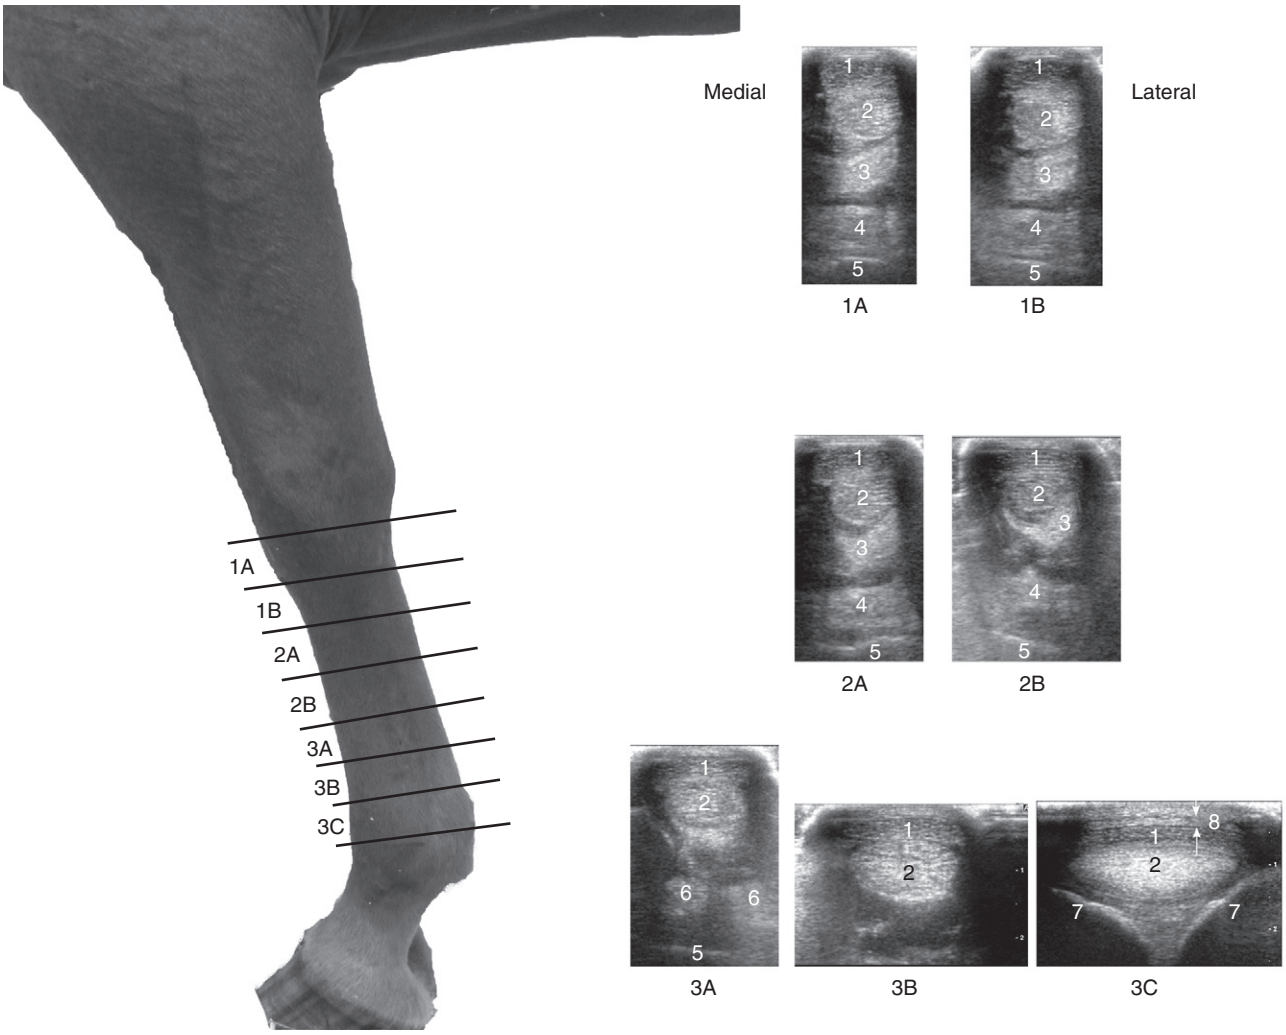

Figure 68-5. The zone method for localizing a lesion on the thoracic limb using ultrasound. *1,* Superficial digital flexor tendon; *2,* deep digital flexor tendon; *3,* distal check ligament; *4,* suspensory ligament; *5,* third metacarpal bone; *6,* extensor branches; *7,* proximal sesamoid bones; *8,* annular ligament.

sustentaculum tali of the pelvic limb. Zones 2A through 4C are similar to those seen in the thoracic limb. The metric measuring method uses a measuring stick or tape and lists the number of centimeters distal to the accessory carpal bone or distal to the tuber calcaneus (point of the hock) as reference to localize the lesion.

Distal Limb

Distal to the proximal sesamoid bones on the palmar and plantar surface of the proximal phalanges, the superficial and deep digital flexor tendons and distal sesamoidean ligaments (Figure 68-6) can be examined. The metacarpophalangeal and metatarsophalangeal (MCP/MTP or fetlock) joints, proximal interphalangeal (PIP, or pastern) and distal interphalangeal (DIP, or coffin) joints can also be imaged. When examining the distal sesamoidean ligaments, the attachment sites of the oblique sesamoidean ligaments can be evaluated as well as the straight sesamoidean ligament. The cruciate ligament of the proximal sesamoid bones can be seen, but are small compared to the other ligaments. In addition, the intersesamoidean ligament, the straight sesamoidean ligament, and the bilobed appearance of the deep digital flexor tendon can be identified. The palmar and plantar structures and collateral ligament of the DIP joint are best evaluated using a high-frequency transducer. A microconvex curvilinear transducer can be used without a stand-off to evaluate the MCP/MTP and PIP joints, though the best-quality images are with a high-frequency linear transducer and stand-off pad.

The collateral ligaments of the MCP/MTP and PIP joints can be evaluated along its full length. Each collateral ligament of the MCP/MTP joint is formed by two distinct structures, the long (more superficial) and short (deeper) collateral ligaments.[9] These two ligaments have slightly different orientation and therefore must be imaged individually. When both the long and the short collateral ligaments of the MCP/MTP joint are in the same image, one can appear more hypoechoic compared to the other because of the difference in fiber direction of the ligament and anisotropism. They will have a normal echogenicity when imaged individually or compared to the contralateral side. The proximal attachment of the collateral ligament of the DIP joint can also be evaluated ultrasonographically. The distal aspect of the collateral ligament of the DIP joint is encased by the hoof capsule, which prevents penetration of the ultrasound beam. The MCP/MTP, PIP, and DIP joints can also be evaluated for the presence of osseous fragments and increased synovial fluid.[10]

Pelvis and Coxofemoral Region

Evaluation of the pelvis with radiography has been described in the equine patient. However, because of the large amount of musculature and the superimposition of the contralateral side of the pelvis, high radiographic settings and oblique angles can make this evaluation difficult in the standing horse. General anesthesia can be used with a specialized table, but the risk of recovering a horse with a possible pelvic fracture makes the potential for exacerbating the fracture not worth the benefit of the diagnostic test.[11] However, ultrasonography is noninvasive and provides a real-time evaluation of the soft tissue and bone surface of the pelvis. A lower-frequency transducer is needed[11] (3 to 5 MHz, macroconvex curvilinear transducer) to obtain the depth necessary to evaluate the coxofemoral joint, whereas a higher-frequency transducer can be used to evaluate the ileum. Indications for pelvic ultrasonography include horses that have a suspected pelvic fracture, hematomas, joint distention, osteoarthritis, and coxofemoral joint luxation. The examination can be performed both transcutaneously and transrectally to evaluate the pelvis and coxofemoral joints[12] (Figure 68-7). Transcutaneous and transrectal ultrasound examination of the sacroiliac joint has been described but never reported.[13] The use of extended view imaging has also been described as a method to

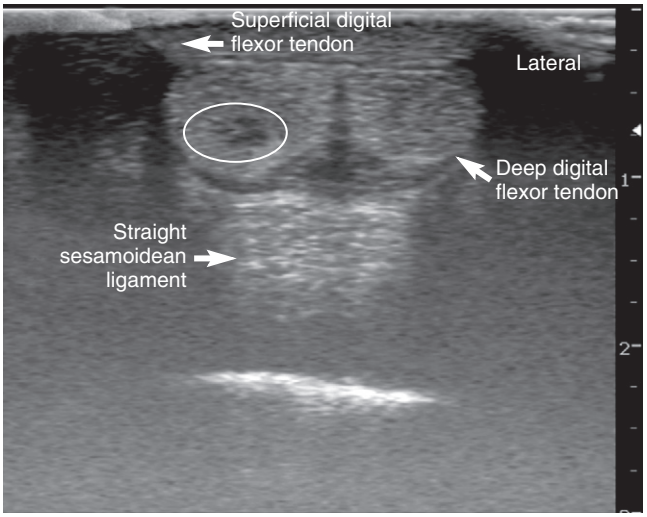

Figure 68-6. Ultrasonographic image of the palmar proximal interphalangeal (pastern) region with the straight sesamoidean ligament and deep and superficial digital flexor tendons identified. In the medial lobe of the deep digital flexor tendon, a focal lesion appears hypoechoic *(circle)*.

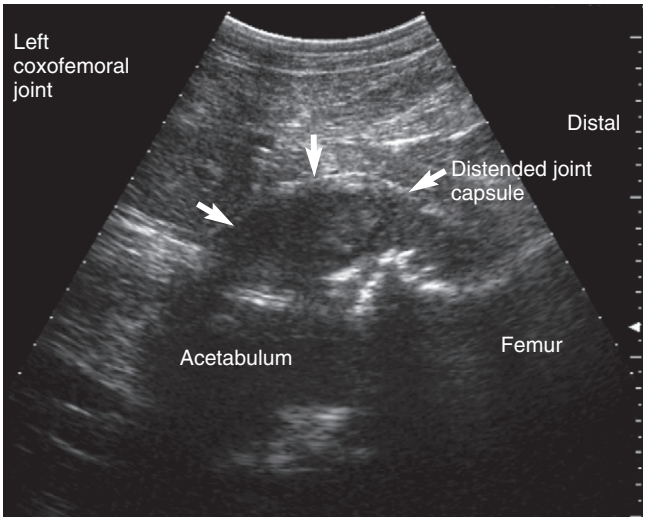

Figure 68-7. A transverse image of the left coxofemoral joint of an adult horse with pain localized to the hip. The large anechoic region is a distended joint capsule and the irregular margin of the femoral head is secondary to osteophyte formation. Ultrasound-guided centesis of the joint space was performed and synovial fluid was obtained that indicated degenerative change rather than infection.

show anatomic information, such as the symmetry of the tuber sacrale with pelvic fractures and to determine if the sacroiliac joint is involved.[10]

Femorotibial Region

Evaluation of the femorotibial region is primarily performed using radiography. However, there are currently many indications for ultrasonography because of the abundance of supporting soft tissues. Ultrasonography can provide valuable information about the three joint spaces (femoropatellar, lateral and medial femorotibial) as well as the menisci and collateral ligaments.[14] A linear transducer can be used to evaluate the joint and even evaluate the trochlear ridges for evidence of osteochondrosis lesions.[15] The patellar ligaments and long digital extensor tendons can also be evaluated in both transverse and longitudinal orientation.

The menisci should have a uniform appearance and the body of the medial meniscus can be observed cranially as it attaches to the tibial tuberosity (Figure 68-8). To image the cranial attachment to the tibial tuberosity (the cranial meniscal-tibial ligament), a microconvex, curvilinear transducer needs to be used to provide a small footprint that allows the ultrasound beam to be perpendicular to the fibers of the cranial meniscal horn. Imaging the insertion of the medial meniscus is important because tears can arise from this region. Additionally, increased joint fluid in one or multiple joint spaces can be seen with meniscal damage.[16]

Abdomen

Ultrasonography of the abdomen is severely limited by the size of the abdomen and the presence of gas primarily within the colon and cecum.[17] Despite this limitation, ultrasonography is extremely useful to evaluate the small and large intestines for displacement or ischemia caused by strangulating lesions. Normal small intestine has good motility and has a wall thickness of approximately 3 to 4 mm.[18] Distinct wall layering of the gastrointestinal tract is routinely seen when using a high-frequency transducer (8 to 10 MHz) (Figure 68-9). A high-frequency microconvex curvilinear transducer provides a large field of view adequate to image most of the abdomen. To image the liver or kidneys, a lower-frequency (3 to 5 MHz) macroconvex transducer can provide more penetration; however, this is done at the expense of image resolution.

Focal ultrasound scans have been recommended for horses that present with acute abdominal pain (colic).[17,19] In these horses, specific sites are scanned to assess specific causes of acute abdominal pain. The term *fast localized abdominal sonography in horses (FLASH)* has been used to describe the evaluation of the equine abdomen not as a complete unit but at focal sites around the abdomen to limit the scanning time to approximately 15 minutes. These sites allow the evaluation of the colon wall thickness for colon torsions (ventral, just caudal to the xiphoid)[17] and right dorsal colitis (right 10th intercostal space)[20] as well as the small intestine (inguinal regions) and the region of a left dorsal displacement (nephrosplenic entrapment; dorsal, left 17th intercostal space).[19] This concept is discussed further in Chapter 36.

CONCLUSION

Ultrasonography is an invaluable tool for surgical planning and evaluation of various equine injuries. From using it on a soft tissue swelling to look for fluid pockets or foreign materials, to evaluating tendons for chronic lameness and imaging the thorax or abdomen for fluid, ultrasonography not only provides a diagnostic modality but can also be used to guide needles for centeses and therapeutic interventions. Because of its portability, lack of invasiveness, and low upkeep costs, diagnostic ultrasound can provide valuable information in patients with both chronic and acute conditions. The largest limitation of ultrasonography is the fact that the image and examination is primarily dependent on the skill of the user, the user's knowledge of anatomy, and allowing adequate time for a thorough evaluation.

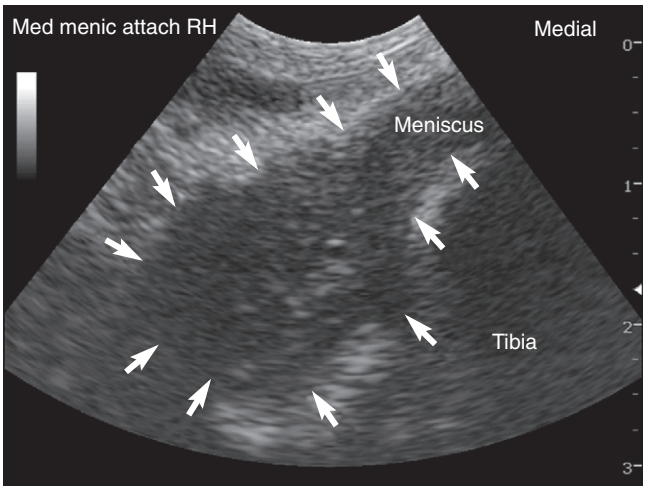

Figure 68-8. Ultrasonographic image of an abnormal appearance of the cranial meniscal-tibial ligament (which attaches the cranial aspect of the medial meniscus to the tibial tuberosity). The ligament should be hyperechoic and uniform in size, but this ligament is large and hypoechoic *(outlined by arrows).*

CHAPTER
69

Nuclear Scintigraphy

Nathan C. Nelson and Elizabeth A. Ballegeer

Nuclear scintigraphy studies are based on the detection of emissions from a radioactive substance introduced into the body. Scintigraphic studies employing a radioactive substance with affinity for bone (bone scans) account for the vast majority of nuclear medicine procedures in the horse. Radiography and ultrasonography, the traditional imaging modalities employed to investigate equine lameness, provide superb anatomic detail. In contrast, bone scan images are poor in anatomic detail but provide information reflecting the physiology of diseased tissues. As a result, scintigraphy may provide definitive information early in a disease process or be a more sensitive supplemental test when traditional imaging methods are equivocal.[1,2] This chapter primarily focuses on bone scan studies, discussing various aspects of the imaging equipment, radiopharmaceutical physiology, imaging artifacts, indications, and some normal anatomic variations for which understanding is necessary for proper image interpretation.

PRINCIPLES

The radioactive substance administered in a nuclear scintigraphy procedure is called a *radiopharmaceutical*, which contains a radioactive atom (called a *radionuclide*) bound to a pharmaceutical compound. Technetium-99m (^{99m}Tc), the most common radionuclide used in nuclear scintigraphic examinations, is a radioactive form of the element technetium and emits a gamma ray with energy of 140 kiloelectron volts. Gamma rays and x-rays are indistinguishable, differing only in their method of production, with gamma rays formed by the breakdown of the nucleus of an atom (as with the natural decay of ^{99m}Tc) and x-rays formed by the ionization of the electron cloud of an atom (as within the anode of an x-ray tube). Detection of gamma rays emitted by ^{99m}Tc is the basis for scintigraphic image formation.

The pharmaceutical component of the radiopharmaceutical determines its biological activity and localization. For skeletal scintigraphy (bone scan), the most common pharmaceuticals are the polyphosphonates, usually methylene diphosphonate (MDP) or hydroxymethylene diphosphonate (HDP). MDP is more readily commercially available than HDP.[3] These compounds are preferentially absorbed by bone, allowing detection of skeletal lesions.

Although less commonly used than MDP and HDP, other pharmaceutical compounds or cells can also be coupled to ^{99m}Tc. Renal and hepatic function can be quantified through use of ^{99m}Tc-mercaptoacetyltriglycine and ^{99m}Tc-mebrofenin, respectively.[4,5] ^{99m}Tc-denatured albumin remains within the vascular bed and can be used to acquire images of vascular anatomy.[6]

^{99m}Tc-hexamethylpropyleneamine oxime (^{99m}Tc-HMPAO) aggregates in white blood cells and can be useful in highlighting areas of active inflammation and infection.[2]

Radiopharmaceuticals are generally purchased through a radiopharmacy and delivered on-site immediately prior to a study. Because ^{99m}Tc decays rapidly, a radiopharmacy must be located nearby for quick delivery. For practices with a high scintigraphy caseload without convenient access to a radiopharmacy, a ^{99m}Tc generator may be employed. These generators contain molybdenum-99 (^{99}Mo), a longer-lived parent radionuclide, which decays to ^{99m}Tc. The ^{99}Mo is separated from the ^{99m}Tc by flushing sterile saline through the generator once or twice a day, creating a solution of sodium ^{99m}Tc-pertechnetate ($Na^{99m}TcO_4$).[7] The $Na^{99m}TcO_4$ may then be bound to the pharmaceutical on-site, using an available kit. Molybdenum generators are generally useful for 1-2 weeks.[7]

As the most commonly used radiopharmaceuticals in equine patients, the biokinetics of ^{99m}Tc MDP and HDP are well known. Following intravenous injection, an initial vascular phase follows the course of the radiopharmaceutical through blood vessels.[2] The radiopharmaceutical then rapidly crosses the vascular endothelial lining to distribute in the extracellular fluid.[3,8] Bone binding subsequently occurs, with maximum uptake at about 60 minutes after injection. These substances bind to exposed hydroxyapatite, with the amount of uptake determined by the rate and extent of osteoblastic activity in bone at the time of administration. In normal bone tissue, proteins line much of the surface of the inorganic matrix, preventing excessive polyphosphonate binding. In areas of bone damage and bone proliferation or in very young animals, more hydroxyapatite is exposed, resulting in greater bone uptake of MDP or HDP. Blood flow is important for delivery but does not affect bone uptake unless severely decreased.[3] By 3 hours after injection, the ^{99m}Tc MDP concentration in normal tissues is proportional to their calcium content, with low concentrations in muscle (approximately 0.005% calcium) and high concentrations in bone (14% to 24% calcium).[8] This dynamic interaction between vascular, extracellular, and bone uptake continues, with relatively greater bone activity and less soft tissue activity over time.

Both ^{99m}TcMDP and HDP are primarily cleared in the urine, with some excretion into saliva and sweat. As a result, the kidneys and urinary bladder are prominently seen on a normal bone scan, occasionally obscuring the anatomy of the caudal spine, pelvis, or proximal hind limbs.[9] Superficial contamination may also occur if voided urine accumulates on the distal limbs (Figure 69-1).

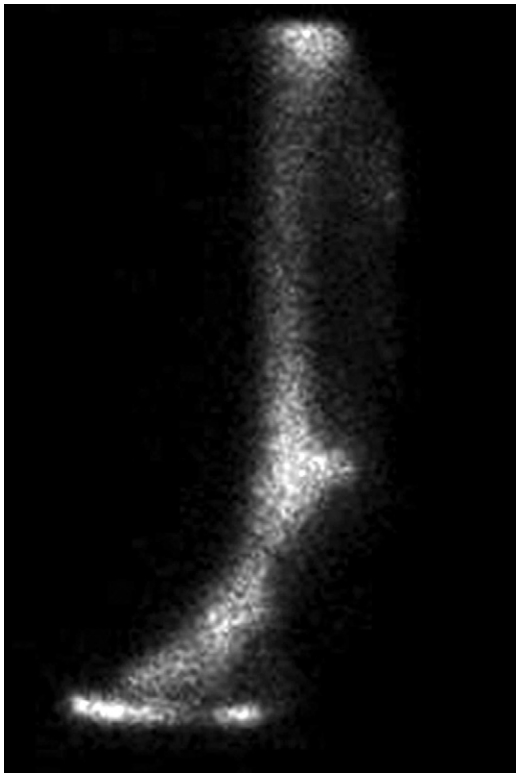

Figure 69-1. Urine contamination on the bottom of the foot. If superimposed over normal anatomy, urine contamination may mimic pathology.

The Gamma Camera

A gamma camera (also called a *scintillation camera* or *Anger camera*) is needed to detect gamma rays emitted from the patient and transpose the data into a clinically useful image that demonstrates areas of radiopharmaceutical uptake. The camera has multiple components that detect gamma rays by converting their energy into an electronic signal sent to an imaging computer (Figure 69-2).

The collimator is a thick lead sheet located on the outermost surface of the camera housing. It is perforated with many small holes that selectively allow only gamma rays that are nearly perpendicular to the collimator surface to enter the camera, blocking off-axis gamma rays and preventing them from being detected by the camera and degrading the image. Without the collimator, the gamma camera does not produce a meaningful image. The gamma rays passing through the collimator form a two-dimensional anatomic image of the patient's anatomy. Different collimator types exist, but the low energy, all purpose (LEAP) collimator is the standard used for routine equine scintigraphic procedures with ^{99m}Tc. High resolution collimators are available, but they attenuate more gamma rays than LEAP collimators and subsequently require longer imaging times. The collimator on most gamma cameras can be removed, but care is necessary as the detector components underneath are easily damaged.

Under the collimator assembly, a sealed large-diameter, flat, fluorescent crystal (usually thallium-activated sodium iodide) approximately 7 to 10 mm thick is located. When gamma rays emitted by the patient strike the crystal, a focal flash of light is emitted (scintillation), with an intensity proportional to the energy of the incident photon. The light from this flash then strikes one or more photomultiplier tubes that are coupled to the crystal. These tubes convert the light energy from the crystal to an electronic signal. An imaging computer records the location where each gamma ray struck the crystal, using signals triangulated from multiple photomultiplier tubes, producing x and y coordinates for each gamma ray recorded by the camera.

EXAMINATION PROCEDURE

The injection of the radiopharmaceutical should always be performed through an indwelling intravenous catheter, which is thoroughly flushed after injection to ensure that the patient receives the entire dose. The radioactivity administered is

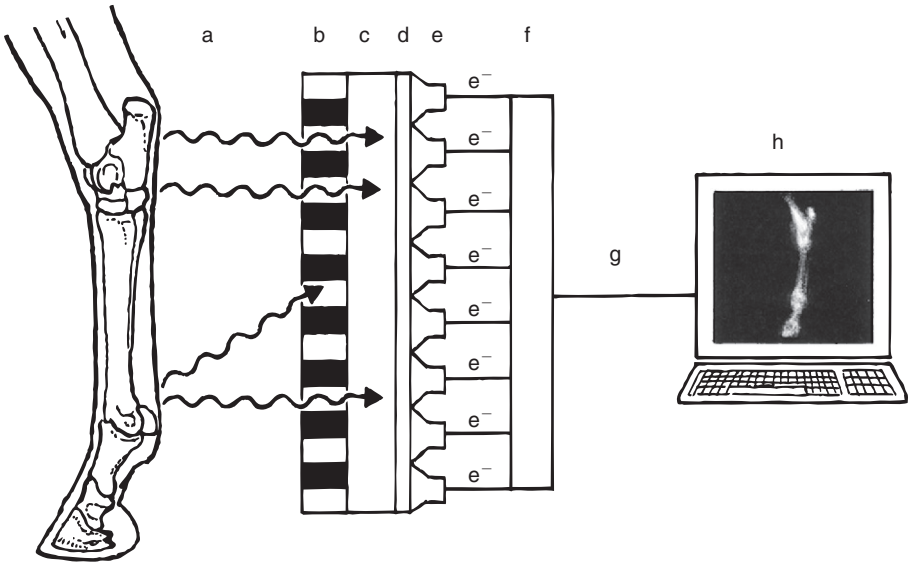

Figure 69-2. Cross-sectional schematic of a gamma camera. Gamma rays *(a)* are produced by the patient and cause scintillation events within the NaI[Tl] crystal *(c)*. The collimator *(b)* prevents nonperpendicular gamma rays from being detected. Photomultiplier tubes *(e)*, which are coupled *(d)* to the crystal, convert the scintillation light to an electric signal that is analyzed *(f)* for positional data *(g)* to create an anatomic image displayed on the imaging computer *(h)*.

measured in the international unit of megabecquerels (MBq) or the traditional unit of millicuries (mCi), with 1 mCi equivalent to 37 MBq. Doses are calibrated for a specific injection time of day, i.e. a dose may be designed for injection at 10 AM. The physical half life of ^{99m}Tc is approximately 6 hours, meaning that if the original dose is 100 mCi, then at 6 hours only 50 mCi will remain. It is therefore important that the dose be administered near the scheduled injection time to achieve the desired level of injected radioactivity and a clinically useful image. A typical dose for an average adult horse is between 120 and 200 mCi 99mTc MDP or HDP. Because a large percentage of radiopharmaceutical is rapidly excreted by the urinary system, the effective half life of ^{99m}Tc within the animal is much shorter than its physical half life.

A complete skeletal scintigraphy study comprises three phases: vascular, soft tissue, and bone. Vascular phase (also called phase I) images are acquired immediately after radiopharmaceutical injection (for 1 to 2 minutes) and demonstrate vascular anatomy before the radiopharmaceutical enters adjacent soft tissues. An image is acquired every 2 seconds, allowing a dynamic view of the body region of interest that may be viewed in series or as a composite image. The short duration of this phase necessitates that the patient be in position in front of the gamma camera when the injection occurs and allows examination of only one body area.

Soft tissue phase (phase II or pool phase) images are acquired when the radiopharmaceutical has entered the extracellular space but has not yet been taken up by bone. This typically occurs between 3 and 10 minutes after injection and is completed at the time bone uptake occurs. Bone uptake may be present by 2 to 3 minutes after injection, especially in young animals or where high bone remodeling is present, or it may be delayed 10 to 20 minutes in older animals.[3]

If bone phase (phase III or delayed phase) images are to be acquired, the onset of imaging is delayed for a longer period. Because of its more rapid bone uptake and increased soft tissue clearance, bone phase HDP imaging may begin approximately 1 hour after intravenous injection, whereas MDP imaging typically begins at 2 hours.[3] Although maximal bone uptake may occur earlier, waiting a longer period allows clearance of MDP or HDP from the soft tissues, giving better images of the bone with less confounding soft tissue uptake.

If the pelvis or upper pelvic limbs will be imaged, furosemide is injected intravenously approximately 60 to 90 minutes prior to imaging. By the time of imaging, the horse should have emptied its bladder, removing excreted radiopharmaceutical that can prevent interpretation of the pelvis or proximal limbs. Protective covers and bandages on the feet and distal limbs, which are removed prior to imaging, protect these areas from radioactive urine contamination.

Sedation is recommended during image acquisition. The amount of sedation used should be sufficient to prevent spontaneous patient motion, but should not make the patient ataxic or wobbly, which can result in significant motion artifact.

Image acquisition may be continued for a fixed time period (time based) or until a certain number of gamma rays are counted (count based). Regardless of method, acquiring a minimum number of gamma ray counts is critical to image quality. In general, distal limb images require at least 75,000 to 100,000 counts and those of the upper limbs and spine require 200,000 to 300,000 counts for satisfactory image quality. Imaging for 60 seconds usually satisfies these count requirements, but 90-second images result in higher counts and often better image quality.

The computer divides the surface of the gamma camera into a row/column matrix of small blocks. Because x and y coordinates for a gamma event are recorded by the gamma camera, the computer bins the event into a block of the matrix.[2] Typically, a 256×256 matrix is employed, although matrices as low as 64×64 have been used. By making each individual block smaller, higher-dimension matrices provide better spatial resolution but require more counts for adequate image quality and thus longer imaging times (Figure 69-3). Matrices with dimensions exceeding 256×256 (i.e., 512×512) exceed the inherent resolution limits of the gamma camera, providing no additional benefit but requiring higher count numbers and longer imaging times.

Whenever possible, orthogonal projections of each body area are acquired, with oblique projections occasionally necessary. For instance, when imaging the pelvis, right lateral, left lateral

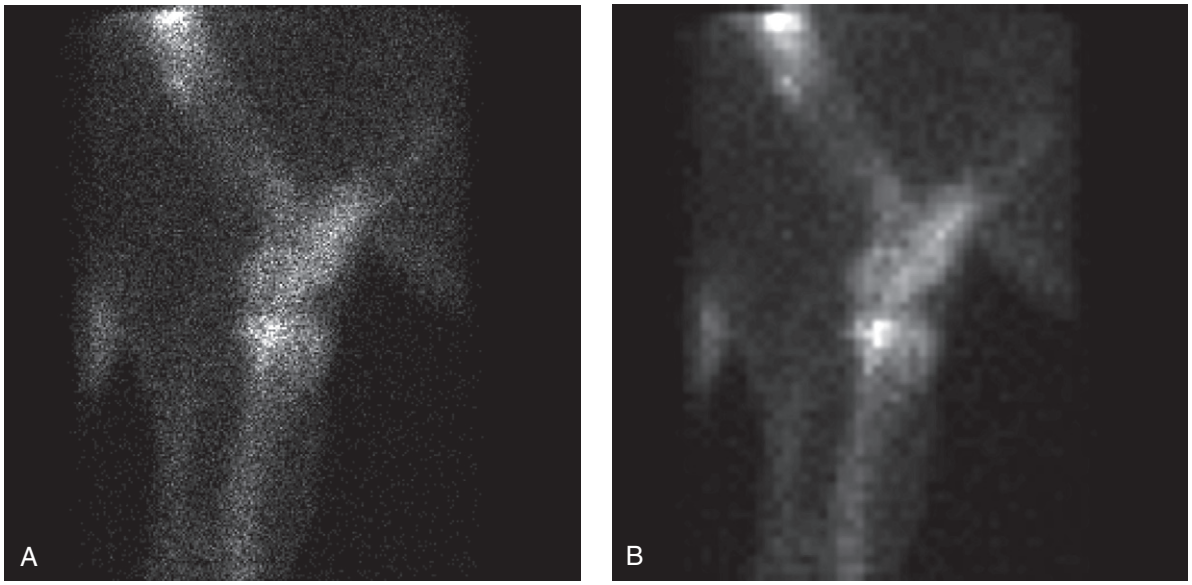

Figure 69-3. Bone phase images of the right stifle acquired with a 256 × 256 matrix **(A)** and a 64 × 64 matrix **(B).** The 64 matrix has a more pixilated appearance and decreased spatial resolution compared to the 256 matrix.

and dorsal projections are routinely acquired, but oblique projections (with the surface of the gamma camera at approximately 30 degrees to horizontal) of the left and right sides of the pelvis provide less anatomic superimposition and can be especially helpful in evaluating the sacroiliac area. For the caudal thoracic and lumbar regions, an oblique angle of approximately 50 to 65 degrees from horizontal is employed, allowing the camera to be closer to the spine than it would be on lateral projections.[10] Dorsal projections of the thoracic limbs or plantar projections of the pelvic limbs include both legs in the same imaging field, allowing direct comparison of the amount of activity within each limb. Because many gamma cameras cannot be placed entirely flush with the ground, the horse can be made to stand on a platform or wooden box to acquire images of the feet.

Flexible or rigid lead sheets should be placed between the left and right limbs when acquiring lateral images, or between the thoracic and pelvic limbs on dorsal and plantar images to prevent *shine through* of the limbs not in the region of interest. For imaging of the spine and pelvis, images should be acquired from both left and right sides. Because of the thickness of the horse and the amount of overlying soft tissues, lesions on the far side of the animal, away from the gamma camera, may not be visible because of gamma photon attenuation by the body.

INDICATIONS FOR NUCLEAR SCINTIGRAPHY

The indications for bone phase (delayed) scintigraphy are many, but in general a bone scan should be seen as a supplemental imaging modality and not a replacement of the basic lameness examination and workup. Bone phase scintigraphy is indicated when:

- The site of lameness cannot be determined because of unclear results of gait evaluation with local anesthesia
- Lameness is localized to a particular area, but injury is not detectable with radiography or ultrasonography
- Multiple limb lameness is present
- Lameness is suspected to originate from the upper limb or pelvis in areas not easily accessible radiographically
- A fracture is suspected (especially a nondisplaced or of a fissure type), but not seen on radiographs
- Lameness is intermittent[1]

Soft tissue phase imaging can be helpful for identifying regions of acute inflammation seen with muscular and tendinous pathologies. Acute inflammatory processes lead to increased regional blood flow and capillary permeability, causing greater radiopharmaceutical uptake in the soft tissue phase. This technique is most useful in the distal limb for lesions such as suspensory desmitis, because the large amount soft tissue surrounding the proximal limb often makes interpretation difficult. Ischemic tissue may be detectable as regions of decreased radiopharmaceutical uptake.

Although classically part of the complete three-phase bone scan, vascular phase images are rarely employed in equine studies, even though they can be helpful to assess the degree of vascular perfusion to an anatomic region.[11] Indications for vascular phase scintigraphy include horses with unusual hindlimb lameness in which there is suspicion of aortoiliac thromboembolism[12,13] and instances in which ischemia or disruption to blood flow is suspected in the distal limb after frostbite, degloving injuries, fractures, or severe lacerations.[2,11] Vascular phase images may be used as part of the complete three-phase bone scan for early detection of osteomyelitis, demonstrating increased regional blood flow to an area.

Rarely employed, radiolabeled leukocytes (with ^{99}Tc-HMPAO) do merit discussion because they can be helpful in imaging orthopedic or soft tissue inflammatory disease. Scintigraphy using ^{99m}Tc diphosphonates demonstrates regions of active bone turnover resulting from infection, fractures, degeneration, and other causes. By selectively labeling leukocytes, ^{99m}Tc-HMPAO allows better discrimination of inflammatory conditions from other causes of bone remodeling and delineates

areas of soft tissue inflammation.[11] Perhaps the most promising indication for radiolabeled leukocyte imaging is the evaluation of orthopedic implants in which infection is suspected but not confirmed by culture, radiography, or diphosphonate bone scanning results.[11,14] ^{99m}Tc-HMPAO has also been helpful to determine the appropriate duration of antibiotic therapy and may be useful for locating sites of infection in animals with fever of unknown origin or persistent leukocytosis.[2] Although early reports using radiolabeled leukocytes in the equine have been promising, few studies exist to determine the true validity of this technique.

INTERPRETATION PRINCIPLES

Correct interpretation of skeletal scintigraphy studies requires familiarity with all factors that can affect radiopharmaceutical uptake, including technical details of image acquisition, the patient's age and use, breed, results of lameness work up, and therapies.[15] Large, well-defined areas of increased radiopharmaceutical uptake (IRU) may be easy to detect and interpret; however, mild to moderate areas of IRU provide greater difficulty, especially for the inexperienced observer.[1] It is important to recognize that increased radiopharmaceutical uptake on a bone scan does not necessarily reflect bone pathology, nor is it synonymous with pain, but it must be interpreted relative to clinical signs and the findings of other diagnostic tests.[1]

Familiarity with normal anatomy and skeletal physiology is helpful when viewing bone scan images. Young animals, because of higher osteoblastic activity, have increased generalized skeletal uptake compared to older animals. The activity in the area of the physes may be particularly intense and varies with the age of the patient. Some physes close scintigraphically at the time of radiographic closure (like the distal femoral physis at 2 to 2.5 years) whereas others may have IRU even after radiographic closure (like the distal radial physis, which may have IRU up to 42 months but closes radiographically at 24 to 32 months).[16] This discrepancy may be explained by the fact that the IRU in the physeal region may not actually represent physeal uptake, but may instead result from histologic architectural changes that expose hydroxyapatite crystals to circulating diphosphonate binding within the adjacent metaphysis and epiphysis, which continue to remodel after physeal activity declines.

Areas of IRU can be present in any horse depending on its stress history and may not be a source of clinical lameness.[15] For example, jumping horses are predisposed to IRU in the phalanges, Standardbreds in the third carpal bone and proximal sesamoid bones, and Thoroughbreds in the distal palmar and plantar third metacarpal and metatarsal bones. Focal intense IRU may be seen on the proximocranial aspect of the tibia in association with middle patellar ligament desmitis, but an identical pattern has been seen in cases of distal limb lameness (where lameness was abolished after blocking the distal limb). In these cases, lameness may have caused increased stress on the patellar ligament, resulting in increased uptake.[17] It must be remembered that an area of IRU is not necessarily a source of pain causing lameness, and normal RU does not mean a lesion is not present that can cause pain or lameness.[17]

In racing horses, the distal third metacarpal bones typically have higher incidence of IRU compared to jumping horses. This is especially seen in Thoroughbreds. Uptake in the dorsal cortex of the metacarpus in Thoroughbreds is unique and may not be associated with lameness. It is likely that IRU reflects a continuum ranging from adaptive stress remodeling to nonadapative modeling that results in lameness.[15]

The effects of perineural anesthesia and joint blocks on the soft tissue and bone phases have been studied. No effect of intra-articular anesthesia is seen on bone phase images, but it can cause some mild IRU on soft tissue phase images. This effect depends on the joint involved and generally persists for 2 to 4 days, but it sometimes lasts as long as 14 days after injection. This is most pronounced in the larger joints of the proximal limb.[18] Similarly, perineural anesthesia has a minimal effect on bone phase images. In the soft tissue phase, low palmar and high palmar blocks result in the greatest focal activity, which are most prominent 1 day after injection and persist to at least 17 days after administration.[19] IRU on bone scan images may be seen after perineural anesthesia more proximally in the limb, where the blocks may involve skeletal muscle, which shows significant sensitivity to the irritant properties of local anesthetics. Focal myositis and necrosis have been reported after local anesthetic injection, resulting in IRU in muscle that persists on bone phase images.[19]

Absence of blood flow on the vascular phase images implies a complete or near complete failure of delivery of radiopharmaceutical, which may result from tourniquet injuries, vascular infarcts, or severe lacerations.[20] Pathophysiologic increases in blood flow, as may be seen with regional inflammation or anesthetic administration, may increase the regional count density.[3] Soft tissue and bone phase images should still be acquired, as collateral circulation may have developed.

The amount of radiopharmaceutical that localizes on the soft tissue phase depends on vascular delivery, autonomic tone in the local area, rates of diffusion into and out of the local extracellular fluid, and the size of the local extracellular fluid space.[3] Any disease process that expands the extracellular fluid compartment will result in increased uptake of ^{99m}TcMDP on soft tissue phase images.[8] Increased soft tissue uptake of radiopharmaceutical usually results from local inflammation, which increases blood flow and vascular permeability with increased delivery and radiopharmaceutical leakage. Early bone uptake can occur as soon as 5 minutes after injection (as mentioned before, particularly in young patients), so soft tissue phase images should be acquired rapidly and interpreted with caution. The clinician should also be cautious in interpreting soft tissue uptake in areas where severe bone uptake is also seen in the delayed bone phase, as early bone uptake may be seen in these regions mimicking soft tissue pathology. Soft tissue phase imaging is likely most effective for soft tissues of the lower limb, as the findings are usually subtle and can be obscured by the significant muscle mass of the proximal limb. If imaging of the soft tissues without the possibility of confounding bone uptake is desired, administration of ^{99m}Tc-pertechnetate (radionuclide in suspension, unlabeled to any pharmaceutical compound) can be performed.

Persistent IRU in soft tissues on bone phase images may be caused by focal dystrophic mineralization, which may occur at sites of chronic inflammatory, necrotic, or infarcted tissue.[9] Uptake may also be seen in tissues that are not obviously mineralized on radiography, particularly in horses with rhabdomyolysis (typing-up syndrome).[21] This occurs as the result of diphosphonates binding with calcium salts secondary to muscle necrosis and influx of calcium into cells, promoting bone tracer uptake.[9] This form of soft tissue IRU is often seen as linear

uptake pattern in muscles on delayed phase images, but it may involve a large muscular region (Figure 69-4).

Poor bone uptake or persistent soft tissue uptake is occasionally encountered, especially of the limbs distal to the carpus and tarsus, and may affect one or more limbs *(cold limb)*.[22] This manifests as a generalized decrease in bone uptake distal to the carpus and tarsus, the metacarpophalangeal or metatarsophalangeal region, or only involving the feet, and may be asymmetric.[22,23] A positive correlation between increasing environmental temperature and better perfusion of the distal limbs and bone uptake of radiopharmaceutical is known to occur.[22] The precise cause is uncertain, but this phenomenon may result in missed lesions or confused interpretation.[22] It has been shown that 15 minutes of exercise at a trot and canter significantly increases hind limb perfusion and uptake of radiopharmaceutical into bone.[22] Bandaging prior to bone scan imaging appears to have no effect on bone radiopharmaceutical uptake.[22] It is therefore recommended that horses be lunged for approximately 15 minutes prior to injection of the radiopharmaceutical, except when a fracture is suspected.[22]

The severity of bone radiopharmaceutical uptake may help determine its cause. Osteomyelitis and fractures tend to have the most intense IRU, with osteoarthritis often more mild (Figure 69-5). Fracture and osteomyelitis uptake is usually intense because of a large increase in blood flow and osteoblastic activity.[24] Overlap in this distinction exists, as enthesopathy

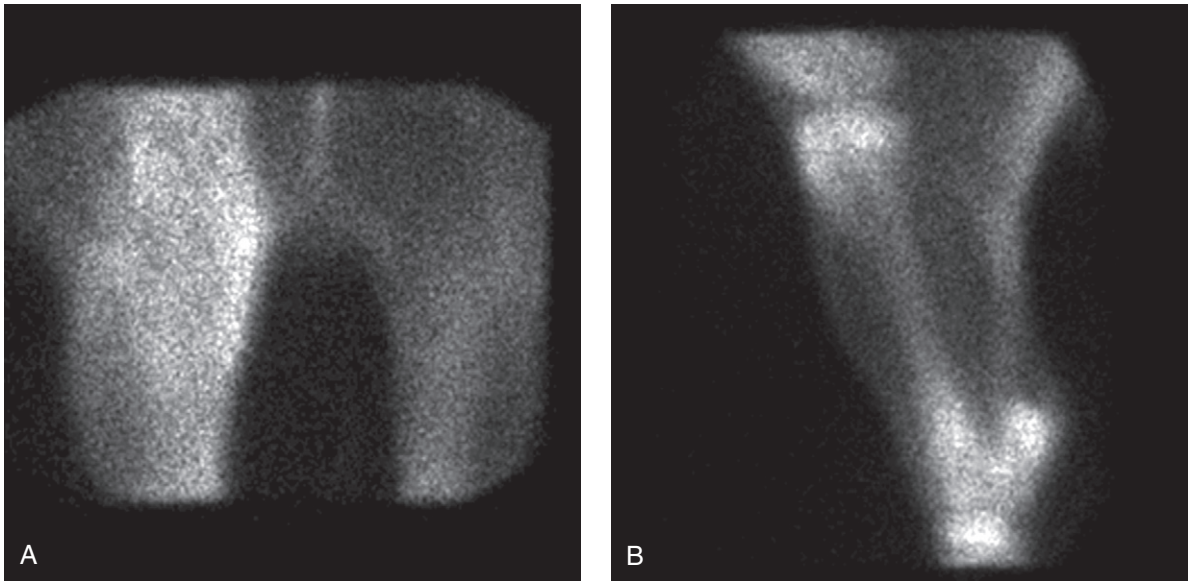

Figure 69-4. Plantar **(A)** and lateral **(B)** bone phase projections of the tibial region in a 7-year-old Quarterhorse examined for swelling of the left proximal hind limb acutely after performance. Intense radiopharmaceutical uptake is seen through the soft tissues despite delayed images (2 hours after injection), consistent with rhabdomyolysis.

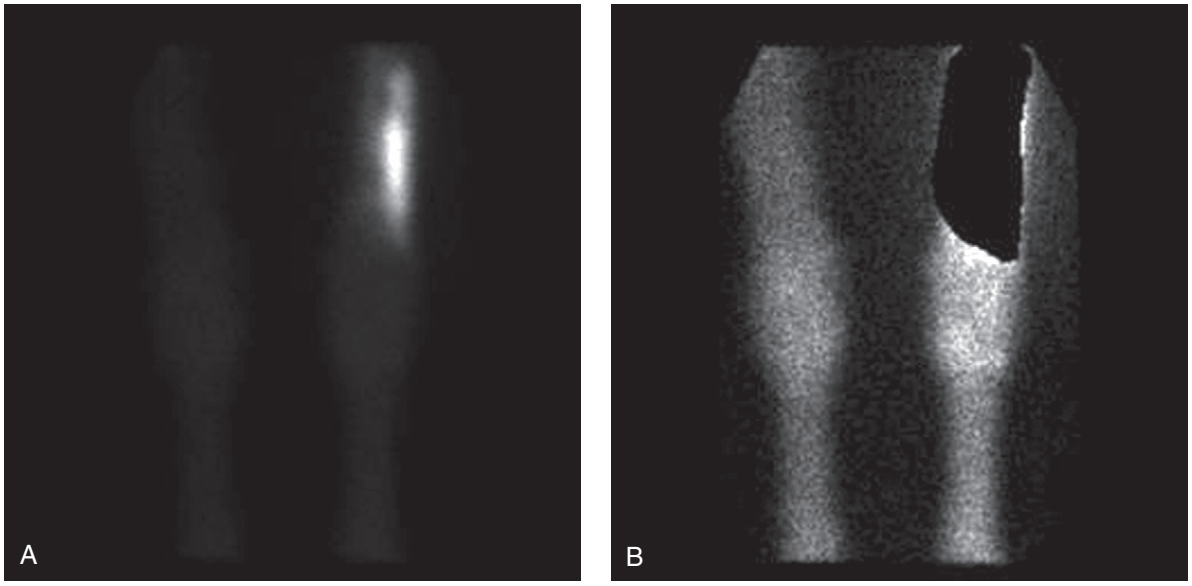

Figure 69-5. Dorsal projections of the carpi, with a fracture of the left distal radius. A digital mask is applied on image **B.** The severe radiopharmaceutical uptake is characteristic of a fracture, causing the normal bone of the distal left limb and the entire right limb to be difficult to see when the mask is not applied. No abnormalities were seen on radiography of this area prior to the bone scan procedure.

and osteoarthritis may also have very intense uptake, which may be focal. Some conditions, such as osteochondritis diseccans and subchondral bone cysts, may have little associated osteoblastic activity, resulting in little or no radiopharmaceutical uptake.[3] When imaging fractures, the time since injury is important to consider. Chronic and subacute fractures (more than 2 days) have more uptake than acute fractures. Fractures less than 24 hours old may have little to no uptake, as osteoblastic activity has not yet increased beyond levels seen in adjacent bone. The pattern of uptake may also be helpful to determine the cause of IRU, with linear uptake along the cortical surface often occurring with stress remodeling and uptake occurring along joint margins in cases of osteoarthritis.

ARTIFACTS AND IMAGE QUALITY

Imaging artifacts may arise from problems with the imaging technique, the gamma camera, or the radiopharmaceutical. A complete review of imaging artifacts and quality control is beyond the scope of this chapter, but the most common causes of poor image quality are discussed.

Poor Image Resolution

Poor image resolution (blurry, indistinct anatomic images) is a common imaging artifact with many causes. Image resolution decreases as the patient moves farther from the surface of the gamma camera (Figure 69-6). Increased distance from the camera allows nonperpendicular, off-axis gamma rays to traverse the perforations of the collimator into the gamma camera, resulting in a blurry image. Ideally, the skin surface of the horse should be within 1 to 2 cm (½ to 1 inch) of the gamma camera face.

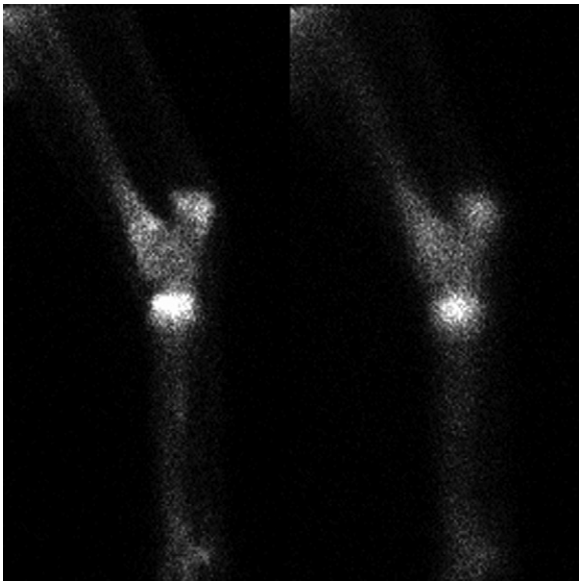

Figure 69-6. Increasing distance between the subject and gamma camera has a negative impact on image quality. The image on the *left* was acquired with the gamma camera 2 cm from the patient and margins of different structures are distinct. The image on the *right* was acquired with a distance of 30 cm between the patient and the gamma camera face. Margins of bone are blurry and indistinct. Moderate IRU at the level of the tarsometatarsal joint is secondary to degenerative joint disease.

Poor image resolution can also be seen with patient motion. Even subtle swaying of the patient can be enough to cause a blurry image. Motion of the gamma camera head during an acquisition can also decrease image resolution and is a problem with older, less-stable gantry-mounting mechanisms. Patient or gamma camera motion artifact can be corrected to some extent by motion-correction software packages. Systems with this capability acquire a series of 1- to 2-second long imaging frames. After the series is acquired, the computer analyzes and corrects for motion-between frames, then sums the frames to create the final bone scan image. This software should be seen as an additional method to improve image quality and does not take the place of patient sedation and restraint.

Gamma Ray Count Density

Adequate *gamma ray count* density is critical to image quality. Adequate numbers of counts ensure that small or subtle lesions are visible and that anatomic margins are well defined. An examination is a tradeoff between achieving adequate numbers of counts for an image and duration of the imaging examination. Acquiring higher count numbers improves spatial resolution but increases the probability of patient motion and total examination time. Many horses will not stand still for more than 60 to 90 seconds, resulting in motion that degrades the image.

Time-Based Acquisition

Time-based acquisition has advantages over count-based acquisition. If the urinary bladder or urine contamination is in the field of view, these highly radioactive areas may cause premature termination of image acquisition if count-based imaging is being used. If lateral images of the right and left limbs are to be compared, time-based acquisition ensures that an area of increased uptake in one limb does not prematurely terminate image acquisition, preventing an "apples to apples" comparison of the two limbs.

Impurities in the Radiopharmaceutical

Persistent soft tissue activity can be caused by impurities in the radiopharmaceutical. The most common impurity is ^{99m}Tc-pertechnetate unbound to any pyrophosphate compound. This impurity arises when air enters the vial during radiopharmaceutical creation, causing oxidation of the reducing agent. Because ^{99m}Tc-pertechnetate acts as an iodine analog (with similar size and valence), uptake in the thyroid gland on bone scan images should alert the clinician to this possibility. Poor bone uptake may also be present. This problem is prevented through careful handling of the radiopharmaceutical kit. Routine quality control assays to the finished radiopharmaceutical product should also be performed.

Gamma Camera

The gamma camera is complex, with many independent parts that may cause artifacts. As examples, photomultiplier tubes may fail or require calibration, the NaI[Tl] crystal may crack, or the camera may be calibrated to the wrong gamma ray energy. The sheer number of potential problems with the physical equipment emphasizes the need for routine quality control

practices such as visual and quantitative assessment of gamma camera field uniformity, tests of linearity and spatial resolution, and calibration of the gamma camera to the appropriate gamma ray energy. Details of these tests and their recommended frequency are available from equipment manufacturers and independent resources.[25]

RADIATION SAFETY AND PERSONNEL EXPOSURE

Principles of modern radiation safety are based on the concept of ALARA, which stands for *as low as reasonably achievable*. Although some radiation exposure to personnel is unavoidable during a scintigraphy procedure, ALARA requires that all reasonable methods should be employed to lower radiation dose to humans and patients.

Time, Distance, and Shielding

Time, distance, and shielding are the three primary methods to achieve ALARA. The fewest personnel necessary should be in the imaging room with the patient, and those present should limit the time spent there to the absolute minimum. Increased distance from the patient can be a very effective method of limiting personnel exposure. Radiation exposure decreases by the square of distance from the source (called the *inverse square law*). Therefore, moving twice as far from a patient decreases radiation dose to personnel by a factor of four, moving four times farther away decreases dose by 16, and so on. When possible, positioning aids are used to maintain patient position without the need for personnel to directly support the patient. Finally, when feasible, radiation shielding should be employed. Prior to injection, the dose should be shielded with a lead syringe casing. During the examination, lead body and thyroid shields (0.5-mm lead equivalent) provide personnel dose reduction factors of approximately four to six.[26] Because of their close proximity to the horse, personnel restraining the horse receive as much total dose as those drawing up and injecting the radiopharmaceutical and operating the imaging equipment.[27]

Excretion

Excretion of many radiopharmaceuticals occurs in body waste. The diphosphonates such as ^{99m}Tc-MDP have high, fairly rapid excretion in the urine, with 70% of the dose excreted through the kidneys within 4 hours.[9] Based on radiation measurement rates for bone scan studies, the biggest radiation hazard to personnel performing these studies is from the radioactive urine and not the horse itself.[28] Latex examination gloves, boot covers, and protective clothing should be worn at all times when dealing with the radiopharmaceutical, the patient, a contaminated stable, or biological waste.[28] Compared to straw, wood shavings are a superior bedding material for the isolation stable because they are more absorbent and result in less drainage of urine and greater control over the area of contamination.[28]

Dosimeters

Personnel dosimeters must always be worn when dealing with scintigraphy studies. Film badges are a common type of monthly or quarterly recording system for radiation dose. These badges contain a small emulsion of radiographic-type film, which becomes exposed to radiation during a time period. Radiation dose is then estimated based on the film exposure. Ring badges are also used to monitor exposure to the hands, which can be significantly higher than that to the body because of the proximity of the fingers to the patient and injected dose. These contain a small lithium fluoride crystal, which stores radiation energy in a manner that can be measured later.

Patient Isolation

Patient isolation is enforced after the imaging procedure has been performed. Release criteria vary by state, but most patients receiving a bone scan are able to be released the following day. Stalls housing the patients should be monitored for radioactivity and cleaning should be delayed until sufficient time has passed for radioactive decay. Geiger-Mueller detectors or ion chambers are used to monitor for radioactive spills or excretions that must be isolated or cleaned.

CHAPTER 70

Computed Tomography

Jennifer Kinns and Anthony P. Pease

Computed tomography (CT) has been used in human clinical medicine since 1972 and in veterinary medicine since the early 1990s. Its use in equine practice was initially limited to very few institutions, but reports of CT in musculoskeletal and craniomaxillofacial imaging are now widespread. CT uses x-ray beam technology to create tomographic slices of the patient's anatomy. The modality has superior contrast resolution compared to radiographs, allowing fluid and soft tissue to be differentiated. It also eliminates the problem of superimposition that can render radiographs of complex anatomic structures difficult to interpret. Although CT is not as good as magnetic resonance imaging (MRI) for imaging soft tissues because of an inferior contrast resolution, it is the modality of choice for imaging bone.

The use of CT in the horse can be limited by availability, the need for general anesthesia for most systems, and sometimes by the size of the patient. Availability of CT is increasing, and with secondhand systems readily available for purchase from human hospitals, the cost of setup can be relatively low. Many university hospitals and tertiary referral centers now have equine CT capabilities. Anesthesia is necessary for positioning in standard systems. The CT opening, or *gantry*, is a horizontally oriented short-bore cylinder, requiring the horse to be dorsally or laterally recumbent. The length of scan time is very quick, however, and anesthesia times can be kept short. Patient weight and size can limit the ability to perform a CT scan. A specially designed equine CT table is necessary; it must support the weight of the patient, integrate with the existing CT table, and allow the anatomy of interest to move through the CT gantry. The diameter of this gantry opening generally ranges from 50 to 85 cm (20 to 34 inches), and imaging of limb and torso structures above the carpus or tarsus is therefore limited in adult horses.

Standing CT is possible. At the time of writing, it is only described as a prototype for CT of the head and for *ex vivo* imaging of the foot[1,2] but if successful its use is likely to become more widespread.

INDICATIONS

CT evaluation is recommended for a variety of surgical conditions. It can be of particular use in accurately delineating lesions of complex anatomic structures, such as the skull. It is the best modality for evaluating bone and is the method of choice for assessing intracranial hemorrhage in acute trauma.

CT has been used extensively in studies of the equine head.[3-5] Sinonasal disease is a common clinical presentation for which radiographs often provide only limited information and CT can be very useful.[6,7] The CT appearance of dental disease has been described, and the modality is particularly useful for surgical planning in this region,[7] especially with three-dimensional reconstruction. CT is also particularly beneficial in evaluating the temporomandibular and temporohyoid joints, delineating infectious, degenerative and traumatic processes that may be difficult to evaluate radiographically.[8-10] Patients presenting with centrally referable neurologic signs may also be evaluated with CT. Although MRI is the modality of choice for brain imaging, CT can provide important diagnostic information, such as the presence of a mass effect, hemorrhage, or abnormal contrast enhancement, and it is more rapidly acquired than MRI images. CT evaluation of external mass lesions of the head allows a more thorough evaluation of the associated soft tissue and bone involvement than radiographs alone do.

Computed tomography can be used in evaluating appendicular musculoskeletal disease, and it is particularly useful in accurately delineating bone lesions, particularly those associated with trauma. In almost all cases, CT should be used as an adjunct to survey radiographs when additional information is necessary. Clinical use has been described in association with fractures of the middle phalanx[11] and tarsus.[12] In the future, CT may be useful as a method for the early diagnosis and monitoring of stress-associated bone injury.[13] The ability to perform volume-rendered, three-dimensional reconstruction should also make the modality ideal for accurate evaluation of angular

limb deformity. Degenerative bone lesions may be evaluated with CT,[14,15] and this imaging technique has provided excellent detail of new bone formation in horses with proximal suspensory desmitis that has proved refractory to conservative treatment.[16] CT can be used to evaluate musculoskeletal soft tissue, such as the distal deep digital flexor tendon,[17] providing an alternative to MRI when use of the latter is limited by availability.

BASIC PHYSICAL PRINCIPLES AND EQUIPMENT

Hardware

The basic components of the CT scanner are the image gantry and the CT table. The gantry contains the x-ray tube, x-ray detectors, and the data acquisition system; the CT table is an integral part of the system that moves the patient through the scanner at a specific and predetermined speed. Rotation of the x-ray tube within the gantry allows radiographic projections to be obtained at intervals around the patient, and the data obtained from these projections allows construction of an image. The x-ray detectors measure the intensity of the x-ray beam after it has passed through the patient and the data are used to calculate the degree of attenuation of the x-ray beam at each interval. Movement of the patient through the gantry then allows this process to repeat at predetermined locations, resulting in a *slice* image at each location. Certain helical systems operate with a moving gantry rather than a moving table (see later) although the effect is the same.

An image is formed by the mathematical reconstruction of the data acquired by the detectors, generally using a technique called *filtered back projection*. There is a short time delay between scanning and image display while the integral computers perform this function. Various specific algorithms can be applied to the data set to emphasize certain features. In *bone imaging*, for example, spatial resolution can be maximized using a bone, or high-frequency, algorithm. Spatial resolution is defined by the ability to differentiate two points that are close together. Improved spatial resolution therefore allows better definition of fracture margins, for example. For *soft tissue analysis*, a low-frequency algorithm is more appropriate to maximize contrast. Contrast resolution is defined by the ability to differentiate two structures that are similar in attenuation. Improved contrast resolution therefore allows better visualization of changes in tissue structure. Many modern machines allow the application of different algorithms to the data after acquisition, so the patient is only scanned once.

Axial and Helical Scanning

Older CT systems acquired data through *axial scanning*, also called *computed axial tomography (CAT) scan*. Data would be acquired around the patient's anatomy, then the table would slide forward a specified intervening distance and the process would be repeated. This stop-start method takes time, as the gantry had to be stopped after each slice was acquired to allow the electronic cables to be retracted. *Helical scanning* removes the time constraints of axial acquisition; the table moves at a constant speed as the data are collected at intervals around the patient. It is possible because of *slip-ring* technology, meaning that wires are not required to provide power to the x-ray tube, which eliminates the coiling limitations of cables at the end of each slice acquisition, allowing the gantry to rotate continuously. Most modern scanners have both axial and helical capabilities. Helical scanning is much faster and is appropriate for scanning any large area or for angiographic studies.

Specific helical CT systems are now available that allow movement of the gantry rather than the table. They run on rails with a fixed table, and although custom table construction is still required for equine use, a gantry width of up to 80 cm (32 inches) increases the possibilities for equine scanning. As the horse can be kept in one position, it is possible to maintain position with partial suspension on the hoist (Figure 70-1).

Pitch is an important concept in helical scanning, which must be understood by any CT operator. To create the image in helical scanning, a mathematical *interpolation* step is used to fill in the gaps in the data set created by patient motion. This does not have an impact on the quality of the image unless the patient is moved a large distance relative to the gantry rotation. The term *pitch* is therefore used to quantify the movement of the CT table relative to the gantry rotation, and is described by the equation:

$$\text{Collimator Pitch} = \frac{\text{Table movement (mm) per 360° rotation of the gantry}}{\text{Collimator width (mm)}}$$

A pitch of 1 is essentially the same as axial mode acquisition, the gantry rotates 360 degrees around the slice and no data are lost. A pitch of less than 1 implies over-scanning, and the additional information acquired is not likely to markedly improve the diagnostic quality of the image. Pitches of greater than 1 improve the efficiency of scanning and by definition reduce scan times; pitches of up to 1.5 are commonly used where at least 66% of the gantry rotates around a given slice and the remaining 34% is extrapolated from the slice before and the slice after.[18]

Single and Multiple Detector Array Scanning

CT systems are also available as single detector array or multiple detector array scanners. With *single detector array scanners* the

Figure 70-1. Positioning of a horse for scanning in a helical CT system with a moving gantry. As the horse can be kept in one position (without the need for table movement), this position can be partially maintained on a hoist.

slice thickness is determined by opening or closing a collimator. When *multiple detector arrays* are used the slice thickness is determined by the width of each detector in the array, and this can improve spatial resolution. For the same volume of data, multiple detector array scanners reduce tube heating because of increased efficiency, which can avoid tube cooling delays when scanning a large area. The speed of data acquisition is also much faster when multiple detector arrays are used because more than one slice is obtained during one tube rotation. Therefore, multiple array scanners reduce the chance for patient motion and are better for time-dependent angiographic studies.

Choice of Slice Thickness

In single detector array systems the slice thickness is determined by adjustment of lead collimators, whereas in multiple detector array systems it is determined by the number of detectors from which data are grouped together. The choice of slice thickness is important, because it contributes to the contrast and spatial resolution of the study. CT images acquired as thicker slices have a greater number of x-ray photons that are detected. This greatly increases the available signal and improves the inherent contrast of the image. Conversely, thinner slices improve spatial resolution and reduce partial volume averaging (see "Artifacts," later). The choice of slice thickness depends on a number of factors. Tube heating can prohibit the acquisition of thin slices through a large volume, and the size of the anatomy to be scanned may therefore limit the acquisition to thick slices. In general though, thin slices are chosen when spatial resolution is important (such as distal limb bone imaging) and thick slices are chosen when soft tissue contrast is important.

Image Formation

The tomographic slice is an image of a slab of patient anatomy. Like radiographs, it still represents compression of a three-dimensional volume in to a two-dimenisonal image, but the third dimension (slice thickness) can be less than 1 mm and is uniform across the image. The image is composed of pixels, each one representing a volume, or voxel, of tissue. The objective measure of attenuation of the x-ray beam is the Hounsfield unit (also called a CT number). Specific tissues have characteristic levels of attenuation (Table 70-1), and measurement of the Hounsfield units can therefore be used in part to crudely determine tissue type (fluid versus soft tissue) and to measure levels of contrast medium enhancement.

TABLE 70-1. The Characteristic Hounsfield Units (CT Number) for Different Tissue Types

Tissue Type	Characteristic Hounsfield Units
Bone	1000
Fat	–90
Muscle	50
Hemorrhage	70
Gray matter	40
White matter	50

Artifacts

Several CT-associated artifacts can cause diagnostic difficulty, and many of these are accentuated when imaging larger structures.

Beam Hardening

Beam hardening refers to dark or light bands across the anatomy caused by changes in the intensity of the x-ray beam. CT and radiography both use a polyenergetic x-ray spectrum, with the kVp referring to the peak energy of the beam. When the x-ray beam passes through the patient, lower-energy x-rays are attenuated more than those of higher energy. Where the beam encounters a highly attenuating tissue, such as bone, the lower-energy photons are removed and the beam that continues is of higher energy or hardened. Artifacts are produced (Figure 70-2) because rays from some projection angles are hardened more than others, confusing the reconstruction algorithm.

Motion Artifacts

Motion artifacts occur if the patient, or part of the anatomy, moves during image acquisition. Small movements lead to blurring and larger movements can lead to double images, because that part of the patient is scanned in more than one slice.

Partial Volume

Partial volume is a problem with any modality that compresses three-dimensions in to a two-dimensional image. As each pixel on the image represents a voxel (volume) of tissue, more than one tissue type may be represented. This is not usually a problem, but it can lead to misinterpretation if the edge of a curved surface of bone is included in an area of soft tissue (Figure 70-3). The Hounsfield unit measure of that pixel will be an inaccurate representation of tissue content, and the subjective appearance could lead to a misdiagnosis of pathology. Thinner slices limit partial volume artifacts, and careful viewing

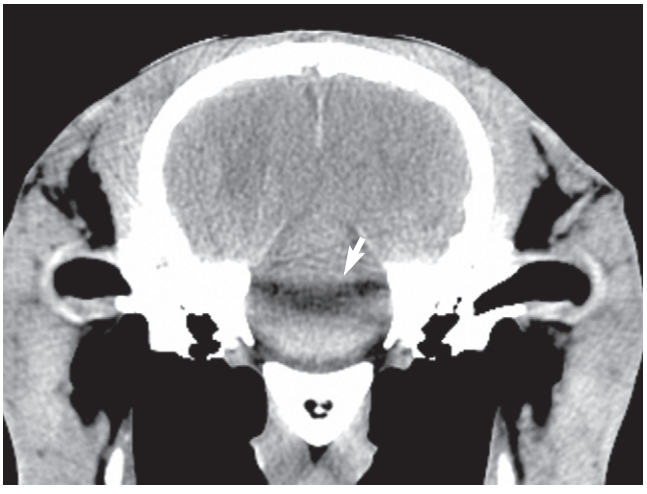

Figure 70-2. Beam hardening artifact in the caudal fossa region of the equine skull. The thick hypoattenuating band across the brainstem *(white arrow)* is an artifact and would prevent evaluation of the parenchyma in that region.

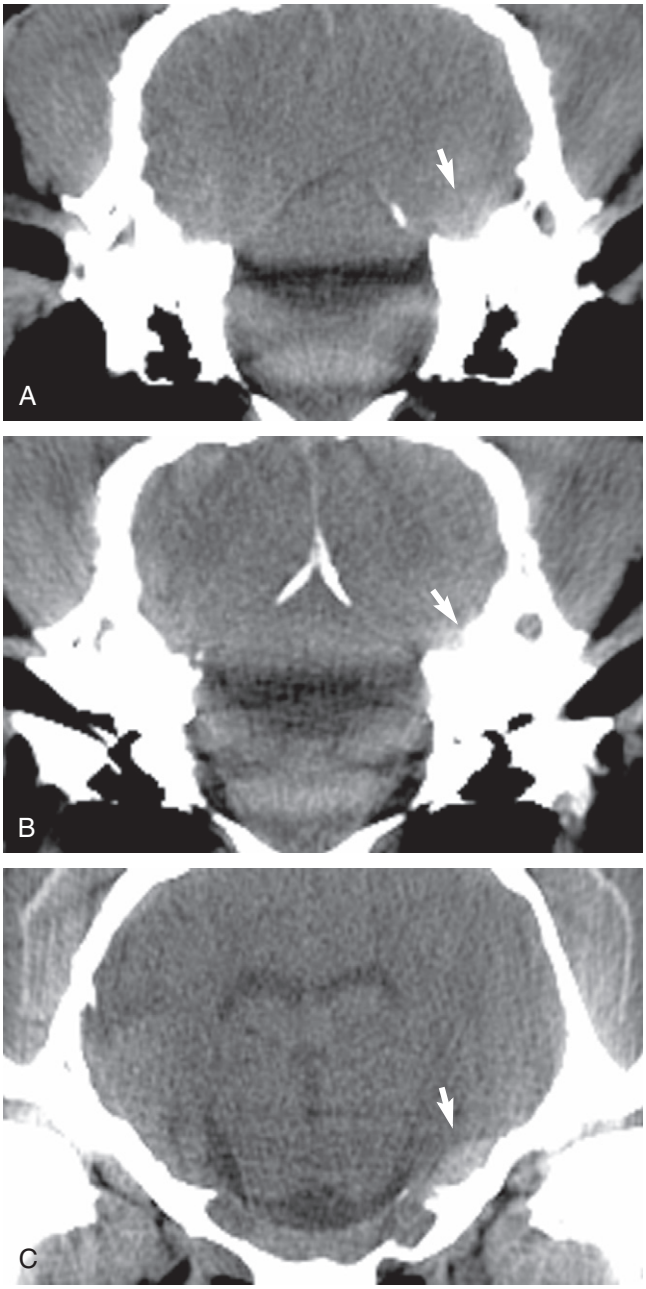

Figure 70-3. A, Partial-volume artifact. The hyperattenuating region *(arrow)* in the ventrolateral aspect of the temporal lobe could be misinterpreted as a parenchymal lesion. **B,** The adjacent slice shows that the curved bone in this region extends axially, and the hyperattenuating appearance was therefore likely due to the presence of both soft tissue and bone material in the projected voxel (the three-dimensional volume of tissue that is compressed in two-dimensions on the image slice). **C,** A true hyperattenuating lesion in a similar location. This represents a subdural hematoma. It can be differentiated from partial-volume artifact by the sharply demarcated margins and absence of an equivalent appearance on the opposite side.

of transverse slices and two-dimensional reconstructions usually identifies the true anatomy.

The equine caudal fossa presents a specific problem in CT. The occipital and petrous temporal bones cause beam hardening, leading to streaks across the region, and partial volume causes inappropriate hyperattenuation of regions in the brain

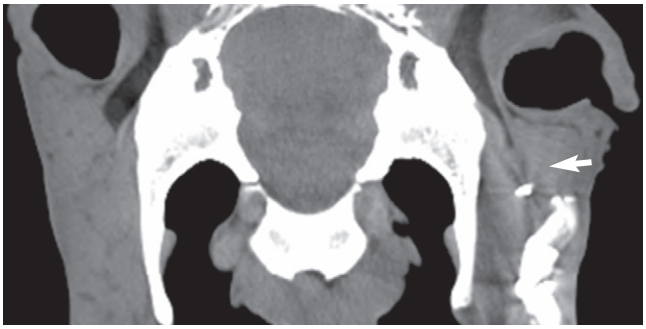

Figure 70-4. Artifact associated with regional injection of nondiluted contrast medium. There is marked streaking artifact *(arrow)* around a contrast-filled blood vessel. Metallic implants create a similar though more marked artifact.

stem. Acqusition with thin slices that are reformatted as thick slices for viewing can help reduce the problem.[19]

Metallic Artifacts

Metallic artifacts occur if there is any metallic implant within the imaged anatomy. Although this is not usually a problem in equine imaging, a similar artifact can occur if nondiluted contrast medium is used for fistulography or regional perfusion studies (Figure 70-4). Severe streaking artifacts occur. A combination of factors lead to the artifact; beam hardening and partial volume are present in addition to the fact that the computer cannot interpret information from material as dense as metal. A number of software corrections are available to limit this and are manufacturer specific.

Use of Contrast Media

Contrast media can be used in CT in a number of ways. For all contrast procedures, a non–contrast medium–enhanced scan must be obtained initially as a baseline. Most typically, contrast medium is used to evaluate tissue perfusion. After intravenous injection of an iodinated contrast medium, tissue that has a vascular supply will enhance. Pathological enhancement, as seen with inflammation or neoplasia, will be greater than that of surrounding normal tissue, although certain tissues such as lymph nodes or salivary glands have a higher normal degree of enhancement because of their blood supply or affinity for iodine. To evaluate contrast enhancement, a time delay of at least 5 minutes is recommended before the postcontrast scan is obtained to facilitate recirculation of contrast. A dose of at least 200 mL of 300 mg/mL iodinated contrast medium is recommended. This is significantly less than the dose used for small animal imaging, but it is typically adequate for evaluating perfusion. The typical small animal dosage of 80 mgI/kg is not technically feasible because of the time necessary for injection, and the likelihood of side effects with a full dose is unknown.

CT Angiography

CT angiography refers to the use of contrast to highlight the vasculature, with the timing of the CT scan set to highlight arterial or venous contrast. This technique has been used in the equine foot.[17] It can be used to define the arterial and venous vascular anatomy of a region for diagnostic purposes or prior

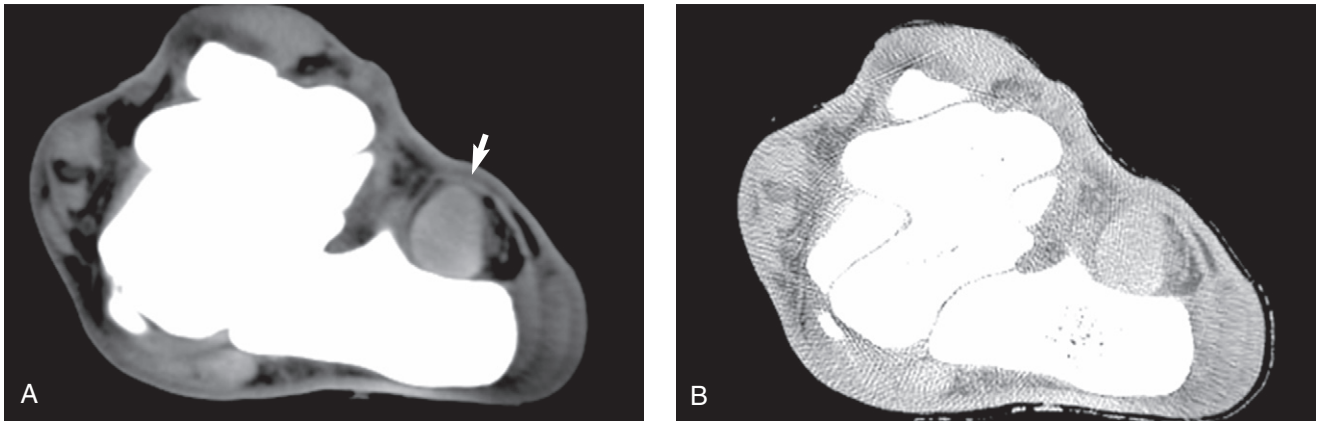

Figure 70-5. A, Transverse image of the carpal canal acquired with thick slices and a soft tissue algorithm demonstrating good delineation of the flexor tendon *(arrow).* **B,** This is the same region acquired with thin slices and a bone algorithm. The increased noise on the image makes it more difficult to differentiate tendon from surrounding tissue, and any lesion could be missed.

to surgery, and to differentiate vascular anomalies, such as arteriovenous fistulas from other vascular lesions. If a peripheral vascular injection is used, an initial test bolus is usually required, from which the timing of the arterial or venous scan is calculated using a dynamic scan obtained in one location. Alternatively, the vascular region of interest may be specifically catheterized, thus avoiding the time delay and dilution associated with peripheral injection. If specific catheterization is used, contrast medium should be diluted to 50 to 100 mgI/mL to avoid excessive artifact.

CT Fistulography

CT fistulography can be a useful method to evaluate the path of a draining tract and involvement of critical structures. For the skull in particular, being able to view the anatomy without superimposition, is a great advantage. Use of a Foley catheter, where possible, can help avoid leakage of contrast medium. Contrast media should be diluted with saline or sterile water to obtain a concentration of 50 to 100 mgI/mL to avoid excessive artifact, and CT acquisition is then performed immediately after injection to the point of back pressure. This procedure is most useful in conjunction with intravenous contrast enhancement, because inflammation of the tract seen with the latter may provide better delineation of the extent of the lesion.

Dacryocystography

Dacryocystography is the use of a contrast medium to evaluate the nasolacrimal system. CT-dacryocystography can be useful in horses presenting with chronic epiphora or facial and orbital trauma. The nasolacrimal duct is catheterized, and diluted iodinated contrast is injected, followed by an immediate CT scan.[20]

INTERPRETATION PRINCIPLES

Image Viewing

CT studies are viewed using different window widths and levels to highlight different types of structures. The *window level* refers to the Hounsfield number around which the other shades of gray are centered. For soft tissue viewing, this should be about 50, whereas for bone viewing it is approximately 500. The *window width* is the number of shades of gray that are portrayed on an image. The human eye can only visualize 30 to 90 shades of grey; a CT image has many more subtle differences in grey scale (typically 4,096), but they will not be detected. To visualize soft tissues, the number of shades of gray on the screen are decreased so that subtle tissue differences become more apparent (Figure 70-5). When contrast is maximized in this way, it is at the expense of spatial resolution, and bone margins are not well defined. For bone imaging, spatial resolution is maximized by increasing the window width to about 2000, at the expense of soft tissue contrast (Figure 70-6). All CT studies should be viewed using both bone and soft tissue settings in order that lesions are not missed or overinterpreted. Suggested window settings for different structures are listed in Table 70-2. Bone windowing is not the same as using a bone algorithm for data reconstruction. Where maximum spatial resolution is necessary, both a bone algorithm (at the data processing stage) and a bone window (at the viewing stage) should be used.

TABLE 70-2. Suggested Window and Level Settings for Viewing Different Regions of Interest

Tissue Imaged	Window	Level
Bone	2000	500
Brain	150	40
Soft tissues	400	50

Reconstruction in Multiple Dimensions

One of the advantages of CT imaging is that images can be reconstructed in multiple two-dimensional planes after image acquisition. This is referred to as *multiplanar reconstruction (MPR)*, which allows reconstruction of a two-dimensional image in any plane. Sagittal, dorsal, and oblique plane reconstructions aid in defining the location and specifications of a lesion. They are particularly useful for fractures or luxations, where the transverse slices alone could miss a lesion if the fracture line is parallel to the transverse axis. MPR reconstruction is recommended for all musculoskeletal or dental imaging as an adjunct to transverse image viewing. The quality of the

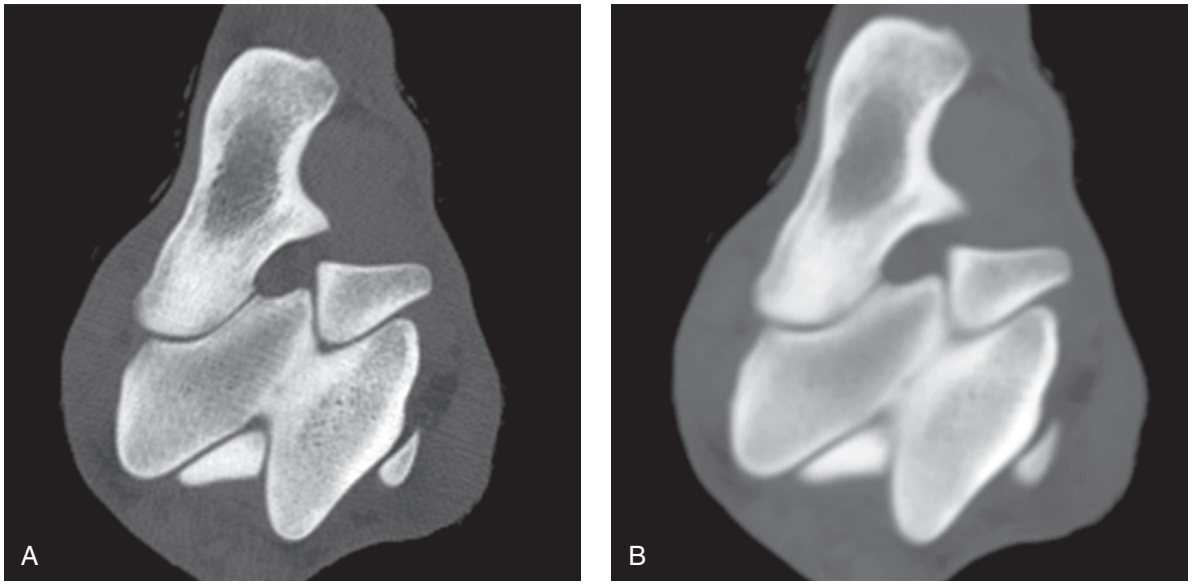

Figure 70-6. A, Transverse image through the tarsocrural joint acquired with thin slices and a bone algorithm. There is exquisite detail of the bone. **B,** The same image acquired with thick slices and a soft tissue algorithm. Although it is viewed with a bone window, the spatial resolution is not as good, resulting in blurred margins and a loss of trabecular detail.

Figure 70-7. A sagittal reconstruction of the tarsus.

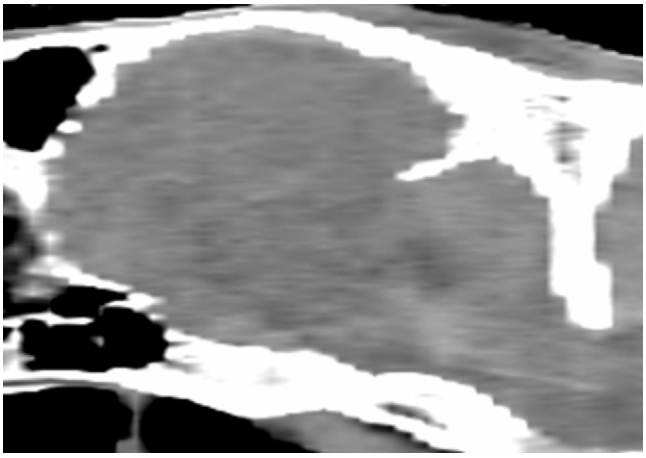

Figure 70-8. A sagittal reconstruction of a thick slice helical acquisition of the caudal skull with significant stair step artifact.

reconstruction depends on the slice thickness used for acquisition and the use of helical or axial modes. Thinner slices always produce a smoother reconstruction with better spatial resolution in the selected planes (Figure 70-7). Helical reconstructions, particularly when acquired as thick slices, are susceptible to a *stair step* artifacts, where the surface of the reconstruction is interrupted by multiple regularly spaced fluctuations (Figure 70-8). This can be reduced by using overlapping slices.

Three-Dimensional Volume Rendering

Three-dimensional volume rendering can be a very important tool in surgical planning (Figure 70-9). It allows visualization of the anatomy in a lifelike perspective, and it can be used to understand lesion orientation. It can also be important in explaining lesions to the client for whom transverse slices of anatomy are harder to understand. Three-dimensional reconstruction should not be used as a substitute for evaluation of MPR or transverse images in diagnosis. This is because a smoothing and shading algorithm is used, which can make small fracture lines or nondisplaced fracture fragments difficult to impossible to see. The resolution of the three-dimensionally rendered image is poor, and superimposition is limiting.

Curvilinear Reconstruction

Curvilinear reconstruction methods allow the operator to select a curved reconstruction plane to follow a structure of interest, thus flattening that portion of the anatomy that could not otherwise be visualized in one plane. In imaging the cranial cervical

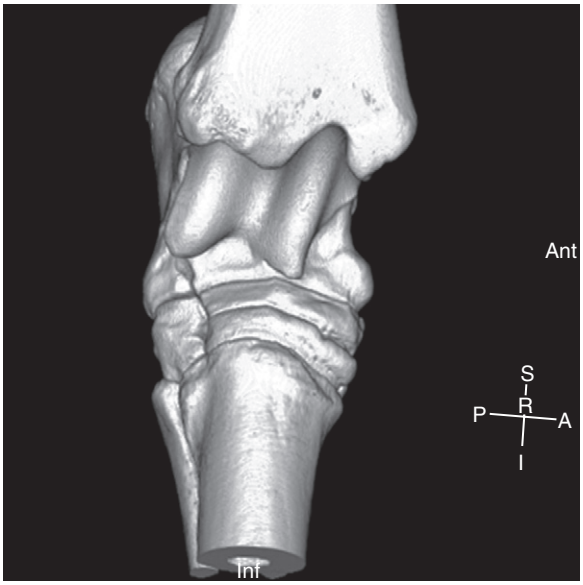

Figure 70-9. A volume-rendered three-dimensional reconstruction of the tarsus.

region, for example, the spinal cord could be flattened such that it appears on one dorsal plane image, allowing better evaluation of lateralizing compression.

CHAPTER 71

Magnetic Resonance Imaging

Joana Chaby L.S. Coelho and Jennifer Kinns

For the past several years, magnetic resonance imaging (MRI) has been increasingly used as a diagnostic tool for investigation of equine lameness. MRI has numerous advantages compared to other imaging modalities. Unlike radiography and ultrasonography, MRI allows concurrent detailed evaluation of osseous and soft tissue structures. Additionally, MRI allows evaluation of soft tissue structures that are not accessible with ultrasonography, such as several structures within the hoof capsule and the intraarticular ligaments of joints, such as the carpus and tarsus. MRI provides physiological information that, unlike nuclear scintigraphy, is anatomically specific. The soft tissue contrast and detection of fluid within bone are superior with MRI compared to computed tomography (CT). In contrast to CT, the evaluation of cartilage with MRI does not require intraarticular contrast injection. When compared to radiography, CT, and ultrasonography, MRI has reduced spatial resolution. However, this apparent limitation is greatly outweighed by MRI's excellent contrast resolution. The exceptional ability of

MRI to distinguish different tissues is because several parameters related to tissue's biochemical environment can be manipulated to accentuate tissue differences. MRI can identify lesions not detectable by other imaging modalities[1-5] and often adds information about lesions that have been previously diagnosed. Equine MRI should be considered when the cause of lameness cannot be determined based on clinical examination and other imaging modalities, specifically radiography and ultrasonography. The number of sequences and planes necessary to produce a diagnostic study mean that imaging one anatomic region can take up to 45 minutes. As horses are either under general anesthesia or standing (still) under sedation, localization of the lameness is essential so that the MRI examination can be limited to a specific anatomic region.

EQUIPMENT, PHYSICS OVERVIEW, AND SAFETY

Equipment and Logistics

The main components of any MRI system are the magnet, gradient coil, radiofrequency generator, and computer, the last of which controls the interplay among the other components and the reconstruction, storage, and display of images.[6] The strength of a magnet's main magnetic field is measured in tesla (T), where 1 T equals 10,000 gauss (G), which is 20,000 times the strength of Earth's magnetic field.[7] Both high-field (more than 1 T) and low-field (less than 1 T) MRI systems are currently used to image the equine limb. Either of these systems must be built in a room shielded from extraneous radiofrequencies that otherwise would interfere with the scan. Caution must be taken with electronic equipment that is brought into the shielded room because it may degrade image quality. All horses undergoing MRI must have their horseshoes and nails removed prior to conducting the study to avoid artifacts (see "MRI Artifacts," later). Support tables for equine MRI are custom built with nonferrous material. Thick plywood or synthetic material and stainless steel can be used. Plenty of padding is important to provide adequate support.

Anesthesia equipment should contain as little ferromagnetic material as possible and should be placed in the room far enough from the magnet to not interfere with the magnetic field. All high-field and most low-field MRI systems require the horse to be under general anesthesia. An MRI examination of both feet takes approximately 60 minutes. Additional time is required for anesthetic induction and positioning of the horse in the magnet. Complications from general anesthesia have not been observed at institutions where numerous horses have undergone MRI since 1997.[8] However, the scan should be limited to a specific anatomic location. Scanning more than one region on each limb not only increases scanning time, it also requires extra time to reposition the limb in the coil and the horse in the magnet. Therefore, prolonged anesthesia can be avoided by isolating the source of lameness to one region. Some low-field MRI systems allow the horse to be imaged while standing under sedation.

Motion artifact is an important limiting factor of the diagnostic quality of the images acquired with these systems. Low-field systems have lower signal-to-noise ratio compared to high-field systems, which translates into lower-resolution images. To increase signal-to-noise ratio when using low-field systems, the scanning times must be longer, which further increases the chance of motion artifacts. Furthermore, the field of view is relatively small when using low-field systems, which limits the size of the anatomic region to be imaged on each scan.

The *configuration of the magnet* is the factor that limits the anatomic region that can be imaged. Most high-field systems have a closed-bore (tubelike) configuration, which makes the length of the bore and diameter of the gantry the limiting factors. Most bores are 50 to 60 cm (20 to 24 inches) in diameter; one system currently in the market has a 70 cm (28 inches) diameter gantry. The open vertical low-field magnets are limited by the dimension of the vertical gap (where the imaged region is positioned), which is relatively small (usually 45 cm [18 inches]). Both high- and low-field (with the horse under general anesthesia) systems allow imaging of the distal limbs up to and including the carpus and tarsus, and the equine head. Most high-field systems are not able to image the equine neck, although the wide-bore configuration magnets can image as caudal as the fourth cervical vertebra in smaller horses. Certain open low-field systems can also image the neck up to this level. The width of the shoulders prevents imaging of the more caudal cervical region. A limited number of short-bore wide-gantry high-field systems can image the equine stifle, if the horse meets specific measurement criteria.[9] The caudal cervical spine, thorax, and abdomen of an adult horse cannot be imaged. Low-field standing systems also allow imaging of the limb up to the carpus and tarsus. However, motion artifacts usually render nondiagnostic images.

For an MRI examination of the head or limbs, adult horses are positioned in lateral recumbency on a wheeled custom-built table that is placed next to the back of the magnet (opposite side from the magnet's table). Foals under 90 kg can be positioned in dorsal recumbency on the magnet's built-in table.[10] Unlike in most CT scanners, the customized support table for adult horses remains stationary during the MRI.

When using any MRI system, it is important to position the region to be imaged in the isocenter of the magnet because image quality deteriorates as the area being imaged is farther away from the isocenter. Positioning the region of interest in the isocenter can be a challenge, especially when using closed-bore, high-field systems. The horse's body is pushed as close as possible to the magnet and the imaged limbs are pulled into the bore of the magnet with ropes that are applied at the level of the pastern. Additionally, removing the built-in table from the magnet's bore may give more room for the limbs to be pulled farther into the magnet. To ensure that the limb being imaged is correctly labeled as right or left, vitamin E capsules can be taped on the lateral aspect of the hoof. For example, one capsule can be used for the right foot and two for the left. The vitamin E capsules show as rounded homogeneous high-signal intensities (Figure 71-1).

Physics Overview

Signals generated during MRI come from hydrogen protons. Hydrogen protons are the basis of MRI because they are much more abundant in the body than other atoms and have favorable magnetic properties.[7] During an MRI exam, the hydrogen protons are placed under the influence of a strong magnetic field. The protons are excited by an applied radiofrequency (RF) pulse. When the RF pulse is removed, the protons relax and through this process emit a signal, which is used to create an electronic image. The proton's relaxation occurs through three different processes: T1 relaxation (or T1 recovery), T2 relaxation

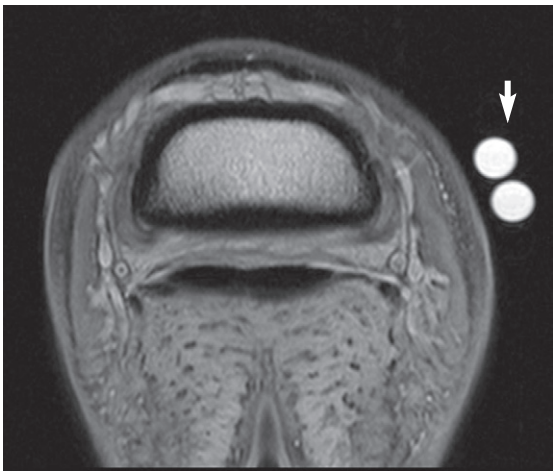

Figure 71-1. Transverse proton density image of the distal limb, at the level of mid second phalanx showing two vitamin E capsules *(arrow)* taped to the lateral aspect of the limb. The normal bilobed deep digital flexor tendon is seen palmar to the second phalanx. (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

(or T2 decay) and T2* (read *T2 star*) decay. T1 recovery refers to the relaxation achieved through energy released from the protons into their environment. T2 decay results from the energy transfer between the protons themselves. These two relaxation processes depend on the environment that surrounds the protons. Thus, protons in different tissues have different relaxation properties. T2* decay depends solely on field inhomogeneities. Field inhomogeneities are inherent to all magnets, being greater in magnets with open (versus closed) bores and in magnets with wider (versus narrower) bores.

In MRI, differences in tissue contrast result from differences in the various tissues' relaxation properties (T1 and T2 relaxation), proton density (PD), and parameters that are operator dependent. Magnetic resonance pulse sequences that emphasize T1 relaxation properties of the tissues are designated T1-weighted and sequences that emphasize T2-relaxation properties of the tissues are called *T2-weighted*. The image contrast in PD-weighted sequences depends solely on the number of hydrogen protons present in the tissues.

Repetition time (TR) and echo time (TE) are key parameters for creating image contrast that can be manipulated during the MRI. TR is the time (in milliseconds) between the application of the RF pulse and the start of the next RF pulse. TE is the time (in milliseconds) between the application of the RF pulse and the peak of the signal received by the coil to produce the image. Both parameters affect MRI contrast because they provide varying levels of sensitivity to the relaxation properties of different tissues. TR and TE affect contrast on T1- and T2-weighted images, respectively. Images with short TR are T1-weighted, whereas images with long TE are T2-weighted. PD images use long TR and short TE, so the effects of T1 and T2 relaxation, respectively are minimized and the number of protons present in the tissue is the main factor contributing to image contrast.

The ideal parameters to image a specific anatomic region vary among different magnets. Thus, scanning protocols must be optimized for each individual MRI system.

Spin echo (SE) and gradient echo (GRE) pulse sequences are the two fundamental types of MRI pulse sequences, both of which are used for equine imaging. The two major advantages of GRE sequences are shorter acquisition time, which reduces artifacts resulting from motion and time under general anesthesia, and volumetric (three-dimensional) acquisition, which allows thinner contiguous slices (1.5 mm compared to 3 to 4 mm with SE) to be obtained without compromising signal-to-noise ratio.[11] GRE sequences are used in standing MRI systems where motion artifacts and relatively low signal to-noise-ratio are of most concern. On the other hand, GRE sequences have poorer contrast resolution compared to SE sequences, because of increased susceptibility to field inhomogeneities.[12] Fast (or turbo) SE sequences (versus conventional spin echo sequences) are often used for equine imaging to decrease acquisition times. However, these sequences still require longer acquisition times than do GRE sequences.

Different MRI pulse sequences highlight different types of tissues and lesions. In one examination, various *combinations of pulse sequences* can be used depending on the imaged region and type of lesion that is suspected. Magnetic resonance pulse sequences commonly used to image the equine limb are fast (or turbo) SE (T2, PD, or T1), short tau inversion recovery (STIR), and GRE (T2*-weighted, PD or T1) sequences. (Because GRE sequences do not cancel out magnetic field inhomogeneities, unlike SE, GRE sequences are called *T2*-weighted* instead of *T2-weighted*.)[11] *PD* and *T1* sequences are useful for demonstrating anatomic detail and are especially useful to evaluate tendons and ligaments. On *T2 sequences*, fluid has high signal intensity (white). Given that tissues that are diseased often have increased water content and consequently have a high signal on T2 images, they can be easily identified with this sequence. Most lesions within the bone, such as edema-like lesions and osseous cystlike lesions, result in high signal intensity on most MRI sequences. To most easily identify these lesions, sequences using fat suppression techniques are used. Fat suppression can be achieved by using STIR sequences (a spin echo sequence) or by using a technique called *fat saturation*.[11-13] In both STIR and fat-saturated images, bone has low signal intensity (black). Thus, pathologic changes that result in increased signal intensity within the bone are easily depicted with these sequences. The main advantage of fat saturation is that it can be applied to SE and GRE sequences.[11] On the other hand, fat suppression in STIR sequences is more complete than in fat-saturated sequences.[13]

Safety

Contrary to imaging modalities, such as radiography and CT, that use ionizing radiation, there is no evidence that there are any long-term or irreversible biological effects associated with the magnetic fields used in MRI.[11,14] However, other hazards do exist when using MRI. Given the strong magnetic fields and the strong force that they exert on ferromagnetic metal objects brought close to them, rigid safety procedures must be used. Ferrous objects (such as clippers, hoof knives, and oxygen tanks) must not enter the magnet room because they can become harmful or even lethal projectiles. Prop materials (such as sand bags) should be inspected because some are not filled with sand but with steel shot, which is highly magnetic. Credit cards and magnetic media can be erased by the magnetic field and should not be taken near the magnet. Objects may be tested with a hand-held bar magnet before being taken into the room. Personnel must be educated about potential hazards, and signs

should be attached to all entrances to the magnetic field (including the fringe field) to deter entry of people who may be wearing pacemakers, have metallic ferrous implants, or are carrying ferromagnetic objects.

INTERPRETATION PRINCIPLES

Clinical MRI has been used to evaluate multiple structures of the equine limb including tendons, ligaments, bone marrow, joints, and articular cartilage. On an MRI examination, regardless of whether the lameness is unilateral or bilateral, both limbs are often concurrently imaged. Because of the high level of symmetry between the right and left equine distal limbs,[15] imaging both limbs allows subtler lesions to be more confidently identified and most normal variants to be correctly interpreted.

On MRIs, high signal intensity refers to brighter areas (white) and low signal intensity refers to darker areas (black), intermediate signal refers to structures with various shades of gray. The terms *hyperintensity* and *hypointensity* can also be used to designate areas of higher and lower signal intensity, respectively. Cortical bone has low signal intensity on all sequences. Medullary bone has high signal intensity on most sequences because of the high fat content of the bone marrow. In general, tendons and ligaments have low signal intensity in all sequences.

Similar to CT, the data acquired with MRIs are tomographic (acquired slice-by-slice) although, unlike CT, MRI slices can be obtained in any anatomic orientation without loss of image quality. Orthogonal slice planes (sagittal and transverse) are routinely performed. Additional planes oriented through specific anatomic parts can help identify certain lesions.

MRI examinations result in a large number of serial images to be evaluated. Interpretation of MRIs requires thorough knowledge of the regional anatomy, as well as an understanding of pathologic processes and physics of MRI. The remainder of this chapter focuses on the principles of interpretation of MRI of specific anatomic regions of the equine limb with a brief reference to MRI of the equine brain.

INTERPRETATION OF MAGNETIC RESONANCE IMAGES

The Foot

The region most commonly examined with MRI is the foot. MRI can identify osseous and soft tissue lesions in the foot that are not depicted by other imaging modalities.[2,5,16-19] Today, because of MRI, it is recognized that the soft tissues within the hoof wall play a major role in the various pathologies encountered in the navicular syndrome.[2,5,8,20-22] Affected structures that are commonly recognized on the MRI examinations of horses that present with palmar foot pain are the distal sesamoid (navicular) bone, podotrochlear bursa, deep digital flexor tendon, distal sesamoidean impar ligament, and collateral sesamoidean ligaments. Several of these structures are often concurrently affected.[2,5,20,21,23-25] The higher sensitivity and specificity of MRI for lesions in most structures within the foot allows more-specific therapeutic protocols to be prescribed earlier in the disease process.

Distal Sesamoid Bone and Podotrochlear Bursa

MRI can reveal abnormalities of the distal sesamoid bone that are not detectable with radiography and provides additional information in horses with radiographic changes. Changes of the distal sesamoid bone that can be seen with MRI and often not on radiographs include (1) medullary cavity changes (abnormal increase or decreased signal intensity), (2) flexor cortex erosions, and (3) fragmentation of the distal margin of the distal sesamoid bone, at the origin of the impar ligament (Figure 71-2) and at the distal angles of the distal sesamoid bone. Distal sesamoid bone lesions are most often seen concurrently with different combinations of lesions of the deep digital

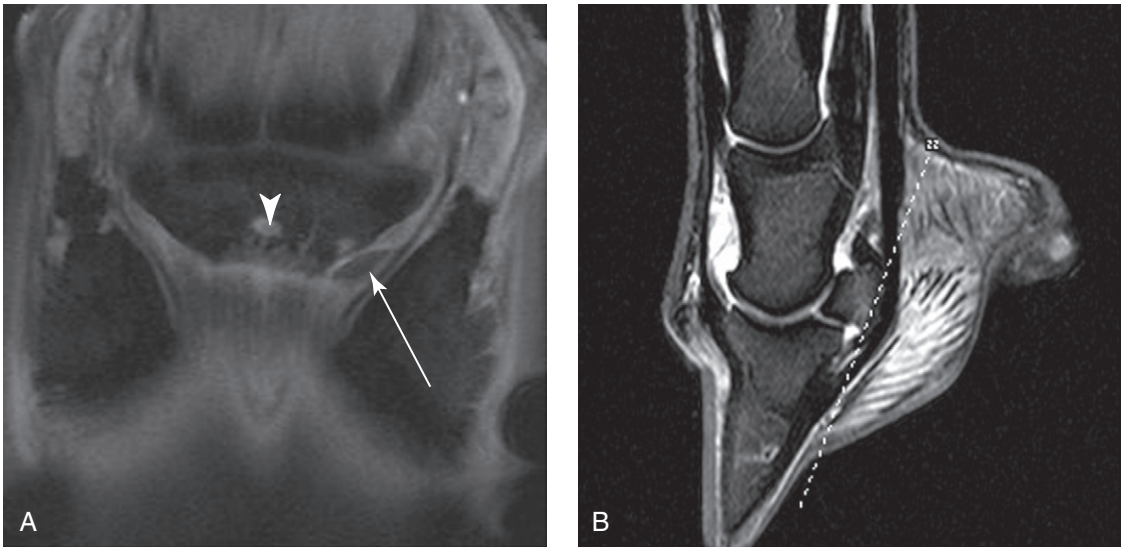

Figure 71-2. A, Dorsal gradient echo image (GRE) of the distal sesamoid bone. Note the fragment next to the distal margin of the distal sesamoid bone at the origin of the distal sesamoidean impar ligament *(arrow).* Also note the enlarged rounded distal synovial invaginations *(arrowhead);* **B,** Sagittal short tau inversion recovery (STIR) image of the foot showing the plane image from which **A** was obtained. (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

flexor tendon, collateral sesamoidean ligament, and distal sesamoidean impar ligament.

The majority of horses with palmar foot pain or navicular syndrome have *high signal intensity* within the medullary cavity of the distal sesamoid bone on STIR and fat-saturated images.[2,5,21] In addition, more focal hyperintensity is often seen in the region of the synovial invaginations when these are enlarged (Figure 71-3). On histopathology, the areas of high signal intensity within the medullary cavity of distal sesamoid bones of horses with advanced "navicular disease" correspond to areas of fat degeneration and necrosis, osteonecrosis, fibrosis, hemorrhage and edema.[15,21] Concurrent *low signal* within the medullary cavity on PD, T1, and T2 sequences may, or may not, be present (Figure 71-4). Regions of low signal intensity within the distal sesamoid bone can result from chronic blunt trauma and represent areas of decreased bone marrow fat content and replacement of marrow trabecular bone with compact trabecular bone.[19,21]

Regions of altered signal in the distal sesamoid bone can also be found in the proximal, distal, and palmar/plantar aspects of the bone. Distal sesamoid bone flexor cortex erosions are seen on MRI as areas of intermediate or high signal intensity along the cortical bone.[19,26] A normal synovial fossa present in the middle third of the sagittal ridge of the distal sesamoid bone may be seen on sagittal MRI as a smooth concavity in the flexor margin of the bone.[27] This should not be interpreted as an erosion or degeneration of the palmar fibrocartilage.

Podotrochlear bursitis, characterized by distention of the bursa with fluid with or without proliferation of the soft tissues, can be seen on MRIs. Fluid within the bursa has a high signal intensity on T2 and PD images. In the normal bursa a small amount of fluid is seen in the proximal and distal recesses. Most commonly fluid is not seen in the bursa between the distal sesamoid bone and the deep digital flexor tendon, and if fluid is seen in this region it is only a thin line.[28] An increased amount of fluid within the podotrochlear bursa is more easily identified in its proximal recess, between the collateral sesamoidean ligament and the deep digital flexor tendon. The distal recess of the bursa does not distend as much as the proximal, and larger amounts of fluid must be present to separate the distal sesamoid bone from the deep digital flexor tendon.[29]

Deep Digital Flexor Tendon

Deep digital flexor tendon injury is an important cause of lameness in horses with foot pain.[15,17,21-23,30,31] On MRI, the normal deep digital flexor tendon has regular margins and uniform low signal intensity (black) on all standard sequences. In some horses, on T1 images, a stippled appearance may be present in the tendon because of small intermediate signal intratendinous foci. These foci correspond to normal loose connective tissue septa.[28] In the distal limb, the deep digital flexor tendon is formed by two symmetric rounded lobes separated by a well-defined midline sagittal high-signal-intensity septum.[28,32] From the level of the proximal distal sesamoid bone distally, the tendon becomes progressively flatter (in a dorsopalmar/plantar direction) and at its insertion, it is crescent shaped with minimal lobe separation.[32] Because of magic angle effect, high signal intensity is commonly seen in the distal aspect of the deep digital flexor tendon when pulse sequences with short TE are used (see "MRI Artifacts," later).[33-35]

Deep digital flexor tendon lesions are easiest to identify on transverse images because of the loss of symmetry in shape, size and/or signal between the two lobes of the tendon. The majority of the lesions within the deep digital flexor tendon are seen as increased signal intensity on T2 and PD images. Deep digital flexor tendon lesions can be (1) core lesions (focal high signal intensity) (Figure 71-5), (2) parasagittal splits (linear parasagittal increased signal intensity) (Figure 71-6), or (3) dorsal irregularities or abrasions (irregularities of the dorsal margin) (Figure 71-7). Enlargement of one lobe or both tendon lobes is often seen concurrently with these lesions, but significant tendon enlargement has only been found at the site of core lesions.[32] The type of lesion or combination of deep digital

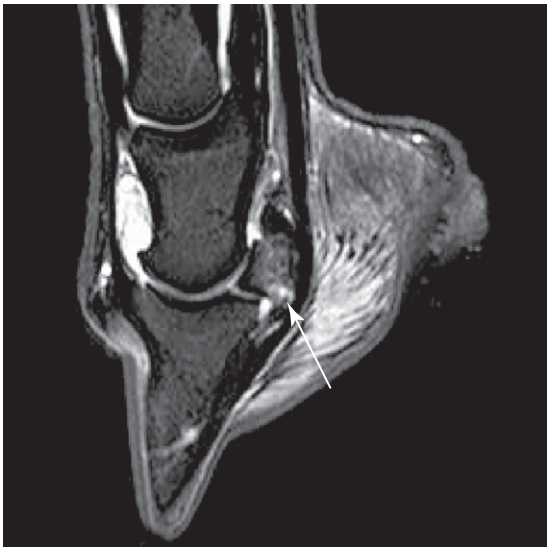

Figure 71-3. Sagittal short tau inversion recovery (STIR). The distal sesamoid bone is diffusely hyperintense. In addition a more focal hyperintensity is present in the region of the enlarged synovial invaginations *(arrow).*

Note the focal high-signal-intensity lesion *(arrow)* at the insertion of the deep digital flexor tendon onto the distal phalanx. **B,** Sagittal T2 image showing the same lesion. This lesion is not caused by magic angle effect given that this image is obtained using a long echo time (TE). (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

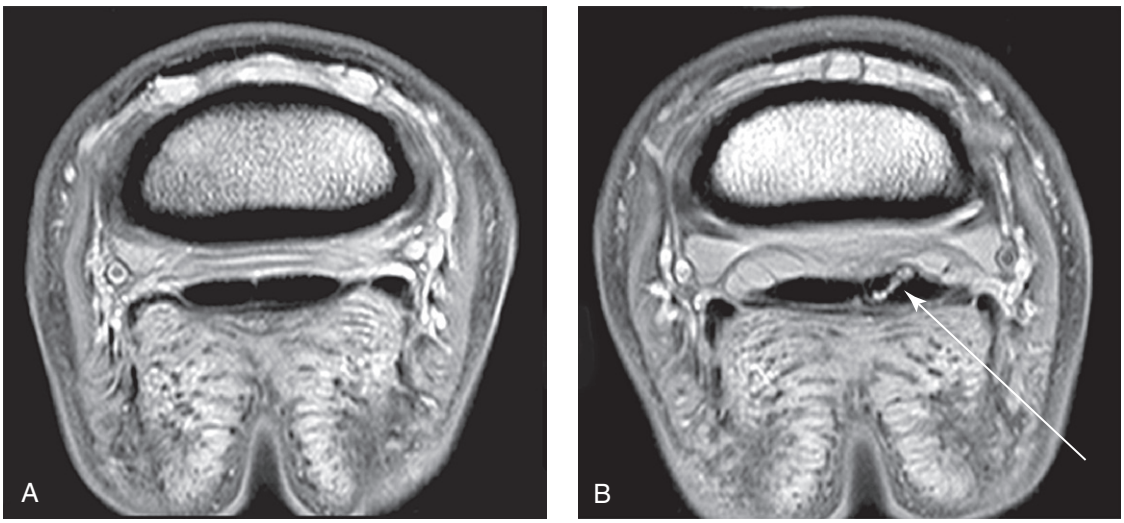

Figure 71-6. A, Transverse proton density image of the distal limb at the level of the proximal aspect of the second phalanx. Note the high signal-intensity parasagittal split through the lobe of the deep digital flexor tendon *(arrow)*. **B,** The normal contralateral limb is shown for comparison.

flexor tendon lesions varies depending on their anatomic location.[21,23] Lesions of the distal deep digital flexor tendon can occur proximal to the distal sesamoid bone, at the level of the collateral sesamoidean ligament and proximal recess of the podotrochlear bursa, at the level of and distal to the distal sesamoid bone. Horses may present with a single lesion or concurrent lesions at different sites. Deep digital flexor lesions may or may not be associated with distal sesamoid bone changes in horses with heel pain. Histopathology of lesions of the deep digital flexor tendon, identified with MRI, in horses with advanced distal sesamoid disease[21] and in horses with lameness of at least 2 months' duration[30] abolished with a palmar (abaxial) nerve block, revealed degenerative changes of the deep digital flexor tendon without evidence of inflammation. Because the appearance of degenerative lesions of the deep digital flexor tendon is similar to the ones reported in other studies (without histopathology confirmation) as tendinitis, the term *tendinopathy* is considered to be more appropriate when describing lesions of the deep digital flexor tendon localized to the foot. Although it is likely that inflammation is present at some point soon after the initial injury, its MRI appearance has not been correlated with histopathology findings. Adhesions of the deep digital flexor tendon can occur to the collateral sesamoidean ligament and distal sesamoid bone.[15,27] Adhesions of the deep digital flexor tendon are most easily seen when fluid is injected into the podotrochlear

Figure 71-7. Transverse proton density image of the distal limb, at the level of mid middle phalanx. Note the irregularities of the dorsal margin of both lobes of the digital flexor tendon *(arrows).* (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

bursa.[36] However, because of time constraints and logistics, this may not be practical in the clinical setting. Tendon adhesions in and around the podotrochlear bursa may benefit from débridement during bursoscopy.[37]

Distal Sesamoidean Impar Ligament

The distal sesamoidean impar ligament can be easily seen on MRI because of the high signal intensity of the synovial fluid within the distal interphalangeal joint and distal recess of the podotrochlear bursa, which outlines its dorsal and palmar borders, respectively.[28] The normal distal sesamoidean impar ligament is symmetric with smooth margins, and it has a striated signal intensity pattern with higher signal intensity compared to the deep digital flexor tendon. Increased signal intensity within this ligament should be interpreted with caution because of its fan shape and synovial in-pouchings between fiber bundles.[15] Moreover, when subject to magic angle effect its signal is homogeneously increased (see "MRI Artifacts," later).[28] Thickening of the ligament can be seen with or without signal intensity changes. Lesions of the distal sesamoidean impar ligament are often associated with abnormalities of the distal sesamoid bone, involving not only the distal margin but also the proximal margin and medullary cavity. Osseous changes at the origin of this ligament include entheseous new bone formation and avulsion fractures. Fragmentation at the origin of the distal sesamoidean impar ligament can be clearly seen when a thin slice plane is oriented proximad to distad over the distal sesamoid bone, perpendicular to its distal margin (see Figure 71-2).

Collateral Sesamoidean Ligament

The collateral sesamoidean ligament is obliquely oriented, which makes its full evaluation more difficult. On transverse images, the ligament is formed by two thin branches (lateral and medial), which originate from the dorsal distal aspect of the proximal phalanx. Proximal to the distal sesamoid bone, the branches merge with the ligament's body. At this level, the ligament has a narrower central body and symmetric lateral and medial branches (Figure 71-8). On T2 images the collateral sesamoidean ligament has signal intensity similar to the deep digital flexor tendon. Normal ill-defined symmetric increased signal intensity is commonly seen within the ligament's branches just proximal to the point where they merge with the ligaments' body. Injury of the collateral sesamoidean ligament can be present by itself; however, most commonly it is associated with distal sesamoid bone and/or deep digital flexor tendon lesions.[5] Lesions of the collateral sesamoidean ligament can be seen as thickening of its body and/or braches, diffuse or less commonly focal increased signal intensity, and loss of separation from the deep digital flexor tendon (see Figure 71-8). Entheseous new bone formation and avulsion fractures can be seen at the insertion of the ligament onto the distal sesamoid bone.

Collateral Ligaments of the Distal Interphalangeal Joint

The normal collateral ligaments of the distal interphalangeal joint have mildly heterogeneous low signal intensity on T2 images, and mild variations in signal intensity can be present in sound horses.[38] Increased signal intensity from magic angle effect can be seen in the collateral ligaments of the distal interphalangeal joint (see "MRI Artifacts," later).[38-40] To assess the size, the collateral ligament can be compared to the other collateral ligament in the same foot and with the collateral ligament in the contralateral foot. Focal or diffuse increased signal intensity, poorly defined margins, and osseous changes at the attachment sites of these ligaments can be seen in lame horses. Osseous lesions are commonly seen concurrently with ligament lesions. Osseous lesions are more common at the ligaments' insertion onto the distal phalanx than at their origin.[41,42] Also, the most severe lesions have been identified in the distal aspect of the ligaments,[41] which are not accessible ultrasonographically. Histopathology of the collateral ligaments of horses with lameness of more than 2 weeks' duration revealed mostly degenerative changes with little evidence of inflammation.[41] Given that the MRI appearance of degenerative and inflammatory processes is similar, the term *desmopathy* (versus desmitis) is considered more accurate to describe MRI changes of these ligaments.

Distal Digital Annular Ligament

The distal digital annular ligament is mostly located within the hoof capsule. This makes its ultrasonographic evaluation difficult. On MRI, this ligament is seen as a discrete thin structure with homogeneous low signal intensity. Distal digital annular ligaments with focal or diffuse thickness greater than 2 mm and heterogeneous signal intensity are considered abnormal.[43] Adhesions between this ligament and the deep digital flexor tendon may be seen with high-field MRI. Horses with distal annular ligament desmopathy may benefit from tenoscopic surgical transaction of the ligament.[43]

The Distal Sesamoidean Ligaments

Desmopathy of the distal sesamoidean ligaments is a cause of lameness that has been most commonly diagnosed with ultrasonography. The medial and lateral distal oblique sesamoidean ligaments are symmetric and on MRIs have low signal intensity,

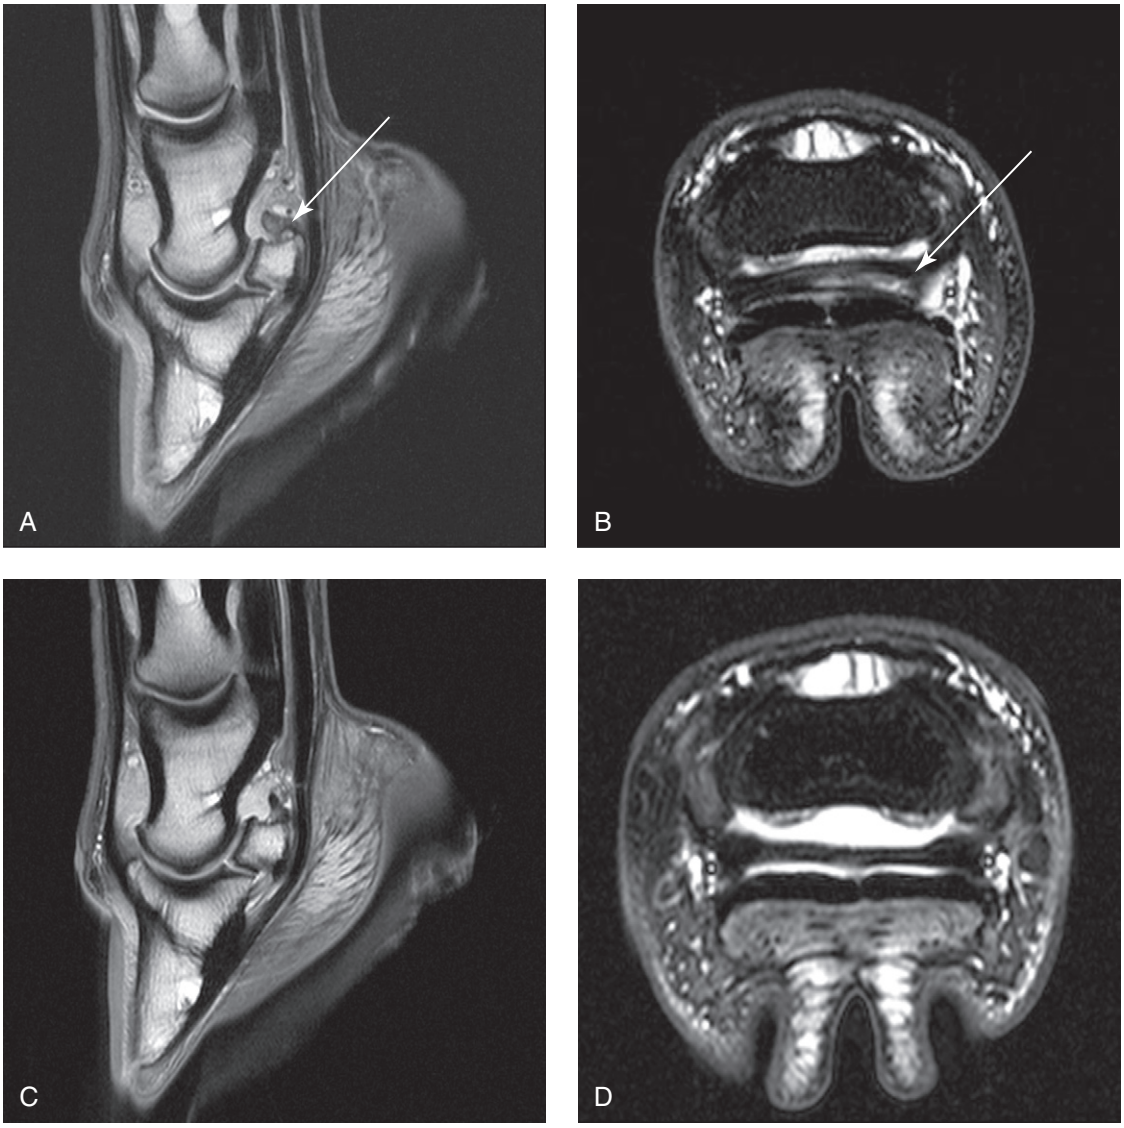

Figure 71-8. A, Sagittal proton density (PD) image of the foot. The collateral sesamoidean ligament is thickened with high signal intensity *(arrow)* close to its insertion onto the distal sesamoid bone. **B,** Transverse short tau inversion recovery (STIR) image at the level of mid second phalanx. The collateral sesamoidean ligament is thickened *(arrow)* with increased signal intensity consistent with desmopathy. Sagittal PD **(C)** and transverse STIR **(D)** images of the contralateral foot of the same horse as **A** and **B,** showing a normal collateral sesamoidean ligament. (**C** and **D,** Courtesy Dr. Russel L. Tucker, Washington State University, Pullman, WA.)

with several thin linear intermediate to high signal areas throughout it giving it a heterogeneous appearance.[44] Because of the variation between the amount of heterogeneity in the distal oblique and straight sesamoidean ligaments among horses, comparison with the contralateral limb (if normal) is important. As magic angle effect can be observed in the oblique sesamoidean ligament when using standing MRI systems, care should be taken when interpreting increased signal intensity within this ligament (see "MRI Artifacts," later).[40] Magic angle effect has not been reported in the oblique distal sesamoidean ligaments with high-field systems. However, because magic angle effect occurs in several other ligamentous and tendinous structures with both high- and low-field systems, it is likely that the same happens with the distal oblique sesamoidean ligament.

The Metacarpal and Metatarsal Region

Suspensory Ligament

As seen with ultrasonography, the appearance of the proximal aspect of the suspensory ligament on MRI is variable among horses.[45,46] This variability is attributed to the differences in the amount, pattern, and location of muscle and adipose tissue within the ligament.[46] The muscle and adipose tissue within the ligament are seen as areas of intermediate to high signal intensity and are unequally distributed between the medial and lateral lobes. In addition, the lobes of the proximal suspensory ligament are asymmetric in size and shape. Because of these variations, comparison with the contralateral limb (if normal) is essential for accurate interpretation of the proximal suspensory ligament. Injury of the suspensory ligament can be seen as

abnormal signal, enlargement and indistinct and/or irregular borders.[47] MRI allows evaluation of the abaxial margins of the suspensory ligament, which cannot be easily seen ultrasonographically. High-field MRI allows identification of adhesions between the suspensory ligament and exostoses of the second metacarpal bone.[48] In normal limbs a small space of intermediate to high signal intensity, corresponding to loose connective tissue, is present between the suspensory ligament and the second metacarpal bone. Adhesions are seen as loss of this space, which is filled with low signal intensity.[48] The loss of the normal space between the suspensory ligament and the second metacarpal bone, in conjunction with suspensory ligament changes and splint bone exostoses in a horse with chronic or recurrent lameness localized to the proximal metacarpal region, is highly suggestive of adhesions between the suspensory and the splint bone. These horses will likely benefit from surgical release of the adhesions and partial splint bone osteotomy.[48] The low signal intensity between the suspensory ligament and the second metacarpal bone should, however, be interpreted with caution because osseous proliferation and an enlarged suspensory ligament could result in a similar appearance. MRI has demonstrated that some fibers of the lateral lobe of the suspensory ligament originate from the proximal fourth metacarpal bone in normal limbs.[45] Also, compared to the medial lobe and the second metacarpal bone, the lateral lobe of the suspensory ligament is overall closer to the fourth metacarpal bone, and in some areas it contacts the bone. Therefore, adhesions between the suspensory ligament and the fourth metacarpal bone may be more difficult to assess than adhesions to the second metacarpal bone.

Accessory Ligament of the Deep Digital Flexor Tendon

Large individual variation exists in the MRI appearance of the accessory ligament of the deep digital flexor tendon. In a large percentage of horses, areas of heterogeneous signal intensity may be present.[45] Comparison with the contralateral limb is important so as not to overinterpret these areas.

Cartilage and Bone

On MRI, articular cartilage has a uniform high signal intensity adjacent to the low signal intense subchondral bone. Articular cartilage injury can be seen as loss of the normal high signal intensity, corresponding to defects or thinning. These changes are more easily identified on three-dimensional GRE sequences because they allow thin slices to be obtained without loss of resolution. It can be difficult to confidently identify cartilage lesions when no concurrent subchondral bone lesions are present. This is because the articular cartilage is thin and several artifacts can create signal changes that are not related to injury. These artifacts include motion, volume averaging, and magic angle effect. High-field MRI has moderate sensitivity in identifying full-thickness cartilage erosions in the metacarpophalangeal joint, and these lesions are often underestimated.[49]

MRI is sensitive for detecting subchondral bone sclerosis and subchondral bone osseous cystlike lesions. Osseouscystlike lesions are seen as intermediate to high signal intensity focal areas on T2, GRE, and fat-suppressed sequences (Figure 71-9).[3,4,17] These lesions may be surrounded by a low signal intensity rim.

Areas of increased signal intensity within trabecular bone are commonly designated bone bruise or bone edema. These lesions have been reported in the horse's distal sesamoid bone, proximal metacarpal region, and carpal bones and are best seen on fat-suppressed sequences (STIR and fat-saturation sequences). On histopathology of human knees with osteoarthritis, bone bruises represent bone marrow necrosis and fibrosis, edema, and hemorrhage.[50] Edema and hemorrhage represent a minor component of these lesions.

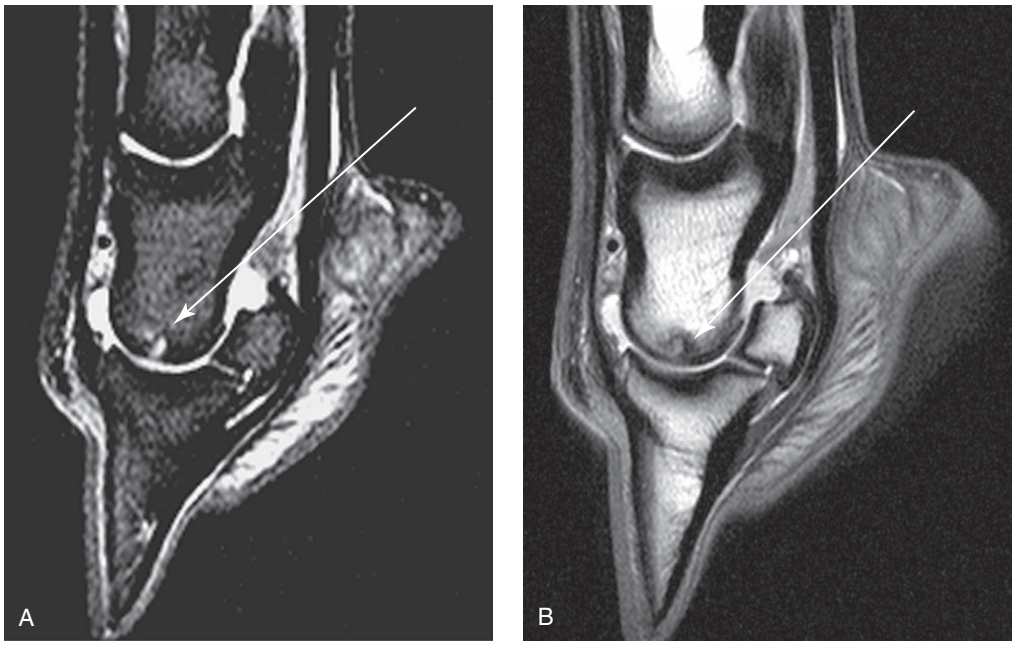

Figure 71-9. A, Sagittal short tau inversion recovery image of the foot. Note the focal high signal intensity in the subchondral bone of distal second phalanx consistent with an osseous cyst-like lesion *(arrow).* **B,** Sagittal proton density image shows a rim of hypointensity surrounding the subchondral bone lesion consistent with sclerosis *(arrow).*

The Head

MRI is the gold standard modality to image the brain in humans and animals. The use of intravenous contrast media is indicated when imaging the equine brain. The contrast material used with MRI is a gadolinium derivate. Doses of 0.02 mmol/kg in adult horses and 0.1 mmol/kg in foals of gadolinium-diethylenetriamine penta-acetic acid (gadolinium-DTPA) have been reported for imaging the brain.[10,50] However, an optimal dose of intravenous gadolinium contrast in horses has not been established. T1 images are used for evaluating contrast enhancement. Many congenital, toxic, inflammatory or infectious (including equine protozoal encephalopathy), and neoplastic processes affecting the brain can be identified with MRI.[10,51-53]

MAGNETIC RESONANCE IMAGING ARTIFACTS

Magnetic Susceptibility Artifact

To avoid magnetic susceptibility artifacts from ferrous material, prior to undergoing MRI, horses must have horseshoes and nails carefully removed and the feet should be cleaned. Because even small pieces of metal can cause a substantial artifact, a 60-degree dorsopalmar/plantar oblique radiographic projection of the distal phalanx should be obtained prior to the MRI examination to identify small fragments of nail that may be left behind after shoe removal. Also, materials that have ferrous content should not be used to pack the foot for radiography. For example, blue Play-Doh is produced using a ferrous blue dye, and it should be avoided in horses that may have subsequent MRI performed. Susceptibility artifact appears as areas of signal void (black) surrounded by high signal intensity (white), often accompanied by various degrees of anatomic distortion (Figure 71-10).[12] GRE sequences are subject to more severe susceptibility artifacts than SE sequences.[6,12]

Magic Angle Effect

It is important to recognize magic angle effect because it can mimic lesions in tendons and ligaments. In horses, magic angle effect can occur in the distal aspect of the deep digital flexor tendon and collateral ligaments of the distal interphalangeal joint in low-field and high-field systems, standing, or under general anesthesia.[33-35,38-40] Magic angle effect has also been reported in the distal sesamoidean impar ligament using a high-field system[28] and in the oblique sesamoidean ligaments with a standing system.[40] Normal tendons and ligaments, being built of tightly bound collagen fibers, have low signal intensity (black). When using MRI sequences with a short TE (T1, PD, T2*), increased signal intensity is seen within tendons and ligaments in regions where the collagen fibers are aligned at 55 ± 10 degrees with the magnet's main magnetic field (B0). This increase in signal intensity is referred to as *magic angle effect*, and it does not correspond to a pathologic change within the tendon or ligament (Figure 71-11). Magic angle effect can occur in any imaging plane, be it sagittal, dorsal, or transverse.[33,35,39] To differentiate a hyperintensity caused by a true lesion from magic angle effect, sequences with a long TE (T2) must be used. High signal intensity regions (hyperintensity) within one of the tendinous or ligamentous structures mentioned earlier, on sequences with long TE, likely represent a true lesion. The presence of other concurrent changes, such as altered size, shape, and irregular margins, can further corroborate the presence of a true lesion.

Zipper Artifact

All magnet rooms are shielded to eliminate the interference from local radiofrequency broadcasting stations or from electronic equipment that emits an electromagnetic signal that could interfere with the MRI signal. Zipper artifact is caused by leakage of electromagnetic energy into the magnet room. Leakage can be caused by electronic equipment brought into

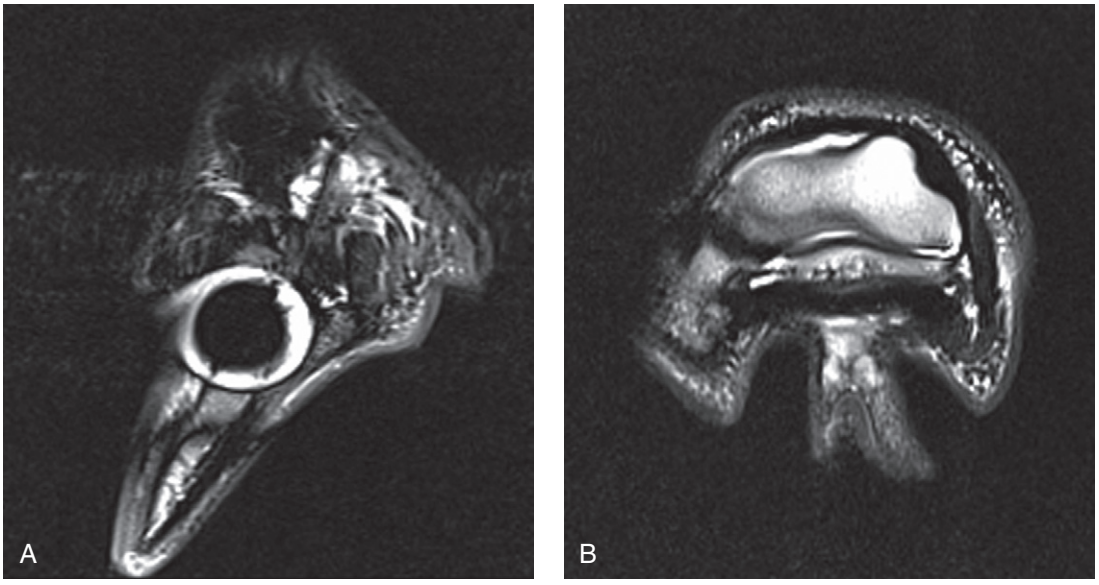

Figure 71-10. A, Sagittal short tau inversion recovery image of the foot, showing a round signal void *(black)* surrounded by a high signal intensity *(white)* rim in the region of the distal phalanx. This appearance is caused by severe magnetic susceptibility artifact because of an incompletely removed shoe nail; **B,** Transverse T2-weighted image of the same foot, at the level of the distal phalanx. Note the anatomic distortion of the distal phalanx because of a magnetic susceptibility artifact (*left side*).

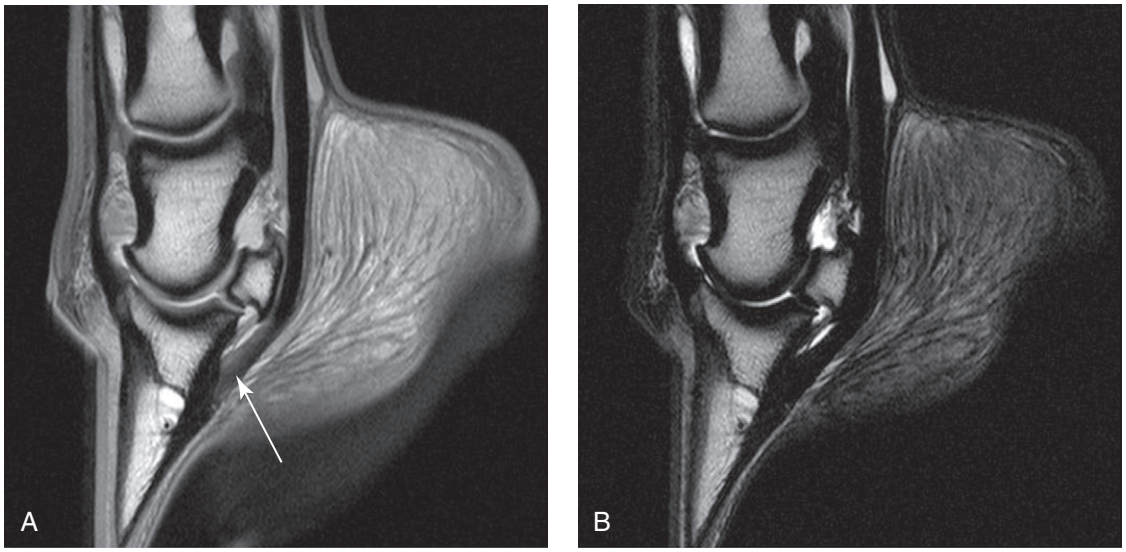

Figure 71-11. A, Sagittal proton density image of the foot. Note the increased signal intensity within the deep digital flexor tendon (DDFT) *(arrow)* distal to the distal sesamoid bone because of magic angle effect. **B,** Sagittal T2-weighted image of the same foot. Because of the long echo time of the T2 sequence, the hyperintense region in the distal DDFT is no longer seen. (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

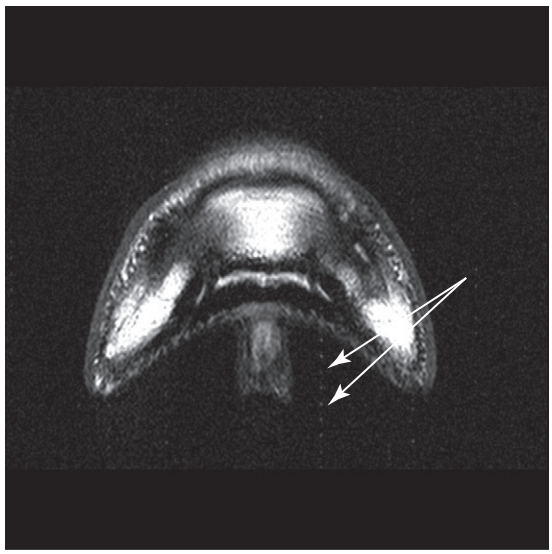

Figure 71-12. Transverse T2-weighted image of the distal third phalanx, at the insertion of the deep digital flexor tendon. Note the small (pinpoint) high signal intensity dots oriented vertically in the image because of zipper artifact *(arrows).* This artifact is caused by extraneous radiofrequencies entering the magnet's room when the room's door is opened during scanning. (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

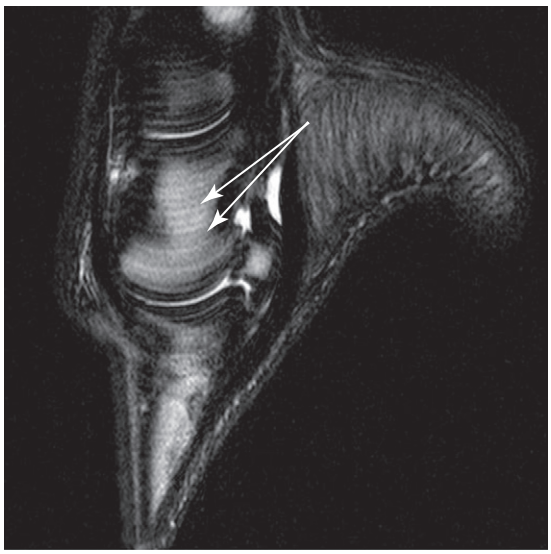

Figure 71-13. Sagittal T2-weighted image of the foot. Note the repeated hypointense curved lines *(arrows)* that repeat themselves through the first and second phalanges. These lines are caused by motion artifact. (Courtesy Dr. Russell L. Tucker, Washington State University, Pullman, WA.)

the magnet room or when the door of the room is opened while the scan is in process. This artifact appears as a region of increased noise with a width of 1 or 2 pixels that extends as lines of white and black dots in the frequency encoding direction (Figure 71-12).[6]

Motion Artifact

Motion artifact appears as blurring of the image and ghosting (the same region repeated multiple times) (Figure 71-13).[12] Motion artifact is particularly a problem with standing magnets. In horses under general anesthesia, respiratory motion can result in substantial movement of the upper limb. Respiration-related motion can be minimized by placing sandbags on top of the distal limbs.

Volume Averaging Artifact

Each pixel on an MRI represents a voxel or three-dimensional volume of tissue. Voxels can include more than one tissue type,

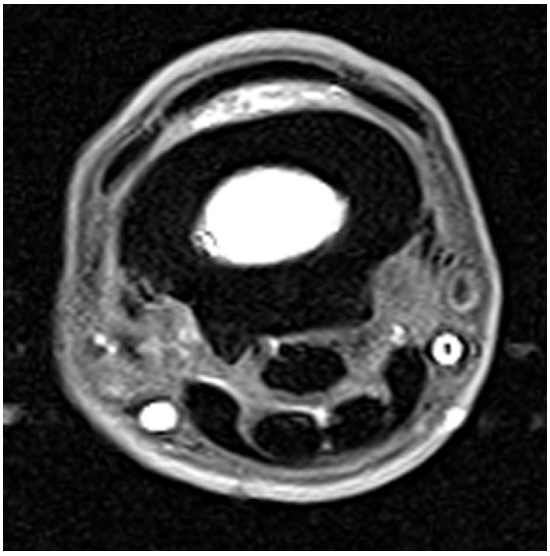

Figure 71-14. Transverse T1-weighted (T1) image of the proximal aspect of the proximal phalanx. Note the ghosting of the palmar digital veins (*arrows*) due to flow artifact.

and the intensity of the signal represents an average of those tissue types. Volume averaging should be considered at the edges of all structures. If the structure adjacent to the one being evaluated is, for example, a joint with fluid, the high signal of the fluid may average with the edge of the tendon, ligament, or bone, making it appear that a lesion is present within that structure. Volume averaging is more likely to occur with thicker slices.

Flow Artifact

Flowing blood is a specific source of motion artifact. Flow artifact is seen as ghosting of the vessel in the phase encoding direction (Figure 71-14). To remove flow artifact from an area of interest, the phase encoding direction can be changed.

Diagnostic Anesthesia

Anton E. Fürst

During a lameness examination, diagnostic analgesia is carried out to assist in determining of the anatomic site of lameness. It is generally used in horses that are obviously lame or that show a positive response to a flexion test or other provocation tests. A detailed discussion of diagnostic analgesia can be found in textbooks dealing mainly with lameness.[1,2] Perineural anesthesia is preferred over intra-articular anesthesia because it creates less morbidity.

TECHNICAL ASPECTS

General Considerations

Injectable solutions, needles, and syringes must be sterile. It is advisable to use new needles for each injection, and the gauge of needle should be as small as practicable, so the patient will not react adversely. Diagnostic anesthesia of the distal limb up to the carpus or tarsus is carried out with the affected limb held in a non–weight-bearing position by the clinician, if possible, whereas the limb is usually bearing weight for proximal analgesia. For temperamental horses, the limb may be held up for analgesia of the proximal regions as well.

Mechanism of Action

Pain stimuli caused by an injury are transmitted to the central nervous system by peripheral nerves, mainly thinly myelinated A delta and nonmyelinated C fibers. Local anesthetics block nerve conduction by preventing the increase in membrane permeability to sodium ions that occurs when nerves are stimulated. Local anesthetics exert their effect by inhibiting the rapid inward flow of sodium ions, thereby inhibiting depolarization of the membrane. This is achieved by the dissociation of local anesthetic, which alters the electrical forces across the membrane. The order and degree of neural blockade correlate with the diameter and type of nerve fiber and the degree of myelination. As a local anesthetic takes effect, the first nerve fibers blocked are the B fibers; the A delta and C fibers are next, and the last nerves blocked are A gamma, A beta, and A alpha.[3] Hence, sensory nerves are the first to be desensitized, followed by sympathetic and eventually motor nerves.[3] For more details on pain management see Chapter 23.

Choice of Local Anesthetic Agent

Mepivacaine is the local anesthetic agent of choice for perineural and intrasynovial analgesia.[3] Its duration of action is 2 to 3 hours, and it causes less tissue irritation than other local anesthetics. Once a bottle of local anesthetic is opened, the efficacy of the drug diminishes rapidly, so it should be used within a few days. Generally, 2% solutions (20 mg/mL) of local anesthetic are used. As a rule, because of the irritant properties of anesthetic agents, as little as is necessary to obtain anesthesia should be injected. In severely inflamed or abnormal tissues, a higher concentration or amount of local anesthetic is commonly needed to achieve the desired effect. This can occur because local anesthetics penetrate membranes less effectively in an acidotic area, such as an infected wound or joint.[3] Additionally, diffusion of the anesthetic to its intended site of action is diminished in edematous or scarred tissues, and the anesthetic effect is therefore less reliable.

Adrenalin at a low concentration is sometimes added to a local anesthetic when it is used for perineural anesthesia to induce a certain degree of vasoconstrictionin the area.[4] Although it prolonges the duration of analgesia, adrenalin also imparts a more selective analgesia. Therefore, adjacent structures including other nerves and ligaments are affected to a lesser degree.[3] However, the disadvantage of adrenalin is that severe swelling may occur 1 day later. Adrenalin may be responsible for the occurrence of skin necrosis and white hair, which are sometimes observed after diagnostic analgesia.

Perineural Anesthesia

Long or dirty hair should be trimmed with a No. 40 clipper blade, and all injection sites should be thoroughly cleaned with antiseptic soap and gauze sponges. A combination of 70% alcohol and chlorhexidine is often used for this purpose. Aseptic preparation of the skin is required before injection of synovial spaces. The clinician's hands must also be clean because they are used to palpate and locate the nerves under the skin immediately prior to injection.

Synovial Anesthesia

Anesthesia of synovial spaces is performed only after thorough cleaning of the relevant area. Hair should be clipped and the skin cleaned first with a surgical scrub, such as chlorhexidine, followed by a disinfectant as described previously. The skin should be cleaned for 5 to 10 minutes. Clipping the hair has two advantages: it aids in cleaning the skin and in identifying the injection site. However, in two studies, infection rates after intrasyovial anesthesia were not decreased by clipping or shaving the hair.[5,6]

Anesthesia of synovial spaces requires sterile gloves, needles, and syringes. Generally, the synovial space is injected using an 18-gauge (1.2-mm–diameter) or 20-gauge (0.9-mm–diameter) needle. Large-gauge needles are better for collecting synovial fluid, but horses tolerate their placement less well than smaller-gauge needles. The needle is inserted alone without the syringe attached. Depending on the temperament of the horse, a twitch may be used for restraint. This is particularly useful when needles are inserted through large muscle masses—for example, over the shoulder, elbow, and hip joints. A twitch also should be used when injecting complex joints, such as the stifle. The operator should always use a competent assistant to restrain the horse, so that sudden movements, which may result in damage to the joint cartilage or needle breakage, are prevented. When the needle is to be inserted over a large distance (shoulder or hip joint), the skin over the injection site should be anesthetized using a small amount of anesthetic and a small-gauge needle. For certain procedures, a spinal needle is used because it is flexible and less likely to break. After injection of the synovial space, the horse is walked to promote distribution of the anesthetic agent.

Needle Positioning for Intrasynovial Anesthesia

For most synovial spaces, the needle is correctly positioned when synovial fluid flows spontaneously out of the hub of the needle. Sometimes, the needle must be rotated several times until synovial fluid flows out. When this fails, aspiration of synovial fluid may be attempted, although this rarely works because the synovial villi become lodged in the tip of the needle, thereby blocking the flow. Injection of air often produces a characteristic bubbling of synovial fluid in the joint, and a larger amount of injected air sometimes results in backflow of foamy synovial fluid. Another indication of correct needle placement is minimal resistance to the injection of local anesthetic. In special cases, the joint can be radiographed after intrasynovial injection of contrast medium (see Chapter 67).

Animal Restraint

Whenever possible, horses should not be sedated for diagnostic anesthesia even though the risk of injury while working on the hind limbs is high. A twitch applied to the nose is an excellent restraining method and makes diagnostic anesthesia easier and safer. However, sedation may be necessary in intractable horses. Detomidine (0.002 mg/kg intravenously) is ideal and can be reversed.[7] Alternatively, acepromazine (0.002-0.01 mg/kg intravenously) may be used. The use of α_2-agonists for sedation is not recommended because the horse may react violently when the needle is inserted. Additionally, these drugs have two other effects that may be confusing during a lameness evaluation: they induce some analgesia and they produce ataxia.

EVALUATION OF ANESTHESIA

Testing

The clinician must determine whether diagnostic perineural anesthesia has achieved the desired effect and the nerve in question has been desensitized before re-evaluating lameness. A pointed instrument, such as a ballpoint pen, can be used to assess the sensitivity of the skin and deeper structures including tendons and ligaments. A convenient device consists of a stick approximately 1 m long, with a blunt nail positioned at one end. The nail can be conveniently placed on the region of temporarily neutralized sensory innervation of the horse to test the efficacy of analgesia without bending down. Hoof testers, joint flexion, and digital pressure (Tables 72-1 and 72-2) are also used to evaluate desesitization of the nerve or joint. Lameness can be evaluated only when the nerve or joint have been correctly desensitized.

Onset and Duration of Effect

Depending on the site, lameness should be re-evaluated 5 to 50 minutes after the injection of local anesthetic. Not waiting long enough leads to false-negative results. Local anesthetic effects begin within a few minutes after injection, but it takes variable periods of time for the horse to become sound. The first re-evaluation of lameness should always be done 5 to 10 minutes after injection. Before performing the next nerve block in the distal limb, the clinician should wait a minimum of 20 minutes, and for the proximal limb, a minimum of 45 minutes. Generally, the horse is re-evaluated 5 to 60 minutes after analgesia of a synovial space, although this time depends greatly on the joint—for example, it takes as little as 5 minutes for desensitization of small synovial spaces, such as the distal interphalangeal joint, and up to 60 minutes for the desensitization of large synovial spaces, such as the stifle joint. The goal of intrasynovial analgesia is desensitization of the nerve fibers of synovial structures. Studies show that additional structures outside the synovial space are also desensitized.[8,9] This occurs because of the close proximity of large nerves to the synovial space and the rapid diffusion of the anesthetic agent into the surrounding tissue. Therefore, the selectivity of joint analgesia comes into question; in a cadaveric study, it was shown that 15 minutes after injection of mepivacaine with an added radiodense dye into one synovial space, mepivacaine was present in adjacent synovial spaces.[10]

Interpretation

Lameness is re-evaluated after each injection of anesthetic. The horse should be walked and trotted "in hand" on a hard flat surface. All the tests (flexion, moving the horse in a tight circle, hyperflexion, extension) that were positive in the initial examination should be repeated. The horse can also be lunged on soft ground if required (see later). The response to diagnostic anesthesia can be negative, positive with residual lameness, positive, or positive with lameness in the contralateral limb. A positive response with residual lameness may be difficult to interpret. The most difficult interpretation is that of a lameness that gradually improves after each injection. It must be emphasised that an explanation must be found for each improvemet of the lameness after each anesthestic injection. The results of diagnostic anesthesia may be incorrectly assessed, yielding false-positive or false-negative results.[11,12] Negative results, in particular, must be carefully interpreted; failure to desensitize a nerve may be caused by an individual variation in the course of a nerve in some horses or by loss of efficacy of the local anesthetic agent. Furthermore, excessive diffusion of the anesthetic agent may lead to erroneous results. Certain types of lameness may become less pronounced during the evaluation, as a result of a warming-out effect (some arthritic conditions

TABLE 72-1. Perineural Analgesic Blocks of the Forelimb

Number	Nomenclature	Targeted Nerves or Region	Injection Site	Gauge (G) of Needle and Amount of 2% Local Anesthetic	Testing the Analgesia	Desensitized Nerves or Region	Differential Diagnosis, Remarks
F1 (Figure 72-1)	Distal palmar digital nerve block, palmar digital block	Lateral and medial palmar digital nerves	The needle is inserted subcutanously directly over the nerve, just proximal to the cartilages of the foot	24 G, 2 mL per site	Deep pain is assessed with hoof testers; loss of skin sensation proximal to the heels	80% of the hoof and a large part of the digit	Navicular disease; disorders of the DIP and PIP joints; fissure fractures and fractures of distal, middle, or proximal phalanx; pedal osteitis; abscess in the hoof capsule; pododermatitis, laminitis, hoof cracks, tendinitis, and insertional desmitis of the deep digital flexor tendon cysts in the distal, middle, or proximal phalanx
F2 (Figure 72-1)	Proximal palmar digital nerve block, basis sesamoid block, mid pastern ring block, pastern nerve block	Lateral and medial palmar digital nerves and dorsal branches	The needle is inserted in the mid pastern region directly over the nerve and subsequently advanced farther dorsally; the nerve is easily palpated	24 G, 3-5 mL per site	Hoof testers are used to assess entire hoof; loss of skin sensation dorsal to the coronary band	100% of the hoof, the dorsal pastern region	The same as F1, but structures further dorsal are desensitzed
F3 (Figure 72-1)	Abaxial sesamoid block, mid sesamoid block	Lateral and medial palmar digital nerves and dorsal branches	The needle is inserted subcutanously directly over the nerve on the abaxial side of the proximal sesamoid bones	24 G, 3 mL per site	Loss of skin sensation over the pastern region	Same as F2 plus parts of the metacarpophalangeal joint: foot, digit, metacarpophalangeal joint, proximal sesamoid bones	Often performed in combination with other nerve blocks; otherwise rarely performed because interpretation is difficult

F4 (Figure 72-1)	Low metacarpal nerve block	Medial and lateral palmar metacarpal nerves	With the limb held up, the needle is inserted between MCIII and the distal free end of MCII and MCIV, respectively, and advanced subcutaneously, axially, and subfascially, *or* the needle is inserted just at the distal aspect of the MCII/MCIV and directed axially, where the metacarpal nerves course more superficially.	22 G, 5 mL per site	Loss of skin sensation in the MCP area	Parts of the phalangeal region and parts of the MCP joint and the proximal sesamoid bones	Predominantly performed in conjunction with other more distal nerve blocks
F3, F4 (Figure 72-1)	Low four point, abaxial sesamoid block and low palmar metacarpal nerve block, low palmar anaglesia or block, low palmar ring block, distal metacarpal nerve block	F3 and F4	F3 and F4	22 G, 5 mL per site	Forceful flexion of the IP and MCP/MTP joints; loss of skin sensation distal to the injection site	The same as F3 and F4	The same as F3 and F4
F5 (Figure 72-1)	High palmar nerve block	Lateral and medial palmar nerves	Local anesthetic is first deposited subfascially on the lateral aspect, immediately proximal to the digital flexor tendon sheath between the deep digital flexor and the suspensory ligament. The needle is then advanced and the injection is repeated on the medial aspect of the limb.	20 G, 5 mL per site	Loss of skin and tendon sensation distal to the injection site	The same as for F3 plus parts of the flexor tendon sheath, parts of the superficial and deep flexor tendons, and the suspensory ligament

TABLE 72-2. Perineural Analgesic Blocks of the Hind limb

Number	Nomenclature	Targeted Nerves or Region	Injection site	Gauge (G) of Needle and Amount of 2% Local Anesthetic	Testing the Analgesia	Desensitized Nerves or Region	Differential Diagnosis, Remarks
H1 (Figure 72-4)	Low plantar nerve block, plantar digital block	Digital plantar nerve	The same as F1	24 G, 6 mL	The same as F1	The same as F1	
H2 (Figure 72-4)	Mid pastern ring block, pastern nerve block	Digital plantar nerve and its dorsal branch; deep branch of the fibular nerve	The same as for F1 plus lateral and medial to the long digital extensor tendon	22 G, 16 mL	The same as F2	The same as F2	
H3 (Figure 72-4)	Abaxial sesamoid block, basis sesamoid block	Digital plantar nerve and its dorsal branch; deep branch of the fibular nerve	The same as for F1 plus lateral and medial to the long digital extensor tendon	22 G, 12 mL	Loss of skin sensation below the injection site	The same as F3	
H4 (Figure 72-4)	Low metatarsal nerve block	Medial and lateral plantar metatarsal nerves	The same as F4	22 G, 6 mL	The same as F4	The same as F4	
H5 (Figure 72-4)		Superficial and deep fibular nerves	Lateral and medial to the long digital extensor tendon In the groove between MTII and MTIII	22 G, 6 mL	Partial loss of skin sensation below the injection site	Skin below the injection site	This anesthesia is never carried out on its own
H3, H4, H5 (Figure 72-4)	Low plantar ring block, distal metatarsal nerve block	Medial and lateral plantar nerves, medial and lateral plantar metatarsal nerves, dorsal metatarsal nerves	H3, H4, H5; see above	22 G, 15-20 mL	Forceful flexion of the interphalangeal and MTP joints	All structures distal to the injection sites: hoof, interphalangeal joints, MTP joint	
H6 (Figure 72-4)	High plantar nerve block	Medial and lateral plantar metatarsal nerves	The same as F5	22 G, 12 mL	The same as F5	The same as F5	
H4, H5, H6 (Figure 72-4)	Middle plantar ring block, middle metatarsal nerve block	H4, H5, H6	H4, H5, H6; see above	22 G, 15-20 mL	Forceful flexion of the interphalangeal joints	All structures distal to the injection sites: hoof, interphalangeal joints, metatarsophalangeal joint, and parts of the tendons	
H7 (Figure 72-4)	Subtarsal nerve block	Medial and lateral plantar nerves	The needle is inserted 3 cm into the subcutaneous and subfascial tissue, distal to the tarsometatarsal joint axial to MTII and MTIV, respectively	20 G, 2 × 5 mL			

H8 (Figure 72-4)		Medial and lateral plantar metatarsal nerves	The needle is inserted 3 cm distal to the TMT joint axial to MTII and MTIV until contact is made with MTIII	20 G, 2 × 5 mL			
H5, H7, H8 (Figure 72-4)	High plantar ring block, proximal metatarsal nerve block	The same as H7 and H8	The needle is inserted 3 cm distal to the TMT joint axial to MTII and MTIV until contact is made with MTIII; the needle is withdrawn and a second depot is injected subfascially; the needle is advanced subcutaneously farther dorsally to the long digital extensor tendon	20 G, 6 × 5 mL	Forceful flexion of the interphalangeal joints; deep palpation of the tendons	All structures distal to the injection sites, hoof, interphalangeal joints, MTP joint, most of the tendons, part of the TMT joint, part of the tarsal sheath	
H9 (Figure 72-5)	Analgesia of the tibial nerve, tibial nerve block	Tibial nerve; the nerve lies in a groove between the calcaneal tendon and the deep digital flexor tendon	The needle is inserted 8 cm proximal to the calcaneus, from medial (or lateral); the anesthetic should be injected into a larger region subfascially. Caution is advised because horses can react violently to the injection. It is preferable to pick up the ipsilateral forelimb. The nerve can be palpated as a firm cordlike structure with the tarsus flexed.	20 G, 20 mL	Loss of skin sensation on the plantar surface of the tarsus	Plantar structures of the tarsus	
H10 (Figure 72-5)	Analgesia of the fibular nerve, fibular nerve block	Superficial and deep fibular nerves; fibular nerve	The needle is inserted approximately 10 cm proximal to the tarsal joint, between the long digital extensor muscle and the lateral digital extensor muscle. First, 10 mL is injected subcutanously, and then the needle is inserted slightly caudal to the tibia. Analgesia of the deep fibular nerve is not always satisfactory; the superficial nerve can be easily palpated.	20 G, 2 × 10 mL	Loss of skin sensation on the dorsal tarsus and dorsolaterally on the tarsus and metatarsus		
H11 (Figure 72-5)	Analgesia of the saphenous nerve	Saphenous nerve	Cranial and caudal to the saphenous vein, approximately 15 cm proximal to the tarsus	20 G, 2 × 10 mL	Loss of skin sensation dorsomedially on the tarsus and metatarsus		
H9, H10, H11 (Figure 72-5)	Triple block	H9, H10, H11; see above	H 9, H10, H11; see above	H9, H10, H11; see above		Entire distal hindlimb, tarsus, and distal tibial region	Useful analgesia to differentiate disorders located distal and proximal to the tarsus

are less painful as exercise progresses and the horse is said to "warm out" of the lameness), or the lameness may be overshadowed by agitation of the patient. Sometimes, the horse must be re-evaluated the next day, and all perineural injections repeated.

PRECAUTIONS

Interpretation of the results of perineural anesthesia in horses being treated with systemic antiinflammatories and analgesics can be difficult. Therefore, diagnostic analgesia should not be performed until the effects of the systemic analgesics have worn off.

Horses with Suspected Incomplete Fractures

In severely lame horses (e.g., with tendon rupture, bone fracture), the cause can usually be diagnosed without diagnostic anesthesia, and in these cases, the area is merely radiographed or examined ultrasonographically. In selected cases, diagnostic analgesia may be carried out before or after radiography to confirm a diagnosis. However, incomplete fractures can progress into complete fractures with displacement after diagnostic anesthesia. Therefore, the horse with a suspected incomplete fracture should be walked or trotted in a straight line, in hand, for only a few strides to determine the effects of the anesthetic, if this becomes necessary.

With mild to moderate lameness, the question always arises as to whether horses should be lunged after diagnostic anesthesia. In my experience, several displaced fractures have developed in horses that were lunged after perineural anesthesia. Interestingly, the hind limbs were more often affected than the forelimbs. The bones most commonly affected are the proximal aspect of the proximal phalanx and the distal third metacarpal (MCIII) or third metatarsal (MTIII). Fractures of other bones after lunging are rare. The following general rules should be observed:

- Horses with acute lameness (up to 6 weeks) should not be lunged.
- The horse must be quiet and under the control of the examiner during lunging; otherwise, lunging should be discontinued.
- Trotting the horse in hand in a straight line is always safer than lunging in a circle.

Every diagnostic anesthetic injection proximal to the palmar digital nerve block increases the risk of fracture; therefore, if an incomplete fracture of the proximal phalanx is suspected, blocks should not be continued above this point.

Bandaging and Stall Rest

At the end of the diagnostic analgesia procedure, a bandage moistened with disinfectant solution should be applied to the leg for 12 to 24 hours. This is to prevent swelling associated with the injections in the distal limb. The horse should remain in a box stall for 24 hours. Under no circumstances should a horse be turned out after diagnostic analgesia. Horses should be rested for 3 days after intrasynovial analgesia.

COMPLICATIONS

Swelling often occurs for a few days in limbs that have had multiple perineural anesthetic injections. In these cases, the limb must be kept under bandages for several days. In rare cases, skin necrosis can develop after perineural analgesia.

In fractious horses, the needle may break and one part of it remain under the skin. Whenever possible, an attempt should be made to remove the part of the needle buried in the tissues.

Adjacent structures may be damaged; however, the risk of this is low if a correct approach and proper injection technique are applied.

Infection of synovial structures or cellulitis after perineural or intrasynovial anesthesia is very rare, particularly when aseptic technique has been followed. The risk of cartilage damage and joint infection or inflammation is also very low provided that intrasynovial analgesia is performed correctly. Therefore, it usually is unnecessary to advise the owner explicitly of these risks (in my opinion). Joint hemorrhage, which can occur after joint puncture, does not appear to have any long-term adverse effects, but it may dilute the local anesthetic and result in a false-negative test.[13]

APPLICATION

Perineural analgesia must be carried out in a systematic and logical manner. The aim is to be specific and exact, while avoiding an excessive number of nerve blocks. Generally, the procedure is begun distally, and progresses proximad. The more distal the nerve block, the more specific is the diagnostic anesthesia. Perineural anesthesia is usually applied medially and laterally at the specific location at the same time. In addition to perineural anesthesia, which usually desensitizes a single nerve (medially and laterally), ring blocks are frequently used to block the entire region distal to the anesthetized area.

Nomenclature

The names of the various diagnostic nerve blocks vary depending on the literature consulted. Because of this confusion, a simple classification system was chosen for the tables and figures in this chapter. *F* corresponds to forelimb and *H* to hind limb. Numbers indicate perineural injection of a nerve or nerve pair. When a ring block is used, it is referred to by the number of the nerve anesthetized.

Perineural Anesthesia in the Forelimb[14-19]

In the forelimb, a distal palmar digital nerve block is carried out, followed by a proximal palmar digital nerve block, a low four point (abaxial sesamoid and low palmar metacarpal nerve block), and a high four point (high palmar ring block, also termed proximal metacarapal nerve block).[8,9,12-19] These are followed by an ulnar nerve block and by desensitization of the medial and cutaneous nerves of the antebrachium. Each positive perineural anesthesia can be followed by a more-specific anesthesia, such as intrasynovial anesthesia or anesthesia of a specific nerve after the effect of the previous anesthetic has worn off. In some instances, it may be helpful to block only the medial or lateral palmar digital nerve. The detailed information for these nerve blocks is summarized in Table 72-1 and illustrated in Figures 72-1 through 72-3.

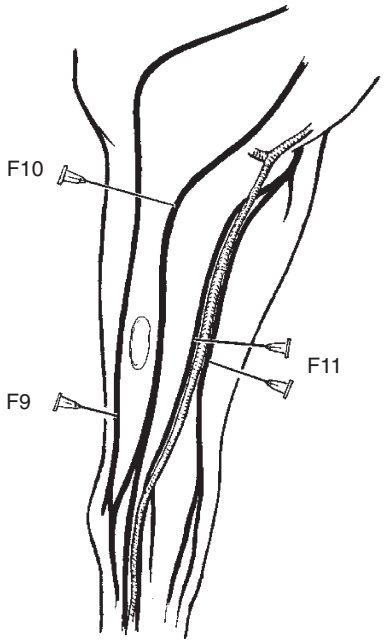

Figure 72-3. The medial aspect of the left antebrachium, with location of needle placement for perineural anesthesia. For an explanation of each needle position, see Table 72-1. *F9*, Ulnar nerve block; *F10*, median nerve block; *F11*, musculocutaneus nerve block.

Perineural Anesthesia in the Hind Limb[20,21]

Perineural anesthesia in the distal hind limb is similar to that described for the forelimb.[17] However, there are important differences in innervation, such as the dorsal metatarsal nerves, that must be taken into consideration. Safety of the examiner and horse handler is crucial, so in most cases diagnostic anesthesia is started farther proximally, provided that a lower limb problem is not suspected. In some instances, where a problem is expected distal to the metatarsophalangeal joint, a nerve block is first performed in the pastern region and then followed by a nerve or ring block proximal to the metatarsophalangeal joint (middle metatarsal ring block). These blocks are followed by a high metatarsal ring block and by fibular and tibial nerve blocks. The detailed information for these nerve blocks is summarized in Table 72-2 and illustrated in Figures 72-4 and 72-5.

Local Infiltrations

The detailed information for the different local infiltration sites is summarized in Table 72-3.

INTRASYNOVIAL ANESTHESIA

Intrasynovial Anesthesia in the Forelimb

The detailed information for the different intrasynovial injection sites in the forelimb is summarized in Table 72-4 and illustrated in Figures 72-6 through 72-9.

Intrasynovial Anesthesia in the Hind Limb

The detailed information for the different intrasynovial injection sites in the hind limb is summarized in Table 72-5 and illustrated in Figures 72-10 through 72-14.

TABLE 72-4. Intrasynovial Analgesia in the Forelimb

Name of the Joint, Bursa, or Tendon Sheath	Location for Injection	Alternative Approach	Technique	Needle Gauge (G) and Amount of Local Anesthetic	Onset of Effect	Important Anatomic Structures that Are Often Partly or Completely Anesthetized
Distal interphalangeal joint	1 cm dorsal to the coronary band, abaxial from, or through, the common digial extensor tendon, horizontally or slightly distad to the hoof capsule (Figure 72-6, *a*)	Lateral or palmar approach to the distal interphalangeal joint	The limb is held up and flexed or the limb may be weight bearing	20 G, 5-10 mL	5-10 min	Proximal interphalangeal joint, navicular bone and navicular bursa, insertion of the deep digital flexor tendon
Navicular bursa	Palmar midline approach (Figures 72-6, *b*, and 72-7)	Proximal palmar injection technique, lateral or medial approach	The hoof is positioned in the Hickman block and thus slightly flexed. The needle is inserted through the palmar midline, just proximal to the coronary band, and directed toward the distal sesamoid bone, which is located 1 to 2 cm distal to and halfway between the dorsal and palmar aspects of the coronary band	20 G, spinal needle, 9 cm long, 3-5 mL	5-15 min	Distal sesamoid bone, parts of the hoof caspule, insertion of the deep digital flexor tendon
Proximal interphalangeal joint	The needle is inserted 1 cm proximal to the joint space in the midline, or slightly paramedian, and directed horizontally or slightly distad into the joint space (Figure 72-6, *c*)	Proximal palmar pouch	The limb is held up and flexed, or the limb may be weight bearing	20 G, 5-10 mL	5-15 min	
Metacarpophalangeal joint	Proximopalmar or proximoplantar pouch (Figure 72-6, *d*)	Dorsal pouch, distopalmar pouch	With the limb held up and flexed, the needle is inserted immediately proximal to the condyle of MCIII between MCIII and the lateral branch of the suspensory ligamant and directed distally	20 G, 10-15 mL	10-20 min	Proximal sesamoid bones, branch of the suspensory ligament

Digital flexor tendon sheath	Outpouching of the sheath proximal to the palmar annular ligament (Figure 72-6, *e*)	Between the proximal and distal digital annular ligaments; distal to the proximal sesamoid bones, between the palmar annular ligament and the proximal digital annular ligament	With the limb held up and flexed, the needle is inserted directly into the outpouching	20 G, 10-20 mL	10-20 min	Distal and proximal interphalangeal joints, metacarpophalangeal joint, navicular bursa
Middle carpal joint	Lateral or medial to the extensor carpi radialis tendon (Figure 72-8, *f*)	Palmar pouch of the middle carpal joint	With the limb held up and flexed, the needle is inserted in a palmar direction into the joint	20 G, 10-15 mL	10-20 min	Middle carpal joint, origin of suspensory ligament, palmar metacarpal nerves
Antebrachiocarpal joint	Lateral or medial to the extensor carpi radialis tendon (Figure 72-8, *g*)	Palmarolateral pouch of the antebrachiocarpal joint	With the limb held up and flexed, the needle is inserted in a palmar direction approximately 2 cm into the joint	20 G, 10-15 mL	10-20 min	Antebrachiocarpal joint
Carpal flexor tendon sheath	Proximal aspect of the carpal sheath (Figure 72-8, *h*)	Distal aspect of the carpal sheath	The needle is inserted proximal to the accessory carpal bone between the lateral digital extensor and ulnaris lateralis tendons	20 G, 10-20 mL	10-20 min	Origin of the suspensory ligament
Elbow joint	Proximolateral aspect of the caudal pouch (Figure 72-9, *i*)	Cranial pouch	With the limb bearing weight, the needle is inserted 3 to 4 cm caudal to the lateral epicondyle and advanced 4 to 8 cm in a distal, slightly cranial and medial direction	20 G, 10-20 mL	20-40 min	
Shoulder joint	Lateral pouch of the joint (Figure 72-11, *j*)	No alternatives	The needle is inserted cranial to the infraspinatus tendon in the notch between the cranial and caudal eminences of the greater tubercle of the humerus, in a caudomedial direction (about 45 degrees) and slightly distad	20 G, spinal needle, 9 cm long, 10-20 mL	20-40 min	Bicipital bursa
Bicipital bursa	Lateral pouch of the bursa (Figure 72-11, *k*)	Proximal approach	The needle is inserted 3 to 4 cm proximal to the deltoid tuberosity, cranial to the humerus, and is directed proximad, mediad, and slightly craniad	20 G, spinal needle, 9 cm long, 10-20 mL	20-40 min	Bicipital bursa

MC, Metacarpal nerve.

TABLE 72-5. Intrasynovial Analgesia in the Hindlimb

Name of the Joint, Bursa, or Tendon Sheath	Location for Injection	Alternative Approach
Tarsometatarsal joint	Lateral approach (Figure 72-11, *l*)	
Distal intertarsal joint	Medial approach (Figure 72-10, *m*)	
Tarsocrural joint	Dorsomedial outpouching (Figure 72-10, *n*)	Dorsolateral and plantar pouches
Cuneal bursa	Medial approach (Figure 72-10, *o*)	
Calcaneal subtendinous bursa	Medial or lateral approach (Figure 72-11, *p*)	
Tarsal sheath	Medial or lateral approach (Figure 72-11, *q*)	
Femoropatellar joint	Craniomedial or craniolateral approach (Figure 72-12, *r*)	Lateral approach, subpatellar site in a flexed position
Medial compartment of the femorotibial joint	Medial approach (Figure 72-12, *s*)	Cranial approach
Lateral compartment of the femorotibial joint	Lateral approach (Figure 72-12, *t*)	Cranial approach
Coxofemoral joint	Lateral approach (Figure 72-13, *u*)	
Sacroiliac joint (Periarticular infiltration)	Medial approach; middle or caudal third of the sacroiliac joint (Figure 72-14, *v*)	Cranial third of the sacroiliac joint

MT, Metatarsal nerve.

Technique	Needle Gauge (G) and Amount of Local Anesthetic Agent	Onset of Effect	Important Anatomic Structures that Are Often Partly or Completely Anesthetized
The needle is inserted just proximal to MTIV, at the level of the palpable depression, in a craniomedial and distal direction	20 G, 3-6 mL	10-20 min	Origin of suspensory ligament, proximal aspect of MTIII, tarsometatarsal joint
The needle is inserted horizontally between the fused first and second tarsal bones and the third and central tarsal bones in a small depression just distal to the cunean tendon; this is halfway between the talus and the head of MTIV	22 G, 3-6 mL	10-20 min	Distal intertarsal joint
Dorsolateral approach: 2 to 3 mm lateral to the long digital extensor tendon 6 to 8 mm proximal from the head of the splint bones or 1 cm distal to the lateral trochlea, 70 degrees to the sagittal plane in plantaromedial direction			
Medial (or lateral) to the saphenous vein	20 G, 20-30 mL	20 min	Proximal intertarsal joint
The needle is inserted between the distal tarsal bones and the medial branch of the cranial tibial tendon at the distal edge of the tendon	22 G, 3-6 mL	20 min	
The needle is inserted proximal or distal to the tuber calcanei in the lateral or medial outpouching	20 G, 10 mL	15-30 min	
The needle is inserted in the proximal or distal outpouching of the tarsal sheath	20 G, 20 mL	15-30 min	
The needle is inserted either lateral or medial to the middle patellar ligament until the needle tip contacts the articular cartilage of the distal femur; the needle is then withdrawn slightly	20 G, 20 mL	20-60 min	Lateral and medial femorotibial joint
Alternative: Recessus subextensorius			
The needle is inserted just caudal to the medial patellar ligament, 1 to 2 cm proximal to the medial tibial plateau, perpendicular to the skin	20 G, 20 mL	20-40 min	Lateral femorotibial joint, femoropateral joint
The needle is inserted caudal to the long digital extensor tendon, 1 to 2 cm proximal to the lateral tibial plateau, horizontally and slightly cranially	20 G, 20 mL	20-40 min	Medial femorotibial joint, femoropateral joint
The spinal needle is inserted between the caudal and short cranial processes of the greater trochanter of the femur in a slightly craniomedial direction and slightly distally until the joint capsule is penetrated.	Spinal needle, 20-30 mL	20-40 min	
The needle is inserted 2 cm cranial to the opposite sacral tuberosity and directed to the midpoint of the distance between the cranial aspect of the tuber coxae and the greater trochanter	Spinal needle, 15-18 G, 20-25 cm, 20-30 mL	20-40 min

CHAPTER
73

Emergency Treatment and Transportation of Equine Fracture Patients

Anton E. Fürst

In horses, the initial treatment of injuries to skin, muscles, joints, tendons, tendon sheaths, and bones greatly affects the chances for ideal healing. Especially for long-bone fractures, a successful surgical outcome is forfeited with improper initial care. Unfortunately, most fractures are exposed to substantial additional trauma during the transportation of the injured horse. In certain situations, it is necessary to use a rescue net and crane or even a helicopter to rescue a horse from a dangerous location. A large-animal rescue unit operating in Switzerland and in neighboring countries specializes in the rescue of large animals involved in automobile accidents or trapped in wells, ditches, gullies, lakes, or rivers.[1]

Rescue efforts can be conducted with the animal standing or in lateral or dorsal recumbency. Rescuing horses is a very complex procedure that must be well planned and calmly executed. A veterinarian experienced with horses should be on hand to prepare and accompany the horse during the rescue operation. Additionally, sedation or short-term anesthesia may be required in special situations. Although every rescue operation must be carried out as quickly as possible, time is of secondary importance. In emergency situations, it is imperative to remember that the horse may be in pain and that hastily improvised rescue methods will probably be inadequate and result in additional trauma. For example, narrow, flat belly bands are painful for the horse and usually fail because the animal slips out of the bands and cannot be rescued or falls out while being lifted, resulting in severe additional injury or even death.

EXAMINATION OF THE PATIENT

A thorough clinical examination is mandatory for horses with fractures.[2] Lacerations or lesions that are overlooked can affect the diagnosis and prognosis considerably. A fracture should be suspected with severe lameness and an acute onset of signs. When in doubt, the horse should be treated and handled as a fracture patient. All too often, the assessment of injuries underestimates the extent of the injury, and incomplete and nondisplaced fractures initially can be overlooked. This is particularly true in horses that have been kicked in a region where the bone lies directly beneath the skin—such areas include the scapular spine, the major tubercle of the humerus, the deltoid tuberosity, the cutaneous plane of the radius, the metacarpus, the metatarsus, the tuber coxae, the third trochanter, the sustentaculum of the talus, the calcaneus, and the tibia (Figure 73-1).[3]

TREATMENT OR EUTHANASIA

Despite great advances in veterinary orthopedic surgery and anesthesia, there are several injuries and fractures in horses that cannot be treated successfully. When the prognosis is hopeless, euthanasia should be suggested to the owner. A smooth and quiet euthanasia is of utmost importance for the owner and for potential spectators of the procedure.[4] In all cases, a veterinarian should examine the horse thoroughly before carrying out the euthanasia.

Conversely, the number of injuries and fractures that have a good prognosis with state-of-the-art treatment is increasing. Good-quality radiographs are necessary to establish an exact diagnosis and to arrive at a prognosis. When the decision has been made to treat the horse, adequate emergency treatment is the initial step, and the horse is then referred to a hospital that specializes in managing such problems.[5] It is imperative that the patient be given the opportunity to receive optimal care and treatment. However, frequently, horses with fractures are transported without adequate emergency treatment, which not only compromises or eliminates the chance of a successful surgical repair but also is extremely painful for the horse (Figure 73-2).

OPTIMAL EMERGENCY TREATMENT

Optimal emergency treatment should include the following steps: sedation and possibly anesthesia, initial wound management, stabilization of the fracture, administration of proper analgesia and anti-inflammatory medications, prophylaxis for infection, intravenous fluid therapy, and careful and safe rescue with proper transportation to a specialty clinic.

Sedation

The use of sedation is dictated by the circumstances presented. What is indicated for one horse may be hazardous for another. The use of sedatives depends on the fracture and, in particular, the type and character of the horse. In most cases, judicious use of a sedative facilitates the examination and emergency treatment of an acutely traumatized horse, especially when the horse is stressed from competing in an event or is in severe pain. The sudden inability to place weight on a limb as a result of a

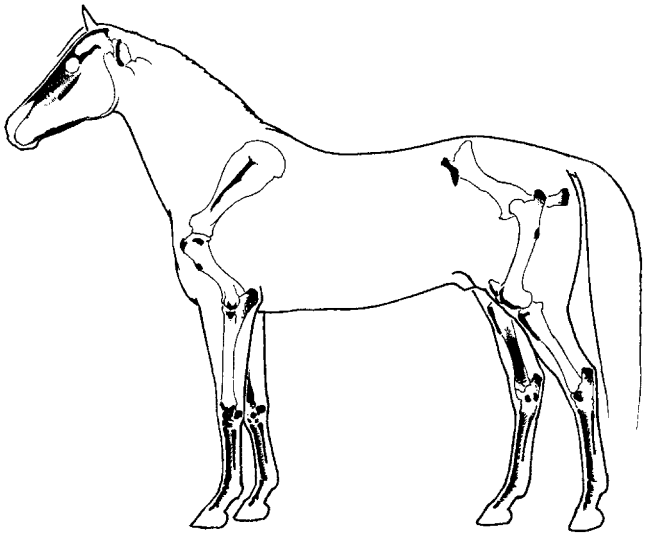

Figure 73-1. Sites on the horse (*shaded areas*) where bones are covered only by skin with no muscle protection, making them susceptible to open fractures when kicked by another horse.

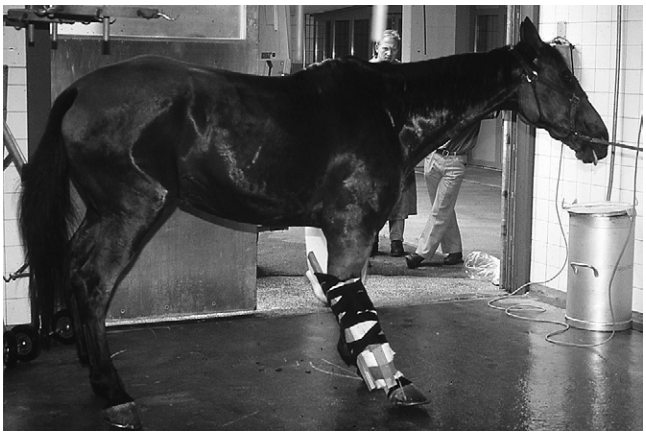

Figure 73-2. Inadequate attempt at stabilization of a radial fracture using a splint that is too short. The fracture remains unstable and the limb is now weighted by the inadequate splint bandage, which compounds the bone and soft tissue trauma. The patient is sweating profusely—a clear sign of pain.

long-bone fracture causes anxiety, which may lead to sudden violent reactions. A twitch can be useful to control a fractious or anxious horse, avoiding the ataxia that accompanies sedation.[2] Furthermore, horses do not tolerate external coaptation well, especially when the fixation extends above the carpus or tarsus. Therefore, the use of a sedative may be necessary to induce acceptance of the external coaptation device. α_2-Agonists are the drugs of choice, because they have few side effects and provide some analgesia and reliable sedation. Xylazine HCl is suitable for short procedures and detomidine HCl is used for longer sedation, which is necessary in most cases. For additional sedation and analgesia, a morphine derivative should be administered as well. Butorphanol tartrate has a wide variety of applications in horses and is an ideal drug for this scenario.

The dosage of these drugs varies according to the type of emergency. Agitated horses usually respond poorly to sedatives and require a higher dosage than normal. In contrast, a lower dose is needed when the horse's condition is compromised by shock or severe blood loss. After intravenous injection of the sedative, a minimum of 5 minutes is required to determine the effects of the sedation. This time period may seem quite long in an emergency situation, but it is prudent to wait without administering additional drugs to avoid an overdosage that could induce an unacceptable degree of ataxia or compromise the cardiovascular status of the patient. It should be remembered that cold-blooded horses require less sedative on a per-weight basis, and the dosage should not exceed that used for a 550-kg horse. Foals usually require heavy sedation to facilitate good stabilization of a fracture, and it is advantageous and often necessary to have them restrained in lateral recumbency when a splint is applied.

I favor a combination of detomidine HCl (Dormosedan) and butorphanol tartrate (Torbugesic or Morphasol). The two drugs can be combined in one syringe and given intravenously, or intramuscularly if the intravenous administration is not possible. A suggested dosage for a 400- to 500-kg horse would be 5 mg detomidine combined with 10 mg of butorphanol tartrate, intravenously. Xylazine can be used instead of detomidine. It leads to more rapid but less reliable sedation. The addition of a neuroleptic agent, such as acepromazine (0.02 mg/kg), can substantially increase the duration of sedation. However, acepromazine should not be used in stallions or physiologically severely compromised patients because of its vasodilatory effects which could compound neurogenic shock. Additional information on chemical restraint can be found in Chapter 22.

Anesthesia

For certain rescue procedures, short-term anesthesia may be necessary. Various drug combinations, such as xylazine-diazepam-ketamine or xylazine-myolaxin-ketamine, provide reliable anesthesia even in an emergency situation. (See Chapter 20 for more on anesthesia.)

Wound Management

Skin wounds must be treated with care. The hair around the wound is removed after covering the wound with water-soluble ointment. Then, a general cleaning of the area around the wound is completed with mild soap and water. The wound itself is cleaned, disinfected and covered with a water-soluble antibiotic ointment and sterile dressing, followed by a bandage. With open fractures, the bone must be cleaned also and covered with a sterile dressing.

Fracture Stabilization

Stabilization of the fractured limb in an anatomically normal position is the most important aspect of the initial treatment. This allows the patient to bear some weight without excessive damage to the fracture ends and the soft tissues. A very important additional effect of fracture stabilization is the attenuation of anxiety and pain for the patient, thereby preventing further compromise of the patient.

Goals

The goals of fracture stabilization include:

Reduction of pain and anxiety and facilitation of partial weight-bearing. Horses attempt to move a fractured limb constantly in an effort to find a stable position. Pain from this movement and the instability is extremely stressful for the fracture patient, and they often panic. Prompt and effective stabilization of the fracture by itself substantially improves the general well-being of the animal. Therefore, the fractured limb should be stabilized so that the horse is able to bear some weight on it [6-9] The concomitant reduction of pain renders the patient in better physiological condition for referral, and surgical repair can be attempted sooner.

Prevention of further compromise of the patient. Because horses cannot balance well on three limbs and repeatedly attempt to use the fractured limb, especially during transport, the continued movement of the fractured bones not only traumatizes the fragment ends, thus preventing anatomic reconstruction of the bone, but also injures the soft tissues, the integrity of which is critical for fracture healing. The skin of horses is quite thin, and the worst complication is its perforation by sharp bone fragments, resulting in contamination of the bone ends. Horses with open fractures of long bones have a very poor prognosis, and the use of modern and expensive antibiotics does not change this situation significantly. Therefore, all efforts must be made to prevent the conversion of a closed fracture to an open one.which occurs quite readily in the distal region of the limb and the medial aspects of the radius and tibia, because there is little tissue between the bone and the skin.

Immobilization of the adjacent joints. The joints above and below the fractured bone should be immobilized using some type of external coaptation, and the stabilization should extend well beyond the fracture line. In no case should the end of the coaptation device be near the fracture line, because then it acts as a lever to further displace the fracture. A cast should not end at the mid-diaphysis, and when possible it should include the hoof. These requirements severely limit the number of fractures that can be stabilized with external coaptation techniques.

Types of Stabilization

For emergency stabilization of fractures, robust materials must be used. Detailed information on bandaging and external

coaptation materials and their application can be found in Chapter 17.

ROBERT JONES BANDAGE

A Robert Jones bandage consists of many layers of cotton, each held in place and tightened by elastic gauze. Each layer is applied more tightly than the previous one. The finished Robert Jones bandage for a normal-size horse requires 10 to 15 rolls of cotton, and its diameter is about three times the diameter of the limb. This type of bandage cannot be used to stabilize a fractured limb for long without the addition of splints. When splints are added, the bandage does not have to be as thick.

SPLINTS

A variety of splints are suitable for stabilizing fractures in horses. The splints must be applied to the cranial or caudal and lateral aspects of the limb and held in place with nonelastic tape. For optimal stabilization, the splints are applied in two planes at right angles (90 degrees) to each other. Sufficient padding and good fixation are necessary to prevent slippage of the splint.

Polyvinyl chloride (PVC) splints are very stable and inexpensive, but they are difficult to mold unless heated using a propane torch. The commercially available Fraktomed splint (Fraktomedschiene), made of a polyvinyl alcohol polymer, is also suitable for immobilizing a fracture, but it is rarely available in an emergency situation. This type of splint is very rigid when cold and must be heated in steam to facilitate molding it to fit the limb. Within a few minutes, the splint hardens and becomes stable. Splints can also be improvised using metal rods, broom handles, wooden boards, and other sturdy materials. The Thomas splint is generally unsuitable for horses and should not be used to splint a fractured limb, especially in an emergency situation.

CAST

The equine cast, also referred to as a *synthetic splint*, is formed from fiberglass tape impregnated with a polyurethane resin. These materials are very well suited for immobilizing equine limbs. They are very strong, cure quickly, are easy to apply, and are very light. While the cast is being applied, the horse should stand quietly to prevent the development of microfractures and folds in the cast, which can reduce its strength and cause pressure sores. Preventing movement of the cast during application can be better achieved if the horse can be supported in a special harness. In this way, the fractured limb can be stabilized in the correct position (Figure 73-3). In some situations, especially in very unstable fractures, this may be difficult, so splints are usually the first choice for stabilization. To prevent penetration of the skin by sharp bones, a window can be made in the cast over these locations (Figure 73-4).

Figure 73-3. A horse with a fractured radius is supported in a special harness. This way the fractured radius can be stabilised in the correct position, and the cast is not subjected to movement during application, which may weaken it.

Figure 73-4. To prevent penetration of the skin by sharp ends of fractured bones, a window was made in the cast over the distal end of the proximal tibial fragment *(arrow)* in this horse.

Principles of Stabilization

PREVENTION OF SOFT TISSUE DAMAGE

Good stabilization does not inflict additional damage to the limb. Because swelling of the surrounding tissues is common after an injury, stabilization may result in pressure and friction sores as well as tissue strangulation if the splint or cast is not sufficiently padded. Therefore, the padding should be layered, with each layer being tightened with nonadhesive gauze. However, layers that are too thick (2 to 4 cm) allow movement of the bone fragments or slippage of the splint, and should be

avoided. Ideally, the thickness of each layer of the padding should be about 1 to 2 cm.

REGIONAL IMMOBILIZATION

Techniques for immobilization of equine long-bone fractures have been established.[7-9] The limbs can be divided into four distinct regions to establish principles for stabilization techniques (Figure 73-5).[8] The regions for the forelimb are (1) the hoof to the distal metacarpus, (2) the distal metacarpus to the distal radius, (3) the distal radius to the elbow joint, and (4) the elbow joint to the distal scapula. The regions for the hindlimb are (1) the hoof to the distal metatarsus, (2) the distal metatarsus to the tarsus, (3) the tarsus to the stifle, and (4) the region proximal to the stifle.

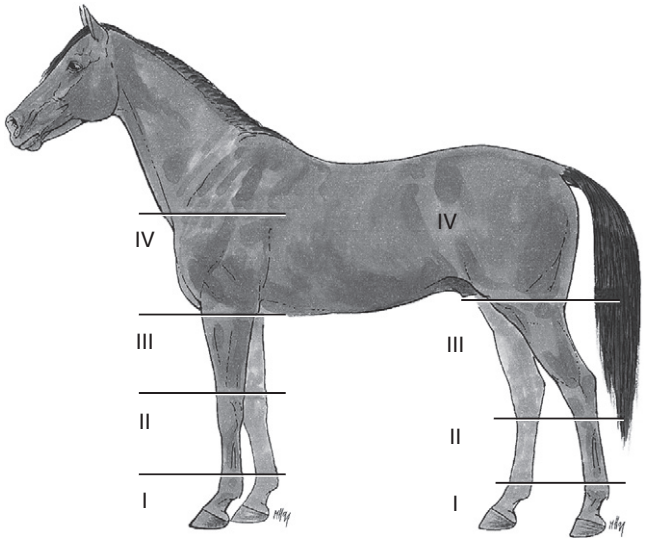

Figure 73-5. Biomechanically important divisions of the forelimb *(left)* from distal to proximal: *(1)* distal to the distal quarter of the third metacarpal (MCIII), *(2)* from the distal MCIII to the distal radius, (*3*) from the distal radius to the elbow joint, and *(4)* from the elbow joint to distal scapula. Biomechanically important divisions of the hindlimb *(right)* from distal to proximal: *(1)* distal to the distal quarter of the third metatarsal (MTIII), *(2)* from the distal MTIII to the tarsus, *(3)* from the tarsus to the stifle joint, and *(4)* proximal to the stifle joint. (From Bramlage LR: Compend Contin Educ Pract Vet 1983;5:S564.)

Region 1: Fractures of the Proximal, Middle, and Distal Phalanges and the Distal Sesamoid Bone

Incomplete and complete fractures of the proximal, middle, and distal phalanx and the distal sesamoid bone are easily stabilized with either a cast or a splint.[9] With fractures of the proximal or middle phalanx, the third metacarpal/metatarsal bone (MCIII/MTIII) and the proximal and middle phalanx must be stabilized in an almost straight line to prevent movement in the frontal plane at the fracture line. To achieve this, the heels are raised with a wedge, which also serves to facilitate the attachment of the cast distally. With the limb in this position, a cast is applied from the heels to the proximal end of the MCIII/MTIII. To obtain optimal stabilization, the entire hoof, or at least the heels, should be included in the cast. If nonmoldable splints are used instead of a cast, they are preferably fixed dorsally (see Figure 17-20).

Holding the forelimb off the ground makes application of the synthetic splint easier because the horse is less likely to move. However, this is not possible with the hindlimb because of the reciprocal apparatus, which causes flexion of all the joints when the limb is held off the ground. However, with proper sedation, most horses stand quietly for a few minutes with the injured limb lightly touching the ground and in a fairly normal position. Various other splints, such as the Kimzey (Figure 73-6) or monkey splint (Figure 73-7), can be used in breakdown injuries of the suspensory apparatus instead of a cast.

Region 2: Fractures of the Third Metacarpal, Third Metatarsal, Carpal, and Tarsal Bones

With fractures of MCIII/MTIII, a cast or splint is applied from the hoof to the elbow or stifle joint, respectively (Figures 73-8 through 73-10). Depending on the temperament of the horse

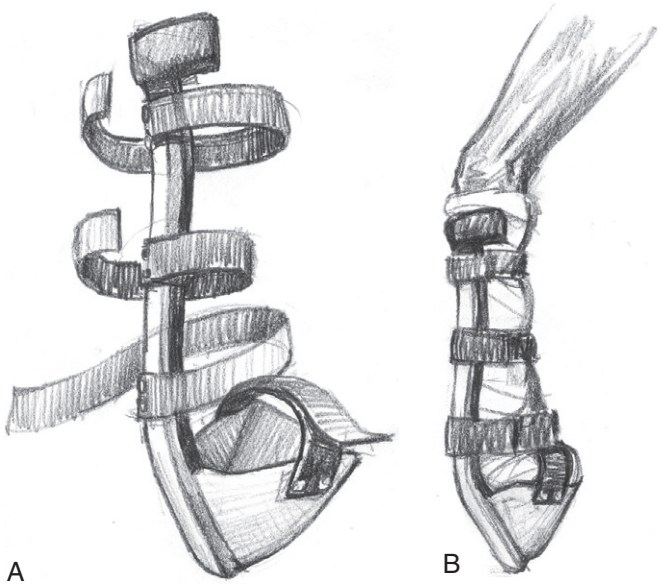

Figure 73-6. A, A Kimzey splint showing nylon straps fitted with hook-and-loop patches. **B,** The splint applied to the distal limb of a horse over a bandage. These splints are well suited for first aid for disruptions of the suspensory apparatus.

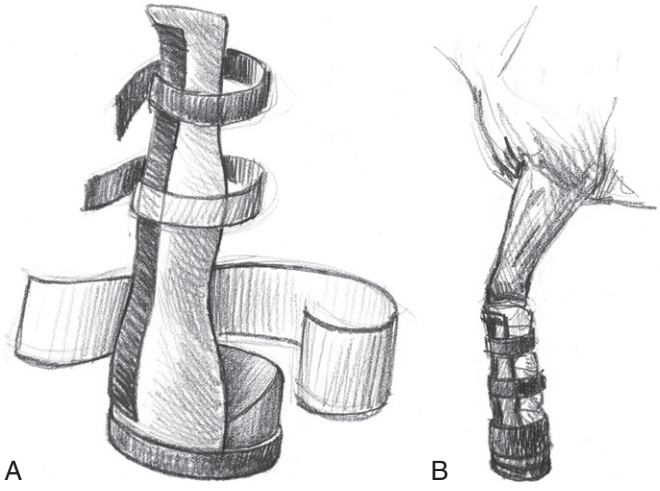

Figure 73-7. A monkey splint **(A)** applied to the distal limb of a horse **(B).** These splints align the phalanges and third metacarpal into one plane.

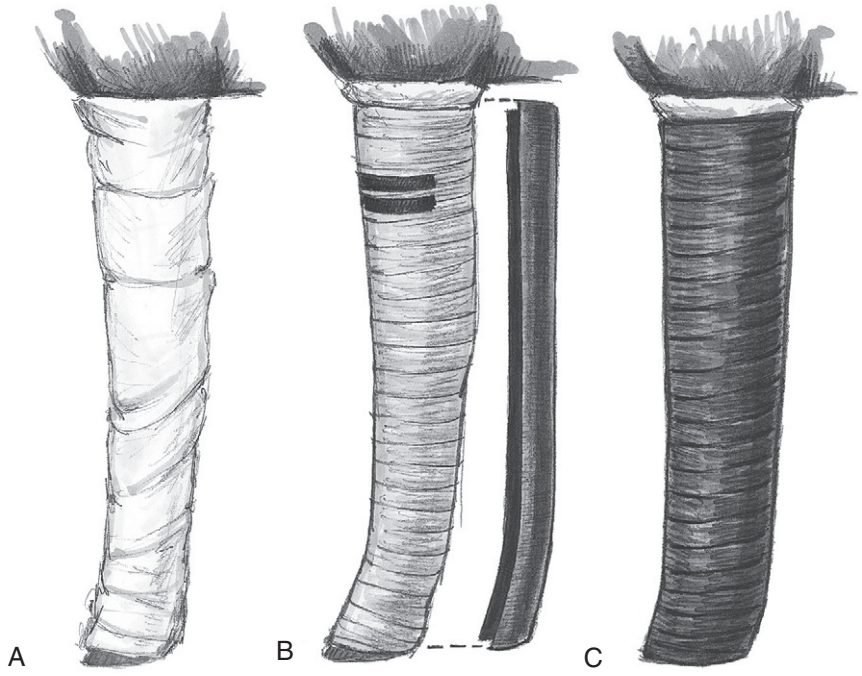

Figure 73-8. Application of a full forelimb splint. **A,** The padding is applied evenly in several layers over the entire limb, and each layer is tightened separately. **B,** A PVC-pipe splint is applied to the caudal aspect of the bandage and can be augmented with one pole medially and laterally (not shown). **C,** The splints are incorporated into the bandage with tape.

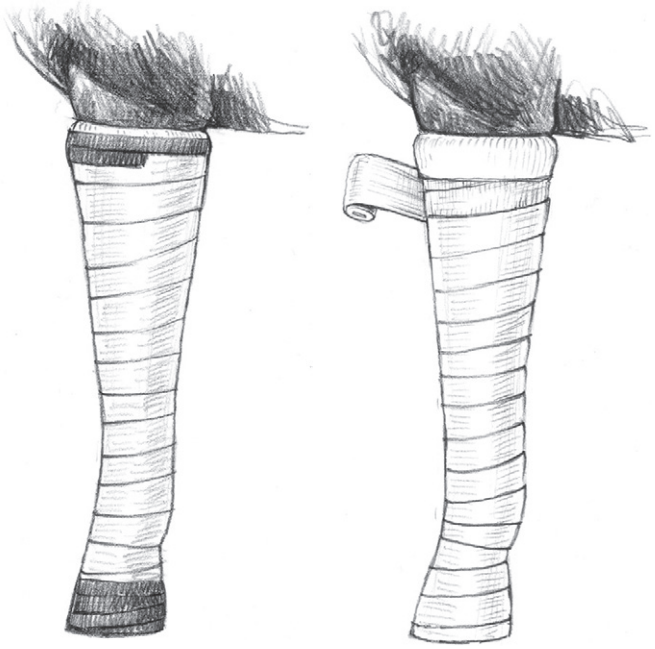

Figure 73-9. Application of a full forelimb cast using the technique described in Chapter 17 but extending over the entire forelimb up to the elbow joint. Care is taken to apply the cast material evenly along the entire limb and to fold back the stockinette over the top of the cast, incorporating it into the last layer to provide a smooth top edge.

Figure 73-10. A horse with a fracture of the metacarpus, which has been stabilized with a full limb cast. The horse is loaded in an emergency trailer and is ready for the transport. The harness supports the patient during transport.

and the location of the fracture, the splint or cast may reach only the top of the calcaneus for fractures of the distal metatarsus. However, this does not produce optimal stabilization and should be looked at as an exception rather than the rule. Extending the external coaptation above the tarsus should always be the goal and should in most cases be possible with the use of adequate sedation.

Region 3A: Fractures of the Radius and Tibia

Fractures of the radius and tibia present special difficulties because the large muscle masses most often prevent fixation of the elbow and stifle joints. Furthermore, contraction of the extensor tendons, located craniolaterally on the limb, causes abduction of the limb below the fracture line, which can produce skin perforation on the medial aspect of the radius or

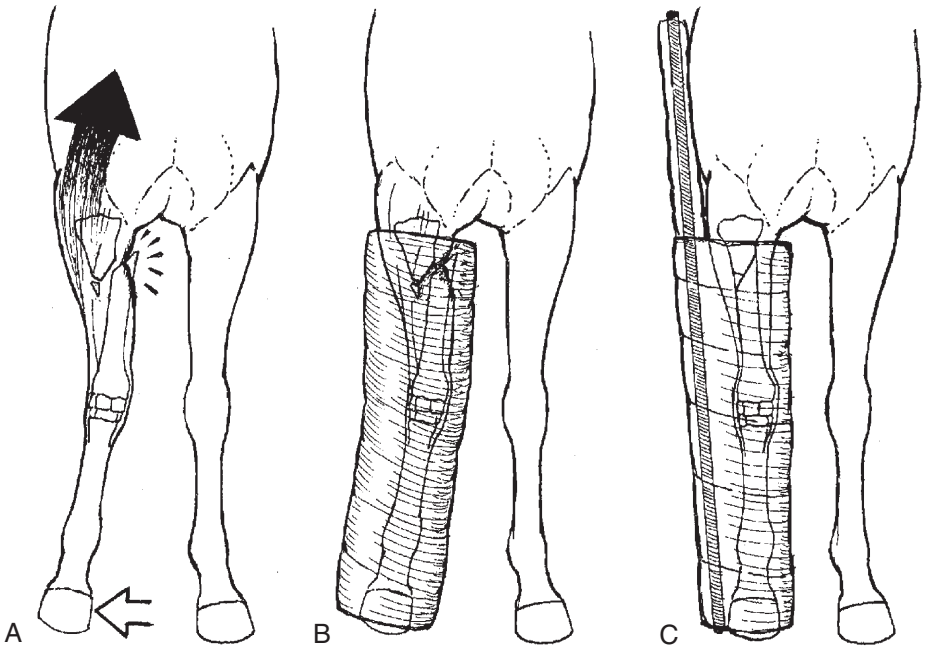

Figure 73-11. Splinting of a proximal radial fracture: **A,** All the muscles are arranged cranially, laterally, and caudally, which results in a lateral deviation of the limb when the muscles contract to provide support to the fractured limb. This may result in perforation of the skin at the medial aspect of the limb by sharp bone edges; **B,** A Robert Jones dressing or cast has been applied to the limb. It ends near the fracture site and provides only limited support. Also, it increases the leverage arm, causing more tissue damage; **C,** The incorporation of long splint or wooden plank to the lateral aspect of the bandage effectively counteracts the valgus-inducing forces and adds significant stability to the splint bandage. With such a splint, the patient may load the fractured limb.

tibia (Figure 73-11, *A*). Therefore, stabilization up to the elbow or stifle is not sufficient and will not prevent abduction. In these fractures, a stable splint or cast should first be applied up to the elbow or stifle joint (see Figure 73-11, *B*) and when possible, even higher up. This should subsequently be augmented with an additional splint applied laterally and reaching from the hoof to the point of the shoulder or hip, respectively. Additional padding is added to the splint so that it conforms to the contour of the limb (see Figure 73-11, *C*). Immobilization is difficult in the hindlimb because of the reciprocal apparatus. Flexion of the stifle, which cannot be prevented, results in flexion of the hock via the superficial digital flexor muscle and the peroneus tertius muscle. This results in large forces acting on the tibia so that dislocation of the fragments is unavoidable. Regardless, these fractures are stabilized as well as possible using this technique. In some foals, a cast can be applied proximal to the elbow and stifle joint (Figure 73-12), which improves the stabilization of a fracture of the radius and tibia. Moreover, the horse must be properly padded and stabilized in the emergency trailer (Figure 73-13) or van.

Region 3B: Fractures of the Ulna

Fractures of the ulna result in failure of the passive stay apparatus of the forelimb (triceps apparatus), which allows the horse to stand with little muscular effort for prolonged periods of time. Hence, the horse assumes a typical stance with the carpus in flexion (Figure 73-14). Therefore, the limb should be stabilized with a splint that extends the carpus so that the horse can bear weight on the limb. The splint should be applied caudally and should extend from the metacarpophalangeal region to the level of the elbow joint (Figure 73-15).

Figure 73-12. In some foals, a cast can be appplied proximal to the stifle joint, which improves the stabilization of a fracture of the tibia (region 3).

Region 4: Fractures of the Humerus and Femur

Fractures of the humerus and femur do not require a bandage or a splint because they cannot be adequately immobilized and there is enough muscle mass to protect the bone. These fractures are rarely open and a bandage would be counterproductive, because it would only add weight without providing stabilization. In some cases, fractures of the humerus or neck of the scapula can be helped with a splint that extends the carpus, similar to the situation with fractures of the ulna.

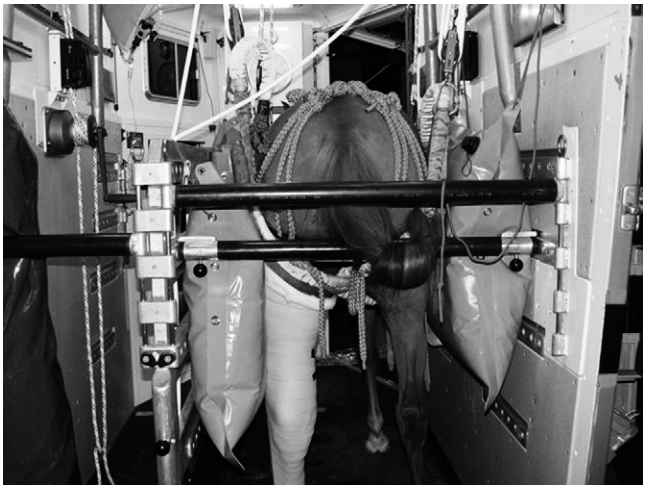

Figure 73-13. The horse with a tibial fracture is properly stabilized and padded in the emergency vehicle. Notice the dunage bags that are inflated to prevent side-to-side movement of the horse.

Analgesia and Anti-Inflammatory Medications

Systemic analgesics should be given to the horse as soon as the fracture is stabilized. Nonsteroidal anti-inflammatory drugs, such as phenylbutazone or flunixin meglumine, are the most commonly administered anti-inflammatory therapy for musculoskeletal injuries in horses. Control of inflammation is an important step in limiting the risk of thrombosis, maximizing perfusion of the limb, and preparing the limb for surgical repair. However, when fracture stabilization is inadequate, the use of a potent analgesic is contraindicated, because this leads to an overload of the injured limb with associated complications.

Antimicrobial Therapy

Immediate administration of systemic antibiotics is indicated in horses with open fractures or large wounds. Otherwise, antibiotic therapy can be delayed until the time of surgery. Antibiotics administered intravenously immediately prior to a surgical intervention achieve effective blood and tissue concentrations within approximately 20 minutes. The regimen of choice is a combination of 30,000 IU/kg of crystalline penicillin and 7 mg/kg of gentamicin sulfate, both administered intravenously. (For details on surgical site infection and antimicrobial use, see Chapter 7).

Intravenous Fluid Therapy

Fractures are rarely associated with severe hemorrhage. However, pain can induce neurologic shock (see Chapter 1), leading to substantial fluid shifts, which should be supported using intravenous fluid therapy. After an indwelling intravenous catheter

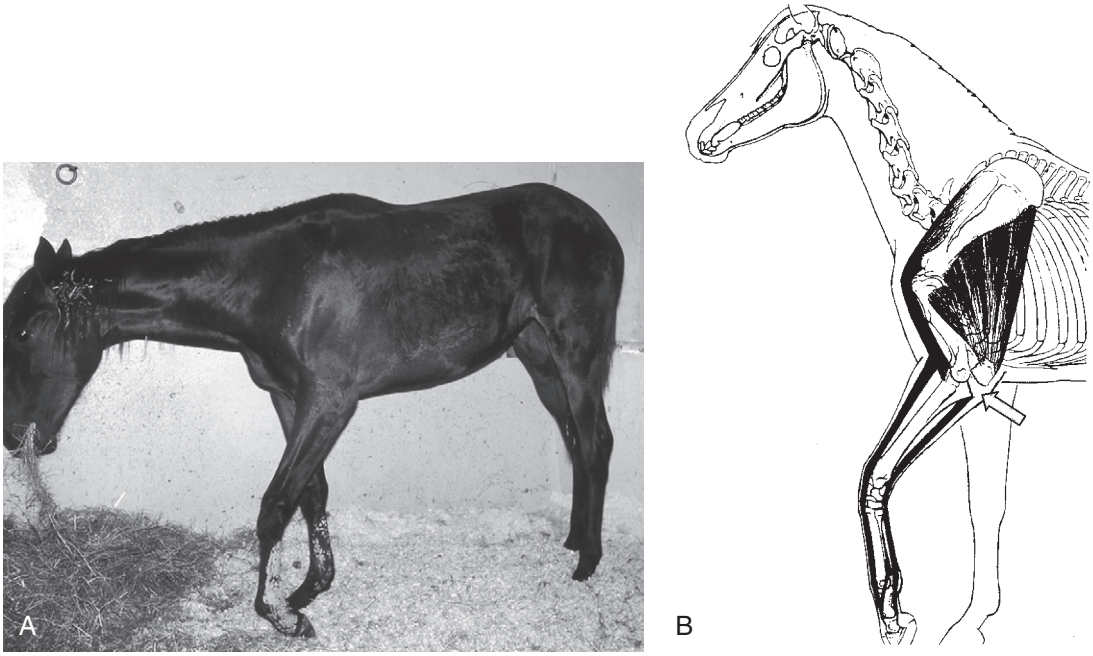

Figure 73-14. A, Typical posture of a horse with a fracture of the olecranon process of the ulna; **B,** Illustration of the forces that affect a horse's limb movement in the presence of an olecranon fracture. The carpus cannot be maintained in extension because the triceps muscle inserts only on the proximal fragment, which results in the formation of a fracture gap *(arrow)* when it contracts.

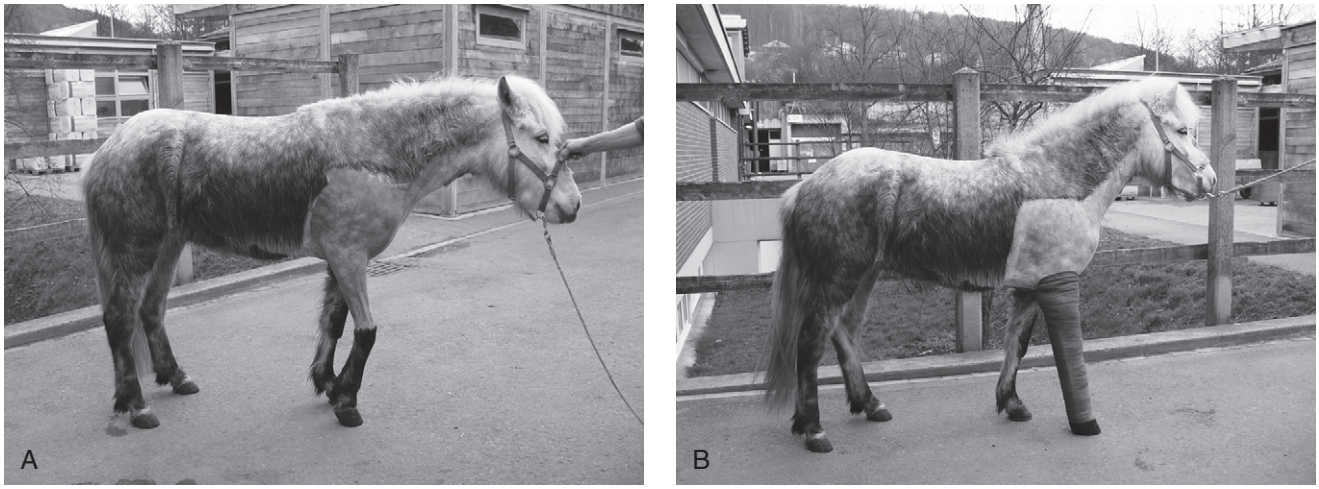

Figure 73-15. A, An Icelandic Horse with a fracture of the olecranon process of the ulna. **B,** The same horse after correct application of a caudal splint.

is placed and secured to the skin, a solution of electrolytes and glucose (up to 2% of body weight) should be administered with the drip rate set at maximum. (See Chapter 3 for details on fluid administration.) Horses out in the open should be kept warm with a horse blanket or an aluminum emergency blanket. (See Chapter 1 for details on physiologic response to trauma.)

Transportation of the Horse

The injured horse must be transported carefully and humanely, according to animal welfare legislation.[7-10] It is advantageous to have a specialized large-animal trailer or van and the support of an experienced veterinarian or assistant.[9,10] However, some controversy exists: there are those who think that this kind of transportation can be accomplished with normal horse trailers that are minimally adapted.[11] In my experience, horses with a fracture should be transported by a specialized large-animal trailer built to transport injured horses.

Equipment

The emergency trailer or van should have enough room for two standing horses or one recumbent horse.[9] Ideally, there should be enough space to handle the horse from all sides. The ceiling of the trailer should be approximately 30 cm higher than in standard horse trailers, and it should be equipped with a nonslip floor. It should be well ventilated and spacious with a good lighting system for night transport. Additionally, the vehicle should be solidly built, preferably of aluminum. The loading and unloading ramps should be long enough so that the slope is minimal, which is especially important for horses wearing a splint. The ramp must have an even, nonslip surface, and the end must be flush with the ground. The vehicle must be equipped with a winch and a strong frame to support a harness. Different sizes of suspensory harnesses are required with a minimum carrying weight of 1200 kg. Other requirements are a gurney or a mat on which a recumbent animal can be pulled into the trailer. Curtains or movable lightweight walls are helpful when the working area needs to be blocked off from the view of spectators. For safety reasons, the driver of the vehicle must be able to observe what is going on via a video camera in the trailer and able to have audio contact with the support assistants caring for the horse during the transport. The vehicle should be equipped with a heater and the floor should be well padded (e.g., with an air mattress) to minimize vibrations during the transport of a recumbent animal. The interior installations should be adjustable to accommodate horses of different breeds and sizes. The emergency trailer or van should be stocked with all the necessary medical supplies for various emergency treatments including shock therapy.

Loading Injured Horses

It is best to maneuver the vehicle as close to the injured horse as possible to avoid unnecessary walking.[9] As the steepness of the loading ramp increases, so must the interior height of the trailer (minimum height, 2.35 to 2.5 m), particularly when a forelimb is injured. Increasing the height of the nose of the trailer using the jack will lower the height of the ramp somewhat. Horses also load better when the trailer is positioned so that the horse can walk in the same direction as the barn. The horse should be acclimated to the cast or splint by walking a few steps before being loaded.

Application of a bridle over a halter is recommend for better control during loading. Two readily available lunge lines are tied to either side of the trailer and are used to direct the horse into the vehicle. For injured horses, the stall partition should be moved to one side to provide the maximal amount of space for loading. Before loading, the service door and the front-unloading door should be opened and the interior lights turned on at night to illuminate the interior as much as possible. Two assistants hold the lunge lines and move slowly toward each other, progressively narrowing the space between them. Touching the horse with the lines may help loading and is not necessarily discouraged. As soon as the horse is in the trailer, the rump bar is replaced, the ramp is closed, and the service door

and the front-unloading door are closed. The stall partition and chest bar are the last barriers to be put in place.

It has been recommended that horses with forelimb fractures be transported facing backward in an attempt to relieve the stress on the forelimbs during braking.[12] However, almost all standard European two-horse transporters do not provide enough space for the horse to comfortably stand backward; when the chest and rump bars are in place, the horse would have to keep its head either very high or turned to the side because of the ramp (the back door) in front of it. This would be very uncomfortable for the horse. Furthermore, the head and neck are important for balance but they have to be free to perform this function properly. Finally, it is very difficult if not impossible to load an injured horse backward or to turn it around after it is inside the trailer. Loading the horse via the front unloading ramp is not practical because the space is limited and the slope of the front ramp is usually steeper than that of the rear ramp. For a horse standing backward in the trailer, the injured forelimb would then be positioned at the back of the transporter between the rear axle and the ramp, where the ride is the roughest.

The horse has to balance not only during breaking but also during acceleration and in curves. Therefore, the driver must take the time to ensure a comfortable ride for the horse. An assistant in the trailer with the horse helps to calm it and relay any developing problems directly to the driver. For horses with hindlimb injuries, the driving speed must be as slow as possible, because the ride is the roughest behind the rear axle.

Transport in a Supporting Harness

A harness should be used to transport horses with severe injuries.[10,13] Horses that are transported with a harness arrive at the hospital in much better general condition than those that are not. Transportation in a harness can provide tremendous relief for an injured horse. Many horses allow the harness to support their entire weight during transport. Most horses alternately rest one limb and then the other. After some time, horses with a properly splinted limb frequently bear some weight on the fractured limb while being supported by a harness, thereby resting the healthy contralateral limb. For this type of transport, a person experienced in large-animal rescue operations should always be present in the trailer to provide optimal care for the patient. In extreme cases, a veterinarian may be required to travel with the horse as well. Most horses can be easily positioned in a harness provided that it is applied snugly and gives support to the patient from the front as well as from the back. The harness must be fitted so that it does not interfere with the horse's respiration and balance. During transportation, the bellyband is tightened several times, and the front and hind belts are adjusted until the horse is comfortable. It is imperative that everything be checked repeatedly throughout the transport so that problems can be immediately identified and corrected (Figure 73-16).

Unloading Fracture Patients

As a general rule, the horse should get off the trailer using the sound limbs first. With a forelimb injury, the horse should be backed off the transporter. With hindlimb injuries, the horse should be unloaded via the front ramp. As for loading, the trailer jack can be adjusted to provide the optimal ramp angle for unloading.

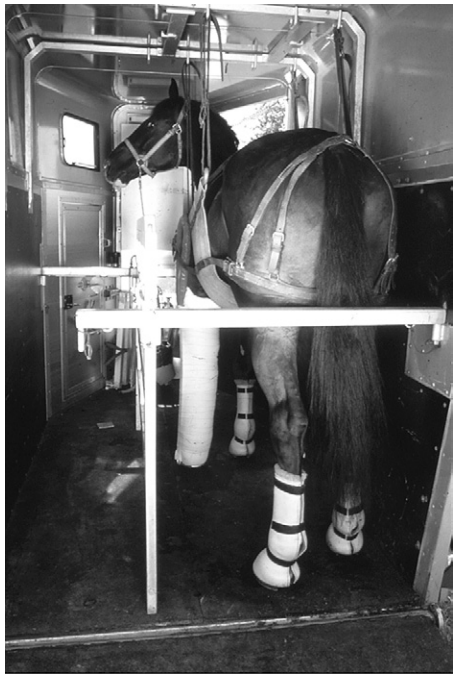

Figure 73-16. A fracture patient supported by a harness is ready to be transported to a specialty clinic.

Injured horses, particularly those with fractures, should be sedated for unloading. Most horses feel insecure when they are presented with new surroundings and when forced to use the injured limb after having been supported in a harness. This stress may result in hectic or hesitant and uncontrolled movements during unloading. Sedation dampens these reactions, and unloading is safer for both the horse and the handlers.

Transport of Recumbent Horses

As a general rule, horses should be transported standing whenever possible. Horses that are unable to stand are transported in lateral recumbency, and anesthesia may be induced for the ride to the clinic.[9] Transportation of horses under general anesthesia is rare; the anesthesia must be carried out and maintained by a veterinarian, who must travel with the horse. The duration of transportation in such cases must be as rapid as possible, perhaps assisted by a police escort, and it should not exceed 90 minutes.

A mechanical or electric winch, transport mat, insulated air mattress, head protection for the horse, and hobbles are some of the equipment needed for transportation of recumbent horses.

When the decision has been made that the horse is to be transported in lateral recumbency, an indwelling intravenous catheter is placed and intravenous fluids are started. This is the only way of ensuring rapid treatment at any time. Horses that cannot rise are sedated and those that can rise are anesthetized so they can be transported in recumbency. After induction, anesthesia must be maintained during the entire transport period. General anesthesia is usually induced and maintained using injectable drugs, some of which can be administered via a drip (see Chapter 20). The van is positioned as close to the

Figure 73-17. A recumbent patient was anesthetized and pulled into the trailer using a winch and rests comfortably on an air mattress, which was inflated after the horse was positioned in the trailer. Two assistants help with anesthesia.

horse as possible, and the stall partition is placed to one side so that the entire interior space can be used. The winch wire is pulled out to the desired length and the horse is placed on the rubber transport mat or another device so that it can be pulled into the van. Either a hand or electric winch can be used, but there should be a backup if the electric one fails.

For recumbent horses, leather boots are placed on the hooves to reduce the risk of injury, and hobbles are applied to all limbs. The head and especially the eyes must be well protected. This is best achieved with padded leather headgear after the halter has been removed to prevent damage to the facial nerves. The horse can be pulled into the van using a slide mat.

Recently, special air mattresses have been developed for the transport of recumbent horses; these mattresses are used by the large-animal rescue unit operating in Switzerland and Liechtenstein (Herr Ruedi Keller, Embrach).[9] Before inflation, the air mattress is placed between the horse and the transport mat, which are then pulled into the van together. The mattress is subsequently inflated using compressed air. This procedure takes about 2 minutes and ensures a comfortable ride for the patient. Horses can be transported great distances without the risk of pressure necrosis or nerve damage (Figure 73-17). Often, the amount of drugs used to sedate the horse can be reduced as well.

For long distances, a mobile anesthetic machine operated by experienced assistants may be necessary. This enables the administration of intravenous fluids and air supplemented with oxygen (approximately 2 to 12 L of oxygen per minute). Unloading the recumbent horse is straightforward and is achieved by pulling the transport mat out of the van with a winch or crane or by hand.

CHAPTER 74

Bone Biology and Fracture Healing

Mandi J. Lopez and Mark D. Markel

The bones of the skeleton are dynamic structures that protect internal organs, provide rigid segments for muscles to generate forces of motion and locomotion, and serve as the largest reservoir of calcium and phosphate in the body.[1] Bone has an intricate, tightly regulated structure composed primarily of mineral, organic matrix, cells, and water. Although mineral composes two thirds of the dry weight of bone, the relative amounts of all components convey mechanical properties crucial to bone function.[2] In turn, maintenance of normal bone performance depends on constant structural renewal through a dynamic remodeling process. In addition to contributing to the renewal process, cells that line the internal and external surfaces

of the bone, with their secreted growth factors and interactions with the microenvironment, give bone a unique ability to repair itself without a scar following fracture.[3] Bone healing is a highly orchestrated series of biological events that depend upon the site and severity of the injury as well as fracture management. Fractures in the horse pose distinct challenges associated with size, anatomy, and locomotion that contribute to fewer successful repairs than comparable fractures in other species. Noninvasive mechanisms to assess healing quality and strength are critical to fracture management in the horse. Methods to accelerate fracture healing have been the subject of extensive research aimed at reducing complications and improving success rates in the horse. Information in this chapter includes the structure, function, and biomechanical characteristics of bone, as well as the forces that result in specific fracture configurations. The natural process of bone healing, how fracture stability influences the process, mechanisms to determine fracture healing strength, and treatments to accelerate fracture healing are also presented.

STRUCTURE AND FUNCTION OF BONE

Anatomy

Bones are divided into the major categories of long, cuboidal, and flat. In general, flat bones surround vital structures, cuboidal bones compose complex joints, and long bones make up the majority of the peripheral and appendicular skeleton. Equine long bones have a mechanical advantage compared to other species because their proportionately greater length contributes to superior power and speed. Three regions are recognized in long bones. The long, narrow, central region is the diaphysis (Figure 74-1). On each end of the long bone is a wide epiphysis that contains an articulating surface. Distribution of loads across the wide epiphyseal surfaces reduces the stresses experienced by the joints. The metaphysis serves as the transition between the diaphysis and each epiphysis. The physis, or growth plate, separates the metaphysis and epiphysis on each end. Initially, all axial bones form by ossification of a cartilaginous model, endochondral ossification, whereas membranous bones like the skull form from a fibrous precursor.[4,5] Long bone growth in length occurs at the physis via continued *endochondral ossification*. When growth ceases at skeletal maturity, the physis becomes inactive and remains as a narrow, indistinct demarcation between the epiphysis and metaphysis.

Briefly, endochondral ossification, responsible for long bone longitudinal growth, occurs as chondrocytes arranged in columns parallel to the long axis of the bones differentiate and form histologically distinct zones. The zone of *resting cartilage,* containing the least metabolically active chondrocytes, is closest to the epiphyseal end of the growth plate. In the next zone, the *zone of proliferation,* cell division occurs in a plane perpendicular to the long axis of the bone and thereby increases the length of the cell column.[6] Chondrocytes mature, become encased in extracellular matrix, and assume a round morphology in the *pre-hypertrophic* zone just prior to the *hypertrophic zone,* where chondrocytes cease dividing, increase in size, and hypertrophy. Finally, hypertrophic chondrocytes are replaced by mineralized bone and bone marrow via vascular invasion, cartilaginous matrix resorption, and recruitment of osteoblasts that deposit bone matrix in the *zone of calcification*.[7] All mammalian physeal long bone growth follows this same general pattern.

Independent of macroscopic anatomy, all skeletal segments have an outer cortex of compact (cortical) bone and an inner medulla containing bone marrow as well as spongy (cancellous) bone. About 90% of the long bone diaphysis is calcified with both cortical and cancellous bone, but the medulla also contains hematopoietic bone marrow in immature animals and yellow, fat-replete non-hematopoietic bone marrow in adults. The ratio of cortex to medulla varies with bone and function. Cortical bone thickness gradually decreases closer to the metaphyseal zone, and cuboidal bones as well as the metaphysis and epiphysis have comparatively thinner cortices. Cancellous bone is composed of three-dimensional networks of fine supporting rods of bone or trabeculae and hence is referred to as *trabecular bone.* Trabecular bone is more metabolically active and responsive to metabolic homeostasis changes than cortical bone. Cortical and trabecular bone have similar basic composition but significantly different porosities. The porosity of trabecular bone is significantly greater than cortical bone, primarily because of vascular and bone marrow intratrabecular spaces in the former.

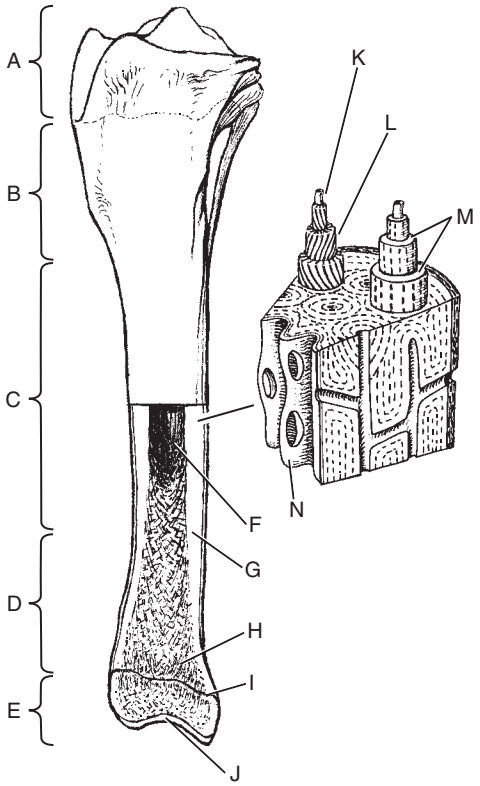

Figure 74-1. Illustration of an immature equine femur with the regions and types of bone indicated. The *inset* is a schematic of bone microstructure showing major osteonal components. *A,* Proximal epiphysis (the separate ossification center of the tibial crest is not shown); *B,* proximal metaphysis; *C,* diaphysis; *D,* distal metaphysis; *E,* distal epiphysis; *F,* medullary cavity; *G,* caudal cortex (compact bone); *H,* cancellous bone; *I,* distal physis; *J,* articular cartilage; *K,* central capillary in Haversian canal; *L,* collagen fibers (alternating their orientation in each lamella); *M,* concentric lamellae (3-7 μm) with osteocytes *(dots); N,* endosteum.

Cortical and trabecular bone are composed of osteons (see Figure 74-1). *Cortical osteons* are called Haversian systems (Figure 74-2) and *trabecular osteons* are called packets. Haversian systems have a cylindrical shape and form a branching network within cortical bone. Concentric, flat, platelike layers of bone, or lamellae, form the walls of Haversian systems. Trabecular osteons are also composed of concentric lamellae, but they are semilunar in shape. Osteons are further classified according to

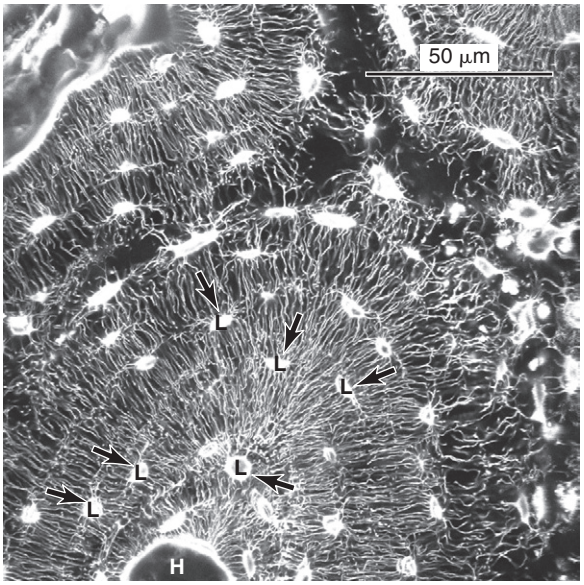

Figure 74-2. Gray-scale composite of Z-stacked confocal photomicrographs of osteocytes surrounding an osteon *(lower left)* in the third metacarpal bone in a racing Thoroughbred. A dense syncitial network of vital osteocytes *(small arrows)* and their canaliculi are demonstrated connecting adjacent lacunae *(L)* before ultimately reaching a Haversian canal *(H).* Scale bar equals 50 μm. (Courtesy Peter Muir, University of Wisconsin, Madison.)

the arrangement of the collagen fibers within their lamellae. Different collagen fiber arrangements have characteristic birefringent patterns when viewed with polarized light. The arrangement of collagen fibrils within the lamellae of osteons confers differing biomechanical characteristics that are reflected in the heterogenous mechanical properties of a whole bone.[8] The spaces between osteons, often called *cement lines,* are composed of matrix components and interstitial lamellae. The composition and protein arrangement within cement lines make them more flexible than the osteons they surround. Osteons can also be classified according to the time of formation. Primary osteons form during *appositional bone growth* (growth resulting in increased bone thickness). Secondary osteons are created throughout life when osteoblasts deposit bone at the end of bone tunnels (cutting cones) created by osteoclasts during the process of bone remodeling.

Periosteum is a thin layer of osteogenic and fibroblastic cells within a well-developed nerve and microvascular network located along the periosteal cortex of cortical bone.[9] Long bones are covered by a periosteum, except on articular surfaces or points of ligament, tendon, or joint capsular attachment. Periosteum is composed of two distinct layers. The *outer fibrous layer* of periosteum is composed of fibroblasts, collagen and elastin fibers, and a nerve and microvascular network.[10] The *inner cambium layer,* which directly contacts the bone surface, contains adult mesenchymal progenitor cells, differentiated osteogenic progenitor cells, osteoblasts, fibroblasts, microvessels, and sympathetic nerves.[11] It provides the cells for fracture healing and appositional bone growth. The periosteum is attached to the outer cortical surface by thick collagenous fibers, Sharpey's fibers. Bones widen through periosteal apposition when osteoblasts add mineralized tissue on the periosteal bone surface. Toward the bone ends, the periosteum continues directly into the perichondral ring that encircles the periphery of the growth plate.[12] Both the periosteum and the perichondrium are firmly attached to the epiphysis. The endosteum is a membranous structure covering the inner surface of cortical bone, trabecular bone, and the blood vessel canals (Volkman's canals) that contains blood vessels, osteoblasts, and osteoclasts.

Long bones have afferent and efferent vascular systems. The afferent vascular system consists primarily of nutrient arteries, proximal and distal metaphyseal arteries, and periosteal arterioles. The efferent vascular system includes the large emissary and nutrient veins that drain the medullary contents, cortical channels, and periosteal capillaries.[13] The direction of blood flow in the efferent (venous) system is primarily away from the cortex toward the medulla (centripedal) and volume is about six- to eightfold greater than the afferent (arterial) system. In mature animals, about 70% of the afferent blood flow within the diaphysis of mature bone is toward the cortex away from the medulla (centrifugal) and 30% toward the medulla (centripedal).[14] The endosteal circulation supplies the medullary areas and the inner two thirds of cortical bone, whereas the periosteal arterioles supply the outer third. Periosteal capillaries are connected to those of the underlying cortex, but under normal conditions little to no blood passes centripetally from periosteum to cortex because of the centrifugal pressure gradient across the cortical capillaries in mature animals.[15] However, because of anastomoses between periosteal and endosteal circulatory networks, blood can flow in either direction, and the relative contributions of centrifugal and centripedal blood flow in the afferent vascular system are affected by growth and injury. The primary blood supply and direction of blood flow in the afferent vascular system changes during long bone growth, and in the young animal, the periosteal contribution is much greater than at skeletal maturity.[16]

Bone is a composite material consisting of organic and inorganic components. Inorganic, organic, and water components are approximately 40%, 30%, and 25% by volume, respectively.[17] The inorganic component is mostly crystalline *hydroxyapatite*: $[Ca_3(PO_4)_2]_3Ca(OH)_2$ and 90% of the organic matrix is composed of type I collagen. Bone hydroxyapatite crystals are very small, approximately 200Å in their largest dimension. Their structure makes them more soluble than geologic hydroxyapatite crystals, allowing them to support mineral metabolism.[18] In normal bone, the mineral provides stiffness and strength, and collagen conveys ductility (the ability to plastically deform without fracture) and toughness (the ability to absorb energy).[19] *Type I collagen* is a triple helix that contains three polypeptide chains, α-chains, each approximately 1000 amino acids (Figure 74-3). Two of the three polypeptides are identical (α_1) and the third is structurally similar but genetically different (α_2). Individual α chains of type I collagen consist of repeating glycine, proline, hydroxyproline, and hydroxylysine amino acids. The polypeptide chains are cross-linked by hydrogen bonds between charged residues. They form linear molecules that are aligned parallel to each other to form collagen fibrils. Collagen fibers are composed of grouped fibrils.

The organic *extracellular matrix* is composed predominantly of collagens, noncollagenous glycoproteins, hyaluronan, and proteoglycans. In addition to type I collagen, almost 30 noncollagenous proteins have been identified in bone. The extracellular matrix provides *structural strength* to tissues to maintain the complex architecture and the shape of organs. It is a scaffold for the cells and a reservoir for growth factors and cytokines, and it modulates cell activation and turnover. In general, the extracellular matrix is a dynamic network of molecules secreted by cells that in turn regulate cell behavior by modulating their

Figure 74-3. proliferation and differentiation. Various cell types secrete different matrix molecules, the nature and amount of which change with age.

Cytokines (such as osteocalcin, bone sialoprotein, osteopontin, and osteonectin, among others) play important roles in bone matrix mineralization.[20] It is thought that the proteins help regulate mineral deposition by binding calcium and phosphate to control the size and number of hydroxyapatite crystals.[18] *Proteoglycans* are biological molecules composed of a specific core protein with covalently linked glycosaminoglycan (GAG) chains (see Figure 78-10). Glycosaminoglycans are linear, negatively charged polysaccharides, which can be divided into two classes of (1) *sulfated GAGs*, comprising chondroitin sulfate (CS), dermatan sulfate (DS), keratan sulfate (KS), heparin, and heparin sulfate (HS); and (2) *nonsulfated GAGs*, such as hyaluronan. Proteoglycans provide *flexibility* and *resilience* to the organic matrix.

Osteoblasts, osteocytes, and osteoclasts are the predominant cell types in bone. *Osteoblasts* are derived from self-renewing, multipotent stem cells through a multistep differentiation pathway.[21] The multipotent cells give rise to osteoprogenitor cells, which differentiate into preosteoblasts and then mature into ostoeblasts. Osteoblasts synthesize new collagenous organic matrix and regulate its mineralization by releasing small, membrane-bound matrix vesicles that concentrate calcium and phosphate and enzymatically destroy mineralization inhibitors.[22] When embedded in matrix, the osteoblasts become *osteocytes*, which have extensive filopodia, actin-based morphological structures at the periphery of cells, within canaliculi in mineralized bone. An extensive cannalicular network connects osteocytes to bone surface lining cells, osteoblasts, and other osteocytes. Connexins are proteins that maintain gap junctions between cells to allow direct communication through intercellular channels.[23] Osteocytes are linked metabolically and electrically through gap junctions, which are required for their maturation, activity, and survival. At the completion of bone formation, 50% to 70% of osteoblasts undergo apoptosis, and the remainder become osteocytes or bone-lining cells. The *bone-lining cells* regulate mineral ion influx and efflux into and out of bone extracellular fluid, and they retain the ability to redifferentiate into osteoblasts.[24] They also function in mechanosensation by transducing stress signals from bending and stretching of bone into biologic activity. Fluxes of calcium across gap junction are believed to stimulate transmission of information between osteoblasts on the bone surface and osteocytes within bone.[25]

Activated *osteoclasts* are derived from mononuclear precursor cells of the monocyte-macrophage lineage originating in bone marrow.[26] Osteoclast formation, activation, and resorption are regulated by interleukin 1, interleukin 2, colony stimulating factor, parathyroid hormone, 1,25-dihydroxyvitamin D, calcitonin, receptor activator of nuclear factor κB ligand (RANKL), and osteoprotegerin (OPG), among others.[27] However, RANKL and macrophage colony-stimulating factor (M-CSF), both produced by stromal cells and osteoblasts, are the two cytokines essential for osteoclast development. RANKL is part of the tumor necrosis factor family and is required for osteoclast formation, whereas M-CSF is necessary for differentiation of osteoclast precursors, osteoclast survival, and cytoskeletal changes for bone resorption. OPG is a membrane-bound and -secreted protein that binds RANKL to inhibit its action at the RANK receptor. Activated osteoclasts secrete hydrogen ions via H^+-ATP proton pumps and chloride channels in their cell membranes to lower the pH and mobilize bone mineral.[28] They also secrete enzymes including tartrate-resistant acid phosphatase, cathepsin K, matrix metalloproteinase 9, and gelatinase from cytoplasmic lysosomes to digest the organic matrix and form saucer-shaped Howship's lacunae on the surface of trabecular bone and Haversian canals in cortical bone.[29] Osteoclasts bind to bone matrix peptides via integrin receptors in osteoclast membranes.[30] They attach to the bone matrix via podosomes rather than by focal adhesions formed by most cells. After binding, a ruffled cell border forms when enzyme-containing vesicles fuse with the membrane. Additionally, a sealing zone forms around the periphery of the osteoclast attachment to the matrix, isolating the acidified resorption compartment.[31] Disruption of either the ruffled border or the sealing zone interferes with bone resorption.

BIOMECHANICAL DEFINITIONS

Mechanics is the study of the effect of forces on objects. The strength of a bone is determined by geometric factors like size, shape, and internal structure, as well as such material factors

as composition. Bone functions much like an elastic material under normal physiological loads with little to no change in external appearance, and this function is reflected by its mechanical properties, especially strength and stiffness. Mechanical properties can be assessed by evaluating the response of bone to externally applied forces called *loads*. When forces act on an object, they alter its shape and size, a process known as *deformation*. Mechanical studies can be divided into two broad categories, static and dynamic. Static studies evaluate bodies at rest, and dynamic studies evaluate moving bodies and can be subdivided into kinematics and kinetics. The vast majority of bone and bone-implant testing is static.

Descriptions of standardized mechanical testing fixtures and protocols are available from the American Society for Testing and Materials (ASTM), but many investigators use custom testing fixtures and protocols for the particular specimens to be evaluated. In most mechanical tests, the applied force is measured by a load cell, and changes in specimen dimensions are measured by motion of the load application system, a strain gauge or extensometer, or another real-time mechanism such as a motion-detection system. Testing is usually performed under load or displacement control, which refers to the test's *end point*. Specifically, investigators can define the end point as a predefined travel distance of the load-application system *(displacement control)* or a predefined load on the load cell *(load control)*. The primary criterion for selecting load or displacement control is whether the dependent variable is displacement or load, respectively.

It is often useful to separate the mechanical properties of the composite materials of a bone (i.e., *material properties*), from those that depend on its dimensions (i.e., *structural properties*). In general, the testing protocols and raw data may be similar for both types of testing. When testing *structural properties* of a bone, the relationship between load and displacement can be represented graphically on a load-deformation curve (Figure 74-4). The initial curved segment of the curve is the *toe region*, a low-force, high-deformation region that reflects a typical response of tissues to physiologic forces characterized by fluid motion as well as straightening and stretching of protein fibers like collagen and elastin. The following linear segment of the curve is the *elastic region* and shows the ability of the bone to resist deformation. In this region, the structure maintains the capacity to return to its original form upon removal of the load. The slope of the curve is often referred to as the *stiffness*. It is critical to understand that the stiffness refers to the composite structure or construct and depends on the shape and interaction between separate components when applicable. As loading continues through the elastic region, the *yield point* is reached, beyond which permanent deformation occurs in the plastic segment of the curve. That is, the structure will not return to its original shape when the load is removed. The amount of plastic deformation, like elastic deformation, depends on the applied load. With increasing load, the bone or construct will eventually undergo significant plastic deformation at a load and deformation defined as the *failure point*. The amount of plastic deformation corresponding to failure depends on the parameters defined in the investigation. The ultimate load is the load beyond which the structure essentially loses all capacity to withstand increasing forces. The ultimate load may be identical to or higher than the failure load. Taken together, the information on a load-deformation curve largely depends on the bone configuration and the relative orientation of the load.

Material properties may be of greatest interest in investigations surrounding properties of fracture callus or the effects of exercise or diet on bone. For material properties testing, areas of interest are typically included in specimens prepared from larger structures. The specimens are generally identical in size, shape, and microstructural orientation. As indicated earlier, the testing process may be very similar to the testing of structural properties, but the load and deformation recorded are stress and strain, respectively. Stress (σ) is the intensity of the force divided over the area that it acts upon. Common stress units include pounds per square inch (psi) and pascals (Pa) (Table 74-1).

A good series of relationships to know is megapascals [MPa] = 10^6 Pa = 1 N/mm^2 ~ 145 psi. Stress is further defined as normal or shear. *Normal stresses* occur when forces are applied perpendicular to the surface of a structure, and *shear stresses* occur when forces are applied parallel to the surface. Tension results in positive normal stress, and compression results in negative normal stress. Strain (ε) is the change in dimension divided by the

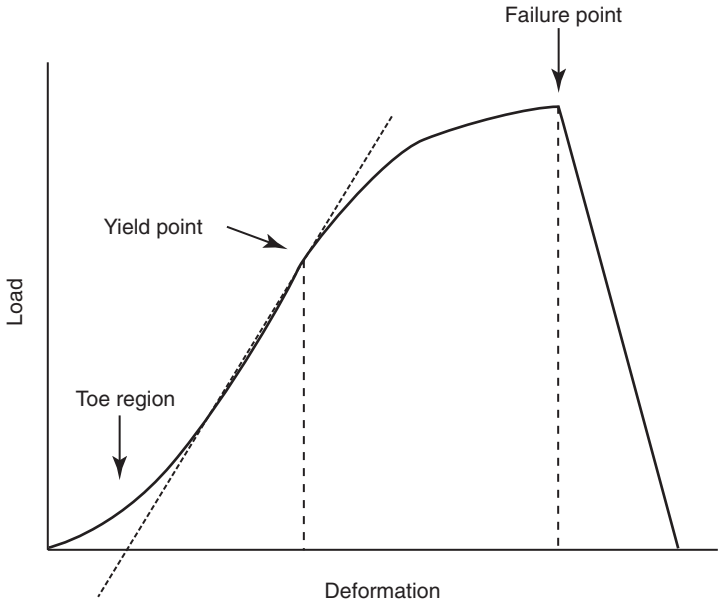

Figure 74-4. Representative load-deformation curve characteristic of a *whole bone structure* (mechanical testing of the *structural properties* of the whole bone).

TABLE 74-1. Stress and Strain Definitions, Symbols, and Units

	Stress	Strain
Definition	The intensity of the force divided over the area that it acts upon	Change in dimension divided by the original dimension (x_1-x_0/x_0)
Symbol	Sigma (σ)	Epsilon (ε)
Units	Kilopounds per square inch (ksi), kilopounds per square foot (ksf), pounds per square inch (psi), pounds per square foot (psf), tons per square foot (tsf), pascals (Pa), megapascals (MPa), kilopascals (kPa)	Normal strain is dimensionless and sometimes expressed as a percentage ($[x_1$-$x_0/x_0] \times 100$). Shear strain is often measured in radians.
Normal	Perpendicular to the surface	Perpendicular to the surface
Shear	Parallel to the surface	Parallel to the surface
Poisson's ratio (ν)	Ratio of lateral normal strain to longitudinal normal strain	Ratio of lateral normal strain to longitudinal normal strain

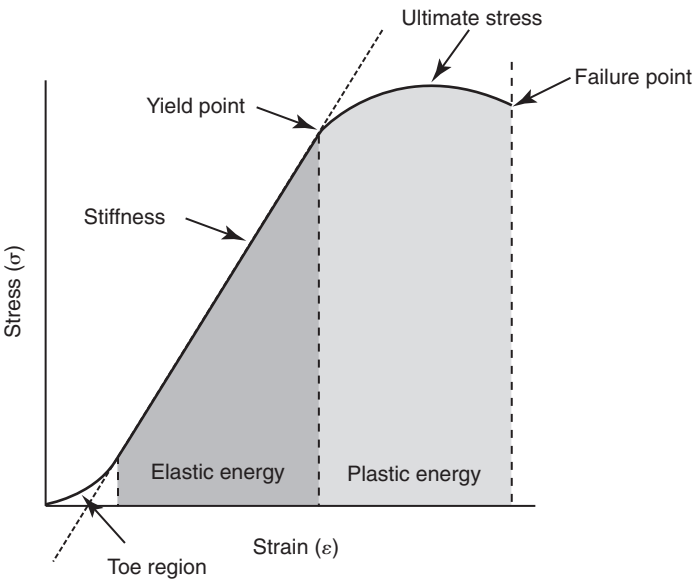

Figure 74-5. Stress-strain curve typical of a *bone sample* (mechanical testing of the *material properties* of the bone sample). (Courtesy P. Daigle, Louisiana State University, Baton Rouge)

original dimension, and the same conventions, normal and shear, apply to strain relative to changes in dimension. Strain is dimensionless, though it is sometimes expressed as a percentage. The ratio of lateral normal strain to longitudinal normal strain is called Poisson's ratio (ν). Shear strain, often measured in radians, refers to deformation in which a plane in the body is displaced parallel to itself. Quantitatively, it is the displacement of a plane relative to a second plane divided by the perpendicular distance between them, half the change of an original 90 degree angle, or the angle between original and deflected locations of the edge of a structure.

A *stress-strain curve* typically looks very similar to a load-deformation curve with stress on the ordinate versus strain on the abscissa (Figure 74-5). The slope of the elastic segment of the stress-strain curve is called *Young's Modulus* when the stress is normal and the strain is linearly proportional to the applied stress. The slope is the shear modulus when the stress is primarily shear. The yield and failure points are similar those described earlier, with the notable exceptions of the units and that they represent material versus structural properties. Additionally, the ultimate stress and strain may be different from the failure stress and strain. Toughness is the energy absorbed by the structure during the loading process. It is equivalent to the area under the curve, and is often expressed as the work of fracture. Brittleness is the opposite of toughness, which is not to be confused with strength. A structure can be tough and have a low or high fracture strength, and the same can be said for brittleness. The yield or failure energy is dissipated when the structure yields *(yield point)* and then fails *(failure point)*. When a crack starts to form, energy is released as two new surfaces are created. If the amount of energy released is less than that required to form the crack, it will stop. Otherwise, it will continue to spread and more cracks will form, consistent with catastrophic failure. The more energy stored in a bone prior to failure, the greater the comminution and/or soft tissue damage that will be caused when a fracture occurs.

The mechanical properties of bone depend on direction of the applied forces, a property called *anisotropy*. In contrast, a material that exhibits neither structural orientation nor dependency on loading orientation is said to be isotropic. *Bone is strongest in compression, weaker in shear, and weakest in tension.* Protein fiber arrangement, osteon composition, and bone mineral distribution contribute to the anisotropic properties of cortical bone. The same factors contribute to anisotropy in trabecular bone with the added component of bone porosity. Cortical bone is more brittle than trabecular bone and fails at a significantly lower strain, albeit a higher load. Trabecular bone stores more energy prior to failure compared to cortical bone

because of a higher toughness. Isolation of the contribution of each bone component to diverse loading to prevent injury and advance treatment of orthopedic injuries is often the goal of many biomechanical studies.

The deformation and strain response of bone to load depends upon many factors, including bone anatomy and composition as well as direction, rate, magnitude, frequency, and duration of applied load. During normal daily activities, bone is subjected to complex loading conditions, most of which include forces applied from numerous directions simultaneously. Replication of complex loading conditions in the laboratory is possible, but data reduction and interpretation is quite complex. Hence, loading strategies are often reduced to single-axis loading in tension, compression, bending, shear, torsion, or a combination of compression and torsion (Figure 74-6).

Equal and opposite loads are often applied to the ends of the bone for *tension* testing. Maximum stresses occur on a plane perpendicular to the applied tensile load and result in transverse fractures (Figure 74-7), and bone fails as a result of osteonal pullout. Transverse fractures from tensile forces occur in the proximal ulna, the proximal sesamoid bones, the patella, and the calcaneus. When loaded in *compression*, maximum stresses again occur in a plane perpendicular to the load as the bone shortens and widens. The fracture configuration that results from compression is about 45 degrees offset from the direction of maximum shear forces. This is largely because of the pattern of microstructural failure at the level of the osteons. Current knowledge suggests that the tough cement lines impose high resistance to microcrack formation and propogation. However, with increasing loads, the microcracks propagate along the relatively more brittle and stress-concentrating structures of the Haversian system, which results in a fracture that is about 45 degrees from the long bone axis.[32] Such fractures are probably best exemplified by dorsal metacarpal stress fractures in the horse.

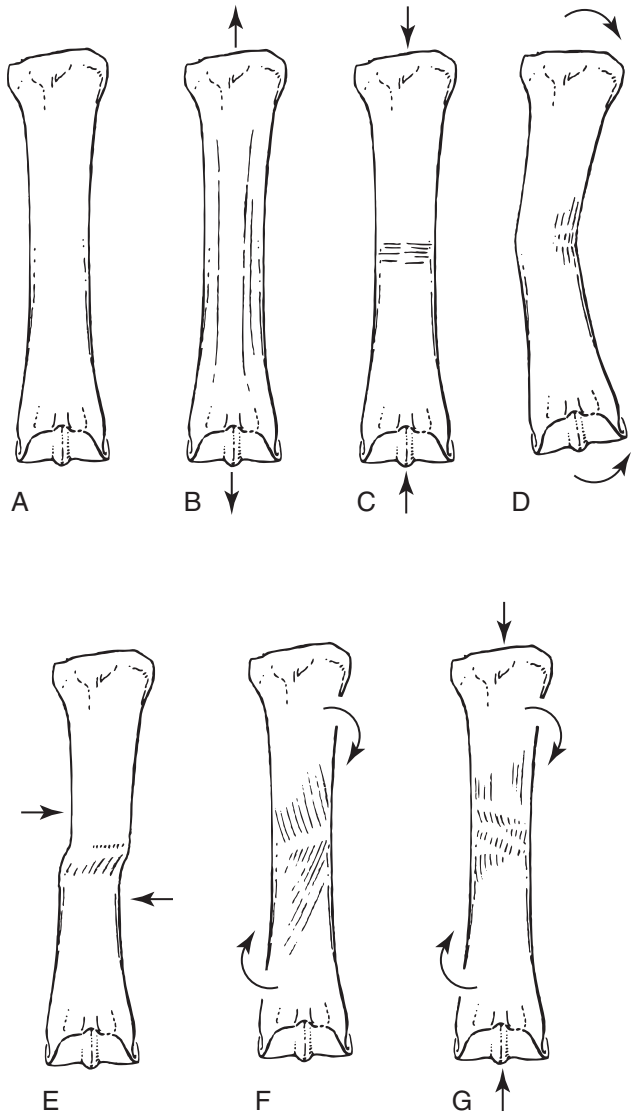

Figure 74-6. Schematic representations of bone loading conditions. **A,** No load; **B,** Tension; **C,** Compression; **D,** Bending; **E,** Shear; **F,** Torsion; **G,** Combined compression and torsion.

Torsion testing causes rotational displacement of bone ends around a central axis relative to each other and generates torque in the structure (see Figure 74-6, *C*). Shear stresses are distributed over the entire bone, and their magnitude increases proportionately with increasing distance from a neutral axis, usually located at the central axis of rotation. Specifically, the shear stresses are the product of the distance from the central axis and the torque from the applied load divided by the polar moment of inertia of the bone, which in turn depends on the bone structure. Based on beam theory, maximal shear stresses occur in planes parallel and perpendicular to the neutral axis. In turn, maximum tensile and compressive forces occur in mutually perpendicular planes where there are zero shear forces. Taking into consideration the variations attributable to bone anatomy and composition, a bone loaded in torsion generally begins to fail in shear parallel to the neutral axis of the bone and continues to fail along the tension plane, around 45 degrees offset from the neutral axis. The pattern continues along the length of the bone to produce a spiral fracture.

Bending results in a combination of tension and compression (see Figures 74-6, *D*, and 74-7, *D*). Tension predominates on one side of the neutral axis and compression occurs largely on the side directly opposite. As stated earlier, the neutral axis is a plane within the bone that does not experience any stresses, and the greater the distance from the neutral axis, the larger the tensile and compressive stresses. Three- or four-point bending is often applied experimentally to test the bending properties of bone (Figure 74-8). As indicated by the names, the differences are in the number of force application points, three or four, which are typically arranged equidistant from one another. For *three-point bending*, three forces produce two equal moments. Each moment is the product of one of the two peripheral forces and its perpendicular distance from the middle force. A typical three-point bending fracture in a horse occurs at the top of a cast or when a horse steps in a hole and the limb hits the top edge. Failure typically begins on the tensile surface of the bone and propagates along the maximum tension plane toward the compressed surface until the maximum shear force at about 45 degrees from the neutral axis is reached and exceeds the tensile forces and the fracture continues along them. The typical fracture contains a butterfly fragment on the compressive side. *Four-point bending* describes two force couples producing two equal moments. The bending moment is the same in the areas between the force couples. Four-point bending rarely results in a fracture clinically, but it is often used for bone testing. Because

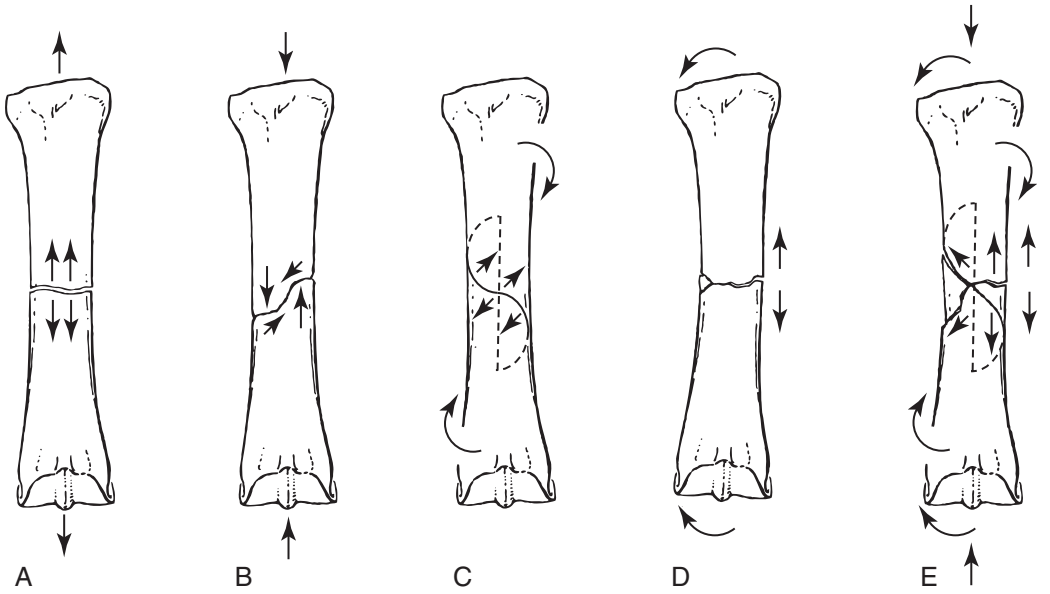

Figure 74-7. Long bone fracture configurations associated with specific force application. **A,** Transverse fractures are characteristic of pure tension. **B,** Oblique fractures occur in compression. **C,** When loaded in pure torsion, fractures initiate parallel to the bone surface and then propagate along the oblique tensile forces to give a spiral fracture configuration. **D,** In pure bending, the bone initially fails in tension and then continues along shear planes, resulting in a butterfly fragment on the compression surface. **E,** In combined compression and rotation, comminuted fractures with characteristics of both loading conditions can occur.

the bending moment is uniform between the two central force couples, bone fractures at the weakest point between the two.

Shear loading refers to application of loads applied parallel to one surface of a bone. A bone subjected to shear loading experiences shear stress and strain and deforms in an angular manner (see Figure 74-6, *E*). Shear loading should not be confused with shear stresses that are produced by the angular deformations caused by the loading mechanisms discussed earlier. Physeal fractures are examples of fractures that result from shear loads.

Bone is rarely loaded in one direction but usually experiences multiaxial loads.[33] Hence the study of *multidimensional loading* on equine bones is essential to predict, prevent, and stabilize fractures.[34] *In vivo* bone loading can be difficult to assess given typical bone anatomy and that loading is affected by a multitude of factors including gait, animal signalment, and ground surface, among others. Multiaxial loading applies the same concepts as uniaxial loading, but outcomes are assessed in two or three dimensions. Three-dimensional analysis generally provides the most realistic assessment of the complexity of bone-loading behavior. Analysis is sometimes simplified with assumptions of symmetry and/or isometry in one or more planes.

Bone anatomy contributes significantly to the structural mechanical properties of whole structures. The overall amount of bone based on cross-sectional area and volume, the relative distribution of bone throughout the structure, and the proportion of cortical versus cancellous bone all influence the structural properties. The cross-sectional area of bone contributes to stiffness and strength characteristics. When comparing two bones with identical anatomy, the bone with the greater surface area usually has higher stiffness, yield, and failure point. The *area moment of inertia* is a value that takes into account the contributions of surface area and bone distribution around the neutral axis to resist deformation with higher values corresponding to higher resistance. A *bending moment* is equal to applied force multiplied by length. Hence, longer bones tend to experience higher moments, or internal loads, from the same force given the greater distance between force-application points.

The response of bone to load depends on the rate of application of the load. This is related to the viscoelastic properties of bone. As bone deforms, it stores the applied energy as strain energy, a form of potential energy. The energy is released when the bone fractures. Largely because of its microstructure, bone is stiffer when loaded at a faster rate, and hence it stores more energy prior to failure compared to slower loading rates. Therefore, a *bone loaded rapidly fails at a higher load and releases more energy than if it is loaded slowly*. At a lower loading rate, bone is less stiff, fails at a lower load, and stores less energy prior to failure. High-energy fractures have significant communition and soft tissue injury, whereas low-energy fractures have little comminution and less damage to surrounding structures.

Fractures can occur as a result of a single incident or secondary to repeated loading cycles. Bones that fail secondary to *repeated cyclic loading* are typically viewed as failing secondary to fatigue. Under cyclic loads, the susceptibility of bone to fracture is related to its crystal structure and collagen orientation reflected by its viscoelastic properties. Cortical bone is particularly vulnerable to tensile and compressive cyclic stresses. Fatigue load under certain strain rates can cause progressive accumulation of microdamage in cortical bone. If the process continues, the bone may eventually fail through coalescence and propagation of the cracks. Although cortical bone is relatively brittle and has poor fatigue resistance *in vitro*, it is a living tissue that can remodel and repair during and after loading, as occurs in bucked shins in horses. Periosteal new bone formation near microcrack formation can arrest crack propagation by reducing the stresses encountered at the tip of the crack. In a

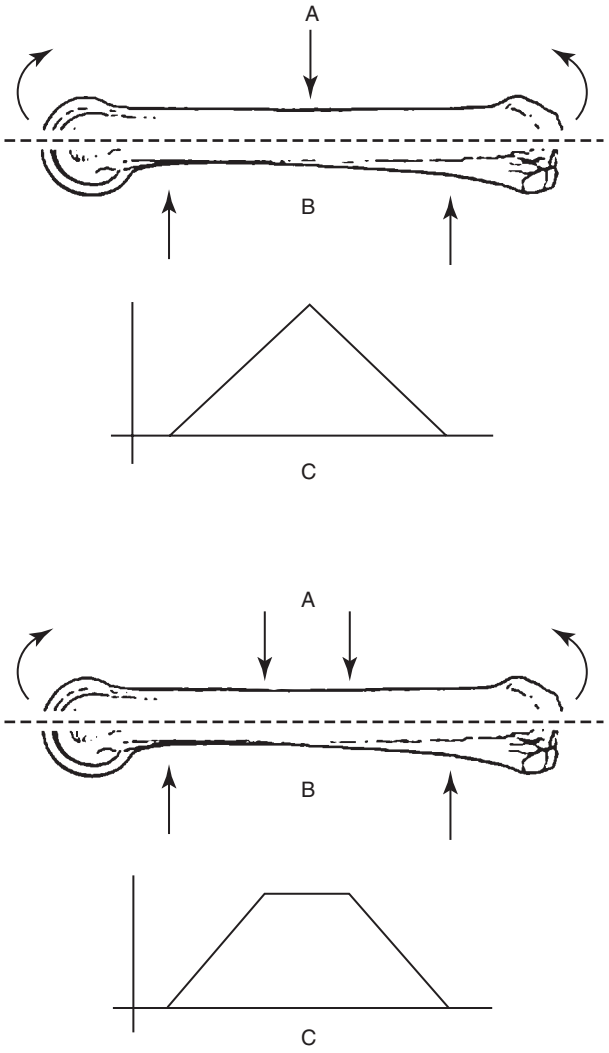

Figure 74-8. Schematic representation of three-point *(top)* and four-point *(bottom)* bending. Three-point bending consists of three forces acting on a bone to produce two equal moments. Each moment is the product of one of the two peripheral forces and its distance from the middle point of force application. Four-point bending occurs when two force couples act on a bone to produce two equal moments. The bending moment magnitude is the same between the central force couples. *A,* Compression; *B,* tension; *C,* bending moment (Nm).

fatigue test, the endurance limit of a bone is the stress level under which no fractures can develop regardless of the number of loading cycles applied. Therefore, for the repair process to be effective following fatigue-induced microcracks, relatively low loads must be present and be maintained to allow sufficient time for the repair process to occur.

BIOLOGICAL REACTION AND HEALING OF BONE

Fracture healing is a highly orchestrated series of complex biological events driven by intracellular and extracellular signaling that follows a defined temporal sequence. Molecular mechanisms that regulate embryologic skeletal development are recapitulated during the process of fracture repair.[35] Local and systemic factors including growth and differentiation factors, hormones, and cytokines interact with primordial cells recruited locally or from the circulation. Research provides significant understanding of the molecular mechanisms of the bone healing process.

Fracture healing is divided into direct (primary) and indirect (secondary). *Direct fracture healing* occurs when there is anatomic reduction of the fracture fragments by rigid internal fixation that minimizes interfragmentary strain. The process involves direct regeneration of the Haversian system between abutted fracture fragments to restore mechanical integrity. Healing occurs by direct growth of secondary osteons from one fragment to another and by intramembranous bone formation. Vascular endothelial cells and perivascular mesenchymal cells provide osteoprogenitor cells that differentiate into osteoblasts. During the process, little or no periosteal callus is formed. *Indirect fracture healing,* most common in horses, occurs through the process of endochondral bone formation when the fracture fragments are not sufficiently immobilized or approximated for direct healing (Figure 74-9).

Fracture healing can be described as a series of biological stages (inflammation, repair, and remodeling) that follow each other in sequence, with some degree of overlap.[36] Like all repair responses, fracture healing begins with induction of an immune response.[37] Cytokines, platelets, bone morphogenetic proteins (BMPs), and mesenchymal stem cells (MSCs) are key to this stage that begins immediately after fracture and lasts between 2 and 3 weeks, the shortest phase of the repair process.

During the initial *inflammatory stage,* lysosomal enzymes from disrupted osteocytes trigger the destruction of the organic matrix, and the necrotic material induces an intense inflammatory reaction. Acute-phase proteins activate proteolytic enzyme cascades. Cytokines secreted by inflammatory cells recruit MSCs and have a chemotactic effect on other inflammatory cells. A hematoma forms, and attached platelets are activated by thrombin and subendothelial collagen to release platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β). The proteins induce MSC migration, activation, and proliferation, induce platelet aggregation, and have a chemotactic effect on inflammatory cells. At the same time, BMPs are released from bone matrix and expressed by MSCs.[38] The earliest soft callus is rich in type III collagen. The stromal cells proliferate and differentiate into chondrogenic and osteogenic lineages within the matrix template for the calcified callus. Additionally, *angiogenesis*, a prerequisite for continued regeneration, occurs during this early phase and is regulated by such factors as fibroblastic growth factor (FGF), vascular endothelial growth factor (VEGF), and angiopoietin 1 and 2.[39] The initial blood supply to the periosteal callus originates from the surrounding soft tissues. It is transient and distinct from periosteal arteries. In spite of the initial vascular proliferation, the callus is relatively hypoxic. As healing progresses, the extraosseous blood supply diminishes.

The *repair phase* follows and overlaps with the inflammatory phase when the majority of the callus consists of unmineralized matrix. The matrix subsequently mineralizes to form *woven bone*, a form of bone that has randomly distributed collagen fibrils and is deposited only during initial bone formation and fracture repair.[40] Bone formation in the callus proceeds by both intramembranous and endochondral ossification, the relative amount of each depending on the degree of immobilization of the fracture ends and physiologic loading. Endochondral ossification initially occurs adjacent to the fracture site periosteum.

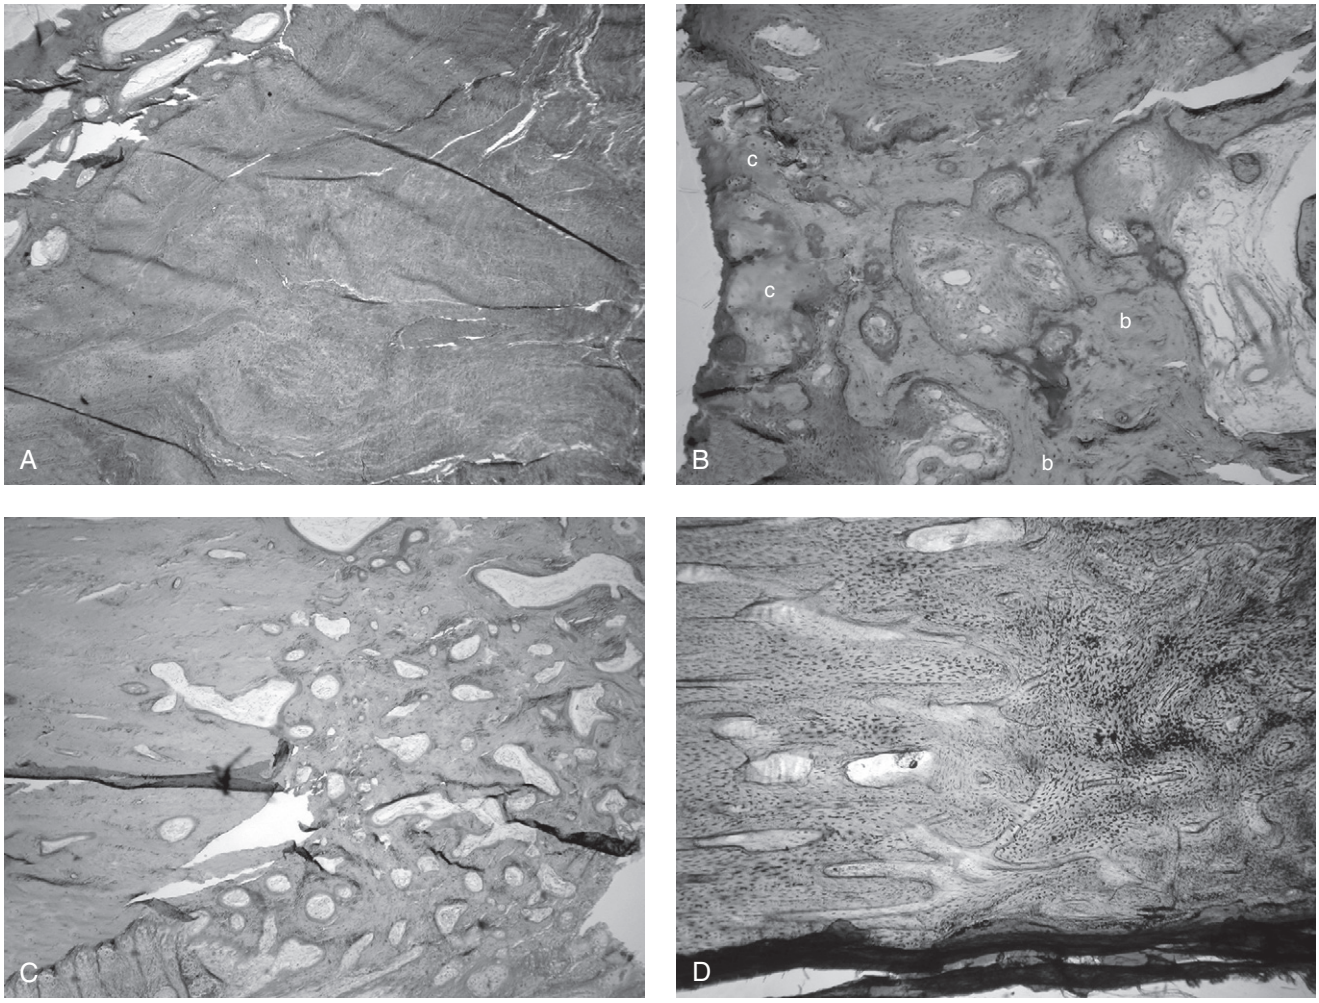

Figure 74-9. Light microscopy of 5 μm undecalcified specimens of a fracture gap (Goldner, ×20). **A,** Two weeks after fracture when the gap is filled with undifferentiated tissue. **B,** Four weeks after fracture with islands of cartilage *(c)* and woven bone formation *(b)*. **C,** Eight weeks after fracture with bone filling the gap. **D,** Twelve weeks after fracture with cortex almost entirely reconstituted, although it is still significantly more porous than normal cortical bone.

Within days after fracture, recruited MSCs begin to proliferate and subsequently differentiate into chondroblasts. The cells synthesize and secrete cartilage-specific matrix including type II collagen and proteoglycans. When mechanical stability is established, the cartilage undergoes hypertrophy and mineralization in a spatially organized manner. As vessels invade, the calcifying, hypertrophic chondrocytes are removed by chondroclasts and woven bone formation occurs by MSCs that have undergone osteogenic differentiation. Type I collagen is superimposed on the early cartilagenous matrix, and types II and III are removed. Crystals of calcium hydroxyapatite become clustered around the fibrils, eventually forming a rigid callus. Blood vessels begin to pass through the fibrous callus to unite the vasculature of the fragments. Eventually, the soft callus is replaced by mineralized callus and woven bone. Bone mineralization always begins on a solid surface that can include the external or internal surfaces of the bone ends at the fracture site and the surfaces of larger fragments. Formation of a bony bridging callus is the final step in the reparative phase of fracture healing and is considered the point of clinical union. The mineralized callus then undergoes the process of remodeling. The repair phase can take between 2 and 12 months.

The *remodeling phase* is the third and longest stage of fracture healing, when mineralized cartilage continues to be replaced by woven bone, which is remodeled into *lamellar bone*. Lamellar bone is the most abundant form of bone in most mammals. Sublayers of mineralized collagen fibers compose individual lamellar units. The sublayers are variably oriented relative to each other to create a complex, layered structure. Osteoclasts remove woven bone to create bone tunnels known as *cutting cones,* which are filled with lamellar bone around a central capillary channel by osteoblasts (Figure 74-10). Bone remodeling is largely regulated by the mechanical environment and the resultant piezoelectric charges generated in the crystalline bone. Weight-bearing stresses cause concave surfaces to become electronegative and convex surfaces to be electropositive. Osteoblastic activity is enhanced on electronegative surfaces and osteoclast activity is higher on electropositive surfaces. This activity is part of Wolff's law. The final result of the remodeling stage is regenerated bone with organic and mineral phases suited and aligned to resist physiological stresses and strains.

The ultimate goal of fracture healing is to reconstruct the original cortical bone. The cortical ends of the fracture site become avascular and necrotic immediately following fracture.

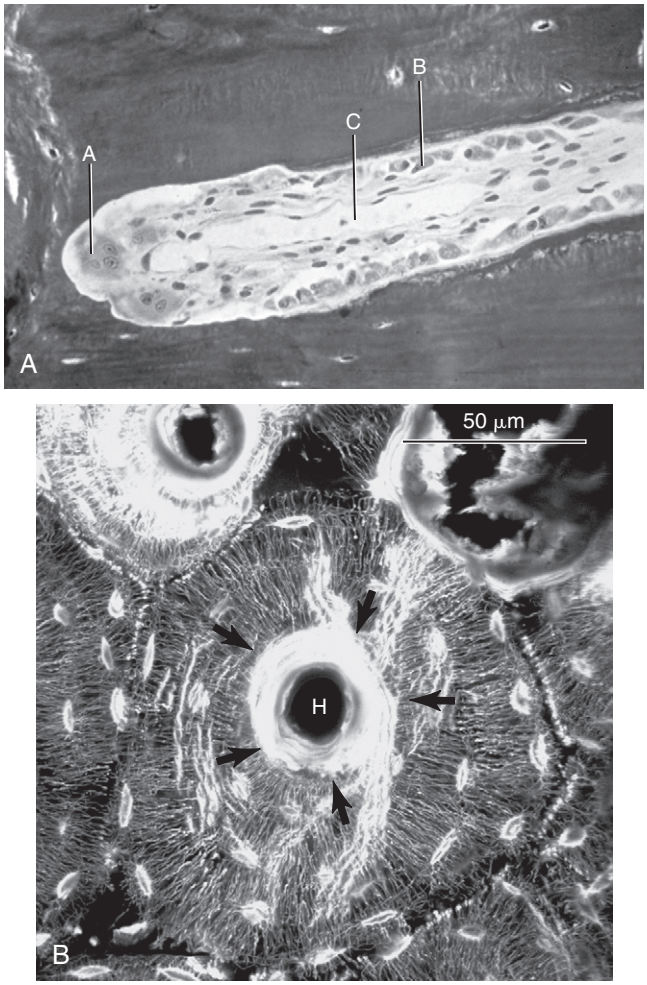

Figure 74-10. A, Photomicrograph of a longitudinal section of a bone metabolic unit (BMU) depicting osteoclasts *(A)* at the tip and the corresponding "Howship lacunae," the osteoblasts *(B)* lining the peripheri of the BMU and the centrally located blood vessel *(C)* in the Haversian canal. **B,** Gray-scale composite of Z-stacked confocal photomicrograph of a BMU in cross section depicting the central Haversian canal *(H)* surrounded by brightly fluorescing mineralized matrix *(arrows)* recently deposited in a cutting cone. Fortunately, this vascular compromise does not prevent the avascular ends from providing important biomechanical roles by serving as supportive elements for fracture-fixation devices. Haversian remodeling of the uniting fracture serves two principal functions, including the revascularization of necrotic bone at the fracture site and the reconstitution of the interfragmentary gaps. There are three specific requirements for Haversian remodeling to occur across a fracture site. These include adequate reduction, rigid fixation, and sufficient blood supply. Haversian remodeling of the fracture typically begins in the second to third month after fracture healing. It is unknown exactly what factors initiate the dramatic increase in secondary osteon formation that occurs during fracture healing, although it has been postulated that the activation of Haversian remodeling is related to tissue damage at the fracture site.

Progression of a secondary osteon from one fracture fragment to another does not require intimate contact of fracture fragments. Even with perfect reduction and rigid internal fixation, there are incongruencies at the fracture site that result in small gaps between areas of contact. These gaps are typically filled within weeks after the fracture occurs by direct lamellar or woven new bone. Secondary osteons use this gap tissue as a scaffold to grow from one fragment to another. Although the growth and progression of secondary osteons are critical for final union, their growth typically results in a transitory reduction of cortical bone density because of the increased porosity. It is apparent that fracture healing progresses through a variety of pathways that are strongly influenced by a number of factors. Fortunately, the process tends to have a high level of tolerance and adaptability.

EVALUATION OF HEALING FOR CLINICAL JUDGMENTS

Determination of effective osseous fracture union can be a diagnostic challenge. Clinical assessment requires a comprehensive consideration of numerous factors including the initial injury, standard healing period, fracture site pain, palpable callus, lameness, and stability on manual examination.

Radiographic evaluation is the standard modality to assess fracture healing. Secondary bone healing is the most common mechanism of equine fracture healing, and radiographic changes coincide with the three phases of fracture repair described earlier. Up to a week following the initial trauma, sharp fracture margins are typically visible.[41] After the inflammatory phase is established, necrotic bone is removed by osteoclasts and phagocytes. During this period, approximately 2 to 3 weeks after fracture, *the fracture gap appears to widen* and develops an indistinct margin. During the ensuing repair phase, periosteal, endosteal, and intercortical *calluses become evident*, though they vary in radiographic visibility depending on their degree of mineralization; which, in turn, depends upon local blood supply and tissue oxygenation. Initial callus formation occurs within 5 days after trauma, but bony callus requires significant mineralization to be evident radiographically. As healing progresses, fracture lines disappear and the external callus increases in opacity relative to adjacent bone. The size and shape of an external callus is significantly influenced by motion at the fracture site, with greater motion resulting in a larger callus. In the remodeling phase, the woven bone of the callus transitions to lamellar bone. As remodeling progresses, the callus assumes the original bone configuration. Traditionally, bony union is characterized radiographically by a bony callus, obliteration of the fracture line by bony trabeculae, and cortical bone bridging of the fracture gap.[42]

Methods to improve evaluation of equine bone healing are an area of ongoing research. Nuclear scintigraphy is one modality that has been used to evaluate equine fracture healing.[43-45] It is advantageous in that it provides a clear assessment of fracture vascularity for prognostic purposes. Both computed tomography and nuclear scintigraphy are used to detect and assess equine fractures.[43,46-49] Dual x-ray absorptiometry (DEXA), magnetic resonance imaging (MRI), and ultrasonography are popular modalities to evaluate fracture healing in human and small animal patients, but they are less routinely applied to the horse.[50-52] Some fractures, such as incomplete metacarpal stress fractures, are best identified and monitored with MRI.[53] Methods to enhance traditional radiographic assessment of equine fracture healing like MRI and ultrasonography are becoming more

common with development of equine-specific equipment and methodologies. Combinations of various imaging modalities can augment fracture diagnosis and determination of healing progress. Radiography and ultrasound are used to assess some fractures and their healing, especially those that have articular components or are in bones that are difficult to isolate radiographically such as the pelvis and scapula.[54-56] A combination of complementary modalities allows optimal assessment of some fractures.

COMPLICATIONS

Equine fracture healing complications may include infection, fixation failure, delay or failure of bony union, laminitis, and, in foals, contralateral angular limb deformity. These broad generalizations simply represent some common problems associated with fracture repair. Each fracture and patient is unique and subject to individual variation and associated complications. Complications should be specifically addressed as they arise.

Perioperative antibiotic administration and improved surgical techniques and equipment have significantly reduced the incidence of nosocomial equine orthopedic infections, but severe soft tissue damage often associated with the initial injury can result in exposed bone and severe contamination. In spite of appropriate surgical débridement and antibiotic administration, compromised blood supply, swelling, edema, and necrotic tissues make an ideal environment for bacterial proliferation. Local infection can easily proceed through the cortex, marrow, and articulating surfaces of injured bones. Based on a recent retrospective study, *closed fractures* are 4.23 times more likely to remain uninfected, and these patients are 4.59 times more likely to be discharged from the hospital than those with open fractures.[57] Additionally, *closed reduction* and internal fixation is associated with a 2.5-fold reduction in rate of postoperative infection and a 5.9 times greater chance for discharge from the hospital compared to open reduction and internal fixation. Treatment of osteomyelitis following fracture stabilization requires individualized assessment and therapy. Additional information on bone infection and its treatment can be found in Chapters 7 and 85.

There are many factors associated with delay or failure of fracture union including, but not limited to, fracture and incisional infection, inadequate reduction and immobilization, and soft-tissue disruption. Long bone fractures are expected to heal within approximately 4 months in adult horses and 3 months in foals, but there is no definite timetable to define delayed union or nonunion. For delayed union and nonunions, potential systemic conditions that may inhibit normal bone formation should be ruled out. Healing progresses, but at a slower rate than normal in cases of *delayed union*. Radiographic signs may include a persistent fracture line, minimal callus, and intramedullary sclerosis. Treatment depends on the suspected cause of the inadequate healing response. Noninvasive mechanisms to stimulate the healing response have variable success. Improved stabilization, fracture dynamization, and/or surgical débridement with implantation of osteogenic substances may be employed to stimulate the healing process. *Nonunion* occurs when fracture repair ceases before the bony structure is restored. Radiographic findings may include lack of bridging bone or callus across the fracture site; sclerotic, blunt fracture edges; persistent fracture lines; and lack of progressive change toward union on serial radiographs. There are many types of nonunion including hypervascular, oligotrophic, avascular, comminuted, and defect. *Hypertrophic* nonunions, in contrast to the other types, have abundant blood supply and exuberant callus (Figure 74-11). They are typically treated with improved stabilization. The other forms of nonunion require steps to address the nonviable and/or missing tissue. Typical treatment consists of débridement and addition of graft or other substances to stimulate osteogenesis and provide a bony template for bone ingrowth as appropriate. Additionally, careful consideration of fracture stability is necessary.

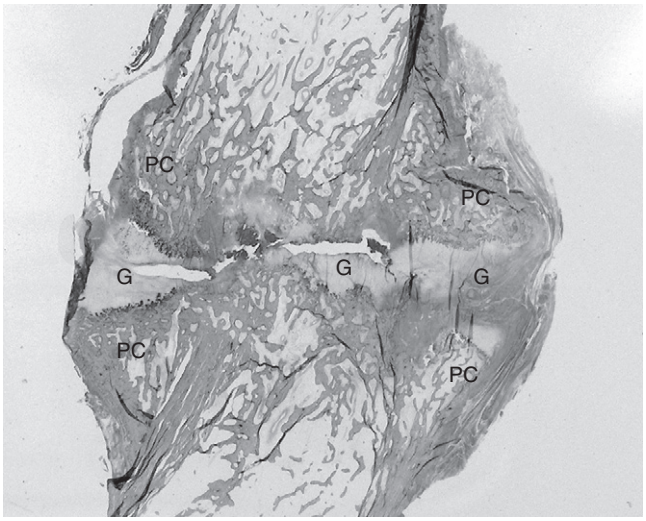

Figure 74-11. Light microscopy of an undecalcified specimen illustrating hypertrophic non-union (Goldner, ×4). Note abundant periosteal callus *(PC)* without bridging of the fracture gap *(G)*.

Stress-induced laminitis is a compounding factor in many fracture repairs. The basic cause of the condition is related to continued severe lameness after fracture fixation. The primary goal of any form of fracture stabilization is return to weight bearing on the affected limb as quickly as possible. In spite of appropriate, stable reduction and analgesic administration, continued pain in some fractured limbs results in increased weight bearing on the contralateral limb. Stress-induced laminitis generally does not have a metabolic component. It can result in rotation and even sinking of the distal phalanx as the germinal layers separate from the horny tissues within the hoof capsule. In contrast to adult horses, foals are rarely affected by laminitis, but instead can develop angular limb deformities in the uninjured limb if severe lameness persists in the fractured limb as a result of the prolonged tripod stance.

Fixation failure can occur for any number of reasons in the horse, not the least of which are forces inherent to the equine limb. Use of an equine external skeletal fixation device designed specifically for horses to bear full weight immediately in cases of severely comminuted fractures of the distal aspect of the limb fracture historically was complicated by fractures of the third metacarpus through pin holes in up to 22% of cases.[58] New device designs have significantly reduced fracture complications, but external coaptation is often applied after the device is removed.[58] Hybrid external fixators are used on occasion to stabilize fractures in foals and ponies.[59] External coaptation is not routinely used alone for fracture stabilization but is used more often to protect surgical implants in the postoperative period or to protect fractures after implant removal. Transfixation casts

are used on occasion, but they are typically reserved for foals or fractures distal to the carpus or tarsus in adult horses.[60] Cast complications, pin breakage or loosening, pin hole fracture and lysis, and pin track infections are reported problems.[61] Surgical implant complications are often associated with inadequate fixation rigidity compared to the mechanical demands placed upon the repair. Construct failure may occur when forces are experienced that exceed implant strength such as during recovery, or when the period of bone healing is longer than the implant's fatigue life. Implant loosening as a result of localized implant or bony failure can result in an unstable fracture and delayed healing. Fracture instability related to inadequate fracture fixation technique is often associated with an unsuccessful outcome.[62] Although no amount of caution can prevent all fixation-associated problems, appropriate preoperative planning, optimal fracture stabilization, and supportive postoperative care improve chances of success considerably.

DISTRACTION OSTEOGENESIS

Distraction osteogenesis or callostasis is a technique used to correct skeletal deformities. It involves forming new bone by controlled separation of stabilized bone ends on each side of a corticotomy or osteotomy.[63,64] Application of gradual traction promotes regeneration and progressive growth of bone and soft tissues at a rate that is well tolerated by the tissues, resulting in minimal trauma. To achieve bone formation, there must be adequate fixation stability, periosteal and medullary blood supply, minimal soft tissue disruption, and physiologic use of the bone.[65,66] Bone formation also depends on the appropriate distraction rate and rhythm, length of distraction and number of distraction increments every 24 hours. New bone, referred to as *regenerate bone,* forms according to a general principle called *the tension-stress effect*.[67] Specifically, early callus tissue subjected to slow steady traction is metabolically stimulated to differentiate and proliferate in the distraction gap.

The process of distraction osteogenesis is divided into three periods; latency, activation, and consolidation.[63,64] The *latency period* is the time between bone transection and the initiation of distraction, which is postulated to enhance cellular and vascular responses and improve osteogenesis. The *activation period* is characterized by bony in-growth as distraction is applied. Within 3 to 7 days after bone transection, osteoblast or osteoclast progenitor cells on the bone surface differentiate according to the mechanical and biological environment and begin to proliferate. The generally accepted distraction speed is 1 mm/day. This can be divided into two or three segments to be applied during a 24-hour period. Osteoid is laid down in parallel columns extending centrally from each bone surface.[67] Lamellar bone typically develops within the columns, but fibrous tissue can form if the fracture site is sufficiently unstable. The distraction device remains in place to serve as rigid skeletal fixation until maturation of new bone is achieved during the *consolidation period*. Metaphyseal cancellous bone heals differently than cortical bone because cancellous bone is inherently more stable.[68] Periosteal callus formation does not occur unless there is significant instability. Instead, osteoblasts deposit new bone on trabeculae, and the fracture gap fills with woven bone, bridging the trabeculae prior to cortical union. As with any fracture, distraction osteogenesis must be based on the patient's age and health, the bone involved, the osteotomy type and location, and the degree of soft tissue trauma.

Distraction osteogenesis has limited potential for equine application. Circular external fixator strength is usually inadequate for stabilization of equine long bones with the potential exception of small foals. Successful correction of a deviated nasal septum and premaxilla in a yearling filly and mandibular brachygnathia in a yearling colt has been accomplished using this technique.[69-71] With careful case selection and appropriate external or internal fixator construction, distraction osteogenesis may be a useful treatment in certain equine patients.

STIMULATION OF BONE HEALING

Enhancement of fracture healing for rapid restoration of skeletal function will greatly benefit the equine patient. Both biological and mechanical methods to accelerate the process of bone repair have been evaluated in the horse. Historically, autogenous corticocancellous bone grafts have been the gold standard to facilitate bone repair, though both autogenous and allogeneic demineralized bone matrix and autologous cortical bone have also been used.[45,72,73] A novel application of an allogeneic bone graft in the form of an implant was recently described in a report on the mechanical properties of proximal sesamoid fractures stabilized with cortical bone screws machined from allogeneic cortical bone.[74] Bone grafts may provide cells *(osteogenesis)*, induce bone formation by host cells *(osteoinduction)*, or provide a scaffold for bone formation *(osteoconduction)*. Graft quality is affected by donor condition and comorbidities. Additionally, transmission of pathogens through allogeneic grafts remains a significant concern. Successful graft incorporation requires an appropriate match of the biological graft activity, the surrounding host tissues, and the mechanical environment (for more information, see Chapter 77).

One of the most highly investigated mechanical techniques to stimulate fracture healing in the horse is application of energy in the form of pulsed ultrasound and electric and electromagnetic fields.[75-79] The premise for many of the treatments are based on Wolff's law; living bone adapts its structure in response to mechanical stress by producing electric potentials, which optimize bone growth. There is a large body of evidence demonstrating that metabolic activity and mechanical deformation in living bone generate steady direct current and time-varying electric fields, respectively.[80] Numerous basic research and clinical investigations surrounding stimulation of bone repair with energy application have been conducted across species. Though there are anecdotal reports of treatment success in the horse, clinical efficacy has yet to be clearly established.[75,81,82]

Technological advances are evident in recent research surrounding equine fracture treatment. The three native benefits of bone grafts—osteogenesis, osteoinduction, and osteoconduction—have yet to be fully replicated by a single product. However, research has been focused on the ability to confer all or some of the same benefits by other means. Biodegradable bone cement has been used experimentally to adhere equine bone fragments to parent bone and support fracture healing.[83] Administration of BMPs, other growth factors, and cytokines to fractures via biocompatible carriers, adenoviral vectors, and genetically engineered cells have shown promising results to accelerate equine fracture repair in controlled studies (Figure 74-12).[84-88] Adult mesenchymal stromal cells exhibit osteogenesis *in vitro* and have significant promise to enhance current equine fracture repair strategies. The number of osteoprogenitor

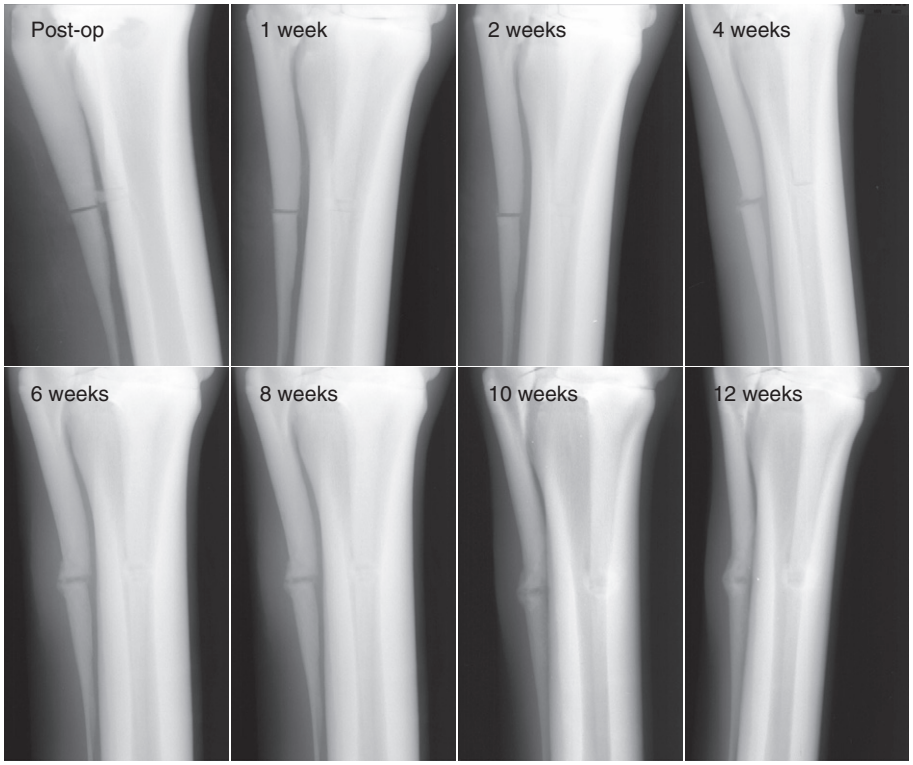

Figure 74-12. Radiographic images of fourth metatarsal osteotomy from immediately postoperative to 12 weeks after surgery following treatment of the gap with rhBMP-2 combined with calcium phosphate cement, demonstrating progression toward union by 10 weeks.[86]

cells varies among donor sites, and the number and multipotentiality of MSCs declines with age. Hence, use of culture-expanded or otherwise purified and concentrated equine MSC populations will likely be necessary to obtain sufficient cells with appropriate osteogenic potential. A number of reports have evaluated the *in vitro* potential of progenitor cells from various equine tissue sources to differentiate toward the osteogenic cell lineages,[89-93] but their *in vivo* use to enhance bone repair following culture expansion or other means of purification is not well established. Continued efforts to optimize fracture diagnosis and stabilization and to enhance the natural repair process will undoubtedly contribute to a better quality of life for equine companions.

CHAPTER
75 Metallic Instruments and Implants

John A. Disegi

METALLIC INSTRUMENT MATERIALS

Stainless Steel

The types of stainless steel that are used for instruments may be classified according to their microstructure, magnetic attraction, corrosion resistance, and hardness.[1] A general comparison of commonly used stainless instrument materials is shown in Table 75-1.

The term *martensitic* describes the type of microstructure associated with 400 series stainless steel, which is highly magnetic and has moderate corrosion resistance. The martensitic compositions contain 12% to 18% chromium, a medium to high carbon content, and other minor elements. Common types of martensitic alloys of the 400 series of stainless steel include 420A, 431, and 440B; each grade has an equivalent Deutsches Institut für Normung (DIN) designation. The 400 series nomenclature refers to various well-defined alloys, which include compositional trends related to carbon and chromium content. For instance, the suffix letters A, B, or C define an increasing carbon range for a given alloy (420C > 420B > 420A) and the chromium range increases as the three digit 4XX number increases (440 > 431 > 420). The alloys are fabricated into various instruments in the soft condition and are heat-treated to develop full mechanical properties. Heat treating[2] is a hardening process that transforms the microstructure with temperatures in the range of 930° to 1150° C, followed by a controlled quench in air or a liquid. The hardened alloy is then tempered at an intermediate temperature of 150° to 370° C to develop the final optimal properties.[2] For a given alloy, the hardness typically decreases as the tempering temperature increases. Martensitic alloys are very hard and resistant to wear, which makes them ideal for cutting instruments (such as drills, taps, countersinks, reamers, chisels, and bone-cutting forceps) and for use in noncutting tools (such as screwdrivers and wrenches).

Precipitation hardenable (PH) stainless steels contain substantial amounts of chromium, nickel, and copper, plus controlled levels of secondary elements.[2,3] The PH compositions are usually fabricated in the annealed (partially heat-treated) condition, and the heat treatment is finished in a one-step aging treatment that promotes hardening as a result of precipitation of a secondary strengthening phase within the martensitic matrix structure. Various age-hardened techniques (e.g., H900 and H950) are used, and the final hardness is inversely related to the age hardening temperature. PH stainless steels are used for a variety of noncutting instruments that require a moderate hardness level. The PH grades do not contain a high carbon content, so edge retention and wear resistance are inferior when compared with the 400 series martensitic compositions. A commonly used PH-grade alloy contains 17% chromium plus 4% nickel (17-4PH) and is identified as Type 630.

The term *austenitic* describes the type of microstructure associated with 300 series stainless steel, which may be slightly magnetic and has excellent corrosion resistance. The austenitic compositions[3] usually contain 16% to 18% chromium and 8%

TABLE 75-1. Classification of Stainless Steel Instrument Materials

Microstructure	Magnetic Attraction	Corrosion Resistance	Hardness	Common Types
Martensitic	High	Moderate	High	400 series
Precipitation hardenable	High	Moderate	High	PH grades
Austenitic	Low	High	Moderate	300 series

to 10% nickel. The low carbon grades, such as 304L (*L* indicates low carbon), meet a compositional requirement of a maximum of 0.03% carbon. Other major elements may be added to improve the microstructure stability and corrosion properties. The 300 series stainless steels may be strengthened by cold working, but they do not have outstanding cutting or wear properties because of the low carbon content. The austenitic alloys, except for 316 and 316L, which contain 2% to 3% molybdenum, also become slightly magnetic as the amount of cold-work increases. Some of the austenitic stainless steels can be cold-worked to a very high tensile strength and may be used for some noncutting applications including drill guides, clamps, hollow sleeves, springs, and washers. Table 75-2 compares some typical stainless steel instrument materials.[1]

TABLE 75-3. Typical Tensile Properties for Aluminum and Aluminum Alloys

Alloy, Temper	Ultimate Tensile Strength* (MPa)	0.2% Yield Strength† (MPa)	Elongation‡ (%)
1100-O	90	35	45
2024-T4	470	325	19
5052-H32	227	193	18
6061-T6	310	276	25

*Ultimate tensile strength: Failure stress (maximum load ÷ cross-sectional area).
†Yield strength: Stress at start of permanent deformation (at 0.2% stress to strain offset deviation).
‡Elongation: A measure of ductility (amount of total extension under load).

Aluminum

Aluminum is available in various purities. An aluminum composition frequently used for bone plate or rod templates is known as *Grade 1100*. This grade of aluminum meets a minimum aluminum content of 99% and is supplied in the soft annealed condition (O temper). Aluminum templates are low in strength, highly ductile (malleable), nonmagnetic, and lightweight. They may be color-anodized to complement color-coded instrument systems. The anodized color produced on aluminum is a result of an organic dye that is infiltrated into the aluminum oxide surface.[4] The surface is then chemically sealed, and other additives may be incorporated into the coating. Additional details regarding surface treatments for aluminum are covered later.

Aluminum Alloys

Aluminum alloys have more strength and less ductility when compared with pure aluminum. The alloys are grouped according to 2xxx through 8xxx identities, depending on the major alloying elements that are present. Aluminum alloy compositions that are frequently used for instruments include 2024, 5052, and 6061. The alloys are usually produced at a designated temper, which covers the heat-treating and/or other finishing operations that define the supplied metallurgic condition. A 5052-H32 designation indicates a 5052 alloy with a H32 temper (strain hardened/stabilized/quarter hard). Another common designation is 6061-T6; the T6 temper refers to solution–heat-treated plus artificially aged condition. Aluminum alloys are used for depth gages, intramedullary (IM) nail-insertion instruments, hollow external-fixation rings, graphic case modules, and screw racks. Table 75-3 shows typical tensile properties for annealed pure aluminum and aluminum alloys with designated tempers.[5]

Aluminum alloys are nonmagnetic and lightweight. Machined or forged aluminum alloy instruments may be given specialized anodizing treatments to provide modified surface characteristics. The anodizing process for aluminum consists of detergent cleaning, rinsing, electrolytic anodizing, dyeing (optional), rinsing, and sealing. Conventional anodized aluminum films may be clear (not dyed) or may be produced in a variety of colors that meet standardized dye color charts. Conventional anodizing increases the corrosion resistance and surface hardness. Another specialized anodizing treatment is known as *hard anodizing* or *hard coat*. Hard anodizing provides an increased surface hardness of around 60 to 65 HRC (Hardness Rockwell C) for improved wear resistance.[4] Hard-anodized films may also be produced that contain a polytetrafluroethylene polymer impregnated into the aluminum oxide film or the polymer may codeposited during formation of the aluminum oxide coating.[6] In both instances, the polymer plus hard coat provides reduced frictional properties and improved wear and galling resistance. *Galling* refers to the adhesive wear that occurs when two metals rub together at high points on their mating surfaces. Chemical cleaning solutions containing chlorine, iodine, or certain metal salts may attack the anodized coating. Aluminum contact with strong alkaline cleaners must be avoided to prevent aggressive chemical attack.

Other

Titanium alloys, such as Ti-6Al-4V or Ti-6Al-7Nb, occasionally are used for noncutting instrument applications. The

nonmagnetic alloys have high strength and low weight, and they may be anodized for color-coded systems. External fixation components have been designed to take advantage of these properties. Cobalt-base alloys have a high modulus of elasticity, which is beneficial for small-diameter guide wires and aiming instruments that require high stiffness.

METALLIC IMPLANT MATERIALS

Commonly used metallic implant materials for fracture fixation include stainless steel, unalloyed titanium (also known as *commercially pure titanium*), and titanium alloys. Some cobalt-base alloys are also used for specialty applications. Standardization of implant materials is covered by the International Organization for Standardization (ISO) and the American Society for Testing and Materials (ASTM). Trade names vary from each supplier, but all implant materials must meet industry requirements for composition, microstructure, mechanical properties, and corrosion resistance.

Stainless Steel

ISO 5832-1 or ASTM F 138 (bar and wire)/ASTM F 139 (sheet and strip) stainless steel is used extensively in the orthopedic implant industry. The iron-based stainless composition is known as *wrought 18% chromium-14% nickel-2.5% molybdenum implant alloy* and it contains minor additions of residual elements.[7] This material is also referred to as *implant quality 316L stainless steel* in the United States. The alloy is composed of chromium to provide corrosion resistance, nickel for microstructural stability, and molybdenum for improved resistance to pitting and crevice corrosion. The alloy contains a low carbon content (maximum, 0.03% carbon) for improved resistance to intergranular corrosion.[8] Special melting techniques ensure that the implant alloy has a low amount of nonmetallic inclusions, no secondary magnetic phases, and elevated chromium and molybdenum levels. The material must meet a compositional index defined by the equation: $\%Cr + 3.3 \times \%Mo \geq 26$ to ensure adequate *in vivo* resistance to pitting and crevice corrosion.[8] For multicomponent devices, such as plates and screws, it is not advisable to mix stainless steel and titanium implants because an accelerated form of corrosion, known as *galvanic corrosion*, can occur.[7] Implant stainless steel may be used in the annealed or soft condition for reconstruction plates that are highly contoured or for cerclage wire that may be subjected to a large degree of twisting and torsional deformation.

The alloy may also be supplied in the cold-worked or moderate-strength condition to resist the stress loading encountered by bone plates and bone screws. *Cold-working* refers to a metalworking operation that permanently deforms the material at room temperature to increase the strength, usually by reducing the cross-sectional area by drawing or rolling. Small-diameter products (such as Kirschner wires, Schanz screws, and Steinmann pins) may be fabricated from extra-hard or highly cold-worked material with a very high tensile strength (greater than 1350 MPa) for improved bending resistance.[9] Table 75-4 shows relative tensile property requirements of stainless steel bar used for these applications according to ASTM F 138 specification.

The excellent corrosion resistance of stainless steel is primarily a result of a chromium oxide film, known as the *passive layer*, which is present on the surface. Chemical passivation in nitric acid is a commonly used method of surface finishing for stainless steel implants.[10] Immersion in 20 to 45 volume-percent nitric acid passivation solution removes surface contaminants, such as cutting tool transfer films, oxide from heat treatment, imbedded particles, and burned-in lubricants. The passivation process restores maximum corrosion resistance but does not affect part dimensions.

Electropolishing is another surface treatment that consists of applying an electric current to an implant immersed in a specially formulated chemical solution under specified conditions of time and voltage.[11] The treatment removes a microscopic amount of metal, decreases the surface roughness of the implant, provides a low coefficient of friction, improves corrosion resistance, and creates a chemically passivated surface (Figure 75-1). Repeated steam autoclaving will not disrupt the passive film or alter the mechanical properties of stainless steel implants. For applications requiring improved fatigue strength, some implants undergo *shot-peening* before electropolishing. The implant surface is subjected to high-velocity impaction by metallic or ceramic particles under well-defined conditions. Shot-peening produces a roughened surface with increased residual compressive stress for enhanced fatigue life.[12] Implant quality stainless steel is completely nonmagnetic in all conditions, and implants will not exhibit torsional movement or displacement during MR scans. Long and thin implants like Kirschner wires and Steinmann pins with specific length-to-diameter ratios may show an RF temperature rise because of ½ wavelength resonance heating

TABLE 75-4. ASTM F 138 Minimum Tensile Properties for 316L Stainless Steel Bar

when tested in an MR scanner according to ASTM F 2182.[13] Signal artifacts may obscure complete MR visualization in the vicinity of the stainless implant. The size of the artifact induced by an implant in a specific MR environment has a complex relationship to implant size, shape, and composition.

The 15% nickel content may provoke a *metal sensitivity reaction* and is responsible for about 90% of the metal allergies that are clinically observed in people.[14] Metal sensitivity reactions in animals are not well documented, but the best animal species for predicting human metal sensitivity is the guinea pig when evaluated according to intradermal, topical, or repeated dermal patch-testing methods.

Titanium

Commercially pure (CP) titanium, also known as *unalloyed titanium*, is available in five implant compositions designated Ti Grade 1 ELI, 1, 2, 3, and 4, according to ISO and ASTM implant industry standards.[15,16] The extra-low interstitial (ELI) grade has the lowest content of nitrogen, carbon, iron, and oxygen. Each grade in the annealed condition has a different combination of tensile strength and ductility. The strength increases and the ductility decreases as the grade changes from the lowest designation (grade 1 ELI) to the highest designation (grade 4). Table 75-5 shows the minimum tensile properties for CP titanium bar according to ISO 5832-2. Cold-working may be used to increase the strength of titanium that is designated Grade 4B in ISO 5832-2, but a minimum 10% elongation must be met. CP titanium has better biocompatibility than stainless steel and typically contains less than 0.05% nickel.[17] Unalloyed titanium implants will not cause metal allergy reactions and are recommended for humans in situations where metal sensitivity is preoperatively verified or where 316 L stainless steel implants have provoked an allergic response.[18]

Titanium also exhibits unique biocompatibility properties, which include soft tissue and bone adhesion to the implant surface.[19] A major advantage of tissue integration at the surface has been the possibility of less bacterial colonization and reduced infection.[20] Tissue adjacent to pure titanium implants becomes well vascularized, with less tendency toward capsule formation. The major disadvantage associated with titanium implants is the possibility that implant removal may be difficult, especially for well-osseointegrated implants. The pitting and crevice corrosion resistance of titanium is superior to stainless steel. Titanium implant materials also have a lower density, have a lower modulus of elasticity, and provide significantly less MR artifact when compared to stainless steel.[21] The density of titanium is 57% of the density of stainless steel and represents a weight reduction of nearly 50% when implants of similar dimensions are compared.

The *modulus of elasticity* is a constant physical property that describes the stress per unit strain in the elastic region. A material with a high modulus of elasticity will transfer less stress from the implant to the bone. This may produce a condition known as *stress shielding*, which is not ideal because bone must be adequately stressed to consolidate properly during the bone-healing stage.[22] The modulus of elasticity of titanium is about 55% of stainless steel, and the low modulus is desirable because of increased stress transfer. The modulus consideration is less important for implants with a small cross-sectional area.

Titanium implants may have a special *anodized surface* finish that increases the thickness of the protective titanium oxide passive film. The anodizing treatment for titanium is different from the electrolytic anodizing treatment used for aluminum. The titanium implants are immersed in a chemical solution and a known electrical voltage is applied for a specified time. Visible light diffraction within the oxide film creates a distinct color, which depends on the thickness of the oxide film.[23] No pigments or organic coloring agents are present in the anodized titanium film. The titanium anodizing process is capable of producing a variety of colors that permit the design of color-coded implant systems (see Figure 75-1). Multiple steam sterilization cycles will not significantly change the appearance of anodized titanium implants. However, fingerprint contamination from skin contact should be avoided when handling the implants between autoclave cycles.[18] Gloved handling of anodized titanium implants prevents the discoloration of isolated areas during steam autoclaving.

Titanium Alloys

Titanium-6 aluminum-4 vanadium alloys, which have approximately 6% aluminum and 4% vanadium, are available in two compositions that are identified as Ti-6Al-4V or Ti-6Al-4V ELI. The ELI designation denotes lower oxygen content and lower hydrogen content. Another titanium alloy widely used as an implant material contains titanium, 6% aluminum, and 7% niobium; it is identified as Ti-6Al-7Nb. Unique characteristics of titanium alloys include higher tensile strength capability, lower ductility, similar modulus of elasticity, and equivalent density when compared to CP titanium. Important physical properties[18] of CP titanium, titanium alloy, and stainless steel are compiled in Table 75-6. Data on anodic polarization, pitting, and stress corrosion cracking indicate that Ti-6Al-7Nb is an extremely corrosion-resistant alloy.[24] Unalloyed titanium and titanium alloys have well-documented notch sensitivity

ASTM, American Society for Testing and Materials; *ELI*, extra-low interstitial.

properties. *Notch sensitivity* is a term that describes the relative effect that local irregularities or stress raisers have on mechanical properties.[25] The notch sensitivity resistance of implant-quality stainless steel is similar to unalloyed titanium and is somewhat better than conventional titanium alloys. Titanium-base biomaterials are not classified as notch-sensitive materials on the basis of notch tensile data that have been published.[26] Some newer β-titanium alloys, such as Ti-15Mo, actually have improved notch sensitivity properties when compared to stainless steel. Implant design and manufacturing methods can influence the notch sensitivity resistance, and clinical factors, such as surgical technique and handling, must also be considered.

Titanium alloys may be color anodized in the same manner as CP titanium. The major difference is that the anodized film is an oxide mixture composed of thermodynamically stable oxides (i.e., TiO_2 + Al_2O_3+ Nb_2O_5).[27] Retrieval analysis of human hip joint prostheses concluded that Ti-6Al-7Nb alloy is extremely biocompatible as evidenced by osseous integration at the implant surface.[28]

Cobalt-Base Alloys

Cobalt-base alloys are used primarily for prosthetic implants, such as total hips, total knees, and total disc replacement. Co-28Cr-6Mo is the predominant alloy that is fabricated for joint replacement applications. The nickel content of this alloy is typically less than 0.5%, and nickel sensitivity reactions have not emerged as a clinical problem. This alloy may be *hot forged* into complex shapes, the tensile strength can exceed 1172 MPa,[29] and the wear resistance is outstanding. Overall, corrosion resistance is considered to be superior to stainless steel but inferior to titanium.

Other implantable cobalt alloys have been used for specialty trauma products, such as orthopedic cable, Kirschner wire, and implantable distractor components. Unique properties of cobalt-base alloys include a high modulus of elasticity, which may be 25% greater than stainless steel. Cold-working increases the strength of cobalt-base alloys, and thermal aging heat treatments can significantly increase the yield strength and ultimate tensile strength. Certain cobalt base alloys contain greater than 10% nickel, which may provoke a nickel allergy reaction.[30,31] The excellent corrosion resistance of the cobalt-base alloys is predominantly the result of the chromium content, which typically exceeds 19%. Chromium and cobalt are considered metal-sensitizing agents but the clinical incidence of sensitivity reactions are relatively rare when compared with nickel.[14]

METALLIC IMPLANT FAILURE

Fatigue

Fatigue is a phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the ultimate tensile strength of the material.[32] The fatigue loads are well below the level that normally would be required to cause fracture within a single load cycle. The fatigue cycle is the time interval during which the stress is regularly repeated. One common measure of the fatigue properties is known as the *endurance limit*, which is the maximum stress below which a material can presumably endure an infinite number of stress cycles.[3]

Many material variables influence fatigue test results, such as grain size, processing history, surface finish, and degree of cold-work. Testing variables include type of alternating load, specimen geometry, frequency, and test environment.

A common method of expressing the fatigue properties of a material is known as the S-N curve. The *S-N curve* is a best-fit plot of the individual test values, where *S* refers to the applied cyclic stress and *N* is the number of cycles required to fracture the test specimen or to achieve runout. *Runout* is defined as the maximum cyclic stress that does not create fatigue fracture at a predetermined number of cycles (usually 10^6 cycles or greater). Various types of fatigue tests are configured to evaluate either multiple numbers of a single implant, multicomponent devices, or constructs. Artificial bone materials are usually selected for construct fatigue testing to minimize the mechanical property variability associated with human and animal bones.

Methodology related to *bending fatigue testing* of various types of bone plates is documented in ASTM F 382.[33] A bone plate is placed in a four-point bending fixture and oriented in a manner that mimics clinical bridging of a fracture site. The bone plate is subjected to a constant frequency cyclic load in four-point bending. The test method establishes a uniform four-point bending fatigue test to characterize and compare the fatigue performance of different plate designs. Bending fatigue curves for 3.5 mm DCP and 3.5 mm limited-contact dynamic compression plate (LC-DCP) tested in air at a frequency of 5 Hz with runout defined as 10^6 cycles are shown in Figure 75-2. The bone plate fatigue curves reveal that the DCP has increased resistance to maximum compressive fatigue loads when compared to LC-DCP in the low load–high cycle region (greater than 10^5 cycles). Maximum runout load for the DCP (n = 4) was 323 N, whereas the maximum runout load for the LC-DCP (n = 5) occurred at 268 N.

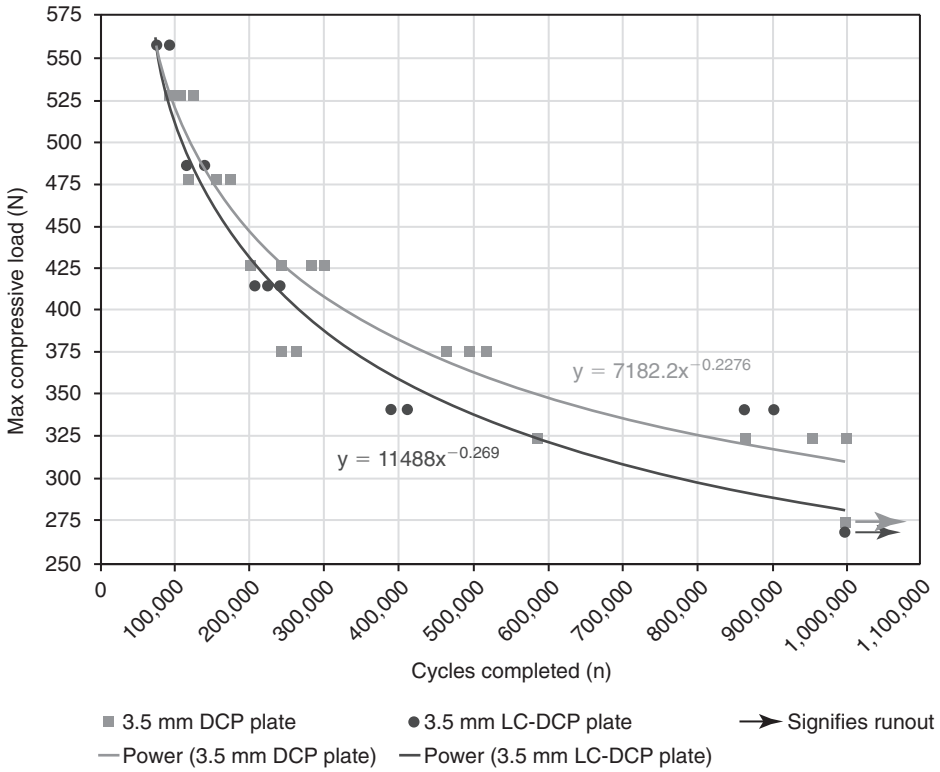

Figure 75-2. S-N four-point bending fatigue curve for 3.5 mm dynamic compression plate (DCP) and 3.5 mm limited-contact dynamic compression plate (LC-DCP).

The endurance limit for 316L stainless steel and CP titanium increases as the percentage of cold-work increases.[7,34] Cross-sectional area is a factor because only small to moderate-size cross sections can be obtained in the highly cold-worked condition. Many fracture-fixation implants require a certain balance between strength and ductility (i.e., ability to contour a bone plate) so that specifying the highest attainable tensile strength is not always desirable. Titanium alloys exhibit a greater 0.2% yield strength when compared with CP titanium, and this factor is primarily responsible for the superior fatigue properties of titanium alloys when compared with CP titanium.

The majority of well-designed metallic fracture fixation and reconstruction implants will not fracture during clinical use, but fatigue failures represent a failure mode that may be encountered. Long bone and spinal implants, especially, may be subjected to relatively high *in vivo* loads after implantation. All load-sharing implants have a finite fatigue life that may be compromised when delayed healing or persistent nonunion are clinically verified. This relationship is often referred to as the race between bone healing and fatigue failure.[35]

Failure Analysis

Failure analysis of retrieved implants is performed by implant device manufacturers to gain a better understanding of the factors responsible for device failure. Clinically retrieved implants are cleaned and disinfected before transport in approved biohazard packages. It is especially important to cover or isolate the fractured implant specimens to preserve the features of the original fracture surfaces. In certain instances, permission to perform destructive testing must be obtained before any failure analysis investigation can be initiated. Light microscopy examination at low-power magnification is used to survey the region of interest. Pitting, crevice corrosion, wear tracks, fretting corrosion,* or other unusual macro-features may be observed during light microscopy examination. Nondestructive portable x-ray fluorescence analysis or conventional destructive analytical techniques can be used to verify the material composition. Metallographic examination may be performed on specimens that are cut adjacent to a fracture surface. Samples are mounted in plastic media, polished, and etched to reveal grain size, secondary phases,† microstructural anomalies, and surface discontinuities. Accurate Knoop or Vickers microhardness measurements on mounted samples may be used to obtain approximate tensile strength values from conversion charts.

Fracture surface examination with the *scanning electron microscope (SEM)* is the primary method for detecting and identifying device failure modes. This is especially true for fatigue failures, which account for the majority of fracture-fixation

*Fretting corrosion is an accelerated form of corrosion that can occur when the protective passive film is mechanically disrupted in a corrosive environment. The relative motion of the underside of a bone screw head with the contact surface of a bone plate is a typical example.

†Implant quality 316 L stainless steel is composed of a single-phase austenitic microstructure, and secondary phases such as delta ferrite, chi phase, and sigma phase must be absent. Delta ferrite is a magnetic phase that is undesirable because of MR scanning considerations, molybdenum-rich chi phase decreases the corrosion resistance of the surrounding austenitic matrix structure, and sigma phase may contribute to embrittlement.

implant failures that are investigated. SEM analysis is generally considered a nondestructive test, but specific geometric features may require cutting a retrieved implant without disturbing the fracture surface so the implant can be inserted into the vacuum chamber. A retrieved 4.5 mm 12-hole broad DCP that fractured during implantation is shown (Figure 75-3). Low-amplitude motion between the underside of the screw head and the bearing surface of the screw hole created a fretting corrosion pattern because of passive film disruption at the screw-plate interface. The amount of fretting corrosion was not excessive and did not appear to be the primary cause of failure. The fracture surface next to the right side of a screw hole is highlighted in the SEM image (Figure 75-4). Multiple slip bands, which are the group of parallel lines observed under an optical microscope that signify plastic deformation due to crystal structure displacement in a definite crystallographic direction, were present near the screw hole, and this suggested that significant plastic deformation occurred before failure. Fatigue beach marks, which appear as concentric clamshell striations, were present and confirmed that fatigue fracture was the primary failure mode. Analysis of the fatigue striation pattern revealed the origin of the crack initiation. The shear lip (the narrow, slanting ridge along the edge of an implant fracture surface) in the upper-right area coincided with the location of the final overload fracture site.

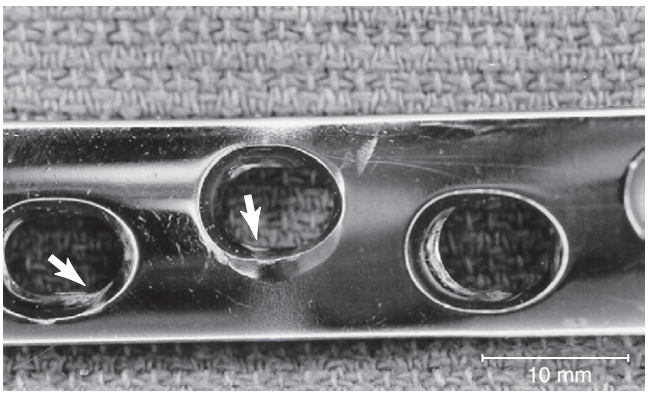

Figure 75-3. Evidence of fretting corrosion around some of the screw holes *(arrows).*

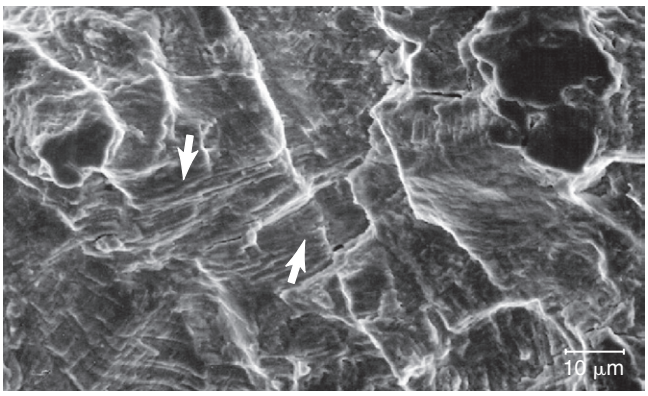

Figure 75-4. The scanning electron microscope shows fatigue striations *(arrows),* which are parallel lines commonly observed on fracture surfaces that are transverse to the direction of local crack propagation.

CHAPTER 76

Principles of Fracture Treatment

Jörg A. Auer

Fractures are diagnosed in practically every bone of the horse and encountered at all ages. Fractures vary in clinical presentation and significance, ranging from exercise-induced fractures causing only relatively minor lameness, such as chip fractures of the carpus, to fractures causing a non–weight-bearing lameness, such as a transverse failure of the third metacarpal bone (MCIII). The management of intra-articular chip fractures and osteochondrosis lesions is discussed in Chapters 80 and 88, respectively. In this chapter, the nonsurgical and surgical principles of major fracture treatment are presented.

Fracture treatment in the horse follows the same basic guidelines developed for humans[1] and small animals.[2,3] Many techniques can be derived from them, but some principles in the treatment of equine long bone fractures are unique.[4,5] These differences are discussed in detail, with emphasis given to surgical fracture treatment, including external coaptation and internal fixation.

NONSURGICAL MANAGEMENT

Some fractures heal sufficiently with nonsurgical management to allow the animal to return to an athletic career. Nonsurgical management techniques include stall rest and external coaptation.

Stall Rest

Frequently, horses are admitted in a "fracture-lame" state without a visible or palpable fracture. According to the anamnesis, these patients can be found on pasture with the non–weight-bearing lameness, or they do not return to the stable in the evening with the other horses. The physical examination may reveal a small wound over a vestigial metacarpal or metatarsal bone, the radius, or the tibia. In the case of splint bone fracture, radiography may reveal a fracture or even multiple fractures. In selected cases, these fractures are amenable to nonsurgical management with a bandage alone. Additional information on the treatment of these fractures is found in Chapter 93.

Other fractures amenable to management by stall rest include fractures of the deltoid tubercle, nonarticular patellar fractures, and fractures of the scapular spine. However, for the vast majority of fractures, nonsurgical management is not the treatment of choice and should not be advocated.

External Coaptation

For a detailed description of the indications and applications of external coaptation devices, such as fiberglass casts and splints, please review Chapter 17. In this chapter, external coaptation is discussed as it pertains to fracture treatment.

Splints

The indications for limb splints as a sole means of fracture treatment are limited. More commonly, they are used as a form of emergency fixation (see Chapter 73). This type of external coaptation may be employed as treatment modality in fissure fractures of the diaphysis of the radius and tibia or as adjunct treatment to internal fixation of a fracture, either during the immediate postoperative period or as an intermediary step after removal of a cast.

In acute fissure fractures of the radius and tibia, radiography may not show a fracture. Affected animals are usually reluctant to bear any weight on the limb. Initial management should include not only applying a splint bandage but also preventing the animal from lying down. It is frequently during the process of lying down or getting up that these fissure fractures evolve into complete fractures. Tying the horse with a short rope and providing a filled hay net to allow them to eat is an effective management method. Nonsteroidal anti-inflammatory agents are indicated to provide some comfort. However, the dosages should not be so high that they abolish the lameness completely. A complementary or independent management option involves applying a sling or rescue net (Figure 76-1).[5] Usually the animals tolerate these slings very well. They allow the patient to rest their intact limbs for some time by lowering their abdomen into the sling. It is important that the sling be installed

Figure 76-1. An adult horse suffering from a fissure fracture of the tibia, supported by a rescue net. The net, which is applied relatively snugly to allow the horse to apply some weight to it, is tolerated very well.

Figure 76-2. Craniocaudal *(left)* and lateromedial *(right)* radiographic views of a fissure fracture in the proximal metaphysis of the tibia of an adult horse.

such that the body has to be lowered only a few centimeters to allow it to rest in the sling. If the body has to be lowered too much, complete fractures of the bone may still occur. The Anderson Sling developed in California has also proved to work very well as a recovery system and for prolonged support of horses during their postfracture fixation period.[6]

If initially no fracture can be found on radiographs, additional images should be taken a few days later. Usually, at this point, fractures may be seen radiographically (Figure 76-2). Depending on the configuration of the fissure fracture and the width of the fracture gap, the management may be modified. When the fissure lines are small with a barely visible gap, no bandages are needed, but the animal is maintained in the sling for 2 to 3 weeks. If the fracture line is long and associated with a significant gap, the splint bandage should be maintained.

Splint bandages should be changed every 3 to 4 days, and in hot and humid climates they should be changed more frequently. Caution should be used during the process because bearing weight on the limb without the splint or bandage could have deleterious effects on fracture healing. Caution: Fissure fractures penetrating a joint should be treated surgically.

Casts

External coaptation using fiberglass cast material as the primary treatment technique of a fracture may initially be considered as a conservative, less expensive type of treatment. However, soft tissue problems may require frequent cast changes, usually carried out under general anesthesia, which frequently increase the costs until they exceed that of a state-of-the-art internal fixation performed upon admission. Additionally, the advantages of early return to function, achieved through internal fixation, are lost. Cast materials selected for fracture treatment should be fiberglass because it allows the skin and the limb underneath the cast to breathe. Also, fiberglass weighs less, so the animal is more comfortable.

Casts should be palpated daily and evaluated for hot areas. Any odor from the cast should be investigated, and weight-bearing on the limb should be evaluated. Sudden changes in weight-bearing patterns, edema above the proximal cast end, and a foul odor or wet spots on the cast are signals of skin damage and possible necrosis underneath the cast. The same is true when hot areas develop in the fetlock region or at the dorsal aspect of the cast in the region of the proximal MCIII or third metatarsus (MTIII). All of these signs signal the need for cast removal.

The first cast should be changed after 3 to 4 days, because during this time initial swelling has subsided, resulting in a loose cast that is ineffective in stabilizing the initial fracture and may even cause some additional damage to the soft tissues. Casts applied to foals should be changed at 10- to 14-day intervals and eliminated as soon as possible. In adult animals, longer intervals are tolerated. If the condition of the skin beneath the cast and the weight-bearing patterns permit, up to 5 or 6 weeks may be allowed before the cast is changed. Longer intervals reduce costs and, in most cases, are followed by better results. Some horses have thinner and more sensitive skin, which is more likely to be traumatized by a cast; in these cases, shorter intervals between cast changes may be required.

Complications

Nonsurgical management of fractures is associated with various complications (see Chapter 17). When internal fixation is not applied, the fracture fragments are not stable. The resulting callus formation often impinges on soft tissue structures or tendons and may prevent future athletic use. However, bone remodeling after fracture healing may reduce such a callus, eliminating impingement on the soft tissue structures.

Skin trauma from casts and splints can be severe enough to endanger the outcome of fracture healing. It is important that the skin remain dry and healthy. Development of cast sores should be prevented whenever possible. Occasionally skin damage occurs at the time of injury or during the transport to the referral clinic, the latter as a result of inappropriate first aid. In thoses cases, special care has to be taken during cast application. If pressure sores do develop, casts must be changed

frequently and padded so that the pressure on the skin is redistributed.

If infection develops underneath the cast, swelling causes increased pressure within the tissues. Because the skin cannot expand beyond the inner limitations of the cast, a compartment syndrome develops, resulting rapidly in tissue necrosis. Additionally, drainage from the limb accumulates within the cast, and the skin is damaged by enzymes. Hosing down the fiberglass cast with copious amounts of water on a daily basis prolongs its usefulness and postpones a necessary change, but an infected limb should be maintained under a cast only if no alternative exists.

During the time that the limb is maintained in the cast, the joints are unable to move and the articular cartilage is poorly nourished. This results in loss of proteoglycans and subsequent degeneration of the cartilage. Additionally, the soft tissue structures surrounding the joint are not flexed and stretched, which causes them to become weak and inelastic. When prolonged external coaptation is used, these pathologic changes are exacerbated and are referred to as *cast disease.*

If a foot is maintained under a cast while a limb fracture is allowed to heal, it is prevented from expanding during weight-bearing and the structures underneath the hoof wall constrict. After the cast is removed and the limb is loaded once again, the foot expands, which causes pain for several days.

Flexing of the joints after a prolonged fixation in one position causes pain and an initial unwillingness to bear weight. This, however, is overcome after a few days in most cases and can be facilitated with anti-inflammatory drugs.

SURGICAL MANAGEMENT

Equine bone reacts to trauma and fracture with active new bone formation and subsequent remodeling. Many osteons are mobilized to facilitate remodeling of the cortex. However, fracture healing in the horse occurs at a slower pace than in most other animals, especially ruminants, small animals, and humans.[7] Therefore any adjunct treatment that benefits bone healing is advantageous.

External Fixation

External fixation using intraosseous or transosseous pins and clamps is common in humans[8] and small animals but less so in the horse.[8] This type of fixation is employed frequently as emergency treatment in open fractures or in severely comminuted fractures when anatomic reduction, reconstruction, and internal fixation of the fracture are not possible. External fixation techniques can be applied using three types of constructs: transfixation-pin casts, external fixators, or external skeletal fixation devices.

Transfixation-Pin Casting

Transfixation-pin casting was popularized around 1990.[9] This efficient and relatively easily applied treatment method is indicated for comminuted fractures of the phalanges, the distal MCIII/MTIII, and breakdown injuries of the metacarpophalangeal joint.[10] A retrospective study involving more than 50 horses and ponies treated by means of transfixation-pin casting showed that comminuted fractures had better results (86% healed) than simple fractures (23% healed).[9] It is assumed that the micromotion between the fragments after fixation was distributed between more fragments in the comminuted fracture and therefore was decreased compared with simple transverse fracture, where distribution was not possible, leading to reduced strains and stresses exerted upon the bone fragments and the granulation tissue bridging them initially.

Under aseptic conditions, two or three cross pins that are 4 to 6 mm in diameter are introduced in the metaphyseal region of the bone. The use of positive-profile pins (IMEX) is preferred.[10] A 30-degree divergence of the pins in the frontal plane results in a stronger fixation and lower risk for postoperative fracture.[11,12] The pins should be separated by 2 to 4 cm. A stab incision is made down to the bone and, using tissue protection, the predetermined-size hole is prepared. An effective method of heat control is to initially drill a smaller hole, followed by stepwise enlargement through larger drill bits. Simultaneous flushing with approximately 500 mL of cold sterile saline solution per drill hole, applied with a bulb syringe, is effective in reducing friction and thereby heat production. The saline lubricates the drill bit because of its special construction. Production of heat is associated with bone necrosis around the pin and its resultant loosening.

A pin with a diameter that is 0.1 mm larger than the prepared hole (radial preload of 0.1 mm) provides the best pin holding strength with the least weakening of the bone surrounding the implant.[1] If positive-threaded pins are used, appropriate threads have to be cut in the predrilled hole before pin insertion. Newer pin generations are equipped with a self-tapping device at the beginning of the threaded part. Care has to be taken to engage the threaded pin portion with both cortices. Protruding portions of the pins are cut off at a length of 3 to 5 cm from the limb, which allows their incorporation into the cast.

After applying a double layer of stockinet, followed by a double layer of resin-impregnated foam padding (3M Corporation), a 5-mm layer of fiberglass cast is applied as described in Chapter 17. The ends of the pins can be covered by hoof acrylic and incorporated in an additional layer of fiberglass cast tape (Figure 76-3). An alternative approach involves applying dowels over the pin ends, fastened with set screws on the pins, just adjacent to the layer of casting tape. These dowels are subsequently covered by an additional solid layer of cast material. These two methods prevent migration of the pins after loosening, because they are fixed within the cast. It was shown in an *in vitro* study that the fixation of the pin within the cast plays a minor role.[13] The fiberglass cast material appears to be the major determinant of axial stability. However, because it was an *in vitro* study, the long-term effect of such a fixation could not be evaluated. The originally proclaimed beneficial effect of incorporating the horizontal pins in a U-bar fastened around the distal limb[9] has been abandoned because it could not be shown that it was more effective in supporting the loads.[14] A combination of transfixation-pin casting and strategic lag screw placement across major fracture fragments to ensure anatomic reduction of intra-articular fractures may speed up fracture healing.

Centrally threaded, positive-profile transfixation pins have greater resistance to axial extraction in the diaphysis than in the metaphysis of equine MCIII bone *in vitro*.[15] Again, this observation resulted from an *in vitro* study and may lead to the conclusion that it is advantageous to introduce the pins into the diaphyseal region of the long bone. However, my experience is that diaphyseal pins lead to more complications, which include

ring sequestrum formation and subsequent pathologic fractures (see later under "Complications").

A sleeve pin cast representing a modification of the external transfixation device[16] has been developed. It consists of smooth pins with negative threads on either side over which tapered sleeves are applied and fixed with nuts aginst the bone; the pins were then incorporated in fiberglass cast material and tested in a servo-hydraulic material testing machine (MTS Bionix 858) (Figure 76-4).[17] The results showed that the mean load to failure for the tapered-sleeve transfixation-pin cast was significantly greater than that for a standard transfixation pin cast. This device has not been tested clinically yet.

Recently a novel *pin-sleeve cast* (PSC) transfixation system was introduced.[18] The system consists of a 45-mm long hollow cylinder of 8.2 mm outer diameter and 1 mm wall thickness that is implanted into the bone proximal and distal to the fracture (Figure 76-5, *A*). The inside surface of the cylinder contains two circular supports measuring 1.0 mm in width and 0.5 mm in thickness; they are mounted 5 mm from either end. A 5-mm diameter pin of 120 mm length with a smooth central portion is introduced through the cylinder, contacting it only at the circular supports (Figure 76-5, *B*). Each end of the pin contains metric screw threads of 15 mm length. The pin is incorporated

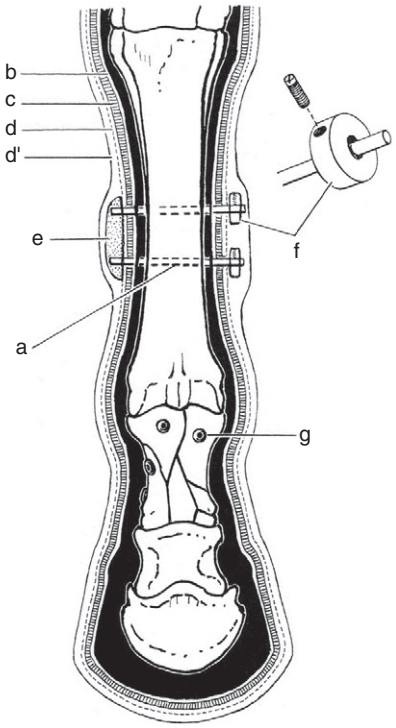

Figure 76-3. Transfixation cast for the treatment of a comminuted fracture of the proximal phalanx, partially managed by strategically placed lag screws. *a,* Parallel inserted Steinmann pins (they differ in the orientation within the frontal plane); *b,* stockinet; *c,* custom foam; *d,* initial, and *d',* second layer of fiberglass cast; *e,* hoof acrylic covering the Steinmann pin ends on the left side; *f,* custom-made dowels with set screw stabilizing the ends of the Steinmann pins on the right side; *g,* cortex screws placed in lag fashion to reduce fracture fragments.

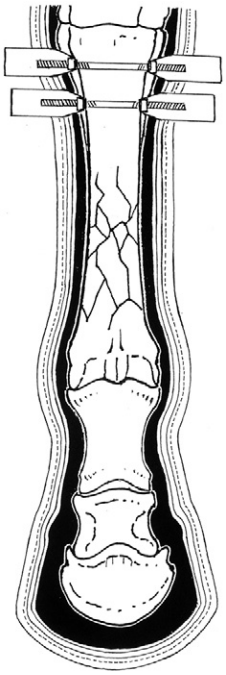

Figure 76-4. Schematic representation of a pin-sleeve cast. The sleeves (the same as shown in Figure 76-8) are mounted over a smooth pin containing negative threads at both ends. With the help of nuts, the sleeves are fixed to the bone and subsequently incorporated in a standard transfixation cast.

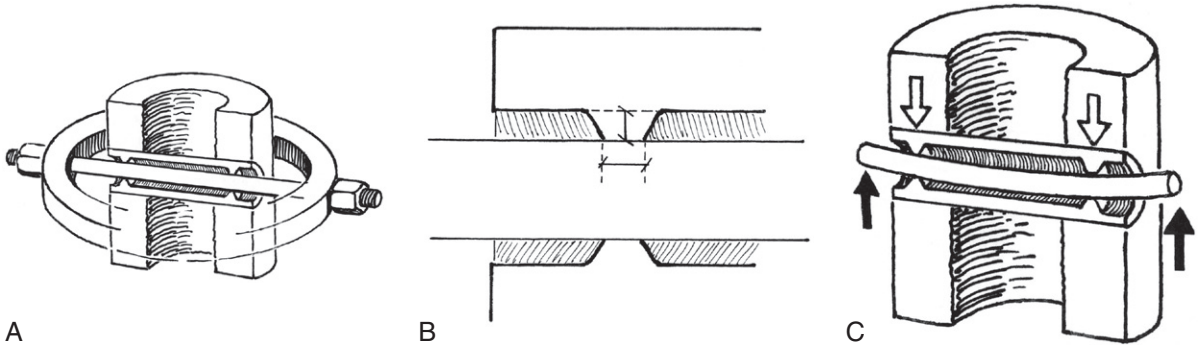

Figure 76-5. Schematic representation of a novel pin-sleeve cast (PSC) transfixation system. **A,** Representation of the sleeve inserted into the bone and the central smooth pin tightened to the ring fixator (the pin is under tension). **B,** Close-up of the contact support of the pin within the intraosseous sleeve. **C,** During weight-bearing the pin is slightly bent without contacting the sleeve and surrounding bone, leading to minimal strain at the bone–sleeve interface.

(before introduction across the bone) into a 15-mm-wide hollow ring of 70- or 90-mm inside diameter through 5-mm holes. Using metric nuts, the pin is tightened to the outside of the circular ring around the limb, and in doing so an axial preload can be applied similar to an Ilizarov ring fixator. The rings are subsequently incorporated into a fiberglass cast. *In vitro* testing using calf metacarpal bone and an MTS testing machine (see earlier) and a 25 kN load cell (Type U-10M, 25kN, 250Nm) revealed that application of a pin preload significantly reduced strain measurement compared to the transfixation pin cast, which may prevent or retard pin loosening.[19] Because the pin only has contact with the two support rings, the pin can bend somewhat without exerting additional strain on the bone (Figure 76-5, *C*). Given that pin loosening is the result of cyclic strain at the pin–bone interface over time (at the periosteal side at the proximal aspect and at the endosteal side at the distal aspect), the significant strain reduction at the cylinder–bone interface should be an improvement.[19] Clinical tests will tell if the theoretical advantages can be transformed into empirical advantages.

Advantages of transfixation-pin casting include no or only minimal load on the fracture site and minimal distraction and movement between the fragments. Also, the tissues are spared additional trauma and further disruption of the blood supply. All the disadvantages of external coaptation, such as the development of cast disease, osteoporosis, contracted feet, and tendon laxity, apply to this type of treatment. Pin tract infection with ring sequestrum formation can occur and is preceded by a sudden onset of lameness. This usually occurs in heavy horses (greater than 500 kg of body weight) after approximately 2 weeks and warrants immediate removal of the proximal transfixation pin. Another pin can be inserted at a different location to prolong unloading of the fracture, or, alternatively, the limb can be placed in a new cast without the most proximal pin. A new pin can be expected to form a similar sequestrum within the next 2 weeks, and the procedure can be repeated. If three pins are inserted initially, transfixation may be maintained for 6 to 8 weeks before simple casting is applied. At that time, a full-limb cast is applied to prevent rotation of the MCIII/MTIII. (Rotation can occur in a half-limb cast and may lead to a fracture across a pin tract.)

External Skeletal Fixator

Application of an external skeletal fixator allows immediate, although subnormal, weight-bearing on the limb. The Steinmann pins and Schanz screws (Steinmann pins with a threaded end) used with this fixation device cause minimal additional trauma to the injured soft tissue. Because in most cases no external coaptation is used, there is easy access to an open wound, which facilitates débridement and management. Application of an external fixator also allows additional correction and fracture alignment after the initial operation, whereas a fracture treated with internal fixation can be adjusted only through an additional surgery.[20] However, this technique has not been very successful in equine patients.

An external fixator uses transversely inserted (cross) Steinmann pins or Schanz screws proximal and distal to the fracture site. These pins are firmly connected to external rods through special clamps, which may be applied in many configurations.[8] An *in vitro* study showed that the best results are achieved with an elaborate three-dimensional design, including three Steinmann pins proximal and distal to the osteotomy, inserted at different angles in the frontal plane and obliquely from proximal to distal, and connected to four external rods.[20] Such a configuration is expensive and very heavy and therefore not practical, especially for horses.

The *Seldrill Schanz screw* improves the bone-holding properties of Schanz screws. The design features a pin with a diameter that is 0.1 mm greater than the hole drilled for it (larger radial preloads result in microfractures and deformation of the bone surrounding the pin, with subsequent loosening).[1] The Seldrill Schanz screw is manufactured of pure titanium and stainless steel and has a self-drilling, self-tapping tip.[21] This implant is inserted through a stab incision without predrilling the bone or pretapping the hole, even in hard equine bone. The Seldrill Schanz screw contains a relatively thick core and thin threads and includes a portion with a built-in radial preload of 0.1 mm, immediately adjacent to the self-drilling, self-tapping tip. Because the sharp tip should not exit the opposite cortex, this implant is to be used in half splints (type I: a construct that contains one or two sidebars on one side of the bone), where the external tube or rod is located only on one side of the bone. Additionally, this device can be used in three-dimensional (type III: a construct that contains sidebars at three sides of the bone that are interconnected externally) configurations, where a half splint is connected to a full, bilateral splint (type II: a construct that contains a sidebar medially and laterally), which uses nonthreaded pins.

A modification of an external fixator, the Pinless External Fixator (Synthes Inc.), is available for selected fractures in large animals.[22] This device is manufactured in three sizes and configurations of clamps, which are applied over a bone without completely penetrating the cortex (Figure 76-6). The clamps are fastened through a connection rod, which is attached to an external fixator tube or carbon rod. This device is not rigid enough to support weight bearing of a large animal with a fractured limb, but it is effective in stabilizing mandible fractures in cattle and horses (see Chapter 102) and fractures of the tail in the horse. *In vivo* studies showed that the clamping force is maintained over several weeks while inducing only minor bony changes where the clamps contact the bone.[23] Animals tolerate the device well. The advantage of this type of external fixator is the minimal damage to bone and tooth roots.

The use of *circular external skeletal fixators* (CESFs) has become routine practice in small animal surgery for the management of developmental, traumatic, and degenerative orthopedic problems.[24,25] The advantages of this system include immediate weight bearing, excellent mechanical properties, ability to stabilize short segments, ability to adjust the frames after their application, and preservation of joint mobility.[26] The use of CESFs in large animals is mainly limited to cattle.[24,27] Sporadic case reports are published where a CESF was applied to a long bone fracture in a horse (Figure 76-7).[24] It is not very likely that this fracture fixation system will become very popular in horses in the future.

External Skeletal Fixation Device

The external skeletal fixation device (ESFD) was developed for horses with severely comminuted fractures of the phalanges, fractures of the distal MCIII/MTIII, and breakdown injuries of the metacarpophalangeal joint. The ESFD uses two or three transfixation pins in the intact bone proximal to the fracture,

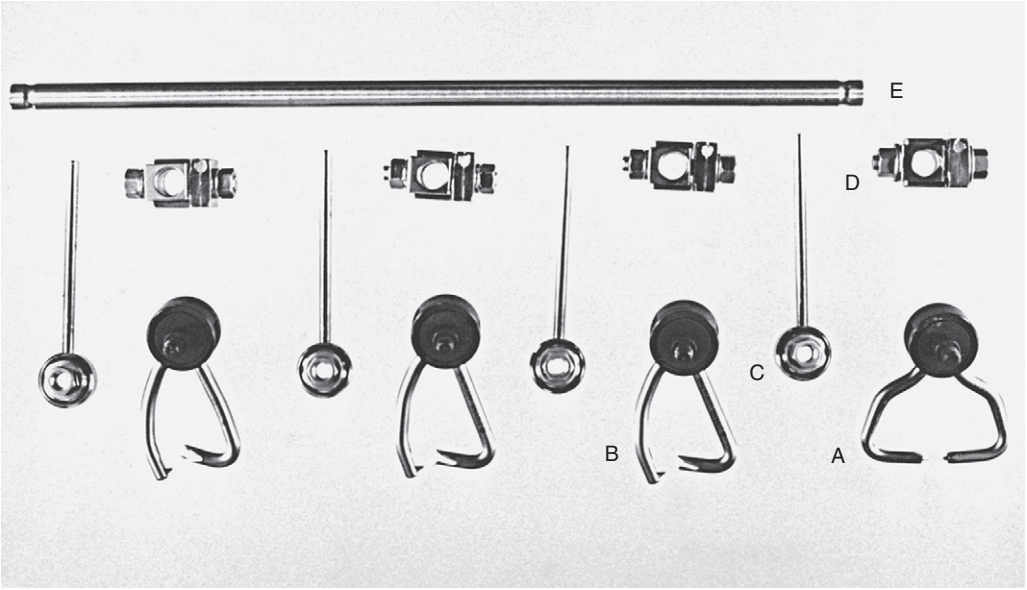

Figure 76-6. One symmetric *(A)* and three asymmetric *(B)* titanium pinless fixator clamps are shown with connecting rods *(C),* clamps *(D),* and longitudinal rod *(E).* This configuration is used to treat mandibular fractures.

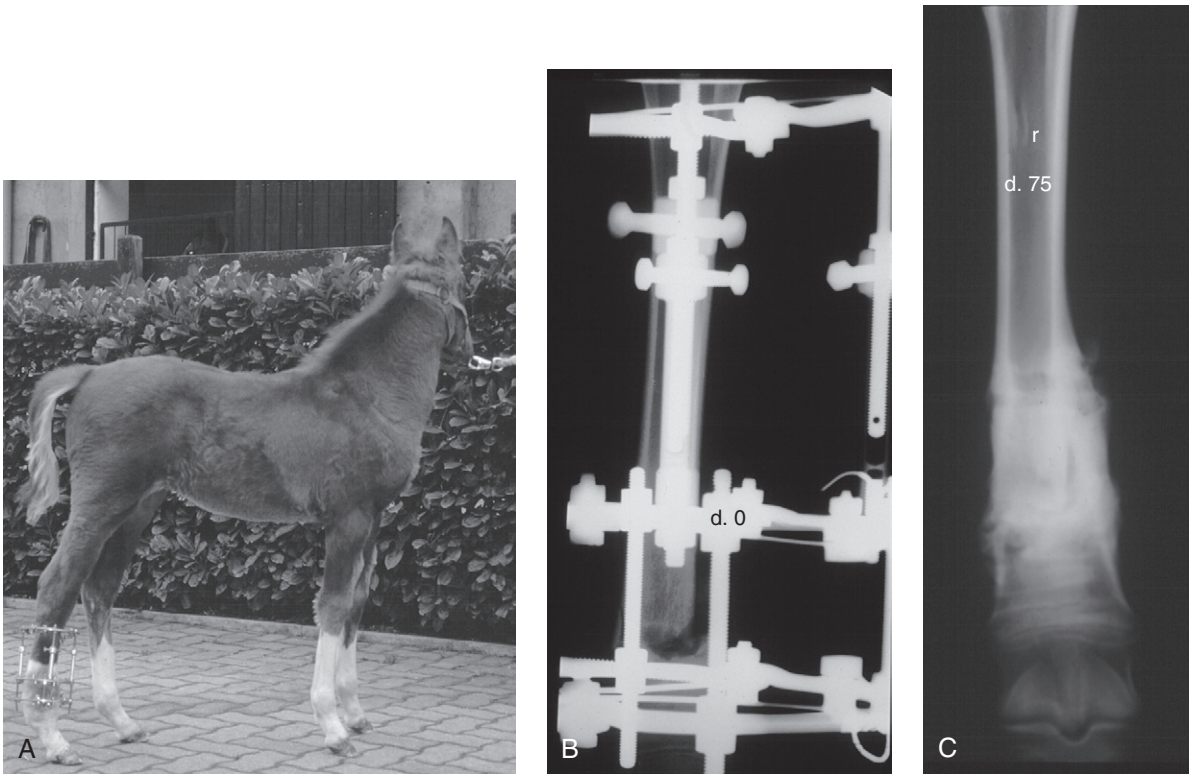

Figure 76-7. Application of a circular external skeletal fixator to distal MTIII fracture in an Arabian foal. **A,** The foal wearing the circular fixator. **B,** Radiographic view of the device in place immediately postoperatively. **C,** The healed fracture 75 days later. (Courtesy A. Ferretti, Legnano, Italy.)

and sidebars and a base plate. Weight-bearing forces are transmitted via the pins and sidebars around the fracture to the ground, allowing the animal to immediately bear full weight without loading the fracture.[16,28-30] The original report described the device and 15 cases, only four of which survived long-term.[28] Through a meticulous study of the design, an effective ESFD transfixation system has been developed and is commercially available.[16] Early complications included fractures through the pin tract while the device was worn or during recovery after implant removal. These complications were almost completely abolished with the latest generation ESFD.[30] Removal of the device on the sedated, standing animal eliminates some

problems encountered after device removal, but the risk of fracture while wearing the device continues.[30]

Up to 90% of the stresses generated at the bone–pin interface contribute directly to pin bending, resulting in uneven stress distribution, with peak stresses concentrated at the outer bone cortex.[31] The tapered-sleeve design was developed to reduce transcortical pin bending with weight-bearing. Large-diameter, tapered sleeves are applied over the transfixation pins (biaxially loaded in tension and shear) and are incorporated in a stronger, lighter frame (Figure 76-8).[32] *In vitro* tests applying cyclic loading to this ESFD showed that significant increases in stiffness, reduced bending, and increases in load-to-failure-of-bone could been achieved with the tapered-sleeve design.[32] Since bone failure occurs at a finite strain level, it appeared that the larger loads to failure indicated lower strains in the bone at the working stress level. To facilitate adjustments in tranfixation pin placement and their incorporation into the sidebar, a modular sidebar was developed consisting of several elements that could be assembled to the length needed for a specific fixation. The four elements fit on top of each other and are not separated by more than 10 mm. The modular components are connected using 4-mm-thick rubber tubing and sealed with duct tape. Once in place, the hollow connecting bar construct is filled with polymer that also enters the connecting elements.[18]

The ESFD was compared in an *in vitro* study to a transfixation-pin cast and a modular sidebar construct (see later).[33] The solid ESFD has a greater stiffness, higher yield and failure load, and a lower yield and failure displacement than the transfixation-pin cast and the pin-sleeve cast. Mean cycles to failure for the transfixation-pin cast was 2996 ± 657 at a load of 16,000 N, and that for the solid ESF was 6560 ± 90 cycles at a load of 25,000 N. These results are encouraging and the new fixation device may prove to be a great alternative to transfixation-pin fixation.

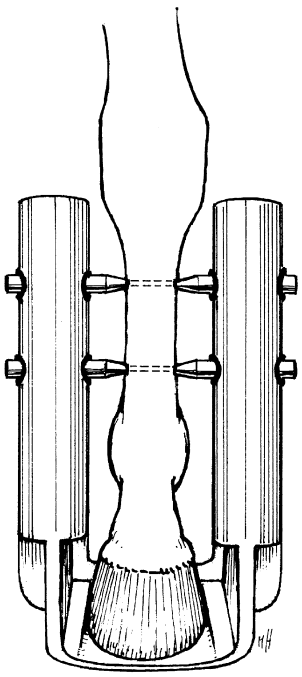

Figure 76-8. Graphic representation of the external skeletal fixation device design.[32] Two tapered sleeves are mounted and tightened on transosseous pins, which are then incorporated into the U-shaped apparatus, providing additional stability.

Aftercare

Application of an external fixator or ESFD allows easy wound management of open fractures. Débridement should be performed under aseptic conditions, and every measure should be taken to prevent additional contamination. Broad-spectrum antibiotic coverage is indicated in any horse treated with external fixation during the entire time the device is in place. The skin around the cross pins should be cleaned daily with alcohol-soaked swabs and dried before reapplying the bandage. Internal fixation of the fracture may be considered once the infection has subsided and healthy granulation tissue has formed. At that time, the external fixation device is removed.

Any sudden changes in weight-bearing patterns are indications for close scrutiny of the fracture and the fixation device. Radiographs should be taken at the onset of any complication and repeated in routine fashion at 2- to 4-week intervals without complications. Once fracture healing has occurred, the device is removed. The abrupt change in stability caused by removing the external fixator can be minimized through partial destabilization of the device. This is best achieved by moving the vertical connecting bars farther away from the limb. An alternative approach involves the strategic removal of one or two pins at 2- to 3-week intervals. After a few weeks in this configuration, the device is removed.

Complications

Loosening of the pins, infected pin tracts, and fracture through a pin hole are the main complications of external fixation in horses.[14] Loosening of cross pins is the most frequent complication of external fixation.[8,34] Weight-bearing on the affected limb causes osteolysis around the pins, followed by infection of the pin tract and subsequent loosening.[34] Once a pin loosens, pain develops. A loose pin should be removed immediately, because it no longer serves a useful function, and infection around it will not subside as long as the pin remains *in situ*. Curetting and flushing of the tract facilitates cessation of draining within a few days. If drainage persists, the skin should be reopened, followed by an additional curettage of the pin tract. Removal of a loose pin destabilizes the fixation. Depending on the degree of fracture healing, it is important that pins be removed one at a time. Premature removal of the implants results in total instability.

Removal of a loose transfixation pin is performed on the standing, sedated horse. If external coaptation was used, cast material immediately adjacent to the pin is removed and the pin is pulled out. The tract is flushed and the hole is filled with a surgical sponge soaked in an antiseptic solution and fixed in place with tape. If the pin is fixed within the cast through a dowel or a hoof acrylic pad (see Figure 76-3), a complete cast change under general anesthesia is necessary.

Osteomyelitis may develop as an extension of pin tract infection or at the open ends of the fracture. Treatment of orthopedic infections is discussed in Chapter 85. When osteomyelitis is rampant and uncontrollable, euthanasia may be the only alternative.

Soft tissue swelling occurs frequently in animals wearing an external fixator. This is a normal reaction to the implants, local

insult, trauma, and controlled infection. Therefore adequate distance between the skin and the vertical bars and clamps has to be allowed to accommodate the swelling. This will prevent skin necrosis near contact areas of the clamps.

Pathologic fracture is a common problem encountered in horses treated with the external skeletal fixation device or external fixator.[30,35,36] Frequently, a doughnut-shaped cylinder of bone is walled off around the pin (Figure 76-9). This creates a relatively large defect in the bone and significantly reduces its strength. The bone within the fixator becomes weakened by osteoporosis (disuse atrophy depending on the duration of fixation), and bearing weight on the limb can result in failure through one of the pin tracts (see Figure 76-9). If the animal is not euthanized at once after failure, the fracture must be treated immediately by either internal fixation or a full-limb cast. Changing the arrangement of the Steinmann pins as well as the threads may limit the recurrence of this complication.[35]

Internal Fixation

At the turn of the twentieth century, compression in rigid fixation was recognized as an important component of rapid fracture healing. Rigid internal fixation became an important step in reaching the goal of early return to full function for the fractured limb and the patient.[37,38] The devastating effects of prolonged external coaptation—cast disease—were prevented when this goal was attained. Early return to function allows movement of the joints, associated nourishment of the articular cartilage, and prevention of proteoglycan loss. Additionally, disuse osteoporosis is prevented, and the soft tissues surrounding the fractured bone are maintained in physiologic condition.

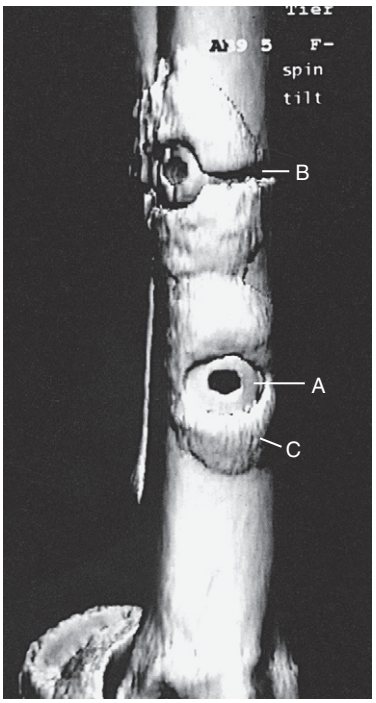

Figure 76-9. Three-dimensional reconstruction of a computed tomographic study of the third metacarpal showing ring sequestra *(A)* as a result of transfixation pinning, and a pathologic fracture *(B)* through the proximal pin tract or ring sequestrum. Periosteal new bone formation *(C)* surrounds the ring sequestra.

Early return to function is achieved through anatomic reduction of the fracture and stable internal fixation.[1]

Internal fixation is achieved through opening of the skin. This may occur through a stab incision, as with intramedullary pinning, transcutaneous interlocking, and minimally invasive plating techniques, or through opening the skin over a greater distance, followed by separation of the soft tissues surrounding the fractured bones when bone plates are applied.

Principles

Fracture fragments fixed to each other under compression heal without callus formation.[7] Precise anatomic reduction of the fracture is of paramount importance for this type of bone healing (primary union). It is also critical when the articular surface is involved, because if the reconstruction is not nearly perfect, osteoarthritis will develop (Figure 76-10).

In the last 50 years, tremendous progress has been made in the art of equine fracture treatment. The greatest influence on this achievement can be ascribed to the AO Foundation. Founded in 1958 by four Swiss surgeons, the AO (Arbeitsgesellschaft für Osteosynthesefragen) quickly developed into a worldwide organization.[1] In 1984, the AO Foundation was established, to which all the rights for royalty income were bestowed. Recently the three manufacturers that supplied surgeons with a large variety of sophisticated, high-quality implants (Mathys AG, Bettlach, Switzerland; Stratec Medical, Oberdorf, Switzerland [formerly Institut Strauman, Waldenburg]; and Synthes [USA], Paoli, PA) have merged to form a single worldwide company, Synthes, with its headquarters in Solothurn, Switzerland. For every implant sold, Synthes pays a certain amount of royalties to the AO Foundation to support teaching and the development of new instruments—a genuine approach to the improvement of fracture fixation. Techniques developed for human patients were quickly adopted by veterinarians, and many are applied in daily practice with good success.[1-4]

After the merger of the three companies, all patents were sold to Synthes, and with the interest from the investments, most of the activities of the AO Foundation can be offset. Additional income is generated through other sources. In 2008, the veterinary specialty within the AO Foundation, AOVET, was accepted

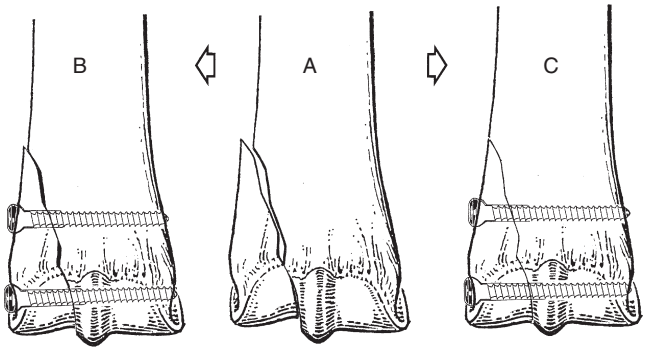

Figure 76-10. *A,* A displaced articular fracture of the lateral condyle of the distal third metacarpal. *B,* Inadequate reduction was achieved after interfragmentary compression via two cortex screws applied in lag technique. The articular surface is not congruent, which would lead to osteoarthritis. *C,* Adequate anatomic reduction was achieved before screw fixation, reestablishing the articular surface and normal bone-to-bone contact.

as a fully funded specialty next to to AOTRAUMA, AOSPINE, and AOCMF (cranio-maxillo-facial). The goal of AOVET is to establish itself as the world leader in the treatment of musculoskeletal disorders of animals, including fractures.

The implants, their function, and their application as discussed in this chapter are mainly those developed by the AO group. Included are screws, plates, pins, wires, and specially designed plates and nails. Only the instruments and implants used in equine fracture treatment are discussed.

Approach to and Manipulation of Bone

Before surgically approaching the bone, a careful diagnostic imaging study should be conducted that includes multiple radiographic views from a variety of angles. Ultrasonography, scintigraphy, and computed tomographic scans may aid standard radiography in the selection of the locations where implants are applied and the direction of their insertion. Potential interference of interfragmentary screws and plates with soft tissue structures must be considered. In articular fractures, reconstruction of the joint should be the deciding factor in the decision of how to approach the fracture and apply the implants. For some fractures, surgery should not be attempted. For example, a comminuted fracture of the radius with substantial defects in the caudal cortex has no chance to heal because continuous cycling of the implants eventually leads to implant failure. It is prudent to conduct a detailed discussion with the owners of equine patients about the chances for a successful surgical outcome, the potential complications, and the costs of the particular fracture repair before surgery. Availability of all implants and instruments needed at the time of surgery is an absolute prerequisite for a successful result. The approach to the bone should be carried out rapidly and carefully and with respect for Halsted's principles of good surgical technique. Special attention should be paid to the blood supply, avoiding severance of major blood vessels. The periosteum should be maintained with the underlying bone whenever possible. Periosteum is stripped off the bone only immediately under selected implants, such as dynamic compression plates (DCPs). More recently developed implants, such as the limited contact dynamic compression plate (LC-DCP), the point contact fixator (PC-Fix), and the locking compression plate (LCP), are applied over the periosteum (see later). Massive dissection should be avoided, because it facilitates the accumulation of blood and serum. Planning the approach relative to the application of selected implants is of great importance for a successful outcome of the surgery. For example, the approach to the MCIII is made through longitudinal splitting of the common or lateral digital extensor tendon, which facilitates secure closure of the soft tissues and skin over the implants after the fracture is repaired.[39,40]

In human and small animal osteosynthesis, biological fracture fixation has become very popular.[41] This technique abandons the dogma of anatomic reconstruction and accepts that proper axial and rotational alignment of the bone, despite incomplete reconstruction, followed by fixation of the fracture with strategically placed implants is preferred. Longer plates are used, providing better leverage conditions. Screws are inserted through the biomechanically most important holes, but not all holes in a plate are filled with screws. If possible, the plate is prebent (to conform to the shape of the contralateral intact bone), slid along the fractured bone through a small incision, and fixed with screws implanted through stab incisions. Such minimal fixation cannot be used successfully in horses. However, the principle of applying the implant by a minimally invasive technique is applicable to the horse, even if the implant has to be modified to meet the demands placed by the horse's size.

Instruments

Basic instruments used for fracture treatment include a variable-speed air or electric drill with forward and reverse gears. To facilitate mechanical preparation of the threads in the bone, switching between forward and reverse should be easy. Drill bits and guides of different types and sizes are needed (Table 76-1). Drill guides allow application of concentric pressure, and they stabilize the drill bit, which prevents breakage. The bit is also less likely to slip off the bone surface, especially when it is obliquely applied. The guides protect tissues around the hole from frictional trauma generated by the drill bit and the tap. It has been shown that drilling at maximal speed (about 90 psi of air pressure) results in less heat production than drilling at low speeds.[3] The drill bits should be sharp and should be exchanged frequently, because dull drill bits create heat in the hard and dense equine bone. This is especially true in adult animals. Continuous application of saline solution throughout the drilling procedure is important to reduce heat production.[3] The drill bits are designed to allow penetration of the fluid along their outside perimeter, which facilitates lubrication and reduction of friction. However, not enough water can be flushed into the drill hole to effectively cool the drill bit. Frequent cleansing of the drill bit to remove the swath material is the single most important factor in reducing heat production. During drilling, axial pressure is applied to the drill bit without bending it. Bending causes the drill bit to become dull too rapidly because of interference with the drill guide. More importantly, the hole will be of a larger diameter than intended. Adequate but not excessive pressure should be applied. The instruments used for screw insertion are discussed later, in the paragraphs about the lag technique. Other instruments such as various drill guides, special reduction forceps, bone clamps, rongeurs, curets, osteotomes, and a mallet (for more information, see Chapter 11) aid in bone handling as well as in maintaining compression during fracture reduction and the insertion of the desired implants.[27]

The newly developed Equine Large Fragment Set consists of several trays: the instrument set containing the different instruments (Figure 76-11), the plate set containing the different plates selected by the veterinarian, a screw set containing cortex screws, and one screw set for locking head screws.

Implants

SCREWS

Various types of screws serving different functions were developed by the AO together with Synthes (see Table 76-1). The parts of a screw include the head, shaft, core, and thread. Its attributes include pitch, shaft length, thread length, and total screw length.

Screw types

Cortex screws have a 0.7-mm thread width, and a thread length that depends on the screw length (see Table 76-1). A cortex screw does not contain a shaft portion and is referred to as a *fully threaded screw.* These types of screws are the most frequently

TABLE 76-1. Veterinary Large Animal Screw, Drill Bits, and Tap Chart

Screw Name	3.5 mm Cortex	4.5 mm Cortex	4.5 mm Shaft	4.5 mm Cannulated	3.5 mm Locking	4.0 mm Locking	5.0 mm Locking	5.5 mm Cortex	6.5 mm Cancellous	7.3 mm Cannulated

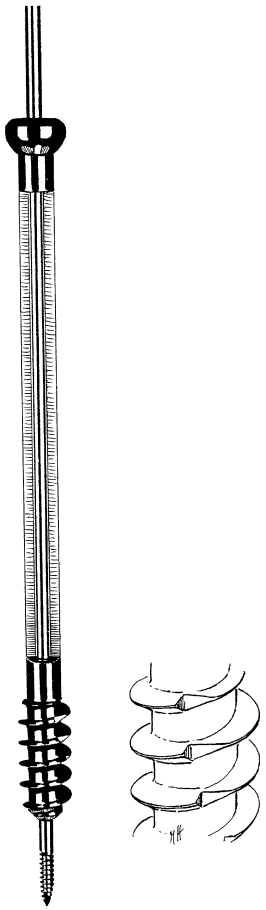

Figure 76-12. Schematic drawing of 7.3-mm cannulated screw with the guide pin inserted and half of the shaft removed. Insert: the reverse-cutting design of threads, which facilitates screw removal after healing of the fracture. (From Nixon AJ: Equine Fracture Repair. Saunders, Philadelphia, 1996.)

applied in equine osteosynthesis. The *shaft screw* (see Table 76-1) is an exception and therefore a special cortex screw. The shaft screw contains a shaft portion of the same diameter as the outside diameter of the threads.[42] The threads have the same geometry as the cortex screws. Shaft screws are available in various shaft and thread lengths. Because of the smooth shaft portion, these screws are ideally suited for lag screw fixation, especially through LC-DCPs, where up to 40 degrees of angulation relative to the long axis of the plate can be achieved.

Cancellous screws have a wider thread diameter than the cortex screws and they have a different pitch (see Table 76-1). This screw is designed to improve holding power in soft cancellous bone, but it is only rarely used in equine internal fixation.

Cannulated screws contain a central canal for a guide wire (see Table 76-1).[43] The design resembles the cancellous screw, because it has a thinner shaft and a wider thread portion. The 7.3-mm cannulated screw contains a self-drilling and self-tapping tip, as well as a reverse cutting device at the back end of the threads (Figure 76-12).[44] An *in vitro* study using equine cadaveric femurs revealed that the 6.5-mm cancellous and the 7.3-mm cannulated screws vary in insertion properties (the 7.3-mm cannulated screw requires significantly greater insertion torques), but they have similar pullout properties in the mid, proximal, and distal metaphyses of foal femurs.[45] Both screw types have greater holding power at the mid-diaphyseal location than at metaphyseal locations. Because of the overall similar holding power of 6.5-mm cancellous and 7.3-mm cannulated screws, it is unlikely that increasing the screw diameter beyond 6.5 mm will provide increased holding power in foal bones. The use of the 7.3-mm cannulated screw should be considered for foal femoral fracture repair when greater accuracy is needed or when bone threads for the 6.5-mm cancellous screw have been stripped.[45]

Self-tapping cortex screws contain the same thread-cutting device at the tip as the tap, obviating one step of the standard screw insertion technique (see Table 76-1).[46] These screws are popular in human surgery and are gaining more acceptance in equine surgery.[47] An *in vitro* study revealed that the mechanical properties of regular and self-tapping 4.5-mm cortex screws are similar with regard to pullout strength from the adult equine MCIII and that the self-tapping cortex screws require less than half the total insertion time required by standard screws.[47] Interestingly, bone failure and bone comminution during the pullout tests were more commonly associated with self-tapping screws.[48]

Locking head screws were introduced with the less-invasive stabilization system (LISS) and subsequently also applied in the locking compression plates by Synthes (Figure 76-13). The conical shape of the PC-Fix screw (which is no longer manufactured) served as a basis for the new design.[49] The screw head was modified with a threaded profile, which complemented the one in the LISS plate hole. This design provided a stable angular

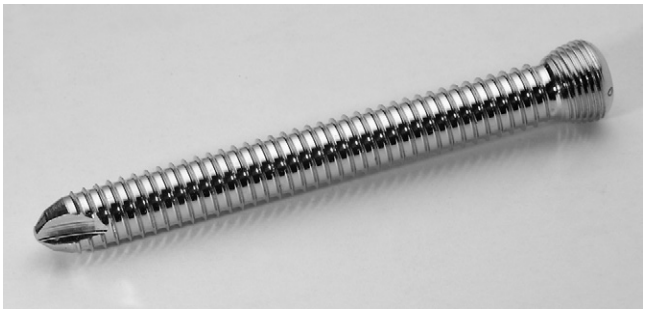

Figure 76-13. A self-tapping locking-head screw. Note the threads manufactured into the conical screw head. These interlock with complementary threads in the plate. The self-tapping ends are visible at the tip of the screw.

fixation of the screw–plate (fixator) junction: the screw head is self-centering in the hole, and it keeps the screw from backing out of the LISS and LCP fixator (see later). The pitch of the threads at the screw head is identical to that of the threads on the shaft. Because of the larger diameter of the screw head, the pitch seems larger than on the shaft. However, the threads on the screw head catch after turning only 180 degrees instead of 360 degrees in the shaft. This facilitates faster fixation of the screw head into the plate and reduces the development of plate deformation through tightening of the screw. It is important to remember that this screw must be at 90 degrees relative to the long axis of the plate.

The screw was also adapted to the unique mechanical demands of an internal fixator. The core diameter of the screw was enlarged to resist the increased bending moments and higher shear forces induced by a fixator.[47] This, plus the threaded screw–plate interface, allows the use of unicortical screw fixation in the diaphysis. The stability of unicortical fixation with locking head screws was established in a cadaveric biomechanical study.[50]

Unicortical screw fixation, in turn, allows the application of self-drilling or self-tapping screws, which was made possible by reducing the thread pitch and adding drill and tap sections to the screw tip (see Table 76-1).[39] These design changes have additional benefits: screw length determination is no longer needed because all diaphyseal screws can be the same length; therefore screw lengths are not needed in increments of 2 mm, which results in a smaller inventory; predrilling and tapping are no longer needed, and the thread profile cut into the bone is more precise (because each screw is used once and therefore the drill and tap parts are sharp), which results in a better anchorage of the screw in the bone.[49]

In the horse, self-drilling and self-tapping screws are rarely used because of their high price, and screws are usually inserted bicortically. Therefore most of the advantages just listed do not apply to this species. However, self-tapping screws are used in the horse in bicortical applications.

Currently, locking head screws for the variable axis plates are available. As the name says, these screws do *not* need to be introduced at a right angle relative to the long axis of the plate. This is possible because of the slightly curved surface along the axis of the screw head and the special configuration of the plate hole (see later).

Other screws include the Herbert screw (Zimmer Orthopedics), an example of a self-contained compression screw.[51] This screw is fully threaded and contains threads not only over its entire length but also on the head. The head is wider than the rest of the screw and can be completely buried in the bone. It has been used in condylar fractures of MCIII/MTIII.

Recently, a cannulated, tapered, variable-pitch, self-compressing screw was developed (Acutrack Equine Screw). This screw is 45 mm long, and it has a diameter of 6.5 mm at its base that tapers to a diameter of 5.0 mm at its apex. Because of the tapered shape, no glide hole is needed. The screw is manufactured of titanium. Biomedical studies comparing Acutrack to 4.5-mm AO cortex screws inserted in lag fashion revealed that the screws had similar biomedical shear properties.[52] The self-compressing action of the Acutrack Plus screw generated 65% of the compression pressure and 44% of the compressive force achieved with the 4.5-mm AO cortex screw.[53] The overall pushout strength was higher in the Acutrack Plus screw.[53] Simulated midbody fractures of the medial proximal sesamoid bone repaired with Acutrack self-compressing screws compared with 4.5-mm AO cortex screws showed mechanically comparable strengths.[54] Both constructs were mechanically inferior to intact proximal sesamoid bones.[54] A recent study compared compression pressures of the Synthes cortex screw and the Acutrack Plus screw in simulated equine MCIII lateral condylar fractures of varying fragment thicknesses. The results revealed that significantly lower compressive forces were achieved with the Acutrak Plus screws.[55]

Sizes

The size of a screw is determined by the outside diameter of the threads. The standard screws for the horse are the 4.5- and 5.5-mm cortex screws. Pertinent data on each screw type as well as drill sizes needed are summarized in Table 76-1. The 5.5-mm screw was developed for compact equine bone. This screw has advantages over the 4.5-mm screw when used in adult horses.[56-58] The 6.5-mm cancellous screw is available in three configurations: a 16-mm thread length, a 32-mm thread length, and fully threaded. Since the introduction of the 5.5-mm cortex screw, the 6.5-mm cancellous screw has diminished in importance, because the 5.5-mm screw can also be inserted when a 4.5-mm hole has been stripped. A stripped 5.5-mm hole can still be engaged by a 6.5-mm cancellous screw. Cannulated screws are manufactured in 3.5-, 4.5-, 7.0-, and 7.3-mm diameters, but only the latter two sizes are interesting for the equine surgeon, and they can be used if a 6.5-mm cancellous screw hole is stripped.

The 3.5-mm cortex screw is used to achieve interfragmentary compression of certain fractures, such as third carpal bone slab fractures. It is also applicable for anatomic reduction of long bone fractures and interfragmentary compression of the fragments. The screw has such a small head that it can be completely buried in bone, which allows plating over the screw.[30] This is a great advantage, especially if two plates have to be applied.

The recently developed 5.0-mm locking-head screws are the strongest screws available for equine fracture treatment, because of their large core diameter (4.3 mm) (see Figure 76-13). The thread width is much smaller than standard cortex screws, but these screws are tightened into the thread hole within the combi-hole of the plate, facilitating solid fixation. These screws can be applied only through the LISS and the LCPs. They are available as nontapping; self-tapping; and self-drilling, self-tapping screws. Only the first two types are of interest for equine

surgeons. The self-drilling, self-tapping screw is very expensive, and because of its design it is impossible to predetermine the depth of the screw hole. Also, in equine fracture treatment it is important to achieve screw purchase in both cortices. If a self-drilling, self-tapping screw was inserted, the sharp self-drilling part of the screw would protrude out of the trans-cortex, which could produce soft tissue damage.

The 4.0-mm locking head screw can be used with the 4.5/5.0 mm LCPs. They have the same head design as the 4.3-mm locking head screw but a thinner screw design. These screws are rarely used in equine osteosynthesis.

The 3.5-mm locking head screws have a core diameter of 2.9 mm and are therefore stronger than the cortex screw of the same size. To ameliorate the excessive rigidity of the locking plates experienced in human surgery, a dynamic locking head screw (DLS) was recently developed. This screw type was tested in recent *in vivo* studies in sheep and resulted in additional callus formation around the osteotomy site.[59,60] The DLSs are not justified for equine applications because they are expensive and the same problems are not encountered in the horse as in people.

Additional smaller screws (2.7 mm, 2.4 mm, 1.5 mm, etc.) are available as regular cortex screws or in some instances as locking head screws. These implants may be applied with the corresponding plates for the repair of skull fractures (see Chapter 102).

Most screws are available either with a hexagonal or a stardrive hole in the screw head, into which the corresponding screwdriver is inserted to power the screw into the bone.

The preparation of the screw surface plays an important role in the holding power of the implant.[56] Special surface preparation of stainless steel and titanium screws showed superior holding characteristics over the plain stainless steel and titanium screws.[61]

Functions

Screws can be used as lag screws, position screws, and plate screws.[62] There is a difference between a partially threaded cancellous or cannulated screw, which automatically produces a lag effect, and a cortex or shaft screw used in lag fashion.[3] The cancellous and cannulated screws are inserted so that all of the threads pass the fracture line. Thus tightening of the screw provides interfragmentary compression (Figure 76-14, *A*).[1-4] If the threads of a cancellous screw bridge the fracture gap, no compression can be achieved (see Figure 76-14, *B*). The same holds true for a cortex screw placed as a position screw (i.e., with no lag effect): its threads engage bone on both sides of a fracture, and because no glide hole was prepared in the near cortex, no interfragmentary compression is achieved. A plate screw lags the plate to the bone.[1,2] The lag technique may, however, also be applied through a plate hole. In this case, the screws are inserted through the plate and they cross the fracture line.[1-4]

The *lag technique* is used to insert cortex screws so that they act in lag fashion. This technique is not necessary when using partially threaded screws (such as cancellous or cannulated screws) as lag screws when applied as discussed in later paragraphs. The cis-cortex or near cortex is drilled with a drill bit having the same diameter as the outside thread diameter of the screw (Figure 76-15, *A*). This is referred to as overdrilling. Therefore, at insertion of the screw, the threads do not engage bone in that cortex but glide through, so this portion of the hole is called the *glide hole*. The outside diameter of the insert drill sleeve is the same as that of the glide hole, and the inside diameter is the same as that of the smaller drill bit, which has a diameter identical to that of the core of the screw. Insertion of this drill sleeve into the glide hole ensures concentric drilling of the trans-cortex and subsequent accurate reduction of the fracture (see Figure 76-15, *B*). The hole drilled through this sleeve across the trans-cortex or far cortex is referred to as the *thread hole*.

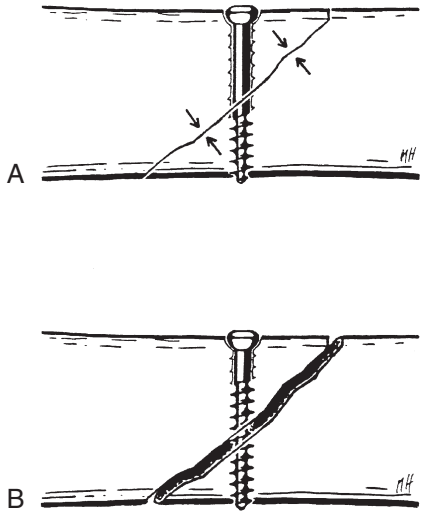

Figure 76-14. Lag screw technique. **A,** A cancellous screw of the correct thread length. All threads are located past the fracture plane, allowing interfragmentary compression. **B,** Selection of a cancellous screw with too long a thread length. Threads are located on both sides of the fracture plane, preventing interfragmentary compression.

To allow a greater contact area between the screw head and the bone, a depression is created at the near cortex using the countersink (see Figure 76-15, *C*). This decreases stress concentration at the screw head–bone interface. It is important to use the countersink in a 360-degree motion rather than in a to-and-fro motion; otherwise, an imperfect indentation is cut, preventing proper seating of the head. Countersinking is especially important in screws inserted at nonorthogonal angles relative to the surface of the bone. Care is taken to insert the nozzle at the tip of the countersink axially into the glide hole and to remove the bone making contact with the instrument. If this is not done, tightening of the screw results in stress accumulation at the screw head–bone junction, and bending of the screw head will result.

The depth gauge is then used to determine the total length of the screw, including the head (see Figure 76-15, *D*). Therefore, the length of the screw is measured to include the head. The depth gauge has a small hook at the end of its thin shaft that is inserted through the thread hole. By slightly tilting the instrument to one side, the hook catches the opposite cortex, and by sliding the movable portion toward the countersink depression, the exact length of screw is determined. In human and small animal osteosynthesis, 2 mm is added to the determined length to ensure that the tapered tip of the screw that does not engage the precut threads in the trans-cortex is positioned outside the bone. In equine bone, however, with the relatively thick cortices, the tapered tip is usually maintained within the bone, resulting in a loss of holding power of approximately 2 mm of screw. Because adequate bone stock is present

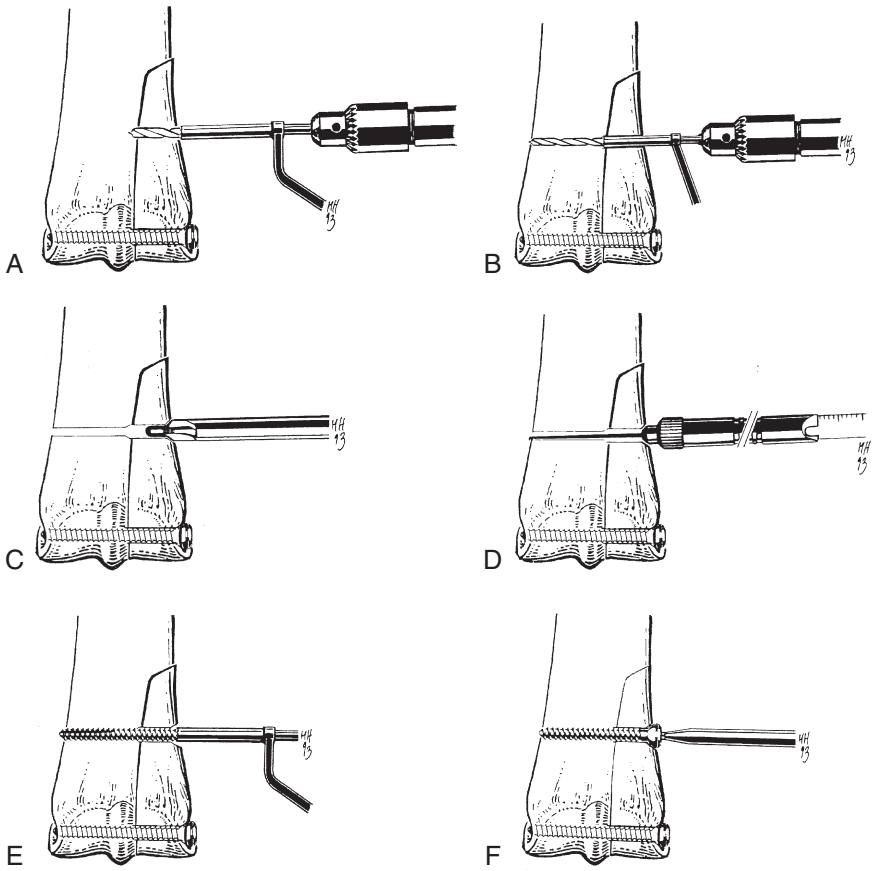

Figure 76-15. Lag technique, shown on a lateral condylar fracture of the distal third metacarpal. **A,** The cis-cortex is overdrilled. **B,** The insert drill bit is placed into the glide hole and advanced past the fracture plane, and the concentric thread hole is drilled across the trans-cortex. **C,** A depression for the screw head is prepared with the countersink. **D,** The required length of the screw is determined with the depth gauge. **E,** The threads are cut into the thread hole with the tap. **F,** The screw of predetermined length is inserted and solidly tightened with the hexagonal-tipped screwdriver. (From Nixon AJ: Equine Fracture Repair. Saunders, Philadelphia, 1996.)

to ensure secure fixation of the screw in the prepared hole, the screw that is used is either the exact length determined by the depth gauge or is 1 to 2 mm shorter.

Using the tap sleeve to protect the soft tissues as well as to help guide the tap, the tap is inserted into the glide hole and the threads are cut into the thread hole (see Figure 76-15, *E*). The threads are cut by advancing the tap three half-turns clockwise, followed by one half-turn counterclockwise. The counterclockwise action allows transport of the swath material into the flutes of the tap and ensures precise cutting of the threads without interference of the swath material cut from previous threads. An experienced surgeon may tap the thread hole with the air drill (power tapping) to speed up the procedure. This is especially advantageous when many screws are to be inserted. It requires experience, however, or serious complications may arise, such as stripping of the thread holes, cross threading of the tap, and instrument breakage. If a self-tapping screw is used, this step is not necessary. The small AO air drill and the Colibri air drill (small battery-powered drill) are not powerful enough to insert a self-tapping screw without applying a to-and-fro "power-tapping" technique. The Synthes ComPact Air Drive II, however, has one third more power and easily inserts self-tapping screws without to-and-fro movement.

Once the hole has been tapped, it is flushed to clean out swath debris and to lubricate it. A screw of the predetermined length is inserted, using the hexagonal tipped or stardrive screwdriver (see Figure 76-15, *F*) either by hand or with an air drill. Final tightening is always carried out by hand. Care is taken to avoid excessive force, which may result in failure of the screw head, or in stripping of the threads cut into the thread hole.[47] This is not a common problem in dense equine bone.

The shaft screw is inserted by applying the identical lag technique. However, care has to be taken that the glide hole is made slightly longer than the screw shaft. If the shaft is longer than the glide hole, no interfragmentary compression is achieved.

In the *lag screw technique*, a lag screw (either a partially threaded cancellous screw or a cannulated screw) is inserted after using a drill bit of only one size across the entire bone. Threads are cut along the total length of the hole with the cancellous tap, and the lag screw is inserted. The threads in the cis-cortex should not be engaged by the screw threads but only those of the trans-cortex, allowing achievement of interfragmentary compression.[1-4] Because the hardness of equine bone makes screw insertion difficult, it may be advisable to enlarge the cis-cortex with a 4.5-mm-diameter drill bit after first drilling the entire hole with the 3.6-mm drill bit.

Insertion of cannulated screws employs the same technique. However, the initial step involves placement of a guide wire in the desired location.[44] A special drill sleeve allows insertion of parallel screws close together. It is advisable to predrill equine cortical bone with a small drill bit before inserting the guide wire to prevent bending it. All instruments are cannulated to accept the guide wire. The size of the drill bit depends on the size of the screw to be implanted and the size of the guide wire. Once the guide wire is in place, its correct position and depth is ensured through radiography. If necessary, adjustments are made at this time. The measuring device is then placed over the portion protruding out of the bone. The length of guide wire

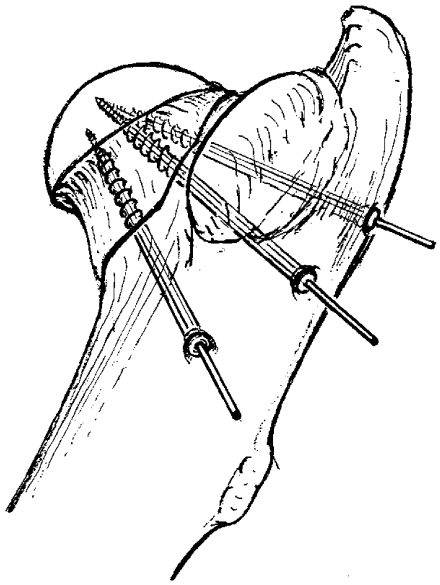

Figure 76-16. A capital femoral fracture is repaired with three cannulated screws. After the screws are inserted over a guide pin and tightened, the guide pins (which penetrated farther than the screws) are removed.

located in the bone is determined, and this determines the length of screw required. It is advisable to select a screw 3 to 5 mm shorter than the length of the guide wire inserted within the bone, to ensure secure seating of the wire throughout the implantation procedure. Subsequently, the cannulated drill bit is placed over the guide wire and the hole of predetermined length is prepared. The hole is tapped and finally the selected screw is inserted and firmly tightened (Figure 76-16). At the end, the guide wire is removed.

The 7.3-mm cannulated screw has a self-drilling and self-tapping tip. Therefore a screw of predetermined length is inserted without drilling a thread hole. Because of the initial insertion of the guide pin and the ability to select a screw of correct length, the danger of implanting a screw that is too long and protrudes from the opposite side of the bone is negligible. In equine bone, insertion occurs in the same manner as tapping, meaning that the screw is advanced three half-turns, followed by a half-turn in the opposite direction. Care has to be taken with power insertion.[39]

The *position screw* is used to maintain two pieces of bone at a certain distance apart and to prevent interfragmentary compression. This is achieved by drilling a hole of only one size (thread hole) across both cortices, followed by tapping. Only fully threaded cortex screws may be inserted as position screws. Because the threads catch in the cis- and trans-cortex, interfragmentary compression is prevented. No lag effect is achieved. It is advisable to apply a washer onto the bone surface to distribute the forces applied by the screw, because it is not possible to use the countersink. Its nozzle doesn't fit into the drill hole without overdrilling it for 13 mm (½ inch). In some instances the latter is not possible because it would result in a lag effect.

The *plate screw* is inserted by the technique described for the position screw. Any type of screw may be used in this manner. With the plate screw, the plate hole serves as a glide hole and allows compression of the plate onto the underlying bone, providing friction and stability.

Figure 76-17. Removal device for stripped 3.5-mm screw heads. An intact hexagonal hole in the screw head is shown. It is smaller than the tip of the screw. However, once the hole in the screw head is stripped, the tip of the device (whose threads are oriented in the direction opposite to those in the screw) will fit.

Screw removal

Cortex and locking-head screws are easily removed because of their fully threaded design. Similarly, shaft screws are easy to remove, because the shaft completely fills the glide hole. However, after a fracture has healed, a cancellous screw may be impossible to remove from hard equine bone, because during fracture healing, the precut threads in the cis-cortex fill in with solid bone. Removal of the screw requires the threads to cut their own way through the cis-cortex, a task for which they are not designed. This frequently results in the screw breaking, usually at the head–shaft or the shaft–thread junction. Therefore partially threaded cancellous screws should not be used when implant removal may be necessary at a later stage. Smaller cannulated screws have the same problem as cancellous screws. The 7.3-mm cannulated screw, however, contains a reverse-cutting edge at the caudal end of the threads, which facilitates recutting of the bone threads during screw removal (see Figure 76-13).[43]

Occasionally, the hexagonal indentation in the screw head is stripped during screw removal. This occurs if the screwdriver is improperly inserted in the hexagonal hole. Alternatively, if the hole is partially filled with tissue, the screwdriver cannot be inserted completely. Subsequent application of extraction force (counterclockwise motion on the screwdriver) may strip the hole within the screw head. This problem is mainly encountered with the hexagonal tipped 3.5-mm screw head and not in the stardrive head because of its smaller screw head. A special screw retrieval instrument has been designed for such situations (Figure 76-17). A shaft with a conical, threaded tip is inserted into the hexagonal indentation of the screw head. The threads of the tip have a reversed orientation compared with the screw threads. Therefore when the cone is tightened in the screw head with a counterclockwise motion, an extraction force is applied to the screw, allowing it to be easily removed. These screw-retrieval devices are available for all sizes of screws.

When a screw head is broken off, a special hollow drill bit is available to remove the bone surrounding the screw. Because it rotates counterclockwise, the threads on the inside of the hollow drill bit interlock with the screw, and advancing the drill

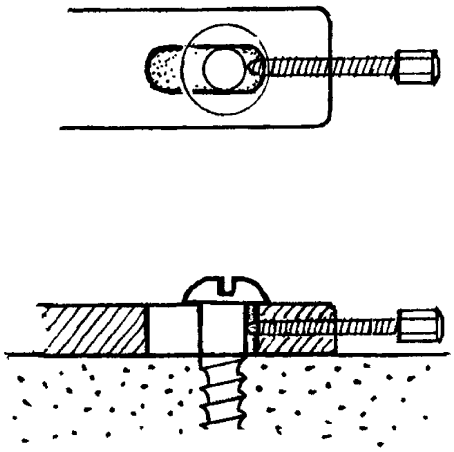

Figure 76-18. The Danis plate, developed in 1947. The plate screw is inserted into an oblong hole, and by tightening a smaller screw placed parallel to the long axis of the plate, the initial screw is displaced, providing axial compression of the fracture.

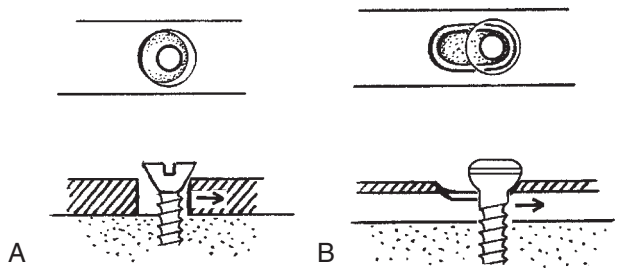

Figure 76-19. The Bagby plate, developed in 1958. **A,** A screw with a slanted screw head is inserted under load conditions into a larger plate hole, and through tightening of the screw, the axial compression is achieved across the fracture, similar to the dynamic compression plate principle shown in **B.**

bit removes the broken screw. For screws of all sizes that have broken off, a special screw retrieval set has been developed.

PLATES

The first plates to contain an axial compression device were developed by Danis in 1947.[63] They consisted of a plate with an oblong hole on one end. At the head of the plate, a compression screw could be introduced, which pushed the screw placed through the oblong plate hole toward the fracture line and in doing so provided axial compression to the fractured bone ends (Figure 76-18). Ten years later, Bagby introduced an impacting bone plate.[64] The heads of the screws he designed had a conical underside. If the screw was inserted eccentrically into the plate hole, the conical underside made contact with the edge of the plate hole. By tightening the screw, the bone into which the screw was implanted was displaced toward the fracture site and thus induced axial compression (Figure 76-19). The first plates developed by the AO in 1958 contained round holes (Figure 76-20, *A*).[63] Axial compression was applied with the help of a tension device (see later). Plate hole designs are shown in Figure 76-20 and described in the following paragraphs. The specific data on the different plates used routinely in equine osteosynthesis are summarized in Table 76-2.

The dynamic compression plate (DCP) was considered the basic plate in equine fracture treatment for a long time. Recently there has been a move away from this plate toward limited-contact dynamic compression plates (LC-DCPs) and locking compression plates (LCPs) (see later). Therefore, the detailed steps of plate application and discussion of the general principles of plate application in the horse are discussed under LC-DCP.

Dynamic compression plate

The 4.5-mm Dynamic Compression Plate is available in two plate widths. The narrow plate has holes arranged in a straight line, and the broad plate has holes offset to the left and right of the midline. The 3.5-mm broad plate, developed mainly for small animals, is manufactured from the same plate stock as the 4.5-mm narrow DCP. However, because of the smaller size of the plate holes, this basic plate is stronger than the narrow

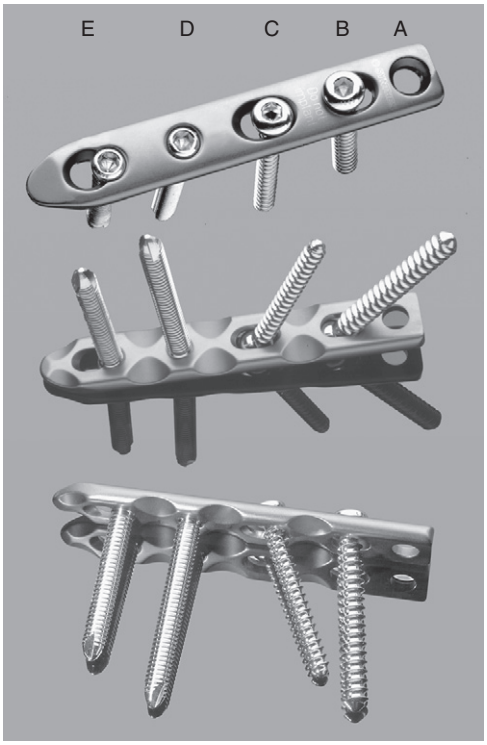

Figure 76-20. The plate holes designed for Synthes plates. *A,* The initially developed round hole. *B,* The dynamic compression plate (DCP) hole, which allows compression from one side. The screws can be angulated axially up to 25 degrees. *C,* The dynamic compression unit hole, which allows compression from either side and is used in the limited compression (LC)-DCP. The screws can be angulated axially up to 40 degrees. The plates have undercuts. *D,* Locking head plate holes used in the less-invasive stabilization system (LISS) plate, allowing only orthogonal insertion of the screws. The plates have undercuts. *E,* The combi-hole used in the locking compression plate allows the insertion of locking head screws—as shown here—and standard screws. The plates have undercuts and a pointed end that allows minimally invasive insertion through a small incision.

4.5-mm DCP and therefore may also be applied in foals.[65] The holes in a DCP are designed to achieve dynamic compression with tightening of screws inserted in the "loading" position. The holes are machined according to the sliding spherical principle with an incline or slope pointing downward towards the central portion of the plate (see Figure 76-19, *B*).[66] When a screw is inserted in the load position (offset 1 mm from the

center of the drill guide), the screw head contacts the plate at the top of the incline. During tightening, the screw head moves down the slope until it comes to rest at the bottom of the incline, just about in the center of the oval screw hole. Because the screw is introduced into the bone, screw movement toward the fracture line results in compression of the fractured bone ends. The center of the plate should be located over the fracture site, and this offset drilling can be carried out on either side of the fracture plane. Two screws on either side of the fracture can be used in the load position; using the plate holes alone will provide a maximum of 4 mm compression. Before tightening the second screw, the first screw on the same side of the fracture plane has to be loosened to achieve the additional 1 mm compression. Following tightening, the loosened screw is tightened again. Additional compression requires the external tension device.

Limited-contact dynamic compression plate

The DCP, up to now the workhorse for equine fracture treatment, was for a while replaced by the LC-DCP, especially in the United States. Studies in human medicine showed that the DCP caused osteoporosis under the plate, although this is not encountered in equine surgery (see later).[1] This led to the development of biologically improved plates.

In the conventional DCP, the plate holes provided the least resistance to failure. This problem was somewhat offset in equine fracture treatment by inserting screws through all plate holes. By designing a plate that contained at each cross-section along its entire length the same amount of metal, an implant of uniform bending stiffness was developed.[62] To achieve this, half-moon–shaped pieces of metal were removed from the underside of the plate. This resulted in limited contact between bone and the plate, which led to the name of the plate: LC-DCP (Figure 76-21). The limited contact surface was welcomed in human surgery to fight the problem of osteoporosis developing under the plate.[62] Extensive tests comparing the LC-DCP with the conventional DCP revealed that the LC-DCP had an equal bending stiffness and a 50% increase in the continuity of the bending stiffness.[62] This reduces local stress concentration near fracture gaps. Additionally, the blood supply of the bone under the plate was significantly improved.[67] Early mechanical tests conducted in the AO Research Institute in Davos revealed that the design of the LC-DCP provided increased resistance to cycling failure compared with the DCP.[65] The undercuts of the plate allow the development of some callus bridges over the fracture gap, which led to a significant increase in stability, despite the fact the these bridges are small. The trapezoidal cross section allows the formation of shorter but stronger bone lamellae on either side. Also, it prevents the bone from growing over the plate. The dynamic compression unit (DCU) hole design in the LC-DCP, which allows axial compression to be applied from either side of the hole, replaced the conventional DCP hole design (see Figure 76-20). This allows the distribution of the plate holes evenly along the entire plate and obviated the need for a center in the plate. The DCU hole is also undercut at each end to allow the insertion of screws up to a 40-degree angle relative to the orthogonal direction. In the DCP hole, only a 25-degree angulation can be achieved.[64]

There are two plate widths; the narrow plate has holes arranged in a straight line, and the broad plate has alternating offset holes.

The DCU holes are specially designed to allow dynamic compression as the screw is tightened. The holes are arranged according to the spherical gliding principle, with an incline, or slope, toward the center portion of the plate (Figure 76-22).[65,66] This offset drilling can be carried out on either side of each hole and therefore on either side of the fracture line.[65] The application of the LC-DCP requires the use of the special LC-DCP double drill guide identified by its undercuts on the handle, identical to the ones under the plate itself (Figures 76-23 to 76-26). (Note: the DCP drill guide should not be used with the LC-DCP.) An alternative to the LC-DCP drill guide is the *universal drill guide*, which contains a spring-loaded tip (see Figure 76-23). Pressing down on the drill guide places it near the center of the hole (see Figure 76-26, *B*). Placing the spring-loaded tip on the far end of the DCU hole relative to the fracture line (without pressing down on the drill guide) allows a 1-mm compression of the fracture line (see Figure 76-25, *A*).

The technique of application is as follows. The fracture is reduced (Figure 76-27, *A*), and it is maintained in that configuration initially with pointed reduction forceps until one or two interfragmentary cortex screws, 3.5 or 4.5 mm in diameter, can be applied in lag fashion (see Figure 76-27, *B*). The plate is then contoured, overbent at the fracture site, and applied to the bone (see Figure 76-27, *C*). The first screw hole is drilled toward one end of the plate in neutral position (green LC-DCP drill guide

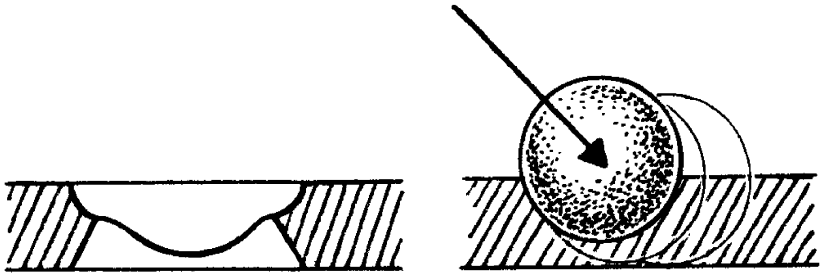

Figure 76-22. Design of the dynamic compression unit (DCU). Both sides of the hole are shaped like an inclined cylinder. Like a ball, the screw head slides down the incline. Because the screw head is fixed to the bone via the shaft, it can move only vertically relative to the bone. The horizontal movement of the head, as it impacts against the angled side of the hole, results in movement of the bone fragment relative to the plate and leads to compression of the fracture. With the DCU, compression can be achieved on either side, obviating the need for the plate to have a center, as in the dynamic compression plate.

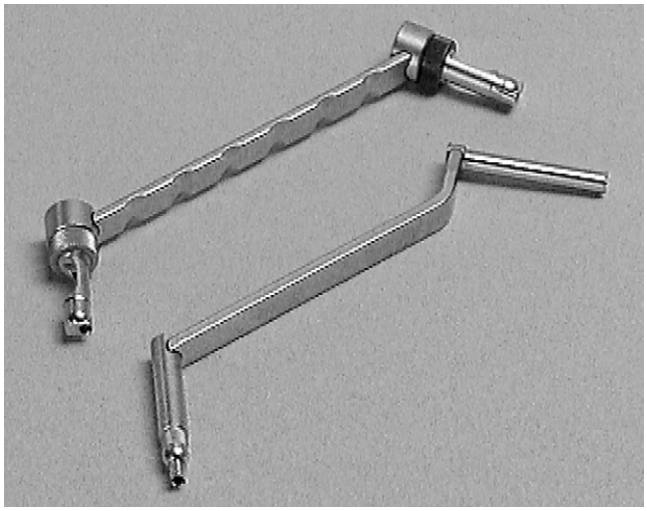

Figure 76-23. The limited-contact dynamic compression plate (LC-DCP) double drill guide *(top)* contains undercuts like those of the corresponding plate to distinguish it from the DCP double drill guide. The dark ring (green) represents the neutral guide, the light ring (yellow) the load guide. The universal drill guide *(bottom)* contains a spring-loaded guide for the thread hole and a larger guide for the glide hole. The universal drill guide is available for the different screw sizes.

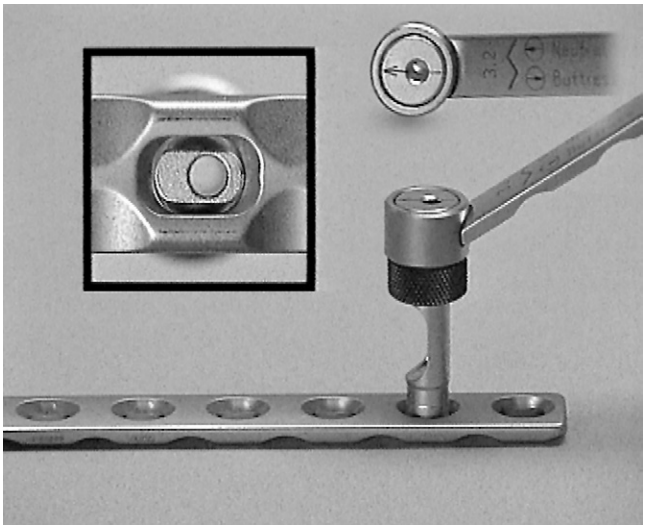

Figure 76-24. The neutral LC-DCP drill guide inserted into a dynamic compression unit (DCU) hole *(bottom).* From below the plate, it can be seen that there is a gap between the right end of the DCU hole and the drill guide hole *(top left).* From the top, the arrow pointing toward the fracture line is visible *(top right).* In the DCP neutral guide, there is no arrow.

or pressed-down universal drill guide). The screw is inserted but not completely tightened. This allows the plate to be pulled into a loaded position. The same can be achieved by drilling the initial hole through the load (yellow) LC-DCP guide or the universal drill guide placed at the far end of the hole, and maintaining the plate in the same position (see Figure 76-27, *D*). The hole for the second screw is drilled on the other side of the fracture line through a plate hole near the other end, using the load drill guide (see Figure 76-27, *E*), if additional compression is needed. Care is taken to ensure correct plate position before drilling the second hole. The hole is prepared for the screw, which is subsequently inserted. Interfragmentary compression is achieved through alternate tightening of the two screws (see Figure 76-27, *F*). More screws may be applied in the loaded position on either side of the fracture. A maximum of two screws can be placed under load conditions on either side of the fracture line. Therefore a maximal compression of 4 mm can be achieved. Before the second loaded screw is completely tightened, the first one on the same side has to be slightly loosened. This allows the additional compression to be applied. As

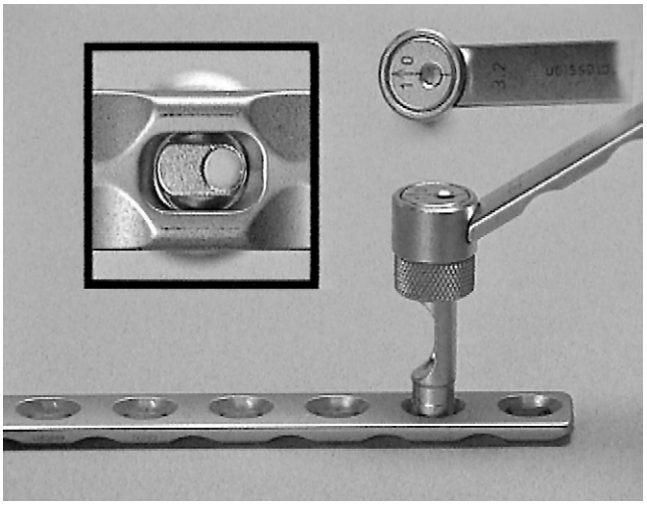

Figure 76-25. The load LC-DCP drill guide inserted into a dynamic compression unit (DCU) hole *(bottom).* From below the plate, it can be seen that there is no gap between the right end of the DCU hole and the drill guide hole *(top left).* From the top, the arrow pointing toward the fracture line is visible *(top right).*

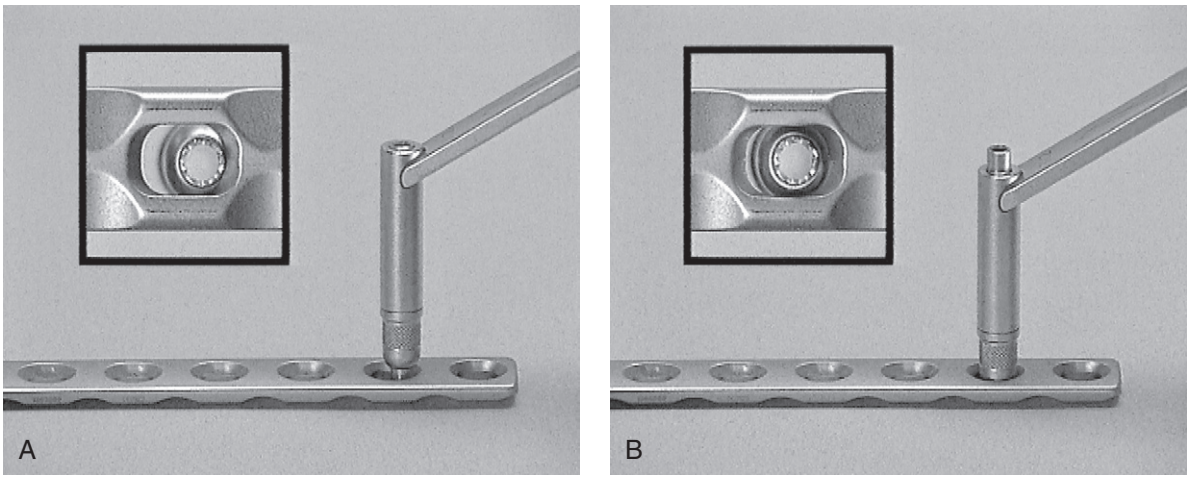

Figure 76-26. A, The universal drill guide placed into a dynamic compression unit (DCU) hole without applying pressure onto the guide. Viewed from below, the hole in the guide can be seen very close to the right end of the DCU hole. **B,** The universal drill guide placed into a DCU hole under pressure. The spring-loaded part of the guide is sticking out on top. From below, a gap can be seen between the hole in the guide and the right end of the DCU hole.

mentioned before, without this loosening, no additional compression is achieved and the two screws that are "compressed" toward each other are stressed.

The remaining screws are implanted in neutral position. Any screw placed through a plate across a fracture line is introduced using the lag technique (see Figure 76-27, *G*). All the screws are finally tightened (see Figure 76-27, *H*). A cortex screw inserted through a plate in lag fashion perpendicularly across a fracture may not achieve the desired effect, because the threads in the glide hole cut into the cortex and prevent any gliding.[65] To correct this undesirable effect, the shaft screw was developed. The shaft, which fills out the glide hole completely, does not cut into the cortex.

Any cortex or shaft screw can be inserted under load (at the far end of the oblong plate hole) or in neutral position (at the center) of each plate hole. Under load, 1-mm centripetal displacement or compression of the fracture gap is implemented. In neutral position, 0.1-mm compression is achieved. If double plating is applied, only two screws are placed under load in the second plate, which in most cases is arranged 90 degrees to the first plate.

Plates are contoured with the help of a plate-bending press to fit the surface of the bone. A perfectly contoured plate, however, compresses only the cortex immediately under the plate, whereas the opposite cortex remains decompressed (Figure 76-28, *A*). By slightly overbending the plates at the fracture site (see Figure 76-28, *B*), compression is achieved along the entire circumference of the bone (see Figure 76-28, *C*).[1-3]

Axial interfragmentary compression under a plate may also be implemented with the help of a tension device (Figure 76-29). The plate is applied to the bone with several screws in neutral position on one end of the fracture. The tension device is hooked into last hole on the other end of the plate and attached to the underlying bone through a unicortically applied 4.5-mm cortex screw. With the help of a wrench, the tension device is tightened, which pulls the plate toward the tension device and thus applies compression to the fracture site. Once adequate compression is applied, screws are inserted on the other side of the fracture through the plate in neutral position and tightened. The tension device is subsequently removed and the remaining screws are inserted in empty plate holes.

An *in vitro* study comparing the broad 4.5-mm DCP with the 4.5-mm LC-DCP revealed that the LC-DCP provided increased stability in static overload testing; however, it was significantly weaker in cyclic fatigue testing, which contradicted an earlier study that was not performed on cadaveric equine bone.[68] The results of another *in vitro* study conducted by the same group comparing the 4.5-mm LC-DCP with the 5.5-mm LC-DCP in the same model used above are interesting.[69] It showed that the 5.5-mm LC-DCP was superior in resisting static overload forces in palmarodorsal four-point bending. There was no significant difference in resisting static overload in torsion, but the 5.5-mm LC-DCP offered significantly less stability in cyclic fatigue loading. The 5.5-mm LC-DCP was previewed as the equine plate for fracture fixation and arthrodesis of the metacarpophalangeal joint. Because of the rapid gain in popularity of locking plates, the 5.5-mm LC-DCP was abandoned and replaced with a 5.5-mm LCP (see later).

The stability of the fixation is derived from friction between the implants and the bone. A technique called *plate luting* has been developed to obtain 100% plate–bone contact by applying bone cement (methyl methacrylate) between the plate and the bone.[70] This is achieved after all the screws of the plate are inserted. All the screws are then loosened, the plate is lifted off the bone, the soft bone cement is placed underneath it, and the screws of the plate are retightened, preferably with the power drill. Entrance of bone cement into the fracture line must be prevented because it retards or prevents bony union in that area. Once the screws are tightened, the soft cement fills the oblong plate holes around the screw heads and provides additional support, making the fixation extremely rigid.[70-72] When only the oblong plate holes are filled with bone cement, a similar but lesser increase in strain protection occurs.[72] Excess bone cement is rapidly and carefully removed. Plate luting is especially useful on bones with anatomically complex surfaces that make contouring of the plate difficult.[72] The addition of gentamicin into the bone cement facilitates long-term release of this antibiotic and provides effective protection against postoperative infections (see Chapter 85). Plate luting is not used in humans and

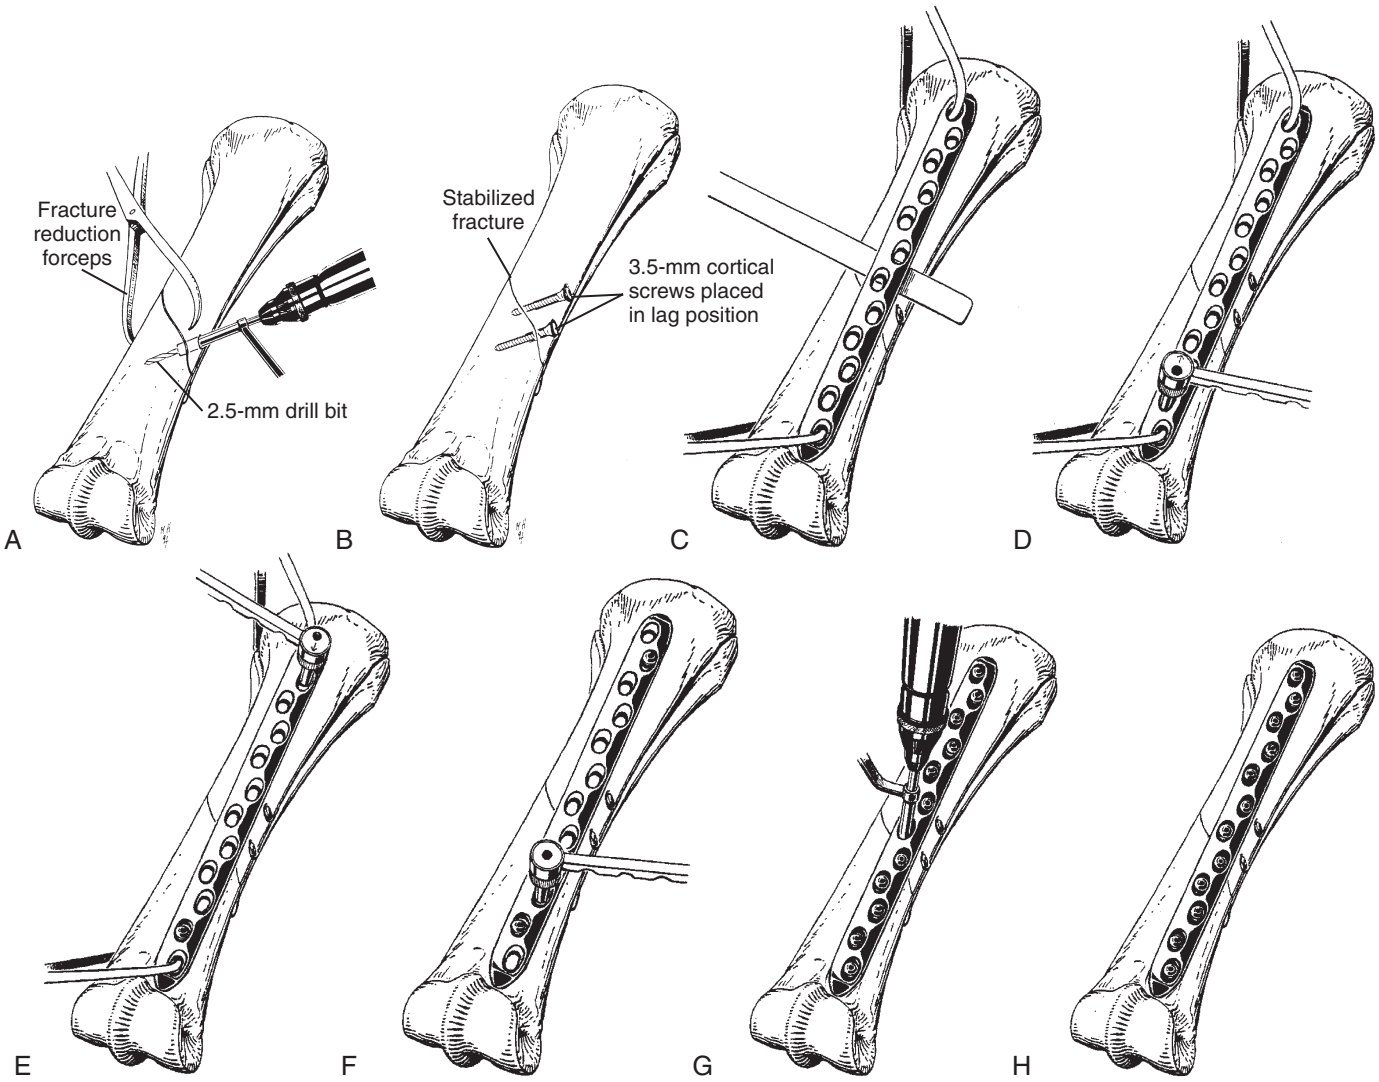

Figure 76-27. Repair of a simple oblique fracture of the third metacarpal with two cortex screws applied in lag technique combined with a broad LC-DCP as a neutralization plate. **A,** The large pointed reduction forceps maintains alignment of the fractured bone during implantation of the two 3.5-mm cortex screws. **B,** The two screws are implanted and the reduction forceps is removed. **C,** A 10-hole broad LC-DCP is applied to the dorsolateral aspect of the bone, distal from the two interfragmentary 3.5-mm cortex screws. The plate was overbent at the fracture site, allowing introduction of an aluminum template between the bone and the plate. **D,** A thread hole is drilled across the bone through the second most distal plate hole with the help of the yellow load drill sleeve. **E,** The screw is inserted but not completely tightened, followed by preparation of an identical hole at the opposite end of the plate. **F,** The second screw is inserted and both are alternately tightened, placing the fracture under axial compression. The remaining screw holes are prepared through the green neutral drill guide. **G,** A cortex screw is implanted in lag fashion across the fracture plane. **H,** All the screws are tightened. (From Nixon AJ: Equine Fracture Repair. Saunders, Philadelphia, 1996.)

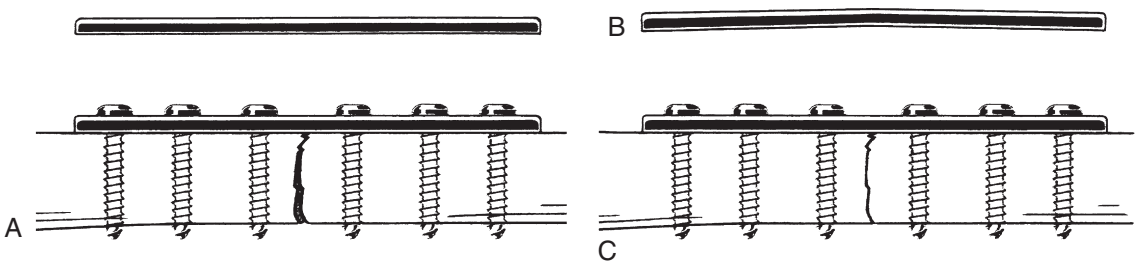

Figure 76-28. Application of a plate onto a bone. **A,** If a plate is perfectly contoured to the surface of the bone, a narrow gap develops at the fracture site opposite the plate after insertion and tightening of the screws. **B,** To overcome this problem, the plate is overbent (prestressed) about 1 mm, right at the fracture site. **C,** When the screws are reinserted, the entire circumference of the fracture is under compression.

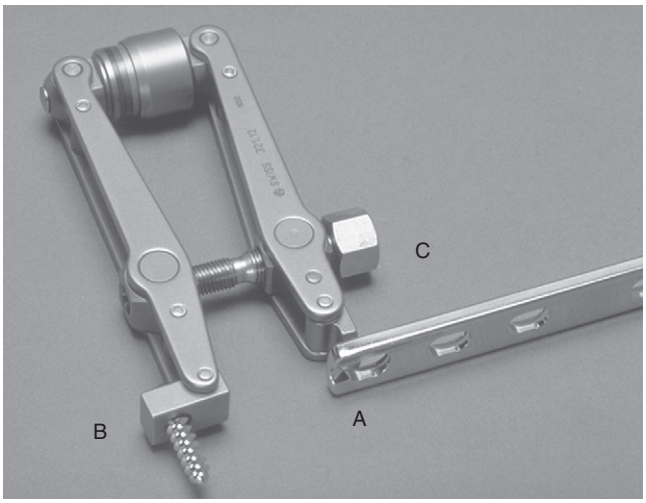

Figure 76-29. *A,* The tension device is hooked in the last plate hole. *B,* The device is attached to the bone with a short screw. *C,* Twisting of the hexagonal screw head pulls the plate toward the left side and applies axial compression to the underlying fracture.

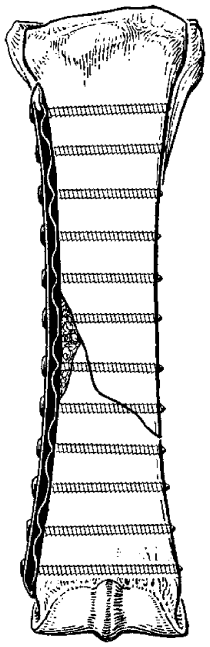

Figure 76-30. Comminuted midshaft fracture of the third metacarpal showing a bone defect. The defect is filled with cancellous bone graft, and a broad 12-hole LC-DCP is applied over the defect in buttress function. For better visualization, the dorsally applied LC-DCP, routinely used in a clinical case, is not shown.

small animals because vascular necrosis of the bone develops under the plate, resulting in pathologic fractures after implant removal. This complication has not been reported in horses. With the use of locking plates, the importance of plate luting has decreased because the locking head screws effectively prevent micromovement of the screw heads within the oblong plate holes (see later).

Screws should be inserted perpendicular to the surface of the bone. If a second plate is used, it should be positioned to allow the screw holes to be located between the screws of the other plate.[39,73,74] This reduces the likelihood of inadvertent contact between the screws of the two plates. Every hole in a plate should be filled with a screw.[39] Should a hole traverse a fracture line, the lag technique should be applied by overdrilling of the cis-cortex, and the screw should be directed so that it engages the opposite cortex next to the fracture line. Where no support can be achieved in a cortex, bone cement may be placed and the screw implanted. After the cement hardens, the screw will be solidly fixed.

Application of 4.5-mm screws through a 4.5-mm plate allows 40 degrees of longitudinal angulation and 7 degrees of lateral angulation.[65] Application of a 5.5-mm screw through the same hole allows only about 25 degrees of longitudinal angulation. The plates applied for fixation of a long bone fracture ideally extend over the entire length of the bone.[4] Shorter plates must be staggered to ensure plate coverage of the total length of the bone. The most distal end of the proximal fragment in an oblique long bone fracture should be wedged between a plate and the opposing distal fragment. Therefore the configuration of a fracture dictates to a certain extent the location of the plates to be applied (not just the tension side of the bone; see later).[39] Implants should be applied at a distance from severely bruised skin or areas of frank skin defects.

Plate functions include compression, neutralization, tension band, and buttressing. The design of a plate does not dictate its function, because the same plate may be used for different functions, and a plate may serve more than one function at a time. The compression and neutralization functions are the most frequently applied. When a plate serves in *compression* function, two screws on either side of the fracture line are placed under a load.[3] A plate serves a *neutralization* function after anatomic reconstruction and interfragmentary compression of a simple or comminuted fracture is accomplished by several screws placed in lag fashion.[1-4,39] The various diverging shear, bending, and rotational torque forces exerted by these screws on the surrounding bone are neutralized by one or two plates. Such plates effectively bridge the proximal and distal aspects of the bone and protect the fixed fracture. The screws are inserted in the neutral position. Application of neutralization plates has to be planned ahead of time to avoid interfering with the reduction screws or eliminating options for their placement. Most plates applied satisfy both compression and neutralization functions.

A plate applied in the *tension band function* transforms the tensile forces applied to the fractured bone underneath into compressive forces. The classic example of such a plate is one that is applied to fix an olecranon fracture. Because these plates are subjected mainly to tensile forces, they may be smaller than the plates used in compression or neutralization functions.

Cortical bone defects that persist after anatomic reconstruction of the fracture cause instability of the repair because of stress concentration. Such areas need to be protected and bridged by an implant, maintaining length by preventing collapse of the fixation (Figure 76-30). A plate applied in such a fashion is called a *buttress plate.* It is advisable to fill the defect in the bone with a cancellous bone graft or bone replacement material. Any screw placed through the plate in the region of the defect should engage the trans-cortex. All the other principles for plate fixation are applied.

One-third tubular plate

One-third tubular plates are very thin and, depending on the size of the hole, may be applied with a 3.5- or a 4.5-mm screw (see Table 76-2). The 3.5-mm plate is applied using standard technique in fracture treatment of proximal MCII, MCIV, MTII, and MTIV fractures in adult horses and of nondisplaced ulnar fractures in very young foals.

T-plates

T-plates are available for 4.5- and 5.5-mm screws as well as in a smaller version for the 3.5-mm screws. These plates are suited to areas where tension is applied without bending and sufficient space is not available for the application of a straight, regular plate. T-plates have been used for arthrodeses of the tarsometatarsal and distal intertarsal joints. The popularity of these plates has drastically decreased during the last few years.

Dynamic condylar screw and dynamic hip screw system

Dynamic condylar screw (DCS) and dynamic hip screw (DHS) plates are implant systems that were developed on the principles of the angled blade plate (ABP).[75] The set contains the instruments, screws, and selected plates. These plates consist of a long lag screw with a 12.5-mm (½-inch) thread width, a 25-mm (1-inch) thread length, and an 8-mm shaft diameter. The shaft is flattened on two opposing sides to prevent rotation of the screw after it is introduced into the barrel of the plate. The DCS or DHS is inserted at a predetermined angle (95 degrees for the DCS plate and 135 degrees [standard] for the DHS plate) (see Table 76-2). The most important step in the application of the DCS and DHS plate systems is the correct insertion of the 2.5-mm guide pin. Drill guides aid in the placement of the guide pin, which is best verified intraoperatively with an image intensifier. (Intraoperative radiographs, despite being more time consuming, are satisfactory as well.) Predrilling of the cortex with a 2.5-mm drill bit facilitates insertion of the guide pin. Care has to be taken that all of the four points on the base of the drill guide under the handle are in contact with the bone during drilling, even if the drill guide tip does not make contact with the underlying bone (Figure 76-31, *A*). Tilting of the drill guide with its tip down to bone results in false orientation of the DCS, which prevents the plate from making contact with the bone. This requires complicated adjustments of the plate angulations to make the plate contact the bone and prolongs the surgical procedure. If the plate–barrel junction is not in direct contact with the bone, the gap may be bridged with polymethyl methacrylate (PMMA). Once the guide pin is correctly placed, the subsequent steps are easily accomplished because all instruments are hollow and accept the guide pin.

The measuring device is placed over the guide pin, and its depth in the bone is determined (see Figure 76-31, *A*). The triple reamer placed over the guide pin allows simultaneous drilling of the core hole, the portion for the plate barrel, and the beveled plate–barrel interface (see Figure 76-31, *B*). The reamer is assembled and adjusted to a length measuring 5 mm less than the pin portion located within the bone. This ensures persistence of the pin in its position throughout the screw insertion procedure. After preparing the screw hole, the threads are cut using routine technique (see Figure 76-31, *C*), and the screw of appropriate length is introduced, followed by application of the plate (see Figure 76-31, *D*). Once the shaft of the screw and the barrel are aligned, the barrel slides easily over the shaft and the plate position can be adjusted before impacting it onto the bone (see Figure 76-31, *E*). The barrel has the same inside diameter as the screw shaft cross section (8 mm and flattened at two opposite sides). The DCS plate has a barrel length of 25 mm, whereas the standard DHS has a barrel length of 38 mm (1½ inches). A special version of the DHS plate has a 25-mm barrel length. After their implantation, the lag screw and the plate are joined with a connecting screw, making the two components work as one unit (see Figure 76-31, *F*). Tightening of the connecting screw creates interfragmentary compression, provided the lag screw has passed the fracture line.

The DHS plate is the strongest plate available from Synthes.[73] The DCS and DHS plates are versatile, rapidly implanted, and a real asset to large animal surgery, especially when treating long bone fractures in adult horses.[76,77] The DCS system is useful in metaphyseal fractures of the MCIII or MTIII (Figure 76-32), the proximal radius, and even the femur. The DHS may be applied for arthrodesis of the metacarpophalangeal joint and in selected femoral fractures.[75] Combined with 5.5-mm screws, these plates produce extremely strong fixations.

Recently, the DCS/DHS plates were upgraded and equipped with combi-holes to allow insertion of locking head screws (see later, under "Locking Compression Plate").

Point contact fixator

The point contact fixator (PC-Fix) plate, which is no longer manufactured, is mentioned here for historical purposes, because it represented the first type of internal fixator developed by Synthes.[77-79] It was manufactured from pure titanium, and it had round, conical screw holes, evenly distributed along the plate, and a specially designed underside that represents a further development of the LC-DCP. One row of points is arranged along either side of the plate, with the points being located between two plate holes. Between two points, the plate is undercut in an arcuate pattern, similar to the LC-DCP but to a greater extent. The short unicortical screws contained a conical head that locked in the plate hole while being tightened, forming a solid unit between plate and screws, without applying any load onto the screw threads (Figure 76-33). The first clinical tests conducted with the PC-Fix were done on large animals, mainly cattle (Figure 76-34).[80] The subsequently developed PC-Fix II was manufactured only as a 3.5-mm implant system. It had a slightly altered plate design and was applied with self-tapping screws.[81] A special plate-bending device was developed to prevent altering of the plate holes during bending. Development of this system led to the next generation of titanium implants: the LISS, which is described next.

Less-invasive stabilization system

The less-invasive stabilization system (LISS) consists of forged titanium plates, manufactured for the bones and sides of the bones (lateral versus medial aspect) to which it will be applied. The plates cannot be bent and are applied to the bone with self-cutting, self-tapping titanium screws of predetermined length. The shape of the plate is predetermined and forged accordingly.[49,82] A guide system for transcutaneous insertion of the screws is mounted on the plate head (Figure 76-35, *A*). This bar also facilitates insertion of the plate through a small surgical incision at one end of the bone and subsequent advancement of the plate along the periosteum, therefore bridging the approximately reduced fracture. Once in place, the last plate hole is approached through a stab incision and connected

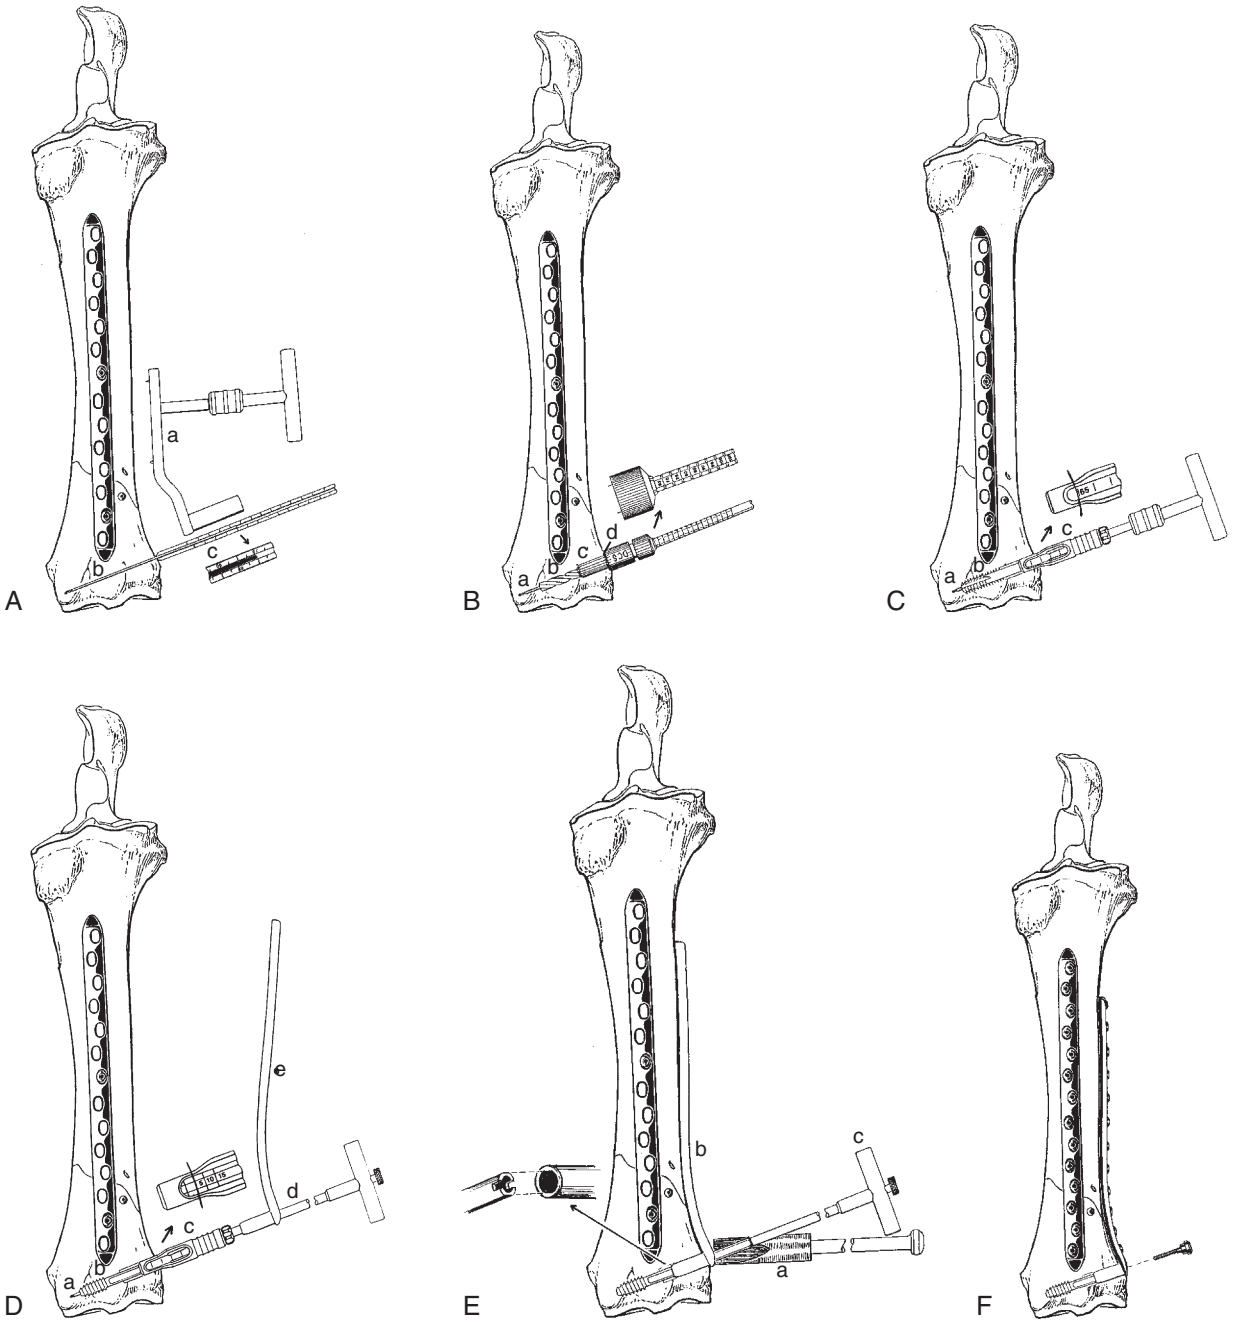

Figure 76-31. Application of an LC-DCP and a dynamic condylar screw (DCS) plate to a radius fracture. **A,** The fracture is initially repaired with two interfragmentary 3.5-mm cortex screws, applied in lag fashion. Subsequently, a 14-hole LC-DCP is applied to the cranial bone surface (tension side) under compression. The guide pin *(b)* is applied through the special drill guide *(a).* The measuring device *(c)* applied over the guide pin allows determination of the length of the pin inserted in the bone (70 mm). **B,** The DCS triple reamer is assembled and set for the 65-mm drilling depth, which is 5 mm less than the pin length in the bone and ensures maintenance of the pin during DCS screw insertion. The triple reamer is placed over the guide pin *(a)* and the shaft hole for the DCS screw *(b),* the barrel hole for the plate *(c),* and the barrel–plate junction *(d)* are prepared. **C,** The DCS centering sleeve *(c)* is placed over the tap *(b),* which is subsequently placed over the guide pin *(a).* After inserting the centering sleeve into the barrel hole, the tap is advanced to the desired depth (65 mm). **D,** The DCS coupling screw *(d)* is placed through the T-handle and the DCS plate *(e)* is selected (12-hole) and connected to the DCS screw *(b)* of the desired length (60 mm). The centering sleeve *(c)* is applied over the coupling screw. After placing the assembly over the guide pin, the screw is inserted to a depth of 65 mm, which is marked on the centering sleeve as 5 mm. **E,** After tightening the screw and adjusting the horizontal bar of the T-handle parallel to the long axis of the bone, the DCS plate is seated over the shaft of the DCS screw with the help of the DCS impactor *(a)* and a mallet (not shown). Orientation of the instruments and implants is important, because the DCS screw *(left insert)* and the plate barrel *(right insert)* contain complementary parallel contours, which have to be aligned to allow sliding of the barrel over the screw shaft. **F,** The DCS compression screw is inserted through the plate barrel, inserted into the back end of the DCS screw, and tightened. This unites the three components (DCS screw, DCS plate, and connecting screw) into one unit. Insertion of all remaining screws and tightening of them completes the procedure.

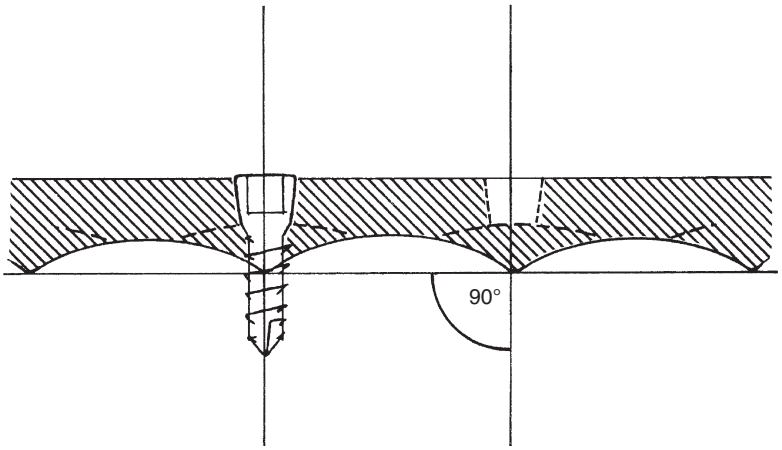

Figure 76-33. Side view of PC-Fix. The arcs under the plate are easily recognized and lead to the points in contact with the bone. The unicortical screws are implanted perpendicular to the long axis of the plate, where the conical screw heads lock within the plate holes. This is an internal fixator. The plate is applied over the periosteum.

through the last hole in the aiming device with a drill sleeve, which is threaded into the plate. This establishes a solid frame, which maintains its angles during screw application and ensures that the screws are inserted orthogonal to the long axis of the plate so that they may be threaded into the plate holes. The remaining screws are inserted transcutaneously through stab incisions. An anatomic plate–bone interface is not important, because the screw heads interlock with the round, threaded plate holes, establishing a solid internal fixator. If the correct implant is selected, implantation of the system is efficient. This system is especially well suited to foals. A successful fixation has also been accomplished in a tibial fracture in a calf (see Figure 76-35, *B* and *C*).[83]

Locking compression plate

The locking compression plate (LCP) is an implant system that combines the two treatment methods in one implant: compression plating and internal fixation.[84] The LCP was developed to include the axial loading capabilities of the DCP and LC-DCP, the decreased plate–bone contact of the LC-DCP, and the rigidity and stiffness of the LISS, where locking screws were first used.[82,84] The goals were met by designing a combi-hole where either a standard screw or a locking screw can be inserted. It is not necessary to only apply locking head screws.[85] An *in vitro* study comparing the application of two LCPs at right angles to each other with identical constructs using DCPs, LC-DCPs, and the clamp-rod internal fixators (CRIFs) in four-point bending showed that implanting two locking screws on either side of an oblique saw-cut across the artificial bone composite (Canevasit) provided significantly increased stiffness to the construct.[86] Because the strength of a screw depends mainly on the core diameter and not thread width, the thicker core of the locking screws and the thin threads make the screw several times stronger than the conventional cortex screws.[79]

The LCP uses a combi-hole, which is a combination of a DCU and a LISS hole (see Figure 76-20). The surgeon may select the type of screw to be inserted at any given place—either a 4.5-mm or a 5.5-mm cortex screw (or even a cancellous screw) at an axial angle up to 40 degrees, or a 4.0-mm or 5.0-mm locking head screw with a thick core and thin threads and

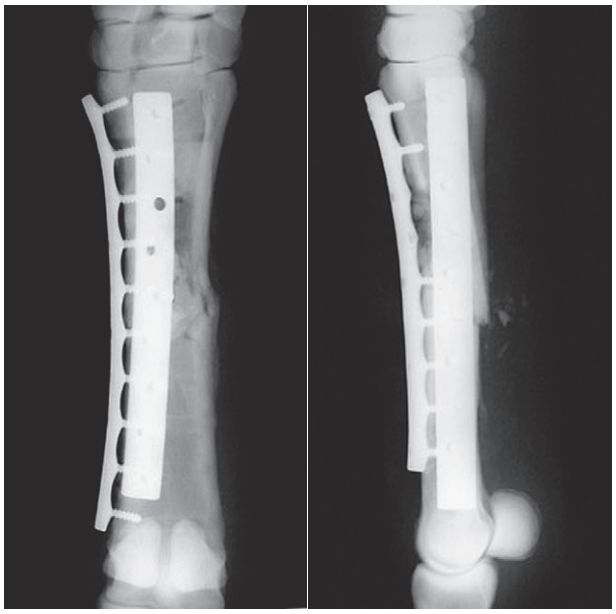

Figure 76-34. Two PC-Fix plates are applied at right angles to each other in a comminuted and open third metacarpal fracture in a horse. Note the different configurations of the plates and the unicortical screws. With time, the empty spaces under the plate filled with bone.

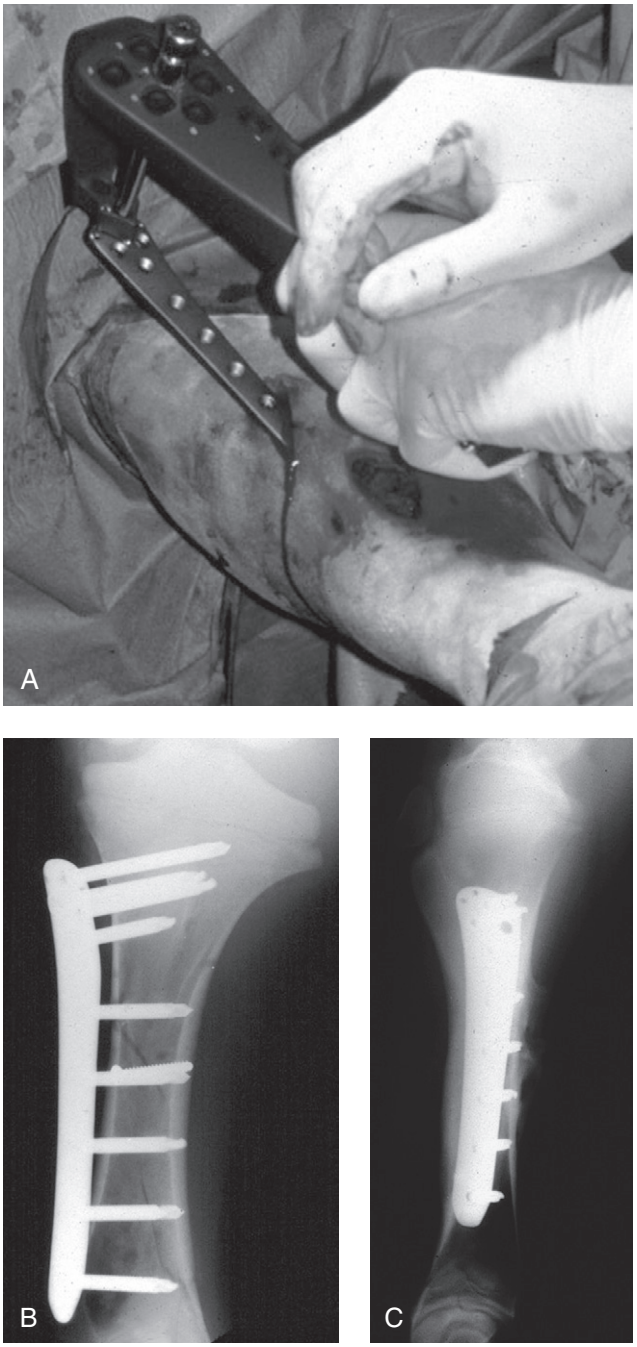

Figure 76-35. A, A less-invasive stabilization system (LISS) is inserted through a small proximal incision to repair a tibial fracture. **B** and **C,** Postoperative radiographs show the plate attached to the bone, but only the screws make contact with the bone. The fracture healed without problems.

additional threads at the screw head (Figure 76-36). The locking head screw, however, has to be inserted orthogonal to the long side of the plate. The original plate contained two beveled ends to allow insertion through a small incision and sliding of the plate along the periosteum of the fractured bone. Because the locking part of the combi-hole is positioned toward the center, insertion of a locking screw next to an articular surface left the bevelled tip extended over the joint. This led the veterinary specialists to modify the plate. Together with Synthes, the plate was redesigned with a pointed, bevelled tip at one end and a rounded edge at the other end. The plate has a slightly oval stacked hole, allowing insertion of either a locking head screw (the hole contains threads) or a cortex screw, the latter of which could be slightly angled away from the joint (Figure 76-37). A special tissue spreader has been developed to prepare the future plate bed. The thin beveled end separates the soft tissues from the periosteum. After the plate is contoured with the help of the intact contralateral bone, it can be fixed to the bone via a minimally invasive procedure. It is inserted through a small incision at one end of the bone, and the screws are then placed transcutaneously through stab incisions.

By substituting cortex screws through some holes, costs can be significantly decreased without jeopardizing the stability and stiffness of the construct. Without application of the push-pull device (Figure 76-38) or standard cortex screws, both of which press the plate onto the surface of the bone, a gap of 2 mm will be present between the plate and the bone after its application. Therefore a basic decision has to be made at the onset of any LCP application regarding whether the plate has to be in close contact with the bone or not. In horses, it is desirable to have close contact between the bone and the plate to increase friction, which further stabilizes the construct.

Once the fracture is anatomically reduced and stabilized by cortex screws placed in lag fashion, the first plate is positioned with the plate holder, and the push-pull device is inserted at a slight angle through the DCU portion of the combi-hole (Figure 76-39, *A*). By turning the piston clockwise, the plate can be pressed onto the bone surface. At the same time, it temporarily fixes the plate to the bone. A second such device can also be applied through the stacked combi-hole on the other end of the plate, if desired. Next, all the strategic cortex screws are inserted and tightened to facilitate axial compression (if deemed necessary) and solid bone–plate contact at both ends of the bone

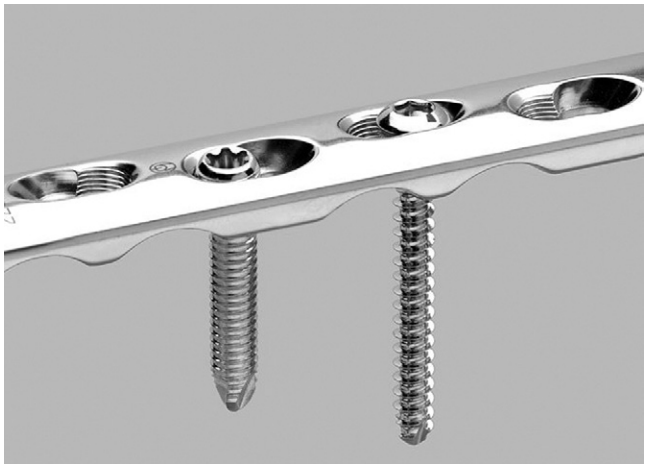

Figure 76-36. A narrow LCP shown with a 4.5-mm cortex screw and hexagonal drive *(right)* as well as a 5.0-mm self-tapping locking screw with a stardrive *(left)*. (Courtesy Synthes Vet, West Chester, PA.)

Figure 76-37. A 10-hole veterinary LCP. The plate has one rounded end containing a stacked combi-hole through which either a locking head or a cortex screw can be inserted. The other end has a tapered and pointed tip that facilitates minimally invasive plate insertion. Note that the DCU parts of the combi-holes are arranged on both sides of the center of the plate toward the ends, whereas the threaded parts of the combi-holes point toward the center. (Courtesy Synthes Vet, West Chester, PA.)

(see Figure 76-39, *B*). After removal of the push-pull device and the plate holder, the second plate is applied at a 90-degree angle to the long axis of the first plate, using the same technique (see Figure 76-39, *C*). Next the locations where the locking screws will be implanted are selected to avoid contact with interfragmentary screws and the cortex screws of the other plate. Planning how screws are to be inserted is very important, even more so when LCPs are applied, because the locking screws *must* be inserted perpendicular to the plate. Screw position is different if a locking screw or a cortex screw is used through a combi-hole, which represents additional complexity when planning the surgery. Further complications arise if an original DCS containing mainly DCP holes and an LCP are combined, because the hole lengths and their spacing along the two plates differs. As mentioned before, the DCS is now available with combi-holes. Once locking screws are applied, the plate is solidly fixed in its position.

The LCP drill guide is carefully twisted into the threaded part of the combi-hole at a right angle to the long axis of the plate. To facilitate perpendicular insertion and subsequent solid engagement of the threads in the plate hole, the drill guide is placed onto the combi-hole and then twisted backward until a click is heard, which happens when the drill guide slips from the upper thread onto the one just below it. Then the drill guide is twisted forward to engage the threads of the combi-hole. When the drill guide is solidly seated, its position relative to the plate is evaluated once again, ensuring its perpendicular orientation. All the LCP drill guides provided in the set can be fixed

Figure 76-38. The push-pull device, which presses the LCP into close contact with the bone, resulting in increased stability of the construct. (Courtesy Synthes Vet, West Chester, PA.)

to the plates to speed up the procedure. Once their position perpendicular to the long axis of the plate and parallel to each other is confirmed, all the holes are drilled (see Figure 76-39, *D*). The drill guides are removed, and the screw lengths are determined using the depth gauge. The 4-N torque-limiting device is attached to the power drill followed by the insertion of the power attachment of the stardrive. By pressing the screwdriver into the stardrive indentation of the LCP screw in the rack, the correct screw is selected and inserted into the predrilled hole using a power-tapping technique. The screw is fully inserted until the torque-limiting device is idling in the plate hole, meaning that the 4-N insertion force has been reached. This precautionary step was initially introduced in human surgery to prevent cold welding between the titanium plate and screws. Because stainless steel is predominantly used in equine surgery, the danger of cold welding is circumvented. Nevertheless the use of the torque-limiting device is encouraged. Equine bone is hard, and if long screws are inserted, the 4 N threshold may be reached before the screw head threads are completely engaged in the plate. It is therefore prudent and good technique to complete final tightening with the hand screwdriver (see Figure 76-39, *E*).

Once all locking screws in the first plate are implanted, the same procedure is repeated in the second plate (see Figure 76-39, *F*). Any empty plate holes in both plates are filled by applying a cortex screw through the DCU portion of the combi-hole at the angle necessary to prevent contact with screws in the other plate.

Because the threads of the screw head and the threads in the plate are solidly intertwined, they form a unit. This prevents the screw head from moving within the plate hole if certain strains are applied, which significantly increases the stiffness of the construct. All the locking screws applied to a plate feel very solid, because the threads in the screw head engage the corresponding threads in the plate. This does **not** mean that the screw is solidly inserted in the bone underneath the plate. This is a new experience for the surgeon and must always be kept in mind. Under certain circumstances, it may be difficult to twist the drill guide perpendicularly into the threaded portion of the combi-hole, because major muscle bellies may be in the way. In these occasions, separate stab incisions through the muscle bellies are necessary to access the combi-hole at a right angle. The drill guides can be extended by threading one on top of the other, and in doing so, attain correct engagement in the plate and correct position for drilling.

The LCP has, in a short period of time, established itself as the preferred plate of equine fracture fixation despite its higher costs, mainly caused by the screws.[87] A recent study comparing 4.5-mm LCPs with 4.5-mm LC-DCPs confirmed the superior strength and stiffness of the LCP.[88]

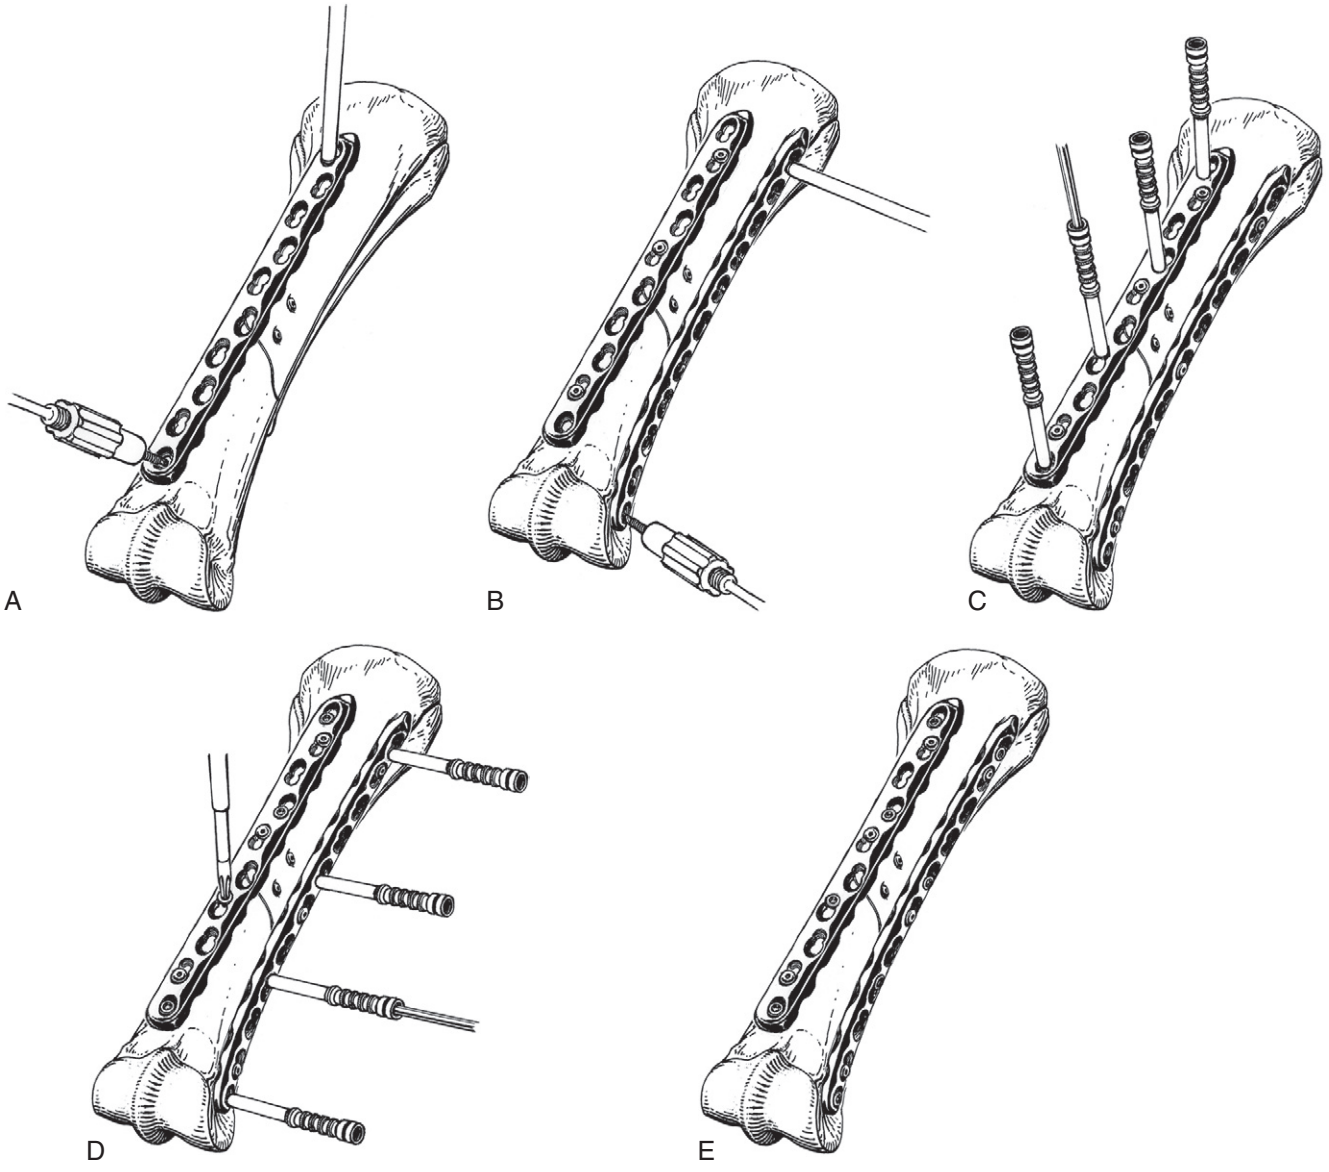

Figure 76-39. Application of two LCPs to an oblique midshaft third metacarpal fracture. **A,** The fracture is reduced and stabilized by the two 3.5-mm cortex screws applied in lag fashion. A 10-hole broad veterinary LCP is applied to the bone with the plate holder and temporarily fixed in place with the push-pull device. By turning the piston clockwise *(arrow),* the plate is pressed onto the bone surface. **B,** To facilitate good plate–bone contact along the entire plate, cortex screws are implanted and tightened using plate screw technique at both ends and in the center near the fracture. Once in place, the lateral 11-hole narrow veterinary LCP is applied to the bone using the same technique. Note that the plate can be applied farther distad on the lateral aspect of the bone than on the dorsal aspect. **C,** Next the holes where locking screws are to be inserted are selected and the drill guide is twisted into the threaded portion of the combi-hole. Because the plate is solidly fixed to the bone, all four drill guides provided in the set are applied, followed by drilling all four holes. **D,** The locking head screws are inserted and tightened. The four drill sleeves for the locking head screws are then placed into selected plate holes, making sure that screws can be placed perpendicularly without interfering with previously inserted implants. **E,** All the remaining plate holes are filled with cortex screws inserted using the plate screw technique. Where indicated, lag technique is applied to increase interfragmentary compression.

Because of the rapidly increasing popularity of locking plates, a 5.5-mm LCP especially designed for equine fracture repair has been developed. Again, this plate was tested in an *in vitro* study against the 4.5-mm LCP.[89] The 5.5-mm LCP was superior in resisting static overload in palmarodorsal four-point bending and cyclic fatigue testing. These results were superior to those achieved with the 5.5-mm LC-DCP. Taken together, these findings have established the 5.5-mm LCP as the premier equine plate for long bone fracture fixation and arthrodesis of the metacarpo- or metatarsophalangeal joint.

The human femoral LCP is ideal for lateral application to the equine radius. This bone has a slight craniocaudal curvature when viewd from the side. It is therefore not possible to apply a straight plate to its lateral aspect and span the entire bone. Either the middle holes are behind the bone or the proximal holes are in front of the bone. The human femoral LCP has a slight bend that matches the equine radius perfectly. The ideal combination is a 5.5-mm equine LCP applied cranially and a human femoral LCP applied laterally (Figure 76-40). The implants are available in stainless steel in all sizes (see Table 76-2).

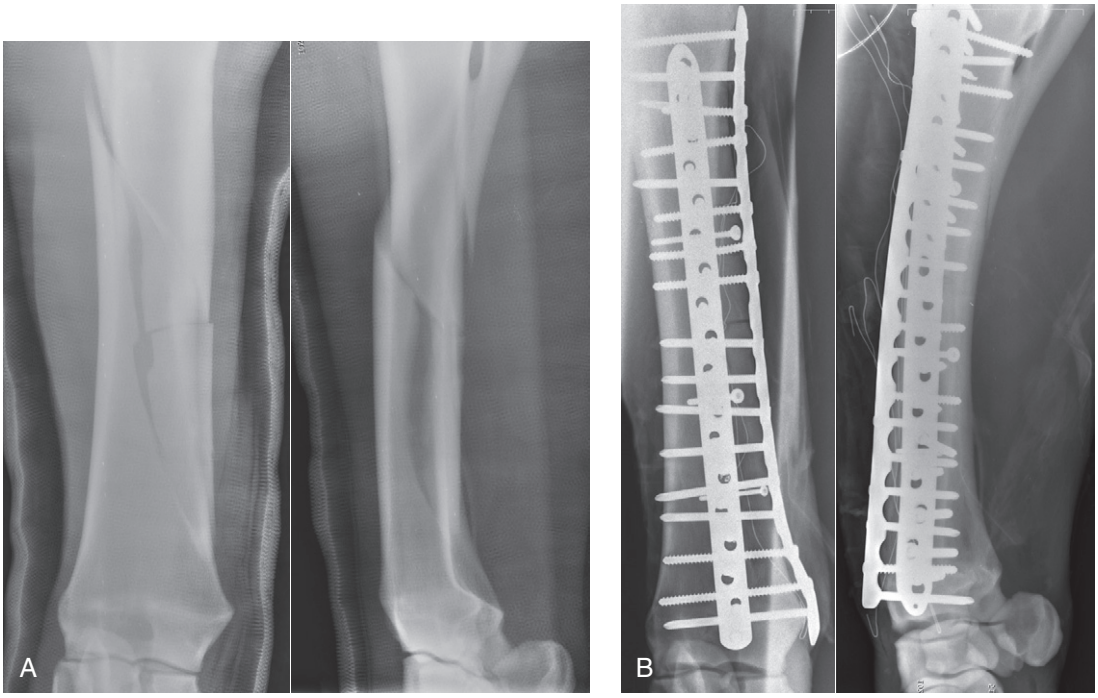

Figure 76-40. Preoperative **(A)** and postoperative **(B)** radiographs of an oblique, spiral radial fracture. The fracture was repaired with a 17-hole 5.5 mm veterinary LCP cranially and a 17-hole 4.5-mm human femoral LCP (a slightly axially bent plate) laterally.

A, The top portion of a variable angle LCP (VA-LCP) demonstrating the angles a screw can be inserted through the holes. **B,** Close-up side view of the screw head, depicting its threads on the rounded head and the stardrive design for the screw driver. (© by Synthes Inc, West Chester, PA.)

Because of the disadvantages posed by the need for locking head screws to be inserted perpendicular to the long axis of the plate, attempts were made to develop a locking mechanism that allows the insertion of locking head screws at various angles. Thus the variable angle LCP (VA-LCP) was created. Screws can be angled anywhere within a 30-degree cone around the central axis of the plate hole (Figure 76-41, *A*). The plate hole has a cloverleaf shape (see Figure 76-41, *B*) containing four threaded ridges, where the specially constructed screw head can interlock with the plate. The head of the variable angle locking screw is rounded to facilitate various angles within the locking hole (see Figure 76-41, *C*). A special double drill guide has been developed that facilitates drilling of the variable angle screw holes on one side and fixed angle drilling on the other (Figure 76-42). The nozzle of the drill guide inserts coaxially into the central hole. In contrast to standard drill guides, which support the drill bit along its entire length, the funnel shape of the angle screw hole guide allows the drill bit to glide along the guide wall at a 30-degree angle in any direction selected (Figure 76-43). The first application of these holes was implemented in the 2.4-mm Variable Angle LCP Distal Radius System (Synthes Inc.) for humans. The plate is anatomically contoured to the volar aspect of the distal radius and is designated to address both simple and complicated fractures. If this plate hole design

Figure 76-42. Double drill guide: left for fixed-angle drilling, right for off-axis drilling. (© by Synthes Inc, West Chester, PA.)

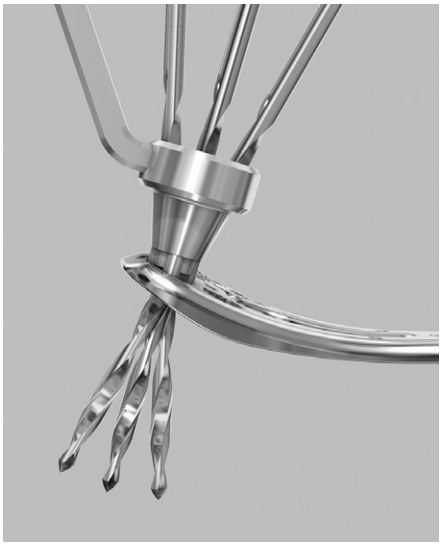

Figure 76-43. The off-axis drill guide is coaxially inserted into a plate hole. With the drill bit leaning onto the side-wall of the drill guide, total angles of 30 degrees can be achieved through the same plate hole in all directions. (© by Synthes Inc, West Chester, PA.)

is considered an improvement in human surgery, it will hopefully be applied to other locking plates.

The LCP is the ideal plate for the veterinary surgeon. It can be applied in the same manner as a DCP with only cortex screws. Because the plate possesses the same type of undercuts as the LC-DCP, it can be used as such. In other words, the LCP fulfills all the desired demands and by purchasing only LCPs the veterinarian can reduce the armamentarium considerably. The price of the LCP is slightly higher than the DCP and LC-DCP and therefore costs are not a problem. So all the veterinary surgeon needs to decide is whether to apply cortex screws, locking head screws, or a combination thereof.

Addendum

Thorough knowledge of the basic principles of internal fixation and familiarity with the instruments and numerous implants are prerequisites for successful surgery. Everyone interested in treating long bone fractures should complete a basic and advanced AOVET course on internal fixation.

CERCLAGE WIRE

Cerclage wire is used frequently in humans and small animals.[90,91] Tension band fixations with pins and wire are often carried out in dogs and cats. Cerclage wires are also applied around oblique long bone fractures in small animals. Also, this type of fixation has been used with small Steinmann pins to temporarily stabilize comminuted long bone fractures before plate and lag screw application.[3] Application of cerclage wire in equine long bone factures has not been successful because of a lack of stability and breakdown of the fixation. However, cerclage wires may be applied in a few situations. Proximal sesamoid fractures have been successfully treated with cerclage wires,[92] but this technique was recently abandoned because of unsatisfactory long-term results.

One frequent application of cerclage wire is growth retardation surgery, even though the wire is not applied in cerclage fashion (see Chapter 86). Cerclage wires have been used to treat nondisplaced ulnar fractures in foals.[93,94] The wires are passed through holes placed in the frontal plane across the proximal and distal fragments of the ulna. A small loop created before entering the hole in the distal fragment allows even tightening on both sides of the bone after the wire is applied in figure-of-eight fashion, and the ends are twisted together. This type of fixation results in reduced trauma to the ulna and radius, and it prevents inadvertent fixation of the ulna to the radius, which can occur when using a plate in a young foal. (This may induce subluxation of the cubital joint.) A total of three or four figure-of-eight wires are applied.

Cerclage wire is used in arthrodesis of the fetlock joint.[95] In comminuted fractures of the proximal sesamoid bones associated with complete breakdown of the suspensory apparatus, a tension band is inserted in figure-of-eight fashion through the palmar/plantar aspect of the metacarpophalangeal joint, before applying the dorsal plate (see Chapter 81).[95]

One frequent application of cerclage wires is their use as a tension band to manage mandibular and maxillar fractures (see Chapter 102).

Wire tightening is carried out with utmost prudence. Initially, the wires are loosely twisted by hand. Then, with a pair of flat pliers, the two ends are grabbed, pulled at a right angle away from the bone, and, while decreasing the pulling force, evenly twisted around each other. Care must be taken not to twist one wire end around the straight end of the other wire (this type of fixation slips off under tension). Overtightening may result in wire breakage and breakdown of the fixation.

CABLES

Two types of cables have been introduced into orthopedic surgery as treatment modality for specific fractures. Ultrahigh-molecular-weight polyethylene (UHMWPE) cable has been tested in an *in vitro* model for the repair of proximal sesamoid bone fractures and compared with the commonly used stainless steel cerclage wire (SSCW).[96] The ultimate tensile strength of UHMWPE cable constructs was 34% greater than that of SSCW constructs. Fatigue strength was 2 to 20 times greater for UHMWPE cable constructs than for SSCW constructs. Separation of fragments was 153% less for limbs repaired by the cable construct compared with those repaired by the transfixed cerclage technique.[96] These cables may also be beneficial in the use of fetlock breakdown injuries as a palmar figure-of-eight tension band.

Another type of cable consists of multiple woven stainless steel, titanium alloy, or cobalt chromium alloy strands. It is available as 1.0- and 1.7-mm-diameter cables, consisting of a central bundle of 19 strands surrounded by eight outer bundles of seven strands each. It is designed to be used with all Synthes stainless steel and titanium plates. Specially designed positioning pins are used in empty plate holes, and the cable is threaded through an oblong hole in the pin. Once the cable is tightened,

the pin cannot move because it is pressed into the plate hole and therefore confined. A special tensioning device is used to tighten the cable before it is crimped with a cable crimper. Care should be taken to not exceed 50 kg of tension. Applying tension at levels higher than 50 kg may cause the cable to cut through soft or osteopenic bone (which is not a problem in horses). This product is used mainly in human orthopedic surgery in the management of periprosthetic fractures in elderly adults, where other internal fixation devices are not successful.[97] Additionally, it is used as a tension band in the management of patellar fractures and olecranon osteotomies. Indications for these cables in horses are similar to those for the UHMWPE cables. Recently these implants were adopted for mandibular fractures (see Chapter 102).

PINS

Steinmann pins

Steinmann pins are rarely used in fracture treatment in horses, mainly because they do not provide stability.[97] They are used as transfixation pins in conjunction with external coaptation (see earlier discussion).

Intramedullary application of Steinmann pins is used only in humeral fractures in foals.[98] Multiple pins are introduced parallel to each other to fill the entire medullary space at its isthmus at the distal third of the bone. This "stacked-pin" method is presently the treatment of choice in these fractures. For additional stability, these pins may be encircled by cerclage wires and placed into the medullary cavity, possibly through a cortical defect or a drill hole. The wires are subsequently tightened. In cases with a cortical defect, the cerclage may also be applied intramedullarly. The advantage of the stacked-pin method is an increase in rotational and bending stability. A single pin provides no rotational stability. Collapse of the fracture along the single pin is a frequent complication.

Application of multiple pins across a capital femoral physeal fracture has been advocated and has met with some success. Steinmann pins have also been used in the treatment of olecranon fractures in the very young foal in combination with a tension band made of multiple cerclage wires.[96]

Rush pins

The Rush pin method of fracture treatment was popular before bone plating was introduced. Fracture fixation using these devices is an art.[99] The slightly prebent pins are introduced obliquely into the distal fragment and advanced toward the opposite cortex. The tip, which is flattened on one side, slides off the opposite cortex and is redirected toward the cis-cortex. The pin length has to allow the tips to engage in the cis-cortex both proximally and distally to the fracture, providing four-point contact. Usually two pins are introduced, one from each side of the bone. When performed correctly, rotational stability is achieved with a minimum of implants and surgical trauma. The Rush pin fixation technique is not applicable to comminuted or open fractures.

NAILS

Intramedullary nails have a place in equine long bone fracture repair, but the ideal implant has not been developed despite recent efforts.[10,43] Initially, intramedullary nails manufactured for human application were tried in equine fractures with mixed success.[100] For example, in two reports, a solid titanium nail was inserted through the middle carpal joint after removing the articular cartilage of the middle carpal and carpometacarpal joints.[101,102] The joints were fused to facilitate solid fixation. Transfixation was achieved with 4.5-mm screws inserted through the proximal aspect of the nail. Although good results were achieved, the fact that the joints had to be fused to facilitate healing of MCIII was undesirable. These fractures can heal with plating techniques without fusing a joint.

A system of intramedullary interlocking nails (IINs) has been developed for equine humeral and femoral fractures (Figure 76-44).[103-106] Comparison of this method of fracture repair to fracture plating has met with mixed results in experimental studies. A cadaveric *in vitro* biomechanical study on immature equine femurs revealed that a diaphyseal osteotomy fixed with two DCPs at 90 degrees to each other provided superior strength and stiffness compared with an IIN and a construct of an IIN and cranially applied DCP.[104] In another *in vitro* study on osteotomized tibias, a construct composed of a 16-mm stainless steel nail with a wall thickness of 4 mm and four 8-mm interlocking screws was compared with a human unreamed femoral interlocking nail (UFN) and to tibias treated by means of double plating.[107] The interlocking nails achieved similar loads until failure, but the plates demonstrated higher yield loads. *In vitro* cadaveric studies tested several interlocking nail configurations in MCIII and femurs in foals and in MCIII with and without a gap in adult horses.[108-110] All constructs were weaker than the intact bone, and the parallel alignment of the holes for the interlocking screws were stronger than the offset screws.[109] One study compared IIN with a combination of an IIN and a DCP and with two DCPs in a 1-cm gap model in foals, showing the double-plating construct to be closest to the intact bone in most aspects, followed by the combination and the IIN alone.[107]

Several application principles have been advocated in foals for the presently used equine IIN.[111] The location and configuration of the fracture significantly affects the ultimate outcome of the repair. If possible, three interlocking screws should be inserted on either side of the fracture. Fractures near the epiphysis are less readily stabilized with an IIN, and the epiphyseal segment is at an increased risk for secondary fracture through the interlocking screw holes. In these instances, some type of supplemental fixation is desirable to decrease the potential of catastrophic failure of the fixation. In long oblique fractures, the IIN should be positioned to allow one or two interlocking screws placed in lag fashion across the fracture plane, if possible. In a nail–plate construct, the plate is applied 90 degrees to the interlocking screws. Whenever possible, bicortical screws are inserted through the plate.

A lateral approach is used to expose the fractured humerus and femur. Before reduction, the fracture is débrided and the medullary cavity of the distal fragment is reamed. Reaming is accomplished with rigid reamers of increasing size to arrive at an ultimate hole diameter of 13 mm. This procedure destroys the intramedullary blood supply and slows healing. Unreamed intramedullary interlocking nails have not been successfully applied in living horses. Additional exposure is usually necessary to provide access to the proximal end of the bone for normograde reaming of the proximal segment. After both fragments are reamed, the fracture is reduced and held in that position with bone clamps. A nail of appropriate length is chosen, and with the targeting jig attached, the nail is inserted into the reamed medullary canal. Washers are used to prevent the conical heads of the cortex screws from penetrating the cortical bone.

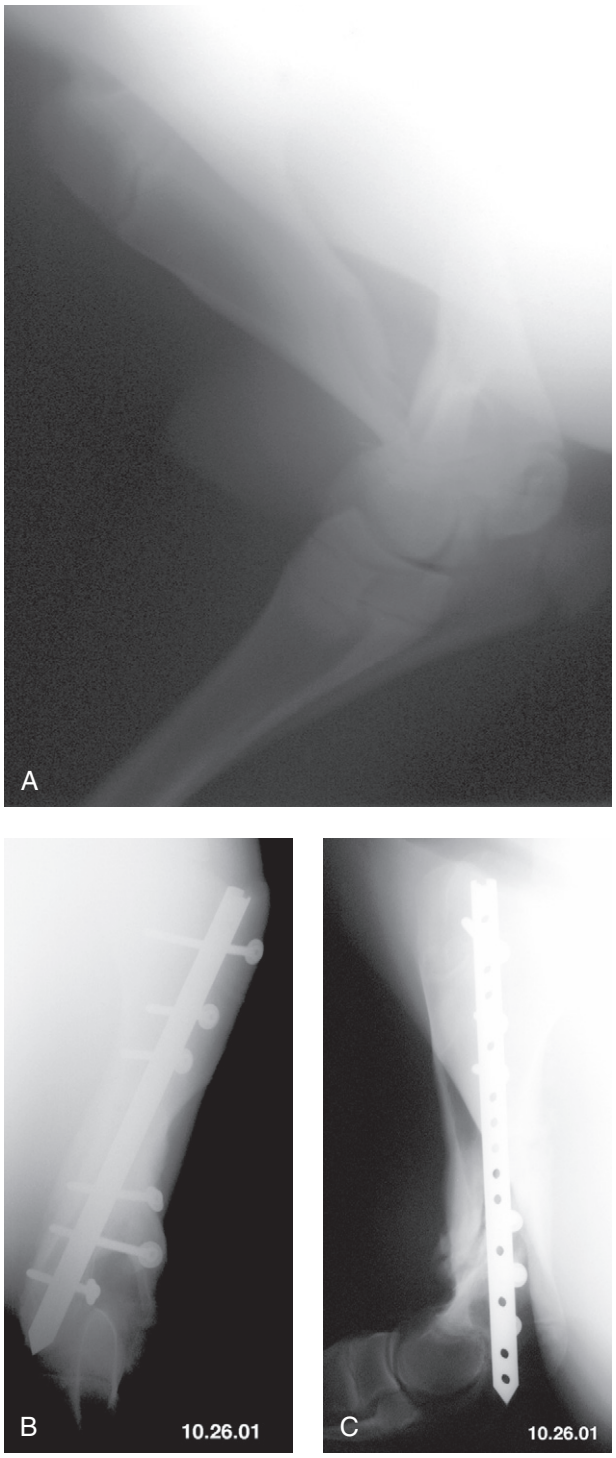

Figure 76-44. This long oblique humeral fracture **(A)** was treated with an intramedullary interlocking nail. To provide a greater screw–bone contact area, washers were used. The craniocaudal **(B)** and lateromedial **(C)** 2-month follow-up radiographs show progressive bone healing in the fracture gap. Bone length is maintained. (Courtesy J. P. Watkins, Texas A&M University.)

A successful result was achieved with an IIN in 5 of 10 foals with humerus fractures; the foals ranged in weight from 136 to 204 kg. They attained athletic soundness and performed their intended purpose without complications. Three out of three neonates with femoral fractures healed after IIN fixation. Four out of six older foals with short oblique femur fractures also were successfully treated in this manner. In these foals, a DCP was applied to the cranial aspect of the bone in addition to an IIN.

AFTERCARE

After fracture fixation with any of the internal fixation devices and techniques described here, overlying soft tissues and skin are closed in routine fashion. The use of of continuous suture patterns is advocated to reduce surgery time. Depending on the type of fixation and the technique of recovery from anesthesia, application of some type of external coaptation may be considered, because the animal has to be able to get up and place weight on the limb immediately after surgery. If a pool recovery is implemented, the limb and skin incision is in most cases protected only by a plastic adhesive sheet (Ioban 2) after applying cyanoacrylate superglue to the skin incision. This sheet is covered with elastic adhesive tape (Elasticon), which is exchanged for a regular bandage or splint bandage after successful recovery from anesthesia (see Chapter 21).

External coaptation may consist of a fiberglass cast or a heavy splint bandage (see Chapter 17). Depending on the type of fixation, external coaptation is maintained for a few days to weeks. A fiberglass cast can be applied over a bandaged limb, and after the cast has cured, it can be split in half along the frontal plane. These "half shells" are reapplied using nonelastic adhesive tape. Such coaptation allows evaluation and, if necessary, wound management of the limb underneath. The unaffected contralateral limb should be protected and supported by a pressure bandage. In young foals, too much support is to be avoided to prevent temporary weakness of the flexor tendons. It is important to keep the patient comfortable with the help of moderate amounts of anti-inflammatory and analgesic drugs. These drugs should be used judiciously to prevent toxic reactions and to allow some residual amount of pain, so the patient will protect the injured limb. If a non–weight-bearing lameness lasts for a prolonged period, other problems develop in the healthy limbs, especially in foals. Therefore close observation of the patient is important until the animal starts to increase weight-bearing on the fractured limb.

Application of a frog pad in adult horses may prevent the development of laminitis in the contralateral foot. Aside from postoperative infection (see Chapter 85), laminitis is the major complication that occurs after fracture repair. Again, administration of anti-inflammatory drugs in moderate amounts may prevent this problem. As early as possible, the animals should be allowed to walk. Although controlled exercise is advocated, free pasture exercise is discouraged. This is especially important if a weight-bearing fixation was performed and the animal is not placed in an external coaptation device. Patients with casts should not be exercised at all.

Implant Removal

Implants are foreign bodies and may have to be removed, particularly in young athletes. Therefore, implant removal depends on the use of the horse, the type of fracture treated, the type of implants employed, and the potential development of complications, including postoperative infection. Lag screws are not removed in horses unless they produce pain or bone reactions. The practice of removing lag screws in young racehorses has gained popularity. Frequently the reason for implant removal is

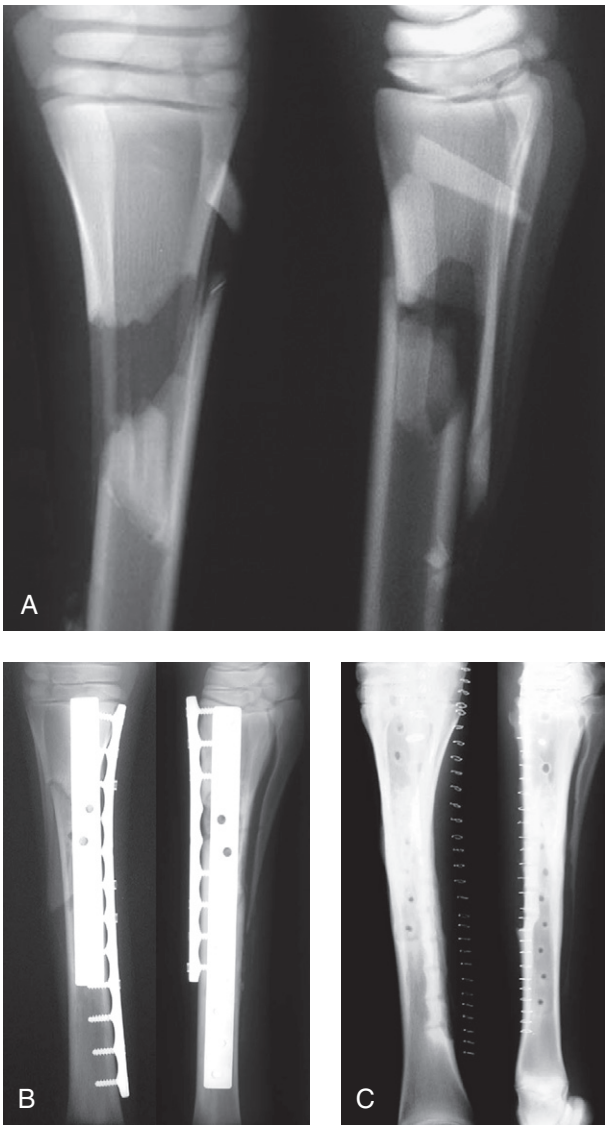

Figure 76-45. A, A 2-month-old Thoroughbred colt was admitted with a comminuted fracture of the third metatarsal. **B,** The fracture was treated with two PC-Fix plates applied over the periosteum, which prevented adequate visualization and resulted in suboptimal fracture reduction. An infection developed, which was managed with parenteral broad-spectrum antibiotics, daily flushing of the surgical site, and local antibiotic application. Within a month, the infection had resolved. Bacterial cultures taken at the time of implant removal revealed no growth. **C,** The healed fracture after implant removal. The foal developed into a successful racehorse.

a request by the owner. Cerclage wire used for fracture fixation does not need to be removed unless the wire breaks, as it does frequently in the treatment of transverse fractures of the proximal sesamoid bones.[92]

Plates applied to long bones of horses should be removed in most cases. This is especially important in foals and if the animal enters or resumes an athletic career. Implants applied to the femur or olecranon and for arthrodeses purposes are left in place. This presupposes that no problems are encountered with the implants.

The time to remove implants after the fracture has healed depends on the age of the animal, the type of fracture treated, and the implants used. In a condylar or stress fracture of MCIII/MTIII, screws may be removed about 2 months postoperatively. Plate removal in foals may be carried out at an average of 4 to 6 months after fracture treatment. Staggered removal of the implants is advocated if two plates were applied, because it reduces the risk of refracturing the bone through one of the screw holes. (Filling the empty screw holes in the bone with a bone graft has been recommended in humans.[79])

An important reason for implant removal is infection surrounding the implants. An infection, once established around implants, persists and does not resolve until after the implants have been removed, even in the presence of broad-spectrum antimicrobials.[38] Fractures can heal in the presence of infection if rigid internal fixation is maintained. However, it is frequently a race between loosening of the implants caused by the infection, and healing of the fracture. Once an infected fracture is healed, the implants are removed to allow resolution of the infection. If the implants are removed too early, before adequate healing of the fracture has occurred, refracture of the bone is likely. In one case, however, where titanium implants were applied to a comminuted open fracture of the proximal MTIII in a Thoroughbred foal, a postoperative infection resolved completely before implant removal (Figure 76-45).

CHAPTER 77

Bone Grafts and Bone Replacements

Jörg A. Auer, Brigitte von Rechenberg, Marc Bohner, and Margarethe Hofmann-Amtenbrink

Biological bone grafts are distinguished from synthetic bone replacements because they come from different sources and require a variety of pretreatments.[1,2] However, the mechanism by which both are integrated into host bone is similar. All grafts are eventually replaced with host tissue by a process called *creeping substitution*.[1,3] Mesenchymal stem cells or osteoprogenitor cells and capillary sprouts from either adjacent bone marrow, periosteum, endosteum, or surrounding soft tissues grow into the porous structure of the grafts. There, stimulated by various local substances, they differentiate into osteoblasts, producing new mineralized osteoid that is deposited either on the bone matrix or on the synthetic ceramic structure. Osteoclasts

precursors are recruited from the vascular system, and they differentiate to facilitate physiologic remodeling of the graft into mature lamellar bone.[1,3,4] Pretreatment of allogeneic or xenogeneic bone grafts is necessary to reduce antigenicity that could lead to graft rejection.[1]

TYPES AND DEFINITIONS

A distinction is made between *fresh biological bone grafts* and preserved ones. A bone graft may be transferred immediately from the donor to the implant site, in which case it is a fresh graft. *Preserved grafts* include specially prepared pieces of dead bone—for example, decalcified, freeze-dried, irradiated, or sterilized bone. In a third category are *synthetic bone replacements*, which consist of ceramics such as tricalcium phosphate (TCP) or hydroxyapatite (HA), but also polymers and composites.[5]

Bone grafts can be classified according to their origin. A graft harvested from one site and applied to another in the same individual is an *autograft*. An *allograft* refers to tissue removed from one individual and given to a genetically different individual in the same species. Tissue transferred between two members of different species is a *xenograft*. If the transferred tissues are applied in an anatomically similar location, the graft is an *orthotopic* graft; if the implantation site is dissimilar, the graft is referred to as *heterotopic*. Bone grafts may be composed of purely cancellous or cortical bone, or they may be composed of a combination—for example, a corticocancellous graft or, in combination with articular cartilage, an osteochondral graft. In equine orthopedic surgery, fresh bone grafts are always autografts. The most frequently used fresh grafts are autogenous cancellous bone grafts, but cortical chips taken from the fracture site, free cortical grafts, and vascularized cortical bone grafts may be used. Free cortical grafts depend on the ingrowth of host vessels for their nutrition, whereas vascularized cortical bone grafts are harvested with their blood vessels to be anastomosed to the local blood supply.

Preserved grafts are pretreated with either freezing alone, freeze-drying, radiation, sterilization, or complete or surface decalcification.[1,6] The process of pretreatment kills viable bone cells, reducing antigenicity considerably, and allows safe and sterile storage of the bone grafts. These grafts are kept in bone banks, which makes them easily available on request.[6,7] Their ease of accessibility prevents the need for a second surgery to harvest the autografts and thus decreases surgery time.

Bone grafts are used most often to facilitate healing after long bone fracture repair, arthrodesis, and comminuted phalangeal fractures in the horse, and autogenous cancellous bone grafts are the most frequently applied type.[8] Therefore the major emphasis in this chapter is on this technique. Bone banking is discussed for the sake of completeness. In humans and small animals, a variety of bone grafts are used, most of which are not readily applicable to the horse.

BONE GRAFTS

Jörg A. Auer, Brigitte von Rechenberg

Bone is the second most commonly implanted material in the human body, after blood transfusion, with an estimated 600,000 grafts performed annually. Although the market for synthetic bone replacements (bone graft substitutes) is more than $1 billion, the sales of bone grafts is still more than half that amount.[9] Reports of autologous bone grafting date back to the ancient Egyptians, yet the modern scientific study of grafting began in the early nineteenth century. Since then, the indications, methodology, and science of bone grafts in patients with nonunion fractures and bone loss have been established and refined, and new methods of harvesting and treatment are being developed and implemented.[9]

Functions

Depending on the type of bone grafts, their main function is osteoinduction or osteoconduction.[1] *Osteoinduction* refers to the local triggering of osteogenesis (new bone formation), whereas in *osteoconduction*, the matrix of the graft acts as a scaffold into which mesenchymal cells grow.[6] In fresh autogenous grafts, osteogenesis occurs partially as the result of the activity of viable osteoblasts aligned on the surface of the living bone graft. Therefore the greater the surface is, the more living cells are available and the greater is the osteogenic activity that is observed. However, up to 90% of living cells die after bone graft transfer, with only the surface cells surviving. Therefore the greater the number of surface cells transferred, the larger is the number of osteogenic cells that survive in the graft bed. As a result of this, loosely arranged cancellous bone grafts are the most desirable in the horse. The number of surviving cells is also influenced by the handling of a graft during surgery, where dehydration and compacting of the graft are to be avoided.[6]

Some systemic influences and local factors, such as local and systemic cytokines, inflammatory mediators, and growth factors, are very important for the mechanism of osteoinduction.[10-12] Cytokines are polypeptide molecules capable of signal transduction in cells through specific surface cell receptors. Inflammatory mediators elicit changes in cell metabolism through activating either cyclic guanosine monophosphate (cGMP) or cyclic adenosine monophosphate (cAMP).[11,13] Cytokines, such as interleukins (ILs) and tumor necrosis factors (TNFs), and inflammatory mediators, such as nitric oxide and prostaglandin E_2, may be produced either by local mesenchymal, fibrous, or vascular tissue cells. On the one hand, these signals attract and recruit undifferentiated mesenchymal cells from the environment to the local area, which differentiate into osteoblasts; on the other hand, they also induce bone biodegradation, facilitating bone graft replacement (creeping substitution). Through the locally invading cells and ongoing bone matrix biodegradation, a myriad of local growth factors are released that allow the mesenchymal cells to proliferate and differentiate. Through various cell generations, the graft undergoes enchondral ossification into woven bone. This bone is replaced later with mature lamellar bone. Growth factors (GFs) involved in fracture healing and graft incorporation are platelet-derived GF (PDGF), fibroblast GF (FGF), insulin-like GF (IGF), transforming GF (TGF), and the bone morphogenetic proteins (BMPs), including osteogenic proteins (OPs).[10] The BMPs and OPs belong to the TGF-β superfamily.[12] Various BMPs are now produced synthetically by recombinant processes with molecular biology technologies and are used to promote graft incorporation.

Research has detected differences in activity of bone marrow cells of different bones and between cortical and cancellous bone.[14] *In vitro* explant cultures of cortical and cancellous osteogenic cells revealed that on average, cortical bone sites yielded significantly greater activity than did cancellous bone sites. Between cortical bone sites, there was no significant difference in osseous activity. Among cancellous sites, the radial cancellous

bone yielded significantly more activity than did the tibial cancellous bone. Among appendicular skeletal sites, tibial metaphyseal bone yielded significantly less activity than did all other long bone sites. This study detected evidence of heterogeneity of equine osteogenic cell populations at various skeletal sites. Further characterization of the dissimilarities is warranted to determine the potential role heterogeneity plays in differential rates of fracture healing between skeletal sites.[14] Differences were also detected in a human study, where iliac and tibial bone grafts were compared in their efficacy in ankle fusion.[15] This histologic investigation revealed that iliac bone grafts contained active hematopoietic marrow, whereas quiescent medullary fat predominated in tibial grafts.

Support, another important function of bone grafts, is mainly derived from corticocancellous or osteochondral bone grafts. These grafts may be transferred as fresh autogenous, vascularized grafts or as allogenous grafts. With allogenous cortical grafts, there are fewer surviving cells than with cancellous bone grafts, and nutrition depends on the formation of new haversian and Volkmann canals and canaliculi, which means it is a slow remodeling process that may take longer than 1 year, depending on the size of the graft.[16] This type of bone grafting is not very important in fracture repair in horses.

The successful incorporation of a bone graft depends on the interplay of the following six parameters[6,7]: (1) the host bed, (2) the viability of the bone graft, (3) the volume of bone to be grafted, (4) the growth factor activity of the host bed, (5) the metabolic activity index, and (6) the homostructural function of the bone graft.

The condition and location of the *host bed* determines the response to osteoprogenitor cells and perivascular connective tissue. Different bones exhibit different fracture healing rates, depending on local blood flow and bone marrow activity. The more viable and uncompromised the host bed, the better the acceptance of the bone graft.

The better the *viability of the bone graft* is, the better the acceptance of the graft. Therefore, cancellous and vascularized corticocancellous or cortical bone grafts may have the greatest chance of acceptance.

The larger the *volume of bone to be grafted,* the longer it takes to become completely incorporated into and remodeled by the host tissue. The longer the time needed for complete incorporation, the greater is the likelihood for development of complications. In large defects, there is a greater need for incorporation of a bone graft with a large surface, such as a cancellous graft. Such a graft demands absolutely rigid internal fixation until structural rigidity is achieved.

Growth factor activity of the host bed and bone graft induces proliferation of perivascular connective tissue, facilitating osteogenesis. Augmentation of the bone graft can be achieved by GFs through recruitment of additional cell populations as well.

The *metabolic activity index* (MAI), which is composed of parameters such as heart rate, blood flow, basic metabolic rate, respiratory rate, and body temperature, is correlated with the capacity to incorporate bone grafts, repair fractures, and respond to local growth factors.[7] The MAI of humans is 1.0, which is close to the MAI of the dog (1.5). The MAI of the horse has not yet been determined. The closer the MAI of two species is, the better is the correlation of the factors influencing bone healing and the more meaningful are comparative studies conducted between them.

The *homostructural function* of a bone graft, such as "spacer" function or support function, together with the fixation technique, influences the incorporation of the graft considerably. It may take years until it is completely incorporated or rejected.[7]

Bone grafts in diffent forms, with or without augmentations, have been studied experimentally or applied in clinical studies with mixed results. The following are some examples. Bilateral augmentations of the sinus floor in six adult sheep with mesenchymal stem cell–augmented bovine bone mineral on one side and autogenous bone in the other side revealed better results on the augmented side.[17] Composite graft material consisting of allogenic cancellous bone combined with autologous red marrow was used in the treatment of fresh traumatic bone defects and chronic nonunions of 38 human patients with good results.[18] The authors judged this combined graft as being safe and effective. In another clinical study reporting on 68 patients suffering from nonunion fractures, autologous bone grafts (47 patients) were compared to homologous grafts (21 patients).[19] No statistically significant differences in the effectiveness and time to bone union were found between recipients of autogenous versus homogenous grafts. One group of researchers added platelet-rich plasma (PRP) to autologous cancellous bone grafts and compared the effects to autologous bone graft alone in an experimental study in minipigs.[20] The results in the PRP group were superior to the control group, even in the semiquantitative assessment of the osseous bridging in both observed areas of the defect. Within the limits of the present study it could be demonstrated that PRP combined with autologous cancellous graft leads to a significantly better bone regeneration compared to isolated application of autologous cancellous graft in an *in vivo* critical size defect on load-bearing long bones of minipigs.[g] From these studies, it can be anticipated that further progress in grafting techniques, especially augmented autologous and homologous grafts, can be expected in the near future.[20]

Surgical Techniques

General Guidelines

It is advisable to use a separate surgical team for harvesting the cancellous bone graft and to plan it so that it can be immediately embedded into the recipient site by the surgeons repairing the fracture.[21] If there is any time lag between harvesting and implantation, the graft should be stored in blood-soaked sponges. It has been shown that exposure to air or to saline-soaked sponges decreases cell survival.[21] Additionally, exposure of the bone graft to antibiotics before and during harvesting is detrimental to survival of the cells.[22]

The bone graft should be lightly packed into the host site (Figure 77-1). Excessive packing should be avoided to allow the host tissues and fluids ingress to nourish the graft. The graft should be exposed as much as possible to bone marrow and endostium of the parent portion of the bone.[1] It is of paramount importance to ensure rigid internal fixation of the fracture in the presence of a bone graft to allow adequate ingrowth of a healthy vasculature. Otherwise, the cells in the bone graft may not survive, as a result of the lack of oxygen, compounded by mechanical damage.[21] Absolute asepsis is a prerequisite for successful application of a bone graft.

Locations

The principal donor sites for cancellous bone grafts in the horse include the tuber coxae (Figure 77-2, *A*), the sternum

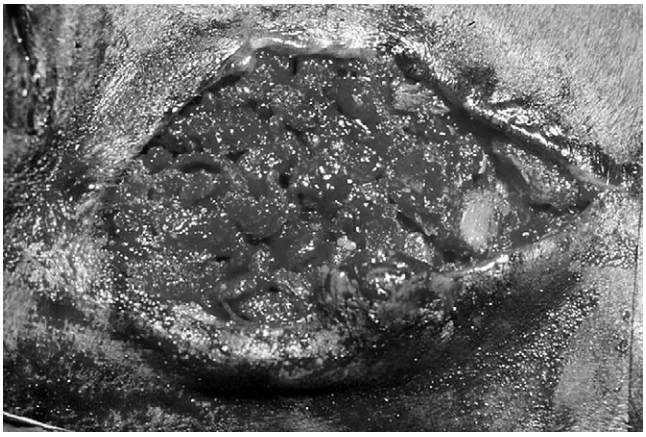

Figure 77-1. A cancellous bone graft placed in a bone defect of the skull.

(Figure 77-2, *B*), and the medial aspect of the tibia (Figure 77-2, *C*). All these sites are easily accessible, and large amounts of (viable) cancellous bone may be harvested.[23] There is little danger of a fracture through a cortex portal in the proximal tibia, provided the holes are appropriately located.[24] Cancellous bone samples from these conventional donor sites were evaluated for the presence of osteoprogenitor cells and compared to samples taken from the fourth coccygeal vertebra and tibial periosteum.[25] Sternal and tibial bone yielded viable osteogenic cells from 25% and 50% of horses, respectively, whereas yields from tuber coxae, coccygeal vertebra, and periosteum were 75%, 100%, and 100%, respectively. Tuber coxae and tibial periosteum had significantly greater numbers of osteoprogenitors compared with the fourth coccygeal vertebra.[25] Although one study proposed the proximal humerus as an additional graft site, it is not recommended as a viable option.[26]

TUBER COXAE

A straight 3-cm (1-inch) skin incision should be made over the tuber coxae, through the fat pad and subcutaneous tissues to the bone (see Figure 77-2, *A*).[27] Using a 5.5-mm drill bit passed through the 5.5-mm drill guide, a hole is prepared across the thin cortex. With the help of a curet, the cancellous bone located within the ilium is harvested in the quantity needed. Care is taken to avoid breaking through the thin inner cortex of the ilium, which could cause complications. If needed, additional holes may be drilled adjacent to the first one at a different angle.

A bone graft–harvesting drill (Figure 77-3) has been introduced. With this device, 4-mm-diameter cancellous bone plugs can be harvested through a stab incision (Figure 77-4). These plugs are an ideal size when implanted into drill holes of the same diameter during arthrodesis of the distal intertarsal joint (see Chapters 81 and 97).

The fat and subcutaneous tissues are closed over the bone in a simple-continuous pattern; an interrupted tension-relieving pattern is used in the skin. In selected cases, the skin may be stapled. A stent bandage, consisting of a gauze sponge rolled up tightly and placed in a longitudinal direction, is sutured over the incision. This bandage protects the skin edges and reduces movement in this region, facilitating skin healing. It might be advisable to cover this area with additional padding, especially during the recovery phase and in horses with a tendency to rest in a recumbent position.

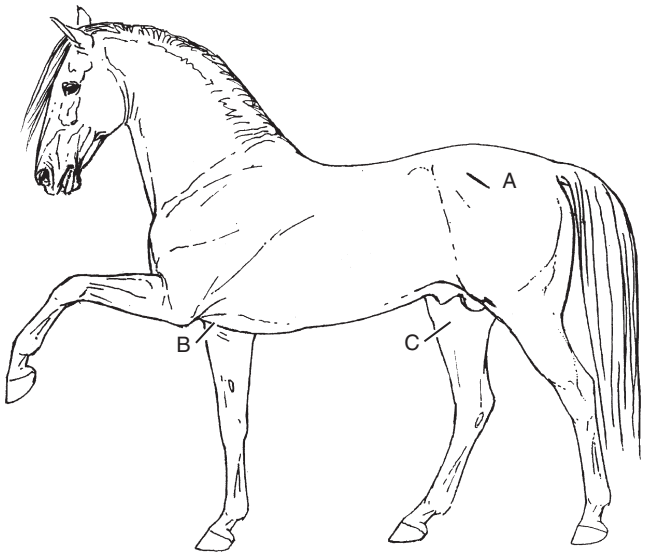

Figure 77-2. Skin incision sites used for harvesting cancellous bone for autologous bone grafting purposes. *A,* Tuber coxae, the most frequently used site. *B,* The sternum, ideal when the horse is positioned in dorsal recumbency. *C,* The proximal and medial aspect of the tibia.

Figure 77-3. The bone graft harvesting drill with 4.0-mm-inside-diameter hollow drill bits is shown being applied to the tuber coxae of an anesthetized horse.

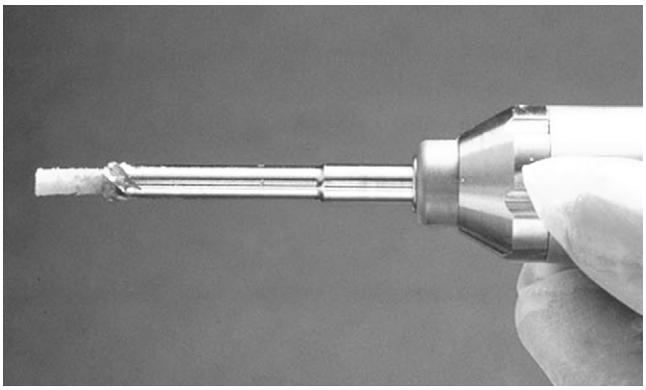

Figure 77-4. A 4.0-mm-diameter cancellous bone plug is shown protruding from the hollow drill bit.

STERNUM

The sternum is an especially advantageous donor site, because, when the animal is placed in dorsal recumbency, access is easy for harvesting (see Figure 77-2, *B*).[28] The sternum may also be approached with the animal in lateral recumbency; however, this is somewhat more cumbersome and the surgeon may have to perform the surgery standing in an undesirable position. Fracture treatment in a forelimb using internal fixation augmented by an autograft of cancellous bone from the sternum would be difficult to perform with two surgical teams working simultaneously, because of the proximity of the two surgical incisions.
