This is the most suitable technique for the rare cases of chronically (sometimes of many years' duration) apically infected cheek teeth, where progressive, dense cement deposition has occurred around the infected apex and adjacent reserve crown, making this area and its surrounding alveolus larger than the more occlusal aspect of the alveolus and thus mechanically preventing repulsion or oral extraction of the tooth. Under general anesthesia, a surgical approach is made directly through the skin and subcutaneous tissues to the lateral wall of the affected alveolus. A horizontal incision (to reduce the risk of cutting the buccal nerves) is made in the skin and soft tissues overlying the affected mandibular cheek teeth. The buccal nerve (and possibly the parotid duct) should be identified and isolated to prevent damage, if they cross the surgical field. A vertical incision is now made in the periosteum over the lateral aspect of the affected cheek teeth, and the periosteum is reflected. Through use of an oscillating bone saw or burr, the lateral wall of the alveolus is removed. The full length of the crown of the exposed diseased tooth is sectioned longitudinally with a diamond wheel or large solid carbide burr before the cheek tooth is extracted in sections.

The occlusal aspect of the alveolus is plugged with dental wax and the remaining alveolus is packed with an iodine-impregnated gauze bandage, which is gradually withdrawn through a small stab incision adjacent to the surgical site. A potential major disadvantage of this technique for extraction of the mandibular cheek teeth is that it can cause parotid duct rupture and buccal nerve damage with nasal paralysis.[61] In athletic animals, the former sequela is a disaster, as active dilation of the nostrils can no longer occur. Prolonged anesthesia is also required for this technique, which is a further disadvantage.

Figure 30-40. This horse had 206 and 207 repulsed some years previously, leaving it with a chronic, nonresponsive oro-nasal-facial fistula. After incision of the lips for access, a sliding hard-palate flap was used to close the large oral defect.

ENDODONTIC THERAPY

A number of workers have attempted to treat apically infected cheek teeth by use of endodontic (pulp canal) therapy. A major advantage of endodontics, if successful, is that the infected tooth is preserved and thus continues to erupt normally (at about 2 to 3 mm per year). This prevents the development of overgrowth ("stepmouth") of the opposing cheek teeth and drifting of the adjacent cheek teeth into the site of the extracted tooth. This drifting eventually causes focal overgrowths ("hooks") on the caudal and rostral aspects of the opposing cheek teeth row.

Equine cheek teeth endodontic treatment has been performed mainly through the apex of the affected cheek teeth, but it is also performed via an occlusal approach (as is used in brachydont teeth endodontics).[62-64] Endodontic treatment cannot be applied in cheek teeth with gross sepsis of the apex or where there is extensive periodontal disease (e.g., descending apical infections due to deep periodontal disease at a diastema). Apical endodontic therapy is performed via surgical approaches through the mandibular or maxillary bones (Figure 30-41). A consequence of this approach is the need for prolonged general anesthesia and surgical exposure of the overlying bone and affected apex for endodontic therapy. The exposed apex is visually assessed, and grossly infected or discolored calcified dental tissue is removed by high-speed, water-cooled burrs.

The large, common pulp (in young horses) or individual pulp horns (five pulp horns in all mature cheek teeth, except the 06s, which have six, and 11s, which have six or seven [see Figure 30-3]) are subsequently assessed for viability and removed with barbed broaches if found to be nonvital. Any impacted vegetable material (as a result of occlusal pulpar

Figure 30-41. Apicectomy and retrograde endodontic treatment of an apically infected 108 being performed under general anesthesia. Following a skin incision, the maxillary bone dorsal and lateral to the infected apex has been removed to allow exposure of apex. Note the row of needles inserted subcutaneously ventral to the surgical site and the row of skin staples dorsal to this site to provide radiographic landmarks for the procedure.

exposure) is removed and the canals are then filed using long endodontic files until normal-appearing dentine is reached (as adjudged by the color of the filings, i.e., changes from discolored to white or cream-colored dentine). The pulp canal can be sterilized by irrigating it with 2.5% sodium hypochlorite solution (household bleach) followed by lavaging with water and air-drying. The canal lining is subsequently etched with a phosphoric acid preparation and lavaged and dried again. The surface is coated with a dental bonding agent (some agents need to be cured by UV light) and the pulp canal filled, in layers, as completely as possible, with a modern composite restorative material, some of which also need to be cured by UV light in stages. Air pockets may preclude complete filling of the occlusal aspects of some long, narrow equine cheek teeth pulp canals in mature horses.

Baker described an 84% success rate with (apical) endodontic therapy for mandibular 08s and 09s but poor success with maxillary cheek teeth.[62] Other clinicians have had poor results in trying to treat infected teeth with apical endodontic therapy, with some horses requiring two or three courses of treatment, under general anesthesia, sometimes taking over 2 hours per treatment.[63] The most comprehensive report to date has shown a positive response in only 58% of cases and partial success in 17%.[64] Such repeated and prolonged surgery under general anesthesia is costly and has safety considerations for the horse. It is believed that in younger horses, the presence of a very large common pulp cavity is one reason for the failure of this technique in this age group. Success may increase if endodontic treatment is reserved for more mature teeth (e.g., cheek teeth that have been erupted for at least 2 years). Specialized training and equipment (including long drills and reamers) are required for endodontic therapy of the long equine pulp canals. Additionally, the debate continues over what is the most suitable material (e.g., modern two-part composites, self- or light-cured; amalgam or glass ionomers) for pulp canal filling in horses. Endodontic therapy offers much potential benefit in treating apical infections, but until larger studies have more fully evaluated case selection criteria, long-term efficacy, costs, and the safety of this technique, its wider role in equine dentistry remains unclear.

More recently, endodontic therapy via the oral cavity has been advocated in cases of pulpar exposure on the occlusal surface of cheek teeth. However, many such horses have deeply impacted vegetable matter down their pulp canals[5,6] that may be impossible to fully remove, even with use of high-pressure silicate or aluminium powder aerosols, and after completely drilling out the full occlusal surface of these canals. After cleaning, exposed pulp cavities are sealed with restorative material as previously described. If the affected canal still contains food material or if inaccessible areas of caries have not been removed, it is possible that endodontically sealing off its occlusal drainage may transform a nonclinical apical infection to one with clinical involvement of the supporting bones and sinuses. Notwithstanding these theoretical arguments against occlusal endodontic therapy, some clinicians have anecdotally reported success with this therapy.

ORAL CAVITY SOFT TISSUE TRAUMA

The soft tissues of the oral cavity are susceptible to traumatic injuries by harness bits or other oral tack, sharp external objects, blows to the head, injury during recovery from general anesthesia, and iatrogenic damage during intraoral procedures, such as administration of oral medications, dental extraction, or transoral epiglottic entrapment release.[65-69] The soft tissues of the face and oral cavity have a tremendous capacity for repair. Minor superficial lacerations of the mucosa, lips, and tongue can heal effectively by second intention, usually within 2 weeks, without leaving a scar. Management may entail flushing the oral cavity after meals with an antiseptic solution, warm saltwater, or clean water and the use of NSAIDs. Larger wounds should be considered for surgical repair, to maintain tissue function, and for cosmesis. For these repairs, antimicrobial therapy may be needed in selected cases.

Tongue

Lacerations of the tongue occur occasionally and can be severe, with transverse lacerations more frequent than longitudinal ones.[65,70,71] The free portion of the tongue is usually involved because of bit location and because this part has more exposure to the external environment. Clinical signs include oral hemorrhage, ptyalism, inappetence, anorexia, dysphagia, malodorous breath, pyrexia, and tongue protrusion from the mouth. Management of tongue lacerations is guided by the severity, duration, and location of the injury. Partial glossectomy, primary wound closure, or secondary wound healing are approaches to treatment. Surgical procedures are most easily performed on the anesthetized patient; however, the tongue can be operated on in the standing horse with effective sedation and infiltration of local anesthetic. Traction on the tongue for exposure can be achieved by placing towel clamps in the tongue caudal to the laceration or by using a gauze snare at this site, which also serves as a tourniquet.[70,72]

Partial glossectomy is reserved for cases in which the rostral tongue tissue is devitalized and minimal attachment is left between the severed section and the remaining body. Tissue color, temperature, and evidence of bleeding at an incision can

be used to assess viability. Observation of fluorescence after intravenous administration of sodium fluorescein allows a more objective assessment of tissue vascularization.[72] After amputation, the remaining stump is meticulously débrided of nonviable tissue. Mucosal-to-mucosal closure of the stump is not imperative but can be performed to aid hemostasis and hasten wound healing.[71] Correct dorsal to ventral apposition is assisted by removing a wedge of intervening musculature and closing the created space with multiple rows of interrupted absorbable 2-0 or 0 sutures (walking sutures, see Figure 16-9, *E*). The mucosal edges are subsequently closed with buried sutures of a similar size (Figure 30-42).[70] Involuntary loss of saliva from the mouth may be observed after amputation of a large part of the free portion of the tongue.[71]

Primary closure of severe tongue lacerations is encouraged whenever possible. The wound edges are débrided of necrotic and contaminated tissue and lavaged vigorously. A multilayer closure to eliminate dead space is recommended.[65,66,70,72] To relieve tension on the closure, vertical mattress sutures are preplaced deep in the muscular body of the tongue with absorbable or nonabsorbable size 0 or 1 monofilament suture material. Buried rows of simple interrupted 2-0 to 0 monofilament absorbable sutures are subsequently used to appose the muscles, obliterating dead space. The vertical mattress sutures are tied, and the lingual mucosa is apposed with simple continuous or interrupted vertical mattress sutures (Figure 30-43).

Second-intention wound healing for management of tongue lacerations is a viable option, particularly when economic constraints preclude surgical repair and for chronic and less-extensive lacerations. Oral lavage with a clean antiseptic solution two to three times a day and careful attention to the horse's ability to eat and drink are indicated. Lacerations that have healed by second intention but result in poor tongue functionality can be reconstructed using primary closure techniques after sharp débridement of scar tissue.[67,70]

After lingual surgery, most horses eat normally, and temporary feeding via a nasogastric tube is rarely required. Gruels of pelleted feeds mixed with water, bran mashes, and wetted hay can be given before introducing drier feeds.[65,69,70] NSAIDs are administered, and antimicrobial therapy is used according to the level of tissue devitalization. Nonabsorbable sutures are removed after 2 weeks. Postoperative complications include excessive swelling of the tongue and suture dehiscence. The cosmetic appearance is usually highly acceptable.

Lips

Lip trauma occurs from protruding rigid objects in the horse's environment, such as metal buckets, nails, bolts, and hooks, or from iatrogenic bit damage.[66,67] In cases with major disruption, surgery is indicated to preserve lip function and cosmetic appearance. Injuries with extensive tissue contusion and devitalization should be managed by delayed primary closure to optimize the amount of healthy tissue for suturing; otherwise, most lacerations can be repaired at presentation.[66] General

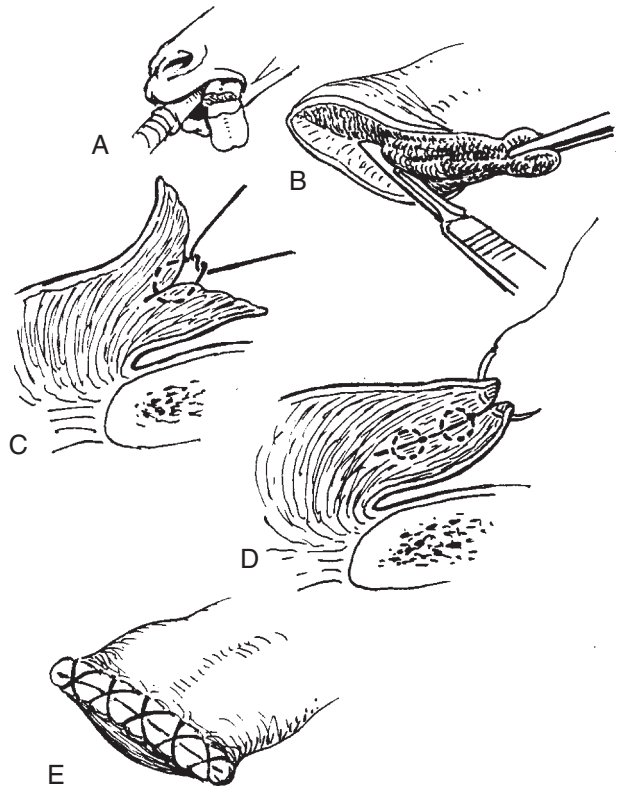

Figure 30-42. Closing the tongue stump after partial glossectomy. After amputation of the severely lacerated tongue **(A),** a wedge of intervening musculature is removed **(B).** The created space is closed with multiple interrupted rows of sutures **(C, D)** before closing the mucosa **(D, E).**

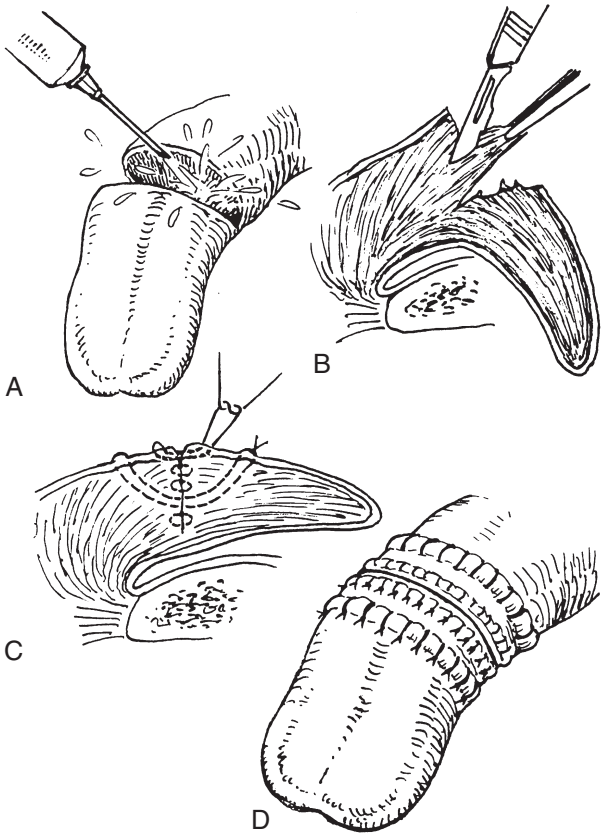

Figure 30-43. Tongue laceration repair. anesthesia facilitates a meticulous repair, but standing surgery is possible with regional anesthesia techniques. The wound edges are prepared routinely by sharp débridement and lavage. The lips are highly mobile tissues, and close adherence of the mucosa and skin to underlying musculature results in excessive motion at suture lines during prehension. This leads to a high incidence of dehiscence unless techniques are employed to stabilize the repair.[66,67,72]

To reduce motion on the suture lines, the margins of the skin and oral mucosa are sharply undermined for 1 to 1.5 cm from the edges of the wound. Vertical mattress 0 to 1 nonabsorbable sutures are subsequently preplaced from the extraoral side through the lip musculature and tied over quills of soft rubber tubing[66] or through buttons (see Figure 16-9, *C*).[67] The mucous membrane is closed with simple continuous or interrupted 2-0 monofilament absorbable suture. The skin is apposed with simple interrupted or vertical mattress 2-0 to 0 nonabsorbable monofilament sutures. At the mucocutaneous junction, a vertical mattress pattern is recommended for precise apposition.

Chronic lip lacerations are reconstructed using similar principles as for the repair of acute injuries. A three-layer closure is employed, with the layers being created by sharp dissection of the skin and mucous membrane from the intervening lip muscle and granulating scar tissue. When repairing lacerations involving the commissure of the lips, additional vertical mattress tension-relieving sutures are placed rostral to the primary repair for increased support in this highly mobile area (Figure 30-44).[66] For an extensive lower lip laceration with loss of tissue, a rotational flap may be used.[73] Avulsions of the lower lip should be supported with large mattress sutures passed through the mandibular symphysis. Wire or nonabsorbable suture material is threaded through holes drilled from the outside of the lip and chin to exit caudal to the incisors in the oral cavity, and stents of soft tubing or buttons are placed under the sutures on the oral and external sides.[66,67] Primary closure of the lip and gingival mucosa is performed if practical.

NSAIDs are administered, and the oral cavity is lavaged with a dilute antiseptic solution or water from a hose two to three times a day. Antibiotic administration is not required in most cases. A normal diet can be offered after surgery, and feeding by nasogastric tube or esophagotomy is unnecessary.[66] The stent sutures can be removed after 7 to 10 days and skin sutures after 2 weeks. Mattress sutures used for repair of avulsion injuries are removed 2 to 3 weeks postoperatively. The most common postoperative complication is dehiscence of the repair. Horses have a tendency to rub the repair site, which can be limited by muzzling or cross-tying.[67]

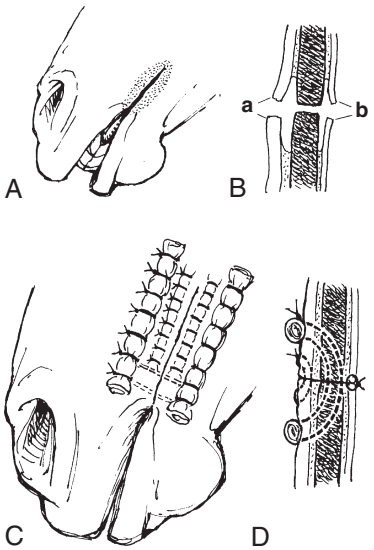

Figure 30-44. Repair of a laceration involving the commissure of the lips. **A** and **B,** After appropriate débridement and lavage of the laceration, the skin and mucous membrane margins of the laceration are undermined 1.0 to 1.5 cm (*stippled area* in **A**). **B** is cross-sectional view with *a*, skin; *b*, mucous membrane. Next, vertical mattress sutures tied over stent material are preplaced through the lip musculature before closing the mucous membrane and skin layers to reduce motion at the suture lines **(C, D).** Extra vertical mattress sutures can be placed rostral to the repair to further stabilize the site **(C).**

Cheek and Gums

Partial-thickness labial vestibule and buccal cavity lacerations are managed by second-intention wound healing with oral lavaging after meals and NSAIDs. Large, full-thickness injuries may be reconstructed to prevent orocutaneous fistula development. Repairing the oral aspect of the wound is difficult because of limited space. Suturing the wound from the external side, starting with the mucosal layer, is more practical. Tension-relieving vertical mattress sutures should be used for the musculature.

ORAL CAVITY FOREIGN BODIES

Various types of metallic, usually linear, foreign bodies can penetrate the soft tissues of the oral cavity after inadvertent ingestion, or penetration may occur iatrogenically during administration of oral medications.[69,74-76] Plant matter, such as grass awns or wood splinters, is also a frequent cause of foreign body reaction.[77] External clinical signs include focal or diffuse intermandibular, retropharyngeal, and facial swelling, depending on where the foreign body has lodged or what it is migrating through. Swellings typically have increased heat, and the horse has evidence of pain when they are palpated. Often, antibiotic therapy reduces the size of the swelling but it recurs when drugs are discontinued. A swollen, painful tongue; ptyalism; and partial to complete anorexia are the most common clinical signs of a tongue foreign body.[76] Other clinical signs may include halitosis, dysphagia, tongue paralysis, and fever. There may be a painful response and difficulty when attempts are made to open the jaw. Oral and oropharyngeal examinations (float the teeth before performing the latter to prevent lacerations of the operator's hands and arms) can reveal firm, painful swellings; the end of the foreign body; ulcerated mucosal surfaces where the foreign body has penetrated the tissue; or the site of spontaneous abscess rupture.

Diagnosis requires a combination of thorough history taking, external and oral examination, and imaging aids. Radiography is indispensable for detecting metallic foreign bodies, but care must be taken not to miss a fine, short structure. Open-mouth head radiographs can prevent tongue soft tissues from being superimposed over radiodense dental elements that may conceal a subtle metallic body (Figure 30-45). Ultrasonography is very useful to help pinpoint the exact location of a foreign body, and imaging via the intermandibular space and via oral direct

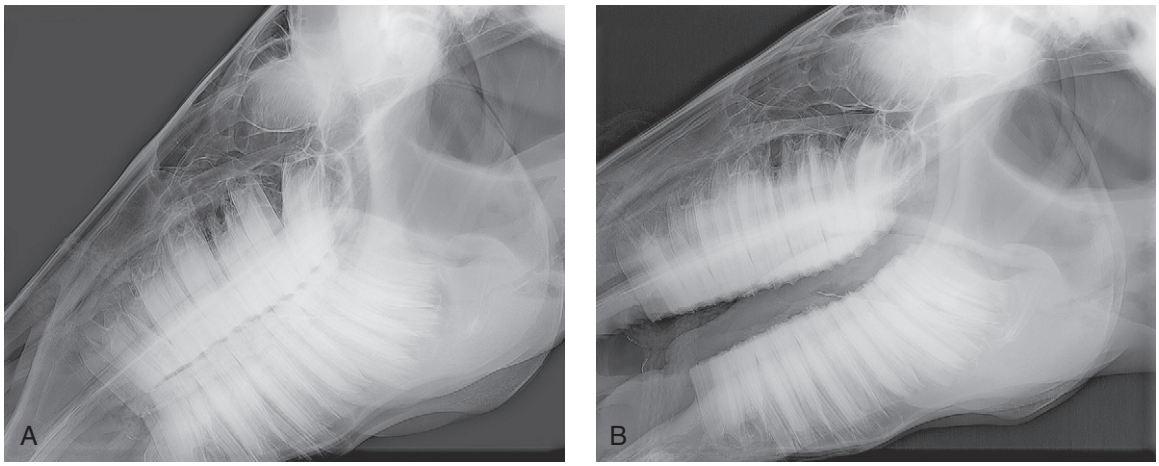

Figure 30-45. A, Closed-jaw, lateral radiographic view of a horse's skull. A barely discernable horizontal, linear opacity is visible superimposed under the mandibular cheek tooth (09s and 10s). **B,** Open jaw, radiographic lateral view of the same horse's skull. Separation of the dental arcades allows easy visualization of the opaque foreign body located in soft tissue (in this case, determined to be the tongue), surrounded by a lucent cavity.

contact with the tongue is recommended.[76,78] Direct tongue ultrasonography may be performed in the standing, sedated horse, with a speculum in place, or in a horse under general anesthesia. A 5 to 10 MHz rectal transducer provides excellent contact with the tongue surface. Ultrasonography is very useful for detecting the presence of lingual abscesses, and the combined imaging from two approaches identifies the best surgical access to the foreign body.[76] Nonmetallic foreign bodies such as wood splinters are best recognized with the help of ultrasonography.

Once a diagnosis is established, the treatment of choice is removal of the foreign body. In a few select cases, medical therapy alone may suffice if tongue function is normal and intralingual abscesses are minor or not present.[76] In other cases the foreign body can be removed manually if it is palpated during examination. Surgical approaches may have to be creative. An external approach to a foreign body that has migrated into the deep part of the masseter muscle requires care to avoid trauma to facial nerve branches, parotid duct, and blood vessels in that region. Foreign bodies associated with intraoral swelling may be approached by incising the mass on the oral side and draining exudate into the mouth. Digital or instrumental exploration and débridement of the cavity can then be performed. The cavity is lavaged and allowed to heal by second intention. Lingual foreign bodies can be very difficult to find and awkward to reach when they have implanted or migrated into the caudal body or base of the tongue.[75] Surgery can be associated with significant hemorrhage if large lingual vessels are invaded. An ulcerative defect on the tongue surface provides a useful starting point for exploring the necrotic tract that is associated with the path of the foreign body. A ventral approach between the hemimandibles is necessary in some cases and allows triangulation techniques to narrow down the field of exploration when a second instrument is also passed via the oral cavity into the tongue body. When necessary, the caudal body or base of the tongue can be exposed more effectively after a mandibular symphysiotomy.[75] An oral speculum, a bright light, and long-handled instruments are valuable aids. The mouth should not be fully opened with a speculum for prolonged periods of time (more than 30 to 45 minutes), to prevent muscle and temporomandibular joint soreness postoperatively. Intraoperative ultrasonographic, fluoroscopic, and radiographic guidance may be required to locate the foreign body. Oral endoscopy can aid visualization.

Surgical and necrotic tracts in the tongue are left to heal by second intention. Postoperative care may consist of a combination of oral lavaging, necrotic tract lavaging, and antibiotic and anti-inflammatory therapy. Ptyalism and tongue swelling can be a feature of the early recovery period. Soft feeds and gruels are fed after extensive tongue exploration, until the horse is more comfortable eating. The prognosis is excellent for complete recovery.

PERSISTENT LINGUAL FRENULUM

Ventral ankyloglossia (persistent lingual frenulum) is a very rare congenital condition in foals and may accompany other congenital craniofacial anomalies.[79] The tongue cannot be protruded normally because of a mucosal attachment between the ventral rostral free part of the tongue and the floor of the oral cavity. Difficulty with suckling may also occur. The condition is diagnosed by oral examination and is usually noted during the first routine neonatal assessment. Frenuloplasty is the treatment of choice, taking care not to incise the normal lingual frenulum. This may be performed under sedation and local anesthesia or under short-acting general anesthesia. The membrane is sharply transected with scissors. Electrocautery and laser division of the tissue are alternative approaches. With adequate release, the tongue should be easily extended from the mouth.

ORAL CAVITY SOFT TISSUE NEOPLASIA

Neoplasia of the oral cavity soft tissues is rarely encountered but is of considerable clinical significance when identified. The most common primary oral neoplasm is squamous cell carcinoma, affecting any of the mucosal surfaces.[80-82] Other primary or metastatic tumors include melanoma, fibrosarcoma, hemangiosarcoma, lymphosarcoma, rhabdomyoma, rhabdomyosarcoma, and chondrosarcoma of the tongue.[77,80,83-87] Clinical signs include ptyalism, halitosis, tongue protrusion, quidding, nasal

discharge with food material in it, dysphagia, inappetence, anorexia, and weight loss.[82,83,87,88] Tumor invasion of local bony and soft tissues is often advanced, and regional metastases may have already occurred before clinical signs become apparent and prompt veterinary attention. Manual examination and direct visualization (using a speculum and bright headlamp) or endoscopy of the oral cavity reveals most tumors. Caudal oropharyngeal tumors can be very difficult to see, even with oral endoscopy. They may also be difficult to palpate, and general anesthesia should be considered to facilitate thorough examination in select cases. Radiography can determine osseous involvement and soft tissue anomalies, and nasal endoscopy can indicate soft tissue masses on the tongue base displacing the soft palate dorsal to the epiglottis.[83] The definitive diagnosis requires biopsy and histopathologic examination. Often, submandibular lymphadenopathy in horses with oral neoplasia is caused by reactive inflammation rather than metastatic disease, so biopsy results of these lymph nodes are usually negative.

Successful treatment depends on the type and size of tumor present and its accessibility. Tumors of the lips and rostral tongue are most readily resolved, as they are often noticed early and can be adequately excised or are accessible for intralesional chemotherapy and radiotherapy. Invasive squamous cell carcinomas have a high recurrence rate after surgical excision and have often metastasized by the time they are diagnosed.[82,88]

Complementary radiotherapy after radical surgical excision of squamous cell carcinoma may prevent or prolong time to recurrence.[89] Fibrosarcomas also tend to recur after excision and are less responsive to radiation therapy. The prognosis for resolution of oral squamous cell carcinoma and fibrosarcoma is generally poor.[77] Lingual rhabdomyosarcoma and chondrosarcoma can be managed by surgical excision, with an unknown definitive long-term prognosis.[83,87]

Nonneoplastic conditions that should be differentiated from tumors are focal gingival hyperplasia, epulis, and exuberant granulation tissue.[77,86,90,91] These masses can appear neoplastic, but they carry a more favorable prognosis. Other rare conditions reported include vascular hamartoma of the tongue, which resulted in euthanasia of the horse,[92] and an atypical perineurial cell proliferative disorder identified in a horse with multiple focal and coalescing masses along the tongue.[93]

SALIVARY GLANDS

Anatomy

The major salivary glands in the horse are the paired parotid, mandibular (submaxillary), and polystomatic sublingual glands. There are also smaller buccal, labial, lingual, and palatine salivary glands.[94] The distribution of serous and mucous cells within the salivary glands determines the nature of the saliva secreted. The parotid salivary gland secretes mainly serous fluid, whereas the mandibular and sublingual glands produce a combination of serous and mucous fluids.

The largest of the salivary glands, the parotid, is located in the retromandibular fossa between the vertical ramus of the mandible and the wing of the atlas. The rostral border reaches and may partially overlap the temporomandibular joint and the masseter muscle along the caudal border of the mandible. The caudal border extends to the wing of the first cervical vertebra. Dorsally, the gland extends to the base of the ear, and ventrally it extends into the intermandibular space. The surfaces of the parotid gland are associated with important vascular and neural structures.[94] Glandular secretions are drained by multiple small ducts that converge at the rostroventral aspect of the gland and exit as the single parotid (Stensen) duct. The parotid duct initially passes along the medial surface of the mandible in close association with the facial artery and vein. The three structures then travel rostrolaterally around the ventral border of the mandible at the location of the easily palpable facial artery pulse. The duct ascends along the rostral edge of the masseter muscle and opens into the buccal cavity opposite the maxillary fourth premolar tooth (108, 208). A parotid papilla identifies the buccal ostium.

The mandibular salivary gland extends from the atlantal fossa to the basihyoid bone. Most of its lateral surface is covered by the parotid salivary gland and partly by the mandible, and its medial surface covers the larynx, common carotid, vagosympathetic trunk, and guttural pouch. Many small radicles unite to form a common duct that travels rostrally, ventral to the tongue. The duct opens a few centimeters rostrolateral to the lingual frenulum, at the sublingual caruncle. The small sublingual gland lies beneath the oral mucosa between the body of the tongue and the mandible. It extends from the level of the mandibular symphysis to approximately the first or second mandibular molar (09s and 10s). Sublingual ducts (about 30) open independently at small papillae on the sublingual fold.[94]

Disorders

Trauma

Lacerations or penetrating wounds to the salivary glands occur rarely. The superficially located parotid salivary gland and duct are subject to traumatic injury more often than the better protected mandibular and sublingual glands.

The hallmark of disruption of the gland or duct is the flow of saliva from the wound. This flow is accentuated when the horse is fed, and observation of the wound while offering feed to the horse provides a simple test to confirm that the discharge is saliva.

Diagnosis of parotid duct disruption may be facilitated by catheterizing the duct via the buccal ostium, with the horse under general anesthesia, and visualizing the catheter exiting the wound. Locating and accessing the parotid papilla for retrograde catheterization occasionally requires a buccotomy at the level of the 108 (or 208).[95] A second incision can be made a few centimeters rostral or caudal to the buccotomy to allow tunneling of the tubing subcutaneously to the buccotomy site. Contrast sialography can also be used to determine communication with a salivary gland and duct patency in the case of a suspected salivary fistula.[96,97] If there is no clear indication that a salivary duct or gland has been damaged, it is recommended that parotid wounds be left to heal by second intention.[98] When the duct has been disrupted but this was not recognized at the time of injury, horses may be presented later with a chronically draining tract.[99] Surgical management of salivary gland and duct trauma is fundamentally aimed at repairing the damaged structure or, alternatively, at eliminating saliva secretion. Most salivary fistulas spontaneously close within 1 to 3 weeks, so deferring treatment for a period of weeks is a worthwhile option.[99]

Fresh wounds of the parotid gland can be débrided and reconstructed with a multilayer closure, starting with the parotid

capsule. The potential for suture material that penetrates the glandular tissue to provide a nidus for calculus formation should be considered. Open wound management and healing by second intention is an alternative for older or heavily contaminated wounds and for economic reasons, and this often allows successful healing without the development of a salivary fistula.[98,99]

Treatment of lacerated salivary ducts may also be by primary surgical closure or secondary wound healing. Primary closure of an acutely lacerated duct or a nonhealing salivary fistula is facilitated by suturing it over an intraluminal tube or by placing three sutures to appose the two cut ends as a triangle and suturing between the apices.[95,96,98-100] Cannulation of the parotid papilla may not be practical in some cases.[100] Alternatively, size 2 nylon suture is threaded normograde through the distal lacerated duct end to the parotid papilla. Tubing is passed via a 14- to 16-gauge needle cannula inserted through the cheek tissue externally to internally to enter the oral cavity just rostral to the parotid papilla. The tubing is subsequently guided over the nylon suture into the duct, and the nylon and needle are removed.[95] When the tip of the tube emerges from the lacerated duct at the wound, it is redirected into the proximal part of the duct and passed to the ventral aspect of the parotid gland. The duct is closed with fine absorbable or nonabsorbable suture (4-0 to 7-0) using a simple interrupted pattern.[95,96,98,100] The external end of the tube is sutured to the side of the face, allowing ease of later removal and the ability to check for continued patency of the duct. The need to leave the stent tube in place while the duct is healing after anastomosis and how long to leave it are unclear.[99-101] The tubing may support the suture line and prevent stricture development while maintaining saliva flow.[95] For tears involving one side of the duct wall, suture repair without use of an *in situ* stent should be adequate.[96] A gauze mask can be placed over the horse's head to help prevent premature tube removal. If anastomosis of the duct is not possible because of loss of too much intervening tissue, an interposition polytetrafluoroethylene tube graft may be successful in restoring duct continuity.[102] Other options for salvaging salivary secretion capacity are to create a fistula from the duct to the buccal cavity proximal to the injury or alternatively perform duct translocation.[97-99] These techniques divert saliva from the distal wound site, allowing it to heal, but they are no longer favored because of inconsistent results.

Attempts to reduce salivation after duct or gland repair by withholding feed and water or feeding through a nasogastric tube for a few days have been recommended.[101] Others believe this management to be unnecessary and the continued flow of saliva to be important to prevent obstruction.[98-100] Perioperative NSAIDs and antibiotic therapy are administered.

The alternative approach to managing a chronic parotid salivary duct fistula is to attempt to eliminate saliva secretion. Horses can tolerate the loss of one parotid gland.[98,99] This may be performed by surgical removal of the gland, duct ligation, or chemical ablation of the gland. Parotid gland extirpation is difficult, as very careful avoidance of intimately associated large vessels and nerves is required, and removal of all glandular tissue may be impractical because of intervening vital structures.[103,104] Consequently extirpation has been largely replaced by chemical ablation.[99]

Chemical ablation and duct ligation are more economical and easier procedures to perform than major duct reconstruction. For ligation, the parotid duct is readily located where it crosses the tendon of insertion of the sternomandibularis muscle close to its origin from the gland. A catheter is passed retrograde through the duct from the salivary fistula site, toward the gland. The catheter can be palpated in the duct, and this allows definitive isolation of the duct during dissection. Two or three heavy-gauge nonabsorbable sutures should be used for duct ligation and should not be tied too tightly to prevent cutting through the duct wall.[105] The distal suture is tied first to distribute resulting back-pressure after ligation.

Successful chemical involution of the parotid gland was first described using Lugol iodine, with 1 to 2 mL injected transcutaneously into the gland at multiple sites.[105] However, patient discomfort, severe swelling, and the potential for nasopharyngeal collapse and consequent airway obstruction make this method unacceptable today. Other agents that have been examined critically are 10% formalin, 2% chlorhexidine, and 2% and 3% silver nitrate.[106] Of these chemicals, 10% formalin produces the least amount of necrosis and suppurative inflammation, so it is currently recommended.[98,106] Water-soluble iodinated contrast material is also effective in eliminating glandular secretions.[99,106] This must be considered when retrograde sialography is undertaken to investigate a draining fistula or duct atresia. Allowing the contrast material to drain out followed by lavage of the duct and gland with sterile saline solution before injecting the chemical agent is recommended. When using 10% formalin, the duct is cannulated and a ligature tied to prevent leakage. Thirty-five milliliters of formalin is injected through the cannula into the gland. It is left in for 90 seconds and then allowed to drain out. The cannula is left in place for 36 hours. Cessation of salivary secretions occurs by 3 weeks. NSAIDs are administered after treatment for pain relief. Postoperative complications after chemical ablation include periocular and facial swelling, transient facial nerve paralysis, anorexia, and dyspnea. Most of these complications have been associated with chlorhexidine and silver nitrate and not with formalin.[98,106]

Sialoliths

Sialoliths are hard concretions composed mostly of calcium carbonate and organic matter that develop within a salivary duct or less commonly a gland.[107-112] Plant material is often found as a nidus of the sialolith formation.[107-110] Sialoliths appear smooth or slightly spiculated, and gray, yellowish, or white.[113] They are rarely recognized but when they occur, they tend to affect older horses, and the parotid duct is most commonly involved. Typically, a nonpainful, movable, firm structure is palpable on the lateral aspect of the face near the rostral end of the facial crest (Figure 30-46), and it can be present for many years before additional clinical signs develop and lead to veterinary attention.[107,108] In some cases, the sialolith may be palpable orally.

Obstruction of the duct is often incomplete, and saliva may continue to pass around the sialolith. However, with acute or chronic complete obstruction, back pressure may cause duct and gland distention, which is noticed as a possibly painful swelling in the intermandibular and retromandibular space.[95,109] Other clinical signs, including the presence of purulent material in the mouth, reddening at the parotid papilla, mild icterus, fever, difficulty masticating, quidding, halitosis, decreased appetite, and acute development of a painful swelling that was previously nonpainful have also been reported in association with sialoliths.[95,107,109,110] Sialoliths usually occur singularly. If multiple

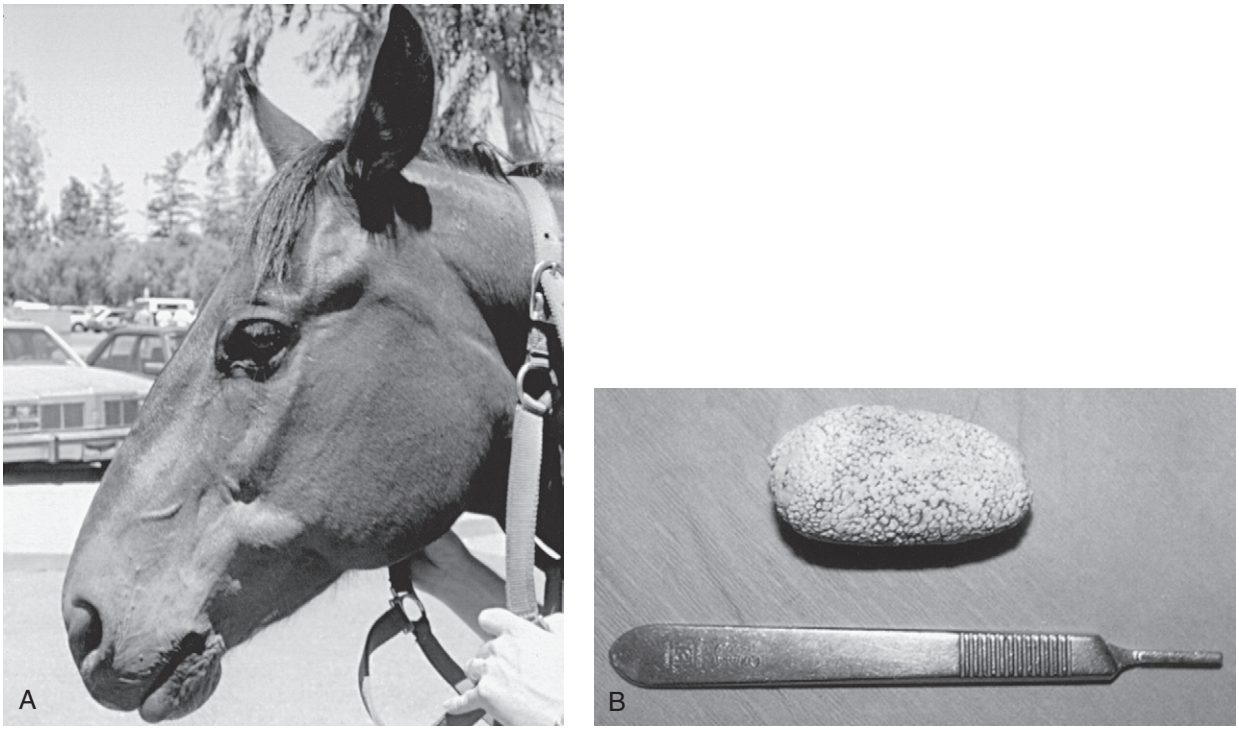

Figure 30-46. A, Photograph of a horse with a sialolith located in the left parotid duct near the rostral edge of the facial crest. **B,** Sialolith removed from a parotid salivary duct. (**B,** with permission, Equine Vet Educ 7:315, 1995.)

calculi are present in the same duct, a grating sound or sensation may be heard or felt on palpation.[112] Septic sialoadenitis is a rare occurrence in domestic animals but may precede or be a consequence of a developing sialolith.[101] Inflammation and infection of the duct (of ascending, hematogenous, or traumatic origin) results in obstruction by exudates, desquamated cells, and mucus. This material may provide the nidus necessary for a sialolith to form. Partial obstruction of the duct by a sialolith may decrease natural clearance of secretions, resulting in stasis and facilitating proximal movement of bacteria. Diagnosis of sialolithiasis is assisted by radiographs, but soft tissue swelling can impede identification of a concretion.[95,107-110]

Definitive treatment is by removal of the sialolith. Smaller calculi may be massaged out of the parotid papilla. If this is not possible, and the calculus is palpable orally in the buccal soft tissues, direct intraoral incision over the sialolith, leaving the wound to heal by second intention, is preferred.[97,98,105,107,108] This approach prevents external salivary fistula development. Calculi inaccessible by the intraoral route must be removed by external longitudinal incision of the duct. This can be performed as a standing surgery with local anesthesia. Cannulation of the parotid duct via the parotid papilla can be helpful to locate the exact calculus position and may act as a stent for suturing the duct if primary closure is performed.[109] The entire duct and gland should be lavaged with sterile polyionic solution. Closure of the duct is with a simple interrupted or continuous pattern of fine absorbable suture material. The incision can also be left to heal by second intention, recognizing the risk that a fistula may develop. Postoperative care is similar to repair of a duct laceration or fistula. Antibiotics and lavage of the duct and gland via catheterization of the oral papilla are recommended in infected cases.[109]

Atresia of the Parotid Salivary Duct

Congenital or acquired functional discontinuity of the parotid salivary duct is very rare in the horse.[103,114,115] Proximal to the obstruction, the dilated duct is characterized by a nonpainful, tortuous, subcutaneous, fluid-filled tube that extends caudad from a point rostral to the masseter (where the obstruction often is located) along the ventral surface of the mandible to the base of the ear on the affected side (Figure 30-47).[99,114,115] In congenital cases, swelling is present at birth and can increase with time. Swelling may also increase temporarily when the horse is presented with food. Aspirated fluid has the consistency of saliva with an alkaline pH and an acellular, proteinaceous background.[99,115] The swelling recurs after needle drainage, and occasionally saliva continues to drain into subcutaneous tissues after aspiration, setting up a severe inflammatory reaction, followed by persistent sialocele. Diagnosis is based on clinical appearance but can be confirmed with positive-contrast sialography and analysis of aspirated fluid. Dilated glandular radicles are seen coalescing into a single grossly distended parotid duct that terminates distally before reaching the buccal cavity.

Treatment options include surgically creating a new buccal ostium, duct excision and proximal ligation, gland extirpation, and chemical ablation of the salivary gland. Creation of a buccal fistula is not recommended because of its probable spontaneous closure and the potential for ascending contamination of the duct.[99] In one case, removing a large portion of the distended duct and ligating individual radicles was successful.[115] Duct ligation may not be appropriate in a chronic case, as severe dilation may not allow enough back pressure to be generated to cause atrophy of the gland and cessation of secretory activity.[116] Chemical ablation of the gland is an economical, effective, and practical solution and is recommended for most cases. Surgical

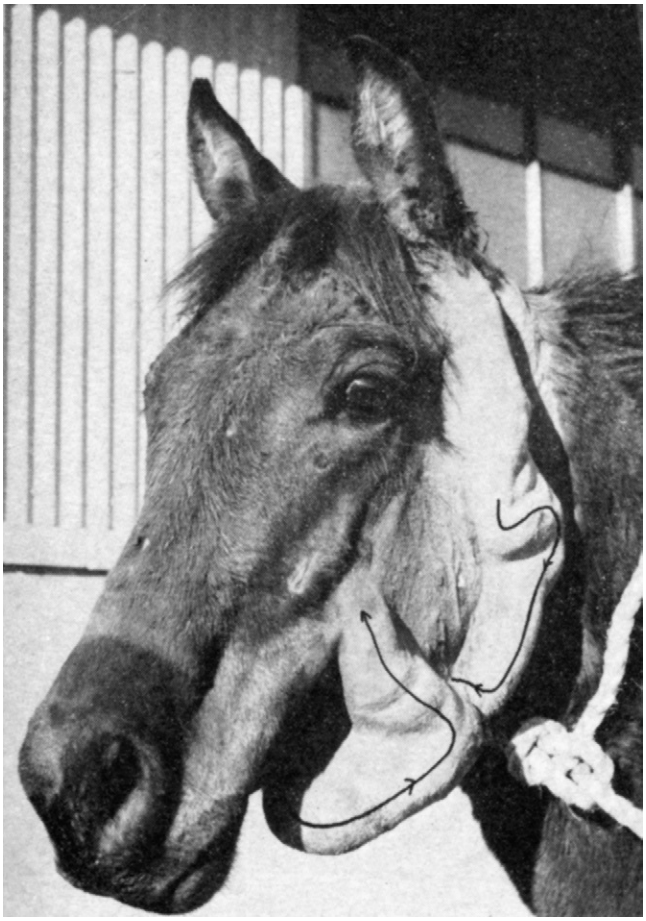

Figure 30-47. Severely dilated parotid salivary duct and gland of a 1-year-old Quarter Horse gelding with congenital atresia of the parotid duct. The duct ended blindly approximately 1.4 cm from the normal site for the buccal ostium. Line arrows mark the course of the duct. (With permission, J Am Vet Med Assoc 146:1404, 1965.)

removal of the duct can be performed for cosmetic reasons after ablation of the gland, but it is a difficult procedure.[99]

Salivary Mucocele and Ranula

On rare occasions accumulations of saliva occur in spaces adjacent the local gland or duct, possibly when an external wound has healed but the duct or gland continues to leak. A mucocele or sialocele refers to a pocket of saliva in a space not lined by epithelium. A ranula ("honey cyst") represents a mucocele of one of the sublingual salivary gland ducts and is seen as a bluish-tinged cyst on the floor of the mouth.[113] Fluid aspirated from a sialocele is generally brown and mucinous with a higher concentration of calcium and potassium than is seen in other accumulations of fluid.[101] Salivary fluid also contains amylase. Contrast sialography can determine any communication between the cavity and duct or gland. In some cases, complete surgical removal of the structure is appropriate. Ranulas respond well to marsupialization into the oral cavity.[99,101] A catheter can be sutured in place for 2 to 3 weeks to create a permanent fistula. Marsupialization of a mucocele into the buccal cavity is less likely to be successful because of a lack of epithelial lining.[99] Chemical ablation of the parotid gland would be effective and may be the simplest approach if this gland is known

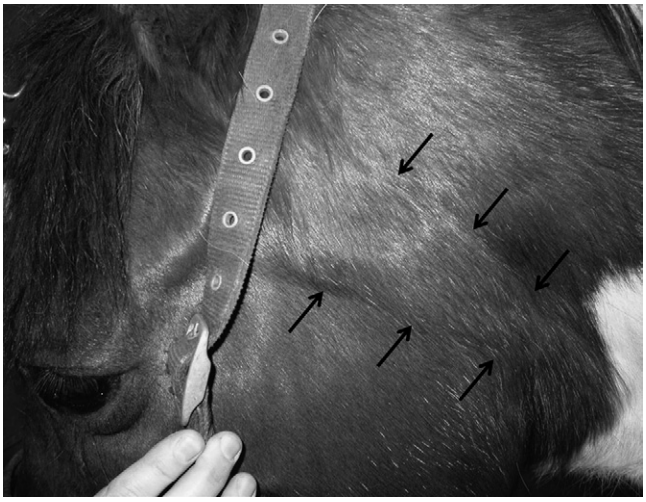

Figure 30-48. Parotid region of a pony showing a nonpainful swelling *(arrows)* that occurred when the pony was at pasture but resolved when it was kept stalled. (Courtesy Dr. P. Dixon, Edinburgh University.)

to communicate with the mucocele directly or via the duct.[98,99] Later, the mucocele can be drained without expected recurrence.

Heterotopic Salivary Tissue

Salivary tissue found in an abnormal location is a rarely diagnosed disorder and is described as heterotopic salivary tissue. It is possible that this condition goes unrecognized more frequently than it is confirmed; for example, unclassified subclinical lateral nasopharyngeal masses seen endoscopically may be heterotopic salivary tissue.[99] Heterotopic tissue associated with seromucoid draining tracts has been reported in the temporal region and the mid cervical region.[99,117] Drainage of saliva from heterotopic tissue does not increase when the horse is presented with feed. Definitive diagnosis is by histopathology, and complete surgical removal resolves the condition. Chemical ablation of the tissue may also be performed, if the nature of the tissue can be ascertained beforehand.[99]

Idiopathic Parotiditis, "Grass Glands"

Idiopathic parotiditis, or grass glands, refers to a syndrome of recurrent salivary gland swelling that occurs acutely in association with pasture turnout.[118,119] Typically, the parotid salivary glands become swollen during the day while the horse is on pasture, and the swelling resolves overnight when the horse is stalled. The condition is well recognized in Europe and Australia but is uncommon in the United States. Characteristically, there is a rapid development of bilateral swelling of the parotid gland. Glandular swelling is innocuous, firm, and nonpainful, occasionally causes edema at the caudal mandible, and can be mistaken for guttural pouch disease or enlarged lymph nodes (Figure 30-48). Once the horse is removed from pasture, the glandular swelling resolves. A pasture toxin is suspected but has not been identified. Sporadic or herd outbreaks are possible.

Neoplasia

The salivary glands are a rare site for neoplasia in the horse. Adenocarcinoma, acinar cell tumors, lymphomas, melanomas,

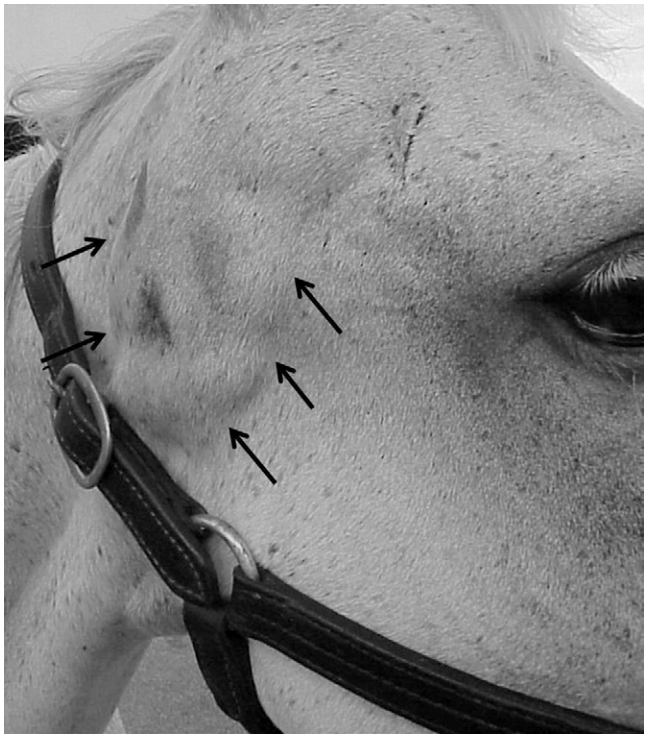

Figure 30-49. Parotid region of an aged Thoroughbred mare showing an irregular-surfaced, firm, nonpainful swelling *(arrows)* caused by melanoma development in the parotid salivary gland. Similar masses were present on the opposite side, and melanomas were visualized in this mare's guttural pouches.

and mixed cell tumors have been reported.[113,120,121] Melanomas are commonly seen in the parotid salivary gland of gray horses and may represent a primary or metastatic tumor.[84,121] Tumors in the parotid region can be identified by the presence of external swelling and are occasionally painful on palpation. Melanomas typically appear as nonpainful, firm, irregular- or smooth-surfaced masses (Figure 30-49), and endoscopy of the guttural pouches of affected horses will show focal black submucosal areas or the presence of melanomas, which will confirm the diagnosis. Diagnosis of other types of parotid region neoplasia may require endoscopy, radiology, ultrasonography, and cytology of a fine-needle aspirate. Biopsy and histopathology are indicated for a definitive diagnosis. Most parotid melanomas are slow growing and do not need to be treated. Treatment of other types of parotid tumors is often palliative, because wide surgical margins frequently fail to prevent benign mixed cell tumors or acinar tumors (and likewise, melanomas) from recurring. As previously mentioned, total parotidectomy is challenging and generally considered impractical in the horse.[99] Adenocarcinomas often metastasize.[120] Lymphomas can respond to radiation therapy.[122] Cimetidine may help with melanomas, but often this treatment is not justified because they are slow growing and most have low malignancy.[123-125]

CHAPTER 31

Esophagus

John A. Stick

The clinical signs, diagnosis, and therapy of esophageal disease are specific and unlike those of the rest of the alimentary system. Clinical evaluation of the equine patient with esophageal disease includes physical, radiographic, and endoscopic examinations. Early and definitive diagnosis is paramount when dealing with esophageal injury, especially when signs of disease recur after initial treatment. Therapy of esophageal disorders often centers around conservative medical and manipulative management, with dietary alterations being a primary component of therapy. However, surgical management of esophageal disease in the equine patient has become commonplace and necessitates discussion of surgical anatomy, diagnostic and therapeutic considerations, surgical techniques, and complications.[1-3]

SURGICAL ANATOMY

The esophagus of adult horses varies in length from 125 to 200 cm (49 to 78 inches), depending on the size of the animal, and consists of cervical, thoracic, and abdominal parts. As it courses caudad, it deviates from a position dorsal to the trachea in the cranial one third of the neck to the left side of the medial plane in the middle one third of the neck. (In a small percentage of horses, the esophagus courses to the right side of the median plane.) It comes to lie ventral to the trachea at the thoracic inlet.[4] The cervical part of the equine esophagus is most accessible to surgery and makes up over 50% of the total length of the esophagus.

The wall of the esophagus is composed of four layers: a fibrous layer (tunica adventitia), muscular layers (tunicae muscularis), a submucosal layer (tela submucosa), and a mucous membrane (tunica mucosa). The muscular layers are striated from the pharynx to the base of the heart, where they gradually blend into smooth muscle. As the esophagus courses caudad, its muscular layers increase in thickness, whereas the lumen diminishes. Except at the upper esophageal sphincter, the two muscular layers are arranged spirally and elliptically.[5] On surgical incision, the esophageal wall separates easily into two distinct layers. The elastic inner layer, composed of mucosa and submucosa, is freely movable within the relatively inelastic outer muscular layer and adventitia (Figure 31-1). The mucosa, which provides the greatest tensile strength on closure of an esophageal incision, is covered with stratified squamous epithelium and lies in longitudinal folds that obliterate the lumen

except during deglutition. The mucosa is very heavily colonized by facultative and obligate anaerobic bacteria,[5,6] and therefore surgery on this organ necessitates the use of prophylactic antimicrobial agents (Figure 31-2).

The arterial supply to the cervical part of the esophagus originates from the carotid arteries. The thoracic and relatively short (2- to 3-cm [¾- to 1¼-inch]) abdominal esophagus is supplied by the bronchoesophageal and gastric arteries. The vascular pattern is arcuate but segmental, without generous collateral circulation, necessitating careful preservation of vessels during surgery.

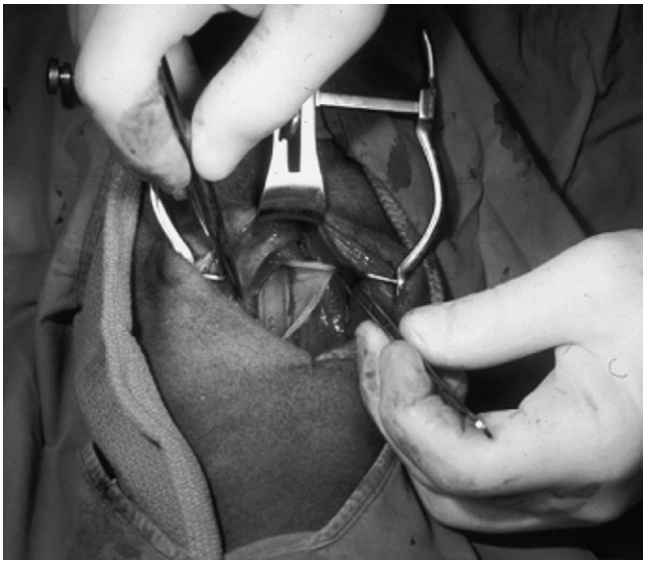

Figure 31-1. Traction on the incised esophagus, with a nasogastric tube in place, shows the elastic properties of the mucosa and submucosa (inner layer).

Innervation of the esophagus is derived from the ninth and tenth cranial nerves and the sympathetic trunk, as well as mesenteric ganglion cells within the muscle layers.

CLINICAL MANIFESTATIONS AND EVALUATION OF ESOPHAGEAL DISEASE

The obstructive disease of "choke" may be manifested by ptyalism, dysphagia, coughing, and regurgitation of food, water, and saliva from the mouth and nostrils. Attempts at ingestion are often followed by odynophagia (painful swallowing), repeated extension of the head and neck, and other signs of distress or agitation. The time interval from swallowing until these signs are shown by the patient depends on the location of the lesion within the esophagus. With obstruction of the distal esophagus, odynophagia and retching may occur 10 to 12 seconds after swallowing. With proximal esophageal obstruction, the signs may be evident immediately. This occurs because the propagation speed of the equine esophagus is about 9.4 cm/sec in the proximal two thirds but only 4.6 cm/sec in the distal one third. Therefore, over an average length of 116 cm (45¼ inches), a bolus of food would take about 16 seconds to traverse the body of the esophagus.[7,8] Intermittent signs of choke followed by periods of relief may indicate a disease other than simple feed impaction, and further diagnostic procedures are warranted. Anorexia, electrolyte imbalances, and dehydration accompany cases of long duration (see "Complications of Esophageal Surgery," later). Aspiration pneumonia frequently follows esophageal obstruction, and the clinical signs may be present as early as 1 day after the onset of choke.

Physical Examination

A thorough oral examination should be performed to rule out an oral foreign body, dental disease, cleft palate, or

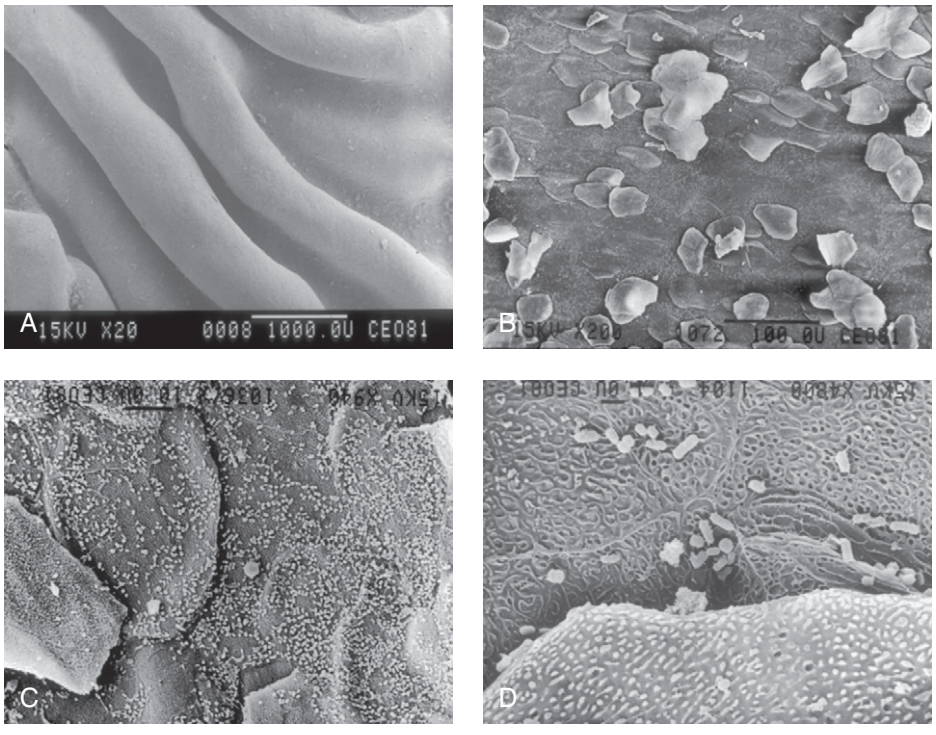

Figure 31-2. Scanning electron micrographic images of the esophageal lumen. **A,** Longitudinal mucosal folds. **B,** At a higher power, squamous epithelial cells. **C,** Colonization of bacteria on squamous cells. **D,** Close-up of squamous cells with mixed populations of bacteria. Because the lumen of the esophagus is heavily colonized under normal circumstances, prophylactic antibiotics are necessary any time this organ is incised.

oropharyngeal neoplasms. Observation and palpation of the neck in the area of the jugular furrows may reveal enlargement of the cervical esophagus. Simple food impaction of the cervical esophagus may be localized in this manner. Crepitation of a diffuse, firm enlargement may indicate loss of integrity of the esophageal wall. Passage of the nasogastric tube often confirms luminal obstruction and localizes the site of involvement. Gentle lavage of warm water through the tube may permit material to be flushed free of the obstruction if feed or consumption of bedding is the cause of the problem. At this time, sedation of the animal with xylazine (1.1 mg/kg IV) lowers the horse's head and prevents further aspiration. Lavage may be continued until the obstruction is relieved, and further diagnostic studies may be unnecessary. However, reobstruction indicates that other esophageal disease may be present, and the diagnosis should be pursued.

With any esophageal disease, auscultation and diagnostic imaging of the thorax are indicated to monitor development of aspiration pneumonia. This complication is common when an esophageal problem is encountered.

Diagnostic Imaging

Ultrasonographic examination of the cervical esophagus is easily performed and may aid in the determination of the etiology of the obstruction. Simple impactions can be localized and extramural masses may be identified. Rupture of the esophagus will be apparent as gas and free fluid outside the esophageal lumen. The extent of cellulitis and phlegmon development may also be determined ultrasonographically.[9]

Esophagography in horses provides diagnostic evidence of disease in most instances and should be considered a part of the complete esophageal examination in problems other than simple obstruction. A survey film is necessary to establish radiographic technique and the presence or absence of disease without contrast media (e.g., feed impaction or foreign body) (Figure 31-3). Barium liquid mixed in grain and fed results in a positive contrast esophagram, but preferably, barium paste (85% wt/vol with water, 120 mL) given by mouth outlines the longitudinal mucosal folds of the esophagus with the lumen undistended and localizes the obstruction or any disruption of the lumen (Figure 31-4). The feed bolus impacting the esophagus becomes coated with the barium, allowing it to be visualized on radiography; a complete obstruction halts barium flow orad to the bolus or lesion (Figure 31-5), and rupture of the esophagus permits barium to escape into surrounding soft tissues. If possible, the patient should not be sedated during this procedure because sedation suppresses the swallowing reflex and causes barium to be held in the mouth, reducing the amount available to coat the esophagus.

Liquid barium (72% wt/vol with water, 480 mL) may be administered under pressure by a dose syringe through a cuffed nasogastric tube to prevent reflux into the pharynx (Figure 31-6). This technique demonstrates strictures and associated prestenotic dilation of the esophagus, as well as space-occupying masses that displace the esophagus. Liquid barium (480 mL) followed by air (480 mL), delivered by dose syringe under pressure, provides a double-contrast study (Figure 31-7), permitting examination of mucosal folds with the esophagus distended. This latter technique gives the best definition of mucosal lesions,

Figure 31-4. Barium paste (120 mL) given by mouth outlines the normal longitudinal folds of the mucosa in the undistended lumen of the esophagus.

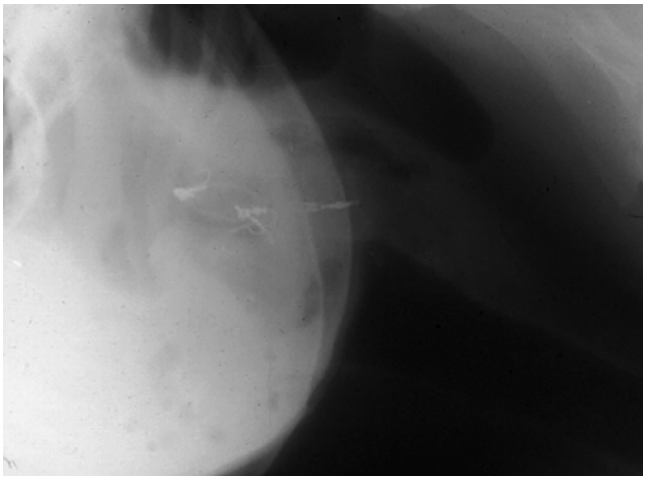

Figure 31-3. Lateral cervical radiograph of a 9-year-old gelding with anorexia and odynophagia. A metallic foreign body (fishing lure) is lodged in the cranial esophageal sphincter.

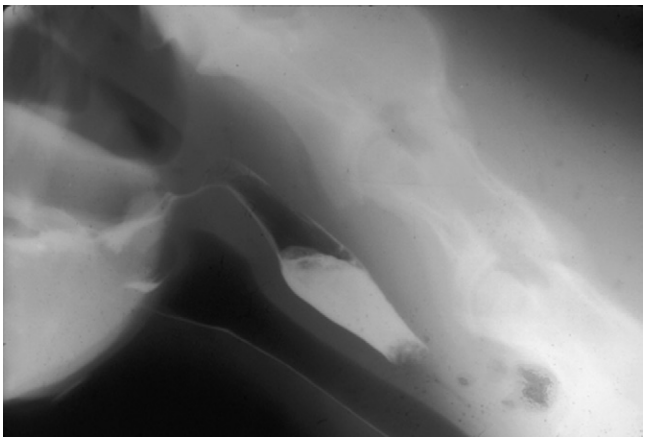

Figure 31-5. Complete obstruction of the esophagus is localized on esophagography after barium paste swallow. This adult horse had an esophageal stricture. Note the prestenotic dilation.

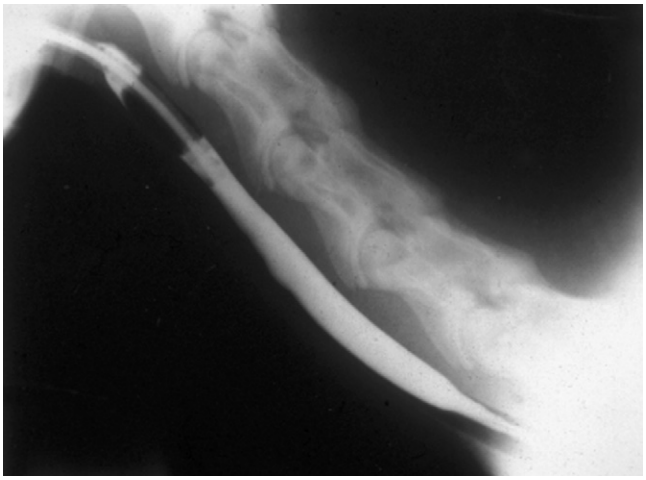

Figure 31-6. Positive-contrast esophagogram (using liquid barium administered under pressure through a nasogastric tube fitted with an inflatable cuff) shows the distended lumen of the normal esophagus. The cuff prevents reflux of barium into the pharynx and aspiration into the trachea.

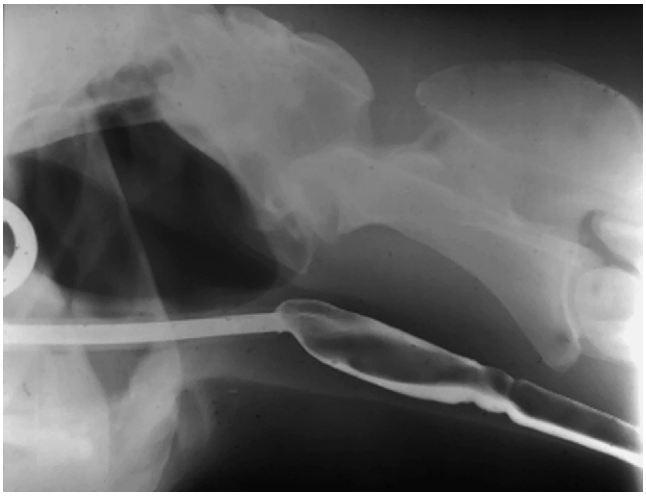

Figure 31-7. Double-contrast esophagogram (using liquid barium followed by a bolus of air) shows the esophagus with the lumen distended. This technique outlines any abnormal transverse mucosal folds and identifies a circumferential ulcer in this horse.

such as circumferential mucosal ulcers after feed impaction. Although a diagnosis can often be made without using all three techniques, each demonstrates lesions not seen with the other two.

In the cranial cervical area, where the esophagus lies dorsal to the trachea, lesions that restrict distention of the esophageal lumen can be demonstrated with negative-contrast radiography (Figure 31-8). A flexible endoscope can be used to localize the lesion and permits insufflation of the esophagus during radiography. Alternatively, air (480 mL) can be delivered by dose syringe under pressure through a cuffed nasogastric tube to achieve the same results. However, negative-contrast radiography alone does not yield much information about the caudal cervical and thoracic portions of the esophagus because of superimposition of the air density of the trachea and lungs.

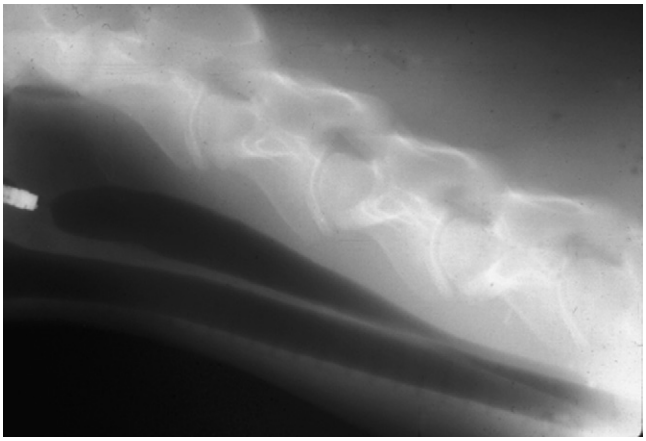

Figure 31-8. Negative-contrast esophagogram (using air insufflation introduced through the flexible endoscope) permits visual localization of the lesion with the endoscope and demonstrates a stricture.

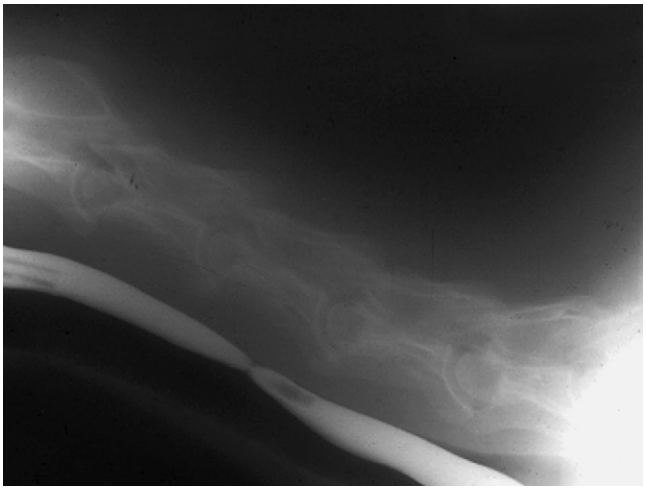

Figure 31-9. Barium esophagogram shows false signs of a stricture when barium is administered under pressure and the radiograph is made during swallowing. This swallow artifact can be avoided if xylazine is administered 5 minutes before the study is begun.

Swallowing during contrast studies, when the lumen is being distended, produces false signs of esophageal stricture (Figure 31-9). Xylazine (1.1 mg/kg IV), 5 minutes before the barium-under-pressure, double-contrast, or negative-contrast esophagogram, helps eliminate this swallow artifact by decreasing the reflex "secondary swallows" that follow luminal distention. However, if detomidine is used, false signs of megaesophagus can persist for more than 30 minutes.[10]

Endoscopic Evaluation

Esophagoscopy may better define the severity and extent of esophageal lesions diagnosed on radiography and can be used as an ancillary diagnostic aid. Additionally, endoscopic examination should always be performed when radiographic findings are not diagnostic. If the endoscope is 200 cm (78 inches) or longer, the entire esophagus may be examined, and esophageal lesions in the thorax of the adult horse undetected on radiographic examination can be diagnosed. A flexible endoscope

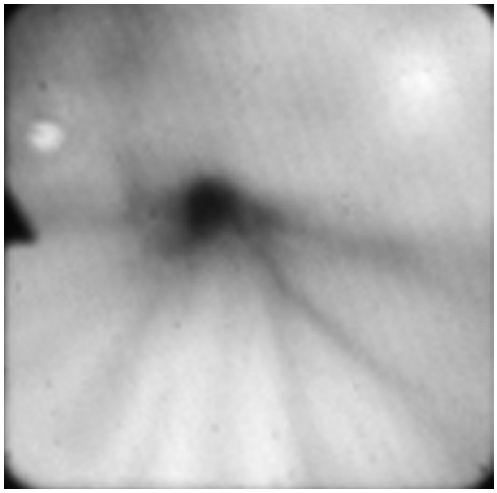

Figure 31-10. Appearance of the normal longitudinal mucosal folds of the undistended esophagus when the endoscope is pulled craniad.

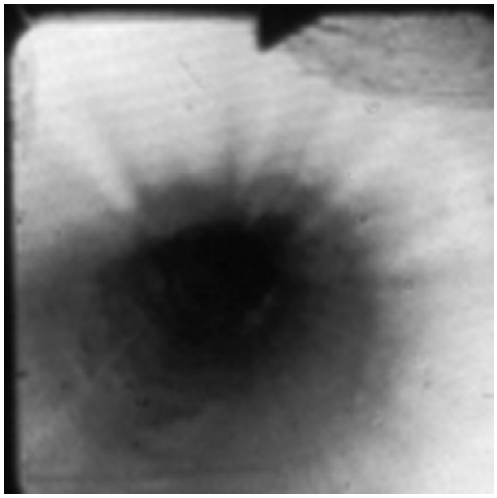

Figure 31-11. Appearance of the normal esophageal lumen when it is insufflated and the endoscope is pulled craniad.

that allows irrigation and insufflation is necessary to provide good observation of mucosal lesions and changes in luminal size.

Endoscopic examination may be performed safely on the restrained standing animal in most instances. Diagnostic observations are best made by starting with the endoscope fully inserted and the esophageal lumen insufflated, followed by slowly withdrawing the endoscope tip toward the horse's head. After each swallow, the endoscope should be cleared by irrigation and the esophagus dilated before further withdrawal. Several passes should be made over any area of suspected disease.

Longitudinal mucosal folds in the esophagus are normally seen when the endoscope tip is moved proximad and the esophagus is in the relaxed position (Figure 31-10). Insufflation flattens these folds and permits observation of luminal size (Figure 31-11). Inability to insufflate the esophagus and flatten the longitudinal mucosal folds usually indicates disease. This is noted cranial and caudal to a stricture. Transverse folds can be produced iatrogenically by moving the endoscope tip toward the stomach. When the cervical esophagus is insufflated, the outline of the trachea can often be seen through the esophageal wall. Swallowing produces changes in the lumen that give the appearance of diverticula or strictures to the untrained observer. The normal mucosa is white to light pink; reddened discolorations are evidence of mucosal disease.

The cranial aspect of the cervical esophageal sphincter is difficult to examine because the swallowing reflex is stimulated repeatedly and the larynx directs the endoscope tip dorsad. Radiographic assessment of this area may be more diagnostic. Additionally, the longitudinal mucosal folds along the rest of the esophagus are absent in this area.

Frequently, the endoscopic appearance of an esophageal obstruction is obscured by saliva mixed with ingesta that collects proximal to the obstruction. This should be removed by suction through a nasogastric tube, and the endoscope should be reinserted immediately to observe the area of obstruction.

Manometric Evaluation

Esophageal dysfunction in humans is routinely evaluated using intraluminal pressure manometry. Manometric techniques have been developed, and reference esophageal pressure profiles have been established in healthy horses. The four functionally distinct regions of the esophagus demonstrated were cranial esophageal sphincter, caudal esophageal sphincter, and "fast" (cranial two thirds) and "slow" (caudal one third) regions in the body of the esophagus (Figure 31-12). In some physiologic disorders of the equine esophagus, manometry better defines problems in which more conventional methods have not yielded a diagnosis. Manometry has yielded new information on clinical manifestations of esophageal obstruction and the effect of drugs used to treat it.[11] However, the availability and technical difficulty of manometry have limited its use as a diagnostic tool in equine practice.

Figure 31-13 outlines a systematic scheme of examination using physical, radiographic, and endoscopic findings to diagnose esophageal disorders. Alternative pathways may be used, depending on the disease, clinical signs, available diagnostic aids, and experience of the clinician. Physical examination, including passage of a nasogastric tube and esophageal lavage, and diagnostic imaging yield a diagnosis for most common esophageal problems. Endoscopy allows definitive diagnosis of some anatomic disorders not observed with radiography. Manometry, cineradiography, and electromyography are seldom necessary and have not been commonly used in diagnosis of esophageal diseases.

SURGICAL APPROACHES

Three surgical approaches to the equine esophagus can be used. Each approach is dictated by anatomic location of the lesion and purpose of the surgery. The ventral cervical approach is best used for esophagotomy, esophagomyotomy, and resections involving the proximal third of the cervical esophagus. A ventrolateral approach is recommended for placing a feeding tube in the midcervical esophagus (esophagostomy) or for approaching the distal one fourth of the cervical esophagus, especially near the thoracic inlet. Thoracotomy is necessary to approach the distal half of the esophagus; the choice of intercostal space is dictated by the aim of the surgery and location of the lesion.

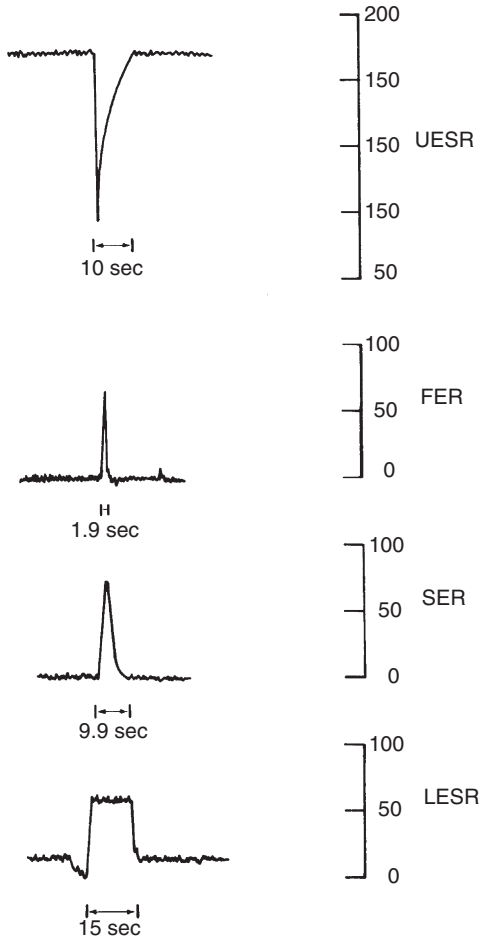

Figure 31-12. Manometric recording of a swallow as it passes through the four functionally distinct regions of the esophagus. *FER,* Fast esophageal region; *LESR,* caudal, or lower, esophageal sphincter region; *SER,* slow esophageal region; *UESR,* cranial, or upper, esophageal sphincter region; units in mm Hg.

If the surgeon expects to invade the esophageal lumen, broad-spectrum antibiotics are indicated and should be chosen on the basis of sound surgical principles, expected complications, and recognized bacterial colonization of this organ.[6,12] Before induction of anesthesia, a nasogastric tube should be passed as far into the esophagus as the surgical site (or beyond if possible) to facilitate identification of the esophagus at surgery. It also is necessary to avoid damage to the recurrent laryngeal nerve and vagosympathetic trunk, which are easily traumatized when retracting the carotid artery away from the esophagus. Owners should be advised that laryngeal hemiplegia is a common complication of esophageal surgery.

Ventral Approach

Surgical procedures are conducted with the animal under general anesthesia and placed in dorsal recumbency. A 10-cm (4-inch) skin incision permits exposure of about 6 cm (2½ inches) of the esophagus. The skin and subcutaneous fascia are divided sharply using a scalpel. The paired sternothyroid, sternohyoid, and omohyoid muscles are separated along the midline to expose the trachea (Figure 31-14). Blunt separation of fascia along the left side of the trachea permits identification of the esophagus containing the nasogastric tube. Retraction of the trachea to the right of the median plane and gentle sharp dissection of overlying loose adventitia expose the ventral wall of the esophagus.

Ventrolateral Approach

Placement of a feeding tube using the ventrolateral approach facilitates firm anchorage of the tube to the skin and permits it to lie in a comfortable position on the patient's neck while preventing impingement of the feeding tube on the trachea (Figure 31-15). This approach also affords better access to the middle and distal cervical esophagus, where the ventral cervical musculature becomes more heavily developed, making the ventral approach less desirable. This surgical approach may be performed with the horse standing, using local anesthesia, or with the horse in dorsal or right lateral recumbency under general anesthesia.[12,13]

A 5-cm (2-inch) skin incision (for feeding tube placement) is made just ventral to the jugular vein. The sternocephalicus and brachiocephalicus muscles are separated, and the deep cervical fascia is incised to expose the esophagus. It may be necessary to incise the cutaneous colli muscle in the distal cervical area.

Approach to the Thoracic Esophagus

An approach through the thoracic esophagus can be used for vascular ring anomalies (in my experience, the left fourth or right fifth interspace was used in two patients) or when the suspected lesion can be resolved surgically without entering the esophageal lumen. A 5-month-old foal was successfully treated for an intrathoracic esophageal stricture with esophagomyotomy through the eighth intercostal space, and an intrathoracic esophageal pulsion diverticulum was resected in a 7-month-old foal by resecting the left eighth rib.[14,15]

The patient is placed in right lateral recumbency under general anesthesia, and positive-pressure ventilation is used. The skin, subcutaneous tissue, cutaneous trunci, serratus ventralis, and latissimus dorsi muscles are sharply divided. A subperiosteal rib resection has been described. However, in my experience, this is not necessary in foals, because rib retractors provide adequate exposure.

MANAGEMENT OF ESOPHAGEAL DISORDERS

Impaction

The most common type of obstructive esophageal disease is impaction with ingesta or bedding.[9] It can occur in the normal esophagus of a gluttonous animal and has a typical radiographic appearance (Figure 31-16). Nasogastric tube passage and gentle warm water lavage are usually successful in relieving the obstruction. Xylazine sedation to lower the patient's head during this procedure greatly reduces the hazard of aspiration of ingesta that is flushed free and passes retrograde through the esophagus into the nasopharynx.

Several alternative techniques may be necessary if gentle lavage is unsuccessful. A cuffed nasogastric tube may be placed, the animal sedated, and water lavaged under pressure with a dose syringe or stomach pump. The tube helps prevent reflux or ingesta from entering the pharynx while permitting pressure of the water to push the obstruction distad. External massage and to-and-fro movement of the water resolve most impactions.

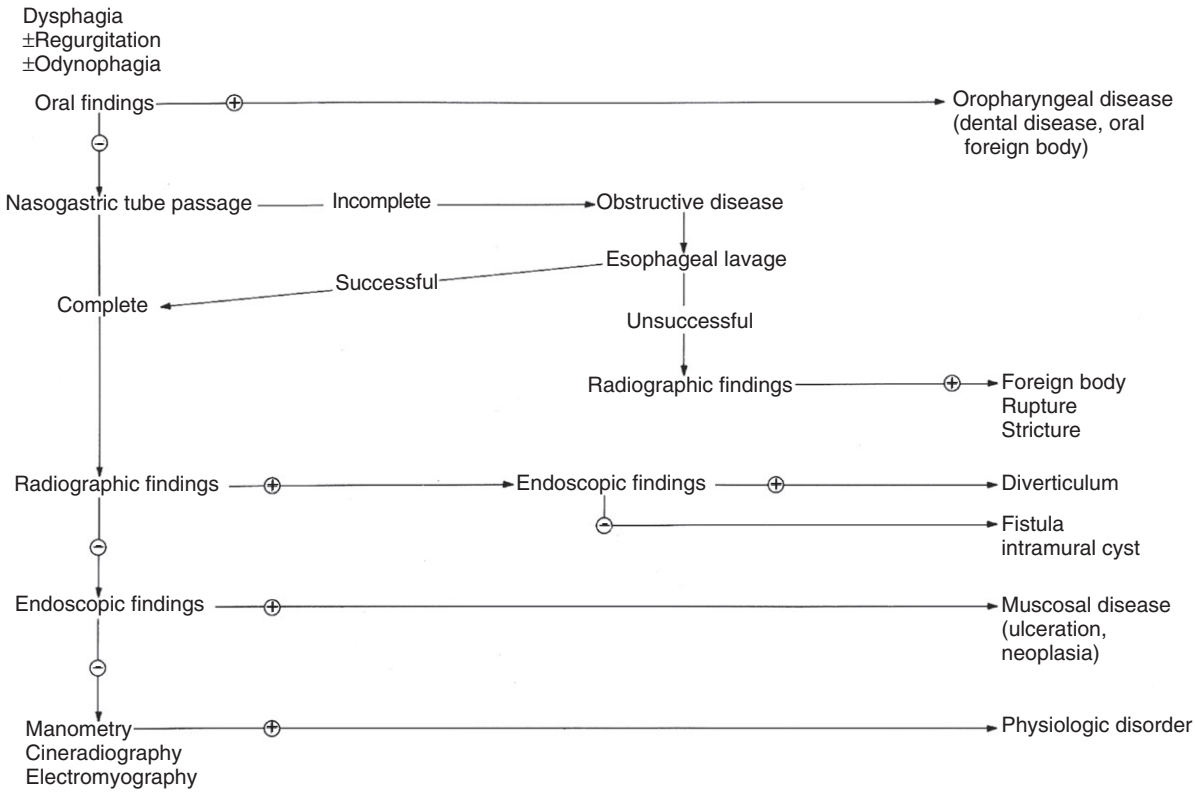

Figure 31-13. Scheme of examination of esophageal disorders. *Arrows* outline pathways that are usually diagnostic for the conditions shown at the right.

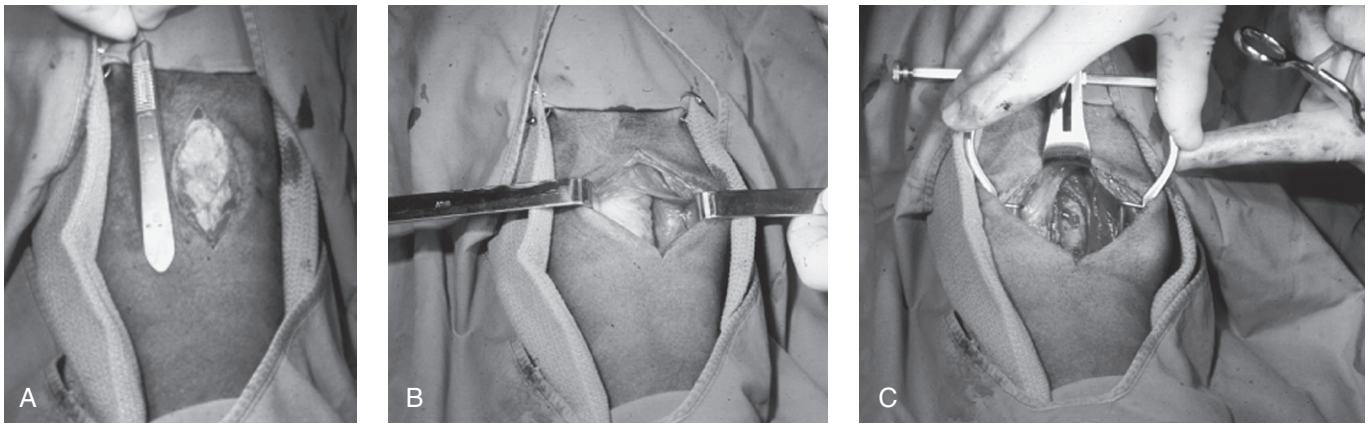

Figure 31-14. A, A 10-cm (4-inch) incision through the skin and subcutaneous fascia, which is sharply divided using the scalpel. **B,** The paired muscles of the sternothyroid, sternohyoid, and omohyoid are separated along the midline to expose the trachea. **C,** A baby Balfour retractor placed through the incision allows easy access to the esophagus.

If this technique is not successful, the animal should be muzzled to prevent food and water intake and left alone for 8 to 12 hours, and the treatment should then be repeated. Frequently, the initial treatment softens the impaction and it becomes dislodged by swallowing or is easily relieved by a second treatment. Some clinicians claim that atropinization (0.02 mg/kg) for a horse with esophageal impaction aids dissolution of the impaction by promoting esophageal relaxation and reduction of salivary secretions that might otherwise be aspirated. The effect of acepromazine on esophageal relaxation is supported in one experimental study.[16] However, oxytocin administered intravenously (at 0.11 and 0.2 IU/kg) results in short-term significant relaxation of esophageal musculature in experiments, and it has become popular as an adjunct treatment for esophageal impaction.[11] Because xylazine has similar effects, these drugs could be used together to reduce the tone of the esophageal musculature, allowing passage of the obstructions with reduced risk of esophageal injury.

Refractory cases or intractable horses may benefit from general anesthesia and water lavage under pressure. This method has the advantages of providing some relaxation of the esophageal musculature, reducing the chances of aspiration (because

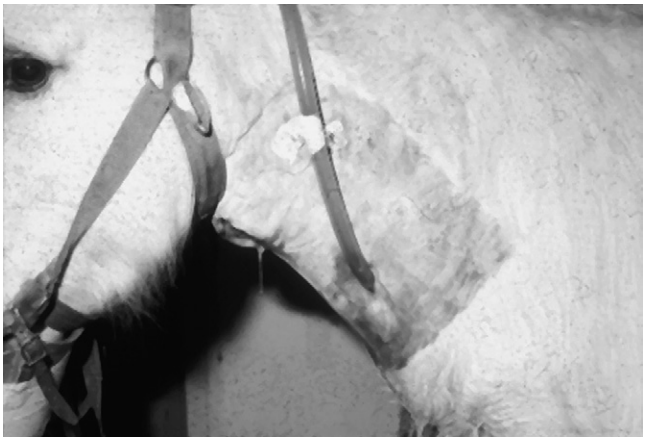

Figure 31-15. Placement of a feeding tube ventral to the jugular vein permits it to lie in a comfortable position on the neck. Note the butterfly tape bandage sutured to the skin to firmly anchor the tube, along with saliva loss around the tube.

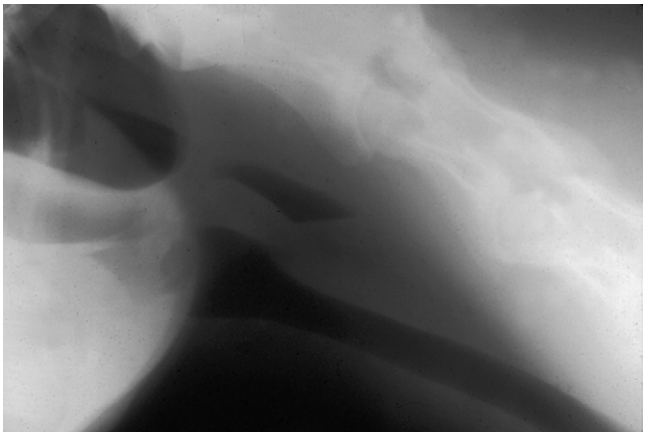

Figure 31-17. Lateral cervical radiograph of a horse after impaction of the esophagus has been relieved shows a fluid line in an area of dilation that extends from the distal point of obstruction proximad to the upper esophageal sphincter. The fluid line is produced by saliva that has collected in the dilated area.

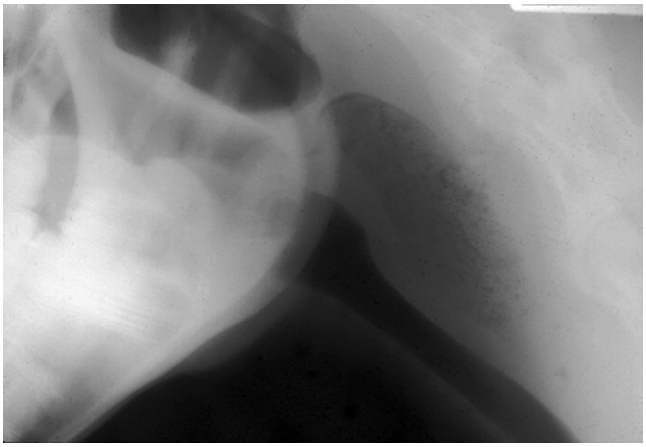

Figure 31-16. Lateral cervical radiograph shows typical appearance of impaction of ingesta in the cranial cervical esophagus.

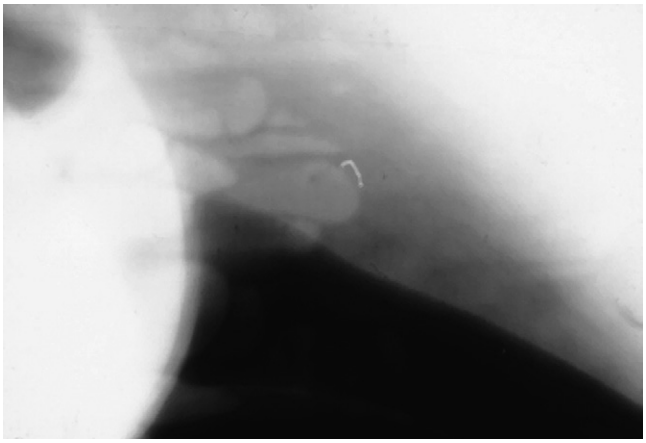

Figure 31-18. Lateral cervical radiograph of a 5-year-old Quarter Horse gelding with cervical swelling, dysphagia, and odynophagia. A metallic foreign body (wire) is lodged in the lateral wall of the cranial esophagus. A nasogastric tube passed easily. Note the gas in the tissues.

the horse's head is lowered), and decreasing the risk of esophageal perforation with the tube in an intractable horse. Gentle manipulation is mandatory with this technique to avoid rupture of the esophagus. Impactions that do not respond to conservative therapy should be definitively identified by radiographic and endoscopic examination and, if amenable, relieved by longitudinal esophagotomy (see "Foreign Body," next). Surgery is preferable to repeated trauma of the esophagus through attempts to relieve the obstruction with a nasogastric tube. Use of the nasogastric tube as a probang is not recommended and can result in severe trauma to the larynx and esophagus.[17] Cervical esophagotomy can be performed with the horse standing or under general anesthesia, and obstructions can be lavaged through the incision if necessary.

One aftermath of simple impaction is fusiform dilation of the esophagus that predisposes to reobstruction (Figure 31-17). This condition resolves in 24 to 48 hours, provided the dilation is kept free of ingesta. Food should be withheld or only small quantities of a soft diet fed for 2 days after an episode of choke to permit the lumen to resume its normal diameter. Glucose–electrolyte solutions for drinking should be provided in addition to fresh water so the electrolyte abnormalities secondary to salivary loss can be compensated.

Broad-spectrum antimicrobial therapy is indicated for 5 to 7 days because the risk of aspiration pneumonia is high after choke. If pneumonia is not the major limiting factor in this disease, simple obstruction has a favorable prognosis.

When an obstruction has been present for several days or is refractory to initial treatment, examination using radiography or endoscopy is warranted after the obstruction has been relieved. Circumferential mucosal ulceration occurs occasionally in these cases and can result in esophageal stricture.

Foreign Body

Small pieces of wood, wire, fishing tackle, and medication boluses can become esophageal foreign bodies in horses.[18,19] They often perforate the esophageal wall, resulting in phlegmon or abscessation (Figure 31-18). The swelling that accompanies

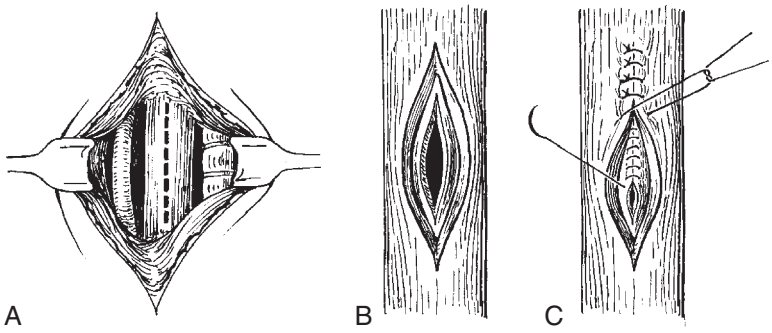

Figure 31-19. A, Longitudinal skin incision exposes the carotid artery *(left)*, esophagus *(center)*, and trachea *(right)*. **B,** In this longitudinal esophagotomy, a scalpel is used to incise both the outer layer (muscularis and adventitia) and the inner layer (mucosa and submucosa). **C,** The esophagotomy is closed with simple-continuous sutures in the inner layer (mucosa and submucosa) and simple-interrupted sutures in the outer layer (muscularis and adventitia).

these conditions usually obstructs the esophageal lumen and results in impaction. Diagnosis is made by radiography or esophagoscopy.

Retrieval of small sharp foreign bodies under endoscopic guidance is possible but difficult; general anesthesia is recommended to prevent the swallowing movements during manipulation that may produce pain and further esophageal trauma. It is necessary to relieve the impaction before attempting this method of treatment. Blunt or round foreign bodies may be treated similar to feed impactions. Although the nasogastric tube may be used as a probe to push the object into the stomach, the risk of perforation is great. Gentle manipulation is mandatory to prevent rupture. Additionally, this technique has the risk of moving the foreign body from the cervical region only to have it lodge in the thorax, a less-accessible site. Longitudinal esophagotomy with primary closure results in minimal complications when performed in a region of normal esophagus and has become the accepted method of removing a foreign body.[20,21]

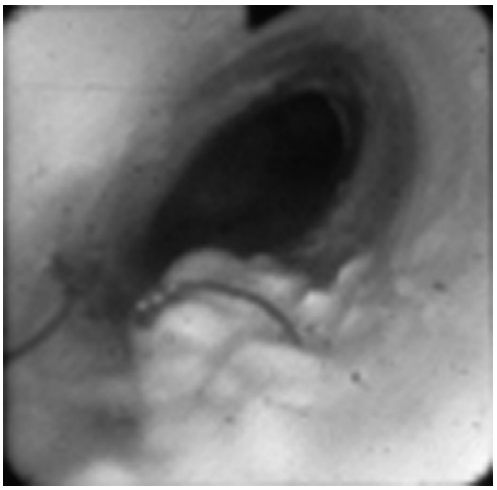

Figure 31-20. Endoscopic appearance of a longitudinal esophagostomy that healed by first intention 48 days after surgery. One loop of the suture remains in the healed esophagotomy site.

Esophagotomy

Passage of a nasogastric tube as far as the foreign body (or beyond, if possible) facilitates identification of the esophagus during surgery. General anesthesia is preferred if closure is to be attempted. The patient is placed in dorsal recumbency, and the skin of the ventral surface of the neck is prepared and draped for aseptic surgery. A 10-cm (4-inch) skin incision is made and the esophagus is approached (see earlier in this chapter). Care should be taken to preserve the small vessels that supply the esophagus. Elevation of the esophagus from its bed of adventitia should be avoided. The left carotid sheath, containing the carotid artery and vagus and recurrent laryngeal nerves, should be retracted laterally. Pediatric-size Balfour abdominal retractors aid exposure of the esophagus, which then can be sharply incised through the muscle, submucosa, and mucosa cranial to, caudal to, or directly over the foreign body (Figure 31-19). The exact location of the incision into the esophagus depends on the mobility of the foreign body within the lumen and the amount of swelling in and compromise to the esophageal wall.

After removal of the foreign body, if the esophagus has a normal appearance in the area of the incision, closure should be completed using a simple-continuous suture of 3-0 polypropylene suture material with the knots tied in the lumen (see Figure 31-19). Esophageal musculature may be apposed with simple-interrupted sutures of 3-0 absorbable or monofilament nonabsorbable suture material, at the surgeon's preference. Muscular layers, subcutaneous tissue, and skin may be apposed with 0 suture material in a simple-interrupted pattern. A polyethylene drain with an outer diameter of 0.63 cm (¼ inch) is placed beside the esophagus and exited ventral to the skin incision through a small stab wound. This drain is maintained under constant suction for 48 hours to remove serum and blood from the surgical site and to provide early detection of salivary leakage should dehiscence occur.

Postoperatively, feed should be withheld for 48 hours. Parenteral administration of electrolyte solution, the composition of which depends on the horse's acid-base and hydration status, may be used to maintain hydration. Small quantities of pelleted feed in a slurry should be fed over the next 8 days before normal feeding can be resumed. Most esophagostomy incisions heal by first intention, and the intraluminal suture will slough into the lumen within 60 days (Figure 31-20).

If removal of the foreign body is necessary through an obviously diseased segment of the esophagus, the incision may be closed and an esophagostomy tube placed through a separate incision closer to the stomach or directly into the esophagotomy incision (see "Esophagostomy," later). Feeding of a complete pelleted diet through the esophagostomy tube can begin immediately after surgery. Particular attention to the patient's water and electrolyte balance is necessary when closure of the esophagus is not possible (see "Acid-Base and Electrolyte Alterations," later, and Chapter 3).[22]

Ulceration and Esophagitis

Mucosal ulceration and esophagitis commonly occur secondary to long-standing impactions. Longitudinal mucosal ulcers can be produced from impactions; more frequently, circumferential ulcerations occur. Other causes of esophageal ulceration in foals include phenylbutazone toxicity, in which generalized gastrointestinal mucosal disease is a feature, and severe gastroduodenal ulcer disease that produces secondary reflux esophagitis. Diagnosis of esophageal ulceration is best made by endoscopy (Figure 31-21), although contrast radiography frequently defines the margins of the ulcer (see Figure 31-7).

Conservative management should be instituted to minimize trauma to the mucosa, reduce inflammation, and control infection. A low-bulk, minimally abrasive diet (mash), nonsteroidal anti-inflammatory drugs (NSAIDs) (only if they are not implicated as causative agents), and broad-spectrum antimicrobial therapy are indicated. Because this diet results in hunger, the patient should be muzzled between feedings, or all bedding should be removed from the stall to avoid ingestion of straw or wood chips. Reexamination is recommended every 10 to 14 days. Stricture (see later) may occur within 30 days of the original insult, when the circumferential ulcer is more than 2.5 cm (1 inch) long.[23] Longitudinal mucosal ulcers (especially if they are not extensive and are localized to one area of the esophagus) and circumferential ulcers less than 2 cm (¾ inch) long usually heal without stricture.

Rupture, Perforations, and Lacerations

Rupture of the esophagus can occur secondary to long-standing obturation, repeated or aggressive nasogastric tube passage, foreign body perforation, external trauma to the cervical area (usually a kick), or extension of infection from surrounding strictures.[24-27] Cervical swelling usually prevents successful passage of a nasogastric tube, even after irrigation of the esophagus with water. Swallowed air escapes from the rupture and causes subcutaneous emphysema; this can be recognized ultrasonographically or radiographically (see Figure 31-18). Positive-contrast techniques demonstrate escape of barium into surrounding tissues (Figure 31-22).

Ruptures that cannot drain to the outside lead to leakage of saliva and ingesta into tissues of the neck, resulting in severe infection and phlegmon development. Ruptures or perforations that allow escape of saliva and ingesta through the skin are less likely to cause systemic illness and extension of infection into the thorax. Early establishment of drainage, preferably on the ventral midline, is necessary with all ruptures of the esophagus to avoid mediastinitis, pleuritis, and even septicemia (Figure 31-23). This should be followed with daily lavage.

Perforation or lacerations of the esophagus accompanied by minimal escape of saliva and ingesta can be repaired using the technique described for esophagotomy. Drainage and the feeding regimen used after esophagotomy should be employed. Secure closure of a ruptured or perforated defect is usually possible only in patients operated on shortly after the perforation has occurred (within 12 hours). In early cases, when esophageal tissues are too damaged to hold sutures or when infection or contamination with ingesta has already occurred, some means of draining the esophageal contents to the outside must be provided. The patient should receive systemic antibiotics and water; electrolyte and nutritional requirements should be met by tube feeding. In some cases, the feeding tube can be placed through the site of rupture into the stomach (Figure 31-24). An alternative method of feeding allowing spontaneous healing of the rupture or successful repair of the rupture when edema and infection have been controlled is an esophagostomy performed distal to the rupture (closer to the stomach).

Esophagostomy

Cervical esophagostomy is an excellent method of extraoral alimentation that prevents the discomfort and irritation of the indwelling nasogastric tube. An additional advantage is prevention of deleterious influences on healing of an esophageal wound by an intraluminal tube located in the immediate region.[28] To use this advantage, the esophagostomy should be placed distal to the area of esophageal injury. The surgery can be performed with the horse in lateral recumbency under general anesthesia or standing under mild tranquilization and

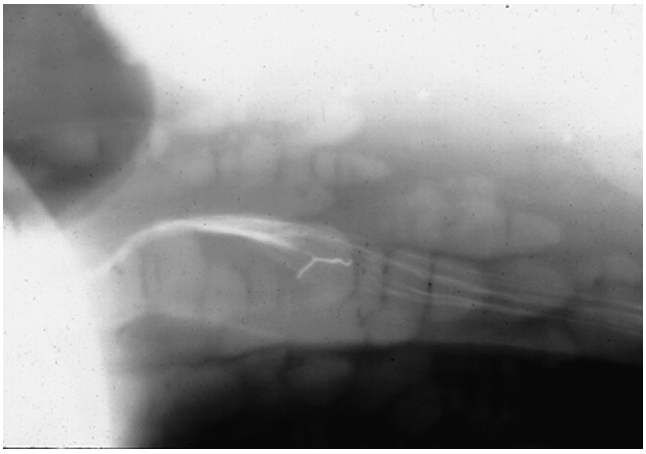

Figure 31-22. Barium swallow in a horse with a penetrating foreign body (wire) shows swallowed air and barium that has escaped into the periesophageal tissue (same horse as in Figure 31-18).

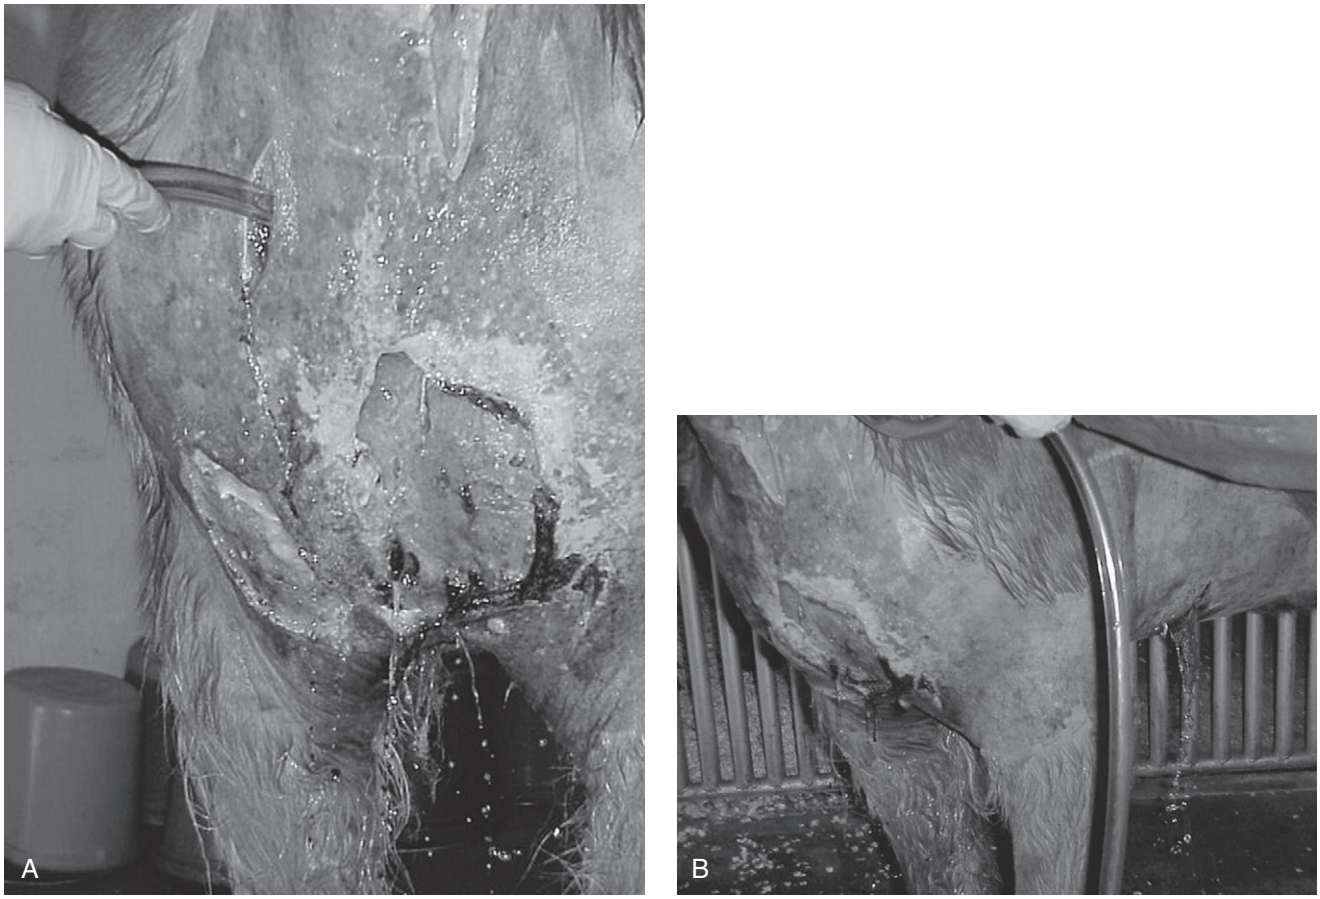

Figure 31-23. A, Establishment of ventral drainage following esophageal rupture in which multiple incisions needed to be made to drain food material from the cranial pectoral area. **B,** Daily lavage with copious amounts of water through the incisions shows the communication between the caudal cervical esophageal incisions and incisions in the pectoral area and caudal chest area behind the elbow.

Figure 31-24. Slurry made of complete pelleted feed is used to meet the nutritional needs of the patient.

local anesthesia. Passage of a nasogastric tube facilitates identification of the esophagus at surgery.

The skin over the left jugular furrow is prepared for surgery in the desired area. The esophagus is occasionally located on the right side of the trachea and should be approached over the right jugular furrow in those horses. A 5-cm (2-inch) skin incision is made ventral to the vein. The esophagus is sharply incised longitudinally for 3 cm (1¼ inches) down to the indwelling nasogastric tube. The nasogastric tube is removed, and a polyethylene nasogastric tube (with an outer diameter of 14 to 24 mm [¼ to 1 inch]) is placed into the stomach through the esophagostomy. Failure to place the tube into the stomach allows easy dislodgement. Care should be taken to ensure that the end of the tube is placed into both the elastic inner layer and the inelastic outer muscle layer of the esophagus. Difficulty in tube placement is usually an indication that the incision in the muscle layer is inadequate to accommodate the diameter of the tube. Sutures can be placed in the mucosa to form a seal around the tube but probably are unnecessary because they do not prevent leakage of saliva. The tube should be secured firmly, first with butterfly tape bandages sutured to the skin (see Figure 31-15) and then with elastic tape bandages. Tubes of large diameter are preferred to prevent plugging with ingesta during feeding. They should be capped between feedings and flushed with water at the end of each feeding to maintain patency.

Figure 31-25. Esophagostomy tube should remain in place for a minimum of 7 to 10 days to permit granulation tissue to form a true stoma.

Esophagostomy tubes should remain in place for a minimum of 7 to 10 days to permit granulation tissue to form a true stoma (Figure 31-25). A longer period is necessary if the tube is placed in the area of a rupture or perforation. When the tube is removed, normal feeding may be resumed. A large portion of swallowed feed may be lost through the stoma when the patient is fed from the ground (Figure 31-26). When feed is placed at the height of the withers, however, less of the bolus is lost through the stoma with each swallow. The stoma heals spontaneously after the tube is removed, and fistula formation is rare (Figure 31-27).

However, complications of this form of alimentation are well documented and can result in death. Early detection and ventral drainage of infections that dissect along the trachea and esophagus are vital for a successful outcome. Patients should be maintained on antimicrobial therapy until a mature stoma develops (7 to 10 days).

Resection of the esophagus after rupture is warranted if the muscular layer is obviously necrotic and does not act as a tube along which the mucosa may regenerate and if the proximal and distal segments of the esophagus can be anastomosed without undue tension (see "Partial Resection" and "Resection and Anastomosis," later). Few ruptures of the esophagus requiring resection occur without necrotizing cellulitis. Usually a delay in repair is necessary to permit acute inflammation to subside before surgery. During this period, the patient may be accommodated with a change in diet and tube feeding.

Stricture

Narrowing of the esophageal lumen due to stricture formation is usually an annular lesion and can be classified into the following three types, depending on the anatomic location of induration and fibrosis: (1) mural lesions that involve only the adventitia and muscularis, (2) esophageal rings or webs that involve only the mucosa and submucosa, and (3) annular stenosis that involves all layers of the esophageal wall. Stricture of the esophagus may be acquired as a result of external or internal trauma to the esophageal walls (especially after impactions that produce circumferential ulceration), leakage of saliva or dehiscence after surgery, or external compression by or attachment to adjacent structures. In most instances, strictures are less likely

Figure 31-26. After removal of the esophagostomy tube, a large portion of masticated feed and saliva may be lost through the stoma when the patient is fed from the ground. Placing the feed at the height of the withers allows less of the bolus to be lost through the stoma with each swallow. The horse may electively eat the masticated feed, and this should be encouraged because the salt content from the saliva will be reswallowed and eventually ingested.

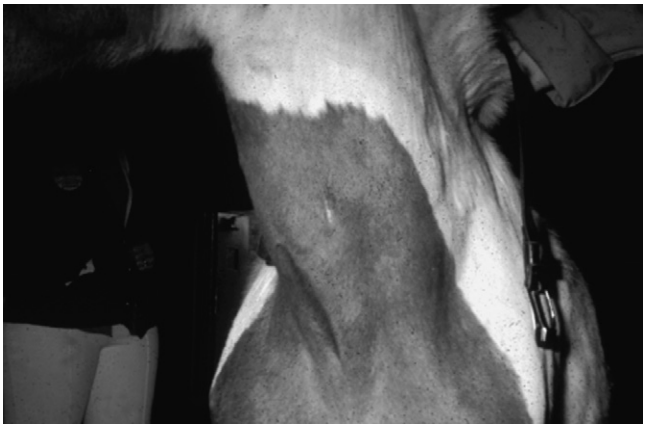

Figure 31-27. The stoma heals spontaneously after the tube is removed, and fistula formation is rare. (Three weeks after tube removal from the animal seen in Figure 31-25.)

to occur when traumatic insults involve only a portion of the circumference of the esophagus. For this reason, mobilization of the esophagus from its fascial attachments during surgery should be avoided when possible.

Strictures usually impede complete passage of the nasogastric tube and are best demonstrated by positive-pressure contrast esophagograms (Figure 31-28). Conservative management of a stricture is aimed at dilation of the stenotic segment. Bougienage or pneumatic or hydrostatic dilators have limited practical value in adult horses because of the inaccessibility of special equipment and the chronicity of the problem. There is a report describing resolution of an esophageal stricture in a 1-month-old colt using a balloon dilation procedure,[29] but in my experience, repetition of the procedure is often necessary and is rarely successful. However, early lesions, such as postsurgical strictures or those following circumferential ulceration, can be dilated with the frequent feeding of small quantities of soft food over a period of several months.

In seven horses that developed stricture after esophageal impaction, observation over 2 months revealed that the esophageal lumen was maximally reduced (strictured) 30 days after circumferential ulceration was observed (Figure 31-29), after which lumen diameter increased to normal by 60 days.[23] This also has been documented after experimental resection and anastomosis and has been observed in a series of cases involving foals.[30] Therefore a low-bulk diet and anti-inflammatory and antimicrobial therapy should be used, and surgical intervention should be delayed for 60 days after the original insult. It is important to impress on horse owners that several episodes of choke may occur up to 40 days after the original obstruction.

Strictures more that 60 days old have usually matured to the point where the cicatrix is too firm to yield to dilation by this method and therefore may be classified as chronic (Figure 31-30). Chronic strictures of the esophagus may be corrected by esophagomyotomy, partial or complete resection and anastomosis, or patch grafting. Complications may occur with any of these surgical treatments, and the surgeon should take care to pick the most conservative therapy that will meet the aim of treatment. Leakage of luminal contents and reformation of the stricture requiring prolonged medical management are to be expected after resection and patch grafting. Strictures that are mural in origin respond to myotomy and have the best

Figure 31-28. Positive-pressure esophagogram showing a stricture in a foal. Note the prestenotic dilation. The lesion was resolved by partial resection and anastomosis.

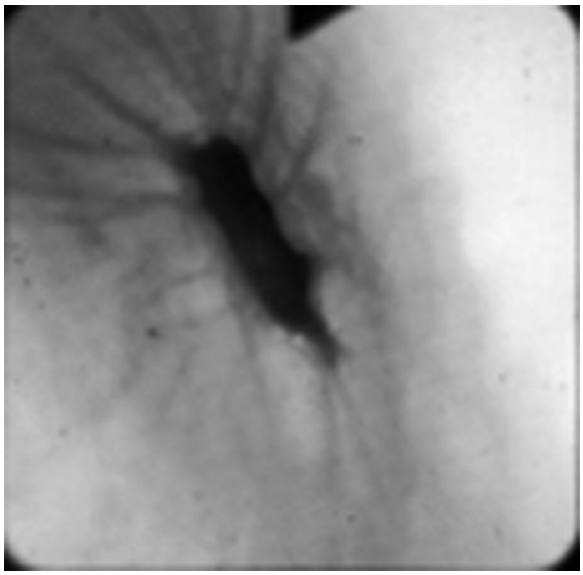

Figure 31-29. Endoscopic appearance of a stricture 30 days after circumferential ulceration.

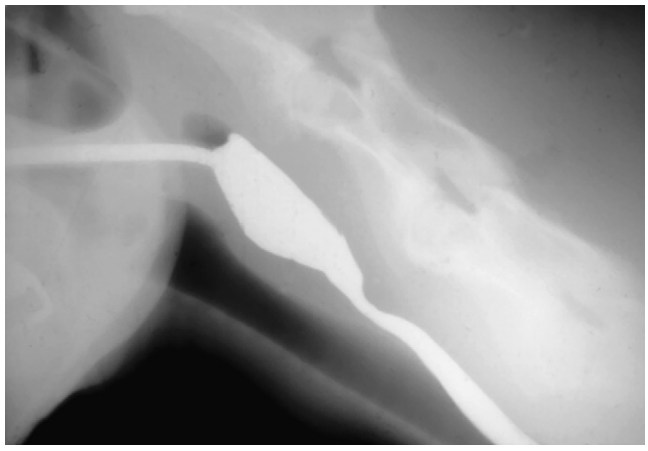

Figure 31-30. Positive-contrast esophagogram using liquid barium administered under pressure through a cuffed nasogastric tube shows stricture with prestenotic dilation. The stenosis was subsequently resolved by esophagomyotomy.

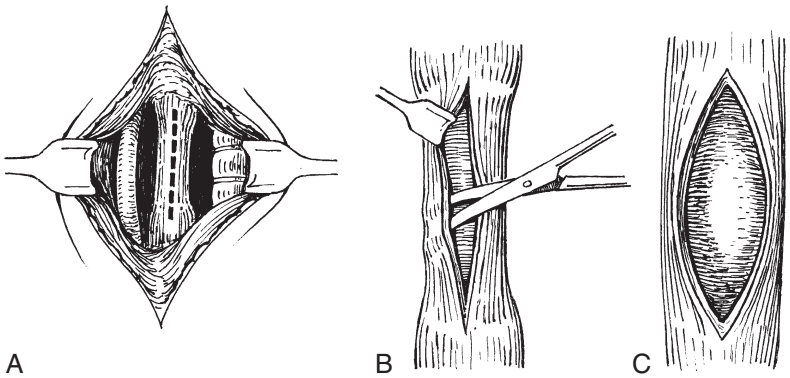

Figure 31-31. A, Esophagomyotomy: longitudinal incision of the outer layer of the esophageal wall. **B,** Elevation and separation of the outer (muscularis and adventitia) and inner (mucosa and submucosa) layers of the esophageal wall to complete the esophagomyotomy. **C,** The muscularis and adventitia are not sutured.

prognosis for recovery without restricture. Three successful reports appear in the literature; I have had similar experience with five other horses.[31,32] The surgery should be performed with the horse under general anesthesia, with a nasogastric tube passed to the level of the stricture to permit easy identification of the involved area.

Esophagomyotomy

The esophagus is incised longitudinally to the level of the mucosa, through the stricture, and 1 cm (½ inch) distal and proximal to it (Figure 31-31, *A*). The nasogastric tube may be passed through the stenotic area at this point. From this single incision, the muscularis is separated by sharp dissection from the mucosa around the entire circumference of the esophagus (see Figure 31-31, *B*). When the mucosa is freed in this manner, removal of a portion of the muscularis or multiple myotomy incisions are seldom necessary. The myotomy is not sutured (see Figure 31-31, *C*), and the approach incision is closed and drained in a routine manner. If the mucosa is opened inadvertently, it should be closed immediately with 3-0 polypropylene sutures in a simple-continuous pattern. Postoperatively, frequent feeding of small quantities of soft feed may be necessary if a prestenotic dilation was present before surgery. When this dilation is no longer evident radiographically, normal feeding may be resumed.

Recurrence of postsurgical cicatricial stricture is slow to develop, with clinical signs occurring weeks or months after the operation. Conservative treatment (changing from hay to a complete pelleted diet) may be all that is necessary to resolve recurrent obstructions. A postsurgical stricture seen long after the original operation usually is the result of a mature nonresilient cicatrix and may not respond to dilation. If surgery is necessary, the surgeon should not hesitate to perform a second esophagomyotomy; however, performing another surgery in a stenotic area of the esophagus before allowing the acute inflammation of the previous surgery to subside greatly increases the propensity for restricture. If such is the case, a more hazardous procedure may have to be selected eventually to try to correct the problem.

Partial Resection

Longitudinal esophagomyotomy combined with mucosal resection provides relief of stricture caused by esophageal rings or webs or annular stenosis of all muscle layers.[33,34] Performed under general anesthesia, the procedure is indicated when the cicatrix involves the mucosa and prevents passage of a nasogastric tube after myotomy.

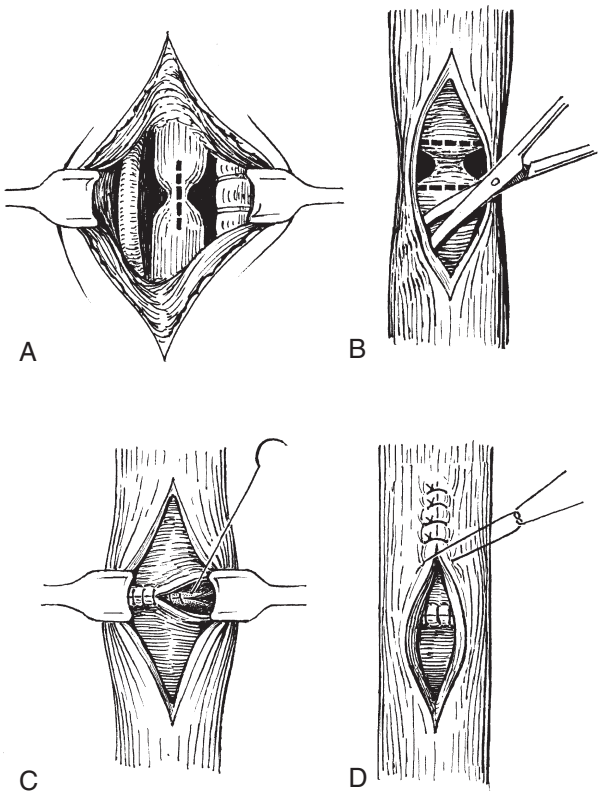

Figure 31-32. Partial resection and anastomosis. After longitudinal incision of the outer layer **(A),** the inner layer is resected **(B)** and, when possible, closed transversely using several simple-continuous sutures **(C).** The outer layer is then closed with interrupted sutures **(D).**

The esophagus is exposed and incised as described previously for esophagomyotomy. A longitudinal incision is made through the mucosa long enough to permit identification of the diseased segment (Figure 31-32, *A*). The mucosal scar is separated by sharp dissection from normal or diseased muscle layer. Circumferential incisions are made at the proximal and distal edges of the mucosal cicatrix and it is removed, leaving the muscular tube intact (see Figure 31-32, *B*).

If cut edges of the mucosa can be brought into apposition without undue tension, they are apposed by three equally

spaced 3-0 polypropylene simple-continuous sutures with the knots tied in the lumen (see Figure 31-32, *C*). When mucosal rings or webs are the cause of stenosis, the normal esophageal muscle should be apposed over the mucosal anastomosis (see Figure 31-32, *D*), but in the case of an annular stenosis that involves the entire esophageal wall, the muscularis should not be sutured. A drain is placed next to the esophagus, and the approach incision is closed. If space permits, tube feeding through an esophagostomy placed through a separate incision distal to the stricture is ideal. When this is not possible, frequent feeding of small quantities of soft food may begin 48 hours after surgery and should be continued for 10 days before normal roughage is offered to the patient.

When the stricture is extensive and the mucosa cannot be sutured, regeneration of the mucosa within the muscle tube occurs readily. The muscularis may be sutured if it is healthy, or it may be left open if only scar tissue remains. Spontaneous healing is aided if esophagostomy tube feeding (located closer to the stomach than the operative site) is used. When the stricture is located too close to the thoracic inlet to permit placement of a separate esophagostomy incision, the tube may be inserted directly through the stricture site. Recurrence of stricture after this procedure may be an indication for esophagomyotomy or an esophagostomy tube placed through the stricture.

Resection and Anastomosis

Complete resection and anastomosis should be reserved for rupture of the esophagus in which the muscularis is not viable. The esophagus is exposed as described previously. The area to be resected and several centimeters of normal esophagus distal and proximal to it are mobilized. Umbilical tape or rubber drain tubing (0.63 cm [¼ inch]) is placed around the esophagus and held in place with hemostatic forceps to occlude the lumen a convenient distance from the area to be resected. Crushing clamps of any type should not be used on the esophagus. A point is selected proximal to the diseased segment, where the esophagus is sharply transected, leaving healthy tissue for closure. This procedure is repeated distad, and the diseased portion is removed. The mucosal-submucosal layer is apposed with 3-0 simple-interrupted monofilament nonabsorbable polypropylene sutures placed about 3 cm (¼ inch) from the cut edge, 2 to 3 mm (1/12 to ¼ inch) apart, with the knots tied in the lumen. Tension of the sutures is adequate to form a tight seal without interference of the blood supply.

The esophageal muscle is apposed with interrupted horizontal mattress sutures of 2-0 polydioxanone or monofilament nonabsorbable suture material. The muscle layer has limited elasticity and, if necessary, a relief incision in the form of a circular myotomy 4 to 5 cm (1½ to 2 inches) proximal or distal to the anastomosis can decrease tension on the repair. The approach incision is closed as described previously.

Alternative successful methods of closure have been described, but postoperative management is a major determinant of the outcome of this procedure, regardless of closure technique.[35,36] Prevention of undue tension on the anastomosis by use of a standing martingale and special feeding regimen is necessary (Figure 31-33). If oral alimentation is elected, soft foods should be given only after 48 hours and until endoscopic or radiographic evaluation of the surgery shows primary healing has occurred. Esophagostomy is the preferred method of feeding, if possible. An extensive cervical esophageal stricture produced by annular stenosis of the entire wall may preclude successful repair by techniques described previously. The diameter of the equine esophageal lumen can be increased by using a patch graft of the sternocephalicus muscle or by esophgopexy to create a diverticulum.[37,38]

Figure 31-33. When complete resection anastomosis is performed, undue tension frequently results in dehiscence. Undue tension on the anastomosis can be prevented by using a standing martingale, as shown, which prevents extension of the head and neck.

Patch Grafting

Antibiotics should be given preoperatively and maintained for 6 to 10 days after surgery. With the horse under general anesthesia, a ventral midline or lateral approach to the esophagus is made and, depending on location of the defect and the approach used, the brachiocephalicus and sternocephalicus muscles serve as donors for the graft. With a nasogastric tube passed to the level of the stenosis, a longitudinal incision is made through the muscularis from a point 3 cm (1¼ inch) distal to and extending 3 cm proximal to the stricture. The mucosa and submucosa are sharply incised as the nasogastric tube is passed into the stomach. A caudal portion of the muscle belly of the brachiocephalicus or sternocephalicus is mobilized by blind separation of muscle fibers. The strip of muscle should maintain its proximal and distal attachments and should be freely movable so as not to exert tension on the closure when the patient's head and neck are moved. The graft should be wide enough to appreciably increase the lumen of the esophagus.

The edges of the mucosa and submucosa are sutured to the muscle graft using 3-0 polypropylene interrupted through-and-through mattress sutures, and the edges of the muscularis are sutured to the graft with 3-0 simple-interrupted sutures of monofilament polypropylene. Preplacement of mattress sutures and closure of both layers on one side of the esophageal defect at a time facilitate repair. The nasogastric tube should be removed before the second edge is closed. Suction drains are placed next to the esophagus, and the approach incision is closed.

Postoperatively, extraoral alimentation is preferred for 10 days (by esophagostomy, if space allows, or intravenous feeding), but soft foods may be given *per os* as early as 48 hours

if salivary leaking has not occurred. An indwelling nasogastric tube provides a stimulus for salivation and increases the incidence of fistula formation.

Fistula

Fistulas of the esophagus result from causes previously described for ruptures and may be treated similarly. However, small fistulas may be a diagnostic challenge. Occasionally, they are observed endoscopically (Figure 31-34). More frequently, findings of endoscopic examinations and barium swallow esophagograms are normal. Esophageal fistulas should be included in the differential diagnosis when cervical swelling, fever, and dysphagia are present; a nasogastric tube can be passed to the stomach; and endoscopic findings are normal. Contrast radiography, using liquid barium administered under pressure, best demonstrates the lesion (Figure 31-35). When ventral drainage has been established, fistulas almost always heal spontaneously. During this time, food and water may be expelled through the cloaca (Figure 31-36). Large fistulas can extrude copious amounts of masticated food and saliva. Elevating the food and water sources will decrease the amount lost. If healing does not occur, resection of the sinus tract and closure of the esophageal stoma may be necessary (Figure 31-37). Closure of the esophageal defect should be performed as for esophagotomy.

Diverticulum

In horses, diverticula of the esophagus only occasionally cause esophageal dysfunction. Usually they are acquired lesions that result from contraction of periesophageal fibrous scar tissue, causing outward traction and tenting of all layers of the esophageal wall (traction, or true, diverticulum). They can also occur from protrusion of mucosa and submucosa through a defect in the esophageal muscularis (pulsion, or false, diverticulum) (Figure 31-38).

A traction diverticulum commonly develops at the site of a healed esophagostomy, at the site of a postsurgical or posttraumatic wound of the esophagus that is allowed to heal by second intention as a fistula, or after penetration of the esophageal lumen (traumatic or surgical) in which leakage of saliva has caused inflammation or abscess formation. Pulsion diverticula are caused by fluctuations in esophageal intraluminal pressure and overstretch damage to esophageal muscle fibers by impacted feedstuffs. A more probable cause is external trauma to the cervical area.[39-41]

Diverticula in the cervical esophagus should be considered when an enlargement in the neck results in dysphagia and yet a nasogastric tube can be passed. On barium swallow

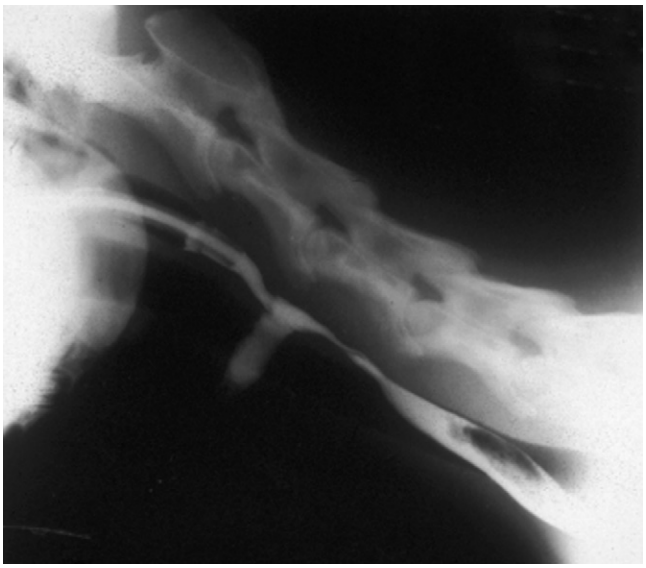

Figure 31-35. Positive-contrast esophagogram shows a large fistula remaining after removal of the esophagotomy tube. The cuff on the nasogastric tube prevents reflux of barium into the pharynx.

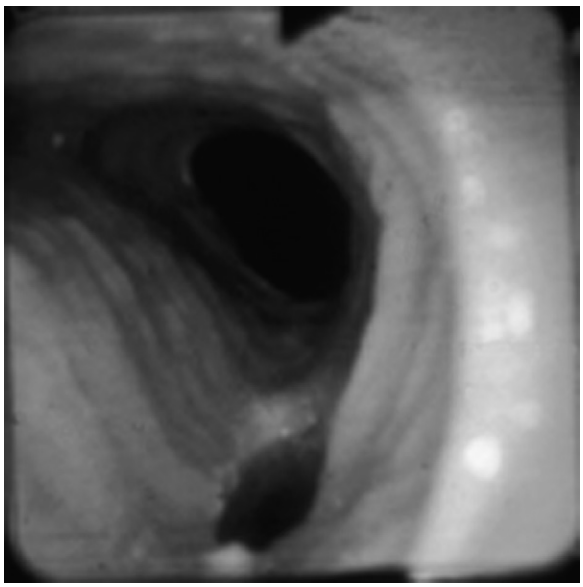

Figure 31-34. Endoscopic appearance of a large esophageal fistula. Smaller fistulas are often difficult to locate endoscopically.

Figure 31-36. A horse drinking, with a large esophageal fistula. When the water source is below the head, almost all of the water is lost. Therefore food and water should be elevated to decrease the amount lost through the fistula.

Figure 31-37. An esophageal fistula resulting from placement of the esophagostomy tube through a ruptured esophagus. Redundant mucosa prevented this fistula from healing spontaneously, and it was closed using the techniques described for esophagotomy.

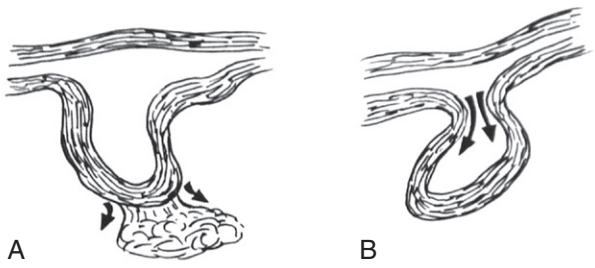

Figure 31-38. A, Traction diverticulum or true diverticulum develops at the site of a postsurgical or posttraumatic wound of the esophagus that is allowed to heal by second intention (e.g., a fistula or penetration of the esophageal wound). This type of diverticulum has a wide neck that seldom needs surgical correction. **B,** Pulsion diverticulum is caused by external trauma to the cervical area that ruptures the muscular layer. This type of diverticulum has a narrow neck and may continue to enlarge or ferment feed within the lumen, requiring surgical correction.

esophagograms, traction diverticula are spherical and have a wide neck (Figure 31-39), whereas pulsion diverticula are flask-like in configuration, with a narrow neck. Differentiation of these two types of diverticula can be aided by additional contrast techniques that distend the esophageal lumen and outline

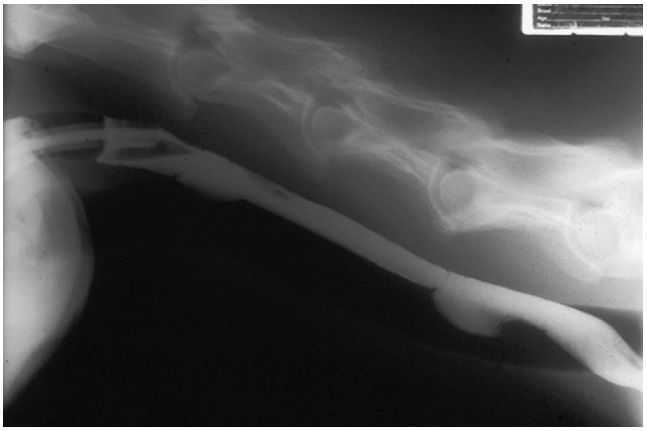

Figure 31-39. Barium swallow procedure in a horse with an esophagotomy that healed by second intention shows a traction diverticulum. Note the wide neck of the diverticulum.

the opening into the evagination. Esophagoscopy also defines the relative size and configuration of the opening of a diverticulum (Figure 31-40).

A traction diverticulum, even when quite large, produces few clinical signs and seldom requires treatment. A pulsion diverticulum, however, has a tendency to enlarge progressively so that risk of obstruction and rupture increase with time. Surgical repair is indicated. A pulsion diverticulum can be repaired by diverticulectomy with resection of the mucosal-submucosal sac, followed by reconstruction of the mucosa, submucosa, and muscularis, or by inversion of the mucosal-submucosal sac with reconstruction of the muscular layer. Diverticulectomy should be used when the mucosal sac is very large and the neck of the diverticulum very narrow. There are reports of repair of apparent congenital esophageal diverticula using this technique.[42]

However, mucosal inversion is the preferred technique because it decreases the chance of postoperative leakage, infection, or fistula formation and does not appear to predispose to postoperative obstruction complications.

Mucosal Inversion

The esophagus is exposed, and the diverticulum and defect in the muscularis are identified by careful dissection (Figure 31-41). Inadvertent perforation of the mucosa and submucosa should be repaired immediately. The edges of the muscular defect should be débrided back to healthy-appearing tissue. The sac is inverted, and the edges of the muscularis are apposed with simple-interrupted sutures of 3-0 polypropylene in a manner to avoid undue tension on the closure and prevent stenosis of the esophageal diameter. Postoperatively, feeding should consist of soft foods for 4 to 6 weeks.

Intramural Cyst

Esophageal cysts are rare in all species, but several equine cases have been documented.[43-45] I have seen three additional horses with esophageal cysts: a 3-year-old Morgan mare, in which the cyst lining had radiographic signs of calcification, and two yearling Quarter Horse colts, both admitted for dysphagia. In all horses, an epithelial inclusion cyst (lined by stratified squamous

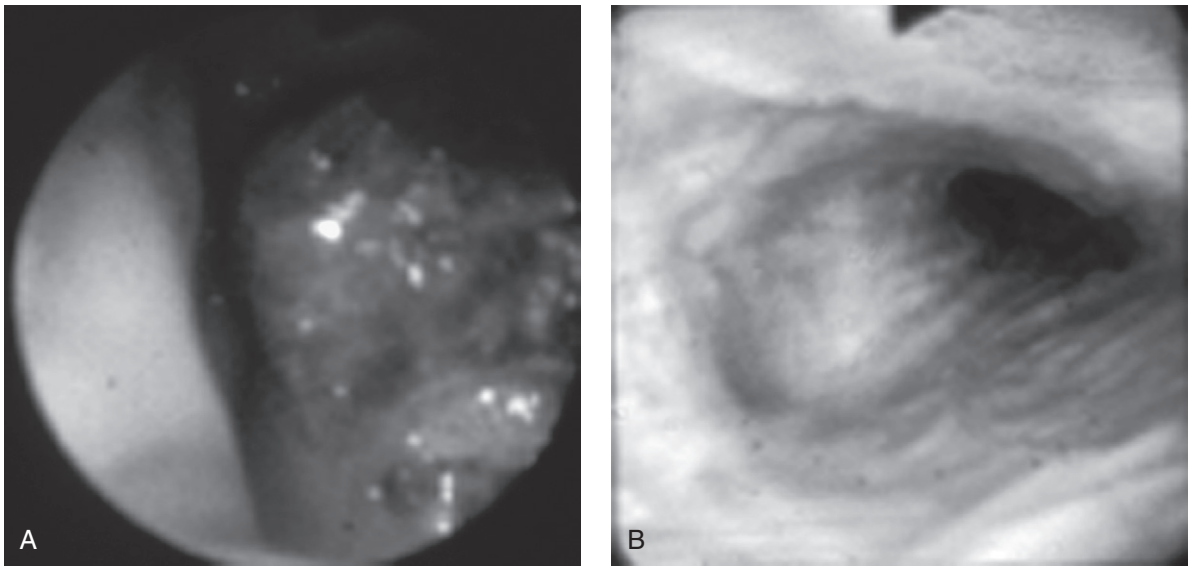

Figure 31-40. Endoscopic appearance of an opening into a traction or true esophageal diverticulum. Note feed in the diverticulum **(A)** and the normal-appearing mucosa **(B)** after lavage via drinking.

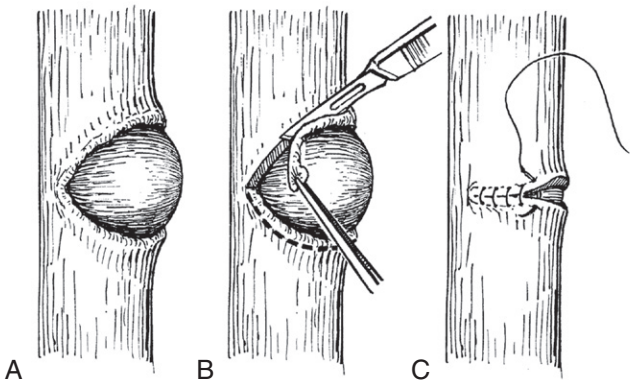

Figure 31-41. A, A pulsion diverticulum repaired by inversion of the mucosal/submucosal sac with reconstruction of the muscular layer. **B,** The edge of the muscular defect should be débrided back to healthy tissue. **C,** The sac is inverted, and the edges of the muscularis are apposed with simple-interrupted sutures of 3-0 polypropylene in a manner that avoids undue tension on the closure and prevents stenosis of the esophageal diameter.

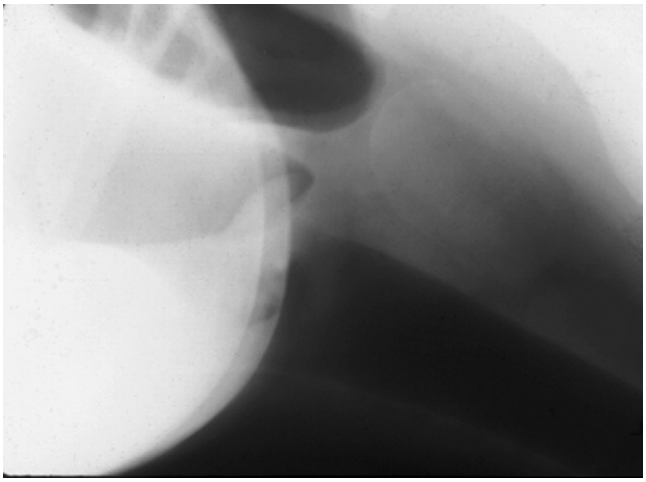

Figure 31-42. Radiographic appearance of an inner mural inclusion cyst of the esophagus in a 3-year-old Morgan mare in which the cyst lining had radiographic signs of calcification. This is an unusual finding, as survey films are usually nondiagnostic.

epithelium and filled with keratinaceous debris) was found in the esophageal wall. Mural cysts are probably a developmental anomaly.

Clinical findings include dysphagia, regurgitation, a palpable soft tissue mass in the neck, and resistance to passage of a nasogastric tube at the site of the cyst. The diagnosis can be made on survey films if the cyst has started to calcify (Figure 31-42). However, it is better confirmed on contrast radiography by the classic appearance of a filling defect caused by a mural lesion (Figure 31-43). Endoscopically, the esophageal lumen may appear partially occluded, but significant gross changes are usually not observed because the mucosa appears normal. Intramural esophageal cysts may be removed through enucleation with inversion or resection of redundant mucosa. The esophagus is exposed, and the cyst is identified by manipulation of a nasogastric tube within the esophageal lumen. A longitudinal incision is made through the muscularis over the cyst. By careful dissection, the cyst is separated from its position between the mucosa/submucosa and the muscularis and is removed intact (Figure 31-44). The cyst can be mistaken for an abscess if it is inadvertently incised by the inexperienced surgeon. Positioning the nasogastric tube caudal to the cyst helps prevent inadvertent perforation of the mucosa. After the cyst is removed, it leaves an area of redundant mucosa, or a sac, which may be treated as a pulsion diverticulum (i.e., by inversion, preferably, or by diverticulectomy). The muscularis is closed with simple-interrupted 3-0 sutures of polydioxanone or polypropylene at the surgeon's preference.

Megaesophagus

Megaesophagus refers to dilation and muscular hypertrophy of the esophagus oral (proximal) to a constricted distal segment. Although idiopathic muscular hypertrophy does occur in the horse (without dilation), it is an asymptomatic and an incidental finding at necropsy.[46] Therefore the term megaesophagus, as used here, includes congenital ectasia (dilation of unknown origin), achalasia (failure of the distal esophagus to relax because of neural dysfunction, resulting in proximal dilation), and megaesophagus secondary to vascular ring anomalies. One case of vascular ring anomaly causing megaesophagus in a foal has been reported.[47] The anomalous defect was a result of a persistent right aortic arch and was suspected on radiographic examination and confirmed on necropsy. Another case of megaesophagus was reported secondary to chronic gastroesophageal reflux.[48]

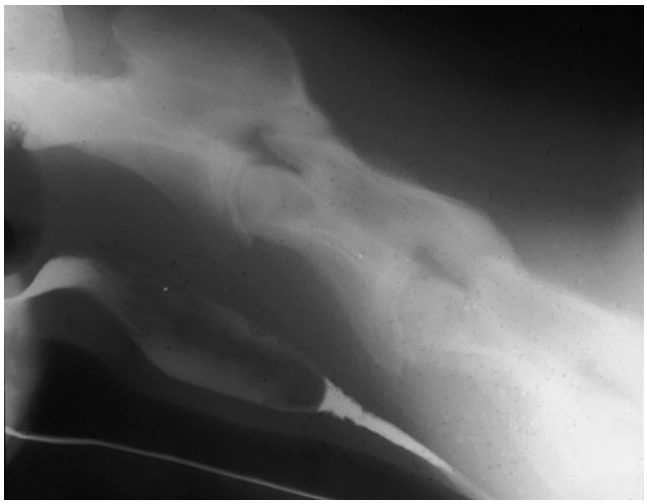

Figure 31-43. Barium esophagogram shows the classic appearance of an intramural lesion of the esophagus—in this case, an epithelial inclusion cyst. The esophageal lumen is narrowed caudad and is dilated but not filled with barium craniad because the mural mass produces a filling defect.

Although hypomotility of the esophagus has been documented in one foal and neural defects of the esophagus were found in another, achalasia as defined in dogs and humans has not been reported.[49,50] Treatment of these horses was not successful, even with a modified Heller myotomy in one foal. I have treated congenital ectasia conservatively with good results. A 5-month-old foal was admitted because of recurrent choke that began at the time of weaning. Esophageal lavage produced 8 L of feed regurgitated through the nasogastric tube. On radiography and endoscopy, generalized ectasia was found from the midcervical to the midthoracic esophagus (Figure 31-45), with an annular ring noted at the point where the esophagus passed through the thoracic inlet (Figure 31-46). The foal was fed a mash diet (pellets mixed with warm water) for 6 months, with the feed trough elevated above the animal's withers. The mash diet was changed to complete pelleted feed for an additional 6 months before the horse was fed normal feed. Although fluid did not pool in the lumen of the esophagus after 6 months of the mash diet and the size of the dilated

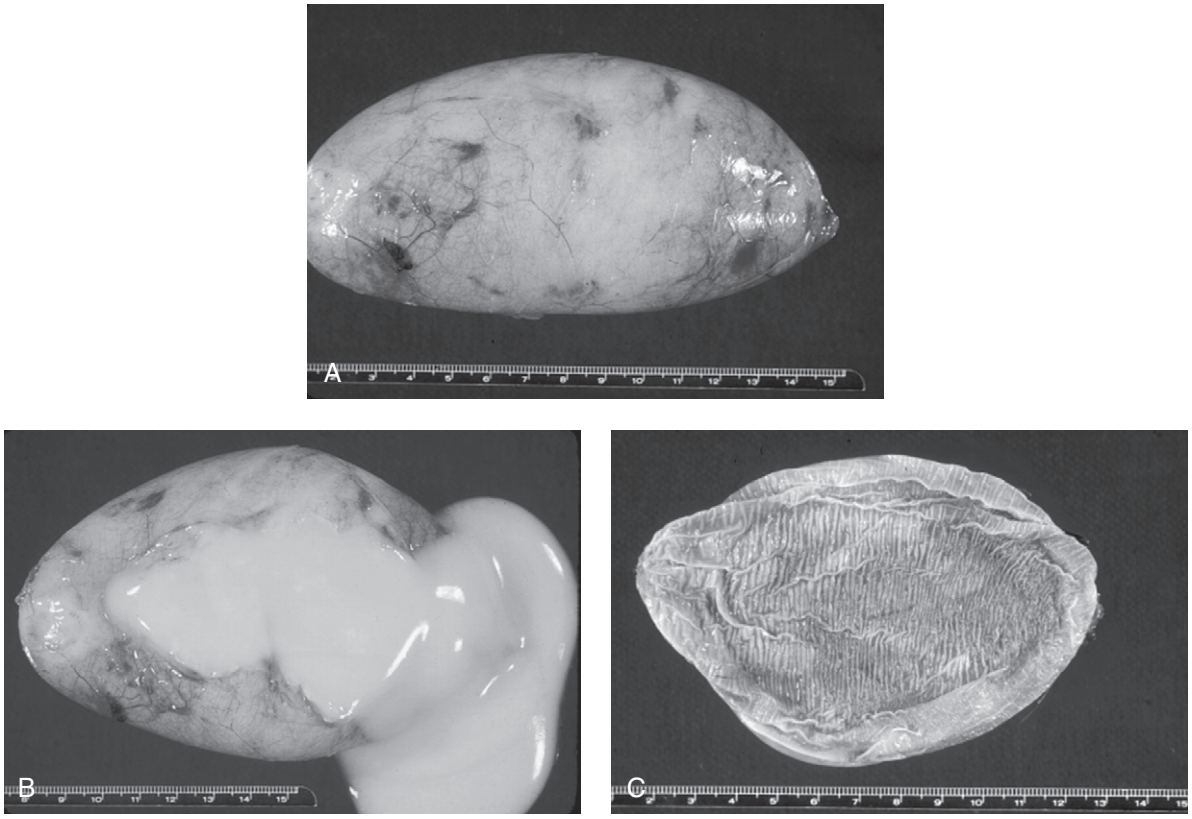

Figure 31-44. An excised intramural inclusion cyst **(A)** following puncture **(B).** The epithelial cell contents could be mistaken for an abscess ruptured during surgery. The cyst lining is normal esophageal mucosa **(C).**

esophagus did not change over the next 24 months during several radiographic examinations, the horse could eat normally and is being used for show and pleasure riding. Conservative management of this problem should be considered if the owners are willing to provide the extensive nursing care (no access to roughage, including bedding in the stall, and total confinement, with exercise in-hand only) and are willing to face the possibility of several episodes of choke requiring treatment.

Reduplication

It is not clear whether reduplication of the esophagus is a congenital or an acquired condition, but it is included here for the sake of completeness. This condition has been reported twice.[51,52] Clinical signs were similar to those of other forms of esophageal obstruction. Diagnosis may be difficult, but the problem does appear to be amenable to surgery. This condition closely resembles one of the complications of esophagostomy tube feeding, in which a dissecting tract develops parallel to the esophageal wall or within it, causing signs of obstruction.

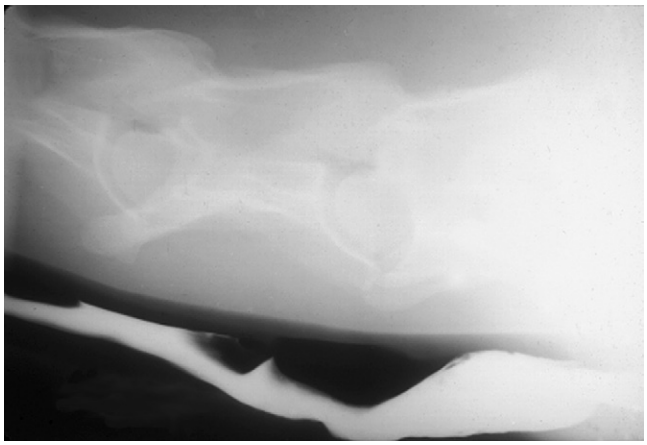

Figure 31-45. Positive-contrast esophagogram shows megaesophagus at the mid-cervical level. The foal was managed with a mash diet and recovered esophageal function over a 1-year period.

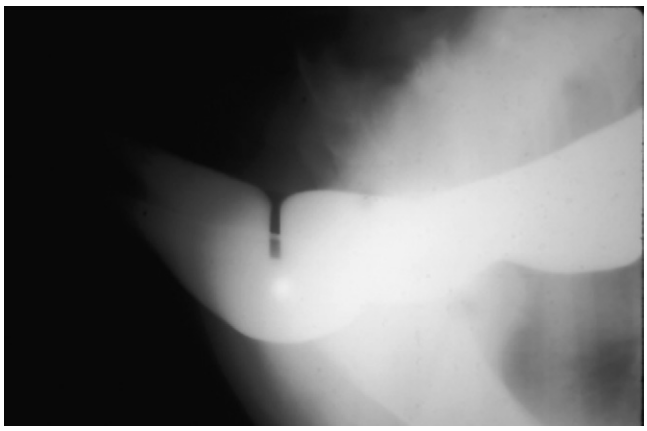

Figure 31-46. Barium pressure esophagogram shows megaesophagus in the foal seen in Figure 31-45. Note the narrowing of the esophageal lumen as it passes through the thoracic inlet.

Neoplasia

Neoplasms causing signs of esophageal obstruction are rare.[1] Squamous cell carcinoma is the most common neoplasm and has been reported in detail in four cases. One was an extension of gastric carcinoma, one was located in the tracheal bifurcation, and two were located in the distal cervical esophagus.[53-56] Biopsy and cytologic examination of brush samples obtained through the endoscope may provide an early diagnosis before stenosis of the esophagus develops, but advanced cases may be detected on radiography. The value of resection is questionable.

COMPLICATIONS OF ESOPHAGEAL SURGERY

The surgeon has the following three clinical objectives: (1) to obtain leakproof healing of a primary anastomosis or incision, (2) to dilate a restricted aperture, and (3) to return the enlarged or disrupted esophagus to near-normal size and function. Despite meticulous technique, complications can occur. If managed properly, however, they can be resolved with a favorable outcome for the patient.

Dehiscence and Stricture

The keys to handling breakdown of a sutured esophageal incision are early recognition and treatment. For this reason, a suction drain placed next to the esophagus at the time of surgery

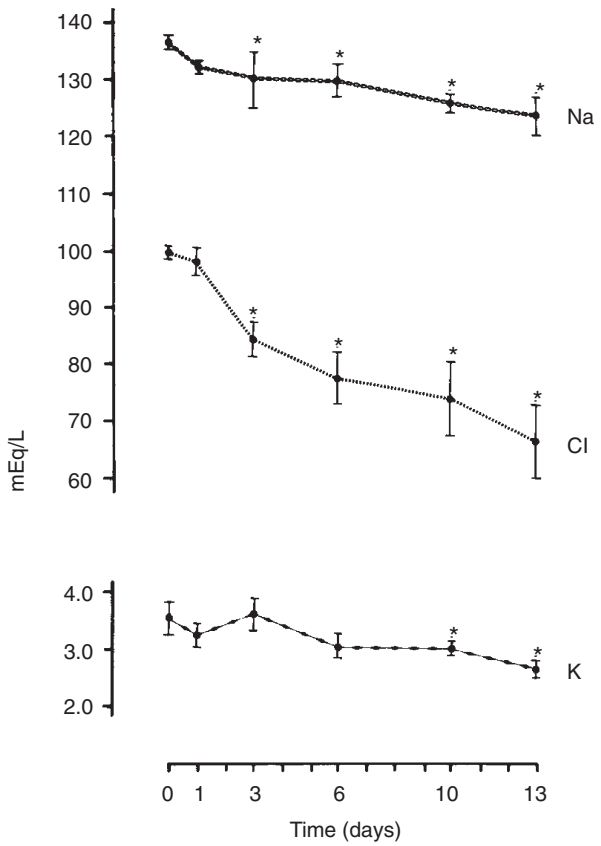

Figure 31-47. Influence of salivary depletion on serum electrolyte levels (Na, K, Cl) before (day 0) and after the esophageal fistulation. *Bars* indicate ± 1 SE ($N = 6$). *Stars* indicate days on which serum electrolyte levels were significantly different from baseline values (day 0).

serves a second function in addition to drainage of the serum and blood from the surgical site. It provides a method to detect salivary leakage. Not all incisions that leak saliva dehisce, especially if the saliva is removed from periesophageal tissues. However, if extreme amounts of saliva are leaking through the incision or complete dehiscence occurs, the original approach incision should be completely opened and lavaged daily to remove any ingesta or saliva. Dissection planes ventrally along the trachea should be drained to the outside to prevent eventual mediastinitis or pleuritis. Dissecting infections can occur after esophagostomy as well, and inadvertent placement of a dislodged feeding tube into a dissection plane or the thorax would clearly have an unfavorable outcome.

The patient may be permitted to drink, which in many cases lavages the wound. Nutritional requirements may be met by oral feeding or placement of a feeding tube into the esophagus at the point of dehiscence or distad through a separate esophagostomy. The outcome of this complication from this point depends on management of water and electrolyte balance. The most common complication after treatment of an annular lesion is stricture (see Figure 31-30). This complication is the bane of the esophageal surgeon, and its successful treatment is limited by the owner's financial commitment.

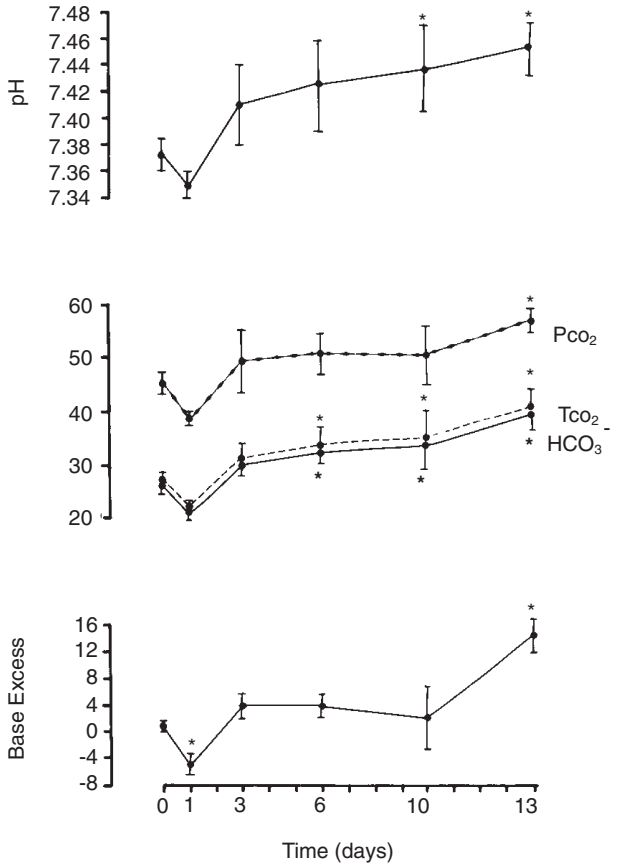

Figure 31-48. Effect of salivary depletion and serum electrolyte alterations on acid-base values (pH, P_{CO_2} [mm Hg], T_{CO_2} = total CO_2 [mEq/L], HCO_3^- [mEq/L], and base excess [mEq/L]) before (day 0) and after esophageal fistulation. *Bars* indicate ± 1 SE ($N = 6$). *Stars* indicate days on which each value was significantly different from baseline values (day 0).

Acid-Base and Electrolyte Alterations

In the face of adequate nutrition, daily losses of large amounts of saliva result in hyponatremia, hypochloremia (Figure 31-47), and transient metabolic acidosis followed by progressive metabolic alkalosis (Figure 31-48).[57] The alkalosis probably results from renal compensation for electrolyte imbalances. Oral administration of sodium chloride daily reverses the electrolyte imbalance (potassium requirements are adequately met in feed); alkalosis is corrected through renal mechanisms.

Laryngeal Hemiplegia

Manipulative procedures or disease of the esophagus in the cervical area can easily result in laryngeal hemiplegia because of the proximity of the recurrent laryngeal and vagus nerves. The surgeon should be aware that apparently minor manipulations of these nerves can have deleterious effects on their function.

Carotid Artery Rupture

Chronic feeding tubes placed in the distal third of the cervical esophagus can lead to jugular vein or carotid artery ulceration. Bleeding episodes should be an indication for exploratory and vessel ligation to prevent exsanguination.

CHAPTER
32 Stomach and Spleen

David A. Wilson and Anthony T. Blikslager

STOMACH

Anatomy

The equine stomach is small relative to the body size of the horse, having a capacity of approximately 5 to 15 L.[1] Even when the stomach is filled to capacity, it does not reach the ventral body wall. It is located predominantly on the left side of the abdomen under the cover of the ribs, with only the pyloric region of the stomach to the right side of the midline. Its most caudal component is the fundus, which lies adjacent to the 14th and 15th rib spaces (Figure 32-1).[2] The stomach can be divided into several regions, including the cardia at the opening of the esophagus, the fundus (which forms a blind sac), the body, and

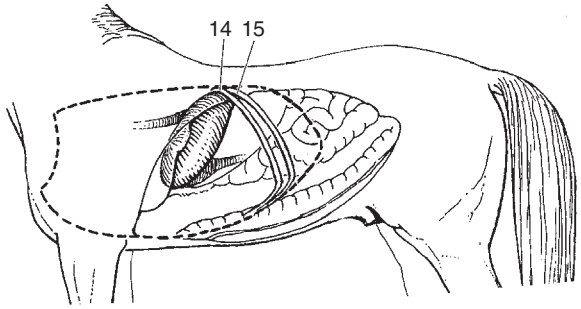

Figure 32-1. Diagram of the anatomic location of the equine stomach in the abdomen.

the pyloric region. The stomach is sharply curved at its lesser curvature so that the cardia and pyloric regions lie adjacent to each other.[2] The cardia is attached to the diaphragm by the gastrophrenic ligament. This ligament is a continuation of the phrenicosplenic ligament and the gastrosplenic ligament on the left side of the abdomen. The greater omentum attaches along the greater curvature of the stomach, and it blends into the gastrophrenic ligament.[1,2] The greater omentum forms a blind potential space called the *omental bursa*. The entrance to this bursa is the epiploic foramen, which is located between the caudate process of the liver and the right lobe of the pancreas. The epiploic foramen is also bordered dorsally and ventrally by the caudal vena cava and portal vein, respectively. The lesser omentum, which connects the stomach and duodenum to the liver, consists of the hepatogastric and hepatoduodenal ligaments.[2] The stomach receives its blood supply from the celiac artery. Venous drainage from the stomach is via gastric veins to the portal vein.[1]

Physiology

During digestion, the stomach is capable of dramatically lowering the pH of its contents and of secreting pepsinogen to begin breaking down protein. However, both HCl and pepsinogen (the latter being converted to pepsin) are inherently damaging to mucosa, which possesses a number of mechanisms to prevent injury, depending on the region of the stomach. There are four regions of the stomach based on the type of mucosal lining (in an orad-to-aborad order): nonglandular stratified squamous epithelium, cardiac epithelium, proper gastric mucosa (glandular mucosa), and pyloric mucosa.[3] The equine stomach has a very extensive region of stratified squamous mucosa that occupies approximately half of the stomach mucosal surface area, and this changes abruptly to cardiac glandular mucosa at a line of demarcation called the *margo plicatus*.[4] The function of the stratified squamous mucosa in the horse is unknown, since this region of the stomach does not have any secretory ability, although the squamous mucosa may protect underlying tissues from abrasion by roughage.[3] However, the squamous mucosa does not frequently come into contact with stomach contents, as the gastric fill line is typically the margo plicatus. The cardiac epithelium forms a belt of tissue adjacent to the margo plicatus. Relatively little is known about this mucosal region, although it has the ability to secrete bicarbonate in other species and has been shown to contain cells capable of secreting somatostatin in equine mucosa, which serves as a negative feedback mechanism for gastric acid secretion. The proper gastric mucosa contains secretory glands containing HCl-secreting parietal cells and pepsinogen-secreting zymogen cells. In addition, this segment of mucosa contains enterochromaffin-like (ECL) cells that secrete histamine in response to various stimuli, which in turn amplifies HCl secretion by the parietal cells. The pyloric mucosa contains both G-cells, which secrete gastrin, and D-cells, which secrete somatostatin. These hormones enhance or reduce gastric acid secretion, respectively.[4]

Gastric Barrier Function

Mechanisms by which the stratified squamous mucosa resists injury are critical in the horse, where ulceration is prevalent.[5-7] When mounted in Ussing chambers for the purpose of measuring epithelial transport function, equine stratified squamous epithelium has baseline transepithelial resistance measurements of approximately 2000 to 3000 Ω/cm^2, which is an order of magnitude higher than that of the adjacent cardiac mucosa.[5] Since transepithelial resistance is essentially a measure of ion permeability, the stratified squamous mucosa is exceptionally impermeable. This is the only mechanism of defense against injury in this type of mucosa. The stratified squamous epithelium consists of four layers: the outer stratum corneum, the stratum transitionale, the stratum spinosum, and the basal stratum germinativum. However, not all of these layers contribute equally to barrier function. Interepithelial tight junctions in the stratum corneum and muco-substances secreted by the stratum spinosum are mainly responsible for barrier function.[5,8] The stratified squamous mucosa in other species is relatively impermeable to HCl, suggesting that although most of the literature on equine ulceration pertains to the effects of HCl and inhibitors of HCl secretion, other factors may be critical to the development of gastric ulcer disease.[9-13] Nonetheless, exposure of equine stratified mucosa to acid (pH 1.7) results in significant reductions in measurements of transepithelial electrical resistance, regardless of whether other injurious compounds are added, indicating that acid alone can damage the mucosa.[14] It is not clear whether less-acidic solutions can also cause damage in the presence of other injurious factors, such as bile or pepsin.

The site of HCl secretion (proper gastric mucosa) is protected from back diffusion of H^+ ions by a relatively high transepithelial electrical resistance (compared to cardiac mucosa), but there are also a number of other critical mechanisms to prevent acid injury. The gastric mucosa secretes both mucus and bicarbonate, which together form an HCO_3^-–containing gel that titrates acid before it reaches the lumen.[15,16] However, the mucus layer does not form an absolute barrier to back diffusion of acid. Thus, for acid that does diffuse back into the gastric mucosa, epithelial Na^+/H^+ exchangers are capable of expelling H^+ once the cell reaches a critical pH.[16]

Gastric Mucosal Pathophysiology

Mechanisms of Gastric Ulceration

Ulceration in horses most commonly involves the stratified squamous epithelium and is somewhat analogous to gastroesophageal reflux disease in people.[5] This may occur because the glandular portion of the stomach has a number of protective mechanisms, including mucus and bicarbonate secretion, whereas the squamous mucosa has none of these protective mechanisms and is periodically exposed to acid contents.[4] Although stratified squamous epithelium is relatively impermeable to HCl, a number of factors can dramatically enhance the damaging effects of HCl in this epithelium. In particular, bile salts and short-chain fatty acids are capable of breaking down the squamous epithelial barrier at an acid pH, thereby exposing deep layers to HCl, with subsequent development of ulceration. Relatively high concentrations of short-chain fatty acids normally exist in the equine stomach as a result of microbial fermentation.[5] These weak acids penetrate squamous mucosa, and they appear to damage Na^+ transport activity, principally in the stratum germinativum. Bile salts may also be present in the proximal equine stomach as a result of reflux from the duodenum. Although such reflux has a relatively high pH, it appears that bile salts adhere to stratified squamous epithelium, becoming lipid soluble and triggering damage once the pH falls below

4.[17] Diet and management (e.g., periods of fasting) also play crucial roles in the development of conditions conducive to gastric ulceration. Typically, there is a pH gradation in horses from proximal to distal compartments of the stomach, with the lowest pH values in the distal stomach.[18] However, during periods of fasting, this stratification is disrupted, so that low pH values may be recorded in the proximal stomach.[19] Fasting conditions also increase the concentration of duodenal contents within the proximal stomach, particularly bile.[17] The type of diet also influences the stratification of stomach contents.

Mechanisms inducing injury to proper gastric mucosa may be entirely different from those inducing injury to stratified squamous mucosa. In people, the majority of gastric mucosal ulcers is induced by infection with *Helicobacter pylori*, which has the effect of raising gastric pH because of disruption of gastric glands. Such an infection also induces an inflammatory response that causes damage.[20] In particular, *H. pylori* containing the *cagA* gene is most pathogenic. However, there is very little evidence that this organism is involved in gastric ulcers in domestic animals. In the absence of a known role for infectious agents in equine gastric ulcer disease syndrome, ulceration most likely develops from an imbalance between protective mechanisms and injurious factors, which include gastric acid, bile, and nonsteroidal anti-inflammatory drugs (NSAIDs). However, some factors that are important to inducting squamous epithelial ulceration may not be important in development of proper gastric mucosal ulceration. For example, feed deprivation and intensive training reproducibly induce squamous epithelial ulceration in horses, but they have little effect on proper gastric mucosa in horses.[21] Gastric acid very likely plays a key role, whereas other factors such as NSAIDs serve to reduce gastric defense mechanisms. In particular, inhibition of prostaglandin production reduces mucus and bicarbonate secretion, while also reducing gastric mucosal blood flow, and would be expected to induce ulceration of proper gastric mucosa.[22] In addition, some of the NSAIDs also have a topical irritant effect, but this appears to be of minor significance, since the route of administration (oral or parenteral) seems to have little influence on development of ulceration.[23] Other risk factors for the development of gastric ulcer syndrome in the horse include stress, transportation, high-protein diet, stall confinement, intermittent feeding, racing, illness, and management changes.[24,25]

Gastric Reparative Mechanisms

Mechanisms of gastric repair are highly dependent on the extent of injury. For instance, superficial erosions can be rapidly covered by migration of epithelium adjacent to the wound—a process termed *epithelial restitution*. However, ulceration (full-thickness disruption of mucosa and penetration of the muscularis mucosae) requires repair of submucosal vasculature and matrix. This is initiated by formation of granulation tissue, which supplies connective tissue elements and microvasculature necessary for mucosal reconstruction. Connective tissue elements include proliferating fibroblasts that accompany newly produced capillaries that form from proliferating endothelium. Studies indicate that nitric oxide is critical to both of these processes, which probably explains the reparative properties of NO in the stomach.[26-28] Once an adequate granulation bed has been formed, newly proliferated epithelium at the edge of the wound begins to migrate across the wound. In addition, gastric glands at the base of the ulcer begin to bud and migrate across the granulation bed in a tubular fashion.[29] Epidermal growth factor is expressed by repairing epithelium, and it appears to facilitate these processes.[30] In addition, these events are facilitated by a mucoid cap, which retains reparative factors and serum adjacent to the wound bed. Importantly, this cap maintains a neutral pH to facilitate healing.[22] Once the ulcer crater has been filled with granulation tissue and the wound has been reepithelialized, the subepithelial tissue remodels by altering the type and amount of collagen.[31]

Diagnostic Techniques

Endoscopy

Before gastric endoscopy, foals up to 20 days of age should be held off feed for 3 hours, whereas older foals require up to 10 hours to sufficiently empty the stomach. Adult horses should be held off feed for 24 hours to allow complete visualization of the stomach.[1] A 3-m endoscope is required to adequately visualize the stomach, including the pylorus, in adult horses, whereas a 1-m endoscope may be sufficient for foals.[1] Although endoscopy is the principal diagnostic aid for detecting gastric ulceration, a study comparing endoscopic to histologic scoring of the severity of ulceration indicated that endoscopy tends to underestimate the number and severity of gastric ulcers of the nonglandular equine stomach. Furthermore, endoscopy may not allow detection of glandular gastric ulcers. Therefore clinicians should realize that ulceration is frequently more severe and extensive than that observed via the endoscope.[32]

Ultrasonography

Ultrasonography can be used to image the wall of the stomach, and it may be particularly useful in foals with suspected gastric outflow obstruction. The stomach is best imaged from the left side of the abdomen between rib spaces 8 and 14. If gastric outflow obstruction is present, a distended stomach with a gas–fluid interface may be detected. The duodenum can also be imaged at this site, and it may show evidence of thickening and reduced motility. The duodenum can additionally be imaged from the right paralumbar fossa, cranial to the right kidney, where there may be additional evidence of thickening or obstruction.[33,34]

Radiography

Contrast radiography can be performed to allow visualization of the stomach. In a series of foals with gastroduodenal obstruction, barium sulfate solution was administered.[35] In addition, functional gastric emptying can be determined by the administration of barium sulfate after a 12- to 18-hour fasting period. In normal horses, barium appears in the small intestine by 10 minutes, and none remains within the stomach by 35 minutes. With pyloric outflow obstruction, barium may remain in the stomach for up to 8 hours.[1] Barium sulfate solutions should be diluted 1:1 with water, and a volume of approximately 1 L should be administered into the thoracic portion of the esophagus by nasogastric tube.[36] Double-contrast radiography with insufflation of air, followed by administration of a barium sulfate suspension, can enhance visualization of the stomach. This technique has been useful in the diagnosis of gastric outflow obstruction and gastric neoplasia.[1,37]

Measurement of Gastric Emptying

Assessment of gastric emptying can be performed by nuclear scintigraphy, acetaminophen absorption, or breath testing after the administration of ^{13}C-octanoic acid.[38-40] For scintigraphic determination of gastric emptying, one study involved administration of 370 megabecquerels (MBq) of technetium-99m (^{99m}Tc) sulfur colloid incorporated into egg albumin (to determine solid phase gastric emptying) and 37 MBq of diethylenetriamine pentaacetic acid (DTPA) labeled with indium-111 in 120 mL of water (to determine liquid phase gastric emptying). These labeled products were administered via a nasogastric tube after a 12-hour fasting period. Scintigraphic images obtained from the left and right flanks were subsequently used to assess gastric emptying. Liquid phase and solid phase 50% gastric emptying times are 30 and 90 minutes, respectively, in normal horses.[41] In experimental trials assessing efficacy of breath testing, ponies were fasted for 14 hours, after which they ingested a test meal with ^{13}C-octanoic acid. Breath samples were analyzed by mass spectrometry for the appearance of the isotope.[40] This method correlated closely with gastric emptying documented with nuclear scintigraphy after administration of sulfur colloid labeled with technetium-99m.[39] Similarly, acetaminophen absorption has been shown to closely correlate with scintigraphic measurements of gastric emptying. For example, in one research trial, acetaminophen (20 mg/kg) and ^{99m}Tc-pentetate (10 mCi) were administered in 200 mL water, and their clearance from the stomach was shown to be similar, based on serum acetaminophen and scintigraphic analyses, respectively.[42]

Disorders

Gastric Ulcer Clinical Syndromes

The clinical syndromes of gastric ulceration are age dependent; the age categories being neonates, weanling foals, and horses older than 1 year.[43] In neonates, ulceration of the glandular mucosa is the most clinically important. Clinical signs include poor appetite, colic, and diarrhea, but foals may have ulcers and not demonstrate overt clinical signs of gastric pain or failure to thrive.[44] The pH of neonatal gastric contents is not typically as low as that of older foals or adults, suggesting that other factors may be important in the pathogenesis of ulceration.[13]

In suckling and weanling foals, ulceration frequently occurs in the squamous mucosa adjacent to the margo plicatus. Severe ulceration of the squamous portion of the stomach in foals of this age group is frequently associated with diarrhea, but foals may also appear unthrifty, with a rough hair coat and a pot-bellied appearance.[43] Diffuse ulceration is also typically associated with teeth grinding and colic. This age group of foals may also be affected with gastroduodenal ulceration, which may result in gastric outflow obstruction (see later).

In yearlings and adult horses, lesions occur predominantly in the squamous portion of the stomach adjacent to the margo plicatus. These horses may have very subtle signs of disease, such as poor performance, reduced appetite, and failure to thrive, but they do not typically suffer from diarrhea. The diagnosis of gastric ulcers is confirmed with gastroscopy.[7] When evaluating squamous lesions in foals, it is important to differentiate ulceration from desquamation.[8] The latter involves shedding of sheets of epithelium without ulceration, and it is unlikely to be clinically important.[45] Treatment is aimed at elevating the pH of the gastric contents, which may be achieved with a number of histamine receptor (H_2) antagonists, such as ranitidine (6.6 mg/kg, PO every 8 hours, or 1.5 to 2 mg/kg IV every 6 to 8 hours) or proton pump inhibitors such as omeprazole (2 to 4 mg/kg PO every 24 hours).[24,25,44,46]

Gastric Impaction

Impaction of the stomach typically consists of excessive dry, fibrous ingesta, but it may also consist of ingested materials that form a mass, such as persimmon seeds or mesquite beans.[47-50] Other feeds that tend to swell after ingestion, such as wheat, barley, and sugar beet pulp, may also cause impaction. Furthermore, dental disease may increase the likelihood of gastric impaction because of improper chewing of feed. Clinical signs include colic that ranges from acute and severe to chronic and mild. For example, in one report on four horses with gastric impaction, colic was moderate or severe and of 8 to 12 hours' duration,[51] whereas in another report on a pony with gastric impaction, colic was chronic (7 days' duration) and associated with prolonged recumbency, anorexia, and lethargy.[49] Additional signs may include dysphagia, dropping of feed, and bruxism.[49,52]

The diagnosis is frequently made at the time of surgery, although endoscopy reveals gastric impaction and may provide information on the specific nature of the impaction. Medical treatment includes nasogastric intubation and frequent attempts at softening the ingesta with water, followed by refluxing the fluid contents, or by using back-and-forth agitating movements of water with a 16-ounce dose syringe attached to the nasogastric tube. Nasogastric lavage with a carbonated cola soft drink was successfully used in a pony with persimmon seed impaction of the stomach.[53]

At surgery, the impaction can be massaged and infused, most commonly via insertion of a needle adjacent to the greater curvature, followed by infusion of a balanced polyionic fluid such as saline. There is also a report including the details of a pony and a horse in which the impacted stomach was packed off from the abdomen with towels, and an incision was made parallel and caudal to the attachment of the omentum on the greater curvature of the stomach. The stomach contents were evacuated, followed by a double-layer inverting closure. In the horse in this report, the ventral midline incision was extended craniad to the xiphoid process.[52] However, this aggressive approach is rarely necessary, as the impaction can usually be resolved with more conservative management.

Chronic Gastric Impaction and Dilation

Typically, gastric impaction develops relatively quickly and the diagnosis is often made at surgery. In contrast, chronic impaction and dilation of the stomach develops slowly over weeks or months with minimal clinical signs of abdominal pain. Clinical signs are often mild, with weight loss, reduced performance, bruxism, and salivation reported. Gastric endoscopy may reveal fibrous ingesta, which does not change after 24-hour starvation. A large mass may be palpable *per rectum*. Abdominal radiographs or ultrasonography may demonstrate a large distended and impacted stomach. Gastrotomy to remove ingesta and partial gastrectomy to remove flaccid stomach wall have been unsucessful. Postmortem findings include marked transmural hypertrophy of the nonglandular region of the stomach near the cardia and large chronic ulcers along the margo plicatus.[54-56]

Gastric Rupture

Rupture of the stomach appears to have two general causes: primary, as a result of excessive accumulation of ingesta, or no identifiable cause; and secondary, in association with another causative condition, such as obstruction of the small intestine.[57] The site of the rupture is most commonly the greater curvature of the stomach, although other sites of rupture have been identified, including the lesser curvature of the stomach.[58] The condition is almost universally fatal, because release of stomach contents into the abdomen through the gastric tear causes septic shock that cannot be adequately reversed with abdominal lavage and repair of the defect. However, there are some case reports of partial gastric tearing that have been repaired. In one report, a subserosal hematoma associated with a focal serosal perforation was repaired by use of a two-layer inverting closure, and the horse survived.[59] In another report, a seromuscular tear with intact mucosa bulging from the tear was noted, and it was oversewn with an inverting suture pattern. However, in neither case was there any evidence of abdominal contamination with gastric contents.[60]

In a report on 54 horses with colic taken to surgery, 11% of deaths were attributable to gastric rupture. Interestingly, at least 6 of the 54 horses had indwelling stomach tubes, indicating that nasogastric intubation does not negate the possibility of gastric rupture.[57] In a separate report on gastric rupture, it was determined that 5.4% of all colic accessions had gastric rupture. One of the striking clinical findings was that the abdominal fluid cell counts were frequently inaccurate, most likely because the acid stomach contents lysed cells infiltrating the abdomen. However, a number of abdominal fluid samples were not analyzed because they had the appearance of ingesta. This report also determined a number of risk factors for gastric rupture, including a diet exclusively of grass hay or of grass and alfalfa hay and drinking water from a bucket, stream, or pond. Alternatively, horses fed grain had a reduced risk.[58] The cases in this study were principally primary gastric ruptures (60%). Predisposing factors may include the opportunity to consume excessive water or roughage, leading to expansion and subsequent rupture of the stomach.

Gastric Neoplasia

Neoplasia of the stomach is rare. The most common form of gastric neoplasia is squamous cell carcinoma, which typically forms in the cardia of the stomach. In one report, a tumor encircled the esophagus at the cardia of the stomach, where it caused recurrent esophageal obstruction.[61] Clinical signs may include anorexia, weight loss, abdominal distention, abnormal chewing behavior, lethargy, coughing, hypersalivation, colic, dysphagia, fever, and ventral abdominal edema.[62-66] The diagnosis can be based antemortem on results of gastric endoscopy and biopsy or on thoracoscopy and biopsy.[67,68] In addition, approximately 50% of horses have had neoplastic cells evident in abdominal fluid or in thoracic fluid.[63,69,70] Other nonspecific laboratory findings have included anemia, neutrophilia, and hypoalbuminemia.[63] Additionally, one horse had a clinical diagnosis of pseudohyperparathyroidism in association with gastric carcinoma, based partially on evidence of hypercalcemia and hypophosphatemia.[70] In a case series on gastric squamous cell carcinoma, horses have had multiple metastases, including masses throughout the abdomen. Therefore the prognosis is grave, and the condition has been universally fatal. The reported median time from onset of clinical signs to death is 4 weeks.[63,64,66,69]

Other neoplasms that have been identified in the stomach include leiomyosarcoma (leiomyoma), mesothelioma, and adenocarcinoma. A leiomyosarcoma was diagnosed in a 12-year-old Thoroughbred gelding that was evaluated because of anorexia, weight loss, and intermittent fever. At surgery, an inoperable mass was discovered in the cranial abdomen, which was found to be a leiomyosarcoma after histopathologic analysis. The mass was associated with the distal portion of the esophagus and the cranial two thirds of the stomach.[71] Adenocarcinomas have been documented in the glandular portion of the equine stomach.[1,72]

Gastric Outflow Obstruction

Gastric outflow obstruction may be the result of pyloric stenosis, which can be caused by congenital muscular hypertrophy, or by development of a mass at the pylorus that reduces gastric outflow.[73,74] A mass may develop at the pylorus associated with gastroduodenal ulceration or neoplasia.[75-80] Clinical signs include weight loss, reduced appetite, abdominal pain, teeth grinding, ptyalism, frequent recumbency, and poor performance. Foals with gastric outflow obstruction are typically 2 to 6 months of age, with signs of gastric ulceration and an unthrifty appearance. However, foals may also have a history of enteritis and an absence of clinical signs typical of foals with gastric ulcers.

Gastric outflow obstruction can be diagnosed using endoscopy, radiography, ultrasonography, and gastric emptying tests, as described previously. Medical treatment for foals includes decompression of the stomach, antiulcer medications, broad-spectrum antibiotics, prokinetics, and intravenous fluids. However, surgery is indicated if medical treatment does not reverse clinical signs within a short period.[33] The principle of surgery for treatment of gastric outflow obstruction is bypass of the pylorus, typically by performing a gastrojejunostomy. Pyloric stenosis has been relieved in a 2-month-old Thoroughbred by a modification of the Heineke-Mikulicz technique, in which a full-thickness longitudinal incision through the pylorus was closed transversely.[74] The pylorus was mobilized by severing the hepatoduodenal ligament.

Alternatively, a series of bypass techniques can be performed, depending on the location of the obstruction.[35,81,82] In one series evaluating surgical results in 13 foals with gastroduodenal obstruction, bypass procedures included gastroduodenostomy, duodenojejunostomy, or gastrojejunostomy (Figures 32-2 to 32-4).[35] A jejunojejunostomy was also performed with the latter two surgical procedures to allow outflow of proximal small intestinal contents.[35,82] Aligning the jejunum from left to right (oral to aboral portions of the jejunum) along a relatively avascular region of the caudal ventral aspect of the stomach for a gastrojejunostomy has been reported to substantially improve long-term outcome in 40 foals (Figure 32-5).[82] These anastomoses can be hand-sewn or performed with automated stapling equipment. However, hand-sewn anastomoses may be simpler to perform because of the limited space within a foal's abdomen, which reduces maneuverability of larger stapling instruments.[36] Although a three-layer hand-sewn technique has been described (seromuscular, muscular, and mucosal layers), one case report suggested that a two-layer hand-sewn anastomosis (seromuscular and mucosal layers) was sufficient and more rapidly performed in a foal in which a gastroduodenostomy was created.[36]

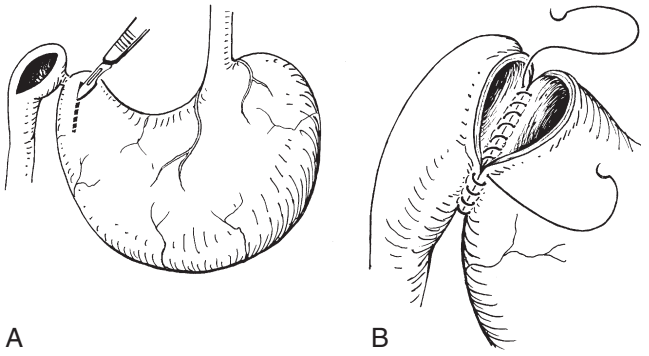

Figure 32-2. A, Locations for incisions for a gastroduodenostomy to bypass a pyloric stenosis. **B,** A three-tiered hand-sutured anastomosis to complete the gastroduodenostomy. (Redrawn from Orsini JA, Donawick WJ: Surgical treatment of gastroduodenal obstruction in foals. Vet Surg 15:205, 1986.)

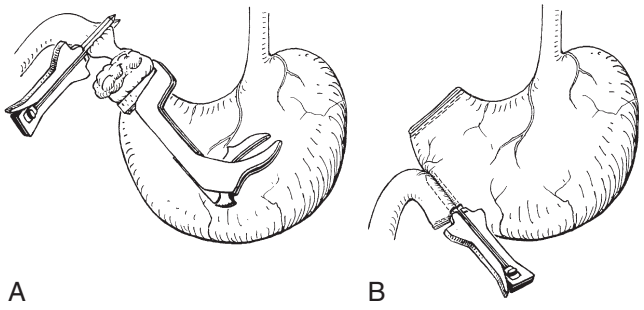

Figure 32-3. Partial gastrectomy **(A)** and gastroduodenostomy **(B)** to relieve pyloric obstruction. Stapling instruments have been applied proximal and distal to the obstruction, allowing resection of the distal stomach. Care is taken to avoid the hepatic duct in the proximal duodenum by stapling proximal to it. The blind-ending duodenum is subsequently anastomosed to the distal stomach using an automated stapling device. (Redrawn from Orsini JA, Donawick WJ: Surgical treatment of gastroduodenal obstruction in foals. Vet Surg 15:205, 1986.)

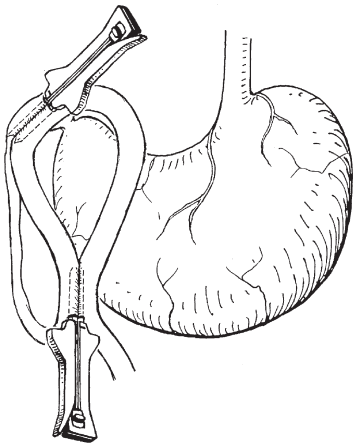

Figure 32-4. Duodenojejunostomy. The duodenojejunostomy and jejunojejunostomy are performed using an automated stapling device or a three-tiered suturing technique. The duodenojejunostomy is performed with the duodenal component proximal to the hepatic duct, and the jejunojejunostomy is performed with a segment of jejunum distal to the duodenocolic ligament. (Redrawn from Orsini JA, Donawick WJ: Surgical treatment of gastroduodenal obstruction in foals. Vet Surg 15:205, 1986.)

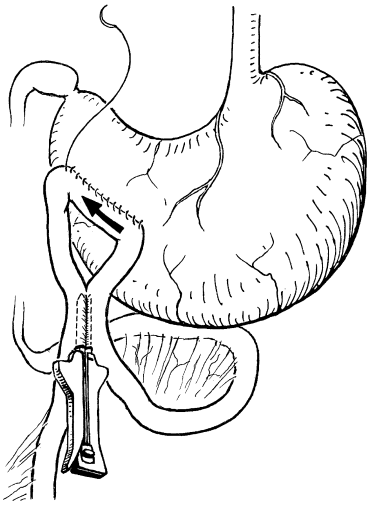

Figure 32-5. Completed left to right gastrojejunostomy with jejunojejunostomy. *Black arrow* indicates oral to aboral direction of the jejunum. (Redrawn from Zedler ST, Embertson RM, Bernard WV, et al: Surgical treatment of gastric outflow obstruction in 40 foals. Vet Surg 38(5):623, 2009.)

The prognosis for foals with gastric outflow obstruction is fair to guarded.[33,82] In one report on results of surgical intervention in foals with gastroduodenal obstruction, 6 of 13 foals (46%) survived.[35] One report indicated that foals with a localized pyloric obstruction should have a more favorable prognosis than foals with pyloric and duodenal obstructions, because the surgery for the former (gastroduodenostomy) is simpler than the surgery for the latter (gastrojejunostomy and jejunojejunostomy).[36] In a more recent report, 25 of 36 foals (69%) for which follow-up information was available were alive more than 2 years after surgery.[82] Obstruction of the duodenum, adhesions to the duodenum, and postoperative ileus were significantly associated with decreased long-term survival.

SPLEEN

Anatomy

The spleen is a falciform or sickle-shaped organ located in the left mid-dorsal part of the peritoneal cavity (Figure 32-6). The exact position of the spleen varies, depending on, for example, the amount of the stomach filling, intestinal distention or displacement, and splenic disease. The cranial border of the spleen is concave and the caudal border is convex. The parietal or lateral surface is slightly convex and is in intimate contact with the diaphragm.[83] The visceral or medial surface is generally concave and contains a longitudinal ridge, the hilus, in which the vessels and nerves are located. The area cranial to the hilus is in contact with the left side of the greater curvature of the stomach. The area caudal to the ridge is more extensive and is

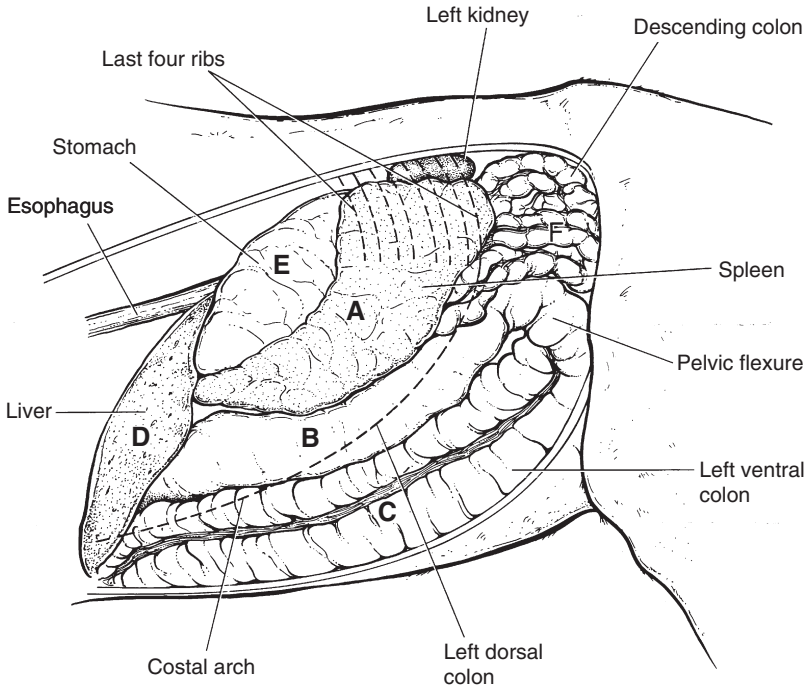

Figure 32-6. Relative topography of the abdominal viscera as viewed from the left side. The lateral and ventral walls are removed. The proximal one third of the last four ribs *(short dotted lines)* shows the relative position of the spleen protected by the rib cage (*long dotted line* defines the ventral and caudal border of the rib cage). *A,* Spleen; *B,* left dorsal colon; *C,* left ventral colon; *D,* liver; *E,* stomach; *F,* small bowel.

variably in contact with the descending colon, the left parts of the ascending colon, and the small intestine. The dorsal extremity or base of the spleen is located between the left crus of the diaphragm and sublumbar muscles dorsally and on its medial surface by the pancreas and left kidney. The base generally corresponds to the last three or four ribs, exceeding the 18th rib caudad in the paralumbar fossa by 2 to 3 cm. Only the caudodorsal angle (between the base and the caudal border) can be palpated *per rectum*. The ventral extremity or apex is small and usually found opposite the 9th, 10th, or 11th rib, proximal to the costal arch. The spleen is suspended within the peritoneal cavity by means of the phrenicosplenic and the renosplenic (or nephrosplenic) ligaments, and attached to the stomach by the gastrosplenic ligament. The latter continues with the superficial wall of the greater omentum.[84]

The size and weight of the spleen vary greatly, both among and within animals, depending on the amount of blood it contains. Its weight varies from about 0.5 to 3.5 kg. The spleen is approximately 50 cm (20 inches) long and about 20 to 25 cm (8 to 10 inches) wide. It is usually bluish red to purple.[83,85]

The hilus protects the vessels and nerves of the spleen. The splenic artery, a branch of the celiac artery, runs within the groove of the hilus and branches to supply the spleen and short gastric arteries that nourish the greater curvature of the stomach (Figure 32-7). The splenic vein is an affluent of the portal vein and lies caudal to the artery in the hilus. The splenic lymph nodes are scattered along the splenic artery and drain lymph to the celiac lymphocenter. The splenic plexus, branching from the celiac plexus, supplies the spleen with both sympathetic fibers from the major splanchnic nerve and parasympathetic fibers from the vagus nerve.

The splenic tissue is intimately covered by a fibrous capsule, which sends numerous trabeculae into the substance of the spleen. The capsule consists of collagen and elastin fibers and contains many smooth muscle cells.[84,86] The trabeculae form a spongy framework, which is the support of the splenic pulp. The splenic pulp is mostly red or dark red and is known as the *red pulp*.[86] The red pulp consists of arterial capillaries, small venules, and a reticulum filled with macrophages and blood. Throughout the red pulp are scattered gray foci just visible to the naked eye, which are known as the *white pulp*. The white pulp represents the lymphatic tissue of the spleen organized as lymphatic nodules.[85,87] Lymphocytes and macrophages supported by a scaffozlding of branched connective cells called *reticular cells* make up the lymphatic tissue. The reticulum is made up of a meshwork of supporting cells and extracellular fibers. The white pulp is distributed along the course of the arterial vessels, and it is almost as abundant as the red pulp.[85,88]

Physiology

The spleen has several important functions, including storage of erythrocytes and platelets, removal of aged or damaged erythrocytes and platelets, hematopoiesis during fetal development, iron recycling, and immunologic functions.[88] Unlike human spleens, animal spleens have the ability to store red blood cells. The equine spleen is particularly well adapted and can regulate the red cell storage by relaxation and contraction. The equine spleen can store up to 50% of circulating red blood cells.[89] The contractile ability is under sympathetic control and, in times of stress or strenuous exercise, is stimulated to release the stored red blood cells into the circulation, increasing the red cell concentration of the blood. At least one report has questioned the role of splenic emptying in exercise-induced changes in red cell indices.[90] Phenylephrine (an α_1-adrenergic receptor agonist) administration has been reported to cause a transient, dose-dependent splenic contraction of up to 83% of the original splenic mass and may be useful for certain medical or surgical procedures in the horse, such as during splenectomy or as an adjunct to nonsurgical correction of nephrosplenic entrapment of the ascending colon.[91] Epinephrine has also been reported to

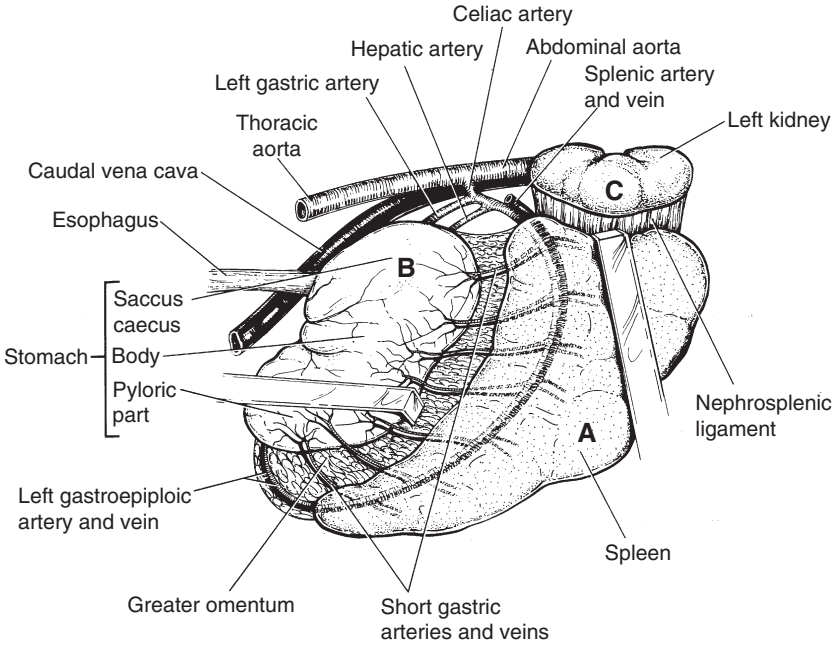

Figure 32-7. Left view of the spleen *(A)*, stomach *(B)*, and left kidney *(C)* with pertinent vascular supply. Retractors are placed along the greater curvature of the stomach to reveal the short gastric arteries and veins and along the dorsal extremity of the spleen to show the left kidney.

transiently reduce splenic length approximately 68% when administered as a bolus.[92]

The removal of aged or damaged erythrocytes occurs in the spleen owing to its unique structure. Blood is circulated through the splenic red pulp, terminating in small, highly porous capillaries. The blood cells pass out of the capillaries into the cords of the red pulp and eventually return to circulation through the endothelial wall of the venous sinuses. The red pulp and venous sinuses are loaded with macrophages (reticuloendothelial cells), which phagocytize unwanted debris and old or abnormal red blood cells. Also removed by the phagocytic cells are abnormal platelets, bloodborne parasites, and bacteria.[86]

In addition to its filtering and phagocytic activity, the spleen has another role in the immune-mediated defense against disease. It has a direct effect on the pattern and level of antibody response of the body. The spleen is the site of production of IgM, the homing hub for B cells, and the resevoir for immunocompetent lymphocytes.[88,93]

The resistance of the horse to disease caused by blood protozoa such as *Babesia* or *Theileria* species is significantly decreased after splenectomy.[94-97] Subclinical infections by protozoa may become patent infections after removal of the spleen.

Diagnostic Procedures

Surgical disorders of the spleen may be relatively difficult to diagnose because of their rare occurrence and nonspecific clinical signs. Rectal palpation usually reveals thickening and rounded margins of an enlarged spleen. Ultrasonography either *per rectum* or through the left abdominal wall may also reveal an enlarged spleen. Ultrasonography is useful to help determine the cause of the splenic abnormality (Figure 32-8).[98] A splenic biopsy may be performed for histologic evaluation of splenomegaly. Normal coagulation function should be determined before a percutaneous biopsy is performed. Laparoscopy may also be used to aid in the diagnosis of splenic abnormalities and to help with the decision between medical therapy and splenectomy.[99-101] Laparoscopic ultrasonography allows video-guided ultrasound examination of targeted organs and tissues within the abdomen. Laparoscopy can also be used to guide biopsy and needle aspiration to minimize the risk of bleeding, intestinal puncture, and exudate leakage.[101]

To examine the spleen, a long (30 cm [12 inch]) laparoscope is introduced into the dorsal aspect of the left paralumbar fossa facing craniad. The head of the spleen, left kidney, and renosplenic ligament can be readily identified in the left dorsal quadrant of the abdomen. The caudal edge and lateral wall of the spleen can be visualized as the laparoscope is swept down

toward the left ventral quadrant, and abnormalities over most of the body of the spleen can be identified. Lesions in this region can be biopsied with additional instruments placed through separate portals in the left paralumbar fossa. Biopsies can be obtained with laparoscopic scissors as wedge biopsies or with an instrument similar to a uterine biopsy forceps. Hemorrhage should be expected and may be controlled with bipolar cautery forceps or a vessel sealing device (LigaSure; EnSeal—see Appendix B).[100,102] Additional diagnostic procedures used to differentiate disorders of the spleen include a complete history and physical examination; complete blood cell count, including total plasma protein and plasma fibrinogen; coagulation profile; abdominocentesis; the Coggins test (agar gel immunodiffusion test for equine infectious anemia); Coombs test; and aerobic and anaerobic bacterial cultures.

Indications for Surgery

Splenectomies are performed primarily for research purposes, to aid in the evaluation of the cardiovascular system during exercise and to alter the reticuloendothelial system, which controls to a great extent the infections caused by blood protozoa such as *Babesia* spp. or *Theileria* spp.[94-97,103-108] Splenomegaly with or without splenic infarction and rupture have been the only reported disease processes requiring splenectomy.[109-114] Other possible indications for surgery include neoplasia, trauma, infarction, and possibly an autoimmune disease in which the spleen would play a role in erythrocyte destruction.[115]

Splenomegaly

Splenomegaly in the horse may be primary or idiopathic, caused by congestion or hyperactivity, or it may be secondary.[112] Secondary splenomegaly has been attributed to subcapsular hematoma, equine infectious anemia, lymphoma-leukemia (lymphosarcoma),[116] metastatic melanoma, isoimmune hemolytic anemia, salmonellosis, babesiosis or theileriosis, ehrlichiosis and borreliosis, and anthrax.[109,112,117,118] Infarctions have also been reported as causes or consequences of splenomegaly.[110,111,119] Splenectomy is indicated for splenomegaly for chronic congestion, thrombosis, or primary tumors of the spleen with no evidence of metastases. Clinical signs of horses with splenomegaly include tachycardia, anemia, colic, arching of the back, and standing with the limbs drawn together beneath the body.[110,117,119]

Neoplasia

Lymphosarcoma (malignant lymphoma), metastatic melanoma, and hemangiosarcoma are the only primary neoplastic diseases of the equine spleen.[116,120-124] Lymphosarcoma is a neoplastic disease of lymphoid cells. Splenic lymphosarcoma is classified as an alimentary form of the disease. The cells metastasize via the lymphatics (i.e., in the spleen, the white pulp is first infiltrated). In later stages of the disease, the spleen's architecture may become so distorted that the pathway of spread is not apparent. Leukopenia and anemia are often present.

Melanomas may occur as a primary tumor of the spleen of horses, but the spleen is more likely a site of metastases.[125-128] Hemangiosarcoma or hemangioendothelioma is a frequent primary tumor of other domestic animals and humans but has been only rarely reported as a primary tumor in the horse.[124,129] This tumor is more commonly reported in the spleen of the horse as a site of metastasis.[124,130-132] All of these tumors may cause splenomegaly and may manifest with clinical signs of an acute abdominal disease owing to an increased weight of the spleen and stretching of the splenic ligaments.[124,125,133]

Splenic Infarction and Splenic Abscesses

Splenic infarction occurs concurrently with splenomegaly.[110,111] Venous thrombosis and infarction may occur any time the spleen is enlarged. Splenic arterial or venous thrombosis, or both, is seen with autoimmune hemolytic anemia, purpura, hemorrhagic pancreatitis, and splenic abscesses. The last have been reported to be caused by *Habronema*, *Strongylus*, *Bacteroides*, *Clostridium*, *Streptococcus*, and *Mycobacterium* spp.[98,134,135]

Splenic Rupture

Splenic rupture is relatively rare in horses.[113,114,136-140] It may be caused by direct, severe trauma, or it may occur secondary to anthrax, lymphosarcoma, echinococcus infestation, splenic hematoma, or hemorrhage. In most reported cases, horses have been found dead, died during the course of the illness, or were euthanatized shortly thereafter. The cause of rupture is usually unknown, but in one report, it was thought to be as a result of a previous splenomegaly.[139] Most of the ruptures occur on the visceral surface of the spleen. Very few cases of rupture to the parietal surface have been reported.[138,139] Three cases of nonfatal subcapsular hematoma on the parietal surface have been reported.[99,117,141] The clinical signs associated with splenic rupture include serosanguineous or sanguineous peritoneal fluid, pale mucous membranes, anemia, tachycardia, dyspnea, profuse sweating, anorexia, and colic. Immediate surgery is indicated to control hemorrhage. The clinical signs reported for splenic hematoma include pancytopenia, anorexia, depression, and abdominal distention.[141]

Preoperative Considerations

Preoperative considerations for splenectomy include assessment of hydration, acid-base status, and clotting function. The presentation of horses requiring a splenectomy is usually on an emergency basis (i.e., acute abdominal disease, acute blood loss), and therefore the horses may be dehydrated and in shock. Careful assessment should differentiate those with pain because of stretching of the splenic ligaments from those with pain as a result of acute blood loss from splenic rupture.

Surgical Techniques

Splenectomy

APPROACHES

Several reports have described the technique for splenectomy.[94,109,110,115,142-148] All the methods describe an approach from the left side, with the animal standing or in right lateral recumbency. The variations in the techniques center on the exact position of the skin incision. Originally, the procedure was described as a paralumbar approach (i.e., caudal to the last or 18th rib).[142] Because of the difficulty in accessing the base of the spleen, and therefore its primary vessels, various techniques

have been proposed to gain better access. Techniques have been described for access to the spleen between the last two ribs or by resection of the 18th rib, the 17th rib, or the 16th rib.[94,110,144-148] One report also describes removal of the distal aspect of the last three ribs.[143] Another report describes removal of the 17th and transecting of the 16th and 18th ribs for removal of an enlarged spleen.[109]

Laparoscopic splenectomy has been reported in humans, but its potential use in the horse at this time is only speculative.[149-152] Laparoscopic-assisted splenectomy has been reported in one horse.[112] Hand-assisted techniques may soon be developed similar to those reported for removal of diseased kidneys and ovarian tumors in horses.[153,154] The friability of the diseased spleen and its vascular supply may complicate potential laparoscopic procedures, although the visualization afforded by laparoscopy may well offset the potential complications. The caudal reflection of the pleural cavity should be considered when determining the technique to be used. The lateral thoracic wall attaches to the diaphragm along a line called the *diaphragmatic line of pleural reflection*. This line extends from the eighth and ninth costal cartilages dorsocaudally in a gentle increasing curve, so that its most caudal aspect is at about the middle of the cranial border of the last rib forming the caudal border of the pleural cavity.[155] Therefore, resection of either the 16th or 17th rib is almost always associated with opening the pleural cavity, resulting in a pneumothorax. This is not necessarily a significant problem, because many horses have an intact mediastinum. However, if the mediastinum is incomplete, assisted ventilation is required to maintain respiration.

17TH RIB RESECTION TECHNIQUE

The horse is placed under general anesthesia in right lateral recumbency and prepared for aseptic surgery. A vertical incision is made over the 17th rib from the lumbar muscles (iliocostalis thoracis and longissimus muscles) proximally to the costochondral junction distally. The dissection continues through the subcutaneous tissues and the cutaneous trunci, serratus dorsalis caudalis, and external abdominal oblique muscles to expose the lateral periosteum of the 17th rib. The periosteum is incised and elevated from the lateral aspect of the rib with a periosteal elevator starting at the costochondral junction and continuing proximad. Circumferential elevation of the periosteum over the full length of the exposed rib is achieved using a large Doyen, Alexander, or other similar periosteal elevator. An obstetrical cable (Gigli wire), bone-cutting forceps, or oscillating bone saw is used to transect the rib as far proximad as possible. The body of the rib is disarticulated at the costochondral junction through lateral and ventral pull and is removed. The medial periosteum and underlying peritoneum are incised. Proximally, the pleural cavity may be entered. The cavity should be closed by suturing the diaphragm to the intercostal muscles using an absorbable suture material in a continuous pattern. While the pleural cavity is open, the horse's respiration may need to be assisted with mechanical ventilation or intermittent manual compression of the rebreathing bag.

SURGICAL PROCEDURE

The edges of the incision should be draped with saline-moistened laparotomy sponges and separated with a Finochietto rib spreader. The dorsal part of the spleen may be elevated into the incision (Figure 32-9). The nephrosplenic ligament is transected to expose the splenic vein. The vein is located more superficial or lateral than the artery and may be isolated for separate ligation. Care should be taken not to tear the vein. Intravenous infusion of phenylephrine will result in significant, transient splenic contraction to reduce the weight of the spleen and allow better access to its visceral portion. Some specialists recommend separate ligation of the vessels, with the artery being ligated first followed by massage of the spleen to remove any excess blood from the organ. A variation involves injecting 10 to 15 mL of 1:1000 epinephrine at several sites in the spleen to expedite its contraction. The vessels should be triple-ligated and transected between the distal ligatures, leaving two ligatures on each (if ligated separately) of the vessels (Figure 32-10). The remainders of the nephrosplenic, phrenicosplenic, and gastrosplenic ligaments are transected near the hilus. Ligatures or stainless steel hemostatic clips are applied to the short gastric vessels as needed. As the spleen is separated from its attachments, the free cut edge of the greater omentum may be sutured to the free cut edge of the gastrosplenic ligament. This is most easily performed while the spleen is still attached (Figure 32-11).

Abdominal wall closure is accomplished in three layers as per the surgeon's preference. The initial layer includes the peritoneum and periosteum, the second layer consists of the

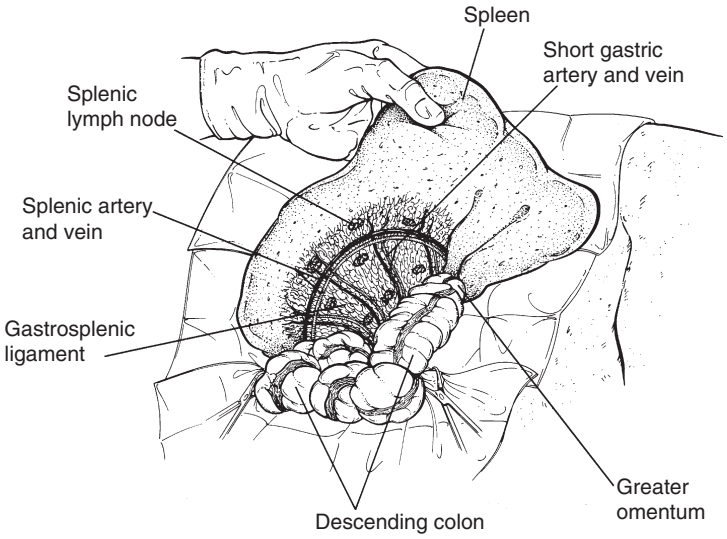

Figure 32-9. Intraoperative view showing elevation of the dorsal part of the spleen into the incision. The renosplenic ligament prevents complete elevation of the spleen.

(Courtesy Dr. Shannon Reed, University of Missouri, Columbia, MO.)

subcutaneous tissues, and the skin represents the final layer. Either active or passive drains are recommended between muscle layers to minimize serum accumulation and subsequent wound dehiscence.

Splenorrhaphy and Partial Splenectomy

Lacerations of the spleen, such as may occur during abdominocentesis or minor ruptures of the splenic capsule, may be corrected by splenorrhaphy. Absorbable sutures placed across the

Figure 32-12. Intraoperative view of a partial splenectomy. **A,** A splenic mass confined to the distal third of the spleen was identified via a midline laparotomy *(black arrows)*. The patient was admitted with a history of chronic colic. **B,** An automated stapling device was used to resect the distal third of the spleen. The resection margin was covered with an oxidized cellulose product *(white arrows)* to reduce minor hemorrhage from the spleen.

defect are usually sufficient to control hemorrhage. Large vessels may need to be individually ligated. Partial splenectomy or splenorrhaphy has not been reported in the horse. Various techniques have been described in humans and canines, including the use of mattress sutures, stapling devices, hemostatic (hemostyptic) agents, ultrasonic cutting devices, CO_2 lasers, a microwave coagulator, an argon-beam coagulator, and absorbable mesh consisting of polyglycolic acid or polyglactin 910.[156-167] The authors have applied a TA-90 stapling device, followed by application of an oxidized cellulose hemostatic agent (Surgicel), to accomplish partial splenectomy without complication in a horse with a splenic mass (Figure 32-12).

Closure of the Renosplenic Space

Closure of the renosplenic space has been advocated to prevent recurrence of left dorsal displacement of the large colon.[168] More recently, laparoscopic techniques have been described for closing the renosplenic space (see Chapter 37).[169-172] The techniques involve suturing the most dorsal visceral surface of the spleen to the renosplenic ligament to eliminate the area between

the spleen and the left kidney to which the large colon frequently becomes displaced.[168-172] The use of polypropylene mesh has been described to obliterate the space in five horses.[171] Etilefrine (Effortil), a sympathomimetic drug, has been reported to aid in the procedure by inducing splenic contracture.[172] There have been no reported cases of left dorsal displacement after closure of the renosplenic space. The only reported complication of the procedure was adhesion formation of the descending colon to the polypropylene mesh.[171]

Aftercare

After recovery from anesthesia, the animal should be placed in a stall and hand-walked for the first 7 to 10 days. Body temperature, pulse and respiratory rates, and appetite should be monitored regularly. The incision should also be monitored for signs of heat, swelling, drainage, seroma formation, or infection. Antibiotics may be administered as indicated by clinical signs and the results of bacterial culture and sensitivity testing. Analgesics such as flunixin meglumine, ketoprofen, or phenylbutazone should be administered during recovery and for at least 24 hours after surgery to control pain. Drains placed at the time of surgery should be removed after 2 to 3 days. Drainage and lavage of the incision site should occur if evidence of seroma formation or infection is noted.

Complications

The most serious complication after splenectomy is intra-abdominal hemorrhage.[115] Incisional complications include drainage, seroma, edema, infection, and dehiscence.[94,115,143] Additional complications related to the transthoracic approach include pyothorax, pneumothorax, and pleuritis.[115] Complications in humans after splenectomy include atelectasis, pleural effusion, pneumonia, hemorrhage, subphrenic abscess formation, pancreatic fistula and pancreatitis, gastric fistulation, thrombocytosis and thrombosis, and sepsis.[173] Overwhelming postsplenectomy infection syndrome is a rare but fatal complication recognized in humans.[174] Therefore, splenectomy should not be considered an innocuous procedure. The spleen is an important component of the immune system and its removal may predispose the horse to subsequent infections.[93] Therefore, conservative therapy and partial splenectomy should be attempted as alternatives to splenectomy whenever possible, particularly in young horses.

CHAPTER
33

Colic: Diagnosis, Surgical Decision, and Preoperative Management

John F. Marshall and Anthony T. Blikslager

The veterinarian presented with an equine colic faces a true emergency and a diagnostic challenge. Through the combination of history, physical examination, and diagnostic procedures, the veterinarian must determine and communicate to the owner the source of the abdominal pain, the prognosis for recovery, the correct treatment strategy, and the estimated costs. Although a great deal of valuable information can be gained from an accurate signalment, history, and physical examination, a range of further diagnostic procedures are necessary to aid in this process. It is therefore essential to understand the indications, significance, and limitations of these techniques. This information may then be interpreted, and a decision to continue medical treatment or perform an exploratory celiotomy can be made.

DIAGNOSIS

History and Signalment

The signalment of the colic patient is important when determining the specific information that should be obtained during history taking, and which physical examination and diagnostic procedures are indicated. The signalment itself can often lead to an early differential diagnosis that may be investigated during the subsequent history and physical examination. The information obtained from the owner should include both the medical history and management practices. Details of the medical history related to the current and previous episodes of colic, other illnesses or surgery, and current and previous medications administered are essential. A history of recent nonsteroidal anti-inflammatory drug (NSAID) use may suggest a possible impaction of the ascending colon or right dorsal colitis.[1] Knowledge of all analgesics and sedatives administered before presentation is crucial when interpreting signs of pain and physical examination findings, as they may alter clinical signs. A description of the current management of the horse and any changes to diet, exercise, stabling, and anthelmintic regimen is important in identifying potential risk factors for certain conditions. These include the association between the feeding of coastal Bermuda hay and the risk of ileal impaction,[2] and the association between the behavior of crib biting and epiploic foramen entrapment.[3]

Physical Examination

The physical examination of the colic patient should be conducted in a thorough, logical order and should not be limited to the abdomen. The measurement and recording of the temperature and the heart and respiratory rates on initial examination allows the response to medication and therapy to be quantified. The heart rate is an indicator of the physiologic response to pain, dehydration, and endotoxemia and is useful in determining prognosis in both large and small intestinal disease.[4,5] Conditions associated with pyrexia include anterior enteritis, colitis, and pleuropneumonia and do not generally require immediate surgical intervention. Therefore, complete auscultation of the thorax to rule out conditions of the respiratory tract should be performed. Examination of the oral mucus membranes, including measurement of capillary refill time, aids in the determination of hydration status and the diagnosis of endotoxemia. In the endotoxemic horse, the capillary refill time is prolonged and the mucous membranes develop a brick red or purple color. A dark "toxic line" may be apparent along the gum line of the horse.

Auscultation of abdominal borborygmi allows the subjective assessment of large intestinal motility. Cecal motility may be auscultated over the right flank, whereas the pelvic flexure and ascending colon are auscultated over the left flank. Audible movements of the cecum and ventral colon include propulsive, retropulsive, and mixing contractions.[6] Propulsive contractions of the cecum and colon occur approximately every 3 to 4 minutes but are decreased in frequency by conditions including anorexia and sedation (e.g., α_2-adrenergic receptor agonists).[7] Ileus of the large or small intestine will result in the absence of intestinal borborygmi and is therefore a significant physical examination finding. Intestinal borborygmi can also be increased in certain conditions, including the early stages of distention and inflammation.

A critical aspect of the examination of any horse presented for colic is the assessment of the degree and persistence of signs

of pain.[8] It is often easiest to observe a horse in a box stall where it may display signs of pain that are not apparent during handling or restraint in stocks. Obvious signs of pain include pawing at bedding, looking at the flank, kicking at the abdomen, repeated lying down and standing, and rolling. Abdominal pain may also manifest itself by more subtle behavior including a dull appearance, lowered head position, and reluctance to move.[9] The severity of pain is often related to the degree of intestinal injury, which is in turn related to the need for surgical intervention. A large colon volvulus resulting in large colon distention and ischemic injury will cause severe pain that is refractory to treatment with analgesics and sedatives. In contrast, a nonstrangulating obstruction results in lower grade pain that responds to analgesia. Observation of the response to treatment with NSAIDs or sedatives is important when characterizing the type of pain.[8] Mild pain typically responds to treatment with an NSAID alone for a period of 8 to 12 hours. In contrast, moderate pain will respond to analgesia for a limited period and requires repeated administration. Severe pain is manifest by violent behavior and may not respond to analgesia, which is frequently an indicator of the need for immediate abdominal surgery.

During the physical examination, when indicated, it may be prudent to place an intravenous jugular catheter and begin fluid therapy while further diagnostic procedures are performed.

Rectal Examination

Rectal examination should be performed using a suitable combination of physical and chemical restraint to allow palpation of the cecum, left dorsal and ventral colon, pelvic flexure, descending colon, and reproductive tract. If sedation does not provide adequate relaxation to allow a safe examination, the instillation of lidocaine into the rectum or administration of *N*-butylscopolammonium bromide can reduce straining, improve the quality of the rectal examination, and reduce the risk of rectal tearing.[10,11] Careful palpation should be performed to prevent rectal tears and allow diagnosis of any existing tear. The position and size of each palpable organ may be assessed as well as the content, which may be ingesta, fluid, or gas. Entrapment of the large colon in the nephrosplenic space may be palpable in the upper left abdominal quadrant. The small intestine is not normally palpable *per rectum* and is therefore an abnormal finding on rectal examination. The small colon is normally distinguished by the presence of fecal balls and a broad antimesenteric band. If these features are not palpable it suggests impaction of the small colon. In the pregnant mare, the broad ligaments should be palpated to diagnose a possible uterine torsion. If a tight broad ligament is palpated, the direction of the torsion should be determined to allow correction.

Nasogastric Intubation

The passage of a nasogastric tube should be performed during all colic examinations to allow decompression if necessary and prevent gastric rupture. Water is flushed through the tube to begin a siphoning action, and should be measured to allow the net volume of fluid recovered to be determined. The color and smell of the fluid should be assessed. It is normal to recover up to 2 L of green, nonodorous fluid. Excessive fluid indicates either gastric outflow obstruction or decreased small intestinal motility resulting in an accumulation of fluid in the stomach. Anterior enteritis cases often yield a large volume of malodorous orange or yellow fluid. Large amounts of feed in the gastric fluid may indicate gastric impaction. Gastric outflow obstruction may also be caused by gastroduodenal ulceration or neoplasia. The cause of gastric outflow obstruction may be further investigated by endoscopy. Following decompression of the stomach, the nasogastric tube may be left in place during surgery to prevent fluid aspiration and allow intraoperative decompression.

Clinical Pathology

The use of clinical pathology has become a crucial part of the assessment and treatment of the colic patient. The measurement of the blood packed cell volume (PCV) and total protein (TP) can be performed using a centrifuge and refractometer to quickly assess the patient's hydration status. A high PCV has been shown to be associated with a poor prognosis in horses with both small and large intestinal disease.[4,12,13] In contrast, a low TP has been associated with a poor prognosis in horses undergoing surgery for the treatment of small intestinal disease.[5,12] The introduction of point-of-care analyzers has created widespread availability of blood electrolyte and acid-base balance information. When using a point-of-care analyzer it is important to store and prepare the cartridges for use according to the manufacturer's instructions to ensure accuracy.[14] Although the majority of changes seen on hematology are nonspecific, it is useful in diagnosing inflammation, endotoxemia, or sepsis. These changes may be evident as leukopenia, neutropenia with appearance of immature and toxic neutrophils, lymphopenia, and thrombocytopenia.

The blood electrolyte profile of horses losing fluids through gastric reflux or diarrhea often reveals abnormalities, including low sodium, potassium, calcium, and bicarbonate levels that may be addressed during fluid therapy. Because lactate is a product of anaerobic glycolysis, its measurement may reflect ischemic injury and may aid in determining the prognosis.[15] Among horses with large colon volvulus, a serum lactate concentration greater than 6 mmol/L has been associated with a poor prognosis for survival.[16] Measurement of the anion gap allows the indirect measurement of blood lactate and is of value when determining prognosis.[17] A study of horses with large colon displacement revealed an increased serum γ-glutamyltransferase (GGT) in 49% of right dorsal displacement cases but in only 2% of horses with a left dorsal displacement.[18] This increase in GGT in horses with right dorsal displacement of the large colon is due to obstruction of the bile duct. Additional information on acid-base derangements and their management can be found in Chapter 3.

Abdominocentesis

Peritoneal fluid can be examined as both a diagnostic and prognostic aid. Peritoneal fluid can be collected by clipping and aseptically preparing the most dependant part of the abdomen, on or slightly right of midline to avoid the spleen, and inserting an 18-gauge needle. Alternatively, following local anesthesia, a small incision can be made using a No. 15 scalpel blade and inserting a teat cannula. Care must be taken during the collection of fluid to avoid enterocentesis, particularly in horses with distended viscera, or amniocentesis in the pregnant mare.

Where fluid is not easily obtained, abdominal ultrasonography can be performed to identify an area of fluid accumulation for collection. The abdominal fluid should be collected in a plain tube for the measurement of protein concentration and in an EDTA tube for a cell count and hematology.

Immediately following collection, the gross appearance of the fluid should be visually assessed. Normal peritoneal fluid has a clear, colorless to light yellow appearance. When a strangulating lesion is present, there is movement of protein followed by red blood cells and finally leukocytes into the peritoneal cavity. This results in the peritoneal fluid becoming turbid and red to brown. The presence of ingesta in the peritoneal fluid suggests a ruptured viscus and a hopeless prognosis. In this situation, care must be taken to ensure that the sample was not obtained by enterocentesis. The normal total protein concentration of abdominal fluid is less than 2 g/dL, but this will increase with intestinal disease. The appearance of red blood cells in the abdominocentesis sample may be the result of an intestinal strangulation or an iatrogenic source. A small amount of blood contamination may occur if a vessel in the abdominal wall is punctured. If the peritoneal fluid is normal, on centrifugation a small pellet of red blood cells will collect, leaving fluid with a normal appearance.[19] It is also possible to insert the needle into the spleen, resulting in the collection of a sample with a PCV similar to blood.

Clinical biochemistry may be performed on peritoneal fluid to determine other factors, including fibrinogen, lactate, phosphate, glucose, and pH. A high peritoneal lactate has been shown to be a more sensitive indicator of a strangulating obstruction of the intestine than plasma lactate.[15] In those horses with suspected septic peritonitis, the serum and peritoneal fluid glucose levels can be compared. A difference of greater than 50 mg/dL between the serum and peritoneal fluid glucose level, a low peritoneal fluid glucose level (less than 30 mg/dL), and pH of less than 7.3 are indicators of septic peritonitis.[20]

Ultrasonography

Ultrasonography has become an important part of the diagnosis, treatment and management of the colic patient.[21] Abdominal ultrasonography is generally performed using a percutaneous approach following preparation of the skin by clipping and application of alcohol or coupling gel. A low-frequency (2.5 to 5 MHz) linear, curvilinear, or sector transducer will produce a diagnostic quality image while providing sufficient penetration to identify deeper structures. It is possible to identify the stomach, small intestine, cecum, and large colon and determine their size, position, wall thickness, and motility.[21] The stomach may normally be imaged cranially on the left of the abdomen between the 11th and 13th intercostal spaces. The gastric volume can be estimated and stomach decompression confirmed by measurement of the gastric wall height at the 12th intercostal space.[22]

The small intestine can be identified in the cranial ventral abdomen and can be examined for wall thickness, diameter, and motility. The normal wall thickness of the small intestine is less than 3 mm, and an increase may indicate enteritis or strangulating obstruction (Figure 33-1). Obstruction results in distention of small intestinal loops, which can be identified and measured ultrasonographically (Figure 33-2). The motility of these loops should be assessed, because ileus may be diagnosed as hypomotile small intestine on ultrasonographic examination.

A cross section of the jejunum can be identified, and measurement reveals a thickened wall (1.01 cm) characteristic of enteritis. (Courtesy M.K. Sheats, North Carolina State University, Raleigh, NC.)

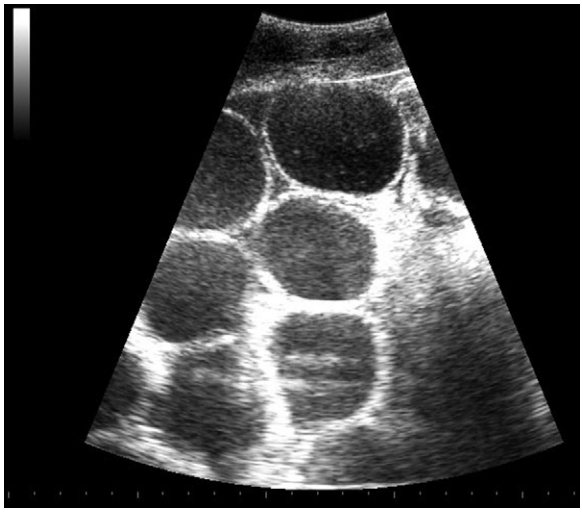

Figure 33-2. Ultrasonographic examination of the ventral abdomen of a horse using a 3.5 MHz curvilinear probe. Several cross-sectional loops of distended jejunum can be identified with a normal intestinal wall thickness. These findings are characteristic of a functional or obstructive ileus. (Courtesy M.K. Sheats, North Carolina State University, Raleigh, NC.)

Ultrasonography has been demonstrated to be extremely useful for the diagnosis of large colon volvulus in the horse.[23,24] The colon is identified on the ventral abdominal midline, and the appearance and thickness of the wall and motility are assessed. Normally, the sacculated ventral colon with a wall thickness of less than 5 mm is identified. If a large colon volvulus of 180 or 540 degrees is present, the nonsacculated dorsal colon can be identified on the ventral abdomen.[24] Measurement of the colonic wall thickness has been shown to be useful in the diagnosis of large colon volvulus (Figure 33-3). A colonic wall thickness measurement of greater than 9 mm had a sensitivity of 67% and a specificity of 100% in diagnosing large colon

Figure 33-3. Ultrasonographic examination of the ventral abdomen 2 cm caudal to the xyphoid of a horse using a 3.5 MHz curvilinear probe. A longitudinal image of the ventral colon reveals significant thickening (1.97 cm) diagnostic of a large colon volvulus. (Courtesy M.K. Sheats, North Carolina State University, Raleigh, NC.)

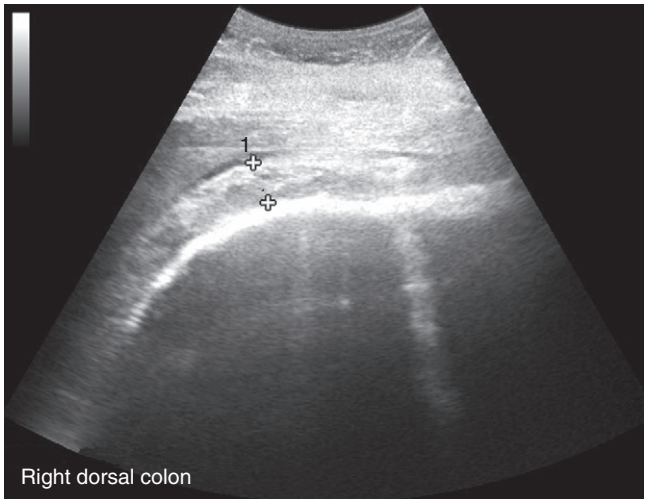

Figure 33-4. Ultrasonographic examination of the 11th intercostal space on the right side of a horse using a 5 MHz curvilinear probe. The right dorsal colon is thickened (1.46 cm), and a hypoechoic layer of edema, cellular infiltrate, and granulation tissue is visible. These changes are consistent with right dorsal colitis. (Courtesy M.K. Sheats, North Carolina State University, Raleigh, NC.)

volvulus.[23] In addition to the diagnosis of large colon volvulus, ultrasonography can be used to monitor postoperative recovery of the colon.[25]

The horses in which right dorsal colitis is suspected, a diagnosis can be confirmed using ultrasonography performed between the 10th and 14th right intercostal spaces.[26] Ultrasonographic changes associated with right dorsal colitis include a thickened colon wall and a hypoechoic layer of submucosal edema and inflammatory infiltrate (Figure 33-4).[26] Left dorsal displacement of the large colon can be diagnosed ultrasonographically through identification of the large colon lateral

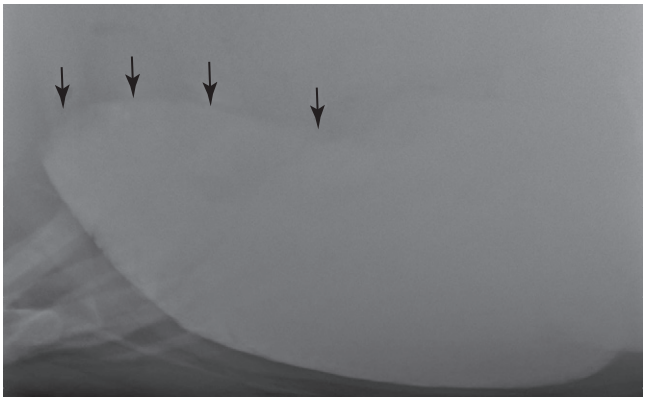

Figure 33-5. Lateral radiograph of the ventral abdomen of a horse. Accumulation of sand is apparent in the ventral colon *(arrows)*.

or dorsal to the spleen.[27] The displaced colon prevents visualization of the right kidney. If nonsurgical management is performed, ultrasonography can be used to confirm correction of the displacement.[27] Although radiography remains the gold standard for diagnosing sand impaction of the colon, ultrasonography can identify sand, which produces a hyperechoic signal and acoustic shadowing of deeper structures.[28] The presence of a sand impaction can also reduce colonic motility.

Radiography

In the examination of the adult horse presented for colic, radiography is useful when the presence of radiopaque material is suspected. Therefore, abdominal radiographs are particularly useful for the diagnosis of sand accumulation and enterolithiasis (Figure 33-5).[29,30] When performing abdominal radiography, adequate exposure is critical to maximize diagnostic quality and reduce the incidence of false negative examinations. The sensitivity and specificity of radiography for the diagnosis of enterolithiasis have been described as 76.9% and 94.4%, respectively.[30]

The improved image quality of abdominal radiography in the foal and small horse allows examination of the stomach and small and large intestines. Radiography can be performed using both plain film and contrast techniques to allow diagnosis of obstruction, intussusception, and radiopaque foreign bodies. Contrast radiography can be performed using 30% wt/vol barium sulfate suspension administered orally or rectally.[31] This technique is useful for identifying delayed gastric outflow obstruction and obstruction of the small, transverse, and large colons.

ANCILLARY DIAGNOSTIC AIDS

Endoscopy

Examination of the esophagus, stomach, and duodenum can be performed in the adult horse using a 3-m flexible endoscope. During a colic examination, endoscopy can be used to confirm gastric decompression and diagnose gastric ulcer disease, gastric impaction, and gastric squamous cell carcinoma. Endoscopic examination of the rectum allows the minimally invasive investigation of rectal tears.

Laparoscopy

The use of laparoscopy has been described for investigation of both the acute and chronic colic patient.[32] Laparoscopy is an option in those patients with controlled abdominal pain. Its use is limited in the horse by the inability to completely visualize the abdominal contents and by the difficulties associated with manipulating the large viscera of the horse. The sensitivity and specificity of laparoscopy as a diagnostic technique are greater in horses with acute colic than chronic colic.[32] When performing laparoscopy in the acute colic patient, care must be taken to prevent penetration of gas-distended abdominal viscera. Although laparoscopy is generally a diagnostic technique in the acute equine colic patient, its use has been described for correcting left dorsal displacement of the large colon.[33]

Laparoscopy is suitable for diagnosis of a range of abdominal conditions, including mesenteric tears, uterine rupture, intestinal adhesions, small intestinal strangulating lesions, large colon displacement (Figure 33-6), and visceral rupture.[32]

DECISION FOR SURGERY

Following the examination and diagnostic procedures, there are three general options available for the management of the colic patient. In patients with a poor prognosis, the owner may elect to have the horse euthanized. If that is not the case, the veterinarian must decide whether an immediate exploratory celiotomy is required or if medical management and further observation should be instituted. The decision to perform an exploratory celiotomy is largely based upon the ability to control pain and the abnormalities identified by physical examination and diagnostic procedures. Prompt surgical intervention is critical in maximizing the probability of a successful outcome, whereas a delayed exploratory celiotomy may result in visceral rupture or deterioration in the patient's condition. Therefore surgery is often performed before a definitive diagnosis of the cause of the colic has been reached.

The response to immediate medical therapy and analgesia is often a strong indicator of the need for an exploratory celiotomy. An exploratory celiotomy is often necessary in those horses with uncontrolled abdominal pain, even if other diagnostic procedures find no abnormalities. The presence of distended, hypomotile small intestine on rectal and ultrasonographic examination is commonly associated with the need for surgical intervention. Serosanguineous peritoneal fluid with an increased total protein and white blood cell count is an indicator of significant pathology and requires an exploratory celiotomy. The continued production of gastric reflux or deterioration in physical parameters including hydration status may suggest an exploratory celiotomy is necessary for both diagnostic and therapeutic purposes.

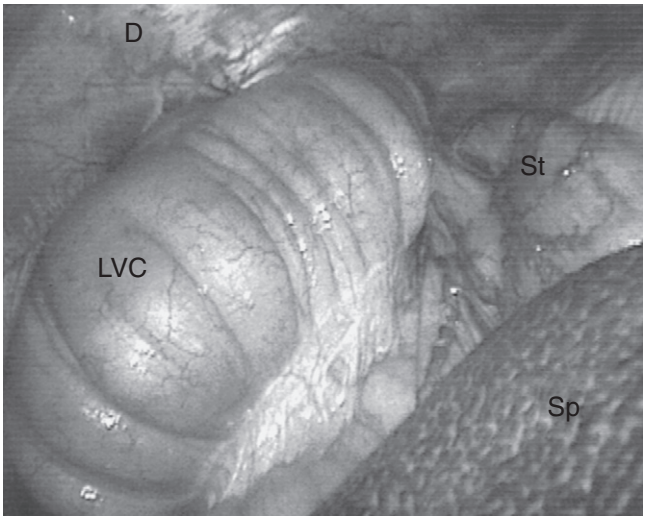

Figure 33-6. Left-sided laparoscopic view of a large colon displacement (i.e., retroflexion of the pelvic flexure). *D*, Diaphragm; *LVC*, left ventral colon; *Sp*, spleen; *St*, stomach.

PREOPERATIVE MANAGEMENT

The preoperative management of the colic patient requires preparation to undergo anesthesia and administration of prophylactic antimicrobial and anti-inflammatory agents. Although an exploratory celiotomy is frequently an emergency surgery, it is important to attempt fluid therapy to address hydration status and acid-base and electrolyte abnormalities before anesthesia. Because the duration of an exploratory celiotomy may be long and the gastrointestinal tract is often entered, prophylactic antimicrobials should be administered 30 to 60 minutes before surgery and repeated during surgery if necessary. If the colic patient has not already received an NSAID, flunixin meglumine (0.25 to 1.1 mg/kg) may be administered preoperatively to reduce inflammation and treat endotoxemia.

Before surgery, a nasogastric tube should be placed to allow stomach decompression during surgery as necessary. The horse's mouth could be rinsed to prevent aspiration of feed material during intubation. Any bedding or other material in the horse's hair coat should be removed with a dry brush to reduce contamination of the operating room.

CHAPTER 34

Surgical Approaches to the Abdomen

Martin R. Kummer

Surgical approaches to the abdomen are laparotomies of different sizes and locations. A laparotomy is a surgical procedure involving an incision through the abdominal wall to access the abdominal cavity, also known as celiotomy. Using this definition, even the portals created for laparoscopic approaches can be considered small laparotomies.

VENTRAL MIDLINE APPROACH

The most common approach applied in equine abdominal surgery is performed through the ventral midline, specifically through the linea alba (Figure 34-1) because it allows exteriorization of 75% of the intestinal tract (Figure 34-2). The stomach, duodenum, distal ileum, dorsal body and base of the cecum, distal right dorsal colon, transverse colon, and terminal descending colon are the only segments that cannot be exteriorized. The ventral midline approach creates minimal hemorrhage, is easy to perform, can be extended if needed, and contains strong fibrous tissues for closure.

After positioning the patient in dorsal recumbency and clipping the hair of the surgical field, an indwelling urinary catheter should be placed in male horses to prevent the possibility of urine contamination during surgery. The penis is carefully snared with a gauze bandage, properly cleaned, and positioned in the prepuce after prior cleaning. The preputial cavity is subsequently sutured closed, allowing only the catheter to exit the suture line. Routine aseptic preparation of the surgical field is the next step.

The linea alba extends from the xiphoid process to the prepubic tendon and contains the median fibrous raphe of the external oblique and the transverse abdominal muscle aponeuroses. It consists of dense connective tissue composed of sheets of cross-linked collagen bundles and fibroblasts. The thickness of the linea alba gradually increases from craniad, where it measures about 3 mm, to caudad, where it reaches a thickness of approximately 10 mm.[1] The midline incision should be large enough to allow exteriorization of viscera without applying excessive pressure on the intestines, which would increase the risk of iatrogenic tears. The time saved during the procedure and the increased safety of a larger incision more than compensate for the extra time required to close a longer incision. Additionally, a smaller incision will be traumatized more during the manipulations of a surgical procedure than a larger one, which may delay its healing and lead to postoperative infection and herniation, especially after colic surgery. After incising the skin and subcutaneous tissue, the linea alba is incised beginning in the umbilical region where it is the widest and thickest. The incision is subsequently continued craniad to its desired length,

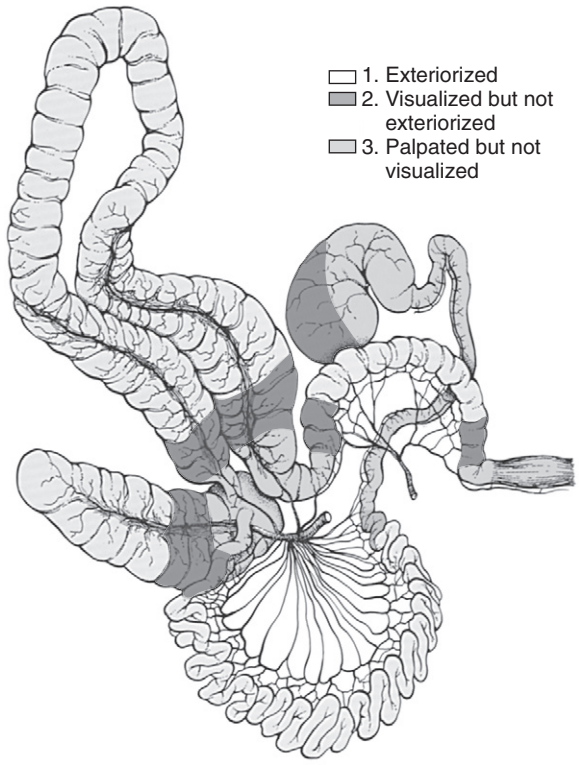

Figure 34-2. Anatomic drawing of the equine intestinal tract. Differential shading indicates the portions that may be *(1)* exteriorized, *(2)* visualized and palpated but not exteriorized, and *(3)* palpated only via a standard ventral midline approach. (Redrawn from Sack WO: Guide to the Dissection of the Horse. Edwards Brothers, Ann Arbor, MI, 1977.)

avoiding penetration of the rectus abdominus muscle. The latter structure can easily be palpated as a local thickening at the internal side of the ventral abdominal wall. Incisional hemorrhage is only encountered in the skin and the subcutaneous tissues.

Although there are different suture patterns that can be used to close the celiotomy, a continuous suture pattern with loops positioned 1.2 to 1.5 cm from the incisional edge of the linea alba provides the most strength.[1,2] Likewise, various suture materials can be used for incisional closure, but in adult horses I prefer polydioxanone (USP size No. 7, metric size No. 9) or polyglactin 910 (USP size No. 6, metric size No. 8).[3] To increase the bursting strength in heavy horses or pregnant mares, two to four single cruciate sutures can be placed 2 to 3 cm from the incisional edge after the continuous suture has been placed. In my experience a full abdominal bandage with an adhesive bandage applied before recovery decreases the strain on the incisional closure and covers the sutures during recovery phase. This reduces the risk of postoperative infections and incisional hernias (personal experience).

VENTRAL PARAMEDIAN APPROACH

The ventral paramedian incision, the second most common approach used in colic surgery, is performed 8 to 12 cm lateral to the midline (see Figure 34-1). Some surgeons use this approach for cystotomy, cesarean sections, ovariectomy, cryptorchidectomy, and repair of ruptured bladders in foals.[4,5] The incision may be performed on either side of the midline through the rectus abdominis muscle. Surgical exposure of the abdominal cavity is not significantly reduced, but the border of the incision is thicker than when it is made in the linea alba. Care must be taken not to injure the superficial and deep epigastric vessels, when encountered. With this approach, hemorrhage is more extensive than with the linea alba incision, but that does not compromise wound healing. The main indication for a ventral paramedian incision is to avoid a previous linea alba incision if there are signs of infection, excessive inflammation, or adhesions.

Closure of the paramedian incision involves suturing the facia of the rectus abdominis sheath. Suturing the muscle does not appear to contribute to the strength of the closure. For bladder surgeries in adult male horses I prefer a combination of a ventral midline and ventral paramedian approach (see Figure 34-1). The skin incision starts caudad just lateral to the prepuce and continues in a slightly curved line around the prepuce to join the midline and continues along that plane craniad. The prepuce is undermined along the fascial plane and reflected to extend the ventral midline incision through the linea alba caudad as needed.

INGUINAL APPROACH

The inguinal approach (see Figure 34-1) is used in conjunction with a ventral midline incision when performing surgeries on stallions with inguinal or scrotal hernias. The inguinal approach usually does not allow a thorough exploration and decompression of the prestenotic and poststenotic bowel. The inguinal herniorrhaphy is often combined with unilateral castration and closure of the external inguinal ring with USB 2 or 3 (Metric 5 or 6) absorbable suture material in a simple-continuous or simple-interrupted pattern with sutures placed 1.5 cm apart. An

abdominal testis can also be removed by a lengthened inguinal incision. Generally, after skin incision over the superficial inguinal ring, blunt dissection through the inguinal soft tissue is performed to prevent damage to the large veins around the inguinal ring. At this point, the gubernaculum can be used to retrieve the testis from the abdomen. If this is not successful, the dissection is carried down to the annulus vaginalis, which is perforated with a finger to enter the abdominal cavity. After bluntly dilating the peritoneal opening, the whole hand can be inserted into the abdomen. Closure of this approach is completed by suturing the superficial inguinal ring described in Chapter 59, followed by suturing two to three inguinal fascia layers and an intradermal skin suture pattern.

FLANK APPROACH

Nowadays, the indications for a flank approach are rare. A longer incision in the flank may be necessary to remove normal or neoplastic ovaries, with or without combined laparoscopy. A standing flank approach can also be used for surgical correction of uterine torsions.[6] With the exception of surgeries of the small colon, intestinal problems cannot be solved through a flank approach.

The grid technique is most commonly used. After aseptic preparation and local infiltration of the skin and muscle layers of the flank region the skin incision is centered between the tuber coxae and last rib, just proximal to the palpable dorsal edge of the internal abdominal oblique muscle. The external abdominal oblique muscle is subsequently sharply divided vertically, whereas the internal abdominal oblique and transverse abdominal muscles are bluntly divided parallel to their fiber directions, usually with just the surgeon's hand. The peritoneum is perforated by a short thrust with the fingers. Closure of the incision is performed by apposition of the different muscle layers with absorbable sutures and stapling or suturing the skin.

OTHER OPEN APPROACHES TO THE ABDOMEN

The parainguinal or suprapubic paramedian approach (see Figure 34-1) can be used for cryptorchidectomy (for more details see Chapter 59). A caudal ventral midline approach, performed in the same plane as the ventral midline incision but beginning 10 cm caudal to the umbilicus is the most commonly used approach for cesarean section (see more details in Chapter 62).[7] The modified low flank approach (Marcenac) (Figure 34-3) is performed under general anesthesia with the horse positioned in lateral recumbency. The incision is carried out in the ventral flank region, preferably in an oblique craniodorsal to caudoventral direction. The muscle layers are separated bluntly to reduce hemorrhage.[8] For nephrectomy or surgeries at the base of the cecum, a transcostal approach with removal of the 16th or the 17th rib or an intercostal approach at the 15th or 16th intercostal space (see Figure 34-3) is necessary (for more details see Chapter 64).

LAPAROSCOPIC APPROACHES TO THE ABDOMEN

Laparoscopic surgical procedures are distinguished between those performed in dorsal recumbency under general anesthesia and those conducted on standing sedated horses.

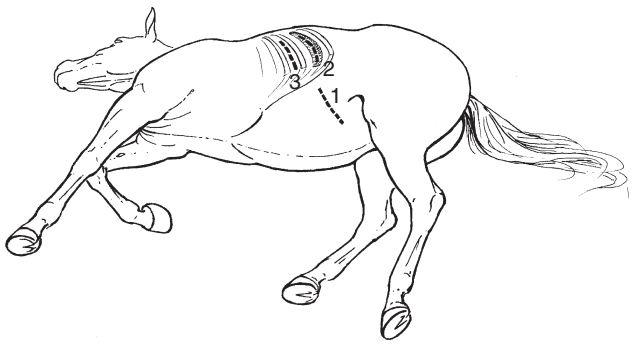

Figure 34-3. Abdominal approaches in lateral recumbency: modified low flank (Marcenac) *(1)*, transcostal *(2)*, intercostal *(3)*.

Laparoscopic Approaches to the Abdomen in Standing Horses

To safely perform a standing laparoscopic surgery in a horse, an optimal protocol for sedation is needed. My preference is to sedate the patient with a bolus of 0.005 mg/kg (0.002 to 0.01 mg/kg)[9] IV detomidine hydrocloride (Dormosedan) and 0.1 mg/kg (0.02 mg/kg) IV butorphanol tartrate (Torbugesic).[9] This is followed by a continuous infusion of 12 mg detomidine in 250 mL 0.9% saline administered at a rate of 2 drops per second. The infusion rate is adapted to the depth of sedation. The horse is placed in stocks with its head supported either with a padded stand or by a well-padded special halter that is tied to a solid contraption above its head (see Figure 30-2). Also, it is prudent to tie the tail to a crossbar of the stocks. Before starting surgery, all the feces accumulated in the rectum are manually removed and the positions of abdominal organs are checked to ensure that none are in direct contact with the abdominal wall of the flank region. After aseptic preparation of the whole flank region, each of the planed insertion sites for the trocars is locally desensitized with 10 to 15 mL of 2% mepivacaine, 2% lidocaine, or carbocaine. Linear cutaneous infiltration (line blocks) or local anesthesia also can be used for standing laparoscopic procedures in the paralumbar fossa. However, an epidural analgesia technique (combination of xylazine at 0.17 mg/kg and lidocaine at 0.2 mg/kg)[10] only partially anesthetizes the paralumbar fossa and has the potential risk of inducing ataxia and falls.

It is beneficial to place the initial laparoscopic portal in the left flank without prior insufflation, because presence of the base of the cecum on the right side presents an increased risk for injury to the viscera. A 1.5-cm incision is made through the skin and the superficial fascia at the level of the proximal border of the internal abdominal oblique muscle, equidistant between the last rib and the tuber coxae (Figure 34-4).[9,11,12] The laparoscopic cannula with a blunt obturator is carefully inserted horizontally and in a slightly caudad to distad direction through the skin and muscle layers. A mild resistance is felt when reaching the peritoneum, which is perforated with a quick, short thrust. After entering the abdominal cavity, a rush of room air will enter the trocar because of the negative pressure normally found within the abdominal cavity. To reduce the risk of inadvertent traumatization of intra-abdominal organs during insertion of the first cannula, an initial pneumoperitoneum can be induced by insufflation via a Veress cannula. An open approach or the use of an Endopath Optiview surgical trocar are other

options. For additional information on this subject (please review Chapter 13).

Secondary portals are always established under direct visualization. The vessels of the abdominal wall are protected by fat and can usually be avoided when inserting the trochar for the instrument portal. Standard instrument portals are created 3 to 10 cm dorsal and ventral to the initial portal containing the laparoscope to provide a triangulation approach.[9] Modifications of the instrumental portals are described for laparoscopic ovariectomy.[11,12] For closure of the nephrosplenic space, the portal for the laparoscope is selected between the 17th and 18th ribs. The two instrument portals are located caudal to the 18th rib.[13]

Laparoscopic Approaches to the Abdomen in Recumbent Horses

Under general anesthesia, the horse should be securely supported on the table in the Trendelenburg position (see Figure 13-16). Mechanical ventilation is mandatory in horses anesthetized for laparoscopy. Positive inspiratory pressure ventilation is used to assure adequate ventilation despite the increased pressure exerted upon the diaphragm by the cranially shifted intestines. Also, higher peak inspiratory pressures (25 to 35 cm H_2O) are often necessary to maintain appropriate ventilation and oxygenation.[9] Placement of a urinary catheter facilitates decompression of the bladder.

Generally, a 1.5-cm incision is created in the midline at the level of the umbilicus. The abdomen is insufflated with a teat cannula to a pressure of 15 to 20 mm Hg. The abdomen should be well insufflated before inserting the sharp trocar in the umbilical region. In foals, the teat cannula and the portal for the endoscope is placed about 2 cm lateral of the umbilicus to avoid penetration of umbilical structures. For surgeries in the region of the testis (cryptorchidectomy) and the inguinal region (herniorrhaphy) two instrument portals are created 10 cm lateral to the midline and 10 to 15 cm cranial to the external inguinal ring. For ovariectomy and removal of granulosa cell tumors, working with four instrument portals is beneficial. The first instrument portal is created midway between the umbilicus and the mammary gland, about 10 cm lateral to the midline. A second portal is established between the first instrument portal and the mammary gland. If the instrument portals are positioned at the right locations, identical portals are created on the opposite side of the midline. A very useful technique for removing uroliths is a laparoscopic-assisted cystotomy with the scope at the umbilicus and the instrument portal 2 to 3 cm medial to the left external inguinal ring, followed by enlarging the instrument portal to exteriorize the apex of the bladder.[14] Instrument portals cranial to the umbilicus are described for a laparoscopic colopexy.[15]

CHAPTER 35

Principles of Intestinal Injury and Determination of Intestinal Viability

Anthony T. Blikslager and John F. Marshall

Intestinal injury, although typically associated with ischemic lesions, occurs during any obstructive intestinal disease to varying degrees depending on the type of obstruction and the extent of vascular compromise. In addition, in some instances the intestinal lumen is patent, but there is vascular compromise—for example, in nonstrangulating infarctions. Intestinal obstructive lesions are classified as either simple or strangulating obstructions. A great deal of work has been done to assess the level of injury encountered with these lesions at surgery and during the postsurgical phase following correction and reperfusion of these lesions. Although more is known about mucosal injury than about injury encountered in other intestinal layers, it is clear that substantial injury also occurs at the levels of the serosa and the muscularis, which very likely contributes to postoperative complications such as adhesion formation and ileus. Understanding the pathophysiology of these lesions allows the surgeon to more adequately perform surgical and postoperative procedures to optimize patient survival. For example, attention has been focused on the development of intestinal injury during reperfusion and the possibility of inhibiting these lesions with various treatments. Furthermore, to combat the postoperative complication of serosal inflammation and secondary adhesion formation, surgeons have adopted a number of new treatments.

TYPES OF OBSTRUCTION

Simple Obstruction

Although simple obstruction, most commonly caused by an intraluminal impaction, does not initially result in intestinal injury, studies show that as distention progresses, mucosal lesions similar to those encountered during ischemic injury occur.[1,2] More specifically, there are critical intraluminal pressure levels beyond which intramural vascular compression takes place, reducing tissue perfusion.[3,4] Furthermore, direct compression of the intestinal wall by obstructive masses may lead to a lesion that has the appearance of an infarction as a result of occlusion of the local arterial supply. Causes of these compressive lesions tend to be hard masses such as enteroliths or fecaliths, which, if not recognized during early lesion formation, may result in intestinal rupture.[5] Injury caused by progressive intestinal distention, particularly in the case of fluid accumulation proximal to a small intestinal obstruction, is more difficult to recognize clinically than compressive infarctions, but nonetheless it is important to be aware of it to minimize postsurgical morbidity.

Strangulating Obstruction

Strangulating obstruction results from simultaneous occlusion of the intestinal lumen and its blood supply. The clearest examples of such lesions include large colon volvulus, and strangulation of the small intestine within an internal hernia or via an abnormal band of tissue such as the stalk of a pedunculated lipoma. The degree of injury attributable to occlusion of the blood supply depends on the nature of vascular occlusion. In most instances, the veins are occluded earlier in the course of strangulating obstruction than the arteries because of their thinner and more compliant walls. This results in a disparity in blood flow during the early phases of strangulating obstruction, with continued pumping of arterial blood into the intestinal wall, which, in the absence of patent outflow, causes a hemorrhagic lesion termed *hemorrhagic strangulating obstruction*. This results in not only ischemic injury but also tremendous congestion of the tissues. Alternatively, the strangulation may exert sufficient pressure on the veins and arterial supply that both are occluded simultaneously, resulting in so-called ischemic strangulating obstruction. This results in rapid degeneration of the mucosa.[6]

Clinically, hemorrhagic or ischemic strangulating obstruction may be noted in horses with large colon volvulus. In horses with a 360-degree large colon volvulus, hemorrhagic strangulating obstruction is most frequently noted, particularly if there is ample ingesta within the lumen to reduce how tightly the intestine twists around its mesenteric axis. However, there are also cases of ischemic strangulating obstruction, particularly in horses with a volvulus that exceeds 360 degrees or in horses with little ingesta in the lumen.[7]

Nonstrangulating Infarction

Nonstrangulating infarction most commonly occurs secondary to cranial mesenteric arteritis caused by migration of *Strongylus vulgaris*, which has become a relatively rare disorder since the advent of broad-spectrum anthelmintics.[8] Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases. These findings suggest that vasospasm plays an important role in this disease.[8] Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved.[8] These lesions have no obvious cause of obstruction, but they have clearly demarcated regions of degeneration or necrosis, depending on the extent of vascular occlusion.

MECHANISMS OF INJURY

Luminal Distention

Investigators have examined the role of small intestinal intraluminal distention and decompression on the microvasculature. In one study, distention of the jejunum to an intraluminal hydrostatic pressure of 25 cm H_2O for 120 minutes resulted in a significant reduction in the number of perfused vessels in the seromuscular and mucosal layers, and vascular perfusion remained abnormal after decompression.[2] This in turn led to epithelial sloughing, similar to that noted in ischemic lesions.[9]

Earlier studies indicated that there was no histologic evidence of epithelial sloughing with pressures up to 18 cm H_2O for 4 hours, although the authors did note mucosal and submucosal edema.[3] Thus it is clear that the nature of mucosal lesions depends on the degree of intraluminal pressure. In experimental studies on the effects of distention, the seromuscular layer appeared to be more severely affected, and it had evidence of mesothelial cell loss, neutrophil infiltration, and edema that progressed after decompression, suggesting reperfusion injury in this tissue.[10]

This type of inflammatory seromuscular lesion has also been noted in studies of the proximal resection margins of naturally occurring small intestinal strangulating obstructions, indicating that distention leads to seromuscular injury proximal to obstructive lesions, despite the fact that this intestine may appear grossly normal.[11] Experimentally, this seromuscular injury and inflammation leads to adhesion formation. Thus foals subjected to intraluminal distention of a segment of jejunum to 25 cm H_2O for 2 hours in one study developed bowel-to-bowel and bowel-to-mesentery adhesions within 10 days of the surgical procedure.[12] Similar experiments in the large colon have revealed that the colon is far more resistant to seromuscular injury than the small intestine.[10]

Mucosal Ischemic Injury

To understand how the mucosa becomes injured during ischemia, critical anatomic features of the mucosa have to be considered. In the equine small intestine, the villus tip is the region most susceptible to ischemia, largely because of the countercurrent exchange mechanism of blood flow in the small intestinal villus.[13] This countercurrent exchange is attributable to the vascular architecture, which consists of a central arteriole that courses up the core of the villus, arborizes at the tip, and is drained by venules coursing down the periphery of the villus.[14] As oxygenated blood enters the central arteriole, oxygen diffuses across the wall of the arteriole, through the interstitial tissues, and into the peripheral venules, which are flowing in the opposite direction. Although this enhances intestinal absorption, it short-circuits the oxygen supply, resulting in a villus tip that is relatively hypoxic even under normal conditions. Countercurrent exchange is exacerbated when the rate of the arterial blood flow is reduced, essentially providing more time for the oxygen to diffuse out of the arteriole across to the venules. When the arterial flow is reduced to a critically low level, the tip of the villus becomes absolutely hypoxic, with attendant epithelial injury.[13,15] This mechanism may explain why the small intestinal mucosa is more susceptible to ischemic injury than the colon, which has no villi. For example, the time required to produce severe morphologic damage to the equine colon is approximately 25% longer than that for the small intestine.[16]

Mucosal epithelium is particularly susceptible to hypoxic injury because of the relatively high level of energy required to fuel the Na^+/K^+–ATPase mechanism that regulates epithelial ion and nutrient transport. The first biochemical event to occur during hypoxia is a loss of oxidative phosphorylation. The resulting diminished ATP concentration causes failure of the energy-dependent Na^+/K^+–ATPase mechanism, resulting in intracellular accumulation of sodium and water. The pH of the cytosol drops as lactic acid and inorganic phosphates accumulate from anaerobic glycolysis, which damages cell membranes and results in their detachment from the basement membrane.[17]

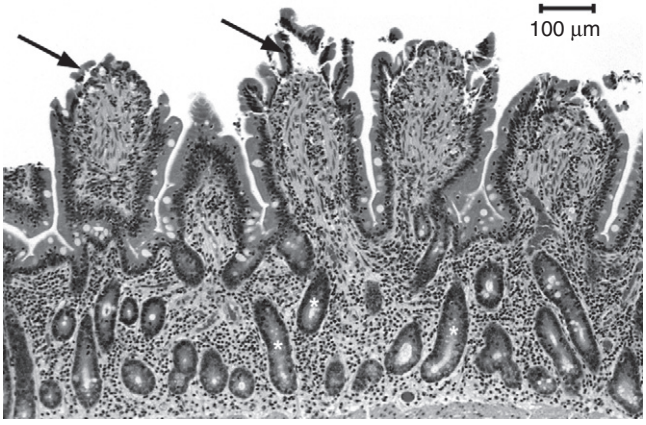

Figure 35-1. Photomicrograph of jejunal mucosa from a horse subjected to complete ischemia, similar to that seen in natural cases of ischemic strangulating obstruction. Note sloughing of epithelium into the lumen *(arrows)*. This sloughing progresses from the tips of the villi toward the crypts *(asterisks)* as the duration of ischemia progresses.

As epithelium separates from the underlying basement membrane in the small intestine, a fluid-filled space termed *Grüenhagen's space* forms at the tip of the villus.[15] The fluid accumulation exacerbates epithelial separation from the basement membrane. Subsequently, epithelium progressively sloughs from the tip of the villus (Figure 35-1) toward the crypts, which are the last component of the intestinal mucosa to become injured.[18-20] The relative resistance of the crypts to injury probably relates to their vascular architecture, since crypts receive a blood supply that is separate from the vasculature involved in the villus countercurrent exchange mechanism. The early morphologic changes observed in the equine large colon during ischemia are similar to those described in the equine small intestine, with initial loss of the more superficially located surface cells, followed by cellular injury and sloughing within the crypts.[16,21]

Reperfusion Injury

Events that culminate in reperfusion injury in the small intestine are initiated during ischemia when the enzyme xanthine dehydrogenase is converted to xanthine oxidase, and its substrate, hypoxanthine, accumulates as a result of ATP use.[22,23] However, there is little xanthine oxidase activity during ischemia, because oxygen is required as an electron acceptor. During reperfusion, xanthine oxidase rapidly degrades hypoxanthine in the presence of oxygen, which acquires a single additional electron, producing superoxide.[22] This reactive oxygen metabolite contributes to oxidative tissue damage, but it is relatively lipid insoluble, limiting the level of injury.

However, the more important role for superoxide is in the generation of neutrophil chemoattractants.[24,25] Superoxide interacts with lipid membranes, triggering arachidonic acid metabolism and generation of lipid neutrophilic chemoattractants such as leukotriene B_4. Because of the critical role of xanthine oxidase, inhibition of this enzyme in feline studies of intestinal ischemia and reperfusion injury prevented infiltration of neutrophils and subsequent mucosal injury.[25,26] Studies went on to show that reperfusion injury could be inhibited at several levels of the reperfusion cascade, including scavenging

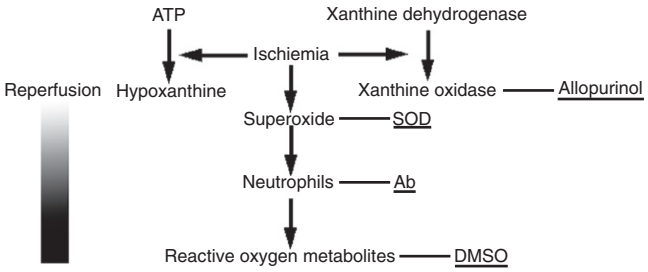

Figure 35-2. Diagram of the events that lead to reperfusion injury. Note that as reperfusion progresses *(shaded bar)*, the concentration of reactive oxygen metabolites amplifies as neutrophils are attracted to the site of injury. Points of experimental therapeutic intervention to block critical stages of reperfusion injury are *underlined*. *Ab,* Antibodies; *ATP,* adenosine triphosphate; *DMSO,* dimethyl sulfoxide; *SOD,* superoxide dismutase.

superoxide with superoxide dismutase, inhibiting neutrophil infiltration with monoclonal antibodies directed against neutrophil adhesion molecules, and scavenging neutrophil-released reactive oxygen metabolites.[22,25] Researchers were initially optimistic that this would provide practical therapeutic interventions, because many of the treatments tested, including the xanthine oxidase inhibitor allopurinol, could potentially be administered before reperfusing an ischemic lesion at surgery (Figure 35-2).

Unfortunately, treatment of mucosal reperfusion injury has not proved to be highly effective in most cases of strangulating obstruction. One important reason for this is that strangulating obstruction induces maximal mucosal injury during the ischemic phase, as compared with studies in laboratory animals in which "low-flow" ischemia was used.[27] The latter involves reduction but not cessation of arterial flow, which induces relatively minor levels of injury while priming tissues for injury during subsequent reperfusion.[28,29] Studies in horses using low-flow ischemia indicate that equine tissues are susceptible to reperfusion injury after this type of ischemia.[9,30-32] For example, studies of equine jejunum have shown that increased capillary permeability is associated with neutrophil infiltration during reperfusion.[30] Although a direct link to xanthine oxidase has not been shown, equine small intestine expresses substantial levels of xanthine dehydrogenase, which is converted to xanthine oxidase during ischemia.[33] Low-flow ischemia studies in equine colon have shown continued mucosal degeneration during reperfusion associated with marked neutrophil infiltration, despite the fact that equine colon does not express appreciable levels of xanthine oxidase. Alternative oxidant enzyme sources such as aldehyde oxidase have been offered as potential sources of reactive oxygen metabolites.[31]

Once the capacity of equine tissues to develop reperfusion injury was shown, additional studies were performed to determine whether reperfusion injury occurs after clinically applicable models of ischemia that simulate strangulating obstruction. For example, in one study assessing either arteriovenous or venous occlusion in equine jejunum, a small degree of reperfusion injury was documented after 3 hours of ischemia. However, the level of ischemic injury was nearly maximal after 3 hours, and the additional injury that developed during reperfusion was not sensitive to allopurinol, a xanthine oxidase inhibitor, or dimethyl sulfoxide, a reactive oxygen metabolite scavenger.[34] The likely cause of reperfusion injury in this instance was initiation of epithelial injury during ischemia that could not be reversed during reperfusion.[17] More recent studies in equine small intestine and studies in equine colon using ischemic models relevant to strangulating obstruction have failed to detect any level of reperfusion injury.[18,35] Studies in laboratory animals on strangulating obstruction have also shown that this type of ischemic insult is less likely to develop into reperfusion injury.[36,37]

In a veterinary review of the pathogenesis of intestinal reperfusion injury in the horse, the concept of a therapeutic window wherein treatment of reperfusion injury would be beneficial was suggested.[22] The basis of this concept is that there are certain conditions under which ischemic injury is minimal, and that tissues are severely damaged during reperfusion.[36] Thus, under conditions of low-flow ischemia, very little injury is demonstrated during 3 hours of ischemia, but remarkable injury occurs during 1 hour of reperfusion.[24-26] However, a very narrow therapeutic window may exist under conditions of strangulating obstruction, where severe injury occurs rapidly during ischemia, leaving relatively little potential for further injury that can be potentially offset with treatments such as antioxidants during reperfusion.

Nonetheless, this does not mean that treatments directed against reperfusion injury have no potential place for treatment of horses with strangulating obstruction, particularly as these treatments become more effective. For example, multimodal therapies involving intravascular or intraluminal infusion of solutions containing antioxidants, intestinal nutrients, and vasodilators have proven very effective *in vitro* and *in vivo*, although these treatment modalities have been used predominantly in low-flow ischemia models.[38-41] The recent study of lidocaine for the treatment of intestinal ischemic injury, rather than its more recognized use as a treatment for postoperative ileus, has has been of considerable interest based on its ability to improve the clinical outcome in colic patients.[42] Using a model of strangulating obstruction and recovery of the equine jejunum, the effect of a continuous rate infusion of lidocaine on the function of the mucosal barrier has been examined.[43] The administration of flunixin meglumine alone inhibits the recovery of the mucosal barrier following injury and increases permeability to lipopolysaccharide (LPS).[43] In contrast, when a continuous-rate infusion of lidocaine is combined with flunixin meglumine, this reduced barrier function and increased permeability to LPS is prevented. Furthermore, the combination of lidocaine with flunixin meglumine prevented the mucosal infiltration by neutrophils associated with flunixin meglumine treatment alone.[44] However, an *in vitro* study did not find an inhibitory effect of lidocaine on the migration or adhesion of equine neutrophils.[45] Therefore the anti-inflammatory mechanism of lidocaine in the horse is currently unclear.

It is also becoming apparent that the consequences of reperfusion injury are widespread and involve tissues other than the intestinal mucosa. For instance, low-flow ischemia models have demonstrated neutrophil infiltration into the seromuscular layers that very likely contributes to important complications such as adhesions and postoperative ileus.[12,46] This neutrophil infiltration appears to be relevant to strangulating obstruction, because similar neutrophil infiltrates were noted in the resection margins of resected strangulated small intestine.[11] Thus, although antioxidant-based therapies may be unable to reduce mucosal injury because of its rapid onset during ischemia, they may be able to reduce neutrophil infiltration in other layers of the intestine.

DETERMINATION OF INTESTINAL VIABILITY

Clinical Assessment of Bowel Viability

The viability of intestinal tissue is most commonly assessed by clinical observation—observing the color of the serosa and assessing the color of the mucosa, which may in some instances be observed before resection. For example, when a pelvic flexure enterotomy is performed in horses with large colon volvulus, the mucosa can be directly observed before making any decisions on recovering the horse or performing a resection. Changes in coloration are not uniform between the mucosa and the serosa, suggesting that much information can be gained by observing both of these layers of the intestine. For example, in one study on naturally occurring cases of large colon volvulus, the serosa was noted to turn from various shades of purple to pink in some instances as the colon was reperfused, whereas the mucosa consistently remained black. This probably relates to the metabolic demand of mucosa, which requires tremendous energy reserves to fuel the Na^+/K^+–ATPase mechanism that is responsible for driving mucosal transport function. Although there has been some concern about the utility of assessing mucosal color at the pelvic flexure and about whether this accurately reflects the level of injury in the more proximal regions of the colon, studies suggest that injury is uniform throughout the strangulated portion of the large colon.[47]

Clinical determination of viability has the obvious advantage of being noninvasive and rapid to perform, but it has the disadvantage of being inaccurate for fully determining the level of injury. For example, in a study assessing the resection margins after small intestinal resection, it was noted that there was marked serosal inflammation at the proximal resection margin, a region where surgeons would have had the choice to resect additional intestine if needed.[11] In other instances, when the resection margins are forced by anatomic considerations, surgeons can often discern substantial intestinal injury, but they have to decide whether the horse can survive if injured intestine is left in place. This is a particular problem with ileal resection and with large colon resection. Generally, if the intestine appears completely nonviable (on the basis of dark coloration, a dull appearance to the serosa, and an inability of the surgeon to rehydrate the surface of the intestine with lavage solutions), owners are advised that euthanasia is the most reasonable option.[7]

However, bowel that appears nonviable sometimes does survive. For example, in a study of ponies subjected to small intestinal venous strangulation obstruction, in which assessment of viability was based on color, wall thickness, peristalsis, and palpable mesenteric arterial pulsation, clinical assessment was only 54% accurate in predicting viability. In particular, clinicians were misled by intramural hemorrhage and edema, which resulted in the faulty judgment of nonviable tissue in some instances.[48] Ultimately, histopathology is the gold standard for determining viability, but when this service is unavailable because the situation is an emergency, any change in coloration during reperfusion or evidence of bleeding from the vasculature during resection may be used as evidence that there is some likelihood of survival. On the other hand, hemorrhage and edema within the tissues must be interpreted with caution, because some apparently devitalized bowel may survive.

Ancillary Methods of Determining Intestinal Viability

Fluorescein Dye

Fluorescein dye may be administered intravenously (6.6 to 15 mg/kg), after which it is rapidly distributed throughout the body, including the intestinal tract. Perfusion can be detected by illumination of the bowel with an ultraviolet light within 60 seconds of administration. Although there are distinct patterns of fluorescence in different segments of the intestinal tract, this technique has not gained wide clinical use, most likely because of inconsistencies of the technique in enhancing accuracy of determining viability. In particular, a complete lack of fluorescence may be noted in clinical cases of ischemic small intestine that has subsequently been documented to survive.[49] This may be caused by the degree of intestinal distention or by the compromised systemic cardiovascular status, both of which are common problems in horses with colic. One way to overcome this problem is to carefully compare a segment of suspected ischemic intestine with adjacent normal-appearing intestine. A generalized lack of fluorescence over the entire region would indicate that the technique should not be used to make definitive decisions in that particular case, whereas fluorescence in adjacent normal intestine would at least suggest that fluorescein is adequately perfusing the intestinal segment of interest.

In a study comparing the accuracy of fluorescein administration with clinical judgment and Doppler ultrasound in determining viability in strangulated small intestine, fluorescein administration uniformly predicted viability correctly in cases of ischemic strangulating obstruction, but it was very poor in predicting viability in cases of hemorrhagic strangulating obstruction. The latter may result from reduction in fluorescence as a result of the presence of hemorrhage and edema, leading to an overly pessimistic interpretation of viability.[48] As opposed to viability of the small intestine, large intestinal viability may be more adequately assessed using the fluorescein technique. However, great caution has to be exercised when interpreting the results. For example, a patchy pattern of fluorescence is not necessarily an indication of nonviability, but if the fluorescent patches constitute a minor portion of the colonic surface, nonviability is likely. On the other hand, a diffuse granular pattern of fluorescence usually indicates that tissue is viable.[49]

Surface Oximetry

An alternative technique for assessing viability is the measurement of intestinal serosal surface oximetry, which is an indirect measure of tissue oxygenation. As with other techniques for assessing viability, other circulatory factors have to be considered, including the overall cardiovascular status of the patient. A contact probe may be placed on the intestinal serosal surface, which measures surface oxygen partial pressure (PSO_2). Normal PSO_2 values for the jejunum, ileum, and pelvic flexure of healthy anesthetized horses are 71 ± 20 mm Hg, 61 ± 8 mm Hg, and 55 ± 13 mm Hg, respectively.[50] This information has been used to assess the viability of the colon after correction of large colon volvulus. Overall, the accuracy of surface oximetry in predicting colonic viability was 88%, using a set point of 20 mm Hg surface oxygen tension.

Additional analyses revealed that a horse with a PSO_2 value of 20 mm Hg or less was 7.4 times more likely to die than a

horse with a higher PSO_2 value. However, PSO_2 values have to be interpreted cautiously. In particular, the sensitivity of the technique was only 53% (calculated as the number of horses with an oximetry value of 20 mm Hg or less divided by the total number of horses that died), whereas the specificity was 100% (calculated as the number of horses that survived with an oximetry value of greater than 20 mm Hg divided by the total number of horses that survived). Thus the technique is very useful for detecting horses that will survive, but predicting nonsurvival in horses with low PSO_2 values is very inaccurate.[51] The other major disadvantage of this technique is that it measures surface oxygen tension in focal areas of application and cannot be used to indicate the viability of an entire region of intestine.[48]

Doppler Ultrasonography

Doppler ultrasonography has been used to discern viability on the basis of detection of flow through the microvasculature. A study described earlier (see "Fluorescein Dye") compared Doppler ultrasonography to use of clinical judgment and intravenous fluorescein.[48] Doppler ultrasonography was shown to be the most accurate technique for detecting viability in poststrangulated small intestine (accuracy values of 88%, 53%, and 53% for Doppler, clinical judgment, and fluorescein, respectively). The increased accuracy for Doppler ultrasonography was particularly evident in horses with experimental small intestinal hemorrhagic strangulating obstruction, in which viability was far more accurately determined with Doppler than other techniques. However, clinical judgment and fluorescein were slightly more accurate than Doppler for determining viability in experimental small intestinal ischemic strangulating obstruction.[48] In general, this lesion-dependent variability in diagnostic accuracy has resulted in limited clinical application of Doppler ultrasound and fluorescein for determination of intestinal viability.

Luminal Pressure

Increased intraluminal pressure is correlated with nonsurvival in horses with small intestinal obstruction and is probably related to the degree of mucosal injury generated by compression of the intramural blood supply. For example, in one study, survivors and nonsurvivors with small intestinal lesions had mean pressures of 6 cm H_2O and 15 cm H_2O, respectively.[4] Although 15 cm H_2O is lower than the level that induced epithelial sloughing in experimental studies, the duration of the pressure changes may be far greater in horses with naturally occurring lesions.[3] Thus a single pressure measurement may not be predictive of the severity of mucosal lesions without factoring in the duration of the disease. In horses with large colon volvulus, an increasing pressure is also correlated with nonsurvival.[52] Using a set value of 38 cm H_2O, survivors were separated from nonsurvivors (with a sensitivity and specificity of 89% and 91%, respectively), indicating that this test is highly accurate for predicting survival of horses with large colon volvulus.

Histopathology

The gross and histopathologic appearances of tissues were carefully evaluated in horses with naturally occurring large colon volvulus,[16] and a number of parameters described in this study were subsequently used to predict survival in horses with large colon volvulus. Biopsies were taken from the pelvic flexure (previously shown to accurately reflect mucosal changes along the length of the colon) and histologically examined.[47,53] The study used biopsies fixed in 10% neutral buffered formalin or frozen in liquid nitrogen. Although the latter technique resulted in some loss of tissue detail, the authors did not feel that this impaired the use of these biopsies for determination of survival. Furthermore, frozen tissues would be required if this technique were to be used intraoperatively. However, postoperative evaluation of formalin-fixed specimens may provide useful information on horses that have survived surgery but that are experiencing major problems in the postoperative period. Owners may elect euthanasia in some cases, if the lack of postoperative progress is reinforced by histopathology that suggests nonviability of bowel remaining in the horse.

Specific parameters recorded on histologic evaluation in these studies included the percentage loss of surface epithelium, the percentage loss of glandular epithelium, and the widths of the crypts and of the interstitial space between the crypts. The latter measurements were expressed as an interstitium-to-crypt width (I:C) ratio. Normal values for this ratio are 1 or less. Additional scored parameters included the degree of hemorrhage and the degree of edema (0, no edema or hemorrhage; 4, marked edema or hemorrhage), but these scores were not used in overall survival analyses. Colonic tissue was considered to be nonviable when the I:C ratio was greater than 3 and the loss of glandular epithelium was greater than 50%. Using these parameters, survival was correctly predicted in 94% of horses.[53]

CHAPTER
36

Small Intestine

David E. Freeman

ANATOMY

The equine small intestine varies from 10 to 30 m in length, with an average length of approximately 25 m.[1] The duodenum, with an average length of 1 m, extends from the pylorus to the right of the midline, along the right dorsal abdomen, to a point caudal to the root of the mesentery. The duodenal ampulla and cranial flexure bend the first segment into the S-shaped sigmoid ansa. The major duodenal papilla (opening of the bile and pancreatic ducts) and the minor duodenal papilla (opening of the accessory pancreatic duct) are located in the cranial flexure. Caudal to the right kidney, the duodenum is attached to the

transverse colon by the duodenocolic fold. It forms the duodenojejunal flexure at its junction with the jejunum.

The jejunum measures 17 to 28 m in adult horses and is situated mainly in the left dorsal quadrant of the abdomen, between loops of small colon. The arterial supply from the cranial mesenteric artery is carried in arcades in the long mesojejunum, which allows the jejunum much mobility. Each vascular arcade is composed of a major jejunal vessel, an arcuate vessel that forms a loop with the next jejunal vessel, and several vasa recta that pass from the arcuate vessels to the intestinal wall. Veins run parallel to the arterial supply and enter the portal vein. The ileum is 0.7 m long, and its length is marked by the distinct ileocecal fold that attaches its antimesenteric side to the dorsal band of the cecum.[1] The arterial supply is provided by the ileocecal artery, a branch from the cranial mesenteric artery that travels along the ileum to anastomose with the jejunal arteries.[2]

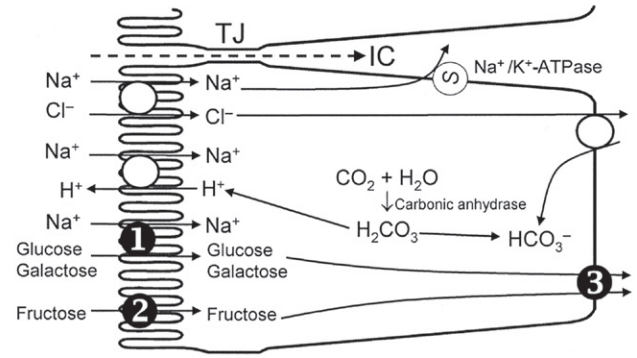
The terminal ileum forms a papilla that projects into the cecum. The ileal orifice is located in the center of the papilla, surrounded by the cecal musculature, an annular fold of mucous membrane, and a venous network.[2-4] The muscle of the ileocecal papilla is composed of three layers: an inner circular layer, a central longitudinal muscle layer from the ileum, and an outer layer formed from the circular muscle of the cecum and arranged into two semicircular lips.[3,4] The papilla lacks a true sphincter, although the lumen of the ileum appears reduced at the ileocecal junction.[5] The proposal that the venous network and annular fold contribute to the sphincter mechanism is rendered less tenable by the observation that the veins are most engorged when the ileum is discharging its contents into the cecum.[3,4] A functional sphincter does exist and appears to contract in synchrony with contractions of the cecal base.[5,6] Endoscopic studies of the cecal base of the horse have demonstrated that the ileal papilla is very prominent and that it becomes more prominent when the cecum is active.[4]

Digestive Anatomy

Digestion and absorption of nutrients take place predominantly in the upper half of the small intestine.[7] Unique to the small intestine in adults are fingerlike projections of the epithelial surface called villi, and each villus is surrounded by approximately six to nine crypts of Lieberkühn.[8] The equine small intestine lacks mucosal folds and/or plicae circulares.[9]

Columnar absorptive cells or enterocytes constitute about 90% of the small intestinal epithelial cells, and the remainder are mucous (goblet) cells, enteroendocrine cells, Paneth cells, and undifferentiated columnar cells.[10] After at least two divisions within the crypt, the columnar cells migrate onto the villus as mature absorptive cells, and they are finally extruded at the villous tip, usually with a turnover time of 2 to 3 days.[8,11] Cells in the upper third of the villi are capable of surface digestion of nutrients and active transport of digestion products.

The apical surface of a mature enterocyte is arranged into microvilli that form a brush border membrane. Enterocytes are connected to each other by tight junctions that restrict the transmucosal flux of large molecules, although they are permeable to water and many low-molecular-weight substances (Figure 36-1).[12,13] The intercellular space and the tight junctional complexes form the paracellular channel, and the intercellular space expands during water absorption.[13,14] Enzymes that complete digestion of carbohydrates (disaccharidases) and proteins (peptidases) as well as various specific transport systems for absorbing digestive end products are located within the microvilli (Figure 36-2).



Lumen	Cell interior	Blood
[Na+] = 150 mM	[Na+] = 15 mM	[Na+] = 150 mM
[Cl−] = 150 mM	[Cl−] = 50 mM	[Cl−] = 150 mM
0 mV	− 40 mV	+ 5 mV

Figure 36-1. Role of sodium in providing energy for different transport systems in a surface epithelial cell of the small intestine. Examples are cotransport with chloride and exchange with hydrogen generated within the cell, as well as cotransport with glucose by the SGLT1 transporter *(1)*. Fructose movement from the lumen into the cell by facilitated diffusion through the GLUT5 transport system *(2)* does not require sodium. All absorbed monosaccharides diffuse down their concentration gradient into plasma through a GLUT2 passive transport mechanism *(3)*. The *bottom panel* gives approximate concentrations of sodium and chloride and potential differences across cell membranes. This illustrates that sodium enters the cell down its electrical gradient (–40 mV) and chemical gradient (15 mM, interior concentration) but exits against its electrochemical gradient, hence the need for the sodium pump, or Na^+/K^+–ATPase. *Arrow with a broken line* designates diffusion through the paracellular route, composed of the tight junction *(TJ)* and intercellular space *(IC)*.

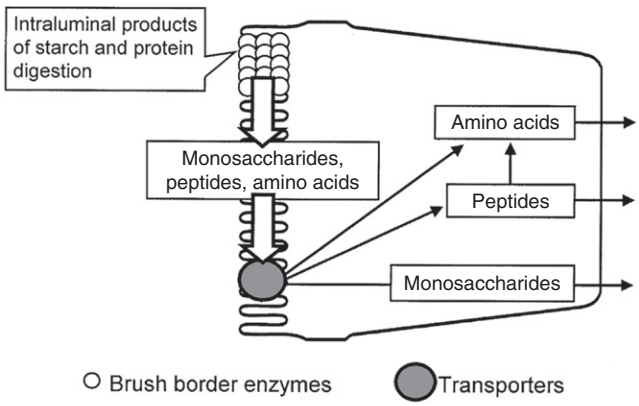


Figure 36-2. Role of brush border membrane in both digestion and absorption of products of intraluminal digestion of carbohydrates and proteins. Enzymes and transporters are simplified, but several oligosaccharidases, disaccharidases, and peptidases exist in the membrane, as well as highly selective carriers for their breakdown products. The largest peptides that can be transported into the cell are tripeptides.

PHYSIOLOGY

Intraluminal Digestion

Dietary carbohydrates, fats, and proteins are broken down by pancreatic enzymes in the small intestine, and their breakdown

products are hydrolyzed further by brush border enzymes.[8,15] Hydrogen ions in the duodenum cause the release of secretin from S-cells, which stimulates the pancreas and liver to secrete HCO_3^- and water.[11,16] Bicarbonate neutralizes H^+ ions in the proximal small intestine and thereby prevents acid-pepsin damage to duodenal mucosa, provides a functional pH for pancreatic and brush border enzymes, and increases solubility of bile acids and fatty acids.[7] Protein and fat in the duodenum stimulate the release of cholecystokinin (CCK) from I-cells, and CCK causes the pancreas to secrete enzymes for the digestion of carbohydrates (amylase), fat (lipase), and protein (trypsin, chymotrypsin, carboxypeptidase, and elastase), as well as cofactors (colipase) that aid in enzymatic digestion.[7,16] Trypsinogen, the precursor form (or zymogen) of trypsin, must reach the small intestine to be activated by the brush border enzyme enterokinase.[7] Other enzymes that are secreted as zymogens can be activated only by trypsin.

Resting pancreatic secretions in the horse are profuse, apparently continuous (10 to 12 L/100 kg body weight per day), and increase to very high rates by eating and by neural or hormonal stimulation.[17] Hormonal stimulation can be mediated through CCK and secretin, as in other animals, but the horse is unique in the marked secretory response elicited from the pancreas by gastrin.[17] The concentration of HCO_3^- is low, so that Cl^- remains the predominant inorganic anion in the horse's pancreatic secretion at all rates of flow.[17,18] Therefore the pancreatic secretion may provide a source of anions (Cl^-) for exchange with HCO_3^- in the terminal ileum to buffer products of fermentation in the cecum and colon.[17,18]

Compared with other animals, content and output of enzymes in pancreatic secretion is small in the horse,[17] and cellular concentration and specific activities of pancreatic enzymes are low, with the exception of lipase.[19] Nonetheless, nutrient digestion and absorption appear to be as efficient as in other species,[17,20] although horses are unique because they also ferment starches in the stomach and small intestine.[21] Also, starch digestibility in horses is largely related to its botanical origin, with almost complete digestion of starch from oats and wheat in the small intestine.[22]

In the liver, cholic acid and chenodeoxycholic acid combine with glycine and taurine to form conjugated bile salts.[23] Lipolysis in the small intestine requires emulsification of fat by bile salts.[7] Micelles form when the bile salts reach the critical micellar concentration (CMC) in the small intestine to aid in fat absorption (see "Fat Absorption," later). Approximately 94% of bile salts are reabsorbed by the small intestinal mucosa, pass to the liver, and are then resecreted, a process called *enterohepatic circulation of bile*.[7,23] Active transport by a Na^+-dependent process in the ileum and by passive absorption in the jejunum combine to reclaim intraluminal bile. Secondary bile salts are produced from bacterial deconjugation and dehydroxylation of bile salts that are not absorbed in the small intestine and enter the colon. These secondary bile salts are lost in feces and are replaced continually by liver cells.[7,23]

Absorption of Ions and Water

Most water absorption takes place in the distal third of the small intestine, but the bulk of intestinal water is absorbed by the large intestine.[18] However, Na^+ and water absorption in the small intestine is important in absorption of nutrients and other ions.

The routes for transepithelial movement of ions and water (see Figure 36-1) are through the cells (transcellular) and through the paracellular space (extracellular).[13,14] Transcellular movement of Na^+ involves entry from the lumen into the cell, down an electrochemical gradient. However, exit of Na^+ from the cell is against an electrochemical gradient and is therefore an active process that requires energy from the Na^+ pump (Na^+/K^+–ATPase), located along the basal and lateral membranes.[14,18] The active transport of Na^+ across the cell creates a transmucosal electrical potential difference.

The electrochemical gradient for Na^+ across the apical membrane has sufficient potential energy to move Cl^- into the cell against its electrical gradient. The cotransport of both ions is brought about by a carrier mechanism on the luminal membrane that is specific for Na^+ and Cl^- (see Figure 36-1). The net movement of Cl^- by this mechanism is called *secondary active transport*.[24] The Na^+ gradient also energizes uptake of hexoses (glucose), amino acids, and most B vitamins against their chemical gradients into the cell.[24]

Water transport is passive, closely coupled to solute movement, and is primarily paracellular (see Figure 36-1).[14] As absorbed Na^+ is pumped across the basolateral membrane, it creates an osmotic gradient that draws water into the intercellular space.[14,24] Water accumulation in this space increases the hydrostatic pressure, and this pressure forces the water across the basolateral membrane toward the capillary bed. Although the tight junction restricts backflow of absorbed water and electrolytes into the lumen, paracellular permeability and back-leak through this route in the jejunum is high. Therefore Starling forces have a considerable influence on ion and fluid transport in the proximal bowel, just as in the proximal tubule of the kidney.[13,18]

Net water movement from lumen to plasma through the paracellular route will "drag" permeant ions and low-molecular-weight substances with it (sugars, amino acids, Ca^{2+}, and Mg^{2+}), and this mechanism is called solvent drag, or convection.[13,18] Fluid absorbed by the epithelium moves into the central lacteal of the villus, from which it moves into the deeper lymphatics.[14] There is little proof that the intestinal villus has a countercurrent multiplier that could enhance water and solute absorption, at least in the dog.[25]

Carbohydrate Absorption

Several brush border oligosaccharidases and disaccharidases hydrolyze initial products of starch digestion by amylase to produce monosaccharides, such as D-glucose, D-fructose, and D-galactose (see Figure 36-2).[8] In horses on a grass-based diet, sucrase activity in the proximal small intestine is comparable to that reported in other nonruminants.[26] Maltase distribution is constant along the equine small intestine, and its activity is higher than in other species.[26] Lactase activity is higher in equine jejunum than in other parts of the small intestine, and it does decrease with maturity.[26]

Transport of D-glucose and D-galactose across the enterocyte membrane is through a high-affinity, low-capacity, Na^+-dependent cotransporter type 1 isoform, SGLT1 (see Figure 36-1).[18,26,27] The major site of D-glucose uptake by the SGLT1 transporter in grass-fed horses is the duodenum, followed by the jejunum and then the ileum.[26] Fructose moves from the lumen into the cell by facilitated diffusion through the GLUT5 transport system, which is a high-capacity, low-affinity, Na^+-independent transporter with highest activity in the duodenum in horses.[8,28] The monosaccharides diffuse down their intracellular concentration gradient in the absorptive cell to leave

through the basolateral GLUT2 passive transport mechanism and enter the portal venous system.[7,8]

Compared with a pasture forage diet, a dietary increase in soluble carbohydrate in the form of oats, corn, or barley can change glucose transport along the equine small intestine without affecting disaccharidase activities.[29] The change induced by hydrolyzable carbohydrate compared with pasture forage diet is evident as increased glucose transport rates and SGLT1 expression from approximately two times higher in the jejunum to three to five times higher in the ileum, but with no change in the duodenum.[29] A gradual switch in hydrolyzable carbohydrate in the diet from low to high has a similar effect on SGLT1 expression.[29] In all, these findings indicate that horses can adapt during a change to a high-carbohydrate diet in a manner that could reduce their risk of diet-induced colic, provided the dietary transition is gradual.[29]

Protein Absorption

Small neutral peptides yielded by pancreatic peptidases are broken down by brush border oligopeptidases (see Figure 36-2) into dipeptides and tripeptides or amino acids.[7,15] In the enterocyte, the peptides are hydrolyzed by cytoplasmic oligopeptidases into their constituent amino acids, which move passively into portal blood down a concentration gradient. Consequently, many dipeptides and tripeptides are transported into the cell, but mostly free amino acids enter portal circulation.[15] The intestine has several distinct amino acid transport systems, with varying degrees of specificity for amino acids and differences in Na^+ dependence.[15] The transport systems for small peptides are H^+ dependent,[15] although additional work is needed to confirm this in equine jejunum.[27] Circulating and intraluminal amino acids can also be used by the intestinal epithelial cells as energy sources.[11]

Fat Absorption

Long- and medium-chain triglycerides are split into constituent fatty acids and monoglycerides by pancreatic lipase interacting with colipase.[7] The resulting long-chain fatty acids and 2-monoglycerides, as well as fat-soluble vitamins and cholesterol, must combine with bile acids to form a water-soluble mixed micelle.[30] This micellar solubilization facilitates movement of lipids through the unstirred water layer to the brush border, where the micelles release their components for absorption.[23] Because of their fat solubility, the released long-chain fatty acids and 2-monoglycerides can traverse the membrane down a concentration gradient. Fatty acids and 2-monoglycerides in the mucosal cell undergo reesterification and formation of chylomicrons, and chylomicrons are taken up by the lymphatics.[23]

Fat digestion in horses is affected by compostion of the diet and concentration of dietary fat. It is lowest for forages followed by grains, and with a true digestibility approaching 100% in diets with added triglycerides.[31] Digestibility is low when dietary fat is low, which could have a negative effect on vitamin A and E status.[31] Increasing dietary fat slowly through supplementation can increase lipolysis of fat in the equine small intestine after accomodation is complete, without any negative associative effects on fiber digestion in the large intestine.[31] Adding fat increases its digestibility through added substrate concentration and through delayed gastric emptying and increased residence time in the small intestine.[31] These observations indicate that lipolytic activity in horses is upregulated in response to increasing dietary fat and that horses might require greater supplementation with fat-soluble vitamins, especially during growth and pregnancy.[31]

Absorption of Iron, Calcium, and Magnesium

Iron transport is closely regulated to meet the body's needs. Some absorbed iron combines with an intracellular protein, called *apoferritin*, to form an iron complex called *ferritin*.[12,24] If no binding protein is available, absorbed ferrous iron is transported out of the cell through transferrin receptors and is released to the circulation.[24,32] If iron stores are low in the body, crypt cells migrating to the villus tip are low in apoferritin but high in basolateral transferrin receptor.[32] As ferrous iron enters the cell from the lumen, it is not bound and is therefore free to enter the circulation to replenish iron stores. On the other hand, with a large iron store in the body, the crypt cell reaches the villus tip as a mature cell high in apoferritin. As ferrous iron enters the cell from the lumen, it is therefore bound and stored, and this bound iron is lost as the cell exfoliates at the end of its life span.[12,32]

Lumen-to-plasma flux of calcium is highest in the duodenum.[12,20] A high concentration of dietary magnesium can decrease calcium absorption through competition for the calcium transport site.[12] Absorbed calcium enters the cell down an electrochemical gradient and is transported through the cytoplasm complexed with a specific calcium-binding protein.[12] This protein is regulated by the biologically active form of vitamin D, 1,25-dihydroxycholecalciferol. Extrusion from the cell is against an electrochemical gradient through the Ca^{2+}-ATPase.[12]

Magnesium absorption is of interest because magnesium sulfate is used as a laxative in horses, and the extent of absorption could alter its laxative effects and the risk for magnesium toxicity.[33] Mean magnesium absorption is approximately 40% to 70% in growing foals and mature ponies, and the absorption occurs primarily in the proximal small intestine.[34]

Intestinal Secretion

Crypts of Lieberkühn are located over the mucosal surface of the small intestine and they secrete an almost pure extracellular fluid that maintains chyme in a fluid state, delivers secretory IgAs, and flushes crypts of noxious and infectious agents.[14] Intestinal water and electrolyte secretion is determined primarily by Cl^- secretion by crypt cells, with movement of Na^+ and water following. In equine jejunum, as in other species, chloride secretion can be mediated through cyclic adenosine monophosphate (cAMP) and a calcium-activated pathway.[27] Intestinal secretion is under a degree of neural and eicosanoid tone.[35]

Protective mucus is secreted by mucous cells located extensively over the surface of the intestinal mucosa, and by Brunner glands, which are located in the first 9.6 m of the equine small intestine.[9] The function of mucus from Brunner glands is to protect the duodenal wall from digestion by gastric secretions.

Motility

Small intestine has an outer longitudinal smooth muscle and an inner circular muscle layer, and the latter is divided into a thick outer lamella and a thin inner lamella.[36] Rhythmic segmentation in circular smooth muscle and synchronous shortening of the longitudinal muscle causes aborad transit during

peristalsis.[37] The interstitial cells of Cajal (ICC) are thought to act as pacemakers for the generation of electrical slow waves that propagate into the longitudinal muscle layer.[36,38] The equine small intestine has two types of ICC, one associated with the muscle layers and one with the myenteric plexus,[39] and the latter is probably responsible for pacemaker activity.[40] The density of myenteric ICC was found to be higher throughout the equine small intestine than in other parts of the intestinal tract and the density of ICC in the muscle layers was highest in the ileocecal junction.[39] The ICC distribution and density in the small intestine seems to have reached full development in the neonatal foal, whereas ICC development in the distal parts of the large intestine continues after birth.[40]

Two basic components of myoelectrical activity of gastrointestinal smooth muscle are the slow wave (basic electrical rhythm, or electrical control activity) and the action potential ("spike potential"). Slow waves are phasic oscillations of the smooth muscle resting membrane potential that are considered responsible for the rhythmicity and polarity of intestinal contractions.[38,41] In the pony, as in other animals, slow-wave frequency is greater in the duodenum and decreases toward the ileum.[41] This determines the direction and propagation rates of associated motility.[42]

An action potential is generated if something lowers the threshold of the smooth muscle cells, allowing a slow-wave oscillation to reach a threshold and cause a rapid depolarization that triggers intestinal contractions.[42] Mechanical (stretch), neural, and hormonal stimuli determine if that threshold will be reached. Action potentials do not necessarily occur with every slow wave, but slow-wave frequency determines the maximal frequency of action potentials.[42]

These wave forms produce a distinct pattern of myoelectrical activity called the *migrating motor complex (MMC)*.[42] Three phases of activity are recognized. Phase I, or no spiking activity (NSA), has slow waves only and no action potentials (Figure 36-3). Phase II, or intermittent or irregular spiking activity (ISA), has intermittent action potentials on some slow waves. Phase III, or regular spiking activity (RSA), is evident as an action potential for every slow wave and thus is associated with intense, sustained contractions.[42-44] The MMC is always present during an interdigestive state (time between meals when stomach and small intestines are essentially empty) and plays an important role in reducing bacterial colonization in the small intestine.[42] Phases II and III are associated with intestinal contractions, and most of an ingested meal is moved through the small intestine by phase II activity.

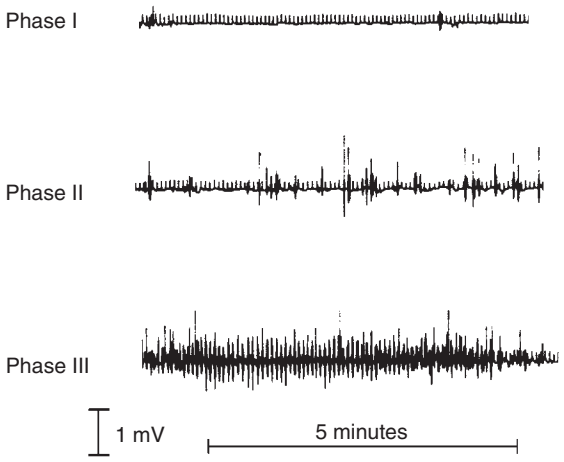

Figure 36-3. Myoelectrical activity of the duodenum of a clinically normal horse, demonstrating all components of the migrating motor complex (phases I through III). The slow wave frequency is about 14 per minute in all segments. (Modified from Merritt AM, Burrow JA, Hartless CS: Effect of xylazine, detomidine, and a combination of xylazine and butorphanol on equine duodenal motility. Am J Vet Res 59:619, 1998, with permission.)

Control of Motility

Control of motor events in the small intestine involves myogenic, neural, and hormonal mechanisms. Neural control involves the vagus nerve and components of the sympathetic nervous system, as well as an intrinsic system called the *enteric nervous system*.[38] The enteric nervous system consists of ganglia in the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus, and it mediates reflex behavior independent of input from the brain or spinal cord.[38] Myenteric neurons are the main source of innervation of longitudinal muscle and the outer lamella of circular muscle.[36] Submucosal neurons innervate the inner lamella of circular muscle.[36] Hormonal control of motility involves neurotransmitters and other neural agents that act on intestinal smooth muscle. Motilin, a peptide produced by endocrine cells in the mucosa of the proximal small intestine, is released during fasting, and it regulates the interdigestive migrating motor complex.[45] A coordinated release of excitatory and inhibitory transmitters coordinates the peristaltic reflex responsible for propulsive activity.[36] Histochemical and immunohistochemical studies have identified patterns of cholinergic, nitrergic, and peptidergic innervation of the horse small intestine that correlate with functional observations.[46] The cholinergic subpopulation is larger than the nitrergic in several locations of the small intestine, and ganglia are more numerous in the small intestine than in the large.[47]

Motility of the Ileum

The migrating action potential complex (MAPC) can be recorded in the pony ileum as intense spike bursts of short duration that propagate rapidly in aboral direction, but they are absent in the pony jejunum.[43,48-51] In the ileum of mature ponies, all phases of the MMC can be recorded, but irregular spiking activity (phase II) predominates during the interdigestive period (the period between feeding).[48] Withholding food for 24 hours decreases the frequency of ileal MAPC, but it has no effect on mean slow-wave frequency, MMC phase distribution, MMC phase duration, MAPC conduction velocity, or conduction velocity of spike bursts in RSA.[48] Differences between the ileum and the jejunum in ponies might be related to the unique position of the ileum at the junction of the small and large intestines.

The MAPC is seen directly before retrograde cecal myoelectric activity 73% of the time, indicating a possible myoelectric coupling of the ileum and cecum, and it may be responsible for transit of digesta from the ileum to the cecum.[48] Also, ileal contents are discharged into the cecum at times when the cecum is inactive.[4] Ileal and cecal filling appear to be more important in regulating ileocecal motility events in ponies than stimuli associated with feeding.[48]

Local stimulation of chemoreceptors could be important in the regulation of ileal motility in the horse and humans.[5,6,52] Also, the human ileum, and possibly the equine ileum, act as reservoirs, discharging contents into the cecum in response to intraluminal stimuli.[6] At neutral pH, tonic activity of the human ileum, but not of the jejunum, is increased by intraluminal short-chain fatty acids, whereas bile acids and lipids can induce ileal relaxation.[6] In the pony, serotonin and luminal fatty acids increase ileal peristalsis.[5] The response to luminal acidification could stimulate ileal emptying of refluxed bacteria and cecal contents[6] and could thereby augment the sphincter function of the ileal papilla.[5,52] Although tone of the ileal papilla increases during contractions of the cecal base in horses, some cecal contents do reflux into the ileum.[5,52]

Sympathetic relaxation of ileal smooth muscle is mediated mainly by activation of atypical β-adrenergic receptor subtypes, and increased ileal sphincter tone is mediated through α_1-adrenergic receptors.[6,53] Whereas epinephrine decreases ileal and cecal activity, it increases ileal sphincter tone through α_1-adrenergic receptors.[5,52]

Altered Motility

Xylazine, atropine, meperidine, butorphanol, and pentazocine can increase the mean duration of the MMC in pony distal jejunum, whereas flunixin meglumine, dipyrone, metoclopramide, and panthenol have no effect.[43,51] Xylazine and butorphanol (as separate treatments) reset the duodenal MMC in the horse, but without serious disruption of proximal gastrointestinal tract motility.[54,55] However, routine doses of xylazine, detomidine, or a xylazine and butorphanol combination significantly reduce pressure peaks in the duodenum.[56] The marked, immediate decrease in amplitude of duodenal contractions following detomidine administration can last for 50 minutes.[57] In one study on conscious horses, acepromazine, butorphanol, or *N*-butylscopolammonium bromide did not affect duodenal motility.[58] Common anesthetic regimens decrease myoelectric activity in horse ileum for up to 150 minutes after induction.[44] Fasting decreases motility in the jejunum and large intestine, based on ultrasonographic examination, and renders the jejunum and cecum sensitive to the depressant effects of xylazine.[59] Drugs that can enhance small intestinal motility are discussed in Chapter 40.

After small intestinal resection and anastomosis in the dog, the aboral progression of the MMC stops at the anastomotic site, and alternate pacemakers initiate regular spiking activity distal to the anastomosis.[60] In the distal segment, the number of phases are reduced, disrupted, and delayed, and transit time is delayed also.[60,61] Therefore timing of the MMC appears to depend on bowel continuity and integrity of intrinsic innervation.[62]

Nonstrangulating obstruction of distal jejunum causes immediate continuous spiking activity proximal to the obstruction.[63] This response is not associated with fluid distention and does not cause signs of colic until accompanied by increased intraluminal pressures.[63] Occlusion of blood supply to the pony ileum decreases motility in the ischemic bowel, increases motility in the more proximal segment, and has no effect on the distal segment.[64] A low dose of endotoxin and intravenous infusion of prostaglandin E_2 alter regular spiking activity in pony jejunum, which suggests a role for endotoxin in postoperative ileus.[65,66] The effects of endotoxin can be partly blocked by pretreatment with phenylbutazone and flunixin meglumine. Increased sympathetic stimulation could decrease intestinal motility in horse jejunum and be relevant to development of ileus.[37] Nitric oxide also appears to act as an inhibitory neurotransmitter to circular smooth muscle of equine jejunum and could be released from invading macrophages in distended or inflamed small intestine.[67]

PATHOPHYSIOLOGY

Small Intestinal Distention

Intestinal obstruction causes prestenotic distention with gas, fluid, and ingesta that can compress intestinal veins.[68] Most of the resulting increase in venous pressure is transmitted to the capillary beds, and consequently capillary pressure increases.[69] The intestinal wall becomes thicker because of edema induced by increased capillary filtration.[69] The resulting filtration of fluid from capillaries into the interstitium is opposed by changes in Starling forces that attempt to maintain the tissues in a more dehydrated state.[69] As these compensatory mechanisms become overwhelmed, continued capillary filtration increases tissue edema and movement of fluid in large volumes into the intestinal lumen, producing a net secretion of fluid into the intestine.[70,71]

An experimentally induced intraluminal pressure of 25 cm H_2O (18.4 mm Hg) for 120 minutes in equine jejunum causes shortening of villi, loss of mesothelial cells, neutrophil infiltration, edema in the seromuscular layer, and a decreased number of perfused vessels in the seromuscular layer as well as in the mucosa.[72] Decompression of distended equine jejunum may not prevent progression of the morphologic lesions, but it permits partial recovery of vascular density.[72] Serosal edema and infiltration with erythrocytes and leukocytes increases significantly after distended equine jejunum is decompressed, and to a greater extent than in reperfused ischemic jejunum.[73] These serosal changes could contribute to complications in distended bowel proximal to an obstructive lesion, such as serosal adhesions.[72,73]

Small Intestinal Ischemia

Venous occlusion occurs rapidly when thin-walled veins are compressed by the edges of a hernial ring or by twisting of mesentery. The increased venous pressure causes edema and net secretion of fluid, as well as a myogenic response (the Bayliss effect) that protects the tissues from an increased vascular load.[69] This effect increases vascular resistance to arterial inflow, which combines with the decreased pressure gradient from artery to vein to reduce blood flow.[69] This response, coupled with arterial compression caused by displacement, eventually blocks arterial inflow and causes ischemia. Erythrocytes extravasate through altered capillaries and cause the characteristic intramural hemorrhage, which is known as hemorrhagic infarction.[74] Equine jejunum strangulated in a closed space develops tissue changes more slowly than in the open abdomen model and therefore might be more representative of a naturally acquired strangulation.[74-76]

Because ischemia reduces oxygen delivery to the metabolically active mucosa, morphologic changes develop that can be graded in severity from grade I (development of a subepithelial space, called Gruenhagen space, and slight epithelial lifting at the villus tip) to grade V (complete loss of the villus architecture, with severe mucosal hemorrhage and loss of the lamina propria).[77] The intermediate grades represent a progressive loss

of the epithelial layer, starting at the villus tip.[77] As a consequence of this mucosal damage, the important epithelial barrier is lost, and endotoxin can leak across to the peritoneum and be absorbed into the circulation, causing endotoxemia.[78]

In a pattern similar to that seen in other animals, the equine jejunal villus is supplied by an eccentrically placed arteriole that spirals to the villus tip and then "fountains" into a meshlike capillary network that descends along the periphery of the villus to drain into one to three venules.[79] This creates a countercurrent mechanism that allows capillaries near the villus base to shunt oxygen from the tip, rendering it more sensitive to hypoxia relative to the rest of the villus.[78] However, this does not appear to be the only or even the most important explanation for the sensitivity of villus cells to anoxia, because anoxic injury to equine jejunum *in vitro* causes the same progression of epithelial damage.[80] Most likely, cells on the villus tip are the first to succumb to anoxia because they are closer to the end of their life span.

Intestinal smooth muscle is more resistant to hypoxia than mucosa, and crypt cells are more resistant than villus cells—factors that can play a part in recovery from an ischemic insult.[76,77] In the early stages of mucosal repair, viable cells migrate from the crypts to cover the exposed villus stroma, whereas damaged cells are removed by detachment and phagocytosis.[81] This repair process is called *restitution*, and it explains how equine jejunum subjected to a grade IV injury becomes covered with stunted villi lined with cuboidal epithelium within 12 hours.[76,81] Normal architecture of the mucosal lining is restored rapidly from this point. Although the intestinal wall can recover from venous strangulating obstruction, mesentery subjected to hemorrhage and edema is prone to fibrosis, shortening, and adhesions.[74,76] Serosal edema and infiltration with erythrocytes and leukocytes increase significantly after ischemia and reperfusion in equine jejunum to an extent that could predispose to adhesions.[73]

Other factors that can contribute to the mucosal injury in ischemic intestine are those that alter capillary permeability, such as endotoxin, reactive oxygen metabolites, histamine, and activated neutrophils (for an in-depth discussion of intestinal injury, see Chapter 35).[78]

DIAGNOSIS OF SMALL INTESTINAL OBSTRUCTION

Preoperative prediction of a small intestinal versus large intestinal lesion is highly successful, but identification of the specific intestinal lesion is rarely possible, except for strangulation in an external hernia.[82] Clinical findings vary enormously, and small intestinal diseases that require surgery are difficult to distinguish from those that can zrespond to medical treatment, such as duodenitis–proximal jejunitis and ileal impaction. Although degree of pain, response to analgesic drugs, cardiovascular condition, abdominal ultrasonographic findings, and peritoneal fluid changes can be strongly predictive of the need for surgery, no single diagnostic test should be interpreted in isolation from others.

Horses with small intestinal strangulating obstruction usually exhibit signs of acute, severe abdominal pain and hypoperfusion, have an elevated heart rate and packed cell volume (PCV), and develop acidosis. The signs of distal obstructions develop more slowly, and the electrolyte imbalances and cardiovascular responses are less severe initially than with proximal lesions. Horses with proximal jejunitis may have severe abdominal pain initially; this progresses to depression and less pain than in horses with ileal impaction or strangulating obstruction.[83,84] After gastric decompression, horses with proximal enteritis usually improve in overall attitude and their heart rate decreases, whereas horses with mechanical obstructions do not improve.

The need for surgery should be considered more strongly in older horses with colic compared to younger mature horses.[85] Horses 16 years or older can have similar durations of colic and admitting heart rate, PCV, plasma creatinine, and blood lactate concentrations as younger mature horses.[86] However, they are more likely to demonstrate signs of moderate pain, are less likely to have normal borborygmi, and are less likely to be bright and alert compared with younger mature horses.[86] Also, peritoneal fluid total protein concentration can be higher in older horses.[86] Physical examination findings in geriatric horses are suggestive of a more serious disease compared with mature horses,[86] and this is consistent with the finding that they are 1.5 times more likely to need surgery and 3 times more likely to be euthanized if surgery is not an option.[85] On a percentage basis, horses at least 20 years old are 3 times more likely to have a primary small intestinal lesion compared with younger mature horses and a greater likelihood that the small intestinal lesion will be strangulating.[87] Strangulating lipomas are most likely responsible for these differences and should be high on the differential diagnosis list when examining an old horse with colic.[88]

Distended loops of small intestine on rectal palpation indicate small intestinal obstruction from any cause. In studies on horses with small intestinal strangulation, distended loops were palpated in 50% to 98% of horses on which a rectal examination was performed.[89-91] In some horses with small intestinal strangulation, a large colon abnormality can be found on palpation *per rectum* that may not be evident at surgery.[89,90] Many severely dehydrated horses with small intestinal diseases develop a "vacuum-packed" large colon, evident on rectal palpation as dehydrated colon contents contained within prominent colon haustra. These impactions should not be mistakenly interpreted as the primary cause of colic but might be considered as highly suggestive of small intestinal strangulation.[90] The degree of intestinal distention is very variable, with severe distention more likely to be associated with a strangulating lesion than with proximal enteritis. The amount of gastric reflux varies from none in the early stages of a lesion in the distal part of the small intestine, to several liters with a long-standing lesion or a lesion in the proximal part of the small intestine. Borborygmi are usually diminished or absent in all small intestinal diseases.

Abdominal distention is negligible to moderate in adult horses with small intestinal obstruction but can be pronounced in foals. Abdominal pain can be difficult to assess in foals with small intestinal strangulation because they can alternate between periods of violent colic and periods of depression. The latter can be interpreted erroneously as evidence of improvement. Inability to perform a rectal palpation in foals further complicates their examination, but ultrasonography is very informative in foals.

Peritoneal Fluid Analysis

Analysis of peritoneal fluid is important, but abdominocentesis is not necessary if other clinical findings indicate the need for surgery. Although the complications of enterocentesis are rare, peritonitis and abdominal wall cellulitis may develop after puncture of distended bowel.[92] The risk of enterocentesis is greater in foals than in adult horses, although ultrasonography

can identify fluid pockets to be sampled and also gives an impression of the volume and solid contents of the fluid.[93] Omentum can prolapse through the puncture site in a foal if a needle of 18 gauge or larger is used. For adults, an 18-gauge 3.75-cm (1½-inch) needle, a teat cannula (7.5 cm [3 inch]), or bitch catheter is inserted using aseptic technique on the midline in the most dependent part of the abdomen, behind the xiphoid cartilage.

The nucleated cell count in peritoneal fluid of normal adult horses ranges from 5000 to 10,000 cells/μL, but more than 1500 nucleated cells/μL should be considered elevated in foals.[93,94] Peritoneal fluid protein concentration is within the same range in foals as adults (0.3 to 1.8 g/dL).[93,94] Peritoneal fluid usually becomes serosanguineous with a strangulating lesion, but this is not a consistent finding, especially early in the disease. Accidental blood contamination does not appear to significantly affect nucleated cell count and total protein concentration in a peritoneal fluid sample.[95] Although strangulated bowel in an inguinal hernia or intussusception is less exposed to the peritoneal cavity than other intra-abdominal strangulating lesions, these diseases can produce serosanguineous fluid with elevated nucleated cell count and total protein.[96-99] Small intestinal rupture or perforation will produce changes in peritoneal fluid suggestive of digesta contamination, such as cloudy or green discoloration, increased protein and cell count, and intracellular bacteria; however, normal cell counts and protein can also be recorded and plant material may not be evident.[100]

Peritoneal fluid from horses with proximal enteritis is rarely serosanguineous, and nucleated cell count and total protein concentration increase to a lesser extent than with a strangulating obstruction.[84,101] Therefore peritoneal fluid is of some value in distinguishing between these diseases. Total protein can be elevated and eosinophils can be found in peritoneal fluid from horses with focal eosinophilic enteritis, a cause of small intestinal obstruction in horses.[102] Peritoneal and serum phosphate levels can be used to predict major intestinal injury, although the ranges in horses with surgical and nonsurgical colic can have considerable overlap.[103]

Factors that strongly correlate with the presence of a strangulating obstruction are changes in the gross appearance of the peritoneal fluid and values of peritoneal fluid chloride, pH, and $\log_{10}$ lactate.[104] Peritoneal fluid lactate is a better predictor of intestinal ischemia secondary to a strangulating obstruction than blood lactate and therefore could be used for early detection of small intestinal lesions.[104] Also, peritoneal fluid lactate is a more useful and sensitive prognostic indicator than plasma lactate in horses with colic.[105] A portable analyzer can be suitable for biochemical analysis of samples of blood and peritoneal fluid from horses with colic and provides lactate measurements comparable to an in-hospital analyzer.[106] Other potential peritoneal markers of severe intestinal damage are myeloperoxidase (MPO), which would be expected to indicate neutrophil activation,[107] and D-dimer concentration, a useful marker of the intense fibrinolytic activity that follows intestinal ischemia and peritonitis.[108] (For an in-depth discussion of diagnostic approaches to the horse with colic, see Chapter 33.)

Gastrointestinal Tract Imaging

Ultrasonography

Ultrasonography is invaluable for examining horses with small intestinal obstruction. Liberal application of gel or alcohol to the horse's hair coat are sufficient to improve acoustic coupling in most horses without clipping, but clipping of long hair coats can improve image quality.[109] Most abnormalities gravitate to the ventral abdomen, where they are accessible for ultrasonography.[109] A lower-frequency ultrasound transducer should be used (2 to 3.5 MHz) to penetrate deeper into the abdomen (approximately 24 cm or 9 inches), and higher-frequency transducers (5.0 or 7.5 MHz) can improve image detail in foals or superficial structures.[109]

The *jejunum* can be observed along the ventral and visceral surface of the spleen and dorsal to the left dorsal colon.[110] Time of feeding relative to the examination could explain inconsistencies in locating the jejunum, because it is seen more frequently in the ventral abdomen of fasted horses compared with fed horses.[59] Jejunal motility can be difficult to assess consistently because of depth and motion effects, but it can be decreased in the jejunum by fasting alone and combined with xylazine.[59] The jejunum should not be distended in a normal horse, although isolated hypomotile jejunal segments with hypoechoic contents can be found infrequently.[110] The clinical significance of static images of dilated loops of small intestine can be supported by an associated lack of motility.[111] An indwelling nasogastric tube causes minimal alterations in jejunal, cecal, or colonic visibility and activity.[59]

The *duodenum* can be found consistently in a relatively superficial location between the liver and the right dorsal colon, in the 14th to 15th intercostal space, on a line from the olecranon to the tuber coxae (dorsal part of middle third of the right side of the abdomen).[110-112] It can also be located ventral to the caudal pole of the right kidney at the 16th to 17th intercostal spaces.[112,113] Wall thickness in the duodenum, jejunum, cecum, and stomach is less in ponies than the published values for normal horses.[110] The mean duodenal wall thickness is greater in that segment deep to the liver than at the base of the cecum and the caudal pole of the kidney.[110] The mean duodenal contractility is greater for ponies than the published normal range for horses (0.5 to 2.8 contractions per minute).[110] Contractions and distentions of the duodenum are reduced by fasting.[113] Peritoneal fluid can be found ventrally and around the duodenum.[110] It should be anechoic and can be transient in location.[110]

The *stomach* can be found on the left side of the abdomen between the 11th and 13th intercostal spaces, at the level of the shoulder, dorsal to the splenic hilus and its large splenic vein.[109] It is normally gas-filled and amotile on ultrasound examination.[59] The greater curvature of the stomach is seen as a bright gas echo that curves toward the skin surface, deep to the spleen. When horses are fasted, the stomach can be found ventral to the costochondral junction, and placement of an indwelling nasogastric tube causes it to return to its normal location.[59] Xylazine does not alter the position or activity of the stomach in fed or fasted horses.[59] The stomach of normal ponies can be imaged further caudally and over a greater number of intercostal spaces than reported for normal horses, possibly because of a conformational difference.[110]

If ultrasonography is used after gastroscopy, the stomach wall becomes undulating and even folded on ultrasound examination as air leaves the stomach, and rugal folds may become evident.[112] Feeding increases stomach size compared with fasting and insufflation by gastroscopy, based on an increase in dorsoventral height and increased number of intercostal spaces that it spans.[112]

Small intestinal strangulating obstruction, small intestinal distention, intestinal wall thickening, peritonitis, peritoneal

effusion, gastrointestinal rupture, intussusception, inguinal hernia, diaphragmatic hernia, cholelithiasis, abdominal neoplasia, abdominal abscess, idiopathic muscular hypertrophy, intramural hematoma, intestinal lymphangiectasia with chylous peritoneal effusion, and ascarid impactions can be detected by ultrasonography.[93,96,114-119] An intramural hematoma can be recognized as a biconvex mass of anechoic loculated fluid in the intestinal wall with laminar flow in the center of the mass.[118] Transabdominal ultrasonographic findings of small intestine that is edematous (wall thickness greater than 3 mm), distended, and amotile strongly suggest strangulating obstruction (see Figures 33-1 and 33-2).[93,114] As obstructed small intestine fills with fluid, its contents become more hypoechoic. The five ultrasonographic layers of the intestinal wall are lost in strangulated segments.[120] Ultrasonography may be helpful in assessing gastric distention and in determining the efficacy of gastric decompression. Distention of the stomach can displace the spleen caudad or obscure it.[109]

Abdominal ultrasonography can provide a sensitivity of 98%, a specificity of 84%, a positive predictive value of 62%, and a negative predictive value of 99% for small intestinal strangulation obstruction from a variety of lesions.[114] Under the same conditions, palpation *per rectum* can provide a sensitivity of 50% for small intestinal strangulation obstruction, which means that it is considerably inferior to ultrasonography in finding a small intestinal abnormality when one does exist.[114] In horses with small intestine strangulated in the epiploic foramen, ultrasonography could accurately detect small intestinal distention in 94% to 100% of horses, compared with 74% to 78% for palpation *per rectum*.[90,121] With this lesion, distended or edematous small intestine is found more often in the ventral right paralumbar fossa, caudal ventral abdomen, and middle right paralumbar fossa.[114] For strangulating lipomas, similar intestinal changes are found more often in the caudal ventral abdomen, middle ventral abdomen, and ventral right paralumbar fossa than in other regions.[114] Ultrasonographic evidence of distended small intestine in the left cranial abdomen between the stomach and the spleen could be used to make a presumptive diagnosis of strangulation in the gastrosplenic ligament[122] (see Chapter 33).

Fast localized abdominal sonography of horses (FLASH) was developed to allow clinicians without extensive experience in ultrasonography to rapidly detect major intra-abdominal abnormalities that cause colic.[111] FLASH uses seven topographic locations that can be sufficient to determine the need for surgery and cover most of the windows where small intestine might be observed in colic patients.[111] These seven locations are the ventral abdomen, the gastric window, the splenorenal window, the left middle third of the abdomen, the duodenal window, the right middle third of the abdomen, and the cranial ventral thorax.[111] In agreement with previous studies,[114] the presence of dilated turgid small intestinal loops was highly sensitive and specific for small intestinal obstruction and had high positive and negative predictive values.[111] Ability to distinguish ileal impaction and proximal enteritis from surgical cases was difficult.[111]

Ultrasonographic examination of healthy ponies that had an exploratory celiotomy revealed hypocontractile segments of jejunum that had hypoechoic contents on postoperative day 1, consistent with mild functional ileus.[123] In general, there were minimal changes in bowel wall thickness, contractility, degree of distension, luminal contents, and peritoneal fluid in these ponies in the first few days after an exploratory celiotomy.[123]

Radiography

Abdominal radiography is useful in the foal with gastroduodenal obstruction, necrotizing enterocolitis, enteritis, impaction, displacement, intussusception, ruptured viscus, congenital anomalies, and inguinal hernia and in the adult horse and foal with diaphragmatic hernia.[93] In foals, radiographs can distinguish small intestinal distention from large intestinal distention with gas.[124] Contrast radiography has been used in foals to demonstrate abnormalities of gastrointestinal transit time and gastrointestinal obstruction (see Chapter 33).[125]

Laparoscopy

Although diagnostic laparoscopy has a sensitivity of 82% and a specificity of 66% for horses with acute abdominal pain, localized lesions or lesions inaccessible to the selected portals cannot be detected, and ileal lesions, such as ileocecal intussusception and ileal hypertrophy, can be missed.[126] Duodenal lesions can be seen in the standing horse.[126] Standing laparsocopic techniques have been used successfully for duodenal biopsies in horses and could be applied for evaluation of small intestinal diseases caused by inflammation, neoplasia, or grass sickness.[127,128] Care must be taken when inserting the trocar assembly into the abdomen in a horse with colic to avoid damage to distended viscera (for details on this technique, see Chapters 13 and 33).[93]

SURGICAL DISEASES OF THE SMALL INTESTINE

Small intestinal diseases can account for 25% to 64% of all colic cases treated at veterinary hospitals (Table 36-1), with a median of 34%.[90,129-136] The proportion was the same in foals as in adults.[135,137] The ileum was involved in 41% to 46% of all small intestinal obstructions.[134,136,138] The majority of small intestinal colics (58% to 85%) are caused by strangulating lesions and the remainder by nonstrangulating obstruction (simple and functional obstructions).[129,130,133,136,139] Rankings of disease prevalence can vary considerably among clinics (see Table 36-1).

Nonstrangulating Obstruction

Ileal Impaction

Impaction of the ileum is usually a primary condition in an apparently normal ileum, but it can occur secondary to other ileal diseases. The impaction forms a doughy to solid, tubular mass up to 90 cm long that extends proximally from the ileocecal junction.[83,140-143] The disease has a regional distribution in the United States, with most cases diagnosed in the Southeast, where the high prevalence may be related to feeding coastal Bermuda grass hay.[83] Ileal impaction also occurs in parts of the United States and in Europe where coastal Bermuda grass hay is not fed.[130,138] The disease appears to be more common in the United States from June through November, especially in the fall, although a seasonal effect is not consistent.[140,143,144] The risk for impaction is not consistently reduced by combining coastal Bermuda hay with other hay; it appears to be increased by recent introduction or feeding poor-quality hay,

TABLE 36-1. Prevalence of Small Intestinal Diseases that Cause Colic

Disease	% of Total Cases of Colic	% of All Cases of Small Intestinal Colic	Ileum Involved as % of All Ileal Obstructions	References
Volvulus	3.8-7.3	7-28	3	129, 130, 131, 133, 138, 178, 257, 392

Diseases are recorded for all ages combined, but prevalence among foal diseases is also given, where available. Not all diseases were listed in all reports.
*This is an unusually high prevalence for this lesion among all small intestinal lesions, but it was the most common small intestinal lesion in this study.[137]

and it appears to be lowered by feeding a pelleted-concentrate feed in addition to hay.[144] The disease has been reported in a wide age range, including newborn and older foals.[135,140,141,145] In a large series of cases, mares and Arabian horses were significantly overrepresented.[142]

In the United Kingdom, where coastal Bermuda grass hay is not fed, ileal impaction was strongly associated with both coprologic and serologic evidence of tapeworm infection in horses.[146] This was supported by a study of 78 horses in North Carolina, which showed that feeding coastal Bermuda hay and failure to administer an anthelmintic effective against tapeworms placed horses at risk for ileal impaction.[144] Mucosal ulceration and submucosal edema caused by tapeworms at the ileocecal valve is proportional to the number of parasites present and could predispose to obstruction at that site.[146] Orbatid mites are the intermediate hosts for *Anoplocephala perfoliata* and their preference for humid regions (southeast) could also contribute to the geographic predisposition to ileal impaction in the United States.[146]

Early pain from ileal impaction is attributed to spasmodic contraction of the bowel around the impaction, but pain becomes more severe and constant as small intestinal distention progresses.[83] Small intestinal distention is generally a consistent rectal examination finding, and the impacted ileum is more easily palpated early in the disease course before small intestinal distention becomes severe.[83,140,141] Gastric reflux can be obtained in most horses but not all, depending on the duration of obstruction.[140,142,143] Distinction between ileal impactions, strangulating obstructions, and proximal enteritis cases can be difficult (see preceding). Small intestinal distention can be palpated *per rectum* in 87% of cases and and can be located on ultrasound examination in 99% of cases.[147]

Medical treatment is a viable alternative if surgery is excluded by a lack of finances and can be successful early in the disease, when the impaction can be felt *per rectum*.[83,141,147] Medical treatment consists of a balanced electrolyte solution administered intravenously at 5 L every 2 hours and flunixin meglumine at a rate of 0.5 mg/kg three or four times daily.[83] Mineral oil should be administered when gastric reflux has ceased. If surgery is required, the impaction is broken down by manual massage, aided by mixing it with fluid from the proximal bowel or from saline infusion.[143] Although dioctyl sodium sulfosuccinate can be included in the infusion, this is very irritating to mucosal surfaces. Excessive manipulation can cause serosal damage and subsequent adhesion formation. Therefore the intestinal surfaces should be generously lubricated with sterile physiologic saline solution or sodium carboxymethylcellulose while manipulations are being conducted. Enterotomy is recommended for very stubborn impactions, but jejunocecostomy is not recommended in the absence of a predisposing lesion or severe changes in the muscle wall.[83,142-144]

If treated early, the prognosis is favorable, although ileus, gastric rupture, laminitis, mucosal necrosis, and perforation of the ileum are complications when the diagnosis is delayed.[140,141,143] Compared with surgery, aggressive and successful medical treatment reduces hospital stay, cost of treatment, and expense of lost time for recuperation and hastens return to athletic activity.[147] Reimpactions are rare.[148] Because tapeworms may play a role in this disease, anthelmintics are recommended, such as pyrantel pamoate at 6.6 mg/kg to 13.2 mg/kg and dewormer combinations approved by the U.S. Food and Drug Administration, with praziquantel as the active ingredient against tapeworms.[144]

Muscular Hypertrophy of the Ileum

Muscular hypertrophy of the ileum can cause ileal impaction, but it is more likely to cause recurrent colic. Unlike the muscular hypertrophy that develops proximal to a chronic

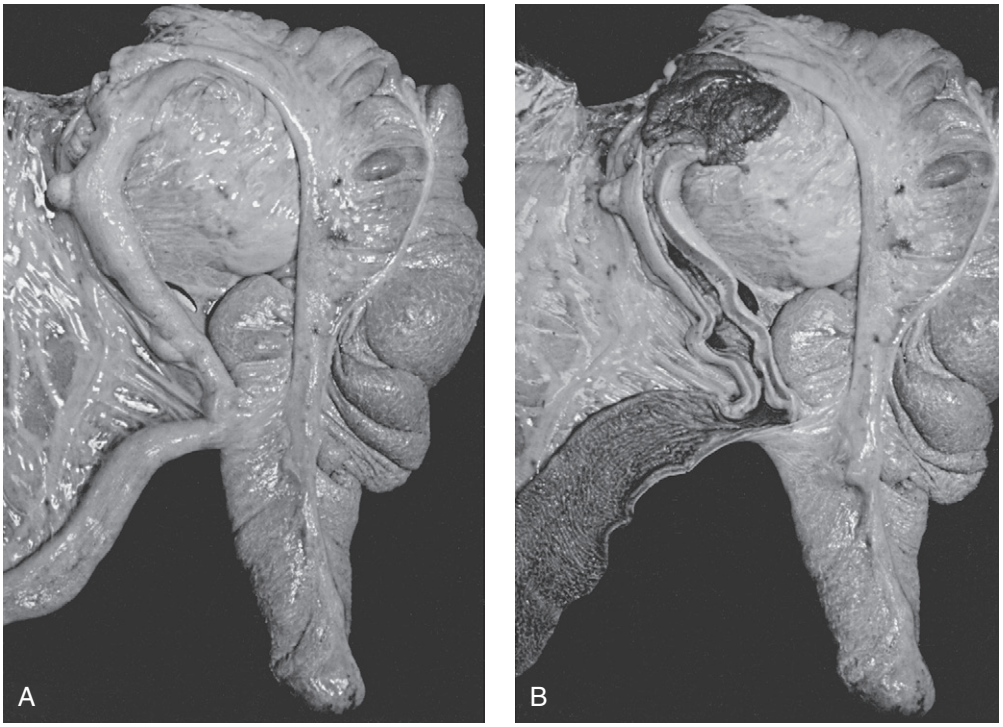

Figure 36-4. A, Ileal muscular hypertrophy treated 1 year previously by side-to-side incomplete bypass. Note the prominent diverticula and tubular appearance of the ileum. Death was from a nonrelated cause. **B,** The horse seen in **A,** with jejunum and ileum opened to demonstrate the thick wall of the ileum and the narrow lumen compared with normal bowel, as well as the diverticula.

obstruction, ileal hypertrophy causes marked luminal constriction (Figure 36-4). The condition is considered idiopathic.[149] Chronic mucosal inflammation can cause smooth muscle hypertrophy in rats, but mucosal inflammation may or may not be evident in ileal hypertrophy in horses.[150-152] Ileal hypertrophy and rupture were documented in a pony distal to an ileocecostomy that had been performed 3 years previously to bypass a short, reducible ileocecal intussusception.[153] At the time of the original surgery, that segment of ileum had been judged to be normal.

The affected segment is usually 1 m long, and both the circular and longitudinal layers are increased in thickness and diverticula are common (see Figure 35-4).[149,154] Full-thickness rupture can occur.[149,154,155] The terminal segment of the ileum and the ileocecal junction are spared in some cases.[117,134,149] The jejunum proximal to the obstruction can undergo compensatory hypertrophy in long-standing cases but with an increase in lumen diameter.[154] An unusual variant was reported in an American Miniature horse that involved multiple, separated segments of jejunum and proximal ileum, with the the ileal segment the least affected.[117]

The disease has been reported in horses over a wide age range, including foals, but it is most common in mature horses.[134,149,151,152,154,155] There does not appear to be a breed predilection.[154] Most horses are presented with a history of recurrent, low-grade colic of variable duration, up to 2.4 years in one case.[154] Partial anorexia and weight loss are common. The involved segment was palpated *per rectum* in 20% of horses in one study.[154] Abdominal ultrasonongraphy can also be helpful in diagnosing this disease based on finding severe annular thickening in the muscle wall and a collapse of the lumen in affected segments.[117] Clinical findings and history are similar to those of horses with chronic ileocecal intussusception, but most cases have been described in older horses (older than 5 years).[134,149,151,152,154]

Side-to-side ileocecostomy or jejunocecostomy with or without transection or removal of part of the ileum (incomplete bypass) is usually successful (see Figure 36-4).[134] The stoma is made proximal to the constricted segment, and if the space between the ileum and cecum is large, it is not closed.[134] *En bloc* resection of the affected bowel is required if there is extensive jejunal involvement.[117]

Ascarid Impactions

Intestinal stages of *Parascaris equorum* can cause small intestinal obstruction, intussusception, abscessation, and rupture in foals and weanlings (median age of 5 months, range of 4 to 24 months).[156] Because *P. equorum* induces absolute acquired immunity that eliminates patent infection by 1 year of age, ascarid impactions can be found in 2-year-olds.[157,158] Affected foals usually appear parasitized and unthrifty, and impaction usually (54% to 72%) follows shortly after anthelmintic treatment.[156,157] Ascarids in gastric reflux do not indicate ascarid impaction. Ultrasonographic examination can demonstrate ascarids in the small intestine.[115] The widespread resistance of *P. equorum* to ivermectin means that foals and young horses are at increased risk for this disease.[159,160]

Some ascarid impactions can be resolved at surgery by massaging the impaction into the cecum, with or without typhlotomy, and these cases seem to have the best prognosis, possibly because they have minimal small intestinal damage.[157,161] Enterotomy is required to evacuate the impaction in more severe cases (Figure 36-5), although resection is indicated if the bowel is devitalized[135,156] or there are concurrent lesions, such as volvulus or intussusception.[157] Not all the worms can be removed at surgery, regardless of method, and anthelmintic treatment is indicated after surgery.[161]

Postoperative mortality can be as high as 92%, with focal necrotizing enteritis, peritonitis, abscess formation, and

Figure 36-5. Removal of impacted ascarids through an enterotomy in the jejunum. Note that small intestine on the left is dimpled at sites where ascarids remain attached as they are drawn through the incision.

adhesions accounting for most deaths.[156,161] Reasons for such a poor prognosis after surgery include undetected ascarid-induced damage in the intestinal wall, release of toxins from the ascarids, release of antigenic proteins after organophosphate-induced rupture of the cuticle, preexisting debilitation, low-grade liver disease, low-grade pneumonia, and failure to remove all worms at surgery.[161] Although a recent study described an improved survival rate (64%) after surgery, prognosis for survival for longer than 1 year was guarded, with most deaths caused by adhesions.[157]

Prevention of ascarid impaction requires a sound deworming program based on current recommendations, not traditional practices.[158] Ascarid control should involve (1) using only those anthelmintics known to be effective against indigenous populations, (2) initiating anthelmintic treatment no sooner than 60 days of age, (3) repeating treatments at the longest intervals required to prevent serious pasture contamination with *Parascaris* eggs, and (4) recognizing that the passage of modest numbers of ascarid eggs by some foals is required to decrease selection pressure for anthelmintic resistance.[158] Between 14 and 21 days after treatment, fecal samples are collected and fecal egg counts are compared with pretreatment counts with the help of the Fecal Egg Count Reduction Test for the anthelmintic used, recognizing that correlation between egg counts and worm burdens has not been demonstrated for *P. equorum*.[158] In heavily parasitized foals at high risk for impaction, mineral oil can be given with an anthelmintic agent.[161] Ranking of anthelmintic drug activity on ascarids from highest to lowest in a 2007 study in central Kentucky was oxibendazole, fenbendazole, pyrantel pamoate (very poor), and ivermectin (no effect).[160]

Duodenitis–Proximal Jejunitis

Duodenitis–proximal jejunitis (DPJ), also called gastroduodenitis-jejunitis, hemorrhagic fibrinonecrotic duodenitis, proximal jejunitis, proximal enteritis, and anterior enteritis, involves inflammation of the proximal part of the small intestine, fluid accumulation in the stomach and small intestine, and endotoxemia. The cause is unknown. Severity of clinical signs varies over a wide range, and age, breed, and sex predispositions have not been established. Although usually diagnosed in horses older than 1½ years, it does occur in nursing foals.[84] The prevalence of the disease has been reported as 3% to 22% of all small intestinal colics.[129-132] Prevalence in California is lower than in other parts of the United States and Europe, and the disease appears to be more severe in the southeastern United States than in the Northeast.[84,101]

The clinical hallmark of the disease is nasogastric reflux of a large volume of fluid (usually greater than 48 L in the first 24 hours) in a horse that demonstrates signs of mild to severe pain initially and then depression.[162] Most horses with DPJ have tachycardia, prerenal azotemia, dehydration, hypotension, and electrolyte abnormalities. In contrast to horses with strangulating lesions, horses with DPJ are more likely to have a fever, leukocytosis, and a greater volume of gastric reflux.[84,101] Affected horses can have significantly higher serum liver enzyme activities than horses with small intestinal strangulating lesions.[163] They also have a trend toward higher prevalence of gastric ulceration compared to those with other GI lesions.[164]

After gastric decompression, a horse with DPJ usually demonstrates relief from pain and becomes quiet, and its heart rate decreases, whereas a horse with mechanical obstruction improves little if at all. On rectal examination, the degree of small intestinal distention with DPJ is subjectively less than with ileal impaction.[83] Peritoneal fluid from horses with DPJ is rarely serosanguineous, and nucleated cell count and total protein concentration increase to a lesser extent than with a strangulating obstruction.[83,84]

The most important goals in treatment of horses with DPJ are frequent gastric decompression, correction of disturbances in water and electrolyte homeostasis, and restoration of normal intestinal function. Horses must be kept off food and water until it is concluded that the condition has resolved, and attention should be paid to plasma concentrations of calcium and potassium, both of which can become depleted in horses with intestinal injury and decreased food intake. The rate of fluid administration and the types given should be largely determined by clinical and laboratory evidence of hydration status and electrolyte balance.

Flunixin meglumine can attenuate the hemodynamic responses to lipopolysaccharides (endotoxin) and reduce lipopolysaccharide-induced increases in plasma concentrations of thromboxane and prostaglandins.[165] Nonsteroidal anti-inflammatory drugs also could block the effects of lipopolysaccharides on intestinal motility that could exacerbate or sustain ileus in horses with DPJ. Antilipopolysaccharide antibodies in plasma products, such as J5 *Escherichia coli* or Re *Salmonella* mutants could be used; however, there is some controversy regarding efficacy.[165] The amphipathic cyclic polypeptide antimicrobial drug polymyxin B can avidly bind with the lipid A and thereby remove lipopolysaccharide from the circulation, although nephrotoxic side effects in dehydrated horses are valid concerns with the use of this drug.[165] Pentoxifylline, a methylxanthine derivative, can reduce lipopolysaccharide-induced production of cytokines and thromboxane in horses.[165]

Antibiotic use in DPJ is controversial, but horses in one study received metronidazole (2 g IV, followed by 1 g IV twice a day) and procaine penicillin (20,000 IU/kg IM twice a day), based on a high rate of positive cultures of gastrointestinal contents for *Clostridium perfringens*.[166] Treatment could include prokinetic drugs or lidocaine to improve gastric emptying and small intestinal motility (see paragraphs on postoperative ileus in Chapter 40). Prophylaxis against development of laminitis should be considered, including the preceding treatments, confinement in a sand stall or on deep wood shavings, application of frog support, and application of ice to the lower limbs and feet.

Surgery is performed in at least 6% of cases.[84,162] Although the prognosis is considered to be reduced by surgery in some areas in the United States, in two studies survival was similar regardless of whether horses underwent surgery.[162,167] In one report, 40 of 42 horses (95%) recovered rapidly and completely after surgical decompression, suggesting that a prompt recourse to surgery could be indicated for this disease.[166] This was not confirmed in another study, which demonstrated that survival was decreased and the risk of diarrhea was increased in surgical cases compared with medical cases.[168] Also, the longer period of inactivity necessitated by the abdominal incision and the risk for obstructive adhesions could be disadvantages of surgery. The major advantage of surgery is to use it as a diagnostic procedure when distinction between DPJ and a physical cause of obstruction is difficult.

Reported survival rates for DPJ range from 25%[101] to 94%, and recurrence is rare.[84,162,167] By univariate analysis, anion gap, abdominal fluid total protein concentration, and volume of gastric reflux in the first 24 hours were significantly associated with death.[162] Laminitis is a life-threatening complication of DPJ, and the risk is greater in horses with hemorrhagic reflux at the time of admission.[169] The considerable cost of prolonged medical treatment can necessitate euthanasia in protracted cases.

The lesions of DPJ are usually confined to the proximal half of the small intestine.[101] The serosa may appear normal or may be dark pink and edematous and have hemorrhagic patches. The mucosa can be normal, light red, dark red, hemorrhagic, and even necrotic and ulcerated.[101] Microscopic lesions range from hyperemia and edema of the mucosa and submucosa to some sloughing of villus epithelium; hemorrhage; and neutrophil infiltration from the lamina propria and submucosa to the tunica muscularis and serosa.[101,167] The liver is moderately to markedly congested in most horses, and histopathologic changes can include congestion, vacuolization, periportal fibrosis, bile duct hyperplasia, inflammatory cell infiltrates, and necrotizing hepatitis.[101,167] Liver damage could be caused by reflux of duodenal contents and ascending infection through the common bile duct, absorbed endotoxin or inflammatory mediators from the portal circulation, or hepatic hypoxia caused by systemic inflammation and endotoxemic shock.[163]

Neoplasia

Obstruction of the gastrointestinal tract by intestinal wall tumors is rare. Arabian horses are 4.5 times more likely to have a diagnosis of intestinal neoplasia than are other breeds, there is no sex predisposition, and the small intestine is the most common segment of intestine affected for all neoplasms.[170] Lymphosarcoma, lymphoma, adenocarcinoma, adenoma, leiomyosarcoma, leiomyoma, ganglioneuroma, and intestinal carcinoid have been reported to cause small intestinal obstruction in horses.[170-179] Horses with intestinal neoplasia can be presented with a single bout of acute colic or with repeated bouts of mild colic, weight loss, anorexia, and fever.[170] The most consistent clinical signs are poor body condition, tachycardia, tachypnea, fever, and diarrhea.[170] Antemortem diagnosis can be made on rectal examination, routine blood analyses, abdominocentesis, ultrasonographic examination, rectal biopsy, and exploratory celiotomy. A favorable outcome can follow surgical removal of the tumor if it is discrete, focal, and accessible.[171,173,174,176,179] Resection of an isolated lymphosarcoma lesion can be curative, but this is generally a multiorgan disease with a grave prognosis.[172]

Gastroduodenal Obstructions

Duodenal inflammation, ulcers, stenosis, and perforation can develop in foals, particularly those treated with phenylbutazone or subjected to stress, surgery, transportation, or illness.[180] Foals younger than 4 months are at greater risk, although duodenal obstruction has been reported in yearlings and in an adult horse.[125,180-182] The incidence of gastroduodenal obstructions has decreased because of increased awareness and earlier treatment with antiulcer medication.[125] Duodenal obstruction can cause reflux of duodenal contents into the bile and pancreatic ducts, inducing diffuse cholangiolitis, perilobar hepatitis, and pancreatitis, with acute erosive and fibrinous inflammation of the large ducts.[180]

Many affected foals are depressed, weak, and anorectic in the days or weeks preceding diagnosis. Clinical signs of duodenal ulcers and obstruction are teeth grinding (odontoprisis), salivation, gastric reflux, fever, diarrhea, and signs of colic (e.g., dorsal recumbency).[125] Abdominal pain may be worse after nursing. Rupture of duodenal ulcers causes signs of peritonitis.[180]

Diagnostic signs on plain radiographs include aspiration pneumonia, dilated fluid-filled esophagus, and gastric distention.[125] Gas may be evident in the hepatic duct.[125] Endoscopy is more sensitive and specific than radiography in diagnosing gastric and duodenal lesions, although ultrasonography could be used to demonstrate any abnormalities in duodenal peristalsis, wall thickness, and lumen size.[93,113,125,183]

Surgical bypass of the obstruction should be followed by medical treatment of gastric ulcers (see Chapter 32).[125,182] Contrast radiographs are recommended 24 hours after surgery to confirm successful bypass of the obstruction. Barium in dilated bile ducts after surgery is indicative of cholangitis or cholangiohepatitis.[125]

Intestinal Inflammation and Fibrosis

A number of diseases characterized by inflammation or fibrosis in the small intestinal wall have been identified as causes of colic in horses. Intestinal fibrosis has been reported as a cause of weight loss and colic in horses in a small geographic distribution in Colorado, but the disease appears to be more widespread and the signs more variable than originally reported.[184,185] Equine proliferative enteropathy from *Lawsonia intracellularis* infection in the small intestine causes weight loss, colic, hypoproteinemia, and diarrhea in weanling foals.[186,187] Although erythromycin alone or with rifampin is an effective treatment, resection or bypass of the affected segment may be required.[186,187]

Eosinophilic gastroenteritis is a well-known but poorly understood cause of colic, diarrhea, and weight loss in horses.[102] In one series of cases, weight loss was not a feature, but affected horses had colic from jejunal obstruction with a red intramural mass or circumferential plaque of fibroplasia and infiltration on the antimesenteric surface.[102] The seasonal distribution of the cases corresponded to the grazing period, suggesting a dietary association.[102] Treatment by complete or wedge resection was successful because of the focal nature of the lesions.[102]

A similar type of acute or chronic colic is characterized by small, focal to multifocal, well-demarcated areas of intestinal thickening and fibrosis that form constrictive mural bands in the jejunum and other parts of the intestinal tract.[188] These are free of mucosal ulceration and granulomatous response, but they have histologic evidence of lymphocytic, plasmacytic, and eosinophilic infiltration of all layers, and most lesions are associated with the vasculature.[188] A similar idiopathic focal eosinophilic enteritis (IFEE) has also been diagnosed in the United Kingdom and Ireland.[189,190] Affected horses can be treated by resection of the diseased segment[188,189] or by decompressing the affected small intestine into the cecum, without resection.[190] The decision to resect could be based on the severity of the constrictions,[190] because obstruction can recur at nonresected lesions after surgery.[189] Medical treatment with corticosteroids can also be effective.[188]

Pythiosis caused by *Pythium insidiosum* is a granulomatous disease, typically of skin and subcutis, that is most commonly diagnosed in the Gulf Coast States but also in the Midwest.[191] Jejunal obstruction caused by *P. insidiosum* granuloma can cause weight loss and signs of mild intermittent abdominal pain.[191] Reported cases have been amenable to resection, which can be successful.[191,192]

Miscellaneous Simple Obstructions

Duodenal obstruction in horses can cause severe pain, gastric reflux is voluminous, and some horses have spontaneous gastric reflux through the nostrils.[83,193] Impactions of the duodenum and jejunum are rare, and causes include impacted feed material, compressed cracked corn, trichophytobezoar, compacted wood fragments, persimmon fruit, molasses-based stable treats, baling twine, and cholelithes.[83,193-202] Consumption of ripe persimmon fruits by horses during fall and winter in the South cause intermittent impaction of the stomach, duodenum, and jejunum, and weight loss.[199,200] The ripe persimmons at that time are palatable to animals, and water-soluble tannins in the fruit form a solid phytobezoar when exposed to gastric acid.[199,200] Diagnosis can be confirmed by identifying persimmon seeds in the gastric impaction on gastroscopy.[199]

Small intestinal perforation by wire, a porcupine quill, ulcers, and unidentified objects may lead to diffuse or localized peritonitis, localized intestinal necrosis, and even occlusion of mesenteric vessels.[203-207] Localized lesions can be resected,[206,207] although the extent of adhesions and peritonitis can complicate access and prognosis in many cases.[205] Single discrete perforations, 1.5 cm or smaller, have been described in otherwise healthy jejunum in three young horses that were presented with fever, acute colic, depression, and hypovolemic shock.[100] No cause could be identified.[100] These perforations could be similar to idiopathic perforating ulcers that have been described on the jejunal mesenteric attachment with leakage into the jejunal mesentery.[208] Affected horses present with a history of low-grade colic, depression, and inappetance, and clincial and laboratory findings that support a diagnsosis of peritonitis.[208]

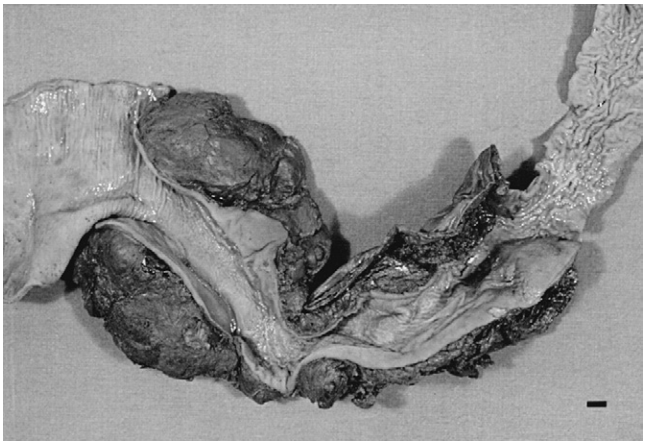

Figure 36-6. Intramural hematoma that caused an obstruction in the jejunum by collapse of the intestinal lumen. Note the healthy mucosa in the affected segment. *Bar,* 1 cm.

Congenital segmental aplasia of jejunal lymphatics may cause chyloperitoneum and colic in foals within 12 to 36 hours after birth.[119,209-212] A presumptive diagnosis can be made on the basis of ultrasonographic findings of loops of thick-walled small intestine, anechoic peritoneal fluid, and thickened mesentery.[119,211] Resection of the thickened intestine can produce a satisfactory outcome, but mild cases can respond to conservative treatment.[210,211] Ruptured lymphatics and chyloperitoneum can also develop secondary to tearing of postsurgical mesenteric adhesions and other intestinal lesions.[212] An ileal diverticulum that is not a remnant of the omphalomesenteric structures (see later), other rare forms of intestinal malformation, and congenital jejunal duplications have been described as causes of recurrent small intestinal obstruction in horses.[213-215] Extraluminal causes of simple obstruction include intra-abdominal abscesses, intramural hematoma (Figure 36-6), and adhesions.[118,133,216]

An idiopathic disease of the duodenum reported in three horses older than 12 years is characterized by mural thickening and marked distention in approximately 30 cm (12 inches) of duodenum.[217] The distention starts 20 cm (8 inches) from the pylorus and ends in a contracted segment with aganglionosis immediately proximal to the caudal duodenal flexure.[217] Primary gastric and small intestinal ileus of undetermined cause has been described as responsible for acute colic in postparturient mares.[218] The outcome following treatment by decompression is good.[218]

Strangulating Obstruction

Volvulus

Volvulus is defined as a rotation in a segment of jejunum, or in jejunum and ileum, about the mesentery so that the intestine becomes twisted into into distinct spirals (Figure 36-7). Most are 360-degree rotations and involve long segments of intestine (see Figure 36-7).[89] Volvulus may develop as a primary displacement or as secondary to preexisting lesions, such as an acquired inguinal hernia, a mesodiverticular band, a Meckel

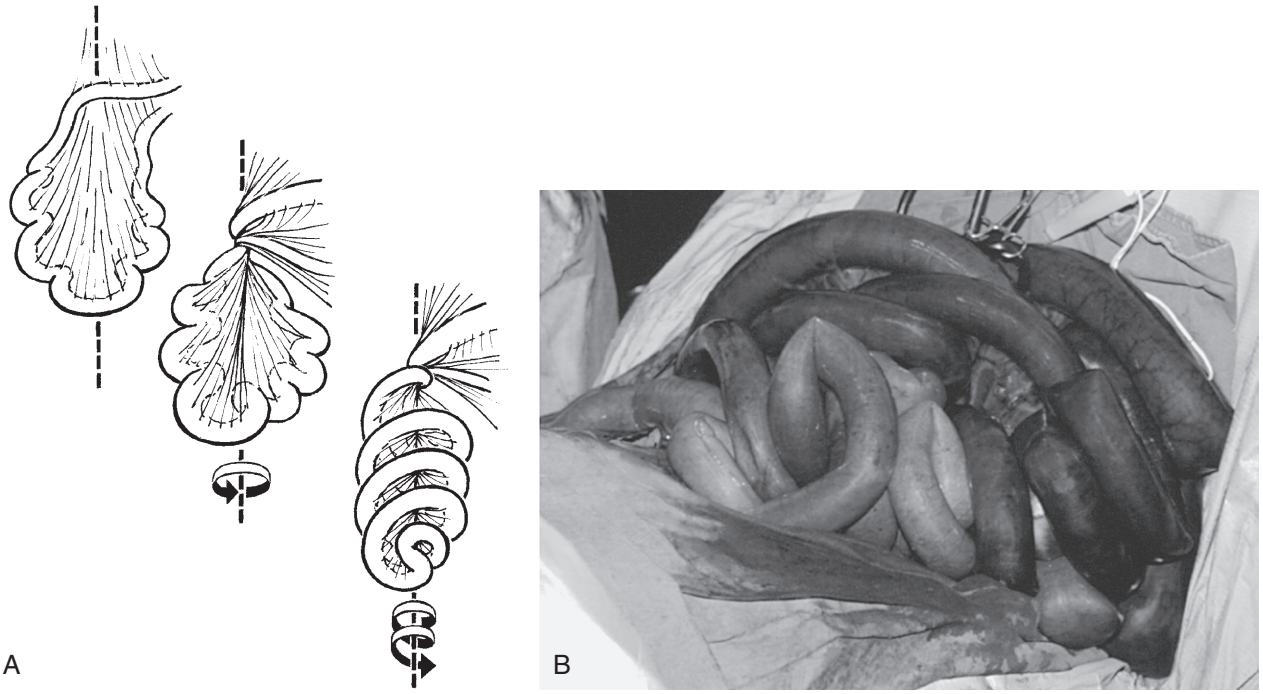

Figure 36-7. Small intestinal volvulus. **A,** Diagram. **B,** Intraoperative presentation. Note the typical appearance of numerous coils of distended and ischemic small intestine stacked one on another.

diverticulum, strangulation in mesenteric rents, distention from any cause, fixation by vitelloumbilical bands[219] and adhesions.[96,220-224] Primary volvulus can affect a horse of any age, but most affected horses are at least 3 years old.[89] It is the most common indication for intestinal surgery in foals, especially those between 2 and 4 months of age (see Table 36-1).[89,135] Volvulus nodosus is a less common form of volvulus, formed by the ileum and jejunum undergoing a 360-degree torsion that forms a mesenteric pouch in which prestenotic jejunum becomes entrapped.[225,226] Distention of the entrapped bowel draws the ileum into the mesenteric pouch to form a tight loop that knots the entrapment.[226] Volvulus nodosus is seen typically in foals 2 to 7 months of age, and it can account for 27% of small intestinal lesions that require surgery in foals.[124,226] Duodenal torsion has been reported but is rare.[217]

Although clinical signs are typical of acute small intestinal strangulating obstruction, admitting clinical signs and heart rates can vary.[89] Typically, stacks of tightly distended small intestine can be palpated *per rectum*, although distended small intestine was palpated in only 69% of horses in one study.[89] In foals, severe pain seems to alternate with periods of depression, and the abdomen becomes markedly distended. Foals with small intestinal volvulus are usually afebrile,[89] which should help distinguish them from foals with enteritis.

Treatment involves correction of the volvulus, followed by resection and anastomosis (see later), and the prognosis for survival to hospital discharge is good (80%).[89] Correction of volvulus nodosus can be difficult in foals and adults, but it can be accomplished by massaging the contents of the entrapped loop into the proximal segment, thereby allowing the bowel to be pulled through the ring formed by the ileum.[225,226] If the bowel involved in a volvulus nodosus is necrotic, time can be saved by resecting the entire lesion without reduction, followed by a jejunocecostomy.[226]

Figure 36-8. Epiploic foramen as viewed from the right side with the duodenum in the foreground, the liver dorsally, and with the cranium to the right. The *arrow* points to the ventral edge of the foramen formed by the gastropancreatic fold. *C,* Caudate lobe.

Entrapment in the Epiploic Foramen

The epiploic foramen, or foramen of Winslow, is the 4-cm–wide (1½ inch) entry into the vestibule of the omental bursa from the peritoneal cavity. Its dorsal and craniodorsal boundary is the visceral surface of the base of the caudate process of the liver (Figure 36-8).[227] The portal vein contributes to the cranioventral border, and the gastropancreatic fold becomes evident as a band where it forms the ventral border of the foramen.[227] From 8 cm (3 inches) to 18 m (60 feet) of intestine can become incarcerated in this space.[90,91,228,229] Variations include simultaneous

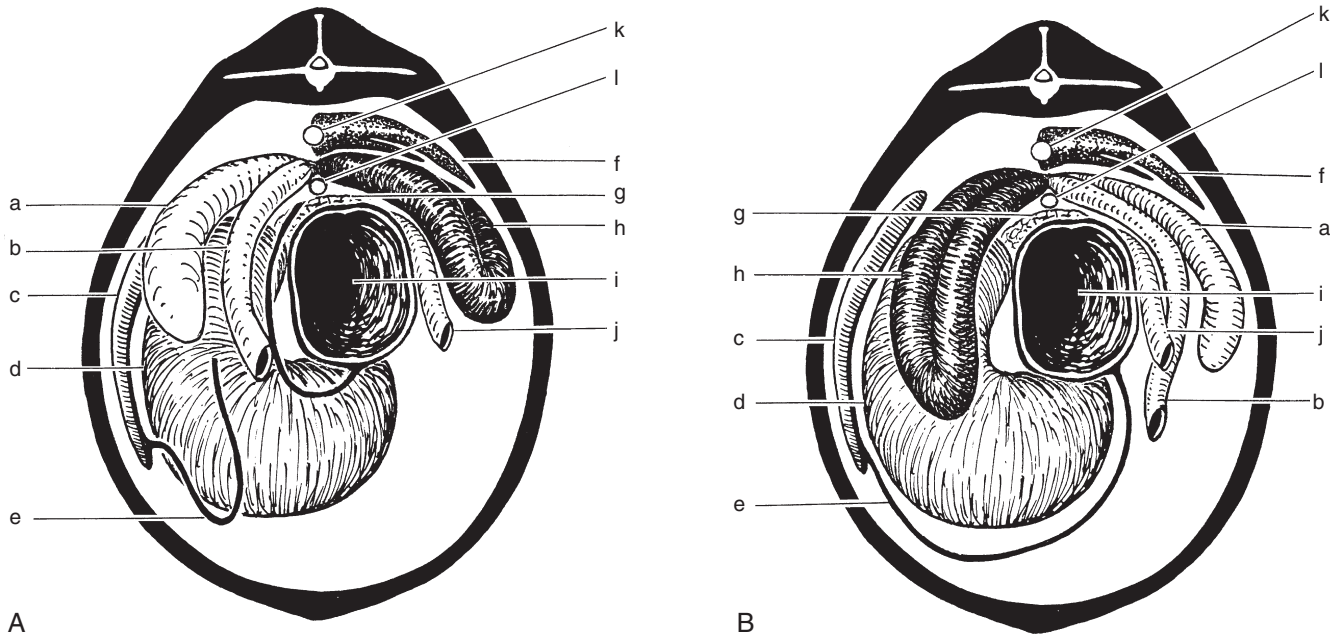

Figure 36-9. Epiploic foramen strangulation. Left to right **(A)** and right to left **(B)** herniation of the small intestine through the epiploic foramen. *a,* Jejunum proximal to strangulation; *b,* jejunum distal to strangulation; *c,* spleen; *d,* stomach; *e,* greater omentum, torn during strangulation; *f,* liver; *g,* pancreas; *h,* strangulated loop; *i,* right dorsal colon; *j,* duodenum; *k,* vena cava; *l,* portal vein.

strangulation of two loops of small intestine, strangulation of the cecum by the involved small intestine, simultaneous incarceration of the cecum and jejunum, incarceration of a Meckel diverticulum (Littre hernia), a parietal (or Richter) hernia of the ileum, a parietal hernia of the duodenum, and impaction in the incarcerated segment.[91,221,230-232] Although entrapment in the epiploic foramen (EFE) can occur from right to left in rare cases, one study reported left-to-right entrapment (Figure 36-9) in all of 53 horses, another reported it in 138 of 143 horses, and another in 97% of horses.[90,91,228,233] The ileum was involved in 66% to 81% of cases, either alone (12% to 25%) or in combination with the jejunum (41% to 60%), and involvement of the jejunum alone occurred in 28% to 34% of cases.[90,91,121,233,234] Ileal involvement for this disease (81%) was found to be significantly greater than for strangulating lipoma (31%) and miscellaneous small intestinal diseases (46%) in one study.[234] The longer the duration of colic, the more likely that ileum will become involved in the strangulation.[91]

The apparent predisposition to EFE in older horses and the predisposing enlargement of the epiploic foramen with age[235] were not confirmed in several studies.[88,227,233] Horses of all ages can be affected, including foals, and horses 11 months to 3 years.[88,90,91,124,227-229,236,237] In some of the larger studies, 47% to 71.3% of horses were younger than 11 years, and horses older than 20 years were rarely affected.[88,90,91,227,229,233] Some studies found Thoroughbreds and Thoroughbred crosses to be at a higher risk, and males constituted 68.5% and 76% of cases.[90,91,228,233,238] In one study from the United Kingdom, 77.5% of cases were seen between October and March, mainly in January, suggesting that stabling played a role in cause of this disease.[233,239] According to data from one U.S. and one U.K. university hospital, up to 68% of horses with EFE were cribbers before surgery, compared with 6% to 10.4% in the control groups, significant evidence that cribbing is associated with this disease.[240] In a prospective case-control study, a history of colic in the previous 12 months, increased time in a stall in the previous 28 days, and greater height of the horse increased the risk of EFE.[239,241] Horses that are easily frightened, sweat up when excited, or go off their food in response to a stressful situation appear to be at reduced risk of EFE.[239,241]

Clinical findings can be confusing. In one study, 38% of horses with herniation of small intestine through the epiploic foramen did not show signs of abdominal pain at the referral hospital, and in 52% of these horses no gastric reflux was obtained.[90] The signs of abdominal pain were sufficiently mild in one case to cause delay of referral for 2½ days.[242] Changes in the peritoneal fluid do not always represent the extent of intestinal damage.[90,229] Traction on the ventral band of the cecum is reported to induce a painful reaction in horses with the ileum incarcerated in the epiploic foramen[221]; however, this test was not reliable in one report.[229] With transabdominal ultrasonography, distended or edematous small intestine is found more often in the ventral right paralumbar fossa, followed by the caudal ventral abdomen and the middle right paralumbar fossa.[114]

At surgery in most cases, strangulation in the epiploic foramen can be corrected by careful traction combined with pushing of the strangulated bowel in the same direction. Careful milking of fluid into the empty and collapsed distal segment may be necessary to decompress the strangulated bowel. If possible, nonstrangulated bowel can be drawn into the foramen so that distention of the strangulated segment can be reduced by spreading its contents into the nonstrangulated bowel.[90] To avoid tearing the dorsal aspect of the portal vein and causing fatal hemorrhage during traction,[90,228,243] bowel should be drawn in a horizontal direction and not upward to the abdominal incision.[244]

When bowel cannot be drawn back through the epiploic foramen by these methods, jejunum approximately

1 m proximal to the obstruction must be emptied through an enterotomy or by transection.[244] Lumen of the empty segment of jejunum is closed and that segment can then be drawn through the foramen. After reduction, abnormal bowel is resected to include the transection or the enterotomy sites.

The short-term survival rate after completed surgery for EFE varies from 18% to 95%, and the long-term survival rate varies from 35% to 70%.[90,91,121,130,229,234,237,245] More recent trends have been toward improved survival rates to hospital discharge after surgery for this lesion, and one study reported a significantly better short-term survival after surgery for EFE (95%) than after surgery for strangulating lipoma (84%) and miscellaneous strangulating diseases of the small intestine (91%).[234] In studies on long-term survival after colic surgery, EFE was the only categorical variable associated with decreased survival, and horses with this lesion were more than 4 times as likely to have relaparotomy than horses with other colics.[246,247] In one study, horses with EFE had a shorter median survival time than those with other types of colic, and recurrence was reported in 2 of 49 horses (4%) that left the hospital.[233] Fatal hypoglycemia, a large thrombus in the portal vein, and areas of ischemic necrosis in the liver have been reported in a horse after treatment of an epiploic entrapment.[248] Rupture of the portal vein is a complication of correction, as discussed previously.[90,228,243]

Pedunculated Lipoma

A pedunculated lipoma is a benign, smooth-walled fat tumor that is suspended by a thin mesenteric pedicle of variable length. It can be a solitary tumor, or several of them can be found in the same horse, with 89% found in the small intestine and 10% in the small colon.[249] Some can develop in the omentum. Mesenteric lipomas cause strangulating obstruction when the pedicle wraps around intestine and its mesentery (Figure 36-10). A large lipoma attached close to the intestine can cause simple, recurrent obstruction, but this is rare.[250,251] In general, the length of the stalk rather than the size of the tumor seems to influence the risk for strangulation.

Intestinal strangulation by a mesenteric lipoma is a disease of older horses, with a mean age of 14 to 19.2 years at diagnosis, and the youngest reported at 8 years.[88,131,249,251,252] Incidence of lipomas is 5 times higher in horses older than 15 years compared with 10- to 15-year-old horses.[227] Ponies, Arabians, Saddlebreds, Quarter Horses, and geldings have been reported to be at a higher risk, and Thoroughbreds are at a lower risk for this disease.[227,249,251,252] Not all affected horses are overweight.[251]

Pedunculated lipomas should always be suspected in old horses with clinical evidence of strangulating obstruction, although clinical signs can be subtle and not always suggestive of this lesion.[251] In one study, 6 of 17 horses did not show signs of pain at the referral institution.[251] Consequently, this disease can be confused with duodenitis–proximal jejunitis, especially in horses with a large volume of reflux.

At surgery, the lipoma can be found wrapped in the jejunal mesentery, and the involved intestine can be difficult to exteriorize. Blind resection of the pedicle is necessary in many cases but carries the risk of creating a mesenteric rent and mesenteric bleeding. Spontaneous rupture of the lipoma pedicle and correction of the obstruction has been reported, based on surgical findings.[253] Incidental lipomas with distinct pedicles should be removed with the ligate divide stapler (LDS) (see Figure 16-14) by ligation and transection. A significant association between postoperative ileus and strangulation by lipoma has been reported, and published short-term survival rates for this strangulation range from 48% to 84%.[234,247,251,252]

Intussusception

Jejunojejunal, jejunoileal, and ileoileal intussusceptions have been reported in horses.[99] Suspected predisposing factors are segmental motility differences caused by enteritis, heavy ascarid burden, infection with the tapeworm *Anoplocephala perfoliata*, mesenteric arteritis, and abrupt dietary changes.[99,254] A transverse enterotomy, functional side-to-side anastomosis, end-to-end anastomosis, and pedunculated mucosal mass, such as a papilloma, leiomyoma, cryptococcal granuloma, granuloma of unknown cause, and carcinoid, can form the leading edge of a jejunojejunal intussusception in horses.[98,99,255-260] In one horse with weight loss and colic, jejunojejunal intussusception was associated with proliferative enteropathy with pseudodiverticula formation, jejunal muscular hypertrophy, and diverticulosis.[261]

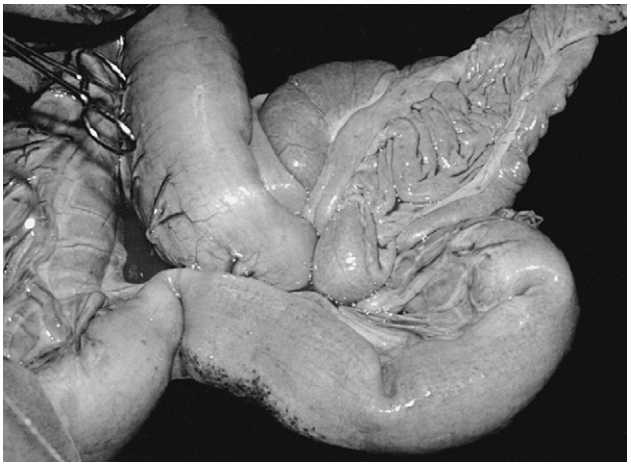

Figure 36-12. Compensatory changes in the jejunum proximal to a chronic ileocecal intussusception. The bowel is dilated but empty; its wall is thick, which is especially evident at the folds; and it has ecchymoses on the antimesenteric surface. (From Ford TS, Freeman DE, Ross MW, et al: Ileocecal intussusception in horses: 26 cases [1981-1988]. J Am Vet Med Assoc 196:121, 1990.)

Ileocecal intussusception is the most common type (74% of all small intestinal intussusceptions), with 27% of them causing chronic, intermittent colic.[97,131] Chronic ileocecal intussusceptions represented approximately 1% of all surgical colic cases in one study.[262] Horses with a chronic intussusception usually have a short intussusceptum that is not strangulated but causes an incomplete obstruction. Ileoileal intussusceptions usually form a short, doughnutlike lesion, and most cause chronic recurrent colic.[99,263-265] Jejunojejunal intussusceptions (Figure 36-11) usually involve long segments of bowel and cause complete obstruction,[98] although short jejunojejunal intussusceptions can cause recurrent colic.[98,265]

With chronic intussusceptions, the repeated bouts of obstruction cause compensatory changes in almost half the jejunum proximal to the lesion (Figure 36-12), including marked jejunal dilation, even when empty; thickening of the muscular coat; and areas of ecchymosis along the antimesenteric surface.[97,262] These changes do not appear to contribute to the obstruction.

Females accounted for six of seven (86%) intussusceptions in one study, and this was significantly different from the sex distribution in the hospital population.[238] However, the female predisposition was less pronounced in five larger studies, ranging from 45% to 68%.[97,99,254,262,264] One study reported an apparently higher risk for Thoroughbred horses, and another reported a higher risk for ponies.[99,264]

Although regarded mainly as a disease of foals, intussusceptions have been reported over a wide age range up to 24 years, with few reported in young foals.[97-99,135] Intussusceptions were the most common cause of surgical colic in horses 3 to 12 months of age in one study, particularly ileocecal intussusceptions.[137] In younger foals, intussusceptions were less common, and only jejunojejunal intussusceptions were recorded.[137] Ileocecal and ileoileal zintussusceptions, both of which are more likely to cause recurrent mild to moderate colic, are more common in horses 3 years of age and younger.[97,99,254,262-265]

Intussusceptions of long segments cause signs of severe small intestinal obstruction.[97-99] Short intussusceptions cause colic that is mild, intermittent, usually postprandial, and associated with reduced appetite and feces, elevated temperature, weight loss, and failure to thrive compared with herdmates.[97] An ileal intussusception should be strongly suspected in a horse between weaning and 3 years of age that is unthrifty and has a history of recurrent mild colic.

Rectal examination may reveal distended loops of small intestine, and the intussusception can be palpated as a firm, painful, tubular structure in some cases.[98,99] Ileocecal intussusceptions were palpated in the right dorsal quadrant of the abdomen in 31% of horses in one report and in 50% in another.[97-99] During an episode of pain in a horse with a chronic intussusception, the hypertrophied small intestine proximal to the obstruction (see Figure 36-12) can be palpated *per rectum* as large-diameter, moderately distended loops with thick walls.[97] In young horses and foals too small for rectal palpation, a cross-sectional view of a jejunojejunal or ileocecal intussusception can be seen on ultrasonography as concentric rings with a bull's-eye appearance (Figure 36-13).[93,116]

White blood cells and protein concentration may be increased in the peritoneal fluid of horses with acute ileocecal intussusceptions and jejunojejunal intussusceptions.[97,98] Peritoneal fluid protein concentration alone can increase in chronic ileocecal intussusceptions.[97] In one study, 8 of 16 horses with acute ileocecal intussusceptions had serosanguineous fluid.[97]

SURGERY: ILEOCECAL AND ILEOILEAL INTUSSUSCEPTIONS

In chronic intussusceptions of ileum, short segments (approximately 10 cm or 4 inches) are involved. Reduction is difficult, even in the absence of adhesions, because of chronic folding of the intestinal wall.[97] Reduction was impossible in 11 of 16 ileoileal intussusceptions and in 6 of 7 chronic and 10 of 19 acute ileocecal intussusceptions.[97,264] Ileocecal and ileoileal intussusceptions have been treated successfully by reduction only or by reduction and myotomy.[263,264,266] Incomplete bypass

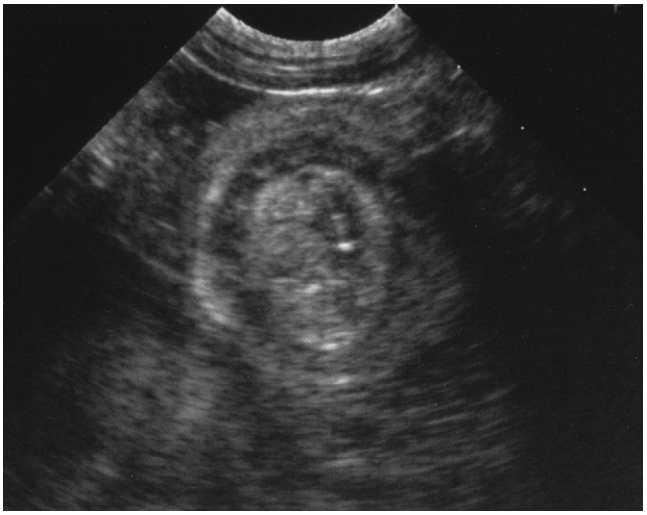

Figure 36-13. Ultrasonographic image of a small intestinal intussusception in a foal demonstrating the typical bull's-eye or target appearance. In this cross-sectional view, two concentric hyperechoic rings are evident, the outer intussuscipiens and inner intussusceptum with some hypoechoic spaces in both that represent fluid in the lumen.

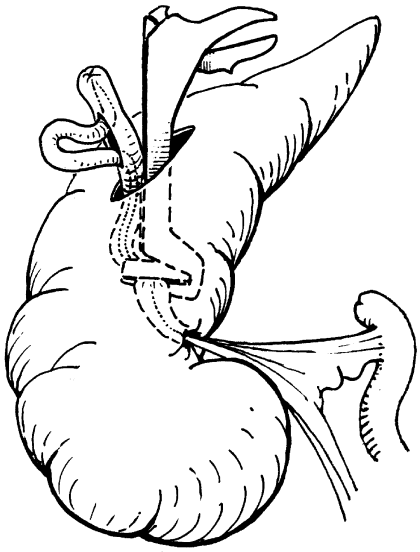

Figure 36-14. Method for resecting the intussusceptum of an acute ileocecal intussusception with the TA-90 stapler applied through a typhlotomy.

by ileocecostomy is recommended if there are concerns about permanent ileal changes and the risk of recurrence, and a hand-sewn technique is recommended over stapling instruments because the ileal wall is so thick.[97,262,267] There is no need to resect the involved ileum or the hypertrophied jejunum in chronic cases.

Ileocecostomy for chronic ileocecal intussusception has excellent short-term results, but apparently rare long-term complications include stomal impaction, ileal hypertrophy, and rupture distal to the stoma.[97,99,153] Also, the stoma can become smaller over time, which could predispose to these complications.

In acute cases, the intussuscepted ileum and jejunum can be too edematous and hemorrhagic to allow reduction. Bypass by a jejunocecostomy without reduction can cause postoperative hemorrhage.[97] Removal of the intussusceptum through a typhlotomy can cause severe contamination, although suturing an impermeable plastic drape around the typhlotomy can contain leakage.[97,218] In a technique devised to facilitate this surgery, the jejunum proximal to the intussusception is transected with the gastrointestial anastomosis (GIA) or the intestinal linear anastomosis (ILA) stapler as close to the ileocecal junction as possible.[268,269] A 10-cm (4-inch) incision is made in the cecum to allow the intussusception to be exteriorized, and another incision is made through the outer wall of the intussusceptum to expose the inner loop (Figure 36-14). This inner loop then is pulled through the incision in the outer layer until the closed transected end is distal to the selected site for transection.[269] If too much bowel is drawn through this incision, or if the jejunal transection was made far from the ileocecal junction, mesenteric vessels will tear and cause fatal hemorrhage.[268,269] Much of the necrotic bowel is removed by incision along the edge of a thoracoabdominal (TA-90) stapler applied across the inverted ileum within the cecum (see Figure 36-14).

SURGERY: JEJUNOJEJUNAL INTUSSUSCEPTION

A jejunojejunal intussusception forms a corkscrew configuration because of tension on the mesentery of the intussusceptum, and short to long segments can be involved.[259] Reduction is accomplished by slow traction on the intussusceptum and gentle massage of the distal end of the intussuscipiens.[259] If it is nonreducible, the entire intussusception can be removed by resection only,[98] although this can make ligation of mesenteric vessels difficult.[99]

Prognosis is favorable for all intussusceptions, but the bowel wall and intussuscepted mesenteric vessels can be torn during reduction.[97] Some horses can have a protracted recovery after surgery for a chronic ileocecal intussusception, with slow weight gain and mild episodes of colic.[97] Because *A. perfoliata* may be involved in the pathogenesis of ileocecal intussusceptions in horses, the treatment of affected horses and pasturemates with pyrantel pamoate and praziquantel is recommended.[97,254,270]

Mesenteric Rents

Mesenteric rents can be congenital in origin, secondary to mesodiverticular bands (Figure 36-15), or may develop as primary lesions of unknown cause. Trauma or mesenteric stretching by another lesion may play a role, and some can develop years after a small intestinal surgery at a site remote to the anastomosis.[90,271] Horses of a wide age range appear to be prone, although females are more likely to be affected, especially in the postpartum period when the tear is possibly induced by vigorous movements of the foal, as has been implicated in tears of the small colon mesentery.[271,272] Such tears in postparturient mares can cause segmental ischemic necrosis of the related segment of jejunum or predispose to later strangulation of a more distant portion of small intestine.[273] The jejunal mesentery is involved in most cases, although tears in the ileal and duodenal mesentery have been reported, as well as tears in multiple sites.[271,273]

Prognosis for surgical treatment appears to be worse than after other strangulating lesions of the small intestine.[271] Possible reasons for this are inability to reduce the hernia, the long segments of bowel involved, hemorrhage from the affected mesentery, and failure to close the entire mesenteric defect.[271]

Figure 36-15. The mesodiverticular band is evident as a thin fold extending to the antimesenteric surface of the jejunum. The jejunum was strangulated in a mesenteric rent at the point of attachment of the band and mesentery.

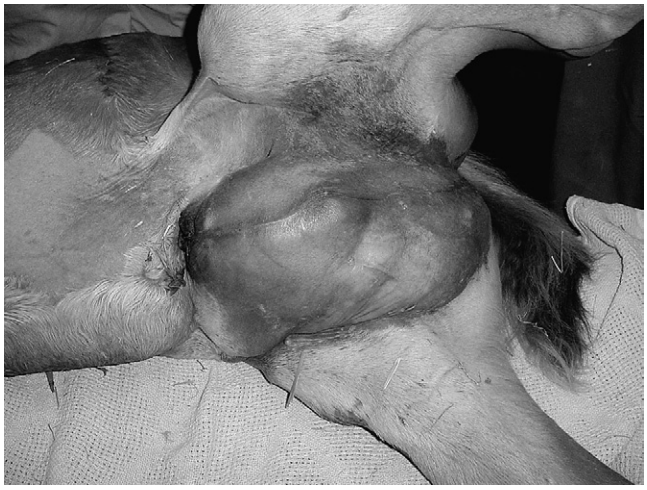

Figure 36-16. Direct inguinal hernia in a foal, with massive preputial and scrotal swelling from loops of small intestine beneath the skin. The tunic ruptured, allowing bowel to escape into a subcutaneous position. (From Bartmann C-P, Glitz F, von Oppen T, et al: Diagnosis and surgical management of colic in the foal. Clin Tech Equine Prac 1:125, 2003, with permission.)

Complete closure of the defect can be difficult or impossible through a ventral midline approach.[274] Elective laparoscopic closure of the full defect can be accomplished as a standing procedure shortly after the ventral midline celiotomy is performed to treat the original strangulation.[274] Both sides of the abdomen may need to be examined to locate the tear.[274]

Inguinal Hernia

An indirect inguinal hernia is the most common form in horses, and it involves small intestine passing through the vaginal ring into the vaginal tunic (see also Chapters 39 and 59). In the less common direct inguinal hernia, jejunum and occasionally the testicle escape through a rent in the peritoneum and transverse fascia, adjacent to the vaginal ring, to lie in the subcutaneous space of the scrotum and prepuce (Figure 36-16).[275-277] Direct hernias are more common in foals than in adults, but they can involve greater lengths of intestine in adults than are recorded with indirect hernias.[275-280]

Figure 36-17. Dissected vaginal tunic in a foal with a congenital scrotal hernia, demonstrating the jejunum and the testicle above it and to the left. The cremaster muscle is evident on the left side.

Indirect inguinal hernias in adult horses involve short segments of small intestine (median of 15 cm [6 inches]) and are usually acquired and nonreducible, whereas congenital inguinal or scrotal hernias in foals involve long segments and are reducible.[280] In acquired hernias in adults, the loop of intestine rarely advances to the level of the testicle before it becomes strangulated, whereas a variable length of intestine (approximately 1 m [3 feet]) can reach the fundus of the vaginal tunic in foals and remain viable (Figure 36-17). This difference can be attributed to the shorter, wider, and more direct configuration of the foal's inguinal canal. Contrary to popular misconception, the size of the external inguinal ring is irrelevant to development of an inguinal hernia, because it is the last structure for the bowel to traverse and is always sufficiently large for intestine to negotiate easily. The vaginal ring is the first structure to be negotiated by herniated intestine, but the intestine is actually strangulated in an adult horse by a ring 2 to 3 cm further distad, formed by merging of the internal spermatic fascia into loose connective tissue in the neck of the vaginal process.[221,281]

Ileum, alone or with jejunum, was involved in 49% to 53% of adult inguinal hernias in three reports, but some hernias involve jejunum only.[96,278,280,282] Ileal involvement may be more likely with increased duration of strangulation.[221]

Many breeds can be affected, but a higher prevalence of inguinal/scrotal hernia has been reported in Standardbreds, Tennessee Walking Horses, and American Saddlebreds.[96,238,282,283] Standardbreds also appear to be at a higher risk for intestinal eventration after an open castration.[284] In acquired inguinal hernias, almost all age groups over 1 year are at risk.[227,283] Predisposing factors are not always evident but include a history of recent strenuous exercise, recent breeding, and trauma.[96,282,283] Direct and indirect inguinal hernias are rare in geldings.[279,283,285,286]

Congenital scrotal hernias are noted shortly after birth, are easily reduced when the foals are rolled onto their backs, and usually resolve spontaneously within 3 to 6 months. Intestinal strangulation is rare. Although the problem is usually unilateral, bilateral cases can occur. Direct or ruptured inguinal hernias in foals are evident within 4 to 48 hours after birth and cause intermittent colic, depression, severe scrotal and preputial swelling (see Figure 36-16), and edema, with skin excoriation and splitting caused by abrasion against the inside of the thigh.[275,276] These hernias are not reducible and are treated as surgical emergencies, although strangulation is rare.

Acquired inguinal hernias in adult horses cause signs of mild to severe colic.[282] As it becomes strangulated, the intestine compresses the testicular vessels and causes the testicle to become swollen, firm, and cold. Although the strangulated intestine may not be evident on external examination, rectal examination reveals small intestine entering the vaginal ring and distention of the small intestine. Bilateral cases are very rare.[282,287] Ultrasonography can facilitate early diagnosis and is especially useful if rectal palpation is not possible.[96]

SURGERY: CONGENITAL HERNIAS

Surgical correction is indicated if the hernia does not resolve spontaneously, the owner is concerned because of an apparent increase in size of the hernia, or the vaginal tunic ruptures. Surgical correction can be accomplished in foals through an inguinal approach with exposure of the tunic and its contents (see Figure 36-17), removal of the cremaster muscle, twisting of the testicle and tunic to force the bowel into the abdomen, and then closed castration combined with a transfixation ligature of 0 polydioxanone through the tunic (see Chapter 39). Closure of the external inguinal ring is suggested but not essential and may not prevent reherniation.[244,276,278,288] Alternative methods are laparoscopic repair with or without castration, an inguinal approach without castration, or a midline celiotomy with closure of the vaginal ring.[289,290] The testicle can atrophy after the latter two methods.

For repair of a direct or ruptured inguinal hernia in foals, the torn edges of the common vaginal tunic are identified and drawn upward to create a funnel through which the bowel is returned to the abdomen. The bowel can be directed into the abdomen by careful digital manipulation or by grasping the bowel gently in partly closed sponge forceps. The torn tunic should be repaired as much as possible to the level of the vaginal ring. Usually, the intestine is viable and does not require resection, although delayed necrosis has been reported.[276] Castration facilitates the repair and closure of the vaginal tunic.

SURGERY: ACQUIRED HERNIAS

In the early stages, a direct hernia in an adult may correct spontaneously after the anesthetized horse is placed in dorsal recumbency or can be corrected by applying gentle traction to the bowel *per rectum*, with or without external massage of the scrotum.[278,283,242] External massage alone may also be effective and can be guided by laparoscopy, which also allows assessment of intestinal viability.[281] In such cases, laparoscopic inguinal herniorrhaphy may be performed 1 week later to prevent recurrence, using either a mesh onlay graft or a cylindrical mesh plug.[291,292] Spontaneous reduction or reduction by traction does not rule out the possibility of complications from progressive intestinal necrosis.[278]

A nonreducible inguinal hernia is corrected through an inguinal incision directly over the external inguinal ring and along the spermatic cord. The abdomen should be prepared for a ventral midline celiotomy, if needed, to allow intra-abdominal traction on the bowel, to assess viability of the released bowel, to decompress or examine proximal bowel, or for a jejunocecal anastomosis. The tunic is dissected from the surrounding tissues, with care taken to not damage the pudendal vein and its branches. A cranial incision is made in the vaginal tunic, which needs to be extended far enough distad to cut the constricting ring formed by the internal spermatic fascia and release the strangulated intestine.[281] The tunic edges should be grasped with hemostats to maintain access for closure. Medial and cranial retraction on the edge of the internal abdominal oblique muscle with a Deaver retractor will improve exposure to the tunic edges, and a finger is used to direct bowel away from the suture line.

Because short segments (approximately 25 cm or 10 inches) of intestine are usually involved, resection is rarely needed if appearance of the bowel improves markedly after the strangulation has been released.[278,280] A unilateral castration is recommended to allow more complete closure of the vaginal tunic and abolish the risk of recurrence.[283] In addition, the involved testicle can become cystic or nonfunctional in time, and postoperative swelling could induce degeneration of the other testicle. Techniques to correct the hernia and prevent recurrence have been described.[289-292]

If the vaginal ring can be closed, closure of the external inguinal ring is not essential and does not ensure against evisceration.[278] However, if the vaginal ring closure is not secure, closure of the external inguinal ring is recommended. Closure of the thick subcutaneous fascia and skin incision is accomplished in two layers. After surgery, the scrotum on the castrated side usually lies against the prepuce, and swelling is minimal. Any method of correction that does not involve exploration of the abdomen would fail to detect a concurrent small intestinal volvulus, a rare complication of inguinal hernia that could cause postoperative colic.[96,220,221]

A survival rate of up to 76% has been reported for acquired inguinal hernia.[278,282,283] Adhesions at the vaginal ring are rare causes of later strangulation.[282]

Incarceration through the Gastrosplenic Ligament

Small intestinal incarceration through the gastrosplenic ligament is an rare cause of colic, with no breed or age predilection detected, although geldings appear to be at increased risk.[293] The jejunum is the segment most likely to be involved.[122,293] The gastrosplenic ligament is a broad but thin attachment between the left part of the greater curvature of the stomach and the hilus of the spleen.[1] Small intestine can pass from caudad to craniad through acute tears in this ligament so that the strangulated loop is lateral to the stomach and craniolateral to the spleen (Figure 36-18).[293,294] At surgery, the strangulation is easily corrected by traction, and enlarging the rent does not cause problems or predispose to recurrence. No attempt is made to repair the mesentreric defect, and the edges are not readily identified at surgery. If the most ventral edge of the defect in the ligament is accessible, it can be transected between two ligatures to disrupt continuity of the ring.[295] With appropriate surgical intervention and postoperative management, the short- and long-term prognosis for surgically treated horses is good.[293]

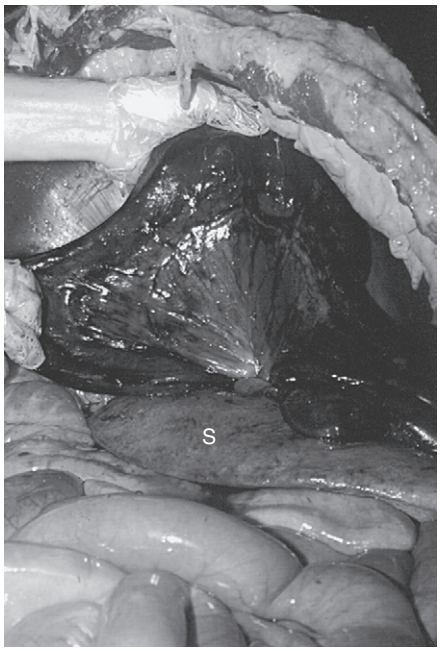

Figure 36-18. The jejunum is strangulated in a rent in the gastrosplenic ligament and lying in the left cranial part of the abdomen. *S,* Spleen.

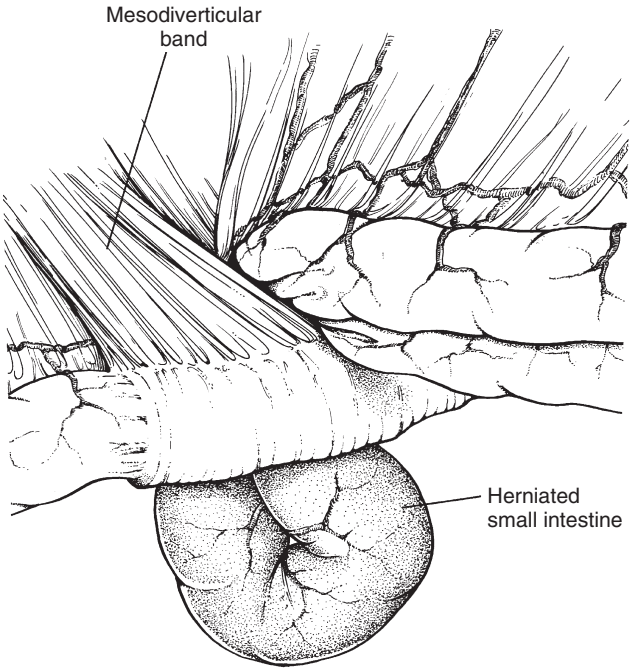

Figure 36-19. A mesodiverticular band and secondary mesenteric rent resulting in incarceration of the small intestine. (Redrawn from McIlwraith CW, Turner AS: Equine Surgery: Advanced Techniques. Blackwell, Oxford, UK, 1987.)

Vitelline Anomalies

A mesodiverticular band develops from a vitelline artery and associated mesentery that fail to atrophy during early embryonic development.[222] The band is usually found in the distal jejunum, approximately 1.5 m from the ileocecal junction. It extends from one side of the mesentery, usually the left, to the antimesenteric surface of the small intestine to form a triangular space (see Figure 36-15). Intestine may become strangulated in a mesenteric rent that forms in that space (Figure 36-19), and secondary volvulus of the small intestine follows.[222] A mesodiverticular band alone can also cause a volvulus because the band shortens the mesentery at the point of attachment.

Meckel diverticulum is a remnant of the omphalomesenteric (vitelline) duct that provides a communication between the yolk sac and early embryonic gut. It forms a conical blind extension from the antimesenteric surface of the distal jejunum or ileum, 40 to 120 cm (16 to 47 inches) from the ileocecal junction (Figure 36-20).[296,297] It can be up to 35 cm long, but it is usually 10 to 15 cm (4 to 6 inches) long and 5 to 10 cm (2 to 4 inches) in diameter.[222] Occasionally, a fibrous band persists from the apex of Meckel diverticulum to the umbilicus—the vitelloumbilical band—and creates an axis for volvulus of the jejunum and ileum.[219]

In one review of 15,000 necropsies, Meckel diverticulum was responsible for the death of all five horses (0.03%) in which it was found.[296] Meckel diverticulum can become impacted and achieve enormous proportions or become necrotic and rupture to cause fatal peritonitis.[296,298,299] Meckel diverticulum can also entangle and strangulate small intestine or form an axis for volvulus nodosus.[223,297,298,300] In one horse, a Meckel diverticulum was found adhered to and impacted in an umbilical hernia, thereby forming a Littre hernia.[301] Although Meckel diverticulum is a congenital anomaly, it can cause colic in horses of a wide age range and be an incidental finding at necropsy.[222,296-300]

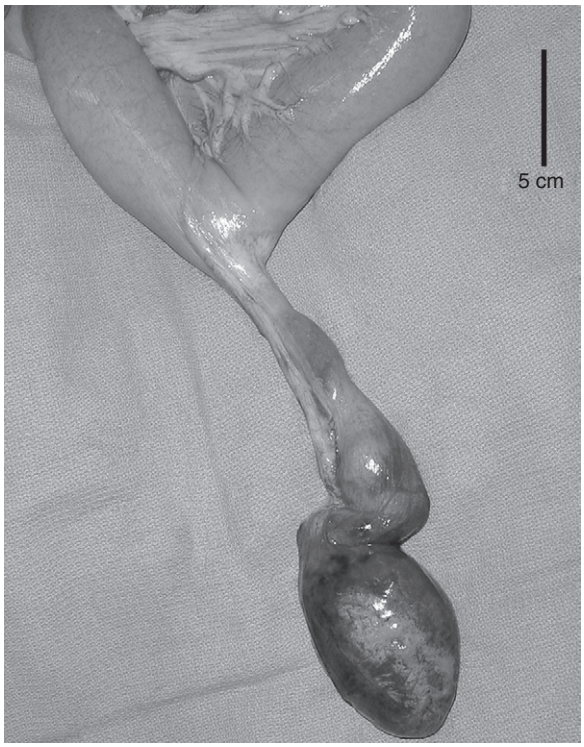

Figure 36-20. Meckel diverticulum that was knotted around the jejunum in a 5-month-old Clydesdale foal. The diverticulum was resected and the linear defect in the jejunum was oversewn. (From Bartmann C-P, Glitz F, von Oppen T, et al: Diagnosis and surgical management of colic in the foal. Clin Tech Equine Prac 1:125, 2003, with permission.)

Strangulated Umbilical Hernia

Strangulation of a loop of small intestine in an umbilical hernia is rare, and the involved intestine can rupture through the hernial sac and dissect subcutaneously in a caudal direction to cause an inguinal enlargement (see also Chapter 39).[302] More commonly, only a portion of the antimesenteric wall of the ileum is incarcerated, and this is termed a *parietal*, or *Richter*, *hernia*.[302,303] A parietal hernia should be suspected when an umbilical hernia acutely becomes nonreducible, large, firm, edematous, and painful to palpation. A parietal hernia can cause umbilical abscessation, which may lead to rupture of the hernia and formation of an enterocutaneous fistula.[302,303] Ultrasonography may be used to evaluate the hernia and its contents.[125] Colic can develop in horses with a parietal hernia, but it is not observed in all cases with an umbilical abscess or enterocutaneous fistula.[302,303] Surgical correction of these umbilical lesions is successfully accomplished by making a 10- to 15-cm (4- to 6-inch) celiotomy cranial to the ring and digitally guiding *en bloc* removal of the umbilical lesion through this incision. Resection and anastomosis of involved intestine may be required.

Diaphragmatic Hernias

A diaphragmatic defect can be congenital or acquired, although the distinction is difficult (see also Chapter 39). Small intestinal strangulation in diaphragmatic defects has been reported in foals as the cause of death at 7 hours to 8 days after birth.[304] A congenital diaphragmatic defect or a diaphragmatic tear inflicted by a rib fracture, usually at or close to the costochondral junction of ribs 3 to 8, are likely causes of diaphragmatic hernia in foals.[304,305] The most common causes of diaphragmatic hernia in adult horses are trauma, parturition (particularly dystocias), and recent strenuous activity.[306] In some horses, the presence of omental adhesions to a callus on fractured ribs on the thoracic side of the defect is suggestive of previous trauma, possibly at birth.[307,308] Although several abdominal organs can enter the diaphragmatic defect, small intestine is the most commonly reported.[309] There does not appear to be an age, breed, or sex predisposition to this disease.

Large defects are more likely to cause dyspnea from pulmonary compression by intrathoracic displacement of the colon, but they do not incarcerate bowel and cause colic.[306,310] Small defects are more likely to strangulate small intestine and manifest as acute and severe colic, clinically indistinguishable from strangulation by any other cause. Abnormalities can be detected on auscultation and percussion of the thorax in some horses.[311]

Both radiography and ultrasonography allow preoperative diagnosis.[312-315] Ultrasonography may be superior to radiography in evaluating diaphragmatic hernias in horses, especially for small tears with little visceral displacement, or when pleural effusion obscures the ventral portion of the diaphragm.[316] The diaphragm can be imaged with 5- or 7.5-MHz transducer adjacent to and parallel with the body wall ventrally, then diverging dorsally and medially to lie behind the echogenic lung.[316] The curved shape of the diaphragm may prevent complete evaluation.[316]

SURGERY

A diaphragmatic hernia can be missed at surgery.[317] If strangulated bowel is found free in the abdomen, a careful search must be conducted to ensure that it did not fall out of a diaphragmatic defect when the horse was placed in dorsal recumbency.[317]

Ideally, a respirator should be used to provide controlled positive-pressure ventilation and correct the diminished pulmonary function. An advantage of preoperative diagnosis is that the abdominal incision can be placed further craniad than the standard approach. Access to ventral defects is not difficult, but access to more dorsal defects can be improved by extending the cranial end of the incision laterally for approximately 12 to 15 cm (5 to 6 inches) at an angle of 60 to 90 degrees in a paracostal fashion (J-shaped incision). The table can be tilted to raise the cranial end of the horse's abdomen so abdominal contents can fall away from the diaphragm.

A small defect may have to be enlarged with scissors or a curved fetotome to release the bowel.[244,307,311,313] Most defects can be closed with a continuous pattern using heavy absorbable or nonabsorbable material, and the suture line should be completed at full inspiration to reduce the pneumothorax present. Mesh coverage is required for defects that cannot be sutured because of their large size or because the edges are too firm to allow apposition.[244] Successful repair of a dorsal rent that was inaccessible for suture placement was accomplished by blind fixation of a doubled polypropylene mesh (Marlex Mesh No. 1266) with 4-mm stainless steel staples (disposable skin stapler).[315] Another inaccessible defect was repaired in the standing horse by suture closure through a thoracic rib resection that was placed by guidance from thoracoscopy and manual direction through a flank incision.[318] Indwelling chest tubes covered by a Heimlich valve (see Chapter 17) can be placed to correct pneumothorax and fluid accumulation in the chest.[244]

Successful repairs of diaphragmatic hernias have been reported in adult horses and foals, and horses can race, participate successfully in various forms of competition, and deliver foals after repair.[244,306,307,310,312,313,315] One horse with a small defect that was inaccessible for repair returned to a full athletic career.[313] Unrepaired diaphragmatic defects can partly seal by adhesion of adjacent stomach, omentum, or liver to the edges, but recurrence of intestinal incarceration immediately after anesthetic recovery is also likely.[315,318]

Miscellaneous Strangulating or Ischemic Diseases

Small intestine can become strangulated in mesenteric ligamentous bands that cannot be exteriorized at surgery and must be cut blindly with scissors. Small intestine can also become strangulated by uterine torsion; through rents in the mesometrium, gastrohepatic ligament, small colon mesentery, lateral ligament of the urinary bladder, cecocolic fold, and mesentery of the large colon; by components of the spermatic cord, particularly the mesoductus deferens; and by omental adhesions.[129-131,133,221,319-323] Evisceration through a lacerated vaginal fornix, a defect in the bladder and urethra, or a castration wound may cause small intestinal strangulating obstruction.[284,324] Entrapment of small intestine within the nephrosplenic space has been reported in two horses, with the bowel passing from craniad to caudad.[325] Both horses were presented alert and in stable condition, and the affected segments of bowel did not require resection.[325] Mesenteric hematomas of unknown origin can cause colic and ischemic necrosis of affected intestine.[326] Surgical access to the source of hemorrhage may be difficult.[326]

Adhesions after small intestinal surgery or any intra-abdominal procedure can form an axis around which attached small intestine can form a volvulus, or adhesions can form fibrous bands through which small intestinal loops can become strangulated.[224,327] Nonstrangulating infarction and necrotizing

enterocolitis in the small intestine are rare and have a poor prognosis.[125,328]

SURGICAL TECHNIQUES

Success of small intestinal surgery in the horse is dependent on (1) identification and correction of the primary problem, (2) intraoperative decompression of distended small intestine, (3) resection of all intestine identified as nonviable or altered by an irreversible disease, (4) preservation of anatomic and physiologic continuity of the mesentery and intestine, (5) rapid completion of the surgery with minimal trauma, (6) early return of intestine to normal function, and (7) appropriate postoperative support, including repeat laparotomy when indicated.

If the lesion is not revealed quickly by a cursory examination of the abdomen, the cecum should be found and the ileocecal fold traced to the ileum, followed by progressive examination of the jejunum toward the duodenum until the involved segment is found. If several discontinuous loops of small intestine are exteriorized through the incision, they form tight bands of mesentery that can prevent extraction of other distended loops. Rarely, a horse has two apparently unrelated strangulating lesions of the small intestine.[221,329] However, it is more common for a horse to have a concurrent large intestinal lesion, such as volvulus, displacement, or impaction.[89,330]

Viability Assessment

Viable small intestine refers to the ability of strangulated or ischemic intestine to survive without developing adhesions and other complications (for additional information, see Chapter 33). The observation that increased duration of surgery and length of bowel resected can adversely affect prognosis provides impetus to improve viability assessment and thereby avoid resection whenever possible.[246] Clinical criteria of viability are serosal color, improvement in color after correction of the strangulation, presence or absence of mesenteric arterial pulses, and intestinal motility, spontaneous or evoked (by snapping a finger against the intestinal wall). Clinical judgment tends to be pessimistic. Fluorescein fluorescence offers little improvement over clinical judgment but is accurate when it produces a viable fluorescent pattern.[331]

Intestine can be considered viable if the predominant clinical findings are hemorrhage and edema in the bowel wall, especially if the color improves within approximately 15 minutes after release of the obstruction.[332] Spontaneous or evoked motility appears sluggish in viable strangulated bowel because of "splinting" of the muscle wall by edema and hemorrhage. Enterotomies are not recommended for viability assessment in the small intestine because of the risk for adhesion formation and because mucosal changes are usually sufficiently severe to cause an incorrect prediction in viable bowel. With long segments of questionable viability, the risk for adhesions must be balanced against the risks of additional anesthesia time and the occurrence of adhesions after resection and anastomosis.

Resection

After the lesion has been corrected, the bowel must be arranged in its correct orientation and then decompressed, if necessary. Decompression is accomplished through the strangulated bowel, but only after the bowel has been freed from its mesentery and mobilized from the surgical field. For this purpose, a ligature of 2-0 polydioxanone (PDS) is applied to the first mesenteric vessel in the strangulated bowel, level with the proposed line of mesenteric resection. The mesenteric vessel is then transected distal to the ligature with the LDS (see Figure 17-14). The short end of the ligature is secured with a hemostat, and the long end is used to gather the trimmed edge of mesentery as each mesenteric vessel is transected with the LDS instrument (Figure 36-21). Ideally, the line of mesenteric resection should remain at a constant distance from the bowel, because any deviation toward the mesenteric root will shorten the mesentery and kink the bowel.[244] The two ends of the suture are tied to close the gathered mesentery after the bowel is decompressed, and a gap will remain to be closed between the bowel and the line of mesenteric resection (see Figure 36-21). With this method, ligated vessels can be retained in view outside the abdomen for continued inspection, and formation of a large mesenteric gap, which would allow rotation or entrapment of bowel, is prevented.[244]

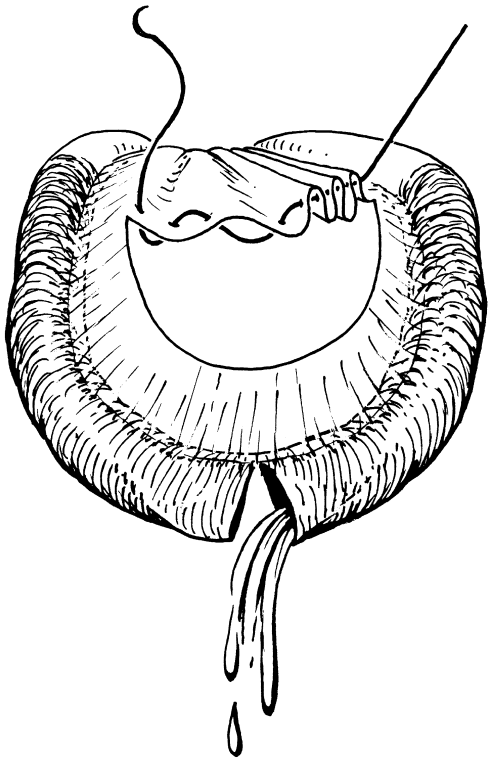

Figure 36-21. Method of resecting and gathering the mesenteric edge and then draining the bowel through the strangulated segment. Note that the line of resection should stay parallel to the bowel. (Redrawn from Freeman DE: Surgery of the small intestine. Vet Clin North Am Equine Pract 13:261, 1997.)

The nonviable intestine can now be exteriorized from the abdomen, far from the surgical field, to drain into a container, taking care not to stretch and tear remaining mesenteric attachments. As much intestine as possible proximal to the site of transection is manually stripped of its fluid and gas contents, with care taken not to tear the mesentery. This amount of intestinal handling does not appear to cause problems, and decompression seems to minimize the risk of postoperative reflux. If resection is not needed, small intestinal distention should be relieved through a typhlotomy and not a small intestinal enterotomy, to reduce the risk of adhesions to the latter.

Strangulated bowel is removed along with approximately 30 to 50 cm (12 to 20 inches) of contiguous healthy intestine at

each end. A large arcuate artery, no more than 10 cm (4 inches) from its origin from the major mesenteric vessel, is left to supply the anastomosed ends. Approximately 2 to 10 cm (1 to 4 inches) of mesentery is left beyond the last major vessels and branches to prevent inadvertent vascular occlusion or puncture during closure of the mesenteric gap. After the anastomosis is complete, the bowel is lavaged. The defect remaining in the mesentery is closed with 2-0 or 3-0 PDS in a simple continuous pattern, with care taken to avoid mesenteric vessels or creating an accordion effect that could kink the bowel.[244] If the mesenteric stump is inflamed and hemorrhagic, adjacent healthy mesentery can be wrapped around it.[130]

Hand-Sewn End-to-End Jejunojejunostomy

To prevent leakage into the surgical field, a Penrose drain may be applied 45 cm (18 inches) proximal to the anastomosis site to avoid trauma to this critical area (Figure 36-22). Penrose drains are less traumatic than Doyen clamps and facilitate manipulation and positioning of the bowel. To create a large stoma, the intestine should be transected at approximately 50 to 60 degrees from the mesenteric attachment; an S-shaped line of transection will increase the diameter further without creating sharp angulations in the incision edges. A suture is placed through the mesenteric and antimesenteric edges of both segments to draw them into alignment and to maintain them at similar diameters. With all end-to-end anastomoses, special care must be taken to appose the mesenteric border first, because rapid edema formation at this area can make it difficult to identify the seromuscular layer.

A popular method for end-to-end anastomosis of equine small intestine is a two-layer continuous pattern.[333] This involves a simple continuous pattern of 2-0 or 3-0 absorbable suture for the submucosa and mucosa, followed by a continuous Lembert or Cushing pattern in the seromuscular layer (see Figure 36-22). The Lembert pattern can be placed to minimize inversion. Mucosal and seromuscular rows are interrupted at the mesenteric and antimesenteric margins or at thirds of the circumference to prevent a purse-string effect. The Cushing pattern exposes less foreign material to the serosa and therefore poses less risk for adhesion formation than the Lembert pattern, but the Cushing is more likely to purse-string the bowel. The degree of inversion is greater with the Lembert pattern, so special care is needed to minimize this effect (see Figure 36-22). Combinations of patterns that involve two layers in the seromuscular wall, such as continuous appositional, Lembert, Cushing, or Connell oversewn with Lembert or Cushing, produce excess seromuscular inversion, stomal constriction, and a high risk for postoperative obstruction.[258,298,334,335] There is ample evidence that single-layer anastomoses work well in equine small intestine (for additional details on suture patterns, see Chapter 16).[139,244,333-336]

The Gambee and other interrupted patterns are more likely to cause anastomotic adhesions in the horse than continuous patterns,[333,337] although results of one study did not confirm this.[335] Larger sizes of suture material, such as 0 PDS or polyglactin 910 (Vicryl), could predispose to adhesions because they place a greater volume of foreign material along the anastomosis than 3-0 PDS, which is preferred.[244,333,337] An interrupted Lembert pattern is used with approximately 6- to 8-mm

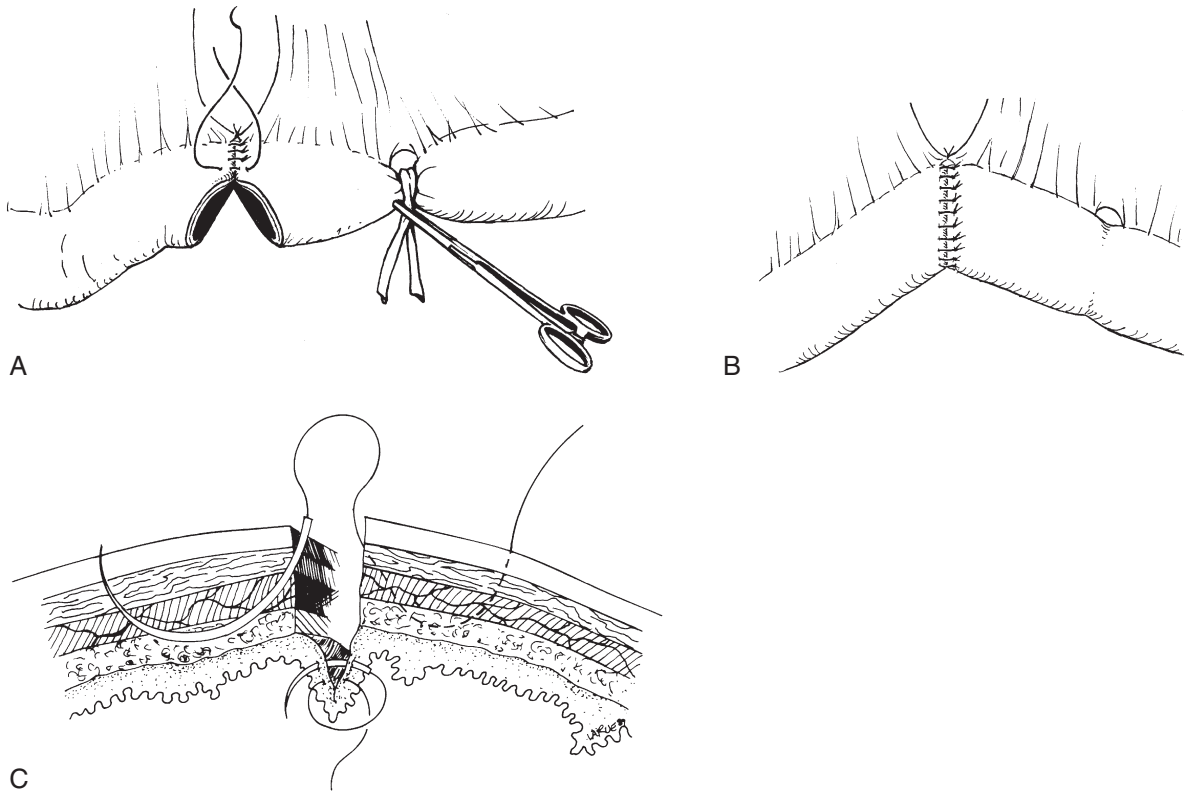

Figure 36-22. A and **B,** The lumen of the small intestine is occluded temporarily with a Penrose drain proximal to the anastomosis site. A one-layer closure consisting of interrupted Lembert sutures is carried out. **C,** Close-up of an alternative (two-layer) anastomosis technique: a simple-continuous apposition of the mucosa over three times a third of the circumference, followed by a minimal inversion pattern of the seromuscular layer.

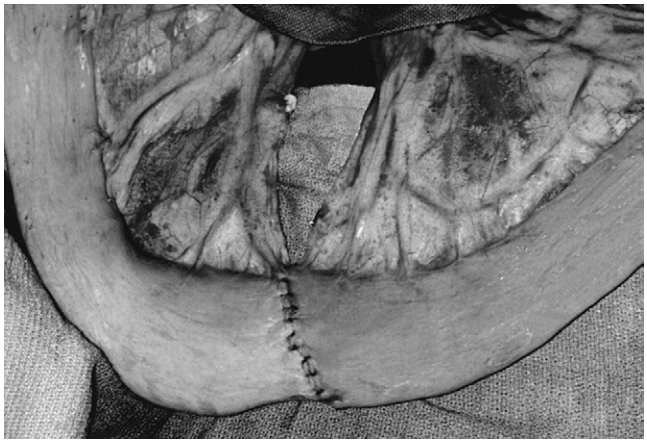

Figure 36-23. End-to-end anastomosis with interrupted Lembert sutures before the mesentery is closed. Note the darker discoloration of the bowel to the right, which is caused by prestenotic distention.

bites that penetrate the cut edge of the seromuscular layer and are 6 to 8 mm apart (Figure 36-23). This pattern may be less likely to induce adhesions than the Gambee method, and it is faster.[244]

A single-layer anastomosis with 3-0 PDS through the full thickness of the equine jejunum and wrapped with a sodium carboxymethylcellulose and hyaluronate membrane was faster than mucosal closure followed by a Cushing pattern.[336] Also, the single-layer anastomosis reduced lumen diameter from normal adjacent lumen by 35.6%, compared with a 44% reduction for mucosal closure and a Cushing pattern.[336] It also developed significantly fewer perianastomotic adhesions than a single-layer anastomosis without the membrane.[336] With this single-layer pattern, care must be taken to minimize mucosal eversion, because mucosa does tend to protrude between the seromuscular edges, which could lead to adhesion formation.[336]

Stapled Jejunojejunostomy

The major advantages of stapling instruments are speed, reduced tissue handling, improved tissue blood flow, and minimal contamination.[338] If the staple line is oversewn, the first two advantages are lost and the prevalence of adhesions becomes comparable to that with hand-sewn anastomoses in horses.[338] The most important disadvantage of staples is expense, and there is no evidence that anesthesia time is sufficiently shortened to compensate for this in colic surgery.[257,287] The security of the closure with staples can be affected by tissue thickness, and the 4.8-mm staples (green cartridge) are preferable to the 3.8-mm staples (blue cartridge) for equine gastrointestinal surgery.

With the exception of the end-to-end anastomosis instrument, which is too small for adult equine intestine, other available stapling instruments are used in a side-to-side manner. By necessity, side-to-side anastomoses disrupt the normal anatomic and physiologic polarity of the bowel. In canine jejunum, 91% of MMCs can cross an end-to-end anastomosis at 12 weeks after surgery compared with 56% at 2 years after a functional end-to-end anastomosis.[339] Stomal dilation and delayed obstruction have been reported after stapled side-to-side anastomoses in dogs and after a hand-sewn version of a side-to-side anastomosis in horses and rats.[130,339] In a study on dogs, the functional end-to-end anastomosis also altered intraluminal flora compared with a hand-sewn end-to-end anastomosis, evidence that it imposed some nonphysiologic changes on intestinal function.[339] In addition, increasing the number of raw edges (although inverted) and the number of suture lines and staple lines increases the number of potential foci of inflammation in a side-to-side anastomosis. In a retrospective study in horses, no difference was found between hand-sewn end-to-end anastomoses and stapled side-to-side and stapled functional end-to-end anastomoses with regard to short- and long-term survival, duration of surgery, or prevalence of postoperative ileus.[257] However, the stapled side-to-side anastomoses had a shorter duration of postoperative ileus than the others, a finding weakened by a lack of critical details about the types of hand-sewn anastomoses used in the study.[257] Also, a more recent study described an increased risk of postoperative ileus (POI) after side-to-side jejunojejunostomy.[340]

Side-to-Side Stapled Jejunojejunostomy

The isoperistaltic side-to-side technique involves creating blind stumps of the proximal and distal ends of the jejunum with either a Parker-Kerr technique (see Figure 16-8, *D*) or stapling instruments (see Figures 16-12 and 16-13).[244] The gastrointestinal anastomosis (GIA) instrument is used to create the stoma in the overlapped segments. This places two parallel rows of staggered staples on each side of a stoma cut simultaneously by advancement of the knife blade (Figure 36-24). If the GIA-50 is used, it is placed orad and then aborad through the same stab incisions on the antimesenteric side, effectively doubling the size of the stoma. Care must be taken to ensure that the staple lines overlap on the far side of the stab incisions or that any defect on that side is oversewn.[341] If the Multifire GIA-80 or ILA-100 is used, a single application is sufficient. The two mesenteric edges are sutured to the adjacent mesenteric surfaces at the points of overlap.

Functional End-to-End Stapled Jejunojejunostomy

With the functional end-to-end anastomosis, the bowel ends are lined up in antiperistaltic fashion, the stoma is created with the GIA instrument along apposing surfaces, and bowel ends are closed.[244,342] A closed, stapled, one-stage, end-to-end jejunojejunostomy can realign itself into an end-to-end configuration as it heals and did not cause adhesions in normal horses.[342] Intussusception of a functional end-to-end anastomosis has been reported in ponies at 2 and 26 days after surgery and in a horse at 8 months after surgery.[256,257]

Jejunocecal and Ileocecal Anastomoses

Jejunocecal and ileocecal anastomoses are indicated when a portion of the ileum is involved in a strangulating lesion. These techniques can constitute 36% to 68% of all small intestinal anastomoses.[91,245,343] Proponents of the side-to-side jejunocecostomy believe that it creates a larger stoma than is possible with the end-to-side technique and that it is associated with fewer postoperative problems from stomal edema.[130,344] In a study that compared the two techniques in clinical cases, 83% of horses with a side-to-side jejunocecostomy were discharged from the clinic, compared with 37% that had an end-to-side jejunocecostomy.[345] The latter also had more repeat celiotomies,

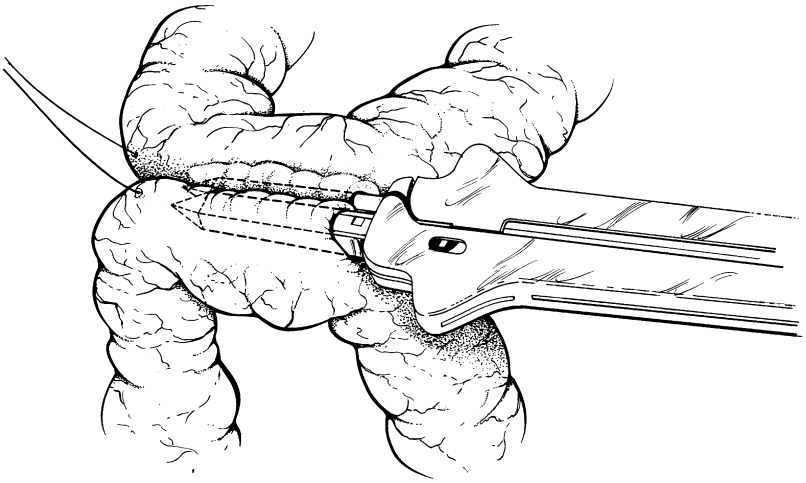

Figure 36-24. GIA-50 Premium stapler with disposable cartridge used for a side-to-side anastomosis. Stay sutures are placed at either end of the proposed anastomotic site to approximate the bowel segments side by side, and a stab is made into both bowel segments large enough to accommodate each fork of the instrument. The instrument forks are inserted fully to maximize stomal size. The stab incisions are apposed with an inverting suture pattern (not shown). (Copyright 1974, 1980, 1988, 1998, 2005 United States Surgical, a division of Tyco Healthcare Group LP. All rights reserved. Reprinted with permission of United States Surgical, a division of Tyco Healthcare Group LP.)

necessitated by such complications as bowel kinking at the anastomosis, adhesion formation, impaction, intussusception of the anastomosis, and volvulus or torsion.[345] An angled line of transection of the jejunum or ileum, with or without a longitudinal incision on the antimesenteric side, allows construction of a stoma of adequate size with the end-to-side technique.[244]

The mesentery and small intestine are prepared as for an end-to-end anastomosis except that the ileum is transected and oversewn using a Parker-Kerr technique (see Figure 16-8, *D*).[244] The ileal stump should be as short as possible, because an intussusception can form into the cecum over time,[346] and a long stump can progress into and obstruct the cecocolic orifice.[347,348] The ileal stump remains nonfunctional and therefore can tolerate more severe ischemia than would be acceptable in bowel that is expected to regain normal activity. One method proposed to reduce problems from an ischemic stump is to suture omentum over the suture line.[349]

For extensive ileal necrosis, the TA-90 can be used for a distal transection down to the ileocecal orifice.[350] The 4.8-mm staples are recommended for this purpose.[90] An incision is made in the mesentery dorsal to the ileal artery and in the ileocecal fold, and it is continued to the level of ileal transection to create a tract for passage of a loose ligature to that point.[350] This ligature is tied to compress all mesenteric tissues at the level of transection, including the ileal artery and vein. The disadvantage of this and other methods of deep ileal transection is that they create a large mesenteric defect that could entrap bowel.[350] An alternative method is to attach the ileum to a length of stomach tube that can be used to invert the necrotic stump into the cecum.[351]

End-to-Side Anastomosis

The stoma should be created as close to the base of the cecum as possible to reduce the gravitational effects of cecal contents.[244,352] The stoma is made midway between the dorsal band and the medial band, and the small intestine is aligned so that it is directed toward the base of the cecum (Figure 36-25).

A noncrushing intestinal clamp can be used to clamp off a pouch of the cecum; however, elevation of a pouch of cecal wall by upward tension on stay sutures or on Babcock forceps is preferable, because it is less traumatic and allows more proximal access on the cecal body. After the mesenteric and antimesenteric ends of jejunum are attached to the selected area on the cecum by simple-interrupted sutures of 3-0 PDS, a Lembert or Cushing pattern apposes the back side of the jejunum to the cecum. An incision is then made in the cecum 5 mm from the suture line that corresponds with the opening in the jejunum. The next row is a simple continuous, full-thickness pattern, interrupted at the mesenteric and antimesenteric borders before it is continued for 360 degrees. A Cushing pattern on the near side completes the anastomosis. The free edge of mesentery is sewn to the cecum and then to the ileocecal fold, ending at the oversewn end of the ileum and the previously gathered mesenteric stump (see Figure 36-25). Failure to close this mesenteric defect can lead to subsequent passage of small intestine through it, followed by obstruction and even strangulation.[271,353]

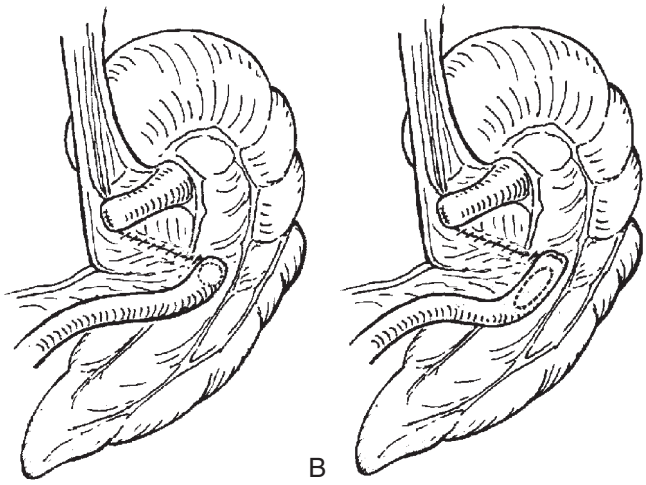

Figure 36-25. Completed end-to-side **(A)** and side-to-side jejunocecal anastomoses **(B).** In both methods, the ileum is oversewn by the Parker-Kerr technique and the mesenteric defects are closed. (From Freeman DE: Surgery of the small intestine. Vet Clin North Am Equine Pract 13:261, 1997, with permission.)

Side-to-Side Anastomosis

After the strangulated segment of small intestine is resected, the jejunum is transected and oversewn as for the ileum. The jejunum is attached to the selected area on the wall of the cecum (see "End-to-Side Anastomosis," earlier) with interrupted sutures of 3-0 PDS at the oversewn end and 10 to 12 cm (4 to 6 inches) proximal to this point (see Figure 36-25). Either a hand-sewn side-to-side method, GIA stapling instruments, or the cutting thread or saw technique can be used.[349,354] The saw

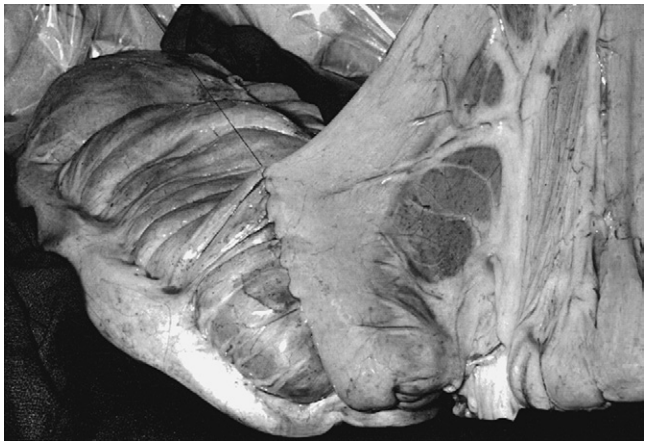

Figure 36-26. Side-to-side jejunocecostomy with the oversewn end of the jejunum in the foreground and facing the cecal base. The apparent divergence of the jejunum toward the medial band of the cecum is not real but the result of close positioning at the edge of the incision.

technique with wire or suture can effectively achieve a side-to-side anastomosis and reduces contamination more than the stapling method and without the cost.[354] A hand-sewn semi-closed single-layer jejunocecal side-to-side method has been shown to have some promise for this anastomosis.[355] Regardless of method, the oversewn end of the jejunum should not extend beyond the stoma or a stagnant loop will form, and it should be directed toward the cecal base (Figure 36-26). If the ileum is obstructed by a tumor, muscular hypertrophy, or chronic intussusception, an incomplete bypass can be used.[97]

The colon of horses with small intestinal strangulation is usually tightly contracted around dehydrated contents ("vacuum-packed" appearance), although it is not truly impacted in every case. Removal of these contents could eliminate some downstream resistance and provide a more favorable pressure gradient for emptying the small intestine into the cecum in horses with ileocecal or jejunocecal anastomoses.[356]

Jejunoileal Anastomosis

Jejunoileal anastomosis is an alternative to jejunocecal anastomosis (if sufficient ileum is available) and can be performed more quickly because fewer steps are required. The potentially greatest advantage over a jejunocecal anastomosis is preservation of normal anatomic and physiologic conditions in this critical part of the intestinal tract, particularly the ileocecal valve.[352] This anastomosis does have a tendency to obstruct,[244] although it functions very well in clinical use.[357] A two-layer anastomosis, with a simple-continuous pattern in the mucosa and a simple-continuous pattern in the seromuscular layer,[336] can prevent inversion and the associated risk of obstruction with this anastomosis.[357] In a study that compared an end-to-end jejunoileal anastomosis with an end-to-end jejunojejunal anastomosis in two groups of horses with similar preoperative parameters and types of lesions, postoperative complications and survival rates were similar between the two groups.[358]

Surgery of the Duodenum and Duodenal Bypass (See also Chapter 32)

Access to duodenum through a ventral median celiotomy is considerably easier in a foal than in an adult horse.[125,183] The abdominal incision should be extended to the xiphoid cartilage, and a J-shaped incision is required in an adult horse.[182] In addition, the table should be tilted to elevate the front end of an adult horse.[182] Access can be improved by retraction, packing of the abdomen with saline-soaked towels, and suction to remove some unavoidable contamination.[182]

Pyloric stenosis has been successfully corrected by pyloromyotomy, Heineke-Mikulicz pyloroplasty, gastrojejunostomy, or gastroduodenostomy.[125,182,183] For a side-to-side gastroduodenostomy, a hand-sutured anastomosis is preferred over GIA stapling, because stapled incision edges can heal together at the commissures of the stoma and cause stomal occlusion.[125] Additionally, stapling instruments are difficult to use in the limited space.[125] In one foal, a focal duodenal stricture was corrected by transverse closure of a full-thickness longitudinal incision that spanned the lesion.[359] Choledochojejunostomy and duodenojejunostomy have been used successfully in foals with obstruction of the common bile duct and duodenum at the level of the hepatopancreatic ampulla.[125] A duodenojejunostomy can be used to bypass a duodenal stricture beyond the hepaticopancreatic ampulla.[125] A side-to-side jejunojejunostomy can be performed distal to bypass procedures to prevent intestinal contents from stagnating in the blind loop between the obstruction and the stoma.[125] The contents of this loop can pass aborad through this stoma, without entering the stomach.

After surgical treatment of gastroduodenal ulcer disease in foals, the survival rate to hospital discharge is excellent and the long-term prognosis in restoring the patient to a reasonable level of performance is good.[360,361] Obstruction of the duodenum (rather than the pylorus), adhesions to the duodenum, and postoperative ileus were significantly associated with decreased long-term survival.[361] Factors that may improve survival compared with earlier reports include better case selection and performing the gastrojejunostomy with the jejunum oriented so that the oral end is to the left of the abdomen.[361]

A side-to-side gastrojejunostomy has been used in an adult horse with DPJ.[362] In protracted cases of DPJ that do not respond to appropriate medical therapy, bypass procedures have been developed to drain the affected segment of small intestine into more normal distal segments, so that the large volumes of fluids can be reclaimed by intestinal absorption. In one method, a temporary duodenocecostomy is performed through a 25- to 30-cm-long (10- to 12-inch-long) incision between the 17th and 18th ribs to approach the duodenum before it turns through its caudal flexure behind the base of the cecum.[363] Adjacent portions of duodenum and cecum are joined by the "cutting-thread" technique, which creates a stoma 2 cm in diameter. The goal is to allow the distended duodenum to drain into the cecum, with spontaneous closure of the fistula when the condition has resolved. A carbohydrate absorption test can be used during the recovery stage to determine if the stoma has healed spontaneously. A duodenojejunostomy through a ventral midline celiotomy is an alternative procedure for horses with DPJ and is effective in reducing gastric distention and reflux.[101] An adult horse that had a gastrojejunostomy for DPJ became lethargic for 1 to 2 weeks after a grain diet, suggesting that it had developed the "dumping syndrome," a metabolic consequence of rapid influx of gastric contents into the jejunum.[362] Although this horse did well for a follow-up period of 8 years after gastrojejunostomy, it had trouble maintaining body weight for the first year after surgery.[362]

Duodenal impactions can be treated successfully with massage of the intestinal contents into the stomach for removal

by gastrotomy or into the jejunum for manual disruption or removal by enterotomy.[193,197,199] Failure of these methods can be followed by enterotomy through an incision in the dorsal paralumbar space, 3 cm caudal to the 18th rib.[195] Location of this incision over the duodenal obstruction could be guided with some precision by ultrasonography.

Small Intestinal Enterotomy

A longitudinal enterotomy on the antimesenteric surface of the small intestine can be required for removal of impactions with food components, foreign material, or ascarids (see Figure 36-5) or to empty a segment of distended bowel to facilitate reduction of a strangulation in the epiploic foramen.[244] Methods to prevent adherence of intestinal contents to the serosa around the incision include constant lavage of the bowel with warm saline or precoating the proposed enterotomy site with sodium carboxymethylcellulose. The enterotomy can be closed with a single layer (Lembert or Cushing pattern) using 2-0 PDS on a taper needle, or in two layers, such as a simple-continuous pattern in the mucosa followed by an inverting pattern. Advantages of the Cushing pattern for the final row are that less suture material is exposed to the peritoneal cavity, and there is minimal inversion. Any closure method should minimize lumen reduction and risk for adhesions.

An enterotomy is indicated to a lesser extent in small intestinal surgery than in colon surgery, and it should be avoided if possible and if other options are available, to prevent creation of a focus for adhesion formation. As mentioned before, intestinal viability should not be assessed by mucosal inspection through an enterotomy made specifically for this purpose, and seromuscular changes can be used instead (see earlier). Extensive strangulating lesions can be corrected without removing fluid contents, although gas can be removed through a 14-gauge needle tunneled beneath the seromuscular layer and connected to a suction device. The tunnel staggers puncture sites in the different layers so suture closure is unnecessary. A focal impaction with dehydrated intestinal contents can be softened by injecting saline through an 18-gauge needle into its substance or by mixing it with more proximal liquid contents. If a resection is not indicated, distended small intestine can be decompressed by massaging contents into the cecum, from which they can be removed by typhlotomy.

AFTERCARE FOR SMALL INTESTINAL SURGERY

Routine use of an indwelling nasogastric tube does not ensure against gastric rupture in horses[96,364] and can delay gastric emptying of liquids in normal horses.[365] Therefore repeated passage of a nasogastric tube to decompress the stomach when indicated by clinical findings, such as pain and increased heart rate, might be preferable to an indwelling tube.

Most horses can be offered a small handful of good-quality hay within 18 to 24 hours after surgery and this is well tolerated.[244] This can be repeated at 3- to 4-hour intervals and the amount increased slowly to a full ration within 3 to 4 days. The refeeding process requires great care and close observation, but it can stimulate return of intestinal function.[244] A high-fiber diet stimulates intestinal propulsive motility, probably through increased intestinal bulk from the copious secretions evoked.[366] Hay in small amounts is the most potent accelerator of intestinal transit in horses, especially when divided into small meals throughout the day.[22] There is also growing evidence that healing of an anastomosis is enhanced by flow of intestinal contents through it, compared with inactivity or bypass.[367]

Broad-spectrum antibiotics and flunixin meglumine are administered before surgery and continued for 3 days afterward. Intravenous fluids are administered at 2 L/hr to a 450-kg horse for the initial 12 hours after surgery; the rate is subsequently adjusted for changes in PCV and total plasma protein (see Chapters 3 and 40).[356] Prokinetic drugs are used almost routinely by some surgeons or as needed by others.[244,356]

REPEAT CELIOTOMY

Repeat celiotomy is a lifesaving procedure and can be required for 12% to 27% of small intestinal diseases and for 4% to 12.5% of all colic surgeries.[90,91,133,139,245,353,368-371] The need for repeat celiotomy is far greater after small intestinal surgery than after large intestinal surgery, and it is greater after jejunocecostomy than after jejunojejunostomy.[139,350,370,372] Although making the distinction between postoperative ileus and mechanical obstruction from anastomotic impaction, ischemia, adhesions, or others can be difficult, horses with mechanical obstruction usually demonstrate a greater degree of pain and have a progressive increase in heart rate.[139,356,370] The median time to relaparotomy in one study was 48 hours, with 67% of horses undergoing surgery within 72 hours of the first procedure.[370] The most common findings at relaparotomy are ileus, obstruction or impaction at an anastomosis site, and secondary intestinal ischemia.[371]

Two important disadvantages of a second abdominal exploratory are the risk for incisional infection and the expense; however, the benefits of this procedure can outweigh the risks and disadvantages in most cases, including prompt termination of hopeless cases and salvage of others with treatable lesions.[133,139] Survival after a repeat celiotomy ranges from 36% to 56.4% and can be as low as 20% on a long-term basis.[90,91,139,245,368-371] However, in one study, 74% of horses that were recovered after a second celiotomy were alive at 1 year after the second surgery.[370]

COMPLICATIONS AND PITFALLS

The most commonly reported complication of small intestinal surgery in the horse is POI, although the clinical distinction between this and anastomotic obstructions (Figure 36-27) is difficult. Typically, a mechanical obstruction is associated with greater and more persistent signs of abdominal pain than with POI, but this is not a consistent finding, especially later in the postoperative course. Technical errors are not well tolerated in small intestinal surgery in horses and can account for many complications. In a study of 74 horses that recovered from general anesthesia after small intestinal surgery, technical errors and errors in judgment were responsible for 8 of 14 repeat celiotomies (57%) and for 7 of 11 deaths during hospitalization (64%).[139]

Anastomotic Obstruction

Mechanical obstruction of the anastomosis can be caused by impaction, hematoma, constriction, excessive shortening of the mesentery, and other errors in technique. Stomas of marginal size are prone to obstruction because they are further reduced by postanastomotic edema.[373] This would seem to especially

Figure 36-27. Effects of prolonged (5 days) anastomotic obstruction caused by excessive shortening of the mesentery at the anastomosis. Note the hemorrhage in the proximal bowel to the right and the fibrinous adhesions in the loops in the right foreground.

jeopardize a two-layer anastomosis with inversion, because this construction can reduce the lumen size by approximately 25%.[334] Prolonged obstruction of an anastomosis can lead to peritionitis and adhesion formation (see Figure 36-27).

Small intestinal volvulus may develop in distended jejunum and at points of small intestinal fixation, such as at a jejunocecal anastomosis. Risk of this complication is increased in a jejunocecal anastomosis by failure to decompress intestine during surgery, by decompression into the cecum, and by placement of the jejunum toward the apex of the cecum, which twists the jejunum 180 degees.[139] Intussusception of the anastomosis has been reported in horses and ponies after functional end-to-end anastomosis, hand-sewn anastomosis, and inverting closure of a transverse enterotomy[255-258,337,374]

Jejunocecal and ileocecal anastomoses are usually associated with more postoperative complications than jejunojejunostomy,[139,350,372] except when performed as a bypass procedure without resection.[178] Problems with jejunocecostomy with resection can be explained by the bypass of the ileocecal valve and by the creation of a sharp transition between intestinal segments of dissimilar functions.[244] The jejunum must overcome intracecal pressure to empty, without the coordinating mechanism of the ileum and ileocecal valve.[4,5,48] Another factor that could contribute to postoperative complications is the presence of adhesions to a devitalized ileal stump and mesentery. In addition, after a jejunocecostomy, all the remaining small intestine was subjected to distention before surgery that could delay return of function afterwards,[72,73] whereas only a portion of the remaining intestine was subjected to distention with jejunojejunostomy.

Postoperative Pain

Abdominal pain in the early postoperative period is one of the most comon early postoperative complications and has been reported in 28.2% of horses after a single surgery for treatment of colic.[340] The prevalence of postoperative pain is higher after small intestinal surgery (43%) than after large intestinal surgery, and it is higher after surgery for ischemic lesions than for simple obstructions.[340] It is usually associated with postoperative gastric reflux.[340] If postoperative pain persists especially after medication, and the pain level is regarded as moderate to severe, a repeat exploratory celiotomy should be strongly considered. This is especially true if pain is associated with postoperative endotoxemic shock and reflux. If a colonic impaction is supected, especially if identified at surgery, mineral oil (2 to 4 L as needed) should be given by stomach tube.

Postoperative Endotoxemia

Postoperative endotoxemia was diagnosed in 60% of horses after small intestinal resection in one study.[245] Injection of the oral mucous membranes, combined with depression and persistently high heart rate, would support this diagnosis. Postoperative endotoxemia would seem difficult to explain after the ischemic small intestine is removed and would suggest that a serious complication has developed in the anastomosis or proximal to it that would warrant a repeat laparotomy.

Postoperative Ileus

Postoperative ileus has a reported prevalence that varies from 10% to 55.6% and a mortality rate of 13% to 86%, accounting for 9% to 43% of all deaths after small intestinal surgery.[139,375,376] In three studies on POI in horses, high heart rate, high PCV, small intestinal involvement, increased duration of anesthesia, and increased duration of surgery emerged as significant risk factors.[376-378] Additional risk factors identified in another study were high PCV at admission, increasing age, and length of intestinal resection.[379] The prevalence of POI can be the same after surgery for ischemic lesions of the small intestine as it is after surgery for simple obstructions. In addition, prevalence can be the same in horses that have resection and those that do not.[380] In one study on small intestinal surgery, no horse developed POI after jejunojejunostomy, whereas 20% of horses that had a jejunocecostomy did develop POI.[139]

Although prokinetic drugs can be used for treatment (see Chapter 40), the role of mechanical obstruction must not be overlooked, because this delays the use of repeat celiotomy. Many horses with postoperative ileus might benefit from decompression at a second surgery.[90] Pelvic flexure enterotomy (see Chapter 37) may reduce the risk for POI,[377] although this is not a consistent finding.[378]

Adhesions

Adhesions have been documented in 6% to 26% of horses after small intestinal surgery, with a marked decline in prevalence over time.[90,133,139,327,343] Adhesions usually cause signs of intestinal obstruction in the first 2 months after surgery, but adhesion-related obstruction can arise at any time. Although foals are considered to be especially prone, adhesion formation in juvenile Thoroughbreds after surgery for lesions of all parts of the gastrointestinal tract has been reported at 8%, similar to the percentage reported for adult horses.[381,382] Foals aged 15 days to 6 months seem more likely than weanlings and yearlings to develop adhesions and require multiple surgeries.[382] Factors that could contribute to adhesions are postoperative ileus, ischemia, foreign material, serosal abrasion by towels, excessive handling of bowel, and use of large suture material. Intra-abdominal sodium carboxymethylcellulose (SCMC) at the end of surgery improved survival rate in one study, presumably by

preventing adhesions, although necropsy results were not provided to demonstrate the role of adhesions in postoperative deaths.[383] Also, the results might have been an artifact of experimental design, such as use of SCMC only on the most recent cases in the series, which could benefit from overall improvements in colic management, and disproportionately fewer resections in the SCMC group.[383]

Short Bowel Syndrome

Short bowel syndrome has been documented in horses after extensive small intestinal resection, although horses can tolerate loss of 10 m to 10.7 m of small intestine.[90,139,259,343,364] According to one study, resection of 60% or more of small intestine can lead to malabsorption.[384] A subsequent study demonstrated that resection of 70% of the small intestine of ponies is well tolerated.[385] Clinical experience supports this conclusion, although the limit for resection can vary among horses, and residual bowel can compensate over time.[139,259] Mural congestion caused by venous strangulation can increase the length of the affected segment of small intestine by as much as 36%, so some correction for an increase in length after strangulation is needed to avoid an overly pessimistic estimate of the risk for short bowel syndrome.[386] A correction factor that would apply to different severities of strangulation encountered in clinical cases is difficult to establish, and therefore assessment of the remaining length of small intestine could be a more meaningful predictor of postoperative absorptive capacity.[386] A minimal length of 4.5 m (15 feet) of remaining small intestine would be adequate in an adult horse, which approximates what would be left after resection of 75%.[90,386] Removal of longer segments does not appear to be well tolerated, although one 450-kg horse left with 3.7 m (12.3 feet) did not develop short bowel syndrome, which is evidence of a tremendous individual variation.[139]

Other potential complications of extensive small intestine resection are liver disease and anorexia.[244,384] Bypass of the ileocecal junction by jejunocecal anastomosis without resection can allow cecal bacteria to seed the small intestine and cause an abnormal xylose absorption test in ponies, which is apparently not the case in horses.[384,387] Although based on findings from laboratory animals, postoperative dietary recommendations that may apply to horses with short bowel syndrome include complex nutrients as potent stimulants of intestinal adaptation, and fiber to increase colonic production of short-chain fatty acids (see Chapter 6).[386] Carbohydrates should be fed sparingly, as they are more likely than fats and proteins to induce osmotic diarrhea.[386]

Miscellaneous

Anastomotic dehiscence and peritonitis were rare in most studies, but they were a leading cause of death when staples (oversewn or reinforced with suture) were used for all small intestinal anastomoses in horses in one study.[178] Failure to effectively ligate mesenteric vessels can lead to postoperative hemorrhage. Occlusion or kinking of vessels or postoperative thrombosis of mesenteric vessels for unknown reasons can cause anastomotic necrosis.[139] Mesenteric rents at sites remote to the anastomosis have been described as causes of recurrent small intestinal strangulation and death years after the original surgery.[90,271] Other complications include pyrexia, jugular vein thrombosis, long-bone fracture, cecal impaction, myositis, gastric ulceration, recurrent colic, incisional infections, diarrhea, and pulmonary aspergillosis.[90,121,245-247,271,388] Horses that are treated for abdominal pain and require surgery have a lower prevalence of gastric ulceration compared with those that respond to medical therapy.[164] A concurrent large intestinal displacement can be found at surgery for a small intestinal lesion, or large intestinal distention or impaction can develop after small intestinal surgery.[89,139]

PROGNOSIS

Reported survival rates to discharge range from 80% to 94.4% in horses that had surgery of the small intestine and were allowed to recover from anesthesia.* Horses with lesions involving the small intestine tend to have lower survival rates than horses with diseases of the small or large colon.[380] There is strong evidence that survival rates in recent decades have improved over previous ones,[249,343,330] which might reflect earlier referral and improvements in surgical technique and postoperative care. These same improvements probably also reduce the severity of complications such as endotoxemia, jugular thrombosis, postoperative ileus, and wound infection.[247] Colic is one of the most common complications after discharge of horses that had small intestinal surgery, especially those that had resection and postoperative ileus, most likely the result of adhesion formation.[390]

In horses with small intestinal strangulating lesions, variables associated with low survival rates are high heart rates, long capillary refill time, pale mucous membranes, severe hemoconcentration, abnormal color of peritoneal fluid, exudation of cells and protein into peritoneal fluid, and failure to achieve a mean arterial pressure of at least 100 mm Hg.[249,330,391] After small intestinal resection, postoperative factors that were associated with nonsurvival were ileus, heart rate greater than 60 beats per minute at 24 hours, postoperative colic, and repeat celiotomy.[245,383] In 143 horses with entrapment in the epiploic foramen, survival was 75.6% if surgery was performed within 8 hours from the onset of colic, compared with 45.1% survival in horses that underwent surgery 12 hours or more after onset.[91] Multiple logistic analysis demonstrated that duration of surgery was not a factor associated with short-term survival in horses that had small intestinal resection, in contrast to its negative effect on survival when all types of colic are considered.[245,392] In two studies on small intestinal surgery, surgeons with more experience had significantly better survival rates than less experienced surgeons.[139,249]

In horses with colic from small intestinal disease, survival after simple obstruction can be similar to survival after strangulation obstruction[133,139] or worse.[380] Although length of resection does not appear to influence outcome, a trend toward lower survival has been reported after resection of greater than 2 m of intestine.[245,343,330,391] The length of bowel strangulated in the epiploic foramen was longer in nonsurvivors than survivors in another study.[91] Lesions that appear to have an adverse influence on survival are strangulation in the epiploic foramen and in mesenteric rents, and ascarid impactions.[156,246,271,392] Some of the increased risk associated with strangulation in the epiploic foramen can be explained by an associated lower preoperative total protein and longer duration of surgery in these horses.[391] Survival tends to be better after a jejunojejunostomy than after a jejunocecostomy or ileocecostomy, and jejunocecostomy is associated with increased likelihood of postoperative

*References 89, 130, 139, 178, 229, 234, 257, 379, 389.

abdominal pain and repeat celiotomy.* Volvulus at the anastomosis site, infarcted jejunum at the anastomosis site, and technical errors accounted for most complications from jejunocecostomy in one study,[139] whereas problems with the ileal stump caused 47% of surgery-related complications in another.[372] However, survivals after jejunojejunostomy and jejunocecostomy become similar over the long term.[139] Survival after jejunocecostomy or ileocecostomy without resection is better than after the same procedures with resection.[178] Correction without resection, as by reduction, bypass, enterotomy, decompression, or "kneading," has a better prognosis than after resection and anastomosis.[136,139,178,249]

Both hand-sewn and stapled jejunocecal anastomoses have similar long-term survival rates, although both types of anastomosis have inferior long-term survival and greater cumulative probability of developing colic than jejunojejunostomy.[393] Another study confirmed that short-term and long-term survival were comparable between hand-sewn and stapled jejunocecostomies (the latter not oversewn), and demonstrated that the probability of survival for up to 90 months was greater than 50% for both methods.[389] However, horses in the stapled group had a significantly greater prevalence of postoperative colic and combined postoperative colic and reflux than horses in the hand-sewn group during hospitalization.[389] They also tended to have greater need for repeat celiotomy and a greater prevalence of colic after discharge, although both of these differences were not significant.[389]

The survival rate after completed surgery for small intestinal strangulating lesions, including treatment by jejunojejunostomy, is similar for horses 16 years or older compared to mature horses, although there tends to be an overall decrease in survival after surgery with increase in age.[85] However, geriatric horses presenting with colic are more likely than mature horses to be subjected to euthanasia without surgery or during surgery,[85,87] probably because of a misconception about prognosis based on age, short remaining life expectancy after surgery, financial constraints, or presence of concurrent disease (e.g., Cushing's disease). Draft horses weighing more than 680 kg that have colic surgery can have longer durations of anesthesia, more postoperative complications, and higher mortality rates than draft horses weighing less than 680 kg.[394] Heavy draft horses that undergo small intestinal surgery have a worse prognosis for short-term survival than those undergoing large intestinal surgery[394] and poorer survival rates than reported for small intestinal surgery in predominantly light breed horses.[139] Small intestinal obstruction is rare in American Miniature Horses,[395] but aftercare of these horses and ponies is complicated by their high risk for developing hyperlipemia or hyperlipidemia.

In a report on foals with surgical colic, only 10% of those younger than 14 days survived to maturity compared with 45.8% of foals 15 to 150 days old.[135] In one study, 59% of foals that had surgery for colic survived to discharge, with 25% being euthanized while under anesthesia.[124] The survival for foals that had a small intestinal lesion (46%) was worse than for those with large intestinal lesions (80%).[124] Survival in foals is also greater after nonstrangulating lesions or simple obstruction than after strangulating obstruction.[124,137]

The pattern of survival after surgery for horses with small and large intestinal colics follows a triphasic pattern.[392] Most deaths occur during the first 10 postoperative days, with 69% during the first 100 days after surgery and a slower decline in death rate after that.[392] A study on horses that had small intestinal surgery confirmed this observation and also demonstrated that the risk for death from surgery-related problems diminishes markedly after 12 months.[139]

CHAPTER
37 Large Intestine

Peter C. Rakestraw and Joanne Hardy

CECUM

Anatomy and Physiology

The cecum is positioned between the small intestine and the large colon and located primarily on the right side of the abdomen.[1] It is a large cul-de-sac with an average length of 1.25 m and an average capacity of 30 L.[1] It has a comma-shaped appearance and is divided into three parts—the base, body, and apex (Figure 37-1). The base, which is the most dorsal part, is positioned in the right iliac and sublumbar region. It has a greater curvature dorsally and lesser curvature ventrally.[2] It extends craniad to the 14th or 15th rib, forming a blind end pointing ventrad. A transverse fold arising from the floor of the cecal base craniad to the ileocecal junction divides the base into a cranial and a caudal portion.[3] The cranial part of the base is developmentally part of the ascending colon and is called the *cupula*.[1-2] The cranial and caudal parts of the cecal base appear to function separately. The body of the cecum travels cranioventrad from the cecal base. Caudally, it lies against the right flank moving to a slightly more medial position as it extends craniad along the ventral body wall, narrowing toward the cecal apex, which is situated between the right and left ventral colon approximately 20 cm (8 inches) caudal to the xiphoid cartilage.[1-2] The cecal base is attached dorsally to the ventral surface of the right kidney, to the right lobe of the pancreas, and to a part of the abdominal wall caudal to these structures.[1-2] The cecal base is attached medially to the transverse colon and the root of the mesentery, from which the vascular supply reaches the cecum.

The body of the cecum has four longitudinal bands (teniae) located on the dorsal, ventral, medial, and lateral surfaces. The dorsal and medial bands end at the cecal apex. The ventral band usually joins the medial band near the cecal apex, and the lateral band may extend to the apex or fade out before reaching the apex.[1] The ileocecal fold runs from the antimesenteric border of the ileum to the dorsal cecal band. The cecocolic fold (ligament) runs from the lateral cecal band to the lateral free band of the right ventral colon.

The cecal blood supply derives from the cecal artery, a branch of the ileocolic artery. The cecal artery divides into the medial and lateral cecal arteries, which run with the corresponding veins in the medial and lateral cecal bands, respectively. The medial cecal artery is the major vascular supply to the cecal apex. The cecum is thought to be at risk for thromboembolic disease, since both cecal arteries arise from a single vessel without collateral circulation, and since the lateral and medial cecal arteries have minimal mixing of their two circulations.[4] However, microvascular studies indicate that there is a cecal rete arising from each of the cecal arteries that supplies an extensive submucosal plexus and that may provide an alternative blood supply in the event of a cecal embolus (Figure 37-2).[4]

The ileocecal orifice is located in the lesser curvature of the cecal base approximately 5 to 7 cm to the right of the median plane and at the level of the first or second lumbar vertebra.[1] The end of the ileum is partly telescoped into the cecum, which positions the ileal orifice in an elevation of an annular fold of mucous membrane. The annular fold contains a network of veins, which can distend the annular fold when engorged.[2] In this way, the ileocecal orifice is narrowed, preventing reflux of cecal contents back into the ileum. The lack of this functional sphincter may contribute to cecal reflux into the small intestine after a jejunocecostomy. The cecocolic orifice is located distal to

Figure 37-1. Figure 37-2. Schematic diagram of the cecal arterial rete that forms a meshlike network around the cecal veins before continuing on into the submucosal network plexus. The extensive rete and submucosal network may provide an alternative route for blood flow in the case of an arterial embolus. *1,* Marginal artery; *2,* marginal vein; *3,* secondary arcade; *4,* long artery and vein; *5,* teniae; *6,* branch supplying the teniae; *7,* vascular rete; *8,* lymph node and lymph vessels (shown only at one place).

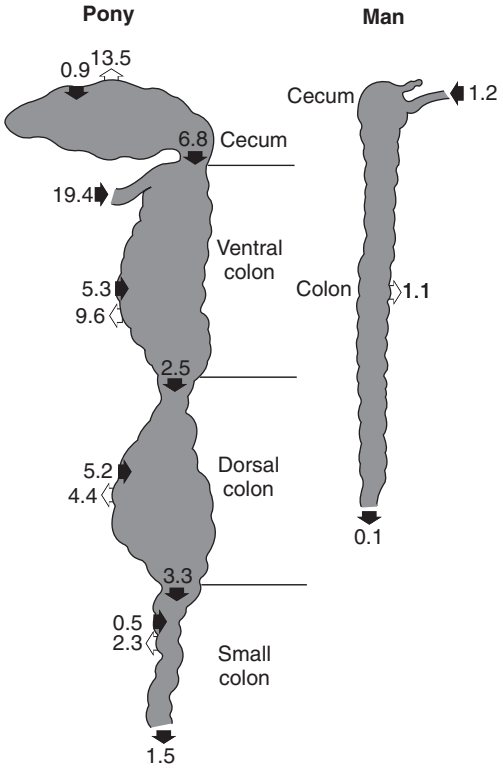

Figure 37-3. Net water movement through the large intestine of a 70-kg man and a 160-kg pony. Both species absorb approximately 90% of ileal outflow, but in a pony, this represents approximately 30 L/day. The volume is roughly equivalent to the animal's extracellular fluid volume. Note that the cecum of the pony has the greatest net water absorption. (Redrawn from Argenzio RA, Lowe JE, Prickard DW, et al: Digesta passage and water exchange in equine large intestine. Am J Physiol 226:1035, 1974.)

the ileocecal orifice. Because the cranial cecal base curves ventrally and caudally, the cecocolic orifice is positioned caudal and lateral to the ileocecal orifice (see Figure 37-1, *B*). It lies between two folds of tissue, which form the cecocolic valve. There is no sphincter at the cecocolic orifice.[2]

The two primary physiologic functions of the cecum (as well as of the large colon) are to absorb electrolytes and water and to serve as a site of microbial digestion.[5] The large intestine of a 160-kg pony reabsorbs a total of approximately 30 L of water a day, a volume equivalent to its extracellular space.[5] The cecum appears to be the site of greatest quantitative net water absorption (Figure 37-3). In an experimental model in ponies, the cecum demonstrated a net transmucosal influx of water during the first 2 hours after a meal, followed by a net absorption of approximately 600 to 800 mL/hr during the next 10 hours between meals.[6] Net increases in daily absorption of water from the ventral and small colon can compensate for decreased cecal water absorption.[6] Microbial digestion is the other important physiologic function of the cecum. A significant amount of soluble and most of the insoluble (e.g., cellulose, hemicellulose) dietary carbohydrate is digested by microbial enzymes in the cecum (and large colon) with production of organic acids (volatile fatty acids).[5] The marked decrease in bicarbonate in the cecum is because of the buffering effect of the organic acids. Although osmotic changes in organic acid (or volatile fatty acid) production has been speculated to control net water movement, sodium transport is probably more important.[5-6]

Cecal Motility

The transit time for liquid and particulate markers through the cecum is relatively rapid compared with that in the large colon.[5] There does not appear to be any retrograde movement of ingesta through either the ileocecal or the cecocolic orifice. Several studies have described normal cecal motility by examining cecal myoelectric activity patterns.[7-9] Ingesta enters the cecum from the ileocecal orifice propelled by the migrating action potential complex, a rapidly progressive electrical event extending from the ileum to the cecum. In the cecum, four different patterns of activity have been characterized. Three are associated with mixing of cecal ingesta: pattern I begins at the cecal apex and is conducted to the cranial base, and patterns II and III begin at the caudal and cranial cecal base, respectively, and are conducted to the cecal apex.

Pattern IV, a progressive pattern, begins at the cecal apex and is conducted through the cecal base and cecocolic orifice and into the right ventral colon (RVC). Pattern IV occurs once every 3 minutes in the fed horse, is associated with a loud distinctive "rush" of digesta (heard on auscultation), and is probably responsible for the transit of digesta from the cecum to the RVC.[7,9] In endoscopic studies of cecal emptying, ingesta was seen to move from the body up to the cranial aspect of the cecal base (cupula), which was separated from the caudal base by a ring of constriction. The cupula then contracted and the cecocolic orifice was elevated and opened, allowing ingesta to flow into the RVC.[10-11] In the RVC, both aborally directed propulsive spike bursts and orally directed retropulsive spike bursts were seen. The orally directed spike bursts may allow the RVC to function as a reservoir. The oral spike bursts were not propagated onto the cecum. An electrical pacemaker region is thought to be located near the cecal apex.[10] There is also indication of possible myoelectric coupling between the ileum, cecum, and RVC.[10,12] Abnormal cecal motility is thought to contribute to

several cecal problems, most notably cecal impaction caused by cecal dysfunction.

Cecal motility has been shown to be altered by pharmacologic agents. Xylazine hydrochloride (0.5 mg/kg IV) depresses the progressive motility pattern and mechanical activity for 20 to 30 minutes, and it prolongs cecal emptying.[12-16] Butorphanol tartrate (0.04 mg/kg IV) also depresses the progressive cecal motility pattern for 10 minutes.[15-16] The combination of xylazine and butorphanol prolongs the inhibition of spike bursts.[15-16] Neostigmine methylsulfate (0.025 to 0.033 mg/kg IV or SC) produces a significant increase in the frequency of progressive cecal motility and rate of cecal emptying.[14,16] Bethanechol chloride (0.025 mg/kg IV) increases the rate of cecal emptying.[14] Erythromycin lactobionate (1.0 mg/kg or 0.10 mg/kg) administered as an IV infusion over 60 minutes increases the rate of cecal emptying.[17] All of these studies have been performed in normal horses, so caution should be exercised when extrapolating the results to horses with pathology of the cecum.

Cecal Impaction

Pathogenesis

The most common pathologic condition of the cecum is cecal impaction, and it accounts for between 40% and 55% of cecal disease, 5% of all intestinal impactions, and 2% of all referral colics.[18-21] Fatalities as high as 43% have been reported, primarily because of perforation or rupture.[20-21] The etiology of cecal impaction is most likely multifactorial. Suggested predisposing factors include poor dentition, feeding of poor-quality roughage, decreased water intake, parturition, and parasite-induced thromboembolism.[22-27] In a recent study, feeding coastal hay appeared to be a risk factor for horses developing cecal impactions.[28] In this study the incidence of cecal impaction was 4.1 % of all horses examined because of abdominal pain compared to 2% in previous studies.[21] The increased incidence was thought to be related to the feeeding of coastal hay. Tapeworms *(Anoplocephala perfoliata)* located at the cecocolic orifice have been associated with cecal impaction and perforation, possibly as the result of disruption of motility.[29-31] In one study, Arabian, Appaloosa, and Morgan horses, as well as horses older than 15 years, were at an increased risk for developing cecal impactions, whereas in another study, age (older than 13.2 years) but not breed was a risk factor for cecal impaction.[19]

Another predisposing factor for cecal impaction, which may lead to cecal perforation, is hospitalization or prior surgery (within the previous 5 days). Often these horses are hospitalized or have surgery for reasons not related to the gastrointestinal tract, such as elective arthroscopy.[23,28,32-35] Some of these impactions may be related to a motility dysfunction. During and after general anesthesia, motility of the gastrointestinal tract is disrupted, with the cecum taking the longest time to return to normal function.[36] Use of nonsteroidal anti-inflammatory drugs (NSAIDs) and lack of exercise have also been associated with the development of cecal impaction or rupture in these cases.[19,34,37] The association of NSAIDs with cecal rupture has been attributed to masking of gastrointestinal pain associated with cecal impaction, exacerbation of existing ulceration associated with concurrent disease, and primary ulcer development.[3,19,24,38] There is also a group of horses that develop cecal "impactions" that do not appear to have a mechanical obstruction. In these horses, the accumulated ingesta is of normal or often fluid consistency instead of the firm, dry, compacted ingesta typically associated with feed impactions. A functional motility obstruction has been suggested in this group of horses. A disruption in the progressive motility pattern, which starts at the cecal body and propagates aborad to the cecal base and into the right ventral colon, would lead to accumulation of ingesta in the cecum.[3,8-9,19,24,38] Although altered blood flow secondary to parasite damage, dietary changes, and other clinical conditions has been hypothesized to disrupt the cecal pacemaker located at the cecal apex and to result in interruption of progressive motility, no predisposing cause can be found in many of these cases.

Chronic recurrent cecal impaction has also been associated with hypertrophy of the muscle layers in the cecal base or body.[39] The muscular hypertrophy is thought to result from chronic uncoordinated hypercontractility because of neuronal deficits in the myenteric plexus of the cecal base.[39-40] Ingesta accumulates in the cecum as a result of failure of the motility patterns to move ingesta from the cecum into the RVC. These horses have chronic weight loss with mild signs of colic. To our knowledge, this type of cecal disease has not been recognized in the United States.

Clinical Signs and Diagnosis

Often, horses with cecal impaction show only mild signs of pain, with intermittent periods of increased severity, that may continue for several days to several weeks.[19,23,28,41-42] The mild signs of colic include lying down, looking at the flank, decreased appetite, and depression. The heart rate is often normal to slightly elevated. Borborygmi are decreased, and feces may be soft with decreased production. Because gas, fluid, and some ingesta may pass through the cecum over the impaction, the small intestine proximal to the cecum is usually not distended. Although some horses may be presented with or may develop moderate to severe pain as the impaction progressively worsens, some affected horses remain relatively comfortable as the cecum becomes tightly distended. Horses with cecal impaction may be presented with cecal rupture with no history of significant abdominal pain.[3,19,38] There are reports of horses with cecal impaction deteriorating so rapidly, even when being monitored in a hospital environment, that surgical intervention before cecal rupture was not possible.[23-24,34] Laboratory evaluation is often normal in horses with cecal impactions. Although changes in peritoneal fluid may help in determining when and if surgical intervention should be performed, they are not always a sensitive predictor of cecal deterioration and may occur too late to be of any value in the decision-making process.[19,23-24,28,35]

The diagnosis is confirmed by rectal palpation in most cases. The first indication of a cecal impaction may be increased tension in the ventral cecal band. As the impaction enlarges, the cecal body begins to fill and the sacculations in the cecal body and a rounded cecal base are palpable. With increasing filling, the sacculations disappear and a large distended structure can be felt filling the right side of the abdomen. Because the cecum is attached dorsally to the body wall, the examiner is not able to pass a hand dorsally over the impaction.[38] This may help differentiate a cecal impaction from a large colon impaction. However, rectal palpation in some cases is not definitive in distinguishing between a distended cecum and a distended colon.[26] Additionally, some horses have cecal impaction involving only the cupula. Since the cupula of the cecum lies more

craniad than the body, these can be missed on rectal palpation.[39] Cecal impaction and rupture has also been reported to occur in foals, especially during the immediate postoperative period.[35] Since their size prohibits rectal palpation, the presumptive diagnosis depends on close attention to clinical signs.

Primarily on the basis of rectal palpation findings, cecal impactions have been divided into two types of obstruction.[21,43] One type has firm, dry, or doughy ingesta at the base or body of the cecum. The mass can be indented with the fingers on rectal palpation, and the cecal wall does not feel thickened. Peritoneal fluid is usually normal in these horses. These cases are thought to include the mechanical obstructions and will be referred to as type 1 cecal impactions. In the other type of cecal impaction, referred to here as type 2 cecal impactions, the cecum is tightly distended with gas and ingesta of normal or fluid consistency. These have been described as cecal dysfunction.[21,43] These horses may have an increased level of pain and an increased heart rate compared with type 1 cecal impactions. They may also show signs of endotoxemia. The cecal wall is usually tightly stretched and may feel thickened. Peritoneal fluid may have elevated protein, and as the disease progresses it becomes serosanguineous. At surgery, the cecal wall appears thickened and hyperemic, and it has decreased motility.[21,43] Although this categorization may be helpful in selecting a treatment modality (see "Treatment," next), it is not without limitations. First, it can be difficult to place a horse accurately into one of the two categories, even with physical, rectal, laboratory, and surgical findings. Second, although the progression of the disease and the response to treatment modalities may be more similar between horses within a group than between horses in different groups, clinically there are significant exceptions.

Treatment

The treatment of cecal impactions is quite controversial. Some reports suggest that cecal impactions can routinely be successfully treated with medical therapy, whereas other reports recommend surgical intervention.[3,23-24,28,38,42] To differentiate horses that will respond to medical therapy from those that will not, attempts have been made to correlate the characteristics of the impaction (the nature of the material in the cecum) with the response to medical therapy. Type 1 cecal impactions, thought to be mechanical obstructions from impacted ingesta, should be more likely to respond to medical therapy.[21,43] Type 2 cecal impactions, thought to be caused by a cecal motility dysfunction, should be less likely to respond to medical therapy and so be more likely to require surgical intervention. Although type 1 cecal impactions can initially be treated with medical therapy, some may not respond. Since these horses may not show much pain at any stage of the disease, they should be carefully monitored by rectal examination to determine which ones are not responding.

Another area of controversy is whether to perform a surgical bypass of the cecum. This question arose out of a retrospective study that identified horses that had recurrent cecal tympany or impaction after a prior typhlotomy without bypass to treat a previous cecal impaction.[44] The nature of the impaction has been used to help with this decision. Type 1 impactions should be more likely to respond to decompression only, whereas cecal dysfunction, the type 2 impactions, should be more likely to require a bypass. However, this has been questioned by some authors.[26] In our opinion, cecal impactions that occur in the postanesthetic period can be initially treated medically if they are diagnosed early while the cecum is mildly to moderately distended. However, it should be stressed that the clinical signs may be mild and their clinical significance underestimated. In a retrospective study of cecal perforation, 13 of 66 horses with cecal disease developed cecal perforation while in a hospital setting without having a prior diagnosis of cecal disease. All of these horses had some sort of painful condition, many related to a musculoskeletal condition. Seven of these 13 cases had general anesthesia several days before cecal perforation. Although these horses exhibited signs such as reduced fecal output and mild abdominal pain, the signs were not recognized as clinically significant before cecal perforation or sudden death. These horses were found to have a large and firm cecum filled with ingesta and an empty colon at necropsy.[45] In another study, 6 of 12 horses that developed cecal impaction while hospitalized survived, 2 of 4 treated medically and 4 of 6 treated surgically.[28] Increased awareness of the risk of cecal impaction and rupture in hospitalized horses leads to earlier diagnosis with improved outcome. If surgery is required for evacuation of postoperative cecal impactions, or if horses develop cecal impaction while hospitalized for other conditions, most should not need a bypass. The logic is that the dysfunction is temporary and related to anesthesia (for the horses who had surgery) or to a painful condition, to treatment with NSAIDs, or to a change in management, such as decreased exercise, and therefore the patients should respond to a more conservative surgical treatment (i.e., evacuation only).[28,36,43] These horses should be held off hay for the first 36 to 48 hours postoperatively, exercised with hand-walking and limited grazing to stimulate motility, and slowly reintroduced to a more laxative diet.

MEDICAL THERAPY

The goal of medical therapy in type 1 impactions is to soften the ingesta to allow cecal contractions to empty the cecal contents into the right ventral colon. Feed should be withheld and the horse started on intravenous fluid therapy. Oral laxatives administered by nasogastric tube may assist in softening the impaction. Mineral oil (5 to 10 mL/kg every 12 hours) is commonly used as a lubricant but may have difficulty penetrating the mass. Magnesium sulfate (1 mg/kg) is a saline laxative that exerts an osmotic effect, pulling water into the intestinal lumen. It can be administered once or twice a day for 2 to 3 days if the horse is well hydrated. Magnesium toxicity has been reported after the use of magnesium sulfate in dehydrated horses and in horses that have been treated with a combination of magnesium sulfate and dioctyl sodium sulfosuccinate (DSS), which is thought to increase the absorption of magnesium.[46] Psyllium hydrophilic mucilloid (1.0 kg every 6 to 8 hours) has also been recommended for treatment of cecal impactions.[38] Because complete fasting causes cessation of cecal motility, stimulating motility by walking and limited controlled grazing may be beneficial.

Analgesics such as flunixin meglumine (0.5 to 1.1 mg/kg IV every 12 hours) can be used if necessary for pain relief in both types of impactions. Caution should be exercised in using xylazine and butorphanol, since both drugs have been shown to decrease cecal contractile activity and their analgesic effect may inappropriately delay the decision for surgical intervention.[13,15-16] There is no consensus on the use of prokinetics. Erythromycin, bethanechol, and neostigmine have all been shown to increase contractile activity in the normal cecum as

stated previously.[16-17] Given the apparent large force of drug-induced activity in the normal cecum, some authors do not recommend the use of neostigmine in horses with cecal impaction.[14] The clinical efficacy and safety of bethanechol and erythromycin for the treatment of cecal impaction are not known.

Although separation into type 1 and type 2 cecal impactions provides some guidance in choosing which cases are more likely to respond to medical therapy, horses undergoing medical therapy for cecal impaction remain at risk for developing cecal rupture.[24,38] Consequently, close monitoring of their physical status, including heart rate and level of pain, as well as transrectal monitoring of the impaction are imperative when treating any cecal impaction medically. Surgery should be considered if there is no improvement on rectal palpation during a 24- to 36-hour period, if there is any sign of systemic deterioration, if there is a significant increase in pain, or if the cecum feels tight enough to rupture.[38] Mean systemic packed cell volume (PCV), peritoneal total protein concentration, and nucleated counts have not been found to be very sensitive indicators in determining whether a horse should be treated medically or surgically.[28]

The prognosis with medical therapy is difficult to assess from previous reports. One study reported a good prognosis for horses with cecal impactions treated with medical therapy when they lived longer than 24 hours after admission.[38] However, horses that may have been treated medically initially and that developed cecal rupture before the 24 hours were not included in the medically treated group. Consequently, it is difficult to interpret the significance of the reported survival rate (89%) of medically treated cecal impactions. Nine of 10 horses (90%) and 44 of 54 (81%) were treated successfully medically in two other studies. In the second study, surgical treatment was recommended and refused by the owners in 5 of 10 horses treated unsuccessfully medically.[28] In another study, medical therapy alone was unsuccessful in 12 out of 21 horses with cecal impaction.[23] Poor results with medical therapy have been reported by other authors.[3,24]

SURGICAL THERAPY

The ventral midline celiotomy is the most common approach for surgical access to the cecum. Because the cecal base is firmly attached to the dorsal body wall, only the apex and a portion of the body of the cecum can be exteriorized. The entire base (including the cupula), a portion of the cecal body, and the cecocolic and ileocecal orifices will remain within the abdominal cavity. A right paracostal approach made through an 18th rib resection has been described for complete typhlectomy or enlargement of the cecocolic orifice in horses with cecal impaction associated with cecal hypertrophy.[47-48] In Europe, enlargement of the cecocolic orifice has met with limited (50%) success in treating this particular type of cecal disease.[39]

Surgical options are infusion of fluid with massage of cecal contents, typhlotomy with evacuation of cecal contents, and bypass procedures including cecocolic anastomosis, ileocolostomy, and jejunocolostomy with and without ileal resection.[23,44,49-50] Poor to good results have been reported with infusion combined with massage.[23,44] This technique has been of limited value in our experience. For type 1 impactions, the mass of ingesta is usually too large and too tightly packed for infusion and massage to be of significant benefit in breaking down the impaction. Type 2 impactions already contain a significant amount of fluid and so are not likely to respond to additional fluid infused to break them down. There is still controversy concerning the criteria to use in deciding when to perform a bypass procedure. As a general rule, horses fitting into the type 2 category should be considered candidates for a cecal bypass. Some authors state that if the cecal wall appears normal and has reflex motility, and if the ventral colon contains a normal amount of ingesta, the cecum is not bypassed, whereas if the cecal wall is thickened and hyperemic and has minimal motility after evacuation, and if the ventral colon is almost empty, suggesting a cecal motility problem, the cecum should be bypassed.[21,43] These are valid guidelines, although there appear to be exceptions.[26]

Typhlotomy

The preferred surgical approach for a typhlotomy is through a ventral midline celiotomy, although the procedure can be performed through a flank laparotomy in the standing animal.[23-24] The cecum is usually quite large and tightly distended, sometimes making it difficult to exteriorize a sufficient portion of the apex to perform the typhlotomy. Extending the celiotomy incision improves the exposure. The cecum should be manipulated carefully with hands and arms placed around the body of the cecum, lifting the cecal body to allow exteriorization of the apex. Tilting the table, or tilting the horse slightly to the right side, can also facilitate exposure of the apex for the typhlotomy procedure.[43] The exteriorized apex should be isolated from the sterile field over the side of the horse. Stay sutures can be placed adjacent to the typhlotomy site to stabilize the cecum and prevent the apex from retracting back into the abdomen.[43] We prefer having an assistant stabilize the cecal apex with their hands, as stay sutures may tear, allowing the cecal apex to retract. An 8- to 12-cm (3- to 5-inch) typhlotomy incision is made between the lateral and ventral cecal bands. The size depends on the consistency of the ingesta. The surgeon manipulating the base of the cecum should continue to exteriorize an additional portion of the body of the cecum as the distention is relieved. A tube is placed through the typhlotomy site, and warm water is infused to aid in flushing out the cecal contents.[21,23,28,43] The cupula may be difficult to empty since it forms a pouch at the base of the cecum. In a rare case, we have placed a large-bore tube into the cecum through the typhlotomy along with the lavage tube to siphon cecal contents as the lavage loosened the ingesta. By using these lavage techniques, placing an arm into the cecum to remove contents from the caudal cecal base is rarely required as described in some reports.[43] Once the cecal contents have been evacuated, the contaminated region around the typhlotomy site should be thoroughly rinsed with electrolyte solution. The typhlotomy is closed with a double-inverting suture pattern or an appositional followed by an inverting pattern using 2-0 or 0 polyglactin 910. Some surgeons have recommended resecting the apex of the cecum and closure with the TA-90 stapling instrument if the apex becomes excessively contaminated during the typhlotomy.[3,43] With copious lavage, partial typhlectomy of the apex is usually not necessary.[28]

In one case series, 7 of 8 horses (88%) with cecal impaction treated only by typhlotomy and evacuation survived.[23] In another study, 36 of 37 horses (97%) treated by typhlotomy and evacuation only survived to discharge, and 25 of 28 (89%) of these survived long term.[28] Recurrent cecal impaction occurred in only 1 of the 3 that did not survive long term. The high success with evacuation only was attributed to coastal hay

causing a type 1 impaction in these horses. In another study, 9 of 10 horses (90%) that survived with evauation only had the impactions categorized as cecal dysfunction.[26] However, in two other studies, 4 of 14 horses (29%) were euthanized because of recurrence of the impaction after typhlotomy only, and cecal filling continued to occur postoperatively in horses in the other study, with only 1 of 5 surviving after typhlotomy only.[41,51]

Cecocolic anastomosis

This procedure was developed because of the poor response seen in horses with cecal impactions managed by typhlotomy only.[44] In this technique, a cecocolic anastomosis (CCA) is performed to create an alternative route for ingesta to pass from the cecum to the right ventral colon. The rationale is that cecal impactions may be caused by a cecal outflow problem, possibly because of motility dysfunction.[44] The cecum is approached by a ventral midline celiotomy. In most cases, a typhlotomy is recommended to evacuate the cecum before performing the anastomosis.[44] The CCA is performed between the lateral and dorsal bands of the cecum and between the lateral and medial free bands of the right ventral colon. Although the anastomosis can be hand-sutured with a two-layer side-to-side technique, it is recommended that the CCA be performed with intestinal stapling instruments to reduce peritoneal and serosal contamination.[44] For the stapling technique, stay sutures attaching the cecum and colon are placed at each end of the selected anastomosis site, approximately 20 cm (8 inches) apart. The seromuscular layer of the cecum and colon are apposed on one side of the intended stoma in a simple-continuous pattern using 2-0 polyglactin 910. Two small stab incisions are made on either side of the midpoint of the 20-cm (8-inch) suture line, one into the cecum and the other into the colon to allow insertion of the stapling instruments. The GIA-90 or ILA-100 stapling instrument is used twice, once orad and once aborad, taking care to overlap the staple lines, which makes a stoma between 15 and 20 cm (6 to 8 inches) in length. The stab incisions are closed and the front side of the stapled seromuscular layer is oversewn. To reduce the possibility of internal hernia formation between the cecum and the colon, the seromuscular closures are continued dorsally to the level of the cecocolic ligament.

In one study, 3 of 4 horses survived after this technique.[38] In another case series of 14 horses treated by CCA, the long-term survival (12 months) was 71%. However, 4 of the 10 long-term survivors experienced chronic, intermittent, mild abdominal pain thought to be associated with gaseous distention of the cecum.[44] This was considered to be a result of failure of normal gas transit between the two organs, or reflux of gas from the colon into the cecum.[44]

Because of the number of horses continuing to experience postoperative problems related to the cecum after the CCA, alternative techniques that bypass the cecum have been recommended in horses with cecal impactions.

Jejunocolostomy or ileocolostomy

For cecal impactions arising from abnormal cecal motility or compromised outflow at the cecocolic orifice, procedures that bypass the cecum entirely have been recommended to prevent cecal tympany or the recurrence of cecal impaction. In these bypass procedures, an anastomosis is made between the ileum or jejunum and the right ventral colon. A partial bypass has been described in which the ileum is not transected.[49] However, in an experimental study comparing a partial to a complete cecal bypass, the partial cecal bypass failed to decrease the size of the cecum or volume of ingesta in the cecum. Consequently, this was thought to be a risk for reimpaction and perforation.[52] Additionally, intermittent colic with cecal distention has been reported after partial cecal bypass.[44] The complete bypass, by taking the cecum out of the flow of ingesta, results in cecal atrophy and prevents postoperative cecal filling and rupture.[52-53] For these reasons, the complete bypass is recommended over the partial bypass.[3,24,52]

The cecum is approached through a ventral midline celiotomy and the cecal impaction is evacuated through a typhlotomy. The ileal vascular arcade is double-ligated on both sides of the area of transection. The transection can be completed by hand, with the TA-90 stapling instrument positioned on the distal end and sharply transecting proximal to the instrument, or with a GIA-90 or ILA-100 that will cut between stapled proximal and distal ends.[52,54-55] Doyen intestinal clamps are placed across the ileum oral and aboral to the line of transection for hand-sutured techniques. The proximal and distal ends of the hand-transected ileum are closed with a full-thickness continuous appositional or inverting pattern followed by a partial-thickness inverting pattern using an absorbable suture material. All stapled ends should be oversewn with a partial-thickness inverting pattern. The proximal blind end of the ileum is directed orally, toward the base of the cecum, as it is positioned on the most proximal exteriorized portion of the right ventral colon between the lateral and medial free bands (Figure 37-4). Stay sutures are placed 15 cm (6 inches) apart to attach the distal end of the ileum to the RVC. A Penrose drain is placed proximal on the ileum, and intestinal clamps are placed on the RVC to minimize contamination during the anastomosis. Although a hand-sutured side-to-side anastomosis can be performed, the use of intestinal stapling equipment shortens surgery time and decreases contamination. Stab incisions are made in adjacent areas of the attached ileum and RVC. The arm of a GIA or ILA stapling instrument is inserted into one stab incision and the anvil is inserted into the other stab incision. The stapler is discharged and the blade is pushed to form the stoma of approximately 10 cm (4 inches) in length.[55] The stab

incisions are oversewn, followed by a single inverting-suture pattern circumferentially around the entire staple line at a distance of 5 to 8 mm. The ileocecal fold, portions of the cecocolic fold, and the bowel serosa are apposed in a simple-continuous pattern to close the mesenteric defect and eliminate the potential for an internal hernia.[54-55]

Several modifications of the previously described bypass procedure have been described. In one report, the authors describe the resection of a 15- to 30-cm (6- to 12-inch) segment of the ileum or ileum and distal jejunum before performing the anastomosis. By constructing the distal free end of the small intestine adjacent to a jejunal mesenteric vascular arcade, some surgeons feel the chances of an inadequate blood supply to the anastomosis are decreased.[54] In another report, a jejunocolostomy or ileocolostomy is performed without transection of the ileum and distal jejunum.[50] To make this procedure a complete bypass, once the jejunocolostomy or ileocolostomy is performed, four rows of staples are applied using the TA-90 stapling instrument immediately distal (aboral) to the anastomosis to occlude the lumen of the distal jejunum and ileum (Figure 37-5). This technique should reduce the length of the surgery and chances of contamination.

Several studies have reported on prognosis and complications after cecal bypass.[19,52,54] In one case series, 5 of 6 horses (83%) with cecal impaction treated by ileocolostomy returned to their previous activity with a minimal follow-up period of 6 months.[52] Surviving until discharge were 6 of 7 (86%) in another study.[19] In a third study, 9 horses that failed to respond to medical therapy were treated with an ileocolostomy or jejunocolostomy.[54] All horses survived until discharge, with all 7 horses available for long-term follow-up (range, 7 to 54 months; mean, 1.5 years). Several important observations were made relative to complications in this study. Positioning the small intestine aborad on the RVC makes closure of the mesenteric defect technically difficult, predisposing the horse to entrapment or strangulation of the small intestine in the mesenteric defect. To prevent this problem, the authors recommend that the small intestine be placed on the RVC facing orally and the mesentery closed. Another problem encountered was kinking at the anastomosis. Suturing a 5- to 10-cm (2- to 4-inch) segment of the distal small intestine to the colon proximal to the anastomosis is recommended to prevent this problem.[54] A further recommendation was to thoroughly evacuate the cecum before performing the anastomosis to prevent cecal impaction in the postoperative period. The authors emphasized the importance of gradual return to feed, because the most common postoperative complication was mild signs of colic within several days of reintroduction to feed. Although the cecum plays an important role in water absorption and bacterial degradation of dietary fiber, no detrimental consequences related to hydration and nutritional states have been observed with the bypass procedure.

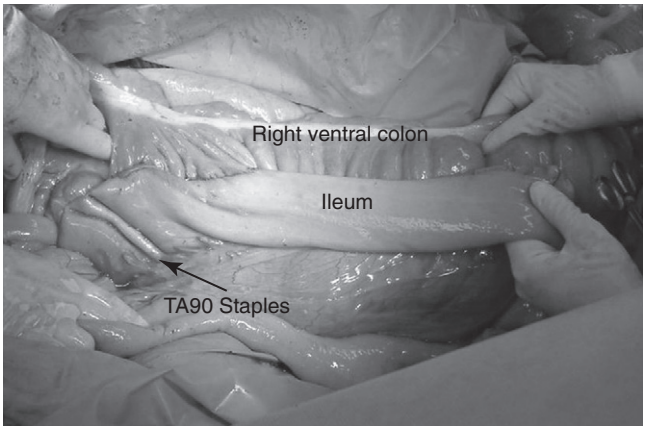

Figure 37-5. Complete cecal bypass without ileal transection. The ileum and right ventral colon are labeled. Four rows of staples are placed using a TA-90 distal to the ileocolostomy site to prevent feed from entering the cecum.

Postoperative Care

Horses are treated with broad-spectrum perioperative antibiotics and NSAIDs. The antibiotics may be discontinued 24 hours after surgery or continued for a therapeutic treatment course of 5 to 7 days, depending on the amount of contamination that occurred during the surgical procedure. The NSAIDs are continued for 3 to 5 days. During the initial postoperative period, intravenous fluids should be provided at a slow but constant rate. After 12 to 24 hours, the horse should be offered small amounts of water. Once it has demonstrated a tolerance for oral fluid, the water intake is increased and the intravenous fluids are decreased. Postoperative feeding is very important. It has been recommended that feed be withheld for a minimum of 36 to 48 hours, followed by grazing and feeding a bran mash with small quantities of good-quality hay at frequent intervals.[54]

Cecocecal or Cecocolic Intussusception

Pathogenesis

Cecocecal and cecocolic intussusception occur when the cecal apex invaginates into the cecal body (cecocecal) or continues through the cecocolic orifice and enters the large colon (cecocolic). Intussusception of the cecum was the most common cause of cecal obstruction in a report from the United Kingdom, whereas it accounted for only 3% to 3.5% of horses with primary cecal disease and for 1.3% of horses undergoing exploratory laparotomy for colic in other reports.[19,32,47,56-59] The relative frequency of cecocecal compared with cecocolic intussusception varies markedly depending on the study.[47,57,59-60] The etiology is unknown, but altered motility has been suggested to play a role. Dietary changes, cecal wall abscess, *Salmonella*, *Eimeria leuckarti*, *Strongylus vulgaris* arteritis, organophosphate exposure, and administration of parasympathomimetic drugs have all been implicated as potential risk factors.[58-59,61-62] Tapeworm infestation is often encountered in horses with cecal intussusception, leading some to speculate a causative association, possibly from mucosal inflammation initiating the intussusception.[30,58,61-63] However, other studies have not found a difference in tapeworm infestation rates between horses with and without cecal intussusception. Young horses (younger than 3 years) and Standardbreds appear to be at increased risk.[56-58,61,64]

Clinical Signs and Diagnosis

Clinical signs may vary considerably depending on the degree of vascular compromise and mechanical obstruction of the ingesta.[19,57-58,60-61,64] Approximately 55% of horses in one report presented with acute, moderate to severe pain requiring immediate surgical intervention, and 30% presented with a subacute

form (3 to 8 days) characterized by intermittent mild to moderate pain with soft feces or diarrhea. A smaller group (13%) presented with a chronic form (6 to 180 days) characterized by weight loss, scant soft feces, and mild abdominal pain.[61] Fever is common in horses suffering from this problem over a longer period of time. Cecocecal intussusceptions are more likely to be nonstrangulating, incomplete obstructions producing mild pain, and they develop into a chronic disease.[61] Cecocolic intussusceptions typically develop ischemic necrosis of the distal end of the intussusceptum, including the cecal apex and part of the body.[65] Rectal examination may be unremarkable in horses with cecocecal intussusception, as the intussuscepted cecal apex may not be palpable and the colon and small intestine are usually not obstructed. In horses with cecocolic intussusception, the cecum may feel malpositioned or may not be palpable at all. A mass or edematous bowel may be palpable in the right caudal abdomen.[64]

Ultrasonography may facilitate making the diagnosis.[56,61,64,66] Frequently, the compromised portion of the cecum is sequestered within the colon (or cecum), rendering peritoneal fluid analysis an insensitive indicator of pathology.[56] With time and progression of the disease, peritoneal fluid changes may be seen.[58,61-62] Often, the diagnosis is made at surgery after the horse fails to respond to medical therapy.[19,58,61-62,65]

Treatment

SURGICAL REDUCTION WITH PARTIAL TYPHLECTOMY

The surgical approach is through a ventral midline celiotomy. During the abdominal exploration, the cecal apex is found to be intussuscepted into the body of the cecum in the case of a cecocecal intussusception, whereas the cecum is "absent" from its normal position (with a palpable mass in the right ventral colon) in the case of a cecocolic intussusception. In rare cases, the base of the cecum may be intussuscepted into the colon while the cecal apex remains everted. In these cases, the cecum cannot be exteriorized to the normal extent while the invagination is palpable at the cecal base. Manual reduction is attempted by inserting one hand to grasp and place traction on any portion of the cecum within the intussuscipiens, while the other hand is placed on the colon over the intussuscepted cecum to gently massage the inverted cecum to an everted position. Approximately one third of cecal intussusceptions may be reduced in this manner.[61] The intussusceptum is frequently vascularly compromised, necessitating a partial typhlectomy. To prepare for the partial typhlectomy, the lateral and medial cecal vessels are double-ligated with 0 absorbable suture. Doyen intestinal clamps are placed proximal to the intended amputation site across the cecum to decrease fecal contamination, and the surgical area is draped off. The compromised cecum is often too edematous to allow the use of intestinal stapling instruments during the resection. After sharply resecting the compromised cecal apex and body, the cecum is closed using either an inverting or an appositional pattern, followed by an inverting suture pattern with No. 0 absorbable suture.

CECAL AMPUTATION THROUGH A COLOTOMY

Manual reduction of cecocolic intussusceptions is frequently not successful because of edema and adhesion formation (Figure 37-6, *A*). In these cases, reduction of the intussusception should be approached through a colotomy.[58,61,67] The large colon should be exteriorized from the abdomen and first evacuated through a pelvic flexure enterotomy if it contains an appreciable amount of ingesta. After closure of the pelvic flexure enterotomy, a second enterotomy is made on the ventral surface of the right ventral colon centered over or immediately distal to the intussusceptum. A sterile plastic bag or a plastic enterotomy drape with a 25-cm (10-inch) hole in the center can be sutured to the colon before the enterotomy is made to limit contamination during the colostomy (see Figure 37-6, *B*).[67] Attempts can be made to manually reduce the intussusception through the colotomy, but this is often unrewarding. In these cases, a partial resection of the invaginated cecum will facilitate reduction of the remaining cecum. The medial and lateral aspects of the inverted cecum are blindly ligated with two parallel transfixation sutures to occlude the cecal vessels. Overlapping mattress sutures, staples, or an encircling ligature with umbilical tape or a natural rubber ligature are placed to occlude the lumen of the cecum (see Figure 37-6, *C*).[67-68] The invaginated cecum is subsequently transected and the remaining cecal stump is reduced by both placing gentle traction on the cecal body and pushing the remaining inverted cecum out. The colotomy incision is closed with a two-layer inverting pattern using 2-0 or 0 absorbable suture material. The now everted cecal stump is subsequently examined for viability. If necessary, further resection of the cecum is performed (see Figure 37-6, *D*). The cecum is closed with a double-inverting pattern using No. 0 absorbable suture material.

If the cecum cannot be reduced after partial resection within the colon, or if the remaining cecal stump is friable and necrotic, the cecal stump is left invaginated within the colon and a cecal bypass procedure is performed.[62,69] In these cases, a partial typhlectomy is performed to remove as much of the necrotic cecum from inside the colon as possible, after which the cecal stump is sutured in a horizontal overlapping mattress pattern followed by a simple-continuous pattern. The colotomy incision is then closed and the surgical area is lavaged. To prevent leakage of ingesta, the serosal surface of the cecum at its point of invagination into the colon is oversewn.[62] However, complete oversewing at the point of intussusception may not be possible and may be unnecessary.[69] The ileum is subsequently transected, and an ileocolostomy or jejunocolostomy is performed adjacent to the closed colotomy incision (see "Jejunocolostomy or Ileocolostomy," under "Cecal Impaction"). The devitalized cecal stump is thought by some to slough inside the colon and pass in the feces, whereas others question whether this occurs.[61-62]

There are several reports where irreducible cecocolic intussusceptions were treated with bypass procedures without partial typhlectomy.[56,64] In one report, four of six horses survived long term after jejunocolostomy or ileocolostomy with ileal transection without a partial typhlectomy.[56] In a recent report describing three cases with cecocolic intussusception, irreducible by manipulation of the cecum within the colon and traction on the ileum, the horses were treated with a side-to-side ileocolic anastomosis without ileal transection and without partial typhlectomy.[64] In these cases the entire cecum, the ileocecal valve, and the distal ileum were left intussuscepted within the colon. The bypass procedure without ileal transection was performed as described earlier (see "Jejunocolostomy or Ileocolostomy," under "Cecal Impaction"), except that the ileal lumen distal to the anastomosis was not occluded with staples, because it was occluded by compression in the intussusception.[50] No attempt was made to oversew aboral to the intussusception. All three horses recovered with minimal complications and were clinically normal 12 months after the procedure.

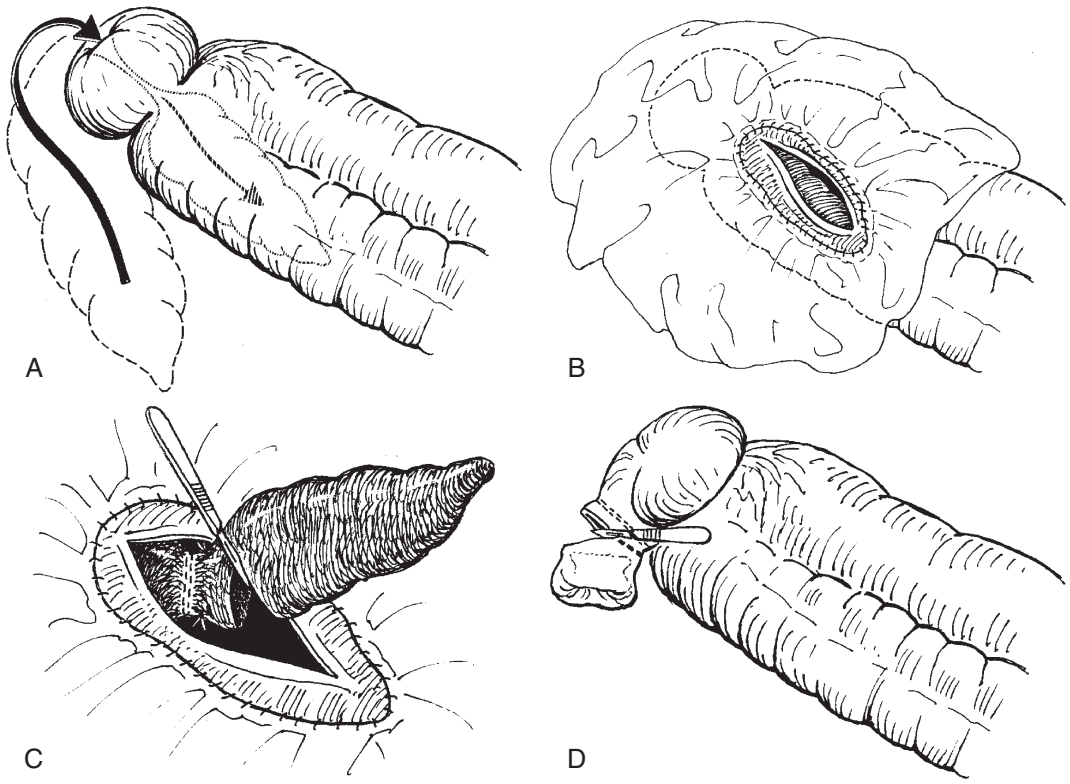

Figure 37-6. Cecal amputation within the right ventral colon (RVC) for nonreducible cecocolic intussusception. **A,** Cecum intussuscepted into the RVC through the cecocolic orifice. The *dashed lines* represent the outline of the invaginated cecum. **B,** Right ventral colostomy exposing the cecal intussusception. A sterile plastic bag or drape has been sutured to the seromuscular layer of the RVC before the colostomy to help contain contamination. **C,** Occluding mattress sutures (or TA staples) have been placed across the inverted cecum to facilitate removal of as much of the cecum as possible, thus enabling reduction of remaining invaginated tissue. The intussusception is then amputated through the RVC. **D,** After eversion of the cecal stump, the remaining compromised part of the remaining cecum is amputated, repeating the technique used for the amputation in the colon.

Postoperative Care and Prognosis

The horses are treated with intravenous fluids, broad-spectrum antibiotics, and NSAIDs. In cases of cecocecal intussusception with minimal contamination, the antibiotics may be discontinued 24 hours after surgery. Horses with cecocolic intussusceptions requiring cecal amputation within a colostomy are more likely to have been exposed to contamination and consequently require a therapeutic course of antimicrobial therapy. Postoperative abdominal lavage for 2 to 3 days also may aid in reducing the incidence and severity of postoperative peritonitis. The horse can be started back on feed 24 hours after surgery if there is no evidence of pain.

The prognosis is related to the amount of cecum intussuscepted, the ability to manually reduce the intussusception without opening the colon, the amount of contamination at surgery, and the viability of the cecum or the remaining cecal stump.[3,24,57,58,61,70] The prognosis after surgical correction of cecocecal intussusception is good.[70] Although a poor prognosis was associated with correction of cecocolic intussusceptions by partial typhlectomy through a colotomy in one report, other studies revealed a good prognosis associated with this technique.[58,61,67] Despite some contamination, which is inevitable during reduction through a colostomy, even with careful packing of the abdomen, clinical evidence of postoperative peritonitis is infrequent.[61,67] Bypass procedures with partial typhlectomy without reduction of the remaining cecal stump[62,69] or without partial typhlectomy have been reported to be effective in a limited number of cases.[56,64] More cases are needed to assess possible complications and long-term results associated with leaving part or all of the intussuscepted cecum within the colon. Until that information is available, the bypass procedures should be reserved for those cases where reduction after partial typhlectomy is not possible or for cases where ileal viability is compromised as assessed after reduction of cecal intussusception.[58,61,67,71]

Cecal Perforation or Rupture

Cecal perforation or rupture has been described in several retrospective studies.[19,32,34-35,38,72] Cecal perforation secondary to cecal impaction is well recognized.[3,19,28,35,38] Primary cecal perforation, unrelated to cecal impaction, has been described to occur in horses during treatment for an unrelated disease. In these horses, it appears to be associated with hospitalization, NSAID administration, or anesthesia. Primary cecal perforation has also been reported in periparturient mares.[19,24,27,34,73] Dystocia has been observed in approximately 50% of these horses. Horses with cecal perforation typically exhibit signs of pain soon after foaling, presumably as a result of cecal rupture from excessive pressure placed on the cecum during parturition. Primary cecal perforation has also been associated with tapeworm infestation.[74] As discussed previously, in some horses

with cecal impaction caused by cecal dysfunction, rupture can occur without significant clinical signs.[19,34] Consequently, it is not possible to know how many of these cases that have been described as primary cecal perforation have in fact been caused by a cecal dysfunction resulting in cecal distention caused by gas and fluids that went unnoticed before cecal perforation.

Cecal Volvulus or Torsion

Cecal volvulus or torsion secondary to large colon volvulus is uncommon.[3] Because of the substantial dorsal attachments of the cecal base to the body wall and colon, it is not common for the cecum to develop a primary torsion or volvulus. Incidental displacements of the cecum may be encountered at surgery and are sometimes classified as a torsion (usually 90 degrees). These typically are not a pathologic problem.[55] Primary volvulus may be related to anatomic abnormalities such as hypoplasia of the cecocolic fold and the normal cecal attachments to the body wall.[45,75] However, in one report, 9 of 96 horses (9%) with cecal disease were described as having primary cecal torsion with no apparent anatomic abnormalities.[19] Horses with cecal torsion or volvulus are presented with a sudden onset of severe abdominal pain. Rectal palpation is typically not diagnostic. Peritoneal fluid protein and nucleated cell count may be elevated. The diagnosis is made during an exploratory laparotomy. Partial typhlectomy with resection of the compromised cecum is recommended. The prognosis will depend on the viability and amount of compromised cecal tissue remaining after partial typhlectomy. In one report, three of five horses (60%) with cecal torsion treated by partial typhlectomy survived until discharge.[19] If extensive cecal damage extending to the cecal base is found at surgery, complete cecal amputation can be performed through a right flank approach with an 18th rib resection.[48] Cecal amputation leaving part of the cecal cupula to form a conduit between the ileocecal and cecocolic junctions has also been described in a case with extensive cecal ischemia from prolapse through a flank wound.[76] Recurrence has been reported after surgical correction in one horse with abnormal mesenteric attachments.[45]

Cecal Infarction

Cecal infarction has been reported to occur in 10 of 96 (11%) horses with cecal disease.[19] Verminous arteritis from *Strongylus vulgaris* infestation and multifocal infarction from larval cyathostomes are two proposed etiologies.[19,77] Mild abdominal pain increasing in severity over 24 hours is the most common clinical sign. Diarrhea, sudden severe pain, and acute cardiovascular collapse have also been described.[3,19] Peritoneal fluid evaluation reveals changes consistent with intestinal ischemia.[3,19] Rectal palpation may reveal a hard mass in the area where the cecum is located in approximately one third of the cases.[19] Surgical intervention is based on persistent abdominal pain and peritoneal fluid abnormalities, with the diagnosis of cecal infarction made at surgery. Subtotal typhlectomy is the recommended treatment.[19] In one report, seven of eight horses (88%) with cecal infarction treated by subtotal typhlectomy survived to discharge.[19] Although complete typhlectomy requiring an 18th rib resection in left lateral recumbency has been described, the favorable prognosis with partial typhlectomy indicates that the more difficult procedure performed through a right flank approach is usually not necessary.[19,48]

Cecal Tumors

Primary cecal tumors have rarely been reported in horses.[19,78-79] Three of 96 horses (3%) with cecal disease had primary tumors.[19] All three horses were 20 years or older and were presented for chronic weight loss rather than abdominal pain. Histologic diagnoses were leiomyoma, hemangiosarcoma, and papillary adenoma. Treatment should be surgical resection if possible and feasible.

Miscellaneous

Other reported conditions include cecal abscesses that may be associated with adhesions.[19,80] Horses may be presented with mild abdominal pain and peritoneal fluid changes consistent with peritonitis. Transrectal or transabdominal ultrasonography may aid in the diagnosis of cecal abscessation.[19,80] The treatment consists of surgical resection of the abscess and adhesions. Cecocutaneous fistulas have also been described, occurring after repair of body wall hernias with hernia clamps.[81] We have repaired several enterocutaneous fistulas that developed with entrapment of the cecal wall in an umbilical hernia with no history of hernial clamps. The prognosis after surgical repair is good.

LARGE COLON

Anatomy

The equine ascending colon begins at the cecocolic orifice and ends in the transverse colon. It measures approximately 3 to 3.7 m in length and has a capacity of 50 to 60 L. It is composed of the ventral and dorsal areas of the colon, which are connected by a short mesentery. Only rarely does a mesenteric defect occur between the ventral and dorsal colons (Figure 37-7). *In situ*, the large colon is further folded such that four segments are designated as the right and left ventral colon and the right and left dorsal colon. The transition from the left to the right ventral colon forms the sternal flexure, and the transition from the left to the right dorsal colon forms the diaphragmatic flexure. The maximal diameter is seen in the right dorsal colon and can reach 50 cm (20 inches). The narrowest diameter occurs in the left dorsal colon, which measures about 8 to 9 cm (3 to 3½ inches). The bands of the colon (teniae coli) support the colon. The ventral colon has four bands, of which the two ventral ones are free and the two dorsal ones are associated with the mesentery. The medial dorsal band is associated with the colonic vasculature. The pelvic flexure has one band, which can be palpated on rectal examination. The left dorsal colon has one band, which is joined by two other bands in the right dorsal colon. The roles of the teniae coli are to provide mechanical support to the colon, to maintain orientation of the colon within the abdomen, and to allow distention and contraction of the intestinal segments depending on the degree of ongoing fermentation. The teniae are composed of smooth muscle and collagen in varying proportions, depending on the role of each intestinal segment. In the ventral colon, the site of bacterial fermentation, the teniae have a greater proportion of elastin than in the dorsal colon. In the right dorsal colon, the site of transport and regulation of ingesta through the transverse colon, smooth muscle cells are present in greater proportion.[82]

The blood supply to the ascending colon is derived from the cranial mesenteric artery. The colic branch of the ileocecocolic

artery supplies the ventral colon to the pelvic flexure, where it joins the right colic artery, another branch of the cranial mesenteric artery. The middle colic artery, also a branch of the cranial mesenteric artery, provides blood supply to the transverse colon and to the initial part of the small colon. The microvascular circulation of the ascending colon has been well described.[83] The arteries branch from the colonic vessels every 2 cm and anastomose with vessels lying orally and aborally to form a colonic rete before continuing into the colonic tissue. The function of the colonic rete is unclear, but it may provide collateral blood supply, increasing the resistance of the colon to thromboembolic disease.[8] Vessels enter the submucosa through the tunica muscularis to form a complex anastomosing network of submucosal vessels. The extensive collateral supply to the colonic tissue can be expected to enhance healing, particularly where there are areas of devitalized tissue. Arterioles ascend from the submucosal plexus to the mucosa, where an extensive capillary network forms around the colonic glands (Figure 37-8). This capillary network is drained by more sparsely distributed venules (Figure 37-9). The submucosal venous plexus is characterized by regular mural helical smooth muscle constrictions that give the veins a sacculated appearance. The venous network is proposed to act as a capacitance system, storing large volumes of blood, which can be actively or passively directed into the systemic circulation as required. Alternatively, because of the large volumes of blood stored within

the ascending colon, these smooth muscle constrictions may aid in maintaining blood flow through a low-pressure system.[83] The abundant colonic blood supply makes it more susceptible to severe intraluminal hemorrhage after enterotomies.[84]

Physiology

The most critical functions of the equine large colon are storage, microbial digestion, and fluid absorption. In a 24-hour period, the large intestine must recover a quantity of water approximately equivalent to the extracellular fluid volume of the horse (approximately 20% to 30% of body weight, or 90 to 135 L for a 454-kg horse). The storage function of the large colon allows time for microbial digestion and absorption of volatile fatty acids, the main source of energy in the horse.[85] The principal mechanism for delay in transit is the retropulsive activity initiated in a pacemaker region near the pelvic flexure (approximately 30 cm (12 inches) aboral to the termination of the medial and lateral free teniae of the left ventral colon).[86,87] The coordinated contractions originating at the pelvic flexure pacemaker promote physical separation of small, well-digested particles, which are propelled aborally, and of coarser particles, which are propelled orally for further digestion.[88] This may explain the roles of poor-quality feed and dentition in the development of large colon impaction.

Large Colon Tympany

Large colon tympany (gas colic, spasmodic colic) is the most commonly reported colic in horses.[89-91] It is thought to result from excessive gas fermentation in the colon, resulting in distention and pain. In one study evaluating risk factors for simple colonic obstruction and distention colic in horses (including large colon impaction), an increased risk was associated with crib-biting or windsucking, increasing number of hours spent in a stable, recent change in the regular exercise program, lack of administration of ivermectin or moxidectin anthelmintics in the previous 12 months, and a history of travel in the previous 24 hours.[92] Other factors that increased the risk of simple colonic obstruction and distention included history of previous colic, recent (less than 4 weeks) lameness, and increased time since last dental care.[92] An association between tapeworm infestation and spasmodic colic has been demonstrated.[93] Horses fed a hay and grain diet containing large amounts of soluble carbohydrates and less fiber had decreased water content in ingesta and increased gas, which predispose to gas colic.[94] Although large colon tympany can be self-limiting, it is thought to precede large colon displacements; therefore identification of risk factors in affected horses may help decrease the risk of future occurrences.

Diagnosis

Horses examined for large colon tympany have acute pain and may show signs of visible external abdominal distention. Although in pain, they are minimally compromised, and clinicopathologic parameters including abdominocentesis remain within normal reference range. The challenge for the clinician is to differentiate this type of colic from other, more serious causes of abdominal pain. The differential diagnosis for gas colic resulting in large colon distention includes large colon displacement, large colon torsion, ileus (impending colitis), and aboral obstruction (transverse or small colon obstruction). Rectal palpation reveals moderate to severe gas distention of the large colon.

Treatment

Treatment includes administering analgesics and withholding feed. The response to medication is favorable and, if the diagnosis is correct, the horse will remain comfortable. Lack of response to analgesics may indicate a more serious problem. If the response to treatment is unsatisfactory, early referral is recommended, considering that large colon volvulus is in the differential for this condition.

Large Colon Impaction

Large colon impaction is the second most commonly reported cause of colic in horses, and it is the most frequent type of simple obstruction.[90,95] It represents up to 13.4% of colics examined at referral centers.[37,96] Risk factors identified in one study included crib-biting or windsucking, increasing number of hours spent in a stable, recent change in the regular exercise program, absence of administration of ivermectin or moxidectin anthelmintic in the previous 12 months, and a history of travel in the previous 24 hours.[92] Additional factors identified in that study included history of previous colic, recent (less than 4 weeks) lameness, and increasing time since last dental care. In another study, 79 of 147 horses (53.7%) had a change in routine in the 2 weeks before development of a large colon impaction, and 17 of 147 (11.5%) developed the impaction while hospitalized for a reason other than gastrointestinal disease.[37] Decreased water intake and parasites are factors also mentioned although not well documented. High-grain diets may predispose to colonic impactions, since grain feeding was shown to be associated with an internal fluid flux and subsequent dehydration of ingesta, setting the stage for impaction.[97] Right colon dry-matter content was higher when grain was part of a free choice hay diet.[98] In another study, water consumption was 40% greater in ponies offered warm drinking water under cold weather conditions, suggesting that cold weather may predispose to colonic impaction.[99] Hospitalization and general anesthesia have been suggested as risk factors for the development of impaction colic.[37,100] In one study, 37 of 85 hospitalized horses (43.6%) developed postoperative reduced fecal output, and 10 horses (12%) developed signs of colic; 2 of 9 horses that had a rectal examination had pelvic flexure impactions. In that study, administration of phenylbutazone decreased the risk of reduced fecal output.[100] In contrast, *in vitro* studies have shown a negative effect of NSAIDs on large colon intestinal smooth muscle motility.[101,102] The benefits of NSAID administration for pain control, considering their negative effects on intestinal health, remains a matter of debate.[100,103,104]

Amitraz, an acaricide, has been used to induce experimental large colon impaction in horses.[105] Topical spraying of horses with amitraz was associated with systemic illness and impaction colic in three horses.[106] Amitraz, atropine, glycopyrrolate, and morphine significantly prolonged intestinal transit time in horses.[107] Atropine (0.044 mg/kg and 0.176 mg/kg IV) resulted in decreased intestinal motility and decreased appetite for 2 to 7½ hours after injection; signs of abdominal pain were observed in 3 of 10 ponies after administration.[108] Topical ocular administration of 1 mg of atropine hourly resulted in decreased

intestinal motility (as assessed by auscultation for 2 to 18 hours after administration), and signs of abdominal pain were observed in four of six horses.[109] Subconjunctival administration of 3 mg of atropine resulted in decreased intestinal sounds in three of six horses and signs of abdominal pain in one.[109] Lowering the luminal temperature to 20° C (room temperature) over a 100-cm (40-inch) length of colon cranial and caudal to the pelvic flexure for 2 hours significantly decreased conduction velocity as well as amplitude and duration of pressure peaks in the intestinal wall. These findings have direct relevance to surgery of the large colon, where the colon is exteriorized from the abdomen, sometimes for prolonged periods of time, and where luminal lavage is performed. Minimizing the time of exteriorization and using warm water for luminal lavage may help the colon recover from the effects of reduced temperature.

The role of intestinal parasites on pelvic flexure motility has been evaluated. In one study, arteritis of the cranial mesenteric artery induced by inoculation of *Strongylus vulgaris* larvae resulted in reduced relative colonic blood flow; but it did not cause altered motility patterns.[110] In another study, increased motility patterns were observed in the cecum and colon at intermittent intervals for several days after infection.[111] Horses with chronic (more than 24 hours) obstructions of the large colon or with previous obstruction had decreased neuron density in the pelvic flexure, which may predispose to future obstructions.[40] Megacolon with myenteric hypoganglionosis has been described in a 6-month-old foal with severe large colon impaction and colic.[112] Recurrent impactions of the large colon were diagnosed in a mare with eosinophilic enterocolitis.[113] In that mare, diarrhea, hypoproteinemia, and weight loss characteristic of the disease were absent, and the intestine appeared grossly normal at surgery and at postmortem examination. These cases support the use of intraoperative intestinal biopsies in horses with unexplained recurrent large colon impaction.

Large colon impactions usually affect horses older than 1 year, although miniature horses may be predisposed to impactions as foals. Historically, horses are presented to referral centers for chronic colic (i.e., lasting longer than 24 hours).[37]

Diagnosis

The most common location for large colon impaction is the pelvic flexure, followed by the right dorsal and transverse colons. On physical examination, horses typically show mild to moderate abdominal pain, decreased or absent intestinal sounds, decreased or absent fecal production, and occasionally mild to moderate abdominal distention.[37] Nasogastric reflux is rarely present. Rectal palpation is diagnostic in cases of pelvic flexure impaction. However, impactions of the right dorsal and transverse colons can be difficult to palpate in adult horses. When a large colon impaction is suspected on the basis of rectal palpation, it is essential to differentiate that from a large colon displacement with secondary right dorsal colon impaction.[114] Prolonged treatment of a large colon displacement with fluids and cathartics could result in preoperative or intraoperative colonic rupture.

In the case of a large colon displacement, the right dorsal colon may become severely impacted; during rectal palpation, when the hand follows the colon, it travels to the right, and lateral to the cecum. This is in contrast to a pelvic flexure impaction, where the end of the pelvic flexure can readily be identified. Another important differential diagnosis of large colon impaction is small intestinal obstruction, which can result in dry fecal contents in the large colon as identified by palpation. In contrast to large colon impaction, the teniae and haustra of the ventral colon in such cases become more prominent and distinguishable.[114] Laboratory data typically observed in horses with large colon impaction show mild to moderate dehydration, a normal leukogram, and normal electrolyte data and blood gas analysis. The abdominocentesis results should be within normal range. Deteriorating cardiovascular status or peritoneal fluid changes are an indication of bowel degeneration.[37]

Treatment

Medical treatment of large colon impaction includes fluid therapy, analgesics, cathartics, and withholding of feed until the impaction is resolved. Intravenous fluids are reserved for impactions of longstanding duration (more than 24 hours), when dehydration is documented, or when nasogastric reflux is present, precluding the use of enteral fluid therapy. Balanced electrolyte solutions are administered at twice the maintenance rate, or 120 mL/kg per day, both to restore circulating blood volume and to allow secretion of fluid into the large colon in response to cathartics. Overhydration in combination with an oral cathartic such as magnesium sulfate is thought to promote rehydration of ingesta.[115,116] Systemic rehydration should be performed before cathartics are administered.

Enteral fluid therapy can complement and even supplement intravenous fluids. Advantages of enteral fluid therapy include administration of fluid directly in the gastrointestinal tract, stimulation of colonic motility through the gastrocolic reflex, decreased expense, and decreased need for precise adjustment of fluid composition.[116] Enteral fluids can be administered by intermittent nasogastric intubation or by nasal placement of an indwelling feeding tube (18-French equine enteral feeding tube), allowing continuous fluid administration. An isotonic electrolyte solution can be made by mixing 5.27 g of NaCl, 0.37 g of KCl, and 3.78 g of $NaHCO_3$ per liter of tap water.[116] This solution results in electrolyte concentration of 135 mEq/L of Na, 95 mEq/L of Cl, 5 mEq/L of K, and 45 mEq/L of HCO_3, with a measured osmolality of approximately 255 mOsm/L, representing a slightly hypotonic electrolyte solution compared to plasma.[116] Plasma electrolyte concentrations remained within normal range with this solution compared with the marked hypernatremia and hyperchloremia observed when 0.9% saline is administered enterally.[116] Despite the fact that normal horses can tolerate up to 10 L hourly through intermittent nasogastric intubation, it is usually not possible to administer more than 5 L every 2 hours in horses with impactions, because these horses start to reflux when more fluid is administered.[117] Therefore, intermittent intubation is used, allowing administration of approximately 60 L of fluids per day. When continuous enteral fluids are given, a greater rate of administration is tolerated, and horses can be given between 4 and 10 L/hour. At the higher rate of 10 L/hour, mild signs of abdominal pain were observed in normal horses, and in horses with large colon impaction, a rate of 5 L/hour is better tolerated.[116] For enteral fluid therapy, the fluid used can be water, or water and electrolytes. In one study, right dorsal colon ingesta hydration was

significantly increased after enteral fluid therapy compared with intravenous fluid therapy combined with enteral administration of magnesium sulfate.[116] Enteral fluid therapy with an isotonic electrolyte solution with or without intravenous fluid therapy was successful in resolving 99% of colon impactions in one study.[118]

Cathartics are useful to increase the amount of water in the large colon or to promote ingesta transit. Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum; it is indigestible and absorbed to a limited extent. It is an intestinal lubricant that can also serve as a marker of intestinal transit. Administration of 5 to 10 mL/kg is usually recommended, and oil should be evident in the feces 12 to 24 hours after administration. Unformed feces were apparent 18 to 24 hours after its administration in normal horses.[119] Administration to normal horses decreased glucose absorption and intestinal transit time.[120,121] Chronic use can result in a foreign body reaction in the intestinal mucosa.[122] Careful administration is necessary, since inadvertent administration into the lungs results in lipid pneumonitis, which is severe and often fatal.[123,124] Mineral oil is easily confused with propylene glycol, used in the treatment of ketosis in cattle; inadvertent administration of propylene glycol was the cause of death in a horse.[125]

Dioctyl sodium sulfosuccinate is an anionic surface-active agent that by lowering surface tension may facilitate penetration of the fecal mass by water and fats. Effects on motility and secretion are also attributed to this product. The recommended dosage range is 16.5 to 66 mg/kg, and the maximal recommended dose is 200 mg/kg. Death because of circulatory shock can occur at dosages of 1 g/kg.[126] In one study in normal horses, toxic signs were observed at a dosage of 50 mg/kg.[115] It is important to correctly label the product to avoid overdosing. Its advantage is that it requires a low volume of administration. However, the drug's low margin of safety and lack of efficacy at low dosages make its use questionable. Concurrent absorption with mineral oil may result in emulsification and subsequent systemic absorption of oil. Therefore the use of the combination is frequently discouraged, although the significance of this finding is unknown.

Osmotic or saline cathartics such as magnesium sulfate or sodium sulfate are effective products to increase colonic water content.[115,127] Because of their efficacy, these products should be used after systemic rehydration. Recommended dosages are 0.5 to 1 g/kg. Absorption of magnesium resulting in signs of toxicity was reported in two horses that had received a combination of dioctyl sodium sulfosuccinate and magnesium sulfate.[128] Raw linseed oil produced from flaxseed was a commonly used laxative for the treatment of impactions. The addition of metallic salts and boil oil or boil pure oil enhances its properties as a wood preservative and is highly toxic. Only raw linseed oil should be used. Administration of 2.5 mL/kg to normal horses resulted in watery diarrhea, anorexia, mild signs of colic, and neutropenia.[119] Although raw linseed oil has greater laxative effects than mineral oil, the toxic effects may preclude its use, particularly in horses with compromised intestinal mucosa.[119]

Polyethylene glycol 3350 is an effective osmotic laxative that is used in humans for the treatment of constipation or for colonic cleansing.[129-130] This product has not been evaluated rigorously in horses, although we have used it successfully to treat large colon impactions. Its cost is much greater than that of the other cathartics mentioned. Castor oil has been used as a model for experimental colitis in ponies.[131] Its use for the treatment of impaction colic is not recommended.

Analgesics are indicated as part of the management of large colon impaction. NSAIDs are commonly used. Use of low-dose flunixin meglumine may help control pain without affecting large colon motility. In the course of treatment of severe impactions, some horses may require intermittent dosing with xylazine to relieve intestinal spasm.[132] Alternatively, a constant-rate infusion of lidocaine can be used to modulate pain.

Prognosis

Most horses respond well to medical therapy. In one study, only 24 of 147 horses required surgery.[37] Indications for surgery included uncontrollable pain, deteriorating cardiovascular status, or peritoneal fluid changes indicating bowel compromise. Of the horses that went to surgery, five were euthanized after tearing of the colon during exteriorization.[37] Surgical management of large colon impaction involves evacuation of the colon by pelvic flexure enterotomy. Complications of surgery include intraoperative rupture of the colon, postoperative diarrhea, incisional drainage, and, rarely, septic peritonitis.[37] The prognosis for large colon impaction is excellent, and the majority of horses respond to medical therapy. The prognosis is better for horses treated medically than surgically. In one study, long-term outcome for horses treated medically was 95.1%, compared with 57.8% for horses treated surgically.[37] However, the lower outcome associated with surgically treated horses reflects a worse condition rather than a surgical failure. The most common complication was jugular vein thrombophlebitis, so catheter sites should be monitored carefully. In the management of these horses, it is important to avoid risk factors that predispose to impactions. These horses are at risk for reimpaction if the same conditions remain. A small number of horses require permanent dietary modifications to prevent reimpaction.

Sand Impaction

Accumulation of sand in the equine large colon can result in variable signs, including colic, diarrhea, weight loss, and poor performance. Sand should be considered in the evaluation of chronic diarrhea in foals and adult horses.[133,134] Risk factors for sand impaction include insufficient roughage in the diet, access to sand, and mineral composition of the soil. Sand impaction has been diagnosed in horses that were exposed to sand 3 to 8 weeks before examination.[135] Higher incidences of sand colic are reported in California, Arizona, Florida, Michigan, and coastal regions. Although most horses with sand impaction are older than 1 year, sand accumulation has been documented in foals.[135-137] Miniature horses may also be predisposed to sand impaction because of environmental and management practices.

Diagnosis

Horses with sand impaction manifest signs similar to those of large colon impaction, unless a concurrent large colon displacement or torsion is present. Large colon displacements or torsion were identified in 10 of 40 (25%) and 26 of 48 (54%) of horses with sand impaction.[135,136] These clinical signs include mild to

moderate abdominal pain, reduced fecal production, and decreased intestinal sounds. The sound of sand may be heard when the ventral abdomen is auscultated behind the xyphoid. These horses are responsive to analgesics, and signs can be present for several weeks. The cardiovascular status should be normal unless dehydration or intestinal devitalization has occurred. Occasionally, horses with sand impaction show signs of endotoxemia, presumably as a result of mucosal or intestinal damage associated with the weight and abrasiveness of the sand.[137]

Diagnostic procedures that are used to detect the presence of sand include observation of sand in the feces, sand obtained or palpated during abdominocentesis, abdominal auscultation, rectal palpation of a sand-filled viscus, abdominal radiography, and abdominal ultrasonography.[136-138] In one study, 23 of 40 horses (58%) were diagnosed with intestinal sand before surgery by one or more methods.[136] Fecal sedimentation is performed by adding water to six fecal balls in a rectal sleeve, and allowing the sand to settle to the bottom. The presence of more than 1 teaspoonful of sand is considered excessive. The presence of sand on sedimentation, however, may be incidental, and horses with sand impaction may not have sand in their feces at the time of examination. The appearance of sand in the feces during treatment is considered a sign of clearance of the sand.[137] Abdominocentesis results often are normal or show an increased total protein. Abdominocentesis is not diagnostic for sand colic but rather indicates the degree of intestinal compromise. However, the weight of the colon makes it easy to perform an unintentional enterocentesis during the procedure, and sand can be palpated with the tip of the needle or cannula.[135] In one study, 13 of 23 horses with correctly diagnosed sand impaction before surgery were identified by the presence of sand obtained or palpated during abdominocentesis.[136] Abdominal auscultation for the detection of sand is performed on the ventral abdomen, with emphasis on the area caudal to the xiphoid process.[139] The sound produced has been described as similar to the sound produced by sand in a partially filled paper bag that is slowly rotated.[139] The intensity of sound is loudest with larger accumulations of coarse as opposed to fine sand. In an experimental study of sand impaction in horses, all horses had, at some time, sand sounds that could be auscultated, but in most cases only after receiving several doses of sand and after several repeated 5-minute auscultation periods.[139] Rectal palpation of horses with sand impaction most commonly reveals distention of the cecum or large colon. The impaction is rarely palpated on rectal examination; however, if coarse sand is present, it may be palpated through the intestinal mucosa.

Abdominal radiography provides the best method to evaluate the amount of sand accumulation, and it serves as a tool for monitoring disappearance of sand with treatment (Figure 37-10).[137] The cranioventral abdomen is the most useful location for imaging.[137] Abdominal ultrasonography can be used to diagnose sand impaction, but it is best used in combination with abdominal radiography to monitor clearance of the sand.[140] Ultrasonographic evidence of sand accumulation is more subjective and includes close and increased contact of the large colon with the ventral body wall, decreased or absent intestinal motility, and hyperechoic acoustic shadowing. In one study, radiography and ultrasonography outcomes were similar in only 50% of cases.[138] Because ultrasonography is more readily performed and can be easily repeated, it is thought to be a useful tool for monitoring once a diagnosis has been made, although repeated radiographs may be indicated when results of the ultrasonography are equivocal.[138]

Figure 37-10. Lateral radiographic projection of the ventral abdomen of a horse showing accumulation of sand in the ventral colon *(arrows).*

Treatment

Medical treatment of sand impaction includes removing the horse from access to sand, rehydrating by intravenous or oral methods, and using laxatives. Mineral oil is usually not effective, as it will pass around the sand. Magnesium sulfate or psyllium is used to promote evacuation of sand. In one study, psyllium failed to increase evacuation of sand in an experimentally induced model of sand impaction.[141] However, numbers were small and the model may not reflect naturally occurring disease. In a clinical study, horses that had sand impaction refractory to treatment were responsive to administration of magnesium sulfate and mineral oil.[137]

Resolution of the impaction can be monitored using abdominal radiography or ultrasonography.[137,138] Horses with sand impaction can develop abnormal motility patterns and subsequent large colon displacement. These horses have more pain and develop gas distention of the large colon. Surgical intervention is indicated when a displacement is suspected or diagnosed, when abdominal pain is uncontrolled, in the presence of deteriorating cardiovascular parameters, or when there is evidence of intestinal devitalization.[135-136] Standing flank laparotomy does not allow sufficient access to the large colon for evacuation in the presence of sand, and injection of the impaction is not successful in providing relief.

Therefore a surgical approach through a ventral midline incision is recommended. At surgery, the sand is evacuated through a pelvic flexure enterotomy (Figure 37-11). The most common location for accumulation of sand is the right dorsal colon, but any location, from the ileocecal junction to the small colon, is possible, and multiple impaction sites are commonly encountered. Care must be exercised during exteriorization of the large colon, since the weight of the sand predisposes the colon to rupture, especially in chronic cases. To facilitate exteriorization,

Figure 37-11. Pelvic flexure enterotomy for evacuation of a gravel impaction in the large colon of a horse.

the horse may be tilted toward the left side of the abdomen. In addition, only the minimal length of large colon necessary to safely perform a colotomy should be exteriorized; as the colon is evacuated, more of its length can be carefully exteriorized from the abdomen.

Prognosis

Reports of surgical treatment of sand impaction indicate a good long-term survival. The most common complication is postoperative diarrhea, but this complication is commonly noted after surgical evacuation of the large colon for any reason. Other complications include peritonitis associated with intestinal devitalization from pressure necrosis.

Prevention of sand impaction includes providing adequate roughage, feeding off the ground, and providing additional roughage when pastures are insufficient. The use of different formulations of psyllium (pellets or flakes) has been advocated at different dosage regimens (once a day for 3 weeks, then 1 week off, to twice a day for 2 weeks, then 1 week off), but the efficacy of these different dosage regimens in prevention of further sand accumulation has not been documented. There is concern that long-term use of psyllium alters the colonic microflora with subsequent bacterial digestion of the psyllium and decreased efficacy; this is the rationale behind interrupted administration.[141]

Enterolithiasis

Obstruction of the large or small colon by enteroliths is a well-documented cause of intestinal obstruction in the horse. Risk factors include geographic location (with California and Florida having high prevalence for this cause of colic), breed predisposition (e.g., Arabians and Arabian crosses, Morgans, American Saddlebreds, donkeys, and Miniature Horses), feeding alfalfa hay, and less than 50% of time spent outdoors.[142,143] Other factors to explain why other horses fed the same diet in the same geographic area do not develop enteroliths are as yet unidentified.

Diagnosis

Enterolithiasis can result in acute severe luminal obstruction or cause intermittent mild signs of colic, depending on the location and size of the enterolith. Those in the large colon are usually localized in the right dorsal colon and cause mild signs of intestinal discomfort. Once they migrate into the transverse or small colon, signs of acute luminal obstruction develop, with progressive abdominal distention. Although this condition causes a simple colonic obstruction, transmural pressure necrosis can occur. Critical attention to results of the abdominocentesis helps determine such occurrence. An increase in total protein above the normal range and an increase in WBC count can alert the clinician to such occurrence.

Physical examination parameters also vary, depending on the location of the enterolith and whether intestinal devitalization has occurred. Rectal palpation may be normal or may reveal large colon distention. The enterolith can rarely be palpated. Results of the abdominocentesis are often normal, although an increased total protein is an early sign of intestinal devitalization. Radiographs are a useful diagnostic method for detecting of enteroliths, although the sensitivity and specificity vary depending on the location of the enterolith and the prevalence of the disease for the hospital population.[144] In one study performed in a high-prevalence area for enteroliths, the sensitivity of radiographic diagnosis of enterolithiasis was 84.3% for those located in the large colon, compared with 50.0% for those located in the small colon.[144] The mean overall positive predictive value for radiographs was 96.4%, and the negative predictive value was 67.5%.[144] Surgical removal is indicated. If the enterolith is located in the large colon, the large colon is evacuated via a pelvic flexure enterotomy. A second enterotomy may be required in the right dorsal colon if the enterolith is too large to be evacuated through the pelvic flexure enterotomy. If the enterolith is lodged in the transverse colon, retrograde flushing by enema can facilitate its movement back into the dorsal colon. If the enterolith is in the small colon, it is removed by a small colon enterotomy. A partial-thickness enterotomy can facilitate movement of the enterolith to a more accessible portion of the small colon.[145] If there is significant pressure necrosis of the intestinal wall at the site of the obstruction, a resection may be required.

Prognosis

The prognosis is usually excellent. However, local necrosis of the intestine in an area that cannot be exteriorized, such as the transverse colon, is associated with a grave prognosis. In one study, bypass of the transverse colon by end-to-side anastomosis of the ventral colon to the small colon was successful in a Miniature Horse with intestinal necrosis after obstruction by a fecalith in the transverse colon. The recurrence rate of enteroliths is unknown, but dietary modifications such as avoidance of alfalfa hay are usually recommended. Other recommendations include removing horses from dirt or gravel, which can serve as a nidus, adding psyllium to the diet, and adding cider vinegar (1 cup twice daily) to the diet. In geographic areas where the water has a high mineral concentration, providing an alternative source of water can be useful.[143] Wheat bran should be minimized because of its high phosphorus content. Control of the dietary cation–anion balance (DCAB) has been suggested, although the benefits are unproven.[146] The target DCAB is calculated by the following equation:

$$DCAB = ([Na] + [K] + 0.15[Ca] + 0.15[Mg]) - ([Cl] + 0.25[S] + 0.5[P]),$$

is +200 to 300 mEq/kg. Grass hays and cereal grains have a DCAB within that range, whereas that of alfalfa is higher.

Large Colon Displacement

The equine large colon, because of its lack of mesenteric attachment to the body wall, is freely mobile and prone to displacement. In addition, normal longitudinal shortening of the left colon, promoted by contractions of the longitudinal layers, move the pelvic flexure toward the diaphragm, followed by backward movement toward the pelvis during relaxation; alterations in this motility pattern, initiated at the pelvic flexure pacemaker, could result in displacements and torsion.[88] The normal equine diet is composed of soluble and insoluble carbohydrates, the latter of which are digested by microbial fermentation, resulting in production of volatile fatty acids that are absorbed for energy production. When excess soluble carbohydrates are fed, alterations in the microbial population of the large colon may result in excessive fermentation, gas distention, and subsequent displacements.

Large colon displacements have been classified into left dorsal displacement of the large colon (also referred to as nephrosplenic entrapment or renosplenic entrapment), right dorsal displacement of the large colon, and nonstrangulating volvulus of the large colon. The large colon may adopt a location intermediate to these displacements, such that the exact description of the displacement can be difficult to describe.

Nephrosplenic Entrapment

Nephrosplenic entrapment (also termed renosplenic entrapment or left dorsal displacement of the large colon) is a form of nonstrangulating large colon displacement in the horse, in which the left dorsal and ventral colons migrate lateral to the spleen in a dorsal direction until entrapped in the nephrosplenic space (Figure 37-12). It has been reported in horses of any age, and in foals as young as 9 months.[147] Although one report mentions the increased prevalence in male horses, others have not substantiated that finding.[147-149] Miniature Horses and pony breeds have not been reported to acquire this problem. It is theorized that excessive gas formation within the left colon, perhaps in association with abnormal motility, causes the left colon to displace lateral to the spleen and dorsad into the nephrosplenic space; alternatively, displacement can occur during rolling episodes.[91,150-152] In most cases, there is also ventromedial rotation of the left colon, such that the left dorsal colon is rotated ventral to the left ventral colon. The weight of the colon causes the spleen to displace medially and ventrally and to become congested. Because of impaired flow of ingesta over time, with duration there is also concurrent impaction of the left dorsal colon. With continued gas formation, the sternal and diaphragmatic flexures can migrate craniad and dorsad to the stomach and become lodged between the stomach and the left lobe of the liver, a displacement classified as type II in one report.[153,154] Nephrosplenic entrapment is a nonstrangulating lesion of the large colon; however, when duration of the condition increases to longer than 24 hours, colonic congestion and edema can develop, and mural damage may follow.[152] Obstruction to gastric outflow occurs because of pressure of the colon on the duodenum or tension on the mesentery. Entrapment of the small colon or small intestine in the nephrosplenic space have been described, but these conditions are rare.[155,156]

Horses with nephrosplenic entrapment show variable degrees of pain depending on the location of the colon, the amount of gas distention, and the presence of secondary gastric distention. Location of the colon lateral to the spleen is associated with minimal to no discomfort and is found in the resolving stages of the displacement. Entrapment of the colons within the nephrosplenic space with the spleen in a relatively normal position is a very painful condition. Affected horses crouch, want to go down, and often lean to the left. When the spleen is pushed away from the body wall and displaced ventrad by the colons, effectively opening the nephrosplenic space, there is less pressure on the colon, and horses show only mild signs of abdominal pain.

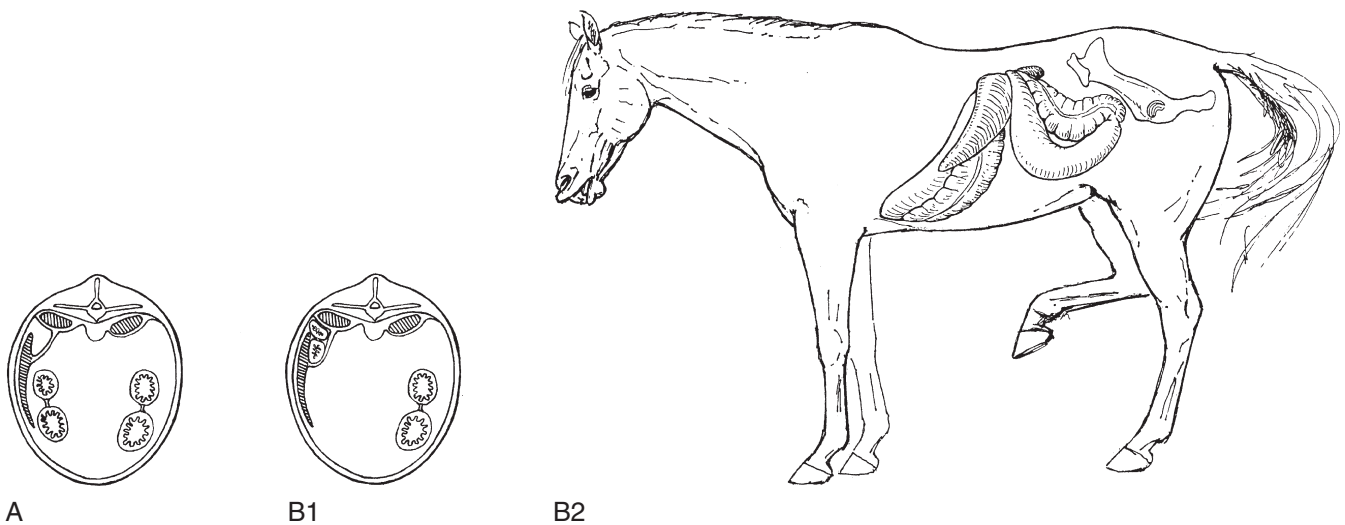

Figure 37-12. A, Left dorsal displacement of the ascending colon. The normal anatomic relationships of the colon to the spleen are shown. **B,** The dorsal and ventral colon may displace and become trapped in the nephrosplenic space. **B1,** Cross-sectional caudocranial view. **B2,** Side view.

DIAGNOSIS

The diagnosis of nephrosplenic entrapment is based on the presence of abdominal pain (which can be mild to severe, depending on the location of the colon and the degree of gas distention) and relatively normal cardiovascular parameters, consistent with a simple obstruction. The complete blood count and blood chemistry values should be normal or consistent with mild dehydration. A low PCV in the face of dehydration has been reported as an indication of red blood cell sequestration in the spleen. The abdominocentesis results should be within normal range, and collection of splenic blood (characterized by a higher PCV than in peripheral blood) supports of a diagnosis of nephrosplenic entrapment. In one study, these results were obtained in 25% of horses at admission.[148] Horses with an increased WBC in the peritoneal fluid were more likely to suffer from a longer duration of the condition and to be treated surgically.[148] Nasogastric reflux is commonly obtained in horses with nephrosplenic entrapment as a result of pressure on the duodenum or mesenteric tension. Up to 43% of horses with nephrosplenic entrapment were reported to have nasogastric reflux.[147] In one study, resistance to nasogastric intubation was encountered in horses with displacement of the sternal and diaphragmatic flexures dorsal to the stomach.

An ultrasonographic examination of the abdomen may serve as an adjunctive tool in the diagnosis of nephrosplenic entrapment, and it was diagnostic in 88% (36 of 41) horses with nephrosplenic entrapment.[157] A 2.5- or 3.5-MHz ultrasound probe is placed over the 15th to 17th intercostal space in a direction parallel to the ground, and the spleen is imaged. In the normal horse, the left kidney is imaged deep to the spleen. In horses with nephrosplenic entrapment, the presence of gas-filled colon dorsal to the spleen precludes imaging the kidney. Finding ventral displacement of the dorsal aspect of the spleen is also consistent with nephrosplenic entrapment. If the colons are displaced lateral to the spleen, then imaging of the spleen is obscured as well. It is important to direct the probe in a horizontal direction; if the probe is angled in a dorsoventral direction, the kidney can occasionally still be imaged, giving a false-negative diagnosis. The inability to image the left kidney supports only a diagnosis of a nephrosplenic entrapment and should be used in conjunction with rectal palpation. Nonspecific large colon distention or the normal presence of small colon in the nephrosplenic space can impair imaging of the left kidney.[158] In addition, if the colon is filled with fluid, imaging of the left kidney is still possible, but the entrapped bowel is also seen.[157] Rectal palpation remains the mainstay of diagnosis of nephrosplenic entrapment. On palpation, the left colon is most often gas distended, and the ventral colon is located dorsal to the left dorsal colon; often, an impaction of the left dorsal colon is present as well. The colon can be followed up into the nephrosplenic space. It is important for the correct diagnosis to follow the colon into the nephrosplenic space, because in other conditions (ranging from gas colic to large colon torsion), the colon may assume a dorsal position within the abdomen, leading to a false diagnosis of nephrosplenic entrapment.[159] This could be disastrous if nonsurgical management is attempted and the horse effectively has a large colon torsion. Rectal palpation correctly identified left dorsal displacement of the large colon in 61.2%, 68.7%, and 72% of cases in three studies, although an early study reported a much lower rate of correct identification (only 18%).[147-149,153] Rectal palpation can be impaired by the patient's size and temperament or the presence of severe distention.

A thorough physical examination, rectal palpation, and abdominal ultrasonography should be performed in horses with nephrosplenic entrapment, because a small number of them have another primary lesion involving another segment of the gastrointestinal tract. Gastric rupture, small intestinal volvulus, ileal impaction, large colon displacement, large colon volvulus, cecal torsion, and small colon obstruction have been documented in association with nephrosplenic entrapment.[148,149,157,160]

TREATMENT

Once a diagnosis of nephrosplenic entrapment has been made and the clinician is confident that there are no other abnormalities, options for treatment are evaluated. These include medical therapy with intravenous fluids and withholding of feed; exercise with or without the use of a pressor agent; rolling under general anesthesia, with or without the use of pressor agents; standing flank laparotomy; and ventral midline celiotomy.

Medical treatment

Medical therapy with intravenous fluids supplemented with calcium gluconate is indicated when the colons are located lateral to the spleen or dorsal to the spleen but not in the nephrosplenic space. This type of treatment was successful in nine affected horses.[147] Medical therapy with enteral fluids consisting of isotonic electrolyte solution, with or without intravenous fluids, was successful in 25 of 30 horses (83%) with nephrosplenic entrapments.[118] In that report, it is not clear where the left colons were located, or the number of horses with suspected as opposed to confirmed nephrosplenic entrapment.

When the colons are localized in the nephrosplenic space and the horse is in pain, nonsurgical management can be attempted. In one study, horses that were successfully treated nonsurgically had a shorter duration of clinical signs, a lower peritoneal fluid WBC, and a higher blood lymphocyte count than horses treated surgically.[148] In that study, failure at nonsurgical correction was also felt to be related to severity of gas distention, which would also increase with duration. It is important to emphasize again that the diagnosis must be certain before attempting this option.

With all nonsurgical options, *phenylephrine* is often used to cause splenic contraction and facilitate correction. Bleeding the horse was described in the early literature to reduce splenic size, but this seems unnecessary and possibly detrimental.[161] Phenylephrine (Neo-Synephrine, 10 mg/mL) is an α_1-adrenergic receptor agonist that causes vasoconstriction in most vascular beds, as well as splenic contraction. In one study, the splenic area was reduced to 28% of baseline and thickness to 48% of baseline after administration of phenylephrine at 3 μg/kg/min over 15 minutes.[162] Side effects were minimal at that dosage and included hypertension and reflex bradycardia. We use a total dose of 10 mg for horses with a body weight of 450 kg or less and 20 mg for larger horses, diluted in 50 mL of saline and given slowly intravenously over 5 minutes. There are anecdotal reports of fatal hemorrhage (hemothorax most commonly, and hemoabdomen) after phenylephrine administration to older horses. It is unknown whether these horses had preexisting systemic or pulmonary hypertension, but the drug should be used with caution in older animals.[163] It is also important to administer the drug properly, following dilution and slowly; there is one report of severe hemothorax following an intravenous bolus of the undiluted drug.[164] Vigorous exercise is an option for correction of this

problem, providing the horse is not lame. This is more successful when performed early in the course of the disease, before large colon distention develops.[147,159] If there is significant distention of the left colon, it can be trocarized before exercise. For trocarization, an area over the left flank is clipped and prepared for aseptic surgery. A 14-gauge angiocatheter with a catheter extension is used to puncture the flank in a perpendicular direction. The end of the catheter extension is placed in a water container to facilitate observation of gas exiting the colon. Once in place, the trocar portion of the catheter is withdrawn for a few millimeters to avoid lacerating the bowel. The catheter may need to be inserted farther as the colon is deflated. When doing so, care must be taken not to lacerate the tip of the catheter with the trocar. Rectal palpation can help manipulate the colon to facilitate gas evacuation. Once gas is evacuated, the trocar portion of the catheter is removed and 1 to 2 mL of gentamicin is injected as the catheter is withdrawn. Once the trocarization is completed, phenylephrine is administered and the horse is exercised either on a lunge line or in a small paddock for approximately 15 to 30 minutes. Rectal palpation is performed to ascertain the position of the colon. Exercise can be repeated if correction is not achieved.

Correction by rolling under general anesthesia is another nonsurgical option for this disorder.[160,161] This has also been reported useful in a small number of horses with other forms of large colon displacements.[165] This option is preferred if the horse is lame, or if there is marked large colon distention. Previous abdominal surgery may preclude it, however, as splenic adhesions may prevent successful correction of the displacement.[166] For this procedure, the colon is not trocarized unless the distention is severe, as gas translocation is used to achieve correction of the displacement. The horse is prepared for short-term intravenous anesthesia. Sedation is induced, followed by phenylephrine infusion as described previously. The horse is subsequently anesthetized and dropped into right lateral recumbency. Using a knee or two-handed fist, the clinician then vigorously shakes the abdomen in the region of the right flank, as the horse's hind legs are being hoisted dorsally. If a hoist is not available, the horse is slowly rolled into dorsal recumbency while abdominal compressions are performed. With the hoist, the hind legs are elevated until the horse's body reaches a 60-degree vertical position, while the clinician continues to vigorously shake the abdomen. After 1 or 2 minutes, the horse is replaced in right lateral recumbency. At this stage, some clinicians prefer to place the horse in left lateral recumbency, roll the horse into sternal position, and return it to right lateral recumbency. The procedure is repeated two more times. After the last manipulation, the horse is returned into left lateral recumbency for recovery. Between manipulations, the clinician may check the position of the colon. In our experience it is difficult to determine successful correction of the entrapment, either by ultrasonography or rectal palpation, with the horse under general anesthesia. Therefore we always recover the horse to determine if correction was achieved. Some clinicians prefer to follow immediately with surgical correction without recovery if it is suspected that correction was not achieved.[159] One author describes manipulation of the colon *per rectum*. With the horse in right lateral recumbency, the hand lifts the colon off the spleen as the horse is being turned to left lateral recumbency. The use of muscle relaxants to loosen the rectum is recommended when this procedure is used. Rectal manipulation must be performed with extreme caution, as rectal tears represent a definitive risk of the procedure.[160] Rectal palpation after manipulation often reveals that the colon is lateral to the spleen and has not completely resumed its normal position. Administration of fluids and calcium often results in complete correction within a few hours. Some horses show mild abdominal pain after manipulation, even though it is suspected that correction was achieved. This is probably a result of residual large colon distention or impaction, and it is usually responsive to analgesics.

Surgical treatment

If nonsurgical manipulations are unsuccessful, surgical intervention is indicated. Standing flank laparotomy or ventral midline celiotomy are options to consider. The advantages of the standing flank laparotomy are avoidance of general anesthesia, direct access to the problem, access to the nephrosplenic space for closure as an option for preventing recurrence, and more rapid return to use of the horse. The major disadvantage, as is the case for nonsurgical manipulation, is if an incorrect diagnosis was made, precluding correction of the condition by this approach. The advantages of the ventral midline celiotomy are that it ensures successful correction, particularly in cases where the colons are located dorsal and cranial to the stomach, and it allows correction of other undiagnosed problems. The disadvantages include the need for general anesthesia, longer postoperative recovery, and increased cost.

Standing flank laparotomy

The horse is restrained in stocks with the tail bandaged and tied to avoid contamination of the incision. Sedation with xylazine, with or without butorphanol, is sufficient for most horses. After standard preparation of the surgical site, local anesthesia is performed. This can be accomplished with a paravertebral block, an L-block, or a line block, taking care to add local anesthesia for placement of towel clamps.[167] In our experience, the paravertebral block often requires additional local anesthetic in the distal aspect of the planned incision. Draping is routine, with the addition of a drape folded to form a pocket to support the exteriorized bowel. The standard surgical approach for a flank laparotomy is midway between the last rib and the cranial aspect of the tuber coxae, starting approximately 2 cm above the palpable internal oblique muscle. In the standing horse, the modified grid approach is preferred, as the muscles will contain the intestinal contents after surgery. In the modified grid approach, the external oblique muscle is incised in a vertical direction but the internal oblique and transverse abdominal muscles are bluntly separated along the course of their muscle fibers by finger dissection. Additional topical application of anesthetic may be required before perforating the peritoneum. Once the abdomen is entered, the spleen and large colon are located. In our experience, it is easier to push the spleen down and under the large colon than to lift the large colon over the spleen. Once the colon is lateral to the spleen, it is gently pushed down into the ventral abdomen. Closure is routinely performed.

Standing laparoscopic correction

There is one report of a standing laparoscopic approach for diagnosis and correction of a nephrosplenic entrapment in an adult horse.[168] An important point in this case is that the left ventral and dorsal colons were not impacted or gas distended. This allowed the surgeon to place a 53-cm-long (21-inch-long)

stainless steel bar in a laparoscopic portal and use it to reposition the entrapped large colon off the spleen, in combination with systemic administraiton of phenylephrine. This approach would be contraindicated if significant feed impaction or gas distention of the large colon was present or if the horse showed significant abdominal pain.

Ventral midline celiotomy

This approach is recommended for correction of nephrosplenic entrapment if nonsurgical management is unsuccessful and the surgeon is not comfortable with the flank approach. It is also the suggested approach if there are clinical or clinicopathologic findings that indicate either the loss of intestinal integrity or the presence of another lesion. Ventral midline celiotomy is also used when a presurgical diagnosis is not possible because the small size of the patient precludes rectal palpation or because excessive large colon distention is present. A routine ventral midline approach is performed. To facilitate access to the nephrosplenic space the horse may be slightly rotated to the right. In the presence of excessive splenic congestion, or excessive weight of the colon, phenylephrine may be administered to reduce splenic size and facilitate correction. The base of the spleen is grasped, and the spleen is lifted and pushed medial to the colon, thus freeing it from the nephrosplenic space. The colon is subsequently cradled over the forearm and lifted out of the abdomen. Although there is often feed accumulation in the dorsal colon, evacuation is usually not necessary because the feed redistributes when the displacement is corrected. The colon is assessed for signs of devitalization. Rarely, a large colon resection has to be performed.

Reported recurrence rates of nephrosplenic entrapment are between 7.5% and 8.5%.[147,148] Considering this relatively low risk of recurrence, surgical intervention procedures for prevention of recurrence are not recommended after a first incidence. However, feeding and management practices should be carefully reviewed to minimize the risk of gas formation in the large colon and subsequent displacement.

PREVENTION OF RECURRENCE

Procedures that have been advocated to prevent recurrence of left dorsal displacement of the large colon include closure of the nephrosplenic space, large colon colopexy, and large colon resection. Refer to later sections for discussions of large colon resection and colopexy procedures.

Closure of the nephrosplenic space does not prevent migration of the large colon lateral to the spleen, or the occurrence of other forms of large colon displacement. The procedure can be performed through a flank laparotomy or though a minimally invasive laparoscopic approach.[169a-c] The flank approach is performed in the standing or laterally recumbent horse. The abdomen is entered either through a modified grid or laparotomy approach. The spleen and nephrosplenic ligament are identified, and the nephrosplenic space is verified to be free of intestine. Cruciate sutures are then placed between the ligament and the tip of the spleen, using a nonabsorbable suture material such as 2-polypropylene. Approximately 6 to 12 sutures are preplaced and tied. The abdomen is closed in a routine fashion. Alternatively, laparoscopic ablation of the renosplenic space can be performed in the standing horse.[169a-c-171] The procedure is performed using three laparoscopic portals and polyglactin 910 suture material in a simple-continuous pattern. Alternatively, laparoscopic placement of a polypropylene mesh has been used to obliterate the nephrosplenic space.[169a]

In a small series of 10 horses, where 15 episodes of left dorsal displacement of the large colon and 21 episodes of colic were recorded before laparoscopic closure of the nephrosplenic space, a significant decrease in the total incidence of colic, incidence of nephrosplenic entrapment, and incidence of ventral celiotomy was identified. However, no difference was found in the number of horses that had colic peroperatively compared with postoperatively, which was probably due to small sample size.[170]

Right Dorsal Displacement of the Large Colon

This type of displacement is thought to be initiated by retropulsive movement of the pelvic flexure, with subsequent migration of the left colon craniad and then to the right abdominal quadrant, until the right ventral and dorsal colons are located between the cecum and the body wall (Figure 37-13). The colon can also rotate on its long axis, resulting in variable degree of venous congestion.

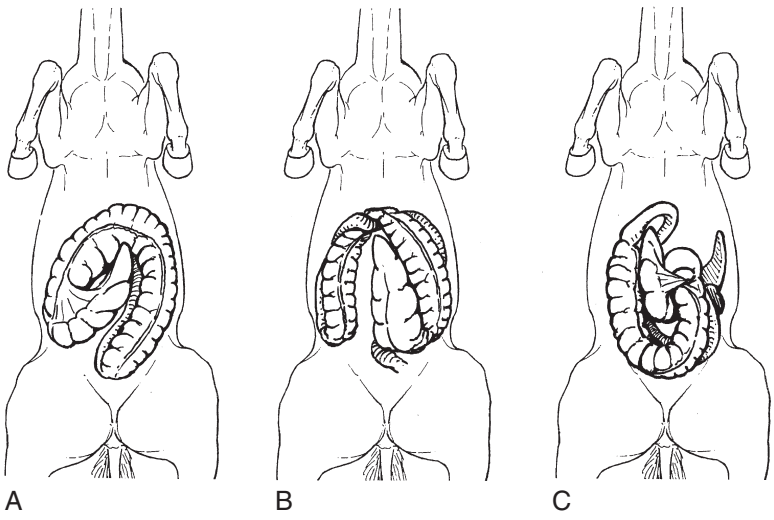

Figure 37-13. Right dorsal displacement of the ascending colon (ventral views). **A,** The normal anatomic relationship of the ascending colon. **B,** The most common direction for a right dorsal displacement is migration of the pelvic flexure in a counterclockwise direction when viewed from the caudal and ventral aspect of the horse at the time of surgery. **C,** Although less common, the ascending colon may develop a right dorsal displacement characterized by a clockwise migration of the pelvic flexure when viewed from the caudal and ventral aspects of the horse at the time of surgery.

DIAGNOSIS

The location of the colon at the time of examination is related to the clinical signs. When the colon is displaced craniad, all parameters are within normal limits, and abdominal pain is mild and intermittent. These horses may be comfortable when held off feed, and continue to pass small amounts of manure, with abdominal pain recurring when feed is reintroduced. On rectal palpation, there is no abdominal distention, but the examiner is unable to find the pelvic flexure. As the colon continues to migrate in a clockwise direction, the flow of ingesta is impaired, and a secondary impaction of the right dorsal colon may develop. Gas distention also becomes more significant, as does the associated abdominal pain. When a dorsal colon impaction develops, it is important not to mistake it for a pelvic flexure impaction, because continued medical treatment may result in rupture of the colon. This condition can be differentiated from a pelvic flexure impaction by the fact that the colon travels craniad to the right, and that the pelvic flexure cannot be identified. In right dorsal displacements, the cecum can be enlarged and filled with fluid.

Horses with right dorsal colon displacements are presented with mild to moderate abdominal pain. Depending on the degree of displacement, rectal palpation reveals absence of the pelvic flexure, presence of large colon lateral to the cecum, large colon distention, and right dorsal colon impaction. Nasogastric reflux may be present if there is large colon distention. Laboratory data are usually unremarkable, although a significant number of horses are presented with an elevated γ-glutamyltransferase, probably related to partial obstruction of the duodenum.[171]

TREATMENT

When horses are presented early, with normal parameters, mild abdominal pain, and minimal to moderate large colon distention, medical therapy may be attempted. Intravenous fluids are administered and the horse is monitored for resolution of the distention and relocation of the large colon.

When the pain is severe or there is marked large colon distention or a severe secondary impaction, surgical intervention is recommended. Although in some specific circumstances we have successfully corrected right dorsal colonic displacements via a standing flank laparotomy, a ventral midline celiotomy is preferred because of ease of exposure and correction.

At surgery, the pelvic flexure is identified, the large colon is exteriorized, and the displacement is corrected. When a severe large colon impaction coexists, the large colon is exteriorized at the pelvic flexure, but an attempt to correct the displacement is not made until the large colon has been evacuated, to avoid rupture during colonic manipulations. Although there is one report of successful treatment of a horse after intraoperative rupture during surgery, most of these cases are fatal.[172]

PROGNOSIS

The prognosis for large colon displacement is excellent. Recurrence is possible, and we have seen horses redisplace within 48 hours of the first procedure. In our opinion, it is important not to completely evacuate the large colon but to leave some ingesta and to return these horses to feed within 8 hours of surgery, again to try to maintain bulk in the large colon.

In one study of 154 horses treated surgically for right dorsal displacement of the large colon, it was found that those horses were significantly more likely to experience recurrent episodes of colic requiring veterinary intervention postoperatively compared to other types of displacements.[173]

Nonstrangulating Volvulus of the Large Colon

Nonstrangulating volvulus of the large colon is identified when the colon is rotated from 90 to 270 degrees along its long axis, a step that precedes the 360-degree large colon volvulus.

DIAGNOSIS

Horses with this type of displacement have a clinical presentation very similar to that of other simple large colon displacements; minimal cardiovascular compromise, mild to moderate abdominal pain, normal abdominocentesis, and mild to moderate large colon distention on rectal palpation. As in other displacements, medical management may be attempted. Horses that are still in pain or that have worsening of abdominal distention are candidates for surgical intervention. At surgery, the colon is replaced in its normal position.

As in all forms of large colon displacements or volvulus, prevention of recurrence should be considered. Colopexy and large colon resection are two procedures that are performed in an attempt to prevent recurrence. Usually these procedures are not recommended on a first occurrence, but they should be considered for horses that have had two or more displacements.

Other Simple Obstructions of the Large Colon

Congenital malformation of the large colon was reported as a cause of recurrent colic in a horse, and we have identified it in several horses.[174] Resection and anastamosis of the colon orad to the malformation successfully resolved the problem.

Fibrosis and stricture of the large colon caused by focal fibrosis at the pelvic flexure was identified in three horses and corrected by transverse closure of a pelvic flexure enterotomy performed at the site of the fibrosis.[175] Pelvic flexure adhesions resulting in impaction were reported in a filly with peritonitis. Laparoscopic adhesiolysis was successfully performed to allow return of transit.[176]

A massive duplication cyst of the ascending colon was reported in a 27-year-old mare with a history of recurrent colic and a pendulous abdomen. The cyst was successfully removed and the mare made an uneventful recovery.[177]

We have observed defects in the mesentery of the large colon in several horses (see Figure 37-7). The presence of the defect allows displacement or torsion of the colon upon itself, since it is no longer confined by the mesentery. The problem can be corrected by closure of the defects with the help of sutures. In one report, rupture of the mesocolon of the ascending colon was the cause of recurrent colic in a mare, and closure of the defect resolved the problem.[178]

Large Colon Torsion or Volvulus

Large colon volvulus is one of the most painful and devastating gastrointestinal problems in the horse (Figure 37-14). Successful management depends on rapid referral and prompt surgical intervention. Without intervention, death occurs in a matter of hours in horses. The prevalence of large colon volvulus is increased in geographic areas with high concentration of brood

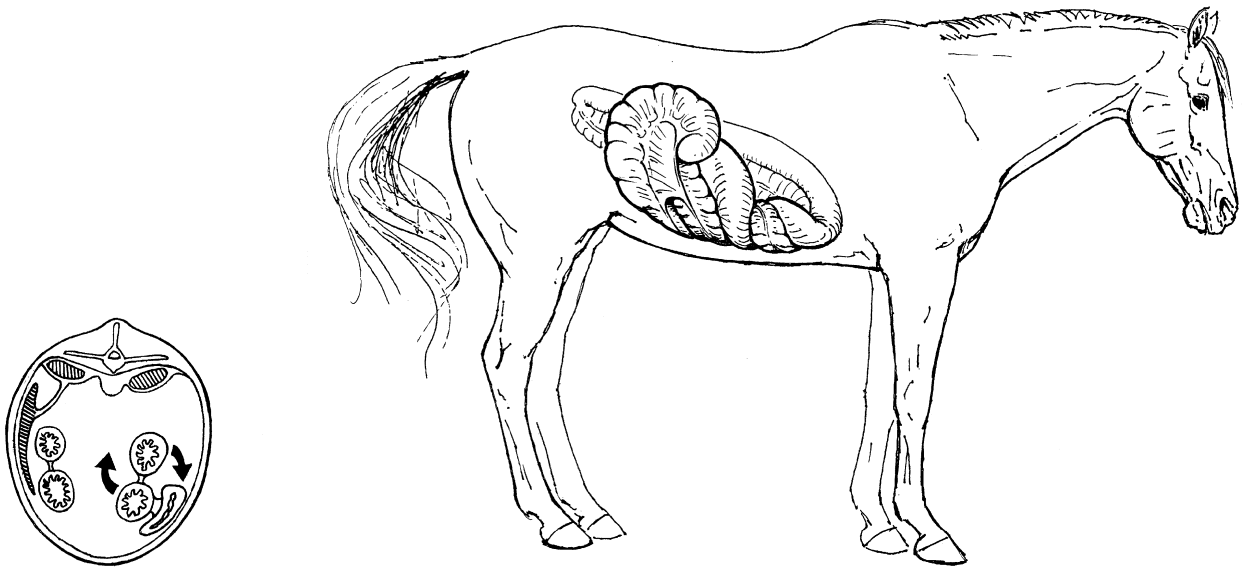

Figure 37-14. A schematic diagram representing the two directions in which the ascending colon may twist during torsion. The *arrows* indicate the more common dorsomedial torsion.

mares. Risk factors include recent parturition, recent dietary changes, and recent access to a lush pasture.

Diagnosis

The history of horses with large colon volvulus varies depending on the rapidity and totality of the development of a complete volvulus. Some horses are presented with a history of chronic (more than 24 hours) colic that suddenly worsens to intractable pain; others are presented with an acute onset of uncontrollable pain. Initially, despite the severe pain, horses maintain normal cardiovascular parameters, and rectal palpation can be unremarkable. As time elapses, these horses develop progressive large colon distention and accompanying progressive cardiovascular collapse. In mares, the color of the vaginal mucosa changes and reflects the degree of compromise of the large colon. If untreated, horses with large colon torsion die of hypovolemic shock caused by abdominal compartment syndrome associated with the severe distention, by pooling of blood in the strangulated large colon, and by poor pulmonary expansion because of severe distention.

Treatment

The treatment of large colon torsion is surgical. However, during preparation for surgery, resuscitative measures should be initiated to increase circulating blood volume and decrease abdominal pressure. Shock fluid therapy, including hypertonic saline, colloids, and crystalloids, needs to be initiated (see Chapter 3). Trocarization to relieve abdominal distention may improve lung expansion and venous return, and it can help sustain the horse during induction, until the colon can be exteriorized and decompressed.

In preparation for surgery, the horse can be tilted to one side to facilitate exteriorization of the colon and remove pressure on the caudal vena cava. Administration of intravenous lidocaine allows a decrease in the concentration of inhalant agents. A long ventral midline incision is made to help exteriorize the colon. A more cranial approach is preferred, to facilitate exposure of the colonic base.

The direction of the torsion is best described in relationship to the position of the ventral colon, which obviates the need to describe it from the observer's position. Thus a dorsomedial volvulus indicates rotation of the right ventral colon medially and dorsally.[179] Most are in a dorsomedial direction, and the location of the volvulus is at or proximal to the cecocolic ligament. Occasionally, a volvulus involving the sternal and diaphragmatic flexures is encountered. Volvuli of 270 to 720 degrees have been described.[180] Correction of the volvulus can be difficult, particularly if the colon is full or edematous, which places the colon, particularly the right dorsal colon, at risk for rupture during surgical manipulation. The ascending colon is exteriorized. If the colon is full or edematous and friable, a pelvic flexure enterotomy is performed to empty the colon before manipulation. To correct the volvulus, the surgeon, situated on the left side of the horse, places both hands in the abdomen around the base of the colon and gently manipulates it in a clockwise direction. The surgical assistant can facilitate manipulation by rotating the exteriorized portion of the colon in the same direction. Gas translocation and return of serosal color are indications that the colon is manipulated correctly. Once a 360-degree rotation has been achieved, the surgeon must ascertain that the volvulus is corrected and that another rotation of the colon is not needed. This is accomplished by examining the normal position of the cecum and the normal position of the cecocolic ligament, and by ensuring by palpation that the mesenteric attachment of the right dorsal colon to the dorsal body wall is straight. Palpation of the duodenum cranial to the right dorsal colon is possible after the volvulus is completely corrected.

Once the colon has been returned to its normal position, the surgeon must decide between euthanasia, recovery of the horse without further intervention, colopexy for prevention of recurrence, and large colon resection. It is essential to involve the owner in the decision-making process, particularly if the colon is compromised, since the cost of further intervention and

postoperative care can be significant. The surgeon must also understand that if the colon is not resected and the horse is recovered, it is unlikely that a second laparotomy will be an option. By the time clinical signs indicate that a second laparotomy with a possible large colon resection is warranted, the horse's condition will have deteriorated to the point that the chances of survival after a resection will be poor. Several factors are useful to help the surgeon reach a decision. A critical one is the horse's systemic condition both preoperatively and intraoperatively. A PCV above 50% (and increasing during surgery) associated with a decreasing total protein is a poor indicator of survival. An inability to maintain mean arterial blood pressure (despite the use of pressor agents), persistent hypoxemia, and persistent tachycardia during surgery is also associated with poor survival. Examination of the colon can provide some additional information. Return of a normal pink serosal color after volvulus correction is a positive indicator, but it does not relate to mucosal viability; severe postoperative endotoxemia may still occur if the mucosa is devitalized. Visual examination of the mucosa made through a pelvic flexure enterotomy provides additional information. The presence of dark red or black mucosa with no active bleeding is a poor prognostic indicator. Frozen sections allow calculation of the interstitial-to-crypt (I:C) ratio and percentage loss of epithelium, which correlate well with survival. An I:C ratio of 3:1 or greater, or loss of greater than 95% of the epithelium, was associated with a 95% death rate in one study. However, this requires that personnel be able to obtain and evaluate frozen sections immediately. Other research tools that have been used to evaluate colonic viability include surface oximetry, fluorescein dye, and Doppler flow; none of these tools has gained popularity in a clinical setting (see Chapter 35).

The decision to perform a colon resection should also be based on the location of the volvulus. If the line of devitalized bowel is located distal to the cecocolic ligament, the outcome of a large colon resection is much more favorable, because resection of the affected bowel is possible. However, in most instances, the line of devitalization is located at the base of the colon orad to the cecocolic ligament; resection must be performed in a compromised portion of the bowel, which places the resection site at risk for dehiscence. Surgeons who are advocates of large colon resection for the treatment of large colon volvulus make a case that removing the majority of the diseased colon decreases the endotoxic load and therefore increases the likelihood of survival; in addition, removal of the large colon prevents recurrence of the condition. Surgeons who do not routinely perform large colon resections for large colon volvulus state that the procedure in itself has a high risk of complications and that in most cases it does not result in removal of the entire diseased colon. In addition, the increased anesthesia time may be detrimental to the animal. These debates emphasize the complexity of the decision-making process in these cases, the importance of experience and familiarity with surgical techniques, and the influence of types of cases on the decision-making process. For example, horses that are referred quickly and have a short duration of illness rarely require a large colon resection.

Prognosis

Preoperative parameters that indicate poor survival include PCV greater than 50%, rectal temperature greater than 39.5° C (102° F), and a heart rate greater than 80 beats per minute.[181] Intraoperative factors associated with a poor survival include black mucosal color, poor return of perfusion after detorsion, and an increasing PCV and decreasing total protein during surgery.[155] Abdominocentesis is usually normal in horses with large colon volvulus; an increase in total protein in the abdominal fluid is associated with decreased survival.[155] Abdominocentesis therefore does not provide information that will alter the decision for surgical treatment, and it has an increased risk of enterocentesis or injury to personnel because these animals are in severe pain.

Reported mortality for large colon volvulus varies from 56% to 65%. However, in one study, the short-term survival rate was 84%; this higher survival rate was thought to be related to a shorter duration of illness and faster intervention time.[182] Although short-term mortality is high after surgical correction of large colon volvulus, a long-term probability of survival of 80% has been reported once discharge from the hospital occurred.[181] The prognosis for short-term survival (discharge from hospital) following large colon resection in horses in one study was 57.7% but was decreased to 47% when only strangulating lesions of the large colon were considered.[183]

Right Dorsal Colitis

Right dorsal colitis is a specific type of ulcerative colitis observed in the right dorsal colon of the horse, specifically the aboral segment of the dorsal colon as it joins the transverse colon. The condition is recognized in association with administration of NSAIDs, and it has been reproduced experimentally by administration of phenylbutazone. Horses with a nervous predisposition seem more prone to develop the disease despite the administration of appropriate dosages of NSAIDs. Although NSAID administration is commonly associated with this condition, it has also been documented in the absence of NSAID administration.

Diagnosis

Clinical signs of right dorsal colitis can manifest as acute colic, endotoxemia, diarrhea, and even death. The disease is more common in the chronic form, where horses are presented for weight loss, hypoproteinemia, intermittent signs of colic, and intermittent diarrhea.

The diagnosis of right dorsal colitis is based on anamnestic information, particularly related to NSAID administration, and ruling out other causes of weight loss, hypoproteinemia, and diarrhea. Diagnostic ultrasonography of the right dorsal colon may help identify the thickened colon (Figure 37-15).[184] More recently, scintigraphy with radiolabeled white blood cells has been described to diagnose the condition.[185]

Treatment

Medical management is recommended for the initial treatment of right dorsal colitis. This includes discontinuing NSAIDs, modifying diet, and giving anti-inflammatory drugs, intestinal protectants, and metronidazole. Dietary modifications are important to help control the signs of colic.

In cases of protracted colic, or when intermittent colic is so frequent as to prevent the horse from maintaining itself, surgical exploration may be recommended. At surgery, the right dorsal

Figure 37-18. Mural infarction in a horse with colitis associated with salmonellosis.

colon feels markedly thickened, and it may be strictured with scar tissue (Figure 37-16). Once the disease is identified at surgery, treatment options include right dorsal colon bypass, resection of the affected portion of the colon, large colon resection, or large colon resection and bypass.

Bypass of the affected area of the large colon is performed by exteriorizing the large colon on a colon tray. The small colon is then exteriorized and a 20- to 30-cm (8- to 12-inch) side-to-side anastomosis between the right dorsal colon (orad to the lesion) and the small colon approximately 1 m distad to the transverse colon is performed (Figure 37-17).[186] When this procedure is performed, transient diarrhea has been observed. This procedure does not remove the affected portion of the colon, so the patient can continue to suffer from weight loss and hypoproteinemia until the colitis has resolved. Resection of the affected colon through a 16th rib resection has been reported in one horse.[187] This approach requires either prior knowledge of the disease or a second celiotomy approach once the diagnosis has been made. Resection and end-to-end anastomosis is possible only if the lesion does not extend too far aborad. In cases of severe right dorsal colitis with stricture of the right dorsal colon, large colon resection and anastomosis in a side-to-side fashion can be performed to restore intestinal transit. However, complete removal of the ulcerated area would not be possible with this approach. Another approach, which has not been described for the treatment of this condition, would be to amputate the large colon, particularly the dorsal colon, as far aborally as possible, and to perform an end-to-side anastomosis between the right ventral colon and the small colon. This approach has been reported for the management of nonfunctional dorsal colon lesions in two horses.[188,189]

Mural Infarction (Thromboembolic Colic)

Compromise to the mesenteric vasculature without evidence of strangulation has been described in association with arteritis resulting from *Strongylus vulgaris* larval migration, or in horses with severe colitis and coagulopathies (Figure 37-18).[190] Cases of larval arteritis can be acute (with signs of ischemic bowel disease and peritonitis) or chronic (with signs of recurrent colic and weight loss). Horses with acute thromboembolic colic demonstrate significant changes in their abdominocentesis,

consistent with those seen with peritonitis; horses with recurrent colic often have a normal abdominocentesis.

In acute cases, the decision for surgical intervention is based on the signs of colic and the presence of peritonitis. At surgery, mural infarction is identified, and if possible, resection of the affected segment of intestine is performed. Careful palpation of the cranial mesenteric artery should be performed; identification of severe enlargement, aneurysm, or abscessation is an indication for a guarded to poor prognosis. A regular systemic deworming program should be instituted as part of the postoperative care.

When horses with colitis show acute signs of abdominal pain and abdominal distention, thromboembolic colic and necrotizing colitis should be suspected. Many of these horses have extensive lesions that preclude surgical intervention. In addition, their systemic status, as a result of the primary colitis, makes them poor surgical candidates.

Other Strangulating Lesions of the Large Colon

Other strangulating lesions of the equine large colon that have been reported include incarceration in the epiploic foramen or the gastrosplenic ligament, large colon intussusception, and volvulus associated with abnormal mesenteric bands or defects.[45,191-195] Surgical intervention is dictated in these cases by the increasing degree of abdominal pain, abnormal rectal palpation, and abdominocentesis indicating intestinal compromise. Inguinal herniation of the large colon has been reported to occur spontaneously[196] and 4 weeks after castration.[197] Treatment was not attempted in these cases. Resection and anastomosis of the affected colon is required to correct strangulating lesions of the large colon.

Figure 37-19. Modified colon tray used to evacuate the large colon. In this case, the contents are collected in a modified trash can with a strainer that allows fluids to be evacuated through the drainage system.

Surgical Procedures

Large Colon Enterotomy

The most commonly performed procedure in the large colon is pelvic flexure enterotomy for evacuation of the large colon. Enterotomy procedures are also performed to remove foreign bodies, usually in the right dorsal colon. Finally, right ventral colon enterotomy is used to access the cecum in cases of cecocolic intussusceptions.

PELVIC FLEXURE ENTEROTOMY AND LARGE COLON EVACUATION

For this procedure, the large colon is exteriorized and placed on a colon tray (Kimzey Enterotomy Surgery Table—see Appendix B), either on the left side of the horse or caudally between the horse's hind legs. If a colon tray is not available, the colon is best exteriorized between the hind legs. Some surgeons place the end of the laparotomy drape onto the tray to create a shelf for the colon to rest on. The enterotomy drape is then placed on top of the laparotomy drape and secured with towel clamps. The colon tray is angled at about 20 degrees. A modified trash can with an ingesta strainer and a liquid outflow hose is used in some clinics to collect and evacuate the contents of the colon (Figure 37-19).[198] Alternatively, the end of the tray can be positioned over a disposal system built into the surgery room (Figure 37-20).[199] In anticipation of colonic evacuation, a lavage system should be established. This can be done by using two garden hoses, or one hose with a Y-connection. One hose is used for

Figure 37-20. Built-in disposal system for collecting fecal material during evacuation of the intestine.

intraluminal lavage and evacuation of the colon, and the other for extraluminal lavage, using warm water (37° C (98.6° F)).[199] If these are not available, stomach tubes, buckets, and pumps are used.

A full-thickness, 8- to 12-cm (3- to 5-inch) incision is made on the antimesenteric border of the pelvic flexure.[198] One hose is inserted and gently advanced into the colon, while the other is used to continuously lavage the serosal surface to prevent fecal contamination. During the evacuation procedure, it is useful to lift the colon and ensure that the underside is lavaged as well. With sterile technique, an assistant helps to feed the hose into the colon and massage its contents. Although a modified colon tray has been described to evacuate the colon, it is not deemed necessary by most surgeons.[200] At this time, if colonic evacuation is performed as part of the correction of a large colon torsion, an intestinal biopsy can be collected. Closure of pelvic flexure enterotomies is performed using 2-0 absorbable suture material in two layers: a simple-continuous seromuscular layer followed by a Lembert or a Cushing pattern.[201] The colon is rinsed thoroughly with sterile saline and replaced in the abdomen.

Enterotomies in the right dorsal or ventral colon are performed after the colon has been draped off from the main surgical field. In the ventral colon, enterotomies are performed between teniae, since the fibrous nature of the teniae precludes successful inversion during suturing. In the dorsal colon, the location of the enterotomy is not as critical. Enterotomies performed at these sites are more likely to suffer from postoperative luminal hemorrhage; a full-thickness closure (simple-continuous or Connell) is therefore performed on the first layer to achieve better hemostasis.[84] A Lembert or Cushing pattern is used as the second layer.

A modified Heineke-Mikulicz technique for pelvic flexure enterotomy closure has been described in two horses with extensive stricture of the large colon.[175] A longitudinal incision was centered over the stricture and closed using a transverse closure, effectively increasing the diameter of the colon at that site.

Large Colon Resection

Resection of the large colon is performed to remove full-thickness mural defects in the large colon. Causes include strangulation, infarction, thromboembolic disease, neoplasia, and scar tissue formation.[177,197,196,202-208]

Removal of 50% to 95% of the large colon has been described.[208-213] Techniques for resecting the large colon include resection and end-to-end anastomosis, and resection and side-to-side anastomosis. End-to-end procedures are performed to remove the colon up to 10 to 12 cm (4 to 5 inches) from the cecocolic ligament.[179] When resection of the colon closer to or proximal to the cecocolic ligament is required, a side-to-side technique is preferred because the end-to-end technique exerts too much tension on the anastomotic site, placing it at risk for dehiscence. In our experience, it is important to ensure that apposition of the colons in an end-to-end fashion is achieved without tension, and this requires that a substantial amount of colon remain distal to the cecocolic fold.

RESECTION AND END-TO-END ANASTOMOSIS

For a *resection and end-to-end anastomosis,* the colon is exteriorized on a colon tray and draped off; the cecum is replaced in the abdomen. All ingesta are massaged into the segment to be removed. If the colon is full, a pelvic flexure enterotomy is performed to evacuate the colon; care must be taken to remove all ingesta and water from the right dorsal and ventral colons to minimize contamination during the resection. For the resection, a site is chosen that is located in the healthy part of the colon (if possible) and that is easily held by the assistant surgeon without tension on the mesentery.[179] The colon is positioned to expose the right colic artery and the colic branch of the ileocolic artery within the mesocolon; the colonic vessels are isolated by blunt finger dissection and double-ligated using 1 polyglactin 910 (Figure 37-21). Alternatively, two double rows of staggered staples (TA-90 Premium) are applied across the mesocolon, followed by a third double-staggered row 4 cm distal. The mesocolon is transected between the proximal and distal staple lines. Hemostasis is verified and any bleeding vessels are ligated. The right ventral colon is transected in a line transverse to its long axis, whereas the dorsal colon is transected at a 30-degree angle to its long axis, with the antimesenteric border shorter so that the diameters of the colons are similar (Figure 37-22, *A*). In the original description of the procedure, a V-shaped stoma was then created between the mesenteric border of the dorsal and ventral colons using an inverting linear anastomotic instrument (GIA Premium 55) reinforced with a double-layer, simple-continuous pattern. This step was omitted in later descriptions of the procedure.[214] Starting at the mesenteric border and suturing from the lumen, the colons are apposed with a double-row, simple-continuous pattern using 0 polydioxanone or Vicryl. The second layer should be full thickness to achieve hemostasis (see Figure 37-22, *B*). Once the mesenteric portion of the anastomosis is completed, suturing is approached from the serosal side, and the colons are apposed using a double layer, starting with a Connell followed by a Lembert pattern (see Figure 37-22, *C*). The colon is lavaged and replaced in the abdomen.

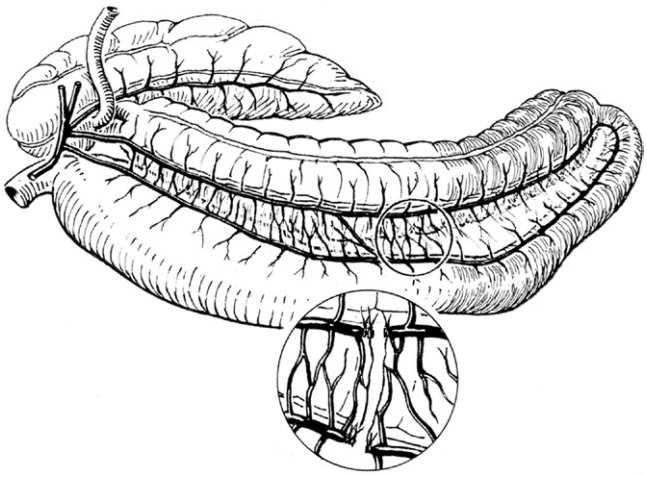

Figure 37-21. The ascending colon is placed on a colon tray with the vessels facing uppermost. The colonic vessels are isolated by blunt finger dissection and double- or triple-ligated before transection *(inset).*

SIDE-TO-SIDE ANASTOMOSIS AND RESECTION

For a *side-to-side anastomosis,* the site of resection is usually more proximal, at the cecocolic ligament or orad to it. The colon is exteriorized to the left of the horse on a colon tray and the colonic vasculature is transected as previously described. The

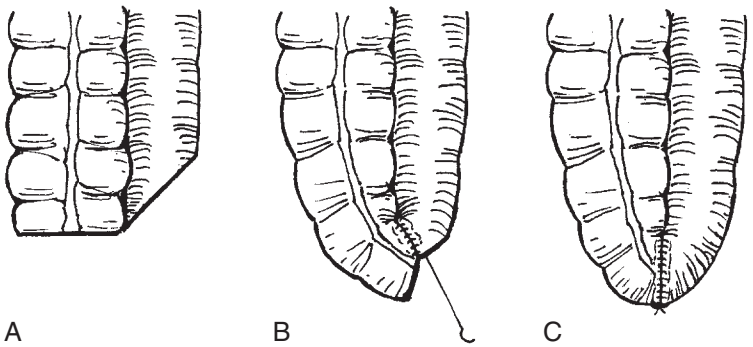

Figure 37-22. Amputation of the large colon. **A,** The right ventral colon is transected in a line transverse to its long axis, whereas the dorsal colon is transected at a 30-degree angle to its long axis. **B,** Starting at the mesenteric border, and suturing from the lumen, the colons are apposed with a double-row simple-continuous pattern using 0 polydioxanone or Vicryl. **C,** Once the mesenteric portion of the anastomosis is completed, suturing is approached from the serosal side, and the colons are apposed using a double-layer pattern, starting with a Connell and followed by a Lembert.

stoma is then created before the resection, taking advantage of the weight of the colons to facilitate exposure of the anastomotic site. The site for creating the stoma is identified, taking care to end it just proximal to colonic vessel ligation, so that a blind sac is not formed. A three-tier side-to-side stoma is created; the first layer apposes the seromuscular layers of the colons using 1 polyglactin 910 in a Lembert or Cushing layer for a length of 20 cm (8 inches) (Figure 37-23, *A*). A full-thickness incision is made in each colon and a full-thickness simple-continuous circumferential closure interrupted at 180 degrees is made to create the stoma (see Figure 37-23, *B* and *C*). The upper layer is subsequently apposed using a Cushing or Lembert pattern (see Figure 37-23, *D*). Alternatively, the stoma can be created using stapling instrumentation. This may minimize contamination, but it may not be possible if the colons are too thick and edematous as a result of the underlying disease process. For an adequate-size stoma, the stapling instrument is fired twice if the ILA-100 or the GIA-90 is used and three times if the GIA-55 is used (the staples for the GIA-55 are smaller). Staple lines should be oversewn. Once the staples have been applied, the down layer cannot be approached for oversewing. This layer should therefore be established first, before application of the stapling instrument. Once the stoma is created, the colons are resected, starting with the ventral colon, taking care to resect them at the site of colonic vessel ligation. The lumens are closed using a full-thickness simple-continuous or Connell pattern, and oversewn with a Lembert or Cushing pattern (Figure 37-24). The resected colons are lavaged and replaced in the abdomen. Although resection of the large colon has been reported using stapling instrumentation, this is usually not possible after correction of large colon torsion, since the intestinal edema and congestion do not allow proper closure of the instrument and adequate formation of the staples.

An early method of large colon resection has been described that uses a luminal approach to create the side-to-side anastomosis, followed by closing the ends of the colons.[211] The technique described earlier for resection and end-to-end anastomosis represents a modification of this technique.

Successful bypass of the right dorsal colon for the treatment of large colon volvulus has been described in one horse.[189] In that report, the large colon was judged to be nonviable after correction of a large colon volvulus. The right dorsal colon was transected as far distally as possible within the abdomen, using a TA-90 stapling instrument, and the suture line was partially oversewn. The right ventral colon was transected 10 cm (4 inches) from the cecocolic ligament, and an end-to-side anastomosis between the right ventral colon and the descending

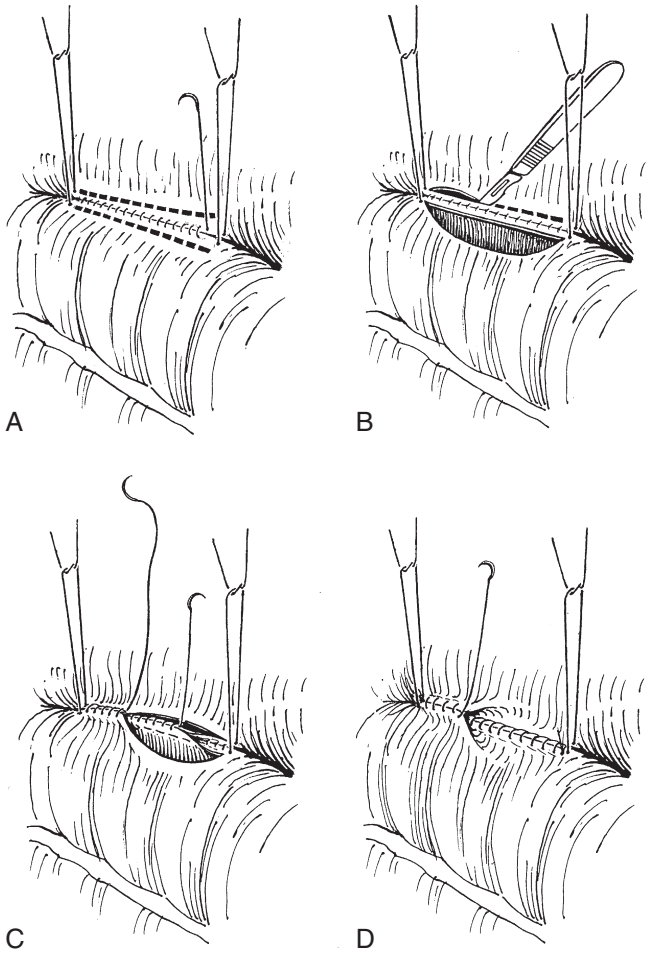

Figure 37-23. A hand-sutured side-to-side anastomosis of the ascending colon. **A,** Placement of stay sutures at either end of the intended stoma. Note that the anastomosis is performed with the diseased part of the colon still *in situ*. The seromuscular layers of the ventral and dorsal colons are apposed with a Lembert or Cushing pattern, using an absorbable suture material. **B,** A full-thickness incision is made in each colon, and a full-thickness simple-continuous circumferential closure, interrupted at 180 degrees, is made to create the stoma, shown in **(C). D,** The upper layer is then apposed using a Cushing or Lembert pattern.

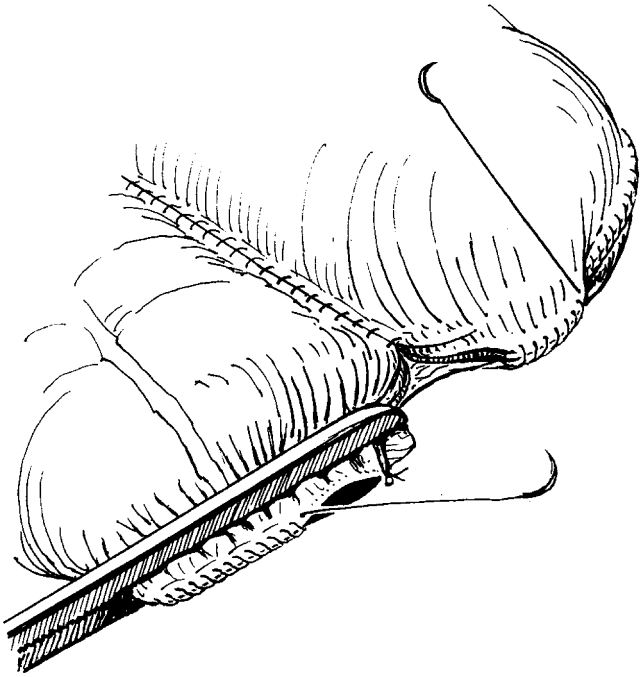

Figure 37-24. The amputated ends of the large colon are closed with a hand suture technique. Note that the amputation of the colon occurred next to the anastomosis site to prevent the formation of a blind end. The lumens are closed using a full-thickness simple-continuous or Connell pattern, oversewn with a Lembert or Cushing pattern.

colon was performed using a double-layer inverting pattern. Two mild episodes of colic and diarrhea for 1 week were the reported complications. In a similar fashion, anastomosis of the right ventral colon to the descending colon to bypass a nonfunctional descending colon anastomosis in a miniature pony was reported.[188] A two-layer hand-sewn end-to-side anastomosis was performed between the right ventral colon and the small colon. One episode of colic successfully treated with medical therapy was the only postoperative complication encountered in this case.

COMPLICATIONS

Complications from large colon resection are usually a result of the primary disease. They include persistent endotoxemia and peritonitis caused by continued bowel devitalization. This is because the site of torsion is usually at or proximal to the site of resection, so that some portion of compromised large colon cannot be removed. It is therefore essential for the surgeon to remove as much of the devitalized colon as possible. In our experience, this requires a side-to side resection at or proximal to the cecocolic fold. Even then, a segment of devitalized colon may remain in the abdomen, leading to subsequent complications. Most horses that succumb to endotoxemia and peritonitis do so within 3 to 7 days postoperatively after requiring considerable intensive care. In contrast, survivors see an improvement in clinical signs within 24 hours of the procedure.

Postoperative pain is common in horses after large colon resection. It is a painful procedure, even in normal horses. Administration of NSAIDs, lidocaine, and opiates can help alleviate the pain.

Signs of endotoxemia are common after large colon resection for large colon volvulus. Signs include fever, tachycardia, injected mucous membranes, dehydration, and hypoproteinemia. Signs of large colon ileus, such as distention, which can be quite severe, may also occur. Supportive care with fluids, plasma, and antiendotoxin modalities are important (see Chapter 2). Horses should be monitored for signs of postoperative hemorrhage, which is more prevalent with large colon procedures and occasionally requires a blood transfusion.

Postoperative diarrhea is commonly observed after large colon resection, because of mucosal damage or the reduced surface area available for fluid absorption, or both. The diarrhea is usually self-limiting and resolves within a few days if it is not of infectious origin. However, isolation procedures should be followed as dictated by hospital protocol, and infectious diseases should be ruled out.

Horses with successful resection of the large colon usually regain normal fecal consistency within 5 to 7 days. Because of the decreased surface area available for digestion and water absorption, these horses have increased water and phosphorus requirements and require a highly digestible diet.

PROGNOSIS

The prognosis after large colon resection depends on the reason for performing the resection, but the procedure does carry inherent risks, as demonstrated by a study where large colon resection performed in normal horses resulted in 3 of 10 horses dying directly as a result of the procedure.[209] In a group of horses having undergone large colon resection, there was a significant difference in short-term survival (discharged from the hospital) between horses with a nonstrangulating lesion (77.8%) compared to a strangulating lesion (47%), and horses that underwent a large colon resection for nonstrangulating lesions were 3.9 times more likely to survive.[183]

SMALL COLON

Anatomy

The transverse colon is the continuation of the right dorsal colon. It begins at the level of the 17th or 18th thoracic vertebra where the right dorsal colon narrows significantly in diameter as it turns medially.[1-2] The transverse colon is short and passes from right to left, cranial to the cranial mesenteric artery. It is connected dorsally to the pancreas, to the dorsal aspect of the abdominal cavity, and by a short transverse mesocolon to the root of the mesentery. These attachments prohibit visualization of the transverse colon during a celiotomy. To the left of the root of the mesentery, the transverse colon continues as the descending colon, also known as the small colon. The small colon occupies the left caudodorsal quadrant of the abdominal cavity. It is approximately 3.5 m long and maintains a 7- to 10-cm width throughout its entire length. It is suspended by a long descending mesocolon, which allows good surgical access to all but the most proximal and distal portions of its length. The descending mesocolon originates from the left surface of the root of the mesentery and continues caudad attached to the dorsal body wall until it turns into the mesorectum at the pelvic inlet.[1-2] The mesocolon often contains a significant amount of fat. The small colon is attached to the terminal duodenum by the duodenal colic fold, which is an important surgical landmark when exteriorizing the proximal jejunum. The small colon has two longitudinal muscular bands called teniae, one within the mesocolon and the other on the antimesenteric

border. Contractile activity of the longitudinal bands and circular muscle produce sacculations in which feces are formed into fecal balls.[215]

The vascular supply to the small colon is derived from the caudal mesenteric artery with anastomoses cranially from the cranial mesenteric artery and caudally from the middle and caudal rectal arteries. The caudal mesenteric artery divides into two major branches, the left colic artery and the cranial rectal artery, with the left colic artery supplying the proximal three fourths of the descending colon and the cranial rectal, the distal one fourth.[215] The left colic artery branches into four to eight arcuate arteries, each dividing into a cranial and caudal branch, which run parallel to the small colon to anastomose to adjacent arcuate arteries (Figure 37-25). The cranial rectal artery gives off similar arcuate vessels. These anastomosing arcades running parallel to the bowel are called *marginal arteries*. A secondary anastomosing arcade branching off the marginal arteries runs between the marginal artery and bowel wall, sending off short branches that perforate the mesenteric teniae and long branches that anastomose in the antimesenteric teniae with branches from the other side (see Figure 37-25).[215] Venous return parallels the arterial supply. The presence of fat in the mesentery makes identification of blood vessels difficult.

Pathology of the Small Colon

Horses with small colon disease make up 1.9% to 18.5% of horses admitted to referral centers with signs of gastrointestinal disease.[96,155,214-218] The incidence of small colon disease is approximately 4% in horses undergoing surgical treatment for colic.[96,214-218] Arabian horses, ponies, and American Miniature Horses are more predisposed to diseases of the small colon.[155,219] Female horses and horses older than 15 years are more likely to have small colon disease, whereas horses younger than 5 years are less likely to be affected.[155] Diseases may be broken down into congenital abnormalities, such as atresia coli and colonic aganglionosis; simple obstructions, including fecal impaction, fecaliths, phytobezoars, trichobezoars, enteroliths, and retained meconium; vascular lesions, including intramural hematomas and mesocolon tears; strangulating lesions such as lipomas, internal hernias, and volvulus; and neoplasia. (Distal iatrogenic tears, described as rectal tears, although frequently occurring in the small colon, are discussed in Chapter 38.)

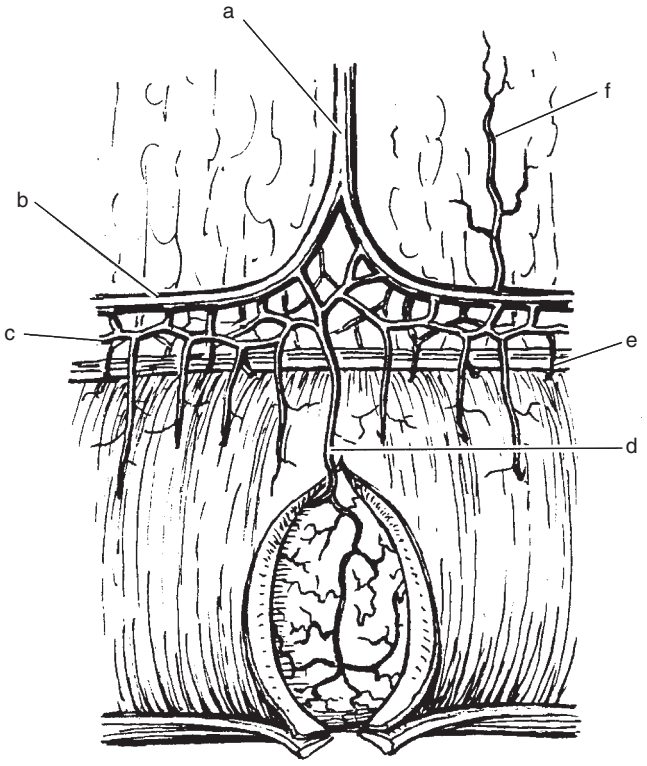

Figure 37-25. Vascular supply of the descending colon, lateral view. *a,* Arcuate artery; *b,* marginal artery; *c,* secondary arcade; *d,* long artery; *e,* small branch supplying mesenteric teniae; *f,* small branch to mesocolon.

Diagnosis

According to one report, 84% of surgical conditions of the small colon were simple obstructions, whereas 16% were vascular or strangulating lesions.[155] Because the obstruction generally affects the distal part of the gastrointestinal tract, horses with small colon disease exhibit slow deterioration of physical status and slow worsening of clinical and laboratory evaluations, making the decision for both referral and surgical intervention more prolonged than is seen with other surgical conditions of the gastrointestinal tract.[20,155,215,220,221] Early clinical signs are nonspecific and include lethargy, dullness, and inappetence. As the obstruction progresses, signs include abdominal pain, diarrhea, decreased fecal production, tenesmus, and abdominal distention. Strangulating lesions may have a more sudden and severe onset of clinical signs, although the level of pain at admission was reported to be mild or moderate in 25 of 31 cases requiring a small colon resection in a recent study.[221] Gastric reflux is uncommon with impactions but may occur as a sequela of the distal obstruction, leading to distention of the ascending colon, which places pressure on the proximal small intestine and obstructs gastric outflow. Gastric reflux has been reported in 30% of horses with strangulating lesions.[221] Changes in the nucleated cell count and the total protein concentration in peritoneal fluid, along with rectal palpation findings, are the key indicators for surgical intervention.[155,214,218] Abdominal ultrasonography may also aid in making a diagnosis.[222] Medical and surgical interventions often carry a good to excellent prognosis.

Simple Obstructions

Fecal Impaction

Horses with small colon fecal impaction represent 1.9% to 2.5% of all those admitted for signs of abdominal pain. Fecal impaction has been reported to be the most common pathologic condition of the small colon except in regions with a high incidence of enterolithiasis.[155,216,217] Suggested risk factors are poor dentition, poor-quality hay, lack of water, parasite damage, lack of exercise, submucosal edema, and motility problems.[218,220,223] Horses with small colon impactions were found to be 10.8 times as likely to have diarrhea at the time of admission than were horses with large colon impactions.[223] The fall and winter seasonal predilection observed in some studies may be the result of inadequate water consumption or change of feed.[216,217] Older horses (older than 15 years), American

Miniature Horses, and ponies were at an increased risk in several studies, but age, breed, and sex were not significant risk factors in other reports.[20,155,216-218,224]

DIAGNOSIS

The most common clinical signs, in order of decreasing frequency, are abdominal pain, decreased manure production, diarrhea, anorexia, fever, straining to defecate, and depression.[217,218] The colic is initially manifested as mild abdominal pain with a slow progression of signs. The heart rate can be mildly to moderately elevated. Leukopenia with a left shift is common in horses with small colon feed impactions, whereas serum biochemical and peritoneal fluid values are typically within normal ranges.[217,218] The diagnosis can frequently (i.e., in 75% to 87% of cases) be made by palpation of the impaction *per rectum*.[217,218,225] Other palpation findings that have been noted are distention of the large intestine and cecum, edematous or rough rectal mucosa, blood on the rectal sleeve or manure, and unformed feces.[217,218,226] Nasogastric reflux is occasionally obtained. The presence of diarrhea, fever, leukopenia, and irritated rectal mucosa often encountered in a subset of these cases suggests that colitis may predispose some horses to small colon impaction, possibly through motility disturbances.[155,223] Conversely, the gastrointestinal stasis and inflammation associated with small colon impaction may predispose horses to colitis.[217,227]

TREATMENT

Medical treatment

Most fecal impactions of the small colon are initially managed medically. The goal is to improve hydration, stimulate motility, and soften the impaction. All feed should be withheld and the impaction hydrated. This is accomplished through administering both intravenous fluids (two to three times the maintenance volume) and oral fluids (2 to 4 L every 4 to 6 hours).[217,223] Oral fluids have the additional benefit of initiating a gastrocolonic reflex, whereby gastric distention stimulates contractile activity of the colon.[115,228] Oral laxatives such as mineral oil, dioctyl sodium sulfosuccinate, or magnesium sulfate administered by nasogastric tube are commonly used to soften the impaction. Mineral oil (5 to 10 mL/kg every 12 hours) is frequently used to lubricate the impaction, and its presence in the perineum is an indication that the obstruction is incomplete. Magnesium sulfate administered to normal horses at 1 g/kg in 6 L of water has been shown to increase total weight of fecal excretion and fecal water excretion compared with administration of a lower dose (0.5 mg/kg), whereas DSS (50 mg/kg in 6 L of water) failed to increase the weight of feces excreted or fecal water excretion.[115] Magnesium sulfate can be administered once daily for 2 to 3 days if the horse is well hydrated. Magnesium toxicity appears more likely to develop in dehydrated horses or in horses treated simultaneously with DSS.[128] Flunixin meglumine (0.25 mg/kg three times a day, or 1.1 mg/kg twice a day IV) is administered to treat endotoxemia and to control pain if necessary. Antibiotics may be indicated in horses with signs of septicemia, severe leukopenia, or concurrent diarrhea. Other antiendotoxin therapy such as polymyxin B (2000 to 6000 IU/kg IV) or *Salmonella typhimurium* antiserum may also be beneficial.[217] Standing enemas may be used in selected cases to break down impactions in the distal small colon, but extreme caution should be exercised to avoid producing a rectal or small colon tear.[216,217] The horse should be adequately sedated and restrained, and epidural anesthesia should be performed. The enema should be administered, without pressure, by gravity flow. Because of the potential for iatrogenic trauma, some authors do not recommend enemas for treatment of small colon impactions.[214,216,217]

Surgical treatment

Surgical management is indicated in horses with increasing abdominal pain, increasing abdominal distention, or changes in abdominal fluid indicating deterioration of the bowel.[155,218,224] In some horses, large colon displacement or volvulus occurs secondary to gas distention proximal to the impaction. The small colon is exteriorized through a ventral midline celiotomy. The most common technique to relieve the impaction is intraluminal lavage with warm water introduced by stomach tube inserted through the anus by an assistant. The surgeon manipulates the tube to the distal extent of the impaction and then manually clamps off the small colon lumen caudal to the end of the tube to allow water distention around the distal extent of the impaction. Extraluminal massage is used to gently work the fluid into the feces to break up the distal portion of the impaction. These manipulations are repeated working orad until the impaction is relieved. To decrease mechanical damage to the serosa during the massage, sterile carboxymethylcellulose should be placed on the small colon that is being massaged.[217] In some cases, when the small colon impaction cannot be relieved by intraluminal lavage with external massage, a small colon enterotomy is performed in the antimesenteric teniae adjacent to the impacted small colon, and lavage is used to evacuate the impacted fecal material through the enterotomy (see "Small Colon Enterotomy," later). In rare cases, mural ischemia or thrombosis of the mesenteric vessels necessitates resection of a segment of small colon (Figure 37-26) (see "Small Colon Resection and Anastomosis," later). Ingesta in the large colon should be evacuated through a pelvic flexure enterotomy to prevent postoperative impaction in the edematous and inflamed small colon.

Postoperatively, horses should be started back on feed slowly. Feeding a complete pelleted diet for several weeks may help prevent reimpaction.[221] Extension of perioperative use of antibiotics (24 hours postoperatively) to therapeutic

Figure 37-26. An intraoperative photograph of a horse with a descending colon impaction showing an area of compromised tissue.

use of antibiotics (5 to 7 days postoperatively) is made on a case-by-case basis, dictated by surgical findings and clinical and laboratory evaluation of the horse. In most cases, antibiotics can be discontinued within 24 hours.

PROGNOSIS

Survival after medical therapy has been reported to be good to excellent (72% to 100%), and survival after surgical therapy has been reported to be fair to excellent (47% to 95%).[155,217,218,224] The most common complications after medical or surgical therapy are diarrhea and jugular thrombophlebitis.[155,218,224] Other complications seen are fever, laminitis, peritonitis, incisional infection, incisional hernia, recurrent colic, recurrent impaction, and small colon adhesions.[155,218,224] Surgical cases in which the colon was not evacuated at surgery are more likely to develop postoperative pain.[217] Fecal cultures for *Salmonella* are positive in up to 43% of surgically treated horses.[217,223] Postoperative antibiotic therapy may increase the risk of these horses developing salmonellosis by altering gastrointestinal flora.[217,221]

Intestinal Concretions and Foreign Bodies

Enterolithiasis

The small colon is the site of the obstruction in approximately 45% to 57% of horses with enteroliths, accounting for up to 35% of all small colon diseases in certain geographic regions such as California.[142-143,155,229] The etiology was discussed in the large colon section of this chapter.

DIAGNOSIS

Horses commonly exhibit multiple episodes of mild colic, most likely from intermittent obstruction in the large colon or proximal transverse colon, before the enterolith enters the small colon. Once the enterolith enters the small colon, the clinical course is determined by the size of the enterolith. Although some are small enough to pass through the small colon without clinical problems, it is common for the enterolith to become wedged within the lumen of the transverse or small colon, usually the proximal third.[230] Horses typically show signs of increasing abdominal pain, although in some horses rupture occurs with little or no observed abdominal pain. On rectal examination, the large colon may have palpable gaseous distention. Peritoneal fluid analysis should be monitored closely. It is common for enteroliths wedged in the transverse and small colons to cause pressure necrosis at the area of obstruction.[231] A slight elevation in peritoneal fluid protein may indicate the need for surgical intervention. Radiographs successfully diagnose small colon enteroliths in approximately 40% of horses, as compared with 83% of horses with large colon enteroliths.[144] In one case series, horses with enteroliths in the descending colon had a shorter duration of clinical signs and were more likely to be tachycardic and leukopenic than horses with ascending colon enteroliths. Surgical exploration is based on signs of increasing pain, increasing abdominal distention, peritoneal fluid changes, and radiographic evaluation.[142-144,232] The most common site of gastrointestinal tract rupture in horses with enteroliths is in the descending colon.[143] Since some horses show little pain before rupture, careful monitoring of horses with suspected enterolithiasis is critical to ensure timely surgical intervention.

TREATMENT

Treatment is surgical removal through an antimesenteric small colon enterotomy or retropulsion and removal through an enterotomy in the dorsal colon or pelvic flexure.[143,230] Horses are administered broad-spectrum antibiotics, and a ventral midline celiotomy is performed. Retropulsion with lavage can be accomplished by inserting a hose up the rectum. Alternatively, a hose can be inserted through a pelvic flexure enterotomy and advanced to the transverse or small colon obstruction, and lavage can be used to distend the small colon on the oral side with the anal side being clamped off manually. The most important aspect of these techniques is letting the water gradually distend the bowel to aid in dislodging the enterolith. Pressure necrosis can make the bowel wall susceptible to rupture.[233]

When enteroliths are removed by a small colon enterotomy, it is important to ascertain if there are additional enteroliths located proximally, as nearly half of horses with descending colon enteroliths have additional stones in the ascending colon.[143,232] Particular attention should be paid to the right dorsal and transverse colon, since it may be difficult to palpate a small enterolith if there is an appreciable amount of ingesta in the large colon. Commonly, a pelvic flexure enterotomy is performed before the small colon enterotomy to evacuate ingesta from the large colon. This also will decrease the amount of fecal material passing over the small colon enterotomy site in the immediate postoperative period.

PROGNOSIS

Horses recovering from surgery for enteroliths in the small colon have a good to excellent prognosis (up to 92.5%).[142-143,232] In most cases, antibiotics are discontinued 24 hours after surgery. It is common for the area where the enterolith was wedged in the small colon to slough some of the mucosa after surgery with absorption of endotoxin. NSAIDs should be continued for 3 to 5 days, depending on the extent of intestinal insult found at surgery. Complications noted after surgery are diarrhea, incisional infection, incisional hernia formation, positive fecal cultures for *Salmonella*, laminitis, septic peritonitis, and adhesions.[142-143,230,232] In one study, there was no significant difference in short-term complications between horses that had an enterolith in the ascending compared to the descending colon, although more horses with descending colon enteroliths were euthanized on the table, and of those recovered, more had a transient fever and anorexia.[232] Dietary and management changes have been discussed in the large colon section of this chapter. Recurrence has been identified in 7.7% of cases.[143]

Fecaliths, Phytobezoars, Trichobezoars, Phytotrichobezoars, and Phytoconglobates

Fecaliths are inspissated balls of fecal material that form as a result of poor-quality diet, poor mastication, or reduced water intake.[226,234] They have been reported to occur in approximately 7% of horses with small colon disease, but they probably make up a larger proportion of small colon disorders in regions where enteroliths are not common.[155] Small colon fecaliths have a tendency to occur in young (less than 1 year old) and older (more than 15 years old) horses. Ponies, American Miniature Horses, and mixed-breed horses appear to be at an increased risk.[155,235,236] *Phytoconglobates* are concretions of matted plant residues formed into balls. *Bezoars* are combinations of concretions of magnesium ammonium phosphate and plant material

(phytobezoars) or hair (trichobezoars). Concretions composed of hair and plant material are called *phytotrichobezoars*.[220,225] Obstruction caused by ingestion of fibrous, nondigestible material occurs most commonly in horses less than 3 years old and in horses with poor dentition.[226] Fecaliths, phytobezoars, trichobezoars, and phytotrichobezoars form in the large colon and become symptomatic as they pass into the small colon and obstruct the lumen. Clinical signs are similar to those of foreign body obstructions. Treatment is surgical removal by small colon enterotomy or by retropulsion into and removal from the large colon.

Foreign Body Obstructions

Obstruction of the small colon with foreign objects has been reported in several studies.[25,236-238] The obstructing objects include rubberized fencing and nylon tires, baling twine, rope, disposable plastic sleeves, feed sacks, and cloth material.[25,236-238] Young horses (less than 3 years of age) with indiscriminate eating habits are thought to be more likely to develop these foreign body impactions. Poor pasture may also contribute to consumption of inappropriate material.[238]

Signs reported are similar to those seen in other small colon obstructions, such as getting up and down, stretching, anorexia, and scant passage of feces.[25,236-238] Walking backward and dog sitting have also been reported.[236] The heart rate can be normal to markedly elevated. Depending on the configuration of the foreign body, the obstruction may be incomplete, allowing some passage of gas and ingesta, or complete, producing tympany and impaction proximal to the obstruction. With complete obstruction and proximal distention, the abdominal pain becomes more severe. Nasogastric reflux from the distended large intestine compressing the proximal small intestine may occur. In horses with a distal obstruction, tenesmus is common.[226] On rectal palpation, horses frequently exhibit marked abdominal straining, have a large intestine distended with gas and feces, and have no fecal balls in the small colon. In some cases, the obstructing mass is palpable *per rectum*, although frequently the obstruction is in the proximal small colon out of reach of rectal palpation.[238]

Foreign bodies may produce pressure necrosis of the wall of the small colon where they are lodged. In these cases, peritoneal fluid analysis reveals an elevated protein concentration and sometimes an increase in nucleated cell count. Treatment is surgical removal via a small colon enterotomy in the majority of cases, or through retropulsion into the dorsal colon if the obstruction is at an inaccessible portion of the proximal small colon or transverse colon.

Meconium Impaction

Meconium is a mucilaginous material in the intestine of the fetus, composed of intestinal glandular secretions, bile, epithelial cells, and swallowed amniotic fluid.[214,239] Typically, peristaltic activity moves meconium into the colon or rectum before birth, and it is evacuated between 3 and 24 hours after birth.[214] Meconium is considered retained if the foal makes frequent attempts but fails to produce meconium by 12 hours of age.[239] Retained meconium is the most common cause of colic in the neonate.[96,214,239] Meconium impaction accounted for 0.8% of all cases of equine colic in one study, with a mortality rate of 15.2%.[240] Ingestion of colostrum promotes gastrointestinal activity and may have a laxative effect to aid in expulsion of meconium from higher up in the colon. Delayed ingestion of colostrum and conditions that compromise the foal such as asphyxia, dystocia, prematurity, low birth weight, and dehydration are thought to be risk factors for meconium impaction.[241] Males are more commonly affected, most likely because of their smaller pelvis.[242]

DIAGNOSIS

Clinical signs begin with restlessness, tail switching, straining to defecate, and disinterest in nursing.[239] As the condition progresses, foals develop signs of more severe colic, such as lying down and getting up, rolling, lying upside down, and abdominal distention.[239] The diagnosis is based on clinical signs, historical absence of meconium passage, and detection of a firm mass on digital rectal palpation. Plain and retrograde contrast abdominal radiography can show tympanic bowel and often dense meconium.[243,244] Ultrasonography may show a distended large colon. The differential diagnosis is ruptured bladder, atresia coli, ileocolonic aganglionosis, and enteritis.

TREATMENT

The preferred method of treatment is multiple administration of enemas along with intravenous fluids and nasogastric administration of laxatives for more persistent obstructions. Commercially available phosphate enemas (Fleet enemas) are frequently used. A 4% acetylcysteine enema solution has been recommended for treatment of retained meconium.[244,245] The compound cleaves the disulfide bonds in the mucoprotein molecules and decreases the tenacity of the meconium. The 4% solution can be made by mixing 40 mL of a commercial 20% acetylcysteine solution with 160 mL of water. Because the activity of acetylcysteine increases with increasing pH (pH 7 to 9), 20 g (1½ level tablespoons) of $NaHCO_3$ powder (baking soda) is added to the 200 mL of diluted solution. Alternatively, 8 g (1 packed tablespoon) of a powdered form (*N*-acetylcysteine) can be mixed with 200 mL of water to which 20 g of $NaHCO_3$ is added. Commercial kits are also available (E-Z Pass Foal Enema Kit). The foal is restrained, sedated with diazepam (0.2 to 0.4 mg/kg IV), and placed in lateral recumbency. A 30-French Foley catheter with a 30 mL bulb is inserted about 2.5 to 5 cm into the rectum. The balloon is slowly inflated, using care to not damage the rectum. Between 100 and 200 mL of the 4% solution is administered slowly by gravity flow and retained for 30 to 45 minutes.[239] This can be repeated up to three times over a 24-hour period. The prognosis after acetylcysteine enemas has been reported to be excellent.[239] High meconium retention can be treated with intravenous fluids and mineral oil administered by nasogastric tube.

Surgery should be performed only on foals that have failed to respond to aggressive medical therapy. Postoperative complications involving adhesion formation are common after gastrointestinal surgery of neonates.[78,246] In one study, 8 of 28 foals with meconium impactions failed to respond to medical therapy and required surgery.[247] Two of seven surgical cases available for follow-up were euthanized as a result of serosal adhesions.[247] These results suggest that if surgical treatment is required, techniques to reduce adhesion formation, such as minimal handling of the bowel, and topical 1% sodium carboxymethylcellulose during bowel manipulation, should be practiced. In one study, administration of penicillin, gentamicin, and flunixin meglumine, or DMSO (20 mg/kg diluted twice daily) were the most

effective treatments to prevent adhesions induced by ischemia and reperfusion in foals; the efficacy of sodium carboxymethylcellulose (a 3% solution was used in that study) was less effective than these treatments.[248]

Vascular Lesions

Intramural Hematoma

The incidence of small colon intramural or submucosal hematoma is very low, less than 1% of surgical colics.[47,249,250] Most often the cause of the lesion is unknown, although focal ulceration with infection and iatrogenic trauma have each been described in one horse.[249,250] Although it has been stated that older horses are at an increased risk, the low number of reported cases makes this difficult to ascertain. Four of seven cases were 10 years old or younger, and one of seven was older than 20 years in two case series.[249,250] In another report of six horses, the age range was between 9 and 18 years.[218]

The intramural hematoma causes obstruction of the small colon lumen initially with subsequent ischemic necrosis of the bowel wall leading to septic peritonitis, endotoxemia, circulatory shock, and death if not treated.[218] Horses are often presented with varying degrees of abdominal pain that may become acutely severe. Heart rate is mildly to markedly elevated. Rectal palpation findings may reveal gas distention of the large intestine, decreased fecal content, and occasionally dark or clotted blood.[218,249,250] In some cases, a solid mass is palpable *per rectum*.[249,250] During surgical exploration, the lesion is readily identified as a soft, dense, circumscribed mass occupying the bowel lumen and attached to the bowel wall. The lesion has been described as involving between 20 and 55 cm (8 and 22 inches) in a series of six cases.[218] Treatment is surgical resection and anastomosis. The prognosis can be good if the lesion is located in a region that allows its complete resection and if surgical intervention occurs before transmural necrosis or bowel rupture leads to bacterial peritonitis.[220,249] Colostomy should be considered if the lesion is too far caudal to allow exteriorization.[220]

Mesocolic Rupture

The incidence of rupture of the mesocolon has been reported to be between 0.4% and 2.5% in horses undergoing exploratory laparotomy for colic.[24,47,251] Rupture of the mesocolon leading to segmental ischemic necrosis of the small colon has been described as a complication of parturition in the mare.[47,252,253] The vigorous reflex kicking and head movement of the foal that allows it to rotate into a dorsal position for delivery is thought to mechanically tear the mesentery that is caught between the uterus and dorsal body wall.[220,251,252] Mesocolon rupture may also occur as a consequence of type III or IV rectal prolapse, often associated with tenesmus after parturition.[32,47,252,253] If more than 30 cm (12 inches) of the rectum prolapses, ischemic necrosis of the rectum and small colon should be expected from disruption of the mesocolon and vascular arcade.[32,47,220,252,253] Mares are typically middle aged and pluriparous. Foaling may have been normal or required assistance.[43,252,253]

Time from foaling to the onset of colic is variable, ranging from 0 to 24 hours, with referral 12 to 48 hours later. The severity of abdominal pain varies greatly from no demonstrable pain to severe pain. The initial mild abdominal discomfort may be incorrectly attributed to uterine involution, delaying the recognition of a surgical problem. There is a consistent lack of feces. Rectal examination findings vary from normal to feed-impacted small colon with gas-distended large intestine. Peritoneal fluid has an elevated protein and nucleated cell concentration, with intra-abdominal hemorrhage seen in some cases.[253] The decision for surgery is often based on duration of pain and peritoneal fluid changes.[252] Laparoscopy can be useful in making the diagnosis and determining the extent of damage.

Treatment consists of surgical resection and anastomosis if viable proximal and distal small colon is accessible for the anastomosis. A temporary colostomy to divert feces away from the compromised bowel has been suggested to facilitate healing if an anastomosis can be performed.[253] In most cases, tears resulting from rectal prolapse do not have sufficient viable distal small colon to allow an anastomosis. A permanent colostomy is required in these cases.[254] Often the prognosis is poor as a result of the extent of the tear or the delay in surgical intervention.[220,252,253]

Nonstrangulating Infarction

Nonstrangulating infarction of the small colon is uncommon, perhaps because the majority of the blood supply to the small colon is through the caudal mesenteric artery, which is not a common site of occlusive verminous arteritis.[214,218] In a review of 38 cases of small colon obstruction, the 3 cases with nonstrangulating infarction of the small colon showed no evidence of verminous arteritis.[218] Clinical signs are similar to those described previously for mesocolic rupture, with mild intermittent abdominal pain of 10 to 72 hours' duration. Peritoneal fluid most likely has an elevated protein concentration and nucleated cell counts. Treatment consists of surgical resection and end-to-end anastomosis. Since, in most cases, viable proximal and distal small colon is accessible for the anastomosis, the prognosis should be good as long as surgical intervention occurs before ischemic necrosis of the infarcted segment causes septic peritonitis. When the infarcted segment cannot be exteriorized through a laparotomy, a colostomy or transrectal exteriorization followed by rectocolostomy should be considered.[220]

Strangulating Lesions

Strangulating Lipomas

Strangulating lipomas of the small colon account for approximately 11% of small colon disease.[155] They are most commonly seen in horses older than 15 years and are not reported in horses younger than 8 years.[155,218,255] Geldings may be at an increased risk compared with mares and stallions.[218,255] Ponies have been reported to be at increased risk.[218] It is common for lipomas to form in the mesentery of the small colon because of the amount of fat it contains. However, unlike in the small intestine, many do not cause clinical problems, as the thickness and diameter of the small colon wall and the fecal balls within its lumen prevent the pedunculated lipoma from encircling and s trangulating the bowel. In horses with strangulating pedunculated lipomas, approximately 7% are located in the small colon and 93% are located in the small intestine.[218,255] In some cases, the pedunculated lipoma encircles the small colon, causing obstruction without significant vascular impairment.[218]

Although some horses with small colon strangulating lipomas demonstrate signs of severe colic, others do not show the amount of abdominal pain commonly seen with strangulating lesions involving other areas of the gastrointestinal tract.[221] Peritoneal fluid changes include increased nucleated cell count and protein concentration. The predominant abnormal rectal findings are gas distention of the large colon and cecum with absence of fecal balls in the small colon. In certain cases, the clinician's hand can be advanced to the area of the constriction.[221] A fibrous band encircling the colon may be palpable. Transrectal ultrasonography may indicate increased thickness of the small colon wall with intestinal distention.[222] Treatment consists of surgical removal of the lipoma with resection and anastomosis of any compromised small colon.[155,214,218,220,221]

Volvulus, Herniation, Intussusception

Volvulus of the small colon is a very rare cause of colic, most likely as a result of its fixed extremities and its relatively short length.[256] The firm fecal balls within the lumen and its fatty mesentery may also prevent the small colon from twisting around its mesentery. Adhesions and abscesses have been associated with small colon volvulus.[257] Herniation of the small colon, which may result in a strangulating obstruction, has been reported to occur with umbilical, inguinal, and body wall hernias, as well as through omental, mesenteric, uterine, vaginal, broad ligament, and gastrosplenic ligament tears.[214,257,258] Intussusception not associated with rectal prolapse has been reported in foals and one broodmare.[70,259,260] If the point of invagination is at the distal end of the small colon, the intussusceptum may protrude from the anus. In this case, a finger can be inserted between the protruding bowel and the anal sphincter and advanced cranially until reaching a blind end.[70]

Clinical signs are similar to those seen with strangulating lipomas of the small colon. There is usually a sudden onset of colic, although the clinical course may be more prolonged than is seen with strangulating lesions of the more proximal gastrointestinal tract.[220] Rectal examination reveals lack of feces and gas distention of the large colon. In some cases, the small colon is under considerable tension, limiting the rectal examination.[256,258] Blood staining of feces may be present with an intussusception.[259] Peritoneal fluid is often serosanguineous in color, with increased nucleated cell count and protein concentration.

Treatment involves surgical resection and anastomosis through a ventral midline laparotomy. Rectocolostomy has been described as a treatment for distal intussuscepted small colon protruding through the anus in an 8-week-old foal.[218] In this transrectal procedure, an encircling incision was made in the outer layer of the intussusception 4 cm caudal to the anal sphincter. Ligatures were placed around the mesenteric vessels. Continuity was restored by a colorectostomy using simple-interrupted sutures of 2-0 polyglactin.

Atresia Coli

Atresia coli is a very rare condition in the foal, involving the large, transverse, or small colon. It should not be confused with ileocolonic aganglionosis, seen in the recessive lethal white foal syndrome of the overo foal. In the lethal white syndrome, which is always fatal, foals are born with no pigment (except for the eyes) and have stenotic colons that have thin muscular walls and few myenteric plexuses, leading to megacolon and death.[226,261] Although the cause of atresia coli remains unknown, it has been proposed that a vascular injury during fetal development leads to focal ischemic necrosis of the intestinal segment.[261-263] Atresia coli does not appear to have a breed or sex predisposition.[264]

Three basic types of intestinal atresia have been recognized. Type 1, membrane atresia, is caused by a membranous diaphragm occluding the lumen of the intestine. Type 2, cord atresia, is characterized by a fibrous band or muscular cordlike remnant of gut connecting the blind ends. Type 3, blind end atresia, is caused by an absence of a segment of intestine, with disconnected ends and a gap in the mesentery. Atresia coli in foals is typically described as type 3.[263-266] Foals with atresia coli develop acute signs of colic within the first 24 hours after birth (mean, 8.2 hours; range, 2 to 26 hours).[264] The most consistent finding on physical examination is absence of meconium staining after repeated enemas. Radiographic examination may indicate gas distention of the gastrointestinal tract proximal to the atretic segment. Radiographic evaluation after a barium enema may indicate a blind end.[264,267] Surgical repair is often unsuccessful, since the remaining intestine lacks sufficient length or diameter to perform an anastomosis.[264,265,268] If surgical repair is attempted, it is recommended that the severely dilated proximal portion be resected to obtain a normal vascularized segment.[268] Also recommended is an end-to-end or end-to-oblique-end anastomosis to avoid a "blind loop" syndrome. Suggested alternative surgical approaches include colostomy and a pull-through procedure suturing the small colon to the anus.[214] Other congenital abnormalities have been found in some of these foals, such as ventricular septal defect, common truncus arteriosus, hydrocephalus, cerebellar dysplasia, dermal hemangioma, and renal agenesis.[264,268]

Neoplasia

Small colon neoplasia is very rare. Lipomas were discussed previously. A leiomyoma of the small colon found during exploratory laparotomy for a large colon displacement was successfully treated with resection and anastomosis in a 4-year-old Thoroughbred.[269] Leiomyoma has been reported to cause an intussusception in the small colon, and a lymphoma causing perforation of the small colon has been reported.[270,271]

Miscellaneous Conditions

Other conditions of the small colon that have been reported are partial obstruction by an abdominal testicular teratoma, obstruction from an ovarian pedicle in a foal, obstruction from a granulosa cell tumor in three mares, obstruction by colonic lipomatosis, and secondary chronic idiopathic intestinal pseudo-obstruction (myenteric ganglionitis) in a 4-year-old Standardbred causing recurrent impaction.[218,272-278] Colonic ganglioneuromatosis involving the small colon has been reported in a horse as an incidental finding on necropsy examination.[279]

Surgical Procedures

Small Colon Enterotomy

Small colon enterotomy is indicated to remove various types of intraluminal obstruction of the small colon, such as

fecal impactions, enteroliths, fecaliths, and foreign bodies.[155,215,216,229,280] In most cases, a ventral midline celiotomy is performed to access the small colon. However, in select cases, such as a fecalith or foreign body, if there are financial constraints, a flank incision may provide adequate access to the lesion. The preferred location for the enterotomy is a longitudinal incision on the antimesenteric teniae. Enterotomies in this location have been found to be stronger, to allow easier apposition, to develop less intraoperative hemorrhage, and to maintain an increased postoperative lumen size compared with enterotomies that do not involve the teniae.[280,281]

The segment of small colon where the enterotomy is to be performed is exteriorized and draped separately from the abdomen and the rest of the gastrointestinal tract. Intestinal clamps or Penrose drains are placed proximal and distal to the enterotomy site to prevent spillage of fecal material during the enterotomy. Stay sutures are placed approximately 1 cm from the ends of the enterotomy incision. The incision is made sharply with a No. 10 scalpel blade. A two-layer closure is performed using a full-thickness simple-continuous pattern followed by a seromuscular inverting pattern with 2-0 polyglactin 910, taking care to invert a minimal amount of tissue.

In some horses, the intraluminal obstruction, typically an enterolith, is lodged in the proximal small colon where the short mesocolon prevents adequate exteriorization, increasing the risk of peritoneal contamination during the enterotomy. If retropulsion into the right dorsal colon is not feasible, a modified teniotomy can be performed and may facilitate normograde movement of the obstruction to a more accessible location.[145] In this technique, the large colon is first evacuated to decrease fecal material proximal to the obstruction. The site of obstruction is isolated from the rest of the abdominal cavity with sterile moistened drapes. Stay sutures are placed within the antimesenteric tenia proximal to the site of obstruction and 10 to 15 cm (4 to 6 inches) distal to the site. Fluid and ingesta are stripped away from the area. Topical 2% lidocaine can first be applied to reduce muscular spasm. A 1-cm longitudinal seromuscular incision is made with a scalpel blade in the antimesenteric tenia 10 to 15 cm aboral to the obstruction. The seromuscular incision is continued orally to the widest part of the obstruction using Metzenbaum scissors. Gentle pressure applied through the wall of the small colon is used to advance the obstruction to a more accessible location, where the mucosa is incised and the obstruction is removed. The enterotomy incision is closed as described earlier. This technique is most suitable for obstructions with a smooth surface, such as enteroliths, making them more likely to move distally. In one report, enteroliths were moved distances of 4 to 15 cm (1½ to 6 inches).[145]

Small Colon Resection and Anastomosis

Several techniques have been described for small colon anastomosis. These include hand-sutured single-layer end-to-end anastomosis, hand-sutured double-layer end-to-end anastomosis, and triangulated end-to-end everting stapled anastomosis.[221,282-284] A two-layer technique consisting of a full-thickness appositional pattern oversewn with a partial-thickness continuous inverting layer has less risk for dehiscence, peritonitis, and adhesion formation than the hand-sutured single-layer and stapled closures. Also, it creates less tissue inversion than a double inverting pattern, decreasing the chances of postoperative impaction at the anastomosis site.[282-284] The vascular arcade supplying the compromised small colon is traced back to normal bowel. The marginal artery at the oral and anal side of the lesion is identified and isolated within the mesenteric fat and is triple-ligated. To prevent inadvertent puncture of a vessel to be ligated with the pointed taper needle, especially if the vessel is partly covered by fat, the needle can be advanced around the vessel with its back first, since this blunt end avoids vessels (Figure 37-27). Once the suture is placed around the vessel, tightening the loop and the knot results in secure ligation of the vessel, because firm tightening cuts through the fat tissue surrounding the vessel. The vessels are transected, and the vessels remaining *in situ* are double-ligated. Vessels supplying the intestine to be removed are triple-ligated and sectioned. The ingesta is milked out of the segment of small colon to be resected and Penrose drains or intestinal clamps are positioned approximately 10 to 20 cm (4 to 8 inches) proximal and distal to the resection area to occlude the bowel lumen and decrease contamination from luminal contents during the resection. Doyen intestinal clamps are placed across the descending colon at the oral and anal extents of the resection, angled at approximately 30 degrees from perpendicular so that the length of the small colon at the antimesenteric angle is shorter than the intestine at the mesenteric angle (Figure 37-28).[233] This should improve blood supply to the antimesenteric border and increase the luminal size of the anastomosis compared with perpendicular transection angles. Moistened sterile drapes are used to isolate this region from the abdomen and adjacent bowel. A scalpel is used to sharply transect the colon, cutting adjacent to the Doyen intestinal clamps and using them to guide a straight transection line.

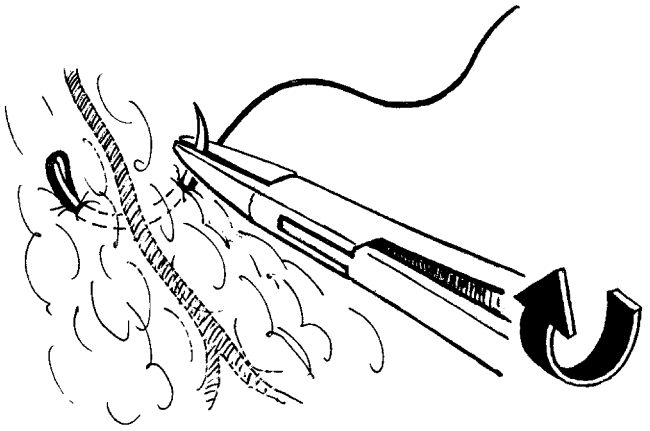

Figure 37-27. Using the blunt back end of a taper-point needle to place a ligature around a semihidden (by fat) mesenteric vessel allows safe placement of a ligature around vessels without inadvertent trauma to the vessel.

The proximal and distal segments are aligned with stay sutures placed at the mesenteric and antimesenteric borders. A slight rotation of the two segments of bowel offsets the mesocolon attachments, allowing a more secure closure at the mesenteric border.[214] The first layer placed is a full-thickness simple-continuous pattern tied at the mesenteric and antimesenteric angles, or a simple-interrupted pattern using No. 0 or 2-0 absorbable suture material. The second layer is a partial-thickness inverting layer using 2-0 absorbable suture interrupted at 180 degrees. The mesentery is closed with a simple-continuous pattern.[214,233,284]

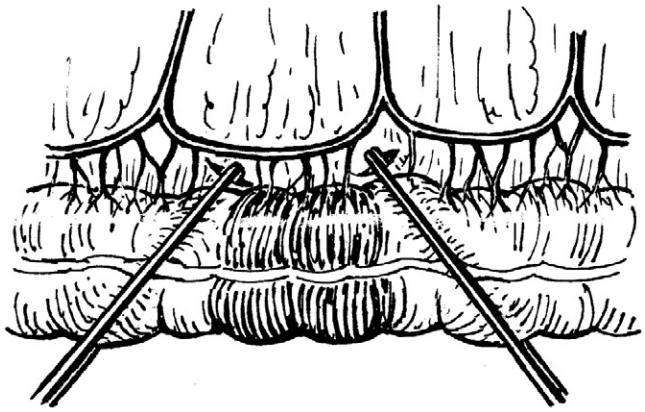

Figure 37-28. Penrose drains or intestinal clamps are positioned approximately 10 to 20 cm proximal and distal to the resection area to occlude the bowel lumen and decrease contamination from luminal contents during the resection (not shown). Doyen intestinal clamps are placed across the descending colon at the oral and anal extents of the resection, angled at approximately 30 degrees from perpendicular so that the length of the small colon at the antimesenteric angle is shorter than the intestine at the mesenteric angle. A scalpel is used to sharply transect the colon, cutting adjacent to the Doyen intestinal clamps and using them to guide a straight transection line.

Postoperative Care and Complications

Because of the high concentration of both aerobic and anaerobic bacteria, broad-spectrum antimicrobial coverage with potassium penicillin (22,000 IU/kg, every 6 hours IV), gentamicin sulfate (6.6 mg/kg, once a day IV), and metronidazole (15 mg/kg, twice a day IV) is recommended. If the bowel is healthy and the surgical procedure is performed with minimal and contained contamination, perioperative (for 24 hours) use of antibiotics can be appropriate. More extended postoperative administration (therapeutic course) of antibiotics (for 5 to 10 days) should be chosen if the horse has compromised bowel, has any signs of peritonitis, or has acquired abdominal contamination during the surgical procedure. Adjunctive antiendotoxin therapy, such as polymyxin B and hyperimmune serum, should be considered in horses with signs of endotoxemia or septicemia.

Postoperative complications with small colon surgery are dehiscence, stricture and adhesion formation, and impaction at the enterotomy or anastomosis.* Other complications, such as peritonitis, diarrhea, thrombophlebitis, and laminitis, are associated with endotoxemia and septicemia.[217,218,221] It has been proposed that several factors specifically affect small colon surgery adversely compared with surgery of other areas of the gastrointestinal tract. These are the high concentration of collagenase in the small colon, the high concentration of bacteria (including anaerobic bacteria), the mechanical stress placed on the surgical site by firm fecal balls passing over the incision, and the poor vascular supply.[226,285,286] Other authors have questioned some of these assumptions. One study has shown that the small colon vascular arcade system has adequate collateral blood supply.[215] If the lesion is in an area that allows adequate surgical access, the blood supply should not be a limiting factor.[215] The small colon is at risk for postoperative impactions because of the character of the feces and the size of the lumen. Impaction places further stress on an enterotomy or anastomosis site, increasing the risk of dehiscence. Although evacuation of the large colon decreases the risk of this occurring, postoperative feeding should also be carefully controlled to further decrease the risk of impaction at the enterotomy or anastomosis site. Reports suggest that with good surgical technique and attention to postoperative management (such as careful reintroduction to feed), horses have a good prognosis after small colon surgery, even after resection and anastomosis.[155,216,218,221,240]

CHAPTER
38 Rectum and Anus

David E. Freeman

The rectum is approximately 30 cm (12 inches) long in an adult horse and extends from the pelvic inlet to the anus.[1] The distance from the anus to the peritoneal reflection is highly variable and is shorter in young horses and in horses with little body fat.[2,3] The peritoneal part of the rectum is attached dorsally by the mesorectum, which is a continuation of the mesocolon.[1] The retroperitoneal part of the rectum forms a dilation called the rectal ampulla, which has thick longitudinal muscle bundles.[1] The anal canal is approximately 5 cm (2 inches) long and is enclosed by the internal anal sphincter, which is a thickening of the circular smooth muscle, and the external anal sphincter, which is composed of striated muscle.[1] The levator ani muscle arises from the ischiatic spine and sacrotuberal ligament and ends under the external anal sphincter.[1] Its action overcomes the tendency of the anus to prolapse during defecation.

RECTAL TEARS

Rectal tears appear to be less common than previously observed, although numbers are not available to support this observation. The percentage of equine malpractice claims from rectal tears in the United States does appear to have declined.[4] One possible explanation for this apparent decline is the use of transrectal ultrasonography for assessment of the mare's reproductive tract and abdominal ultrasonography for examination of horses with colic, both of which provide accurate information rapidly and safely. Evidence that palpation *per rectum* for colic examination and reproductive purposes are the most common causes of rectal tears supports this hypothesis, although the role of ultrasound examination has not been examined.[4] Nonetheless, rectal tears are life-threatening injuries, and the risk of a malpractice claim against the veterinarian can be as much determined by the standard of care applied after the tear was inflicted as by the circumstances that led to its infliction.[5] Copious lubrication of the hand and forearm and adequate restraint of the horse, including sedation if necessary, should be regarded as the minimal measures required to prevent iatrogenic rectal tears. Once a rectal tear is suspected, the veterinarian must assess the tear for severity, inform the owner about the nature of the problem (without making statements that imply admission of guilt or responsibility for payment), and apply appropriate treatment, including referral. Failure to follow these guidelines will weaken a veterinarian's legal defense. The veterinarian should also contact his or her liability insurance company promptly.

Causes

Most rectal tears caused by palpation *per rectum* result from rupture of the rectal wall as it contracts around the examiner's hand or forearm and not from penetration with the finger tips. To avoid a tear, no attempt should be made to force against straining or a peristaltic wave, and intra-abdominal structures should be palpated only when the hand has been inserted beyond the contraction and then withdrawn to that level. Special precautions should be taken with Arabian horses, ponies, small breeds, horses that have had a previous rectal tear or injury, horses that are unaccustomed to palpation *per rectum*, fractious horses, and horses with colic.[2,4,6] Arabian horses, American Miniature Horses, mares, and horses older than 9 years are the breeds, gender and age groups most prone to rectal tears.[4] Most rectal tears are caused by examinations *per rectum* of the reproductive tract in mares and the gastrointestinal tract in horses with colic.[4] Older mares might be at greater risk because of the difficulty in reaching their more pendulous reproductive tracts, the need for frequent examinations of subfertile older mares, the overall greater need to perform rectal examinations on mares than male horses, and possibly age-related degenerative changes in their rectal walls.[4]

Less common causes of rectal tears are enemas, meconium extraction by forceps, sadism, dystocia, parturition without dystocia, animal bites, chronic impaction at a stricture, misdirection of a stallion's penis, spontaneous tears, rectal thrombosis, and sand impactions.[2,3,6-11] In one report of five horses with idiopathic tears, four presented with colic, and the tear developed in one horse during a lameness examination.[12] Idiopathic tears tend to be transversely oriented.[12]

Classification and Locations

Rectal tears are divided into four grades based on severity. In *grade I* tears, only the mucosa and submucosa are torn.[2] In *grade II* tears, only the muscular layer is disrupted, causing the mucosa and submucosa to prolapse through the muscle defect and create a site for fecal impaction.[2] These are rare (2 of 89 recorded in one series,[4] 3 of 85 tears in another[13]), but chronic impactions in the diverticulum may necessitate euthanasia.[13] *Grade III* tears involve all layers except the serosa (grade IIIa) or mesorectum and retroperitoneal tissues (grade IIIb).[5,14] It is not unusual for grade IIIb tears to pack with feces and produce a large plane of dissection cranially and dorsally, even approaching the left kidney. The feces packed in retroperitoneal spaces can be a source of bacterial contamination of the peritoneal cavity (Figure 38-1). A *grade IV* tear involves all layers and is the most serious, since it allows fecal contamination of the peritoneal cavity[2] and, to a lesser extent, evisceration of small intestine or small colon through the rectum and anus.[11] This grade was documented in all six postparturient mares with rectal tears in one series.[11] Most tears involve the dorsal aspect of the rectum regardless of cause, are located 4 to 60 cm from the anus, and are oriented parallel to the longitudinal axis.[2,4,13,14] Distance from the anus is not a reliable indicator of tear location relative to the retroperitoneal reflection.[1,3,5] The size of the tear can vary from 1 to 27 cm, and the only cause that appears to influence the size of the tear is dystocia, with a median size of 25 cm in one study.[4]

Clinical Signs and Diagnosis

Early diagnosis is essential for successful treatment and to avoid legal repercussions. When a tear occurs, the veterinarian may feel a sudden release of pressure or suddenly be able to directly palpate abdominal organs.[6] Alternatively, the examiner may not sense the torn rectum.[6] A rectal tear should be suspected if a large amount of blood is evident on the rectal sleeve on withdrawal of the hand or if the rectum suddenly relaxes while the horse is straining.[2] Within 2 hours after a rectal tear occurs, the horse usually shows signs of peritonitis and endotoxic shock. Signs of colic are also present initially, but these soon give way to depression.[6] Feces can be hemorrhagic initially and defecation can be accompanied by straining.[15] Idiopathic tears are usually presented as colic of variable duration, and because there is no reason to suspect a rectal tear, referral can be delayed.[12]

Before examination of the tear, straining and rectal contractions are stopped with epidural anesthesia or xylazine (0.1 to 0.2 mg/kg body weight IV), alone or in combination with butorphanol tartrate (0.1 mg/kg IV).[13-16] Butylscopolamine bromide (Buscopan), 0.3 mg/kg slowly IV, relaxes the rectum and small colon very well, allowing examination of rectal tears. A lidocaine enema can be given (12 mL of 2% lidocaine in 50 mL of tap water) or lidocaine jelly applied to the rectal mucosa before inspecting the tear digitally or through a tube speculum or endoscope. For digital palpation, the examiner can use the bare hand or wear a surgeon's glove and apply copious lubrication with a water-soluble gel. Because the abundant mucosal folds tend to obscure the rectal tear, more information can be gained from careful palpation than by visual inspection. Failure to accurately grade a tear can cause inappropriate treatment selection. A grade I tear can feel like a flap of mucosa, but a grade III tear can feel as if its edges are rigid and thick and separated, often by packed feces. Abdominocentesis should be performed to assess peritonitis.

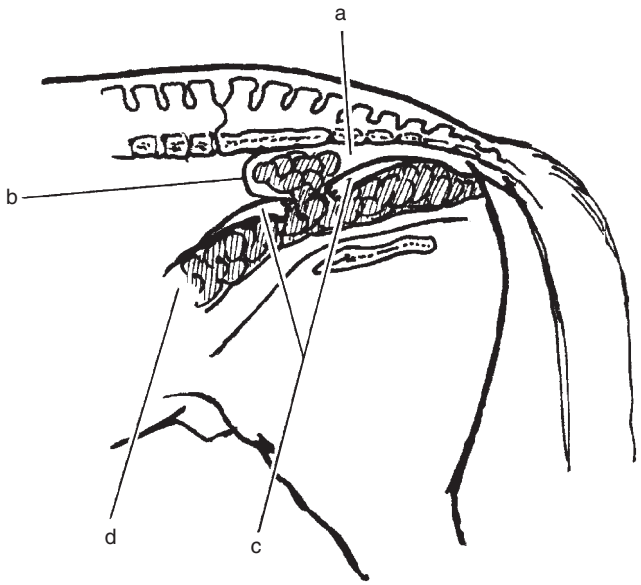

Figure 38-1. Impaction of feces into a grade IIIb rectal tear *(a)*, causing progressive enlargement of the perirectal space and bacterial leakage across the peritoneum *(b)*, swelling of the rectal wall *(c)*, and small colon impaction *(d)*. (From Freeman DE, Richardson DW, Tulleners EP, et al: Loop colostomy for management of rectal tears and small colon injuries in horses: 10 cases [1976-1989]. J Am Vet Med Assoc 200:1365, 1992, with permission.)

Initial Treatment

First aid is applied as soon as the diagnosis is made and can include (1) reduction of activity of the rectum, (2) gentle removal of feces from the tear and rectum, (3) treatment of septic shock and peritonitis, and (4) administration of epidural anesthesia and packing of the rectum.[16,17]

Flunixin meglumine (1.1 mg/kg every 24 hours IV) and antibiotics, such as sodium or potassium penicillin (22,000 IU/kg of body weight every 6 hours IV), gentamicin (6.6 mg/kg every 24 hours IV), and metronidazole (15 mg/kg every 6 hours PO) should be administered and continued as indicated. Intravenous fluids are required to treat shock. Antibiotics and laxatives may be sufficient treatment for grade I and II tears, with daily inspection and careful evacuation of the rectum as needed.[6]

Rectal packing can prevent conversion of a grade III to a grade IV tear and can protect the tear from fecal contamination in the interval before definitive treatment is applied.[5,17] The packing material of choice is a 7.5-cm (3-inch) stockinette filled with 0.25 kg of moistened rolled cotton, sprayed with povidone-iodine and lubricated with surgical gel.[17] The packing should fill the rectum without distention to a point 10 cm proximal to the tear, taking care not to pack the tear itself.[17] The anus is subsequently closed with towel clamps or a purse-string suture, and the epidural anesthetic is repeated as necessary to decrease straining.[6,17]

Bypass Procedures

Bypass procedures can be used to facilitate healing of a tear. A temporary indwelling rectal liner and colostomy divert feces

away from grade III and grade IV rectal tears and thereby prevent contamination and impaction of perirectal tissues, enlargement of the tear, and progression of peritonitis.[18-21] Each can be combined with direct suture repair and thereby used to protect the suture line during healing.

Temporary Indwelling Rectal Liner

A temporary indwelling rectal liner can be constructed by gluing a palpation sleeve with the hand portion removed, or the plastic cover for an arthroscope camera, to a 5-cm-diameter and 7.5-cm-long rectal prolapse ring with holes through which Dacron loops are laced.[6,18] With the horse anesthetized in dorsal recumbency, an unscrubbed assistant passes the well-lubricated ring and liner through the anus so the surgeon can guide it through a ventral midline celiotomy, cranial to the tear but far enough caudad that the sleeve does not retract into the rectum when the horse stands (Figure 38-2).[6,18] A circumferential suture of size 3 surgical gut is placed tightly around the small colon over the central groove of the prolapse ring, and four equidistant retention sutures (2-0 polyglycolic acid) are placed to incorporate the circumferential suture, all layers of the rectal wall, and the Dacron loops in the modified prolapse ring.[18] Then, the serosal surface is apposed over the circumferential suture with a Lembert pattern.[18] The large colon is emptied through a pelvic flexure enterotomy, and the small colon is emptied by flushing with a hose directed through the ring and liner from the anus.[6]

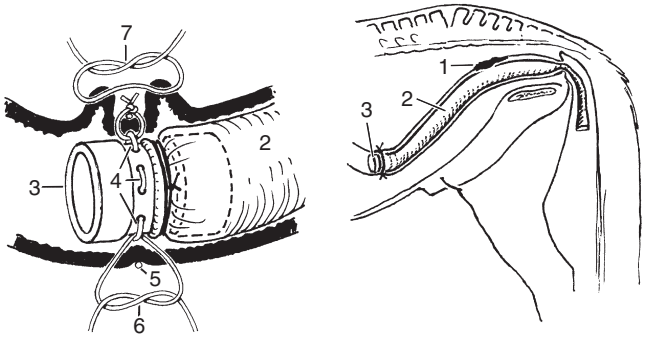

Figure 38-2. Placement of a temporary indwelling rectal liner to divert feces from a rectal tear. The *expanded view* demonstrates the construction of the liner and the method of securing it in place. *1,* Tear; *2,* rectal liner; *3,* rectal prolapse ring; *4,* Dacron anchor suture; *5,* circumferential suture; *6,* retention suture; *7,* interrupted Lembert suture.

The circumferential suture will cut through the rectal wall and allow passage of the ring and liner in feces within approximately 9 to 12 days, by which time the apposed colon walls will have healed.[19] The four retention sutures help maintain the ring in a coaxial relationship with the small colon so that it does not twist and obstruct the lumen.[6,18] Horses are usually cross-tied to prevent them from lying down, which would allow the sleeve to retract forward. Failures have been caused by tearing of the sleeve, retraction of the sleeve into the rectum and uncovering the tear, and formation of a rectoperitoneal fistula.[6,18]

Colostomy

LOOP COLOSTOMY

The loop-colostomy technique (Figure 38-3) is preferred over the end-colostomy technique because it is easier and quicker to establish and to reverse later.[19,20] Concerns about incomplete diversion of feces do not apply to a loop colostomy in horses because gravity, combined with correct construction of the stoma, prevents passage of feces into the distal small colon and rectum.[19-21]

A loop colostomy can be created in a left high flank, a left low flank, or a ventral midline incision, and all have advantages and disadvantages (Table 38-1). A single-incision colostomy

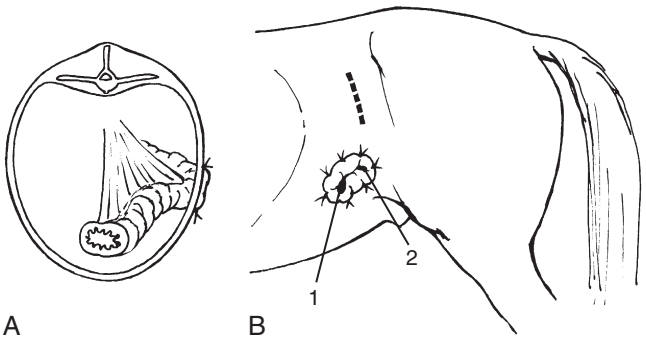

Figure 38-3. A, View through the transverse section of the abdomen shows the placement of the loop in the body wall. **B,** Loop colostomy created with a double-incision technique with the high flank approach *(broken lines)* and placement of the stoma in a small low flank incision. The left opening *(1)* is the proximal opening, and the right opening *(2)* is the distal opening through which the distal part of the small colon is flushed to prevent atrophy. (Redrawn from Freeman DE, Richardson DW, Tulleners EP, et al: Loop colostomy for management of rectal tears and small colon injuries in horses: 10 cases [1976-1989]. J Am Vet Med Assoc 200:1365, 1992.)

TABLE 38-1. Different Types of Colostomies in Horses

Type of Colostomy*	Abdominal Approach	Stoma Placement	Suitable as Standing Procedure	Suitable for Abdominal Exploration	Suitable for Emptying the Colon	Disadvantages
Single-incision	High flank	High flank	Yes	No	No	Fecal soilage of incision and skin
	Low flank	Low flank	No	No	No	Risk of prolapse and herniation
	Ventral midline	Ventral midline	No	Yes	Yes	Risk of prolapse and herniation
Double-incision	High flank	Low flank	Yes	No	No	Difficult construction
	Ventral midline	Low flank	No	Yes	Yes	Difficult construction

*Information applies to both loop and end colostomies.

involves placing the stoma in the same incision used to explore the abdomen and prepare the colon loop, whereas a double-incision colostomy involves a separate flank incision for the stoma.[19] Exploration of the abdomen through the ventral midline is necessary if the horse has a surgical colic that preceded the tear, if intra-abdominal repair of the tear is considered feasible, or if the surgeon elects to empty the large and small colons to reduce stress on the colostomy.[16,20,22] Colostomy placement in the anesthetized horse has the following disadvantages: (1) accurate placement of the stoma is difficult because muscle layers shift and landmarks become distorted in the recumbent horse compared with the standing horse, (2) it is expensive, and (3) dehiscence of the stoma is a risk of rough anesthetic recovery.[19,20] Marking the selected site on the skin with a pen or suture preoperatively while the horse is standing does not obviate the first problem, because the muscle layers disrupt the attachments when the horse stands, even when the skin incision is accurately located. With single-incision colostomies, incorporation of the colostomy in the abdominal closure weakens the body wall repair and makes the ventrally placed stomas, such as the low flank and ventral midline placements, prone to prolapse and herniation.[19] With the double-incision technique, the stoma is placed in a snug low flank incision so that it is surrounded by intact body wall and the risks of prolapse and herniation are reduced.[19]

With the double-incision technique, a high flank incision is used to prepare the colon loop and guide it into a separate low flank incision, midway between the flank fold (just in front of the stifle) and the costal arch, and at the same level as the fold (Figures 38-4 and 38-5).[19] The distal incision is approximately 8 cm long and extends through all layers, and deep dissection is guided by a hand through the high flank incision. It is angled dorsad at its caudal end by 20 to 30 degrees. Small transverse incisions are made in muscles and fascia to eliminate constricting bands that could restrict fecal passage. The stoma should not be large and loose fitting, although this would reduce the risk of stomal obstruction but predispose to the more serious complications of prolapse and herniation.[19,20]

If general anesthesia and ventral midline celiotomy are required, this stage of the surgery should be completed as needed to correct the problem. The horse is subsequently placed in lateral recumbency to complete the colostomy in a separate flank incision.[20] This somewhat reduces problems from shifting muscle layers when the horse stands. A heavy retrieval suture (size 2 nylon) is placed on the antimesenteric band of the prepared loop of small colon before closing the midline incision, so that only a small flank incision is required to form the colostomy.[6,20] The ends of the retrieval suture are placed on a long needle, and that is directed from within the abdomen through the body wall at the site marked for the colostomy.[6,20] The midline incision is closed, the horse is placed in lateral recumbency, and the low flank incision for the stoma is made as described earlier for the double-incision technique.[6,20] Unlike with the double-incision technique, the surgeon must bring the prepared loop of small colon through the small incision at the site of the stoma, without being able to direct the loop though a separate larger incision.

Regardless of the approach, the stoma is made in a segment of small colon at least 1 m from the rectum so that the small colon can be easily exteriorized for colostomy reversal. This segment of small colon is folded to form a loop, and the two arms of the loop are sutured together with an absorbable material in a continuous Lembert pattern for 8 to 10 cm, midway between the mesenteric and antimesenteric teniae.[20] This suture line is brought closer to the mesentery at the folded end of colon to turn the antimesenteric taenia along the outer edge of the fold.[19] The adhesion along this suture line creates a more complete mucosal separation between the proximal and distal segments of small colon and thereby enhances complete fecal diversion. The adhesion can also stabilize the loop within the body wall, reducing the risk of prolapse.[19] The prepared loop of small colon is subsequently inserted into the flank incision so that the proximal loop is slightly ventral to the distal loop and the antimesenteric taenia projects beyond the skin by at least 3 cm.[19]

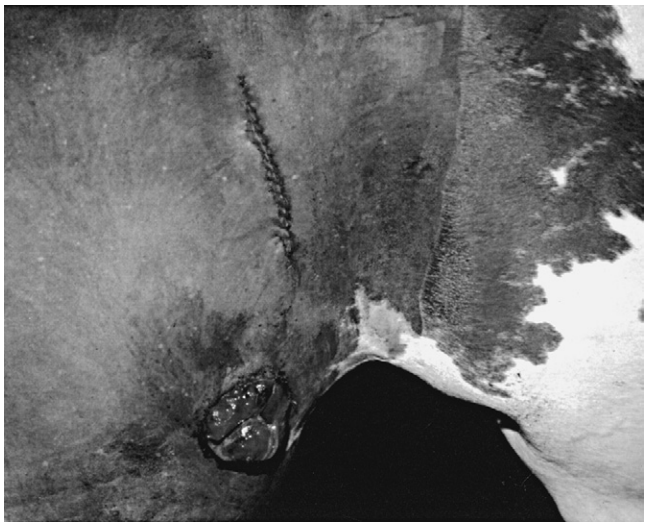

Figure 38-4. Loop colostomy placed in the low flank by a double-incision technique as a standing procedure 2 days earlier. Congestion in the mucosal shelf separating the proximal and distal parts of the small colon is typical for this stage.

Figure 38-5. Loop colostomy placed in the low flank by a double-incision technique as a standing procedure, 60 days later (horse is not that shown in Figure 38-4). The stoma is mature and healed to the surrounding skin; the mucosal shelf is evident as a small bulge in its midpoint.

The seromuscular layer of the colon is sutured to the abdominal muscles and fascia using several interrupted sutures of 0 or 2-0 absorbable material, taking care not to puncture or occlude mesenteric vessels.[19] To form the stoma, an 8-cm incision is made along the exposed antimesenteric taenia of the colon, and the cut edges are folded back and sutured to the skin with simple-interrupted sutures of 2-0 nylon or polypropylene (see Figure 38-3).[19] The opening thus formed is approximately the same size as the small colon lumen[19] (see Figure 38-5). Because fecal balls are eliminated individually as they pass through the small colon, without being stored to form piles, as in the rectum, the risk of obstruction is low.

An alternative method for loop colostomy is to suture the colon loop to skin only and to detach and oversew the stoma at 14 days.[23] The abdominal muscle layers and skin are then closed.[23] Disadvantages of this method are that such an attachment may allow peristomal herniation and that the rectal tear is unlikely to heal in 14 days.[19-21]

END COLOSTOMY

Some surgeons prefer an end colostomy because of the concern about incomplete fecal diversion with the loop colostomy method, a concern most likely carried over from experiences with the supine human patient.[24] However, the loop colostomy method does allow complete fecal diversion, because gravity causes fecal balls to drop away from the stoma rather than turn into the distal segment. For the end colostomy, the colon is transected, the distal segment is closed by the Parker-Kerr method (see Figure 16-8, *D*), and the proximal end is incorporated into the body wall as for the loop colostomy.[24] The distal segment tends to atrophy, so its diameter and length may become reduced by 50%.[24] This makes colostomy reversal by future anastomosis difficult and may cause anastomotic impactions and dehiscence.

AFTERCARE FOR COLOSTOMY

Antibiotics and laxatives (mineral oil, 2 to 4 L/450 kg, and magnesium sulfate, 1 g/kg) are continued for 3 to 5 days. Horses are held off feed or are fed grass and alfalfa hay at half the usual amounts for the first 2 to 3 days after the colostomy is established, and petrolatum-based ointment is applied to the skin around the stoma to protect it from scalding. A cradle is applied because most horses have a tendency to mutilate the colostomy.

When the loop colostomy is created, the mucosal protrusion of the stoma becomes markedly congested over the first 5 to 7 days after surgery (see Figure 38-4) and slowly sloughs, to be replaced with healthy tissue (see Figure 38-5). Considerable ventral edema can develop, but it resolves with time.

Small colon atrophy distal to the stoma plays a large part in failure of colostomy reversal by reducing the distal lumen size to the point that fecal impaction is inevitable.[20,21] With the loop colostomy, it is possible to exercise the distal part of the small colon and prevent the atrophy that complicates anastomoses with the end colostomy.[19,20] When the tear has started to granulate, usually after 5 to 7 days, the distal loop of the small colon and the rectum are flushed daily in normograde fashion with approximately 20 L of warm water through a garden hose.[19] This is more likely to improve lumen diameter than luminal nutrients such as short-chain fatty acids,[21] which would be expected to have a positive trophic effect on the mucosa without the necessary stretching of the muscle layers achieved through lavage.

COLOSTOMY REVERSAL

For colostomy reversal, usually 6 weeks or more after the colostomy, the horse is anesthetized in right lateral recumbency, the stoma is resected *en bloc*, and a colonic anastomosis is performed through the resulting flank incision.[6,19] Even if the colon is not penetrated during dissection, incisional infection is a common complication of stomal resection.[19]

For anastomosis, the distal segment is transected along a more acute mesenteric angle than the proximal segment to correct for a slight reduction in distal diameter. A single layer of interrupted Lembert sutures with 3-0 polydioxanone (PDS) is used for anastomosis (Figure 38-6), but other methods also are suitable.[6] The stapled side-to-side technique is likely to become impacted despite the large stoma.[21] The postoperative feeding, antibiotic, and laxative regimens are similar to those used after the colostomy procedure.

COMPLICATIONS OF COLOSTOMY

Complications of colostomy are dehiscence, abscessation, peristomal herniation, prolapse, prolapse with rupture of mesenteric vessels, infarction, rupture of the colostomy, spontaneous closure, and stomal obstruction, as well as anastomotic impaction and dehiscence after reversal.[6,7,19-21] Herniation and prolapse have been attributed to ventral placement of the stoma and to a stoma that is too large.[20,21] There is a tendency to make the stoma large to prevent stomal obstruction, although stomal obstruction is rare, probably because fecal balls are voided individually.[19]

CHOICE OF DIVERTING PROCEDURE

The choice between colostomy and temporary indwelling rectal liner for definitive treatment of a rectal tear is influenced largely by cost and by the surgeon's preference, because the two methods have comparable success rates.[14,18-21] The outcome is most likely to be determined by complications of the tear that developed before application of the diverting procedure.[19] Colostomy does have inherent, life-threatening risks and is more expensive because it is a two-stage procedure. A potential advantage of colostomy is that it allows the surgeon more complete control over the duration of fecal diversion, which could be important if healing of the tear is delayed.[6,19,20] Colostomy is preferred for large tears, small horses, and a tear that is too far proximal to accommodate a rectal liner.[18]

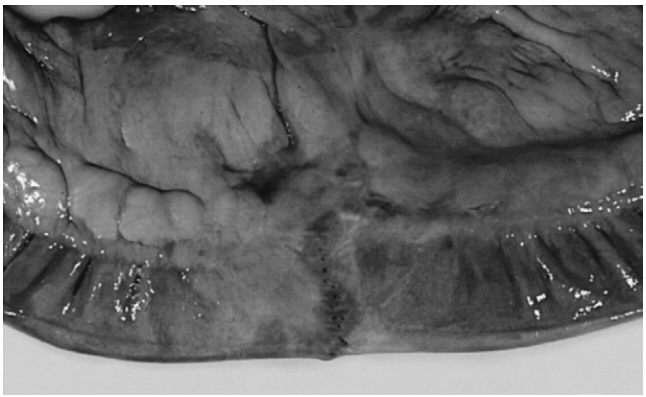

Figure 38-6. End-to-end anastomosis of the small colon with an interrupted Lembert pattern, using a 2-0 silk suture. The colostomy was reversed 21 days earlier, but the horse was euthanized because of laminitis.

The most difficult decision is whether a fecal diversion procedure is required at all, because some horses with grade III rectal tears can make a full recovery without surgery (see later).[3] Although few criteria can be used to guide treatment selection, the decision to use diverting procedures must be made quickly to derive full benefit, preferably within 12 hours after the tear occurred.[19,20] Because the cost of diverting procedures can be considerable, many owners opt for less-expensive procedures, such as direct suturing or medical treatment combined with repeated manual rectal evacuation.[25-27]

Suture Repair

Suture repair can promote healing and prevent progression of a grade III tear to a grade IV tear.[6,14,18] It should be combined with a diverting procedure if there is any concern about the integrity of the repair, but this is not always necessary and can be precluded for economic reasons. The surgery is easiest to accomplish on a thin horse with a tear that is fresh, clean, and close to the anus.[14,16] Long-handled instruments with pistol grips and a 60-cm-long expandable rectal speculum or "cage" have been developed to facilitate suture repair of rectal tears in horses.[28] The anal sphincter can be incised to improve access to a rectal tear, and this can be left open to ease defecation afterward.[29,30] A large wound of long duration can be partly closed or left open to allow drainage, and the defect can be packed with antiseptic-soaked gauze to prevent fecal impaction and dissection.[14,29]

A grade IV tear can be prolapsed through the anus to be closed with the TA-90 Premium stapling instrument, because the tear creates a pneumoperitoneum and equilibration of pressure across the rectal wall that allows it such mobility.[31] This procedure has been used successfully also for grade IV tears in mares in the immediate postpartum period, when the perirectal tissues are sufficiently relaxed to allow retraction of the rectal wall.[11] The staple line can be reinforced with a simple continuous suture pattern.[11] To improve access, four equidistant stay sutures can be used to retract the anal sphincter, which may then be transected at the dorsal commissure.[11] The latter can be sutured after surgery is completed.[11]

If the rectal tear is not accessible through the anus, it can be prolapsed through it from a caudal ventral midline laparotomy or repaired through an antimesenteric enterotomy from a ventral midline approach.[16,22] Suture repair under laparoscopic control appears to be a promising method for the future, but the instruments may be too short in some cases.[32]

A technique for nonvisual direct suturing has been reported to have favorable results and is a simple and inexpensive standing procedure.[17,25] If the tail is elevated and the anal sphincter is relaxed from the caudal epidural anesthesia, the rectum fills with air and the surgeon has more room in which to manipulate the needle.[25] This ballooning effect is poor in rectums with grade IV tears because of the equilibration between intra-abdominal and atmospheric pressure, and it diminishes in grade III tears if surgery is prolonged. Fecal material is digitally removed from the rectum and distal small colon, and the defect and lumen walls are cleaned carefully and thoroughly by wiping with moistened 4 × 4 inch gauze sponges. If the tear does not involve the full thickness of the wall, gentle gravity lavage can be used to clean the tear. In a grade IV tear, the severity of peritoneal contamination determines whether a repair should be attempted.

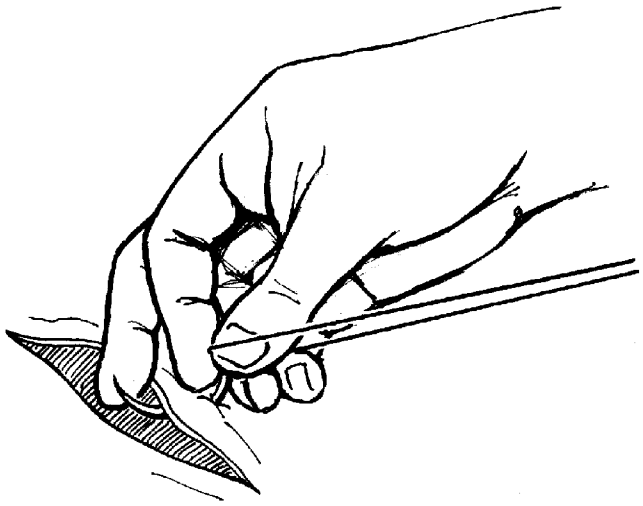

Figure 38-7. Diagram showing the first bite of the nonvisual direct suturing technique being placed in the center of the caudal edge of the tear. The needle, held with the thumb and first two fingers, is inserted approximately 1.5 cm from the edge of the wound and guided into the defect subserosally by the second or third finger. (Drawn from Eastman TG, Taylor TS, Hooper RN, Hague, BA: Treatment of grade 3 rectal tears in horses by direct suturing *per rectum*. Equine Vet Educ 12:63, 2000, with permission.)

The left hand is used for tears on the right side, and vice versa, and gloves are not worn.[25] The preferred suture is size 5 Dacron, 100 to 150 cm long, with a 6- to 8-cm half-circle cutting or trocar point needle placed in the middle of the suture.[25] A cruciate or simple-interrupted pattern is used. With both ends of the suture outside the rectum, the needle is manually advanced to the tear. The first bite is placed in the center of the caudal edge of the tear, holding the needle with the thumb and first two fingers. The needle is inserted approximately 1.5 cm from the edge of the wound and guided into the defect subserosally by the second or third finger (Figure 38-7). The needle is pulled through the tissue, again grasped with the thumb and first two fingers, and then placed in the center of the cranial edge. This bite begins subserosally within the defect and exits 1.5 cm from the edge. The third finger is used to guide the exit point and press the tissue onto the needle. The needle is subsequently brought out the rectum, leaving a single strand of suture in the tear with the other end extending 10 to 15 cm distal to the anal sphincter. The suture is then clamped with a hemostat between the needle and the point of exit from the tear and the needle remains threaded on the proximal half of the suture. An assistant holds the clamped suture to one side to close the defect into a transverse plane, and the needle is carried into the rectum. The suture is then passed through both cranial and caudal edges of the defect in one bite using digital manipulation as before, and finally the needle is brought out the rectum. The hemostat is released and the needle end of the suture is drawn through to form a cruciate suture. The knots are tied outside the rectum and pushed inside with one hand while tension is maintained on the suture with the other hand. Additional throws are placed to secure the knot.

Traction on the first suture should convert the tear to a transverse orientation, which facilitates placement of about two or three more sutures on each side of the first.[25] Care must be taken to prevent lumen reduction by the closed defect as its edges turn

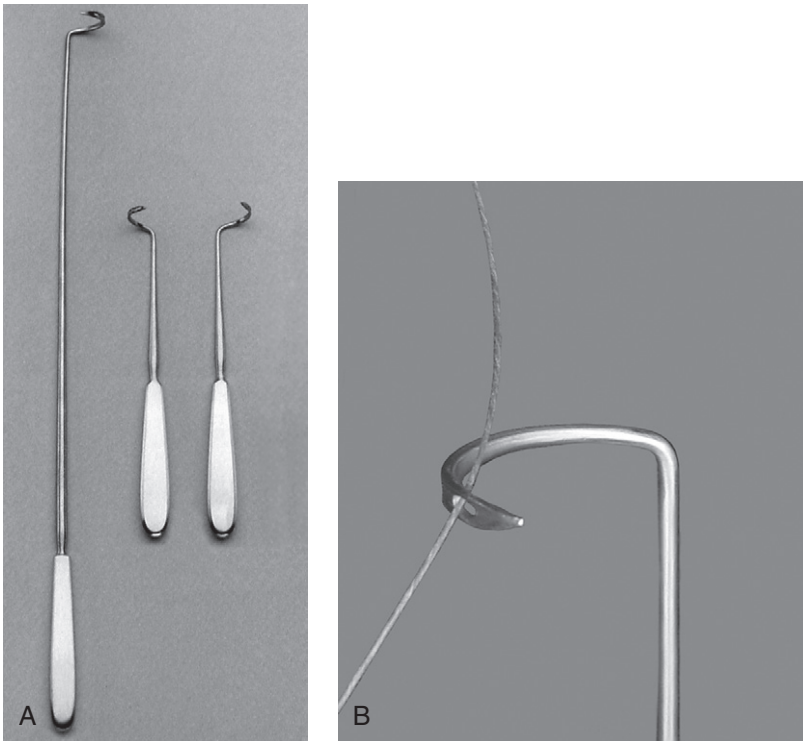

Figure 38-8. A, Deschamps needles, showing the right- and left-handed configurations with 20-cm needles *(right)* and the 45-cm needle that is suitable for rectal tears *(left)*. **B,** Close view of the end of a Deschamps needle. The threaded eye near the pointed tip allows easy retrieval of the suture without the need for complete penetration by the needle. Once the suture is grasped at the tip of the needle, the instrument is rotated backward out of the tissue and can be rethreaded for the next bite.

into the lumen. The suture ends are cut long to facilitate their removal, but if the feces cannot be kept soft, the ends should be cut short so that they do not get pulled out by fecal balls.[25] The sutures are checked at 24- to 48-hour intervals, and any suture that feels slack from loosening or reduction of edema is replaced. The sutures are removed in 12 to 14 days.[25]

Nonvisual direct suturing may not be easily mastered and can require extensive practice.[25] It is a useful technique for tears involving half or less of the rectal circumference and for tears that have very small perforations of the serosa, but it is recommended as an adjunct and not as a primary treatment for grade IV tears.[25]

The 45-cm Deschamps needle, which is made in both right- and left-handed configurations (Figure 38-8), is ideal for one-handed suturing in a deep recess (Figure 38-9) and has been used successfully for standing repair through the anus.[30] The needle tip should be sharp. Both chromic catgut and polyglycolic acid suture have been used. A right-handed surgeon guides the Deschamps needle rectally to the wound, with the left hand serving as protection and the right hand turning the handle (see Figure 38-9).[30] The caudal end of the perforation is grasped with the index finger and thumb of the left hand, and the needle is guided through the mucosa, muscularis, and serosa (if present), about 1 cm away from the wound edge.[30] The ventral wound edge is penetrated, the suture is removed from the eye of the needle, and a surgical knot placed outside the rectum is pushed in with the left hand. An assistant pulls the ends of the first knot through the anus to stabilize the repair and bring the wound edges together. Additional single sutures are placed from caudad to craniad, 1 cm apart, so that the wound closes to form a ridge (see Figure 38-9). If the suture bites exceed 1.5 cm from the wound's edge, the rectum becomes too narrow.[30]

The preferred suture for repair of rectal tears should be long, have low memory, resist stretching, and resist fecal digestion.[25]

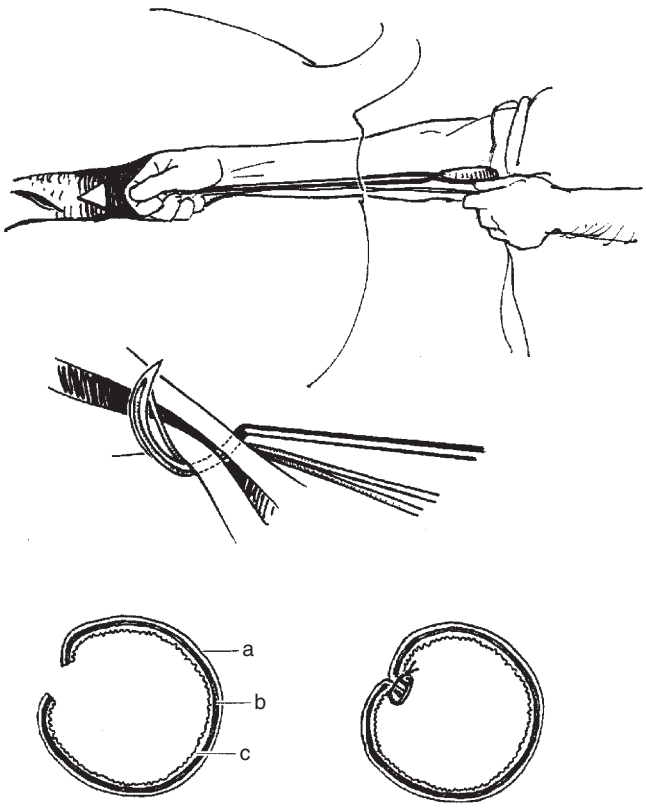

Figure 38-9. Method of inserting the Deschamps needle into the rectum and guiding it to the tear while protecting the tissues with the right hand. The close-up in the middle shows how the Deschamps needle grasps both sides of the tear and pulls the suture through it as well. The lower diagrams show the suture placement for a grade IV tear. *a,* Serosa; *b,* muscularis; *c,* mucosa.

Small suture tends to cut through the friable tissue edges, and catgut tends to stretch.[25] Continuous suture patterns are not recommended because they reduce the lumen diameter, which predisposes to impaction and dehiscence.[25] A complete pellet ration can be fed after a 2-day fasting period to produce a small fecal bulk, and mineral oil can be used to soften feces.[25] Mineral oil is not used if the repair of a grade IV tear is tenuous, because it could leak into the abdomen.[25]

Nonsurgical Treatment

Grade I and II tears rarely require surgical treatment, and grade I tears respond in most cases to antibiotics (e.g., trimethoprim-sulfadiazine, 20 mg/kg PO every 12 hours), and flunixin meglumine (1.1 mg/kg IV or PO, every 12 hours), mineral oil (4 L via nasogastric tube every 24 hours), and dietary changes such as bran mashes, moistened pellets, or grass to reduce fecal volume and soften the consistency. If all or a significant portion of the submucosa layer remains intact, grade I tears should heal with medical management without complications.

Although grade III tears usually require surgical treatment, medical management can be successful and is considerably less expensive than surgical methods.[15,26,27] In one report, six of eight horses with grade IIIb rectal tears were treated successfully with broad-spectrum antibiotics (penicillin, gentamicin, and metronidazole) and nonsteroidal anti-inflammatory agents, maintenance of soft feces with a diet of grass and bran mashes and daily administration of mineral oil by nasogastric tube, and daily manual removal of feces from the rectum after sedation and epidural anesthesia.[27] All horses developed septic peritonitis, and three of the six survivors developed a rectal diverticulum in the tear, without any apparent clinical effects.[27] The authors felt that manual evacuation of feces should be performed only if the tear became impacted, and the procedure should be conducted with extreme care.[27]

In another report on successful medical treatment of four horses with grade IIIb tears, the authors recommended frequent manual evacuation of feces on a daily basis.[26] Frequency of manual evacuation decreased from every 1 to 2 hours to every 6 to 8 hours by the 4th and 5th day, and the evacuations were discontinued between 9 and 21 days.[26] The underlying principle in this approach was to eliminate the storage function of the rectum and thereby eliminate impaction of feces into the tear.[26] Although this treatment is simpler to perform than bypass procedures, it is labor intensive and does require repeated epidurals through an epidural catheter.[26]

Full-thickness tears into the retroperitoneal space may be treated with manual evacuation of feces, antimicrobial therapy, fecal softener, and packing with gauze soaked in antiseptic solution until the defect fills with granulation tissue.[3,16] Perirectal abscesses that follow this treatment can be drained into the rectum (see later). Ventral tears in mares can be drained through the dorsal vaginal wall.[16] As with any method of treatment, peritonitis from the tear can be treated by peritoneal lavage, although this approach was not used in many cases reported in the literature.

Prognosis for Rectal Tears

Complications of grade III rectal tears are extensive and include cellulitis, abscess formation, severe toxemia, peritonitis, laminitis, and recurrent intestinal obstruction from adhesions.[14,16,18,21] The time required for healing of rectal tears varies from 2 to several weeks.[18-21] Most tears heal with little residual damage, but some can form a stricture, a diverticulum, or perirectal abscessation.[19,33] Such abscesses must be drained into the rectum by finger puncture and can delay colostomy reversal for up to 60 days.[19,20] Grade III and IV tears can heal to form a mucosal or submucosal hernia that can subsequently become impacted with feces, and a grade IV tear can form a rectoperitoneal fistula.[16,18]

In one survey of 85 horses, conservative management (medical treatment or no treatment) of 15 horses with grade I tears yielded a 93% survival rate.[13] Grade IIIa rectal tears had a 70% survival rate in this study (16 of 23 horses), and grade IIIb rectal tears had a 69% survival (9 of 13), compared with a 44% survival rate in a previous study.[13,14] Survival for grade IV tears was 2 of 31 horses.[13] In another study, all horses with grade I and II tears survived but only 38% of those with grade III tears and 2% with grade IV tears left the hospital.[4] A variety of different treatments were used, so it was difficult to draw conclusions about treatment effects on survival; however, all horses that had a colostomy (3) survived to hospital discharge.[4]

Nonvisual direct suturing of rectal tears in the horse has a higher success rate than that reported for other techniques.[25] In one study, 75% (15 of 20) of horses treated by this technique survived until discharge. Eighty-one percent of horses (13 of 16) with grade IIIa tears, and 50% of horses (2 of 4) with grade IIIb tears were discharged alive after suture repair.[25] The sutures did not hold in three horses, and the tears converted to grade IV at 1 to 7 days after surgery. One horse died of peritonitis from an unidentified grade IV tear orad to the sutured grade III tear.[25] Long-term follow-up was available for 10 of 15 survivors (66%), all of which survived at least 6 months. Horses discharged alive were hospitalized an average of 15 days (range, 9 to 24 days).

RECTAL PROLAPSE

Causes of rectal prolapse are straining from diarrhea, dystocia, intestinal parasitism, colic, proctitis, rectal tumor, and rectal foreign body.[14,33,34] In many cases, a cause cannot be identified. The condition is more common in females than in males and may affect any age group.[34]

Classification

In a *type I* rectal prolapse, only the rectal mucosa and submucosa project through the anus, sometimes more so on one side than on the other.[29,30] A *type II* lesion represents a complete prolapse of the full thickness of all or part of the rectal ampulla.[35] Type I and II prolapses are the most common.[34] In a *type III* prolapse, a variable amount of small colon intussuscepts into the rectum in addition to a type II prolapse.[35] In a *type IV* prolapse (Figure 38-10), the peritoneal rectum and a variable length of the small colon form an intussusception through the anus.[35] This type of prolapse is seen with dystocia in mares.

Clinical Signs and Diagnosis

The usual presentation of a prolapse is a mucosal mass (types I, II, and III) or tube (type IV) protruding beyond the anus, with

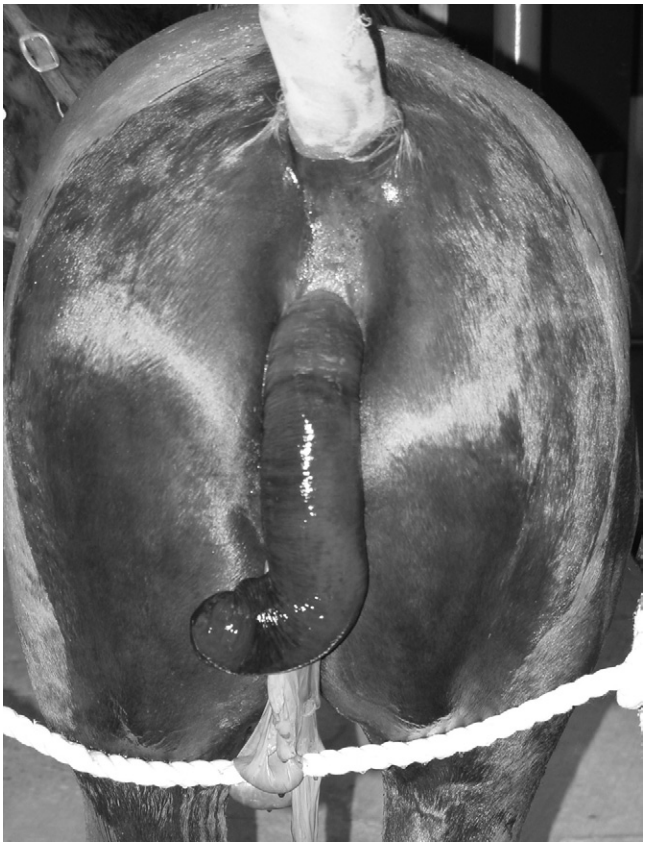

Figure 38-10. Type IV rectal prolapse in a postpartum mare.

a variable amount of inflammation, cyanosis, bruising, or necrosis. Colic and peritonitis develop with types III and IV, and abdominocentesis should be performed in such cases.[36]

Treatment

Most early type I and II prolapses respond to reduction and treatment of the primary problem. In many type I and II prolapses, mucosal edema and irritation can be reduced by topical application of glycerin, sugar, magnesium sulfate, and lidocaine jelly, or lidocaine enemas (12 mL of 2% lidocaine in 50 mL of water). Epidural anesthesia may be applied to reduce straining and to facilitate manual correction. To prevent recurrence, doubled 6-mm (¼-inch) umbilical tape can be placed with four wide bites in loose purse-string fashion, 1 to 2 cm lateral to the anus. Normal feces cannot pass through the purse-string, so it has to be opened every 2 to 4 hours to allow defecation or manual removal of feces. Mineral oil enemas and intragastric infusions of mineral oil or other laxatives should be given as needed, and the horse should not be fed for 12 to 24 hours. From then on, a laxative diet should be fed for at least 10 days. If it is well tolerated, the purse-string suture can be left in place for 48 hours. If a horse with a type IV prolapse is to be referred to a hospital for definitive treatment and if the prolapsed tissue appears nonviable, it might be better to leave it prolapsed so the surgeons can evaluate and treat it. Reduction of necrotic tissue can lead to peritonitis and complicate treatment, because access through a celiotomy is limited, especially compared with access when the rectum is prolapsed.

If type III and IV prolapses are treated by manual reduction alone, serial peritoneal fluid samples should be obtained to monitor changes in bowel wall viability.[34] Frank blood in the rectum after correction of a prolapse may be evidence of bowel necrosis.[36] Laparoscopy can be used to determine whether the mesocolon is ruptured and to assess viability of the involved small colon.[37] Access for resection of the necrotic bowel may be difficult through a celiotomy, and re-creation of the prolapse might be required to allow a submucosal resection outside the anus. A colostomy could be performed, but continued necrosis ultimately leads to failure.[19]

Submucosal Resection

A submucosal resection may be indicated if the prolapsed tissues are devitalized, the prolapse recurs after conservative treatment, or the horse continues to strain.[34] The procedure can be performed with epidural or general anesthesia. After preparation for surgery, two 18-gauge, 15.0-cm (6-inch) spinal needles, or 14-gauge, 13-cm (5¼ inch) Teflon catheters with the stylet in place are inserted at right angles to each other through the external anal sphincter and healthy mucosa to maintain the prolapse during dissection.[34] Starting at the 12 o'clock position, circumferential incisions are made in healthy tissue for one third of the prolapse circumference.[34] These incisions should be combined with deep dissection to elevate a strip of edematous and necrotic mucosa and submucosa. Remaining healthy proximal and distal edges of the mucosa and submucosa are apposed with size 1 or 2 medium chromic gut or PDS in an interrupted, horizontal mattress pattern.[34] These steps are repeated for each of the remaining thirds of the circumference until all necrotic tissue has been removed.[34] Mucosal edges are subsequently apposed with simple-interrupted sutures with buried knots, or preferably with a simple-continuous pattern interrupted at three equidistant points around the circumference.[34] A 2-0 absorbable suture material is used for this layer. The purpose of the mucosal suture is to cover all denuded areas and to prevent extensive granulation, scarring, and stricture formation.[34] Postoperative management includes laxatives, a laxative diet, and, if necessary, careful digital removal of impacted feces from the rectum.

Resection and Anastomosis

Resection and anastomosis may be indicated for type IV prolapse if the prolapsed tissues are devitalized or too much tissue is involved to allow reduction. The procedure can be performed as for submucosal resection, except that full-thickness circumferential incisions are made through the inner and outer walls of the intussusceptum in healthy tissue (Figure 38-11). The healthy proximal and distal edges are apposed with size 1 or 2 PDS in an interrupted, full-thickness, horizontal mattress pattern (Figure 38-12). These steps are repeated for each of the remaining thirds of the circumference until all necrotic tissue has been removed. Care must be taken during resection to identify and ligate any mesenteric vessels in the prolapse. Mucosal edges are then apposed in a simple-continuous pattern with 2-0 PDS, interrupted at three equidistant points around the circumference. The transfixing cross-needles and the weight of the necrotic tissue through most of the procedure maintain the line of anastomosis outside

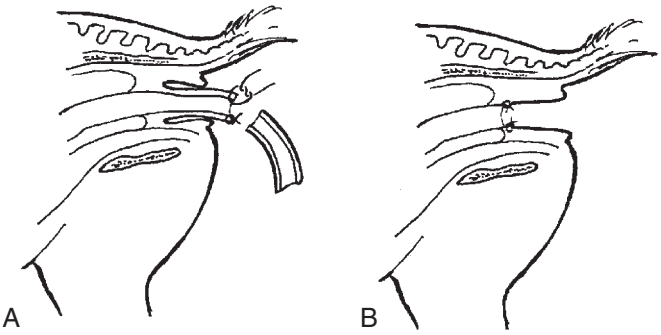

Figure 38-11. Treatment of a type IV rectal prolapse with intussusception of the distal part of the small colon and peritoneal segment of the rectum. **A,** The prolapsed tissues are resected as described and the healthy tissues anastomosed. **B,** When the stabilizing cross-catheters or needles are released, the anastomosis assumes its position in the proximal part of the rectum. (From Edwards GB: Diseases and surgery of the small colon. Vet Clin North Am Equine Pract 13:359, 1997, with permission.)

Figure 38-12. Partially completed anastomosis retained in position outside the anus with crossed 14-gauge, 5¼-inch-long Teflon catheters with the stylet in place. The mucosal closure has been completed on top and the visible sutures are full-thickness horizontal mattress sutures. This mare (the same one shown in Figure 38-10) made a complete recovery.

the rectum. Postoperative management is the same as for submucosal resection.[34]

Prognosis

The prognosis is favorable with types I and II prolapses, but the severity of vascular damage and mesenteric disruption worsens the prognosis for types III and IV prolapses.[35,38,39]

PERIRECTAL ABSCESS

In most cases, the cause of perirectal abscessation is unknown, although possible causes are rectal puncture or tear, rectal inflammation, and gravitation of a gluteal abscess after injection.[40] Enlarged anorectal lymph nodes have been reported as causes of rectal obstruction in young horses (3 to 15 months of age), and such nodes can progress to form abscesses.[41] *Streptococcus zooepidemicus* and *Escherichia coli* have been isolated.[40,41]

Clinical Signs and Diagnosis

The most common signs are low-grade abdominal pain and depression, anorexia, reduced fecal production, dyschezia, tenesmus, and fever.[40,41] Urinary tract dysfunction, manifested as dysuria, may develop from neuritis secondary to regional inflammation.[41] The abscess can form a visible swelling lateral or dorsal to the anus and can be palpated as a firm submucosal mass inside the rectum. Purulent material can be aspirated for culture and sensitivity testing through a needle inserted percutaneously (preferable) or through the rectal mucosa. Ultrasonographic examination is helpful, especially to monitor the response to treatment, but it cannot always provide a clear distinction between a reactive lymph node and an abscess, a hematoma, or a tumor.[41]

Treatment

Epidural anesthesia or sedation and local anesthesia are used for restraint. A lateral abscess can be drained lateral to the anus, a dorsal abscess can be drained into the rectum, and a ventral abscess can be drained into the vagina in mares or ventrolateral to the anus in males. Postoperatively, the abscess cavity is flushed daily for approximately 6 days with a 10% povidone-iodine solution.[40] A laxative diet is fed, mineral oil is given as needed by nasogastric tube to aid defecation, and a nonsteroidal anti-inflammatory drug such as flunixin meglumine is used to reduce discomfort.

Rarely, the abscess involves abdominal organs and causes peritonitis, which is confirmed by abdominocentesis.[40] An exploratory celiotomy may be required to drain the intra-abdominal component by marsupialization or to facilitate drainage into the rectum or vagina.[40] In horses without abdominal involvement, the prognosis for recovery is favorable.[40] Surgical drainage does not appear to be necessary in young horses with enlarged or abscessed anorectal lymph nodes, and a successful outcome is possible with treatment by antibiotics, analgesics, laxatives, and diet modification.[41]

ATRESIAS OF THE ANUS AND RECTUM

Atresia ani is rare and may be associated with atresia coli, atresia recti, persistent cloaca, absence of a kidney, renal hypoplasia and dysplasia, absence of the tail, musculoskeletal deformities, micro-ophthalmia, rectourethral fistula, and other urogenital abnormalities.[42-49] Atresia coli is also rare (0.44% to 1.3% of hospitalized foals), and affected foals have a normal anus but may have a blind and empty rectum.[50]

Clinical Signs and Diagnosis

Signs of atresia ani are evident shortly after birth and include straining to defecate, tail flagging, abdominal discomfort, and abdominal distention. The anus is absent, but an anal sphincter may be present (Figure 38-13). Signs of intestinal obstruction are not seen in foals with atresia and congenital rectovaginal

fistula because they can void feces through the vagina. Three of seven foals in one study on atresia coli had atresia of the rectum or a blind-ending rectum that could be diagnosed by digital palpation.[50] As with all foals with atresia coli, these foals had a history of failure to pass meconium and a lack of meconium staining of the perineum.[50]

Figure 38-13. Atresia ani in a 5-day-old filly, with meconium staining of the perineum caused by defecation through a rectovaginal fistula.

Treatment

In foals with a complete rectal pouch, the persistent anal membrane is incised or a small circular piece of skin is removed, and the anal sphincter is spared, if possible. The rectal wall is subsequently sutured to the skin with simple-interrupted sutures. If the distal rectum is atretic, deeper dissection is needed. Any communication with the urogenital tract should be closed by transection between structures and closure by inverting sutures or by simultaneous closure and transection with autosuture instruments (GIA). The prognosis for life is favorable, but normal anal function may not be obtained. The prognosis for atresia coli, with or without rectal involvement, is poor.[50]

POLYPS AND NEOPLASIA

The most common neoplasms of the perineal region and anus of the horse are squamous cell carcinomas and melanomas.[51-55] Squamous cell carcinomas are necrotic, foul smelling, and locally invasive lesions that metastasize slowly.[51] Diagnosis is based on biopsy. Treatments include surgical excision, cryosurgery, electrosurgery, laser surgery, hyperthermia, radiation therapy, immunotherapy, and combinations of these methods.[51] Colostomy can be used to bypass rectal obstruction by a large tumor.[55]

Approximately 80% of Gray Horses older than 15 years have melanomas.[52] Melanomas may be solitary or multiple, and they most commonly occur in the perineum and along the ventral surface of the tail (Figure 38-14).[51] Although most equine melanocytic tumors are benign, dermal melanomatosis can occur on the perineum and have a high metastatic rate (for details, see Chapter 29).[56] Diagnosis is made by clinical features and biopsy.[56] Treatment is indicated if the lesion is large enough to

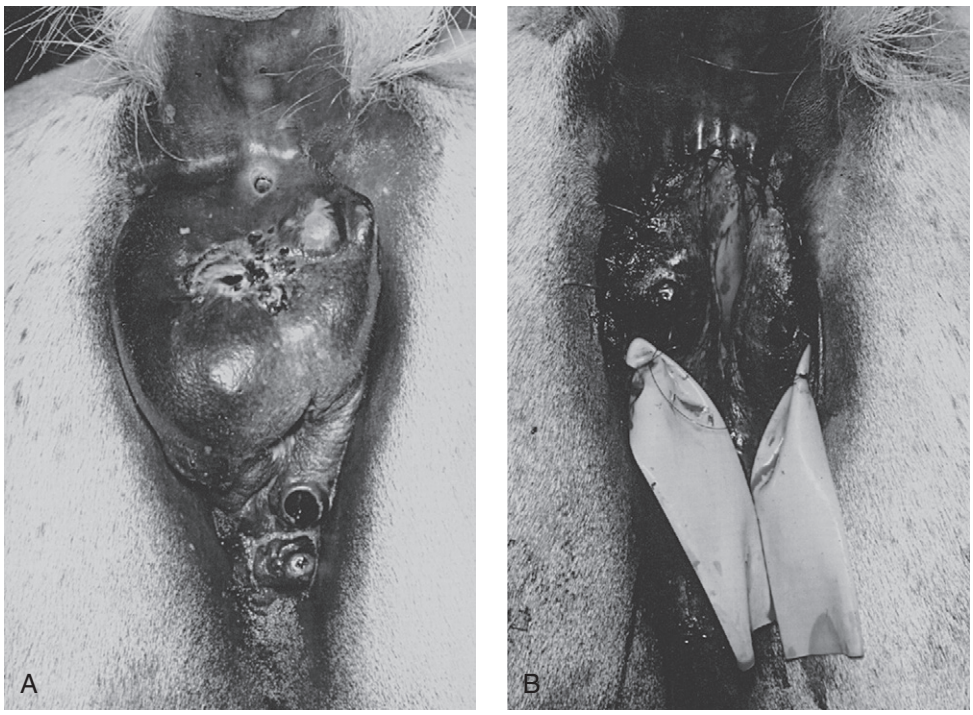

Figure 38-14. A, A large melanoma that deformed the anus and interfered with defecation. **B,** The same horse after excision. Penrose drains are placed in the dead space created by the deep perirectal dissection required to remove the large masses completely. Small tumors were not removed so that sufficient skin remained for closure.

cause clinical problems or is esthetically unacceptable. The treatment of choice is early excision or cryosurgery, although removal of all lesions in a diffuse cluster is not always feasible or necessary.[51] Successful treatment with radiation therapy, cimetidine, and bacillus Calmette-Guérin has been reported.[53]

Rectal polyps, adenocarcinoma, and leiomyosarcoma are rare in horses and can be treated successfully by transection of attachments to the rectal mucosa.[34,43,57] A hamartomatous polyp (focal disordered growth of mature tissue indigenous to the organ affected) obstructed the distal part of the small colon in a 2-day-old Standardbred foal and caused abdominal pain, tenesmus, and rectal bleeding.[58] The mass could be identified on radiographs after a contrast enema, but it was not readily accessible for removal.[58] Rectal strangulation by a mesenteric lipoma has been treated successfully by twisting the lipoma off its pedicle through a colpotomy.[59]

CHAPTER
39 Abdominal Hernias

Martin R. Kummer and John A. Stick

A hernia represents a protrusion of an organ or tissue through an abnormal opening.[1] Hernias usually involve protrusion of abdominal contents through part of the abdominal wall, the diaphragm, or the inguinal canal. The defect or opening in the abdominal wall is an important factor in herniation, whether a protrusion through the opening is present or not.[2]

CLASSIFICATION

Various classification schemes are used to characterize hernias. One scheme names the hernia by the type of herniated tissue, such as intestine or omentum. Another classification scheme uses epidemiology of the hernia, wherein they are referred to as either congenital or acquired hernias. A *congenital* hernia is a defect that is present at birth, although the protrusion may not develop until later. In an *acquired* hernia, the defect occurs after birth and may be the result of blunt trauma, surgical trauma (wound disruption), or degeneration (prepubic tendon rupture in late-pregnancy mares), or it may occur because of an increased diameter of a normal body opening (inguinal canal).

A third classification scheme defines a hernia by the opening or defect. In *true* hernias, the protrusion occurs through a normal aperture in the abdomen and contains a complete peritoneal sac (inguinal or scrotal hernia). These hernias are sometimes referred to as *indirect* hernias. Conversely, in *false* hernias, the protrusion does not arise through a normal aperture in the abdomen. False hernias do not initially contain a complete peritoneal sac and are usually created by trauma to the abdomen or develop after breakdown of a surgical entry (incisional hernias). These are also referred to as *direct* hernias.

Hernias may be further categorized as reducible, incarcerated, or strangulated. A hernia is classified as *reducible* when the protruding hernial contents are freely movable and can readily be manipulated back into the abdominal cavity. When the hernial contents cannot be reduced, the hernia is classified as *incarcerated* (or irreducible), and this is frequently the result of adhesions that form between the contents and the surrounding tissue, effectively fixing the contents in an abnormal location. Incarceration frequently causes obstruction of the lumen of a hollow viscus, and either signs of bladder or bowel obstruction may be the presenting complaint. A hernia is classified as *strangulated* when incarceration obstructs the vascular supply to the herniated tissue, usually at the edge of the defect. Strangulation usually results in tissue necrosis and is the most serious type of hernia.

In a parietal hernia only a portion of the wall of the intestine is involved. These hernias are also called *Richter hernia* and *Littre hernia*. A parietal hernia of an intestine may manifest as draining ingesta from the abdominal wall, without contamination of the abdomen.

The anatomic site of herniation is frequently used for classification and allows the best discussion of etiology, clinical signs, and treatment. In this chapter, abdominal hernias are divided into umbilical, ventral midline (incisional), lateral abdominal, diaphragmatic (internal abdominal), and caudal abdominal (inguinal) hernias.

ANATOMY OF A HERNIA

Hernias consist of three portions: the ring, the sac, and the contents.[2] The ring forms the actual defect in the limiting wall and may be small or quite large. Wound healing leads to thickening of the leading edge of the ring through collagen maturation, which usually allows its borders to be identified through digital palpation. If this healing results in contraction of the scar, contents may become strangulated. Inflammation in the sac from trauma to the contents frequently leads to incarceration. Loops of intestine frequently move in and out of the ring of the hernia through peristalsis. Sometimes this leads to strangulation when the contents enter at a rate faster than they leave. Additionally, secretion of fluid into the bowel segment located in the hernial sac may cause distention and may eventually lead to strangulation.

The hernial sac is made up of tissues that cover the contents. This usually includes the mesothelial covering. In the initial stages, peritoneum may not line the sac of the hernia; however, chronic hernias are frequently completely lined with peritoneum. Although the contents of an abdominal hernia are usually parts of the intestine, other structures such as the omentum frequently are involved. The type of bowel in the hernial sac frequently predicts the clinical signs that are seen.

SIGNS OF HERNIATION

Most external abdominal hernias have swelling as a classic sign. However, internal abdominal hernias (diaphragmatic hernias) frequently show signs attributed to intestinal obstruction or respiratory problems. In uncomplicated external hernias, no pain may be elicited on palpation, and the consistency of the swelling depends on the contents. When inflammation or infection or luminal distention of a viscus is present, a definitive diagnosis is difficult to make on palpation alone. Also, the site of the swelling may be some distance from the actual hernial ring, for example, when contents migrate into the subcutaneous space. However, a tentative diagnosis is frequently made on the basis of clinical signs and location of the swelling. Palpation becomes an important part of the examination to determine if the hernia is reducible, incarcerated, or strangulated. Occasionally, radiography shows luminal gas distention if gastrointestinal structures are herniated. Diagnosis is frequently confirmed by reduction of the hernia and palpation of the hernial ring. The incarcerated hernia presents more of a diagnostic challenge, and ultrasonography is the diagnostic modality of choice in these instances. Use of fine-needle aspiration to rule out hernial contents is contraindicated, because it frequently results in contamination of an otherwise uninfected site.

UMBILICAL HERNIAS

The most common type of hernia in the horse is umbilical in origin and is estimated to occur in 0.5% to 2.0% of foals (Figure 39-1). Most umbilical hernias are congenital and may have a hereditary component. In a recent study of the closure of a body

Figure 39-1. Typical appearance of an umbilical hernia in a 3-day-old foal. The majority of umbilical hernias in foals at this age spontaneously regress within the first 3 weeks of life.

wall defect at the umbilicus, 19 of 44 foals had a defect in the body wall at the umbilicus with a palpable umbilical ring at birth.[3] This defect closed within 4 days in 18 of these foals. Additionally, in this same study, 12 of 44 foals developed an umbilical hernia between 5 and 8 weeks of age.

Etiology

The development of umbilical hernias has been attributed to trauma to the umbilical cord during birth, excessive straining, and umbilical cord infection.[4] Very rarely, evisceration occurs immediately after the birth as a result of trauma to the umbilical cord. This condition necessitates emergency surgical reconstruction in the abdominal wall. However, in most foals, umbilical hernias are chronic, small, and uncomplicated by underlying organic diseases. They usually represent a cosmetic defect but are a potential site of bowel incarceration. In fact, between 8% and 10% of umbilical hernias referred to tertiary hospitals sustain complications that are life threatening and mandate emergency surgery.[5]

Diagnosis

Digital palpation of the hernia is used to assess the size and shape of the hernia ring, the nature of the contents of the sac, and the reducibility of the hernia. Firm, thickened rings hold sutures quite well during herniorrhaphy, whereas a thin and indistinct ring is an indication that repair may be more difficult. Hernial sacs usually contain subperitoneal fat, omentum, or intestine. These hernias are almost always reducible and are rarely incarcerated. However, when incarceration does occur, strangulation of a portion of the intestine is usually suspected. In some instances, only a portion of the intestinal wall is incarcerated (Richter hernia or parietal hernia), and luminal wall destruction usually does not occur. When incarceration is present, any increase in hernia size, firmness, edema, or pain on palpation is an indication that surgery should be undertaken as soon as possible. Umbilical hernias need to be differentiated from abscessation and local infection of the umbilical cord and associated structures. Ultrasonographic examination of the

The umbilical arteries are normal. **B,** Sonogram of the umbilical arteries obtained from a 12-day-old foal with omphalophlebitis. Notice the thickened left umbilical artery with the swollen hyperechoic vessel wall and hypoechoic fluid center.

hernia and ventral abdominal wall is indicated to determine the nature of the contents in complicated hernias of this type (Figure 39-2).

Treatment

Reducible umbilical hernias less than 5 cm in diameter frequently close spontaneously as the foals mature. Daily digital reduction of the hernia is indicated to monitor for changes in size or potential development of incarceration of hernia

contents. Hernias that are not spontaneously regressing by the time the foal is 4 months old should be surgically repaired.

Umbilical hernias greater than 10 cm (4 inches) in diameter are not treated with conservative methods because the risk of strangulating obstruction is so high. Additionally, a hernia of that size very rarely closes on its own. Although most umbilical hernia repairs are elective procedures and are performed on foals for cosmetic reasons, obviously strangulating obstructions of the small intestine necessitate emergency repair.

Two methods have been historically used for repairing hernias. The application of a hernia clamp is one method of management, but this is not commonly practiced and therefore is not part of this discussion. It poses a serious complication if entrapment of the intestine into the hernial clamp occurs, and this has led to intestinal obstruction, peritonitis, and enterocutaneous fistulas. Also, inadvertent dislodging of the clamp has led to evisceration and eventration. Because of these complications, this technique is strongly discouraged.

Surgical repair of umbilical hernias is accomplished with the horse in dorsal recumbency and under general anesthesia. Careful preparation of the surgical site is especially important in male foals, in which the preputial orifice should be filled with cotton and temporarily closed with sutures to reduce contamination during surgery. Surgical repair is initiated by an elliptical skin incision around the hernia, with the points of the ellipse cranial and caudal (Figure 39-3). Skin and loose subcutaneous tissue are removed to expose the external sheath of the rectus abdominal muscle. Sharp dissection generally results in less swelling than blunt dissection in this area, and this dissection is continued to about 1 cm peripheral to the hernial ring. The hernial sac can be inverted and the hernia repaired without removal (closed technique). However, the sac is usually removed (open technique). To do this, the hernial sac is incised along the edge of the hernial ring (see Figure 39-3, *E*). The contents of the sac are examined. It is unusual, but abscesses in the umbilical veins and umbilical remnants can be inadvertently entered at this point, and care should be taken, especially in the caudal aspect of the incision, to prevent such mishaps. Once the contents have been inspected and appropriately treated, the body wall should be closed. Varying suture materials and patterns can be used; however, a nicer closure without a dog-ear can be achieved if the ventral body wall defect is converted before closure to an ellipse with the point cranial and caudal, similar to the skin incision. A *simple-continuous* appositional suture pattern is recommended using appropriate-size absorbable suture material. Synthetic monofilament absorbable suture material (metric size No. 4, 5, or 6, and corresponding USP size No. 1, 2, or 3, respectively) (see Table 16-1) is selected on the basis of the body size of the patient. Thereafter, the subcutaneous tissues and skin are closed independently, once again using absorbable suture material in a simple-continuous pattern.

Aftercare

An abdominal support bandage is applied to decrease dead space and reduce edema for about 48 hours. A foal should be confined in a box stall for 30 to 45 days. Skin sutures do not need to be removed if absorbable suture material has been used. Although laparoscopic surgery is described (see Chapter 63) for disorders of the foal umbilical structures, there are few indications for laparoscopic surgery of umbilical hernias.

VENTRAL MIDLINE HERNIAS

Ventral hernias usually occur as a result of inadequate healing of a previous incision or excessive strain at the site of an abdominal wall scar (Figure 39-4). Obesity, age, and wound infection are the most common predisposing causes in people, and the incidence is between 1% and 11%.[6] Risk factors for incisional hernias in dogs include intra-abdominal pressure because of pain, entrapped fat between hernia edges, inappropriate suture material use, chronic steroid treatment, and infection.[7] Although sequelae to incisional hernias are often serious and costly, the incidence is much lower in small animals.

In horses, large abdominal wall defects commonly arise from partial incisional dehiscence after ventral midline celiotomy or after failed umbilical herniorrhaphy. Incisional herniation is strongly associated with wound separation. With the proper suture placement, suture selection (in terms of size and material), and soft tissue handling using aseptic technique, primary-intention healing of a ventral midline incision usually occurs. The experimentally determined, optimal bite size is 15 mm (½ inch) from the incision edge.[8] Ninety-three percent of sutures fail at the knot, and suture loops fail before complete fascial disruption. The strongest synthetic absorbable suture materials tested in this study were USP No. 6 polyglactin 910 and USP No. 5 polyglycolic acid. Preferably, USP No. 7 polydioxanone or USP No. 6 polyglactin 910 are recommended in adult horses for hernia closure.[9] Because the linea alba is thickest near the umbilicus and tends to become thinner cranially, it has been suggested that the cranial portion of the linea alba may be more susceptible to dehiscence. Clinically, the hernias that develop are usually located in the cranial portion of the incision rather than near the umbilicus. In one study of 210 horses undergoing midline celiotomy for abdominal disease, the rate of incisional hernias was as high as 16%, and all hernias were evident within 4 months of surgery.[10]

We suggest that the incidence of incisional infections and ventral midline hernias can be decreased by applying a belly bandage before recovery (when the horse is hoisted). It not only protects the skin suture line from contamination but may decrease the distracting forces on the sutured linea alba during recovery.

In addition to sepsis, other factors that may affect breakdown of an incision are abdominal distention immediately after recovery and incisional trauma from excessive struggling during recovery from general anesthesia or from rolling associated with uncontrolled postoperative pain. For the purposes of treatment, incisional hernias may be broken down into two types: acute total dehiscence and chronic insidious hernia formation.

Acute Total Dehiscence

Disruption of the abdominal incision that occurs within the first 4 to 7 days after surgery constitutes an emergency to prevent eventration. A belly bandage should be applied for support and the horse anesthetized for the repair. Complete acute dehiscence is detected by observing excessive peritoneal fluid leaking from the incision and palpable gaps in the sutured abdominal wall. The horse is placed in dorsal recumbency, all sutures are removed, and the site is prepared for surgery.

All devitalized tissue is sharply incised and removed. The wound is cultured and thoroughly flushed. The preferred

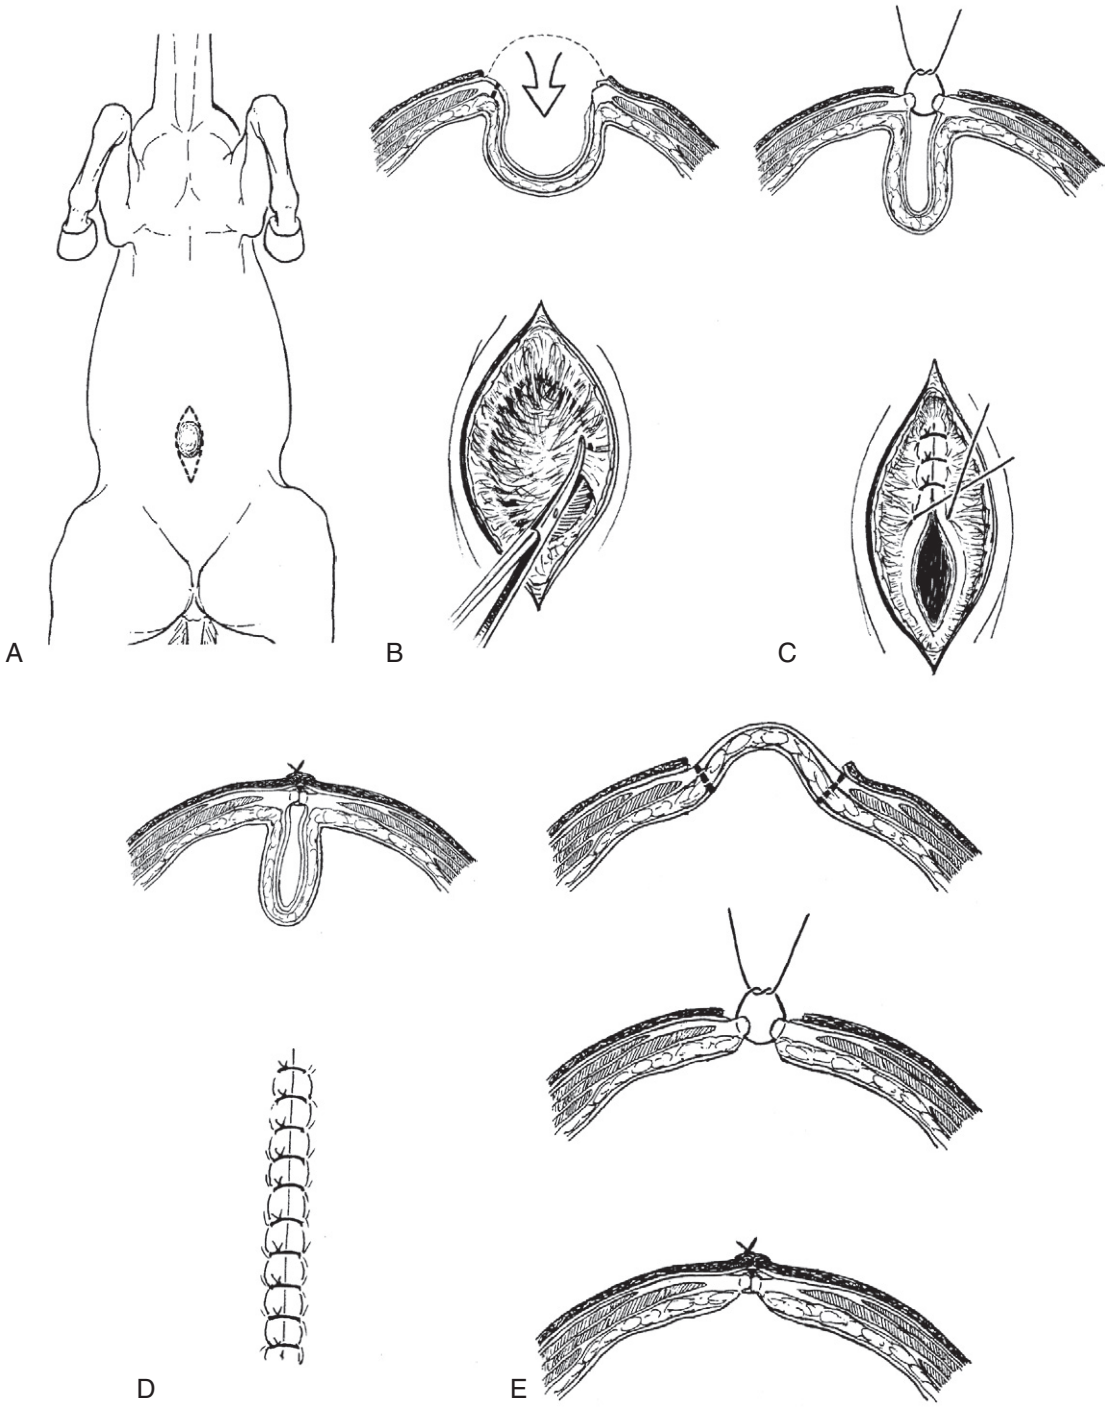

Figure 39-3. Illustrations of umbilical hernia repair. **A,** An elliptical skin incision is made around the hernial sac. The skin is dissected free from the hernial sac and discarded. **B,** The hernial ring is dissected free from the surrounding hernial sac so that the ring can be clearly identified. **C,** The sac can be inverted and the ring prepared for suturing, or the hernial sac can be removed. (The latter technique allows the round hernial ring to be converted into an ellipse for easier closure.) **D,** The ring is closed with a simple-continuous suture of appropriate-size suture material, and the subcutis and skin are closed in separate layers. **E,** In most cases, the open technique is applied: the hernia sac is excised and, after brief inspection of the abdominal cavity, the abdominal wall is closed in three layers.

surgical closure of an infected linea alba is accomplished with monofilament stainless steel wire applied as a through-and-through interrupted vertical mattress pattern, with sutures placed 2 to 3 cm apart. This suture is passed through skin, fascia, and rectus abdominal muscle about 5 cm (2 inches) from the wound edge (Figure 39-5). The wire is passed through hard rubber tubing used as stents before the bites of the vertical mattress pattern are placed. These bites are taken 2.5 cm (1 inch) from the wound edge. The rubber suture is necessary to reduce the tendency of the wire to cut through the skin and underlying tissues. The sutures are preplaced and the wound is closed by applying tension on all sutures simultaneously. The

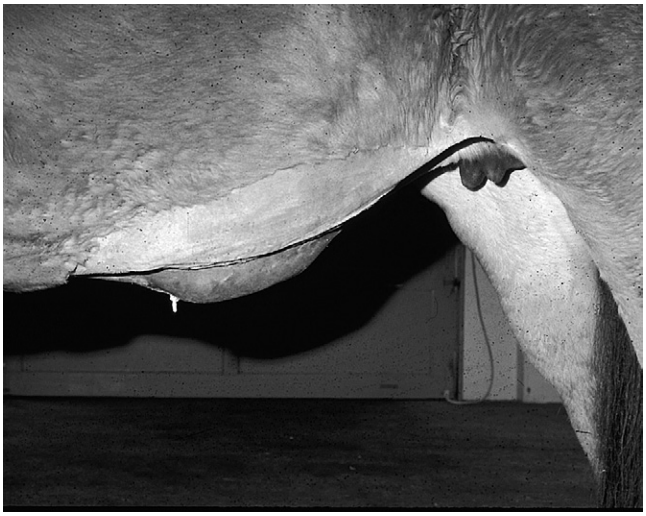

Figure 39-4. Appearance of a ventral abdominal hernia that occurred from dehiscence of a celiotomy incision. Note the purulent material at the cranial aspect of the hernia.

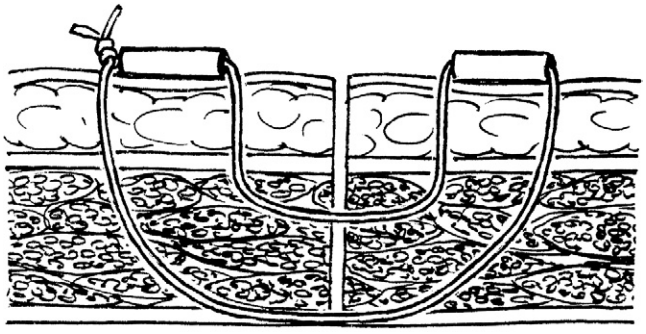

Figure 39-5. Schematic representation of the through-and-through interrupted vertical mattress suture that is used to repair acute total dehiscence of an abdominal incision.

wires are twisted rather than tied, and the cut ends of the wire are bent back into the lumen of the rubber tubing. If tissues are infected, which is usually the case, the skin edges are left unsutured to facilitate drainage.

Before recovery, a self-adhering drape is placed over the incision, and after recovery, a sterile abdominal compress is secured with Elasticon to form an abdominal bandage. The bandage compress should be changed every 24 hours until the incisions have healed (at about 30 days). Beginning on the 14th day after surgery, alternate wire sutures and rubber tubing are removed, and all remaining sutures are removed on day 21. Failure to remove these sutures this early after surgery will result in sutures and stents cutting through the skin, complicating their removal. Daily cleaning and rebandaging of the wound is necessary until the skin is healed.

Chronic Incisional Hernias

The factors responsible for acute total wound disruption usually are the same as the causes of partial dehiscence and eventual hernia formation. Incisional infection is usually part of the medical history preceding hernia formation.[11]

Many hernias can be managed conservatively. If infection is present, the wound should be cultured for bacterial growth and the animal treated with appropriate antimicrobial agents. Establishing a good drainage after removal of some skin sutures at the site of purulent discharge and periodic massaging along the suture line are very important measures in treatment of surgical site infection. Flushing with disinfectants is only recommended if there is good drainage; otherwise, there is the likelihood of disseminating the infection subcutaneously to other sutured portions of the incision. Sterile abdominal compresses may require daily changing. Continuous abdominal bandaging for 1 to 2 months during treatment of the wound infection reduces the size of the hernia. In some cases, chronic wound bandaging for up to 6 or 8 months eliminates the necessity for surgical repair of a wall defect. To decrease the amount of disposable bandaging material necessary to accomplish this, commercially available reusable elastic bandages (Surgimed) can be purchased and have been used successfully in a number of cases.

When a hernia has failed to heal or enlarges after turnout, surgical repair becomes necessary, especially if the horse is used in an athletic capacity. Large defects in the abdominal wall require prosthetic reconstruction with a synthetic mesh and are preferentially repaired in this manner. Knit polypropylene mesh (Marlex) is strong, elastic, and inert, and it resists infection. Other mesh materials with good physical properties include coated polyester (Mersilene) and polyglactin 910 (Vicryl). The main advantage of the polyglactin mesh is that it is absorbable, and in the advent of another infection, it may not have to be removed. Tissue grows through the knit mesh to be incorporated into the healing herniorrhaphy tissue. Failure to use the synthetic mesh in the repair usually results in enough tension to produce a recurrence of the hernia. All infection should be eradicated before prosthetic reconstruction of the defect is attempted. This may require surgical removal of infected suture material from sinus tracts (see Chapter 28). The earliest point in time for mesh implantation is 8 to 10 weeks after resolution of infection. If surgery is attempted sooner, the risk for postoperative infection is increased.

Prophylactic antimicrobial therapy is indicated because most incisional hernias have had some type of infection, and small pockets of bacteria may remain when surgical herniorrhaphy is undertaken. The horse is placed in dorsal recumbency under general inhalation anesthesia, and a strict aseptic technique is used.

Subperitoneal Mesh Placement with Fascial Overlay

The skin is incised for 180 degrees at the margin of the hernial ring (Figure 39-6, *A* to *C*). Likewise, the fascia and fibrous tissue overlying the hernial ring are incised along the same planes. This fascia is removed using retroperitoneal dissection, leaving the peritoneum intact. The mesh is placed retroperitoneally and subfascially. In some cases, this is not possible, because of adhesion formation between the peritoneum and the fascia, or because the fascia is so thin that it cannot be separated. In these cases only intraperitoneal and subfascial placement is possible. A single layer of mesh is cut to correspond to twice the size and contour of the defect, allowing the mesh to be folded over so the sutures pass through a double layer.

Horizontal mattress sutures are placed about 2.5 cm (1 inch) from the edge of the mesh. Each bite is approximately 2.5 cm wide. USP No. 2 sutures, made of the same material as the

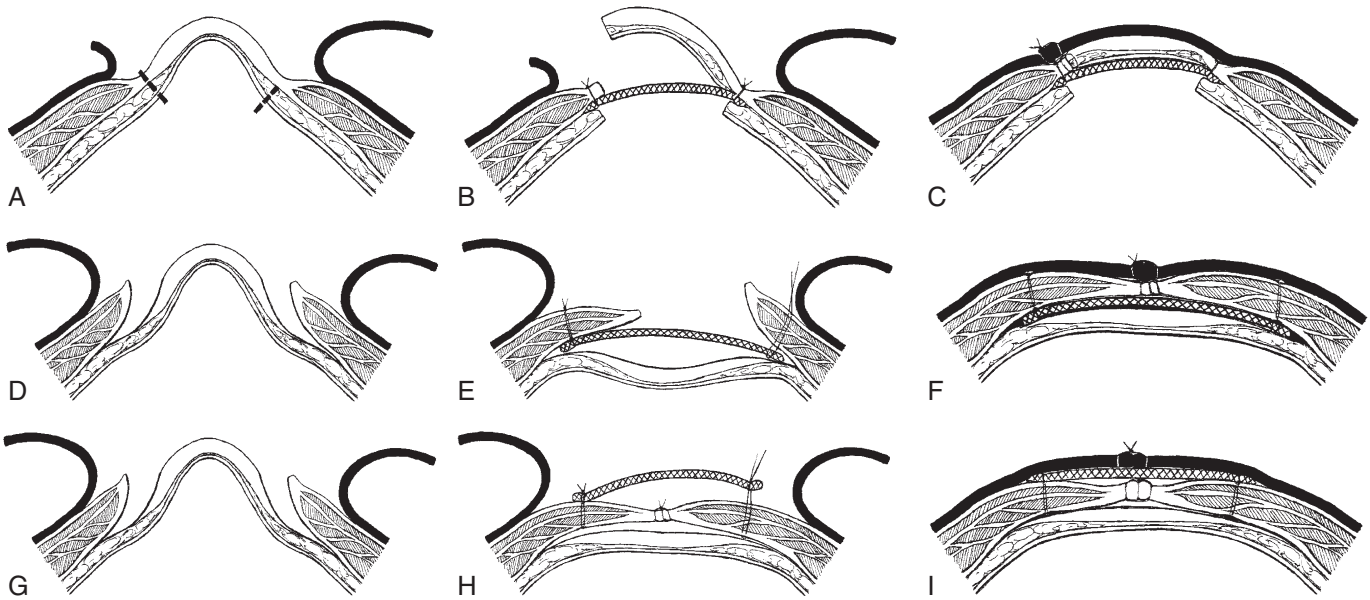

Figure 39-6. Illustrations of different techniques for herniorrhaphy using a synthetic mesh and fascial overlay. **A,** Semielliptical incision extending beyond the cranial and caudal margins of the hernia is made. The skin flap and subcutaneous tissue are reflected off the hernia and held with towel clamps. The fibrous hernial sac is then reflected toward its attached base, leaving the peritoneum in place if possible. **B,** The mesh is anchored on the inside of the abdominal wall with through-and-through horizontal mattress sutures. Some of these are preplaced. **C,** The fascial overlay is then sutured back in place using simple-interrupted or a simple-continuous suture. Routine closure of the skin follows. **D,** A straight incision extending beyond the cranial and caudal margins of the hernia is made. The skin and subcutaneous tissue is dissected from the hernial sac on both sides of the hernial ring. The hernial margin is also dissected free from the peritoneum (2 to 3 cm) on both sides. **E,** The mesh is anchored on the inside of the abdominal wall on one side. The sutures on the other side are preplaced, and then the incisional edges are apposed by tightening the sutures. **F,** The apposed linea alba is sutured and routine closure of subcutis and skin follows. **G,** After a straight skin incision, the hernial ring is prepared as described in **D. H,** After apposing and suturing the prepared linea alba, the mesh is placed in an overlay position and sutured to the abdominal tunic on both sides of the hernial closure (between fascia and subcutis) to reinforce the linea alba. **I,** The subcutis and skin are routinely closed.

mesh, are placed 0.5 cm apart (close enough together to prevent small intestine from becoming incarcerated between the sutures). The sutures are preplaced so that when they are tied, the mesh lies flat and snugly under a moderate amount of tension deep to the hernia ring. The hernial flap is subsequently trimmed and the free edge sutured to the hernial ring for reinforcement of the mesh implant. Simple-continuous synthetic absorbable sutures may be used. Subcutaneous tissues and skin are closed in a routine fashion. All redundant subcutaneous tissues and skin are trimmed so that the skin also is under a moderate amount of tension when closed.

Subperitoneal Mesh Placement with Hernial Ring Apposition

An adaptation of the technique just described starts with a straight skin incision, avoiding chronically scarred skin, which can be removed with an elliptical incision (Figure 39-6, *D* to *F*). The thickened peritoneum is sharply separated from the body wall around the whole hernial ring to expose at least 2 cm of the dorsal aspect of the body wall. The mesh is subsequently positioned between peritoneum and body wall. Using 2 to 4 layers of mesh, it is sutured to one side of the hernia with interrupted horizontal mattress sutures using USP 2 absorbable suture material. The sutures on the opposite side are placed similarly and secured after a single throw on the knots using a hemostatic forceps. After preplacing all sutures on the opposite side, the incisional edges are apposed by pulling on all of the forceps. The sutures are subsequently tightened and the apposed linea alba is closed with USP No. 6 suture material. The subcutaneous tissue and skin are closed routinely.

Subcutaneous Mesh Placement with Hernial Ring Apposition

Positioning of the mesh external to the fascia represents yet another technique for closure of chronic incisional hernias (Figure 39-6, *H* to *I*). After incising the skin incision, the hernial ring is exposed and the unopened hernial sac is inverted. Then the hernial ring is subsequently closed with inverted cruciate or near-far-far-near sutures placed at 1.5 to 2.5 cm intervals with USP 2 synthetic absorbable sutures. The mesh is then sutured to the abdominal tunic overlaying the fascia and placed subcutaneously.[12]

Laparoscopic Intraperitoneal Mesh Onlay

A laparoscopic hernioplasty of incisional hernias in five horses was described by Caron and Mehler.[13] This technique involved positioning a polypropylene mesh subperitoneally, overlaying the inner surface of the internal rectus sheath. The mesh is secured intraperitoneally using transfascial sutures tied extrafascially and subcutaneously.

With all of the described mesh techniques, some potential complications can be experienced. In one study, 62% of horses with a body weight greater than 450 kg showed some degree of

incisional drainage, and 23% experienced tearing of the internal abdominal oblique muscle.[14]

On recovery from surgery, an abdominal bandage is used for 7 to 10 days to prevent edema and seroma formation. Parenteral antibiotics are discontinued on the second or third day after surgery. Horses are confined to a stall for 60 days with hand-walking only.

LATERAL ABDOMINAL HERNIAS

Lateral abdominal hernias are usually the result of blunt traumatic injuries from farm machinery, fence posts, or kicks from other horses (Figure 39-7). Penetrating abdominal wounds may require immediate reconstruction to prevent evisceration, peritonitis, and wound infection. However, more commonly, traumatic wounds are not penetrating, and the horse can be treated with local therapy and abdominal bandaging. After 60 days, small residual defects in the body wall can be treated by direct suture apposition. When they are very large, they can be treated by prosthetic reconstruction with synthetic mesh, as described previously.

Abdominal wall hernias in pregnant mares that do not involve rupture of the prepubic tendon can be similarly repaired. However, it is suggested that the pregnancy be terminated by cesarean section if repair is necessary before parturition.

PREPUBIC TENDON RUPTURE

Rupture of the prepubic tendon occurs rarely in prepartum mares. Predisposing factors include hydrops allantois, hydrops amnions, trauma, twins, and fetal giants, but it is also seen in mares with normal pregnancy.[12,15-18] An increased prevalence of body wall defects in draft breeds and older mares is also reported.[12,16] The clinical signs include colic, development of ventral edema, stretched mammary gland, and most obviously, elevation of the tail head and ischial tuberosity (sawhorse stance).[19] Ross et al. reported that mares with prepubic tendon rupture can be successfully managed conservatively with a good prognosis for survival of the foal.[20] Intervention decreases the chances for the foals because of prematurity.[20]

DIAPHRAGMATIC HERNIAS

Internal abdominal hernias include a multitude of intestinal accidents, including mesenteric hernias, entrapment in the epiploic foramen, and diaphragmatic hernias. Although diaphragmatic hernias are rare, both congenital and acquired hernias have been described.[21-23] Diaphragmatic hernias can be congenital, resulting from failed fusion of many of the four embryonic components of the diaphragm, or acquired from trauma. Diaphragmatic hernias can be classified by anatomic location as peritoneal-pericardial or peritoneal-pleural, depending on where the tear occurs and into which thoracic compartment bowel enters. Congenital defects usually have smooth round edges, and some hernias can be quite small, only 2.5 cm (1 inch) in diameter. On the other hand, acquired diaphragmatic hernias, because they are associated with some form of violence and increased intra-abdominal pressure, are usually large and frequently originate along the dorsal body wall. There is a special form of diaphragmatic hernia called Morgagni hernia with an intact hernial sac where portions of the large colon can be incarcerated.[24]

Diaphragmatic hernias result in low-grade, chronic recurrent abdominal pain and sometimes are found incidentally at necropsy. However, this is the exception; more commonly, horses are presented in distress with either a serious abdominal crisis (found during exploratory celiotomy) or in acute respiratory distress. Diagnosis can be made on physical examination, with borborygmi auscultated during examination of the thorax. However, other signs associated with the acute abdominal crisis may be equivocal, since a rectal examination and abdominocentesis may be normal. Ultrasonography is quite accurate in revealing gas-filled loops of intestine in the thorax (Figure 39-8). Likewise, radiography may show a loss of the diaphragmatic line at the level of the hernia, or, more commonly, radiopacity in the ventral aspect of the chest. Occasionally, gas-filled loops of large colon can be visualized on thoracic radiographs (Figure 39-9).

Repair of the diaphragmatic hernia is accomplished with the horse placed in dorsal recumbency through a ventral midline

Figure 39-7. A horse that has a traumatic hernia in the lateral body wall as a result of blunt trauma.

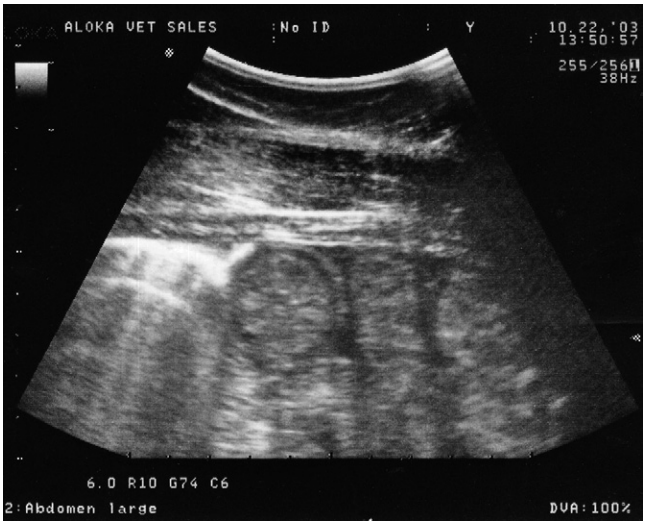

Figure 39-8. Thoracic ultrasonogram in a horse with a diaphragmatic hernia clearly demonstrates a circular viscus (bowel wall) between two ribs.

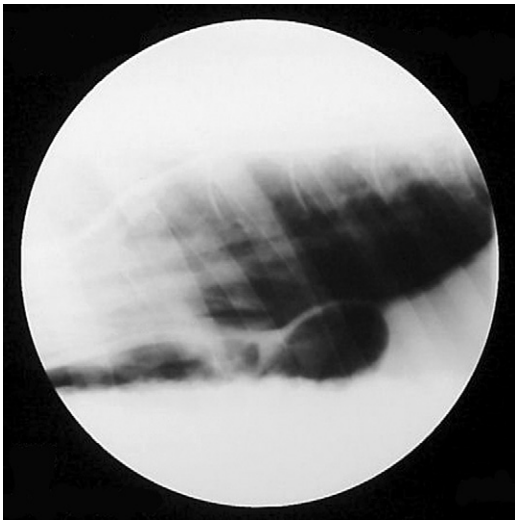

Figure 39-9. Thoracic radiographs of a horse with a diaphragmatic hernia demonstrate a gas-filled loop of bowel in the thorax and loss of diaphragmatic contour. Note fluid in the ventral aspect of the thorax.

celiotomy that extends craniad to the xiphoid. Assisted ventilation is necessary during anesthesia. Abdominal viscera should be repositioned into the abdomen, and tilting the horse with front end elevated may aid in reduction of the hernia. In some cases, especially with small chronic hernias, the incarcerated distended bowel cannot be reduced without enlarging the hernial ring either bluntly with the fingers or sharply.

Small defects (less than 5 cm [2 inches]), particularly those positioned ventrally, may be closed by primary apposition using large-gauge suture material in a simple-continuous pattern. Débridement is usually not performed, because once the hernial ring is removed, the muscular portion of the diaphragm is less likely to hold sutures as well as the hernial ring. Larger defects require prosthetic reconstruction with a synthetic mesh. The mesh is secured to the perimeter of the defect with simple-interrupted horizontal mattress sutures similar to those used for mesh herniorrhaphy for the ventral midline. Sutures are preplaced before tying to ensure that tension is maintained on the mesh. The mesh is preferentially placed on the abdominal side of the incision.

Traumatic diaphragmatic hernias are quite often associated with very large defects, dorsally positioned, and inaccessible, precluding safe closure. In these instances, thoracotomy is used to gain better access. The diaphragm holds sutures quite well if a linear tear has occurred, and mesh reinforcement may not be necessary. Before closing the abdominal incision, the lungs should be maximally inflated to expel as much air as possible from the thorax. A chest tube with a Heimlich valve (see Figure 17-7) should be used to manage a pneumothorax.

Alternatively, diaphragmatic hernia repair may be accomplished using thoracoscopic approaches and rib resection. Thoracoscopic evaluation of the chest immediately before repair helps in accurate placement of the thoracotomy incisions, facilitating mesh placement.[25,26] Repair of a diaphragmatic hernia located in the dorsal tendinous part of the diaphragm without rib resection using a thoracoscopic technique to close the hernia with interrupted extracorporeal surgical knots is described.[27]

Dehiscence of the repair occurs occasionally, and rupture of the diaphragm in another location has been reported. Prognosis for diaphragmatic hernia repair is generally guarded.

CAUDAL ABDOMINAL (INGUINAL) HERNIAS

Bilateral congenital inguinal hernias are often encountered in young colts, but they usually resolve without surgery during the first few weeks of life. The colt is confined to a box stall and observed, and the owner is instructed how to manually reduce the hernia several times daily. Larger hernias may benefit from support provided by an inguinal bandage constructed from rolled cotton and gauze. Reduction of the hernia is usually facilitated by casting the animal in lateral recumbency. For surgical descriptions of repair of inguinal hernias including via laparoscopy, please refer to Chapters 36, 39 and 59.[28]

By definition, inguinal hernias are present when there are intestinal contents in the inguinal canal. Scrotal hernias occur when the contents continue on into the scrotum. However, the term inguinal hernia is usually used to refer to both disorders. Distal jejunum and ileum are the intestinal contents most commonly encountered in inguinal hernias, but omentum and even the small colon are sometimes involved. Equine inguinal hernias usually are indirect (or true) hernias, with the contents passing through the vaginal ring and into the vaginal tunic. In a direct (or false) inguinal hernia, which occurs in humans, the contents do not pass through the ring but protrude through a weakness in the body wall. This occasionally occurs in foals, but it is highly unusual.

The clinical sign of an inguinal hernia is scrotal swelling. The testicle is often cool in the adult horse, probably because of vascular compromise. Frequently, the spermatic cord is enlarged and extremely hard and very painful to the touch. All stallions with colic should be checked for this type of inguinal hernia. Frequently, scrotal herniation in foals occurs without intestinal incarceration and may be the result of abdominal straining. Before repair is undertaken, conservative management for several weeks may be advisable. Diagnosis of inguinal hernias is made on the basis of external palpation; rectal palpation in adult horses permits further evaluation of the internal inguinal ring. Intestinal incarceration in the ring can be easily palpated. The differential diagnosis includes thrombosis of the testicle; testicular artery, seroma, or hematoma of the scrotum; neoplasia; and torsion of the spermatic cord.

CHAPTER
40 Postoperative Care, Complications, and Reoperation

Joanne Hardy and Peter C. Rakestraw

Postoperative management of horses with abdominal disorders should be targeted toward identification and management of pain, support of the cardiovascular system, treatment of endotoxemia, identification and treatment of surgical infection, restoration of gastrointestinal function, and management of secondary complications (diarrhea, thrombophlebitis, laminitis). Disorders of the gastrointestinal (GI) tract can result in significant systemic derangements in affected horses. Strangulating lesions lead to intestinal distention proximal to the lesion, third-space pooling of fluid in the intestinal tract, and intestinal mucosal damage with subsequent endotoxin absorption. Despite correction of the primary condition, problems encountered in the postoperative period usually represent a natural progression of the events triggered by the primary lesion. This chapter reviews the management of horses after abdominal surgery and addresses complications related to specific surgical procedures.

FLUID THERAPY

Dehydration and electrolyte imbalances are commonly encountered as a result of abdominal disorders. Even though a horse is stabilized in the perioperative period and the primary problem is corrected, continued replacement of previous and ongoing fluid losses is critical to a successful outcome. Knowledge of basic electrolyte and fluid homeostasis is essential to the successful management of these cases (see Chapter 3). The daily maintenance fluid requirement in adult horses is 50 to 60 mL/kg, and in foals it is 70 to 80 mL/kg. The volume of GI secretions in adult horses is equivalent to their extracellular fluid volume, approximately 30% of the body weight. With ileus or diarrhea, these fluids are not reabsorbed by the large colon, resulting in considerable fluid losses. These losses must be added to the maintenance requirements. Fluids available for replacement therapy in horses include lactated Ringer's solution, which contains lactate as a buffer and calcium (4 mEq/L), Plasmalyte A, and Normosol-R, which do not contain calcium but have acetate or gluconate as buffer sources. Intravenous fluid administration systems are commercially available and provide a convenient method of administering large volumes of fluid to horses.

A significant complication of endotoxemia, particularly in postoperative cases of large colon torsion with significant mucosal damage, is increased capillary permeability resulting in fluid and protein loss into the interstitium. Vascular volume can be difficult to maintain in these horses because of the tremendous fluid loss in both the interstitium and the GI tract and the development of hypoproteinemia. The goal of therapy is to maintain enough vascular volume to sustain cardiac output. A reasonable indicator is the ability to maintain the heart rate at less than 80 beats per minute, packed cell volume (PCV, hematocrit) at less than 50%, and total protein at greater than

4.1 g/dL. PCV and total protein should be measured every 6 hours and therapy adjusted accordingly. If plasma protein decreases to less than 4.1 g/dL (corresponding to a plasma oncotic pressure of 12 mm Hg), it may be necessary to administer colloids to prevent severe edema and allow continued administration of fluids.[1] In surviving patients, capillary permeability is restored within 24 to 36 hours. Plasma proteins that were lost into the interstitium are quickly reabsorbed, and plasma protein concentration returns to normal range within a few days. Available colloids for administration to horses include plasma and synthetic colloids, such as dextrans and hydroxyethyl starch. Further reading on fluid therapy, colloids, and treatment of endotoxemia can be found in Chapter 2.

PAIN

Control of pain is an essential component of the management of postoperative patients. Drugs used for pain management should provide a good clinical response while minimally affecting GI motility.

Postoperative pain can originate from peritoneal inflammation, abdominal incision, or intestinal distention. *Flunixin meglumine* controls postoperative pain and improves the cardiovascular manifestations of endotoxemia. Flunixin meglumine combined with progesterone supplementation may help maintain pregnancy in mares with endotoxemia in the first trimester of gestation. Flunixin meglumine provides analgesia in a dosage-related manner up to a maximal dosage of 1.1 mg/kg. Smaller dosages (0.25 mg/kg) have been shown to improve cardiovascular parameters after endotoxemia.[1] *Butorphanol* is an agonist-antagonist narcotic that can be used to control postoperative pain and at low dosages (0.01 mg/kg) does not affect GI motility. Continuous-rate infusion of butorphanol (13 mg/kg per hour) to horses after celiotomy improved behavior scores and recovery characteristics and decreased plasma cortisol concentration.[2] However, time to first passage of feces was delayed significantly in treated horses.[2] Therefore, continuous-rate infusion of butorphanol may be contraindicated for certain GI problems. Horses with ileus occasionally require more potent analgesia. In such cases, administration of xylazine or detomidine, both α_2-agonists, may be necessary, even though these drugs can negatively affect GI motility. The duration of analgesia may be prolonged by combined intravenous and intramuscular administration.

Intravenous *lidocaine* has been advocated for the management of visceral pain as postoperative ileus.[3] *In vitro* studies have shown a potential benefit of lidocaine on normal smooth muscle contraction,[4] as well as in smooth muscle subjected to ischemia-reperfusion.[5,6] Lidocaine has also been shown to attenuate the clinical signs and inflammatory response to endotoxemia[7] and to ameliorate the inhibitory effects of flunixin meglumine on recovery of the mucosal barrier.[5] Although use of lidocaine on experimental postoperative ileus did not show benefits,[8] clinical studies support its use.[9,10] The dose of lidocaine recommended for the management of postoperative ileus in horses is a loading dose of 1.3 mg/kg IV, followed by an infusion rate of 0.05 mg/kg per minute IV.[10-12] Prolonged infusion appears to be safe, but concurrent administration of highly protein bound drugs can significantly displace the lidocaine, resulting in increased risk of toxicity.[12] The use of lidocaine is most beneficial with other analgesics and allows the dosage of analgesics to be decreased. (For further information on the mechanism of action of lidocaine on motility, see "Sodium Channel Blockers" later.)

Additional information on pain management can be found in Chapter 23.

POSTOPERATIVE ILEUS

Adynamic ileus is one of the most commonly encountered complications in horses after GI surgery and is often referred to as postoperative ileus (POI). In horses, POI occurs predominantly after correction of lesions involving the small intestine. Occasionally, POI is seen after correction of large colon problems, primarily large colon volvulus. Intestinal ischemia, distention, peritonitis, electrolyte imbalances, endotoxemia, traumatic handling of the intestine, resection and anastomosis, and anesthesia have all been proposed as potential contributing factors. Specific risk factors that have been identified for horses developing POI are age greater than 10 years, Arabian breed, PCV greater than 45%, high serum concentrations of protein and albumin, elevated serum glucose, presence of more than 8 liters of reflux at admission, anesthesia for longer than 2.5 hours, surgery longer than 2 hours, high pulse rate, resection and anastomosis, strangulating lesions of the small intestine and ascending colon, length of small intestinal resection, obstruction of the small intestine, and ischemic small intestine.[13-17] There is evidence that performing a pelvic flexure enterotomy (bowel decompression) and intraoperative administration of lidocaine decreases the risk of developing POI.[14-17]

In the current literature, the incidence of POI in horses undergoing surgical treatment of all types of colic has been reported to range from 10% to 21%.[13,16,18] In two recent studies, the incidence of POI in horses undergoing surgical treatment for small intestine lesions was reported to be 17% and 33%, respectively.[15,17] As expected, the survival rate was lower for horses that developed POI than for those that did not develop POI (87% and 84.1% survival rates in horses with POI, versus 93% and 94.1% survival rates in horses without POI). This is a marked improvement over a previous study that reported a mortality rate of 86% in horses with POI.[19] However, in one recent study of horses that had surgery to correct small intestine lesions, horses that developed POI were 28 times more likely not to survive to discharge compared to horses that did not develop POI, with only 34% of POI horses surviving to discharge.[17] Although management and prognosis of these cases has improved, POI is still associated with 38% to 40% of all postoperative deaths in horses treated for colic.[13,16]

Disruption of propulsive motility results in the sequestration of fluid, gas, and ingesta in the segment of the GI tract that is dysfunctional and in the intestine proximal to the dysfunctional area. Because small intestine strangulating lesions are the most common problems leading to POI, the distention occurs primarily in the small intestine and stomach. With colitis, endotoxemia, or ischemia following a large colon volvulus, distention may occur in the cecum and large colon. Signs of ileus are progressive and directly related to the accumulation of gas and fluid within the GI tract. Gastric distention usually occurs within 12 to 48 hours after recovery from anesthesia as fluid and gas back up from the small intestine. With increasing GI distention, the animal becomes more depressed and shows signs of increasing abdominal pain, such as pawing, flank watching, lying down, and rolling.[20-22] Borborygmi are usually decreased or absent. The heart rate is usually elevated as a result of pain associated with

distention. Hemoconcentration is reflected by increases in the PCV and total protein, as well as in elevated heart rate and increased capillary refill time. Decreases in plasma chloride and potassium are the most commonly observed electrolyte abnormalities, although sodium and calcium may also be low.[19-22] Rectal examination, ultrasonography, and abdominal radiography (in foals) can aid in determining if the small intestine or large intestine is involved. Nasogastric decompression often retrieves from 3 to 10 L of fluid. The response to nasogastric decompression provides an important clue that the problem is functional (i.e., POI). After decompression, the horse should show improvement, with decreased pain and heart rate. If no alleviation of signs is observed after repeated attempts at decompression, careful thought should be given as to the likelihood that the problem may be mechanical, such as a complication with the anastomosis, and not a functional problem. In addition, continued large volume of reflux for greater than 48 hours after surgery should alert the clinician to the possibility of a mechanical obstruction at the surgical site.

Supportive Therapy

Because of the therapeutic limitations of available prokinetic agents (discussed later), the hallmark of treatment of POI in the horse is supportive therapy. Included in this supportive therapy are fluid, acid-base, and electrolyte therapies. Antibiotics are also indicated if there is compromised intestine or the possibility of bacterial contamination resulting in peritonitis. Along with fluid therapy, nasogastric decompression remains the primary method to treat POI in the horse. Questions concerning when to place the tube, whether the tube should be left in place, and when to start feeding have not been adequately investigated. No clinically important impact of 18 hours of nasogastric intubation was found on gastric emptying in healthy horses.[23] In humans, eliminating or decreasing routine nasogastric intubation with early return to enteral feeding has been shown to be safe and may actually reduce POI.[24-26] There is some thought among equine surgeons that early removal of the nasogastric tube or passing the tube only when indicated predicated on pain, heart rate, rectal examination, and volume of previous reflux may attenuate the duration and severity of POI in the horse. This has yet to be substantiated. When providing supportive care for horses with POI, one must always question whether the horse is really experiencing a functional problem or has a mechanical problem and requires repeat laparotomy.[27,28] In a recent study evaluating horses requiring a second laparotomy, complications with the anastomosis was responsible for 16% of the cases.[29] It is likely that POI was diagnosed in many of these horses before the repeat laparotomy.

Prokinetics

It is logical to assume that during POI in the horse, an imbalance of factors controlling excitation and inhibition of GI smooth muscle occurs. Historically, pharmacologic modulation of GI motility in the horse has been directed at increasing excitatory cholinergic activity with administration of parasympathomimetic agents, such as bethanechol or neostigmine, or blocking inhibitory sympathetic hyperactivity with α-adrenergic blockers, such as yohimbine and acepromazine. However, the modulation of motility and mechanisms involved in alterations after insult are significantly more complex.[30] In addition to being affected by sympathetic and parasympathetic input, contractility of gastrointestinal muscle is directly mediated by enteric inhibitory neurotransmitters, such as vasoactive intestinal peptide (VIP), adenosine triphosphate (ATP), nitric oxide (NO), calcitonin gene-related peptide (CGRP) and enteric excitatory neurotransmitters, such as substance P (SP) and acetylcholine (ACh).[31-35] It is likely that abnormalities involving the enteric nervous system and its neurotransmitters, as well as inflammatory insult to the enteric smooth muscle cells and interstitial cells of Cajal (ICCs, astrocytes), which are responsible for generating patterns of electrical activity in the enteric smooth muscle cells that mediate contractile activity, are also involved in the pathophysiology of POI.[30,36-41] At this time, the relative importance of all the contributing mechanisms has not been sorted out. Additonally the treatments of POI in the horse are limited to pharmacologic agents that influence only a small number of the mediators of motility. For these reasons, prokinetics have produced only limited responses in the treatment of POI in the horse. The following is a summary of some of the more frequently used prokinetics in horses as well as some drugs currently being evaluated.

Parasympathomimetics

BETHANECHOL

Bethanechol chloride is a muscarinic cholinergic agonist (cholinomimetic or parasympathomimetic) that stimulates ACh receptors (primarily M_3 but also M_2 receptors) on GI smooth muscles at the level of the myenteric plexus, causing gastrointestinal contractile activity.[34,42] In an *in vitro* study, bethanechol increased contractile activity of smooth muscle preparations from the duodenum, jejunum, cecum, and pelvic flexure of horses.[42] In normal horses, bethanecol (0.025 mg/kg, IV) increased the rate of gastric and cecal emptying as measured by radiolabeled isotopes and increased myoelectrical activity in the ileum, cecum, and right ventreal colon.[43,44] In an equine POI model, bethanechol (2.5 mg SC at 2 and 5 hours postoperatively in ponies) shortened transit time as measured by the passage of beads, and it reduced the time until normal activity levels returned throughout the GI tract when administered in combination with yohimbine, an α-adrenergic receptor blocker.[45] This drug combination, however, was not as effective as metoclopramide in restoring coordinated gastroduodenal motility patterns in these ponies. Although efficacy in treating motility dysfunction has been questioned in the horse and other species, the prokinetic effects in normal horses and the clinical impression of its benefit in treating horses with ileus provides some support for its use in the treatment of certain motility dysfunctions, such as POI and gastric and cecal impactions.[34,43,46] The recommended dosage is 0.025 mg/kg SC, every 3 to 6 hours. The most common side effects of bethanechol are salivation with abdominal cramping and diarrhea.[44,47]

NEOSTIGMINE

Neostigmine methylsulfate is a cholinesterase inhibitor that prolongs the activity of acetylcholine (indirect parasympathomimetic) by retarding its breakdown at the synaptic junction. In studies on normal horses, the effects of neostigmine (0.022 mg/kg IV) varied depending on the portion of the gastrointestinal tract examined.[43,48,49] Neostigmine was shown to delay gastric emptying and decrease propulsive motility in the stomach and jejunum but to increase propulsive motility in

the pelvic flexure.[48,49] These results suggest that the drug would not be appropriate for gastric and small intestinal problems but may be beneficial for large intestinal motility dysfunction. However, neostigmine increased the amplitude of rhythmic contractions in both the resting and distended jejunum in anesthetized ponies, and it induced contractile activity in the ileum and increased the rate of cecal emptying in other studies, supporting its use for motility dysfunction in both small and large intestine.[43,50] There has been no consensus as to the recommended use of this drug for treatment of motility disorders in horses. It is rarely used as a prokinetic agent in humans.[34] There is anecdotal support that neostigmine can reduce the severity of POI in horses, particularly if the large colon is involved. However, its use for impaction colic or in cases with excess GI distention has not been recommended by some authors because of the apparent force of drug-induced contractions.[43] The dosage used clinically is 0.0044 mg/kg (2 mg per adult horse) SC or IV, repeated in 20 to 60 minutes. If there is no response and the horse is not exhibiting any side effects, the amount can be increased by 2-mg increments to a total of 10 mg per treatment. Other dosages have been recommended in a survey of prokinetic use in horses.[51] A side effect commonly seen with this drug is abdominal pain.

Adrenergic Antagonists

Acepromazine maleate is a nonselective α-adrenergic antagonist, and yohimbine, tolazamine, and atipamezole are selective α_2-adrenergic antagonists. Their use as prokinetics is based on the assumption that sympathetic hyperactivity contributes to POI. Afferent stimulation during surgery is thought to activate inhibitory sympathetic efferent neurons. Norepinephrine is released by sympathetic neurons at the enteric ganglia and inhibits the release of the excitatory neurotransmitter acetylcholine by stimulating α_2-receptors located presynaptically on cholinergic neurons. This causes a depression of smooth muscle contraction in the gastrointestinal tract. Elevated serum catecholamines that can last for the duration of POI have been temporally associated with increased synthesis of norepinephrine in the bowel wall in humans after laparotomy.[33,52]

ACEPROMAZINE

Acepromazine facilitates small intestinal transit in normal ponies.[53] On the basis of clinical impression, acepromazine administered at 0.01 mg/kg intramuscularly (IM) intraoperatively and then every 4 hours is thought to reduce the severity of POI in horses with small intestinal lesions. Because acepromazine is a nonselective α-blocker that can produce hypotension through α_1-receptor antagonism, the animal should be well hydrated before the drug is administered.

YOHIMBINE

Yohimbine hydrochloride is a competitive antagonist that is selective for α_2-adrenergic receptors. Yohimbine was shown to antogonize the inhibitory effects of detomidine on jejunal contractions *in vitro* but enhanced the inhibition evoked by xylazine.[54] When administered at 0.15 mg/kg IV at 1, 4, 7, and 10 hours postoperatively in an experimentally induced POI model, it reduced the severity of POI, especially when combined with bethanechol.[45] Yohimbine administered at 0.075 mg/kg was demonstrated to attenuate some of the negative effects that endotoxin has on propulsive motility.[55] Because yohimbine is a selective α_2-adrenergic drug, it should not produce the hypotensive response seen with acepromazine. Neither acepromzaine or yohimbine were reported to be used as prokinetics in a survery of prokinetic use in horses.[51]

TOLAZOLINE AND ATIPAMEZOLE

Tolazoline and atipamezole are selective α_2-adrenergic antagonists that have been proposed as potential prokinetic agents in horses.[54,56] Tolazoline has been shown to increase migrating myoelectrical activity in the duodenum in normal horses, and atipamezole was shown to antagonize the inhibitory effect of xylazine and detomidine on *in vitro* contractile activity of equine jejunal smooth muscle.[54] Although the research data described earlier support the use of these drugs to treat POI in horses, to date there have been no reports of their use in clinical cases in horses.

Benzamides

METOCLOPRAMIDE

Metaclopramide hydrochloride is a first-generation substituted benzamide (contains 5-hydroxytryptamine (5-HT, serotonin) whose prokinetic activity is both through dopamine 1 (DA_1) and 2 (DA_2) receptor antagonism and through 5-HT 4-receptor ($5\text{-}HT_4$) agonism and $5\text{-}HT_3$ receptor antagonism.[34,45,57] Stimulation of DA_2 receptors inhibits the release of acetylcholine, and stimulation of $5\text{-}HT_4$ receptors enhances the release of acetylcholine from the myenteric ganglia.[34] Metoclopramide has been shown to stimulate *in vitro* contractile activity of circular muscle from the stomach and small intestine in the horse.[4] In a POI model in ponies, metoclopramide was more effective in restoring GI coordination than adrenergic antagonists and cholinomimetics used individually or in combination. In horses, metoclopramide is most commonly administered at a dosage of 0.25 mg/kg, diluted in 500 mL of saline, IV over 30 to 60 minutes. In a retrospective study, metoclopramide administered as a continuous infusion (0.04 mg/kg per hour) decreased the total volume, duration, and rate of gastric reflux when used prophylactically after small intestine resection and anastomosis.[58] Metoclopramide may cause extrapyramidal side effects, such as excitement, restlessness, sweating, and abdominal cramping.

CISAPRIDE

Cisapride is a second-generation substituted benzamide, which until recently was the most popular and effective prokinetic in human medicine.[34] Although it has been taken off the human market because of its cardiotoxic effects, it is discussed here because it is still available through some compounding agencies, and drugs with similar mechanisms of action will soon be available.[59] Cisapride functions as an indirect cholinergic stimulant by selectively enhancing the release of acetylcholine from postganglionic neurons in the myenteric plexus.[60,61] Unlike that of metoclopramide, the main prokinetic activity of cisapride appears to be mediated through $5\text{-}HT_4$ receptor agonism and $5\text{-}HT_3$ receptor antagonism and not through dopamine antagonism.[62] In the horse, cisapride has been shown to act partly through a noncholinergic effect mediated by $5\text{-}HT_2$ receptors.[4] In experimental studies and in clinical trials in humans, cisapride's prokinetic effects were consistently equal to or superior to those of metoclopramide and of domperidone, a dopamine antagonist used as a prokinetic in humans.[61,63] In normal horses,

cisapride augments the amplitude of gastric contractions, stimulates jejunal activity coordinated with gastric contractions, enhances contractile activity of the large and small colon, and stimulates coordinated activity in the ileocecocolonic junction.[64] In a clinical trial in horses, cisapride (0.1 mg/kg IM every 8 hours) significantly decreased the incidence of POI.[65] There is also experimental evidence that cisapride can attenuate the motility dysfunction induced by endotoxins.[66]

Cisapride suspended in saline and administered *per rectum* is very poorly absorbed, and suspended in dimethyl sulfoxide (DMSO), it is inconsistently absorbed.[67] Mixing 400 mg of cisapride with 10 mL of tartaric acid and heating at 50° C for 20 minutes, then adding sterile water to bring the volume to 100 mL and mixing for another 20 minutes at 50° C, followed by filtration sterilization, consistently yields a 3 mg/mL solution for IV administration. This should be administered at 0.1 mg/kg every 8 hours. Because cisapride was withdrawn from the market because of a high incidence of cardiac arrhymias, it must be obtained through compounding pharmacies. As a result of this, prokinetics, such as levosulpride with dopamine (D_2) receptor antagonist activity as well as other, newer drugs, mosapride and teagaserod, that act selectively on 5-HT_4 receptors (see later) and drugs, such as levosulapride, that acts on both 5-HT and dopamine (D_2) receptors, are replacing cisapride.[68-70]

MOSAPRIDE

Mosapride citrate is a more recently developed benzamide that acts selectively on 5-HT_4 receptors in the myenteric plexus to stimulate the release of acetylcholine from cholinergic nerves, thus promoting GI motility. In a study in normal horses, mosapride (1.5 to 2 mg/kg PO) promoted motitity in the small intestine and cecum using an electrogastraph to measure percutaneous electrical potential.[71] In an experimental model, mosapride (1.5 mg/kg PO sid for 5 consecutive days) attenuated the decline of small intestinal motility following jejunocecostomy in healthy horses on postoperative days 6 through 31 compared to controls.[69] In a study comparing mosapride, cisapride, metaclopramide, and lidocaine, only mosapride promoted both jejunal and cecal motility in horses.[69] Although the efficacy of mosapride has not been demonstrated in clinical cases at this time, it appears to be a promising prokinetic without the undesirable extrapyramidal side effects of metaclopramide.

TEGASEROD

Tegaserod maleate is another selective 5-HT_4 receptor agonist that has been shown to increase frequency and amplitude of isolated muscle strips of equine ileum and pelvic flexure.[72] Tegaserod (0.02 mg/kg IV bid for 2 days) also accelerated the gastrointestinal transit time of spheres and increased the frequency of defecation and scores of gut sounds in normal horses.[73] In another study looking at the pharmacokinetics of tegaserod in normal horses, a dosage of 0.27 mg/kg PO bid was found to be appropriate to reach therapeutic concentrations.[74] Tegaserod was associated with increased cardiovascular toxicities in humans; consequently the availability of this drug is limited.[75]

Recent work has questioned the use of these selective 5-HT_4 receptor agonists as prokinetics in horses. One group has demonstrated release of serotonin (5-HT) from platelets in compromised bowel and hypothesized it to act as a proinflammatory, vascoconstrictive, and immunomodulatory agent with potential to contribute to POI by interacting with 5-HT_{1a} receptors.[76] The same group also found no functional or immunohistochemical evidence for 5-HT_4 receptors in equine jejunum whereas 5-HT_{1a} receptors were found in both longitudinal and circular muscle,[76] thus questioning the use of selective 5-HT_4 receptor agonists as prokinetics in horses. Additional research is required to assess the efficacy of drugs that interact with specific 5-HT receptors in the treatment of POI in the horse.

Motilin Agonists

ERYTHROMYCIN

Erythromycin lactobionate is a macrolide antibiotic with recognized GI side effects. It can act as a motilin agonist that influences motility partly by acting on motilin receptors on GI smooth muscles. Motilin is a hormone that is released by enterochromaffin cells and stimulates contractile activity in the stomach and small intestine. Erythromycin also acts on enteric cholinergic neurons through motilin and/or 5-HT_3 receptors to stimulate the release of acetylcholine.[34,77] Motilin and erythromycin have been shown to initiate phase III of the migrating motor complex.[78] Motilin infusion in healthy horses causes strong contractions in the proximal jejunum *in vivo*.[79] When administered at subtherapeutic antimicrobial levels, erythromycin has been shown to stimulate gastric emptying, antroduodenal coordination, and phase III activity in the duodenum in humans and laboratory animals.[78]

In vivo, cecal emptying in response to erythromycin (0.1, 1, 10 mg/kg, IV over 60 minutes) was dose dependent.[80] In normal horses, a dosage of 1 mg/kg is effective in stimulating both cecal and small intestinal contractile activity.[80] Dosages higher than 10 mg/kg can potentially disrupt propulsive activity. The dosage that has been used clinically in horses is 0.5 to 1 mg/kg in 1 L of saline infused over 60 minutes, every 6 to 12 hours.[51] The prokinetic response may diminish with repeated treatments. Erythromycin can downregulate motilin receptors, which would explain this desensitization. Additionally, downregulation and decreased production of motilin receptors has been demonstrated in ischemic and distention-traumatized equine jejunum *in vitro*.[81] Although the recommended prokinetic dosage is supposed to be below the effective antimicrobial level, there have been some anecdotal reports of severe colitis associated with its use, making some clinicians reluctant to use the drug as a prokinetic. In support of this clinical impression, an association between low-dose erythromycin (1.25 mg/kg PO every 8 hours) and *Clostridium difficile* colitis was demonstrated in one report.[82] However, in a study on prokinetic use in horses, erythromycin was one of the more frequently used drugs to treat various motility disordes in horses.[51] Erythromycin has been commonly used to treat gastroparesis in humans, but many of the prokinetic therapeutic benefits that were anticipated have failed to materialize. More recently developed motilin agonists are in preclinical trials.[75]

Sodium Channel Blockers

LIDOCAINE

Intravenous administration of the sodium channel blocker lidocaine hydrochloride shortens the duration of paralytic ileus in the colon in humans after abdominal surgery.[76,83] Stimulation of sympathetic inhibitory spinal and prevertebral reflexes as well as influx of inflammatory cells with release of inhibitory

mediators, such as nitric oxide and prostaglandins, are two of the proposed mechanisms involved in the pathogenesis of POI.[33,84-86] Lidocaine may act on several of these mechanisims by (1) reducing the level of circulating catecholamines through inhibition of the sympathoadrenal response, (2) suppressing activity in the primary afferent neurons involved in reflex inhibition of gut motility, (3) stimulating smooth muscles directly, and (4) decreasing inflammation in the bowel wall through inhibition of prostaglandin synthesis, inhibition of granulocyte migration and their release of lysosomal enzymes and cyokines, and inhibition of free radical production.[83]

In an ischemia reperfusion model in horses, intravenous lidocaine reduced plasma prostacyclin E_2 metabolite concentration and mucosal COX-2 expression.[87] In this same study, lidocaine ameliorated flunixin-induced mucosal neutrophil counts. Lidocaine increased contractility of the circular muscle from the proximal duodenum of horses *in vitro* in another study.[4] In a further study, lidocaine-stimulated contractility was more pronounced in jejunal smooth muscle after ischemia reperfusion insult compared to control tissue.[6] These observations suggest that the drug's primary methods of action in reducing POI may be through reduction of inflammation, stabilization of cell permeability, and reduction of pain.

In normal horses, lidocaine did not improve jejunal progressive motility as measured by the duration of migrating myoelectric complexes and spiking activity of the jejunum in one study and delayed transit of feces in another study.[8,88] In clinical trials in horses, lidocaine was effective in decreasing the duration of reflux in horses with POI and in horses with duodenitis–proximal jejunitis.[10] Intraoperative (prophylactic) administration of lidocaine has been shown to decrease the risk of horses developing POI (16 out of 77 [21%] treated prophylactically versus 24 out of 47 [51%] untreated),[17] as well as decreasing severity of POI and significantly enhancing short-term survival in those horses developing POI, with lidocaine treated horses having 3.33-fold higher odds to survive to discharge.[14,17] Lidocaine is reported to be the most commonly used prokinetic in horses with gastrointestinal disease.[17,51]

The recommended protocol requires an initial bolus of 1.3 mg/kg IV administered slowly over 5 minutes, followed by 0.05 mg/kg per minute in saline or lactated Ringer solution over 24 hours to reach a target blood concentration of 1 to 2 μg/mL.[11] Because intraoperative treatment has been shown to decrease the incidence of POI, if a horse is at risk for developing POI (i.e., horses with strangulating small intestinal lesions), prophylactic administration during anesthesia should be considered.[17] Lidocaine CRI should be discontinued 30 minutes prior to the end of surgery to reduce the chance of ataxia during the recovery period and restarted when the horse is stable.[89] It is recommended to administer the initial bolus followed by the continuous infusion each time the medication is stopped for more than 5 to 10 minutes because of the rapid redistribution from the plasma. Side effects include muscle fasciculations, trembling, and ataxia. Moderate to severe hypoproteinemia or reduced cardiac output may increase the risk of these complications. In these horses, lidocaine blood concentration monitoring every 4 to 6 hours should be considered.[10] Although prolonged infusion (96 hours) did not produce any observed adverse effects, accumulation of a potential toxic metabolite was mentioned in one study as a consideration when using lidocaine for extended periods.[11] In a clinical trial, horses that did not stop refluxing in 17.6 hrs and that did not defecate within 16 hours after the initiation of lidcaine CRI were reported to have a poor response rate and the authors stated that alternative therapy should be considered in these cases.[10] In another study, the authors recommended reducing the infusion concentration by 50% for 24 hours before discontinuing treatment in horses that have responded to lidocaine.[17]

Anti-Inflammatory and Analgesic Therapy

A large body of evidence has accumulated to indicate that motility disorders such as POI and ileus associated with enteritis or colitis are, in part, mediated by inflammatory cell infiltrates into the intestinal wall.[84-86] Intestinal manipulation, lipopolysaccharide administration, and ischemia-reperfusion injury have all been shown to produce significant decreases in *in vitro* contractile activity of jejunal smooth muscle. In experimental animals, blocking this influx of leukocytes by antiadhesion antibodies eliminates the disruption of motility, supporting a cause-and-effect relationship between intestinal inflammation and POI.[85] Intestinal distention, ischemia, and trauma inflicted during decompression or during resection and anastomosis induce inflammation in the bowel wall, with production of inflammatory mediators, such as prostacyclin, PGE_2, and TNF. Endotoxemia associated with necrotic intestine also stimulates production of inflammatory mediators. Infusions of endotoxin, PGE_2, and TNF have been shown to disrupt normal motility.[55,90] Both phenylbutazone and flunixin meglumine were shown to significantly attenuate the disruption of gastric, small intestine, and large colon motility elicited by endotoxin infusion.[90] Administration of these nonsteroidal drugs decreases the production of inflammatory mediators that directly inhibit smooth muscle contractility, while reducing postoperative pain and thus attenuating potential inhibitory sympathetic reflexes. On the basis of these observations, nonsteroidal anti-inflammatory drugs (NSAIDs) are recommended for prevention and treatment of motility disorders associated with GI inflammation. As mentioned previously, lidocaine has been shown to decrease the inflammatory response in ischemia models in horses and improve jejunal smooth muscle contractility, indicating lidocaine may attenuate POI through its anti-inflammatory activity.[6,87]

Adrenergic agonists are another class of drugs commonly used in horses to control pain associated with colic. Xylazine and detomidine are α_2-adrenergic agonists that may inhibit presynaptic acetylcholine release in the myenteric plexus, resulting in a decrease in motility.[91] In the horse, xylazine and detomidine have been shown to decrease motility as measured by myoelectrical activity of the distal jejunum, pelvic flexure, cecum, and right ventral colon and to decrease cecal emptying based on radiolabeled markers.[43,48,92-94] However, in another study, xylazine was not thought to seriously disrupt gastrointestinal motility.[56] Because pain stimulates the sympathetic nervous system, which has an inhibitory effect on GI smooth muscle, the potential detrimental effects of adrenergic agonists must be weighed against their benficial effects.

Opioids are occasionally used to control pain in horses. Opioid agonists should be avoided if possible, as they have been shown to depress motility in most species studied.[93,95,96] *Naloxone,* an opioid antagonist, has been suggested by some investigators to be a potentially beneficial drug for treating motility disorders.[64] There is some evidence that naloxone may enhance progressive motility in the horse; however, it has also

been shown to cause diarrhea and colic in the same species.[97] N-*methylnaltrexone*, another opioid antagonist, has been shown *in vitro* to directly stimulate equine jejunal muscle strips as well as attenuate *in vivo* the adverse effects of morphine (0.5 mg/kg, IV bid) when administered simultaneously at a dose of 0.75 mg/kg, IV bid as indicated by increasing defecation frequency fecal weight and by preventing increases in intestinal transit time.[98,99] *Butorphanol tartrate*, an opioid agonist-antagonist, has been shown to inhibit myoelectrical activity in the jejunum, whereas it has no effect on pelvic flexure activity.[100] Butorphanol prolonged xylazine-induced inhibition of myoelectrical activity of the cecum and right ventral colon in one study, but it produced no undesirable effect on antroduodenal activity in another study.[56,94]

Prognosis

In spite of a recent report, in our opinion with support from most studies, the prognosis for resolution of POI is favorable.[13,16-18] Although this discussion has been limited to pharmacologic interventions, good surgical technique and appropriate aftercare, including fluid and electrolyte replacement, antibiotic and analgesic therapy, and nasogastric decompression, are critical to the outcome of these cases. Because of the intensive postoperative medical management of these horses, successful treatment is often costly. Frequently, the limiting factor in determining the outcome is the economic constraint imposed by the owner.

ADHESIONS

Peritoneal adhesions are one of the most common complications seen after colic surgery in horses. Adhesions occur more frequently after surgery for strangulating lesions involving the small intestine compared to ischemic lesions of the colon and nonstrangulating lesions of the intestine.[29] Adhesions causing postoperative signs of pain and intestinal obstruction can occur in up to 22% of horses previously having surgery for small intestinal disease.[101-103] In a retrospective study of horses requiring repeat laparotomy after surgery for acute abdominal disease (10.1%; 113 out of 1014 cases), adhesions were the most common reason for repeat laparotomy, occuring in 28% of cases.[29] Foals seem to be more predisposed to development of adhesions than adults.[104]

Adhesion formation can be viewed as a variant of the normal physiologic healing process. An intact mesothelial cell layer is critical to the prevention of adhesion formation. Ischemia, distention, drying, or abrasion of the peritoneum during manipulation and decompression of the intestine, as well as hemorrhage, the introduction of foreign material, or infection in the peritoneal cavity, can all result in peritoneal inflammation initiating adhesion formation.[105] When the mesothelial cells are disrupted, the underlying connective tissue containing blood vessels, collagen, lymphocytes, fibroblasts, mast cells, macrophages, and plasma cells becomes exposed. The release of vasoactive substances, such as PGE_2, serotonin, bradykinin, and histamine from the exposed submesothelial tissue mediates increased vascular permeability with extravasation of a fibrinogen-rich inflammatory exudate. The release of thromboplastin (tissue factor) and exposure of subendothelial collagen activate both the intrinsic and the extrinsic clotting cascade, leading ultimately to thrombin-mediated conversion of fibrinogen to fibrin, with the fibrin adhering to sites of injury. In the normal healing process, the fibrin tags are lysed by plasmin, and the peritoneal injury is covered within 2 to 5 days by a single layer of mesothelial cells originating from metaplasia of underlying mesenchymal cells, attachment of free-floating mesothelial cells, or transformation of macrophages.[106] However, if there is inadequate fibrinolysis, fibroblasts migrate over the fibrin scaffold with neovascularization and produce collagen by day 4, initiating the formation of fibrous adhesions.[107]

Tissue plasminogen activators are proteases released by mesothelial and endothelial cells that convert inactive plasminogen to plasmin, an important part of the fibrinolysis pathway. After peritoneal injury from mechanical trauma, ischemia, inflammation, or bacterial infection, plasminogen activator activity is decreased. This was thought to occur because of damage to the cells producing plasminogen activator.[108] A more recent finding suggests that there is an increased production of plasminogen activator inhibitor, which reduces the level of plasminogen activator activity.[105,109,110] Extensive damage to either the parietal or the visceral peritoneal surface tips the balance in favor of adhesion formation, first by increasing the extent of fibrin formation and deposition and second by decreasing fibrinolytic activity. Undoubtedly, many other inflammatory mediators are involved in regulating the balance between deposition and lysis of fibrin. Recently, TGF-β was found to be increased in peritoneal fluid in horses with peritonitis and in horses with ischemic lesions of the intestine. Plasma and peritoneal TGF-β concentrations were higher in horses that had colic and did not survive than in survivors.[111] The authors speculated that increased concentration of TGF-β may influence adhesion formation by stimulating synthesis and deposition of extracellular matrix.

Several strategies are currently being used to prevent or minimize adhesion formation. The most important one involves minimizing trauma by paying attention to good surgical technique, such as keeping the bowel moist at all times, providing adequate hemostasis, leaving as little suture material as possible exposed, removing as much damaged tissue as possible, and handling the tissue as gently as possible. Consistent with the hypothesis that surgical trauma is an important stiumulus for adhesion formation, adhesions were not found to be assoicated with the site of the primary lesion or the site of resection in one study.[29] Trauma is also reduced by making the decision to perform surgery in a timely manner. Both ischemia-reperfusion and intraluminal distention have been shown to cause severe changes in the seromuscular layer of the small intestine, such as serosal edema, leukocyte infiltration, and erythrocyte leakage with fibrin accumulation, whereas a similar insult to the ascending colon does not result in comparable seromuscular lesions.[102,112] Prophylactic strategies include intervention in the inflammation, coagulation, and fibrinolysis cascades with anti-inflammatory or heparin therapy, and using therapies that provide mechanical separation of the injured areas.

Perioperative NSAIDs and Antibiotics

Perioperative NSAIDs and antibiotics are used routinely during GI surgery. Because both inflammation and infection may predispose to adhesion formation, this combination of chemotherapy should curtail the production of adhesions. Broad-spectrum antibiotics, potassium penicillin

(22,000 IU/kg IV every 6 hours) and gentamcin (6.6 mg/kg IV sid), should be administered prophylactically or therapeutically, depending on the degree of compromise to the affected segment of bowel. Flunixin meglumine (1.1 mg/kg IV bid) is continued after surgery for 3 to 5 days to reduce the inflammatory response. DMSO (20 mg/kg IV twice a day for 72 hours) may also reduce inflammation. There is experimental evidence that this combination of anti-inflammatory and antimicrobial therapy is effective in reducing adhesion formation in horses.[113,114] In an experimental study of ischemia-induced adhesions in foals, administration of flunixin meglumine and antibiotics or administration of DMSO appeared to be more effective than 3% sodium carboxymethylcellulose or heparin in preventing the formation of adhesions.[114] It is interesting to note that a 3% solution was used in this study, compared with the 1% solution in studies discussed later in this chapter.

Intravenous Lidocaine

As mentioned previously (see "Sodium Channel Blockers/Lidocaine," earlier), intravenous lidocaine reduced plasma prostacyclin E_2 metabolite concentration and mucosal COX-2 expression in an *in vivo* ischemia-reperfusion model in horses. Flunixine was shown to induce an increase in mucosal neutrophil counts. Lidocaine ameliorated the neutrophil response.[87] This would suggest that intravenous lidocaine could potentially reduce adhesions through anti-inflammatory activity. However, in an *in vivo* study, lidocaine did not inhibit neutrophil migration or adhesion formation at therapeutic concentrations, but it increased neutrophil migration and adhesion formation at higher concentrations.[115]

Heparin

Heparin is composed of a family of naturally occurring sulfated glycosaminoglycans that are synthesized by connective tissue mast cells.[116,117] By binding to antithrombin (AT), a glycoprotein synthesized in the liver and vascular endothelium, heparin markedly enhances the rate of AT-mediated inactivation of clotting factors (factors IX, X, XI, and XII and thrombin).[118,119] The AT-heparin complex, by neutralizing thrombin, suppresses thrombin-mediated amplification of the coagulation cascade and inhibits thrombin-mediated conversion of fibrinogen to fibrin.[119] Heparin sodium (40 IU/kg IV intraoperatively, followed by 40 IU/kg SC twice a day for 2 days) decreased adhesion formation in ponies after experimentally induced intestinal ischemia.[103] Based on pharmacokinetic studies using calcium heparin instead of sodium heparin, an initial dose of 150 IU/kg SC followed by 125 IU/kg SC twice a day for six doses followed by 100 IU/kg SC twice a day is recommended to maintain therapeutic anticoagulant levels.[120] Some evidence suggests that calcium ions inhibit the heparin-AT-thrombin reaction. Consequently, a higher dosage of calcium heparin than sodium heparin is required to reach therapeutic levels, although this finding is questioned.[121,122] Plasma AT levels are reported to be decreased in some horses with abdominal disease.[123,124] Because heparin acts as a cofactor to AT, heparin therapy would be of limited value if peritoneal AT were depleted significantly. However, changes in plasma AT levels do not always correlate with changes in peritoneal levels.[125] Peritoneal AT levels have actually been found to be increased in some horses with colic.[126] The most common complication reported with heparin therapy in horses is anemia induced by erythrocyte agglutination, which resolves in 3 to 4 days following cessation of heparin.[127]

Low-molecular-weight heparin (LMWH) is separated from unfractionated heparin (UFH) by solvent or gel filtration and consists of smaller molecules than UFH. It has less antithrombin activity and higher anti–factor Xa activity than UFH. In addition, LMWH has constant anticoagulant activities, greater bioavailability, and longer biological half-life.[128] In horses, LMWH causes fewer side effects and can be conveniently administered once daily.[129,130] When administered to horses with surgical colic, there were fewer jugular vein changes and fewer side effects in horses treated with LMWH compared to UFH.[131] When administered to horses following colic surgery, horses treated with LMWH had a lower prevalence and grade of laminitis compared to control horses where heparin was not administered.[132] Dalteparin can be administered subcutaneously at 50 IU/kg every 24 hours.[130]

Intraperitoneal Sodium Carboxymethylcellulose (SCMC)

Intraperitoneal SCMC is effective in preventing adhesions in experimental models using laboratory animals, and there is evidence to support its efficacy in preventing experimentally induced adhesions in horses.[133,134] The proposed mechanism of action is the "siliconizing" effect that SCMC has on the bowel. This mechanical lubricating barrier minimizes the duration of direct apposition of traumatized tissue, preventing the establishment of fibrin tags between two surfaces, although the effect is most likely transient, because the SCMC is cleared rapidly from the abdomen. A 1% solution of SCMC (7 mL/kg body weight) is infused into the peritoneal cavity through a sterile stallion catheter before tying the last suture in the linea alba,[134] or, preferably, before manipulating the bowel. In several experimentally induced adhesion studies, horses treated with 1% SCMC had reduced frequency of intra-abdominal adhesions compared with controls.[135,136] In one retrospective study, no adverse effects on abdominal incisional wound healing were observed in horses treated with SCMC, however no significant differences were found between treated and control goups for postoperative colic or long term survival.[137] In another study, intraoperative SCMC prolonged survival of horses with small intestinal disease, particularly in horses that had postoperative colic or POI, although interpretation of those results has been questioned.[138,139] The intraoperative use of SCMC can result in visible intracellular accumulation of pink or magenta colored material on cytological examination of peritoneal fluid macrophages if an abdominocentesis is performed postoperatively.[140]

Sodium Hyaluronate (HA)

Sodium hyaluronate (HA) has also been used by itself and in conjunction with SCMC to reduce adhesions. Application of a 0.4% HA solution to the serosal surface of the jejunum significantly decreased the incidence of experimentally induced intra-abdominal adhesion formation in ponies, whereas SCMC did not significantly reduce adhesions.[141] A bio-resorbable hyaluronate-carboxymethylcellulose membrane that is applied over an anastomosis site or an area of localized trauma has also been shown to be beneficial in reducing adhesion formation.[142-144] Recent data indicating that adhesion formation is often not

associated with the site of the primary lesion or with the anastomosis would suggest limitations on the use of a bio-resorbable membrane for prevention of adhesion.[29] Bio-resorbable protective membranes could be used in conjunction with intraperitoneal SCMC to provide a more diffuse protective coating.

Intraperitoneal Crystalloid Solutions

Intraperitoneal instillation of *crystalloid solutions* is often used to prevent adhesion formation, but conflicting results have been reported regarding their efficacy.[107] The proposed mechanism is hydroflotation of the abdominal organs. However, large volumes of fluid in the peritoneal cavity may compromise the host's ability to fight infection by interfering with opsonization and phagocytosis.[145]

Peritoneal Lavage

An alternative approach is the use of peritoneal lavage, which should remove fibrin and other inflammatory mediators while providing mechanical separation of the bowel at the time of lavage. Standing postoperative peritoneal lavage significantly reduced the number of adhesions in horses that received two peritoneal lavages for 2 days postoperatively with 10 L of lactated Ringer solution delivered through a 32-French chest trocar inserted in the abdomen during surgery.[146] Another technique for abdominal drainage is through the use of a closed suction intra-abdominal drain with intermittent peritoneal lavage. This technique has been associated with a high incidence of minor complications, such as partial obstruction of the drain (26%), leakage of fluid around the drain (16%), and subcutaneous fluid accumulation (12%).[147]

SURGICAL COMPLICATIONS

Significant complications, such as hemoperitoneum or peritonitis, may result from surgical procedures. Abdominal surgical procedures must adhere to basic principles of good surgical practice (after Halsted), including accurate homeostasis, gentle tissue handling, approximation of tissue, obliteration of dead space, minimal contamination, accurate ligation, and minimal foreign material. Postoperative hemorrhage can result from ligature slippage or from mucosal hemorrhage following intestinal resection and anastomosis. Fatal hemorrhage resulting from tearing of the portal vein or, less commonly, the caudal vena cava has been reported after manual reduction of epiploic foramen entrapment.[148-150] Therefore, reduction of an epiploic foramen entrapment should be performed with one hand on each side of the foramen and gentle feeding of the entrapped bowel through the foramen in a horizontal direction, because pulling the bowel in an upward direction may lead to tearing of the previously mentioned major vessels. Hemorrhage has also been reported as a complication of enterotomies, particularly those performed in the large colon. Therefore, in these locations, a full-thickness suture pattern may be indicated as a first layer.[151]

Administration of whole blood may be necessary if signs of hemorrhagic shock develop (increased heart rate, pale mucous membranes, weakness, and collapse). Fresh blood collected in plastic bags to preserve platelet activity should be given, as stored blood requires several hours to restore RBC oxygen-carrying capacity. Because signs of hemorrhagic shock develop after loss of 25% to 30% of blood volume, transfusion of 6 to 8L of whole blood may be required (see Chapter 4).

Complications have been reported that are unique to specific surgical techniques. Small intestinal volvulus may develop after side-to-side anastomosis in ponies. Intussusceptions have been reported after small intestinal surgeries. Jejunojejunal intussusception was reported after a stapled functional end-to-end anastomosis in two pony mares and in two ponies after inverting closure of small intestinal transverse enterotomies, suggesting that excessive cuff formation should be avoided during small intestinal closure.[152,153] Chronic intermittent colic with small intestinal distention can occur after functional end-to-end jejunojejunostomies. Significantly dilated anastomoses found on re-laparotomy may hinder the passage of the peristaltic wave and are related to excessive length of the anastomosis.

Internal herniation is a possible complication of small intestinal resection, and care should be taken to obliterate all possible internal spaces. Closure of the ileocecal fold after jejunocecostomy, mesenteric closure after small intestinal resection or ileocolostomy, and closure of potential spaces after intestinal bypass are recommended to avoid this problem.[154,155]

Extensive small intestinal resection (greater than 60%) has been associated with malabsorption, diarrhea, weight loss, and liver damage in ponies.[156] In a separate study, a short-interval feeding program (pelleted ration divided into 8 feedings per day) prevented the development of a clinical malabsorptive syndrome after 70% of small intestinal resections in ponies.[157]

Jejunocecostomy procedures are reported to have an increased risk for postoperative complications. An ileocecocolic intussusception was reported after jejunocecostomy in one horse.[155] Alterations in calcium absorption and fat absorption and microbial derangements in normal flora have been suggested as potential complications. Attaching the jejunum as close to the base of the cecum as possible decreases backflow pressure, discouraging fluid ingesta in the cecum from traveling orally back into the jejunum.

Ileal impactions may recur in the immediate postoperative period, particularly if a bypass procedure was not performed. Horses need to be fed carefully, using a laxative diet, to avoid this complication.

There is a 15% recurrence rate reported for large colon displacements and torsion. Factors contributing to recurrence have not been thoroughly identified. Recurrence of large colon displacements can be prevented by colopexy and large colon resection. Colopexy of the large colon has been reserved for nonperformance animals because of reported intestinal rupture after colopexy in athletes.[158] Extensive large colon resection is associated with short-term decreased absorption of water, decreased absorption of phosphorus, and weight loss.[159] Horses that have undergone large colon resection therefore have increased requirements of water, phosphorus, and better-quality protein.

Recurrence of small colon impaction is also a problem. Surgical evacuation of the large colon is recommended after surgical correction of small colon impactions. These horses should be managed with a laxative diet in the immediate postoperative period.

Management of postoperative complications may require repeat laparotomy. Clinical signs indicating the need for repeat laparotomy include persistent abdominal pain despite successful gastric decompression, marked and progressive intestinal distention, systemic deterioration associated with degenerative changes

in the abdominocentesis, and presence of bacteria. Repeat laparotomies have been reported in 8% to 10% of horses undergoing a celiotomy for colic.[29,160,161] The long-term outcome of horses subjected to a second surgery was significantly worse than that of horses undergoing a single surgery. In one study, the short-term survival rate was 50% and the long-term rate was only 22%. Nearly 40% of horses surviving repeat laparotomy developed acute episodes of colic that necessitated further surgery.[160]

SEPTIC PERITONITIS

Septic peritonitis is one of the most common fatal postoperative complications following exploratory laparotomy in horses (other common fatal complications are adhesions and ileus).[162,163] In one study, 56% of horses with septic postoperative peritonitis did not survive.[164] Postoperative peritonitis may result from necrosis of a segment of the GI tract before or after surgical intervention, contamination occurring at surgery, or leakage from the anastomosis or enterotomy site. In response to bacterial contamination, peritoneal macrophages and mast cells release histamine and prostaglandins, leading to vasodilatation and increased permeability of the peritoneal vessels. The subsequent peritoneal exudate contains fibrin, complement, immunoglobulins, and clotting factors. Chemotaxins (such as IL-1, leukotriene B_4, and TNF) produced by activated macrophages, mast cells, and neutrophils stimulate a further influx of neutrophils, exacerbating the inflammatory response.[165,166] Bacteria and other particles can be cleared from the peritoneal cavity through the diaphragmatic lymphatics. Movement of the diaphragm during respiration facilitates the uptake of peritoneal fluid into stomata, which represent intercellular gaps between mesothelial cells covering the diaphragm. The stomata communicate with lymphatic lacunae, which drain peritoneal fluid into the substernal lymph nodes and subsequently via the thoracic duct into the bloodstream. Systemic effects from peritonitis may be initiated by the entrance of bacteria into the bloodstream, by the action of inflammatory mediators produced by macrophages and neutrophils, or by absorption of endotoxin from the peritoneal cavity into the portal venous system, which then acts on the Kupffer cells of the liver, contributing to the septic response.[167]

Clinical signs commonly associated with peritonitis include mild colic, depression, anorexia, ileus, diarrhea, fever, tachycardia, and tachypnea.[164,165,168] Besides relying on clinical signs, the diagnosis of peritonitis is based on peritoneal fluid analysis.[169] Peritoneal fluid from normal horses has a nucleated cell count of less than 5000 cells/mL and a protein concentration of less than 2.5 g/dL. However, after an exploratory laparotomy, the peritoneal nucleated cell count, percentage of neutrophils, fibrinogen, and protein concentration become markedly elevated.[160,164] The mean nucleated cell count peaks at approximately 200,000 cells/mL at day 4 and remains elevated at 40,000 cells/mL through day 6; the mean protein concentration remains elevated and peaks at 6 g/dL on day 6 after an exploratory laparotomy. Therefore, absolute values and differential counts may not provide sufficient information on which to base a diagnosis of postoperative septic peritonitis. Hence, cytologic evaluation of the peritoneal fluid is crucial for a definitive diagnosis. Toxic or degenerative changes in neutrophils and the presence of intracellular or extracellular bacteria indicate septic peritonitis. Peritoneal pH and peripheral and peritoneal glucose may also be evaluated to diagnose septic peritonitis. A serum–peritoneal glucose difference greater than 50 mg/dL or a peritoneal pH less than 7.2 with a peritoneal glucose of less than 30 mg/dL is highly suggestive of septic peritonitis.[170] An increased abdominal fluid lactate compared to peripheral blood is also an indicator of septic peritonitis.[171] Peripheral blood values determined by complete blood count and fibrinogen should be compared with peritoneal fluid. A left shift, thrombocytopenia, or hypoproteinemia also indicates septic peritonitis.[167] Peritoneal fluid should be submitted for both aerobic and anaerobic cultures and sensitivity.

Treatment should be directed first toward stabilization of the animal and then toward the inciting cause. Intravenous fluids should be administered to correct dehydration and acid-base and electrolyte abnormalities. Patients are often hypoproteinemic (total protein less than 4.4 g/dL) and require plasma. If sepsis is caused by gram-negative bacteria, administration of hyperimmune serum may attenuate the degree of endotoxemia. Flunixin meglumine (0.25 mg/kg IV 3 times a day) attenuates symptoms of endotoxemia. Broad-spectrum IV antibiotics are imperative. The most common organisms isolated from horses with peritonitis include the aerobic bacteria *Escherichia coli*, *Staphylococcus* spp, *Streptococcus* spp, and *Rhodococcus equi* and the anaerobic species *Bacteroides, Clostridium,* and *Fusobacterium*.[164,167,168] If necrotic intestine or leakage of an anastomosis or enterotomy site is considered to be the cause of septic peritonitis, a second exploratory laparotomy is indicated.

Open peritoneal drainage has been described for the treatment of mild inflammatory peritonitis in an experimental model in horses, but the efficacy of this technique in clinical septic peritonitis is not known.[172] However, peritoneal lavage is an important component of the treatment protocol. Placement of an abdominal lavage system in the animal at the time of surgery is indicated if the animal is at risk for developing peritonitis (i.e., with a necrotic intestine or significant contamination at surgery). Enterotomies performed in the large and small colon to remove enteroliths do not significantly increase the risk of the horse's developing septic peritonitis, and a drain is not necessary. A closed fenestrated drain system allows infusion of fluid, and the suction drain system (Snyder Hemovac) provides a continuous active evacuation of residual fluid. Alternatively, a 32-Fr thoracic drain (Pleur-Evac Thoracic Catheter) can be placed, to which additional fenestrations are made to improve drainage. Whenever possible, the omentum should be removed during the surgery, to prevent occlusion of the drain during postoperative lavage. The drains may also be placed in a standing, sedated animal. Approximately 5 to 10 L of lactated Ringer is infused every 6 hours. After infusion of the fluid, the horse is walked for 10 minutes to help circulate the fluid before draining the infusate. Heparin is often added to the lavage solution (5000 IU) or administered systemically. Heparin decreases peritoneal fibrin formation to give the antimicrobial agents better access to the bacteria.[166] The lavage is continued until there is a decrease in the nucleated cell count and protein concentration, an increase in pH and glucose of the peritoneal fluid, and improvement in the cytologic appearance of the cells. By evacuating bacteria, cellular debris, fibrinogen, fibrin, and inflammatory mediators, this technique reduces the systemic effects of peritonitis, helps to resolve the infection, and decreases the incidence of adhesion formation, one of the complications of septic peritonitis.[147,173]

The prognosis for horses with septic peritonitis depends on the extent of the insult and how quickly the initiating cause is

TABLE 40-1. Postoperative Monitoring of Horses After Abdominal Surgery

		Monitoring				
			Hemodynamics			
Surgical Findings	Possible Problems	Exam	TPR	Lab Work	Reflux	Fluids
Small Intestine						
Simple obstruction	Ileus	q 1 hr while on fluids	q 4 hr	PCV/TP q 6 hr until no reflux; monitor electrolyes and creatinine daily until no reflux	q 4 hr	Until no reflux
Anterior enteritis	Ileus, laminitis	q 1 hr while on fluids	q 4 hr	PCV/TP q 6 hr until no reflux; monitor electrolytes and creatinine daily until no reflux	q 4 hr	Until no reflux
Strangulating obstruction	Ileus, endotoxemia, adhesions	q 1 hr	q 2-4 hr	PCV/TP q 6 hr until no reflux; monitor electrolytes and creatinine daily until no reflux	q 2-4 hr	Until cardiovascular status is stable and no reflux
Large Intestine						
Simple obstruction	Postoperative diarrhea	q 4 hr	q 4 hr	If febrile: CBC, monitor for leukopenia	No	Correct preoperative dehydration
Strangulating obstruction	Endotoxemia: dehydration, protein loss; diarrhea; laminitis	q 1 hr	q 4 hr	PCV/TP q 6 hr until no reflux; monitor electrolytes and creatinine daily until no reflux; monitor rise in PCV with protein loss	No	Until cardiovascular status stable

*Preoperative antibiotics are broad spectrum: penicillin and gentamicin. Add metronidazole if significant intraoperative contamination.
†2.2 mg/kg IV over 60 min q 6 hr.
‡Loading dose: 1.3 mg/kg IV slowly over 5 min; maintenance: 0.05 mg/kg/min infusion IV.
§0.0044 mg/kg (2 mg per adult horse) SC or IV.
¶For ileal impaction, feed a laxative diet and limit intake for 4 to 5 days.
**For cecal or large colon impaction, feed a laxative diet, give mineral oil, and monitor for reimpaction.
††For large colon resection, increase water intake and feed alfalfa hay.
CBC, Complete blood count; *IV,* intravenously; *PCV/TP,* packed cell volume/total protein; *SC,* subcutaneously; *TPR,* temperature, pulse, respiration.

corrected. Horses that have extensive contamination because of leakage of the anastomosis or necrosis of devitalized bowel that was not removed during the initial surgery are likely to have a guarded prognosis.[163] Horses with less-severe contamination often respond favorably to the preceding therapeutic protocol, although the cost of postoperative management is substantially increased.

INCISIONAL COMPLICATIONS

Incisional complications after exploratory celiotomy in horses include infection, dehiscence, suture sinus formation, and herniation.

Incisional Infections

The frequency of incisional infections in horses after colic surgery is 10% to 37%.[163,174,175] A frequency of 28.6% was reported after one colic surgery, and 87.5% after two or more celiotomies.[175] Predisposing factors for incisional complications include repeat laparotomy, increased duration of surgery, use of a near-far-far-near pattern, use of chromic catgut, leukopenia, incisional edema, postoperative pain, weight (greater than 300 kg), and older age (older than 1 year).[175-177] In one study, the use of staples for skin closure and surgical site closure by less-experienced surgeons increased the risk for incisional infection.[178] The use of an antibacterial-coated suture did not decrease the likelihood of incisional complications.[179] The use of an abdominal bandage decreased the prevalence of postoperative incisional complications in one study.[180] Incisional hernias are reported in 13% to 16% of horses after celiotomy. The single most important risk factor for herniation is incisional infection, which had a relative risk of 17.8 for causing herniation.[176]

Horses developing incisional infections are initially febrile without any localizing signs. Excessive tenderness and edema are sometimes noted. Most incisional infections develop 3 days or more after surgery, and drainage can sometimes be delayed up to 14 days. Systemic antibiotics delay the onset of drainage. After drainage is noted, it is important to provide a route for exudation by removing a few staples or sutures at the site of the drainage. Culturing of the drainage identifies potential hospital problems. Horses that are afebrile after drainage has been established and in which excessive edema or cellulitis is not evident do not require systemic antibiotics. However, fever and significant tissue reaction are indications for antibiotic therapy. Flushing of the wound should be performed with caution, because

Drugs				Feeding		
NSAIDs	Antibiotics*	Premotility Agents	Other	Time	Type	Frequency
Small Intestine						
Flunixin meglumine 0.25 mg/kg IV tid	Perioperative (24 hr)	Erythromycin† Lidocaine‡		After 2 hr no reflux¶	Wet hay or grass	q 4 hr
Flunixin meglumine 0.25 mg/kg IV tid		Erythromycin† Lidocaine‡	Prevention of laminitis; acepromazine, nitroglycerin	After 12 hr no reflux	Wet hay or grass	q 4 hr
Flunixin meglumine 0.25 mg/kg IV tid	Until 24 hr afebrile	Erythromycin† Lidocaine‡	Plasma, hyperimmune serum, polymyxin B Prevention of laminitis: acepromazine, nitroglycerin	After 12 hr no reflux	Wet hay or grass	q 4 hr
Large Intestine						
Flunixin meglumine 0.25 mg/kg IV tid	Until 24 hr afebrile	Erythromycin† Neostigmine§		At 12 hr**	Grass, hay	q 4 hr
Flunixin meglumine 1.1 mg/kg IV bid, then reduce to 0.25 mg/kg tid	Until 24 hr afebrile	Erythromycin† Neostigmine§	Plasma, hyperimmune serum, polymyxin B Prevention of laminitis: acepromazine, nitroglycerin	When no large colon distention‡	Grass, hay††	q 4 hr

it can propagate the infection along the entire incision line. An abdominal support should be provided, because dehiscence may occur.

Incisional infection rates can be decreased by shortening surgery time, using adequate draping, isolating any enterotomy incision from the clean surgical field, and minimizing trauma to the incision during exploration of the abdomen. A plastic ring drape can be used to protect the incision and is preferred by some surgeons for all exploratory surgeries. Bacterial culturing of the wound does not have predictive value for the incisional infection rate.[181] Closure of the linea alba should be performed with a suture material that is minimally reactive. Chromic gut has been associated with increased incisional drainage in horses, and braided nonabsorbable suture may cause suture sinus formation. Suture patterns do not particularly influence incisional infection rates, although in one study, a near-far-far-near pattern was associated with increased postoperative drainage.[175] Care should be taken, however, not to take overly large bites and to avoid excessive force when tightening sutures; this can lead to ischemia, predisposing to incisional infection. In one study in human abdominal closure using a single-layer running suture, there was a significant decrease in wound complications when a ratio of suture length to wound length of at least 4 was achieved by using a short stitch length rather than a long one.[182]

If incisional infection is present, or in cases of repeat laparotomy in the presence of an infected incision, the wound can be apposed with large stainless steel tension-releasing sutures, placed distant from the incision, which help support the abdominal wall (see Chapter 39). The linea alba is closed, and the subcutaneous tissues and skin can be left open for drainage.[183]

The reported rate of acute incisional dehiscence is low (2% to 2.9%), but this is the most serious acute incisional problem and can be fatal. Violent recovery, severe postoperative abdominal pain, prolonged surgery time, and use of a continuous suture pattern in the linea alba have been associated with early postoperative dehiscence.[175,184] Acute incisional dehiscence is best managed by immediate repair under general anesthesia if the intestine has not been severely traumatized.[185] For details on repair of acute total incisional dehiscence, see Chapter 39.

Incisional Herniation

Incisional herniation is the most significant problem resulting from incisional infection. Incisional hernias do not necessarily require repair if they are small and do not cause deformation

in the body wall. Large hernias that protrude from the abdomen require repair for cosmetic reasons but also because they are subject to repeated trauma. Hernias must be repaired only after the incision is healed and free of infection and the hernial ring has gained strength. This usually requires a minimum of 3 months after the original surgery. No skin abrasions, open wound, or drainage should be present at the time of hernia repair, because these may contaminate the surgical site, which could have serious implications, especially if an implant is used to repair the hernia. In preparation for surgery, the horse should be fasted to decrease abdominal weight. If the hernia is large, a complete pelleted feed can be substituted for hay 2 weeks before surgery to further decrease abdominal contents. For a description of surgical procedures used for incisional hernia repair, see Chapter 39.

A postsurgical abdominal wrap has been advocated for the management of incisional hernias (CM Heal). These abdominal bandages provide firm, even abdominal support, have a special pocket designed to apply direct pressure over the hernia site, and are available in different sizes. Anecdotal reports and our experience are favorable for healing of incisional hernias without surgical intervention. An additional benefit is the ability to start the horse on an exercise program while the abdominal support is in place. Additional indications include the need for additional support after surgery in advanced pregnancies, and correction of umbilical hernias in foals.

POSTOPERATIVE MONITORING

Principles of monitoring horses after abdominal surgery are based on restoration of circulating fluid volume, electrolyte and acid-base equilibrium, and GI function. Table 40-1 summarizes the care of horses after abdominal surgery based on surgical findings. However, these are only guidelines, and therapy should be adjusted to individual cases based on physical and laboratory examination.

As a rule, horses on IV fluid therapy should be observed hourly and their hydration status evaluated every 6 hours by PCV and total protein determination. Horses that had significant bowel damage or ileus should be examined (including body temperature, pulse, respiration rate) every 4 hours until they have stabilized. Creatinine should be monitored daily until values are within the normal range. Postoperative fever is common within the first 24 hours of surgery but should resolve thereafter. A persistent fever should be investigated (impending colitis, peritonitis, catheter sepsis). Small intestinal diseases have a high incidence of postoperative ileus, whereas diarrhea more commonly follows large intestinal disorders. Laminitis is a risk for all horses but is more likely to occur if significant bowel damage was present. For all horses that are at risk for the development of endotoxemia, hyperimmune serum or polymyxin B is administered to bind endotoxin. For all horses that are at risk for the development of laminitis, cooling of the feet with ice boots (therapeutic hypothermia) may be indicated.[186]

Perioperative antimicrobial agents should be of the broad-spectrum type and should have minimal effects on GI flora; an example would be procaine penicillin combined with gentamicin. Perioperative antibiotic therapy is applied in procedures in which the bowel lumen was not entered, and it continues until the horse is afebrile for 24 hours and all systemic parameters have improved after enterotomies or resection and anastomosis procedures. Objective criteria that can be used for the discontinuation of systemic antibiotics include a normal white blood cell count without bands, normal temperature, absence of abdominal discomfort, and return of normal appetite.

Analgesic therapy is indicated after celiotomies. Flunixin meglumine is recommended for a minimum of 24 hours and then as needed, depending on the horse's systemic condition and comfort level.

In small intestinal disorders, feeding is resumed in small amounts after 12 hours if the horse has not developed reflux. The horse should first be offered water, followed by small amounts of wet hay or fresh grass. In large colon disorders, feeding can be resumed as early as 8 hours after surgery, provided there is good intestinal health. In cases of large colon torsion, feeding is delayed until there is evidence of mucosal integrity. Ileal, cecal, and large and small colon impactions should be closely monitored when feeding is resumed, because these animals are at risk for reimpaction. The use of laxatives, such as mineral oil, is recommended in the immediate postoperative period for impactions. For details on nutritional support for the critical surgical patient, see Chapter 6.

CHAPTER
41 Overview of Upper Airway Function

Frederik J. Derksen

The upper airway has complex physiologic functions including olfaction, phonation, deglutition, thermoregulation, filtering and conditioning of the inspired air, and protecting the lower airway from aspiration. Most important, the upper airway also functions as a conduit for airflow to and from the lung, and, because the horse is an obligate nasal breather, a normal upper airway is critical in this species. To accommodate the many diverse demands placed on it, the upper airway was not ideally designed for any one activity. For example, the equine upper airway has a large dead space volume, it has high resistance to airflow, and it tends to collapse in response to negative pressures generated during inspiration.[1-4] Although none of these characteristics is ideal for an airflow conduit, compromises in design are necessary to accommodate the other upper airway functions. For these reasons, the upper airway may well be a limiting factor in the horse's exercise capacity, and tolerances in the upper airway are minimal. Even the smallest lesion before surgery or remaining after completion of a surgical procedure may further limit performance. This makes surgical interventions in the upper airway challenging, and if upper airway function is not fully considered, surgical outcome is often suboptimal. Consequently, surgeons must have a working understanding of upper airway physiology. The purpose of this chapter is to provide the surgeon with information that should be considered when performing upper airway surgery in the horse.

THE UPPER AIRWAY AND PERFORMANCE

The capacity of horses to increase ventilation in response to the demands of exercise is truly enormous. A normal horse at rest breathing 15 times a minute with a tidal volume of 5 L has a minute ventilation of 75 L. During exercise, respiratory rate and tidal volume increase to achieve a minute ventilation of approximately 1500 L.[3] The upper airway must accommodate this twenty-fold increase in airflow by undergoing changes in caliber, rigidity, and shape. In spite of these adaptations to exercise, evidence suggests that in exercising horses upper airway resistance becomes a large portion of total respiratory resistance, and this increase in resistance may limit performance.[5] In strenuously exercising horses, the PaO_2 decreases and the $PaCO_2$ increases. This perturbation in gas exchange is in part caused by insufficient alveolar ventilation, although diffusion limitation also plays a major role. Substituting a mixture of helium and oxygen for air reduces airway resistance, and blood oxygenation is improved.[5] Taken together, this is strong evidence to suggest that upper airway resistance limits arterial blood oxygenation in exercising horses, thereby limiting oxygen delivery to tissues and performance. Thus, if the function of the upper airway as a conduit for airflow is taxed to the maximum during exercise in normal horses, it is easy to understand that small upper airway lesions can significantly affect upper airway function during exercise and further affect performance.

MECHANICS OF AIR FLOW

The respiratory muscles, primarily the diaphragm, provide the force needed for ventilation. The pumping action of these muscles results in large pressure changes in the airways. On exhalation, pressure in the upper airway becomes positive, driving the air out against the atmospheric pressure, whereas on inhalation, pressures are negative, resulting in movement of air from the outside to inside the lung. The greater the exercise intensity, the greater the airflow rates and the larger the pressure changes. During high-intensity exercise, the pressure in the trachea is approximately 15 cm H_2O on exhalation, and it is 30 cm H_2O on inhalation (Figure 41-1).[6] Positive pressure in the upper airway during exhalation encourages upper airway dilation in this phase of the respiratory cycle. On inhalation, however, the negative

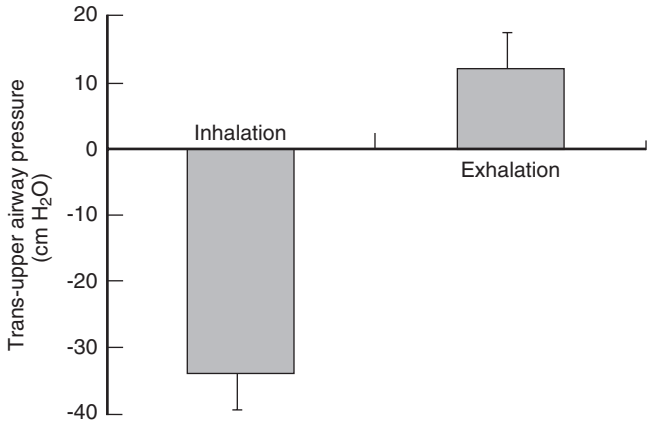

Figure 41-1. Trans-upper airway pressures of normal horses during intense exercise. Note that inspiratory pressures are greater than expiratory pressures.

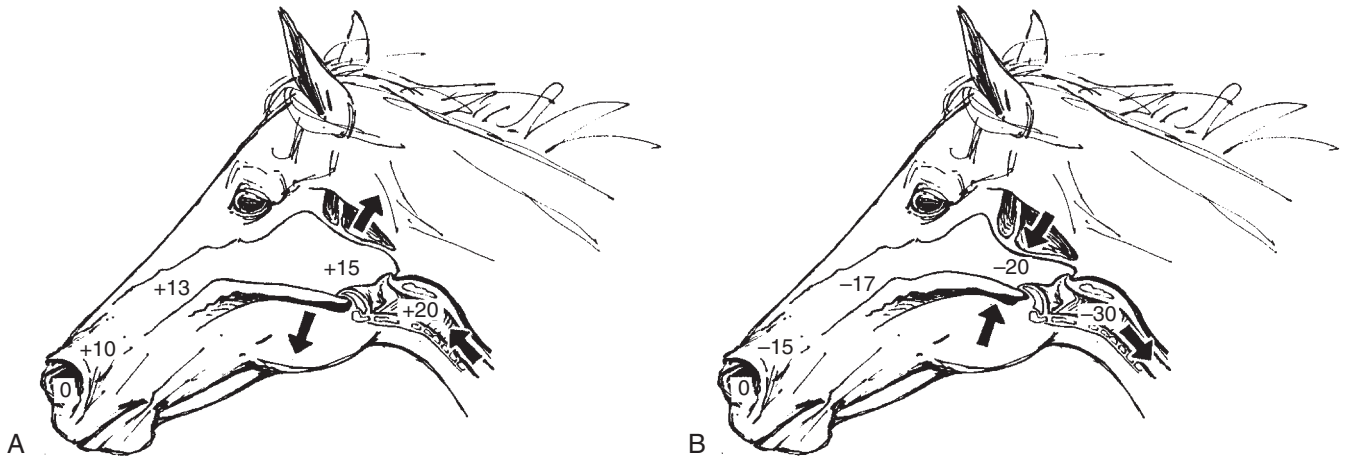

Figure 41-2. A, In exercising horses, upper airway pressures are positive relative to the atmosphere during expiration, facilitating airway dilation. **B,** During inspiration, upper airway pressures are negative, narrowing the airway lumen.

pressure in the upper airway encourages tissues to collapse, thus narrowing the upper airway (Figure 41-2).

The ratio of driving pressure and the resulting airflow is called impedance. Impedance is a very useful calculated variable, because it is a measure of how much the airflow is opposed by the respiratory system. One of the most important determinants of impedance is airway resistance. Airway resistance in turn is primarily determined by airway diameter. Many surgically correctable conditions of the upper airway (e.g., recurrent laryngeal neuropathy) narrow the airway lumen, decrease its diameter, and therefore increase impedance.[7] Measurements of upper airway impedance on inhalation and exhalation demonstrate that, even in normal horses, the upper airway is only partially able to withstand these pressure swings, especially during exercise. During inhalation, subatmospheric intraluminal pressures cause the airway to narrow, whereas positive intraluminal pressures enlarge the airway diameter during exhalation. As a consequence, impedance is higher on inhalation than during exhalation (Figure 41-3).[8]

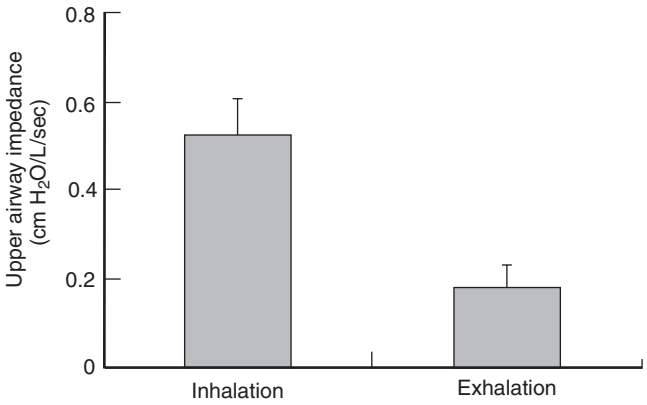

Figure 41-3. Upper airway impedance of normal horses during intense exercise. Note that inspiratory impedance is greater than expiratory impedance.

The anatomical contours of the upper airway are complex, and it is no surprise therefore that the airflow through this structure is equally complex. Recently, computer models of airflow through the upper airway have given new insight into the details of pressure and flow profiles that operate in the upper airway of exercising horses.[9,10] A detailed understanding of airflows and pressures in the upper airway is useful, as it gives clues to why certain upper airway regions are more prone to collapse than others. After the air enters the nostrils during inhalation it is forced through the relatively narrow nasal valve region, which results in a large pressure drop (Venturi effect; Bernoulli's principle) and high flow velocities. This anatomic region is where nasal strips have been used to prevent airway narrowing during inhalation.[11] As air enters the airway further during inhalation, the next narrow area it encounters is the rostral nasopharynx, at the transition between the nasal passages and the nasopharynx. As in the nasal valve area, this airway narrowing increases flow velocity and decreases wall pressure. It is possible that this pressure decrease initiates palatal instability, and predisposes the soft palate to dorsal displacement (DDSP).[10]

Next, the air enters the relatively wide nasopharynx. As airflow transitions from the nasopharynx into the relatively narrow larynx, there is another pressure drop, predisposing the laryngeal region to dynamic collapse involving such structures as the vocal folds, aryepiglottic folds, and arytenoid cartilages. Interestingly, the cross-sectional area of the larynx is approximately 7% greater than the trachea, supporting the idea that in horses with recurrent laryngeal neuropathy treated with laryngoplasty, maximal arytenoid abduction may not be necessary.[10] Computer models of the upper airway with simulated airflows generated in the author's lab provide additional interesting and sometimes unexpected information.[12] For example, the path that the airflow takes during inhalation differs from the route that it takes during exhalation.[12] Furthermore, there are flow eddies, regions of reverse flow, and areas of great turbulence, and wall stress.[9,10,12] As computer models become more sophisticated, a more detailed understanding of upper airway flow complexities is likely to improve our understanding of why upper airway regions are predisposed to collapse.

DISTRIBUTION OF AIRWAY RESISTANCE

In the horse, as in most mammals, upper airway resistance is a significant proportion of total resistance to airflow. In the resting horse, a full two-thirds of the total resistance to airflow resides

in the upper airway.[2] This proportion increases during exercise. Because of this, most animal species switch to mouth breathing during exercise, which provides a low-resistance pathway for the greater airflow required during exercise and minimizes the work of breathing. The horse cannot breathe through its mouth effectively, and the approximately twentyfold increase in airflow that occurs during exercise must be totally accommodated through nasal breathing and therefore, by the upper airway. Obligate nasal breathing is the result of a tight seal between the soft palate and the laryngeal cartilages. When the nasal passages are occluded, this seal may be broken and mouth breathing results. However, in the horse, the resistance to airflow through the mouth is apparently very high.

During exercise, the distribution of airflow resistance changes significantly. In the exercising horse, during inhalation, intrathoracic resistance is less than 25% of total resistance to flow and the remaining resistance is almost evenly divided between nasal and laryngeal resistance. On exhalation, the intrathoracic and extrathoracic resistances are about even.[2]

STABILIZING THE UPPER AIRWAY

The upper airway is designed to prevent collapse on inhalation. The simplest way to prevent a tube from collapsing in response to negative intraluminal pressure is to make the wall rigid. Indeed, for some of its length, the upper airway is rigidly supported by bone and cartilage. In other regions of the airway, such as the external nares, pharynx, and larynx, rigid support by bone or cartilage is incompatible with other functions, such as swallowing and protecting the lower airways. In these regions, the upper airway is supported by muscular activity. Neural reflexes regulate the activity of upper airway dilator muscles.[13-15] On inhalation, these muscles begin to contract just before the diaphragm contracts, and they remain active during inhalation. In this way, the upper airway stiffens before it is exposed to subatmospheric pressures. This phasic activity is finely tuned by pressure- and flow- (temperature-) sensitive receptors in the upper airway that, when stimulated, enhance reflex activation of upper airway dilator muscles. These muscles, then, provide appropriate tension to prevent dynamic collapse of tissues on inhalation.[16,17]

External Upper Airway Support

A nasal strip has been used as an external nasal dilator. It mechanically supports the soft tissue that forms the lateral wall at the narrowest portion of the nasal cavity (nasal valve), located just rostral to the naso-incisive notch. This region is bound medially by the nasal septum, ventrally by the concha, and dorsolaterally by the skin and dorsal conchal fold. The strip consists of three polyester springs sandwiched between two layers of material, and it adheres to the horse's nose. When the strip is applied, endoscopic examination shows that the strip dilates the nasal valve region.[11] Furthermore, in exercising horses, the nasal strip decreases inspiratory impedance.[11] Interestingly, the nasal strip also decreases the severity of exercise-induced pulmonary hemorrhage (EIPH).[18,19] These findings suggest that in exercising horses, the nasal strip reduces upper airway tissue collapse on inhalation. This would result in decreased inspiratory impedance during exercise, and less-negative inspiratory pressures. Less-negative inspiratory pressure may reduce the transmural pulmonary capillary pressure. Because excessive transmural pulmonary capillary pressure is responsible for EIPH, reduction in this pressure very likely accounts for the observed decrease in the severity of EIPH.[20,21]

Head Position

Horses are often required to exercise with their heads and necks in unnatural positions. For example, Standardbred horses are raced with an overcheck, which forces the head and neck into extension. Sport horses, such as dressage horses, commonly exercise with head and neck flexed. Head and neck position significantly affects upper airway impedance.[22] In resting horses that are holding their heads in a natural position, the air entering the upper airway turns approximately 90 degrees to flow from the nasal passages into the trachea. This change in direction contributes to the work of breathing. Normally, horses straighten their head and neck during exercise. When the horse's head and neck are flexed, upper airway impedance during exercise is about 50% greater than that of a horse exercising with head and neck in the extended position.[22]

Straightening of the head and neck not only provides a more direct route to the lung, it also tends to stretch upper airway tissues, making them more rigid and resistant to collapse. It stands to reason, therefore, that dynamic upper airway obstructions, especially those involving the pharynx, are often more apparent when affected horses are exercised with a flexed head and neck position.[23]

External Nares

The external nares of the horse are very mobile and can completely close the upper airway (as occurs during swimming) or fully dilate it (e.g., during intense exercise). The external nares and adjacent nasal valve are among the narrowest portions of the upper airway; therefore, lesions in this region significantly affect performance.[24] The dilator muscles of the external nares, such as the *M. dilator naris late*ralis and the *M. transversus nasi*, are innervated by the facial nerve, and horses with facial nerve dysfunction have marked inspiratory airway obstruction during exercise.

Nasal Turbinate Region

The nasal turbinate region has convoluted conchae that encourage particle deposition and conditioning of the inspired air. This portion of the upper airway is rigidly supported by cartilage and bone. However, marked changes in airway caliber are possible even in this bone- and cartilage-supported region. The upper airway is lined by mucosa that contains vascular sinuses. The purpose of this extensive vasculature is thermoregulation and humidification of inhaled air. These vessels are potentially very large and have the ability to fill with blood, thickening the upper airway mucosa to the point of occlusion. Normally, the size of capacitance vessels is kept small by tonic sympathetic innervation. During exercise, the sympathetic tone increases, capacitance vessels are constricted, and the airway diameter is increased.[25] Injury to the sympathetic trunk innervating this region—for example, in Horner's syndrome—can cause complete nasal occlusion of the affected side. Unilateral airway obstruction is often the longest-lasting condition associated with Horner's syndrome, and it causes significant exercise intolerance. Nasal vascular engorgement also has been identified as

a cause of airway obstruction in horses recovering from general anesthesia after removal of the orotracheal tube. This obstruction is sufficiently severe to cause hypoventilation and hypoxemia. Phenylephrine, an α-adrenoceptor, can be used to decrease nasal vascular engorgement after anesthesia to prevent upper airway obstruction in these horses.[26]

Nasopharynx

The nasopharynx participates in swallowing as well as breathing, and it must be able to constrict to propel a bolus of food into the esophagus and to dilate during exercise to allow unimpeded airflow to and from the lung. These functions are achieved by muscles that are uniquely positioned so that, as a group, they can both constrict and dilate the pharynx.[27-29] In the horse, the exact functions of these muscles are incompletely understood, but from studies in horses and in other species, a general picture is emerging.

The hyoid apparatus is a very important structure that supports the pharynx as well as the root of the tongue and the larynx. The muscles of the hyoid apparatus dilate the pharynx by contracting on inhalation in the following manner. The geniohyoid and genioglossus muscles pull rostrally and ventrally, whereas the sternohyoid and sternothyroid muscles pull in a caudal ventral direction. The net effect is extension of the stylohyoid-ceratohyoid articulation, a ventral movement of the hyoid bone, and nasopharyngeal stabilization or even dilation (Figure 41-4). One of the recommended surgeries for dorsal displacement of the soft palate is sectioning of the sternohyoid and sternothyroid muscles.[30,31] The objective of this surgery is to move the epiglottis craniad, thereby better engaging the soft palate. From the aforementioned discussion, it is clear that sectioning of the sternohyoid and sternothyroid muscles prevents pharyngeal dilation and may encourage pharyngeal collapse. Indeed, measurements in exercising horses have indicated that sternohyoid and sternothyroid muscle sectioning slightly increases upper airway resistance in exercising horses.[32]

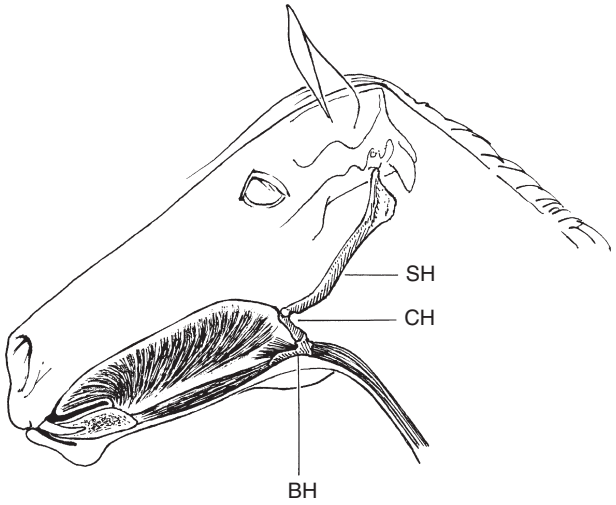

Figure 41-4. The hyoid apparatus and the pharynx. The hyoid apparatus is made up of the stylohyoid *(SH)*, the ceratohyoid *(CH)*, and the basihyoid *(BH)* bones. Contraction of the geniohyoid and sternohyoid muscles stabilizes the hyoid apparatus and the pharynx.

In racehorses, the tongue is often pulled forward and tied down to the mandible to prevent dorsal displacement of the soft palate. The tongue is attached to the hyoid bone via the genioglossus and hyoglossus muscles. Therefore, it is possible that the tongue-tie could dilate the pharynx. However, upper airway flow mechanics and computed tomographic studies have indicated that, in normal horses, the tongue-tie does not pull the hyoid apparatus forward and does not dilate the pharynx.[33,34] In horses with DDSP, the use of a tongue-tie may prevent the condition in individual horses although it is not effective in the majority.[35] Where DDSP is not prevented, application of a tongue-tie does not improve ventilation.[35]

The dorsal pharyngeal wall is supported by the stylopharyngeus muscles. These muscles insert on the dorsal nasopharyngeal wall, perpendicular to it, so that contraction of the stylopharyngeus muscles raises the wall of the dorsal nasopharynx, expanding, supporting, and preventing its collapse as pressures within the airway become more negative during inspiration (Figure 41-5). Blockade of cranial nerve (CN) IX, which innervates these muscles, results in dorsal pharyngeal collapse and inspiratory airway obstruction during exercise.[36]

The upper airway is richly endowed with receptors that, when stimulated, activate upper airway dilator muscles, thereby stiffening the upper airway. For example, when the laryngeal mucosa is anesthetized, exercising horses have nasopharyngeal collapse and upper airway obstruction.[37] During nasal occlusion, these horses can also experience DDSP. This demonstrates that, in exercising horses, sensory and motor functions must be fully coordinated to maintain upper airway patency. The message to the surgeon is that the upper airway is a finely tuned instrument that can be easily disturbed by disease or surgical intervention.

Soft Palate

The soft palate is another upper airway structure with multiple functions. It separates the nasopharynx from the oral pharynx and forms a tight seal around the larynx during breathing. However, during swallowing, the soft palate is elevated and closes the posterior nares, protecting the nasal passages from food and water. The position of the soft palate is determined by four muscles: the *M. tensor veli palatini*, *M. levator veli palatini*, *M. palatinus*, and *M. palatopharyngeus*.[38] Dysfunction of the *M tensor veli palatini* destabilizes the cranial portion of the soft palate closest to the hard palate. In affected horses, the cranial portion of the soft palate bulges into the nasopharynx on inhalation.[39] The pharyngeal branch of the vagus nerve innervates all of the muscles controlling the soft palate, except for the *M. tensor veli palatini*. Blockade of this nerve with a local anesthetic agent results in dorsal displacement of the soft palate.[40] This demonstrates that coordinated activity of these muscles is necessary to stabilize the soft palate during breathing. The pharyngeal branch of the vagus nerve courses through the guttural pouch and lies in close proximity to the retropharyngeal lymph nodes. It is thought that in clinical cases, dorsal displacement of the soft palate is the result of a functional abnormality of this nerve because of retropharyngeal lymph node or guttural pouch inflammation.

Most upper airway conditions cause inspiratory airway obstruction, and expiratory airflow is unaffected. Dorsal displacement of the soft palate is an exception to this rule, since it is an expiratory obstruction. During exhalation, the paralyzed

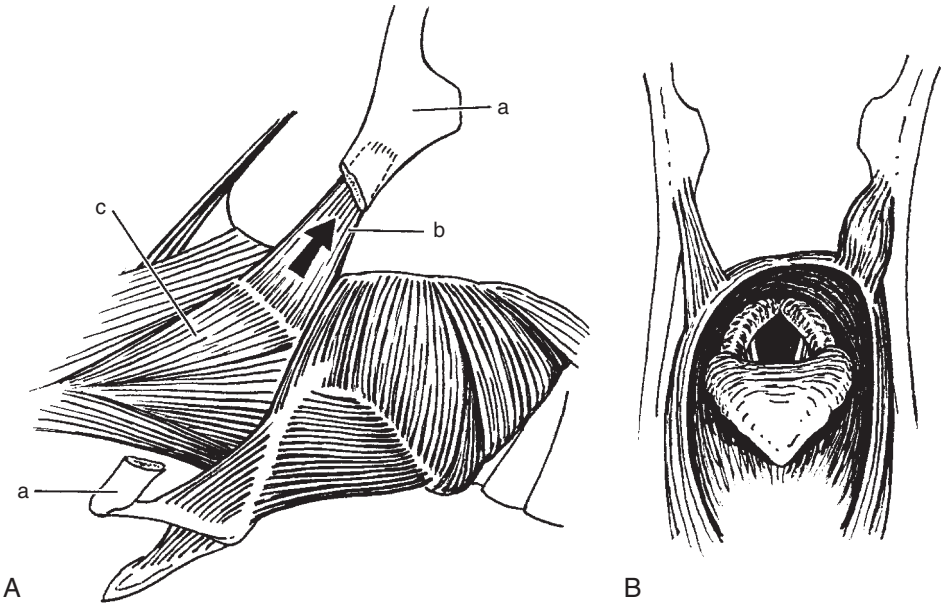

Figure 41-5. A, The stylopharyngeus muscle originates on the stylohyoid bone *(a),* and broadly inserts on the dorsal pharyngeal wall. Contraction of the stylopharyngeus muscle *(b)* stabilizes and dilates the dorsal pharynx during exercise. *c,* Palatopharyngeus muscle. **B,** Note the difference in size of the left and right dorsal pharynx when the stylopharyngeus muscle contracts unilaterally.

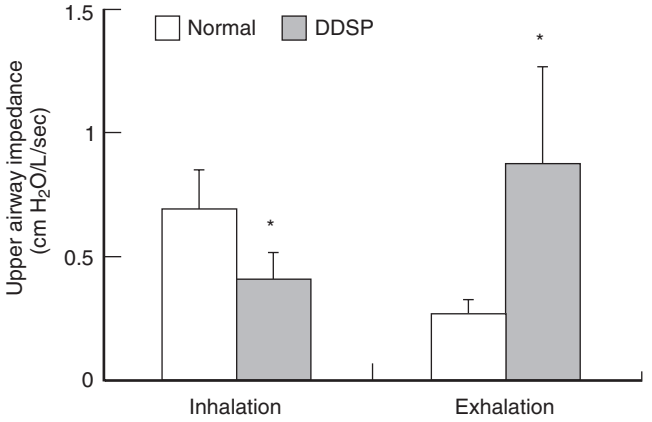

Figure 41-6. Upper airway impedance in intensely exercising horses before and after experimentally induced dorsal displacement of the soft palate. Note that expiratory impedance is increased, whereas inspiratory impedance is decreased. *DDSP,* Dorsal displacement of the soft palate; *, significantly different from normal ($p \leq 0.05$).

soft palate billows dorsally into the nasopharynx, markedly obstructing airflow and causing airway obstruction (Figure 41-6).[40]

Larynx

In the course of deglutition, the larynx functions as a very important guard, preventing food and water from entering the trachea. During swallowing, the arytenoid cartilages adduct completely, and the epiglottis pivots around its base so that the tip of the epiglottis moves dorsad and caudad. These maneuvers close the rima glottidis and prevent aspiration. Of course, during exercise the larynx must be opened maximally to allow unimpeded airflow. The larynx is one of the narrowest portions of the upper airway, and consequently lesions in this region cause significant airway obstruction. A good example of this is recurrent laryngeal neuropathy, also known as idiopathic laryngeal hemiplegia. In this condition, dysfunction of the left recurrent laryngeal nerve prevents appropriate contraction of the *M. cricoarytenoideus dorsalis*, which fails to abduct the arytenoid cartilage during inhalation.[41,42] In affected resting horses, pressure changes are insufficient to move the affected arytenoid cartilage and vocal fold into the airway lumen. On exhalation, positive pressures in the upper airway move the affected arytenoid cartilage abaxially, increasing airway caliber. However, on inhalation during exercise, luminal pressures are sufficiently negative to move the affected arytenoid cartilage and associated vocal fold into the airway, causing significant obstruction. The objective of surgical intervention in horses with recurrent laryngeal neuropathy is to prevent dynamic collapse of the affected arytenoid cartilage. In these cases, prosthetic laryngoplasty is effective because the procedure stabilizes the affected arytenoid cartilage, preventing dynamic collapse. An example of a surgical procedure that is ineffective because it fails to adhere to this principle is subtotal arytenoidectomy.[43] In this procedure, only the body of the arytenoid cartilage is removed, while the muscular process and the corniculate cartilage are left in place to help prevent postsurgical aspiration. However, during exercise the unsupported cartilage moves axially and obstructs the rima glottidis.[43]

As mentioned earlier, during swallowing, the epiglottis pivots around its base, protecting the trachea. However, during breathing and especially during exercise, the epiglottis must be stabilized. This is the function of the *M. hyoepiglotticus*, which originates on the basihyoid bone and inserts on the base of the epiglottis. When the *M. hyoepiglotticus* contracts, the epiglottis is pulled ventrad toward the base of the tongue, stabilizing the epiglottis. The *M. hyoepiglotticus* is innervated by the hypoglossal nerves, and bilateral blockade of this nerve results in epiglottic retroversion during inhalation in exercising horses.[44,45] Clinical cases of epiglottic retroversion have been described and probably are the result of disease interfering with neuromuscular control of upper airway dilator muscles, specifically the *M. hyoepiglotticus*.[46]

MEASUREMENT OF UPPER AIRWAY FUNCTION

Thus it is clear that the upper airway has often-competing functions, that small perturbations in function may cause significant airway obstruction, and that, for the surgeon, tolerance for error is small. Quantitative measurements of upper airway function help determine the effect of a particular condition on upper airway flow mechanics and the efficacy of surgical treatment. The best way to ensure that a surgical procedure is efficacious is to use quantitative methods of evaluation. The simplest method of evaluating upper airway flow mechanics is to measure the pressure needed to move air through the upper airway while the horse is undergoing a standard exercise test. Airway pressures may be measured using a multiple-hole catheter inserted into the trachea via the nostrils or percutaneously.[47] When airway pressures and airflow rates are measured simultaneously, upper airway impedance can be calculated as the ratio of pressure and flow.[7] Measurement of impedance provides a more direct evaluation of changes in airway caliber than pressure measurements alone. Pressure and flow measurements have been used to determine the efficacy of many surgical procedures used in the treatment of upper airway conditions, such as recurrent laryngeal neuropathy and DDSP.[40,48,49]

Quantitative information may also be gained from analysis of airflow rates during the respiratory cycle. Flow-volume loop analysis is a test in which airflow rate is continuously plotted against breath volume. This test is particularly useful when performed in exercising horses, and in some instances it is more sensitive than the measurement of upper airway impedance in the evaluation of upper airway function (Figure 41-7).[8,50]

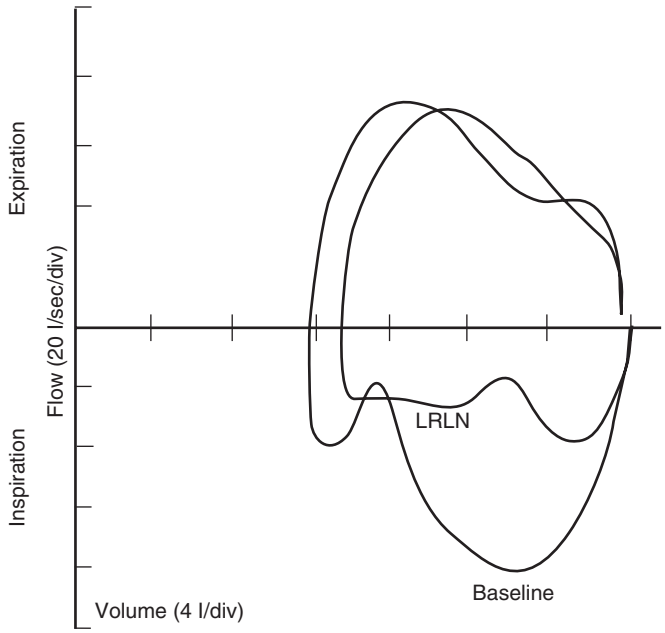

Figure 41-7. Tidal breathing flow-volume loop from a horse exercising at maximal heart rate before *(Baseline)* and after induction of laryngeal hemiplegia *(LRLN).* Note that expiration is unaffected, but there is severe inspiratory flow limitation with LRLN throughout the inspiratory portion of the tidal volume.

CHAPTER
42 Diagnostic Techniques in Equine Upper Respiratory Tract Disease

Eric J. Parente, Samantha H. Franklin, Frederik J. Derksen, Michael A. Weishaupt, Heather J. Chalmers, and Caroline Tessier

PHYSICAL EXAMINATION

Eric J. Parente

Although a large portion of the upper respiratory tract is not easily seen or palpated, a thorough physical examination can provide critical details that assist in the overall assessment of the upper respiratory tract. A physical examination is an essential part of any evaluation, and it cannot only provide information on present pathology but also give clues on previous surgical procedures. Prior to beginning the examination, a complete history should be obtained. Specific questions should be asked about respiratory noise, dysphagia, exercise intolerance, coughing, nasal discharge, and any previous treatments or surgery. All of this information should be interpreted in conjunction with the physical examination findings and the results of the other diagnostic procedures to establish a diagnosis.

The physical examination should begin with visual assessment of any asymmetry of the head and nares and inspection for the presence of any nasal or ocular discharge. Facial deformity in front of the eye is consistent with either primary or secondary sinus disease. This may also have an associated nasal discharge via the nasomaxillary opening, or ocular discharge from occlusion of the nasolacrimal duct. More chronic sinus disease may result in nasal passage obstruction. Placing a hand in front of each nostril will provide a crude indication of airflow from each nostril. Subtle changes are very difficult to detect, but an obstructive lesion in one nasal passage may result in significant asymmetric airflow. Percussion of a normal sinus should result in a hollow sound. The presence of an abnormal structure in the sinus can change the character and intensity of the sound, but this is dependent on many factors and can often be misinterpreted. Nostril disease is rare, but palpation of each nostril and the alar folds in the dorsal aspect of the nares can often determine if a problem is present. If alar fold redundancy and obstruction during exercise is suspected, the alar folds can be tied with umbilical tape over the bridge of the nose during an exercise period. Mitigation of noise confirms the diagnosis.

Palpation of the larynx can be a difficult skill to develop, but when mastered it can be very helpful in assessing laryngeal function. An assistant should hold the horse's head slightly

elevated. The clinician can stabilize the right side of the larynx with one hand and palpate the left side of the larynx with the other hand. Then, by alternating hands, both sides of the larynx can be compared. The muscular processes of the larynx are in a fairly dorsal position and are slightly smaller than a person's knuckle. The caudal border is attached to the *cricoarytenoideus dorsalis* muscle, and when atrophy of the muscle is present, the muscular process feels more prominent than on the other side. Mild asymmetry is a common finding in horses with normal laryngeal function, but more overt asymmetry is usually consistent with the horse's inability to maintain abduction of the affected arytenoid cartilage. If the left muscular process cannot be easily palpated, it may be covered by scar tissue from a previous laryngoplasty or the arytenoid cartilage may be chondritic. A scar from previous laryngoplasty is not easily palpated at the level of the skin, and therefore it cannot be used to definitively determine if surgery was performed previously. Clipping the hair ventral to the linguofacial vein will make it easier to detect a scar if surgery was performed. If the right muscular process cannot be palpated easily, the arytenoid cartilage may be chondritic or a fourth branchial arch abnormality may be present.[1] Infrequently, stertorous breathing can be elicited with firm palpation of the larynx, and this may indicate some inability of the horse to maintain an adequate lumen from such conditions as severe arytenoid chondrosis, bilateral arytenoid paresis, or a combination of both.

Other common sites for respiratory surgery should be evaluated during the examination. Previous surgery involving a laryngotomy will often leave a palpable scar. The skin ventral to the larynx should be palpated for a scar by pinching the skin below the larynx. Often a fibrous band forms between the skin and larynx that can be palpated when drawing your fingers like a rake across the skin in this area. The accessory respiratory muscles (sternothyrohyoideus) should be examined for any sign of a defect secondary to a myectomy, and the tracheal rings should be palpated for any abnormalities associated with trauma or previous surgery.

ENDOSCOPIC EVALUATION

Videoendoscopic Examination at Rest

The endoscopic examination of the upper airway is still the primary diagnostic tool. Most diagnoses can be obtained from a complete resting endoscopic examination. Videoendoscopic equipment has been commercially available for over twenty years and provides the best view of the upper airway. Several large companies produce videoendoscopes with similar specifications, and user preference and cost often determines which system is purchased. The main components of a videoendoscopy system consist of the videoendoscope itself, the video processor, the light source, and the video monitor. A videoendoscope with an outer diameter of less than 9.5 mm can be used easily on all adult horses and most foals. Smaller videoendoscopes with an outer diameter of less than 8.5 mm are also available for younger foals, but the tradeoff is a smaller biopsy channel (2.2 mm versus 2.8 mm). Most videoendoscopes have a field of view of 120 degrees and tip deflection angles of 210 degrees to 90 degrees. The working length for most videoendoscopes is approximately 103 cm (40½ inches), which is ample for upper respiratory work. Light sources are fairly standard xenon lamps with illumination of 300 watts. Fiberoptic endoscopes typically have only half the illumination of the videoendoscopes and a much smaller field of view, which significantly limits the clinician's ability to clearly view all abnormalities.

Image storage is crucial for documentation and reevaluations. It is therefore beneficial to have a recording unit and/or printer with any videoendoscopic system. Multiple digital formats are now available and the most important consideration is compatibility with viewing and editing systems.

Like any examination, the clinician should have a plan of how and what to evaluate during the examination. The patient should not be sedated and should only be restrained with a twitch to ensure no interference with any functional assessments of the airway. It is easiest to have an assistant pass the endoscope down the ventral meatus of one nostril until the tip of the endoscope enters the pharynx. The pharynx and larynx should be evaluated first, followed by the evaluation of the nasal passage while backing the endoscope out of the horse's nose. If a suspected abnormality is present in the nasal passage, the normal side should be evaluated first to minimize any trauma or resentment from the horse before evaluating the abnormal side.

There is a variable amount of lymphoid hyperplasia within the pharynx of the horse, depending upon the age. It is common for the younger horse to have more extensive lymphoid hyperplasia than older horses, but it has not been correlated with any specific dysfunctions.[2,3] The epiglottis should always be positioned dorsal to the palate and have a distinct "serrated" edge with a clear vascular pattern on the dorsal surface. The corniculate processes of the arytenoid cartilages should be evaluated for their overall appearance, relative position, and degree of movement. Thickening, ulcerations, or granulation tissue likely indicate chondrosis (Figure 42-1). Inability to fully abduct one arytenoid cartilage relative to the other side indicates recurrent laryngeal neuropathy (RLN). Although multiple grading systems are used, a I to IV grading system for assessing laryngeal movements at rest established by Rakestraw et al[4] is the basis for most systems (see Chapter 45). Grade I refers to symmetric abduction/adduction and synchronous movement. Grade II refers to asynchronous movement but still symmetric abduction/adduction, and abduction can be maintained. Grade III refers to both asynchronous and asymmetric movement, and abduction

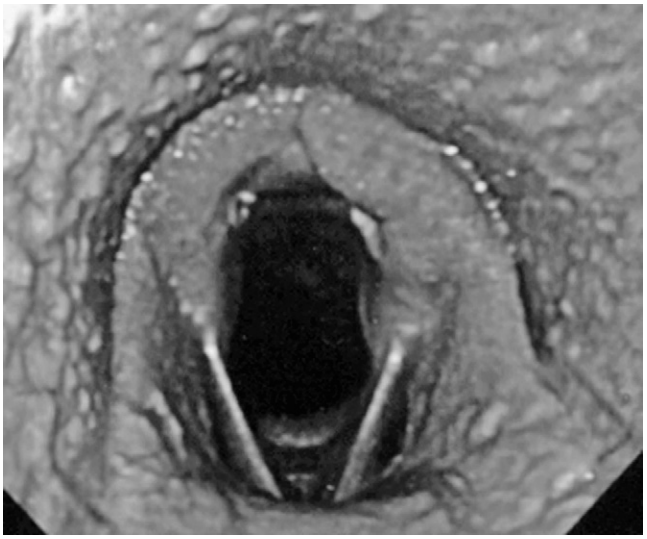

Figure 42-1. Left arytenoid chondritis with a thickened, misshapen corniculate process and incomplete abduction.

cannot be maintained. Grade IV refers to an inability to move one arytenoid hardly at all. Full abduction of the arytenoids should be induced by both swallowing and nasal occlusion. Swallowing will yield only a brief period to evaluate full abduction. Nasal occlusion may result in a longer duration of abduction, but it requires that a horse tolerate nasal occlusion for an extended period of time. Although nasal occlusion can result in negative pharyngeal pressures similar to those experienced by horses during exercise,[5] the degree of abduction after swallowing appears to have a better correlation with the degree of abduction during exercise.[6] Racehorses that are unable to fully abduct one arytenoid (grade III or IV) are much more likely to experience dynamic collapse of that arytenoid during high-speed exercise, but there are exceptions.[7]

Inability to fully adduct one arytenoid may be a result of previous laryngoplasty, and palpation of the larynx and assessing the skin for a surgical scar should help determine the diagnosis. The slap test can be used to induce adduction of the arytenoid cartilages but is not a valuable test to fully evaluate laryngeal function.[8] The vocal cords and saccules should also be examined for any evidence of previous surgery. Incomplete ablation with the laser may yield scarring of the cords, deformation of the cords, or can show an absent cord (Figure 42-2).

The endoscope should be passed into the trachea to determine the presence of any discharge or feed material, indicating aspiration. As the endoscope exits the trachea, it is common for the horse to displace its palate, but a normal horse should replace it quickly. If the horse does not replace its palate quickly, it can be stimulated to swallow by either infusing water into the pharynx or quickly bumping the pharyngeal wall with the endoscope. If the horse still does not replace the palate below the epiglottis, it may indicate some structural abnormality under the epiglottis or some pharyngeal dysfunction that may be best observed during high-speed exercise.[9] If a subepiglottic abnormality is suspected, other imaging techniques may be indicated, but the clinician can also spray the epiglottic region with topical anesthetic through the biopsy channel of the videoendoscope, and then manipulate the epiglottis with a long bronchoesophageal forceps through the contralateral nares to look underneath.

When the examination of the larynx/pharynx is complete, the remainder of the upper respiratory tract should be examined. The guttural pouch openings should be clear of any discharge. The presence of discharge at the opening of the guttural pouch may be an incidental finding caused by discharge originating from another location and becoming lodged at the opening. The suspicion of any guttural pouch disease warrants further endoscopic evaluation of the guttural pouches. This is most often done at the end of the examination, and may require a small dose of intravenous sedation. Temporohyoid disease can often be seen as an enlargement of the stylohyoid bone at the most dorsal aspect of the guttural pouch (Figure 42-3). The ethmoid recess, turbinates, septum, and region of the nasomaxillary openings (caudal middle meatus) should all be evaluated as the endoscope is slowly withdrawn from the nostril. Discharge running down the ventral turbinate, with material exiting the nasomaxillary opening, is often a sign of sinus disease. Both nasal passages should be evaluated if there is any suspicion of a sinus or nasal passage problem. It is often difficult to discern small deviations in the nasal passage because the endoscopic view provides a very magnified but small field of view. Radiographs are a helpful complementary procedure if septal deviation, or some type of sinus disease, is suspected.

Videoendoscopic Examination during Treadmill Exercise

Although a great deal of information can be gained from endoscopy in the resting horse, there are many occasions when a functional abnormality is suspected (e.g., because of exercise intolerance or abnormal respiratory noise during exercise), but no abnormalities are detected during the resting endoscopic examination. Conditions that can lead to this scenario include forms of pharyngeal collapse, axial deviation of the aryepiglottic

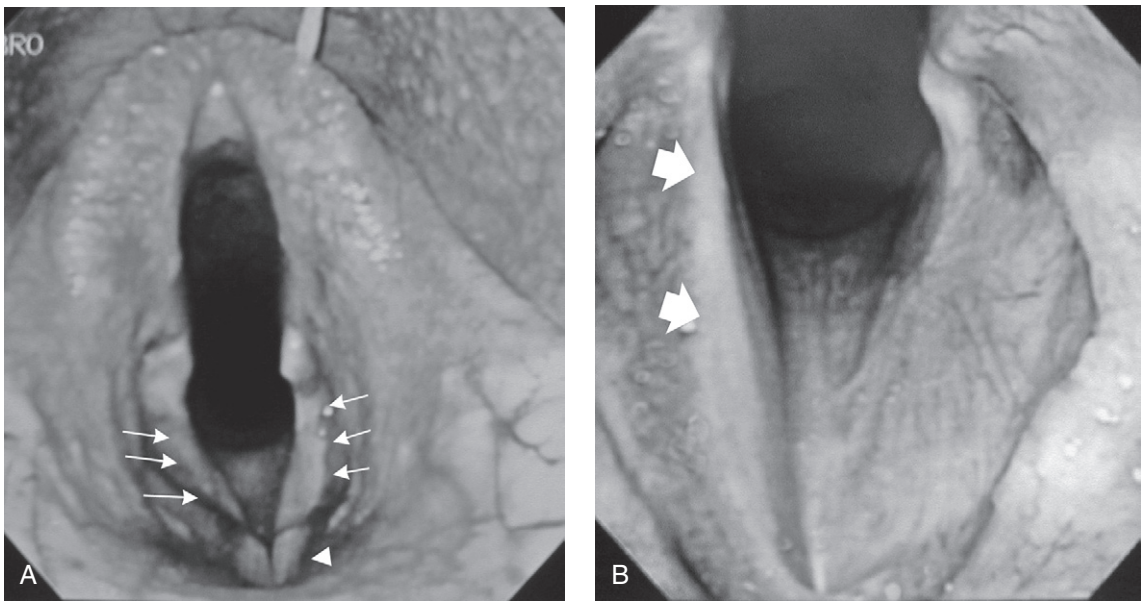

Figure 42-2. A, Scarred vocal cords *(small arrows),* and remaining normal vocal cords ventrally *(arrowhead);* **B,** A close-up videoendoscopic view of the vocal cords. Absent left vocal cord from laser resection. Normal remaining right vocal cord *(arrows).*

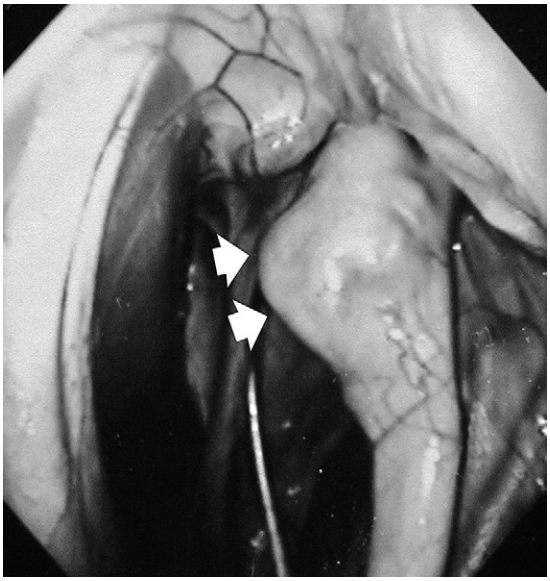

Figure 42-3. Swelling of the stylohyoid bone at the temporohyoid joint within the guttural pouch *(arrows)*.

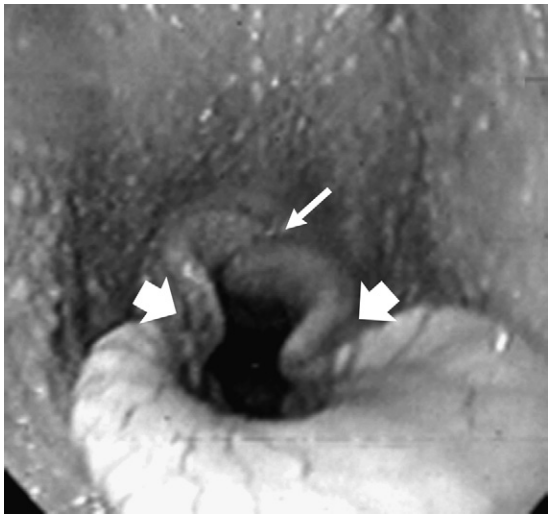

Figure 42-4. Subluxation of the apices of the arytenoid cartilages *(small arrow)* and axial deviation of the aryepiglottic folds *(large arrows)* induced during high-speed treadmill exercise only after increasing head/neck flexion. The larynx was normal without head/neck flexion.

folds, epiglottic retroversion, intermittent epiglottic entrapment, and dorsal displacement of the soft palate (DDSP). Endoscopic examination immediately after exercise may be valuable in some cases, but it can be misleading. Even normal horses have a much more flaccid-looking upper airway and displace more easily when first pulling up after exercise. Therefore, any conclusion based on a post-exercise endoscopic examination, particularly with respect to the functional stability of the pharynx, may be inaccurate.

Accurate conclusions from a "high-speed endoscopic examination" on a treadmill cannot be made from simply performing endoscopy while a horse is running without specifying exertional effort. It is critical to have the exercising conditions simulate the horse's normal working conditions as closely as possible. In the lower respiratory tract, the effects of running a longer distance at a slower speed are not equivalent to the effects of running a shorter distance at a faster speed.[10] This may also be the case in the upper respiratory tract. Furthermore, some of the upper respiratory problems are not only dynamic but also occur intermittently, and if all the same conditions of speed, head/neck flexion, fatigue, and so on are not reproduced, a false negative outcome is likely to result (Figure 42-4). A Holter monitor can be employed to record the horse's heart rate during exercise, and rates of approximately 220 beats/minute or greater, provide evidence that the horse is exercising at or near its maximum heart rate. Of the known upper respiratory abnormalities, DDSP is the most likely disease that will not be reproduced on a high-speed treadmill examination despite circumstantial evidence of the condition under field conditions.

Horses that will be examined by treadmill endoscopy must be as fit as they are for competition. A horse out of work may be too unfit to withstand a maximal exertional effort on the treadmill, and the problem to be diagnosed may not manifest itself. All horses must first be acclimatized to the treadmill before attempting an actual test. This can usually be accomplished with 1 to 2 hours of schooling, taking the horses through the different gaits, and making sure they can obtain adequate speed. During the schooling and testing periods, protective boots and leg wraps are recommended. Hobbles and harness are always recommended for pacing Standardbreds and are applied during the schooling period. The horse must be in condition and prepared for the examination as if it were the date of a competition or race.

The treadmill must be capable of obtaining a speed of at least 14 m/sec with relatively rapid acceleration and deceleration potential for any examinations of racehorses. Padded rails with polycarbonate sides, or an equivalent material, should be present to maintain the animal's position on the belt and protect individuals on either side of the treadmill. Large overhead fans in a temperature-controlled environment are also required. Sweat evaporation is the horse's primary form of body temperature regulation. Under racing conditions, the animal creates its own breeze to enhance evaporation; however, on the treadmill, the horse is stationary, and fans are required to prevent overheating. Two people, holding ropes that are attached to both sides of horse's halter, keep the horse centered on the treadmill. An individual behind the horse encourages the horse forward, and another person closely monitors the horse's gait, and controls the treadmill speed, ensuring the horse's position on the treadmill. One final person is needed to guide the endoscope during the examination (Figure 42-5). For safety reasons, and to ensure a valid test, it is extremely important that the team of individuals carrying out the examination is experienced. The specific protocol used depends on the type of competition the horse is normally engaged in and should mimic these circumstances as much as possible. Generally, after an initial warm-up period, the treadmill is stopped, the endoscope is passed via the right nostril into the pharynx, and its position is maintained by Velcro straps connecting the shaft of the endoscope and the noseband of the horse's halter (Figure 42-6). A typical exercise protocol for the Thoroughbred racehorse is as follows:

- Warm up through a combination of walk/trot/canter for 2000 meters.
- Walk again until heart rate is 80 to 90, stop, and pass the endoscope.

Figure 42-5. Horse during high-speed treadmill endoscopy.

Figure 42-6. The videoendoscope *(black arrow)* is being held in position up the horse's right nostril by a Velcro strip taped to the scope and then attached to the noseband of the halter *(white arrow).*

- Accelerate to 9 m/sec (incline treadmill to 3 degrees for Thoroughbreds).
- Accelerate to 11 m/sec for 400 meters.
- Accelerate to 12 m/sec for 400 meters.
- Accelerate to 14 m/sec for 1600 meters.
- Decelerate to 12 m/sec for 400 meters.

Most horses suffering from a poor performance problem are unable to meet the demands of this protocol. Such horses should be exercised at their own maximal exertional effort. Determination of maximum effort is a subjective assessment by the clinician in conjunction with heart rate evaluation.

Figure 42-7. Overground endoscopy performed on a racehorse exercising on the gallops. (Courtesy John Periam.)

Recording the entire endoscopic examination and reviewing it on slow-motion playback is sometimes necessary because most abnormalities occur rapidly within the respiratory cycle. Occasionally, stimulating a swallow with water through the endoscope or altering the speed of the treadmill during the test will induce the dynamic respiratory problem.

Videoendoscopic Examination during Overground Exercise

Samantha H. Franklin

Videoendoscopy during treadmill exercise enables the diagnosis of dynamic upper airway collapse in horses where resting findings are frequently unreliable or absent. However, there remains much reluctance among trainers and owners to present horses for treadmill evaluations and hence many horses still have a diagnosis made on the basis of clinical history and resting endoscopic findings alone. The reasons for this may include the need to travel long distances to a specialist center, the cost of the procedure and concerns regarding the risk of injury. Very little data are available regarding the risk of injury during treadmill exercise. However, a recent study of 2305 horses from nine different centers in the United Kingdom and Europe suggests that injury rates are no greater than those incurred during strenuous exercise, including racing and eventing, with only 13 (0.6%) horses incurring significant injuries.[11] However, horses that are presented for investigation of poor performance may have underlying or sublinical musculoskeletal disease that is contributing to their suboptimal performance.[12,13] This may be exacerbated during a strenuous exercise test, irrespective of whether this is performed on the treadmill or in the field. Therefore, examination of the musculoskeletal system is recommended prior to exercise testing to rule out any pre-existing lesions.

The need for a system that enables videoendoscopy to be performed in the horse's natural environment has led to the recent development of overground endoscopy (Figure 42-7).[14] This technique is well tolerated by horses and enables a definitive diagnosis of upper respiratory tract (URT) collapse to be made during ridden exercise.[14-18] Advantages of performing field exercise tests include the ability to perform the examination in

the environment in which the horse trains and is likely to be used in competition. This enables external factors to be standardized including jockey, equipment, and ground conditions that cannot necessarily be replicated during treadmill exercise.[19] In addition, there is no need for training sessions and horses do not need to travel such long distances to be examined, thereby reducing both the time and costs involved.

Several commercial systems are now available or are in the final stages of development. These systems incorporate a CCD video chip into an insertion tube of varying length. Some systems are mounted on the horse's head, and others have a longer tube with the processor, telemetry unit, battery pack, and recording equipment mounted either in a saddle pack or in a backpack worn by the jockey. The video image is transmitted wirelessly for real-time viewing by the veterinarian. The transmission distance varies among systems but currently appears to be in the range of 150 to 1000 m. However, the signal relies on line of sight and hence may be lost where obstacles come between the horse and the viewer. Interference may also occur as a result of other electronic equipment or because of reflection of some stray signals off solid surfaces, for example when used in an indoor arena. In addition, legal restrictions for wireless video transmission are likely to limit the transmission distance in some countries. Therefore, most systems also incorporate a recording system on the horse, whereby images are recorded onto a digital recorder or secure digital (SD) card and reviewed after completion of the test.

Factors to Consider when Choosing Equipment

EASE OF USE AND SAFETY

The system should be easy to apply, should stay in place during the examination, and should not provide a safety hazard for horse, rider, and equipment.

QUALITY OF THE IMAGE

This is determined by a combination of the CCD camera chip and lighting. Most systems use LED lighting at the endoscope, which enables miniaturization of the system by negating the need for an external light source. However, the illumination is considerably lower than that of light sources that are used with standard hospital-based videoendoscopes.

ABILITY TO FLUSH THE ENDOSCOPE DURING EXERCISE

The majority of horses have some mucus within the upper airways during exercise. This emanates from the trachea and may be increased in horses with lower airway disease. In many cases, mucus is cleared from the endoscope tip by the passage of air through the nasal passages at high flow rates during expiration. However, where mucus becomes lodged at the tip, this may significantly impair the image. In these instances it may be necessary to flush the endoscope tip with air and/or water. Ideally a system should enable flushing "on demand" by telemetry and care should be taken in interpreting clinical findings that coincide with flushing, such as swallowing or episodes of DDSP that may be induced by the presence of water within the nasopharynx.

ABILITY TO VIEW THE IMAGE IN REAL TIME: TELEMETRY DISTANCE

The ability to view the endoscopic image in real time is important (1) to ensure a diagnostic image is obtained and (2) to identify the timing of events that may occur during the exercise test. In particular, the muscles associated with the nasopharynx relax as the horse slows, which may result in pharyngeal wall collapse and/or palatal instability and displacement of the soft palate at this time, despite functioning normally during strenuous exercise. Also, dynamic airway collapse may be induced or exacerbated by other external factors including poll flexion, whether the horse is pulling hard, or whether the mouth is open.[20] It is important to be able to correlate this information to make appropriate judgments regarding treatment.

It is now possible to measure additional parameters (including speed, distance, and heart rate) during the exercise test using global positioning (GPS) and heart rate monitoring systems.[16,21-23] It would be beneficial to superimpose such data with the endoscopic image to identify the timing of events within the upper respiratory tract.

ABILITY TO VIEW THE IMAGE IN SLOW MOTION AFTER THE EXERCISE TEST

This is important because dynamic changes occur rapidly during strenuous exercise when the breathing frequency is in the region of 120 breaths per minute. It is therefore possible to miss subtle forms of dynamic collapse unless the recording is viewed in slow motion or on a frame-by-frame basis.

Setting up the Equipment and Positioning the Endoscope

Application of the equipment is best performed in a quiet environment (e.g., in a stable) rather than in the arena or start of the gallops, where horses are likely to be more excitable. As for resting endoscopy, passage of the endoscope is via the ventral meatus and is usually straightforward in the majority of horses with or without the use of a nose-twitch. It is useful to have an assistant hold the viewing screen while the scope is being positioned to visualise the nasal passages. The ability to move the endoscope tip is important for accurate positioning. However, in the majority of cases, when the position is set, there is little need to alter it during exercise.

Positioning of the tip of the endoscope (whether for treadmill or field-based endoscopy) is critical. If the endoscope is positioned too far rostrally, it may be difficult to observe all of the structures associated with the larynx (e.g., the vocal cords) and beyond (e.g., the cricotracheal membrane). This is particularly evident if lighting is suboptimal or if there is pharyngeal collapse that obscures the view of the larynx. However, if the endoscope is positioned too close to the larynx, it may not be possible to identify the presence of pharyngeal wall collapse or palatal instability. Ideally, the endoscope should be positioned so that the tip of the epiglottis is clearly visible (Figure 42-8). However, in some horses it may be necessary to readjust the endoscope and repeat the exercise test to visualise different parts of the upper airway.

Exercise Testing

The type of exercise test performed is crucial in enabling an accurate diagnosis of dynamic airway obstruction to be made. In cases where horses make obvious respiratory noise during training conditions, a diagnosis should be straightforward. However, for investigation of those cases, which make

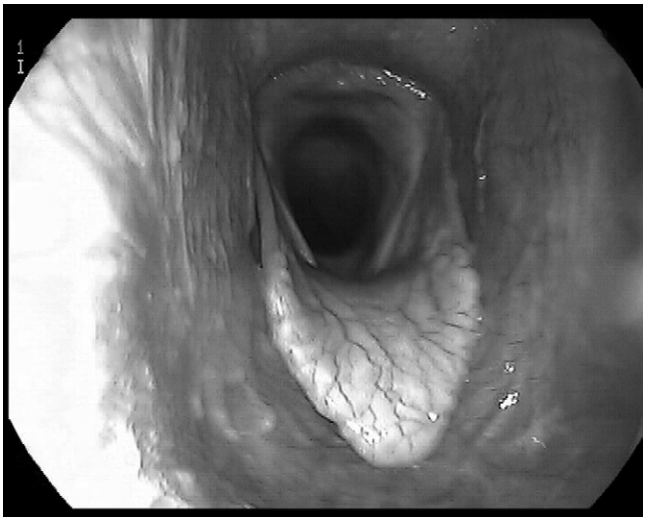

Figure 42-8. Optimal positioning of the endoscope for visualization of the pharynx and larynx during exercise. The tip of the epiglottis and caudal aspect of the soft palate should be clearly visible.

Figure 42-9. Cavison-mounted microphone used to record respiratory sounds in exercising horses.

abnormal respiratory noise only during competition or racing, it is essential to replicate the conditions encountered during competition. This also applies to those horses that present with poor performance and a history of "stopping" in races that are not reported to make abnormal respiratory noise. If the clinical signs reported during competition are not replicated, false-negative findings may occur.

Several studies have compared treadmill and overground endoscopy.[18,23] In pleasure horses, it was found that pharyngeal collapse was more readily diagnosed during overground endoscopy compared with treadmill endoscopy.[18] This is likely because of factors, including enforced poll flexion, that frequently predispose horses to develop dynamic airway collapse.[20,24,25] Changes in poll flexion are easier to recreate during ridden exercise, although it is possible to induce changes in poll flexion during treadmill exercise.[26,27] In racehorses, however, it was found that in some cases, palatal dysfunction and DDSP were easier to recreate on the treadmill than at the track.[8,28] Reasons for this may include a reluctance or inability to exercise horses to fatigue during field testing. DDSP predominantly occurs during the latter stages of a race as the horse starts to fatigue. It has been shown that DDSP is more likely to be observed in horses that undertake longer exercise tests and that tests on circular gallops are preferable to those performed in intervals on short gallops.[28] During treadmill exercise testing, horses are routinely run to the point of fatigue, and therefore there may be circumstances where treadmill assessment of poor performance is preferable. Treadmill exercise tests also have the advantages of being easier to standardize than field exercise tests[23,28] and enable the concurrent measurements of respiratory parameters that cannot currently be performed in the field.[19]

Nevertheless, it is likely that the technique of overground endoscopy will revolutionize the way dynamic airway collapse is diagnosed, thereby enabling a definitive diagnosis to be established in more horses. It also has the potential to facilitate further research into the pathogenesis of upper respiratory tract obstructions.

SOUND ANALYSIS

Frederik J. Derksen

Horses with upper airway conditions often have exercise intolerance and make a respiratory noise. Although reduced performance may be caused by dysfunction of many body systems, respiratory noise during exercise is a specific indication of upper airway disease. Furthermore, in sport horses, the respiratory noise associated with an upper airway condition is often more worrisome to the owner than reduced performance.

One cannot hear respiratory noises in exercising horses very well. Even the jockey, driver, or rider, who is nearest to the source of the noise most of the time, does not hear respiratory sounds well because the noise is obscured by other sounds associated with exercise, such as wind noise and footfall. At best, a listener standing near the track gets "a snapshot" of the noise. Also, respiratory sounds do not always occur throughout the exercise period. In some instances, the sounds are more obvious at maximum exercise, but in other cases the sounds are intermittent, or occur as the horse is finishing the exercise. For these reasons, recording of respiratory sounds in exercising horses is advantageous, and it also permits analysis after the recording. Recording of respiratory sounds in exercising horses is simple and inexpensive and requires minimal equipment. The sounds can be recorded throughout the exercise period, in the field, and under conditions in which the horse normally works. This gives the veterinarian complete and verifiable information about the respiratory noise.

Evaluation of respiratory sound during exercise is also useful in the assessment of effectiveness of surgical procedures used in the treatment of upper airway conditions.[29,30] In many horses with upper airway conditions, the primary objective of surgery is to reduce the respiratory noise. In these cases, evaluation of sound production before and after surgery is a good way to determine surgical success.

Methodology

Although several methods are described in the literature,[31-35] I record respiratory sounds in exercising horses in the following manner.[36] A unidirectional microphone with a cardioid pickup pattern is attached via a flexible wand to a cavison (Figure 42-9).

This type of microphone centers the sound pickup toward the front of the microphone and helps reduce extraneous sounds, such as footfall and track noise, that originate behind and to the side of the microphone. The microphone, covered with a windscreen, is placed equidistant between the horse's nostrils, approximately 4 cm (1½ inches) from the horse's nose. In this way, the microphone is as close to the source of sound to be recorded as possible without being placed in the respiratory air stream. The microphone is attached to an audio recorder with a compression circuit. This kind of recorder automatically adjusts the gain, decreasing the recording of extraneous noises. The advantages of this technique are that it is easily used in the field, and it records respiratory sounds that are also heard by human observers.

Just listening to the audiotape of respiratory sounds made by exercising horses is revealing. The listener can appreciate such factors as respiratory rate and consistency, the number of swallows, the frequency of stride lead changes, and whether abnormal respiratory sounds are present.

Sound can be characterized in terms of time, frequency, and intensity. A sound analysis technique that evaluates these characteristics concurrently is *spectrogram analysis*. A spectrogram is a three-dimensional plot of frequency on the vertical axis, time along the horizontal axis, and sound intensity in the third dimension. Sound intensity is often plotted in terms of color, or relative darkness. This powerful technique has been used commonly to study human voice or biological sounds, such as bird songs, and to evaluate upper respiratory sounds made by exercising horses.[37-40] Spectrogram analysis requires a personal computer and commercially available software. Listening to the audiotape and viewing the spectrogram at the same time is an effective method of evaluating sound.

Upper Airway Sounds in Exercising Horses

In normal exercising horses, most sounds are heard during exhalation and are present throughout this portion of the respiratory cycle (Figure 42-10).[29,30] Inspiratory sounds are less than half as loud as sounds made during exhalation.[29] Sound level increases as speed increases. Almost all of the sound intensity occurs at frequencies below 4 kHz, with most of the sound intensity concentrated at frequencies below 800 Hz.[29]

RLN and experimentally induced laryngeal hemiplegia (LH) are characterized by a loud inspiratory noise. This noise contains higher frequencies than normal expiratory sounds and has three bands in the frequency domain called *formants*. These formants are centered at approximately 300, 1700, and 3700 Hz (Figure 42-11).[29,30] Human hearing is most acute between 2000 and 4000 Hz. The sound formant centered at about 1700 Hz has significant sound intensity and is in the range of acute human hearing, so this is the one that contributes most to the perception of the high-frequency whistle or roar associated with RLN. The highest-frequency formant has the least sound intensity, and it is not present in all RLN-affected horses. The sound intensity of the formant centered at about 300 Hz is in a region where human hearing is less acute, so this lower-frequency noise does not appear prominent to the human ear. Whether the spectral pattern just described is unique for RLN remains to be determined. If this is the case, spectrum analysis of upper airway sounds in exercising horses could be used as a definitive diagnostic tool for RLN.

DDSP occurs intermittently during exercise; therefore, the abnormal noise associated with this condition is also intermittent.[29,35] Often, the soft palate displaces near the end of the exercise or as the horse pulls up. In some horses, the abnormal sound can be heard throughout the exercise period. In affected horses, expiratory sounds are abnormal. The noise is characterized by rattling, which is seen on the spectrogram in the time domain as bars of sound with a periodicity of about 32 msec (Figure 42-12). Most of the sound energy is below 4000 Hz, but the range is up to approximately 10,000 Hz.[29,41] In some horses with DDSP, respiratory sounds are normal, but in others, an inspiratory noise similar to the noise described for exhalation is also heard. In these cases, the inspiratory noise is often less loud than the expiratory noise. During exercise, affected horses often swallow frequently, presumably in an attempt to keep the soft palate in its normal position.

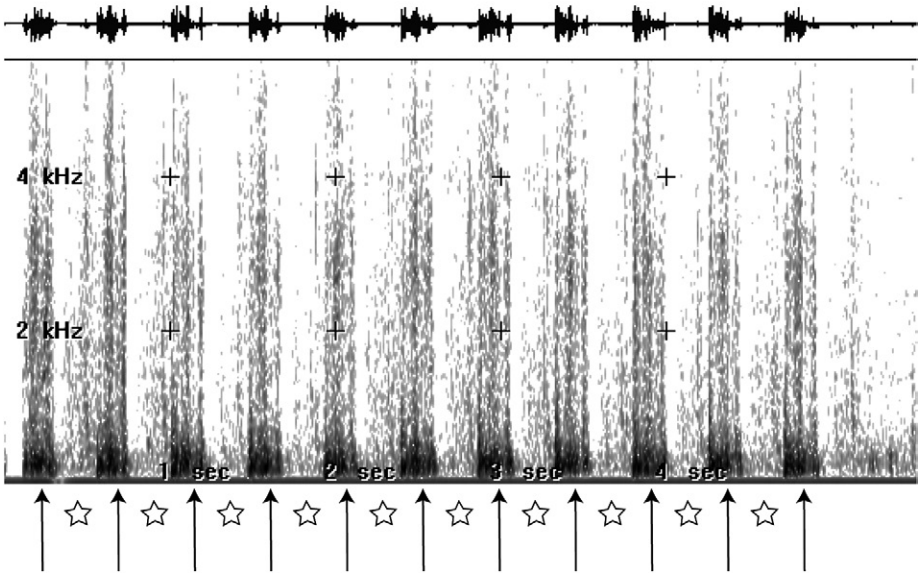

Figure 42-10. Spectrogram of respiratory sounds in a normal galloping horse. Timing is on the abscissa, frequency on the ordinate. The gray scale indicates sound intensity. Inspiration is indicated by a *star*, expiration by an *arrow*.

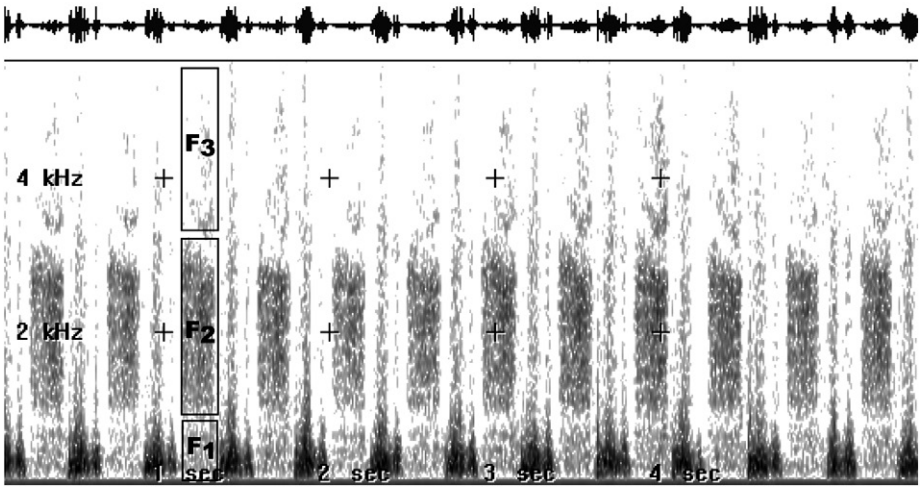

Figure 42-11. Spectrogram of respiratory sounds in a galloping horse with experimentally induced laryngeal hemiplegia. Notice the inspiratory bands of sound (formants) centered at approximately 0.3, 1.7, and 3.7 kHz (*F1*, *F2*, and *F3*, respectively).

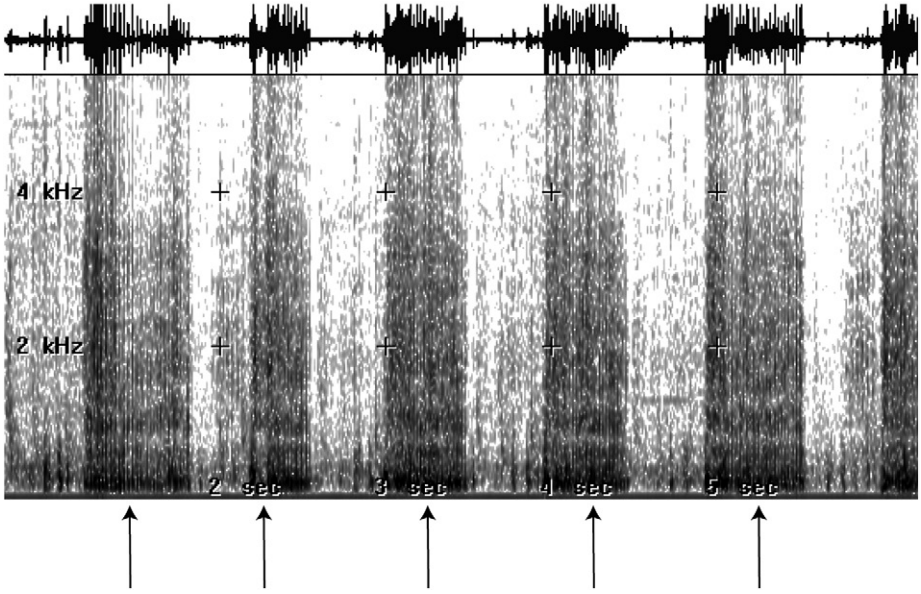

Figure 42-12. Spectrogram of respiratory sounds in a galloping horse with experimentally induced dorsal displacement of the soft palate. Note the "rattling" of the expiratory sound *(arrows)*.

It is likely that vibrations of the DDSP are the source of the upper airway noise.[41] The rate and amplitude of soft palate vibration are a function of the airflow velocity, the compliance of the DDSP, and the geometry of the individual horse's upper airway. Combined, these factors explain why some horses with DDSP make no noise, whereas in others the noise is also apparent during inhalation. Listening to the recorded respiratory sounds made by a horse with DDSP while concurrently viewing the spectrogram is an effective way to diagnose the condition.

RLN and DDSP can be experimentally reproduced and are the most common upper airway conditions of horses.[29,30] Consequently, noises associated with these conditions have been studied best. However, such upper airway conditions as pharyngeal collapse, epiglottic entrapment, aryepiglottic fold collapse, and rostral soft palate collapse are also associated with respiratory noise during exercise. It is possible that in the future each upper airway condition associated with noise production will have a well-described "voiceprint," allowing a presumptive spectrogram-based diagnosis of the condition in the field.

Effect of Surgical Treatment on Upper Airway Noise in Horses with Recurrent Laryngeal Neuropathy

Surgical procedures used to treat RLN include prosthetic laryngoplasty, various combinations of laryngeal ventricle and vocal cord excision, often combined with laryngoplasty, and nerve-muscle pedicle grafting. The effect of these surgical procedures on upper airway function has been well studied.[42-48] Other studies have investigated the possibility of these procedures to reduce respiratory noise.[29,30,49-51] In one study, bilateral ventriculocordectomy effectively reduced respiratory noise in horses with experimentally induced laryngeal hemiplegia.[30] Respiratory noises associated with the condition were almost completely eliminated, although spectrum analysis revealed some residual abnormal respiratory sounds (Figure 42-13). It takes

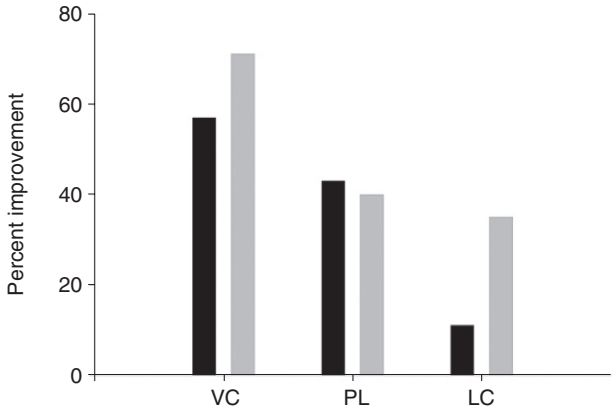

Figure 42-13. Percentage in improvement of inspiratory sound level *(black bar)* and sound intensity of formant 2 *(gray bar)* in galloping horses with laryngeal hemiplegia 90 days after treatment with bilateral ventriculocordectomy *(VC)*, prosthetic laryngoplasty *(PL)*, and unilateral laser cordectomy *(LC)*. Note that respiratory noise reduction is most effective after *VC*, and least effective after *LC*.

Figure 42-14. Horse with mask and ultrasonographic spirometer used to generate flow volume and flow time curves during high-speed treadmill exercise.

up to 90 days after the surgery until the abnormal respiratory sounds decline.

The most commonly used surgical technique to treat RLN is prosthetic laryngoplasty.[43] The procedure significantly improves upper airway flow mechanics in RLN-affected horses,[42] and many horses have raced successfully after surgery.[44,45] Prosthetic laryngoplasty reduces upper airway noise in horses with laryngeal hemiplegia, but it is not as effective as bilateral ventriculocordectomy in this regard (see Figure 42-13). Additionally, respiratory noise is reduced more rapidly than with bilateral ventriculocordectomy.[50] Residual respiratory noise after surgery is often used to determine the surgical success of prosthetic laryngoplasty.[43] This method of evaluation assumes a tight correlation between respiratory noise and airway obstruction. In fact, in horses with experimentally induced LH, the correlation between residual airway obstruction after prosthetic laryngoplasty and residual noise is weak.[50] Therefore, the residual noise during exercise cannot be used as a predictor of improvement in upper airway function in individual horses after laryngoplasty.

Endoscopically guided laser surgery has been used to perform vocal cordectomy in RLN-affected horses.[48] However, unilateral laser cordectomy does not effectively reduce upper airway noise in horses with experimentally induced laryngeal hemiplegia (see Figure 42-13).[51] Unilateral laser cordectomy results in removal of the left vocal cord but not of the entire laryngeal ventricle. Unilateral laser ventriculocordectomy is more effective.[52] These studies suggest that the laryngeal ventricle rather than the vocal cord may be the primary source of LH-associated noise. Recently, I compared the effects of bilateral ventriculectomy and ventriculocordectomy on upper airway noise in draught horses with RLN.[36] It was found that bilateral ventriculectomy and ventriculocordectomy both significantly reduce upper airway noise but that ventriculocordectomy was more effective than ventriculectomy.

In summary, respiratory sound recording in exercising horses is easy and inexpensive and can be accomplished under field conditions. The sound can be analyzed by simply listening to the recording and by spectrogram analysis. Just listening to the recording gives the veterinarian insight into breathing patterns and abnormal noises during exercise. Spectrogram analysis provides a voiceprint that in some cases suggests the presence of a specific upper airway condition. Respiratory sound analysis can also be helpful in evaluating surgical procedures aimed at reducing respiratory noise in horses with upper airway disease.

EXERCISE SPIROMETRY

Michael A. Weishaupt

Exercise spirometry is conducted with ultrasonic flow meters (Figure 42-14), which calculate the mean velocity of airflow passing through the two openings by measuring the absolute time of flight of short ultrasonic beams transmitted upstream and downstream during respiration (Exhalyzer V). Patients are trained to the high-speed treadmill wearing a face mask with an air-tight seal around the nose. When they are comfortable with the mask and with cantering on the treadmill, the spirometer is attached. In horses with obstructive diseases of the upper airways, inspiratory airflow values typically are altered to a much greater extent than expiratory values. Additionally, horses must be exercising at performance speeds for this test to be diagnosic. For example, in horses with unilateral grade 4 RLN, the first signs of inspiratory airflow limitation can be observed at the trot. However, conclusive inspiratory flow limitations usually occur only at canter speeds of 6 to 7.5 m/sec with a 6% incline (heart rates 160 to 210 min^{-1}).

Measurements of airflow mechanics have been performed to objectively assess the functional outcome of different surgical treatments for a variety of upper airway obstructive conditions.[40,42,49,53-57] Tidal breathing flow volume loops have proved to be a sensitive method to detect airway obstruction in exercising horses.[58] Exercise spirometry permits flow-volume loop and flow-time diagram data to be measured so that the significance of the upper airway obstruction can be determined. After clinically diagnosing a specific upper airway disorder, spirometry is then not only used to objectively assess the functional limitation of the obstruction but can also be used to detect the

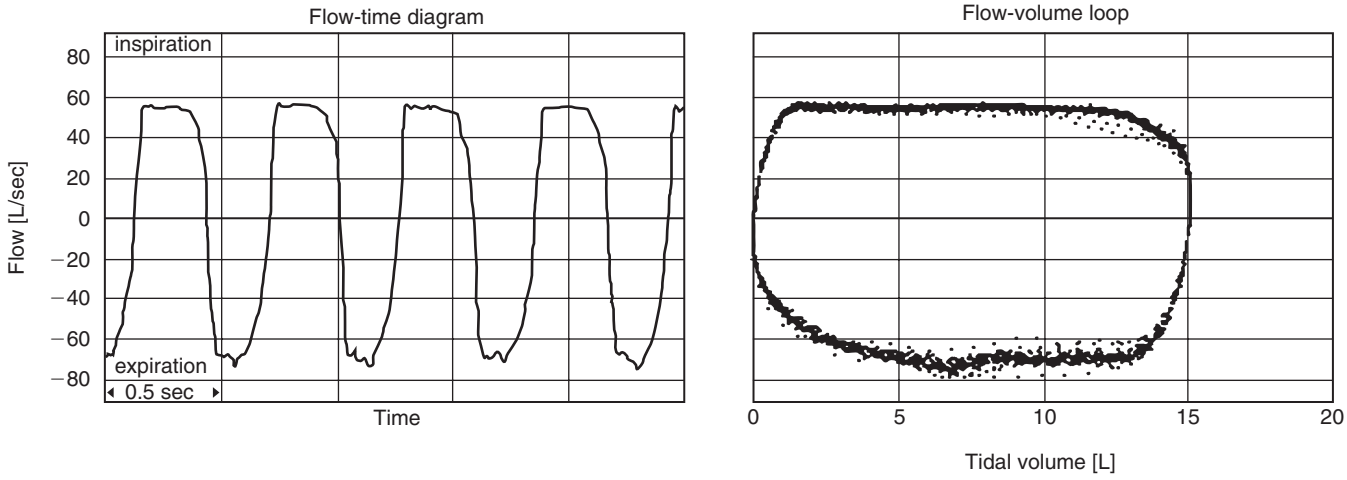

Figure 42-15. Representative flow-time diagram and tidal breathing flow-volume loop of a Warmblood horse with left recurrent laryngeal neuropathy. During the canter only minimal dynamic collapse of the left arytenoid was observed. The flow-volume loop *(right)* shows a typical flattening during inspiration *(top half of the loop)* as flow limitation occurs.

improvement of a surgical intervention in a follow-up spirometric analysis using the identical exercise protocol.

Examples of Airway Abnormalities Analyzed with Spirometry

Recurrent Laryngeal Neuropathy

In horses with grade 3 or 4 RLN with *mild collapse* of the airway, the inspiratory flow curve is characterized by a plateau phase, and peak values are limited between 28 and 60 L/sec (Figure 42-15), whereas at expiration, no limitation of airflow and peak flow values (up to 90 L/sec) occurs. To adapt to peak flow limitation while maintaining the tidal volumes necessary to meet the metabolic cost of the specific exercise intensity, the inspiratory time is prolonged. Inspiratory resistance typically increases so that the inspiratory time fraction is more than 50%.

Horses with *severe* dynamic collapse of the paralyzed arytenoid cartilage show an initial inspiratory flow peak with a subsequent characteristic drop in flow (Figure 42-16). At the canter, an affected horse changes its 1:1 locomotion-to-respiration coupling (LRC) intermittently or permanently to 2:1. When reassessing those patients after laryngoplasty combined with ventriculectomy, the most obvious changes can be observed in peak inspiratory flow (PIF) and minute ventilation (V_E). PIF increases between 30% to 70% and V_E up to 50%.

Dorsal Displacement of the Soft Palate

DDSP affects both inspiration and expiration, but the latter usually to a greater extent. DDSP causes a reduction of V_E and expiratory flow parameters, including peak expiratory flow (Figure 42-17).[25a,59]

Epiglottic Entrapment

An epiglottic entrapment has the potential to cause exercise intolerance in high-performance horses, even though some horses are capable of competing successfully with an entrapped epiglottis. The presence of severely inflamed and swollen entrapping tissue or the entrapment of the epiglottis in a semi-erected position exacerbates airway obstruction. In a case of intermittent epiglottic entrapment, inspiratory as well expiratory flow limitation was documented (Figure 42-18).[60]

DIAGNOSTIC IMAGING

See also Section IX.

Ultrasonographic Examination of the Upper Airway

Heather J. Chalmers

Videoendoscopic examination at exercise is well established as the preferred means of evaluating the upper airway of horses of various disciplines. Ultrasonography has long been considered a key diagnostic tool for the equine respiratory tract, yet routine use of this modality has focused predominantly on the assessment of the lungs and pleural space.[61] More recently, the use of ultrasonography in the examination of the equine upper airway has been described as a useful adjunct diagnostic tool for the clinician.[62-64] Ultrasound examination of the larynx offers several advantages as it can be performed on the standing horse, offers both structural and functional information and allows the nonluminal side of the upper airway to be evaluated. Skillful laryngeal ultrasound can reveal important information about

the location and extent of disease and may be used to corroborate or to question resting endoscopic findings.

Ultrasonography is especially useful in the evaluation of the structural status of tissues, making it highly complementary to the endoscopic evaluation in which the functional status is emphasized and the structural evaluation of tissues is limited to the luminal aspects only. Thus, ultrasonography and endoscopy should be considered complementary diagnostic tools that have the capability to augment the clinical data available for each case. Although laryngeal ultrasonography has not yet been compared to the results of over-ground endoscopy, ultrasonographic findings have been shown to have good agreement with treadmill video-endoscopic findings in horses with various upper airway problems.[62-65]

The upper airway structures that can be assessed with ultrasonography are limited in some locations by the presence of bone, mainly the hyoid apparatus and mandibles, and by the presence of gas within the airway lumen. When ultrasound waves travel through tissues and interact with a bone or gas interface, the waves are absorbed or reflected, which impairs imaging of deeper structures and results in an acoustic shadow.[66] Because of this restriction, and to optimize image acquisition, the use of established acoustic windows is recommended when evaluating the larynx with ultrasonography. Because the upper airway is complex, a thorough understanding of the regional anatomy is necessary to develop competency in this technique. The routine evaluation of the equine laryngeal region has been described using three ventral windows and one lateral window.[62] The structures evaluated at each acoustic window are summarized in Table 42-1. By performing a thorough and systematic evaluation, the operator can increase the information gained from each examination and become accustomed to the expected normal appearance at each site, thereby facilitating the recognition of abnormal findings and reducing the chances that lesions are missed. To date, the evaluation of the laryngeal and pharyngeal region with ultrasonography has been established as a diagnostic aid in several important conditions of the upper airway including DDSP, RLN, bilateral dynamic laryngeal collapse, arytenoid chondritis, and laryngeal masses and malformations.[62-65,67-70]

Dorsal Displacement of the Soft Palate

The ultrasonographic assessment of laryngohyoid position as a predictor of DDSP in horses has been reported.[63] The concept that the position of the larynx and hyoid apparatus could be an important factor in DDSP in horses originated from the finding that bilateral resection of the thyrohyoid muscles could cause DDSP in an experimental model.[59] The paired thyrohyoid muscles have their rostral insertion on the thyrohyoid bone and insert caudally on the lateral aspect of the thyroid cartilage lamina, effectively spanning the space between the larynx and the hyoid apparatus in a parasagittal manner.[71] Based on this anatomic location, the action of these muscles is reported to be to draw the larynx forward and draw the hyoid caudad.[71] The subsequent development of the laryngeal tie-forward procedure was aimed at mimicking the action of these muscles and has been shown to reduce the incidence of DDSP in clinical and experimental models.[59,72-74] These findings surrounding the role of the thyrohyoid muscles in DDSP led to the hypothesis that horses with DDSP could have a different relationship between the larynx and the hyoid apparatus, termed *laryngohyoid conformation*, than unaffected horses. This hypothesis was tested in a study of 56 racehorses undergoing treadmill evaluation for poor performance.[63] The difference in laryngohyoid conformation between affected and unaffected horses was assessed using ultrasonographic measurements taken percutaneously in the resting horse. In this population, a significant difference in laryngohyoid conformation was identified between affected and unaffected horses at the level of the basihyoid bone.[63] More specifically, when the depth of the basihyoid bone was measured at the base of the lingual process, the basihyoid location was significantly more shallow (ventral) in horses affected with DDSP compared

TABLE 42-1. Acoustic Windows Used in Routine Laryngeal Ultrasound Examination and Anatomic Structures Evaluated at Each Site

Acoustic Window (Anatomic Landmarks)	Structures Evaluated	Clinical Importance
Rostroventral (basihyoid bone)	Basihyoid bone including lingual process Base of tongue Ceratohyoid bones Mandibular lymph nodes	Basihyoid depth has been correlated to DDSP Postoperative assessment of laryngeal tie forward Ventral draining abscesses
Midventral (space between basihyoid and larynx)	Base of basihyoid bone Thyroid cartilage (ventral aspect) Strap muscles Thyrohyoid bones Thyrohyoid muscles	Relationship of larynx to hyoid apparatus Postoperative assessment
Caudoventral (cricothyroid notch)	Vocal folds Cricoid cartilage (ventral aspect) Cricothyroid muscle (ventral aspect) Rostral trachea	Vocal fold movement Cricothyroid muscle status
Lateral (right and left sides of larynx)	Cricoarytenoideus lateralis muscles (CAL) Arytenoid cartilage (caudal aspect) Cricoid cartilage (lateral aspect) Cricothyroid muscle (lateral aspect)	CAL muscle echogenicity in RLN Arytenoid movement Characterization of arytenoid lesions in chondritis

DDSP, Dorsal displacement of the soft palate; *RLN,* recurrent laryngeal neuropathy.

to unaffected horses (Figure 42-19). It is not known if this difference is related to the cause of DDSP or is a secondary effect of having DDSP. The reason for the observed differences in basihyoid position may relate to conformational differences and/or differences in strap muscle thickness between diseased and normal horses. The odds ratio (OR) of ultrasonographic assessment of basihyoid position for DDSP in the study population was approximately 17, meaning that for each 1 cm incremental increase in basihyoid depth the odds of DDSP decrease 17 fold.[63] As such, the basihyoid depth may be used in the resting horse as one possible indicator of DDSP; however, to use this criterion exclusively is not recommended. Rather, it is recommended to use the information gained through ultrasonography to ameliorate case selection for video endoscopy during exercise and to reduce the uncertainty about clinically suspected diagnoses. In addition to these diagnostic implications, the identification of an observable difference in laryngohyoid position between normal and affected horses at rest may have important pathophysiologic implications for DDSP, but these have not been fully explored to date.

Recurrent Laryngeal Neuropathy

Ultrasonography is reported as a convenient and noninvasive modality for assessing muscle tissue in normal and pathologic states.[75,76] RLN in horses is known to lead to changes in those muscles innervated by the left recurrent laryngeal nerve, including the *criroarytenoideus lateralis (CAL)* and the *cricoarytenoideus dorsalis (CAD)* muscles.[77,78] The effect of RLN in horses has been characterized as neurogenic atrophy of the muscles that it innervates, causing decreased movements of the arytenoid cartilage.[77] Histopatholigc abnormalities are reported to be present prior to clinical abnormalities, and the CAL muscle is affected first.[77,78] The use of ultrasonography to assess the CAL muscle for signs of neurogenic atrophy was originated to supplement resting endocscopic findings, especially for horses in which the resting grade does not correlate with the exercising grade. The hypothesis that increased muscle echogenicity would be present in horses with RLN was tested in 146 horses and compared with the clinical diagnostic standard of resting laryngoscopic examination.[79] In addition, 92 of these horses underwent upper airway videoendoscopy while exercising.[79] When compared with the resting laryngeal grading system, the test performance of the laryngeal ultrasound examination in the study population is as follows: sensitivity = 90.77% (95% confidence interval [CI], 80.97 to 95.90), specificity = 90% (CI, 81.4 to 95.3), positive predictive value = 88.06% (CI, 77.8 to 94.4), negative predictive value = 92.3% (CI, 84.1 to 96.6), odds ratio = 88.5 (95% CI, 27.43 to 301.94).[79] When compared with the exercising laryngeal grading system, the test performance is as follows: sensitivity = 91.9% (CI, 78.6 to 97.75), specificity = 96.3% (CI, 87.3 to 99.3), positive predictive value = 94.4% (CI, 81 to 99.0), negative predictive value = 94.5% (CI, 84.8 to 98.5), odds ratio = 244.16 (95% Sterne confidence intervals, 40.1 to 2039.1). Agreement between the testing methods was assessed using the kappa statistic; between resting laryngeal grade and exercising laryngeal grade the kappa is 0.7702 (95% CI, 0.636 to 0.904, $p < 0.001$). The kappa for CAL echogenicity and exercising laryngeal grade is 0.886 (95% CI, 78.8 to 98.3, $p < 0.001$). The findings to date demonstrate the capability of ultrasonography in assessing intrinsic laryngeal muscles for evidence of neurogenic atrophy and support the use of this technique to improve diagnostic accuracy in

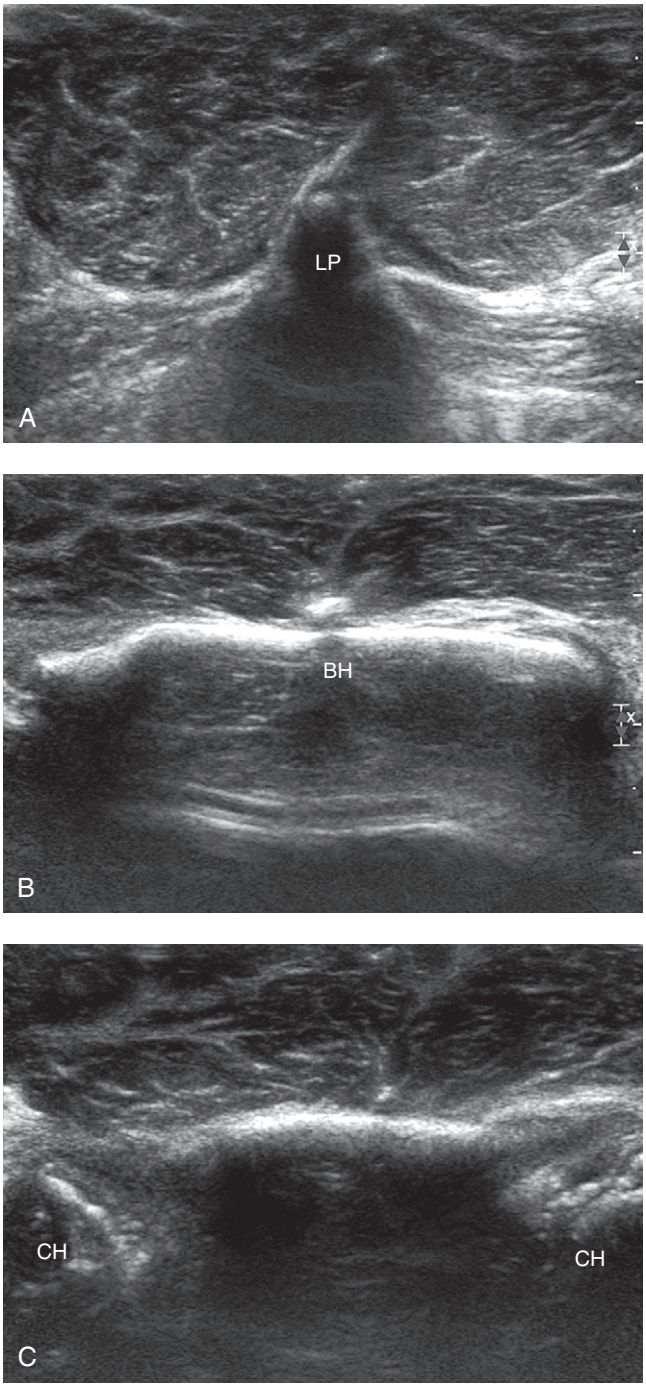

Figure 42-19. Composite images obtained from the rostroventral acoustic window at three different locations in the transverse plane using a 12.5 MHz linear transducer. From left to right the images are progressing from rostral **(A)** to caudal **(C)** within the rostroventral acoustic window. **A,** The lingual process *(LP)* is readily identified as a hyperechoic midline structure immediately dorsal (deep) to the paired *geniohyoideus* muscles. Commencing the exam at this site is recommended because the lingual process is easy to locate. **B,** From the level of the lingual process, moving the probe caudad to follow the lingual process along its entire length leads to the base of the basihyoid bone *(BH).* At this level, there is an association between the basihyoid bone depth and DDSP.[55] **C,** At the junction of the lingual process and base of the basihyoid bone, one can roll the probe slightly rostrad from a midline position to image the left and right ceratohyoid bones *(CH).* The ceratohyoid bones are paired, flat hyperechoic structures coursing dorsad (deep) in the image. Only the more ventral portion of the ceratohyoids is imaged; it is generally not possible to follow them to the level of the stylohyoid bones.

clinical cases (Figures 42-20 and 42-21).[64,79] Further, these findings suggest that ultrasonography may be superior to resting laryngeal grade in predicting the exercising status of the larynx.[79] Of particular interest, in horses in which the resting laryngeal grade does not appropriately predict the exercising laryngeal grade, ultrasonography provided a more accurate diagnosis prior to treadmill examination.[64,79]

Arytenoid Chondritis

Arytenoid chondritis or *chondropathy* is a term used to refer to a range of abnormalities of the arytenoid cartilage(s), which may be inflammatory, infectious, traumatic, or idiopathic in origin.[80-84] The spectrum of abnormalities encountered is broad and can include granuloma formation, draining tracts, distortion and displacement of the corniculate process, and laryngeal malfunction.[80-84] Regardless of the underlying cause, the extent of involvement of the arytenoid cartilages is variable and may include focal pedunculated arytenoid lesions or diffuse involvement of the entire cartilage with internal abscessation. Accurate assessment of disease location and severity has a key role in treatment planning and prognostication.[82-84] Ultrasonography is useful in these cases because it can assess the abaxial aspects and thickness of the arytenoid cartilages.[62] In addition, from the lateral acoustic window, the status of tissues adjacent to the arytnoid cartilage can be assessed to identify any involvement including the thyroid cartilage and the space between the thyroid and arytenoid cartilages.[62]

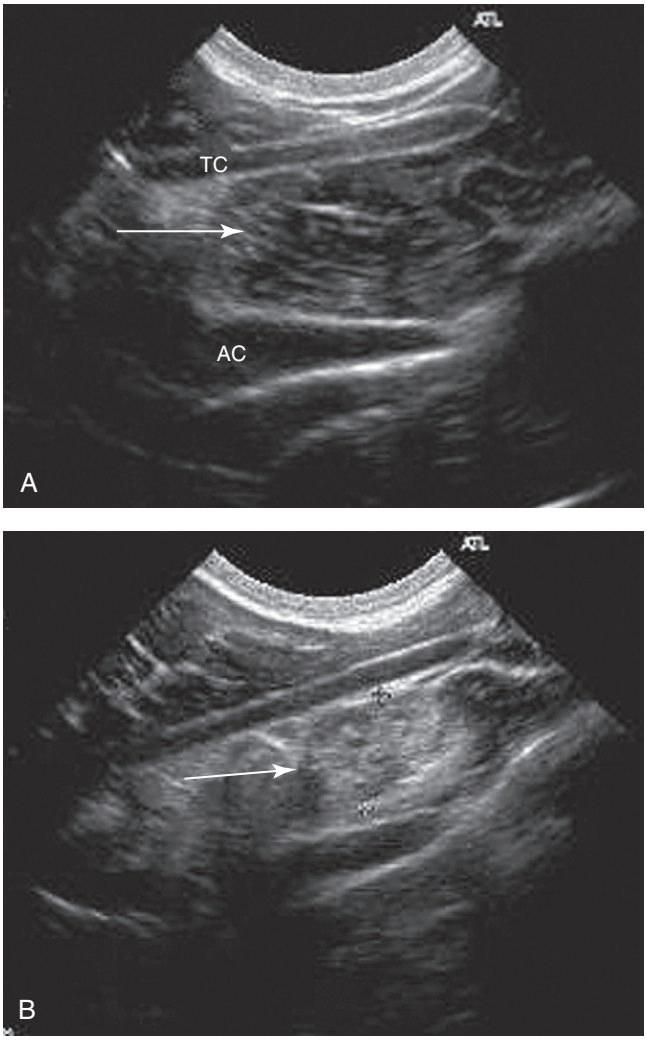

Figure 42-20. The normal right **(A)** and affected left **(B)** lateral acoustic windows from a 3-year-old Thoroughbred with grade 2-C recurrent laryngeal neuropathy obtained using an 8.5 MHz micro-convex probe. The probe is held in a rostrocaudal plane just caudal to the mandibles at a slightly ventral angle so the imaging plane is parallel with the line of the cervical vertebral column. The cricoarytenoideus lateralis *(white arrow)* muscle belly is imaged between the thyroid *(TC)* and arytenoid cartilages *(AC)* and has increased echogenicity with loss of normal muscular fiber pattern on the horses left side **(B)** compared to the normal right side **(A).**

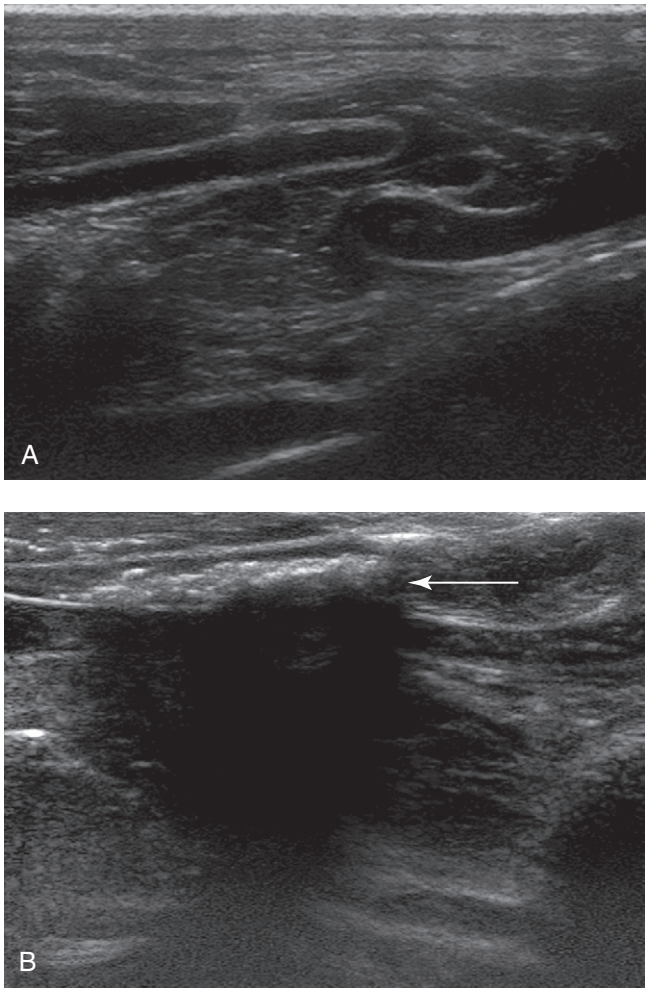

Figure 42-21. Composite image of the lateral acoustic window obtained using a 15 MHz linear array transducer from a yearling standardbred horse **(A)** and a 10-year-old Standardbred horse **(B).** In the yearling, the CAL muscle has normal appearance and the laryngeal cartilages are uniform and hypoehoic. In the older horse **(B)** disruption of the expected appearance of anechoic cartilage is seen with distinct mineralization of the thyroid cartilage *(arrow)* which casts and acoustic shadow over the CAL muscle, making it difficult to image. This type of mineralization, seen in older horses, can range from tiny pinpoint hyperechoic foci to more generalized mineralization that impedes the ultrasound examination as shown here.

Miscellaneous Conditions

The successful use of ultrasonography to evaluate various lesions of the larynx in horses has been reported, including lesions of neoplastic, traumatic, congenital, and infectious eitiology.[67-70] In my experience, routine examination is useful in identifying disease extent and location. Expanded imaging for conditions may include retropharyngeal and mandibular lymph nodes, and extension of the acoustic windows rostrally and caudally to fully trace diseased tissues and to follow draining tracts. Ultrasonography is particularly useful in identifying locations that may be amenable to fine needle aspiration or biopsy to facilitate diagnosis and to differentiate the underlying etiology. The use of ultrasonography as a diagnostic tool in congenital malformation of the larynx has been reported in five horses with fourth branchial arch defect (4-BAD).[70] In these cases, the absence of the cricothyroid articulation is described as a key diagnostic feature and was visible with both ultrasonography and magnetic resonance imaging.[70]

Ultrasound examination of the laryngeal and pharyngeal region is typically normal in dynamic conditions of the upper airway, such as nasopharyngeal collapse and aryepiglottic fold collapse. The use of ultrasonography to assess the larynx in bilateral dynamic laryngeal collapse in Norwegian trotting horses has been described as a useful adjunctive means of assessing the horses at rest.[65] In these patients, the ultrasound examination was performed in different head positions and an association was found between the change in apparent lumen width that occurred with poll flexion and bilateral dynamic laryngeal collapse.[65] Although the potential utility of laryngeal ultrasonography for other conditions of the upper airway is still being developed, the examination appears to be especially contributory in cases of laryngeal and perilaryngeal masses and malformations and when evaluating postoperative complications. Further, because the pathogenesis of most upper airway problems is unclear, the information gleaned from such investigations can contribute to understanding the mechanisms of these diseases. Laryngeal ultrasonography adds a different perspective (i.e., extraluminal) to the assessment of the structural status of a horse's larynx. Skillful ultrasonography of the equine upper airway can reveal important information about the location and extent of disease and may be used to corroborate or question resting endoscopic findings and select cases that would benefit most from exercising evaluation. Laryngeal ultrasonography and resting and high-speed video endoscopy should be seen as complementary, rather than competitive, modalities.

Radiography

Eric J. Parente

Although treadmill endoscopy is invaluable for evaluating the dynamics of the upper respiratory tract during exercise, other imaging techniques, such as radiography and computed tomography (CT), are just as essential in fully evaluating the upper respiratory tract. Radiography and CT are particularly valuable in the assessment of structural abnormalities in areas that are difficult to explore with the endoscope.

The larynx, pharynx, and guttural pouches can be clearly imaged with standard radiographic techniques. Computed radiography and digital radiography provide even greater detail and have the advantage of providing images can be manipulated. To acquire a lateral image of the laryngeal structures, the x-ray beam should be centered just rostral and dorsal to the angle of the mandible. A dorsoventral projection is usually not of benefit in evaluating these structures.

Air throughout the upper respiratory tract provides good contrast for structures within the pharynx and larynx. Any masses or swelling external to the lumen will lead to obvious compression of the pharyngeal vault. The epiglottis should appear as a thin structure on top of the soft palate. Subepiglottic or palatal lesions may cause dorsal displacement of the soft palate (Figure 42-22), but heavy sedation of the horse may also precipitate displacement of the palate, and this finding should not be overinterpreted. Measurements have been made of epiglottic length on lateral radiographs and correlated with dynamic upper respiratory dysfunction.[85] Clinicians depend more often on their endoscopic assessment of epiglottic length and apparent stiffness than on radiography. The arytenoids and the remainder of the laryngeal cartilages can be seen dorsal and caudal to the epiglottis. Mineralization of these structures may be associated with normal aging or with an inflammatory process, such as arytenoid chondritis.[86,87] Infrequently, abnormal air density may be seen around the larynx and could be consistent with severe laryngeal infection. The saccules should be seen as small air densities between the epiglottis and corniculate processes.

The guttural pouches are thin-walled, air-filled cavities that extend from the pharynx and project dorsal to the larynx. The guttural pouches are outpouchings of the eustachian tubes, and normally the stylohyoid bone is seen traversing through the guttural pouch. Enlarged retropharyngeal lymph nodes may lead to compression of the guttural pouch ventrally. Fluid associated with guttural pouch empyema or hemorrhage can typically be seen as increased soft tissue density or a fluid line. Temporohyoid disease may be seen as enlargement of the stylohyoid bone, but this condition is more reliably detected during the endoscopic examination.[88]

Radiography can be very beneficial in imaging most abnormalities within the sinus, but the technique does have limitations. Dorsoventral, lateral, and oblique projections are the minimum of radiographic views that should be taken to fully

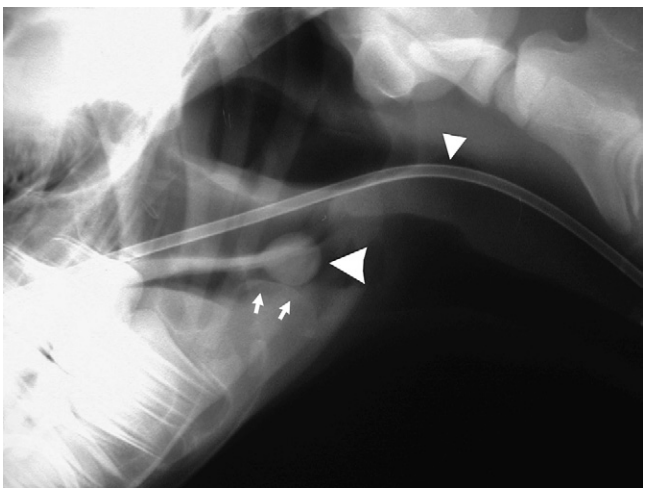

Figure 42-22. Lateral radiographic image of a foal with persistent dorsal displacement of the soft palate. The epiglottis *(small arrows)* is unable to assume its normal position because of a large cyst *(large arrowhead)* on the free edge of the palate. A feeding tube is in the esophagus *(small arrowhead).*

evaluate the sinuses. Although air density provides good contrast, superimposition of structures can make interpretation difficult, and familiarity with normal sinus architecture is essential. A fluid line can be seen in the lateral projection in many cases of sinusitis (Figure 42-23), but if the entire sinus is full, only increased soft tissue density will be seen. Often the borders of the frontal and maxillary sinuses can be discerned easily. The septum between the caudal and rostral maxillary sinuses can be best appreciated on a lateral radiograph, but sinusitis or neoplasia may result in significant distortion of normal anatomy. Contrast sinusography can be used to better help delineate abnormalities. Contrast material can be injected through standard portals for sinus centesis, and filling defects will define the extent of lesions.[89,90]

Sinusitis can be primary or secondary to another problem, such as tooth infection or neoplasia. It can be difficult to make this distinction with standard radiography, but this determination is essential in developing an appropriate treatment plan. If bony lysis is present on standard radiographs, the sinusitis is most likely secondary to some other, primary problem, but the absence of lysis is not definitive for a primary sinusitis. Sinuscopy can be used to visualize the internal aspects of the sinus, but it has limited application (see Chapter 43).[91] More sensitive imaging techniques are often of greater benefit.

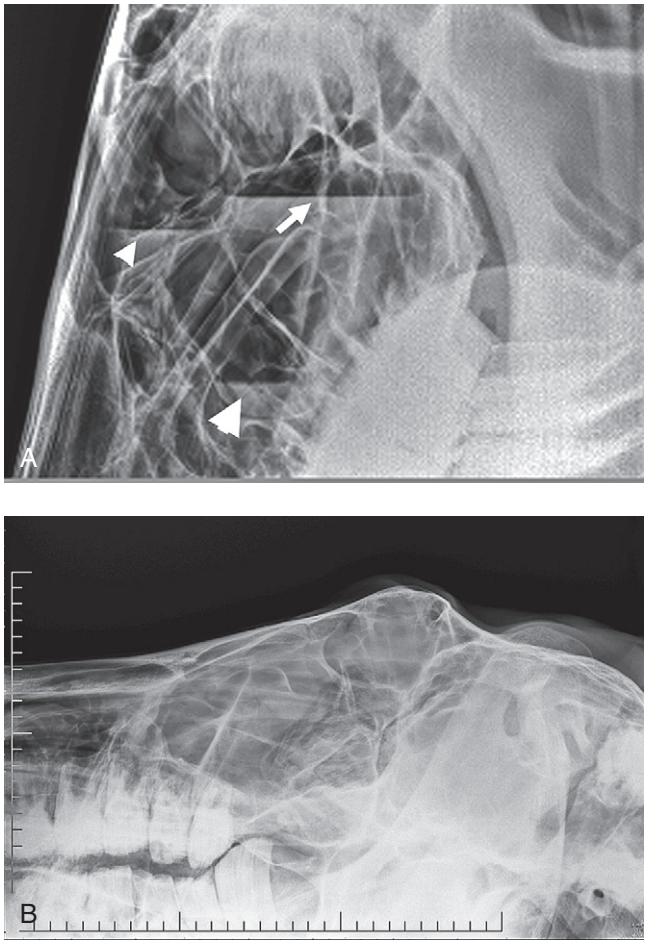

Figure 42-23. A, Lateral skull radiograph with multiple fluid lines. Rostral maxillary sinus *(large arrowhead),* caudal maxillary sinus *(arrow),* dorsal conchal sinus *(small arrowhead).* **B,** Oblique radiograph of the skull with complete opacity of sinus from chronic disease.

Scintigraphy

Eric J. Parente

Scintigraphy is an extremely sensitive technique for detecting bony remodeling. It can be used to evaluate the equine head reliably for the presence of dental disease, and it can be used to distinguish among dental disease, neoplasia, and primary sinusitis.[92] Bone phase images are acquired 3 to 4 hours after an intravenous injection of a radioisotope. The images are obtained by a gamma camera, and regions of interest are analyzed. Although scintigraphy can be used to determine the presence of dental disease, it may be difficult to discern the specific tooth that is involved with great certainty. Scintigraphy has a significant advantage over other imaging techniques because general anesthesia is not required. The images are acquired with the standing animal sedated, and multiple views can be taken to help minimize superimposition of structures. Many hospitals now have scintigraphic capability.

Computed Tomography

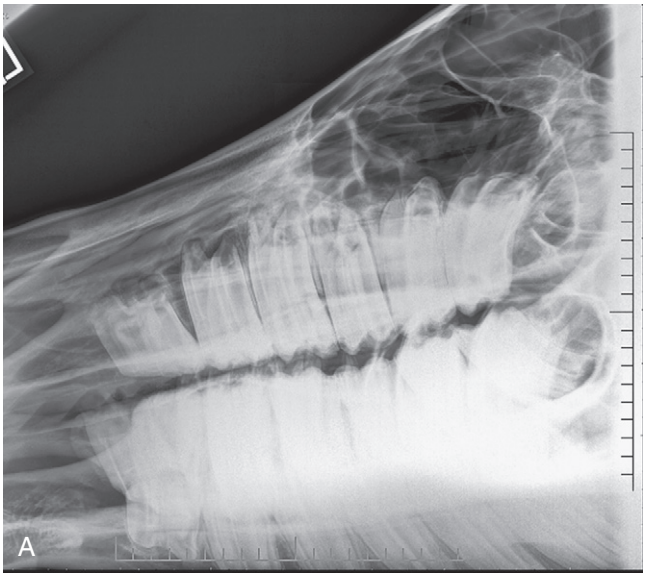
Caroline Tessier

Computed tomography (CT) has a distinct advantage over scintigraphy and standard radiography because highly detailed cross-sectional images of the nasal cavity and paranasal sinuses can be obtained. CT can discriminate tissues with only a 0.5% difference in density, and a 10% change in density is necessary to detect a radiographic difference.[93] The images are obtained using x-rays, but the x-ray tube and detectors encircle the patient, acquiring images from many angles. The resulting images are cross-sectional slices of a specified thickness (Figure 42-24). This eliminates the problem of superimposition encountered with conventional radiography, and it allows precise determination of an abnormality. By knowing the extent of a lesion in greater detail, a more precise surgical plan can be made. CT slices are always oriented perpendicular to the long axis of the table and body region in the gantry. The CT images can be reconstructed with computer software to provide images in other planes, but there is a significant loss of image quality. Imaging techniques[94] and normal CT anatomy of the equine head[95] have been described. CT imaging of the equine head can be performed in a relatively short time; therefore, surgical treatment can often be performed in the same anesthetic episode. It has proved to be a very valuable modality in imaging paranasal sinus lesions in horses[96,97] and is routinely used in some facilities in the preoperative planning of sinus surgery.

Magnetic Resonance Imaging

Caroline Tessier

Magnetic resonance imaging (MRI) enables the generation of high-resolution cross-sectional images of the head in horses. Although its use has become widely accepted for soft tissue lesions of the distal limb, MRI is now recognized also as a valuable tool to image the head of horses. It is generally thought to be a superior imaging technique for soft tissue, but MRI can be just as good at discerning bony abnormalities. The normal cross-sectional anatomy of the equine paranasal sinuses[98] as well as the pharynx and larynx[99] have been described. Distinct advantages of MRI over CT are that MRI can be multiplanar without loss of image quality and that MRI displays anatomy and pathology in the same examination. MRIs are usually



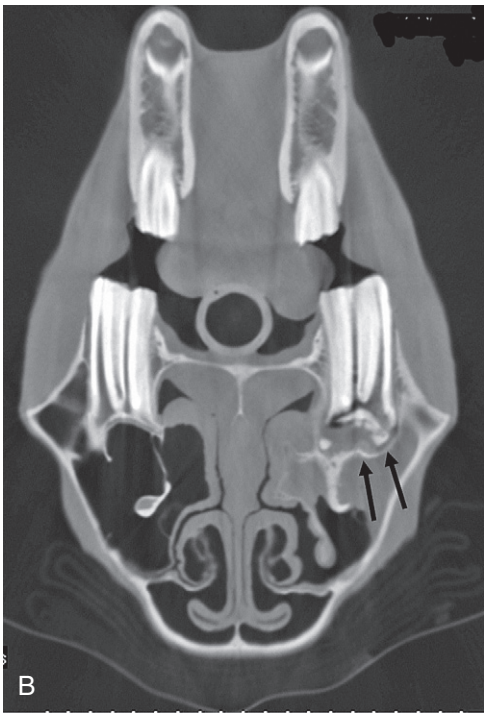


Figure 42-24. A, Lateral radiograph of a horse with purulent drainage from one side of the face and from the ipsilateral nostril. There is no bony lysis around any tooth roots to confirm a suspected diagnosis of tooth root infection. **B,** The cross-sectional CT image at the level of the first molar of the same horse in dorsal recumbency and under general anesthesia. The root structures on the left side are abnormal *(arrows)* and consistent with infection. (Courtesy Section of Veterinary Imaging, Cornell College of Veterinary Medicine.)

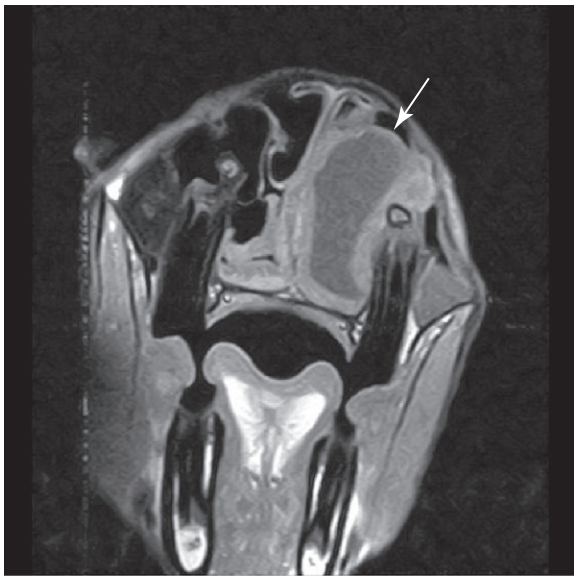

Figure 42-25. Transverse T1-weighted sequence at the level of the first molar of a horse with airway obstruction, facial deformity, and unilateral nasal discharge. There is a space-occupying lesion in the left middle meatus. The fluid is hypointense to the temporal muscles and surrounded by a wall *(arrow)*. The lesion was a paranasal sinus cyst. (Courtesy Division of Clinical Radiology, VetSuisse Faculty of Bern, Switzerland.)

Figure 42-26. Parasagittal T2-weighted sequence of a horse with airway obstruction and nasal discharge. Multiple cystic lesions are visible. (Courtesy Division of Clinical Radiology, VetSuisse Faculty of Bern, Switzerland.)

acquired in transverse, dorsal, and sagittal planes. Slice number and slice thickness can vary according to the area of interest. The most useful sequences to image the equine head are transverse T1-weighted (pre- and postcontrast), transverse T2-weighted and proton density, sagittal T1-weighted (pre- and postcontrast), and dorsal T1-weighted sequences.[100] Imaging of the larynx and pharynx offers excellent three-dimensional display and good soft tissue discrimination. It is particularly helpful in preoperative imaging of complex laryngeal dysplasia.[101] MRI is also a valuable imaging modality in sinonasal disease, particularly in soft tissue lesions (Figure 42-25). The technique is extremely sensitive in detecting inflammatory changes, and fluids with different densities can be identified (Figure 42-26). MRI is the diagnostic modality of choice in patients with suspected neoplasia, as it can display very early the extension of lesions within surrounding tissues

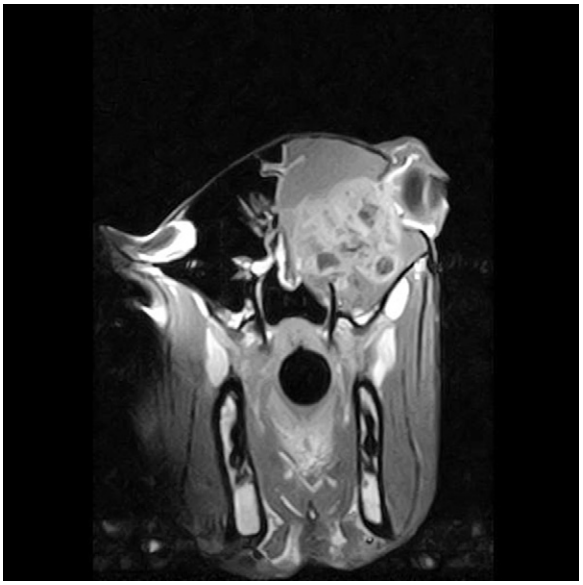

Figure 42-27. Transverse T1-weighted sequence at the level of the orbit of a horse with airway obstruction and facial deformity. There is a large inhomogeneous space-occupying lesion of mixed signal intensity surrounded by hypointense fluid. Destruction and infiltration of the orbital bones can be observed. Displacement of the conchae and ethmoid turbinates can be seen. The lesion was a sarcoma. (Courtesy Division of Clinical Radiology, VetSuisse Faculty of Bern, Switzerland.)

(Figure 42-27). However, the interpretation of images should be complemented by clinical findings. Furthermore, acquisition and interpretation of MRIs is lengthy, and a separate anesthetic episode might be required if surgical treatment is planned.

CHAPTER 43

Nasal Passages and Paranasal Sinuses

Frank A. Nickels

FUNCTIONAL ANATOMY

External Nares

The external nares or nostrils in the horse are the openings into the nasal passages; they are widely placed and have an unusual shape.[1] The dorsal and lateral margins of the nares, the alae, are supported by the alar cartilages, which are attached to the rostral end of the nasal septum dorsally. The thick alar fold divides each naris into dorsal and ventral parts. The dorsal part leads into a blind sac called the nasal diverticulum, which occupies the nasoincisive notch formed by the incisive bone ventrally and the nasal bone dorsally. The ventral part of the naris leads directly into the nasal cavity.

Nasal Cavity

The nasal cavity is divided into equal halves by the nasal septum and the vomer bone. The reserve crowns of the upper cheek teeth and a portion of the paranasal sinus system occupy this area of the skull. Two major nasal conchae (thin scrolls of cartilage and bone) in each nasal cavity divide the nasal passage into the dorsal, middle, ventral, and common meatus. The dorsal concha extends from the cribriform plate of the ethmoid bone to the level of the 106/206 (second premolar in the upper arcade). The ventral concha extends from the level of the 111/211 (third molar) to the level of 106/206 (see Chapter 30).[2] Numerous small ethmoturbinates project into the caudal part of the nasal cavity from the lateral mass of the ethmoid bone.

Paranasal Sinuses

The horse's extensive paranasal sinus system consists of six pairs of sinuses: the dorsal (endoturbinate I), middle (endoturbinate II), and ventral nasal conchal sinuses; the sphenopalatine sinus; the frontal sinus; and the maxillary sinus (Figure 43-1). The major clinically significant sinuses are the frontal and maxillary sinuses. All the sinuses communicate with the nasal cavity directly (maxillary sinus) or indirectly (dorsal, middle, and ventral conchal sinuses; frontal sinus; and sphenopalatine sinuses) through the maxillary sinus. The paranasal sinuses are important clinically because they are susceptible to infections that extend from the nasal cavity or from the alveoli of the caudal upper cheek teeth (see Chapter 30).

Conchal Sinuses

Each conchal sinus is divided into a rostral and a caudal compartment by a septum. The caudal compartment of the dorsal concha forms the dorsal conchal sinus, which communicates with the frontal sinus, forming the conchofrontal sinus. The caudal compartment of the ventral concha forms the ventral conchal sinus, which communicates with the rostral maxillary sinus over the infraorbital canal through the conchomaxillary opening.[2]

Maxillary Sinus

The maxillary sinus is the largest of the sinuses. It is divided into rostral and caudal compartments by an oblique septum. The root of the maxillary first molar tooth (109/209) (see Figure 30-1) usually enters the rostral compartment, and the roots of the second (110/210) and third molars (111/211) usually enter the caudal compartment. The caudal maxillary sinus is partially divided by the infraorbital canal, over which it communicates with the sphenopalatine sinus. It communicates dorsally with the conchofrontal sinus via the frontomaxillary opening at the level of the osseous lacrimal canal and the medial wall of the orbit. It also communicates with the nasal cavity through a compressed nasomaxillary opening into the caudal aspect of the middle meatus. The rostral maxillary sinus is also divided by the infraorbital canal into medial and lateral compartments. The medial compartment of the rostral maxillary sinus communicates with the middle nasal meatus via a narrow slit, the nasomaxillary opening. The rostral compartment communicates with the ventral conchal sinus over the infraorbital canal through the conchomaxillary opening. The volume of the sinus continues to increase from birth through the life of the horse as the teeth continue to erupt and migrate forward. The maxillary sinus is more predisposed to disease than the other sinuses because of direct communication with the nasal cavity and its association with the dental alveoli.

Frontal Sinus

The frontal sinus occupies the dorsal part of the skull. It extends from a point midway between the infraorbital foramen and the medial canthus of the eye to a point midway between the caudal margins of the orbit in the mature horse. An extensive

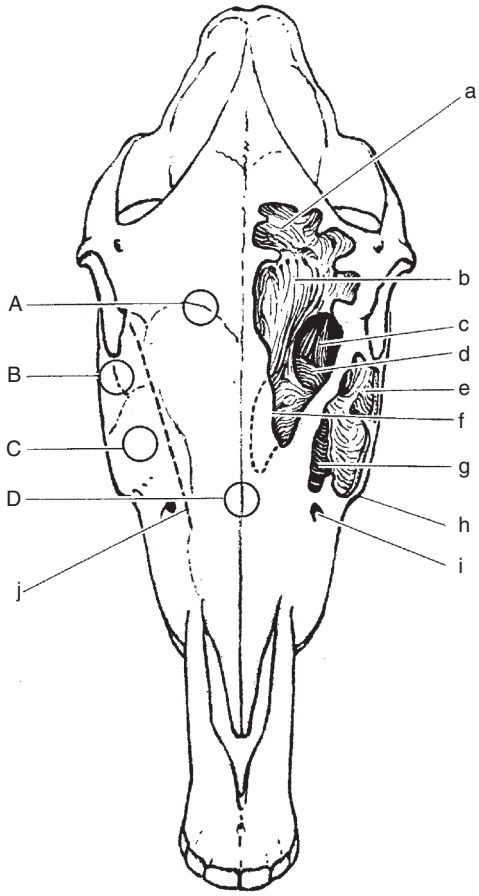

Figure 43-1. Diagram of the skull depicting the location of the equine paranasal sinuses and sites for trephination. *A,* A site for entering the frontal sinus. The sites for entering the caudal maxillary compartment *(B)* and the rostral maxillary compartment *(C)* are above the facial crest and below the nasolacrimal duct *(j).* The nasal bones start to diverge at *(D),* which is the site for exposing the nasal septum. (For a detailed description for entering the frontal sinus over the frontomaxillary opening, see "Sinoscopy.") The *dotted line* outlines the medial floor of the dorsal conchal sinus. *a,* Frontal sinus; *b,* ethmoid mass; *c,* frontomaxillary opening; *d,* dorsal bulla of ventral conchal sinus; *e,* caudal maxillary sinus; *f,* dorsal conchal sinus; *g,* rostral maxillary sinus; *h,* facial crest; *i,* infraorbital foramen; *j,* course of nasolacrimal duct.

communication exists between the rostromedial aspect of the frontal sinus and the dorsal conchal sinus; together they are referred to as the *conchofrontal sinus.*

Sphenoid and Palatine Sinuses

The sphenoid and palatine sinuses are usually contiguous in the horse, forming the sphenopalatine sinus. The sphenoid and palatine sinus compartments communicate under the ethmoidal labyrinth. The sphenopalatine sinus communicates freely with the caudal maxillary sinus.

DISEASES OF THE NARES

Diseases of the nares are relatively rare. The most common clinical signs are reduced airflow, nasal stertor, and occasionally facial distortion. The condition of the nares can usually be determined by observation and palpation.

Epidermal Inclusion Cysts (Atheromas)

These cysts, located in the dorsolateral aspects of the nasal diverticulum, were once thought to be sebaceous cysts and were referred to as atheromas.[3,4] A more recent report describing the histologic appearance found no remnants of sebaceous glands or cells in the cyst wall; thus, a more accurate and descriptive name, epidermal inclusion cysts, has been proposed.[5] These cysts are usually single, unilateral, spherical nodules that can vary from 3 cm to 5 cm in diameter. Epidermal inclusion cysts of the nasal diverticulum are easily identified by visual appearance and location. An accurate diagnosis can be confirmed by cytologic examination of a fine-needle aspirate.[5] Epidermal inclusion cysts are rarely associated with impaired athletic performance and need not be removed unless indicated for cosmetic reasons.

Surgical extirpation can be performed on a standing horse with sedation and local infiltration anesthesia. The skin of the external nares is prepared for aseptic surgery, as is the nasal diverticulum because of the possibility of inadvertent penetration into the diverticulum. The skin and subcutaneous tissue are incised over the lesion, and the cyst is removed by dissection. Care is taken not to rupture the cyst wall. Closure of the incision is routine, and the aftercare is minimal. An alternative method of removal of epidermal inclusion cysts has been described. The cyst is lanced into the nasal diverticulum through a stab incision, and the cyst lining is everted using a roaring burr. The lining is transected using scissors, and the wound is left to heal by second intention. Recurrence has not been reported.[6]

Redundant Alar Folds

The alar fold has been incriminated as a source of respiratory noise in the horse. To determine whether this is the source of abnormal noise or exercise intolerance, a large temporary mattress suture can be placed through the skin of each alar fold and tied over the bridge of the nose. Because the noise is apparent only at exercise, the horse should be exercised after suture placement to determine if the alar fold is the cause of the problem.

Treatment of flaccid or redundant alar folds consists of bilateral resection of the fold. This procedure can be performed through the external nares or by incising the lateral alae of the external nares.[7] Incising the alae facilitates resection of the alar fold, but the resulting scar may be undesirable in show horses.

The patient is anesthetized and positioned in either dorsal or lateral recumbency. Dorsal recumbency provides adequate access if the procedure is performed through the external nares. Lateral recumbency provides the best exposure to the alar fold if the alae of the external nares are incised. The resection involves incising the alar fold caudal to the alar cartilage on the lateral wall of the nasal cavity to the rostral end of the ventral concha (Figure 43-2). A second incision is directed caudad along the medial attachment of the alar fold to join the first incision. Approximately 2 cm of the rostral end of the ventral nasal concha is removed with the alar fold. Profuse hemorrhage may occur when the cartilage has been incised. A 22.5 cm curved Rochester-Carmalt forceps can be used as a guide for the incisions and to control hemorrhage (Figure 43-3). Because ligation of bleeders is almost impossible when the approach through the external nares is used, hemostasis is achieved by closure of the incision using a simple-continuous suture pattern with size

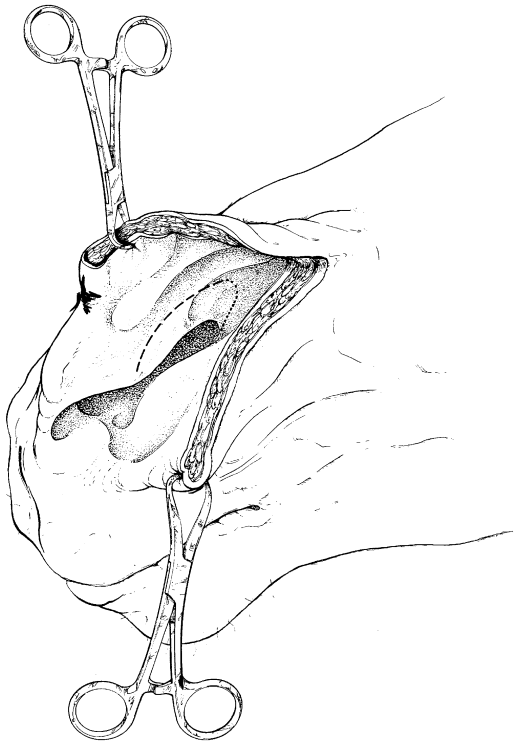

Figure 43-2. Resection of an alar fold. The *dashed line* represents the first incision, which extends caudad from the alar cartilage to the rostral end of the ventral concha. The *dotted line* represents the second incision.

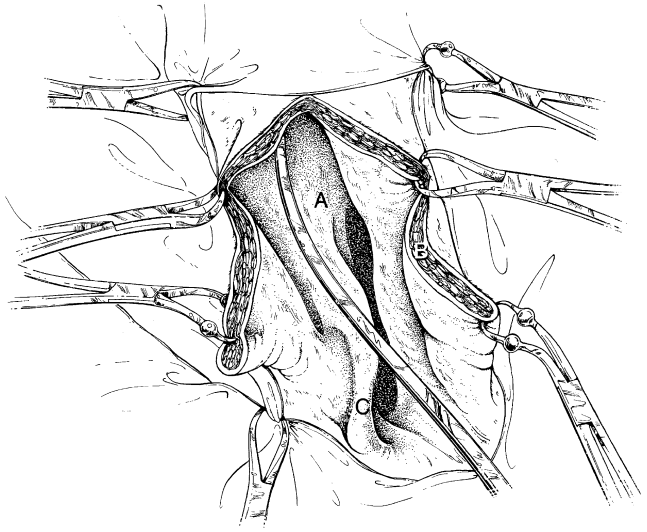

Figure 43-3. Resection of an alar fold. Long, curved forceps are used to control hemorrhage and act as a guide for incisions. *A,* Alar fold; *B,* incised edges of alae; *C,* alar cartilage.

0 absorbable suture material, commencing at the caudal limit. Healing is usually complete within 10 to 12 days, at which time the horse can return to work.

DISEASES OF THE NASAL CAVITY

The most common clinical signs of nasal cavity disease are nasal stertor and unilateral nasal discharge and can include a fetid odor and facial distortion. Endoscopy or radiography or both are usually required for diagnosis.

Facial Fractures

Facial fractures involving the paranasal sinuses and nasal cavities are common and result from direct trauma. Fractures of the paranasal sinuses and nasal cavity most commonly involve the nasal and frontal bones but may also involve the maxillae and lacrimal bones.

Diagnosis of fractures of the paranasal sinuses and nasal cavity is based on history, clinical examination, and radiography. Radiographs of the skull should always be taken to assess the severity of the fracture, but the extent and degree of displacement of the fracture fragments may be more readily determined by palpation. If available, computed tomography provides the best data for complete assessment of the involved structures.

Even though the skin may be intact, these fractures should be considered open, because penetration of the sinus and nasal mucosa usually occurs. Reconstructive surgery should be performed as soon as it is feasible, because primary open reduction provides the best cosmetic results. Some facial fractures of the paranasal sinuses and nasal cavity heal spontaneously; however, failure to treat them may result in chronic sinusitis, bone sequestra, nonhealing wounds, facial deformity, and secondary nasal septal thickening or necrosis.[4,8,9]

Many different reconstructive techniques have been described for facial fractures of the paranasal sinuses and nasal cavity.[9-13] Procedures are performed with the patient anesthetized and positioned in lateral recumbency. Large, slightly curved or S-shaped incisions extending beyond the margins of the fracture are used to expose the traumatized area. Attempts should be made to preserve the periosteal attachments to the fragments. The fracture site is thoroughly débrided and irrigated to remove blood clots and debris. Detached bone fragments devoid of periosteum can be thoroughly cleansed and replaced, but there is the possibility of eventual sequestration. If a paranasal sinus is involved, it should also be thoroughly lavaged to remove blood clots, small bone fragments, and other debris. Some small fractures may be elevated with a thin osteotome or a narrow periosteal elevator, whereas large fragments require other techniques to elevate them into position. The temporary use of orthopedic screws in the fragment and the use of holes drilled in solid bone adjacent to the fracture for insertion of a Langenbeck elevator have been described to assist in elevating the fragments into their normal anatomic position (Figure 43-4).[9,14,15] The use of suture material depends on the stability of the fractured fragments after reduction. Unstable fragments can be held in position using 20- to 22-gauge wire or size 1 monofilament absorbable sutures placed strategically through small holes drilled into the fragment and parent bone.

The incision is closed in two layers. The periosteum is re-apposed when possible using an absorbable suture. A simple-continuous intradermal suture pattern to reappose the skin edges has been reported to provide the best cosmetic results, but skin staples are faster and are also very cosmetic.[9] A pressure bandage placed over a nonadherent dressing is recommended for 3 to 4 days to protect the area and minimize postoperative swelling. Systemic antibiotic therapy should be continued for 5 to 6 days.

A serosanguineous nasal discharge may be present for 1 to 2 weeks postoperatively. If this drainage continues, however, it may indicate the presence of a sequestrum or sinusitis.[8] For additional information on facial fractures, see Chapter 102.

Nasal Septum Diseases

Diseases of the nasal septum are relatively rare and may cause thickening, malformation, or deviation of the septum. Specific diseases include cystic degeneration, malformation of normal tissue (hamartoma), abscess, traumatic thickening and necrosis secondary to septal fracture, longitudinal deviation of the incisive bones and nasal septum, and neoplasm.[4,14,16-20] All of these lesions may produce similar clinical signs, such as decreased airflow or complete unilateral obstruction, nasal stertor, nasal discharge, and occasionally facial distortion. Endoscopy, radiography, and computed tomography are useful to determine the exact site, extent, and nature of the involvement.

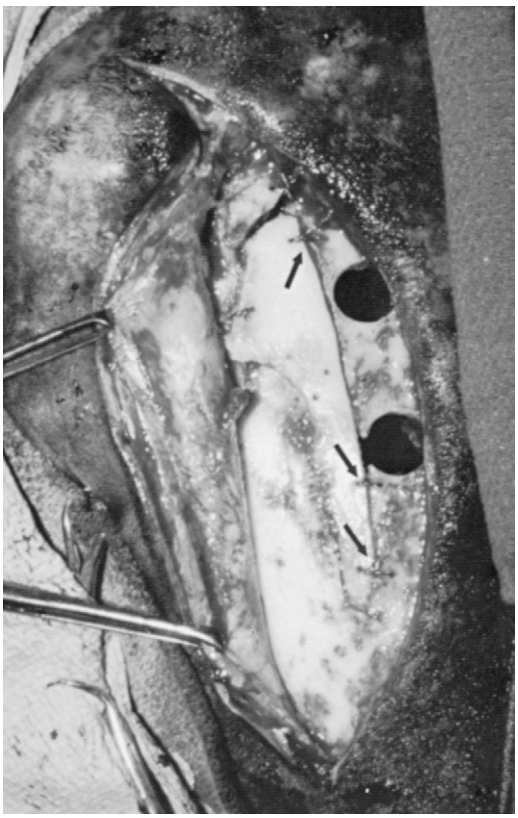

Figure 43-4. Fracture of the nasal and frontal bones. The holes in the parent bone adjacent to the fracture were made to insert a Langenbeck elevator to raise the fragment into its anatomic position. Interrupted stainless steel sutures were used to stabilize the fragment *(arrows)*.

Some of these conditions may improve with removal of the nasal septum. Resection of the nasal septum may involve removing a small portion or the majority of the septum. Incising the lateral alae of the nostril is the best approach for localized lesions of the rostral aspect of the septum, whereas a subtotal resection of the nasal septum or an alternative resection technique is used when the majority of the septum is involved.[16,21,22] Because of the likelihood of profuse hemorrhage during surgery, it is advisable to identify a suitable blood donor and collect 4 to 8 L of blood before surgery in case a blood transfusion becomes necessary. In addition, the administration of large volumes of intravenous fluids during surgery may be necessary to help alleviate hypotension. The most effective method of controlling hemorrhage is to use a nasal tampon after surgery.

The surgery is performed with the horse anesthetized and positioned in lateral recumbency. An airway should be established via a tracheotomy and the anesthetic delivered through it. The surgery for subtotal resection begins by making a 19-mm trephine hole on the bridge of the nose to gain access to the caudal portion of the septum. The center for this opening is located just rostral to the frontal sinuses where the nasal bones begin to diverge (see Figure 43-1, *D*). A curved incision is made through the skin and periosteum, and the periosteum is reflected to provide exposure for the trephine. The nasal septum is easily identified when the bone plug has been removed and the mucosa has been incised. Doyen intestinal forceps or other suitable straight forceps are placed vertically on the nasal septum down to the floor of the nasal cavity (Figure 43-5). The forceps act as a stop for the guarded chisel when severing the dorsal and ventral attachments of the nasal septum, and they act as a guide for making the caudal incision in the septum. The rostral division in the nasal septum is performed by making a curved incision with a scalpel, starting from the ventral aspect

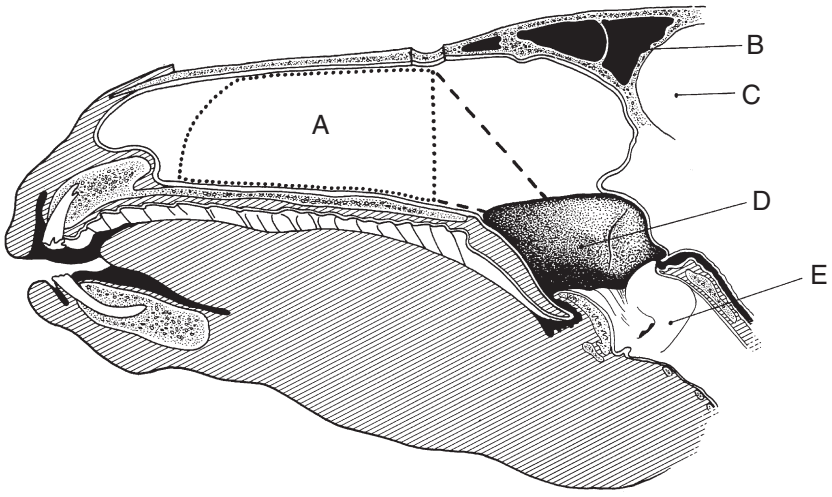

Figure 43-5. Resection of the nasal septum. The *dotted lines* outline the area of the septum removed in the subtotal resection. The *dashed lines* outline the caudal area of the septum removed in addition when a near-total nasal septal resection technique is used. Access to the caudal nasal septum is via a midline trephine opening. *A,* Nasal septum; *B,* frontal sinus; *C,* cranial cavity; *D,* nasopharynx; *E,* larynx.

of the septum and extending in a dorsocaudal direction, leaving at least 5 cm of the rostral septum to support the alar cartilages and external nares. A guarded chisel is used to incise the dorsal and ventral attachments of the septum caudal to the forceps. The caudal incision is made with a narrow osteotome immediately rostral to the Doyen forceps. The septum is then grasped through the external nares with heavy Vulsellum forceps and removed.

Obstetric wire can be used instead of a guarded chisel to incise the dorsal and ventral attachments of the nasal septum. This causes less trauma and hemorrhage. Another advantage of this technique is removal of more of the ventral aspect of the septum than with the guarded chisel. When using obstetric wire for a subtotal resection, the caudal incision is made before the incisions of the dorsal and ventral attachments. The obstetric wire is threaded through the trephine opening on either side of the septum to the external nares. To incise the ventral attachment, the obstetric wire has to be forced to the most ventral aspect of the caudal septal incision. The septal attachments are severed easily with obstetric wire, so care should be taken not to incise beyond the rostral incision of the septum. Digital palpation or visual inspection using a flexible endoscope can be used to determine if all of the ventral attachment of the nasal septum has been removed. Ferris-Smith rongeurs can be used to remove the remaining portions.

An alternative technique has been described to remove the remainder of the nasal septum (see Figure 43-5). The differences between this technique and the subtotal resection are as follows: the caudal incision is made at a 60-degree angle to the nasal bones in a dorsocaudoventral direction, the entire ventral septal attachment is incised up to the rostral incision, and the dorsal and ventral incisions are created by using obstetric wire. The obstetric wire is passed through the ventral meatus around the caudal aspect of the nasal septum and back through the opposite nasal passage to incise the ventral attachment. This is accomplished by passing the wire through the ventral nasal meatus into the nasal pharynx and retrieving the wire through the opposite side using a rat-tooth forceps passed through the biopsy channel in a flexible endoscope. Another instrument that can be used to retrieve the wire is a long flexible grasping forceps (see Chapter 45). For the dorsal incision, the obstetric wire is threaded through the trephine opening on either side of the septum to the external nares. The caudal incision is made at a 60-degree angle to the nasal bones using a long narrow osteotome or a grooved cutting instrument fashioned from a standard wide-tipped screwdriver.[16] The tip of the screwdriver is ground concave and the edges are rounded so that the cutting edge sits better on the septum, reducing trauma to the nasal conchae. The caudal incision can also be done with obstetric wire using a Chamber's catheter to guide the wire around the vomer as far caudad as possible. The wire is retrieved on the side of the vomer as previously with the ventral wire placement. The catheter is used to hold the wire in position while performing the caudal cut.[22]

Packing the nasal cavity with sterile cotton roll gauze controls hemorrhage. Excessive packing of the nasal cavity may cause the nasal tampon to extend into the nasopharynx, where it may be inhaled or swallowed. The end of the gauze should be secured to the skin of the nares to prevent inadvertent removal of the pack.The skin and periosteal incisions are closed in a routine manner. A tracheotomy tube is placed immediately after extubation.

Aftercare includes the use of systemic antibiotic therapy for 5 to 6 days. The nasal packing may be removed after 48 or 72 hours. The nasal cavity should be flushed daily with warm physiologic saline to remove dried blood, debris, and tissue fragments. Complete healing of the septal incisions occurs within approximately 4 to 6 weeks.

The prognosis for restoring normal function is guarded. Such complications as formation of excessive granulation tissue of the caudal septal stump or adhesions to the nasal conchae with subtotal resection may result in a persistent noise or exercise intolerance. Development of the technique that removes additional parts of the caudal septum has minimized these complications. Excellent cosmetic results can be expected except in foals younger than 6 months and in some Standardbreds, in which flattening of the bridge of the nose may occur even when adequate cartilage is left for support.[16]

Ethmoid Hematoma

Ethmoid hematomas are well-encapsulated masses originating in or around the ethmoid labyrinth or occasionally from the paranasal sinuses.[23,24] The cause is unknown, but hemorrhage occurs in the submucosa of an endoturbinate or a sinus, causing the mucosa to stretch and thicken, forming the capsule of the hematoma. An enlarging lesion of the ethmoid labyrinth can extend dorsally into the frontal sinus or ventrally into the sphenopalatine sinus by disrupting the tectorial plate. It may further extend into the maxillary sinus and nasal cavity as it enlarges.[23]

In gross appearance, an ethmoid hematoma has a smooth, glistening surface that may be mottled or green-tinged. Histologically, the lesions are very distinct. The capsule is composed of respiratory epithelium and fibrous tissue. The stroma contains blood, fibrous tissue, macrophages, and giant cells with deposits of hemosiderin and occasionally calcareous deposits.[25] Progressive ethmoid hematomas have been reported in horses ranging from less than 1 year to 20 years of age, with a mean of 9.9 years.[26] Although the condition occurs mostly in middle-aged male horses, it has also been described in young horses and in females; one report found no statistical difference between the occurrence in males and females.[23,26,27] Most cases have been reported in Thoroughbreds, but ethmoid hematomas also have been described in other breeds.[23,24,27-31]

The most consistent clinical sign is mild, intermittent, unilateral epistaxis that is usually spontaneous but may occur with exercise.[23,27] An abnormal respiratory noise may be heard when the hematoma extends into the nasal cavity or causes a distortion of the paranasal sinuses. Other possible clinical signs include malodorous breath, facial swelling, head shyness, and head shaking.[23] A tentative diagnosis can be made from the history, clinical signs, and endoscopic, radiographic, and computed tomographic findings. A definitive diagnosis is made by histologic examination of the tissue. Endoscopic findings early in the development of an ethmoid hematoma can include a trickle of blood from the ethmoidal meatus or middle meatus, and a discoloration or enlargement of the great ethmoturbinate.[23] Hence, small lesions of the sinuses may not be detected endoscopically.[32] However, as the condition progresses, a greenish yellow to purplish red mass may be seen obscuring the fundus of the nasal cavity (Figure 43-6) or the entire nasal passage.

The most characteristic radiographic abnormality is a smooth, discrete, rounded density in the frontal or maxillary sinus;

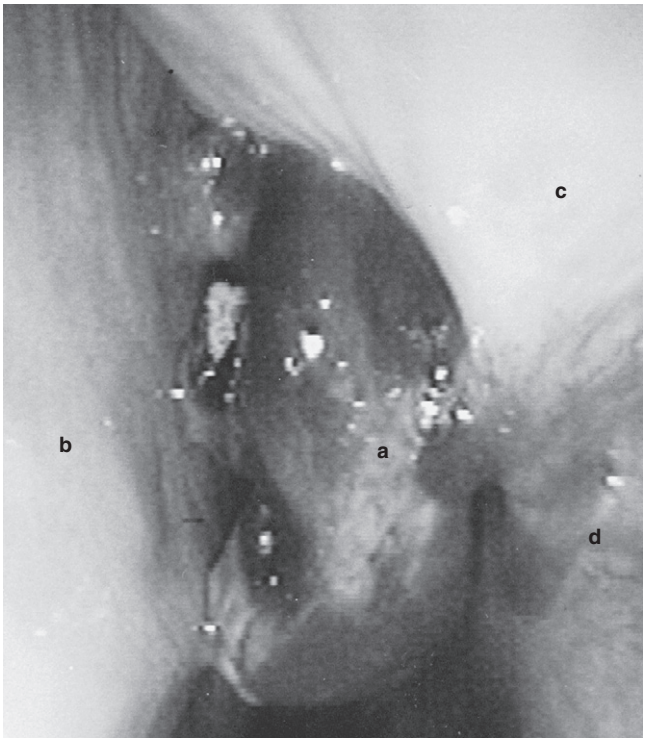

Figure 43-6. Endoscopic appearance of an ethmoid hematoma *(a)* in the left nasal fundus, located between the nasal septum *(b),* the dorsal concha *(c),* and the ventral concha *(d).*

Figure 43-7. A computed tomographic image of a horse's head in a transverse plane at the level of the orbits, demonstrating the right normal ethmoidal labyrinth *(a),* caudal compartment of the maxillary sinus *(b),* frontal sinus *(c),* ventral nasal meatus *(d),* and a soft tissue density *(e)* in the frontal and maxillary sinuses on the affected left side. (The asymmetry of the scan is caused by the horse's lateral recumbency during imaging.)

however, radiographic changes may include fluid lines or diffuse opacities of the sinuses.[23,33] Computed tomography (CT) is useful to determine the exact location and extent of the hematoma (Figure 43-7), because it provides a cross-sectional view of the skull, which eliminates the superimposition of the paranasal sinuses and nasal cavity that occurs with the lateral radiographic projection.

The differential diagnosis includes other conditions that may result in persistent or intermittent epistaxis or blood-stained nasal discharge, such as ulcerative or fungal rhinitis; foreign body; ethmoidal neoplasia; mycosis or neoplasia of the guttural pouch; skull fracture; neoplasia, infection, or cyst of the paranasal sinuses; pulmonary abscess or neoplasm; and infectious pleuropneumonia.[33,34]

The goal of surgery is removal of the mass and destruction of its origin. The surgical approach for removal depends on mass size and location. Lesions limited to the fundus of the nasal cavity and less than 5 cm in diameter can be treated transendoscopically using a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser in a standing patient or by intralesional injection of formalin (see later).[32,35,36]

Lesions that are large and extend into the nasal passage or sinuses are best approached via bone flap techniques, gaining access to the origin of the lesion with the horse standing or anesthetized in lateral recumbency. These techniques can be used to expose the maxillary sinus, frontal sinus, and nasal cavity.[28,30,36-38] One of these techniques, the frontonasal bone flap, gives improved access and has more versatility than other approaches, especially if there is involvement in both the nasal cavity and the frontal sinus.[30] It also allows the creation of a large endoscopic portal to the sinuses, which permits future evaluation for recurrence and treatment with the Nd:YAG laser in a standing patient (Figure 43-8).

Intraoperative hemorrhage is an expected complication from damage to the normal nasal or sinus mucosa, damage to the ethmoturbinates, or from the ethmoid hematoma itself. Various techniques have been described to provide hemostasis during surgery, such as bilateral carotid artery ligation, roll gauze packing, epinephrine-soaked gauze packing, vascular clips, lavage with sterile physiologic saline solution (cold or ice slush), and liquid nitrogen spray.

Cryosurgical removal of the lesion is reported to lower the incidence of recurrence and reduce hemorrhage, but care must be taken to protect the cribiform plate and avoid damage to normal structures.[23] The use of the Nd:YAG laser for removal of the lesion has been reported to decrease the amount of hemorrhage and the chance of recurrence.[32,35] My perference, if surgery is indicated, is extirpation of the lesion with radical débridement.

Thorough presurgical planning reduces delays and significant blood loss. In preparation, besides collecting 4 to 8 L of blood for a possible transfusion, it is advisable to administer at least 10 L of intravenous fluids immediately before the induction of anesthesia and to continue to administer fluids throughout the surgery, thereby alleviating hypotension associated with blood loss. The amount of hemorrhage is usually minimal until disruption of the base of the lesion or other highly vascular structures, such as the tectorial plate of the ethmoid labyrinth or the conchal wall of the conchofrontal sinus. Frequently, it is necessary to invade these structures to gain access to the base of the lesion.

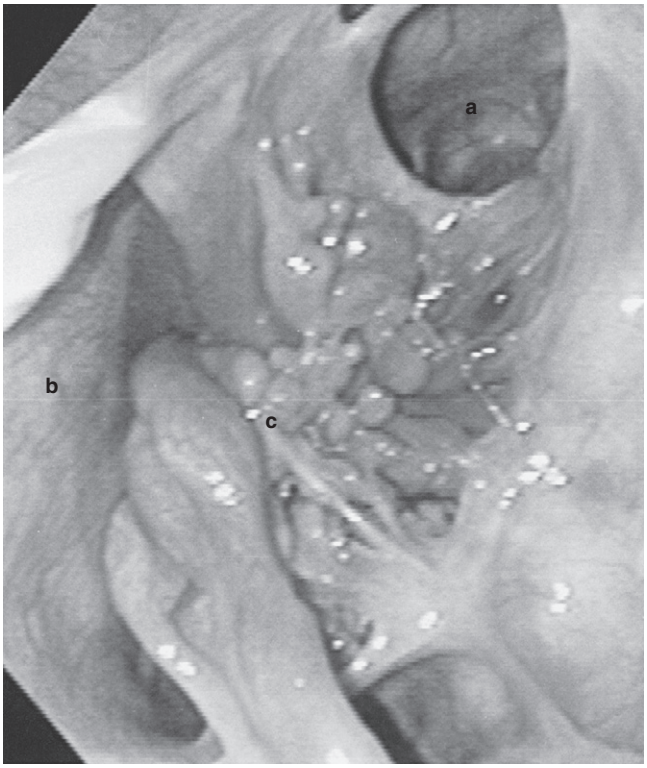

Figure 43-8. Endoscopic appearance of the nasal fundus 4 months after surgery, showing the permanent opening into the frontal sinus *(a)*, the nasal septum *(b)*, and the remains of the endoturbinates *(c)*.

Regardless of the removal technique, the most effective method for controlling hemorrhage is firm packing of the sinus or nasal cavity with sterile cotton roll gauze after surgery. The bone flap is closed in a routine manner. Before the flap is closed, a catheter is placed through the adjacent bone to simplify lavage of the sinus when the pack has been removed. To facilitate removal of the gauze, it can exit either from an aperture on the free edge of the bone flap or through the nasal cavity. The end of the gauze should be secured to the skin of the nares to prevent inadvertent removal of the pack. Administering a sedative and analgesic facilitates removal of the packing 48 to 72 hours after surgery.

Broad-spectrum systemic antibiotics are started before surgery and continued for 3 to 4 days. The use of an indwelling lavage system decreases labor and reduces the horse's resentment of the daily treatment. Lavage of the sinus is helpful in removing exudate, blood clots, and tissue debris, but its effectiveness depends on having adequate drainage through either the nasomaxillary opening or a surgically created opening into the nasal cavity (see later). The horse should be confined to stall rest with only hand-walking for at least 3 weeks. It is common to see fungal and necrotic tissue plaques develop on devitalized mucosal tissues for up to 60 days after surgery, but these usually resolve with no further treatment.

Prognosis is unfavorable without treatment because the lesion is progressive and eventually causes obstruction and dyspnea.[23] The chance of recurrence after routine surgical removal is relatively high (approximately 43%).[23,27] Clients should be advised of the importance of periodic endoscopic examinations after surgery to detect recurrence, so that prompt therapy can be instituted. Because bilateral involvement does occur, endoscopic examination of both nasal passages should always be performed. The use of the Nd:YAG laser on recurrent lesions shows promise in preventing the future recurrence, especially when access to the sinuses via the nasal passage has been provided.

Reported *ablation techniques* for the treatment of progressive ethmoid hematomas in a standing, sedated horse include transendoscopic use of the Nd:YAG laser, intralesional formaldehyde injection, and cryotherapy. The Nd:YAG laser is effective in the standing horse for lesions less than 5 cm in diameter when limited to the nasal fundus only.[35] Therefore, the technique is not applicable for lesions extending into the sinuses. Several laser applications are usually required to ablate the lesion successfully. Lesions are best photo-ablated using noncontact technique at 60 W of power. When a carbonized surface develops, at least a 7-day delay is recommended before the next treatment, to allow sloughing of the carbonized tissue.

Chemical ablation of ethmoid hematomas has been reported to be effective, inexpensive, and apparently safe.[36] Lesions are injected transendoscopically with a 4% formaldehyde solution. The solution is injected through a commercial polypropylene catheter with a retractable, swedged-on 23-gauge needle or a polypropylene tube inserted through the biopsy channel of the endoscope. The end of the tube is beveled to permit penetration of the mass. The volume of the injected solution depends on the size of the lesion. The mass is injected until it begins to distend and leakage of solution is noticed around the tube. The treatment is repeated at 3- to 4-week intervals until the lesion is obliterated or too small to inject. A range of 1 to 18 treatments with a mean of five injections has been reported.[36]

Complications included laminitis in one horse and the risk of nasal obstruction with treatment of bilateral lesions. In one report, a severe complication occurred using this technique: there was erosion and necrosis of the cribriform plate that may have allowed the formalin to reach the brain.[39]

Transendoscopic use of cryogen for the treatment of progressive ethmoid hematomas cannot be recommended because of potential damage to the endoscope, the lack of control of freezing depth, and damage to surrounding tissues with this direct evaporation technique.

DISEASES OF THE PARANASAL SINUSES

The primary clinical features of paranasal sinus disease are unilateral nasal discharge, facial swelling, and decreased nasal airflow. Occasionally seen are externally draining tracts, malodorous breath, ocular discharge, and stertor. The character of the discharge may be serous, purulent, mucopurulent, or serosanguineous, but hemorrhage usually indicates granulomatous or neoplastic lesions.

Diagnosis

A tentative diagnosis of paranasal sinus disease can be made from the history, clinical signs, and physical examination. The physical examination should include percussion of the paranasal sinuses and an oral examination. Endoscopy can be useful for determining the origin of a nasal discharge or evaluating the integrity of the nasal passage of the affected side. Radiography is the most useful diagnostic procedure to establish the location and extent of paranasal sinus disease.[8] Abnormal radiographic findings of the paranasal sinus include opacity, free fluid

accumulation (see Figure 42-23, *A*), dental abnormalities, and related bone pathology. Radiography is more reliable in revealing dental disease in the upper premolars rostral to the maxillary sinus than those located within the sinus.[33] Radiographic evidence of free fluid accumulation in the maxillary sinus is similar in frequency and quantity in both dental disease and primary sinusitis, but opacification of both the maxillary and the frontal sinus rarely occurs in dental disease, whereas it is common with primary sinusitis.

Sinocentesis

Sinocentesis is a useful diagnostic or therapeutic procedure for paranasal sinus disease. When it is performed as a diagnostic procedure, both compartments of the maxillary sinus should be sampled. The area is prepared for aseptic surgery. Anesthesia is provided by local infiltration of a 2% solution of lidocaine. The skin, subcutaneous tissue, and periosteum are readily desensitized by a small quantity of local anesthetic. After a stab incision is made through the skin and periosteum, a hole is made in the bone using a Steinmann pin or bone drill of slightly larger diameter than an indwelling plastic catheter or rigid catheter (such as a canine urinary catheter). If no sample is obtained, 20 to 30 mL of warm saline should be infused before subsequent aspiration, or the sinus may be lavaged with 0.5 L of saline and the nasal discharge examined for evidence of purulent exudate.

Sinoscopy

Sinoscopy of the paranasal sinuses has been reported to be a useful procedure for the examination, diagnosis, and treatment of some disorders of the paranasal sinuses.[40] It can be a valuable diagnostic aid when other noninvasive procedures are inconclusive. It is usually performed in the standing, conscious horse or under general anesthesia. The use of a rigid arthroscope was first reported[40] as means of examination of the paranasal sinusus but did not gain acceptance because of the inability to throughly examine the sinuses even with multiple portals. Inserting the arthroscope through one or two portals in the rostral maxillary sinus does not provide consistent access to the ventral conchal sinus or the rostral maxillary sinus. Direct access to the rostral maxillary sinus is especially difficult in horses younger than 6 years because the reserve crowns of the cheek teeth occupy most of the this sinus.

A flexible endoscope provides superior viewing and allows navigation around structures within the sinuses, facilitating identification of normal anatomy or pathology.[41,42] Inserting the endoscope through the frontal bone via a large trephine opening or a frontonasal bone flap provides direct access to the conchofrontal and caudal maxillary sinus and indirect access to the ventral conchal and rostral maxillary sinus by fenestrating the bulla of the ventral concha. If the bulla cannot be viewed through the portal in the frontal bone, a second portal is recommended into the caudal maxillary sinus.[43] The ventral conchal bulla can be fenestrated with either a Smith-Ferris arthroscopic ronguer or a Matthew aural (crocodile) forceps passed through the same trephine opening as the endoscope or the second portal in the caudal maxillary sinus.

The examination is performed with a 12-mm flexible videoendoscope using portals created with a 15-mm Galt trephine. Anatomic locations for these trephine sites in an adult horse are (1) conchofrontal sinus—60% of the distance from the midline to the medial canthus and 0.5 cm caudal to the medial canthus, (2) caudal maxillary sinus—2 cm rostral and 2 cm ventral to the medial canthus, and (3) rostral maxillary sinus—40% of the distance from the rostral end of the facial crest to the level of the medial canthus and 1 cm ventral to a line joining the infraorbital foramen and the medial canthus. The previously reported trephine site for the rostral maxillary sinus using 50% of the distance from the rostral end of the facial crest to the level of the medial canthus and 1 cm ventral to a line joining the infraorbital and the medial canthus has been shown to signficantly increase the risk of inadvertent entry into the caudal maxillary sinus than when using the more-rostral located site.[44]

Sinusitis

Sinusitis is the most commonly encountered disease of the paranasal sinuses. It may be classified as either primary or secondary and as either acute or chronic. Empyema refers to purulent exudate within the sinus and is not necessarily synonymous with chronic sinusitis. Primary bacterial sinusitis usually results from previous upper respiratory tract infections. *Streptococcus* species are the most commonly reported organisms of primary sinusitis.[14]

Primary Sinusitis

The principles of therapy for primary sinusitis are to provide adequate drainage and to use the appropriate systemic antimicrobial agents based on antibiotic culture results and sensitivity testing. Drainage may be enhanced by lavaging the sinus once or twice daily. Drainage and lavage are accomplished by either placing an indwelling catheter percutaneously into the maxillary sinus (see "Sinocentesis," earlier for the procedure) or by using a sterile 13-mm nasogastric tube through a trephine opening in the frontoconchal sinus. The skin over the site for entering the frontoconchal sinus is anesthetized with 2% mepivicaine (see later). A slightly curved incision is made through all layers of tissue to the bone (based axially). The skin incision is made 10 mm to 15 mm larger than the trephine opening into the sinus. This extra margin between the skin incision and edge of the bone provides support for the skin and periosteum on closure and reduces the risk of complication associated with skin closure. The skin and periosteum are reflected from the bone together, and a circular opening is made using a 19-mm Galt trephine. The disc of bone is discarded. The exudate is most efficiently removed by flushing the sinuses with a mild salt solution consisting of 35 g of salt per 4 L of water (1.2 ounces/gallon) using a sterile nasogastric tube and stomach pump.

Primary paranasal sinusitis usually resolves with systemic antibiotic therapy and lavage, but when the exudate becomes inspissated in the ventral conchal sinus, surgical treatment becomes necessary.[45,46] This condition should be suspected when a primary paranasal sinusitis does not resolve with systemic antibiotics and lavage. Other features of a ventral conchal sinusitis are as follows:

1. The radiographic presence of a soft tissue density over the roots of premolar 108/208 and molars 109/209 and molars 110/210.
2. Distortion of the sinus, seen as a narrowing of the nasal passage caused by an accumulation of inspissated exudate in the ventral conchal sinus

Surgical treatment includes removing the exudate from the ventral conchal sinus and providing additional drainage if necessary. The ventral conchal sinus can be accessed via a maxillary bone flap over the infraorbital canal or by trephining the conchofrontal sinus over the frontomaxillary opening in the standing, concious horse and fenestrating the ventral conchal bulla (see later). Flushing the rostral maxillary and ventral conchal sinus through the fenestrated bulla of the ventral conchal sinus is facilitated by attaching a bent Yankauer suction tip to a sterile, 13-mm nasogastric tube.

Secondary Sinusitis

Secondary sinusitis may be caused by dental disease, facial fractures, granulomatous lesions, or neoplasms. Identifying the cause of sinusitis radiographically can be very difficult with exudate in the sinus. Removal of the exudate via lavage through a trephine opening into the conchofrontal sinus enhances the radiographic and endoscopic examination of the sinuses. After the exudate is removed, the frontoconchal and caudal maxillary and indirectly the ventral conchal and rostral maxillary sinuses can be reexamined either radiographically or endoscopically.

The skin is closed temporarily with skin staples to allow daily flushing for 3 to 4 days. After the final flush, the skin is closed with four simple interrupted sutures to provide additional support to the skin staples. Dental disease is the most common cause of secondary sinusitis (see Chapter 30).[47] Secondary sinusitis is generally more difficult to treat and requires surgical intervention to remove the underlying cause (see "Surgical Approaches to the Paranasal Sinuses," later).

Paranasal Sinus Cysts

Occurrence of paranasal sinus cysts is well documented.[48-53] The exact etiology and pathogenesis are unknown. There is some evidence that these cysts may have a common origin with ethmoid hematomas,[49] but others did not find enough evidence to support this correlation.[50] The condition is usually seen in horses ranging in age from nursing foals to young adults, but it is also seen in adult horses. The most common clinical features are dyspnea, facial swelling, and nasal discharge. As the cysts expand, the pressure causes distortion of the ventral nasal concha, the normal internal structures of the sinus, and the maxilla, resulting in obstruction of the common nasal meatus and possibly deviation of the nasal septum and facial deformity. The cysts are typically filled with a yellow, viscous fluid unless they become secondarily infected. There have been no reports of spontaneous regression. Surgical management consists of removing the cyst lining. Removal of the lining from the wall of the sinus is performed by a combination of digital separation and traction. It may be difficult and impractical to remove all the tissue closely adherent to the infraorbital canal and alveoli. Exposure of the sinus is best provided by a frontonasal[30] or a modified frontonasal bone flap[54] technique. Although the prognosis is usually thought to be guarded because of the accompanying distortion of the ventral nasal concha and nasal septum, there are reports of regression of the nasal obstruction and facial deformity after surgery in young, growing horses.[51,53] A long-term retrospective study reported excellent results with complete resolution of the clinical signs without recurrence in 45 of 48 horses.[55]

Neoplasia

The most common tumor of the paranasal sinuses is squamous cell carcinoma. Other invasive tumors reported include spindle-shaped sarcoma; osteogenic sarcoma, lymphosarcoma, and a poorly differentiated carcinoma; ethmoid carcinoma; hemangiosarcoma; and adenocarcinoma.[20,56-58] Solid, noninvasive neoplasms (such as fibroma, osteoma, and ameloblastic odontoma) have been reported.[58-61] Useful clinical signs that may aid in differentiating neoplasia from other sinus diseases are malodorous breath without evidence of dental disease and radiographic evidence of widespread bone destruction. The prognosis is generally unfavorable unless the neoplasm is a solid noninvasive tumor, because the majority are malignant.[58]

SURGICAL APPROACHES TO THE PARANASAL SINUSES

Surgical access to the paranasal sinuses can be obtained by either trephination or bone flap techniques.[30] The bone flap techniques are superior to trephination because they provide better exposure, visualization, and access for surgical manipulation within the sinuses, and they eliminate the need for multiple trephine openings. The bone flap technique was first described for exploration of the maxillary sinus, but the technique can also be used for the frontal sinus and nasal cavity. The frontonasal bone flap is much more versatile than the maxillary bone flap because it allows thorough exploration of most of the paranasal sinuses including the ventral conchal and rostral maxillary sinuses and better exposure for surgical manipulations.[30] A modified frontonasal bone flap has been described in the standing horse as an alternative to the traditional frontonasal bone flap approach.[54] It was found to be practical, provide adequate exposure and reduce surgery time.

Trephination

Trephination is the traditional approach for surgical access to the paranasal sinuses. It is useful for diagnostic and therapeutic access to the sinuses. The common Galt trephines range in size from 6.4 mm to 25 mm. The size of the trephine selected depends on the intented purpose of the opening. A large trephine (19 mm or 25 mm) opening through the frontal bone over a frontomaxillary opening has become very useful. It provides better exposure for direct and indirect (via fenestration of the bulla of the ventral conchal sinus) endoscopic examination and treatment of the sinus. The trephine opening can be enlarged even more with a curved-jaw Stille Luer ronguer if slight modification in the opening is needed. When enlarging the trephine opening, it is important to leave a 10-mm to 15-mm margin between the skin incision and the bone for skin closure. The approximate sites for trephination of the frontal, caudal, and rostral maxillary sinuses are shown in Figure 43-1 (also see "Sinoscopy," earlier). The trephination sites usually heal within 3 to 4 weeks with minimal blemish. The trephine opening for the so-called "modified frontonasal bone flap technique" (which in fact is a trephine opening) is centered 5 cm axial to the nasal lacriminal duct, 4 cm lateral to the nasal midline, and 2 cm below a horizontal line between the medial canthi.[54] The nasal lacriminal duct can be identified by a line from the medial canthus to the incisive notch. A curved incision is made through the skin and periosteum and reflected from the

bone as one. A 5-cm skull trephine is used to make the opening into the conchofrontal sinus. As with other trephinations, the bone disc is discarded. As mentioned before, the skin flap should be larger than the size of the trephine hole in the bone. Leaving a 10-mm to 15-mm margin of skin is even more important for skin closure and cosmetic results using this technique than when using small trephine openings.

The age of the horse should be considered when selecting the site for trephination of the maxillary sinus. The alveoli of the caudal three cheek teeth form the ventrolateral wall of the maxiallry sinus. In horses 3 years old and younger, the alveoli lie immediately under the osseous infraorbital canal. As the horse ages and the teeth advance, the sinus becomes larger. The trephination sites usually heal within 3 to 4 weeks with minimal blemish.

Bone Flap Approaches

For the *maxillary bone flap* (Figure 43-9), the *rostral* margin is a line drawn from the rostral end of the facial crest to the infraorbital foramen; the *dorsal* margin is a line from the infraorbital foramen to the medial canthus of the eye, the *caudal* margin is a line (parallel to the rostral margin) from the medial canthus of the eye to the caudal aspect of the facial crest, and the *ventral* margin is the facial crest. These boundaries provide maximal exposure of the maxillary sinus while protecting the vulnerable infraorbital canal and nasolacrimal duct. The osteotomy for the ventral margin of the flap should be located just dorsal to the facial crest to prevent injury to ventral border of the flap. Initiating the ventral osteotomy from the caudal aspect also allows safer flap creation because there is more distance to the underlying tooth roots than at the rostral aspect.

Alternatively, for the *frontonasal bone flap* (Figure 43-10), the *caudal* margin is a perpendicular line from the dorsal midline to a point midway between the supraorbital foramen and the medial canthus of the eye, the *lateral* margin begins at the caudal margin 2 to 2.5 cm medial to the medial canthus of the eye and extends to a point approximately two thirds the distance from the medial canthus of the eye to the infraorbital foramen, and the *rostral* margin is a perpendicular line from the dorsal midline to the rostral extension of the lateral margin. The estimated course of the nasolacrimal duct is a line from the medial canthus of the eye to the nasoincisive notch. In some horses, the rostral portion of the lateral margin has to be angled toward the midline to avoid the duct (see Figure 43-10).

When the boundaries of the area to be explored are determined, a skin incision is made along the rostral, ventral or lateral, and caudal borders. The incision is continued through the subcutaneous tissue to the periosteum, which is exposed and incised. The periosteum is reflected from the site of the proposed osteotomy incision approximately 5 mm. The osteotomy can be performed using an oscillating bone saw, a pneumatic drill with a tapered burr, or an osteotome and mallet. The osteotomies should be beveled so that when the bone flap is replaced it will provide a more secure closure. When the osteotomy has been completed on all three sides, the bone flap can be slowly elevated until it fractures along the fourth (or dorsal) side of the rectangle beneath intact tissue. As the bone flap is being elevated for the maxillary approach, the septum between the compartments should be severed using a long, thin

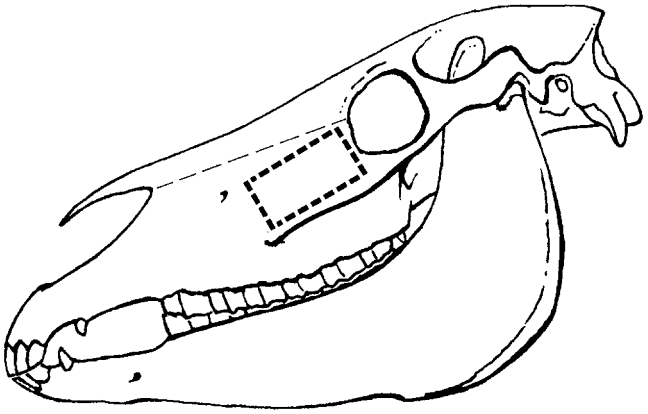

Figure 43-9. Diagram of the skull demonstrating the site for the bone flap technique for exposing the maxillary sinus. The boundaries outlined by *bold dashed lines* provide maximal exposure of the maxillary sinus while protecting the nasolacrimal duct and infraorbital canal. The *long dashed line* from the medial canthus to the incisive notch depicts the approximate course of the nasolacrimal duct. (For a description of the margins of the maxillary bone flap, see "Surgical Approaches to the Paranasal Sinuses.")

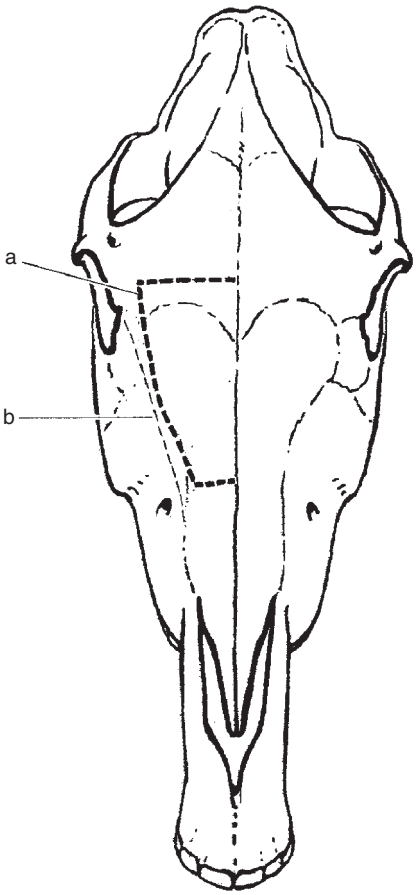

Figure 43-10. Diagram of the skull demonstrating the site for the frontonasal bone flap technique for exposing the caudal aspect of the nasal cavity, dorsal conchal sinus, and frontal sinus *(a)*. The *long dashed line (b)* from the medial canthus to the incisive notch depicts the approximate course of the nasal lacrimal duct. (For a description of the margins of the frontonasal bone flap, see "Surgical Approaches to the Paranasal Sinuses.")

osteotome. The fracture can be controlled by steady, even pressure and the bone flap completely elevated to expose the area.

Before closure, an indwelling lavage system is usually placed through the adjacent bone or a corner of the flap and secured to the skin to facilitate daily lavage. Closure is initiated by pressing the bone flap into its original position and by closing the periosteum with 2-0 absorbable suture using a simple-continuous pattern. A simple-interrupted stainless steel or monofilament nonabsorbable suture placed at each corner of the flap through small drill holes in the respective facial bones occasionally is necessary to secure the flap to the parent bone, but these are frequent sites of fistula formation and should be avoided when possible. The subcutaneous tissue and skin are closed in routine manner. The skin incision usually heals rapidly with minimal scarring.

Frequently, creating a surgical opening into the nasal cavity is necessary to improve drainage. Identifying such a site in the conchofrontal sinus (Figure 43-11) can be aided by passing a mare urinary catheter caudad in the dorsal meatus and feeling the catheter tip through the thin conchal portion of the sinus. The conchal wall is perforated using a curved forceps. The catheter is passed through the opening to aid in the placement of a Seton drain threaded through the nasal cavity from the sinus. The site for establishing communication between the rostral maxillary sinus and the nasal cavity is located dorsally over the infraorbital canal in young horses and ventral to the canal in older horses. Caution should be used to prevent damage to the infraorbital canal. The use of a Seton drain helps maintain the patency of the newly created opening to the nasal cavity; a mushroom catheter is usually used instead of gauze or Penrose tubing with the bone flap technique. After the Seton drain has been removed, the newly created opening might remain permanently open or it might close naturally; therefore, the Seton drain should not be removed until the underlying disease is resolved.

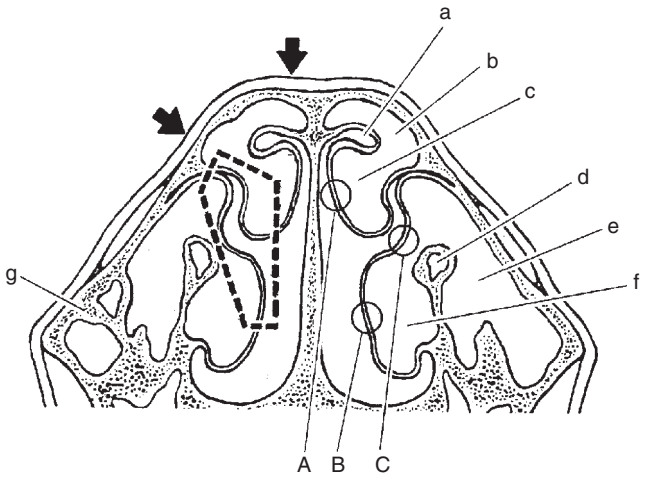

Figure 43-11. Sites for establishing drainage from the paranasal sinuses into the nasal cavity (cross-section of the skull at the level of the first molar). The conchofrontal sinus may be fenestrated at *A* or *B* to establish drainage into the nasal cavity. Fenestration of the ventromedial wall of the dorsal conchal sinus *(C)* creates ventral drainage of the ventral concha sinus into the nasal cavity. This diagram of the skull also demonstrates the medial and lateral edges of the frontonasal bone flap *(arrows)* at this level. The structures within the *dashed lines* have to be removed to provide access to the dorsal conchal and maxillary sinuses and the nasal passage. *a*, Dorsal meatus; *b*, frontal sinus; *c*, dorsal conchal sinus; *d*, infraorbital canal; *e*, rostral maxillary sinus; *f*, ventral conchal sinus; *g*, oblique septum between the rostral and caudal compartments of the maxillary sinus.

Gaining Surgical Access to the Ventral Conchal Sinuses

The ventral conchal sinus can be entered over the osseous infraorbital canal through the conchomaxillary opening in young horses or by penetrating the thin bony plate (see Figure 43-11) below the osseous infraorbital canal in older horses. After the inspissated exudate is removed, the nasomaxillary opening should be assessed for patency by flushing the sinus with saline and observing for nasal outflow. The medial or ventromedial wall of the sinus can be fenestrated to create an opening into the nasal passage if the nasomaxillary opening is not functional. Removal of inspissated exudate from the ventral conchal sinus can also be achieved in the standing horse via a 19-mm or 25-mm trephine opening (a larger trephine opening is better for surgeons with large fingers) into the conchofrontal sinus (see Figure 43-1).[45] The bulla of the ventral conchal sinus is identified by palpating ventral and slightly rostral to the frontomaxillary opening (see Figure 43-1). The bulla can be fenestrated with an index finger, and the thin bony fragments and mucosa are removed with either a Ferris-Smith arthroscope ronguer or a Matthews aural (crocodile) forceps. The exudate is removed by inserting a Yankaue suction tip attached to a sterile, 13-mm (outside diameter) nasogastric tube into the ventral conchal sinus and flushing with a mild salt solution (35 g of salt per 4 L of water) with a sterile stomach pump.

One of the most important aspects of the treatment of sinusitis is lavage of the sinus to remove exudate, blood, blood clots, or tissue debris. The effectiveness of the lavage depends on adequate drainage, either through a patent nasomaxillary opening or through surgically created openings into the nasal cavity. The frequency and volume are probably more important than the type of lavage solution. Sterile physiologic saline or a mild salt solution is as effective as antiseptic solutions in most cases and reduces irritation of the mucous membranes. The use of an indwelling lavage system decreases labor and reduces the horse's resentment of daily lavage. Placing a sterile tube through a small trephine opening and pumping a mild salt solution through a sterile pump is a very simple method of flushing the sinuses but does not deliver volume or pressure obtained by flushing with a sterile nasogastric tube and pump (see treatment modalities under "Sinusitis," earlier).

The use of systemic antibiotic therapy depends on the primary disease and should be based on bacterial cultures and antibiotic sensitivity results. Feeding the horse on the floor enhances drainage and reduces contamination by hay and dust. The use of a sterile dressing or protective hood made from stockinette for a few days reduces contamination and protects the surgical sites from self-inflicted trauma.

CHAPTER 44

Pharynx

Norm G. Ducharme

ANATOMY AND PHYSIOLOGY

The pharynx is a musculomembranous tubular structure unsupported by bone or cartilaginous matrix. It has different roles during breathing, deglutition, and vocalization. The pharynx is composed of the nasopharynx, oropharynx, and laryngopharynx. The pharynx extends from the caudal end of the nasal cavity/oral cavity to the larynx and is divided by the soft palate to form the nasopharynx dorsally and the oropharynx ventrally.[1] Starting at the base of the epiglottis and extending caudad to the arch of the cricoid cartilage is the laryngopharynx. During respiration, the caudal free margin of the soft palate intimately contacts the subepiglottic tissue at the base of the equine larynx (Figure 44-1) and prevents communication between the oropharynx and nasopharynx. The nasopharynx is attached to the pterygoid, palatine, and hyoid bones and to the laryngeal, cricoid, and thyroid cartilages by muscles that cause dilation and constriction of the nasopharynx.[2] In describing the anatomical basis of the respiratory function of the nasopharynx, the oropharynx has been largely ignored in horses. The anatomy of the oropharynx is likely to become more important as our understanding of the disease grows as was evidenced from the role of the hypoglossal nerve on stability of the soft palate at exercise.[3]

Although the nasopharynx is not directly supported by cartilage or bone, it must withstand large changes in intraluminal pressures (from 24 to 50 cm H_2O) that occur at varying airflow velocities (up to 90 L/sec), with minimal changes in diameter. It does this through muscular contraction, whose neural (i.e., sensory drive) inputs are not well understood in horses. Several groups of muscles alter the size and configuration of the nasopharynx and oropharynx, including the muscles that move the tongue, insert on the hyoid apparatus and larynx, and regulate soft palate position.[4-10] Other muscles alter the position of the hyoid apparatus. specifically, ventral displacement of the basihyoid, which increases nasopharyngeal size and stability by increasing the diameter or decreasing the compliance of the nasopharynx.[5,6] The relevant musculature can be classified as intrinsic or extrinsic to the nasopharynx.[11] The intrinsic muscles, which include those of the soft palate and nasopharyngeal musculature, insert on the mucosa or the confined walls and roof of the nasopharynx. The extrinsic muscles include those of the larynx and the hyoid apparatus, which affect either or both the position of the basihyoid bone or the larynx, and probably affect the morphology of the nasopharynx by changes to the oropharynx.

Intrinsic Musculature

The intrinsic musculature contributes to the stability of the nasopharynx mainly by timely muscular contractions that tense and dilate the pharyngeal walls (Figure 44-2). The floor of the nasopharynx is formed by the soft palate extending caudad from the hard palate to the base of the larynx. The soft palate consists of oral mucous membrane that contains the palatine glands and their ductile openings, palatine aponeurosis, palatinus and palatopharyngeus muscles, and nasopharyngeal mucous membrane.[2] The palatine aponeurosis is formed by expansion of the tendon of the tensor veli palatini muscle.[2,10] This aponeurosis attaches to the caudal margin of the hard palate. It is thick cranially and very thin caudally, where the soft palate is more muscular. The caudal free margin of the soft

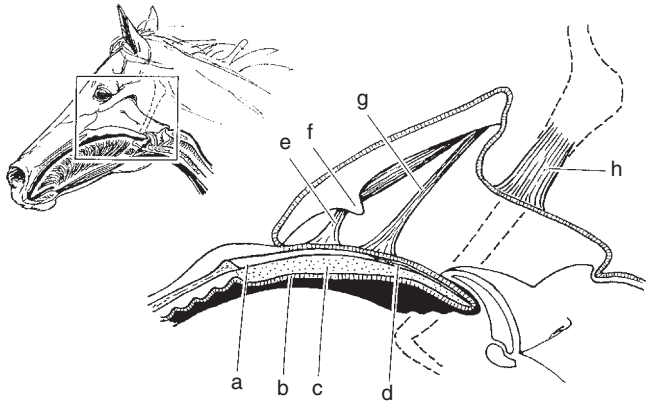

Figure 44-2. The intrinsic structures of the nasopharynx. The nasopharynx forms the passageway that transfers airflow from the caudal aspect of the nasal cavity to the larynx. The floor of the nasopharynx is formed by the soft palate and its relevant structures (*a,* palatine aponeurosis; *b,* oral mucosa; *c,* glandular layer; *d,* palatinus muscle) and is normally in a subepiglottic position during respiration. The hamulus *(f)* of the pterygoid bone, and the tensor veli palatini *(e),* levator veli palatini *(g),* and palatopharyngeus (not shown) muscles are underneath the mucosa of the lateral walls of the nasopharynx. The stylopharyngeus *(h)* with the palatopharyngeus muscles add to the stability of the roof of the nasopharynx.

palate continues dorsad on either side of the larynx, forming the lateral pillars of the soft palate. Muscle fibers of the palatinus muscle course beneath the nasopharyngeal mucosa and extend along the pillars of the soft palate. These pillars unite dorsally, forming the palatopharyngeal arch.[2]

The position of the soft palate is partially determined by the coordinated function of four muscles (see Figure 44-2, and Figure 44-3): the tensor veli palatini, levator veli palatini, palatinus, and palatopharyngeus muscles. The tensor veli palatini muscle is innervated by the mandibular branch of the trigeminal nerve, and the other three are all innervated by the pharyngeal branch of the vagus nerve.[2,7,10] The levator veli palatini muscle arises from the muscular process of the petrous part of the temporal bone and the lateral lamina of the auditory tube and passes along the lateral wall of the nasopharynx to insert within the soft palate dorsal to the glandular layer.[2] This muscle elevates the soft palate during swallowing, closes the nasopharynx, and facilitates oral ventilation in nonobligate nasal breathers. The palatinus muscle consists of a paired fusiform muscle that originates at the caudal aspect of the palatine aponeurosis and courses through the middle of the soft palate, just beneath the nasal mucosa, to ramify in the caudal free margin of the soft palate. The palatopharyngeus muscle arises from the palatine aponeurosis (lateral to the palatinus muscle attachment) and from the palatine and pterygoid bones.[2] The fibers continue caudad on the lateral wall of the pharynx and partially insert into the upper edge of the thyroid cartilage. The remainder of the muscle continues dorsad and inserts at the median fibrous raphe. The palatinus and palatopharyngeus muscles shorten the soft palate and depress it toward the tongue.[4] The tensor veli palatini muscle is a fusiform muscle that originates at the muscular process of the petrous part of the temporal bone, pterygoid bone, and lateral lamina of the auditory tube and travels rostroventrad along the lateral wall of the nasopharynx lateral to the levator veli palatini.[2] The tendon courses around the hamulus of the pterygoid bone and ramifies in the palatine aponeurosis. This muscle tenses the rostral aspect of the soft palate by using the hamulus as a pulley and retracts the soft palate away from the dorsal pharyngeal wall, expanding the nasopharynx and slightly depressing it ventrad during inspiration.[10]

The final intrinsic muscle of the nasopharynx is the stylopharyngeus, which is divided into two parts.[8,12] The rostral stylopharyngeus muscle originates from the medial surface of the rostral end of the stylohyoid bone and inserts on the pharyngeal raphe. It is a pharyngeal constrictor that is not known to be stimulated during exercise, so it will not be discussed further. The caudal stylopharyngeus muscle is a pharyngeal dilator that originates from the medial aspect of the caudal third of the stylohyoid bone and courses ventrally and rostrally to attach on the dorsolateral wall of the pharynx (see Figure 41-5).[8,12] It is innervated by the glossopharyngeal nerve and is responsible for tension on the roof of the nasopharynx (Figure 44-4) that helps it resist collapsing with inspiratory pressure.

The blood supply to the soft palate is derived from the linguofacial trunk, and maxillary artery and venous drainage occurs via the accompanying veins.[2] The lymph vessels drain toward the retropharyngeal lymph nodes. The afferent innervation from branches of the trigeminal, glossopharyngeal, and vagus nerves arises from pressure, mechanical, and temperature receptors lining the mucous membrane of the nasopharynx, including the soft palate.

Extrinsic Musculature

The extrinsic muscles contribute to the respiratory patency of the nasopharynx by indirectly increasing its diameter through change in size of the oropharynx or position of the larynx[13,14] and by a mechanism not yet understood, it increases the stability of the soft palate at exercise. The potential roles of these extrinsic muscles have been identified in horses when interfering with their function, results in dorsal displacement of the

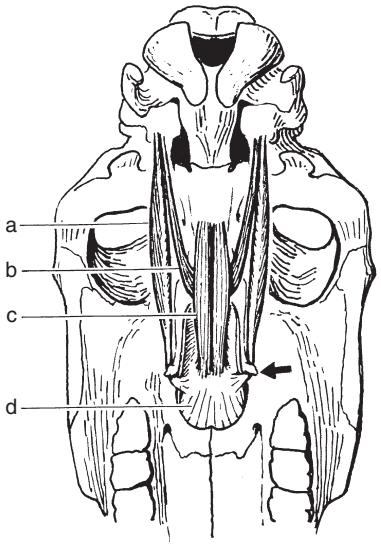

Figure 44-3. The intrinsic structures of the nasopharynx viewed from the ventral aspect of the nasopharynx, showing the muscles of the soft palate, the palatine aponeurosis *(d),* and the hamulus of the pterygoid bone *(arrow). a,* Tensor veli palatini muscle; *b,* levator veli palatini muscle; *c,* palatinus muscle.

soft palate (DDSP) during exercise.[3,15] They are the left and right geniohyoideus, thyrohyoideus, genioglossus, hyoglossus, styloglossus, sternohyoideus and sternothyroideus muscles.

The genioglossus muscle is a fan-shaped extrinsic tongue muscle that originates within the median plane of the tongue and attaches to the oral surface of the mandible, caudal to the symphysis (see Figure 44-1).[2] Contraction of the genioglossus muscle protracts the tongue and pulls the basihyoid bone rostrally. In horses, this activity may be reproduced by the tongue tie,[3] which has been shown to be useful in treatment of DDSP in a recent case-control study.[16] Although this treatment is logical, experimental studies failed to elucidate the anatomic mechanism of action as computed tomographic imaging showed no measurable improvement in nasopharyngeal diameter by using a tongue-tie in normal horses.[17]

In humans, contraction of muscles that insert on the hyoid arch increases upper airway size and stability by increasing the diameter and stiffness of the nasopharynx.[5,6] The rostrohyoid and caudohyoid muscle groups exert rostral and caudal forces, respectively, on the hyoid apparatus. The geniohyoideus is a rostrohyoid muscle that originates, in conjunction with the aforementioned genioglossus, on the medial surface of the mandible near the symphysis and inserts on the basihyoid bone. Its action draws the hyoid apparatus rostrally and protudes the tongue.[2] The styloglossus muscle lies on the lateral aspect of the tongue, which originates on the lateral aspect of the stylohyoid bone and inserts on the tip of the tongue, and its function is to retract the tongue (i.e., retruder). The hyoglossus muscle is located medial to the styloglossus muscle, originates on the hyoid bones (lingual process and stylohyoid and thyrohyoid bone), and inserts on the median plane of the dorsum of the tongue. Its action is to retract (i.e., retruder) and depress the base of the tongue.[2] Because local anesthesia of the hypoglossal nerve at the mid level of the ceratohyoid bone interferes with the action of the geniohyoideus and genioglossus muscles (protuders of the tongue) at the same time as that of the styloglossus and hyoglossus (retruders), the exact function of each muscle is not yet known.[3] The sternohyoideus and sternothyroideus muscles are caudohyoid muscles that originate on the sternal manubrium and extend cranially.[2,18] The sternothyroideus inserts on the caudal abaxial aspect of the thyroid cartilage, and the sternohyoideus muscle inserts on the basihyoid bone and lingual process of the hyoid apparatus. Contraction of these muscles results in caudal traction on the hyoid apparatus and larynx. In dogs and humans, muscles that put rostral traction on the basihyoid bone work in a coordinated fashion with muscles that apply caudal traction, and the sum of these vector forces is a net ventral displacement of the basihyoid bone.[5] This motion increases the angle at the ceratohyoid–stylohyoid joint, increasing the dorsoventral dimension of the nasopharynx. In doing so, the lateral walls of the nasopharynx expand slightly and become taut.[5] Although this has not been demonstrated conclusively in horses, dysfunction of the strap muscles (sternohyoideus and sternothyroideus) in horses has been shown experimentally to increase upper airway pressure at exercise.[17] This suggests that nasopharyngeal impedance is increased by dysfunction of these extrinsic muscles.

Another extrinsic muscle known to increase the patency of the nasopharynx is the hyoepiglotticus muscle (see Figure 44-1), which attaches to the hyoid bone at the base of the epiglottis and, during its contraction, pulls the epiglottis ventrad toward the base of the tongue, thereby increasing the ventral dimension of the rima glottidis.[2,9] The hyoepiglotticus muscle is the only muscle that inserts on the epiglottis.

Finally, the thyrohyoideus muscle, which extends from the lateral lamina of the thyroid cartilage to the caudal aspect of the thyrohyoid bone (see Figure 44-1) was thought to move the larynx rostrad only during deglutition.[2] However, resection of this muscle disrupts the normal stability of the nasopharynx during exercise, resulting in DDSP.[15] Therefore, the mechanism of action of the thyrohyoideus muscle is to enhance soft palate stability during exercise by moving the larynx rostrad so the thyroid cartilage rests more dorsal and rostral in relation to the basihyoid.[15]

The hypoglossal nerve innervates the following muscles: geniohyoideus (main branch), genioglossus (medial branch), styloglossus, hyoglossus (lateral branch), and hyoepiglotticus muscles (main branch).[2,3] The sternohyoideus and sternothyroideus muscles receive motor innervation from branches of the first and second cervical nerves.[2] Although it has been reported that the thyrohyoid branch of the hypoglossal nerve is responsible for innervation of the thyrohyoideus muscle, one investigation suggests that the pharyngeal branch of the vagus is responsible for this innervation (in rabbits).[19] Arterial blood supply to the pharynx is provided by the common and external carotid arteries and the linguofacial trunk.[2] Venous drainage is provided by the accompanying veins.[2] Lymph vessels drain toward the retropharyngeal and cranial cervical lymph nodes.[2] The trigeminal, vagus, and glossopharyngeal nerves provide afferent sensory innervation to the nasopharyngeal mucosa.

ANATOMIC DISORDERS OF THE NASOPHARYNX

Nasopharyngeal Cicatrix

Nasopharyngeal cicatrix was a condition first reported as being more commonly seen in aged female horses, but more recent data suggest only a slight predisposition for mares (60% of 87 horses).[20,21] Affected animals range in age from 5 to 29 years.[20,21] This anomaly is seen almost exclusively in hot climates of the United States (mostly in eastern and southern Texas, with occasional reports from Mississippi, Louisiana, Oklahoma, and Florida) in horses kept on pasture. An environmental allergen is thought to lead to nasopharyngeal inflammation and subsequent damage to the nasopharyngeal and laryngeal mucosa and submucosa. Secondary healing results in a web of nasopharyngeal scarring that reduces the diameter of the nasopharynx, or restricts its function when severe (Figure 44-5).[20,21] In nearly 95% of reported cases, deformed epiglottic, arytenoid, or medial cartilage of the guttural pouch opening is seen (Figure 44-6).[20,21] Because of the larger cross-sectional area of the nasopharynx in comparison to the rima glottidis and extrathoracic trachea, only severe scarring of the nasopharynx causes functional abnormalities. The degree of involvement of other structures determines clinical signs.

Clinical signs for this condition include upper respiratory noise and exercise intolerance, with dysphagia rarely seen. The airway sounds may be variable, depending on whether nasopharyngeal scarring results in DDSP or arytenoid chondritis. Involvement of one or both of the arytenoid cartilages is the most common reason for exercise intolerance and respiratory noise. The degree of performance interference depends on the athletic demands and degree of ventilation interference.

Figure 44-5. Endoscopic photograph of a nasopharyngeal cicatrix in a horse, characterized by scar formation across the floor of the nasopharynx. (Courtesy P. Rakestraw, Texas A&M University.)

Figure 44-6. Endoscopic photograph of a nasopharyngeal cicatrix affecting the larynx and epiglottic cartilage. Note the deformation of right arytenoid cartilage, as well as scar formation across the floor of the nasopharynx. (Courtesy P. Rakestraw, Texas A&M University.)

The diagnosis is made by endoscopic examination. In the earliest stages, hyperemic mucosa is observed; there may also be yellow or discolored areas (plaques) on the pharyngeal walls, even in areas where a cicatrix does not form (Figure 44-7). The cicatrix can be limited to a local area or involve the entire

Figure 44-7. Endoscopic view of early nasopharyngeal inflammation, a precursor of nasopharyngeal cicatrix. (Courtesy P. Rakestraw, Texas A&M University.)

circumference of the pharynx, and it usually includes one or more transverse bands of tissue located between the guttural pouch opening and the larynx (see Figure 44-5). In 20% of the cases reported, one of the guttural pouch openings was involved in the cicatrix.[20] Because this type of cicatrix is generally associated with epiglottic and arytenoid chondropathy (see Figure 44-6), the anatomic integrity of these structures should be assessed as well as the position of the soft palate.

As soon as the diagnosis is made, the horse should be removed from the pasture and anti-inflammatory therapy initiated.[21] Horses housed in a dry lot or box stall do not seem to be affected by this disease. If the cicatrix causes nasopharyngeal obstruction, it can be transected in two or three places under videoendoscopic guidance with the horse standing, using a diode or other appropriate laser; however the cicatrix reforms unless the horse is moved to a different environment.[22] Although nasopharyngeal stenting has been reported, its use does not seem to have significant value.[21,23] Partial arytenoidectomy in this heavily scarred environment leads to an inappropriate diameter of the rima glottidis during postoperative healing and, therefore, should not be performed. If airway obstruction is associated with chondritis, a permanent tracheostomy[22] (as described in Chapter 47) should be performed. Very good long-term results was reported after permanent tracheostomy for treatment of this condition in 59 horses.[22]

Nasopharyngeal Masses

Nasopharyngeal masses occur rarely in horses. When masses are present in the nasopharynx, they usually are extensions of paranasal sinus, guttural pouch, or oropharyngeal diseases. However, primary masses involving the nasopharynx can include benign lesions (such as fungal granulomas and cysts) and neoplastic lesions (such as lymphosarcoma and squamous cell carcinoma).[24-26] Depending on the size and location of these masses, they may result in DDSP, dysphagia, or airflow obstruction. Therefore, clinical signs may include exercise intolerance,

respiratory noise, nasal drainage, and weight loss. If the mass extends into the rostral nasopharynx or nasal cavity, uneven airflow can be detected at the nostril, and mucopurulent drainage may be present. Occasionally, pedunculated cysts or polyps originate near the guttural pouch opening, obstructing the nasopharynx.

The diagnosis of nasopharyngeal masses is made by endoscopic examination on recognition of these clinical signs (Figure 44-8). A thorough evaluation of adjacent structures (nasal cavity, paranasal sinuses, and guttural pouches) is imperative. Radiography and/or general anesthesia followed by oral manual or oral endoscopic examination may help identify masses extending into the oropharynx. A biopsy sample of the mass can be taken by sedating the horse and using uterine biopsy forceps. Two or three samples can be taken with a small amount of local hemorrhage. A biopsy of the mass yields the critical information necessary for appropriately managing and treating the lesion.

Treatment is based on the extent of the lesion and the biopsy results. Surgical access to the nasopharynx is limited, and three main options are available: videoendoscopy-assisted laser resection, intralesional injection of a necrosing pharmacologic agent (10% formaldehyde), and surgical attention through an oral approach or pharyngotomy.

Videoendoscopy-Assisted Laser Resection

Videoendoscopy-assisted laser resection is performed as follows. The average 450-kg horse is sedated with a solution of detomidine (6 mg) and butorphanol (4 mg). One should err toward a smaller dosage of butorphanol, because some horses using this medication experience "head tics" that interfere with the surgical procedure. The videoendoscope is passed into the right nostril, and the mass is desensitized by applying 50 to 100 mL of a topical anesthetic solution (2% lidocaine or mepivacaine hydrochloride) and 10 mL of vasoconstrictive agent (0.15% phenylephrine) through the biopsy channel of the videoendoscope. The videoendoscope is withdrawn to the nasal cavity near the dorsal meatus, and local anesthetic is applied to desensitize this area and thus facilitate forceps manipulation. The videoendoscope is passed through the left nostril, and the bronchoesophagoscopic forceps are passed into the right nostril to grasp or otherwise facilitate access to the base of the mass. Using a diode (12 to 15 watts) or neodymium : yttrium-aluminum-garnet (Nd : YAG, 30 to 35 watts) laser, the base of the mass is incised. (Note: Incision is facilitated when traction is applied to the mass.) A large mass that cannot be removed nasally should be removed in smaller sections. Some masses must be reduced by intra-lesional injection (see later) weeks prior to laser resection. Preoperatively, the horses are administered dexamethasone (0.02 mg/lb) and phenylbutazone (2 mg/lb) intravenously. Postoperatively, the steroids are continued for one or more days and the nonsteroidal anti-inflammatory drug (NSAID) for 3 to 5 days. In addition, 20 mL of throat flush solution (composed of 250 mL of glycerin, 250 mL of 90% dimethyl sulfoxide (DMSO), 500 mL of nitrofurazone, and 50 mL of prednisolone 25 mg/mL) is administered twice a day using a 12 French red rubber feeding tube and alternating nostrils between treatments.

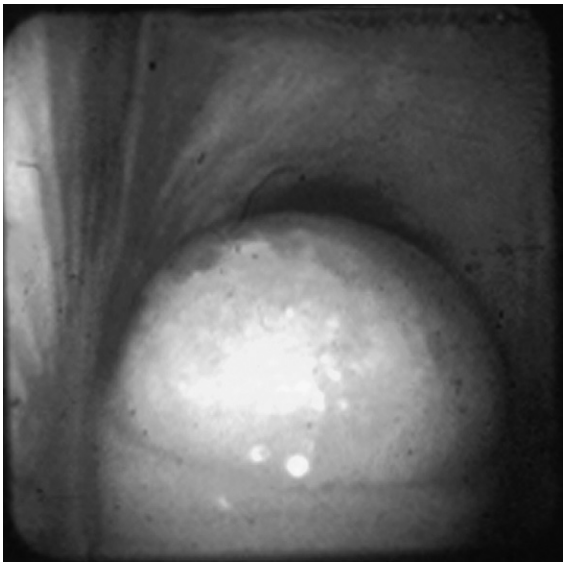

Figure 44-8. Endoscopic view of a pharyngeal mass in a 20-year-old horse. The mass originated at the root of the tongue. (Courtesy J. Stick, Michigan State University.)

Intralesional Injection

Treatments by intralesional injection to induce chemical necrosis of the mass, or local treatment with antimicrobials or antifungal agents, can be used if mass resection is not possible. A polyethylene catheter is passed through the endoscope biopsy channel until it emerges from the biopsy port of the endoscope. A 16-gauge needle is attached to the tubing by removing the needle hub and securing the needle 5 to 7 mm into the tubing. The needle should fit tightly so that it will not dislodge during the injection. The horse is sedated before the injection as described earlier for the laser procedure. Most masses, other than abscesses, are treated with repeated intralesional injection of 10% formaldehyde (10 to 20 mL). The masses are reinjected at 3- to 4-week intervals until resolution or until the size has been reduced. After each treatment, the horse receives a 3- to 5-day course of phenylbutazone (1 mg/lb PO twice a day) or a similar NSAID.

There is little information in the literature to substantiate the optimal treatment of fungal granulomas, such as are seen in coccidioidomycosis.[26,27] Typically they are treated with weekly intralesional injections of amphotericin B (100 mg of a 100 mg/mL preparation) combined with 3 mL of a 90% solution of medical-grade DMSO. More recently, multimodal treatment has been reported.[27] The combined modalities were oral administration of fluconazole (14 mg/kg loading dose, followed by a dosage of 5 mg/kg, PO daily until resolution) and organic ethylenediamine dihydriodide (30 mg of the 4.57% dextrose powdered formulation per kilogram [13.6 mg/lb] PO daily for 4 weeks) and intermittent intralesional injections with fluconazole, amphotericin B (50 mg), and formalin (as described earlier). In addition, potassium iodide (125 mL of a 20% sodium iodide solution IV, once a day for 3 days, followed by 30 g PO once a day for 30 days) is given after clinical remission or until signs of iodine toxicity (dry skin) are noted.

SURGICAL APPROACHES TO THE NASOPHARYNX OR OROPHARYNX

The nasopharynx is best approached through nasal videoendoscopy, although limited exposure can be obtained by a

pharyngotomy with rostral retraction of the caudal free edge of the soft palate. The oropharynx also can be approached orally (see "Tension Palatoplasty" and "Thermal Palatoplasty," later), orally after a mandibular symphysiotomy (see "Surgical Approaches" under "Cleft Palate," later), and through a laryngotomy via incision of the cricothyroid ligament (see "Staphylectomy," later).

Approaches to the oropharynx are performed with the horse under general anesthesia, and the surgical procedures are best performed using long instruments. The pharyngotomy allows access to the caudal third of the soft palate for cleft repair or removal of associated cysts or masses. Likewise, a pharyngotomy provides access to remove a subepiglottic mass or cyst, but a laryngotomy approach has less morbidity, making it preferable. The major disadvantages of the pharyngotomy approach are its limited exposure and the possibility of damaging the hyoepiglotticus muscle (see Figure 44-1) or its innervation. This can result in significant disability, as epiglottic retroversion during exercise is the consequence of neuromuscular damage to the hyoepiglotticus muscle[28] (see Chapter 45). Therefore, the pharyngotomy approach should be reserved for conditions that cannot be approached through the oral route or a laryngotomy and for revision surgery where repeat mandibular symphysiotomy is not indicated.

With the horse under general anesthesia and in dorsal recumbency, the ventral aspect of the basihyoid bone and thyroid cartilage is palpated on the ventral midline (Figure 44-9). The skin incision is extended from the rostral aspect of the thyroid cartilage forward toward the basihyoid bone. The sternohyoideus muscles are separated bluntly on the ventral midline, and the incision is extended to the loose fascia between the thyroid cartilage and the basihyoid bone (Figure 44-10). The hyoepiglotticus muscle is enclosed in elastic fascia (hyoepiglotticus ligament) deep to the loose fascia. The left and right hyoepiglotticus muscles are separated on the midine, and the incision is extended through multiple layers of loose fascia until the oropharyngeal mucosa is reached. The latter is picked up with a rat's tooth forceps and opened with curved scissors. Further exposure is obtained by splitting the basihyoid longitudinally with an osteotome. Malleable or Langenbeck retractors are needed to retract each side of the incision laterad and the root of the tongue rostrad.

The incision is closed using No. 0 poliglecaprone (Monocryl, Ethicon) in a simple-interrupted-continuous pattern on the oropharyngeal mucosa. A few simple-interrupted sutures are used to reappose the loose areolar tissue ventral to the oropharyngeal mucosa. The basihyoid (if it was split) is reapposed using a simple No. 2 steel suture. The sternohyoideus muscle is reapposed using a No. 0 polyglactin 910 or No. 0 Monocryl in a simple-continuous pattern. The subcutaneous tissue and skin are closed only over the split basihyoid bone. Complete closure is not recommended because of the clean-contaminated nature of the incision.

FUNCTIONAL DISORDERS OF THE NASOPHARYNX

Rostral Pharyngeal Collapse

Rostral pharyngeal collapse (i.e., fluttering of the rostral aspect of the soft palate) has been observed during treadmill videoendoscopy and was once thought to be a precursor to DDSP. This condition has been reproduced experimentally by bilateral transection of the tendon of the tensor veli palatini muscle.[10] In this experimental model, rostral instability of the soft palate caused inspiratory obstruction, but DDSP did not occur. The rostral

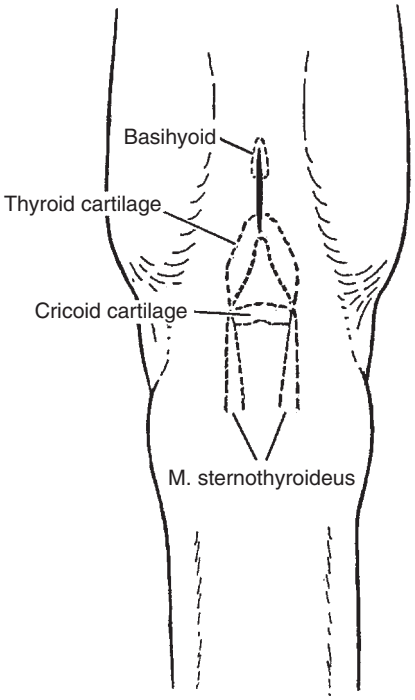

Figure 44-9. Pharyngotomy. Schematic shows the view of the ventral cervical area of a horse in dorsal recumbency and illustrates the landmarks for a pharyngotomy. The *bold line* represents the line of incision extending from the *basihyoid* to the *thyroid cartilage*.

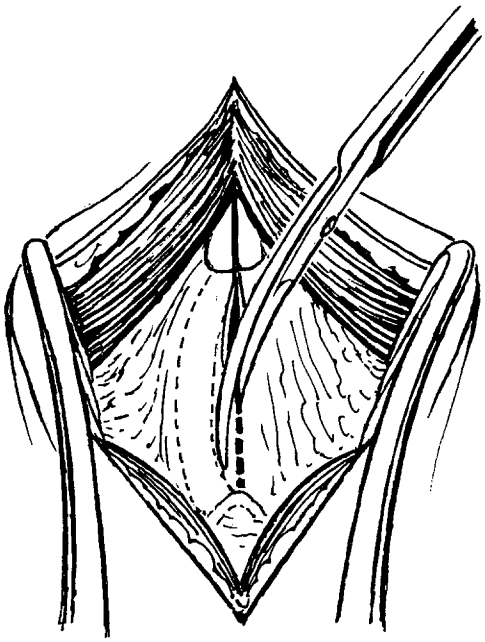

Figure 44-10. Pharyngotomy. The sternohyoideus muscles have been bluntly separated, allowing exposure to the underlying fascia. The basihyoid has been split longitudinally with an osteotome (an optional step), and the superficial fascia is being incised with curved Mayo scissors, exposing the underlying hyoepiglotticus muscle.

Figure 44-11. Endoscopic photograph of the collapse of the rostral portion of the soft palate in a horse exercising on a treadmill.

aspect of the soft palate billows dorsad during inspiration, since it is unable to resist nasopharyngeal pressures (Figure 44-11). It is displaced ventrad during exhalation, so it interferes only with ventilation during inhalation.

Horses with rostral pharyngeal collapse are presented with a history of upper respiratory noise caused by billowing of the rostral soft palate termed *rostral palatal instability (RPI)*. The diagnosis can be obtained only by videoendoscopic examination of nasopharyngeal function while the horse is exercising. The clinical significance of this condition as it relates to athletic performance is unknown, but it is not often performance limiting because of the minor obstruction observed. However, if the entire soft palate billows up and down, a condition known as *palatal instability (PI)* may exist. This may be a precursor of DDSP; therefore, evaluating and perhaps treating the horse for DDSP should be considered if PI is diagnosed.

Medical treatment consists of reducing any nasopharyngeal inflammation with the use of local and systemic anti-inflammatory agents. For an average 450-kg horse, I have used either systemic dexamethasone (30 mg IV or PO daily for 3 days, followed by 20 mg IV or PO daily for 3 days, then 10 mg IV or PO daily for 3 days, and finally 10 mg IV or PO every other day for three treatments) or aerosol fluticasone (3 mg q 12, or 2200 µg 10 puffs once daily) and topical anti-inflammatory solution containing glycerin, DMSO, dexamethasone, and nitrofurazone. I administer 20 mL of a throat flush solution twice a day (composition described earlier). In addition, I empirically recommend a dropped or figure-of-eight nose band to prevent airflow into the oropharynx.

There is no proven surgical treatment, but decreasing the compliance of the rostral aspect of the soft palate is logical.[29-31] However, the methodology to permanently create a sustained decrease in palatal compliance is not known. Indeed, both laser-induced fibrosis[32] and injection of a sclerosing agent (sodium tetradecyl sulfate)[33] failed to show a sustainable biomechanical change in the caudal aspect of the soft palate. Because the rostral aspect of the soft palate is thicker than the soft palate, more-intense fibrosing modalities are used. At this time, it is unknown if these more-aggressive treatment methods used to induce permanent fibrosis on the rostral aspect of the soft palate are effective. With this caveat, I have used laser thermoplasty via nasal approach (diode laser [20 watts] with a contact fiber of 600 µm and pulse duration of 3 seconds) (Figure 44-12) to topically "laser" the soft palate.[29] In addition, it seems rational to consider two other treatments, tension and thermal palatoplasty, which were orginally designed to decrease compliance of the rostral soft palate because their authors hypothesized that this condition was a precursor to DDSP. These two treatments are both performed through an oral approach.

Thermal Palatoplasty

The horse is placed under general anesthesia using an intravenous agent, and a mouth gag is placed. The tongue is pulled rostrad and the head is elevated to facilitate an oral view of the proximal aspect of the ventral soft palate (appropriate lighting is required).[30] A metal instrument is used to protect the tongue during the procedure. Custom-built "irons" are made of two 1-cm–diameter, 50-cm–long steel rods, with a 4- to 6-cm length welded on one end to form a T. After heating the T-shaped metal instrument, the ventral surface of the soft palate (oropharynx) is cauterized, from the hard palate extending caudad to beyond the palatoglossal arch (Figure 44-13, *A* and *B*). Cauterization obliterates the two parasagittal longitudinal folds of the soft palate (see Figure 44-13, *B*), and this results in a scar (see Figure 44-13, *C*), which is thought to decrease the compliance of the soft palate.

Tension Palatoplasty

After general anesthesia induction and placement of a mouth gag, an elliptical incision is made through the oral mucosa,

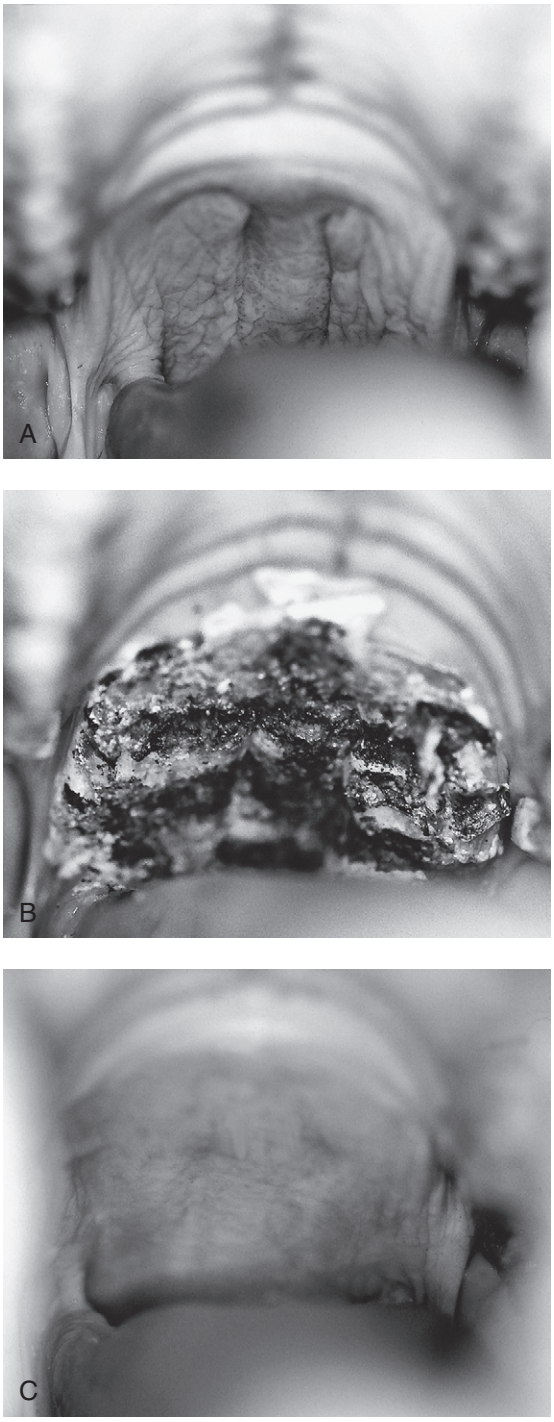

Figure 44-13. Thermal rostral palatoplasty. **A,** Rostral aspect of the soft palate viewed through the oropharynx immediately before surgery. Note parasagittal longitudinal folds on the oropharyngeal mucosa of the rostral aspect of the soft palate. **B,** Appearance of the soft palate immediately after cauterizing. **C,** Appearance of the soft palate 3 months after treatment. starting immediately caudal to the caudal edge of the hard palate. An elliptical section of approximately two thirds of the rostral soft palate mucosa and submucosa is excised (9 to 12 cm long by 1 to 2 cm wide) using long-handled forceps and curved Metzenbaum scissors (Figure 44-14).[31] The mucosal and submucosal edges are reapposed using No. 0 Vicryl or Monocryl in

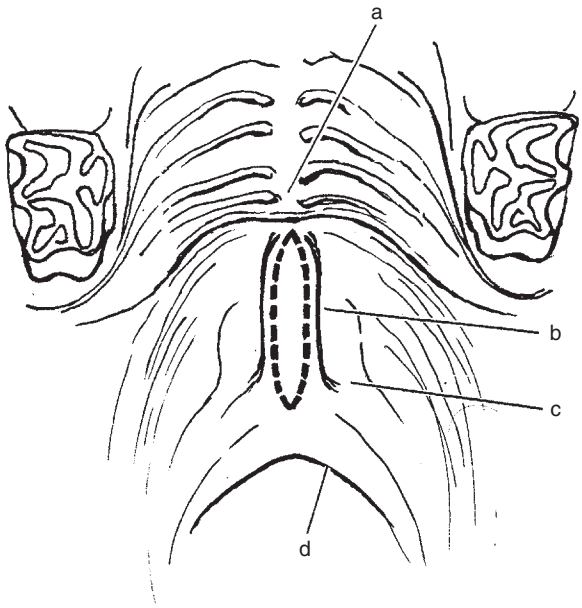

Figure 44-14. Tension rostral palatoplasty. Schematic drawing shows the location of the elliptical incision *(dotted line)* on the ventral and rostral aspect of the soft palate as viewed though the oropharynx. This incision leads to resection of the oropharyngeal mucosa and glandular portion of the soft palate in that specific location. *a,* Hard palate; *b,* isthmus faucium; *c,* sagittal fold; *d,* caudal border of the soft palate.

a simple-interrupted pattern. The procedure can be repeated in 4 weeks (a procedure termed *maximum tension palatoplasty*) to further increase the tension in the soft palate.

Postoperatively, horses are fed mash and wet hay for 3 to 7 days before returning to work. They are administered phenylbutazone for 3 to 5 days and a trimethoprim and sulfonamide combination for 5 to 7 days. Walking exercise is resumed after 2 days (walking and trotting only), and training can resume in 4 weeks. The degree of postoperative pain is reportedly minimal after thermal palatoplasty (2 to 3 days) compared with tension palatoplasty (up to 7 days in some cases).

Prognosis is related to the degree of collapse. A guarded prognosis should be given because the current knowledge of this condition is limited.

Dorsal/Lateral Nasopharyngeal Collapse

Some horses with exercise intolerance and upper respiratory noise are observed to have (1) unilateral or bilateral ventral displacement of the roof of the nasopharynx (Figure 44-15) or (2) medial displacement of the lateral walls of the nasopharynx, or both (Figure 44-16).[34,35] A certain degree of collapse is normal in horses during exercise. For instance, the roof of the nasopharynx does normally displace ventrally at the end of expiration during exercise.[36] At rest, the pressure in the guttural pouches, which form the roof of the nasopharynx, is in phase with nasopharyngeal pressure, and the pressure in the guttural pouches is subatmospheric when no airflow is present at rest.[36] During exercise, guttural pouch pressure does not stay in phase with nasopharyngeal pressure. Nasopharyngeal peak expiratory pressure is reached earlier than in the guttural pouch during the expiratory cycle, so peak expiratory pressure in the guttural pouch lags behind pressure changes in the nasopharynx.[36]

Figure 44-15. Video endoscopic image of the nasopharynx of an exercising horse, demonstrating partial collapse of the dorsal pharyngeal wall. The corniculate processes of the arytenoid cartilages are obstructed from view by the ventral displacement of the roof of the nasopharynx.

Figure 44-16. Endoscopic photograph of medial collapse of the lateral walls of the nasopharynx during treadmill exercise. Note the lateromedial reduction of the nasopharynx.

Therefore, the roof of the nasopharynx normally collapses at the end of expiration, but this should not extend beyond the ventral surface of the fully abducted arytenoid cartilages. It is known from experimental studies that dysfunction of the stylopharyngeus caudalis muscle (see Figure 44-4) results in collapse of the roof of the nasopharynx.[8] Presumably, intraluminal collapse of the lateral walls of the nasopharynx occurs because of dysfunction of the palatopharyngeus muscles. Dysfunction of these muscles may be associated with severe inflammation or neuritis of the pharyngeal branch of the vagal or glossopharyngeal nerve. Alternatively, dorsal and lateral nasopharyngeal collapse may be the result of a sensory dysfunction that prevents appropriate reflex contraction of the intrinsic musculature of the nasopharynx. Guttural pouch distention leads to ipsilateral nasopharyngeal roof collapse. Other systemic diseases, like a hypertrophic periodic paralysis (HYPP) episode, botulism, or equine protozoal myelitis, could be the cause. Finally, nasal obstruction may lead to a more negative inhaling airway pressure, overwhelming the muscular activity of the intrinsic nasopharyngeal musculature.

In the clinical disease, collapse of the nasopharynx occurs during inhalation, causing a greater reduction in the diameter of the lumen of the nasopharynx than in the cross-sectional diameter of the rima glottidis. In my experience, this condition is most commonly seen in 2- and 3-year-old racehorses. Clinical signs of dynamic dorsal pharyngeal collapse include inspiratory upper respiratory noise and exercise intolerance.[34,35] Diagnosis can be suspected by endoscopic examination during nasal occlusion (without sedation). The guttural pouches and both nasal cavities should also be examined, looking for the primary cause of this disease. The diagnosis can only be made accurately, by endoscopic examination during exercise (treadmill or overground).

Treatment should be directed toward resolving the primary condition (e.g., guttural pouch disease, nasal obstruction, systemic disease). In young horses, an anti-inflammatory protocol (as described under "Rostral Pharyngeal Collapse," earlier) should be considered. Affected 2-year-old horses can be allowed to mature until their 3-year season. Some experimental treatments are under investigation, but there is no stabilizing treatment available yet.

Dorsal Displacement of the Soft Palate

Intermittent DDSP is a performance-limiting upper airway condition in horses that was identified in 1.3% of a population of 479 horses examined endoscopically at rest.[37] However, the prevalence of this condition is probably higher, because palate displacement is a dynamic condition that occurs most frequently during intense exercise, making diagnosis at rest imprecise. The prevalence of this condition is probably closer to 10% to 20% of 2- to 3-year-old racehorses.

The horse is an obligate nasal breather, perhaps to allow the olfactory senses to function during deglutition. The normal epiglottis is positioned dorsal to the soft palate and contacts the caudal free margin, forming a tight seal around the base of the soft palate. The pillars of the soft palate converge dorsad, forming the palatopharyngeal arch. When the soft palate displaces dorsad, the epiglottis cannot be seen in the nasopharynx and is positioned in the oropharynx (Figure 44-17). The caudal free margin of the soft palate billows across the rima glottidis during exhalation, creating airway obstruction (see Figure 44-17). Upper airway pressure measurements made in horses clinically affected with DDSP during treadmill exercise indicate that DDSP is an expiratory obstruction.[38] This observation was confirmed by measuring upper airway mechanics in horses in which DDSP was induced by bilaterally blocking the pharyngeal branch of the vagus nerve. Tracheal expiratory pressure and

impedance were increased, minute ventilation was reduced, and horses were more hypoxic and hypercarbic than controls.[37]

From a clinical perspective, DDSP usually interferes only with ventilation during exercise, producing most frequenly, but not always, an upper respiratory noise (approximately 20% to 30% are "silent displacers"). In some cases, there is a digestive disturbance that leads to feed, water, and saliva contamination, predominantly of the upper airways. It is important to identify this digestive disturbance for the following reasons. Horses with DDSP are usually presented with a respiratory deficit that only occurs during intense exercise. This presentation carries a reasonable prognosis, and treatment varies depending on the specific cause. However, true DDSP with dysphagia generally indicates a more-advanced deficit of the palatinus/palatopharyngeus muscles (or its innervation) or an anatomic deficit (such as cleft palate or an acquired deficit of the caudal free edge of the soft palate—that is, staphylectomy or loss of epiglottic cartilage secondary to septic epiglottis or surgical trauma) or a mechanical deficit as after placement of laryngeal prosthesis that allows feed contamination of the nasopharynx from the oropharynx. This should be differentiated from aspiration of feed material into the trachea from laryngeal disease (or its treatment), which can lead to DDSP, presumably by inducing ventral and caudal laryngeal movement-displacement. Equine clinicians should carefully attempt to identify the cause of feed contamination of the upper airway seen in association with DDSP; applying routine treatment of intermittent DDSP to a truly dysphagic horse because of palatimus neuromuscular damage or mechanical deficit after laryngoplasty are not successful and may worsen the aspiration.

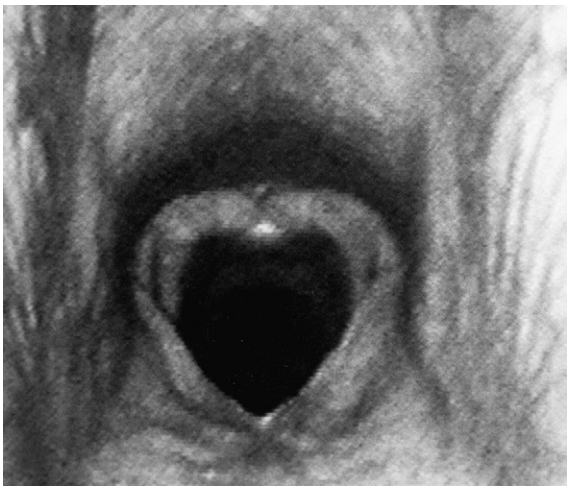

Figure 44-17. Videoendoscopy of the rima glottidis of a horse experiencing dorsal displacement of the soft palate during exercise. The palate moves ventrad relieving obstruction of the the rima glottidis during inhalation, but billows dorsad as air escapes into the oropharynx during exhalation.

Observational Studies on the Etiopathogenesis of Dorsal Displacement of the Soft Palate

The early hypotheses for the occurrence of DDSP was paralysis of the palate muscles[39] followed by elongation of the soft palate[40]; those hypotheses have not been supported by modern investigations. From a clinical perspective, anectodal observation (not evidence-based data) suggests mechanical factors to be associated with the the etiopathogenesis of DDSP. For example, cysts on the caudal free edge of the soft palate have been observed to interfere with the normal subepiglottic position of the soft palate. This seems to be a mechanical effect, since removing the cyst results in immediate postoperative correction of the DDSP. Other lesions that mechanically interfere with the junction of the caudal free edge of the soft palate and subepiglottic tissue are also believed to result in DDSP. They include subepiglottic or palatal granuloma (Figure 44-18), masses, and cysts (see Figure 45-27). The current understanding is that these masses predispose to DDSP, either by mechanically interfering with the seal between the caudal free edge of the soft palate and subepiglottic tissue or by causing irritation or pain that stimulates DDSP.

Epiglottic hypoplasia or deformation has been implicated as a cause of DDSP in horses.[41,42] It was thought that inadequate length or rigidity of an epiglottis might make it unable to "hold" the soft palate in a subepiglottic position.[41,42] Equine practitioners have noted that some horses with intermittent DDSP have

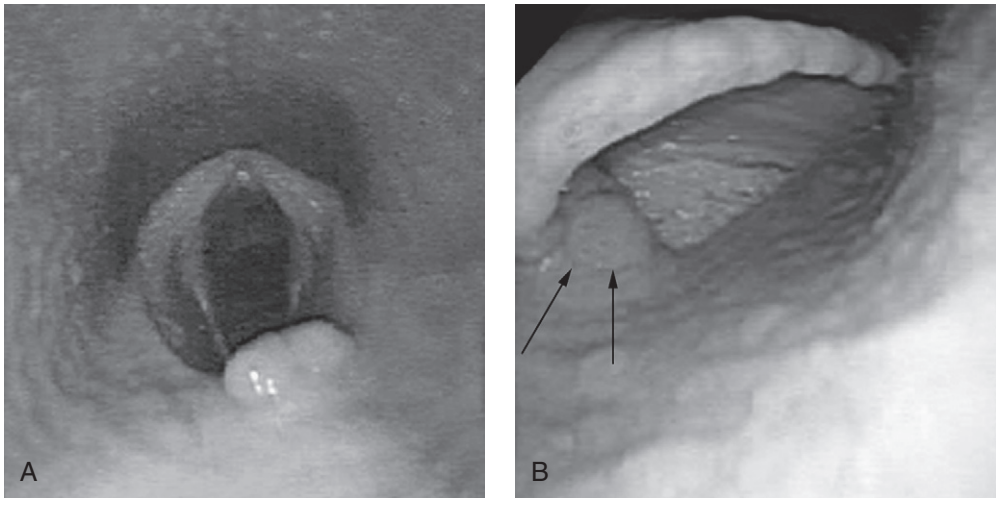

Figure 44-18. A, Palatal granuloma in a 2-year-old Thoroughbred with dorsal displacement of the soft palate. **B,** Appearance of the granuloma dorsal to the palate and ventral to the epiglottic cartilage *(arrows)* with the soft palate replaced.

what appears to be a hypoplastic or flaccid epiglottis. There has a been a clinical association between the endoscopic appearance of short or flaccid epiglottic cartilages in yearlings and decreases in racing performance later.[43] However, the appearance of a flaccid epiglottic cartilage is probably a positional change. I have noted that in horses experiencing DDSP, a progression of morphologic changes in the epiglottis frequently occur prior to DDSP (as observed endoscopically during high-speed exercise). First, caudal retraction of the larynx leads to an increase in "apparent flaccidity" of the epiglottic cartilage by the soft palate being lifted against the ventral surface of the epiglottic cartilage generally accompanied by billowing of the soft palate (termed *palatal instability*) eventually followed by DDSP. A swallow seems to reset the larynx forward and the correct subepiglottic position of the soft palate. This progression of events is repeated a few times before persistent DDSP is seen. The importance of swallowing in the occurrence of DDSP was highlighted by the recent report indicating that during exercise, horses with DDSP swallow more often in the minute immediately prior to displacement than those horses that do not experience DDSP, supporting the hypothesis that horses with DDSP are trying to stabilize an unstable palate by swallowing.[44]

Therefore, a flaccid epiglottis is probably a result rather than a cause of the DDSP. Indeed, the role or importance of an abnormal epiglottis as the initiating factor in DDSP is questionable, because DDSP does not occur despite the fact that epiglottic cartilage is not present to "hold the palate down" when epiglottic retroversion is experimentally induced.[45] Therefore, I no longer believe that epiglottic augmentation (i.e., stiffening) should be used routinely to treat horses with intermittent DDSP.

Other factors implicated in the pathogenesis of DDSP include caudal retraction of the tongue, which was hypothesized to lead to caudal retraction of the larynx.[46] If the tongue is retracted, the base of the tongue may "push" the soft palate dorsad, inducing DDSP. This leads to the belief that a tongue-tie pulls the tongue out of the mouth and prevents this occurrence. However, experimental investigations failed to identify a morphologic or physiologic effect from a tongue-tie.[17,47,48] Despite this, clinical studies support the use of a tongue-tie. One report showed that DDSP was reversed in two out of six horses by using a tongue-tie.[49] Two cohort studies (evidence–based level II-2) have reported a positive preventative effect of a tongue-tie on the occurrence of DDSP.[16,50]

The clinical association of opening the mouth or swallowing during exercise and the induction of DDSP has led to the following hypothesis. Opening the mouth lets air enter the oropharynx, disturbing the stabilizing effect of the subatmospheric pressure on the ventral surface of the soft palate.[46] This has led to the use of a dropped or figure-of-eight nose band to prevent DDSP during exercise. There are no experimental data investigating this hypothesis.

Most recently, three studies reinforce the possiblity that the position of the larynx and hyoid bone are relevant to the occurrence of DDSP. First, it was found that horses with DDSP at exercise have a more ventral position of their basihyoid bone.[51] In parallel with this finding, horses that have a more dorsal position of their basihyoid bone after laryngeal tie-forward surgery have a better postoperative outcome.[52] Finally, horses with permanent DDSP, a presumbly more severe form of DDSP, had a more caudal position of their larynx compared to horses with intermittent DDSP.[53] These static findings of the position of the basihyoid bone may be associated with the observation that a strong pull or "hold" of the drivers on the lines during exercise can lead to DDSP during exercise, perhaps by influencing the position of the basihyoid bone or larynx.[54]

Experimental Studies on the Etiopathogenesis of DDSP

Many studies described earlier have led to the identification of intrinsic and extrinsic factors responsible for the stability of the nasopharynx at exercise, and their anatomical relevance has been described. Functionally, there are three experimental models that result in DDSP in horses. Model 1, *blockade of the pharyngeal branch of the vagus nerve model*, signified that the palatinus and platopharyngeus muscles are important in stabilising the soft palate at rest and at exercise.[7] Deficits of the palatinus muscle function also lead to feed and water contamination of the upper airway.[7] The remaining two experimental models differ from model 1 because DDSP occurs only at exercise. Model 2, *thyrohyoideus muscle model,*[15] indicated that the actions of these muscles decrease the collapsibility of the nasopharynx at exercise; this model supports the beneficial effect of swallowing on palatal stability. Model 3, *blockade of the hypoglossal nerve model*, showed a stabilizing effect on the nasopharynx.[3] The exact mode of action of the affected muscles in the latter two models is unknown, but it is hypothesized that they prevent caudal and ventral movement of the larynx during exercise, a phenomemom that is corrected (at least temporarly) by swallowing.

Summary of the State of the Art on the Etiopathogenesis of DDSP

Structural causes of DDSP, such as palatal cyst, subepiglottic masses, epiglottic entrapment, subepiglottic cyst, epiglottic deformity, and so on, contribute to a small percentage of the cases of DDSP. In the majority of the cases, DDSP is a functional deficit where inappropriate intrinsic muscular contraction results in an increased compliance of the soft palate, which in turn leads to PI and eventually DDSP. A dorsal position of the larynx and basihyoid bone confers stability to the soft palate during exercise, and through a mechanism not yet understood; swallowing can correct DDSP or temporarily decrease the collapsibility of the soft palate into the airway.

History and Clinical Signs

Racehorses with intermittent DDSP generally have a history of exercise intolerance and may make a gurgling or vibrating noise during exhalation.[46] The exercise intolerance is most commonly an acute drop of performance that may be described by the trainer or owner as "choking down"or "swallowing the tongue." Concurrent with these signs is open-mouth breathing, because airflow is directed through the mouth during exhalation. Horses used for show or pleasure riding may exhibit only the respiratory noise described, and the signs are usually exacerbated with head flexion.

Diagnosis

It is now well established that the resting endoscopic examination has a poor predictive value in determining the occurrence of DDSP during exercise.[55-57] Therefore, the accuracy of an endoscopic diagnosis of DDSP in nonexercising horses is poor and

leads to a misdiagnosis 35% of the time.[56] The gold standard for diagnosis of intermittent DDSP is based on a history of poor performance associated with respiratory noise, physical examination, and endoscopic examination at rest and during exercise either on a treadmill or over ground. It should be noted that both treadmill and overground endoscopic examinations in noncompeting horses is likely to miss the occurrence of DDSP in a small percentage of horses. In addition, unlike for the diagnosis of laryngeal hemiplegia, where both techniques are comparable, the treadmill exam has a higher diagnostic rate of DDSP.[58] In my opinion this is because treadmill exercise protocols are well established and exercise protocols for overground exams are not fully established, plus the intensity of exercise during the overground exam is negatively influenced by the trainer's limitation on the exercise intensity). A complete physical examination is important to rule out other concomitant causes of exercise intolerance, such as pulmonary disease, cardiac abnormalities, lameness, and neurologic disease.

Should an endoscopic exam during exercise not be available, an endoscopic examination immediately after cessation of exercise is preferrable. Here, the observation of DDSP would support the diagnosis. If only a resting exam is available, surrogate evidence (but not pathognomonic) of DDSP is an ulcer on the caudal edge of the soft palate (Figure 44-19) and brusing on the nasopharynx (Figure 44-20). To further assess the soft palate and subepiglottic area, displacement can be induced in most horses by introducing the endoscope into the larynx and proximal trachea and inducing a gag reflex. After withdrawing the endoscope, one can see the free edge of the soft palate. A more complete exam is done by sedating the horse and applying 50 to 100 mL of lidocaine hydrochloride on the soft palate and epiglottis. Then, using an appropriate instrument (equine laryngeal forceps), the epiglottic cartilage can be elevated to look for subepiglottic abnormalties.

Treatment

I make treatment recommendations using evidence-based data, when available. There is a paucity of data available and the data are at best only at level II-b, so be aware that some of the following recommendations are based on weaker evidence.

Treatment should be initially directed at modifying or eliminating recognized factors associated with the occurrence of DDSP. If structural abnormalities (cysts, granuloma, entrapment, epiglottis, etc.) are found, they should be adressed. If no structural abnormalities are present, nonsurgical management should be used first.

NONSURGICAL MANAGEMENT OF DDSP

Both nasopharyngeal and guttural pouch inflammation can lead to dysfunction of the pharyngeal branch of the vagus nerve[7] and thus interfere with palatinus and palatopharyngeus muscle tone, leading to PI and/or DDSP. Indeed, horses with intermittent DDSP have an elevated prevalence of upper respiratory inflammatory diseases, such as pharyngitis, that may affect the function of the pharyngeal branch of the vagus nerve.[7,59] If upper respiratory tract inflammation is diagnosed, treatment should include judicious use of systemic anti-inflammatory medication (dexamethasone as described earlier or aerosol fluticasone 3 mg every 12 hours, or 2200 µg 10 puffs once daily)[60] and topical anti-inflammatory solution containing glycerin, DMSO, dexamethasone, and nitrofurazone.

In addition to considering inflammatory conditions, one should take into account that unfit and immature horses should be conditioned and re-evaluated before surgical intervention is considered. Tack changes may be suggested to alter (i.e., elevate) the horse's head position, and a figure-of-eight noseband can be used to keep the horse from opening its mouth and allowing airflow into its oropharynx. The bit may be changed; a bit that secures the tongue (such as a W bit, a spoon bit, or a "Serena

Figure 44-19. Ulcer on the free edge of the soft palate in a 3-year-old Standardbred. This finding supports a diagnosis of DDSP and can also be seen if a subepilgottic mass or lesion is present.

Figure 44-20. Bruising of nasopharynx approximately12 hours following racing in a 7-year-old Standardbred gelding. This supports a diagnosis of DDSP during racing.

song" bit) and/or is designed to restrict caudal movement of the tongue should be used in addition to a tongue-tie.

Tongue-tie use has been popular for many years, and now there are some evidence based data to support its use.[16,4 9,50] Initially the hypothesis was that it prevented "swallowing of the tongue," but most likely it prevents the root of the tongue from applying dorsal pressure on the ventral surface of the soft palate or prevents the basihyoid or larynx from moving caudad. In one study, two out of six horses with naturally occuring disease were improved with a tongue-tie, as evidenced by treadmill videoendoscopy.[49] Additionally, the tongue-tie was part of the medical treatment of horses with naturally occuring disease in two studies, which reported a 53% to 61% success rate.[16,50] Compared to this positive result, others failed to detect a mechanical effect (a change of nasopharyngeal diameter or upper airway patency) when the tongue-tie was used in normal horses.[47,48] A throat-support device (Throat Support Device*) that positions the larynx and basihyoid more dorsad and rostrad similar to the tie-forward surgery (see later) has been shown to prevent DDSP at exercise in experimentally created DDSP[61] and is frequently used in race horses to control DDSP or as a diagnostic tool in horses suspected to have DDSP.

The data are insufficient to draw clear conclusions on all the nonsurgical treatments. However, this type of treatment should be used first when anatomic anomalies are not present. Reports show a 53% to 61% success rate when nonsurgical treatments were used alone, a figure similar to the outcome seen after many surgical treatment techniques.[62,63] If the horse fails to respond to medical or nonsurgical treatment, surgical intervention should then be considered.

SURGICAL OPTIONS

Many surgical options are available. Tension and thermal palatoplasty, described previously for treatment of rostal palate instability, have been shown recently to be ineffective for treatment of DDSP and should no longer be performed for this condition.[16,64] In addition, no technique has been shown to be effective in stiffening the soft palate, so laser staphylectomy or injection of sclerosing agent should be abandoned.[31,32]

The treatments should be directed to the recognized cause of the disease when it can be identified. Structural or anatomic abnormalities involving the nasopharynx or subepiglottic and epiglottic cartilage (such as bacterial or viral epiglottitis, cyst, granuloma, aryepiglottic entrapment) should be addressed medically or surgically through a nasal, oral, or laryngotomy approach. Recent evidence-based data (level II-b) suggest that at present the best treatment is a laryngeal tie-forward combined with a partial bilateral resection of the thyrohyoideus tendon/ muscle.[52] Despite these findings, other surgical treatments are indicated under certain conditions and are discussed later.

Staphylectomy

Staphylectomy, or partial soft palate resection, originally was described as a treatment for an excessively long soft palate.[40] This condition does not exist, except perhaps in neonatal foals,[65] so staphylectomy should also be discontinued as a routine treatment of DDSP. When a staphylectomy is performed one should be aware that resection of more than 0.75 cm (¼ inch) of the soft palate may disturb the seal between the oropharynx and the nasopharynx and allow the passage of water and saliva into the nasopharynx. Staphylectomy should be reserved to resect a granuloma or cyst from the caudal free edge of the soft palate or for treatment of permanent DDSP as an additional step following a laryngeal tie-forward procedure.

For treatment of palatal cysts or granulomas, staphylectomy is performed with the horse under general anesthesia and positioned in dorsal recumbency with the head and neck extended and prepared for a laryngotomy.[62] A 10- to 12-cm (4- to 5-inch) skin incision is made along the midline, centered over the cricothyroid space. The sternohyoideus muscles are divided bluntly using a curved Mayo or Metzenbaum scissors. A self-retaining retractor, such as a Weitlaner or a Hobday, is placed between the separated sternohyoideus muscles, exposing the cricothyroid membrane. The cricothyroid membrane is sharply incised (along with the underlying laryngeal mucosa) with a scalpel along the midline, from the cricoid cartilage to the junction of the thyroid cartilages (Figure 44-21). A small blood vessel is usually also incised at the level of the caudal two thirds of the membrane. The vessel is ligated or cauterized. The self-retaining retractor is subsequently placed within the cricothyroid space. The caudal free margin of the soft palate rostral to the incision is identified. If the horse was intubated nasotracheally, the soft

palate may not be displaced, and the caudal edge of the soft palate may have to be freed from beneath the epiglottis using a pair of sponge forceps. If the horse was intubated orally, the palate will be displaced and the endotracheal tube should be retracted at this time.

The mass or cyst is identified, the mucosa of the caudal free margin of the soft palate is grasped with an Allis tissue forceps on the midline, and a second pair of forceps is used to grasp the left and right mucosa 2 to 2.5 cm lateral to the midline. The caudal free margin of the soft palate containing the mass or cyst is resected using a curved Satinsky thoracic scissors. A crescent-shaped 3- to 4-cm–long piece of mucosa that is less than 1 cm wide on the midline and tapered toward both ends should be resected.

The laryngotomy may be left to heal by second intention, or preferably the cricothyroid membrane is reapposed using No. 0 polyglactin 910 suture material in a simple-continuous pattern. Some surgeons close all layers of the laryngotomy, but this step increases morbidity unnecessarily. Postoperatively, the horse should wear a muzzle for several hours. Systemic antibiotic therapy is continued for 7 days, and anti-inflammatory medication is continued for 3 days. The laryngotomy site should be cleaned twice daily until it is healed (approximately 3 weeks). The horse can resume training 2 to 3 weeks later.

In the treatment of permanent DDSP, the gap between the dorsal aspect of the epiglottis and the overlying soft palate is eliminated by the tie-forward surgery (Figure 44-22, *A* and *B*). When needed, a laser-assisted staphylectomy follows the tie-forward procedure to permit the epiglottis to be repositioned dorsal to the soft palate after a swallow. The goal is to remove the least amount of soft palate needed to allow the epiglottis to remain positioned dorsal to the soft palate without loss of laryngopalatal seal. This is assessed by correcting the displacement with a laryngeal forceps and observing the redundant palate underneath the epiglottis, which needs to be trimmed. It is imperative that the site of intended resection is marked prior to using the laser, because the soft palate is so elastic that inadvertent excessive resection could occur (Figure 44-23, *A*). The edge of the soft palate is then lifted and the soft palate is resected (Figure 44-23, *B*).

Preoperatively, the horse is treated with NSAIDs and broad-spectrum antibiotics. Complications of staphylectomy are rare but can occur if too large a section of the soft palate is resected. These horses may be dysphagic, leading to signs of aspiration that include coughing, expulsion of feed material through the nose, and pneumonia.

Standard myectomy

Standard myectomy (a partial sternohyoideus and sternothyroideus, with or without omohyoideus resection) is performed to reduce caudad retraction of the larynx.[46,62,63,66] Sections of the sternothyroideus and sternohyoideus muscles are removed with the horse standing as the procedure was first described. If the plan is to also remove a section of omohyoideus muscle, the procedure should be performed under general anesthesia with the horse positioned in dorsal recumbency and the head and neck extended. This is because a more-extensive dissection is required when the omohyoideus muscle is resected.

The horse should be treated preoperatively with NSAIDs and broad-spectrum antibiotics. It is restrained in a set of stocks, a stanchion, or a stall doorway. Tranquilization may be necessary or useful. (Alternatively, the horse is anesthetized and placed in dorsal recumbency.) The hair is clipped from the ventral surface of the neck, and the skin is aseptically prepared. Local anesthetic is infiltrated along the midline at the junction of the proximal third and the middle third of the neck.

A 10-cm ventral midline incision is made through the skin, continuing through the cutaneus colli muscles. The paired sternohyoideus muscles are identified. Using curved forceps, the sternohyoideus and sternothyroideus muscles are undermined. The sternothyroideus muscle is positioned caudolateral to the sternohyoideus muscle at this level of the neck. The muscles are elevated through the incision and clamped with a Rochester-Carmalt forceps at the proximal and distal extent of the

incision. The muscle bellies are sharply transected between the forceps, removing a 6- to 8-cm–long section of muscle. The muscle tissue that was removed should be inspected to ensure that sections of both sternohyoid muscles and the smaller sternothyroid muscles were indeed removed. Previously, the omohyoideus muscle was sometime removed; however, significant dead space was created, leading to a higher rate of incisional complications, and therefore resection of the omohyoideus is no longer recommended.

The subcutaneous and skin layers are closed routinely. If a Penrose drain is used, it is placed alongside the ventral aspect of the trachea and tunneled through a stab incision distal to the surgical incision. A firm bandage is applied around the neck and may be removed along with the drain 24 hours later.

NSAIDs can be continued for 3 days, and antibiotics should be continued for 5 to 7 days. The horse is kept in a stall with daily hand-walking for 2 weeks. Training can be resumed 2 weeks after surgery, when the sutures are removed. Complications are usually related to the incision and include incisional seromas and infections. No long-term complications are notable except for the cosmetic defect associated with the lack of muscle tissue at the surgical site. Uncontrolled reports indicate a success rate of 58% to 71% for treating DDSP after this procedure.[67] However, standard myectomy has lost some popularity for treatment of DDSP.

Minimally invasive myectomy

Minimally invasive myectomy (partial sternothyroidectomy or the Llewellyn procedure) is rapidly performed and has minimal morbidity. It is often performed as a first line of surgical treatment because it does not require an operating theater, and it is simpler than the standard myectomy and thus is the field procedure of choice.

Partial sternothyroideus myectomy and tenectomy is performed with the horse under general anesthesia.[68] A 5- to 7-cm ventral midline skin incision is made centered on the cricoid cartilage. The subcutaneous tissue is incised, and the sternohyoideus muscles are divided bluntly using curved Mayo or Metzenbaum scissors. The blunt dissection is continued dorsal to the sternohyoideus muscle, exposing the caudolateral border of the thyroid cartilage. The tendon of insertion of the sternothyroideus muscle at the thyroid cartilage is identified, undermined, and elevated. The tendon is transected 1 cm caudal to its attachment to avoid the caudal laryngeal artery, taking care to avoid damaging the cricothyroid muscle. Damage to the cricothyroid muscles may result in vocal cord collapse.[69] Using one index finger, the sternothyroideus muscle is freed from the surrounding fascia and transected more proximally, thus removing a 3-cm section of muscle. This same procedure is performed on the contralateral sternothyroideus tendon. The incision is closed by reapposing the sternohyoideus muscles, and the skin is closed in a routine manner.

Postoperatively, NSAIDs are given for 3 to 7 days. Training often is resumed 2 to 3 days postoperatively in Standardbreds and 2 to 3 weeks postoperatively in Thoroughbreds. The reported success rate for this procedure is 58% to 70%.[62,63,68]

Laryngeal tie-forward

The laryngeal tie-forward is performed with the horse anesthetized and in dorsal recumbency.[15,52,70] The principle of the procedure is to replace the action of the thyrohoideus muscles bilaterally by sutures placed between the thyroid cartilage and the basihyoid bone (Figure 44-24). The ventral cervical and intermandibular areas extending 10 cm rostral to the basihyoid bone are prepared aseptically. A ventral skin incision is made starting 1 cm caudal to the cricoid cartilage and extending 2 cm rostral to the caudal aspect of the basihyoid bone. The sternohyoideus muscle is separated on the midline and bluntly dissected free of the dorsolateral aspect of the larynx lateral to the thyrohyoideus muscles. The sutures are first passed through the thyroid cartilage. A No. 5 USP polyblend suture (Fiberwire) is passed twice into the right lamina of the thyroid cartilage ventral to the insertion of the sternothyroid tendon (Figure 44-25). Alternatively a metal buttress is placed on the medial side of the thyroid cartilage to minimize cutting of the thyroid cartilage with sutures.[71] The junction of the basihyoid and lingual process is identified with a Crile forceps after limited blunt dissection, and a wire passer is placed under the hyoid

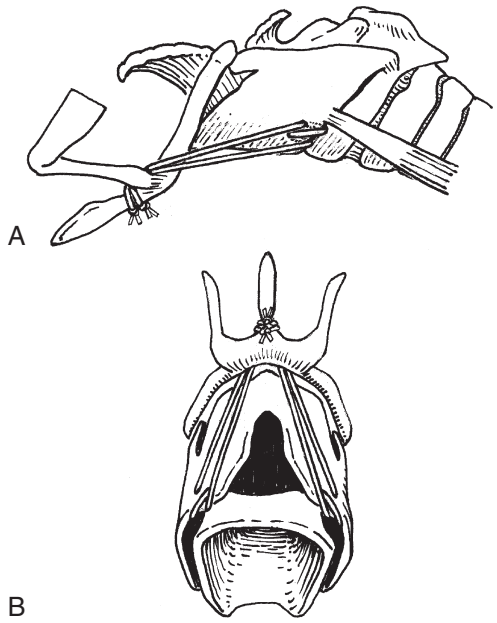

Figure 44-24. Schematic drawing showing the principle of the laryngeal tie-forward procedure. **A,** Lateral view: Note that the sutures are placed from the basihyoid into the lateral and caudal aspects of the lamina of the thyroid cartilage. The suture is passed twice through the thyroid cartilage and the most dorsal bite is immediately ventral to the tendon of the sternothyroid muscle. **B,** Ventral view: The sutures course on the dorsal surface of the basihyoid bone and are tied with a slip knot on the ventral aspect of the junction of basihyoid bone and lingual process.

Figure 44-25. Intraoperative view of the laryngeal tie-forward procedure. contralateral side are passed into the wire passer and retrieved. The procedure is repeated on the other side (Figure 44-27) such that the dorsal (leader) and ventral (trailer) sutures of each side can be tied over the ventral aspect of the basihyoid. A bilateral partial sternothyroidectomy is performed at this time. The sutures on each side are then tied so the rostral aspect of the thyroid cartilage is located immediately dorsal and 0.1 to 1.5 cm rostral to the caudal border of the basihyoid bone. Closure is obtained by reapposing the sternohyoideus muscles with No. 0 poliglecaprone (Monocryl, Ethicon) in a simple-continuous pattern. The loose fascia overlying the larynx is incorporated into that closure; this is an important step to prevent postoperative seromas. The subcutaneous tissues and skin are then closed in a routine manner.

Postoperatively the horses are fed and watered at shoulder height to reduce stress on the sutures. They are administered NSAIDs for 3 to 5 days. Horses are maintained in a box stall for 2 weeks with daily handwalking. Training often is resumed 2 to 3 days after this rest period.

Assessment of postoperative success is obtained by endoscopy where the epiglottis is located more forward and dorsally, often not contacting the soft palate (Figure 44-28). Radiographs could be taken with the head in an extended position,[72] and after surgery one should be able to observe (and measure)[52] a forward and dorsal position of the tip of the epiglottis and larynx on the image (Figure 44-29, *A* and *B*). Success rate of 20% greater than that reported for partial sternothyroideus myectomy and tenectomy (strap muscle resection) is expected.[52,70]

Also the ossification at the base of the thyroid cartilage *(white arrow)* is more rostral and dorsal after surgery. Linear white densities are 5-cm pins used to measure magnification of radiographs.

NASOPHARYNGEAL DISORDERS OF FOALS

Choanal Atresia

Early in embryonic development, a membrane separates the oral and the nasal cavities.[73] Choanal atresia, a rare upper respiratory malformation in horses, is a congenital abnormality associated with failure to resorb this bucconasal membrane during embryonic development.[74-76] Because horses are obligate nasal breathers, bilateral choanal atresia usually results in the foal's death unless an emergency tracheostomy is performed at birth.[74] When the atresia occurs unilaterally, foals exhibit loud respiratory noise and exercise intolerance, and the nasopharynx can be observed through one nostril, whereas a membrane obstructs the caudal nasal passage of the other nostril. These horses are usually asymptomatic at rest; however, asymmetry of airflow from the nostrils can be detected. The diagnosis is made by endoscopic examination, skull radiography, contrast radiography, and computed tomography.[73-77]

Although my experience is very limited, foals with unilateral choanal atresia should be allowed to grow untreated until 1 year of age, for the following reasons. The larger nasal cavity facilitates surgical exposure with less likelihood of postoperative fibrosis, reduced diameter of the choana, or, even worse, complete closure. In addition, the need for a postoperative nasal stent is avoided. Finally, the larger size of the airway allows the procedure to be performed less invasively under endoscopic control with the animal standing.

Three treatment approaches have been used. In the first, the yearling is sedated, usually with a combination of detomidine and butorphanol, and topical anesthesia with phenylephrine (2% lidocaine or mepivacaine hydrochloride and 10 mL of 0.15% phenylephrine) is applied to the membrane and nasal cavity. The endoscope is placed in the affected nostril and the outline of the choanal membrane is identified using equine laryngeal forceps. Using a 600-µm laser fiber placed in the biopsy channel of the videoendoscope and a diode laser at 15 watts (pulse duration, 3 seconds), selected vessels are cauterized by placing the laser tip adjacent to but not on the vessel itself. Then the membrane is incised, creating two lines of incision perpendicular to each other that cross at the center of the choanal membrane. This cross incision is made because the membrane (even though it appears thin) is vascular, and local pressure to stop the bleeding may be needed at times. When excessive bleeding occurs, a nasotracheal tube is passed through the membrane into the nasopharynx, where the cuff is inflated to apply pressure that promotes hemostasis at the surgical site. After a few minutes, the tube is removed and each flap is resected; the aforementioned forceps may be used to apply tension on the flaps as needed. Postoperatively, the animal receives a 5-day course of phenylbutazone (1 mg/lb PO twice a day) or a similar NSAID.

The second treatment approach is used when the choanal membrane is osseous or the condition is bilateral, and a nasal flap giving access to the caudal aspect of the nasal passage is required. The choanal membrane (bone) is resected, as well as part of the nasal septum, using a nasal bone flap. The foal is anesthetized and placed in lateral recumbency, and an endotracheal tube is placed through a tracheostomy. A C-shaped incision (for unilateral lesions) or an S-shaped incision (for bilateral lesions) is made over the nasal bones starting at the level of the medial canthus of the eye and extending rostrad to approximately the middle of the nasal cavity, which is near the level of the infraorbital foramen. The periosteum is incised on the midline, extending laterally to an area near the nasomaxillary suture, taking care to stay at least 1 cm medial to the infraorbital canal. A nasal bone flap is created along the line of the periosteal incision by placing an osteotome at a 45-degree angle to create a ridge for the bone flap to rest on at the end of surgery. The nasal bone flap is made in the shape of the periosteal incision. The procedure must be performed bilaterally if the atresia is bilateral. The nasal mucosa is excised, and the choanal membrane is identified and resected, along with the caudal nasal septum if necessary. The area is packed with sterile rolled gauze, which exits the nostril and is sutured to the false nostril.

If it is necessary to operate on a young foal, the third approach can be used. The membrane is resected through a laryngotomy after placing the endoscope through the nares to illuminate the persistent membrane. My preference is to incise the membrane using endoscopic control and to place a stent in the nostril to prevent stricture.[75] In my limited experience, Nd:YAG laser dissection of the membrane has been unrewarding because profuse hemorrhage associated with recumbency and general anesthesia rapidly obscures the endoscopic view, preventing the application of local pressure in a small foal.[75] The membrane is incised best using laparoscopic scissors with unipolar or bipolar cautery under endoscopic control while the foal is under general anesthesia. A nasotracheal tube is placed through the surgically created fenestration and sutured to the false nostrils. The stents are removed 14 days postoperatively. Appropriate antibiotic therapy is used.

Because of the rarity of this condition, the prognosis is not well known, and persistence of airway obstruction is a possible complication. The heritability of this condition is also unknown.

Nasopharyngeal Dysfunction

Nasopharyngeal dysfunction, characterized by respiratory distress, respiratory stridor, and dysphasia, can occur in foals during the first month of life. Endoscopic examination may reveal severe nasopharyngeal edema, laryngeal edema, milk pooling in the nasopharynx, and persistent DDSP.

The etiology of this obstructive syndrome is unknown. However, on the basis of information obtained from neonatal laboratory animals and human infants, nasopharyngeal dysfunction in neonatal foals may be related to immaturity of the neuromuscular reflexes and defense mechanisms that support the nasopharynx and larynx.[78] Specifically, newborns have a smaller number of pressure and flow receptors in the upper airways than adults, and these receptors discharge at a slower rate.[78] Some of the sensory and motor nerves that supply the larynx and nasopharynx are demyelinated at birth, and they change and mature morphologically until 12 months of age.[78] Perhaps this immature neural circuit causes muscular dysfunction and incoordination in the nasopharynx that results in dysphagia and nasopharyngeal collapse, although this is only speculation.

A thorough physical examination, an endoscopic examination, and radiography of the thorax and pharyngeal region should be performed when evaluating a foal with nasopharyngeal dysfunction. While examining the foal, precautions should be taken to provide it with a patent airway if the examination induces respiratory distress. Appropriate blood work, including serum chemistry, complete blood count, serum immunoglobulin G (IgG) levels, and an arterial blood gas analysis, should be performed.

Treatment may begin by securing a patent airway for the foal. Respiratory distress may be sufficiently severe that an emergency tracheotomy is performed immediately. If the foal has persistent DDSP, a laryngotomy followed by placement of a tracheostomy tube usually corrects this problem. Rarely, a staphylectomy may be needed to correct this problem.[65] However, surgical intervention is not necessary in many foals. It is best to support the foal medically for 1 month to see if the problem resolves. Clearly, surveillance and prophylaxis for possible aspiration pneumonia should be strongly considered. White muscle disease should be identified and treated, because this may also cause nasopharyngeal dysfunction. If edema is present, anti-inflammatory medication may be useful in improving function. If the foal is dysphagic, enteral feeding can be performed through a nasogastric feeding tube, or parenteral feeding can be initiated.

Most often, these foals recover from nasopharyngeal dysfunction in 10 to 30 days. The nasopharyngeal edema resolves and dysphasia dissipates. Long-term survival rates and effects of this episode on future athletic performance are unknown.

Cleft Palate

Cleft palate (palatoschisis) is a rare congenital defect in foals.[79] The cleft is caused by an interruption in embryologic closure that occurs along the midline in a rostrad-to-caudad direction of the palatal folds and may, therefore, involve portions of the soft palate or of the hard and soft palate.[79] Defects in the lips and maxilla that frequently occur with cleft palate in people have never been reported in horses. The exact etiology of this defect is unknown, but genetics, nutrition, teratogens, and traumatic mechanical factors that could affect palatal fold closure during the 47th day of gestation are possible causes.[79]

Clinical signs of a cleft palate include milk draining from the foal's nose after nursing, coughing, and signs of aspiration.[79-82] The cleft may be observed during an oral examination or diagnosed by digital palpation, or both. Endoscopic examination, using a pediatric endoscope, is helpful in making the definitive diagnosis and assessing the extent of the defect. A careful endoscopic examination is necessary because the field of view with a pediatric endoscope is small. A small but clinically significant cleft may be obscured by epiglottic cartilage or saliva. It is helpful to make the foal swallow a few times to ensure that the palate is intact. The margins of the soft palate will be visible, and the epiglottis will be positioned in the oropharynx. Once a cleft palate has been diagnosed, the foal should be examined for other congenital defects.

If the cleft is small (about one third of the soft palate) and tracheal aspiration is minimal, it may be better to delay surgery while closely monitoring the foal so that aspiration pneumonia does not go undetected. Weaning the foal early seems to decrease tracheal aspiration, as feed reaches the trachea less readily than milk. The advantage of delaying surgery is that a larger oropharynx facilitates surgical manipulation and more precise surgical repair. If the cleft is large or tracheal aspiration of milk is significant, treatment options should be restricted to either surgical repair of the cleft palate or euthanasia. Allowing foals to continue with the cleft palate is a poor choice, because of their resultant poor quality of life and morbidity from chronic aspiration pneumonia. Surgical repair of a cleft palate is considered a salvage procedure, and it is fraught with complications.[80-84] Palatoplasty usually results in some degree of failure because of complete or partial dehiscence of the repair.[83] Reoperation is frequently needed and is often unsuccessful.[80] Pneumonia can be a serious, even life-ending, complication despite attempts to repair the cleft, because of the initial aspiration of milk or feed material.

The prognosis is affected by the size of the defect, the length of the soft palate involved, involvement of the hard palate, and pneumonia.[80,82] Repair of asymmetric defects should not be attempted, because there will not be sufficient tissue available for reconstruction.[83] Some authors recommend that if more than 20% of the soft palate tissue is missing, repair should not be attempted.[83] Cleft palate defects that occur on the midline with minimal tissue missing have a successful prognosis of 50%.[83] If the hard palate is involved, the chance of success, defined as an animal that can eat and grow normally, drops significantly. Little information is available on whether the respiratory function of the soft palate during strenuous exercise can be restored (i.e., there are no reports about the prognosis for athletic endeavors).

Surgical Approaches

Preoperative care includes broad-spectrum antibiotic coverage and plasma transfusion if the IgG level is inadequate. If the foal already has pneumonia and is aspirating feed material, the surgery should be postponed, systemic antibiotics continued, and the foal fed enterally through a nasogastric feeding tube or parenterally.

Surgical approaches to the palate include a transoral approach, laryngotomy, pharyngotomy, and mandibular symphysiotomy.[81,83-86] Pharyngotomy with splitting of the basihyoid bone is used to repair a cleft involving the caudal third of the soft palate (see previous description of pharyngotomy under "Surgical Approaches to the Nasopharynx or Oropharynx" and Figures 44-9 and 44-10).[81] Mandibular symphysiotomy provides the best exposure to the hard and soft palate (Figure 44-30).[86] To perform a palatoplasty using the mandibular symphysiotomy approach, the foal is placed under anesthesia and positioned in dorsal recumbency. A tracheotomy is performed, and the endotracheal tube is placed in the trachea (see Figure 44-30, *A*). Hair is clipped from the lower lip to the proximal trachea, and the skin is prepared for aseptic surgery. A skin incision is made from the hyoid to the lower lip (see Figure 44-30, *B*). The skin and gingiva over the mandibular symphysis are completely incised, and the mandibular symphysis is severed using a scalpel blade (in a neonate), an osteotome, or an oscillating bone saw. It is preferable to avoid incising the lip to minimize postoperative dehiscence and discomfort.[80] This is achieved by making a transverse incision at the base of the lip so the lip can first be moved caudad to give access to the symphysis. After splitting the symphysis, the lip is moved orally. The mandible spread achieved is slightly less after splitting the mandibular symphysis compared with splitting the lower lip, but it reduces morbidity. Surgical dissection subsequently proceeds along the right ramus of the mandible, and the attachments of the mylohyoid, geniohyoid, and genioglossus muscles are transected, exposing the buccal mucosa. The buccal mucosa is sharply incised, allowing the rami of the mandibles to be retracted (see Figure 44-30, *C* and *D*). A thin malleable retractor may be inserted through the laryngotomy over the base of the tongue to push the tongue out of the surgical field. Moist towels should be used to retract the mandibles.

After the cleft is repaired, the mandibles are apposed and stabilized with a single cancellous screw or a Steinmann pin supplemented by a hemicerclage, and the central incisors are wired together. The buccal mucosa is closed, and the geniohyoid and mylohyoid muscle layers are apposed and reattached. The lip is reconstructed by closing the gingiva, muscle layer, and skin (see Figure 44-30, *I*). The laryngotomy is left open, and the skin incision from the mandibular symphysis to the laryngotomy is closed with sutures interrupted by 2-cm gaps for drainage.[86]

A successful two-step repair of a cleft palate through a purely transoral approach was reported in a 4-week-old colt.[87] Because the instruments were too short, the procedure had to be stopped 4 cm short of the caudal rim, and it was completed 4 weeks later, after the initial repair had healed. In this procedure, a special mouth speculum with a long, narrow extension into the mouth was used to elevate the tongue out of the surgical field.

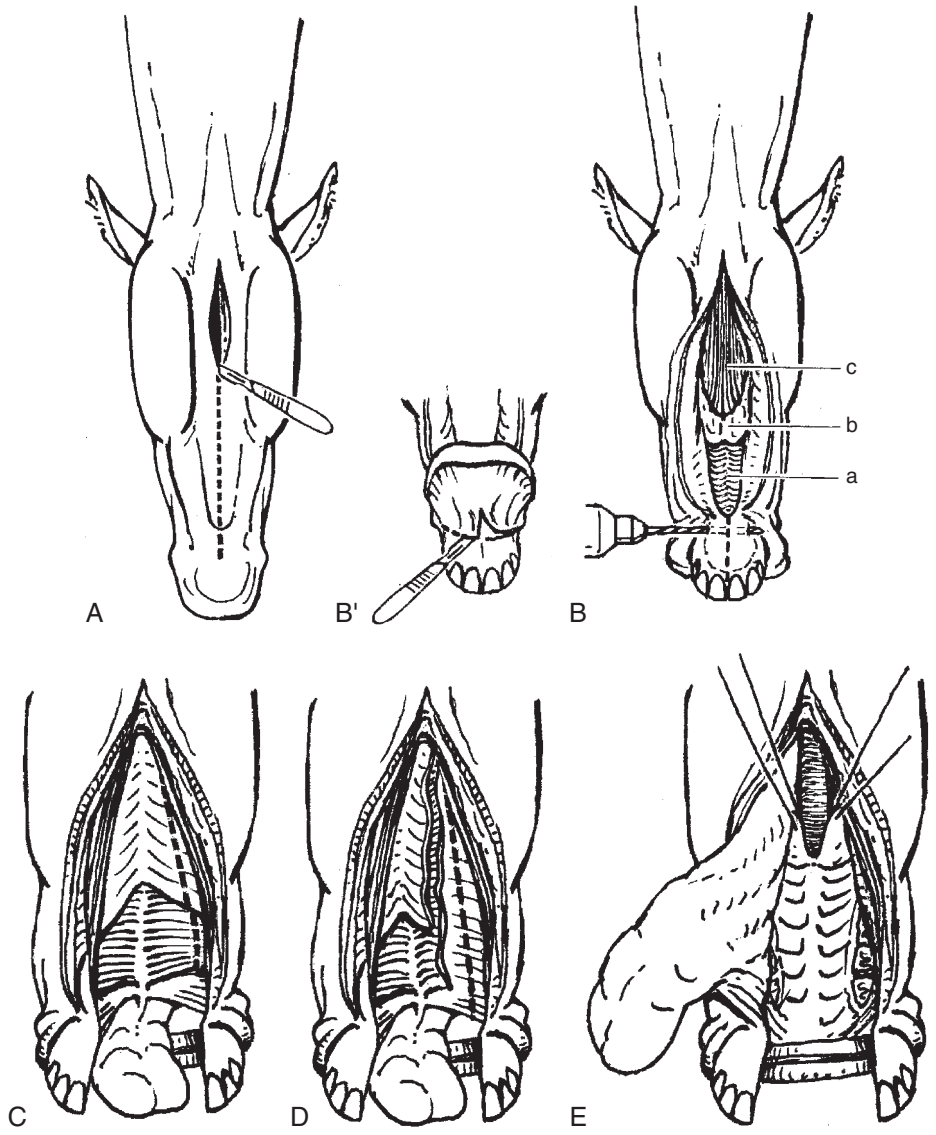

Figure 44-30. A and **B,** A ventral midline incision is made from the angle of the mandible to the lip. Before splitting the symphysis, a hole is prepared to facilitate realignment of the bones during closure. The lip has been moved orally to avoid morbidity associated with incising it. *a,* Mylohyoideus; *b,* mandibular lymph nodes; *c,* sternohyoideus and omohyoideus muscles. **C,** The mandibles are spread, and the rostral oral mucosa is incised. The mylohyoid and geniohyoideus muscles are incised near their tendinous origin. They should be cut with enough tissue left to suture them together for closure. **D,** The exposed ventral surface of the oral mucosa is tensed by further spreading of the mandibles. It is incised as far caudad as possible. Care is taken to avoid the sublingual salivary gland near the mandible and the lingual nerve near the tongue. **E,** The edges of the incision are covered with moistened sponges or towels and spread as far as possible. The nasotracheal tube is visible through the cleft. Two stay sutures are placed at the caudal corners of the cleft.

Illumination of the surgical field was provided by a pediatric endoscope, which was introduced through one of the nasal passages.[87]

Soft Palate Repair

Graffe was the first surgeon to attempt surgical closure of cleft palate in humans in 1816, but he reported poor results.[88] Little progress was made until Langenbeck (1961) described a new technique to close a palatal cleft using two bridge flaps. The technique was further modified in 1967, when Kriens suggested that the main surgical problem with palate repair was caused by the misoriented muscles in the soft palate, which, instead of building a velopharyngeal sphincter mechanism, have an insertion in the hard palate.[89] To solve this problem, the faulty origin of the palatopharyngeus and levator veli palatini muscles was resected from the hard palate and subsequently included in the cleft repair, which resulted in a more anatomically correct reconstruction of the soft palate. The interposition of the palatal muscles between the oral and nasal mucosa led to good functional results in humans.[89]

The soft palate is identified, and the cleft is evaluated. A surgical light is directed into the incision. If a pharyngotomy was used for access, the videoendoscope is placed orally. If a mandibular symphysiotomy was chosen, the endoscope can be positioned through a laryngotomy to improve visibility at the caudal

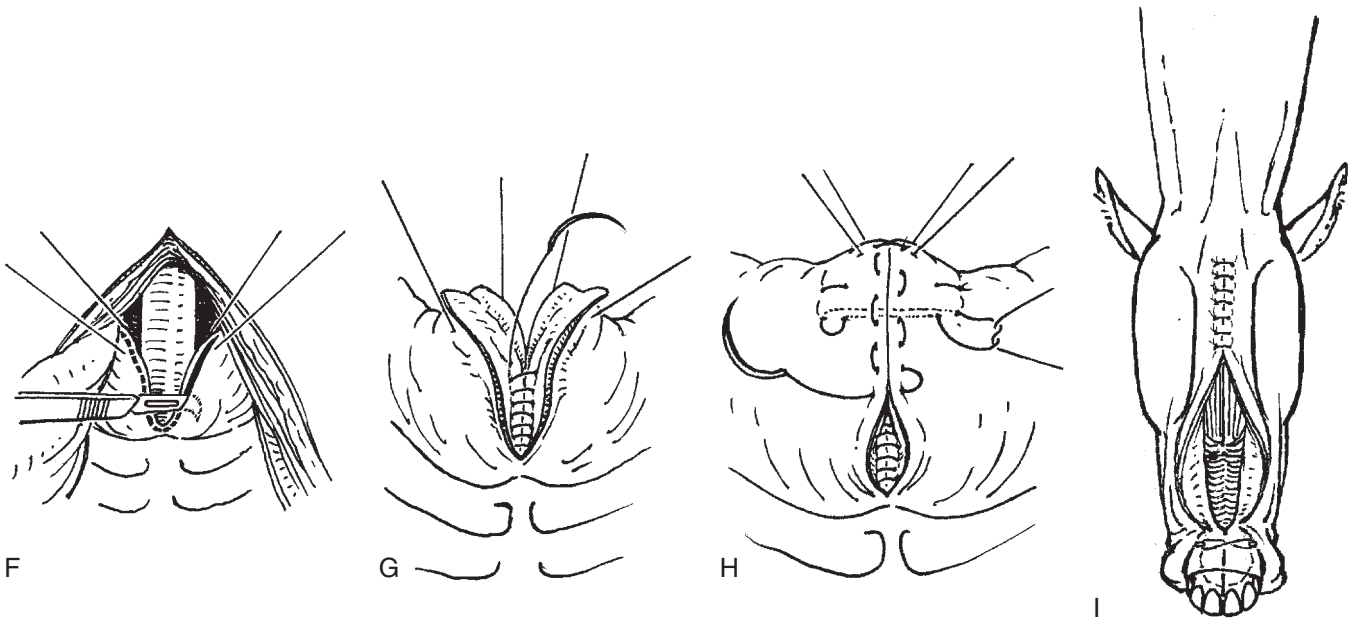

Figure 44-30, cont'd **F,** Tensing the edges of the cleft with the stay suture, a No.12 Bard-Parker blade is used to split the thickness of the tissue. The stay sutures can be held by an instrument inserted through a laryngotomy. **G,** A simple-continuous (or a Lembert) pattern is placed in the nasal side of the split edge in a rostral-to-caudal direction. **H,** A continuous horizontal mattress pattern is placed in the oral side of the split edge. Two to four widely spaced interrupted vertical mattress sutures are placed to reduce tension on the primary suture line. **I,** Soft tissues are apposed and a lag screw or pin with figure-of-eight wire is placed using the previously drilled hole. A cerclage wire around the rostral mandible just caudal to the erupted incisors augments stability.

margin of the soft palate. A stay suture is passed through the soft palate at the caudal extent of the cleft, and these stay sutures are secured at the laryngotomy site to tense the edges of the defect (see Figure 44-30, *E*). A thin strip of mucosa is excised from each edge of the cleft, and a narrow incision is extended into the palate using a No. 12 hooked blade (see Figure 44-30, *F*). The nasal mucosa is closed first, beginning at the caudal free margin of the soft palate, using 2-0 absorbable suture material in a simple-continuous pattern (see Figure 44-30, *G*). The oral mucosa and muscular layers are closed together using horizontal mattress sutures of absorbable material or silk (see Figure 44-30, *H*). Silk has excellent handling characteristics and good knot security.[79] The oral mucosa is closed with absorbable material in a simple-continuous pattern.

Tension on the repair can lead to dehiscence; therefore, tension-relieving incisions are made parallel to the closure plane in the lateral mucosa axial to the molar teeth. Alternatively, widely spaced interrupted vertical mattress sutures can be placed in the palate to relieve the tension. The tendon of the tensor veli palatini muscle can be transected bilaterally or osteotomy of the hamulus of the pterygoid can be performed to decrease tension applied to the caudal half of the soft palate by the tensor veli palatini muscle. These latter procedures should be used with caution, as they can lead to instability of the rostral aspect of the soft palate[10] and may interfere with respiratory soundness at exercise.

Because it is difficult to repair the caudal end of the soft palate, a combined transoral and laryngotomy approach is an alternative to provide good apposition and reconstruction of the cleft palate. To provide better access to the caudal aspect of the soft palate, the thyroid cartilage may be split sagittally (Figure 44-31). The surgical repair of the soft palate is identical to the one previously described. At the end of the procedure, the thyroid cartilage is sutured with three single interrupted sutures of No. 2 monofilament nylon.[88] The incision of the cricothyroid membrane is closed in a simple-continuous pattern with 2-0 polyglactin 910 suture material. The subcutaneous tissues and skin are left to heal by second intention.

Figure 44-31. Laryngotomy approach for repair of the caudal aspect of a cleft palate. The two parts of the cleft palate are retracted with Allis forceps. Good visibility of the cleft palate was achieved by splitting the thyroid cartilage longitudinally. (Courtesy J. Auer, University of Zurich, Switzerland.)

Hard Palate Repair

Repair of hard palate defects is performed using mucoperiosteal flaps.[90] Hemorrhage can be controlled by injecting small volumes of 2% lidocaine with epinephrine along the incision lines in the hard palate. A mucoperiosteal incision is made parallel to the maxilla from the junction of the hard and soft palate to a few centimeters beyond the defect. The entire width of the mucoperiosteum is elevated to the edge of the defect using a periosteal elevator. Care is taken to preserve the palatine artery, which can be seen as it emerges from the palatine foramina at the caudolateral aspect of the hard palate at the level of the second molar tooth. As the flap is elevated, the palatine artery stretches, and the entire flap is moved axially. The rostral (rostral hard palate) and caudal (junction of the hard and soft palates) attachments of the mucoperiosteal flap are preserved. The nasal mucosa of the flap is closed in a simple-continuous pattern using absorbable suture material, and the mucoperiosteal flaps are sutured together with horizontal mattress sutures. The defects along the lateral aspect of each mucoperiosteal flap heal by second intention.

Postoperative Care

If only the soft palate was repaired, the foal is allowed to nurse. If the soft palate defect was extensive or the hard palate was repaired, or both, the foal should be fed enterally through a nasogastric feeding tube or parenterally for 7 to 10 days. Broad-spectrum antibiotics should be continued for 5 days unless the foal has pneumonia, in which case antibiotics are continued until the pneumonia resolves. The repair may be assessed by careful oral examination (by looking in the mouth, not by digital palpation), but endoscopic examination is not recommended during the early postoperative period.

Dehiscence is the most likely and most severe complication. Generally, dehiscence is apparent within the first 7 to 14 days and is evidenced by nasal reflux of food and coughing. Other complications include pneumonia, osteomyelitis of the mandible, salivary fistulas, and incisional infections.[82]

CHAPTER
45 Larynx

Ian C. Fulton, Brian H. Anderson, John A. Stick, and James T. Robertson

ANATOMY

The larynx is a conduit between the pharynx and trachea that contributes to the functions of breathing, vocalization, and deglutition. The architecture of the larynx comprises several individual cartilages and muscles with the lumen being lined by a mucous membrane composed of stratified squamous and pseudostratified columnar ciliated epithelium.[1]

The cricoid, thyroid, and epiglottic cartilages are unpaired, whereas the arytenoid cartilages and attached corniculate processes are paired. The signet ring–shaped cricoid cartilage is positioned rostral to the first tracheal ring and connected to the trachea by the cricotracheal membrane.[1] The thyroid cartilage is the largest of the laryngeal cartilages and is situated rostral to the cricoid cartilage. The arytenoid cartilages are positioned on either side of the cricoid cartilage, being conjoined at the cricoarytenoid articulations. These articulations are diarthrodial joints that allow the arytenoid cartilages to rotate dorsolaterally during abduction, and axially during adduction.[1] Each arytenoid cartilage has a corniculate process forming part of the dorsolateral border of the rima glottidis, a cuneate process and a muscular process that serves as the insertion for the cricoarytenoideus dorsalis muscle. The arytenoid cartilages are the most dynamic of the laryngeal cartilages. The articulations with the cricoid cartilage allow complete closure of the glottis during swallowing (adduction) and maximal opening (abduction) during exercise (Figure 45-1). Any pathologic process that changes the normal function of one or both of the arytenoid cartilages can have an impact on the athletic ability of a horse. Treatment of arytenoid cartilage disease therefore becomes essential for horses undertaking high-intensity exercise. The body or laminar portion of the arytenoids consists of hyaline cartilage, which is subject to ossification with age or trauma. However, the apex of each arytenoid (the corniculate process, which curves upward and backward, forming a pitcher-shaped lip from which the cartilages derive their name) is made of elastic cartilage.

Figure 45-1. Endoscopic image of the normal equine larynx during inhalation, showing maximal abduction of the arytenoid cartilages and a normal epiglottis.

The epiglottis rests on the dorsal surface of the body of the thyroid cartilage and is held there by the thyroepiglottic ligaments. Unlike the cricoid and thyroid cartilages, which consist of hyaline cartilage, the epiglottis is made up of elastic cartilage and has the shape of an oblanceolate leaf.[1]

Movement of the laryngeal cartilages in relation to each other is achieved by intrinsic laryngeal muscles, whereas movement or stabilisation of the larynx as a whole results from extrinsic laryngeal muscles. Contraction of the intrinsic laryngeal muscles produces changes in the caliber of the rima glottidis first by abducting or adducting the corniculate processes of the arytenoid cartilages and second by increasing or decreasing tension of the vocal folds, all combining to alter airway resistance during respiration. The intrinsic muscles include the paired cricoarytenoideus dorsalis (CAD), thyroarytenoideus (ventricularis and vocalis), cricothyroideus and cricoarytenoideus lateralis, plus the unpaired transverse arytenoideus muscle.[2] The CAD muscle is the major abductor muscle that widens the laryngeal aperture by abducting the corniculate process of the arytenoid cartilage and mechanically tensing the vocal folds.[2,3] Contraction of the arytenoid transversus muscle produces arytenoid cartilage adduction by drawing the dorsoaxial margins of the arytenoid cartilages together.[1] The thyroarytenoideus, arytenoideus transversus, and cricoarytenoideus lateralis muscles adduct the corniculate processes of the arytenoid cartilages, narrowing the rima glottidis and protecting the lower airway during swallowing.[1,3] The cricothyroideus muscle tenses the vocal folds during vocalization but receives efferent motor innervation from the external branch of the cranial laryngeal nerve, a branch of the vagus nerve, whereas all other intrinsic laryngeal muscles receive motor innervation from the recurrent laryngeal branch of the vagus nerve.[1,2] The extrinsic laryngeal muscles of the larynx include the thyrohyoideus, hyoepiglotticus, cricopharyngeus, thyropharyngeus and sternothyroideus muscles and are involved in stabilizing the larynx and pharynx during exercise.[1]

The mucosa of the larynx is closely adhered to the cartilages and contains many different types of afferent receptors. The mucous membrane covering the epiglottic cartilage reflects off the lateral border of the epiglottis and blends with the mucous membrane covering the corniculate processes of the arytenoid cartilages, forming the aryepiglottic folds.[1] The mucous membrane lines the vocal ligaments and lateral ventricles and forms the vocal folds and the laryngeal saccules. These saccules are about 2.5 cm (1 inch) deep with a capacity of 5 to 6 mL.[1] They extend between the medial surface of the thyroid cartilage and the ventricularis and vocalis muscles. The laryngeal mucosa contains sensory mechanoreceptors for the detection of different stimuli, including transmural pressure changes, airflow, temperature, and laryngeal motion.[4] These mechanoreceptors

receive afferent neural supply from the internal branch of the cranial laryngeal nerve, a branch of the vagus nerve.[4] This rich sensory nerve supply is the source of many respiratory reflexes that influence upper airway patency and breathing patterns.[4,5]

The larynx receives arterial blood supply from the caudal laryngeal artery and branches of the ascending pharyngeal arteries. Venous drainage is provided by the caudal laryngeal and ascending pharyngeal veins, which flow to the external jugular vein via the thyroid vein. The lymphatic chains that serve the laryngeal area include retropharyngeal, cranial, and deep cervical lymph centers.[1]

RECURRENT LARYNGEAL NEUROPATHY (LARYNGEAL HEMIPLEGIA)

Etiology and Incidence

Although horses can develop unilateral or bilateral paralysis of the CAD muscle leading to dysfunction of the associated arytenoid cartilage,[6-9] unilateral left-sided laryngeal paralysis is most commonly encountered (Figure 45-2). Because the muscle paralysis results from progressive loss of large myelinated axons in the left recurrent laryngeal nerve,[6] recurrent laryngeal neuropathy (RLN) is now considered the most appropriate descriptive term for this condition. Although a genetic basis to the condition is most likely,[9-11] in the majority of affected horses, a precise etiology is rarely evident, and the term *idiopathic laryngeal hemiplegia* has commonly been applied as a synonym. Neurogenic atrophy of the intrinsic laryngeal musculature results in progressive loss of both abductor and adductor arytenoid function.[6] Because of this progressive rather than immediate loss of muscle function, varying degrees of abnormal movements of the arytenoid cartilage(s), depending on presence of CAD muscle paresis or paralysis, is frequently observed endoscopically, which strengthens the use of RLN as the most appropriate diagnostic term. RLN occurs in horses from a few months to 10 years of age and older, with large-breed horses (such as Thoroughbreds and draught breeds) more commonly affected than small-breed horses or ponies.[12,13] The incidence is highest in young horses, often diagnosed before they have started any type of training, or in 2- and 3-year-olds that are racing or are in race training.[13-15] The prevalence of RLN varies between breeds, with the largest population studied being the Thoroughbred, where between 2.6%[15] and 8%[14] of horses are reported to be affected. However, in the heavy draught breeds, an incidence of up to 35% has been reported.[16] Following the introduction of pre- and post-sale endoscopy at Thoroughbred yearling sales, the incidence of RLN has been widely documented.[13-15,17] Although the incidence of complete laryngeal hemiplegia was 2.75% in a study of yearling Thoroughbreds, the overall incidence in the entire yearling Thoroughbred population is thought to be higher.[15,18] In a study of 427 Thoroughbred sale yearlings, 64% had asynchronous arytenoid cartilage movements and 25% had laryngeal asymmetry that was significantly associated with decreased racing performance.[17]

In normal horses during sustained high-intensity exercise, the rima glottidis of the larynx dilates fully to maximize airflow. Full arytenoid cartilage abduction is sustained, despite increasing negative inspiratory pressure that occurs as exercise intensity increases. Horses with RLN cannot achieve maximal abduction of the affected arytenoid cartilage, and as negative inspiratory pressure increases, the rima glottidis progressively reduces in size (Figure 45-3).[19] Subsequently, hypoxemia, hypercarbia, and metabolic acidosis develop more rapidly than in normal horses with the same workload, causing early musculoskeletal fatigue and poor performance.[20,21]

A specific etiology can be identified in some horses with acquired unilateral or bilateral laryngeal paralysis. The recurrent laryngeal nerve can be damaged as a result of perivascular jugular vein injection, guttural pouch mycosis, trauma from injuries or surgical procedures of the neck, strangles abscessation of the head and neck, and impingement by neoplasms of the neck or chest.[9] Organophosphate toxicity, plant poisoning, hepatic encephalopathy, lead toxicity, and central nervous system diseases have also been shown to cause laryngeal paralysis.[22,23] A study of 375 cases of laryngeal hemiplegia in a mixed-breed population of horses indicated 94% (351) were idiopathic in origin.[24] However, in the 6% of nonidiopathic cases of recurrent laryngeal neuropathy, over half were bilaterally affected.

Diagnosis

A diagnosis of RLN can be suspected on the basis of history and a physical examination. Horses with RLN commonly demonstrate exercise intolerance with resultant poor performance during high-speed exercise and produce an abnormal

inspiratory respiratory noise during exercise described as a nonvibratory, single-tone whistle that has resulted in the colloquial term *roaring*. This noise is the result of turbulence created by a narrowed rima glottidis as air passes over the affected vocal cord and ventricle, which acts as a resonator.[23] Physical examination should include palpation of the neck and larynx because horses with significant RLN have palpable atrophy of the left CAD muscle, which manifestes as a percutaneous prominence of the muscular process of the arytenoid cartilage.[18] The larynx should also be palpated for congenital malformation and evidence of arytenoid chondritis.[22,25] If there is suspicion of previous laryngeal surgery, clipping of the hair is advised to allow visual confirmation of palpable laryngotomy or laryngoplasty scars. Ultrasound examination can identify arytenoid cartilage movements but patient cooperation is essential for successful interpretation of this diagnostic mode.[26] (Additional information can be found in Chapter 42.)

A definitive diagnosis of RLN is made on endoscopic examination when there is partial or complete loss of abductor function on the affected side of the larynx (see Figure 45-2). Because the various descriptions of the loss of abductor function (hemiplegia, paresis, complete or incomplete paralysis) can lead to confusion, a variety of grading systems have been developed over the past 30 years by several surgeons to describe arytenoid cartilage movements as assessed endoscopically in the resting horse.[27] Currently a seven-grade system (Grades 1 though 4 with subgrades) (Table 45-1) has been adopted by many surgeons to establish international consistency in reporting this condition.[28] This grading system should make possible a better description of the endoscopic apperance of laryngeal movements and more accurate reporting of treatment outcomes.

To aid assessment of arytenoid cartilage movements, both the swallow reflex and nasal occlusion can be helpful. In the normal horse a momentary full abduction of the arytenoid cartilages can be stimulated by inducing swallowing. Prolonging nasal occlusion for several attempted breaths can also induce maximal abduction of arytenoid cartilages in the normal horse.[29] Trackside endoscopy immediately after strenuous exercise has been used to help establish a diagnosis of recurrent laryngeal neuropathy, but it is not a reliable technique. If doubt exists about the diagnosis and surgical intervention is planned, treadmill videoendoscopy or "over-ground" videoendoscopy[30] are now the "gold standards" for accurate disagnosis (Chapter 42). A video image can be recorded and reviewed in slow motion to accurately observe dynamic collapse of the affected arytenoid cartilage and ipsilateral vocal cord.[31] When high-speed videoendoscopy is not avaibale, momentary full abduction of the arytenoid cartilages after swallowing is thought to be more reliable than nasal occlusion at predicting which horses would demonstrate arytenoid cartilage collapse during treadmill endoscopy at speed. In many horses that cannot achieve full abduction during nasal occlusion the arytenoids will collapse at speed, but not all will. However, horses that showed full symmetrical abduction after swallowing all maintained full

TABLE 45-1. Subjective Grading System of Laryngeal Function Assessed Endoscopically in the Standing Horse[28]

Grade	Description	Subgrade	Description
I	All arytenoid cartilage movements are synchronous and symmetrical, and full arytenoid cartilage abduction can be achieved and maintained.		
II	Arytenoid cartilage movements are asynchronous and/or larynx is asymmetric at times, but full arytenoid cartilage abduction can be achieved and maintained.	A	Transient asynchrony, flutter, or delayed movements are seen.
		B	There is asymmetry of the rima glottis much of he time owing to reduced mobility of the affected arytenoid cartilage and vocal fold, but there are occasions, typically after swallowing or nasal occlusion, when full symmetrical abduction is achieved and maintained.
III	Arytenoid cartilage movements are asynchronous and/or asymmetric. Full arytenoid cartilage abduction cannot be achieved and maintained.	A	There is asymmetry of the rima glottis much of the time owing to reduced mobility of the affected arytenoid cartilage and vocal fold, but there are occasions, typically after swallowing or nasal occlusion, when full symmetrical abduction is achieved *but not* maintained.
		B	There is obvious arytenoid abductor muscle deficit and arytenoid cartilage asymmetry. Full abduction is never achieved.
		C	There is marked but not total arytenoid abductor muscle deficit and arytenoid cartilage aymmetry with little arytenoid cartilage movement. Full abduction is never achieved.
IV	Complete immobility of the arytenoid cartialge and vocal fold.		

abduction at speed.[32] It is well established in horses standing at rest, without clinical evidence of upper respiratory obstruction, that the arytenoid cartilages can be positionned asymmetrically and/or have asynchronous movements. Therefore, it is important to acknowledge that this asymmetry and/or asynchrony may or may not predict failure of arytenoid function during athletic exercise.[17] Whereas the clinical significance of these variations in arytenoid cartilage movement has been controversial, it is generally accepted that as arytenoid cartilage abduction decreases, athletic perfromance reduces and therefore it is an undesirable finding during endoscopy of the equine athlete. Furthermore, it is recognized that horses with RLN, even after treatment with prosthetic laryngoplasty or a nerve muscle pedicle graft, often do not achieve full restoration of athletic performance.[33,34]

Therefore, interpretation and significance of altered laryngeal cartilage movements identified at endoscopy falls to the veterinarian, who must make an educated prediction of how these altered movements will affect the horse's performance. Hence the veterinarian has to determine how severely affected is the larynx and answer the question: "Will these altered laryngeal movements progress to complete laryngeal paralysis?" In 1982, a study of 168 horses over several years demonstrated there was no apparent progression from asynchronous arytenoid cartilage movements to complete paralysis.[35] This led the investigators to conclude that such movements were normal. Subsequently, a four-point grading system describing arytenoid cartilage movements was developed to predict present and future arytenoid cartilage dysfunction based on resting endoscopic evaluation. Although clinical and experimental studies suggested RLN may have been progressive, no factual evidence was available in the literature. In 1997, when 109 young Thoroughbred and Standardbred horses were examined 16 months apart, 12% of horses progressed from normal laryngeal function to that indicative of RLN.[36] In 2002, another study supported the progressive nature of RLN.[37] The long-term histories and clinical findings of 351 horses suffering from RLN were examined for evidence of progression of laryngeal asymmetry. Fifty-two out of 351 cases (15%) had evidence of progressive laryngeal dysfunction over a median period of 12 months. A more recent study has also highlighted the progressive nature of the disease with successive treadmill examinations over time.[38] The fact that 67% of foals with marked arytenoid dysfunction can show improved laryngeal function 12 months later[39] supports the statement that endoscopic findings on a given day may not apply to the future, and periodic re-examination is justified. As well as RLN being progressive, many adult horses have an acute onset of exercise intolerance and loud inspiratory noise.[39] The progression of RLN is assumed to be slow and insidious; however, clinical signs may only become apparent when sufficient muscle atrophy of the cricoarytenoideus dorsalis muscle occurs, permitting complete arytenoid collapse during exercise. This manifestation could result in a history of acute onset. However, rapid progression in as little as 6 weeks has been reported.[37]

Variation of arytenoid cartilage movements in an individual horse has been reported to be common when the horse has multiple endoscopic examinations.[17] This variation, whether examinations are days or even hours apart, is thought to be caused by intra-assessor variation or laryngeal muscular fatigue from multiple reexaminations. Using the seven-grade system, a high degree of reliability in assessing laryngeal movements has been shown, but variation can be seen in the same horse evaluated endoscopically on different days.[40] Differences in clincial and endoscopic findings between veterinarians who perform prepurchase and postpurchase examinations, weeks rather than hours apart, may in some cases simply reflect clinical progression of recurrent laryngeal neuropathy rather than intra-assessor variation.

Treatment

General Considerations

Surgical treatments available for RLN include prosthetic laryngoplasty, ventriculectomy (sacculectomy), ventriculocordectomy, reinnervation of the CAD muscle, and occasionally arytenoidectomy.[31] The choice of surgery is usually based on the presenting complaint, the age and use of the horse and the grade of arytenoid cartilage movement present. When considering this decision, the surgeon should recognize that some horses with RLN can tolerate and work to capacity despite partial upper airway obstruction, especially when high-speed exercise is not expected of the horse. The decision to operate on the upper airway should be based on clear evidence that it is essential to allow the horse to perform to the owner's requirements because complications can be frequent and sometimes devastating. Therefore, treatment of RLN should be reserved for horses in which upper respiratory tract obstruction is reducing performance.

Horses that work and race at speed for farther than 800 meters ($\frac{1}{2}$ mile) are significantly affected by obstructions of the upper airway.[33] At these speeds and distances, reduction in the laryngeal aperture by 50% increases the work of breathing 16-fold. Therefore, some form of surgical intervention to eliminate this obstruction is warranted.[35] The most common technique is the prosthetic laryngoplasty. Frequently, ventriculectomy or ventriculocordectomy is performed with laryngoplasty, but neither prolongs the efficacy of the surgery or improves upper airway flow mechanics during high-speed exercise.[41,42] However, these procedures are often used along with laryngoplasty and laryngeal reinnervation because they reduce noise, and the scar can assist with airflow mechanics. In show and non–racehorses, the respiratory noise caused by RLN is an important clinical problem because being "unsound of wind" may result in judging penalties. Therefore, the primary goal of surgery in these horses is often to eliminate the respiratory noise. A study in 2003 demonstrated that bilateral ventriculocordectomy in grade 4 hemiplegic horses effectively reduced inspiratory noise by 90 days after surgery.[43] Conversely, it was shown that a unnilateral laser vocal cordectomy did not effectively reduce the noise associated with grade 4 laryngeal hemiplegia by 120 days after surgery.[44] Both of these techniques can modestly improve airway flow mechanics and improvement in exercise performance and noise reduction has been identified with ventriculocordectomy.[45]

Clinical experience suggests that bilateral standing ventriculectomy has a very similar result in draft breeds, decreasing airway noise while improving air flow mechanics. Although laryngoplasty reduces respiratory noise in horses with laryngeal hemiplegia, ventriculocordectomy is more efficacious in reducing airway noise in the normal hearing range.[46] A further advantage of ventriculocordectomy over laryngoplasty is that postoperative complications after laryngoplasty are more prevalent and severe. These can include dysphagia, bilateral nasal discharge of feed, water, and saliva, aspiration pneumonia,

chronic coughing, wound infection, prosthesis failure and chondritis.[33] Because many horses still make varying levels of noise during exercise following laryngoplasty, sound production should not be used as an indicator of surgical success in horses where restoration of upper airway flow mechanics is the primary goal of surgery.[46] There is a poor correlation between the sound indices and degree of airway obstruction as measured by inspiratory pressure. A strong positive correlation exists in the degree of arytenoid abduction and sound indices. It would be intuitive that greater arytenoid abduction would be correlated with less respiratory noise, but in fact the opposite was true.[46]

Occasionally, partial arytenoidectomy (the muscular process is left *in situ*) is chosen to treat laryngeal hemiplegia when there is a congenital malformation of the cartilages or when the laryngoplasty technique has failed because of fractures in the cartilage. This technique has been shown to improve airway mechanics to a level similar to laryngoplasty,[47] and Thoroughbred horses have returned to successful careers.[48] The nerve muscle pedicle graft is suitable for horses of all breeds and ages but most commonly is used in young horses, where return to athletic function is not expected before 4 months after surgery. Although successful reinnervation is possible in grade 4 recurrent laryngeal neuropathy, horses with grade 3 arytenoid carilage movements are thought to be better candidates because less muscle atrophy is present in the latter.

In general, before laryngeal surgery, horses are fasted for 8 to 12 hours. Preoperative and perioperative nonsteroidal antiinflammatory medication (phenylbutazone) and broad-spectrum antibiotics are indicated for these surgeries. Disruption of the protective laryngeal mucosa via laryngotomy or cordectomy/ventriculocordectomy can justify prolonged perioperative antibiotics for up to 2 to 3 days because these major laryngeal surgeries induce dead space associated with the approach, increasing the risk of infection from bacteria originating in the lumen of the airway. The anesthetist should be aware that some horses with a longstanding unilateral arytenoid paralysis can be difficult to intubate with a standard-size tube, and a smaller-diameter tube should be available. The smaller tube also allows easier rotation and manipulation of the larynx intraoperatively. Prosthetic laryngoplasty is performed with the horse in lateral recumbency, affected side up. In unique situations, the horse may be first placed in dorsal recumbency to allow visual and digital inspection of the arytenoid cartilages through a laryngotomy. This approach might be taken when endoscopic observations suggest the presence of subtle arytenoid chondritis or when there has been previous laryngeal surgery. If the cartilage is diseased or has lost flexibility and cannot be pushed into an abducted position, the surgeon may elect to proceed directly to an arytenoidectomy rather than perform a laryngoplasty.

Prosthetic Laryngoplasty

Prosthetic laryngoplasty, commonly referred to as a *tie-back*, involves placing a prosthesis (usually a nonabsorbable suture) between the cricoid and arytenoid cartilage (Figure 45-4, *A* and *B*).[49,50] The goal of laryngoplasty is to achieve some degree of permanent abduction of the affected arytenoid cartilage (see Figure 45-4). The ideal result for the horse is an arytenoid cartilage abducted sufficiently to allow adequate airflow during exercise but not allow entry of saliva, food, or water into the laryngeal or tracheal lumen during swallowing. The art of performing this surgery is finding that balance.

Following induction of general anesthesia and placement of the horse in lateral recumbency, the head and neck are extended moderately for best surgical exposure. A videoendoscope can be secured transnasally at this time to allow intraoperative viewing of the larynx by the surgeon. The surgical site is routinely prepared for aseptic surgery and draped, and a 10- to 12-cm (4- to 5-inch) skin incision is made ventral and parallel to the linguofacial vein, extending caudally from a point 4 cm (1½ inch) cranial to the ramus of the mandible. Blunt and sharp dissection with Metzenbaum scissors separates the linguofacial vein from the lateral margin of the omohyoideus muscle along the length of the incision. Often it is necessary to ligate and divide a branch of the linguofacial vein that enters the omohyoideus muscle. Elevation of the linguofacial vein with an Allis tissue forceps attached to perivascular tissues at the middle of the incision allows a natural cleavage plane between the sternocephalicus and cricothyroideus muscles to become evident, which can be digitally opened and enlarged. This exposes the lateral and dorsal aspects of the larynx. A 6- to 8-cm wide malleable retractor placed under the linguofacial vein and sternocephalicus muscle is used to expose and maintain acess to the larynx. The muscular process of the arytenoid cartilage lies beneath the cranial portion of the cricopharyngeus muscle and can be exposed by sharply separating the cricopharyngeus and thyropharyngeus muscles along the junction of their aponeuroses. Alternatively, a plane of dissection can be created off the back edge of the cricopharyngeus muscle, under the vascular plexus that lies over the CAD muscle. Rostral retraction of the cricopharyngeus muscle often exposes almost the entire CAD muscle and muscular process without interference from the cricopharyngeus muscle. The esophagus, thyroid gland, laryngeal and thyroid vessels, and ventral branch of the first cervical and cranial laryngeal nerves should be avoided during site preparation and suture placement.[49]

The choice of prosthetic suture is often based on surgeon preference. Materials that have been used include braided polyester, with (No. 5 Ticron) or without silicone coating, 6-mm surgical stainless steel wire, braided lycra, and nylon. The prosthetic suture is first placed through the cricoid cartilage. The use of two sutures is common and has been shown *in vitro* to be mechanically superior to one[51] and also results in a larger cross-sectional area of the rima glottidis.[52] We prefer the large, swaged-on, reverse-cutting needle on the Ticron, but the suture can be threaded onto a No. 3 Martin uterine reverse-cutting needle and the ends tagged with a small hemostat. (This type of needle is less likely to break off in the laryngeal cartilages than a cutting needle, and it pierces cartilage more easily than a trochar-point needle.) Using the left index finger as a guide, the needle is "walked off" the caudal edge of the cricoid cartilage 2 to 3 mm lateral to the dorsal midline until the point slips under the cartilage. (There is a palpable notch in the cricoid cartilage at this site, but its location can be quite variable.) The needle is advanced in a cranial direction while avoiding penetration into the lumen of the larynx. Then the needle is rotated to penetrate the cricoid cartilage 2 to 3 cm cranial to its caudal border and 1 cm lateral to the dorsal ridge (Figure 45-5, *A*). Before drawing the needle through the cartilage and overlying CAD muscle, inspection of the laryngeal lumen via videoendoscope can ascertain if mucosal penetration has occurred. If the needle has penetrated the larynx, it should be

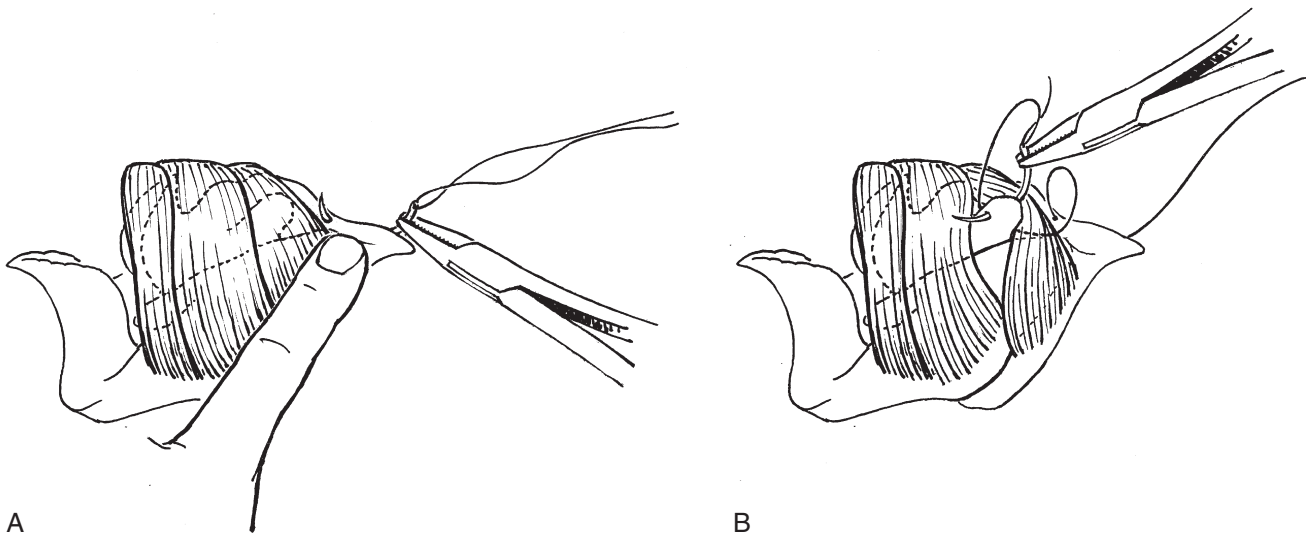

Figure 45-5. Schematic illustration of the laryngoplasty technique. **A,** Placement of the prosthesis behind the caudal border of the cricoid cartilage and exiting through the dorsal portion of the cartilage. **B,** Placement of the prosthesis through the muscular process of the arytenoid cartilage from a caudomedial to craniolateral direction.

backed out, the incision should be lavaged with saline, and the process should be started again with a new needle. When the needle has been drawn through the cartilage and out of the incision, the needle is cut off and the suture ends are tagged with a small hemostat. The second suture is usually placed 10 mm lateral to the first using the same technique. If the cricopharyngeus muscle has not been retracted forward, a large hemostat is passed under the cranial aspect of the cricopharyngeus muscle to bring both ends of the first and second sutured craniad toward the muscular process of the cricoid cartilage.

Placement of the suture through the muscular process can be achieved by a variety of techniques. Use of heavy needle drivers and a reverse cutting No. 6 Mayo needle or No. 6 Martin uterine needle is common. The use of a 3-mm bone trocar to create a tunnel for the suture has been reported to reduce fissure formation and risk of cartilage failure from suture pullout.[53] A 12- to 16-gauge hypodermic needle can also be used to create the tunnel through the muscular process. The prosthesis can be placed through a loop of No. 1 stainless steel wire that is passed through the tunnel to facilatate prosthesis placement through the muscular process. Before needle placement, some surgeons transect the tendon of insertion of the CAD muscle onto the muscular process and open the cricoarytenoideus articulation. After it is open, the joint can be curetted to induce fibrosis and ankylosis to try to reduce the loss of abduction frequently observed in the early postoperative period.[54] To enhance this even further, injection of polymethylmethacrylate has been advocated as a better method of joint ankylosis.[55] Removal of the attachment of the cricoarytenoideus muscle also reduces the opportunity for cycling of the prosthesis in horses with grade 3 RLN, which is thought to increase the early postoperative loss of arytenoid abuction. The shape of the muscular process varies among horses, and cutting the tendon of insertion can help identify these variations. To the inexperienced surgeon, this may help, via palpation, avoid placing the suture along a less than ideal pathway through the muscular process. Typically the needle or trocar is passed through the muscular process from the caudomedial aspect of the process toward the craniolateral aspect (Figure 45-5, *B*). The needle can also be placed in a caudal to cranial (sagittal) direction.[56]

After removal of the needle, firm tension is placed on the cranial and caudal ends of the suture to remove any slack, ensuring the prosthesis is tight against the larynx. If a trocar is being used, both sutures can pass through a single tunnel; otherwise, the second suture is placed approximately 5 mm more caudad in the muscular process. Engaging the spine of the muscular process rather than the tip is essential to achieve maximal biomechanical advantage and to avoid early pullthrough of the prosthesis. The trailing ends of the prosthetic sutures can be drawn under the cricopharyngeus muscle if necessary with a hemostat, and the sutures are tied (see Figure 45-4). Care must be taken to ensure that each trailing suture end is matched to its leading end and that both sutures are placed before one is tied (to avoid cutting the tied suture). When tying sutures, direct vision of the larynx via videoendoscopy is advised to avoid excessive or inadequate abduction of the arytenoid cartilage. The degree of abduction observed intraoperatively by videoendoscope sometimes does not match the immediate postoperative view in the standing horse, but surgical experience can reduce postoperative disappointment. After the prosthetic suture or wire is tied or tightnened, all retractors should be removed to allow the larynx to assume a normal, nonrotated central position to allow accurate assessment of the degree of abduction. When using suture as the prosthesis, leaving the cut ends 1.5 to 2 cm long can allow the knot to be undone and retied if repeat laryngoplasty is performed within the first week of the original surgery (see "Repeat Laryngoplasty," later). Maximal abduction, referred to as grade 1,[56] is not necessary to achieve success (see Figure 45-4, *E*). Abduction to achieve approximately 88% of maximal rima glottidis cross-sectional area (Dixon grade 2) is sufficient to allow adequate airflow[57] (see Figure 45-4, *D*). As a general guide, when the curvature of the corniculate cartilage comes into contact with the wall of the pharynx, this is generally the ideal degree of "pull out." When the sutures have been tied, the thyropharyngeus and cricopharyngeus muscles can be reapposed with simple continuous 2-0 absorable suture, if they were separated, followed by apposition of the fascia adjacent to the linguofacial vein to the omohyoideus muscle with simple-interrupted or continuous sutures of 2-0 synthetic absorbable suture material. The skin is closed with staples or 2-0 nonabsorbable monofilament suture material. A stent bandage sutured over the incision can help protect the incision during recovery and minimize swelling postoperatively. At the conclusion of the laryngoplasty surgery, many surgeons routinely place the horse into dorsal recumbency and perform a bilateral ventriculectomy via laryngotomy (described later).

Varations of the laryngoplasty technique include using one prosthetic suture only or using a crochet-style hook rather than a loop of wire to pull the leading edge of the prosthesis through the muscular process.[49,50] A novel technique to refine the tension applied to create arytenoid abduction involves using a tension and crimping device to adjust and secure the prosthetic suture (Securos Equine Tie-Back System).[58] In an *in vitro* study, an increase in holding strength of a double loop fixation of the suture through the muscular process was shown.[59] Additonally, the use of a Titanium Corckscrew as suture anchor in the muscular process of the arytenoid cartilage and a stress-reducing washer at the cricoid[60] showed significantly higher forces to failure compared with the the original laryngeoplasty technique.[49]

Although individual surgeons often introduce variations in the technique or suture material, the following principles should be observed:

- Tissue trauma associated with the initial blunt dissection over the larynx should be minimized to prevent damage to adjacent structures (particularly nerves) and to reduce the possibility of postoperative dysphagia.[61]
- The prosthetic suture should be placed securely in the cricoid cartilage and the muscular process to minimize cartilage failure.
- Placement of one suture dorsally and one about 10 mm laterally in the cricoid cartilage is important for achieving adequate abduction. Placement of the suture too far laterally results in inadequate abduction. The ideal position is between 10 and 30 degrees from zero (zero degrees is defined as a line through the muscular process of the left arytenoid cartilage and parallel to the wing of the thyroid cartilage when viewed dorsally).[62]
- The suture must not penetrate the lumen of the larynx. Placement of the suture in the cricoid cartilage is the most likely time when the lumen can be penetrated.

Videoinspection intraoperatively allows early identification of this problem.

POSTOPERATIVE MANAGEMENT

Following prosthetic laryngoplasty, confinement to a stall or a walk-in, walk-out yard is recommended for 30 days. Routinely, feed and water are placed at ground level to reduce laryngeal and upper tracheal contamination. This method of feeding should be encouraged long term. Hand-walking is allowed for exercise. During the second postoperative week, the swelling in the laryngoplasty incision area subsides. During the fifth and sixth postoperative weeks (30 to 45 days after surgery), the horse is exercised lightly or turned out in a small paddock or round pen. After this, training is resumed. The owner should be advised to feed hay from the ground and that the horse may develop a chronic cough associated with eating.

COMPLICATIONS

Intraoperative complications

Intraoperative complications include hemorrhage from deep in the surgical site, needle breakage, perforation of the laryngeal mucosa, and prosthetic suture "cut-through" of either the cricoid cartilage or muscular process of the arytenoid cartilage. Significant hemorrhage can arise from the plexus of laryngeal vessels that are inadvertently punctured as the needle is passed through the cricoid cartilage and CAD muscle. Temporary packing with sponges often slows bleeding and allows the placement of the prosthetic suture through the muscular process. Hemorrhage usually stops or reduces significantly when the suture is tightened and tied. Therefore, the surgery should be hastened to accomplish tying of the suture as soon as possible.

Breakage of the needle when passing through cartilage can occur and all reasonable effort should be made to retrieve the broken portion. If unsuccessful because the needle is embedded in cartilage or buried in the adjacent soft tissues and has not penetrated the lumen of the larynx, the needle is left because extensive dissection increases the risk of postoperative dysphagia. The needle is clearly visible with radiography of the horse's larynx, and owners should be informed of the complication.

When the prosthetic suture is tightened, suture pullout from either cartilage is a serious problem. The suture must be replaced, avoiding the damaged portion of the cartilage and using less tension. In this instance, a second suture is always used to secure the arytenoid cartilage in an abducted position. Damage to the muscular process from suture pull out can necessiatate placing the new suture at 90 degrees to the original and farther down the spine of the muscular process to minimize the opportunity of a repeat complication. Perforation of the laryngeal mucosa is most likely to occur when placing the needle under the caudal border of the cricoid cartilage. If this goes unrecognized until after recovery and the suture is seen during postoperative endoscopy, infection of the suture and possibly the cartilage can be expected unless the suture is removed. Intraoperative videoscopic examination immediately after both sutures have been passed through the cricoid cartilage will prevent this complication.

Postoperative complications

Complications in the first 2 weeks postoperatively related to the surgical procedure (as distinct from general anesthesia complications) include seroma, wound infection, wound dehiscence, dysphagia, coughing (often, but not always) associated with eating and mild to excessive loss of abduction. Excessive abduction (see Figure 45-4, *E*) may necessitate a repeat laryngoplasty. Chronic complications include persistent coughing; chronic airway contamination with feed, saliva, and water; chronic tracheitis and bronchitis; lung abscess formation; pneumonia; chondritis with formation of a luminal suture sinus; isolated inflammation and granuloma formation on the corniculate process of the arytenoid cartilage; perilaryngeal abscess formation; suture pullout; progressive loss of abduction; and persistent nasal discharge of feed and saliva, both of which could require repeat laryngoplasty.

After surgery, large seromas can develop at the laryngoplasty site, and an endoscopic examination may show collapse of the pharyngeal vault, especially on the side where surgery has been performed. Provided the horse is eating well and remains afebrile (temperature less than 38.5° C [101° F]) and the swollen area is relatively pain free, warm compresses and anti-inflammatory drugs are usually all that is required to resolve the the seroma. However if the horse develops a fever, systemic antibiotic treatment is warranted. Drainage of the laryngoplasty incision is indicated if medical treatment fails to resolve the swelling. The prosthetic suture rarely becomes infected; however, if this occurs, chronic drainage of purulent material may occur for weeks or even months. Because antimicrobial therapy may resolve the infection, removal of the prosthetic suture is often not necessary and should be delayed for about 4 months, because early removal will result in failure of arytenoid cartilage abduction.

Following laryngoplasty, many horses experience some degree of coughing and dysphagia. Dysphagia can be related to excessive and prolonged retraction of the cricopharyngeus and thyropharyngeus muscles because these are involved with esophageal sphincter function. Initially, pain may result in a reluctance to swallow. In the first few days after surgery, saliva, water, and food material may enter the trachea when the horse eats and drinks, resulting in significant coughing. Intensity of coughing often reduces over 7 to 10 days, although many horses have some degree of residual coughing when eating. The incidence of coughing in the immediate postoperative period has been reported to be as high as 43%.[34,56,61,63] Persistent coughing is most likely the result of continued contamination of saliva, water, or food material into the trachea. This pharyngeal dysfunction resulting in laryngeal and tracheal contamination may have a neurologic origin owing to surgical manipulation or it may be related to overabduction of the arytenoid cartilage.[61] Chronic coughing has been reported in up to 14% of horses more than 6 months after surgery with many of them having concurrent pulmonary disease.[56] Chronic airway contamination causes chronic coughing and, in some horses, repeated episodes of tracheal, bronchial, or lung infection when they resume training. In rare cases, bronchopneumonia may be the long-term result. The diagnosis of airway contamination is easily made by endoscopic examination. Removal of the prosthesis may resolve the contamination problem and even the chronic cough in some horses. Time may allow this problem to resolve in others.

Prosthetic suture pullout resulting in failure of laryngoplasty has been proposed to be more likely in yearlings or 2-year-old horses, although experimentally there is no significant effect of age on the *in vitro* cartilage retention of the prosthesis.[64] Most commonly, suture pullout occurs at the muscular process.[64,65] Partial muscular process cartilage failure is suggested as the

likely cause of postoperative "relaxation" of the suture, with some loss of abduction.[64] This is a well-recognized phenomenon that occurs during the first 30 days after surgery.[46,56] One retrospective clinical study revealed a much higher rate of successful outcome after prosthetic laryngoplasty in horses that were 2 years old or younger than in horses 3 years old or older.[63] Therefore there is no hard evidence to exclude young horses (younger than 2 years) from laryngoplasty treatment, and they are at no greater risk for laryngoplasty failure than older horses.[34,63,64]

Repeat laryngoplasty may be necessary for loss of abduction or when overabduction results in persistent coughing and aspiration of feed. The requirement for repeat surgery has been reported to be as high as 10% for loss of abduction and up to 7% for management of overabduction.[56] Timing of repeat laryngoplasty should considered carefully in the first 10 days after surgery. Undergoing two general anesthesias in close proximity can increase the risk of intestinal disorders, including cecal impaction.[66] The surgical approach mimics the original incision, but care must be taken not to penetrate the linguofacial vein during the dissection between the vein and the omohyoideus muscle as a result of fibrosis. Reoperation weeks or months later presents dense scar tissue, making it difficult to expose the cricoid cartilage and the muscular process of the arytenoid cartilage. Dissection through this scar tissue either digitally or with scissors can cause hemorrhage that will fill the surgical field. Temporary pressure from gauze sponges packed into the incision is often necessary to reduce hemorrhage, but patience may be required and intraoperative suction is essential.

The goal of reoperation in the early postoperative period (first 14 days) is to tighten or loosen the prostheis by twisting if wire was used, to retie the suture if there has not been pullout from either cartilage, or to extract the original laryngoplasty sutures and replace them with another suture (or sutures) that achieves more ideal arytenoid cartilage abduction. If a surgery report from the original surgery is not available, the surgeon should be aware of the possibility of more than one prosthetic suture. After the first 4 weeks, the suture is frequently buried in scar tissue, but the knot can usually be found caudal to the muscular process. The suture is cut beside the knot and removed, although it may break and fragments can be left behind. The scar tissue along the lateral and caudal surfaces of the muscular process must be incised with Metzenbaum scissors and digital guidance to mobilize the arytenoid cartilage. A laryngoplasty suture is subsequently placed and tied ideally under endoscopic observation (Figure 45-6).[22,31,67] If the cartilage is elevated away from the endotracheal tube, it is likely that the goal of improving abduction has been achieved. If not, it is likely that the reoperation attempt will fail. With this intraoperative knowledge, the surgeon can decide whether to place another suture to try to achieve greater abduction or whether to advise of the need for arytenoidectomy.[22]

If overabduction after laryngoplasty produces excessive and persistent airway contamination, the original sutures can be removed. A new prosthesis can be placed that fixes the arytenoid cartilage with less abduction than the original suture if the reoperation is performed within 2 weeks of the initial surgery. When reoperation takes place more than 120 days after the first surgery, removal of the sutures without replacement may be all that is necessary. Minimal dissection around the muscular process during suture removal often leaves sufficient scar tissue to maintain moderate arytenoid cartilage abduction.

Figure 45-6. Endoscopic appearance of the arytenoid cartilages during laryngoplasty. The endotracheal tube has been positioned in the rima glottidis through the mouth, and the displaced palate is seen ventrally. The space between the endotracheal tube and the left arytenoid cartilage indicates that the prosthetic suture tension has produced adequate abduction.

For horses with chronic tracheal contamination with feed, water, and saliva and the resultant range of respiratory tract disease from tracheitis to pulmonary abscessation or pneumonia, removal of the suture is warranted. However chronicity of lung pathology and effect on future athletic performance should be considered and discussed with the owners prior to surgery, as should the increased risk of anesthesia-related complications.

The presence of a draining sinus into the laryngeal lumen usually represents chronic infection of the suture, and in some cases the suture can be seen hanging into the airway. Although resolution of infection has been reported without removal of the suture,[56] some cases require removal of the prosthesis to resolve the luminal sinus and associated infection.

PROGNOSIS

The reported success of laryngoplasty varies widely because of the different criteria used to measure success and the intended use of the horse. Although reported success rates have ranged from 5% to 90%,[18,31,34,61,68-70] it is realistic to expect that between 50% and 70% of racehorses treated with a laryngoplasty will have improved racing performance after surgery.[22,34,63] The outcome will be more successful in horses that are not intended to race after surgery.[63] In a retrospective performance analysis after prosthetic laryngoplasty, the degree of arytenoid abduction achieved did not necessarily correlate to a successful surgical outcome.[63] An *in vitro* analysis has identified that an airway with an opening of 88% of the maximal rima glottidis cross section, allowed what was interpreted as adequate airflow for exercise.[57] Clinically, even in horses with grade 3 abduction following laryngoplasty, satisfactory performance is achievable.[70] Noise production should not be used as a measure of airway obstruction.[46] However, laryngoplasty should be viewed as a salvage procedure in racehorses, because even the horse with near maximal abduction of the arytenoid cartilage will have some flow limitations at racing speeds.[41]

Ventriculectomy (Sacculectomy)

Ventriculectomy (unilateral or bilateral) refers to the removal of the mucosal lining of the laryngeal ventricle located caudal to the vocal fold.[31] The surgery is usually performed to eliminate

noise and can have some beneficial effects on performance. Because ventriculectomy does not produce abduction of the arytenoid cartilage, it is not recommended as a sole procedure for racing horses affected with advanced RLN.[31] However soft tissue collapse during exercise is decreased, and the procedure can be successful when performed on hunters, show jumpers, and eventing-type horses. In draft-type horses, complication rates of laryngoplasty (e.g., failure, myopathy, neuropathy, anesthetic problems, coughing) can be as high as 25%; therefore, bilateral ventriculectomy, either by surgical (via laryngotomy) or laser excision, in the standing horse is an excellent alternative.[71,72] Surgical ventriculectomy is performed via a laryngotomy (see later) under general anesthesia, frequently at the conclusion of a laryngoplasty, but it can also be done as a standing procedure with the horse in stocks with the head elevated and sedated with loading doses of detomidine (4 mg IV) and butorphanol (10 mg IV). Following local anesthesia of the skin and subcutaneous tissues, a detomidine drip using 14 mg added to 250 mL of saline given to effect (approximately 2 drops per second for 15 minutes, then 1 drop per second for 15 minutes and then to effect) is used to maintain sedation during the procedure. For additional information, review Chapter 22.

If surgery is performed under inhalation general anesthesia, and after the laryngotomy has been performed, the endotracheal tube can be removed or left in place while the ventriculectomy is being performed. Use of a smaller endotracheal tube often negates the need for tube removal. A burr (e.g., Blatternburg burr) is introduced into the ventricle to its maximum depth and twisted to engage the mucosa in the projections on the burr (Figure 45-7, *A* and *B*). Occasionally, the ventricle is so large that the surgeon needs to press on the laminar portion of the arytenoid cartilage to enable the burr to engage the mucosa of these large saccules at their apex. The burr is subsequently withdrawn slowly from the ventricle, everting the attached saccule. Swallowing often occurs during this procedure in the standing horse and helps evert the saccule. A large forceps (Carmalt, Lahey Gall) is placed across the everted saccule between the head of the burr and the vocal fold (Figure 45-7, *C*). With traction on the clamp, a second forceps is placed behind it. By applying digital pressure on the opening of the ventricle, the entire saccule is everted and subsequently excised with Metzenbaum scissors (Figure 45-7, *D*). The same procedure is repeated on the opposite ventricle if bilateral ventriculectomy is indicated

POSTOPERATIVE MANAGEMENT

Topical administration of a pharyngeal medication with a mixture of nitrofurazone (Furacin) or pediatric trimethoprim sulfa (oral preparation), dimethyl sulfoxide, glycerin, and prednisolone can be beneficial. A No. 10 French catheter is advanced along the floor of the nasal passage into the nasal pharynx, and 10 to 15 mL of the solution is sprayed slowly through this catheter at 12-hour intervals for 7 days. Use of corticosteroids either in conjunction with phenylbutazone or alone are often advocated, especially with laser surgery of the upper respiratory tract. Regimens used include dexamethasone powder (0.022 mg/kg) given orally once daily in the morning feed for 3 consecutive days, day 4 is skipped, and the same dosage is then given on the fifth postoperative day. If a longer course of corticosteroid therapy is deemed necessary, 0.9 mg/kg of prednisone is given orally, starting the day after surgery, once daily in the morning feed for 7 days. The same dosage is then given every other day for three treatments. The dosage is subsequently reduced to 0.45 mg/kg, given every other day for three treatments. An individual horse's risk of cortisone-induced or -related laminitis should be given prior to administration. The horse is restricted to hand-walking exercise for the first week after surgery and then endoscopically assessed to determine if the horse can return to paddock exercise or if additional rest and anti-inflammatory medication are necessary. The horse should not be returned to training for 60 days.

Ventriculocordectomy

Ventriculocordectomy refers to the removal of the mucosal lining of the laryngeal ventricle as described earlier, as well as the removal of a crescent-shaped wedge of tissue from the leading edge of the vocal fold. Again, this technique does not result in abduction of the arytenoid cartilage, so its use as a sole procedure for most racing horses that have RLN and that run over long distances is not recommended. However, its use to reduce noise in sport and draught horses has been established.[43,71] There is also evidence that ventriculocordectomy can allow improved athletic performance in a subset of horses with RLN.[45,73] Suitable candidates for ventriculocordectomy include:

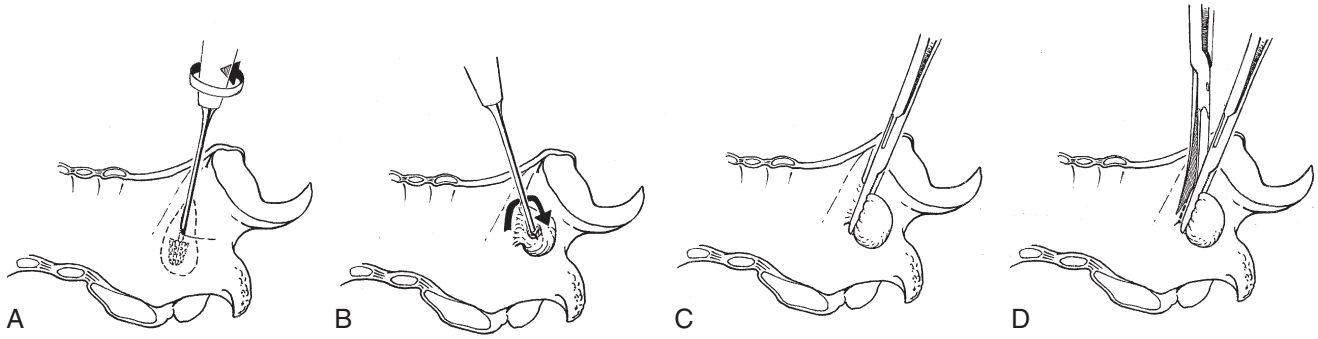

Figure 45-7. Schematic illustration of the ventriculectomy technique with the horse in dorsal recumbency. **A,** The "roaring" burr is placed into the laryngeal ventricle and rotated so that the head of the burr engages the mucosa of the laryngeal saccule; **B,** When the saccule is firmly engaged, it is everted into the lumen of the larynx by steadily pulling on the burr; **C,** A large hemostat is placed across the saccule immediately adjacent to the vocal fold, and the burr is removed; **D,** The saccule is completely excised using Metzenbaum scissors adjacent to the hemostat.

- Sport horses with grade 4 laryngeal movements where the primary complaint is respiratory noise, and exercise intolerance is not a feature (hunters, eventers, draught breeds, and other show horses)
- Race horses with grade 3 laryngeal movements that do not experience arytenoid collapse during high-speed exercise but do experience vocal fold collapse identified with exercising videoendoscopy.
- Race horses that have had a laryngoplasty and still experience vocal fold collapse during high-speed exercise. Caution must be used in performing a ventriculocordectomy in racehorses that have had a laryngoplasty where noise is a complaint because noise cannot be correlated with upper airway obstruction.[46] Again, the use of exercising videoendoscopy is recommended in such horses.

Surgical ventriculocordectomy is performed via laryngotomy (see later). Following the ventriculectomy as described earlier, a 2-cm long and 2- to 3-mm wide, crescent-shaped wedge of tissue is removed from the leading edge of the vocal fold. If the procedure is performed standing, the incisions are left to heal without suturing. If the horse is under general anesthesia, using a continuous suture pattern of 2-0 polydioxanone, the outside (abaxial edge of the vocal fold) and inside (axial) border of the ventricle are apposed. Suturing limits hemorrhage at the time of surgery while lessening cicatrix formation and redundant tissue folds during healing of the surgery site, leaving a smooth surface over the ventral half of the rima glottidis. The procedure is repeated on the other side.

Endoscopically guided laser-assisted ventriculocordectomy can be performed in the standing sedated horse.[72] Commonly a diode laser is used and surgery is performed via manipulation of the vocal fold by bronchoesophageal grasping forceps and a modified Blatternburg burr, which can be passed along the nasal passage.[73-75] Preoperative and postoperative care is the same as that given for ventriculectomy via laryngotomy except wound care is not required.

Laryngotomy

The ventral laryngeal region is clipped, aseptically prepared, and draped (if under general anesthesia) for surgery. The surgery can be performed under inhalation or intravenous anesthesia. A 10- to 15-cm (4- to 6-inch) incision is made along the ventral midline from just rostral to the palpable keel of the thyroid cartilage caudad to just beyond the cricoid cartilage. Careful dissection of subcutaneous tissues allows identification of the septum of the paired sternothyrohyoideus muscles, which are separated along the full length of the incision using Metzenbaum scissors. Blunt Weitlaner retractors are positioned between the paired muscle bellies to expose the ventral aspect of the larynx. Usually there is some loose adventitia overlying the larynx, and this is separated to expose the cricothyroid membrane. Careful attention to hemostasis at this stage of the surgery will maintain a blood-free approach. The cricothyroid membrane and underlying mucosa is incised along the midline with either a No. 10 or No. 11 scalpel blade. If an endotracheal tube is present, care should be taken to avoid penetrating tube or cuff. The membrane is incised from the cricoid to the anterior limit of the thyroid cartilage V. The previously placed Weitlaner retractors can be repositioned in the laryngotomy to maintain good access to the laryngeal lumen. For ventriculectomy and most laryngeal lumen procedures, incising the cricothyroid membrane will provide adequate exposure; however, in some cases (arytenoidectomy), transecting the cricoid cartilage and partially splitting the keel of the thyroid cartilage is acceptable to achieve better surgical exposure.

At the conclusion of the laryngotomy, the surgeon has two choices: to leave the entire incision open or to close the cricothyroid membrane with simple interupted absorbable sutures. Complete closure of the laryngotomy incision is not recommended because up to 52% of horses have been reported to have complications associated with the closure, including subcutaneous emphysema and incisional infection.[76] For horses under genreal anesthesia, a 15-cm (6 inch) sterile roll of gauze can be sutured over the laryngotomy site as a stent bandage for recovery. This helps prevent contamination of the surgical site if head collars are used during recovery and also prevents widespread disemination of blood and mucus throughout the recovery room, which is associated with forceful respiratory efforts that can occur during recovery. The stent is removed immediately when the horse is standing.

POSTOPERATIVE MANAGEMENT

Use of perioperative antibiotics for 48 to 72 hours is recommended any time the respiratory tract is invaded. Anti-inflammatory therapy using either phenylbutazone (4.4 mg/kg, IV) or flunixin meglumine (1.1 mg/kg, IV) should also be given immediately before surgery. Continued phenylbutazone therapy for 7 days postoperatively is recommended (2.2 mg/kg PO, twice a day for 7 days).

Management of the laryngotomy incision initially involves twice-daily cleansing of the skin around the wound and also circumfrentially inside the incision using moist gauze swabs to remove accumulated mucus and exudate. Petroleum jelly should be applied to the surrounding skin to prevent scalding from the exudate that often remains for up to 3 weeks. Under normal circumstances, laryngotomy incisions heal within 21 days and as time progresses, cleaning can be reduced to once daily. The horse is restricted to hand-walking exercise for the first week after surgery and then is endoscopically assessed to determine if the horse can return to paddock exercise or if additional rest and anti-inflammatory medication are necessary. The horse should not be returned to training for 60 days.

COMPLICATIONS

Complications following laryngotomy are rare. Excessive retraction during surgery can cause bruising and trauma to the sternothyrohyiodeus muscle. Necrosis and local infection can follow several days later, resulting in malodorous and excessive wound discharge. Resection of necrotic tissue results in a rapid resolution. Splitting the septum of the sternothyrohyoideus accurately and careful surgical technique will help avoid this complication. Clostridial infection at the laryngotomy site can occur within a 24-hour period after surgery, producing tremendous swelling of the head and neck and resulting in a massive tissue slough with potentially a fatal outcome. The use of perioperative penicillin may prevent such an infection, and if it does occur, early recognition and prompt treatment with intravenous penicillin is critical. Occasionally, excessive granulation tissue forms in the ventricles after sacculectomy but usually resolves with time and the application of anti-inflammatory sprays.[43,77]

Laryngeal Reinnervation

Although any horse with RLN is a candidate for laryngeal reinnervation, younger horses and those with grade 3 laryngeal movements are the ideal candidates for this surgical procedure.[78] The technique involves implanting a nerve–muscle pedicle (NMP) graft into the affected CAD muscle. The first cervical nerve and omohyoideus muscle are used for the NMP graft because the omohyoideus muscle is an accessory muscle of respiration (active on inspiration) and the first cervical nerve is in close proximity to the larynx.

Patient preparation and initial surgical approach is similar to laryngoplasty. Antimicrobial and anti-inflammatory medications are instituted as for other laryngeal surgeries. Surgical instruments should include very small atraumatic thumb forceps, a spay hook, and small blunt Weitlaner self-retaining retractors in addition to the instruments used for laryngeal surgery.

For left RLN, the horse is placed in right lateral recumbency under general anesthesia, and the head and neck are positioned for as for laryngoplasty. A 12-cm (5-inch) linear incision is made along the ventral border of the linguofacial vein, which is carefully separated from the omohyoideus muscle. The first cervical nerve usually lies under a branch of the linguofacial vein that is positioned midway between the rostral and caudal aspects of the incision. The ventral branch of the first cervical nerve emerges through the alar foramen of the atlas and descends over the cricopharyngeal muscle caudal to the larynx before dividing, usually, into a cranial, middle and caudal branch and entering the omohyoideus muscle (Figure 45-8, *A*). This nerve is commonly encountered during dissection for laryngoplasty and can be traced from the atlas to the omohyoideus muscle. The main body of the first cervical nerve is identified, and ventral retraction of the omohyoideus muscle is achieved with Allis tissue forceps. Insertions of the first cervical nerve can be found in the dorsal aspect of the muscle belly (see Figure 45-8, *B*). Meticulous dissection is necessary to expose the fine branches of the first cervical nerve as they enter the omohyoideus muscle. The middle branch of the first cervical nerve often divides into smaller branches and can be traced to a point of muscle entry, allowing creation of two or three nerve-muscle pedicles. The main branch of the first cervical nerve is gently elevated using a spay or nerve hook and is freed from its fascial attachments on the lateral aspect of the larynx. Before creating the muscle pedicles, mepivacaine hydrochloride is used to bathe the area to prevent excessive muscle contraction from occurring during harvesting of the pedicles. Nerve branches that do not penerate the omohyoideus muscle and continue to run over the muscle surface are transected to be used as nerve implants. The NMP grafts are created with fine tenotomy or iris scissors and are about 3 mm^3.

The larynx is subsequently rotated laterally by placing a spay hook through a window created by separating the aponeuroses of the cricopharyngeus and thyropharyngeus muscles and applying traction on the wing of the thyroid cartilage. Exposure of the CAD muscle can either be via the window created between the cricopharyngeus and thyropharyngeus muscles or by blunt dissection off the back edge of the cricopharyngeus muscle and under the vascular plexus overlying the CAD muscle. The window over the CAD muscle can be maintained using a Weitlaner retractor (Figure 45-8, *C*). Longitudinal separation of the CAD muscle fibers, using fine vascular forceps, allows pockets to be created for the pedicles to be placed. Each nerve-muscle

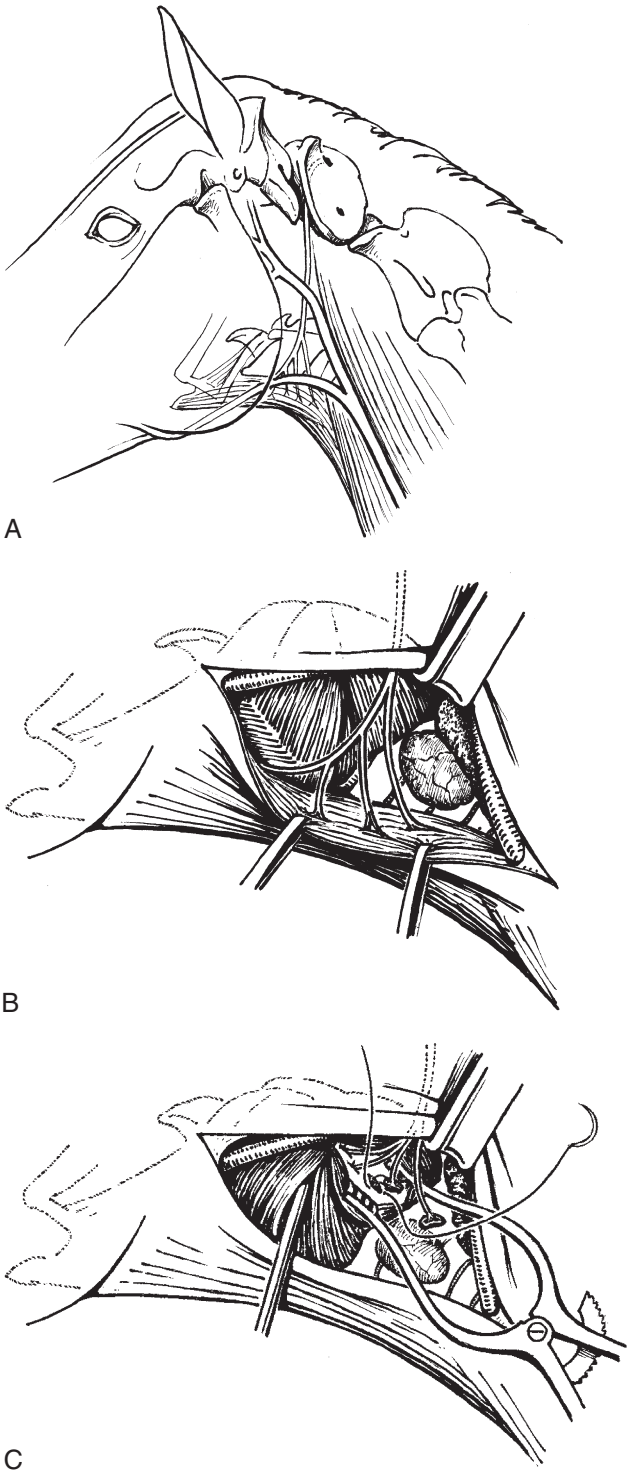

Figure 45-8. Schematic illustration of the neuromuscular pedicle graft technique. **A,** The origin and insertion of the left first cervical nerve into the omohyoideus muscle is shown. This nerve and muscle serve as the neuromuscular pedicle graft donors for treatment of recurrent laryngeal neuropathy. **B,** The first cervical nerve and future pedicle grafts of the omohyoideus muscle, which has been retracted with Allis tissue forceps. **C,** Weitlaner retractors positioned on the edge of the cricopharyngeus muscle and dorsal laryngeal adventitia to expose the atrophied cricoarytenoideus dorsalis (CAD) muscle and allow implantation of the neuromuscular pedicle grafts.

pedicle or nerve branch is sutured into a pocket using 4-0 polydioxanone (see Figure 45-8, *C*). With the mapping of the motor endplates in the CAD muscle, nerve muscle pedicles and nerve implants are now concentrated more along the junction of the dorsal and lateral bellies, concentrating in the caudal third of the muscle, rather than the more dorsal approach originally used.[79] Closure of the incision is routine; however, care should be taken to ensure leaking lymphatic vessels are ligated to help prevent seroma formation.

The horse is confined to a stall for 2 to 3 weeks after surgery until sutures are removed and inflammation has subsided. Perioperative antibiotic therapy is maintained for 3 days and anti-inflammatory medications for 7 days after surgery. After stall confinement, the horse receives paddock turnout for 14 weeks. At this stage (16 weeks after surgery), the horse is put into training. This time frame is based on information from studies on dogs, people, and horses, which indicate that the earliest time to see clinical evidence of reinnervation is around 12 weeks following surgery.[80-83] When the horse is returned to exercise, episodes of fast exercise should be introduced as early and as frequently as possible. Because the omohyoideus muscle is an accessory muscle of respiration, considerable respiratory effort must be undertaken to activate the first cervical nerve and therefore the CAD muscle. Swimming is also considered good exercise because of the head elevation and neck extension.

After 6 weeks of training the horse should have an endoscopic assessment of the larynx. At rest, the left arytenoid cartilage usually appears as it did before surgery. This is because the first cervical nerve is inactive at rest; thus, there is no depolarization of the nerve and no CAD muscle contraction. Two diagnostic reflexes have been developed to stimulate contraction of the omohyoideus muscle and the newly innervated CAD muscle.[78] The first involves stretching the horse's head and neck upward as high as possible while closely observing the larynx through the endoscope. If reinnervation has occurred, there is often a spontaneous flicker or single abduction of the left arytenoid cartilage. The second reflex involves pulling back rapidly with a finger or with the bit, resulting in sudden pressure on the commissure of the horse's lips. Again, a sudden abduction of the left arytenoid cartilage occurs if reinnervation has been successful. This reflex can be stimulated from the left or right side of the head.

Any abduction, no matter how small, of the left arytenoid cartilage indicates that there has been reinnervation of the CAD muscle. When this has been identified, the recommendation to the trainer is to continue training toward a return to racing. If there is no evidence of movement at the first revisit, the horse is turned out again for another 8 weeks, receives 6 weeks of training and is re-examined. Horses can take up to 12 months to show evidence of successful reinnervation.[81] Clinical experience suggests that if there is no arytenoid abduction as a result of reinnervation 9 months after surgery, there is only a small chance of improvement from that point. Reinnervation probably occurs in nearly all patients by 4 to 5 months.

The best evidence of successful reinnervation in an individual horse is derived from a treadmill endoscopic or upper airway flow mechanics study. In treadmill studies, we have found that horses with movement of the left arytenoid cartilage that is visible at rest after laryngeal reinnervation maintained arytenoid abduction during vigorous exercise, but often not maximal.[82] Inability to demonstrate effective arytenoid cartilage movement in the standing horse is an indication that the horse will most likely have dynamic collapse during exercise.

COMPLICATIONS

Complications associated with laryngeal reinnervation are few when compared with prosthetic laryngoplasty. The most frequent complication is seroma formation 3 to 5 days after surgery. The large potential dead space that exists after the nerve graft procedure lends itself to the formation of a seroma. In our opinion, many of the seromas that form are caused by leaking lymphatic vessels that are inadvertently cut during surgery. Large lymph vessels travel along the lateral border of the omohyoideus muscle and can be transected during the surgical approach. Many of these seromas resolve without intervention; however, some require open drainage and daily lavage. Horses have been placed on procaine penicillin therapy until the open tract discontinues draining. Some sinus tracts have become infected, and these have been treated with antibiotics selected from culture and sensitivity results. Because of the ventral position of the incision, the seroma drains easily after it is opened and requires minimal nursing care apart from daily lavage and attention to the skin around the incision. Horses that have suffered a postoperative incisional infection have gone on to have successful reinnervation; thus it would seem that this complication does not necessarily compromise success of the laryngeal reinnervation graft.[78]

PROGNOSIS

From experimental and clinical work, it is clear that reinnervation of the CAD muscle following an NMP graft can take between 6 and 12 months depending on the amount of CAD muscle atrophy.[82-84] Therefore, horses with grade 3 laryngeal movements will respond sooner (in 4 to 6 months) than those that have grade 4 movements (complete paralysis).[84] As a result of this long time period, horses best suited for the transplantation technique are those whose immediate return to performance is not necessary, such as yearling or early 2-year-old racehorses and pleasure horses. Horses that have had previous laryngoplasty for the treatment of RLN are not candidates for this surgery because of disruption of the first cervical nerve during that surgery or trauma and resultant fibrosis of the CAD muscle. To date, Ian C. Fulton has operated on 235 horses. A group of 165 racing Thoroughbreds have been followed to the end of their racing careers. This group of horses were classified at the time of surgery as raced (94) and unraced (71). Unraced horses had an average time of 13.5 months from surgery to race one with a range of 7 to 28 months. Fifty-one of the 71 horses started a race and 63% of these won at least one race. On average, these horses had 14.6 starts.[85] In the raced group of horses, the average time to race one was 8 months. Sixty percent of horses won at least one start and 52% of horses won more prize money in total after surgery. However only 39% earned more money per start after surgery and only 45% had an improved performance ranking.[83] Based on follow-up endoscopy of these horses, 80% were considered to have a successful reinnervation because of the presence of flickering abductory movements of the arytenoid cartilage observed at rest. The inability of the technique to provide a higher success at the track may relate to either insufficient muscle regeneration to withstand racing or, in the unraced group, a natural inability to perform. Laryngeal reinnervation has allowed horses to compete successfully, and improve laryngeal function with time. Current success rate is on

a parity to that of prosthetic laryngoplasty. For young horses that have never been raced and horses of high value because of their breeding potential, the NMP graft can be offered as a viable treatment for RLN. If the result of laryngeal reinervation is unsatisfactory, a laryngoplasty may still be performed.

LARYNGEAL DISORDERS OTHER THAN RECURRENT LARYNGEAL NEUROPATHY

A number of laryngeal conditions that can manifest with clincial symptoms similar to RLN but are separate entities from idiopathic left-sided RLN deserve discussion. They include axial deviation of the vocal fold (collapse into airway),[86] bilateral laryngeal hemiplegia, fourth branchial arch defects, right-sided RLN, collapse of the apex of the corniculate process of the arytenoid cartilage, and axial deviation of the aryepiglottic folds.

Vocal Fold Collapse

Vocal fold collapse can only be observed during high-speed exercise using videoendoscopy (Figure 45-9). Stabilization of the vocal cord occurs when the cricothyroid muscle, which is innervated by a branch of the cranial laygeal nerve, contracts.[86] Occasionally, axial deviation of the fold occurs in horses with grade 3 laryngeal movements (see Table 45-1). Rarely, it is observed in some horses after laryngoplasty when a concurrent ventriculectomy has not been performed. Clinical signs, especially noise production and history, are similar to those of RLN. Treatment for this condition is bilateral ventriculocordectomy (see earlier).

Bilateral Laryngeal Paralysis

Bilateral laryngeal paralysis has been associated with organophosphate toxicity; central nervous system diseases, such as equine protozoal myeloencephalitis (EPM)[7]; hepatic dysfunction; hepatic encephalopathy[87]; temporarily following general anesthesia[88]; associated with lead toxicity[89]; and has been observed in horses with Australian stringhalt (Ian Fulton's personal experience). Horses with bilateral arytenoid cartilage paralysis show severe exercise intolerance with only minimal exercise or stress. Those horses in severe distress make a loud inspiratory noise even at rest. Horses may die of asphyxiation if a tracheostomy is not performed as an emergency procedure. Although both arytenoid cartilages are affected, the degree of paresis may differ between sides. During the endoscopic examination both guttural pouches should be examined and if the horse shows signs of ataxia, a cerebrospinal fluid tap should be performed for EPM testing.

Horses with bilateral laryngeal paralysis that is associated with EPM can show improved laryngeal function after appropriate medical treatment for this condition. Horses that are in danger of asphyxiation require a temporary tracheostomy (Chapter 47). In nonresponsive cases, unilateral laryngoplasty can be performed on the more severely affected side to salvage the horse for nonperformance activities. However, airway contamination with feed, water, and saliva can be severe because adductor function on the contralateral side may be compromised. Therefore, some estimate of adductor function should be made before unilateral laryngoplasty is undertaken. Because bilateral laryngoplasty is not recommended, a permanent tracheostomy should be considered (Chapter 47).

Figure 45-9. Videoendoscopic image (freeze-frame) of the larynx of a horse during exercise, demonstrating left vocal fold collapse.

Fourth Branchial Arch Defects

In the horse, the lateral wings of the thyroid cartilage, cricoarytenoid articulation, and the cricothyroid, thyropharyngeus, and cricopharyngeus muscles are all derived from the embryological fourth branchial arch. Abnormal development of one or more of these structures, unilaterally or bilaterally, produces a syndrome defined as fourth branchial arch defects, commonly abbreviated as 4-BAD syndrome.[90] The term *cricopharyngeal-laryngeal dysplasia* has also been used to describe this syndrome.[91] Although this group of congenital laryngeal deformities has an incidence of 0.02%[92] and has been sparsely reported, [91,93-95] clinicians need to be aware of them to avoid incorrect diagnoses of laryngeal disorders. The diagnosis of 4-BAD syndrome has been made in ponies, Warmblood, draught, and Thoroughbred horses.

The most common presentation of 4-BAD syndrome is exercise-induced respiratory noise secondary to dynamic collapse of soft tissues or cartilaginous laryngeal tissues. Although the CAD muscle is normal in these horses, the abnormal cartilage skeleton renders CAD contraction ineffective. The right side of the larynx is most frequently involved, and bilateral involvement is more common than left-sided involvment. Horses with a severe deformity can show respiratory incompetence, dysphagia, and repeated colic because of a deformity and dysfunction of the cranial esophageal sphincter muscles (cricopharyngeus and thyropharyngeus).

Although endoscopy is the cornerstone of identifying the cause of abnormal respiratory noise, 4-BAD syndrome can be detected with laryngeal palpation. Most affected horses have an obvious palpable deficit of the thyroid wing on one or both sides, or they have an easily palapted gap between the cricoid and thyroid cartilages because of the absence or atrophy of the cricothyroid muscle. Ultrasound or, if available, magnetic resonance imaging of the laryngeal cartilages can provide accurate detail of cartilage anatomy and support palapation findings.[26,96] Endoscopic findings must be assessed carefully, because

unilateral 4-BAD can appear endoscopically like RLN, and bilateral 4-BAD can mimic bilateral laryngeal paralysis. The descriptive diagnosis *rostral displacment of the palatopharyngeal arch* is commonly used to report the abnormal endoscopic findings when the caudal margin of the ostium intrapharyngeum is displaced rostral to the dorsal tips of the corniculate processes of the arytenoid cartilages (Figure 45-10). If laryngeal endoscopy indicates right-sided RLN, 4-BAD should be on the top of the differential diagnosis until proved otherwise. Obvious rostral displacment of the palatopharyngeal arch is not present in all cases of 4-BAD, but it is exacerbated during intense exercise as observed during high-speed video endoscopy. Even though it is not considered mandatory, radiography of the larynx can support a diagnosis of 4-BAD because of air in the upper esophagus will be contiguous with air in the pharynx as a result of dysfunction of the esophageal sphincter. The palatopharyngeal arch may also be seen as a soft tissue mass rostral to the corniculate process.

Although some horses have been operated on following misdiagnosis RLN, and arytenoidectomy has been attempted, in general, there is currently no accepted surgical solution for horses with 4-BAD defects. Some horses can perform athletically, but usually not to their full potential. The tie-forward procedure has been suggested as a possible treatment when dynamic collapse of the palatopharyngeal arch is identified with high-speed videoendoscopy without significant collapse of the arytenoid cartilages.

Right-Sided Laryngeal Hemiplegia

Right-sided recurrent laryngeal neuropathy is rare in horses and an etiology should be sought because the idiopathic form of RLN does not usually affect the right CAD muscle to a level resulting in marked paresis or paralysis. If none of the previously mentioned causes can be detected, the surgeon should suspect 4-BAD in young horses,[25] and palpation of the muscular process of the right arytenoid cartilage and thyroid cartilage is indicated. Ultrasonography should also be employed to assess laryngeal cartilage and muscle anatomy. In a series of horses treated for right-sided laryngeal hemiplegia, 7 of 11 Thoroughbreds had congenital malformation of the laryngeal cartilages resulting in a high percentage of failure of a laryngoplasty in this group of horses. As a consequence of this, partial arytenoidectomy may be selected as a treatment, but as previously mentioned, high-speed videoendoscopy is recommended prior to advising surgery. Although spontaneous recovery from right-sided laryngeal hemiplegia has been reported, it would not be an expected outcome in a 1- to 2-year-old Thoroughbred. A poor prognosis for athletic function should be given to the owner.

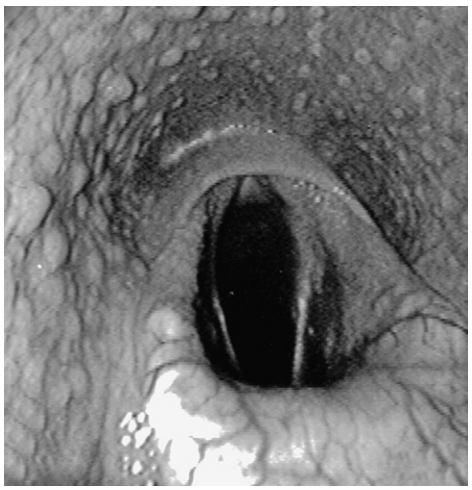

Figure 45-10. Videoendoscopic image of the larynx showing rostral displacement of the palatopharyngeal arch in a case of fourth branchial arch defect. The palatopharyngeal tissue is covering the apical portions of the corniculate processes, and both arytenoid cartilages show very limited abduction.

Collapse of the Apex of the Corniculate Process

Collapse of the apex of the corniculate process of the arytenoid cartilage under the contralateral corniculate process has been reported as a finding on high-speed treadmill videoendoscopy[97,98] and during resting endoscopy after swallowing or nasal occlusion.[98] Initially a high prevalance of the left corniculate process being involved led to the suggestion that muscle atrophy or dysfunction of the transverse arytenoideus muscle, as a component of RLN, could be the cause of this condition. However postmortem studies have not found any pathology in these muscles but rather a significant widening of the transverse arytenoid ligament that normally keeps the tips of the corniculate cartilages in close apposition. Currently, no reported treatment is available for this condition, and further postmortem studies will be necessary to elucidate the anatomic pathology involved.

AXIAL DEVIATION OF THE ARYEPIGLOTTIC FOLDS

Diagnosis

Axial deviation of the aryepiglottic folds occurs during maximal exertion and causes dynamic partial upper respiratory tract obstruction. A diagnosis cannot be made during resting endoscopic evaluation but requires videoendoscopic examination during high-speed exercise (Figure 45-11, *A*). In a study of 15 affected horses, 80% were racing Thoroughbreds, 13% were racing Standardbreds, and 7% were racing Arabians. Abnormal respiratory tract noise and exercise intolerance were the most common clinical manifestations.[99] The condition is almost always bilateral, but unilateral involvement, if present, has been reported to be right-sided.[100]

Treatment

Transendoscopic laser surgery using an Nd:YAG or a diode laser with a 600-µm sculpted tip fiber in contact fashion can be performed on the conscious, standing horse or with the horse anesthetized. The tissue that is collapsing into the airway during exercise is grasped and placed under tension with 600-mm bronchoesophagoscopic grasping forceps, and an approximately 2 cm-wide triangle is excised transendoscopically.[99,101] Alternatively, this surgery can be performed through a laryngotomy in the anesthetized horse. Allis tissue forceps can be used to grasp the tissue, and Metzenbaum scissors are used to trim the redundant tissue (see Figure 45-11, *B*). No suturing is necessary.

ARYTENOID CHONDROPATHY

Definition and Etiopathogenesis

Disease of one or both arytenoid cartilages resulting in abnormal enlargement is referred to as *arytenoid chondropathy.* Pathologic changes identified in affected cartilages include chondritis, chondrosis, chondroma formation, dysplasia, necrosis, perichondritis, granulating laryngitis, and abscessation.[102] The precise etiopathogenesis has not been determined, but it has been proposed that mucosal injury is followed by ascending infection and subsequent inflammation of the underlying cartilage[103-109] This can result in superficial chondritis with formation of granulation tissue and a fistulous tract, or if deeper infection occurs, the development of an abscess. Arytenoid cartilage mucosal injury could have multiple and coexisting causes. Respiratory tract infection is likely very significant and can cause mucositis and mucosal injury. Similarly, trauma-induced mucosal injury from endoscopic examination, from previous laryngeal surgery, concussion from the opposing cartilage, or from inhaled or swallowed foreign objects can occur. Inadvertent trauma of the arytenoid cartilages by nasogastric intubation can result in arytenoid inflammation, but it is unlikely to cause mucosal ulceration leading to chondropathy.[105] A hereditary component has also been suggested in Thoroughbreds.[109] The inflammatory processes involve not only the laryngeal mucosal surface and the arytenoid cartilage(s) but also periarytenoid tissues and dorsal muscular structures[102,110,111] The end result is usually fibrous tissue lamination, necrosis, deposition of poor-quality cartilage matrix, and mineralization of the laminar portion of primarily the body of the arytenoid cartilage.[102,112] Frequently, the affected cartilage has reduced mobility. Partial or complete failure of abduction is caused by the laterally positioned thyroid cartilage physically restricting movement, and/or impaired function of the cricoartyenoid joint because of extension of the inflammatory process to affect the joint or the dorsal cricoarytenoid muscle. The net outcome is a reduced rima glottidis aperture and airflow compromise.[103]

History and Clinical Signs

Arytenoid chondropathy can be acute, but it is more commonly chronic and affects all breeds and ages of horses, causing respiratory obstruction and exercise intolerance. Because of the different respiratory demands required by working and nonworking horses, the clinical presentations are different for each.

In working horses, typically young racing horses, signs are not detected at rest but occur during strenuous exercise, where even small changes in the cross-sectional area of the rima glottidis caused by the chondropathy manifest as respiratory stridor and exercise intolerance.[110,113] The disease can be asymptomatic, but generally there is a slow progression of clinical signs. It is important to note that the history for racehorses with the disease, particularly where cartilage enlargment is not severe, is very similar to that of RLN. Therefore, a careful clinical and endoscopic evaluation is required to differentiate the two conditions.[102,114] In contrast, because of the reduced respiratory demand in nonworking horses, the effects of arytenoid chondropathy are not recognized until there is marked airway narrowing and chronic disease is present. Therefore, these horses commonly present with obvious respiratory noise or dyspnea during mild exercise or at rest.[110] Typically, affected horses are older and have an insidious onset of clinical signs with gradual worsening over months to years. However, in some horses with advanced unilateral or bilateral chronic chondropathy, life-threatening respiratory obstruction occurs, necessitating emergency tracheotomy. Acute inflammatory chondropathy results from generalized laryngitis (perichondral submucosal edema), causing a markedly reduced diameter of the rima glottidis and therefore stridor or dyspnea at rest. Acute chondropathy is more common in older nonworking horses, where clinical signs can be rapid in onset and progress quickly, and depression, fever, and leuckocytosis may be present.[110] In these horses, this acute form of the disease may be an intermittent or severe manifestation of chronic inflammatory chondropathy. Acute disease has also been observed in yearling Thoroughbreds, associated with severe upper respiratory tract infections, including strangles, but respiratory noise at rest is uncommon in our experience.

Diagnosis

A diagnosis of arytenoid chondropathy can usually be made during endoscopic examination of the larynx. On initial observation, RLN might be suspected because the arytenoid cartilage is in an adducted position and shows little movement. However, the affected cartilage is usually mishapen or distorted (Figure

Figure 45-12. Videoendoscopic appearance of the rima glottis of a horse with arytenoid chondritis, showing distortion of the left arytenoid cartilage. The corniculate cartilage is in an abnormally adducted position, often making this condition look like recurrent laryngeal neuropathy or hemiparesis early in the disease process.

Figure 45-13. Endoscopic appearance of arytenoid chondropathy, showing incomplete abduction of the left arytenoid cartilage and granulation tissue on the medial surface of the body of the arytenoid at the entrance to a fistula.

45-12). One of the endoscopic hallmarks of arytenoid chondritis is the presence of intraluminal projections of granulation tissue (Figure 45-13). A fistula or sinus tract in the center of the granulation tissue communicating with the body of the arytenoid cartilage is frequently present. A contact ulcer or projection of granulation tissue is often present on the opposing cartilage ("kissing lesion"). The palatopharyngeal arch on the affected side is often more prominent (see Figure 45-12). Because significant RLN of the right side of the larynx is rare, arytenoid chondropathy should always be a primary consideration in the differential when impaired abductor function of the right arytenoid cartilage is noted endoscopically. In acute chondropathy, the predominant endoscopic feature is mucosal and submucosal perichondrial edema and perilaryngeal swelling with intense hyperemia. The rima glottidis diameter can be markedly reduced, often to a slit-like opening. The degree of underlying cartilage pathology may be highly variable and difficult to determine until medical therapy resolves the edema.[110]

Careful palpation of the larynx with attention to comparison of the percutaneous prominence of the muscular processes on either side of the larynx is important. In cases of significant RLN, the left muscular process is more obvious. In contrast, thickening around the muscular process can be palpated in cases of arytenoid chondropathy and might be the only diagnostic finding. In general, the larynx may feel less resiliant to digital palpation, and firm manual pressure may cause stidor or dsypnea.[110,115] Ultrasonography may be useful in further defining the disease. It can help in detecting abaxial arytenoid cartilage lesions (including abscessation) and in determining if the disease is confined to the arytenoid cartilages or extends into the periarytenoid tissues.[26] Radiographic features of arytenoid chondropathy include abnormal patterns of cartilage mineralization, increased density of the arytenoid cartilages, abnormal contour or size of the corniculate process, obliteration of the laryngeal ventricle, and laryngeal masses.[110] Some mineralization in the larynx occurs with aging in horses, particularly of the thyroid and subsequently the dorsal arch of the cricoid cartilage. Extensive mineralization of the larynx is a poor prognostic sign for successful surgical treatment.[102,110]

Treatment

Management of arytenoid chondropathy depends on the stage of the disease (acute or chronic), the degree of airway dysfunction, and whether athletic activity is required. In the acute form, horses may be presented in respiratory distress (stertor) with laryngeal edema. Medical therapy with broad-spectrum antibiotics, NSAIDs, and/or steroids and pharyngeal throat sprays often resolves the condition, but occasionally an emergency tracheotomy is required. A 7- to 10-day course of treatment is prescribed with endoscopic review. In some animals, the chondropathy regresses and arytenoid cartilage function returns to normal or near normal. In other animals, chronic chondropathy ensues, but if airway obstruction is not severe, it is possible for some athletic animals to continue to compete. Because arytenoid chondropathy is frequently progressive, repeated endoscopic monitoring is recommended, especially if respiratory noise increases.

In cases where rima glottidis size is reduced because of granulation tissue or cartilage abscessation but arytenoid function is acceptable, local excision and drainage using laser therapy or local curretage either in the standing horse or under general anesthesia via larygotomy can be attempted (see later). However, if cartilage function is significantly imparied and/or the laminar portion of the arytenoid cartilage is thickened sufficiently (chronic form), surgical removal of the affected arytenoid cartilage is usually necessary. This condition is most often unilateral and therefore treated with unilateral arytenoidectomy. If the condition is bilateral, unilateral arytenoidectomy of the most affected cartilage may be sufficient. Other surgeons believe bilateral arytenoidectomy is inevitable and prefer a single-stage procedure.[110] Bilateral arytenoidectomy is considered a salvage procedure. Permanent tracheostomy is a valid procedure for bilateral disease in nonathletic animals and has been used with good results in Thoroughbred broodmares with the disease (see Chapter 47).[110]

Arytenoidectomy

Prior to surgery, preparation of the patient should include perioperative broad-spectrum antimicrobial therapy as well as anti-inflammatory medication. The skin should be clipped and prepared for a laryngotomy approach (see earlier), as should the mid-neck region in preparation for placement of an endotracheal tube. If the horse is dyspneic or has such severe disease that tracheal intubation would be difficult or impossible, the tube can be placed before induction of general anesthesia using local anesthetic under sedation. Otherwise a mid-cervcial tracheotomy (see Chapter 47) is performed with the horse positioned in dorsal recumbency. It is important that the tracheotomy be made sufficiently distal so that during recovery the tracheotomy site does not become obstructed. It is helpful to flex the poll toward the chest during this procedure so that the skin and soft tissues of the ventral neck are in a similar position and tension to those in the standing horse.

Two methods of arytenoidectomy have been described: subtotal, in which the muscular process and rim of the corniculate process are left intact; and partial, in which only the muscular process is left intact (Figure 45-14).[116,117] The merits of subtotal and partial arytenoidectomy have been evaluated subjectively on the basis of the assessment of performance and postoperative complications in a series of retrospective studies.[102,116,118] However, in a quantitative evaluation in 1990, it was demonstrated that subtotal arytenoidectomy failed to improve upper airway function in horses exercising on a high-speed treadmill with surgically induced left laryngeal hemiplegia.[119] The effect of partial arytenoidectomy on upper airway function was evaluated by tidal breathing flow-volume analysis, measurement of upper airway impedance, and videoendoscopic examination of the larynx in strenuously exercising horses with surgically induced left laryngeal hemiplegia in 1994.[120] This study showed that partial arytenoidectomy improved upper airway function in exercising horses with surgically induced left laryngeal hemiplegia and was superior to subtotal arytenoidectomy as a treatment for both failed laryngoplasty and arytenoid chondropathy.

A number of methods and modifications for performing partial arytenoidectomy have been reported.[47,117,118,120-123] Controversy exists over whether the mucosa on the axial surface of the arytenoid cartilage should be retained and sutured closed for primary wound healing or whether complete resection of the cartilage with attached mucosa gives the best results.[48,123] We recommend combining a partial arytenoidectomy with a ventriculocordectomy, removing all devitalized and redundant mucosa and suturing the incision so that all excised mucosal edges are apposed and the luminal surface is as smooth as possible. Any redundant tissue left in the airway creates turbulence and noise and may interfere with airway function. This tissue should be removed at 30 days after surgery via laser ablation before cicatrix formation and mineralization make it impossible. Ventral drainage is achieved by leaving the ventriculocordectomy site open, and the most rostral and abaxial mucosa covering the corniculate cartilage should be retained and not sutured under excessive caudal tension because obliteration of the pyriform recess is likely to result in problems with tracheal aspiration and coughing postoperatively.[118,121,122] This is supported by the observation that injection of the rostral mucosa of the repair (with Teflon) in cases of chronic aspiration and coughing has temporarily resolved the problem.[124] Tidal breathing flow-volume loop, respiratory mechanics, and blood gas analysis show that partial arytenoidectomy does not completely restore the upper airway to normal but that the procedure is a viable treatment option for arytenoid cartilage malfunction in the horse.[47,120]

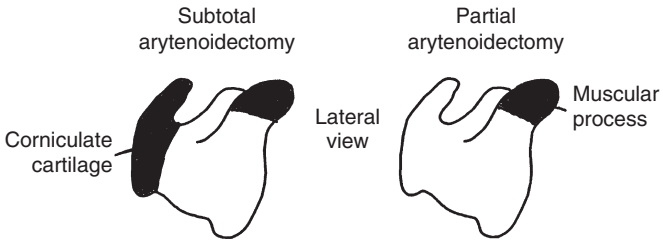

Figure 45-14. Schematic representation of a lateral view of the arytenoid cartilage, demonstrating the portions of the cartilage that are removed *(unshaded)* during subtotal and partial arytenoidectomy.

PARTIAL ARYTENOIDECTOMY

Horses are placed in dorsal recumbency under general anesthesia with an endotracheal tube placed through a tracheotomy incision (Figure 45-15). An endoscope placed via the nostril with the tip positioned in the dorsal pharynx is useful for illumination of the surgical site, as is a headlamp. Suction is critical for removing blood in the surgical field, and gauze soaked in epinephrine solution (1 : 10 000) is helpful to reduce hemorrhage. A ventral laryngotomy is performed (see earlier) and self-retaining retractors are used to allow access to the lumen of the larynx. For increased exposure, the cricoid cartilage can be split longitudinally, as can the body of the thyroid, if needed. On entry to the larynx, granulomatous masses are often observed on the affected arytenoid cartilage (Figure 45-16). A submucosal injection of epinephrine helps to elevate the mucosal membrane and to control bleeding. Using a No. 15 Bard Parker scalpel, a dorsally based U-shaped mucosal flap is made overlying the arytenoid cartilage (Figure 45-17). The mucosal incision starts at the apex of the corniculate cartilage 2 mm caudal to the rostral surface and extends ventrad then caudad and finally dorsad around the outline of the arytenoid cartilage. This forms

Figure 45-15. Preparation of a foal for arytenoidectomy shows an endotracheal tube placed through a tracheotomy incision located distal to the larynx. The tube can be placed in the standing patient just prior to general anestheia if required.

Figure 45-16. A laryngotomy allows full vision of the granulomatous masses observed endoscopically on the arytenoid cartilage with chondropathy. Self-retaining retractors provide good access for arytenoidectomy.

a three-sided U-shaped incision. The mucosa on the luminal side of the arytenoid cartilage is then elevated starting caudad and working rostrad over the corniculate portion. A scalpel is used to sharply undermine the mucosal tissue initially, and then the dissection is completed with a periosteal elevator, leaving the dorsal mucosa attached. Next, the lateral surface of the arytenoid carilage is freed from its soft tissue attachments using blunt dissection, staying close to the cartilage, and the remaining mucosa over the rostral and lateral aspect of the corniculate cartilage is separated using sharp and blunt disection. The arytenoid cartilage is elevated rostrally using Allis tissue forceps or a towel clamp, and the muscular process is transected using heavy Mayo scissors or a scalpel. Any diseased or irregular cartilage attached to the muscular process dorsally is removed with rongeurs. A ventriculocordectomy is subsequently performed by incising the mucosa around the oriface of the ventricle and removing the entire saccule followed by resection of the cord. During closure, the surgeon should take care to smooth the airway as much as possible by removing all redundant tissue. The rostral and lateral corniculate mucosa is retracted slightly caudad and sutured with minimal tension to the leading rostral edge of the mucosal flap using interupted or continuous No. 2-0 absorbable suture. Obliteration of the pyriform recess should be avoided by not pulling the leading edge of this tissue caudal to the palatopharyngeal arch. This can be confirmed by an assistant examining the rima glottidis via videoenoscopy intraoperatively. The remainder of the mucosal flap is sutured to the adjacent larygeal mucosa similarly but leaving the ventral part of the incision open for drainage. The ventriculocordectomy incisions are also not sutured. Large mucosal defects are left unsutured to heal by second intention, and the corniculate mucosa is sutured laterally to the remaining soft tissues. If the cricoid cartilage was divided, the two sides are brought into close apposition by suturing the soft tissues immediately ventral to the cartilage ends using No. 0 absorbable suture in an interupted or cruciate pattern. The sutures should not be placed through the cartilage to prevent chondroma formation. The laryngotomy is left unsutured because of the possibility of laryngeal edema and subsequent airway obstruction. A tracheostomy tube is secured in place to ensure a patent airway during recovery.

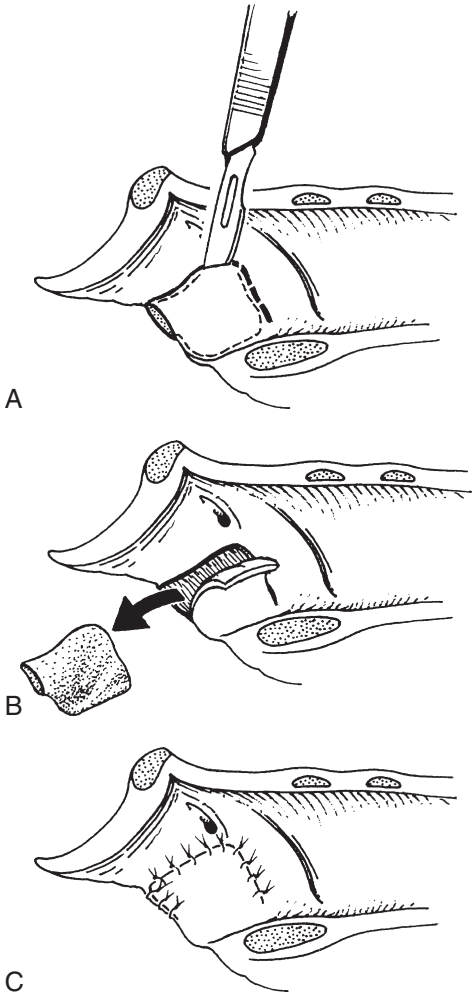

Figure 45-17. Schematic illustration of partial arytenoidectomy technique. **A,** Beginning at the apex of the corniculate cartilage and 2 mm caudal to the rostral surface, a mucosal incision is made that extends ventrad then caudad and finally dorsad around the outline of the arytenoid cartilage *(dotted line)*. **B,** The mucosa is firstly elevated from the arytenoid cartilage using a scalpel then a periosteal elevator, which exposes the laminar portion of this cartilage. The cartilage is then freed from its deep attachments using blunt disecction, staying close to the cartilage. The muscular process is transected with heavy scissors or a scalpel and the dissected cartilage is removed. Then the ventricle and vocal fold are removed. **C,** All remaining mucosal incisions are apposed with simple continuous or interrupted sutures of 2-0 polydioxanone, taking care to remove any redundant tissue during closure. The ventral part of the incision is not sutured to allow postoperative drainage.

Antimicrobial agents, such as penicillin and gentamicin, as well as anti-inflammatory drugs, such as phenylbutazone, are administered before surgery and continued for at least 3 days after surgery. Food is withheld for 24 hours, at which time the larynx is examined endoscopically and airway patency is assessed by plugging the tracheostomy tube together with the laryngotomy wound and listening for respiratory stridor. If there is little postoperative edema or swelling and the airway is patent, the tracheostomy tube is removed; otherwise the tube is removed and cleaned twice daily before eventual removal. The horse is reintroduced to food 24 hours after surgery. At that time, wet hay only should be fed until the horse is able to swallow without coughing, followed by the reintroduction of

Figure 45-18. Endoscopic view of the rima glottidis of a horse 4 weeks after left partial arytenoidectomy and ventriculocordectomy. Note that all redundant tissue has been removed from this airway.

dry feedstuffs. The horse is stall-rested for 4 to 6 weeks prior to complete healing, which usually occurs within 8 to 10 weeks. Postoperative endoscopic evaluations should reveal a hemilarynx devoid of vocal folds, ventricle, and corniculate cartilage (Figure 45-18).

A modification of the earlier technique has been described experimentally and has been used clinically.[47] A flap of mucosa on the luminal or medial side of the arytenoid cartilage is not elevated and retained for suturing; instead, the arytenoid cartilage is removed in two pieces with accompanying mucosa attached, one with the body of the arytenoid and the other with the corniculate process. The rostral and lateral mucosa overlying the corniculate process is retained and together with the contiguous aryepiglottic fold is drawn caudad over the defect left by artenoid cartilage removal and sutured with 3-0 absorbable suture material in a continuous pattern, leaving only the ventral 5 mm of the repair open to drain at the site of the ventriculocordectomy. The proposed benefits of this modification include an easier dissecction, shorter surgery time, and a reduction in the amount of soft tissue lining the airway, which could be subjected to dynamic collapse during fast exercise.[125] Experimental and clinical studies did not show an increased incidence of postoperative dysphagia or coughing using this modification. Improvements in airway mechanics similar to prosthetic laryngoplasty are achieved, and in clinical cases 62% of Thoroughbred horses raced successfully after the treatment of unilateral arytenoid chondropathy.[126]

Complications

Dyspnea and dysphagia are the most important complications. Dyspnea occurs as a result of edema or hemorrhage trapped under the sutured mucosal flap. Therefore, the tracheostomy tube should be left in place until airway patency is confirmed. Antimicrobial and anti-inflammatory medications are continued until laryngeal swelling and associated dyspnea are resolved, and then the tracheostomy tube is removed. Dysphagia with regurgitation of food and water through the nares has been reported in up to 36% of horses after arytenoidectomy.[118] However, significant dysphagia was not encountered in more recent reports.[47,48,120,123,126] It has been proposed that atraumatic transection of the body of the arytenoid from the muscular process and of the soft tissue attachments on the lateral surface of the arytenoid cartilage may reduce problems with deglutition after surgery.[48] Maintaining sufficient rostral mucosa especially of the ventral part of the repair is also suggested to reduce aspiration.[127] Coughing during eating is not uncommon and may continue for some months. Transection of the interarytenoid ligament in the dorsal part of the larynx is to be avoided as this has been associated with significant coughing.[118] Owners are encouraged to feed the animal on the ground, and pasture feeding may be beneficial. Although current techniques have significantly reduced morbidity associated with dysphagia and coughing, it is likely that many horses aspirate feed material and respiratory secretions into the distal part of the respiratory tract to some degree. One study showed horses with induced RLN subjected to a partial arytenoidectomy had significant increases in neutrophils and macrophages containing intracellular bacteria as well as an increase in the number of lymphocytes in transbronchial fluid aspirates taken 30 minutes after strenuous exercise.[47]

The formation of intralaryngeal granulation tissue was identified 1 month after surgery in 17% of horses treated with partial arytenoidecotomy,[48] presumably because of wound dehiscence (typically at the dorsal aspect of the rostral part of the incision). The granulation tissue and any excess mucosa should be excised using a transendoscopic laser at this time. Advanced larygeal cartilage mineralization rendering horses useless for work was reported in 5% of horses treated with a partial arytenoidectomy.[102]

Mucosal Disease and Granulomas of the Arytenoid Cartilages

Mucosal disease of the arytenoid cartilages in young Thoroughbred horses in Australia and New Zealand has been described.[105,108] Bilateral kissing lesions are found on or near the vocal processes just proximal to the attachment of the vocal cords (Figure 45-19). The etiology is uncertain; therefore, the condition has been termed *idiopathic mucosal lesions.*[105] These lesions manifest as small erosions or ulcers or, alternatively, raised areas of epithelial injury. They are often hyperemic and can have small, slightly purulent centers. The incidence of mucosal lesions in two surveys of Thoroughbred yearlings presented to public auction sales (5629 horses) was 0.6% and the incidence of arytenoid chondritis was 0.21%.[105,108] In a population of 774 racing Thoroughbreds, 2.4% had mucosal lesions.[128] These lesions do not affect subsequent racing performance, and many heal uneventfully with or without medical therapy.[105,128] However, treatment is recommended, because in one report in 10% of affected horses lesions progressed to become granulomas and 5% to arytenoid chondritis.[108] Broad-spectrum antibiotics, NSAIDs, and pharyngeal throat washes are recommended for 10 to 14 days.

Occasionally, particularly in Thoroughbred and Standardbred racehorses, a mass projecting from the medial surface of the arytenoid cartilage at its junction with the corniculate cartilage just dorsal to the insertion of the vocal cord is seen on endoscopic examination (see Figure 45-13). These lesions are commonly referred to as "chondromas"; however, histologic

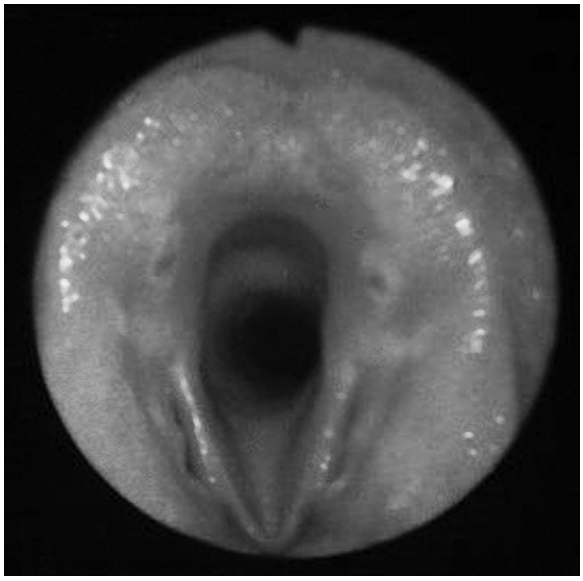

Figure 45-19. Endoscopic appearance of bilateral mucosal ulcerations on the axial surface of the arytenoid cartilages.

examination of the excised tissue invariably reveals granulation tissue.[129] An ulcerated mucosal defect is often seen on the medial surface of the opposing arytenoid where the granulation tissue rubs during laryngeal adduction. In addition, abscessation of some affected cartilages may be present. If abductor function of the affected cartilage is normal or only slightly reduced, the mass should be removed to improve airflow, prevent advancement of chondropathy, and protect the opposite cartilage from contact injury. Excision of the granulation tissue does not alter any preexisting underlying cartilage abnormalities, but it is carried out in an attempt to allow the mucosal defect to epithelialize and to prevent contact injury to the opposing arytenoid. This technique may be temporarily successful when combined with antibiotic and anti-inflammatory therapy in some performance horses and many sedentary patients. However, when dealing with an equine athlete, arytenoidectomy is usually required eventually. Options for treatment include laryngotomy followed by scalpel or laser excision and focal curretage under general anesthesia or transendoscopic laser excision in the standing sedated patient. Drainage of purulent exudate can be achieved at the same time.[130]

Treatment

The horse is sedated and the lesion and surrounding tissue are transendoscopically topically anesthetized. Using an Nd:YAG laser, a 2.2 mm-outer-diameter laser fiber with a chisel probe attached or an 800 µm sculpted fiber is introduced through the endoscope biopsy channel. A diode laser with a sculpted fiber can also be used. When using the chisel probe, the bevelled surface is oriented parallel to the medial mucosal surface of the arytenoid. Beginning at the perimeter of the mass, a dissection plane is established between the granulation tissue and the underlying cartilage. The mass is completely freed up except for small remaining tags of attachment, and it is retrieved with 600-mm–long bronchoesophagoscopic grasping forceps. Any remaining small tags of loose tissue are subsequently débrided with the laser and removed with the forceps. Usually, a crater defect has been created with smooth mucosal margins that are firmly attached to underlying cartilage.

Gaining access to the axial part of the cartilage to completely débride the lesion can be difficult. Placing the endoscope up the nostril opposite the affected cartilage can help. A more direct approach can be made by introducing a laser fiber through a 5 mm × 6.5 mm trocar inserted through a stab incision through the cricothyroid membrane.[130] The lesion can also be explored by passing a 2-mm flexible stainless steel probe through the trocar. A small curette passed through the trocar can also be used to manually débride deeper parts of the tract. In some horses with abscessation of the underlying cartilage, drainage may be achieved with this method.

Exercise is restricted until the defect heals. Systemic NSAIDs and a pharyngeal spray containing anti-inflammatory and antimicrobial medications may be useful in reducing inflammation. Regrowth of the granulation tissue can occur in 16% of horses requiring a second procedure,[129] but in some cases the regrowth regresses with medical therapy and time.

Prognosis

The prognosis following treatment for arytenoid chondropathy depends on the nature and extent of the disease and the respiratory demands placed on the patient.[48,102,110,123,126] If treatment is instituted early, the condition is unilateral, and arytenoid function is minimally affected, medical management can halt progression, and in one study palliative treatment allowed some horses to race for 1 to 2 years.[102] The likelihood of Thoroughbred horses with idiopathic arytenoid mucosal lesions racing more than three times is not different from unaffected control animals.[105] Excision of intralaryngeal granulation tissue in nonracehorses has an excellent prognosis. A group of five racehorses with only slight cartilage thickening and no other larygneal pathology, all returned to racing three or more times with only one having reduced performance after treatment. However, if moderate cartilage thickening is present or concurrent laryngeal pathology exists, only 50% of treated horses returned to racing and usually at a lower level of performance.[129]

Partial arytenoidectomy is very effective in restoring rima glottidis diameter, but prognosis depends on the respiratory demands for exercise. Six of eight horses (75%) with occupations other than racing were useful after partial arytenoidectomy was performed for unilateral chondropathy (5), bilateral chondropathy (1), or failed laryngoplasty (2).[102] In general, the prognosis in nonworking horses treated with partial arytenoidectomy is favorable but is reduced in cases of advanced unilateral chondropathy accompanied by complicating lesions, such as contralateral laryngeal paralysis, periarytenoid inflammation, and pharyngeal cicatrices. Even horses suffering from bilateral arytenoidectomy may have a better prognosis for survival compared to those with advanced unilateral chondropathy and accompanying lesions. In these horses, a permanent tracheotomy might be a better treatment option.[110]

The prognosis for athletic activity after partial arytenoidectomy in working horses, primarily racing Thoroughbreds, has been reported to be between 45% and 80%.[48,102,123,126] Comparison between studies is difficult because of differences in sample size, inclusion criteria, surgical technique, and measures of success.

However, in racing Thoroughbreds it is likely that partial arytenoidectomy for the treatment of arytenoid chondropathy will allow two thirds or more of treated horses to train, race, and earn money. A shortened athletic career is likely, and although there is some evidence that shows a reduced performance after surgery, other studies show similar postoperative earnings per start and similar earnings compared to age- and sex-matched controls. Bilateral partial arytenoidectomy for bilateral arytenoid chondropathy is a salvage procedure and carries a poor prognosis for continued racing (22%).[102] In addition, it is clear that horses treated with partial arytenoidectomy for arytenoid chondropathy still have some limitation to airflow when exercising at racing speed.[47,120] Dynamic collapse of unsupported soft tissue on the left side of the larynx following partial arytenoidecotomy is the likely cause.

Finally, different techniques or modifications for partial arytenoidectomy have been described but not critically compared. Partial arytenoidectomy with or without primary mucosal closure can be performed. Proposed benefits of primary mucosal closure include a faster healing time, reduction in postoperative excessive granulation tissue production, and an ability to streamline or smooth the luminal surface of the wound.[47,48,102,120-122] However, in advanced or extensive chondropathy cases only partial mucosal closure may be possible, and suturing diseased mucosa under tension is not advised. Some surgeons elect to perform all partial arytenoidectomies without mucosal closure citing quicker surgery time, prevention of hematoma formation and no suture dehiscence problems.[123] Healing time in one study of unsutured partial arytenoidectomies was only 8 weeks,[123] similar to that reported for partial arytenoidecotomy using primary mucosal closure. However, the number of horses racing three or more times after surgery was only 55% compared to 63% of horses treated with primary mucosal closure in another report.[48]

EPIGLOTTIS

The epiglottis is an isosceles triangle–shaped structure with the tip projecting rostrad from the base of the larynx. During normal breathing, the epiglottis is positioned above the soft palate with the caudal free margin of the palate interfacing with the epiglottic base. The epiglottis is covered on its dorsal surface by a tightly adherent mucous membrane, whereas the ventral surface has a loosely attached, somewhat elastic mucosa. This loosely folded subepiglottic mucosa allows unrestricted dorsal and caudal movement of the epiglottis during swallowing. The normal epiglottis has a broad base and is narrow at the tip with a convex dorsal surface projecting slightly above but parallel to the soft palate. The lateral margins of the epiglottis have a crenate or scalloped appearance. A normal vascular pattern is present on the dorsal surface with a main vessel on either side that courses from the base toward the tip, parallel to and approximately 8 to 10 mm in from the margin (see Figure 45-1). From these two major vessels, small perpendicular branches are seen coursing toward the epiglottic margins.

Epiglottic Entrapment

The aryepiglottic folds are thickened bands of mucous membrane that attach along the entire free edge of the epiglottis, blending in with the tightly adherent dorsal epiglottic mucosa and the mucosa covering the corniculate process of each arytenoid cartilage.[131] The loose subepiglottic mucosa compresses in an "accordion" fashion when the epiglottis is in the normal resting position. Epiglottic entrapment occurs when the loose subepiglottic mucous membrane becomes positioned above the dorsal epiglottic surface and then appears continuous with the aryepiglottic folds. Epiglottic entrapment is a common cause of abnormal respiratory noise and often, but not always, exercise intolerance, particularly in Thoroughbred and Standardbred racehorses.[131-137] Other, less frequent complaints associated with epiglottic entrapment are coughing and nasal exudate, sometimes after drinking. Epiglottic entrapment is occasionally an incidental endoscopic finding.

Figure 45-20. Endoscopic appearance of epiglottic entrapment showing a thin entrapping membrane where the outline of the epiglottis is still visible. (Courtesy M. Weishaupt, Zurich.)

Diagnosis

On endoscopic examination, the general shape of the epiglottis is still visible, and in the majority of horses it is positioned above the soft palate (Figure 45-20). However as the epiglottis is covered with a fold of mucosa, the crenate margins of the epiglottis and the dorsal epiglottic vessels are obscured. The entrapping membrane may be intermittently relieved when the horse swallows, but in most cases it is persistent (Figure 45-21). The appearance of the entrapping membrane endoscopically varies and can be classified as being thin or thick, narrow (less than half the length of the epiglottis) or wide (greater than half the length of the epiglottis), and ulcerated or nonulcerated (Figure 45-22). Mucosal ulceration can vary from minimal to extensive, with variable amounts of exposed granulation tissue and pale fibrous cicatrix formation around the perimeter of the ulcer (Figure 45-23). Most epiglottic entrapments (97%) are persistent, most (98%) are thick, most (97%) are wide, and 45% are ulcerated.[132]

Horses with epiglottic entrapment may also suffer from varying degrees of epiglottic hypoplasia and/or flaccidity. On endoscopic examination, 31% to 36% of horses with entrapment appear to have epiglottic hypoplasia.[132,136,137] A lateral laryngeal radiograph allows accurate measurement of thyroepiglottic length and information about epiglottic thickness and contour. In one study of 9 Thoroughbreds with epiglottic entrapment, the thyroepiglottic length was 6.59 ± 0.33 cm,[138] and in another study of 35 Thoroughbreds it was 7.28 ±

0.67 cm.[139] These measurements were significantly smaller than those found in normal Thoroughbreds without entrapment, which in two studies was 8.76 ± 0.38 cm and 8.56 ± 0.29 cm.[1,139] The thyroepiglottic length in 44 Standardbreds with entrapment was 7.21 ± 0.62 cm, also significantly less than the length of 8.74 ± 0.38 cm found in normal Standardbreds.[139] Among Standardbred and Thoroughbred horses with epiglottic entrapment, those with apparent epiglottic hypoplasia had significantly shorter thyroepiglottic lengths than horses with entrapment and a normally shaped epiglottis.[139]

Treatment

Surgical correction of epiglottic entrapment has been described using transnasal endoscopically guided contact Nd:YAG or diode laser axial division, using transnasal or transoral axial division using a curved bistoury, using transendoscopic electrosurgical axial division, and by surgical excision through a laryngotomy or a pharyngotomy.[100,131-140] Conventional side-to-side excision of the aryepiglottic and subepiglottic folds performed through a laryngotomy commonly resulted in dorsal displacement of the soft palate.[131,137] Therefore, tissue-sparing techniques that preserve aryepiglottic fold mucosa and minimize scarring are preferred, especially with the knowledge that epiglottic hypoplasia is present in many horses with epiglottic entrapment. Axial midline division of the entrapping membrane is the technique of choice in most horses. This procedure allows the membrane to retract and heal in a normal subepiglottic position, often without removing any tissue. The membrane can be divided with an Nd:YAG, a holmium:YAG, or a diode laser; a curved bistoury transnasally or transorally; or electrocautery to achieve the same effect.

Laser surgery can be safely performed transendoscopically in the standing sedated horse on an outpatient basis with the entrapping membranes topically anesthetized. Using the Nd:YAG laser as an example, a 600-µm sculpted fiber can be used to incise the membrane from caudad to rostrad in contact fashion using approximately 12 W of power. Alternatively, a contact chisel probe attached to a 2.2-mm outer-diameter fiber can be used to divide the membranes from rostrad to caudad with 15 W of power (additional information on laser surgery can be found in Chapter 15). Using these two techniques, the re-entrapment rate in a series of more than 500 cases was approximately 4%, and between 10% and 15% of horses experienced dorsal displacement of the soft palate. Extreme care must be taken to avoid thermal trauma to the epiglottis. Using a transnasally placed bronchoesophageal grasping forceps to elevate the entrapping membrane away from the epiglottis can help avoid laser trauma to the epiglottis. To reduce the opportunity for re-entrapment, some surgeons also remove two small triangles of the mucosal fold from either side after the intial

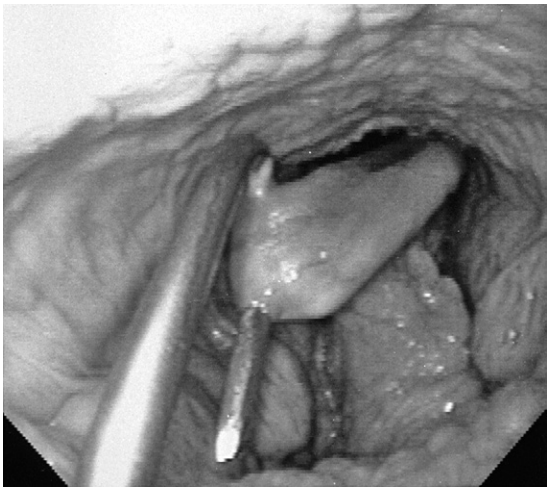

Figure 45-24. Endoscopic appearance of a curved bistoury axially dividing an entrapping membrane via an oral approach. Note the glossoepiglottic fold ventral to the epiglottis.

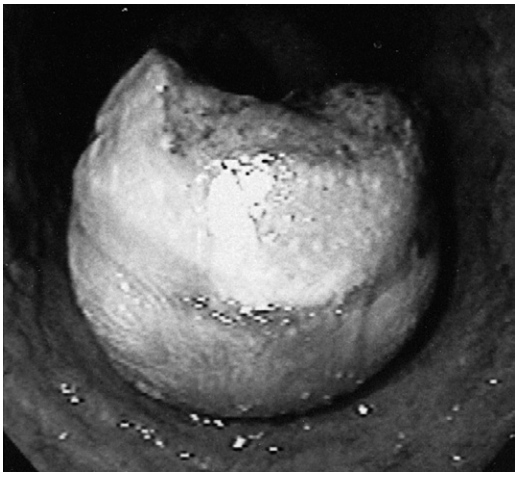

Figure 45-25. Endoscopic appearance of a thick, ulcerated epiglottic entrapment in a Thoroughbred racehorse. Surgical correction was achieved by excising the central third of the aryepiglottic fold through a laryngotomy.

axial split. The bronchoesophageal grasping forceps again are necessary for this maneuver.

With a curved bistoury introduced either transnasally in the standing horse or transorally in the anesthetized or standing horse[140-142] (Figure 45-24), the entrapping membranes can be incised on the midline from caudad to rostrad. The reported re-entrapment rate ranges from 5% to 15%.[133-136] Serious complications can occur after transnasal axial division using a curved bistoury on standing sedated horses, including partial division of the soft palate and lacerations of the epiglottis or pharynx. Therefore, this technique is not recommended unless a protected bistoury is used, which has been shown in a small number of horses to reduce this complication, but operator experience is necessary.[140]

Inadvertent incision of the soft palate can be avoided by performing the hook technique through the mouth with the horse anesthetized. The re-entrapment rate after transoral hook correction varies between 1%[135,136] and 10%, and up to 10% of horses experienced dorsal displacement of the soft palate.[134-136] Transendoscopic electrosurgical division has the highest complication rate of the axial division techniques (in a series of 5 horses, it resulted in a 40% re-entrapment rate[137]), and it has fallen into disuse.

Special Considerations

An excessively thickened, ulcerated, or fibrotic-appearing entrapping membrane is present in approximately 5% of horses with epiglottic entrapment, and often these horses have severe epiglottic hypoplasia (Figure 45-25). Horses with this endoscopic appearance are generally poor candidates for correction by axial division. Surgical excision of the central one third of these bulky membranes is recommended and can be performed via a laryngotomy, with the horse anesthetized and positioned in dorsal recumbency. Through the laryngotomy, the epiglottis is retroverted into view by placing traction on the aryepiglottic fold tissue on the lateral margin with sponge or Allis tissue forceps. Applying instruments directly onto the epiglottic cartilage for traction should be avoided. The aryepiglottic folds are placed under tension and stabilized in a fan shape with three evenly placed Allis tissue forceps (two lateral and one central) and the triangular shape of the epiglottis is identified by visual inspection and palpation. The outstretched aryepiglottic fold is incised on the midline with Metzenbaum scissors to within 2 to 3 mm of the epiglottic cartilage tip. The aryepiglottic fold is then cut for a length of about 1 to 1.5 cm parallel to each margin of the epiglottis. This cut angles out from each epiglottic edge, beginning adjacent to the cartilage and tapering to the free edge of the outstretched aryepiglottic fold. Two roughly triangular pieces of mucous membrane are excised out of the central portion of the aryepiglottic fold, debulking the membrane and, in most horses, preventing re-entrapment. The laryngotomy is left to heal by second intention, with routine wound cleaning provided twice daily. Exercise can be resumed after 4 weeks if healing progresses normally; however, 8 weeks is the preferred rest period. Re-entrapment can occur and is treated by a second excision.

Alternatively, the membrane can be debulked with the horse standing using transendoscopically guided laser excision via the nares. However, care must be taken to avoid thermal damage to the epiglottic cartilage because adhesions and indurated cicatrix often form between the entrapping membrane and the epiglottis, making their delineation difficult and often inducing complications. Owners should be warned that dorsal displacement of the soft palate may be a sequela to correction of epiglottic entrapment regardless of the technique performed, particularly in horses with severe epiglottic hypoplasia.

Acute Epiglottitis

Acute epiglottitis is manifested endoscopically by mucosal edema, reddening, and thickening of the epiglottis (Figure 45-26). Occasionally, the cartilage tip of the epiglottis is exposed through the membrane. Extensive reddening or purple swelling of the mucous membrane ventral to the epiglottis, elevating the epiglottis dorsally into an abnormal axis, can also be present. The cause is unknown but the problem is seen most commonly in racehorses. The chief complaint is usually respiratory noise and exercise intolerance or coughing.

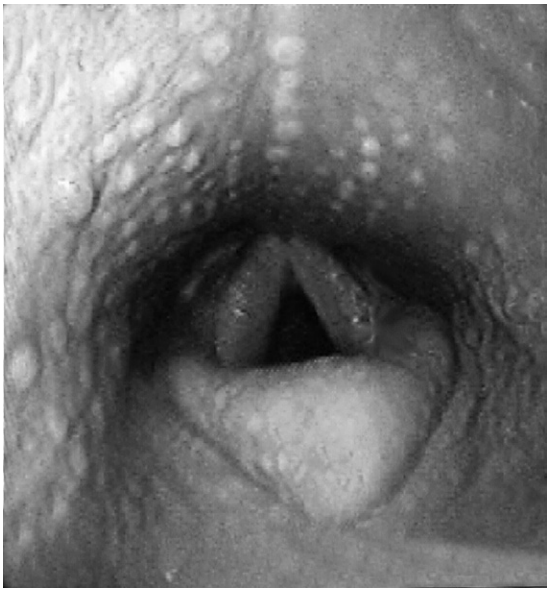

Figure 45-26. Endoscopic appearance of acute epiglottitis shows the typical edema and thickening of the epiglottis with this condition. (Courtesy M. Weishaupt, Zurich.)

Figure 45-27. Endoscopic appearance of a subepiglottic cyst in a foal; the cyst was resected via laryngotomy.

Exercise should be discontinued. Most horses respond well to systemic NSAIDs and antimicrobial medications and pharyngeal sprays containing anti-inflammatory medication. Initially, systemic corticosteroids may be useful in reducing severe inflammation. Substantial improvement in endoscopic appearance is usually seen in 7 to 14 days. Although many affected horses recover completely and successfully return to work, long-term complications occur about 50% of the time and these include epiglottic deformity, epiglottic entrapment, or intermittent or persistent dorsal displacement of the soft palate.[143]

Subepiglotic Cysts

Subepiglottic cysts are particularly prevalent in young Thoroughbred and Standardbred racehorses, suggesting a possible congenital condition.[144,145] In young foals, subepiglottic cysts may cause coughing, dysphagia, and aspiration pneumonia.[146] Subepiglottic cysts may also be acquired; they are occasionally diagnosed in older horses with no previous history of respiratory tract problems. Older horses are usually presented with a complaint of respiratory noise, coughing, and even dysphagia if the cyst is large.[145]

Diagnosis

A diagnosis of a subepiglottic cyst is made on endoscopic examination. A round or oval, smooth, pink, fluctuant, mucosa-covered mass (15 to 40 mm) can be seen beneath the epiglottis (Figure 45-27). The epiglottis may be asymmetrically elevated slightly above the soft palate by the cyst. Some larger, more fluctuant subepiglottic cysts occasionally at rest or during swallowing slip beneath the soft palate into the oral pharynx, temporarily obscuring the cyst from view and causing the epiglottis to have a normal interface with the soft palate. Concurrent intermittent or persistent epiglottic entrapment by the aryepiglottic folds can also be present. Lateral laryngeal radiographs or contrast pharyngography may help define the location and size of the cyst.

An oral endoscopic and/or digital examination (dependent on hand size) can reveal the exact size and position of the cyst. The horse is anesthetized, positioned in lateral recumbency, and nasotracheally intubated to allow unrestricted access to the oropharynx. With the aid of a mouth speculum and rostrad traction of the tongue, the soft palate is manually displaced above the epiglottis. The cyst can be felt or visualized beneath the epiglottis as a variably sized, smooth, fluctuant mass projecting from the area of the epiglottic base superficial to the hyoepiglotticus muscle. The cyst is submucosal in origin, and hence the cyst base may be poorly defined (sessile) rather than reduced to a distinct narrow, pedunculated stalk. When the oral examination is complete, the horse may be placed in dorsal recumbency for approach via laryngotomy or left in lateral recumbency for an oral approach (see "Treatment," later). Histopathology reveals that subepiglottic cysts are usually lined with a combination of stratified squamous and pseudostratified columnar epithelium. Mucous glands, dilated ducts, and homogeneous eosinophilic mucus are usually present.

Treatment

Removal of the secretory lining is important. If the cyst is only punctured and drained, it usually seals over and refills within days. However removal of excessive oral pharyngeal mucosa overlying the cyst may result in subepiglottic cicatrization, possibly altering the normal range of motion of the epiglottis or disrupting the normal synchrony between the epiglottis and the soft palate. Cicatrization after subepiglottic cyst removal can also result in intermittent or persistent dorsal displacement of the soft palate.[145] Traditionally, subepiglottic cysts have been removed through a laryngotomy with the horse positioned in

dorsal recumbency under general anesthesia.[146] The epiglottis is gently retroverted into view by grasping each aryepiglottic fold with a sponge forceps or Allis tissue forceps. By elevating the epiglottic tip, the cyst can be palpated on the ventral epiglottic surface. The mucosa is sharply incised over the cyst and the cyst is excised submucosally with Metzenbaum scissors. The mucosal incision is usually left to heal by second intention or it may be sutured with 3-0 to 5-0 synthetic absorbable suture. The laryngotomy is normally left to heal by second intention with routine twice-daily cleansing. Exercise is resumed in 3 to 4 weeks if the laryngotomy has healed routinely and follow-up endoscopy is normal.

Two techniques are available for excising subepiglottic cysts via an oral approach.[145] The horse is anesthetized and positioned in lateral recumbency, and a nasotracheal tube is positioned. Using a videoendoscope to visualize the cyst, traction is placed on the mucosa and the underlying cyst with 600-mm bronchoesophageal grasping forceps (Universal bronchoesophageal grasping forceps, 600-mm length, 8280.62, Richard Wolf Medical Instrument Corporation). Using either a Nd:YAG laser or a diode laser with a 600-µm sculpted fiber, a fusiform incision into the mucosa over the cyst is made transendoscopically with 15 to 18 W of power. Laser energy is then used to excise the cyst membrane submucosally.[147,148] This can be difficult to achieve without rupture of the cyst, and operator experience is essential. Occasionally, a small amount of digital dissection is necessary to free the cyst's final attachments. Alternatively, an electrocautery snare, passed via the biopsy channel of the endoscope, may be applied. A cyst snare can be fashioned from a mare urinary catheter and obstetrical wire and used to excise the cyst at its base, taking extreme caution to remove as little overlying mucosa as possible. In either technique, hemorrhage is minimal and the defect created is left to heal by second intention.

A standing transnasal approach using either endoscopic guided laser or electrocautery excision can also be performed with the horse sedated and the head elevated in stocks. This technique is usually reserved for small cysts that can be easily manipulated to a position above the palate. The cyst is anesthetized topically through polyethylene tubing introduced through the biopsy channel of the videoendoscope. Five to 10 mL of local anesthetic solution dripped over the cyst will induce local anesthesia in about 5 minutes. The 600-mm bronchoesophageal forceps are introduced up the opposite nasal passage to the one with the endoscope and the mucosa overlying the cyst is grasped. A fusiform mucosal incision and submucosal dissection of the cyst lining is subsequently performed (as previously described for the oral approach) using either an Nd:YAG or a diode laser and a 600-µm sculpted fiber.[100] A single horse has been successfully treated with two endoscopically guided injections, 14 days apart, of 10% neutral buffered formalin directly into the cyst. The contents of the cyst were aspirated prior to injecting the formalin.[149]

Aftercare

Postoperative inflammation and pain are controlled with a combination of corticosteroids, NSAIDs, and pharyngeal sprays as needed. Exercise is restricted until the pharynx appears endoscopically normal, which is usually within approximately 21 days. In horses with concurrent epiglottic entrapment, removal of the subepiglottic cyst usually can correct the epiglottic entrapment; however, epiglottic entrapment can recur, and it should probably be treated using the tissue-sparing technique described earlier. Foals with concomitant aspiration pneumonia should be treated with broad-spectrum antimicrobial agents based on culture and sensitivity of tracheal aspirates before excision of the cyst.

Dorsal Epiglottic Abscess

Dorsal epiglottic abscess is a rare disease that causes coughing, respiratory noise, and exercise intolerance.[147] Palpation of the laryngeal cartilages may elicit pain. On endoscopic examination, there is a smooth, well-circumscribed, round or oval swelling on the dorsal epiglottic surface. Intermittent dorsal displacement of the soft palate may be observed. The abscess can be incised and drained transendoscopically on an outpatient basis with a contact Nd:YAG or diode laser using a sculpted fiber or chisel probe. After decompressing the abscess, débridement can be achieved with 600-mm-long bronchoesophageal grasping forceps. The abscess cavity can be lavaged transendoscopically, if desired, with 240 polyethylene tubing and a dilute 1 : 10 chlorhexidine solution in physiologic saline. Aftercare includes stall confinement and exercise restricted to handwalking. NSAIDs and systemic antibiotics (procaine penicillin G given intramuscularly twice daily) are given at recommended dosages for 3 days. The abscess usually appears healed by 10 days postoperatively. In a small number of cases, clinical signs resolved and the horses resumed normal exercise without recurrence of the abscess[147]; however, the potential for epiglottic deformity does exist.

Subepiglottic Granulomas

Subepiglottic granulomas originate following acute ulceration of the aryepiglottic fold on the ventral aspect of the epiglottis. In response to infection or chronic irritation, excessive granulation tissue forms. This tissue may be confused with subepiglottic cysts. Clinical signs frequently include coughing, exercise intolerance of varying degrees, and occasionally dysphagia. The horse may have a history of poor performance, and intermittent dorsal displacement of the soft palate may be suspected. It may be necessary to drive the endoscope up under the epiglottis to assess this condition. Large lesions may disrupt the normal anatomic seal between the epiglottis and the soft palate. Because dorsal displacement of the soft palate should be suspected with ulcer formation, a high-speed dynamic endoscopic examination is recommended.

Treatment

Small granulomas and ulcers can respond to antimicrobial and anti-inflammatory medical therapy as long as the horse has received forced rest for approximately 4 to 6 weeks. When ulcers do not heal, enlargement of the granulation tissue frequently occurs when the horse is returned to exercise. In these cases, excision either orally or through a ventral laryngotomy is indicated. Sharp surgical excision alone (performed through a ventral laryngotomy) may not result in complete resolution of the problem. Therefore, sterilization of this area with laser cautery of the surface after resection is indicated. Alternatively, laser photo ablation of the surface of the granulation tissue can be performed with the sculpted fiber using contact technique.

It is imperative that extended periods of rest (up to 60 days) accompany any treatment of this condition.[148]

Epiglottic Hypoplasia, Flacidity, and Deformity

Diagnosis

Epiglottic hypoplasia, flaccidity, and epiglottic deformity have been associated with dorsal displacement of the soft palate and epiglottic entrapment, both of which can cause abnormal respiratory noise and exercise intolerance.[131-136,139,150-153] On endoscopic examination, the hypoplastic epiglottis in the adult horse appears short and narrow, particularly from midbody to the tip, or it may appear very thin (Figure 45-28). The epiglottic contour may appear flaccid, conforming excessively to the shape of the underlying soft palate. In some horses, the epiglottic border is irregular or rounder and much flatter without the normal crenations. Occasionally, the epiglottis has a very shrunken and wrinkled appearance. Easily induced intermittent or persistent dorsal displacement of the soft palate may be observed during the endoscopic examination. A lateral laryngeal radiograph and contrast pharyngography may provide additional information regarding thyroepiglottic length, epiglottic thickness and contour, and the relationship of the epiglottis to other adjacent pharyngeal structures. If the soft palate is persistently displaced dorsad, endoscopy and digital palpation of the epiglottis *per os* with the horse anesthetized and in lateral recumbency may provide useful diagnostic information on the extent of the problem. Epiglottic hypoplasia that is severe enough to result in persistent dorsal displacement of the soft palate is associated with a guarded to poor prognosis for optimal exercise potential.[151,152] Other underlying problems causing dorsal displacement of the soft palate, such as epiglottic entrapment, subepiglottic cicatrix formation, or granulation tissue, can also be fully assessed through a detailed endoscopic and digital oral examination. However, persistent dorsal displacement of the soft palate may occur secondary to severe epiglottic hypoplasia without any other underlying abnormalities or previous surgical intervention.[152]

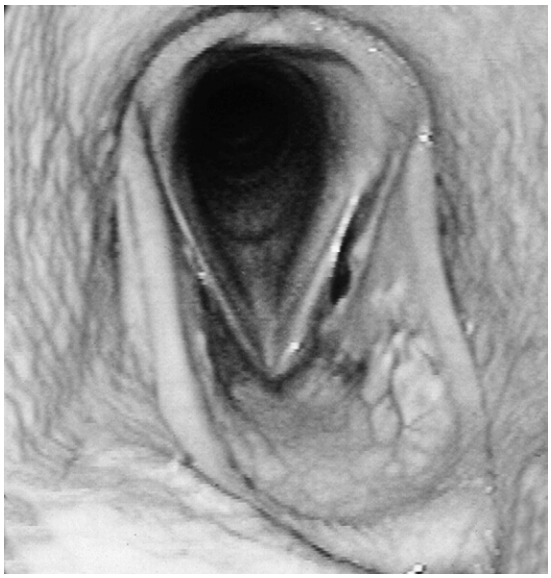

Figure 45-28. Endoscopic appearance of epiglottic hypoplasia/flaccidity, showing how the epiglottis appears very thin. (Courtesy J.T. Robertson, Ohio.)

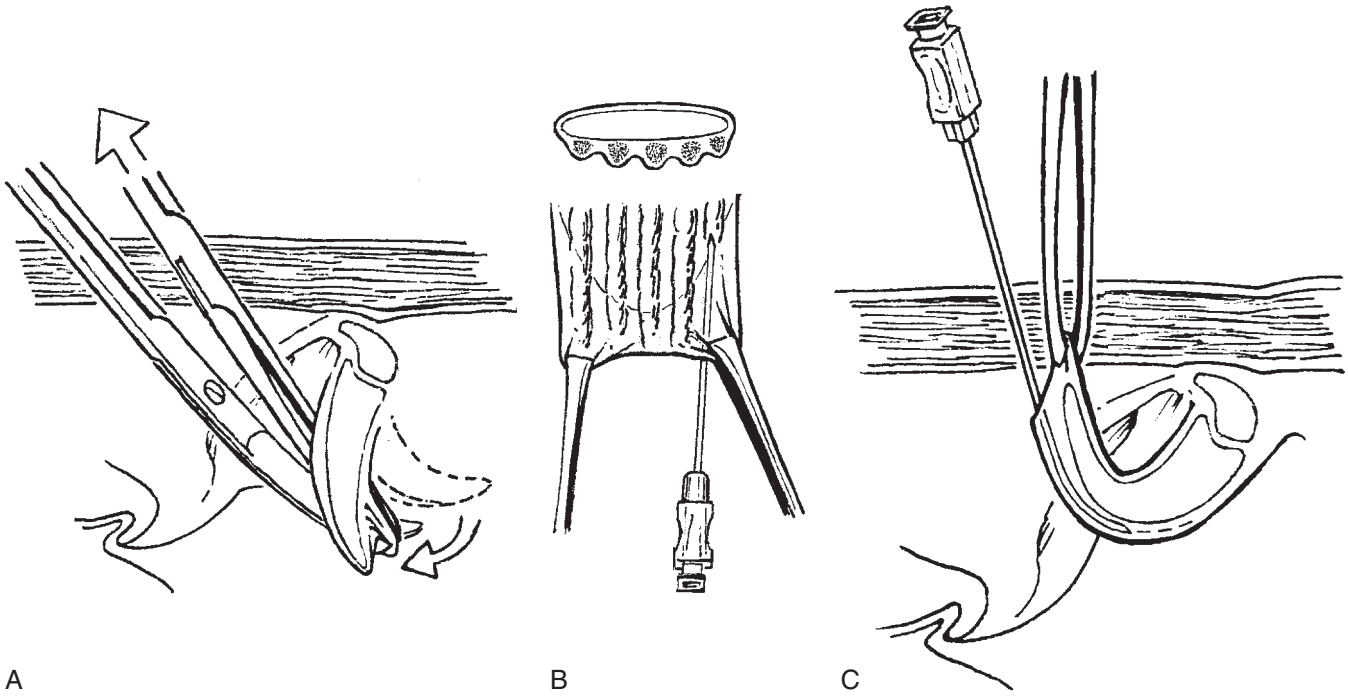

Figure 45-29. Technique used to evert the epiglottis through a laryngotomy incision. **A,** Curved scissors are used to evert the epiglottis until the epiglottic fold can be grasped with Allis tissue forceps. **B,** The endotracheal tube can be replaced and the ventral surface of the epiglottis is injected. **C,** Five linear injections are made equidistant from each other into the aryepligotic fold.

Because epiglottic hypoplasia or flaccidity in adult horses is thought to contribute to epiglottic entrapment and intermittent dorsal displacement of the soft palate, the epiglottis is routinely scrutinized during prepurchase endoscopic examinations in yearling Thoroughbreds. However, no correlation could be found between the appearance of a hypoplastic or flaccid epiglottis in the standing adult horse and dorsal displacement of the soft palate during exercise on a high-speed treadmill.[154] Initially these same visual epiglottic abnormalities in yearlings could not be significantly correlated with racing performance[16]; however, it has now been reported that horses with shorter epiglottises have lower earnings as 2- and 3-year-old race horses.[155] We now recognize that variation exists in the upper airway structure of yearling and adult horses. Compared with adult horses, yearlings have a shorter, narrower, and more flaccid-appearing epiglottis normally, and judgments about epiglottic appearance should be reserved until the horse reaches maturity, except in very severe cases.

Treatment

Epiglottic augmentation is performed only in the adult horse to increase the mechanical rigidity of the epiglottis and to make the hypoplastic or flaccid epiglottis more resistant to dorsal displacement of the soft palate. Several materials including collagen and autogeneic and allogeneic cartilage grafts have been evaluated, but epiglottic augmentation with polytetrafluoroethylene (Polytef Paste; Polytetrafluoroethylene Teflon paste, Mentor polytef paste for injection, Mentor O & O, Inc) has proved to be the most useful.[156,157] Submucosal injection of the ventral epiglottic muosa with polytetrafluoroethylene paste via a laryngotomy (Figure 45-29) using an Arnold-Bruning syringe (Arnold-Bruning intracordal injection syringe, catalog No. 7754) (Figure 45-30) resulted in an increased thickness of approximately 29% to 40% along the margins and midline (Figure 45-31).[157] Epiglottic length was not increased. Polytetrafluoroethylene paste functions by inciting a sterile granulomatous reaction that is incorporated in fibrous connective tissue.

In two studies, an approach to management of intermittent dorsal displacement of the soft palate that most often combined surgical techniques and always included epiglottic augmentation improved racing performance in 66% of treated horses with poor racing performance attributable to epiglottic hypoplasia or flaccidity.[158,159]

Figure 45-30. Photograph of Arnold-Bruning intracordal injection syringe, fully assembled.

Epiglottic Retroversion

Diagnosis

Epiglottic retroversion refers to a condition where the epiglottis assumes a position dorsal to the soft palate and retroverts into the opening of the glottis during inspiration and returns to its normal position with each expiration.[160] Resting endoscopic examination of the pharynx and larynx can appear normal, or on occasion the epiglottis projects slightly above the soft palate. High-speed dynamic or treadmill videoendoscopy is necessary to confirm the diagnosis (Figure 45-32). Retroversion of the epiglottis enables visualization of the ventral (lingual) surface of the epiglottis, but usually the soft palate does not elevate or displace dorsal to the epiglottis. In one horse, the epiglottis rolled up in a tubelike fashion and pointed dorsally, but it did not retroflex into the glottis. During exercise, a respiratory noise may be heard.

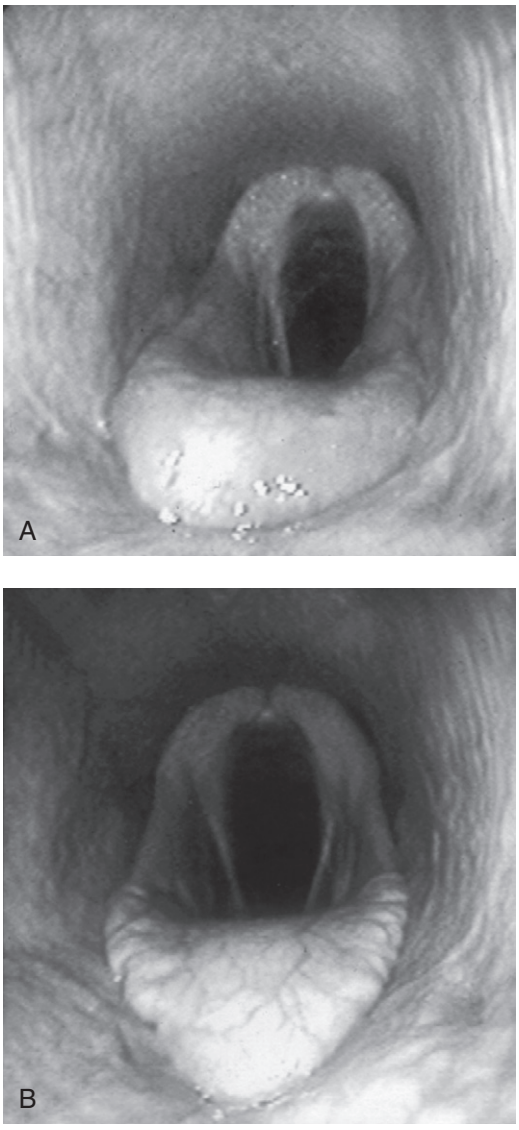

Figure 45-31. A, Twenty-four hours after Teflon injection in the epiglottic fold, the epiglottis becomes edematous; **B,** Thirty days after injection, the epiglottis is clearly thickened and more substantial when compared with its appearance before surgery (see Figure 45-28).

Figure 45-32. Videoendoscopic appearance of epiglottic retroversion as seen during inspiration on a horse exercising on a high-speed treadmill.

Etiology

Experimentally, local anesthesia of the geniohyoid muscle and of the hypoglossal nerves within the guttural pouch have produced epiglottic retroversion during exercise in normal horses.[161] Trauma or inflammation of the normal hyoid musculature or the hyoepiglotticus or geniohyoid muscles may precede epiglottic retroversion.

Treatment

Two horses with this rare problem were treated by epiglottic augmentation with polytetrafluoroethylene paste injected submucosally on the lingual epiglottic surface. One Standardbred was able to return to racing and competed successfully, including winning several races, and one Thoroughbred was retired when it continued to make noise during training after undergoing surgery. In a third horse, a racing Standardbred, a prosthetic suture placed between the epiglottis and the thyroid cartilage was used to stabilize the epiglottis, which allowed it to return to racing.[162]

CHAPTER 46

Guttural Pouch

David E. Freeman and Joanne Hardy

ANATOMY

Guttural pouches are paired extensions of the eustachian tubes that connect the pharynx to the middle ear.[1] They are found in perissodactyls, such as equids, tapirs, some species of rhinoceros (except for the white rhinoceros), some bats, a South American forest mouse, and hyraxes.[2-4]

The pouches are separated from each other on the midline by the rectus capitis ventralis and the longus capitis muscles and the median septum.[1] Each is in close contact rostrally with the basisphenoid bone; ventrally with the retropharyngeal lymph nodes, pharynx, and esophagus; caudally with the atlantooccipital joint; laterally with the digastricus muscle and the parotid and mandibular salivary glands; and dorsally with the petrous part of the temporal bone, tympanic bulla, and auditory meatus. Each guttural pouch is divided ventrally into a medial and a lateral compartment by the stylohyoid bone, and it communicates with the pharynx through the pharyngeal orifice of the eustachian tube. The pharyngeal orifice is a funnel-shaped opening in the dorsolateral aspect of the pharynx that forms an oblique slit rostral and ventral to the dorsal pharyngeal recess. The small end of the funnel opens into the guttural pouch. The medial lamina of each opening is composed of fibrocartilage directed in a rostroventrad-to-caudodorsad direction. The capacity of guttural pouches in adult horses is 472 ± 12.4 mL and the lateral compartment is approximately one third of the capacity of the medial compartment.[5]

Clinical signs of important guttural pouch diseases are referable to injury of specific nerves and arteries in the guttural pouch and acoustic system. The internal carotid artery (ICA), cranial cervical ganglion, cervical sympathetic trunk, and vagus, glossopharyngeal, hypoglossal, and spinal accessory nerves are all contained in a fold of mucous membrane along the caudal wall of the medial compartment (Figure 46-1). The cranial laryngeal nerve and the pharyngeal branch of the vagus nerve lie beneath the mucosa on the floor of the medial compartment (see Figure 46-1).[1] The external carotid artery (ECA) lies along the wall of the lateral compartment and gives off the caudal auricular artery and superficial temporal artery, and it continues as the maxillary artery (MA) along the roof of the guttural pouch. The facial nerve (CN VII) passes for a short distance over the caudal dorsal aspect of the lateral compartment after it emerges from the stylomastoid foramen. The vestibulocochlear nerve (CN VIII) enters the internal acoustic meatus caudal to the facial nerve and divides into vestibular and cochlear branches that innervate components of the middle ear. This nerve does not enter the guttural pouch but can become involved in guttural pouch diseases that affect the middle ear (e.g., temporohyoid osteoarthropathy). The mandibular nerve, a branch of the trigeminal nerve (CN V), emerges from the foramen lacerum, passes close to the muscular process of the petrous part of the temporal bone, and continues rostrad along the roof of the lateral compartment of the guttural pouch.

The guttural pouch is lined with pseudostratified ciliated epithelium containing goblet cells in both adults and foals.[6] The guttural pouch mucosa has the ability to clear foreign substances, but this ability varies among different regions of the epithelium.[6] In a study on the distribution of various immunoglobulin isotypes and sub-isotypes in the guttural pouch mucosa of healthy horses, immunoglobulin G (IgG) was found in the guttural pouch mucosa, mucosal lymph nodules, and submucosal lymph nodules.[5] IgM was scattered in the mucosal lymph nodules and in the germinal centers of the submucosal lymph nodules. IgGc was recognized only in the submucosal lymph nodules, and IgA was detected in glandular epithelial cells and the surface layer of the mucosal epithelium.[5]

Possible functions of the guttural pouches include pressure equilibration across the tympanic membrane, contribution to air warming, a resonating chamber for vocalization, and a flotation device.[7] A role more recently proposed, on the basis of measurement of lower arterial temperatures in the cerebral side of the ICA compared with the cardiac side, is brain cooling.[8,9] Based on cadaver studies, opening of the pharyngeal orifice of the guttural pouch involves the levator and tensor veli palatini muscles and the pterygopharyngeus and palatopharyngeus muscles. Passive opening of the auditory tube involves a reduced tone in the stylopharyngeus and pterygopharyngeus muscles,

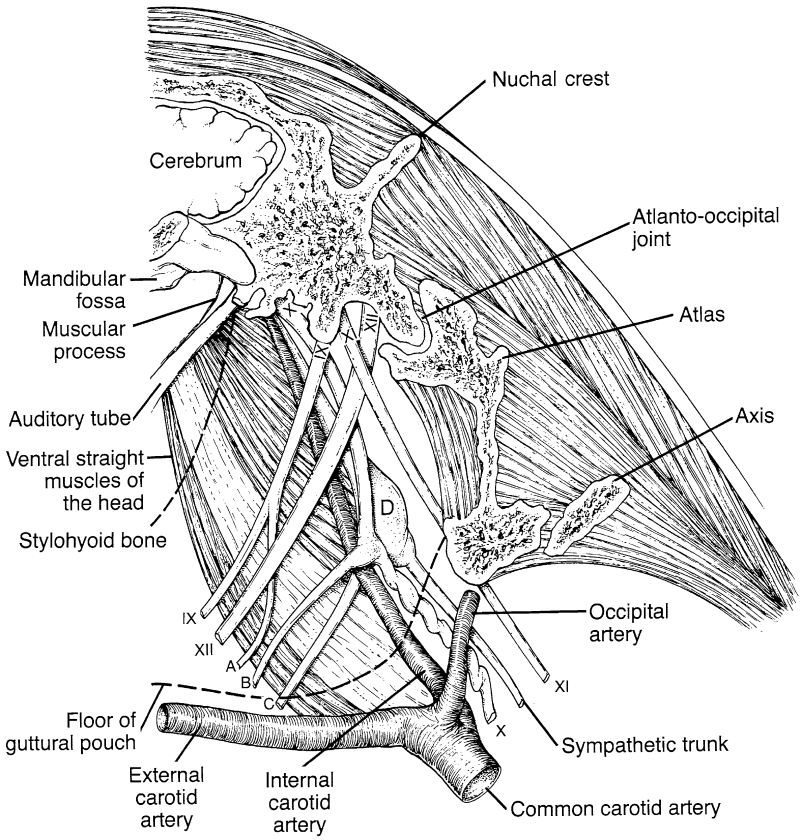

Figure 46-1. Interior of medial compartment of the left guttural pouch, viewed from the lateral aspect in a sagittal section of a horse's head. The section is cut through the styloid process of the petrous temporal bone on a line that divides the guttural pouch into medial and lateral compartments. *IX*, Glossopharyngeal nerve; *X*, vagus nerve; *XI*, accessory nerve; *XII*, hypoglossal nerve; *A,* pharyngeal branch of the glossopharyngeal nerve; *B,* pharyngeal branch of the vagus nerve; *C,* cranial laryngeal nerve; *D,* cranial cervical ganglion. (Redrawn from Freeman DE, Donawick WJ: Occlusion of internal carotid artery in the horse by means of a balloon-tipped catheter: Clinical use of a method to prevent epistaxis caused by guttural pouch mycosis. J Am Vet Med Assoc 176:236, 1980.)

accompanied by increased inspiratory pressure.[10] Although guttural pouch filling was previously reported to occur on expiration, the latter study demonstrated that filling occurs on inspiration.[10]

EXAMINATION

The guttural pouches are examined by external palpation, endoscopy, and various imaging techniques. Enlargement caused by empyema (purulent material in the pouches), but particularly by tympany (air engorgement), can be palpated externally. Guttural pouch endoscopy provides the most information regarding disease. Nonspecific evidence of guttural pouch disease, such as collapse of the pharynx and blood or pus draining from the pharyngeal orifice, can be found on endoscopic examination of the pharynx. However, blood or pus from other respiratory sources may be aspirated into the guttural pouch opening and appear to drain from it, so that direct endoscopic examination of the pouches must be performed (Figure 46-2). With the horse mildly sedated, the biopsy instrument is passed through the biopsy channel of the endoscope and used to guide the endoscope into the guttural pouch. The endoscope is placed so that the biopsy forceps is as close as possible to the lateral wall of the pharynx until successful insertion into the guttural pouch is achieved. Both pouches can be entered in this manner with the endoscope in the same nostril. Alternatively, the pharyngeal opening can be levered open with a Chamber's catheter to allow the endoscope to enter the pouches. The endoscopic appearance of the guttural pouch anatomy is quite consistent between horses (see Figure 46-2), but a double ICA can be seen (Figure 46-3).

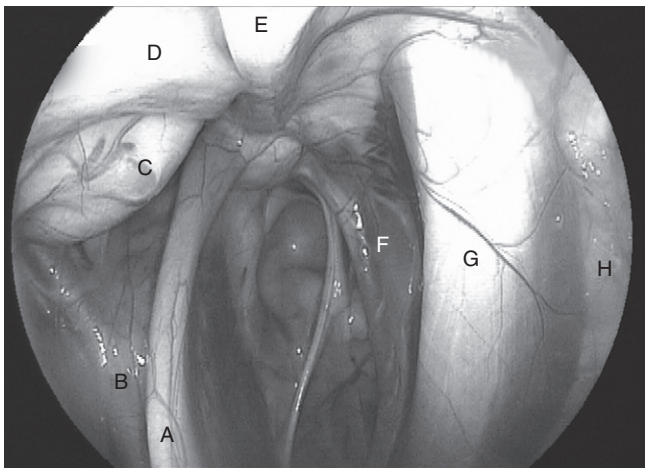

Figure 46-2. Normal endoscopic anatomy of right guttural pouch. The stylohyoid bone *(A)* divides the caudoventral part into lateral and medial compartments. *B,* External carotid artery; *C,* maxillary artery; *D,* tensor veli palatini muscle; *E,* cartilaginous portion of eustachian tube; *F,* internal carotid artery with hypoglossal and glossopharyngeal nerves lateral to it; *G,* ventral straight muscles; *H,* median septum.

Lateral radiographic projections of the guttural pouches can demonstrate fluid lines, fractures and exostoses of the stylohyoid bone, radiopaque foreign bodies, and space-occupying masses.[11] Air distention, as in tympany, can increase dimensions of the affected guttural pouch, sometimes beyond the second cervical vertebra. A dorsoventral or ventrodorsal projection is best used to image the stylohyoid bones and temporohyoid

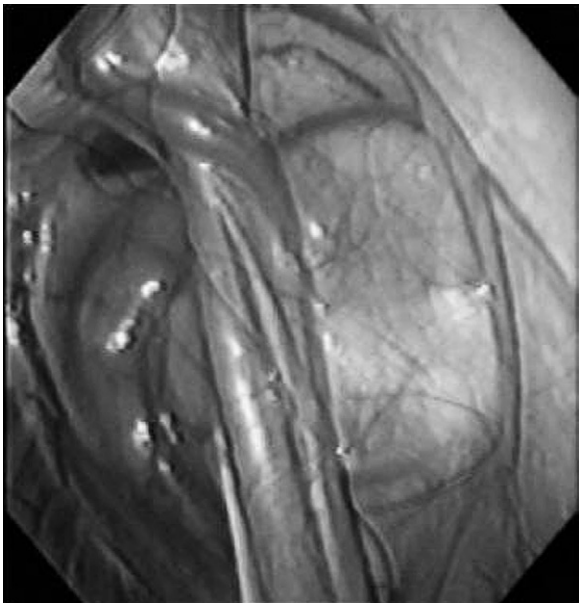

Figure 46-3. Endoscopic photograph of the medial compartment of the right guttural pouch in a normal horse showing a double internal carotid artery.

articulation. Computed tomography can provide an alternative imaging modality, especially for evaluation of the stylohyoid bone, inner ear, and petrous temporal bone in cases of temporohyoid osteoarthropathy.[12-16] Ultrasonography can be used to demonstrate soft tissue lesions in the guttural pouches, such as tumors or muscle damage and associated submucosal hemorrhage.[17,18]

A percutaneous centesis technique through Viborg's triangle has been described for guttural pouch lavage and collection of samples for cytologic and microbiologic examinations.[19] The normal cytologic pattern contains less than 5% neutrophils, a large proportion of ciliated columnar epithelial cells, a few nonciliated cuboidal epithelial cells, and less than 1% monocytes, lymphocytes, and eosinophils.[20,21] The proportion of neutrophils is important, with less than 5% being considered normal and greater than 25% being considered abnormal. There is a high correlation between a high cytologic score and the presence of pathogenic bacteria, such as *Streptococcus equi*.[20,21] The cytologic gradings and neutrophil concentrations of guttural pouch washings are increased in horses whose heads are restrained for more than 12 hours, as would occur during long transportation.[20] Washings from these horses are more likely to contain bacteria and yield potentially pathogenic bacteria.[20]

DISEASES OF THE GUTTURAL POUCH

Tympany

Tympany, as the name implies, refers to the distention of the guttural pouches with air under pressure, sometimes accompanied with some fluid accumulation. This condition is usually unilateral but can be bilateral and is more common in fillies than in colts.[22] In 51 foals with guttural pouch tympany seen at a German clinic between 1994 and 2001, there were approximately three times as many fillies as colts, regardless of breed.[23-26] Significantly more Arabian and Paint horse foals were affected compared to the breed distribution of hospitalized foals at the same clinic.[23] In the 27 Arabian purebred foals affected with guttural pouch tympany, many were from the same stud farm and some were full or half siblings. Complex segregation analyses showed that a polygenic and a mixed monogeneic–polygeneic model best explained the segregation of Arabian foals with this disease.[26] Subsequently, whole genome scan for guttural pouch tympany in Arabian and German Warmblood horses indicated a sex-specific quantitative trait locus, in agreement with the higher prevalence of this disease in fillies.[27]

Possible causes include a mucosal flap (or plica salpingopharyngea) acting as a one-way valve that traps air and fluid in the pouch, inflammation from an upper airway infection, persistent coughing, and muscle dysfunction.[28] In most cases, no gross anatomic abnormality is encountered at the guttural pouch opening.[23]

Clinical Signs

Guttural pouch tympany develops in foals shortly after birth and up to 1 year of age. The affected guttural pouch is distended with air to form a nonpainful, elastic swelling in the parotid region. Although the swelling is most prominent on the affected side, it can extend across the neck and give the impression of bilateral involvement. Severe distention can cause dyspnea, dysphagia, and inhalation pneumonia, and secondary empyema is not uncommon. Because the consequences of the guttural pouch distention are detrimental, it is important to relieve the tympany as quickly as possible.

Diagnosis

Diagnosis is based largely on clinical signs. On endoscopic examination, the pharyngeal openings usually appear normal, but the roof of the pharynx can be collapsed. Guttural pouch enlargement with air and fluid can be seen on radiographs. Distinguishing between unilateral and bilateral tympany can be difficult on radiographs, but usually they can be defined on direct endoscopy of each pouch.[29] The distinction between unilateral and bilateral involvement is important in selecting treatment.

Treatment

Temporary alleviation of guttural pouch tympany can be achieved by needle decompression or by placing an indwelling catheter in the pharyngeal orifice. Chronic catheterization (2 to 3 weeks) using Sovereign catheters has also been anecdotally reported to result in resolution of guttural pouch tympany. However, failure of these methods to eliminate the disease within a brief time can put the foal at risk of developing complications, such as empyema, bronchopneumonia, and permanent deformity and scarring in the cartilage of the pharyngeal ostium.[30] Surgical intervention is aimed at providing a permanent means of evacuating air, either through the unaffected guttural pouch (fenestration of median septum), through the guttural pouch opening (removal of obstructing membrane), or through an artifically created opening into the pharynx (salpingopharyngeal fistula).

For median septum fenestration, the affected guttural pouch is usually entered through Viborg's triangle or through a modified Whitehouse approach (discussed later). The median septum

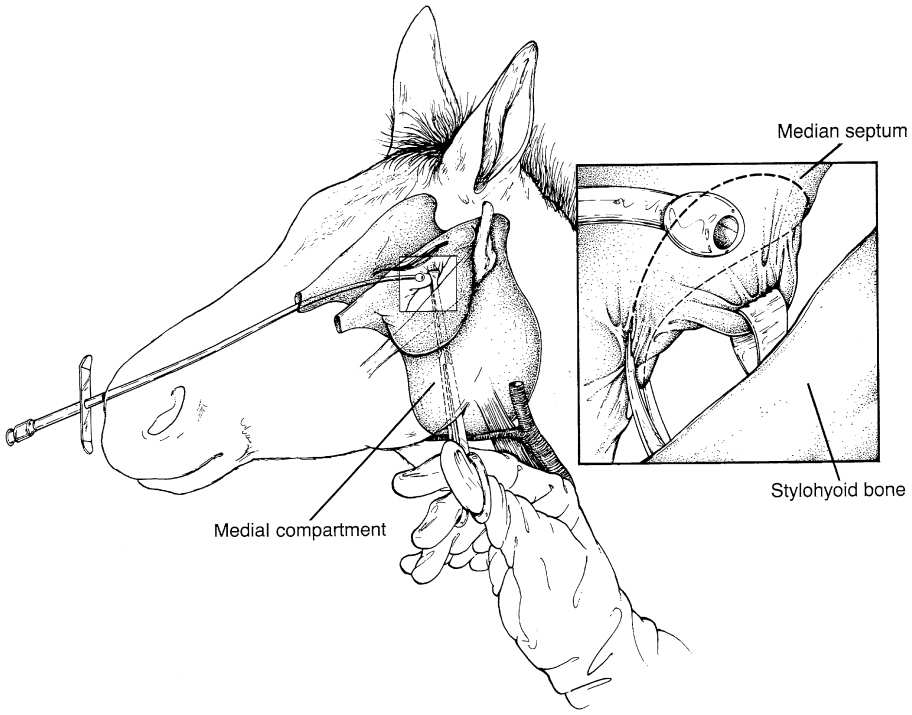

Figure 46-4. Method for creating a fenestration between the abnormal and normal guttural pouches in a foal with unilateral tympany. The affected guttural pouch (on the *left side*) is approached through an incision in Viborg's triangle, and a Chamber mare catheter in the right guttural pouch is used to elevate and expose the median septum. In the *expanded view,* a pair of scissors has been placed to start fenestration *(broken line).* (Redrawn from Milne DW, Fessler JF: Tympanitis of the guttural pouch in a foal. J Am Vet Med Assoc 161:61, 1972; and Deen T: Surgically correcting guttural pouch tympany. Vet Med 83:592, 1988.)

can be fenestrated by removal of a 2 cm^2 segment to allow egress of trapped air from the tympanitic pouch through the normal side (Figure 46-4). A Chambers mare catheter or, preferably, a lighted fiberoptic endoscope can be inserted into the healthy pouch to elevate the septum toward the incision and to facilitate identification (see Figure 46-4). Care must be taken to ensure that the mucosal linings of both sides are removed to complete the opening. Fenestration of the median septum has been completed with laparoscopic instruments, to improve access and reduce the risk of tissue trauma, especially nerve damage.[30] The major disadvantage of the fenestration procedure is that it will only be effective for unilateral cases, because it depends on one functional guttural pouch opening working for two. Fortunately most cases are unilateral, and fenestration can be a simple and effective procedure in such cases.

When bilateral involvement is suspected, the fenestration procedure can be combined with removal of a small segment (1.5 × 2.5 cm) of the medial lamina of the eustachian tube and associated mucosal fold (plica salpingopharyngea) within the guttural pouch orifice; this forms a larger opening into the pharynx.[22,29] The approach incision can be closed or left open to heal by second intention, and systemic antibiotics are given if needed. Alternatively, partial resection of only the plica salpingopharyngea within the gutteral pouch (via a modified Whitehouse approch) as the only procedure has been described with good results.[31]

Uncertainty arises about the true role of the plica salpingopharyngea in the disease process because of inconsistent descriptions of the tissue removed. In one method, the cartilaginous lamina of the eustachian tube and plica salpingopharyngea are removed,[30,32] and in another, only the cartilaginous flap is resected.[33] The plica salpingopharyngea is a mucosal fold on the floor of the tubular entryway into the guttural pouch; it is attached medially to the cartilaginous flap of the eustachian tube and laterally to the lateral wall of the pharynx. It is best viewed during guttural pouch endoscopy as the ventrally located fold that must be negotiated by the biopsy instrument to guide the endoscope under the cartilaginous flap into the pouch.

Transendoscopic electrocautery can be used to create a fenestration in the septum and to make a fistula into the guttural pouch through the pharyngeal recess.[28,34] A high-powered diode or a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser can also be used through a transendoscopic approach to create the fenestration. This can be carried out as a standing procedure or with the horse under general anesthesia.[29,35] An alternative and easier method is to create a salpingopharyngeal fistula using the laser under video-endoscopic control in the wall of the pharynx, caudal to the guttural pouch opening.[35] A Foley catheter is placed through the fistula for 7 to 10 days to act as a stent and to allow lavage of the guttural pouch.[35] The diode laser has been used in contact mode to create bilateral salpingopharyngeal fistulas and thereby successfully treat bilateral guttural pouch tympany in a foal.[36] Location of the salpingopharyngeal fistula is important. If it is placed too far rostrad or ventrad, it could fail to bypass the defective pharyngeal ostium or it could become occluded by inflammation.[30]

Prognosis

The prognosis for complete recovery and a successful racing career is favorable after median septum fenestration by any method,[22,29] although surgery is not always straightforward and repeat surgery is not uncommon. A surgical laser technique was used on 50 foals in one clinic and was successful in 35 foals after one treatment and in 15 foals after two treatments.[23] Long-term follow-up information, available for 44 of the 50 treated horses, revealed no deaths related to the disease or treatment and that all horses up to 2 years of age were healthy.[23]

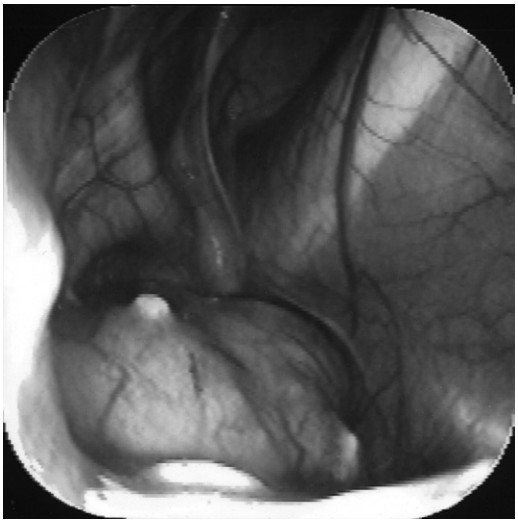

Figure 46-5. Endoscopic view of the interior of the right guttural pouch of a horse with enlargement and drainage from a retropharyngeal lymph node. Note purulent material on floor of the medial compartment.

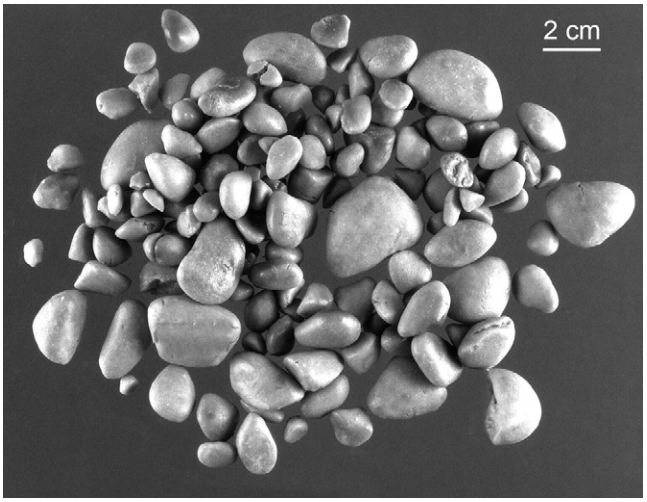

Figure 46-6. Guttural pouch chondroids removed through a modified Whitehouse approach.

Secondary empyema and pneumonia usually resolve spontaneously after successful treatment of the tympany; however, the prognosis is guarded for foals that have aspiration pneumonia and dysphagia secondary to nerve damage induced during surgical correction.[22] The fenestration procedure can fail if the newly created opening seals or the condition is bilateral.[22,29] Resection of the mucosal fold can fail if swelling and inflammation along the cut edges close the pharyngeal orifice.[37] The salpingopharyngeal fistula may seal if the catheter does not stay in place for the period required for the fistula to mature.[35] Horses treated with this method have responded favorably,[35] although effects on upper airway dynamics in the athletic horse need to be determined.[38]

Empyema

Empyema of the guttural pouches is defined as the presence of purulent material (Figure 46-5), and chondroids within one or both guttural pouches. Chondroids consist of inspissated purulent material (usually numerous individual round balls) that forms in some cases (Figure 46-6). Empyema can affect horses of any age but usually occurs in young animals. Upper respiratory tract infections (especially those caused by *Streptococcus* spp); abscessation and rupture of retropharyngeal lymph nodes into the guttural pouch (see Figure 46-5); infusion of irritant drugs; fracture of the stylohyoid bone; congenital or acquired stenosis of the pharyngeal orifice; and pharyngeal perforation by a nasogastric tube may cause empyema.[28,39] Persistence of guttural pouch infection in asymptomatic long-term carriers could be responsible for recurrent outbreaks of strangles.[40] In one study of 91 horses with guttural pouch empyema, 21% had chondroids, and the horses with chondroids were more likely to have retropharyngeal and pharyngeal swelling than those without this complication.[41] The number of chondroids present is variable, ranging from one to many (see Figure 46-6), and both guttural pouches can be affected.[41] Duration of infection does not appear to correlate with development of chondroids.[41]

Clinical Signs

Clinical signs include intermittent nasal discharge in most cases, swelling of adjacent lymph nodes, parotid swelling and pain, extended head carriage, excessive respiratory noise, and difficulties in swallowing and breathing. Many cases with long-standing disease and a heavy load of inspissated pus and chondroids can have a deceptive absence of external swelling. Severe and protracted guttural pouch empyema can cause cranial neuropathy, manifested by dysphagia, recurrent laryngeal neuropathy, and persistent soft palate displacement.[42] Although these signs are rare with this disease, they can persist in some cases after successful resolution of the empyema.[43] The disease can be bilateral.[43]

Diagnosis

On endoscopic examination, a purulent discharge can be seen at the pharyngeal orifice of the affected side, with pharyngeal collapse in some horses. Fluid accompanied by masses seen within the guttural pouch on standing lateral radiographs is suggestive of chondroids.[44] Fluid aspirates or saline washings can be taken from the guttural pouch for culture and sensitivity testing; however, results should be interpreted with caution because microorganisms can be retrieved from the normal guttural pouch and upper respiratory tract. Horses that are carriers of, or are infected with, *S. equi* in the guttural pouches can be identified by culture and polymerase chain reaction tests with repeated swabs.[45]

Treatment

In acute cases, daily irrigation with physiologic saline solution is usually effective. An indwelling catheter, devised from polyethylene 240 tubing with heat-formed coils at one end, can be used for this purpose. Alternatively, a commercially available guttural pouch catheter or one fashioned from a polypropylene dog urinary catheter can be used. Coiled catheters can be straightened to facilitate insertion by inserting a coaxial wire or by passage through a larger curved catheter. The coiled end of the catheter is placed under endoscopic guidance within the

pouch, and the free end is secured by a suture to the alar fold. A Foley catheter can also be used, but it should be advanced until the end is completely in the pouch because distention of the balloon within the pharyngeal opening could cause pressure necrosis. In larger horses, standard Foley catheters are not long enough to reach the guttural pouch. Alternatively, the pouch can be flushed through the biopsy channel of the endoscope, which has the advantage of delivery of the flush solution to areas coated with purulent material. After 7 to 10 days, irrigation should be interrupted briefly to assess the response and allow any inflammation from treatment itself to resolve.

The purpose of lavage with a balanced physiologic solution is to dislodge and remove mucopurulent material from the guttural pouch, which should reduce the bacterial burden and produce a more favorable environment for recovery. Aggressive methods of lavage, such as delivery of large volumes of fluid under pressure through large-bore tubes, are not recommended because they can rupture the guttural pouch lining[43] and spread the infection into tracts from which it cannot be readily removed.[46] In chronic cases with inspissated pus and chondroids, repeated delivery of lavage fluid is usually not effective and could also cause guttural pouch rupture with extension of infection and air into adjacent fascial planes.[46] The cost and potential complications of protracted medical treatment should be weighed against the benefits of surgery if a slow response seems likely.

Hydrogen peroxide or concentrated antiseptic solutions should not be infused because they are irritating and can induce neuritis of the cranial nerves. Topical antibiotic solutions are rarely effective because the contact period is too brief and many are inactivated by the products of inflammation present in the purulent material. However, penicillin gels have gained popularity. Dilute povidone-iodine (1%) is more effective than concentrated solutions because free iodine dissociates more readily from the organic carrier at low concentrations; however, iodine can be neutralized by exudates.[47] Chlorhexidine gluconate at antimicrobial concentrations is not recommended because it can cause severe inflammation of the guttural pouch mucosa.[48] In one horse with empyema that did not respond to saline lavage, infusion of acetylcysteine on four occasions appeared to hasten resolution.[49] However, despite its ability to disrupt disulfide bonds of mucoproteins, acetylcysteine does not alter the viscosity of purulent material in clot tubes compared with the use of saline alone.[49] Additional clinical experiences with acetylcysteine have demonstrated a lack of efficacy for removing inspissated material and chondroids, and there is some concern that it could exacerbate mucosal inflammation.[46] Systemic antibiotics are rarely indicated unless the response to topical treatment is poor or the infection is severe. Drugs of choice are a potentiated sulfonamide, penicillin, or ceftiofur for at least 21 days.[45] Nonsteroidal anti-inflammatory drugs may be used as needed.

Chondroids can be removed by maceration, followed by saline lavage or extraction by endoscopically guided grabbing forceps, a basket snare, or a memory-helical polyp retrieval basket.[45] Another technique involves repeated section of each mass by a diathermic snare or a wire loop, with removal by suction, lavage, or extraction by basket-type endoscopic forceps (Gomco Equipment).[50] In one study, 44% of horses with chondroids were treated successfully by these noninvasive methods, although such methods can be slow and tedious.[41]

If the response to medical treatment is poor or chondroids have formed, surgical drainage of the guttural pouch should be considered (discussed later). Even when accumulated inspissated pus or chondroids have caused little external distention, the amount of material that can be removed surgically can far exceed what one might expect to be the maximum capacity of the guttural pouch. After surgery, the approach incision should be left open to drain and to allow repeated lavage and endoscopy of the pouch. In horses with severe dyspnea caused by guttural pouch distention, a tracheotomy should be performed.

If empyema is the result of occlusion of guttural pouch openings by adhesions, this occlusion may be relieved by blunt division through a surgical approach to the guttural pouch interior.[45] Chronic empyema of the guttural pouches, possibly unresponsive to medical therapy because of poor drainage through the pharyngeal ostia, can be successfully treated by using a laser to establish a permanent pharyngeal fistula into the guttural pouch.[38] In a pony with chondroids and occlusion of the pharyngeal ostium on the affected side by deformity and a fibrotic adhesion, the median septum was fenestrated from the healthy opposite guttural pouch with the Nd:YAG laser as a standing procedure.[51] This allowed immediate drainage of purulent material through the healthy side and repeated access for endoscopic snare or basket removal of all the chondroids. This approach was selected over the creation of a salpingopharyngeal fistula because a catheter could not be inserted into the diseased pouch to guide safe and effective laser penetration from the pharynx.[51]

Prognosis

Response to medical treatment and surgery is usually satisfactory. Neurologic signs usually resolve when the infection is brought under control.

Guttural Pouch Mycosis

Guttural pouch mycosis affects the roof of one guttural pouch, rarely both. There is no apparent age, sex, breed, or geographic predisposition to this disease, and it has been reported in foals.[52,53] The cause of guttural pouch mycosis is unknown, although *Aspergillus* spp can be identified in the lesion, typically as the only fungus or in combination with another.[54] *Aspergillus fumigatus* is the most common isolate, and it is more likely to be found by direct examination of biopsies than by culture.[54] The typical lesion of guttural pouch mycosis is a diphtheritic membrane of variable size, composed of necrotic tissue, cell debris, a variety of bacteria, and fungal mycelia.[28] Aneurysm formation rarely precedes or follows arterial invasion[53] and therefore is not essential to the pathogenesis of arterial rupture.

Clinical Signs

The most common clinical sign is moderate to severe epistaxis, which is caused by fungal erosion of the ICA in most cases (Figure 46-7) and of the ECA and maxillary arteries MA in approximately one third of cases (Figure 46-8, and see Figure 46-3).[52,55-59] However, any branch of the ECA, such as the caudal auricular artery, can be affected. Several bouts of hemorrhage usually precede a fatal episode. Mucus and dark blood continue to drain from the nostril on the affected side for days after acute hemorrhage ceases.

The second most common clinical sign is dysphagia caused by damage to the pharyngeal branches of the vagus and glossopharyngeal nerves (see Figure 46-7).[57] Aspiration pneumonia

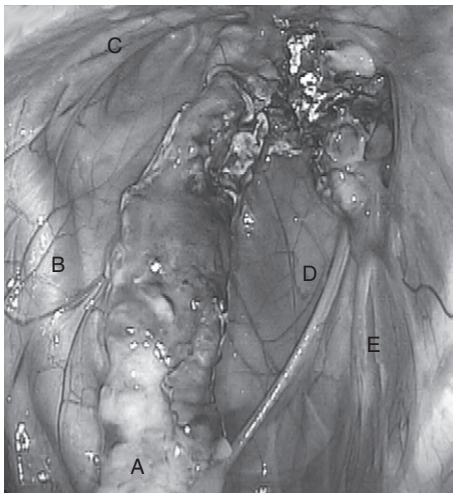

Figure 46-7. Guttural pouch mycosis in the typical location on the roof of the medial compartment (right guttural pouch) involving the internal carotid artery and causing epistaxis. *A,* Stylohyoid bone covered with diphtheritic membrane; *B,* external carotid artery; *C,* maxillary artery; *D,* mucosal fold that contains the glossopharyngeal and hypoglossal nerves; *E,* internal carotid artery. Extension of the plaque along the stylohyoid bone is not unusual and is rarely if ever clinically significant.

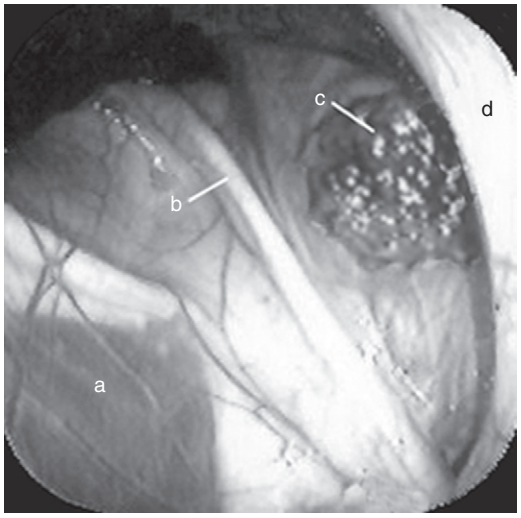

Figure 46-8. Roof of the left guttural pouch as viewed through retroflexion of the endoscope. *a*, Insertion of ventral straight muscles of the head; *b*, cartilaginous flap of the eustachian tube; *c*, mycotic lesion on the left maxillary artery; *d*, dorsal edge of the stylohyoid bone. This approach provides an excellent view of these structures when the rostral end of the guttural pouch is obscured with hemorrhage.

may develop in severe or protracted cases. Abnormal respiratory noise can arise from pharyngeal paresis or laryngeal hemiplegia, the latter as a result of recurrent laryngeal nerve damage.[57] Horner's syndrome may develop from damage to the cranial cervical ganglion and postganglionic sympathetic fibers. The classic signs associated with this denervation are ptosis, miosis, and enophthalmos; patchy cervical sweating; and congestion of the nasal mucosa. The reason for equine sweat glands to increase their activity when denervated is unclear.[60] Equine sweat gland myoepithelium is predominantly under α_2-adrenergic control, with additional α-adrenergic input from receptors.[60] However, sweating after neurectomy may be caused by increased peripheral vasodilation, which increases blood flow and skin temperature.[60] Ptosis is caused by a decreased tone of the superior tarsus muscle, and it is assessed by observing eyelash angles from a frontal view.[60] Pupillary response to decreased sympathetic tone in horses is variable, and the maximal difference in pupil size is usually slight.[60] Enophthalmos, which is the result of decreased smooth muscle retrobulbar tone and unopposed activity of the striated retractor bulbi muscle, is rarely obvious and usually evident as a slight protrusion of the nictitating membrane.[60]

Less common signs of guttural pouch mycosis that can develop singly or in combination with others are parotid pain, mucopurulent nasal discharge, abnormal head posture, head shyness, sweating and shivering, corneal ulcers, colic, blindness, locomotion disturbances, facial nerve paralysis, paralysis of the tongue, and septic arthritis of the atlantooccipital joint.[57-58,61-64]

Diagnosis

Endoscopy is critical for diagnosis, and it should be combined with history and clinical signs. On endoscopic examination of a horse with epistaxis, blood can be seen draining from the pharyngeal orifice. In horses with dysphagia, the roof of the pharynx can be collapsed, the soft palate can be displaced, and the nasopharynx may contain food material. The lesion appears as a white, tan, and black diphtheritic membrane on the roof of the affected guttural pouch (see Figure 46-7), and its size can vary but bears no relationship to the severity of clinical signs. Part of the diphtheritic membrane can coat the stylohyoid bone and the bone can be thickened, but clinical signs usually do not develop from this change. Fistulas may form into the opposite guttural pouch and pharynx[55] and true bilateral involvement has been described in 6 of 31 horses in one report.[53] The presence of serum antibodies to *Aspergillus fumigatus* detected by enzyme-linked immunosorbent assay (ELISA) cannot distinguish between horses with guttural pouch mycosis and healthy horses.[65]

Treatment

NONSURGICAL TREATMENT

The response to topical treatment is generally slow and inconsistent. Daily direct lavage through the endoscope can macerate the diphtheritic membrane, and the biopsy forceps or cytology brush of the endoscope can be used to detach it, provided any eroded artery was occluded beforehand. Topical povidone-iodine or thiabendazole, with or without dimethyl sulfoxide, has been used with mixed results.[55,59,64,66] Nystatin, natamycin, and miconazole have little activity against *Aspergillus* spp, but amphotericin B is effective against this organism, although systemic administration in the horse is limited by its toxicity.[67] Successful delivery of topical medication to the typical site of infection on the roof of the guttural pouch can be accomplished by transendoscopic delivery of a liquid preparation or by insufflation of a powder through a Neilson catheter using an enema syringe.[68]

Successful treatment of dysphagia from guttural pouch mycosis has been reported with a combination of itraconazole (5 mg/kg body weight PO) and topical enilconazole (60 mL of 33.3 mg/mL solution per daily flush) in one horse and with topical enilconazole alone in another.[66,69] Itraconazole at 3 mg/

kg twice a day in the feed can be effective against *Aspergillus* and other fungi in the nasal passage of horses, but treatment may be required for up to 4 or 5 months.[70] Bioavailability of another triazole antifungal agent, fluconazole, can be sufficiently high after oral and intravenous administration in horses to suggest a potential value in treatment of fungal infections.[71]

The response to any treatment method that is measured solely by disappearance of the mycotic lesion should be interpreted with caution because spontaneous regression of the lesion over a variable time course is typical. Horses with blood loss should be treated with polyionic fluids and, if necessary, with blood transfusions, and horses with dysphagia should be fed by nasogastric tube or by esophagostomy and should receive nonsteroidal anti-inflammatory drugs to reduce neuritis.

SURGICAL TREATMENT

The diphtheritic membrane can be detached by gentle swabbing and lavage through a modified Whitehouse approach. This treatment does not eliminate the risk of hemorrhage completely, and it does not retard or reverse progression of neurologic signs, but it does carry the risk of iatrogenic nerve damage and hemorrhage. In horses with epistaxis, the affected artery should be identified by endoscopy and surgically occluded (discussed later). There is some evidence that occlusion of the affected artery hastens spontaneous resolution of the mycotic lesion and thereby renders medical therapy unnecessary.[72] However, this is controversial and must be balanced against evidence that the mycotic plaque can undergo spontaneous regression[57] and within timeframes similar to those described in many horses that underwent arterial occlusion.[53,72] In a report on angiography and transarterial coil embolization in a large series of cases, the fungal lesion regressed completely on endoscopic examination between 30 and 180 days and incompletely between 51 and 269 days.[53] Such timeframes would be difficult to regard as hastened resolution. Also, a single case was reported in which the mycosis progressed and neurologic signs developed after coil embolization of the ICA.[73] Therefore the available evidence suggests that the effects of arterial occlusion on resolution of the mycosis is unknown.

Prognosis

Approximately 50% of horses with hemorrhage die from this complication, but this risk can be abolished or considerably reduced by the occlusion procedures described later.[57] These procedures must be performed as soon as possible after the first bout of hemorrhage to prevent subsequent bouts that could render the horse a poor candidate for anesthesia and surgery.

Although the mycotic lesion disappears with time, this is a very slow process,[53] and neurologic signs can persist after the lesion has disappeared. Recurrent laryngeal neuropathy is one of the more common clnical signs,[53] is typically permanent, but recovery has been reported.[58] Some horses with dysphagia eventually recover, but 6 to 18 months may be required and recovery may be incomplete.[57,58] Most horses recover from Horner's syndrome and facial nerve paralysis.[53]

Rupture of the Ventral Straight Muscles

Rupture of ventral straight muscles of the head (the longus capitis muscle and rectus capitis ventralis muscle) is usually caused by trauma, such as falling over backward, and it can cause severe epistaxis.[17] A nondisplaced impaction fracture at the basisphenoid–basioccipital junction associated with this injury can cause neurologic signs from subdural hemorrhage over the cerebral cortex and brain stem.[74] The same injury may occur without causing epistaxis.[74]

Clinical Signs and Diagnosis

Rupture of the ventral straight muscles causes severe epistaxis, as does guttural pouch mycosis.[18] Some horses show ataxia and other neurologic signs, and hemorrhage from torn muscle into the retropharyngeal tissues can compress the pharynx and even the trachea and cause respiratory obstruction.[17] Rupture of the ventral straight muscles is distinguished from guttural pouch mycosis by a history of trauma with the former, if such history is available, and by endoscopy.[17] In horses with rupture of the ventral straight muscles, the roof of the pharynx is collapsed and both guttural pouches are affected, usually more so on one side than on the other. Unlike in guttural pouch mycosis, the major arteries and the more caudal aspects of the guttural pouches are not involved, and there is no evidence of a diphtheritic membrane (Figure 46-9). Although some dark blood can be seen in the most rostral aspect of the pouch, it usually obscures the view of this area. A more complete view of the source of hemorrhage and swollen muscle bellies can be seen by retroversion of the endoscope (see Figure 46-8).[17] After swelling and inflammation from the original injury have subsided, any displaced bone fragment from a basisphenoid–basioccipital avulsion fracture can be seen on endoscopic examination of the medial compartment of the guttural pouch.[75]

On radiographs, partial obliteration of the guttural pouch by increased soft tissue density, soft tissue impingement on the roof of the pharynx, gas in soft tissues of the head and neck, and even avulsions of the basisphenoid bone may be evident (Figure 46-10).[75] The size and extent of the hematoma and gas in soft tissues can be determined by an ultrasonographic examination.

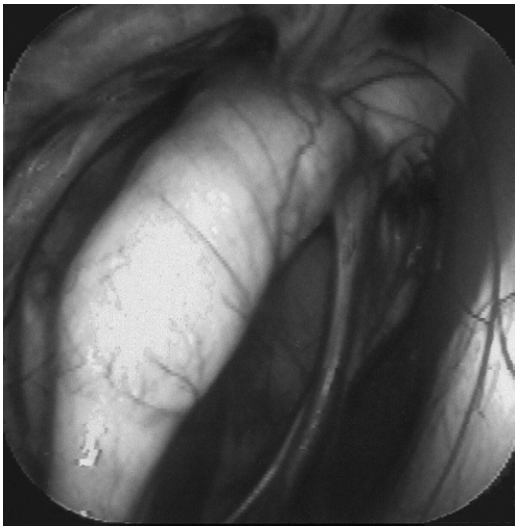

Figure 46-11. Thickened stylohyoid bone with involvement of the temporohyoid articulation in a horse with clinical signs of damage to the vestibulocochlear and facial nerves.

Treatment and Prognosis

Treatment is stall rest for 4 to 6 weeks and limiting head and neck movement that could disturb the damaged muscles and precipitate hemorrhage. Antibiotics are given to prevent secondary infections through the disrupted mucosa. The prognosis is good provided there are no neurologic signs, because these can be permanent and life threatening.[17] Severe neurologic signs, such as inability to rise, depression, and sluggish menace response, may be caused by an associated subdural hemorrhage overlying the cerebral cortex and brain stem and can warrant euthanasia.[74]

Temporohyoid Osteoarthropathy (Middle Ear Disease)

Temporohyoid osteoarthropathy (THO) is a progressive disease of the middle ear and components of the temporohyoid joint, such as the stylohyoid bone, the cartilaginous tympanohyoid, and the squamous portion of the temporal bone.[76] Horses of a wide age range and of any breed or either sex can be affected.[76] The cause is thought to be an inner or a middle ear infection of hematogenous origin that spreads to the aforementioned bones, causing them to thicken and the temporohyoid joint to fuse.[76] Other possible causes range from extension of otitis media or externa infection or guttural pouch infection to a nonseptic osteoarthritis.[77-80] Although guttural pouch mycosis can involve the same bony structures and temporohyoid articulation, clinical signs of temporohyoid osteoarthropathy are rare with this disease.[57] Recent CT and histopathologic evidence of an age-related and bilateral increase in severity of degenerative changes in the normal equine temporohyoid joint, although milder than the changes in horses with THO, suggest that degenerative, rather than infectious processes could underlie development of this disease.[13]

When the temporohyoid joint fuses and the associated bones thicken, forces generated by movement of the tongue and larynx during swallowing, vocalizing, combined head and neck movements, oral or dental examinations, and teeth floating may induce fractures of the petrous part of the temporal bone, resulting in facial nerve (CN VII) and vestibulocochlear nerve (CN VIII) dysfunction.[77-81] Severe new bone production and inflammation can damage the glossopharyngeal and vagus nerves where they leave the medulla caudal to the vestibulocochlear nerve.[1,82] After fracture of the petrous temporal bone, middle or inner ear infection could extend around the brain stem and involve additional cranial nerves and hindbrain structures.

Clinical Signs and Diagnosis

Early signs include head tossing, ear rubbing, refusing to take the bit, refusing to position the head properly when under saddle, resistance to digital pressure around the base of the ears or on the basihyoid bone, and other nonspecific behavioral changes.[76] The disease can cause an acute onset of signs consistently referable to the vestibulotrochlear nerve, including asymmetric ataxia, head tilt with the poll to the affected side, and spontaneous nystagmus with the slow component to the affected side.[76] These signs can be revealed or exacerbated by blindfolding. Signs of facial nerve damage, including paresis or paralysis of the ear on the affected side, deviation of the upper lip away from the affected side, decreased tear production, and inability to close the eyes, are evident in most cases.[81,82] Decreased tear production and inability to close the eyes may cause corneal ulcers, keratoconjunctivitis sicca, and exposure keratitis.[81,82] Dysphagia is rare but can result from damage to the glossopharyngeal and vagus nerves.[76]

Radiographs of the skull may depict proliferation and osteitis of the affected bones; however, endoscopy of the guttural pouch is in most cases a more sensitive method for detecting stylohyoid bone and temporohyoid joint involvement and hence for making the diagnosis (Figure 46-11).[83] Both sides should always be examined, because the disease can be bilateral, with only the more severely affected side showing obvious clinical signs.

Computed tomography (CT) can precisely demonstrate bony and soft tissue changes in the middle and inner ear,[16]

and consistently demonstrates osseous proliferation of the stylohyoid bone and temporohyoid articulation.[12] Also, thickening of the ceratohyoid bone and proliferation of its articulation with the stylohyoid bone can be identified on CT and these changes could have surgical implications.[12] The CT evaluation can also identify subclinical bilateral disease in horses determined to be unilaterally affected based on clinical examination. The stylohyoid bone is significantly wider in horses with neurologic deficits compared with the subclinically affected side.[12]

Treatment and Prognosis

Medical treatment includes broad-spectrum antibiotics for infection, nonsteroidal anti-inflammatory drugs to relieve pain and inflammation, and dimethyl sulfoxide to relieve inflammation.[76,84] Unilateral partial ostectomy of the stylohyoid bone has been used to create a pseudoarthrosis between the cut ends of the bone (Figure 46-12), which decreases the forces on the ankylosed temporohyoid joint and thereby prevents skull fractures.[84] In this procedure, approximately 2 to 3 cm (1 to 1½ inches) of the midbody of the stylohyoid bone is removed (see Figure 46-12). Although this procedure appears to have merit as a prophylactic measure against more-severe bone damage and associated neurologic consequences, it may cause transient dysphagia or injury to the hypoglossal nerve.[84] When performed as a bilateral procedure, it causes permanent problems with prehension.[84]

An additional complication of the partial ostectomy is regrowth of the stylohyoid bone approximately 6 months after surgical resection and recurrence of clinical signs.[82] Because of this complication, a ceratohyoidectomy can be performed as a safer, easier, and more permanent surgical alternative (see Figure 46-12).[82] For this, the horse is placed in dorsal recumbency and the ventral laryngeal region is prepared aseptically. A 10- to 15-cm (4½- to 7-inch) incision is made in the skin medial to the linguofacial vein on the affected side and centered on the basihyoid bone, approximately 2 cm from the midline as it crosses the basihyoid bone.[82] The fibers of the sternohyoid muscle are separated bluntly until the basihyoid bone is exposed. Rostral to the basihyoid bone, the geniohyoid muscle is separated to expose the ceratohyoid bone and, lateral to it, the hypoglossal nerve. The ceratohyoid–basihyoid synovial joint is identified and disarticulated with cartilage scissors. The transected end of the ceratohyoid bone is grasped and the ceratohyoid bone is freed from its attachments to the ceratohyoideus, the hyoideus transversus, and the genioglossus muscles. The hypoglossal nerve and lingual branches of the mandibular and glossopharyngeal nerves can be identified and gently retracted to protect them during these steps. An alternative is to separate the ceratohyoid bone from its soft tissue attachments with a narrow osteotome or periosteal elevator, thereby keeping dissection close to the bone and avoiding the need to expose the adjacent nerves. The cartilaginous articulation between the ceratohyoid bone and the stylohyoid bone is cut by cartilage scissors or continued elevation with the osteotome, taking care to avoid tension on the bone and temporohyoid joint. The separated muscle fibers can be sutured over the defect created by dissection to prevent reattachment of the bone ends, but the benefit of this step is unknown and could be regarded as optional. Subcutaneous tissues and skin are subsequently closed in routine fashion.

Although the prognosis is good according to one report, neurologic signs may persist in the majority of horses, especially if treatment is delayed.[77,83] Some degree of facial nerve paresis can persist.[7] In a study in which most horses were treated medically, some residual cranial nerve deficit persisted in the majority of horses, a year or longer was required for maximal improvement, and prognosis for return to some type of athletic function was fair.[80] In another study, substantial improvement was recorded at 1 year after surgery in 89% of horses that underwent a ceratohyoidectomy and in 87% that had a partial stylohyoid ostectomy, with most of the improvement developping within the first 6 months.[85] The corneal ulcers are difficult to treat, because there is an underlying problem with lid closure and tear production. A temporary tarsorrhaphy may help to manage the ocular complications until facial nerve function returns.

Miscellaneous

Although guttural pouch neoplasia is rare, squamous cell carcinoma, round cell sarcoma, fibroma, hemangioma, hemangiosarcoma, and parotid melanoma have been described.[11,86-92] In one case, bilateral squamous cell carcinoma of the guttural pouches and the left middle ear was initially evident as protrusion of a mass in one external acoustic meatus, without other obvious clinical signs.[89]

Parotid melanomatosis can appear as multilobular or multiple individual firm lumps in the parotid region of gray horses with extension into the guttural pouches (Figure 46-13) and may cause dyspnea and dysphagia from compression of the nasopharynx and larynx and facial nerve paralysis from compression of the facial nerve.[86,88] In one case, a malignant amelanotic melanoma caused halitosis, nasal discharge, and cough by

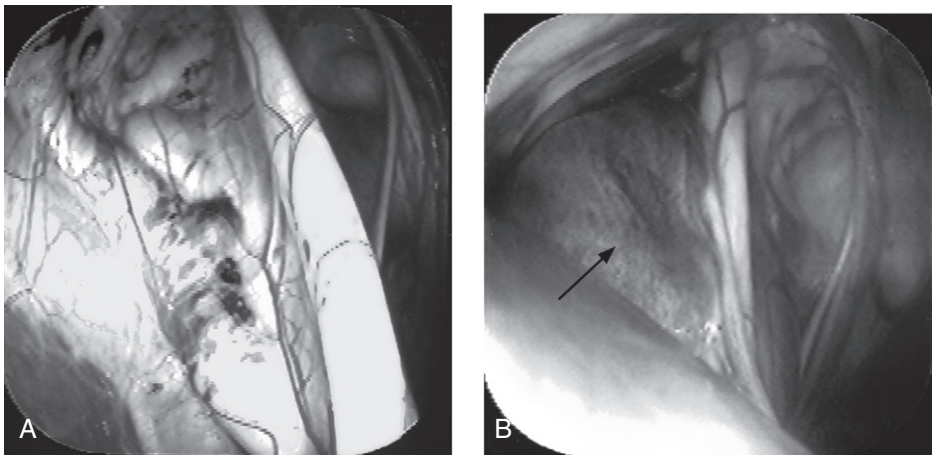

Figure 46-13. Endoscopic views of two horses with melanomas in the lateral compartments of their left guttural pouches that were not causing clinical problems. **A,** Typical melanin staining is scattered along the course of the external carotid artery and branches in an old gray horse without any external evidence of parotid involvement. **B,** A larger lesion *(arrow)* fills the lateral compartment and is evident externally as a firm mass over the parotid gland.

This foal had nasal discharge, but the role of the cysts could not be established, there were no other clinical signs referable to them, and they were not treated.

undergoing central necrosis that extended from the guttural pouch into the pharynx.[18] The rate of growth of melanomas is variable and can be rapid after a prolonged initial growth, but even clinically evident lesions can be well tolerated in sedentary horses and allow years of continued health.[86,88] Smaller lesions may not be evident externally, and it is not unusual to find small discrete and scattered submucosal black patches and nodules in the guttural pouch of gray horses (see Figure 46-13). These are unlikely to cause problems. Extensive tumors may infiltrate the parotid gland without apparent lymph node involvement. Surgical resection is rarely indicated and is impossible in most cases because of the extent of infiltration and the close association with vital structures.[86]

Fracture of the stylohyoid bone can be secondary to guttural pouch mycosis or trauma.[11,28,86] Bone necrosis can follow, and clinical signs include dysphagia, pharyngeal swelling, empyema, keratoconjunctivitis sicca, and abscessation.[11,57,81] Reported foreign bodies include segments of catheters and wire.[93] Cystic structures have been described as causes of guttural pouch swelling and dyspnea in young horses (Figure 46-14) and respond favorably to surgical resection and fenestration in the median septum between the two guttural pouches.[94] The cause is unknown, but this lesion could be congenital or acquired.[94]

SURGICAL DRAINAGE OF THE GUTTURAL POUCH

The following approaches can be used to open the guttural pouch for removal of pus, mycotic plaques, and foreign bodies and to establish drainage.

Hyovertebrotomy

A 10-cm–long incision is made 2 cm cranial to and parallel to the wing of the atlas (Figure 46-15). The dense parotid fascia is incised, and the parotid gland and overlying parotidoauricularis muscle are reflected craniad. The guttural pouch lining is exposed beneath a covering of areolar tissue and grasped with rat-toothed or Allis tissue forceps. It is punctured with the closed tips of scissors or a hemostat, and this opening is enlarged by spreading its edges with a hemostat or the fingers. To establish ventral drainage, the pouch is opened ventrally through an incision in Viborg's triangle, guided by a finger within the

pouch. The hyovertebrotomy can be closed or left partly open for infusion of irrigating solutions.

Viborg's Triangle Approach

Viborg's triangle is bordered by the tendon of the sternocephalicus muscle, the linguofacial vein, and the vertical ramus of the mandible (see Figure 46-15). A vertical or horizontal incision is made in this area, taking care to avoid the parotid duct and branches of the vagus nerve along the floor of the guttural pouch. The incision is usually kept open with a soft rubber drain to establish ventral drainage.

Whitehouse Approach

With the horse in dorsal recumbency, a skin incision is made on the ventral midline over the larynx (see Figure 46-15). Dissection is continued between the paired sternohyoideus and omohyoideus muscles and along the larynx to the affected guttural pouch. The guttural pouch is opened medial to the stylohyoid bone, and care is taken to avoid the pharyngeal branch of the vagus nerve and the cranial laryngeal nerve, which are close to the incision.

Modified Whitehouse Approach

In the modified Whitehouse approach, the 12-cm skin incision is made along the ventral edge of the linguofacial artery and vein as if for a laryngoplasty, except 4 to 6 cm further rostrad (see Figure 46-15). The underlying fascia is incised to expose the lateral aspect of the larynx, and blunt dissection is continued until the guttural pouch cavity has been entered. Dissection through a natural fascial plane and avoidance of an incision between the sternohyoideus and omohyoideus muscles represent the the major advantages of this modification.

Advantages of both Whitehouse approaches are direct access to the roof of the guttural pouch, digital access to the lateral compartment, excellent ventral drainage, and simultaneous access through the septum to both compartments. Although both approaches involve deep dissection, they do not appear to have a higher rate of complications than the other approaches. The modified Whitehouse approach has been used in standing horses for management of guttural pouch empyema with inspissated pus.[43]

Modified Garm's Technique

A modified Garm's technique allows access to the lateral compartment of the guttural pouch and can be performed safely as a standing procedure for lavage and drainage in horses with mild empyema.[95] For this approach, a 6-cm skin incision is made 4 cm more rostrally than in Garm's original technique, between the ramus of the mandible and the submandibular lymph node.[95] Blind digital dissection is continued by this approach to the rostroventral aspect of the lateral compartment, where the mucosa can be perforated without risk to important vessels or nerves.[95] Because of the depth of dissection and the tight path created, little can be accomplished through this route except to insert a tube for lavage.

General Comments

Surgery of the guttural pouch through any approach should be a last resort because of risks of iatrogenic nerve damage. Identification of the guttural pouch lining and underlying nerves is difficult, especially in cases in which there is no distention, and can be facilitated by a lighted endoscope inserted into the medial compartment. A fixed structure, such as the stylohyoid bone, should be used as a guide for deep dissection, and entry through the guttural pouch lining is most safely accomplished by blunt penetration with the closed tips of a hemostat. The mucosa should not be incised with a scalpel, scissors, or other sharp instruments, and sharp-pointed retractors should be applied with care or preferably not at all to avoid nerve damage. Because all approaches enter the pouch cavity in the same approximate area, none provides less risk of nerve damage than others.

Open incisions in the guttural pouch are cleaned daily, and the guttural pouch cavity should be flushed daily with a nonirritating solution. Open incisions close spontaneously within 14 days, and the infection should also resolve within this time. Postoperative antibiotics can be given.

PROCEDURES FOR ARTERIAL OCCLUSION

In a horse with hemorrhage caused by guttural pouch mycosis, the involved artery or arteries should be occluded by one of the following procedures, or a combination of them, as soon as the diagnosis is made. The vessel to be occluded is determined by endoscopy. If accurate identification is impossible because landmarks are obscured by blood and/or a diphtheritic membrane, all arteries in the pouch should be occluded, and this can be done safely.[52] Arteriography may also be used to identify the affected vessel and unusual vascular anatomy.[96]

Ligation of the Common Carotid Artery and Branches

In horses with guttural pouch mycosis, fatal or severe hemorrhage has followed ligation of the affected ICA and could be attributed to occlusion of the wrong vessel or to retrograde flow, as from the cerebral arterial circle (circle of Willis).[56,58,97,98] A study was performed on six anesthetized adult horses to determine the effects of selective arterial occlusion on blood flow through the common carotid artery (CCA) and its branches and to thereby establish the most effective ligation for horses with life-threatening hemorrhage from these vessels.[99] Compared with control values, flow through the left ICA was reduced to 38% by simultaneous occlusion of the left and right CCA and to 19% by occlusion of the left ICA.[99] Occlusion of the left mid-cervical CCA induced retrograde flow through the left ICA that was 40% greater than control flow.[99] In the same study, flow through the left ECA was reduced to 30% of control values by occlusion of the left mid-cervical CCA or by simultaneous occlusion of the left and right CCA. Occlusion of the ECA or combined occlusion of the ECA and the major palatine artery reduced flow through the ECA to 1% of control values.[99] However, these data provide no information on blood pressure, which could remain sufficient after some of these ligations to cause substantial hemorrhage. Blood pressure in the segment of ICA in the guttural pouch is not reduced by ligation and is maintained for at least 3 days afterward at the same level as in the contralateral patent artery.[100]

Based on the preceding findings, ligation of the ipsilateral CCA in a horse bleeding from the ICA would increase flow in the affected artery and would be contraindicated; however, the same procedure may provide some immediate benefit in horses bleeding from the ECA and its branches, although any such benefit could be temporary.[56,58,99] Ligation of the affected ICA would decrease flow but not pressure, so bleeding could persist or recur; however, if access to definitive occlusion procedures is not immediate during a severe bleeding crisis, induction of general anesthesia to quiet the horse and ligation of the affected ICA could be attempted.

Success with ligation of the ICA can be attributed to development of a thrombus distal to the ligature over some time after surgery.[56,58] To prevent backflow, an additional ligature can be placed distal to the mycotic infection; however, this is difficult because the artery must be ligated deep within the guttural pouch, where it is likely to be obscured by the diphtheritic membrane.[98] The site for ligation of the ICA is immediately distal to its origin, outside the guttural pouch, using a similar but more ventral approach to a hyovertebrotomy (see Figure 46-15). The ICA is identified on the cardiac side of the occipital artery and deep to that vessel. In some horses, both arteries arise as a single trunk. If necessary, both ICAs can be ligated simultaneously without any apparent risk.[56,97] A transendoscopic clip ligation of the ICA has been evaluated for the standing sedated horse and was used successfully in 4 horses with epistaxis caused by guttural pouch mycosis.[101] However, critical details about the procedure are lacking.

The ECA can be ligated distal to the origin of the linguofacial trunk through an incision similar to that used for the ICA ligation but after extensive rostral dissection.[59] However, this procedure is generally unsuccessful because the ECA and MA have numerous collateral channels that allow retrograde flow to the affected segment.[1,52] Although ligation of the major palatine artery could prevent retrograde flow, a combination of this procedure with ligation of the ECA and ICA can cause ischemic optic neuropathy and permanent blindness.[102]

Balloon Catheter Occlusion of the Internal Carotid Artery

The balloon catheter technique allows immediate intravascular occlusion of the artery and prevents retrograde flow to the site of hemorrhage from the cerebral arterial circle (circle of Willis).[55,103] The ICA is ligated close to its origin, and an arteriotomy is made distal to the ligature (Figure 46-16). A size 6 French venous thrombectomy catheter is inserted through the

(Redrawn from Caron JP, Fretz PB, Bailey JV, et al: Balloon-tipped catheter arterial occlusion for prevention of hemorrhage caused by guttural pouch mycosis: 13 cases. J Am Vet Assoc 191:345, 1987; and Smith KM, Barber SM: Guttural pouch hemorrhage associated with lesions of the maxillary artery in horses. Can Vet J 25:239, 1984.)

arteriotomy for a distance of approximately 13 cm.[103] At this distance, the balloon tip of the catheter is arrested at the sigmoid flexure of the ICA, within the venous sinuses and distal to the site of infection (see Figure 46-16). Fluoroscopy is not required to confirm placement, but intraoperative endoscopy can be helpful, although this can be difficult if landmarks are obscured by blood or the lesion. The catheter tip should be visible as it passes up the artery, and the balloon can be inflated at intervals to demonstrate its position. However, it does not distend the artery as dramatically as one would like, and this can make it difficult to locate. The balloon is inflated with sterile saline and secured in position by a ligature distal to the arteriotomy, and the redundant portion is buried as the incision is closed.

The horse may resume its usual activity when wound healing is complete and its packed cell volume has returned to normal. Perioperative antibiotics and nonsteroidal anti-inflammatory drugs can be used. It is not necessary to treat the fungal lesion or to remove the catheter after surgery, unless infection tracks along it and invades the surgical incision. For removal of the catheter, the horse is sedated and local anesthetic is infiltrated along and rostral to the original incision. A cut-down procedure is used to locate the coils of the catheter, which are then freed up and elevated. The balloon is deflated and the catheter is removed, usually with considerable traction to get it through the ligature distal to the site of insertion.

Complications

Complications associated with this procedure are rare.[52,55] The catheter rarely penetrates the defect in the artery, and if it does, it can be withdrawn and redirected. Alternatively, the catheter can be left in place to obstruct the hole while another catheter is directed alongside it. This mishap can be detected by intraoperative endoscopy. Infection of the surgical site should be treated by removing the catheter and establishing drainage, and it can be prevented by inflating the balloon to a sufficient diameter (at least 8 mm) to prevent displacement into the infected segment.[55,64] Delayed prolapse of the catheter through the hole in the artery into the guttural pouch is favored by the normal pressure distal to the balloon and the loss of pressure proximal to it (heart side). The use of the more rigid commercially available catheters can also prevent this complication. One of us treated a horse that had undergone balloon catheterization for guttural pouch mycosis 4 years before presenting with a draining tract at the site of catheter placement (Figure 46-17). Although the embolization catheter was removed with some difficulty, the horse developed a fever and severe seizures and was euthanized 2 days after catheter removal. The post-mortem finding of a septic meningitis demonstrates the importance of catheter removal when signs of infection are evident.

Failure to prevent fatal hemorrhage in one case was caused by inadvertent catheterization and occlusion of an aberrant branch from the ICA, which left the affected segment of artery open to retrograde blood flow.[104] To prevent this mishap, approximately 6 cm of the ICA should be exposed to locate any aberrant branch. Such a branch should be ligated so that the catheter can be maintained in the ICA.[104] The most troublesome anatomic aberration is an ICA that leads to the caudal cerebellar artery without following its usual pathway, and that places the inflated balloon in a position that causes neuronal necrosis of the brain stem. If a catheter cannot be inserted to the required distance or passes well beyond the 13-cm mark before it becomes arrested, then it is probably in an aberrant branch.

Figure 46-17. Lateral contrast fistulography of the a horse with a draining tract in the throatlatch of approximately 1 year's duration; the draining tract communicated with a previously placed ballooon-tipped catheter placed 4 years previously.

It may be difficult to distinguish between the occipital artery and ICA in some horses, especially those with a thick throatlatch and those in which both arteries arise as a single trunk and bifurcate at a variable distance from the CCA. If both arteries arise in the normal fashion, the recommended method for identification is to dissect them both free for a couple of centimeters and then elevate each one gently with umbilical tape or a Penrose drain. It should be possible to demonstrate that the ICA lies deep to the occipital artery and that it courses more rostrad.

Balloon Catheter Occlusion of the External Carotid Artery and Its Branches

The most likely source of retrograde flow to the ECA and its branches is the major palatine artery, which is a large continuation of the MA.[1,52] This joins the contralateral major palatine artery behind the upper row of incisor teeth to form a large arterial loop around the upper jaw. Attempts to occlude the MA by a single balloon-tipped catheter in the ECA have failed because the catheter tip can readily enter the superficial temporal artery rather than the MA (see Figure 46-16).[52,55] The following procedure was developed to overcome these difficulties.

To prevent normograde flow, the ECA is ligated after the linguofacial trunk branches and, to reduce retrograde flow, a size 6 French Fogarty venous thrombectomy catheter is inserted into the major palatine artery, 3 cm caudal to the corner incisor tooth.[52] This catheter is inserted retrograde for approximately 40 to 42 cm in a 450 kg horse, or the shortest distance from the arteriotomy to the articular tubercle of the temporal bone.[52] The balloon is partly inflated and the catheter is gently retracted until some resistance is encountered, at which point it is assumed that the balloon is at the caudal alar foramen (see Figure 46-16).[52] It is subsequently fully inflated with sterile saline. At this site, the balloon can obstruct retrograde flow to the MA (see Figure 46-16).

As an alternative to ligation, the ECA can be occluded distal to the origin of the linguofacial trunk by a balloon catheter

inserted through the transverse facial artery.[52] This obviates the difficulty of exposing the artery through a hyovertebrotomy and therefore is most useful in a horse that does not require ligation of the ICA. The catheter is inserted 3 cm rostral to the articular tubercle of the temporal bone and advanced in retrograde fashion until its tip enters the ECA (approximately 12 cm from the arteriotomy site in a 450-kg horse) (see Figure 46-16).[52] The balloon is inflated with saline. The redundant ends of catheters in the transverse facial and major palatine arteries are taped to the head or incorporated into a stockinette hood. These catheters are removed after 7 to 10 days without sedation or local anesthesia.

Although the MA has many collateral branches in the segment between the balloons, this procedure has been effective to date and does not cause blindness, even when combined with occlusion of the ICA.[52] This difference from ligation of the major palatine artery can be attributed to prevention of the "steal phenomenon" that occurs with ligation.[100,105] However, the owner should be warned of the risk of blindness in any procedure that involves occlusion of the ECA and its branches, even if the risk is very low.

Occlusion of the Internal Carotid Artery with a Detachable Balloon Catheter System

A detachable, self-sealing, latex balloon was described to successfully occlude the ICA without the need for catheter removal, as required in some cases treated with the nondetachable balloons.[106] Combined with angiography, the detachable system can also be used to occlude aberrant vessels that originate at a distance from the origin of the ICA.[107]

The ICA is approached as described earlier (see Figure 46-16), and a 3-cm segment, 1 to 2 cm distal to the origin of the ICA, is isolated between two Rummel tourniquets of umbilical tape and polyethylene tubing. The balloon delivery system consists of a Tuohy-Borst adapter (rotating Y adapter) that is attached to an 8-French, 95-cm nontapered, thin-walled guiding catheter (GC 8/95). A 2-French, 135-cm balloon-carrier microcatheter (Mini-Tourquer, CTFN 135) is placed through the adapter and guiding catheter, and an 8.5-mm–diameter, detachable, self-sealing latex balloon (GoldValve Balloon, GVB 17) inflated with 0.5 mL of a 1:1 solution of physiologic saline solution and 66.8% iothalamate sodium (Conray 400) is mounted onto the carrier microcatheter. The balloon is subsequently deflated, the carrier microcatheter is withdrawn so that the balloon is recessed 2 mm inside the guiding catheter, and the microcatheter is held in place by tightening the O-ring of the Tuohy-Borst adapter.[106]

A 19-gauge arterial access needle is inserted into the ICA between the ligatures, and a 0.9-mm guide wire is placed through the needle into the artery.[106] The needle is withdrawn over the wire and an 8-French introducer sheath (Pinnacle Introducer Sheath) is advanced over the wire for 4 cm. The dilator and wire are removed, and retrograde blood flow from the cerebral arterial circle is confirmed by bleed-back through the ancillary fluid port of the introducer sheath. Continuous infusion of heparinized saline solution (4 U/mL, approximately 3 mL/min) is then maintained through the introducer sheath. The balloon delivery system is inserted through the flexible diaphragm of the introducer sheath and advanced approximately 13 cm into the ICA or until resistance is met. The carrier microcatheter is advanced 5 to 10 mm within the guiding catheter while the guiding catheter is retracted 1 cm over the microcatheter. The balloon is subsequently inflated with 0.5 mL of the radiopaque solution, and its appropriate positioning and degree of inflation are confirmed by a single lateral intraoperative radiograph. The balloon is detached by gentle traction on the carrier microcatheter, and all proximal ligatures are secured. All catheters are withdrawn from the introducer sheath and immediate occlusion of the distal ICA is confirmed by lack of retrograde blood flow through the ancillary fluid port of the introducer sheath. The introducer sheath is subsequently removed and the proximal Rummel tourniquet is replaced with two ligatures of No. 0 polypropylene. The subcutaneous tissues and skin are closed in layers.

Transarterial Coil Embolization

A transarterial coil embolization technique can selectively occlude the arterial segments involved in a mycotic lesion in horses with guttural pouch mycosis.[53,108] The coil embolization technique combines angiographic studies to image the affected vessels and identify any unusual vessels and sites of bleeding, followed by a selective embolization or occlusion of the affected vessels. In this procedure, a stainless steel coil of appropriate size expands as it emerges from the catheter so that it becomes lodged within the artery, and the Dacron fibers on its surface induce rapid thrombosis in the occluded segment. Compared with the balloon catheter technique, transarterial coil embolization allows visualization of affected vessels throughout the procedure as it is performed under fluoroscopic guidance. This is critical, because aberrant vasculature has been described in horses with guttural pouch mycosis, and failure to identify and occlude such aberrant branches may result in fatal hemorrhage.[104,109] Also, this procedure eliminates the need to protect redundant ends of catheters, which is necessary when nondetachable balloons are used. It is less invasive than the original balloon catheter procedures and requires shorter anesthesia and shorter hospitalization. Transarterial embolization can be performed during active bleeding. The surgical approach for all arteries in the guttural pouch is the CCA exposed through a single incision.

Under general anesthesia, the horse is placed in lateral recumbency with the affected side uppermost, and the head and neck are placed on a radiolucent surface, such as a 30 × 30 cm sheet of Plexiglas, to allow intraoperative fluoroscopy to be performed (Figure 46-18).[110] The fluoroscopy unit must be mobile and covered with a sterile cover if it is to be manipulated intraoperatively by the surgeon. All surgical and anesthesia personnel must wear protective lead aprons during fluoroscopy (see Figure 46-18). The proximal aspect of the jugular groove is clipped and prepared and draped for aseptic surgery. Drapes must cover the front half of the horse, because catheters and guide wires used for the procedure are long and could get contaminated. All catheters, guide wires, and introducers are flushed with heparinized saline (10 IU/mL) and left soaking in a bowl containing heparinized saline until use. A single surgical approach is sufficient to allow access to all affected branches of the CCA, such as the ICA, the ECA, the MA, and aberrant branches (see Figure 46-18). In general, all four sites are occluded when lesions are extensive (see Figure 46-16) or when preoperative hemorrhage precludes identification of the affected vessel. When the lesion is focal, only the affected vessel is occluded.

Figure 46-18. Room organization for coil embolization techniques. The horse's head rests on a thick Plexiglas sheet supported by the surgery table and a surgery cart so that the fluoroscopy unit can be positioned more accurately. The fluoroscope head can be covered with a sterile drape if the surgeon is to manipulate it into position. The surgeon is directed by the image on the monitor to guide catheter advancement. Note the position of the radiation-shielding panels and that the surgeon is wearing radiation protection beneath the gown. The horse's head is exposed for demonstration purposes but should be covered with a sterile drape to prevent contamination of the long catheters.

Figure 46-19. The carotid artery is elevated with umbilical tape and is punctured with an angiographic needle. A 6-French introducer system (Cook Inc., Bloomington, IN) is inserted into the artery and guided toward the head.

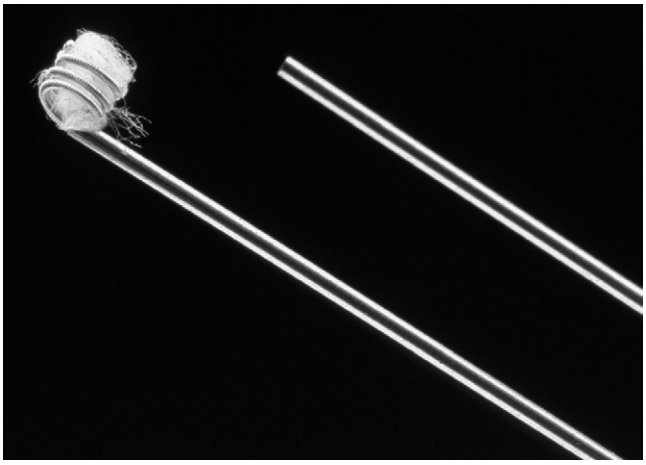

Figure 46-20. Microcoil used for coil embolization. The coils are made of stainless steel coated with Dacron fibers and presented in a stainless steel sheath. Coil formation is achieved by pushing the guide wire into the sheath *(right)* to deliver the coil *(left)* at the desired location.

An 8-cm skin incision is made at the junction of the proximal and middle thirds of the neck, just above the jugular vein.[110] This distal location is important to avoid exposure of the surgeon's hands during fluoroscopy (see Figure 46-18). The brachiocephalicus and omohyoid muscles are bluntly separated, and the carotid sheath is elevated by blunt finger dissection. The vagosympathetic trunk is carefully separated from the CCA and replaced within the incision. Care must be taken to prevent tension on the nerves, which could result in postoperative complications, such as Horner's syndrome or recurrent laryngeal neuropathy. The CCA is elevated with umbilical tape and is punctured with an angiographic needle. A 6-French introducer system is inserted in the artery and guided toward the head (Figure 46-19). The correct position of the introducer is verified by injection of contrast material before proceeding. Misdirection into the cranial thyroid artery precludes advancement of the angiography catheter and requires that the introducer be slightly withdrawn and repositioned into the CCA under fluoroscopic guidance. A 6-French single-end–hole nylon angiographic catheter is advanced rostrad into the CCA to the level of the ICA under fluoroscopic guidance. Coils pass less readily through polyvinylchloride or vinyl catheters, so these should not be used. Angiography is performed during catheter advancement by hand-injection of 3 to 5 mL of a 1 : 2 solution of iohexol in heparinized saline, or iodinated contrast material, to identify the path of each vessel. All injections are made using a double-flush technique through a three-way stopcock. To avoid embolization of thrombi that may have formed within the catheter, heparinized saline is flushed and aspirated before injection of contrast material. Injection of air must be avoided by carefully expelling air from all syringes and by performing injections with the piston of the syringe directed upward.

Preembolization angiography is mandatory for anatomic identification and location of the vessels, exclusion of vascular anomalies, abnormal vascular connections between the ICA and the occipital artery, and correct positioning of the embolization coils.[110] Small or aberrant arterial branches are present in up to one third of horses and require selective embolization. If a connection is present between two embolization sites, continued bleeding could still occur, and therefore such small branches must be occluded separately. The distal (cerebral) side of the lesion in the ICA is embolized first, to protect the cerebral circulation from any intraoperative errors, such as air or clot embolization. The distal ICA is embolized at the level of its superimposition on the basisphenoid bone and caudal to the sigmoid flexure. To select a coil diameter, an estimate of the width of the artery at the embolization site is made by using the known diameter (3 mm) of the angiography catheter as a guide. For the distal ICA coil, diameters of 5 to 8 mm are usually necessary, although 3 mm may be adequate in smaller horses or ponies. A Dacron fiber–covered, stainless steel, occluding spring embolization coil (Embolization Coils) of proper diameter is introduced through the catheter, while its tip is in the desired location, and pushed into the ICA by the stiff end of a guide wire (Figure 46-20). A coil slightly larger than the artery

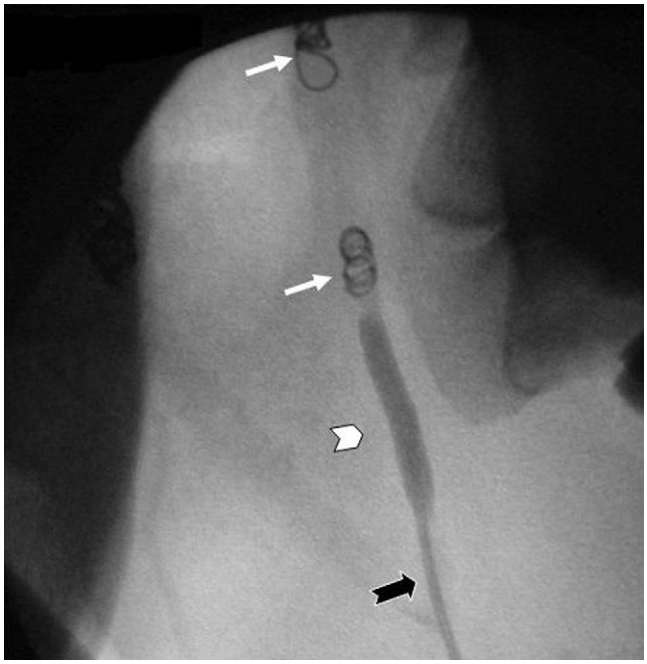

Figure 46-21. Fluoroscopic image obtained during coil embolization showing location of the distal and proximal coils within the internal carotid artery (*white arrows*), the contrast material with complete occlusion of the artery *(arrowhead),* and the angiography catheter within the internal carotid artery *(black arrow).*

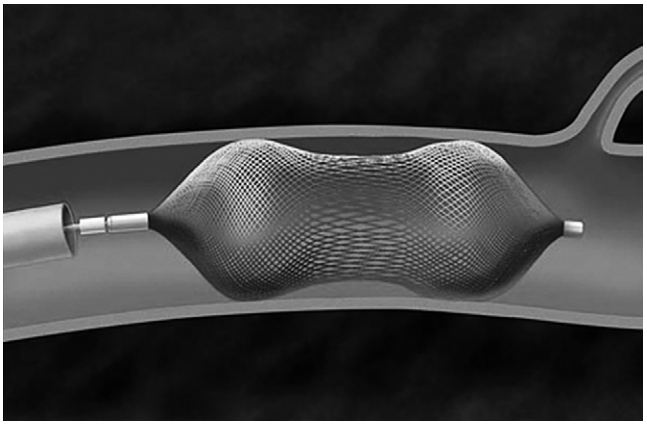

Figure 46-22. Nitinol intravascular plug in an appropriately sized artery demonstrating the dumbbell configuration when impacted at the desired level of obstruction.

is placed first, and additional smaller imbricating embolization coils follow until complete occlusion is obtained. To imbricate the coils, the tip of the catheter is placed within the previous coil.

After occlusion is verified by injection of contrast material, the proximal (cardiac) side of the ICA is embolized next, midway between the first embolization site and its origin from the CCA (Figure 46-21). After occlusion of the ICA, the catheter is withdrawn into the CCA and advanced to repeat the same procedure in the caudal MA and rostral ECA. The MA is embolized distal to the superficial temporal and proximal to the infraorbital, buccal, and mandibular alveolar arteries. Correct identification of the MA is verified by inserting the catheter farther and imaging the ophthalmic artery. The catheter is subsequently withdrawn until it is within the alar foramen, just distal to the curvature of the MA, and cranial to the most cranial aspect of the guttural pouch outline. Coils of 8 to 12 mm in diameter are necessary at this location. The ECA is embolized next, on the caudal (cardiac) side of the origin of the caudal auricular artery. The ECA requires the largest size and greatest number of coils to achieve immediate and complete occlusion, usually 10 to 15 mm diameter.

After coil placement, the catheter and introducer system are removed.[110] The CCA puncture site is closed using 5-0 silk in a cruciate pattern, and the muscle layers and skin are closed in three layers. Phenylbutazone is administered for 3 to 5 days after surgery to minimize inflammation at the incision site. Horses are rested for 30 days and then gradually returned to use.

The disadvantages of this technique are the need for fluoroscopy (and the specialized equipment and expertise involved), positioning of the horse's head for fluoroscopy, and radiation-shielding apparel and equipment. Although these disadvantages would limit this technique to a small number of well-equipped hospitals, coils have been implanted in the ICA using a cut-down procedure similar to that for the balloon catheters.[111,112] Placement can be determined as for balloon catheters and confirmed by lack of backflow through the arteriotomy and assessment of coil placement by radiography.[111] The same approach has been described with an allowance of 10 minutes after coil placement for a clot to form, followed by an injection of contrast material at 200 mm Hg for 3 seconds to determine occlusion.[112] This direct approach to the ICA also obviates the need for a proximal coil occlusion, because a ligature at the site of catheter insertion will prevent normograde flow. The major disadvantages of the cut-down procedure are failure to identify unusual anatomy and aberrant connections and to precisely position the microcoils.

Transarterial Nitinol Vascular Occlusion Plug Embolization

Transarterial occlusion using nitinol plugs was recently described in three horses.[113] A nitinol vascular plug is a self-expanding nickel-titanium wire mesh that deforms from its fully expanded cylindrical shape to a dumbbell configuration when delivered into the vessel to be occluded (Figure 46-22). Both ends are marked with radiopaque platinum marker bands (Figure 46-23) and one end is attached at to a flexible delivery cable from which the plug can be detached as needed by counterclockwise rotation. The procedure is performed under fluoroscopic guidance using an approach similar to that for coil embolization. When the CCA has been isolated, a 7-French vascular access sheath is introduced and angiography is performed. Vascular plugs are placed on the cardiac and cerebral side of the lesion, as with other occlusion techniques; the size needed is based on angiography, with the diameter being 130% to 150% of the angiographic diameter of the artery at the proposed site of occlusion. Available sizes range from 4 to 16 mm.[113] As with other occlusion techniques, if the location of the bleed cannot be identified either preoperatively or intraoperatively, all possible sites should be occluded, because at least one third of the lesions involve the MA. This would require using six vascular

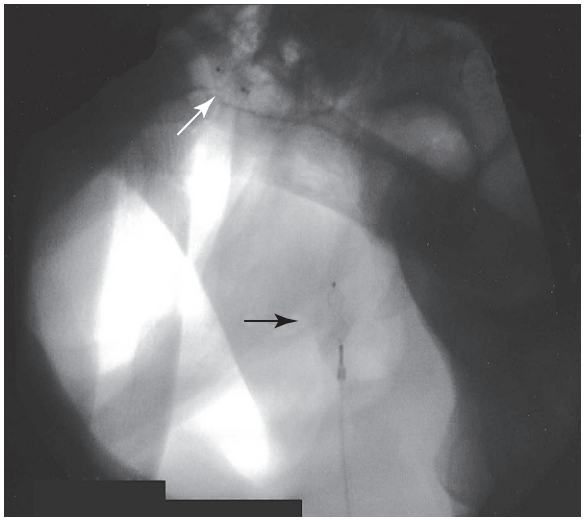

Figure 46-23. Nitinol intravascular plugs placed in the internal carotid artery distal *(white arrow)* and proximal *(black arrow)* to the lesion in a horse with guttural pouch mycosis on this artery. The plugs can be identified by the small radiopaque platinum marker beads at each end. In the case of the proximal plug, the delivery catheter is still attached and the mesh portion of the plug can be seen in its typical dumbbell shape.

plugs. In addition, angiographic identification and possibly occlusion of aberrant vasculature should be performed. In one report, cessation of active bleeding in the MA after vascular plug occlusion took 15 to 20 seconds, but it can take up to 10 minutes when used in large vessels.[113]

Comparisons of Methods for Arterial Occlusion

Since the limitations of ligation methods were recognized, the challenges of occluding the complex vasculature of the terminal branches of the equine carotid arterial system have been addressed through an evolution of methods, such as balloon catheters, detachable balloons, microcoils, and nitinol plugs. The last three transcatheter methods and particularly the last two have emerged as the methods of choice in most university veterinary hospitals, where the necessary equipment is available through an association with small animal cardiologists and interventional radiologists. In fact, the growth of embolization techniques for small animal vascular lesions obviates the need for purchase and storage of expensive equipment in the associated equine hospitals, so that inventory, storage lives, and expertise are no longer limiting factors for use of this methodology in horses in most university hospitals.

The goals of transcatheter techniques should be accurate identification of the involved artery and location of any complicating or affected aberrant branches, accurate and secure placement of the occlusion device, and complete interruption of blood flow to the site of hemorrhage. The transarterial coils and nitinol plugs would seem to come closest to achieving these goals. Atypical anatomy and aberrant branches may be more common than reported with this disease, so preocclusion angiography is critical. The ability to selectively occlude affected vessels with a minimally invasive approach makes transarterial coil or nitinol embolization the preferred treatments.

Coils and plugs are inserted through catheters that can be guided into the relevant arterial branches under fluoroscopic guidance beforehand, and such catheters are designed for accurate placement in multiple vessels remote to a single site of catheter insertion. By comparison, the detachable balloon is delivered without prior selective catheterization of the affected vessel and within the delivery catheter, which is more difficult to manipulate into place if the target segment is a remote branch of the catheterized artery. This can be partly overcome by direct catheterization of the affected artery, such as the ICA, but is a disadvantage if additional arteries need to be occluded. Also, detachable balloons are not currently as readily available as the other devices. We are not aware of a report on use of the detachable balloon system in the ECA and its branches in horses.

One difference between the transarterial coils and the nitinol vascular plug is that a single nitinol plug is delivered at each site whereas at least two transarterial coils are typically used at each site to effectively stop blood flow. The nitinol plug can also be retracted into the delivery cable if unsatisfactory placement is noted, and the plug can also be retrieved after it has been released. Migration or dislodgement from the target vessel is very unlikely because the expanded plug applies radial tension to the arterial wall.[113] There is little difference in cost between the two methods and both suffer from the same disadvantages, such as need for specialized equipment and the expertise of an interventional cardiologist.

Failures following the use of nondetachable balloon catheters and transcatheter embolization methods are rare. In cases of successful arterial occlusion, a small volume of dark blood and serum typically drains from the affected guttural pouch for many days after surgery, but this is from residual blood within the guttural pouch and does not signify ongoing hemorrhage. Hemorrhage from a failed occlusion is typically severe and happens in the recovery stall, leading to death or euthanasia.[53,104] Hemorrhage following occlusion with a nondetachable balloon catheter is typically caused by failure to occlude an aberrant branch that was the site of arterial erosion or that allowed persistent retrograde flow to the site of hemorrhage.[104]

In 27 horses that had transarterial coil embolization for treatment of epistaxis in two hospitals,[53,108] only two had epistaxis after arterial occlusion. In one of these, the disease was bilateral, but arterial occlusion was completed on one side only and the horse subsequently bled to death from the MA on the side that was not occluded.[53] Based on this experience, bilateral arterial occlusion during the same surgery should be considered in such cases.[53] In the second failure, the affected ICA could not be occluded on the rostral (cephalic) side of the lesion and the horse bled in the recovery stall and was euthanatized, despite sucessful occlusion on the cardiac side of the lesion.[53] Failure to place coils in the ICA rostral to the site of hemorrhage has been reported in 3 of 27 horses and attributed to a thrombus in that portion of the vessel or to narrowing of the vessel.[53,110] In another horse, a sharp turn in the MA made it difficult to place a nitinol plug rostral to the lesion.[113] When such difficulties arise, the catheter can dislodge a thrombus and cause intraoperative bleeding.[53,114] Possibly the rigid types of thrombectomy catheter that are commercially available can be advanced beyond any form of distal arterial obstruction or narrowing and can thereby be successfully placed rostral to the site of hemorrhage. Nonetheless, the transcatheter embolization systems (coils and nitinol plugs) remain the methods of choice in those hospitals equipped to use them.

CHAPTER 47

Trachea

John A. Stick

Although conditions of the equine trachea requiring surgery are rare, those that may require surgical intervention include obstruction of the airway rostral to the trachea, perforation or rupture of the trachea, tracheal collapse, tracheal stenosis, bronchial foreign body, and mucosal granulomas within the trachea lumen. Surgical treatments include tracheotomy, tracheostomy (both temporary and permanent), tracheal resection and anastomosis, and tracheal reconstruction.Successful surgical management requires knowledge of normal anatomy and physiology.

ANATOMY AND PHYSIOLOGY

The equine trachea is a membranous and cartilaginous tube extending from the larynx at the level of the first or second cervical vertebra to the level of the fifth or sixth intercostal space, where it bifurcates into the principal bronchi dorsal to the base of the heart.[1] The trachea is median in position except for its very terminal thoracic part, where it is pushed to the right by the aortic arch. From just caudal to the larynx to its bifurcation, the equine trachea is about 70 to 80 cm (28 to 32 inches) long.

When operating on the trachea, its relationship to other structures is important. The arrangement of the muscles around the trachea should be noted, as well as nerve trunks, vessels, and the esophagus. The sternothyrohyoid muscles are located immediately ventral to the trachea, except at the most cranial extremity of the trachea, where it is related only to the sternohyoid muscle. The sternocephalic, omohyoid, and sternothyroid muscles are found lateral to the trachea near the larynx. An easy spot to perform a tracheotomy is where the sternocephalic muscle bellies diverge and the omohyoid muscle converges. From this area cranial to the larynx, the trachea can be easily palpated. The esophagus is located dorsolaterally to the trachea in the middle of the neck but comes to lie lateral to it in the caudal part of the neck and assumes a position ventral to the trachea at the thoracic inlet. This is another reason the tracheotomy should be performed in the proximal half of the trachea. The common carotid artery, vagosympathetic nerve trunk, and recurrent laryngeal nerve all are enclosed in the carotid sheath and lie alongside the dorsolateral aspects of the trachea. These structures come to lie more laterally near the thoracic inlet. Therefore, when surgery is performed in this area, caution needs to be taken. A tracheotomy cannot be performed blindly. In a young animal, the thymus may extend for a distance into the neck from the thoracic cavity and lie on the ventral and lateral aspects of the trachea. Additionally, in the proximal-most aspect of the trachea, the thyroid gland may have an isthmus that could be encountered if the trachea is surgically approached just caudal to the larynx.

The wall of the trachea can be divided into four layers: mucosa, submucosa, musculocartilaginous layer, and adventitia. The adventitia is a connective tissue layer that blends with the musculocutaneous layer and with the connective tissue surrounding the trachea. It is composed of loose areolar tissue that allows a considerable amount of movement of the trachea along its length. The musculocartilaginous layer consists of the cartilaginous plates, fibroelastic tissue (annular ligaments), and the tracheal muscle. The cartilaginous plates number between 48 and 60 and are composed of hyaline cartilage surrounded by perichondrium.[1] Vascular canals are consistently found within the cartilaginous plates and become obvious when they are traumatized or when incisions are made into the cartilaginous plates. These cartilaginous plates are curved and form incomplete hoops that are open dorsad. Tracheal muscle consisting of smooth muscle fibers extends transversely across the dorsal part of the wall and is attached to the inner surface of the tracheal plates, forming the dorsal tracheal ligament. The tracheal lumen can vary considerably in size as the result of the action of the tracheal muscle, which is facilitated in the cervical region by overlapping of the cartilaginous rings when the muscle contracts. The submucosa contains many elastic fibers and fat cells and many small seromucous tubular glands, which open into the lumen of the trachea.[2]

The mucosa has numerous low longitudinal folds and is lined with pseudostratified columnar ciliated epithelium, which contains numerous goblet cells and rests on a basement membrane. The secretory cells and the mucous glands under the epithelium provide the mucous layer that covers the tracheal epithelium. As the cilia move in a coordinated fashion, they create a wave that carries the mucus and inhaled foreign particles orally, and this is referred to as the *mucosal ciliary escalator.* The rate at which tracheal mucus is transported orally has been determined to be 1.6 ± 0.24 cm/min.[3] This mucosal ciliary escalator is important as a pulmonary defense mechanism. Surgical interventions, as well as foreign bodies and endotracheal tubes, can disrupt this mechanism and may predispose the animal to pulmonary disease.

There is a wide variation in the extrathoracic tracheal cross-sectional shape in horses. In the adult horse, tracheal diameter varies from 5.5 cm cranially, where it is almost round, to up to 7 cm or more distally, where it is flattened dorsoventrally.[1] A recent paper has quantified normal radiographic tracheal height for the Thoroughbred horse.[4] It is recognized that as horses (particularly ponies) age, the trachea may undergo some torsion and additional flattening in the cervical area. This is important when performing permanent tracheostomies, because this surgery needs to be centered in the middle of the tracheal ring, which may become rotated with age.

In a recent cadaveric study of 33 freshly slaughtered horses, neither age nor weight of the horse had any influence on the mechanical properties of the trachea.[5] However, extension decreases the compressibility of the tracheal segments, and the shape of the cross-sectional area has a major influence on mechanical properties. Hyperextension of the neck partly facilitates respiration at high levels of ventilation by elongating the trachea and decreasing its collapsibility. Therefore, muscles that cranially retract the larynx (and hence the trachea) may provide some stability of the tracheal luminal diameter during inhalation. In addition, the tracheal cartilages themselves prevent tracheal collapse during inhalation when intraluminal pressures are lower than atmospheric pressure. The incomplete dorsal structure of the tracheal rings allows tracheal expansion when

large volumes of air are exhaled, especially during periods of exercise. Although the fibroelastic annular ligaments positioned between consecutive tracheal rings allow considerable tracheal flexibility during neck movement, they become more stabilized whenever the trachea is elongated, and this probably occurs during exercise.

EXAMINATION

Preventing and managing complications of tracheal surgery in horses requires a thorough examination of the trachea. Preoperative evaluation should include manual palpation of the trachea. Its ventral aspect can easily be palpated in the cranial half of the cervical trachea. The lateral aspects of the trachea and their rings can be palpated further distally in the neck, but it becomes increasingly more difficult as the musculature thickens in the neck near the thoracic inlet. Cartilaginous rings should be compressible except in older horses; if they are not, they may have become mineralized. However, any change in the amount of compressibility of the tracheal rings may indicate a diseased state.

The evaluation should also include direct flexible tracheoscopy, the goal being to identify airway abnormalities (such as recurrent laryngeal neuropathy) and to determine the extent of the tracheal disorder, thus allowing the surgeon to plan surgical management and achieve the best possible outcome for each patient. A technique for clinical bronchography has been developed in the horse using a barium sulfate powder and an ether vaporizer into which compressed air is blown.[6] Although the value of bronchoscopy as a diagnostic procedure has yet to be proved, the method of powder insufflation provides a safe and accurate means of evaluating bronchial conditions in the horse. This could have some application toward tracheal disease.

CONDITIONS REQUIRING TRACHEAL SURGERY

Rostral Upper Airway Obstruction

Surgery of the trachea is often an emergency procedure to bypass a life-threatening obstruction of the upper respiratory tract. It may also be conducted as a route for endotracheal intubation for general anesthesia when routine nasotracheal or orotracheal intubation limits access to the surgical field. Additionally, surgical interventions are performed to physically rest the upper respiratory tract on a temporary basis or to simply bypass an inoperable upper respiratory tract obstruction (such as bilateral arytenoid chondritis).

Tracheotomy

Temporary tracheotomy and tracheotomy with an indwelling tracheal cannula (tracheostomy) may be performed with the horse standing or under general anesthesia. In the standing horse, the ventral midline of the neck is easier to locate (with regard to all tissue layers) and the dissection of the trachea is easier than in the anesthetized horse in dorsal or lateral recumbency, because the trachea shifts within the neck if the neck is not held in a perfectly vertical position. Tracheotomy is performed at the junction of the upper and middle thirds of the neck. The trachea is located superficially at this level. The horse is sedated in the stocks and the surgical site is prepared for aseptic intervention. Local anesthetic is injected on the ventral midline under the skin and into the paired sternothyrohyoid muscles prior to incision.

If the surgery is to be performed in the recumbent animal, a pad is placed under the head to place the neck in a slightly flexed position after the neck and the trachea have been placed in vertical position and as straight as possible. The objective is to align the skin so that it is in the position it will be in after the horse recovers and is standing normally.

With the horse standing or in recumbency, a 10-cm incision is made through the skin, subcutaneous tissue, and cutaneus colli muscle. The paired sternothyrohyoid muscle bellies are bluntly divided along the ventral midline for a distance of about 8 cm and held in a retracted position with a self-retaining retractor (Figure 47-1). The cartilage of the trachea can then be easily palpated. Although vertical and flap procedures are used in dogs, only the transverse tracheotomy technique is used in the horse to prevent problems with tracheal collapse and granulation tissue formation. Therefore, the annular ligament between two adjacent cartilage rings is sharply incised using a scalpel parallel to the orientation of the rings. The incision between the rings is lengthened to allow placement of a tracheal cannula. The incision should not exceed one half the circumference of the trachea. A large hemostatic forceps or an index finger may be inserted between the rings to guide the tracheal tube in the lumen.

A variety of tracheal tubes are manufactured. Self-retaining tubes are popular because they do not require skin sutures for

Figure 47-1. After the paired sternothyrohyoid muscles are bluntly divided along the ventral midline, they can be held in place with Weitlaner or baby Balfour retractors as shown. This provides good exposure to multiple tracheal rings.

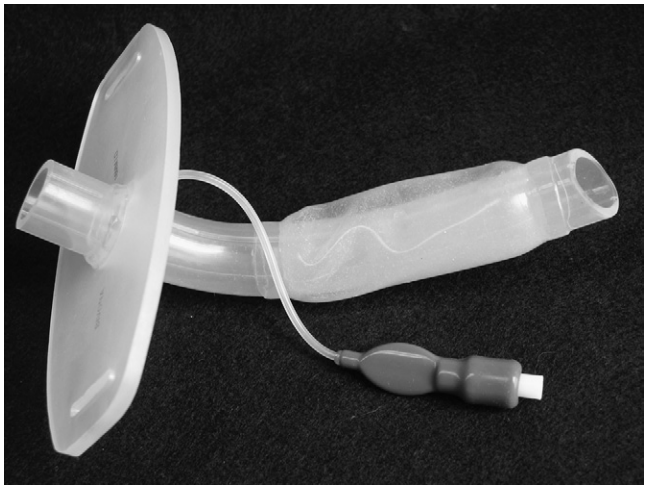

Figure 47-2. A short-cuff tracheal tube made of silicone. The flanges are used to tie the tube in place with gauze passed around the neck, or can be sutured to the skin.

security. Short-cuff silicone tubes are a good choice (Figure 47-2) because their compliance makes them more comfortable than rigid metal tubes. However, the cuff should not be inflated if the tubes are used long term; they will produce mucosal erosions.[7] Therefore, they are usually tied in place using the flanges on either side of the tubes.

In emergency situations, a segment of stomach tube, garden hose, or large plastic syringe casing with the tip removed may provide an airway until a better option is available. In an emergency situation, tracheotomy is difficult when performed on a horse that is struggling because of airway obstruction. It may be necessary to allow the horse to collapse; however, from that point forward, speed is imperative because the horse can die shortly after this stage is reached. The tracheotomy site should be cleaned and the indwelling cannula should be removed twice daily to remove accumulated tracheal secretions that could cause airway obstruction.

When direct tracheal intubation through a tracheotomy is carried out to avoid orotracheal or nasotracheal intubation, the procedure can be accomplished in the standing sedated or recumbent anesthetized horse. Precautions are taken to ensure that the skin incision is made on the ventral midline in the recumbent horse, because inappropriate positioning may create excessive skin tension or stoma obstruction at the tracheotomy site on recovery. The endotracheal tube should not extend past the carina because endobronchial intubation will impair ventilation.

COMPLICATIONS

Early complications can be reduced by using aseptic technique and by performing minimal soft tissue dissection to limit the amount of dead space. Complications after aseptic tube placement are uncommon. Occasionally, the wound becomes infected or the horse develops subcutaneous emphysema. More commonly, obstruction of the tracheal cannula with mucous secretions occurs and needs clearing. This problem should be closely monitored and the tube replaced at least every 24 hours, preferrably every 12 hours. Occasionally, the tracheal cannula is inadvertently placed peritracheally because of the loose areolar tissue around the trachea. This can be recognized immediately by the lack of air movement through the tube while the horse is breathing.

Long-term complications, including damage to tracheal cartilage or intraluminal granulation tissue and mucosal stricture, are extremely rare. Attention to the soft tissue dissection and aseptic technique whenever possible reduces these complications. Removal of the endotracheal cannula as soon as possible also reduces long-term complications. After the cannula is removed, the wound is left to heal by second intention with daily cleansing.

Tracheostomy

Permanent tracheostomy is used for correction of permanent impairment of the laryngotracheal apparatus, such as bilateral laryngeal hemiplegia or chondritis. Permanent tracheostomy has been used to provide a large, stable, permanent tracheal stoma with minimal complications.[8] A retrospective study that followed 42 horses for an average of 4.8 years found that stomas remained functional and 91% of owners would have it done again.[9] Good success also has been had with long-term function of tracheal stomas created in a number of adult horses.

Permanent tracheostomy can be performed with the horse sedated and standing or anesthetized and positioned in dorsal recumbency. The procedure should be performed under general anesthesia until the surgeon is comfortable with it before it is attempted in the standing horse.

Surgical Technique with General Anesthesia

The horse is anesthetized and positioned in dorsal recumbency with the ventral cervical area prepared for surgery. A 10-cm ventral midline incision is made through the skin, subcutaneous tissues, and cutaneus colli muscle in the cranial third of the cervical region just caudal to the larynx (Figure 47-3). The paired sternothyrohyoideus muscles are separated and retracted laterally to expose four tracheal rings. (The most cosmetic appearance is achieved if tracheal rings two to five are removed.) A 3-cm wide band of each of these muscles is bluntly separated and transected on either side of the midline so that the skin will lie easily on the trachea without tension. The area is packed with gauze sponges to stem the bleeding as the rest of the surgery progresses. A ventral midline incision and two paramedian incisions 15 mm on either side of the midline are made through the tracheal cartilages without disrupting the tracheal mucosa underneath. The rectangular cartilage pieces are carefully dissected from the tracheal submucosa and removed. The tracheal mucosa and annular tracheal ligaments are incised in a double-Y pattern and stay sutures used to maintain mucosal traction. The intersection of the legs of each Y in the mucosa is elevated and sutured to the skin with 2-0 polypropylene in a simple-interrupted pattern. The main tracheal mucosa is apposed to the skin lateral to the stoma in a similar manner.

The stoma is cleaned twice daily until the sutures are removed and then once daily afterward. The sutures can be removed 10 to 14 days after surgery; however, by that time many of the sutures have sloughed, and with time all of them will be extruded if they cannot be easily removed. This technique provides a cosmetically acceptable, structurally sound stoma needing minimal aftercare (Figure 47-4). The stoma is unlikely to be obstructed by accumulated secretions, even if daily cleaning is not done.

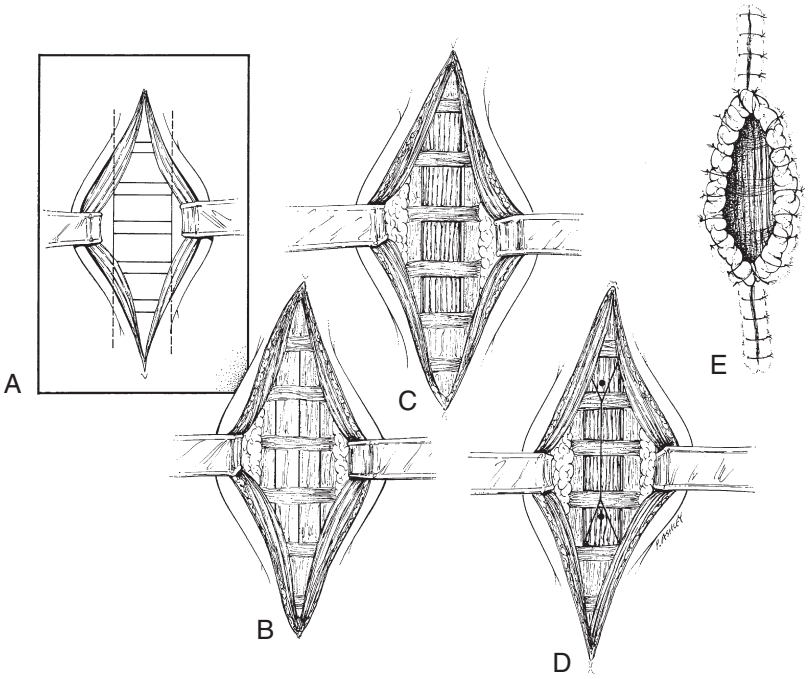

Figure 47-3. Surgical technique for permanent tracheotomy. **A,** Exposure of tracheal cartilage rings after separation of the sternothyrohyoideus muscles. **B,** Incision of tracheal cartilages. **C,** Removal of eight tracheal cartilage rectangles. **D,** Line of incision of tracheal mucosa and placement points for stay sutures *(circles).* **E,** Mucosal epidermal apposition.

Figure 47-4. Permanent tracheostomy provides a cosmetically acceptable, structurally sound stoma requiring minimal aftercare.

The stoma can be located at any site in the proximal third of the neck. However, for best cosmetic results, this stoma can be located beginning at the second tracheal ring. This often provides a permanent stoma that is not easily recognizable to the untrained observer. It is not recommended that the first tracheal ring be removed.

SURGICAL TECHNIQUE IN THE STANDING HORSE

If permanent tracheostomy is performed with the horse sedated and standing, the horse is restrained in stocks and cross-tied with the head extended. The horse is sedated and a local anesthetic infiltrated subcutaneously in an inverted-U pattern dorsal and lateral to the second through the fifth tracheal rings. The 6-cm–long incision is made through the skin centered over the ventral midline beginning 3 cm distal to the cricoid cartilage. The paired sternothyrohyoid muscles are isolated and removed as previously described. The tracheal mucosa is then desensitized by injecting 30 mL of 2% lidocaine with a 1-inch, 23-gauge needle into the lumen of the trachea proximal to the surgery site. The ventral third of the second through the fifth tracheal rings is resected as previously described, leaving the tracheal mucosa intact. The longitudinal double-Y incision is subsequently made through the tracheal mucosa and annular tracheal ligaments, and the stoma is completed by suturing the tracheal mucosa and the submucosa to the skin with simple-interrupted sutures of 2-0 polypropylene in the simple-interrupted pattern.

COMPLICATIONS

Although the permanent stoma affects pulmonary defense mechanisms by reduced airway temperature control and altered humidification of inspired gases, the mucosal ciliary escalator continues to work, and mucus is continuously extruded through the stoma. Horses with existing pulmonary disease may have exacerbation of chronic pulmonary disease, or signs of respiratory disease may be induced, but this has not been my clinical experience.

Tracheal collapse will occur postoperatively if care is not taken to ensure that segments of the cartilage are removed from the ventral third of the cartilage rings only and not close to the trachealis muscle. In older animals, the tracheal ring may become rotated, and if that is the case removing the center third of the cartilage ring is important even if it is off-center. The amount of tension that is experienced from the skin can be adjusted by removing more of the sternothyrohyoid muscle if necessary. Also, to avoid tracheal collapse, no more than one third of the entire circumference of the ring should be removed.

Tracheal Perforation or Rupture

Disruption of the integrity of the tracheal lumen is usually caused by trauma.[10,11] Clinical signs of tracheal trauma depend on the site of the tracheal injury, but trauma can cause tracheal

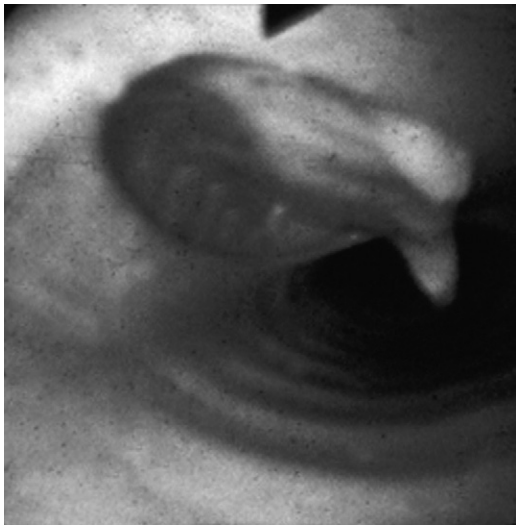

Figure 47-5. Endoscopic view of a tracheal rupture through the annular ligament. This horse had subcutaneous emphysema extending over the thorax.

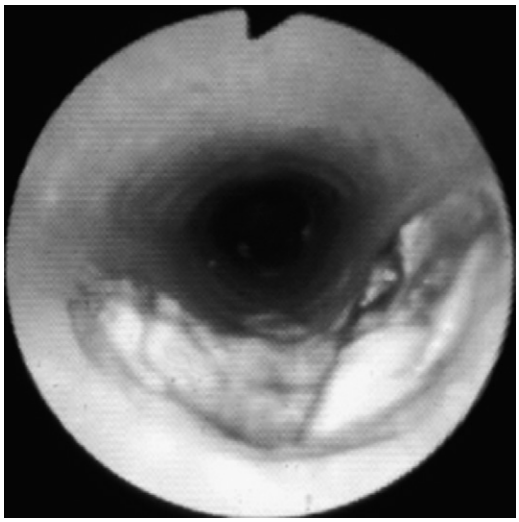

Figure 47-6. Endoscopic view of a tracheal perforation. Although this tear formed a fibrin seal, the presenting signs were subcutaneous emphysema.

perforation without concurrent cartilage damage or obvious skin damage or even rupture of the annular ligament (Figure 47-5). Clinical signs include subcutaneous emphysema and harsh tracheal sounds. Often, the perforation or disruption is not recognized until regional subcutaneous emphysema develops. When these signs occur in mares separated from their foals by wire fences at weaning, tracheal trauma should be suspected. The subcutaneous swelling is usually nonpainful, soft, easily indented, mobile, and crepitant. When tracheal trauma is suspected, thoracic radiographs should be taken to check for pneumomediastinum. Continued leakage into the mediastinum may lead to pneumothorax. Small tissue perforations in the absence of cartilage damage may not be apparent on radiographs, but both large and small lesions are usually apparent with tracheoscopy (Figure 47-6). Although the small tears rapidly form a fibrin seal, large ruptures should be treated promptly to avoid infection, obstruction from peritracheal tissue, progression of subcutaneous emphysema to the mediastinum, and development of pneumothorax. Small defects may respond to a pressure bandage over the affected region, which reduces the subcutaneous emphysema, or alternatively may respond to temporary tracheotomy.[11]

Although small tears can be managed conservatively and generally resolve within 24 to 48 hours, large tears should be managed surgically as soon as the horse's condition allows such an intervention. If there is a wound, the tears in the cervical trachea can be approached and directly sutured after débridement of devitalized tissue.[12] Wound margins are apposed in a simple-interrupted pattern of No. 0 absorbable suture material. Injuries that involve the trachealis muscle or the adventitia of the trachea, or that are rotational in nature, can be repaired by rotating the trachea to expose the dorsal surface. Closed suction drains are recommended in the postoperative period and should be removed between 48 and 72 hours, depending on the appearance of the wound and the amount of drainage. When the tracheal defect is closed, the subcutaneous emphysema usually resolves in 7 to 10 days.

Resection and Anastomosis

When tracheal trauma is extensive or when complete rupture occurs between tracheal rings, tracheal resection and anastomosis is indicated.[13-15] Before attempting a tracheal resection and anastomosis, the horse must be trained to wear a Martingale-type harness, which restricts dorsal movement of the head and reduces tension at the anastomotic site. This is particularly important if sections or rings need to be removed. If sections or rings do not need to be removed and the harness is quickly tolerated, the surgical preparation can occur immediately. Broad-spectrum antibiotics are administered prophylactically and the horse is anesthetized and positioned in dorsal recumbency.

The ventral cervical midline is prepared for aseptic surgery. A ventral midline cervical incision is made through the skin, subcutaneous tissue, and subcutaneous colli muscles over a distance of about 40 cm centered over the affected area. The sternothyrohyoid muscles are divided to expose the trachea. The trachea is separated from adjacent tissues along the entire cervical region within the incision site. If cartilage rings are to be removed, stay sutures are placed in tracheal cartilages adjacent to the segment to be removed. Up to five cartilages can be removed; however, tension on the anastomotic site will be excessive, and as few cartilages as possible should be removed (Figure 47-7). Tracheal mucosa and annular ligament are incised to divide the trachea into proximal and distal segments. The endotracheal tube is removed and replaced in the distal segment. The tracheal mucosa is turned back over the open ends of the proximal tracheal segment and sutured to the adventitia. The same procedure is repeated on the distal segment, working around the endotracheal tube. The head is subsequently flexed at a right angle with the neck. The endotracheal tube is replaced through the mouth and advanced into the distal segment of the trachea. If this is not possible because of the distal location of the injury, the endotracheal tube needs to be placed through another tracheotomy incision proximal to the anastomotic site. Tracheal ends are apposed with towel clamps and anastomosed with 25-gauge stainless steel wire in a simple-interrupted pattern without mucosal penetration. After the anastomosis is

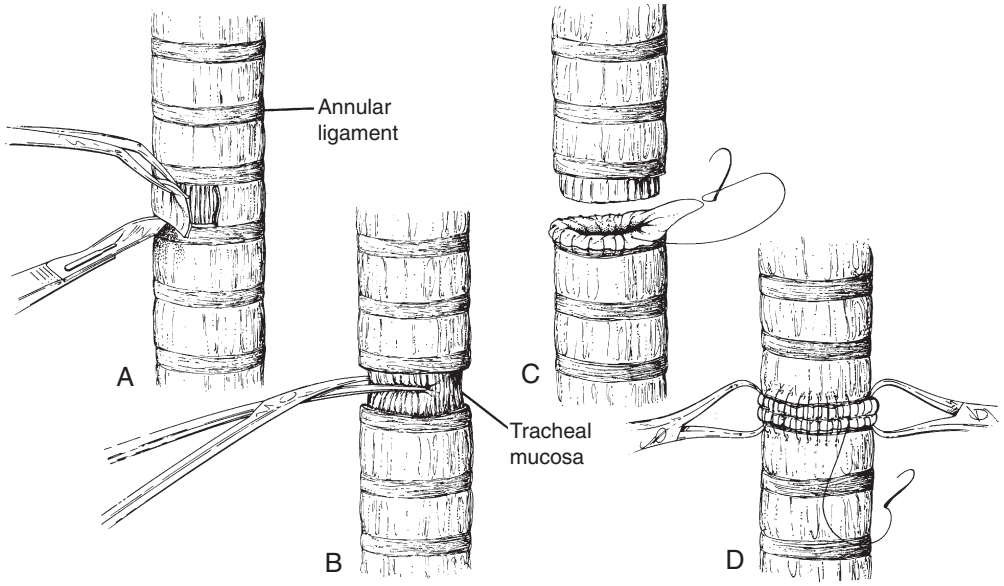

Figure 47-7. Surgical technique for tracheal anastomosis. **A,** Removal of a tracheal cartilage without penetration of mucosa. **B,** A 360-degree incision of mucosa between remaining cartilage rings. **C,** Eversion of mucosa, followed by suturing of mucosa to adventitia. **D,** Anastomosis of tracheal segments with stainless steel sutures.

complete, it is checked for air leaks prior to completely withdrawing the endotracheal tube. A continuous suction drain is placed in the soft tissue, and the remaining tissue layers are closed. The harness is applied before recovery and left in place for 3 weeks. Antibiotics are usually continued for 5 days. Complications include breakdown of the anastomosis and infection. Fistulation around the steel sutures persists if infection is present, and development of intraluminal abscesses in the anastomotic site is possible. Therefore, these sutures may need to be removed if abscesses develop after the trachea is healed.

Tracheal Collapse

Tracheal collapse can be a sequela to peritracheal abscesses, tumors, any injury causing cartilage trauma, malformation of the cartilages, or chronic pneumonia.[16-18] An idiopathic primary collapse syndrome has also been reported in the horse.[19] Primary tracheal collapse is recognized by widespread or segmental dorsoventral flattening of tracheal cartilage rings. Neurologic, congenital, or nutritional abnormalities may cause collapse in other species. Tracheal collapse uncomplicated by trauma is reported only in mature horses. It also occurs after emergency tracheotomy when vertical incisions were made through the rings. When tracheal collapse occurs from dorsoventral flattening of the trachea in aged horses and particularly ponies and American Minature Horses, the tracheal rings form shallow arcs and the dorsal tracheal membrane is stretched, creating an elliptical rather than a circular cross-section.[20]

Clinical signs vary with the degree of tracheal obstruction. Most animals experience varying degrees of respiratory distress and exercise intolerance and usually exhibit some stridor, although some animals may be asymptomatic until they become stressed. Diagnosis can be confirmed by auscultation, palpation, endoscopy, fluoroscopy, and radiography. Turbulent airflow may be auscultated within the cervical trachea and may thus allow localization of the site. Palpation may reveal the lateral edges of flattened tracheal rings in the jugular groove. Endoscopy will show the abnormal shape of the tracheal lumen, fluoroscopy will demonstrate the dynamic collapse of the the trachea, and lateral radiographs will depict the narrowed tracheal outline.

Treatment of tracheal collapse depends on the etiologic factors, length of the trachea involved, and accessibility of the affected area. Tracheal reconstruction has included complete replacement of tracheal segments with prostheses, external prostheses, imbrication of collapsed tracheal rings, plication of the trachealis muscle to reduce laxity of that structure, and resection of damaged cartilages with anastomosis of unaffected tracheal regions. The primary goal of the surgery is to restore the tracheal diameter without affecting the mucosal ciliary apparatus. This is best accomplished with an extraluminal prosthetic device that restores tracheal diameter by limiting redundant dorsal tracheal membrane and providing rigid support for the tracheal wall. Polyethylene syringe cases have commonly been used in ponies, but any nonreactive material of similar shape could be used. Partial chondrotomy is usually required on the ventral aspect of each collapsed tracheal ring to correct some deformities that occur when this dorsoventral flattening has occurred over time. Failure of the prosthesis to work will result in resection and anastomosis as a second choice; however, no more than five rings can be removed, and frequently dorsoventral collapse of a chronic nature involves more rings than this.

Tracheal Stenosis

Tracheal stenosis refers to a narrowing or stricture of the tracheal lumen that can occur during healing of a tracheotomy made by transverse incision through more than 50% of the circumference of the annular tracheal ligament (Figure 47-8). This produces instability and abnormal scarring. Other causes, particularly in foals, include *Streptococcus equi* abscesses in the peritracheal mediastinal lymph nodes and trauma. Tumors occur in this region, but tracheal collapse and stenosis secondary to tumors are unusual. Prolonged endotracheal intubation

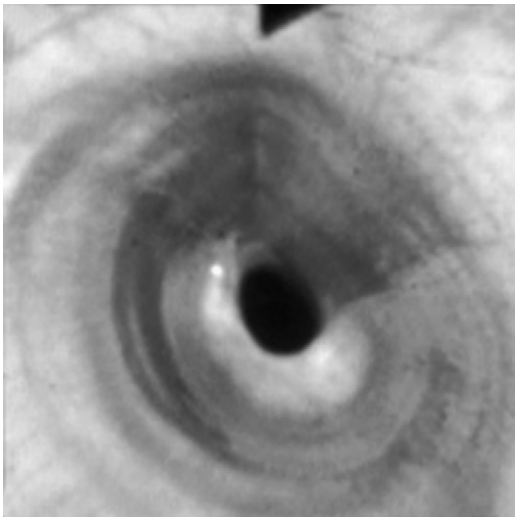

Figure 47-8. Endoscopic appearance of tracheal stenosis after transection of more than 50% of the annular ligament during temporary tracheostomy.

is associated with mucosal hemorrhage, necrosis, and stricture in people, and these lesions are frequently treated with surgery for removal of the circumferential fibrous tracheal stenosis.[21] Additionally, penetrating wounds that disrupt the tracheal mucosa, with or without infection, may lead to tracheal stenosis.

Surgical procedures used in the treatment of tracheal stenosis include tracheal resection and anastomosis, extraluminal polypropylene prostheses, surgical drainage of peritracheal abscesses, and multiple tracheal ring chondrotomies with placement of retention sutures anchored to the skin.

Foreign Body

Tracheal foreign bodies are uncommon in mature horses because of the size of the lumen of the trachea; however, endobronchial foreign bodies, although rare as well, are reported in equine patients.[22-25] They usually contain plant material, which may be inhaled accidentally, particularly during food prehension. The removal of foreign bodies from the respiratory tract is usually accomplished under general anesthesia and by way of tracheotomy. Frequently, removal involves endoscopic retrieval or endoscopically assisted surgical techniques. Foreign bodies in the tracheobronchial tree usually have thorns that cause them to lodge in the bronchi. The clinical signs usually include coughing and epistaxis, and a bloody nasal discharge is not uncommon. Usually, despite the severity of bronchial lesions, improvement in the bronchial mucosa is observed very soon after removal of the plant material, and few long-term effects are reported.

Granulomas

Granulomatous nodules are occasionally observed in the trachea during endoscopic examination. Often these are in the proximal trachea near the larynx, but occasionally they are associated with healing tracheotomy incisions, foreign body irritation, or inappropriate passage of a stomach tube that damages the tracheal mucosa. Although they are usually an incidental finding and not associated with clinical signs, if they are of sufficient size to create airflow obstruction they can be removed using an endoscopically guided laser technique.

CHAPTER
48 Thoracic Disorders

Joel Lugo and Elizabeth A. Carr

Thoracic disorders in horses amenable to surgical intervention are primarily caused by thoracic trauma but also include pleuropneumonia, pleural effusion, and infectious or neoplastic masses. This chapter's emphasis is on thoracic trauma, its associated disorders, and the management of pleuropneumonia.

THORACIC TRAUMA

Thoracic injuries in horses occur as a result of blunt or penetrating trauma. Blunt trauma is commonly seen in neonatal foals and is believed to result from excessive compression of the pelvic canal of the dam during parturition.[1] In adult horses, penetrating trauma caused by collision with an object is most common.[2] The many reported sequelae of thoracic injuries include pneumothorax, hemothorax, rib fractures, flail chest, pulmonary contusion/laceration, and diaphragmatic hernias. These can occur alone or in combination.

The pathophysiology of respiratory distress in horses with thoracic injury is complex. Pain associated with thoracic trauma restricts full expansion of the thorax during inspiration. This can induce hypoventilation, eventually resulting in hypoxia and hypercarbia, which in turn can lead to myocardial dysfunction, lactic acidosis, and ultimately death if not corrected in time.[3] Pneumothorax, hemothorax, and contusion of pulmonary parenchyma can develop secondary to injury and can contribute to respiratory insufficiency.

Evaluation of a horse presented for thoracic trauma must be thorough but rapid. If necessary, potentially life-threatening conditions must be identified and addressed immediately before undertaking further diagnostic measures. Emergency management of thoracic trauma patients is directed at providing respiratory support to restore adequate ventilation and oxygenation, providing analgesia, and managing hypovolemic shock.

Clinical Presentation

Horses with thoracic injuries may be presented with a range of clinical signs all depending on the extent of trauma to external and/or internal thoracic structures.[4] Horses with extenal injuries (e.g., lacerations, rib fractures) may be presented with stiffness at the walk, anxiety resulting from thoracic pain, or severe signs of hypovolemic shock from hemorrhage. Otherwise, clinical signs of internal injuries usually result in respiratory distress including excessive respiratory effort, nostril flaring, tachypnea, dyspnea, accentuated thoracic excursion, and cyanotic mucous membranes.[5,6] Clinical signs may be subtle or dramatic, specific or nonspecific, and immediate or delayed in onset. This is especially true in horses with axillary wounds, where severe subcutaneous emphysema leading to pneumomediastimun can occur days after the injury.[7] Horses with concurrent abdominal involvement may develop colic symptoms because of injury to the viscera as occurr in cases of diaphragmatic hernias. Initial evaluation of the respiratory system should include good observation of the thoracic excursions, auscultation and palpation of the trachea and thorax, thoracic radiographs, thoracic ultrasonography, and arterial blood gas analysis.

Diagnosis

Physical Examination and Triage

The physical examination of a horse with thoracic trauma should be thorough and systematic. Observation of the rate, depth, and effort of respiration may help the clinician identify specific conditions. Rapidly developing respiratory distress is generally the result of pneumothorax or severe pulmonary contusion. Horses with hemothorax and pneumothorax develop a rapid and shallow respiratory pattern because of the restriction of lung expansion caused by the presence of fluid or air in the pleural cavity. A similar pattern of respiration can occur in horses with thoracic wounds or rib fractures, and this is most likely the result of restriction of thoracic wall movements due to pain. Paradoxical movement of the thoracic wall can be observed and is caused by collapse of a portion of the rib cage on inspiration when multiple rib fractures create an unstable flail chest wall. In this situation, the flail segment will move inward during inspiration and outward during expiration. This is sometimes better appreciated by palpation than inspection.

The thoracic wall should be palpated to evaluate the potential presence of subcutaneous emphysema (crepitus), fractured ribs, hematomas, and unstable (flail) segments. Localized crepitus with or without a hematoma suggests the presence of fractured ribs, whereas more diffuse subcutaneous emphysema may indicate the presence of pneumothorax, pneumomediastinum, or axillary wounds.[7,8] Thoracic auscultation and percussion help determine the presence of pneumothorax and hemothorax. The absence of respiratory sounds and increased resonance on percussion strongly suggest pneumothorax. However, auscultation of the thorax should not be relied upon as the sole means of diagnosing pneumothorax in horses. In a retrospective study, only 55% of the horses with diagnosed pneumothorax had decreased lung sounds dorsally.[7] When fluid accumulates in the pleural cavity, as with hemothorax, lung sounds are diminished ventrally, heart sounds resonate over a larger area, and a fluid line can be detected on percussion of the ventral thorax.[5] If crackling lung sounds are heard, pulmonary contusions should be suspected.

Several additional parameters should be monitored during the initial examination. The hematocrit and plasma total solids should be assessed at presentation and periodically afterward to determine if there is ongoing hemorrhage. Moreover, arterial blood gas analyses can help determine ventilatory function and the ability to oxygenate the tissues. If arterial blood cannot be obtained, a venous sample can allow assessment of ventilation. Hypoventilation is present if the PCO_2 is greater than 50 mm Hg, and hypoxemia is identified by an arterial PO_2 of less than 80 mm Hg. Frequent blood gas analyses can help assess if a horse's respiratory system is deteriorating or responding favorably to treatment.

Horses with thoracic trauma may suffer concurrent abdominal injury because of the close proximity of the abdomen to the thorax. Evaluation of the abdominal cavity is especially indicated when lacerations are present caudal to the sixth rib, or when a deep penetration or diaphragmatic trauma is suspected.[7] Abdominocentesis, diagnostic imaging, laparoscopy, thoracoscopy, or exploratory celiotomy can be used to rule out abdominal visceral involvement or diaphragmatic rupture. Musculoskeletal injuries can also accompany thoracic trauma, but they are typically of secondary importance to systemic stabilization.

Radiography and Ultrasonography

Radiography and ultrasonography are valuable diagnostic tools for evaluating of the equine thorax. Animals in severe respiratory distress must be stabilized with thoracocentesis and oxygen therapy before diagnostic imaging. Pneumothorax is evident radiographically by the separation of the lung margins from the diaphragm caudally and the vertebral bodies dorsally, thus allowing the pleural surface of the collapsed lung to be observed (Figure 48-1). Atelectatic lung lobes are radiopaque in contrast to the radiolucent, air-filled pleural space created when the lung collapses and retracts from the parietal pleura. Pneumomediastinum is diagnosed by the presence of air that outlines the mediastinal contents, and it can coexist with pneumothorax, usually secondary to trauma. Radiographs can also reveal other lesions, such as rib fractures, foreign objects, and diaphragmatic hernias. Intrathoracic and pulmonary masses may be seen as areas of increased soft tissue opacity that summate with or displace structures in the mediastinum, lung tissue, or thorax.

Thoracic ultrasonography is more valuable than radiography for confirming the presence of pleural fluid, for identifying rib fractures, and for determining the best site for thoracentesis or placement of indwelling chest tubes. In neonates, ultrasonography is more sensitive than radiography to detect rib fractures and concurrent internal thoracic trauma.[9] Ultrasonographic examination may permit the identification of foreign material, masses in the pulmonary parenchyma and cranial mediastinum, rib fractures, and diaphragmatic hernias.[10-14] However, pneumothorax may be difficult to diagnose because free air in the dorsal thorax and aerated ventral lung lobes appear ultrasonographically similar.

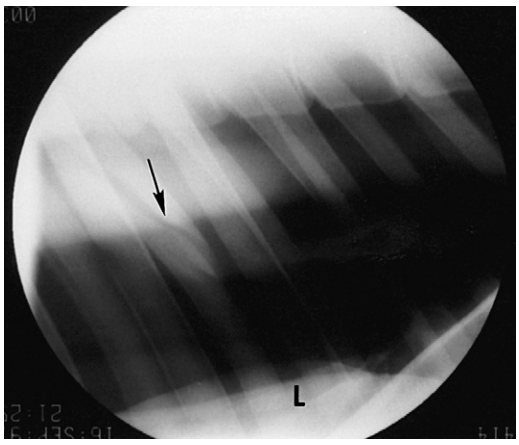

Figure 48-1. Thoracic radiograph of a horse with a rib fracture *(arrow)* that resulted in pneumothorax, as evidenced by air within the chest *(appears black).* The collapsed lung *(L)* lies ventral to the accumulated air.

Thoracocentesis

Thoracocentesis can be performed to obtain a sample of pleural fluid for analysis or to drain air or fluid from the pleural space. Aspirated fluid should be submitted for cytologic analysis, aerobic and anaerobic cultures, and antibiotic sensitivity testing. Sensitivity testing is important when hemothorax is caused by penetrating wounds because the risk of contamination and subsequent infection is great. The site for thoracocentesis is best guided with ultrasonography. Thoracocentesis carries the risk of pulmonary parenchyma injury, which results in iatrogenic pneumothorax or hemothorax; however, proper technique can minimize complications.

Thoracoscopy

Equine thoracoscopy can be used to provide a more accurate diagnosis and prognosis of thoracic diseases when less-invasive diagnostic tools fail to yield an accurate assessment. Common uses of thoracoscopy include the following[15-17]:

- Exploration of the thorax of horses with suspected neoplasia, diaphragmatic hernias, or pleural effusion of unknown origin
- Drain placement for relief of pleural effusion and abscesses
- Transection of pleural adhesions
- Guided pulmonary biopsy
- Window pericardectomy
- Exploration of the thoracic cavity to identify best site for thoracotomy

In addition, thoracoscopic surgery has been used to diagnose and assist in the repair of diaphragmatic hernias (see Chapter 39), to evaluate and repair thoracic esophageal obstruction, and to explore of the thorax in horses with open penetrating wounds.[18-20]

Thoracoscopy can be performed with the horse standing or under general anesthesia. Thoracoscopy in the standing horse has proved to be safe, well tolerated, and associated with minimal detrimental effects to the cardiovascular and pulmonary function of healthy horses and horses with chronic lung disease.[21,22] The presence of a pneumothorax during thoracoscopy can cause a transient hypoxemia attributed to ventilation/perfusion mismatch and a slight decrease in cardiac output secondary to decreased venous return.[21,22] Analysis of arterial blood gases is considered essential to evaluate ventilation and oxygen exchange, especially in horses with compromised lung function.

For thoracoscopy in standing horses, the animal is restrained in stocks and is sedated with xylazine (Rompum) at 0.5 to 1.1 mg/kg IV, romifidine (Sedivet) at 0.04 to 0.10 mg/kg or detomidine (Dormosedan) at 8 to 10 mg/kg or by use of a continuous IV drip infusion of detomidine (an 8 mg/kg loading dose followed by an administration rate of 0.3 to 0.5 mg/kg per minute until the desired effect is observed). During surgery, analgesia is provided by a single bolus of butorphanol tartrate (Torbugesic) (0.04 mg/kg IV) and local anesthesia of the skin, subcutaneous tissue, intercostal musculature, and costal pleura.

(Additional information on sedation for standing surgery can be found in Chapter 22). The thoracic chest wall is clipped and prepared for aseptic surgery. The sites for the telescope and instrument portals depend on the surgical intervention. The thoracic cavity can be better evaluated when the telescope is introduced into the thorax just cranial to the tenth to twelfth intercostal spaces, avoiding the vessels and nerves located caudal to the ribs.[23] The mobility of the ribs at this location allows manipulation of the telescope for extensive exploration of the thorax. Selection of a thoracoscopic portal caudal to the fifteenth intercostal space can result in inadvertent injury of the diaphragm during insertion of the trocar–cannula system.[22] On the other hand, placing portals too far craniad at the eighth intercostal space causes some pain and discomfort during manipulation of the instruments or telescope as a result of distraction of the ribs.[23] A 1-cm stab incision should be made through skin and intercostal muscles just ventral to the epaxial muscles. To prevent damage to the lung by the trocar–cannula system through which the thoracoscope is inserted, a pneumothorax is induced by inserting a teat cannula into the thoracic cavity through the incision and the intercostal muscles into the pleural cavity. This allows atmospheric air to enter the thorax, resulting in an iatrogenic pneumothorax. After the pneumothorax is induced, the teat cannula is replaced by the trochar–cannula system. The trocar is subsequently removed and replaced by the telescope. After the telescope is inserted, a systemic exploration is performed and the desired surgical intervention is performed using the triangulation technique (see Chapter 13). Multiple instrument portals are placed at least 10 to 15 cm apart (two to three intercostal spaces) to avoid obstruction of vision or restriction of instrument manipulations. Thoracoscopic viewing of the surgical field prevents injuries to thoracic structures during insertion of instrument and trocars. At the conclusion of the procedure, the thoracic cavity is inspected one final time and thoracic negative pressure is reestablished by removing all the air from the pleural cavity through a suction system connected to the thoracoscope cannula. Lung reinflation is observed through the telescope, which is retracted to the distal end of the endoscopic cannula, as inflation occurs.[19] The telescope is removed and the skin over the portals is closed with nonabsorbable suture material using simple interruped sutures.

Thoracoscopy under general anesthesia is performed with the horse in sternal, lateral, or dorsal recumbency.[17,19] To perform the procedure under general anesthesia, positive-pressure ventilation is an absolute necessity, because bilateral pneumothorax can occur more easily in the anesthetized than in the standing horse. Single-lung ventilation has been widely used during thoracoscopy in humans and dogs because it provides more surgical space in the operated hemithorax. Although this technique has been clinically used in some horses, the pulmonary effects with this ventilation technique require further investigation. After surgical preparation of the ventral aspect of the thorax, a pneumothorax is induced as previously described, and the telescope and instrument portals are made as dictated by the surgical intervention. Thoracoscopy under general anesthesia improves the viewing of the ventral lung surfaces, ventral thoracic cavities, diaphragmatic surfaces, and lateral surface of the heart.[19]

On some occasions, CO_2 insufflation of the pleural cavity is used to facilitate surgical exposure. A recent investigation demonstrated that CO_2 insufflation for 20 minutes during standing thoracoscopy was not detrimental to the horse's cardiopulmonary parameters.[24] However, the ocurrence of bilateral pneumothorax was more common than without CO_2 insufflation. CO_2 insufflation during general anesthesia is also used, but careful monitoring is essential because intrapleural pressure greater than 3 to 4 mm Hg in dogs resulted in cardiovascular and pulmonary deterioration.[25]

Thoracoscopically guided lung biopsy has been described as a safe and a successful technique to facilitate the harvest of tissue samples for histologic and microbiologic examination.[22] The technique can be performed in normal horses and in horses with pulmonary function impairment (heave-affected horses during clinical exacerbation) without harmful effects.[22] Pulmonary tissue samples are collected from the caudodorsal aspect of the lung, because, when lung disease is diffuse, this site appears to be representative of the remainder of the horse's lung.[26] Direct observation of the surgical biopsy and excellent hemostasis enable surgeons to avoid complications reported by others when performing percutaneous lung biopsies.[27] Furthermore, multiple resections can be performed or larger wedge resections can be obtained when necessary. The main disadvantage of this technique is that the tissue access is limited to the periphery of the lung and therefore samples are useful only for peripheral lesions or diffuse interstitial diseases. If pulmonary lesions are seen during thoracoscopy on the broad surface of the lung, a biopsy can be performed with fine-needle aspirates, endoscopic biopsy forceps, or other biopsy instruments.

Thoracoscopically guided lung biopsy is performed with the horse standing under chemical restraint. The telescope portal is placed at the twelfth or thirteenth intercostal space. One instrument portal is placed one or two intercostal spaces cranial and 15 cm ventral to the telescope, and the other instrument portal is located at the fifteenth intercostal space and approximately 10 cm ventral to the telescope portal. The caudal aspect of the caudal lung lobe can be grasped with atraumatic forceps (Babcock), and the wedge resection sample is obtained by the use of endoscopic staples (Figure 48-2). When necessary, the atraumatic forceps and staple device are interchanged between portals to facilitate the approach to the tissue specimen. Because the tissue sample is usually too large to be withdrawn through the trocar–cannula system, it is withdrawn through the instrument portal with the cannula. The thoracic cavity and biopsy site are inspected for evidence of hemorrhage. Negative pressure in the thoracic cavity is reestablished by removing all the air from the chest, and the skin is closed routinely.

Another reported technique to obtain the lung sample is using a pretied ligating ligature loop and endoscopic scissors instead of the endoscopic staple device. Limitations of this technique include a relatively high rate of complications because of slippage of the ligating loop from the biopsy site (31% of the time) and the inability to predetermine the biopsy size.[28]

Thoracoscopy is not without risk, and complications can occur. The most common complications include (1) injury to lung parenchyma or diaphragm during trochar penetration, especially in horses with lung adhesions to the parietal pleura; (2) injury to intercostal vessels; (3) pain during manipulation of telescope and/or instruments; (4) residual pneumothorax; (5) difficulty exposing the area of interest or manipulating the instruments inside the chest cavity; and (6) mild respiratory distress during induction of pneumothorax or surgery.[20-23]

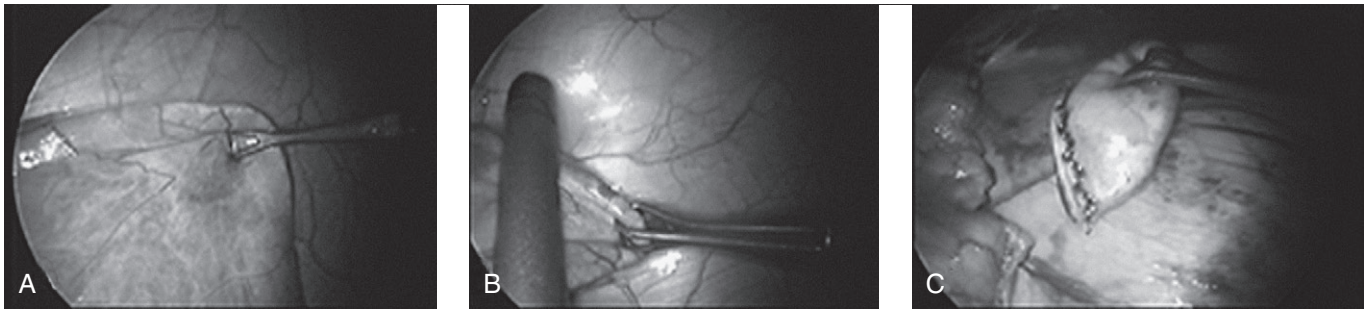

Figure 48-2. Thoracoscopically guided lung biopsy in a horse. The caudodorsal aspect of the lung lobe is grasped with Babcock forceps **(A),** and, using endoscopic staples **(B),** the pulmonary wedge resection is performed **(C).**

PNEUMOTHORAX AND HEMOTHORAX

Clinical Signs

Pneumothorax refers to the accumulation of air in the pleural cavity, which occurs as a result of pulmonary or chest wall injury.[29] When a communication between the atmosphere and the pleural space is created, a pressure gradient between the negative pressure in the pleural space and the alveolar or atmospheric pressure develops. Air enters the pleural cavity until the pressure gradient is eliminated or the communication is sealed. Consequently, the lung collapses to its minimal volume and this compromises pulmonary function. Meanwhile, the increase in pleural pressure causes a shift of the mediastinum to the contralateral side, enlarges the ipsilateral hemithorax, and depresses the diaphragm.[30] Pneumothorax in horses has been reported secondary to thoracic trauma, secondary to pleuropneumonia, and as a complication of upper airway surgery and thoracoscopy.[7,22] Traumatic pneumothorax can be classified by its physiologic nature as open or closed or as a tension pneumothorax. Injury to the chest wall (e.g., from penetrating objects, wounds, gunshots) that creates a communication between the pleural cavity and the external environment produces an open pneumothorax. A closed pneumothorax results from leakage of air from the pulmonary parenchyma or an airway tear and commonly takes place after blunt trauma causing rib fractures that injure the lung parenchyma. Tension pneumothorax results when air leakage, whether from the thoracic wall or lung parenchyma, acts like a one-way valve, allowing entry of air into the pleural cavity but not permitting its escape. Air continues to accumulate inside the pleural cavity during subsequent respiratory cycles, thus progressively increasing intrathoracic pressure to a point that exceeds atmospheric pressure (positive pressure). Increasing intrathoracic pressure causes severe cardiovascular and pulmonary compromise; if not treated promptly and aggressively, this condition can be fatal.[30] Severe pleuropneumonia is another cause of pneumothorax in horses.[7] Slow leaks of air from necrotic pulmonary tissue or the formation of bronchopleural fistulas may be the source of pleural air in these horses.

The main physiologic consequences of pneumothorax are a decrease in the vital capacity of the lung and a decrease in the partial pressure of arterial O_2 (PaO_2).[30] Patients with pneumothorax have a reduced PaO_2 and an increased alveolar–arterial oxygen difference (A-a gradient). The hypoxia in turn may result in myocardial dysfunction and lactic acidosis. These physiologic changes appear to be caused by ventilation/perfusion mismatching (low $\dot{V}/\dot{Q}$ ratio), intrapulmonary shunts, and alveolar hypoventilation resulting in hypercarbia and respiratory acidosis, pulmonary hypertension, and increased work for the right side of the heart.[30,31] Therefore, if pneumothorax is not treated in time can ensue shock, cardiopulmary deterioration, and ultimately death. Unless the mediastinum is sealed by another underlying inflammatory condition (e.g., pleuropneumonia, hemothorax), pneumothorax is frequently bilateral because an incomplete mediastinum exists in the horse.[32]

Clinical signs associated with pneumothorax include restlessness, cyanosis, tachypnea, dyspnea, unilateral expansion of the thorax, and accentuated respiratory excursions. In the absence of lower airway disease, the most probable cause of pneumothorax is trauma, and further examination may reveal evidence of a penetrating wound. Acute clinical signs are usually observed in horses with acute onset of pneumothorax or tension pneumothorax, whereas a more insidious onset of clinical signs is typical in horses with pleuropneumonia.[7] Decreased lung compliance and increased intrathoracic pressure increase the work of breathing.[29] To minimize the work of breathing, respiratory frequency increases and the tidal volume decreases, hence producing the characteristic shallow, rapid breathing pattern observed in horses with pneumothorax.[5]

Hemothorax can develop secondary to any trauma that causes laceration of the intercostal blood vessels, myocardium, pulmonary parenchyma, or thoracic wall musculature. A horse with massive hemorrhage from laceration of the heart or one of the great vessels usually does not survive. Horses with hemothorax commonly present with signs of hypovolemic shock, anemia, and pain. Signs of respiratory distress develop when a large accumulation of blood in the pleural cavity restricts the full expansion of the lungs or when hemothorax is combined with pneumothorax.

Management

The emergency management of patients affected by pneumothorax is aimed at providing adequate ventilation, oxygenation, and systemic perfusion. Immediate therapy includes establishing a patent airway, reestablishing adequate alveolar ventilation by removing the free air, and preventing recurrence. Supplemental oxygen therapy must be initiated for the treatment of hypoxemia (PaO_2 less than 80 mm Hg). Nasal insufflation of oxygen at a flow rate of 15 L/min is recommended in adult horses to increase the inspired oxygen concentration.[5] In addition, patients with evidence of shock, such as tachycardia, weak peripheral pulses, peripheral vasoconstriction, and prolonged

capillary refill time, require aggressive fluid volume replacement therapy.

Treatment of uncomplicated closed pneumothorax (e.g., following thoracoscopy) can be as simple as restricting exercise and close monitoring. An open penetrating wound should be sealed immediately with a sterile, airtight bandage to convert the condition to a closed pneumothorax. After the wound is sealed, thoracocentesis and reestablishment of negative pleural pressure can proceed. A large-gauge needle, teat cannula, or thoracostomy tube is inserted between the twelfth and fifteenth intercostal spaces just below the epaxial muscles.[6] Air should be removed slowly from the pleural cavity, using a 60-mL syringe and a three-way stopcock or a suction device. If negative pressure cannot be reached or repeated air aspiration is required to alleviate respiratory distress (more than three or four aspirations per 24 hours), tube thoracostomy should be considered for intermittent or continuous evacuation. Thoracostomy tubes can be attached to a Heimlich valve (see Figure 17-7) for one-way flow or to a pressure-regulated suction system such as the commercially available Pleuro-Evac. Resolution of pneumothorax results in dramatic improvement in hemodynamic parameters, although abnormalities in gas exchange persist for 60 to 90 minutes after recovery and are associated with a decrease in pulmonary compliance.[31] After reinflation of the lung, some areas of $\dot{V}/\dot{Q}$ mismatch and intrapulmonary shunts persist for several hours.

Unilateral pulmonary edema, also known as reexpansion pulmonary edema, can occur after rapid expansion of the lung following a period of collapse as the result of pneumothorax or pleural effusion.[33] Pulmonary edema acutely develops after reinflation and causes hypoxemia, decreased cardiac output, transient hypotension, and may lead to death.[34,35] The pathophysiology is poorly understood; it appears that multiple factors contribute to increased vascular permeability in the alveolar capillary bed. The inflammatory response occurring after reexpansion of the lung is a strong predisposing factor for the development of pulmonary edema. The increase in capillary permeability is believed to be secondary to (1) mechanical vascular injuries to the alveolar capillary membrane, (2) reperfusion injury as blood flow returns to the now fully expanded lung, and (3) abnormalities in surfactant production and function.[36,37] Typically, the chance for development of reexpansion pulmonary edema is increased if the pneumothorax has been present for several days or when extremely negative pressure is used to evacuate the pleural cavity. A pressure of less than 20 mm Hg should be applied to the pleural cavity, and slow evacuation is recommended to minimize the chances of developing this complication.[38] During surgical reconstruction of diaphragmatic hernias in small animals, current recommendations to prevent reexpansion pulmonary edema call for chronically atelectatic lungs to be reinflated by gradual reexpansion over several hours (8 to 12 hours) after surgery rather than complete reinflation at the end of surgery.[39]

The rate of pleural air absorption can be accelerated by tracheal administration of 100% supplemental O_2.[40] When 100% O_2 is administered, the partial pressure of nitrogen in the pulmonary vessels is decreased to near zero, whereas the partial pressure of O_2, CO_2, and H_2O remain unchanged. The absence of nitrogen in the dissolved gases in the pulmonary vessels establishes a diffusion gradient for nitrogen between the air in the pleural cavity and the gases in the pulmonary vessels. After the nitrogen is absorbed, O_2 is 100% of the gas in the pleural cavity, which results in a gradient for uptake of O_2. This gradient can increase the speed of absorption of free air to approximately 10 times the absorption achieved while breathing room air.[41] This therapy has been proved to be clinically effective in humans, and it would be logical to assume that it would work in horses as well.

Treatment of hemothorax involves restoring the blood volume by use of intravenous fluids, blood transfusion, and pleural drainage. Removing the free blood from the thorax and reexpanding the lung improves ventilation. In horses with open thoracic wounds, free blood should be removed to reduce the risk of septic pleuritis and pleural adhesions. Treatment of the simple hemothorax, a complication of lung biopsy, thoracoscopy, or blunt trauma may be conservative unless the horse displays signs of respiratory distress, but careful monitoring is mandatory.[22,42] In these horses, absorption of blood occurs within days and pleural adhesions are unlikely.

Thoracocentesis is commonly used to reestablish adequate alveolar ventilation in patients with pneumothorax and pleural effusion. Evacuation of air or fluid from the chest improves $\dot{V}/\dot{Q}$ matching and reduces intrapulmonary shunting.[43] The site for thoracocentesis should be based on auscultation or, ideally, on radiography and/or ultrasonography. In the case of hemothorax and pneumothorax, blood and air can be evacuated from the same site. A large area over the selected site, usually the seventh and eighth intercostal space, should be clipped and prepared for an aseptic intervention. Local anesthetic is infiltrated into the skin, subcutaneous tissue, intercostal musculature, and costal pleura. A large-gauge needle, teat cannula, Chamber's catheter, or chest tube can be used for the procedure. The site for thoracocentesis is selected cranial to the rib to avoid the intercostal vessels located caudal to the rib. A small stab incision is made through the skin, and the selected instrument is advanced through the intercostal muscles until resistance is decreased as the pleural space is penetrated. At this moment, fluid or air can be drained and the catheter can be redirected if neither fluid nor air is aspirated. Thoracostomy tubes can be left in place after securing the tubes to the body wall with purse-string sutures. A Heimlich valve may be attached to the tube to provide one-way flow.

THORACIC WOUNDS

Etiology

Injury to the thorax in horses is uncommon but not rare, possibly because automobile accidents involving horses are infrequent. Penetrating wounds to the thorax generally occur after an impact with sharp objects (e.g., running into trailers, gates, trees, fences). Penetrating wounds are usually located in the lateral aspect of the thoracic wall or in the region of the thoracic inlet (axillary region). The defect may look like a simple perforation requiring no specific treatment, or it may be extremely large. Open pneumothorax and subcutaneous emphysema are the most common clinical findings that develop subsequent to penetrating thoracic wounds.[2] The prognosis for horses with penetrating thoracic wounds is favorable if no other abdominal or musculoskeletal injury is present.[2] However, septic pleuritis can alter the prognosis in these horses.[2,44,45] Although a low incidence of septic pleuritis has been reported following thoracic trauma, approximately 50% of horses that develop pleuritis die or are euthanatized.[45]

Axillary wounds create interesting clinical signs for affected horses. The injury might not involve the thorax initially; however, marked subcutaneous emphysema may develop because the wounded tissue becomes a one-way valve for air as the horse moves. When extensive, this subcutaneous emphysema can migrate to the mediastinum (pneumomediastinum) and extend into the thorax, leading to life-threatening pneumothorax.[8] Therefore, horses with axillary wounds should be kept in strict confinement and monitored closely for signs of respiratory distress.

Management

Initial management of horses with thoracic wounds includes (1) immediately covering the wound with a sterile dressing to prevent any further ingress of air to the thoracic cavity and (2) assessing the patient for intrathoracic injuries. Pneumothorax and hemothorax are likely to require treatment. If the wound is properly sealed, a one-time thoracocentesis or needle aspirate can alleviate the pneumothorax and associated ventilatory consequences. Any residual air in the pleural cavity will be reabsorbed within a few days. In horses with tension pneumothorax, emergency thoracocentesis is necessary to equilibrate pleural pressure with atmospheric pressure and relieve the respiratory insufficiency.

An important goal in the management of thoracic trauma is pain relief. All horses with thoracic wounds can suffer from severe pain that limits chest wall excursions, and this often results in ventilatory impairment. Appropriate analgesia allows patients to maintain effective ventilation and oxygenation and to preserve the cough mechanism necessary to eliminate pulmonary secretions. Pain can be reduced by use of systemic analgesics and intercostal perineural anesthesia. Analgesics must be used carefully because of the potential for respiratory depression. Intercostal nerve blocks are performed with long-acting local anesthetic agents, such as 5% bupivacaine. The block is performed dorsal and one to two intercostal spaces cranial and caudal to the injury to provide optimal local analgesia. Deeper infusion of local anesthetics is necessary to desensitize nonmyelinated C fibers located within the parietal pleura, which are a source of pain when stimulated by the penetrating object, fractured ribs, or wounds.[22]

After life-threatening conditions are controlled, thoracic wound care consists of exploration, débridement, and closure. These manipulations can be accomplished with the horse standing under adequate analgesia or recumbent under general anesthesia. Treatment with the horse standing is preferred to avoid potential respiratory and cardiovascular complications that may develop under general anesthesia. General anesthesia is indicated for extensive wounds, for wounds that may involve underlying structures (e.g., the diaphragm), or for fractious animals. The horse must be stabilized by treating shock and respiratory impairments before induction of anesthesia and, if necessary, surgery should be delayed for 2 to 3 days. The wound must be thoroughly explored for the presence of foreign material and bone fragments, which can become the source of septic pleuritis or of recurrent purulent discharge. Thoracoscopy can be used to remove foreign objects while allowing a thorough inspection of thoracic structures. The telescope is initially inserted into the thoracic cavity via a portal away from the wound, and a detailed thoracic exploration is performed. Meanwhile, pleural lavage with sterile saline solution can be performed. The wound itself can also be explored with a rigid or flexible telescope.

Immediate or delayed closure techniques may be used depending on the hemodynamic status of the patient and the degree of contamination and tissue damage. The wound is irrigated with sterile saline solution and subjected to débridement. To facilitate assessment of damaged ribs, diaphragm, and lung lobes, the wound may need to be enlarged. Any foreign body is removed, and, ideally, primary closure of the wound is attempted. However, large thoracic defects may require reconstruction with primary muscle flaps, diaphragmatic advancement flaps, and/or prosthetic mesh. Creation of muscle pedicles from the longissimus dorsi and external abdominal oblique muscles to close a thoracic wall defect in a horse has been described.[46] If the wound defect cannot be closed, the wound is packed and sealed with moist, sterile laparotomy sponges to prevent the entry of air and leave to heal by second intention. A stent and thoracic bandage around the thorax holds the packing in place. The wound is allowed to heal by secondary closure with fresh bandage changes daily until the thoracic cavity seals. Horses should be confined to a stall and in cases with axillary wounds cross-tied to minimize limb motion and limit further air penetration into the tisuues. Horses are also given broad-spectrum systemic antibiotics, nonsteroidal anti-inflammatory drugs, analgesic medications, and tetanus prophylaxis.

FRACTURED RIBS

Rib fractures are common after thoracic trauma. Complications of rib fractures include underlying pulmonary contusion and thoracic wall pain. The most substantial physiologic impairment after rib fracture is a decrease in dynamic compliance, resulting in ventilatory impairment.[47] In addition, underlying pulmonary contusion renders a portion of the pulmonary parenchyma unavailable for adequate ventilation and oxygenation, resulting in hypercarbia and hypoxemia.[48] Chest radiography can be used to assess the presence of pneumothorax or hemothorax, although thorough ultrasonography examination of the rib cage is a better method to identify displaced or nondisplaced fractures as well as concurrent internal thoracic trauma.

Most isolated fractures heal spontaneously and surgical fixation is not necessary. Treatment in adult horses usually consists of managing pneumothorax, hemothorax, pleuritis, pulmonary contussion, wound care, and analgesia. The main goal for management of rib fractures is pain relief. Analgesia can be provided by administering nonsteroidal anti-inflammatory drugs and by using local intercostal nerve blocks. In the case of penetrating wounds, bone fragments are removed and rib edges are smoothed with rongeurs to prevent trauma to the pulmonary parenchyma.[4] The horse should be strictly confined and monitored for signs of respiratory distress.

Flail chest is uncommon in adult horses but when it ocurrs it causes severe ventilatory impairment. Flail chest occurs when multiple ribs are fractured in two places (dorsal and ventral), resulting in the loss of stability of a segment of the thoracic wall, which is known as the flail segment, and consequently exhibits paradoxical respiratory movement.[47] Respiratory efforts are hindered by the failure of the affected flail segment to expand and participate in the normal process of respiration. However, the underlying pulmonary contusion, and not the

mechanical disruption of the thoracic wall, causes the respiratory insufficiency.[47] Fracture stabilization of the flail segment and pain management are necessary to restore adequate ventilation. Surgical stabilization of a flail chest was achieved in a horse using an external splint secured to the ribs with orthopedic wires.[2] However, septic pleuritis developed in this horse as a consequence of ascending infection through the orthopedic wires that surrounded the ribs inside the pleural cavity. The use of internal fixation methods similar to the ones described for foals should be considered.

Rib Fractures in the Neonate

A study revealed that approximately 21% of the foals up to 3 days of age have thoracic trauma, which can include rib fractures and costochondral dislocation.[1] In addition, a study reported that a high number (up to 65%) of neonatal foals presented to equine referral centers experienced fractured ribs.[9] In most foals, no clinical problems develop and the outcome is favorable. However, thoracic trauma and fractured ribs can have harmful effects and are a substantial contributor to morbidity and mortality in affected neonates.[12,49] Hemothorax, pneumothorax, diaphragmatic hernia, and even sudden death can result after laceration of intrathoracic vessels, lung parenchyma, and cardiac tissue by displaced fracture ribs. Underlying pulmonary contusion can also result in pulmonary insufficiency and predispose the foal to the development of pneumonia. Thoracic trauma in neonates usually involves three or more ribs, frequently occurs in one hemithorax, and is consistently located in the cranioventral aspect of the thorax.[50] The most common site for injury is the costochondral junction and the area immediately proximal to it. Dystocia and foaling in primiparous mares are two factors associated with thoracic trauma in foals.[12,50] These clinical findings and the occurrence of this condition during the first week of life suggest that injury occurs during parturition. The cause is believed to be pressure on the thorax during passage of the foal through the pelvic canal, but the thoracic circumference or the foal's weight does not appear to be a factor in the development of thoracic trauma.

Clinical signs that may create suspicion of fractured ribs in foals include asymmetry of the thoracic cavity, groaning or grunting with respiration, plaques of subcutaneous emphysema overlying the ribs or ventral thorax, and crepitation or pain on palpation of the affected ribs. In a field study, 90% of affected foals were detected by palpation with the foal standing, but the thoracic cage asymmetry was better appreciated with the foal in dorsal recumbency.[1] As mentioned before, ultrasonography is better than radiography to determine the number of ribs fractured and the severity of fracture. In addition, ultrasonography permits characterization of associated thoracic abnormalities. The presence of unilateral or bilateral pleural fluid, pulmonary contusion, or pericardial effusion, the number of fractured ribs, and the degree of fragment displacement are better evaluated with ultrasonography than with radiography.[49] Because more than three ribs are usually involved, affected foals can present with flail chest. The flail segment can also develop when ribs fracture in a single dorsal plane and the flexible costochondral junction becomes the second movement plane.[51]

Management of foals with simple rib fractures consists of strict confinement for 1 to 4 weeks and supportive care with analgesics, anti-inflammatory drugs, antibiotics, and antiulcer medications. Foals with flail chest and concomitant pulmonary trauma are kept recumbent with the affected side down, and intranasal oxygen insufflation is administered. Lateral recumbency with the affected lung down minimizes ventilatory impairment of the better-ventilated lung (on top).[12] Foals are kept in recumbency and sedated as necessary until the respiratory difficulties improve. However, lateral recumbency may lead to intrathoracic damage if axial displacement of the fracture is present. In these cases, foals can be placed in sternal recumbency. Surgical intervention is usually not necessary, but it has been pursued in foals when there is a potential for intrathoracic injury, which can occur with axial displacement of fracture fragments. There are reports of the use of both external coaptation and internal fixation of the affected ribs.[49,52] External coaptation was achieved by placing stainless steel suture material around the ribs and fixing the wires to cast material molded to the rib cage.

Internal fixation seems to be a better option to successfully manage foals with complicated rib fractures, or when the risk of intrathoracic injury is high. A report evaluated the repair of rib fractures using internal fixation techniques in 14 foals.[52] Surgery was performed because the foals were considered at great risk for developing life-threatening injuries. A surgical procedure was performed on an average of two ribs (one to three ribs). After fracture reduction was achieved, a 2.7-mm reconstruction plate was contoured to the rib and applied with 2.7-mm–diameter cortex screws engaging both cortices (Figure 48-3). Four to six cortices of fixation on each fracture fragment were recommended. In addition, cerclage wire (18 to 22 gauge) was placed encircling the rib and plate at two sites above and two sites below the fracture. Application of the cerclage wire prevented implant failure from pullout of the cortex screws. Stall confinement was recommended for 4 to 6 weeks or until healing, which was evaluated with the use of ultrasonography. Of 14 foals treated using internal fixation, 12 were discharged from the hospital. Follow-up information on seven foals revealed that all were in good health and performing as expected, with the plates left *in situ*. Complications occurred in six foals and included implant failure, seroma formation, and subcutaneous hematoma.[52]

Another internal fixation technique described to repair multiple rib fractures in foals consisted of using 80-pound nylon strand (SCCLRS).[53] After the fracture fragments are exposed and adequately reduced, the nylon strand is passed in a figure-of-eight fashion through holes drilled in the cranial cortex of the proximal and distal fracture fragment ends and then secured with SCCLRS crimp clamps (Figure 48-4). The technique is repeated for each fractured rib. A similar technique was described by Down and Rodgerson but using commercially available, gas-sterilized nylon cable ties placed through drilled holes in the fracture fragment.[54] The surgical method was successful in the treatment of seven foals, and no complications directly related to the surgical technique were reported. These two similar techniques for rib fracture repair in foals offer a safe, relatively easy, and economically advantageous procedure to use when surgical intervention is deemed necessary.

The use of locking internal fixation implants, such as LCP technology, seems a logical, but more expensive, option (see Chapter 76).

The risk of operating so close to the thoracic cavity is present with any of these methods of fixation. Care must be taken not to enter the thoracic cavity when dissecting the tissue, reducing the fracture, and drilling the implant holes to avoid creating a pneumothorax and injuring internal thoracic organs. In all

cases, broad-spectrum systemic antibiotics, nonsteroidal anti-inflammatory drugs, and analgesic medications are recommended.

PLEUROPNEUMONIA

Pleuropneumonia is a serious disease in the horse, and it has a significant economic impact on the equine industry. Treatment of horses with bacterial pleuropneumonia is frequently expensive, and it is time consuming. Resolution of the infection and response to therapy can be prolonged, even with early detection and aggressive treatment. Survival rates vary from 43% to 75% depending on the microbial pathogens involved, the rapidity of diagnosis, the institution of appropriate treatment, and the development of secondary complications.[55-57] Many survivors are unable to return to their previous level of performance.[55]

Risk Factors

Bacterial pleuropneumonia most commonly occurs in horses subjected to physiologic stress, including long-distance transport, high-speed exercise, general anesthesia, and recent viral infection.[55,56,58,59] Horses subjected to long-distance transport have higher numbers of circulating neutrophils, an increased neutrophil-to-leukocyte ratio, elevated plasma cortisol levels, and decreased phagocytic function of peripheral blood neutrophils.[60,61] In addition, the practice of shipping horses with their heads secured in an elevated position results in increased bacterial and pollutant contamination of the lower airway compared with individuals allowed to lower their heads during transport.[62,63] Many horses refuse to drink appropriately during transport, and subsequent dehydration further compromises mucociliary clearance mechanisms.[64] During extended travel, periodic rest stops allowing the horse to lower its head and drink are necessary to resolve this contamination problem and to facilitate the correction of dehydration. However, rest stops may be infrequent with commercial hauling operations; consequently, the shipped horse is at increased risk of infection of the lower airway.

High-intensity exercise results in transient decreased peripheral blood neutrophil function and oxidative burst activity of pulmonary alveolar macrophages.[65,66] In the United States, Thoroughbred horses in race training are 4.3 times more likely to develop pleuropneumonia than nonracing Thoroughbreds, suggesting that career, not breed, is the risk factor.[59] In contrast, in Great Britain, show jumpers have the highest risk of developing pleuropneumonia.[67] The reason for this difference may be partly because most races are run on turf in the United Kingdom but on dirt in the United States, which would contaminate the airways during races. Additionally, European show jumpers frequently travel long distances for competitions, which may explain the increased risk in horses in this discipline.[67]

Endotracheal intubation, dorsal recumbency, and anesthetic-induced depression of the respiratory defense mechanisms may all increase the risk of lower airway contamination with general anesthesia. Respiratory viral infections result in damage to airway epithelium and breakdown of clearance mechanisms, further increasing the risk of bacterial colonization of the lower airway.[59] Penetrating thoracic injuries and pulmonary aspiration secondary to esophageal obstruction or upper airway dysfunction have also been associated with an increased risk of pleuropneumonia.[56,59,67]

Clinical Signs

Clinical signs vary depending on the chronicity and severity of disease and on the volume of pleural effusion. In the peracute stage, fever, inappetence, lethargy, depression, and exercise intolerance are common. Pleurodynia (pleural pain) secondary to pleural inflammation may be manifested by anxiety, pawing, reluctance to move, abduction of the elbows, and grunting when the thorax is percussed. A soft cough, dyspnea, tachypnea, and tachycardia may or may not be present during the peracute phase. Lung sounds vary depending on the severity of pulmonary and pleural changes, and a rebreathing examination is recommended to increase the depth of respiration and to accentuate audible lung sounds. Although lung sounds may be relatively normal during the peracute stages, the patient often becomes distressed by the rebreathing examination (because of increased pleural pain) and may begin to cough violently.

With progression of the disease and accumulation of pleural effusion (acute to chronic stages of the disease), auscultation reveals ventral dullness with pleural friction rubs and adventitial sounds (crackles and wheezes) in the dorsal lung fields. Areas of dullness can also correlate with pulmonary or pleural abscessation. Cardiac sounds frequently radiate over a larger than normal area as a result of the pleural effusion and improved sound conduction. Nasal discharge can vary between absent and copious and can range in consistency from serous to purulent. A chronic brown, bloody nasal discharge indicate pulmonary hemorrhage and infarction.[68] A foul, fetid odor to the breath is frequently associated with anaerobic infections.[69,70]

Accumulation of pleural effusion results in an increased respiratory effort with a slow prolonged pattern of inspiration and expiration. This pattern is the result of pleural fluid accumulation and its effects on lung volume and expansion of the chest wall.[71] Edema can frequently be palpated between the pectoral muscles and along the ventral midline, and it is a nonspecific finding with pleural effusion. Dramatic weight loss over a relatively short time results from the catabolic nature of the disease coupled with a decreased (or absent) appetite.

Diagnosis

The diagnosis of bacterial pleuropneumonia is based on clinical findings (fever, pleural pain, abnormal lung sounds), abnormalities detected in a complete blood count, ultrasonographic and radiographic findings, and positive bacterial culture of a tracheal wash and pleural fluid sample. Thoracic percussion can be used to detect and outline the extent of pleural effusion or pulmonary consolidation. The line of demarcation between resonant percussive sounds and dull sounds is usually the dorsal margin of pleural fluid accumulation. Fluid results in a horizontal line of percussion abnormality, whereas pulmonary consolidation without effusion generally results in a more irregular outline of dullness.

Thoracic ultrasonongraphy has largely replaced the need for percussion and is a simple and accurate way to assess the volume and type of effusion, if one is present (Figure 48-5). Pleurocentesis is indicated if fluid is detected, and ultrasonography is used to determine the ideal site for the centesis. An ultrasonographic examination of the thorax in the peracute stage may reveal pleural irregularities (Figure 48-6) without significant effusion or evidence of pulmonary consolidation. As the disease process progresses, pleural effusion generally increases and pulmonary consolidation becomes increasingly evident (Figure 48-7). Because of the large reflection of ultrasonic waves at an air–tissue interface, ultrasound is less useful in determining deep lung abscessation or consolidation if the superficial lung is aerated.[72] In this situation, thoracic

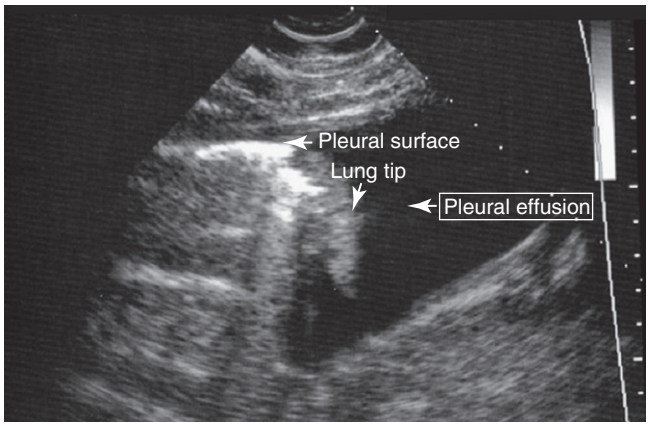

Figure 48-5. Ultrasonographic image of the left thoracic cavity of a horse with pleural effusion. A moderate volume of pleural effusion has resulted in collapse (atelectasis) of the ventral tip of the lung.

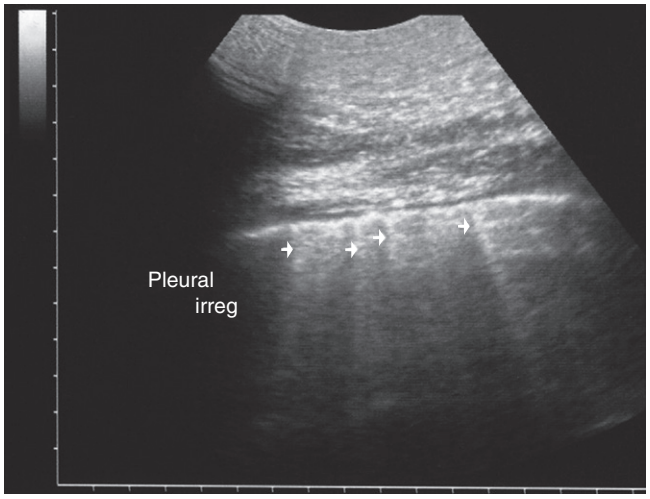

Figure 48-6. Ultrasonographic image of the left visceral pleura of a horse with peracute pleuropneumonia. The pleural surface casts irregular acoustic shadows or "comet tails" *(arrows)*. These irregular acoustic shadows are the result of pleural surface roughening. Subsequent reevaluation revealed progressive accumulation of pleural fluid and pulmonary consolidation.

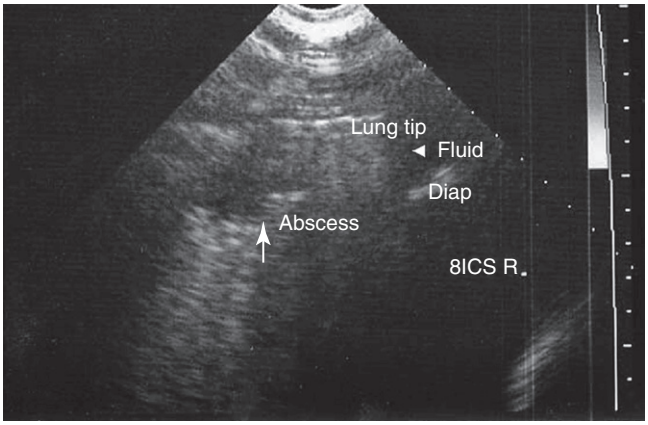

Figure 48-7. Ultrasonographic image of the right thorax of a horse with chronic pleuropneumonia. Minimal pleural effusion is evident *(arrowhead).* Consolidated or abscessed lung is evident by the break in the pleural surface and the ability to image the deeper parenchyma *(arrow).*

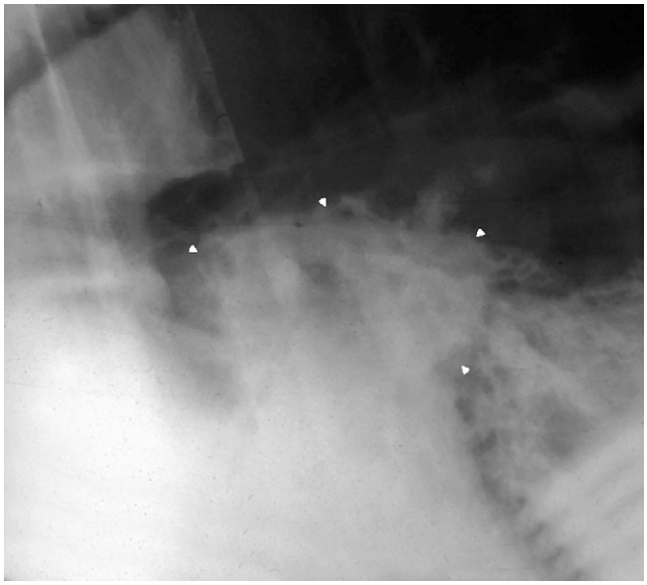

Figure 48-8. Thoracic radiographs of a horse with chronic pleuropneumonia and a large pulmonary abscess *(arrowheads).* Pleural effusion was removed via pleurocentesis prior to radiographic evaluation.

radiography is a more effective tool for evaluating deeper pulmonary parenchymal lesions (Figure 48-8). Drainage of pleural effusion prior to thoracic radiography facilitates accurate evaluation because pleural fluid obscures the lung parenchyma and makes it difficult to evaluate the extent or presence of consolidation or abscessation. Radiographs are useful to determine the extent of pulmonary consolidation and to evaluate progression over time; however, radiographic resolution of disease lags behind clinical resolution and, in our experience, radiographic reevaluation is more useful in evaluating long-term progression than short-term changes.

Complete blood count and serum chemistry abnormalities are relatively nonspecific and reflect the chronicity and severity of the inflammatory processes. Hyperfibrinogenemia and a neutropenia with a toxic left shift are frequently seen in the acute stage of pleuropneumonia. Other common abnormalities include hyperbilirubinemia (or anorexia) and azotemia (prerenal or renal). Neutrophilia is more commonly seen in the chronic stage of pleuropneumonia; an elevated serum globulin and anemia of chronic disease are also common. Although the abnormalities seen are nonspecific, they are useful in evaluating the response to treatment. A gradual decrease in serum fibrinogen and globulin levels, an improvement in the anemia, and a decrease in unconjugated bilirubin concentration (improved appetite) would be considered positive responses to therapy.

Aerobic and anaerobic microbial culture of tracheal wash and pleural fluid samples should be performed prior to instituting antimicrobial therapy. Alternatively, antimicrobials can be withdrawn for 24 hours prior to sample collection. Tracheal wash samples can be collected percutaneously using a nested trocar or via endoscopic techniques. Both methods are effective in experienced hands. Complications of the percutaneous method include localized cellulitis and chondritis; therefore, the site should be monitored carefully for 48 hours after sample collection. If multiple samples cannot be obtained from the chest or if financial constraints exist, the tracheal wash is the preferred sampling technique, yielding positive results with a greater frequency than pleural fluid samples.[51] However, in some cases, only the pleural fluid yields bacterial growth. Consequently, when possible, it is best to submit both sample types for culture. The most common organisms isolated include *Streptococcus, Escherichia coli, Actinobacillus, Klebsiella, Pseudomonas,* and *Staphylococcus* spp.[55,57,67-69,73] Common anaerobes include *Bacteroides* and *Clostridium* spp. Anaerobic bacteria were isolated in 25% to 68% of cases.[56,57,70,73]

In addition to culture, cytologic analysis of a sample of transtracheal aspirate can be useful to assess the type of infectious process present and to aid in determining the appropriate treatment protocol while awaiting culture results. For example, the presence of large, gram-positive coccobacilli from the transtracheal wash of a weanling foal may indicate of a *Rhodococcus equi* infection. Alternatively, the presence of fungal elements, particularly if a horse has been on long-term antimicrobial treatment, may indicate infection with fungal agents.[74]

Pleural fluid cytology alone is of limited value in determining sepsis and should be coupled with the determination of pleural fluid glucose, pH, and lactate.[75] In general, septic effusions are expected to have a low pH and high lactate and low glucose levels when compared with plasma. The finding of sepsis is a clear indication for drainage. Serial pleural fluid protein measurements and cell counts are useful to determine progress and resolution of infection. A trend toward normalization of pleural fluid values is expected with appropriate treatment and control of the infectious agents.

Medical Management

The cornerstone of medical treatment of bacterial pleuropneumonia is early institution of appropriate antimicrobial therapy. Treatment should be initiated with a broad-spectrum antimicrobial combination targeted against the most common bacterial pathogens isolated from equine pleuropneumonia cases, until specific culture results are available. A combination of a penicillin (or cephalosporin) and an aminoglycoside is a typical selection. Although many anaerobes found in equine pleuropneumonia are sensitive to penicillins, the addition of metronidazole is recommended if there is a lack of response to initial

treatment or a resistant anaerobe (such as *Bacteroides fragilis*) is cultured. Depending on the chronicity of the disease, the type of sample cultured, and prior treatment, a culture may not always identify the pathogens involved; consequently, it is critical to monitor the patient's response to treatment. Repeat cultures or alternative antimicrobial therapy is indicated if the response to therapy is inadequate. In our experience, a poor response to treatment typically occurs for one of three reasons: inappropriate antimicrobial treatment, inadequate pleural drainage, or the presence of abscessation or necrotic lung tissue. Therefore, daily assessment including ultrasonography is critically important in the successful treatment of pleuropneumonia. When subcutaneous air prevents an accurate ultrasonographic evaluation, thoracoscopy is a useful and relatively safe tool to assess the development of pleural abscesses or necrotic lung tissue.

The second important part of medical management is drainage of the pleural effusion. In mild cases, with minimal effusion, antimicrobial therapy alone may be effective in the resolution of the infection and effusion. The need for drainage should be determined on an individual basis. Indications include large volumes of effusion with or without evidence of respiratory distress, purulent or septic effusions, the presence of gas echoes consistent with an anaerobic infection, and pleural abscessation or loculation. In the acute stages of pleuropneumonia, drainage of one hemithorax frequently results in bilateral resolution of the effusion. Over time, the accumulation of fibrin and debris results in closure of the mediastinal fenestrations, requiring bilateral thoracocentesis to remove bilateral effusion.

Drainage can be facilitated by ultrasound-guided placement of small cannulas or catheters that are temporarily placed into the pleural space and removed after completion of drainage, or via placement of a semipermanent indwelling tube. Indwelling tubes have the advantage of allowing frequently repeated drainage; however, in our experience, over time these tubes become obstructed with fibrin or debris, necessitating their removal and replacement. Attachment of a one-way valve allows continuous drainage, but this can be risky if the horse rolls or otherwise breaks the valve. Alternatively, the drain can be sealed and opened multiple times during the day to allow more control of the drainage. Localized cellulitis is a frequent complication of indwelling cannulas. Although this is generally not a life-threatening complication, it results in increased thoracic pain and is frequently associated with a poorer appetite and general demeanor. Depending on the severity of the underlying pulmonary parenchymal disease and the type of bacteria involved, drainage can become increasingly more difficult as fibrin is produced and abscessation and loculation develop. Prior to the development of thorascopic techniques, we successfully treated cases with multiple, mature, pleural abscesses by repeated ultrasound-guided pleurocenteses and drainage. Although this was time consuming, it can be a useful technique to manage cases with multiple abscesses or loculations.

The judicious use of anti-inflammatory and analgesic drugs is recommended to control pleural pain and fever, minimize malaise, and improve attitude and appetite. Nonsteroidal anti-inflammatory drugs (NSAIDs) are potent analgesics and block production of inflammatory mediators that produce many of the systemic signs seen with pleuropneumonia. The value of NSAIDs in the treatment of pleuropneumonia needs to be weighed against the risks (nephrotoxicity and gastrointestinal ulceration), particularly in patients that are not eating or drinking adequately. The short-term use of small intramuscular doses or continuous-rate infusions (CRIs) of the α_2-agonist detomidine, a potent analgesic, has been effective in controlling severe, nonresponsive pleural pain.[76] α_2-Agonists should be avoided in febrile or hypovolemic patients until these conditions are corrected. Butorphanol, a potent opiate analgesic, can be administered intramuscularly or via CRI as well, and it may have the added benefit of suppressing the cough response (see Chapter 23).[77] Lidocaine infusions have also been reported to have an analgesic effect and may be an additional choice for pain control.[78] The use of combination therapies offers several advantages over single-drug treatment protocols, including more effective pain control and the ability to minimize potential toxic side effects.

Supportive Care

Intravenous fluid therapy may be necessary in the initial treatment of the hypovolemic or dehydrated patient, but it is rarely required for chronic cases of pleuropneumonia. In addition to fluid therapy, nutritional support should be addressed. Many of these patients have a decreased (or absent) appetite, which, coupled with the catabolic nature of the disease, results in significant, often dramatic, weight loss if not addressed quickly. Feeding of palatable feeds, access to grass, and gradually increasing concentrates in the diet are important methods to increase caloric intake. The addition of corn oil or rice bran to the diet may also be of benefit. In some individuals, enteral supplementation via nasogastric intubation or parenteral nutrition may be required to adequately supply the patient's metabolic needs. Continued anorexia may indicate inadequate pain control, uncontrolled infection, or severe underlying lung pathology (pulmonary necrotic debris, abscessation, or neoplasia). Patients that continue to be anorexic despite aggressive therapy have a poor long-term prognosis.

Surgical Treatment

Surgical intervention is typically used to assist in the medical treatment of equine pleuropneumonia. Long-term antimicrobial therapy is rarely effective in penetrating and resolving large abscesses or loculations when substantial fibrosis or septic fluid is present.[79] Open and closed thoracotomy, with or without rib resection, has been successfully used for drainage of thoracic abscesses and resection of adhesions.[80-83] Surgical manipulations can be used to reduce excessive fibrin, which can result in loculations and adhesions, drain pulmonary or extrapulmonary abscesses, resect necrotic lung tissue, or perform pericardectomy in cases of septic pericarditis.[17,80,84,85]

Vachon and Fischer reported the use of thoracoscopy as a useful therapeutic tool in 16 cases of pleuropneumonia.[17] Thoracoscopy facilitated the placement of thoracic drains in abscesses and loculated pleural effusion and the transection of pleural adhesions to disrupt loculations, and it allowed direct evaluation of the lungs and pleural cavity (Figure 48-9). Thoracoscopy provides a superior exploration of the pleural cavity compared with incisional thoracotomy.[23] Furthermore, the minimally invasive nature of thoracoscopy results in less morbidity and aftercare.

After establishing adequate pleural drainage, pleural lavage can be performed with isotonic balanced fluid solutions through

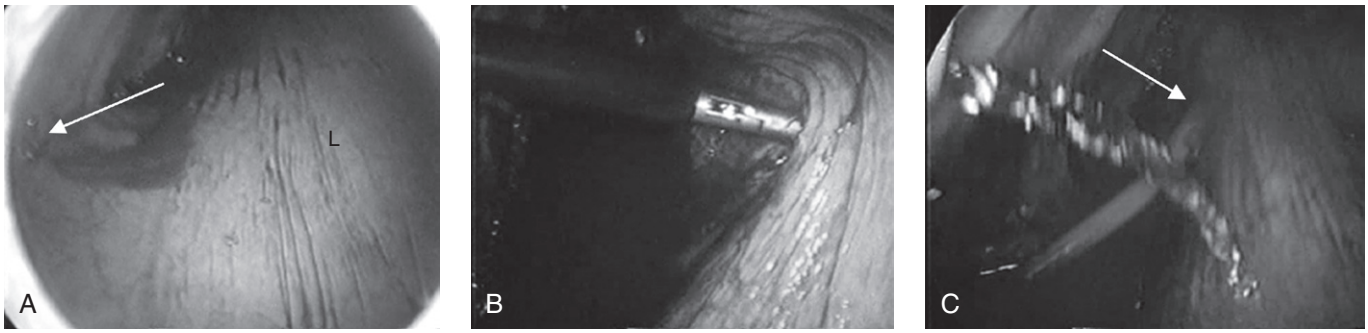

Figure 48-9. Thoracoscopic view of the left pleural cavity in a horse with pleuropneumonia. **A,** The collapsed lung *(L)* is adhered to the parietal pleura by fibrinous adhesions *(arrow).* **B,** With the use of endoscopic instruments, the lung is separated from the adhered parietal pleura. **C,** After adequate drainage was established, a large chest tube *(arrow)* was introduced into the thorax and the pleural cavity was lavaged with isotonic saline.

the cannula system. Adhesions are more readily disrupted the first week after formation when the tissue is fibrinous rather than fibrous. Transection of mature, fibrous adhesions can be difficult and tedious, and it can cause profound hemorrhage. Therefore, conservative transection of mature adhesions is recommended. Careful insertion of instruments or portals into the thorax is mandatory in horses with severe pleuropneumonia and with extensive pleural adhesions or anaerobic infections. Adhesions between the lungs and the thoracic wall may not allow complete collapse of the lung, making the manipulation of the instruments more difficult and limiting the view of the pleural cavity. This can increase the risk of injury to vital organs (e.g., lungs, diaphragm).[17] Before introducing the trocar–cannula system in horses with possible adhesions, digital palpation of the lungs and pleura through the endoscope portal is recommended to avoid iatrogenic injury to these structures. In addition, the use of CO_2 insufflation (at less than 5 mm Hg) can facilitate and maintain collapse of the lung, improving surgical exposure.

Open drainage via thoracotomy should be considered for a chronic pleural effusion that has responded poorly to medical therapy, for localized or unilateral disease processes, for walled-off abscesses, or when tube drainage is inadequate.[79,85] Before performing open thoracic drainage, the horse's tolerance for pneumothorax must be assessed. This can be done with thoracoscopy or by inserting a large chest tube into the targeted cavity and leaving it open prior to thoracotomy.[17,85] If no respiratory distress is observed, the diseased pleural hemithorax is likely to be isolated from the rest of the thoracic cavity and is amenable to open drainage. Because these horses have compromised pulmonary function and are poor candidates for general anesthesia, the procedure is typically performed in a standing position. However, general anesthesia with the horse in lateral recumbency is recommended to drain abscesses in the cranial mediastinum or when an abscess is not isolated from the rest of the pleural cavity.[86] Positive-pressure ventilation with a mechanical ventilator is mandatory. The use of isoflurane or sevoflurane is also recommended for gas anesthesia, because these drugs do not depress the equine myocardium as profoundly as halothane. Therefore, the combination of assisted ventilation, oxygen, and isoflurane or sevoflurane should be used to support horses undergoing a thoracotomy procedure when general anesthesia is required.

The preferred surgical approach to drain intrathoracic abscesses is determined by careful localization of the abscess by radiography and ultrasonography.[87] For the standing approach, local anesthesia is infiltrated into the skin, subcutaneous tissue, intercostal musculature, and costal pleura at the proposed incision site, and a local nerve block of the intercostal nerves is performed two intercostal spaces cranial and caudal to the site. A 15- to 25-cm (6- to 10-inch) incision is made through the skin, intercostal musculature, and pleura over the selected intercostal space into the thorax. Manual exploration and débridement of the purulent material is followed by lavage with isotonic balanced saline solution. The incision is left open and the diseased cavity is irrigated twice daily until the surgical wound heals by second intention.

If thoracotomy with rib resection is elected, a 30-cm (12-inch) incision is made over the selected rib, through the skin to rib periosteum. In the cranial aspect of the thoracic wall, the cutaneus trunci muscle is incised at a right angle to its fibers. The *M latissimus dorsi* and *M serratus ventralis* are subsequently incised separately. The external thoracic vein is identified near the dorsal edge of the pectoral musculature, isolated, and retracted. Careful dissection of thoracic wall musculature avoids damage to the intercostal vessels and nerves, which are located at the caudal aspect of each rib. To expose the entire length of the rib, the fascia from the attachment of the external intercostal muscle is bluntly dissected. The periosteum is incised along the superficial surface of the rib for a distance of 25 cm (10 inches) and reflected circumferentially with a periosteal elevator (Figure 48-10). The periosteum is separated from the rib, and an obstetric wire is passed around the most proximal aspect of the rib and transected. The rib is subsequently disarticulated at the costochondral junction and removed. A small stab incision should be made through the periosteum and pleura, and the opening is enlarged with scissors. A Finochietto rib retractor can be used to separate the ribs for better surgical exposure, but this can cause discomfort in the standing horse. Thoracic exploration and débridement is subsequently performed. Fluid and necrotic tissue are manually removed, taking care not to disrupt any mature adhesions.[87] If a localized abscess is encountered, a Foley catheter can be introduced from a separate stab incision through the thoracic wall into the abscess. The abscess can then be drained and lavaged, and the catheter can be removed or left *in situ* and secured to the chest wall for future irrigation. The thoracic incision is usually left open to heal by second intention.

If the thoracotomy is closed, three layers of sutures are recommended. A rib contraction device (Bailey-Gibbon rib

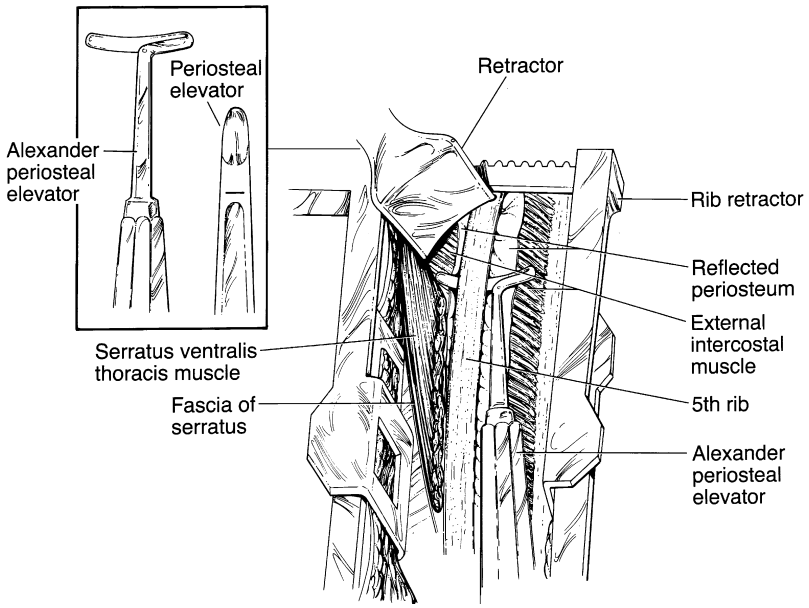

Figure 48-10. Surgical removal of the fifth rib with appropriate rib retractors and periosteal elevators. (Redrawn from the original by Gheorge M. Contantinescu, DVM, PhD, Dr hc.)

contractor) may facilitate the apposition of the thoracic wall. First, the periosteum is carefully apposed with size 0 or 1 absorbable suture material with a simple-interrupted pattern. The final suture in the first layer of the thoracic wall closure should be tightened while the lungs are fully inflated to reestablish the normal negative pressure of the pleural cavity. The intercostal musculature is subsequently closed in routine fashion with size 1 or 2 absorbable sutures. Finally, routine apposition of the skin edges with nonabsorbable suture material is recommended. Thoracic tubes are placed as necessary to alleviate a potentially remaining pneumothorax or to drain pleural fluid.

Complications after thoracotomy include cardiac arrhythmias, thoracic wall abscesses, chronic draining tracts, and severe bilateral pneumothorax.[82,83] In contrast to thoracotomy, only mild discomfort during manipulation of instruments was reported during thoracoscopy in horses affected by pleuropneumonia.[17] However, thoracoscopy is not without risk; complications including injury to vital organs (such as the lung and diaphragm) have been reported.[21,22] Surgical treatment does not replace medical management of equine pleuropneumonia but can, in selected cases, improve the prognosis of these horses.

Prognosis

In retrospective reports, the survival rate for horses with bacterial pleuropneumonia varied from 43% to 75%.[55-57] The presence of anaerobic bacteria has been associated with a poorer survival rate in some studies but not others. Delay between the onset of clinical signs and the diagnosis and start of treatment is also associated with a poorer outcome.[63] The majority of horses that do not survive bacterial pleuropneumonia are euthanized for reasons including poor response to treatment, development of complications, expense involved in treatment, or a poor prognosis for return to performance. In a study of racehorses that survived pleuropneumonia, 61% returned to racing, with 56% of those winning at least one race. However, racing class was not examined in this report.[58] Complications associated with pleuropneumonia include bronchopleural fistulas, spontaneous pneumothorax, cranial thoracic abscessation, jugular vein thrombosis, pulmonary infarction, laminitis, and, rarely, pericarditis and peritonitis.[55-59,67-69,73,86] A positive response to treatment is indicated by resolution of fever, return of appetite, and gradual reduction in the volume of effusion. Negative responses to treatment include recurrent fevers, continued inappetence and weight loss, continued effusion (particularly with progression of the effusion to an exudate), and development of the complications mentioned previously. These findings, coupled with a continued elevation in serum fibrinogen and globulins and an abnormal WBC count, should stimulate careful reevaluation of the individual. Even with appropriate and early treatment, the response is often slow, with treatment durations ranging from 3 weeks to several months. After resolution of the underlying infection at least 3 to 6 months of recovery time should be allowed prior to return to training and performance.

CHAPTER
49

Anatomy and Physiology of the Nervous System

Robert J. MacKay

DEVELOPMENT AND ORGANIZATION OF THE NERVOUS SYSTEM

The nomenclature relating to embryologic, medical, and common description of the parts of the brain is inconsistently applied and can be confusing. Table 49-1 shows the principal naming systems used for the parts of the brain, Table 49-2 gives numeric and medical names for the cranial nerves, and Figure 49-1 depicts the locations of the cranial nerves on the ventral aspect of the brain.

The nervous system derives from a specialized strip of ectoderm, the neural plate, which runs along the dorsal midline of the developing embryo.[1] Ventral to the neural crest is the primordial vertebral organ, the notochord, which develops in concert with the central nervous system (CNS). The sides of the neural crest fold upward and medially to meet in the midline and form the neural tube.

Beginning at the brain–spinal cord junction, the neural tube closes progressively both rostrad and caudad to encircle the developing brain and spinal cord.[2] The rostral part of the neural tube buds large vesicles laterally on either side, which develop caudad and ventrad to form the hemispheres of the cerebrum (telencephalon), leaving the rest of the rostral tube to form the thalamus and hypothalamus (diencephalon) (see Table 49-1). The lumen of the neural tube (the neural canal) forms the interconnected ventricular system of the diencephalon (third ventricle) and cerebrum (lateral ventricles). Together, these structures become the *forebrain* (prosencephalon). Cranial nerves I and II arise from the forebrain (see Table 49-2). Successively more caudal dilatations of the neural tube develop into the *midbrain* (mesencephalon) and *hindbrain* (rhombencephalon), respectively. The brain structures directly derived from the neural tube proper—namely, the diencephalon, midbrain, and hindbrain—comprise the *brain stem*. Development of the *neuropil*, the dense feltwork of interwoven cytoplasmic processes of dendrites, neurons, and glial cells, of the midbrain encroaches on the neural canal until it is a narrow tube, the mesencephalic aqueduct. The rostral part of the hindbrain (metencephalon) develops into the pons and cerebellum, while the caudal part, which is contiguous with the spinal cord, forms the medulla oblongata (myelencephalon). Within the pons and medulla, the neural canal forms the fourth ventricle, connecting the mesencephalic aqueduct rostrally with the spinal (central) canal caudally. Cranial nerves III and IV (midbrain), V (pons), and VI to XII (medulla) develop in the ventrolateral brain stem.

Within the neural tube of the developing spinal cord, primitive neurons become organized into mantle and marginal layers that become white and gray matter, respectively.[2] Ventral mantle neurons grow through the surrounding marginal layer and course outside the neural tube to form ventral spinal nerve roots. Dorsal ganglia and roots form from the growth of neural crest cells centrad into the neural tube and distad to sensory structures. The developing gray matter becomes divided morphologically and functionally into dorsal, intermediate, and ventral columns. Ventral and dorsal roots and gray matter divide spinal cord white matter into three regions called funiculi. These are dorsal, lateral, and ventral on each side of the spinal cord (Figure 49-2).

TABLE 49-1. Naming Systems for Principal Parts of the Brain

Primary Segments	Secondary Segments	Principal Divisions	Common Usage	Cavities
Prosencephalon (forebrain)	Telencephalon	Cerebrum	Brain	Lateral ventricle
	Diencephalon	Thalamus	Brain stem	3rd ventricle
		Hypothalamus		
Mesencephalon (midbrain)	Mesencepahlon	Midbrain	Brain stem	Mesencephalic aqueduct
Rhombencephalon (hindbrain)	Metencephlon	Cerebellum	Brain stem*	4th ventricle
	Myelencephalon	Pons	Brain stem	
		Medulla oblongata	Brain stem	

*Some authors exclude the cerebellum from definitions of the brain stem

TABLE 49-2. Names of Cranial Nerves

Number	Name
I	Olfactory
II	Optic
III	Oculomotor
IV	Trochlear
V	Trigeminal
VI	Abducens
VII	Facial
VIII	Vestibulocochlear
IX	Glossopharyngeal
X	Vagus
XI	Accessory
XII	Hypoglossal

Base of the brain showing cranial nerve roots. *a,* Olfactory bulb; *b,* olfactory tract; *c,* piriform bulb; *d,* pons; *e,* abducens nerve; *f,* facial nerve; *g,* vestibulocochlear nerve; *h,* medulla oblongata; *i,* choroid plexus of the fourth ventricle; *j,* spinal cord; *k,* optic nerve; *l,* optic chiasm; *m,* pituitary gland, *n,* oculomotor nerve; *o,* trigeminal nerve (*o′,* motor root, *o″,* sensory root); *p,* cerebellum; *q,* glossopharyngeal nerve; *r,* vagus nerve; *s,* spinal accessory (medullary root); *s′,* spinal accessory (spinal root); *t,* hypoglossal nerve.

The Cranium

The cranium is made up of the occipital, sphenoid, ethmoid, interparietal, parietal, frontal, and temporal bones.[3,4] These bones enclose a cranial cavity with an approximate 650-mL volume in an adult horse. The roof of the cranium features large rostral and caudal concavities, which accommodate the hemispheres of the cerebrum and cerebellum, respectively (Figure 49-3). The internal occipital protuberance separates these cavities dorsally and provides attachment for the tentorium cerebelli, the tent-shaped extension of the dura mater that forms a partition between the cerebrum and cerebellum. The occipital

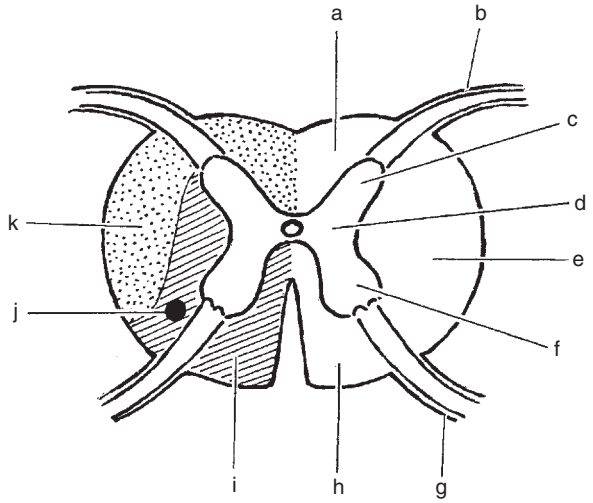

Figure 49-2. Simplified diagram of the functional *(left)* and anatomic *(right)* organization of the spinal cord at the level of the seventh cervical segment. *a,* Dorsal funiculus of the white matter; *b,* dorsal root; *c,* dorsal column of the gray matter; *d,* intermediate column of the gray matter; *e,* lateral funiculus of the white matter; *f,* ventral column of the gray matter; *g,* ventral root; *h,* ventral funiculus of the white matter; *i,* upper motor neuron *(descending)* tracts; *j,* sensory/pain *(ascending)* tracts; *k,* proprioceptive *(ascending)* tracts.

and petrous temporal bones encase the cerebellum dorsally and laterally. The cerebrum is covered dorsally largely by the parietal bones, with smaller contributions from the interparietal bone caudally and the frontal bones rostrally. The rostral or nasal wall of the cranial cavity is formed by the cribriform plate of the ethmoid, which separates the cranium from the nasal cavity. It is perforated by numerous foramina through which olfactory nerve bundles pass. On the dorsal midline is the internal parietal crest, which furnishes attachment to the falx cerebri, the sickle-shaped fold of dura, which separates the cerebral hemispheres. The forebrain may be injured by impact to the frontal or parietal area of the skull.[5] As a consequence of swelling, cerebral lobes may herniate under the falx or tentorium and compress other parts of the brain.

The floor of the cranial cavity is organized into three fossae.[4] The rostral fossa supports the frontal and olfactory parts of the cerebrum. It is formed chiefly by the sphenoid bone. Caudally in this fossa is a bony shelf, which covers the entrance to the optic canals and supports the optic chiasm. The optic nerves are firmly attached within the optic canals and may be injured within the canals by the to and fro motion of the brain after skull impact.[6] From this point caudad to the junction between the basilar portions of the occipital and sphenoid bones is the middle fossa. This is the largest and widest part of the cranial cavity. In its middle is the hypophyseal fossa and the caudal aspect supports the midbrain. On either side are two grooves, the medial one provides passage for cranial nerves III, IV, V (ophthalmic branch), and VI to the optic, trochlear, and orbital foramina; the lateral one leads to the foramen rotundum and contains the maxillary nerve (V). The posterior fossa is formed by the basilar part of the occipital bone. This bone supports the pons and medulla oblongata and the posterior fossa continues dorsad to enclose the cerebellum. On either side of the basilar part of the occipital bone is the foramen lacerum, through which course cranial nerves V (mandibular branch), IX, X, and

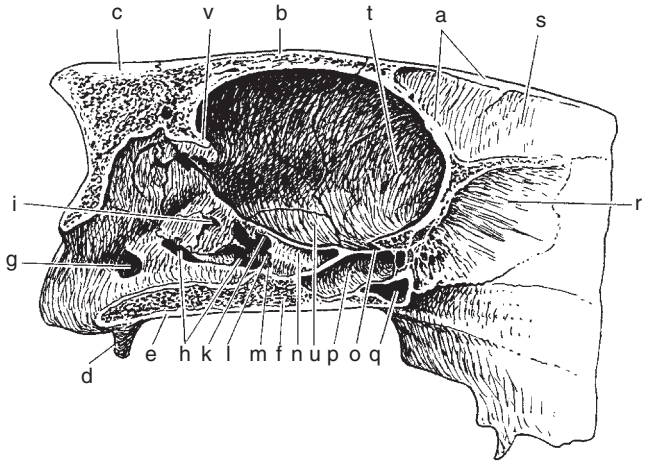

Figure 49-3. Sagittal section of cranium. *a,* Frontal bone; *b,* parietal bone; *c,* occipital bone (squamous part); *d,* paramastoid process; *e,* basioccipital bone; *f,* basisphenoid bone; *g,* hypoglossal foramen; *h,* foramen lacerum; *i,* internal acoustic meatus; *k*, spinous notch; *l,* oval notch; *m,* carotid notch; *n,* groove for maxillary nerve; *o,* optic foramen; *p,* sphenoidal sinus; *q,* central compartment sphenoidal sinus; *r,* perpendicular plate of ethmoid bone; *s,* septum between frontal sinuses; *t,* orbital wing of sphenoid bone; *u,* temporal wing of sphenoid bone; *v,* internal occipital protuberance.

XI. Caudolaterally, at the level of the occipital condyles, is the hypoglossal foramen through which passes cranial nerve XII. The ventral aspect of the basilar bones display tubercles at the points of attachment of the large paired rectus capitis ventralis major (longus capitis) and minor muscles. After poll impact, which typically results from a horse flipping over backwards, the wrenching action of these muscles may fracture or separate the basilar parts of the occipital or sphenoid bones and damage nerves in the adjacent foramen lacerum.[7]

The temporal bone forms most of the lateral wall of the cranium.[4] It is related to the occipital caudally, the parietal dorsally, the frontal rostrally, and the sphenoid bone ventrally. There are two distinct parts, the squamous and petrous bones. The squamous bone is plate-like in shape and overlaps laterally much of the petrous bone. The petrous bone is a dense pyramid-shaped bone that forms the lateral margin of the foramen lacerum. The external acoustic meatus opens on the lateral side. Housed within the petrous temporal bone are the cavities and specialized bones of the auditory and vestibular systems, including the large ventrally-projecting osseous bulla. Medially, the petrous temporal bone is related to the cerebellar hemisphere and transmits cranial nerves VII and VIII through the internal acoustic meatus. The temporal bone is vulnerable to fracture after poll impact.[5] A short rodlike projection, the hyoid process, projects from the base of the petrous slightly in front of the stylomastoid foramen, through which passes cranial nerve VII. The temporohyoid joint is formed by attachment of the hyoid process to the tympanohyoid cartilage and thus to the stylohyoid proper. A condition involving remodeling and fusion of this joint (temporohyoid osteoarthropathy) subjects the petrous bone to unusual stresses, which may result in fracture and signs of cranial nerve VII and VIII injury.[8]

The caudal fossa is continuous with the vertebral canal via the foramen magnum. As a result of increased pressure in the caudal fossa, the caudal part of the cerebellum may be squeezed through the foramen magnum (tonsillar herniation).[9]

Joints between the plates of the cranium are immobile synarthroses[4]; some, such as the joint between the basilar parts of the occipital and sphenoid bones, are bound together by cartilage (synchondroses) and others, such as the temporoparietal joint, are united by fibrous tissue (sutures). These joints usually ossify and become completely fused. The spheno-occipital synchondrosis fuses at about 5 years of age. The suture between the parietal bones ossifies at 4 years, the parieto-occipital suture at 5 years, and the parietotemporal suture at 12 to 15 years.

The Vertebral Column

The vertebral column extends from the skull to the end of the tail. There are five regions: cervical, thoracic, lumbar, sacral, and coccygeal (caudal). The typical formula for the horse is C7, T18, L6, S5, Cy15-21.[3] Although regions of the spine vary as to details, the vertebral structure conforms to a common plan. Each vertebra comprises a body, an arch, and various processes. The body is a cylindrical mass oriented along the median plane and connected to other vertebrae by fibrocartilaginous discs. Together with the dorsal surface of the body, the arch completes the vertebral foramen or ring. The arch consists of two lateral pedicles and a dorsal lamina. The intervertebral foramina, formed by the spaces between the arches of adjacent vertebrae, provide passage for spinal nerves and vessels. Successive vertebral rings are strung together by dorsal and ventral longitudinal ligaments to form the vertebral canal, a protective cylinder for the spinal cord, nerve roots, and cauda equina. The arch gives rise to articular processes at either end, a dorsal spinous process, and laterally projecting transverse processes. In some vertebrae, there are additionally mamillary or accessory processes, or costal facets. There are at least five centers of ossification in each vertebra: one body, two arches, and epiphyseal plates at either end of the body.

The spine can be modeled biomechanically as three "columns." The ventral column is composed of the ventral longitudinal ligament and the ventral half of the vertebral bodies and discs. The middle column is formed by the dorsal longitudinal ligament and dorsal half of the bodies and discs, and the dorsal column consists of the arches, intervertebral joints, and associated ligaments.[10] The degree of instability after spinal injury increases as more columns are impacted; the prognosis for recovery decreases correspondingly.

In its neutral position, the spine presents a series of curves in the median plane. The cranial part of the cervical spine is concave ventrally, the cervicothoracic junction is markedly concave dorsally, the thoracolumbar spine exhibits gentle ventral concavity, and the lumbosacral junction has more marked ventral concavity.[4] The vertebral canal varies in diameter as it progresses along the spine; within the atlas it is wide so as to house the dens and the spinal cord, and there are cervicothoracic and lumbosacral dilations to accommodate the corresponding intumescences of the spinal cord. The sagittal diameters of the cervical vertebral foramina in horses of various sizes have been determined radiographically.[11] Mean sagittal diameters for horses greater than 350 kg varied from 21.3 mm for C4 to 27.4 mm for C7.

The cervical vertebrae are relatively large and long. The arch is thick and strong and forms large articular processes. The cranial articular processes are directed dorsomedially; the posterior, ventrolaterally. Disordered vertebral development, possibly related to osteochondrosis, commonly causes malformation

and arthropathy of the cervical vertebrae in young adult horses (see Chapter 51). These changes may cause cervical vertebral stenotic myelopathy with compression of the spinal cord and ataxia of the limbs and trunk. Horses with these clinical signs are commonly referred to as "wobblers."

The first two cervical vertebrae are modified to accommodate the movements and weight of the head.[4] The atlas is composed of dorsal and ventral arches, lateral masses, and wings. The ventral arch has on its upper surface, the fovea dentis, on which the dens rests. The dens projects forward from the body of the axis and is attached by strong transverse, alar, and apical ligaments to the atlas and occiput. The upper cervical area of performance and racing horses is prone to severe hyperflexion, hyperextension, and/or axial compressive forces caused by collisions at speed.[12] Such stresses may fracture any of the bony components of the upper (cranial) part of the neck or separate the dens from the atlas.

Thoracic vertebrae are relatively constrained in their ranges of intervertebral movement. Added stability is provided to this region by the bracing action of the ribs and sternum. Perhaps because of the comparatively unconstrained movement of the cranial lumbar spine, fractures or dislocations of the vertebrae around the thoracolumbar joint occur quite commonly.

The sacrum is formed by the fusion of five sacral vertebrae.[4] It is wedged between and attached to the ilia. Branches of the first four sacral nerves course through the dorsal and ventral sacral foramina. Fusion proceeds from the front of the sacrum caudad and may not be complete even in adult horses. The sacrum houses the roots of the cauda equina and a small terminal part of the spinal cord that supplies the tail. These nerve roots are vulnerable to damage as a result of sacral fractures. Such injury may manifest as cauda equina syndrome (S2 to S5 roots)[9] and/or gait abnormalities in the pelvic limbs (S1 to S2).

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) envelops, bathes, and protects the CNS.[2,9] It is produced at high rate by the choroid plexuses of the lateral, third, and fourth ventricles and more generally by the meninges and ependyma. CSF passes from sites of production in the ventricles, out through the lateral apertures of the fourth ventricles, and subsequently flows forward over the cerebrum and caudad over the spinal cord (Figure 49-4). The rate of production is independent of CSF pressure. Absorption takes place in convoluted arachnoid structures, which project, mushroom-like, into cerebral veins or venous sinuses. Flow at these arachnoid villi is pressure dependent and unidirectional from CSF to blood.

The CSF plays an extremely important role in CNS homeostasis. Changes in CSF composition, as occur in subarachnoid hemorrhage[13] or bacterial meningitis, cause clinical changes out of proportion to the minor structural changes found in the underlying neuropil.

Cerebrospinal fluid is a modified transudate with lower potassium and calcium and higher chloride, sodium, and magnesium concentrations than are found in plasma. Protein (60 mg/dL or more) and cell (6 cells/μL or more) concentrations are lower than in most other body cavities. In disease, changes in CSF composition are a useful diagnostic tool. CSF collection and analysis and myelography are described in Chapter 50.

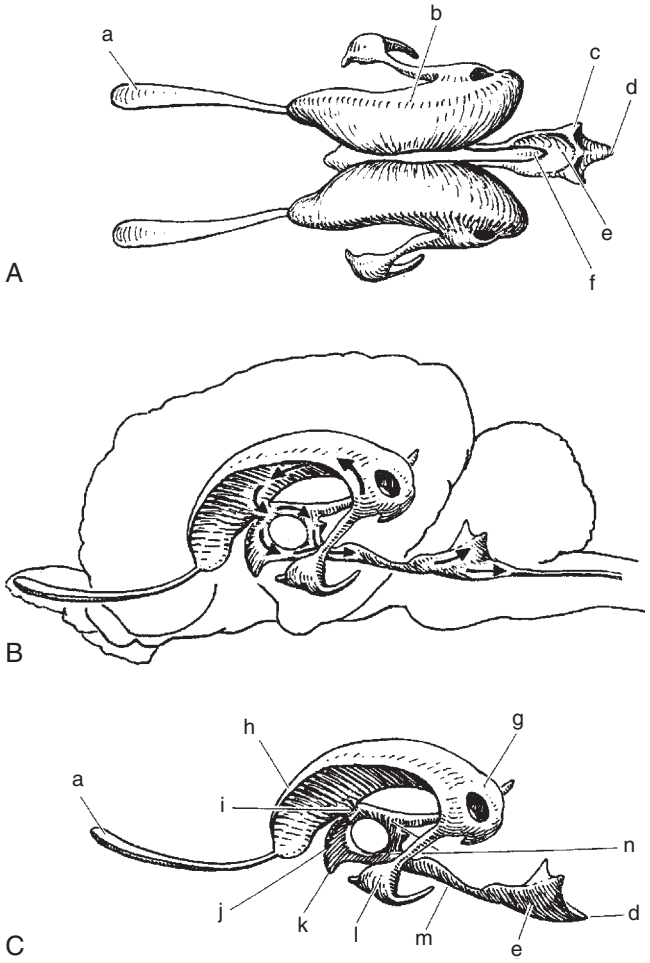

Figure 49-4. Ventricular system of the horse. **A,** Dorsal view; **B,** Lateral view showing direction of flow of cerebrospinal fluid; **C,** Lateral view. *a,* Cavity of olfactory bulb; *b,* lateral ventricle; *c,* lateral recess of the fourth ventricle; *d,* central canal; *e,* fourth ventricle; *f,* suprapineal recess, third ventricle; *g,* body of the lateral ventricle; *h,* rostral horn of the lateral ventricle; *i,* interventricular foramen; *j,* optic recess; *k,* infundibular recess; *l,* caudal horn of the fourth ventricle; *m,* mesencephalic aqueduct; *n,* third ventricle.

The CNS is physically separated from circulating blood by an extensive blood-brain barrier and a relatively minor blood-CSF barrier.[14] The blood-brain barrier is formed by endothelial cells, support cells such as astrocytes of the neuroglia and pericytes of the vascular system, and basal lamina. Endothelial cells of CNS capillaries are cemented together by continuous tight junctions. Foot processes of astrocytes (end feet) and long cytoplasmic processes of pericytes are closely adhered to the basal (i.e., nonlumenal) surfaces of CNS endothelial cells. These cells affect and support the barrier function of the endothelium. The basal lamina surrounds the endothelial cells and pericytes. A biochemical barrier against potentially injurious endogenous substances is provided by various endothelial enzymes including monoamine oxidases (e.g., epinephrine degradation) and aminopeptidases (e.g., enkephalins). Carrier and transport systems control traffic of some molecules across the blood-brain barrier. There is a Na/K-ATPase pump to regulate Na^+ and K^+, glucose transporters (including GLUT-1), amino acid

transporters, and transcellular endocytosis systems for receptor-mediated transfer of insulin, immunoglobulin G, and transferrin into the CNS. Generally, diffusion of molecules across the blood-brain barrier depends on physicochemical properties such as lipid solubility, polarity, and molecular weight. There is a close association between lipid solubility of compounds and their ability to cross the blood-brain barrier. The free, non–protein-bound, nonionized form of most drugs can passively diffuse into the CNS.

In healthy animals, the blood-CNS barrier limits the passage of immunoglobulins, complement, and potentially injurious unconjugated bilirubin. Penicillin and aminoglycosides are excluded from the normal CNS; however, the blood-brain barrier reportedly allows passage of therapeutic amounts of sulfonamide-trimethoprim, chloramphenicol, enrofloxacin, and ceftriaxone into the CNS of horses.

PHYSIOLOGY OF NEUROTRANSMISSION

The transmission and processing of information in the nervous system depends on the presence and distribution of different ion channels in neurons, the localization of synaptic circuits, and the synaptic effects of neurotransmitters.[14]

The nervous system functions through propagation of electrical signals via changes in cell membrane potential. The resting membrane potential is determined by flow of K^+ through channels open at rest and by the activity of the Na-K/ATPase pump. In response to stimuli, neurons generate local potentials that can summate. When these potentials reach the threshold for opening voltage-gated Na^+ channels, an action potential is triggered. The opening of Na^+ or Ca^{2+} channels produces neuronal depolarization, whereas opening of K^+ and Cl^- channels decreases neuronal excitability.

Neurochemical pathways in the CNS can be divided into two main groups: relay systems and diffuse projection systems.[2] *Relay systems* include the long sensory and motor pathways that connect neurons of peripheral nerves to centers in the brain. Spinothalamic, visual, vestibulospinal, and reticulospinal pathways are examples of relay systems. *Diffuse projection systems* modulate brain function by distributing signals from individual nuclei to multiple other (usually higher) areas of the brain. They consist of cholinergic and monoaminergic neurons in nuclei of the brain stem and subcortical areas.

The excitatory neurotransmitter for *relay systems* is L-glutamate and, in some areas, aspartate. Local inhibitory circuits along these relay systems use γ-aminobutyric acid (GABA) or glycine. Numerous studies in experimental animals have implicated glutamatergic neurotransmission in toxicity associated with trauma, ischemia-reperfusion, and epilepsy. Experimental inhibitors of the glutamatergic system are being investigated as therapy for brain injury.[15] GABA is synthesized from glutamate by the action of glutamic acid decarboxylase (GAD). Impaired GABAergic transmission is involved in some forms of epilepsy, and autoantibodies against GAD are thought to be the cause of the spastic gait seen in horses with stiff-horse syndrome.[16]

Diffuse projection systems include cholinergic, dopaminergic, noradrenergic, serotonergic, and histaminergic neurons. These systems are targets for numerous drugs used for psychiatric and movement disorders in humans. Dysfunction of cholinergic neurotransmission is responsible for the signs of fluphenazine (an antipsychotic sedative drug) and metaclopramide (a prokinetic agent) reactions in horses.[17]

CLINICAL NEUROANATOMY

The following section is designed to group neurologic functions according to major areas of the CNS. This section complements the information provided in Chapter 50.

Whole Brain

Level of Consciousness

One of the critical functions of the reticular formation of the brain stem is activation of the cerebral cortex for the awake state. This component of the formation, known as the ascending reticular activating system (ARAS), is an ill-defined meshwork of cells that richly invests the rostral half of the brain stem but also extends into the medulla oblongata. The ARAS receives afferent input from all parts of the CNS and projects excitatory stimuli cortically.

Focal to extensive lesions anywhere in the brain stem may reduce the level of consciousness, whereas cortical injury must be diffuse to cause noticeable obtundation. Injury to the rostral sections of the brain stem is more likely to cause severe obtundation than is injury to the medulla. The ARAS also is involved in the initiation and maintenance of sleep. Abnormalities of production or action of hypothalamic arousal peptides (hypocretins/orexins)[18] or imbalances of brain stem neurotransmitters may result in narcolepsy/cataplexy sleep disorders.

Upper Motor Neuron System: Voluntary Movement

The upper motor neuron (UMN) system is responsible for the initiation of voluntary movement and regulation of posture through support against gravity.[2] The latter is effected in part by modulation of the anti-gravity myotatic reflexes of the limbs. The component of the UMN system originating in the hypothalamus is responsible for the control of muscular activity associated with visceral functions (respiratory, cardiovascular, urinary).

Direct cortical influence over motor activity in the horse via the *pyramidal* system is largely limited to fine control of the muzzle and lips.[9] The much more important *extrapyramidal* system is a multisynaptic pathway from the brain to the lower motor neurons (LMNs) of the spinal cord and brain stem. The frontal and parietal lobes of the cerebrum, basal nuclei, diencephalon, midbrain, and hindbrain all contribute to the UMN system. Upper motor neurons, particularly those originating in the midbrain, generally are inhibitory to myotatic reflexes. Damage to the neurons or axons of these tracts in the caudal midbrain, hindbrain, or spinal cord, increases extensor tonus and may result in limb spasticity ("stiffness"). With UMN injury there also is limb weakness, hyperactive extensor reflexes, and crossed extensor reflexes, all in the ipsilateral limbs.

Movement disorders are characteristic of UMN disease in the rostral brainstem. Abnormal involuntary movements include dystonia (writhing movements of the muscles of the head and spine), ballism (violent flailing of a limb), chorea (repetitive jerky movements of different muscle groups), and myoclonus (repetitive movements of a single muscle group).[14] Nigropallidal encephalomalacia is a disease of this type in horses that is caused by the chronic consumption of the neurotoxin repin in yellowstar thistle or Russian knapweed plants.[19] There is dystonia and rigidity of the muscles of the head resulting in lip retraction, tongue protrusion, and inability to prehend food.

More generalized extrapyramidal syndromes in horses reportedly are associated with reactions to fluphenazine (an antipsychotic sedative drug) and metaclopramide (a prokinetic agent).

Forebrain

Behavior (Limbic System, Temporal Lobes)

Normal behavior requires integration of signals from the entire CNS but principally involves the forebrain. Most important in controlling intrinsic behavior is the *limbic system:* a connected series of structures in the cerebrum and diencephalon. A minor component is also found in the midbrain. Included are the amygdala, hippocampus, fornix, cingulate gyrus, and septal area. A closely associated region, which is important in primate behavior, is the temporal lobe of the cerebrum.[2] It is thought that behavior based on conditioning and experience (i.e., learning) is controlled by the temporal lobes. Structural, metabolic, or psychological disturbances affecting these areas may result in behavioral abnormalities (i.e., dementia). Dementia can be defined as changes in normal habits, personality, attitude, reaction to the environment, or loss of learned skills. Some of the signs that may be seen include disorientation in a familiar environment; failure to recognize familiar humans, animals, or objects; loss of the ability to be led; frequent yawning; head-pressing; irritability; unprovoked kicking or biting; compulsive walking or circling; and dramatic changes in eating or drinking habits.

Almost any disturbance of the forebrain potentially can cause dementia. Encephalitis, head trauma, space-occupying lesion, malformation, infarct, and metabolic disorders all are likely to cause changes in behavior. Important examples in horses include rabies, eastern equine encephalomyelitis (EEE), leukoencephalomalacia, neonatal encephalopathy (neonatal maladjustment syndrome), cerebral abscess, cholesterol granuloma, frontal/parietal trauma, post-seizure encephalopathy, hepatic encephalopathy, hyperammonemia, and hydrocephalus. It is likely that structural or metabolic forebrain disease is the cause of dementia if other neurologic abnormalities are found by neurologic examination or imaging studies. In the absence of such supportive findings, abnormal behavior (such as self-mutilation[20]) may have a psychological basis.

Seizures

Seizures are sudden, transient attacks of abnormal motor and/or behavioral activity attributable to paroxysmal depolarization of part to all of the brain.[9] Depolarization either occurs simultaneously throughout the brain or originates from a hyperirritable focus somewhere in the forebrain. Seizures originating from a focus likely will initially have asymmetric clinical signs and there may be additional signs of forebrain disease between seizures that are revealed by neurologic examination.

Seizures frequently originate in the frontal (motor) cortex and involve muscle fasciculations and tremors around the head or abnormal movements of the jaws and tongue ("chewing gum fits"). Convulsions characteristic of neonatal encephalopathy often are of this type. In their severest (generalized) form, seizures manifest as sudden recumbency, with a brief phase of extensor tonus, followed by clonic ("galloping") movements of the legs, loss of consciousness, and a variety of signs of autonomic discharge (e.g., sweating, urination, defecation, pupillary dilation). Mild motor seizures are often accompanied by behavioral signs such as obtundation, compulsive walking, vocalization, hyperresponsiveness to stimuli, or other signs of dementia. Seizure foci in the forebrain may occur at sites of previous or current trauma or inflammation. Examples include skull trauma, equine protozoal myeloencephalitis (EPM), EEE, intracranial neoplasia, and aberrant parasite migration. Causes external to the brain include hyperammonemia, hyponatremia, hyperthermia, and hepatic or renal failure. Juvenile epilepsy of Arabian foals occurs because of transiently increased susceptibility to seizures and manifests as repeated generalized seizures without other evidence of brain disease in foals 1 to 9 months old.[9]

Perception of Pain (Parietal Cortex, Cranial Nerve V)

Pain sensation is transmitted from the body to the brain in multisynaptic spinothalamic tracts.[2] Signals initiated by stimulation of pain receptors on one side of the body pass through spinothalamic tracts on both sides of the spinal cord. Axons in these tracts course rostrally to terminate in the thalamus. From there, cell bodies project axons to the sensory (somesthetic) cortex for conscious perception of pain or other sensory modalities. It is thought that the somesthetic cortex is located principally in the parietal lobe of the cerebrum.

The pathways for pain perception in the head pass through the maxillary, ophthalmic, and mandibular branches of the trigeminal nerve. The central component of this pathway is predominantly contralateral. Unilateral lesions of the sensory parts of the forebrain (thalamus, internal capsule, sensory cortex) thus cause contralateral facial hypalgesia. Because the central components of vision and facial pain perception are close anatomically, it is common to find unilateral facial hypalgesia and blindness (on the same side) in the same horse.

Diseases associated with abnormalities of facial pain perception are the same as those described later for disorders of vision perception.

Smell (Olfactory Bulbs, Cranial Nerve I)

Olfactory nerves pass through the cribriform plate and into the olfactory bulbs of the cerebrum. Information on smell is relayed through the thalamus to centers in the unconscious (limbic system) and conscious cerebrum.

Vision (Thalamus, Occipital Cortex, Cranial Nerve II)

In horses, 80% to 90% of optic nerve fibers from one eye cross at the optic chiasm and 80% of fibers in the optic tracts synapse at the lateral geniculate nucleus in the thalamus.[2] The remainder course to the midbrain to function in the pupillary light reflex (see later). Neurons in the lateral geniculate nucleus project via the internal capsule to the visual cortex in the occipital lobe of the cerebrum. This area is caudal in the cerebrum, immediately rostral to the tentorium cerebelli and caudal to the parietal cortex. The pathway from the eye to the contralateral visual cortex via the optic nerve, lateral geniculate nucleus, and internal capsule must be intact for normal vision. Although the pathways for vision and menace responses are assumed, for clinical purposes, to completely cross over at the optic chiasm, a thin medial slice of the nasal visual field does project to the ipsilateral cortex.

Lesions in the pathway caudal to the optic chiasm result in blindness in the opposite eye and lesions in the optic

nerve rostral to the chiasm affect vision in the ipsilateral eye. Damage to the cortex should not affect the pupillary reflex pathway.

Visual perception is evaluated by obstacle tests (with and without blindfolding of one eye) and by the menace response. The menace response requires the central visual pathway just described plus normal facial nerve function. Integrity of the cerebellar cortex is also needed, although it is not known if the pathway that mediates this response actually passes through the cerebellum. *It is important to note that the menace response does not develop in foals until they are 1 to 2 weeks old.*

Any disease that causes diffuse, severe cerebral dysfunction is likely to cause blindness. Examples include EEE, post-seizure encephalopathy, hyperammonemia, leukoencephalomalacia, and frontal/parietal trauma. Asymmetric frontal/parietal skull trauma, EPM, cerebral abscess, and cholesterol granuloma are diseases that may cause unilateral visual deficits by affecting the forebrain on the opposite side. Arabian foals with cerebellar abiotrophy have normal vision, but menace responses are absent.[21]

Midbrain

Pupillary Light Reflex, Pupil Size (Midbrain, Cranial Nerves II, III)

In the normal horse, pupil size reflects the balance of sympathetic (dilator) and parasympathetic (constrictor) influences on the smooth muscle of the iris. Preganglionic neurons for sympathetic supply to the head arise in the gray matter of the first four thoracic segments of the spinal cord and subsequently course rostrally in the cervical sympathetic trunk. After synapse in the cranial cervical ganglion adjacent to the guttural pouch, the postganglionic sympathetic neurons continue to the smooth muscle of the orbit and act to cause pupillary dilation. Emotional and other influences on sympathetic pupillary tone are governed by hypothalamic centers that act through UMN tracts descending from the midbrain.

Interruption of pre- or postganglionic sympathetic nerves to the eye causes Horner's syndrome, with miosis of the pupil, enophthalmos, ptosis, and spontaneous sweating and vasodilatation over the side of the face. Injury to the sympathetic UMN tracts in the brain or spinal cord not only may cause Horner's syndrome but also may result in increased sweating over the entire side of the body. Preganglionic neurons may be injured in the proximal thorax or along the neck in the vagosympathetic trunk. The cranial cervical ganglion and postganglionic neurons may be destroyed by fungal invasion in horses with *guttural pouch mycosis.*[22] Rarely, signs referable to interruption of sympathetic UMN tracts are found in horses with brain stem or spinal cord lesions (e.g., EPM, spinal cord trauma).

Parasympathetic preganglionic neurons arise in the midbrain and exit the skull in the oculomotor nerve (CN III). These neurons synapse behind the eye in the ciliary ganglion. Postganglionic neurons pass along the optic nerve to innervate the ciliary muscle and constrictor of the pupil. This system is responsive to the amount of light received by each eye. The afferent part of the pupillary light reflex passes via the optic nerves and optic tracts, past the thalamus, to terminate in the midbrain. There is extensive decussation of these tracts both in the chiasm and midbrain, so light directed into one eye causes reflex pupillary constriction in both eyes.

Injury to an optic nerve renders the ipsilateral pupil unresponsive to direct light, but it remains responsive to light directed into the contralateral eye. In contrast, injury to the midbrain or oculomotor nerve causes mydriasis in the ipsilateral eye that is unresponsive to light directed into either eye. Focal diseases (such as EPM, aberrant parasite migration, or midbrain hemorrhage) potentially could involve the oculomotor nuclei, although this is rare. More commonly, the oculomotor nerves are compressed by swelling and subtentorial herniation of the cerebral hemispheres. Early in the process of cerebral injury, pupils often are miotic; progression to bilateral mydriasis is a grave prognostic sign.[2]

Midbrain/Hindbrain

Eye Position (Midbrain; Pons; Cranial Nerves III, IV, VI)

From nuclei in the midbrain and pons, the oculomotor, trochlear, and abducens nerves exit the cranial cavity through the orbital fissure and ramify in the periorbital tissues to innervate the rectus and oblique muscles of the eye. The oculomotor nerve also supplies the levator palpebrae and pupillary constrictor muscles and the abducens nerve innervates the retractor bulbi muscle. Lesions in these nerves (or nuclei) cause abnormal eye position (strabismus). The direction of eye deviations resulting from specific nerve lesions is not known for the horse and cannot necessarily be inferred from data for other species.[9] Unlike vestibular strabismus, which can be corrected by rotating the head (usually in the direction of the lesion), strabismus caused by lesions in extraocular nerves persist in any head position. The finding of mydriasis (CN III) or defective eyeball retraction (CN VI) may provide additional information on lesion location in horses with strabismus.

Hindbrain

Mastication (Pons, Cranial Nerve V)

The LMNs of the trigeminal nerve arise in the pons and pass through the petrous temporal bone and the foramen ovale adjacent to sensory trigeminal neurons and are distributed to the muscles of mastication: masseters, pterygoids, temporals, and rostral digastricus.

With unilateral damage to the trigeminal nucleus (or nerve), there is deviation of the lower jaw toward the normal side. By 2 weeks after injury, there is obvious muscular atrophy. Bilateral severe involvement of the trigeminal nuclei (or nerves) causes a dropped jaw, weak jaw tone, slight tongue protrusion, and inability to prehend or chew feed. Damage to the nucleus of CN V, either unilaterally or bilaterally, is found in some horses with EPM.[23]

Facial Expression and Movement (Medulla, Cranial Nerve VII)

Normal facial tone, expression, and movements are dependent upon the integrity of the facial nerves. These nerves arise from nuclei in the rostral medulla (hindbrain) and exit the calvarium with cranial nerve VIII via the internal acoustic meatus. The nerve courses through the facial canal in the petrous temporal bone adjacent to the middle ear and emerges through the stylomastoid foramen. The facial nerve is distributed to the muscles of facial expression including those of the ear, eyelid, nose, and lips, and the caudal belly of the digastric muscle.

The effects of interruption of this motor pathway depend upon the site of damage. With involvement of the nucleus or proximal nerve, there is drooping of the ear and lip, ptosis, and collapse of the nostril, and the muzzle is pulled toward the normal side. Saliva often drools from the affected side of the mouth, and the horse has difficulty prehending food, especially grain. There may be exposure keratitis secondary to eyelid paralysis.

The facial nerve also contributes parasympathetic neurons to lacrimal glands (and some salivary glands). Damage to the facial nerve proximal to the middle ear likely will affect tear production by this mechanism. Tear production can be measured and compared between sides using the Schirmer tear test. The sensory component of the facial nerve contains fibers from the tongue (taste) and middle ear.

Facial nerve motor function is evaluated by testing "flick" reflexes of the lip, eyelid, and ear. These reflexes involve afferent sensory input via trigeminal neurons that terminate in the medulla on the LMN of the facial nerves. Note that these reflexes do not involve the forebrain and thus can occur without conscious perception. Because they are close together in the hindbrain and skull, the facial and vestibulocochlear nerves are often damaged together. Examples of diseases that often affect both nerves are West Nile virus encephalomyelitis, EEE, EPM, migrating parasite (central), polyneuritis equi, lightning strike, petrous temporal bone fracture, temporohyoid osteoarthropathy, or extramedullary neoplasm (peripheral). To distinguish clinically between central and peripheral causes, it is important to look for other signs of brain disease. For example, a horse with a lesion in the medulla affecting the nuclei of cranial nerves VII and VIII, may also be obtunded with weakness and ataxia of ipsilateral limbs.

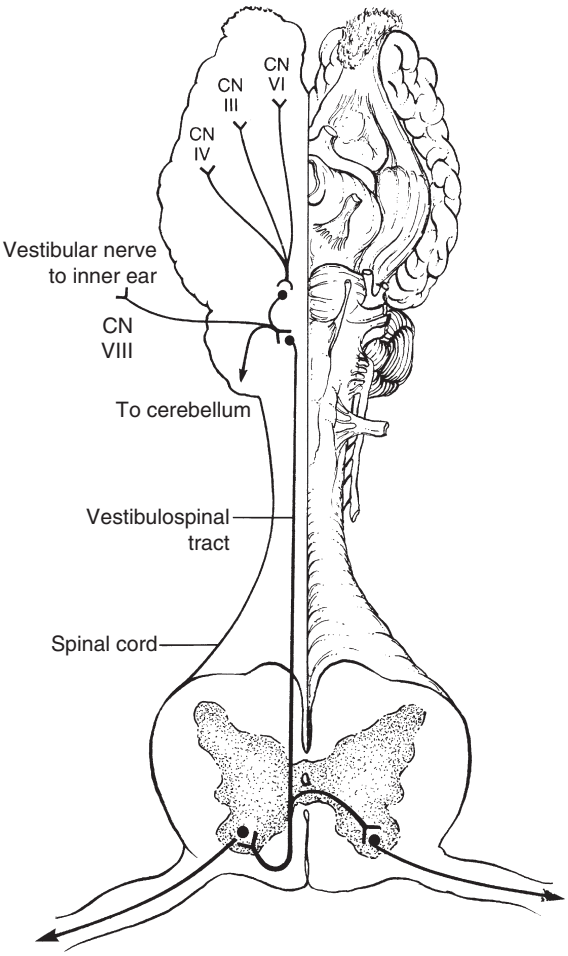

Figure 49-5. The vestibular system showing afferent input from the inner via cranial nerve VIII *(CN VIII)* to the vestibular nuclei in the hindbrain. There is complex integrated output to the cranial nerves controlling extraocular muscles *(CN III, CN IV,* and *CN VI),* the cerebellum, and the trunk and limbs *(vestibulospinal tracts).*

Balance and Equilibrium, Hearing (Medulla, Cranial Nerve VIII)

The vestibular system is responsible for orientation of the horse relative to gravity (Figure 49-5). The receptor is in the bony labyrinth of the inner ear. The membranous labyrinth includes three semicircular ducts containing endolymph that connect to vestibular nerve endings at the cristae ampullares. Vestibular neurons pass centrally through the internal acoustic meatus to penetrate the rostral medulla and terminate in four vestibular nuclei. The first pair or two of cervical nerves also contributes to vestibular function via sensory fibers, which pass to the vestibular nuclei. These nuclei have numerous projections to the cerebellum and the spinal cord and to nuclei controlling extraocular muscles.

The vestibular system controls the conjugate movements of the eyes during movement of the head through extensive connections with the nuclei of cranial nerves III, IV, and VI. Vestibular-cerebellar pathways pass through the caudal cerebellar peduncle. These pathways function to smoothly coordinate the movements of the eyeballs, trunk, and limbs with those of the head. Vestibulospinal tracts descend ipsilaterally to synapse on LMN and facilitate extensor muscles of the limbs while inhibiting flexor muscles. Some vestibulospinal tracts cross and reduce extensor tonus in contralateral limbs.

Unilateral disease involving the peripheral part of the vestibular system causes asymmetric ataxia *with preservation of strength*. The poll rotates towards the side of the lesion and the head and neck may be turned toward the lesion. The body leans, falls, or rolls toward the side of the lesion and the horse may stagger in tight circles. This type of circling should be distinguished from the compulsive walking in circles (without head tilt) that is characteristic of horses with asymmetric frontal cerebral lobe lesions. Because there is some visual compensation for vestibular ataxia, blindfolding exacerbates the signs and is a useful clinical test in mild cases of suspected vestibular disease.

In horses with central vestibular disease, there usually are additional signs of hindbrain disease (e.g., obtundation and *limb weakness*) and head tilt may be either toward or away from the side of the lesion. The latter presentation is known as paradoxical central vestibular disease and usually follows involvement of vestibular connections within the cerebellum. Unilateral vestibular disease often causes spontaneous or positional nystagmus and physiological (vestibular) nystagmus may be absent or abnormal. In *peripheral disease*, the nystagmus is always horizontal, rotatory, or arc-shaped, with the fast phase away from the lesion. With *central involvement* of the vestibular system, nystagmus also may be vertical. Typically, the eye on the affected side rotates ventrally in the orbit while the eye on the normal

side rotates dorsally (especially when the head is extended). This abnormal eye position is termed *vestibular strabismus.* Bilateral vestibular disease is characterized by severe symmetric ataxia and wide, sweeping movements of the head from side to side. In addition to the diseases described earlier that also affect the facial nerve, an idiopathic vestibular syndrome is reported to occur in the horse, possibly as a result of viral neuritis or labyrinthitis.[9]

Neurons of the cochlear division of cranial nerve VIII pass from receptors in the middle/inner ear to auditory centers in the midbrain and thalamus. A variety of local reflexes are initiated by stimulation of the cochlear nerve. In addition, there is projection of conscious pathways for hearing from the thalamus to the cortex (temporal lobe?). Deafness is rarely detected in the horse.

Taste (Cranial Nerves VII, IX, X)

Taste buds are found on the surface of the tongue and also in the soft palate, pharynx, lips, and cheeks. Sensory gustatory innervation is provided by the facial nerve (rostral two thirds of the tongue), glossopharyngeal nerve (caudal one third of the tongue), and vagus (pharynx and palate). General sensory innervation provided by the trigeminal nerve probably also contributes gustatory information. Perception of taste involves the forebrain including the limbic system. Deficiencies in the sense of taste are very difficult to detect by clinical testing.

Movement of Pharynx and Larynx (Cranial Nerves IX, X, XI)

Motor innervation of the larynx and pharynx originates in neurons in the nucleus ambiguus, a fusiform structure extending the length of the medulla. This nucleus provides axons for the glossopharyngeal, vagus, and spinal accessory (internal branch) nerve roots. These roots form nerves that innervate the soft palate, pharynx, larynx, and cranial esophagus via the pharyngeal plexus and cranial and recurrent laryngeal nerves. The nucleus ambiguus is continued in the spinal cord as the nucleus of the external branch of the spinal accessory nerve (innervation of trapezius and parts of brachiocephalicus and sternocephalicus). The facial and hypoglossal nerves innervate several of the muscles that control movements of the hyoid apparatus; therefore, impaired movement of the hyoid apparatus caused by paralysis of these nerves could affect movements of the larynx and pharynx. Clinically, such effects are minor in horses at rest, but they can be revealed by intense exercise.

Unilateral (hemiplegia) or bilateral pharyngeal paralysis interferes with swallowing and manifests as signs of dysphagia: coughing and gagging during eating with return of saliva, feed, and water through the nostrils and mouth. With complete unilateral laryngeal hemiplegia (i.e., paralysis of adductors and abductors), there is exercise-induced respiratory stridor and aspiration of feed into the trachea. In horses with bilateral laryngeal paralysis, inspiratory stridor occurs at rest and there is aspiration pneumonia. Some or all of these pathways can be affected peripherally in horses with botulism, guttural pouch mycosis, extramedullary neoplasia, or basilar skull fracture. Examples of diseases affecting the hindbrain that may cause laryngeal or pharyngeal dysfunction are EEE, EPM, leukoencephalomalacia, bacterial meningitis, and West Nile viral encephalomyelitis (WNVE).

Tongue Movement (Cranial Nerve XII)

The muscles affecting movement of the tongue are supplied by the hypoglossal nerve. Neurons of the hypoglossal nerve originate in the hypoglossal nucleus in the caudal aspect of the medulla and emerge from the medulla as a horizontal row of rootlets, which combine to form the nerve as it enters the hypoglossal foramen. After emerging from this foramen, the hypoglossal nerve runs forward and ventrad in association with the guttural pouch and stylohyoid bone to innervate the geniohyoideus and muscles of the tongue.

Interruption of the hypoglossal pathways causes hemiparesis of the tongue, evident as deviation of the apex of the tongue toward the affected side. Within 1 to 2 weeks, atrophy of the tongue will become noticeable. The peripheral nerve may be damaged by extramedullary neoplasia, upper cervical or caudal skull trauma, or guttural pouch mycosis. Tongue hemiplegia and atrophy has been seen in horses with EPM although any cause of caudal hindbrain disease can damage the hypoglossal nuclei.

Cerebellum

The cerebellum sits in the caudal fossa of the skull and is separated from the cerebral hemispheres by the tentorium cerebelli. It is divided into the flocculonodular lobe, also known as the vestibular cerebellum, and the much larger body of the cerebellum. The cerebellar body consists of a median region, the vermis, and two lateral cerebellar hemispheres. Connections with the rest of the CNS are via three peduncles: efferent connections pass through the rostral peduncle and afferent pathways enter the cerebellum via the middle and caudal peduncles.

The cerebellum regulates and smoothes motor activity initiated by the UMN system. It also acts to maintain equilibrium and appropriate body posture during rest and motion. Proprioceptive information is gathered via afferent connections from the spinal cord (spinocerebellar tracts) and vestibular system and is notified of UMN activity via extensive connections with brain stem UMN nuclei (including the olivary nucleus). Efferent cerebellar neurons project to vestibular nuclei and other parts of the brain stem including the thalamus. There is virtually no projection of cerebellar efferents into the spinal cord.

Cerebellar disease is usually diffuse and manifests as symmetric ataxia without weakness. There is defective regulation of the rate, range, and force of movement. Limbs may appear spastic with excessive (hypermetric) or inadequate (hypometric) flexion during protraction. Signs are most obvious when there is a change in the force or direction of voluntary movement. At rest, the body may sway, laterally or backward and forward, and there may be coarse head bobbing or tremor that is exacerbated by voluntary movement, such as reaching the head out for food. Extensor muscle tone is increased and limb reflexes may be hyperactive. With diffuse cerebellar cortical disease, the menace response is absent, although vision is normal (see earlier).

Signs of diffuse cerebellar disease are seen in Arabian horses[24] or Götland pony foals with cerebellar abiotrophy. This inherited disease first manifests at any time from birth to 3 months of age and may be stable or progressive for weeks to months. Rarely, horses with poll trauma have a head bob indicating cerebellar injury. The rhabditid nematode *Halicephalobus gingivalis* has a propensity to invade the caudal fossa and cause cerebellar destruction.[25] Tremorgenic mycotoxins produced by

parasitized perennial ryegrass or *Paspalum* species cause signs suggestive of cerebellar dysfunction, although other parts of the CNS are also affected.

Spinal Cord

Upper Motor Neuron: Muscle Tone and Voluntary Movement

Axons of the UMN extrapyramidal and vestibular systems travel from cell bodies throughout the brain and pass predominantly in reticulospinal and vestibulospinal tracts to LMN in the ventral and intermediate columns of the gray matter of the spinal cord. As described in the section on UMN of the brain, this system provides tonic support of the body against gravity and recruits spinal reflexes for the initiation of voluntary movement. UMNs act by influencing α and γ motor neurons in the spinal cord. These LMNs, in combination with afferent nerves and stretch receptors in the neuromuscular spindles and tendons, control muscle tone and movement by myotatic and antimyotatic reflexes. Most descending UMN tracts are inhibitory to extensor motor neurons. Removal of these influences by transection through the midbrain causes extension of head, neck, trunk, and limbs, signs that are characteristic of decerebrate rigidity.[2] Basic locomotor activity involves recruitment and control of these reflexes by distinct postural and voluntary UMN systems.

Interruption of UMN tracts in the spinal cord causes signs of ipsilateral weakness of the trunk and limbs. Signs of paresis range in severity from slight toe-dragging and delayed protraction to recumbency and inability to rise. Because myotatic reflexes are released from inhibitory UMN influences, there may also be spasticity (stiffness) of limb movement. This is most obvious in the thoracic limbs, which may appear to "float" during walking. The stiff appearance reflects decreased flexion of the limb during the protraction phase of the stride. Interference with UMNs also may manifest as delayed initiation of voluntary movement or alterations in gait cadence. For example, some horses with spinal cord disease have a lateral "pacing" gait at walking speed. If LMNs are not affected, spinal reflexes (e.g., patellar) are either normal or exaggerated on the side of the spinal cord lesion and crossed extensor reflexes may be seen. *It should be noted that crossed extensor reflexes are normal in newborn foals.*[9]

Spastic paresis is especially common with focal compression of the cervical spinal cord in horses with cervical stenotic myelopathy (CSM) or spinal cord trauma. Other significant causes of UMN disease (in the spinal cord) include EPM, equine degenerative myeloencephalopathy (EDM), spinal cord abscess or tumor, and aberrant parasite migration. In keeping with the basic principles of neuroanatomic localization, UMN lesions from C1 to T2 (inclusive) may cause neurologic signs in all four limbs, lesions from T3 to S2 can only affect the pelvic limbs, and lesions caudal to S2 do not directly affect gait. With external compression of the cervical spinal cord (as in CSM), signs typically are worse in the pelvic limbs than in the thoracic limbs. The principles of neuroanatomic localization of spinal cord lesions are discussed more fully in Chapter 50.

Lower Motor Neuron and Spinal Cord Reflexes

The function of the CNS is exerted entirely through the actions of LMN on striated (skeletal) and smooth muscle. LMNs to skeletal muscles are found in the ventral columns of the gray matter, and those of the autonomic nervous system are located in the intermediate columns. In the horse, there are 8 cervical, 18 thoracic, 6 lumbar, 5 sacral, and a variable number of coccygeal (caudal) spinal cord segments. LMNs originating in the gray matter of a segment form a ventral root, which then exits the vertebral canal through the intervertebral foramen of the vertebra of the same name. The ventral root joins with the dorsal sensory root to form the segmental spinal nerve. In the cervical vertebrae, this foramen is at the cranial end of each vertebra. For the remaining roots, the foramina are at the caudal end. The more caudal spinal cord segments have long nerve roots because the spinal cord segments are shifted cranially with respect to the vertebrae. The first three sacral segments are in the sixth lumbar vertebra and the spinal cord ends within S2.[2]

The LMNs form the efferent part of spinal reflexes, which are central to the neurologic examination and the process of neuroanatomic localization. The neurons of the afferent (sensory) component of reflexes course from receptors in the skin, muscle, or tendon, through the spinal nerve and dorsal root, into the dorsal horn of the gray matter where they terminate on interneurons. The interneurons then complete the pathway by passing to the LMN. An exception to this is the patellar reflex, wherein the sensory neuron terminates directly on the LMNs in the ventral horn. Long (i.e., multisegment) spinal cord reflexes, including slap tests, cervicofacial and cutaneous trunci reflexes, and caudal reflexes, including anal and tail-clamp, are routinely evaluated during neurologic examination. Limb reflexes, including withdrawal, patella, and triceps, are always evaluated in neonatal foals and in older horses that are recumbent. The specifics of individual spinal cord reflexes are covered in Chapter 50.

Abnormalities of LMN (in gray matter, ventral root, peripheral nerve, or neuromuscular junction) manifest as flaccid muscle weakness (paresis, paralysis) with hypotonia and hyporeflexia. Within 1 to 2 weeks, muscle atrophy is noticeable, and this neurogenic muscle atrophy progresses rapidly.[9] *Note that neurogenic atrophy is a consequence only of LMN disease; UMN involvement results in weakness without atrophy.* Ventral nerve roots contribute to multiple peripheral nerves, and peripheral nerves are derived from multiple roots, so injury to gray matter of an individual segment or to a ventral nerve root produces less-severe neurologic signs than does loss of function in a peripheral nerve.[2] Examples of diseases that affect the LMN in horses are botulism (neuromuscular junction), trauma, ischemia associated with recumbency, neuritis of the cauda equina/polyneuritis equi, EPM, postanesthetic myelomalacia, and equine motor neuron disease (EMND).

Proprioception

Through a system of receptors in muscles, tendons, and joints, the general proprioceptive system is able to monitor the position of the body or limbs in space. Proprioceptive information is passed centrally in sensory nerves that terminate in the dorsal gray column on cell bodies of neurons in the spinocerebellar tracts. These tracts pass cranially and provide information for the cerebellum to use in its role of regulating posture, muscle tone, locomotion, and equilibrium. Other proprioceptive pathways pass from the spinal cord to the somesthetic sensory cortex via relay nuclei in the midbrain and thalamus.

Interruption of spinal cord proprioceptive pathways interferes with recognition by the brain of the positions in space of

the body and limbs. This is manifest as ataxia (incoordination). Signs of proprioceptive deficit in the horse include base-wide or base-narrow limb placement, swaying of the trunk and torso during walking (but not usually at rest), and overstriding, especially in the pelvic limbs. During circling, limb ataxia is evident as circumduction in the pelvic limbs and interference in the thoracic limbs.

Urination

Parasympathetic LMNs to the bladder's smooth muscle (detrusor) originate in the intermediate column of the gray matter of sacral segments 2 to 4. These neurons exit in ventral roots and contribute to the pelvic plexus, a network that supplies autonomic innervation to the smooth muscle of the bladder and rectum. Sympathetic LMNs to the bladder begin in the gray matter of L1-4, exit the vertebral canal, and course to the pelvic plexus. Postganglionic sympathetic neurons terminate on smooth muscle in the body and neck of the bladder and proximal urethra. These autonomic LMNs function in local reflexes. Afferent neurons pass from stretch receptors in the bladder wall and enter the spinal cord in dorsal sacral nerve roots to exert inhibitory influences on parasympathetic and sympathetic LMN. Striated muscle of the urethra is innervated by somatic LMN in the pudendal nerve. Urination occurs when there is stimulation of parasympathetic nerves to the detrusor muscle, inhibition of sympathetic nerves to the detrusor muscle, and inhibition of sympathetic and somatic nerves to the urethra. The net effect of this activity is contraction of the smooth muscle of the body of the bladder and relaxation of the proximal urethra. Centers in the midbrain and hindbrain receive sensory information from the bladder and modulate reflex activity via UMNs passing caudad in the spinal cord. Forebrain influence on these centers is responsible for initiation of voluntary voiding.

In horses with severe spinal cord disease cranial to S2, there may be loss of voluntary control of urination. Within 2 weeks, "spinal-reflex bladder" function develops, which results in intermittent voiding with retention of small amounts of urine. Horses with severe CSM, EPM, vertebral trauma, or epidural abscess may present in this way. When there is a spinal cord lesion between L4 and S2, reflex pathways for inhibition of sympathetic activity may be interrupted, resulting in increased urethral tone and functional obstruction of urinary outflow. This is the case in some horses with equine herpesvirus type 1 (EHV-1) myeloencephalopathy, although others have signs of LMN bladder (see later).[26]

With injury to the sacral spinal cord segments or nerves, the bladder and urethra are atonic and distended and there is overflow incontinence. Although a small amount of intrinsic reflex bladder contraction ("automatic bladder") may occur, it is ineffectual, and large volumes of urine and sediment remain. Trauma, epidural abscess or tumor, EHV-1 myeloencephalopathy, sorghum-Sudan grass toxicity, and neuritis of the cauda equina are diseases that can cause these signs. Idiopathic atonic bladder (also known as sabulous cystitis) is found in middle-aged geldings and some stallions and resembles the presentation of horses with cauda equina syndrome; however, the idiopathic syndrome does not appear to be caused by denervation of bladder muscle and there are no other signs of cauda equina syndrome. In cases of LMN urinary incontinence, additional nonurinary signs of sacral nerve injury are expected. These are the signs of cauda equina syndrome and include fecal incontinence, paralysis of the anus, tail, and penis, and perineal analgesia.

Defecation

The smooth muscle of the rectum and anus is innervated by postganglionic parasympathetic neurons in a way that parallels that described for the bladder. Innervation of striated muscle of the anus is provided by the pudendal nerve. Spinal cord lesions cranial to S2 are unlikely to affect defecation; however, involvement of the sacral segments results in rectal obstipation and may cause colic. Diseases causing rectal paralysis are the same as those described under the section on urination.

Sensation

Sensory information from pain, thermal, and touch receptors is conveyed to the spinal cord by peripheral nerves, spinal nerves, and dorsal roots. Branches pass several segments both craniad and caudad from the site of spinal cord penetration and terminate on spinothalamic neurons or interneurons involved in spinal reflexes. Spinothalamic pathways servicing a single dorsal nerve root course craniad on both sides of the spinal cord. Pain perception requires interpretation of afferent information by the forebrain and was described earlier. The flexor (withdrawal) reflexes require only sensory nerves, contiguous spinal cord segments, and LMNs. In the thoracic limbs, spinal cord segments C6 to T2 are required and L6 to S2 are involved in the pelvic limb reflex. Evaluation of sensation over the trunk and limbs requires knowledge of the common autonomous zones for sensory nerves. This is described in more detail in Chapter 54.

CHAPTER
50 Diagnostic Procedures

Robert J. MacKay

NEUROLOGIC EXAMINATION

A competent neurologic examination is not unlike an evaluation for lameness, where the initial evaluation is by systematic, "passive" examination and this is followed by an assessment of the gait. This chapter contains a description of an ordered approach to neurologic examination (Box 50-1 is a summary). There is considerable emphasis on evaluation of symmetry during each element of the examination. To accurately assess symmetry, it is essential that a mirror-image technique be used when comparing sides—that is, if the right hand of the examiner is used to test one side, the left hand should be used for testing the opposite side. The only equipment needed is a transilluminator, a hemostat, and a patella hammer (for neonatal examinations). The findings are used to localize a lesion or lesions. This is the basis for formulation of an initial rule-out list and for planning additional diagnostic tests.

In this discussion, all abnormal findings are interpreted in the context of a neurologic explanation. It is clear that many of these signs could be caused by lesions outside the nervous system. Full general physical and lameness examinations should also be performed to assess possible involvement of other body systems.

BOX 50-1. Items for Neurologic Examination

Mentation
Orientation and coordination of the head
Muscles of mastication
Facial tone
Facial sensation
Menace response
Size of pupils and pupillary light reflex
Position and movement of the eyeballs
Swallowing
Tongue
General examination of the neck, trunk, and limbs
Slap test
Cervicofacial reflex
Cutaneus trunci reflex (panniculus)
Back reflexes
Tests for limb strength
Gait
Testing of recumbent horses
Tail and anus

Mentation

Alertness and behavior are not evaluated by specific testing but are assessed from the history and general observation throughout the examination.

Alertness

Assess level of consciousness or alertness on a continuous scale from normal (i.e., bright and alert) to comatose. Progressive levels of obtundation are termed *lethargy, stupor, semicoma,* and *coma*. With lethargy, there is a somewhat blank facial expression with slight drooping of the ears and eyelids, sluggish responsiveness to stimuli, and reduced voluntary activity. It should be noted that some conditions cause horses to lose facial expression while maintaining normal alertness. Botulism is a disease of this type. A stuporous horse stands in one place with the head held low and responds only to strong stimuli. Stuporous horses that are recumbent are defined as semicomatose, and recumbent horses that do not respond to any stimulus are comatose. Some horses with reduced alertness appear irritable and anxious, walk compulsively, or otherwise interact abnormally with handlers. An obtunded horse showing such behavior may be termed *delirious.*

It is very unlikely that a horse with hypersomnia (excessive sleepiness) or narcolepsy/cataplexy will have a sleep attack while being examined; thus, assessment of possible narcolepsy usually rests on description by the owner or video recordings of an attack. Occasionally, neonatal foals collapse during examination and briefly appear comatose. These are typically benign

episodes of cataplexy and are probably an exaggerated version of the collapse response by which a normal foal can be cast into recumbency.

Behavior

Abnormalities of behavior are termed *dementia.* Behavior is assessed from history and general observation in the course of the examination. Typical abnormal behaviors resulting from central nervous system (CNS) disease include self-mutilation, head-pressing, compulsive walking (often in a circle), yawning, aggression (including unprovoked biting or kicking), hyperresponsiveness to normal stimuli, timidity, loss of affinity of a foal for its dam, and loss of learned behaviors and skills. Inability or refusal of a trained horse to follow when being led is a form of dementia that may be obvious during neurologic examination.

Lesion Location

Obtundation reflects damage anywhere in the brain stem or diffusely in the cerebrum. Injury to the rostral half of the brain stem often causes severe obtundation. Dementia is a sign of forebrain damage.

Associated Clinical Signs

Limb ataxia or weakness and signs of cranial nerve dysfunction are common in horses with obtundation secondary to brain stem disease. Compulsive turning of the head and neck in one direction, blindness, and seizures are other signs of forebrain dysfunction that may be seen in demented horses.

Orientation and Coordination of the Head

Examination

Evaluate the orientation of the head from directly in front. Any head tilt is described from the patient's perspective; thus, if the poll is rotated to the horse's left (i.e., clockwise from the examiner's point of view), the abnormality is described as a left head tilt. Repeatedly straighten and release the horse's neck and head and observe whether or not the head returns to one side. Asymmetric disease of the vestibular system causes the head to tilt and turn, whereas asymmetric cerebral disease may cause the head and neck to turn without tilting. Carefully blindfold the horse and observe the effect on head position (Figure 50-1). Blindfolding removes visual input to head position and exacerbates abnormalities caused by either vestibular or cerebral disease. Observe the head and neck from the side. Persistent horizontal or low position of the head may indicate neurologic or muscular weakness of the neck, whereas extended head position may be found in horses with upper cervical vertebral problems or guttural pouch disease. Offer feed or a treat to the horse and observe the way the horse moves its head in response. Horses with cerebellar disease often make jerky or bobbing movements of the head as they move toward the offered feed.

Lesion Location

Head tilt suggests involvement of the vestibular labyrinth, nerve, or root peripherally, or the vestibular nuclei and connections in the medulla oblongata or cerebellum centrally. It has also been suggested that lesions in the first one or two pairs of cervical

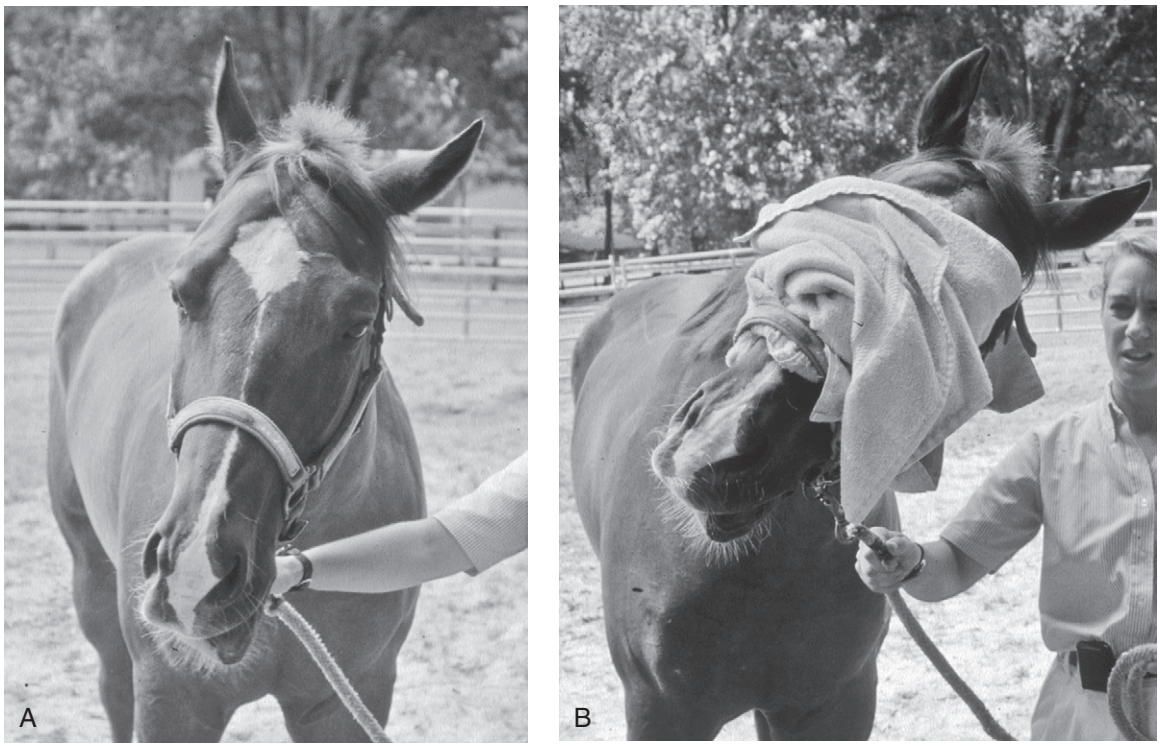

Figure 50-1. Head tilt associated with temporohyoid osteoarthropathy (THO). Six days earlier, this 7-year-old Quarter Horse gelding was presented with signs of acute-onset left-sided vestibular disease and facial paralysis. **A,** With anti-inflammatory therapy, the head tilt improved gradually to the time of presentation. **B,** Blindfolding removed visual input and exacerbated the head tilt.

sensory nerves may cause signs suggestive of vestibular disease.[1] If the head is turned without tilting, involvement of the forebrain is likely. Coarse or fine head bobbing, especially intentional, indicates diffuse cerebellar dysfunction.

Associated Clinical Signs

Because of the close association of cranial nerves (CNs) VII and VIII, facial paralysis is often seen in horses with vestibular disease. With peripheral vestibular disease, there often is spontaneous horizontal or arc-shaped nystagmus with the fast phase directed away from the side of the lesion. In horses with involvement of the central components of the vestibular system, there may be horizontal or vertical nystagmus. Damage to adjacent structures in the hindbrain may additionally cause obtundation, other signs of cranial nerve dysfunction (such as dysphagia and masseter atrophy), and weakness or ataxia of the limbs on the side of the lesion. Horses with cerebellar cortical disease may lack menace responses despite having normal vision.

Muscles of Mastication

Examination

If the mouth hangs open and the tongue protrudes, there is probably bilateral paresis of the muscles that close the jaw (temporalis, masseter, and pterygoid). Grasp the upper and lower jaws at the level of the interdental space and attempt to pull the lower jaw downward. The jaws pull apart easily in horses with bilateral paresis of the masticatory muscles. Tuck the forelock behind one of the ears and compare the temporalis muscles from in front of the horse. Asymmetry may indicate neurogenic atrophy of the smaller side (Figure 50-2). Turn the head from side to side and observe and palpate the masseter muscles. The pterygoid muscles and cranial belly of the digastricus muscle (the only muscle innervated by CN V that is devoted to opening the jaws) are located on the medial side of the mandible, so they are not readily palpable; however, atrophy of the pterygoids on one side is often evident as relative deepness of the supraorbital fossa on the same side. Peel back the upper and lower lips and examine the alignment of the symphyses of the upper and lower jaws. With acute unilateral paresis of the masticatory muscles, even before atrophy is apparent, the lower jaw may be deviated toward the normal side (see Figure 50-2).

Lesion Location

Weakness or atrophy of the muscles of mastication indicates involvement of the motor division of the trigeminal nerve, its roots, or the trigeminal motor nucleus in the pons.

Associated Clinical Signs

Injury to the proximal part of the trigeminal nerve may also affect the sensory component, resulting in reduced facial sensation (hypalgesia) over one side of the face. With trigeminal damage at the level of the pons, there may be additional signs of hindbrain disease, such as obtundation, other signs of cranial nerve involvement (e.g., dysphagia, head tilt, or facial paralysis), and weakness and ataxia of the limbs on the same side.

Facial Tone

Examination

Examine the head carefully for symmetry of facial expression, particularly with respect to the ears, eyes, and muzzle. With complete unilateral facial paralysis, there is drooping of the ear, upper eyelid (ptosis), and lower lip and immobility, narrowing, and lengthening of the affected external naris (Figure 50-3). The muzzle is deviated away from the affected side, and saliva may drool from the mouth. Any or all of these components can be affected separately. Next, evaluate facial nerve function by testing "flick" reflexes on each side of the face. Each of these reflexes requires intact trigeminal sensory branches, central

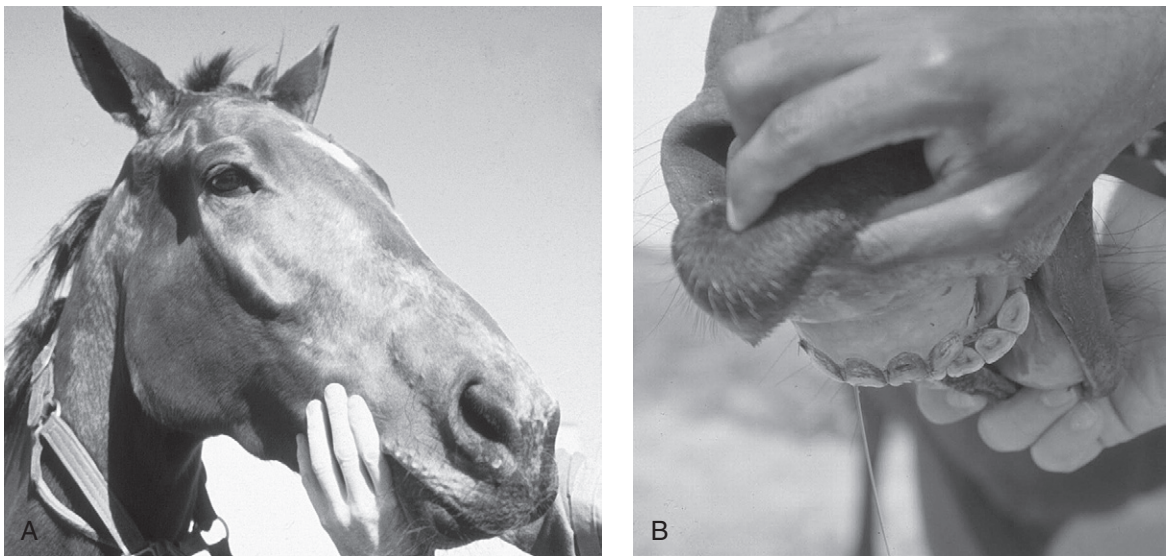

Figure 50-2. Atrophy of the muscles of mastication in a horse with equine protozoal myeloencephalitis. Beginning about a month after foaling, this 11-year-old Thoroughbred mare had an insidious onset of ataxia and limb weakness. **A,** Six weeks later, ataxia and weakness were worse, especially in the left limbs, and there was obvious atrophy of the masseter and temporalis muscles on the right side. **B,** The lower jaw was deviated away from the affected side.

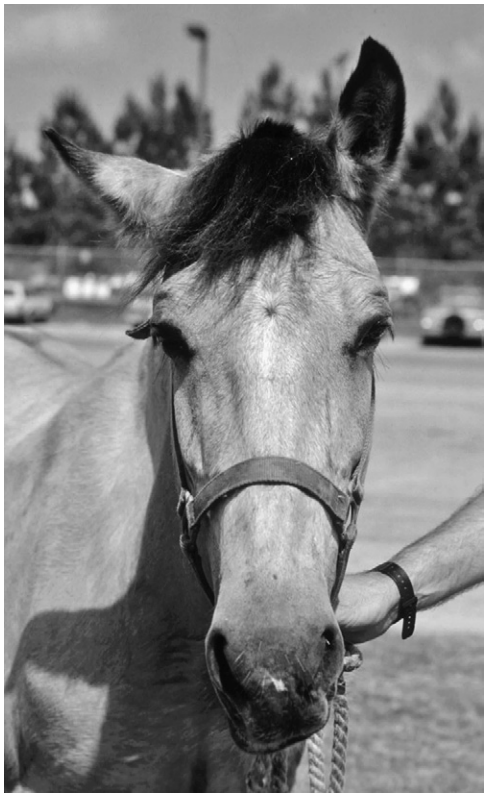

Figure 50-3. Facial paralysis in a horse with polyneuritis equi (neuritis of the cauda equina). Over the previous 2 weeks, this 13-year-old Quarter Horse mare had several exacerbations and remissions of right-sided facial paralysis. Beginning 3 days ago, there were also signs of cauda equina syndrome, including a weak tail and paralysis of the anus.

connections in the hindbrain, and functioning facial nerves. To test these reflexes, touch in turn the commissure of the lips, the medial and lateral canthi of the eye and the supraorbital fossa, and the ear. Appropriate responses are retraction of the commissure of the lip, blinking of the eye, and flick of the ear, respectively. It is helpful to have the handler cover the ipsilateral eye during testing of the lip and ear.

Test facial innervation of lacrimal glands by performing Schirmer tear tests. If tear production is reduced to less than 50% of normal on the side of the face that is paralyzed, there is likely to be a lesion affecting secretomotor fibers proximal (central) to the middle ear. Further test the symmetry of facial tone by using the thumbs or fingers to assess resistance simultaneously on both sides to retraction of lip commissures, elevation of upper eyelids, and forward extension of the ears. Examine the throat latch area. If there has been facial paralysis for more than 2 weeks, there usually is an obvious subcutaneous depression running ventrad from the base of the ear along the back of the mandible. This reflects atrophy of the parotidoauricularis muscle. Finally, test the cervicofacial reflex (see later) as part of the examination of long spinal reflexes. This reflex is not used as a primary test of facial nerve function but, clearly, its interpretation is affected by facial nerve paralysis.

Lesion Location

Abnormalities of facial tone reflect damage to the facial nucleus in the medulla oblongata, facial nerve root, or facial nerve or its motor branches, including dorsal and ventral buccal nerves, posterior and internal auricular and auriculopalpebral nerves, and the digastric nerve. If the Schirmer tear test gives a normal result on the affected side, the lesion is most likely at or peripheral to the middle ear; if tear production is reduced more than 50%, the lesion is central to the middle ear.

Associated Clinical Signs

Commonly there is also head tilt and spontaneous nystagmus because of involvement of the vestibular system. In horses with facial paralysis caused by brain disease, there may be other signs of hindbrain disorder (such as obtundation), signs of abnormal cranial nerve function (such as dysphagia or masseter atrophy), or limb ataxia and weakness on the same side as the lesion. Nonneurologic signs include exposure keratis or keratoconjunctivitis sicca and inspiratory stridor during exercise.

Facial Sensation

Examination

The sensory branches of the trigeminal nerve have already been tested as flick reflexes of the lip, eye, and ear. While standing in front of the horse, place the palm of the right hand on the muzzle, work the thumb into the right nostril, and touch the nasal septum on that side. In mirror-image fashion, use the left thumb to stimulate the left side of the septum. The normal response to this noxious stimulus is vigorous movement of the head away from the side of the stimulus. Compare the intensities of the response on each side. If there is obvious asymmetry of response, test cutaneous sensation at multiple locations over the face by pinching the skin with hemostats.

Lesion Location

The pathway for perception of this noxious stimulus is input through the sensory division of the trigeminal nerve to the pons and, from there, to the somesthetic area of the contralateral cortex. If flick reflexes are normal, a reduced or absent response to a noxious stimulus suggests involvement of the contralateral forebrain. In contrast, hypalgesia and hyporeflexia of flick reflexes of part to all of one side of the head indicates involvement of the trigeminal nerve or branches.

Associated Clinical Signs

Blindness, obtundation, and abnormal behaviors may be seen when hemifacial hypalgesia is a result of forebrain disease. Peripheral lesions of the trigeminal nerve may involve motor fibers and result in weakness and atrophy of masticatory muscles.

Menace Response

Examination

Test menace responses while standing in front of the horse. Use the palm of the hand to make a threatening gesture toward the eye. Test from both temporal and nasal directions on each side. Stimulate the horse just before each menace gesture by tapping the skin below the eye. For safety reasons, always hold the noseband of the halter with one hand while using the other for testing. A normal menace response is blinking of the eye,

sometimes accompanied by evasive movement of the head and neck. Compare carefully the intensity of the menace responses elicited from each side. In this regard, menace should be considered a quantitative response. Unlike simple reflexes, which are assessed as present or absent, a menace response can be considered abnormal if it is less vigorous than that elicited from the opposite (normal) side.

Lesion Location

The menace response can be interrupted anywhere in its pathway from the eye via the optic nerve to the contralateral optic tract, diencephalon, internal capsule, and visual cortex. From the visual cortex, the menace response pathway continues to the facial nucleus and nerve on the side being tested and receives essential input from the cerebellum. If there is no other sign of cerebellar involvement, and if facial nerve function and pupillary light reflexes are intact, the lesion is contralateral, central to the optic chiasm, and most likely in the forebrain. In normal neonates and in older horses with diffuse cerebellar cortical disease, there is no menace response, but the horse can see. In these settings, vigorous threatening gestures toward the eye may cause evasive movements of the head without blinking of the eye.

Associated Clinical Signs

There may be other signs of asymmetric forebrain disease, such as compulsive walking in circles, dementia, head and neck turn, obtundation, seizures, and facial hypalgesia on the side opposite the lesion (i.e., the same side as the defective menace). If the site of the lesion causing a menace deficit is the optic nerve or fundus of the eye, the pupillary light reflex on the same side should be abnormal. Head-bobbing, dysmetria, and ataxia are expected in horses with defective menace responses resulting from cerebellar dysfunction. If eyelid paralysis is preventing the menace response, the palpebral (eyelid flick) reflex should also be abnormal and there may be additional signs of facial paralysis.

Size of Pupils and Pupillary Light Reflex

Examination

If possible, examine the eyes in subdued or dim light so that the pupils are large enough to easily allow appreciation of reflex constriction. Stand in front of the horse while holding the noseband of the halter and swing the light back and forth from one side to the other so as to obliquely and briefly illuminate each eye without causing constriction of the pupils. Unequal pupillary size is termed *anisocoria*, a constricted pupil is *miotic*, and a dilated pupil is *mydriatic*. From this examination, determine whether or not the pupils are of equal size and if the diameter of each pupil is appropriate for the conditions. In this way, refine the diagnosis of anisocoria to miosis or mydriasis affecting a single eye.

Next, move closer to the horse and aim the light at the skin below one eye. Redirect the beam directly into the eye. This strong light should elicit both a dazzle reflex in the ipsilateral eye and pupillary light reflexes (PLRs) in both eyes. The dazzle reflex refers to eyelid closure in response to bright light. The full dazzle response also includes retraction of the eyeball and movement of the head away from the light. A normal PLR is immediate constriction of the pupils of both eyes in response to light directed into one eye. Next, test consensual (indirect) reflexes. To perform the consensual reflex, watch the pupil in one eye while an assistant shines the light into the opposite eye.

Lesion Location

The dazzle reflex is a subcortical reflex that is mediated via afferent input through the optic nerve to regions of the midbrain distinct from those required for the PLR and by efferent output along the facial nerve. It is possible for a horse to be cortically blind but still have dazzle reflexes, or to have PLRs but not dazzle reflexes. For a PLR, the stimulus pathway is via the optic nerves and optic tracts to the midbrain and thence to the efferent parasympathetic fibers of the oculomotor nerve. Fibers in the afferent limb of the reflex (i.e., optic nerve, optic tracts) can either pass on the same side or cross over at the optic chiasm and in the midbrain. Results of testing of menace responses along with direct and consensual PLRs usually allow anatomic localization of a lesion in the PLR pathways. In brief, without consideration of effects on consensual PLR, a lesion in an optic nerve affects the direct PLR and the menace on the same side; a lesion in an optic tract (rostral to the thalamus) affects the contralateral menace but does not affect direct PLR from either side, and a lesion in the midbrain or oculomotor nerve affects the ipsilateral PLR but not the menace responses.

Mydriasis is caused either by increased sympathetic dilator tone, by interference with the afferent arm of the PLR, or by damage to the oculomotor nucleus or nerve. Mydriasis caused by sympathetic overstimulation is usually bilateral, and PLRs are normal. With a complete optic nerve lesion on one side, slight ipsilateral mydriasis is seen. Light directed into the opposite eye constricts the mydriatic pupil. With complete oculomotor nerve lesions, the ipsilateral pupil is fixed and dilated and unresponsive to light directed into either pupil; however, light directed into the fixed pupil causes reflex constriction of the pupil on the opposite side.

Miosis occurs because of removal of sympathetic dilator influence to the pupil or possibly because of excessive stimulation of pupillary constrictors. The sympathetic pathway can be affected anywhere along the three-neuron pathway from the midbrain to the eye. With damage anywhere along the preganglionic (second) or postganglionic (third) neurons of the sympathetic supply to the head, there are signs of Horner's syndrome in addition to ipsilateral miosis. If the lesion affects the first (upper motor) neuron, there most likely will be widespread areas of spontaneous sweating over one half of the head, neck, and torso, with additional signs of brain stem or spinal cord disease (such as obtundation and ataxia and weakness of limbs). Early in the course of cerebral swelling, there often is miosis bilaterally. This is thought to be the result of either removal of sympathetic influences to the eyes or facilitation by upper motor neurons of the constrictor effects of oculomotor nerves.

Associated Clinical Signs

Horses with abnormal PLR because of cerebral swelling have other signs of forebrain disease, such as obtundation, dementia, and cortical blindness. Within 4 weeks of optic nerve injury, abnormal pigmentation of the fundus develops and there is

atrophy of the vasculature of the optic disc. In addition to miosis and ptosis, interruption of the sympathetic supply to the head causes other signs of Horner's syndrome, including spontaneous facial sweating and hyperemia of mucous membranes.

Position and Movement of the Eyeballs

Examination

While continuing to stand in front of the horse, observe the position and size of the pupils while the head is held level (i.e., a line through the center of each eyeball is parallel to the ground). While keeping the head level, lift the chin slowly. The eyeballs should remain stationary while the chin moves upward; thus, the eyes rotate ventrad relative to the long axis of the head. In horses with vestibular disease, abnormal eye positions are exaggerated by this maneuver.

If the pupils are in abnormal positions, try to position the head in such a way (usually by rotation) that the pupils are normally oriented relative to the transverse axis of the head. For example, a horse with vestibular disease often has ventral deviation of the eyeball on the side of the lesion and dorsal deviation on the opposite side (Figure 50-4). Eye position can be normalized relative to the axis of the head simply by rotating the head in the direction of the ventrally deviated eye. The abnormal position of the eyes in horses with vestibular disease is termed *vestibular strabismus.* True strabismus is eye deviation that cannot be corrected by repositioning the head and usually reflects dysfunction of nerves to the extraocular muscles (i.e., oculomotor, trochlear, or abducens nerves). In horses with strabismus, the eyeball may be rotated medially or laterally, clockwise or counterclockwise. Newborn foals normally have slight dorsomedial rotation of the pupils compared with older horses.

Further assess abducens nerve function by performing a modified corneal reflex. Hold the eyelids closed and, through the eyelid, push the eyeball medially. The normal response to this maneuver is retraction (adduction) of the eyeball. This reflex requires intact sensory branches of the trigeminal nerve, central connections in the hindbrain, and motor fibers of the abducens nerve.

Move the horse's head in a horizontal arc from side to side and observe the movements of the eyeballs. Signs of physiologic nystagmus should normally be elicited—namely, a series of horizontal movements of the eyeball consisting of a rapid phase in the direction of head movement followed by a slow phase in the opposite direction. Each fast phase is accompanied by an eye blink. Physiologic nystagmus is normal and should be distinguished from eye movements characteristic of vestibular disease: spontaneous nystagmus, which occurs when the head is stationary and in a neutral position, and positional nystagmus, which occurs only when the head is moved to certain positions. In horses with asymmetric vestibular disease, physiologic nystagmus is often abnormal or absent when the head is moved toward the side of the lesion.

Figure 50-4. Vestibular strabismus in a horse with eastern equine encephalomyelitis (EEE). This yearling Quarter Horse presented initially with high fever and a left head tilt. When the head was straightened out and the chin lifted, the left eye deviated downward and the right eye deviated upward.

Lesion Location

For horses with vestibular strabismus, the causative lesion could be anywhere in the peripheral or central vestibular system (including connections with the cerebellum and nerves to the extraocular muscles), usually on the same side as the ventrally deviated eye (described more fully under "Orientation and Coordination of the Head," earlier). A horse exhibiting true strabismus most likely has a lesion in CNs III, IV, or VI (or its roots or nuclei). These nerves exit the midbrain or hindbrain and pass a short distance to the oblique and rectus muscles of the eye.

Associated Clinical Signs

The roots of the nerves to the extraocular muscles are subject to dorsal pressure exerted by the cerebrum as it swells and herniates under the tentorium cerebelli. Other signs associated with cerebral swelling are obtundation, blindness, seizures, and fluctuant to dilated, fixed pupils. There may also be jerky head movements as a result of pressure on the cerebellum. As compression of the midbrain and rostral hindbrain becomes more severe, obtundation progresses to coma with decerebrate posturing. With more focal lesions of the nerves or their nuclei, mydriasis (III) or defective modified corneal reflex (VI) is likely.

Swallowing

Examination

It is difficult to assess competence for swallowing during a physical examination. On the basis of history and observation, note whether feed, water, or saliva return through the nose, especially when the horse eats or drinks. Pass a nasogastric tube into the pharynx and assess effectiveness of swallowing movements as the horse attempts to move the tube into the esophagus.

Lesion Location

Involvement of the nucleus ambiguus in the hindbrain, or the roots or peripheral parts of one or both glossopharyngeal, vagus, or spinal accessory nerves, can cause dysphagia. These nerves are particularly vulnerable to damage as they pass over the guttural pouches.

Associated Clinical Signs

There is frequently coughing, especially during eating, and signs of pneumonia secondary to aspiration of feed. With bilateral laryngeal paresis because of involvement of the vagus nerves or branches, there may be inspiratory stridor at rest. At exercise, minor or unilateral laryngeal paresis (involvement of CN X or branches) may be evident as a "roaring" sound during inspiration; involvement of CNs IX, X, XI, and possibly XII may lead to displacement of the soft palate and expiratory stridor. The slap test, which is described later, is negative on the paralyzed side.

Tongue

Examination

Pull the jaws slightly apart and observe the movements of the unrestrained tongue. With unilateral weakness, the tongue curls toward the normal side. Grasp the tongue from one side after inserting the hand through the interdental space. Note resistance of the tongue to being stretched and look for atrophy (Figure 50-5) and muscular fasciculations. Gently pinch the side of the tongue with a hemostat and look for reflex retraction and behavioral response. Pull the tongue out one side of the mouth, release it, and look for retraction of the tongue back into the mouth. In normal horses, one or two chewing movements occur as the tongue is quickly retracted.

Lesion Location

Tongue deviation, muscle atrophy, and/or fasciculations reflect involvement of a hypoglossal nucleus, root, or nerve. Delayed or absent retraction of the tongue back into the mouth can occur with any brain disease, probably because of involvement of upper motor neurons that regulate the actions of hypoglossal nerves.

Figure 50-5. Unilateral tongue atrophy in a horse with possible equine protozoal myeloencephalitis. Note the characteristic longitudinal folds on the atrophied (right) side. The tongue intermittently deviated toward the left side when the mouth was held open.

Associated Clinical Signs

With delayed retraction caused by extensive brain disease, there is usually profound obtundation, often with ataxia and weakness of the trunk and limbs. Because the hypoglossal nerve is close to CNs IX, X, and XI as they pass over the guttural pouch, signs of dysphagia and respiratory paralysis may accompany tongue atrophy in horses with guttural pouch disease.

General Examination of the Neck, Trunk, and Limbs

Examination

With the horse standing squarely, assess muscle mass, paying particular attention to asymmetries. Note any circumscribed or asymmetric areas of sweating. Firmly press the cranial edge of each of the cervical transverse processes from C3 to C6 on each side to test for a pain response. Put pressure on the C6-C7 intervertebral joints by pushing medial to the deep pectoral muscle in front of the shoulder on each side. Test lateral neck flexion by enticing the horse to move its head toward feed held at the point of the elbow.

Lesion Location

Neck pain revealed by palpation or reluctance to turn laterally may follow any neck trauma but usually reflects arthritis of intervertebral joints.

Severe or rapidly developing muscle atrophy indicates denervation and is a localizing sign. Neurogenic muscle atrophy is caused by damage to the lower motor neuron in the ventral column of the gray matter, ventral nerve roots, or peripheral nerves supplying that muscle. Neurogenic atrophy of thoracic limb musculature results from lesions of the C6 to T2 spinal cord segments or roots, brachial plexus, or peripheral nerves, whereas atrophy of pelvic limb muscles reflects involvement of L3 to S2. Anesthesia of a strip of skin is caused by loss of the segmental sensory nerve, dorsal nerve root, or connections in the spinal cord. Because sympathetic fibers are distributed with spinal nerves, spontaneous sweating may occur over denervated skin.

Associated Clinical Signs

Arthritic neck pain may be detected in wobblers, especially those older than 2 years. Neurogenic atrophy usually causes limb weakness and gait abnormality and may be associated with other signs of spinal cord disease. For example, there may be ataxia and weakness in a pelvic limb because of upper motor neuron damage at C6, and there may be atrophy of the triceps and weakness of the thoracic limb on the same side because of a gray matter lesion in the same segment.

Slap Test

Examination

While standing on the left side, reach under the horse's neck and hook the index and middle fingers of the left hand over the highest palpable point of the right side of the larynx—the

muscular process of the arytenoid. Have the handler move the head slightly to the left of midline. Gently strike the horse behind the withers with the palm of the right hand. The expected response is slight palpable movement (adduction) of the arytenoid in response to each slap. The adductor response is most reliably obtained if the withers region is slapped when the horse is breathing out. Repeat the procedure from the right side. More information on this test is found in Chapters 42 and 44.

Lesion Location

Sensory input to this reflex is the sensory nerves and roots under the area that is slapped (approximately T7 to T11). Central pathways are thought to cross to the other side at this level and then pass rostrad to the nucleus ambiguus. Next, efferent fibers pass out in the vagus nerve via the recurrent laryngeal nerve to innervate the contralateral laryngeal adductor muscles. Severe cervical spinal cord disease often affects this test bilaterally, and the vagus and recurrent laryngeal nerves may be affected at the guttural pouch or within the jugular groove. Variations in neck anatomy make this reflex easy to palpate in some horses but difficult or impossible in others.

Associated Clinical Signs

Other signs of cervical spinal cord disease include ataxia and weakness of the trunk and limbs. Dysphagia and aspiration pneumonia are further signs of guttural pouch disease, and Horner's syndrome may also be seen when there is involvement of the vagosympathetic trunk deep to the jugular groove.

Cervicofacial Reflex

Examination

Place the left index and middle fingers at the left commissure of the lips, then strike the skin over the brachiocephalicus muscle with the closed tip of the hemostat. Begin at the cranial end of the neck and continue back to the shoulder. The expected responses are facial contraction (detected as retraction of the commissure of the lip) and contraction of the brachiocephalicus and cutaneus colli (observed as shrugging of the shoulder, lateral jerking of the head, and twitching of the skin of the neck).

Lesion Location

Interruption of reflex components in the facial nerve, cervical nerves or roots (sensory or motor), or local cervical spinal cord segments can affect the cervicofacial reflex. This reflex is typically reduced at the level of a cervical spinal cord lesion but is normal cranial and caudal to the lesion.

Associated Clinical Signs

There may be other signs of facial paralysis or cervical spinal cord disease (e.g., limb ataxia and weakness). With involvement of cervical sensory nerves or roots, there may be a strip of cutaneous anesthesia that corresponds to the area of diminished cervicofacial reflex. Asymmetric damage to the most cranial cervical nerves may lead to signs suggestive of peripheral vestibular disease.

Cutaneus Trunci Reflex (Panniculus)

Examination

When examining the reflex on the left side of the horse, use the extended right thumb to firmly prod the skin of the sensory field, beginning cranially just behind the shoulder and extending caudad to the last intercostal space. Check every intercostal space both ventrally and dorsally. For safety, firmly grasp the back of the mane with the left hand and face backward when testing the reflex, because horses that resent this test will try to kick the examiner. A normal response is twitching of the skin, with or without indication of conscious perception of the stimulus. Irrespective of the site of stimulation, the twitch response is the same.

Lesion Location

The reflex pathway is input from sensory thoracic nerves to the ipsilateral spinal cord, where it courses rostrad via interneurons to end in the C8 and T1 segments, and then via the brachial plexus to the lateral thoracic nerve and the cutaneus trunci muscle. Interruption of this pathway in the spinal cord white matter results in loss of the reflex from approximately the point of the lesion caudad. A lesion of the sensory nerve will affect only the reflex within the same dermatome (skin strip), whereas loss of lateral thoracic nerve function ablates the entire ipsilateral reflex.

Associated Clinical Signs

A strip of cutaneous anesthesia may overlay the cranial edge of the hyporeflexic zone when the spinal cord lesion affects interneurons coursing cranially and sensory connections from the segmental spinal nerve. Ataxia and weakness of the ipsilateral pelvic limb is usually found in such cases.

Back Reflexes

Examination

After making sure that the pelvic limbs are positioned equally and squarely, stroke the closed tip of the hemostat caudad along the skin over the longissimus dorsi muscle, from mid thorax caudad to the level of the tuber coxae. For safety, hold the back part of the mane with the other hand. The expected response is brisk extension of the back and pelvis followed quickly by return to normal posture. Next, stroke the hemostat caudad along the skin over the gluteal muscles. This should elicit flexion, followed by relaxation of the lumbar spine and pelvis. Common abnormal reactions to these tests include (1) partial collapse in the pelvic limbs, (2) wobbling of the pelvis from side to side, and (3) no response.

Lesion Location

Abnormal results of the back tests correlate with truncal and pelvic limb weakness and ataxia caused by spinal cord disease.

Associated Clinical Signs

Expect other signs of pelvic limb weakness and ataxia, such as toe-dragging and circumduction.

Tests for Limb Strength

Examination

During the passive part of the examination, it is difficult to detect mild thoracic limb weakness. Only very weak horses buckle a thoracic limb in response to downward pressure exerted over the withers. The hopping test is more sensitive. From the left side, hold the halter with the left hand. Pick up the left leg, then push the head toward the right side while leaning against the left shoulder (Figure 50-6). Normal horses use the right limb to hop briskly around a circle centered on the pelvic limbs. With limb weakness, the response may be delayed so that the horse leans markedly before hopping, or the limb may buckle after landing.

Strength of the pelvic limbs is evaluated by resistance to pressure over the pelvis and to a sideways pull on the tail. Additional insight is provided by the back reflexes described earlier. To test resistance to dorsal pressure, stand on one side of the horse and hook the fingers over the opposite tuber sacrale. Use maximal effort to try to collapse the near limb. Only weak horses buckle in response to such pressure. The tail-pull test is done both at rest and while the horse is walking in a straight line. With the horse standing squarely, take the tail and pull sideways with gradually increasing force. After initial slight movement in the direction of pull, normal horses usually cannot be moved sideways, even with strong pressure. Next, pull sideways on the tail while the horse is walking in a straight line. Always work on the same side as the handler. Exert moderate lateral pressure during all phases of the stride, and then rhythmically increase pressure as the horse supports weight on the near leg. Normal horses of 450-kg body weight can be moved only slightly to the side. Response to this test varies according to the size and strength of the examiner and the bodyweight and temperament of the horse. Perform the test in mirror-image fashion from the right side (i.e., with the horse being led from the right side). Interpretation of this test requires practice and experience on the part of the examiner.

Figure 50-6. Force the horse to hop on each front limb to evaluate limb strength.

Lesion Location

If a full-size adult horse can easily be pulled sideways at rest, there is probably interruption of the antigravity myotatic reflex pathway. Practically, such a lesion most likely is located either in the ventral gray matter, in the roots (L3 to L5) that form the femoral nerve, or in the femoral nerve itself. If cutaneous sensation over the saphenous vein is absent or reduced, the lesion is central to the ventral aspect of the shaft of the ilium (the site at which the sensory saphenous nerve joins the femoral nerve). The much more common finding—namely, lack of resistance to tail-pull only during walking—is consistent with an ipsilateral spinal cord lesion affecting descending upper motor neurons anywhere from C1 to S2, inclusive.

Associated Clinical Signs

Depending on the location of the lesion, there may be interference with long spinal reflexes, hypalgesia of skin strips, spontaneous sweating of skin strips, or atrophy of musculature, in addition to alterations in gait.

Gait

Examination

Have the handler walk the horse in straight lines, leading alternately from the left and the right side. The handler should be instructed to keep the horse's head and neck as straight as possible during walking. When the horse turns its head to one side, there is reciprocal and potentially confusing movement of the pelvis toward the same side. Follow directly behind the horse. From this vantage point, evaluate leg position and stride symmetry. Also, watch for excessive (1) side-to-side (wobbling) movement of the pelvis, (2) up-and-down movement of the tuber coxae (pelvic roll), and (3) side-to-side swiveling of an imaginary line from the tailhead to a point between the tuber sacrale (pelvic yaw). Next, watch the gait from the side while walking in stride with the pelvic and then thoracic limbs. Note any toe-dragging, knuckling, stride-length asymmetries, and abnormal protractive movements, such as hyperflexion, stiffness (hypometria), or excessive range of movement (hypermetria). Often, these signs are most obvious as the horse transitions from standing still to walking. Repeat this part of the examination with the horse's chin lifted and with the horse walking up and down a modest slope. These maneuvers exacerbate most gait abnormalities, especially stiffness of the thoracic limbs.

Take the horse in hand for the next part of the examination. Hold the lead rope with the left hand and, by walking backward, lead the horse in counterclockwise circles (Figure 50-7). It is very important that the horse be always walking forward

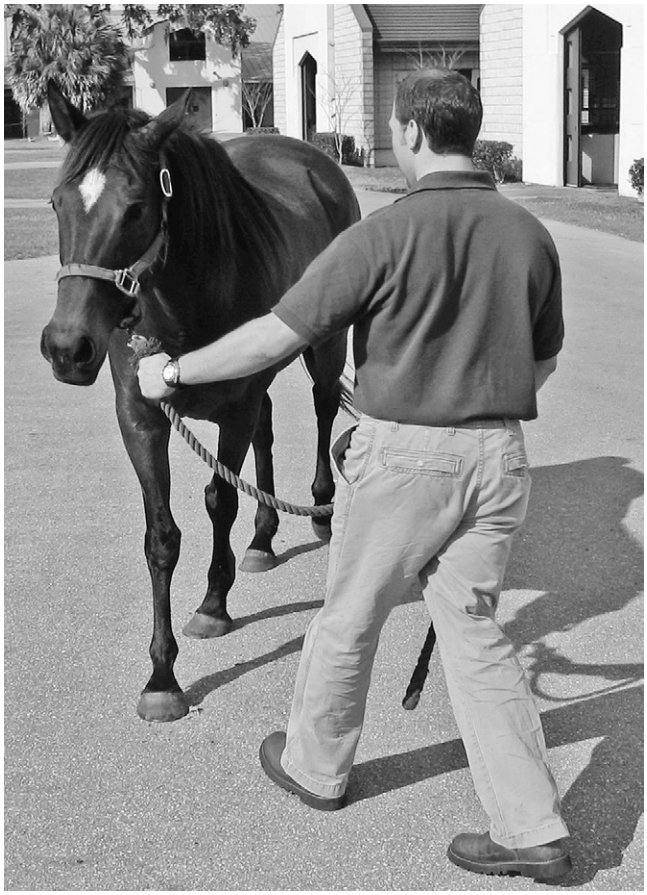

Figure 50-7. Testing for strength: walk backward and pull the horse in counterclockwise circles, then repeat in mirror-image fashion in clockwise circles.

Figure 50-8. Gait analysis: pull the horse sideways and backward in tight circles so that it pivots around a point midway between the thoracic and pelvic limbs. Repeat on the right side.

in these circles. Vary the diameter, making the circles alternately small and large. Observe carefully the motion of the right (outside) pelvic limb by looking under the horse's torso. This limb will often arc out widely on the outside of the circle (i.e., circumduct) in horses with spinal cord disease. In mirror-image fashion, lead the horse from the right side in clockwise circles.

Next, pull the horse sideways in tight circles in either direction. This is done from a position slightly behind the shoulder by pulling the lead rope at an angle sideways and caudad (Figure 50-8). If done correctly in normal horses, the opposite thoracic limb should cross in front of the supporting limb and the pelvic limbs should move reciprocally, causing the horse to pivot around a point midway between the thoracic and pelvic limbs. Horses that are weak and ataxic tend to sag backward in the hindquarters before they start to move, and then pivot the front part of the body around one or both pelvic limbs. There is often also interference between or otherwise inappropriate and inconsistent placement of thoracic limbs.

Use the lead rope to push the horse straight backward. A normal horse should move backward in two-beat fashion, with simultaneous movement of diagonally opposite pairs of limbs (e.g., left thoracic and right pelvic limbs). A horse with spinal cord disease may sag backward before moving and slide its hooves along the ground rather than picking them up and placing them.

Lesion Location

Signs of limb weakness and ataxia suggest spinal cord (or, rarely, peripheral nerve) damage at or cranial to the affected limb. If there is obvious ataxia and weakness in thoracic and pelvic limbs, there is likely to be at least one lesion in the spinal cord somewhere between or within the C1 and T2 spinal cord segments. When the signs are caused by external compression of the cervical spinal cord (e.g., in cervical vertebral stenotic myelopathy), signs in the pelvic limbs are usually worse than those in the thoracic limbs. When, in such cases, the pelvic limb signs are mild, thoracic limbs may appear normal. In contrast, when thoracic limbs are normal but there is moderate or severe ataxia and weakness in the pelvic limbs, there is likely to be at least one lesion caudal to T2 and cranial to S3. If one or both thoracic limbs are abnormal in a horse that has normal pelvic-limb gait, the gray matter of the C6 to T2 spinal cord segments (without white matter involvement), the roots or nerves of the brachial plexus, or the peripheral nerves to the thoracic limbs are probably affected. Asymmetric lesions in the spinal cord cause signs that are more severe on the side of the lesion. Occasionally, there are signs of weakness without ataxia (e.g., botulism, equine motor neuron disease) or ataxia without weakness (e.g., cerebellar abiotrophy, peripheral vestibular disease). Additional signs, such as defective reflexes (cervicofacial, slap, or cutaneus trunci), neurogenic muscle atrophy, or cutaneus anesthesia, often help to localize the spinal cord lesion.

Associated Clinical Signs

Abnormal responses to tests for limb strength, reduced or absent long spinal reflexes, and strips of cutaneous anesthesia or spontaneous sweating may accompany lesions of the spinal cord or peripheral nerves.

Testing of Recumbent Horses

Examination

Note whether or not the horse moves its limbs voluntarily without stimulation. If possible, assist and stimulate the horse in such a way as to assess which of the following best describes the horse's maximal voluntary motor function: (1) lifts head off the ground; (2) rolls shoulders and chest into a sternal position; or (3) straightens thoracic limbs and assumes a "dog-sitting" position.

Check long spinal reflexes (cervicofacial, cutaneus trunci, slap) and test cutaneous sensation systematically over the limbs and torso. Test sensation at each site by grasping a fold of skin between the jaws of the hemostat and firmly squeezing the skin and watching for evidence of a conscious response by the horse. This is a behavioral reaction and must be distinguished from a reflex response. Sensory fields for some peripheral nerves of horses have been described.[2]

Test pelvic limb reflexes and function. First, assess extensor tone in the limb by testing resistance to passive flexion. Next, perform the flexor test by pinching skin on the distal limb with a hemostat. If there is no response, try pinching skin elsewhere on the leg. A normal response is flexion of the limb, usually with some evidence that the horse can feel the skin pinch. When abnormal, the flexor response may be reduced or absent, and it may be accompanied by reflex extension of the contralateral digit (crossed extensor reflex). To test the patella reflex, hold the pelvic limb in a moderately flexed position, and strike the skin over the middle patella ligament (Figure 50-9). A twitch handle works well for this purpose in full-sized horses; a patella hammer or reversed hemostat can be used in foals. The expected response is brisk extension of the stifle. If the reflex is absent, move the leg into different positions and retest. Classify the response as absent, normal, or increased. Other extension reflexes in the pelvic limb cannot be elicited reliably but should be tested for comparison with the opposite leg. These include (1) the tibial reflex—tap just behind the greater trochanter; (2) the gastrocnemius reflex—strike the Achilles tendon close to its insertion; and (3) the long digital extensor reflex—strike the middle of the long digital extensor muscle.

Test thoracic limb reflexes and function. Assess extensor tone and evaluate the flexor reflex as described for the pelvic limb. No other reflex can be obtained consistently in the thoracic limbs, but, for comparison with the opposite limb, test the (1) triceps reflex—with the limb in flexed position, strike the triceps muscle and watch for elbow extension; (2) test the biceps reflex—strike the front of the elbow and watch for extension of the shoulder and flexion of the elbow joint; and (3) strike the middle of the extensor carpi radialis muscle and look for extension of the carpus.

Lesion Location

If a horse can dog-sit, the principal spinal cord lesion is probably behind T2. Inability of a horse to roll from lateral into sternal recumbency is associated with severe lesions (usually involving gray matter) of the caudal cervical or rostral thoracic segments, whereas serious injury to the spinal cord in the rostral part of the neck may also prevent a horse from raising its head off the ground.

With involvement of lower motor neurons to limb muscles, there is reduced or absent extensor tone. Limb reflexes are reduced or abolished if the sensory nerves, motor nerves, or central components of the reflexes are affected. The afferent, central, and efferent parts of important reflexes are listed in Table 50-1. In contrast, extensor tone and limb reflexes may be exaggerated beginning several days after injury to descending upper motor neurons. For example, after trauma to the spinal cord at the T13 segment, patella reflexes and pelvic extensor muscle tone may be exaggerated.

If there is no response to strong pinching of the skin over caudal regions of the body, there is probably catastrophic

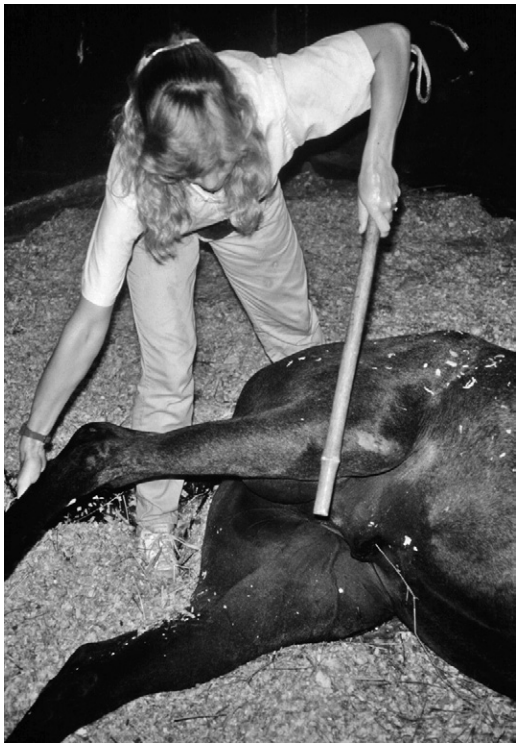

Figure 50-9. Testing the patella reflex in a recumbent horse. The limb is held in a flexed and slightly abducted position, and the skin over the middle patella ligament is struck with a twitch handle.

TABLE 50-1. Limb and Tail Reflexes

Reflex	Spinal Cord Segments	Peripheral Nerves
Flexor (thoracic)	C6-T2	Median, ulnar, axillary, musculocutaneous
Triceps	C7-T1	Radial
Biceps	C7-C8	Musculocutaneous
Patella	L3-L5	Femoral
Flexor (pelvic)	L5-S2	Sciatic
Anal	S3-S4	Pudendal
Tail clamp	S3-S4	S1 to coccygeal segments

damage to the spinal cord cranial to the anesthetic area. If there is no response to deep pain for more than 24 hours, there is at least functional transection of the spinal cord.

Associated Clinical Signs

Large horses that remain recumbent for more than a few hours often have reduced skin sensation in the distal limbs secondary to pressure-induced injury of superficial sensory nerves. This complicates interpretation of tests for flexor reflexes and for presence of deep pain.

Tail and Anus

Examination

Assess tail strength by lifting (extending) the tail. Prod or pinch the skin adjacent to the anus and observe the anal contraction and tail-clamp reflexes. If these reflexes are abnormal or if the history suggests possible cauda equina syndrome, perform a rectal examination to assess rectal tone and bladder size and tone. Assess muscular symmetry of the tail and test cutaneous sensation over the tail and caudal structures.

Lesion Location

Anesthesia and areflexia of the tail, penis, and perineum and paralysis of the anus, rectum, bladder, and penis are signs of cauda equina syndrome. Lesions of the spinal cord or nerve roots caudal to the S2 spinal cord segment cause some or all of the signs of cauda equina syndrome. The bundled roots forming the cauda equina are vulnerable as they pass through the sacrum and proximal coccygeal vertebrae.

Associated Clinical Signs

With involvement of S2 and more rostral nerve roots, expect to see signs of pelvic limb weakness in addition to cauda equina syndrome. Colic caused by obstipation may be the presenting sign of rectal paralysis, and urinary overflow incontinence is a sign of bladder paralysis.

CEREBROSPINAL FLUID COLLECTION

Atlantooccipital (AO) cerebrospinal fluid (CSF) collection under general anesthesia is simple, and iatrogenic blood contamination is seldom a problem. Lumbosacral (LS) collection has the advantage of not requiring anesthesia, but the procedure is technically more challenging than AO collection and significant blood contamination may occur. Because CSF flows caudad over the spinal cord from sites of production in the brain, LS samples can theoretically reflect changes anywhere in the CNS, whereas AO samples may not reflect caudal spinal cord disease. In general, in cases where the horse's physical condition does not dictate the procedure used, select the collection site that is closer to the likely site of the lesion.

Atlantooccipital Cerebrospinal Fluid Collection

Anesthetize the horse (e.g., 1 mg/kg of xylazine and 2 mg/kg of ketamine, both given IV) and position it in lateral recumbency. This procedure should not be performed in standing horses. Clip and surgically prepare a rectangle of skin approximately 10 cm wide and 15 cm long centered on the dorsal midline and beginning just behind the forelock. Extend the prepared area on the side facing up so that a 2.5 cm strip is clipped over the cranial border of the wing of the atlas. In horses heavier than 100 kg bodyweight, use an 8.23 cm 18- or 20-gauge stiletted spinal needle.[3] In foals, use a regular 3.75 cm 20-gauge needle. Flex the atlantooccipital joint in the median plane to an angle of 90 degrees or less. This is conveniently done if the collector kneels in such a way as to flex the head with the inside of the knee while leaning over the neck to place the needle. The needle is inserted at the intersection of lines running along the front of the atlas and along the dorsal midline (Figure 50-10). Insert the needle through the skin and then pass it in the median plane by aiming at the middle of the lower jaw. The needle is passed through the funicular part of the ligamentum nuchae and advanced until there is a popping sensation as the needle penetrates the atlantooccipital membrane, the cervical dura, and arachnoid mater. In practice, the stilette is withdrawn from the needle each time there is a popping sensation. CSF should flow freely from the hub when the subarachnoid space is entered. This can happen anywhere from 2.5 to 8.3 cm beneath the skin surface, depending on the size, sex, breed, and condition of the horse. Collect two or three aliquots of 1 to 5 mL of CSF, depending on need, either by aspirating drops as they fall from the hub of the needle or by attaching a syringe to the hub and aspirating directly. The last aliquot is least likely to be contaminated with blood and should be retained for analysis. Replace the stilette and withdraw the needle.

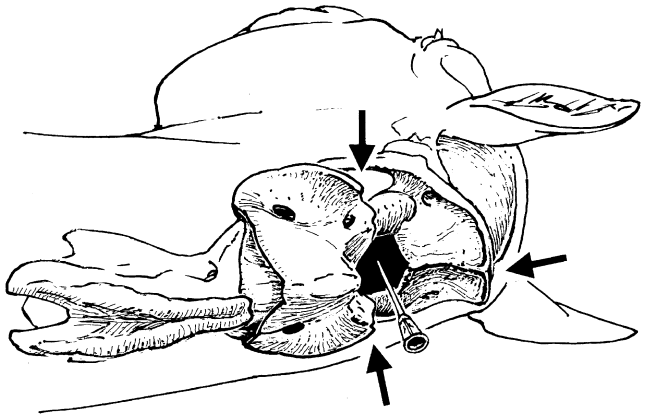

Figure 50-10. Atlantooccipital cerebrospinal fluid collection. The needle is inserted through the midline using the cranial border of the wings of the atlas and the nuchal crest of the skull *(arrows)* as landmarks.

There is very little morbidity associated with this procedure; however, occasionally a horse will hold its head stiffly in an extended position for a few days afterward. This is not associated with fever (in which case infection would be likely) and may be analogous to the headache that occurs in some humans after CSF aspiration. The condition responds well to the use of a nonsteroidal anti-inflammatory drug (NSAID).

Lumbosacral Cerebrospinal Fluid Collection

This procedure is conveniently performed in stocks so that the collector can stand on a raised platform alongside the horse; however, it also can be done in a stall with the horse pushed

against a wall. In either case, it is preferable that only a nose twitch be used. If a sedative must be given, use the lowest dose that controls the horse without causing the hindquarters to sway and wobble unduly.

The key landmarks for this procedure are the tuber sacrale and the dorsal spinous process of the second sacral vertebra. The paired tubera sacrale are located near the midline and can be found between the caudal margins of the tuber coxae at approximately the highest point of the rump. The dorsal (superficial) edge of each sacral tuberosity can be palpated through the skin as a slender ridge beginning adjacent to the sacral spine and progressing craniad and slightly laterad for several centimeters. When viewed from above, the paired tubera sacrale thus form a V with the vertex caudal. The correct tap site is located on the midline within or slightly in front of the V. To find the site, palpate the dorsal spinous processes of the caudal sacrum with the thumb, then slide the thumb forward until a 2- to 3-cm–long depression is located on the midline (between the spinous processes of the second sacral and sixth lumbar vertebrae). Clip and surgically prepare a rectangular section of skin centered on this site (Figure 50-11).

Infiltrate 0.5 to 1 mL of local anesthetic into the skin of the tap site, and make a sagittally oriented stab through the skin with a No. 15 scalpel blade. Rest both forearms on the horse's back while holding the hub of the needle with both hands. The needle is inserted along the intersection of median and transverse planes. It is helpful to have an assistant watch from behind the horse to guide side-to-side orientation of the needle. Advance the needle until (1) a slight "pop" is felt as the needle traverses the ligamentum flavum, (2) there is an involuntary response from the horse (usually brisk extension of the tail and pelvis), or (3) the point of the needle strikes the bottom of the vertebral canal. Remove the stilette, attach a syringe, and apply gentle aspiration pressure. To obtain flow of CSF, it may be necessary to rotate the needle or slightly retract it (or both) during attempted aspiration. Advance the needle only if the stilette is in place. CSF may flow more easily if both jugular veins are occluded (thus increasing intracranial pressure). Collect an initial sample of 2 to 5 mL (or more if the sample is visibly contaminated with blood) to "clear" iatrogenic blood contamination; then collect another sample for analysis. Reinsert the stilette and remove the needle.

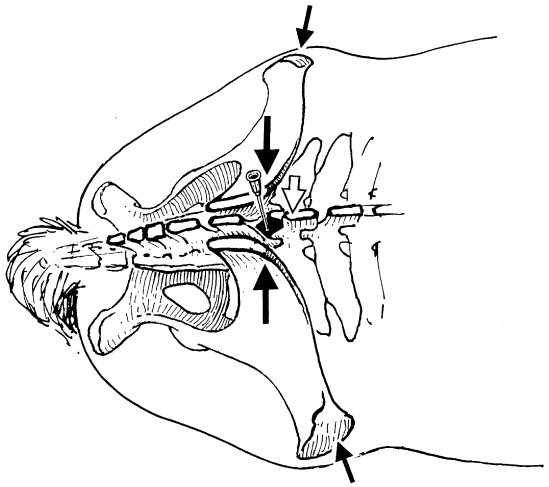

Figure 50-11. Lumbosacral cerebrospinal fluid collection. The caudal border of the tuber coxae *(small dark arrows),* the cranial edge of the tuber sacrale *(large dark arrows),* and the spine of L6 *(open arrow)* are used as landmarks.

Rarely, horses are sensitive to touch near the tap site for several days after the procedure. Occasional cases of cauda equina syndrome have occurred because epidural abscessation develops at the tap site.

CSF Analysis

At least 1 mL of CSF anticoagulated with ethylenediaminetetraacetic acid (EDTA) should be submitted for cytologic examination. A slide for this purpose should be prepared within 2 hours of collection by low-speed centrifugation of the sample. Alternatively, cell morphology can be preserved by mixing the sample with an equal volume of 50% ethyl alcohol. Standard chemistry analyses and immunoassays can also be performed on these samples. Normal values are shown in Table 50-2.[4,5] It is important to minimize blood contamination of the sample so that results do not reflect admixture of plasma and CSF. For most purposes, a red blood cell count of less than 50 µL is acceptable.

DIAGNOSTIC IMAGING EXAMINATION

Survey Radiographs

The primary reference for "Survey Radiographs" is reference 6.

Head

Lateral, oblique, and dorsoventral (in the standing animal) or ventrodorsal (in the anesthetized animal) views of the cranium and associated soft tissues can be obtained with portable film-screen or digital systems. On lateral radiographs, the ovoid shell of the cranial vault is seen. In foals younger than 3 months, the dorsal profile of the cranial cavity is interrupted by the fontanel. Other relevant structures on lateral radiographs are the petrous temporal bone, basilar bones, occipital condyles, ethmoid turbinates and ethmoid plate, frontal sinus, hyoid apparatus, guttural pouches, soft palate, and epiglottis. Oblique radiographs are useful to separate the paired stylohyoid bones and petrous temporal bones. Ventrodorsal or dorsoventral views compare these structures more directly and also show the tympanic bullae.

The parietal-occipital suture and the synchondrosis between the basisphenoid and basioccipital bones disappear by 5 years of age.

Radiographs of the head are used to diagnose frontal and parietal fractures, fractures or separation of the basilar bones, fractures of the petrous temporal bone, hemorrhage into and around the guttural pouches, soft palate displacement, stylohyoid fractures, and orbital fractures.

Cervical Spine

Radiographic examination of the cervical spine is indicated when there is deformity or palpable abnormality of the neck, ataxia or weakness of the limbs, or neck trauma, stiffness, or pain.

Acceptable views of C1 to C6 are readily obtained in standing horses with portable equipment, especially with fast rare-earth screens, grids, and appropriate film, imaging plates used for

computed radiography, or direct digital systems. For normal 450-kg horses, more powerful equipment (75 to 100 kV, 75 to 100 mAs) is required for views of C7 to T1. Complete radiographic assessment of the cervical spine of a full-size horse requires four or five overlapping views: occiput and C1, C1 to C3, C3 to C5, C5 to C7, and C7 to T1 (Figure 50-12). It is very important to obtain true lateral projections, because a slight obliquity complicates interpretation of the image. In anesthetized horses, additional views including lateral-flexed, lateral-extended, and ventrodorsal (C1 to C5 or C6), can be obtained.

The horse has seven cervical vertebrae. The cervical spine of the standing horse adopts a reverse-S shape when viewed from the left, with gradual flexion at the cranial end and extension caudad. Within each vertebra is a rectangular-appearing vertebral foramen; the continuous cylinder formed by these foramina is the vertebral canal. Absolute values for minimal sagittal diameter, sagittal ratio, and corrected minimal sagittal diameter of the cervical vertebral canal within each vertebra have been reported. Preliminary normal ranges for minimal intervertebral sagittal diameters and sagittal ratios have been published. Measurement of sagittal diameter is used to detect stenosis of the vertebral canal and is described in detail in Chapter 51.[7-10]

The atlas (C1) has no body or articular processes. The axis (C2) has a large dorsal spinous process and a cranially projecting dens (odontoid process). There are separate ossification centers for the dens, head, body, and caudal epiphysis of C2. The body of each of the C3 to C7 vertebrae has cranial and caudal epiphyses, and there is an extra center of ossification in the ventral processes of C6. The transverse processes of C6 differ from those of C3 to C5 by presenting an additional ventral process. This ventral process contributes to the ventral profile of C6 in lateral projections. The caudal aspect of each of the bodies of C3 to C7 is smoothly concave and accommodates the convex cranial aspect of the next vertebra caudally. Intervertebral discs are radiolucent and of uniform width dorsal to ventral. The cranial and caudal articular processes of C3 to C7 form pairs of true articulations (facet joints) that are visible as smooth ovoid radiodense structures at the dorsal aspect of each intervertebral foramen. C7 is a relatively short vertebra with a small dorsal spinous process. In most horses, the dens fuses with the head of C2 at about 7 months of age, and the cranial and caudal physes of C3 to C7 close by 2 and 5 years, respectively.

Vertebral abnormalities including occipitoatlantoaxial malformation, cervical vertebral stenotic myelopathy, degenerative arthritis of the facet joints, osteomyelitis, fracture, discospondylitis, and multiple myeloma are examples of cervical spinal diseases that can be diagnosed in plain radiographs.

Thoracolumbar Spine

Thoracolumbar radiography may be performed on horses that have a history of trauma to the back, deformity of the back, acute or chronic back pain, or signs of limb weakness and ataxia that localize to this area.

Radiography of this area of the spine is difficult and requires specialized and powerful (75 to 120 kV, 100 to 250 mAs) equipment and fast rare-earth screens and grids or computed radiograph cassettes. With this equipment, it is technically possible to obtain lateral views from T1 to L3. Caudal to L3, superimposition of the ilial wings over the lumbar vertebrae precludes useful views. Ventrodorsal images from about T9 to L6 are possible in anesthetized horses. For all areas of the thoracolumbar spine, two lateral exposures are needed for film-screen systems: one optimized for the vertebral bodies and one for the dorsal spinous process. In some cases, separate processing algorithms can be used to obtain optimized images of bodies and spinous processes from a single exposure when a computed radiography system is used.

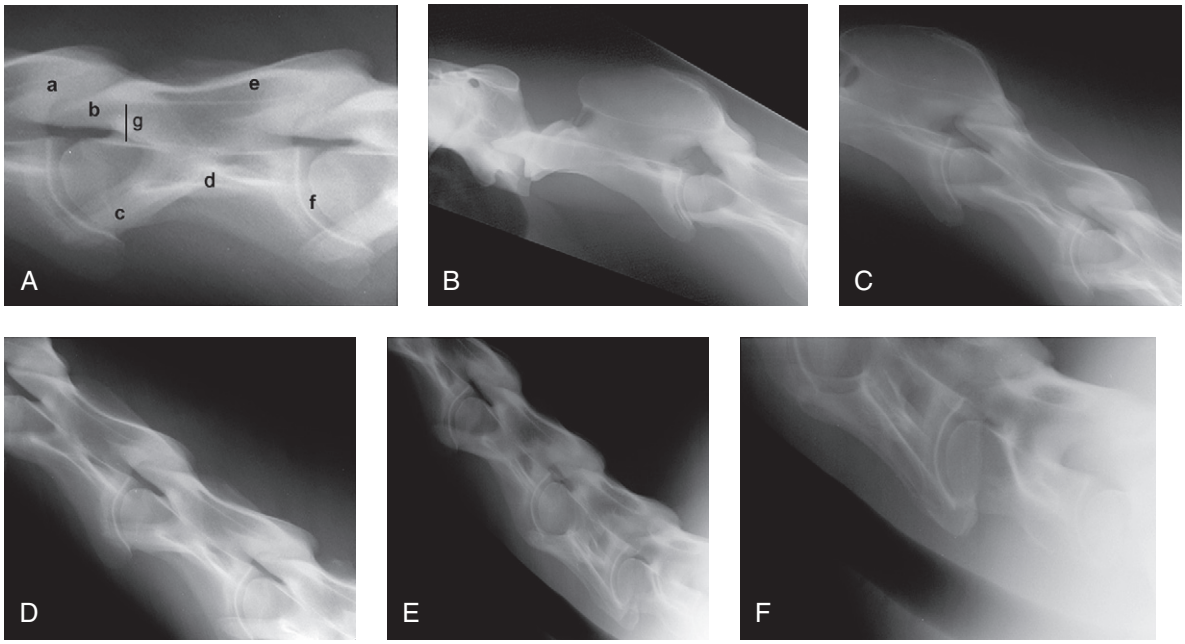

Figure 50-12. Survey radiographs of the neck of a standing normal horse. **A,** Fifth cervical vertebra. *a,* Caudal articular process of C4; *b,* cranial articular process; *c,* transverse process (cranial branch); *d,* vertebral body; *e,* dorsal lamina; *f,* intervertebral disc space; *g,* vertebral body. The *line* shows the sagittal diameter of the vertebral foramen. **B** to **F,** Five overlapping views of a complete cervical series. (Courtesy Dr. Greg Roberts, University of Florida.)

There are 18 thoracic vertebrae and usually six lumbar vertebrae. Some horses and all donkeys have only five lumbar vertebrae. Vertebral bodies are rectangular and the vertebral canal is of uniform sagittal diameter throughout. Disc spaces are curved and of uniform thickness, whereas facet joints vary over the length of the thoracolumbar spine. Thoracic and lumbar facet joints are difficult to image on lateral radiographs. In thoracic vertebrae, ribs articulate dorsal to the disc spaces. The dorsal spinous processes of the thoracic vertebrae increase in length to T6 or T7 and become shorter in the more caudally located vertebrae. Separate ossification centers are present in the dorsal spinous processes of T2 to T8. Thoracic dorsal spinous processes slope caudally, T15 is vertical (anticlinal), and the dorsal spinous processes of lumbar vertebrae slope cranially. The transverse processes of lumbar vertebrae are larger than those of the thoracic vertebrae and can be identified on lateral projections.

The cranial physes close by 12 months and the caudal physes by 4 years of age.

Degenerative joint disease, ossifying spondylosis, osteomyelitis, discospondylitis, and fractures and dislocations can be seen on plain films of the thoracolumbar vertebrae (see Chapter 53).

Sacrococcygeal Spine

Reasons for sacrococcygeal radiography include signs of cauda equina syndrome and pain or deformity over the sacrum or tail. Lateral views of the sacrum may be obtained with techniques similar to those used for the lumbar spine. The sacrum is usually poorly resolved because of overlying soft tissues, but the ventral profile can usually be seen as a straight horizontal line. The last segment of the sacrum (usually S5) is variably separated from the main body of the sacrum and may be confused with the first coccygeal vertebra. Ventrodorsal images can be obtained under anesthesia by using the pelvic technique described in Chapter 53. The sacroiliac joints can be seen on this projection.

Scout films of this area are most often useful in horses with signs of cauda equina syndrome caused by sacral or coccygeal fractures or dislocations.

Myelography

Myelography involves introducing contrast medium into the subarachnoid space followed by radiography of the brain and spinal cord to outline the spinal cord and adjacent structures. In the horse, cervical myelography is commonly used and is indicated when cervical survey films or clinical examinations have suggested the presence of a cervical spinal cord lesion.

Myelography should be performed under general inhalation anesthesia. An NSAID (preferably flunixin meglumine or ketoprofen) should be given prior to the procedure. All of the following views should be completed within 90 minutes, and preferably within 60 minutes. Begin in lateral recumbency and take plain lateral survey films. For these views, the head and neck need to be supported in horizontal position by radiolucent cushions. Perform atlantooccipital cisternal puncture with an 18-gauge 8.3-cm needle as described earlier. Connect a short extension tube to the needle and slowly withdraw 10 mL CSF per 100 kg bodyweight (e.g., 50 mL in a 500-kg horse). Retain a sample of CSF for analysis. Next, inject the same volume of contrast material (iopamidol or iohexol) into the subarachnoid space at constant rate over 5 minutes. Withdraw the needle, then elevate the head and neck at approximately 30 degrees from the horizontal and allow another 5 minutes for caudad flow of contrast material to occur. Bring the head and neck back to the horizontal position and repeat the radiographs of the cervical spine. Next, tie the horse's head in position to exert flexion pressure focused on the middle of the neck. Radiograph C1 to C5. Retie the head so that the caudal part of the neck is

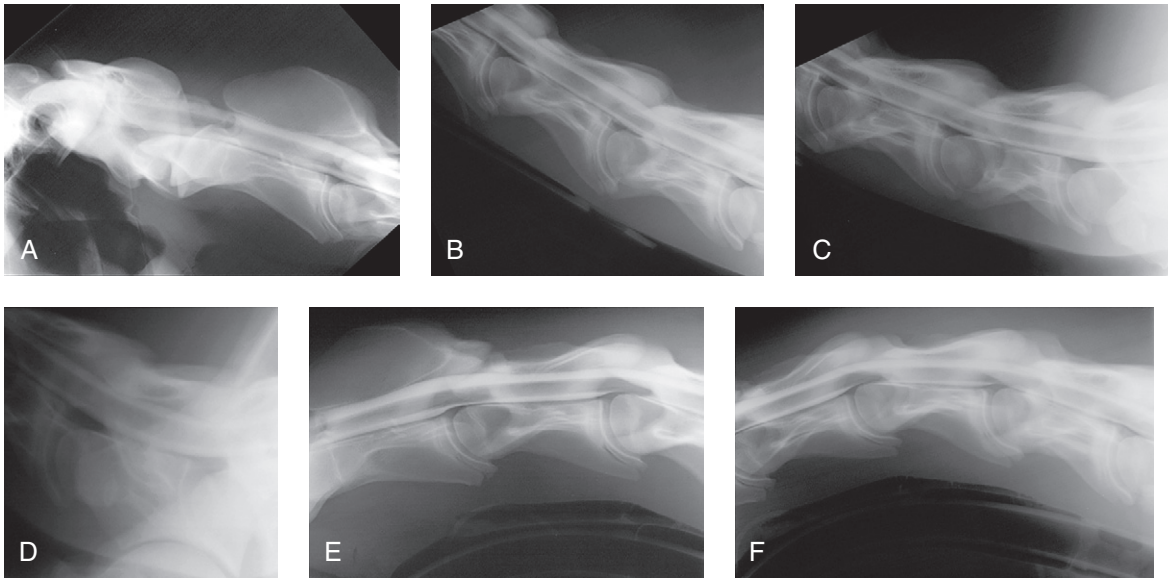

Figure 50-13. Cervical myelographic series in a normal horse. **A** to **C,** The neck is in a neutral position. Note that the transverse processes of C6 in this horse do not have the typical ventral extension. **D,** Now centered caudally, the neck is in extended position. **E** to **F,** Cranial and middle views of the neck in flexed position. (Courtesy Dr. Greg Roberts, University of Florida.)

hyperextended, and radiograph C5 to C7 (Figure 50-13). If indicated, position the horse in dorsal recumbency and take ventrodorsal views. Such views are possible from C1 to the cranial half of C6.

Neutral, flexed, and extended views are examined for evidence of dynamic or static vertebral canal stenosis or extradural compression by soft tissue. Typically, flexion reveals dynamic compression in the middle and cranial part of the neck, whereas extension views are best for dynamic compression in the caudal part of the neck. Criteria for interpretation of myelograms in cases of suspected cervical vertebral stenotic myelopathy have been reported and are described in Chapter 51.

NSAID therapy should be continued for 3 to 5 days after the procedure, and the horse should be closely observed and monitored during the first week. Fever and inappetence are common during this period if NSAIDs are not given, and they occasionally occur after NSAIDs are stopped. Seizures occur occasionally, usually within 24 hours of myelography. These are usually controlled with diazepam (0.05 to 0.1 mg/kg IV) and the horse is put on preventive antiseizure medication (e.g., phenobarbital, 5 mg/kg PO twice a day) for at least 7 days.

Computed Tomography

Computed tomography (CT) is a cross-sectional imaging method that provides additional diagnostic information in situations where survey radiography is unsatisfactory.[11] This is particularly true of the skull, where multiple soft-tissue and bony structures are superimposed on each other in two-dimensional radiographic images. Even in the cranial neck, where radiography is very useful, contrast-enhanced CT had better specificity for detection of spinal cord compression than did cervical myelography.[12] Compared to radiography, CT can discriminate much smaller differences in density (0.5% versus 10%). The gray matter of the brain can be distinguished from white matter, and acellular fluids can be distinguished from blood and pus.

The principles of CT have been reviewed (see Chapter 75).[11] In brief, CT images are produced in slices by an x-ray beam that rotates in a circular gantry around the object. The gantry and table carrying the patient move in precise relation to each other in a series of increments or slices. Slice thickness is typically 0.4 to 1 cm. As in radiographs, images are rendered in gray scale. Iodinated contrast medium can be administered to enhance vascular mass lesions and to better detect diseases that disrupt the blood–brain barrier. Intravenous doses for equine CT contrast enhancement have been reported.[13] Data can be reconfigured to produce images in alternative planes or in three dimensions.

CT-based studies of the anatomy of the head in adult horses and foals have been reported.[14,15] At present, the technique is usually performed under general anesthesia, although techniques and equipment for standing CT of the head are being developed. The skull and first four or five cervical vertebrae can be imaged in adult horses, whereas the entire body of the neonatal foal can be passed through the gantry (50 to 60 cm in diameter). The technique has been used to detect or evaluate temporohyoid osteoarthropathy, brain abscess, cholesterinic granuloma of the choroid plexus, fracture of the basisphenoid and calvaria, and guttural pouch disease.[16]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the skull and spine is a cross-sectional imaging technique that is less widely available than CT (see Chapter 76).[11,16] The strong magnets (0.5 to 1.5 tesla) required for this type of imaging preclude the use of "standing" units designed for imaging distal limbs. Horses must be anesthetized and all metallic objects removed.

MRI provides a gray-scale map of the behavior of tissue protons in a strong magnetic field, and it yields cross-sectional slices in any plane. Data can be used to reconstruct images in three dimensions. T1-weighted images reveal fine anatomic

detail but lack tissue contrast. T2-weighted images are grainier than T1-weighted images, but they are more useful for detecting fluid and pathologic change. Additional contrast during T1 pulse sequence can be provided by injecting gadolinium.

Reference studies for the head have been published, and cases of intracranial neoplasia, abscesses, temporohyoid osteoarthropathy, hydrocephalus, and cholesterinic granuloma have been diagnosed.[16] MRI is generally regarded as superior to CT for soft tissue images, whereas CT is better for bone images.

Ultrasonography

The last 10 years has seen rapid development of techniques for ultrasonographic examination of the equine spine and its component intervertebral disks, dorsal intervertebral joints, sacroiliac joints, interspinous and supraspinous ligaments, segmental spinal nerves and blood vessels, and paraspinal muscles.[17-20] Most examinations are performed transcutaneously; caudal components of the spine are also imaged *per rectum*. The spinal cord, CSF, and meninges can be imaged ultrasonographically in cross-section at the atlanto-occipital and lumbosacral spaces.[21,22] Although the principal use of spinal ultrasonongraphy has been for strictly musculoskeletal abnormalities (see Chapter 68), several applications are suitable for neurologic examination and treatment and many more will be developed over the coming decade. The principal such application already in use is ultrasonongraphic guidance of needles for injection of corticosteroids into the arthritic cervical dorsal intervertebral joints of horses with limb ataxia or stiff necks.[23] Ultrasonography also is used to detect fractures or osteomyelitis of the vertebrae and skull, to facilitate CSF collection at AO and LS sites, and to guide injection of contrast for myelography at the AO site.[21,22]

Endoscopy of the Vertebral Canal

Direct examination of the epidural and, to a lesser extent, intrathecal spaces by endoscopy is an important tool for diagnosis and therapeutic intervention in human neurology.[24] Techniques for cervical epidural and intrathecal endoscopy of horses[25] and epiduroscopy of the sacrum in cattle[26] have recently been published and likely will have clinical application in equine specialty practices.

ELECTRODIAGNOSTIC TECHNIQUES

Electromyography

Needle electromyography (EMG) is the diagnostic recording of the electrical activity of muscle.[27] The EMG records spontaneous activity and response to needle insertion, voluntary or reflex muscle activity, and nerve stimulation. Abnormal results are consistent with muscle damage or motor denervation of at least 2 weeks' duration.[1] Use of the EMG allows objective mapping of the size and margins of involved muscle. This is discussed more fully in Chapter 87.

Electromyography requires needle electrodes, amplifier, cathode-ray oscilloscope, and speaker. Concentric and monopolar electrodes combine reference, ground, and exploring electrodes in different combinations. The examination can be performed standing, with or without sedation, or under general anesthesia. After the needle is pushed into muscle, insertional activity, motor unit action potentials (MUAPs) during muscle contraction, and abnormal spontaneous activity are measured. Normal and abnormal responses have been described for horses. Abnormal responses include fibrillations, fasciculation potentials, positive sharp waves, complex repetitive discharges, and myotonic discharges. Each of these has characteristic electrical profiles and sounds. Reference values for amplitude and duration of normal MUAPs in conscious horses have been published.[28,29] Values for horses with myopathies differed markedly from these normal values, and it is expected that values in denervated muscle would also be abnormal.

Nerve conduction studies combine nerve stimulation with EMG recording to evaluate conduction speeds in large motor nerves. These studies are performed under general anesthesia. Techniques have been described for the radial and median nerves in horses, and tibial nerve testing has been performed in horses with stringhalt.

Electroencephalography

Electrical activity arising from the cerebral cortex is recorded by subcutaneous electrodes inserted over the frontal/parietal area and displayed graphically on paper or captured for computerized analysis. Electroencephalography (EEG) is a useful tool for determining the presence, location, and extent of cerebral disease. Because of the expanded use of CT and MRI for evaluation of brain disease, the EEG is now used less frequently than it was 20 years ago.

Evoked Response Testing

The integrity of various parts of the central and peripheral nervous systems can be tested by providing a stimulus at one site and recording the electrical activity at another site. Techniques that have been used in horses include magnetic motor-evoked potentials, brain-stem auditory-evoked responses, and cortical somatosensory-evoked potentials.[30-32]

CHAPTER 51

Developmental Vertebral Anomalies

Bonnie R. Rush

Cervical stenotic myelopathy (CSM) and occipitoatlantoaxial malformation (OAAM) are the most notable developmental abnormalities of the vertebral column of the horse. Other congenital vertebral anomalies, such as hemivertebrae, block vertebrae, and spina bifida, occur rarely in horses, with individual reports involving a small number of foals. The pathogenesis of vertebral malformations is largely unknown, but it is suspected to be multifactorial, including heredity, dietary imbalance, and *in utero* insult (trauma and toxin). After a brief description of normal vertebral development, the clinical presentation and pathogenesis of vertebral malformations and anomalies are described.

NORMAL VERTEBRAL DEVELOPMENT

The critical phase of vertebral development is during gastrulation (the formation of the three primary germ layers: ectoderm, mesoderm, and endoderm) and neurulation (the formation of the notochord, neural crest, and the precursors of the nervous system).[1] The spine has its embryologic origins in the cell that is induced to migrate out of the somite, toward the notochord and the neural tube. A mass of sclerotomal cells collect segmentally at the embryonic midline, surrounding the neural tube and the notochord, and these cells begin to separate into a cranial portion and a caudal portion. Failure of segmentation produces a block vertebra. The cranial portion of each sclerotome recombines with the caudal portion of the directly superior sclerotome in a resegmentation process known as *metameric shift*. Failure of recombination produces hemivertebrae.[1] After the metameric shift, spinal nerves, which originally left the neural tube to go to the center of the sclerotome, are able to pass between the precartilaginous vertebral bodies to innervate the segmentation myotomes.

The atlas and axis form by a mechanism that is different from that of the other vertebral bodies. Part of the first cervical sclerotome plus the cranial portion of the second cervical sclerotome contribute cells to form the odontoid process and the arch of the atlas.[2] In the cervical region, eight cervical somites generate only seven cervical vertebrae because the cranial portion of the first cervical sclerotome contributes to the formation of the occiput, and the caudal portion of the eighth cervical sclerotome contributes to T1. This is the process by which eight cervical spinal nerves become associated with seven cervical vertebrae.[1] Because the occiput, atlas, and axis are formed from shared sclerotomes, developmental abnormalities of these structures occur concomitantly, as in OAAM of Arabian foals. The first cervical spinal nerve passes between the base of the skull and the first cervical vertebra. The eighth cervical nerve exits below the seventh cervical vertebra and above the first thoracic vertebra. The remainder of the nerve roots exit below their corresponding vertebral bodies.

As the sclerotomes undergo shift to form the vertebral bodies, the adjacent visceral organs are differentiating, so that a noxious influence affecting development of a particular

vertebral segment may affect adjacent organs at the same time. Hence, cardiac anomalies may occur with congenital malformation of the thoracic spine, and renal anomalies may be associated with congenital malformation of the lumbar spine. During axial embryogenesis, interdependence exists between the spinal cord and the axial skeleton. If this balance is distorted by genetic, traumatic, toxic, or nutritional factors, a malformation may occur. The type of malformation depends on the stage of development of the nervous system at the time of insult.[3] Vertebral anomalies can be divided into three categories from the standpoint of basic developmental pathogenesis: malformation, disruption, and deformation.[4]

Malformation results from a failure of embryologic differentiation of a specific anatomic structure, causing it to be absent or improperly formed during the embryonic stage of gestation. Hemivertebrae, butterfly vertebrae, and block vertebrae are examples of malformation abnormalities. Once the malformed vertebra is anatomically established, the defect may continue to adversely affect spinal development throughout the subsequent fetal and postnatal periods. The eventual type of malformation and its severity depend on the stage of the developmental or maturation cycle that is specifically affected.

Disruption is a structural defect resulting from destruction of an anatomic part during the fetal stage of gestation that formed normally during the embryonic period. This mechanism involves distal structures (e.g., flexural limb deformity or wry nose) more frequently than the axial skeleton.

Deformation is defined as alteration in the shape or structure of an individual vertebra or vertebral segment that had initially differentiated normally, during the fetal and/or postnatal periods (e.g., cervical stenotic myelopathy). Deformation abnormalities are not considered true congenital abnormalities.

CERVICAL STENOTIC MYELOPATHY

Etiology

Cervical stenotic myelopathy (CSM) (cervical vertebral malformation, wobbler syndrome) is a common cause of spinal ataxia in young horses. This developmental disorder is characterized by postnatal deformation of the cervical vertebrae, resulting in stenosis of the vertebral canal and spinal cord compression.[5-7] The etiology of CSM appears to be multifactorial, and genetic predisposition and nutrition appear to play the most significant roles in the development of the disease.[7-9] Cervical stenotic myelopathy has been reported in most light and draft horse breeds; however, Thoroughbreds, Tennessee Walking Horses, and Warmblood breeds appear particularly predisposed, and male horses are more frequently affected than females.[10,11] The age of onset is typically 6 months to 3 years, although mature horses (4 to 20 years) are identified with acute onset of spinal cord compression due to cervical stenosis and arthropathy.[11] Affected horses often demonstrate rapid growth and are more likely to have developmental orthopedic disease of the appendicular skeleton than peers.[8]

Vertebral deformation associated with spinal cord compression includes flaring of the caudal epiphyses of the vertebral bodies, abnormal ossification of the articular facets, malalignment between adjacent vertebrae, osteoarthritis of the articular facets, and extension of the dorsal laminae.[12] In addition to these bony deformations, the vertebral canal is narrowed from C3 through C6, regardless of the specific site of spinal cord compression.[13] Spinal cord compression nearly always occurs in a dorsoventral plane, although lateral compression of the spinal cord has been demonstrated via computed tomography. Caudal epiphyseal flare occurs secondary to abnormal biomechanical forces on the vertebral growth plate because of subluxation and malalignment between adjacent vertebrae. Vertebral subluxation produces dynamic compression of the spinal cord during ventroflexion and is most commonly observed at C3-4, C4-5, and C5-6. Extension of the dorsal laminae contributes to spinal cord compression, because it ventrally displaces the roof of the vertebrae to produce a funnel shape, or "coning," of the vertebral canal.[12] Abnormal ossification of the articular facets often results from osteochondrosis of the joint surface, which quickly progresses to osteoarthritis.[12] Degenerative arthropathy of the articular processes occurs most frequently from C5 through C7 and is associated with spinal cord compression with the neck in the neutral (static) or hyperextended position.

Histopathologic evaluation of the spinal cord reveals necrosis of the white matter, with focal loss of neurons. Neuronal fiber (wallerian) degeneration is observed in ascending tracts cranial to the site of compression and descending tracts caudal to the site of compression.[6]

Clinical Signs

The clinical signs of CSM result from focal compression of the cervical spinal cord between C1 and C7. Compression may occur at a single vertebral site or at more than one site in the same horse. Horses with CSM demonstrate upper motor neuron deficits to all four limbs, characterized by symmetric weakness, ataxia, and spasticity.[3] At rest, affected horses may have a base-wide stance and demonstrate delayed responses to proprioceptive positioning. At a walk, weakness is manifested by stumbling and toe dragging; horses with prolonged clinical signs of CSM may have hooves or shoes that are chipped, worn, or squared at the toe. Ataxia (proprioceptive loss) appears as truncal sway at a walk and is manifested by circumduction and posting (pivoting on the inside limb) of the hind limbs during circling. Moderate to severely affected horses have lacerations on the heel bulbs ("wobbler heels") and medial aspect of their forelimbs from overreaching and interference. Spasticity, characterized by a stiff-legged gait and decreased joint flexion, is often observed in moderately affected horses. Clinical signs can be exaggerated during the neurologic examination by manipulation such as tight circling, walking on a slope, or walking with the animal's head elevated. When prompted to back, horses may stand base-wide, lean backward, and drag their forelimbs. In most instances, the rear limbs are more severely affected than the forelimbs; neuronal tracts to the rear limbs are more superficial and thus susceptible to external compression. Occasionally, forelimb ataxia may be more severe in horses with stenosis of the caudal cervical vertebrae (C6 through C7) because of compression of the cervical intumescence.

Asymmetric ataxia may be observed in horses with dorsolateral compression of the spinal cord by proliferative, degenerative articular processes; periarticular soft tissue proliferation; or a synovial cyst.[11] Rarely, clinical signs of nerve root compression are seen, such as cervical pain, atrophy of the cervical musculature, cutaneous hypalgesia, and hyporeflexia of cervical reflexes adjacent to the site of spinal cord compression.[14] These signs are more commonly observed in horses that are older than 4 years and that have moderate to severe arthropathy of the caudal

cervical vertebrae (C5 through C7), and they result from peripheral nerve compression by proliferative articular processes as the nerve root exits the vertebral canal through the intervertebral foramen.[5,11] In some instances, arthropathy of the caudal cervical vertebrae may produce cervical pain and forelimb lameness as a result of peripheral nerve compression, without producing clinical signs of spinal cord compression.[15] Affected horses typically travel with a short cranial phase of the stride and a low foot arc of one or both forelimbs, and they may stand or travel with their head and neck extended.

Diagnosis

The diagnosis of CSM requires collection of an accurate history, thorough physical and neurologic examinations, and radiographic evaluation of the cervical vertebrae.[7] The clinical signs of spinal cord compression often progress for a brief period and then stabilize.[5-7] Owners often report a traumatic incident with the onset of clinical signs of CSM. The traumatic incident may be the result of mild neurologic deficits, with the injury exacerbating the clinical signs of spinal cord compression. The following neurologic disorders should be considered in the differential diagnosis for cervical stenotic myelopathy: equine protozoal myeloencephalitis (EPM), equine degenerative myeloencephalopathy (EDM), equine herpesvirus myelitis, OAAM, spinal cord trauma, vertebral fracture, and vertebral abscess. Cerebrospinal fluid analysis may be performed during the diagnostic process, and it is usually unremarkable in horses with CSM. In CSM-affected horses with acute compression, mild xanthochromia or increases in protein concentration may be observed.

Assessment of plain film radiographs of the cervical vertebrae can determine the likelihood of CSM in horses with spinal ataxia.[13] Cervical radiographs should be evaluated for subjective assessment of vertebral deformation and objective determination of vertebral canal diameter. The five characteristic deformations of the cervical vertebrae in horses with CSM include flare of the caudal epiphysis of the vertebral body, abnormal ossification of the articular processes, subluxation between adjacent vertebrae, extension of the dorsal laminae, and osteoarthritis of the articular processes (Figures 51-1 and 51-2).[15,16] Osteoarthritis of the caudal cervical vertebrae is the most frequent and severe deformation observed in CSM-affected horses. Nonetheless, degenerative arthropathy occurs in 10% to 50% of nonataxic horses, and it is the most frequent and severe vertebral deformation in horses without CSM.[17] Therefore, subjective evaluation of osteoarthritis of the articular processes leads to a false-positive diagnosis of CSM. Although the presence of characteristic deformations supports the diagnosis of cervical stenotic myelopathy, subjective evaluation of cervical radiographs does not reliably discriminate between CSM-affected and unaffected horses.[18] Objective assessment of the vertebral canal diameter is more accurate than subjective evaluation of vertebral deformation for identifying CSM-affected horses.

The intravertebral sagittal ratio measurement was developed to objectively determine the vertebral canal diameter in horses.[12] The sensitivity and specificity of the sagittal ratio for identifying CSM-affected horses is approximately 89% for vertebral sites C4 through C7.[7] Generalized stenosis of the vertebral canal may be the most important factor in the development of CSM. The sagittal ratio is calculated by dividing the minimal sagittal diameter of the vertebral canal by the height of the vertebral body. The minimal sagittal diameter of the vertebral canal is obtained by determining the narrowest diameter measured from the dorsal aspect of the vertebral body to the ventral border of the dorsal laminae (see Figure 51-2). The vertebral body width is measured perpendicular to the vertebral canal at the widest point of the cranial aspect of the vertebral body. Because the vertebral body is located within the same anatomic plane as the vertebral canal, determination of this proportion negates the effects of magnification that result from variability in object-to-film distance. The sagittal ratio should exceed 52% from C4 through C6, and 56% at C7, in horses heavier than 320 kg.

Intervertebral measurements may provide additional information to identify horses with CSM based on plain film radiography.[19] The minimum intervertebral sagittal diameter ratio

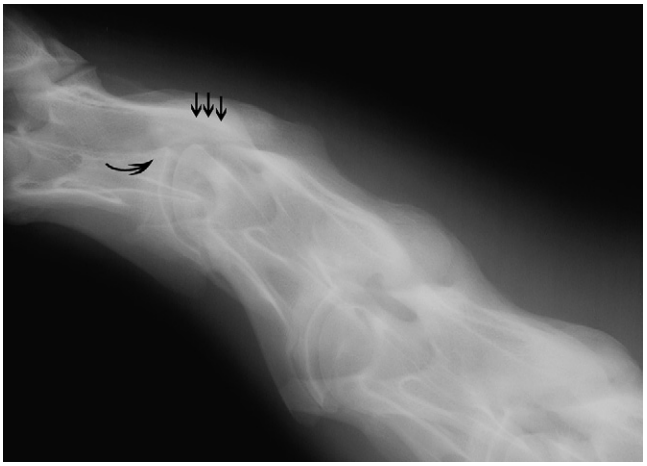

Figure 51-1. Lateromedial cervical radiograph of a 2-year-old Quarter Horse filly with spinal ataxia as a result of cervical stenotic myelopathy (CSM). Bony deformations consistent with CSM include flare of the caudal epiphysis *(curved arrow),* caudal extension of the C3 dorsal lamina *(arrows),* and malalignment of the C3-to-C4 articulation.

Figure 51-2. Lateromedial cervical radiograph of a 13-month-old Thoroughbred filly with spinal ataxia as a result of static spinal cord compression at C4-5. Severe osteoarthritis of the articular processes *(arrows)* is present at C4-5, and moderate osteoarthritis of the articular processes is seen at C5-6. The sagittal ratio is determined by dividing the intravertebral minimal sagittal diameter *(double arrow)* by the width of the vertebral body *(line),* as demonstrated using C5 in this radiograph.

is measured from the caudal aspect of the dorsal lamina of the vertebral arch of the more cranial vertebra to the dorsocranial aspect of the body of the more caudal vertebra, or from the caudal vertebral body of the more cranial vertebra to the cranial dorsal lamina of the vertebral arch of the more caudal vertebra, whichever is smaller. For vertebrae C2-3 to C5-6, the minimum diameter is typically based on the former measurement. Similar to the intravertebral sagittal ratio, the intravertebral measurement is divided by the width of the vertebral body. Horses with an intervertebral sagittal ratio of 0.485 or less should be classified as having CSM at that site. The diagnostic cutoff for intervertebral sagittal ratio parameter was based on evaluation of eight CSM-affected horses.

The clinician's goal for interpretation of radiographic projections of the cervical vertebrae is to classify the patient into one of the following categories:

- Low sagittal ratio (less than 48% at C4 through C6), moderate to severe bony deformation: perform myelographic examination to identify sites of spinal cord compression and classify lesions as static or dynamic.
- Marginal sagittal ratio (48% through 56%), mild to moderate bony deformation: perform myelographic examination to confirm or exclude CSM.
- High sagittal ratio (greater than 56%), minimal bony deformation: pursue alternative diagnoses.

Accurate assessment of cervical radiographs requires a precise lateral radiographic projection of the cervical vertebrae. Obliquity of the cervical vertebrae results in indistinct margins of the ventral aspect of the vertebral canal, producing erroneous values for minimum sagittal diameter (MSD) and vertebral body width. It is difficult to obtain precise lateral radiographs of the cervical vertebrae in recumbent horses. Plain film radiographs should be obtained in the standing sedated horse whenever possible.

Although plain film radiography can determine the likelihood of CSM, myelographic examination is indicated to confirm the diagnosis, identify lesion location and number of affected sites, and classify spinal cord compressive lesions. Spinal cord compression has been defined myelographically in three ways: (1) as a 50% or greater decrease in the sagittal diameter of the dorsal and ventral contrast columns, (2) as a 20% reduction in the dural diameter (DD), or (3) as a dorsal contrast column of less than 2 mm.[16,18,20] Methods that use a relative decrease in contrast column as diagnostic criteria (i.e., 1 and 2) compare the suspected site to the midvertebral site, cranial or caudal to the compressed site. The ventral column, however, is often obliterated at the intervertebral space in normal studies, particularly in the flexed position. A 20% reduction in DD is an effective diagnostic criterion for identifying CSM at C6-7.[20] Identification of spinal cord compression in the midcervical region is the most challenging. In the midcervical area, with the cervical spine in the neutral position, a 20% DD reduction has high specificity, but it does not detect all cases (low sensitivity). During hyperflexion, midcervical compression is easier to detect; however, false positive diagnosis is more common (low specificity). Most clinicians agree that the criterion of a less-than-2-mm dorsal contrast column is no longer recommended, because it is associated with unacceptable specificity.[20]

In addition to providing the definitive diagnosis of CSM, myelographic examination can differentiate between dynamic (type I) and static (type II) spinal cord compression.[18] Horses with dynamic spinal cord compression (type I) demonstrate narrowing of the dorsal and ventral contrast columns during ventroflexion of the neck, whereas spinal cord compression is not apparent with the neck in the neutral position (Figure 51-3). Dynamic spinal cord compression usually occurs in younger horses (less than 2 years old) and is associated with instability of the cervical vertebrae, particularly from C3 through C6. Dorsal laminar extension, caudal epiphyseal flare, and abnormal ossification patterns often occur in horses with dynamic spinal cord compression. Static vertebral canal stenosis (type II) is characterized by constant spinal cord compression, regardless of cervical position (Figure 51-4). Static compression usually occurs in slightly older horses (2 to 4 years) and results from osteoarthritis of the articular processes and proliferation of periarticular soft tissue structures. In some cases of caudal cervical arthropathy, flexion of the neck stretches the ligamentum

Figure 51-3. Myelographic examination of C2 through C4 of a 2-year-old Quarter Horse filly with dynamic spinal cord compression between the C3 and C5 articulations. The dorsal and ventral contrast columns are obliterated with the neck in the ventroflexed position. Spinal cord compression was not apparent with the neck in the neutral position (not shown).

flavum and relieves spinal cord compression, whereas extension exacerbates compression.

A complete myelographic study should include neutral and stressed (flexed and extended) views of the cervical vertebrae.[18] In horses with obvious sites of spinal cord compression on neutral myelographic views, excessive flexion and extension of the neck should be avoided while obtaining dynamic views to prevent exacerbation of spinal cord injury. Horses should be monitored for 24 hours after the myelographic procedure for depression, fever, seizure, and worsening in neurologic status. Worsening of the neurologic status after myelography may result from spinal cord trauma during hyperflexion, iatrogenic puncture of the spinal cord, or chemical meningitis. Administration of phenylbutazone (4.4 mg/kg PO every 24 hours) 1 day before and through 1 day after the myelographic examination will attenuate fever and depression associated with chemical meningitis.

Treatment

Nutritional Adjustments

Successful conservative management of CSM has been achieved using the "paced diet" program in foals younger than 1 year.[15] The goal of this dietary program is to retard bone growth, enhance bone metabolism, and allow the vertebral canal diameter to enlarge to relieve spinal cord compression. Serial radiographic examinations demonstrate improvement in the sagittal ratio; however, osteopenia may be observed. This dietary program is restricted in energy and protein (65% to 75% of National Research Council [NRC] recommendations) but maintains balanced vitamin and mineral intake (minimum, 100% of NRC recommendations). Vitamins A and E are provided at three times NRC recommendations, and selenium is supplemented to 0.3 ppm. Roughage is provided by pasture or low-quality (6% to 9% crude protein) Timothy hay. Dietary regimens are individually formulated according to the age and weight of the foal. Solitary stall confinement is recommended to minimize repetitive spinal cord compression because of dynamic instability. This program of dietary management and restricted exercise has been successful for preventing neurologic signs in foals with radiographic evidence of CSM and treatment of foals demonstrating clinical signs of CSM.[15]

Medical Management

Administration of glucocorticoids, dimethyl sulfoxide (DMSO), and nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce edema and provide transient improvement in neurologic signs. Spontaneous recovery from CSM without dietary management or surgical intervention has not been reported.[21]

Horses with cervical pain and forelimb lameness as the result of cervical vertebral arthropathy may benefit from intra-articular administration of corticosteroids or chondroprotective agents, or both.[22] Arthrocentesis of the cervical vertebral articulations (facets) is performed under ultrasonographic guidance using a 15-cm (6-inch) 18-gauge spinal needle in the standing sedated or recumbent horse. The cranial facet of the caudal vertebra appears superficial to the caudal facet of the cranial vertebra. The articular space is accessed at the cranioventral opening of the articular facet, which is angled approximately 60 degrees from the ultrasound beam. The needle should be introduced 5 cm cranial to the facet and inserted at a 30-degree angle relative to the skin surface. Joint penetration should be confirmed by aspiration of synovial fluid. If the neck is extended, the transverse process of the cranial vertebra may obscure the path to the articulation. Intra-articular triamcinolone (6 mg per joint, not to exceed 18 mg total dose) or methylprednisolone (100 mg per joint) has produced a positive clinical response in more than 50% of horses with arthrosis of the articular processes. The goal of intra-articular anti-inflammatory therapy should be to decrease cervical pain or eliminate forelimb lameness. It is unlikely that intra-articular therapy will significantly improve clinical signs of spinal ataxia.

Surgical Management

Surgical treatment of CSM is discussed in detail in Chapter 52.

OCCIPITOATLANTOAXIAL MALFORMATION

Occipitoatlantoaxial malformation (OAAM) occurs most frequently in Arabian foals, although it has been reported in Morgan horses, Appaloosas, a Friesian, a Miniature Horse, and Thoroughbreds.[23-27] In Arabians, it is inherited in an autosomal recessive manner with no sex predilection.[23,24] In other breeds, a nongenetic congenital defect occurs at random during development of the vertebral column.[25-27]

In OAAM, the developmental error occurs during embryogenesis, before the end of the sixth week of gestation.[23-25] The atlas of affected foals is characterized by a small vertebral body, vertebral arches, and peglike transverse processes. The atlas is often fused to the occipital bone, resulting in synchondrosis or a barely detectable atlantooccipital joint (occipitalization of the atlas). The odontoid process of the axis (dens) is malformed and hypoplastic. In some cases, the axis may be luxated ventral to the atlas, leading to fracture of the dens. The fusion between the atlas and the occipital bones may be asymmetric, leading to the development of scoliosis.

Clinical Signs and Diagnosis

OAAM may be obvious at birth or detected within the first few weeks of life. Affected animals demonstrate marked weakness and ataxia when walking and may have an extended head and neck position. A clicking sound may be elicited by manipulation of the head, resulting from the dens slipping under the body of the atlas.[23-25] Clinical signs worsen over time as a result of repetitive or persistent compression of the spinal cord. The malformed vertebrae lead to the formation of excess fibrous tissue within the atlantoaxial joint and adjacent ligaments, which in turn creates additional compression of the spinal cord.

Pathologic changes of the nervous system associated with OAAM include a dorsoventral flattening of the medulla oblongata and cranial cervical spinal cord. Histolopathologic evaluation of affected neuronal tissue reveals gliosis, astrofibrosis, neuronal fiber degeneration, and perivascular fibrosis.[23]

Treatment

In Arabian foals, euthanasia is recommended because of the heritable nature of the condition. In other breeds, surgical intervention may be used to correct atlantoaxial subluxation and scoliosis. Young horses and foals with malformation of the

occiput, atlas, and axis should be managed conservatively if they do not demonstrate neurologic gait deficits.

ATLANTOAXIAL SUBLUXATION

Atlantoaxial subluxation (AAS) results from a developmental abnormality of the odontoid process of the axis (dens), such as malformation, absence, or separation from the axis. The excessive mobility of the atlantoaxial joint results in repetitive or constant spinal cord compression.[28] Congenital absence of the dens, the most extreme from of AAS, produces significant loss of stability between the atlas and the axis.

Clinical Signs and Diagnosis

The clinical signs of AAS include weakness, spasticity, and ataxia in all four limbs, consistent with focal compressive lesions of the cervical spinal cord.[28,29] Progression of signs is quite variable and depends on the degree of laxity between the axis and atlas. Clinical signs may slowly progress over weeks to months or may begin acutely, making spinal cord trauma important in the differential diagnosis. Severe compression may produce tetraplegia.
