Designer: Paula Catalano

Printed in the United States

Last digit is the print number: 9 8 7 6 5 4 3 2 1

The Fourth Edition is dedicated to:

Our colleagues and fellow diplomates in the European and American Colleges of Veterinary Surgeons, without whom this book would never have been realized.

To the horses we so value, which inspire us to improve our craft.

To Anita and Claudette, our loving wives, who support us with great appreciation of our chosen profession.

Preface

Our goal for the fourth edition of *Equine Surgery* was to maintain the high standard of the last edition and continue its position as the leading worldwide clinical reference and teaching textbook for clinicians, practitioners, surgery residents, and students. We, the editors, continued the format of the last edition by taking direct responsibility for inviting authors in the sections for which we were in charge; however, we exchanged the assignment of some sections between us. Prior to embarking on the detailed planning of the fourth edition, we asked a group of senior surgeons, ACVS and ECVS diplomates who recently passed their board examinations, and residents preparing for the certifying examination to evaluate the third edition for omissions that would improve the textbook as well as for chapters that could be excluded to make room for new material. The results of these evaluations were passed on to each contributor to this edition, and it greatly improved the content of the book. We thank Dr. Gary Baxter from Colorado State University, Dr. Larry Galupo from the University of California, Davis, Dr. John Peroni from the University of Georgia, Dr. Kimberly Johnston from Michigan State University, Dr. Rich Redding from North Carolina State University, Dr. Gabor Bodo from Budapest, and Dr. Jan Kümmerle from the University of Zurich in Switzerland for their service in review of the third edition.

We have continued to focus on the clinically relevant aspects of equine surgery, presenting information in a concise, understandable, and logical format. Extensive use of figures, tables, cross-referencing within and among sections, and a comprehensive index help make the fourth edition of *Equine Surgery* a quick and easy-to-use reference textbook.

ORGANIZATION

The book contains twelve sections, starting with surgical biology, surgical techniques, and recent advances in anesthesia, and followed by sections pertaining to all organ systems with one new section on diagnostic imaging. Each section is logically structured and supported extensively by photographs and tables. A comprehensive list of references completes each chapter. Additionally, we prepared appendixes that list drugs and products, their American and European manufacturers (where applicable), and the chapters where they were mentioned throughout the text.

KEY FEATURES OF THE FOURTH EDITION

We have retained all of the features that were popular in the first three editions and have significantly updated all chapters in the fourth edition. We continued to select known and novel contributors who are recognized as experts in their fields to author the chapters in this edition.

New Features

The new features include:

- Thoroughly revised and updated content with expanded coverage on current and new topics throughout the textbook
- Expanded use of the expertise of more ECVS authors to acquire additional international representation
- The addition Chapter 8, Regenerative Medicine, responding to the current trend in equine therapeutic medicine
- Expansion of the new science and expertise in diagnostic imaging, which was compiled into a section of its own—Section XI, Diagnostic Imaging Examination
- Reorganized and updated Section VIII, Eye and Adnexa
- Added Chapter 101, Temporomandibular Joint Disorders, and Chapter 103, Postoperative Physiotherapy for the Orthopedic Patient

Acknowledgments

We are very proud that we were able to produce this textbook in a timely fashion so that the content will continue to represent current "state-of-the-art" surgical procedures and techniques. To our contributors, once again, thank you for the marvelous work.

We would like to extend our sincerest thanks to Penny Rudolph, our motivating, joyful, and very competent publisher at Elsevier. Our thanks also go to Brandi Graham, who kept us patiently on track, helped us to stay on time, and did it all in a very gracious manner. We also thank Laura Loveall, our Project Manager, who oversaw copyediting, made sure all the authors turned in their edited version to us on time, and aided the process of continuity in the book. A special thank you goes to Matthias Haab of Zurich, Switzerland, who continued to do a marvelous job in preparing all of the new artwork. Not only is the quality of the artwork outstanding, he did this work with great efficiency, which made the final product first-rate.

CHAPTER 1

Shock: Pathophysiology, Diagnosis, Treatment, and Physiologic Response to Trauma

Elizabeth A. Carr

DEFINITION OF SHOCK

In 1872 the trauma surgeon Samuel D. Gross defined shock as "the rude unhinging of the machinery of life." Shock is the progression of a cascade of events that begins when cells or tissues are deprived of an adequate energy source (oxygen). Shock occurs as a result of inadequate tissue perfusion; the lack of an adequate energy supply leads to the buildup of waste products and failure of energy-dependent functions, release of cellular enzymes, and accumulation of calcium and reactive oxygen species (ROS) resulting in cellular injury and ultimately cellular death. Activation of the inflammatory, coagulation, and complement cascades result in further cellular injury and microvascular thrombosis. The amplification of these processes coupled with increased absorption of endotoxin and bacteria (due to liver and gastrointestinal dysfunction) lead to the systemic inflammatory response syndrome (SIRS) (see Chapter 2), and multiorgan dysfunction and if uncontrolled, ultimately death.

Classifications of Shock

Tissue perfusion is dependent on blood flow. The three major factors affecting blood flow are the circulating volume, cardiac pump function, and the vasomotor tone or peripheral vascular resistance. The interplay of these three factors can be seen in the formula for cardiac output (CO):

$$\text{Cardiac output (CO)} = \text{Stroke volume} \times \text{Heart rate}$$

CO ultimately determines the blood flow to tissues and is regulated, in part, by the stroke volume. Stroke volume is affected by the preload (amount of blood returning from the body and entering the heart), the cardiac contractility (muscle function), and the afterload or arterial blood pressure the heart must overcome to push blood through the aortic and pulmonic valves. Preload is directly affected by the circulating blood volume or amount of blood returning to the heart. Causes of decreased preload include loss of volume, hypovolemia, decreases in vasomotor tone, and vasodilation, which results in pooling of blood in capacitance vessels and decreased return to the heart. In this situation, although the total volume of blood remains unchanged, the effective circulating volume decreases. Afterload, the third component of CO, is directly affected by vasomotor tone or peripheral vascular resistance. If vascular resistance or tone increases, afterload also rises (hypertension) with a resultant fall in CO and perfusion. The opposite extreme is a severe fall in vascular resistance, which results in pooling of blood in capacitance vessels and a fall in blood pressure and preload, and it ultimately results in inadequate perfusion and shock. CO or flow can, therefore, also be described by the equation:

$$\text{CO} = \text{Blood pressure}/\text{Total peripheral vascular resistance}$$

Shock most commonly occurs because of one of three primary disturbances and can be classified accordingly. *Hypovolemic* shock is the result of a volume deficit, either because of blood loss (e.g., resulting from profound hemorrhage), third space sequestration (e.g., occurring with a large colon volvulus), or severe dehydration. *Cardiogenic* shock or pump failure occurs when the cardiac muscle cannot pump out adequate stroke volume to maintain perfusion. *Distributive* shock or microcirculatory failure occurs when vasomotor tone is lost. Loss of vascular tone can result in dramatic fall in both blood pressure and venous return. Although the drop in blood pressure will initially decrease afterload (which will improve CO), the pooling of blood and loss of venous return results in a severe decrease in preload and consequently, decreased CO and perfusion.

Common causes of distributive shock include neurogenic shock, septic shock, and anaphylactic shock. Because distributive shock is a loss in effective circulating volume, fluid therapy is indicated to help restore perfusion. In contrast, cardiogenic shock is the result of pump failure, and fluid therapy may actually worsen clinical signs. Less commonly, shock can develop when increased metabolic demand results in relative perfusion deficits or when oxygen uptake is impaired because of mitochondrial failure, sometimes termed relative hypoxia or dysoxia.

It is important to recognize that although the inciting cause may differ, as shock progresses, there is often failure of other areas as well. For example, untreated hypovolemic shock can result in microcirculatory failure (loss of vasomotor tone) as oxygen debt causes muscle dysfunction and relaxation. Alternatively, hypovolemic shock can result in myocardial failure as perfusion deficits affect energy supply to the

myocardium (coronary artery blood flow), resulting in decreased cardiac contractility. Consequently, as shock progresses, treatment may require addressing all three disturbances.

An additional category called obstructive shock is described where the mechanism underlying shock is the obstruction of ventilation, or CO. This process is most commonly caused by tension pneumothorax (resulting in decreased venous return) or pericardiac tamponade, resulting in inadequate ventricular filling and stroke volume. Over time as aortic blood pressure falls, coronary artery blood flow is reduced, and myocardial ischemia and finally myocardial failure may develop. Because obstructive shock is ultimately a combination of the other three categories and rarely occurs in large animals, we will not discuss it further.

PATHOPHYSIOLOGY OF SHOCK

A blood loss or hypovolemic model of shock will be used to describe the pathophysiology of shock.

Shock is usually defined by the stage or its severity. Compensated shock represents an early or mild shock, during which the body's response mechanisms are able to restore homeostasis. As blood volume is depleted, pressure within the vessels falls. Baroreceptors and stretch receptors located in the carotid sinus, right atrium, and aortic arch sense this fall in pressure. These receptor responses act to decrease inhibition of sympathetic tone while increasing inhibition of vagal activity and decreasing the release of atrial natriuretic peptide (ANP) by cardiac myocytes. The increase in sympathetic tone and fall in ANP results in vasoconstriction, which increases total peripheral resistance and thereby increases blood pressure. Increased sympathetic activity at the heart increases heart rate and contractility, hence increasing stroke volume (SV) and CO. In addition, peripheral chemoreceptors stimulated by local hypoxia respond by enhancing this vasoconstrictive response. In mild to moderate hypovolemia these responses are sufficient to restore perfusion. Because these compensatory responses result in tachycardia, increased SV (increased pulse pressure), and shortened capillary refill time (CRT), the term hyperdynamic is often used to describe this stage of shock.

The vasoconstrictive response will vary between organ systems, with the greatest response occurring in the viscera, integument, and kidney. Cerebral and cardiac flow is preferentially maintained in mild to moderate hypovolemia. Although this response improves blood pressure and flow, it also decreases perfusion to individual microvascular beds, worsening local hypoxia. Consequently, as volume depletion worsens, certain tissues and organs will become ischemic more rapidly than others.

Other compensatory responses help to restore blood volume. An increase in precapillary sphincter tone results in a drop in capillary hydrostatic pressure, which favors movement of fluid into the capillary bed from the interstitium. This transcapillary fluid movement helps restore circulating volume by creating an interstitial fluid deficit. Transcapillary fill is sufficient to restore circulating volume with blood loss of 15% or less.

In addition to transcapillary fill, a decrease in renal perfusion results in secretion of renin from juxtoglomerular cells located in the wall of the afferent arteriole. Renin stimulates production of angiotensin I, which, after conversion to angiotensin II, increases sympathetic tone on peripheral vasculature and promotes aldosterone release from the adrenal cortex. Aldosterone restores circulating volume by increasing renal tubular sodium and water reabsorption. Vasopressin, released from the posterior pituitary gland in response to decreased plasma volume and increased plasma osmolality, is a potent vasoconstrictor and stimulates increased water reabsorption in the renal collecting ducts. Finally, an increase in thirst and a craving for salt is mediated by both the renin-angiotensin system and a fall in ANP (Figure 1-1).

With more severe blood loss (15% or more), compensatory mechanisms become insufficient to maintain arterial blood pressure and perfusion of vital organs. This stage is termed uncompensated or hypodynamic shock. Ischemia to more vital organs including the brain and myocardium begins to develop. Blood pressure may be maintained, but clinical signs including resting tachycardia, tachypnea, poor peripheral pulses, and cool extremities are present. Mild anxiety may be apparent as well as sweating from increased sympathetic activity. Urine output and central venous filling pressure will drop. As blood loss progresses, compensatory mechanisms are no longer capable of maintaining arterial blood pressure and perfusion to tissues. Severe vasoconstriction further worsens the ischemia such that energy supplies are inadequate and cellular functions (including the vasoconstriction responses) begin to fail. In addition, accumulations of waste products of metabolism (lactate and CO_2) cause progressive acidosis and further cellular dysfunction.

At the cellular level the combination of decreased oxygen delivery and increased accumulation of waste products results in loss of critical energy-dependent functions, including enzymatic activities, membrane pumps, and mitochondrial activity, leading to cell swelling and release of intracellular calcium stores. Cytotoxic lipids, enzymes, and ROS released from damaged cells further damage cells, triggering inflammation. Inflammatory cell influx, activation of the arachidonic acid cascade, the complement cascade, and the release of enzymes and ROS cause further cellular injury. Mitochondrial failure, calcium release, and reperfusion, if present, further increase production (and decrease scavenging) of ROS. Endothelial cell damage and exposure of subendothelial tissue factor further activate the coagulation and complement cascades. Formation of microthrombi coupled with coagulopathy impedes blood flow to the local tissues, worsening the already deteriorating situation. The lack of energy supplies coupled with accumulation of toxic metabolites, microthrombi formation, and the inflammatory injury ultimately result in vascular smooth muscle failure and vasodilation. The end results of decompensated shock are a pooling of blood and additional decreases in blood pressure, venous return, CO, and perfusion, ultimately resulting in organ failure (Figure 1-2). Failure of the gastrointestinal tract manifests itself as loss of mucosal barrier integrity resulting in endotoxin absorption and bacterial translocation. Renal ischemia leads to renal tubular necrosis and the inability to reabsorb solutes and water and excrete waste products. At the cardiac level, the continued fall in blood pressure and venous return decreases coronary blood flow. Cardiac muscle ischemia leads to decreased contractility and CO and ultimately to further deterioration of coronary artery blood flow. Acidosis and ischemia accentuate the depression of cardiac muscle function. These changes in combination with decreased venous return worsen hypotension and tissue perfusion (Figure 1-3).

As the situation deteriorates, compensatory mechanisms designed to continue to perfuse more vital organs like the heart

and brain will continue to limit flow to other organs. This response results in the sparing of one organ with irreversible damage to another. Consequently, an individual may recover with aggressive intervention only to succumb later because of failure of these "less vital" organs. If blood flow is restored, these activated cellular and immunochemical cascades are washed into the venous circulation and lead to SIRS, multiple organ failures, and death (see Chapter 2). Intervention can no longer stop the cascade of events, and cellular, tissue, and organ damage is too severe for survival.

CLINICAL SIGNS OF SHOCK

Clinical signs of shock depend on the severity and persistence of blood loss. The American College of Surgeons advanced trauma life support guidelines divide shock into four categories with progressive blood loss.

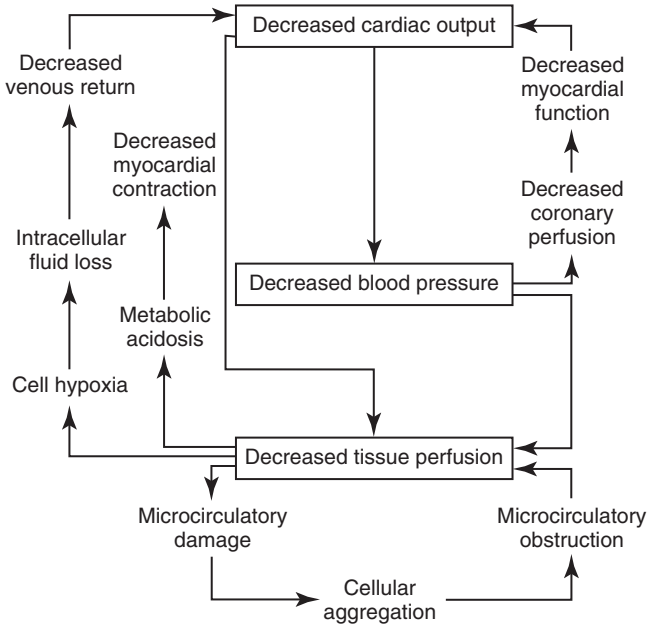

Figure 1-3. Viscious cycle of cellular and organ failure in shock.

With mild blood loss of less than 15% blood volume (Class I), the body is capable of restoring volume deficits via compensatory responses and there may be little to no change in physical parameters other than a fall in urine output. Blood pressure is maintained. Clinical signs typically become apparent when blood loss exceeds 15%. Early Class II blood loss (15% to 30%) is defined as the onset of hyperdynamic shock. Clinical signs include tachycardia, tachypnea, and bounding pulses (increased CO and peripheral vascular resistance). Mental agitation or anxiety is present, and increased sympathetic output results in pupil dilation and sweating. Although these compensatory mechanisms can normalize blood pressure, perfusion deficits will persist and can be detected by blood gas analysis (increased lactate and an anion gap metabolic acidosis). If blood loss continues, or if hypovolemia persists, compensatory mechanisms can become insufficient to restore circulating volume and decompensatory shock begins (Class III or moderate hypovolemic shock). At this time profound tachycardia and tachypnea, anxiety, and agitation are present. Urine output may desist, jugular filling and CRT are prolonged, pulse pressure is weak, and extremity temperatures are decreased. If blood gases are collected, a high anion gap acidosis and significant hyperlactatemia will be present (Table 1-1). Blood pressure will fall despite increases in heart rate, cardiac contractility, and total peripheral resistance. Without intervention, continued cellular hypoxia and acidosis result in failure of compensatory mechanisms, causing peripheral vasodilation and decreased cardiac contractility. A vicious cycle ensues with decreased coronary artery perfusion causing decreased cardiac function, resulting in decreased CO and a further fall in perfusion (see Figure 1-3). If uncontrolled, clinical signs will progress from tachycardia and anxiety to bradycardia, obtundation, anuria, profound hypotension, and circulatory collapse.

TREATMENT

Fluid Administration

Regardless of the underlying etiology of shock (cardiac failure, blood loss, or distributive problems), the greatest need is to restore perfusion and oxygen delivery to the tissues. Delivery of oxygen is determined by the concentration of oxygen in the blood as well as the amount of blood perfusing the tissue. The

TABLE 1-1. Clinical Assessment of the Different Stages or Progression of Shock

Parameter	Mild Compensated Shock Class I	Moderate Hypotension/ Shock Class II-III	Severe Hypotension/Shock Class III-IV
Extremity temperature	May be normal or cool	Cool	Cool to cold
Mentation	Normal to anxious	Agitation to lethargy	Obtunded
Urine output	Decreased	Decreased	Anuria possible
CRT	Normal to prolonged	Prolonged	End stage shock may be shortened because of blood pooling in peripheral tissues
Heart rate	Normal to tachycardia	Tachycardia	Severe tachycardia; bradycardia at end stage
Respiratory rate	Normal to tachypnea	Tachypnea	Tachypnea; bradypnea possible at end stage
Blood pressure	Normal	Normal to decreased	Decreased
Oxygen extraction ratio	May be normal	Increased	Increased
PvO_2	May be normal	Decreased	Decreased
Blood lactate	Mild increase	Increased	Markedly increased
Arterial pH	Normal to acidotic	Normal to acidotic	Acidotic
Central venous pressure	Normal to low	Low	Low

CRT, Capillary refill time.

concentration of oxygen per volume of blood is determined by the amount of hemoglobin or red cell mass and the saturation of that hemoglobin. It is important to assess both the hemoglobin concentration and the oxygen saturation because these will affect oxygen delivery. Decreased oxygen delivery is most commonly the result of decreased perfusion, not decreased oxygen content, but it is critical to evaluate all contributing factors when planning a treatment protocol for an individual in shock. Because hypovolemia is the most common cause of shock in the adult horse, fluid therapy is usually vital to restoring oxygen delivery. Extensive research efforts have addressed the determination of the ideal types and volumes of fluid for treating hypovolemic shock.

In the past, recommendations have been to rapidly infuse large volumes of isotonic crystalloids to replace circulating volume (shock dose). Because of their accessibility and low viscosity, crystalloids can be rapidly given and quickly restore volume. However, approximately 80% of the volume of administered crystalloids will diffuse out of the vascular space into the interstitial and intercellular space. Consequently, when using crystalloids, replacement volumes must be 4 to 5 times greater than the volume lost in order to restore the intravascular volume. In acute blood loss or hypovolemic states, this approach will result in excess total body water and extreme excesses of sodium and other electrolytes. This movement of fluid out of the vascular space is further exacerbated if the underlying disease process causes vascular leak syndrome, because intravascular colloid oncotic pressure will fall, favoring greater fluid movement out of the vascular space. In addition, if the electrolyte constituents of isotonic crystalloids differ from those in the intracellular space, cellular swelling will ensue. Cellular swelling affects the activity of various protein kinases; increases intracellular calcium concentrations; alters ion pump activity, membrane potential, and cytoskeletal structure; and activates phospholipase A_2.[1] Consequently, crystalloids can trigger or potentiate an inflammatory response and have a negative impact in the face of ischemia and reperfusion. Furthermore, large-volume infusions can result in significant complications including abdominal compartment syndrome, acute respiratory distress syndrome, congestive heart failure, gastrointestinal motility disturbances, and dilutional coagulopathy.[2]

Clinical trials have questioned the need for complete and rapid restoration of volume to maximize survival. In multiple hemorrhagic shock models, aggressive fluid therapy before hemorrhage control was associated with more severe blood loss, poorer oxygen delivery, and a higher mortality rate compared to more controlled, limited fluid therapy.[3,4] In a porcine model of uncontrolled hemorrhage, researchers studied the effects of three resuscitation regimens designed to mimic triage in the field before admission to a trauma center. One group received aggressive fluid resuscitation using crystalloids to restore CO to original levels, the second group received limited fluid therapy to restore CO to 60% of baseline, and the third group received no prehospital fluid therapy. Compared to aggressive fluid therapy, the limited resuscitation group lost less blood overall and had increased oxygen delivery (although survival was similar in all groups). In a prospective randomized clinical trial, subjects presented to a major trauma center with penetrating torso injuries and hypotension were assigned to either an immediate resuscitation or a delayed resuscitation group. Patients in the immediate resuscitation group received standard care including placement of bilateral IV catheters and rapid infusion of crystalloids during transport and triage at the emergency room. The latter group did not receive resuscitative fluid therapy until emergency surgery was begun. A total of 598 adults were included in the study; survival was 70% in the delayed resuscitation group compared to 62% ($p = 0.04$) in the immediate resuscitation group. In addition, patients in the immediate resuscitation group had more in-hospital complications (30%) including acute respiratory distress syndrome, sepsis, acute renal failure, coagulopathy, wound infection, and pneumonia compared to the delayed resuscitation group (23%). Although later studies have contradicted these results, the study does call into question the use of rapid, large-volume crystalloid fluid therapy for all hypovolemic shock cases.[5,6]

Clearly there are pros and cons to immediate, large-volume fluid resuscitation in the treatment of hypovolemic shock. Perfusion deficits need to be addressed, but the goal of therapy may need to be considered in light of the potential negative effects of infusing a large volume of fluids. The original idea of supranormal resuscitation (i.e., a shock dose of fluids) was based on the theory that tissue injury results in additional losses and sequestration of fluid into a third space, as well as the recognition that the majority of isotonic fluid infused into the vascular space will shift to the extravascular compartments. However, this additional third space loss has not been proved, and there may be negative consequences to supranormal resuscitation protocols. Large-volume fluid therapy has also been associated with cardiac and pulmonary complications[7,8] in both healthy human patients undergoing elective surgery and patients with risk factors for cardiopulmonary disease. Large-volume fluid therapy in patients with underlying SIRS or patients that have a low colloid oncotic pressure can result in significant edema, which can negatively affect gut motility and gut barrier function[9] and affect the function of other organ systems.

Despite this discrepancy in the literature, the reality is that shock is a manifestation of perfusion deficits, and the goal of therapy should be to restore perfusion and improve oxygen delivery. Prompt fluid therapy is indicated in the emergency situation to increase vascular volume, restore CO and blood pressure, and ultimately perfusion to the tissues. The amount and type of fluids should be determined by the individual needs of each patient. Careful, frequent monitoring to assess responses and prevent overload is recommended.

Types of Fluids

ISOTONIC CRYSTALLOIDS

Commercially available isotonic crystalloids for large animal medicine are designed to be replacement fluids, not maintenance fluids, meaning that the electrolyte composition is designed to closely approximate the electrolyte composition of the extracellular fluid and not the daily replacement needs. The isotonic crystalloids available to horses include lactated Ringer solution, Plasma-Lyte, and Normosol-R and are principally composed of sodium and chloride with varying amounts of calcium, potassium, and magnesium. Physiologic saline solution (0.9%) differs in that it contains only sodium and chloride and no other electrolytes.

These solutions are very useful in restoring fluid deficits in simple dehydration. Because the electrolytes are freely diffusible, approximately 80% of these fluids will diffuse into the interstitial and intracellular space from the extravascular space. This means that approximately 2 L of a 10 L fluid

bolus will remain in the vascular space. Consequently, a larger volume is needed to restore and maintain effective circulating volume.

The recommended method of administering isotonic crystalloids for hypovolemic shock is to calculate the fluid deficit and initially infuse fluids in doses of 10 to 20 mL/kg. Because the assessment of deficits is inexact, it is important to monitor the response during infusion and not to simply infuse the calculated amount. In cases of blood loss, infusion of crystalloids alone will cause dilutional anemia and hypoproteinemia. Depending on the severity of blood loss and amount of crystalloids infused, dilutional coagulopathy resulting from thrombocytopenia and dilution of clotting factors can occur, leading to further bleeding and deterioration. These patients may require subsequent plasma or whole blood transfusions to improve coagulation, oncotic pressure, and oxygen content of blood. Patients with endotoxemia or SIRS often have underlying coagulopathies as part of their disease process, leaving them at particular risk for further problems with aggressive crystalloid therapy.[10-12]

HYPERTONIC CRYSTALLOIDS

Hypertonic saline solution (HSS) is available in several concentrations, with 7.2% and 7.5% being the most commonly used formulations. The osmolarity of this concentration range is approximately 8 times the tonicity of plasma. An intravenous infusion of hypertonic saline will expand the intravascular space 2 to 4 times the amount infused, pulling fluid from the intracellular and interstitial spaces. This expansion is short-lived and, similar to the effects of isotonic crystalloids, the majority of fluid will ultimately diffuse into the interstitium. Hypertonic saline was initially developed for use in the battlefield because it allowed medics to carry small volumes of fluids and still provide resuscitative triage. The rapid and significant expansion of the intravascular volume using small-volume resuscitation allowed field stabilization of the patients before transport to a hospital unit. Because of the variation in reflection coefficients for sodium, HSS principally pulls volume from the intracellular space, not the interstitial space. This is particularly beneficial in the shock state, where endothelial volume rises with loss of membrane pump function. The decrease in endothelial cell volume increases capillary diameter and improves perfusion. In addition, HSS appears to blunt neutrophil activation and may alter the balance between inflammatory and anti-inflammatory cytokine responses to hemorrhage and ischemia.[13] The recommended dose of HSS is 2 to 4 mL/kg or 1 to 2 L for a 500-kg horse. Hypertonic saline is invaluable in equine surgical emergencies when rapid increases in blood volume and perfusion are needed to stabilize a patient before general anesthesia. The use of these fluids enables the clinician to quickly improve CO and perfusion to allow immediate surgical intervention. Additional blood volume expansion will be needed and can be provided during and after surgery to further restore homeostasis.

COLLOIDS

Colloids are solutions containing large molecules that, because of their size and charge, are principally retained within the vascular space. Because colloid concentrations are higher in the intravascular space, they exert an oncotic pressure that opposes the hydrostatic pressure and helps retain water in or draw it into the intravascular space. Normal equine plasma has a colloid oncotic pressure (COP) of about 20 mm Hg. Colloids with a high COP can actually draw additional fluid into the intravascular space. Consequently, infusion of certain synthetic colloids such as hetastarch (HES) (COP ~30 mm Hg) will increase intravascular volume by an amount that is greater than the infused volume. Although this effect is similar to HSS, the benefits of colloids are prolonged. Colloid therapy is recommended in patients that are hypo-oncotic, patients with capillary leak syndrome, patients with cardiac disease where fluid overload may be detrimental, and patients with fluid excess (edema) in which fluid therapy needs to be carefully titrated to prevent further overload.

Both synthetic and natural colloids are available. Natural colloids include plasma, whole blood, and bovine albumin. The advantage of natural colloids is that they provide protein, such as albumin; antibodies; critical clotting factors; and other plasma constituents. Because fresh frozen plasma must be thawed before infusion, it is often not useful in an emergency situation where immediate fluid therapy may be indicated. In addition, hypersensitivity reactions occur in up to 10% of horses receiving plasma.[14] The most common synthetic colloids are HES and dextrans, with HES being the most commonly used product in equine practice. HES contains amylopectin molecules of sizes ranging from 30 to 2300 kDa (average 480 kDa) and exerts a COP of 30 mm Hg. The elimination of HES occurs via two major mechanisms: renal excretion and extravasation. Larger molecules are degraded over time by α-amylase. The presence of molecular substitutes on the amylopectin chains slows this process of degradation to smaller colloid particles, and consequently the effect of HES is prolonged. A dose of 10 mL/kg will significantly increase oncotic pressure for longer than 120 hours.[15] Though evidence of spontaneous bleeding in healthy horses has not been documented, an increase in the cutaneous bleeding time was seen with larger doses (20 mL/kg) and has been associated with a decrease in von Willebrand factor antigen (vWf:Ag). Consequently, the use of large volumes of HES should be considered in light of bleeding tendencies of patients.[15] Measurement of COP must be used to assess the response to HES, because its infusion is not reflected in the total solids or total protein measurements, making these inaccurate estimates of the COP after HES infusion. HES infusions will actually decrease total protein because of the dilutional effect of the volume expansion.

HYPERTONIC SALINE SOLUTION AND DEXTRAN

The combination of hypertonic crystalloids and synthetic colloids offers the advantage of both rapid and persistent volume support and also provides some of the anti-inflammatory benefits of hypertonic saline. HSS with dextran (HSS-D) has been shown to expand the plasma volume,[16,17] restore hemodynamics,[18,19] and improve microcirculatory perfusion[20,21] in animal models of hemorrhagic shock. In addition, HSS-D has been shown to decrease neutrophil adhesion and blunt the hemorrhage-induced inflammatory response. The majority of human clinical trials have yet to show that it has a benefit over other fluid therapies.

WHOLE BLOOD

Whole blood is the ideal replacement fluid in shock due to blood loss. The use of blood or plasma provides clotting factors and prevents dilutional coagulopathy. By providing red blood cells (RBCs) and protein it helps retain fluid within the intravascular space and improves oxygen content of the blood. However, there are several disadvantages to whole blood. It is unusual for

most equine referral hospitals to store whole blood; consequently, it must be collected each time it is needed. In addition, because of its viscosity, it is difficult to rapidly infuse large volumes in an emergency situation. However, despite these drawbacks, the use of blood or blood components can be a valuable adjunct in preventing some of the potential side effects of large-volume resuscitation, namely dilutional coagulopathy, dilutional hypoproteinemia, and anemia. Ironically, data in human medicine suggests that blood products should be replaced in a ratio of plasma, RBCs, and platelets that approximates whole blood.[22] Because the most commonly available blood product in equine clinics is whole blood, the determination of an ideal ratio is a moot point! The use of whole blood is generally unnecessary in the patient with mild to moderate hypovolemia because restoration of perfusion often results in adequate oxygen delivery despite dilutional anemia. In more severe cases of hypovolemia or in cases with ongoing bleeding, whole blood may be indicated to provide oxygen-carrying capacity, colloid oncotic support, platelets, and coagulation factors.

CURRENT RECOMMENDATIONS

The debate regarding the use of crystalloids versus colloids is extensive. Despite this intense focus, clear benefits of colloids or hypertonic solutions over isotonic crystalloids have not yet been demonstrated. Rather than always using one or the other, the choice should depend on the situation. In a case of severe blood loss, hypovolemia, and impending circulatory collapse, the rapid expansion of blood volume using hypertonic and isotonic crystalloids may be imperative. The addition of colloids, whether synthetic or natural, and whole blood should depend on the severity of shock and the underlying disease process as well as the response to initial treatment.

When presented with an adult horse in hypovolemic shock it is critical to use a large 10- or 12-gauge catheter and large bore extension set to maximize flow rate in the initial resuscitation phase. Because crystalloids have the lowest viscosity, they can be infused more rapidly than colloids or blood. If necessary, a fluid pump can be used to increase the rate of infusion. The general recommendation is to calculate a shock dose of fluids using the following formula: percent blood volume (L/kg body weight $\times$ 100) $\times$ body weight. In an adult horse the percent blood volume is estimated to be 7% to 9% of the total body weight or 35 to 45 L for a 500-kg horse. Given the pros and cons of large-volume resuscitation fluid, goals should be estimates and not absolutes. Frequent reassessment of the patient's cardiovascular status and blood gases is important for adequate resuscitation without causing secondary problems. Signs of improved intravascular volume include a decreased heart rate and improved capillary refill time, skin temperature, and mentation. If possible, the measurement of urine output is extremely useful in assessing perfusion, although urine specific gravity is less accurate because it will be affected by the infusion of large quantities of crystalloids and will no longer accurately reflect hydration status. In humans, the assessment of blood pressure can be useful in monitoring trends (i.e., an improvement of pressure toward normal). In situations where bleeding is uncontrolled, normalization of blood pressure should not be the goal because this may promote continued bleeding.

VASOPRESSORS

Vasopressors are rarely used in the standing adult horse in hypovolemic shock. Restoration of volume is the primary treatment goal. However, if the administration of appropriate fluid volumes and types is insufficient to stabilize the patient, vasopressors may be indicated, particularly as shock progresses and vasomotor tone and cardiac ischemia cause a further fall in perfusion. The most commonly used drug in the awake, adult horse is dobutamine. Dobutamine is a strong β_1-adrenoreceptor agonist with relatively weaker β_2- and α-adrenoreceptor affinity. Its primary use is to improve oxygen delivery to the tissues via its positive inotrophic action. Dobutamine has been shown to have benefit in improving splanchnic perfusion in multiple species, although clinical data are currently lacking in the horse. Recommended dosages are 1 to 5 µg/kg/min. Higher doses have been reported to cause hypertension in the adult horse.[23]

Norepinephrine has been reported to be useful in neonatal foals to restore adequate organ perfusion in vasodilatory shock. Norepinephrine has strong β_1- and α-adrenergic affinity, resulting in vasoconstriction and increased cardiac contractility. Norepinephrine has been successfully used in combination with dobutamine in persistently hypotensive foals with improved arterial pressure and urine output reported.[23] The use of norepinephrine in the awake adult horse has not yet been evaluated.

At this time, there is little published information on the use of vasopressors to treat hypovolemic shock in the awake adult horse. Consequently, it is difficult to make recommendations for their use at this time. Close monitoring of urine output and blood pressure is recommended when using vasopressor therapy. Readers are directed to Chapter 2 for additional treatment recommendations for septic shock.

Monitoring

The body's compensatory responses are designed to restore many of the parameters used to assess hypovolemia or perfusion deficits. Consequently, in the early stages of shock, there is no perfect measure to assess progression. Despite this, there are several physical and laboratory parameters that can be useful in monitoring the patient's progression and response to treatment.

Repetitive physical exams focusing on assessment of CO and perfusion may be the most sensitive method to assess a patient, especially during early compensated shock when subtle changes may indicate impending decompensation. Heart rate, CRT, jugular venous fill, extremity temperature, pulse pressure, and mentation are all useful when repeatedly evaluated. Steady improvement and stabilization of these parameters in response to treatment would suggest a positive response. Continued tachycardia and poor pulse pressure, CRT, jugular fill, and deteriorating mentation despite treatment suggest that additional blood loss or decompensation is occurring.

Capillary Refill Time

Capillary refill time (CRT) is usually prolonged in hypovolemic shock. However, CRT can also be affected by changes in vascular permeability such as seen with endotoxemia or sepsis. In these situations, CRT may actually decrease because of vascular congestion and pooling of blood in the periphery. Though CRT at any one time point can be misleading, if assessed over time, it is useful in evaluating the progression of shock. Jugular fill is a relatively crude assessment of venous return or central venous pressure.

Central Venous Pressure

Central venous pressure (CVP) assesses cardiac function, blood volume, and vascular resistance or tone. Holding off the jugular vein should result in visible filling within 5 seconds in a normally hydrated horse that is standing with an elevated head. If filling is delayed, venous return or CVP is decreased. A more accurate estimate of CVP can be obtained with a water manometer, attached to a large-bore jugular catheter and placed at the level of the heart base or point of the shoulder. Normal CVP in standing horses ranges from 7 to 12 mm Hg, with pressure measured by inserting a catheter into the right atrium.[24-26] Measurement of pressure in the jugular vein using a standard IV catheter will result in falsely elevated CVP; however, this measurement can still be a useful estimation. During an experimental blood loss model, CVP fell to zero or below with a loss of 15% to 26% of circulating volume. Because CVP is a measure of venous return it can be used to assess the adequacy of fluid resuscitation and prevent fluid overload, especially in patients at risk for edema. If clinical signs are deteriorating despite a normal CVP, hypovolemia alone is not the cause. Low CVP can occur with hypovolemia or a fall in effective circulating volume, as occurs with distributive shock. Cardiogenic shock (or fluid overload) can result in an elevated CVP, because forward failure of the cardiac pump results in backup of blood within the venous side of the system. In this case, jugular veins may appear distended even with the head held high. Cardiogenic shock is a relatively uncommon cause of shock in adult horses.

Urine Output

Urine output is a sensitive indicator of hypovolemia with normal urine production being approximately 1 mL/kg/hr or more, depending on how much water an individual is drinking. Urine production of less than 0.5 mL/kg/hr suggests significant volume depletion, and fluid therapy is indicated to prevent renal ischemia. Urine output is rarely measured in adult horses, though it is relatively simple to perform and commonly done in neonatal medicine. Urine production can be useful for monitoring resuscitative strategies and determining endpoints in such therapies. Urine production coupled with improvement in physical exam parameters suggests a positive response to treatment. Though urine specific gravity can be used to assess renal concentrating efforts and consequently the water balance of the animal, it will be affected by intravenous fluid therapy and is not an accurate reflection of dehydration or volume status once bolus intravenous fluids have been begun.

Arterial Blood Pressure

Arterial blood pressure is a reflection of CO and total vascular resistance. Consequently, the measurement of a normal blood pressure does not directly correlate with adequate perfusion. Because of the compensatory increase in peripheral resistance, blood pressure does not consistently fall below normal until blood volume is profoundly decreased (30% or more). Though a normal blood pressure does not rule out hypovolemic shock, a low blood pressure is often an indicator of significant blood loss. Treatment goals should be to maintain mean arterial pressure above 65 mm Hg to ensure adequate perfusion of the brain. Blood pressure can be measured directly via arterial catheterization of the transverse facial artery in the adult horse or the transverse facial, metatarsal, radial, and auricular arteries in a neonate. Indirect measurement of the blood pressure can be achieved using the coccygeal artery in adult horses and the metatarsal artery in foals.[27] In healthy individuals there is good agreement between both direct and indirect measurements.[27-29] Direct, invasive blood pressure monitoring is more accurate during states of low flow and significant vasoconstriction.[28,29] Normal systolic blood pressure using indirect measurement at the coccygeal artery is 80 to 144 mm Hg. Because blood pressure will increase with increased vascular resistance, it is not an accurate reflection of oxygen delivery.

Lactate

Lactate is the end product of the anaerobic metabolism of glucose. Aerobic metabolism of glucose results in the production of 36 moles of adenosine triphosphate (ATP) per molecule of glucose. In the absence of adequate oxygen to meet energy demands, anaerobic metabolism of glucose to lactate results in production of only 2 moles of ATP. The shift to anaerobic metabolism of glucose with inadequate oxygen delivery to tissue increases blood lactate concentrations. Less commonly, hyperlactatemia can result from hepatic dysfunction (impaired clearance), pyruvate dehydrogenase inhibition, catecholamine surges, and sepsis or SIRS, although the increase in lactate level is generally less than what is seen with hypovolemia. Because lactate level generally correlates with oxygen delivery and uptake by the tissues, it is a useful marker for determining perfusion deficits and response to treatment. Delayed lactate clearance has been shown to be associated with a poorer prognosis in many human and veterinary studies.[30-34] A decrease in lactate following therapy indicates improved oxygen delivery and use, suggesting improved perfusion. Conversely, an increased or persistently elevated lactate level indicates continued tissue oxygen deficits. The anion gap will mimic lactate changes and has been used to assess oxygen debt; however, it can be affected by changes in other anions, such as plasma proteins, and is therefore not as accurate as blood lactate concentration.

Oxygen Extraction

The normal response to a decrease in perfusion or CO is to increase the oxygen extraction ratio (O_2ER) of the blood as it moves through the capillaries. By increasing the oxygen extraction, the body is able to maintain oxygen delivery to the tissue despite a fall in blood flow. Oxygen extraction is determined by the difference between the oxygen saturation of arterial blood (SaO_2) and oxygen saturation of venous blood (SvO_2):

$$O_2ER = SaO_2 - SvO_2$$

and can be determined by measuring central venous saturation and arterial oxygen saturation. Alternatively, it can be estimated by measuring jugular venous saturation and by using a pulse oximeter to assess arterial oxygen saturation. In the normovolemic, healthy individual, oxygen delivery (DO_2) far exceeds oxygen need or uptake (VO_2), and the O_2ER ranges from 20% to 30%. The O_2ER can increase with decreased perfusion to a maximum of 50% to 60%, at which point oxygen delivery becomes supply or flow dependent and a further drop in perfusion will result in a decrease in oxygen delivery. Because of this relationship, the O_2ER can be used to estimate the severity of

global perfusion deficits and is also a useful measurement in evaluating the response to resuscitative strategies.

Mixed Venous Partial Pressure of Oxygen

Mixed venous partial pressure of oxygen (PvO_2) is a useful measure to assess oxygen delivery for the same reasons that O_2ER is. In low-perfusion states, more oxygen is extracted per volume of blood and, consequently, PvO_2 will fall. Mixed venous blood is ideally measured by catheterizing the pulmonary artery, because a sample from the jugular vein or cranial vena cava only assesses venous blood returning from the head. Jugular venous PvO_2 is usually greater than mixed venous blood in the shock state, but it still has utility in estimating global tissue hypoxia.[35,37] Normal jugular vein PvO_2 ranges from 40 to 50 mm Hg and SvO_2 from 65% to 75%.[35,36] Increased PvO_2 in the presence of significant perfusion or supply deficits (DO_2) can signify impaired oxygen consumption caused by mitochondrial or cellular dysfunction, termed dysoxia. This syndrome has been recognized in septic shock or after cardiopulmonary resuscitation.

Cardiac Output

Cardiac output monitoring evaluates both volume return to the heart and cardiac function.[38] With prolonged or specific types of shock (septic), cardiac function may deteriorate and increasing fluid resuscitation will not resolve clinical signs of end organ perfusion deficits. The gold standard for CO monitoring is the pulmonary thermodilution method, which requires catheterization of the pulmonary artery. This technique is rarely performed in the equine clinical setting. An alternative technique, lithium dilution, is relatively easy to use once experienced and has been validated in the equine clinical setting. Injection of lithium dye into the venous system results in generation of a lithium concentration–time curve, which is used to calculate CO. Lithium dilution has been used successfully to monitor CO in adult horses and critically ill foals,[39-42] although repetitive sampling can result in toxic accumulation of lithium.[43] Alternatively, ultrasound measurement of CO has been validated using both transesophageal and transthoracic Doppler measurements.[40,44] Because Doppler measurement requires the beam to be parallel with flow there is large variability in the accuracy of this technique. Transesophageal measurements improve this accuracy but can be difficult to obtain in the standing horse.[40,45] A recent paper described an ultrasound velocity dilution method in foals.[46] This technique uses a bolus injection of saline and an arteriovenous loop connected to ultrasound velocity sensors.

CO measurement has its greatest benefit in cases with cardiac disease and is of great help in monitoring the response to vasopressor treatment. Because CO does not assess local tissue perfusion, its accuracy in evaluating tissue oxygenation is poor. Many of the standard monitoring techniques are limited because they principally assess global function (CO) and global oxygen debt (mixed venous lactate), not regional tissue deficiencies. These global measures, while helpful, do not assess the perfusion to high-risk organs such as the gastrointestinal tract, and they may provide a false sense of security when used to monitor treatment response. With the exception of urine output, none of the measurements just described evaluate perfusion to regional vascular beds. Because of the large variation in perfusion to specific tissues, such as the gastrointestinal tract and the brain, these global measures have poor sensitivity in determining oxygen delivery and uptake to "less important tissues."

Regional Perfusion

Several techniques have been developed in an effort to more specifically assess these differences in regional perfusion. Noninvasive measures of regional tissue perfusion include sublingual capnometry, near-infrared spectroscopy to monitor muscle tissue oxygen saturation, transcutaneous tissue oxygenation, and capnometry.[47-49] Slightly more invasive techniques include gastric tonometry, which evaluates CO_2 production in the stomach wall; infrared spectroscopic assessment of splanchnic perfusion; and measurement of bladder mucosal pH.[50,51] These alternative techniques are based on the idea that the body preferentially shunts blood away from the skin and gastrointestinal tract to spare more vital organs. As such, these techniques will detect abnormalities in perfusion before many of the more established techniques. Although these techniques have yet to be evaluated in the veterinary field, they have been shown to be sensitive markers of regional perfusion deficits manifest in early shock in humans.

Hypotensive Resuscitation and Delayed Resuscitation

As previously discussed, aggressive large-volume fluid therapy to restore blood pressure to normal values has potentially negative consequences. In situations of uncontrolled bleeding, this treatment will result in increased blood loss. Dilution of blood components (platelets and clotting factors) may additionally worsen bleeding. Increasing systolic blood pressure to normal values may dislodge or "blow out" a tenuous clot, leading to further bleeding. Hypotensive resuscitation has been advocated to prevent or minimize further blood loss until surgical control or formation of a stable clot has occurred. In these situations resuscitation to a lesser end point is recommended. The ideal end point or goal in hypotensive resuscitation is unclear. Strategies include achieving a mean blood pressure (MBP) of 40 to 60 mm Hg, using a predetermined, lower fluid infusion rate, or in some situations, completely delaying resuscitation until bleeding is surgically controlled.[22] In multiple animal models, controlled resuscitation (goal of MBP 40 to 60 mm Hg, or systolic blood pressure of 80 to 90 mm Hg) resulted in decreased blood loss; better splanchnic perfusion and tissue oxygenation; less acidemia, hemodilution, thrombocytopenia, and coagulopathy; decreased apoptotic cell death and tissue injury; and increased survival.[3,52-59] In cases of severe or ongoing bleeding, resuscitation with blood components is recommended to minimize the risk of coagulopathy, although data with respect to outcome compared to resuscitation with crystalloids is currently lacking. This strategy of hypotensive resuscitation (with whole blood as part of the fluid plan) is indicated in situations such as a bleeding of the uterine artery in a pregnant mare, where ligation of the vessel is unlikely and of great risk to the mare and fetus. There are currently no specific recommendations for end points of treatment in large animal species. If using blood pressure as the end point, direct measurement is currently recommended to ensure accuracy.

PREDICTING OUTCOME

In a critical review, high-risk surgical patients were used as a model for shock because time relationships were precisely documented.[60] In this study, nonsurvivors had reduced CO and DO_2 in the intraoperative and immediate postoperative period. Survivors had lower O_2ER; higher hematocrits, VO_2, and blood volume; and normal blood gases. In human trials, time is a strong predictor of survival, with survivors showing improvement or normalization in indices of CO, perfusion, oxygen uptake, and clinical parameters.[61] To this end, rapid control of hemorrhage, restoration of perfusion, normalization of blood gas values, and prevention of dilutional coagulopathy are predictors of survival. In patients with ongoing blood loss, controlled hypotension has been shown to decrease in-hospital complications and possibly increase survival rates. Lactate values, particularly lactate clearance, have been shown to be strongly associated with survival in both clinical and experimental studies of shock.[30-33] Though the data are not as robust, single lactate measurements and delayed lactate clearance have been shown to be associated with higher mortality rates in both adult horses and foals.[62-64] A poor or absent response to resuscitative attempts with continued evidence of perfusion deficits or the development of clinical evidence of organ dysfunction, or both, are associated with a poorer outcome.

ON THE HORIZON

Treatment

Although a perfect fluid protocol for treatment of hypovolemic shock remains elusive, liposome encapsulated hemoglobin may offer more benefits than other fluids because of its oxygen-carrying capacity. The presence of hemoglobin reduces the need for blood products, thereby lowering the associated risks to the patient.[65,66] In contrast to other synthetic oxygen carriers, liposome encapsulated hemoglobin vesicles do not appear to cause peripheral vasoconstriction and in a rat model of hemorrhage appear to be as effective in restoring hemodynamic and blood gas parameters.[67]

Monitoring

The ideal method to assess shock and treatment response would enable measurement of oxygen delivery at the tissue level as well as oxygen uptake and use. The ability to measure end organ perfusion, particularly in "less important" organs like the epidermis and gastrointestinal tract, in our veterinary patients has potential implications in assessing the severity of the shock state, developing treatment goals, and predicting outcomes. The implementation and evaluation of these techniques in equine critical care medicine is warranted.

Prognostic Indicators

Recent epidemiologic and experimental data have shown a sex-specific difference in the response to trauma and shock. Estrogen administration to castrated male mice improved immune responses after trauma and hemorrhage compared to castrated untreated mice.[68] Treatment of intact male mice with estradiol improved the survival rate and immune response to trauma, hemorrhage, and sepsis.[69-70] In a prospective study that evaluated more than 4000 trauma patients, hormonally active women tolerated trauma and shock better than men.[71] Dehydroepiandrosterone (DHEA) has estrogenic effects and has been shown to decrease morbidity in mice after trauma or hemorrhage. Because DHEA is used clinically to enhance the immune response, it may have use in the trauma or hemorrhage patient. Conversely, it may be the lower levels of male hormones in women that confer protection. Male mice depleted of testosterone either through castration or by treatment with the drug flutamide had improved cardiovascular and immune function compared to intact mice after hemorrhage and resuscitation. In the future, the use of hormone therapy may help improve outcome in hemorrhagic shock.

In addition to gender, genetic markers have been found to segregate with response to hemorrhage and trauma.[72,73] Currently, genomic markers are being evaluated as prognostic factors; however, there may come a time when genetic markers are used to direct therapy.[74]

Physiologic Response to Trauma

The metabolic response to trauma or injury has classically been divided into two phases—the ebb phase, which occurs during the first several hours after injury, and the flow phase, which occurs in the ensuing days to weeks. The ebb phase is characterized by hypovolemia and low flow or perfusion to the injured site. Once perfusion is restored, the flow phase begins. The flow phase is divided into a catabolic period and an anabolic period. The catabolic period is triggered by many of the same mediators discussed in the earlier section on the pathophysiology of shock, and many of the clinical signs will mimic those seen in shock. The anabolic period is characterized by the return to homeostasis. Cortisol levels fall during this final period and normalization of physiology occurs. The physiologic response to trauma is complex, and the duration and progression will vary depending on the injury site, severity, and underlying condition of the patient. For more specific information regarding trauma of specific organs or body cavities, the reader is referred to chapters dealing with those specific systems. This section is designed to provide an overview of the complex pathophysiology of trauma.

Mediators of the Stress Response: Ebb Phase

The stress response to trauma is initiated by pain, tissue injury, hypovolemia, acidosis, shock, hypothermia, and psychological responses. Direct tissue injury, ischemia, and inflammation activate afferent nerve endings, which exert local and systemic effects via the central nervous system. Hypovolemia, acidosis, and shock exert their effects via baroreceptors and chemoreceptors located in the heart and great vessels. Fear and pain have conscious effects in the cortex, and they stimulate cortisol secretion via the hypothalamic-pituitary-adrenal axis (HPA), which increases sympathetic output. Because of this effect, modulation of pain has been shown to be important in controlling the stress response to trauma, and pain control should be strongly considered in the trauma patient.

The sympathoadrenal axis is stimulated through direct input from injured nerves and by hypovolemia, acidosis, shock, and psychological responses (fear, pain, anxiety). Catecholamines have widespread effects on cardiovascular function (see "Pathophysiology of Shock," earlier in this chapter) and metabolism (see "Metabolic Response to Injury" in Chapter 6), and they

stimulate release of other mediators, including cortisol and opioids. The catecholamine response is beneficial; however, prolonged sympathoadrenal stimulation can be detrimental because of its effects on general body condition. Catecholamines increase peripheral vascular resistance, so ongoing stimulation leads to long periods of tissue ischemia.

Other triggers of cortisol secretion in trauma and shock include vasopressin, angiotensin II, norepinephrine, and endotoxin. The degree of hypercortisolemia correlates with the severity of injury and persists until the anabolic phase of healing begins. Cortisol secretion results in sodium and water retention (edema), insulin resistance, gluconeogenesis, lipolysis, and protein catabolism. Cortisol also affects leukocytes and inflammatory mediator production and, although cortisol is critical for recovery from acute injury, prolonged cortisol secretion can result in pathologic suppression of the immune response.

Vasopressin and the renin-angiotensin system are important mediators of the stress response. The reader is referred to the section on pathophysiology of shock for a review of these mediators.

Endogenous opioids released from the pituitary gland as well as from the adrenal glands in response to sympathetic stimulation are important mediators in the modulation of pain, catecholamine release, and insulin secretion. Endogenous opioids modulate lymphocyte and neutrophil function and may act to counter cortisol's effect on immune function.

Local mediators released in response to injury trigger a multitude of cascades. Tissue factor exposure activates the coagulation and complement cascades and ultimately stimulates the inflammatory response. Cell membrane injury results in release and activation of the arachidonic acid cascade and production of various cytokines, including prostaglandins, prostacyclines, thromboxanes, and leukotrienes. These mediators have a multitude of functions, including further activating coagulation and platelets, altering blood flow via vasoconstriction and vasodilation, and increasing chemotactic activity mediating the influx and activation of inflammatory cells, with subsequent release of lysosomal enzymes and reactive oxygen species. Microvascular thrombosis at the site of endothelial damage causes further pathologic changes in perfusion. If perfusion is restored, further damage may ensue because elevated local concentrations of reactive oxygen species coupled with influx of desperately needed oxygen can induce further oxidative stress with production of highly toxic reactive oxygen species and further tissue injury. Amplification of this response coupled with reperfusion can lead to the development of SIRS and multiorgan dysfunction (see Chapter 2).

Response to Trauma: Catabolic Period

Psychological response to trauma and shock is manifest in changes in behavior, withdrawal, immobilization or reluctance to move, fear, anxiety, aggression, and malaise. These psychological responses can persist for long periods depending on the severity of the injury and pain. In people, the psychological effect may persist long after the injury has resolved. Whether the same happens in horses has yet to be determined.

Many of the changes in vital signs will mimic those seen with hypovolemic shock. Cardiovascular changes including tachycardia, tachypnea, and other clinical signs of the hyperdynamic response may be seen. Fever during the early period after injury is typically a response to injury and inflammation itself, particularly in patients with head trauma. Infectious causes of fever should be suspected if fever persists or is recurrent days after the injury. Other clinical signs will depend on the severity of blood loss and the organ injured. Cardiovascular changes including hypotension, decreased perfusion, decreased urine output, and reduced cardiac contractility are likely to occur with significant blood loss or thoracic contusion. Endotoxemia and bacteremia are likely with gastrointestinal injury, such as strangulating injury to the intestine.

Edema at the site of injury is caused by vascular injury from both the trauma and the inflammatory response, which results in loss of capillary integrity and extravasation of protein and fluid. In severe injury, edema may become generalized. This generalized edema results from systemic inflammatory, hormonal, and autonomic responses that increase capillary pressure and salt and water retention. The presence of hypoproteinemia can exacerbate clinical edema as colloid oncotic pressure is decreased.

The metabolic response to trauma is complex and results in changes in the metabolic rate as well as the mobilization and utilization of energy stores. Decreased appetite and malaise are also seen in response to pain, cytokines, and hormones. The reader is referred to Chapter 6 for a more detailed description of the metabolic changes occurring with injury.

Coagulation is activated by endothelial injury and the expression of tissue factor. Tissue factor also activates complement and inflammation. These changes combined with release of arachidonic acid from damaged cell membranes stimulate production of multiple inflammatory mediators, platelet activation and adhesion, and fibrinolysis. Blood loss coupled with crystalloid replacement can further dilute platelets and coagulation factors, which, in combination with factor consumption to control bleeding at the site of injury, can result in development of a hypocoagulable state. Coagulation dysfunction is recognized in many types of injury including large colon volvulus, severe traumatic injury, SIRS, and septic shock.

Circulating leukocytes increase in the initial response to injury with subsequent accumulation in injured microvascular beds. This accumulation may be exacerbated by vasoconstriction in response to hypovolemia and catecholamine surges and may play a role in reperfusion injury, because activated neutrophils are a major source of reactive oxygen metabolites. In addition to changes in circulating leukocytes, the immune response can be altered significantly with severe trauma. Decreases in antibody production, neutrophil chemotaxis, and serum opsonic activity; increases in serum immunosuppressive factors; and activation of T-cell suppressors mediated by neurohormonal stress response are just some of the changes that may occur.

Response to Trauma: Anabolic Period

The final stage in recovery is the anabolic phase of flow. During this period many of the responses return to normal. Appetite returns, body protein is synthesized, and weight is restored, resulting in improved organ function and energy stores. Metabolic demands diminish, water balance is restored, and as hormonal levels decrease, a generalized feeling of well-being develops. The length of this period will depend on the severity of the injury, the number and type of complications, the patient's condition before injury, and the length of the catabolic period of recovery. Healthy individuals that do not develop complications will likely recover more rapidly than debilitated

patients that suffer complications, such as infection, and have a prolonged catabolic phase of recovery.

CHAPTER 2

The Systemic Inflammatory Response

Michelle Henry Barton and John F. Peroni

The systemic inflammatory response and failure of multiple organ systems are syndromes that result from an inappropriate and generalized inflammatory response to stimuli, which may or may not result from an infectious process. Although it appears that the phagocytic activation of the monocyte/macrophage cell lineage is directly responsible for the development of clinical signs and symptoms, identifying the bacteria and neutralizing their toxins has not drastically changed the outcomes of patients affected by these syndromes. As a result, current management strategies and research efforts have been directed at addressing infectious and noninfectious causes and identifying effective ways of modulating the associated immune-mediated responses. The pathophysiology of these inflammatory-based syndromes has not been clarified in people or lab animal models, and very little original work has been produced in the horse. A generally accepted summary of these conditions is that bacteria or their endotoxins, or both, induce and sustain a marked inflammatory response by the host, which eventually overwhelms sensitive organs and often results in a fatal outcome. This chapter reviews the pathophysiology of systemic inflammatory response and multiple organ failure with the viewpoint that inflammation, not bacterial overgrowth, may directly generate these syndromes in the horse.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

With microbial invasion or any process that results in tissue damage, the ultimate goal of the immune system is to contain infection, alarm the host to defend, and to promote tissue repair. Whether these goals are achieved or defeated, the host relies on a defense and repair response that is appropriate for the insult. If the host overzealously responds, the same innate components that are meant for protection and repair may ironically turn out to be just as detrimental or even more harmful to the host than the initial insult. When the response to infection and injury results in an incongruous and exaggerated systemic inflammatory reaction, the clinical state is referred to as the *systemic inflammatory response syndrome,* or *SIRS,*[1] which can be initiated by infection, endotoxemia, or noninfectious insults, such as severe trauma, ischemia, immune-mediated disease, surgery, hypothermia, hyperthermia, or intense hypoxemia (i.e., hemorrhagic shock). To counteract the proinflammatory response and deter the state of SIRS, the host relies on anti-inflammatory opposition that includes production of cytokines, soluble cytokine receptors, receptor antagonists, prostaglandin E_2, and corticosteroids.[2] If there is over-recruitment of the anti-inflammatory processes, a state of anergy, increased

susceptibility to infection, and inability to repair damaged tissues ensues. This scenario is referred to as *compensatory anti-inflammatory response syndrome,* or *CARS*.[1] In some circumstances, a *mixed anti-inflammatory response syndrome,* or *MARS*, arises in which surges of both SIRS and CARS coexist.[1] In the circle of equilibrium, if SIRS and CARS are ultimately appropriately balanced, then homeostasis resumes. Predominance of SIRS may culminate in adverse pathophysiologic events, such as disseminated intravascular coagulopathy (DIC), shock, organ failure, and death. In this later scenario, dissonance has occurred and the patient is defined as having *multiple organ dysfunction syndrome (MODS)* or the presence of organ dysfunction associated with acute illness in which homeostasis cannot be restored without intervention (see "Multiple Organ Dysfunction Syndrome," later).[1]

Pathophysiology of SIRS

The key event in the initiation and propagation of SIRS is the release of endogenous molecular substances by host cells, each with a diverse array of biological activities. The enormity of the molecular response to injury, redundancy in action and location in various tissues, the dynamic discovery of new molecules, and rediscovery of new roles for previously identified molecules complicates their discussion and classification. There are literally thousands of molecules involved in the inflammatory cascade of injury. This discussion will focus on the main molecular categories of cytokines, lipid-derived autocoids, acute phase proteins, reactive oxygen species, and vasoactive and neutrophil-associated substances, as they relate to the horse.

Cytokines

Cytokines are protein substances that are the "early responders" to infectious agents or tissue damage. The cytokines can be further classified by whether their biological activities are primarily proinflammatory or anti-inflammatory and by their cell of origin. Examples of pro-inflammatory cytokines include tumor necrosis factor (TNF); interleukin 1, 6, and 8 (IL-1, IL-6, IL-8); and interferon-γ (INF-γ).[2,3] Monocytes and macrophages are universal sources for the pro-inflammatory cytokines, though other cell types contribute as well, including neutrophils (TNF), endothelial cells (IL-1, IL-8), fibroblasts, keratinocytes, lymphocytes (IL-1, IL-6) and natural killer cells (TNF, INF-γ). Some of the main functions of TNF, IL-1, and IL-6 are to initiate coagulation, fibrinolysis, complement activation, the acute phase response, and neutrophil chemotaxis. TNF and IL-1 also induce pyrogenic activities and augment further cytokine production. The importance of TNF and IL-1 is clearly exemplified by the fact that administration of these substances to otherwise healthy laboratory animal species mimics many of the events of septic shock. In horses, experimental infusion of endotoxin results in increased circulating levels of TNF and IL-6 (see "Endotoxemia" later). Less specific information is known about the anti-inflammatory cytokines (IL-4, IL-10, IL-11, IL-13, transforming growth factor-β [TGF-β]) in the horse, though in septic foals that did not survive, IL10 gene expression was significantly greater than in surviving ones.[4] The anti-inflammatory cytokines are released from monocytes, macrophages, and T-helper cells and serve to restrain the inflammatory campaign by inhibiting macrophage activation, proinflammatory cytokine release, antigen-presenting cells, and chemotaxis.

Lipid-Derived Mediators

Arachidonic acid is a 20-carbon fatty acid that is a major constituent of the phospholipids of all cell membranes.[2] It also serves as the parent molecule for eicosanoid synthesis, but it must first be released from the cell membrane. Endotoxin, TNF, and IL-1 all upregulate the activity of phospholipase A_2, the enzyme responsible for cleavage of arachidonic acid. Once released, arachidonic acid is further metabolized by either lipoxygenase, to form the family of leukotrienes, or cyclooxygenase, to form the prostanoids: thromboxane A_2 (TxA_2) and the prostaglandins (PGs). The prostanoids are vasoactive substances: TxA_2 and $PGF_{2\alpha}$ are potent vasoconstrictors, whereas PGI_2 and PGE_2 are vasodilators. The prostanoids also play important roles in primary hemostasis: TxA_2 promotes platelet aggregation, but PGI_2 inhibits aggregation. Finally, PGE_2 is a pyrogen. The prostanoids have been extensively studied in endotoxemic horses (see "Endotoxemia" later). Less specific attention has been given to the investigation of the leukotrienes in horses, although they serve as chemoattractants and increase vascular permeability.

Platelet-Activating Factor

Like the eicosanoids, platelet-activating factor (PAF) is released from cell membrane (mononuclear phagocytes, endothelial cells, and platelets) phospholipids by phospholipase A_2. The released alkyl-lyso-glycerophosphocholine is then acetylated to form PAF. The biologic effects of PAF include vasodilation, increased vascular permeability, platelet aggregation, and recruitment and activation of phagocytes. It also is a negative inotrope. Use of a PAF receptor antagonist in horses experimentally challenged with endotoxin significantly delayed the onset of fever, tachycardia, neutropenia, and lactic acidosis.[5]

Acute Phase Proteins

An acute phase protein is any protein whose blood concentration significantly increases (or decreases) during an inflammatory response.[6] Collectively, the hundreds of acute phase proteins are responsible for many of the well-recognized reactions to microbial invasion, such as fever; anorexia; depression; alterations in metabolism, hemodynamics, and coagulation; and leukocyte activation. The liver is a key site of synthesis. Cytokines, principally TNF, IL-1, and IL-6; glucocorticoids; and growth factors stimulate and modulate gene expression and the transcription of the acute phase proteins. The serum concentrations of the major acute phase proteins, serum amyloid A (SAA) and C-reactive protein (CRP) can each increase as much as 100-fold during the acute phase response. Interestingly, despite their intense synthesis during the acute phase reaction, the roles of each of these major proteins are still not entirely clear. SAA may be involved in cholesterol regulation, chemotaxis, and mediation of anti-inflammatory events, such as downregulation of fever, phagocytosis, and prostanoid synthesis. CRP can activate complement, induce phagocytosis, and stimulate cytokine and tissue factor expression. In horses, SAA and CRP concentrations have been determined by several methodologies. Using the latex agglutination immunoturbidimetric assay, the expected SAA concentration in healthy neonatal foals and adult horses is less than 27 mg/L.[7] SAA nonspecifically increases with either infectious or noninfectious (but inflammatory) conditions, with values greater than 100 mg/L, suggestive of an infectious process in foals. In horses with acute gastrointestinal diseases, higher

SAA levels are correlated with risk of death. Using radial immunodiffusion, CRP concentrations have been established in healthy foals and adult horses (5 to 14 mg/mL).[8] Although CRP increased 3 to 6 times in experimentally induced inflammation in adult horses, its utility in determining an inflammatory or infectious response in naturally occurring diseases in the horse has not been established.

The remaining acute phase proteins have widely diverse pathophysiologic effects. The complement system is represented by the acute phase synthesis of C3a, C4a, C5a, C4b, C3b, C5b-C9, factor B, and C1 inhibitor.[9] Collectively, these compounds induce bacteriolysis, increase vascular permeability, are chemotactic for neutrophils, and enhance opsonization of both microbes and damaged host cells. Balanced activation of the coagulation and fibrinolytic systems by the acute phase response of factor VIII, fibrinogen, plasminogen, tissue plasminogen activator, plasminogen activator inhibitor, fibronectin, von Willebrand factor, and tissue factor leads to formation of intravascular and extravascular "clots" that capture and contain infectious organisms and inflammatory debris and provide a scaffold for tissue repair. Of these coagulation factors, hyperfibrinogenemia is a well-recognized clinicopathologic finding in horses with inflammation. The release of the acute phase transport and scavenger proteins, such as ceruloplasmin, haptoglobin, lipopolyscharride-binding protein, soluble cluster of differentiation antigen 14 (CD14), and lactoferrin, bind bacterial nutrient components, such as copper and iron, and neutralize or transport toxic bacterial components.

Reactive Oxygen Species

The reactive oxygen species encompass all oxygen-derived toxic mediators that most commonly originate from mononuclear phagocytes or neutrophils.[10] Oxygen free radicals are oxygen-containing molecules that contain an unpaired electron (superoxide anion O_2^-; hydroxyl radical, $OH^\bullet$). Free radicals can react with essentially any molecular component in their quest to "repair" the unpaired electron. In doing so, more radicals are generated and molecular damage ensues with loss of protein function, cross-linking of DNA, lipid peroxidation, vasoconstriction, and pain. Oxygen free radicals also induce cytokine production and endothelial adhesion molecules. Other reactive oxygen species that do not contain unpaired electrons include hydrogen peroxide (H_2O_2) and nitric oxide (NO). NO is generated enzymatically in phagocytes by inducible NO synthetase, which is activated by endotoxin and cytokines.

Vasoactive Mediators

In addition to the prostaglandins and NO, bradykinin, a by-product of activation of the contact coagulation system, and histamine are vasodilators. Angiotensin, endothelin, TxA_2, and leukotrienes (LTC_4, D_4, and E_4) have vasoconstrictive activities. Numerous molecular substances promote vascular leakage, including PAF, leukotrienes, complement components (C3a, C5a), NO, and bradykinin.[2]

Diagnosis of SIRS

In 1992, Bone and colleagues[1] proposed the following specific diagnostic criteria for SIRS in human patients. More than one of the following clinical manifestations had to be present: (1) a body temperature greater than 38° C (100.4° F) or less than 36° C (96.8° F); (2) a heart rate greater than 90 beats per minute; (3) tachypnea, manifested by a respiratory rate greater than 20 breaths per minute, or hyperventilation, as indicated by a $PaCO_2$ of less than 32 mm Hg; or (4) an alteration in the white blood cell count, such as a count greater than 12,000/mL, a count less than 4000/mL, or the presence of more than 10% immature neutrophils ("bands"). There has not been a similar consensus on diagnostic criteria for SIRS in horses; however, with some adjustments that would be appropriate relative to normal findings in the horse, these criteria could be applied to the horse (Table 2-1). Since the average adult horse's body temperature is higher than the average human's, a rectal temperature greater than 38.6° C (101.5° F) or less than 36.6° C (98° F) would seem more appropriate for horses. The heart rate criterion is based on an approximately 25% increase over the high end of the normal average adult human heart rate. Thus for adult horses, a heart rate greater than 60 beats per minute would represent a similar rate increase. Because the upper end of the normal total white blood cell count for horses is 12,000/mL, a white cell count greater than 14,000/mL might be a more appropriate upper cutoff for SIRS in the horse.

Criteria for SIRS in foals would have to be adjusted by age-relative criteria. Since the most common trigger of SIRS in foals is sepsis, the sepsis score system developed in the 1980s for foals[11] might be an equally effective SIRS score (Table 2-2). Note that in the sepsis score, the human SIRS criteria for rectal temperature and white blood cell count are included.

TABLE 2-1. Diagnostic Criteria for SIRS in Adult Horses*

Parameter	Criteria
Rectal temperature	>38.6° C (101.5° F) or <36.6° C (98° F)
Heart rate	>60 beats/min
Respiratory	Respiratory rate >20 breaths/min or $PaCO_2$ <32 mm Hg
White blood cell count	>14,000/μL or <4000/μL or >10% bands

*The diagnosis of SIRS can be made when at least two parameters' criteria are present.

Treatment of SIRS and Prognosis

The treatment of SIRS is largely directed at controlling the primary disease process that triggered the response. Considering the underlying theme of overzealous inflammation in SIRS, anti-inflammatory agents are indicated. In light of the complexity of the pathophysiology of SIRS and the diverse array of endogenous mediators, there is unlikely to be a single therapeutic panacea. In people with SIRS, scoring systems have been developed that offer prognostic information.[1] Because SIRS is not defined by consensus in horses, similar comparisons are not directly possible. However, there is evidence that foals meeting proposed criteria for SIRS had a higher mortality rate than those without SIRS.[12]

TABLE 2-2. Sepsis Score System for Neonatal Foals: Each of the Following Parameters is Evaluated and a Score is Assigned[11]

	Score					
Parameter	**4**	**3**	**2**	**1**	**0**	**Score for This Case**
HISTORY						
1. Placentitis, vulvar discharge, dystocia, long transportation of mare, mare sick, induced, prolonged gestation (>365 days)		Yes			No	
2. Premature (days of gestation)		<300	300-310	311-330	>330	
CLINICAL SIGNS						
1. Petechiae, scleral injection		Severe	Moderate	Mild	None	
2. Fever			>102° F	<100° F		
3. Hypotonia, coma, depression, seizure			Marked	Mild	Normal	
4. Anterior uveitis, diarrhea, respiratory distress, swollen joints, open wounds		Yes			None	
LABORATORY DATA						
1. Neutrophil count (per µl)		<2000	2000-4000 or >12,000	8,000-12,000	Normal	
2. Bands (per µl)		>200	50-200		None	
3. Any toxic change in neutrophils	Marked	Moderate	Mild		None	
4. Fibrinogen (mg/dL)			>600	400-600	<400	
5. Blood glucose (mg/dL)			<50	50-80	>80	
6. IgG (mg/dL)	<200	200-400	400-800		>800	
7. Arterial oxygen (mm Hg)*		<40	40-50	50-69	>70	
8. Metabolic acidosis*				Yes	No	
				Total points for this case: _____		

A score of ≥11 predicts sepsis.
*If these two parameters are included, the positive cutoff value is 12.
IgG, Immunoglobulin G.

MULTIPLE ORGAN DYSFUNCTION SYNDROME

Multiple organ dysfunction syndrome (MODS) refers to the presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.[1] Any disease process inducing a well-defined injury that affects the function of organs at the initial site of insult (primary MODS) or organs remotely positioned from the primary injury (secondary MODS), not as a direct response to the insult, but as a consequence of the host's response to the injury, can culminate in MODS. Multiple organ dysfunction syndrome can be relative or absolute and is best characterized as a dynamic process that is a continuum of pathophysiologic change over time.[1]

The same key inflammatory catalysts that are responsible for the development of SIRS (see earlier) can subsequently progress to MODS.[13] In essence, MODS is simply an extension and potential consequence of SIRS. In people, disease processes commonly associated with induction of MODS include sepsis, endotoxemia, DIC, ischemia, surgery, anesthesia, massive trauma, thermal injury, drug reaction, and anaphylaxis. Immune-mediated inflammatory injury, altered hemodynamics, and reduced tissue perfusion are the pivotal pathophysiologic events that drive MODS. Because appropriate function of one organ often depends on adequate function of another, the systemic effects of single organ failure can contribute to a self-perpetuating cycle of multiple organ involvement and ultimately, multiple organ dysfunction and failure.

Pathophysiology of MODS

The gastrointestinal, hemostatic, cardiovascular, hepatic, musculoskeletal, renal, respiratory, adrenal, and nervous systems are commonly affected by MODS in people.[13] Each of these organ systems will be briefly discussed here with particular reference to what is currently recognized in the horse.

Because the *gastrointestinal tract* is a frequent site of injury in adult horses and is a major portal of entry of bacterial pathogens in the neonatal foal, gastrointestinal dysfunction is a common manifestation of primary MODS in horses. In people with MODS, gastrointestinal dysfunction is defined as the presence of ileus, inability to tolerate enteral nutrition, and the presence of mucosal ulceration.[14] Intestinal injury and ileus are major complications of acute gastrointestinal disease of the horse and are addressed elsewhere in detail (see Chapters 35 and 40). Additional signs and complications of primary inflammatory insults (enteritis and colitis) and strangulation obstruction of intestine (see "Ischemia," later) are gastrointestinal reflux, alteration in enteric resident flora, diarrhea, and protein-losing enteropathy. Protein-losing enteropathy will compromise oncotic pressure, and electrolyte derangements can further affect distant organs, especially cardiac, muscular, and neural tissue function. Mucosal damage enhances the translocation of luminal bacteria and endotoxin with subsequent septicemia and endotoxemia, further fueling the drive of SIRS and MODS.

In its most simplified description, the major elements that define dysfunction of the *coagulation system* associated with the development of MODS are (1) excessive procoagulation, (2) loss of controlled fibrinolysis, and (3) loss of natural anticoagulant activities.[15,16] These events promote clot formation, especially in the microvascular space, which contributes to reduction of blood flow to vital tissues.[16] With prolonged or excessive thrombi formation, platelets, coagulation, anticoagulation, and fibrinolytic factors are consumed, balance is lost, and hemorrhage may ensue. This state of clinical coagulopathy is referred to as DIC.[16] Endotoxemia and sepsis are commonly reported primary ailments that initiate DIC,[16] rendering the coagulation system probably one of the most frequently described and studied systems affected by SIRS and MODS in horses.[15,17-21] Approximately 30% of horses with acute colitis,[22] 70% of horses with a colon torsion,[23] and 25% of septic foals[24] fit diagnostic criteria for DIC at admission. Evidence in both humans and horses suggests that the primary mechanism responsible for the initial hypercoagulative state of DIC is activation of the extrinsic coagulation cascade (see Chapter 4) via enhanced expression of membrane tissue factors (i.e., thromboplastin).[25,26] Constitutively expressed membrane tissue factor on endothelial cells and mononuclear phagocytes in the circulation and tissues is upregulated, either *directly* by pathogen-associated molecular pattern antigens such as lipopolysaccharide (endotoxin), or *indirectly* by cytokines that are generated in the process of self defense or response to injury.

In addition to events that activate coagulation, failure of appropriate fibrinolysis and consumption of anticoagulation factors further promote thrombosis. In horses, endotoxin appears to favor activation of plasminogen activator inhibitor (PAI) over tissue plasminogen activator (tPA). In a large study of 153 horses with acute colic, mean plasma PAI activity increased approximately fivefold, whereas tPA activity dropped twofold.[18] Both PAI and α_2-antiplasmin were significantly greater in septicemic foals, compared to healthy age-matched foals.[19] These types of responses would be expected to enhance clot formation and be negatively correlated with prognosis for survival in equine colic patients.[18] The natural anticoagulants antithrombin (AT) and protein C are rapidly consumed in sepsis or inactivated by neutrophil enzymes released during the inflammatory response. AT and protein C also have several anti-inflammatory effects, including induction of prostacyclin synthesis, diminution of endotoxin-induced cytokine and tissue factor synthesis, and reduction of chemotaxis and neutrophil adhesion.[26] Clinical studies on horses with acute gastrointestinal disease and septic foals consistently report that these populations at risk for endotoxemia have significantly reduced AT and protein C activity. Correlation of these activities with the development of complications such as jugular thrombi, peritoneal adhesions, and laminitis is significant and is associated with a reduced chance of survival.[19,20,27] The ultimate consequence of insufficient AT and protein C activity is both increased clot formation and heightened inflammatory response, the latter effect serving to "fuel the fire" of driving thrombus formation. Ultimately, platelets, coagulation, anticoagulant, and fibrinolytic factors are consumed and the normally regulated balance between clot formation and dissolution is lost, culminating in unregulated hemorrhage, shock, multiple organ hypoxia, and thus organ dysfunction and failure.

The exact mechanism for *cardiac dysfunction* and failure in MODS is not entirely understood, though both systemic changes in autonomic nervous system balance and direct effects of pathogen-associated molecular patterns and SIRS-induced cytokines on the myocardium play key roles. Specifically, upregulation of sympathetic drive relative to vagal tone and direct endotoxin impairment of the signal transduction pathways and (or) ion channels mediating the autonomic nervous signals in cardiac pacemaker cells contribute to reduced myocardial contractility, increased heart rate, and reduced heart rate variability.[28] Furthermore, electrolyte disturbances that may be present as a result of the primary insult or subsequent to renal or gastrointestinal dysfunction can also negatively affect myocardial function. Reduced cardiac output, arrhythmias, and hypotension ensue, further compromising hemodynamic homeostasis. There is little information on myocardial function in horses with SIRS or MODS; however, serum cardiac troponin concentration, a sensitive biochemical marker of acute myocardial injury, is increased in foals with septicemia[29] and horses with small intestinal strangulating lesions that underwent surgical correction.[30] In the latter, there was a significant association between serum lactate and troponin concentrations, indicating a correlation between hypoperfusion and ischemic myocardial degeneration.

Overt *hepatic failure* is not commonly recognized in horses with MODS; however, alterations in hepatic perfusion, via local or systemic effects, and delivery of endotoxin to the liver from both intestinal and systemic sources, can contribute to hepatic injury. The presence of gastrointestinal reflux, ileus, and obstruction of bile flow may lead to ascending infection of the biliary system or pressure necrosis around the bile cannaliculi, or both. In a review of horses with acute small intestinal disease, horses with proximal enteritis were 12 times more likely to have increased γ-glutamyltransferase activity, as serum biochemical evidence of acute hepatic injury, compared to horses with strangulating small intestinal disease.[31] The liver is a remarkable organ with a diverse range of functions, including protein, carbohydrate, and lipid nutrient regulation, metabolism, and storage; synthesis of albumin, coagulation factors, and components of the acute phase response; digestion; detoxification; vitamin storage; and extramedullary hematopoiesis. Loss of any of these functions is detrimental and can lead to the development of nutrient crisis, encephalopathy, and coagulopathy.

The laminae of the equine digit are highly susceptible to direct concussive damage and altered weight distribution, as well as injury evoked by the systemic response to endotoxemia, acute gastrointestinal disease, sepsis, metabolic disease, dietary changes, or acute renal failure. Thus *laminitis* represents a unique manifestation of MODS in the horse. In a recent retrospective case-controlled study in hospitalized horses, endotoxemia was the only risk factor in multivariate analysis that significantly correlated with development of laminitis.[32] The pathophysiology of laminitis is complex and incompletely understood, though alterations in systemic and local hemodynamics; local endothelial dysfunction; and inflammatory, enzymatic, endocrine, and metabolic components all appear to contribute to the development of laminitis.[33] Laminitis is discussed in detail in Chapter 90.

Acute *renal failure* is defined as the presence of azotemia or oliguria, or both, in a normovolemic patient that does not have signs of postrenal obstruction.[14] In people, the primary mechanism leading to the development of acute renal failure is acute tubular necrosis.[34] The mechanism for renal tubular necrosis follows the same general theme of systemic or local reduction in blood flow, leading to cellular hypoxemia and cell death. Swelling of epithelial cells and infiltration with inflammatory

cells contributes to renal tubular obstruction. Ischemic glomerular damage further contributes to reduction in glomerular filtration. The combined effects are loss of autoregulation of renal blood flow, vasoconstriction, fluid retention, protein-losing nephropathy, and electrolyte derangement. These effects are often confounded by the adverse renal side effects of drugs that are used to combat the primary initiating cause of MODS, such as aminoglycosides for treatment of sepsis, or drugs that are used to control the systemic inflammatory response of MODS (nonsteroidal anti-inflammatory drugs [NSAIDs]). Although the exact incidence of acute renal failure in horses with MODS is not known, in a recent retrospective study on horses with acute gastrointestinal disease, azotemia was a frequent finding at admission.[35] Furthermore, those horses in which azotemia resolved within 72 hours had a better survival rate than those in which azotemia persisted.

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) have been defined as the clinical conditions of acute onset of *respiratory failure* characterized by hypoxemia and diffuse bilateral pulmonary infiltrates on thoracic radiographs, in the absence of left atrial hypertension.[36] ALI and ARDS develop when injury to the alveoli and pulmonary endothelium causes thromboembolism and protein-rich pulmonary edema. Subsequently, type II pneumocytes and fibroblasts are recruited to replace damaged areas in the alveoli. Collectively, these injuries severely impair gas exchange. Likely triggers for ALI and ARDS in horses include sepsis, aspiration of gastric contents, smoke inhalation, severe trauma, and transfusion reaction.[37] ALI and ARDS have been described in foals in which the primary insult was pulmonary in origin and apparently triggered by bacterial or viral infection.[38] Fulminant pulmonary edema without left-sided heart failure has also been reported in adult horses with transient airway obstruction and air embolism as anesthetic complications.[39,40]

The term *critical illness–related cortisosteroid insufficiency (CIRCI)* is used to describe the clinical scenario in which the cortisol response is insufficient for the degree of stress induced by illness.[41] Mechanisms that have been proposed for CIRCI are cytokine-induced inhibition of any component of the hypothalamic-pituitary-adrenal axis, downregulation and sensitivity of tissue cortisol receptors, and direct inflammatory, hemorrhagic, or hypoxic damage to the adrenal gland (Waterhouse-Friderichsen syndrome). CIRCI has been recently described in septicemic foals.[42,43] Furthermore, septic foals that met diagnostic criteria for CIRCI were more likely to have clinical signs of shock and MODS and were less likely to survive.[43]

Hypoxia, electrolyte derangements, alterations in glucose homeostasis, hepatic encephalopathy, and microthrombosis all affect neural function. *Encephalopathy* of MODS could be easily overlooked when it simply manifests as depression or altered behavior. In severe cases, stupor and coma may develop.

Diagnostic Criteria for MODS

Multiple organ dysfunction is a syndrome that is definition dependent, and unfortunately a consensus definition has not yet been proposed for horses. When the definition of MODS was first suggested for human patients, criteria for organ dysfunction had not yet been defined. Currently the syndrome is defined by identifying criteria for individual organ dysfunction and dysfunction that are correlated to prognosis. Unfortunately, with the exception of ALI/ARDS, consensus definitions for individual organ systems have not been established for the horse. Therefore, diagnostic criteria supporting dysfunction or failure are proposed in the following sections. They are based on current practical information pertaining to the horse, as guided by criteria used in human patients.

Respiratory Criteria

Clinical signs of ALI and ADRS in horses would include tachypnea, labored breathing, nasal flare, cough, bilateral foamy nasal discharge, and pulmonary crackles. Acute lung injury and ARDS can be suspected in animal species in which the following criteria are met: (1) the patient has acute onset (less than 72 hours) of respiratory distress at rest; (2) the patient has a known risk factor for ALI or ARDS; (3) there is pulmonary capillary leakage without increased pulmonary capillary pressure as evidenced by the presence of any one of the following: bilateral/diffuse infiltrates on thoracic radiographs, proteinaceous fluid within the conducting airways, or increased extravascular lung water; and (4) there is inefficient gas exchange evidenced by hypoxemia (defined as one of the following: partial pressure of oxygen in arterial blood/fraction of inspired oxygen ratio (PaO_2/FIO_2) of less than 300 mm Hg for ALI and less than 200 mm Hg for ARDS, increased alveolar-arterial oxygen gradient, increased venous admixture, or increased dead space ventilation.[37]

Hemostasis Criteria

Clinical signs of DIC include thrombi, petechiae, and ecchymoses; any sign of excessive hemorrhage at sites of trauma or at mucocutaneous orifices; or compartmental hemorrhage. Disseminated intravascular coagulopathy can be suspected in the presence of at least three of the following: thrombocytopenia; prolonged prothrombin; activated partial thromboplastin time; decreased fibrinogen concentration or prolonged thrombin time; increased fibrin degradation products or D-dimer concentrations; or decreased antithrombin activity.

Gastrointestinal Criteria

Diagnosis of gastrointestinal dysfunction is mostly subjective and dependent on the clinical signs of ileus. In the horse this would include colic, decreased borborygmi, abdominal distension, diarrhea, and excessive gastrointestinal reflux or colic-like signs that necessitate withholding of enteral nutrition. The presence of gastric ulceration, protein-losing enteropathy, and intra-abdominal hypertension would also fit criteria for gastrointestinal dysfunction in people.

Renal Criteria

Clinical signs of renal dysfunction include decreased urine production and subcutaneous or pulmonary edema. In people, acute renal failure is defined diagnostically by the presence of (1) an increased serum creatinine concentration or (2) oliguria with normovolemia (acceptable central venous pressure and systolic pressure), without signs of postrenal obstruction with either criterion.[13] Exact quantification of urine output is not easy or practical in adult horses, though it is possible in catheterized neonatal foals. In the latter, mean urine production is 6 mL/kg/hr.[44]

Hepatic Criteria

In people, liver dysfunction is defined by progressive increases in plasma transaminase activities and bilirubin concentration. Since icterus is a common feature of anorexia in the horse, progressive hyperbilirubinemia would not be an appropriate criterion. Liver-specific indices in the horse would include persistently increased serum sorbitol dehydrogenase or γ-glutamyltransferase activities, and increased serum bile acid concentration.

Cardiovascular Criteria

There is no consensus on criteria for cardiovascular failure in people. However, several parameters have been suggested, including lactatemia; the presence of hypotension (either decreased systolic or mean arterial pressure); the presence of pathologic arrhythmias, particularly ventricular in origin; evidence of myocardial ischemia (such as increased cardiac troponin concentrations); loss of heart rate variability; decreased cardiac output and contractility; and the need for vasopressor therapy. In people, pressure-adjusted heart rate (PAR) is frequently used to quantify cardiovascular dysfunction. It is the product of the heart rate (HR) and the ratio of central venous pressure (CVP) to mean arterial pressure (MAP) (HR × [CVP/MAP]). Increasing values reflect worsening cardiovascular dysfunction. Reference values for lactate and cardiac troponin concentration are available for horses. They can be run "stall side" and thus are practical biochemical markers of cardiovascular health in horses.[45] Accurate measurement of blood pressure in adult horses would require arterial catheterization. Most clinically significant pathologic arrhythmias would be detected via auscultation and confirmed with electrocardiography. Fractional shortening is frequently used as an echocardiographic parameter of cardiac contractility in horses. Normal fractional shortening for most light-breed adult horses is 28% to 45%.[46]

Musculoskeletal Criteria

Clinical signs suggestive of musculoskeletal dysfunction include weakness, recumbency, and reluctance to move. Laminitis is a unique and common manifestation of MODS in the horse; therefore, signs specific to digital pain would be present, such as Obel grades of lameness (see Chapter 90), increased digital pulse quality, hoof wall heat, and depression at the coronary band. A positive response to hoof testers or mitigation of signs following digital nerve block would be sufficient evidence for diagnosis of early acute laminitis. Persistently increased serum concentrations of creatinine phosphokinase activity would be evidence of skeletal muscle damage.[47]

Neurologic Criteria

Diagnosis of neurologic dysfunction is mostly dependent on the presence of clinical signs of alteration in behavior, depression, weakness, ataxia, and stupor.

Treatment of MODS and Prognosis

Identification and treatment of the primary initiating cause should be undertaken, with particular attempts to control the proinflammatory response and to maintain adequate hydration, tissue perfusion, oxygenation, and nutrition. Specific therapy for individual organ failure is indicated. As one might logically assume, with an increasing number of organ systems that fail, the likelihood of death increases. Mortality is typically close to 100% in human patients with four or more failing organ systems.[48]

COMMON CAUSES OF SIRS AND MODS IN HORSES

Sepsis

Colonization, or the presence of proliferating microbes without a host response, is an expected, and in many tissues, beneficial event that prevents invasion by unwanted microbes. However, if microbial exposure or colonization leads to invasion of normally sterile tissue or evokes a response from the host, infection has been initiated. Sepsis is the systemic inflammatory response to infection. In association with infection, manifestations of sepsis are the same as those previously defined for SIRS.[1]

Infection is initially prevented by innate immunity, the branch of the host defense system that does not require previous exposure to a microbe to immediately counteract with a protective response. The innate immune system is composed of phagocytic cells (principally monocytes, macrophages, and neutrophils) and an extensive array of molecular substances that are present in the circulation, on cell surfaces, and inside cells. Whether microbial tissue invasion is contained locally or continues to spread depends heavily on an appropriate and competent response from the innate immune system. Common portals of entry for microbes include the respiratory, gastrointestinal, and urogenital tracts and the skin. Microbial invasion into the bloodstream, with a concurrent systemic host response, is termed *septicemia*. Septicemia is often cited as one of the most common causes of illness and death in neonatal foals and primarily involves gram-negative bacterial invasion.[49] However, septicemia appears to be far less common in mature horses.

A main feature of the innate immune system that enables immediate discrimination is *pattern-recognition receptors* (PRRs) that are capable of detecting a variety of microbial ligands, referred to as *pathogen-associated molecular patterns* or PAMPs.[9] These ligands are evolutionally conserved molecules that are unique to microbes, are often shared by a broad range of organisms, and are usually essential for microbial survival or virulence. Examples of PAMPs include bacterial cell wall extracts, such as endotoxin, peptidoglycan, and lipoteichoic acid, and prokaryotic DNA. Ultimately, the interaction of a PRR with its PAMP can directly neutralize the PAMP or microbe, or it may activate other components of the host immune system to deploy further defense mechanisms, initiate an inflammatory response, or commence tissue repair. There is a complex and overlapping arsenal of mammalian PRRs; however, they can generally be divided into three main types: (1) secreted PRRs, such as defensins; (2) cell membrane PRRs that are involved in phagocytosis; and (3) cell membrane PRRs that are involved in signal transduction. A well-characterized cell signaling PRR-ligand relationship is CD14–Toll-like receptor (TLR) and its well-characterized PAMP, endotoxin (see later section, "Endotoxemia").

In summary, infection results from a combination of exposure to microbes and colonization of host tissue coupled with failure of the innate immune system to prevent microbial proliferation and invasion into deeper sterile tissue. By the definition of Bone and coworkers,[1] sepsis is the systemic response

evoked from the host to serve as an alarm of invasion and thus to activate defense and repair mechanisms. The outcome of infection is determined by the appropriateness of the host's defense response. If the response is appropriate, the host is altered, defense is activated, and infection is contained. When the innate immune system is overwhelmed by infection, the infection advances and cannot be overcome without intervention. Severe sepsis is defined when organ dysfunction and shock ensues (see shock in Chapter 1 and MODS in this chapter).[1]

Diagnosis of Sepsis

Sepsis can be documented cytologically by the presence of microbes in normally sterile tissue with evidence of an inflammatory response, such as the presence of neutrophils, particularly degenerative neutrophils or neutrophils with intracellular organisms. Isolation of microbes by culture provides convincing proof of infection, especially when consistent with morphologic findings on cytology. Because microbial isolation and identification can take several days, the sepsis score system was developed to identify foals at risk for septicemia. The score includes historical, physical, and laboratory findings that were statistically associated with the diagnosis of sepsis, as based on culture or necropsy.[11] This score system was developed before Bone and colleagues proposed their criteria for SIRS, and thus it is particularly interesting to note that several criteria used for SIRS in people, such as fever and leukogram changes, are included in the sepsis score for fools (see Table 2-2).

Treatment of Sepsis

Successful treatment of sepsis-induced SIRS depends on identification of the invading organism coupled with appropriate antimicrobial therapy.

Endotoxemia

German scientist Richard Pfeiffer first described endotoxin in 1892 as a toxin that was an integral part of gram-negative bacteria that was distinctly different from actively secreted heat-labile exotoxins.[50] These observations led to adaptation of the term *endotoxin*. Indeed, endotoxin is a heat-stable toxin consisting of lipopolysaccharide comprising approximately 75% of the outer cell membrane of gram-negative bacteria. It serves as a structural permeability barrier that is an essential component for survival of gram-negative bacteria. Pfeiffer's original observations were correct: bacteria do not actively secrete endotoxin. Rather, when gram-negative bacteria multiply or lyse upon bacterial cell death, endotoxin is released from the outer cell membrane. Thus the enormous resident population of gram-negative bacteria in the equine intestinal tract serves as a tremendous reservoir of endotoxin. This source of endotoxin is normally confined to the lumen of the healthy intestine by protective mucosal barriers. However, if the intestinal wall is damaged, as occurs in acute gastrointestinal diseases that cause mural inflammation or ischemia, the otherwise contained endotoxin gains access to the circulation. Although endotoxemia is often associated with acute gastrointestinal disease in horses, the release of endotoxin during log-phase bacterial growth puts any horse with gram-negative bacterial infection at risk of becoming endotoxemic. For example, as many as half of neonatal foals with gram-negative septicemia are endotoxemic at the time of admission to referral hospitals.[19] Septic metritis, pleuropneumonia, and septic peritonitis are other common primary diseases associated with endotoxemia in mature horses. Whether released from endogenous sources from the intestinal lumen or from overwhelming gram-negative sepsis, the net effects of endotoxin are similar once it accesses the circulation.

Pathophysiology of Endotoxemia

Endotoxin consists of three structural domains: a highly variable outer polysaccharide "O-antigenic" region, a core region consisting mostly of monosaccharides, and the highly conserved toxic moiety, lipid A. Variation in the number, length, saturation, and position of fatty acids on the glucosamine disaccharide backbone of lipid A confers its degree of toxicity. Endotoxin is not directly toxic to mucous membranes or skin; rather, it must enter the circulation to fully manifest its pathologic effects. Once in the blood, endotoxin's amphipathic properties cause it to form aggregates resembling micelles that otherwise spontaneously disperse into monomers at a very slow rate.

Lipopolysaccharide binding protein (LBP) is a 65-kDa plasma constituent that is primarily synthesized by the liver and belongs to the family of lipid transfer proteins.[51] It efficiently extracts molecules of endotoxin from aggregated micelles in the blood and transports them to various locations. LBP is not consumed by this transfer, which appears to be catalytic. As an acute phase protein, the blood concentration of LBP can increase several hundredfold within 24 hours following an inflammatory stimulus. In a 2005 clinical study, serum concentrations of LBP at admission were up to 30 times greater in horses with acute gastrointestinal disease, as compared to healthy horses, though LBP concentrations did not correlate with the cause of colic or the outcome.[7] Through its interaction with lipid A, LBP effectively imprisons endotoxin, with its potential for toxicity determined by the complex's final destination. LBP can rapidly deliver monomers of endotoxin to the cell surface of host inflammatory cells to evoke an inflammatory response or it can be transferred to other neutralizing lipoproteins, such as high-density lipoprotein, for eventual removal from the blood. Thus LBP may both enhance and hinder the biologic activities of endotoxin. Although LBP greatly facilitates "disaggregation" and transport of endotoxin to the surface of inflammatory cells, its presence is not mandatory for the interaction of endotoxin at the cell surface.

Once at the cell surface, endotoxin is transferred to CD14, a well-conserved receptor attached by a glycosylphosphatidylinositol anchor.[52] Mononuclear phagocytes (monocytes and macrophages) express abundant CD14, though other inflammatory cells also express minute amounts. CD14 is a 53-kDa glycoprotein that exists as both a cell membrane receptor (mCD14) and a soluble form (sCD14) in the circulation, the latter being essentially identical to membrane bound CD14 minus the glycosylphosphatidylinositol anchor. Similar to LBP's roles, sCD14 is normally present in the circulation and has dual functions. It may bind and neutralize circulating endotoxin, thereby competing with membrane CD14. However, it may also enhance endotoxin's toxic effects by transferring it to membrane CD14 or to cells that do not express it. CD14 does not structurally cross the cell membrane. Thus it must associate with a secondary protein, TLR that contains a transmembrane portion that is capable of communication with the intracellular domain.

Both CD14 and TLR are classified as bacterial recognition receptors, indicating that they are evolutionarily conserved receptors that are a part of the innate immune system. These receptors accept a wide variety of bacterial, fungal, and viral ligands that express a similar "pattern of recognition." Previous exposure to the pathogen is not required for recognition by these receptors, which therein provide an immediate response to infection. CD14 binds to isolated monomers of endotoxin, intact bacteria, and several components of gram-positive bacteria, including peptidoglycan and lipoteichoic acid. The name "Toll-like" receptor was adapted because of homology with a receptor found in *Drosophila*, called *Toll*, that is responsible for dorsal-ventral polarity and innate immunity in fruit flies. Approximately a dozen TLRs have been identified, but TLR type 4 (TLR4) appears to be the most important isotype in the recognition of endotoxin, whereas TLR type 2 primarily confers recognition of gram-positive bacteria.[53] The presence of TLR4 is mandatory for responsiveness to endotoxin, and transfection experiments have clearly demonstrated that the type and degree of response is conferred by the species of origin of the TLR4.[54] Furthermore, polymorphism in TLR4 is associated with differences in the degree of response to endotoxin in people and offers an explanation for the well-recognized clinical phenomenon that some individuals react violently to endotoxin, whereas others have little to no response.[55] The development of tolerance, or the tachyphylactic response to prolonged endotoxin exposure, has been linked to downregulation of TLR4 and CD14 mRNA. CD14, TLR4, and TLR2 have been cloned and sequenced in the horse.

Once the CD14-TLR4-endotoxin complex is compiled at the cell surface, TLR4 requires the help of a 160–amino acid helper molecule, MD2, to transmit a signal to the cytosol.[53] Numerous intracellular signaling pathways have been reported to link endotoxin-occupied cell surface receptor to a response from the cell, including protein tyrosine kinases, mitogen-activated tyrosine kinases (ERK, JNK, p38), protein kinases A and C, G proteins, various phospholipases, and translocation of nuclear factor κB (NFκB). The latter pathway is well characterized in mammalian endotoxin-induced cell signaling, including horses.[53,56] In the NFκB pathway, the cytosolic domain of TLR4 associates with myeloid differentiation factor 88 (MyD88) that recruits interleukin-1 receptor-associated kinase (IRAK), resulting in its phosphorylation. Phosphorylation of IRAK promotes its association with tumor necrosis factor receptor–associated factor (TRAF6), NFκB inducing kinase, and inhibitor (IκB) kinase (IKK). IKK phosphorylates IκB, which cleaves IκB from the IκB-NFκB complex. NFκB is a heterodimer of two proteins, p50 and p65. Once freed from IκB, the NFκB dimers translocate to the nucleus to activate the promoter sites for genes encoding inflammatory mediators.

Although there is more to learn about the regulation of the intracellular signaling systems involved in endotoxin-induced cell activation, there is solid agreement that most of the deleterious effects of endotoxin are the result of overzealous endogenous synthesis of proinflammatory mediators and initiation of SIRS. The most widely studied of these mediators are the metabolites of arachidonic acid (the prostaglandins, thromboxane, and the leukotrienes), PAF, cytokines (TNF and interleukins 1, 6, and 8), vasoactive and chemotactic peptides (histamine, serotonin, bradykinin, complement components), tissue factor, proteolytic enzymes, and reactive oxygen species. Several of these endogenous mediators have been quantified in horses with both experimentally induced and naturally occurring endotoxemia.[4,5,19,57-60] Correlation of peritoneal and serum concentrations of these mediators with adverse sequelae and mortality in horses solidifies the importance of their roles in endotoxemia.[59,60] The culmination of events in endotoxemia is uncontrolled inflammation, immunosuppression, hemodynamic changes, and coagulopathy. Decreased peripheral vascular resistance, myocardial depression, hypovolemia, and microvascular thrombosis all contribute to reduction of blood flow to vital organs. If flow is sufficiently reduced, it may become irreversible (see "Common Causes of SIRS and MODS in Horses").

Clinical Findings and Diagnostic Approach

The clinical signs of endotoxemia are often overshadowed by signs of the primary disease process that initiated the response. However, through experimental infusion studies with purified lipopolysaccharide, the response to endotoxin is well characterized in horses.[25,57,61-64] Within the first 30 to 60 minutes of sublethal intravenous challenge with endotoxin, horses yawn frequently; develop mucous membrane pallor; become depressed, anorectic, tachypneic, tachycardic, and restless; develop fasciculations and mild to moderate signs of colic; and pass loose feces. This period is the *early hyperdynamic phase of endotoxemia* that is characterized by pulmonary hypertension (increased pulmonary arterial and wedge pressures and increased pulmonary vascular resistance) and ileus associated with increased levels of thromboxane A_2, though other vasoconstrictors likely contribute. By 1 to 2 hours after challenge, depression and anorexia continue and are affiliated with the onset of fever and hypotension. This *hypodynamic phase of endotoxemia* is caused by decreased systemic vascular resistance from the release of prostaglandins. Mucous membranes are often hyperemic, and capillary refill time is prolonged. With reduced tissue perfusion, the classic "toxic line" develops as a red to blue-purple line (a few millimeters in width) at the periphery of the gums. This is particularly notable at the upper incisors. If hypotension advances, mucous membranes become diffusely congested, progressing to cyanosis and then a grayish-purple pallor.

As per its definition, endotoxemia technically means the presence of endotoxin within the blood. The gold standard for measurement of endotoxin, the limulus amebocyte lysate (LAL) assay, has been used to detect endotoxin in the plasma, portal circulation, or peritoneal fluid of horses and foals with naturally occurring endotoxemia.[59,60,65,66] The lower limit of detection of the assay is picograms per milliliter, though nanograms of endotoxin per milliliter of plasma or peritoneal fluid have been identified in horses with acute gastrointestinal diseases and foals with septicemia.[60,66] As might be expected in horses with colic, peritoneal fluid and plasma endotoxin concentrations are greatest in horses with inflammatory or ischemic gastrointestinal injuries. Although the LAL assay is a highly specific test for the detection of endotoxin, its tedious nature makes it impractical as a routine diagnostic test. Likewise, quantification of specific endotoxin-induced inflammatory mediators can provide a presumptive diagnosis as well as prognostic information, though again, these types of assays are rarely available in clinical settings. Therefore the diagnosis of endotoxemia relies heavily on identification of clinical signs and diagnostic markers in diseases known to be associated with the release of endotoxin.

One cardinal diagnostic marker of endotoxemia and acute overwhelming bacterial infection is profound neutropenia with toxic neutrophil morphology (basophilic cytoplasm, vacuolization, Döhle bodies) with a left shift. Neutropenia will occur within an hour of onset of endotoxemia and is proportionate to the degree of endotoxemia. Other diagnostic markers of endotoxemia typically reflect nonspecific secondary changes from stress (hyperglycemia), hypovolemia, (relative polycythemia, hyperproteinemia, azotemia, metabolic acidosis, increased anion gap, and lactic acidosis), and specific organ damage from decreased perfusion (azotemia; increased creatine phosphokinase, liver enzyme, or cardiac troponin activities).

Clinical Management

The rapid response to endotoxin coupled with the diverse biologic actions of the endogenous mediators present a difficult therapeutic challenge. Although neutralization of endotoxin or blockade of a single class of mediators may provide some benefit, no single treatment is a panacea. Rather, treatment of endotoxemia should include a combination of therapeutic targets. Many different treatments for endotoxemia have been evaluated in the horse and other species, both experimentally and clinically. The following discussion will be limited to therapies that have been specifically evaluated in the horse or are available for clinical use.

When treating endotoxemia, the first goal should be diminishing the source. When endotoxemia is the result of acute intestinal inflammation or ischemia, translocation of luminal endotoxin might be abated by administering smectite orally (4 ounces orally, twice daily), which absorbs bacteria and bacterial toxins, and by specifically treating the underlying disease, such as surgically removing the ischemic intestine. If endotoxemia is the result of gram-negative sepsis, tissue débridement and lavage should be undertaken when possible. Caution should be exercised when antimicrobials are used, because the bactericidal actions of certain drug classes, particularly the β-lactam family, may increase the release of endotoxin, and in such scenarios, concurrent treatment with endotoxin-neutralizing drugs (see later) is indicated.[67,68]

Once endotoxin enters the circulation, the most effective therapeutic strategy is to bind and neutralize endotoxin before it interacts with inflammatory cell receptors. Although this may seem to present a narrow therapeutic opportunity, until the source of endotoxin is controlled, use of endotoxin-neutralizing drugs is beneficial. Furthermore, there are several clinical situations in which development of endotoxemia can be anticipated; specific examples include the release of endotoxin following use of bactericidal antimicrobials in the face of gram-negative infection, following grain engorgement, and immediately after correction of a strangulating lesion.

Currently, there are two commercially available products for horses that directly bind to endotoxin: anti-endotoxin antibodies and polymyxin B. It must be noted that both of these products directly bind endotoxin, and thus their effectiveness is a factor of both the dose administered and the amount of free, unbound circulating endotoxin. Anti-core antibodies have been used in several clinical and experimental trials, often with conflicting results.[69-71] Endoserum (Immvac Inc., Columbus, MO), hyperimmune serum from horses vaccinated with the *Salmonella typhimurium*, Re mutant, has the disadvantage of requiring refrigeration. Dilution of this product with sterile isotonic saline or lactated Ringer solution (1:10 to 1:20) and administration of the diluted product intravenously over 1 to 2 hours may reduce the risk of another complication: hypersensitivity reactions. Hyperimmune anti-core plasma to *Escherichia coli* J5 (Equiplas J, Plasvacc USA Inc., Templeton, CA) can be used in foals for the concurrent treatment of endotoxemia, septicemia, and failure of transfer or passive immunity, given at the dose recommended for treatment of failure of transfer of passive immunity (20 to 40 mL per kg body weight) or in adult horses. The disadvantages in using plasma products are that they are expensive, require freezer storage, and must be thawed before administering, which delays treatment.

Polymyxin B is a cationic antibiotic that, in addition to its bactericidal properties, also binds to and neutralizes endotoxin through direct molecular interactions with the lipid A region. Because lipid A is structurally conserved among gram-negative bacteria, polymyxin B hypothetically should have broader endotoxin-binding capabilities than anti–core-endotoxin antibodies. In one study in foals, polymyxin B provided more protection against endotoxemia than did anti-core antiserum.[72] Polymyxin B has the additional advantage of being a lyophilized product that may be stored at room temperature. Clinical use of polymyxin B has been hindered by its inherent nephrotoxic and neurotoxic side effects when used intravenously at bactericidal doses. Recent studies in human patients, foals, and horses have shown that doses considered suboptimal for bactericidal treatment are remarkably effective in neutralizing endotoxin without causing toxic side effects. Currently, in horses and foals, the recommended dose of polymyxin B is 1000 to 6000 IU per kg body weight, administered intravenously every 8 to 12 hours.[72-75] As with anti-core antibodies, the effectiveness is dose related. If large circulating concentrations of endotoxin are anticipated, the higher dose range for polymyxin B is warranted. Although nephrotoxicity has not been reported in experimental trials with polymyxin B at doses less than 6000 IU per kg body weight, polymyxin B should be used judiciously in azotemic patients.

In many clinical scenarios, endotoxemia has not been anticipated and thus its recognition is delayed until clinical signs of endotoxemia are well established. Unfortunately, at this point, halting the multitude of biologic actions of the numerous endogenous mediators presents a difficult therapeutic challenge. To this end, seemingly countless antidotes for specific mediators or regimens for general shock therapy have been studied as treatments for endotoxemia; however, none have been shown to dramatically improve survival in the clinical setting. Thus, the mainstays of treatment that are most commonly employed are general supportive fluid therapy and the use of anti-inflammatory drugs. Therapy directed specifically for shock (see Chapter 1) or organ failure should be addressed if these complications develop in advanced endotoxemia. The following discussion will be limited to drugs that have been specifically tested in endotoxemic horses and are available for use in the clinical setting.

NSAIDs were one of the first classes of drugs described for the treatment of endotoxemia in horses. In this regard, flunixin meglumine, a nonspecific cyclooxygenase inhibitor, is highly effective in preventing endotoxin-induced prostanoid synthesis and associated clinical signs of endotoxemia. Administration of 0.25 mg/kg body weight intravenously every 8 hours is commonplace. Advantages of this low-dose flunixin meglumine regimen are reduced risk of potential toxic side effects and

effective inhibition of prostanoid synthesis without completely masking physical manifestations of endotoxemia that are necessary for accurate clinical assessment of the patient's progress.[57] However, if the underlying cause of endotoxemia has clearly been identified, and a more effective level of cyclooxygenase inhibition is desirable for more potent analgesic and anti-inflammatory effects, higher doses (1.1 mg/kg) may be used. Other NSAIDs, such as ketoprofen, phenylbutazone, and firocoxib, have either not been fully evaluated in endotoxemic horses or do not appear to offer any advantage over flunixin meglumine when used for endotoxemia.

Inhibition of other mediators associated with endotoxemia is more difficult. Although monoclonal antibodies to TNF and PAF receptor antagonists have been shown to be advantageous in experimentally induced endotoxemia in horses, these drugs are prohibitively expensive to use in horses or they are not commercially available. There is a general lack of conclusive evidence that blockade of lipid peroxidation is beneficial in experimentally induced endotoxemia in horses. Nonetheless, dimethyl sulfoxide (DMSO) frequently is used intravenously at doses ranging from 0.1 to 1 g/kg body weight, diluted to at least 10% in isotonic fluid. In an experimental model of endotoxemia in horses, DMSO had minimal effects on clinical signs with the only effect being reduction of endotoxin-induced fever.[76] Other anti-inflammatory agents that have been used in endotoxemic horses are pentoxifylline and lidocaine[77,78]; however, the clinical efficacy of these drugs has not been critically evaluated.

CHAPTER
3

Fluids, Electrolytes, and Acid-Base Therapy

Joanne Hardy

Fluid administration for maintenance or replacement purposes is one of the mainstays of equine critical care, and the technology should be readily accessible in any equine hospital. The availability of commercial materials and fluids for use in large animals makes fluid administration easy and cost effective in most situations. This chapter reviews fluid and electrolyte balance, materials needed, and principles to follow when planning fluid administration.

NORMAL FLUID AND ELECTROLYTE BALANCE

Distribution of Fluids

Fluids in the body are distributed in two compartments: the *intracellular fluid (ICF)* volume and the *extracellular fluid (ECF)* volume. The ECF is composed of interstitial fluid, plasma, lymph, and transcellular fluids such as synovial, pleural, abdominal, and cerebrospinal fluids. The transcellular fluids do not normally contribute to signficant fluid losses, but in disease states such as pleuropneumonia or peritonitis, they can contribute significantly to volume deficits. For example, it is not unusual to drain 10 to 20 L of fluid from the pleural cavity of horses with severe pleuropneumonia. Additionally, the volume of gastrointestinal secretions in horses plays an important role in fluid distribution. The normal volume of gastrointestinal secretion in horses is approximately equivalent to the extracellular fluid volume, representing about 100 L every 24 hours in a 500-kg horse.[1] Therefore significant fluid sequestration and loss can occur with intestinal obstruction or colitis. The volume of total body water (TBW) represents 60% of body weight in adults and up to 80% in neonates. The ECF volume represents ⅓ of TBW or 20% of body weight (in adults) to ½ of TBW or 40% of body

weight (in neonates) of water, and the ICF volume represents approximately ⅔ of TBW or 40% of body weight. Recent estimates of fluid distribution in horses report values of 0.67 L/kg (67%) for TBW, 0.21 L/kg (21%) for ECF, and 0.46 L/kg (46%) for ICF.[2,3] In neonates, the ECF is approximately 40% of the TBW, and it decreases to approximately 30% by 24 weeks of age.[4] For calculation purposes on substances distributed across the ECF, a factor of 0.3 is used for adults and 0.4 for young animals. Blood volume in sedentary horses represents approximately 8% of body weight.[5] In fit horses, this value can reach 14% of body weight.[6] In neonates, blood volume represents 15% of body weight and decreases to adult values by 12 weeks of age.[4]

Body solutes are not distributed equally through TBW. In plasma, sodium is the main cation, and bicarbonate and chloride are the main anions. Proteins contribute to the negative charges, and they also provide oncotic pressure. Albumin or molecules of similar size are the main contributors to oncotic pressure. The *interstitial fluid* accounts for about 75% of the ECF, and it is composed mainly of sodium, bicarbonate, and chloride, but the concentration of protein there is lower than in plasma. The slightly increased concentration of anions and decreased concentration of cations in interstitial fluids occurs because of the greater concentration of protein in plasma (according to the Gibbs-Donnan equilibrium). In clinical practice, this difference is small, so that the measured concentration of solutes in plasma is thought to reflect the concentration of solutes throughout the ECF. Table 3-1 lists normal plasma concentrations of electrolytes in adult horses. The composition of the intracellular fluid compartment is different: the important cations are potassium and magnesium, and the important anions are phosphates and proteins (Figure 3-1).

Transfer of fluid between compartments is an important consideration when planning fluid administration. Some important concepts govern these mechanisms. *Osmolality* is defined as the concentration of osmotically active particles in solution per kilogram of solvent (mOsm/kg), whereas *osmolarity* is the number of particles of solute per liter of solvent (mOsm/L). In biologic fluids, the difference between the two concentrations is negligible, and the two terms are often used interchangeably. Normal plasma osmolality in adult horses ranges from 275 to 312 mOsm/kg, and it varies slightly between breeds. Lower values are reported for normal foals.[7,8] The effective osmolality, or tonicity, is the osmotic pressure generated by the difference in osmolality between two compartments. Colloid oncotic pressure is the osmotic pressure generated by proteins, mainly albumin, and is measured using a colloid osmometer (Wescor, Logan, UT). Normal values of 15.0 to 22.6 mm Hg for foals and 19.2 to 31.3 mm Hg for adult horses have been reported.[9,10] Water and ionic solute exchange between the vascular and

TABLE 3-1. Normal Hematologic Values in Adult Horses

Plasma Parameter (Units)	Normal Concentration Range
CATIONS	
Sodium (mmol/L or mEq/L)	132-146
Potassium (mmol/L or mEq/L)	2.4-4.7
Calcium (mmol/L)	2.8-3.4
Ionized calcium (mmol/L)	1.0-1.3
Magnesium (mmol/L)	0.9-1.15
Ionized magnesium (mmol/L)	0.4-0.55
ANIONS	
Chloride (mmol/L or mEq/L)	99-109
Total CO_2 (mmol/L or mEq/L)	24-32
VENOUS BLOOD GAS	
pH	7.32-7.44
PCO_2 (mm Hg)	38-46
PO_2 (mm Hg)	37-56 (arterial, 80-100)
HCO_3^- (mmol/L or mEq/L)	20-28
Base excess (mmol/L or mEq/L)	−2 to +2
OTHER	
Creatinine (mg/dL)	0.9-1.9
Plasma protein (g/dL)	5.8-8.7
Albumin (mg/dL)	2.9-3.8
Plasma lactate (mmol/L)	1.11-1.78

interstitial compartments occurs at the capillary level and is rapid; equilibrium is reached within 30 to 60 minutes. The rate of exchange or net filtration that occurs between these compartments is controlled by a balance between the forces that favor filtration (capillary hydrostatic pressure and tissue oncotic pressure) and the forces that tend to retain fluid within the vascular space (plasma oncotic pressure and tissue hydrostatic pressure). These relationships are described by *Starling's law:*

$$\text{Net filtration} = K_f\,[(P_{cap} - P_{int}) - \sigma(\pi_p - \pi_{int})]$$

where K_f is the filtration coefficient, which varies depending on the surface available for filtration and the permeability of the capillary wall; P_{cap} and P_{int} represent the hydrostatic pressures in the capillary or in the interstitium; π_p and π_{int} are the oncotic pressures in the plasma or interstitial fluid; and σ is the reflection coefficient of proteins across the capillary wall.

Exchanges between the interstitial and the intracellular compartment are governed by the number of osmotically active particles within each space. Sodium is the most abundant cation in the ECF. Consequently, sodium accounts for most of the osmotically active particles in the ECF. Other osmotically active compounds that make a significant contribution to ECF osmolarity are glucose and urea. The most commonly used formula for estimation of serum osmolarity is as follows[11]:

$$\text{ECF osmolality} = 2[Na^+] + \frac{\text{glucose}}{18} + \frac{\text{urea}}{2.8}$$

Cell membranes are permeable to urea and K^+. Therefore the effective osmolarity is calculated as follows:

$$\text{ECF osmolality} = 2[Na^+] + \frac{\text{glucose}}{18}$$

The osmolar gap is the difference between measured osmolarity and calculated osmolarity; an increased osmolar gap can exist when unmeasured solutes, such as mannitol, are present.[12]

Exchanges between the extracellular and intracellular compartments are comparatively slow, taking up to 24 hours to reach equilibrium.

Acid-Base Balance

The concentration of hydrogen ions, and therefore the pH, is closely regulated in the body to vary between 7.35 and 7.45. This narrow range is maintained by the presence of buffers within different body compartments; a buffer is a compound that can accept or donate protons to maintain the pH within a narrow range. In the body, bicarbonate is the primary buffer system of the extracellular fluid, whereas protein and inorganic and organic phosphates represent the principal intracellular buffers.

The importance of bicarbonate as a buffer in the ECF stems from the fact that it is an open system. The dissociation of carbonic acid is expressed by the law of mass action:

$$H^+ + HCO \rightleftharpoons H_2CO_3 \rightleftharpoons CO_2 + H_2O$$

In the body, this system is open, and carbonic acid, in the presence of carbonic anhydrase, forms CO_2, which is eliminated entirely from the system by alveolar ventilation.

The relationship between pH, bicarbonate, and carbonic acid is expressed in the Henderson-Hasselbalch equation:

$$pH = 6.1 + \log\left[\frac{HCO_3^-}{0.03PCO_2}\right]$$

where PCO_2 is the partial pressure of carbon dioxide. This is the clinically relevant form of the equation, which shows that in body fluids, pH is a function of the ratio of HCO_3^- to PCO_2; this ratio is normally approximately 20:1.

The responses to acid or base alterations in the body all combine to normalize pH. For example, an acute increase in hydrogen ions from a fixed acid load is immediately buffered by bicarbonate and intracellular buffers. This is the acute physiochemical response. Alveolar ventilation is subsequently modified, and this is complete within hours to further minimize changes in pH by normalizing the ratio of HCO_3^- to PCO_2. Finally, renal responses result in regeneration of HCO_3^-, resulting in a long-term response. The renal response begins within hours and is complete within 2 to 5 days. An acute increase in volatile CO_2, in contrast, cannot be buffered by HCO_3^-; therefore, the hydrogen ions generated from the dissociation of carbonic acid must be buffered by intracellular buffers. Renal adaptation, characterized by increased HCO_3^- reabsorption and net acid secretion, takes 2 to 5 days to achieve maximal effectiveness.

ACID-BASE DISORDERS

Terminology

Acidosis and alkalosis refer to the *processes* that cause net accumulation of acid or alkali in the body, respectively. Acidemia and alkalemia refer to the pH of the ECF: in acidemia, the pH of the ECF is lower than normal, and in alkalemia the pH of the ECF is higher than normal. The distinction between these terms is important; for example, a horse with chronic reactive airways disease may have a normal blood pH because of effective renal compensation, but in this setting the patient will have increased bicarbonate. This patient has alkalosis but does not have alkalemia.

Primary Acid-Base Disorders

There are four primary acid-base disorders: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. The metabolic disorders refer to the net excess or deficit of nonvolatile or fixed acid, whereas the respiratory disturbances refer to a net deficit or excess of volatile acid (dissolved CO_2).

Metabolic acidosis is present when there is a decrease in HCO_3^- caused by either loss or buffering of nonvolatile acids. Common causes of metabolic acidosis in horses include accumulation of lactic acid as a result of poor perfusion, and HCO_3^- losses in the gastrointestinal tract resulting from diarrhea. *Metabolic alkalosis* is present when there is an increased concentration of HCO_3^-. Metabolic alkalosis is commonly associated with a disproportionate loss of chloride ions. *Respiratory acidosis* is present when the PCO_2 is increased in response to alveolar hypoventilation. *Respiratory alkalosis* is present when the PCO_2 is decreased. Table 3-2 lists examples of primary acid-base disorders in horses.

For each primary acid-base disturbance, there is a secondary or adaptive response that involves the component opposite the primary disturbance in an attempt to return the pH toward

normal. The secondary response never restores the pH completely to normal. For metabolic disorders, the secondary or adaptive respiratory response begins immediately and is complete within hours. In respiratory disorders, the adaptive response begins with an acute, immediate titration by nonbicarbonate buffers that results in an initial change in plasma HCO_3^- concentration. This is followed by a chronic response mediated by the kidney that involves net acid secretion and bicarbonate resorption. This response begins within hours and takes 2 to 5 days to be complete. Table 3-3 lists expected adaptive responses to acid-base disorders. These expected responses vary slightly across species.[13]

Mixed Acid-Base Disorders

When a primary disorder occurs with the expected secondary response, it is considered a simple acid-base disorder. A mixed disorder means that two separate primary disorders are present in the same patient. A mixed disorder is suspected when the adaptive response is lower or higher than the expected response from the primary disorder.

MEASUREMENT AND INTERPRETATION OF BLOOD GASES

Measurement

For accurate blood gas analysis, appropriate sampling methods should be followed. Blood (arterial or venous) is collected anaerobically from the puncture site using a syringe that contains the appropriate anticoagulant for the analyzer, usually lithium heparin, taking care to not dilute the sample with excess heparin. Introduction of room air into the sample will falsely increase the PO_2 and decrease the PCO_2. If a delay in analysis is anticipated, the blood should be placed on ice to decrease cell metabolism. Most blood gas analyzers perform their analysis at 37° C. At extremes of body temperature, a patient's actual value may differ from expected values according to the gas law: with increases in temperature, gas is less soluble and therefore its partial pressure in the solution increases; this will increase the PO_2 and PCO_2 of a solution. Similarly, with extreme hypothermia, gas is more soluble, resulting in decreases in PO_2 and PCO_2. Although available in many blood gas analyzers, temperature correction is usually not performed for several reasons: (1) the small changes in body temperature usually do not affect blood gas analyses significantly; (2) the patient's temperature, if extreme, will usually be corrected shortly; and (3) there are no established normal values for extremes in body temperature.

Routine blood gas analyzers provide three measured values, pH, PCO_2, and PO_2, and three calculated values, total CO_2 (TCO_2), HCO_3^-, and base excess (BE). Measured values that are outside of physiologic ranges should be considered a malfunction of the analyzer.

- pH is the negative base 10 logarithm of hydrogen concentration and is a measured value.
- PCO_2 (mm Hg) is the measured partial pressure of dissolved carbon dioxide in the sample. A venous sample will have a

TABLE 3-2. Traditional Approach* to Simple Acid-Base Disorders in Adult Horses

Parameter	Metabolic Acidosis	Metabolic Alkalosis	Respiratory Acidosis	Respiratory Alkalosis (Arterial Sample)
pH	7.390	7.49	7.30	7.50
PCO_2 (mm Hg)	28.4	49	60	32
PO_2 (mm Hg)	42	43	38	55
HCO_3^- (mEq/L)	16.5	34	28	22
Base excess (BE) (mEq/L)	−5.8	+9	−1	−2
Comments	There is a secondary decrease in PCO_2 to compensate for the primary disorder.	There is a secondary increase in PCO_2 in an attempt at compensation.	This is an acute disorder with increased bicarbonate of 1-2 mEq/L per 10 mm Hg increase in PCO_2. Note that the BE is normal, indicating no metabolic disturbance.	Increased ventilation in response to hypoxemia is the cause of this disorder.

*This traditional approach to the diagnosis of simple acid-base disorders depends on interpretation of the clinical parameters in the left-hand column, without examining the contribution of electrolytes, unmeasured anions, or protein concentrations.

TABLE 3-3. Secondary (Adaptive) Responses to Primary Acid-Base Abnormalities

Disorder	Primary Change	Secondary Response
Metabolic acidosis	↓ HCO_3^-	PCO_2 decreases by 1.2 mm Hg for every 1 mEq/L decrease in bicarbonate
Metabolic alkalosis	↑ HCO_3^-	PCO_2 increases by 0.6-1 mm Hg for every 1 mEq/L increase in bicarbonate
Acute respiratory acidosis	↑ PCO_2	[HCO_3^-] increases by 1 mEq/L for every 10 mm Hg increase in PCO_2
Chronic respiratory acidosis	↑ PCO_2	[HCO_3^-] increases by 3-4 mEq/L for every 10 mm Hg increase in PCO_2
Acute respiratory alkalosis	↓ PCO_2	[HCO_3^-] decreases by 1-3 mEq/L for every 10 mm Hg decrease in PCO_2
Chronic respiratory alkalosis	↓ PCO_2	[HCO_3^-] decreases by 5 mEq/L for every 10 mm Hg decrease in PCO_2

From Brobst D: J Am Vet Med Assoc 183:773, 1983.

slightly higher (5 mm Hg) value than an arterial sample. An increase in PCO_2 is termed *hypercapnia* or *hypercarbia*, and it usually reflects alveolar hypoventilation.

- PO_2 (mm Hg) is the measured partial pressure of dissolved oxygen in blood. This is different from oxygen content, which is the total concentration of oxygen carried by blood and includes the portion carried by hemoglobin.
- TCO_2 (mEq/L) is the concentration of total CO_2 in the sample, obtained by adding a strong acid to the sample and measuring the amount of CO_2 produced; it includes both dissolved CO_2 and HCO_3^-. Because HCO_3^- represents 95% of total CO_2, this measurement is indirectly a measurement of HCO_3^-, and it is 1 to 2 mEq/L higher than the concentration of HCO_3^-.
- HCO_3^- (mEq/L) is reported as actual bicarbonate, which is the calculated concentration of bicarbonate in the sample, and standard bicarbonate, which is the calculated concentration of HCO_3^- after the sample has been equilibrated to a PCO_2 of 40 mm Hg.
- BE (mEq/L) is the amount of strong acid or base required to titrate 1 L of blood to a pH of 7.40 at 37° C with the PCO_2 held constant at 40 mm Hg. Because the base excess is changed only by nonvolatile fixed acids, it is considered to reflect metabolic acid-base disturbances.

Normal values for the horse are presented in Table 3-1.

Interpretation

To interpret blood gases, a practiced method should be followed. First the pH is examined, and if it is outside the normal range, an acid-base disorder is present. The clinician examines next the HCO_3^- level and PCO_2 and determines if an abnormality is present that could explain the abnormal pH. An *acidemia* is caused by an increase in PCO_2 or a decrease in HCO_3^-, whereas an *alkalemia* is caused by a decrease in PCO_2 or an increase in HCO_3^-. Once the primary disorder has been characterized, the clinician determines whether a secondary response is present. The absence of a secondary response, or a change in the direction opposite the expected response, is an indication of a mixed disorder. The clinician then determines whether the acid-base disturbance is consistent with the patient's history and clinical findings. Table 3-2 lists examples of simple acid-base disorders in horses.

Another important component of blood gas interpretation is the PO_2. The normal PO_2 of arterial blood (PaO_2) is approximately 5 times the fraction of inspired oxygen (FiO_2), or 80 to 100 mm Hg in room air at sea level (FiO_2, 21%). *Hypoxemia* refers to a decreased PaO_2; common causes include a decreased FiO_2 (an example is a decreased barometric pressure associated with high altitude), hypoventilation, ventilation/perfusion mismatch, shunt, or diffusion impairment. The normal PO_2 of venous blood (PvO_2) is 40 mm Hg. A low mixed PvO_2 (mixed refers to a sample collected centrally, ideally from the pulmonary artery) in the presence of normal PaO_2 should alert the clinician that tissue perfusion is poor.

Anion Gap

The anion gap (AG) is the difference between the sum of the commonly measured cations and the sum of the commonly measured anions in serum, calculated as follows:

$$AG = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]).$$

The sum of cations always exceeds the sum of anions, and the difference is an attempt to estimate the concentration of unmeasured anions—for example, lactate. A normal AG of 10.4 ± 1.2 mEq/L has been reported in adult horses.[14] Neonates have a slightly higher AG because of their increased levels of phosphates and globulins.[14] In exercising horses, the AG is useful to estimate plasma lactate concentrations in the presence of relatively normal plasma protein concentrations.[15] In horses with abdominal pain, the correlation between lactate concentration and the AG is excellent, but the presence of other strong ions results in a higher AG than would be expected from lactate measurement.[16] The AG is considered a good prognostic indicator of survival in horses with abdominal disorders: a value greater than 25 mEq/L is associated with a significantly lower survival rate.[17,18]

Lactate

Measurement of lactate concentration is now a routine part of the assessment of perfusion in equine patients, and it is available in most chemistry and point-of-care analyzers.[19] Samples should be analyzed immediately to prevent *in vitro* lactate production by erythrocytes; alternatively, collection in fluoride-containing tubes, storage on ice, and separation of plasma can help minimize this problem. Lactate is the end product of anaerobic glycolysis, and its concentration is another indicator of tissue perfusion and oxygen delivery; an increased blood lactate concentration is most often a result of tissue hypoxia. Although inadequate oxygen delivery to tissues as a result of hypovolemia, decreased oxygen content, or impaired myocardial function (absolute hypoxia) is the most common cause of hyperlactatemia, hypermetabolic states or impaired oxygen use as a result of mitochondrial dysfunction (relative hypoxia) can also increase blood lactate concentration. Less commonly, increased lactate may result from impaired clearance because of hepatic dysfunction, thiamine deficiency, or increased catecholamine production.[20] Normal blood lactate concentrations in resting adult horses are less than 2 mmol/L; concentrations higher than this in the adult are an indication of inadequate oxygen delivery. Neonates have higher blood lactate concentrations that decrease to adult values by 24 hours of age.[21] Serial measurement of lactate is a useful tool to monitor the adequacy of fluid therapy (see Chapter 1).

Nontraditional Approach to Acid-Base Evaluation

In the traditional approach, the relationship between PCO_2, HCO_3^-, and pH is explained by the Henderson-Hasselbalch equation and appears to stand alone as an explanation for acid-base derangements. This is still the approach most commonly used by clinicians, and it serves to initiate and target therapeutic intervention. However, what this approach fails to do is provide explanations for the influence of other electrolytes, weak acids, and plasma protein on acid-base balance.

The nontraditional approach (or Stewart's approach) to acid-base balance is based on three physical laws: maintenance of electroneutrality, satisfaction of dissociation equilibrium for solutes that are incompletely dissociated, and conservation of mass. In this approach, independent variables are those that can be altered externally; dependent variables change only when

independent variables change. Independent variables include the strong ion difference (SID), PCO_2, and the total concentration of weak acids, or A_{tot}. The SID is the difference between the concentration of strong cations and the concentration of strong anions. The most important cation is sodium; chloride and other unmeasured anions make up the strong anions. Because many strong anions are not routinely measured, the normal SID accounts for the presence of these anions. An increase in SID indirectly indicates an accumulation of unmeasured anions. The concentration of weak acids in plasma mostly derives from protein and phosphates. Bicarbonate is a dependent variable that changes in response to a change in independent variables. Hypoproteinemia (a decrease in weak acid) results in alkalosis (an increase in HCO_3^-); conversely, an increase in phosphates, such as that occurring with acute renal failure, causes an acidosis.

In Stewart's approach, the primary disturbance is therefore defined as a change in one or more of the independent variables: SID, PCO_2, or A_{tot}. To calculate the contribution of these variables to an acid-base disturbance, determination of the total concentration of nonvolatile weak acids and the effective dissociation constant for weak acids is required, which is impractical in most clinical situations. A simplified version of Stewart's approach, proposed and validated for equine plasma, allows the determination of A_{tot} and the effective dissociation constant for plasma weak acids (K_a) and accurately predicts pH.[15]

Another approach to Stewart's concepts involves the characterization of four components of base excess: changes in free water reflected by changes in sodium, changes in chloride, changes in serum albumin concentration, and changes in unmeasured anions. This method has also been used successfully in horses to better characterize acid-base disorders.[22] The example in Table 3-4 illustrates the contributions of protein, chloride, and unmeasured anions to acid-base balance, and it shows how the traditional approach to acid-base balance can sometimes fail to recognize abnormalities when complex disorders are present.

The preceding discussion emphasizes the complexity of interactions between solutes in body fluids and the importance of recognizing the limits of the traditional approach to acid-base interpretation. Although the traditional approach provides a working method for identification of problems, it falls short in complex mixed acid-base disorders and does not provide a satisfactory explanation when electrolyte, colloidal, and unmeasured anion disorders coexist.

TABLE 3-4. Example of Acid-Base Measurements in a Horse with Intestinal Strangulating Obstruction

Parameter	Value
pH	7.49
PCO_2 (mm Hg)	37
Base excess (BE) (mEq/L)	4.6
Na^+ (mEq/L)	137
Cl^- (mEq/L)	93
HCO_3^- (mEq/L)	32.7
K^+ (mEq/L)	2.7
Total protein (g/dL)	4.4
Packed cell volume (%)	58
Anion gap (mEq/L)	25
BE_{fw} (mEq/L)	0.9
BE_{Cl} (mEq/L)	9
BE_{tp} (mEq/L)	7.5
BE_{ua} (mEq/L)	−12.8

From Whitehair KJ, Haskins SC, Whitehair JG, et al: J Vet Intern Med 9:1, 1995. Using the traditional approach to diagnosing acid-base disorders, the interpretation of blood gas analyses on this horse would indicate a metabolic alkalosis with no secondary or adaptive response (PCO_2 is normal). Further examination reveals hypochloremia and hypoproteinemia, which are responsible for the alkalosis (as indicated by the calculation of their respective base excesses [BE_{Cl} and BE_{tp}]). However, examination of the anion gap and calculation of the BE contributed by unmeasured anions (BE_{ua}) reveal an underlying acidosis that was masked by the hypoproteinemia and hypochloremia. Measurement of lactate would be indicated in this case to further characterize the disorder. Most likely, lactic acidosis is present as a result of poor perfusion (indicated by the marked increase in packed cell volume). BE_{Cl}, BE contributed by chloride; BE_{fw}, BE contributed by free water; BE_{tp}, BE contributed by total protein; BE_{ua}, BE contributed by unmeasured anions.

DESIGNING A FLUID THERAPY REGIMEN

Volumes of Fluid to Administer

Fluids can be administered for the purpose of maintenance or replacement. Maintenance regimens are often provided via the oral route in equine patients, and oral electrolyte formulations are available for this purpose (see later in this chapter). Intravenous maintenance fluids are lower in sodium and higher in calcium, potassium, and magnesium than replacement fluids. An appropriate maintenance fluid is 0.45% saline to which potassium, magnesium, and calcium were added.

More commonly, a replacement fluid therapy regimen is given to equine patients to replace fluids lost through dehydration and ongoing losses. When designing a replacement fluid therapy regimen, three questions must be answered:

1. What volume of fluid must be given?
2. What type of fluid will be given?
3. What will be the rate of administration?

Furthermore, the volume of fluids given must equal the maintenance requirements plus the volume needed to correct hypovolemia plus that needed to compensate for ongoing losses.

Maintenance

In adult horses, maintenance fluid requirements have been estimated at 60 mL/kg/day. This figure probably overestimates the actual needs of a resting, fasted animal in a normothermic environment, but it appears to be safe in most situations. In horses with renal failure, when elimination of excess fluids is difficult, monitoring of body weight and central venous pressures is indicated to help prevent fluid overload. If weight gain, edema, or increased central venous pressures are noted, the fluid rate should be decreased.

Dehydration

Dehydration is the general term used to indicate loss of total body water; hypovolemia is a form of dehydration resulting from loss of effective circulating volume. This distinction is important; for example, when the lack of water intake is prolonged, heart rate and parameters of perfusion remain within normal limits, as fluid shifts from the intracellular space to maintain normal circulating volume. In this case, intracellular

fluid volume should be replenished relatively slowly, to allow time for slow fluid shifts to occur. In contrast, acute intestinal obstruction results in loss of circulating blood volume manifested by altered cardiovascular parameters, such as increased heart rate, poor perfusion, and decreased pulse quality. Rapid reinstitution of effective circulating blood volume is important in this situation. Parameters that may be used for estimation of dehydration include serial body weights, heart rate, mucous membrane color, capillary refill time, skin elasticity (skin tenting), palpation of extremities, and urine output. Useful laboratory parameters include packed cell volume (PCV), total protein, creatinine and lactate concentrations, and urine specific gravity. Table 3-5 lists parameters useful for estimating hypovolemia (loss of effective circulating volume) in the horse.

Once an estimate of hypovolemia has been obtained, the amount of fluids to administer is calculated as follows:

$$\text{Correction of hypovolemia} = \text{Estimate of loss (\%)} \times \text{body weight (kg)}$$

Ongoing Losses

Ongoing losses can sometimes be measured and recorded—for example, when nasogastric reflux is present—but usually they must be estimated. Therefore patient monitoring is used to determine if the calculated fluid volume is meeting the ongoing losses. Monitoring, which may include serial measurements of cardiovascular parameters, PCV and total protein, lactate concentration, and blood gas analyses, is done at least twice a day when patients are on intravenous fluids, but it should be done more frequently (every 2, 4, or 6 hours) depending on the severity of cardiovascular compromise. Creatinine concentration should also be monitored at least once daily when initially elevated, to ensure adequate return to normal. Additional means of monitoring adequate fluid delivery include measurement of central venous pressure, arterial blood pressure, and urine output (see Chapter 1).

Type of Fluid

The type of fluid chosen depends on the evaluation of the chemistry profile and on the disease state. The first step is to choose a baseline fluid (saline or balanced electrolyte solution), and the second is to decide which additives to include in the baseline fluid. The choice of additives depends on the specific deficits or excesses, such as hypoglycemia or acid-base disorders, or when concentrations of sodium, potassium, calcium, or magnesium ions are too high or too low.

The two categories of crystalloids commonly used for fluid replacement are 0.9% saline and balanced electrolyte solutions (BESs). Table 3-6 lists the compositions of various commercially available fluids. In general, BESs are chosen when serum electrolytes are close to normal. The BES provides a bicarbonate precursor, which is either lactate, or acetate plus gluconate. Lactate requires hepatic metabolism for conversion to bicarbonate, whereas acetate and gluconate are metabolized by other tissues. All BESs contain some potassium. As noted in Table 3-6, calcium or magnesium is present in different types of BES. Saline (0.9%) is higher in sodium and much higher in chloride than serum concentrations and is used when $[Na^+]$ is lower than 125 mEq/L. Saline is also used in disease processes associated with high $[K^+]$, such as hyperkalemic periodic paralysis or renal failure, where a potassium-free solution is preferred. In cases of long-term maintenance fluid therapy (greater than 4 to 5 days), if the oral route is not available, half-strength basic fluids, to which potassium, calcium, and magnesium are added, should be considered. Long-term fluid therapy solely with a BES will result in hypernatremia, hypokalemia, hypomagnesemia, and hypocalcemia.

TABLE 3-5. Parameters to Estimate Degree of Hypovolemia in Adult Horses*

% Loss of Effective Circulating Volume	Heart Rate (beats/min)	Capillary Refill Time (sec)	PCV/TP (%, g/L)	Creatinine (mg/dL)
6%	40-60	2	40/7	1.5-2
8%	61-80	3	45/7.5	2-3
10%	81-100	4	50/8	3-4
12%	>100	>4	>50/>8	>4

*These parameters are useful to estimate the degree of hypovolemia in adult horses, assuming a normal packed cell volume (PCV) of 35% and total protein (TP) of 6.5 g/dL.

TABLE 3-6. Composition of Commonly Used Intravenous Solutions

Fluid	Na^+ (mEq/L)	K^+ (mEq/L)	Ca^{2+} (mEq/L)	Mg^{2+} (mEq/L)	Cl^- (mEq/L)	Buffer Source (mEq/L)	Osmolality (mOsm/L)
Plasma	132-146	2.8-5.1	9.0-13	1.8-3	99-110	(TCO_2) 20-36	285 ± 10
Lactated Ringer	130	4	3	0	109	(lactate) 28	274
Normosol-R	140	5	0	3	98	(acetate, gluconate) 50	295
0.9% NaCl	154	0	0	0	154		308
5% Dextrose	0	0	0	0	0		253
2.5% Dextrose in 0.45% NaCl	77	0	0	0	77		280
1.25% $NaHCO_3$	149	0	0	0	0	149	298

Adapted from Morris DD: Vet Med 34:164, 1987.

In horses, routine fluid replacement also includes calcium, potassium, and magnesium supplementation, particularly when there is no oral intake because of gastrointestinal disease. Low concentrations of serum ionized calcium (iCa) and magnesium (iMg) are more prevalent in horses with surgical gastrointestinal disease, particularly in those with small intestinal or large and small colon nonstrangulating infarction or strangulation and in horses with postoperative ileus.[23-25] Horses with enterocolitis also have low iCa and iMg and a decreased fractional clearance of calcium.[26] Total magnesium and calcium concentrations are less reliable for identification of calcium and magnesium status—it is preferable to determine ionized concentrations.[23-25] Measurement of total calcium can be misleading if total protein is low (ionized calcium may still be normal) or if the horse is alkalotic (total calcium may be normal, with a low ionized fraction). Fractional excretion of magnesium has been suggested as a diagnostic tool for assessment of magnesium status in horses.[27] Based on this information, supplemental calcium and magnesium appears beneficial for fluid therapy in horses.

Administration of 50 to 100 mL of 23% *calcium* gluconate in every 5 L of fluid is usually sufficient to maintain normocalcemia. In the presence of severe hypocalcemia (iCa less than 4.0 mg/dL), administration of 500 mL of calcium gluconate in 5 L of BES is indicated. Hypocalcemia that is refractory to calcium therapy may indicate hypomagnesemia, and concurrent magnesium replacement is required. The maintenance requirement of *magnesium* in horses is estimated at 13 mg/kg/day of elemental Mg, which is provided by 31 mg/kg/day of MgO, 64 mg/kg/day of $MgCO_3$, or 93 mg/kg/day of $MgSO_4$.[28] In critically ill patients, the requirement may be increased, as indicated by the high prevalence of hypomagnesemia in hospitalized patients.[25] When considering magnesium supplementation, the concentration of elemental magnesium in the compound should be considered. Some crystalloid fluids such as Plasma-Lyte A and Normosol-R contain 3 mEq/L of elemental Mg. This amount may be insufficient to account for the increased losses in sick horses. Administration of 150 mg/kg/day of $MgSO_4$ (0.3 mL/kg of a 50% solution), equivalent to 14.5 mg/kg/day or 1.22 mEq/kg/day of elemental magnesium, administered in saline, dextrose, or polyionic fluids, would provide the daily requirement for the horse.[28]

Hypokalemia may develop because of lack of intake, diuresis, and gastrointestinal loss through diarrhea. Horses with a metabolic acidosis can become hyperkalemic, and potassium excretion can occur after correction of the acidemia. Measurement of serum potassium as an estimate of total body potassium can be misleading, because most of the potassium ions are intracellular. Routine *potassium* supplementation is indicated if lack of intake and fluid therapy are continued for more than 24 hours. To prevent complications, it is recommended that animals not receive more potassium than 0.5 mEq/kg/hr. Most horses will benefit from the addition of 20 mEq of potassium in the form of potassium chloride per liter of fluids.

Bicarbonate supplementation may also be required in horses with metabolic acidosis. Because the most common cause of nonrespiratory acidosis is lactic acidemia resulting from poor perfusion, providing fluid replacement should be the first and principal means of correcting this problem. The following are rules of thumb for bicarbonate supplementation in acute metabolic acidosis:

- The horse should have normal respiratory function. If it is unable to exhale the generated CO_2 because of a respiratory problem, worsening of the acidosis will result.
- The blood pH should be less than 7.2. In acute acidosis associated with dehydration, fluid replacement will result in restoration of urine output, and renal compensation will follow and usually be complete if the pH is greater than 7.2.
- Half of the calculated amount should be administered rapidly, followed by the rest over 12 to 24 hours.
- IV bicarbonate should not be given with calcium-containing solutions.

The amount of bicarbonate required can be calculated using the following formula:

$$\text{mEq of bicarbonate} = \text{Base excess (mEq/L)} \times \text{BW (kg)} \times 0.3$$

Alternatively, total CO_2 (TCO_2) can be used, remembering tCO_2 represents bicarbonate content:

$$(\text{Normal } tCO_2 - \text{actual } tCO_2) \times \text{BW (kg)} \times 0.3$$

In chronic metabolic acidosis, particularly when there are ongoing losses of bicarbonate (e.g., with diarrhea), the full calculated amount is usually required, partially because the bicarbonate loss is distributed over all fluid compartments, not just the extracellular fluid. Oral supplementation is a good means of dealing with ongoing losses in horses with diarrhea. Bicarbonate is available as an injectable solution in two concentrations: a 5% solution, which contains 0.59 mEq/L of bicarbonate, and an 8.4% solution, which contains 1 mEq/L. To make an isotonic solution for intravenous administration, 1 part of 5% bicarbonate can be diluted in 3 parts of sterile water. Alternatively, 150 mL of 8.4% bicarbonate can be added to 850 mL of sterile water. Bicarbonate can be given orally as a powder (baking soda), where 1 g $NaHCO_3$ = 12 mEq HCO_3^-).

Administration of *dextrose* is indicated for the treatment of hypertonic dehydration, for animals that are susceptible to or that have hyperlipemia (miniature horses and donkeys, adult horses with azotemia), and for pregnant mares as a source of energy for the fetoplacental unit.[29,30] Because glucose is metabolized rapidly, administration of dextrose in water results in the administration of free water, which is useful for the correction of intracellular dehydration. As a source of energy, 5% dextrose can be administered at a rate of 1 to 2 mg/kg/min.

Administration of *colloids* is indicated when the total protein concentration is less than 4 g/dL, the albumin concentration is less than 2.0 g/dL, or the colloid oncotic pressure is less than 12 mm Hg. Plasma and hetastarch are commonly used colloids in horses (see Chapter 1). Plasma administration is indicated when administration of other plasma products such as coagulation factors or antithrombin is desired in addition to administration of colloids. The amount of plasma to be administered can be calculated as follows:

$$\text{Plasma to be administered (L)} = \frac{(TP_{des} - TP_{pt}) \times 0.05\text{BW (kg)}}{TP_{don}}$$

where TP_{des} is the desired protein concentration, TP_{pt} is the total protein concentration of the patient, TP_{don} is the total protein

concentration of the donor plasma and 0.05BW (kg) is an estimate of the plasma volume. If the goal of colloid therapy is to restore oncotic pressure, then synthetic colloids can be used. Before the advent of hetastarch, dextran was commonly used, but its administration was associated with more anaphylactic reactions, and because of its lower molecular weight average, it was effective for a shorter duration.[5] Hetastarch is preferred and is used at a dosage of 10 mL/kg. Higher dosages (20 mL/kg) were associated with increased coagulation times caused by a decrease in von Willebrand factor antigen (vWf:Ag) activity and factor VIII coagulant (FVIII:C), and should probably not be used in sick animals with increased susceptibility to coagulopathies.[9] Hetastarch registers at a lower value than protein on a refractometer and can therefore decrease the value of the total protein concentration that is measured. To accurately monitor hetastarch therapy, use of a colloid osmometer is indicated.

Administration of blood or blood substitutes (see Chapter 4) is indicated when loss of oxygen-carrying capacity has occurred through red blood cell loss. Ideally, fresh whole blood collected in a plastic container (to preserve platelet function) from a donor that is negative for the red blood cell antigens A and Q should be given. The blood should also contain an appropriate anticoagulant. Commercially available kits (Dynavet, Plasvacc USA Inc., Templeton, CA) consist of 2-L collection bags, collection and administration sets, and sodium citrate as an anticoagulant. This anticoagulant is not suitable for blood storage for longer than 24 hours. For longer storage, acid citrate dextrose (ACD) can be used. However, blood stored in ACD for greater than 10 days has a decreased concentration of 2,3-diphosphoglycerate, resulting in decreased oxygen release into tissues, increased red blood cell fragility, and increased potassium concentration. For prolonged storage of equine blood, the use of citrate phosphate dextrose with supplemental adenine is recommended.[31] In cases of chronic blood loss, the amount of blood required can be calculated as follows:

$$\text{Amount required (L)} = \frac{(\text{PCV}_{\text{des}} - \text{PCV}_{\text{pt}}) \times 0.08\text{BW (kg)}}{\text{PCV}_{\text{don}}}$$

where PCV_{des} is the target packed cell volume, PCV_{pt} is the patient's packed cell volume, PCV_{don} is the PCV of the donor, and BW is body weight. When the blood loss is acute, the packed cell volume does not reflect the amount of blood lost for up to 24 hours. If blood loss is considered severe, 10 to 20 mL/kg of whole blood can be administered. When a large volume of anticoagulated whole blood is administered, the patient should be monitored for anaphylactic reaction and hypocalcemia.

Hemoglobin glutamer-200 of bovine origin (Oxyglobin, Biopure Corp, Cambridge, MA) is a glutaraldehyde-polymerized bovine hemoglobin solution that has been administered safely to horses for restoration of oxygen-carrying capacity.[32-34] After administration, volume expansion also occurs because of the colloidal nature of the solution. In one study performed in ponies with experimentally induced normovolemic anemia, administration of 15 mL/kg given at the rate of 10 mL/kg/hr improved hemodynamics and oxygen transport parameters without adverse renal or coagulation effects; however, one pony suffered an anaphylactoid reaction during infusion.[32] The half-life of Oxyglobin is relatively short; therefore, the patient should be monitored if the need for another transfusion may arise.[31] Expense may limit its use in adult horses.

Rate of Administration

In severe shock, a shock dose of fluids (60 to 90 mL/kg or 30-45 L per 500 kg horse) should be administered in the first hour. This can be done only with pressurized bags or a pump. In other situations, the rate of administration is calculated on the basis of 24-hour requirements and estimated as a volume per hour. It is important to keep a tally of the fluids given to ensure that the correct amount is reached.

Oral Fluids

Although the oral route of fluid administration has been neglected with the advent of commercially available intravenous fluids for horses, interest is being revived, particularly in the treatment of impaction colic. Oral fluids should be considered when the gastrointestinal tract is functional and maintenance requirements are needed, for example, in a dysphagic horse. Oral fluids also may be the principal treatment of impaction colic. Enteral fluid therapy may complement and even supplement intravenous fluids. Advantages of enteral fluid therapy include administration of fluid directly into the gastrointestinal tract, stimulation of colonic motility through the gastrocolic reflex, decreased expense, and decreased need for precise adjustment of fluid composition.[35] Enteral fluids may be administered by intermittent nasogastric intubation or by placement of an indwelling feeding tube (18-French equine enteral feeding tube), allowing continuous fluid administration.

An isotonic electrolyte solution can be made by mixing 5.27 g of NaCl, 0.37 g of KCl, and 3.78 g of $NaHCO_3$ per liter of tap water.[36] This solution results in the following electrolyte concentrations: 135 mEq/L of Na^+, 95 mEq/L of Cl^-, 5 mEq/L of K^+, and 45 mEq/L of HCO_3^-, with a measured osmolarity of approximately 255 mOsm/L, representing a balanced, slightly hypotonic electrolyte solution compared with plasma. Plasma electrolyte concentrations remain within normal range with this solution compared with the marked hypernatremia and hyperchloremia observed when 0.9% saline is administered enterally.[35]

Although normal horses can tolerate up to 10 L hourly, it is usually not possible to administer more than 5 L every 2 hours to horses with impactions, because they start to reflux when more fluid is given.[37] As a consequence, intermittent intubation allows administration of approximately 60 L of fluids per day. When continuous enteral fluids are given, a greater rate of administration is tolerated, and horses can be given between 4 and 10 L/hr. At the higher rate of 10 L/hr, mild signs of abdominal pain were observed in normal horses, and in horses with large colon impaction, a rate of 5 L/hr is better tolerated.[36] In one study, right dorsal colon ingesta hydration was significantly increased after enteral fluid therapy compared with intravenous fluid therapy combined with enteral administration of magnesium sulfate.[38]

FLUIDS USED FOR RESUSCITATION

Isotonic Crystalloids

Isotonic crystalloid fluids are administered intravenously and immediately reconstitute the circulating volume. However, because they are crystalloids, they are distributed to the entire extracellular compartment within a matter of minutes. Because the ECF compartment is approximately 3 times the volume of

blood, three times as much isotonic crystalloid must be administered to gain the desired amount of circulating volume expansion. As an example, if blood loss is estimated at 30% of blood volume, representing 12 L for a 500-kg horse, then 36 L of a crystalloid fluid is required. An estimated shock dose for crystalloids is therefore 60 to 90 mL/kg/hr.

Hypertonic Crystalloids (7.2% NaCl)

Hypertonic crystalloid fluids (7.2% NaCl) have approximately 8 times the tonicity of plasma and ECF (composition: Na^+, 1200 mOsm/L; Cl^-, 1200 mOsm/L). Their immediate effect is to expand the vascular volume by redistribution of fluid from the interstitial and intracellular spaces. Each liter of hypertonic saline will expand blood volume by approximately 4.5 L. However, this effect is short-lived. As the electrolytes redistribute across the ECF, fluids shift back and the patient once again becomes hypovolemic. Because the principal effect of hypertonic saline is fluid redistribution, there still exists a total body deficit, which must be replaced. The duration of effect of hypertonic solutions is directly proportional to the distribution constant, which is the indexed cardiac output. In horses, the duration of effect is estimated at approximately 45 minutes. The recommended dosage is 4 mL/kg or 2 L per 500 kg horse, administered as rapidly as possible. Because of its short duration of effect, hypertonic saline administration must be followed with isotonic volume replacement at shock doses (see earlier).

Colloids

Colloids are fluids that contain a molecule that can exert oncotic pressure. These molecules do redistribute to the ECF, but at a much slower rate than crystalloids, so the effect is prolonged compared with crystalloids. Hetastarch, because of its long duration of effect, is the most commonly used fluid for volume expansion in horses. Each liter of administered colloid will further expand the circulating blood volume by approximately 1 L, resulting in a total fluid expansion of 2 L. If hetastarch is used at a dosage of 10 mL/kg or 5 L per 500 kg horse, the resulting increased colloid pressure will be significant for up to 120 hours in horses.[9] For shock therapy, the combination of hypertonic saline at 4 mL/kg and hetastarch at 4 mL/kg will prolong the resuscitation efforts and be more beneficial than either fluid alone.[39,40]

MATERIALS FOR FLUID ADMINISTRATION

Intravenous Catheters

Intravenous catheters are available in varying materials, constructs, lengths, and diameters (Tables 3-7 and 3-8). In choosing a catheter, the desired fluid rate, the fluid viscosity, the length of time the catheter will remain in the vein, the severity of the systemic illness, and the size of the animal should be considered. The rate of fluid flow is proportional to the diameter of the catheter and inversely proportional to the length of the catheter and the viscosity of the fluid. Standard adult horse catheter sizes are usually 14 gauge in diameter and 13 cm (5.25 inches) in length. For more rapid administration rates (shock), a 12- or 10-gauge catheter should be used. Plasma and blood products flow more slowly because of their increased viscosity, so if volume replacement is also needed, administration of these fluids can be combined with a BES. Teflon catheters should be changed every 3 days, whereas polyurethane catheters may remain in the vein for up to 2 weeks. Horses that are very ill (bacteremic, septicemic, endotoxic) are more likely to encounter catheter problems and benefit from polyurethane or silicone catheters.

The catheter construction needs also to be considered (see Table 3-8). Through-the-needle catheters are most common for standard size adult horses. An over-the-wire catheter is best for foals and miniature horses or when the lateral thoracic vein is

TABLE 3-7. Commercially Available Catheter Materials

Material	Comment
Polypropylene, polyethylene tubing	Highly thrombogenic
Teflon	Less thrombogenic
Polyurethane	Much less thrombogenic
Silastic	Least thrombogenic

TABLE 3-8. Catheter Constructs Commercially Available

Type	Description	Advantage	Disadvantage
Butterfly	Needle is attached to tubing	Ease of use	Laceration of vessel Vessel puncture Extravascular administration
Over-the-needle	Stylet is inside catheter for venipuncture	Available in large diameter	Limited length of catheter Insertion more difficult Break at junction of catheter and hub
Through-the-needle	Short needle is inserted, catheter is threaded through needle	All lengths available	Trocar must be removed or protected
Over-the-wire	Needle serves as guide to insert wire, which is the guide for catheter	Trocar is removed after catheter insertion Long catheters available Ensures proper catheter placement	More technical expertise required Expensive

catheterized. Short and long extension sets are available, as well as small- and large-bore diameters. It is best to use an extension that screws into the hub of the catheter, to prevent dislodgement. In horses with low central venous pressures, disconnection of the line may result in significant aspiration of air and cardiovascular collapse. Double extensions are also available when other medications need to be administered with the fluids.

Sites for Intravenous Catheterization in Horses

Common sites for insertion of intravenous catheters in horses include the jugular, lateral thoracic, cephalic, and saphenous veins. The lateral thoracic vein makes an acute angle as it enters the chest at the fifth intercostal space. Therefore a short (7.5-cm [3-inch]) or an over-the-wire catheter is best used when catheterizing this vein. When catheters are placed in any location other than the jugular vein, more frequent flushings (every 4 hours) are required, because these catheters tend to clot more easily. Limb catheters are usually bandaged, because they are more prone to dislodgment than jugular catheters.

Catheter Maintenance

In adult horses, catheters usually are not covered with a bandage but rather are sutured in place, so that any problem is quickly identified. Bandages may need to be applied in foals if they are tampering with the catheter. A triple antibiotic ointment or antiseptic skin sealant, an iodine/alcohol disinfectant solution (DuraPrep, 3M US, St. Paul, MN) (see Chapter 10), may be applied at the insertion site on the skin to decrease the risk of infection. Catheters should be flushed with heparinized saline (10 IU/mL) four times a day if they are not used for fluid administration. When administering a medication, the injection cap should be wiped with alcohol before insertion of the needle. The injection cap should be changed daily. All infected catheters should be cultured for identification of the causative organism and for possible nosocomial infection. In addition, culturing noninfected catheters at removal is a good practice in preventing hospital-wide nosocomial events.

Coil Sets and Administration Sets

Coil sets are used for in-stall fluid administration. They are essential as they allow the horse to move around, lie down, and eat without restraint. An overhead pulley system with a rotating hook prevents fluid lines from getting tangled.

Administration sets are used for short-term fluid or drug administration and are available at 10 drops/mL and 60 drops/mL. When using a calibrated fluid pump, care should be taken to use the appropriate set calibrated for the brand of pump. Long coiled extension sets may then be used to introduce fluids into the horse. Foal coil sets (18-French equine enteral feeding tube) are also available that deliver 15 drops/mL.

Pump Delivery

Calibrated pumps are available that allow delivery at various rates. These pumps have alarms that signal when air is in the line, fluid bags are empty, or there are problems with the catheter. The maximum fluid rate these pumps can deliver is 999 mL/hour, which is usually not rapid enough to provide fluid replacement in adult horses, but they are useful for foals or for constant-rate infusions. For large-volume fluid delivery, peristaltic pumps are available that can deliver up to 40 L/hr. These must be constantly supervised, because the pumps will continue to run even if fluids run out. Large-bore catheters should be used to prevent trauma from the jet effect on the endothelium of the vein.

Oral Feeding Tubes

Oral fluid administration offers a good alternative to intravenous fluid therapy in animals that require maintenance fluids because of an inability to swallow, or in horses with impaction colic. Enteral nutrition (see Chapter 6) can also be administered for complete or partial nutrition in foals and adults. Commercially available feeding tubes for foals, weanlings, and adults enable fluid or liquid diet supplementation while the horse continues to nurse or eat.

CHAPTER
4

Hemostasis, Surgical Bleeding, and Transfusion

Margaret C. Mudge

PHYSIOLOGY OF HEMOSTASIS

Physiologic hemostasis is required for the control of bleeding related to surgery and trauma. A delicate balance of procoagulant, anticoagulant, fibrinolytic, and antifibrinolytic activities is required for effective control of bleeding without pathologic thrombosis. Over the last two decades, our understanding of physiologic hemostasis has evolved to include the pivotal role of the cells, rather than just the coagulation factors. It is still useful to understand the more simplistic cascade model of coagulation, because this is the basis for many coagulation tests. The surgeon should be familiar with predisposing factors for bleeding and coagulopathy as well as management of the bleeding patient, including blood transfusion and topical hemostatic agents.

Blood Vessels and the Role of the Vascular Endothelium

The vascular endothelium is critical in preventing inapproriate clot formation. Healthy, intact endothelium has antiplatelet, anticoagulant, and fibrinolytic properties. Anticoagulation and fibrinolysis are discussed in further detail later in this chapter, but an initial understanding of the role of the endothelium is needed to understand how coagulation events are set in motion after vessel trauma.

The synthesis of prostacyclin (PGI_2) and nitric oxide (NO) is largely responsible for the antiplatelet properties of the endothelium. Both of these substances inhibit platelet aggregation, and NO also inhibits platelet adhesion.[1] The vasodilation induced by NO also helps to prevent clot formation by promoting low-turbulence blood flow. Platelet aggregation and adhesion are also prevented by enzymes on the endothelial surface that degrade adenosine diphosphate (ADP).

The electronegative charges on endothelium and platelets physically prevent adhesion. Additionally, endogenous heparin-like substances are present on the endothelial surface, contributing substantially to anticoagulation. Glycosaminoglycans act as cofactors for antithrombin, which inactivates thrombin and coagulation factors VIIa, IXa, Xa, and XIa. Endothelial cells also express thrombomodulin, tissue plasminogen activator, and tissue factor pathway inhibitor, contributing further to anticoagulation and fibrinolysis.

The immediate response of the blood vessel to injury is vasoconstriction. This is mediated through local signaling from damaged endothelial cells, perhaps through interruption of the release of endothelial-derived relaxation factors. Prompt vasoconstriction prevents unnecessary blood loss and promotes rapid fibrin formation. Alternatively, inappropriate or excessive activation of these procoagulant properties may play a role in the hemodynamic dysfunction and end-organ failure often

observed in severe endotoxemia or sepsis.[2] The endothelium is metabolically active and able to respond to changes in environment, including hypoxia, shear stress, pH, and trauma. When vessel injury occurs, endothelial cells can express tissue factor (TF) and downregulate expression of thrombomodulin, becoming procoagulant. Activated endothelial cells release von Willebrand factor (vWF) from the Weibel-Palade bodies, promoting platelet adhesion. Local vasoconstriction is a crucial component of primary hemostasis, along with platelet activation, adhesion, and aggregation, all leading to formation of a temporary platelet plug.

Platelets and Primary Hemostasis

The interaction of activated platelets with the exposed subendothelium of blood vessels is the basis of primary hemostasis. Platelets also play a key role in secondary hemostasis: once activated, they undergo conformational changes, exposing binding sites for specific coagulation factors.

Platelets are derived from the cytoplasm of bone marrow megakaryocytes. They contain dense granules, α-granules and lysosomes, which store the majority of platelet proteins needed for the initiation of coagulation. The α-granules are the largest and most prevalent storage granules, comprising the majority of the storage capacity of platelets. They contain a number of proteins involved in platelet aggregation and cohesion, including fibrinogen, factor V (FV), factor VIII (FVIII), fibronectin, vWF, platelet-derived growth factor (PDGF), and platelet factor 4. Dense granules store calcium, a common cofactor in platelet–phospholipid interactions, as well as ADP, adenosine triphosphate (ATP), and serotonin. Thrombin is the strongest stimulant for the release of the contents of the dense granules, but other agonists for release have also been reported. Platelet lysosomes contain predominantly acid hydrolases, responsible for degradation of unwanted cellular debris after complete activation of fibrin formation.[3]

The platelet is the initial responder to vascular damage and subsequent endothelial exposure. Platelet adhesion is mediated by expression of P-selectin on the activated endothelium and by the platelet receptor GPIbα, which attaches to vWF. Once attached to the endothelium, platelets rapidly change shape and provide an effective monolayer in what is known as the adhesion phase. This results in a primary platelet plug (primary hemostasis) that is responsible for preventing leakage of blood from the minute vessel defects that occur daily. If blood flow in this area remains nonturbulent, further platelet aggregation does not occur, and the monolayer generally suffices to plug the small defects or the area of vascular attenuation.[3]

With large vessel disruption, blood flow becomes quite turbulent, resulting in large platelet aggregates coating the exposed endothelium. Activation of platelets results in degranualation of platelet contents, releasing agonists. Thrombin, collagen, ADP, and thromboxane A_2 promote platelet activation. After the platelet plug bridges the gap between endothelial cells, prostacyclin, produced by neighboring healthy endothelial cells, prevents unwanted expansion of platelet aggregates by decreasing further ADP release. The activated platelet serves as a congregation site for the coagulation factors via the integrin $\alpha_{IIb}\beta_3$ receptor (see "Secondary Hemostasis and Models of Coagulation").

Secondary Hemostasis and Models of Coagulation

Secondary hemostasis involves the activation of soluble coagulation factors, ultimately resulting in formation of a stable fibrin clot. The traditional cascade model divides coagulation into intrinsic, extrinsic, and common pathways. These pathways are useful when interpreting *in vitro* plasma-based coagulation tests. The more recently described cell-based model of coagulation demonstrates that these traditional pathways are quite interconnected and are dependent on cell signals and receptors.

Coagulation Cascade

The coagulation cascade is the traditional model that describes the process of coagulation. This model is centered around the coagulation factors and is an excellent model for *in vitro,* plasma-based coagulation. The *intrinsic pathway,* or "contact activation" pathway, is initiated by the activation of factor XII (FXII) and subsequently factor XI through the exposure of blood to a negatively charged surface (Figure 4-1). Contact proteins such as high-molecular-weight kininogen (HMWK) and prekallikrein interact with FXII to acclerate its activation. Factor XIa (activated factor XI) in turn activates factor IX in the

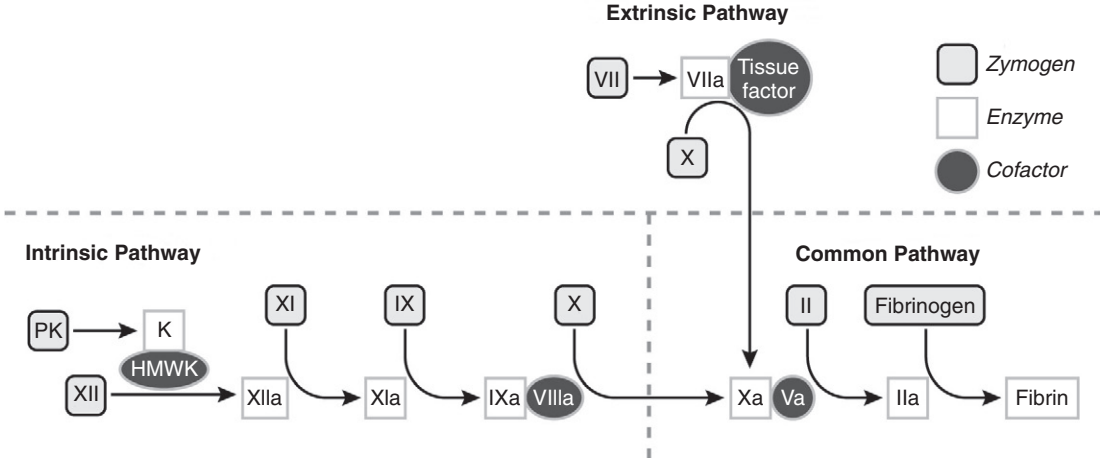

Figure 4-1. The traditional coagulation cascade: intrinsic, extrinsic, and common pathways. Roman numerals indicate factors. *HMWK,* High-molecular-weight kininogen; *PK,* prekallikrein.

presence of calcium. Factor IXa then binds to procoagulant VIIIa in the presence of calcium. It is this complex that activates the common coagulation pathway, marked by the activation of factor X.

The *extrinsic pathway* is initiated by the activation of factor VII by TF present in fibroblasts or other tissue factor–bearing cells. The TF-FVIIa complex activates factor X, leading into the common pathway. The common pathway is initiated by the activation of factor X, which, in the presence of activated factor V (Va), calcium, and a platelet phospholipid, converts prothrombin (factor II) to thrombin (IIa). In the final step of clot formation, factor IIa converts fibrinogen to fibrin. Factor XIIIa stabilizes the fibrin clot by cross-linking strands of fibrin monomer in the presence of calcium.

Cell-Based Model

Physiologic hemostasis occurs in three overlapping phases: initiation, amplification, and propagation.[4,5] The intrinsic and extrinsic coagulation pathways are still incorporated in this model, but the pathways are shown to be highly interconnected (Figure 4-2).

INITIATION

When there is disruption of the endothelium, tissue factor–bearing cells such as fibroblasts are exposed to blood, and coagulation is initiated. TF is the primary initiator of coagulation, and the first steps of coagulation are limited to the cell membrane. Under pathologic (inflammatory) conditions, TF can be upregulated on endothelium, monocytes, and other cells and cell particles. Factor VII circulates in plasma and is available to bind to TF, leading to activated FVII. The TF-FVIIa complex then activates factor X and factor IX. Although FXa in plasma is readily inactivated, the membrane-bound FXa can combine with FVa to produce small amounts of thrombin.

AMPLIFICATION

Once a small amount of thrombin is formed during initiation, the coagulation process can move to the platelet surface. The adherence, activation, and aggregation of platelets, along with the accumulation of activated cofactors, constitute the amplification of coagulation. Some platelets have already adhered to the site of injury, but thrombin fully activates platelets via protease-activated receptors. Factor V is present in the α-granules of the platelet, and during platelet activation, FV moves to the surface of the platelet. FV is then fully activated by thrombin and FXa. Thrombin cleaves vWF/FVIII, allowing vWF to stimulate platelet adhesion. FVIII is bound to the platelet surface and is available to continue the propagation phase of coagulation. FXI is also activated by thrombin on the platelet surface.

PROPAGATION

Coagulation complexes assemble on the activated platelet surface and the resulting generation of large amounts of thrombin leads to the propagation of the coagulation process. FIXa is able to reach the platelet surface via diffusion, since it is not inactivated by antithrombin (AT) and other plasma protease inhibitors. FIX is also activated on the platelet surface by FXIa. FIXa and FVIIIa combine as the tenase complex on the platelet surface, and subsequently activate FX on the platelet surface. FXa and FV combine to form the prothrombinase complex, which produces a thrombin burst.

Fibrinolysis

Simultaneous activation of the fibrinolytic system occurs with activation of coagulation. This is the primary mechanism of clot dissolution and is responsible for prevention of excessive fibrin deposition and restoration of nutrient blood flow to affected tissues. Fibrinolysis, in conjunction with prostacyclin released by surrounding healthy endothelial cells, inhibits unwanted expansion of the fibrin clot.

Plasminogen, an inactive zymogen produced primarily in the kidney and liver, is the principal component of the fibrinolytic system. Plasminogen activators such as tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA) convert plasminogen to plasmin. Plasmin degrades fibrinogen and fibrin into soluble fibrin(ogen) degradation products (FDPs).

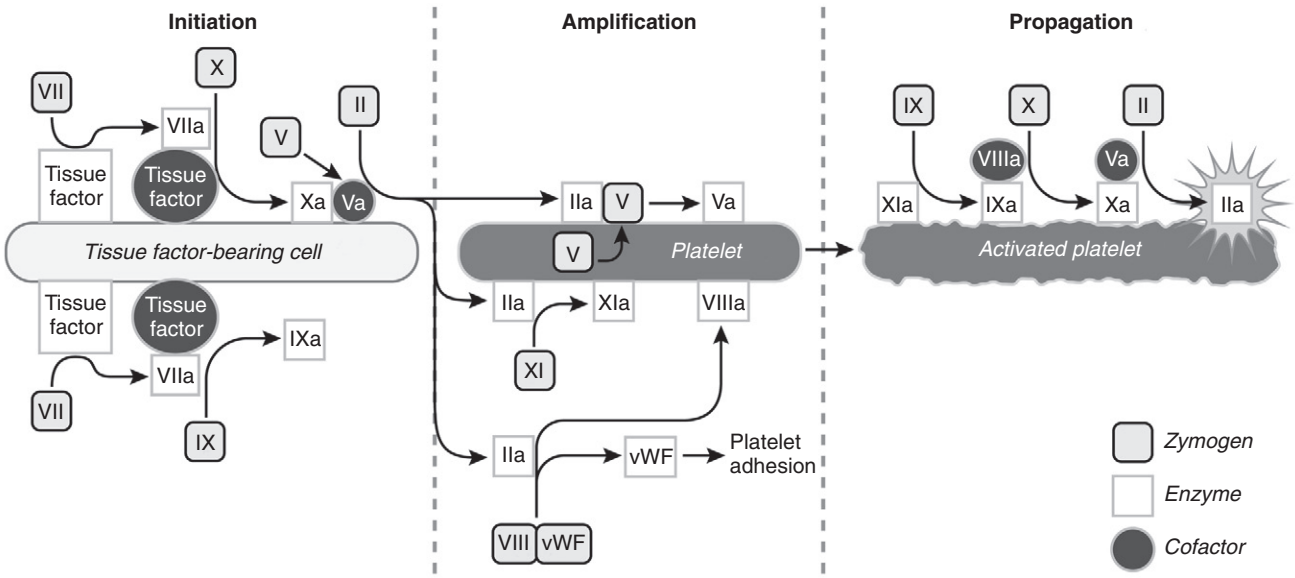

Figure 4-2. The cell-based model of coagulation: initiation, amplification, and propagation. Roman numerals indicate factors. *vWF,* von Willibrand factor.

The activation of the intrinsic pathway also activates plasminogen conversion to plasmin, through the action of kallikrein. Plasmin also inactivates other members of the coagulation cascade, such as factors Va and VIIIa, and actively degrades prekallikrein and HMWK. Through these mechanisms, plasmin not only degrades fibrin(ogen) but also downregulates coagulation.

The products of fibrinogen or fibrin degradation are the FDPs designated fragment X, fragment Y, and fragments D and E.[6] Plasmin degradation of cross-linked fibrin results in the D-dimer fibrin degradation product. These fragments are removed by the mononuclear phagocytic system of the liver, and accumulation of these fragments indicates increased fibrin production (and degradation) or liver dysfunction. During the maintenance of physiologic hemostasis, a critical balance between fibrin formation and degradation exists. Proper functioning of the fibrinolytic system controls unwanted clot expansion, prevents premature fibrin lysis, and provides appropriately timed restoration of nutrient blood flow to tissues. Increased levels of FDPs, D-dimers, or soluble fibrin monomer in the circulation lead to increased fibrinolysis. This can be interpreted either as being the result of a thrombogenic disease process, or as the patient being in a hypercoagulable state.

Inhibitors of Coagulation and Fibrinolysis

Inibitors of Coagulation

Inhibitors of coagulation are composed of a family of proteins that enzymatically bind with coagulation factors to form inactive complexes. In some instances, coagulation cofactors or surface receptors are destroyed to downregulate clot formation. The principal inhibitors of coagulation are antithrombin, heparin, protein C, protein S, and tissue factor pathway inhibitor (TFPI) (Table 4-1).

AT is responsible for 70% to 80% of thrombin inhibition in the coagulation system. It is the key player in a family of serine protease inhibitors responsible for modulation of clot formation. Antithrombin is a glycoprotein produced in the liver and in endothelial cells that binds aggressively to thrombin. A stable thrombin-antithrombin (TAT) complex is the result of this reaction, and this complex is removed by the reticuloendothelial system. The cofactor heparin alters the arginine site of AT and dramatically increases its ability to interact with thrombin. AT is also capable of neutralizing factors XIIa, XIa, Xa, and IXa. The AT–heparin complex also slowly inactivates factor VIIa.[7] The horse appears to have higher concentrations of AT than some other species, such as dogs and humans.[8]

Heparin is a highly sulfated glycosaminoglycan, ranging in molecular weight from 3 to 30 kDa. It is produced primarily in mast cells located in the lung, liver, kidney, heart, and gastrointestinal tract. Heparin causes a conformational change in AT, which increases the activity of AT 1000-fold.[7] Its presence in an area of coagulation activation decreases thrombin-generated fibrin formation significantly. Heparin also releases TFPI from endothelial cells, thereby liberating one of the most effective inhibitors of the factor VIIa-TF complex.

The thrombomodulin–protein C–protein S pathway has received a lot of attention in recent years. Protein C is a vitamin K–dependent zymogen with primary inhibitory action on factors Va and VIIIa. Protein C is activated by thrombomodulin-thrombin complexes. This reaction is potentiated by the endothelial protein C receptor, which is located mainly in large vessels. When activated protein C is released into circulation, it associates with protein S and is able to inactivate factors Va and VIIa. Activated protein C is also profibrinolytic, since it inhibits plasminogen activator inhibitor-1 (PAI-1) and indirectly inhibits thrombin-activatable fibrinolysis inhibitor (TAFI) as a result of thrombin inhibition.

TFPI is a group of lipoprotein-bound proteins produced primarily by platelets and endothelial cells. Heparin enhances the release of TFPI into the circulation. In the presence of calcium, TFPI inhibits factor VIIa-TF activation of factor X, thereby dramatically decreasing the primary cellular initiator of coagulation.

TABLE 4-1. Anticoagulation Factors and Their Inflammatory Effects

Factor Name	Action	Changes Associated with Inflammation
Antithrombin	Anticoagulant Inhibits factors VIIa, IXa, Xa, XIa, XIIa	Decreases
Protein C	Anticoagulant Inhibits factors Va, VIIa Decreases fibrinolysis	Decreases
TFPI	Anticoagulant Inhibit factors Xa and TF-VIIa complex	Variable
PAI-1	Antifibrinolytic Inhibits plasminogen	Increases
TAFI	Antifibrinolytic Reduces conversion of plasminogen to plasmin	Increases

PAI-1, Plasminogen activator inhibitor-1; *TAFI*, thrombin-activatable fibrinolysis inhibitor; *TFPI*, tissue factor pathway inhibitor.

Inhibitors of Fibrinolysis

PAI is the principal regulator of plasminogen through inhibitory effects on tPA (see Table 4-1). PAI is present in endothelial cells and is stored in α-granules of platelets.[9] The main physiologic inhibitor of plasmin is α-2-antiplasmin. An alternative inhibitor of plasmin, α-2-macroglobulin, may inhibit plasmin in a limited fashion, particularly if α-2-antiplasmin is overwhelmed. Prevention of premature fibrinolysis and clot dissolution is mediated principally through these inhibitors of plasminogen and plasmin. Another inhibitor of fibrinolysis, TAFI, is activated by thrombin, the thrombin-thrombomodulin complex, and plasmin. As a negative-feedback mechanism, plasmin can also activate TAFI.

Coagulation Testing

Screening tests consist of assays of primary and secondary hemostasis. Coagulation inhibitors and fibinolytic pathway inhibitors can also be assayed, including AT, FDPs, and D-dimer. Many point-of-care tests are available, and automated blood coagulation analyzers can perform a variety of coagulation tests, including activated partial thromboplastin time (APTT), prothrombin time (PT), fibrinogen, and AT testing (see later).

Tests of Primary Hemostasis

Defects in primary hemostasis are suspected with clinical signs of mucosal bleeding, petechiation, ecchymoses, and epistaxis. The platelet count is the first step in the evaluation of primary hemostasis. Horses tend to have lower platelet counts than other species, typically in the 150,000 to 250,000/μL range. A platelet count of less than 100,000/μL is considered abnormal, although clinical bleeding may not be seen until the platelet count is below 30,000/μL.

Platelet function tests should be performed when there are clinical signs of thrombocytopenia with a normal to increased platelet count. Template bleeding time (TBT) can be performed on the buccal mucosa or on the caudolateral aspect of the forelimb. TBT will be prolonged with thrombocytopenia, thrombocytopathia, and lack of vWF, and it may also be prolonged in cases of vasculitis. Unfortunately, TBT has been shown to have poor reproducibility and a very wide reference range in horses.[10] Additional platelet function tests include platelet aggregation studies and platelet function analysis (PFA-100, Siemens, Deerfield, IL). The PFA-100 has been validated in the horse.[11]

Prothrombin Time

PT measures the function of the extrinsic and common coagulation pathways. Platelet-poor plasma is mixed with thromboplastin and calcium, and time to clot formation is measured. Deficiencies in FV, FVII, FX, prothrombin, and fibrinogen can result in prolonged PT. Typically, an increase in time by 20% indicates an abnormal test result. In human patients, PT becomes prolonged when fibrinogen is less than 100 mg/dL, prothrombin is less than 30% of its normal plasma concentration, or factors VII, V, and X are decreased to 50% of their normal concentrations.[12]

Activated Partial Thromboplastin Time

APTT measures the function of the intrinsic and common coagulation pathways. The test is performed by adding an activating agent to platelet-poor plasma in a glass tube containing phospholipid emulsion and calcium. Deficiencies of FXII, FXI, FX, FIX, FVIII, FV, prothrombin, and fibrinogen can result in prolonged APTT. FXII, HMWK, or prekallikrein deficiencies can prolong APTT but are not associated with bleeding tendencies in humans.[13] As with PT, an increase in time by 20% is usually considered abnormal.

Both PT and APTT serve as variables to evaluate the coagulation cascade portion of the hemostatic system. Although PT and APTT are certainly useful indications of significant problems with the coagulation cascade, they may not be sensitive enough to adequately identify early stages of hypercoagulability or DIC. Prolonged PT or APTT may be associated with body cavity bleeding, significant hematuria, or hematochezia. Normal reference ranges for PT and APTT should be established for individual laboratories, and separate reference ranges for neonatal foals should be determined.

Activated Clotting Time

Activated clotting time (ACT) measures the time required for whole blood to clot after contact with diatomaceous earth, simulating the intrinsic and common coagulation pathways. Blood is collected directly into a tube containing the diatomaceous earth and is incubated at 37° C. The ACT will be prolonged with deficiencies of FVIII, FIX, prothrombin, and fibrinogen. ACT has the advantage of being a rapid, patient-side test; however, it is less sensitive than APTT for coagulation factor deficiencies.

Anticoagulant Testing

AT is the most commonly measured anticoagulant. It is measured by chromogenic assay in an automated analyzer, and results are reported as a percentage of activity. A decrease in AT levels may occur through consumption via increased thrombin formation; through protein loss, such as nephropathies or enteropathies; or via failure of adequate production. Protein C can also be measured with a chromogenic assay. Decreased AT and protein C levels are associated with hypercoagulability. AT is an acute phase reactant, so AT levels may be increased with some acute inflammatory conditions.

Thrombin-antithrombin (TAT) is an irreversible inactive complex between thrombin and antithrombin. TAT levels can be measured using a sandwich enzyme-linked immunosorbent assay (Enzygnost), which has been evaluated and validated for use in the horse.[14] Activation of coagulation and the procoagulant state result in elevated plasma levels of TAT. In human patients, TAT is elevated in states of disseminated intravascular coagulation (DIC) and sepsis.[15]

Fibrin(ogen) Degradation Products

FDPs are produced by the proteolytic degradation of fibrin(ogen) by plasmin. They are routinely cleared by the mononuclear phagocytic system (MPS), and an accumulation of FDPs indicates a failure of the MPS to adequately remove them from the circulation. This can be the result of local or systemic hyperfibrinolysis, and it may be indicative of a dramatic increase in clot formation. FDP evaluation is usually performed as a semiquantitative test, resulting in the following possible ranges for FDPs: 0 to 10 μg/mL, 10 to 20 μg/mL, 20 to 40 μg/mL, or greater than 40 μg/mL, with FDPs greater than 10 μg/mL considered abnormal. An evaluation of FDP assays in horses with severe colic demonstrated that FDP assays had a very low sensitivity and were not useful for the diagnosis of DIC in this patient population.[16]

Fibrinogen

The measurement of fibrinogen as part of a standard coagulation profile is an attempt to document hypofibrinogenemia, which is a somewhat consistent feature of overt DIC in humans. Fibrinogen can be measured by the heat precipitation method, von Clauss technique, or automated photometric detection. It is not unusual for human patients with significant hemostatic dysfunction to develop a fibrinogen level of less than 100 mg/dL. This does not seem to be a consistent feature of DIC in the horse, however, since fibrinogen increases with inflammatory conditions.[17,18] Horses with DIC do not consistently demonstrate true hypofibrinogenemia, but they do have lower fibrinogen concentration than would be expected for horses with inflammatory conditions.[19]

D-Dimer

D-dimer is an epitope resulting from the plasmin degradation of fibrin. It is a cross-linked dimer of the two smallest fibrin degradation products, fragment D-D. The D-dimer assay is specific for plasmin degradation of fibrin, as opposed to FDPs, which indicate degradation of either fibrin or fibrinogen. D-dimer can be measured semiquantitatively by latex agglutination or by latex-enhanced turbidimetric immunoassay performed on a standard coagulation analyzer.[16] Increased D-dimer levels indicate increased fibrinolysis or inability to clear the products from the circulation. In critically ill human patients, D-dimer has been used to better characterize acute pulmonary thromboembolism and to diagnose deep vein thrombosis. D-dimer can be increased in horses as a physiologic response to the primary disease or surgical procedure or as a pathologic coagulopathy.

Viscoelastic Monitoring

Viscoelastic analyzers may hold some promise for evaluation of coagulation in the veterinary surgical patient. Thromboelastography (TEG), rotational thromboelastometry (ROTEM), and the Sonoclot analyzer are three currently available analyzers that use viscosity, elasticity, or both to evaluate clot formation in whole or citrated blood samples. These analyzers evaluate all phases of clot formation and retraction from a single small volume (i.e., 330 µL) of blood. A tracing or signature is provided from which values can be derived to assess platelet or coagulation function. Software is provided with each analyzer, resulting in a user-friendly interface and easy storage of data.

In human surgical patients, viscoelastic analyzers are most commonly used as point-of-care testing to monitor coagulation inhibition during cardiopulmonary bypass procedures and liver transplantations and to evaluate perioperative hemorrhage. TEG has been used to identify hypercoagulable states in dogs with parvoviral enteritis, neoplasia, and immune-mediated hemolytic anemia.[20-22] Normal values have been reported for adult horse TEG and neonatal foal Sonoclot, and viscoelastic testing has been used in populations of septic foals and adult horses with gastrointestinal disorders.[23-28] There appears to be significant individual variation in TEG values in horses, and this variability may limit the use of TEG as a first-line point-of-care coagulation test.

HEMOSTATIC DYSFUNCTION

Hypocoagulability with subsequent surgical bleeding may be related to an inherited condition in the patient or to an acquired coagulopathy or thrombocytopathy. Hemostatic dysfunction may also consist of hypercoagulability, thrombotic tendencies, and DIC, especially associated with acute inflammatory diseases.

Inherited Conditions

Inherited conditions that result in coagulopathy or thrombocytopathy are relatively uncommon in the horse and much more common in the dog, cat, and human. These conditions include von Willebrand disease, thrombasthenia, hemophilias, and specific coagulation factor deficits. In horses, deficits of prekallikrein and of factors VIII, IX, and XI have been reported.[29,30] These may be difficult to detect preoperatively; a thorough history obtained from the client or observation of clinical signs may indicate a need for specific coagulation testing. If a deficit is identified, adequate preparation for surgery is critical, possibly consisting of pretreatment with plasma or component therapy.

Acquired Conditions

Acquired conditions resulting in hemostatic dysfunction may manifest clinically as DIC or as a specific coagulopathy or thrombocytopathy. Hemostatic dysfunction can be the result of inappropriate use of heparin (particularly unfractionated), aspirin, or other anticoagulants. The administration of certain drugs such as sulfonamides, penicillin, phenylbutazone, ibuprofen, estrogens, antihistamines, and cardiovascular drugs has been associated with thrombocytopenia in humans and animals. Other diseases associated with hemostatic dysfunction in the horse are severe liver disease, equine infectious anemia, *Anaplasma phagocytophilum*, and equine viral arteritis. In general, if any acquired condition that could result in a coagulopathy is noted in the history or detected in the clinical progression of a surgical candidate, appropriate and complete evaluation of the hemostatic system must be performed. If the surgeon is presented with an emergency situation, arrangements should be made for the availability of a blood donor or possible component therapy to attenuate the situation.

Inflammation and Coagulation

Hemostatic dysfuction has long been recognized in horses with severe inflammatory diseases such as gastrointestinal disease and sepsis, and there is a growing body of evidence that demonstrates the intricate interplay between inflammation and coagulation. Severe inflammation can cause increases in coagulation, decreases in anticoagulation, and inhibition of fibrinolysis, resulting in a *procoagulant state*. Cytokines and endotoxin can induce increased expression of tissue factor on monocytes, macrophages, and microparticles.[7,31] Endotoxin and proinflammatory cytokines can also activate platelets and induce the release of vWF from endothelium. Levels of AT are decreased as a result of impaired synthesis, increased consumption (because of increased thrombin generation), and negative acute-phase response. Protein C also decreases as a result of increased consumption, decreased production by the liver, and decreased activation by thrombomodulin. Fibrinolysis is impaired because tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) stimulate an increase in PAI-1. Coagulation derangements can acually contribute to further inflammation, since AT and protein C have anti-inflammatory effects. Activation of protease-activated receptors during coagulation also enhances inflammation through increased production of TNF-α, IL-6, and IL-8.[31]

This procoagulant state induced by inflammatory conditions can lead to DIC. The initial hypercoagulable state does not commonly lead to clinically evident thrombotic events in horses, except for catheter-related jugular thrombophlebitis.[32] There are only single reports of a few cases of thrombosis (distal limb and pulmonary) related to gram-negative bacteremia or endotoxemia.[33,34] In the early stages of DIC (subclinical), there will be clinicopathologic evidence of platelet consumption, coagulation factor consumption, and hyperfibrinolysis. With severe activation of coagulation, DIC can lead to massive fibrin deposition in tissues in the lungs, liver, and kidneys, potentially

leading to multiorgan failure.[35] The syndrome of DIC places patients at risk of bleeding if intravascular coagulation is severe enough to result in coagulation factor depletion and thrombocytopenia, although the bleeding form of DIC is rare in the horse. Primary diseases that could result in DIC and that may be encountered by a surgeon include neoplasia, sepsis, trauma, severe acute hemorrhage, clostridial myositis, and severe endotoxemia associated with acute gastrointestinal disease.

The diagnosis of DIC requires the horse to have a primary disease that places it at risk, as well as clinicopathologic evidence of coagulopathy. The testing recommended for diagnosis of DIC includes platelet count (thrombocytopenia), clotting times (prolonged PT and APTT), fibrinogen concentration (decreased), and D-dimer concentration or FDPs (increased).[36] Scoring systems have been developed to aid in the diagnosis of DIC in human and canine patients, but there is not a comparable consensus scoring system for the equine patient.[37,38]

Reports of DIC in the equine veterinary literature most commonly describe the process as occurring secondary to a gastrointestinal disorder. Earlier reports describe clinical DIC, in which horses had overt clinical signs such as epistaxis, surgical bleeding, and venipuncture bleeding, whereas more recent reports have documented larger numbers of horses with subclinical DIC (an abnormal coagulation profile but lacking signs of a thrombohemorrhagic crisis).[17,19,39,41] Ischemic and inflammatory conditions of the large colon are most commonly associated with clinicopathologic coagulopathy, but simple obstructions such as large colon impaction are rarely associated with coagulopathy. Approximately one third of horses presenting to a referral facility with acute colitis had evidence of subclinical DIC, defined as abnormal findings in at least three of six coagulation tests.[19] The coagulation testing included platelet count, fibrinogen, PT, APTT, AT, and FDPs. Horses with subclinical DIC were 8 times more likely to die than those without evidence of DIC. Although fibrinogen was not below the reference range in coagulopathic horses, it was lower in horses with DIC compared to horses with no evidence of DIC, and fibrinogen decreased over the first 48 hours of hospitalization in nonsurvivors. Despite the frequent diagnosis of subclinical DIC, none of these horses with acute colitis demonstrated a clinical bleeding condition.

Horses with large colon volvulus commonly demonstrate subclinical DIC, with 70% reported to have at least three of six coagulation tests abnormal.[41] In this group of horses, development of prolonged PT, increased TAT, and thrombocytopenia were associated with a poor prognosis. Horses with four of six abnormal coagulation tests were also more likely to be euthanized. Other investigators have demonstrated that increased TAT, PT, APTT, PAI-1 and FDPs and decreased AT, protein C, and platelet count are associated with nonsurvival in horses with colic.[14,18,42-46]

Neonatal foals with sepsis have been shown to have a high incidence of clinicopathologic coagulopathy. Compared to healthy foals, septic neonates have prolonged PT and APTT; increased levels of fibrinogen, FDPs, α-2-antiplasmin, and PAI-1; and decreased levels of AT and protein C.[47] Foals with septic shock were reported to have coagulopathy (at least three abnormal coagulation tests) in 25% of cases, with 67% demonstrating clinical bleeding disorders, including petechiation and epistaxis.[48] Septic foals (not in shock) had clinical signs of bleeding in 39% of cases. Because horses with inflammatory conditions such as gastrointestinal disease and sepsis are at risk of coagulation abnormalities, hemostasis testing should be strongly considered in these patient populations, and treatment should be initiated if indicated.

Treatment of DIC

Since DIC is not a primary disease, there is no specific treatment that will effectively reverse the process of coagulopathy. Identification of horses at risk and aggressive treatment of the primary underlying disease are the best strategies for preventing DIC. Prevention and treatment of endotoxemia, including treatment with hyperimmune plasma, polymyxin B, and nonsteroidal anti-inflammatory drugs, are reasonable strategies for prevention of DIC (see Chapter 2). In both human and veterinary patients, plasma and platelet transfusions are recommended in cases with active bleeding or with a high risk of bleeding (e.g., surgical procedure).[49,50] Transfusions with specific coagulation factors such as prothrombin complex concentrates are not recommended as prophylactic treatment in nonbleeding human patients, because the addition of activated factors may worsen intravascular coagulation.[50] Antithrombin concentrate is not available for horses, but treatment with fresh frozen plasma will provide AT, an anticoagulant factor, which is frequently decreased in critically ill and septic horses.

Anticoagulant treatment early in the course of DIC may limit the activation of coagulation. Heparin is the anticoagulant most commonly used for this purpose in human and veterinary medicine. Heparin increases the activity of AT, thereby inhibiting thrombin and factor Xa. Low-molecular-weight heparin (LMWH) has greater inhibition of FXa, dose-dependent clearance, and a longer half-life than unfractionated heparin (UFH).[51] In horses, administration of UFH has been associated with prolonged APTT and decreased packed cell volume (PCV), whereas these side effects are not seen with administration of LMWH.[52] The following regimen is recommended: heparin calcium, 150 IU/kg SQ initially, then 125 IU/kg SQ q12h for 3 days, followed by 100 IU/kg SQ q12h. When using sodium heparin, a dose of 40-80 units/kg q12h is recommended. The following regimen for LMWH is recommended: Dalteparin 50 to 100 anti-Xa units/kg SQ q24h; enoxaparin 40 to 80 anti-Xa units/kg (0.35 mg/kg) SQ q24h. Although the use of heparin has been reported for treatment of DIC in horses, there are no controlled studies to evaluate treatment of DIC in horses.[17] There is some evidence to support heparin anticoagulant treatment for DIC in human patients; however, studies indicate that the use of exogenous heparin may negate some of the beneficial anti-inflammatory effects of AT, which are mediated via endogenous heparans on the endothelium.[53,54] Treatment with recombinant human activated protein C was shown to be beneficial in human patients with severe sepsis and DIC.[55] A recombinant equine protein C is not available, and therefore this drug has not been evaluated in horses.

Risk of Surgical Bleeding

Certain surgical procedures in equine surgery are associated with a significant risk for intraoperative and postoperative hemorrhage. Surgery involving the sinuses or ethmoid area, the cranial reproductive tract, the spleen, or certain neoplasias may result in significant intraoperative hemorrhagic challenges. Because some of these surgeries can be performed electively, careful preoperative planning may alleviate many of the complications of

perioperative hemorrhage. Options include planned autologous transfusion and normovolemic or isovolemic hemodilution, preoperative crossmatch and subsequent whole blood transfusion (see later), or availability of stored blood products and components. Autologous transfusion and normovolemic hemodilution involve collection of the patient's blood in the weeks before surgery (banking) or in the immediate preoperative period, followed by administration of crystalloids before induction. Throughout any surgical procedure, it is critical to employ proper hemostatic techniques (see Chapter 12).

BLOOD TRANSFUSION

Indications

Whole Blood

Whole blood (WB) transfusions are most often indicated for horses that have suffered acute blood loss from trauma, surgery, or other conditions such as splenic rupture or uterine artery hemorrhage. In cases of blood loss, the transfusion serves to restore blood volume as well as oxygen-carrying capacity. Although there are no set variables that serve as "transfusion triggers," a combination of physical examination and clinicopathologic parameters can be used to guide the decision to transfuse. It is important to remember that the PCV may remain normal for up to 12 hours following acute hemorrhage because of the time required for fluid redistribution and the effects of splenic contraction. Serial monitoring of PCV and total solids (TS) as the horse is rehydrated with intravenous fluids will give an indication of the extent of blood loss. Suspicion of large-volume blood loss, combined with tachycardia, tachypnea, pale mucous membranes, lethargy, and decreasing TS may lead to the decision to transfuse.[56] A blood transfusion is likely needed during an acute bleeding episode when the PCV drops below 20%, although in acute severe cases, transfusion may be needed before there is a significant drop in PCV.

Estimation of blood loss at surgery can be used to guide the decision to transfuse, with loss of greater than 30% of blood volume generally requiring transfusion.[57] Anesthetized horses may have very stable heart rate and PCV despite massive blood loss; pale mucous membranes with prolonged capillary refill time (CRT), decreasing TS, hypotension, and hypoxemia are better indicators of blood loss.[58]

Oxygenation status can help to determine the need for blood transfusion in cases of both acute hemorrhage and chronic anemia. A rise in blood lactate concentration despite volume replacement with crystalloid or colloid fluids may indicate continued tissue hypoxia and a need for blood transfusion.[59,60] Oxygen extraction ratios are also useful measures; a ratio greater than 40% to 50% in the context of blood loss may indicate a need for blood transfusion (Box 4-1).[61]

Transfused red blood cells (RBCs) have been reported to have a very short half-life; however, a recent study indicates that autologous transfused red blood cells have longer survival than originally reported, and allogeneic (donor) transfused RBCs may also have a longer half life than was reported in the original chromium label studies.[62-64] Red blood cells from allogeneic transfusions do have a much shorter half-life than autologous red cells, so transfusion should still be considered a temporary measure to restore oxygen-carrying capacity, relying on the horse's erythropoeitic response or resolution of underlying disease to provide long-term resolution.

Box 4-1. Formulas

OXYGEN EXTRACTION RATIO

O_2 ER = ~(SaO_2 – SvO_2)/SaO_2

O_2 ER = Oxygen extraction ratio

SaO_2 = Arterial oxygen saturation

SvO_2 = Mixed venous oxygen saturation

BLOOD TRANSFUSION VOLUME (L)

Body weight (kg) × 0.08 × [(Desired PCV – Actual PCV)/Donor PCV]

PLASMA TRANSFUSION VOLUME (mL)

Body weight (kg) × 45 mL/kg × [(Desired TP – Actual TP)/Donor TP]

ER, Extraction ratio; *PCV,* packed cell volume; *TP,* total protein.

Fresh whole blood can also provide platelets, though generally not in concentrations high enough to treat severe thrombocytopenia. For patients with primary thrombocytopenia or thrombocytopathia, platelet concentrates can be given. Platelet concentrates can be obtained by plateletpheresis or by centrifugation using a slow-spin technique.

Packed Red Blood Cells

Packed red blood cells (pRBCs) are indicated for normovolemic anemia, such as neonatal isoerythrolysis, erythropoietic failure, and chronic blood loss. In cases of chronic or hemolytic anemia, markers of tissue oxygenation, such as lactate and oxygen extraction are still useful. PCV is a better "transfusion trigger" for chronic anemia compared to acute hemorrhage, with transfusions suggested for horses with evidence of tissue hypoxia and a PCV less than 10% to 12%. Transfusions may be given at a higher PCV for horses with concurrent conditions (e.g., respiratory disease, anesthesia, sepsis) or risk of further blood loss. When pRBCs are not available, WB may be used for the same indications, although attention should be paid to the total volume given so that volume overload is avoided.

Plasma

Plasma transfusion is indicated for the treatment of clotting factor deficiency, hypoalbuminemia, and neonatal failure of transfer of passive immunity. Fresh and fresh frozen plasma (FFP) contain immunoglobulins, coagulation factors (fibrinogen and factors II, VII, IX, X, XI, and XII), and cofactors (factors V and VIII), and the anticoagulant proteins antithrombin, protein C, and protein S. Plasma has also been used for treatment of DIC in horses.[17]

Colloid support is generally recommended in patients with a total protein less than 4.0 g/dL or serum albumin concentration less than 2.0 g/dL. Other indications for colloid support are colloid oncotic pressure less than 14 mm Hg, clinical signs such as ventral edema, and conditions that increase microvascular permeability, such as sepsis. When plasma is not necessary for clotting factor replacement, a synthetic colloid such as hydroxyethyl starch (hetastarch) is preferred for volume expansion and more effective oncotic support. For more information on this subject please review Chapter 1.

Preoperative evaluation of neonatal foals should include testing IgG concentration. Failure of transfer of passive

immunity (FPT) in neonatal foals greater than 12 hours of age is best treated by plasma transfusion, because colostrum absorption is greatly diminished after 12 hours.[65] An IgG concentration less than 200 mg/dL is considered complete FPT, and IgG between 400 and 800 mg/dL is considered partial FPT. Although plasma transfusion is not always needed for foals with partial FPT, it is recommended for foals that have preexisting infection or exposure to pathogens. Commercially available fresh frozen hyperimmune plasma is most commonly used for treatment of neonatal foals. Equine FFP is licensed by the U.S. Department of Agriculture, and most products have a minimum guarantee for IgG concentration and a 2- to 3-year shelf life when frozen. Although commercially available hyperimmune plasma has very high IgG concentrations (1500 to 2500 mg/dL), plasma from local donor horses may provide better protection against specific local pathogens.

There are multiple hyperimmune plasma products with bacterial- or viral-specific antibodies. There is some evidence for the efficacy of *Escherichia coli* (J5) and *Salmonella typhimurium* hyperimmune plasma for the treatment of equine endotoxemia; however, there are also reports that dispute the efficacy of such products.[66,67] The use of *Rhodococcus equi* hyperimmune plasma for the prevention of *R. equi* infection has also been controversial.[68,69] Other plasma products available for specific disease treatment include botulism antitoxin, West Nile virus antibody, and *Streptococcus equi* antibody.

Oxyglobin

Oxyglobin is a hemoglobin-based oxygen-carrying solution that is indicated for treatment of anemia. Oxyglobin has been used experimentally in ponies with normovolemic anemia.[70] In this study, Oxyglobin improved hemodynamic and oxygen transport parameters; however, one pony had an anaphylactic reaction. The use of Oxyglobin was also reported for treatment of a pony mare with chronic hemorrhage and a history of acute transfusion reactions.[71] Although Oxyglobin is currently commercially available, the cost and volume (125 mL) per bag limit its utility for equine treatment.

Donor Selection and Management

There are 8 recognized equine blood groups, and 30 different factors identified within 7 of these groups.[72] Because of the large number of blood groups and factors, there are no true universal donors for horses. The ideal equine blood donor is a healthy, young gelding weighing at least 500 kg. Donor horses should be up-to-date on vaccinations, including rhinopneumonitis, tetanus, eastern and western equine encephalomyelitis, rabies, and West Nile virus. Donors should be tested annually for equine infectious anemia. Because RBC antigens Aa and Qa are the most immunogenic, the ideal donor should lack the Aa and Qa alloantigens. There are breed-specific blood factor frequencies, so a donor of the same breed as the recipient may be preferable, especially when blood typing is not available. Horses that have received blood or plasma transfusions and mares that have had foals are not suitable as donors because they have a higher risk of carrying RBC alloantibodies. Donkeys have an RBC antigen known as "donkey factor," which is not present in horses; therefore, donkeys or mules should not be used as donors for horses, because the horses receiving transfusion can develop anti–donkey factor antibodies.[73] In the referral practice setting, it may be practical to establish a group of blood donor horses. These donor horses should be blood typed and should also be tested for alloantibodies.

When a surgical procedure is planned in advance and there is a high risk of substantial blood loss, preoperative autologous donation should be considered, because the horse would be its own ideal blood donor.[74] The life span of transfused autologous RBCs after 28 days of storage is approximately 30 days, compared to a 14-day half-life for fresh, crossmatched allogeneic blood.[64,75] Intraoperative or posthemorrhage cell salvage is also an option for autotransfusion, and its use has been reported in a horse with postcastration hemorrhage.[76] RBC recovery can be performed with specialized cell salvage equipment, which washes and filters collected blood, but cell salvage can also be performed with simple anticoagulation and filtration.[77] The technique of cell salvage is limited to cases in which the salvaged blood is not in an area of infection or malignancy, unless specialized washing and filtering equipment is used.

Blood Typing and Crossmatching

In an emergency situation, an immediate blood transfusion may be given without a crossmatch for the first time, with a very minor risk of serious transfusion reaction. Horses can develop alloantibodies within 1 week of transfusion, so blood typing and crossmatching are recommended before a second transfusion is performed.[78] However, a second blood transfusion may be performed safely within 2 to 3 days of the first transfusion without a blood crossmatch.

Blood typing and alloantibody screening can be used to help find the most appropriate donor horse for the patient requiring transfusion. Unfortunately, since blood typing is time-consuming and laboratories performing blood typing are very limited, this is not often a practical method of donor selection. Blood typing and antibody screening before initial transfusion are more important for horses that may require subsequent blood transfusions and for broodmares that may produce foals with neonatal isoerythrolysis (NI) if sensitized to other blood group factors.[78] A rapid agglutination method for detection of equine RBC antigens Ca and Aa has been developed that may be a more practical method of pretransfusion testing.[79]

A blood crossmatch is recommended before a transfusion, especially for any horse that may have previously been exposed to RBC antigens. Hemagglutination crossmatching is widely available and rapidly performed; however, it will not predict all transfusion reactions, namely the hemolytic reactions. Rabbit complement can be added to the reaction mixture to detect hemolytic reactions.[80] The major crossmatch involves mixing the donor's washed red blood cells with the recipient's serum, whereas the minor crossmatch involves mixing the recipient's red cells with the donor's serum. If the minor crossmatch is incompatible, but the major crossmatch is compatible, the transfusion can still be performed after washing the donor red blood cells.

Blood Collection and Administration

Collection Technique

Blood is collected from the jugular vein of the donor horse, either via direct needle cannulation or catheterization. When a large volume of blood is needed, a 10- or 12-gauge catheter is recommended, although a 14-gauge catheter is also sufficient.

Blood flow may be improved by placing the catheter opposite the venous blood flow (catheter directed toward the head). A healthy horse can donate approximately 20% of its total blood volume every 30 days.[81] When 15% or greater blood volume is collected, volume replacement with intravenous crystalloid fluids is recommended. The donor horse's heart rate, respiratory rate, and attitude should be monitored during the blood collection. Vital parameters should normalize within 1 hour of collection.

Plastic bags and vacuum-collection glass bottles are available for blood collection in sizes ranging from 450 mL to 2 L. The glass bottles are preferred by many because of the speed of collection; however, the glass inactivates platelets and causes some damage to RBCs.[82,83] When blood is collected for immediate transfusion, anticoagulation with 3.2 % sodium citrate (1:9 anticoagulant to blood ratio) is adequate. However, when blood is stored for later transfusion, optimal pH and support of RBC metabolism are necessary to sustain RBC viability. Biochemical and hematologic parameters suggest that WB may be stored in citrate-phosphate-dextrose-adenine (CPDA)-1 bags for at least 3 weeks.[82] A posttransfusion viability study on equine blood stored for 28 days demonstrated a 24-hour labeled RBC survival of 73% and a half-life of 29 days.[64] RBC concentrates stored in saline-adenine-glucose-mannitol solution may be suitable for transfusion for up to 35 days after collection.[84] Blood should be stored in a dedicated blood bank refrigerator at 4° C.

Equine blood can be processed to provide plasma and pRBC components. Because of the rapid sedimentation of equine RBCs, the RBC component can be administered without specialized processing; however, the pRBCs will still contain plasma components unless centrifugation and repeated washing are performed. Washing of RBCs is the preferred technique when a transfusion is given to an NI foal using the mare as a donor. When RBC washing or other processing is planned, blood should be collected into bags rather than bottles because of ease of centrifugation and sterile transfer.

Plasma processing can be performed by gravity sedimentation, centrifugation using a double-bag system, or plasmapheresis. Plasmapheresis is the preferred technique because it is more rapid than WB collection and processing and yields plasma with minimal RBCs and leukocytes.[85] Plasmapheresis of 4 to 11 L can be performed every 30 days on donor horses.[86] Immunoglobulins are well-maintained for at least 1 year in FFP; however, coagulation factor activity may decrease after 2 to 4 months of storage.[87]

Administration and Adverse Reactions

The volume of blood to be transfused depends on estimated blood loss, estimated total blood volume, and donor PCV. In cases of acute blood loss, PCV is often not useful for estimates of volume to be transfused since it does not accurately reflect blood loss. Instead, estimates of blood loss and evaluation of clinical parameters are used to determine the volume of blood needed. From 25% to 50% of the total blood lost should be replaced by transfusion since much of the circulating volume will be replaced by fluid shifts. It is important to remember that up to 75% of RBCs lost into a body cavity (e.g., hemoperitoneum) are autotransfused back into circulation within 24 to 72 hours.[88] Therefore lower percentages of blood volume replacement may be needed in cases of intracavitary hemorrhage. The volume of blood required to treat horses with normovolemic or chronic anemia can be estimated based on the target PCV (see Box 4-1). Blood and plasma products should be delivered with an in-line filter to remove small clots and fibrin.

Volumes of plasma for treatment of hypoproteinemia can be estimated by total protein or albumin concentrations (see Box 4-1), although the use of plasma to normalize severe hypoproteinemia can be prohibitively expensive in the adult horse. Volume of plasma given for treatment of hypoproteinemia or coagulopathy is often determined by clinical and clinicopathologic response. A starting point for treatment of coagulapathy is approximately 4 to 5 mL/kg plasma. Follow-up monitoring with hemostatic testing is recommended to help determine the end point of treatment.

To facilitate monitoring for transfusion reactions, blood should be delivered at a rate of approximately 0.3 mL/kg over the first 10 to 20 minutes, while monitoring heart rate, body temperature, and respiratory rate. Horses should also be monitored for signs of muscle fasciculation, piloerection, and urticaria. Adverse reactions reported in horses receiving blood transfusions include urticaria, hemolysis, and acute anaphylactic reactions. The rate of adverse reaction to WB transfusion has been reported as 16%, with 1 of 44 horses (2%) having a fatal anaphylactic reaction.[56] If no signs of reaction are seen, the rate of administration can be increased to 5 mL/kg/hr for normovolemic horses and up to 20 to 40 mL/kg/hr for hypovolemic horses. If signs of anaphylaxis are present, epinephrine (0.01 to 0.02 mL/kg IV of 1:1000 solution) should be administered immediately. More mild transfusion reactions, such as urticaria, fever, and tachypnea, may be treated with an NSAID (e.g., flunixin meglumine 1.1 mg/kg IV) or an antihistamine (e.g., tripelennamine 1.1 mg/kg IM).

Similar to the risk in other veterinary species, bacterial contamination of blood, transmission of blood-borne disease from donor to recipient, and hypocalcemia associated with citrate toxicity are all potential concerns related to transfusion in the equine patient. An additional concern in horses is the possible sensitization of a broodmare to blood group antigens, leading to the risk of NI in subsequent foals.[78] Although plasma transfusions are not commonly associated with serious adverse reactions, serum hepatitis has been reported in association with transfusions of commercial plasma.[89]

TOPICAL HEMOSTATIC AGENTS

Topical hemostatic agents are needed for control of diffuse capillary bleeding from bone or parenchymal organs, such as liver or spleen. These agents can also be useful for control of bleeding during dental and nasal surgery. Surgical hemostasis techniques, including mechanical, thermal, chemical, and physical hemostasis are discussed in Chapter 12. This section will focus only on topical products available for augmentation of hemostasis. The most common veterinary use of topical hemostatic agents is in canine spinal surgery, and there are no specific equine studies available to guide the use of these hemostatic agents.

Mechanical Hemostatic Agents

These topical agents exert their main hemostatic effect by applying pressure on the area of diffuse bleeding. Some of these products also act as a scaffold for platelets and coagulation factors. The mechanical hemostatic agents are generally

appropriate for control of smaller areas of discrete bleeding rather than more severe bleeding. Although there are numerous topical hemostatic products on the market, the major long-standing products are described later.

Purified Gelatin Sponge

The gelatin sponge is made from purified animal gelatin. It binds well to tissue and exerts a hemostatic effect by swelling as it is soaked with blood. Gelatin sponges can be soaked in thrombin to help promote coagulation directly.[90] Gelatin sponges can potentiate infection, and their use should be avoided in contaminated wounds. This product is absorbed over a period of 4 to 6 weeks.

Oxidized Regenerated Cellulose

Oxidized regenerated cellulose is a chemically altered form of cellulose, which is particularly useful to control diffuse bleeding from broad surfaces. Surgicel has mechanical hemostatic effects as a result of swelling from blood absorption, and it activates coagulation on the collagen surface. Surgicel also acts as a caustic hemostatic agent because of its low pH. The low pH additionally confers antibacterial properties and therefore is preferred over gelatin foam for use in contaminated areas.[91] Surgicel should not be soaked in thrombin, because the biologic agents will be inactivated in the low-pH environment. The low pH may also lead to tissue inflammation and delayed wound healing, so any excess product should be removed from the surgical site. This product is absorbed in 7 to 14 days, although residue from the material may persist for several months to years.[92]

Microfibrillar Collagen Hemostatic Agents

Microfibrillar collagen agents (Avitene, Instat) are derived from bovine dermal collagen, and are available in fibrous (flour), sheet, and sponge forms. These products are absorbed in 8 to 10 weeks. Microfibrillar collagen agents do not swell, and they do not rely as much on their mechanical effect as does Gelfoam. The product does bind tightly to the bleeding surface, so there is likely some mechanical blockage of injured vessels. Platelets adhere to the collagen and are activated, and the resultant platelet degranulation and aggregation lead to hemostasis. These products are less effective in patients with thrombocytopenia.[93] Microfibrillar collagen products have been associated with allergic reactions in human patients, likely related to the bovine origin of the materials. Microfibrillar collagen can interfere with bacterial clearance and wound healing, and it is therefore recommended that it be removed from the surgical site before closure of the wound.[90]

Polysaccharide Hemostatic Agents

Microporous polysaccharide hemispheres (TraumaDex) have a porous surface that allows absorption of blood, thereby concentrating platelets and coagulation factors and reducing the time required for coagulation. This product is absorbable and does not appear to inhibit wound healing.[94] It does not appear to be as effective for severe arterial or venous bleeding compared to other topical hemostatic agents. Another type of polysaccharide, chitosin, is present in hemostatic dressings designed to control bleeding from traumatized extremities (HemCon Bandage).

Bone Wax

Bone wax is composed of beeswax and petroleum jelly and, as its name suggests, is used to control bleeding from bone surfaces. It mechanically stops blood flow from vessels in bone, and it does not have any biologic hemostatic effect. Bone wax inhibits bone healing, so it should not be used when fracture union is desired. It has also been shown to inhibit bacterial clearance from cancellous bone, and therefore it should not be used in areas of bacterial contamination or infection.[95] Bone wax has been reported to cause additional adverse effects such as allergic reaction, granulomatous reaction, and embolization.[90]

Adhesives and Sealants

Thrombin Products

Thrombin is available as a stand-alone product and is also a component of other biologic hemostatic agents.[92] Bovine-derived thrombin actively promotes coagulation by converting fibrinogen to fibrin and activating platelets. The stand-alone thrombin products (Thrombin-JMI) are packaged as a powder that is reconstituted for use. The liquid solution can be difficult to apply accurately during surgery. Thrombin is also available in a variety of combination preparations. A combination of human thrombin and collagen-derived gelatin matrix (FloSeal) is available as a "flowable" product, applied to the bleeding surface. Bovine-derived thrombin has been shown to induce antibody formation in human patients, especially to factor V. Recombinant human thrombin products are available, but similar veterinary recombinant products do not exist.

Fibrin-Based Sealants

These products are applied directly to the tissue and promote hemostasis by adhesion and formation of a fibrin clot, reducing the size of the open bleeding defect. Fibrin glues (TISSEEL) contain thrombin and fibrinogen, which are combined at the time of application through a dual-chamber syringe. Fibrin sealants replicate the last stage of coagulation and do not require that the patient have normal platelets or coagulation factors. Fibrin sealants are biodegradable and have not been associated with tissue inflammation or foreign body reaction.

CHAPTER 5

Wound Healing

Patricia J. Provost

CLASSIFICATION OF WOUNDS

Wound healing is inherent to all species and is the biologic process by which the body repairs itself after injury, whether it be traumatic or surgical. Understanding the basics of wound healing can improve patient outcome, reducing morbidity and often expense. Wounding may be restricted to the skin but often will involve underlying and adjacent tissues. Wounds have been traditionally classified as open or closed, and further as clean or contaminated.[1] These traditional classification schemes are useful because they provide a basis for general therapeutic guidelines. Closed wounds include crushing or contusion injuries, which at the time of impact do not have skin loss. However, substantial disruption to the underlying blood supply can occur, which may lead to future skin loss and often a prolonged recovery period. Open wounds can be classified by the type of trauma, such as abrasions, avulsions, incisions, and lacerations (Table 5-1); partial or full-thickness; or alternatively, they can be classified based on their potential for bacterial presence.[1]

Surgical wounds created under aseptic conditions are *clean* wounds. *Clean-contaminated* wounds are surgical wounds in which the respiratory, alimentary, or urogenital tracts are entered under controlled conditions without unusual contamination, whereas *contaminated* wounds are open, acute, accidental, or surgical wounds in which there has been a major break in sterile technique. *Dirty* or *infected* wounds are those that are old, have devitalized tissue, or have gross contamination with foreign debris. Clean, clean-contaminated, and contaminated wounds by definition contain less than 1×10^5 bacteria per gram of tissue, whereas those with greater than 1×10^5 are infected.[2] When in doubt, all nonincision open wounds should be handled as if they are infected, as should any incision from which there is purulent drainage. In the past, open wounds were often classified on duration since the time of injury and the degree of contamination: Class 1 (less than 6 hours duration with minimal contamination), Class 2 (6 to less than 12 hours duration with significant contamination), and Class 3 (longer than 12 hours duration with gross contamination).[3] This type of classification is less useful in equine veterinary medicine because all wounds regardless of the duration have the opportunity for marked contamination considering the environment in which horses live.

TABLE 5-1. Wound Classification

Classification	Description
Crush	Injury occurring when the body part is subjected to a high degree of force between two heavy objects.
Contusion	A blow to the skin in which blood vessels are damaged or ruptured.
Abrasion	Damage to the skin epidermis and portions of the dermis by blunt trauma or shearing forces.
Avulsion	Loss of skin or tissue characterized by tearing of the tissue from its attachments.
Incision	A wound created by a sharp object that has minimal adjacent tissue damage.
Laceration	An irregular wound created by tearing of tissue. Skin and underlying tissue damage can be variable.
Puncture	A penetrating injury to the skin resulting in minimal skin damage and variable underlying tissue damage. Contamination with dirt, bacteria, and hair is common.

Choice of wound closure primarily depends on the type of wound (i.e., puncture versus laceration) and the degree of contamination. Closure of open, full-thickness wounds may be by *primary*, *delayed primary*, or *secondary closure* techniques, or they may be left to heal by *second intention* (Table 5-2).[1] The decision to proceed with one method versus another is guided by the wound's location, its initial classification, and often the surgeon's past experience with similar injuries. The biology of wound healing is similar regardless of the choice of wound closure, but outcome results can be directly influenced, especially in horses, by knowledge of the processes involved.

PHASES OF WOUND HEALING

Wound healing is a dynamic process, similar in all adult mammalian species, that is initiated whenever there is a break in tissue integrity. The repair process involves complex interactions between cellular and biochemical events that coordinate healing (Tables 5-3 through 5-5), which are similar whether injury is confined to the skin or extends to deeper structures. Our understanding of what is occurring is continually evolving. This is especially true in the horse. For the sake of simplicity, the healing process has been divided into three phases: (1) the *inflammatory* or *lag* phase, which involves hemostasis and acute inflammation; (2) the *proliferative* phase, during which tissue formation occurs; and (3) the *remodeling* phase, during which the healing tissue regains strength.[4] These three phases overlap

TABLE 5-2. Wound Closure

Classification	Wound Type	Recommendations
Primary closure	Clean or clean-contaminated wound converted to clean wound	Immediate suture closure without tension
Delayed primary closure	Clean-contaminated or contaminated wound with questionable tissue viability, edema, skin tension	Performed 2-5 days after injury; tissue débridement and wound lavage before closure
Secondary closure	Contaminated or infected wound	Performed at least 5 days after injury; granulation tissue and epithelialized skin edges excised at the time of closure
Second intention healing	Wound tissue unsuitable for closure; large skin defect and/or extensive tissue devitalization	Healing by granulation tissue, wound contracture, and epithelialization

TABLE 5-3. Inflammatory Cells in Tissue Repair

Cell Type	Function	Mediators
PMN	Phagocytosis of microbes	Reactive oxygen species, cationic peptides, eicosanoids, proteases
	Macrophage activation	
	Amplify inflammatory response	TNFα, IL-1β, IL-6
	Stimulate repair process	VEGF, IL-8
Macrophage	Phagocytosis of PMN, damaged tissue, and microbes	TNFα, IL-1β, IL-6
	Amplify repair process	PDGF, VEGF, bFGF, TGF-α, and TGF-β
	Stimulate angiogenesis and fibroplasia	
	Fibrolysis	tPA, uPA (tissue and urokinase-type plasminogen activator)
Mast cell	Control vascular permeability	Histamine
	Control influx of PMN	Chymase, tryptase
	Regulate tissue remodeling	

bFGF, Basic fibroblast growth factor; *IL,* interleukin; *PDGF,* platelet-derived growth factor; *PMN,* polymorphonuclear; *TGF,* transforming growth factor; *TNF,* tumor necrosis factor; *VEGF,* vascular endothelial growth factor.

TABLE 5-4. Cytokines Involved in Wound Repair

Name	Abbreviation	Source	Major Function
Colony-stimulating factor	CSF	Macrophage, lymphocyte, fibroblast, endothelial cell	Differentiation and maturation of hematopoietic stem cells
Interferon	IFN	Monocyte, macrophage, lymphocyte, mesenchymal cell	Proinflammatory; release of other cytokines; inhibit fibrosis
Interleukin	IL	All nucleated cells, in particular macrophage and lymphocyte	Proinflammatory; enhances epithelialization, angiogenesis, and remodeling
Tumor necrosis factor	TNF	Macrophage, lymphocyte, mast cell	Proinflammatory; enhances angiogenesis, epithelialization, and remodeling
Connective tissue growth factor	CTGF	Fibroblast	Mediator of TGF-β activity (cell proliferation and ECM accumulation)
Epidermal growth factor	EGF	Platelet, saliva	Epithelialization; chemotactic and mitogenic to fibroblast; protein and MMP synthesis (remodeling); angiogenesis (TGF-α)
Transforming growth factor-α	TGF-α	Macrophage, epithelial cell	
Fibroblast growth factor	FGF	Inflammatory cell, fibroblast, endothelial cell	Chemotactic and mitogenic to fibroblast and epithelial cell; protein synthesis; angiogenesis
Insulin-like growth factor	IGF	Liver, platelet	Chemotactic and mitogenic to epithelial cell; migration of epithelial cell; fibroblast proliferation, protein and GAG synthesis
Keratinocyte growth factor	KGF	Fibroblast	Chemotactic and mitogenic to epithelial cell
Platelet-derived growth factor	PDGF	Platelet	Chemotactic to inflammatory cell and fibroblast; mitogenic to mesenchymal cell; protein synthesis, contraction?
Transforming growth factor-β	TGF-β	Platelet, lymphocyte, mast cell, monocyte and macrophage, endothelial cell, epithelial cell, fibroblast	Chemotactic to inflammatory and mesenchymal cell; fibroblast proliferation; protein synthesis; ECM deposition (inhibition of MMP; induction of TIMP); wound contraction
Vascular endothelial growth factor	VEGF	Macrophage, fibroblast, endothelial cell, epithelial cell	Angiogenesis

ECM, Extracellular matrix; *GAG,* glycosaminoglycan; *MMP,* matrix metalloproteinase; *TIMP,* tissue inhibitor of metalloproteinase.

in time, with numerous interactions occurring at all levels (Figure 5-1). When wounds proceed through these steps in a timely manner and achieve functional and anatomic integrity, they are considered acute wounds. Alternatively they become chronic, which is not an uncommon outcome in horses.[5]

Inflammatory Phase

Known also as the *lag* phase of wound healing, this early response, which involves hemostasis and inflammation, is a very metabolically active period lasting for several days, during which wound healing is jump started. The response is directed at stopping blood loss, protecting against infection, and providing the substrate and cellular signals that will facilitate the subsequent steps in the process of healing.[4] Hemostasis is initiated immediately through the contributions of vasoconstriction, platelet aggregation, and fibrin deposition.

Reflex vasoconstriction occurs by smooth muscle contraction mediated by release of endothelin and thromboxane A_2 from the injured vessels and platelet-derived serotonin. The response is transient, lasting only 5 to 10 minutes, after which vasodilators such as prostacyclin, histamine, and nitric oxide predominate, facilitating diapedesis of cells, fluid, and protein into the

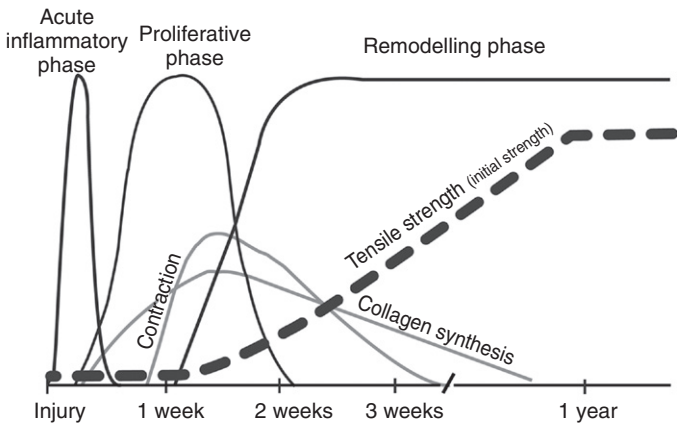

Figure 5-1. Temporal profile of various processes and gain in tensile strength occurring during normal cutaneous wound repair. (From Theoret CL: Wound Repair. p.45. In Auer JA, Stick JA (eds): Equine Surgery, 3rd Ed. Saunders Elsevier, St. Louis, 2006.)

TABLE 5-5. Matrix Metalloproteinases Involved in Wound Repair

MMP Name	MMP Number	Substrates	Source
COLLAGENASES			
Interstitial collagenase	MMP-1	Collagen (I, II, III, VII, IX)	Epithelial cell, fibroblast
Neutrophil collagenase	MMP-8	Collagen (I, II, III)	PMNs
Collagenase 3	MMP-13	Collagen (I, II, III)	–
STROMELYSINS			
Stromelysin 1	MMP-3	PGs, laminin, fibronectin	Epithelial cell
Stromelysin 2	MMP-10	Collagen (III, IV, IX, X)	Epithelial cell, fibroblast
Stromelysin 3	MMP-11	Collagen IV, fibronectin, gelatin, laminin	–
GELATINASES			
Gelatinase A (72 kDa)	MMP-2	Gelatin, collagen (I, IV), elastin	Most cells
Gelatinase B (92 kDa)	MMP-9	Gelatin, collagen (IV, V), elastin	Inflammatory cell, epithelial cell, fibroblast
Matrilysin	MMP-7	PGs, elastin, fibronectin, laminin, gelatin, collagen IV	Epithelial cell
MEMBRANE-TYPE (MT) MMPS			
MT1-MMP	MMP-14	Collagen (I, III), fibronectin	Membrane bound
MT2-MMP	MMP-15	Vitronectin, pro-MMPs	–
MT3-MMP	MMP-16	–	–
MT4-MMP	MMP-17	–	–
MT5-MMP	MMP-20	–	–

MMP, Matrix metalloproteinase; *PG,* proteoglycan; *PMN,* polymophonuclear granulocyte.

wound and extracellular space.[6-9] Hemostasis is ultimately achieved through compression of vessels by soft tissue swelling and formation of a fibrin-platelet plug within the wound defect. Thrombin, the principal factor in clot formation, is instrumental in this process.[10,11]

Released by activation of both the intrinsic and extrinsic coagulation pathways, thrombin cleaves fibrinogen into fibrin monomers, which upon polymerization into fibrin fibers interact with plasma fibronectin to stabilize the hemostatic plug that fills the wound site.[12-14] This early wound clot is known as provisional wound matrix. If left unbandaged, the surface of the clot dessicates to form a scab, beneath which the provisional matrix will be replaced by granulation tissue during the proliferative phase of healing. Although the clot provides tenuous protection and stability to the wounded area and adjacent skin edges, there is no meaningful return of tissue integrity or breaking strength, hence the descriptive term *lag*.[15] Despite this, blood and fluid loss is halted, and microbial invasion through the open wound is minimized.

The activated platelets within this fibrin plug complex direct and amplify the early inflammatory phase of healing through the release of wound repair mediators, most importantly platelet-derived growth factor (PDGF) and transforming growth factor beta (TGF-β), from their storage granules.[12,14] As early wound healing progresses, polymorphonuclear cells (PMNs), macrophages, and fibroblasts can bind selectively to the provisional wound matrix through expression of cell surface integrin receptors as they migrate into the wound to initiate immune and synthetic functions.[16,17]

Leukocyte migration into the wound is activated by exposed collagen, elastin breakdown products, complement factors, and cytokines. PMNs are the first cell type to enter the wound in large numbers.[4] They appear soon after injury, with numbers peaking on about day 2, and decline as debris is cleared from the injured site. The neutrophils have two primary roles: to remove damaged tissue and bacteria, and to release chemoattractants to further augment the early cellular inflammatory response. The principal degradative proteinases released by PMNs to remove damaged tissue include cathepsin G, neutrophil-specific interstitial collagenase, and neutrophil elastase.[18] By 24 hours, circulating monocytes begin to enter the wound and differentiate into macrophages.[4] Macrophages are regarded as the major inflammatory cells responsible for regulating most of the important molecular signals for wound repair mechanisms through generation and release of oxygen free radicals, inflammatory cytokines, and tissue growth factors.[19] Macrophages proliferate in the wound and, similar to neutrophils, remove necrotic tissue as well as bacteria. The proteinases released by macrophages—elastase, collagenase, and plasminogen activator—aid in the débridement. Macrophages may be present for a period lasting from a few days to weeks, depending on wound characteristics. Their synthesis and release of tissue growth factors initiates the proliferative phase of the repair process, including angiogenesis, fibroplasia, and epithelialization. Neutrophil and macrophage apoptosis occurs as the inflammatory phase subsides.

Despite the fact that animal models of wound healing have demonstrated that neither neutrophils nor macrophages are essential to wound healing in sterile conditions, in the presence of bacteria, healing is delayed compared to that in animals with available PMNs.[2,18-20] In wound healing studies in horses and ponies, their presence has always been noted.

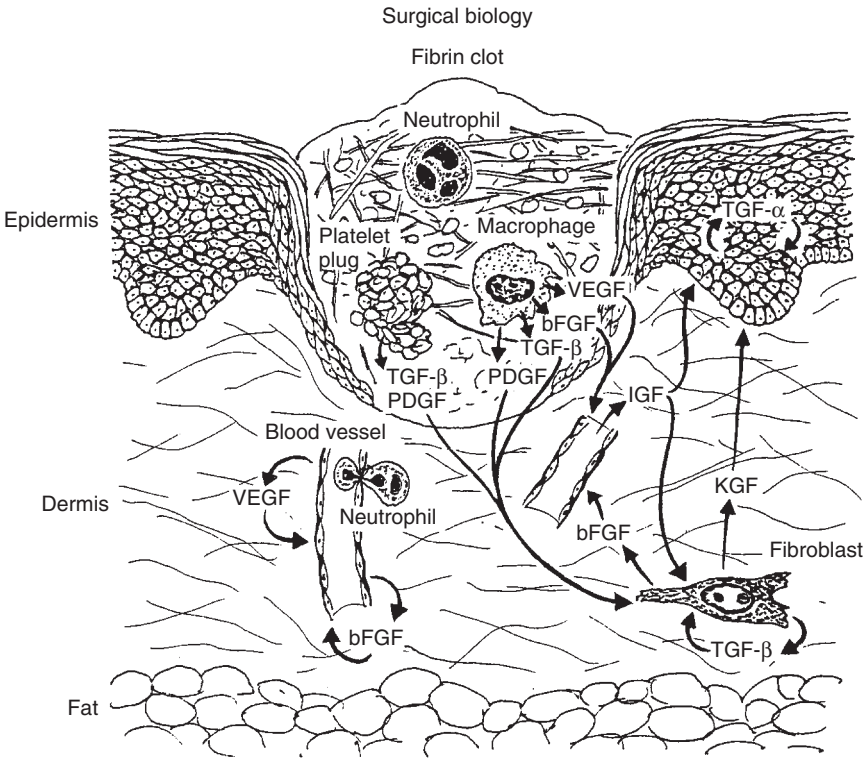

Figure 5-2. Cutaneous wound 3 days after injury. *bFGF,* Basic fibroblast growth factor; *IGF,* insulin-like growth factor; *KGF,* keratinocyte growth factor; *PDGF,* platelet-derived growth factor; *TGF,* transforming growth factor; *VEGF,* vascular endothelial growth factor. (Modified from Singer AJ, Clark RAF: N Engl J Med 341:738-746, 1999.)

Tissue Formation Phase

The *proliferative* phase of acute tissue repair is active by the third day following injury. It is characterized by angiogenesis, fibrous and granulation tissue formation, collagen deposition, epithelialization, and wound contraction (Figure 5-2).[21,22] As in the previous phase of wound healing, steps in the proliferative phase do not occur in series but rather overlap in time.

Angiogenesis

The wound healing process requires a continuous oxygen and nutrient supply. Decreased oxygen tension, high lactate levels, and low pH within the wound initiate the process of angiogenesis.[21] The endothelial cells at the tips of capillaries adjacent to the wounded area are attracted to the area by fibronectin, found within the provisional matrix, and grow in response to cytokines released by platelets and macrophages at a rate of 0.4 to 1.0 mm per day.[23] The development of vascular outgrowths requires endothelial cell proliferation that organizes into vessel architecture. Growth factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) play central regulatory roles in neovascularization and subsequent tissue repair.[24] The tissue in which angiogenesis has occurred is dense in capillary loops, resulting in the characteristic granular red appearance of granulation tissue.[23] When macrophages and other growth factor–producing cells are no longer in a hypoxic, lactic acid–filled environment, their production of angiogenic factors stops.[25] Thus when tissue is adequately perfused, migration and proliferation of endothelial cells is reduced through the action of matrix metalloproteinases (MMPs). Eventually blood vessels that are no longer needed undergo endothelial cell apoptosis.[18]

Fibroplasia and Granulation Tissue Formation

Fibroblasts begin to arrive by the second day after injury, and by the fourth day they are the major cell type in the wound bed.[4,26-28] Recruitment from adjacent tissue, local proliferation, and transformation of undifferentiated local and systemic mesenchymal stem cells into fibroblasts all contribute to the peak in fibroblast numbers at 7 to 14 days after injury.[29] Fibroblast migration into the wound and their subsequent proliferation is largely regulated by PDGF, TGF-β and bFGF.[11] In the first several days after injury, fibroblasts proliferate and migrate, whereas later they synthesize and reorganize the components, which will eventually replace provisional matrix within the wound site. Fibroblasts synthesize and release collagen; glycosaminoglycans, including hyaluronan (which facilitates cell migration); glycoproteins (fibronectin and laminin); and proteoglycans.[30] Simultaneously they also secrete proteases, including MMPs, which digest the fibrin clot so that replacement with the new components can occur.[17]

Collagen production begins slowly on the second or third day after wounding and reaches peak production within 1 to 3 weeks.[4,17] Although wound fibroblasts produce type I collagen, which predominates in unwounded dermis, almost 30% to 40% of the collagen found in the acute wound will be type III. This is reflective of the dense population of blood vessels containing type III collagen, which then comprises granulation tissue. As the wound heals and vascularity is reduced, there is a shift in the balance of the collagen content toward type I.[4] In addition to collagen production, fibroblasts within the wound organize the collagen molecules into fibers and then into bundles, which are aligned parallel to the wound surface, usually along lines of maximum tension. The presence of collagen and its arrangement contribute to tissue strength. When

the wound defect is filled and homeostasis of collagen production and collagen degradation is achieved, macrophage and fibroblast numbers are reduced by apoptosis, and tissue maturation and remodeling begin.[31,32]

Epithelialization

The slow process of reepithelialization, to restore the barrier function of skin, starts immediately after wounding.[33] Suprabasal keratinocytes residing above the basement membrane of the epidermis and lining hair follicles and the sweat and sebaceous glands facilitate the repair.[34] Reepithelialization initially begins with the migration of these existing cells, but within a few days keratinocyte proliferation at the wound margins contributes to the number of available cells.[4,35] The location, and therefore the number of the keratinocytes available, depends on the type of injury. There is rapid reepithelialization in superficial injuries, such as an abrasion, as the basement membrane and epidermal appendage populations of keratinocytes remain available across the entire wounded area to participate in the repair. In contrast, in full-thickness wounds there is no residual epithelium, or epidermal appendages, from which keratinocytes can be recruited. In wounds of similar surface area, it is this last type of injury that requires the longest duration to heal, because reepithelialization can only occur through centripetal movement of the keratinocytes from the wound margins.[7,36]

Participating keratinocytes undergo phenotypic changes in response to a loss of contact inhibition and exposure to cellular products, including nitric oxide, which enable them to migrate and to phagocytize debris in their way.[37] The interaction between keratinocytes and fibroblasts is quite important. Keratinocytes stimulate fibroblasts to synthesize and release growth factors and cytokines, which in turn stimulate keratinocyte proliferation.[38] Upon detaching from neighboring cells they develop pseudopods that contain actin filaments.[36,39] During migration, integrins on the pseudopods attach to the extracellular matrix (ECM), and the actin filaments enable the pseudopod to pull the cell along.[39] Keratinocyte migration, however, requires healthy tissue over which to migrate.[36] Migration is impaired by fibrin, by inflammatory products, and by the presence of exuberant granulation tissue.[40,41] In surgical incisions, the tissue is healthy and the wound surface area following suture apposition is small, which enables epithelialization to occur within days.[7] In open traumatic injuries, however, there is a delay in epithelialization, because the necrotic tissue must first be eliminated and then a bed of healthy granulation tissue must be developed. Keratinocytes synthesize and release collagenases, proteases (MMPs), and plasminogen activator to clear a path across the wound surface.[33,36,42,43] Thus the time of onset of migration is variable, and new epidermis is often not apparent at the wound edges until 4 to 5 days following wounding. In most instances, because they must dissolve any scab that forms, keratinocyte migration is best enhanced by a moist environment, because the drier the environment, the thicker the eschar.[35,44,45]

Keratinocytes continue centripetal migration across the wound bed until cells from either side meet in the middle, at which point contact inhibition causes them to stop migrating, assume their normal phenotype, and begin the process of reestablishing the strata found in normal skin.[18,46,47] The new epidermis differs from that found in uninjured skin; it lacks rete pegs, which anchor it into the underlying connective tissue matrix; and in full-thickness wounds it lacks a dermal layer, without which there is a loss in tissue strength and elasticity.[4,48] There is no regeneration of lost epidermal appendages such as sweat glands and hair follicles. The fragile nature of the resultant epithelium makes the process of healing by epithelialization alone without the contribution of wound contraction less than ideal.[4] Time until complete reepithelialization occurs depends on the wound surface area and, in horses, on the location of the wound.

Contraction

Contraction usually begins in full-thickness wounds in the second week following injury, once the wound is heavily populated by fibroblasts, and can continue for several weeks.[4] The process is beneficial because it reduces the surface area of the original wound by 40% to 80%.[49] The centripetal movement of the adjacent uninjured dermis and epidermis over a full-thickness wound minimizes the area that requires epithelialization. In areas with loose skin, rates of contraction can be as high as 0.75 mm per day.[50]

The differentiation of fibroblasts into myofibroblasts is considered by most investigators to be necessary for contraction to occur.[31,51] The primary inducer of fibroblast-to-myofibroblast differentiation appears to be TGF-β1 released from macrophages and keratinocytes.[52,53] Fibroblast density and mechanical tension on fibroblasts within the ECM can also impart transition.[14,54-56] The acquisition of an alpha smooth muscle actin microfilament system signifies the change from the fibroblast to myofibroblast phenotype.[57] Although not completely understood, myofibroblasts form specialized connections between themselves and molecules, including collagen and fibronectin, within the ECM at the wound's edges.[47] When the actin filaments within the myofibroblast contract, force is transmitted through these connections to the edges, causing wound contraction.[35,58,59] Fibroblasts lay down collagen to reinforce the contracted wound.[60] Contraction usually does not occur symmetrically, rather, most wounds have an "axis of contraction," which allows greater organization and alignment of cells with collagen.[61] The process slows and ceases when either the wound edges meet, tension within the surrounding skin becomes equal to or greater than that generated by the contracting myofibroblasts, or when the number of myofibroblasts within the wound bed become low. At the conclusion of contraction, myofibroblasts either disappear by apoptosis or revert back to a fibroblastic phenotype.[61]

Remodeling and Maturation Phase

Remodeling and maturation of the extracellular matrix found in granulation tissue represents the final phase of wound healing. It is a phase that begins during the second week of repair and ends in the formation of scar tissue 1 to 2 years later, which remains 15% to 20% weaker than the original tissue (Figure 5-3).[18] The processes occurring during this phase begin with the replacement of the hyaluronan content within the provisional matrix by proteoglycans in the extracellular matrix. This gradually stops fibroblast proliferation and migration.[62] The cellular content within the ECM slowly decreases as cytokine and growth factor signals decline and the collagen content increases. Angiogenesis decreases and wound metabolic activity slows. The collagen deposited during the period of fibroplasia is oriented randomly, providing minimal tissue

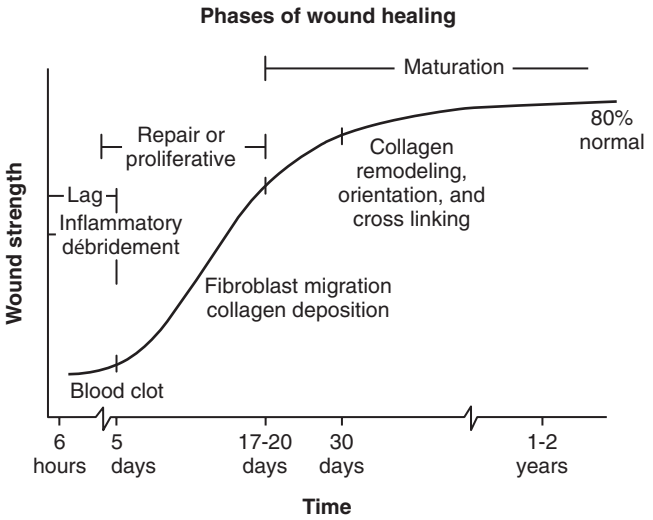

Figure 5-3. Changes in wound strength during the phases of wound repair. Note that the time axis is not to scale. (From Bassert JM: McCurnin's Clinical Textbook for Veterinary Technicians. 7th Ed. Saunders, Philadelphia, 2010.)

strength. During remodeling, collagen synthesis continues, but because of simultaneous lysis there is no net gain in content. MMPs (collagenase, stromelysins, and gelatinases), which are derived from macrophages, epithelial cells, endothelial cells, and fibroblasts within the ECM, are responsible for the degradation of collagen within the wound. Collagen fibers, which were once haphazardly arranged, are reestablished in bundles, cross-linked, and aligned along lines of tension by fibroblasts to progressively increase the tensile strength. There is a gradual gain in tissue strength from 20% of that of normal tissue at 3 weeks, to 50% within 3 months, and 70% to 80% of the strength of original tissue at the conclusion of maturation.[63]

These phases of acute wound healing normally progress with efficiency to stop blood loss, reestablish an immune barrier, and replace lost tissue. Yet of the six possible reported outcomes for acute wounds in humans, five are undesirable: dehiscence, herniation, wound infection, delayed healing, and keloid formation. Although the latter is rare in horses, it can easily be replaced with the problem of excessive or exuberant formation of granulation tissue.[64] In a retrospective study of traumatic wounds involving both ponies and horses, of the 217 wounds in horses and 41 wounds in ponies closed by primary intention, 74% of those in horses and 59% of those in ponies dehisced.[5] Uncomplicated healing in a timely manner is not always a given. Several factors are known to complicate the process.

WOUND HEALING DIFFERENCES IN THE HORSE

Wound healing in horses can be distinguished from that in other animals by several unique characteristics, including marked *differences within the equine species, variations in the rate of healing based on body location,* and a great propensity for the *development of exuberant granulation tissue* during the healing process.

Ponies Heal Faster

The ability of ponies to heal more rapidly than horses was first reported in 1985 and confirmed later in a large retrospective study and a series of experiments.[5,65-69] These found both primary and second intention wound healing in ponies to proceed more rapidly than that of horses. In the experimental studies, 2×3.5 cm full-thickness wounds created on the metatarsus and buttocks of horses and ponies and allowed to heal by second intention yielded a quicker and more intense inflammatory response in ponies than in horses. Leukocytes produced higher levels of reactive oxygen species, interleukin-1, tumor necrosis factor, chemoattractants, and TGF-β1, likely explaining why ponies' wounds are more resistant to infection and why wound contraction is greater than in horses. In ponies, unlike horses, within 2 weeks after wounding, myofibroblasts were found organized and oriented parallel to the wound surface for optimal wound contraction.[68] Metatarsal bone involvement resulted in a greater periosteal reaction and new bone formation in horses than in ponies, leading to prolonged enlargement of their limbs.[66] In all five experimental ponies, body and limb wounds healed within 7 to 9 weeks, whereas only two body wounds in the five horses had healed by the conclusion of the 12-week study.[66]

Not surprisingly, outcome in clinical cases involving traumatic wounds undergoing primary closure was also found to be better in ponies than in horses. Wounds dehisced less frequently in ponies, and ponies developed fewer bone sequestra despite receiving, in many instances, less optimal treatment than their larger counterparts.[5] Based on the results of the experimental studies, the less intense but more chronic inflammatory response, which occurs in horses likely increases their risk for wound infection and for the development of exuberant granulation tissue, both of which can explain the clinical findings and, in general, their tendency for delayed wound healing. Although there is no definitive explanation for why these differences exist between horses and ponies, it is speculated that during domestication of the horse, humans took on the role of wound care provider, which decreased natural selection for efficient healing.[41] Pony breeds were spared because they were less popular and therefore subjected to less intensive breed selection. Lastly, horses incurring wounds precluding them from performing are often retired and kept as breeding stock, which would also contribute over time to the genetic selection for poor wound healing. Regardless of the reason, in patients with similar injuries, a better prognostic outcome should be associated with ponies over horses.[41]

Distal Limb Wounds

In horses, delayed healing of wounds on limbs compared to those involving the upper body has been recognized for many years.[40,70] Experimental, full-thickness, excisional wounds of the metacarpus or metatarsus allowed to heal by second intention have repeatedly been shown to heal more slowly than those of equal size created on the upper body.[40,66] Current knowledge indicates that this occurs because of differences in the rate of epithelialization and the rate of contraction, both of which are adversely influenced by excessive motion, infection, and the development of exuberant granulation tissue.[66] The latter is a result of an inefficient inflammatory response (in horses), an imbalance in collagen homeostasis, a shift towards a profibrotic

environment, microvascular occlusion, and inappropriate cell apoptosis.[71] For the process of epithelialization to proceed in a timely manner, keratinocytes require healthy granulation tissue on which to migrate. This is impaired by chronic inflammation, as is the process of wound contraction.[41]

Wound Expansion

Acute wounds in horses, regardless of their location, expand in size in the first 1 to 2 weeks because of the tensional forces of the adjacent tissues. Expansion can be significant. This contributes to the duration of healing.[65,72] In 2.5 × 2.5 cm full-thickness limb wounds, wound areas expanded 1.4 to 1.8 times the original size during the first 2 weeks.[73] This is then followed by progressive contraction of the granulation tissue bed, once it is formed, and a visible decrease in the wounded area, provided the process is undisturbed. In second intention healing, contraction is desirable; coverage of the wound site with full-thickness skin containing epidermal appendages is more cosmetic and durable than coverage by epithelium alone. Contraction rates of 58% to 76% for 2.5-cm^2 full-thickness lesions created on the metacarpal and metatarsal areas were reported.[74,75] With published rates of reepithelialization as slow as 0.09 mm/day for small experimental distal leg wounds, it is not surprising that traumatic clinical wounds require a prolonged period for healing.[76]

Effect of Motion

The shape of the wound does not influence the rate of contraction, but location does.[77] Wounds on the body contract more efficiently (0.8 to 1 mm/day) than those located on the legs (0.2 mm/day).[76] In addition, wounds in ponies contract more rapidly than those in horses.[66] Unlike wounds of the upper body, leg wounds commonly involve areas of high motion and high tension, or tissues that are poorly vascularized.[72] Wounds located over or adjacent to a joint, over tendons, or in opposition to the lines of skin tension contract more slowly or cease contraction before complete epithelialization, delaying wound healing.[40,65] Full-thickness 4 × 3 cm wounds created over the dorsum of the fetlock took significantly more time to heal compared to wounds of identical size over the metatarsus.[65]

Exposed Bone

The process is further delayed if bone is exposed, whether it is extensive, as with degloving injuries, or it involves a much smaller area. Exposed bone, devoid of periosteum, develops granulation tissue slowly because of the poor vascularity present.[78] Ironically however, development of granulation tissue occurs more rapidly in horses than in ponies.[66] In the interim, dessication of the bone's surface may lead to formation of a sequestrum, further delaying granulation tissue development and ultimately contraction and epithelialization.[78]

Infection

Infection also contributes to delays in wound healing and is the primary reason for wound dehiscence.[20] In contaminated traumatic wounds, those located on the limb are at a greater risk of infection than those of the upper body, because soil and fecal contamination are more likely in distal wounds. Soil components have been shown to reduce white blood cell effectiveness, decrease humoral defenses, and neutralize antibodies, thereby significantly reducing the number of bacteria needed to overburden the host's immune system. It has been reported that contamination with as few as 100 microorganisms in the presence of soil can result in infection.[79] As mentioned earlier, horses are unable to mount a rapid, intense inflammatory response after wounding, which facilitates the establishment of bacteria.[68] Regional differences in the number of tissue macrophages have been documented, less in the leg than in the neck, which may also affect the adequacy of the immune response and difference in healing rates.[68] Considering these findings and that feces may harbor up to 10^{11} bacteria per gram, it is not surprising that infection is often more problematic in the limb than body.[80] Use of systemic, regional, or topical antimicrobial therapy, or a combination of these three, is often warranted.

Development of Exuberant Granulation Tissue

Prolonged Inflammatory Phase

The development of exuberant granulation tissue can be considered both a cause and a result of delayed healing in traumatic wounds that are allowed to heal by second intention. Characterized by an abundance of capillaries surrounded by collagen, exuberant granulation tissue, or *proud flesh*, is a common development in wounds involving the limbs of horses managed by second-intention healing. The production of excess granulation tissue can be traced back to the horse's inefficient protracted inflammatory phase, which leads to an excessive proliferative phase in which fibroblasts retain their synthetic role rather than differentiate into myofibroblasts or disappear.[81] Although the influx of PMNs in horses was much slower than that seen in ponies, PMN numbers remained higher in horses than in ponies for a longer period of time, resulting in chronic inflammation.[68] It is hypothesized that the imbalance of the mediators released by PMNs, including TNF-α (tumor necrosis factor alpha), interleukin 1 and 6 (IL-1, IL-6), PDGF, TGF-β, and bFGF, contributes to a profibrotic state leading to the formation of exuberant granulation tissue.[41] TGF-β1 enhances migration and proliferation of fibroblasts and subsequent collagen production. It also delays fibroblast apoptosis.[82,83] In experimental limb wounds, its presence persists beyond the initial inflammatory phase, which is significantly different than in thoracic wounds.[84-86] Simultaneously, there is a downregulation of the MMPs required for collagen turnover and, in leg wounds compared to those of the thorax, an increase in tissue inhibitor of metalloproteinase (TIMP).[86] TIMP inhibits the activity of MMP-1. Granulation tissue becomes excessive, which contributes to wound expansion, delays contraction, and inhibits epithelialization (Figure 5-4).[60,66]

Microvascular Occlusion

Other mechanisms leading to exuberant granulation tissue also appear to be important. *Microvascular occlusion* of the small capillaries within granulation tissue has been documented (and found to be three times more likely to occur in limb wounds than in thoracic wounds).[81] The resultant local hypoxia signals upregulation of angiogenic and profibroblastic signals. Hypoxia stimulates the synthesis of TGF-β1, which in addition to its

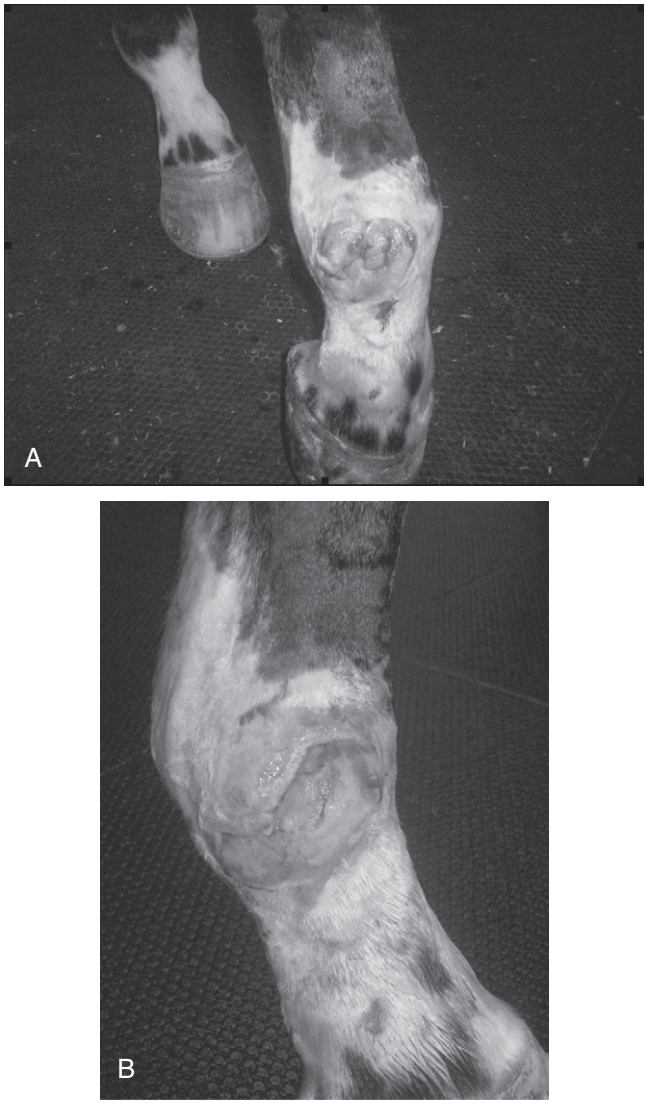

Figure 5-4. A, Traumatic wound over the dorsomedial aspect of the hind fetlock of several months duration. Chronic inflammation and movement has led to development of exuberant granulation tissue and fissures within the granulation bed. Wound contraction and epithelialization is delayed. **B,** Excessive granulation tissue has been excised to below the level of the adjacent skin edges to allow contraction and epithelialization to proceed. Removal of the excess granulation tissue also removed the fissures, which decreases the accumulation of exudates and bacteria that can lead to chronic inflammation and the development of exuberant granulation tissue.

antiapoptotic effect on fibroblasts, is an inhibitor of keratinocytes.[81] Keratinocyte migration is further delayed when the height of the granulation tissue exceeds that of the adjacent skin edges. In the absence of migrating keratinocytes, signaling for apoptosis of fibroblasts is delayed, thus perpetuating the development of granulation tissue.[25] Hence exuberant granulation tissue can be both the cause and the result of delayed wound healing.

Bandaging

Interestingly, bandaging of limb wounds in horses and ponies has long been associated with development of excessive granulation tissue and has been reported to be "detrimental to the goal of healing."[75] This has led to recommendations to eliminate its use when possible.[75,87] Bandaging contributes to local hypoxia, which stimulates angiogenesis, and to the accumulation of exudates on the dressing against the wound surface, which provide a constant source of inflammatory mediators. However, bandaging in clinical cases is often unavoidable and may be beneficial if used during an appropriate time frame. Bandaging can reduce environmental contamination, protect vital structures, provide mechanical stabilization, and reduce edema. Several studies have examined the effects of bandaging and dressing types.[73,75,88,89]

Although a moist wound environment is desirable in most species for optimum healing, this has not been found to be uniformly true in horses.[74,75] Wound dressing development in human health care is a multibillion dollar industry resulting in an abundant number of dressings that equine veterinarians can use. General guidelines are to use occlusive dressings in clean, acute wounds until a healthy bed of granulation tissue develops, then switch to a semiocclusive dressing. In dirty or infected wounds, adherent, hydrophilic, or antimicrobial dressings should be used until healthy granulation tissue develops. The use of a semiocclusive dressing should then follow (for more information on the management of wounds see Chapters 26 and 27).[90]

Management of Granulation Tissue

Control of exuberant granulation tissue should be aimed at minimizing inflammation once healthy granulation tissue fills the wound site. Excessive granulation tissue can be managed by excising it when it protrudes above the wound margins.[87] When this method is employed as needed, no delay in healing occurs regardless of bandaging.[75,91] For wounds that need to be bandaged beyond the initial development of the granulation bed, but in which excision of granulation tissue is undesirable, use of either topical corticosteroids or a nonadherent silicone dressing (CicaCare, Smith-Nephew Canada Inc, St-Laurent, QC, Canada) have been shown to be successful at eliminating development of exuberant granulation tissue.[92,93] Equine amnion applied as a dressing is another option. It has been shown in some but not all studies to decrease development of granulation tissue and to accelerate epithelialization.[74,88] Methods for collection and storage of amnion have been reported.[88] Proponents recommend applying amnion after a healthy granulation bed has developed.[90] Skin grafting and delayed closure techniques are strongly recommended in all large granulating wounds to reduce their area and associated inflammation to eliminate the problem of exuberant granulation tissue (see Chapter 25).[94]

GENERAL FACTORS THAT INFLUENCE WOUND HEALING

To further optimize wound healing in the horse, it is important to acknowledge not only the differences unique to the species but also to appreciate other general factors and management techniques that are known to influence wound healing. Many of the factors cannot be manipulated to the benefit of healing, such as the type of injury incurred or the nutritional status of the patient at the time of injury, but they should remain thought-provoking when determining a treatment plan for a given patient.

Age

Although advancing patient age is known to influence the rate of healing in humans and in many experimental animal models, this has not been investigated in horses.[95,96] In humans as well as companion animals, with increasing age many comorbid conditions are encountered, including diabetes, chronic renal insufficiency, cardiac insufficiency, and acute or chronic liver disease, that are known to affect healing. These, however, with the exception of Cushing's disease, are generally not age-related problems common to horses.[97] In horses with pars intermedia dysfunction, high endogenous cortisol levels may delay wound healing through suppression of the inflammatory phase and increase the risk of wound infection because of immunosuppression.[97]

Nutritional Status

Tissue repair is an anabolic process, and data suggest that healing may be improved with diets containing adequate protein.[98,99] Malnutrition preceding surgery or at the time of trauma can greatly influence outcome. In animal studies, protein deficiency directly delayed the rate of wound healing through the suppression of fibroblast proliferation, angiogenesis, collagen synthesis, and remodeling.[100] In a large study involving war veterans, low preoperative serum albumin level was identified as the most significant variable for predicting surgical complications, including wound infection and acute wound failure.[101] Although comparable studies do not exist for the horse, it seems reasonable to expect similar results. Vitamins and micronutrients are also known to affect healing when either deficient or in excess.[4,102] Vitamin A is essential for normal cell differentiation, and deficiencies can result in impaired collagen synthesis and cross-linking and in delays in epithelialization.[103] Vitamin C and the B vitamins (thiamine, pyridoxine, and riboflavin) are important cofactors in collagen cross-linking reactions, whereas vitamin E stabilizes cell membranes. Iron not only is necessary for red blood cell production but also is required as a cofactor in collagen synthesis. Zinc is a cofactor in many enzymatic reactions including DNA and protein synthesis. All of these mechanisms are necessary steps in the healing process.

Type of Injury

Injuries can be classified into one of seven types based on cause (see Table 5-1). The greater the force of impact, the greater the soft tissue damage will be, and the greater the risk of subsequent wound infection.[104,105] Of the seven types, those with the least risk of developing infection are caused by sharp objects (e.g., an incision, a laceration caused by a nail). Contusion and crush injuries, which often include vessel thrombosis, are those most prone to infection. Puncture wounds, although seemingly innocuous, often develop infection because the puncture tract heals at the surface before the deeper soft tissues, thereby creating an ideal environment for bacterial growth. Horses with these latter types of injuries are also most prone to developing tetanus. In general, infection prolongs wound healing, decreases wound tensile strength, and is the most common reason for wound dehiscence.[20,106]

Tissue Perfusion

Wound healing depends on adequate arterial circulation to supply tissue with oxygen. The surgical practice of débriding wounds until bleeding tissue is reached is supported by clinical and experimental findings that "healing progresses more quickly in optimally perfused tissues."[4] In human patients, transcutaneous oxygen tension ($TcPO_2$) and tissue oxygen levels are good indicators of ischemia and can be used to predict healing.[107,108] Repair processes, including fibroblast replication, collagen production, and epithelialization, are impaired when $TcPO_2$ is less than 40 mm Hg; with tensions less than 10 mm Hg, tissues die.[21] Anemia has less of an impact on wound healing, provided blood flow to the wound is maintained and the patient is able to increase cardiac output. Even profound hemodilution does not appear to interfere with wound healing.[109] However, shock and hypotension, even if brief, can negatively impact wound healing.[4] Tissue oxygen tensions can be improved provided arterial circulation is intact by increasing the fraction of inspired oxygen and by increasing the pressure at which oxygen is delivered, as with hyperbaric oxygen therapy (HBOT). However, if arterial circulation to the wound is interrupted, the two management actions proposed earlier will not improve oxygen tension within the wound.[110] Use of HBOT has shown benefits in human surgery and in many skin graft animal models, but no advantage over nontreated horses was found in experimental acute skin grafting studies.[111,112] Horses receiving HBOT had diminished neovascularization, which affected graft take. Angiogenesis and the delivery of oxygen remain necessary steps in the process of wound healing.

Hemostasis and Hematoma Formation

Seromas and hematomas impede wound healing by mechanically distracting the wound edges, by reducing capillary perfusion secondary to exertion of pressure, and by increasing the risk of infection.[4] The incidence of acute hematoma formation can be influenced by surgical technique (Halsted's principles—see Chapter 12). A surgical plan that minimizes undermining of tissue edges and includes techniques that minimize dead space should be pursued. Drains should be placed in areas that are at risk of fluid accumulation and removed when nonproductive.[113] Electrocautery should be used judiciously because excessive use can delay wound healing.[114] Within the last 10 years, vacuum-assisted wound closure (see Figure 17-8) has become commonplace in human medicine. The technique applies negative pressure to the wound and removes accumulated fluid. It has been shown to promote wound healing in part by decreasing the duration of wound drainage and by reducing hematoma development.[115] Its use for treatment of deep cervical wounds in a horse has been reported.[116] The procedure was tolerated well and resulted in the horse returning to light work within 4 weeks. Other benefits attributed to vacuum-assisted wound closure include improved wound perfusion and decreases in wound infection rates.[115] In select cases, incorporation of vacuum-assisted wound closure may be advantageous.

Débridement

Early wound débridement affects wound healing positively. The goal is to reduce bacterial numbers, foreign debris, and the necrotic tissue that would otherwise need to be removed during the cellular inflammatory phase. Repeated débridement benefits chronic and indolent wounds. Fibroblasts within these wounds become senescent. Surgical removal can initiate the healing

process by resulting in platelet accumulation, thereby re-initiating the wound-healing process.[4]

Débridement can be performed surgically using a scalpel, CO_2 laser, or hydrosurgical unit or nonsurgically with dressings, topical compounds, or maggots.[104] Surgical débridement has the advantage of being quick but can be imprecise and painful. Serial or staged sharp débridement over a period of several days can reduce the uncertainty by allowing time for wounded tissues to clearly demarcate themselves as either healthy or not.

Nonsurgical débridement can be divided into mechanical, chemical (enzymatic and nonenzymatic), and autolytic methods, all of which are slower than sharp dissection but in general are tissue sparing and less painful. Wet-to-dry dressings mechanically débride the surface of the wound when removed without re-wetting. This method is efficient at removing fibrin but can also remove newly formed epithelial cells if use is continued too long. Mechanical débridement can also be achieved using wound irrigation. For maximum benefit, fluid should be delivered at an oblique angle to the tissue surface and at a pressure of 7 to 15 pounds per square inch.[104,117,118] A 35-mL syringe combined with a 19-gauge needle is a simple tool that meets these guidelines, although other methods may also be employed.[104] There are also battery-operated handheld pulsed irrigation units with a variety of irrigation tips (e.g., Interpulse, Stryker Corporation, Kalamazoo, MI) that are convenient to use. Autolytic débridement is achieved by placing an occlusive dressing over the wound, trapping the body's own proteases within the wound to liquefy necrotic tissue. Granulex spray, meat tenderizers containing papain and bromelain, and papain/urea-based proteinase are examples of chemical débridement agents. Granulex, which contains trypsin, peruvian balsam, and castor oil, is the product more commonly used in veterinary medicine. It is reported to hydrolyze a variety of proteins, increase perfusion, and possibly promote epithelialization.[119] Collagenase-containing products digest collagen and elastin but do not degrade fibrin.[4] The papain/urea combination degrades fibrin and denatures collagen and skin.[4] Their use therefore is not appropriate for all wounds. Traditional gauze dressings hydrated in saline were found to be 47% more effective in removing fibrin in blood clots from horses than enzymatic formulations.[120]

A unique method of débridement is to use sterile maggots from the common green bottle fly *Lucilia sericata*. Maggots produce potent proteolytic enzymes and can consume up to 75 mg of necrotic tissue per day.[121-123] In addition, they are capable of destroying bacteria.[123] Maggots can be applied to the wound in either a direct (free range) or indirect (contained) manner. Successful outcomes have been associated with their use in penetrating hoof wounds of the horse (see Chapters 26 and 27 for more information on wound dressings).[124]

Wound Closure Technique

The appropriate size and type of suture for a given wound site should be selected. The goal should be to select a suture that is similar in strength to the tissue in which it is to be used.[125] Appropriate selection limits the foreign body effect that each suture possesses, and therefore the risk of infection.[126,127] Suture placement should be directed at minimizing excessive tension at skin edges. Blood flow to the skin edge is inversely proportional to the wound closure tension.[128] Suture tension, which increases the interstitial pressure within the center of the incision above capillary pressure (30 to 40 mm Hg), can lead to tissue necrosis. Study results examining the effects of suture tension on incision strength over time favored loosely apposed skin edges.[129] In most tissue locations simple interrupted sutures are preferred if excessive tension is present and there is a potential of impaired wound healing.[130]

Topical Therapy

A plethora of topical products available to horse owners and veterinarians claim to improve wound healing. Unfortunately some are beneficial and some are not. Treatment choice can affect outcome. Selection should be based on sound information regarding the effects of the product selected and the phase of wound healing. Use of commercially available soaps, such as Ivory or Dove, should be avoided in favor of wound cleansers with neutral pH.[131] Low pH, such as that occurring with products containing benzethonium chloride, is associated with cell toxicity. Tap water can be safely used initially during cleaning to reduce bacterial load, but it should be replaced with an isotonic fluid once a granulation tissue bed has developed to avoid cellular swelling and destruction.[119,132-135] Fluids should be warmed to approximately 30° C to prevent vasoconstriction, which may cause further tissue ischemia.[136] Antiseptics, such as chlorhexidine diacetate and povidone-iodine (10%), should be diluted appropriately when added to lavage solutions. Chlorhexidine solutions (2%) diluted to 0.05% (25 mL/975 mL solution) or less is recommended.[137] Concentrations higher than this are cytotoxic to both tissue and bacteria.[138] If povidone-iodine is used, it should be diluted to a concentration of 0.1% to 0.2% (10 to 20 mL/L).[139-141] Concentrations greater than this have been shown to be toxic to canine fibroblasts, lymphocytes, and monocytes and to inhibit neutrophil migration. Concentration of the antiseptic ointments and gels should also be kept in mind when used topically. Povidone-iodine ointment (10%) had deleterious effects on wound healing in human patients, but in a study in horses, no delay was encountered.[75,142] Lastly, hydrogen peroxide is cytotoxic to fibroblasts and its routine use cannot be recommended.[143]

When selecting a topical antibiotic for use, knowledge of its antimicrobial spectrum and the potential complications should be considered before choosing. Triple antibiotic ointment (bacitracin, polymixin B, and neomycin) and silver sulfadiazine (SSD) have broad spectrums of activity, but silver sulfadiazine, unlike triple antibiotic, is effective against *Pseudomonas* spp. and fungi. Both have been reported to increase epithelialization but both may decrease wound contraction.[119] When used in combination with a bandage, investigators found SSD cream increased development of exuberant granulation tissue.[75] Gentamicin sulfate has a narrow spectrum of activity, primarily against gram-negative organisms. The 0.1% oil-in-water cream is reported to slow wound contraction and epithelialization.[141,144] The use of nitrofurazone ointment, despite its broad spectrum of antimicrobial activity, has several drawbacks.[145] It has been shown to decrease epithelialization and to delay wound contraction. It also possesses carcinogenic properties.[119]

Topical application of individual growth factors has had generally disappointing results during attempts to accelerate wound healing in horses. Recombinant TGF-β1 was selected to stimulate granulation tissue development and enhance wound

contraction in a second-intention wound healing model in horses. No benefit was found over untreated wounds.[146] Platelet-rich plasma (PRP) on the other hand has shown promise. Platelets are rich in TGF-β, PDGF, epidermal growth factor (EGF), transforming growth factor-α (TGF-α), VEGF, serotonin, and histamine. They also secrete fibrin, fibronectin, and vitronectin, which act as provisional matrix and provide a surface for epithelial migration. This characteristic of platelets may explain the positive advantage of PRP over that of topical use of individual cytokines.[147,148] In PRP, platelet numbers are increased over that of whole blood, increasing TGF-β1 concentration nearly threefold.[149] In rabbits, the application of PRP to the full-thickness skin wounds improved overall healing in full-thickness wounds by reducing contraction, stimulating angiogenesis, and producing a trend toward more rapid epithelialization.[148] PRP has been used for the treatment of a variety of equine musculoskeletal pathologies and was reported to induce accelerated epithelial differentiation and well-organized collagen bundles in healing skin wounds.[147] In a larger study, no improvement was found in the quality or speed of wound healing in the treatment of experimental acute 6.25 cm^2 wounds in horse limbs.[149] The authors of this latter study speculate that PRP use may be more appropriate for larger or more chronic wounds. Harvesting autologous PRP is quick and relatively inexpensive and its use may be warranted in many cases.[94]

Various other wound products are also available. Many have little but anecdotal support for their use. Application of products containing lye, gentian violet, or pine tar can lead to further damage of wounded tissues and are not recommended.[119] Other products can be beneficial when used during the appropriate wound phase. Ketanserin-containing products (Vulketan gel, Jannsen Animal Health, Toronto, Canada) block serotonin-induced macrophage suppression and vasoconstriction and can be used during the inflammatory phase to promote a strong inflammatory response.[150] Acemannan, the active ingredient of aloe vera, stimulates macrophages to release fibrogenic and angiogenic cytokines. Its use can be beneficial during the inflammatory phase and early period of fibroplasia and will accelerate the development of granulation tissue over exposed bone.[143,151] Once a granulation bed has developed, its use should be discontinued. In the later phases of wound healing, the use of topical corticosteroids may be warranted to limit fibroblast and endothelial cell proliferation.[93,152] Lanolin cream may be useful to increase the rate of epithelialization.[153] Identifying the phase of wound healing and understanding the product being used is important to facilitate rather than impede the process of wound healing.

Pharmaceuticals

Many drugs are known to impair wound healing. Chemotherapeutic drugs, which target rapidly dividing cells, comprise the largest group. Based on information from human medicine, risks for wound complications are greatest when drugs are given preoperatively, although drug, dose, and frequency also matter.[154] Data in horses receiving biweekly local treatment of cisplatin (1 mg/cm^3) during the perioperative period did not reveal any adverse affect on wound healing. Rate of epithelialization was similar to that reported in other wound-healing studies, although some primarily sutured wounds developed partial dehiscence.[155]

Local Anesthetics

Local anesthetic agents are commonly used to facilitate wound cleansing, débridement, and suture repair in standing equine patients. The use of 2% mepivacaine or lidocaine is most common. Studies in animal wound healing models report conflicting results on the impact that surgical wound infiltration of local anesthetics have on healing. In a rat model, use of 2% lidocaine was found to reduce wound breaking strength and to impair healing of acute wounds.[156,157] In another study, 1% lidocaine had no effect on wound breaking strength at 8 days after wounding.[158] In a recent study, wounds treated with local infiltration of lidocaine (0.5% or 1%) or bupivacaine (0.25% or 0.5%) healed at similar rates to control wounds when wound areas and extent of reepithelialization were compared. Neutrophil numbers increased in a dose-dependent manner.[159] However, a trend was seen by the third day for reduced collagen levels and an increase in MMP-2 (collagenase).[159] Based on the available literature, it seems reasonable whenever possible to avoid local infiltration of anesthetic in areas where wound breaking strength is important, even when diluted. Because of its vasoconstrictive effects, adding epinephrine to local anesthetics should also be avoided.

Anti-Inflammatory Drugs

Anti-inflammatory drugs, in general, inhibit the normal inflammatory response to wounding. Systemic and local use of glucocorticoids have global effects: decreased fibroblast proliferation, protein synthesis, and wound contraction; inhibition of keratinocyte growth factor (KGF) production; and reduced angiogenesis.[160-162] Single-dose administration of a therapeutic dose at the time of surgery likely has no untoward effect, but frequent administration or high concentrations can lead to impairment. Chronic behavioral stress has also been shown to suppress inflammatory gene expression during early wound healing, resulting in delayed healing.[163]

Administration of nonsteroidal anti-inflammatory drugs (NSAIDs), through repression of cyclooxygenase (COX) activity, has been implicated in several studies to adversely affect migration and degranulation of neutrophils, angiogensis, infection rate, and healing.[162-168] In ponies, flunixin meglumine administration delayed linea alba repair.[169] The decision to use an NSAID during wound healing should be made on a case-by-case basis and tailored according to the phase of wound healing. If possible, NSAIDs should be avoided during the inflammatory phase because the influx of inflammatory cells and mediators are important for efficient healing. This, however, must be balanced with the need to control pain and minimize tissue swelling, which may further contribute to tissue ischemia.

Malignancy

Neoplastic transformation should be ruled out in all chronic nonhealing wounds. Squamous cell carcinoma and equine sarcoid can be similar in appearance to granulation tissue. Both are known to occur at previous wound sites.[170]

SUMMARY

Wound healing is a dynamic process involving complex interactions between cellular and biochemical events that coordinate healing. In the horse it is important to support an initial strong

inflammatory response and to prevent chronic inflammation for optimum results. Hippocrates stated, *"Healing is a matter of time, but it is sometimes also a matter of opportunity."*[171] Although wound healing is a physiologic process, our actions can directly influence it, positively or adversely. Understanding the basics of wound healing can lead to improved patient outcome.

CHAPTER

6 Metabolism and Nutritional Support of the Surgical Patient

Elizabeth A. Carr

Tremendous advances in the care and treatment of the critically ill equine patient have occurred during the last two decades. Survival rates from colic surgery have increased, and large animal intensive care units are found in most, if not all, major university hospitals and referral practices across the United States and most of Europe. Critical to this success is presurgical evaluation and patient triage. The physical examination data as well as laboratory and diagnostic information are carefully collected and analyzed to determine the severity of the disease process. Any underlying abnormalities and any metabolic derangements that may affect the outcome negatively are carefully determined. Patients may receive fluids, anti-inflammatories, colloids, oxygen insufflation, and other medications before anesthesia to ensure that a hemodynamically and metabolically stable patient is taken to the induction stall. The surgical technique is designed to minimize trauma, resolve the underlying problem, and keep postoperative complications at a minimum. After recovery, the patient usually continues a regimen of intravenous fluids to maintain hydration and other therapeutics that minimize or prevent postoperative complications, including ileus, pain, and infection, and maximize the chance of recovery. Despite this proactive approach to treatment and support of adult equine patients, rarely is their nutritional status considered in the initial therapeutic plan. Preoperative and postoperative nutritional status and support are clearly linked to morbidity and mortality in humans.[1,2] Malnutrition has been shown to reduce survival, immune function, wound healing, and gastrointestinal function, and it probably negatively affects numerous other processes.[2-6]

This chapter will discuss the metabolic consequences of food deprivation, the pathologic metabolic responses to illness, nutritional requirements in health and disease, and the indications for and types of nutritional supplementation.

INDICATIONS FOR NUTRITIONAL SUPPORT

The need for interventional nutritional support depends on a number of factors. The healthy adult horse that is undergoing elective surgery and has a body condition score of 4 or 5 (out of 9) rarely requires nutritional supplementation (Box 6-1). These individuals can easily tolerate food deprivation for 48 hours. The majority of healthy adult horses undergoing elective surgery have food withheld for 6 to 12 hours preoperatively, and it is reintroduced after recovery when the animal is deemed capable of eating and swallowing effectively. During this period of starvation, energy demands are met by glycogen reserves, with little effect on overall metabolism.

Regardless of the type and complexity of the surgical procedure, nutritional support should be considered in patients with an increased metabolic rate (e.g., young growing animals), individuals presenting with a prior history of malnutrition or hypophagia, patients with underlying metabolic abnormalities that could worsen with food deprivation, and individuals with disorders such as severe trauma, sepsis, or strangulating bowel obstruction that result in an increased energy demand. Underweight horses require nutritional support earlier. Obese or overconditioned individuals, particularly pony breeds,

Box 6-1. Body Condition Score

1. Poor: Animal extremely emaciated. Spinous processes, ribs, tailhead, hooks, and pins projecting prominently. Bone structure of withers, shoulders, and neck easily noticeable. No fatty tissue can be felt.
2. Very thin: Animal emaciated. Slight fat covering over base of spinous processes, transverse processes of lumbar vertebrae feel rounded. Spinous processes, ribs, tailhead, hooks, and pins prominent. Withers, shoulders, and neck structures faintly discernible.
3. Thin: Fat buildup about halfway on spinous processes, transverse processes cannot be felt. Slight fat cover over ribs. Spinous processes and ribs easily discernible. Tailhead prominent, but individual vertebrae cannot be visually identified. Hook bones appear rounded but easily discernible. Pin bones not distinguishable. Withers, shoulder, and neck accentuated.
4. Moderately thin: Negative crease along back. Faint outline of ribs discernible. Tailhead prominence depends on conformation; fat can be felt around it. Hook bones not discernible. Withers, shoulders, and neck not obviously thin.
5. Moderate: Back level. Ribs cannot be visually distinguished but can be easily felt. Fat around tailhead beginning to feel spongy. Withers appear rounded over spinous processes. Shoulders and neck blend smoothly into body.
6. Moderate to fleshy: May have slight crease down back. Fat over ribs feels spongy. Fat around tailhead feels soft. Fat beginning to be deposited along the sides of withers, behind the shoulders, and along the sides of the neck.
7. Fleshy: May have crease down back. Individual ribs can be felt, noticeable filling of fat between ribs. Fat around tailhead is soft. Fat deposited along withers, behind shoulders, and along the neck.
8. Fat: Crease down back. Difficult to feel ribs. Fat around tailhead very soft. Area along withers filled with fat. Area behind shoulder filled in flush. Noticeable thickening of neck. Fat deposited along inner buttocks.
9. Extremely fat: Obvious crease down back. Patch fat appearing over ribs. Bulging fat around tailhead along withers, behind shoulders, and along neck. Fat along inner buttocks may rub together. Flank filled in flush.

Scoring is based on visual appraisal and handling (particularly in scoring horses with long hair).

miniature horses, and donkeys, as well as lactating mares are at risk for developing hyperlipemia and should receive nutritional support if their serum triglycerides are higher than normal values. Older horses, or individuals diagnosed with equine Cushing's syndrome or equine metabolic syndrome, are insulin resistant and at greater risk for developing hyperlipemia and fatty infiltration of the liver. If food deprivation is prolonged or there is a concern regarding the individual's desire or ability to eat, early intervention is indicated to prevent more severe malnutrition.

PURE PROTEIN/CALORIE MALNUTRITION

The average, healthy adult horse can easily tolerate food deprivation (pure protein/calorie malnutrition [PPCM] or simple starvation) for 24 to 72 hours with little systemic effect. A decline in blood glucose concentration occurs with food deprivation, insulin levels fall, and energy demands are initially met via glycogenolysis, which increases the breakdown of liver glycogen stores. As starvation progresses, glycogen is mobilized within other tissues, including muscle. Lipid mobilization is triggered by alterations in insulin or glucagon levels and the activity of hormone-sensitive lipase. As glucose becomes limited, many body tissues begin to rely on fatty acid oxidation and the production of ketone bodies as energy sources. Glycerol produced from lipid degradation, lactate from the Krebs cycle, and amino acids from muscle tissue breakdown continue to be used for gluconeogenesis to provide energy to glucose-dependent tissues (central nervous system and red blood cells). This response to starvation correlates with an increase in circulating levels of growth hormone, glucagon, epinephrine, leptin, and cortisol and a decrease in insulin and thyroid hormones. These hormone fluxes are an afferent stimulus for the hypothalamic response to starvation, which increases the drive to eat and decreases energy expenditure. Metabolism slows in an effort to conserve body fuels, and the body survives primarily on fat stores, sparing lean tissue.

Individuals with preexisting PPCM are at a disadvantage when intake is restricted because of surgery or illness. In the malnourished or cachectic human patient, presurgical nutritional supplementation has been shown to positively influence both survival and morbidity. Early nutritional supplementation should be strongly considered in animals presenting with preexisting PPCM.

METABOLIC RESPONSE TO INJURY

The metabolic response to injury (e.g., surgical manipulation, critical illness, sepsis, trauma), unlike the response to PPCM, is characterized by an increased metabolism and the onset of a catabolic process leading to excessive breakdown of tissue proteins. This metabolic state results from a complex interaction of inflammatory cytokines (interleukin [IL]-1, IL-2, IL-6, tumor necrosis factor [TNF]-α, and γ-interferon; see Chapters 1 and 2) released at the site of injury or inflammation, circulating hormones released in response to stress and injury (hypothalamic-pituitary-adrenal axis), and neurotransmitters (sympathoadrenal axis).[7] Infusion of cytokines including IL-6 and TNF-α results in stimulation of corticotrophin, cortisol, epinephrine, and glucagon, leading to an increase in the resting metabolic rate and lipolysis.[8,9] TNF-α activation of nuclear factor kappa B (NFκB) results in stimulation of proteolytic pathways.[10] In response to injury, there is an increased metabolic activity of the brain. Afferent nerve activity and brain stimulation may cause autonomic nerve stimulation with direct effects on hormone secretion; for example, splanchnic nerve stimulation caused by injury increases glucagon secretion and hyperglycemia.[11] Afferent nerve activity from the injured site also results in hypothalamic-pituitary activation, increasing activity of cortisol, catecholamines, growth hormone, aldosterone, and antidiuretic hormone.[7] In fact, in humans, prolonged infusions of glucagon, cortisol, and epinephrine increase protein breakdown and elevate resting metabolic rate.[12] Prolonged elevation of cortisol is associated with onset of insulin resistance. In addition, peripheral nerve endings have been shown to exist on adipocytes, and the stimulation of adipocytes increases lipolysis.

During illness or after trauma, food intake frequently falls. However, despite this decline, the adaptive responses to starvation do not occur. Hepatic gluconeogenesis continues and rapid protein catabolism develops. There is an increased mobilization of stored fuels and metabolic cycling, resulting in heat production and energy loss. Insulin resistance develops and hyperglycemia may occur despite the absence of food intake. In severe metabolic stress, the body appears to preferentially use skeletal muscle as a metabolic fuel (as opposed to the situation in PPCM, when fat metabolism is the principal source of energy). The adaptive switch to fat use is limited, in part because of increased levels of circulating insulin. The result is an increase in lean tissue breakdown, visceral organ dysfunction, impaired wound healing, and immunosuppression.[7,13] Nitrogen losses during this catabolic response may be as high as 20 to 30 g/day versus 4 to 5 g/day in an adult human experiencing PPCM. Excess protein breakdown and muscle disuse because of inactivity cause muscle weakness and increased morbidity. Because sodium and water retention are a component of this response, weight loss frequently goes unnoticed. Cytokine production results in behavioral changes, including anorexia and decreased activity. Food deprivation during this hypermetabolic and catabolic state causes a much greater loss of lean muscle mass and visceral protein than would be expected during simple starvation. A healthy human allowed access to water can survive approximately 3 months with food deprivation or PPCM. In contrast, the same individual with a critical illness would survive approximately 1 month, and those with preexisting malnutrition, less than 2 weeks.

Although nutritional supplementation will reverse the catabolic processes occurring during simple starvation, it will not completely reverse those occurring during metabolic stress. As long as tissue injury persists, catabolic processes are maintained. In the critically ill patient, protein catabolism continues despite protein supplementation in the diet. However, nutritional supplementation does have benefits in minimizing the severity of protein loss, providing both essential and conditionally essential amino acids, vitamins, and minerals, and in decreasing morbidity associated with illness.

Although the metabolic response to surgical injury is not likely to be as severe as that expected with sepsis, severe trauma, or other critical illnesses, an increase in metabolic rate is seen postoperatively in humans undergoing simple elective surgery. The combination of an increased energy demand and the metabolic processes already discussed can cause significant loss of lean body mass. These changes may not affect survival, but they can inhibit the return to performance of a competitive

athlete. In equine patients with severe surgical trauma, prolonged recoveries, or complications such as infection and laminitis, food deprivation almost certainly affects overall recovery.

METABOLIC REQUIREMENTS

The total energy of a feedstuff is divided into the digestible energy (DE) and the nondisgestible energy. Digestible energy is further divided into metabolic energy (which is used to provide energy) and lost or nonmetabolizable energy, such as gases produced and urea excreted in the urine. By convention, energy requirements are calculated in terms of digestible energy.

Adults

The amount of DE needed to meet the maintenance energy requirements (DE_m) of the normally active, nonworking horse can be estimated using the following formulas:

- For horses weighing less than 600 kg,

$$DE_m\ (Mcal/day) = 1.4 + (BW \times 0.03)$$

- For horses weighing greater than 600 kg,

$$DE_m\ (Mcal/day) = 1.82 + (BW \times 0.0383) - (BW \times 0.000015)$$

where BW is body weight in kilograms, and 1 Mcal equals 1000 kcal. Alternatively, these requirements can be estimated to be approximately 33 kcal/kg/day.

The resting energy requirement (DE_r) is the amount of energy required for maintenance (neither weight gain nor weight loss) of the completely inactive animal and is determined using a metabolism stall in a thermoneutral environment. The result is approximately 70% of the maintenance energy, and it can be calculated using the following formula:

$$DE_r\ (Mcal/day) = (BW \times 0.021) + 0.975$$

The maintenance energy requirements of a horse can be affected by several factors, including its age, size, and physical condition; the amount and type of activity; and environmental factors. Even when all these factors are controlled, individual variation occurs.

Increased Energy Demand

Energy requirements in the pregnant mare do not significantly increase until late gestation and are estimated to be 1.1, 1.13, and 1.2 times the DE_m, respectively, in the last 3 months of gestation. During lactation, energy demands peak over the first 3 months and then decline toward weaning. They can be calculated using the following equations:

- In the first 3 months of lactation
  - For 300- to 900-kg mares,

$$DE\ (Mcal/day) = DE_m + (0.03 \times BW \times 0.792)$$

  - For 200- to 299-kg mares,

$$DE\ (Mcal/day) = DE_m + (0.04 \times BW \times 0.792)$$

- After 3 months of lactation
  - For 300- to 900-kg mares,

$$DE\ (Mcal/kg) = DE_m + (0.02 \times BW \times 0.792)$$

  - For 200- to 299-kg mares,

$$DE\ (Mcal/day) = DE_m + (0.03 \times BW \times 0.792)$$

The energy and protein requirements for the hospitalized surgical patient are not known and probably vary depending on disease state, environment, and level of fitness of the individual. However, they are likely to be close to the resting or maintenance energy requirements. In humans, multipliers have been used to estimate the energy requirements in certain conditions, including severe sepsis, trauma, and burn injuries. However, the increased metabolic demands of illness or surgical trauma and recovery are likely to be balanced by the inactivity of the patient during hospitalization. Consequently, these multipliers may overestimate the caloric requirement of certain illnesses. The exceptions to this are individuals with extreme trauma, burns, or severe sepsis; surgical conditions that require intestinal resection; and patients with large areas of devitalized tissue (e.g., patients with clostridial myositis undergoing multiple fasciotomies). When estimating the energy requirements of the majority of surgical patients, resting energy requirements are an acceptable target. If the patient tolerates nutritional supplementation at this rate, the amount can be gradually increased to meet maintenance needs.

Foals and Weanlings

Foals and young horses that are growing have the highest energy demands. Mare's milk has been reported to provide between 500 and 600 kcal of energy per liter. A healthy 1-week-old neonatal foal drinks between 20% and 30% of its body weight in milk a day, which means that a 45-kg foal drinking 9 to 13.5 L of mare's milk consumes between 4500 kcal (4.5 Mcal) and 7800 kcal per day. This equates to a metabolic rate of between 100 and 173 kcal/kg/day. The resting metabolic rate in the healthy sedated foal has been calculated to be between 45 and 50 kcal/kg/day. As previously discussed, it is unclear whether a sick individual truly has a higher metabolic rate than a healthy individual. A recumbent sick foal is expending significantly less energy than its healthy counterpart in terms of activity level, but disease and its effect on metabolic rate and catabolism must be considered. As with adults, it is probably best to start nutritional supplementation at approximately the DE_r, particularly if starting with the enteral route. If supplementation is tolerated, it is recommended that this be gradually increased toward growth requirements over a shorter time than might be used to increase the adult animal's caloric intake. If using mare's milk or a milk replacement of similar caloric content, DE_r would equate to feeding the equivalent of 10% of the foal's body weight per day. Clinical experience suggests that this would be sufficient in the initial 12 to 24 hours, but additional nutritional support would be required to ensure adequate intake for healing and growth.

The largest growth rate occurs during the first month of life.[14] The following formula can be used to estimate and adjust the

energy requirement, in Mcal DE per day, for growth of weanlings and young growing horses:

$$DE_m + \{[4.81 + (1.17 \times M) - (0.023 \times M^2)] \times ADG\}$$

where M is months of age, ADG is average daily weight gain in kilograms, and BW is body weight.

More comprehensive reviews related to the metabolic needs of active and young growing horses are available for readers who need them.[15-17]

PROTEIN REQUIREMENTS

Protein intake must be adequate not only for energy requirements but also to ensure that protein catabolism is minimized. Maintenance requirements for crude protein (CP) in the adult horse can be estimated using the following equation:

$$CP\ (\text{in grams}) = 40 \times DE_m\ (\text{in Mcal/day})$$

For example, a 500-kg horse with a DE_m of 16.5 Mcal/day would require 660 g of protein per day. Alternatively, protein requirements can be estimated as 0.5 to 1.5 g protein per kilogram of the horse's body weight per day, or 250 to 750 g/day for a 500-kg horse. The middle to higher end of this estimate should be used when calculating protein needs in a sick patient.

VITAMIN REQUIREMENTS

Vitamins are organic compounds that are important in many enzymatic functions and metabolic pathways. Fat-soluble vitamins include vitamins A, K, D, and E. Water-soluble vitamins include the B vitamins and vitamin C. Vitamin K and all the B vitamins with the exception of niacin are synthesized by the microbial population in the horse's large colon and cecum. Vitamin D, vitamin C, and niacin are produced by the horse, whereas the precursors to vitamin A, β-carotene, and vitamin E must be ingested. The need for supplemental vitamins and minerals depends on the type and duration of supplementation. Fat-soluble vitamins are stored in body tissues and generally do not require supplementation for short periods of anorexia. Complete pelleted diets have vitamins and minerals added to meet the requirements set by the National Research Council. When feeding a component diet or a parenteral diet, vitamin and mineral supplementation is necessary to ensure adequate intake.

ASSESSMENT OF NUTRITIONAL SUPPORT

Body weight should be measured daily to determine if nutritional support is adequate to maintain body weight. The most accurate method is to use a walk-on floor scale. A weight tape is a useful alternative when a scale is not available. Weight tapes are used to measure the girth just behind the elbow; the circumference correlates with pounds or kilograms. Weight tapes are relatively accurate in predicting the weight of small horses (less than 350 kg) and large ponies (350 to 450 kg). Weight tapes have been shown to be less accurate in estimating weight in heavy stock breeds and Thoroughbred horses.[18] However, in the hospital setting, their value lies in determining the overall trend of body weight, not the actual number.

Body condition scores are used to subjectively determine the animal's body fat stores and are useful to evaluate the long-term nutritional status of the animal (see Box 6-1). Body condition scores are less useful than a scale for determining smaller weight gains and losses in a hospital situation, but they are more accurate for predicting fat stores.

Diet and hydration status can alter body weight by as much as 5% to 10%. For example, a 500-kg horse that presents with colic may be 7% dehydrated at admission. Rehydration of this animal would result in a weight increase of 35 kg. At the time of exploratory celiotomy, the large colon may be emptied to facilitate correction of a surgical lesion. The large colon and cecum can hold between 75 and 90 L of ingesta; removal of a portion of the contents could result in a weight loss of 50 kg or more. Consequently, weight changes need to be considered in light of hydration status, feed intake, and any procedures that have occurred. In an ideal situation an animal should be weighed postoperatively after rehydration to try to remove variables that can affect weight assessment.

ENTERAL NUTRITION

In the critically ill patient with poor perfusion and decreased oxygen delivery to the tissues, the gastrointestinal tract is frequently the most vulnerable organ. Decreased oxygen delivery has been shown to increase mucosal permeability, resulting in increased translocation of bacteria and absorption of bacterial toxins.[19,20] Inflammatory mediators, produced in the gut as a result of ischemia, are absorbed across the damaged mucosa and enter the portal and systemic circulations; this absorption has been implicated in the onset of septic shock or multiorgan failure.[21] Enteral nutrition increases total hepatosplanchnic blood flow in healthy patients, resulting in greater oxygen delivery to the mucosa. In a rat model of *Escherichia coli* sepsis, enteral feeding of glucose improved intestinal perfusion rates.[22] Enteral nutrition maintains functional and structural integrity of the gut; the absence of enteral nutrition causes mucosal atrophy, increased gut permeability, and enzymatic dysfunction in critically ill human patients.[23]

Enteral nutrition is a trophic stimulus for the gastrointestinal tract both directly via the presence of nutrients and indirectly via stimulation of trophic hormones such as enteroglucagon. Early enteral nutrition (EEN) refers to the initiation of enteral feeding within 48 hours after surgery. In a large clinical study of surgical and trauma patients, EEN significantly decreased morbidity and length of stay when compared with delayed enteral nutrition and parenteral nutrition.[21] Enteral nutrition has a protective effect against bacterial translocation across the ischemic intestinal wall. In addition, EEN has been shown to blunt the hypermetabolic and catabolic responses to injury in several human and animal models.[2] During the hypermetabolic, catabolic state seen with injury or illness, many amino acids, such as glutamine, become conditionally essential. Glutamine is an important fuel for lymphocytes, hepatocytes, and mucosal cells of the gut. During catabolism, glutamine levels may become insufficient to meet these energy demands. The addition of glutamine to both enteral and parenteral diets may improve gastrointestinal function and mucosal cell healing.[24]

Although the decision to supply supplemental nutrition may be clear, the route of supplementation must be considered in light of the original insult, surgical manipulations, and postoperative status of the patient. The enteral route is always preferred

when the gastrointestinal tract can be used. Patients with extensive bowel ischemia, intestinal resection, and anastomosis or postoperative ileus may not be the best candidates for EEN. However, concerns about the strength and diameter of anastomotic sites after surgical resection and about the risk of leakage if enteral feeding is introduced prematurely are not valid. Enterally fed dogs had higher bursting pressures at colonic anastomotic sites and better wound collagen synthesis than unfed controls.[25] Because horses are commonly fed high-fiber diets, the risk of obstruction at the anastomotic site is a valid concern; consequently, when enteral feeding is to be instituted, the type of diet should be carefully considered. Patients with a high risk of postoperative ileus or with a narrow anastomotic site may be better off if they are initially fed parenterally and gradually reintroduced to enteral nutrition. Alternatively, a liquid enteral diet may be instituted until healing is sufficient to allow introduction of roughage.

Types of enteral nutrition can vary from normal feedstuffs (i.e., grains, hay, and complete pelleted diets), to slurry diets composed primarily of normal feedstuffs (Table 6-1), and liquid diets containing component requirements (Table 6-2). In horses with decreased appetite or complete anorexia, the choices are limited to those diets that can be administered through a nasogastric tube. Complete pelleted diets offer several advantages: they are relatively inexpensive, they are well balanced for the maintenance requirements of the adult horse, and they contain fiber. Fiber is beneficial in increasing colonic blood flow, enzymatic activity, colonic mucosal cell growth, and absorption.[26] The major disadvantage of pelleted diets is the difficulty of administering them via nasogastric intubation. Both human and equine liquid formulations are available and have been used as enteral nutrition support in horses.[27-30]

Alternatively, diets prepared using specific components have been described.[31] Corn oil may be added to the diet to increase the caloric content. The use of human products for the full-size horse can be very expensive, and these products have been associated with diarrhea. Liquid diets may be given via continuous flow through a small nasogastric tube, or larger meals may be given by periodic intubation. When using pelleted diets, approximately 1 kg of a pelleted complete feed is soaked in approximately 4 L of water. Once the feed is dissolved, an additional 2 L of water is added and the slurry is administered via a large-bore nasogastric tube. Slurry diets made from complete pelleted feeds will not pass through a nasogastric tube using gravity alone and must be pumped in with a marine supply bilge pump. If a bilge pump is not available or a large-bore tube cannot be passed, pulverizing the pellets before adding water may improve flow. The horse should be checked for the presence of gastric reflux before administration, and the slurry should be pumped slowly with attention paid to the horse's attitude and reaction.

The stomach volume of an adult, 450-kg horse is approximately 9 to 12 L, and a feeding should not exceed 6 to 8 L. This volume should be adjusted for smaller horses. Long-term placement of nasogastric tubes is not without the risk of complications.[32] Small-bore, softer (polyurethane) tubes are recommended if intubation is prolonged, but these generally preclude the use of slurry diets. Alternatively, intermittent placement of a nasogastric tube is effective in decreasing complications, but this can be difficult and at times traumatic for the patient. When instituting enteral feeding, particularly in a patient with prolonged anorexia, it is best to start gradually, increasing the amount fed over several days. The recommended regimen is to feed a maximum of 50% of the calculated requirements during the first 24 hours. If the patient tolerates the supplementation, it can be increased over the next few days until full supplementation is achieved. Rapid changes in intake, particularly with component feeding or high-fat diets, may be associated with colic or diarrhea.

TABLE 6-1. Nutritional Contents of Selected Horse Feeds

Component	Equine Senior	Strategy	Purina Horse Chow
Crude Protein	14%	14%	10%
Fat	4%	6%	2%
Fiber	16%	8%	30%
Kcal/kg feed	2695	3300	454

TABLE 6-2. Nutritional Content of Selected Liquid Diets

Component	Vital HN	Osmolite	Critical Care Meals/Packet
Cal/L	1000	1008	1066
Protein	41.7 g/dL	40 g/dL	12%
Fat	10.8 g/dL	34 g/dL	1%
Carbohydrate	185 g/L	135.6 g/L	73%

PARENTERAL NUTRITION

Parenteral nutrition (PN) is used to supply nutrition when the enteral route is unavailable. Parenteral nutrition can provide partial nutritional support (PPN) or total nutritional support (TPN). In the adult horse, it is most commonly used to supply partial nutrition when oral intake is insufficient or inappropriate. Horses with proximal enteritis, colitis, postoperative ileus, esophageal lacerations, or obstructions can receive nutritional support until resolution of the underlying problem allows reinstitution of enteral feeding. Recumbent or dysphagic animals at risk for aspiration pneumonia, individuals with preexisting protein calorie malnutrition or increased energy demands (late gestation, early lactation, and young, growing animals), and those with decreased feed consumption should also be considered as candidates for PPN or TPN.

Depending on the desired goals and duration of supplementation, solutions containing various amounts of carbohydrates, amino acids, lipids, vitamins, electrolytes, and minerals may be formulated. Carbohydrates are commonly provided with 50% dextrose solutions (2525 mOsm/L) that contain 1.7 Kcal/mL. Isotonic lipid emulsions contain principally safflower and soybean oils, egg yolk phospholipids, and glycerin and come in 10% and 20% solutions. Amino acid preparations are available in several concentrations; 8.5% and 10% solutions are most commonly used in veterinary medicine. Solutions containing both essential and conditionally essential amino acids are preferable.

Although not always ideal, providing calories with dextrose infusions alone is a simple and inexpensive method to supply limited nutritional support to a postsurgical patient for a brief

period (2 days) before transitioning to oral nutrition or more complex parenteral nutrition. Intravenous dextrose has been shown to help reverse serum hypertryglyceridemia and more severe hyperlipemia, and therefore it may be useful in preventing these metabolic derangements in postsurgical patients.[33,34] Dextrose is less calorie dense than lipids and provides no amino acids for protein production; therefore it cannot be recommended as a long-term solution for nutritional support. Hyperglycemia can occur, particularly when attempting to provide a large percentage of energy requirements (as an example, 50% of resting energy levels) to a patient. Accordingly, blood glucose should be monitored during dextrose therapy.

Components that may be added to parenteral nutrition include electrolyte solutions and vitamin and mineral supplements. Multivitamin supplements for humans are available and may be added directly to PN solutions. Some vitamins can be given orally (vitamins C and E) or added to crystalloid solutions (B vitamins). Fat-soluble vitamins are stored in body tissues and rarely need to be supplemented unless prolonged periods (weeks) of anorexia occur. Macrominerals, if required, are best supplemented in separate crystalloid solutions, because divalent cations may destabilize lipid emulsions. Although sick animals require trace minerals, such supplementation is rarely given except to patients receiving parenteral nutrition as their sole nutritional source for prolonged periods (greater than 7 days).

Resting energy requirements should be used when calculating PN volumes for adult animals, but protein requirements should be based on maintenance needs (see Box 6-1) or estimated using the following formula (as described under "Protein Requirements," earlier):

0.5 to 1.5 g protein per kilogram BW per day

The higher end of this formula is recommended for sick, compromised patients. The ratio of nonprotein calories to nitrogen should be at least 100 : 1 in the final solution. We often use lipids to provide approximately 30% to 40% of the nonprotein calories if possible, although many clinicians prefer to use solutions containing amino acids and dextrose but not lipids in the formulation. The addition of lipids to PN is beneficial in patients with persistent hyperglycemia or hypercapnia, because this reduces the dependency on glucose as the principal energy source. The amount of fat use will depend on the amount of carbohydrate provided, with fat storage occurring in the presence of excess carbohydrate calories.

PN formulas should be prepared in a laminar flow hood using aseptic techniques. Lipids should be added last to prevent destabilization of the emulsion in acidic dextrose solutions. Parenteral solutions are an excellent medium for growth of bacteria and should be used within 24 hours of preparation. Before use, they should be kept in a dark, cool area to minimize degradation and loss of vitamins. Because these solutions are hyperosmolar, delivery through a central venous catheter is recommended. Ideally, a separate catheter or portal is designated for PN only. Catheter placement and line maintenance should be performed using strict aseptic technique, and all lines should be changed daily. I generally place a 14-gauge double-lumen catheter (Arrow catheter) and designate one port for PN. Gradual introduction of PN is recommended to decrease risk of complications. Initial infusion rates should provide approximately 25% to 50% of the calculated requirement during the first 24 hours. If tolerated, the rate of infusion can gradually be increased over the next few days to provide 100% of the calculated requirement.

Complications of PN include hyperglycemia, hyperammonemia, hyperlipemia, elevation of serum urea nitrogen, thrombophlebitis, and sepsis.[13,35-38] Lipid infusions have been associated with allergic reactions, hyperlipemia, alterations in liver function, and fat embolism. Insulin resistance seen with systemic inflammatory response syndrome can result in hyperglycemia and rebound hypoglycemia when rates are altered too rapidly. Although solutions containing lipids are very useful in providing additional calories, their use should be determined on a case-by-case basis. Lipids should be avoided in patients with a predisposition to or a preexisting hyperlipemia or an underlying liver dysfunction. Thrombocytopenia, fat embolization, coagulopathies, and alterations in cellular immunity are reported with lipid infusions. Triglyceride levels and platelet counts should be monitored regularly when lipids are added to PN solutions.

Monitoring should include daily assessment of serum electrolytes, blood urea nitrogen, triglycerides, and ammonia and liver function during the acclimation period. Blood glucose should be monitored every 4 to 6 hours and the rate adjusted to maintain blood glucose within the established normal range. If costs are a concern, blood values may be monitored less frequently once a steady state has been achieved.

Box 6-2. Sample Calculations for Feed Supplementation

- Daily nutritional requirements of a 450-kg horse:
  DE_r = (450 kg × 0.021 Mcal/kg) + 0.975 = 10.4 Mcal
  DE_m = (450 kg × 0.03 Mcal/kg) + 1.4 = 14.9 Mcal
  Crude protein requirement = 40 g/Mcal × 14.9 Mcal = 596 g protein
  Alternatively, 0.5 to 1.5 g protein/kg × 450 kg = 225 to 675 g protein

ENTERAL FORMULATION

Equine Senior (horse feed) = 2695 kcal/kg
Corn oil = 1.6 Mcal/cup

- To meet daily DE_r requirements:
  10.4 Mcal/2.7 Mcal/kg = 3.8 kg Equine Senior
- Daily protein requirements (maintenance):
  12% protein = 120 g/kg feed
  3.8 kg × 120 g = 456 g crude protein
- To meet daily DE_m requirements:
  4.9 kg Equine Senior (2.7 Mcal/kg × 5.0 kg) = 13.3 Mcal
  plus 1 cup corn oil = 1.6 Mcal = 14.9 Mcal
  4.9 kg × 120 g protein/kg = 588 g protein

PARENTERAL FORMULATION

1 L of 50% dextrose = 1.7 Mcal
1.5 L of 10% amino acids = 0. 57 Mcal and 150 g of protein
0.5 L of 20% lipids = 1.0 Mcal
Total = 3.27 Mcal/3 L or 1.09 Mcal/L
DE_r = 10.4 Mcal/day
10.4 Mcal/day ÷ 1.09 Mcal/L = 10 L/24 hours = 416 mL/hour
500 g protein/day
Ratio of nonprotein calories to nitrogen = 117 : 1

DE_m, Maintenance energy requirement for active horse; *DE_r*, resting energy requirement.

The same approach should be used when discontinuing PN. The infusion rate should be gradually decreased over at least 24 hours. Frequent monitoring of blood glucose during withdrawal is warranted because of the risk of transient hypoglycemia. For examples on how to calculate PN requirements, see Box 6-2.

CHAPTER
7 Surgical Site Infection and the Use of Antimicrobials

Benjamin J. Ahern and Dean W. Richardson

Probably the single most important advance in surgery throughout history was the understanding and application of aseptic technique. Before the 1840s, Semmelweis in Austria and Holmes in the United States independently demonstrated that the simple act of hand washing before seeing each patient could dramatically reduce morbidity and mortality in obstetrical wards.[1] When Pasteur more fully developed the germ theory of disease, these practices were validated, but application in surgery was slow to develop. Surgery was a last resort, for good reason, because the consequences of hospitalization and surgery were

virtually always worse than the disease itself. The first champion of primitive aseptic technique was Sir Joseph Lister in the late 1860s.[2] He used carbolic acid (phenol) as an antiseptic and made history when he made a surgical incision to repair a fractured patella and was able to achieve healing of the wound without infection. These early surgical discoveries are common pillars of modern surgical technique. Despite the earlier and more modern continued advances in preventing and managing surgical site infections (SSIs) in the equine patient, it remains a significant problem. The importance of SSIs cannot be overestimated; in humans 77% of deaths among patients with SSIs were directly attributable to the SSI.[3] Similarly, equine orthopedic patients with a SSI were 7.25 times less likely to survive to discharge from hospital than patients without an SSI.[4]

SURGICAL SITE INFECTION CLASSIFICATION

The identification of SSIs involves the combined interpretation of clinical and laboratory findings. To ensure uniformity in the reporting of SSI, it is essential that standardized classification systems be used. Variation in the definition of what constitutes an SSI results in marked variation in reported rates and results in confusing and potentially misleading information.[5,6] The Centers for Disease Control and Prevention (CDC) has developed standardized surveillance criteria for defining SSIs that were redefined in 1999.[3] There are three different types of SSI defined by the CDC: superficial incisional, deep incisional, and organ/space (Table 7-1). An alternative system that has been more commonly used in veterinary medicine is based on the National Research Council's wound classification and is based on the extent of operative contamination (Table 7-2). This system has four classification levels—clean, clean-contaminated, contaminated, and dirty—as the degree of contamination increases.

INFECTION AND SOURCES OF MICROORGANISMS

The goal of aseptic technique is the elimination of all infection-causing organisms from the surgical environment. Although this is not actually possible, it is important that surgeons proactively pursue the objective of preventing SSIs. To achieve this goal, knowledge of the common sources and types of bacteria

TABLE 7-1. Classification of Surgical Site Infections

Surgical Site Infection	Qualifications	Includes at Least One of the Following
Superficial incisional	Within 30 days after operation Involves only skin or subcutaneous tissue of the incision	Purulent drainage from the superficial incision Organisms isolated from aseptically obtained culture of fluid or tissue from the superficial incision At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat *and* superficial incision is deliberately opened by surgeon, *unless* incision is culture negative Diagnosis of superficial incisional infection by surgeon or attending clinician
Deep incisional	Within 30 days after operation if no implant Within 1 year if implant is in place and infection appears to be related to the operation *and* involves deep soft tissues (fascial and muscle layers)	Purulent drainage from the deep incision but not from the organ/space of the surgical site Deep incision spontaneously dehisces or is deliberately opened by surgeon when patient has one of the following symptoms: fever, localized pain, or tenderness, unless site is culture negative An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination Diagnosis of a deep incisional SSI by a surgeon or attending clinician
Organ/space	Within 30 days after operation if no implant Within 1 yr if implant is in place and infection appears to be related to the operation *and* involves any part of the anatomy (organs and spaces) other than the incision, which was opened or manipulated during an operation	Purulent drainage from a drain that is placed through a stab wound into the organ/space Organisms isolated from aseptically obtained culture of fluid or tissue in the organ/space An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination Diagnosis of an organ/space SSI by a surgeon or attending clinician

TABLE 7-2. Classification of Surgical Wounds

Classification	Criteria
Clean	Elective, primarily closed, and undrained Nontraumatic, uninfected No break in technique No inflammation encountered Respiratory, alimentary, genitourinary tracts not entered
Clean-contaminated	Gastrointestinal or respiratory tracts entered without significant spillage Oropharynx entered Vagina entered Genitourinary tract entered in absence of infected urine Minor break in technique
Contaminated	Major break in technique Gross spillage from gastrointestinal tract Traumatic wound, fresh (<4 hr after trauma) Entrance of genitourinary tract or biliary tract in presence of infected urine or bile
Dirty	Acute bacterial inflammation encountered Transection of "clean" tissues for the purpose of surgical access to a collection of pus Traumatic wound with retained devitalized tissues, foreign bodies, fecal contamination, and/or delayed treatment (>4 hr) after trauma

for any given surgery is essential. There are four basic sources of bacteria in any surgical procedure: the air, the patient, the surgeon, and the surgical instrumentation used. The relative importance of each of these sources obviously varies greatly according to the surgical environment. For example, a surgery performed in a horse's stall will have a greater likelihood of infection from the air compared to that in a hospital operating suite. Thus, attention must be focused as is appropriate for the surgical situation.

Airborne bacteria and debris should be controlled by locating the operating room in a low-traffic location of the hospital and by minimizing the number and activity of personnel. Published guidelines in 2003 from the CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC) may not be readily achievable in an equine hospital but can serve as guides. It recommends maintaining positive air pressure in the operating room, filtering greater than 90% of the air, exchanging air 15 times per hour, and ensuring that air is introduced from the ceiling and exhausted at the floor. It does not recommend the use of ultraviolet light to reduce SSIs.[7]

Preparation of the horse when possible should include basic grooming to minimize overall contaminants. Hair is not directly associated with an increased risk of SSIs, but it is harder to clean and may make aseptic preparation of the surgical site more difficult.[8,9] Hair removal did not affect the number of colony-forming units (CFUs) postscrub over the midcarpal or distal interphalangeal region.[10] If the hair is removed, shaving is associated with an increased risk of SSI compared to clipping, especially if performed earlier than immediately before surgery.[9] This increased risk of SSI has been attributed to microscopic cuts in the skin that later serve as foci for bacterial multiplication.[3] A No. 40 blade is commonly used to clip horses. Preparation of the patient's skin can be performed using a variety of agents, the most common of which are iodophors, alcohol-containing products, and chlorhexidine gluconate (see Chapter 9).[11] Final draping by the surgeon (see Chapter 10) completes the patient preparation before surgery and produces a surgical field that is isolated from contamination. Draping has not been conclusively shown in humans to reduce SSIs, but because of the nature of the equine patient it is highly likely to reduce wound contamination.[12] A newly developed microbial sealing approach has had good success in reducing human SSIs and may be applicable to equine surgery in the future (see Chapter 10).[13,14]

Surgical aseptic preparation and attire are discussed in Chapter 10. Studies evaluating the efficacy of gloves in maintaining a sterile field have demonstrated that surgical contamination is common and that culture results will be positive on gloves after only 15 minutes of surgical time.[15,16] Techniques such as double gloving and discarding the outer layer after draping should reduce glove contamination and resultantly reduce SSIs.[16-18]

Surgical instrumentation is the only component of the surgical procedure that can be sterilized. A variety of sterilization methods are available, with some types of instruments being more suited to different techniques (see Chapter 9). Sterilization indicators should be checked before instrument use to ensure appropriate sterilization conditions have been met. If possible, instruments should not be opened before completion of patient preparation and draping, because airborne bacteria counts are significantly higher at this time.[19]

Microbial contamination of the surgical site is virtually unavoidable. However, development of an SSI depends on many factors. Operating room design, patient, surgeon, and instrument preparation are designed to reduce the number of bacteria at the surgical site. Quantitatively, it has been shown that if a surgical site is contaminated with more than 10^5 microorganisms per gram of tissue the risk of SSI is markedly increased.[20-22] However, the dose required to result in an SSI is a complex interplay between the quantity of bacteria, the virulence of the inoculum, and the immune resistance of the patient.[23] The presence of foreign material in the surgical site, such as suture material or orthopedic implants will dramatically reduce the dose required to produce a SSI.[24-26] Doses of 10^2 *Staphylococcus pyogenes* per gram of tissue produced infections in the presence of foreign material, such as suture material, in humans.[23,27] Microorganisms can adhere to foreign material and evade the host immune response.[28-31]

Infection of a surgical wound occurs most commonly as a result of direct inoculation of the patient's *endogenous* flora from the skin, mucous membranes, or hollow viscera. The most common musculoskeletal pathogen in humans and animals is *Staphylococcus aureus* and has been reported to cause between 19% and 21% of equine orthopedic infections; furthermore,

Staphylococcus spp. are reported to cause up to 60% of equine cases of cellulitis.[4,32,33] This is not surprising because staphylococci are a common part of the resident flora of the skin and nasopharynx. *Enterobacter* spp. were the most common isolate (25%) in a large retrospective study of equine long bone fractures and arthrodeses, similar to other orthopedic (23%) and musculoskeletal infections (28%) reported.[4,32,34] *Enterobacter* spp. are endogenous bacteria that are common resident flora of the genitourinary and gastrointestinal tracts. These opportunistic bacteria cause infection if the host's defense mechanisms are impaired. Bacteria isolated from equine distal limb skin were *Staphylococcus, Bacillus,* and *Micrococcus*.[10] Table 7-3 summarizes reported common bacterial isolates from horses.[4,34-41] *Exogenous* sources of bacteria include surgical personnel, the operating room environment, instrumentation and materials bought to the sterile field during the surgical procedure. These bacteria are primarily aerobes, especially gram-positive organisms (e.g., staphylococci and streptococci).[3] Fungi from endogenous or exogenous sources rarely cause SSIs and their pathogenesis is not well understood.

TABLE 7-3. Common Bacterial Isolates in Horses

Disease Process	Bacterial Isolates
Orthopedic surgery	Enterobacteriaceae, *Staphylococcus, Streptococcus, Pseudomonas*
Cellulitis	*Staphylococcus, Streptococcus*
Chronic wounds	*Pseudomonas, Staphylococcus, Serratia, Enterococcus, Providencia*
Enterocolitis	*Salmonella, Clostridium*
Iatrogenic septic arthritis	*Staphylococcus aureus*
Wounds	*Streptococcus, Staphylococcus,* Enterobacteriaceae, *Pseudomonas,* and anaerobes
Peritonitis after abdominal surgery	*Streptococcus,* Enterobacteriaceae, *Actinobacillus,* anaerobes
Penetrating wounds to synovial structures	Enterobacteriaceae, anaerobes
Septic physitis/arthritis (foals)	*Escherichia coli, Rhodococcus equi*
Paranasal sinus and guttural pouch	*Streptococcus equi* subsp. *equi, Streptococcus zooepidemicus, Aspergillus, Cryptococcus*

RISK FACTORS FOR SURGICAL SITE INFECTION

The risk of SSI is a result of the complex interplay of microbe, host, and surgery-related factors (Table 7-4). This can be conceptualized according to the following relationship, in which surgery-related factors can affect the dose and the innate resistance of the host[3]:

$$\frac{\text{Dose of bacterial contamination} \times \text{virulence}}{\text{Resistance of host}} = \text{Risk of SSI}$$

TABLE 7-4. Risk Factors for SSIs in the Horse

Risk Factors	Examples
Host-related factors	Extremities of age Gender (female) Immunocompromise (failure of passive transfer, corticosteroid administration) Weight (>300-325 kg) Distant sites of infection Hypoxia—systemic and local Foreign material—e.g., clay, dirt
Surgery-related factors	Emergency procedures Patient and surgeon preparation—shaving, scrubbing technique Duration of surgery Surgical skill Foreign material—suture and prostheses Bandage—Incise drape reduces SSI, stent >3 days increases SSI, postcolic abdominal bandage reduces SSI

Microbe-Related Factors

Many types of microorganisms may be present at a surgical site, however they do not always cause an infection. A microorganism's virulence, or its ability to adhere to eukaryotic cell surfaces, multiply, and evade the host immune response, is variable. Resultantly, a low number of virulent *S. aureus* will cause an SSI, whereas a large number of less virulent microorganisms may not. Bacterial adhesion molecules are one type of virulence factor and referred to as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs).[42,43] The exact role of each bacterial adhesion molecule has been difficult to elucidate in animal models.[44] However, bacterial adherence is thought to play a key role in the pathogenesis of *S. aureus* infections.[45] Fibronectin-binding genes, *fnbA* and *fnbB*, were detected in 98% and 99% of *S. aureus* infections recovered from human orthopedic infections, respectively.[46] Bacteria, including *S. aureus,* can also produce a variety of exotoxins such as hemolysin and leukotoxins that are produced to avoid the host immune response.[46] Virulence or antibiotic resistance can be conferred by secreted proteins, including flagellar proteins, type III secretion factors, pili, and enzymes such as proteases and β-lactamases.[47,48] A promising new approach to combat emerging antibiotic resistance is by targeting bacterial virulence, rather than bacterial viability.[49] For example, *Pseudomonas aeruginosa* expresses a periplasmic protein, DsbA, that is essential for the folding and function of almost all exported virulence factors.[47] The development of drugs targeting these important virulence determinants may allow the development of more effective drugs with a lower propensity for inducing bacterial resistance.[50]

Production of a biofilm is another virulence factor. Microorganisms such as gram-positive staphylococci that can adhere to foreign materials and produce a biofilm, or extracellular glycocalyx, are resultantly resistant to host defenses and antimicrobial agents. These microorganisms are problematic in horses.[28,51] SSIs involving implants with biofilm formation can be so effective that removal of the implant may be required to resolve the infection.[4] Novel implant coatings are being developed that are

resistant to this biofilm formation and may offer an attractive option to reduce SSIs in horses.[52]

Host-Related Factors

Systemic Risk Factors

Intrinsic, patient-related, and preoperative risk factors are important considerations for SSIs. Extremes of age are an important risk factor in humans, although the relationship between age and SSIs may be secondary to comorbidities (the appearance of multiple illnesses) or immune senescence (aging).[3,53] In horses, increasing age has been identified as a risk factor for infection during arthroscopic surgery but not for orthopedic repair of long bone fractures and arthrodeses.[4,36] This is likely because there was a broader age range in patients undergoing arthroscopic surgery, and as a result the effect of age became more evident. Concomitant infections such as pneumonia or separate sites of infection (e.g., foals with umbilical infections) should be evaluated and appropriately managed before surgery, when possible, to reduce the incidence of SSI secondary to bacteremia.[3,54] In humans, remote infections result in a twofold to threefold increase in SSIs.[55] Complication rates are lower in young (younger than 1 year but older than 1 month, ~15%) horses compared to adults (older than 1 year, ~43%) with ventral midline incisions.[56] However, in cases of long bone fracture repair in horses younger than 1 year, there was an increased rate of SSI in one study, but interestingly this was not associated with a reduced rate of overall survival.[4] One possible explanation for the increase in SSIs in younger horses is that attempts to treat complicated fractures, which carry a higher risk of SSIs, were more likely to be made in the younger rather than the older patients.

Female horses have an increased risk of SSIs in arthroscopic and orthopedic surgery compared to males and geldings.[4,36] This gender relationship with SSI has not been evident in other types of equine surgery and may potentially be because of the increased economic and breeding value of female horses and the acceptance of greater risk before surgery.

Obesity (20% over ideal body weight) is strongly related to increased SSI in humans.[3,57] In horses, the relationship between weight and SSI is not as clear. Horses weighing greater than 300 kg and undergoing a ventral midline celiotomy were twice as likely to have incisional complications than lighter horses.[56] This may actually result from anesthesia-related hypotension and reduced tissue perfusion rather than absolute weight.

Host resistance against infection is a function of the immune system and is an important factor in determining if a surgical site becomes infected. In adult horses, immunocompromise is infrequently a concern. However, it certainly is a concern in neonates, and preoperative failure of passive transfer (IgG less than 800 mg/dL) should be evaluated and corrected before surgery.[39] In general, the immune status can be suppressed by local or systemic administration of corticosteroids, which may increase rates of infection.[53,58] The direct causative effect of corticosteroids has not been conclusively agreed upon in human medicine.[3,53,57] The role of endocrine diseases, such as pituitary pars intermedia dysfunction, on SSI has not been clearly delineated in the horse. Nutritional status has been found to be important in severely malnourished human patients and has been managed with preoperative and postoperative nutritional support.[3] However, the effect of nutritional status in horses undergoing surgery has not been determined. As a basic principle, where possible, patients should be maintained in a good nutritional status. Cardiovascular disease and severe metabolic derangements are important risk factors for SSIs in humans.[55] These systemic states have a detrimental effect on the host's ability to resist infection. Hypothermia (temperature lower than 36° C/96.8° F) triples the rate of SSI in human surgery, and it may be a concern in foals and miniature horses, particularly if the skin and hair coat becomes wet.[59,60] Maintenance of normothermia positively affects a patient's immune system and therefore improves its ability to resist SSIs.

Other factors that are important in humans, such as nicotine use, diabetes, and the perioperative transfusion of certain blood products, are not or are unlikely to be important in the horse.

Local Risk Factors

The perioperative supplemental supply of oxygen to the surgical site has been linked to a reduction in SSIs in human surgery.[61-64] The use of hyperbaric oxygen therapy as an adjunctive treatment to improve healing for skin grafts in horses was not effective in one recent study.[65] The effect of supplemental oxygen on reduction of SSI in horses has not been examined. In humans, wound infection rates decrease as tissue oxygen tension increases to 100 mm Hg.[66] Surgical site perfusion and resultantly oxygenation should be maintained as a surgical priority. The distal limbs of horses have little muscle and soft tissue coverage and as a result are more likely to suffer from regional hypoxia and as such heal more slowly compared to the head.[67] This may lead to an inhibition of the host's local resistance to infection and increase the incidence of SSIs.

Disruption of the physical barrier (skin) at the surgical site because of wounds, dermatitis, or inappropriate surgical preparation (e.g., shaving) can increase rates of SSI.[53] Long bone fractures that are open at presentation were 4.2 times more likely to become infected after surgical repair compared to closed fractures.[4] This results from disruption of the host's normal barrier to infection (an intact epidermis) in addition to likely direct inoculation of the fracture. More extensive long bone fractures are 5.1 times more likely to develop an SSI than fractures only involving the articular surface.[36]

Any foreign material, such as sutures, prostheses, or organic materials, alter the local immune response and may result in SSI, even with relatively low levels of contamination. These materials allow biofilm formation and serve as a nidus for infection.[51] Careful débridement of contaminated surgical sites to remove foreign material is a basic principle of surgery. Foreign materials have differing abilities to potentiate an SSI. Silk suture material is 3.4 times more likely than polyglactin 910 (Vicryl) to be correlated with an infection.[24] Furthermore, a single strand of silk suture reduces the number of *S. aureus* required to cause an infection by a factor of 10^5.[68] Similarly some soils, most notably montmorillonite clay, contain highly charged particles and are very potent potentiators of infection.[69] Surgical techniques to remove and minimize the presence of foreign material at the surgical site will reduce the incidence of SSIs by allowing efficient function of the host immune response.

Careful attention to surgical technique will reduce the presence of blood clots, ischemic tissue, dead space, and pockets of fluid that will prolong the inflammatory phase of wound healing and potentiate SSIs.

Surgery-Related Risk Factors

Factors related to the surgical procedure are readily manipulated by the surgeon and resultantly should be an important consideration. A summary of the reported rates of SSI for common surgical procedures are shown in Table 7-5. With attention to detail and a systematic approach, many of the following surgery-related risk factors can be controlled and therefore significantly reduce SSIs.

Surgical Procedure

Patients undergoing gastrointestinal surgery are at an increased risk of wound complications when treated during an emergency rather than an elective procedure.[70,71] Horses undergoing surgery for acute abdominal discomfort had a 39% incidence of incisional complications compared with 9% for elective celiotomies.[56] In horses with abdominal discomfort requiring immediate surgical intervention, this cannot be altered; however, in patients with concomitant infections, surgery should be delayed if possible.[39] Stabilization of the patient will improve the physical status of the patient (lower the American Society of Anesthesiology [ASA] score—see Chapter 18) and likely be associated with a reduced risk of SSI in horses as it is in humans.[72,73]

Patient and Surgeon Preparation (See Chapters 9 and 10)

Basic grooming of the equine surgical candidate before induction will reduce bacterial contamination. Preparations include picking the feet, cleaning the coat of debris and loose hair, and possibly covering the feet and tail.[39] Surgery of the foot should involve trimming and soaking the hoof overnight to reduce bacterial contamination before surgery.[22] Preoperative hair removal is acceptable, because it may help reduce anesthesia duration but should not be done by shaving. In human medicine, when hair was removed using a razor, the rate of SSIs was 5.6% compared with 0.6% when hair was removed by depilatory agents or when hair was not removed.[9,73,74] This increased rate of SSI is attributed to microscopic cuts in the skin that later serve as foci for bacterial infection. Hair removal with clippers immediately before surgery reduced SSIs (1.8%) compared with removal the night before (4.0%).[3] The initial patient preparation ideally should be performed in a designated area separate from the operating room to reduce contamination of the surgical field.

Antiseptics available for skin preparation include iodophors (e.g., povidone-iodine [PI]), alcohol-containing products, and chlorhexidine gluconate. Iodophores or chlorhexidine have broad antimicrobial activity, are either aqueous- or alcohol-based, and are common choices for skin preparation.[3,11,75,76] Recently, preoperative cleansing of the patient's skin with chlorhexidine-alcohol (CA) was shown to be superior to PI for preventing SSIs associated with superficial skin incisions (4.2% with CA; 8.6% with PI) and deep incisions (1% with CA; 3% with PI), but not organ space infections.[76] Additionally, chlorhexidine-alcohol was found to have greater residual antimicrobial activity compared to 4% chlorhexidine gluconate and 7.5% PI.[77] In horses undergoing ventral midline incisions, evaluation of iodophor-alcohol and a film-forming iodophor complex as the means of skin preparation revealed no difference between the techniques.[78] Other factors that influence the effectiveness of the surgical scrub are appropriate technique and duration of scrub.[3,77] Scrub duration of at least 2 minutes has been shown to be as effective as 10-minute scrubs in reducing bacterial colony counts.[3] Another study found that a 1-minute scrub with povidone-iodine followed by an alcohol foam was superior to a traditional 5-minute scrub.[79] Overall, the best length of time to scrub is unclear and depends on the antiseptic used.[80] Newer alcohol-based rubs (e.g., Avagard [chlorhexidine gluconate 1% solution and ethyl alcohol 61% wt/wt]) have been shown to be an effective alternative to traditional aqueous scrubbing.[57,80] In Europe, a similar product consisting of 2-propanol (45%), 1-propanol (30%), and mecetronium ethyl sulfate (0.2%) (Sterillium) has shown significantly better results than chlorhexidine gluconate and povidone-iodine.[81] Before the

TABLE 7-5. Rate of SSIs for Common Surgical Procedures

Procedure	Rate of SSI	Risk Factors	Protective Factors
CELIOTOMY			
Emergency	7.4%-39%	Reoperation, inexperienced surgeon, near-far-far-near suture pattern, staples, polyglactin 910	Lavage of linea alba, topical antibiotics to surgical site at closure, incise drape for recovery, minimize surgical duration
Elective	9%		
CASTRATION			
Routine	2%-3.2%	Lack of drainage, lack of antibiotic prophylaxis, standing nonsutured technique	Laparoscopic technique, recumbent sutured technique
Laparoscopic cryptorchid	0%		
Laryngoplasty	0%-4%	Laryngotomy, draft breed	
Arthroscopy	0.5%-1.5%	Draft breed, tibiotarsal joint	
ORTHOPEDIC PROCEDURES			
Clean	8.1%	Procedure classification, long bone affected, surgical duration >90 min, female patients	
Clean-contaminated	52.6%		
Long bone fractures	28%-32%	Open fracture configuration, surgical duration >180 min	Minimally invasive reduction

See references 4, 36, 78, 102, 103, 114, 115, 150, 172-184.

first scrub of the day using these products, the nail bed should be cleaned and briefly washed to remove soil and debris.[82]

Drapes, Gloves, and Gowns

Scrub suits, surgical masks, caps and hoods, and shoe covers are all parts of traditional surgical attire. Though there is limited evidence demonstrating a direct effect on SSI by surgical attire, it seems prudent to limit the exposure of patients to potential contamination from members of the surgical team. Surgical gloves fail during about 20% of operations.[57] Wearing two pairs of gloves has been shown to reduce the incidence of failure.[3] Careful attention should be paid to inspection of glove integrity during procedures in an attempt to identify and correct breaks in barrier integrity promptly. In one study of gloving procedure using either open or closed technique there was a 100% incidence of contamination, and scrub staff–assisted technique was associated with no contamination.[15] A barrier type of gown should be worn and disposable impervious drapes used when possible, although the effectiveness of this has been disputed.[3,83] However, distal limbs of dogs wrapped with impervious drapes resulted in reduced bacterial contamination compared to more traditional techniques.[84] Any option that may reduce contamination in cases where infection is devastating, such as equine orthopedic repair using metallic implants, should be actively pursued by surgical teams.

Duration of Surgery

Increased surgical duration has been strongly associated with increased SSI in horses.[4,36,56,67,85] For general equine orthopedic procedures, a surgical duration longer than 90 minutes increased the risk factor for SSI by 3.6 times.[36] For long bone fractures and arthrodeses, as surgical duration increased so did the risk of SSI.[4] Postoperative incisional complications in horses are twice as likely after abdominal surgery longer than 2 hours.[85,86] The exact effect of increasing surgical duration is likely a combined result of many factors, including more complicated procedures, tissue drying, reduced tissue perfusion, and increased tissue trauma. Obviously, surgery should not be rushed to prevent SSIs. However, careful surgical planning and surgeon training are essential components that will help to minimize surgical duration and possibly reduce SSIs.[4]

Surgical Technique (See Chapter 12)

Surgical skill and careful attention to and adherence to Halsted's principles play an important role in SSIs.[3] Techniques focusing on careful tissue handling, débridement of devitalized tissue, eradication of dead space, appropriate use of drains and suture materials, and effective hemostasis while maintaining perfusion are essential to reduce the incidence of SSIs.[3,39,54,67,87] Careful attention to appropriate surgical and aseptic technique have a direct effect on the amount of contamination at the surgical site. Regardless of the host immune status or specific bacterial virulence, poor technique will result in increased SSIs. Excellent surgical training, anatomic knowledge specific to the procedure being performed, and attention to detail are vital factors in prevention of SSIs.

The presence of foreign material in a surgical site should be reduced and minimized by the surgeon to reduce the incidence of SSIs. Greater than 10^5 microorganisms per gram of tissue will increase the risk of SSIs, and the presence of foreign material will dramatically reduce this number.[20-23,27] Surgical techniques to reduce the presence of these materials in surgical sites, such as débridement and lavage, coupled with appropriate use of suture materials, drains, and implants will result in reduced SSIs.[39,54,67] Selecting appropriate suture and minimizing excessive tension on the skin edges will likely reduce SSIs in horses undergoing celiotomies.[85]

Incision

Skin incisions can be made using either a conventional scalpel, laser tools, or electrosurgical devices.[88-91] A benefit of laser and electrosurgical devices is improved hemostasis compared to the traditional scalpel.[88,90] However, these devices also cause collateral tissue damage, resulting in eschar formation.[92,93] Numerous electrosurgical devices are available for surgical use, such as monopolar and bipolar cautery, harmonic scalpel, and LigaSure units. The LigaSure unit and harmonic scalpel are associated with less lateral thermal damage compared to cautery devices and thus are less likely to produce necrotic tissue that may serve as a focus for infection.[39,91] Conventional scalpels cause the least collateral damage compared to CO_2 laser and electrosurgical tools, and skin incisions made with steel scalpels heal faster.[88,90,93,94] As a result a conventional scalpel should be used unless surgical circumstances dictate otherwise.

Minimally Invasive Techniques

The advent and application of minimally invasive techniques in humans and subsequently in horses has been a major advance in surgical practice.[4,87,95-101] In humans, SSIs are reduced in laparoscopic procedures compared to conventional surgical approaches.[57,95] In horses there is little information regarding SSI rates for these procedures. However, minimally invasive plate fixation and laparoscopic procedures will likely be associated with reduced infection rates, but more cases are required before definitive conclusions can be drawn.[4,99-101] The reduced rate of SSI has been attributed to preservation of immune function and reduction in the inflammatory response compared to open surgery.[57,100]

Suture Materials and Surgical Implants

Any foreign material in a surgical site will increase the likelihood of developing an SSI. All appropriate methods to minimize the amount of material introduced to a surgical site will reduce bacterial colonization and resultantly SSIs. The strength and elasticity of the tissue should be matched to the selected suture material to minimize excessive retention in the surgical site. Suture patterns can affect SSI; for example the near-far-far-near suture pattern is associated with an increased rate of SSI compared to a simple interrupted patttern.[102] The use of polyglactin 910 has been associated with increased SSI when used to close the linea alba in horses.[103] In contaminated surgical sites, multifilament, nonabsorbable suture materials should be avoided (e.g., silk), because these materials are prone to contamination by drug-resistant bacteria and cause SSIs.[24,104] The use of tissue glue (cyanoacrylate) to close surgical incisions has been associated with reduced rates of SSIs in humans and may warrant evaluation in the horse.[105]

An alternative method to reduce SSIs that has recently been developed is the incorporation of antibacterial materials in the suture material or to the surface of implants.[52,86,106-109] Coating suture material with triclosan has been shown experimentally to prevent in vitro and in vivo bacterial colonization.[110,111] However, use of triclosan-coated polyglactin 910 to close ventral midline celiotomies in 100 horses did not reduce the rate of incisional infection.[86] In fact, the use of this material was associated with a slight increase in incisional edema in these horses.[86] The principle of coating implants with various materials to prevent or reduce the likelihood of bacterial adherence has been extended to include virtually any type of implant material.[52,109,112,113] These emerging technologies are very exciting for equine surgeons because the consequences of an implant related infection is often devastating to our patients.[4]

Bandages and Drains

Despite the best efforts of equine surgeons, horses are returned to relatively dirty housing environments immediately after surgery. It has been shown that application of an abdominal bandage postoperatively may reduce the rate of SSIs following celiotomies.[114] Also, the application of an Incise drape (Steri-Drape) to ventral midline incisions for recovery has been associated with a reduced rate of SSI.[102] Application of bandages for longer than 24 to 48 hours is likely not warranted, and the beneficial effect on SSIs is unclear.[3] In horses, application of a stent bandage for 3 days following celiotomy procedures increased rates of incisional infections.[115] Drains should exit distant to and not from the primary surgical incision.[3] Where possible, use of a closed suction drain is preferable to an open one, and drain removal as early as appropriate will help to reduce the likelihood of infection.[3]

NOSOCOMIAL INFECTIONS

Nosocomial, or hospital-acquired, infections are caused by exposure in a hospital to pathogens that were not present or incubating in a patient before admission. They commonly occur after at least 48 hours of hospitalization. In human medicine, the estimated cost of nosocomial infections may be as high as $4 billion annually.[116] In equine hospitals the financial cost is much lower but still considerable. For example, in one large equine hospital the cost of a nosocomial outbreak of *Salmonella* was $4.12 million.[117]

Perhaps the most devastating disease agent associated with nosocomial infection in horses is *Salmonella* spp.[116,117] Horses undergoing abdominal surgery are at a high risk of developing salmonellosis postoperatively.[35,118] In these situations it may be difficult to determine if the infection was truly nosocomial or if the horse was subclinically shedding the organism at the time of admission. Research has demonstrated that in the general horse population 0.8% to 1.8% of horses shed *Salmonella*.[116] From 1.4% to 20% of horses admitted to veterinary teaching hospitals have been estimated to be shedding *Salmonella*.[118] Pulsed-field electrophoresis testing during *Salmonella* outbreaks has shown that they are nosocomial.[119] Other bacteria that are reported to cause nosocomial infections in horses include *Clostridium* spp., *Pseudomonas, Enterobacter, Citrobacter, Proteus,* and *Klebsiella*.[118,120,121]

S. aureus is the most common cause of SSI in humans.[95] The development of methicillin-resistant *S. aureus* (MRSA) is an emerging veterinary and zoonotic pathogen of great concern to both the veterinary and human medical communities. In horses, the colonization rate with MRSA has been reported to be 2.3% of admissions.[122] Clinical MRSA nosocomial infections occurred in 0.18% of admissions.[122] Currently, the MRSA infection rate is low in horses. Strict attention to appropriate antimicrobial guidelines will hopefully ensure that the prevalence of MRSA does not increase as it has in human medicine.

PREVENTION AND MANAGEMENT OF SURGICAL SITE INFECTIONS

Many factors are involved in development of SSIs. It is a delicate balance between the type of bacteria, the degree of contamination, and the innate resistance of the patient. Fortunately many of these factors can be inexpensively and effectively altered by careful attention to detail by the surgeon and the surgical team as a unit (Table 7-6). An infection at the surgical site, even when successfully treated, normally has dramatically adverse effects on treatment costs and the cosmetic and functional outcomes. The financial cost of SSIs in horses has not been determined. In humans it is estimated that SSIs extend the length of hospital stay by an average of 9.7 days and increase the cost by $20,842 per admission, which amounts to more than $1.5 billion annually that is expended to treat SSIs. In horses undergoing complicated orthopedic procedures, an SSI significantly increased the length of hospitalization from 13.4 to 45.5 days.[4] Furthermore, an SSI increased the duration of antimicrobial therapy from 4.5 to 21.8 days.[4] The results of a SSI associated with other surgical procedures are likely to be less dramatic than those occurring with orthopedic procedures but will still be very detrimental to the case outcome. Therefore it is very important that surgeons are aware of SSIs and how they can reduce their effects.

Diagnosis of Surgical Site Infections

Clinical Signs

An important principle for SSIs is that the earlier the intervention, the better the chance of resolution. A careful physical examination will often reveal the early onset of infection allowing appropriate measures to be taken regarding further diagnosis and treatment. Clinically apparent general signs suggestive of SSI include a fever that cannot be otherwise explained, postoperative swelling that either increases or does not decrease, pain or heat on palpation of the surgical site, erythema, and drainage. Lameness is a useful clinical sign for detecting and monitoring orthopedic and synovial infections in the horse.[54] Palpation and manipulation of the surgical site may elicit a painful response when a SSI is present. Any early signs of infection should prompt further investigation to determine an appropriate treatment plan as required.

Clinical Pathology

Complete blood counts may reveal a leukogram suggestive of infection; however, this is rarely reliable. Neutrophil and lymphocyte counts are variably high, low, or normal in the face of infection and as a result are not particularly useful in the diagnosis of SSI.[123] A marked leukopenia (less than 5000 cells/μL) can be a sensitive indicator of possible nosocomial enterocolitis when coupled with other supporting clinical signs.[35]

TABLE 7-6. Interventions to Decrease SSI in the Horse

Timing	Interventions
Preoperative	Minimize surgical duration by careful planning
	Thorough preoperative exam and CBC/fibrinogen to detect underlying disease
	Remove gross foreign material (bath) before induction
	Remove hair immediately before induction
	Remove hair using clippers, do not use razors
	Perform emergency surgery only when necessary
	Delay surgery to treat distant sites of infection
	Pay strict attention to aseptic preparation/technique
	Minimize movement and personnel in operating room
	Ensure instrument availability, quality, and sterility for the procedure
	Use appropriate perioperative antimicrobials
Intraoperative	Double glove during draping and use orthopedic gloves for fracture repairs
	Open surgical instruments/implants as required during surgery
	Administer antimicrobials as appropriate
	Strictly adhere to aseptic scrubbing/technique
	Drape appropriately – drape to isolate enterotomy
	Adhere to Halsted's principles
	Place exit drain distant to surgical incision
	Use close suction drains and remove before 48-72 hr postoperatively
	Débride infected/devitalized tissues
	Lavage contaminated surgical sites
	Minimize foreign material incorporated in surgical site
	Maintain patient's body temperature
	Use expedient surgical procedure as appropriate
	Consider changing gowns and gloves for procedures longer than 2 hr
	Ensure appropriate perfusion and tissue oxygenation
	Select appropriate suture material and patterns
	Follow appropriate surgical technique
Postoperative	Protect surgical site with bandages—colic (incise or abdominal bandage)
	Use therapeutic antimicrobials as appropriate
	Minimize duration of hospital stay
	Provide thorough discharge instructions on wound care and suture removal

Acute phase proteins (APPs) are the result of a highly organized physiological response to inflammation.[124] Although not specific for SSIs, they are a very useful means of indirectly detecting and monitoring the inflammation that results from SSIs. The most commonly measured APPs in horses are fibrinogen (FB), serum amyloid A (SAA), and less commonly haptoglobin. FB is a soluble plasma protein synthesized by the liver with a wide reference interval in horses (200 to 400 mg/dL, 2 to 4 g/L).[124] The lengthy response period after an inflammatory stimulus, such as SSI, means that FB is a fairly insensitive APP. SAA, in comparison, has rapid and large changes (up to a hundredfold) in response to stimuli (less than 0.5 to 20 mg/L in normal horses) and is particularly suited for real-time monitoring of disease process in horses.[124,125]

Fluid samples from surgical sites or in adjacent synovial or pleural spaces are useful indicators of SSIs. The color, turbidity, total protein, cell count, and cell morphology can be determined to evaluate potential infection. Normal synovial fluid generally contains fewer than 500 nucleated cells/mL, with a predominance of mononuclear cells. A cell count greater than 30,000 cells/mL and a protein level of 4.0 g/dL with greater than 90% neutrophils is specific for infection.[126] Infected synovial fluid is usually turbid or flocculent, cloudy, and nonviscous. Newspaper print cannot be read through the samples with a cell count of greater than 30.0×10^9/L, which is strongly suggestive of infection.[126] However, care must be exercised in interpretation solely of cell counts. Recent injection or sampling of synovial structures alone will significantly elevate synovial cell count and protein without SSI. Peritoneal and synovial pH (normal 7.30 ± 0.06) can be decreased when sepsis occurs.[127] A difference in peritoneal and peripheral serum glucose of greater than 50 mg/dL has been shown to be a good indicator of septic peritonitis.[127] Another potential, although not very specific, indicator of synovial infection is synovial fluid lactate (normally less than 3.9 mmol/L), which will rise with infection (greater than 4.9 mmol/L).[128] Trends in synovial fluid lactate may be more useful in monitoring synovial infections than the absolute number.

Microbiology

The definitive diagnosis of a SSI is a positive bacterial culture, and sensitivity testing is extremely useful in guiding subsequent appropriate therapeutic choices. However, a negative culture does *not* preclude a diagnosis of a SSI.[54] Bacterial culture at the time of surgical closure has not been useful in identifying incisional contaminants in horses undergoing a celiotomy.[85] Bacterial culture from infected synovial structures is negative in

almost 50% of clinical cases, but this rate is improved to 73% when enrichment media are used.[40] The identification of bacteria with Gram stains only occurs in approximately 25% of cases of synovial infection.[40] Obtaining fluid samples for culture before administering antibiotics, or delaying administration for 24 hours, may improve isolation of the cause of the SSI. Blood culture media are excellent for aerobic culture and are superior to directly plating onto agar plates.[54] Use of a sterile vial with transport media or direct injection into an enriched medium (brain heart infusion [BHI] agar or thioglycolate) are preferred. After the site is aseptically prepared, the sample should be obtained from deep in the surgical site.[67] Aspirates from a pocket of fluid suspected to be infected can be effective samples to use for early diagnosis of SSIs. Tissue samples, such as synovial membrane, have been shown to be beneficial for improving culture results, but in our experience this is not always reliable.[129] Careful and expedient handling of the samples in coordination with the receiving laboratory will greatly improve the likelihood of a successful bacterial culture and resultantly an antibiogram. It is important to remember to submit samples for fungal culture, especially if there is a history of intra-articular injections or wounds, and to repeat attempts to obtain a culture if initially unsuccessful.

Imaging Techniques

Ultrasonography of a suspected SSI can be useful. It may allow identification of a pocket of infection that can be sampled for culture and sensitivity, facilitating earlier diagnosis of the causative agent. Ultrasonography also can guide accurate aspiration for surgical drainage to ensure maximal effectiveness.[28,130-132]

Radiographic signs of acute infection are often limited to increased soft tissue swelling or possibly separation of tissue planes.[54] Signs progress to include radiolucency developing adjacent to metal implants and periosteal proliferative changes unassociated with fracture healing. Even later radiographic signs include lysis extending into cancellous bone, medullary cavity, or both. The radiographic appearance of an SSI is often not reflective of the severity of the underlying infection.

Scintigraphy is not commonly used to diagnose SSIs but can be a helpful tool for identifying deep infections without typical external localizing signs. The use of radiopharmaceutical-labeled liposomes or white cells may offer a novel and useful technique for identifying problematic SSIs in the future.[133]

More advanced diagnostic imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) may be beneficial in select cases of infection that have atypical presentations.[28,134,135]

Pathogenic Bacteria Associated with Equine Surgical Site Infections

Knowledge of the common bacterial infections that occur globally in addition to locally at each surgical facility is very useful in the prevention and treatment of SSIs. Monitoring and surveillance for SSIs is essential to allow scientific, evidence-based decisions to be made related to prevention of SSIs.

In long bone fracture repairs and arthrodeses, SSIs are mostly polymicrobial in origin (40%), the remainder being half gram-positive (32%) and half gram-negative (28%).[4] In two other orthopedic-related studies, polymicrobial infections constituted 60% and 19%, respectively.[34,40] In equine long bone fractures the most common gram-negative bacterial isolate was *Enterobacter cloacae* (24.5%), which is very similar to other studies, and the most common gram-positive bacterium was coagulase-negative *Staphylococcus* (21%).[4,32,34] Other bacteria that are commonly associated with orthopedic SSIs are *Pseudomonas, Streptococcus,* and anaerobes.[4,32,34,40] *S. aureus* is the most common (31%) isolate in postoperative synovial structure infections.[40] Mixed bacterial isolates are commonly obtained from SSIs after gastrointestinal, urogenital, and respiratory tract infections, which means that obtaining a representative culture is extremely important for developing a successful targeted therapy.[67] *Actinobacillus* species have been reported as a cause of SSI following soft tissue surgery.[136] Common skin isolates from the ventral midline before surgical preparation for celiotomies were *Bacillus, Staphylococcus, Micrococcus, Streptomyces,* and *Streptococcus* species.

Treatment of Surgical Site Infections

Rapid and accurate identification of a SSI is essential. Once an SSI has been identified, the treatment options are varied depending on the relative importance of the SSI to the outcome, the location of the surgery, the type of procedure performed, and possible implants used. The following are basic principles that always apply: (1) drainage of infected tissues should usually be performed with the aid of gravity, (2) devitalized and infected tissue should be débrided, and (3) appropriate therapeutic antimicrobial therapy should be initiated based on accurate culture and sensitivity results.[67,85,137,138]

A key consideration for both surgical and antimicrobial therapy is whether any implanted prosthetic material is infected.[137] The formation of a biofilm around a surgical implant can be extremely resistant to antimicrobial therapy, and removal of the implant may be required to resolve the infection.[4] Treatment of SSIs related to orthopedic implants has improved markedly over the last decade, primarily because of improved local delivery of antibiotics.[4,139-144] There is little doubt that improved outcomes are possible when extremely high doses of appropriate antimicrobials can be instilled and maintained close to infected tissues and implants. Systemically administered antimicrobials, even combined with drainage and lavage, fail so frequently that equine surgeons have enthusiastically embraced local delivery techniques.

Antimicrobial Prophylaxis Against Surgical Site Infections

Perioperative Antibiotic Therapy in Horses

The use of antimicrobials in veterinary medicine has been and will continue to be an extremely controversial issue.[145,146] The development of multidrug-resistant bacteria and their effect on human medicine has widespread health consequences.[147,148] Antimicrobials should be carefully selected, achieve effective tissue concentrations at the time of surgery, and act against likely pathogens. The intelligent and optimal use of antimicrobials is essential for effectively preventing SSIs while minimizing the development of antimicrobial resistance.

Antibiotic Classification

Antibiotics can be broadly classified as either bactericidal or bacteriostatic or by their mechanism of action (Table 7-7).

TABLE 7-7. Antibiotics Commonly Used in Horses

Antimicrobial	Mechanism of Action	Adverse Effects
BACTERICIDAL		
Penicillin	Inhibit cell wall synthesis by binding to penicillin-binding proteins, leading to cell lysis	Autoimmune hemolytic anemia, anaphylaxis, transient hypotension, increased large intestinal motility, cardiac arrhythmia
Cephalosporins	As for penicillin	Enterocolitis
Aminoglycosides	Inhibit protein synthesis by binding to 30S ribosomal subunit	Nephrotoxicity, neuromuscular blockade, ototoxicity
Fluoroquinolones	Inhibit bacterial DNA gyrase	Cartilage disorders in young (<3 yr) horses, oral ulceration
Metronidazole	Disrupt bacterial DNA by free radicals and unstable intermediate compounds after structural change once in target organism	Enterocolitis, inappetence
Trimethoprim/sulfonamide	Synergistic action to inhibit folic acid synthesis (sulfonamides block first step and trimethoprim the second step in folic acid synthesis pathway)	Idiosyncratic reactions
BACTERIOSTATIC		
Tetracyclines	Inhibit protein synthesis by reversibly binding to 30S ribosomal subunit	Nephrotoxicity, discoloration of urine and erupting teeth
Chloramphenicol	Inhibit protein synthesis by reversibly binding to 50S ribosomal subunit	Reversible aplastic anemia (use carefully; it may causes idiosyncratic anemia in humans)
Macrolides	Inhibit protein synthesis by reversibly binding to 50S ribosomal subunit	Intestinal prokinetic

Additionally, there are two general categories of antimicrobials: concentration dependent and time dependent. Both are commonly used in equine surgery to prevent SSIs but require an understanding of the principles of actions.

CONCENTRATION-DEPENDENT ANTIMICROBIALS

Concentration-dependent antimicrobials, such as aminoglycosides and fluoroquinolones, are reliant on the ratio of the peak plasma concentration of the antibiotic to the minimum inhibitory concentration (MIC) for the bacteria.[148] A ratio of greater than 10:1 or 12:1 is optimal for concentration-dependent antimicrobial effect.[148] This commonly results in a longer dosing interval with higher doses used at each point. Controlled dosing and dose intervals can be achieved by monitoring the peak and trough concentrations of the administered drug. Knowledge of the MIC for the commonly occurring bacteria at a surgical facility will allow calculation of the desired peak concentration (more than 10 times MIC). Renal clearance of the antimicrobials may be monitored by the trough concentrations immediately before redosing. If the trough concentration is not suitably low (e.g., below 2 μg/mL for gentamicin), the dose interval must be increased.[148]

TIME-DEPENDENT ANTIMICROBIALS

Time-dependent antimicrobials include the β-lactams and macrolides. These antimicrobials have a saturable concentration-dependent effect on bacterial killing. This means that at a certain point above MIC, there is no additional benefit to higher concentrations of the antimicrobial. Bacterial killing is optimized for these types of antibiotics by maintaining the concentration above the MIC for a longer period.[148] Time-dependent antimicrobials are commonly given more frequently and at lower doses to achieve this effect.

Prophylactic Antibiotic Use

Surgical antimicrobial prophylaxis refers to a very brief application period of an antimicrobial agent just before a surgical intervention. This practice has had an enormous effect on improving surgical outcomes historically.[3,148] Therapeutic antibiotics refer to the treatment of an established infection. As previously outlined, the development of an SSI is an interaction of the infectious dose, bacterial virulence, and the host's resistance. Prophylactic antibiotics are given to reduce the bacterial dose at the surgical site at the time of surgery and as a result reduce the incidence of SSIs.[149] Four basic principles must be followed to maximize the benefits of prophylactic antibiotics and avoid potential complications: (1) antimicrobials should only be used when the benefits of their use have been demonstrated by clinical trials or when an SSI associated with a surgical intervention would have catastrophic results,[3,39]; (2) a safe, inexpensive, and bactericidal antibiotic should be selected that covers the most commonly occurring contaminants of the operation[3,39,57]; (3) the time of administration is essential in achieving an effective tissue concentration at the time of surgery[39,57,148]; and (4) tissue levels of antimicrobials should be maintained throughout the procedure and at most for a few hours after the skin incision is closed.[39,57]

SELECTION OF PROPHYLACTIC ANTIBIOTICS

When selecting an antibiotic, pharmacokinetics, drug distribution, cost, and potential side effects should be considered.

Overall, antibiotic use should be restricted to patients in which the incidence of infection exceeds 5% without prophylactic antimicrobial use or when an infection would have devastating results.[148] Using the classification system outlined earlier, this generally means that all procedures that are not "clean" have an indication for antimicrobial prophylaxis.[57,148] The use of antimicrobials in clean surgery is controversial in both human and veterinary medicine.[39,57] In equine arthroscopy, the use of antibiotics is probably not indicated with the infection rate being reported to be 1.5%.[150] General clean orthopedic procedures with a reported rate of SSIs of 8% and clean-contaminated procedures with a rate of 52% to 57% are obviously clear indications for prophylactic antimicrobial use.[4,36] Similarly, abdominal surgery in the horse (emergency SSI of 39%; elective SSI of 7%) has good evidence to support the use of prophylactic antimicrobials.

A very important factor in the rational selection of antimicrobials is recognition and awareness of risk factors for SSIs. Furthermore, knowledge of the common causative agents of SSIs and the antibiogram commonly encountered at a surgical facility will also facilitate directed antimicrobial therapy.

TIMING AND DURATION OF ANTIBIOTIC ADMINISTRATION

The appropriate administration of prophylactic antimicrobials has been demonstrated repeatedly in a large number of studies.[57,148,149,151] Despite this common knowledge, compliance in human and veterinary medicine is truly staggering. In human studies, the appropriate administration of prophylactic antibiotics (1 to 2 hours before surgery) to achieve effective tissue levels at the time of surgery is only achieved in 55% to 61% of cases.[151] In a retrospective study of perioperative antimicrobial use in horses undergoing arthroscopic surgery, only 6.3% received penicillin within 60 minutes of the first incision.[147] The average time before surgery for administration of penicillin in this study was 142 minutes.[147] In humans, when the prophylactic antibiotic was administered 2 to 24 hours before surgery, the relative risk of SSI increased by 6.7 times; if it was administered more than 3 hours after the incision was made, the relative risk increased by 5.8 times.[152] Antibiotics should be administered within 1 hour before the skin incision.[137,149,151] Additional intraoperative doses of antibiotic are advised if the duration of the procedure exceeds 1 to 2 times the half-life of the antibiotic used.[57,149]

The prolonged administration of prophylactic antibiotics (longer than 24 hours) is of no benefit.[28,57,149] Within 24 hours of a surgical procedure, the surgical site is believed to be sufficiently sealed and resistant to microorganism entry so that antimicrobial use beyond this time should be unnecessary.[148] The common trend in human medicine has been to decrease antimicrobial administration from multiple days to 24 hours.[28,149] In fact, a single dose of antibiotics is currently thought to be as effective as administration of multiple doses for 48 hours. In equine surgery, the use of antibiotics can be substantially improved and has started to follow human medical trends.[148] Knowledge of risk factors, the likelihood of infection, and the potential consequences of a SSI will allow the rational selection and administration of prophylactic antibiotics.

POSTANTIBIOTIC EFFECTS

The postantibiotic effect (PAE) refers to the period of time after which the antimicrobial concentration has fallen below the MIC, during which growth of the target bacteria is suppressed.[153-155] The PAE depends on several factors: the antibiotic concentration, the duration of exposure to the antibiotic, the bacterial species, and the antimicrobial used. All antibiotics appear to be able to produce a PAE against gram-positive cocci, but β-lactam antibiotics induce almost no prolonged effects against gram-negative bacilli.[154,155] Aminoglycosides, fluoroquinolones, and protein-synthesis inhibitors exhibit the most pronounced PAEs. The greater the magnitude above the MIC, the longer the PAE is for concentration-dependent antimicrobials.[155]

PROPHYLACTIC ANTIBIOTICS USED IN HORSES

β-Lactam antibiotics

β-Lactam antibiotics, such as penicillin and cephalosporins, are commonly used prophylactic, time-dependent antimicrobials.[54,148] The effect of this group of antibiotics is saturable, and as such their effect is maximized by the percentage of the dosing interval above the MIC. At plasma concentrations of two to four times the MIC of a certain bacteria, there is no benefit to further increases in the antimicrobial concentration.[148] β-Lactam antibiotics are readily inactivated by bacteria that produce β-lactamase.

Aminoglycoside antibiotics

Aminoglycoside antibiotics inhibit bacterial protein synthesis by binding to the 30S ribosomal subunit, resulting in disruption of mRNA function and aberrant amino acid sequencing.[156] Commonly used aminoglycosides include gentamicin and amikacin. Aminoglycosides must be transported into the bacterial cell, which requires energy and oxygen; as a result, anaerobic bacteria are commonly resistant. Aminoglycosides are *concentration-dependent* antimicrobials and as such are reliant on the magnitude to which the bacteria are exposed.[54] A ratio of aminoglycoside concentration to MIC greater than 10:1 or 12:1 is optimal for concentration-dependent antimicrobial effect.[148,156,157] Additionally, higher concentration to MIC ratios potentiates the aminoglycoside PAE.[156] These pharmacodynamic properties have lead to extended-interval dosing strategies, or once-a-day dosing regimens.[148,154,156,158] In contrast to the concentration-dependent antimicrobial activity of aminoglycoside, the toxic effects depend on the duration of host tissue exposure, not the absolute concentration. The nephrotoxic and ototoxic effects of aminoglycosides are related to the plasma trough concentration immediately before repeated administration.[156] There are several benefits of extended-interval dosing: (1) concentration-dependent bactericidal activity can be maximized by optimizing the peak plasma concentration, (2) time-dependent toxicity is minimized, (3) duration of PAE is maximized, and (4) adaptive resistance is limited.[156] Bacterial resistance is commonly caused by downregulation of the necessary influx pathways, leading to decreased intracellular drug concentrations.

Trimethoprim-sulfonamides

Trimethoprim-sulfonamides are less commonly used than the previously mentioned antibiotics as prophylactic antimicrobials. However, trimethoprim-sulfonamides act synergistically to inhibit the synthesis of folic acid, a compound that is required for microbial DNA production. Formulations are usually at a ratio of 1 : 5 for potentiated sulfonamides and the trimethoprim respectively. Sulfonamides prevent the conversion of *para*-aminobenzoic acid (PABA) to dihydrofolic acid by substituting competitively for PABA; when sulfonamides are used alone,

they are bacteriostatic. Trimethoprim inhibits the subsequent conversion of dihydrofolic acid to tetrahydrofolic acid by inhibiting dihydrofolic acid reductase. The combined activity of trimethoprim-sulfonamide as a result inhibits two successive steps in the folic acid pathway, producing a bactericidal effect.

Special Routes of Administration and Dosages

As mentioned before, there is little doubt that improved clinical outcomes are possible when extremely high doses of appropriate antimicrobials can be instilled and maintained in proximity the infected tissue and implants. The advantages of local antimicrobial therapy include (1) the ability to expose the pathogens to extremely high concentrations of the drug, (2) the avoidance of adverse side effects because of high doses of systemic antimicrobials, and (3) the ability to deliver high doses of antimicrobials that would otherwise be economically unfeasible in large animals. It is important to note that appropriate antimicrobial selection based on culture and sensitivity results are essential to effective therapy and should be considered the gold standard.[28]

ANTIBIOTIC IMPREGNATED POLYMETHYL METHACRYLATE OR PLASTER OF PARIS

The use of *antibiotic impregnated polymethyl methacrylate (PMMA)* or *plaster of paris (POP)* are reliable tools for delivering high levels of local antibiotics to a site of infection.[28,54,159] The advantages of PMMA as an antibiotic delivery device are that its biocompatibility has been well studied, elution profiles for many antibiotics have been documented, and the material is readily available in a sterile, easily used form. The major disadvantages of PMMA are that it is not absorbable, and heat-labile antibiotics cannot be incorporated within it. Although it is easier to mix a powdered antibiotic with the PMMA, liquid injectable forms can also be used. The authors typically use 1 to 2 g of antibiotic for each 10 g of PMMA. Some authors suggest using 5% of the weight of the PMMA (i.e., amikacin, 0.5 g, and PMMA, 10 g) because of concern when PMMA sets.[28] Additionally it should be noted that addition of greater than 10% of antimicrobials weakens the biomechanical properties of the PMMA.[28] If a liquid antibiotic is used, the volume of liquid methacrylate is decreased by half the volume of the added antibiotic. The materials are mixed routinely and formed into cylinders or beads as the material becomes claylike. The ambient temperature of the room will affect the speed of this process. If the PMMA is to be put on a suture (e.g., No. 2 monofilament with multiple bulky knots) to facilitate later removal, that suture should be prepared before mixing. Another alternative frequently used is to simply make beads or cylinders that are not attached to suture and pack them in position. Removal of the PMMA is not necessary unless the plastic is interfering with function. Antibiotics that have been successfully used include gentamicin, amikacin, tobramycin, multiple cephalosporins, and enrofloxacin.[28,54] Premade beads can be resterilized by ethylene oxide (gas) sterilization. The major benefit of POP over PMMA is in situations where removal of PMMA will be particularly problematic. In addition, the plaster is very inexpensive and slowly degraded and absorbed by the body. The antibiotics leach at a fairly rapid rate; about 80% is eluted within the first 2 days.[28] The major disadvantage of POP versus PMMA is that the set-up time is slow in plaster. It is easiest to make the beads up aseptically well in advance and then keep them in a sterile container. They also can be sterilized using ethylene oxide but they become more brittle.

BOVINE COLLAGEN SPONGES

Other popular and easily used local antimicrobial delivery devices are bovine collagen sponges sold to augment surgical hemostasis in human surgery. The advantage of this material is that it is readily available as sterile packaged product, easily fits into any space, and is readily absorbed. We have not seen any allergic responses to its use in horses.

MISCELLANEOUS PRODUCTS

Other products have been used, and newer, improved materials will undoubtedly replace PMMA and POP. Polylactide derivatives, various hydrogels, alginates, polyanhydrides, calcium sulfate, chitosan, and fibrin are all being studied for the local delivery of antimicrobials. It seems likely that a variety of products with different mechanical properties, elution profiles, and absorption will eventually be available to clinicians.

REGIONAL LIMB PERFUSION

Regional limb perfusion (RLP) with antimicrobials is possible in situations where a peripheral vessel is accessible and an effective tourniquet can be applied to isolate the infected region. The major disadvantage of regional perfusion in postoperative cases is the condition of the tissues and the need to avoid vascular damage near the surgical site. Some antibiotics, notably enrofloxacin, will induce significant vasculitis when used for regional perfusions.[28]

If possible, a tourniquet is placed above and below the area to be treated. The key is to have an accessible peripheral vein distal to the proximal tourniquet. The latter should be placed after heavy sedation. If necessary, regional analgesia is used, but many horses will stand with sedation alone. A 25- to 27-gauge butterfly catheter seems to cause the least vascular trauma. Because repeated treatments are usually indicated, it is imperative to keep the vessel in the best possible condition. The application of topical anti-inflammatories such as diclofenac (Surpass) has been shown to decrease postinjection swelling and makes repeated treatments easier to perform.[139] In our opinion, repeated infusions using these very small butterfly catheters allow far more perfusions to be performed before the veins become difficult to use. Even well-placed indwelling catheters in the lower limb seem to cause more problems. Dosage varies, but around one third of a systemic dose diluted to about 30 mL is typical for the distal limb, 60 mL if the tourniquet is above the carpus or tarsus. We have been using systemic doses for regional perfusions without other antibiotic administration. The injection is administered slowly over a period of about 15 minutes, and the tourniquet is left in place for approximately 30 minutes, if possible. These very high doses given regionally subjectively seem to result in the best clinical responses, but more vascular irritation can be a complication with the more concentrated doses of antimicrobials. It is essential to the effectiveness of an RLP that the tourniquet is sufficiently wide and movement of the horse is minimized.[139]

Both intraosseous and intra-articular antibiotic administration are also used to maximize antibiotic levels at the desired site of action. Commercial intraosseous catheters (Cook) and homemade cannulated screws can be inserted for repeated intraosseous treatments. An even simpler technique is to drill a 4.0-mm hole into the medullary cavity at the desired location.

The male end of a Luer-tip extension set will fit snugly into the hole, allowing direct injection. Both intraosseous and intra-articular perfusions should ideally be administered under tourniquet for 30 minutes to maximize tissue levels.

Toxic Side Effects of Antibiotics

The use of antibiotics in horses is rarely associated with toxic side effects. A thorough understanding of the risk factors associated with the use of each type of antibiotics will help prevent these complications.

Antibiotic-induced diarrhea or colitis has been most commonly attributed to *Salmonella* species or *Clostridium difficile* in horses. Horses with colic are particularly susceptible to salmonellosis and are reported to have 4.2 times greater risk of developing salmonellosis than horses presented for other reasons.[160] Additionally, the use of parenteral and enteral antibiotics increased the risk 40-fold, whereas treatment with only parenteral antibiotics increased the risk by 6.4-fold compared to untreated horses.[160] This corroborates the clinical impression that oral antibiotics are associated with a higher incidence of antibiotic-induced diarrhea compared to parenteral administration. In horses undergoing elective arthroscopy, 6.3% of horses that had received antibiotics developed diarrhea within 7 days of surgery.[147] In most circumstances the diarrhea was mild and resolved readily; however, and especially in horses with abdominal surgery, the mortality rate can be as high as 40%.[147,148,161]

Nephrotoxicity is the most common side effect associated with aminoglycoside therapy in horses. The renal toxicity is linked to aminoglycoside accumulation in proximal tubule cells following uptake via the organic ion transport system.[162] This is a saturable process, and as a result the degree of accumulation and toxicity depends more on time than on absolute dose.[162] Because of this mechanism and the concentration-dependent antimicrobial killing effect of aminoglycosides, once-daily dosing routines have been developed to reduce nephrotoxicity and increase efficacy.[148] We routinely use an 8.8 mg/kg sid dose rate of gentamicin in horses undergoing elective and emergency procedures without adverse effects.

Neuromuscular blockade in horses is a potential, although very unlikely side effect of aminoglycoside administration in horses. The use of 6 mg/kg in horses anesthetized with halothane resulted in no significant neuromuscular blockade in horses.[163] Gentamicin has been shown to augment the neuromuscular blockade of atracurium under anesthesia, but the effect was minimal.[164]

Fluoroquinolones, such as enrofloxacin, have been linked to detrimental effects on tendon, cartilage, and bone in horses.[165-168] The detrimental effect of enrofloxacin is of greater severity in younger horses, so it should be used with caution in these situations.[168,169]

Emergence of Bacterial Resistance to Antibiotics

Antimicrobial drug resistance is a very serious issue for both human and veterinary medicine. The cost of antimicrobial resistance to the U.S. human health care system was estimated to be $100 million to $30 billion annually.[170] Unfortunately, the use of antibiotics in animals has been maligned in the lay press, mostly inappropriately, as a cause of antimicrobial resistance. The emergence of drug resistance has been seen in equine pathogens between 1992 and 1997, and in a German study there was a 75% increase in resistance of *E. coli* to tetracyclines, 80% increase to ampicillin and 90% increase to sulfonamides. Furthermore, for *S. aureus,* resistance increased by 50% to 60% to penicillins and by 400% to gentamicin.[171] Bacteria develop resistance to antibiotics through many and varied mechanisms. These include β-lactamase inactivation of penicillins and cephalosporins, enzymatic deactivation of aminoglycosides, and chromosomally based reduction in susceptibility to trimethoprim. The excessive and often inappropriate use of antimicrobials in both human and veterinary medicine must be avoided to ensure the long-term efficacy of antimicrobial prophylaxis.

Summary of Antibiotic Prophylaxis

The use of perioperative antimicrobials in horses must be based on educated and scientifically proven principles. A large number of studies evaluating the use of antimicrobials in surgical facilities, both human and veterinary, have unanimously demonstrated noncompliance to multiple established antimicrobial principles. To prolong the efficacy of our antimicrobial options it is imperative that these principles and guidelines be followed.

CHAPTER 8

Regenerative Medicine

Sarah Ricco, Lindsey Boone, and John F. Peroni

The impetus for regenerative therapy in horses originated in part from promising results obtained in a clinical retrospective study in which autologous bone marrow concentrate was injected intralesionally into 100 horses with suspensory ligament desmitis.[1] The results of this large study indicated that this form of therapy was a safe, effective, and economical way to treat horses with this condition. Nearly 90% of the horses responded favorably, with a significantly higher percentage of treated horses returning to soundness without reinjury than had been reported previously with traditional treatments.[1] These promising results, however, were obtained comparing treated horses against data from the literature (i.e., historical controls), and no data were available regarding the cellular composition of the bone marrow used.

Since this study, many different approaches have been employed in equine practice to aid tissue healing. The majority of these have included the use of autologous *nonexpanded* material, such as conditioned serum, platelet-rich plasma, bone marrow concentrate, and adipose-derived progenitor cells (stromal vascular fraction). The advantages of these products include rapid turnaround times, lack of immunogenic concerns, and absence of federal regulatory control. More recently, the use of autologous or allogeneic products that have been *expanded* in a laboratory setting have gained in popularity. These include mesenchymal stem cells (MSCs) derived from adipose tissue, bone marrow, and neonatal tissues such as cord blood and tissue. These cell-rich products cannot be used as point-of-care treatments because they may take several weeks to expand. It is possible, however, to preserve these expanded products for multiple future allogeneic or autologous uses, if prepared by following rigorous laboratory protocols, which may require more stringent regulation as cellular preparations for medical use.[2]

In contrast to this relative abundance of therapeutic options, regenerative veterinary medicine is still lacking thorough scientific awareness and practical applicability. Although steps have been made in the understanding of the biology behind regenerative approaches in equine practice, there are still many areas that deserve in-depth investigation. For example, no precise recommendations can be made regarding the selection of a specific regenerative regimen for a given lesion. Prospective clinical trials are lacking that would help determine the appropriate timing of the treatment and the outcomes the veterinarian should expect following the treatment. Finally, regulatory bodies that would ensure that appropriate standards of care are followed when using regenerative approaches are still in their infancy in veterinary medicine. These and many other issues remain unresolved in defining the role of alternative approaches to healing equine injuries.

The purpose of this chapter is to review the concepts underlying the use of nonexpanded and expanded regenerative medicine therapies in horses, including blood-derived products and adult stem cells.

AUTOLOGOUS CONDITIONED SERUM

Interleukin-1 (IL-1) and tumor necrosis factor-alpha (TNF-α) are two primary proinflammatory cytokines that initiate and participate in the destructive cytokine cascade in osteoarthritis, leading to catabolic morphological changes within the joint, most notably, erosion of articular cartilage.[3,4] In the course of osteoarthritis, the number of available IL-1 receptors (types I and II) expressed increases, enhancing the detrimental effects of IL-1.[3,4] Therapeutic modalities aimed at diminishing the biologic activity of IL-1 through targeted inhibition of the interaction of IL-1 with its receptor have been proposed and investigated primarily in human but also veterinary medicine for over 30 years.[5] Some of these inhibitors are based on the delivery of IL-1 receptor antagonist protein (IL-1ra), which prevents the interaction between IL-1 and its receptor.[3] IL-1ra availability within the joint has been increased through direct injection of recombinant human IL-1 receptor antagonist protein,[6-8] gene therapy,[7,9-11] or "conditioning" of serum to stimulate production of IL-1ra.[4]

Autologous conditioned serum (ACS) is produced by conditioning certain blood components (primarily monocytes) to increase endogenous production of IL-1ra. Originally, ACS was produced by stimulating blood-derived monocytes with molecules such as immunoglobulin,[12,13] lipopolysaccharide (LPS), phorbol myristate acetate (PMA), IL-1, and TNF-α.[14] In the early 1990s, a clinically more applicable method for production of IL-1ra through exposure of whole blood to medical grade chromium sulfate–treated glass beads was discovered.[15] This method of conditioning was found to not only enhance production of IL-1ra, but also increase production of additional disease-modifying anti-inflammatory cytokines, including IL-4, IL-10, and IL-13.[15] In vitro experiments have established that a 10- to 1000-fold increase of IL-1ra to IL-1 must occur to block all of the available IL-1 receptors that are upregulated during osteoarthritis.[14] IL-1ra has been reported to be increased up to 140 times more than the other anti-inflammatory cytokines present in ACS.[16] The cytokine profile of ACS has been further expanded to include other anti-inflammatory cytokines (IL-6 and osteoprotegerin), growth factors (transforming growth factor-β1 [TGF-β1], fibroblast growth factor [FGF], hepatocyte growth factor [HGF], insulin-like growth factor-1 [IGF-1], platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF]), and interestingly, proinflammatory cytokines such as IL-1β, oncostatin M, and TNF-α.[4] The concentrations of these cytokines have been shown to vary greatly among individuals, leading to wide standard deviations of cytokine concentrations in ACS.[14] Despite the controversial discovery of significant levels of proinflammatory cytokines in ACS, no major differences were found in proteoglycan metabolism of human osteochondral explants obtained from osteoarthritic knees incubated in media with or without ACS.[4]

The possibility of interrupting cytokine based cartilage destruction prompted the commercial development of the human-based product known as Orthokine[15] by Orthogen. Since 1998 Orthokine has been used in human medicine to treat osteoarthritis,[14,15] rheumatoid arthritis,[14,15] muscle injuries,[17,18] and spinal disorders.[14] The preparation is formulated by aseptically exposing whole venous blood to medical grade chromium sulfate–treated glass beads.[4] The blood is incubated at 37° C for 24 hours, then the serum is obtained after centrifugation and stored at −20° C. Six (2 mL) injections of ACS are given over the course of 3 weeks.[4]

Several studies evaluating the effects of ACS use in humans with osteoarthritis have been conducted. One study using validated patient-administered outcome assessments evaluated the long-term clinical effects of the intra-articular injection of ACS, hyaluronan, or saline. There was statistically significant improvement in the scores of those patients treated with ACS after 2 years.[14,19]

In the United States, Orthokine is marketed by Arthrex Vet Systems and is known more commonly in the equine industry as IRAP, the acronym selected to define IL-1ra protein. Indications for use in the horse include patients with synovitis, capsulitis, and mild to moderate osteoarthritis. There have been few controlled trials evaluating the use of ACS in horses. One study evaluated clinical (lameness, range of motion, response to flexion, synovial effusion), biochemical (synovial fluid analysis, glycosaminoglycans [GAGs], prostaglandin E_2 [PGE_2] , IL-1ra), and histological effects (synovium, cartilage) of intra-articularly administered ACS in an experimental model of equine osteoarthritis.[20] In this study, joints were injected four times, approximately 1 week apart, with either IRAP or placebo. No adverse reactions to the injections were noted. A significant increase in IL-1ra within the ACS-treated horses compared to unconditioned serum was seen.[20] In addition, mean synovial fluid IL-1ra concentration increased over time in treated joints. Interestingly, IL-1ra concentration was increased in both the osteoarthritic and the sham-operated joint, indicating a possible systemic effect because of an endogenous production of IL-1ra.[20] There was no significant difference in the degree of joint effusion, response to flexion, or response to joint manipulation, but on day 70, there was a significant improvement in the degree of lameness in the horses treated with ACS.[20] The degree of synovial membrane hyperplasia was also significantly decreased in those horses treated with ACS.[20] This was the first controlled study in horses to identify significant clinical improvement in osteoarthritic joints after ACS administration. ACS is currently being used clinically across the United States and Europe for various joint, tendon, and ligament injuries despite the lack of further substantial evidence regarding its use. Prospective controlled clinical trials are warranted to establish the effectiveness of ACS in treating naturally occurring osteoarthritis in horses.

PLATELET-RICH PLASMA

The intralesional and topical use of blood derivatives for the treatment of equine musculoskeletal trauma and cutaneous injuries has gained popularity and has been recently reviewed.[21-23] The use of blood components in trauma is based on the concept that the delivery of growth factors and proteins of the clotting system may optimize tissue healing. Studies have been aimed at identifying specific cytokines contained in these preparations,[24] assaying their content in platelet concentrate preparations, determining their in vivo and in vitro mechanisms of action, and standardizing the production methods.[25,26]

Platelet-rich plasma (PRP) is derived from centrifugation of whole blood after red blood cells and the buffy coat have been separated from the plasma, which is rich in platelets. PRP has been used successfully in a variety of human ailments, treating lateral epicondylitis (tennis elbow) with percutaneous injections,[27] enhancing early bone formation during lumbar spinal fusion,[28] and increasing the healing rates of chronic foot ulcers in diabetics.[29] Also, PRP gel is widely used in wound therapy and oral or maxillofacial surgery. The platelet-rich gel matrix is formed by coincubation of PRP with calcium ions or enzymes such as thrombin to activate the coagulation process.[29-32] The main idea behind the use of these products is to enhance tissue repair by delivering growth factors directly to the area of injury.

Platelets are a vital source of growth factors, chemokines, and cytokines, all of which are released during the reparative processes occurring in the early phases of tissue healing. It is thought that the delivery of PRP and platelet gel mimics and enhances the physiological processes of clotting and wound repair, thereby stimulating intrinsic tissue regeneration in which endogenous platelets are a vital component.[32,33] Furthermore, PRP may also stimulate chemotaxis of macrophages, angiogenesis, proliferation and migration of fibroblasts, and collagen synthesis, which are all vital components of tissue healing.[33] Following activation, the alpha granules contained within the platelet cytoplasm degranulate and release a series of growth factors. Some of these are known to participate in healing of soft tissues and include PDGF, IGF-I and IGF-II, TGF-β1, VEGF, FGF, and platelet-derived epidermal growth factor (PDEGF). Other growth factors also present in PRP, such as osteocalcin (Oc), osteonectin (On), fibronectin (Fn), and thrombospondin-1 (TSP-1), are more important in assisting bone and cartilage healing.[34-36]

Biology and Preparation of Platelet-Rich Plasma

PRP is thought to be advantageous in tissue healing because it has a direct regulatory effect on cellular processes such as mitogenesis, chemotaxis, differentiation, and metabolism.[37,38] As described earlier, growth factors released from PRP improve and enhance the healing of soft tissues and promote bone regeneration processes. The secretion of growth factors begins a few minutes after the introduction of PRP into the site of injury when the clotting cascade starts; over 95% of the growth factors are secreted within 1 hour.[39,40] Growth factors bind to the outer surface of cell membranes through specific transmembrane receptors. Studies have shown that adult mesenchymal cells, osteoblasts, fibroblasts, and endothelial cells express transmembrane receptors for growth factors contained in PRP.[33] Via specific signaling pathways, activated receptors induce the expression of genes responsible for a variety of cellular processes, including cell proliferation, tissue matrix and osteoid production, and collagen synthesis.[32,41] It is important to note that PRP does not act directly on the cell nucleus, thereby eliminating any possible risk of mutagenic activity and tumor formation.[42] This has been considered a risk with the use of other cell-based regenerative approaches such as treatment with embryonic stem cells. Under normal circumstances, platelets may continue to release growth factors for several days after reaching the injury site, because the half-life of platelets has been estimated to be 5 to 7 days.[42]

The regenerative potential of PRP depends on the levels of proteins and growth factors that are secreted by activated platelets. Attempts to quantify the concentration of growth factors released by activated platelets revealed that there is a substantial variability among species and individuals. Other factors may alter the content of growth factors in PRP at the time of delivery into tissues, including platelet enrichment technique and activation of platelets during processing. Platelet concentrates have also been shown to have a dose-dependent trophic effect on the proliferation of adipose-derived mesenchymal stem cells and tenocytes in culture. In fact, rates of proliferation were more pronounced in adipose-derived mesenchymal stem cells than tenocytes; proliferation began at 24 hours and was maintained for up to 72 hours after the introduction of PRP.[43]

There are many different systems on the market that produce PRP, with a high variability in the final products' characteristics, including platelet concentration, output volume, and fibrinogen concentration. These commercially available medical devices rely on two fundamental principles of platelet isolation: centrifugation and filtration. With the first method, specialized equipment has been designed to process whole blood via sequential centrifugation steps, which yields deliverable PRP with a known platelet concentration. An alternative method uses specifically designed filters with appropriate pore sizes that are adapted to whole blood collection devices and rely on gravity flow to isolate platelets.

Regardless of the technique used, it has been suggested that an optimal PRP formulation should concentrate platelets at least three to five times the baseline platelet count for that individual, or alternatively to a concentration of at least 1×10^6 platelets/μL.[44] Therefore, before each clinical use, platelets and the resultant concentrations of growth factors should be quantified. Unfortunately, commercially available PRP kits should be scrutinized carefully in equine practice because quality control standards used in people may not apply to horses. Centrifugation speeds needed to separate platelets are known to vary across species and likely influence the final composition of PRP.[45] Specifically, important interspecies differences have been found in blood viscosity, platelet density, and degree of platelet activation and aggregation.[44-50] Because there are few precise recommendations regarding PRP concentration and volume, clinicians should use the product with the highest platelet concentration possible.

In a laboratory setting, the preferred method for PRP preparation is the differential centrifugation technique. Venous blood is collected using commercially available blood collection bags containing acid citrate dextrose (ACD) solution, which is usually 10% of the volume of blood collected. ACD contains dextrose as an energy substrate to sustain cell viability; citrate, which chelates calcium ions, thus inhibiting the coagulation cascade; and sodium citrate, which is known to preserve platelet morphology and function.[51]

To obtain PRP, venous blood is drawn and separated into sterile 50-mL test tubes and initially centrifuged at low speed. The sedimentation of cellular elements during centrifugation is determined by their size and the difference between their density and that of the surrounding fluid. Therefore red blood cells and leukocytes settle more quickly than platelets and plasma. Plasma and platelets are carefully recovered above the buffy coat layer and maximally concentrated with subsequent centrifugations at higher speeds to achieve the desired volume. Quality control policies should be implemented in laboratories where a sample of PRP preparation is used for platelet count, aerobic culture, and growth factor analysis.

Platelet-Rich Plasma Applications in Horses

The repair process of tendon and ligament injuries, which are common in both human and equine athletes, is slow, and the quality of the repair tissue is inferior to the original tendon tissue. Consequently, healed tendons and ligaments are predisposed to reinjury.[52] Limitations in the healing potential of tendons and ligaments have been ascribed to a relatively poor vascularization and the need for essential growth factors to be present to guide the healing response.[52-54]

PRP is an attractive alternative to traditional means of therapy in soft tissue injuries in horses because it is known to contain specific growth factors that participate in tendon and ligament repair.[55-58] As one example, a study using a collagen-induced superficial digital flexor tendonitis model showed that serial treatments with IGF-1 (a growth factor found in PRP) improved cell proliferation, collagen content, mechanical stiffness, and sonographic appearance of treated tendons during 8 weeks of treatment.[59,60]

Drawing from this and similar experiments, a study was conducted to determine the temporal release of growth factors from PRP, bone marrow aspirate, and a commercially available freeze-dried, stabilized, platelet product (PP). The effects of growth factor release were tested by measuring gene expression patterns in tissue explants of equine superficial digital flexor tendon and suspensory ligaments. The authors pursued the study in part to determine the possibility of using PP as a readily available off-the-shelf product that would decrease preparation time and cost. The results of this study indicated that growth factor concentrations were proportional to platelet concentrations and that the highest platelet counts were found in PRP and PP, both of which had significantly higher TGF-β1 and PDGF concentrations compared to bone marrow aspirate. Interestingly, growth factor release was sustained in these tissue explants for 4 days without exogenous induction of platelet activation. Furthermore, gene expression profiles in both PP and PRP were more favorable than those obtained after exposure to bone marrow aspirate.[37]

Gene expression patterns, DNA, and collagen content were also evaluated in explants obtained from equine superficial digital flexor tendon and cultured in media containing blood, plasma, PRP, platelet-poor plasma (PPP), and bone marrow aspirate. Concentrations of growth factors TGF-β1 and PDGF were higher in PRP than all other blood products tested. Additionally, tendon explants cultured in 100% PRP had superior tendon matrix gene expression patterns without simultaneous stimulation of catabolic cytokines.[61] A similar *in vitro* study was aimed at evaluating the effect of blood-derived products on synthesis of suspensory ligament matrix. In contrast to the previous study in which PRP was found to be more anabolic in flexor tendon explants, this study indicated that acellular bone marrow and not PRP increased matrix molecule expression, without concurrent increased catabolic gene expression. This study seemed to highlight differences in the matrix metabolism between the superficial flexor tendon and the suspensory ligament and indicated that acellular bone marrow might be preferred over plasma, blood, PRP, or PPP as a biological means to enhance suspensory ligament regeneration.[62]

Additional evidence that different regenerative approaches may be indicated for different tissues comes from another study that compared effects of acellular bone marrow, PRP, and serum on cultured suspensory ligament fibroblasts. These products were tested to determine their ability to stimulate production of cartilage oligomeric matrix protein (COMP), a component of ligament healing response and a marker of appropriate ligament matrix (re)modeling.[63] The study found that although all preparations had increased COMP levels, exposure of the tissues to acellular bone marrow resulted in the greatest increases in both COMP and total protein synthesis by the suspensory fibroblasts. The conclusion drawn from this study was that treating suspensory desmitis with bone marrow aspirate may enhance healing by providing anabolic factors, which stimulate matrix production.[64]

Among the growth factors abundantly present in PRP, VEGF is a powerful stimulator of angiogenesis. In a model of surgically induced superficial digital flexor tendon injury, the effect of PRP on neovascularization was studied using color Doppler ultrasonography and immunological staining of factor VIII.[65] PRP induced significantly more neovascularization than the placebo treatment until at least 23 weeks after treatment. The authors of this study speculated that a prolonged increase in neovascularization might suggest a long-lasting effect of a single intratendinous injection with PRP.[65] Furthermore, in a similar but separate study, PRP-treated tendons had a better organization of the collagen network, a higher content of glycosaminoglycans, and a higher strength at failure when compared to placebo treated tendons.[26] Using different investigative approaches, these studies highlight a prolonged effect of PRP treatment, which may corroborate the clinical notion that in naturally occuring tendonitis and desmitis, frequent PRP injection is not necessary.

A single PRP treatment and a controlled exercise rehabilitation program were, in fact, recommended in nine Standardbred racehorses with moderate to severe midbody suspensory ligament desmitis. All nine horses returned to racing within a median time period of 32 weeks, competing at least once during the first and second years after returning to racing. Although only five horses raced during the third year from the injury, the authors suggest that combining intralesional PRP and a careful rehabilitation program afforded these horses an excellent prognosis for returning to racing.[66]

Platelet-Rich Plasma in Osteoarthritis

Although PRP has been used more frequently to treat soft tissue injuries, it is steadily gaining popularity in the treatment of joint disease. Initial evaluations of the intra-articular use of PRP in animal models and in people have ascribed some of its success to modulation of pain response via an anti-inflammatory effect.[67] It is also possible that growth factors in PRP aid cartilage repair, preventing the progression of osteoarthritis.[68,69] In a retrospective cohort study in humans with knee arthritis, PRP was significantly better than hyaluronic acid preparations in reducing pain and improving function.[70] Furthermore, in a prospective clinical trial, patients undergoing total shoulder arthroplasty demonstrated lower postoperative pain scores and improvement in functional internal joint rotation index.[71]

Guidelines for joint injection of PRP in horses have not been established. Currently no recommendations of volume, platelet concentration, and frequency of injection can be given, although anecdotal evidence suggests administration of up to 3 injections at 2-week intervals. A review of five horses with osteoarthritis in which this approach was used showed improvement in degree of lameness and joint effusion that was maximal 2 months after the last PRP injection and persisted up to 8 months.[72]

ADIPOSE-DERIVED STROMAL VASCULAR FRACTION

Proof that adult stem cells could be obtained from adipose tissue was initially demonstrated in 2001, when an adipose aspirate was found to contain large numbers of mesenchymal stemlike cells that could be induced to differentiate into adipogenic, chondrogenic, myogenic, and osteogenic lineages.[73,74] Since then, many horses with soft tissue injuries and joint disease have been treated with a nonexpanded adipose-derived autologous preparation called stromal vascular fraction (SVF) (data from Vet-Stem; www.vet-stem.com). This fat-derived mononuclear cell fraction contains MSCs, T regulatory cells, endothelial precursor cells, preadipocytes, and macrophages.[74,75] When compared to bone marrow, adipose tissue is easier to obtain and has a proportionally higher content of MSCs, which according to some may also be easier to expand *ex vivo* and cryopreserve.[76,77]

Primary adipose tissue–derived cells such as those found in the SVF preparation are an attractive option because they do not require the 3 to 4 weeks necessary to expand MSCs, or the laboratory costs and expertise needed to avoid contamination during *ex vivo* expansion. Additionally, because SVF is considered a minimally manipulated autologous preparation, it is unlikely to undergo scrutiny or require approval of the U.S. Food and Drug Administration. Unfortunately, there are few studies that have critically addressed the clinical merit of SVF in veterinary medicine. Nonetheless, the abundant use of these products has supported the anecdotal notion that SVF may have benefit in healing of tendon and ligament injuries without any ill effects locally or systemically.[78,79]

In a blinded placebo-controlled study, SVF was used to treat collagenase-induced tendonitis in horses. The results of that study showed an improvement in inflammatory cell infiltrate, collagen fiber uniformity, polarized collagen fiber crimping, overall tendon healing score, and collagen oligomeric matrix protein scores.[80]

Furthermore, the intra-articular injection of adipose-derived stem cells significantly improved lameness, range of motion, and overall quality of life in double-blinded, multicenter, randomized studies conducted in dogs with osteoarthritis of the elbow joint.[81] However, the results were different when a well-established model of osteoarthritis of the equine middle carpal joint was used, and the efficacy of intra-articularly administered SVF and bone marrow–derived MSCs was compared.[82] Although no adverse effects were noted, this study was unable to demonstrate significant differences in clinical, biochemical, and histologic parameters between horses in the placebo or treatment groups. The one exception in that study was that synovial fluid obtained from joints treated with bone marrow–derived MSCs had decreased production of PGE_2 when compared to fluid from placebo-treated joints.[82] The obvious discrepancy that exists between anecdotal clinical impressions and controlled studies regarding the use of SVF in horses should motivate

researchers and clinicians to conduct well-designed, multicenter, prospective clinical trials.

MESENCHYMAL STEM CELLS

Stem cells can promote tissue regeneration, regulate the inflammatory response caused by trauma, and reduce scar formation during the processes of tissue repair.[83-85] Clinicians, researchers, and members of industry have explored the option of harvesting stem cells from the horse to promote tissue healing and explore their commercial value as a therapeutic agent. As often occurs in the equine industry, this new and exciting treatment has found widespread clinical applications without the development of a corresponding thorough scientific understanding of equine stem cell biology. Although equine researchers and clinicians are expanding our understanding of stem cell use in the horse, most of the concepts that currently underpin their use are extrapolated from a wealth of information in the human literature. Even an incomplete review of this work allows one to conclude that scientists have approached stem cell biology from many directions. Researchers have dedicated themselves to understand the role of stem cells in the maintenance of homeostasis during physiological tissue turnover,[86-88] to elucidate their phenotypic and genotypic characteristics in a variety of species,[89-92] and to explain the mechanisms underlying the interactions of these cells with the host environment.[93-96] Furthermore, the potential therapeutic value of stem cells is supported by the multitude of completed and ongoing clinical trials aimed at resolving many pathologies, including cancer, graft-versus-host disease, multiple sclerosis, and many others (see clinicaltrials.gov, a service of the National Institutes of Health).

Stem cells are able to replicate through a process of self-renewal and differentiate into various mature cell types. These characteristics are important in organogenesis during embryonic development, in the maintenance of tissue homeostasis during the normal processes of cellular turnover, and in tissue regeneration following injury.[97] Stem cells are generally divided into two groups, embryonic and adult. Embryonic stem cells are considered pluripotent because they are able to differentiate into cells belonging to all three germinal tissues, including endoderm, mesoderm, and ectoderm.[97,98] They are derived from the blastocyst stage of the mammalian embryo and are capable of unlimited, undifferentiated proliferation *in vitro*. Embryonic stem cells have been isolated from equine embryos, cultivated up to the blastocyst stage, and phenotypically and genotypically characterized.[99-101] Equine embryonic stem cell lines have been determined to be pluripotent *in vitro*, but to date there are no *in vivo* studies to support this quality.[102,103] Various companies have begun to explore commercial opportunities associated with embryonic stem cells (i.e., Celavet, Oxnard, CA; ViaGen, Austin, TX), although ethical and moral concerns that have beleaguered human embryonic stem cell research and applications are likely to pose similar concerns within the equine industry.[2]

After birth, adult stem cells, also known as somatic stem cells, can be found in various tissues in an environment known as a "niche," the characteristics of which depend on the nature and type of tissue in which they are located.[104,105] Although the concept of a niche as a reservoir seems to be well established, there are several aspects of somatic stem cell biology *in vivo* that are unclear. For example, it appears that injury will activate quiescent MSCs and stimulate self-renewal, but aging and disease states cannot.[105,106] The signaling pathways responsible for preserving these cells within a niche in an undifferentiated state and those regulating their activation are poorly understood.[107-109]

Because they are relatively easy to harvest, the adult stem cells that were initially studied and used for their regeneration capacity were the hematopoietic stem cells, which are responsible for reconstituting the cellular fraction of blood. These cells have played vital roles in the treatment of diseases in many systems, especially of the hematopoietic system. They are primarily isolated from bone marrow but have also been found in umbilical cord blood and peripheral blood.[110-112] In addition to the hematopoietic cell fraction, the bone marrow serves as one of the main niches from which adult mesenchymal stem cells are obtained. These cells are often referred to as bone marrow stromal cells, which are established in the developing marrow cavity within sinusoids near the branching of terminal marrow arterioles.[113] Although neither *mesenchymal* nor *stromal* are terms that adequately describe the properties of adult stem cells, they have been used interchangeably[114,115] and the term *mesenchymal stem cells* (MSCs) will be used from this point forward in this chapter.

MSCs were first described as adherent, clonogenic, nonphagocytic, and fibroblastic cells. They were isolated from the adult bone marrow stroma and under appropriate experimental conditions were able to differentiate into a variety of connective tissues, including cartilage, bone, adipose tissue, and fibrous tissue.[113,116-118] MSCs have since been characterized as undifferentiated cells capable of asymmetric cell division, a process by which one daughter cell develops into a somatic cell type while the other retains stem cell identity within the niche tissue.[119]

Several studies have demonstrated that MSCs obtained from human, canine, rabbit, rat, mouse, and horse can differentiate both *in vitro* and *in vivo* into somatic mesenchymal phenotypes, including bone,[120,121] cartilage,[122] tendon,[123,124] muscle,[125] adipose tissue,[125] and hematopoietic-supporting stroma[126,127] and unexpectedly into neural cells,[128] cardiomyocytes,[129] and pneumocytes.[130]

Regulation of Inflammation and Modulation of Immune Responses

In addition to their capacity to differentiate into various cell lineages and their potential use in tissue repair, MSCs are potent regulators of immune responses. For example, MSCs inhibit T-cell activation, B-cell function, and dendritic cell maturation *in vitro* and efficiently protect against allograft rejection and experimentally induced autoimmunity.[131-134] Moreover, MSCs recently were proved to be highly effective in the treatment of a murine model of acute and chronic colitis.[135,136] In those studies, a single systemic injection of MSCs at the onset of the disease ameliorated clinical signs and histopathologic lesions, and they reduced mortality rates.

The results of several studies have shown that the beneficial effects of MSC therapy are not restricted to administration of autologous cells, but that allogeneic cells are just as efficient in improving outcomes of colitis, myocardial infarction, and renal disease.[137-139] These findings suggest that the immunosuppressive action of MSCs is not restricted by class I major histocompatibility complex, and that the infused MSCs are tolerated by the host's immune system.[140]

One recent study explored the location and tissue interaction of autologous and allogeneic MSCs following injection into the equine superficial digital flexor tendon.[141] Follow-up examinations revealed that viable fluorescently labeled MSCs had remained within the lesions created in the tendons for up to 8 weeks posttreatment and that no visible cell-mediated immune response to the allogeneic treatment could be detected histologically.[141] Although more research is needed, this report suggests that allogeneic MSCs may not trigger an immune response, opening the exciting possibility of using banked allogeneic cell lines in equine regenerative medicine.

An emerging body of data indicates that MSCs reduce proliferative responses by allogeneic lymphocytes and the synthesis of inflammatory mediators by stimulated lymphocytes cocultured with MSCs.[142,143] Furthermore, evidence suggests that a profound anti-inflammatory effect can be elicited by using the supernatant obtained from cocultures of MSCs and stimulated lymphocytes. For example, studies have shown that MSCs alone or cocultured with lymphocytes secrete IL-10, a well-recognized growth factor for regulatory T cells.[144,145] IL-10 can subsequently antagonize the effects of IL-12 during induction of inflammatory immune responses.[145] Similarly, TGF-β1, which also plays a role in T-cell suppression, is secreted into media in cocultures of human MSCs and immune cells and can be used as an acellular preparation to modulate inflammation.[146,147] The potential application of MSCs in horses to control inflammation has not been explored, although modulation of wound healing and control of sepsis, endotoxemia, and other common equine inflammatory conditions may be researched in the very near future.

MSC Isolation from Horses

MSCs have been isolated with success from equine bone marrow and adipose tissue.[93,148-150] Equine MSCs have been also successfully isolated from prenatal tissues, such as placenta, umbilical cord blood, fetal bone marrow, and blood.[151-154]

Although bone marrow has been the most popular source of MSCs in horses for research and clinical applications, harvesting adipose tissue as a source of regenerative cells is advocated because it is readily available in large quantities beneath the subcutaneous space. The procedure is also less painful and lacks the possible complications associated with bone marrow aspiration.[155] Investigations into the superiority of one source of MSCs over the other have conflicting conclusions. Several studies have indicated little difference in the regenerative and differentiation potential, growth kinetics, cell senescence, and efficiency of gene transduction of MSCs obtained from the two sources.[156,157] Yet other research has supported the notion that fat yields more MSCs than bone marrow (2% versus 0.002%), and that adipose-derived MSCs demonstrate faster rates of proliferation and have a greater immunosuppressive ability.[158,159] One possible explanation for the superior yield of MSCs from fat may be derived from recent evidence of a link between cultured MSCs and vascular density of the tissue of origin. MSCs were associated with the vasculature, validating the use of adipose tissue as a source of mesenchymal progenitor cells for clinical purposes.[160]

Attesting to the lower number of MSCs found in the bone marrow, a study showed that only 0.01% to 0.001% of mononuclear cells isolated from the bone marrow form fibroblast-like colonies,[161] and this number decreases with age.[114] This is likely to be the case in horses where the quality of MSC harvest seems to decrease in older animals. When cells are harvested, plated, and near confluence, they can be divided among several culture flasks for amplification. As this process continues, cells assume a more homogeneous phenotype and may continue to proliferate for up to 40 generations, which has also been found in equine embryonic stem cells.[103]

Equine bone marrow is commonly obtained from the sternebrae, and bone marrow–derived mesenchymal stem cells (BM-MSCs) have been expanded and characterized.[162] An adequate sample of marrow can also be collected from the cancellous portion of other bones, such as the crest of the ilium or the proximal humerus and tibia. When harvesting from the sternum, horses are restrained in stocks and sedated with a combination of detomidine hydrochloride (10 μg/kg) and butorphanol (20 μg/kg). After clipping the midline area over the sternum, the intersternebral spaces are identified by ultrasonography. Aseptic preparation and local infiltration of anesthetic solution allows a stab incision to be made with a No. 15 scalpel blade on the sagittal plane of the sternum. A 10-gauge Jamshidi biopsy needle is introduced through the stab incision and advanced until it contacts the chosen sternebra. The needle is subsequently further advanced 3 or 4 cm with slow rotational motions. Syringes containing anticoagulant are attached to the needle, and marrow aspiration is completed. Occasionally, hemorrhage occurs at the biopsy site and is usually controlled by applying pressure with sterile gauze.

Once transferred to the laboratory, the bone marrow aspirate is processed using several cell isolation techniques, including direct adherence to a plastic tissue culture plate or density gradient centrifugation followed by adherence. With either of these methods, MSCs are grown using specific essential growth media, typically containing fetal bovine serum, and "purified" from the mononuclear cell fraction of the marrow because of their selective adherence to the plastic. The MSC amplification process involves the regular removal of nonadherent cells to obtain a more homogeneous cell culture, a process that requires between 2 and 4 weeks, depending on the number of cells harvested and the desired final cell number. Of interest is that when MSCs are seeded at low density they demonstrate a classic spindlelike shape, but when they are near confluence they begin to proliferate in layers and become flat with irregular cellular margins.[163]

Intra-Articular Use of MSCs

Regeneration of articular cartilage presents unique challenges because of its lack of vascularity and innervation, which leads to an inefficient and slow intrinsic healing capacity. Frequently, the tissue that regrows following injury consists of scar tissue or fibrocartilage that lacks the necessary mechanical properties to withstand the normal physiological strain of the joint, resulting in further articular degeneration.

Equine MSCs have been chondrogenically differentiated in monolayer culture, micromass pellets, or matrices. The micromass is a three-dimensional tissuelike construct that requires a minimal number of cells to induce the differentiation of mesenchymal precursors along the chondrogenic and osteogenic pathways.[164,165] Various growth factors have been studied, including TGF-β1, TGF-β3, and FGF. TGF-β1 at concentrations of 0, 1, 5, or 10 ng/mL were added to equine BM-MSCs monolayer cultures. In these studies, cells and media harvested after

4 days in culture. The media and cells were analyzed for evidence that the cells were being pushed to a chondrocytic phenotype. TGF-β1 at 5 ng/mL was shown to increase cellular density, cell layering, nodule formation, collagen type II mRNA expression, and collagen type I mRNA expression over controls.[166]

A study evaluating the effects of TGF-β3 supplementation compared BM-MSCs and adipose derived MSCs from 11 horses. Both cell types were cultured as micromass pellets with TGF-β3 (10 ng/mL) and bone morphogenetic protein (BMP)-6 (10 ng/mL) supplementation.[167] Pellet cultures were harvested at 3, 7, 14, and 21 days and analyzed for cross-sectional size, tissue composition, Alcian blue staining for GAG content, collagen type II immunostaining, and transmission electron microscopy. BM-MSCs obtained hyaline-like cartilage morphology by day 14 with lacunae formation and rounded chondrocytes, but adipose-derived MSCs produced a mature fibroblastic morphology for the duration of the study. BM-MSCs had more intense GAG staining and showed superior chondrogenic potential compared with adipose-derived MSCs.[167]

Another study compared the differentiation capacity of adipose-derived and BM-MSCs from three horses. BM-MSCs and adipose-derived MSCs were culture-expanded in growth media supplemented with 1 ng/mL TGF-β1 to prime the cells, then trypsinized and encapsulated (10×10^6 cells) in an agarose or a self-assembling peptide construct molded into 1.6-mm thick flat slabs. TGF-β1 supplemented BM-MSCs cultures had 5-fold higher ^{3}H-proline incorporation, 28-fold higher ^{35}S-sulfate incorporation, and 10-fold higher GAG concentration compared to adipose-derived MSC cultures supplemented with TGF-β1.[150] BM-MSC cultures supplemented with TGF-β1 produced extensive synthesis of aggrecan-like proteoglycan monomers and increased type II collagen gene expression. Histological analysis of the TGF-β1 supplemented BM-MSCs cultures revealed a continuous proteoglycan and type II collagen–rich extracellular matrix.[150] The results of this report would attest to superior chondrogenic differentiation capacity of BM-MSCs over adipose-derived MSCs when seeded in a hydrogel culture.[150]

Equine BM-MSCs and umbilical cord blood–derived MSCs (UCB-MSCs) have also been compared in their capacity for chondrogenic differentiation while maintained in a micromass pellet. UCB-MSCs were found to produce larger pellets with hyaline-like cartilage morphology, higher concentrations of cartilage-derived retinoic acid–sensitive protein, and higher gene expression of collagen 21, aggrecan, and CD-RAP. Sox 9 (marker of chondrogenic differentiation) expression, however, was similar in BM-MSCs and UCB-MSCs. This suggested that UCB-MSCs possess a higher capacity for chondrogenic differentiation than BM-MSCs.[168]

Unfortunately, production of extracellular matrix (ECM) by chondrogenically differentiated cells is not perfect. For example, a study comparing cartilage production of bovine-derived articular chondrocytes with bovine MSCs seeded on agarose gels and cultured with TGF-β3 under chondrogenic conditions showed that BM-MSCs underwent chondrogenic differentiation, but the amount of ECM produced and the mechanical properties of the ECM produced by the BM-MSCs was inferior to that produced by the articular chondrocytes.[169] In contrast, a more recent study compared chondrogenic differentiation of harvested chondrocytes and BM-MSCs from foals and a skeletally mature adult horses.[170] Constructs seeded with immature and mature BM-MSCs produced tissue that was mechanically superior to constructs seeded with immature and mature chondrocytes. BM-MSCs also produced longer core protein and longer chondroitin sulfate chains than chondrocyte-seeded constructs independent of age. BM-MSCs also produced cartilage-like ECM that was mechanically superior to age-matched chondrocytes.[170]

The majority of studies evaluating the use of BM-MSCs in articular regeneration use three-dimensional scaffolds and growth factors to chondrogenically differentiate MSCs and promote ECM formation. However, a large body of research has been dedicated to the implantation of undifferentiated BM-MSCs in suspension and relying on the synovial environment to influence the BM-MSCs toward the chondrocytic phenotype.[171] Injection of BM-MSCs in suspension would be clinically superior to scaffold implantation because injection is not as invasive as arthrotomy. Reduced cost, reduced morbidity, and decreased recovery time are also important advantages. Furthermore, injections of BM-MSCs would theoretically treat the synovial environment as a whole rather than only the local environment of the articular cartilage defect. Unfortunately, little is known regarding the intra-articular behavior of MSCs *in vivo*. Many pertinent questions remain unanswered regarding the differentiation of MSCs into the surrounding host tissue; also unknown is the possible trophic effect they may have on the surrounding cells through release of growth factors or cytokines to produce extracellular matrix.[171] The answers to all of these questions are likely to be complicated when accounting for the various permutations of the osteoarthritic synovial environment.

In one of the first studies conducted to evaluate intra-articular use of BM-MSCs in a large animal model, an experimentally induced osteoarthritis caprine model with anterior cruciate ligament transection and medial meniscectomy was used.[172] Approximately 10×10^6 autologous BM-MSCs suspended in 20 mg of hyaluronic acid were injected intra-articularly 3 weeks after osteoarthritis was induced. This study found that the degree of cartilage destruction, osteophyte formation, and subchondral sclerosis were all reduced in the treated joints compared to the control joints, and meniscal restoration was observed 6 weeks after injection. After 20 weeks, the repaired menisci had large areas that stained positive for proteoglycan and type II collagen with the typical appearance of fibrocartilage.[172] This study highlighted the potential of a therapeutic intra-articular injection of BM-MSCs in large animals with concurrent femorotibial soft tissue disease.

One subject of debate is the engraftment of intra-articularly administered MSCs. Researchers have expressed concern that cells may not adequately adhere to the areas of defective cartilage, which would diminish their effectiveness. One group implanted fluorescently labeled MSCs suspended in a gelatin matrix into full-thickness chondral defects in a caprine model. They found that the MSCs were gradually lost from the implant and that large fragments of the gel could be found in deep marrow spaces.[173] In another study, human MSCs were implanted *in utero* in sheep and then followed to assess engraftment and survival.[174] It was found that MSCs underwent site-specific differentiation into chondrocytes, adipocytes, myocytes, cardiomyocytes, bone marrow stromal cells, and thymic stroma. However, cartilage engraftment was found to be inefficient. [174] Despite these concerns about articular cartilage engraftment, cell therapy has been positively correlated with improvements in clinical symptoms of disease.

Regarding the intra-articular use of MSCs in horses, there is substantial contrast between the paucity of research and clinical trials and the relatively numerous anecdotal reports of horses benefiting from injections of autologous MSCs (see data from Vet-Stem; www.vet-stem.com). It is important to note that there are no controlled clinical trials that evaluate the use of MSCs in naturally acquired equine joint disease. One study had approximately 12 million equine BM-MSCs suspended in a self-polymerizing autogenous fibrin matrix implanted into 15-mm cartilage defects in the lateral trochlear ridge of the equine femur.[175] Arthroscopic evaluation 30 days postinjection revealed significant improvement in arthroscopic scores for cartilage defects treated with BM-MSCs. Biopsy of the defects at 30 days revealed increased fibrous tissue with predominant production of type II collagen. Unfortunately, 8 months after injection, no significant differences were detected in arthroscopic scores and biopsy assessments for proteoglycan and collagen type II. This led to the interpretation that BM-MSCs helped early chondrogenesis but did not significantly improve the long-term outcomes.[175]

Following this study, a technique was developed in which the nucleated cell fraction from equine bone marrow was heavily concentrated, suspended in a fibrin construct, and used to treat full-thickness articular defects. Twelve weeks after treatment, concentrated fibrin-based bone marrow aspirates yielded positive arthroscopic scores that were also visible 8 months postinjection. In fact, treated horses continued to show significant improvement over control animals in gross, histological, and MRI grades.[176]

In contrast, and as reviewed more in detail in the section on stromal vascular fraction, intra-articular injection of BM-MSCs, adipose derived stromal-vascular fraction, and a placebo were compared in an established experimental model of equine osteoarthritis.[82] The only reported beneficial effect of BM-MSC treatment was a significant decrease in the PGE_2 concentration in synovial fluid in both the sham operated and treated joints, indicating a possible systemic effect of the BM-MSCs.[82]

Despite these results, a report was published on 162 equine cases treated with BM-MSCs from six equine referral centers. A total of 97 horses with 101 treated lesions were available for follow-up. Three horses that were injected intra-articularly had adverse reactions, but they improved and were able to return to work. Fifty-two of 61 (85%) horses with soft tissue injuries and 29 out of 40 (73%) with orthopedic injuries were able to return to work with mean follow-up time of 21 months. No significant association with outcome was found for age, sex, breed, discipline, or severity of lesion.[149]

Application of MSCs in the Treatment of Tendonitis and Desmitis

Tendon and ligament injuries in horses are a major cause of unsoundness in part because these injuries require prolonged healing times and are often the cause of reinjury and further loss of soundness.[177] As occurs in other tissues, tendon healing follows a sequence of events consisting of an acute inflammatory phase, a proliferative (fibroblastic) phase, and a remodeling phase, during which fibrous scar tissue replaces the originally well-arranged collagen network. The elasticity of a scarred tendon is vastly inferior to that of healthy tendon, which increases the risk of reinjury.[177] For more information see Chapter 83.

The use of MSCs as candidates for tendon and ligament regeneration has been recently reviewed.[57,178,179] MSCs have been considered as viable candidates to support the healing of soft tissue injuries because of their differentiation into tenocytes that may occur following *in vivo* transfer.[178-180] It is also possible that MSCs provide the injured area with growth factors that may guide the tissues toward an improved healing response.[181-183]

An original report described the implantation of expanded BM-MSCs into a superficial digital flexor tendon lesion in a horse. This report was the first to describe the expansion and intralesional injection of BM-MSCs using plasma as the vehicle. It also highlighted the need to expand the use of cell therapies in horses with tendonitis by designing carefully controlled clinical trials.[184] Similarly, racehorses with naturally occurring superficial digital tendonopathy were successfully treated via the injection of undifferentiated autologous BM-MSCs.[185] In this study, 90% of racehorses returned to previous levels of competition following treatment, without evidence of reinjury for more than 2 years, whereas in the non–MSC-treated control group, reinjury occurred in all horses after a median time of 7 months.[185]

Intralesionally administered BM-MSCs were shown to cause tendon regeneration in a collagenase-induced tendonitis model in Standardbred horses.[186] A similar tendonitis model was used to assess the potential of adipose-derived nucleated cell fractions for improving tendon repair. The study concluded that cell fractions improved the overall tendon architecture and fiber organization and supported the use of such a preparation to aid in the therapy for tendonitis.[80]

The reader should be aware of the difficulties arising from comparing adipose-derived nucleated cell fractions (discussed previously in "Adipose-Derived Stromal Vascular Fraction") and culture-expanded MSCs in the therapeutic approach to tendonitis and desmitis. Expanded cell cultures have the disadvantage of requiring several weeks of preparation before clinical use, although the most appropriate timing of any regenerative treatment remains subject of debate. Expanded MSCs offer the opportunity to manipulate the cells before introducing them into the injured tissue. As an example, a recent study evaluated the effects of MSCs as well as IGF-1 gene-enhanced MSCs on tendon healing *in vivo* using an equine collagenase model of flexor tendonitis.[187] The study reported that following treatment, tendons had improved biomechanical characteristics; this supports the use of MSCs alone and IGF-1–enhanced MSCs into tendonitis core lesions, although the differences between the two treatments were not significant.[187]

Only a few reports are available that describe the long-term outcome of horses with naturally occurring tendonitis treated intralesionally with MSCs.[179] One large study reviewed 168 horses with superficial digital flexor tendonitis treated with approximately 10×10^6 expanded BM-MSCs. That study found that the reinjury rate was significantly lower (13% and 18% for horses in full training) than had previously been reported for both race and sport horses.[179] Furthermore, another report of 120 cases where BM-MSCs were used to treat tendonitis and desmitis reported that nearly 80% of horses with superficial digital flexor tendonitis and over 70% of horses with suspensory ligament desmitis had returned to their previous level of performance.[188]

In an additional clinical study, adipose-derived MSCs grown in the presence of autologous platelet lysate were inoculated into injured equine flexor tendons after the cells had been dispersed in activated PRP.[189] A total of 14 out of 16 treated horses

showed a functional recovery and were able to return to their normal activity. The authors of this report attributed the success of the treatment in part to the biological effects of PRP, which acted as a scaffold, maintaining MSCs in the tendon defects and contributing to tissue healing.[189]

More recently, efforts have been made to promote MSC differentiation *in vitro* before implantation into tissue. Researchers have explored the possibility of genetically manipulating BM-MSCs by introducing growth factors such as BMP within the cells, thereby using them as a delivery vehicle for tissue regeneration.[190] BMPs are a group of related proteins in the TGF-β superfamily known for osteoinductive capacity. However, BMP-12, has been implicated in the biological processes leading to the formation of tendon and ligament-like tissue *in vivo* and has been shown to promote tenocyte differentiation *in vitro*.[191] As an example of such an effort in equine research, one investigator cultured superficial digital flexor tendon–derived tenocytes and BM-MSCs, either untreated or transduced with adenovirus encoding green fluorescent protein, adenovirus encoding BMP-12, or adenovirus encoding BMP-2.[191] Both cell types had increased BMP-12 gene expression, were viable up to 6 days, and became mineralized with BMP-2 but not BMP-12. The study concluded that BM-MSCs may be able to serve as a cell delivery method for BMP-12.[191] In a similar study, BM-MSCs were shown to differentiate into tenocytes following exposure to BMP-12, as assessed via the measurement of tendon-related markers such as tenomodulin and decorin.[192]

Safety Concerns

The most commonly cited concerns when considering MSC-based therapeutic approaches are development of tumor cells and the contamination of the injected cells with infectious biological and nonbiological substances during the laboratory cell process. MSCs are capable of forming teratomas, although this aspect of their biology has been poorly characterized in animal models. Veterinarians need to be acutely aware of the possible transmission of infectious diseases, especially with the more frequent application of allogeneic transplants of MSCs. Consideration should also be given to the possible introduction of biological components that may be immunoreactive to the recipient. These components may be derived from exposure of MSCs to culture media elements such as fetal bovine serum.[148,153]

Surgical Methods

Jörg A. Auer

CHAPTER
9

Instrument Preparation, Sterilization, and Antiseptics

David E. Freeman and Jörg A. Auer

In human medicine, national regulations demand that quality control and assurance be observed for reprocessing medical devices and instruments, including resterilization for aseptic surgical use. In the veterinary field, the veterinarian, practice manager, or head of the department is responsible for evaluating the risks, classifying the various risk areas, providing written standards and detailed instructions, and ensuring adequate documentation for quality control. Validated cleaning, disinfecting, and sterilization processes, supplemented by defined configurations for loading the washer-disinfectors and autoclaves, are essential for quality assurance.[1] Other requirements result from good veterinary practice.

It is particularly important to follow the manufacturer's instruction manual, because ignoring these instructions could lead to expensive and untimely replacements or repairs and also because incorrect reprocessing or product failure may endanger the patient or third parties.

Sterilization refers to the complete destruction or elimination of vegetative bacteria, bacterial spores, viruses, and fungi, by physical or chemical methods.[2] Antisepsis signifies the inhibition of the growth and development of microorganisms without necessarily killing them. Therefore, antiseptics can be applied to living tissues.[2] Physical methods of sterilization include heat (thermal energy), which is the most commonly used type in veterinary hospitals, and filtration and radiation, which are usually applied in the industrial preparation of sterile materials. Ethylene oxide is the most widely used method of chemical sterilization, but physical methods are considered to be more uniformly reliable.

INSTRUMENT PREPARATION AND PACKING

Cleaning

Instruments cannot be sterilized until they are completely clean, because steam cannot penetrate materials such as oil, grease, dried blood, and other organic material.[3-5] Ideally an assistant should wipe every instrument used during surgery, before it is replaced on the surgery table, to prevent blood drying on the instrument. Once the instruments are returned to the sterilizing room, they are prepared for autoclaving by immediately rinsing in cold water to remove any remaining blood and debris.

Water plays an essential role in cleaning and sterilizing instruments: it dissolves cleaners and other treatment agents; transmits heat and other mechanical forces; dissolves unclotted blood, dirt, and impurities; removes cleaning fluids and detergents; and is used for steam sterilization.[1] Experiments have shown that increasing water hardness reduces the removal of blood in cold water prewashes.[1] It is therefore of utmost importance to use good quality water, ideally fully demineralized or at least softened water, because high concentrations of dissolved particles in the water can induce or facilitate surface pitting, even in high-quality stainless steel. Chloride concentration of the water that is greater than 120 mg/L (equivalent 200 mg/L NaCl) at room temperature increases the risk of surface pitting.[1] Even water evaporation during the drying process leads to drastic increases in chloride concentration in water droplets that exceed the limit just mentioned.[1] Other substances, such as silicilates or silicic acids, may cause brownish, bluish, gray-black, or iridescent discolorations even when present in small quantities. However, these discolorations are harmless and do not facilitate corrosion.[1] Tap water occasionally contains rust particles from corroded water pipes, and these tend to adhere to the instrument surfaces during processing, causing rust spots that lead to subsequent corrosion.[1]

After prewashing, the instruments should be cleaned with a mildly alkaline, low-sudsing detergent or in an ultrasonic cleaner. Prerinsing in an enzymatic detergent solution is an acceptable alternative to manual cleaning.[1,6] Enzymatic detergents used for cleaning medical devices (Endozime, Enzol, Sterizyme, and MetriZyme) help remove proteins, lipids, and carbohydrates, depending on the formulation.[7] Many of the available enzymatic detergents have a minimum contact time of 2 to 5 minutes (Endozime AW Plus, Asepti-Zyme, Gzyme, Optim22, Adi-Zyme, and Klenzyme) or 10 minutes (MetriZyme), and the recommended temperature for most is room temperature.[7] For the majority of them, a maximum soaking time of 30 to 45 minutes is recommended.[7] No commercially available detergents combine cleaning efficiency with microbial killing, with the exception of a newly formulated hydrogen peroxide–based cleaning detergent (Hydrox).[7] The advantages of Hydrox are in the realms of protection of health care workers from infectious risk and reduced bioburden on instruments before sterilization or disinfection.[7]

Instruments containing narrow lumens, such as cannulas, flexible tubes, and egress portals, are difficult to clean. Therefore it is important to ensure that all internal and external surfaces are completely wetted by cleaning solutions. Care must also be

taken to see that the lumens are patent. Soft, lint-free cloths or towels, plastic brushes, or cleaning air guns should be used to clean these channels. Following cleaning, both the external surfaces and internal surfaces should be rinsed, ideally with fully demineralized water. After rinsing, the instruments must be dried carefully. The drying method of choice is compressed air drying, because it is gentle and extremely effective.[1]

Ultrasonic cleaners use high-frequency vibratory waves that clean through cavitation.[7] As the ultrasonic waves propagate through the liquid, this liquid is subjected to alternating negative and positive pressures as the compression and rarefactions of the sound waves pass. During the phase of negative pressure, numerous gas bubbles are formed and enlarge in the liquid. This formation of gaseous cavities in the liquid is called cavitation. During the subsequent phase of ultrasonic compression (i.e., phase of positive pressure), the pressure exerted on the newly expanded gas bubble compresses the same until the bubble collapses on itself, imploding with a consequent shock wave of energy. This shock wave of energy—a mini vacuum—provides the energy used to assist cleaning. Ultrasonic action effectively dislodges impacted debris from holes, jaws, box joints, channels, and complex surfaces, and it disrupts air pockets, ensuring thorough wetting during the cleaning process.[6] The instruments are loosely loaded in wire mesh trays for this process; all box locks are left open; complicated instruments, such as dynamic compression plate (DCP) drill guides, are taken apart; and instruments are thoroughly rinsed afterward to remove detached particles.[8] For ultrasonic cleaning, as used for the manual cleaning step, a nonfoaming enzymatic type of detergent solution is preferable (Endozime AW Plus, Asepti-Zyme, Gzyme, Sterizyme, Adi-Zyme, Klenzyme, and MetriZyme).[9] Ultrasonic cleaning times in modern equipment are approximately 3 minutes at frequencies of around 35 khz.[1]Following ultrasonic cleaning, the instruments must be thoroughly rinsed, preferably with fully demineralized water, to remove all cleaner residues. It is also advisable to treat hinged and articulated instruments with a special lubricant such as Sterilit Power Spray. These lubricants withstand sterilization and maintain proper functioning of the instrument during use.

Minimally invasive surgery instruments, rigid endoscopes, and high-frequency instruments must be disassembled for machine processing according to the manufaturer's instructions, and only those parts approved by the manufacturer may be cleaned ultrasonically. Camera units, optics, and optic cables should never be cleaned with this technology.[1]

Packing

All packs should be marked as to content, date of sterilization, and person responsible for their assembly, and the pack should be stored for times appropriate for the material and the method of storage (Table 9-1). For muslin wraps, double layers and two wraps are recommended for each pack. Alternatively, pima cotton can be used, which is a more effective barrier than muslin because of the smaller pore size. Pima cotton wraps can be reused approximately 75 times, after which so much fabric has been lost that no effective barrier against microorganisms exists.[5] Sterilization fleece, an interleaved security product, is the preferred synthetic wrapping material because of its superior durability and handling qualities and because its safe storage time is longer than that of fabrics.

Instruments can also be sterilized in stackable containers of aluminum composite material (Figure 9-1) that are dent resistant, are available in a variety of sizes, are easy to store and transport, and allow safe storage times of up to 1 year (Amsco Sterilization Container System). The aluminum composite increases the thermal conductivity of the container during drying to help ensure dry contents. The system is suitable for use in steam, ethylene oxide, and gas plasma sterilization. Three types of filters—cartridge (with internal chemical indicator), disc, or ceramic—are available for this system. A retainer ring maintains the filter in the filter access portal in the lid and base of the unit. Selection of the type of filter is determined by the sterilization cycle to be used, such as prevacuum steam, gravity steam, flash, ethylene oxide, or gas plasma.

Although pima cotton and sterilization fleece are well suited for instrument packs, these materials are rarely used to wrap single instruments. For this purpose, special sleeves have been

TABLE 9-1. Storage Times for Sterilized Packs

	Open Shelf	Closed Cabinet
Single-wrapped muslin (2 layers)	2 days	7 days
Double-wrapped muslin (each 2 layers)	3 wk	7 wk
Crepe paper (single-wrapped)	3 wk	8 wk
Heat-sealed paper and transparent plastic pouches	At least 1 yr	—

From Mitchell SL, Berg J: Sterilization. p. 158. In Slatter D (ed): Textbook of Small Animal Surgery. 3rd Ed. Saunders, Philadelphia, 2003.

Figure 9-1. Stackable Steriset sterilization container with the lid removed, showing a standard soft tissue instrument set. The instruments located in the bottom of the set are covered by a special paper sheet. On top of it, sponges, towel clamps, the cautery including its electric cord, two sterile light handles, and a sponge forceps are visible. The inside of the lid shows the two valves. In each of the valves, one of three types of filter systems (steam, ethylene oxide, or plasma gas) can be inserted, depending on the type of sterilization being carried out.

developed that are paper on one side and clear cellophane on the other. The sleeves come in different sizes to allow the packing of instruments of different sizes. Also, different sizes are required because the instruments should be double wrapped. The ends of the sleeves are heat sealed. The sharp points of all instruments must be protected by special paper or plastic covers. The paper side allows penetration of steam, ethylene oxide, or gas plasma, and the cellophane side provides a view of the contents (Figure 9-2). These single packs should be identified by date of sterilization and the person who packed it.

Autoclave Indicators

Autoclave indicator systems include *chemical indicators* that undergo a color change on exposure to sterilizing temperatures and biologic indicators, such as heat-resistant bacterial spores. An indicator tape on the outside of the pack provides no information about the sterility of the pack's contents, so an additional indicator should be placed in the center of the pack. Many of the currently available indicators of sterility are more reliable than simple physical indicators, such as tape, because they indicate that both temperature and time are sufficient for providing sterility (Figure 9-3), whereas tape merely indicates to the surgeon that the pack was subjected to heat. *Biological indicators,* however, provide more security that the contents of the pack are sterile. For most of the commonly used sterilization processes, special reference biological germs have been selected, such as *Bacillus stearothermophilus* for steam, formaldehyde, and hydrogen peroxide sterilization processes; *Bacillus subtilis* for ethylene oxide and dry heat sterilization processes; and *Bacillus pumilus* for radiation sterilization processes.[5,8,10] Depending on the type of sterilization process, a special resistance characteristic of biological indicators is required to prove the success of a defined sterilization process. During such a sterilization process, the spore population always decreases because of the exponential kill characteristic called reaction kinetics of first order. The population however, will never reach an absolute 0 value. Therefore modern definitions of goods declared sterile do not specify the absolute absence of biological activity, but determine aseptic conditions with certain probability, called sterility assurance level (SAL).[11]

Figure 9-2. A single wrapped catheter in a paper-cellophane sleeve. These wrappers may also be used for single instruments.

PHYSICAL STERILIZATION

Thermal Energy

Dry heat kills by a combination of oxidation and removal of water, whereas moist heat kills by the coagulation of critical proteins. Moist heat sterilization can coagulate and denature cellular protein at lower temperatures than those required by dry heat and thus can decrease the temperatures and exposure times necessary for sterilization.[3,4]

Exposure time and temperature required to kill microbes are functions of their individual heat sensitivities, which vary with type of organism and the environment to which they are accustomed.[4] For example, bacterial spores are more resistant than the vegetative form of the bacteria.[4] Recommended sterilization times and temperatures are designed to kill all microorganisms, even those that are heat resistant (Table 9-2). Minimum guidelines are an exposure time of 15 minutes at 121° C (249.8° F) and 15 psi or 2 atmospheres of pressure in a steam autoclave. Because microbial death occurs in a logarithmic fashion, exposure time is as important as temperature. The greater temperatures and water saturation attained by pressurized steam allow shorter sterilization times. Steam gives up its heat to materials to be sterilized by the process of condensation, and it is able to penetrate porous substances more rapidly than dry heat.[4]

The prion scare that surfaced a few years ago also had an impact on sterilization methods. Regimens had to be developed to ensure sterility of prion-contaminated medical instruments.[12,13] Although prions do not represent a major threat to equine surgery, it is worthwhile to become familiar with the proper techniques and protocols developed, in case a similar situation arises in our field.[12,13] Table 9-3 lists the appropriate regimens developed for the different prion sterilization techniques. The present European standards ask for a temperature setting of 134° C and a maintenance time of 18 minutes. This standard may be reversed, because the prion threat has drastically diminished. Such a change would be welcomed to increase efficiency in busy hospitals.

Figure 9-3. Example of a chemical indicator used to confirm that sufficient exposure conditions have been met in the center of the pack. In this 3M Comply (SteriGage) Steam Chemical Integrator, the chemical pellet contained in a paper, film, and foil laminate envelope melts and migrates as a dark color along the paper wick. The distance or extent of migration shown at the bottom (compare with unused, *top*) depends on exposure to steam, time, and temperature. The dark color should enter the Accept window for an Accept result.

TABLE 9-2. Exposure Times and Temperatures for Autoclave Sterilization Systems

Procedure and Conditions	Time (min)	Temperature	Comments
Heat-up time (prevacuum and pulse type)	1	Up to 120° C (250° F)	Timing of exposure begins when exhaust line reaches 120° C.
Minimum standard*	13	120° C	5-10 min destroys most resistant microbes; an additional 3-8 min provides a safety margin.
Present European standards	18	134° C (273° F)	Introduced because of prion scare; may be reversed
Emergency/"flashing" (prevacuum)†	3	131° C (270° F)	Instruments sterilized in perforated metal trays
Large linen packs (gravity-displaced)	30	120° C	—
Large linen packs (prevacuum)	4	131° C	—
Drying period	20	NA	—

*Times are given for gravity displacement autoclaves. Extra time is required for pack contents to reach sterilization temperatures (heat-up time).
†Emergency sterilization is best accomplished in prevacuum autoclaves, which have shorter heat-up times required.
From Southwood LL, Baxter GM: Instrument sterilization, skin preparation, and wound management. Vet Clin North Am Equine Pract 12:173, 1996 (with permission).

TABLE 9-3. Efficacy of Sterilization Processes in Inactivating Prions

Ineffective (≤3 $\log_{10}$ reduction within 1 hr)	Effective (>$\log_{10}$ reduction from 18 min to 3 hr)
Autoclave at standard exposure conditions (121° C for 15 min)	Autoclave at 121° C to 132° C for 1 hr (gravity displacement sterilizer) or 121° C for 30 min (prevacuum sterilizer)
Boiling	Autoclave at 134° C for 18 min (prevacuum sterilizer)
Dry heat	Autoclave at 134° C for 18 min immersed in water
Ethylene oxide	Hydrogen peroxide gas plasma (Sterrad NX)
Formaldehyde	Radiofrequency gas plasma
Hydrogen peroxide gas plasma, Sterrad 100S (ASP) (ionizing radiation)	Sodium dodecyl sulfate, 2%, plus acetic acid, 1%, plus autoclave at 121° C for 15-30 min
Microwave	Sodium hydroxide (NaOH), 0.09 N or 0.9 N, for 2 hr plus autoclave at 121° C for 1 hr (gravity displacement sterilizer)
UV light	Vaporized hydrogen peroxide, 1.5-2 mg/L

Note: The same process may be listed as both effective and ineffective because of differences in sterilant concentration, exposure time, temperature, etc., or differences in testing methods. All of these experiments were performed without cleaning.
Modified from Rutala WA, Weber DJ: Creutzfeldt-Jakob disease: Recommendations for disinfection and sterilization. Clin Infect Dis 32:1348, 2001; from Rutala WA, Weber DJ: Guide for disinfection and sterilization of prion-contaminated medical instruments. Infect Contr Hosp Epidemiol 31:107, 2010.

A recent experimental study that evaluated short-duration sterilization techniques in a resistometer (at 134° C, 273° F) used different models (threads, gap, empty tube, tube with insert, sliding surface, etc.) contaminated with test microorganisms to simulate situations encountered during sterilization. After 90 seconds in the threads model, no organisms could be isolated.[14] In the gap model, micoroorganisms could be isolated after 90 seconds but were inactivated after 180 seconds.[14] In the empty tube, tube with insert, and sliding-surface models, test microroganisms could still be isolated even after 5 minutes.[14] Repeating the same experiment in a test autoclave at 134° C after 90 and 180 seconds, viable microorganisms could only be detected in some of samples in the tube with insert model.[14] When the temperature was lowered to 132° C (270° F) at 2 and 4 minutes, only the 2-minute test with the tube with insert model revealed visible microorganisms.[14] These results indicate that a secure sterilization result can be guaranteed on various surfaces at 134° C with a maintenance time of 4 minutes, conditions that cover the vast majority of situations a practitioner faces daily.

Most autoclaves used in veterinary hospitals use steam pressure to drive air downward and out of the pressure vessel in a process called gravity displacement (Figure 9-4).[4] Air displacement by steam is critical to achieve condensation on all surfaces, and air reduces the temperature of steam at any given pressure.[4] Arrangement of trays or bowls within the autoclave must be such that air cannot be trapped by the downward

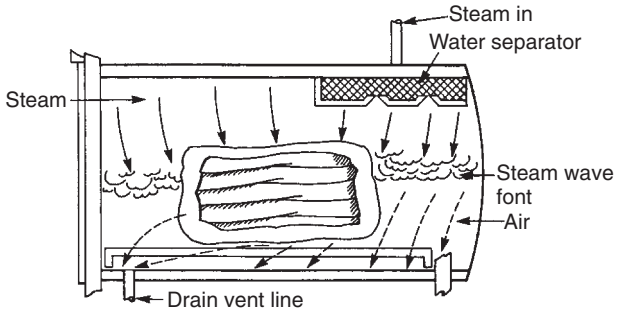

Figure 9-4. Schematic drawing of a gravity displacement autoclave, showing downward displacement of all air by steam in this system. (From Lawrence CA, Block SS: Disinfection, Sterilization, and Preservation. Lea & Febiger, Philadelphia, 1991.)

Figure 9-5. A typical sterilization unit in a large hospital, loaded and ready for use. Note that the contents are loosely arranged to facilitate access of steam around each item.

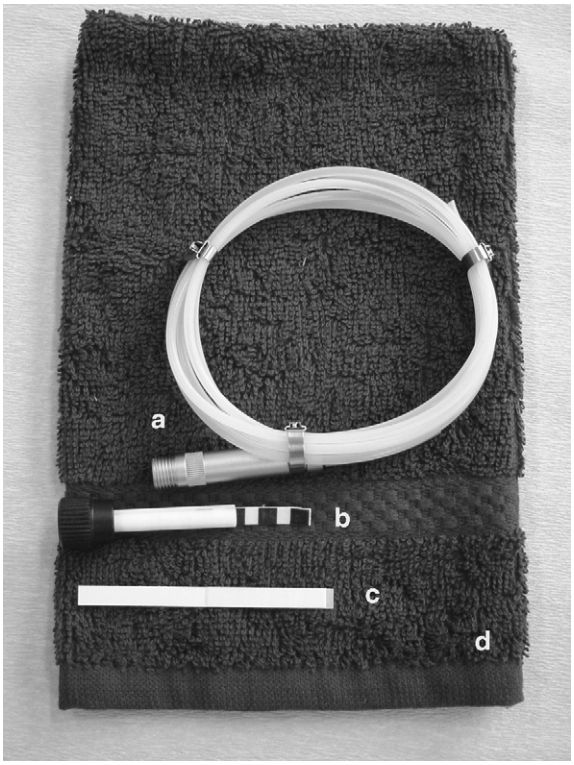

Figure 9-6. The gke Steri-Record Helix Bowie-Dick simulation (BDS) test kit. *a,* Metal test capsule attached to the polytetrafluoroethylene tube; *b,* lid of the metal capsule holding the integrating indicator (the *dark dots* indicate proper function); *c,* unused indicator strip; *d,* cloth container for the BDS kit.

progression of the steam, and bowls should be placed with their openings to the side or facing down.[8,10] Also, packs should be loosely loaded into the autoclave to ensure distribution and circulation of steam around each pack without the formation of air pockets between them (Figure 9-5).[10] Valves in cannulas should be left open to ensure adequate steam penetration.[15] Because air trapped in closed, impervious containers can inhibit steam penetration, items in glass tubes should be sealed with cotton plugs.[3-5,8] Many newer or more sophisticated types of autoclaves use a vacuum to displace air from the materials to be sterilized.[10] This allows shorter sterilization times but adds to the cost of the equipment. Other modifications use pulsed steam pressure and special valve systems to hasten air removal before sterilization. Prevacuum steam sterilizers evacuate air from the chamber before steam is admitted, so the time lag for complete air removal is eliminated and the problem of air entrapment is minimized.[4] This system is well suited for flash sterilization.[4]

It is also recommended that the steam sterilizer be periodically tested for functionality. The Bowie-Dick test can be used to prove that air removal and steam penetration were complete.[6] The Steri-Record (gke-GmbH) provides two simulation tests for different applications, depending on the sterilization programs used.[11,16] These Bowie-Dick tests simulate hollow devices, such as trocars, which require more demanding air removal and penetration conditions than porous cotton. The indicator systems consist of a process challenge device (PCD) with an indicator inside. One of the systems is the Helix-PCD, consisting of a polytetrafluoroethylene (PTFE) tube and a metal test capsule holding the integrated indicator (Figure 9-6). The second system is the Compact-PCD, consisting of an external plastic casing with a stainless steel coil inside that holds the indicator. To ensure proper functioning of the sterilizer, such a kit should be included in each sterilizer charge.

Filtration

Sterilization by filtration is used for air supply to surgery rooms (laminar flow ventilation), in industrial preparation of medications, and for small volumes of solutions in practice settings.[10,14] The laminar air filtering system for surgery suites is discussed in Chapter 10. For fluids, two types of filters are commonly used—depth filters and screen filters.[10,17] Screen filters function like a sieve to remove any microorganisms or particulate matter larger than the pore diameter of the screen.[10,17] Depth filters trap microbes and particles by a combination of random absorption and mechanical entrapment.[17]

Radiation

Sterilization by radiation is used in the industrial preparation of surgical materials that are sensitive to heat or chemical sterilization.[10] The facilities required for ionizing radiation render them unsuitable for use in veterinary hospitals.[10] Although radiation is suitable for items that cannot tolerate heat sterilization, it can change the composition of some plastics and pharmaceuticals.[10,18]

CHEMICAL STERILIZATION

Ethylene Oxide

Ethylene oxide (EO) is the most commonly used agent in chemical sterilization. Because it is a gas, it rapidly penetrates

TABLE 9-4. Requirements for Ethylene Oxide Sterilization

Variables	Range	Comments
Concentration	450-1500 mg/L	Doubling the concentration approximately halves the sterilization time.
Temperature	21°-60° C	Activity is slightly more than doubled with each 10° C increase.
Exposure time	48 min to several hours	Room temperature, 12 hr 55° C, 4 hr or less "Oversterilization" period allowed
Humidity	40%-60% (minimum, 33%)	Can be provided by vials of water or sponges

From Southwood LL, Baxter GM: Instrument sterilization, skin preparation, and wound management. Vet Clin North Am Equine Pract 12:173, 1996 (with permission).

packaging and items to be sterilized at temperatures tolerated by almost all materials. However, its use is limited by the size of the equipment, the time requirement, and concerns about toxicity. It is recommended for use only for items unsuitable for steam sterilization, including laparoscopes, light cables, and camera heads.[15,19] In fact, because of environmental concerns, EO sterilizers are now required by law to be retrofitted with abaters that reduce more of the exhausts to water vapor. Despite the use of abaters, the Environmental Protection Agency has outlawed the use of EO sterilizers altogether in some areas. Gas plasma sterilizers are a logical replacement choice (see later).

EO is an alkylating agent that kills microorganisms by inactivation of proteins, DNA, and RNA, and it is effective against vegetative bacteria, fungi, viruses, and spores.[20] It is supplied as a gas mixed with a carrier agent (Freon or CO_2) to reduce flammability.[5] Mixed with air or oxygen, EO is explosive and flammable.[5] Carbon dioxide is the preferred diluent because of environmental concerns about fluorinated hydrocarbon (Freon) release, although EO has a tendency to stratify from carbon dioxide in storage containers, which could affect sterilization.[5]

Sterilization by EO is influenced by gas concentration, temperature, humidity, and exposure time (Table 9-4).[21] The more sophisticated equipment for EO sterilization includes methods for temperature elevation to shorten sterilization times.[19] Spores require time for humidification to allow optimal killing by EO.[10,20,21] The humidity should not be raised by wetting the materials to be sterilized, because EO forms condensation products with water that may damage rubber and plastic surfaces. Also, the effectiveness of EO sterilization may be reduced below the lethal point by moisture left in needles and tubing.[22] Instruments need to be cleaned as described for steam sterilization.

Because EO penetrates materials more readily than steam, a wider variety of materials may be used in packaging items for sterilization and storage. Films of polyethylene, polypropylene, and polyvinyl chloride are commercially available, but nylon should not be used, because it is penetrated poorly by EO.[10,20-22] Positioning of packs is less critical than with steam, but overloading and compression in the sterilizer can prevent adequate penetration.[5]

After sterilization by EO, materials must be aerated to allow dissipation of the absorbed chemical (Table 9-5), because residual EO can damage tissues.[23,24] For example, inadequate aeration of endotracheal tubes sterilized by EO caused tracheal necrosis and stenosis in horses and dogs.[25,26] Although some EO chambers are equipped with mechanical aeration systems to reduce aeration times, those commonly used in veterinary hospitals use natural aeration in well-ventilated areas.[7] EO sterilization indicator strips should be used on the outside of surgery packs, and chemical or biologic indicators of EO exposure are used inside.[22] The 3M Comply EO chemical integrators demonstrate a color change and migration on an absorptive strip in response to all the critical aspects of EO sterilization, such as EO concentration, relative humidity, time, and temperature. Safe storage times are 90 to 100 days for plastic wraps sealed with tape, and 1 year for heat-sealed plastic wraps.[22]

TABLE 9-5. Average Minimal Aeration Times after Ethylene Oxide Sterilization

Material	Aeration Time*	
	Natural (days)	Mechanical (hr)
Rubber products	1-2	46
Latex	7	46
PVC ⅛ in (thick)	12	46
1/16 in (thin)	7	46
Polyethylene	2	46
Vinyl	3	32
Plastic-wrapped supplies	3	32
Implants	10-15 (recommended)	32

*Times are given for natural aeration and, where available, for mechanical aeration. Ethylene oxide sterilizers equipped for mechanical aeration produce significantly shorter aeration times (hours instead of days).
From Clem M: Sterilization and Antiseptics. p. 107. In Auer J (ed): Equine Surgery. Saunders, Philadelphia, 1992.

Exposure to EO can cause skin and mucous membrane irritation, nausea, vomiting, headache, cognitive impairment, sensory loss, reproductive failure, and increased incidence of chromosomal abnormalities.[10,23] Ability to detect the gas by smell is lost after prolonged exposure.[24] Ethylene chlorohydrin is a highly toxic degradation product of EO that is formed most readily in products that have been previously sterilized by radiation.[10,20,21] This risk is greatest with polyvinyl chloride products.[9]

Gas Plasma

Gas plasma sterilization (Sterrad Sterilization System) (Figure 9-7) allows short instrument turnaround time, has no recognized health hazards, and operates at a low temperature (less than 50° C).[9] An aqueous solution of hydrogen peroxide is injected into the chamber and converted to gas plasma by radio waves that create an electrical field.[5] In this field, hydrogen peroxide vapor is converted to free radicals that collide with and inactivate microorganisms.[8,9] Gas plasma is suitable for heat- and moisture-sensitive instruments (rigid endoscopy lenses and

Figure 9-7. Gas plasma sterilization unit (Sterrad) that uses H_2O_2 to generate free radicals, which inactivate microbes.

instrument sets, objective lenses for microscopes, nonfabric tourniquets, medication vials, insulated electrosurgery and cautery instruments, and metal instruments).[8,9] Also, the process does not dull the sharpness of delicate microsurgical instruments.[8] Gas plasma is unsuitable for flexible endoscopes, liquids, and items derived from plant fibers (paper products, linens, gauze sponges, Q-tip applicators, cast padding, wooden tongue depressors, gloves, and single-use items), because these materials absorb hydrogen peroxide and inhibit sterilization.[8] Very long narrow lumens, lumens closed at one end, folded plastic bags, and sheeting are unsuitable for sterilization by gas plasma.[9]

DISINFECTANTS

Several disinfecting agents have been developed for medical purposes and are widely used in the sterilization of inanimate objects, such as surgical instruments, endoscopes, hospital surfaces, and fixtures. They are well suited for complex surgical instruments and endoscopes that are heat sensitive. High-level disinfection refers to the use of a chemical sterilant for exposure times that are insufficient to achieve sterilization (elimination of all microorganisms *and* spores) but sufficient to inactivate all microorganisms (bacteria, fungi, viruses, and mycobacteria), *but not* all bacterial spores.[27] However, in typical use, high-level disinfection appears to provide the same efficacy as sterilization.[27] An ideal chemical sterilant as a high-level disinfectant should have broad-spectrum antimicrobial activity, rapid effect, compatibility with materials to be sterilized, and long reuse life and shelf life, nontoxic to human beings and the environment, odorless, nonstaining, free of disposal restrictions, and should be easy to use, resistant to organic material, readily monitored for concentration, and cost-effective.[27] Unlike antiseptics (Table 9-6), disinfectants are not intended for use on living tissue and actually can be harmful to tissues at the concentrations required

TABLE 9-6. Characteristics of Selected Antiseptics and Disinfectants

Agent	Trade Name	Action	Effects	Disadvantages
Isopropyl alcohol	Propanol	Protein denaturation	Bactericidal, effective against vegetative bacteria only	Poor against spores, fungi, viruses Cytotoxic in tissue
Propan-2-ol and Propan-1-ol	Sterillium	Protein denaturation	Bactericidal, fungicidal Effective against many important viruses	Cytotoxic in tissue
Ethanol 96% and Biphenyl-2-ol	Desderman pure	Protein denaturation	Bactericidal (MRSA), fungicidal Effective against many important viruses	Cytotoxic in tissues, avoid contact with the eyes, easily flammable
Glutaraldehyde	Cidex Omnicide Abcocide	Protein and nucleic acid denaturation	Bactericidal, fungicidal, viricidal, sporicidal	Long (10-hr) exposure time required for sporicidal effect Limited shelf life once activated Tissue irritant/toxicity
Chlorhexidine	Nolvasan	Cell membrane disruption and cellular protein precipitation	Bactericidal, fungicidal; variable activity against viruses	Not sporicidal
Povidone-iodine	Betadine	Metabolic interference	Bactericidal, viricidal, fungicidal	Poorly sporicidal Some inactivation by organic debris

MRSA, Methicillin-resistant *Staphylococcus aureus.*

to achieve full efficacy. In fact, the broader the range of microbes it eliminates and the faster it acts, the more corrosive and toxic it is.[28]

Aldehydes

Because heat and moisture are damaging to certain instruments, such as endoscopes, arthroscopes, and laparoscopes, cold disinfection with glutaraldehyde, a saturated dialdehyde (Cidex, Omnicide 28, Abcocide), can be used for these items.[7] Olympus, Pentax, and Fujinon list glutaraldehyde as compatible with their endoscopes, but manufacturer recommendations need to be closely followed for all such instruments.[8] Although glutaraldehyde is effective against a wide range of susceptible organisms (see Table 9-6), Cidex is now classified as a disinfectant by the manufacturer, rather than as a sterilant, and therefore its use on arthroscopic and laparoscopic instruments is questionable.[29] Peracetic acid (PAA) would be preferable to sterilize these items, as discussed later.

Glutaraldehyde has broad-spectrum antimicrobial activity and is the most widely used chemical for the high-level disinfection of endoscopes and other such instruments.[27] Glutaraldehyde owes its biocidal activity to alkylation of sulfhydryl, hydroxyl, carboxyl, and amino groups, which alters microbial RNA, DNA, and protein synthesis.[27] The antimicrobial activity of glutaraldehyde is greatly enhanced in alkaline solutions (pH 7.5 to 8.5), although high pH hastens its polymerization and therefore limits its shelf life. To overcome this problem, glutaraldehyde is supplied as an acidic colorless solution that is activated at the time of use by adding an "activator" that converts it to a green (Cidex, Abcocide) or blue (Omnicide) alkaline solution with a sharp odor.[9,29] Acid glutaraldehydes also are available and do not require activation, but they lack the microbiocidal activity of alkaline preparations.[27]

Repeated use of an activated solution or placing damp instruments into the solution can dilute it to less than the effective concentration. Solutions should be reused only when the minimum effective concentration, as determined by the appropriate test strip, is assured, and when the pH and temperature are correct (Table 9-7). Solutions should be discarded after the specified reuse period has elapsed, even if the appropriate conditions have been met.

Antimicrobial activity of Cidex increases with increased temperature and decreases with organic matter.[29] Therefore presterilization cleaning and drying are important, and an enzyme-based presoak detergent can be used.[8] Instruments soaked in glutaraldehyde must be thoroughly rinsed with sterile water before they touch tissue, and gloves must always be worn when removing items from glutaraldehyde baths.

The potential hazards of glutaraldehyde for staff are considerable. Toxicity has been suspected in 35% of endoscopy units, with harmful or potentially harmful problems in 63% of these.[9] Direct contact with glutaraldehyde is irritating to skin and other tissues, and repeated exposure can result in sensitization and allergic contact dermatitis, rhinitis, and asthma.[25] Vapor may cause stinging sensations in the eye, excess tear production, redness of the conjunctiva, a stinging sensation in the nose and throat, nasal discharge, coughing, symptoms of bronchitis, and headache.[9] Glutaraldehyde is not ideal for chemical disinfection of instruments that are hinged, are corroded, or have deep or narrow crevices, and it should not be used for critical, single-use devices, such as catheters. Prolonged use of glutaraldehyde can corrode metals and some plastics.[30,31] As with all aldehydes, glutaraldehyde can fix proteins by denaturing and coagulating them, and this creates a biofilm on instruments that can make them difficult to sterilize.[9]

TABLE 9-7. Recommended Conditions for Use of Three Glutaraldehyde Preparations

	Cidex (Activated)	Cidex 7 (Long-Life Activated)	Cidexplus (28-Day Solution)
Concentration (%)	2.4	2.5	3.4
Maximal reuse period	14 day	28 day	28 day
AS A STERILANT			
Temperature (° C)	25	20-25	20-25
Minimal immersion time	10 hr	10 hr	10 hr
AS A HIGH-LEVEL DISINFECTANT			
Temperature (° C)	25	25	25
Minimal immersion time	45 min	90 min	20 min
AS AN INTERMEDIATE-LEVEL DISINFECTANT			
Temperature (° C)	20-25	20-25	20-25
Minimal immersion time	10 min	10 min	10 min

Sterilant conditions apply to surgical instruments and devices that penetrate skin or are used in sterile tissues; the longer times are required for spores. High-level disinfectants are used for semicritical devices that do not penetrate sterile tissues (endoscopes, anesthesia equipment). Intermediate-level disinfectants are used for noncritical devices that contact skin surface only. Recommendations for other glutaraldehyde preparations may vary—the manufacturer's advice should be followed.

From Southwood LL, Baxter GM: Instrument sterilization, skin preparation, and wound management. Vet Clin North Am Equine Pract 12:173, 1996 (with permission).

Ortho-phthalaldehyde (OPA; Cidex OPA) is a high-level disinfectant that contains 0.55% 1,2-benzenedicarboxaldehyde. OPA completely destroys all common bacteria in 5 minutes of exposure, does not produce noxious fumes, does not require activation, is compatible with many materials, does not coagulate blood or fix tissues to instrument surfaces, and is stable at a wide pH range (3 to 9).[9,27] Exposure to OPA vapors may be irritating to the respiratory tract and eyes, and it can stain linens, clothing, skin, instruments, and automatic cleaning devices.[9]

Succindialdehyde with dimethoxytetrahydrofuran and anticorrosion components (Gigasept FF) is recommended for flexible endoscopes and ultrasonic probes by well-known manufacturers (e.g., Fujinon, Olympus, Hewlett Packard, Acuson, Toshiba). It is a broad-spectrum cold-sterilizing or disinfecting solution with excellent material compatibility and a pH of approximately 6.5. It does not require activation additives and might be preferable when there is a desire to avoid formaldehyde or glutaraldehyde products.

Peracetic Acid

Peracetic acid or peroxyacetic acid (PAA) is an oxidizing agent that functions in much the same way as hydrogen peroxide, through denaturation of protein, disruption of cell wall permeability, and oxidation of sulfhydryl and sulfur bonds in

proteins, enzymes, and other metabolites.[24] PAA is available under numerous brand names with different chemical formulations (Nu Cidex 0.35%, STERIS 0.20%, Anioxyde 1000, and Sekusept Aktiv). The STERIS Corporation has marketed STERIS 20 Sterilant Concentrate, a 35% peroxyacetic acid concentrate, for use in the STERIS System 18 (Figure 9-8). An arthroscopic camera and telescope can be processed, rinsed, and dried in this system in a 20-minute cycle. It is routinely used to sterilize flexible endoscopes as well. A contact time of 10 or 15 minutes and a concentration of greater than 0.09% PAA are recommended for destruction of bacteria, fungi, viruses, and spores, if used manually.[9] Compared with glutaraldehyde, PAA has a similar or even a better biocidal efficacy and is claimed to be less irritating for staff and safer for the environment. PAA does not fix proteins and therefore does not create a biofilm. It has the ability to remove glutaraldehyde-hardened material from biopsy channels, and its activity is not adversely affected by organic matter.

Potential adverse effects are strongly linked to the pH value of the application solution, with minimal effects in a pH range of 7.5 or higher. PAA is less stable than glutaraldehyde, can be corrosive, and has a strong, vinegar-like odor. PAA has additional drawbacks when used on immersible instruments; it can cause serious eye and skin damage in a concentrated form, it can dull aluminum anodized coating, instruments treated with it cannot be stored, and it is expensive.[9,27] PAA is also a weak carcinogen.[28] Therefore, when using manual immersion methods, PAA should be used with adequate ventilation and personal protective measures. PAA also causes cosmetic discoloration of endoscopes, but without any functional damage, if used manually; the STERIS System 1 sterilizer does not have this problem, however, because adequate rinsing is automatic.

Hydrogen Peroxide

Hydrogen peroxide is an oxidizing agent that can be used as a high-level disinfectant.[27] It produces destructive hydroxyl radicals that attack membrane lipids, DNA, and other cellular components when used at recommended concentrations.[27] Its antimicrobial activity is very slow.[27,28] It is marketed as Sporox as a premix that contains 7.5% hydrogen peroxide and 0.85% phosphoric acid.[27] The minimum effective concentration (i.e., 6.0%) must be checked regularly. It is compatible with many tested endoscopes, but black anodized metal finishes can become discolored.[27] Hydrogen peroxide can be corrosive to flexible endoscopes.[28] It can enhance removal of organic matter, is easily disposed of, and is neither malodorous nor irritating.[27]

A solution of 0.5% hydrogen peroxide (Hydrox) has been shown to combine microbial killing with a cleaning efficiency on medical devices that is superior to that of many detergent solutions.[7] A new high-level disinfectant has been developed as an accelerated hydrogen peroxide (AHP) product obtained by blending with commonly used safe ingredients that dramatically increase the germicidal potency of hydrogen peroxide.[28] This AHP product, Accel HLD 5, is a blend of 2% hydrogen peroxide, anionic surfactants, nonionic surfactants, and stabilizers, that is odorless and has a pH of 2.5 to 3.0. In studies, it proved to be a broad-spectrum and fast-acting microbicide that is effective in the presence of soilage and safe to end users and the environment. It is considered to be compatible with flexible endoscopes.[28]

Figure 9-8. Peracetic acid sterilizer (Steris System 1), which is used to sterilize endoscopes, arthroscopes, and other equipment.

Electrolyzed Acid Water

At present, two types of electrolyzed acid water (EAW) are available—electrolyzed strong acid water with a pH of less than 3 (e.g., Cleantop WM-S) and electrolyzed weak acid water, with a pH of between 6 and 7.[9] EAW is produced by using water and salt under electrolysis with membrane separation. The process generates hydroxy radicals that have a rapid and potent bactericidal effect. Additionally, the low pH (pH 2.7) and high oxidation-reduction potential (1100 mV) are toxic to microorganisms.[9] EAW breaks the bacterial cell wall and degenerates various inner components of the bacterium (including chromosomal DNA). EAW is nonirritating, has minimal toxicity, and is safe and inexpensive, but the bactericidal effect is drastically decreased in the presence of organic matter or biofilm. Also, EAW is unstable, and the full disinfecting potential of EAW and its long-term compatibility for endoscopes remain to be examined.[9]

Sterilox, often referred to as superoxidized water, is a dilute mixture of mild oxidants at neutral pH derived from salt by electrolysis in a proprietary electrochemical cell.[9] The primary active species is hypochlorous acid, an extremely powerful disinfectant that is completely nontoxic in the low, clinically effective small concentrations produced in Sterilox. It is generated on site, as needed, and stored no longer than 24 hours. The active agents decompose slowly to harmless species.[9]

Chlorine Dioxide

Chlorine dioxide (e.g., Tristel, Dexit, and Medicide) is a powerful oxidizing agent and is active against nonsporing bacteria, including mycobacteria and viruses, in less than 5 minutes, and is rapidly sporicidal (10 minutes).[9] Chlorine dioxide is more damaging to instruments and components than glutaraldehyde[9]; it discolors the black plastic casing of flexible endoscopes and irritates the skin, eyes, and respiratory tract.[9] Chlorine dioxide emits a strong odor of chlorine and should be stored in sealed containers and handled in well-ventilated areas.[9]

Miscellaneous

The monomer of 2-butanone peroxide is a novel peroxygen derivative that has exhibited biocidal activity against several

bacteria and has good fungicidal and virucidal activities.[32] Results of toxicity assessment and material compatibility studies were favorable.[32] Peracetic acid (0.08%) plus 1.0% hydrogen peroxide, marketed as Cidex PA, can inactivate all microorganisms, but not bacterial spores, within 20 minutes.[27] It is unfortunately not endorsed by Olympus for any Olympus endoscopes. The product has required reformulation to improve its material compatibility.[27]

Peroxygenic acid (Virkon) owes its oxidizing activity to its three major components, potassium monoperoxysulfate (primary ingrediant), potassium hydrogen sulfate, and potassium sulfate. At a concentration of 1%, it is a low-level disinfectant, rapidly biocidal against vegetative bacteria and viruses, with some activity against yeasts and nontuberculous mycobacteria in suspension tests.[33] It has a limited spectrum of activity, because it cannot destroy endospores and molds within a practical time frame, and it is potentially corrosive. Although it is unsuitable as a disinfectant for medical devices, its biodegradability and low toxicity would make it a good environmental disinfectant. In veterinary hospitals, this disinfectant has received favorable reviews for use in footbaths and foot mats as a means of reducing bacterial contamination on the soles of boots and thereby potentially reducing the risk for spread of nosocomial infections.[34,35]

ANTISEPTICS

Antiseptics are intended for use on living tissue, whereas disinfectants are intended for use on inanimate objects and can harm tissue (see Table 9-6).[9] An agent can be an antiseptic at low concentrations and a disinfectant at higher concentrations.[9]

Alcohols

Alcohols are commonly used in veterinary medicine, but they are effective only against vegetative bacteria (see Table 9-6).[36] They have a mild defatting effect but they are inactivated by a variety of organic debris and have no residual activity after evaporation.[5,36] Alcohols have a higher and more rapid kill rate than chlorhexidine, and third best is povidone-iodine.[37] The bactericidal efficacy of 1-propanol can be regarded as superior to that of 2-propanol, and third best is ethanol.[38]

Either alcohol or sterile saline can be used to rinse the surgical scrub solution from the surgery site. Alcohol does not inactivate chlorhexidine gluconate *in vitro* and has no significant effect on its protein-binding property *in vivo*.[37] However, isopropyl alcohol rinse can inactivate hexachlorophene-based preparations (e.g., pHisoHex).[10,39,40] Alcohol is a commonly used rinse in veterinary hospitals[39] and is preferred over sterile saline when used for soaking sterile sponges in "community" jars, because it is more likely to maintain sterility of jar contents over the long term.[40] Isopropyl alcohol potentiates the antimicrobial efficacy of povidone-iodine by increasing the release of free iodine, so it should be used as a rinse after this surgical scrub.[41,42]

Chlorhexidine

Chlorhexidine diacetate (2%) and chlorhexidine gluconate (4%) have a rapid onset of action and a persistent effect[43] but variable and inconsistent activity against viruses and fungi (see Table 9-6).[8] Chlorhexidine binds to protein of the stratum corneum, forming a persistent residue that can kill bacteria emerging from sebaceous glands, sweat glands, and hair follicles during surgery.[44] Another approved antiseptic for preoperative skin preparation, 2% chlorhexidine gluconate plus 70% isopropyl alcohol (ChloraPrep), provided significantly more persistent antimicrobial activity on abdominal sites at 24 hours after application than either of the components used separately.[45]

Chlorhexidine has low toxicity as a skin scrub or as an aqueous solution for wound disinfection, oral lavage, and mucous membranes of the urinary tract.[43] Although it can be toxic to fibroblasts *in vitro*, *in vivo* lavage with dilute chlorhexidine (0.05%) is not harmful to wound healing.[42] However, the least known bactericidal concentration (0.05%) of chlorhexidine diacetate causes synovial ulceration, inflammation, and fibrin accumulation in the tarsocrural joints of horses.[46] Chlorhexidine (0.0005%) potentiated with 3.2 mM EDTA and 0.05 mM Tris buffer (hydroxymethylaminomethylamine) is 90% lethal to *Escherichia coli*, *Staphylococcus aureus*, and *Streptococcus zooepidemicus* and is not harmful to the synovium or articular cartilage of the tarsocrural joints of ponies.[47] Chlorhexidine (0.02%), like 1% povidone-iodine, promotes intra-abdominal adhesion formation and therefore should not be used for peritoneal lavage.[48]

Iodine Compounds

Inorganic or elemental iodine has a very broad antimicrobial spectrum compared with other agents (see Table 9-6) and a very short kill time at low concentrations, and organisms do not develop resistance to it.[49] Its undesirable characteristics are odor, tissue irritation, staining, radiopacity, and corrosiveness.[49] Iodophors are complexes of elemental iodine with a carrier, such as polyvinylpyrrolidone (PVP), which forms povidone-iodine (PVP-I_2; Betadine surgical scrub). The complex retains the bactericidal activity of iodine, while reducing tissue irritation and staining. Povidone-iodine is usually supplied as a 10% solution with approximately 1% available iodine, which is not equivalent to free iodine but must be converted to free iodine to become bactericidal.[49] However, iodine is so tightly bound to PVP that the standard 10% solution contains as little as 0.8 parts per million of free iodine.[46] This concentration may not be sufficient to kill bacteria, especially as some free iodine is readily neutralized by protein and by conversion to iodide *in vivo*.[49] However, dilution of the 10% solution of povidone-iodine liberates more free iodine than is present in the undiluted solution—thus the diluted solution is more bactericidal.[49] Contamination of 10% povidone-iodine solution by bacteria has been reported, apparently because it liberates an insufficient amount of free iodine at this concentration.[49] At least 2 minutes of scrubbing is required to release free iodine from povidone-iodine.[37] Addition of detergents, as in surgical scrubs, further reduces the release of iodine.[50] Inadequate release of free iodine from povidone-iodine causes some concern about its efficacy in skin preparation.[49]

Before application of iodophor compounds, hair should be removed and the skin well cleaned to remove organic debris that can reduce the bactericidal activity of the iodophor. However, when arthrocentesis sites in the midcarpal joint and the distal interphalangeal joint region of horses were not clipped of hair, a 5-minute surgical scrub with povidone-iodine followed by a rinse with 70% alcohol was as effective as the same

regimen on corresponding clipped sites.[51] Although a scrub with povidone-iodine, followed by a 24-hour soak in povidone-iodine solution, could reduce bacterial numbers on the surface of the equine hoof, especially if the superficial layer of the hoof capsule was removed, bacterial populations capable of inducing wound infection still remained.[52]

The toxicity of iodine-releasing compounds is low, although individual sensitivities can occur and some horses may develop skin wheals about the head and neck (e.g., at the laryngoplasty site). Undiluted povidone-iodine solutions have no effect on numbers of viable bacteria in wounds, and povidone-iodine surgical scrub can potentiate infection and inflammation.[47] The practice of lavaging the peritoneal cavity with povidone-iodine has been abandoned because of evidence that even dilute solutions can cause a sterile peritonitis in ponies and induce metabolic acidosis.[49,53] Although 0.1% povidone-iodine has been reported to be bactericidal and to have minimal deleterious effects on the equine tarsocrural joint, it was ineffective in the treatment of experimental infectious arthritis in horses.[54,55] Concentrations greater than 0.05% *in vitro* can disrupt neutrophil viability and migration.[56]

A one-step surgical preparation technique using DuraPrep Surgical Solution is as effective as a two-step povidone-iodine preparation.[41] The antimicrobial properties of the solution are the result of 70% isopropyl alcohol in an iodophor-polymer complex that forms a water-insoluble film with sustained chemical and physical barrier properties on skin.[41] In a study on skin preparation for ventral midline incisions in horses undergoing celiotomy, DuraPrep was as effective as povidone-iodine and alcohol in reducing colony-forming units (CFUs) up to the time of skin closure, and both methods had comparable rates of incisional drainage.[57] However, preparation time was significantly shorter for DuraPrep than with the routine skin preparation technique.[57]

Antimicrobial film drapes with adhesive backing (Ioban 2) contain an iodophor and come in different sizes that make them suitable for equine surgery. After the skin has been prepared with an accepted surgical scrub, it is rinsed with isopropyl alcohol and may need to be dried with a sterile towel to improve adherence.[57] In some clinics, the proposed surgery site is shaved with a size 40 blade to improve adherence beyond that achieved by clipping.[57] A medical grade adhesive spray can also be used (Medical Adhesive, EZ Drape Adhesive), but this is not essential. Adherence to smooth flat surfaces, such as the ventral abdomen, may be better than to the irregular contour of a joint. A tight adherence of the drape in areas of complicated contours can be achieved by applying the adhesive drape circumferentially while pressing the excess edges of the drape tightly together behind the limb on the side opposite the surgical site. Care should be taken that small pieces of the drape not be torn off and dragged into joints by arthroscopic instruments, to end up as free-floating objects in the joint cavity. Although iodophor skin preparations do not produce a radiopaque artifact on intraoperative radiographs, folds in iodophor-impregnated plastic drapes can produce confusing radiographic images.

The value of antimicrobial adhesive drapes is questionable.[37] In a study on human patients undergoing hip surgery, bacterial contamination of the wound at the end of surgery was reduced from 15% with conventional preparation to 1.6% by use of an iodophor-impregnated plastic adhesive drape (Ioban).[58] In a prospective randomized clinical trial on 1102 patients, isolates of normal skin organisms were less frequent when an iodophor-impregnated plastic incise drape was used in clean and clean contaminated abdominal procedures than when the drape was not used.[59] However, no difference was found between wound infection rates for patients on whom the iodophor drape was used compared with those patients on whom it was not used.[59,60] In a study on dogs that underwent elective ovariohysterectomy or stifle surgery, adhesive incise drapes did not reduce wound contamination based on number of CFUs counted for positive cultures from the surgical incisions.[61] Although it is logical that skin flora reduction might translate into reduced surgical site infections, that relationship has not been established in this or other studies.[62]

Chlorhexidine versus Povidone-Iodine

In tests with *E. coli* and *S. aureus* on canine skin, 2% chlorhexidine diacetate was superior to hexachlorophene and povidone-iodine in rapid removal of bacteria and in residual activity.[63] In another study, chlorhexidine and povidone-iodine were effective in reducing bacteria from the surgeons' hands, but the apparently greater residual effect of chlorhexidine (120 minutes) was not statistically significant.[64] Such a residual effect could be of value during long surgical procedures, in which rates of glove puncture could be as high as 17% and many perforations are unnoticed by the surgeon.[65] In one study, 4% chlorhexidine gluconate was found to be superior, on the basis of efficacy and prolonged effects, to 7.5% povidone-iodine throughout a 3-hour period after hand antisepsis.[66] Compared with iodine preparations, chlorhexidine preparations are less susceptible to inactivation by organic debris.[43]

Although chlorhexidine's wider range of antimicrobial activity, longer residual action, minimal inhibition by organic material, and greater tolerance by skin would render it superior to povidone-iodine, both agents perform comparably in the surgical setting.[37] In a prospective randomized study of 886 human patients, there were significantly fewer wound infections with chlorhexidine preparations for surgical hand washing and patient skin preparation than with povidone-iodine (hand washing and skin preparation) in operations on the biliary tract and in "clean" nonabdominal operations; however, there were no significant differences in a number of other types of surgery.[67] The authors concluded that "on the evidence of this study, there is no overwhelming case for using one compound rather than the other as an all-purpose preparation and scrub."[67]

The preceding results were confirmed in a study on cattle, which showed that povidone-iodine and 4% chlorhexidine gluconate scrubs rinsed with 70% isopropyl alcohol decreased skin microflora and had similar frequencies of surgical wound infection.[55] CFUs were lower with chlorhexidine and alcohol immediately after scrubbing, but there was no difference in residual effect between the two scrubs.[68] In an experimental comparison in dogs between povidone-iodine and 70% isopropyl alcohol rinse, 4% chlorhexidine gluconate with 70% isopropyl alcohol rinse, and 4% chlorhexidine gluconate with saline rinse, there were no significant differences in percentages of bacterial reduction immediately and at 1 hour after scrub, and the percentages of negative cultures and cultures with more than 5 CFUs.[39] However, when the study was repeated in a clinical trial on 100 dogs undergoing a variety of procedures, 4% chlorhexidine gluconate with 70% isopropyl alcohol rinse was not superior to povidone-iodine and was actually inferior in residual microbial activity.[40] However, this was based only on percentage of

negative cultures, and the overall postoperative infection rate was too low to allow a meaningful statistical comparison.[40]

In a recent study on human adults undergoing clean contaminated surgery in six hospitals, enrolled patients were randomly assigned to a skin preparation at the surgical site with a preoperative scrub with an applicator that contained 2% chlorhexidine gluconate and 70% isopropyl alcohol (ChloraPrep), or preoperative scrub and then the site painted with an aqueous solution of 10% povidone-iodine (Scrub Care Skin Prep Tray).[69] Chlorhexidine-alcohol was significantly more protective than povidone-iodine against both superficial incisional infections and deep incisional infections.[69] The benefit for the chlorhexidine-alcohol scrub was a 41% overall reduction in infection rates and elimination of 50% of *S. aureus* infections.[69] This is consistent with findings of other studies,[70] including one that demonstrated an approximately 50% reduction in catheter-associated infections after a chlorhexidine-alcohol solution compared with povidone-iodine.[71] However, in a single hospital study on general surgery patients, the lowest surgical site infection rate was obtained with iodine povacrylex in isopropyl alcohol (DuraPrep) compared with 2% chlorhexidine and 70% isopropyl alcohol (ChloraPrep) and with povidone-iodine scrub paint.[62] Both iodine preparations were superior to chlorhexidine in that study, which unfortunately suffered from some limitations in experimental design.[62] Therefore these conclusions must be considered in that context.

Based on the available evidence, chlorhexidine would appear preferable to povidone-iodine for preparation of surgery sites and the surgeon's hands. Povidone-iodine solutions are inferior to chlorhexidine for wound lavage.[72] Also, an undesirable side effect with povidone-iodine is a greater risk of skin reactions than with chlorhexidine preparations, as demonstrated in dogs[39] and observed in horses. However, chlorhexidine is more expensive than povidone-iodine.[8]

Hydroalcoholic Solution versus Chlorhexidine and Povidone-Iodine

A new study surveying 951 ACVS and 349 ECVS diplomates, with a return rate of 42.6%, revealed that 81.4% of the surgeons used chlorhexidine, 12.2% povidone-iodine, and 6.7% hydroalcoholic solution (Sterillium) for presurgical hand desinfection.[73] The same study reporting preliminary data revealed significant differences between the three products tested in immediate and sustained activities. The hydroalcoholic solution showed a significant reduction of CFUs after presurgical hand antisepsis compared to povidone-iodine and a significant reduction after 3 hours of gloving compared to the other two products. As a matter of fact, the hydroalcoholoic solution led to an additional reduction of CFUs during the 3-hour gloving period. This study shows that a solution consisting of 45% 2-propanol, 30% 1-propanol, and 0.2% mecetronium ethylsulfate is more effective in reducing bacterial counts on hands before surgery in a veterinary setting than are chlorhexidine and povidone-iodine soap. Nevertheless it is only a small, mainly European group that uses this effective hand antiseptic.

Sterillium is currently not available in the United States. However an ethanol-based product (Sterillium is propanol-based), Avagard (61% ethanol and 1% chlorhexidine gluconate), is currently only available in the United States. Very few trials have been performed with this product, although one study comparing the infection rates in pediatric urologic procedures found no differences between using Avagard and scrubbing with an antiseptic-impregnated hand brush.[74] In another study, the antimicrobial efficacy of the product was shown to be superior to 4% chlorhexidine scrub and 61% ethanol alone, both immediately after use and after 6 hours.[75] A crossover trial conducted by the prEN 12791, however, could not demonstrate the effectiveness of Avagard as a suitable surgical hand disinfection method because the product did not meet the requirements for either immediate or sustained effect in comparison to the reference alcohol.[76]

Octenidine

Octenidine dihydrochloride is a cationic antiseptic that belongs to the bispyridine class of chemicals. It has activity against Gram-positive and Gram-negative bacteria.[77] It was effective in oral hygiene, preventing plaque and gingivitis, as a whole body wash for methicillin-resistant *S. aureus* decolonization[78] and for skin disinfection of premature newborn infants.[79] Octenidine concentrations of less than 1.5 μM (0.94 μg/mL) reduced each microbial population by more than 99% within 15 minutes. *Staphylococcus epidermidis* was the most susceptible of the test organisms, and *E. coli* and *Candida albicans* were the least susceptible. Octenidine was more active than chlorhexidine against each test strain.

This antiseptic has not been established in veterinary medicine for skin preparation, but it is used for wound cleansing.

Phenols

Phenol, cresol, and other coal tar derivates, such as hexachlorophene (pHisoHex; see Table 9-6), are generally considered to be inferior to chlorhexidine and povidone-iodine.[10,37]

Hexachlorophene has a relatively slow onset of action but a prolonged residual activity, and it is not adversely affected by organic materials. Hexachlorophene-based preparations are inactivated by alcohol.[10,37] Use was largely curtailed after hexachlorophene was shown to be neurotoxic at levels obtained with dermal exposure.[80]

Quaternary Ammonium Compounds

Quaternary ammonium compounds, such as benzalkonium chloride, are cationic surfactants that dissolve lipids in bacterial cell walls and membranes.[81] Drawbacks to the group are ineffectiveness against viruses, spores, and fungi; formation of residue layers; and inactivation by common organic debris and soaps.[9]

Miscellaneous

Hydrogen peroxide is used to clean severely contaminated wounds, but it is a poor antiseptic and is mainly effective against spores, and concentrations lower than 3% are damaging to tissues.[82] Chloroxylenol, or parachlorometaxylenol, a synthetic halogen-substituted phenol derivative, and triclosan, a diphenyl ether, do not appear to offer any advantages over the more commonly used antiseptics in veterinary medicine.[37,65,83]

Current trends in surgical hand disinfection have evolved very rapidly in the last several years and now include alcohol-based and quaternary ammonium compounds using brushless

techniques. A complete discussion on these newer products and techniques can be found in Chapter 10, under "Surgeon's Skin."

CHAPTER
10

Preparation of the Surgical Patient, the Surgery Facility, and the Operating Team

John A. Stick

Having the capacity for sound clinical judgment is the ultimate characteristic of the mature veterinary surgeon. To attain this capacity, the surgeon needs to be able to provide an accurate assessment of operative risk. This can be done only if there is thorough preparation of the surgical patient combined with knowledge of the primary problem, experience, and an open mind.

ASSESSMENT OF OPERATIVE RISK

When determining operative risk, each surgeon must consider the relative rewards and risks in treating a specific illness.[1] The surgical risks encompass not only the odds of surviving surgery but also the long-term prognosis, the potential for the develpoment of complications, and the patient's future use and quality of life.[1,2] Basic factors affecting operative risk include age, overall physical status, elective versus emergency operation, physiologic extent of the procedure, number of associated illnesses, and projected surgery time. Although the surgeon can informally consider all this information and make a guess as to the surgical risks based on experience in similar cases, formal assessment schemes are useful and their adoption is encouraged. Two main components comprise a logical formal determination of surgical risk: the primary disorder and the general health of the patient.

Primary Disease

Primary diseases with a tendency to progress rapidly and involve other body systems are associated with more risks than those that progress slowly and do not affect the patient's systemic health. The procedure's invasiveness and potential for complications are also considered in risk assessment.

Complications and the risk of death increase with the duration of surgery. The risk of surgery also varies with the system

involved. For example, diseases involving the gastrointestinal tract have a tendency to cause shock and sepsis early in their course. Elective orthopedic surgery has a much lower associated risk than nonelective general surgeries and major trauma. When emergency surgery is necessary, the surgical risk increases. When a disorder is fatal without surgery but has the potential for a surgical cure, surgery is likely to be recommended despite a high surgical risk.

General Health Assessment

Surgery and anesthesia are never without risks, and unexpected complications can occur even in the healthiest patient undergoing a minor procedure. However, the risks are increased by a variety of conditions. Risk is increased in the very young and the very old patient. Neonatal animals are predisposed to hypothermia, hypoglycemia, and infection. Morbidity and mortality increase with age in human and veterinary surgical patients.[2]

The effects of concurrent disease on an animal's general health are important determinants of surgical risk. Animals with normal physical findings and no history of cardiovascular, respiratory, renal, or liver disorders have a relatively low surgical risk. Additionally, the preoperative nutritional status is an important determinant of surgical risk (see Chapter 6). Cachectic animals may experience delayed wound healing and a higher incidence of postsurgical wound infection and susceptibility to multiple organ disorders.

The importance of establishing the physical status cannot be overstated. The American Society of Anesthesiologists (ASA) has created a classification system for human patients based on evaluation of their physical status, and the rankings can be used to determine surgical risk (Table 10-1). In humans, physical status was second only to albumin level in its accuracy in predicting survival and postoperative complications.[3,4] Similar findings were observed in high-risk canine surgical patients: 92% of canine patients assigned to ASA class II survived, compared with 73% in class III and 38% in class IV.[5] In fact, in a recent study on surgical site infections in 97 human hospitals, admission illness severity was significantly associated with higher mortality and increased length of stay and cost.[6]

Personal Relationships

A bond of communication, cemented with personal responsibility, is established between the surgeon and the client (usually the animal's owner), whenever a surgical procedure is being considered. The confidence of the well-informed client is based on a true understanding of the situation, which allows the client to participate in decisions regarding operative risks, outcomes, the process of postoperative recovery, and financial implications. Legal action is rare when a careful effort has been made by the veterinarian to achieve such understanding before a surgical intervention.

Veterinary surgeons should also appreciate the importance of an effective relationship with the referring veterinarian. In many situations, patients are referred to surgeons by veterinarians with valuable skills and expertise. It is important to understand the wishes and views of the referring veterinarian.

TABLE 10-1. American Society of Anesthesiologists Classification System for Physical Status and Recommended Tests for Each Class

Physical Status	Definition	Example	Recommended Laboratory Tests		
			Minor*	Major†	Prognosis
I	Healthy with no organic disease	Elective procedures not necessary for health (ovariohysterectomy)	PCV, TP, urine specific gravity	CBC, U/A, surgical panel‡	Excellent
II	Local disease with no systemic signs	Healthy nonelective surgery (skin laceration, simple fracture)	PCV, TP, urine specific gravity	CBC, U/A, surgical panel‡	Good
III	Disease causes moderate systemic signs that limit function	Heart murmur, anemia, pneumonia, mild chest trauma, moderate dehydration	CBC, U/A, surgical panel‡	CBC, U/A, biochemical panel§	Fair
IV	Disease causes severe systemic signs and threatens life	Gastric torsion, diaphragmatic hernia, severe chest trauma, severe anemia, or dehydration	CBC, U/A, biochemical panel§	CBC, U/A, biochemical panel§	Guarded
V	Moribund, not expected to live for more than 24 hours with or without surgery	Endotoxic shock, severe trauma, multiorgan failure	CBC, U/A, biochemical panel§	CBC, U/A, biochemical panel§	Grave
E	Emergency	Qualifier of previous classes	PCV, TP, urine specific gravity	Depends on facilities available	Variable

CBC, Complete blood cell count; *PCV,* packed cell volume; *TP,* total protein; *U/A,* urinalysis.

*Duration less than 60 minutes.

†Duration longer than 60 minutes or patients older than 7 years.

‡Surgical panel: urea, creatinine, alkaline phosphatase, alanine aminotransferase, glucose, sodium, potassium, chloride, and total protein levels.

§Biochemical panel: the full panel is the surgical panel tests plus bicarbonate, anion gap, calcium, phosphorus, cholesterol, total bilirubin, γ-glutamyltransferase, and albumin levels.

Differences in judgment must be discussed. Both the surgeon and the referring veterinarian should be aware of the expected course of treatment and the extent of the referring veterinarian's participation in postoperative care. This prevents communication errors and contradictory efforts.

True informed consent is attained when there is a full and frank discussion with the client in the presence of an appropriate professional witness.[1] The surgeon should record a summary of this encounter in the hospital chart. The surgeon should also record why the operation is needed, the operative risks, and the problems anticipated intraoperatively and postoperatively. When a condition is expected to have a clinically significant course beyond the duration of the early follow-up period, the client should be told how much continuing commitment will be needed.

PREPARATION OF THE SURGICAL PATIENT

History

The first step in the assessment of a patient is interviewing the owner to determine the animal's medical history, its overall health, and the impact of the presenting complaint.[2] At this time, the surgeon should determine the owner's wishes and expectations.

The patient's signalment should be reviewed to determine the potential for problems related to age, breed, and sex. Questions about the animal's general health and environment can contribute to making the diagnosis. The animal's intended use and the owner's expectations of its future performance are explored to gauge the future satisfaction of the owner with the proposed procedure. Past medical problems should be discussed, because they may influence the outcome.

Physical Examination

Despite a surgeon's natural tendency to focus on the presenting problem, a thorough physical examination should include an assessment of each system. A general physical examination determines the need for in-depth assessment and preoperative stabilization. It is this examination that is most likely to identify risk factors affecting surgical outcome.[2] The animal should first be examined for general demeanor, nutritional status, and gait. Temperature, pulse, and respiration rate are noted because the respiratory and cardiovascular systems are emphasized.

Finally, the affected area and related systems are evaluated. A physical status ranking, based on the American Society of Anesthesiologists classification system (see Table 10-1), should be assigned. This will allow a more accurate determination of what supplemental testing should be performed.

Supplemental Testing

Laboratory testing is not a substitute for the thorough examination, and all abnormal findings in the laboratory data should be interpreted in light of the initial physical findings. When abnormalities in the function of organs (e.g., the heart, kidneys, and respiratory system) are detected, testing may be expanded to include chest radiography, urinalysis, and biochemical profile. However, although preoperative tests that screen for clinically silent disease will not replace the physical examination, some basic laboratory data are recommended for use with the American Society of Anesthesiologists classification system for physical status (see Table 10-1).

Physiologic Preparation

In preparation for elective surgery, steps should be taken to correct physiologic deprivations. Surgical procedures in chronically anemic patients should be delayed until the anemia can be corrected. If fluid deficits exist, plasma or fluids should be administered in appropriate volume, concentration, and composition (see Chapter 3). Although not all volume and concentration deficits need to be corrected before the surgery, a significant fraction of the total deficit should be replaced to enhance the safety of the anesthesia, even in emergency patients. Nutritional replenishment supplementation should be provided for a patient that awaits an elective operation if deficits are obvious.

Infection is a major source of morbidity and a disconcerting source of mortality in some surgical patients. Badly injured or traumatized horses, and those that undergo an operation and survive despite the development of secondary shock and electrolyte disturbances, are at a very high risk for serious infection.

Infection rates of surgical wounds in horses are higher than those seen in people and dogs. Overall infection rates for equine orthopedic surgeries have been reported to be 10%, compared with 4.7% in people, and 5.1% in dogs and cats.[7-10] Infection rates for abdominal surgery in horses have been reported to be 25.4% and 30%.[8,9] Therefore a primary consideration in preparing the patient is antibiotic prophylaxis. Because equine patients do not live in particularly clean environments, antimicrobial drugs are frequently administered prophylactically even for elective orthopedic surgeries. For additional information on surgical infections and management of sepsis, see Chapters 7, 9, and 85.

Skin Preparation

The patient is the primary source of pathogens involved in surgical wound infections and therefore should be groomed before surgery, or even bathed if the hair coat contains a lot of organic material, and the tail should be wrapped.[10] Preparation of the surgical site should include hair removal and cleansing to remove dirt and oil and to reduce resident skin flora. The suggested procedure is to clip the entire surgical area using a No. 40 clipper blade, then scrub and apply an antiseptic solution. Additionally, wrapping the limb with a sterile bandage overnight reduces the chance of contamination in orthopedic cases. However, clipper blades used repeatedly without sterilization have high levels of bacterial contamination and therefore are a potential source of infection.[11] Sterilization of clipper blades between uses has been shown to decrease bacterial counts and would lessen this problem. A study in humans revealed that using razors for the close removal of hair caused significant injury to the skin and increased bacterial colonization by altering wound defense mechanisms and delaying healing.[12] Consequently, if the surgical site is to be shaved, it should be done immediately before surgery and not the night before.

Clipping should be performed whenever possible outside of the surgical theater, as should the initial skin preparations. For surgical sites on the mid to distal limb, the hair from the elbow and stifle distad should be clipped circumferentially.

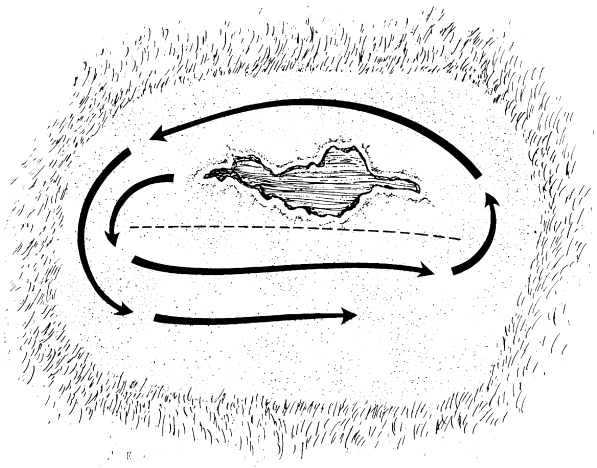

Figure 10-1. Proper method of skin preparation. In the initial preparation, the scrub begins at the anticipated incision site *(dotted line)* and moves outward in expanding concentric circles. The process is repeated until the sponges are free of visible soiling.

Additionally, the hair should be clipped 10 cm (4 inches) further proximad and distad relative to the intended surgery site to facilitate appropriate skin preparation and draping. If possible, only the final skin preparation should be performed in the surgical theater to prevent dust, dander, and exfoliated skin cells from contaminating the environment.

The optimal scrub time for maximal reduction of skin flora and lowest wound infection rates has not been determined for the horse. A povidone-iodine or chlorhexidine diacetate aqueous or alcohol solution used for 10 minutes, alternating with an alcohol rinse, is currently recommended,[13,14] and other scrub solutions are available (see Chapter 9). A recently available method of preventing infection is a cyanoacrylate-based microbial sealant (IntéguSeal Microbial Seal, Kimberly-Clark), which mechanically blocks migration of pathogens to the surgical wound.[15,16] It has been shown to reduce the pathogens commonly implicated in surgical site infections (SSIs) by 99.9% and improves the effects of povidine-iodine by fixing it on the skin and preventing it from being washed off. Another commonly used final application product that has a similar mechanism of action is DuraPrep Surgical Solution (iodine povacrylex [0.7% available iodine] and isopropyl alcohol, 74% wt/vol).

Surgical scrubs are applied to an area starting at the expected surgical incision and moving outward in expanding concentric circles, extending to the outer margins of the clipped area (Figure 10-1). This maneuver is repeated, alternating rinse solutions with the antiseptic until the sponges are free of visible soiling. Then a final application of the disinfectant is applied and left in place. In the distal limbs, the entire circumference of the limb is aseptically prepared, applying the scrub at the proposed surgical site and expanding distad and proximad, as just described.

Draping the Surgical Field

Ideally, barrier materials prevent the movement of debris and bacteria from nonsterile areas onto the surgical field for the duration of surgery. Bacterial penetration is time dependent, and colony-forming units (CFU) increase after 90 minutes of surgery.[17] Therefore drapes should be economical and easy to sterilize, and they should retain their barrier properties for at least 90 minutes, even after they are washed, sterilized, and reused. Woven fabrics that are intended for reuse consist of interlacing fibers that cross at right angles. The number of threads per square inch reflects the tightness of the weave, and the higher the number is, the tighter the weave and the more effective the barrier.

Reusable woven fabrics fall into two categories: cotton muslin with 140 threads per square inch, and pima cotton with tightly twisted fibers woven into 270 threads per square inch (58 threads/cm^2).[2] The cotton muslin is not a good barrier. It instantly allows passage of bacteria when wet (termed *strikethrough*), and dry penetration of bacteria may also occur because its pore size is 50 to 100 µm, which is large enough to allow bacteria (5 to 12 µm) to pass through.[18] On the other hand, pima cotton has a weave tight enough to prevent penetration by skin squames, but it readily allows penetration of bacteria when wet. A chemical treatment process, Quarpel, makes cotton fabric water resistant by providing a fluorochemical finish in combination with pyridinium or a melamine hydrophobe. This process renders pima cotton an effective barrier for up to 75 washings.[19] It is necessary to record the number of washings each piece of fabric undergoes to ensure that it is replaced before the barrier properties become ineffective.

A disadvantage of reusable woven fabrics is that they can sustain tears or punctures from towel clamps (therefore only nonpenetrating clamps should be used at the surgical site) and needles, which destroy their barrier function, although holes can be repaired with vulcanized fabric patches. These patches generally resist autoclave steam penetration, so this material becomes a less than ideal barrier.

Disposable materials are made from cellulose, wood pulp, polyesters, or synthetic polymer fibers formed into sheets and bonded together. The barrier properties of the various nonwoven materials differ a great deal.[17] Polymeric ingredients in these barriers tend to be more impermeable, but only those with a reinforced polyethylene or plastic film prevent moist and dry penetration at pressure points.[2] Although disposable drapes result in lower particle counts in the operating room (because of the lack of lint from cotton), the air bacterial counts are similar to those of reusable drapes. However, they are reported to decrease the number of bacteria isolated from the surgical wound by up to 90% compared with the cloth draping systems, and surgical wound infection rates decrease by a factor of up to 2½.[20,21] Because the difference between the two materials appears to be small, the choice is often based on economics and convenience. Even though the cost of single-use gown and drape sets is higher than for reusable sets, single-use sets provide the highest benefit rates. When large volumes of liquids are expected in the surgery (e.g., in colic and arthroscopic surgery), nonwoven disposable materials should be the material of choice for barrier drapes.[22]

Before moving the patient into the operating theatre, the patient should be covered with a clean drape and its feet should be covered with plastic bags or other water-impervious coverings to prevent contamination from the foot and distal limbs. After the patient is positioned in the room and the final preparation of the surgery site is completed, draping begins at the surgical site and moves outward.

Drapes are applied to all visible surfaces of the patient, providing a barrier to aerosolization of debris from nonsurgically prepared portions of the animal's skin. When applying drapes,

Figure 10-2. Four-quadrant draping method with separate drapes in each quadrant, leaving a rectangular area of the surgical field exposed. Note how the surgeon's hands are protected by the drape.

the surgeon's gloved hands are positioned on the side of the drape away from the animal's skin and are protected by curling the outer surface of the drape over the hands (Figure 10-2). The portion of the drape that is to be adjacent to the incision is positioned first and then moved peripherally to the desired location, never the reverse. It is desirable to drape closely, leaving no unnecessary skin exposed. Drapes are generally positioned in a four-quadrant method, with separate drapes in each quadrant, leaving a rectangular area of the surgical field exposed. It is recommended that this process be repeated to double drape the area immediately adjacent to the surgical site.

Self-adhering drapes are helpful when larger areas need to be exposed for topographic orientation and palpation. The goal of multiple layers of draping is to build a waterproof barrier that extends to cover the entire patient. When the distal limb is draped, the quadrant method may be used. However, providing access to the entire circumference of the limb is often preferred, especially during orthopedic procedures. In such a case, the foot is often covered with a rubber glove, and circumferential draping is applied, by wrapping first around the foot and then around the proximal limb. Next, a self-adherant sterile drape (Ioban 2, Ethicon, Somerville, NJ) is applied over the foot and the half sheet that has been applied to the proximal limb. Then an extremity sheet with a fenestration is passed over the foot and secured around the limb proximal to the surgery site (Figure 10-3).

Because there is a risk of contamination during draping, it is best to practice double gloving for the act of draping, removing the outer gloves immediately thereafter.

The surgical field is defined by areas above and level with the surgical wound (Figure 10-4). Even if draped, areas below the level of the wound should be considered contaminated and not part of the surgical field.

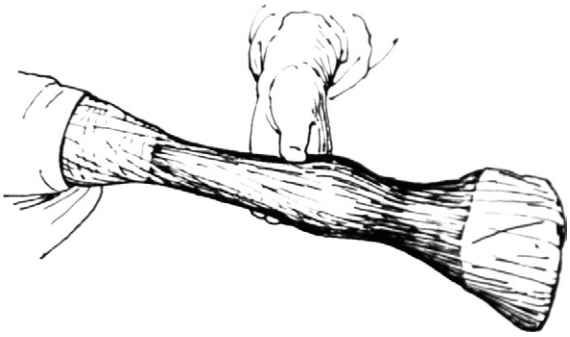

Figure 10-3. After drapes are applied circumferentially above and below the surgery site, they are covered with a self-adherant drape. An extremity sheet for fenestration can be passed over the foot to complete the draping.

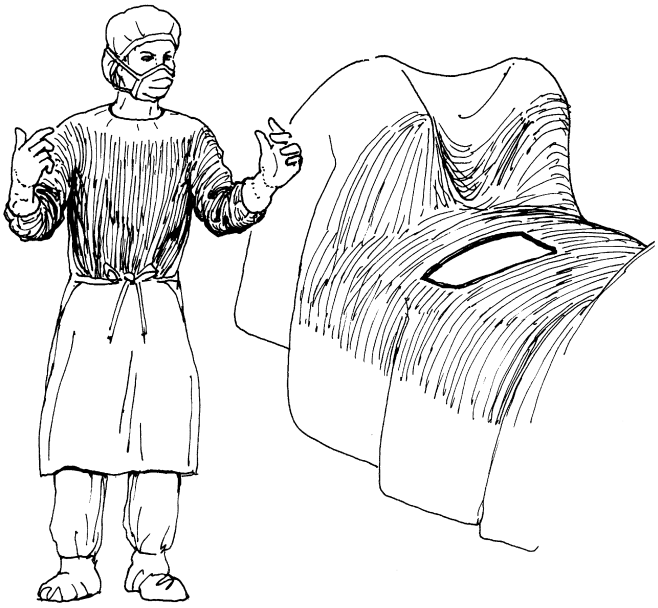

Figure 10-4. The surgical field is defined by the areas above and level with the surgical wound *(shaded area).* It is extended to include the front of the surgical gown from below the surgeon's shoulders to the waist *(shaded area).* Areas that are not shaded should be considered to be outside the surgical field.

THE SURGICAL FACILITY

With the increasing sophistication of surgical techniques and instrumentation available today, surgeries outside a proper surgical facility are becoming less common. If the procedure to be performed is expected to be lengthy, complicated, or sophisticated, use of a designated operating room is the standard of care. Surgical operating facilities should be equiped with separate induction, preparation, and recovery rooms. There should be a minimum of two surgical suites, so that clean procedures can be performed in one surgical suite dedicated to strict aseptic surgical procedures, and the other suite can be used for procedures on contaminated or infected sites (Figure 10-5). The surgery suite should be convenient to the work and have adequate room for the patient, anesthesia equipment and team, surgery team, and equipment. The average size of an equine operating room should measure 15 m^2 (135 square feet). Separate induction and recovery rooms should be available for each surgical suite. Floors and walls should be surfaced so that cleaning is efficient, and drains should be placed so that water does

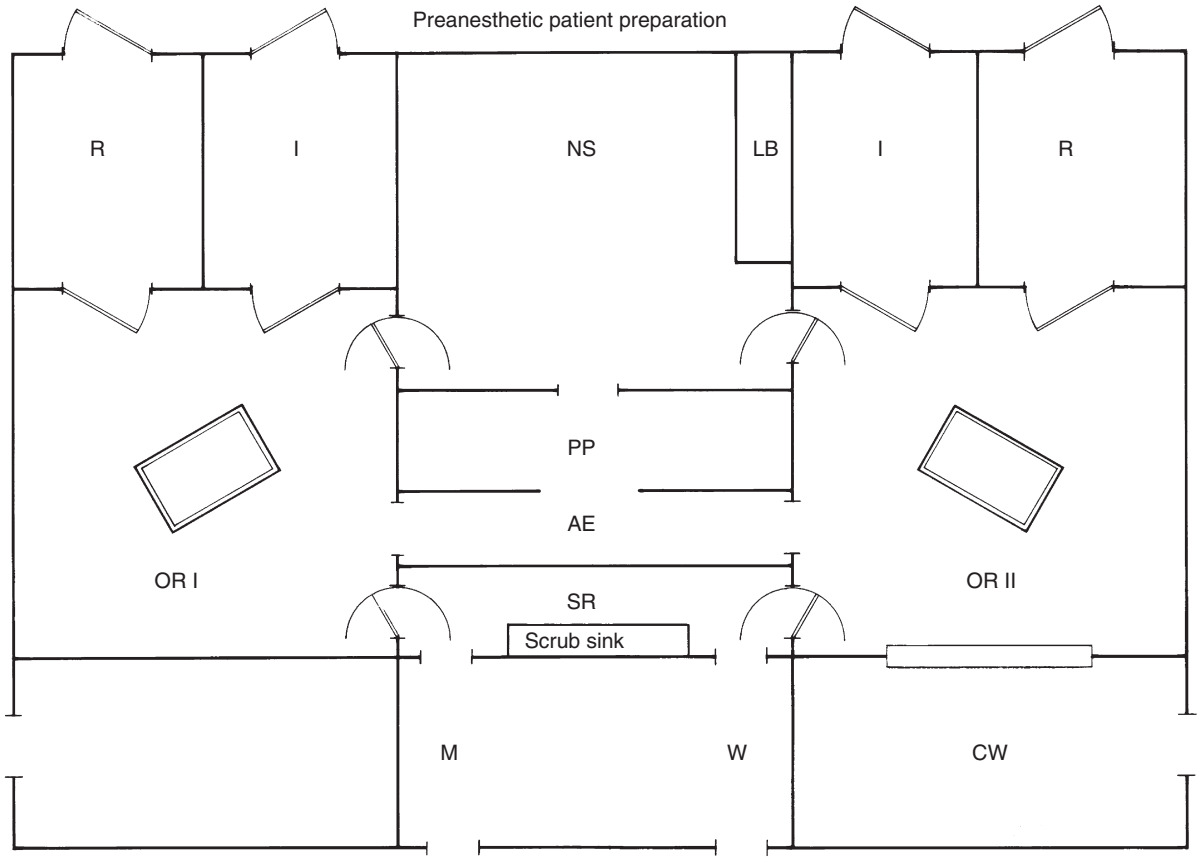

Figure 10-5. Suggested layout for an equine surgical facility. Separate rooms are provided for clean procedures and for contaminated or infected procedures, and a central station supplies both suites. *AE,* Anesthesia equipment; *CW,* client waiting room; *I,* induction stalls; *LB,* laboratory bench; *M,* men's dressing area; *NS,* nurses' station; *OR,* operating room; *PP,* pack preparation and storage; *R,* recovery stalls; *SR,* scrub room; *W,* women's dressing area.

not pool anywhere in the surgical suite after cleaning. Drains should be of sufficient diameter to remove the material and should contain a flushing system so that they do not harbor potentially dangerous mixtures of blood, feces, and bacteria.

One-way traffic should be maintained from the patient preparation area to the operating suite and then to the recovery room. After induction of anesthesia, the patient should be properly positioned on the surgery table and prepared for aseptic surgery, and then the table with the horse should be transported into the surgery suite. The suite should not be a high-traffic area, and proper surgical attire, including caps, boots, mask, and surgical caps, should be worn over the scrub suit when in the operating theater.

A room temperature of approximately 20° C (70° F) with a relative humidity of 50% provides a comfortable environment.[23] Air within the operating room should be under low positive pressure, so that when the doors open, air flows out of the room rather than into it. A minimum of 25 air exchanges per hour is recommended if the air is recirculated, and 15 air changes per hour if the air is exhausted to the outside. In selected human surgery suites, especially those used for joint replacement, laminar air filtering systems are installed to reduce the number of airborne microorganisms in the surgery suite. The filtering system measures about 3 × 3 m (Figure 10-6). The air is directed in a vertical flow of 0.5 m/sec initially through a rough, then through a fine, and ultimately through a high-efficiency particulate air (HEPA) filter. The ultraclean air reaches the surgical field and is directed around the patient to the floor. From there it is aspirated into exhaust outlets located all around the walls at the ceiling. The air is recirculated through the filtering system. Ideally, the outline of the filtering system is marked on the surgery room floor, which facilitates the positioning of the surgery site, the instrument tables, and surgeons within the field (Figure 10-7). Such ultraclean filtering systems are rarely found in equine hospitals and may not be necessary.

The door should be wide enough to allow the surgery table with the horse and other large equipment, such as the digital capture C-arm and radiography machines, to pass through easily. Electrical outlets should be located waist high or suspended from the ceiling so they do not become wet during cleaning of the room. Ideally, several locations for hooking up the anesthetic gases and the exhaust pipes of the anesthetic machine should be available. Also, devices should be placed in the wall to allow the application of traction pulleys for reducing fractures. Some provision should be made for emergency lighting, either by battery units or with an emergency generator that starts automatically when needed. At least one surgery light in each room should be wired to the emergency system. All cabinets should be recessed into the wall so that the floor can be adequately cleaned after each surgery. Viewing windows are desirable in operating rooms. This is done not only for direct viewing from a doctor or nurse's station but also so the public can view surgeries from an outside hall. Another option is the installation of a closed-circuit video camera system, which can

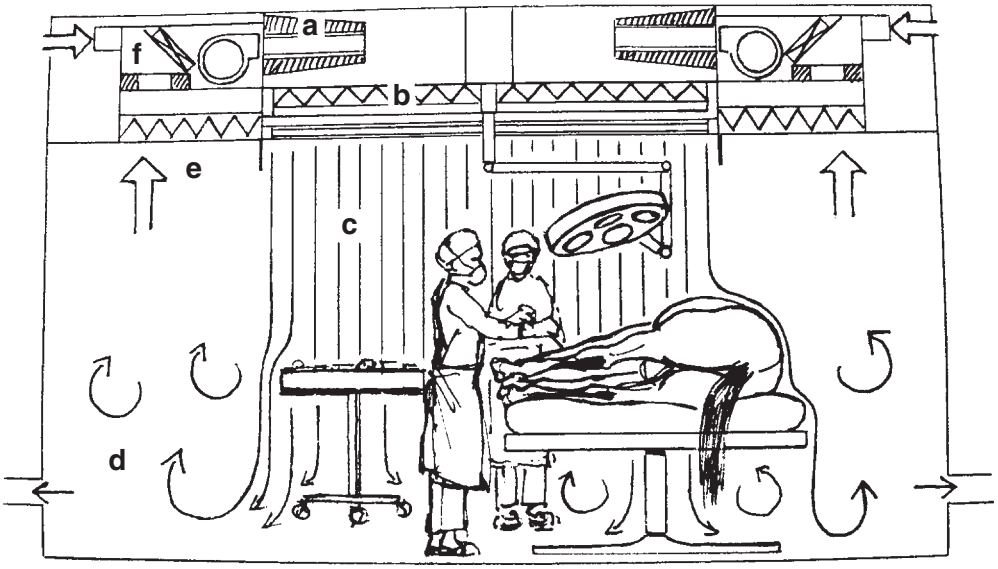

Figure 10-6. Schematic drawing of a laminar air filter system. The surgical site, the surgeons, and the instrument tables must be situated in the field of filtration. *a,* Blower to force filtered air through the pores in ceiling. *b,* Laminar air filter in the ceiling (frequently illuminated). *c,* Laminar air stream gently falling towards the floor. All objects within the field are surrounded by this air. *d,* Once at or near the floor, the air is directed toward the periphery, and some of it is lost through doors and other openings. The rest is gently pulled up toward a filter system mounted along the walls in the ceiling. *e,* After being extensively filtered and mixed with clean air from outside, the air is directed through the blower *(f),* again and reentered into the cycle.

Figure 10-7. be operated by the owners or students from an observation room distant from the surgery facility.

Biosecurity and infection control practices are becoming more important considerations when designing the surgcial facility, especially if the surgical caseload is large.[24] Ultimately the success and reputation of a surgical practice can depend on having surgical personnel trained in infection control with awareness toward SSI and the impact of antimicrobial-resistant microbes such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Salmonella* ssp.[6,25,26] Sometimes the facility itself will prevent optimal minimization of SSI if the design does not support easy cleaning and proper storage of waste materials. It may behoove the director of the facility to enlist the advice of an infection preventionist in planning the facility, then training the personnel, and developing an effective infection control program.[27] Infection control programs should include monitoring, surveillance, hygiene, disinfection protocols, and education.[28]

THE OPERATING TEAM

Scrub Attire

The operating team consists of the people performing the surgery and administering the anesthesia, nonscrubbed assistants, and observers within the operating room. All individuals, regardless of their role in the surgical intervention, contribute to operating room contamination and potential infection of the wound. Therefore scrub suits, caps, masks, sweat bands, shoe covers, gowns, and gloves are worn to prevent shed particulates and microorganisms from reaching the surgery site.

Scrub suits usually have separate pants and shirts and should be clean, comfortable, and dedicated to the operating room (Figure 10-8) Many blended cotton materials are available for this purpose. Although the design is relatively standard, optimally sized garments will cover the surgeon effectively from neck to ankle while leaving the arms exposed. The bottom of the scrub shirt is tucked into the pants to prevent shedding of hair, skin cells, and bacteria between the top and the pants. For those not needing to gown and glove for the procedure, long-sleeved cuffed jumpsuits are also quite useful, because they provide a barrier against shedding of skin debris and microorganisms. The scrub suit should not be worn outside the surgery suite without being covered by a clean laboratory coat, and it should be laundered after each case or at least daily. This scrub clothing should be steam sterilized weekly to ensure removal of the microorganisms that can remain after routine laundering. Alternatively, bleach can be added to the laundry cycle to reduce the number of bacteria.

Air in an operating room contains approximately 250,000 particles (bacteria, lint, and skin squames) and 11 to 13 bacteria per cubic foot.[29,30] These particles and bacteria increase with the number of people and level of activity in the room, the amount of uncovered skin area, and the amount of talking. Bacterial levels in excess of 400 per cubic foot may be seen in a busy operating theater. Therefore barrier apparel is worn to minimize these numbers and their effect on surgical wound rate.

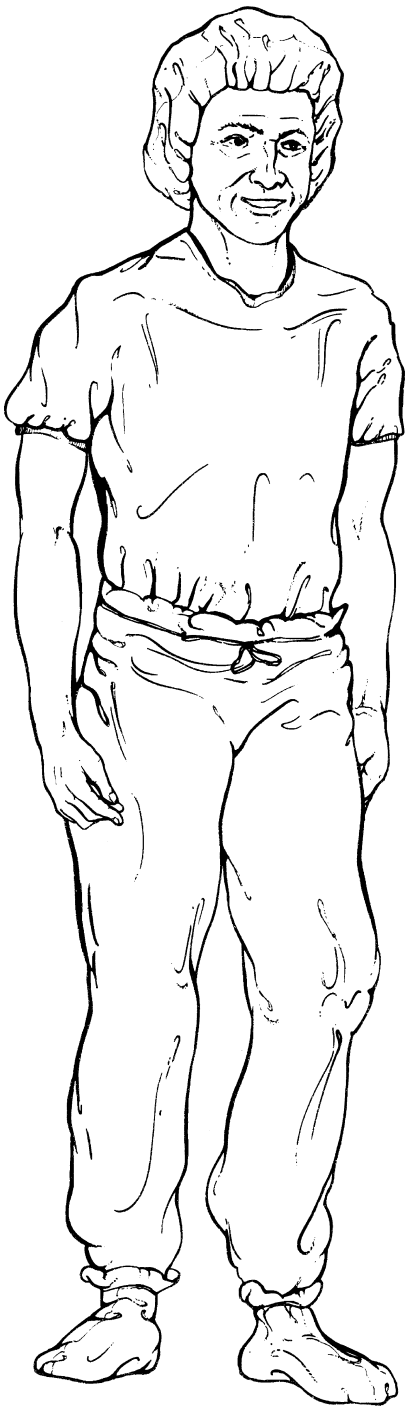

Figure 10-8. Scrub suit recommendations. The scrub shirt should be tucked into the pants. Although not always practical, the pants legs may be tucked into boots or shoe covers. Peripheral personnel may wear long-sleeved tops with elastic cuffs to further limit transmission of skin debris.

Head Covers

Human hair is a major source of bacteria. Because the uncovered hair of the surgeon, who stands over the incision, is frequently a major source of surgical wound contamination, head covers are worn to reduce the shedding of hair and bacteria. All people in the operating room should wear head covers—caps, hoods, or bouffants (Figure 10-9). These are available in reusable cloth and disposable nonwoven material and should cover all the hair on the head, including moustaches and beards. The reusable head covers should be washed after every

Figure 10-9. Headcover styles are shown in order of increasing barrier capability, from left to right. Surgeon's caps, bouffant caps, and hoods offer protection against shedding hair and debris into the surgical wound. Coverage by the old style surgeon's cap is obviously limited compared with the other types.

procedure (up to a total of 75 times and then, like the reusable drapes, discarded).

Gowns

Gowns provide an aseptic barrier between the skin of the operating team and the patient. The gown should be water resistant as well as comfortable and breathable. It should not produce lint. Gowns are packaged individually and folded so the interior back region is outermost, allowing this area to be handled without contaminating the gown's exterior surface. Once the gown is donned, the sterile surgical field extends only above the waist (see Figure 10-4).

Gowns, like the draping materials, can be made of either reusable woven fabric or nonwoven disposable material. The most effective barrier gown contains some type of polyester or plastic film over a breathable material. Preventing strikethrough when becoming wet is an attribute that is mandatory for surgical gowns. Gore-Tex gowns with double-layered barriers in the elbows, chest, and abdominal areas have become popular because they are comfortable and meet the necessary criteria. Gore-Tex is a barrier material consisting of an expanded film of polytetrafluoroethylene between two layers of fabric with a maximal pore size of 0.2 μm, which resists strikethrough by water and bacteria.[31] It allows evaporation of perspiration, which increases comfort for the surgeon. Gore-Tex fabrics are more durable than Quarpel-treated pima cotton and will retain barrier quality characteristics for up to 100 washings.

Gloves

Surgical gloves are made of natural rubber latex and are provided in a sterile, single-use package. Gloves should fit tightly, because gloves that are loose will impair dexterity, but they should not be so tight that the surgeon's fingers lose sensitivity. Modified cornstarch is preapplied to most gloves for easier application, and therefore the outside of the gloves should be rinsed before patient contact.[32] Cornstarch is referred to as "absorbable powder." Magnesium silicate (talcum) powder is no longer used in powdered gloves because it potentiates latex allergies and causes granulomas in patients even when gloves are thoroughly rinsed. However, even absorbable powdered gloves contribute to natural rubber latex allergies (which cause contact dermatitis), and the powder acts as an airborne carrier of natural latex proteins (which can cause respiratory allergies). Therefore most surgical gloves are treated with multiple washings to reduce the latex proteins. If allergies to latex develop, powderless latex gloves are available, which are chlorinated during manufacturing to decrease their tackiness. (However, these gloves do not store well, and inventory should be monitored to prevent use of these gloves beyond the expiration date, because failure becomes common.) Alternatively, vinyl gloves are available to eliminate this problem, although their performance is less desirable (i.e., dexterity is reduced).

The accepted industry standard for surgical gloves is that 1.5% contain punctures before use.[33] One study found that 2.7% of latex and 4.1% of vinyl gloves leak when filled with water. By the end of surgery, up to 31% of gloves have perforations, and when double gloves are worn, 16% to 67% of the outer gloves and 8% to 30% of the inner gloves contain perforations. Holes are most common on the thumb and index finger of the nondominant hand. Closed gloving techniques are preferred over open techniques because the surgeon's skin will not contact the outside of the gown cuff. If soiling of the gloves is expected or extra protection is needed during a surgical procedure (i.e., during most orthopedic procedures), many surgeons elect to apply and wear a second pair of gloves. Cuffs of the surgeon's gown should be completely covered, because cuff material is not impervious to water penetration. The use of plastic safety sleeves often helps when the surgeon's hands and arms may be submerged, such as during colic surgery. Extra-thick gloves are available for orthopedic surgeries, where there is an increased risk of puncturing the gloves from sharp bone spikes and implant materials.

Face Masks

Facial coverings are not effective bacterial filters. When properly fitted, they redirect airflow away from the surgical wound and in doing so reduce the potential for surgical wound infection

Figure 10-10. Potential leakage sites of the standard surgical mask *(arrows).* Transmission of contaminants around the edges of the mask can be limited by properly conforming the nosepiece to the nose and tying the mask snugly.

(Figure 10-10). Despite clinical reports that facial coverings do not reduce surgical site infections, the use of a face mask is considered mandatory during surgery. Tie-on face masks are tied over the head first, the wire on the top of the mask is fitted tightly over the surgeon's nose, and the lower ties are pulled around and tied behind the neck.[2] The mask should fit tightly around the sides of the face and over the tip of the chin. Cup masks with elastic bands provide a better fit and offer less chance of bacterial contamination.

Disposable surgical face masks are recommended over washable gauze because of improved efficiency and comfort. Masks should be worn by all personnel entering the surgery room at any time. Failure to wear masks even when surgery is not in progress promotes contamination of the surgical area. Masks should not be removed and replaced, pushed on the top of head, dangled from the chin, or tucked in a pocket. Each of these common practices risks contamination of scrub clothing with bacteria from inside the mask, which may be transmitted to the patient. The effectiveness of masks and other barriers in a surgery room should probably not be relied on for more than 2 hours.[2] A frequent change of masks, caps, and other apparel is warranted when this time period is exceeded. Bearded surgeons should wear a hood that covers all facial hair in addition to a face mask, which alone is insufficient.

Foot Covers

Disposable shoe covers are usually made of light nonwoven material and sometimes have polypropylene coatings to avoid strikethrough. Shoe covers help keep the surgeon's feet dry and thus more comfortable during surgical procedures, but they are not believed to be useful in reducing the soil brought to the operating room floor in an equine surgery suite, because of the obvious soiling that occurs with this type of patient. Therefore, shoes dedicated to the operating room are a better option for reducing environment contamination; these shoes should never be worn outside the surgery area without shoe covers, which are then removed before reentering the surgery suite.

Surgeon's Skin

A surgeon's hands have higher bacterial counts and more pathogenic organisms than the hands of other medical personnel because of increased exposure to scrub solutions (which irritate the skin) and contaminated wounds.[34] The objective of a surgical hand scrub is to remove gross dirt and oil and decrease bacterial counts, and just as importantly to have a prolonged depressant effect on transient and resident microflora of the hands and forearms. Surgical scrub protocols are based either on scrubbing time or on stroke counting. Principles of the scrub procedure are standard. Fingernails are kept short, clean, and free of polish and artificial nails (chipped nail polish and polish worn for more than 4 days foster an increased number of bacteria on the fingernails, even after a surgical hand scrub).[35] All surfaces of the hands and forearms below the elbow are exposed to antiseptic scrub. Special attention is paid to the area under the nails. The ideal scrub time is controversial, but 2 to 5 minutes seems to be safe and effective, depending on the agent used. Ten-minute scrubs are no longer used because they do not result in additional reductions in bacterial counts (and in one study, counts were increased) and are more irritating to the skin. A 2-minute scrub results in bacterial count reduction similar to that of a longer scrub.[36] It is currently recommended that soft brushes or sponges be used for the first scrub of the day, but subsequent scrubs can be brushless.

The residual activity of antisepsis is widely accepted as being useful in the preoperative disinfection of the surgeon's hands. The residual activity of either chlorhexidine gluconate or alcohol chlorhexidine is reported to be superior to that of aqueous povidone-iodine against resistant bacteria. Therefore, for procedures lasting less than 1 hour, aqueous povidone-iodine is acceptable, but if the procedure is going to exceed 1 hour, either alcohol chlorhexidine or chlorhexidine gluconate is the antiseptic of choice.[10] The primary objective of surgical hand disinfection is destruction or maximal reduction of the resident flora; the secondary objective is elimination of the transient flora. Surgical hand disinfection with alcohol-based hand rubs, many of which contain emollients, is growing in popularity over surgical hand washes made of an antiseptic-based liquid soap, because the rubs have a rapid and immediate action, do not require water or a scrub brush, are considerably faster than the traditional hand scrubs, and cause less skin damage after repeated use.[10] Recent meta-analyses of human studies show that alcohol-based antiseptics or rinses and products, including povidine-iodine combinations, and alcohol rubs between scrubs are the most effective method of hand preparation.[25,37,38]

One large veterinary clinic in Europe (University of Zurich) uses a combination of three products in sequence. A disinfectant solution, Bactolin (Bode Chemie, Hamburg, Germany), is applied with a soft brush or foam pad as the initial wash. Then the hands are dried, and 10 mL of Sterillium (Bode Chemie, Hamburg, Germany) is applied for 3 minutes. Postoperatively, Baktolin Balm is applied for rehydration. Sterillium contains 2-propanol (45%) and 1-propanol (30%), and mecetronium ethyl sulfate (MES), a nonvolatile quaternary ammonium compound with skin soothing and mild antiperspirant effects. Manufacturer's claims are exceptionally good skin protection and

skin care, even with long-term use; efficacy against a broad range of microorganisms and viruses (bactericidal, fungicidal, tuberculocidal, virus inactivating); and excellent residual effect. The manufacturer also claims that this preparation permits penetration deep into the stratum corneum of the skin, where it forms a defensive barrier against organisms that emerge with perspiration.

Bacterial examination after disinfection was conducted in two ways. The volunteer rubbed the distal phalanges of one hand (randomly selected) for 1 minute in a petri dish containing 10 mL of tryptic soy broth (TSB) supplemented with neutralizers (immediate effect). The other hand was gloved for 3 hours for the assessment of the sustained effect. After removal of the glove, sampling was done as for the immediate effect. From the sampling fluid, two 1-mL and two 0.1-mL aliquots were seeded, each in two petri dishes with solidified TSB. A 1:10 dilution of the sampling fluid in TSB was prepared, and two 0.1-mL aliquots of this were seeded as described earlier. Dishes were incubated at 37° C for 24 to 48 hours. For each dilution the mean number of colony-forming units (CFUs) scored in duplicate dishes was calculated. This was multiplied by the dilution factor to obtain the number of CFUs per milliliter of sampling liquid.[25] The examination technique described earlier has confirmed that rubbing the hands with an antiseptic is significantly more effective than scrubbing with brushes.[39] Hand rubbing with 0.2% chlorhexidine and 83% ethanol (Hibisoft) suppressed the number of bacteria and prolonged sterilization for more than 3 hours. In a study conducted according to two European standards for bactericidal efficacy, all alcohol-based surgical hand rubs (Sterillium and Softa Man) and the hand washes, chlorhexidine (Hibiscrub), and povidone-iodine (Betadine) fulfilled the requirements of a bacterial suspension test.[40] However, only the hand rubs met the requirements of the *in vivo* test of efficacy on resident skin flora, and chlorhexidine failed that test. In another study on surgical hand scrubs, Sterillium was superior to Hibiscrub and alcoholic gels in terms of skin tolerance and microbicidal efficacy.

A 1% chlorhexidine gluconate solution and 61% ethyl alcohol with moisturizers (Avagard) is currently in use as a hand cleaner in the United States. Advantages claimed are greater preservation of the skin's own moisture, pliability, and integrity; rapid microbial kill; and activity against a wide range of organisms, including MRSA. It has been shown to have residual activity comparable to that of chlorhexidine gluconate alone and greater than that of aqueous povidone-iodine. A similar product, 0.5% chlorhexidine gluconate plus 70% isopropanol (Hibisol), has greater residual activity against clinically significant test organisms than chlorhexidine digluconate skin cleanser (Hibiscrub), povidone-iodine surgical scrub (Betadine), or 60% isopropanol.

Despite growing evidence in favor of alcohol-based hand rubs for preoperative preparation, many surgeons remain reluctant to switch from an antiseptic soap to an alcohol-based hand rub. Large-animal surgeons pose a considerable challenge to methods employed in human hospitals, because they so often handle heavily contaminated areas on their patients before surgery. Therefore thorough prewashing is strongly encouraged before using alcohol-based hand rubs.

Additionally, recently developed microbicide products containing substituted phenolic and quaternary phospholipids have 30-second kill times and are used in 2-minute brushless scrubs (Techni-Care). These products are less irritating to the skin and are being used in several hospital applications, even including the direct applications to infected and open wounds. All of these products are recommended to be used with a skin balm after surgery to prevent the surgeon's skin from drying with multiple uses.

Staffing the Surgery Area

Equine surgery requires a team of at least three people. A surgeon, an anesthetist, and a dedicated surgical technician form the minimal operating team for most efficient operation and least risk to the patient. The properly trained anesthetist allows the surgeon to concentrate entirely on the surgical procedure and must be able to restrain patients effectively, place catheters, calculate drug dosages, and be familiar with various sedative and anesthetic agents and regimens. The surgical technician becomes an extension of the veterinary surgeon and usually is more adept than the surgeon in the support areas.

An operating room supervisor is important regardless of the size of the facility. The supervisor is responsible for ordering and stocking all supplies, maintaining a surgery log, and recording all controlled substances and their use. The dedicated surgical technician can fill this role. Additionally, a surgical assistant is invaluable, and technicians with the proper basic training skills and attitude can be acceptably competent in a relatively short time with minimal training, rounding out the team to a perfect four.

CHAPTER
11 Surgical Instruments

Jörg A. Auer

Instruments are the verterinary surgeon's best friends. It is therefore important to be surrounded by the "best friends possible." In other words, for a specialist in veterinary surgery, it is very worthwhile to acquire top-quality instruments and to take good care of them. The veterinary surgeon can choose from an abundant selection of instruments manufactured predominantly for human surgery. However, the number of instruments specially designed for veterinary applications is steadily increasing. Practically speaking, the instruments used by a surgeon are determined by a combination of economics, predicted use, specialty considerations, and personal preference. The costs involved in the purchase of instruments are substantial and demand a clear understanding of manufacturing procedures, maintenance, and potential applications during surgery.[1-4]

Surgical instruments are offered by a large number of manufacturers, all competing for the same customers. There are still no international standards for instrument quality. Therefore, caution must be exercised before purchasing instruments at bargain prices. When costs for replacement of prematurely worn-out instruments are combined with the frustrations encountered during surgery because of poorly functioning equipment, the higher costs of high-quality instruments are justified. On the other hand, some disposable instruments intended for human surgery can be used repeatedly by veterinary surgeons, which reduces costs for such high-tech instruments considerably.

MATERIALS

A description of the different compositions of stainless steels used for manufacturing instruments is found in Chapter 75. Here, only some general comments referring to instrument materials are made.

High-quality stainless steel has become the material of choice for most surgical instruments. In its various forms, hardened, corrosion-resistant stainless steel exhibits a number of desirable instrument characteristics, such as elasticity, tenacity, rigidity, ability to hold an edge, and resistance to wear and corrosion. Variation in the carbon content of the steel results in changes in the handling characteristics of the material to meet special needs. Currently, most stainless steels used for instrument manufacturing contain a high content of carbon. Although high-carbon stainless steel is resistant to wear and allows the instrument to hold its sharp edge, tungsten carbide inserts have been introduced to replace stainless steel cutting and gripping surfaces (Figure 11-1).[5] These inserts are even harder and more resistant to wear, prolonging the life of the instrument considerably. The bond between these inserts and the body of the instrument represents a potential problem area, because it may loosen

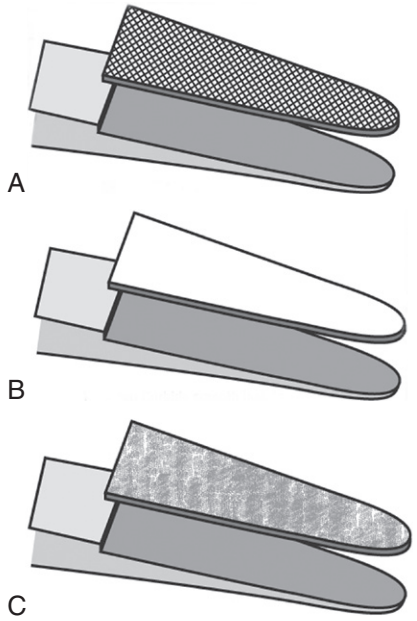

Figure 11-1. Three different types of tungsten carbide inserts for instruments. **A,** Serrated inserts. **B,** Smooth inserts. **C,** Tungsten carbide dust inserts. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

through frequent use and repeated sterilization.[6] Although the inserts on the needle holders can be exchanged, tungsten carbide cutting surfaces in scissors cannot be replaced once they are damaged; instead, a new instrument has to be purchased. Some manufacturers offer a reduced price, if the original instrument was purchased through them.[5]

The fine edges and working surfaces required for microsurgery have led to the use of titanium alloys for this specialty instrumentation. Titanium alloys can be produced with excellent corrosion resistance and temperature strength. The brittleness of such alloys complicates the manufacturing process and dictates particular care during use and maintenance. Manufacturers' recommendations for cleaning and sterilization of titanium alloy instruments should be closely followed. Recently, titanium nitrite–coated scissors became available. The glide quality is considerably improved by electrophysical smoothing, which results in fewer abrasions and reduced wear. The coating renders the surface three to five times harder, which multiplies the lifetime of the cutting edges and makes the instrument extremely resistant to scratches and other damage. The use of this material is also reflected in the increased cost of manufacturing and therefore also in the purchase price.

Before the wide availability of low-cost stainless steel, many instruments were manufactured from chrome-plated carbon steel. The chrome plating provided corrosion resistance unavailable with carbon steel alone. Unfortunately, the chrome plating itself is susceptible to early deterioration from frequent rough use and exposure to acidic solutions. Failure of the chrome coating exposes the underlying carbon steel, allowing oxidation and rust formation. Although deteriorated instruments can be refurbished and replated, replacement with higher-quality, longer-lasting stainless steel instruments is more cost-effective and is strongly encouraged.

Corrosion resistance can also be improved by the process of passivation. This process uses nitric acid to remove foreign materials from the stainless steel surface, while covering it with a thin coat of chromium oxide. Both actions contribute to corrosion resistance of surgical stainless steel. Polishing provides a very fine instrument surface, further increasing corrosion resistance.

One popular surface finish for increased corrosion resistance is a dull satin finish. Created by abrasion or sandblasting techniques, the satin finish reduces light reflection and thus eyestrain. A black finish, which serves a similar purpose, is also available. Gold electroplating of instrument handles does little to improve working surfaces but is generally recognized as a symbol of high-quality instrumentation.

Instrument companies use various colors on the handles to designate different quality of instruments or cutting edges. Sontec Instruments uses plain handles to represent standard quality instruments, gold handles for tungsten carbide (TC; see Figure 11-5) inserts, gold handles with an additional gold stripe or black anodized handles for power-cut blades (PC), which are the sharpest cutting edge available, and one gold and one black anodized handle for tungsten carbide inserts with power-cut blades.

Hundreds of different instruments are available today, and it is impossible to know them all by name, function, and design. Frequently, instruments are modified and manufactured under different names. In this chapter, instruments are discussed in groups according to function, and differences within the groups are mentioned where appropriate.

INSTRUMENTS FOR GENERAL SURGERY

All surgeons must be familiar with all basic instruments, which will aid in the selection of the appropriate instrument for a specific procedure and expedite communication during surgery. The parts of a typical surgical instrument are identified in Figure 11-2. Specialty instruments will be covered in subsequent chapters where applicable. Instruments that fall into more than one category are described only once.

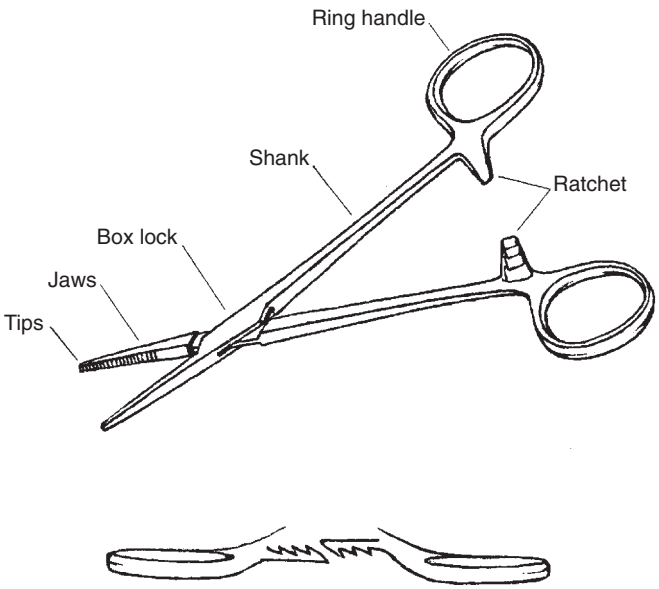

Figure 11-2. *Top:* Labeled parts of a typical surgical instrument. *Bottom:* End-on view of the ratchet mechanism. The ratchets should be slightly separated when the jaws are closed.

Scalpels

Steel Scalpels

Scalpels are available with detachable blades, as disposable units with blades attached, and as reusable units with blades attached. In most clinics, scalpel handles with different detachable disposable blades are used (Figure 11-3). The No. 3 scalpel handle is the most frequently used and comes in different shapes (see Figure 11-3, *A-C*). Most surgeons prefer the No. 10 blade; the No. 15 blade is a smaller version in a similar shape (see Figure 11-3, *E*). The No. 11 blade is frequently used for stab incisions during arthroscopic surgery, and the No. 12 blade is used for periosteal stripping (see Figure 11-3, *E*). The No. 4 handle (see Figure 11-3, *D*) accepts larger blades such as No. 22 to 24 (see Figure 11-3, *F*) and is used in less delicate surgical procedures, such as debulking granulation tissue and resecting large wounds with proud flesh. A detachable blade should not be used in joints or deep within heavy connective tissues, where they could break off and be lost from view. The primary advantage of disposable blades is that replacement blades are consistently sharp.

The reusable scalpel with attached blade has a single advantage over the disposable units: the blade will not detach when used in heavy connective tissue, within joints, or in deep tissue planes, where visibility and access for removal are poor. Ethylene oxide or gas plasma sterilization (see Chapter 9) is recommended, because heat and chemicals will dull the reusable blade.

Different types of scalpel handles and blades. **A,** Knife handle No. 3, fits surgical blades 10-15. **B,** Knife handle No. 3, long, fits surgical blades 10-15. **C,** Knife handle No. 4, fits surgical blades 20-25. **D,** Knife handle No 7, fits surgical blades 10-15. **E,** Different scalpel blades for the No 3 scalpel handles (f.l.t.r.): Nos.10, 11, 12, 15. **F,** No 22 scalpel blade fits scalpel handle. No. 4 (there are additional modifications of the blade available).

Disposable Scalpels

Disposable scalpels with nondetachable blades are frequently used in the field or for bandage removal. In a surgical procedure that requires no other instruments, such a scalpel may be used instead of opening an entire set of instruments.

High-Energy Scalpels

High-energy cutting instruments include the electrosurgical scalpel, the plasma scalpel, the water scalpel, and various forms of lasers. Although their energy sources differ, they share a common cutting mechanism of action. Energy is focally transmitted to tissue, and the effect depends on the water content of the tissue. The result is vaporization of cells along the line of energy application, a variable degree of thermal necrosis of the wound edges, and a relatively bloodless incision. Electrosurgical incisions are by far the most frequent applications of high-energy cutting.

Electrosurgery uses radiofrequency current to produce one or more of the following effects: incision, coagulation, desiccation, or fulguration of tissues. Most modern electrosurgery units use controlled high-frequency electrical currents ranging between 1.5 and 7.5 mHz.[6] The predominant effect depends on the waveform of the current. Continuous undamped (fully rectified, fully filtered) sine waves provide maximal cutting and minimal coagulation, and they produce the least amount of lateral heat and tissue destruction.[6] On the other hand, interrupted damped (partially rectified) sine waves maximize coagulation and minimize cutting capabilities. Modulated, pulsed (fully rectified, nonfiltered) sine waves allow simultaneous cutting and coagulation, or "blended" function. The magnitude of the selected effect is directly proportional to the duration and power (in watts) of the applied current.[6]

Because most modern units can be used with unipolar and bipolar instruments, adequate electrical grounding of the patient is required for the unit to function properly in the monopolar mode (Figure 11-4). The desired function (cutting or coagulation) can be selected by activating a button on the handle. Cutting and coagulation tips are available and can be exchanged as desired. Frequently, needles are used for cutting tissue because of their limited contact area, which reduces the amount of tissue necrosis. Correct technique dictates that the tissue be placed under tension and that the contact area of the point be minimized to prevent adjacent tissue destruction. Skin and fascia incise easily, whereas muscle and fat are more easily incised using a cold scalpel. Units can also be used to coagulate vessels less than 1 mm in diameter (see Chapter 12). Coagulation time should be minimized to limit the amount of tissue destruction. The bipolar forceps for direct coagulation of smaller vessels speeds up hemostasis, because the vessel can be grasped directly by the bipolar forceps, bypassing the initial placement of a hemostatic forceps.

Scissors

Surgical scissors are available in various lengths, weights, blade types (curved or straight), cutting edge types (plain or serrated), and tip types (sharp-sharp, sharp-blunt, and blunt-blunt). The two most commonly used operating scissors for tissue dissection are the Mayo and the Metzenbaum scissors (Figure 11-5). The sturdier Mayo scissors, available in 14- to 40.5-cm (5½- to

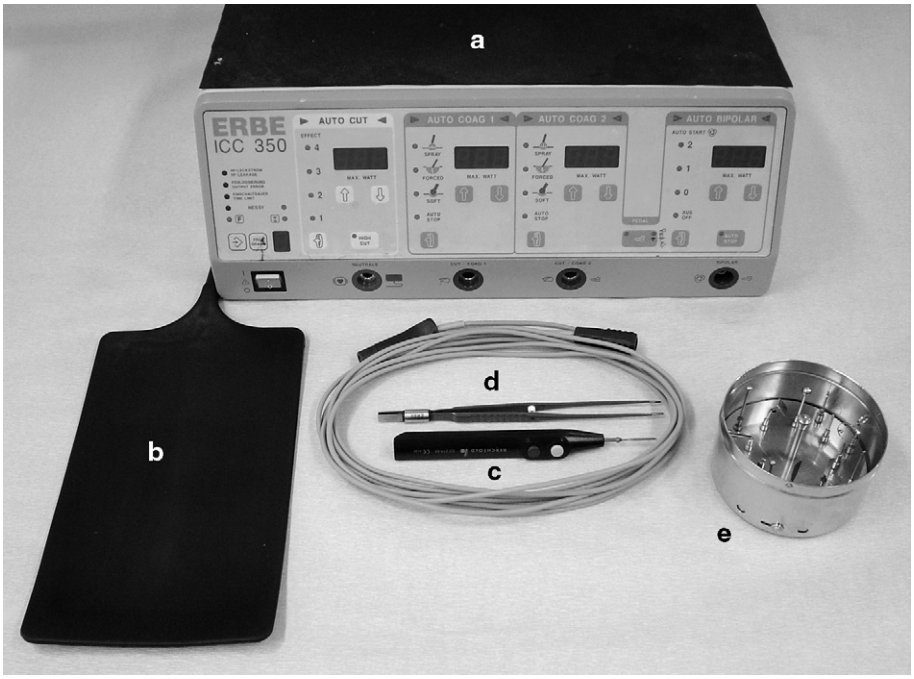

Figure 11-4. Electrosurgical instrumentation; *a,* electrocautery unit with capacity for monopolar modes of cutting and coagulation, and for bipolar coagulation mode; *b,* patient grounding plate; *c,* monopolar handpiece with thin knife; *d,* bipolar electrode forceps with connection cable; *e,* exchangeable electrodes for the monopolar handpiece.

16-inch) lengths, should be used for cutting connective tissue. Metzenbaum scissors are reserved for delicate soft tissue dissection and should not be used for dense tissue dissection. They are available in 11.5- to 40.5-cm (5- to 16-inch) lengths.

Specially designated and marked suture scissors are used during surgery to cut the sutures. It is important to use only the suture scissors for cutting sutures, because this job rapidly dulls the blades, making them less effective for soft tissue dissection.[7] The Olsen-Hegar needle holders are equipped with cutting edges (see later) to cut sutures, which obviates the need for a special set of suture scissors. Suture removal scissors (Figure 11-6, *A*) are lighter in weight, and they have a sharp, thin point and a concave lower blade that facilitates blade placement underneath the suture, which reduces suture tension as it cuts. Wire-cutting scissors (see Figure 11-6, *B*) have been designed specifically for wire suture removal and are typically short and heavy and have serrated blades.

Of the bandage scissors, the Lister (see Figure 11-6, *C*) and the all-purpose utility scissors are the best known. The lower blade of these scissors has a blunt tip that allows it to be inserted underneath the bandage without damaging the patient's skin. The all-purpose scissors comes with a needle destroyer and a serrated blade (see Figure 11-6, *D*). The serrated blade reduces bandage material slippage during cutting. Both scissors can be autoclaved.

As a general rule, scissors should be used only as intended by their design. Misuse dulls the edges and causes blades to separate, rendering them ineffective. Properly functioning scissors should open and close with a smooth, gliding action, and their tips should meet when closed. Scissors should be sharpened only by a qualified person. Incorrect blade sharpening causes the metal to overheat and lose temper, and the cutting edges to become soft, resulting in loss of a sharp edge. Scissors with tungsten carbide inserts maintain sharpness longer. The insert can be replaced when dull.

Needle Holders

A needle holder is selected on the basis of the type of tissue to be sutured, the needle and suture material used, and personal preference. The grasping surfaces of the needle holders are cross-hatched with a central longitudinal groove that facilitates the holding of curved suture needles. The two most commonly used needle holders are the Mayo-Hegar and the Olsen-Hegar (Figure 11-7). The Olsen-Hegar is a combination of needle holder and scissors and is available in lengths between 15 and 30 cm (6 to 12 inches). It allows the surgeon working without an assistant to place, tie, and cut suture material swiftly. Its major disadvantage is the occasional inadvertent and premature cutting of suture material, which occurs usually from inexperience with the instrument. The Mayo-Hegar needle holder (see Figure 11-7, *B*) has approximately the same shape as the Olson-Hegar, minus the scissors, and is available in lengths between 14.5 and 19.5 cm (5¾ and 7½ inches). Both needle holders are available in various jaw widths. The choice of jaw width is based on the size of the needle. Narrow jaw widths are recommended for small needles to prevent needle flattening as the ratchet is tightened, whereas wider jaws prevent larger needles from rotating as they pass through dense tissue.

The Mathieu needle holder (see Figure 11-7, *C*) is also popular in equine surgery. It lacks finger holes and has an open box lock that is released by further closing of the handles and is available in lengths between 14 and 20 cm (5½ and 8 inches). Unfortunately, this can occur when a firm grip is applied to the

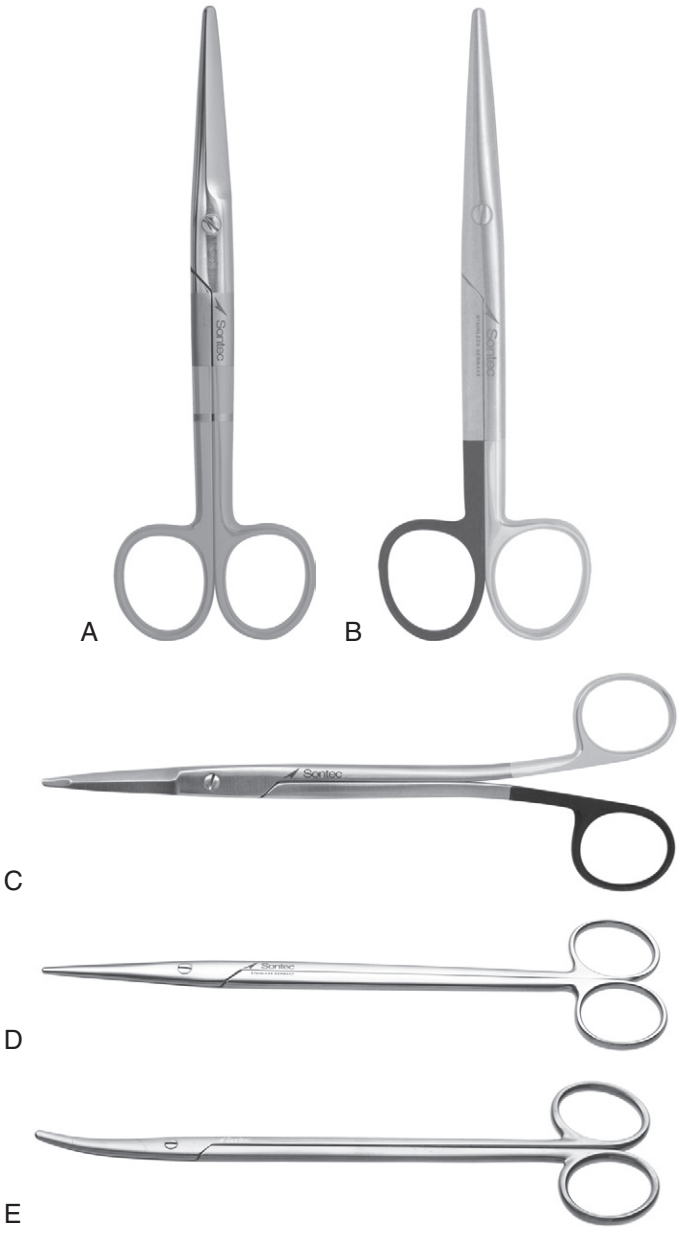

Figure 11-5. Scissors. **A,** Mayo scissors, power-cut, straight. **B,** Mayo Stille scissors, tungsten carbide, power-cut, straight. **C,** Freeman-Kay scissors, TC with ergonomic spread handle. **D,** Metzenbaum scissors, classic model, long style straight. **E,** Metzenbaum scissors, titanium nitrate coated. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

instrument while passing a needle through resistant tissue, which restricts its use somewhat. The efficient use of this needle holder requires practice.

The needle holder is the instrument that receives the most use and, through its constant metal-on-metal action, the most wear. It is advisable to purchase good-quality needle holders with tungsten carbide (TC) inserts that facilitate needle grip and instrument durability. The inserts lack a longitudinal groove and are designed with pyramidal teeth to provide a nonslip grip on needles. Instrument life can be prolonged by choosing the appropriate needle for the size of the needle holder. The lock box will be damaged if the instrument is used

to grasp too large a needle. Repair or replacement is necessary if the needle can be rotated by hand when the instrument is locked at the second ratchet position. New needle holders will hold an appropriately sized needle securely when locked in the first ratchet tooth.[1]

Forceps and Clamps

Forceps and clamps are available in many designs, each intended to perform specific functions or tissue manipulations. They range from simple thumb forceps to instruments containing various hinge configurations and ratchet locks. The selection of appropriate forceps for inclusion in surgical packs can greatly facilitate some maneuvers. Improper use can compound tissue trauma during surgery, increasing inflammation and delaying healing. Also, improper use may alter the shape of the jaws, rendering them useless for the intended application.

Thumb Forceps

Thumb forceps (Figure 11-8) are designed to grasp and hold tissues and small objects, such as suture needles, and thus they serve as an extension of the surgeon's fingers. They consist of two blades attached at the proximal end, and the tips come together to hold tissue as finger pressure is applied on the blades. The outer surfaces of the blades are grooved to increase digital purchase. Thumb forceps are distinguished by the configuration of the tips. Forceps with smooth tips (without grooves or teeth) crush tissues because a considerable amount of force is necessary to gain purchase on the tissues. These smooth-tipped forceps are called traumatic (or anatomic) thumb forceps and should not be used for surgery.

A variety of serrated and toothed (or surgical) thumb forceps are available. The serrations and teeth allow a secure hold on tissues with minimal digital crushing pressure. The most aggressive of the thumb forceps is the rat tooth or tissue forceps (see Figure 11-8, *A*), which is available with 1-to-2 to 4-to-5 (see Figure 11-8, *A*) interlocking tooth patterns and comes in lengths between 11.5 and 30 cm (4½ and 12 inches). They are used primarily for manipulating skin and tough connective tissue. The Adson forceps has a 1-to-2 toothed tip but affords precise control of instrument pressure (see Figure 11-8, *B*). The Adson forceps is used to grasp thin skin and light fascial planes. The Brown-Adson forceps has two longitudinal rows of small, fine, intermeshing teeth (see Figure 11-8, *C*). The tooth configuration provides a broad but delicate tissue grip and facilitates grasping of the suture needle. The Russian forceps, which is not so frequently used, is very sturdy (see Figure 11-8, *D*). It has a broad, round tip with a grooved perimeter and a concave center. This

thumb forceps has a grip that is considered less traumatic than the Adson and Brown-Adson forceps, because pressure on the tissues is spread out over a larger area and it lacks teeth, making it less likely to tear or puncture tissue. The DeBakey (Figure 11-9) and Cooley forceps lack teeth but are still considered atraumatic forceps because of the serrations in the tips. These forceps are designed with longitudinal grooves and fine, horizontal striations that grip tissue without injury. They are considered ideal for vascular, thoracic, and intestinal surgeries. The DeBakey and Cooley serrated groove patterns are also available on hemostatic forceps.

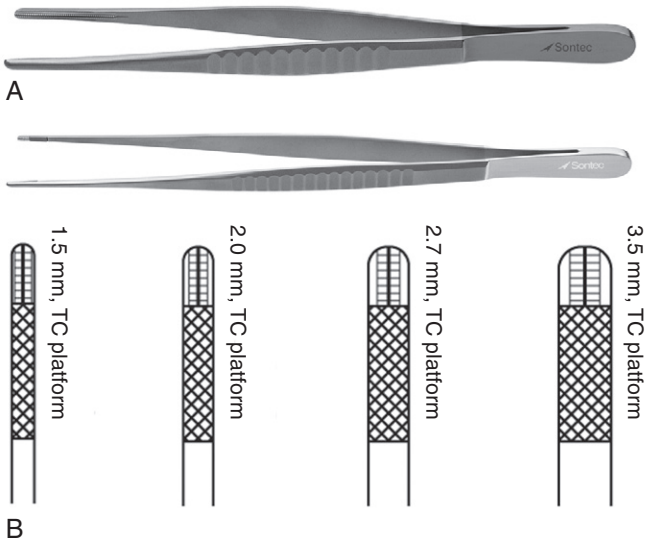

Figure 11-9. Specialty forceps. **A,** DeBakey tissue forceps flat handle. **B,** DeBakey needle pulling forceps with tip illustrations. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

Hemostatic Forceps

Hemostatic forceps are crushing instruments, designed to collapse vessels until hemostasis occurs or until electrocoagulation or ligation is accomplished (Figure 11-10). Most of these forceps have transverse grooves on the inner jaw surface that increase tissue purchase. The Halstead mosquito forceps (see Figure 11-10, *A*) are the smallest and most frequently used of these. They are available in standard and delicate configurations,

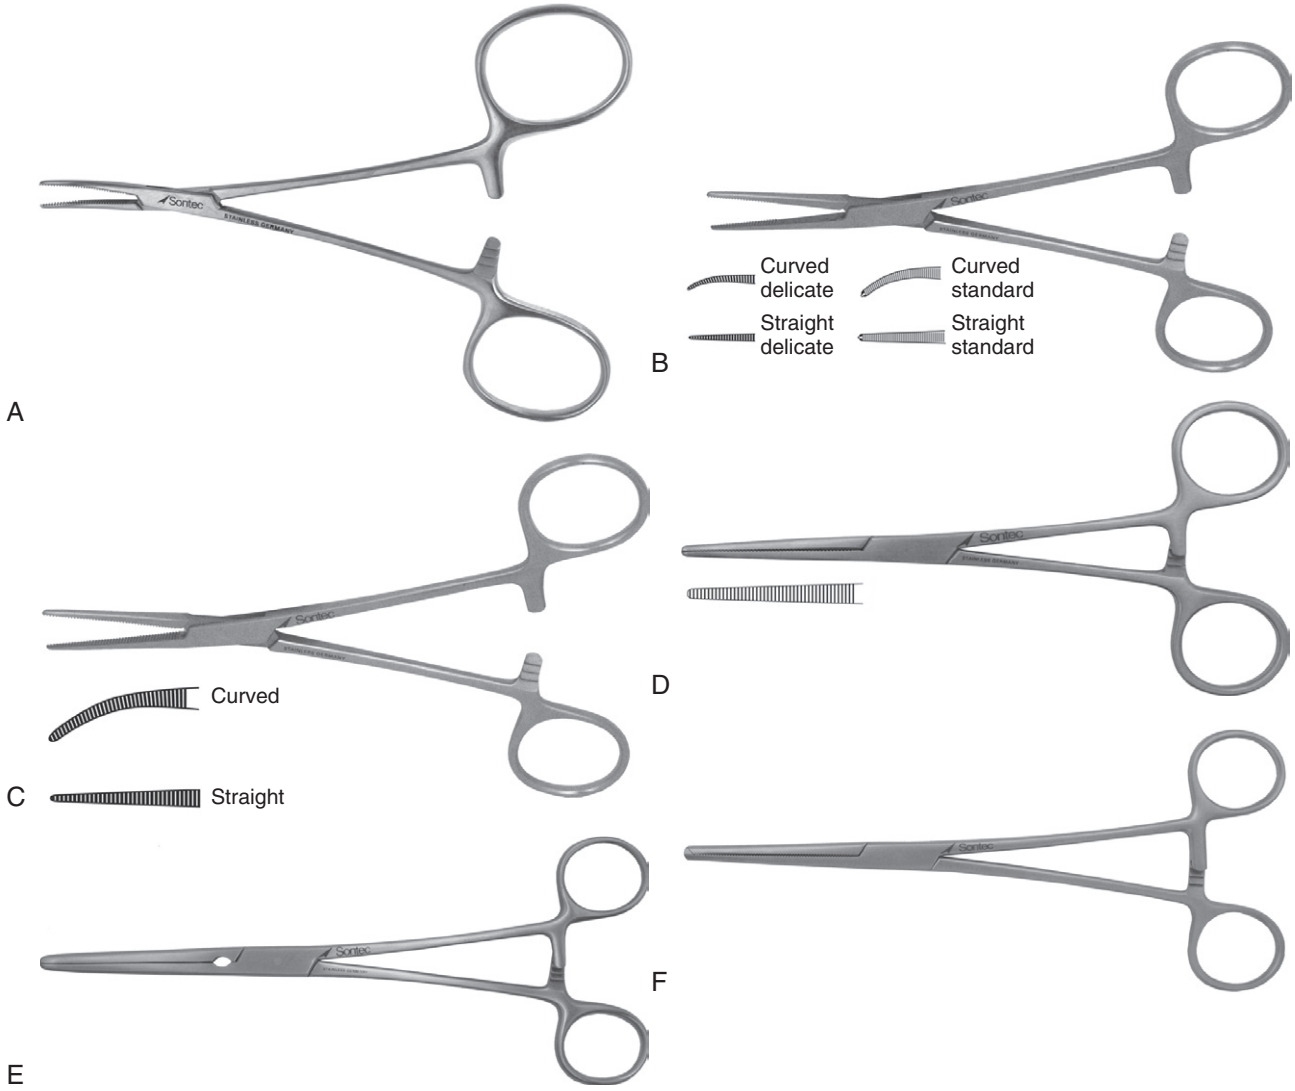

Figure 11-10. Hemostatic forceps. **A,** Halstead mosquito standard. **B,** Kelly straight with the details. **C,** Crile, curved with details. **D,** Rochester-Pean with details. **E,** Rochester-Carmalt. **F,** Rochester-Ochsner. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

as well as in 9- and 12.5-cm (3½- and 5-inch) lengths, with thin or standard width, curved or straight jaws. They should be used only on small vessels. The Kelly and Crile forceps (see Figure 11-10, *B* and *C*) are sturdier hemostatic forceps. These instruments are available in a standard 14-cm (5½-inch) length, with curved or straight jaws. The two differ in that the transverse grooves are restricted to the distal half of the jaw on the Kelly forceps, whereas the entire surface is grooved on the Crile forceps. Both are used for manipulating larger vessels.

To clamp large tissue bundles and vessels, Rochester-Pean forceps (see Figure 11-10, *D*) are recommended. They have deep transverse grooves over the entire jaw surface, are available in 14- to 30-cm (5½- to 12-inch) lengths, and come with straight or curved jaws. Rochester-Carmalt forceps (see Figure 11-10, *E*) are made to assist in pedicle ligation. Their jaw grooves run longitudinally with a few horizontal cross-striations at the tips. The groove design facilitates removal during ligation. Rochester-Ochsner forceps (see Figure 11-10, *F*), available in 16- to 25-cm (6¼- to 10-inch) lengths and with curved or straight jaws, have transverse grooves and 1-to-2 interdigitating teeth located at the jaw tip to help prevent tissue slippage. Rochester-Ochsner forceps are considered traumatic and should be reserved for use on tissue that is to be removed.

Tissue Forceps

Tissue forceps (Figure 11-11) are available in many shapes and sizes, and for a variety of uses. Doyen-DeBakey intestinal forceps, when properly used, are the least traumatic to tissue (see Figure 11-11, *A*). They are manufactured with slightly bowed, flexible jaws with longitudinal serrations. The longitudinal serrations allow easy removal from the intestine. The instrument is available in 13- to 33-cm (5- to 13-inch) lengths with straight or curved jaws, and it can be obtained with a wing nut to secure the tips in a clamping position, which is especially useful for longer forceps. The tips of the jaws should just meet when the ratchet's first tooth is engaged. The instrument will traumatize tissue if the ratchet is closed too tightly.

Allis tissue forceps vary in length between 14 and 25 cm (6½ and 10 inches) and form 4 × 5 to 5 × 6 teeth at the tip (see Figure 11-11, *B*). Designed to grip tissue, the teeth are oriented perpendicular to the direction of pull. The teeth can be traumatic, especially when excessive compression is applied to the handles, and this forceps should be used only on heavy tissue planes or on tissue that is to be excised.

Babcock intestinal forceps, like the Allis tissue forceps, pull in a direction that is perpendicular to the tissue, but the Babcock forceps are considered less traumatic (see Figure 11-11, *C*). The instrument is available in lengths from 16 to 30 cm (6¼ to 12 inches) and has tip configurations that vary from standard to micro tip, to closed jaws, to TC.

Sponge forceps are used to grab sponges and clean or swab specific tissues or cavities (see Figure 11-11, *D*). They are available as straight or curved instruments of 18- to 24-cm length (7 to 9½ inches) with serrated or smooth fenestrated, oval tips.

Hemostatic and tissue forceps should regularly be inspected for instrument wear and damage. When the instrument is closed, the jaws should align perfectly and the teeth, if present, should interdigitate. When clamped on tissue, the instrument should not spring open.

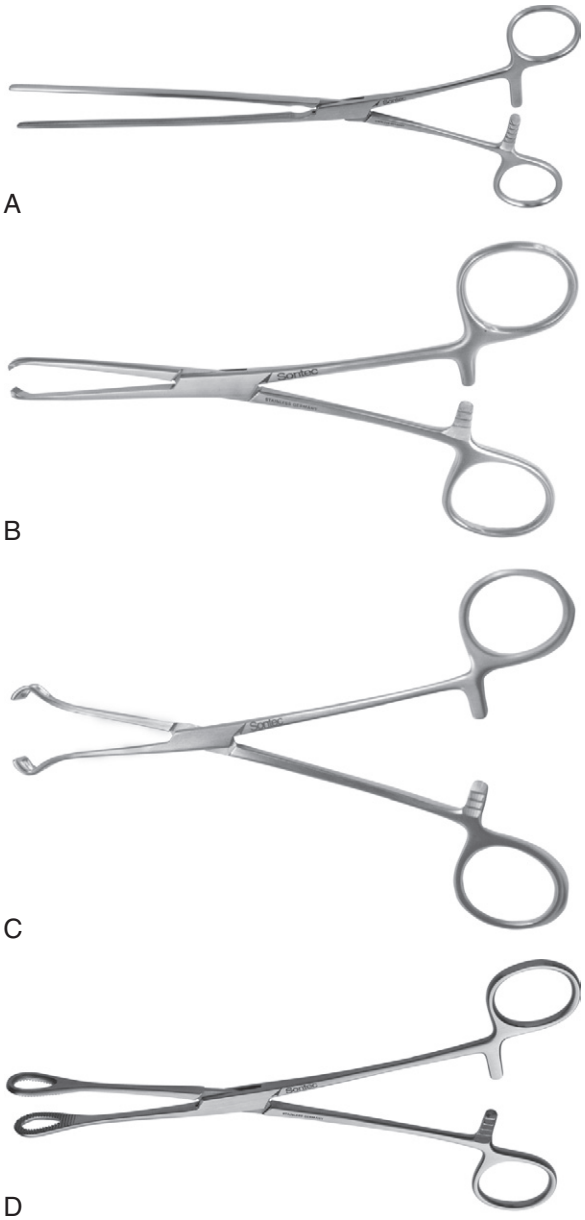

Figure 11-11. Tissue forceps. **A,** Doyen-DeBakey intestinal forceps straight. **B,** Allis tissue forceps. **C,** Babcock tissue forceps. **D,** Foerster sponge forceps, serrated straight. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

Clamps

Satinsky clamps have atraumatic longitudinally grooved jaws that contain two bends. They vary in length from 17 to 28 cm (6¾ to 11 inches) (Figure 11-12). This type of clamp is mainly used for vascular surgery, because it provides a good view of the vessel held in the clamp.

Retractors

Soft tissue retractors are designed to spread the wound edges to facilitate exposure of the surgical field. A classification used by many manufacturers includes the finger-held, the hand-held, and the self-retaining retractors. All three types require an adequate length of incision to prevent tissue tearing when retraction is used. The finger-held and hand-held retractors require a surgical assistant.

Finger-Held Retractors

Senn, Volkman, Meyerding, Farabeuf, and Parker retractors are typical representatives of this group (Figure 11-13). The Senn retractor (see Figure 11-13, *A*) is available with either blunt or sharp retractor prongs at one end and a right-angled fingerplate on the other. It is used to retract skin and superficial muscle layers, but is less useful for retracting a large muscle mass. The Volkman finger retractor (see Figure 11-13, *B*) is available with sharp or blunt retractor prongs and a single-ring handle. The Parker retractor (see Figure 11-13, *C*) are larger, with deeper, flat blades on both ends that allow the retraction of more tissue.

Figure 11-12. Satinsky clamp.

Hand-Held Retractors

Common hand-held retractors are the Army-Navy, Hohmann, Kelly, and Meyerding retractors (Figure 11-14). Army-Navy retractors are available in a standard 21.5-cm (8½-inch) length (see Figure 11-14, *A*). They have double-ended retracting blades of two different lengths, which allow the surgeon to select a blade according to tissue depth. Hohmann retractors are available in 16.5- to 24.5-cm (6¼- to 9¾-inch) lengths, and with blade widths from 6 to 70 mm (see Figure 11-14, *B*). The blade has a blunt projection that is useful in exposing bone while retracting the muscle in orthopedic and reconstructive procedures. The Kelly retractor (see Figure 13-14, *C*) has a loop handle and broad blade that projects at a right angle relative to the long axis of the instrument with a rounded, bent-down tip.

Figure 11-13. Finger-held retractors. **A,** Senn retractor. **B,** Volkmann retractor. **C,** Parker retractor. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

Figure 11-14. Hand-held retractors. **A,** Army-Navy retractors. **B,** Hohman retractor with an 18-mm blade. **C,** Kelly retractor. **D,** Meyerding retractor. **E,** Lahey retractor. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

Meyerding retractors are available with three different blade widths and depths (see Figure 11-14, *D*). The largest blade is 9 cm (3½ inches) wide and 5 cm (2 inches) deep. The Lahey retractor (see Fig 11-14, *E*) has a smooth handle and a rectangular narrow blade that provides good tissue visibility.

Self-Retaining Retractors

The Gelpi, Weitlaner, Balfour, and Finochietto retractors (Figure 11-15) are representatives of the available self-retaining retractors. The Gelpi retractor has a grip-lock mechanism that maintains tension on its two outwardly pointed tips (see Figure 11-15, *A*). The instrument is available in sizes ranging from the 9-cm (3½-inch) pediatric size to the 20-cm (8-inch) standard size. The larger version is available with ball stops to prevent excess tissue penetration. There are two other variations on this retractor: a sturdy retractor for more robust tissues, and a deep angled version, which has longer shanks from the point of the angle to the tip.

Weitlaner retractors range in size from 10 to 24 cm (4 to 9½ inches) and are available with 2-to-3 or 3-to-4 outwardly pointed blunt or sharp teeth (see Figure 11-15, *B*). A hinged Weitlander retractor (see Figure 11-15, *C*) is also available in sizes between 14 and 20.5 cm (5½ and 8 inches) containing

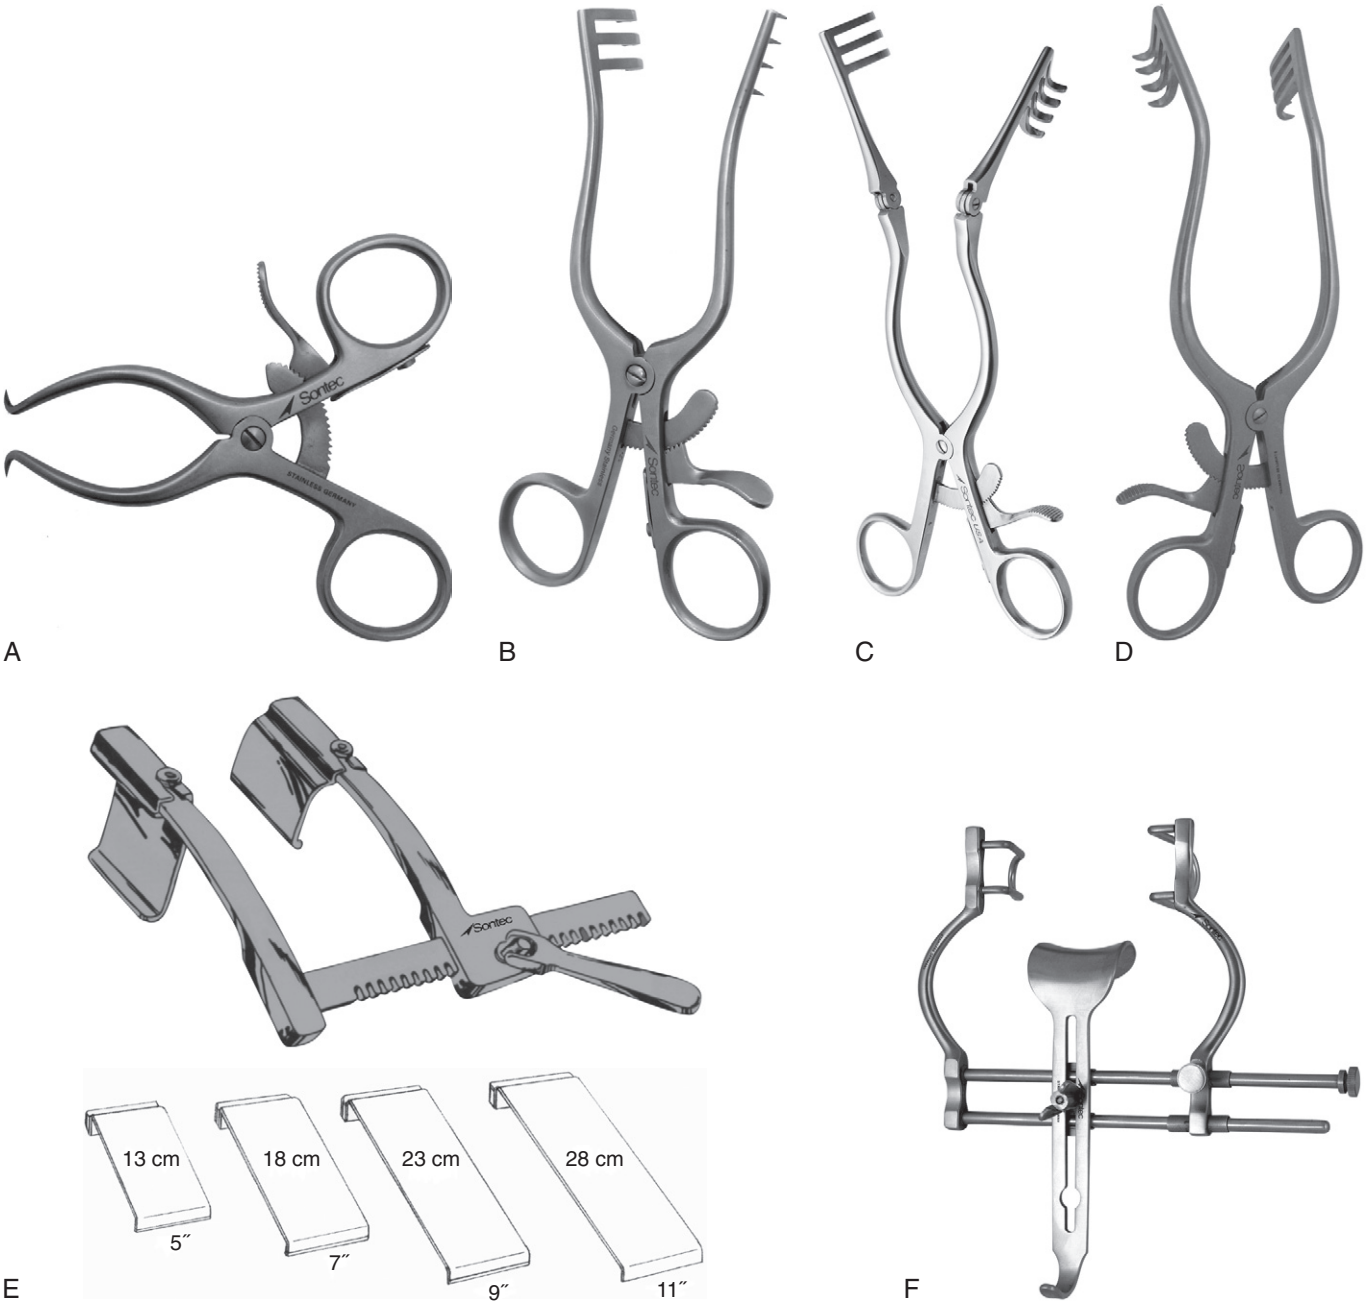

Figure 11-15. Self-retaining retractors. **A,** Gelpi retractor. **B,** Weitlaner retractor. **C,** Weitlaner retractor with hinged blades. **D,** Adson Cerebellar retractor. **E,** Aanes retractor/speculum with the different blades. **F,** Balfour retractor. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

3 × 4 blunt or sharp prongs that allows placement of the prongs deep in the tissues. The Adson Cerebellar retractor (see Figure 11-15, *D*) has 4 × 4 sharp prongs that has either straight or angled arms, the latter, again, to facilitate seating the instrument deep in the incision. The Aanes retractor/speculum (see Figure 11-15, *E*) is a modification of the Finochietto retractor with the benefit that the blades can be exchanged for deeper exposure. The blades range from 13 to 28 cm (5 to 11 inches). The Balfour self-retaining abdominal retractor is available in 10- to 36-cm (4- to 14-inch) spreads and with 6.5- to 10-cm (2½- to 4-inch) deep, solid, and fenestrated side blades (see Figure 11-15, *F*). These retractors are distinguished as pediatric, adoloscent, and elite retractors and are used to allow vision into the depth of a body cavity, such as the abdomen.

Towel Clamps

Several types of towel clamps are available (Figure 11-16). Backhaus towel clamps are the most commonly used (see Figure 11-16, *A*) and are available in 9- and 13-cm (3½- and 5¼-inch) sizes. The Jones towel clamps (see Figure 11-16, *B*) are spring-loaded and available in smaller sizes as 6- and 9-cm (2½- and 3½-inch) instruments. The Lorna-Edna towel clamps are non-penetrating and therefore ideal for securing suction lines and cables to drapes (see Figure 11-16, *C*). These towel clamps are available as 10- and 14-cm (4- and 5½-inches) sizes. Penetrating towel clamp tips should meet when closed, and they should be sharp and free of burrs.

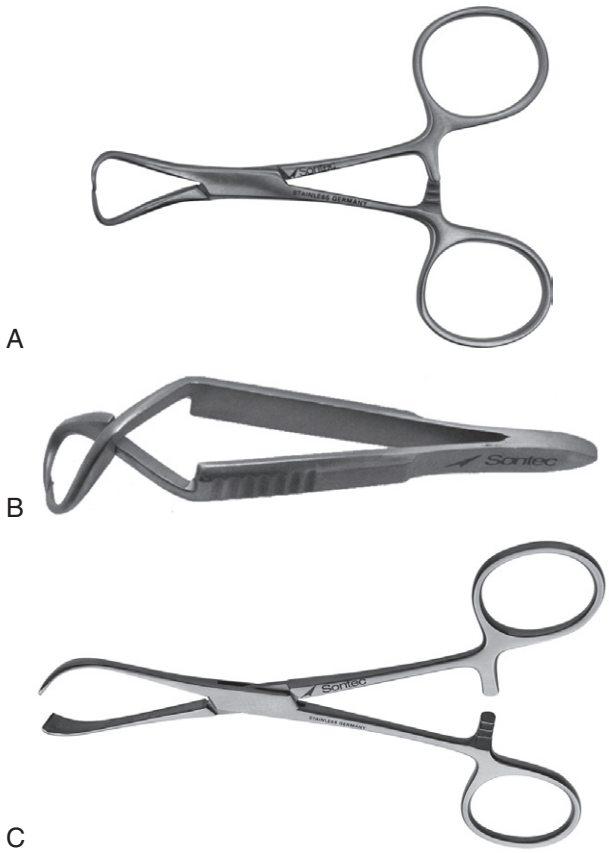

Figure 11-16. Towel clamps. **A,** Backhaus towel clamps. **B,** Jones towel clamps. **C,** Lorna-Edna towel clamps. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

Suction Tubes

There are three basic types of suction tubes available (Figure 11-17). The Yankauer tip is relatively large, allowing the removal of large volumes of blood or fluid from the surgical site (see Figure 11-17, *A*). The Frazier-Ferguson suction tube is available with a curved or straight tube (see Figure 11-17, *B* and *C*). It has diameters ranging from 4- to 15-French. The suction intensity of these tubes can be varied by placing the index finger over the hole on the handle. Both models are available in stainless steel and in disposable plastic. The Poole suction tube has multiple ports along the tube, making it ideal for use within the abdomen, where single-orifice tubes are easily plugged by omentum (see Figure 11-17, *D*).

ORTHOPEDIC INSTRUMENTS

A wide variety of instruments are available for orthopedic surgery. Those presented here are used outside the realm of fracture repair. For information regarding instruments used for reconstruction and fracture treatment, the reader is referred to Chapter 76.

Rongeurs

Rongeurs have opposed cupped cutting jaws that allow precise removal of bone, cartilage, and fibrous tissue (Figure 11-18). Most contain either a single- or a double-action mechanism and curved or straight jaws. The double-action rongeurs are stronger and have a smoother action. Ruskin rongeurs (see Figure 11-18, *A*) are available with 2-, 3-, 4-, 5-, or 6-mm wide jaws in straight, slightly curved, curved, and full curve shapes

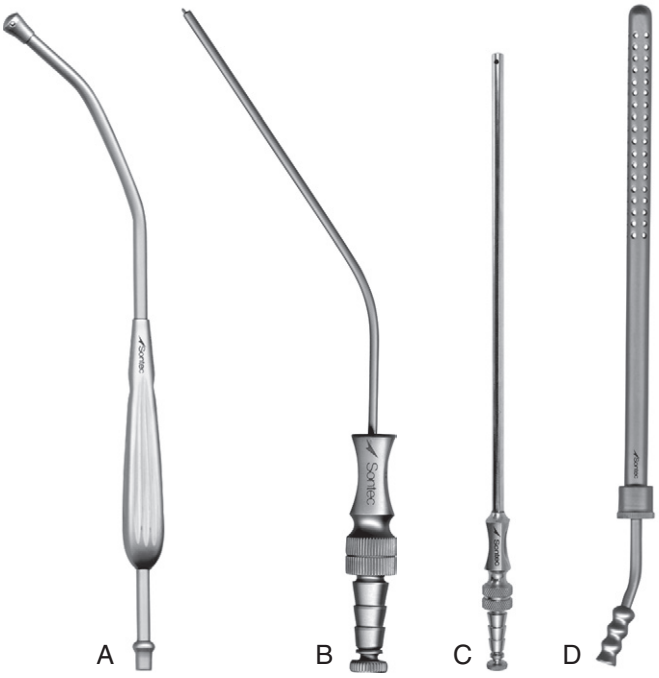

Figure 11-17. Suction tubes. **A,** Yankhauer suction tube. **B,** Frazier suction tube, angled. **C,** Frazier suction tube, straight. **D,** Poole suction tube. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

and are 15.5, 18.5, and 23 cm (6, 7¼, 9 inches) long. They are available in black as well. The slightly larger Stille-Luer Duckbill rongeurs (see Figure 11-18, *B*) are available with straight or curved jaws in width-length combinations of 6 × 13, 6 × 15, and 8 × 18 mm.

Curettes

Curettes are easily recognized by their cuplike structure (Figure 11-19). The sharp, oval, or round edges are useful for removing diseased bone, cartilage, debris, and damaged tissue from dense tissue surfaces. Their shape also makes them ideal for harvesting cancellous bone grafts. A wide variety of sizes and types of curets are available. The Burns curettes (see Figure 11-19, *A*) have a straight or angled single oval cup at the end of a grooved handle, whereas the Volkman curettes (see Figure 11-19, *B*) are double-ended, having an oval cup on one end and an oval or round cup on the other.

Periosteal Elevators

As their name suggests, periosteal elevators are designed to elevate periosteum and muscle attachments away from bone. Common elevators include the single-ended Adson, McIlwraith, and Foerner elevators and the double-ended Freer elevators (Figure 11-20). The Adson elevator (see Figure 11-20, *A*) is available with either a blunt or sharp, and a straight, curved, or full curve tip. The McIlwraith elevator (see Figure 11-20, *B*) has only a sharp tip, and the Foerner knife elevator (see Figure 11-20, *C*) is the sharpest of all, designed to free the attachment of the interosseus ligament from the proximal sesamoid bone. The double-ended Freer elevators (see Figure 11-20, *D*) are narrow and have one end that is blunt and one that is sharp.

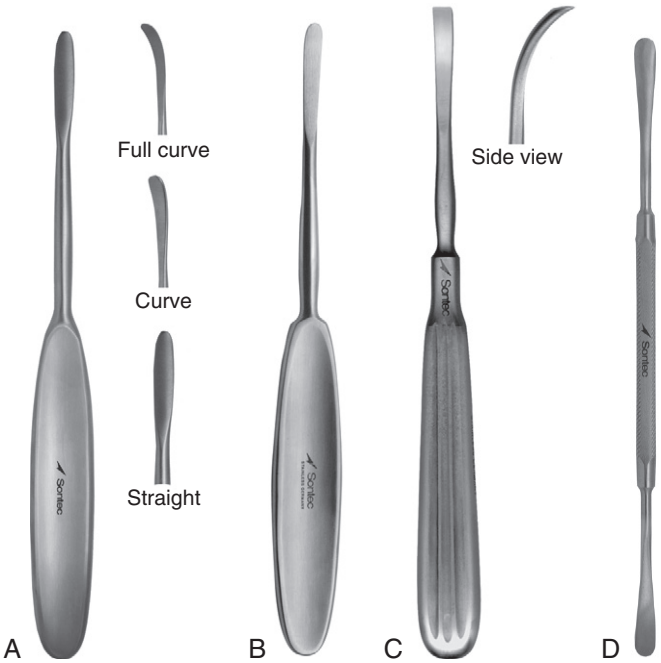

Figure 11-20. Periosteal elevators. **A,** Adson periosteal elevator with details. **B,** McIlwraith periosteal elevator. **C,** Foerner knife elevator. **D,** Freer periosteal elevator. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

Bone-Cutting Instruments

Osteotomes, chisels, and gouges are all hand-held instruments that are used in combination with a mallet (Figure 11-21). Osteotomes (see Figure 11-21, *A*) are double-beveled at their cutting tip, and chisels are single beveled. The cutting widths vary from 2 to 38 mm (1 to 15 inches). The chisel (see Figure 11-21, *B*) tends to move away from the beveled edge. Therefore it needs to be applied at a somewhat steeper angle relative to its axis. This allows the chisel to move along the bone surface on its beveled edge. If the chisel is reversed, it tends to dive into the bone, leaving sharp edges on the surface. The chisel is the preferred instrument to remove exostoses, but when the direction of bone cutting needs to be more precise, it is better controlled with an osteotome. Common types for these three cutting instruments are Army-Navy, Hibbs, and Smith-Peterson. Gouges (see Figure 11-21, *C*) are easily distinguished by their concave shape. They are available in 4- to 30-mm (1½- to 12-inch) widths.

The mallet can be solid stainless steel or have an aluminum handle and a stainless steel head. Polyethylene-capped stainless steel heads are quieter and prevent the production of metal particle flakes during striking. There is a mallet available with a stainless steel head on one side that can be exchanged for a nylon head (see Figure 11-21, *D*).

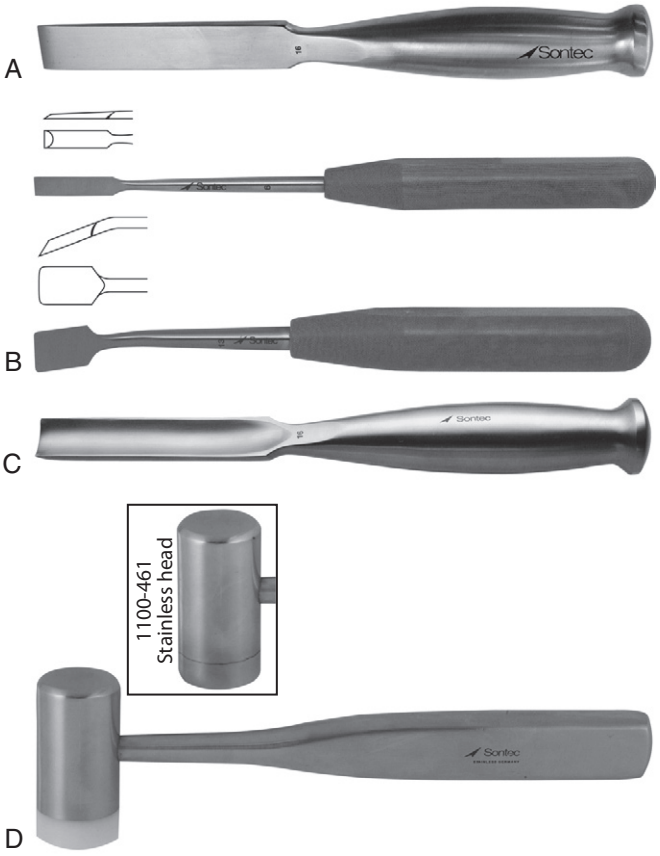

Figure 11-21. Bone cutting instruments. **A,** Smith Peterson osteotome. **B,** Chisel, also called elevator/raspatory; straight *(top);* curved *(bottom).* **C,** Smith Peterson gouge. **D,** Sontec bone mallet with removable stainless steel and nylon head. (Reprinted with permission from Sontec Instruments, Inc. Centennial, CO. 2010.)

Bone-cutting forceps can be single- or double-action and straight or angled. The Liston bone-cutting forceps (Figure 11-22, *A*) are representatives of single-action, and Ruskin-Liston (see Figure 11-22, *B*) and Stille-Liston are double-action bone-cutting forceps.

Bone Clamps

Bone clamps or bone-holding forceps come in a variety of shapes and sizes and are used for fracture reduction. Verbrugge, Kern, Stefan bone clamps are typical representatives thereof (Figure 11-23). The Verbrugge bone-holding forceps is curved to the side with one arm longer than the other, contains a speedlock, and is available in sizes from 15 to 29 cm (5¾ to 11¼ inches). Modifications of this forceps are a swivel jaw (see Figure 11-23, *A*) and a reverse jaw configuration that is more suitable in specific situations. The Kern bone-holding clamp has symmetric, straight, strong jaws and a ratchet at the end to maintain the bone-holding force (see Figure 11-23, *B*). It comes in sizes between 12 and 33 cm (4¾ and 13 inches) and is well suited for equine long bone fracture reduction. The Stefan bone-holding forceps comes in sizes between 15.5 and 24 cm (6 and 9½ inches) and contains a speedlock. The jaws are rounded and sturdy (see Figure 11-23, *C*). The bone-reduction clamp has two pointed and thin jaws (see Figure 11-23, *D*). It comes with either a speedlock or a ratchet; an extra-long ratchet is also available. This is the most frequently used bone clamp.

Cerclage Wire Instruments

Instruments used for application of cerclage wires include flat-nosed pliers, pointed pliers, and wire twisters (Figure 11-24). A universal flat-nosed plier/wire cutter is shown in Figure 11-24, *A*. The wire cutter is mounted on one side and cuts wires to

Figure 11-22. Bone-cutting forceps. **A,** Liston bone-cutting forceps. **B,** Ruskin-Liston bone-cutting forceps. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

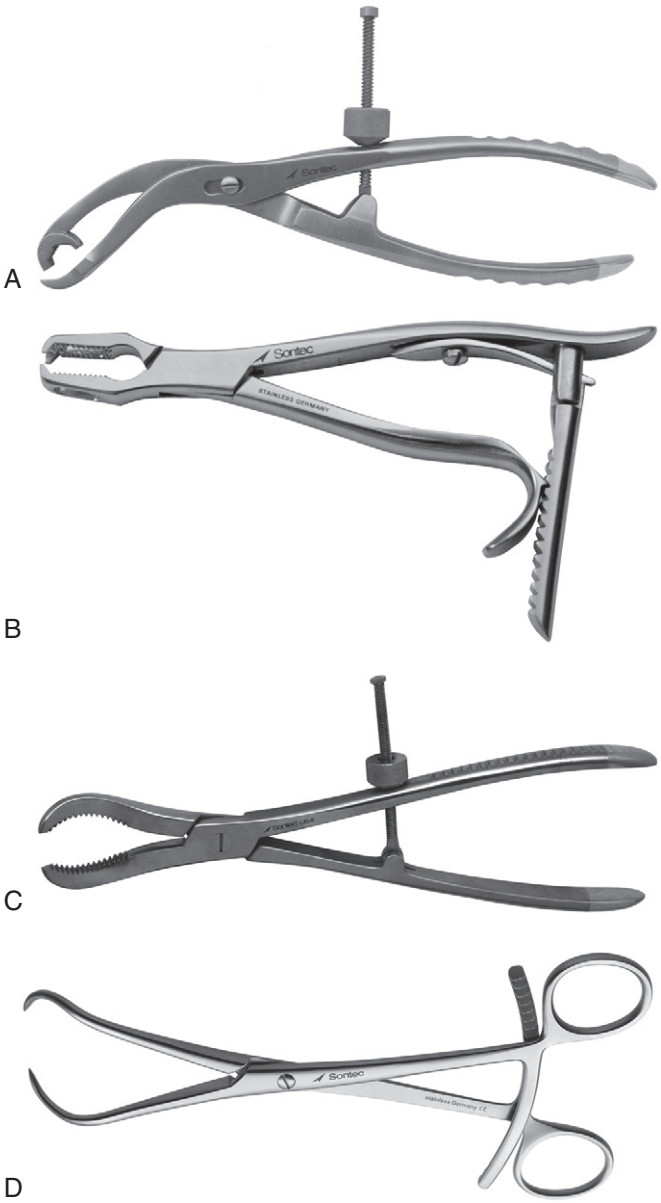

Figure 11-23. Bone clamps. **A,** Verbrugge swivel jaw bone clamp. **B,** Kern bone clamp. **C,** Stefan bone-holding forceps. **D,** Bone-reduction clamp with extra-long ratchet. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

1.6 mm (⅔ inch). The universal pliers are pointed and allow excellent maneuvering of the wire in many different situations (see Figure 11-24, *B*). The Axel wire twister (see Figure 11-24, *C*) feeds each wire through a hole on the side of the blade and fixes the wires by closing the ratchet at the end. The instrument is subsequently pulled axially away from the bone while twisting the instrument evenly around its axis. This action twists the wire ends around each other. The same can be achieved by grabbing the wire ends with the flat-nosed pliers.

Pin Insertion and Pin-Cutting Instruments

Pins are not frequently applied in horses, but occasionally the need arises. Aside from a drill, the Jacobs chuck is the most

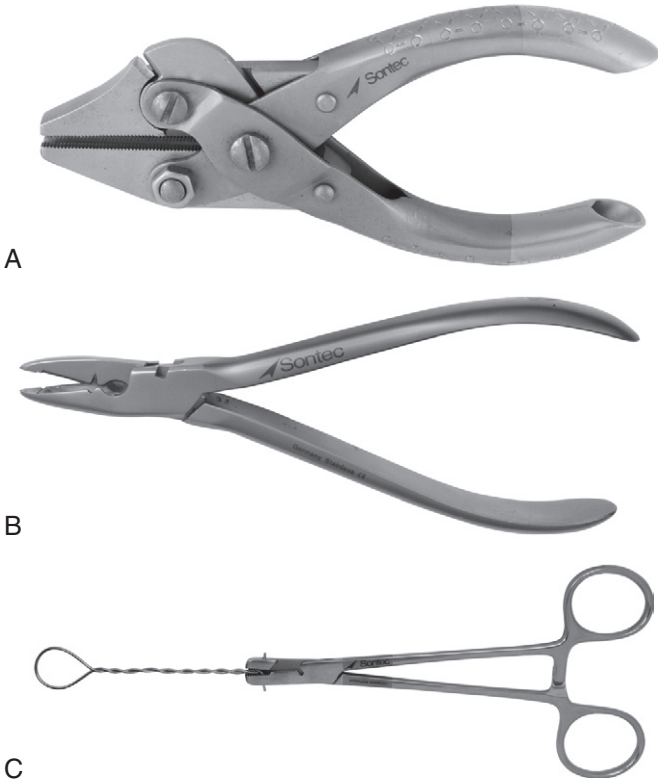

Figure 11-24. Cerclage instruments. **A,** Pin puller/side cutter. **B,** Waldsachs universal pliers. **C,** Axel wire twister. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

versatile instrument for such an occasion (Figure 11-25, A). It accepts pins up to a diameter of 0.6 mm (¼ inch). An extension can be applied to its back end to protect the surgeon from the sharp pin end protruding behind the end of the chuck. The small pins can be cut with a sturdy wire cutter (see Figure 11-25, *B*). Larger pins must be cut with a pin cutter (see Figure 11-25, *C*).

Trephines

Two types of trephines are available, Galt and Michele (Figure 11-26). Both are T-shaped and capable of drilling a cylinder of bone. The Galt trephine (see Figure 11-26, A) can cut bone at the end of the shaft and along the outside perimeter of the shaft. It is available in graduated sizes from 1.25 to 2.5 cm (½ to 1 inch) in diameter and has an adjustable central trocar. The trocar centers the trephine and stabilizes it until a circular trough is cut in the bone. The Michele trephine is available in graduated inner diameters of 0.6 to 3.1 cm (¼ to 1¼ inch). It contains a graduated scale along its shaft, allowing the penetration depth to be measured. It cuts through bone on the end of the shaft only. The plug cutter trephine is similar to the Michelle trephine but has a saw blade–like front rim that is better suited for equine bone (see Figure 11-26, *B*). This trephine is available with diameters ranging from 3 mm inside/5 mm outside up to 22 mm inside/25 mm outside.

MICROSURGICAL INSTRUMENTS

At present, reconstructive vascular and neural surgeries are rarely performed in equine patients. The exceptions are

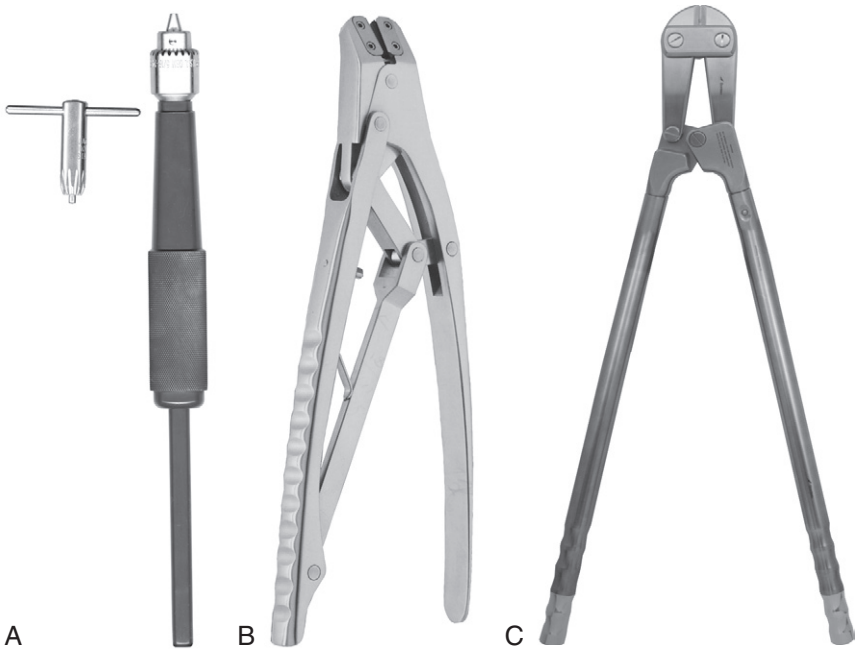

Figure 11-25. Pin insertion and cutting instruments. **A,** Jacobs pin chuck. **B,** Big gold-cut Hercules wire cutter. **C,** Pin cutter. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

thrombectomies, which may be performed with the help of catheters (see Chapter 13). Because horses are rarely used as research animals, microsurgical techniques play a minor role in this species. The microsurgical instruments used for ocular surgery can be found in Chapters 55 and 57.

INSTRUMENT MAINTENANCE

Proper care maintains long-term instrument serviceability. Instruments should be cleaned immediately after use. Sharp and delicate instruments should be separated from other instruments that may damage them. When washing them by hand, it is best to use warm water, a neutral pH detergent, and a soft bristle brush. Ultrasonic cleaners are more effective than hand washing; however, the manufacturer's recommendations for type of water, such as deionized or distilled, and detergent used should be followed (see "Cleaning" in Chapter 9). If cleaning cannot be done immediately, instruments should be submerged, in the open position, in a solution of water and neutral pH detergent. Hard water, saline solution, and nonneutral pH detergents (dishwashing liquids) should be avoided, because surface discoloration, corrosion, and poor mechanics of the joints may result.[7] Once cleaned, instruments should be rinsed with deionized or distilled water. Instruments with a working action should then be treated with an instrument lubricant (instrument milk). The lubricant, which often includes a rust inhibitor, should not be rinsed off. Instruments are then dried and stored or resterilized.

A German group called Arbeitskreis Instrumentenaufbereitung (Working Circle Instruments Reprocessing) offers on its website (www.a-k-i.org) valuable information on the handling and use of surgical instruments. Several brochures can be downloaded and among those, *Green Brochure* discusses the handling of surgical instruments.

Proper care of the instruments also must include the use of high-quality cleaning products. It is wise to use top-quality products, such as those offered by the Ruhof Corporation and distributed for veterinarians in the United States by Sontec Instruments, Centenial, CO, because these products significantly extend the life of the surgical instruments.

Instrument refurbishing programs are available through most instrument manufacturers. In addition to resharpening cutting edges and replacing tungsten carbide inserts, instruments are cleaned, polished, and refinished to retard corrosion. Refurbishing generally costs less than replacement.

IDENTIFICATION

Instruments are frequently marked to identify their owner or the instrument set they belong to. Various identification methods are available. Commercially available engraving should be avoided, as should any other method that damages the surface of the instrument. Surface damage, with removal of the corrosion-resistant coating, will shorten instrument life. Electrochemical etching units are acceptable as long as they are properly used. After etching, the instrument must be thoroughly rinsed to neutralize the acid etching fluid.

Autoclavable plastic tapes for instrument identification are available in different colors and are easy to apply. Color coding with tape does not harm the instrument's surface. All instruments belonging to a specific set can be marked with the same color. This is helpful in large clinics, where different surgical teams work parallel to each other with different instrument sets. During cleaning and resterilization, instruments belonging to different sets may be mingled. The color coding allows easy and efficient separation. Poorly applied tape, however, may begin to peel off, creating crevices that could harbor debris and

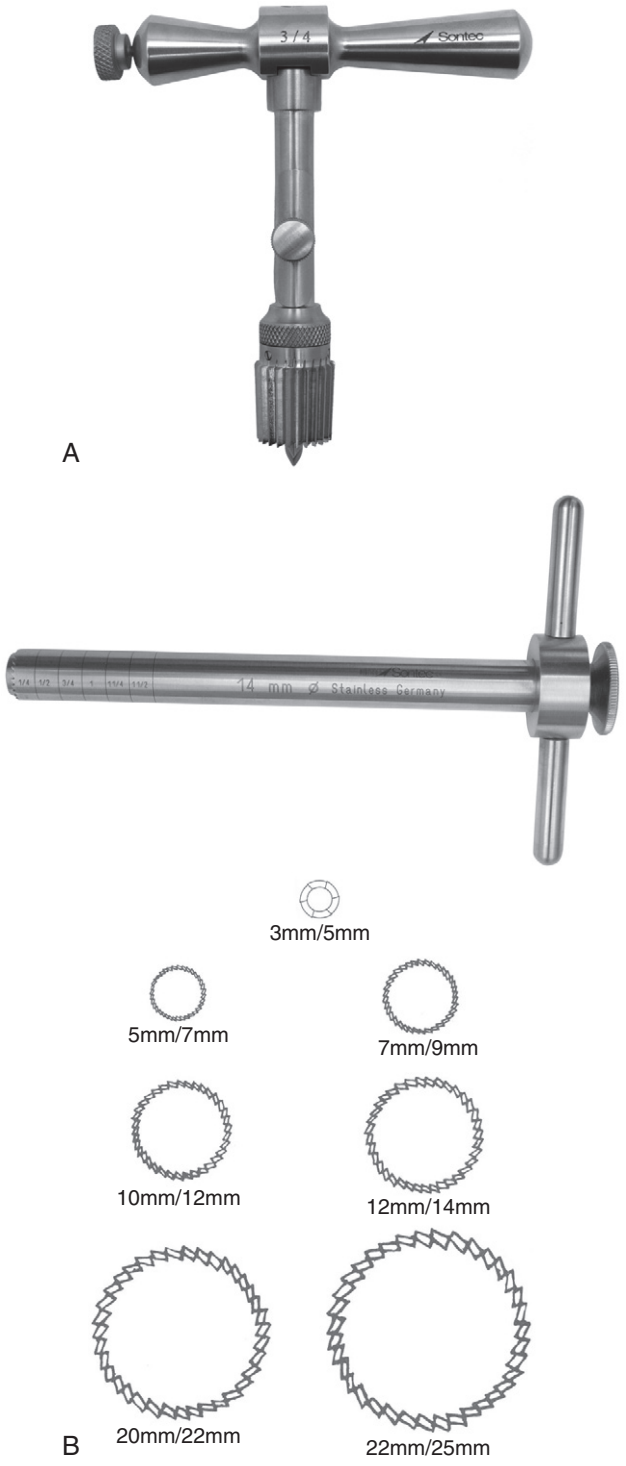

Figure 11-26. Trephines. **A,** Galt trephine. **B1,** Plug cutter with obturator. **B2,** Plug-cutter tips. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

microorganisms. Proper selection of a tape marking system should include considerations of color, durability, and adhesive properties to ensure a long life once applied to the instrument. Higher-quality marking systems are frequently marketed through instrument manufacturing companies.

PACK PREPARATION AND STORAGE

Tightly woven linen drapes have long been used to package instrument sets. Their disadvantages include short shelf life and the cost of laundering for reuse. Because microorganisms can fairly rapidly penetrate linen wrappers, it is prudent to double wrap the sets with linens. Safe storage times have been established[7] (see Table 10-1).

A variety of paper products have been developed to replace linen wrappers. Although these products share some of the disadvantages of linen, they offer longer safe storage times, because the sterilization process closes the pores within the sheet. As a result, these paper products cannot be reused and are therefore disposable, so laundry expenses are avoided. On the other hand, disposal costs and the burden on the environment through exhaust gases (e.g., CO_2) from incinerators rise. Many of the newer paper wrappers handle like linen.

Both paper and linen prevent visualization of the instruments within the pack. In the case of sets, this is not a problem because the contents are known. However, if instruments are separately wrapped, visualization is important. Therefore special wraps that consist of a sheet of paper on one side and a clear plastic sheet on the other have become popular. The plastic side allows the instrument to be seen inside, and the paper side allows steam or ethylene oxide to penetrate the package. Sharp points of instruments have to be covered by plastic or paper caps to prevent inadvertent damage to the paper layer. These wrappers are available in tube rolls in several sizes, and most of them contain sterilization indicators (see Chapter 10). The ends are heat sealed. Safe storage time is extended with this type of wrapping, but the paper side is still susceptible to microorganism penetration when wet. The best effect is achieved by double wrapping the instruments. Regardless of the type of wrapping chosen, the instruments should be loosely packed with the jaws slightly opened to allow circulation of steam, ethylene oxide, or gas plasma (Figure 11-27).[7] All instrument packs should be dated and labeled for easy identification, as well as for resterilization if they are not used within the safe storage time frame. For prolonged storage life, the packs may be placed within a plastic envelope or into a glass closet. It is equally important to have the initials of the person wrapping the set marked on the set or pack. This allows direct communications with this person should an instrument be missing during the surgery.

Lately, reusable metal sterilization containers enjoy renewed popularity, after having almost disappeared in the late 1980s

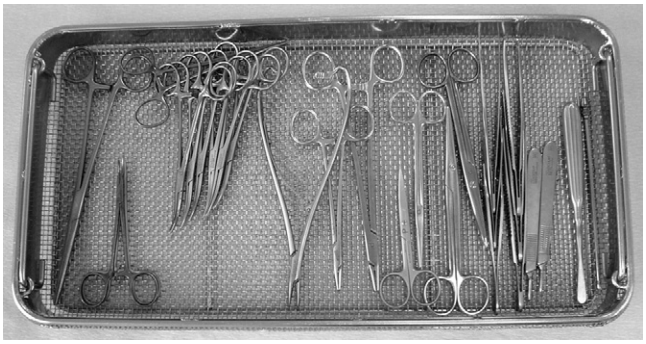

Figure 11-27. Example of a standard soft tissue set. The instruments are neatly arranged in a logical sequence.

(Steriset Containers, Wagner GmbH, Munich, Germany) (see Figure 9-1). These containers are used for holding surgical instrument sets or textiles during vacuum steam sterilization procedures and for maintaining sterility of the contents during storage and transport under hospital conditions. They operate with either filters or valves. The filter units are single-use filters or reusable textile filters with known service life spans. SteriSet valve containers have a closed base and permanent stainless steel pressure-sensitive valves in the inner lid. The sterilization valves react to the change in pressure during the sterilization process. During the vacuum phase, the valves open upward, and the air and steam mixture can escape from the container. During the pressurization phase, the valves open inward and allow steam to enter the container. The system is automatically flushed and sterilized by the hot steam rushing through the valve with every sterilization cycle. Outside the sterilizer (i.e., during storage or transport), the valve is closed and serves as a barrier to microorganisms.

CHAPTER
12

Surgical Techniques

Jörg A. Auer

Surgery can be defined as goal-oriented violence to tissue, and therefore considerations related to minimizing tissue damage are an important part of adequate preoperative planning and proper surgical technique.[1] Since time in surgery is directly proportional to tissue damage, adequate preparation for each surgery is the best prevention of unnecessary delays that prolong surgery. Before embarking on an unfamiliar or complicated surgical task, the operator should plan the procedure step by step, from skin incision to closure. This chapter describes those aspects of surgical manipulations that are basic to the performance of any procedure—namely, the different techniques of incision, excision, and dissection of tissue; the methods of surgical hemostasis and tissue retraction and handling; and surgical irrigation and suction. Adherence to the basic principles of state-of-the-art surgical technique, described by Halsted, minimizes tissue trauma and blood loss and decreases the risk of wound dehiscence, resulting in a better overall surgical result.[2]

William Stewart Halsted (1852-1922) was one of the most influential human surgeons of his time. He taught at Johns Hopkins Hospital in Baltimore and was the first one to list basic principles for aseptic surgery. These priniciples became known as "Halsted's Principles" and are as follows: (1) apply strict asepis during preparation and surgery, (2) assure good hemostasis to improve conditions for the procedure and limit infection, (3) avoid the formation of dead space, (4) minimize tissue trauma through careful handling thereof, (5) maintain blood supply, (6) avoid undue tension on tissues, and (7) carefully adapt the corresponding tissue layers.[1] Additional information on tissue handling will be discussed later in this chapter.

BASIC MANIPULATIONS OF SURGICAL INSTRUMENTS

Incising or cutting into tissue represents the initial step of every surgical intervention. The instruments used for this procedure and the manner in which they are applied provide the surgeon with the means to vary the type of incision and its effects on the surrounding tissue. The scalpel and scissors are the basic instruments for incising or excising tissues. Separation along tissue planes is usually accomplished through blunt or digital dissection. Electrosurgery and laser surgery complement the instruments used for incisions and excisions.

Scalpels

Steel Scalpel

The steel scalpel with disposable blades is the instrument most frequently used to incise skin and other soft tissues. It is prudent to apply the blade to the scalpel handle with the help of a needle holder or similar instrument to prevent inadvertent puncture of the surgery gloves or, even worse, cutting of the surgeon's fingers.

There are three ways to hold the blade handle: the pencil grip, the fingertip grip, and the palm grip.[3] With the pencil grip, very precise cuts can be performed. The distal end of the scalpel handle is grasped between the thumb and index finger and rests on the middle finger, while the tip of the middle finger contacts the patient (Figure 12-1). The surgeon's hand also rests lightly on the patient and the fingers are moved rather than the entire arm, which allows better control of the blade. This grip works best for short incisions where precision is important.[4] Contact with the patient controls precisely the depth of penetration. The disadvantage of this grip compared with the others is the relatively steep angle with which the scalpel is held, thereby decreasing contact of the cutting edge with the skin.

For the fingertip grip, the tips of the third, fourth, and fifth fingers are placed underneath the handle, while the tip of the thumb is placed on the other side. The index finger rests on the top surface of the blade to carefully control downward pressure (Figure 12-2). This grip is useful for long straight, curved, or sigmoidal incisions, because it places the long surface of the blade against the tissue, providing greater cutting surface, better control of the blade angle, and optimal control of incision depth. The blade movement originates in the shoulder, with the entire arm participating in directing the incision.[5]

The palm grip is not commonly used. Some surgeons prefer it for standing flank incisions. It provides the strongest grasp of the scalpel. The scalpel is grasped with the fingers and palm wrapped around the handle, while the thumb is placed on the top edge of the blade to create downward pressure (Figure 12-3). The small finger is rested on the patient to steady the hand.

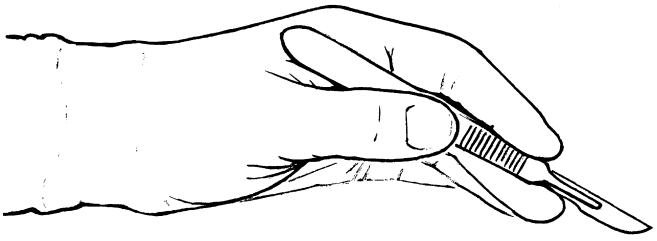

Figure 12-1. The pencil grip for holding a surgical scalpel.

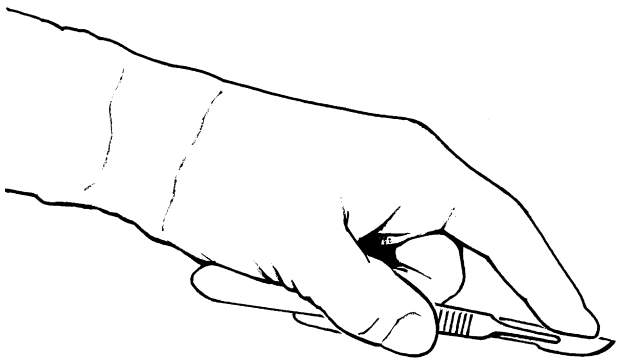

Figure 12-2. The fingertip grip for holding a surgical scalpel.

Electro Scalpel

Proper cutting technique with the electro scalpel differs markedly from that with the steel scalpel. A modified pencil grip is used to hold the instrument almost perpendicular to the tissue surface to be cut, to minimize the area of energy contact at the point of incision. The use of a needle scalpel further minimizes the contact area. The handpiece is held between the thumb and the middle fingertips, leaving the index finger free to activate the trigger button of the handpiece. The best effect is achieved when an assistant streches the skin or tissue to be transected.

Scissors

Operating scissors cut tissues by moving edge contact between two blades that are set slightly toward one another.[6] This action is most effective near the tips of the instrument, dictating their use for precise tissue cutting. Tissues that are too thick or too dense to be cut with the tips of the scissors should be separated with either a larger pair of scissors or a scalpel blade. The blade near the hinge should not be used for cutting, because the tissues are crushed more than cut, resulting in additional trauma.

As shown in Chapter 11, many scissors are available either with straight or slightly curved blades and with long or short handles. The mechanical aspect of scissor cutting is best achieved with straight blades. Therefore straight-bladed scissors should be used in dense tissues. Curved scissors provide a more comfortable positioning of the surgeon's hand and better visualization of the tips in deeper planes, but these instruments are less efficient in cutting tissues.

The classic tripod grip provides the best functional result. The tip of the thumb and last digit of the third finger are placed in the rings of the scissors, while the index finger stabilizes the instrument along the shaft toward the tip of the blades. The wide-based tripod grip or thumb-ring finger grip involves the last digit of the fourth finger instead of the last digit of the third finger (Figure 12-4). This grip is best suited to surgeons with large hands. The tripod formed by the thumb, third or fourth finger, and index finger creates a stable and powerful base for cutting.

Suture scissors are usually held in the classic tripod grip to cut the sutures at the designated spot. Because it is the surgeon who is responsible for the lengths of the suture ends, an

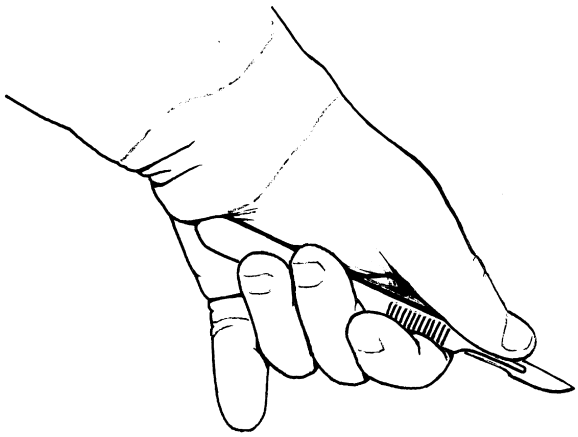

Figure 12-3. The palm grip for holding a surgical scalpel.

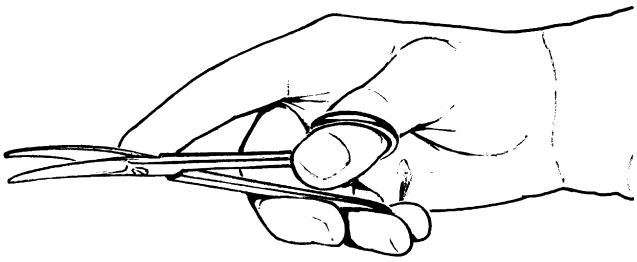

Figure 12-4. The tripod grip for holding surgical scissors.

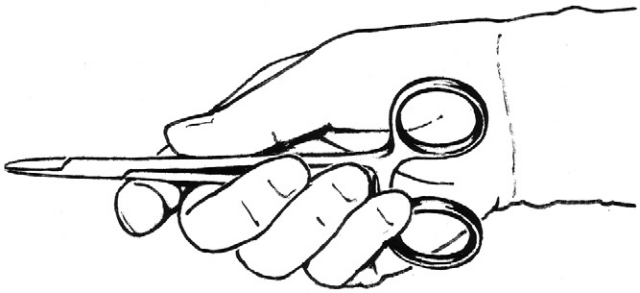

Figure 12-5. The palm grip of a needle holder.

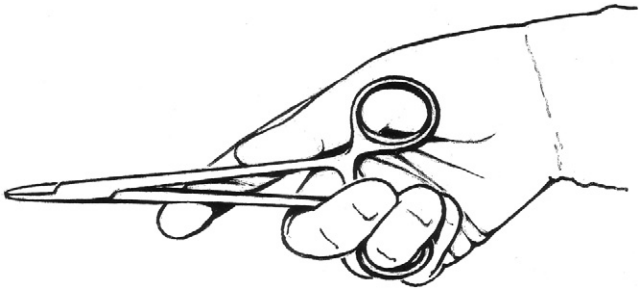

Figure 12-6. The thenar grip of a needle holder.

adequate length must be presented to the assistant so that the scissors can be applied at the desired spot.

A surgeon working without an assistant may use an Olsen-Hegar needle holder with built-in suture scissors (see Figure 11-7, *A*), or the suture scissors can be held in the same hand as the needle holders, in the manner described for handling multiple hemostats (see later).

Needle Holders

There are three methods for holding needle holders. One is the classic tripod grip just described for scissors. The greatest advantage of the classic tripod or thumb–ring finger grip is that it allows precision when releasing a needle. Although slower than the palm or thenar grip, it is preferred when tissue is delicate or when precise suturing is required.

The palm grip is useful for rapid instrument manipulation in closure of tissue when precision is not essential; however, the palm grip is not universally accepted as proper technique.[3] With the palm grip, also referred to as the modified thenar eminence grip, the surgeon places the instrument in the palm of the hand with the one ring resting against the thenar eminence of the thumb but no finger placed in one of the rings of the needle holder (Figure 12-5). The index finger stabilizes the instrument along the shaft. The lock mechanism is disengaged by lateral pressure applied to the instrument using the thenar eminence. The tips of the instrument may be opened and closed by adduction and abduction of the thumb. This method of manipulation is useful for rapid closure, because it allows the needle to be more easily grasped, extracted, and readied for the next pass.[7] It is also advantageous for suturing robust tissue that requires a strong needle-driving force; however, the needle cannot be released and regrasped after guiding the needle through tissue without changing to another grip, making suturing less precise.[8] Please note that left-handed surgeons cannot "palm" right-handed instruments because the boxlock closes rather than opens with pressure.

The thenar grip, where the upper ring rests on the ball of the thumb, and the ring finger is inserted through the lower ring (Figure 12-6), allows the needle to be released and regrasped for extraction without changing grips. Although it allows mobility, releasing the needle holder by exerting pressure on the upper ring with the ball of the thumb causes the needle holder handles to pop apart, and some needle movement occurs during this process.

The pencil grip, where the index finger and thumb rest on the shafts of the needle holders, is used with very delicate needle holders (Castroviejo) used in ophthalmic surgery and microsurgery.

A needle holder grips the suture needle along its shaft so that the needle is perpendicular to and near the tip of the instrument. The needle is usually grasped midshaft, but it can be grasped closer to the needle tip for greater precision.[7,8] The needle is passed through tissue by rotation of the surgeon's hand, always following the curve of the needle. Care should be taken to advance the needle so that it protrudes from the tissue enough to allow the needle holder or tissue forceps to grasp it far enough behind the tip to prevent dulling or bending the needle. When using the needle holder, the surgeon may pronate the hand for greater precision or supinate the hand for greater speed.[7]

Forceps

Thumb Forceps

Thumb tissue forceps are used to manipulate and stabilize tissue during incising and closing. Thumb forceps are usually held in in a pencil grip with the nondominant hand. When not in use, they may rest in the palm.[7] If the surgeon's hand becomes fatigued, the natural tendency is to switch to a palm grip. This grip is less precise and more likely to incite unnecessary tissue trauma.

When closing deep tissue layers, thumb forceps are useful for retracting superficial layers during needle placement, starting on the far side of the incision (Figure 12-7). As the needle is passed, the forceps moves to the layer being closed, exposing the exit point. The process continues with the tissue forceps being used to grasp tissue layers in opposite order on the near and far side of the incision.[5]

Hemostat Forceps

Mosquito and other tissue forceps used for hemostasis are held in the classic tripod grip to grasp the vessel to be ligated. When

a surgical assistant is not available and several hemostats have to be applied, time can be saved by introducing the ring finger through the left ring of several such instruments and holding them in the palm of the right hand, while applying a hemostat to a vessel in the tripod grip with the same hand (Figure 12-8). By arranging the hemostats so that the tips point toward the thumb, the instruments can one by one be rotated into the tripod grip and applied to a bleeding vessel.

Tissue Forceps

The most commonly used tissue forceps in equine surgery are towel clamps, mosquito forceps, Allis tissue forceps, Ochsner forceps, and Carmalt forceps. All these forceps are applied to tissues with the tripod grip. Towel clamps (except the Lorna-Edna clamps [see Figure 11-16, *C*]) are useful during some procedures for tissue manipulation, even though their primary purpose is to secure drapes on the patient. Towel clamps attached to skin edges provide an atraumatic method of retraction for exposing deeper tissues. Because Allis tissue forceps and Ochsner forceps are traumatic and crush the tissue, they are best reserved for securing tissue that can be excised.

TISSUE INCISION AND EXCISION

Slide Cutting

The skin is usually incised with a scalpel, because this is the method that is least traumatic and most conducive to primary healing. The incision should be made in one smooth pass of the scalpel through the skin, using the slide-cutting technique, transecting the dermis without cutting deep fascial tissue. The surgeon's free hand should stabilize and stretch the skin being incised (Figure 12-9). When skin is properly transected, the edges will retract. In a longer incision, it may be necessary to reposition the free hand to put tension on the skin along the entire incision. During this repositioning, the scalpel should not be lifted from the tissues. Each time the scalpel leaves and returns to the tissue, a jagged edge is created that will adversely affect healing (Figure 12-10).[9]

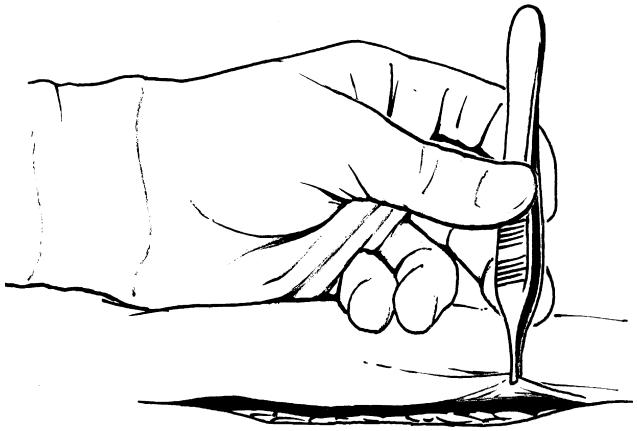

Figure 12-7. Proper technique for holding and using thumb forceps.

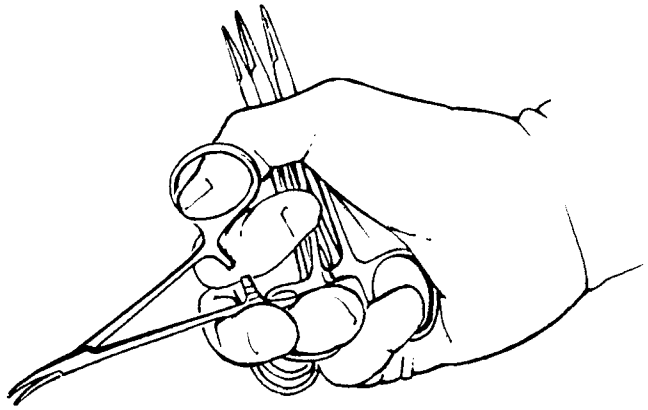

Figure 12-8. Several mosquito forceps are held in the surgeon's palm, allowing effective sequential application to a number of vessels.

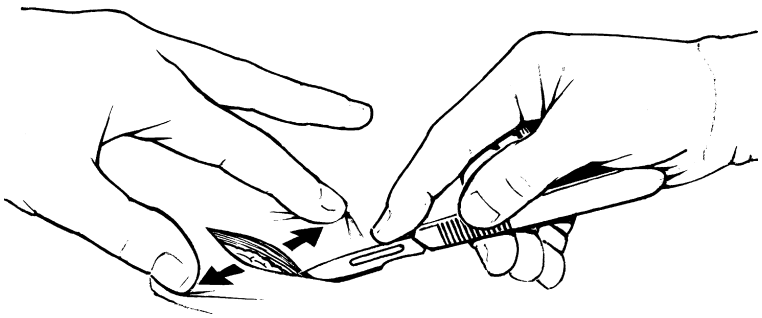

Figure 12-9. Stabilizing and stretching the skin between the thumb and index finger facilitates the incising of the skin.

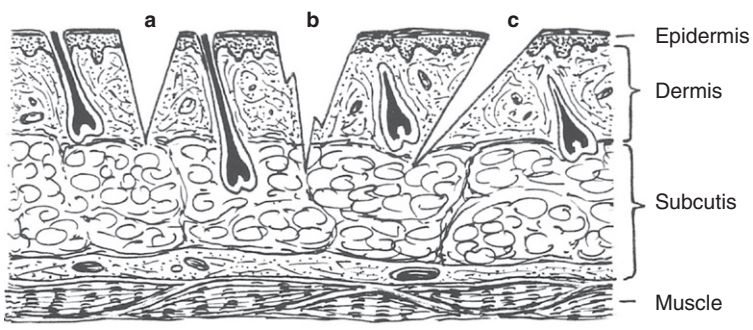

Figure 12-10. Skin incisions. *a,* Correctly performed incision. *b,* Timid slide cutting resulted in jagged incision edges. *c,* Slide cutting with a sideways-angled blade resulted in an obliquely angled skin incision.

Stab or Press-Cutting Incision

Stab or press-cutting incisions are generally performed with the scalpel held vertically in the pencil grip (Figure 12-11). A stab incision results when the bursting threshold of the tissue being incised is exceeded. Press cutting is applied to initiate incisions into hollow, fluid-filled structures, such as the bladder. For this technique to be effective, the tissue to be entered should be under tension. Press-cutting incisions are also used frequently during screw fixation of an anatomically reduced condylar fracture of the third metacarpal/metatarsal bone (MCIII/MTIII) or of the proximal phalanx. The scalpel is held in a pencil or palm grip, perpendicular to the surface of the tissue. The tissue is entered with a slight thrust, and the incision is extended carefully by pushing the cutting edge of the scalpel through the tissue. With this technique, depth control is poor, but it can be improved by using the index finger as a bumper (Figure 12-12), effectively limiting penetration of the blade to a predetermined depth.[7] Press cutting with an inverted blade (Figure 12-13) elevates the tissues to be transected and provides more safety for deeper structures, while preventing fluid from exiting a fluid-filled structure or organ.

Two rarely applied techniques are the sawing (or push-pull slide cutting) and the scalpel scraping techniques, the latter of which is used for separation of fascial planes or for subperiosteal dissection and elevation of muscles.[7]

Scissor Incision

The scissor tips are often used to transect tissues. Before this technique is used, the tissue to be incised must be isolated from underlying tissues using blunt scissor dissection (see later). This isolates the tissue structures to be cut. Some tissues can be effectively transected by partially opening the scissors, holding the blades motionless relative to each other, and pushing them through the tissue. Allowing the scissors to slide through the tissue creates a clean, atraumatic incision. This method is appropriate for opening fascial planes over muscles or subcutis, or for opening tissue planes in which the start and finish points of the incision are well defined.

Electroincision

Because lateral heat production during electroincision increases with the duration of trigger activation and tissue contact time,

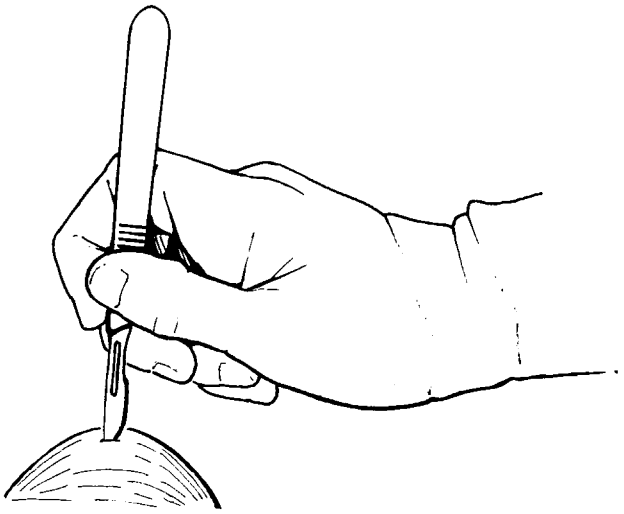

Figure 12-11. Stab or press cutting into a hollow organ.

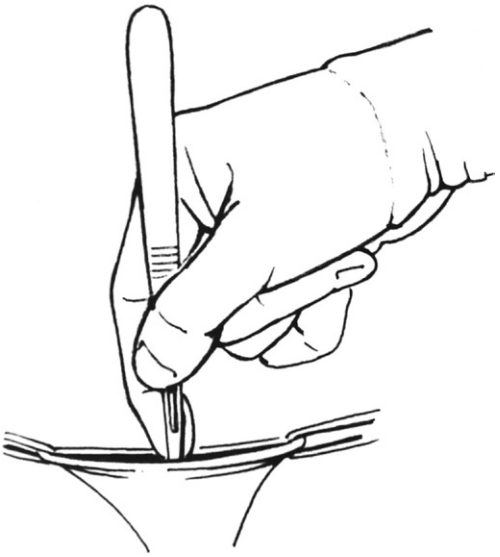

Figure 12-12. Bumper cutting into a structure elevated and stretched between two Allis forceps.

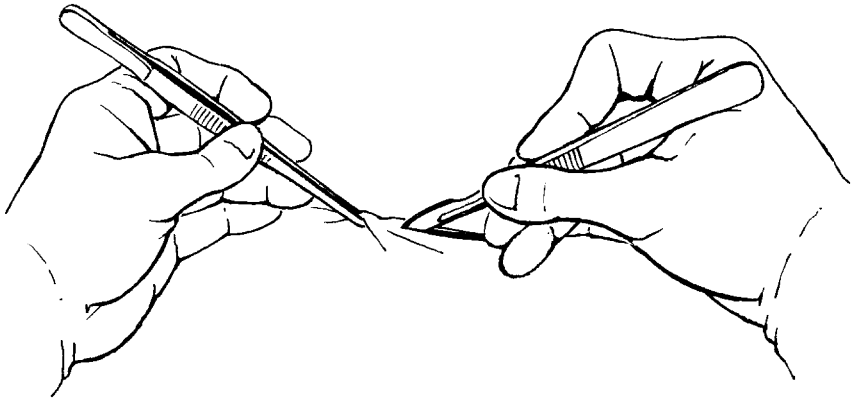

Figure 12-13. The technique of inverted-blade press cutting facilitates blade control.

the blade is moved at a speed of about 7 mm/sec.[7] Only one tissue plane is cut at a time, using only the tip of the blade. Depth control with the electro scalpel is less precise than with the cold scalpel. Because the electrode cuts all tissue it contacts, visual control is of paramount importance. Electrosurgical incision should not be used in areas with poorly defined anatomic planes. Thermal necrosis at the wound edges can be reduced and depth control can be improved by using the lowest setting on the controls that allows clean cutting.

The electrode should be cleaned frequently to ensure proper function. Charred tissue that accumulates at the tip of the electrode acts as an insulator and decreases effective cutting. Three undesirable effects are associated with a charred electrode: (1) higher power is required to incise tissues; (2) current is dispersed to a larger area of tissue, diminishing control; and (3) thermal necrosis of the wound edges is increased.[2] If the buildup of charred material at the tip is rapid or excessive, the power setting may be too high or the cutting speed may be too slow.[10]

Advantages reported for electrosurgical incisions over those made with a steel scalpel are (1) reduction in total blood loss; (2) decreased need for ligatures, and thus reduction in the amount of foreign material left in the wound; and (3) reduced operating time.[11,12] These advantages come at the expense of delayed wound healing and decreased resistance of wounds to infection. Controlled experiments revealed that there is no overall difference in epithelial healing between incisions made with the electro scalpel and those made with the steel scalpel. However, a difference in the initial response of the connective tissue was recorded.[5] Electro incisions of the skin heal primarily, but there is a definite lag time in reaching maximal strength. Because of this delay, skin sutures or staples should remain in place an additional 2 to 3 days if the incision was made with an electro scalpel. Electrosurgical incisions should be avoided in the presence of cyclopropane, ether, alcohol, and certain bowel gases because of the risks of ignition and explosion.[7]

Tissue Excision

Most tissues are excised primarily by scalpels or scissors. Skin, hollow organs, contaminated subcutaneous tissues, and neoplastic tissues are best excised with a scalpel. This is performed by a single passage of the scalpel along or around the periphery of the tissue to be removed. However, repeated passes or a sawing action with the scalpel may be necessary to complete excision of the tissue. This is especially true for thick, dense tissue or en bloc excision. Precise excision of tissue deep within surgical wounds or body cavities is best performed with scissors.

BLUNT DISSECTION

Blunt dissection is used to reduce or prevent the risk of damaging deeper vital structures during a surgical approach. The technique is performed digitally or with surgical scissors. Blunt dissection is generally carried out along natural tissue planes or parallel to tissue fibers. Excessive dissection and undermining should be avoided, because creation of dead space impedes wound healing and potentiates infection. If scissors are used—blunt scissors work best—the tips are placed in a closed position into the tissue, and the jaws are opened parallel to the tissue fibers or along natural tissue planes (Figure 12-14). Forceps can be used to stabilize the tissue during dissection. When digital dissection is applied, the gloved index finger of each hand is placed side by side in the same tissue plane and pulled in opposite directions to stretch and separate the tissue, thus increasing surgical wound exposure.

Scissors are useful for dissecting tissues, especially the subcutaneous tissue. The plane of dissection is parallel to the skin, along the incision edges. Limited dissection underneath the skin allows further retraction of the skin away from the center of the incision and facilitates visualization of deeper tissues. Scissor dissection is less useful, and potentially dangerous, in deeper dissections, where vessels or nerves could be severed before they are seen.

SURGICAL HEMOSTASIS

Proper hemostasis prevents the surgical field from being obscured by blood, and it decreases the potential for infection. Hemostasis minimizes blood loss and postoperative hematoma or seroma formation, which may delay healing or potentiate wound dehiscence. Additionally, excessive or uncontrolled hemorrhage can lead to anemia or hypovolemic shock.[7] Therefore the goal of hemostasis is to prevent blood flow from incised or transected vessels. This is accomplished primarily by interruption of blood flow to the involved area or by direct closure of the vessel walls.[13] There are mechanical, thermal, and chemical techniques to achieve hemostasis.

Mechanical Hemostasis

Pressure

Using the fingers or the hand, pressure can be applied directly over the site of a major vessel, or over a major vessel at a site remote from the wound. Oozing from small vessels is best controlled by direct pressure using sterile gauze. Although this is the least traumatic means of vascular hemostasis, it is not adequate for medium-sized and larger vessels, which require some other means of hemostasis.

Gauze packing is used to control hemorrhage from open body cavities (such as the nasal cavity, paranasal sinuses,

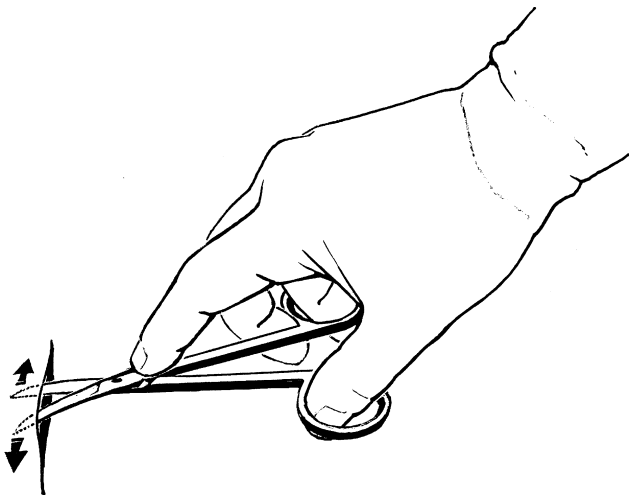

Figure 12-14. Blunt dissection of subcutaneous tissue can be performed by spreading the jaws of the scissors in the tissues.

urogenital tract, and defects created in the hoof wall or sole) and from large body wounds. Hemorrhage is controlled through pressure, allowing time for clot formation. The gauze can be soaked in iced or chilled saline solution, or diluted epinephrine can be added to a diluted antiseptic (e.g., povidone-iodine) or saline solution to help control the bleeding. Several gauze rolls tied together may need to be used to effectively pack large defects. The end of the packing is best secured to the body to ensure its presence at the time of removal.

Ligatures

Hemostats can be applied to small, noncritical vessels and held there for a few minutes. The vessel tissue trapped in the jaws is crushed, effectively occluding the vessel.[13] A combination of vasospasms and intravascular coagulation maintains hemostasis when the clamp is released. To facilitate these events, the vessel can be stretched or twisted before the instrument is released. If bleeding from a critical vessel needs to be controlled, atraumatic hemostatic clamps can be used to limit damage and allow repair.

Suture ligation is commonly used to control bleeding from larger vessels. Absorbable suture material is preferred over nonabsorbable material, because the latter can result in extrusion or sinus tract formation.[13] The number of ligatures required to maintain occlusion depends on vessel size and the material used. A simple circumferential ligature is generally used for small vessels (Figure 12-15, *A*), whereas pulsating or large vessels, such as arteries, should be ligated with two ligatures, a circumferential followed by a transfixation ligature placed more distally (Figure 12-15, *B*). In most situations, a hemostatic clamp is applied to the vessel before ligation. The clamp's crushing effect facilitates ligature placement and vessel occlusion. The following steps for proper use of hemostatic forceps should be kept in mind[4]:

1. The smallest forceps that will accomplish the needed hemostasis should be used.
2. Only the minimum amount of tissue should be clamped—preferrably only the vessel itself.
3. The tip of the instrument should be used rather than the middle or the base.
4. The mosquito forceps should be applied to small bleeding vessels perpendicular to the cut surface.
5. Other forceps should be applied perpendicular to the long axis of the vessel to be ligated.
6. The mosquito forceps should be applied to surface bleeders so that they come to rest lateral to the incision, with the concave part of the curved blades pointing down. In deeper locations, such as in the abdominal cavity, the forceps should be placed with the tips pointing upward.
7. The assistant should pick up the hemostat and direct it with the tip pointing toward the surgeon.
8. The hemostat should be held in the nondominant hand. One ring is held between the index finger and the thumb, and the other ring rests on the middle and ring fingers (Figure 12-16).
9. At the time of the final tightening of the first half hitch around the vessel, the surgeon should give the assistant the sign to release the hemostat.
10. The assistant should release the hemostat by pushing up with the middle and ring fingers while pressing down with the thumb, carefully releasing the ratchet mechanism of the hemostat.
11. Before releasing the hemostat, the instrument should be directed into the incision to relieve tension on the vessel and prevent it from slipping out of the ligature before the ligature is completely tightened.
12. The surgeon should apply a second half hitch over the first one, forming a square knot.
13. Then, the assistant should cut the suture ends at the level indicated by the surgeon, with the suture scissors held in the dominant hand.
14. If double ligation is indicated, clamps should be placed at each ligature site, approximately 2 to 3 mm apart. Once the vessel is clamped, a circumferential ligature should be placed around the vessel adjacent to the proximal hemostat. As the ligature is tightened, the clamp is released. The ligature should fall into the area of the vessel crushed by the clamp. The distal clamp should be released and replaced with a transfixation ligature.

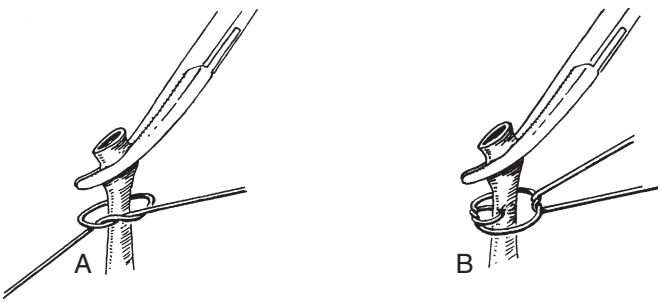

Figure 12-15. Circumferential **(A)** and transfixation **(B)** ligatures.

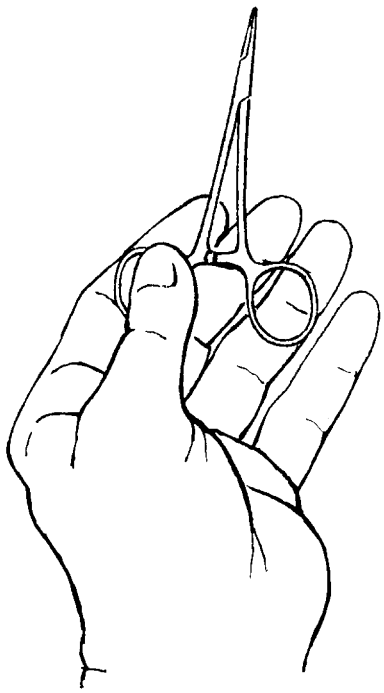

Figure 12-16. The hemostat is held in the nondominant hand. One ring is held between the index finger and the thumb, and the other ring rests on the middle and ring fingers. Pressing the rings toward one another releases the hemostat handle lock.

Large pedicles are preferably divided into smaller units, and each is separately ligated. After ligating the last unit, a suture is placed around the combined units and tied as one pedicle ligation. This is called the "divide and conquer" method (Figure 12-17, *A*).[7] The three-forceps method (Figure 12-17, *B*) involves initial clamping of the pedicle with three parallel forceps, 1 to 1.5 cm apart, incorporating the entire pedicle. The pedicle is transected between two such forceps, leaving one side with one forceps and the other with two forceps. A loose ligature is applied around the entire pedicle with the two forceps between the base of the pedicle and the first forceps. The forceps closest to the pedicle base is then partially taken off, leaving a strand of crushed tissue behind. The ligature is now solidly tightened, making sure that it comes to lie over the crushed line of tissue. While the surgeon tightens the ligature, the assistant carefully removes the forceps completely. If the pedicle is too large, insufficient hemostasis is often achieved with this technique.[7] In such cases, the divide and conquer technique should be used.

Ligation of vessels obscured by perivascular fat accumulation, such as occurs in the omentum, may be a challenge because occasionally the vessel is traumatized by trying to blindly pass a needle around the vessel. In these cases, the blunt end of the needle can be used to place the suture around the vessel. This part of the needle pushes the vessel aside if it is in its path rather than penetrating it. Subsequent ligation of the vessel is routine (see Figure 37-28).

Staples

Vascular staples, which can be used to occlude vessels up to 7 mm in diameter, are an alternative to suture ligation. They offer the advantage of speed and precision in placement. A specially designed instrument (the Ligate and Divide Stapler [LDS, US Surgical]) first applies two vascular staples that are crimped around the vessel simultaneously and then divides the vessel between the staples (see Figure 16-14). In cases of extensive intestinal resection with multiple mesenteric arcades, time is saved using this instrument. Disadvantages of staples are expense and potential failure when used on large vessels.

Surgical Repair

Management of lateral wall defects in vital vessels can be very difficult. Suturing the defect is recommended, incorporating the tunica adventitia and tunica media—the major holding layers within the walls of large vessels.[5,10] Fine suture material (4-0 to 6-0) is recommended, using a continuous pattern with bites placed close together. If a vessel is inadvertently lacerated parallel to its length, closure with the help of a simple continuous or interrupted suture pattern may reduce the vessel diameter such that effective blood supply to afferent tissue or drainage from the efferent tissue is no longer ensured (Figure 12-18, *A*). In such a case, closure of the laceration perpendicular to the long axis of the vessel increases the vessel diameter to ensure circulation (Figure 12-18, *B*).

Esmarch System

The Esmarch and pneumatic tourniquet systems are excellent methods of temporarily occluding blood flow to a distal extremity (Figure 12-19). They are used to maintain a bloodless operative field. An inflatable pneumatic cuff is placed around

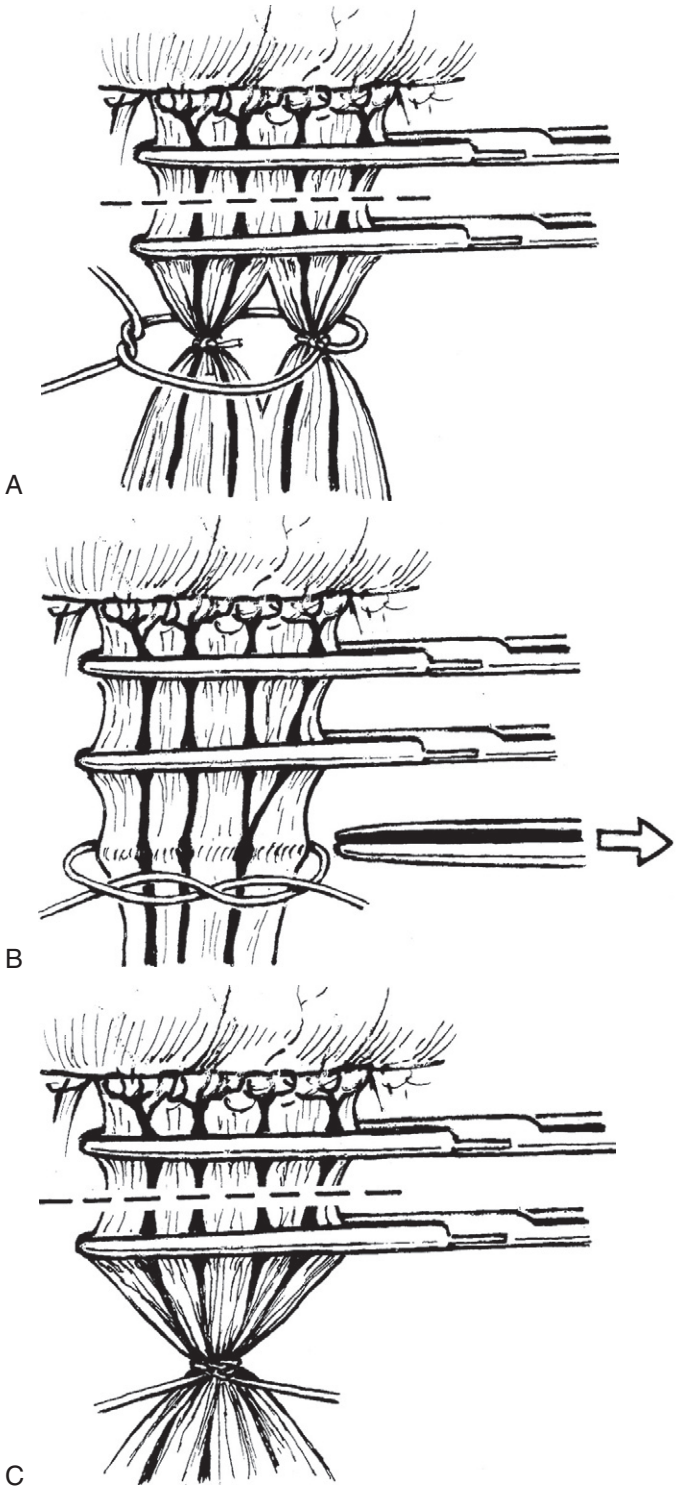

Figure 12-17. Ligation of large bundels of tissues. **A,** Divide and conquer technique. **B** and **C,** Three-forceps technique. The third hemostat has been removed *(arrow)* and in its place a ligature is applied **(B)**. The bundle is separated between the two remaining hemostats and ligatures are applied at the location of the hemostats or immediately adjacent to them (on the distant hemostat side relative to the division line) **(C)**.

the limb, 10 to 15 cm proximal to the surgical site, before preparing and draping the surgical site. If the cuff is applied proximal to the carpus or the tarsus, a gauze roll is placed on the medial and lateral sides of the limb over large vessels underneath the tourniquet to facilitate blood flow occlusion. Starting over the hoof and proceeding proximally, a long latex rubber bandage is tightly wrapped around the limb, overlapping the previous turn by 50% to force the blood from the limb. Once the Esmarch bandage reaches the level of the pneumatic tourniquet, the cuff is inflated above systolic pressure to occlude blood flow into the limb (approximately 600 mm Hg) (see Figure 12-19). Subsequently, the Esmarch is removed, beginning again at the hoof until the pneumatic cuff is reached. Nonpigmented skin will appear blanched. The tourniquet is generally left on the limb for no longer than 2 hours. When the procedure takes longer than that, the tourniquet should be partially deflated for 2 to 3 minutes, followed by reapplication of a sterile Esmarch bandage and reinflation of the tourniquet.

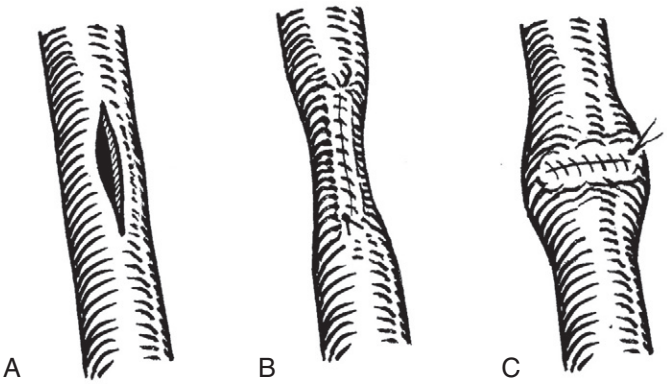

Figure 12-18. A, Surgical repair of a lacerated blood vessel. **B,** Application of a suture pattern parallel to the long axis of the vessel may decrease the lumen of the vessel resulting in its clotting. **C,** Application of a suture pattern perpendicular to the long axis of the vessel enlarges the lumen but also relatively shortens it.

Thermal Hemostasis

Electrocoagulation is a commonly used method of hemostasis. Heat generated from high-frequency alternating electrical current traveling between two electrodes denatures proteins inside cells.[11] Tissue damage from heat occurs between 3000 and 4000 Hz. Electrosurgical units can generate currents ranging between 1.5 and 7.5 MHz, and if the current applied is too high, the intracellular fluid boils instantly, potentially causing the vessel to explode without achieving coagulation.[12]

Electrosurgical units can produce different types of currents. A partially rectified waveform achieves the most effective hemostasis.[11] Vessels up to 2 mm in diameter can be coagulated in two ways. Obliterative coagulation is performed by direct contact between the handheld electrode and the vessel. This causes the vessel wall to shrink, occluding the lumen by thrombosis and coagulum formation.[11,14] Alternatively, hemostasis can be achieved by coaptive coagulation. In this method, the vessel is initially occluded by a hemostatic forceps. The electrode of the electrosurgical unit then contacts the occluding instrument, which conducts the energy to the vessel, inducing its permanent occlusion. This technique allows precise electrocoagulation of a vessel.

Cryogenic hemostasis, as the name implies, refers to coagulation caused by rapid freezing of vessels. The technique of cryosurgery is discussed in detail in Chapter 14.

Chemical Hemostasis

Occasionally, epinephrine is used to control hemorrhage. Epinephrine is a potent α-adrenergic agonist that causes peripheral vasoconstriction.[15] A solution of 1:100,000 to 1:20,000 is used to control superficial bleeding of mucosal and subcutaneous tissues.[13] Gauze packing soaked with a dilute epinephrine solution is an effective way to control bleeding.

Intravenous injection of 10% buffered formalin at a dosage of 0.02 to 0.06 mL/kg body weight diluted 1:9 in physiologic saline solution has been shown to be effective in controlling diffuse bleeding.[15] The exact mechanism of action is unknown, but it may be the result of induction of coagulation on the endothelial cell surface. Close monitoring of the patient during application is recommended. This technique is applied to stop bleeding after castrations, colic surgeries, and surgical interventions of the upper airways.

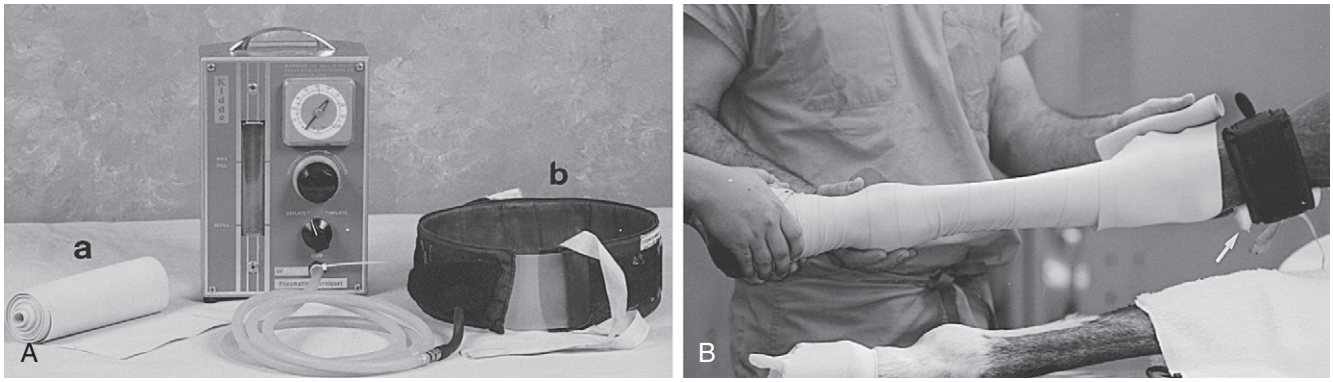

Figure 12-19. A, An Esmarch bandage *(a)* and pneumatic tourniquet *(b)* used for occluding blood flow in a limb. **B,** Application of an Esmarch bandage and a pneumatic tourniquet. Gauze rolls are placed over vascular pressure points under the tourniquet *(arrow)*.

Physical Hemostasis

Soluble sponge materials control hemorrhagic oozing by promoting clot formation. Various types of hemostatic materials include gelatin foam, oxidized cellulose, oxidized regenerated cellulose, and micronized collagen (see Chapter 4 for more details). While these materials press against the wound surface, the material's interstices provide a scaffold for clot organization.[5] These materials are most beneficial for low-pressure bleeding and in friable organs that cannot be readily sutured.[7] The materials are nontoxic, but they will delay wound healing and can potentiate infection because they are absorbed by phagocytosis.[2]

Bleeding from the bone can be controlled with the help of bone wax, which consists of purified and sterilized beeswax. The wax is physically packed onto the bone to block oozing of blood from cut cortical and cancellous bone. The material is relatively nonirritating, but it will remain in contact with the bone for years.[7]

TISSUE RETRACTION AND HANDLING

Retraction

Unnecessary tissue trauma induces inflammation, which can delay healing. Therefore incisions should be made only long enough to allow adequate exposure. However, trying to complete a surgical intervention through small incisions, which are currently trendy, often results in excessive trauma of the wound edges. Such manipulations delay wound healing. Therefore the proper length of incision is the goal of a good surgeon. Gentle manipulation of tissue with respect to blood supply, innervation, and hydration is essential for atraumatic surgical technique. To achieve this, instrument retraction may be preferred over direct hand retraction in selected situations.

Handheld retractors are designed with a single handle and blade to be used as an extension of the assistant's hand. Alternatively, self-retaining retractors are designed with a locking mechanism on the handles to keep the blades in an open position. The blades of the retractor are placed within the incision and opened until the tissues on each side are spread maximally. Occasional repositioning or relaxation of the instrument blades, in conjunction with padding (i.e., moist gauze sponges placed between the blades of the retractor and tissue), minimizes tissue damage.

Careful retraction and stabilization of nerves and neurovascular bundles with Penrose drains or umbilical tape should always be considered in place of metallic retractors.[13] This both facilitates atraumatic manipulation of the vessels and nerves and prevents inadvertent traumatization.

Careful and atraumatic tissue handling is as important as applying aseptic technique during surgery. Rough handling of the tissues may induce inflammation and subsequent delayed wound healing.

Tissue Handling

An incision heals from side to side, not from end to end. Therefore the incisions should be long enough to facilitate a clear view of the surgical site. Inadequate exposure may increase tension on the tissues through overzealous retraction, jeopardize hemostasis, increase the risk of traumatizing a nerve or vessel, and delay healing.

Sharp dissection should be carried out with sharp instruments. The use of dull scalpel blades and dull and worn-out scissors only increases tissue trauma. Whenever possible, natural tissue cleavage planes should be followed during dissection; this prevents inadvertent transection or tearing of fibrous tissues that heal poorly, if at all. Excessive undermining of tissues should be avoided, because it leads to the formation of dead spaces, which allow hematoma and seroma formation.

Most tissues should be handled with appropriate instruments; fingers should only be used for blunt disection. In small wounds, the introduction of a surgeon's finger prevents adequate evaluation of the deeper structures. Probing with a thin instrument allows simultaneous observation and manipulation. Tissue forceps are available for just about any manipulation necessary. Hemostatic forceps should only be applied to tissues that will be excised, because the tissues between the jaws are crushed and devitalized. Allis forceps are designed to hold tissues. However, excessive compression of the tissues in the clamp should be avoided. Stabilization and retraction of tissue may be accomplished with methods that do not involve tissue forceps. In selected situations, the assistant's fingers may be used for temporary occlusion of bowel to facilitate an enterotomy without additional trauma. Alternatively, a pair of self-retaining Doyen clamps may serve the same purpose.

Stay sutures can be used in a variety of situations—for example, to stabilize vessels and bowel. These sutures can be placed through very small amounts of tissue and still allow manipulations without tearing of the structure being repaired. Handheld and self-retaining retractors can be used in many surgical procedures to facilitate certain manipulations.

Nerves and vital vessels should be spared whenever possible. Once they are isolated, they should be manipulated with great care. The identification of these structures with the help of a Penrose drain is atraumatic and effective.

SURGICAL IRRIGATION AND SUCTION

Surgical Irrigation

Operative wound lavage has been associated with reduced rates of postoperative infection for both clean and contaminated wounds in direct proportion to the volume of irrigation solution used.[16,17] This phenomenon has been attributed to the removal of surface bacteria and debris from contaminated wounds, dislodgement and removal of bacteria and exudate from infected wounds, and dilution and removal of toxins associated with infection.[18] An additional benefit of wound lavage and suction is the moistening of tissues to counteract the dehydrating effects of air and surgical lights. Wound lavage removes blood from the surgical site, which also improves visibility. Various types of lavage solutions, delivery systems, and suction devices have been developed for various body regions (e.g., body cavity, skin), wound types (e.g., traumatic, surgical), and degrees of contamination or infection.

The ideal lavage solution is sterile, nontoxic, isoosmotic, and normothermic.[18] Sterile 0.9% physiologic saline, lactated Ringer solution, and Plasmalyte) are examples of available solutions that approach these criteria. Antibiotics are often added to a lavage solution as prophylaxis against possible infection or if contamination has occurred. Even though some effect has been reported, conclusive evidence that this technique is superior to saline lavage alone is lacking.[7,19] Infection implies bacterial penetration of tissues, and adequate blood and tissue

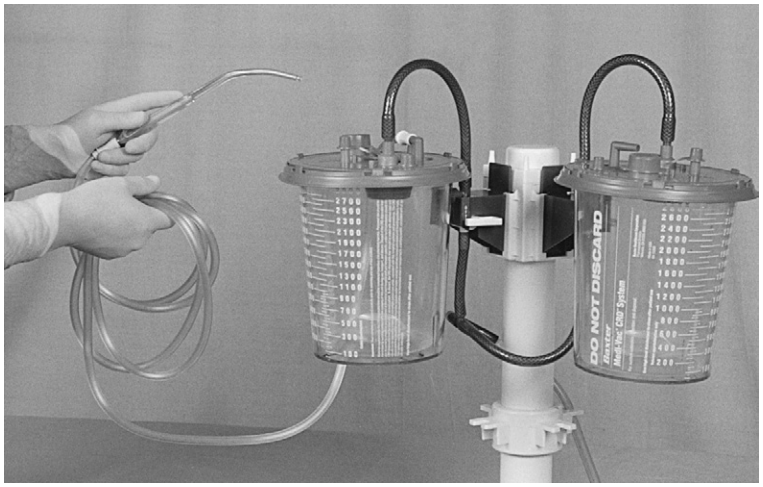

Figure 12-20. A suction tip is connected to sterile tubing to evacuate fluid from the surgical site into a reservoir.

concentrations of antibiotics via systemic administration are required for effective bacterial destruction.[7] Some antibiotics, such as tetracycline, are irritating when applied to exposed tissue or peritoneal surfaces and should be avoided.[20] Antiseptics such as povidone-iodine and chlorhexidine may be added to lavage solutions.[21]

Fluid delivery systems used for irrigation vary with location on the body and degree of contamination or infection. Lavage of body cavities is accomplished by flooding the cavity with large volumes of sterile solution, followed by suctioning to remove the fluid. Common methods involve pouring the sterile solution from the bottle or a bowl into the cavity or using a system capable of delivering large volumes of fluid at low pressure (referred to as diuresis).

Alternatively, traumatic and surgical wounds of the limbs are usually lavaged with the solutions under pressure. This is especially important if contamination or infection is present, because it dislodges bacteria or debris.[7] A bulb syringe or a 60-mL dose syringe is adequate for keeping tissues moist and removing débrided tissue particles in some circumstances, but automated systems that deliver a high volume of lavage solution at pressures not exceeding 10 to 15 pounds per square inch should be used on heavily contaminated tissues (additional information on wound lavage techniques can be found in Chapter 26). Alternatively, a sterilized squeeze hand pump can be inserted into a sterile fluid bag, and a fluid spray of the desired intensity can be applied to the selected tissue by squeezing the handle.[20]

Suction

Suctioning efficiently removes blood and fluid from the surgical site. A suction tip attached to sterile tubing connected to a suction pump that delivers a vacuum of 80 to 120 mm Hg is recommended (Figure 12-20).[8] When gentle suction is indicated, such as in deep incisions where exposure is limited, a Frazier tip is used. This tip has a side-hole port near the handle, which can be used to vary the amount of suction by either leaving the port uncovered or covering it with the index finger. When suctioning a large volume of fluid, a Yankauer suction tip with a single port can be used. The multifenestrated sump type of design of the Poole tip makes it ideal for use in body cavities, where a single-port tip will plug or injure viscera.[7] Figure 11-17 shows these special tips.

Figure 12-21. Proper technique for holding a curette.

CURETTAGE

Curettage refers to the removal of a growth or other tissue from the wall of a cavity or other surface with a curette. Curettage can be used in all types of surgical interventions, but it is mainly applied in orthopedic procedures. Débridement of sequestra, excess bone production such as periosteal exostoses, damaged or diseased articular cartilage, and subchondral bone during an articular procedure (arthroscopy or arthrotomy) represent some surgical procedures that may involve curettage. It is important to note that normal cortical bone cannot be removed with a curette; however, periosteal new bone formation or necrotic bone is easily removed with this instrument. Therefore, when initially efficient progress in bone removal is followed by a sudden increase in difficulty, the level of underlying normal bone has been reached.

The curette can also be used to remove necrotic soft tissue and debris from wounds, such as the tissue covering the bone after removal of a bone plate. The curette is used in an axial rotational motion (using its cuplike design at the instrument tip) to scoop out tissue, or with a pulling motion to scrape tissue from the surgical site. The handle of the instrument is grasped in the palm of the dominant hand and the index finger is placed on the shaft of the instrument to help stabilize the tip against the tissue (Figure 12-21).

CHAPTER
13

Minimally Invasive Surgical Techniques

Andrew T. Fischer Jr., Joanne Hardy, Astrid B. Rijkenhuizen, and Jörg A. Auer

The evolution of minimally invasive human surgery that reached critical mass in the 1980s has been matched by a parallel development in minimally invasive surgical techniques in the horse. The evaluation of joints by arthrotomy, which was common until the mid 1980s, has been replaced by arthroscopy for almost all indications. Laparoscopic surgical techniques have continued to replace previous open techniques, such as cryptorchidectomy, ovariectomy, and inguinal hernia repair. In some cases, new techniques have been developed that were not previously available in the horse (e.g., testicle-sparing mesh repair of the inguinal ring). Thoracoscopic techniques are also continuing to evolve but at a slower pace because of the infrequency of surgical disease of the equine thorax. Hybrid procedures (laparoscopically assisted removal of cystic calculi, laparoscopically assisted nephrectomy, etc.) have also been developed that incorporate the improved visualization realized with laparoscopy but still maintain the tactile feedback of open surgery. The three major applications of rigid endoscopy (laparoscopy, arthroscopy, and thoracoscopy) share common surgical techniques and basic equipment. This chapter describes specialized equipment unique to each application and the basic procedures.

Additional minimally invasive surgery techniques include embolization and thrombectomy, which can be conducted through catheters introduced into vessels. These are effective procedures for treating disorders that a few years ago could be attempted only with great risk to the patient. Furthermore, computer-assisted surgery has only recently been introduced into equine surgery and may play a major role in orthopedic surgery of the future. It allows the accurate insertion of implants through small stab incisions, obviating the need for open approaches.

In addition to smaller surgical incisions, minimally invasive surgical techniques are characterized by vastly improved visualization. This has led to improved surgical outcomes and better overall understanding of regional anatomy. Minimally invasive techniques continue to evolve and replace previous open techniques as more surgeons become comfortable with them and as more thought is devoted to their development.

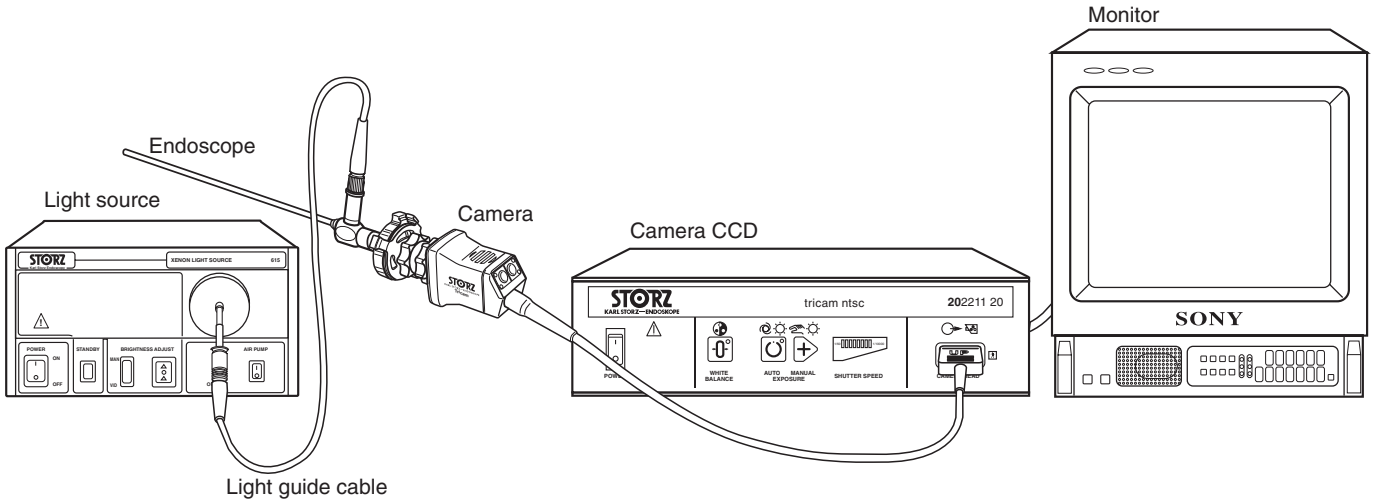

Figure 13-1. Basic equipment set up for minimally invasive surgery, consisting of light source, light cable, video camera with camera processor, and monitor. *CCD,* Charged capacitance device.

ENDOSCOPY

Andrew T. Fischer

Equipment

Illumination

Most minimally invasive procedures require a means of illuminating the body cavity and a telescope for viewing the target organs.[1-3] The supply of light into the patient's body cavity was a limiting factor until the development of cold light sources, which allowed high-intensity illumination of the cavity without danger to the patient or surgeon from excessive heat. The next major limitation of early arthroscopy and laparoscopy was the lack of video imaging equipment, which prevented an assistant from participating in the surgery. Without the aid of an assistant, the only procedures that could be performed were those that could be accomplished with one hand. Beam splitters were developed to share the image on the surgical telescope, but they were unwieldy and they markedly decreased the amount of light, resulting in a poor image. As video cameras were developed and refined, arthroscopy, laparoscopy, and thoracoscopy became popular. With time, the complexity of procedures markedly increased, as did the number of surgeons performing them.

Currently, light sources are capable of providing intense illumination to the selected cavity (Figure 13-1). Most manufacturers produce light sources with 300 watts of output from xenon bulbs. Xenon light sources are preferred, because they offer more lumens per watt than halogen light sources, and the light is whiter, offering more accurate reproduction of colors. A flexible fiberoptic or liquid light cable is needed to transmit the light from the light source to the telescope. Light cables are available in many lengths, but a 10-foot cable is generally preferred for equine endoscopy. A fiberoptic light cable must be checked regularly for broken fibers and must be well maintained by thorough cleaning. Poor illumination of the cavity can frequently be traced to a light cable with many broken bundles. However, a liquid light cable does not have this problem. Although a bit more expensive, they are quite durable and not subject to fiber bundle breakage.

When the light source is on and the light cable is connected to the light source, it is important that the distal end of the light cable or the telescope does not contact the patient, drapes, or any other combustible material, because burns may occur or fires may start as a result of the heat produced at the tip.

Figure 13-2. Laparoscopic and arthroscopic trocar/cannula assemblies. Note the pyramidal tip of the laparoscopic trocar and the conical tip of the arthroscopic obturator.

The three areas of rigid endoscopy all use a trocar and cannula assembly to first enter the body cavity (Figure 13-2). The cannula protects the telescope after insertion and has stopcocks allowing fluid infusion or gas insufflation for distending the cavity. The cannula has seals to prevent leakage of fluid or gas through it. Safety trocar cannulas may be used when entering the abdomen or thorax. These trocars rely on the tissue resistance encountered when inserting the trocar through the body wall to retract the safety shield and expose the blade system. Once the insufflated abdomen is entered, there is a loss of resistance and the safety shield snaps back over the blade, protecting the underlying viscera.

Telescopes

A high-quality surgical telescope is very important for all endoscopic procedures (Figure 13-3).[1-3] The Hopkins rod lens system provides more light transmission for illumination of the cavity and a wider field of view than traditional optical systems. Light is provided by optical fibers that surround the lens system. Telescopes of 5 mm or less in diameter provide adequate light and visualization for arthroscopy but not for laparoscopy or thoracoscopy. The reasons for this are that the cartilage covering the articular surfaces of the bones in the joints is bright and reflective, and the cavity is smaller, requiring less light for visualization. The most common telescope size used in equine laparoscopy and thoracoscopy has a 10-mm outside diameter. The large size allows adequate light transmission with good visualization. The standard length for human laparoscopes is approximately 30 cm, but a specially designed 57-cm laparoscope is available for equine use. The standard length for arthroscopes is 15 to 25 cm with an extra-long 4-mm diameter arthroscope of 35 cm. The distal ends of endoscopes are designed with different lens angles. The most commonly available distal angles are 0, 25, or 30 degrees of visualization. The zero-degree telescope allows more light transmission into the body cavity but does not offer the panoramic view that the 30-degree telescope provides. Panoramic visualization, which facilitates triangulation techniques, is accomplished by rotating the scope (not possible with the zero-degree telescope). For special procedures, a 70-degree arthroscope is available, but it is rarely used.

Video Equipment

A video camera that connects to the telescope is necessary to ensure aseptic surgical technique and allow assistance during surgery.[1-3] Most cameras contain either one or three chips—the charged capacitance devices (CCDs) used in the camera. Three-chip cameras have one chip for each of the primary colors (red, green, and blue) and generally offer better resolution than single-chip cameras. Newer video cameras have an increased light sensitivity, which is very helpful for laparoscopy and thoracoscopy in horses. Zoom features, gain changes, and multimedia image capture may also be offered as options on the various cameras. The video camera should be connected to a good-quality monitor in the direct line of sight of the surgeon. In some cases, it is helpful to have multiple monitors for the benefit of the assistant surgeon. The choice of cable connections affects monitor image—digital video cables offer the highest resolution. Multimedia digital capture of video-assisted surgery is becoming standard procedure and can be accomplished with personal computers, stand-alone video documentation systems, or video recorders incorporating hard disk storage and DVD burners. Many hospitals have central digital storage systems, also known as picture archiving and communication systems (PACS), that allow real-time collection of digital images into an electonic medical record.

Fluids and Gases

Arthroscopic, laparoscopic, and thoracoscopic procedures all require the creation of an optical cavity separating the joint capsule or body wall from the contents of the cavity, which facilitates a thorough visual exploration.[1-3]

Adequate visualization during arthroscopy is accomplished by the use of fluid or gas distention of the joint. Fluids used for joint distention are pH-balanced polyionic solutions such as lactated Ringer solution or Plasmalyte. If electrosurgical instrumentation within the joint is going to be used, fluids specially formulated for this are needed. Fluid distention is usually achieved with pressure or manually controlled pumps, but another possible driving force is gravity. Excessive fluid pressure is associated with extravasation of the fluid, resulting in marked subcutaneous edema and poor visualization because pressure on the skin and subcutaneous tissues compresses the joint capsule. Fluid extravasation can be minimized by making the skin incision slightly larger than the joint capsule incision. Gas insufflation may be used when the joint surfaces must remain dry during arthroscopy (e.g., when inserting cartilage grafts

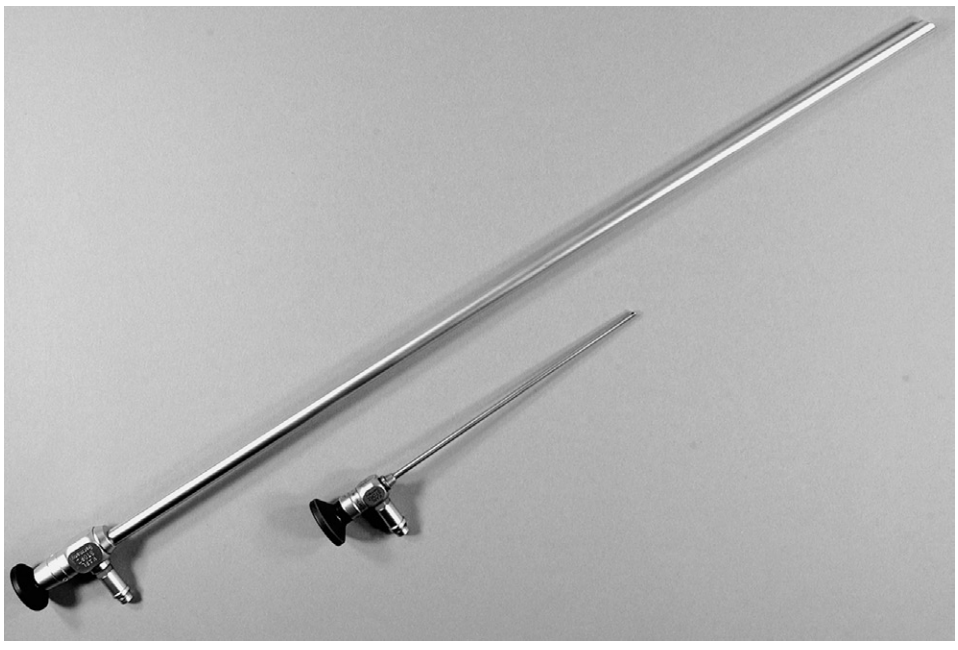

Figure 13-3. Laparoscopic and arthroscopic telescopes.

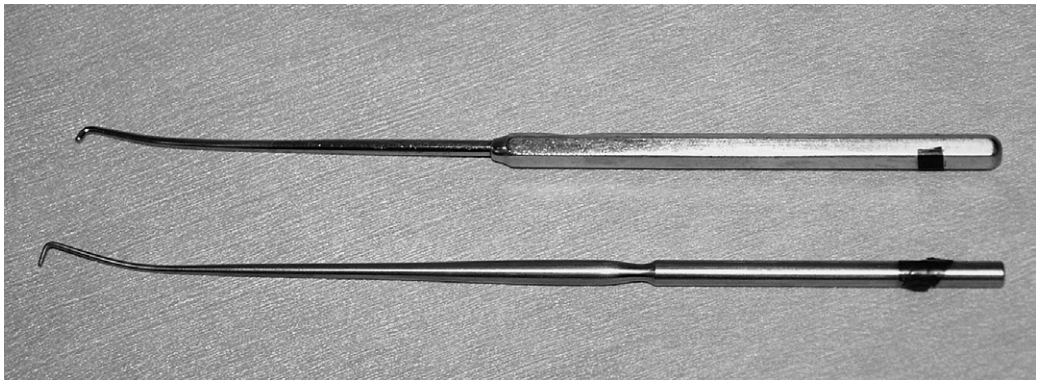

Figure 13-4. Arthroscopic probes.

or injecting gels into subchondral bone cysts). The pictures obtained with gas insufflation are clearer and truer to actual intra-articular colors. The insufflation technique is identical to the one described for laparoscopy.

The abdominal cavity requires insufflation for optimal viewing, which is accomplished by controlling the flow of gas into the patient's cavity. The insufflator should have settings that limit flow rate and pressure in the cavity to be examined. Insufflators for equine use should have flow rates that can exceed 10 L/min, and 20 L/min is desirable. Insufflators with slower rates require too much time for adequate initial inflation or reinflation of the cavity if it becomes deflated during manipulations. Initially the rate of gas flow into the patient is limited by the smallest diameter in the circuit, which is typically the insufflation needle. Needles such as the Veress needle have flow rates of less than 3 L/min, whereas teat cannulas can accomplish flows of 6 to 7 L/min. Once the laparoscopic trocar is inserted, the limit on flow rate is usually the insufflator.

The most commonly used gas for insufflation is carbon dioxide. Other inert gases have also been used in human medicine. The patient's abdominal pressure is usually 15 mm Hg or less. Higher pressures are associated with increased patient discomfort and respiratory compromise and are not necessary for visualization. Insufflation is less commonly used in thoracoscopy because the lung tends to collapse when air enters the thorax passively. In the rare case where insufflation is necessary during thoracoscopy, 5 mm Hg is usually adequate. The use of high intrapleural pressures is unnecessary and painful; high pressure decreases cardiac return and interferes with ventilation. Selective bronchial intubation may be performed for thoracoscopy in cases requiring general anesthesia.

Surgical Instruments

ARTHROSCOPY

The basic instruments necessary for arthroscopy include probes, rongeurs, grasping forceps, chisels, mallet, curets, periosteal elevator, flush cannula, and a bone awl (some of these instruments are described and depicted in Chapter 11).[3] Probes are used to evaluate looseness of fragments, determine stability of cartilage, and manipulate structures, testing their integrity or improving visualization (Figure 13-4). Multiple rongeurs may be used in a single surgery, and the choice is dictated by the operative target. Ferris-Smith rongeurs are available in different sizes and jaw angles (straight, angled up, and angled down),

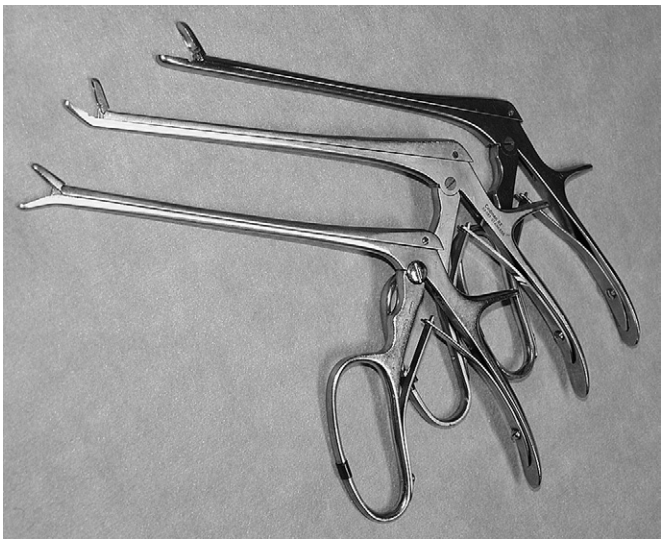

Figure 13-5. Ferris-Smith rongeurs with different cups.

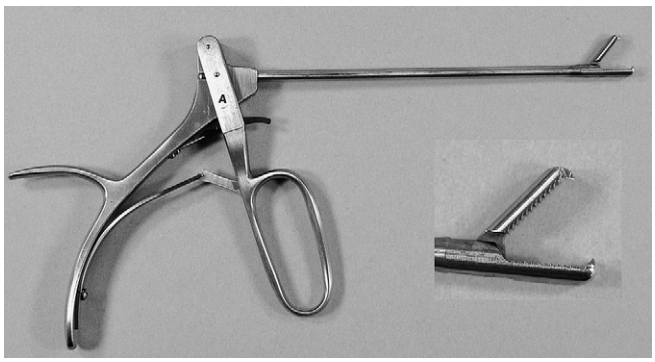

Figure 13-6. Grasping forceps.

and an assortment should be available in each surgical pack (Figure 13-5). Grasping forceps with small teeth in the jaws are preferred over rongeurs to to remove fragments from the joint (Figures 13-6 and 13-7). The EASY CLEAN line of rongeurs (Sontec Instruments, Inc., Centennial, CO) represents a new technology that allows cleaning between the two bars of the rongeur. It is anticipated that all rongeurs will be manufactured

Figure 13-7. The Maxi Grasper with specially designed jaws with radically enlarged multiple teeth and an oval gap between the jaws. Even when fully closed the jaws can securely hold the chips being removed. (Reprinted with permission from Sontec Instruments, Inc., Centennial, CO. 2010.)

with this technology. A recently developed suction arthroscopic rongeur facilitates removal of small chips and fibrin debris that has been disconnected from its origin (Figure 13-8). A 5-mm cannula that can be attached to a suction pump removes the debris immediately, obviating the removal of the rongeur after each piece has been detached. This speeds up surgery and reduces irritation at the incision site by constantly removing and reintroducing the rongeur into the joint. Chisels, osteotomes, and periosteal elevators are used to elevate osteochondral fragments with or without the use of a mallet. Curettes are used to débride cartilage edges and remove devitalized bone (see Chapter 12). Several different sizes and angles should be available to maximize access to the base of the defect. Bone awls (Figure 13-9) are used to produce microfractures in the subchondral bone plate, which are thought to improve cartilage adhesion after bone débridement of the articular surface (see Chapter 80). Flush cannulas are useful for lavaging the joint and removing any remaining bits of cartilage or bony debris (Figure 13-10). Motorized equipment (Figure 13-11) is useful for synovectomy, meniscectomy, tendon débridement, and removal of cartilage flaps. Different blades are used according to the structure being débrided.

LAPAROSCOPY, THORACOSCOPY, AND UROGENITAL PROCEDURES

The basic instruments used for laparoscopy include probes, Semm claw forceps, scissors, Babcock forceps, and biopsy forceps.[1] Probing organs provides tactile feedback regarding the consistency of the target and can be used to evaluate organ attachments. Semm claw forceps provide good security when grasping tissue that is to be removed from the patient (Figure 13-12). Atraumatic forceps such as Babcock forceps allow tissue manipulation without injury and are useful in exploratory laparoscopy or thoracoscopy (Figure 13-13). Endoscopic scissors are used for dividing tissue after adequate hemostasis has been obtained (Figure 13-14). Biopsy forceps are used for visceral biopsy (spleen, kidney, liver, and other solid organs) or tumors. Vessel sealing devices, such as LigaSure (Covidien, Mansfield MA) and SurgRx EnSeal (Ethicon, Somerville, NJ), have become one of the primary tools for controlling bleeding during minimally invasive procedures (Figure 13-15). These devices are modifications of previous bipolar electrosurgical units, which incorporate tissue impedence monitors that automatically adjust the current and output voltage, allowing lower settings to be used with improved outcomes.[4] The collagen and

Figure 13-12. Semm claw forceps used for tissue removal.

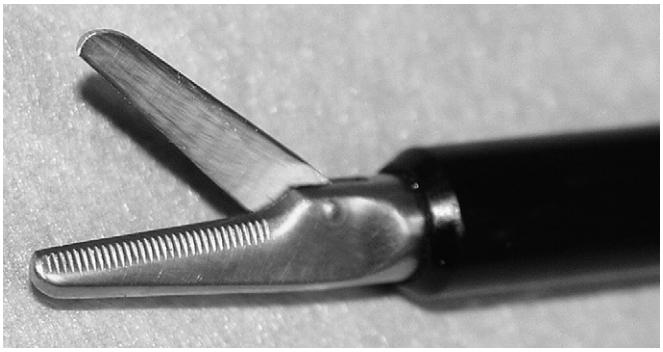

Figure 13-14. Scissors used for laparoscopic surgery. Note the increased length and size needed for efficient cutting.

elastin in the vessel wall are denatured by the high current and low voltage. This denaturation coupled with the mechanical pressure from the device causes coagulum formation, resulting in permanent sealing of the vessel. These devices allow permanent fusing of vessels up to 7 mm in diameter and tissue bundles without dissection within 2 to 4 seconds. The seals are capable of withstanding pressures up to 3 times normal systolic blood pressure. The feedback-controlled response system automatically discontinues energy delivery when the seal cycle is complete. The I-Blade Technology (Ethicon, Somerville, NJ) provides uniform compression forces along the clamping device and in the center of the blade that separates the tissues. The clamps are designed such that the tissue in between is trapped by atraumatic teeth before it is separated and uniformly clamped. Subsequently, separate electrical circuits permanently seal the tissues in each hemisphere of the jaw (Figure 13-16). Special insulation materials used for the clamps ensure that the tissues surrounding the jaws of the clamp are sealed only to a

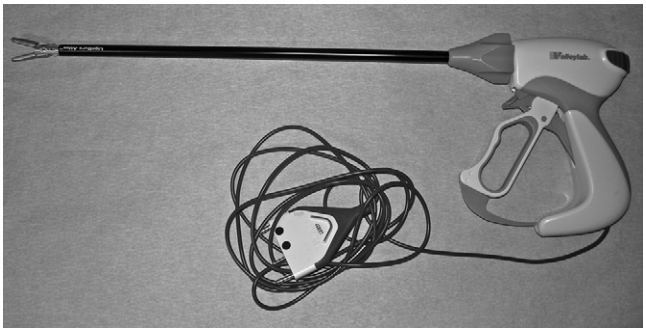

Figure 13-15. LigaSure electrosurgical instrument.

distance of about 1 mm. Other hemostatic devices such as endoscopic staplers, electrosurgical units, ultrasonic scalpels, and different types of lasers are routinely used and will be discussed in appropriate chapters.

Triangulation Technique

Arthroscopic, laparoscopic, thoracoscopic, and urogenital endoscopic surgical procedures all share the common technique of triangulation. Triangulation refers to the placement of telescope and instruments through separate portals so that they converge on the operative target. Mastering the technique of triangulation is essential to becoming competent in minimally invasive endoscopic techniques. The visual target should be in front of the surgeon, with the monitor directly behind the visual target. The surgeon should be able to look from the operative field on the monitor to the surgical site on the patient by only looking up or down. The camera must be oriented so that true vertical and horizontal axes are maintained; this facilitates proper movement of the surgical instruments toward the surgical target (Figure 13-17). Triangulation techniques should be learned with training boxes before surgery is attempted on clinical cases. In general, the diagnostic evaluation in all minimally invasive surgeries should be performed before instrument portals are established, because they can collapse the optical cavity and interfere with visualization. An exception to this occurs when instrumentation must be introduced to manipulate viscera to facilitate exploration. Once the diagnostic exploration has been accomplished, additional instrument portals are established for the surgical procedure. The details for specific procedures are found in subsequent chapters and specialized texts.[1-3]

Basic Laparoscopic Technique

Standing Laparoscopic Surgery

Feed is withheld from the horse for approximately 24 hours before the procedure. Access to water is generally not restricted. Tetanus prophylaxis and routine perioperative antibiotics are provided. Nonsteroidal anti-inflammatories are also typically administered. The horse is restrained in standing stocks and the tail is tied to prevent contamination of the operative field. The head is either supported with a well-padded stand under its muzzle or tied up in an approximately horizontal position. Both flank regions are prepared for aseptic surgery. Sedation and analgesia typical for standing procedures is administered. Some surgeons prefer the use of bolus injections, whereas others use constant rate infusion techniques. For additional information on sedation and analgesia for surgical procedures that require standing for long periods, the reader is referred to Chapter 22. Once the horse is adequately prepared, local anesthesia is infiltrated at the site of desired trocar introduction. It is important to infiltrate both the subcutaneous tissues and muscle layers. The site of the first trocar is typically placed through the crus of the internal abdominal oblique muscle, midway between the last rib and the iliac crest. A 1.5-cm incision is made through the skin, and the trocar assembly that is large enough to accommodate the desired laparoscope is used. At insertion, the trocar is aimed toward the contralateral coxofemoral joint. If the peritoneum has not been penetrated at this point, a 30-degree laparoscope is used to ensure final penetration with a quick thrust. Insufflation with CO_2 is then started to a pressure of 10 to 15 mm Hg. Additional instrument portals are established under direct visualization to prevent damage to underlying structures. Once the desired surgical procedure has been completed, the abdomen is deflated and only the skin is sutured with simple

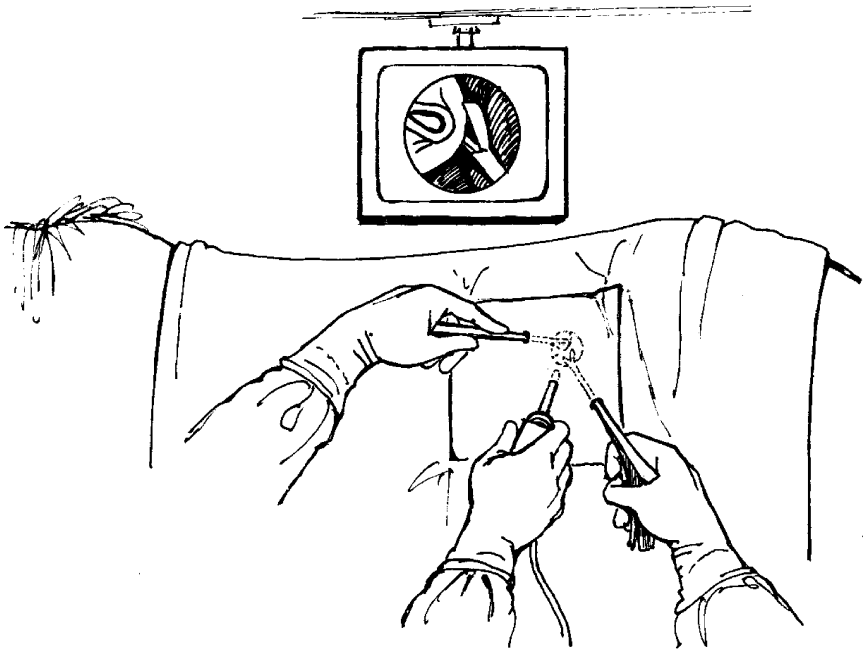

Figure 13-17. The proper use of the triangulation technique.

interupted sutures. Some authors prefer to insufflate the abdomen before inserting the trocar, but this is not necessary and may lead to insufflation of the retroperitoneal space, obscuring visualization for the rest of the procedure. At the end of the procedure the skin incisions and portals that are 10 mm or larger are closed in different layers; smaller ones are only closed with skin surtures.

Dorsally Recumbent Laparoscopic Surgery

Preoperative preparation for dorsally recumbent laparoscopic surgery is the same as that used for standing surgery. The horse is anesthetized and placed in dorsal recumbency and secured to the operating table to prevent the horse from shifting if it is tilted into Trendelenburg position (head down). The ventral abdomen is prepared for aseptic surgery. A 1.5-cm incision is made through the umbilicus and a teat cannula is inserted into the abdominal cavity. CO_2 insufflation is started. When the intra-abdominal pressure reaches 10 to 15 mm Hg, a trocar assembly large enough to accommodate the desired laparoscope is inserted into the abdomen. Safety trocars may also be used. Additional instrument portals are established under direct visualization. Skin closure is performed as described earlier.

Effects of Abdominal CO_2 Insufflation in Standing and Recumbent Horses

Abdominal insufflation with CO_2 is commonly used to create an optical cavity in horses that are undergoing laparoscopy for either standing or recumbent procedures. CO_2 insufflation causes a mild inflammatory reaction within the abdominal cavity, which is seen by an increase in peritoneal WBCs and should be remembered if serial abdominocentesis is necessary for evaluation of the horse's original problem.[1,5] Increasing the horse's intra-abdominal pressure with CO_2 does have effects on cardiopulmonary parameters, with more significant alterations noted in horses in dorsal recumbency.[1,5,6] Pneumoperitoneum in horses undergoing standing laparoscopic surgery had no significant effect on cardiopulmonary parameters.[5] Horses undergoing laparoscopic cryptorchidectomy in Trendelenburg position were noted to have a decrease in pH and an increase in $PaCO_2$ and mean arterial pressure, and these changes persisted while the horse was in Trendelenburg position but returned to baseline upon return to normal dorsal recumbency. PaO_2 decreases throughout the procedures but does not reach levels classified as hypoxemia, and it does not improve upon return to normal dorsal recumbency and normal intra-abdominal pressure.[6] Heavier horses have a greater change in pH, $PaCO_2$, and PaO_2 than lighter horses subjected to Trendelenburg position and abdominal insufflation.[6] Though cardiopulmonary parameters certainly change during laparoscopic procedures, little clinical effect has been noted. Positive pressure ventilation and blood gas analysis capabilities are suggested for use in horses undergoing laparoscopy under general anesthesia, particularly if Trendelenburg position is to be employed.

EMBOLIZATION

Joanne Hardy

Arterial embolization refers to catheter-directed delivery of particulate material for the purpose of embolizing selected arteries. Microcoils are a popular embolization material. They have been used for occlusion of normal and abnormal vasculature and for creating ischemia of neoplastic tissue (Figure 13-18). In dogs, coil embolization has been used to treat vascular occlusion of patent ductus arteriosus, occlusion of portosystemic shunts, and epistaxis; it has also been used in experimental treatment of cerebral aneurysms.[7-19] In horses, coil embolization has been used to occlude branches of the common carotid artery, usually involved in guttural pouch mycosis.[20-23] More recently, nitinol vascular plugs have been used for arterial embolization procedures in both dogs and horses.[24,25] The use of emulsions for embolization of tumors to create ischemia and reduce tumor size has also been described.[26] Chemoembolization refers to selective intra-arterial delivery of chemotherapeutic agents with particulate material to embolize arteries supplying blood to a tumor.[27] Numerous studies describe its use in humans and dogs, using various chemotherapeutic agents.[28-32]

Surgical Technique

Catheter-directed embolization involves accessing a peripheral artery, where an introducer is inserted. A catheter is then directed, under fluoroscopic guidance, within the artery until the tip of the catheter is located at the desired site of embolization. Accessing the proper site requires knowledge of local vascular anatomy and variances among individuals. Navigation through the arterial tree is facilitated by a gliding guide wire inserted within the catheter. Once the site of embolization is reached, the embolization material is delivered. The catheter and introducer are removed, and hemostasis at the arterial puncture site is achieved by direct pressure or suturing.

The sizes and materials used for embolization techniques are very specific, and correct selection of product characteristic for the desired purpose is essential. For example, catheters made of polyvinyl chloride (PVC) or vinyl do not allow the coils to glide within the catheter, resulting in occlusion of the catheter.

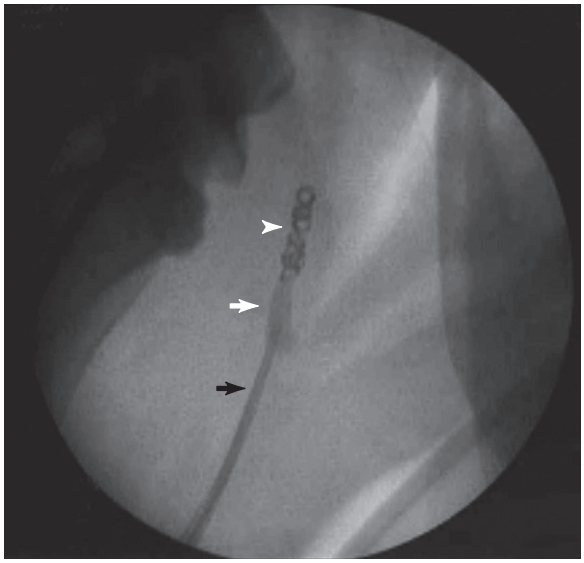

Figure 13-18. Fluoroscopic image of embolization coils *(white arrowhead)* occluding the internal carotid artery of a horse affected with guttural pouch mycosis. Note the position of the catheter *(black arrow)* within the artery, and injection of contrast material demonstrating arterial occlusion *(white arrow)*.

Similarly, selection of too small a coil diameter allows the coil to travel farther into the arterial vasculature, where it might embolize an undesired vessel. For details on use of this technique to control bleeding from guttural pouch mycosis, see Chapter 46.

THROMBECTOMY

Astrid B.M. Rijkenhuizen

Thrombectomy is performed in chronic arterial occlusive disease of the aorta and its caudal arteries, also referred to as aortic-iliac thrombosis (TAI). At first the symptoms are only induced by exercise, but in a later stage they also occur at rest. They signal ischemia in the hind limb tissue because of insufficient perfusion. The disease is progressive with a gradual onset. The clinical signs are related to the degree of vascular occlusion, the presence of collateral circulation, and the rapidity of the onset of the occlusion.[33,34] Affected horses could be asymptomatic or show only vague performance complaints. The most common manifestation is a predictable exercise-induced lameness that ceases with a resting period of 5 to 10 minutes. Patients who are forced to train "through the pain" show a more severe lameness and might require significantly more time for the symptoms to resolve. After physical activity, absence of sweating, retarded vein filling, and hypothermia of the distal extremity of the affected limb(s) can be observed.

Occasionally a thrombus embolizes from a proximal source and acutely occludes a distal peripheral artery. After training, acute coliclike signs can develop (pawing, straining, sweating, lying down and rolling), mostly combined with a severe lameness. The diagnosis is based on history, clinical presentation, rectal palpation combined with ultrasonography, and scintigraphy.[35-42] Information on the onset of ischemic symptoms, the duration of symptoms, the characteristics of pain, and any alleviating factors are helpful. The absence of a palpable pulse in an extremity is probably the most common physical finding. Rectal ultrasonography is used to recognize the thrombus in the aorta and the internal and external iliac arteries. Doppler-based ultrasonography renders both an anatomic and a functional assessment of the femoral artery condition in the inguinal region and is used to estimate the severity of a the arterial occlusion.[11] The femoral artery is visualized in the femoral triangle, which is bordered caudally by the pectineus muscle and cranially by the sartorius muscle, over a distance of approximately 15 cm (6 inches). In unilateral cases, the unaffected hind limb can be scanned as a reference.

To monitor the development of hypoxemia in the affected hind limb the oxygen pressure in venous blood samples before and after a workload can be measured.[37] The samples are taken from the right and left saphenous veins as far proximally as possible, at the level of the stifle joint. Samples are collected anaerobically in heparinized 2-mL syringes, which are immediately sealed so they are airtight and then immersed in melting ice. Within 15 minutes after the first sample is taken they are tested in a blood gas analyzer (ABL 505, Radiometer, Copenhagen, Denmark).

Treatment with exercise programs and pharmacologic therapy with sodium gluconate, with or without fibrinolytic enzymes, anticoagulants, and vasodilatators, have thus far been unsuccessful.[34,38,39,41,43,44] Promising results can be obtained by restoring blood supply to the ischemic regions through vascular surgery such as thrombectomy. For this purpose a Fogarty graft thrombectomy catheter (length of 50 cm [20 inches], a closed diameter of 4 mm, and an expanded diameter of 16 mm) is used to improve the blood flow to the limb.

Surgical Technique[37]

The horse is anesthetized and positioned with the hind quarters in dorsolateral recumbency with the affected limb close to the table and the head and neck in lateral recumbency. The uppermost hind limb is secured in flexion and abduction. The incision (approximately 10 cm) is made medially over the saphenous vein where its course changes from superficial to deep. Subsequently, the vein and the surrounding muscles are bluntly separated and the femoral artery is identified. Just before the artery is clamped 20 mL of a heparin solution (Heparin Leo (LEO Pharma A/S, Ballerup, Denmark), 250 IU heparin/mL physiologic saline) is injected into the femoral artery in distad and proximad directions. Careful blunt dissection allows mobilization of the artery and placement of ligatures and two vascular clamps (aortic forceps, DeBakey-Morris) proximally and distally to prevent excessive loss of blood during surgery. Small arterial branches of the femoral artery are ligated. A transverse arteriotomy is made and the blood flow is tested by loosening the vessel clamp and letting the ligature slip. Visible thrombi are loosened from the arterial wall and removed with forceps (Figures 13-19 and 13-20). The Fogarty catheter is subsequently inserted into the femoral artery in collapsed form, directed proximally, and positioned beyond the thrombi. The catheter has a flexible wire coil at the distal end that expands when retracted to form a double-helix ring (Figure 13-21). The sliding knob on the handle of the catheter is retracted slowly, which causes the wire loops to expand partially and carry the thrombi along as the catheter is withdrawn. This procedure is repeated with the diameter of the coil more expanded until no resistance during withdrawal of the catheter is felt and no more thrombi are retrieved. By removing this blockage, blood flow is restored from the proximal side. When indicated, an additional thrombectomy is performed distal to the incision. Before closure of the artery, blood is allowed to flow freely for a short period to remove detached thrombi and air. The incision in the femoral artery is sutured using a simple continuous pattern of monofilament polypropylene (USP 5-0). Fascia and subcutis are closed with a simple continuous suture; then the skin is closed using an intradermal continuous pattern.

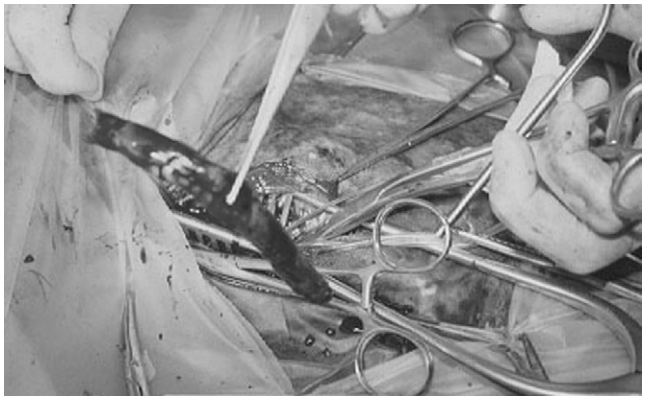

Figure 13-19. A thrombus is removed with the help of a forceps.

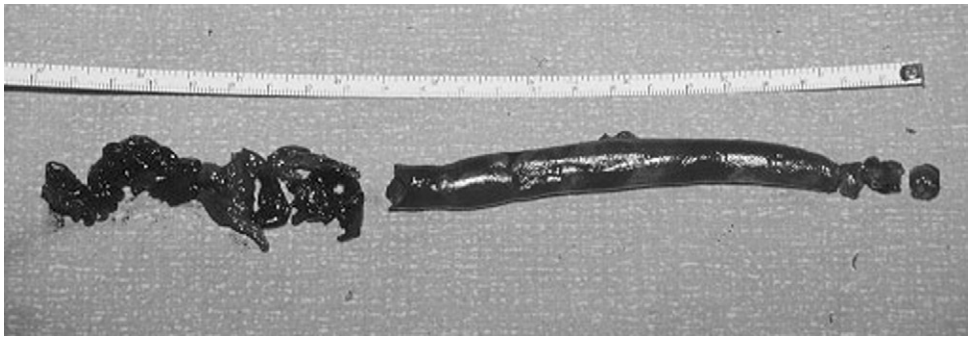

Figure 13-20. Removed thrombi.

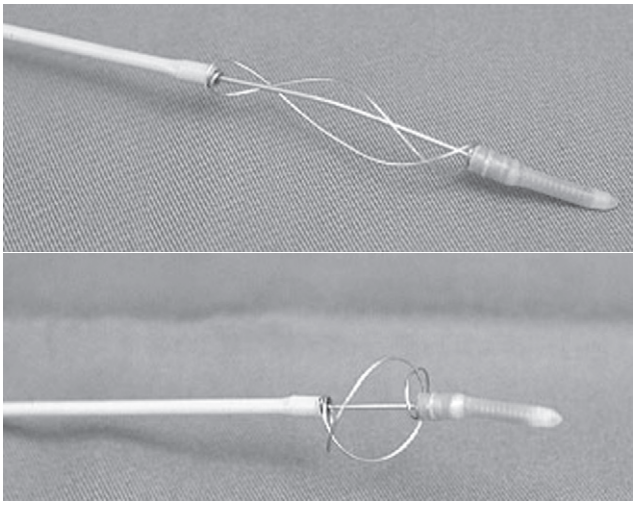

Figure 13-21. Fogarty catheter in closed *(top)* and expanded *(bottom)* positions.

Anticoagulation is initiated intraoperatively just before the arteriotomy through the administration of 100 IU heparin/kg or 50 IU/kg low-molecular-weight heparin (Dalteparin Natrium Fragmin, Pfizer, New York) intravenously. This is followed postoperatively by the administration of 50 IU heparin/kg or low-molecular-weight heparin subcutaneously once plus Carbasalate calcium 5 mg/kg (Ascal, MEDA Pharma, Solna, Sweden) or acetylsalicylate (5 mg/kg) orally once daily for at least 3 months. If there is diffuse intraoperative bleeding, heparin administration can be omitted or delayed, or low-molecular-weight heparin can be used, which lowers the risk of bleeding.[45]

Hand-walking is advised immediately after surgery. Light exercise can be initiated at 2 weeks postoperatively.

A severe complication is the appearance of TAI in the contralateral limb after surgery as a result of thromboembolization induced by clot fragments. Postanesthetic myopathy is seen in 24% of the cases in the affected limb.[46] This condition is assumed to be primarily caused by local hypoxemia of various muscle groups.[44] Horses with TAI that have preexisting hypoxemia before surgery are therefore at high risk for this complication. Providing adequate padding, positioning the horse correctly, preventing hypotension, and limiting surgical time are extremely important in the surgical management of these patients.[44]

The prognosis after surgical intervention is reasonable. In a recent study where 17 horses had been operated on, 65% of the horses regained athletic activity and 53% performed at their previous level.[46] No association could be made between the duration or the severity of the clinical signs and the clinical outcome. The success of this procedure depends on the length of time that the thrombus developed and adhered to the arterial wall.[46]

COMPUTER-ASSISTED SURGERY

Jörg A. Auer

Internal fixation of fractures is usually planned on the basis of a radiographic study. Occasionally, computed tomography (CT) is used to determine the exact course of the fracture line as it courses along the bone. Such a study allows the surgeon to determine exactly where to implant screws. Recently, intraoperative CT imaging has been introduced into equine surgery to aid in complicated and difficult-to-approach fractures, such as abaxial fractures of the distal phalanx.[47] With the help of radiodense markers, the ideal positioning of the implant can be preplanned and accurate measurements taken. Nevertheless, the actual result depends greatly on the surgeon's skill at inserting the implants according to the preoperative plan. Computer-assisted surgery (CAS) allows the surgeon to accurately implement the preoperative plan and to implant screws at the desired location and at the correct angle relative to the fracture plane.[48] CAS has been shown in numerous publications to improve accuracy in the placement of screws and other devices in humans.[49-51]

Technical Equipment

The equipment is composed of instruments with passive infrared light-emitting diodes (LEDs), the Vet*GATE* navigation system, (ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Switzerland) and the Arcadis Orbic 3D C-arm (Siemens Healthcare, Erlangen, Germany) (Figure 13-22). These instruments together define a fractured bone in three dimensions, and they allow real-time planning and observation of the implantation of the screw in three planes simultaneously.[52,53]

Arcadis Orbic 3D provides higher power and faster scan times in addition to enhanced image quality. Its 3D image data is acquired with 50 or 100 images recorded with a 1024 × 1024 resolution and is calculated in only 30 or 60 seconds, respectively. The acquisition can be repeated as often as necessary to include any anatomical changes that may occur in the operating field during surgery. The Arcadis Orbic mobile C-arm is suited for intraoperative 3D imaging of bones and joints of the upper and lower extremities, and the cervical region. It is important that the region to be scanned is either freely accessible or

positioned on a carbon pad, which allows transmission of x-rays. The isocentric design of the Arcadis Orbic 3D (see Figure 13-22) features a 190-degree orbital movement. Further, both the patient and clinician can benefit from time and radiation dose savings through the isocentric design. Arcadis Orbic 3D can be equipped with Vet*GATE* 3D, an interface for direct 3D navigation. This interface combines the imaging capabilities of Arcadis Orbic 3D with high-precision surgical navigation, eliminating the need for manual alignment of the anatomy to the 3D images. This results in increased accuracy of surgical navigation and optimized clinical work flow. The 3D image data record compares the real patient anatomy through a matching free registration automatically. The C-arm incorporates a digital imaging chain from image acquisition to image processing and documentation. All image information is saved and administrated with a resolution of 1024 × 1024 pixels. With its electromagnetic brakes and ergonomic handles, the system is extremely easy to use.

Surgical Technique

First, the dynamic reference base (DRB) (Figure 13-23) is securely attached either to a Schanz screw, which was previously inserted into each of the main fragments of the bone involved. An alternative option available for the hoof is a studded clamp that can be attached to the hoof capsule (see Figure 13-23). Subsequently, the fractured bone is isocentrically positioned between the two components of the C-arm. Positioning is assisted by two laser beams positioned at 90 degrees to each other. The position of patient and table must allow movement of the C-arm over a 190-degree arc without interference (e.g., the surgery table, foot stands). The C-arm and the DRB must be located in the identifiable range of view window of the navigation camera. Over a 1-minute period, the C-arm takes 100 still radiographs (high-resolution mode) over an arc of 190 degrees, which are processed into 256 single pictures. The same number of radiographs can be taken at half the time (i.e., 30 seconds), but in lower resolution. The radiographic images can be viewed in three planes oriented at right angles to each other (in the horizontal, sagittal/parasagittal, and frontal planes).

The Vet*GATE* system consists of a two-eyed navigation camera (see Figure 13-22), a computer unit with sophisticated 3D software (see Figure 13-22), the instruments (e.g., power drill, awl), and a calibration unit that allows the surgeon to navigate within the system and to calibrate the instruments under aseptic conditions during surgery (see Figure 13-23). The data collected with the Arcadis Orbic 3D, the predecessor, the SIREMOBIL Iso-C 3D, is subsequently transferred to the Vet*GATE* computer (see Figure 13-22), where the future location of each screw is planned on the screen and marked in length and size. The Vet*GATE* system is then changed to the real-time navigation mode to guide the surgeon during the actual implantation. This is carried out by observing the computer screen and matching the drill and subsequently needed instruments with the planned image in three planes, similar to an arthroscopic technique (Figure 13-24). Once the location is matched, drilling is initiated. As soon as the drill bit crosses the fracture plane, which can be seen on the screen, the drill bit is changed to prepare the thread hole (see Figure 13-24). Insertion is then routine.

Three-dimensional navigation systems such as the Vet*GATE* in combination with the Arcadis Orbic 3D have great potential to be a real advantage for the precise and accurate implantation of lag screws in fractures in the horse. It has been used successfully in a limited number of clinical cases. Three controlled studies on cadaveric limbs were conducted with the predesessor of the Vet*GATE* system to evaluate the value of the system.[54-56] It could be shown that 3D navigation significantly improve accuracy compared to conventional surgery with C-arm assistance, especially with screw insertion into the distal sesamoid bone. The two studies conducted with the Vet*GATE* system showed significant improvements in accuracy compared to the Surgi*GATE* (Praxim-Medivision, Grenoble, France, no longer exists) system.[52,53] A significant part of the improvement is attributed to the use of a navigated drill guide with exchangable guides for the different sizes of drills and taps used to prepare the screw holes. With the Surgi*GATE* 1.0 system, the drill guide was not equipped with active LEDs. Therefore even the slightest

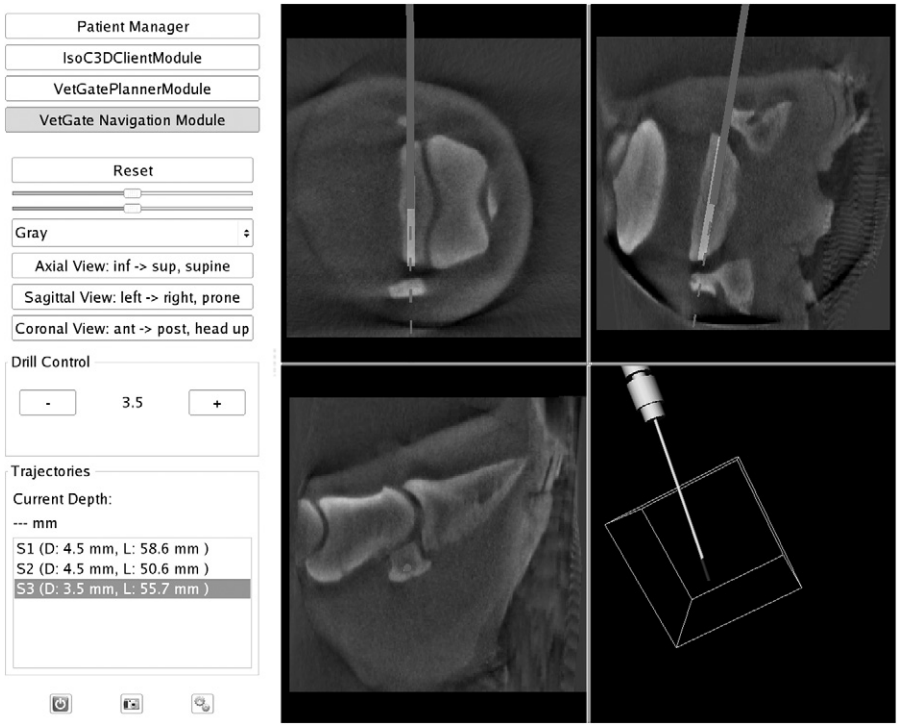

Figure 13-24. Screen shot of the navigation monitor during the insertion of a 3.5-mm screw into the distal sesamoid bone. Drilling is performed while constantly observing the monitor screen. The *lighter line* shown in the distal sesamoid bone represents the preplanned location of the screw within the bone. The *darker line* represents the drill bit and shows of the depth of penetration into the bone (in this case, half way). *Top two pictures* show the drill over the preplanned line in different projections. *Bottom left*, Only a round circle of the drill bit size can be seen on this lateral projection. *Bottom right*, A computer animation of the actual situation, where the drill *(lighter thick line)* is following the preplanned screw location *(dark thick line)* in space. The preplanned screw length measures 55.7 mm *(bottom line, far left)*.

bending of the drill bits resulted in inaccuracies in implant placement.

Other indications for CAS include fractures of the distal, middle, and proximal phalanx; condylar and saucer fractures of MCIII and MTIII; tarsal and carpal fractures, and cystic lesions of the various bones.

CHAPTER
14

Cryosurgery

John A. Stick

PRINCIPLES OF CRYOBIOLOGY

Mammalian cells are destroyed when cooled to a temperature of –20° C (–4° F).[1] Primary injury begins with the formation of ice crystals, both intracellular and extracellular. The cell's outer membrane becomes ruptured by intracellular crystals, and ice formation outside the cell dehydrates the cellular environment, resulting in lethal electrolyte concentrations and pH changes. When organelles are damaged, the cell loses its ability to regulate ion permeability and cell death ensues. Secondary injury from freezing occurs from vascular stasis. As the permeability of vessels is increased, loss of plasma causes local hemoconcentration. Damaged endothelium in arterioles and venules induces thrombus formation of the vessels, and infarction of frozen tissue occurs within hours of freezing. The cryogenic lesion is a volume of coagulation that closely responds to the extent of the induced ice ball.

Rapid freezing results in the greatest intracellular concentration of ice. Thereafter, slow thawing of the tissue results in recrystallization, during which small crystals enlarge, producing

more cell damage. To ensure that all target tissue receives a lethal dose of cold, a second freeze/thaw cycle is used. Because precooled tissue freezes faster than normal tissue, repeating this cycle causes necrosis of the target tissue more consistently.

Variations in vascularity, noncellular structure, and water content cause tissues to respond differently to cryonecrosis. Dry tissues (e.g., the cornea) do not readily form ice crystals and therefore do not respond to cryotherapy very well. The cellular components of peripheral nerves are destroyed by freezing, but because the fiber scaffolding of the epineurium is not damaged, regeneration is possible.[2] Tissues near major blood vessels or in highly vascular areas are difficult to freeze rapidly and tend to thaw quickly without loss of function.[3] The use of epinephrine or temporary regional vessel occlusion may be necessary to ensure proper treatment in those tissues. Future developments in cryotherapy may include the use of nanoparticles to improve freezing efficiency. The basic principle is to deliver these particles into target tissues to maximize the freezing heat-transfer process, to regulate freezing scale, to modify ice-ball formation, to enhance ice-ball margin ultrasonographic imaging, and thus to prevent healthy tissues from being frozen.[4]

Immune responses directed against tumor cells have been documented after cryosurgery, and cryoablation-induced anticancer immune reaction is a well documented phenomenon in people and other animals.[5,6] Although this has not been proved clinically in horses,[7] numerous case reports suggest secondary tumor regression does occur as a result of cryosurgical treatment of a primary tumor.[8,9]

Although liquid nitrogen, nitrous oxide, and carbon dioxide are all cryogens used in veterinary medicine, liquid nitrogen is the most versatile and therefore the most commonly used. Liquid nitrogen has a boiling point of –195.8° C (–320.4° F). Cryogens, usually stored in liquid form in Dewar flasks (Figure 14-1), can be delivered as a spray or used by super-chilling a probe. Two types of probes are used: hollow probes and solid probes. When hollow probes are used, liquid is circulated through the probe and exits under pressure through a small opening. When solid probes are used, they are chilled by immersion into the liquid cryogen.

Indications

Cryosurgery does not require a sterile field. Therefore, it is a good choice for the treatment of benign and neoplastic cutaneous lesions. It can also be used in the mouth and in ocular surgery. By far the most common tumor that is treated with cryotherapy is the equine sarcoid. However, a plethora of skin conditions amenable to surgery can be treated by cryotherapy (see Chapter 29). Because there is frequently no need for general anesthesia of horses afflicted with skin lesions, cryosurgery has an advantage over other types of surgical extirpations—it frequently can be done on an outpatient basis.

INSTRUMENTATION

Sprays

Self-pressurizing spray guns (Figure 14-2) deliver a combination of vapor and droplets of liquid cryogen and are a most effective

Figure 14-1. Insulated Dewar flasks are used to store liquid nitrogen. This tank is fitted with a special adaptor lid and spray gun attachment. Note the pressure gauges used to regulate the liquid nitrogen.

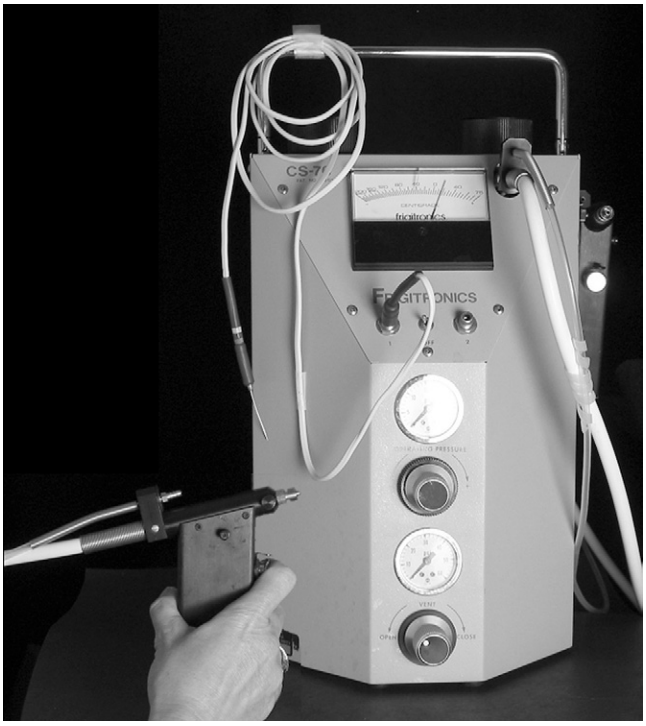

Figure 14-2. Special container used to deliver liquid nitrogen through a self-pressurizing spray gun. A thermocouple needle is to the left of the pyrometer, which is used to measure the temperature achieved beyond the limits of the targeted tissue. This single-channel monitor allows the needle to be placed into the tissue adjacent to the deepest portion of the target. When the temperature reaches –20° C, all unwanted tissue is destroyed.

method of cryogen delivery. As liquid nitrogen contacts the tissue, it evaporates, or changes from the liquid to the gas phase. This has been shown to remove a greater amount of heat from treated tissue than is achieved with probes. The volume and size of the spray droplet are controlled by the diameter of the needle orifice (Figure 14-3) and the trigger in the pressurizing gun. The surgeon can gauge the volume of the cryogen so that the wetting conforms to the shape of the tumor's surface. However, care must be taken to prevent excess liquid cryogen from running off onto surrounding skin. It is common to pack the surrounding area with Vaseline-impregnated sponges to prevent this runoff. Alternatively, a spray cup can be used that has the advantage of controlling runoff. A cup size (Figure 14-4) is chosen that fits over the tumor, and as the spray is applied, droplets form a liquid pool over the tumor.

Probes

Hollow probes are cooled by circulating a liquid cryogen through them. Hollow probe freezing is easiest to control, but the rate at which it cools an area is slow compared with the rate achieved by spray and solid probes. Hollow probes can be used for either contact or penetration freezing, depending on the configuration of the probe (Figure 14-5). During freezing, traction can be used to lift the tumor away from underlying structures as an ice ball is extended to the monitored limits.[10] Penetration freezing can be performed in larger lesions where a core biopsy specimen is removed from the center of the tumor (Figure 14-6) and the cryoprobe is placed within the mass. Contact freezing with solid probes is a very efficient manner of delivering cryotherapy to variously sized tumors, based on the size of the probe (Figure 14-7). As multiple probes are placed within the liquid nitrogen (Figure 14-8), they can be removed

Figure 14-3. Two examples of needles that attach to the spray gun to deliver liquid nitrogen sprays directly onto the tissue to be frozen. The volume and size of the spray drop is determined by the diameter of the needle orifice.

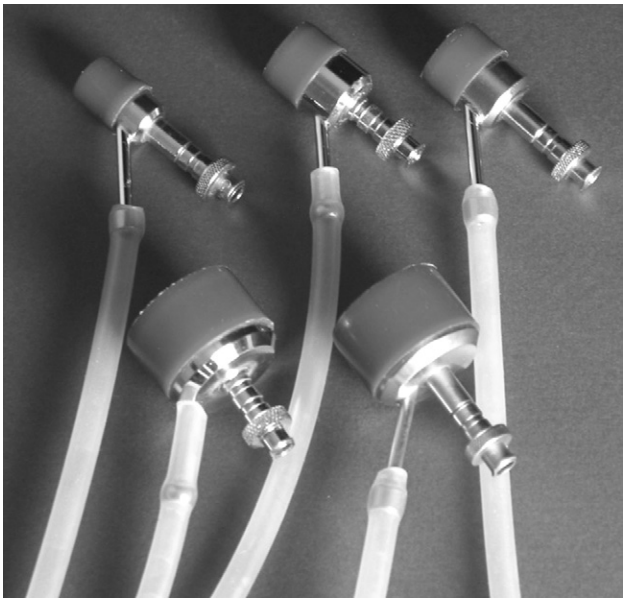

Figure 14-4. Spray cups come in a variety of sizes, so the cup can be fitted over a tumor, and as the spray is applied, droplets form a liquid pool contained by the cup. This prevents runoff generated by the spray method.

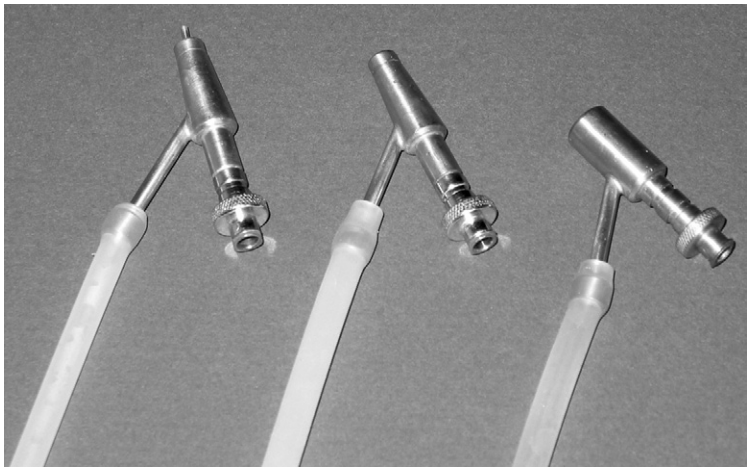

Figure 14-5. Hollow probes come in a variety of shapes and can be used for either contact or penetration freezing.

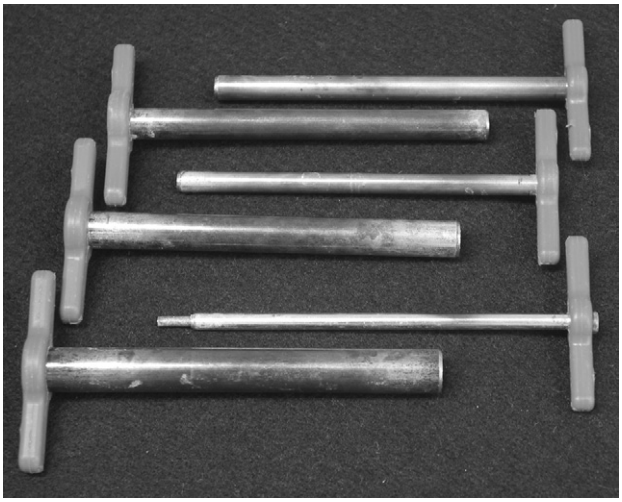

Figure 14-6. Core biopsy instruments used to remove the center of a tumor so that the same size of hollow spray probe can be inserted into the center of the tumor to perform penetration freezing.

Figure 14-7. Solid probes come in a variety of sizes, each fitted with a separate plastic handle that does not become chilled as the probe is immersed in liquid nitrogen. Various sizes and shapes allow these probes to become a heat sink when pressed onto the surface of the tumor.

and used to freeze tumors quite rapidly—a large advantage when multiple tumors need to be frozen in the same patient.

CRYOSURGERY TECHNIQUES

When using either contact or penetration cryotherapy, monitoring the depth of freezing can be done either by subjective inspection or by objective measurement of temperature changes. Subjective assessment is made by visual inspection or palpation of the ice ball. The outer edge of the ice ball is about 0° C (32° F), which is inadequate for tissue destruction. Seventy-five percent of the tissue within an ice ball is destroyed by freezing. The depth of contact freezing is estimated to be slightly less than the radius of the ice ball. Pyrometers can be used to measure the temperature achieved beyond the limits of the target tissue. Single- or multiple-channel monitors are available (see Figure 14-2). Needle probes are placed into the tissue adjacent to the deepest portion of the target. When temperatures of −20° C (−4° F) are recorded, all unwanted tissue is destroyed. Alternatively, ultrasonic evaluation of the margin of the ice ball

Figure 14-8. A special container is used into which liquid nitrogen is poured and the contact probe is submersed to attain the proper temperature before applying it to a tumor.

can be an accurate method of determining the extent of the freeze. If the tumor has a distinct ultrasonic appearance, it enables more accuracy in controlled freezing.[11,12]

COMPLICATIONS

Normal biologic reactions to freezing include swelling, bleeding, necrosis, depigmentation, and odor of varying degrees. Swelling occurs within hours of freezing because of increased vascular permeability and vasodilation. This is usually self-limiting and resolves in 48 hours. When lesions are biopsied or ulcerated and undergo cryotherapy, vasodilation after freezing can cause hemorrhage to become more obvious and may become cosmetically objectionable to an owner. Therefore, some form of hemostasis should be used during the biopsy procedure and on ulcerated lesions.

Necrosis occurs in 14 to 21 days. The wound contracts and epithelializes under a dry eschar that forms over the necrotic tissue. When the eschar sloughs, it usually reveals healthy granulation tissue or recurrence of the tumor. Because melanocytes and hair follicles are destroyed by freezing, the skin will show depigmentation and will not regrow hair. Owners need to be advised of this prior to treatment.

Offensive odors accompany necrosis of large tumors: cleansing of the area daily and excision of the necrotic tissue may be

necessary to ameliorate this problem. Freezing cortical bone causes cell destruction and reduces the strength of the bone by 70%. Spontaneous fractures have been reported months after cryotherapy treatment. Additionally, bone tumors do not respond well to cryotherapy, although aneurysmal bone cyst recurrance has been suppressed in people with cryotherapy used as an adjuvant to curettage.[13] Auricular cartilage does not respond well to cryotherapy either and can result in shortening or deformity of an ear. Therefore, cryotherapy should be used on skin tumors in the ears with caution.

FUTURE DIRECTIONS

The origins of cryotherapy in human medicine began in the 1960s, but enthusiasm for its use in cancer treatment dissipated in the 1980s. However, technologic advances in three areas have led to a renaissance in the interest in cryotherapy.[12] These advances are (1) intraoperative ultrasonography, as a technique for monitoring the tissue freezing process, (2) improved cryosurgical equipment, such as vaccuum-insulated small-diameter probes supercooled to –200° C, and (3) advances in instrumentation in mimimally invasive surgery. Additionally, the discovery that cryotreated tumor tissues are biophysically altered to allow enhancement of chemotherapy transport has sparked interest in combined cancer therapy.[14] Although these techniques are unlikely to be adopted into equine surgical practice anytime soon, because cancer is not a predominent problem in horses, some of these advances will make it into the hands of the equine surgeon as minimally invasive techniques become more commonplace.

CHAPTER 15

Lasers in Veterinary Surgery

Kenneth E. Sullins

Lasers expand surgical capabilities by facilitating minimally invasive surgery, by reaching areas that would otherwise be completely inaccessible, and by interacting with tissue in ways impossible with conventional instruments. Procedures previously requiring hospitalization, general anesthesia, and prolonged convalescence may be accomplished in an outpatient visit. However, lasers are not the most appropriate method for some procedures and the "fit" should not be forced.

Laser is an acronym for light amplification by stimulated emission of radiation. The excitation of a contained medium (for which the laser is often named) produces coherent electromagnetic radiation: light. The coherent beam remains intact almost indefinitely instead of diverging and can be manipulated by lenses. Lasers are typically monochromatic (a single wavelength or "color"), which determines interaction with tissue (Figure 15-1).[1]

FUNCTION OF LASERS

Surgical lasers produce a range of wavelengths (Figure 15-2) with varying tissue interactions, and understanding this is required to predict the laser's effect upon tissue. Behavior is determined by the degree to which the tissue absorbs the particular wavelength of laser energy. The more a tissue absorbs laser energy, the less it penetrates into the tissue and the more profound is the effect that is concentrated on the surface. Although deeper penetration allows controlled coagulation (denaturation of protein) of a larger volume of tissue, it may put associated deeper structures at risk of being injured. Complete lack of absorption of a wavelength by a tissue allows complete passage, thus affecting only a deeper tissue. Interaction between laser light and a tissue that preferentially absorbs that wavelength (apart from surrounding tissue allowing selective coagulation/necrosis of that tissue) characterizes the

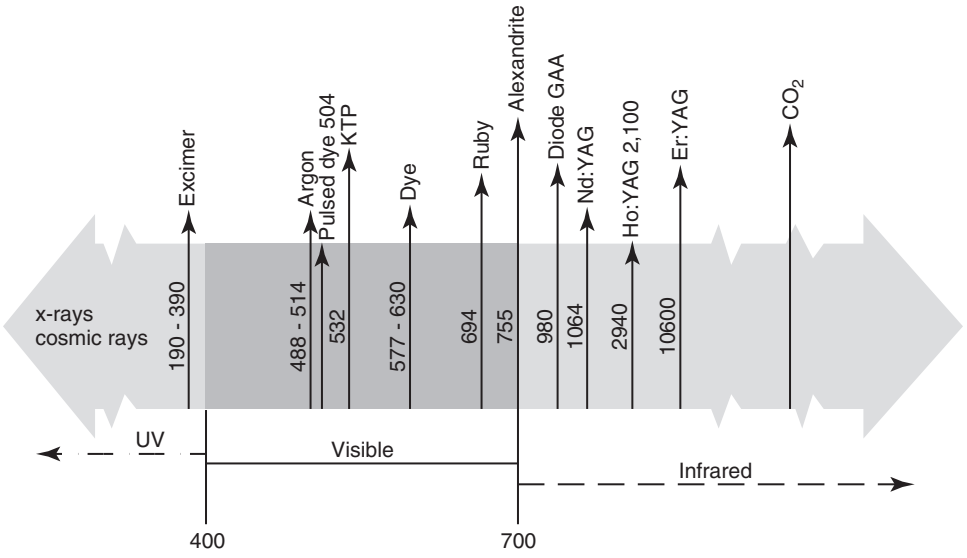

Figure 15-1. Wavelengths of surgical lasers. Ultraviolet wavelengths are generally absorbed by protein, whereas the visible and infrared wavelengths are generally absorbed by water or pigmented melanin or hemoglobin. Wavelengths in common veterinary use are in gray. *Er,* Erbium; *GAA,* gallium aluminum arsenide; *Ho,* homium; *KTP,* potassium titanyl phosphate; *Nd,* neodymium; *YAG,* yttrium aluminum garnet.

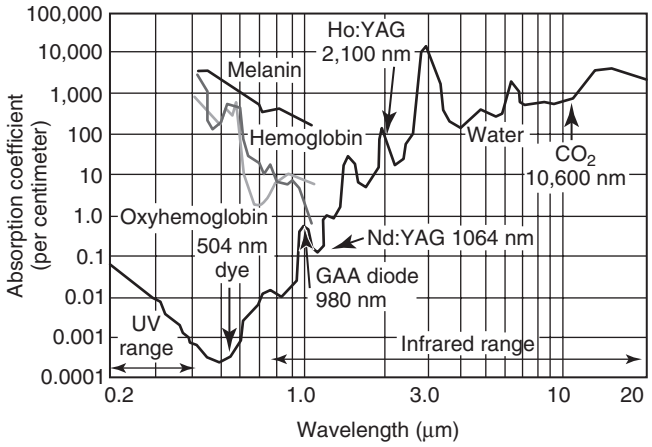

Figure 15-2. Tissue absorption of common surgical laser wavelengths. The visible spectrum is beneath the visible range. The near-infrared GAA Diode and Nd:YAG lasers are highly absorbed by dark pigment. However, note the increased absorption of the GAA Diode on the water curve compared to the Nd:YAG laser. The Ho:YAG and CO_2 lasers are both highly absorbed by water. *Er,* Erbium; *GAA,* gallium aluminum arsenide; *Ho,* homium; *Nd,* neodymium; *UV,* ultraviolet; *YAG,* yttrium aluminum garnet.

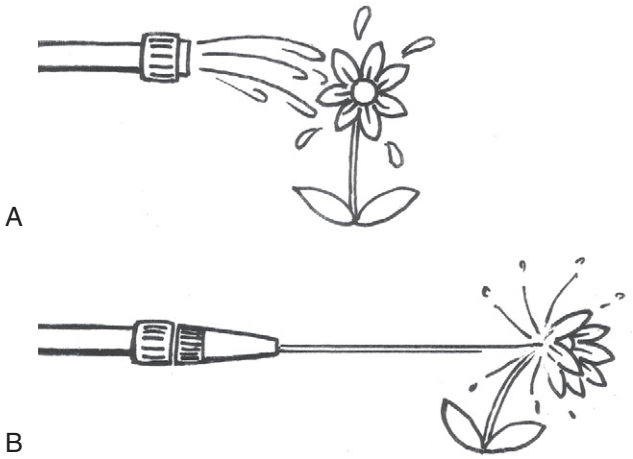

Figure 15-3. Power density profoundly affects rate of tissue effect and collateral heating of tissue. Both water hoses transmit identical flows of water. **A,** The wider aperture of delivery in the top image produces no mechanical effect on the flower. **B,** The narrower aperture in the lower image produces a jet of water that can disrupt the flower.

principle of *selective photothermolysis.*[2,3] By heating the target tissue above physiologic temperature but below that which would produce overt sloughing of tissue, the lesion will regress.

To "create" selective photothermolysis, pharmaceutical agents that absorb light of a particular wavelength may be administered systemically or locally. After these agents localize in a target tissue, such as a tumor, *photodynamic therapy* can be applied by using a laser emitting a wavelength that the agent concentrated in the tumor can absorb.[4-6]

A laser's effect upon tissue is due to optical and thermal interactions.[7] *Optical* interaction is the true result of absorption (or lack of it) of electromagnetic energy and usually results in a *thermal* effect when absorbed by tissue. Depending upon amount, heat may "boil" the cytosol, thereby vaporizing the tissue into the smoke plume, or simply denature tissue proteins. Optical interaction is the "true" effect of laser physics of the particular wavelength. When the optical interaction cannot achieve the desired effect, the irradiation is sometimes "artificially" converted to heat before applying it to tissue, which causes the energy to be absorbed at the tip of the fiber, thus producing heat and a profound surface effect on the tissue while minimizing penetration to deeper structures. Energy is measured in *joules* or calories (1 joule = 0.24 calories). Lasers are rated by power or the rate at which they can deliver energy, which is expressed in *watts* (W) (1 W = 1 joule/second). The total amount of energy delivered per unit area is *fluence,* expressed in Joules/cm^2, which depends upon time of exposure as well as *power density*. Power density (W/cm^2) is a critically important value that expresses the amount of energy delivered per unit area of tissue. Similar to water at a constant flow in a hose, laser energy delivered through a wider aperture will have a less profound effect than the same amount of laser energy delivered through a narrower aperture (Figure 15-3). Power density is varied by changing the output of the laser, by changing spot size of the laser beam delivered to the tissue (Figure 15-4), by changing the distance from the delivery device to the

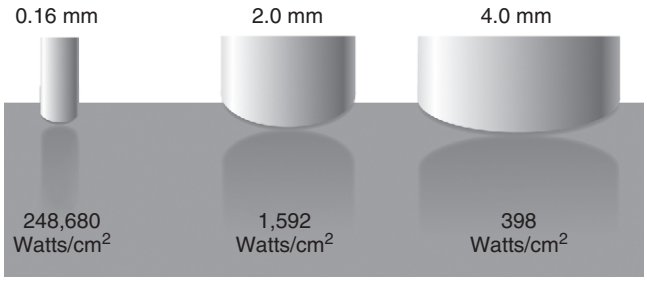

Figure 15-4. Power density decreases with the square of the increase in spot size, which in turn increases with distance from the surface. The beams depicted are all CO_2 laser beams from machines set to 50 W. The power densities shown below each demonstrate the profound reduction in tissue effect by increasing spot size. Moving the handpiece away from the tissue increases spot size.

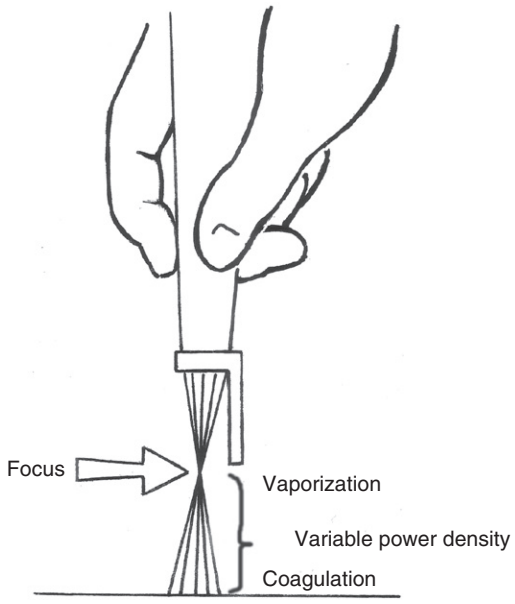

Figure 15-5. Focusing handpiece that would be used on an articulating arm of a CO_2 laser. The *arrow* points to the spot of maximum focus for creating a precise incision with minimal effect on margins of wound. The stylus contacts the tissue to fix the focal point and provide a feel on the tissue for making the incision. Below that point, power decreases with distance from the end of the stylus. Slight defocus allows vaporization of tissue with a relatively high power density, and more distance reduces power density to coagulation of tissue protein.

tissue (Figure 15-5), or by changing the delivery device. Power density (PD) varies with the square of the spot size and is calculated by the following formula, where s is the spot size in millimeters and W is the power setting of the laser.

$$PD(W/cm^2) = W/\pi[(0.1s)/2)]^2$$

Practically speaking, delivery of identical fluence values in different periods of time will produce different results. An acceptable full-thickness skin incision would be created with a 10 W laser beam delivered as a 0.4 mm spot size advanced along the skin for 5 seconds. (It just penetrates the skin completely.) If the rate of advancement is doubled (total time halved), the incision will be shallower because the total laser energy (fluence) has been halved. Conversely, if the original

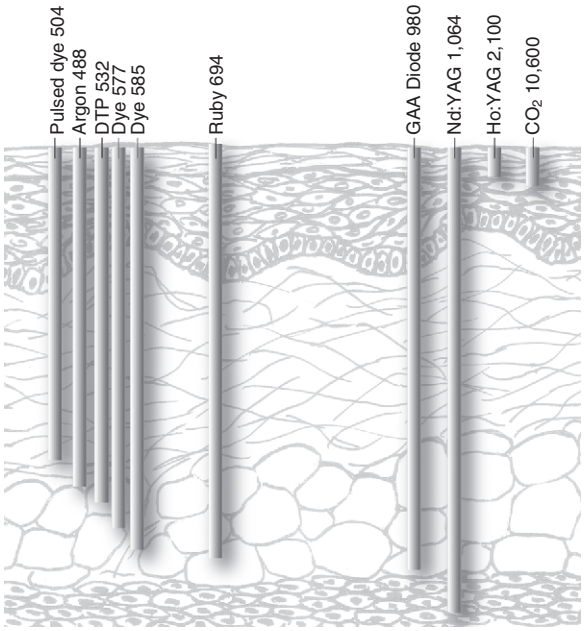

Figure 15-6. Absorption length of various wavelengths of surgical lasers in unpigmented skin. Wavelengths commonly used in veterinary medicine are in dark gray; wavelengths (nm) are stated beside the names. The far-infrared Ho:YAG and CO_2 lasers are highly absorbed by water; therefore, they penetrate minimally into skin, whereas the near-infrared Nd:YAG or GAA Diode lasers are absorbed more by the darker pigments of the deeper layers. *DTP,* Diagnostic and therapy systems for psychology; *GAA,* gallium aluminum arsenide; *Ho,* homium; *Nd,* neodymium; *YAG,* yttrium aluminum garnet.

time were doubled (slowed), the depth of the incision would increase beyond the skin. The same principle applies to any type of laser exposure.

The objectives of laser surgery fall broadly into three categories: incision/excision, ablation, and coagulation of tissue. Which of these occurs depends upon power density and absorption length of the laser, which in turn influence the rate of heat generation in tissue (Figure 15-6).[7] Incision/excision and ablation result in cell disruption and "vaporization" of tissue into smoke. Coagulation here refers to denaturing of tissue proteins, which grossly appears as blanching and contraction of tissue.

Excision is simply incising to dissect and remove tissue, and ablation refers to vaporization of tissue into smoke. Highly concentrated laser energy (i.e., high power density) is required to efficiently cut tissue with minimal heating of surrounding tissue. Because laser energy has no mass to separate tissue, tension on the tissue is necessary to separate the incised surfaces; without tension, excess heat will accumulate and the margins will be jagged and eventually necrotic. Collateral heating of tissue can be a substantial contribution to wound dehiscence because it produces a zone of necrosis along the wound margin. A small zone of necrosis has no effect on an open wound after resecting a mass, but it profoundly affects healing of a primarily sutured incision. Adequate power density to incise quickly[8] is critical to create a precise incision with healthy adjacent tissue to achieve primary wound healing.

A CO_2 laser in continuous mode at 50 W delivered with a 0.16-mm focused spot size yields a power density of 248,880 W/cm^2; a waveguide-delivered CO_2 laser at 8 W through a 0.4-mm

ceramic tip delivers approximately 6,300 W/cm^2. The former will produce an incision more efficiently, but it should be moved quickly across the tissue to limit penetration to the skin. The latter will produce an acceptable incision if tension is adequate to separate tissue and the waveguide is passed once and quickly across the skin. The skin defect will be 0.24 mm wider than the former with a perfect incision, which is clinically insignificant. With a small spot size, a single pass with efficient movement across the tissue and adequate tension on the tissue, 5,000 W/cm^2 is a minimally sufficient power density to avoid collateral thermal necrosis (Figure 15-7).[8] However, most experienced surgeons apply a significantly higher power density and work efficiently (Table 15-1). While learning, the tendency is to reduce the power setting and move tentatively or in multiple passes causing the laser to remain on the tissue longer and increasing the width of the wound and collateral heating. Incisions often dehisce because the margins necrose from thermal injury.

Reports of laser research should be examined closely to detect flawed methods. Incisions created with the CO_2 laser were reported to have reduced tensile strength upon healing, with more necrosis and inflammation compared to steel (scalpel) incisions, but the laser incisions were created using a power density of 1,990 W/cm^2, which resembles comparing a scalpel to electrosurgery.[9]

Laser energy is often delivered in *continuous mode* (i.e., uniform throughout application of the energy to tissue); some lasers have no other mode available. However, *pulsed modes* tremendously increase efficiency and minimize collateral heating of tissue. The principle is that spikes of laser energy at 200 Hz or more increase power density substantially while the interruptions allow tissue to cool slightly, which minimizes diffusion of heat into adjacent tissue.[10-12] A CO_2 laser in continuous mode at 50 W delivered with a 0.16-mm focused spot size yields a power density of 248,880 W/cm^2. In its pulsed mode,

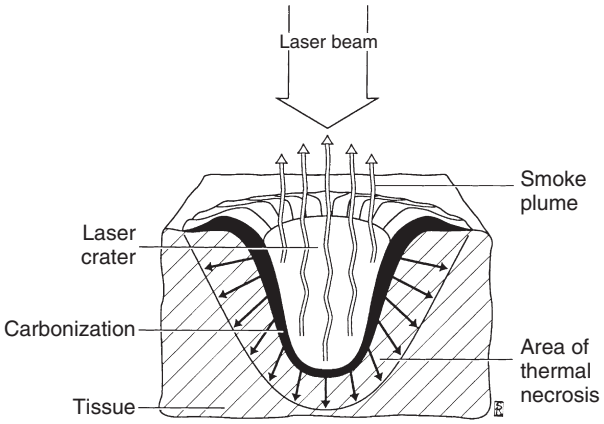

Figure 15-7. Range of tissue changes from laser beam. With sufficient power density, a laser beam has a central area of tissue vaporization/ablation shown by the crater in this drawing. A layer of carbonization occurs when tissue that has been significantly heated cools to produce char. The area of thermal necrosis is where tissue is heated beyond physiologic limits and sloughs later. The goal of incisive surgery is to use adequate power density to create as little carbonization and thermal necrosis as possible.

TABLE 15-1. Common Laser Techniques

Laser	Description	Capacity	Accessories	Preference for Skin Incision	Comments
GAA diode laser	Quartz fiber delivery	25-50 W	600 and 1000 µm quartz fibers. Handpiece to hold fibers.	1000 micron fiber sculpted down to approximately 600 µm at the tip.	25 W is insufficient for noncontact vaporization. 600 µm fiber too fragile for general surgery. Sterilize fibers for aseptic procedures.
Nd:YAG laser	Quartz fiber delivery	100 W	Gas cooled	Conical sapphire tip	Impractical to own both diode and Nd:YAG lasers.
CO_2 laser Articulated arm delivery	125-mm focusing handpiece. Minimum spot size 0.16 mm	Minimum 30 W	Computerized pattern scanner very useful for partial-thickness ablation of skin tumors or corneal tumors	30-50 W pulsed mode. Better hemostasis in continuous mode if wound is to be left open.	Sterilize handpiece and use sterile sleeve for aseptic procedures
CO_2 laser Waveguide delivery	0.25-4 mm (spot size) tips	15-40 W		Super pulse available	No lens focus of laser beam. Power density varied with distance, power setting or changing diameter of tip.
Laser smoke evacuator	Many brands available		Spare filters		Performance drops off quickly when filter fills. Sterilize hose for aseptic procedures.

GAA, Gallium aluminum arsenide; *Nd*, neodymium; *YAG*, yttrium aluminum garnet.

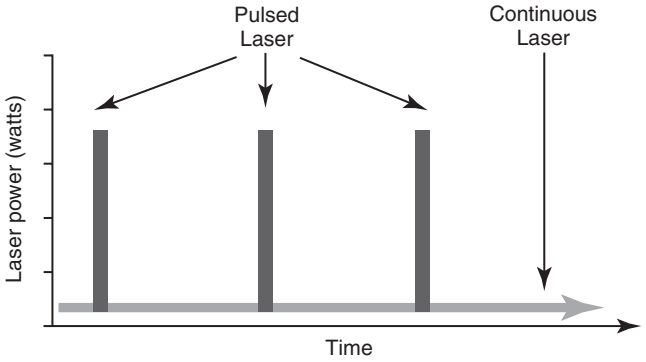

Figure 15-8. Pulsed laser energy compared to continuous laser energy. Pulsing higher power densities for short durations (vertical bars) produces a more efficient tissue effect with less collateral tissue heating compared to a continuous beam (horizontal bar) emitting the same average power (fluence). The tissue cools slightly between the pulses.

400-W power spikes provide power densities of 1,990,446 W/cm^2 while producing a fluence that is no more than with the continuous delivery (Figure 15-8). The technique depends upon the interval between laser exposure to avoid exceeding the thermal relaxation time of the tissue, which is the time required to cool 50% of the heat applied without conducting heat to the surrounding tissue. By supplying a second pulse before the tissue cools further, potential char is vaporized and tissue debris is evacuated as smoke or steam. This feature produces a skin incision with less collateral thermal injury than from a continuous wave.[13]

Laser energy can be delivered to the tissue in a *noncontact* or *contact* manner. As the term implies, with noncontact, nothing touches the tissue except the laser light, imparting a purely optical interaction. Sapphire tips touch tissue to deliver intense heat, and tips of quartz fibers produce varied interactions depending upon wavelength.

LASERS COMMONLY USED IN VETERINARY SURGERY

Carbon Dioxide Laser

The CO_2 laser is the classic instrument of general surgery. With only optical delivery, it has the convenience of having no fibers to stock or maintain (Figure 15-9, *A*). More CO_2 lasers than any other wavelength are in use in human and veterinary surgery.[14] This laser emits energy at 10,600 nm in the far infrared range; water absorbs this wavelength so completely that energy penetrates only 0.03 mm into tissue.[14,15] The ability to precisely control the effect makes the CO_2 laser safe for application to tissue overlying critical anatomic structures. Corneal squamous cell carcinoma can be ablated down to stroma without a deeper effect. However, heat can be conducted into normal tissue beyond the laser effect, which is of particular concern when applying laser to a thin structure, such as the cornea or an ear. A computerized scanner considerably reduces this risk (see later). When using continuous energy without a scanner, an ice pack on the back side of an ear is helpful.

When 50 W of energy is administered through a 125-mm handpiece to focus through a lens to a 0.16-mm spot size, the power density is 248,680 W/cm^2, which incises skin with 0.1 mm of collateral tissue effect. Microscopically, the "incision" actually has removed tissue; the narrower the spot size, the more natural the closure. Without changing settings, the handpiece can be retracted to defocus the laser beam to a 2-mm spot (1592 W/cm^2) or a 4-mm spot (398 W/cm^2), substantially changing the laser effect. The power density changes with the square of the spot size (see Figure 15-4). The surgeon must acquire the experience to achieve the spectrum of incision, ablation, or coagulation.

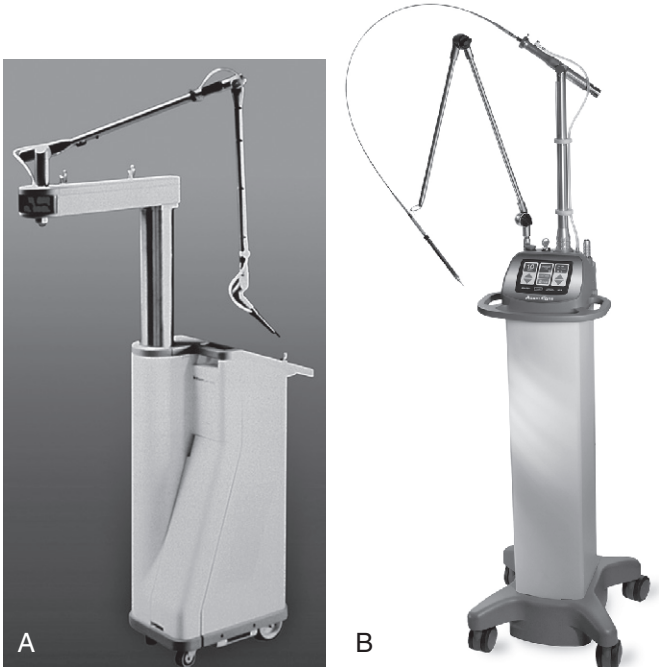

Figure 15-9. A, Typical higher-powered CO_2 laser delivered through an articulated arm with a lens-focusing handpiece. **B,** Typical CO_2 laser delivered through a flexible waveguide and handpiece with variable aperture tips. (**B,** Courtesy of Aesculight, LLC, Woodinville, WA.)

Hemostasis during CO_2 laser surgery is significant but not as profound as with lasers that penetrate tissue more deeply, even though lack of penetration is one advantage of using this laser. Hemorrhage from vessels 0.5 mm or less in diameter and lymphatic drainage are largely eliminated[14,16]; larger vessels or visible lumens should be ligated.

There is too much water in a quartz fiber to transmit CO_2 laser energy, so CO_2 lasers transmit the energy by reflection from mirrors through an articulating arm with a handpiece and lens to focus the beam (see Figure 15-9, *A*). Some models deliver the laser beam through a flexible waveguide with a handpiece, and spot size is varied by using interchangeable tips instead of a lens (Figure 15-9, *B*). CO_2 lasers are often equipped with pulsed modes (described previously), thus making incisional surgery similar to that of a steel scalpel possible.

Devices that attach to articulated arms of CO_2 lasers can deliver the beam laparoscopically, bronchoscopically, or arthroscopically. However, none of the instruments are flexible, and a gas medium is always required. The arthroscopic instrument has been applied to horses,[17] and it may be possible to adapt the other instruments for equine applications.

Some CO_2 lasers can be fitted with semiflexible waveguides to access deeper surgical sites. Waveguides are actually tubes and are not as flexible as quartz fibers. Many waveguides can be passed through the biopsy channel of some endoscopes, but they are fragile. Excessive bending will reduce the laser energy

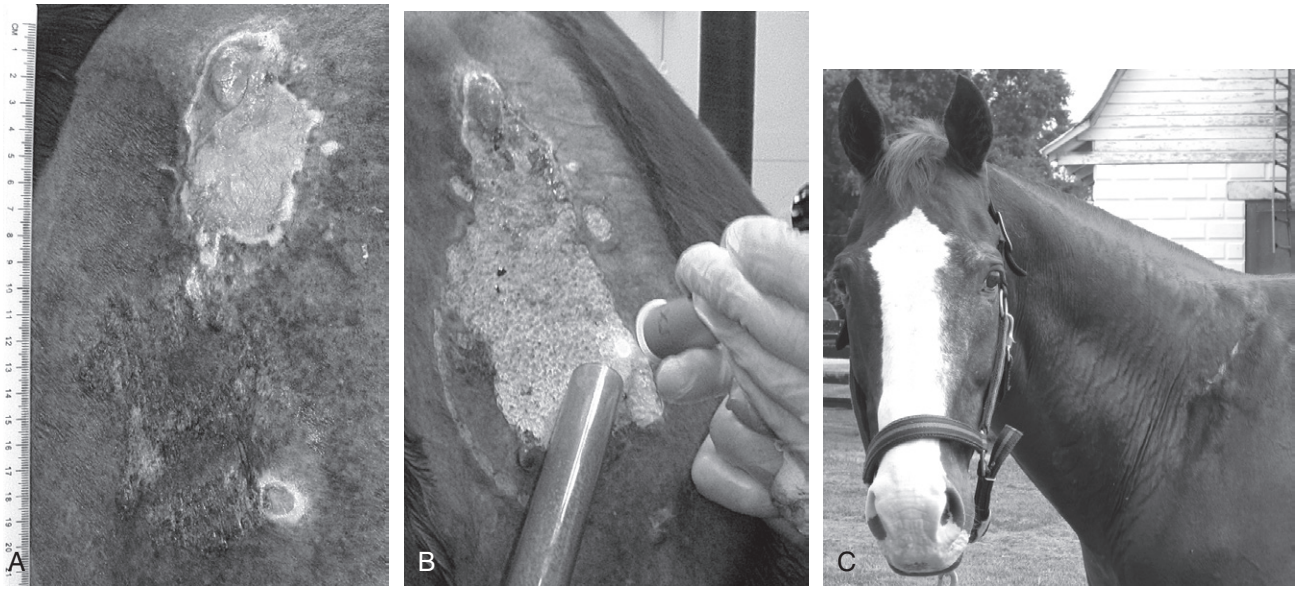

Figure 15-10. A, Preoperative image of large mixed sarcoid covering the scapular region of a horse. **B,** Computerized scanner attached to a CO_2 laser performing a partial (skin) thickness ablation of the sarcoid shown in **A.** The surface is even and there is no char formation. The entire lesion will be treated. Leaving the dermis intact facilitates healing and minimizes chance of recurrence. Topical fluorouracil was also used. **C,** End result of lesion shown in **A** and **B.**

or damage the waveguide, leading to a burnout; these should be kept relatively straight. One waveguide can function in a flexible endoscope, but it must be purchased with its specific laser (Omniguide).

Computerized pattern scanners are accessories that manipulate the focused laser beam across a preset scan size at a constant velocity to ablate tissue. Without a scanner, a slightly defocused beam is used to create a manual crosshatch pattern to vaporize a surface lesion, but char must be removed with a gauze sponge. The manual technique is workable but generates more heat and is less uniform than with the scanner (Figure 15-10). The difference between manual delivery and computer scanning is that scanners deliver focused laser energy, which ablates tissue completely. The beam moves away before collateral heating occurs and returns before the tissue cools sufficiently for char to form; less heating of deeper tissue occurs. The surgeon must acquire the "feel" of the scanner and keep it moving appropriately or it removes excessive tissue. The power settings should be kept low until the proper technique is acquired. Because this is focused laser energy, reducing the power simply slows the rate of surgery and produces no detrimental effect.

Equine general surgery holds many applications for the clean, efficient, and safe CO_2 laser.[18-20] Proper CO_2 laser surgery produces much less thermal injury than electrosurgery,[21] and tissue generally swells less than with conventional surgery. Surgical dead space tends to fill less with serum after laser dissection than with conventional surgical dissection.[22] In a gas medium, CO_2 laser energy can be used arthroscopically for specific applications.[17,23] Procedures requiring incision/excision of tissue or ablation of masses are all candidates.

Neodymium Yttrium Aluminum Garnet (Nd:YAG) and Gallium Aluminum Arsenide (GAL) Diode Lasers

The 1064-nm Nd:YAG and 980-mn GAL diode laser wavelengths behave almost identically in tissue, so the following discussion applies to both wavelengths. Many Nd:YAG lasers have been replaced by the less-expensive diode units. Nd:YAG lasers are generally sold with outputs up to 100 W, and GAL diode lasers are most often in the 15 to 50 W range. Higher power output is a reason some continue to use Nd:YAG lasers.

The immediately apparent difference between the two is the size of the "box" that produces the laser energy. The Nd:YAG laser is large and on wheels, whereas the GAL diode laser is on a table top or cart. The capability of the laser energy to be generated within very small semiconductor diodes versus a generating chamber results in this difference. The relatively few moving parts involved in the diode "box" cause it to be a very reliable instrument. Because lasers are manufactured with several semiconductors in the diodes, the more-specific term, *gallium aluminum arsenide (GAL) diode*, is used for this surgical laser.

In their purely optical forms, these lasers are absorbed by dark pigment (such as melanin and hemoglobin) and poorly absorbed by water (see Figure 15-2). When the tissue is not obviously dark, the laser energy will convert to heat more slowly as it encounters sufficient pigment or protein deep to the surface, which may take several seconds. That distance could be a few millimeters in pale skin or mucous membrane or a few centimeters in an eye if only cornea and clear aqueous or vitreous humor is encountered. As tissue blackens, more laser energy is absorbed until black char accumulates and limits penetration. To continue, the char must be physically removed or time for tissue to slough must be allowed.

Coagulation results in physical contraction of tissue, which will slough during the ensuing several days if the blood supply has been occluded. Vascular stasis occurs when melanin-rich tissues absorb the laser energy and conduct heat to the vascular endothelium, where the coagulation cascade is activated. In tissues with low melanin concentrations, hemostasis occurs when hemoglobin absorbs the laser energy and conducts thermal energy to plasma protein.[24,25]

The 980-nm diode laser is absorbed by water three times more than the Nd:YAG laser and lower-wavelength diode lasers.

The practical effect is a much more efficient contact incision in tissue in the upper airway with the 980-nm diode laser.

Deeply scattered laser energy can damage subsurface tissues, such as nerves or vessels, or coagulate darkly pigmented skin on the ear after passing through white cartilage of the pinna. Misdirected Nd:YAG laser energy in the pharynx can leave a horse dysphagic from damage to the pharyngeal branch of the vagus nerve, which lies deep to the dorsolateral pharyngeal wall. When deeper tissues are at risk, the beam should be directed tangentially across the surface or a contact technique should be used, and the integrity of the sculpted fiber or sapphire tip should be ensured (see later).

Diode and Nd:YAG lasers are the instruments of choice for equine endoscopic surgery because the energy is delivered through flexible quartz fibers, which can be inserted through the biopsy channels of video endoscopes. Two types of quartz fibers are in general use.

The *"bare" fiber* is covered with a plastic coating similar to insulation on an electrical wire. That plastic is stripped from the tip for use because it will melt and burn. After stripping, the end is cleaved by scoring the quartz and fracturing the fiber or cutting with scissors to yield a symmetric circle from the aiming beam. A uniformly circular shape of the aiming beam indicates the coherence of the light emitting from the fiber, which is important for uniform delivery of laser energy in a noncontact fashion. With normal use, bare fibers gradually crystallize and burn out, requiring cleaving back to a new area of the fiber, a continuous process until they are too short to use. Activating the laser only when the fiber is in contact with tissue prolongs the fiber life because tissue dissipates the heat. Bare quartz fibers are commonly available in diameters of 600 to 1000 µm.

Bare quartz fibers (Figure 15-11, *A*) used in contact fashion may be "sculpted" to a point to maximize the power density for incisive surgery. The sculpted tip burns away rapidly, leaving a fiber that is the same diameter as the entire fiber. The free beam (noncontact) effect of the fiber returns when the tip wears out. Adequate power density for cutting is generally provided with a 600-µm fiber at an output of 20 W. Larger-diameter fibers require more laser output or sculpting to maintain effective power density for incision and may emit excess laser energy into the deeper tissues at higher power settings. Sculpted 1000-µm fibers cut very well, and the sculpting will last for approximately one procedure. They are stiff enough to have a real tissue feel but may have difficulty bending to reach tissue during endoscopic surgery. Blackening the tip of a bare fiber by firing it on a tongue depressor or, more conveniently, with a black permanent marker causes the energy to be absorbed at the fiber tip so it cuts efficiently (Figure 15-11, *B*).

Noncontact application of laser energy requires relatively high power settings and high power densities for an adequate tissue effect. Smaller fibers transmitting 20 to 25 W can vaporize small areas but burn out very rapidly. With higher outputs, such as 50 W, more tissue effect is accomplished, but bare fibers still tend to overheat at these levels. A fiber burning out inside an endoscope can badly damage the scope.

Gas-cooled coaxial fibers contain a 600-µm quartz fiber passed through a plastic tube that conveys cooling gas or liquid (Figure 15-11, *C*). A metal tip joins the two at the end of the fiber, enabling the fiber to be used to deliver noncontact laser energy, or it can be fitted with a sapphire tip for contact lasing. Compared to the bare quartz fiber, higher powers can be transmitted without burning out the fiber. Care must be taken not to touch tissue with the cooling port because clogging will cause the fiber to burn out. If the fiber tip burns out, a new tip must be refitted or the tip must be replaced.[26] If the metal tip flares during burnout, it should be cut off from the fiber before withdrawing the fiber from the endoscope or the metal edges could lacerate the biopsy channel in the endoscope. Because they are generally higher powered machines, Nd:YAG lasers are equipped with mechanisms for gas or liquid cooling of coaxial quartz fibers. This capability can be added to diode lasers.

Holmium:YAG (Ho:YAG) Laser

The near-infrared (2100 nm) Ho:YAG laser is a pulsed laser that has been used in orthopedics, but more recently it has been applied in urology. The wavelength is substantially absorbed by water, an advantage for endoscopic ablation of soft tissue while protecting deeper structures.[27] The effect is enhanced in a water medium, which concentrates the energy within an air bubble formed where the laser contacts tissue. In an air medium, the delivery is noisy, and tissue is displaced slightly with each pulse. In the upper airway, the noise can be distracting for horses, and the delivery is not as precise as with the continuous Nd:YAG or diode lasers. This laser will ablate or "drill" cortical bone. I experimentally attempted distal tarsal articular cartilage débridement, but the fiber would not follow the contour of the joint and drilled into the depths of the distal tarsal bones.

The Ho:YAG laser has been used in equine arthroscopic surgery to remove palmar and plantar chip fractures of the proximal phalanx with good results.[28] The laser tip facilitated separation of the chip from the underlying bone and removal of hypertrophied synovial villi without bleeding. Additionally the fibrous tags could be vaporized to leave a smooth surface. However, this type of surgery was more time-consuming than the conventional chip removal with comparable results, which led to the cessation of Ho:YAG laser application.

The Ho:YAG laser is used for human[29,30] and small animal lithotripsy.[31] The Ho:YAG laser effect on uroliths has been described as primarily photothermal drilling of the stone[32,33] or surface ablation[34] compared to the broader effect described for the pulsed dye laser. The overall performance has been inefficient in horses,[35,36] but some smaller, less-compact equine uroliths have been successfully addressed.[37]

Pulsed Dye Laser

The laser-generating medium is an organic dye that is activated by a flash lamp or another laser, resulting in a visible 400 to 700 nm wavelength absorbed by hemoglobin and urinary calculi.[33] Some machines allow variation (tuning) of the wavelength.[33] Lithotripsy is performed in a water medium, producing a combination plasma formation and the photoacoustic effect derived from the pulsed delivery. Plasma formation is the result of focal accumulation of charged gas and ion particles resulting from the true optical laser-tissue interaction; mineral disappears in a manner similar to smoke in an air medium. Subsequently, expansion of minute cavities of steam along with the photomechanical energy from the pulse cause the stone to fragment.[33] Quartz fibers, which are generally smaller (200 to 320 µm) than for other lasers, are used for lithotripsy. Fiber rigidity is not necessary because it is strictly a contact "end-on" procedure. However, the small-diameter fibers are fragile and expensive.

The pulsed dye laser has proven useful for equine laser lithotripsy.[38,39] Calcium carbonate uroliths can be removed from

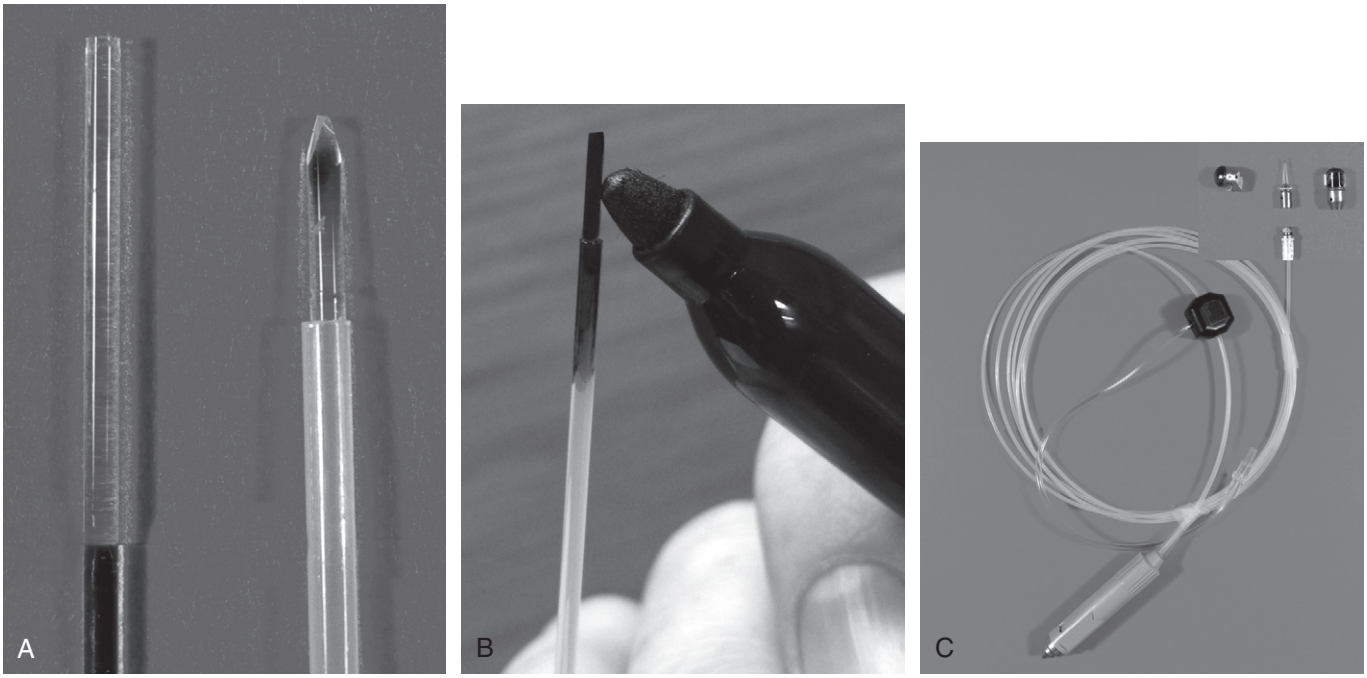

Figure 15-11. A, Bare quartz fibers (1000-μm) for use with Nd:YAG or diode lasers. The fiber on the *left* is a plain cylindric tip for free beam (noncontact) transmission of laser energy. The fiber on the *right* has been sculpted into a chisel point to increase power density for contact laser surgery. Both ends eventually burn out, requiring stripping back the plastic coating and cleaving the quartz in a fresh site. Although it is possible to manually resculpt the tip, it is tedious and not as accurate as replacing the fiber. **B,** A bare quartz fiber is being blackened with a permanent marker. The black pigment absorbs the laser energy for an immediate effect on tissue and limits deeper penetration of laser energy. As the marker pigment burns off, the heat itself and tissue char blackens the fiber for continuing until the tip must be cleaved again. **C,** Gas-cooled fiber for use with the Nd:YAG laser. The quartz fiber inside the plastic tubing can transmit 50-100 W of energy without burning out because the gas circulating in the tubing cools it. The ports in the tips *(inset)* must remain clean for cooling to continue. The fiber can be used in noncontact fashion with the bare tip only, or sapphire tips of various types can be screwed onto the tip. Illustrated in the *inset, left to right,* are right angle, conical, and end-on sapphire tips. The conical tips are used for incisions, and the others are used for contact ablation of tissue.

geldings by access with a videoendoscope through the penile urethra (see later). The Ho:YAG laser has largely replaced this instrument for human lithotripsy because of its applicability to multiple procedures and reduced maintenance requirements.

GENERAL SURGERY

The CO_2 laser is the workhorse of general surgery. As a scalpel or scissors replacement, it makes incisions or dissections that are clean, dry and efficient. Because the laser beam has no mass to separate tissue, as a blade does, tension on the tissue is absolutely necessary to achieve the separation and minimize collateral heating of adjacent tissue for optimal wound healing. For a conventional incision, thumb and forefinger suffice; tissue forceps or towel clamps provide extra purchase for more extensive dissections. Tissue will separate along planes with the proper combination of laser energy and traction. The power density (see earlier) can be varied with distance of the handpiece from the tissue to facilitate seamless transition from precise incision to coagulation or ablation of tissue. Small vessels will be sealed; blood flow must be stemmed with pressure to coagulate walls of larger vessels. Larger vessels can be included in the deep coagulation, but ligation is advisable for visible lumens. Subtle superficial coagulation of surfaces of dead spaces will minimize seroma formation, but dead spaces should also be minimized during closure by using conventional techniques. Some surgeons "paint" the wound surfaces with defocused laser energy to vaporize remaining tumor cells after resection. The CO_2 laser effect is significantly less than a millimeter; intentional heating of the tissue may result in delayed necrosis and slough of tissue. The laser should be considered the same as a scalpel in this respect; that is, margins for tumor resection should be adequate. Local chemotherapy widens the margins.

The Nd:YAG and diode lasers with handpieces can also be used for incisive procedures, but the skin margins will never be as precise as with a properly created CO_2 laser incision. Good results can be obtained in this manner, but primary closures should have sutures set back 2 to 3 mm from the margins. Mass excisions with wounds to be left to heal by second intention will heal normally, but smaller fiber diameters will require frequent cleaving, so a sculpted 1000-μm fiber or a sapphire tip will be more efficient. Hemostasis can be accomplished by using the contact tip to compress the vessel to stem the flow and applying *low* energy (3 to 5 W). Higher power densities will simply transect the vessel.

One advantage of laser over conventional surgery is the capability to ablate (vaporize) tissue, particularly masses. The CO_2 laser ablates all tissues efficiently because most tissues have high water content. Any handpiece can be used to ablate tissue by backing away from the tissue to reduce power density slightly from the incisive mode and increase the spot size for more efficiency. The effective distance for the specific handpiece can be quickly determined by observing of the effect; deeper tissues

are safe because of the limited absorption length of the CO_2 wavelength. The handpiece is patterned across the tissue until the desired depth is obtained. Occasional interruptions limit overheating of deeper tissues. On thinner structures, such as ears, holding an ice pack on the opposite side will minimize overheating of tissue.

A computerized scanner (see earlier) is a significant advantage of ablating with a CO_2 laser. The result is a very clean wound bed with healthy tissue remaining (see Figure 15-10). Partial-thickness ablation of thin cutaneous equine sarcoids, ablation of corneal cell carcinoma, or reduction of granulation tissue are examples of procedures that commonly use the scanner.

Noncontact ablation of tissue with the Nd:YAG and diode lasers is possible as well. Unpigmented or pale tissues respond only after a few seconds of lasing has caused the tissue to darken. The surgeon must remember that transmission of this wavelength of laser energy can be several millimeters, so deeper structures must be respected.[40] Darkly pigmented skin or melanomas begin to vaporize readily. As the process continues, superficial (black) char will accumulate and completely absorb the laser energy, necessitating its removal before proceeding.

Noncontact ablation requires a high power density to span the distance to the tissue and vaporize. To be effective with a plain fiber, a higher wattage laser with a larger diameter fiber is needed. Gas-cooled fibers can transmit much higher power and are much more efficient for vaporizing tissue; the gas ports in the tips must be kept clean for proper cooling.

ENDOSCOPIC SURGERY

Endoscopic laser technique has expanded the breadth and depth of upper airway and urogenital tract surgery as well as in laparoscopy. New applications appear as needs arise. Endoscopic surgery is much different from endoscopic examination and requires instruction and practice to avoid injury to the patient or damage to the equipment. Video endoscopy vastly improves execution of procedures. For some procedures, a dual channel endoscope improves efficiency because one channel can be used for suction to evacuate blood or fluid without taking time to remove the laser fiber from the other channel. Efficient completion of the surgical procedure is very important because hemorrhage and swelling (which hinder visualization and laser delivery) generally increase with time. A consistent operating space tremendously improves efficiency and outcomes (Figure 15-12).

Because quartz fibers pass readily through endoscopic biopsy channels, Nd:YAG and diode lasers dominate this area of veterinary surgery. In general, contact incision is more precise and safer for deeper tissues than noncontact ablation, particularly in the upper airway. However, if the target tissue mass is known to conceal no critical structures (such as an ethmoid hematoma), noncontact ablation may be the best choice. In contact incision, the laser energy is applied at the tip of the laser fiber, which must contact the tissue to be effective. Take care to not place the side of the fiber on the target tissue (like a scalpel would be placed) because the tip of the laser could burn tissue beyond the field of view. The laser should never be activated if the target tissue cannot be visualized. Movement of the tip of the fiber or sapphire tip across tissue is a practiced feel; it should be moved slowly to allow the laser to cut while traction is held on the tissue. If insufficient or no laser activity is occurring, immediate cessation of the procedure and inspection of the fiber is critical. A malfunctioning fiber may be damaging the endoscope. The fiber should be allowed to cool a few seconds after lasing stops before retracting into the biopsy channel to prevent damage to the endoscope.

Figure 15-12. Operating facility for standing endoscopic surgery. The video endoscopic monitor faces the surgeon, making all the movements in the patient mimic those on the screen. The floor around the surgeon and assistants is free of cables or other debris.

Accessory instruments are necessary to provide traction and retrieve tissue, such as a long tissue-grasping forceps. The preferred forceps is a heavy-duty 75-cm forceps with Oschner-type jaws (Figure 15-13). The vertical action of the jaws is universally effective, but instruments with horizontal action or rotating jaws are on the market. Other instruments may be adapted or built for specific needs for various procedures.

All standing upper airway laser procedures require profound sedation for the patient to tolerate an endoscope in one nostril and accessory instruments in the other. Access to the caudoventral pharynx and larynx is facilitated by complete extension of the head; support of the rostral mandible or suspension of the halter is helpful (see Figure 30-2). Topical mepivacaine sprayed over the target tissue and normograde through the opposite nostril via the endoscope reduces reactivity. Persistent swallowing is addressed more effectively by increasing sedation whereas pharyngeal spasm requires additional topical analgesia.

Horses undergoing upper airway laser surgery are treated with local and systemic anti-inflammatory medications (Table 15-2). Excessive granulation tissue can be a serious postoperative complication if medications are not administered.

Laser Thermoplasty of the Soft Palate

Dorsal displacement of the soft palate (DDSP) is a poorly understood condition affecting racehorses. The rationale for laser thermoplasty is that the ensuing scar tissue formation will stiffen the soft palate, making it more difficult to displace from beneath the epiglottis.[41] Immediately before the standing laser thermoplasty, perform a standing bilateral sternothyroideus tenectomy to facilitate rostral movement of the larynx into the caudal margin of the soft palate where possible.

Horses with significant pharyngeal inflammation from many causes may present with secondary DDSP, which is not the same

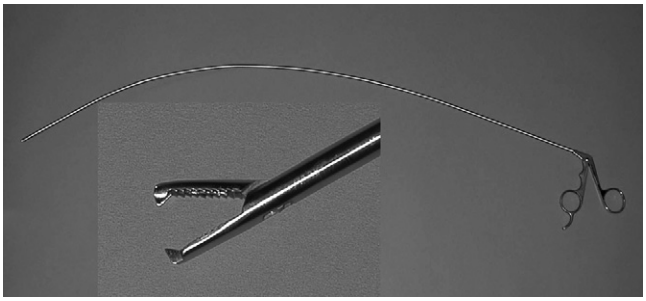

Figure 15-13. Esophageal grasping forceps (75-cm) used to provide traction for endoscopic laser surgery in the upper airway. (1404-881MT, Sontec Instruments, Centennial, CO.)

TABLE 15-2. Medications for Upper Airway Laser Surgery

Drug	Dosage
Dexamethasone*	20 mg IV
Prednisolone	1 mg/kg PO sid × 5 days 0.5 mg/kg PO sid × 5 days 0.5 mg/kg PO sid every other day 5 times
Phenylbutazone	2.2 mg/kg PO bid × 14 days
Oral antibiotic	PO 14 days
Throat spray†	20 mL bid via nasal tube × 21 days

*Given preoperatively.
†Formula: 225 mL glycerine, 50 mL dimethyl sulfoxide (DMSO), 50 mg dexamethasone, qs to 500 mL with saline.

situation as described previously. Correcting the underlying problem often corrects the DDSP, and laser thermoplasty in the presence of inflammation would be contraindicated.

Unless the soft palate will remain displaced (rare), the epiglottis must be elevated for access to the caudal margin of the soft palate, but the epiglottic cartilage should not be grasped or abraded. Use a diode laser set at 20 W with a 600-µm fiber applied in a "pin fire" contact fashion. The laser fiber is lifted from the tissue just as the pedal is released to prevent its sticking to the tissue; keeping the laser activated too long causes the fiber to burn out rapidly. A rhythm is soon acquired. Particular attention should be given to the caudal margin of the soft palate without injuring the subepiglottic mucosa; the entire treated area is slightly wider and longer than the epiglottis in its normal position, which requires approximately 1500 J. Care is taken to make pinpoint contacts and not linear incisions in the soft palate (Figure 15-14). Postoperatively, horses are treated with prednisolone, phenylbutazone, and an oral antibiotic (see Table 15-2). Training can be resumed approximately 10 days postoperatively, provided that the soft palate has healed completely and pale scar tissue has formed. More time is required if the surface remains ulcerated or hyperemic because fibrosis is incomplete.

Laser Ventriculocordectomy (LVC)

The ventricle and/or vocal cord (also called vocal fold) have been variably removed with or without prosthetic laryngoplasty (PL) for many years. Bilateral conventional ventriculocordectomy without laryngoplasty reduces the noise associated with

Figure 15-14. Laser thermoplasty of the soft palate. The epiglottis is elevated for access to the soft palate. A 600-µm quartz fiber is being applied to cover slightly more than the area of the epiglottis. Particular attention is given to the caudal margin.

left laryngeal hemiplegia (LLH),[42] and left LVC using a laser reduces airway noise and restores airway pressures to normal in experimental horses with LLH.[43] Those horses were shown to have complete removal of the ventricle and a solid arytenoid-thyroid cartilage fibrous adhesion to prevent arytenoid collapse during exercise.[44] From these data, LVC using the laser would seem to stabilize the arytenoid position after PL, and PL (when performed) would seem to facilitate the position of the adhesion following LVC. Although all horses with LLH can return to normal work with a left LVC, occasional failure of that scar has been observed in racehorses presumably as a result of repetitive and prolonged negative upper airway pressures. Perform LVC in all horses with LLH,[45] but racehorses and other high-level athletes also have a prosthetic laryngoplasty (see Chapter 45).

Noncontact laser mucosal ablation to obliterate the ventricular space has been reported.[46] Contact excision of the ventricle and vocal fold is preferred to obtain a tight arytenoid-thyroid adhesion[44]; no ventricular mucoceles have been reported using this technique. The dissection can be performed using a single grasping forceps for everting the ventricle and dissection of the vocal fold.[47] A transnasal sacculectomy burr that everts the ventricle and provides traction and tension on the vocal fold facilitates the procedure (Figure 15-15, *A* and *B*).[43,48]

Perhaps the single most important factor in performing LVC is efficient execution of the surgery because delay allows hemorrhage, which obscures vision and absorbs laser energy. The most consistent significant vessel encountered is located at the ventral aspect of the vocal fold, so it helps to save this area until traction can be applied to minimize the hemorrhage. Using the burr, dissect ventrad-to-dorsad while rotating the burr clockwise to elevate and retract the tissue. Repulsion and traction with the burr or manipulation with long grasping forceps may be required to complete the procedure; each case is slightly different. Care should be taken not to apply direct thermal energy to the arytenoid cartilage. Leaving a small amount of soft tissue on

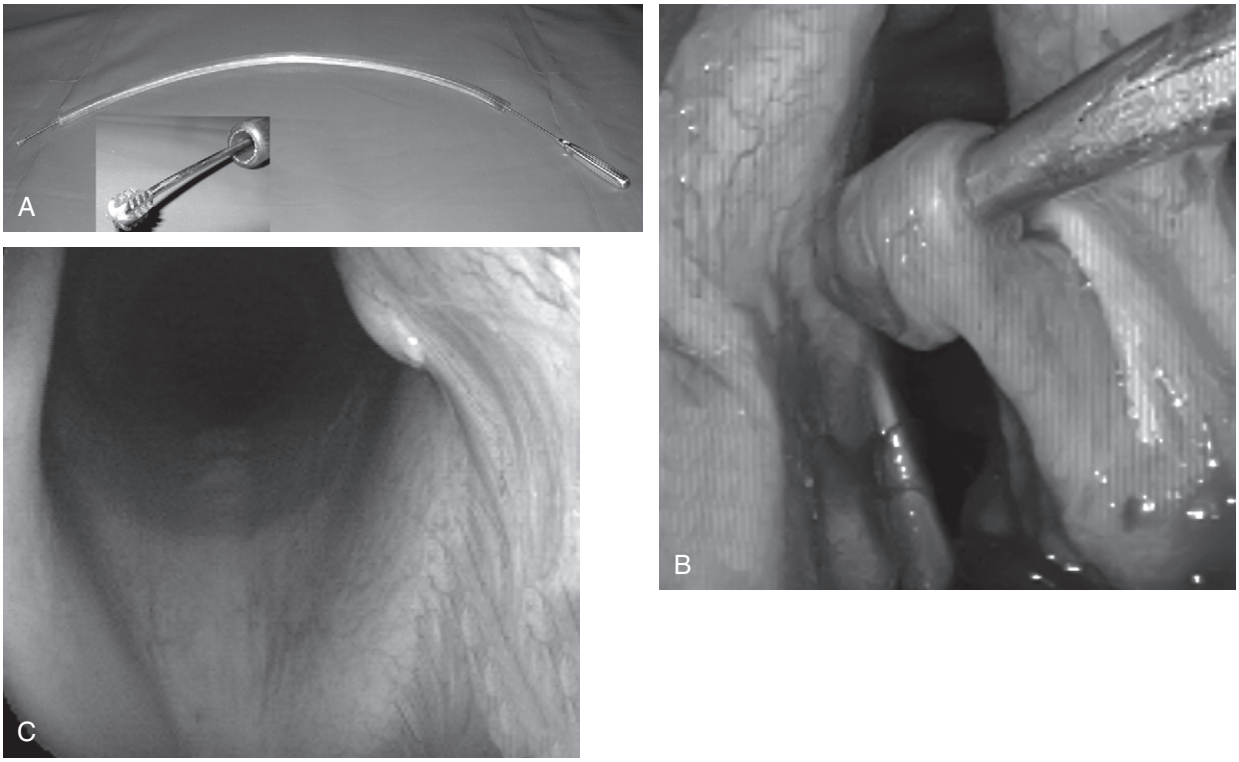

Figure 15-15. A, Transnasal sacculectomy burr shown in a segment of stomach tube used to safely conduct the burr to and from the larynx. (Virginia Roaring Burr, 1271-283 engages clockwise for the left ventricle. 1271-284 engages counterclockwise for the right ventricle. Sontec Instruments, Centennial, CO.) **B,** The transnasal sacculectomy burr has everted the ventricle. The clockwise torsion of the tissue provides traction, facilitating laser dissection of the tissue, and minimizes hemorrhage. **C,** Laser ventriculocordectomy site after healing.

the vocal process of the arytenoid cartilage facilitates faster healing. Approximately 10,000 J is required to efficiently complete the procedure using a 600-µm quartz fiber with the diode laser set to 20 W.

Postoperative care consists of 30 days of stall rest with unlimited hand walking and 30 days of light turnout in a small paddock. Training can resume during the third month but speed should be reserved for the fourth month to allow complete maturation of the adhesion (Figure 15-15, *C*). Early airway turbulence (including continuous screaming) or failure to properly medicate may cause excessive granulation tissue to develop; small to moderate granulation tissue masses usually shrink without treatment. Medications include the entire list in Table 15-2.

Epiglottic Entrapment

Epiglottic entrapment (EE) refers to the dorsal displacement of the aryepiglottic fold to stretch over and envelop the epiglottic cartilage (see Chapter 44). The goal of surgery to correct EE is to transect the restricting aryepiglottic fold effectively, lengthening it so it can no longer maintain the position; the procedure effectively converts the entrapment to a subepiglottic ulcer. The advantage of endoscopic laser transection is that neither general anesthesia nor laryngotomy is required.

Contact[49] and noncontact[50] laser techniques have been described. Both consist of sequential rostrad-to-caudad removal of tissue covering the epiglottis until it divides. The contact technique requires a wedge-shaped sapphire tip to separate the tissue without a separate traction instrument. With more substantial long grasping forceps available, the entrapment can be grasped and elevated from the epiglottic cartilage and transected in a vertical caudad-to-rostrad manner, which is more efficient and keeps the laser fiber away from the epiglottic cartilage (Figure 15-16). For thicker entrapments, a small dorsal incision may be created for the forceps to grasp. A diode laser set at 20 W using 600-µm quartz fiber can accomplish the transection in 5 minutes or less.

Some entrapping membranes are attached just ventral to the tip of the epiglottis and will not fall away when transected; care must be taken not to damage the cartilage before this is known. The membrane can be repositioned ventral to the epiglottis with the grasping forceps as the incision nears the epiglottis to evaluate how much should be transected. If the aryepiglottic fold remains tight enough to partially entrap when no more tissue is available to transect at the tip, releasing incisions in the aryepiglottic folds can be created along the sides of the fold. When transection is completed, the horse should be stimulated to swallow several times. Extremely thick entrapments may not disappear below the soft palate. If the epiglottis has been released, remaining tissue will contract with rest and medication. Further dissection of thick soft tissue from the ventral surfaces of the epiglottis is not advisable because increasing scar tissue may limit mobility of the epiglottis.

Postoperative care consists of topical and systemic medications and airway rest. All the medications listed in Table 15-2 are administered. The time required to heal depends upon the ulcer created by the transection. Thin entrapping membranes heal rapidly and horses can return to training relatively quickly,[49] but chronically thickened entrapments already have a granulating mass that must regress. If the subepiglottic mass fails to

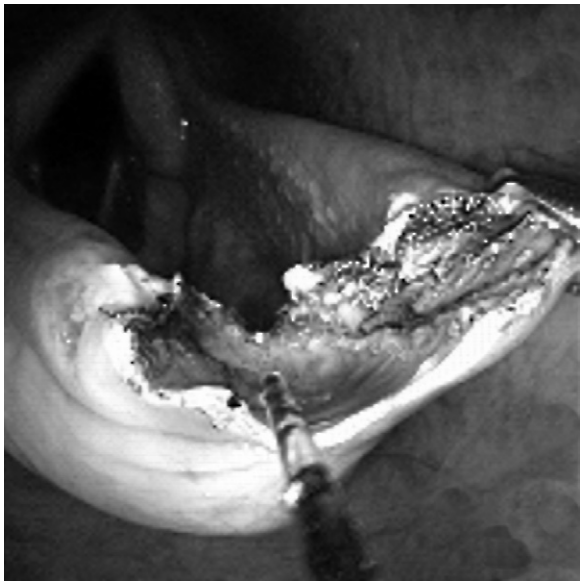

Figure 15-16. Transection of a moderately thickened epiglottic entrapment. The grasping forceps elevates and stabilizes the entrapping membrane while the laser fiber transects the membrane dorsally to ventrally. The membrane should be reduced below the epiglottis periodically to be sure the laser doesn't contact the cartilage.

regress or enlarges, it may physically displace the soft palate from its normal position ventral to the epiglottis. Monitoring of the healing process requires elevation of the epiglottis to examine the healing ulcer. Ideally, mucosal healing will be complete before training resumes, but a few horses will retain a small, mature-looking ulcer that will not seem to cover with mucosa or be a problem for training.

Occasionally a healing subepiglottic lesion granulates seemingly out of control; airway stertor at rest may appear. It should be checked endoscopically, but the throat spray should be given four to six times daily until it subsides. Further surgery on an inflamed area is not advisable.

When the entrapment has been relieved, the tip of the epiglottis may appear swollen and hyperemic from the pressure that has been there. Some of these epiglottic cartilages shorten in time in apparent atrophy from this inflammation, which may predispose to future DDSP. If that occurs, procedures to correct DDSP may be needed (see Chapter 44).

Although most horses with EE are having performance problems, one endoscopic survey of horses in training found EE as an incidental finding.[51] Additionally, some horses with EE and an obviously deformed epiglottis perform at least acceptably. If these horses are taken from training for surgery and then must regain their fitness with a shortened epiglottis, they may never regain their previous level of performance. The entire situation should be considered before deciding when to remove a horse from training to correct EE.

Guttural Pouch Tympany

Inflation of the guttural pouch(es) (GP) is a rare condition of young foals caused by the salpingopharyngeal orifice(s) functioning as a one-way valve. Unilateral or bilateral outward distention gives the foal a chipmunk-like appearance (see Chapter 46). The majority of cases are unilaterally affected, and treatment consists of perforating the median septum separating the two guttural pouches, thus allowing air to escape through the normally functioning side.[52] Another option is the creation of a new salpingopharyngeal opening on the affected side.[53] Bilaterally affected foals must have the median septum perforated and at least one salpingopharyngeal communication established. Alternatively, two salpingopharyngeal communications can be created without perforating the median septum.[54]

The procedure(s) can most often be performed in the standing foal. If general anesthesia is contemplated, pneumonia may be a factor. Laser division of the median septum is accomplished by driving the endoscope axially immediately after entering the GP. The membrane lies rostral to the vertical longus capitus muscle and may be slightly thicker than normal in affected foals. Entering the unaffected GP in unilateral cases usually reveals the septum displaced convexly into the unaffected GP, facilitating the initial contact. Cranial nerves IX through XII lie along the caudal margin and axial floor of the medial compartment, making the more-controlled contact laser perforation the preferred technique.

A 600-µm quartz fiber makes the axial bend easily; a diode laser set at 20 W is sufficient for the incision. Using an endoscope with the biopsy channel at 6 o'clock in the field of view, it is helpful to rotate the endoscope 90 degrees so the fiber presses easily against the membrane. The fiber is positioned well into the dorsal half of the septum at the caudal margin in preparation for a caudad-to-rostrad incision toward the endoscope. When the membrane is perforated, the fiber must be advanced appropriately to maintain contact of the tip of the fiber with the tissue. The hot fiber tip should not come too close to the endoscope. The incision will open a respectable hole in the membrane that is certainly adequate for airflow. However, many such perforations will heal closed[52]; removing a segment of the membrane is more apt to create a permanent opening (Figure 15-17, *A*). A section of membrane is removed by creating two parallel horizontal incisions followed by vertical transection of the rostral attachment. The dangling tissue is subsequently grasped with a long forceps inserted into the opposite GP opening to retract the tissue while the caudal attachment is severed. If the surgeon elects not to resect a piece of the membrane, the perforation should be monitored for a few weeks (Figure 15-17, *B*). If it begins to close, a Foley catheter can be placed for 3 weeks.

The simplest salpingopharyngeal orifice creation is ablation of the pharyngeal mucosa just caudad to the cartilage flap (Figure 15-18).[53] A Chambers catheter is inserted into the GP flap and rotated so the round tip presses axially, creating a bulge in the mucosa caudad to the external cartilage. The perforation must be created caudad enough to prevent the inner cartilage from obstructing the new opening. A noncontact Nd:YAG or diode laser can be used to vaporize the tissue overlying the catheter tip or a contact fiber can be rotated over the area until the fenestration is complete. A Foley catheter must be placed in the new opening for 7 to 10 days or until the tendency to close has passed. Alternatively, the pharyngeal cartilage flap of the GP opening may be dissected away using a contact technique and long grasping forceps for traction on the tissue.

Rarely, pharyngeal collapse caused by guttural pouch distention occurs in an adult horse. Although the affected guttural pouch will be asymmetrically distended and confirmed by radiography, the external distention typical of foals is not present. Treatment for adults is the same as for foals.

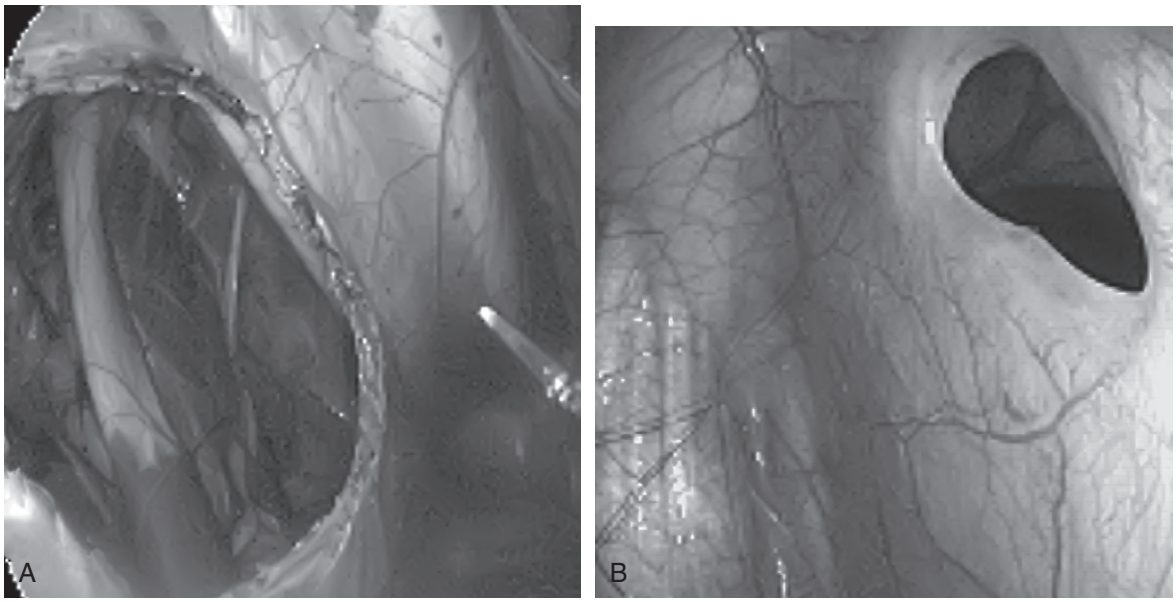

Figure 15-17. A, A segment of the guttural pouch septum has been resected, creating a large defect. This should be monitored for a few weeks to be sure it does not heal closed. **B,** The healed defect in the guttural pouch septum is usually much smaller than it was immediately postoperatively and often closes completely.

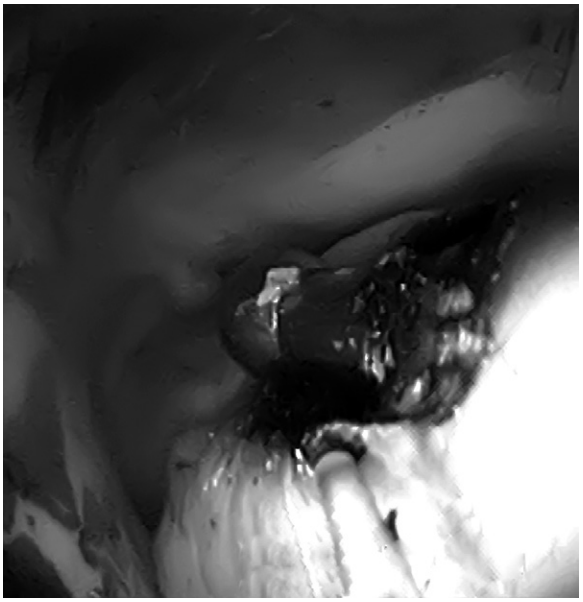

Figure 15-18. A salpingopharyngeal opening has just been created caudad to the left guttural pouch to correct tympany. The Chambers catheter *(arrow)* is protruding through the new opening; a Foley catheter will be placed through the guttural pouch flap opening and out this new opening to hold it open while it heals. The dorsal pharyngeal recess is visible in the upper left of the photo.

Progressive Ethmoid Hematoma (PEH)

Although usually progressive, in that these lesions enlarge over time, PEH is not always located on the ethmoturbinates and is not a simple hematoma. The laser is of limited value for lesions requiring frontonasal bone flaps for access because they must be conventionally debulked. Lesions visible by nasopharyngeal endoscopy may or may not be confined to the nasopharynx. Particularly lesions located against the lateral wall above the ethmoid shelf may also involve the frontal sinus. The laser is useful for lesions confined to the nasopharynx or ethmoid region. Radiographs should be taken to rule out sinus involvement, although these may be interpreted more easily after removal of obvious nasopharyngeal masses.

If the lesion is small, noncontact ablation with a higher-power Nd:YAG laser transmitted through a gas-cooled quartz fiber is feasible. For larger masses, it is important to treat the base of the PEH definitively; how the (usually) more rostral portion of the mass is removed matters little. Choices for debulking the larger masses include: formalin injection; snaring and amputation with obstetrical wire looped through a stomach tube; or simply grasping the lesion with a long instrument, such as a long sponge forceps, and pulling it out. If removal is incomplete, a combination of these methods is possible.

When the base of the lesion is visible, vaporization with the Nd:YAG laser is effective. Packing the ethmoid shelf with gauze sponges soaked in formalin is an effective ancillary treatment. The sponges are tethered to a long heavy suture that is stapled to the skin outside the external nares for overnight at least. The packing can be recharged with formalin through an endoscope or an endoscopically guided artificial insemination pipette if desired; injecting with the instrument held tightly against the packing soaks better and minimizes formalin dripping. The area should be endoscopically monitored for recurrence periodically for the first year.

Subepiglottic Cysts

Subepiglottic cysts (SCs) occur in foals and adults (see Chapter 45). These lesions may be associated with upper airway noise, respiratory disease, dysphagia, or poor performance[55,56] and may be asymptomatic at rest. Small SCs can be found in epiglottic entrapments and may provide inertia for the displacement. The SC must be removed completely to prevent recurrence.

SCs have been resected using contact laser decompression,[55] contact laser excision,[55,56] obstetrical (OB) wire amputation,[55,56] and electrosurgical loop amputation.[56,57] Decompression alone

led to recurrence. Although results were generally satisfactory, laser dissection and OB wire amputation were associated with a case of dorsal displacement of the soft palate; subepiglottic scar formation was responsible for one. The thermal effect of laser dissection on the ventral epiglottis was expressed as a concern.[56]

Some prefer electrosurgical amputation of SCs,[56,57] which may be performed standing or *per os* in the anesthetized horse. The unit is set to "pure cutting" and 100 W. The least amount of tissue possible should be in the snare when the amputation is performed. Small lesions that can be snared and retracted completely from the surrounding epiglottic cartilage and soft palate can be amputated with the horse standing. The typical SC in an adult horse is accessed more safely *per os* with the horse in dorsal recumbency.

The soft palate is left in its normal position ventral to the epiglottis to prevent the apex of the epiglottis from curling "up" (ventrally) and obstructing access to the SC. The electrosurgical loop is placed over the SC just "south of its equator" and tightened (Figure 15-19, *A*). The snare will gather mucosa and stretch it dorsally against the ventral surface of the epiglottis thus minimizing the amount of mucosa removed. Traction is placed on the snare, which is activated to amputate the SC in its entirety (Figure 15-19, *B*).

Postoperatively the horse is rested from airway turbulence approximately 2 weeks or until the subepiglottic ulcer has healed. Prednisolone, phenylbutazone, and an oral antibiotic are administered (see Table 15-2).

Neonates are treated the same but some additional caution may be needed. If respiratory disease is present, general anesthesia may be delayed; foals with large SCs may require tracheotomy as the respiratory disease improves. In one young foal with a large SC, for example, there was possible airway obstruction or difficulty intubating after general anesthesia was induced. With the foal sedated, the SC was endoscopically decompressed using an endoscopic injection needle. When the foal was intubated and in dorsal recumbency, the SC was reinflated with saline and amputated using electrosurgery.

Endometrial Cysts

Endometrial cyst ablation has been reported using the Nd:YAG laser in contact or noncontact fashion. With reasonable caution, there is little chance of full-thickness damage to the uterine wall.[40] Uterine distention for visibility is much better with the mare out of estrus.

For the noncontact technique, at 50 W or less, the gas-cooled fiber is positioned approximately 1 cm from the cyst wall, which is "painted" to visibly coagulate the visible tissue; the serous cyst fluid is heated in the process, further coagulating the cyst's lining. When all of the visible tissue has been blanched, the laser fiber set at 75 to 100 W is used to puncture the cyst and ablate all visible cyst tissue.[40] A similar contact technique is effective with a bare quartz fiber at lower power settings.[58]

Contact laser energy has been used to initially puncture the cyst so the fluid will heat and coagulate the cyst wall. The cyst wall will blanch and contract around the fiber; lasing is continued until it is only a small pale mass on the endometrial surface.

Complete electrosurgical removal of the structure with the fluid cyst intact is preferred.[59] The process is more efficient, and there is no potential for recurrence. However, extremely large cysts still require laser ablation. The electrosurgical loop/snare is tightened around the base of the cyst, distending the fluid contents. With the electrosurgical unit set at "pure cutting" and 100 W, the intact cyst is amputated and removed with suction through the endoscope or snaring with the electrosurgical loop. Postoperatively, the mare is short-cycled and examined again by the theriogeniologist.

Lithotripsy

Cystic or urethral uroliths can be removed completely endoscopically with laser energy transmitted through a quartz fiber inserted through the biopsy channel of the endoscope. The

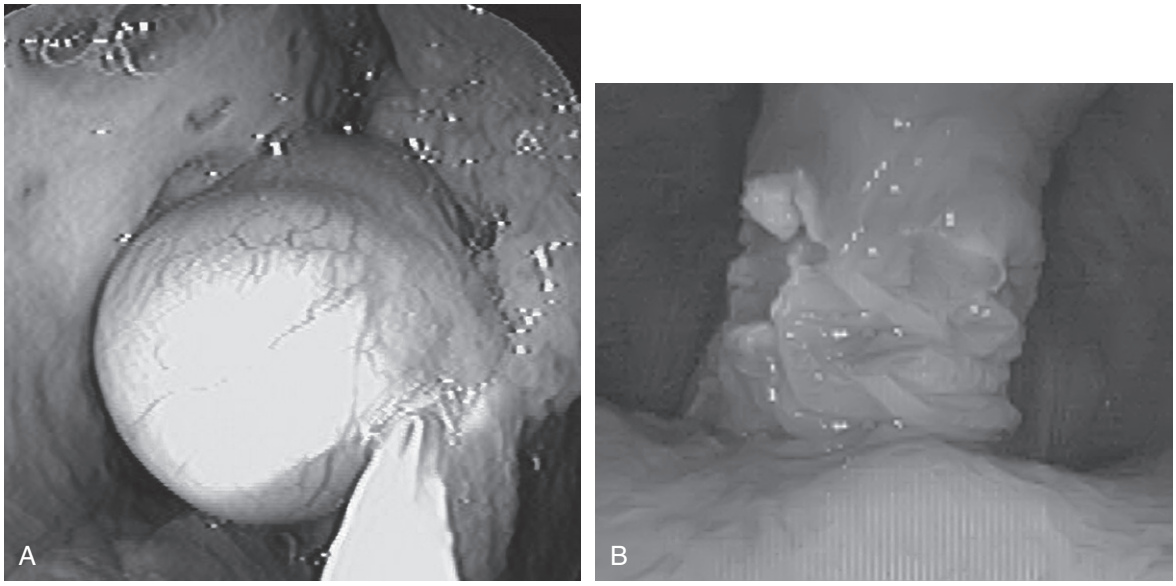

Figure 15-19. A, The electrosurgical snare is tight around the base of the subepiglottic cyst, ready to amputate. **B,** The site of amputation of the subepiglottic cyst is minimal if the mucosa is stretched tightly around the cyst. Excessive mucosal removal or damage may lead to excessive scar tissue immobilizing the epiglottis.

pulsed dye[38,60] and Ho:YAG[36-38] lasers have been used. Although the Ho:YAG laser is widely used in human and small animal urology, the pulsed dye laser is more efficient with large equine uroliths. The Ho:YAG laser essentially pulverizes the mineral, which is a lengthy process in dense stones; however, more porous smaller stones have been effectively addressed.[37] The pulsed-dye laser vaporizes the mineral into a plasma, and the pulsed hydraulic pressure fragments the stone.

Preoperative urine culture is advisable so treatment can be started in advance. If sabulous cystitis is present, preoperative lavage as needed with 0.5% acetic acid will dissolve the debris and sanitize the bladder. Cases with extreme sabulous cystitis should be evaluated carefully before surgery; for example, one urolith has been observed that was tightly adhered to the cystic wall, which perforated when it was separated endoscopically. No laser surgery had been performed.

Although it is possible to perform the procedure through the penile urethra with the horse standing, surgery is much more efficient with the horse in dorsal or lateral recumbency. The procedure is performed under water within the bladder (or urethra) with the fiber passed through the biopsy channel. Tubing from an arthroscopic fluid pump is attached to the biopsy channel and perforated with a needle to accommodate the very small quartz fiber. Fibers are expensive, so efficiency is helpful. When the bladder is distended with fluid, the urolith is located and the fiber is placed directly against the stone. When the laser is activated, the plasma will float away in the fluid medium and fragments will fall away (Figure 15-20). When the accumulation of fragments hinders access to the stone, the endoscope is replaced with sterile plastic tubing with the largest internal diameter the horse can accommodate. Place a hand on the bladder *per rectum*, which is inflated using the arthroscopic pump. When inflated, the tip of the tube is retracted to the neck of the bladder to funnel debris as the bladder is allowed to rapidly decompress; the bladder is "bounced" with the hand to keep the debris suspended. The process is repeated until the bladder is completely empty.

Figure 15-20. Endoscopic laser lithrotripsy of a cystic urolith. The pulsed-dye laser is turning the substance of the stone to a "plasma," which is floating away. Fragments that have fallen from the stone litter the foreground.

In most cases, the uroliths can be completely fragmented, but complete removal of the debris may be completed with the horse standing if anesthesia becomes prolonged. It is important to remove all the mineral debris; manual removal of small fragments may require the use of endoscopic biopsy forceps if they won't wash out.

Depending upon the horse, standing laser lithotripsy through a perineal urethrostomy may be preferable. General anesthesia may not be advisable; standing surgery for horses with extremely large stones is recommended. A sterile access tube can be placed in the bladder through the urethrostomy, significantly expediting the procedure.

Laser Treatment of Distal Tarsal Joints

Horses that have chronic distal tarsal disease (bone spavin) and that are refractory to medical therapy and corrective shoeing become candidates for surgery. Among the several approaches that have been reported is Nd:YAG or diode laser treatment of the tarsometatarsal and distal intertarsal joints.[61] Radiographic fusion of the joints does not occur, so the term *arthrodesis* does not apply, and fusion is apparently not required to resolve the lameness. The mechanism is more likely desensitization of the capsular sensory nerves. Compared to surgical drilling and sodium monoiodoacetate injection, laser-treated horses were more comfortable.[62] For additional information, review Chapters 81 and 97.

The procedure consists of fluoroscopically guided insertion of needles into the tarsometatarsal and distal intertarsal joints. Laser energy must not be applied to the proximal intertarsal joint, which communicates with the tarsocrural joint. Each joint must have ingress and egress to evacuate steam if the pressure is sufficient so superheating is prevented; the joint fluid reaches 100° C during the procedure. Because the joints are abnormal, they will typically not allow lavage across the entire joint, requiring two medial and two lateral needles in most cases. Laser energy is applied only if there is fluoroscopic confirmation of correct needle placement, and sterile saline will flush out at least one egress (may not be the adjacent needle). If one side of a joint cannot meet both criteria, that side is not treated. Lack of treating a part of a joint has not affected the outcomes to date.

Surgery is performed with the horse in dorsal recumbency, so the fluoroscope can be moved conveniently between limbs. I use a diode laser set at 20 W with a sterile 600-µm fiber. Sixteen-gauge needles are required to accommodate the laser fiber, but 18- or 20-gauge needles may be used for egress. Total energy per joint approximates 1500 J divided between the medial and lateral aspects of the joint, if needed. Gentle pressure is kept on the laser fiber as lasing progresses; some of the fiber will dissipate in the process (Figure 15-21). Removal of the needle and the fiber at once prevents the fiber from breaking inside the needle. Amikacin (250 mg) is placed in each joint after laser treatment. The needles become hot enough to cause skin necrosis, so sterile iced saline–soaked sponges are held over the needles and skin as lasing is performed. This is difficult on the down side of a horse in lateral recumbency, so dorsal recumbency is recommended.

Postoperatively, the horse is monitored for lameness and local swelling. Perioperative antibiotic and postoperative

Figure 15-21. Laser treatment of the distal tarsal joints. The horse is in dorsal recumbency and the needles are in the medial aspect of the tarsometatarsal and distal intertarsal joints. Laser energy is being applied to the more proximal joint and a plume is escaping from the vent needle.

NSAIDs are administered. If lameness or swelling appears, systemic DMSO (1 L 10% DMSO IV bid) is added and the affected areas are iced; topical NSAID is also helpful. Handwalking for 5 days followed by another 5 days of shed row or light turnout followed by return to training is prescribed.

LASER SAFETY

The authority for laser safety in the United States is American National Standard (ANSI) for Safe Use of Lasers in Health Care Facilities Z136.3. All surgical lasers are secured with a key lock and a separate interlock that is required to operate the machine. A designated laser safety officer responsible for lock security, warning signs during surgery, and other required safety measures is advisable.

Appropriate eye protection is required for all surgical laser wavelengths. Clear glass with protection from all angles is adequate for the CO_2 laser, but optical density recommendations are specific for the near-infrared and other wavelengths and should be followed for the wavelength of the laser. The patient's eyes must be considered as well. Because surgical lasers discussed here are not in the visible spectrum, a low-energy helium neon laser aiming beam is used. However, prolonged direct exposure, particularly to the eye, can cause damage.

All smoke generated from tissue should be evacuated using a filtered laser smoke evacuator. In spite of reports that insignificant concentrations of bacteria become aerosolized[63] and that horses are not adversely affected by routine upper airway laser surgery,[64] there is sufficient evidence that infectious, carcinogenic, and irritant material is present in laser smoke.[65] The vaporized debris and potentially viable cells or pathogens should not be inhaled by humans or the patient. Surgical suction is inadequate for this task because it is less efficient and the suction lines will eventually foul.

The surgical field should be protected by barriers when possible. Towels or lap sponges soaked with sterile water limit CO_2 laser energy from burning tissue off the field or drapes. Wet sponges should be held behind tissue when the laser might penetrate completely.

Accelerants should be avoided. Saline should be used instead of alcohol for surgical prep. Heliox (oxygen diluted with helium) can be substituted for pure oxygen when operating close to the airway with the horse under general anesthesia. If these few simple rules are followed, laser surgery is as safe as any other surgery.

CHAPTER 16

Suture Materials and Patterns

Jan M. Kümmerle

The history of surgery is intrinsically tied to the development of suture materials. The use of silk and catgut was already described in AD 150 by Galen of Pergamon, who used these materials to suture wounds sustained in gladiator fights, a popular entertainment in the Roman Empire.[1] Since that time, tremendous advances have been made in the development of biomaterials, and today the veterinary surgeon can choose from a variety of suture materials. However, the one ideal suture material for every indication does not exist, and the surgeon needs to know the specific properties of each material to make an appropriate choice for each application.

SUTURE CLASSIFICATION

Sutures can be classified by several criteria[2]:

- Degradation behavior: absorbable versus nonabsorbable
- Composition: natural versus synthetic
- Structure: monofilament versus multifilament.

Absorbable sutures undergo degradation and loss of tensile strength within 60 days.[3] Degradation is mediated by hydrolysis, enzymatic digestion, or phagocytosis. Natural materials are degraded by proteolytic enzymes, whereas the new synthetic absorbable sutures are degraded by nonenzymatic hydrolysis of ester bonds that occurs independent of inflammation. After hydrolysis separates the ester bonds and depending on particle size, phagocytosis may take place.[4] Nonabsorbable suture materials are not significantly degraded after implantation and are indicated where extended wound support or implant function is required.

Sutures are made from naturally occurring substances, synthetic polymers, or metallic fibers. Natural materials tend to invoke a significant inflammatory reaction and currently have been replaced by synthetic materials.

Multifilament suture materials are composed of several filaments twisted or braided together. Generally, this leads to good handling and knot-tying properties and offers superior knot security. On the other hand, their braided structure increases capillarity, facilitates penetration of bacteria, and increases drag resistance while being pulled through tissue. Multifilament sutures may be coated to reduce tissue drag and capillarity. However, coating can reduce knot security, and the coating layer may be damaged during the suturing process, thus leading to recurrence of the aforementioned disadvantages of multifilament sutures.[5] A monofilament structure results in lower tissue drag, less risk of infection, reduced tissue reaction, and less tendency of pretied loops to collapse. On the other hand, the higher bending stiffness and greater memory of monofilament sutures as well as their lower coefficient of friction result in poorer handling properties and less knot security. In addition, their stiff cut ends can cause tissue irritation and mucosal ulceration.

SUTURE CHARACTERISTICS

Suture Size

The United States Pharmacopoeia (USP) standard for suture size (i.e., cross-sectional diameter) is still commonly used. This system uses 0 as the baseline average suture size. As suture diameter decreases, 0s are added or numbers followed by a 0 (2-0, 3-0, etc.; e.g., 000 and 3-0 are the same size). As suture diameter increases above 0, increasing numbers are assigned (1, 2, etc.). Another system is the European Pharmocopoeia. It was established in 1973 and uses a metric system. Suture size is expressed as a number (4, 5, etc.) that corresponds to 1/10 of the suture diameter in mm (Table 16-1).

TABLE 16-1. The USP and ESP Classification System for Suture Sizes of Synthetic Suture Materials

US Pharmacopoeia	European Pharmocopoeia	Suture Diameter
USP SIZE	METRIC SIZE	mm RANGE
11-0	0.1	0.010-0.019
10-0	0.2	0.020-0.029
9-0	0.3	0.030-0.039
8-0	0.4	0.040-0.049
7-0	0.5	0.050-0.069
6-0	0.7	0.070-0.099
5-0	1	0.100-0.149
4-0	1.5	0.150-0.199
3-0	2	0.200-0.249
2-0	2.5	0.250-0.299
2-0	3	0.300-0.349
0	3.5	0.350-0.399
1	4	0.400-0.499
2	5	0.500-0.599
3; 4	6	0.600-0.699
5	7	0.700-0.799
6	8	0.800-0.899
7	9	0.900-0.999
8	10.0	1.000-1.099

Flexibility

The torsional stiffness and diameter of a suture determine its flexibility.[6] Flexible sutures are required to ligate vessels or to perform a continuous suture pattern.

Elasticity

Elasticity is the capability of a material to undergo elastic deformation under tension, returning to its original length after stretching. High elasticity will allow the suture to stretch with wound edema but return to its original length when swelling has subsided.

Surface Characteristics and Coating

The surface characteristics of a suture determine the tissue drag (i.e., the resistance and subsequent trauma when pulled through tissue) and the coefficient of friction.[6] Rough sutures cause more injury than sutures with a smooth surface. In delicate tissues, such as the eye or a thin-walled viscus, low tissue drag is particularly important. However, sutures with a smooth surface and low tissue drag require greater tension to achieve good apposition of tissues and they have lower knot security. Multifilament sutures have more tissue drag than monofilament sutures. The coefficient of friction is a measure of the slipperiness of a suture that affects the tendency of the knot to loosen after it has been tied: multifilament sutures have higher frictional values[7] and thus knot security.[8] Coating provides a smoother surface, reducing tissue drag and the coefficient of friction.

Capillarity

Capillarity is the process by which bacteria and fluid are carried into the interstices of a multifilament suture material. Cells of the body's immune defense system are too large to enter these interstices, and therefore a persistent infection can result, particularly if a nonabsorbable suture is used. Coating can reduce the capillarity. Suture materials with significant capillarity should not be used in contaminated or infected surgical sites.

Memory

Memory refers to the capability of a suture to return to its original shape after deformation by tying. Sutures with a high degree

of memory, particularly monofilament sutures, are stiff and difficult to handle.

Tensile Strength

The suture material's tensile strength (TS) is the force that the untied suture strand can withstand before it breaks when the force is applied in the direction of its length.

Knot Holding Capacity

The knot holding capacity (KHC) is the maximum load to failure when tension is applied to the knotted suture material.

Relative Knot Security

Relative knot security (RKS) has been recommended as a standardized way to describe the knot-holding capacity. It is the knot-holding capacity expressed as a percentage of the unknotted suture's tensile strength by the formula RKS (%) = (KHC/TS) × 100.

SELECTION OF SUTURE MATERIALS

To select an appropriate suture out of the wide range of suture materials, its specific composition and structure as well as biological and biomechanical behavior as they relate to the requirements needed should be considered. The details on characteristics of relevant suture materials are summarized in Tables 16-2 and 16-3.

Selection of the Biomechanically Appropriate Suture Size and Material

Certain biomechanical principles should be taken into account when selecting a suture material and its size:

- The selected suture should be as strong as the normal tissue through which it is placed.
- Tensile strength reduction over time of the chosen suture material should correspond to the healing characteristics and gain in wound strength of the sutured tissue.
- A suture is not needed after a wound has healed.
- The strength of a wound is more dependent on the involved tissue's ability to hold a suture than the strength of the suture material itself.
- Elastic suture materials are indicated for skin closure to adapt to wound edema; suture materials with high stiffness are required to serve as a prosthesis and for abdominal closure, herniorrhaphy, or joint imbrications.
- The use of an oversized suture material may weaken the repaired wound by causing excessive tissue reaction.
- For a wound under tension, increasing the number of sutures applied (and/or the use of tension sutures) is preferable to increasing the suture size.[9]

SURGICAL NEEDLES

Surgical needles are manufactured from surgical steel and come in various shapes: straight, half-curved, or curved with 1/4-, 3/8-, 1/2- or 5/8-circle shapes (Figure 16-1). Easily accessible tissues, such as the skin, may be sutured by hand with straight needles, but curved needles are generally preferred because they are easier to use with instruments. There is limited indication for 1/4-circle needles, except for ophthalmologic surgery. For suturing in confined and deep locations, 5/8-circle needles are useful. In most instances, 3/8- or 1/2-circle needles are preferred because they do not require extensive rotational movement of the hand to penetrate tissue and allow precise wound adaptation.

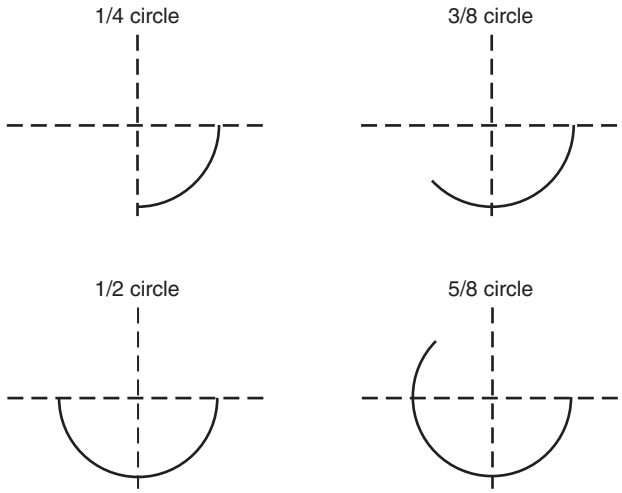

Figure 16-1. Various shapes of curved needles.

The three basic components of a surgical needle are the suture attachment end (i.e., swaged or eyed), the body, and the point[6] (Figure 16-2). In eyed needles, the suture must be threaded through the eye and a double strand of suture pulled through the tissue. Eyed needles are reusable and thus less expensive. However, they can become dull with reuse and this can exacerbate tissue trauma. Swaged needles have the suture attached to their ends. They are easier to handle, and tissue penetration results in less trauma than that caused by eyed needles because only a single strand of suture material is pulled through the tissues. Currently, the hole to introduce the suture material into the back of the needle is prepared with lasers. This process is more precise and has led to downsizing of the needles, which results in decreased trauma during suturing.

Needle length should be considered when choosing a suture-needle combination. The needle should be long enough to allow penetration of both wound margins. Chord length and needle radius become important factors in laparoscopic surgery when the needle needs to be inserted through a laparoscopic cannula.[10]

The shape of the point and body of the needle (Figure 16-3) are main determinants of its behavior in the patient's tissue. Taper point needles should be used wherever possible because they are least traumatic to adjacent tissue and minimize inadvertent damage to vessels and nerves. Indications include suturing muscle, subcutaneous tissue, or viscera. Cutting needles provide sharp edges that cut through dense connective tissue thus rendering them suitable for closing skin, tendon, and fascia.[11] Both the regular cutting needle and the reverse cutting needle have a triangular cross-sectional area. The regular cutting needle possesses a sharp edge on the inner curvature of the needle point and shaft. This may promote "cut out" of

TABLE 16-2. Absorbable Suture Materials

Suture Type	Trade Name	Composition	Structure	Absorption	Tensile Strength	Advantages	Disadvantages
Surgical gut	Catgut, Plain Gut, Chromic Gut, Catgut Chrom	Collagen obtained from bovine intestinal serosa or ovine intestinal submucosa; chromic gut is treated with a chromic salt solution	Multifilament	Evokes a moderate inflammatory reaction in tissue as it is broken down through a combination of enzymatic degradation and phagocytosis; rate of absorption is increased in the presence of infection and in tissues with high levels of proteolytic enzymes	Has less tensile strength than most synthetic absorbable sutures	Inexpensive; adhesion promotion can be desirable in some indications; good handling characteristics	Production and use of catgut was prohibited in the European Union in 2001 as the entire bovine intestine is classified as specific TSE risk material; chromic coating reduces soft tissue reaction and rate of absorption; chromic gut is difficult to handle and has poor knot security when wet
Polyglactin 910	Vicryl	Copolymer of glycolide and L-lactide; coating: polyglactin and calcium stearate	Braided multifilament; coated	Resorption time: 56-70 days	Tensile strength reduction by 25% at day 14, 50% at day 21, and by 100% at day 35	Good size-to-strength ratio; greater initial breaking strength and stiffness than polydioxanone; minimal tissue reaction; excellent handling properties	May cut through friable tissue (especially if not coated)
Polyglycolic acid	Dexon, Dexon II, Safil	Polymer of glycolic acid; Dexon II is coated with polycaprolate	Braided multifilament; can be coated	Resorption time: 60-90 days	Tensile strength reduction by 35% at day 14 and by 65% at day 21	Good handling characteristics	Very rapid absorption in the oral cavity; tends to drag through tissues; less knot-breaking strength than polyglactin 910
Braided lactomer	Polysorb	Copolymer of glycolide and lactide; coating: mixture of a caprolactone/ glycolide copolymer and calcium stearoyl lactylate	Braided multifilament; coated	Resorption time: 56-70 days	Tensile strength is 140% of minimum knot strength requirements of the European/ United States Pharmacopoeia initially, 80% at day 14 and 30% at day 21; biomechanically superior to polyglactin 910	High initial tensile strength; good knot security; excellent handling properties	

Glycomer 631	Biosyn	Combined polymer of glycolide, dioxanone and trimethylene carbonate	Monofilament	Resorption time: 90-110 days	Tensile strength is 75% of minimum knot strength requirements of the European/ United States Pharmacopoeia at day 14 and 40% at day 21.	Monofilament suture with only minimal memory and excellent handling properties; minimal tissue reaction	
Polyglytone 6211	Caprosyn	Copolymer of glycolide, caprolactone, trimethylen carbonate, and lactide	Monofilament	Resorption complete within 56 days	Loses almost all tensile strength within 21 days	Provides short-term tensile strength combined with very rapid absorption	
Polydioxanone	PDS II	Polymer of poly-*p*-dioxanone	Monofilament	Resorption time: 180 days	Tensile strength reduction by 25% at day 14, 30% at day 28, 50% at day 42	Absorbable suture material that maintains tensile strength over a prolonged period of time; less memory effect than polyglyconate	Moderate knot security, moderate handling characteristics
Polyglyconate	Maxon	Copolymer of glycolide and trimethylene carbonate	Monofilament	Resorption time: 180 days	Tensile strength reduction by 25% at day 14, 50% at day 28, 75% at day 42	Slow resorption and loss of tensile strength; three times stronger than polyglactin 910 at day 21 of wound healing; good knot security	Much memory effect, limited pliability and moderate handling properties
Polyglyconate	Monosyn	Copolymer of glycolide, trimethylene carbonate, caprolactone	Monofilament	Resorption time: 60-90 days	Tensile strength reduction by 30% at day 7, 50% at day 14 and 80% at 21 days	Very good handling properties and good knot security	
Poliglecaprone	Monocryl	Copolymer of glycolide and caprolactone	Monofilament	Resorption time: 90-120 days	Tensile strength reduction by 50% at day 7 and 80% at day 14; complete loss of tensile strength within 21 days	Very low tissue drag owing to smooth surface; only minimal memory effect and high pliability; provides high initial tensile strength and rapid absorption; minimal tissue reaction	

TABLE 16-3. Nonabsorbable Suture Materials

Suture Type	Trade Name	Composition	Structure	Tensile Strength	Advantages	Disadvantages
Silk	Sofsilk, Silkam	Raw silk, spun by silkworm	Braided multifilament; coated or uncoated		Excellent handling characteristics; useful for ligatures	Does not maintain tensile strength more than 6 months; may potentiate infection—should be avoided in contaminated sites; has significant capillarity; incites some inflammatory reaction
Surgical steel	Steelex	Alloy of iron	Monofilament or as a multifilament twisted wire	Greatest tensile strength of all sutures	Greatest knot security of all sutures; no inflammatory reaction	Tissue movements against the inflexible ends may cause inflammation and necrosis; poor handling properties; cannot withstand repeated bending without breaking; multifilament wire can fragment and migrate, leading to sinus tract formation
Nylon	Dafilon	Polymer of polyamide	Monofilament or multifilament	Intermediate tensile strength; monofilament nylon loses about 30% of its original tensile strength by 2 years because of chemical degradation; multifilament nylon retains no tensile strength after 6 months	Suitable for use in contaminated wounds; degradation products act as antibacterial agents	Poor handling characteristics and poor knot security; not recommended for use within serous or synovial cavities because buried sharp ends may cause frictional irritation
Polycaprolactam	Supramid	Polymerized caprolactam (=polyamide 6)	Multifilament with a polyamide coating	Better tensile strength than nylon	Excellent handling properties, high knot security	Intermediate tissue reactivity; has a tendency to form sinuses on implantation in tissues and is therefore best suited for use in the skin

Polyester	Mersilene, Synthofil, Dagrofil, Ethibond, Ticron	Polyethylene terephtalate	Monofilament or multifilament; uncoated or coated with polybutilate or silicone or polyethylene/vinyl acetate	Very high and sustained tensile strength		Noncoated polyester fibers have a high coefficient of friction; knot security is poor and is further reduced by coating; causes marked tissue reaction and fibrous encapsulation; should not be used in contaminated wounds
Ultra-high molecular weight polyethylene	FiberWire	Ultra-high molecular weight polyethylene	Multifilament with a polyethylene/ polyester coating	Superior strength; greater tensile strength and less elongation under load than polyester sutures	High abrasion resistance; good knot security; less tissue drag than polyester sutures	
Polypropylene	Premilene, Prolene, Surgipro	Polyolefin plastic	Monofilament	Moderate tensile strength	Greatest knot security of all synthetic monofilament sutures; least thrombogenic suture material makes it suitable for vascular surgery; minimal tissue reactivity and least likely to potentiate infection; high elasticity	Slippery handling and tying characteristics
Polybutester	Novafil	Copolymer of butylene terephthalate and polytetramethylene ether glycol	Monofilament		Good handling characteristics and knot security; more flexible than polypropylene or nylon; elongates elastically under load or tension when wound edema occurs and returns to its original form when edema subsides; minimal tissue reaction	

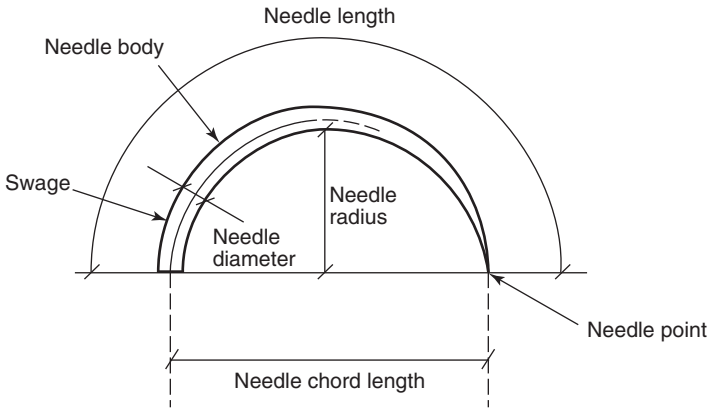

Figure 16-2. Anatomy of a surgical needle.

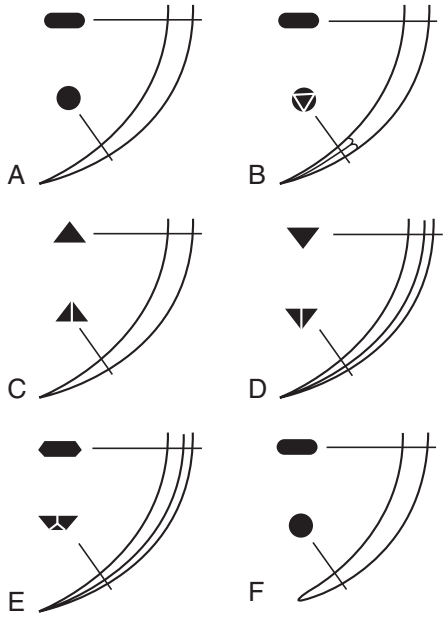

Figure 16-3. Various points and shaft designs of surgical needles. **A,** Taperpoint; **B,** tapercut; **C,** regular cutting; **D,** reverse cutting; **E,** spatula point; **F,** blunt point.

tissue because it cuts toward the edges of the wound or incision. Reverse cutting needles have the cutting edge located on the convex, outer curvature of the needle. This makes them stronger than similarly sized conventional cutting needles and reduces the risk of tissue cut out.[6] A tapercut needle combines the reverse cutting point that readily penetrates through tissue with a round shaft that does not cut through or enlarge the needle hole when passed.[11] These needles can be used to suture a delicate tissue to a denser one (e.g., suturing epithelium/mucosa to the skin as in urethrostomy, colostomy, or tracheostomy) or for dense but delicate tissues (e.g., periosteum). Spatula needles are flat on the top and bottom and have a side cutting action. They are indicated for certain procedures in ophthalmologic surgery.[12] Blunt-point needles have a rounded, blunt point that can penetrate friable tissue without cutting. They can be used to suture soft, parenchymal organs, such as the liver or kidney.[6]

The Deschamps needle (Figure 16-4) is a long thin instrument with a palm-held handle and a thin needle-like extension

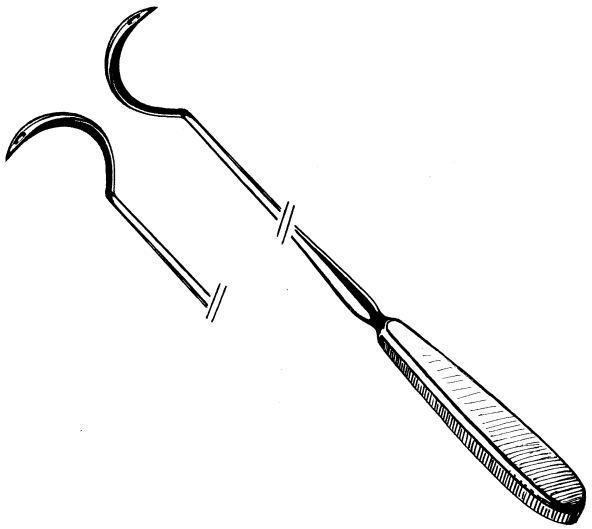

Figure 16-4. Deschamps needles, showing the left- and right-handed configuration, respectively. The threaded eye near the pointed tip allows easy retrieval of the suture without the need for complete penetration by the needle. When the suture is grasped at the tip of the needle, the instrument is rotated backward out of the tissue and can be rethreaded for the next bite.

that bends laterally at right angles at its tip and then continues as a semicircle in the same plane. The tip has a needle eye and a pointed but not sharp end. It is designed to place ligatures around vessels in poorly accessible sites and can be used for suturing in deep, confined areas.

SUTURE CONFIGURATIONS

Knots and Ligatures

Knot tying is an essential part of almost any surgical procedure. However, even a perfectly tied knot is the weakest part of a suture.[6,13] Therefore, it is of tremendous importance to perform knot tying correctly to prevent unnecessary weakening of this critical part of the suture, which could potentially leading to subsequent dehiscence.

Knot Tying Techniques

A knot is constructed by laying at least two throws on top of each other and tightening them. If the direction of the throws is reversed, a square knot results (proper); otherwise a granny knot is obtained (improper). During knot tying, opposing suture ends should be pulled perpendicular to the long axis of the incision except if sutures are placed deep in the tissues. In the latter situation, the suture ends are pulled parallel to the direction of the suture line and in doing so the tissues positioned above the knot are not pulled apart. Reversal of throw direction combined with pulling mainly on one end of the suture results in a half-hitch; if tension applied by the pulling hand is directed away from the incision by lifting this hand, a sliding half-hitch is formed (Figure 16-5). Granny and half-hitch knots are prone to slip.[13] However, this feature can be beneficial if the knot needs to be slid into a deep and confined space.

Generally, a superimposition of square knots is considered the most reliable knot configuration.[6] When the first throw of a square knot does not hold the wound margins in apposition,

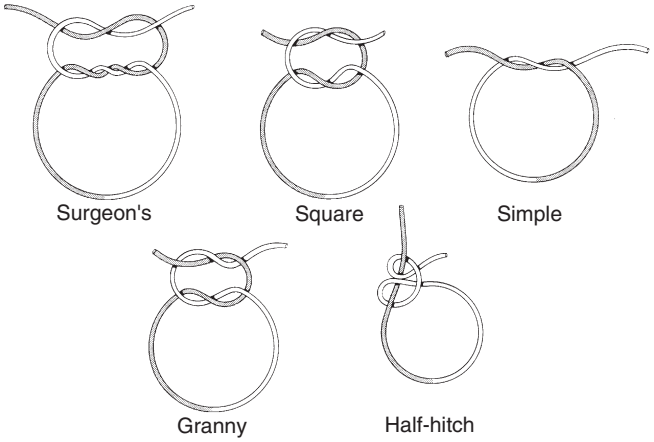

Figure 16-5. Surgical knots.

a surgeon's knot may be tied. However, the surgeon's knot should be avoided when not needed because it places more suture material into the wound and can decrease structural stiffness of a knot with some suture materials.[14] Clamping the first throw of a square knot to maintain tissue apposition after the first throw does not negatively affect mechanical properties of common multifilament suture materials; however, clamping can reduce breaking strength of monofilament sutures by 10%.[13,14] A square knot but not a surgeon's knot should be used to ligate vessels.[6] Knots can be tied using instruments or by hand. In veterinary surgery, instrument ties are more commonly used because there is less waste of suture material. If a square knot is formed at the end of a continuous suture line and a needle holder is used to tie the knot, it is important to grasp exactly at the center of the looped end to avoid asymmetric loads placed on either end of the loop. By applying tension to the suture loop with an open needle holder, the tension along the loop equalizes on its own. Hand ties are particularly useful in confined areas, when sutures have been pre-placed or to precisely adjust tension on the suture. Hand ties require that the suture ends be left longer than for an instrument tie. A one-handed or two-handed technique can be applied.

The knots of subcutaneous and intradermal suture patterns should be buried to reduce irritation caused by knots rubbing against more superficial tissue and to prevent suture extrusion.

Knot Efficiency

Loop security and knot security are ways of measuring a knot's effectiveness.[8] Loop security is the capability to maintain a tight suture loop as a knot is tied. Inadequate loop security results in loss of tissue apposition during knot tying.[15] Knot security is defined as the effectiveness of the knot at resisting slippage when load is applied. Knot security depends on the structural configuration of the knot and the type of suture material.[16] The characteristics of a suture material mainly affecting knot security are memory and coefficient of friction. Remember that body fluids come in contact with the suture material during surgery, which affects frictional behavior and thus the knot security of a suture.[17]

In addition to suture material and knot configuration, the number of throws and suture end length also influence knot security. A suture end length of at least 3 mm is recommended to optimize knot integrity.[18,19] The minimal number of throws needed (including the first) for a secure square knot using No. 2-0 USP suture materials is three for polyglycolic acid, polyglactin 910, and polypropylene and four for nylon and polydioxanone.[20,21] For larger-diameter suture materials, sufficient knot security is achieved with five throws. This was demonstrated for polyglactin 910 No. 2 USP, polyglactin 910 No. 3 USP, and polydioxanone No. 2 USP.[13] Knots at the end of a continuous suture line are constructed using one looped and one free end. These knots require two or three more throws to ensure knot security than do knots constructed from two single suture strands.[22] The Aberdeen knot represents a special configuration to end a continuous suture line and is recommended in human surgery when monofilament suture material is used (the configuration of the knot can be studied in the cited publication).[23] A recent *in vitro* study demonstrated superior relative knot security and reduced knot volume of Aberdeen knots compared to square knots to end a continuous suture pattern of polydioxanone.[21]

Another factor to consider is the wound environment. A fatty wound environment can increase the number of throws needed to achieve a secure knot. This was confirmed by the finding that fat-coated No. 2-0 USP polydioxanone requires one additional throw to form a secure square knot at the beginning of a continuous pattern compared to plasma-coated No. 2-0 USP polydioxanone.[21] Asymmetric knots like sliding half-hitch or asymmetric granny knots usually need two additional throws to achieve knot security. This was demonstrated in one study for polyglactin 910.[24] However, the superior knot security of braided lactomer (Polysorb) provided sufficient knot security even without additional throws.[24] In the clinical situation, the number of throws should be adequate to ensure knot security but not excessive to limit the amount of bulky foreign material in the tissues.

Finally, the suture diameter is also a determinant of knot security. Knot security decreases with increasing suture diameter.[13,16]

Loop Sutures

As an alternative to knots, the use of a loop suture to apply a simple continuous pattern has also been described in equine surgery.[25] The use of loop sutures reduces the number of knots and the double suture strand provides a larger surface area as the suture passes through the tissue; however, they result in an increased total amount of suture material remaining in the wound and the placement of a bulky four-stranded knot at the end of the suture line. In an *in vitro* experiment, USP No. 2 braided lactomer loop sutures applied in a simple-continuous fashion provided sufficient security for closure of the equine linea alba based on single-cycle to failure testing, with fascial failure being the main failure mode and without occurrence of suture or knot failure.[25]

Knot-Tying Techniques for Minimally Invasive Surgery

Minimally invasive surgical techniques require modifications in knot-tying techniques. In equine surgery, laparoscopy is increasing in importance, and extracorporeal knotting requires safe and efficient sliding-knot techniques. The first reliable sliding knot described for human laparoscopy was the Roeder knot.[26] Knot security was further improved by Sharp et al.[27] by

developing the 4S-modified Roeder knot (Figure 16-6). *In vitro* studies revealed that the 4S-modified Roeder knot outperformed several other slipknot ligatures in terms of knot security.[28,29] Monofilament suture materials are suitable for laparoscopic surgery because they perform well for knot rundown, have low tissue drag, and, unlike multifilament sutures, do not loose loop characteristics when wet. With regard to suture material and size used for the 4S-modified Roeder knot, polydioxanone and polyglyconate are biomechanically superior to polyglactin 910 and polyglycolic acid and sizes USP No. 1 or 2 are superior to smaller suture sizes.[28,29]

Suture Tension

Suture tension can be classified as intrinsic or extrinsic. Intrinsic tension refers to the tension on the tissue constricted within the suture loop. Excessive intrinsic tension can cause ischemic necrosis. Extrinsic tension represents the pulling tension from outside the suture loop. It depends on wound size, location, relationship to skin lines, and the amount of surrounding loose tissue.[30]

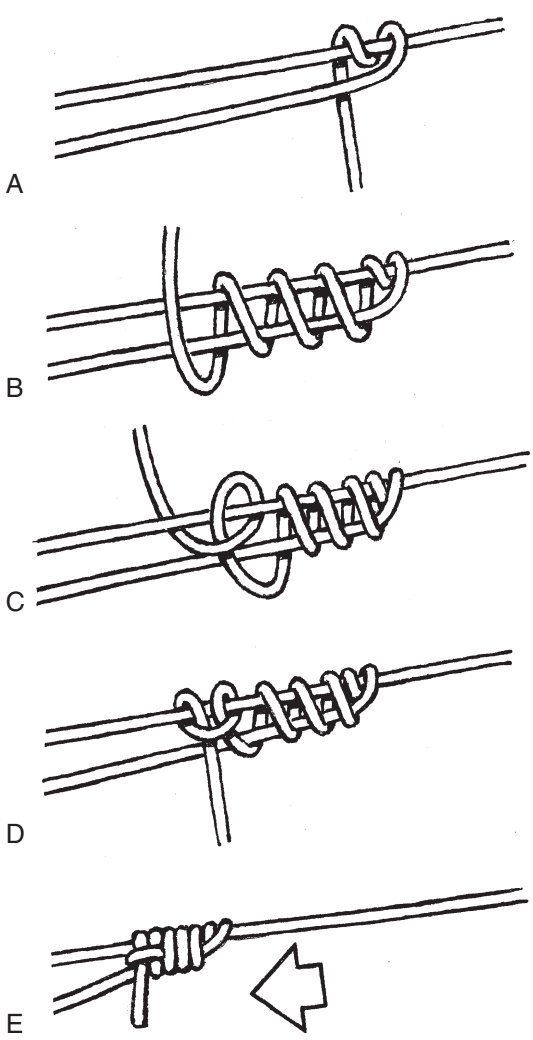

Figure 16-6. The 4S-modified Roeder knot is tied by: **A,** starting the knot with a single throw; **B,** wrapping the tail of the suture three times around both strands of the loop entering the abdomen; **C,** completing the knot with a half hitch knot around the standing part of the suture; **D,** completed knot is tightened by alternately pulling on the standing part and strand of the abdominal loop that exits from the cannula; **E,** the tightened knot is then slid into the abdominal cavity using a knot pusher.

Suture Patterns

Suture patterns can be classified as interrupted or continuous. Interrupted suture patterns have the following advantages over continuous patterns: increased security because failure of one suture does not jeopardize the entire suture line, precise reconstruction of irregular wound margins, precise control of tension at each point of the wound margin, less interference with blood supply of the wound margins, and no purse-string–like effect when tightening the suture applied in hollow viscera. Additionally, a part of the suture line can be re-opened in the postoperative period if drainage should be necessary.

On the other hand, the advantages of continuous patterns include: a smaller volume of suture material (in the form of knots) in the tissues, decreased surgery time, more even distribution of tension, better holding power against stress, and a tighter seal of skin and hollow viscera.

Suture patterns can be further characterized by the way they appose tissue: appositional sutures bring the tissue in direct approximation of the two cutting surfaces, everting sutures turn the tissue edges outward, and inverting sutures turn tissue inward. Appositional sutures are useful for anatomically precise closure. Inverting suture patterns are indicated to close hollow viscera or, in the form of the Lembert pattern, for fascial imbrication. Everting sutures eliminate dead space and counteract the tendency of wound edges to invert during healing. Most tension sutures have everting characteristics. Tension sutures redistribute the tension across the wound edges, thus drawing the wound edges together and minimizing marginal strangulation and necrosis. The capability of a suture pattern to withstand tensile forces is related to the number of segments that are parallel to the line of tension.[31] In horses, tension sutures are frequently used to close traumatic lacerations and surgical wounds over bone plates. Tension sutures are pre-placed well away from the wound margins, the skin edges can be apposed with the aid of towel clamps followed by tying of the tension sutures. Finally, the wound is closed with an appositional suture pattern.[9] Gauze, rubber tubing, or buttons can be incorporated into the tension sutures to reduce the risk of cutting out of sutures. This technique is termed "quilled" or "stented" suture. To approximate severed ends of a tendon or to secure one end of a tendon to bone or muscle, special tension suture configurations are indicated.

Tables 16-4 through 16-6 summarize the most common suture patterns. These patterns are illustrated in Figures 16-7 through 16-9.

Sutures for Specific Tissues

Skin

Monofilament suture materials are indicated for skin closure to reduce capillary transport of bacteria into deeper tissues. Nonabsorbable materials like nylon, polypropylene, and polybutester are preferred for skin sutures. Polybutester combines good handling characteristics with adequate elasticity to adapt to wound edema. A simple interrupted pattern is commonly used. Slight eversion is desirable to counteract the tendency of the

TABLE 16-4. Appositional and Everting Suture Patterns

Suture Pattern	Tissue Apposition	Characteristics
Simple interrupted (SI) (Figure 16-7, *A*)	Appositional; excessive tension may cause inversion	Easy and quick to place; precise anatomic closure and tension adjustment possible; knot should be offset so it does not rest on the incision
Interrupted intradermal/ subcuticular (Figure 16-7, *B*)	Appositional	Upside down SI suture placed in dermis/subcutis
Cruciate (Figure 16-7, *C*)	Appositional; excessive tension causes inversion	Stronger closure than SI; resists tension and prevents eversion; gains more space per suture than SI pattern
Gambee (Figure 16-7, *D*)	Appositional	Reduces mucosal eversion compared to SI pattern; may reduce wicking of bowel contents from the intestinal lumen to the exterior
Interrupted vertical mattress (IVM) (Figure 16-7, *E*)	Appositional to slightly everting	Precise apposition of wound edges; minimal interference with vascular supply; can be used for concurrent closure of skin and subcutis; places more suture material into the wound than SI
Allgöwer corium vertical mattress (Figure 16-7, *F*)	Appositional	Minimally traumatic suture pattern that provides good skin apposition and excellent cosmetic outcome; less holding strength than IVM
Interrupted horizontal mattress (Figure 16-7, *G*)	Everting	Degree of eversion depends on suture tension and distance to the wound margin; more everting than IVM; can also be applied in a continuous pattern
Simple continuous (SC) (Figure 16-7, *H*)	Appositional	Provides maximal tissue apposition; time and material saving; provides a relatively airtight and fluidtight closure; if used for skin closure: excessive tension can cause strangulation of the skin; anatomically less precise adaptation than SI pattern
Continuous intradermal (Figure 16-7, *I*)	Appositional	Bites are placed intradermally and parallel to the long axis of the incision; knots must be buried; superior cosmetic outcome; no need for suture removal; provides less strength than percutaneous skin closure
Ford interlocking (Figure 16-7, *J*)	Appositional	Synonym: Reverdin pattern; provides precise adaptation and offers greater security in the event of a partial failure; may be difficult to remove; may cause pressure necrosis and become buried when placed under tension

skin edges to invert during healing, and it results in the most cosmetic outcome. As mentioned earlier, wounds of traumatic origin or skin closure over implants may require the application of tension sutures.

To close a surgical incision, the needle enters the skin approximately 3 to 5 mm lateral to the incision line. Collagenase activity remains high within 5 mm of a skin incision, and sutures placed too close to the incision may be at greater risk of cutting through tissue.[9] Wounds of traumatic origin may manifest with traumatized or inflamed tissue margins that may require partial resection of the skin edges and larger needle bites. Suture spacing depends on skin thickness and the direction and magnitude of tension lines. Wounds along tension lines are pulled into better apposition and require fewer sutures than those oriented perpendicular to a tension line.[30] Placing interrupted sutures too closely together can result in excessive tissue reaction and unwarranted interference with cutaneous blood supply. Generally, it is recommended to place interrupted sutures 5 mm apart.[9]

As an alternative to percutaneous skin sutures, a continuous intradermal suture pattern using absorbable synthetic materials can be applied. Advantages of an intradermal suture are no need for suture removal, lack of skin irritation, lack of suture track infection, and excellent cosmetic outcome. Disadvantages include increased time for placement and less security than percutaneous skin patterns.[30]

Subcutis

Subcutaneous sutures are placed to eliminate dead space and decrease tension across the wound margin before placement of skin sutures. If drainage might become necessary, they can be placed in a simple interrupted pattern, otherwise a simple continuous pattern with the bites made perpendicular to the long axis of the incision is generally used.[6] Intermittent incorporation of the underlying soft tissue can reduce dead space. Synthetic absorbable suture materials are usually used.

Fascia

Fascia is considered a slowly healing tissue. Therefore, nonabsorbable or slowly absorbable synthetic suture materials are indicated for its closure.[32]

Concerning the equine linea alba, an experimental study on tissue strength after ventral midline celiotomy and closure of the linea alba using braided lactomer USP No. 2 in an interrupted cruciate pattern found a return to baseline tensile

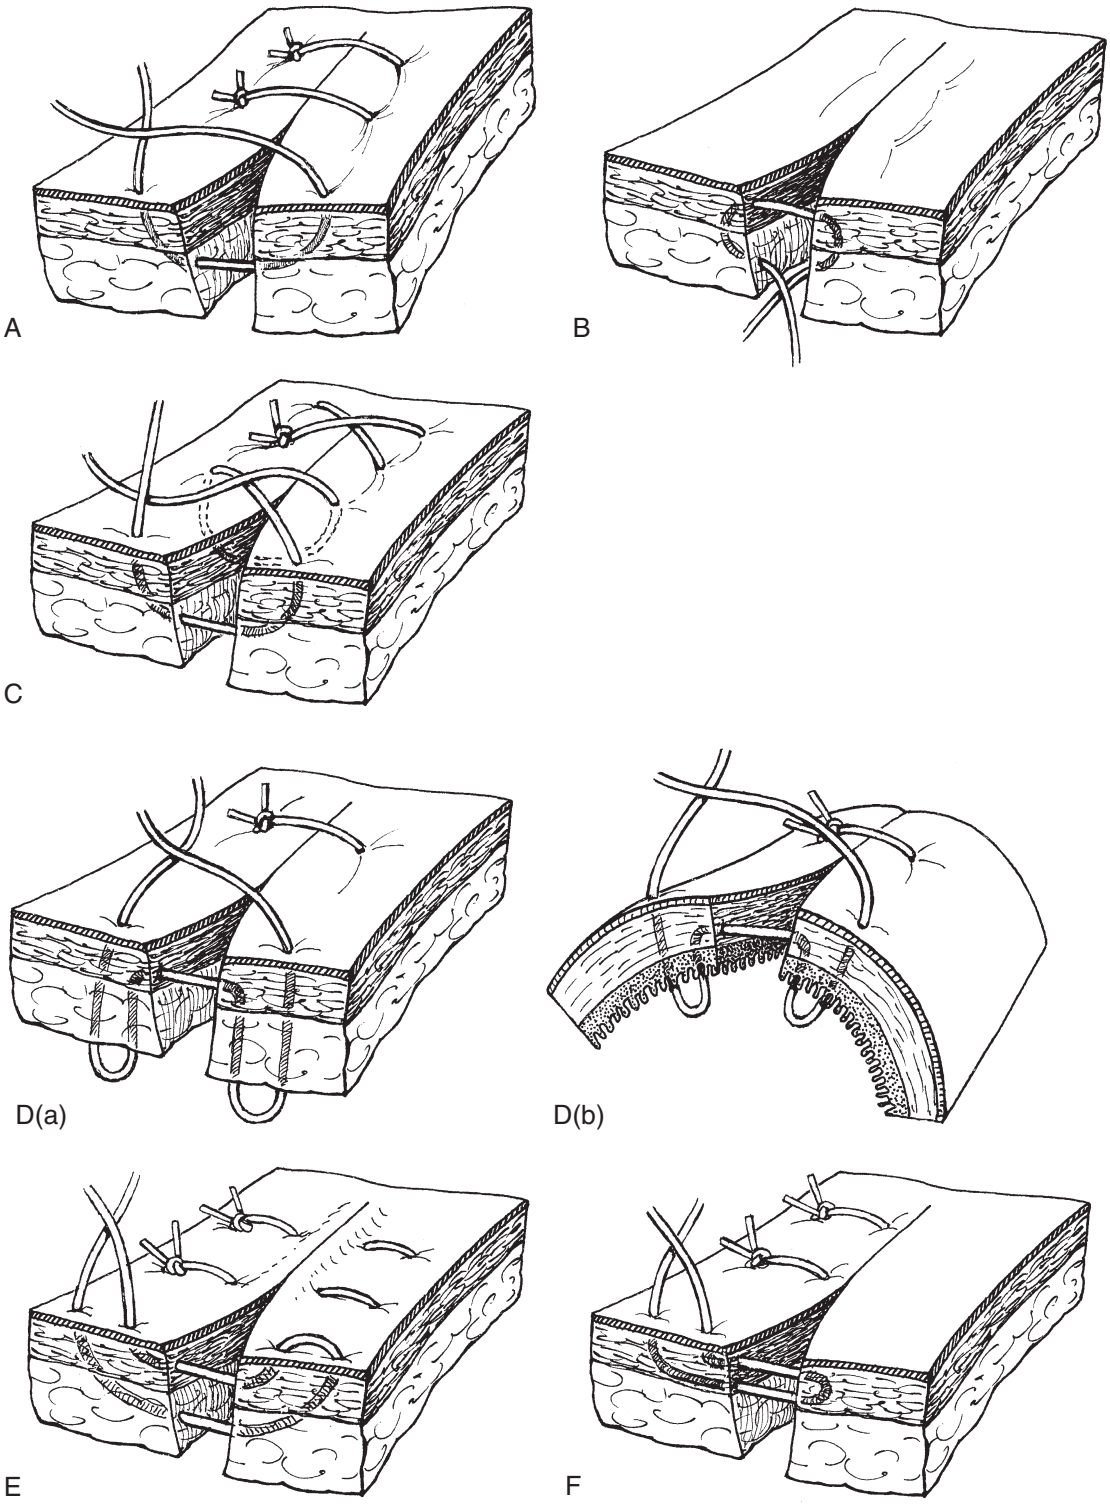

Figure 16-7. Appositional and everting suture patterns: **A,** Simple interrupted; **B,** interrupted intradermal/subcuticular; **C,** cruciate; **D,** Gambee; this pattern can be used as an appositional suture pattern for skin *(a)* or intestine *(b);* **E,** interrupted vertical mattress; **F,** Allgöwer corium vertical mattress.

strength values at 8 weeks postoperatively.[33] Furthermore, suture sinus formation has been reported following the use of polypropylene sutures for closure of the equine linea alba.[34] For this reason, synthetic absorbable suture materials like braided lactomer,[25,35] polyglactin 910, or polydioxanone are recommended. Suture size for closure of the linea alba in adult horses ranges from USP No. 2 to USP No. 7.[25,35] A simple continuous pattern sustains higher loads to failure than interrupted patterns.[36] Tissue bite size should be 15 mm[37] and the interval between the suture bites should be 15 mm as well.[25] This results in a ratio of suture length to wound length of 4:1 or more. This ratio is considered optimal for providing sufficient reserve suture material to accommodate incisional lengthening during episodes of abdominal distention.[25]

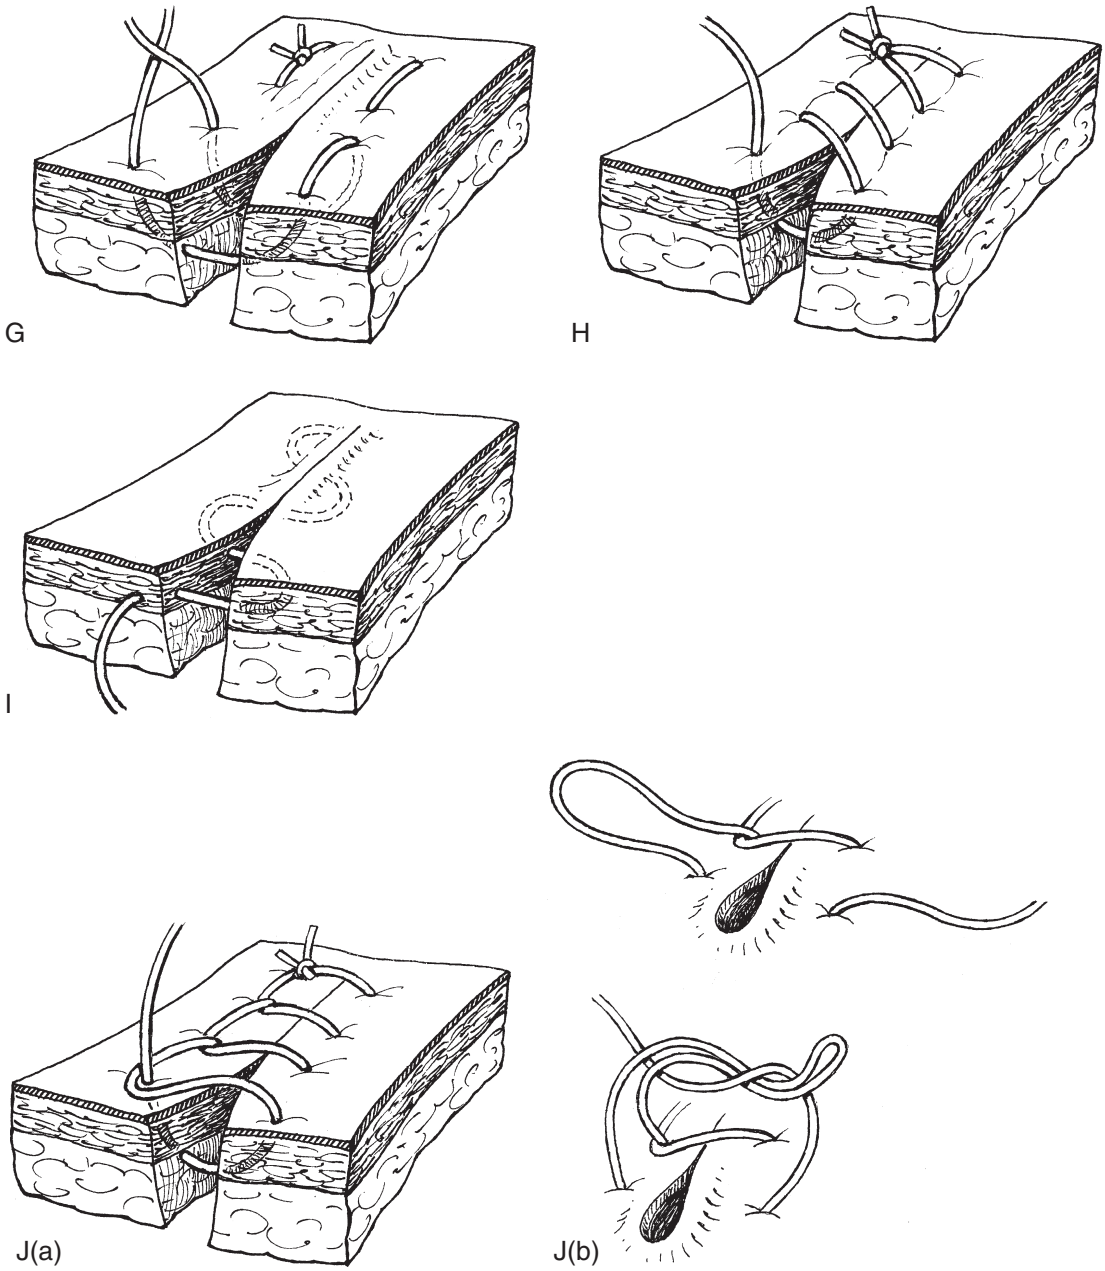

Figure 16-7, cont'd. G, Interrupted horizontal mattress; **H,** simple continuous; **I,** continuous intradermal; **J,** Ford interlocking *(a);* to terminate this pattern, the needle is introduced in the opposite direction from that used previously, and the end is held on that side; the loop of the suture formed on the opposite side is tied to the single end *(b).*

TABLE 16-5. Inverting Suture Patterns

Suture Pattern	Characteristics
Cushing (CU) (Figure 16-8, *A*)	Penetrates the submucosa but not the lumen of hollow viscera; results in a watertight seal, adequate inversion but less luminal reduction than the LE pattern
Connell (Figure 16-8, *B*)	Similar to CU pattern but penetrates all layers of the bowel; subject to wicking of visceral contents
Lembert (LE) (Figure 16-8, *C*)	Penetrates the submucosa but not the lumen of hollow viscera; results in considerable inversion; can also be used for imbrication procedures; can be used as interrupted or continuous pattern
Parker-Kerr (Figure 16-8, *D*)	Indicated to close hollow visceral stumps: a combination of a CU suture sewn over a clamp and pulled tight as the clamp is removed, oversewn by a continuous LE pattern
Pursestring (Figure 16-8, *E*)	Can be used to close the preputial cavity or anus temporarily; if used to close visceral stumps, the stump must be held inverted as the suture is tightened

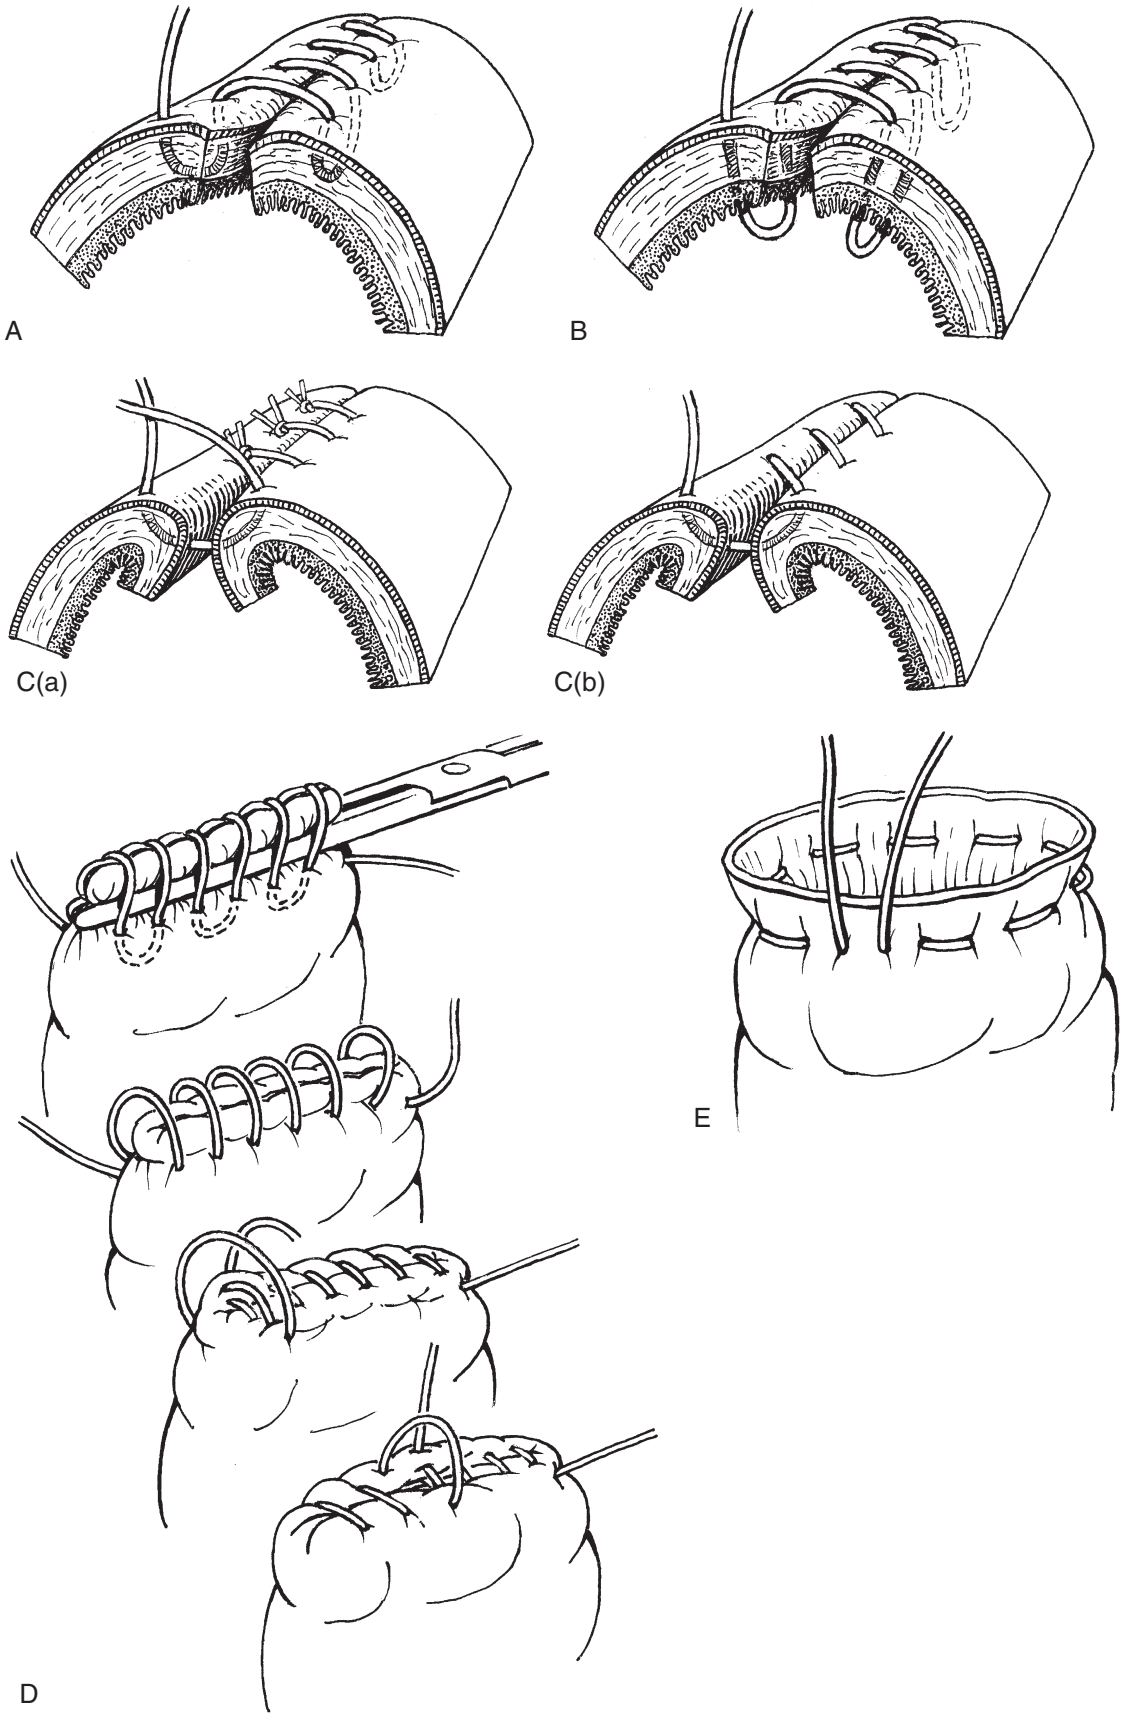

Figure 16-8. Inverting suture patterns: **A,** Cushing; **B,** Connell; **C,** Lembert; this pattern can be applied as an interrupted *(a)* or continuous pattern *(b);* **D,** Parker-Kerr; **E,** pursestring.

TABLE 16-6. Tension Suture Patterns

Suture Pattern	Characteristics
Interrupted vertical mattress (IVM) (Figure 16-9, *A*)	Appositional to everting; stronger under tension and less interference with vascular supply than IHM; stents of soft rubber tubing can be placed under the suture to prevent suture cut-through and impairment of skin circulation
Interrupted horizontal mattress (IHM) (Figure 16-9, *B*)	Degree of eversion depends on suture tension and distance to the wound margin; more everting than IVM; distributes tension over a wider area but is weaker under tension than IVM; higher potential for tissue strangulation and interference with blood supply than IVM; can also be applied in a continuous pattern
Quilled/stented (Figure 16-9, *C*)	Variation of IVM or IHM that loops over a stent/button/plastic tube on either side of the wound to reduce suture cut-through
Near and far (Figure 16-9, *D*)	Can be applied as near-far-far-near or far-near-near-far pattern; provides tension relief (far component) and apposition (near component); high resistance to tension because all suture passes are in the same vertical plane; places more suture material in the wound than other patterns do
Walking suture (Figure 16-9, *E*)	A buried tension suture that moves skin progressively toward the center of a wound; can be placed in rows no closer than 2-3 cm apart; walking sutures evenly distribute tension and obliterate dead space; can potentially damage cutaneous blood supply; large number of walking sutures can increase tissue reaction and foreign body response
Locking loop or modified Kessler (Figure 16-9, *F*)	Strong tension suture for tendon repair; maintains gliding function of the tendon owing to limited amount of suture material on the tissue surface; two locking loop sutures can be combined to form a double locking loop
Three-loop pulley (Figure 16-9, *G*)	Very strong tension suture for tendon repair with increased resistance to gap formation; may compromise gliding function because of a large quantity of suture material on the tendon surface

Infected or Contaminated Wounds

Sutures should be avoided in highly contaminated or infected wounds because even the least reactive suture can exacerbate infection. Multifilament nonabsorbable sutures should not be used in infected tissue because they potentiate infection and may lead to fistulation.[6] If a suture is required in a contaminated or infected wound, absorbable and ideally monofilament suture material is indicated. If implantation of a nonabsorbable suture is unavoidable, monofilament nylon and polypropylene are least likely to elicit infection in contaminated tissues.

Muscle

Muscle is difficult to suture because it has poor holding power. Sutures placed parallel to the muscle fibers are prone to pull out; therefore, sutures should be placed perpendicular to muscle bundles when possible. Whenever achievable, the fascial layer should be incorporated to improve holding capacity. Synthetic absorbable or nonabsorbable sutures may be used to suture muscle layers.

Gastrointestinal Tract

Gastrointestinal incisions demonstrate rapid postoperative healing. Physical strength is dependent on suture or staple strength during the lag phase (i.e., the first 4 days postoperatively) of wound healing. During the proliferation phase (3 to 14 days postoperatively), wound strength increases rapidly and the maturation phase has little clinical relevance.[38] Absorbable synthetic sutures are indicated for gastrointestinal sutures. Prolonged retention of tensile strength is not necessary. Low tissue reactivity is desirable to prevent further luminal reduction and adhesion formation. Polyglycolic acid, polyglactin 910, and polydioxanone can be used. The monofilament suture material glycomer 631 has the advantage of combining reduced capillarity and tissue drag with an appropriate resorption profile. Although the use of a simple interrupted or the Gambee pattern has been described for equine intestinal anastomoses,[39,40] a Lembert pattern or a simple continuous pattern oversewn with a Cushing pattern are more commonly used.[41,42]

Urinary Tract

Compared with healing of the gastrointestinal tract, the urinary bladder has a more rapid healing rate and gain in tensile strength.[43] Sutured cystotomy wounds need to withstand voiding pressures of 90 cm H_2O.[44] Suture materials used in cystotomy closure should provide adequate strength during the lag phase of wound healing, followed by rapid absorption to avoid lithogenesis in case of mucosal penetration. In addition, low tissue reactivity is needed to further reduce the risk of calculus formation.[45] Exposure to alkaline urine—as found in herbivores—results in accelerated hydrolysis of absorbable suture materials.[46,47] Urinary tract infections with pathogens like *Proteus mirabilis* can further accelerate loss of tensile strength if suture materials are exposed to urine.[47] Nonabsorbable sutures and metallic staples may be calculogenic and should be avoided.[48] Absorbable synthetic sutures are recommended, and monofilament sutures have the additional benefit of reduced capillarity and tissue drag. The use of quickly absorbable suture materials like poliglecaprone has not been evaluated in horses but seems a possible choice, given the rapid healing capacity of the urinary bladder. The suture pattern should be continuous to provide a tight seal and should be inverting. Penetration of the transitional epithelium should

Figure 16-9. be avoided. For urinary tract procedures that result in exposure of the suture material to urine, polyglyconate or polydioxanone are recommended to avoid premature loss of tensile strength.[16,46]

Tendon

The most common suture patterns for tendon repair are the locking loop and the three-loop pulley suture (see Figure 16-9). The three-loop pulley suture pattern is more resistant to gap formation under tensile loading.[49] Appropriate suture materials include strong, nonabsorbable sutures or slowly absorbable materials with high tensile strength retention, like polydioxanone or polyglyconate. However, none of these sutures can maintain flexor tendon apposition under normal loading conditions in an adult horse[50] and additional external coaptation is required if tenorrhaphy is attempted. Application of bioresorbable tendon plates has resulted in superior immediate failure strength compared to 3-loop pulley sutures but has only been evaluated biomechanically in a cadaveric study.[51]

Blood Vessels

Vessels should be ligated with absorbable suture material. Vascular repair or anastomosis is performed with monofilament nonabsorbable suture material. Polypropylene is the material of choice because it is the least thrombogenic suture.[6]

Nerves

Nonabsorbable sutures with low tissue reactivity, like polypropylene or nylon, are recommended for nerve repair.[32]

Implant Prostheses

Strong nonabsorbable suture materials can be implanted to serve as a permanent prosthesis (e.g., for laryngoplasty, tie-forward or joint stabilization). Polyester sutures can be used for these purposes. However, the newer ultra-high molecular weight polyethylene sutures are stronger,[52] have less tissue drag, and provide better knot security.[53]

ANTIMICROBIAL-COATED SUTURE MATERIAL

Surgical site infections (SSIs) remain an important problem in the surgical community. There is some evidence that the suture knot may play a role as a repository for bacterial colonization and replication that can ultimately result in an SSI (see Chapter 7).[54] To achieve active inhibition of bacteria at the surgical site, antimicrobial-coated suture materials were developed. The agent most commonly used for this purpose is triclosan, chemical name 5-chloro-2-(2.4-dichlorophenoxy)-phenol.[55] Triclosan has antiseptic properties and good biocompatibility.[56] Experimental studies confirmed the inhibitory effects of triclosan-coated polyglactin 910,[57] polydioxanone,[58] and poliglecaprone[59] suture material on bacterial colonization. Most clinical studies in human medicine report reduced wound infection rates with the use of triclosan-coated suture materials,[54,60] although these results were questioned in one study.[61] Up to now, there is only one study published on clinical application of triclosan-coated suture material in the horse. This study could not find a beneficial effect on incisional complication rates when triclosan-coated suture material was used for subcutaneous closure following exploratory celiotomy.[62] However, the serious complications experienced with SSI in horses would make these materials attractive for further evaluation.

SUTURE ANCHORS

Suture anchors serve to attach soft tissues to bone or to fix a suture as a prosthetic implant. These devices are commercially available in a variety of configurations. Typically, they have a metal end configured as either a screw or a toggle bar and an "eye" for suture attachment (Figure 16-10).[63] Suture anchors have been used in equine patients for surgical repair of collateral ligament instability of the carpal and metacarpophalangeal joint in two foals[64] and for a prosthetic capsule technique in a pony with coxofemoral luxation.[65]

SURGICAL STAPLERS

Surgical stapling devices are commonly used in equine surgery, especially for intestinal resections, anastomoses, ligation of blood vessels, and skin closure. Potential benefits of stapling include reduced surgery time, less tissue trauma, less intraoperative contamination, preservation of blood supply, and utility in areas of difficult accessibility.[3,66]

Stapling Devices

Thoracoabdominal Stapler

Thoracoabdominal (TA) staplers (Figure 16-11) are loaded with a cartridge (also called *single-use loading unit*) and fire one double-staggered row of B-shaped staples to seal tissues and vessels with preservation of microcirculation. Titanium staples are commonly used but absorbable lactomer staples are available as well. Cartridge sizes for reusable stainless steel TA stapler devices are 30, 55, or 90 mm in length. Cartridges for disposable re-loadable staplers are available in 30, 45, 60, and 90 mm lengths.[66] Staple cartridges are color coded to indicate staple

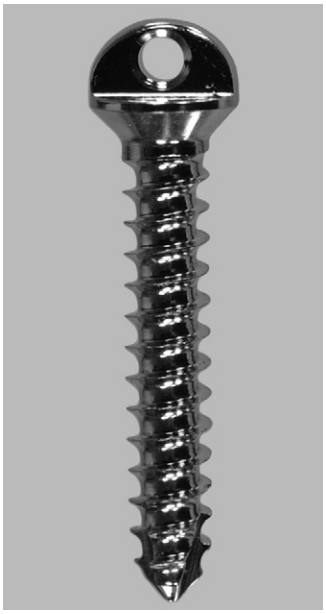

Figure 16-10. Example of a suture anchor: a self-tapping 3.5 mm diameter cortex screw with an eyed head.

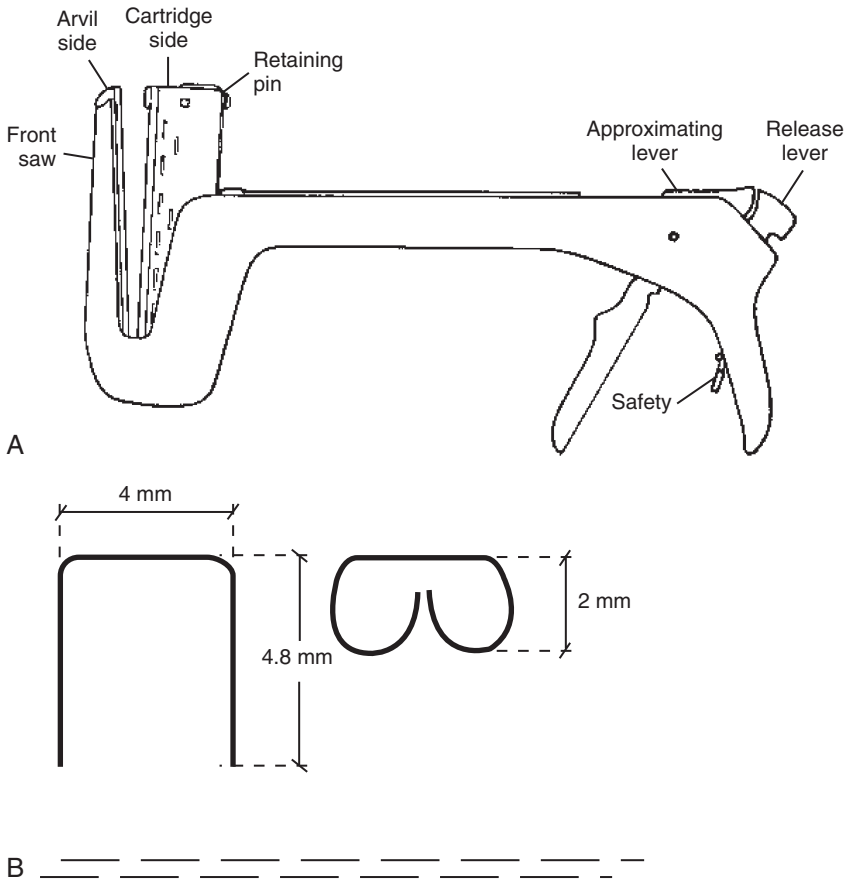

Figure 16-11. A, TA-90 Premium stapler with a disposable cartridge, schematic labeled view; **B,** the TA-90 Premium 4.8 loading stapler fires 33 staples arranged in a double-staggered row 91.5 mm long, schematic labeled view. The staples of the green cartridge have a crown width of 4 mm, a leg length of 4.8 mm, and a closed height of 2 mm.

size. Green cartridges contain staples that have a leg length of 4.8 mm, crown width of 4.0 mm, and closed height of 2.0 mm. The staples in the blue cartridge have a leg length of 3.5 mm, a crown width of 4.0 mm, and closed height of 1.5 mm (see Figure 16-11). TA staplers have a U-shaped opening through which the tissues are inserted. Tissues are secured within the device by a retaining pin. Activating the approximating lever closes the cartridge. After releasing the safety device, squeezing of the handle forces the staples out of the cartridge against the anvil. After firing, the instrument head can be used as a guide for tissue transection. The TA stapler is released by retracting the release lever and loosening the approximating lever.

In equine surgery, the 4.8-mm staples are commonly used because of the longer staple leg. The TA-90 is useful for colon resection,[67] jejunocecostomy,[68] jejunocolostomy,[69] ovariohysterectomy,[70] partial lung lobe resection,[71] rectal tear repair in postparturient mares,[72] and partial splenectomy.[73] It can also be beneficial to achieve hemostasis in areas that are difficult to access, such as bleeding from the testicular or ovarian artery after neutering.[74]

Gastrointestinal Staplers

Gastrointestinal anastomosis (GIA) and intestinal linear anastomosis (ILA) staplers are linear stapling instruments with two interlocking halves (Figure 16-12). Like the TA staplers, they are loaded with cartridges (single-use loading units). Cartridge sizes for reusable stainless steel GIA instruments are 50 or 90 mm in length.[66] Disposable reloadable GIA staplers are available in 60, 80, and 100 mm lengths. The reusable ILA stainless steel stapler is available in 52 and 100 mm lengths.[66]

Gastrointestinal staplers apply four staggered rows of staples; cartridges contain cutting blades that divide tissues between the second and third row of staples. The instrument separates into two halves so that each fork of the instrument can be placed into a bowel lumen or on either side of a hollow viscus (Figure 16-13). After closure, the push bar handle of the device is slid forward to fire the staples and the blade. The incision cut by the knife blade is 8 mm short of the last staple at the distal end.[66] Staples are made of stainless steel or titanium and, as with TA staplers, are B-shaped when closed. The B configuration of the closed staple permits blood flow through the tissue enclosed by the staple.[3] Color coding of cartridge size is the same as for TA staplers. Staples in green cartridges have a 4.8 mm leg length that compresses to a final height of 2.0 mm, whereas staples in blue cartridges have a 3.8 mm leg length that compresses to a final height of 1.5 mm. Staples in both cartridges are 4.0 mm wide. Reusable GIA instruments are only available with 3.8 mm staples.[66] When used for side-to-side or functional end-to-end anastomosis, the result is a stoma with two rows of staples on either side. The instrument insertion site remains open and must be closed by suturing or by applying of a TA stapler. When used for viscus resection, two rows of staples provide an everted seal along the cut margin of the healthy organ; the resected portion of the viscus is also sealed with two rows of staples, reducing intraoperative contamination.[66]

Common indications for use of GIA or ILA staplers in equine surgery include jejunojejunostomy,[75] jejunocecostomy,[68] and jejunocolostomy.[69]

Endoscopic versions of gastrointestinal staplers are also available in variable sizes and have been used for laparoscopic

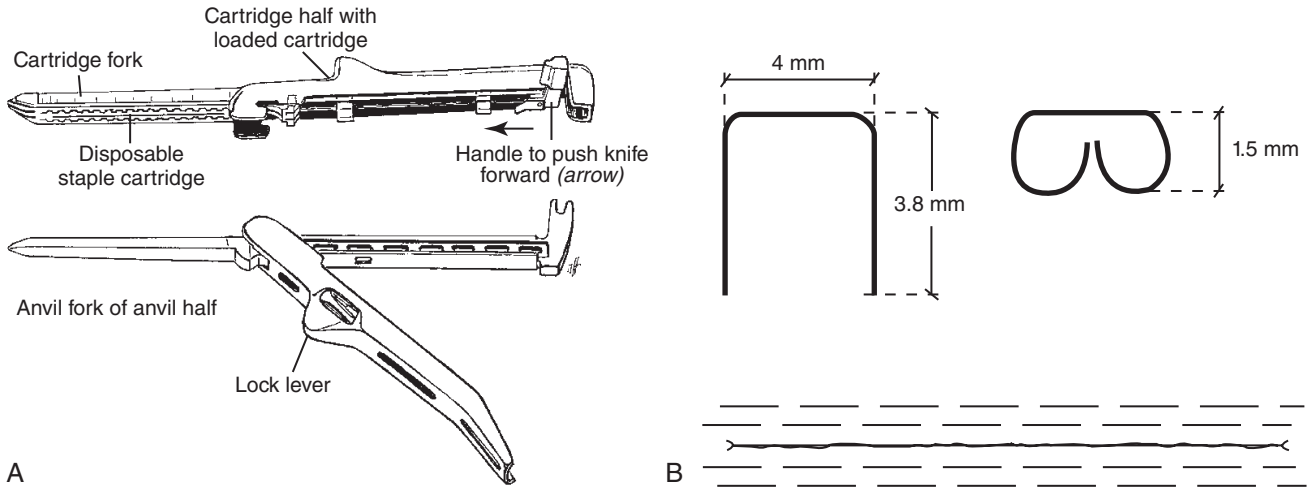

Figure 16-12. A, GIA-90 Premium stapler with disposable cartridge, schematic labeled view; **B,** The GIA stapler fires two double, staggered rows of staples. Staples of the blue cartridge for reusable GIA instruments have a crown width of 4 mm, a leg length of 3.8 mm, and a closed height of 1.5 mm. The instrument's knife blade cuts between the two sets of staple lines, ending approximately 5 mm short of the last staple in the distal end.

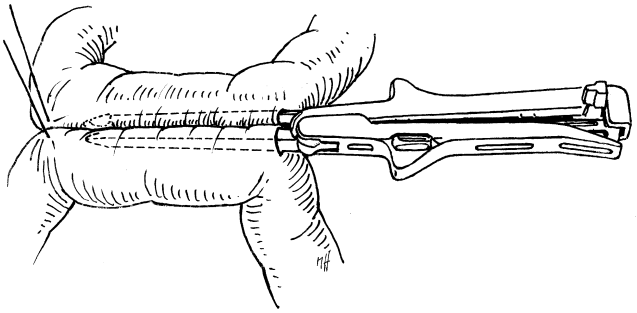

Figure 16-13. Each fork of the GIA instrument is placed into the bowel lumen; after closure, the push bar handle of the device is slid forward to fire the staples and the blade.

ovariectomy[76] and laparoscopic small intestinal biopsy in horses[77] as well as for laparoscopic sterilization of male donkeys.[78]

Ligating Dividing Stapler

The ligating dividing stapler (LDS) is a pistol-shaped instrument that places two vascular staples simultaneously while a cutting blade divides the blood vessel–containing tissue between them (Figure 16-14). In the horse, this instrument is mainly used for rapid ligation of mesenteric vessels during colic surgery. Metal staples are commonly used with this device and are made of surgical steel or titanium.

The U-shaped staples come in two sizes: regular, which is 5.8 mm wide × 5.2 mm tall, with a final closure width of 5.3 mm and a distance between staples of 6.35 mm; and wide, which is 8.0 mm wide × 7.2 mm tall, with a final closure width of 7.3 mm and a distance between staples of 9.53 mm.

The closed staple forms a thin crescent shape with the ends of the staples meeting at the center of its outer rim. Vessels that need double ligation require placement of a ligature or a single vascular clip before LDS application. The LDS should not be used on tissues that cannot be compressed to 0.75 mm.[66] In an experimental study in horses evaluating jejunal artery occlusion, mean arterial bursting pressure achieved with the LDS was significantly lower than after LigaSure application or 2-0 PDS

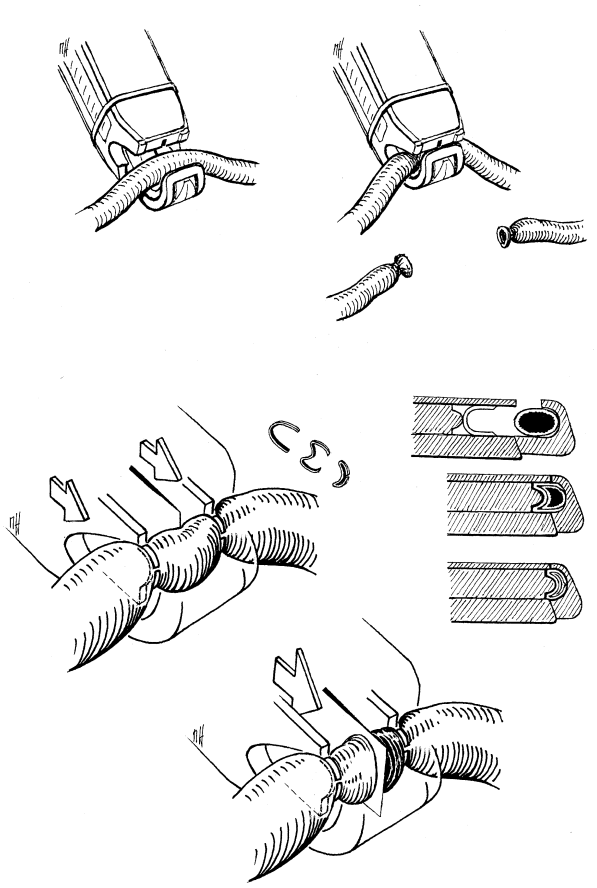

Figure 16-14. The ligating dividing stapler is a pistol-shaped instrument that places two vascular staples simultaneously while a cutting blade divides the blood vessel–containing tissue between them. The closed staple forms a thin crescent shape with the ends of the staples meeting at the center of its outer rim.

ligation but still far above systolic pressure values.[79] However, in the clinical patient, hemorrhagic strangulating obstruction is commonly associated with congested vessels and hemorrhagic changes of the associated mesentery. The subsequent increase in tissue thickness makes application of the LDS less reliable, and an additional suture ligation may be required.

Ligating Clips

Ligating clips can be useful to achieve hemostasis. Metal clips are commonly used but synthetic absorbable clips are available as well. The advantages of ligating clips include ease of application in poorly accessible areas, structural stability, and reduction of surgery time. To provide safe hemostasis, the diameter of the vessel should be one third to two thirds the size of the clip, the vessel should be dissected free of surrounding tissue before the clip is applied, and 2 to 3 mm of vessel should extend beyond the clip to prevent slippage.[6]

Manufacturer recommendations should be reviewed regarding clip size selection for specific vessel diameters. Potential disadvantages of ligating clips include the relative instability of the clip in the applicator, insecurity of an inadequately applied clip, potential slippage, and permanence of metallic clips in the tissue.[3] Caution should be used when manipulating tissues after placement of vascular clips because they are more easily dislodged than suture ligations.[66]

Skin Staples

Surgical skin staples are fabricated from surgical stainless steel. Before application, the skin staple is U-shaped. During application, the cross member is bent over an anvil, crimping it at two sites and bringing the legs together. This results in a rectangular shape of the closed staple, which is narrower than the original staple.[66] Staple removal is performed by a staple extractor, which compresses the cross member of the staple and straightens the legs, permitting easy extraction (Figure 16-15). Skin staples are suitable for rapid closure of surgical incisions that are not subjected to appreciable tensile forces. They provide excellent wound edge eversion without strangulation of tissue[80] and incite only minimal tissue reaction.[30] They are commonly used in equine surgery with excellent functional and cosmetic results. However, an experimental study in pigs demonstrated some inflammatory responses after skin staple application.[81] A recent meta-analysis found a significantly higher risk of developing a wound infection after orthopedic surgery in humans when the surgical wound was closed with staples rather than sutures.[82] Similarly, a large case series of horses undergoing exploratory celiotomy identified the use of staples for skin closure as a significant risk factor for development of an SSI.[83]

A novel form of skin closure that uses absorbable lactomer subcuticular staples is available. They are inserted into the subcuticular tissue with the help of a staple applicator and forceps. Subcuticular staples produced less inflammatory response and a superior cosmetic outcome than metal skin staples in human surgery[84] and in a porcine experimental model.[81] Application of absorbable subcuticular staples in equine surgery has not been described yet.

TOPICAL TISSUE ADHESIVES

2-Octylcyanoacrylate

Tissue adhesives based on 2-octylcyanoacrylate are available as a dermal suture replacement. Their advantages include faster closure, reduced cost, ease of application, and no need for suture removal. In human medicine, they are considered equivalent to other methods of skin closure in terms of cosmetic outcome, infection rate, and dehiscence rate.[80] Tissue adhesives should not be applied to tissues within wounds; instead, they should be applied to intact skin at the wound edges to hold the injured surfaces together. Adhesives are particularly useful in superficial wounds or wounds in which the deep dermal layers have been closed with sutures. Furthermore, 2-octylcyanoacrylate can be used to attach intravenous or nasolacrimal catheters, skin grafts, or wound dressings.[63]

Currently, the use of topical tissue adhesives in the equine patient is limited because they should not be used for wounds in mucous membranes, contaminated wounds, large or deep wounds, and wounds under tension.[80]

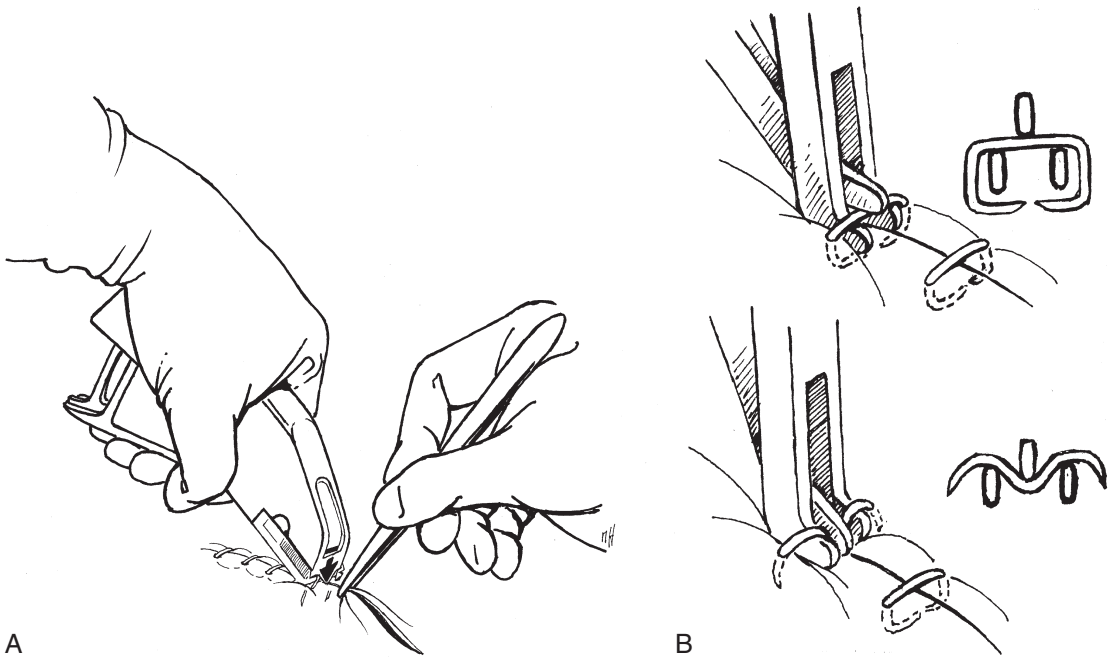

Figure 16-15. **A,** Skin staplers are applied with the help of a forceps to achieve slight eversion of the skin. **B,** Staple removal is performed by a staple extractor, which compresses the cross member of the staple and straightens the legs, permitting easy extraction.

Fibrin Glues

Fibrin glues are mainly composed of concentrated fibrinogen, thrombin, and calcium chloride, thus duplicating the final stage of the coagulation cascade. Fibrin acts as a hemostatic barrier, adheres to surrounding tissue, and serves as a scaffold for migrating fibroblasts.[85] Fibrin glues are used as a tissue adhesive for a variety of surgical procedures in human and small animal medicine (e.g., control of hemorrhage from parenchymal tissues, as a supplementary sealant in intestinal, parotid duct or vascular anastomoses, as a carrier or adhesive agent in bone regeneration–enhancing procedures, and for augmentation of skin closure).[86-89] Fibrin glues can also be applied in minimally invasive surgery. An experimental study in pigs demonstrated superior results achieved with the application of fibrin glue for laparoscopic closure of a ureterotomy compared to laparoscopic suturing or laser welding.[90] The main advantages of fibrin glues are tissue compatibility, biodegradability, and efficacy when applied to wet surfaces.[86] Few studies have evaluated the application of fibrin glues in equine surgery. One study showed no difference in graft acceptance between split-thickness skin grafts applied with cyanoacrylate alone or with a combination of cyanoacrylate and fibrin glue.[91] Another group used fibrin glue to fix a periosteal autograft over an osteochondral defect.[92] Use of fibrin glue as a carrier matrix for mesenchymal stem cells or bone marrow mononucleated cells for treatment of tendinitis represents a more promising application in the equine patient.[93] Further potential applications include laparoscopic and endoscopic procedures and its use as a sealant in wound closure in combination with other techniques.

Tapes: Steri-Strips

Modern cutaneous tapes play an important role in wound closure in human surgery. Closure with microporous tape produces more resistance to infection than other closure techniques.[80] Tapes maintain the integrity of the epidermis and thus result in less tension to the wound. They are indicated for linear wounds in areas with little tension. Tapes do not adhere to mobile areas under tension or to moist areas. These tapes can also be used over sutures to provide a partially closed environment and improve cosmesis. Wound edge approximation is less precise with tape alone than with sutures. Wound edema can lead to blistering at the tape margins and to eversion of taped wound edges.[80] Because of these disadvantages, tapes are not routinely used in equine surgery but may be used for certain specific indications.

CHAPTER 17

Drains, Bandages, and External Coaptation

Jörg A. Auer

The application of drains, bandages, and external coaptation is an important step in state-of-the-art wound management. The different dressings used in association with bandages are discussed in Chapter 26.

DRAINS AND DRAINAGE

History

Hippocrates, in the 4th century BC, was the first to use drains in the form of hollow tubes, to treat empyemas. In the 2nd century AD, Celsus and Galen used conical tubes of brass and lead to drain ascites, and these devices were used for 1500 years. In 1719, Heisler introduced capillary drainage via a gauze wick inside a metal tube.[1,2] In 1859, Penrose used soft rubber tubing as a drain, known today as the Penrose drain. Kehrer modified this technique in 1882 by placing gauze inside the Penrose drain to facilitate drainage, thus creating the "cigarette drain." Today's version of the cigarette drain consists of semirigid vinyl or polyvinyl tubing inserted into a Penrose drain to prevent soft tissue obstruction and increase capillary action.[3,4] All of these drains were applied in a passive system, allowing gravity, capillary action, natural pressure gradients, or overflow to control fluid and gas emanations. Negative pressure was subsequently applied to the semirigid tubes to provide an active system, and finally Raffle developed the technique of continuous suction in 1952.[5]

Purposes

Drains are implants designed to channel unwanted fluids (such as wound secretions, purulent material, bile, urine, blood, or gases) out of the body.[6] Proper use of drains generally speeds up healing time, whereas inappropriate use usually delays healing, occasionally even increasing morbidity and mortality. There are three reasons to place a drain: (1) to facilitate elimination of dead space, (2) to evacuate existing fluid and gas accumulations, and (3) to prevent anticipated formation of fluid collections.[7] Understanding the principles of drain selection, placement, and management minimizes the risks associated with these implants.

Materials

The ideal drain is inert, soft, nonreactive, and radiopaque. Table 17-1 lists common drain types and materials. Soft latex is frequently used in drains; it allows excellent passive drainage of wound fluids. Because it is pliant and does not maintain a rigid lumen, it fits comfortably within the wound. Polyvinylchloride (PVC) drain tubes provide excellent wound fluid evacuation, especially from body cavities and deep surgical wounds. They are less flexible than latex and have a rigid lumen, allowing them to be used for passive or active systems. Frequently, PVC drains are multifenestrated to permit fluids to exit the wound or body. Other drains are manufactured out of silicone, an organic compound in which all or part of the carbon has been replaced by silicon (a nonmetallic element occurring in nature as silica).[8] Silastic is the trade name for polymeric silicone substances having the properties of rubber; it is biologically inert and frequently used in applications other than drains.[8] It is softer than PVC, but at some diameters it maintains a rigid lumen. Therefore, Silastic can be used for active or passive drainage systems. The compliance of the material increases the animal's comfort and makes this type of drain ideal for placement in sensitive areas, next to bone, and within small spaces.[9,10]

Placement

The basic principles of wound management, such as clipping of the hair, aseptic preparation of the implantation site, and possibly local anesthesia, are considerations when placing a drain. In sterile wounds, the drain should be applied under aseptic conditions. Additionally, this sterile environment should be maintained as long as possible by covering the wound and by making frequent bandage changes. Passive drains should exit ventral to the most dependent aspect of the wound or dead space.

The drains should be placed into the space requiring the most drainage. Occasionally, several drains are needed to evacuate a large area or several different tissue layers. The shortest and most direct avenue for evacuation of secretions should be selected. Drains cause some mechanical irritation and therefore should not be placed in the immediate vicinity of blood vessels, nerves, and suture lines. To reduce the risk of suture dehiscence, drains should exit through separate incisions, and not through the suture line (Figure 17-1, *A*). It is important to secure the drains with individual sutures to prevent their loss into or out of the wound. A suture is placed from the skin into the wound, through the drain, and back through the skin, where it is tied (see Figure 17-1, *B*). The suture used for securing the drain should be easily distinguishable from the skin sutures to avoid inadvertent premature removal of an incisional suture. If a drain is placed into a wound that is to be closed, care should be taken to avoid inadvertent incorporation of the drain into the suture line, because drains are usually removed before incisional sutures (see later). The drain end should be long enough to prevent its disappearance into the wound when the patient moves and to evacuate drainage fluids. It is also important to protect the drains from attempts by the patient to remove them. Large openings provide better and longer-lasting drainage. Small exit incisions frequently become blocked, even with a drain in place, preventing effective evacuation of drainage material.

TABLE 17-1. Drains

	Material	Mechanism of Action; Function	Advantages	Disadvantages
PASSIVE DRAINS				
Gauze drains*	Fine mesh gauze	Gravity Capillary action	Economical	Adherence of fibrin clots to gauze
Penrose drain†	Soft, pliable latex available in various sizes Hollow tube	Gravity Capillary action Mostly drainage around periphery	Economical Many applications	May easily kink Not applicable in body cavities No suction possible May facilitate ascending infection
Silicone Penrose drain‡,§	Soft, pliable, nonreactive silicone	As Penrose drain	Less irritating Use in latex-sensitive patients Contains radiodense marker	Not applicable in body cavities No suction possible
Rubber tube drains	Red rubber Smooth surface	Gravity Capillary action	Because of relative stiffness, rarely compressed or occluded Suction may be applied	Increased foreign body reaction
Well drain¶ (German for "waved drain")	Waved sheet of red rubber, stiff, can be cut to size	Gravity Capillary action	Because of relative stiffness, rarely compressed or occluded	Increased foreign body reaction
Flexi-Drain§	12 silicone tubes, 3 mm in diameter, joined together parallel to each other	Gravity Capillary action Good drainage along the tubes where they join	Can be split longitudinally to adjust size of drain Suction may be applied	Main drainage externally
ACTIVE DRAINS				
Redon drain¶	Round, multifenestrated PVC tube with nonfenestrated extension	Closed or open drainage system	Can be used as closed or open drainage system Excellent for evacuation of fluids from body cavities	Depending on location, attaching the container may be difficult Tube cannot be used universally
Jackson-Pratt drain¶	Flat Silastic, multifenestrated drain with nonfenestrated extension	Closed or open drainage system	Can be used as closed or open drainage system Excellent for evacuation of fluids from body cavities Less reactive	Depending on location, attaching the container may be difficult
Blake drain*	Round pliable Silastic drains with slits at the end	Closed or open drainage system	Multifaceted slits reduce the risk of clogging up Minimal tissue irritation	Reactively voluminous Suction function possible only when skin suture is tight
Trocar catheter#	Round, multifenestrated tube Inserted with blunt trocar into the chest	Drainage of thoracic cavity	Minimal reaction and irritation Effective fluid drainage from thorax	Relatively easily disloged, interrupting effective drainage

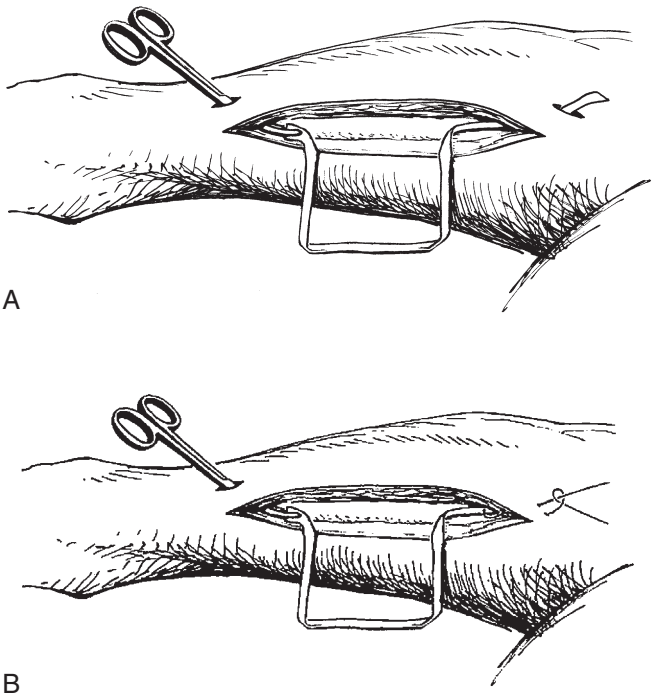

Figure 17-1. Proper placement of a Penrose drain for passive postoperative drainage. **A,** The two exit portals for the drain are placed distant from the primary incision. The ends of the drain are secured with a suture each (using sutures of a different type from the skin sutures for easy recognition). **B,** Only the distal exit portal is made, and the proximal-most aspect of the drain is secured within the wound with a suture that enters proximal to the wound through the skin, passes through the drain, and exits the skin again, where it is tied. The wound is subsequently closed.

Management

The amount of drainage and its consistency dictate the frequency with which bandages need to be changed or vacuum containers emptied. The exit site should be cleaned with antiseptic solutions at every bandage change. If a passive drain is used, it is advisable to protect the adjacent skin from irritation by covering it with a thin layer of Vaseline. Passive drains should seldom if ever be back-flushed, and active drains should not be back-flushed unless obstructed because of the risk of transporting microorganisms into the wound. Additionally, healing may be interrupted by the mechanical disturbance of flushing.

Re-establishing drainage in an obstructed drain exit wound should be performed carefully. If the drain exit site is obstructed, it should be reopened. First the site is prepared for aseptic surgery, followed by inserting a sterile hemostatic forceps into the opening and gently spreading its jaws to separate the wound ends. If needed, some surrounding tissues are removed with scissors or a small scalpel. Because round wounds heal much more slowly than triangular or square/rectangular wounds, it is advisable to create a round drainage opening to ensure an exit portal that will be open for a longer period of time.

Removal

As a general rule, drains should be removed as quickly as possible. An average time for maintaining drains is 2 to 4 days, the duration of the débridement period of wound healing. However, there are exceptions to this rule:

- When evacuating blood from small cavities, the drain may be removed after approximately 24 hours.
- When treating bacterial infections, the drain should be maintained for 48 to 72 hours.
- If large dead spaces remain, for example, after tumor removal, the presence of a drain may be necessary for as long as 2 weeks.

The best indicator for drain removal is an abrupt decrease in the drainage volume and a change in its characteristics to a serous, non-odiferous, slightly turbid fluid. Because drains are foreign material, they induce the production of secretions. At the time of drain removal, exit sites are prepared for aseptic surgery. While the proximal end is held in place, the distal securing suture is removed, followed by application of slight tension to the distal end of the drain, before it is cut off at skin level. This ensures that the contaminated external part of the drain is not pulled through the wound bed, possibly recontaminating it. The proximal suture is removed, and the rest of the drain is pulled out of the wound bed through the distal portal. The two incisions are left to heal by secondary intention. In cases where only one exit portal exists, the securing suture(s) is (are) cut and the drain is removed through the distal portal.

If gauze packs are used as tamponade in a bleeding or actively secreting wound bed, they are removed in stages, with a portion withdrawn and cut off daily, each time leaving a protruding stump to facilitate removal of the next portion.

Complications

Foreign body response and ascending infection are the most common complications associated with drain use. Because drains are foreign bodies, a certain adverse response to the drain cannot be avoided. If a portion of the drain is accidentally left in the wound, wound drainage will persist until it is removed. Therefore, the removed drain should be carefully examined to verify that it is intact. Ascending infection may aggravate an already existing infection, and the microorganisms in the wound may be resistant to previously used antibiotics. Cultures should be obtained from the drain if the character of the wound fluid changes or the volume increases while a drain is in place.

Loss of function may be encountered, especially if the distal exiting portal is too small. It is therefore advisable to initially remove a triangle of skin and subcutaneous tissue at the exiting portal. Cutting a round hole ensures longer persitance of a patent drainage hole. Another cause of loss of function is the kinking of a tube drain, effectively obliterating the drain lumen. Repositioning of the drain and gentle traction may restore function.

Suture dehiscence is an occasional complication that may be attributed to the placement of a drain. Also, vessels and nerves may be damaged during drain placement through stab incisions and blind implantation. Rigid drain tubes may cause pain if they are located near osseous protuberances.

Types of Drains

Drain selection depends on the wound and on expected activity level of the patient. Additionally, the preference of the surgeon,

based on experience, plays an important role in the drain selection.

Passive Drains

GAUZE DRAINS

Gauze drains are prepared from gauze rolls or gauze sponges. They may be soaked with an antibiotic or even with a mild or diluted antiseptic. The antibiotic may be added at the time of drain placement, or the gauze may come commercially prepared (Figure 17-2, and see Table 17-1). If a large amount of gauze is used to pack a cavity, several rolls are tied together securely to ensure that eventually all of them are completely removed. Drainage occurs by gravity and capillary action.

Gauze drains are applied as packing in profusely bleeding cavities (e.g., after nasal septum removal) or in abscesses that cannot be drained at the lowest point. They can be used to evacuate a hematoma (after closed castration). In Europe, gauze drains are frequently attached to the stump of the spermatic cord after castration to facilitate drainage and prevent fluid accumulation in the periscrotal tissues. The advantages of gauze drains include cost effectiveness and ease of removal in stages. The adherence of fibrin clots to the gauze is a disadvantage because it may result in bleeding after removal. Conversely, the aderance of fibrin to the drain may also support débridement of the cavity.

PENROSE DRAINS

Penrose drains are the most commonly used drains because they are soft, pliable, easily sterilized, readily available, and economical, and they cause little foreign body reaction (see Table 17-1).[4] They are available in lengths from 30 to 45 cm (12 to 18 inches) and in widths from 6 to 25 mm (¼ to 1 inch) (see Figure 17-2). Most drainage occurs extraluminally and is driven by gravity and capillary action. To facilitate intraluminal drainage, the drain may be installed inside the body at its most proximal aspect or fenestrated. However, despite providing access of drainage to the inside of the drain, fenestrations reduce the surface area, which decreases the drain's efficacy.[4] Also, the fenestrations weaken the drain and may result in breakage when traction is applied to remove it. The risk of subsequent incomplete removal if adhesions between the drain and the soft tissues develop obviates any advantage that fenestration might provide.

Penrose drains can be successfully used in wounds that cannot be completely débrided and in the presence of residual foreign material, massively contaminated tissue, questionably viable tissue, and fluid-filled dead spaces.[3,5,7] Additionally, these drains have been applied with favorable results underneath skin grafts, in open wounds left to heal by secondary intention, and even in septic joints and tendon sheaths left open for lavage.[11-14] Penrose drains are not suitable for use with suction (because they collapse under a vacuum), in the abdominal cavity (because they are walled off within a short time in the abdomen), or in the thoracic cavity (because they allow air to pass into the thorax).[7]

SHEET DRAINS

Frequently, large wounds over muscular areas have to be drained. In these instances, several drains are needed to effectively drain the entire wound. The sheet drain represents an alternative in these situations (see Figure 17-2 and Table 17-1). The drain is manufactured of red rubber and has a cross-section shaped like a sine wave. The sheet can be trimmed to the desired size and width. To facilitate additional space in the field to be drained, the sheet can be folded or rolled over. Because of its inherent stiffness, there is a gap between any two layers of drain when folded or rolled, which resists obstruction. Because red rubber generally induces a significant foreign body reaction, these drains are left in place for only a couple of days, but they work efficiently during that time.

TUBE DRAINS

Tube drains differ in form and material. They can be relatively stiff, single tubes of red rubber; contain a cross-sectional wave pattern; be of soft, pliable, ribbed, flat Silastic; or be tubular silicone drains that consist of 12 single tubes joined together, each with a diameter of 3 mm (Figure 17-3, and see Table 17-1). These drains function by extraluminal and intraluminal flow and have been successfully applied for draining fluids from wounds as well as from the abdomen and thorax. The more rigid tube drains have a tendency to induce a greater tissue irritation than Penrose-type drains. Simple tube drains provide only weak capillary action but they are effective for gravity drainage.[4,7] The outer and inner surfaces of the tubes should exhibit a low coefficient of friction to facilitate evacuation of blood clots as well as the drain's removal. Some of the drains can be connected to a suction apparatus to evacuate fluids without lumen collapse and to allow irrigation. These drains are inexpensive and readily available, and they cause less interference with tissue healing than Penrose drains.[4]

One disadvantage of tube drains in a passive system is that they are easily obstructed by debris, so that they become ineffective until they are back-flushed to render them patent again, and this may have to be repeated frequently. Therefore, the use of these drains is limited to grossly contaminated areas where bacterial contamination by back-flushing is not too worrisome. Some materials (such as red rubber) induce greater inflammatory reactions than others (such as PVC or Silastic). Polyethylene contains certain impurities that support bacterial growth.[3,7] When used intra-abdominally, omentum can easily obstruct tube drains.

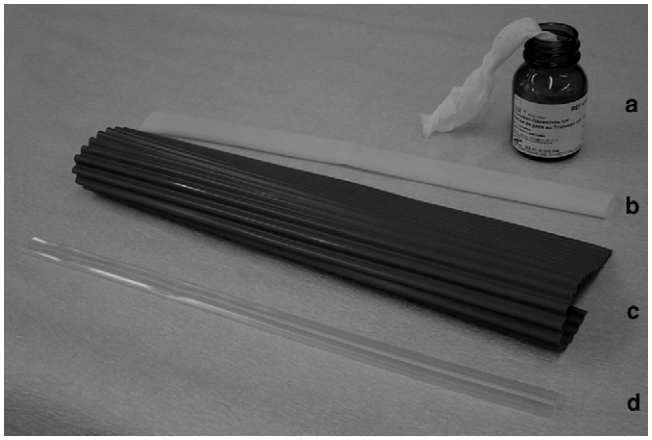

Figure 17-2. Materials frequently used as drains. *a,* Gauze drain soaked with Triclosan (antibiotic) (IVF Hartmann, Neuhausen, Switzerland). *b,* Latex Penrose drains (Sherwood Medical; St. Louis, MO). *c,* Sheet drain of waved red rubber (Ruesch, Belp, Switzerland). The sheet is folded over. *d,* Easy-Flow silicone drain (Degania Silicone LTD, Degania Bet, Israel).

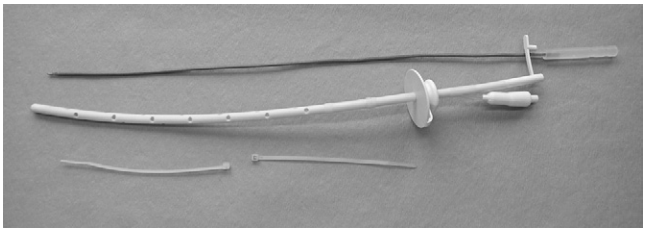

Figure 17-4. A Lepage drain (Cook Veterinary Products, Eight Mile Plains, Queensland, Australia) shown with its insert to provide rigidty during insertion. Two plastic arm bands are shown that are used to attach the negative suction device at the bandage.

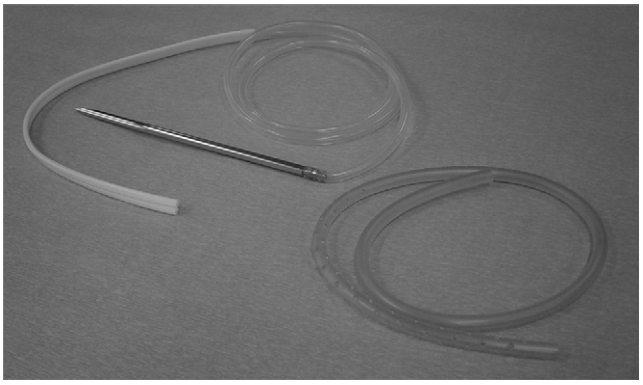

Figure 17-5. A Blake drain (Johnson & Johnson, New Brunswick, NJ) and a multifenestrated Snyder-type tube drain (Zimmer, Inc, Dover, OH). The insert represents the cross-section of the Blake drain. The trocar at the other end is used to place the drain through the skin.

Active Drains

CLOSED SUCTION SYSTEMS

In equine practice, simple tube drains attached to a suction apparatus providing either intermittent or continuous suction are frequently used in infected joints and in large, deep wounds to evacuate the pleural space and under full-thickness skin grafts. Fenestrated tube and Blake drains are often used in these situations (Figures 17-4 and 17-5; see Table 17-1), and occasionally Snyder Hemovac drains are used (Figure 17-6; see Table 17-1). Either the end of the drain is multifenestrated or the cross-section consists of a modified cloverleaf pattern with four slits and protected spaces (i.e., the Blake drain). The external end is made of smooth tubing and is connected through a three-way stopcock, most frequently to a syringe; the plunger of the syringe is withdrawn and held in that position by introducing a large needle or a small pin across a hole prepared across the plunger and resting it on the syringe end to achieve the desired persistent negative pressure (see Figure 17-6). This provides the most economical suction apparatus. The three-way stopcock allows interruption of the suction action prior to removing the syringe for emptying. This is also an effective means to fight against ascending infection. A study comparing Penrose drains to closed suction drains showed that at 24 hours, 34% of the Penrose drains were contaminated compared with none of the closed suction drains.[2,4,7] If suction is applied in a continuous manner, soft tissues can rapidly occlude the drain. High negative pressure may cause injury to tissues, and if the system is suddenly disrupted, reflux of evacuated fluid may occur, increasing the risk of infection. Adding a Heimlich valve to a suction system can prevent reflux of fluid (Figure 17-7).

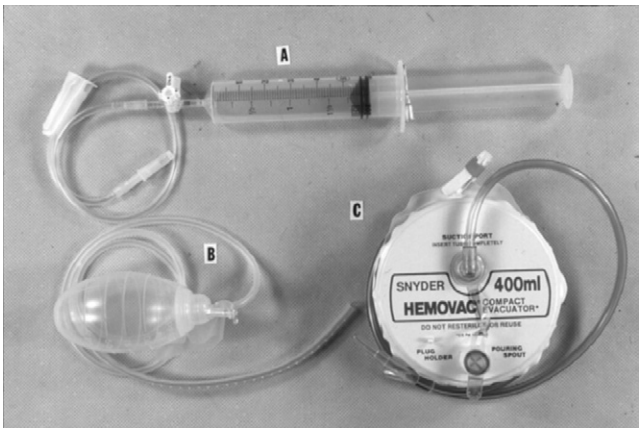

Figure 17-6. Devices used as active drainage systems. *a,* Syringe-adapted closed-suction device made from a 60-mL syringe by drilling a hole in the shaft, near the plunger. A three-way stopcock and extension set is attached to the syringe and fixed to the drain. The syringe is held open by a 14-gauge needle whose tip is ground flat, placed across the syringe shaft. *b,* Snyder Hemovac–100 mL (Zimmer, Inc, Dover, OH) with a flat silicone fenestrated drain. *c,* Snyder Hemovac–400 mL (Zimmer, Inc).

A special closed suction system has been used in humans to promote granulation tissue production in large open wounds,

Figure 17-7. *Top:* A spontaneous pneumothorax aspiration system (Heimlich valve) (Cook Veterinary Products, Eight Mile Plains, Queensland, Australia) used to prevent access of ascending air and microorganisms into the cavity to be drained. *Bottom:* A PVC thorax drain (Trocar Catheter, Mallinckrodt Medical, Athlone, Ireland).

Figure 17-8. The wound in Figure 17-9 was covered with a suction device and sealed under a plastic bandage.

Figure 17-9. A, An old, infected, nonhealing wound over the dorsomedial aspect of third metatarsal bone. The granulation tissue is unhealthy looking and nonresponsive to treatment. **B,** The same wound 4 days later, after removal of the suction device. Healthy granulation tissue covers the wound. The size of the wound is significantly reduced.

especially when there is bone involvement. This device has been successfully applied in horses. The wound to be treated by suction is prepared for aseptic surgery and the wound edges are clipped and trimmed. A sponge is cut to slightly overlap the wound size. The continuous suction device is installed into the sponge. The entire sponge and the suction device are covered by a special adhesive tape, which provides an airtight seal between the wound and the normal skin (Figure 17-8). A bandage is applied to protect the device and maintain external pressure. When suction is applied, the evacuated fluid accumulates in a container. Movements of the horse must be restricted to ensure continuous suction. This method of wound treatment can change an infected, odiferous wound into one covered with healthy granulation tissue within 4 days (Figure 17-9).

OPEN SUCTION SYSTEMS

Open suction is rarely applied in equine surgery. One system involves a sump drain, consisting of a large drain tube with a second, smaller tube in the wall or within the lumen of the larger tube. This "vented" suction apparatus allows air to enter the wound through the narrow lumen tube while debris and fluid are evacuated through the larger tube. Suction may be applied in continuous or intermittent form.[4,7] The airflow improves drainage and decreases the risk of occlusion. However, sump drains do not adapt well to many veterinary hospital situations. Large, portable, or built-in wall units are needed. Also, the large quantities of air needed to keep the suction end open may increase the risk of infection and tissue irritation. Bacterial filters over the air inlets have been shown to effectively reduce infection rates.[2]

The application of a Heimlich valve provides an effective barrier to ascending infection in open drainage of body cavities. This device prevents inflow of air but facilitates drainage of fluid and debris (see Figure 17-6).

Drainage of Body Spaces

Drains in Synovial Spaces

Removal of purulent debris from synovial spaces is facilitated by drain placement. Passive or active drainage systems can be employed for this purpose, but the passive Penrose drains are best. It is important that they be placed in the distal dependent aspect of the synovial space and maintained beneath a sterile bandage. Conversely, active drainage systems can be uncomfortable and abrasive to articular cartilage and tendons because of the rigidity of the material. However, Jackson-Pratt drains, made from Silastic, are multifenestrated and can be placed in these small spaces to provide efficient active drainage.[8]

Drains in Body Cavities

ABDOMEN

Passive drainage of the abdominal cavity requires dependent placement of a rigid-lumen drain tube.[7] PVC and Silastic drains can be used effectively for this purpose. (Penrose drains are not functional for this purpose and should not be used.) Intraoperative placement of multifenestrated drains should be considered after abdominal lavage or when large volumes of exudate or transudate are expected. The drain is placed in a dependent position away from the abdominal incision and sutured to the skin to prevent dislodgement. A sharp trocar with a threaded end is provided to facilitate entrance of the drain at the desired location (see Figure 17-4). It is important to use the trocar to prepare the drain exit portal so that it is just large enough to allow drainage to occur through the drain lumen but not around it. An exit wound that is too large may allow eventration of omentum through it. Bandage placement over abdominal drains is impractical because of the drainage volume obtained. If used, the drains should be removed as soon as drainage slows or ceases. Protecting the drain end is important to prevent ascending infection. A simple method to reduce this risk is to cut off the end of a latex condom, or a finger from a surgical glove, and to place it over the drain, where it acts as a one-way valve. Such valves are commercially available under the name of Heimlich valves (see Figure 17-7).

Thoracic trocars made from PVC and Silastic can be placed percutaneously for drainage of air, urine, exudates, or lavage fluid from the abdominal cavity. Functional time may be limited by the number of fenestrations in the commercial products, so it is helpful to provide additional fenestrations. Square holes in the drain may provide better drainage than round holes.[4] To place the drain, a dependent position is identified. If a long-standing peritonitis is present, or if there has been previous surgery, ultrasonographic guidance may be indicated to identify bowel adhered to or near the body wall. The site is prepared for aseptic surgery, and local anesthetic is infiltrated. A 1-cm incision is made through the skin and the external rectus sheath. An appropriate-diameter thoracic trocar is selected (16-30 Fr) and carefully inserted through the rectus abdominis muscle, internal rectus sheath, and peritoneum. When the abdominal cavity is penetrated, the obturator is removed, minimizing the risk of inadvertent bowel puncture. The drain is subsequently positioned properly and secured. Drains can be sutured to the skin in a variety of patterns. Two useful patterns are the *Chinese finger trap* suture and the *double clove hitch* pattern (Figure 17-10).[9] If the drain is left in place, its end is protected, as previously described, or a Heimlich valve may be added.

In cases that benefit from open peritoneal drainage, polypropylene mesh can be used to provide drainage over several days.[7] After correction of the primary problem, the mesh is secured into the abdominal closure with sutures, leaving a gap for fluids to escape. The mesh is left in place until drainage subsides, and it is removed during a second surgical procedure (Figure 17-11).

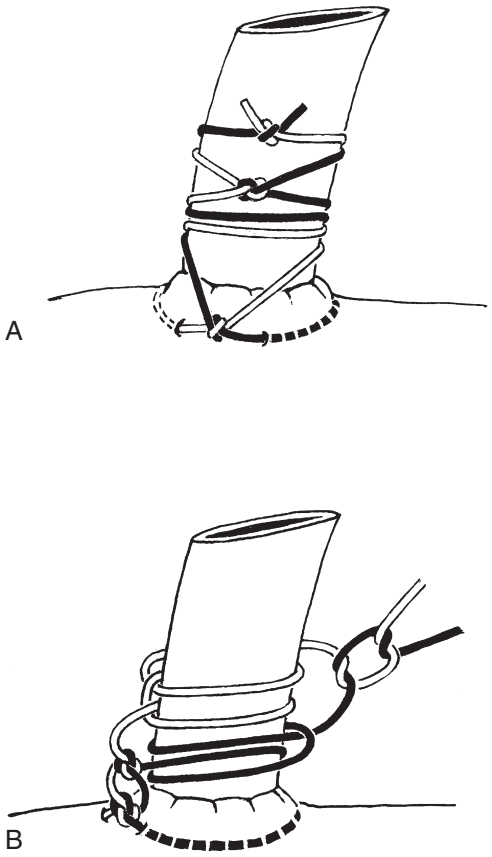

Figure 17-10. Suture patterns used to secure a drain to the body wall. **A,** The "Chinese finger trap" suture pattern. **B,** The "double clove hitch" pattern.

Figure 17-11. Polypropylene mesh used for open peritoneal drainage. The mesh, seen interposed between the wound edges, is ready for removal.

THORAX

Thoracic drainage presents special problems because negative pressure needs to be maintained in the chest despite the frequent presence of air. The use of a rigid drain tube is necessary. Removal of air can be achieved through active or passive mechanisms. To place a drain for removal of air, a dorsal site is selected and prepared for aseptic surgery. Local anesthetic is infiltrated prior to establishing a 1-cm stab incision through the skin. A thoracic trocar is inserted and tunneled cranially for one or two rib spaces, followed by insertion into the thorax along the cranial edge of the rib, avoiding the intercostal vessels located on the caudal border of the ribs (Figure 17-12). When the thorax has been penetrated, a Heimlich valve is placed on the drain end. The Heimlich valve has a rubber liner, which allows air to exit during expiration, and it collapses on inspiration,

restricting backflow of air (see Figure 17-7). If a large volume of air is present, suction can be applied to the open end of the Heimlich valve, rapidly removing air and reestablishing negative pressure. The drain is secured by one of the means previously described. If the primary problem is corrected, the drain can usually be removed within 24 hours if an active drainage system was used initially to drain fluid from the lower thorax. Multifenestrated PVC drains surgically placed or thoracic trocars percutaneously placed are suitable for this purpose. A closed suction device is applied to the catheter and is maintained until drainage subsides. It is important that the closed suction device not become dislodged from the drain because this would cause a rapid loss of negative pressure and introduce environmental contaminants into the thorax (see Figure 17-12).

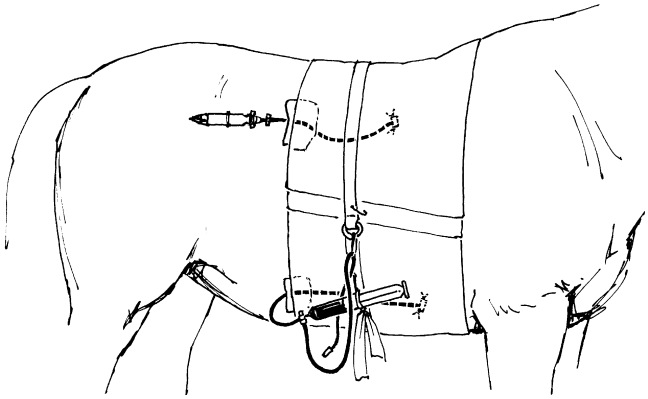

Figure 17-12. Proper placement of thoracic drains. A drain in the dorsal thorax is placed with a Heimlich valve (Heimlich chest drain valve, Bard Parker, Becton Dickinson, Inc., Lincoln Park, NJ) to prevent the backflow of air. A ventral drain uses a syringe-adapted closed-suction device to provide safe removal of fluid accumulating in the ventral thoracic cavity.

BANDAGES

Bandages are applied to cover wounds protected by dressings, to prevent edema formation after injuries of the limb, and to support the limb in conjunction with an added splint in the case of a ligament injury or fractured bone.[15,16] The type of bandage is chosen on the basis of the location and the nature of the injury.

Foot Bandage

Foot bandages are applied to manage a variety of problems. Part of a roll of cotton is placed over a primary wound dressing (Figure 17-13). The padding is secured with gauze, and it can be held in place with either cohesive or adhesive bandaging tape. Duct tape placed over the bottom of the bandage will render the bandage more durable and less permeable to urine and water (see Figure 17-13).[15] Moisture can be kept from entering the bandage by placing plastic over the foot. An empty 5-L fluid-bag can be opened with a pair of scissors and placed over

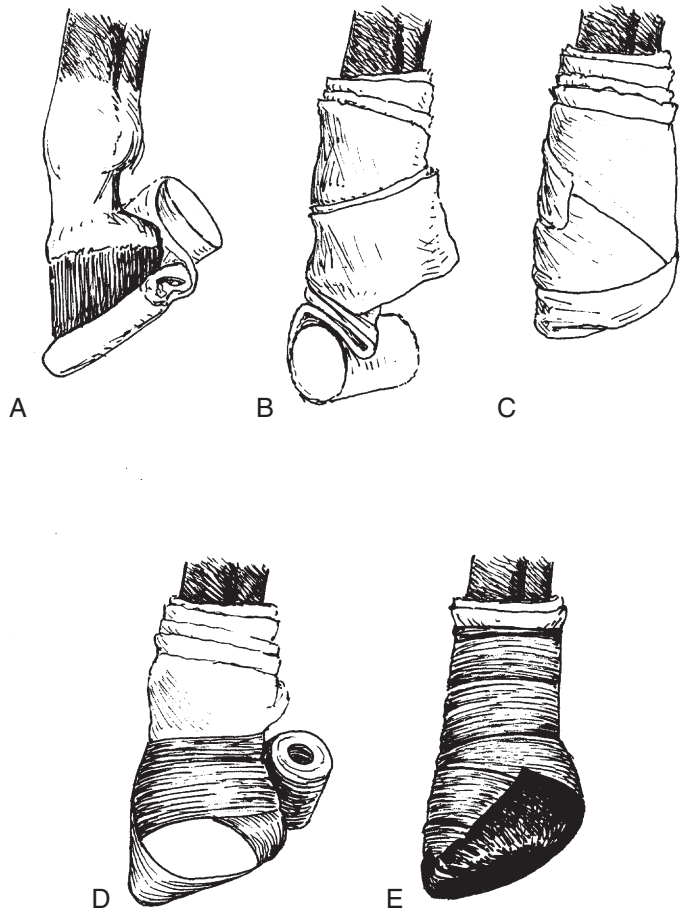

Figure 17-13. A, Several layers of folded-up cotton are placed over the sole of the foot. **B** and **C,** The roll of cotton is subsequently applied in several layers over the foot and fetlock area. **D,** A roll of elastic adhesive tape, tightly applied, finishes the bandage. **E,** Some protection may be applied to the sole to prevent wearing of the bandage. If deemed necessary, the bandage may also be covered with several layers of casting tape to further reduce motion in this region and to stabilize an injury of the bulbs of the heel.

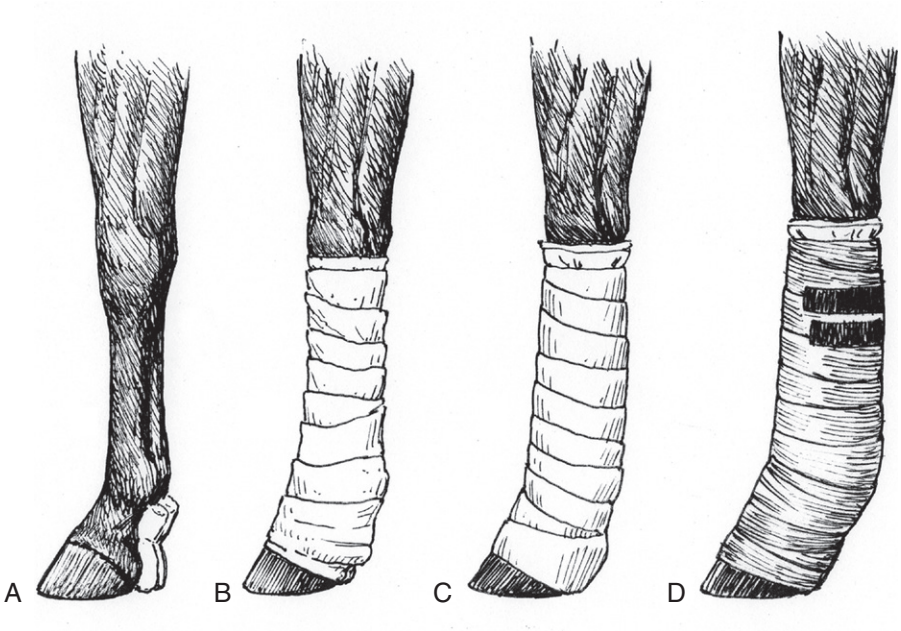

Figure 17-14. A, The heel area is first padded with some cotton. **B,** The first layer of the lower limb bandage is placed on the hind limb. **C,** After tightening the first layer with gauze, a second layer is applied. **D,** The bandage is covered with elastic adhesive tape and secured with two pieces of duct tape. To finish the bandage, adhesive tape is applied to its top and bottom to prevent bedding and dirt from gaining access to the wound (not shown).

the hoof capsule and fastened with adhesive tape, attaching it effectively to the foot. This type of bandage is useful if it is desirable to exclude water from the wound environment, when a poultice or soak is applied to the foot, or when preparing a foot or pastern for any type of aseptic surgery.

Lower Limb Bandage

A lower limb bandage is applied from the bulbs of the heel up to just below the carpus or tarsus. It usually consists of a roll of cotton or sheet, applied in the standard clockwise fashion (pulling the tendons to the inside) (Figure 17-14). The underlying medical problem dictates the thickness, or number of layers, of the bandage. Each layer is secured with conforming roll gauze, wrapped snugly in a spiral pattern overlapping half the tape width, to prevent the padding from slipping or bunching. The gauze is overlaid with either adhesive or cohesive bandaging tape to secure the bandage in position. A single wrap of adhesive tape around the bottom of the hoof and the top of the bandage prevents bedding materials from gaining access to the underlying skin or wound, respectively. Care should be taken to extend the bandage to the level of the carpometacarpal or tarsometatarsal joint and to prevent inadvertent tendon damage if a considerable amount of tension is applied to the elastic bandage tape. At the level of those joints, the tendons are lodged between the vestigial metacarpal bones, which provide protection. Additionally, the coronary band should be included in the bandage so that tape can be applied directly to the hoof capsule.

Full Limb Bandage

Forelimb

A full limb bandage is applied from the bulbs of the heel up to the elbow region (Figure 17-15). When applying a full limb bandage, movement of the carpus requires that special attention be given to this area to prevent decubitus ulcers. The bandage is usually *stacked,* beginnning with a lower limb bandage followed by proximal limb bandages, to prevent slippage and subsequent irritation over bony prominences. Padding materials are the same as for the lower limb bandage and therefore require placement in two stages. The distal bandage is initially applied as previously described. The proximal part is subsequently added on top of the lower limb bandage, overlapping it for 5 to 10 cm. Applying a doughnut-shaped cotton ring or incising the gauze over the accessory carpal bone helps prevent skin irritation over that area and potential development of skin ulcers. Tightening of the bandage in layers provides more stability and increases the support. If the bandage becomes displaced distally, it is imperative that it be changed at once to prevent skin ulcers from developing over bony prominences.

Hindlimb

Motion of the tarsus requires special attention when applying a bandage to that region. Primary wound dressings are held in place using gauze applied in a figure-of-eight pattern (Figure 17-16). The crossing of the "8" occurs over the dorsal aspect of the tarsus, with the loops applied around the proximal metatarsus and the distal tibia of the limb, leaving the point of the hock open. Caution should be used in applying tension over the gastrocnemius tendon. The bandage is also applied in two steps, as described for the forelimb. The proximal part of the bandage overlaps the distal bandage. Applying soft cotton patches medially and laterally between the tibia and the gastrocnemius tendon provides support and reduces the pressure of the latter, thereby serving as protection against tendon damage that could result from excessive tension. Each layer of padding material is first secured with gauze, applied at a right angle to the limb, as opposed to the figure-of-eight pattern for the primary dressing. Application of cohesive or adhesive tape completes the bandage (see Figure 17-16). The bandage is finished by applying elastic adhesive tape around the hoof capsule below and to the skin on top of the proximal end of the

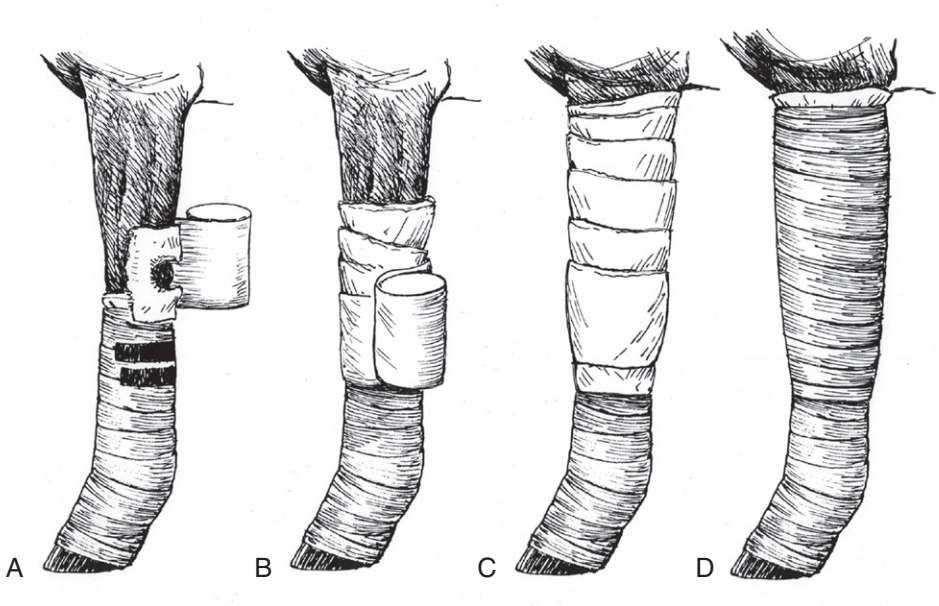

Figure 17-15. A full limb bandage applied to the hind limb. **A,** The distal part of the bandage (shown in Figure 17-14) is first applied. Cotton arranged in a doughnut shape or a piece of felt with a central hole is placed over the accessory carpal bone before roll cotton is applied to the proximal aspect of the limb. **B,** The carpal area is covered with roll cotton in figure-of-eight fashion. **C,** The proximal limb is evenly covered with cotton layers, each separately tightened with heavy gauze. **D,** The bandage is covered with tightly applied elastic adhesive tape, and the top and bottom are sealed to prevent access of bedding and dirt.

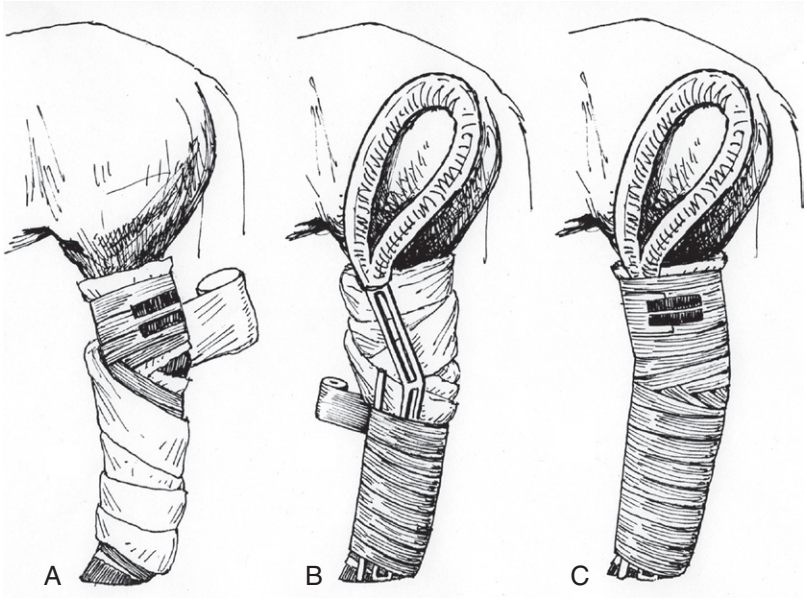

Figure 17-16. A Robert Jones bandage with a lateral splint applied to immobilize a distal tibial fracture prior to surgery. **A,** First, a multilayered full limb bandage is applied to the limb using a technique similar to that described in Figure 17-15. The tarsus is covered with a figure-of-eight bandage. **B,** The proximally padded commercial metallic splint is applied to the lateral aspect of the limb and attached to the bandage with broad nonelastic tape. **C,** The bandage is tightly applied up to the stifle. The padded loop in the hip area provides counter-pressure and resists the development of a valgus deformity during weight bearing. It is prudent to surgically prepare the skin and use a sterile dressing in the first layer in the event the fracture becomes open after the bandage is applied or during transport.

bandage, thus preventing access of bedding to the skin underneath the bandage.

The application of a full limb bandage to the hind limb decreases the movement of all joints in the limb because of the reciprocal apparatus. Some horses have more problems coping with this situation, especially when rising from recumbency. Therefore, the patient will need to be observed for a while after such a bandage is applied.

Splints

A special type of full-limb bandage is the Robert Jones dressing (RJD), for which several layers of cotton are evenly applied over the entire limb, each layer tightened separately with elastic nonadhesive tape. The final cover of the RJD consists of a layer of tightly applied elastic adhesive tape. The size of the RJD should be approximately double the size of the limb and produce a dampened "ping" when snapped with the finger on the outside. This type of bandage provides good support to a severely injured or fractured extremity, because it adds rigidity, especially if a splint of some kind is incorporated into the bandage. An RJD with an incorporated splint allows weight bearing on a fractured limb.

Splints must be applied carefully to prevent decubitus ulcers. Splint materials commonly used include: wood, PVC pipe, or metal, or they can be assembled from cast material incorporated into the bandage. Wood splints are not ideal because they lack strength in small conforming widths, and larger boards do not conform well to the limb. This limitation is overcome by incorporating several small-width slats into the bandage. The sum

of the slats used increases the bandage rigidity and achieves the desired result. With adequate padding in place, 1 × 4-inch (2.5 × 10 cm) boards can be incorporated into a bandage and arranged in at least two right-angle planes. Board splints should extend from the hoof to the joint proximal to the affected area in at least one plane. If the radius or tibia is to be immobilized, a padded lateral splint extending beyond the top of the bandage should be incorporated to prevent adduction of the limb (see Figure 17-16).

Excellent rigidity can be achieved by using PVC pipe as splints. The diameter of the schedule 40 PVC pipe selected depends on the size and location of the limb to which it is applied. The material should be split longitudinally in half. The splint may be modified by removing half-moon–shaped portions at strategic locations to allow access to regions with a wider diameter, such as the carpus. A good compromise has to be found between the PVC pipe diameter and the diameter of the widest part of the limb to be incorporated into the splint.

Neither PVC pipe nor wood conforms well to the limb, however. By applying a hot air gun to strategic locations of the PVC pipe some adaptations to anatomic locations are possible. Casting tape, on the other hand, conforms well to the bandaged limb, but it does not provide the bandage rigidity that can be achieved with wood or PVC pipe. Splints may be made from casting tape rolls, or they can be purchased in that configuration as a longuette. The addition of a casting tape splint reduces the amount of padding needed and provides suitable immobilization in most circumstances. Casting tape splints cannot be applied to extend to the shoulder or hip to prevent adduction of the limb for immobilization of the antebrachium or crus, respectively.

Stainless steel splints are commercially available for temporary immobilization of the distal limb, including the metacarpus in the forelimb. These splints are used as emergency fixation for breakdown injuries of the suspensory apparatus, for flexor tendon injuries, for fractures of the metacarpal condyle, and for phalangeal fractures when a strut of bone remains to support the limb. They are especially useful for transport of horses with such injuries (see Chapter 73).

Boots

A variety of commerical equine boots are manufactured from different materials and in different sizes and styles, ranging from low to high profiles and for the front and rear limbs. Low flexible boots are used to replace conventional horse shoes. Some boots reach the pastern region and contain a thick, rugged sole (Easyboot, EasyCare, Inc., Tucson, AZ). Silicone pads are available that can be trimed to fit the sole of the foot to be placed into the boot (Figure 17-17). This boot is well suited to raise the opposite foot of a horse placed in a cast (see later in this chapter).

Other boots are available to apply to an injured horse on an emergency basis (Figure 17-18). Indications for these boots are breakdown injuries and phalangeal fractures. A tight bandage is applied to the distal limb to ensure a tight fit in the boot. These boots can also be applied following internal fixation of phalangeal and distal metacarpal or metatarsal fractures. When the horse has recovered from anesthesia, the boot is usually removed. However, in selected cases it can be maintained for a longer period of time. The same control measures have to be applied similar to casts (see later in this chapter).

Figure 17-17. A high profile Easyboot (EasyCare, Inc., Tucson, AZ) with a thick sole and a silicone pad for the support of the sole. Additional pads can be added to elevate the foot in cases where a cast was applied to the opposite foot.

Figure 17-18. A distal limb boot (Equine Bracing Solutions, Trumansburg, NY) used for emergency treatment of distal limb fractures and to protect an internal fixation of such fractures during recovery from anesthesia. (Courtesy L. Bramlage, Rood & Riddle Equine Hospital, Lexington, KY.)

EXTERNAL COAPTATION (CASTS)

Cast Application

Materials

Historically, plaster of Paris casts have been popular for external coaptation. Plaster is still a viable casting material because it is easy to apply, has good molding capability, and is inexpensive. Unfortunately, plaster casts also are heavy, disintegrate when wet, and do not allow tissues to be exposed to air, which makes this type of cast uncomfortable when worn for a prolonged period.[17] Furthermore, plaster is not as strong as fiberglass and thus requires more material to prevent breakage. This results in a heavier cast.

The shortcomings of early fiberglass casts were corrected and they are now manufactured from materials of superior quality; they are lightweight, strong, and radiolucent, and they have excellent molding capability. Additionally, the porosity of the material allows air to reach the skin. Although these types of casts are more expensive than plaster casts, they are more durable and require less material for adequate strength. A variety of fiberglass casting materials are currently available on the market. In 1983, the mechanical properties of several of these materials were compared, and the differences were recorded.[18] However, since then, major improvements in handling capability and strength have been implemented. For practical purposes today, there are no significant differences between the various fiberglass products on the market.

The strength of a cast is determined mainly through bonding between the tape layers, so swift cast application to avoid lamination is necessary to produce a strong cast. Fiberglass casts are about 20 times stronger and 4 times lighter than plaster casts. All cast materials exhibit an exothermic reaction (they release heat) during setting; the more layers applied, the greater the reaction. Immersion in water hotter than 27° C (80.6° F) immediately before application also results in heat production. However, warm water reduces the curing time considerably. Therefore, veterinarians inexperienced in the application of casts should use cool water, which permits a longer application time but ensures that all tape layers will bond together as the cast hardens. Unlike in the procedure for application of plaster casts, water should not be expressed from the fiberglass material before application, because the cooling effect of the water is lost. Also, freshly applied casts should not be covered with bandage materials before they have set, as is frequently done to facilitate intertape-bonding and ensure good rigidity of the cast. The casts usually set within 4 to 5 minutes and allow weight bearing within 20 to 30 minutes.

Indications

External coaptation by casting is indicated in selected fractures of the phalanges, as adjunct treatment to internal fixation of fractures, for immobilization after tendon repair, and to stabilize wounds that are healing in regions of continuous motion, such as heel lacerations (see Chapter 90). Casts are also applied to protect a limb during recovery from anesthesia—for example, after repair of a condylar fracture of the distal third metacarpal or metarsal (MCIII/MTIII). Tube casts may be applied to foals with incomplete ossification of the cuboidal carpal and tarsal bones to facilitate ossification while weight is distributed evenly across the joints (see Chapter 86).

Technique

Most casts are applied with the horse under general anesthesia. This prevents the animal from moving during the application and setting of the cast, which may weaken the cast or cause pressure points, with subsequent development of decubitus ulcers. However, with adequate sedation, casts can also be successfully applied in standing horses.

Before starting, all materials should be laid out for efficient and swift cast application. The entire portion of the limb to be covered with a cast should be cleaned and dried. It is not advisable to clip the hair unless that is required for a surgical procedure. Special attention should be given to the hoof. It should be trimmed and all excessive sole and frog material removed. It is advisable to paint the sole and frog with a solution containing iodine. Any lacerations or wounds should be débrided, sutured if necessary, and covered with a sterile nonadhering dressing. This dressing should be secured by a gauze or elastic bandage. It is advisable to apply boric acid to the portion of the limb that will be covered with a cast. Boric acid is a drying agent with antibacterial properties. Applying zinc-containing soft gauze is an alternative method to provide protective properties to the skin. These measures are especially important if the cast is to be left in place for an extended period of time. A piece of stockinette somewhat longer than twice the proposed length of the cast is prepared by rolling it from each end toward its center. One side is rolled outward and the other side inward (Figure 17-19). For foals, a 5-cm (2-inch) diameter stockinette should be selected. A 7.5- or 10-cm (3- to 4-inch) stockinette is adequate for adult horses. The stockinette should be neither too loose nor too tight.

The stockinette is applied to the limb with the portion previously rolled up in the outward direction (viewed from the stockinette). The rolled up portion is now unrolled, and in doing so the stockinette is applied to the limb (see Figure 17-19). When the first layer of stockinette is applied, it should be pulled distally for about 2 cm (¾ inch) to ensure normal alignment of the hair along the limb. The other half of the stockinette is then twisted at the sole region and unrolled like the first half (the previously inwardly rolled part can now be rolled outwardly). At this stage, the stockinette should extend about 5 to 10 cm (2 to 4 inches) past the proximal end of the cast to be applied. Generally, a ring of orthopedic felt, about 7 cm (3 inches) wide, is applied to the most proximal aspect of

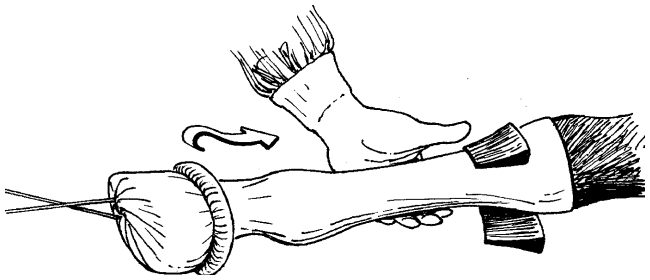

Figure 17-19. The limb is placed in traction and the inner layer of stockinette is rolled up along the limb. The outer layer of stockinette, which was initially rolled up in an inward direction, is twisted axially 360 degrees at the bottom of the foot and rolled up along the limb as well. At the proximal aspect of the cast, a wedge-shaped piece of thick felt is fitted to the limb, secured with tape, and covered with the outer layer of stockinette.

the cast between the two layers of the stockinette (see Figure 17-19). This ring of felt should not be overlapped but should be adjusted to the correct length to perfectly appose both ends. The ends are held in place temporarily by nonelastic adhesive tape.

For plaster casts, a cotton stockinette usually is used, whereas synthetic stockinettes are preferred for fiberglass casts. Because synthetic stockinette is manufactured from acrylic fiber that has little capacity to hold moisture, moisture is transferred away from the body. Also, synthetic stockinette maintains greater bulk, adding to the padding. Some clinicians prefer to add a thin layer of synthetic cast padding between the two layers of stockinette. Additional attention should be given to potential pressure points, such as over the accessory carpal bone, ergot, or calcaneus regions. Extra padding, consisting of a silicone doughnut or orthopedic felt with an elliptic hole, should be applied to these areas. After the stockinette and padding have been applied, the limb should be positioned for application of the cast.

In most cases, the limb should be extended with the metacarpal and phalangeal regions in the same frontal plane. In special cases, it may be preferable to cast the limb in a normal weight-bearing position. For this purpose, the carpus is flexed and slight pressure is applied either to the dorsum at the fetlock region or to the sole in a dorsal direction (Figure 17-20). An assistant must hold the limb in the desired position. The palm of the hand, not the fingertips, should be used to apply pressure to a specific region and thereby help prevent pressure point development. It must be kept in mind that attempts to cast a limb in its normal angulation fails in most cases when the cast is applied with the horse in a non–weight-bearing position (i.e., on the surgery table). Casting a limb in an "almost weight-bearing" position renders it more vulnerable to the development of pressure sores than if the limb is cast with the metacarpal/metatarsal and phalangeal regions aligned in the same plane. Therefore applying the cast in the standing, weight-bearing horse that is properly sedated is the method of choice for a normal weight-bearing position.

The polyurethane, resin-impregnated foam (3M Custom Support Foam) introduced in the early 1990s is an efficient means to reduce cast sores.[15,19] This material is immersed in warm water for about 1 minute. After minimal squeezing, the soft foam is applied evenly over the stockinette. Care is taken to overlap each turn half of the width, with the result that a double layer of foam is applied evenly over the part of the limb being covered with a cast. Minimal tension is applied. Wearing gloves during application of the foam is strongly encouraged.

To facilitate cast removal under practice conditions, one Gigli wire attached to a long felt strip (Figure 17-21, *A*) may be placed medially and laterally over the padded limb (see Figure 71-21,

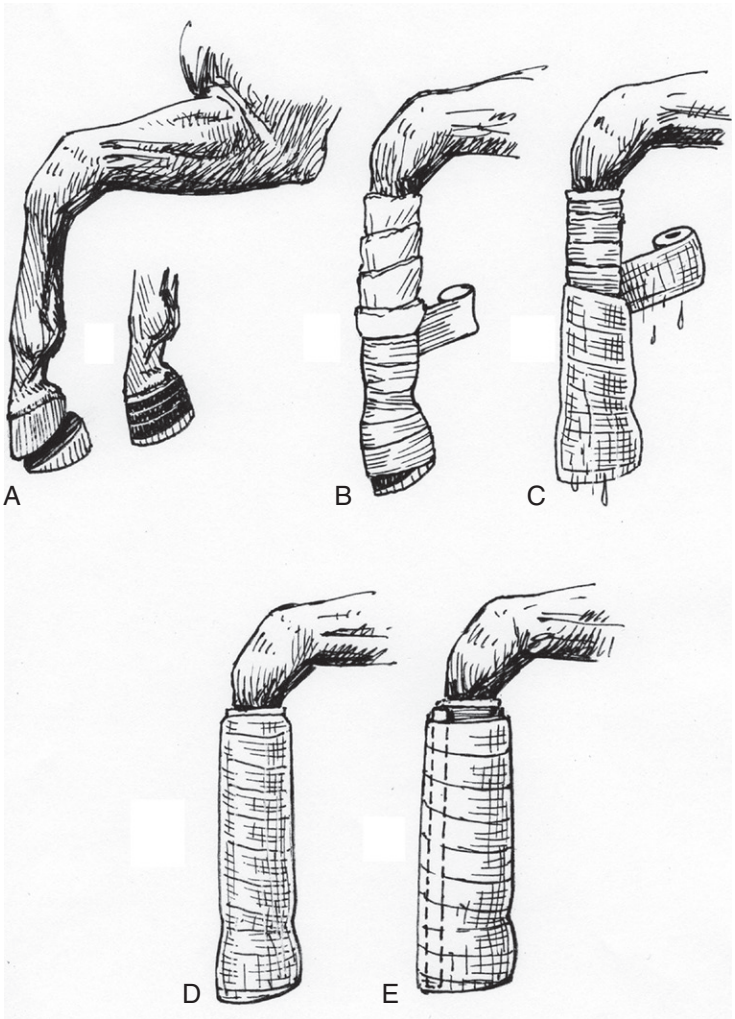

Figure 17-20. A short limb cast applied to the forelimb. The phalanges and third metacarpal are aligned in the same plane. **A,** A wooden wedge is applied to the foot with adhesive tape. **B** through **D,** The cast material is evenly applied over the synthetic foam in several layers. **E,** If deemed necessary, a straight dorsal splint may be incorporated into the cast.

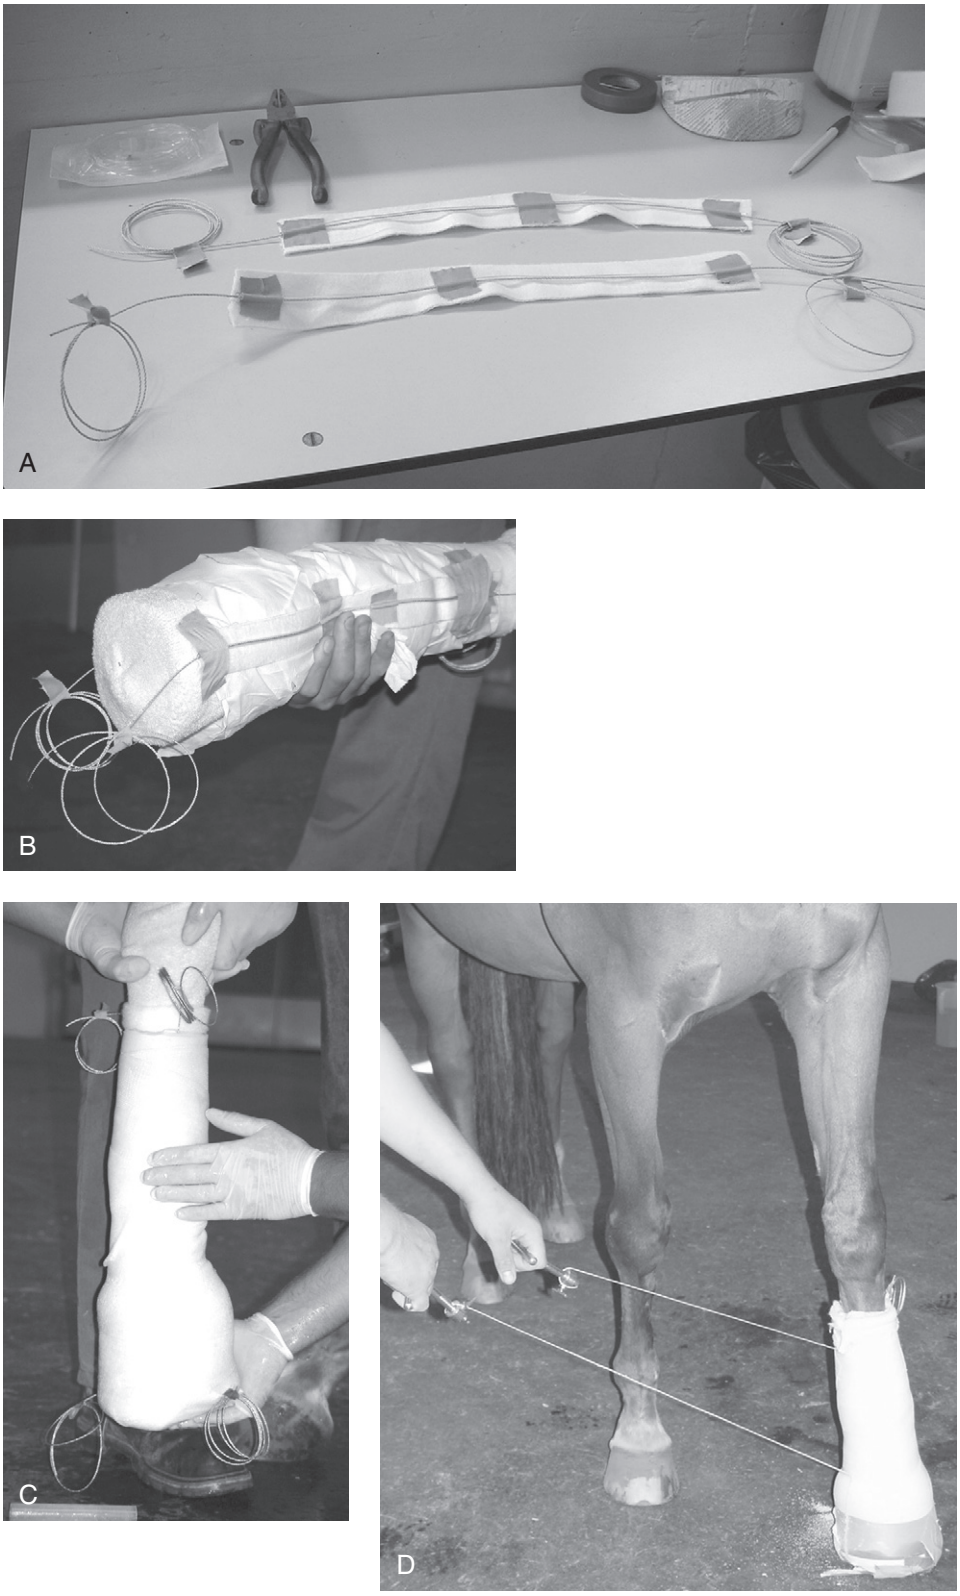

Figure 17-21. A, Two pieces of Gigli wire are attached to felt strips. The two ends are rolled up. **B,** The felt strips with the wire are applied medially and laterally to the padded limb. **C,** The cast is applied in routine fashion. The rolled-up ends of the wire are covered with tape at the end of cast application. **D,** At the time of cast removal, the ends of the wire are attached to the handles, and by slow sawing movements, the medial and lateral sides of the cast are severed apart. Finally, the two shells still connected at the sole are split dorsally and palmarly, allowing the limb to be removed from the cast. (Courtesy C. Lischer, Zurich, Switzerland.)

B).[20] The wire should be long enough that some excess wire protrudes proximally and distally on either side of the leg. When the cast is finished, the excess wire is rolled up and placed underneath the elastic tape applied to this region (see Figure 17-21, *C*).

Latex gloves must be worn when applying a fiberglass cast. The airtight packages of the fiberglass tape are opened immediately before application. The fiberglass tape is held with both hands, separating the free end from the rest of the material, before submerging it in the water.[21] The fiberglass tape is held in water at about 21° to 27° C (70° to 80° F) for 5 seconds. During this time, the tape is squeezed four or five times to encourage complete penetration by water. The fiberglass tape is removed from the water dripping wet and immediately applied to the limb. Cast application is started at the foot and progresses in a proximal direction, overlapping at least half the width of the roll until the most proximal aspect is reached. After applying two layers at the top, the cast material is directed distally and applied evenly over the limb. As a rule, the cast bandages are applied in progression by continuing with the next bandage where the previous one ended. Changing direction during cast application is done by folding the cast material at one place and smoothing out the fold with the flattened hand. The newer materials adapt so well that in most cases directional changes can be carried out without folding the material over. Care should be taken to follow the contours of the limb and not to apply too much tension to the tape, which could interfere with circulation.

After the first few layers of cast material are applied, the extra stockinette extending on top of the cast is folded distally and covered by the following layers of cast tape (see Figure 17-20). Fiberglass cast material is applied until the cast reaches a thickness of 7 to 8 mm (¼ to ½ inch) throughout the total length of the cast. This requires four to six rolls of 12.7-cm (5-inch) fiberglass casting tape for a half-length cast in an adult horse and 10 to 12 rolls for a full-length cast.

If deemed necessary, a straight splint, which could be an old hoof rasp or any similar type of material, may be incorporated into the cast on its dorsal aspect (see Figure 17-20, *E*). This splint should be covered with cast material to prevent accidental trauma to another limb. Such a splint would reduce the amount of cast material needed for a weight-bearing cast and is proposed only for preoperative support of phalangeal fractures.

When sufficient cast material is applied, the cast is molded over its total length and the surface is smoothed out. It is important not to flex the joints under the cast from the time cast application begins until the cast has set. Most casts harden within 5 to 7 minutes after the final roll is applied.

If the limb is cast in an extended position, a wedge should be incorporated in the cast under the heel (see Figure 17-20). The wedge permits weight to be applied over a greater surface than just at the toe. It is advisable to protect the bottom of the cast with a layer of hoof acrylic, a piece of old inner tube, or the bottom of a gallon plastic bottle taped to the bottom of the cast with nonelastic tape.

To prevent foreign material, such as wood shavings or straw, from entering at the top of the cast and causing irritation, a collar of adhesive elastic tape should be loosely placed around the top of the cast and continued about 6 cm (2¼ inches) proximally up the limb.

Casts applied with the limb in extension result in a longer limb than the ipsilateral counterpart. Therefore, the cast limb is usually held in an extended or non–weight-bearing position. This may lead to continuous overload of the good limb, which increases the risk of foundering. It is advisable to tape a rubber pad to the ipsilateral foot and in so doing to lengthen it as well, preferably to the same extent as the cast limb. This comforts the patient and facilitates even weight bearing.

Generally, hindlimb casts are applied in the same way as casts for the forelimb. The most likely areas for pressure sore development are the Achilles tendon and the dorsal aspect of the tarsus. It is advisable to attach a wedge to the sole of the foot to facilitate weight bearing and prevent upward fixation of the patella. The tarsal region presents an additional problem in a full-leg hind limb cast because of the reciprocal apparatus. Attempts of the horse to flex the hind limb in a full limb cast may cause the peroneus tertius tendon to avulse from its attachment or rupture in the tarsal region, allowing flexion of the stifle without flexion of the tarsus. Treatment of this problem is discussed in Chapter 97.

Exercise should be limited for a horse with a cast. It is preferable to keep the horse in a cool environment to prevent excessive sweating under the cast. In this respect, fiberglass casts are superior to plaster casts because fiberglass casts are porous and dissipate heat from the body.

It is advisable to palpate the cast every day, especially over possible pressure points. A localized area of increased heat, palpable through the cast, is an early sign of a developing skin ulcer. Sudden decreased use of the limb under a cast or increased lameness of the affected limb are signs of irritation under the cast. Another sign of such a problem is cast abuse through chewing, stomping, or rubbing. Swelling above the cast and/or a fetid odor usually signify a far more serious problem under the cast. Should any of these signs be noted, the cast should be changed or removed to alleviate the problem. Repairing a cast or making adjustments is rarely successful and is therefore not recommended.

Cast Removal

Removal of the cast with the horse under general anesthesia is usually uneventful. Removal of the cast while the horse is standing may be more complicated. In most cases, some degree of chemical or physical restraint is necessary to permit safe removal of the cast. If Gigli wires were incorporated into the cast, the ends can be freed up and connected to their handles, and with slow sawing motions the cast can be split in half (see Figure 17-21, *D*). If cast cutters are used, the cast should be grooved medially and laterally along its entire length to ensure the correct location of the cut. Then, the proximal aspect of the cast is cut completely through, down to the foam or orthopedic felt. This allows assessment of the thickness of the cast and gives the person removing the cast an indication of how deep to cut. Using excessive force may result in perforation of the underlying skin. When the proximal area of the cast is cut through, the rest of the cast should be cut by maintaining the blade at the same location until the cast is cut through completely before moving distally. Cutting through the entire thickness of the cast is appreciated by a little faster progression of the cast cutters, which should be anticipated by the person using the cast cutters and immediately reacted to by retracting the machine and reapplying it somewhat further distally. Dragging the cast cutter parallel to the limb when it rests on the

skin will promote skin lacerations. After the entire thickness of the cast has been cut through, the two portions of the cast tend to separate somewhat.

The cast covering the foot should be split carefully, because the density of the hoof is similar to that of the cast, and it is often difficult to differentiate between them, resulting in inadvertent penetration of the hoof wall by the saw blade. Although a standing horse may object to such treatment, there will be no reaction to this in the anesthetized animal.

When the cast is split into two half shells, a cast spreader is applied to widen the gap and allow transection of the adhering cast padding with scissors. The cast is removed and the limb is washed thoroughly. If radiographs are taken after cast removal, it is advisable not to wash the limb with soap containing iodine. After cast removal, the limb should be covered with a pressure bandage for some time to allow gradual relief of external pressure. Any sores that developed under the cast should be treated immediately using routine wound management.

In selected cases, a bivalve cast is applied to the limb. This can be made on the standing and sedated horse or with the horse under general anesthesia. In either case, the padding of the cast is made somewhat thicker and usually consists of a thin bandage, which can later be changed at regular intervals. The cast is subsequently applied using routine technique. It is advisable to let it set for about a day before splitting it into two half-shells. After the bandage is changed, the two shells are reapplied and maintained in apposition by tightly wrapping the two half-shells with nonadhesive tape.

Complications

Cast complications may develop from an overly tight application, resulting in dermal pressure necrosis (which will damage deeper structures if undetected) or in an overly loose application. If the cast is too loose, the limb can shift in the cast, which may result in the development of skin pressure in areas not anticipated. Cast loosening may result from a decrease in the limb swelling, from muscle atrophy, or from compacting of cast padding materials. Application of too-short a half-cast may result in severe tendon injury, because the limb may be partially flexed, causing the top end of the cast to apply a considerable amount of linear pressure on the unprotected tendons. In a properly applied cast, the tendons are protected by the proximal ends of the vestigial metacarpal or metatarsal bones. Wear on the bottom of the cast will also cause the limb to shift within the cast, resulting in serious dermal pressure necrosis.

CHAPTER 18

Balanced Inhalation Anesthesia

Regula Bettschart-Wolfensberger

The concept of balanced general anesthesia is based on the theory that administration of a mixture of small amounts of several neuronal depressants summates the advantages but not the disadvantages of the individual components of the mixture. Therefore, with a combination of different drugs, desired effects are achieved and untoward side effects are minimized. In horses, longer procedures (more than 2 hours) are usually performed under inhalation anesthesia. All currently used inhalation anesthetics depress cardiopulmonary function in a dose-dependent manner.[1,2] Hence, a minimal dose (just enough to induce unconsciousness) should be used, and analgesia and muscle relaxation should be provided by adding other drugs to the anesthetic protocol. In horses, maintenance of good intraoperative cardiopulmonary function followed by calm and coordinated anesthetic recovery is crucial. Therefore, balanced anesthetic techniques for horses should be directed at these two goals.

This chapter provides an overview of the use of modern inhalation anesthetics in combination with sedatives, analgesics, and/or muscle relaxants. Table 18-1 lists the recommended dose regimens and the respective dose rates.

ANESTHETIC RISK

The fatality rate in horses undergoing general anesthesia is much higher than in companion animals or humans and varies between 1% and 0.1% depending on the study design.[3-7] Horses undergoing colic or emergency surgery and horses undergoing fracture repair carry a several-fold increased risk compared to horses undergoing elective surgical procedures.

Only a few risk factors can be influenced by the choice of anesthetic agent. Nevertheless, it is generally accepted that most equine fatalities are related to either poor cardiopulmonary performance during anesthesia or to fatal injuries during violent, poor-quality anesthetic recovery.

Further studies investigating factors that might influence morbidity and mortality are necessary to determine drugs or anesthetic techniques that will improve outcome.

MODERN INHALATION ANESTHETICS

Inhalation anesthetics currently used in equine anesthesia include isoflurane (IsoFlo ad us. vet.), sevoflurane (Sevorane), and desflurane (Suprane). These drugs are usually used for maintenance of anesthesia. Their use for induction of anesthesia in foals is not recommended, because they are associated with an increased fatality rate compared to intravenous drug induction.[5]

Modern inhalation anesthetics are less potent and less soluble than older agents, such as halothane (Halothane B.P.). Drug potency is represented by the minimum alveolar concentration (MAC), defined as the alveolar concentration of inhalation anesthetic that prevents movement in 50% of subjects in response to a noxious stimulus. Thus, the MAC of novel drugs is higher than that of the older drugs (halothane: 0.88%,[8] isoflurane: 1.31%,[8] sevoflurane: 2.31%,[9] desflurane: 7.6%[10]). That means that with modern inhalation anesthetics, higher concentrations are needed to keep the horse anesthetized.

The lower blood solubility of the modern inhalation anesthetics means that changes in anesthetic plane can be achieved more readily and onset or disappearance of clinical effects is faster. The quicker disappearance of clinical effects might influence recovery characteristics, which led to several studies comparing recovery following different inhalation anesthetics (see Chapter 21). Biodegradation of modern inhalation anesthetics is very low (isoflurane, sevoflurane, and desflurane are metabolized by the liver at a rate of 0.2%, 3% to 5%, and 0.02%, respectively)[11] and probably does not influence recovery.

In general, cardiovascular depression from inhalant anesthetics is dose dependent. Dose-dependent decreases in cardiac output, stroke volume, and blood pressure as well as respiration in spontaneously breathing horses are common. While cardiovascular variables between isoflurane and halothane MAC multiples were similar in one study, they were less depressed by isoflurane and sevoflurane than halothane in another.[1,12] Under controlled ventilation, isoflurane causes less depression of cardiac output and stroke volume than halothane, and it causes similar changes in blood pressure. Vascular peripheral resistance decreases with isoflurane more than with halothane.[12]

Isoflurane, sevoflurane, and desflurane lower blood pressure as a result of decreased peripheral resistance and tend to cause less depression of cardiac output and contractility than does halothane. The effects of isoflurane and sevoflurane on cardiac output are very similar,[1,13] and desflurane does not depress cardiac output at 1 MAC.[2] Based on these findings, isoflurane, sevoflurane, and probably desflurane provide better tissue blood flow and therefore may be safer, especially in the critically ill patient.

Halothane-anesthetized horses breathe at a faster rate than horses on isoflurane. The respiratory rate also decreases progressively with increasing doses of isoflurane or sevoflurane but less

TABLE 18-1. Drugs Recommended for Reducing Minimum Alveolar Concentration in Combination with Inhalation Anesthesia, to be Administered Following Anesthesia Induction

Drug Name	Dose Rates	Comments
Lidocaine	Bolus: 0.65-1.2-(2.5) mg/kg (over 15 min) followed by 25-50-(100) µg/kg/min	Dose carefully in cardiovascularly compromised patients Toxic effects masked by anesthesia Prolonged use (more than 2 hrs) might result in ataxia during recovery; to reduce this, switch off 30 minutes before the end of anesthesia
α_2-Adrenoceptor agonist	Bolus for sedation before inducing anesthesia	Increased urinary production, urinary catheter mandatory Smoother recoveries than with lidocaine or ketamine
Medetomidine Romifidine	3.5 (-5) µg/kg/hr 0.3 µg/kg/min	CRI can be used for several hours without accumulation
Ketamine	0.5-1 (-2) mg/kg/hr	Sympathetic stimulation
S(+)-Ketamine	0.5-1 mg/kg/hr	Rough recoveries following prolonged use (more than 1.5 hrs), less with S(+)-ketamine; switch off infusion 15-20 min before end of surgery and sedate the horse during recovery to reduce this

CRI, Constant-rate infusion.

with halothane.[1,12] Despite these differences, $PaCO_2$ tends to be similar with all inhalant anesthetics, indicating similar minute-ventilation with all of them. This is most probably the result of an increased tidal volume in horses receiving isoflurane or sevoflurane, to compensate for the slower respiratory rate and a smaller tidal volume in horses receiving halothane.

DRUGS USED FOR BALANCED ANESTHESIA

Lidocaine

Lidocaine (Lidocain HCL 5%) has gained widespread popularity in equine inhalation anesthesia during the last decade to reduce the requirements for the volatile agents, in addition to its use perioperatively to improve gut motility or to provide analgesia.

Lidocaine is highly metabolized by the liver and has a very short half-life.[14] It has to be administered by constant-rate infusion (CRI). To achieve constant plasma levels within an acceptable time, an initial bolus has to be injected followed by CRI. A study conducted by Doherty and Frazier,[15] who administered a bolus of lidocaine (2.5 mg/kg/min) to six experimental ponies followed by either saline or two doses of lidocaine, 50 µg/kg/min or 100 µg/kg/min for 1 hr, revealed that lidocaine reduces MAC of halothane in a dose-dependent fashion. The same authors[15] also stated that with these dose rates no steady state was achieved and that lidocaine plasma levels were very variable between 1 and 4 µg/mL with the lower infusion rate and between 3 and 7 µg/mL with the higher rate. Plasma levels less than 2 µg/mL had a minor effect on MAC (maximal effect 20% MAC reduction) whereas levels more than 5 µg/mL reduced MAC by 50% to 70%. In another clinical study that compared isoflurane-lidocaine anesthesia to pure isoflurane anesthesia, lidocaine was administered as a bolus dose of 2.5 mg/kg (given over 10 min) followed by 50 µg/kg/min in combination with isoflurane anesthesia and administered for 75 min. This resulted in an average MAC reduction of 25%. Plasma levels of 0.03 to 4.23 µg/mL were recorded without causing any untoward side effects.[16] The horses in the lidocaine group recovered with less excitement from anesthesia.[16] In contrast to this, following a similar anesthetic period, horses had significantly worse recoveries with lidocaine (125-minute infusion) in comparison to balanced anesthesia with medetomidine.[17] Another clinical study that investigated the influence of lidocaine CRI on recovery from isoflurane or sevoflurane anesthesia showed that horses receiving lidocaine until the end of surgery had a significantly higher degree of ataxia and a tendency toward a lower quality of recovery.[18] Therefore, this study recommended the discontinuation of lidocaine CRI 30 minutes before the end of surgery to reduce ataxia during the recovery period.

In healthy awake horses, it has been shown that signs of lidocaine intoxication such as muscle tremors and ataxia occur at plasma levels as low as 1.85 to 4.53 µg/mL.[19] Feary et al.[20] showed in clinical cases undergoing routine arthroscopy that anesthesia with sevoflurane has a profound effect on lidocaine disposition. Lidocaine plasma levels were considerably higher during anesthesia than in awake horses. These authors recommended lower dosage rates in anesthetized horses than generally advocated because general anesthesia might mask neurologic manifestations of toxicosis. In another study that investigated the effects of lidocaine on small intestinal function and recovery after colic surgery, considerably lower dosage rates were used than in previous studies (0.65 mg/kg loading dose followed by 25 µg/kg/min).[21] Nevertheless these authors measured lidocaine plasma levels as high as 2.72 µg/mL in one horse and advocated prudent intraoperative dosing, especially in compromised patients. Contrary to this, Driessen reported in a retrospective clinical study the successful use of lidocaine in combination with isoflurane or sevoflurane in 25 horses undergoing colic surgery.[22] A bolus of 1.5 mg/kg lidocaine was administered immediately before surgery and the infusion of 30 µg/kg/min was stopped when the surgeon started to close the abdomen. In this comparison, horses with lidocaine did not show worse recoveries than those without, and no signs of toxicity were noted.

To summarize, a lidocaine bolus (0.65 to 2 mg/kg administered over 10 to 15 min) followed by CRI 25 to 50 µg/kg/min) can be used as part of a balanced anesthesia regimen in horses. It decreases MAC dose dependently. Higher dosage rates might induce toxicosis, especially in compromised patients with impaired cardiovascular function and thus reduced liver blood flow and metabolism. Toxicosis only becomes apparent after the effect of the inhalant anesthetic has vanished and might negatively influence recovery. Thus lidocaine should be administered with care and stopped 30 minutes prior to the end of

anesthesia, to reduce the occurrence of ataxia and uncontrolled recoveries.

α_2-Adrenoreceptor Agonists

α_2-Adrenoreceptor agonists are potent analgesics, and they reduce MAC of inhalation agents dose dependently.[23,24] Therefore, all available α_2-adrenoreceptor agonists are commonly used for balanced anesthesia in horses. Boluses of α_2-adrenoreceptor agonists impair cardiopulmonary function considerably for 20 to 120 minutes at clinically used dosage rates.[25,26] However, medetomindine is different in this regard. A bolus of medetomidine followed by a CRI results in a drop in heart rate and cardiac output for the first 10 minutes only.[27] Throughout a 2-hour medetomidine infusion, heart rate and cardiac output do not differ from pre-sedation values.[27] Among all available α_2-adrenoreceptor agonists being used for balanced anesthesia in horses, medetomidine has been investigated most intensively.[27-32]

Medetomidine's high clearance rate and short half-life necessitate its use as a CRI to achieve a persistent effect.[28] A CRI of medetomidine (3.5 μg/kg/hr) during experimental desflurane anesthesia in ponies decreased MAC by 28%.[29] In 40 clinical patients, the use of medetomidine CRI (3.5 μg/kg/hr) in combination with isoflurane resulted in significantly reduced isoflurane requirements compared to isoflurane anesthesia alone.[30] With medetomidine in this study, CRI adjustment of anesthetic depth was easier, requiring less additional drug to deepen anesthesia. Another clinical study applying balanced anesthesia in 69 cases that compared lidocaine/isoflurane (1.2 mg/kg bolus followed by 50 μg/kg/min) with medetomidine/isoflurane (7 μg/kg bolus for sedation prior to anesthesia induction followed by 3.5 μg/kg/hr throughout anesthesia) revealed that following a mean anesthesia time of 2 hours, recovery with medetomidine was longer but of better quality.[17] Maintenance of anesthesia was also easier with medetomidine, and less additional drug had to be administered to maintain a stable plane of anesthesia. The cardiac index was higher in horses anesthetized with lidocaine/isoflurane, but this was related to very high cardiac index values in some horses that were insufficiently anesthetized rather than to depressed cardiovascular function with medetomidine/isoflurane. Contrary to this, an experimental study that compared the use of either lidocaine CRI or lidocaine in combination with medetomidine CRI showed no differences in cardiopulmonary function but better-quality recoveries when medetomidine was added.[31]

A retrospective study that reported the use of medetomidine/isoflurane anesthesia in 300 clinical cases with a mean anesthesia duration of 146 minutes (range: 40 to 420 min) outlines the safety of this drug combination in horses, with only 1 poor recovery reported.[32] In comparison to other clinical studies, the incidence of hypotension or hypoxemia was similar or even lower. These authors emphasize that anesthesiologists need to be aware that judgment of depth of anesthesia is different from other inhalation anesthesia regimens.[32] Under medetomidine/isoflurane anesthesia, eye reflexes are brisker. Only the appearance of nystagmus may serve as an indicator of insufficient depth of anesthesia. Further, α_2-adrenoreceptor agonists and especially medetomidine increase urine production, and catheterization of the urinary bladder after induction of anesthesia is mandatory.

The use of romifidine (Sedivet ad us. vet.) for balanced anesthesia was tested in a clinical study in 20 horses.[33] All horses were premedicated with romifidine (80 μg/kg), and anesthesia was induced with ketamine (3 mg/kg) and diazepam (0.1 mg/kg). Ten horses were maintained under anesthesia with isoflurane only, and in the other 10 horses isoflurane was supplemented with 0.3 μg/kg/min of romifidine. Although horses with romifidine CRI needed less isoflurane, had sufficient spontaneous ventilation, and needed less dobutamine for maintenance of appropriate blood pressures, the results of this study should not be overinterpreted. There were two different anesthesiologists administering isoflurane to effect, and the duration of anesthesia was only 45 to 80 min. Furthermore, the impact of mechanical ventilation on cardiovascular function was completely neglected, even though ventilatory support was used only in some horses in the study group. A description of the recovery characteristics was also lacking in this study.

Detomidine (Equisedan ad us. vet.) CRI for balanced anesthesia in combination with halothane was used in an equine study that also investigated the effect of neurectomy on cardiopulmonary function.[34] Five horses were maintained on halothane in combination with detomidine, and four horses were maintained on halothane alone. Administration of detomidine began following anesthesia induction with a target-controlled infusion device that aimed at a plasma level of 25 ng/mL. Duration of detomidine administration was 1 hour 40 minutes to 2 hours 50 minutes and the average infusion rate was 0.18 μg/kg/min. With halothane only, horses had higher heart rates, but otherwise no other differences between the groups concerning cardiopulmonary function or recovery were noted.

In conclusion α_2-adrenoceptor agonists reduce MAC by about 30%. With medetomidine CRI at a dosage rate of 3.5 to 5 μg/kg/hr, cardiopulmonary function is relatively well maintained, and large trials showed that recovery after medetomidine/isoflurane anesthesia is better than after lidocaine/isoflurane anesthesia, and in comparison with other regimens it seems to be generally of better quality. Data of balanced anesthesia including other alpha$_2$-agonists is limited.

Ketamine

The currently licensed form of ketamine is a racemic mixture containing 50% S-ketamine and 50% R-ketamine. Ketamine (Narketan 10 ad us. vet.) is a dissociative agent, which in systemically healthy horses induces analgesia, amnesia, and immobility without depressing cardiovascular function. On the other hand, there is some sympathetic stimulation, which might help to maintain cardiovascular function in combination with inhalation anesthesia. Respiratory function is only minimally impaired by ketamine.

These properties make ketamine an ideal agent for balanced anesthesia in horses. During inhalant anesthesia, ketamine has been administered in incremental intravenous doses (0.1 to 0.2 mg/kg) or as a CRI. Muir and Sams[35] investigated ketamine's halothane-sparing effects by continuously administering the drug at several infusion rates while administering halothane in oxygen at different concentrations. The authors found halothane reduced MAC by up to 37%, and cardiopulmonary function was better in horses with ketamine-halothane in comparison to only halothane. Another study investigated ketamine in combination with isoflurane.[36] With a target controlled-infusion pump, the investigators aimed at an arterial concentration of S-ketamine (Keta-S ad us. vet.) of 1 μg/mL. The initial ketamine loading dose was approximately 0.3 to 0.4 mg/kg IV followed by a linearly decreasing infusion rate beginning at 9 mg/kg/hr and eventually reaching 5 mg/kg/hr. At these infusion rates,

ketamine was found to decrease nociception during isoflurane anesthesia in a more pronounced fashion than when the inhalant anesthetic was used alone.

Unfortunately, ketamine as well as its metabolites exhibit undesirable excitatory central nervous system effects. Following prolonged ketamine infusions (more than 1 to 2 hours) or repetitive IV boluses, horses might show those side effects. Ketamine can provoke emergence reactions during the anesthetic recovery period characterized by muscle tremor and rigidity, mydriasis, oculogyric movements, sweating, excitation, ataxia, and schizophrenia-like behavior that can turn into a fatal event in horses.[35,37] These phenomena are related to the plasma concentration of the drug, the length of drug infusion, and the concurrent formation of S-norketamine.[38] To minimize such reactions, ketamine infusions can be reduced progressively and/or be stopped 15 to 20 minutes before the end of the procedure, and patients should receive additional post-anesthetic sedation with alpha$_2$-adrenoceptor agonists.[39] Another option to reduce such unwanted reactions is to use S-ketamine, which has been used mostly under clinical circumstances instead of the racemic ketamine. S-ketamine has been tested in a study in horses undergoing elective arthroscopy.[40] Following xylazine (Xylazin Streuli ad us. vet.) injection (1.1 mg/kg), S-ketamine was administered (1.1 mg/kg IV) and anesthesia was subsequently maintained with a CRI of S-ketamine (0.5 mg/kg/hr) in conjunction with isoflurane in oxygen. This balanced anesthesia regimen resulted in better quality of anesthetic recovery than when horses received twice the dosage of racemic ketamine, especially when the anesthetic episodes lasted for more than 2 hours. Similarly, Filzek et al. found that guaifenesin (Myolaxin 15% ad us. vet.)–S-ketamine–xylazine combinations provided better recovery qualities than guaifenesin–racemic ketamine–xylazine combinations in horses undergoing castration.[41] In a clinical study in 50 horses, balanced anesthesia with S-ketamine and isoflurane resulted in better cardiovascular function than with medetomidine and isoflurane but worse recovery scores.[42]

Dissociative anesthetics preserve some reflexes usually used to evaluate anesthetic depth, such as swallowing or eye blinking, and thus horses undergoing balanced anesthesia with ketamine may not seem to be at an adequate surgical plane.[37] Therefore, special attention should be given while evaluating these patients to avoid drug overdosing. Also, sympathomimetic effects of ketamine may impair judgment of anesthetic depth. Increases in heart rate and/or arterial blood pressures should be considered indicators of an inadequate plane of anesthesia only if they are associated with surgical stimulation. Thus, if ketamine-based balanced anesthesia protocols are chosen, one may better use other parameters such as respiratory rate in spontaneously breathing horses, muscle relaxation, and absence of nystagmus to evaluate adequacy of depth of anesthesia for surgical procedures. The presence of reflex activity can be disturbing when performing surgery in the upper airway or ophthalmologic procedures. It has therefore been suggested to avoid ketamine for such procedures.[43]

In conclusion, low-dose IV infusions or repetitive boluses of racemic ketamine or S-ketamine might be beneficial when administered in conjunction with other anesthetic agents. This applies in particular to horses in need of additional analgesia and/or improved hemodynamic function. When racemic ketamine is used, the additional boluses should not exceed 2 mg/kg, and a CRI (1 mg/kg/hr) should not be used for anesthesia exceeding 90 to 120 minutes, to avoid violent recoveries. CRI should be discontinued 15 to 20 minutes prior to transferring the patient to the recovery stall. Administration of an α_2-adrenoceptor agonist before emergence from anesthesia is highly recommended.

Opioids

The intraoperative use of opioids as part of a balanced anesthesia regimen has not yet gained widespread popularity in horses, contrary to other species and humans. Their effect is debated by many authors. Several experimental and clinical studies have tried to determine the influence of opioids on MAC.[44-49] Morphine (Morphin HCl sintetica 10 mg), butorphanol (Alvegesic 1% forte ad us. vet.), or alfentanil (Rapifen) did not consistently reduce MAC.[44-46] Individual horses within each study showed either an increase in MAC, a decrease, or no change at all. Individual horses recovered violently from anesthesia, showing signs of central nervous excitement, especially when high doses of opioid agonists were used.[46]

The use of *naloxone* (Narcan) did not prevent this excitement during recovery.[46] A clinical study tested the use of a bolus of morphine (0.15 mg/kg) followed by infusion of the drug (0.1 mg/kg/hr) in comparison to halothane anesthesia alone.[47] No significant differences between the groups were identified. The same authors also tried to show a beneficial effect of morphine on recovery from anesthesia but were unable to do so.[48] Morphine's influence on MAC of halothane was also tested when administered concurrently with xylazine.[49] The results of this study indicate that xylazine reduces inhalant anesthetic MAC but morphine does not enhance this effect any further.

In one study, the isoflurane MAC-sparing effects of fentanyl, dosed based on previously determined pharmacokinetic data in individual horses, were tested.[50] It was concluded that there may be a therapeutic dosage range of fentanyl that consistently decreases MAC, even though with the different plasma levels that were tested some horses showed an increase in MAC and others showed a decrease or no change at all. Furthermore, in the same study,[50] two horses needed active cooling with ethanol to maintain their body temperature below 38.6° C and one of eight horses showed a violent recovery during which it frantically attempted to circle in both directions, falling over several times. This observation is in agreement with studies in awake horses.

A recently published retrospective study showed that butorphanol deepened anesthesia when administered in conjunction with isoflurane and that sympathetic stimulation caused by surgery was blunted when butorphanol was used.[51] The fact that opioids when used for balanced anesthesia reduce propulsive gastrointestinal motility[52] and may slow respiration needs to be considered.[46]

In conclusion, only very few studies support the regular pre- or intraoperative use of opioids for MAC reduction in horses. Nevertheless, it is advisable to administer 0.1 mg/kg morphine at the end of every anesthesia to provide some additional analgesia. This results in a smoother recovery with no untoward effects.

Centrally Acting Muscle Relaxants

Guaifenesin

Formerly known as glyceryl guaiacolate, guaifenesin is used as an adjunct to balanced anesthesia in horses to induce muscle

relaxation. Guaifenesin has a wide margin of safety and sedative properties that can potentiate other sedative drugs.[53] It provides good relaxation of laryngeal and pharyngeal muscles, allowing easier intubation, and also produces relaxation of skeletal muscles. Clinical dosages (in the range of 100 to 150 mg/kg) do not affect diaphragmatic function, preserve respiratory function, and exert no significant effect on cardiac output and arterial blood pressure.[54] Whether guaifenesin has mild analgesic properties in horses is still under debate. For this reason, the use of guaifenesin as the only adjuvant to inhalation anesthetics is not advised.

Spadavecchia et al. combined guaifenesin (1 to 0.3 mg/kg/min) with ketamine (39 to 13 μg/kg/min) to reduce the required halothane dosage in horses that were presented for a variety of surgical procedures, including emergencies.[39] The combination of these two drugs resulted in a more stable surgical anesthesia compared with halothane alone, with fewer episodes of patients moving in response to surgery. The quality of recovery was acceptable and similar to horses receiving halothane alone. Similarly, infusions of ketamine/guaifenesin or ketamine/guaifenesin/romifidine facilitated a reduction in isoflurane dosages in horses undergoing various surgical procedures and resulted also in more stable and better cardiovascular performance than when isoflurane was used alone.[55] The authors attributed these observations to the anesthetic-sparing effects and the analgesic properties of the drug combination. Infusion of guaifenesin, ketamine, and medetomidine to horses anesthetized with sevoflurane resulted in better transition and maintenance phases while improving the cardiovascular function and reducing the attempts needed to stand up during the recovery phase, compared with inhalation of sevoflurane alone.[56]

Thrombophlebitis can occur especially with solutions containing 10% guaifenesin, and hemolysis has been reported after administering IV solutions containing a concentration greater than 10% of guaifenesin.[57,58]

In conclusion, although the effect of guaifenesin alone on MAC has never been quantified, and neither have its analgesic properties, this drug can be added to balanced anesthesia protocols because it improves muscle relaxation. Administration to horses at risk of thrombophlebitis is not recommended.

Benzodiazepines

Traditionally, benzodiazepines (such as midazolam [Dormicum]) have been used in equine anesthesia to reduce the muscle contraction produced by ketamine, especially during the induction phase of anesthesia. Water-soluble benzodiazepines have been incorporated in balanced anesthesia protocols in an attempt to potentiate muscle relaxation and to reduce the dose of volatile agents required to maintain a surgical plane of anesthesia.[59] Controversy exists with regard to their analgesic effects. Although literature on the pharmacologic properties of benzodiazepines did not consider them as being analgesics, more recent studies provide some evidence to suggest that they might enhance the analgesic properties of co-administered drugs.[60]

Kushiro et al. administered CRI of ketamine, medetomidine, and midazolam to six horses undergoing a 4-hour surgery twice at an interval of 1 month.[60] The horses were mechanically ventilated and received sevoflurane in oxygen. With this drug combination, cardiovascular function was well preserved and sevoflurane delivery could be reduced to an end-tidal concentration of 1.7%, which is lower than the MAC value (2.3%) reported in horses.[61] In these horses, recovery from anesthesia was uneventful, although ataxia was recorded for 15 to 20 minutes after standing, and an assisted recovery technique with use of head and tail ropes was advised. To minimize the postanesthetic ataxia induced by benzodiazepines, it has been suggested to antagonize their effects by administration of specific benzodiazepine antagonists, such as sarmazenil (Sarmasol).[37]

In conclusion, water-soluble benzodiazepines can be administered together with α_2-adrenoceptor agonists or ketamine to enhance muscle relaxation. Their role as analgesic co-adjuvants remains to be determined. Antagonization with a specific antagonist at the end of the anesthesia is advised to reduce the risk of postoperative ataxia.

CHAPTER
19

Modern Injection Anesthesia for Horses

Regula Bettschart-Wolfensberger

The use of inhalation anesthesia is generally limited to larger clinics because of equipment costs, the requirement for an oxygen source, and the need for a scavenging system for waste gases. There is also strong evidence that inhalant techniques are associated with a higher mortality rate in horses (see Chapter 18). Therefore, the use of safe intravenous anesthesia techniques in practice is both desirable and advantageous. The most important features of intravenous protocols are a smooth, excitement-free induction phase with a slow lowering of the body into sternal and lateral recumbency, minimal

cardiopulmonary depression, no reactions to surgical stimuli, and a calm recovery with a single attempt to stand and minimal ataxia. Other factors include good muscle relaxation and analgesia, as well as the possibility to assess depth of anesthesia and to modify depth and duration of anesthesia in a quick and predictable manner.

Injectable anesthetic combinations are currently used for anesthesia induction and for short, minor surgical procedures up to 30 minutes. Longer surgeries are performed with intravenous anesthesia induction followed by inhalation, or less commonly by total intravenous anesthesia (TIVA). Features of short-duration injection anesthesia are discussed separately from long-duration (anesthetic duration more than 30 minutes) TIVA. Anesthetics discussed in this chapter include ketamine and propofol and useful combinations of these two drugs. Unfortunately there are only very few recent reports that further investigated these drugs or new combinations. The only new drug in equine intravenous anesthesia is alphaxalone (Alfaxan 10 mg/mL). Its first use in horses has been reported in anesthesia conferences.[1,2] Further clinical studies are necessary to determine whether this drug has advantageous properties compared to the currently used injectable anesthetics. Older agents, such as barbiturates, chloral hydrate, and drugs suitable for the anesthesia of wild Equidae, such as Immobilon (etorphine-acepromazine), will not be discussed.

SHORT-DURATION INJECTION ANESTHESIA

For anesthesia induction, ketamine (Narketan 10 ad us. vet.), tiletamine/zolazepam (Zoletil ad us. vet.), or propofol (Propofol 1% MCT Fresenius) can be used. Adult horses must be adequately sedated before anesthesia induction with a calculated dosage of the selected drug. Only in very young foals and in recumbent, severely compromised horses can anesthesia be induced with administration of an anesthetic to effect. For compromised horses, a mixture of equal volumes of diazepam (Valium 5mg/mL) and ketamine (100 mg/mL) represents a safe method for anesthesia induction and usually requires 1 mL/25 kg of the mixture (0.1 mg/kg diazepam plus 2 mg/kg ketamine). This protocol avoids the cardiovascular-compromising side effects of α_2-agonists. In foals, the administration of propofol to effect is a good alternative (see Chapter 20).

Ketamine

Ketamine is the most widely used drug for anesthesia induction in horses. It provides good, mainly somatic analgesia without inducing hypnosis. However, it is not suitable as a sole agent because it may cause seizure-like activity and muscle rigidity. Appropriate sedation with α_2-agonists and/or acepromazine (Prequillan), eventually in combination with opioids, prior to anesthesia induction is very important.[3-16] In a stressed, not well-sedated horse, ketamine does not result in a satisfactory quality of anesthesia. The addition of such drugs as guaifenesin (Myolaxin 15% ad us. vet.) or benzodiazepines (diazepam or midazolam [Dormicum]) will further improve muscle relaxation.[17-23] Guaifenesin is a safe drug with minimal side effects at clinical dosages. It should be used as a 5% (50 mg/mL) solution, because higher concentrations are associated with significant irritation of the veins and intravenous hemolysis.[24]

Guaifenesin is administered to the sedated horse to effect (preferably under pressure, because effective dosages are large: 50 mg/kg, or 500 mL for a 500-kg horse). When the horse begins to buckle at the knees, the induction drug, most commonly ketamine (2 mg/kg), should be administered.

Benzodiazepines can be used instead of guaifenesin and can be given together with ketamine without causing irritation of the vein. Depending on the dosage used, these drugs may increase the respiratory depression caused by ketamine. To reduce the risk of apnea (under field conditions where respiratory support is not available) and ataxia during recovery, low dosages of benzodiazepines (0.02 to 0.04 mg/kg diazepam or midazolam IV) are advocated. For anesthesia induction followed by inhalation anesthesia, higher dosages (up to 0.2 mg/kg IV) can be used and will facilitate intubation. Mechanical ventilation will counteract respiratory depression. To guarantee adequate muscle relaxation in the field where low dosages of benzodiazepines should be used, very deep sedation with relatively high dosages of α_2-adrenoceptor agonists, such as xylazine (Xylazin Streuli ad us. vet.), detomidine (Equisedan ad us. vet.), or romifidine (Sedivet ad us. vet.), is recommended.

A recent study investigated the effect of a bolus of 3 mg/kg lidocaine in ponies anesthetized with xylazine/ketamine for castration.[25] The use of lidocaine did not reduce the need for top ups with xylazine/ketamine for maintenance of unconsciousness and recumbency during castration. Only time-to-standing was prolonged by lidocaine (Lidocain HCl 2%), indicating an analgetic effect of this drug. The significance of this for clinical practice remains to be tested.

Ketamine is a safe anesthetic for horses. Properly sedated, undisturbed horses will slowly sink into sternal and then lateral recumbency. Recovery at the end of anesthesia is usually quick and coordinated.[3-16] Respiratory depression is minimal. Ketamine's sympathomimetic action is ideal to counteract the bradycardia and hypotensive effects of the drugs used as sedatives.[26] For example, xylazine has been shown to have only minimal influence on cardiovascular function in combination with ketamine in the horse.[9] Because the eyes remain open and the reflexes are only minimally depressed, the assessment of anesthetic depth is difficult and requires some familiarization time. Movements as a result of awakening may occur very suddenly and may be of a strong nature. Preferably, administer ketamine in healthy horses according to a fixed time scheme rather than to effect (Table 19-1).

S(+)–Ketamine

The currently licensed form of ketamine is a 50 : 50% racemic mixture of the S(+) and the R(−) enantiomers. The S(+)-ketamine (Keta-S ad us. vet.) is the active compound, and several studies have tested its use in horses.[27,28] At a dosage rate of 50% to 66% of the racemic ketamine the effects were similar to the racemic ketamine. Recoveries were smoother and of better quality when S(+)-ketamine was used in combination with xylazine[28] administered as boluses (xylazine 0.5 mg/kg, S[+]-ketamine 0.5 mg/kg) every 10 minutes for 50 minutes to perform castration. S(+)-ketamine given as a constant rate infusion (0.5 mg/kg/hr) in combination with inhalation anesthesia also resulted in better recoveries than the racemic ketamine at double the dosage rate.[27] Other effects were identical.

TABLE 19-1. Protocols for Use of Ketamine for Short Surgical Procedures

Sedation		Anesthesia Induction		Duration of Anesthesia	Prolongation
α_2-AGONIST		**MUSCLE RELAXANT AND ANESTHETIC**			
Administer slowly to effect; wait 5 (xylazine)-10 (others) min	Xylazine 0.5)-1 mg/kg IV	*Either* guaifenesin 25-50 mg/kg IV Administer under pressure before ketamine to effect (until horse starts to become wobbly)	Ketamine 2 g/kg IV	10-25 min Duration of anesthesia tends to be longer with detomidine or romifidine sedation	Xylazine-ketamine: half the initial dose of each drug every 10 min
Combine with butrophanol (0.02 mg/kg) *or* methadone (0.1 mg/kg to increase sedation	*or* detomindine 20-(40) mcg/kg IV *or* romifidine (80)-100 mcg/kg IV	*or* benzodiazepine 0.02-(0.2) mg/kg IV (diazepam, midazolam, climazolam) administer together with ketamine	Ketamine 2 mg/kg IV	Shorter duration in stressed, nervous animals	Ketamine: 0.5-1 mg/kg every 10 min following detomidine or romifidine sedation
Administer (IM) detomindine *or* romifidine to uncooperative horses					Triple drip (see Table 19-2)

Tiletamine

Tiletamine is a drug similar to ketamine, and both are classified as dissociative agents. Tiletamine is commercially available as a powder in a fixed (1:1) combination with zolazepam, a benzodiazepine, and it is reconstituted with sterile water immediately before use. It has been used in horses and other Equidae at dosage ranges of 1.1 to 1.65 mg/kg IV after sedation with α_2-adrenoceptor agonists.[29-33] Depending on the dosage selected, the recumbency time was considerably longer than with ketamine combinations, and respiratory depression was more pronounced. Ataxia during recovery was more accentuated than with ketamine, with horses making several attempts to stand up. These features make this combination less desirable than xylazine-ketamine, especially under field conditions.

Propofol

Propofol is a short-acting anesthetic that provides very good hypnosis and muscle relaxation but poor analgesia. It is not suitable as a sole agent in adult horses because anesthesia inductions are unpredictable, and the large volumes required make it impractical and prohibitively expensive.[34] Propofol has been used mainly after sedation with α_2-adrenoceptor agonists under experimental conditions.[35-38] Only a few investigations have looked at propofol in clinical patients.[39-41] Some authors were happy with propofol as an induction agent.[39] Others reported that the quality of anesthesia induction in individual horses was "not ideal" or "unacceptable."[40,41] It was hoped that slow administration of propofol would smooth anesthesia induction, but other factors, such as respiratory depression and lack of inherent analgesia in addition to cost, have prevented widespread use of propofol for anesthesia induction and its maintenance during short surgical procedures.[40]

In the neonatal foal, the use of propofol administered to effect for anesthesia induction (approximate dosage, 2 mg/kg IV) is, however, a good alternative to ketamine; the duration of action of propofol is short and not dependent on liver function. Relaxation is better and thus endotracheal intubation is easier than with ketamine. Propofol is contraindicated in hypotensive foals, because it will further compromise these patients. For additional information on foal anesthesia, refer to Chapter 20.

TOTAL INTRAVENOUS ANESTHESIA OF GREATER THAN 30 MINUTES' DURATION

Table 19-2 summarizes drugs and dosages suggested for maintenance of anesthesia with TIVA in horses.

In modern equine practice, TIVA of longer duration is commonly maintained with constant infusions of the so-called triple-drip (ketamine–guaifenesin–α_2-agonist), ketamine-climazolam (Climasol ad us. vet.), or propofol in combination with various drugs.

Ketamine combinations can be safely used for up to 1.5 hours to perform minor surgeries under clinical practice conditions. A recumbent horse breathing air will, however, become hypoxic. To prevent complications associated with hypoxia during procedures of 30 minutes or longer, inspired air should be supplemented with oxygen (15 L/min, via a nasal or endotracheal tube). If the duration of anesthesia exceeds 2 hours, ketamine should not be used, because it produces active metabolites that are eliminated very slowly and thus influence the recovery period negatively.[42,43]

TABLE 19-2. Dosage Regimens for Maintenance of Ketamine-Based TIVA in Horses

Technique	Drugs	Approximate Dosage	Comments
Triple drip	500 mL guaifenesin 10% + 1 g ketamine + 10 mg detomidine	1 mL/kg/hr	Even higher dosage during initial 10-15 min; try to reduce dosage rate after 1 hr of infusion
	500 mL guaifenesin 5% + 650 mg ketamine + 325 mg xylazine	2 mL/kg/hr	
	500 mL guaifenesin 5% + 500 mg ketamine + 250 mg xylazine	2.75 mL/kg/hr	Better relaxation than with preceding mixes (because guaifenesin dose is higher); more ataxia during recovery
Ketamine-climazolam	Ketamine + climazolam	6 mg/kg/h + 0.4 mg/kg/hr	20 minutes after the end of infusion, sarmazenil 0.04 mg/kg must be given IV to prevent ataxia
Medetomidine-ketamine-midazolam	0.1 mg/mL medetomidine + 40 mg/mL ketamine + 0.8 mg/mL midazolam	0.1 mL/kg/hr	Tested for anesthesias up to 60 mins; sarmazenil 0.04 mg/kg can be given IV to prevent ataxia in recovery

Ketamine–Guaifenesin–α_2-Adrenoceptor Agonist (Triple-Drip)

The triple-drip drug combinations are the most widely used for TIVA. Cardiovascular and respiratory depressions are minimal, and these combinations have been successfully used to perform major surgical procedures as well as to prolong field anesthesia in a relatively controlled manner.[44-47] The use of triple-drips should be restricted to procedures of up to 2 hours in duration, not only because of the cumulative effects of metabolites of ketamine but also because large doses of guaifenesin may result in severe ataxia during recovery. Anesthetic induction performed prior to triple-drip anesthesia should not include guaifenesin, so that the total amount of guaifenesin given to the individual is as low as possible. A suitable induction technique is xylazine followed by ketamine. Another successful protocol tested by Mama et al. applies xylazine, guaifenesin, and ketamine and maintains anesthesia with only xylazine and ketamine at various dosage rates.[48] The horses went through a good to excellent recovery phase but took relatively long (mean times to standing, 46 to 69 minutes) following anesthesia durations of 66 to 73 minutes.

During painful procedures, analgesia should be provided with local anesthesia or the inclusion of opioids, such as butorphanol (Alvegesic 1% forte ad us. vet.) or morphine (Morphin HCl sintetica 10 mg).

Ketamine–Midazolam–α_2-Adrenoceptor Agonist

Because guaifenesin is not available in some countries, some authors have tried to replace the guaifenesin with midazolam (Dormicum). A protocol using medetomidine (Dorbene) for sedation and ketamine (2.5 mg/kg IV) and midazolam (0.04 mg/kg IV) for anesthesia induction was followed by a mixture containing 0.8 mg/mL midazolam, 40 mg/mL ketamine, and 0.1 mg/kg medetomidine at a rate of about 0.09 mL/kg/hr for maintenance of anesthesia was used satisfactorily for castrations lasting 38 ± 8 minutes.[49] Whether this protocol is useful for longer-duration surgeries remains to be tested.

Ketamine-Climazolam

The infusion of climazolam (a long-acting benzodiazepine) together with ketamine causes less cardiovascular depression than triple-drip techniques.[19,50] Because climazolam causes severe ataxia, its action has to be reversed with sarmazenil (Sarmasol) for recovery. Analgesia is sufficient to perform superficial surgeries causing somatic pain. To provide adequate analgesia for visceral procedures, local anesthesia or additional analgesia (opioids, α_2-agonsits) must be administered.

Propofol

In contrast to ketamine, propofol is an ideal anesthetic for prolonged TIVA. It possesses a short context-sensitive half-life, permitting rapid recovery.[42] It has been used in combination with different α_2-adrenoceptor agonists, guaifenesin, ketamine, and opioids.[40,41,51-54] In combination with medetomidine, anesthesia was maintained for up to 4 hours, and major surgical interventions could be completed successfully. Although recovery was uneventful and relatively quick in all reports, problems, mainly of a respiratory nature (apnea and severe respiratory acidosis) and the relatively high cost of propofol have prevented widespread use of propofol in clinical practice. It offers no major advantages over commonly used inhalation anesthetic protocols, which represents an additional reason for its limited use.

CHAPTER 20

Anesthesia and Analgesia for Foals

Bernd Driessen

Foals are born after a gestation period of approximately 11 months (335 to 342 days)[1] and birth takes place quickly, consistent with the status of a horse as a prey and flight animal. Unlike many other species, the foal is developmentally much more mature at the time of birth, reaching the status of a juvenile physiologically within 6 to 8 weeks of life.[2] Based on physiological parameters, anesthesiologists may classify foals from birth to 1 month of age as neonates and as pediatric and then juvenile animals when they are 1 to 3 and 3 to 4 months old, respectively. They may be treated anesthesiologically like young adults when they have acquired mature cardiopulmonary function and metabolic pathways at 4 to 5 months of age.[2,3]

Foals may require deep sedation; local, regional, or general anesthesia; and analgesia care for a variety of reasons, most commonly for abdominal, urogenital, traumatic, orthopedic, endoscopic, and diagnostic imaging procedures. In 1995, the overall perioperative mortality rate for equine patients under 1 year of age was reported as high as 1.9%, which was higher than the rate reported for the general horse population.[4] However, recent data indicate that the perianesthetic mortality rate can be reduced to 0.2% or less, similar to that reported in adult horses,[5] provided anesthetic techniques and analgesic regimens applied are tailored to the developmental stage and the specific needs of the individual foal.

PHYSIOLOGICAL AND PHARMACOLOGICAL CONSIDERATIONS AS THEY RELATE TO ANESTHESIA IN THE NEONATAL AND MATURING FOAL

In the first days and weeks of life, the newborn foal undergoes major physiological changes that will affect almost all organ systems and functions, including circulation, respiration, oxygen (O_2) and nutrient delivery and consumption, central and peripheral neuronal activity, cell and organ metabolism, thermoregulation, and immune system activity. Administering safe anesthesia in the foal requires a thorough understanding of those changes, which are summarized in Table 20-1.

Cardiovascular System

Transition from Fetal to Neonatal Circulation

In mammals, the most dramatic change in cardiovascular function occurs at birth with the transition from fetal to neonatal circulation.[6] The primary function of the circulatory system of both the fetus and newborn is to deliver O_2 and nutrients to metabolizing organs and return deoxygenated blood to the gas exchange organ to replenish the O_2 and eliminate waste products including carbon dioxide (CO_2). In the fetus, the gas exchange organ is the placenta, and its vascular connections are

TABLE 20-1. Most Relevant Aspects of Foal Physiology that Affect Anesthetic Management

System	Neonate (1 Month or Younger)	Pediatric/Juvenile Foal (1-4 Months)
Cardiovascular	Transition from fetal to neonatal circulation Risk of return to fetal circulation HR-, not SV-dependent cardiac output Low systemic vascular resistance	More SV-, less HR-dependent cardiac output Increasing systemic vascular resistance
Respiratory	Maturation of pulmonary microanatomy, neuromuscular control, compliance, surfactant production High RR-dependent V_{min}, low V_T High O_2 consumption but low PaO_2	Respiratory function Higher V_{min} and RR with normal V_T Close to normal PaO_2
Nervous	Immature central, autonomic, and peripheral nervous system function Higher BBB permeability	Matured central, autonomic, and peripheral nervous system function Close to adult BBB permeability
Metabolism and tissue composition	High ECF compartment, CBV, CPV Low glycogen reserves No fiber intake High body surface area (heat loss)	Higher ECF but close to adult CBV and CPV Larger glycogen reserves Increasingly more fiber intake
Hepatic	Maturing liver function in first 3-4 wks	Overall close to mature
Renal	Immature Reduced concentrating ability	Overall mature
Hematology and biochemistry	Physiologic anemia Gradual increase in WBC Elevated serum enzyme activities	Normalizing PCV Adult WBC Elevated serum enzyme activities

BBB, Blood-brain barrier; *CBV*, circulating blood volume; *CPV*, circulating plasma volume; *ECF*, extracellular fluid volume; *HR*, heart rate; *PaO_2*, arterial oxygen tension; *PCV*, packed cell volume; *RR*, respiratory rate; *SV*, stroke volume; *V_{min}*, minute ventilation volume; *V_T*, tidal volume; *WBC*, total white blood cell count.

in a parallel arrangement with the other systemic organs, remote from the pulmonary circulation. To supply deoxygenated blood to the placenta and return oxygenated blood to systemic organs, a series of extracardiac shunts (ductus venosus, patent ductus arteriosus) and an intracardiac communication (foramen ovale) are necessary. At birth, the function of gas exchange is transferred from the placenta to the lungs, and therefore from the systemic circulation to the pulmonary circulation. The venous and arterial circulations are now separated, and not only are the fetal shunts unnecessary, but their persistence may compromise circulatory functions. Therefore, transition from fetal to neonatal circulation includes elimination of the placental circulation; lung expansion and increase in pulmonary blood flow; and closure of the foramen ovale, ductus arteriosus, and ductus venosus. Closing of those pathways does not occur immediately at birth and thus right-to-left shunting may continue and murmurs consistent with a patent ductus arteriosus may be auscultated in normal foals during the first 3 to 5 days of life,[7] with partial reopening possible up to the moment of complete fibrosis of those pathways, which occurs within 2 to 3 weeks.[8] As part of the transition from fetal to neonatal circulation, the left ventricular wall increases in thickness in parallel with a rise in systemic vascular resistance, reflecting the shift from the physiological right ventricular hypertrophy during fetal life to the physiological left ventricular hypertrophy in postnatal life.[9] An understanding of fetal hemodynamics and the acute and chronic changes that occur with transition to the newborn circulation are important for the care of normal newborns and are crucial to the recognition and management of a newborn with significant congenital heart disease or transient hemodynamic changes that may occur during general anesthesia and trigger a reversal to conditions of fetal circulation.

Hemodynamic Function

Cardiac output (CO) is defined as the amount of blood ejected by the heart per minute and is calculated as the product of heart rate (beats per minute) and stroke volume (mL). It is the most appropriate index of overall cardiovascular function and, when normalized to body weight, is referred to as cardiac index (CI, mL/min/kg). Fullfilling the needs of metabolically highly active organs and tissues during the early postnatal life, CI in resting foals up to 2 to 3 months of age is markedly higher when compared to adults and primarily rate-dependent (Table 20-2).[10-14] If CO is adjusted for metabolic size (0.75/kg),[11] the average CI in foals is approximately twice that of adults but the average stroke volume index 30% less.[7,15] Therefore, the normal heart rate of a resting equine neonate is significantly higher to maintain higher CO (see Table 20-2).[16,17] It is in this early period of life that any drug with heart rate–decreasing properties like α_2-adrenoceptor agonists may compromise hemodynamic function to an extent that the neonate cannot tolerate.[3,7] From 4 months of age onward, heart rates reach close to adult values and remain relatively stable throughout the remainder of the first year.[18]

Mean systemic arterial blood pressure is substantially lower in the early days of life but pulse pressure amplitude is higher in the neonate compared to the adult owing to a lower vasomotor tone and hence systemic vascular resistance (see Table 20-2).[7,10,11,13,14] By 1 month of age, foals tend to have a lower CI and heart rate (see Table 20-2) but a larger stroke volume, and their mean arterial pressure increases during this period because of a marked increase in vascular resistance indicative of the maturing sympathetic branch of the autonomic nervous system.[7]

Respiratory System

It is pertinent for every anesthetist to appreciate that any impairment of respiratory function, whether caused by sedative, analgesic or anesthetic drugs, recumbency and positioning, or surgical/diagnostic interventions, may severely compromise vital functions of the newborn. At birth, neither neuromuscular control of ventilation nor the lung itself is fully developed in foals.[7,15,19-21] Pony lungs are microanatomically more mature at birth than horses' lungs,[21] but still sufficient surfactant production is lacking and gas exchange occurs across terminal air spaces and more primitive alveoli.[8] Compliance of the chest wall is large in the neonate but lung elasticity is decreased.[8] Therefore, functional residual capacity (FRC), which is the gas

volume left in the lung after a normal expiration, and tidal volumes are markedly smaller than in the adult (see Table 20-2). Thus, in the immediate postnatal period foals are hypoxemic, with PaO_2 values being significantly lower than during adult life, whereas $PaCO_2$ values being similar. Still, because O_2 needs of the rapidly developing organism are much higher than in the adult, especially in the first week postpartum, O_2 consumption (6-8 mL/kg/min) exceeds that of the adult horse by two- to threefold,[15] requiring increased respiratory minute ventilation. To compensate for the smaller FRC and tidal volume, newborn foals typically breathe up to 60 to 80 times per minute, which in the fourth to sixth week declines to 30 to 40 breaths per minute for the remainder of the first 3 months of life before gradually approaching adult values. In addition, neonates close the upper airway during end expiration and therefore do not allow the lung to collapse easily; however, this protective mechanism (often referred to as "auto-PEEP") is often lost during anesthesia. This in conjunction with a lower sensitivity of the respiratory center to changes in PaO_2 and $PaCO_2$, most prominent after sedation with α_2-adenergic drugs, which particularly predisposes neonatal foals to hypoxemia and hypercarbia.

Nervous System Development

At the time of birth, the nervous system of a newborn still has substantial development to complete, as behavioral, anatomic, and physiologic evidence suggests. Studies in various species, including horses, indicate that the basic anatomical structures of the brain and spinal cord are present at birth as are specific cellular groups, synapses, and neurochemical markers.[22,23] Unlike in other species, neurogenesis of the cerebellar cortex is fairly complete in the newborn foal, indicating the horse's brain is maturing quite rapidly.[22] Because the cerebellum is responsible for coordinated movements and ambulation, this also explains why the foal can rise about 30 minutes after birth and start running minutes later. Although most of the large neurons differentiate early during fetal development, small neurons and neuroglia differentiate later, and myelination of nerve fibers is incomplete at many levels of the nervous system at the time of birth. As a result, transmission of nerve impulses from the periphery to the central nervous system is slower than in the adult and the ability to localize stimuli may be relatively poor. Therefore, when the neonatal foal is traumatized, it may or may not reply quickly enough with target-oriented nocifensive reflex responses. This phenomenon, however, does not preclude functioning nociceptive pathways or pain sensation in the newborn, and it thus calls for appropriate analgesic treatment, local and regional anesthesia, or even general anesthesia whenever a foal is exposed to noxious stimulation.

There is substantial laboratory animal evidence that the blood–brain barrier to proteins and other macromolecules, principally a property of tight junctions between the cells, is well formed early in brain development, whereas postnatal modifications in tight junction structure is in part responsible for the decline in blood-brain and blood–cerebrospinal fluid (CSF) permeability to smaller molecular compounds, such as many endogenous substances, nutrients, and drugs.[24] In addition, during the early postnatal period, the open tubulocisternal endoplasmic reticulum components of cerebral endothelial and chorioid plexus epithelial cells close, thereby restricting more and more diffusion of endogenous substances and drugs from the blood into the central nervous tissue.[25] Those changes, immaturity of the central nervous neuronal function as a whole, and different pharmacokinetic behavior of drugs in neonates may account for differences in responses to agents administered to a foal for purposes of chemical restraint, sedation, analgesia, and anesthesia.

There are numerous age-dependent changes in the autonomic nervous system responsiveness of myocardial contractile and conducting tissue and vasomotor tone reported in laboratory animal species,[26] but little is known in the horse. Those studies suggest that at birth parasympathetic nervous activity dominates while sympathetic innervation of heart and vasculature is still immature, which may in part explain the low systemic vascular resistance and mean systemic blood pressure as well as higher rate of bradyarrhythmias observed in the newborn foal subject to hypoxemia and/or hypothermia.

Early Postnatal Behavior

The significantly advanced development of the nervous system in the equine compared to other species provides the newborn foal with the ability to quickly escape from predators. Immediately postpartum, the equine neonate can maintain sternal recumbency and within 1 hour after birth will stand up and nurse, and soon thereafter can trot and canter.[17] Most can gallop by the next day. The suckle reflex is present within 30 minutes, and the average foal is nursing the mare within 2 hours postpartum. Any deviation from those normal behaviors, similarly to deviation from normal cardiovascular and respiratory parameters in the early phase of a foal's life, should alert the anesthetist to existing or impending problems.

Body Metabolism, Biotransformation, and Excretion

Body Water Content and Body Tissue Composition

Unlike in neonates of most other species, in the newborn foal total body water content is around 72%[27] or 74.4% ± 2.4%[28] of total body mass and hence is relatively low compared to puppies and kittens; and it does not change much over the first 5 months of life.[29] It also is close to the 67% of body weight measured in the adult horse.[30] The extracellular fluid (ECF) compartment is on a per kilograms of body weight basis about one third larger in foals than in adults, as are the blood and plasma compartments (Table 20-3),[27,31,32] which must be accounted for during perianesthetic fluid therapy and intravascular volume substitution. The higher ECF volume implies a larger apparent volume of distribution for many drugs, which must be taken into account for appropriate drug dosing and for predicting of drug uptake and distribution in the body.[25] Furthermore, because of the presumably higher capillary permeability in the neonate yet increasing systemic arterial blood pressures postpartum, intravascular water rapidly redistributes into the interstitial space, where it accumulates.[33] As a result, no sustained increase in intravascular volume occurs, which in the adult animal triggers diuresis by modulating release of vasopressin, renin, and atrial natriuretic peptide.[33] Consequently, neonates, especially ill neonates, retain administered fluid over a much longer time and thus do not handle large fluid loads well. At the same time, the expanded interstitial space in the neonate serves as a reservoir for fluid and can be rapidly mobilized in situations of acute hemorrhage or hypovolemia, restoring total blood volume

TABLE 20-3. Hematologic and Biochemical Parameters in Normal Awake Foals Compared to Adults*

much faster than in an adult.[33] As a result, the neonate can tolerate a greater blood loss before any significant decrease in blood pressure and tissue hypoperfusion is noted.

During the first weeks of life, the mare's milk provides the primary nutrional source the growing foal needs for sustenance. Daily fluid intake (milk plus water) of foals is high, with animals aged 11 to 18 days drinking 246 g/kg and those aged 30 to 44 days consuming 202 g/kg.[34] Maintenance fluid rates in neonatal foals are variable but higher than in adults, and as much as 120 mL/kg per day is required in foals up to 1 month of age.[33]

Glycogen reserves in liver and muscle are smaller in the newborn foal than in neonates of other species and last only for a few hours, making the foal more susceptible to hypoglycemia and energy deficits if the foal does not nurse.[27] However, from 2 to 4 weeks of age onward the foal's diet changes gradually to solid food with high-quality grains and forage increasingly covering the foal's dietary requirements, and by 4 months of age the mare's milk is no longer a significant source of nutrients. Therefore, foals are weaned by 3 to 5 months of age. In parallel, the foal's body mass as a whole (especially skeletal musculature and fatty tissue) increases rapidly over the first 12 to 16 weeks, providing the animal with increasingly larger glycogen stores and rendering it less susceptible to hypoglycemia and loss of energy reserves when food is withheld or the sick animal stops eating. In addition, uptake, distribution, and elimination kinetics of anesthetic drugs change rapidly as the foal's body mass increases. Growth rates of horses are not as well defined as those of other farm animals.[35,36] Studies in Thoroughbreds revealed that in this breed body weight at birth (day 0) ranges from 39 to 67 kg and increases rapidly over the following 6 months to 237 ± 19 kg, which is approximately half that of an adult animal (see Table 20-3).[35,36] Consequently, in the maturing foal, uptake and distribution of anesthetic and other drugs are expected to approach patterns as described for the adult horse more rapidly than in many other species.

Thermoregulation

Rectal temperature of foals ranges from 37.2 to 38.6° C (99 to 101.5° F). The much higher ratio of body surface area to weight, thin skin, and scarce subcutaneous fat tissue (poor insulation) increase environmental heat loss in the neonate compared to the adult horse.[8,37] Conduction, convection, radiation, and evaporation all play a role and can expose the newborn to rapid heat loss. In addition, mature equine neonates have the ability to generate heat through shivering, but they can respond with non-shivering (cellular) thermogenesis and behavioral actions as well.[38] Anesthetic drugs and commonly used sedatives will interfere with thermoregulation and therefore promote extended periods of hypothermia.

Hepatic Function and Development

The liver is the principal site of drug metabolism. The microsomal cytochrome P450 enzyme system is primarily responsible for transformating lipophilic compounds to polar and pharmacologically less-active or inactive substances (phase I reactions), whereas glucuronidation and other conjugation processes (phase II reactions) render the metabolites more hydrophilic, facilitating renal elimination. Functional maturity

of the liver is incomplete at birth and thus the capacity to metabolize endogenous substances such as bilirubin or drugs is markedly lower in newborn foals than in the adult horse.[17,25] As a result, metabolism and half-lives of organic waste products (e.g., bilirubin) are expected to be prolonged causing higher plasma concentrations to persist in the newborn foal (see Table 20-3). Likewise drugs have longer plasma half-lives and may accumulate on repeated dosing, thereby extending effects and slowing elimination from the body.[39] As blood flow to the liver increases after birth, enzyme induction begins with exposure to various endogenous and exogenous substances. In the horse, metabolic pathways seem to mature more rapidly than in other species. In particular, microsomal enzyme activity increases rapidly during the first 3 to 4 weeks of life, while conjugation processes approach activity levels similar to those measured in the adult more gradually.[25,39] Nevertheless, by 6 to 12 weeks postpartum most hepatic metabolic pathways are completely functioning.

Renal Function and Development

In horses, renal development, in terms of glomerular number, is complete by 30 to 40 weeks of gestation, although the kidney volume continues to grow until 50 to 90 weeks of postnatal life.[21] As a result, on a per kilogram of body weight basis, glomerular filtration rate and effective renal plasma flow of the full-term newborn foal is already comparable with that of the adult.[40,41] Foals have a relatively greater renal tubular internal surface area available for reabsorption but reduced renal concentrating ability in the postpartum period as compared to adult animals. Normal urine output in neonatal foals is reported to be approximately 6 mL/kg/hr but then decreases gradually over the subsequent 12 weeks of life.[21,32] Reflecting a high water intake and urine excretion, normal urine specific gravity in newborn foals, after the first 24 hours of life, is usually hyposthenuric (1.008 or less) and is reported to range from 1.001 to 1.027.[32,42] When compared with values reported in adults, excretion, clearance, and fractional electrolyte excretions (FE) in 4-day-old foals are similar for sodium but somewhat higher for potassium, phosphorus, and calcium.[42] Blood urea nitrogen values of 2 mmol/L or less (6 mg/dL or less) are normal up to 3 months of age, whereas the mean adult value is 3.5 mmol/L or less (9.8 mg/dL or less).[42]

Hematology and Biochemistry

Blood volume in neonates is higher than in adults, approximately 13% to 15% of total body weight, and then decreases to near adult values (8% to 10%) by 12 weeks of age.[31] A detailed review on clinical pathology findings in the maturing foal can be found elswhere.[43] Key hematologic and clinical chemistry parameters recorded in foals within the first 6 months of life are listed in Table 20-3. Most noticeable, packed cell volume and hemoglobin values typically increase to maximum values at birth as a result of placental blood transfusion and then gradually decline. In horses and ponies (as in human infants) this physiologic anemia of the newborn develops during the first 2 weeks of life with PCV to remain just below or in the low adult reference range.[31,43] This decline in red blood cells (RBCs) may be further aggravated by neonatal isoerythrolysis, an alloimmune hemolytic anemia caused by antibodies in the mare's colostrum against the newborn's erythrocytes that is accompanied by neonatal icterus.[17,43] Thereafter values increase again, reaching levels of adult animals by about 1 to 3 months of age.

Although there is no fetal hemoglobin in the equine species, levels of 2,3-diphosphoglycerate (2,3-DPG) in fetal and therefore neonatal erythrocytes is slightly lower than in adults, thereby increasing the affinity of hemoglobin toward O_2 and thus facilitating O_2 loading of hemoglobin in the placenta during fetal life and in the lung of the newborn while impeding O_2 off-loading at the tissue sites.[43,44] The impact of this phenomenon, however, is soon reversed in the pediatric/juvenile foal when phosphate substrate becomes available through active bone turnover, and the short-living fetal erythrocytes are increasingly replaced by new RBCs of bone marrow origin.[31] The 2,3-DPG of RBCs of these foals increases and thus O_2 off-loading in the tissues increases. Therefore, fewer RBCs are needed to maintain adequate tissue oxygenation. Data in other species indicate that when rapid bone growth slows, this trend reverts back to normal adult values.

In contrast, total white blood cell count of a foal increases gradually after birth, attributable to an increase in neutrophils, but considerable inter-individual variability exists with regard to total neutrophil numbers.[43] Lymphocyte numbers decrease immediately after birth to resume adult levels by about 3 months of age.[17,43] It is important to recognize that lymphocyte counts per se are not diagnostic in the neonate as numbers may be normal or reduced in foals with immunodeficiency.[43]

At birth, total plasma protein content may vary widely and then increase following colostrum intake, but a wide range persists, although the albumin concentration remains relatively constant.[17,43,45] Marked hyperbilirubinemia in the first week of life is a common finding and can be attributed to an accelerated breakdown of neonatal erythrocytes and immature hepatic function.[43] Serum enzyme activities (including creatinine kinase, sorbitol dehydrogenase, γ-glutamyl transferase, lactate dehydrogenase, and aspartate aminotransferase) have been reported to be transiently elevated in the first few weeks after birth as a result of hepatocellular maturation (see Table 20-3).[17,45] Serum lactate concentrations are high immediately after birth (3 to 5 mmol/L), likely because of temporary tissue hypoperfusion and hypoxia, but then decrease soon to normal values (2 mmol/L or less).[43]

ANESTHETIC MANAGEMENT OF THE SYSTEMICALLY HEALTHY NEONATE AND MATURING FOAL

Since the 1990s the scope of anesthetic management in adult horses and foals has expanded to accommodate new developments in equine surgery (e.g., laser surgery in the airway, laparoscopy, thoracoscopy), medicine, and diagnostic imaging (e.g., computed tomography, magnetic resonance imaging [MRI]). Today protocols for continuous deep sedation, loco-regional anesthesia, and analgesia are techniques that in combination may replace or complement general anesthesia. Methods of general anesthesia in the foal have been described previously.[1,3,7,8,37,46] The rapid maturing of the foal postpartum with all its implications described earlier and both clinical and experimental observations suggest that sedation, anesthetic, and analgesic protocols must be tailored to the needs of the individual foal, such as its developmental stage and health status. For clinical purposes, it is meaningful to distinguish anesthetic management of the neonate foal (up to 1 month of age) from that of the pediatric or juvenile foal (1 to 4 months old).

Weanlings (more than 4 to 5 months old) usually have adult circulatory and respiratory reserves and mature metabolic pathways, and they do not require specific precautions. Therefore, they can be treated anesthetically as adult horses.

Preanesthetic Examination and Preparation

A thorough history and physical examination of the foal in the presence of the mare, involving assessment of mental status and temperament, cardiopulmonary functions (heart rate and rhythm, pulse pressure, capillary refill time, mucous membrane color and moisture, respiratory rate and rhythm), hydration status, and body temperature are essential before any suitable protocol for sedation, anesthesia, and/or analgesia can be formulated. The need for ancillary tests (e.g., chest radiographs, ultrasound, electrocardiogram) and laboratory analyses (e.g., complete blood cell count, clinical chemistry profile, blood gas analysis, urinalysis) is largely dependent on the physical status of the foal, the presenting complaint, and the intended surgical or diagnostic procedure and should take into account age-dependent differences in vital, hematologic, and biochemical parameters between foals and adult horses (see Tables 20-1 and 20-2). As a minimum, packed cell volume, white blood cell count and differential, total plasma protein content, and blood urea and glucose concentrations should be determined in any foal undergoing prolonged sedation or general anesthesia. If the foal is a newborn, the assessment should include a detailed history of the perinatal period and a test of the adequacy of passive antibody transfer; if the foal is more mature, a complete medical history may be all that is necessary.[17]

Nursing foals up to 2 months of age have little fiber intake and should not be muzzled prior to anesthesia but should have free access to their mother. Suckling helps maintain adequate blood glucose levels, liver glycogen reserves, and hydration status. Older foals with increased solid food intake may be muzzled and held off feed for 3 to 6 hours prior to anesthesia. These older foals, particularly when hypovolemic, may profit from antiulcer medication (ranitidine [Zantac] 1.5 mg/kg IV every 8 hr, famotidine [Pepcid AC] 0.3 mg/kg IV every 12 h, omeprazol [GastroGard] 2 to 4 mg/kg PO every 24 h).[47] In foals of any age, the mouth should be rinsed out with water close to the time of induction of anesthesia to prevent feed or bedding material that may be present in the pharynx from being pushed into the airway during the process of endotracheal intubation.

In preparation for long-term sedation or general anesthesia and to ensure safe fluid and/or drug administration, a 16-gauge (18-gauge in minihorse or small pony foals) jugular venous catheter should be placed in the equine neonate using aseptic technique. Catheter placement is facilitated by infiltration of the subcutaneous tissue with local anesthetic (e.g., 2% lidocaine [Lidocaine HCl USP]) at the site of skin and blood vessel puncture. In the healthy neonate, mild sedation (Table 20-4) may be nessary to facilitate aseptic placement of an IV catheter. If anesthesia is being induced using an inhalant anesthetic technique, IV catheter placement may be postponed to the moment following induction of anesthesia. If antibody titers indicate inadequacy of passive immune transfer, the neonate should receive either colostrum or plasma, as appropriate, and antibiotics because newborns are highly susceptible to serious infections when stressed by injury, metabolic disease, anesthesia, or surgery.

Sedation of the Mare

In most instances, it is desirable to have the mare present when handling an awake or mildly sedated foal because separation from the mother may trigger anxiety, excitement, and stress. To facilitate preparation of the foal for anesthesia, sedation of the mare is highly desirable because it prevents her from becoming agitated or even aggressive toward personnel handling the foal.

A physical examination of the mare should precede any administration of sedatives or tranquilizers. Ideally the mare should be tranquilized while still in the stall with her foal. Sedative agents or a combination of drugs with relatively long duration of action are preferred. Depending on the temperament of the mare and the anticipated length of separation of mother from foal, acepromazine alone (PromAce, 0.02 to 0.05 mg/kg IV/IM) or in combination with α_2-adrenoceptor agonists (xylazine [Rompun] 0.2 to 0.3 mg/kg IV, detomidine [Domosedan] 5 to 10 µg/kg IV/IM, or romifidine [Sedivet] 0.02 to 0.04 mg/kg IV/IM) will provide adequate and long-lasting sedation.[3,7,8]

Anesthetic Management of the Neonate (1-Month-Old or Younger)

The immaturity of its central nervous, cardiopulmonary, hepatic, renal, and metabolic systems described earlier in this chapter must be kept in mind when designing the anesthetic plan for a neonate so as not to expose the foal to an increased risk of perianesthetic complications. Sedation and anesthetic drug regimens that are the least likely to impair vital functions and to cause prolonged central nervous depression are preferred.

Sedation

Foals up to 14 to 21 days of age usually do not require any chemical restraint or tranquilization to be handled and instrumented prior to induction of general anesthesia or locoregional anesthesia for brief and less-invasive surgical or diagnostic procedures.[2,3,7,8,37] If, however, sedation is required or the animal is older than 2 to 3 weeks, a benzodiazepine derivative is the preferred choice because it has limited adverse cardiopulmonary effects.[3,7,37] All benzodiazepines listed in Table 20-4 provide sufficient sedation and muscle relaxation, thereby facilitating minor interventions such as radiographic or ultrasonographic examinations, cast application and changes, synovial or cerebrospinal fluid aspiration, rhinolaryngoscopy, intravenous catheterization, or short surgical procedures under local anesthesia or induction of general anesthesia.[2,3,7,8,37] If infusion or repeated drug dosing is anticipated to maintain sedation, midazolam (Versed) may be the better choice because the propylene glycol vehicle in other benzodiazepine preparations (diazepam [Valium], lorazepam [Ativan], climazolam [Climaxolam]) can cause metabolic acidosis and nephrotoxicity.[48] In the more mature neonate (older than 2 to 3 weeks), benzodiazepines may be supplemented with one of the opioids listed in Table 20-4 and/or a low dose of xylazine (0.05 to 0.1 mg/kg) to enhance sedation and provide some analgesia.[3,8,37] If desired, the benzodiazepine effect can be countered at the end of the procedure using flumazenil (Romazicon; 0.025 to 0.1 mg/kg IV) or sarmazenil (Sarmasol; 0.025 to 0.1 mg/kg IV). The opioid can be antagonized with with naloxone (10 to 15 µg/kg IV) or levallorphan (Lorfan; 22 µg/kg IV),[49,50] and

TABLE 20-4. Anesthetic Management of the Systemically Healthy Foal

	Neonate (1 Month or Younger)	Pediatric/Juvenile Foal (1-4 Months)
Sedation (IV)	None (≤2-3 wk) Benzodiazepines (≥2-3 wk) Midazolam 0.05-0.1 mg/kg Diazepam 0.1-0.25 mg/kg Lorazepam 0.02-0.05 mg/kg Climazolam 0.1-0.2 mg/kg α_2-Agonists (not preferred) Xylazine 0.2-0.5 mg/kg Supplementation with: Morphine 0.03-0.06 mg/kg L-Methadone 0.05 mg/kg Butorphanol 0.05-0.1 mg/kg	Benzodiazepines (4-8 wk) Midazolam 0.05-0.1 mg/kg Diazepam 0.1-0.25 mg/kg Lorazepam 0.02-0.05 mg/kg Climazolam 0.1-0.2 mg/kg α_2-Agonists (>8 wk) Xylazine 0.2-0.5 mg/kg Detomidine 0.005-0.01 mg/kg Romifidine 0.02-0.04 mg/kg Phenothiazines Acepromazine 0.03-0.05 mg/kg Supplementation with: Morphine 0.03-0.06 mg/kg L-Methadone 0.05 mg/kg Butorphanol 0.02-0.1 mg/kg
Induction of anesthesia	Pre-oxygenation (2.5-5 L/min) via mask or nasotracheal tube Inhalant anesthetic in O_2 Isoflurane Sevoflurane Desflurane Injectable anesthetics (after sedation) Ketamine 2-2.5 mg/kg Propofol 2-2.5 mg/kg	Injectable anesthetics (in combination with benzodiazepine listed above or guaifenesin 20-50 mg/kg IV) Ketamine 2-2.5 mg/kg Propofol 1-3 mg/kg Ketamine 1.5 mg/kg + propofol 0.5 mg/kg Thiopental 4-6 mg/kg
Maintenance of anesthesia	Inhalant anesthetic in O_2 Isoflurane Sevoflurane Desflurane Total intravenous anesthesia (TIVA) Propofol 0.2-0.4 mg/kg/min	Inhalant anesthetic in gas mixture (FiO_2 > 0.3) Isoflurane Sevoflurane Desflurane Supplementation* with Lidocaine CRI Ketamine + propofol CRI Dexmedetomidine CRI Total intravenous anesthesia (TIVA)* Triple drip CRI Propofol 0.1-0.3 mg/kg/min

CRI, Constant rate infusion; *FiO_2*, inspired fraction of oxygen.
*See text for more details.

xylazine can be reversed with yohimbine (Yocon; 0.1 to 0.2 mg/kg IM).

Induction and Maintenance of Anesthesia

Induction and maintenance of general anesthesia can be achieved with one of the currently approved volatile anesthetics (isoflurane [Isoflo], sevoflurane [Sevoflo], or desflurane [Suprane] in O_2) or an injectable agent such as ketamine (Ketaset) or propofol (Propoflo) (see Table 20-4). Use of only a volatile anesthetic offers several advantages in neonates: (1) rapid uptake and elimination of the anesthetic via the lungs aided by the usually high minute ventilation and CO; (2) easy and rapid adjustment of anesthetic depth if untoward cardiovascular or respiratory depression or arrhythmias occur; (3) elimination of the anesthetic independent of hepatic and renal function. While the previous multicenter study[4] indicated a 4.5 times higher risk of perioperative mortality in neonatal foals that had received an inhalant anesthetic (halothane) versus ketamine for induction of anesthesia, this finding does not coincide with a clinical investigation of the safety of two inhalant anesthetics (halothane and isoflurane) for induction and maintenance of anesthesia in foals.[51] Also personal experiences do not corroborate a higher risk associated with using inhalant anesthesia in foals. Of the 153 neonatal foals anesthetized over the past 10-year period approximately 43% received one of the inhalant anesthetics (predominantly isoflurane) for induction and 57% an injectable anesthetic, yet only one animal with a perforated esophagus in which anesthesia was induced with ketamine suffered a fatal outcome because of an airway obstruction in the recovery period.

Considering the high O_2 consumption and predisposition of neonates to develop hypoxemia when being deeply sedated or anesthetized, it is recommended to have them breathe O_2 or at least an O_2-enriched gas mixture (FiO_2 0.5 or more), independent of technique used. (It is important to administer O_2-enriched gas because the risk of rapid desaturation is fairly high and an FiO_2 more than 0.5 buys valuable time). Circle

rebreathing systems and anesthesia equipment designed for use in humans or small animals are well suited for equine neonates. Dependent on the age and hence size of the animal, 3- to 5-L rebreathing bags or bellows are sufficient. Preoxygenation is recommended in all animals being anesthetized. For this purpose, the foal is intubated using a lidocaine gel (Xylocaine Jelly 2%) lubricated 6- to 9-mm ID cuffed silicone rubber nasotracheal tube of sufficient length (30 to 55 cm [12 to 22 inches]) that is passed through the nostril and ventral nasal meatus into the trachea. Subsequently, with the cuff inflated or alternatively using a tight-fitting mask, O_2 or an O_2-enriched gas mixture is delivered at 40 to 60 mL/kg/min for 3 to 5 minutes before anesthesia is induced.

For induction of anesthesia the volatile agent, like O_2 alone during preoxygenation, can be delivered via the rebreathing circuit using the previously placed nasotracheal tube or face mask. Preanesthetic sedation in neonates is often not necessary. Following preoxygenation the vaporizer output is incrementally increased up to the maximum output setting. At a fresh gas flow rate of 2.5 to 5 L/min, the volatile anesthetic concentration rises rapidly in the breathing circuit with the onset of anesthesia typically occurring within 3 to 8 minutes.[51] Sevoflurane and desflurane are characterized by a 50% and 64% lower blood solubility than isoflurane, respectively, and therefore induction is somewhat faster with these agents than with isoflurane.[52] If anesthesia is induced by mask, the foal should be orotracheally intubated as soon as it has lost consciousness and the swallow reflex. For this purpose, the fresh gas flowmeter shall be momentarily turned off and a lubricated 8- to 14-mm ID cuffed canine endotracheal tube be used. When the foal is intubated, the delivered inhalant concentration can be decreased and carefully adjusted to the individual foal's requirements and the fresh gas flow rate can be reduced to a setting of 4 to 10 mL/kg/min to avoid unnecessary and costly waste of anesthetic gas.

Among the injectable anesthetics, ketamine is currently the most commonly used agent for induction of anesthesia in the equine neonate, typically following sedation with a benzodiazepine derivative alone or in combination with an opioid and/or low-dose xylazine. It will induce anesthesia lasting 10 to 20 minutes (see Table 20-4).[3,8,37] Alternatively, either with or without benzodiazepine sedation, propofol may be administered slowly (over 45 to 60 seconds) to effect (to avoid severe respiratory depression and apnea).[3,8,37,53,54] Induction of anesthesia with thiopental or other barbiturates should be avoided in neonates because of the prolonged recovery period.

In most neonates, anesthesia is maintained with one of the volatile agents to avoid drug accumulation and slow awakening from anesthesia if injectable agents (ketamine or barbiturates) are being infused or repeatedly administered. For isoflurane, an average anesthetic vaporizer concentration setting of 2.8 ± 0.1% has been reported,[51] which accords well with my own observations of an average dial setting of 2.2 ± 0.7% and end-tidal isoflurane concentration of 1.5 ± 0.4% recorded in 152 neonate anesthetics. In foals undergoing major trauma surgery, a balanced anesthesia regimen involving intermittent (every 1 to 2 hours) subcutaneous administration of a low dose of medetomidine (Dormitor, 1 to 2 µg/kg) or dexmedetomidine (Dexdormitor, 0.5 to 1 µg/kg) has advantages over maintaining anesthesia only with an inhalant anesthetic. While providing analgesia, these drugs reduce the need for high doses of volatile anesthetic that typically cause severe hypotension. Recovery (commonly assisted) to standing position usually occurs quickly, within 15 ± 1 minutes after 86 ± 4 minutes of isoflurane anesthesia[51] and within 27 ± 18 minutes after 133 ± 66 minutes of isoflurane anesthesia. If higher doses of a benzodiazepine or xylazine have been used for preanesthetic sedation or if anesthesia was relatively short, reversal of the premedication agents with appropriate antagonists (e.g., flumazenil, yohimbine) should be considered to speed up recovery.

Using propofol in the neonate allows maintenance of anesthesia without risk of untoward drug accumulation and prolonged recovery. It facilitates safe anesthesia administration over extended periods of time when inhalant anesthesia may not be a feasible option, for example, for MR imaging when compatible anesthesia equipment is not available. An anesthetic technique considered suitable under those circumstances in neonates (3 to 6 days of age) includes xylazine (0.5 mg/kg IV) premedication followed 5 minutes later by a bolus (2 to 2.5 mg/kg IV) and subsequent infusion of propofol (0.2 to 0.4 mg/kg/min).[53,54] However, the hemodynamic effects of α_2-agonists at such high doses cannot be ignored in this age group. A study of xylazine sedation in healthy 10- and 28-day-old foals indicated a decrease in heart rate by 20% to 30%, yet without causing second-degree atrioventricular block that is typically seen in adult horses.[55] In addition, a biphasic (initial increase followed by a decrease) change in blood pressure, similar to that in adult horses, occurred, but mean arterial pressure did not fall below 60 mm Hg.[55] Therefore, one should still exercise caution when using α_2-agonists in the very young or sick neonate and keep doses at a minimum. In one study, recovery time after constant rate infusion of propofol (0.30 ± 0.07 mg/kg/min) for 60 to 122 minutes ranged from 15 to 32 min (mean, 27 min), and foals suckled within 10 minutes of standing.[54]

Anesthetic Management of the Pediatric/Juvenile Foal (1 to 4 Months Old)

Beyond 1 month of age, the normally developing foal of common breeds (i.e., Thoroughbreds, Standardbreds, Arabians, Quarter Horses, Warmblood horses, and Paint horses) has arrived at a stage of maturation when anesthetic techniques used in the adult can be applied with some modifications. In parallel with the maturation process, the risk for fatal perianesthetic complications seems to decrease markedly.[4]

Sedation

Systemically healthy foals 4 to 8 weeks of age (more than 120 to 150 kg body weight) or older are more difficult to physically restrain and therefore frequently require adequate tranquilization for preanesthetic catheter placement or other minor procedures. In younger pediatric foals, sedation with one of the benzodiazepine derivatives listed in Table 20-4 again offers the advantage of little adverse cardiovascular and respiratory effects yet profound calming and immobilization.[3,7,37]

In fractious individuals or foals older than 2 months, benzodiazepine administration often causes inadequate sedation and muscle relaxation or even excitement similar to what is described in the adult horse.[49] In these foals α_2-adrenoceptor agonists such as xylazine (0.2 to 0.5 mg/kg IV, 0.5 to 1 mg/kg IM), which is the most widely used drug in this group, as well as detomidine or romifidine, provide more reliable sedation and muscle relaxation, and in addition

profound analgesia (see Table 20-4 for dosages).[2,3,7,8,37] Overall, hemodynamic and respiratory side effects observed after α_2-agonist administration in foals up to 2 to 3 months old are similar to those noted in adults with maybe the exception of atrioventricular blocks occuring rarely in younger foals.[3,7,37,55,56] Of note, xylazine has been shown to cause hypothermia in foals.[57] Unlike in adult horses, α_2-agonists do not seem to produce hypoinsulinemia and hyperglycemia in 4-week old foals, indicating differences in pancreatic responses to α_2-agonists in early life and further emphasizing the need to monitor blood glucose levels during prolonged sedation and anesthesia.[57] Lower dosages of xylazine (0.2 to 0.3 mg/kg IV) usually provide adequate sedation for 15 to 30 minutes and are associated with minimal cardiovascular and respiratory changes,[7] making this drug the agent of choice for use in foals of that age group. In contrast, detomidine and romifidine have a longer duration of action and also carry a higher risk for untoward effects, including arrhythmias.[3,56] When combined with one of the opioids listed in Table 20-4, either the foal will lie down or it can be placed into lateral recumbency, allowing performance of minor surgical (in combination with local and regional anesthesia) or diagnostic procedures of short duration.[2,7] If desired or necessary, the α_2-agonistic effects can be antagonized at the end of the procedure using atipamezol (Antisedan, 0.05 to 0.1 mg/kg IV/IM) or yohimbine (0.1 to 0.2 mg/kg IV/IM).[49]

Acepromazine in clinically common dosages produces overall mild but long-lasting sedation.[3,37] It may be used to enhance and prolong sedation with xylazine. Clinically relevant hypotension secondary to vasodilation is a rare observation in normovolemic foals and therefore is not a concern.[3]

Induction and Maintenance of Anesthesia

Liver and kidney functions are significantly more mature in foals older than 1 month of age, and physical restraint becomes increasingly more difficult as the foal matures. Therefore, an IV technique is often considered the preferred method of induction of anesthesia (see Table 20-4). Ketamine is currently the most commonly used agent for induction of anesthesia in pediatric and juvenile foals and, to obtain good muscle relaxation, it is commonly combined with a benzodiazepine, unless this type of drug had been already administered for purposes of sedation. Alternatively and preferably in foals older than 3 to 4 months of age, ketamine may be coadministered with the centrally acting muscle relaxant guaifenesin (5%; Gecolate), which is administered IV to effect (dropping of head, general muscle relaxation and calmness, fetlock knuckling) at a rate of 2 to 3 mL/kg/min.[3,7,37] To avoid inadvertent guaifenesin toxicity, the infusion container (bag, syringe, or bottle) should only contain up to the calculated maximum dosage for the individual foal, about 50 mg/kg. Following xylazine administration (0.25 mg/kg), ketamine in combination with diazepam produces anesthesia in 4- to 6-week-old foals typically of 10 minutes' duration.[7] Ketamine may be replaced by propofol (see Table 20-4) for induction of anesthesia, but respiratory depression is likely to occur even in the more mature foal, and anesthesia may last only 5 minutes.[3,8,37,54] Alternatively, ketamine and propofol may be combined for induction of anesthesia (see Table 20-4).[37] Thiopental in conjunction with a benzodiazepine or guaifenesin is suitable for induction of anesthesia in the more mature foal and under certain circumstances (e.g., foals with seizures or brain trauma) it is the preferred technique (see Table 20-4).[7,37]

As in neonates, general anesthesia is most commonly maintained with isoflurane (MAC in adults, 1.3% to 1.6%)[52] in O_2 or an O_2-enriched gas mixture in pediatric and juvenile foals[51] although sevoflurane (MAC in adults, 2.3% to 2.8%)[52] or desflurane (MAC in adults, 7.0% to 8.1%)[52] may be used as well. Circle rebreathing systems and anesthesia equipment designed for use in humans or small animals are not suitable for foals when they reach a body weight in excess of 125 to 150 kg. Hence, a large animal anesthesia machine equipped with a 3- to 10-L rebreathing bag (accommodating the threefold increase of an average tidal volume to 10 to 15 mL/kg) is required to administer inhalation anesthesia in older foals.[8,37,51] Following induction with injectable agents, the foal is intubated using a 14 to 18 (70 to 100 kg body weight), 18 to 22 (150 to 200 kg body weight), or 22 to 24 (250 to 400 kg body weight) mm ID cuffed orotracheal tube of sufficient length. Initially, a high fresh gas flow rate of 3 to 5 L/min and vaporizer dial setting of 3% to 5% for isoflurane, 4% to 6% for sevoflurane, and 9% to 10% for desflurane ensures rapid rise of the volatile anesthetic concentration in the breathing circuit and airways of the foal. Within 5 to 15 minutes the dial setting should be carefully adjusted to maintain the required depth of anesthesia and the fresh gas flow rate should be reduced to a lower setting of 4 to 6 mL/kg/min. The foal's body size, previously administered anesthetic drugs, and blood gas solubility of the volatile anesthetic agent used must be considered when adjusting the maintenance dose.

As in adult horses, balanced anesthesia protocols in which an inhalant anesthetic is combined with administration of short-acting analgesic agents and/or injectable anesthetics also have become popular in foals.[37,46] Infusions of lidocaine (50 µg/kg/min after an IV bolus of 1.2 to 1.5 mg/kg)[46] or ketamine (50 µg/kg/min for 45 minutes followed by 25 µg/kg/min) plus propofol (0.1 mg/kg/min)[37] have been used in an attempt to reduce the required dose of the volatile anesthetic and provide better analgesia. In the older foal, combination with an α_2-agonist, such as dexmedetomidine (0.75 to 1.5 µg/kg/hr or 1 to 3 µg/kg IM q 1 to 2 h), also may be considered for painful orthopedic or trauma surgery.

Total intravenous anesthesia techniques have been applied in foals, whereby anesthesia is maintained by constant rate infusion of injectable anesthetics to effect (see Table 20-4). Infusion of 5% guaifenesin solution containing xylazine (250 mg/L) and ketamine (1 g/L), often referred to as *triple drip solution*, is applied most frequently.[7,8,37] This drug combination may also be administered after sedation of the foal at a rate sufficient to rapidly induce anesthesia. For maintenance of anesthesia, the drip can be continued at a rate of 2 to 3 mL/kg/hr. As described for neonates, anesthesia may also be maintained with propofol.[7,8,37,54] Lacking any analgesic properties, propofol administration may be combined with techniques of local and regional anesthesia or infusions of lidocaine, ketamine, or dexmedetomidine as mentioned for use with inhalant anesthesia (see Table 20-4).

Monitoring during Anesthesia

Anesthetic emergencies are typically of short duration and can have dire consequences, but in most instances, warning signs precede fatal developments and if recognized and responded to

in a timely and appropriate manner, emergency situations can be avoided altogether. This applies particularly to the neonate and maturing foal with its limited physiological reserves. Therefore, with the exception of very minor procedures, invasive diagnostic or therapeutic procedures requiring anesthesia of longer duration should only be performed in foals in specialty practices and hospitals that are appropriately equipped and have personnel familiar with foal anesthesia.

Guidelines for anesthesia in horses have been published previously by the American College of Veterinary Anesthesiologists[58] and more recently revised[59] and commented on.[60] Guidelines also have been issued by the equine practioner's association in Germany and recently discussed by the Association of Veterinary Anaesthetists. These guidelines state that a veterinarian or veterinary support staff familiar with foal anesthesia shall monitor the animal at all times during the anesthetic and recovery period and be prepared to intervene, when indicated. All drugs administered (including time, route, and dosage) and monitored variables are to be recorded every 5 to 10 minutes in an anesthesia record. It is important that monitored variables such as anesthetic depth, cardiovascular and respiratory functions, body temperature, hydration, and metabolic and hematological parameters be interpreted as interdependent variables taking into account the developmental stage of the foal and related normal physiology, the disease status of the patient, and the procedure being performed, before decisions to intervene are made. Monitoring techniques used in foals are principally not different from those applied in adult horses. The reader may refer to texts providing a more comprehensive review of monitoring in the anesthetized horse[61,62] and critically ill neonate.[63,64]

Anesthetic Depth and Drug Concentration

Although it is not always obvious, anesthesia is not a static situation but a rather dynamic process. Inadequate depth of anesthesia may be associated with periods of awakening or subconscious responses to noxious, auditory, mechanical and other stimuli, resulting in excessive stress, movement with potential contamination of the surgical site, and injury to the animal.[62] Excessively deep anesthesia is associated with severe depression of the brain stem and hence dangerous impairment of many vital functions, including those of the cardiovascular and respiratory systems. It is therefore essential that the anesthetist repeatedly assess the depth of anesthesia and, if needed, adjust anesthetic drug administration.

Physical signs such as position of the globe, nystagmus, degree of depression of protective eye reflexes (palpebral and corneal), presence or loss of swallowing reflex, rate and depth of breathing, lacrimation, skeletal muscle shivering/trembling or tightening, anal sphincter reflex, and hemodynamic responses to noxious stimulation are commonly evaluated.[62] Multiparameter anesthesia monitors with built-in multigas analyzer modules have become increasingly more affordable and are enjoying great popularity. They allow measurement of the end-tidal concentration or partial pressure of an inhaled anesthetic, which serves as an index of the partial pressure of the inhalant anesthetic in the alveoli and brain. Knowing the concentration or partial pressure of the inhalant anesthetic agent at every moment, the anesthetist has an additional tool at hand to better predict anesthetic depth and adjust anesthetic drug administration.

Cardiovascular System

Routine monitoring of hemodynamic function must include assessment of rhythm and rate of heart beats and arterial pulses, peripheral blood perfusion, and arterial blood pressure. Simple techniques such as cardiac auscultation, digital pulse palpation, and evaluation of capillary refill time and mucous membrane color may be adequate for foals subject to sedation only or brief periods of anesthesia (30 minutes or less). For longer-duration anesthetic periods and those involving inhalation anesthesia; however, more sophisticated monitoring techniques should be applied. Those entail continuous recording and display of the electrocardiogram (ECG) and measurement of arterial blood pressures, using either a noninvasive [ultrasonic Doppler or an oscillometric (Dynamap or Cardell)] or invasive but more accurate method involving catheterization of a peripheral artery (e.g., facial, transverse facial, auricular, or metatarsal artery). For oscillometric measurements, a cuff that is placed around the base of the tail with a bladder width–to–tail girth ratio of 1 : 2 to 1 : 3 provides the best measurements.[65] For invasive blood pressure recordings, the intraarterial catheter is connected via heparinized-saline–filled tubing to a sphygmomanometer or, more commonly, a pressure transducer, which then transmits the signal to an amplifier unit and monitor for continuous display of the pulse waveform and readout of systolic, mean, and diastolic pressures. The use of pulse oximeters with plethysmographic trace display assists in the assessment of peripheral perfusion and hence overall hemodynamic status of the foal.

In the critically ill foal, additional hemodynamic monitoring, such as central venous pressure, urine output, and cardiac output recordings, may become necessary or at least offer advantages in assessing the seriousness of cardiovascular function impairment and providing guidance for volume replacement and inotrope and vasopressor treatment aimed at optimizing systemic organ perfusion.[63,64] Various minimally invasive techniques have been developed in recent years and found to be appropriate for assessing cardiac output in foals under clinical conditions. One of these is the lithium dilution (LidCO) technique,[66] a noninvasive cardiac output technique (NICO) based on the Fick principle and partial rebreathing of CO_2,[67] and another is an ultrasound velocity dilution technique (UDCO).[14]

Respiratory System

Considering the predisposition of the newborn foal to develop respiratory depression after anesthetic drug administration with subsequent hypoxemia and hypercarbia, routine monitoring of respiratory function under anesthesia is warranted and must include at least observations of respiratory rate and rhythm and mucous membrane color. For anesthestic periods in excess of 30 minutes, involving inhalant anesthetics, performed in a hospital setting, or in animals not breathing gas mixtures high in O_2 concentration, continous monitoring of arterial hemoglobin oxygen saturation (SpO_2) by pulse oximetry is highly recommended. This is a noninvasive technique and involves placing a clip-type probe on the ear, tongue, or nonpigmented skin or mucosa. Although generally of great clinical value, device-dependent technology and software algorithms, transducer type, placement site, and tissue perfusion at the site of recording markedly influence the accuracy of a pulse oximeter readout. Therefore, pulse oximetry should be supplemented by

intermittent arterial blood gas analysis whenever the adequacy of respiratory function is a concern.

Capnometry, which is the breath-to-breath measurement of the end-tidal CO_2 tension ($ETCO_2$) at the end of expiration, provides a simple, noninvasive method for assessing ventilation. The usefulness of $ETCO_2$ measurements in isoflurane-anesthetized foals has been documented.[68] The $PaCO_2$ changes proportionately with metabolic activity and hence production of CO_2 in the body and inversely with its elimination (i.e., alveolar ventilation). Under physiologic conditions $ETCO_2$ changes with alveolar PCO_2 ($PACO_2$) and therefore with $PaCO_2$, with some predictable inaccuracy. An $ETCO_2$ value in excess of 45 mm Hg (hypercapnia) indicates hypoventilation, a value below 35 mm Hg (hypocapnia) indicates hyperventilation. In addition, changes in $ETCO_2$, whether sudden or gradual, may reflect changes in circulatory function (CO) as blood transports CO_2 from the periphery to the lungs. Most modern capnometers are equipped with screens that continuously display the $ETCO_2$ concentration over time (capnography), which provides the anesthetist with a valuable tool to recognize anesthetic equipment malfunction and gas flow changes in the airways, such as leaks in the circuit system, kinked endotracheal tubes, airway obstruction, exhausted carbon dioxide absorbent, and incompetent one-way valves.

Arterial blood gas analysis is the most accurate technique for evaluation of pulmonary gas exchange and, depending on equipment, allows direct assessment of arterial O_2 saturation (measured SaO_2), acid-base, and electrolyte status. With the development of portable, cartridge-based analyzers (e.g., Ometech OPTI CCA-TS blood gas analyzer; IDEXX VetStat, i-STAT System) blood gas analysis has become affordable in private practice.

Blood Glucose

Limited glycogen reserves in the neonate make it susceptible to the development of hypoglycemia during prolonged anesthesia (more than 1 to 1.5 hours). Blood glucose levels below 40 mg/dL may produce deleterious central nervous effects such as seizure activity, cerebral depression, and even permanent neuronal damage,[46] all of which are difficult to detect under general anesthesia. Therefore, blood glucose concentrations should be determined on a regular basis throughout a long-term anesthesia by using either bedside glucometers in the operating room or multiparameter laboratory analyzers.

Body Temperature

Foals, more than adult animals, are susceptible to heat loss because of their high ratio of surface area to body weight, lack of subcutaneous fat depots, and compromised thermoregulation under anesthesia.[7,8,37] For this reason, pharyngeal, esophageal, or rectal temperature should be continuously monitored or intermittently measured using either standard thermometers or electronic temperature probes that are connected to a multiparameter monitor for continuous recording.

Fluid Management in the Perianesthetic Period

In foals, use of balanced electrolyte solutions with normal strong ion difference (e.g., lactated Ringer, Plasmalyte, Normosol-R) has been recommended to avoid the acidifying effect associated with fluids without strong ion difference such as physiologic saline solution or 5% dextrose in water.[33] In the systemically healthy, normovolemic foal undergoing anesthesia, an infusion rate of 7.5 to 10 mL/kg/hr has been reported as adequate to maintain an appropriate circulatory volume.[3,7,8] Relative hypovolemia caused by anesthetic drug–induced vasodilation, use of high fresh gas flows causing a greater than normal respiratory loss, evaporative losses, and intraoperative hemorrhage may temporarily justify further increasing the IV fluid rate by up to five times the maintenance rate of 1.5 to 2 mL/kg/hr reported for foals, to a total of 20 mL/kg/hr.[32,33] However, the described differences between the neonate and adult in the response to isotonic fluid loading warrant a judicious approach to prolonged high-volume infusion of crystalloids in the neonate.[33] In adults, 20% to 50% (depending, in part, on state of hypovolemia and dehydration) of an isotonic fluid load is retained in the intravascular space 30 to 60 minutes after infusion, but this is much lower in the neonate, where fluid rapidly accumulates in the interstitial space and escapes regulatory mechanisms of fluid homeostasis. As a result, neonates retain infused fluids for a long time and do not handle large fluid loads well.[33] The situation is further complicated by a decrease in urine output under anesthesia.[69]

Dehydration and absolute hypovolemia as a result of persistent diarrhea, sepsis, septic shock, or acute hemorrhage require immediate intravenous fluid administration.[32,33,70] The previously mentioned balanced electrolyte solutions are adequate fluids whenever volume deficiencies are caused by insensible and isotonic fluid losses and may be administered in volumes of up to 50 to 80 mL/kg, typically given one third at a time followed by reassessment of the foal's volume status.[32,70] They provide rapid extracellular (intravascular and interstitial) rehydration.

Colloids, including synthetic solutions (e.g., dextrans, hetastarch, pentastarch) and plasma, may be required if the total plasma protein or albumin concentrations are low and may be used to supplement crystalloid fluid therapy.[32,70] Hetastarch in doses of 3 mL/kg at a rate of 10 mL/kg/hr may supplement crystalloid fluid therapy under those circumstances for rapid volume support.[64] Alternatively, hetastarch may be administered slowly (0.5 to 1.0 mL/kg/hr) up to a dose of 10 mL/kg/day for treatment in hypooncotic animals.[64]

Oxygen Supplementation and Mechanical Ventilation

Independent of sedation or anesthetic protocol used, supplemental oxygen therapy is principally indicated whenever the SaO_2 or SPO_2 value in a foal decreases below 90% and the PaO_2 value below 60 mm Hg.[44] Oxygen may be delivered via face mask, nasal cannula, or a nasotracheal tube and at a rate of 5 to 10 L/min. Preferably, O_2 shall be humidified by means of a bubble humidifier to minimize nasal and tracheal mucosal irritation and avoidable water losses in the foal, especially if administered over several hours.

In the foal, multiple factors may contribute to severe respiratory depression and impairment of pulmonary gas exchange leading to poor arterial oxygenation and CO_2 retention: persistent pulmonary hypertension, drug-induced central respiratory center depression, reduced FRC, exhaustion of respiratory muscles from increased work of breathing, immature lung, lung disease, and airway obstruction.[44] Therefore, especially in young

foals, ventilatory support is commonly required during general anesthesia as soon as respiratory minute ventilation decreases below 150 to 200 mL/kg/min, significant hypercarbia starts to develop and arterial oxygenation decreases. In spontaneously breathing foals under anesthesia the $PaCO_2$ rises commonly to values in excess of 80 mm Hg. Ventilators designed for use in humans or small animals are suitable for foals up to a body weight of 120 to 150 kg; for larger foals, large-animal ventilators are needed. Among all different modes of ventilation, controlled mandatory ventilation (CMV) is the mode most commonly used during equine anesthesia in general, even in foals. With CMV mode, the ventilator delivers breaths at a preset interval, regardless of any ventilatory effort made by the animal.[44] Typical settings to begin mechanical ventilation in the neonatal foal are a tidal volume of 6 to 10 mL/kg; a rate of 20 to 30 per minute; a peak flow of 60 to 90 mL/min; I:E ratio of 1:2; and a peak inspiratory pressure of 8 to 12 cm H_2O.[44] The initial inspired FiO_2 value should be set based on the preventilation PaO_2 and maybe as low as 0.3 to 0.5. It is not necessary to ventilate foals with 100% O_2. All ventilator settings should be dynamically readjusted based on postventilation blood gas results and tailored to the situation of the individual foal.

Recovery

Foals should recover in a dry, warm and quiet environment, preferably on a soft mattress suitable for the size of the foal to prevent decubitus injuries.[3,7] When the animal resumes spontaneous breathing efforts, it may be positioned in lateral (most frequent) or sternal recumbency and remain intubated at least until it is able to maintain adequate arterial oxygenation (SpO_2 more than 90%) and protect its airways. Continuation of endotracheal or nasal O_2 insufflation is recommended until the foal has resumed a normal breathing pattern and can maintain adequate arterial oxygenation when breathing room air. When the animal makes strong attempts to get up, it may be moved into sternal recumbency and then be given assistance at the moment of rising into standing position. The mare should be reintroduced to the foal when the foal is stable and able to stand on its own.

Perioperative Pain Management

Pain management should be an integral component of the anesthetic plan and perioperative care. A detailed review of analgesic therapy in horses can be found in Chapter 23. Currently no specific approach to pain assessment in neonatal foals has been described. However, the immaturity of hepatic and renal mechanisms in drug metabolism and elimination during the first 1 to 2 months of life would principally favor the use of locoregional techniques of analgesia and anesthesia over systemic pain therapy. As in adult horses, systemic analgesia in foals relies predominantly on administration of nonsteroidal antiinflammatory drugs (NSAIDs), opioids (primarily butorphanol [Torbugesic, Fort Dodge Animal Health]), and lidocaine.[3,71] Table 20-5 lists drug doses.

The NSAIDs flunixin meglumine (Banamine),[72,73] phenylbutazone (Phenylbutazone USP),[74,75] ketoprofen (Ketofen),[76] and ibuprofen (Caldolor)[77] have been studied in neonatal foals. Data from those studies indicate that clearance of these drugs is significantly slower and volume of distribution larger in the neonate than older foals and adult horses, causing prolonged half-lives. As a result, NSAIDs often need to be administered differently in neonatal foals, compared with adults. Under similar clinical circumstances, flunixin meglumine doses administered in neonatal foals during the first 24 hours of their life may be increased by as much as 1.5 times to induce comparable therapeutic concentrations, but in general, dosage intervals should be increased to avoid drug toxicity, including gingival and gastrointestinal ulceration, hypoproteinemia,

TABLE 20-5. Systemic Analgesics for Perioperative Pain Management

	Neonate (1 Month or Younger)	Pediatric/Juvenile Foal (1-4 Months)
NSAIDs	Flunixin meglumine IV/IM q 24-36 hr 1.4 mg/kg (foal <24 hr) 0.5-1 mg/kg (foal 1-4 wk) Phenylbutazone 2.2 mg/kg IV/PO q 12-24 hr Meloxicam 0.5-0.6 mg/kg IV q 8-12 hr Ketoprofen 1-2 mg/kg IV q 24 hr Ibuprofen 10-20 mg/kg IV/PO q 8 hr	Flunixin meglumine 1.1 mg/kg IV/IM q 24-36 hr Phenylbutazone 2.2 mg/kg IV/PO q 12-24 hr Meloxicam 0.5-0.6 mg/kg IV q 8-12 hr Ketoprofen 1-2 mg/kg IV q 24 hr Ibuprofen 10-20 mg/kg IV/PO q 8 hr
Opioids	Butorphanol 0.01-0.04 mg/kg IV Butorphanol 0.02-0.08 mg/kg IM Morphine 0.1-0.2 mg/kg IV, IM L-Methadone 0.05-0.1 mg/kg IV, IM Transdermal fentanyl (100-µg/hr patch)	Butorphanol 0.01-0.4 mg/kg IV, IM Morphine 0.1-0.2 mg/kg IV, IM L-Methadone 0.05-0.1 mg/kg IV, IM Transdermal fentanyl (one or two 100-µg/hr patches)
α_2-Agonists	Xylazine 0.1-0.5 mg/kg IV (use sparingly in foal colic because of adverse effects on cardiovascular and respiratory systems and GI motility) Medetomidine 1-2 µg/kg SC Dexmedetomidine 0.5-1 µg/kg SC	Xylazine 0.1-0.5 mg/kg IV/IM Detomidine 2-5 µg/kg IV/IM Medetomidine 2-5 µg/kg IM/SC Dexmedetomidine 1-3 µg/kg IM/SC

See text for more details.

colitis, nephrotoxicity, and platelet dysfunction, especially in sick foals.

The opioid agonist-antagonist butorphanol (0.05 mg/kg IV/IM) has been tested in newborn foals.[78] In animals up to 3 weeks of age, the elimination half-life was 2.1 hours after IV injection (about twice as long) and bioavailability was 66% ± 12% (twice as high as in adults).[79] In neonates, butorphanol has minimal effects on vital signs but makes the animals more sedate and even mildly ataxic compared to older foals and adults, in which higher doses commonly cause excitement. Morphine or L-methadone (L-Polamivet) at doses similar to those used in adults have been used,[37] but there are no reports on the pharmacokinetics or pharmacodynamics of these drugs in foals. Application of fentanyl patches (Duragesic) has been tested in neonatal foals, but not for analgesic efficacy.[80] After placement of one 100-µg/hr fentanyl patch on the skin above the jugular vein, fentanyl was detected as early as 20 minutes after patch placement, and plasma concentrations peaked after 14 ± 8 hours and returned to baseline concentrations 12 hours after patch removal.[80] All foals satisfactorily tolerated the patch application and showed no significant adverse effects.

Foals undergoing soft tissue surgery and especially those with abdominal pain respond well to lidocaine infusion (50 µg/kg/min following a loading dose of 1.3 mg/kg) and seem to tolerate such an infusion as well as adult animals.[81,82]

Perianesthetic Complications Requiring Intervention

Impaired Cardiovascular Function

Multiple causes may contribute to hemodynamic instability during the perianesthetic period, including an underlying disease process, hypovolemia and dehydration, anemia, endotoxemia, and impaired pulmonary gas exchange causing hypoxemia. Other potential causes include tissue hypoxia, cardiac arrhythmias, congenital heart defects, disturbances in metabolic and electrolyte homeostasis, and anesthetic drug–induced changes. The risk of cardiovascular decompensation is particularly high in the neonate and sick foal and requires careful preanesthetic assessment of the foal, correction of hypovolemia prior to induction of anesthesia, and vigilant monitoring of hemodynamic parameters during the perianesthetic period.

Table 20-6 lists average hemodynamic parameters recorded prior to any intervention aimed at improving hemodynamic or respiratory function in 482 foals undergoing inhalation anesthesia for various reasons. Retrospective analysis of these cases revealed that perianesthetic complications are not necessarily common in this patient population. In only 4% of the foals an arrhythmia was detected during the anesthesia period including, most commonly, second- or third-degree atrioventricular (AV) blocks, occasional ventricular extrasystoles, hyperkalemia-associated changes in ECG trace, and hypoglycemia-, hypothermia-, and/or hypoxia-associated bradycardia. If atropine (Atropine SA, 20 to 40 µg/kg IV) does not restore atrioventricular conduction, the indirect sympathomimetic drug ephedrine (Ephedrine Sulfate Injection, USP, 25 to 50 µg/kg IV) exhibiting both α- and β-adreneric activity may. Ventricular tachyarrythmias are treated if they are associated with significant impact on hemodynamic function with lidocaine as an initial bolus of 1 mg/kg IV followed by subsequent IV doses of 0.5 to 0.75 mg/kg as required or by constant rate infusion (20 to 50 µg/kg/min).

TABLE 20-6. Hemodynamic and Respiratory Parameters Recorded in 482 Anesthetized Foals (1 Day to 6 Months Old)

Parameter	Minimum	Maximum	Average
HR (beats/min)	55 ± 15	80 ± 25	66 ± 18
SAP (mm Hg)	85 ± 13	124 ± 17	103 ± 14
DAP (mm Hg)	44 ± 9	74 ± 16	58 ± 12
MAP (mm Hg)	59 ± 9	95 ± 16	76 ± 12
RR (breaths/min)	6 ± 4	12 ± 5	9 ± 4

DAP, Diastolic arterial pressure; *HR*, heart rate; *MAP*, mean arterial pressure; *RR*, respiratory rate; *SAP*, systolic arterial pressure.
Data recorded prior to drug treatments or mechanical ventilation.

The most frequent hemodynamic complication during anesthesia is systemic arterial hypotension as a result of anesthetic drug-induced decrease in systemic vascular resistance and/or bradycardia. Based on the individual foal's situation, volume replacement therapy as described earlier and/or infusion of dobutamine (Dobutrex, primarily used as a positive chronotropic agent in the neonate; 2 to 8 µg kg^{-1} min^{-1}), phenylephrine (Phenylephrine HCl Injection, USP) 0.1 to 1 µg kg^{-1} min^{-1}), or norepinephrine (Norepinephrine Bitartrate Injection, USP, 0.1 to 1.0 µg kg^{-1} min^{-1}) titrated to effect or IV ephedrine injections at increments of 0.05 to 0.1 mg/kg are used to increase and maintain mean arterial blood pressures above 60 to 70 mm Hg.[12,63,64,83,84]

Impaired Respiratory Function

Most neonatal but also pediatric and juvenile foals hypoventilate or even become apneic after administration of induction agents and inhalant anesthetics. In addition, reduced FRC as a result of pharmacodynamic effects of the anesthetics used, recumbency, development of absorption and compression atelectases, increased respiratory workload imposed by relatively narrow endotracheal tubes and the anesthetic circuit, and ventilation-perfusion mismatching and intrapulmonary shunting all may compromise pulmonary gas exchange in neonates. As a result, arterial CO_2 retention and hypoxemia, possibly even tissue hypoxia, may occur. Retrospective analysis of the anesthesia records of the population of 482 foals undergoing inhalant anesthesia (FiO_2 more than 0.8) revealed that hypoventilation is common with 20% of the foals developing marked arterial hypercarbia ($PaCO_2$ more than 65 mm Hg), but intraoperative hypoxemia (SaO_2 less than 90%) is rather rare with only 1% of foals affected. Adjustment of anesthetic drug administration and mechanical ventilation as described previously are required to improve respiratory function.

Hypothermia

The younger the foal, the higher the risk of developing hypothermia, which promotes bradycardia, slows awakening from anesthesia, and predisposes the animal to a higher risk of infections.[2,3,7,37] To prevent heat loss during anesthesia and surgery, the animal should be placed on a circulating warm water mattress and be covered with forced warm air blankets (e.g., Bair Hugger). Heating of the surgery room, administration of warmed maintenance fluids during anesthesia, avoidance of

cold disinfectant solution for aseptic preparation of the surgical site, and use of body-warm irrigation solutions may further help reduce heat loss.

Return to Fetal Circulation

A return to fetal circulation should be suspected in newborn foals that present without cyanosis but unexpectedly desaturate under anesthesia (SaO_2 less than 80%) and become cyanotic (decreasing to 20 to 40 mm Hg) despite being mechanically ventilated and inhaling 100% O_2.[17,44] This will be accompanied by persistent pulmonary arterial hypertension and massive right-to-left shunting of blood flow through the foramen ovale or ductus arteriosus. It occurs more commonly in compromised animals with respiratory disease, prematurity, or septicemia. Increasing the anesthetic depth in an attempt to reduce pulmonary vascular resistance may successfully reverse this life-threatening situation; however, treatment with sildenafil citrate (slowly, 0.5 to 2.5 mg/kg IV), a type 5 phosphodiesterase inhibitor that produces selective pulmonary arterial vasodilatation and thus ameliorates clinical signs of pulmonary hypertension, appears to be more efficacious and reliable.[44] In addition, an echocardiographic exam should be performed to exclude any primary cardiac cause of cyanosis.[17]

Cardiac Arrest and Cardiocerebral-Pulmonary Resuscitation

Causes of cardiac arrest and the technique for effective cardiocerebral-pulmonary resuscitation (CCPR) in the foal have been reviewed in detail.[85] Pulseless electrical activity (PEA) and asystole are the cardiac rhythms most commonly associated with cardiac arrest in foals.[85] Cardiopulmonary failure in foals usually occurs secondary to systemic disease or anesthetic overdose that initially cause respiratory arrest, followed by development of a nonperfusing bradycardia, PEA, and, finally, asystole. Causes of secondary cardiopulmonary arrest encountered in foals include severe hypovolemia, low cardiac output, severe metabolic acidosis, hyperkalemia (e.g., ruptured bladder), vasovagal reflex, severe hypoglycemia, severe hypothermia, septic shock/endotoxemia, and finally pulmonary arterial hypertension with return to fetal circulation and right-to-left shunting of blood causing systemic tissue hypoxia. Less commonly, cardiac tamponade, tension pneumothorax, or trauma is encountered. Without treating the underlying cause of the arrest, CCPR may temporarily revive the patient but not result in rescue.

The approach to any cardiac arrest situation is guided by the A(airway), B(reathing), C(irculation or cardiac massage), D(rugs) protocol of CCPR.[86] The anesthetized foal is usually already intubated and attached to an anesthetic circuit. Immediate discontinuation of any anesthetic drug administration and flushing of the anesthetic circuit with O_2 to eliminate residual anesthetic gas is essential, as is manual ventilation with the rebreathing bag at a rate of 6 to 10 breaths per minute. Should the animal not yet be intubated, immediate orotracheal intubation with a 7- to 14-mm ID tube followed by manual ventilation (6 to 10 per minute) using 100% O_2 are essential. Of equal priority is the initiation of chest compressions at a rate of 100 per minute as soon as a nonperfusing cardiac rhythm is diagnosed. Cardiac compression can be done most successfully by placing the foal on a firm surface in right lateral recumbency. The resuscitator should place the palm of one hand with the fist closed over the foal's heart, while the other hand is placed on top of the first to reinforce the compressing hand. The elbows should remain straight, and the motion for compression should originate from the waist (with the upper body weight powering the compression for increased endurance). Chest compression results in no more than 25% to 30% of normal cardiac output. Delaying cardiac contractions or ventilation significantly decreases the chances of successful resuscitation. If not established yet, jugular venous access should be obtained as soon as possible to allow reliable drug administration. In addition, ECG leads should be attached to the patient using ECG gel to facilitate conductivity. The use of alcohol could increase the risk of a fire hazard if electrical defibrillation is needed. Also a capnometer or capnography sampling line connected to the adaptor of the endotracheal tube is very useful because the progress of CCPR efforts can best be monitored by recording ECG and $ETCO_2$ changes. In the absence of cardiac contractility and therefore cardiac output to the lungs, no CO_2 is exhaled (alveoli are ventilated but not perfused) but with effective chest compressions cardiac output and lung perfusion resume and thus $ETCO_2$ starts to climb to values of 12 to 18 mm Hg. Capnography provides the resuscitator with the immediate feedback needed to adjust the chest compression technique until an optimal CCPR technique is achieved.

Among all drugs tested in CCPR, only two exhibit significant efficacy in cardiac arrest situations: epinephrine and vasopressin.[85,86] Epinephrine possesses strong vasoconstrictive properties (via activation of α-adrenoceptors) and has been shown to improve coronary perfusion pressure during cardiac arrest, thereby increasing myocardial blood flow during cardiac compressions. This helps resolve myocardial hypoxia and contractile failure. Therefore, epinephrine administration is indicated in any form of cardiac arrest regardless of cause or rhythm. It is appropriate to initially administer a dose of 0.01 to 0.02 mg/kg of epinephrine intravenously or intraosseously every 3 minutes. If jugular venous access is not available, epinephrine may be given by the endotracheal route at a dose of 0.05 to 0.1 mg/kg diluted in 1 to 2 mL of saline. Complications of epinephrine administration include most frequently ventricular fibrillation (V-fib), pulseless ventricular tachycardia (V-tach), and an increase in systemic vascular resistance, all increasing myocardial O_2 demand and cardiac workload. Electrical defibrillation is indicated as soon as V-fib and pulseless V-tach are diagnosed. A paddle should be placed on each side of the chest after shaving the area, and the initial charge should be 2 J/kg, with subsequent defibrillations using a charge of 4 J/kg, delivered 30 to 60 seconds later if no conversion of the rhythm occurs. In between shocks, at least 2 minutes of chest compressions and ventilation with 100% O_2 should continue to ensure coronary perfusion.

Like epinephrine, vasopressin is a potent peripheral vasoconstrictor with particularly high pressor activity in situations of cardiopulmonary failure and sepsis, and thus it may help the return to spontaneous circulation in cardiac arrest. The dose of vasopressin for cardiac arrest is a total of 0.6 IU/kg given as a single dose or divided. Because the effect may last 10 to 20 minutes, repeat doses are not recommended.[85] Postresuscitation hypertension or arrhythmias are much less likely after vasopressin administration.

Lidocaine may be an appropriate antiarrhythmic agent for treatment of V-fib, V-tach, or ventricular extrasystoles after epinephrine administration or electrical defibrillation.[85,86] The

initial dosage is 1 mg/kg IV and additional IV dosages of 0.5 to 0.75 mg/kg up to a maximum dosage of 3 mg/kg may be administered at intervals of 5 to 10 minutes if the arrythmia persists. Alternatively, a constant-rate infusion of 20 to 50 μg/kg/min may follow the initial loading dose.

During the period of cardiac arrest per se, large-volume fluid administration is contraindicated. Even with optimal chest compressions, the cardiac output is only 25% to 30% of normal. If fluids are given rapidly, the venous pressure rises, impeding coronary perfusion and return of a normal cardiac rhythm, despite effective chest compressions and doses of epinephrine.[85] Thus, a low fluid rate should be used until spontaneous cardiac rhythm returns. Thereafter, increased fluid rates may be indicated to maintain adequate systemic circulation.

Provided CCPR measures were successful, continued monitoring of cardiopulmonary and metabolic functions for at least 24 to 36 hours and adjustments in supportive therapy are critical to keep the foal stable and ensure long-term success.

ANESTHETIC CONSIDERATIONS FOR THE CRITICALLY ILL NEONATE AND MATURING FOAL

Foal with Uroperitoneum

The clinical presentation as well as medical and surgical management of uroperitoneum in newborn foals (up to 3 weeks of age) has been summarized.[87-89] Reports in the past suggested a sex predilection for males and emphasized the presence of characteristic electrolyte abnormalities including hyponatremia followed by hyperkalemia and then hypochloremia, in conjunction with azotemia and metabolic acidosis. However, more recent retrospective analyses challenge this traditional view.[88,89] A sex predilection was not observed, nor were the classic electrolyte abnormalities present in more than half of the affected foals. The clinical symptomatology appeared to be different when uroperitoneum was not the primary presenting complaint but rather developed as a secondary complaint during hospitilization. Foals having received fluids for other reasons were more likely to be septic despite having normal serum electrolyte concentrations. However, serum creatinine concentrations were always greatly elevated in foals with uroperitoneum. Of importance for the anesthetist is the fact that most foals develop respiratory distress with increased respiratory rate and respiratory effort as a result of significant abdominal distention, and lung auscultation often reveals wheezes and harsh lung sounds. Arterial O_2 saturation and tensions are frequently reduced. The heart rate is commonly and greatly increased with an irregular rhythm because of abdominal pain, hypovolemia, and hypoxemia, and a grade II systolic murmur commonly can be auscultated.

Urinary tract defects, located in the bladder wall or the urachus, require surgical repair as the treatment of choice, and thus emphasis must be placed on preanesthetic stabilization of the patient. This should include O_2 supplementation via nasal insufflation or mask delivery, restoration of circulating blood volume, correction of electrolyte and acid-base abnormalities (primarily hyperkalemia and metabolic acidosis) and slow drainage of the peritoneal fluid by abdominocentesis or by peritoneal dialysis to prevent the development of hypovolemic shock. Continuous recording of heart rate and rhythm via ECG and noninvasive measurement of blood pressures aids in monitoring the progress achieved with treatments. After initial blood volume restoration, with physiological saline or isotonic crystalloid solutions low in K^+ content (5 mEq/L or less), hypertonic saline may be infused to correct the Na^+ (and Cl^-) deficit. At Na^+ concentrations less than 110 mEq/L, seizures commonly occur.[68] The Na^+ deficit in mEq can be calculated as: normal serum Na^+ in mEq/L: measured serum Na^+ in mEq/L × 0.4 × body weight in kg. The Cl^- deficit is of similar magnitude. If hyponatremia prevails over several days, the brain slowly adapts by altering the osmolality of its cells through loss of intracellular potassium and organic solutes. Therefore, hyponatremia should be corrected slowly (i.e., 0.5 mEq/kg/hr or less) to avoid central pontine myelinosis.[69] Serum K^+ can be effectively decreased to clinically acceptable levels by giving regular insulin at a dose of 0.1 to 0.2 IU/kg slowly IV in 2.5% to 5% dextrose over 30 to 45 minutes prior to induction of anesthesia. The management of metabolic acidosis (pH less than 7.2) may necesiitate administration of sodium bicarbonate ($Na^+HCO_3^-$). The required dose of $Na^+HCO_3^-$ (in mEq) to be administered can be determined based on the base deficit (-BE): -BE in mEq/L × 0.4 × body weight in kg. One half of the calculated bicarbonate dose should be administered first over 20 to 30 minutes and then a blood gas analysis repeated to assess the effect before the second half of the dose is administered.

Sedation is rarely needed in sick foals with uroperitoneum, but premedication with a low dose of a benzodiazepine may be considered in less-compromised animals. Use of α_2-agonists (e.g., xylazine) should be avoided because of their respiratory depressant and proarrythmogenic properties. Induction of anesthesia with any of the modern inhalant agents (isoflurane, sevoflurane, or desflurane in O_2) is rapid and very smooth followed by the use of those agents to maintain anesthesia. Alternatively, a combination of ketamine (2 mg/kg) and diazepam or midazolam (0.2 mg/kg) may be used for induction of anesthesia, especially in the older foal, followed by inhalant anesthesia for maintenance.

The most common life-threatening arrhythmia observed in foals with uremia and hyperkalemia is a third-degree AV-block, which may be precipitated by surgical stimulation. Discontinuation of surgical stimulation and administration of atropine (20 to 40 μg/kg IV) and/or ephedrine (25 to 50 μg/kg IV) may resolve the arrhythmia. If these are not effective, epinephrine (10 to 20 μg/kg IV) and closed chest massage must be initiated.

Foals Affected by Acute Intestinal Disease

Strangulated inguinal hernia, persistent meconium impaction, intestinal intussusception, and intestinal volvulus belong to the most frequently encountered abdominal diseases requiring an emergency laparotomy in young foals.[90] Dehydration and circulating volume depletion as well as bowel distention are the main causes for severe pain and compromised respiratory and cardiovascular functions, which in the neonate rapidly culminates in respiratory and metabolic acidosis, hemoconcentration, lactatemia, and eventually central depression with cardiopulmonary failure. Preanesthetic fluid therapy, in an attempt to restore an adequate circulating volume, O_2 supplementation via face mask or nasotracheal tube as needed, and judicious use of analgesics (preferably an opioid or lidocaine infusion instead of α_2-agonists in neonates) are essential to stabilize the foal prior to anesthesia and surgery. A rapid-sequence induction with ketamine and a benzodiazepine may

be the preferred induction technique in the older or struggling foal followed by maintenance of anesthesia with either one of the inhalant anesthetics. Mechanical ventilation aids in overcoming the problems of reduced FRC as a result of recumbency, abdominal distention, and the effects of anesthetic drugs. Continued fluid administration plus ephedrine or a combination of dobutamine and phenylephrine infusion may be necessary to support the circulatory system. Respiratory system compliance and hemodynamic status usually improve dramatically as soon as the abdominal cavity is opened and gas-filled intenstines are decompressed or exteriorized.

Foal with Thoracic Trauma

Thoracic trauma is frequently encountered in neonatal foals as previous studies indicate.[91-94] Rib fractures may account for as many as 37% of life-threatening fractures in foals younger than 6 months of age with thoracic trauma as the primary cause of death in this age group.[91] The fractures occur most commonly at the costochondral junction or the area immediately above it and are best detected with ultrasonography.[93] Typically three or more ribs are affected with those on the left side of the chest (3rd to 8th) most often involved.[91-93] When performing CCPR, post-resuscitation examination of the rib cage is warranted to exclude the possibility of iatrogenic rib fractures.

External trauma may cause soft tissue injury including severe lung contusions or muscle damage, blood vessel laceration, and rib fractures, with systemic consequences including pain and shock. Depending on the nature of the trauma (blunt or perforating) and dislocation of fractured ribs, internal thoracic structures may be severely affected, resulting in severe complications such as pneumo- or hemothorax, pulmonary laceration, acute parenchymal lung injury with atelectasis formation (ALI), and pleuritis.[92,94,95] Clinical signs in foals commonly include tachycardia; tachypnea or respiratory distress (because of pain and impaired pulmonary gas exchange); subcutaneous emphysema, anemia, and hypovolemia if blood loss was significant; and mental depression.[92,94,96]

Preanesthetic emergency care of the foal with compromising thoracic trauma should include nasal insufflation of O_2 (5 to 10 L/min), IV fluid therapy with isotonic polyionic crystalloid solutions for circulatory volume replacement plus fresh-frozen plasma or fresh whole blood for supplementation of red blood cells, coagulation factors and platelets when indicated. Thoracocentesis may be needed to evacuate the chest in case of pneumo- or hemothorax. Appropriate antiinflammatory, analgesic (e.g., flunixin meglumine, methadone, butorphanol) and antimicrobial treatment should be instituted. Any surgical intervention to repair fractured ribs should be postponed until the foal has been stabilized. If sedation is required, premedication with a benzodiazepine derivative (e.g., midazolam 0.2 mg/kg IV) and potentially another dose of butorphanol (0.2 to 0.3 mg/kg IV) is suitable, followed by induction with IV ketamine (1 to 2 mg/kg) and orotracheal intubation. Any of the inhalant anesthetics is appropriate for maintenance of anesthesia. A constant-rate lidocaine infusion (30 to 50 µg/kg/min following a loading dose of 1.0- to 1.5 mg/kg IV) may help reduce the dose of the inhalant anesthetic and maintain adequate spontaneous ventilation. Positive pressure ventilation with or without positive end-expiratory pressure (PEEP) may become necessary if the foal remains markedly hypercapneic ($PaCO_2$ more than 60 mm Hg) and hypoxemic (PaO_2 less than 55 to 60 mm Hg; SpO_2 less than 85%). Under these circumstances a smaller than usual tidal volume (i.e., 4 to 6 mL/kg) and the lowest PEEP necessary to improve pulmonary gas exchange and arterial oxygenation should be employed in order to avoid ventilation-induced lung injury in an already compromised pulmonary parenchyma. Fluid therapy, nasal O_2 insufflation, and antiinflammatory and analgesic drug treatment should be extended into the postoperative period until the foal can maintain a stable cardiopulmonary status and does not express significant pain.

CHAPTER
21 Recovery from Anesthesia

Regula Bettschart-Wolfensberger

Recovery is one of the most critical phases of equine anesthesia. Recent results from a multicenter prospective study of equine anesthetic fatalities reported that 23% of all nonsurvivors sustained inoperable orthopedic lesions during recovery.[1] Because of the size and temperament of the horse, it is not possible to continue full monitoring, and mechanical ventilation during recovery and even fluid administration is discontinued in most cases. Significant problems, such as hypoxemia or hypotension, that may develop can be recognized only in severe cases. When the horse starts to awaken, intervention is dangerous for personnel and, depending on the size of the horse and its temperament, often simply impossible. This chapter describes all aspects of recovery from anesthesia in horses.

MANAGEMENT OF HORSES DURING RECOVERY

General Aspects

Although a recent study failed to demonstrate a beneficial effect of recovering horses in a darkened room,[2] anesthetists commonly agree that during recovery, external stimuli (e.g., noise, bright light, physical stimuli) should be minimized. The horse's head should be protected by a padded head cover. The recovery box should have a padded floor and walls. Ideally, the box would have an octagonal shape to prevent horses from being trapped in the corners. In some clinics, horses are placed on heavy foam pads for the recovery. Depending on the nature of the surgery, the premises, and the personal preferences of anesthetists and surgeons involved, assistance during recovery (ropes, slings, hoists) may be desirable.[3] Sling assistance is sometimes (6%) not well tolerated, and to prevent self-inflicted injury, the patients may have to be re-anesthetized.[3] Successful use of a sling requires trained personnel. Ideally a horse should be accustomed to the sling at least a day before anesthesia and surgery.[4] In an experimental study, desflurane (Suprane) inhalation anesthesia was prolonged with propofol (Propofol 1% MCT Fresenius) and xylazine (Xylazin Streuli ad us. vet.) to position horses into the Anderson sling suspension system for recovery.[5] The quality of recovery was characterized by a smooth and careful return to a standing position, but a very high number of horses showed apnea caused by propofol and had to be ventilated during recovery. Fracture patients are most successfully recovered in a hydro pool (see "Pool Recovery," later).

In the early stages of recovery, an anesthetist should stay with the horse. Thereafter, continuous observation of the horse will reveal potential problems at an early stage, allowing immediate intervention. Ideally, horses remain recumbent for at least 20 minutes and then roll into sternal recumbency for another 10 to 20 minutes. The attainment of sternal recumbency is associated with the restoration of more normal breathing patterns, and it reduces ventilation-perfusion mismatching in the lung, which should improve oxygenation.[6] Horses that rest in sternal recumbency prior to attempting to stand usually get up without complication. They recover best if they are allowed to exhale most of the volatile anesthetic agent before trying to stand and thus should not be stimulated to get up too soon. If a horse has not attempted to stand within 60 minutes after the end of anesthesia and is still in lateral recumbency, stimulation may be appropriate. If it is reluctant to get up, its status must be reevaluated and any problems treated. Orthopedic patients are frequently exhausted when they are anesthetized for fracture treatment because they had to sustain all their body weight for some time on three legs and had to endure a potentially long transport to a specialized clinic. As a result of this, they

frequently remain for a prolonged time in lateral recumbency following the procedure.

For any surgery longer than 1 hour, the use of a urinary catheter is recommended because it prevents overdistention of the bladder, which is uncomfortable for the horse. Without a urinary catheter, a horse often tries to get up before it is ready to do so. As soon as it is standing, despite being ataxic, it will try to urinate. This can represent a considerable risk because the floor can become slippery and the horse may lose its balance and injure itself.

Maintenance of Adequate Respiration During Recovery

Insufflation of oxygen (15 L/min per 500 kg), first via the endotracheal tube and after extubation via nasal tubes or directly into the nasal cavity, helps to reduce the development of hypoxemia.[7] If apnea is present, the use of a demand valve helps to ventilate the horse until spontaneous respiration resumes.[8] Short periods of apnea (3 to 5 minutes)—for example, during transport from the surgery suite to the recovery stall—are not harmful. One study demonstrated that mechanically ventilated, anesthetized horses maintain higher values of arterial oxygen partial pressures (PaO_2) postoperatively during a brief period of apnea than horses weaned from the ventilator prior to disconnection.[9]

Controversy exists as to the optimal point during recovery for removal of the endotracheal tube. Most anesthetists advocate the removal of the endotracheal tube when the horse is actively swallowing. The presence of an active swallowing reflex helps to ensure that fluid or gastric reflux is not aspirated and that the horse replaces its soft palate into the normal position. Others believe that the tube should be removed only when the horse is standing. Extubation while the horse is in lateral recumbency allows earlier identification of potential respiratory obstruction. The endotracheal tube is then easily reintroduced, and if necessary a tracheostomy can be performed, which would be very difficult in a standing horse with acute dyspnea.

Another reason to remove the endotracheal tube as soon as the horse is swallowing is that some horses object to this foreign body when they regain consciousness. This negatively influences recovery because the animal may try to get up too early. Therefore, I prefer to remove the endotracheal tube before the horse regains a standing position. An alternative approach is to remove the endotracheal tube when the swallowing reflex is regained and to place a small endotracheal tube via the nares for recovery. This technique avoids the inadvertent damage to the endotracheal tube from the teeth and still maintains a patent airway (see later). Preexisting hemiplegia,[10] trauma, or hyperextension of the neck[11]; prolonged duration of recumbency[12]; or surgeries in the upper airway region are all factors that might predispose the upper airway to obstruction. If these factors are present, the endotracheal tube should not be removed until the horse is standing.

Most recumbent horses develop nasal edema, and because horses are obligate nasal breathers, this swelling will impair breathing after removal of the endotracheal tube. In severe cases, significant airway obstruction may occur. Transient airway obstruction during recovery can also be caused by a variety of other problems, such as laryngospasm, laryngeal hemiplegia, dorsal displacement of the soft palate, kinking of the head in a corner of the recovery box, or obstructing foreign bodies in the upper airways.[11] Regardless of the cause, any airway obstruction may lead to pulmonary edema or pulmonary hemorrhage, resulting in cardiovascular collapse and death.[10-15]

Phenylephrine 0.15% (Phenylephrin HCl 1.5 mg/mL) can be instilled into the nares to decrease nasal congestion and help prevent obstruction after extubation.[16] An alternative is to insert nasal tubes approximately 20 cm (8 inches) long into one or both nasal cavities. It is necessary to have various diameters available to fit a wide range of horses. Fractious animals find this tube in their nares uncomfortable, and therefore the use of an anticongestant is preferred. To achieve the optimal effect, the drops are instilled 10 minutes before extubation. If, despite the use of nasal drops, labored breathing or snoring occurs after extubation, nasal tubes should be inserted and the head extended with the tongue pulled out. Should this not result in normal regular breathing, other causes of airway obstruction should be investigated. Orotracheal intubation or a temporary tracheostomy (see Chapter 47) may become inevitable in these cases.

Management of Cardiovascular Function

Administration of fluids, dobutamine (Dobutrex), or other vasopressive agents is usually discontinued before recovery. All inhalation anesthetics and total intravenous anesthesia regimens depress cardiovascular function in a dose-dependent manner.[17] At the end of anesthesia, modern anesthetics are relatively quickly exhaled or redistributed, and thus cardiovascular function improves rapidly during recovery, and it is usually not necessary to administer fluids during the recovery period. If horses suffer from severe blood loss or hypotension (possibly as a result of endotoxemia) during anesthesia, continuing fluid administration and inotropic support during recovery is advocated. Depending on the severity of the hypotension, the horses can continue to lose fluid from their circulating volume and thus have problems in maintaining adequate cardiovascular function despite waning of the depressive effect of anesthetic agents. Such horses, especially if they are large, have great difficulty in getting up.

FACTORS INFLUENCING RECOVERY

Severity of Surgery, Temperament of the Horse

Under clinical circumstances, the quality of recovery and ultimate outcome correlate inversely with duration of anesthesia and severity of surgery.[1,18] On the other hand, an experimental study on horses anesthetized with isoflurane (IsoFlo ad us. vet.) or halothane (Halothane USP) but without undergoing surgery, showed that the temperament of the individual was the major factor determining the quality of recovery.[19] Therefore, the temperament of the patient must be considered during recovery from surgery.

Inhalation Anesthetics

Different inhalation anesthetics possess different physical properties. Blood gas solubility is the major determinant of the speed of action of an anesthetic and thus duration of recovery. With halothane, the relatively high rate of metabolism (about 20%), in comparison to isoflurane (about 0.2%) or sevoflurane (Sevorane Sevoflurane) (2% to 3%), may have an influence on the quality of recovery in compromised patients. An early report

that investigated duration and quality of recovery after 2 hours of anesthesia showed that recovery after isoflurane anesthesia is quicker and of a better quality than after halothane anesthesia.[20] After 3 hours of anesthesia, no difference in duration or quality of recovery was detected between isoflurane and halothane.[19] In another report, the recoveries of horses with or without surgery with isoflurane or halothane were compared.[21] The authors found no difference in the quality of recovery but reported shorter recoveries following isoflurane. This is in contrast to clinical studies that showed that recoveries with halothane are of better quality.[22-24] Another experimental study comparing halothane, isoflurane, and sevoflurane revealed that recovery quality was better with sevoflurane and halothane, and duration was shorter with sevoflurane and isoflurane.[17] Comparison of recovery after just 90 minutes of isoflurane or sevoflurane anesthesia showed that horses recovered significantly quicker and better with sevoflurane than with isoflurane.[25] A clinical study that compared recovery in 100 horses following MRI with either isoflurane or sevoflurane anesthesia could not demonstrate a difference between the two.[26] Desflurane (the least soluble and therefore fastest-acting inhalant agent currently available) was reported to cause a very rapid recovery, but of unacceptable quality.[27] One study used six horses and each of them was anesthetized for 2 hours with each of the three anesthetics sevoflurane, isoflurane and desflurane.[28] The horses were sedated for the recovery with xylazine. No significant differences between the recovery times were found, but with each anesthetic time for horses (which received all three anesthetics), recovery quality became better.[28] These clinical studies were retrospective or not well standardized. The experimental studies included very low numbers and were not able to exclude the recovery "learning factor." This might explain the different results. Use either isoflurane or sevoflurane in combination with suitable drugs in a balanced manner to achieve best possible recoveries (as described in Chapter 18).

Sedation, Analgesia

Pain has a negative influence on recovery in horses. To prevent central and peripheral sensitization, analgesia should be addressed before and during the anesthetic period. To provide maximal analgesia for recovery, especially after long, major surgical procedures, some additional analgesia, preferably using a multimodal approach, should be provided (see Chapter 23). The balanced anesthesia regimen used intraoperatively will influence recovery also (see Chapter 18).

In a clinical study of 25 horses undergoing arthroscopy, the preoperative use of phenylbutazone (Butadion ad. us. vet.) did not alter recovery time but did slightly improve recovery score compared with patients not receiving this nonsteroidal anti-inflammatory drug (NSAID).[29] These results are somewhat in contrast to the previous statements, which advocated continuous administration of analgesics during anesthesia.

The use of opioids in horses is controversial because of the fear of excitement and the effect of the opioids on the gastrointestinal tract. Some authors have tried to show the benefit of using opioids for recovery but have failed to do so, probably because too many other factors also influence this period.[30,31] They were, however, able to show that opioids do not negatively influence and prolong recovery or result in an elevated $PaCO_2$ level compared to untreated horses. Every horse benefits from the administration of morphine (Morphin HCl sintetica 10 mg) (0.1 mg/kg IM) 10 minutes before disconnection from the inhalation anesthetic.

α_2-Adrenoceptor agonists, such as xylazine, slightly prolong the recovery period.[25,32] In clinical cases, this usually results in superior recoveries. The fact that α_2-adrenoceptor agonists act not only as sedatives but also as analgesics certainly adds positively to the calming effect. Most authors advocate the use of 0.1 to 0.2 mg/kg xylazine IV; others use low doses of detomidine (Equisedan ad us. vet.), romifidine (Sedivet ad us. vet.), or medetomidine (Dorbene).[33] Because α_2-adrenoceptor agonists negatively influence cardiovascular function, the use of low doses of the shorter-acting xylazine (especially in compromised patients) is probably safest, because its side effects are less severe and of shorter duration. The α_2-adrenoceptor agonists should be administered only when brisk palpebral reflexes or even nystagmus is present. This guarantees that levels of inhalation anesthetics are lower than during maintenance of anesthesia and that no overdose occurs. Slow administration of the sedative (the full dose over 1 minute or slower) reduces the risk of profound side effects and thus probably increases safety. Two recent experimental studies[34,35] intended to improve recovery quality by exchanging maintenance of inhalation anesthesia with TIVA at the end of anesthesia. A combination of xylazine and ketamine (Narketan 10 ad us. vet.) was used following 90 minutes of isoflurane anesthesia for 30 minutes[34] and a combination of xylazine and propofol was used following 4 hours of desflurane anesthesia.[35] The use of xylazine-ketamine resulted in longer recovery times, whereas with xylazine-propofol, the transition from lateral recumbency to standing was qualitatively better. Propofol caused respiratory depression that might be dangerous under clinical circumstances. The use of propofol in this manner is too dangerous for everyday clinical practice and offers no benefit. As recoveries following short xylazine-ketamine TIVA are usually very coordinated and of good quality, this regimen might offer some potential to improve recovery quality following inhalation anesthesia, but this remains to be tested in a larger number of horses.

RECOVERY SYSTEMS AND AIDS

Recovery Stall Design and Construction

Although there is no literature comparing the influence of different types of recovery stalls on fatality rates, most anesthetists agree on a number of important design features for recovery stalls. First, the recovery box should not be too large; this allows the horses to lean against the walls during their arousal or as soon as they are standing, because most horses show some degree of ataxia immediately after recovery. Ideally, the angles between walls are greater than 90 degrees (Figure 21-1) to prevent horses from getting trapped in a corner with their head in a kinked position. Padding of walls and floor is most important. Floors should provide secure footing with a surface that is not slippery, even when wet (by urine, blood, excessive sweating, obstetrical lubricant, etc.). On the other hand, the surface must be soft enough to prevent abrasion injuries if horses fall during recovery. Last, the padding should be easy to clean. Linatex is a commercially available surface providing these qualities. In one study, recoveries with the aid of a rapidly inflating and deflating air pillow was compared to recoveries in a padded recovery stall.[36] With the pillow, horses rested longer before they attempted to attain sternal recumbency and took fewer attempts to standing. Quality of their standing was better as well.

A recovery stall should also have metal rings (for attaching ropes), an oxygen supply, heating, air conditioning, lights that can be dimmed, a hoist, and easy access for recovery personnel in case of an emergency. Figure 21-2 shows a design for a recovery stall that allows intervention and help for the horse from outside the box, thereby minimizing the risk of injury to people. The ideal size of a recovery box depends on the horse's size. The best option is to have several of different sizes. The octagonal shape with a diameter of 4.4 m of the box in Figures 21-1 and 21-2 has proved optimal for horses ranging in size from 400 to 800 kg.

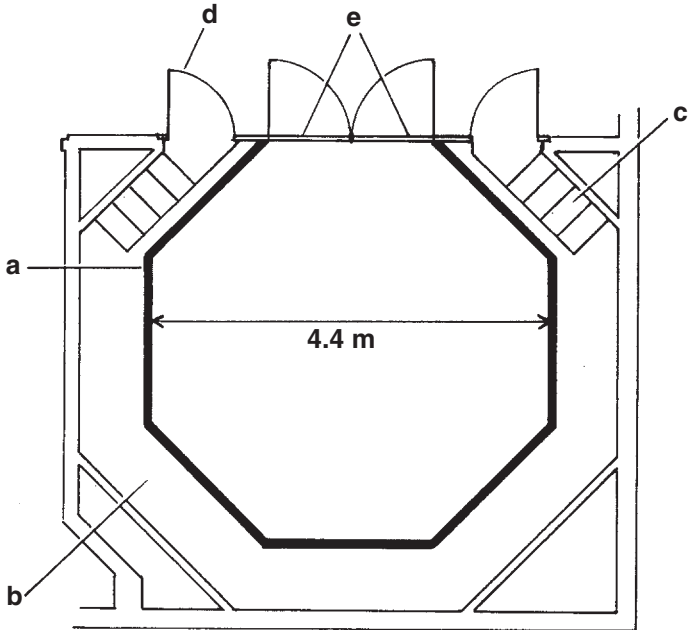

Figure 21-1. Bird's-eye view of a recovery box, including walkway around the box with access to the horse from above. *a,* Recovery stall wall; *b,* the walkway, the floor of which is elevated relative to the recovery box floor, provides the ideal, safe position to assist the horse's recovery; *c,* staircase to walkway; *d,* doors to walkway; *e,* doors to recovery box.

Thick Mattress

A thick mattress prevents the patient from making premature attempts to rise, because it takes a controlled and coordinated effort to "get out" of the mattress and attain sternal recumbency. Frequently, human assistance is necessary to roll the horse from the mattress onto the recovery box floor. Because the patient cannot leave the mattress too early, there is additional time for inhalant anesthetic to be exhaled, which eventually results in a smoother recovery. Soft mattresses may also prevent nerve damage in cases of prolonged recovery.

Rope-Assisted Recovery

As mentioned earlier it is possible to help horses during recovery with the aid of head and tail ropes. The aim should be to support the horse when it is getting up by itself, to stabilize it and not to pull it up. There are no studies comparing the outcome of recovery with or without rope assistance. It is likely that a trained team helps the horse with this support. It remains to be tested as to whether fatalities can be prevented. Care has to be taken not to disturb very heavy, difficult, or fractious horses while they are awakening. This could provoke attempts to stand up too early, resulting in a horse that is not yet able to stand but trying to do so because of the "help."

Pool Recovery

The major benefit of recovery in a hydro pool is that self-inflicted trauma is minimized because the partially submerged

horse struggles against the resistance of the water until it is fully capable of standing. For the personnel involved in recovery, there is minimal danger while the horse is inside the pool. The critical phase is the removal of the horse from the pool. There are two different systems. At the University of Pennsylvania's New Bolton Center, the horse is secured in a raft inside a round pool. The raft contains a sleeve for each leg and a flotation ring that has supports for the head. With this design, the horse has only minimal contact with the water. However, the stabilization of the horse inside such a pool can be difficult and requires several people well familiar with the procedure to remain with the horse during the entire recovery period. Removing the horses from this pool requires it to be lifted out of the raft by a sling attached to an overhead hoist (Figure 21-3). In this critical phase, if horse does not cooperate, injuries might occur. It may be necessary to implement short-term sedation or anesthesia until the horse is safely in a stall.

Another hydro pool system has been designed to facilitate the process of getting the horse out of the water.[37] The pool is a rectangle: 3.5 m long, 1.2 m wide, and 2.5 m deep. The water is heated to 38° C and continuously filtered to remove dirt. Additionally, bacterial contamination is minimized by passing the water through an ultraviolet filter. Because the horse is immersed in the water, it is impossible to totally prevent exposure of the surgical site to water, so application of a routine bandage for recovery is contraindicated. The wound is carefully closed with suture, followed by covering the incision site with cyanoacrylate (super glue) and some adhesives surrounding the incision site. Subsequently the limb region is covered with an Ioban bandage (Ioban 2). The Ioban sheet is further protected by an elastic adhesive tape.

The horse is placed inside the pool restrained by a sling or a rescue net designed for the helicopter rescue of horses (Figure 21-4). The scissor table installed within the pool is lowered all the way to the bottom of the tank. While the horse is unconscious, its head is supported by a floating mattress. The horse is maintained in a sternal position in the water. The head is secured in a vertical position by several ropes attached to metal bars on the sides of the pool (see Figure 21-4). When the horse starts to move, the table is elevated by a hydraulic system and the horse is allowed to "feel" the table underneath its feet. With time, the horse recognizes the presence of the table and with some positive encouragement eventually places its weight on all four feet. After the patient has stood securely on all four feet in the water for some time, the table is elevated, lifting the horse

Figure 21-4. A horse recovering from anesthesia in the pool at the University of Zurich. The head is fixed with four ropes on the side bars, the head rests on an air mattress, and the body is secured in the water with a custom recovery net. The eyes are covered and ear-plugs are in place.

Figure 21-5. A patient quietly standing on the scissor table with the feet still in the water. The recovery net is still in place.

up to the level of the room floor (Figure 21-5). The sling is subsequently disconnected, the bandage removed, the surgical site prepared aseptically, a bandage reapplied, and, when ready, the horse is walked into the recovery box, where it is allowed to dry under an infrared solarium.

This type of hydro pool was originally designed in California and has since been used regularly at Washington State University, Del Mar Race Track, and at the Vetsuisse Faculty University of Zurich, Switzerland. A report on the use of this type of recovery pool on 60 horses documented the following: mean anesthesia time, 182 minutes; mean time in the pool, 108 minutes (range, 20 to 270 minutes).[37] Furthermore, three horses showed severe lung edema (one of them died), two horses showed multiple skin abrasions from violent attempts to leave the pool during recovery, two horses showed incisional infections, and one horse developed septic arthritis following stifle joint surgery. These results demonstrate that hydro pool recovery is not risk free but that it is a relatively safe option when a difficult recovery is anticipated.

During hydro pool recovery, extrathoracic and pulmonary pressures are increased, which may contribute to an increased incidence of pulmonary edema during anesthetic recovery.[38] To minimize the likelihood of edema formation, all anesthetized horses in Zurich are treated with hetastarch (HAES-steril 10%) (4 L/500 kg IV, in addition to Ringer lactate) to maintain plasma oncotic pressure during hydro pool recovery. Furthermore, acepromazine (Prequillan) (0.03 mg/kg) is administered (IM) to produce peripheral vasodilatation and improve perfusion. The administration of acepromazine also provides some calming effect during recovery, without causing ataxia. Supplemental oxygen administration has decreased the incidence of edema at Washington State.[39] As with any surgery, it is very important to provide multimodal analgesia to optimize recovery quality before hydro pool recovery. For any orthopedic surgery, the following are advisable: the presurgical administration of phenylbutazone, α_2-agonists, and possibly opioids (e.g., morphine 0.1 to 0.2 mg/kg IM); the intraoperative use of a balanced anesthesia regimen (e.g., isoflurane in oxygen plus 3.5 µg/kg per hour medetomidine IV); plus additional analgesia for recovery (e.g., 2 µg/kg medetomidine IV plus 0.1 mg/kg morphine IM). The use of a α_2-agonist, such as medetomidine, for recovery is advantageous because it provides analgesia as well as sedation. Using this management protocol, lung edema has not occurred in 50 consecutive pool recoveries.[40]

Anderson Sling Recovery

The Anderson sling (Figure 21-6) is probably the best known sling device and has been tested by several authors.[4,5] It is relatively easy to apply and is tolerated well by most horses, especially when they are accustomed to it a day before surgery.[4] To optimize recovery in the Anderson sling, a recent paper looked at the use of propofol before recovery.[5] The quality of recovery was good and quiet. Whether this regimen improves safety under clinical circumstances remains to be tested because the incidence of apnea (as a consequence of the use of propofol) was high.

PROBLEMS ENCOUNTERED DURING RECOVERY

Reluctance or Inability to Stand

Most problems that become evident during recovery have developed during anesthesia. Hypotension (resulting in poor muscle perfusion), hypoxemia, and malpositioning on the surgery table are the major factors that result in the problems encountered during and immediately after recovery in horses.[41-48] Possible causes of prolonged recoveries include myopathy, neuropathy, and other problems.

Myopathies

Myopathies may affect single groups of muscles or they can occur in a generalized form. Myopathies occur most frequently in cases where hypotension (blood pressure less than 70 mm Hg) is present for more than 15 minutes or anesthesia time exceeds 3 hours.[49,50] Affected muscles are swollen to different degrees, are hard, and are very painful. Depending on the severity of the myopathy, horses may be unable to stand or place full weight on the repaired leg. Therapy of the acute phase is supportive and symptomatic and should aim at reducing pain, swelling,

and anxiety. NSAIDs, opioids, α_2-agonists, and, in severe cases, dimethyl sulfoxide (DMSO 20%), dantrolene sodium (Dantrolen IV "P & G"), and corticosteroids should be administered. A small dose of acepromazine (0.02 to 0.03 mg/kg IM) may help to calm the horse and to improve peripheral perfusion, but this should be administered only if no major cardiovascular disturbances are present. As long as the horse is recumbent, oxygen should be administered via nasal tube or directly into the nasal cavity. Ringer lactate solution or other balanced electrolyte solutions should be infused to help maintain cardiovascular function. In excited horses, the most important factor is to calm them, because repeated attempts to stand up exhaust the horse and increase the likelihood of a catastrophic injury. Human assistance with head and tail ropes helps the horse to lift its weight when getting up and provides some stability, because most affected horses show some degree of ataxia. Some horses resent the pull on the tail, and if this occurs this type of assistance should be abandoned.

When the horse is standing, the major life-threatening problem is myoglobinuria, resulting in kidney dysfunction. Appropriate fluid administration (to ensure maintenance of urine output) and monitoring of urine production are mandatory. Physiotherapy and infrared light may help the horse to relax its muscles and thus will reduce suffering.

Neuropathies

Neuropathies that impair recovery include femoral nerve paralysis, radial or brachial nerve paralysis, peroneal nerve paralysis, and hemorrhagic myelopathy. Neuropathies can also be accompanied by myopathies, and vice versa. Horses suffering from neuropathies of single nerves are not as high risk as horses suffering from severe myopathies, but the risk of fractures during recovery is relatively high in all horses with neurologic weakness. Horses are often unable to cope with paralyzed extremities: they get excited and injure themselves before intervention becomes possible. Therapy during recovery is symptomatic and supportive, as for myopathies.

Miscellaneous Problems

Other, less common causes of reluctance, difficulty, or inability to stand after general anesthesia are hyperkalemic periodic paralysis (HYPP), hypocalcemia, glycogen disease of draft horses, fractures or luxations, severe hypothermia or blood loss, generalized fatigue as a result of underlying disease, and pulmonary embolism.[51]

CHAPTER 22

Chemical Restraint for Standing Surgery

Simone K. Ringer

Chemical restraint is used daily in equine practice because many diagnostic procedures as well as surgical or medical treatments are impossible without a proper restraint. Horses are not as tolerant to mechanical immobilization as are, for example, ruminants, and they may react violently to excessive restraint, pain, or fear. However, many procedures can be performed safely on standing horses using combinations of sedative and analgesic drugs, supplemented by appropriate local or regional anesthesia and physical immobilization.

An advantage of standing sedation over general anesthesia is the decreased risk of mortality. Compared to human anesthesia, mortality rate in equine anesthesia is still very high.[1,2] Further advantages include decreased costs as well as reduction in personnel needed during the procedure. Disadvantages compared to general anesthesia are less ideal surgical conditions because of movement as a result of ataxia or insufficient analgesia, which may lead to an increased risk to personnel. Also, depending on the localization of the surgical field, asepsis may be more difficult to maintain than in a recumbent horse.

The decision of whether to perform a surgical procedure standing or under general anesthesia should be based on type of procedure, temperament of the horse, anesthetic and surgical facilities, personal experience, and pre-existing medical conditions of the patient.[3]

The goal of chemical restraint for standing surgery is to keep the horse calm, sedated, and indifferent to environmental or noxious stimulation and physical manipulation. The horse should remain standing, and only mild ataxia is acceptable. Sedation must be reliable, and ideally the horse should not be arousable by noise, touch, handling, or movement.

Different drugs and protocols will be discussed in this chapter. Whenever painful procedures are performed, standing sedation should be combined with local or regional anesthesia (see Chapter 23).

GENERAL PRINCIPLES OF DRUG ADMINISTRATION

All sedatives work best when given to a quiet horse and in a quiet environment. Drug effects may be suboptimal if the horse is excited before or during drug administration. Also adequate time should be allowed for drugs to exert their maximal effect before starting any manipulation of the horse. Generally, if an intramuscular (IM) route of drug administration is used, longer onset times and higher doses are needed compared to an intravenous (IV) administration. Also, IM sedation will have less-predictable results.

Sedatives are most commonly administered as a bolus and re-dosing is frequently needed for procedures longer than 30 minutes. Therefore, for prolonged procedures, constant-rate infusion (CRI) of sedatives may be advantageous over repeated bolus administration because it is less cumbersome for the veterinarian, may cause less adverse effects, and provides a more constant level of sedation.[4] If CRI is used, a loading dose should be considered; otherwise the desired effects will take a protracted time because 4 to 5 half-lives are needed until steady state plasma concentrations and sedation are reached.

The catheter placed for CRI also serves as a quick access route for intravenous fluid administration needed during prolonged sedation.

DRUG SELECTION

Many drugs have been used and are available. The sedation protocol should be chosen based on health status and temperament of the horse, type and duration of the planned procedure, drug availability, and personal experience.

To achieve optimal sedation, often two and frequently even three drugs are administered simultaneously. The administration of multiple drugs may allow the use of reduced dosages and may be safer and more effective than administering larger doses of a single drug.

DRUGS AVAILABLE FOR CHEMICAL RESTRAINT

α_2-Adrenoreceptor Agonists

α_2-Adrenoreceptor agonists are probably the most commonly used drugs for standing sedation of horses. The most frequently used α_2-adrenoreceptor agonists in equine practice are xylazine (Xylazin Streuli ad us. vet.), detomidine (Equisedan ad us. vet.) and romifidine (Sedivet ad us. vet.) (Table 22-1). Medetomidine (Dorbene) and dexmedetomidine (Dexdomitor), even if not registered for horses, have been used successfully in this species.[4-7]

Mechanism of Action Leading to Sedation and Analgesia

α_2-Adrenoreceptor agonists provide reliable and profound sedation with analgesia and muscle relaxation. The sedative effect of α_2-adrenoreceptor agonists is the result of activation of α_2-adrenoreceptors located on the locus coeruleus in the pons of the brainstem. The exact mechanism for antinociception is currently not completely understood; both supraspinal and spinal sites of action seem to be involved.[8] The increased sensitivity to touch reported clinically with α_2-adrenoreceptor agonists[9] may be induced by modification of the activity of fast conducting non-nociceptive afferent Aβ fibers and seems to be strongest and longest with detomidine compared to romifidine and xylazine.[10]

Uses

For very short procedures a bolus of xylazine or medetomidine can be used, whereas for sedations between 15 and 30 minutes, the longer-acting romifidine or detomidine should be selected. Procedures taking longer than 30 minutes benefit from CRI of α_2-adrenoreceptor agonists.

Even if horses appear deeply sedated with α_2-adrenoreceptor agonists, they may suddenly respond to stimulation, especially to touch.[9] To avoid this, α_2-adrenoreceptor agonists are often combined with other drugs, mainly opioids, to improve quality of sedation (Table 22-2).

Administration, Doses, Routes

α_2-Adrenoreceptor agonists can be administered intravenously (IV) or intramuscularly (IM). Peak effects are reached within the first 3 to 10 minutes with the IV route. For IM administration, approximately twice the dose should be used to achieve the same effect. Time to peak effect may be as long as 30 to 60 minutes.[11] Unlike romifidine,[12] detomidine produces clinical sedation following sublingual administration.[13-15] However, the oral route is less predictable and may require up to 45 minutes for maximum drug effect.[13]

The IV route is the most predictable and should be the route of choice whenever possible. Compared to the IV route, after IM administration, the initial hypertensive response associated with α_2-adrenoreceptor agonists is less dramatic.[9] Therefore, if hypertension is undesirable (i.e., risk of bleeding associated

TABLE 22-1. Recommended Dosages for the Use of α_2-Adrenoreceptor Agonists in Horses

Drug	Dose (mg/kg) and Route (IV)	Comments	Reference
Xylazine	0. 55, 1.1	Stimulation by needle prick	21
Xylazine	2.2	After a period of maximal exercise Administration to effect recommended	33
Detomidine	0.005-0.02	Clinical study: – Radiology: <0.01 – Routine sedation: 0.01 – Difficult horses, prolonged sedation: 0.02	98
Detomidine	0.01-0.02	Normally effective if administered to calm and resting horses	Personal experience
Detomidine	0.01-0.04	Stimulation	99
Detomidine	0.02	Routine dental treatment 3/10 fell down	28
Detomidine	0.04	After a period of maximal exercise To effect recommended	33
Detomidine	0.01	Diagnostic anesthesia lameness examination Can be antagonized by 0.1 mg/kg atipamezole IV	63
Romifidine		Tooth rasping:	28
	0.08	1/10 fell down	
	0.12	1/10 fell down	
Romifidine	0.04-0.08	Stimulation	99

Note: The horse's disposition and physical status will affect dose requirements. If α_2-adrenoreceptor agonists are used alone, even if horses appear deeply sedated they may react violently to stimulation; therefore, α_2-adrenoreceptor agonists are frequently combined with opioids or acepromazine. For painful procedures, local or regional analgesia and systemic analgesics should be added.

with guttural pouch mycosis) the IM route may be preferable. Also in fractious horses, where intravenous injection may be difficult, the IM or oral route may offer an advantage.

Other Effects and Side Effects

Administration of α_2-adrenoreceptor agonists is associated with dose dependent potent cardiovascular side effects including significant changes in blood pressure (BP) and vascular resistance, decreases in cardiac output (CO), and rapid and significant decrease in heart rate (HR) with development of first- and second-degree atrioventricular (AV) block (Figure 22-1) and occasionally other arrhythmias. Changes in BP are characterized by an initial hypertension followed by hypotension.[4,7,9,16-20] The use of atropine (Atropinsulfat 0.1%) to treat AV blocks is normally not necessary. As a matter of fact, its use is controversial because of dose-dependent tachycardia, hypertension, and side effects on the gastrointestinal tract.[21,22]

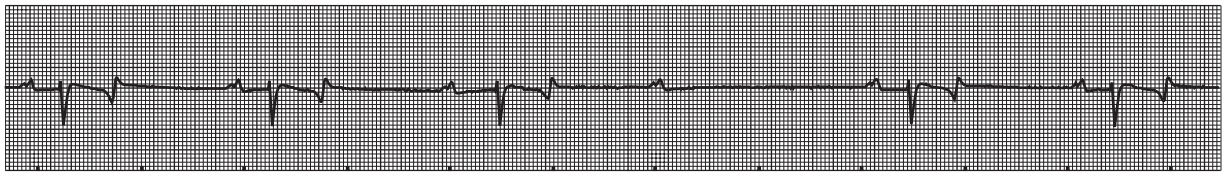

Figure 22-1. Base-apex electrocardiogram (paper speed 25 mm/sec) showing a second-degree atrioventricular block (Wenckebach, Mobitz type I) in a horse. This is a typical arrhythmia observed in horses sedated with α_2-adrenoreceptor agonists. (Courtesy Dr. C. C. Schwarzwald, University of Zurich.)

Respiration is depressed, but the effect is usually not apparent unless other drugs are co-administered or anesthesia is induced. Some horses may demonstrate signs of increased inspiratory effort or initiation of snoring, probably as a result of facial and nasal edema caused by a lowered head position and relaxation of the muscles in the larynx and nares.[12,23,24] The influence of α_2-adrenoreceptor agonists on laryngeal function need to be considered during diagnosis and evaluation of laryngeal hemiplegia.[25]

Other side effects of α_2-adrenoreceptor agonists are reduced gastrointestinal function, hyperglycemia with decreased serum insulin levels, and increased urine output.[9] The penis is relaxed and extended in males and the uterine tone increased in females.[9] The use of α_2-adrenoreceptor agonists has not been associated with an increased risk of abortion in horses.[26,27] Normally horses do not become recumbent, but ataxia may be severe and some cases of tumbling down have been described after α_2-adrenoreceptor agonist administration[28] and after a combination of high doses of α_2-adrenoreceptor agonists with opioids.[29-32]

Intracarotid injection of α_2-adrenoreceptor agonists results in excitement, disorientation, ataxia, violent collapse, recumbency accompanied by paddling, and possibly seizures. Normally horses recover spontaneously within a few minutes. If seizure activity does not stop within a few minutes, symptomatic therapy should be initiated. Benzodiazepines, guaifenesin (Myolaxin 15% ad us. vet.), and thiopental (Pentothal) have been used to control persistent seizures. Oxygen administration may be beneficial.

Special Considerations and Contraindications

Failure to achieve sedation with α_2-adrenoreceptor agonists is often caused by preexisting stress, fear, excitement and pain. These conditions increase endogenous catecholamine levels, which can interfere with the mechanism of action of the α_2-adrenoreceptor agonists. α_2-Adrenoreceptor agonists should be administered to calm horses in quiet surroundings with minimal environmental stimuli. The horse should not be stimulated (clipping, cleaning or injection of local anesthesia) until sedation is appropriate. Repeating or administering large doses may not increase the degree of sedation.[9]

Dosages of α_2-adrenoreceptor agonists that are effective in horses at rest are frequently ineffective when administered to horses after maximal exercise. Twice the standard dosages have been used effectively and safely in healthy Thoroughbred horses after maximal exercise (see Tables 22-1 and 22-2).[33,34] However, lower doses of sedatives may be effective in some horses, and when possible, sedatives should be administered in smaller doses to effect, possibly starting with the standard dose.[33] Draft horses are very susceptible to α_2-adrenoreceptor agonists, and lower dosages must be considered. In patients with impaired cardiovascular function, cardiac disease or arrhythmias caused by other pathologies (e.g., hyperkalemia), α_2-adrenoreceptor agonists should be used with caution.

Potentiated sulfonamides should never be administered IV following α_2-adrenoreceptor agonists,[35] as fatal arrhythmias might occur.

Foals

α_2-Adrenoreceptor agonists are not recommended in very young foals (less than 14 days). In very sick foals younger than 3 months, α_2-adrenoreceptor agonists should be avoided. In these animals benzodiazepines or benzodiazepines combined with opioids provide safe and effective sedation. In foals older than 30 days without systemic disease, presented for wound revision or casting, α_2-adrenoreceptor agonists can be used safely if doses are given to effect (Table 22-3).

Combinations with Other Drugs

Horses sedated with α_2-adrenoreceptor agonists may appear profoundly sedated but react violently to stimulation, especially to touch with rapid and well-directed kicks. Afterwards, if

TABLE 22-3. Recommended Sedation Protocols for Foals

Drug	Dosage (mg/kg)	Comments
AGE YOUNGER THAN 2 MONTHS OR 2-3 MONTHS AND BAD GENERAL CONDITION		
Climazolam	0.1-0.2-0.4 IV	No analgesia
Midazolam	0.05-0.1-0.2 IV	No analgesia

ANTAGONIST BENZODIAZEPINES (CLIMAZOLAM, MIDAZOLAM, DIAZEPAM)		
Sarmazenil	0.04 IV	
Flumazenil	0.04 IV	

Note: For painful procedures, benzodiazepines should be combined with an opioid, for example, butorphanol 0.02 mg/kg IV, and local or regional anesthesia should be added whenever possible. If young foals are sedated for prolonged periods, hypoglycemia and hypothermia may be important concerns requiring antagonization with the help of benzodiazepines.

otherwise undisturbed, they become well sedated again.[9] The combination of opioid drugs with the α_2-adrenoreceptor agonists appears to reduce this response and a synergistic effect regarding sedation and antinociception has been reported.[30,31,36-41] Therefore α_2-adrenoreceptor agonists are often combined with opioids (see Table 22-2).[30,31,36-46] The addition of opioids does not further impair cardiovascular function.[36,40,43] Changes in blood gases have been observed after the addition of opioids to α_2-adrenoreceptor agonists probably because of increased respiratory depression, but not to a clinically relevant extent.[36,47] If high doses of opioids are used, side effects such as excitement (muscle twitching, muzzle tremors, head pressing, increased locomotor activity and circling) can be observed. [30,31,36,38,48] Also ataxia may be increased after the addition of higher doses of opioids to α_2-adrenoreceptor agonists.[29-32]

Acepromazine (Prequillan) has also been combined with α_2-adrenoreceptor agonists or added to a α_2-adrenoreceptor agonist/opioid combination to improve sedation (see Table 22-2).[49,50] Unfortunately, only few studies are available regarding the effect of acepromazine on horses already sedated with α_2-adrenoreceptor agonists, and no clinical study evaluating the addition of acepromazine exists. Very high doses of a combination of xylazine with acepromazine have been used in horses after exercise.[33]

The addition of acepromazine to an α_2-adrenoreceptor agonist prevents the initial increase in arterial blood pressure seen when α_2-adrenoreceptor agonists are used alone.[49,51] Also, an improved cardiac output and a decreased drop in HR have been reported.[51,52] Vasoconstriction induced by α_2-adrenoreceptor agonists is overcome by acepromazine's vasodilative properties, but the exact mechanism by which acepromazine maintains circulatory variables closer to baseline values during sedation with an α_2-adrenoreceptor agonist remains unclear.[51] Arterial oxygenation is better if acepromazine is added.[51]

Uses as a Constant-Rate Infusion

The use of an α_2-adrenoreceptor agonist as a CRI is becoming more and more popular because of more constant sedation and fewer side effects compared to repeated bolus administration.[4] Detomidine, medetomidine, xylazine, and romifidine CRI have been described for standing sedation of horses (Table 22-4).[4,32,53-56]

Opioids, acepromazine, and ketamine (Narketan 10 ad us. vet.) have also been used in combination with CRIs of α_2-adrenoreceptor agonists (see Table 22-4).[6,55-57] Although described in the literature, ketamine should never be given as a bolus or loading dose to awake standing horses, and only low CRI dosing regimens should be used.

Whenever CRI is used, the level of sedation should be assessed frequently and drug delivery adjusted to effect by decreasing or discontinuing the infusion temporarily if weakness or instability occurs or by giving small additional boluses of the α_2-adrenoreceptor agonist or opioid if sedation or analgesia is insufficient. If upper airway obstruction is severe, the head should be elevated. To treat mucosal edema, nasal drops containing phenylephrine (5 mL of 0.15% phenylephrine [Phenylephrin HCl 1.5 mg/mL] into each nostril of a 500-kg horse) can be used or long nasal tubes inserted into the nostrils to maintain patent airways (Figure 22-2).

Antagonists

α_2-Adrenoreceptor agonist can be antagonized by α_2-adrenoreceptor antagonists. The antagonists used in equine practice are yohimbine (Yohimbine hydrochloride), tolazoline (Tolazolin HCl 120 mg/mL) and atipamezole (Antisedan) (Table 22-5). Atipamezole is the most selective α_2-adrenoreceptor antagonist. Severe side effects can occur and antagonists should

Yohimbine	0.12 mg/kg	After xylazine CRI; 2/4 horses had agitation, muscular tremors, and mild excitement	59

Note: Selection of drug and dosage should depend on type and dose of α_2-adrenoreceptor agonist used and time elapsed since administration. The dosage should also be adapted to the degree of sedation. The drugs used should be administered very slowly IV and to effect.
CRI, Constant-rate infusion.

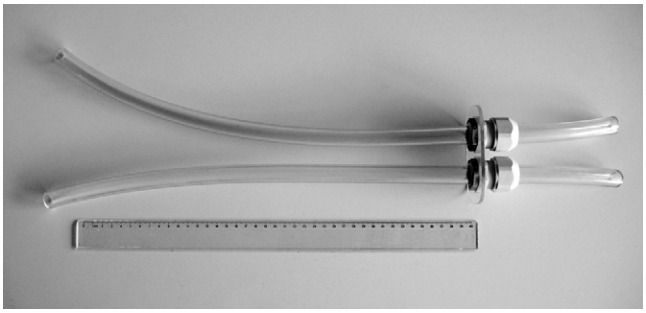

Figure 22-2. Nasal tubes that can be used to facilitate breathing in case of upper airway obstruction caused by nasal mucosal swelling (e.g., during prolonged sedation with low head position). The longer portion is inserted into the ventral meatus.

only be used as a rescue (if possible, slowly to effect), if an exaggerated or unexpected pharmacological or behavioral response occurs, or in case of a severe overdose of α_2-adrenoreceptor agonist.[58] By administering α_2-adrenoreceptor antagonists, the analgesic effect of α_2-adrenoreceptor agonists will be abolished, and cardiovascular and behavioral side effects can occur. Agitation, stress response and overreaction have been noted after all three α_2-adrenoreceptor antagonists listed earlier.[59-62] Dosages of antagonists should be reduced if more selective α_2/α_1 agents are used (medetomidine), if low dosages of α_2-adrenoreceptor agonists where used, and if the agonists were administered more than 45 minutes previous to reversal.

After small dosages of detomidine (10 µg/kg IV) to facilitate anesthetic blocks for lameness diagnosis, sedation can be antagonized with atipamezole 0.1 mg/kg IV to allow continued evaluation.[63]

Phenothiazines

Mechanism of Action

The phenothiazines exert their tranquilizing effect primarily by blocking dopamine receptors in the basal ganglia and limbic system. They produce a calming effect, indifference, and decreased locomotor activity.[64] Phenothiazines do not produce analgesia, and sedation is less than after α_2-adrenoreceptor agonists, rarely achieving reliable restraint in horses.[65]

Uses

The most commonly used phenothiazines in horses are promazine and acepromazine. Acepromazine is a potent phenothiazine derivate and is extensively used in equine practice. Chlorpromazine, propiopromazine (Tranvet Injectable Solution), propionylpromazine (Combelen) and promethazine are no longer used because of their unpredictability and side effects.[64]

Because phenothiazines have no potent tranquilizing effect they should be combined with opioids, α_2-adrenoreceptor agonists (see earlier), or both for more reliable sedation, or they should be used as a sole agent for nonpainful procedures like shoeing, assisted training in young horses, or tranquilization for transport. The phenothiazine acepromazine is a frequently used premedicant before general anesthesia because it reduces MAC,[66] has an antiarrhythmic and antifibrillatory effect,[67] and decreases the anesthetic risk in horses.[1,68]

Acepromazine increases digital blood flow,[69,70] and because of this it has been incorporated into the treatment and/or prevention of laminitis.[71] It has also been used in horses to induce extrusion of the penis from the sheath for examination.[72]

Acepromazine can reduce or inhibit opioid-induced excitement and manic behavior.[73] A positive effect in treatment and prevention of malignant hyperthermia has also been reported.[64]

Administration, Dosages, Routes

Acepromazine can be administered orally, IM, or IV. The degree of tranquilization is related to the dosage and route of administration, with IM injections having a lower maximal effect but longer duration of action than a similar IV dose.[74]

Recommended dosages are 0.02 to 0.05 mg/kg IV or IM. Some cases of excitement and extrapyramidal signs have been reported after higher doses.[64,75] Oral bioavailability is high, and it may be as high as for the IM route. The maximal recommended oral dosage is 0.1 mg/kg.[76,77]

Peak effects are reached after 10 to 30 minutes, 20 to 40 minutes, and 1 hour after IV, IM, and oral administration, respectively. Therefore, acepromazine needs to be administered several minutes before faster-acting drugs such as α_2-adrenoreceptor agonists or opioids if a simultaneous effect is

desired. The effects of acepromazine may last as long as 6 to 10 hours depending on the horse, or even longer with very high doses.[74]

Side effects seem to be less severe after oral or IM administration compared to the IV route, although this may be dose-dependent.[74,76]

Other Effects and Side Effects

Phenothiazine tranquilizers produce hemodynamic effects predominantly related to their α_1-adrenergic blocking activity and resultant arterial hypotension.[49,65,74,78,79] The route and dosage of acepromazine have some influence on the degree and duration of hypotension.[74] After administration via the IM route, hypotension is of slower onset but longer duration compared to the IV route.[74] Hypotension is less of a problem in fit and healthy animals, but horses that are stressed or anxious may be more susceptible to the hypotensive effect, probably because of increased circulating concentrations of epinephrine. Acepromazine blocks α_1-adrenoreceptors receptors, and this combined with β_2-adrenoreceptor vasodilating effects caused by epinephrine may result in "epinephrine reversal," resulting in further decrease in blood pressure.[64] If necessary, hypotension can be successfully treated with fluids. If fluids are not sufficient, the α_1-adrenoreceptor agonist phenylephrine (Phenylephrin HCl 1 mg/mL) should be used to counteract the vasodilation; epinephrine (Adrenalin, Sintetica) should never be used (see earlier "epinephrine reversal"). The effect of acepromazine on HR is controversial; some authors report a decrease,[79] others no change[49] or even an increase in HR.[65,74] The overall effect on the HR does not seem to be clinically important, and the increase observed in some horses may be compensation for hypotension.[74]

Acepromazine produces little respiratory depression and the effect is primarily on respiratory rate with no effect on pH or blood gas tensions.[49,65,74,79,80]

Acepromazine has an important effect on packed cell volume (PCV).[72,79,81] After clinically relevant doses, the PCV decreases by around 20% from presedation values or even more. The decrease is attributed to α-adrenergic receptor blockade leading to splenic capsular relaxation with subsequent red blood cell sequestration, and dilution by interstitial water entering the vascular compartment as a result of hypotension.[64] The decrease in PCV is independent of the route of administration. At dosages less than 0.01 mg/kg, the magnitude of PCV decrease is dosage dependent, whereas at dosages more than 0.01 mg/kg there is only an effect on duration of the decrease.[72,81]

Dosage dependent penile protrusion and penile prolapse have been observed in horses treated with dosages of 0.01 mg/kg and higher.[72] Priapism and paralysis of the retractor penis muscle have been attributed to the use of phenothiazine tranquilizers.[82-84] However, cases also have been described in horses anesthetized without the use of phenothiazines.[85] Whether this complication is dosage dependent is unknown. Also, administration of a phenothiazine derivative without subsequent priapism in an individual horse does not eliminate the possibility of priapism in the same horse after repeated administration of the same drug in the future.[86] Priapism and paralysis seems to be more frequent in stallions than in geldings,[83] although cases of priapism in geldings have been described.[82,84,85,87]

If priapism is observed, blood should immediately be forced out of the penis by manual compression, with the goal to reposition the penis back into the prepuce where it can be retained with a purse-string suture around the prepuceal orifice.[82] Benztropine mesylate (Cogentin) (0.01 to 0.02 mg/kg slowly IV) may be effective in resolving priapism.[84,85] Surgical treatment by creating a shunt between the corpus cavernosum penis and the corpus spongiosum penis has also been described.[86,88] Until the penis is completely retracted, frequent cooling and massage may be beneficial. Overall, treatment should be oriented toward protecting the penis and preventing or reducing swelling. Additional information on this subject can be found in Chapter 60.

Other effects of acepromazine including loss of thermoregulatory control and decreased gastrointestinal motility have been described. The loss of thermoregulatory control should be considered in small horses (ponies, foals), particularly when ambient temperatures are very high or very low.

Because phenothiazines may reduce the seizure threshold, they should be avoided in epileptic patients.[89] However, this contention has been challenged and is discussed controversially in the literature.[90]

The same effects as with α_2-adrenoreceptor agonists are observed after accidental intracarotid injection of phenothiazines (see "α_2-Adrenoreceptor Agonists," earlier).

Special Considerations and Contraindications

The use of phenothiazines is restricted to "healthy" animals, because reduction in blood pressure could impair tissue perfusion, particularly in systemically compromised horses.

Phenothiazines are contraindicated in patients with hypovolemia, horses with low PCV, patients at risk of bleeding because of type of surgery or of bleeding disorders, and in young or debilitated foals. The risks and benefits of their use should be weighed very carefully in breeding stallions and animals with a history of seizures. Acepromazine should be used cautiously in stressed horses.

It is important to remember before sedating a horse with acepromazine that the negative effects on blood pressure and PCV can persist for more than 10 hours[74,81] and there is no antagonist available.

Foals

Foals may not be able to compensate for the hypotension induced by phenothiazines. Also hypothermia may be a problem. Acepromazine is acceptable in older, healthy foals if long-term sedation is necessary. However, it is not recommended in very young or compromised foals.

Combinations with Other Drugs

Acepromazine can be combined with opioids and α_2-adrenoreceptor agonists or both to produce more predictable and prolonged sedation (see Table 22-2).[25,44,49,50,52] Cardiovascular function is good after adding acepromazine to α_2-adrenoreceptor agonists and it even seems to prevent some cardiovascular side effects induced by α_2-adrenoreceptor agonists.[49,52]

A combination of a high dosage of α_2-adrenoreceptor agonists with 0.04 mg/kg acepromazine has been used successfully in horses after exercise (see Table 22-2).[33]

Antagonists

No specific antagonist exists.

Butyrophenones

Butyrophenones are not recommended in horses because of their lack of predictability and severe side effects, especially on behavior. Droperidol (Inapsine), lenperone (Elanone-V), and azaperone (Stresnil ad us. vet.) have been studied in horses.[64]

Benzodiazepines

The benzodiazepines diazepam (Valium 10 mg), midazolam (Dormicum), climazolam (Climasol ad us. vet.), and zolazepam (in combination with tiletamine) (Zoletil ad us. vet.) have been used in horses.

Mechanism of Action

Benzodiazepines produce their pharmacologic effects by facilitating the actions of γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter in the central nervous system.[91] These drugs produce minimal calming effects with excellent muscle relaxation and minimal to no cardiovascular or respiratory depression in awake horses.[92] Benzodiazepines also have an anxiolytic, hypnotic, and anticonvulsive action but no analgesic effects.[64]

Uses

Benzodiazepines should not be used for standing sedation in adult horses because of unreliable sedation and severe ataxia.[92] On the other hand, for neonatal foals, they are reliable and good sedatives (see Table 22-3).

Benzodiazepines are also used as adjuncts to general anesthesia and as anticonvulsants in equine practice (see Chapters 18 and 19).[93]

Very low dosages of diazepam (up to 0.01 mg/kg IV) have been used to produce short-term tongue or jaw relaxation for dental treatments[94] and to increase libido in stallions.[95] Benzodiazepines can produce severe ataxia at higher dosages.

Administration and Routes

Diazepam, midazolam, and climazolam can be administered by the IV route. If only IM administration is possible, midazolam should be used.

Other Effects and Side Effects

After benzodiazepine administration, healthy adult horses may become anxious, apprehensive, and agitated. Also severe ataxia and recumbency have been observed after benzodiazepine administration in adult horses.[92] Benzodiazepines can stimulate food intake in horses.[96]

Foals

Foals become recumbent and reliably sedated with benzodiazepines. Benzodiazepines provide no analgesia, and therefore these drugs should be combined with opioids and/or local/regional anesthesia whenever surgical intervention is planned. If young foals are sedated over prolonged periods, hypoglycemia and hypothermia may be a concern. Because of this, antagonism of benzodiazepines is often recommended at the end of a procedure. Antagonists should also be used if dangerous respiratory depression develops.

Antagonists

Flumazenil (Anexate) (0.01 to 0.04 mg/kg slowly IV) and sarmazenil (Sarmasol) (0.04 mg/kg slowly IV) produce rapid reversal.

Opioids

Opioids are never used as sole sedatives in healthy pain-free horses because dosage-dependent excitement or dysphoria can occur. During standing restraint for surgical procedures opioids are used in combination with sedatives to improve sedation and analgesia (see Table 22-2). Opioids are discussed in detail in Chapter 23.

Mechanism of Action

Opioids act via different opioid receptors (see Chapter 23).

Uses

The combination of opioids with other sedatives such as acepromazine and α_2-adrenoreceptor agonists provides very good quality standing restraint in horses (see Table 22-2). In foals, opioids are frequently administered in combination with benzodiazepines for sedation.

Opioids can also be used for balanced general anesthesia protocols (see Chapter 18) and as systemic or local/regional analgesics (see Chapter 23).

Other Effects and Side Effects

When used alone, opioids can produce restlessness, agitation, shivering and increased sympathetic activation, motor activity, and ataxia in horses.[97] These excitatory effects are less common when α_2-adrenoreceptor agonists or acepromazine are coadministered. The characteristic dosage-dependent increase in "spontaneous" locomotor activity has been blocked or dampened by the administration of naloxone (Narcan) or acepromazine.[73]

Opioids can produce important side effects on the gastrointestinal tract of horses, dosage-dependent effects on cardiopulmonary system, and histamine release.[64] For more details see Chapter 23.

ADJUVANTS

Different adjuvants such as lidocaine (Lidocain HCl 5%) or ketamine CRI can be used in combination with sedatives to improve quality of restraint and analgesia, although no clinical studies exist.

LONG-TERM TRANQUILIZATION

Sometimes injured horses or horses recuperating from major surgery need to be rested in a box stall for long time periods, which may be very difficult, depending on the character of the

individual horse. Long-acting sedatives have been used to tranquilize nervous or fractious horses for several weeks. Drugs like reserpine, fluphenazine, and chlorpromazine have been considered for this purpose, although they may be accompanied by several important side effects and these drugs are not sufficiently studied in the equine species.[93]

CONCLUSION

There is no perfect drug for a specific situation or a specific horse and therefore normally a multimodal approach is beneficial. Sedatives should be combined with local/regional anesthesia and analgesics (e.g., opioids and nonsteroidal anti-inflammatory drugs) whenever painful interventions are planned.

CHAPTER 23

Equine Pain Management

Emma J. Love

PHYSIOLOGIC CONSEQUENCES OF PAIN

The assessment and alleviation of pain in animals is an important part of the veterinary surgeon's role for medical, ethical, and welfare reasons. Pain is a complex, dynamic, physiological, and emotional phenomenon that can be extremely challenging to manage and causes suffering and distress to the animal. It can produce many undesirable effects in both the short and long term. Damage to body tissues as a result of trauma, surgery, or disease processes stimulates neuroendocrine responses, namely increased sympathetic outflow from the spinal cord, increased release of hormones (including adrenocorticotropic hormone, cortisol, and renin), and decreased release of insulin and testosterone. Clinically, this may result in adverse effects on wound healing and predispose to infection. Weight loss because of decreased food intake and increased protein catabolism may be dramatic and the change in feeding behavior, coupled with a significant reduction in gastrointestinal motility secondary to pain, may result in the development of colic. The increase in sympathetic tone upregulates heart rate, which in turn increases myocardial oxygen consumption; causes vasoconstriction, elevating blood pressure, and may lead to potentiation of arrhythmias. An increase in blood pressure may have deleterious effects, for example by upregulating intraocular pressure following intraocular surgery or by increasing bleeding at a surgical site.

Horses' "fight or flight" nature means that they often react to severe pain by behaving violently. This can make them difficult and dangerous to handle with the potential for serious injury to both handler and horse. Even in less extreme cases, horses may still act unpredictably, making thorough examination and treatment a challenge.

One significant long-term adverse consequence of acute pain is the development of chronic or maladaptive pain; a disease process in itself. In this situation, pain persists after the injury has apparently healed. Chronic pain may also be associated with a long-standing pathological process, such as laminitis, although the severity of the clinical condition may not correlate with the degree of pain experienced by the animal. Chronic pain is incredibly difficult to manage because it is often not responsive to "traditional" analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids.

There are different types of pain: physiological, inflammatory, and chronic. Horses may experience more than one type of pain simultaneously.

ACUTE PAIN

Acute pain, following tissue trauma or application of a noxious stimulus, is the result of activation of peripheral sensory nerve endings acting as sensory receptors (nociceptors). Nociceptors have been described in most structures of the body, including the skin and viscera. They transduce and encode noxious stimuli and send impulses to the dorsal horn of the spinal cord via small myelinated (Aδ) and thinly and nonmyelinated (C) afferent nerve fibers. After reaching the dorsal horn of the spinal cord, the Aδ and C fibers from superficial pain pathways (e.g., somatic structures, such as skin) are transmitted via the spinocervicothalamic tract,[1] whereas those from the deep pain pathways (e.g., viscera and periosteum) are transmitted via the spinoreticular tract.[2] Pain is perceived by the animal when the signals reach the somatosensory cortex.

The mechanisms of nociception are complex and dynamic, and modulation, either facilitation or inhibition of the signals, can occur within the central nervous system (CNS). Descending pathways originate in the brain within areas such as the periaqueductal grey matter and the ventromedial medulla and interact with the ascending pathways, particularly at the level of the spinal cord, to form a "negative feedback loop." Neurotransmitters involved in descending inhibitory pathways include glutamate, norepinephrine, serotonin, γ-aminobutyric acid (GABA), and endogenous opioids. The premise behind the *gate theory*, described by Melzack and Wall in 1965,[3] is that the input to the brain is the sum of the excitatory and inhibitory inputs. Therefore, facilitation of inhibitory pathways can be exploited to provide analgesia.

Peripheral Sensitization

Prolonged stimulation of the pain pathways can result in alterations often referred to as peripheral and central sensitization. Peripheral sensitization occurs at the level of the injured tissue. Tissue damage results in release of inflammatory mediators including prostaglandins, bradykinin, histamine, hydrogen ions, potassium ions, and substance P. These mediators may stimulate peripheral nerve endings (nociceptors) directly, or they may increase the sensitivity of the nociceptor to other stimuli. Clinically, peripheral sensitization may result in an avoidance of or aggressive response to a stimulus that would normally be considered innocuous (e.g., light touch). This is referred to as *allodynia*.

Central Sensitization

Plasticity within the spinal cord and brain means that nociceptive pathways may be upregulated in response to acute pain and inflammation. The physiological mechanisms behind central sensitization are complex but ultimately result in enhanced pain transmission by neurons. One of the most important mechanisms is thought to be related to *N*-methyl-D-aspartate (NMDA) receptor stimulation by the neurotransmitter glutamate. The result is hyperalgesia; an exaggerated response to a noxious stimulus. Secondary hyperalgesia occurs in the surrounding noninjured area. When these changes have occurred, effective pain control is more difficult and higher doses of analgesics are required.

CHRONIC PAIN

Central sensitization plays an important role in the development of chronic pain. The mechanisms behind chronic pain are

pathological processes and do not benefit the animal. Chronic pain has significant welfare implications because it can be difficult to diagnose and treat effectively. Following surgery in people, the incidence of the development of chronic pain may exceed 50%.[4] Many procedures associated with the development of chronic pain in people, such as dental surgery and hernia repair, also are commonly performed in horses, so it is reasonable to assume that chronic pain following surgery may also occur in this species. Preemptive and multimodal analgesia—the preoperative administration of analgesics acting on different parts of the nociceptive pathways—may attenuate both peripheral and central sensitization, reduce postoperative pain (compared to when the same analgesics are administered after surgery), and decrease the incidence of chronic pain.

A more commonly recognized cause of chronic pain in horses is laminitis. Laminitis is associated with peripheral sensory nerve damage, which results in chronic pain with a neuropathic component.[5] Pain associated with laminitis can be severe, and failure to adequately control pain may necessitate humane destruction of the horse.

PAIN ASSESSMENT

It is essential to be able to assess and quantify pain to determine when intervention is required and to assess the efficacy of administered analgesics. Physiological variables, such as heart rate and respiratory rate, are easily measured and are objectively quantifiable. However, they have been poorly correlated with subjective assessments of pain in horses[6] so, rather than relying on them in isolation, they should be considered in light of the animal's clinical condition and drug treatments and used as part of a holistic pain assessment.

The development of pain scales for use in horses lags behind progress made in the field in small animals. The reproducibility, specificity, and sensitivity of several parameters selected from a review by Ashley et al[7] have been established in the development of a composite orthopedic pain scale in horses.[8] This scale requires further validation in a clinical setting, but it has the potential to be a useful tool and a helpful basis for further work in this area.

In the meantime, accurate quantification of a horse's pain remains very difficult, but implementing a standardized approach to assessing each individual horse will assist in identifying of signs of pain and has the potential to significantly improve pain management.

Ideally, the same trained person should perform all assessments for each horse to minimize interobserver variability. Demeanor is commonly used for subjective pain assessment in horses[9] and may be influenced by the type of pain that the horse is experiencing. For example, horses with severe abdominal pain may appear excited and violent, whereas horses in significant pain due to laminitis may appear to be very quiet and depressed. The horse's demeanor, posture, and activities should be evaluated first, preferably with the observer outside the sight of the horse, although this is often not possible. Behavioral signs that may indicate pain include low head carriage, horse positioned at the back of the stable, vocalization (groaning, neighing), agitation, restlessness, weight shifting, lifting a limb, tail swishing unrelated to the presence of flies, abnormal distribution of body weight (e.g., uneven weight-bearing on limb), a "tucked-up" appearance, and looking at a painful body part. Interaction between horses housed in groups can also give the observers useful information about the horse's emotional state. More subtle signs that may not be visible from a distance include bruxism, increased jaw tone, sweating, and muscle fasciculations.

In an attempt to get a more complete view of the pain that the animal is suffering, the pain assessment protocol should incorporate dynamic and interactive components.[10] The observer should then approach the horse while noting the horse's response and willingness to interact. In some cases, tissue damage and inflammation is obvious, and wherever possible the examination should include observation of the horse's response to palpation of both the injured and surrounding areas. It is also often helpful to palpate tissue at a site remote from the injury to see how the horse responds to painless touch. In cases where the source of pain is not immediately apparent, palpation may elicit a pain response and aid diagnosis.

Food and water consumption should be monitored. Watching horses eat may give useful information in cases with dental pain and indicate whether a horse is willing to bear weight on its thoracic limbs and lower its head to the ground to eat.

In appropriate cases, the willingness to walk as well as the gait itself should be assessed. Lameness may be immediately apparent in horses with limb pain, but gait is often influenced by pain in other parts of the body. For example, pain following castration may result in reluctance to move and/or a short pelvic limb stride length.

Chronic pain can be even more challenging to diagnose than acute pain, and behavioral signs and changes may be more subtle. In the long term, loss of weight and muscle wasting may be evident. The use of an algometer (Figure 23-1) to assess induced back pain in horses by quantification of the pressure required to elicit a withdrawal response has been described.[11] This objective measure could potentially be a useful method to help monitor the response to treatment in horses with chronic musculoskeletal conditions. Pain intensity and nature change over time. Regularly reassessing the animal is very important to help monitor progression and to ensure that the selection and dosages of analgesics are appropriate.

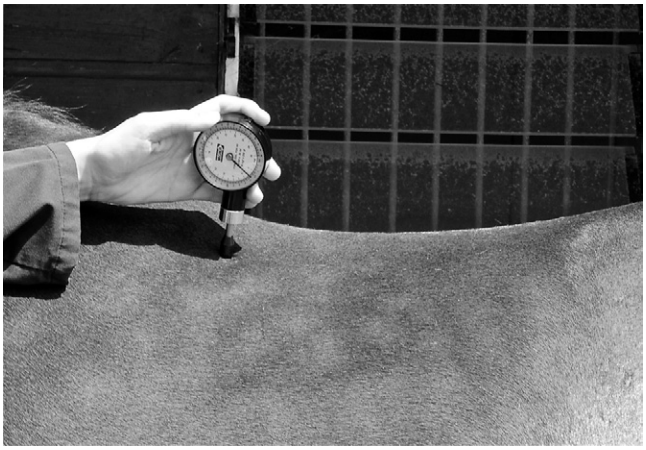

Figure 23-1. Pressure algometry in a horse. The algometer is applied to the horse's skin in the area of interest and pressure is applied until a response (skin twitch, local muscle contraction, or movement of the horse) is observed: "threshold pressure." The algometer is removed from the skin as soon as the response is observed.

ANALGESIA PROTOCOLS

Drugs commonly used for analgesia in horses include nonsteroidal anti-inflammatory drugs (NSAIDs), α_2-adrenoceptor agonists, opioids, ketamine, nitrous oxide, and local anesthetics. Horses are perhaps fortunate in that combinations of these drugs are used frequently in sedative and general anesthetic protocols, and that their simultaneous administration (multimodal analgesia) has a potential additive or synergistic effect on analgesia. Preemptive analgesia can also be accomplished by relatively minor adjustments to protocols, for example administration of NSAIDs on the morning of surgery, and ensuring that all other analgesics are administered before the surgical procedure begins. This approach can optimize the effectiveness of the analgesic technique, thereby reducing the likelihood of the development of central sensitization as well as reducing the postoperative requirements for analgesics.

The surgical procedure and presence of pain preoperatively should be considered when selecting an analgesic protocol; a horse presented for fracture repair requires a greater degree of analgesia than a horse undergoing repair of a small, superficial skin laceration. It is also important to monitor each individual horse's response to analgesics so that drugs and dosages can be adjusted as appropriate.

In addition to pharmacological therapy, other factors may assist with pain management, such as immobilization of a fractured limb or surgery to remove painful focus (e.g., enucleation). The importance of nursing care should not be underestimated and can greatly influence the rehabilitation process.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs play an important role in equine pain management protocols. They are particularly effective against inflammatory pain because they work by inhibiting cyclooxygenase (COX) enzymes, which are necessary for prostaglandin production during the inflammatory response. Traditionally, COX-1 was considered to be a constitutive enzyme and COX-2 inducible following tissue trauma. It was thought that many of the adverse effects associated with NSAID administration were due to inhibition of COX-1. This led to the development of COX-2–selective NSAIDS. Theoretically, these should have had a favorable side-effect profile in comparison to nonselective NSAIDs. Unfortunately, COX-2–selective NSAIDs are associated with an increased risk of adverse cardiovascular events in people, and it has become apparent that the delineation between the two forms of the enzymes is not as unambiguous as initially thought.[12]

Phenylbutazone, flunixin meglumine, and ketoprofen are the most commonly used NSAIDs in horses[13] and are potent COX-1 inhibitors.[14] Adverse effects on the gastrointestinal tract mucosa are potential side effects of NSAID administration to horses.[15] It has been speculated that COX-2–selective drugs, such as firocoxib (Equioxx), will be associated with fewer gastrointestinal adverse events,[16] and it will be interesting to see if this is verified in clinical cases.

Other NSAIDS used in horses include vedaprofen (Quadrisol), suxibuzone (a precursor of phenylbutazone) (Danilon Equidos), carprofen (Rimadyl), and meloxicam (Metacam).

A liposome-based diclofenac cream (Surpass Topical Cream) has FDA approval for use in horses in the United States. The cream is applied topically, for example over a joint, and exerts a local anti-inflammatory effect with minimal systemic absorption. There are conflicting reports in the literature on the efficacy of this cream in experimental models of synovitis and osteoarthritis,[17,18] although more positive results were reported in a clinical field trial.[19]

Opioids

Opioids produce analgesia by binding to mu (μ), kappa (κ) or delta (δ) receptors in the spinal cord and brain. Peripheral opioid receptors are also found in inflamed tissue.

Opioids may be administered by intravenous, intramuscular, epidural, or intraarticular injection. Transmucosal and transdermal routes of administration may be alternative options in "needle-shy" horses.

The use of opioids for analgesia is commonplace in small animal practice, but fear of side effects may have traditionally limited the use of opioids, particularly full μ-agonists, for analgesia in horses. Excitement, thought to be caused by CNS stimulation, is often observed when partial and full agonist opioids are administered alone to pain-free horses.[20,21] In contrast, excitement and locomotor stimulation are rarely observed when opioids are administered to horses undergoing surgery or in combinations with sedatives.[22-24] Morphine has been implicated in the etiology of postanesthetic colic in one institution.[25] However, results from another center demonstrated an absence of effect from perianesthetic morphine as a risk factor for colic in horses.[26] No adverse and some beneficial effects of morphine administration to horses undergoing general anesthesia (0.1 mg/kg[22] and 0.15 mg/kg followed by 0.1 mg/kg/hr[27]) have been reported, although the analgesic effects remain to be evaluated.

Butorphanol is the most commonly used opioid in equine practice in the United Kingdom[9] and is incorporated frequently into sedative and general anesthetic protocols. It is a synthetic opioid, which is thought to act as an agonist at κ-receptors and an antagonist at μ-receptors.[28] The dosage recommended for analgesia (0.1 mg/kg) is approximately 5 to 10 times that recommended for sedation. The short duration of action (30 to 60 minutes) may account for the lack of discernable analgesic effect following castration in ponies,[24] so frequent redosing or administration by continuous rate infusion has been recommended.[28] After exploratory laparotomy, horses that received butorphanol by constant rate infusion (CRI) (0.013 mg/kg/hr) for 24 hours after surgery had lower plasma cortisol levels, lost less weight, and had lower pain scores compared to horses that did not receive butorphanol.[29]

Despite the lack of evidence either way regarding the analgesic efficacy of butorphanol, administration during anesthesia has been recommended by some authors because it appears to blunt sympathetic stimulation during surgery[30] and may improve the subjectively assessed quality of anesthesia.[31]

The analgesic potential of buprenorphine, a μ-agonist opioid, has been investigated in horses. Administration of 10 μg/kg IV provides antinociception to a thermal stimulus for approximately 7 to 11 hours[32,33] and provides long-lasting analgesia without significant side effects following castration in ponies.[34] Buprenorphine is well absorbed from oral mucosa in cats,[35] and a recent case report suggested that sublingual administration of buprenorphine may be a potential option for pain management in horses.[36] Sublingual administration of 6 μg/kg

buprenorphine provided analgesia for approximately 12 hours in a 5-month-old Thoroughbred filly with a suspected fracture of the first cervical vertebra.[36]

Transdermal fentanyl patches have been used as part of analgesic protocols in horses.[37] Dosing recommendations appear to be empirical at present, and for an adult horse two or three 10 mg or 100 μg/hr patches are placed on a shaved area of skin. Marked variations in plasma levels have been reported,[38,39] so monitoring each individual horse's response to treatment is essential.

α_2-Adrenoceptor Agonists

Xylazine, detomidine, romifidine, medetomidine (where allowed), and dexmedetomidine are commonly included as part of sedative and general anesthetic protocols, and their use in these contexts are discussed in Chapters 18 and 22. The mechanisms behind the analgesic effects of the α_2-agonists are not understood fully but are thought to involve receptors in the brain and spinal cord.[40] The sedative effects of α_2-agonists usually outlast the analgesic effects[41] and, although useful as part of a preemptive, multimodal analgesic technique, the profound sedation produced by IV administration usually precludes the use of infusion techniques for long-term pain management. The epidural route can be considered for longer-term pain management because, in the case of xylazine, analgesia can be achieved at lower doses compared to IV administration.

Local Anesthetics

Local anesthetics act by blocking sodium channels in excitable membranes and preventing the transfer of nociceptive information. Local anesthetics are used frequently to assist with diagnosis of lameness and can also be used for therapeutic purposes by topical administration, infiltration, and regional anesthesia. In addition to playing an important role in multimodal pain management strategies, they reduce sedative and anesthetic requirements and also facilitate surgery by improving muscle relaxation and reducing the likelihood of a response to surgical stimuli. The recent trend toward performing surgical procedures, such as selective fracture repair, dental extractions, sinus surgery, and laparoscopy, on standing, sedated horses, rather than under general anesthesia, means that the role of local anesthetic techniques is increasing in importance. Local anesthetic techniques for surgery in the head region have been reviewed,[42] and common perineural injection sites are described in Chapter 30.

Paravertebral anesthesia is commonly used for flank laparotomies in cows but is also a very useful technique for laparoscopy (and flank laparotomies) in horses. The skin, muscles, and peritoneum of the flank region are desensitized by anesthesia of the dorsal and ventral branches of the eighteenth thoracic and first and second lumbar spinal nerves.[43] An alternative approach is segmental thoracolumbar anesthesia with local anesthetic administered via a catheter inserted into the subarachnoid space at the lumbosacral intervertebral space. This requires special equipment and strict adherence to aseptic technique. Ataxia of the pelvic limbs is a potential adverse effect.[44]

Anesthesia of the tail and perineum can be achieved by epidural administration of local anesthetics at the first coccygeal interspace and is described in the section on epidural analgesia (see later in this chapter).

Transdermal lidocaine patches and cream are being used to provide analgesia in small animals, although there are limited data on efficacy. A recent study in horses found that application of 5% lidocaine cream to the carpus reduced the horse's subsequent response to needle insertion, although no effect was evident after application of a lidocaine patch.[45]

A technique has been developed for long-term analgesia of the distal thoracic limb by continuous perineural blockade of palmar nerves.[46] This has the potential to be very useful but requires further development and refinement before introduction into clinical use, because limb swelling developed following infusion of lidocaine, bupivacaine, and mepivacaine over 1 to 2 days.

Lidocaine Infusions

Intravenous administration of lidocaine is used to reduce ileus following intestinal surgery in horses[47] and as part of a balanced anesthetic protocol (see Chapter 18). Intravenous lidocaine administration during anesthesia reduces postoperative morphine requirements and pain in people,[48] although the analgesic effects have not yet been comprehensively evaluated in horses in the clinical arena. In conscious experimental horses lidocaine infusion (2 mg/kg followed by 0.05 mg/kg/min) produced an antinociceptive effect to a thermal stimulus, suggesting that lidocaine may produce somatic analgesia. Further investigations into these analgesic effects are warranted.

Drugs for the Treatment of Central Sensitization

Many drugs developed for indications other than the treatment of pain, such as antidepressants, anticonvulsants, and antiarrythmics, have analgesic or antihyperalgesic properties that make them useful for the management of pain, particularly chronic pain, that is poorly responsive to traditional analgesics.

Ketamine is the only drug used for the treatment or prevention of central sensitization that has a marketing authorization for administration to horses, although the indication is for induction of anesthesia rather than pain management. It is an *N*-methyl *D*-aspartate (NMDA) receptor antagonist, and subanesthetic doses are thought to have an antihyperalgesic effect.[49] No adverse effects on behavior were detected during infusion of ketamine at 0.4 and 0.8 mg/kg/hr in conscious horses.[50] High concentrations of ketamine may also block sodium channels, and this may explain the short duration of analgesia (15 minutes) when used for an abaxial sesamoid nerve block.[51]

Tramadol is a synthetic codeine analogue. It binds weakly to the μ-receptor and inhibits neuronal reuptake of norepinephrine and 5-hydroxytryptamine. The effective dosage of tramadol in horses has not been established; 2 mg/kg IV did not produce any adverse effects but did not result in antinociception to a thermal stimulus.[52] The oral bioavailability of tramadol is very poor, so this route of administration is unlikely to be effective in horses.[53]

Gabapentin was originally developed as an anticonvulsant and is used to treat neuropathic pain in people. The precise method of action is not clear but it is thought to modulate the activity of presynaptic voltage-gated calcium channels, which are upregulated in chronic pain states. It does not act specifically

as an analgesic but can reduce established hyperalgesia. Gabapentin at a dosage of 2.5 mg/kg orally every 12 hours was used as part of an analgesic protocol for the treatment of neuropathic pain caused by femoral neuropathy in a pregnant mare.[54] The pharmacokinetics of gabapentin have been described in horses, and the plasma elimination half-life following a dosage of 5 mg/kg orally is 3.4 hours.[55] Further work is required to determine the clinical efficacy of gabapentin in horses.

Intraarticular Analgesia

Intraarticular administration of opioids and local anesthetics following arthroscopy in horses is increasing in popularity. Opioid receptors are present in equine synovial membranes[56] and this may account for the reported analgesic and anti-inflammatory effects of intra-articular morphine. In a lipopolysaccharide-induced synovitis model, the effects have been reported to last approximately 20 hours after a dose of 0.05 mg/kg[57] and at least 24 hours following 0.05 to 0.1 mg/kg.[58]

Intra-articular local analgesics can provide effective analgesia in the short term. In people, concerns have been raised over the potential toxic effects of local anesthetics on chondrocytes following prolonged postoperative infusions. This effect appears to be dosage- and time-dependent. A recent editorial suggested that in people, a single dose appears to be safe but prolonged administration of high concentrations of local anesthetics should be avoided.[59] In the absence of data relating to the horse it would appear prudent to limit intra-articular administration of local anesthetics to a single dose, until more studies are available.

The use of intra-articular corticosteroids, hyluronic acid, and polysulfated glycosaminoglycans are discussed in Chapter 79.

Epidural Analgesia

Epidural injections can be performed at two sites in horses: the lumbosacral space (cranial) and the first coccygeal interspace (caudal). Cranial epidural injections are rarely performed in horses because they can be technically difficult, carry the risk of dural puncture, and are more likely to result in motor blockade to the pelvic limbs than the more commonly performed and simpler caudal epidural.

Indications for caudal epidural administration of drugs include obstetric manipulations; surgery of the tail, perineum, or genitourinary tract; intraoperative analgesia; and postoperative pain management. Infection at the site of needle placement is a contraindication for the use of this technique. Other relative contraindications include coagulopathies (risk of bleeding within spinal canal), ataxia (risk of recumbency), neurological diseases, and septicemia (risk of spread of infection into epidural space). In addition, the safety of the person performing the procedure should be considered carefully.

The horse should be restrained adequately and, if possible, evenly bearing weight on its pelvic limbs. The first coccygeal interspace may be located by digital palpation (area approximately 5 cm (2 inches) craniad to the start of the tail hairs on the midline) during dorsoventral movement of the tail. Locating the site for injection may be difficult in obese or heavily muscled horses. The site should be clipped and strict aseptic technique should be used. Desensitization of the tissues along the proposed needle path with local anesthetic will reduce the horse's response to subsequent spinal needle placement. An 18 to 20 gauge (G) spinal needle (bevel facing craniad) is inserted through the skin (Figure 23-2). The angle of insertion may need to be altered to ensure that the needle passes through the interspinous and interarcuate ligaments and into the epidural space. A change in resistance to needle advancement may be appreciated as the epidural space is entered. The needle should be withdrawn approximately 5 mm if the floor of the vertebral canal is encountered. Needle placement can be verified by the "hanging drop" technique; a drop of saline or local anesthetic placed on the hub of the needle will be drawn into the epidural space upon its penetration with the needle tip. The syringe containing the drugs for injection should be attached to the needle hub, and no blood should be aspirated into the syringe when gentle suction is applied. The drugs should be injected very slowly and minimal resistance to injection should be encountered if the needle tip is in the epidural space.

For longer-term pain management an epidural catheter may be inserted (Figure 23-3). Careful attention to the maintenance of the catheters and use of aseptic technique is important to avoid introducting pathogens.

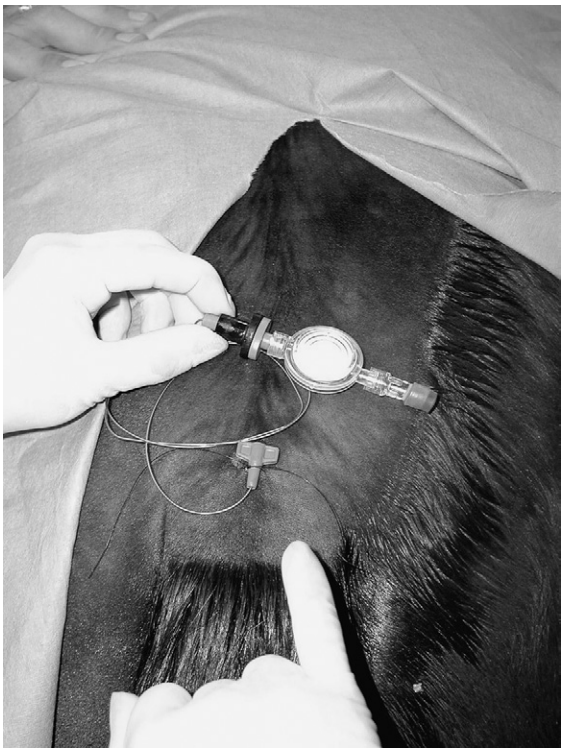

Figure 23-3. Epidural catheter being placed for long-term use.

TABLE 23-1. Doses of Drugs Administered via a Caudal Epidural Injection to Produce Perineal Analgesia in Horses*

Drug	Dosage	Volume	Weight	Onset	Duration	Extent of Analgesia
Lidocaine (2%)[60]	0.22 mg/kg	–	352-482 kg	4 min	1.5 hr	
Ropivacaine (0.5%)[61]	–	8-9 mL	475-565 kg	10 min	3 hr	S2 dermatome in 3/10 mares
Bupivacaine (0.5%)[62]	0.06 mg/kg	3.7 mL (mean)	240-350 kg	6 min	5.3 hr	
Xylazine[63]	0.25 mg/kg	8 mL (with 0.9% NaCl)	420-500 kg	13 min	165->180 min	S3 dermatome
Detomidine[63]	0.06 mg/kg	8 mL (with 0.9% NaCl)	420-500 kg	12 min	160 min	T15 dermatome in one horse, most commonly S1-S2
Methadone[64]	0.1 mg/kg	20 mL (with 0.9% NaCl)	495-593 kg	15 min	5 hr	T13 dermatome
Morphine[65]	0.1 mg/kg	20 mL (with 0.9%NaCl)	511 kg (mean)	5 hrs	6 hr	Thoracic region
Ketamine[66]	0.5, 1, and 2 mg/kg	9 mL	400 kg	5-10 min	30-75 min	Upper pelvic limb
Tramadol[65]	1 mg/kg	20 mL	511 kg (mean)	30 min	4 hr	Sacral region
Lidocaine (2%) + xylazine[60]	0.22 mg/kg + 0.17 mg/kg	6 mL	454 kg	5 min	330 min	

*The maximum extent of analgesia (where investigated) is shown.

Drugs Used

Drugs that have been administered into the epidural space in horses include local anesthetics, opioids, α_2-agonists, ketamine, and tramadol. These have been used as sole agents and in combinations and are summarized in Table 23-1.[60-66] Whenever possible, solutions of drugs used for epidural administration should be preservative-free.

Local anesthetics administered into the epidural space can provide anesthesia of the perineal region. Severe ataxia and recumbency are possible consequences of motor blockage of the pelvic limbs following cranial spread of local anesthetics. It is recommended that the volume for injection be limited to 8 to 9 mL of local anesthetic in a 500-kg horse.[61]

Morphine, methadone, and buprenorphine are available in some countries as preservative-free solutions and have been reported to produce relatively long-lasting analgesia after epidural administration. Adverse effects reported following epidural morphine administration in horses include self-limiting pruritus[67] and wheals in the perineal region.

Epidural administration of xylazine (0.17 mg kg^{-1})[68] or detomidine (0.06 mg/kg)[69] in 10 mL of saline produces analgesia lasting 2 to 3 hours, in contrast to medetomidine[70] and romifidine,[71] which appear to be less efficacious. Sedation may be apparent following epidural administration of α_2-adrenoceptor agonists.

Ketamine has been reported to produce analgesia following epidural administration in horses. The use of epidural ketamine in people is controversial because of concerns about neurotoxicity, although it is not clear if the nerve damage is caused by ketamine itself or by the preservative (benzethonium chloride).[72]

Complementary Therapy

Acupuncture and electro acupuncture are being used more frequently as adjuncts to pain management in horses. They are most commonly used as a treatment for musculoskeletal and visceral pain. Experimental studies have investigated the analgesic efficacy in visceral[73,74] and somatic[75] pain models with mixed results. Acupuncture and electro acupuncture do result in an increase in β-endorphin concentration within cerebrospinal fluid, and this may be involved in mediating the analgesic effects.

Extracorporeal Shock Wave Therapy

Extracorporeal shock wave therapy (ESWT) is increasingly being used in the management of orthopedic conditions in horses. Anecdotal reports suggest that ESWT may produce a short-term analgesic effect. However, one study failed to demonstrate this in horses with navicular disease.[76] One study investigating the effect of this type of treatment in 16 horses suffering from proximal palmar metacarpal or plantar metatarsal pain showed that after 72 hours the weight-bearing discrepancy between affected and contralateral forelimb decreased significantly.[77] Further investigations into the short- and long-term analgesic effects of ESWT in the management of specific conditions are required. It is however interesting to learn that at certain racetracks in the United States these devices are banned.

Therapeutic Ultrasound

Therapeutic ultrasound, magnetic, and laser therapy are also used for pain management, although studies are required to objectively evaluate responses to treatment.

SUMMARY

In summary, a thorough and systematic approach to pain assessment and implementation of a multimodal approach to pain management has the potential to significantly improve patient welfare and outcome after illness, injury, or surgery.

CHAPTER 24

Principles of Plastic and Reconstructive Surgery

Patricia J. Provost and Jeremy V. Bailey

Many of the reconstructive and plastic surgery principles and techniques outlined in this chapter can be used on a routine basis in the execution of elective procedures, such as tissue biopsy, whereas others will be useful in the repair of more extensive, traumatic injuries. Skin has unique physical properties, which can be manipulated to the advantage of the surgeon and patient. Understanding the general process of wound healing, as well as the differences that are unique to the horse, is the basis for formulating a treatment plan (see Chapter 5). The type of injury and its location on the body, degree of contamination, age of the wound, integrity of the local blood supply, and amount of skin loss must all be considered when deciding on the most appropriate method for managing a particular wound.[1-3] In addition to biological factors, the physical size of equine patients and the environment in which they are kept present unique management challenges not encountered in the treatment of soft tissue injuries in other species, including humans.

The overall goal in the management of any wound, regardless of whether it is treated by primary closure or by delayed primary or secondary closure or is allowed to heal by second intention is to achieve a result that is as functional and as cosmetically appealing as possible. Primary closure of traumatic wounds in many instances is not possible or recommended. Only wounds that are classified as clean or clean contaminated with adequate blood supply should be considered for immediate closure. Premature closure of heavily traumatized or contaminated wounds is one of the biggest mistakes made by equine practitioners during early wound management. Wounds managed for 1 to 3 days with treatment directed at reducing edema, contamination, and infection become better candidates for closure. Management of wounds by delayed primary closure (before the appearance of granulation tissue) or secondary closure (after the appearance of healthy granulation tissue) heal more rapidly and with fewer complications. Delaying closure to the fourth day or later has been associated experimentally with reduced wound sepsis.[4] Primary, or even delayed primary, closure may not be a viable option when the contaminated wound is associated with a significant skin deficit. Many of these wounds are best treated by secondary closure or as open wounds. Unfortunately, second-intention healing is often prone to development of exuberant granulation tissue and delays in contraction and epithelialization (see Chapter 5). To get the best cosmetic and functional results, open granulating wounds should be managed in such a way as to allow maximal contraction and optimal epithelialization.

Carefully planned reconstructive and skin-mobilizing techniques can be used in conjunction with primary, delayed primary, or secondary wound closure and as part of an overall strategy of open wound management to minimize the potential cosmetic and functional shortcomings of excessive epithelialization (scarring). Besides traumatic wounds, there are other clinical situations, such as the planned excision of skin lesions, in which reconstructive procedures can be used to facilitate closure of surgical incisions. The extent to which some of these techniques can be used depends on the presence of adequate tissue surrounding the wound. The benefits of successfully using reconstructive procedures include an increased percentage of the wound covered with full-thickness skin, improved cosmetic appearance and function, and a reduction of overall healing time. Ultimately the combination of skin loss and the amount of redundant or loose skin surrounding a wound influences the clinician's ability to close a wound and the extent to which wound contraction will contribute to the final result.

In the quest to minimize wound morbidity, many reconstruction techniques have been developed. Methods vary from use of simple tension relieving sutures, to incorporation of skin mobilization and expansion techniques, to the use of skin flaps. Understanding the principles and limitations of these procedures, adhering to the basic principles of equine wound management, and providing appropriate postoperative care all contribute to a successful outcome.

CUTANEOUS BLOOD SUPPLY

Successful reconstructive surgery relies heavily on an adequate blood supply. In mammals, two types of vessels supply the skin: perforating musculocutaneous vessels and direct cutaneous vessels. Perforating musculocutaneous arteries pass through the muscle to supply the skin. This arrangement is found in both people and pigs. Horses' skin, similar to that of dogs and cats, is supplied by direct cutaneous arteries, which reach the skin by passing through the fascial septa between muscle bodies.[5] Direct cutaneous vessels run subdermally, run parallel to the skin surface, and are closely associated with the panniculus muscle in areas where this structure is present. In the distal extremities,

where no panniculus muscle exists, the direct cutaneous arteries run beneath and parallel to the dermis. In the dog (and hypothesized to occur in the horse), smaller vessels branch off these cutaneous arteries and arborize in the dermis, forming three closely interconnecting plexuses—the deep subcutaneous plexus, the middle cutaneous plexus, and the superficial subpapillary plexus—which together supply the dermis and adnexal structures of the skin.[6] The superficial plexus is an important component of the thermoregulatory system, and all three are crucial in maintaining the integrity of the blood supply and are thus of importance when manipulating skin in reconstructive procedures.

In dogs and cats, a number of skin flaps have been developed based on the major cutaneous arteries of the trunk.[7] These include axial pattern flaps, island arterial flaps, and vascularized free flaps. A skin flap based on the cutaneous portion of the caudal branch of the deep circumflex iliac artery has been described and used in experimental studies of a vascularized free tissue transfer in the horse.[8] More detailed descriptions of the vascular supply to the equine skin, which could be reliably used for the reconstruction of skin deficits, are required to advance development of additional options.

PHYSICAL AND BIOMECHANICAL PROPERTIES OF SKIN

Skin has three structural components, which impart tension and viscoelasticity: collagen, elastic fibers, and ground substance (primarily proteoglycans). It is important to note that these components vary considerably between individuals and between different sites of the body. In humans, they are known to be affected by aging, solar radiation, disease, and chemical and physical trauma.[9] Viscoelastic materials are those for which the relationship between stress and strain depends on time. If the stress is held constant, the strain increases with time (creep); and if strain is held constant, the stress decreases with time (relaxation). Tension is the magnitude of force skin can exert. Understanding these physical and biomechanical properties inherent to skin allows the clinician to manipulate them to his or her advantage.

Lines of Skin Tension

The normal tension that exists in skin is a result of the elastic fibers in the dermis and is the reason skin edges retract when incised. In 1861, Langer mapped lines of tension (Langer's lines or lines of maximal tension) over the surface of the human body but did not take into consideration body or limb position or movement. However, because skin is anisotropic (lacking similar properties in all directions), skin tension lines are influenced by muscle contraction, movement of joints, and other external forces. Thus, Langer's lines are more accurately referred to as relaxed skin tension lines.[10] Incisions made parallel to lines of maximal tension will gap to a lesser extent and heal with a finer scar than incisions made at right or oblique angles to them. Incisions made at oblique angles to the lines become curvilinear whereas incisions made at right angles to lines of tension gape widely, require more sutures for apposition, and heal with scars that, over time, become stretched and less cosmetically acceptable. Tension lines have been described in dogs, but they have been investigated to only a very limited extent in the horse (Figure 24-1).[11,12] Diagrams showing the orientation of tension lines in the dog resemble the color patterns seen on the tiger and zebra, and it has been suggested that the lines of the skin color pattern in these animals closely mimic lines of tension.[10] In the absence of detailed information, these generalities can be used to advantage in planning reconstructive procedures in horses.

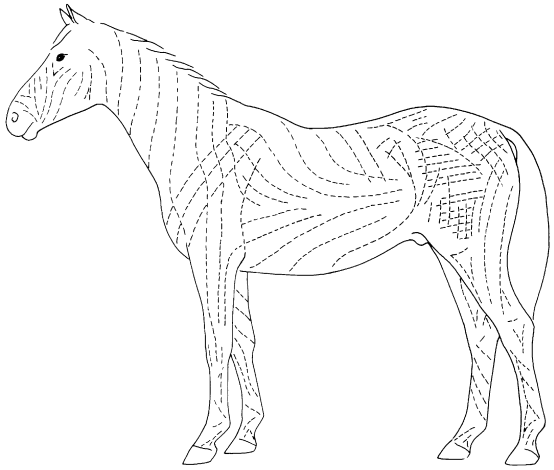

Figure 24-1. Cleavage lines of equine skin. (Redrawn from Hrudka F, Popesko P, Komarek V: Principal Morphology of Domestic Animals, Bratislava, 1962, Slovak Publishing House of Agricultural Literature, based on work by Najbrt.)

Skin Extensibility

Skin extensibility is another important physical property of the dermis that is used to advantage in reconstructive surgery. It refers to the skin's normal stretching capacity while an anatomic part is at rest and represents the physical property that allows wounds to be sutured closed following removal of skin. Lines of maximal extensibility have been shown to run at right angles to Langer's lines, which logically could also be referred to as lines of minimal extensibility.[13] Pinching skin into folds at the site of a proposed reconstructive procedure can be used to roughly determine the extent of orientation of skin extensibility and to assess whether or not the edges of the remaining defect can be brought into apposition after excision of a lesion or the revision of a scar.[13] When excising an elliptical piece of skin, closure is facilitated by ensuring that the long axis of the ellipse is aligned to Langer's lines. Because the lines of maximal extensibility are at right angles to Langer's lines, the width of the ellipse can be wider if the long axis is parallel rather than perpendicular to Langer's lines. Tension lines and lines of extensibility in human skin are well documented, and diagrams showing their locations can be found in most plastic and reconstructive surgery texts. In the horse, lines of maximal skin extensibility were determined for the carpus, which led to the surgical recommendation for making longitudinal versus transverse incisions over the dorsal, medial, and lateral aspects of the carpus.[14]

Creep and Stress Relaxation

Two types of creep can occur within the skin. *Mechanical creep* is a biomechanical property of skin, which allows it to stretch beyond its normal limits of extensibility under a constant load.

This results as the normally convoluted collagen fibers become straight and aligned parallel to the stretching force. *Biological creep* differs from mechanical creep in that the skin does not stretch but instead increases area of coverage by increasing epidermal mitotic activity, upregulation of blood vessels, and increasing dermal cell numbers, resulting in skin development. This phenomenon is seen with pregnancy, growth of subcutaneous masses, body wall hernias, and, to the advantage of plastic surgeons, with tissue expanders.

Stress relaxation occurs when the strain imposed on a piece of skin is kept constant. Over time the amount of strain required to maintain elongation of the skin is decreased as a result of the collagen fiber alignment and lengthening, which occurs with mechanical creep. The process of stress relaxation explains why the tension on a suture line decreases to some extent a few minutes to hours after surgery.

A number of surgical techniques in reconstructive surgery utilize these viscoelastic properties of skin; however, there are only limited documented accounts of the application of these procedures in horses. Used alone or in combination with the other techniques described in the following paragraphs, they provide interesting possibilities for the management and reconstruction of skin wounds in horses.

PRINCIPLES OF WOUND CLOSURE

Incision Orientation

Whenever possible, a plan of attack should be made prior to creating an incision or closing a traumatic wound. The location of the injury or lesion, the elasticity of the surrounding tissue, the available blood supply, and the character of the wound bed should all be considerd when planning reconstructive surgery. The extensibility of the skin should be assessed with the affected region of the body in a relaxed position and during movement. This can be done by grasping the skin surrounding the wound or lesion with a thumb and forefinger while moving the body part. Careful assessment will identify areas from which skin may be mobilized and areas that are under tension. The skin can be marked with an alcohol-resistant marker prior to surgery, outlining the surgical approach.

Whenever possible, planned removal of lesions involving the limb should involve incisions that are parallel to the long axis of the limb. Repair of wounds that are located obliquely or transversely to the limb's axis often require postoperative casting, splinting, or bandage support to prevent excess tension during flexion and extension of the limb. Placement of incisions for the management of lesions of the upper body are site dependent. Positioning the horse's body during surgery so that the affected region is under the greatest tension facilitates selection of closure techniques that minimize the risk of postoperative dehiscence.

Sutures and Patterns

Sutures are used to approximate skin edges, reduce tension, and reduce dead space. The proper placement and use of appropriate suture patterns are important technical considerations in reconstructive surgery. The selection of a suture pattern is often based on personal preference; however, in some instances, there are definite advantages and disadvantages associated with particular patterns that should be taken into consideration. The choice of suture material is of less importance.[7,10] Manipulation of the tissue when placing sutures should be performed as atraumatically as possible. If instruments are used to stabilize or manipulate the skin edges, crushing and abrading tissue, which is detrimental to future healing, should be avoided; using one's gloved fingers is probably the least traumatic method. Most reconstructive procedures can be performed using a standard instrument set; however, the addition of a limited number of special instruments will greatly assist the surgeon. The addition of sharp skin hooks or Lahey traction forceps aids in minimizing trauma when stabilizing tissue. Sterile Backhaus towel clamps are an acceptable alternative. Stabilization of the skin using an instrument that penetrates the tissue is less damaging to the skin and its microvasculature than using an instrument that has a crushing action.

To facilitate optimal healing, accurate apposition of the skin edges with minimal interference to the blood supply should be the goal when suturing wounds. The pattern and technique of suture placement, the number of sutures, and suture line support are all important in ensuring an optimal outcome. The spacing of sutures plays an important role in maintaining optimal apposition of the skin edges. As a rule, sutures should be placed at a distance from the skin edge equal to the thickness of the skin itself.[15] However, other factors, such as the tension on the wound edges and the thickness and stiffness of the skin, must also be taken into consideration. The collagenolytic and inflammatory processes that take place during early wound healing serve to weaken the suture-holding ability of skin, and as a result, sutures should be placed at a distance of at least 0.5 cm from the skin edge for improved security.[16] Clinical experience with equine wounds treated by secondary closure shows that wound edges where newly epithelialized tissue exists have little or no holding strength, making it important to place the sutures well back from the skin edge to ensure optimal holding strength. In laboratory animals, the levels of matrix metalloproteinases (MMPs) have been shown to be higher in keratinocytes during re-epithelialization, and in a porcine model, the levels of these collagenolytic enzymes have also been shown to be higher and to persist longer in granulating wounds than in sutured wounds.[17,18] Neutrophil-derived MMPs have been associated with nonhealing wounds in human patients, and overexpression of this particular collagenase may be part of the pathogenesis of chronic ulcers.[19] Tissue strength and not suture size or number are more important determinants as to whether or not a wound will dehisce. A sound working knowledge of the biology of wound healing improves clinical judgment and reduces the risk of failure of repair (see Chapter 5).

Sutures should be placed as close together as is necessary to approximate the skin edges accurately. Wounds along tension lines close with fewer sutures than do those perpendicular to the line of tension. More sutures are required in thinner skin than in thicker skin.[20] For wounds under tension, increasing suture numbers is preferable to increasing material size.[20] In human surgery, placing interrupted sutures 0.5 cm apart provides tissue apposition and minimizes tension on individual sutures.[16] The suggestion that the distance between individual sutures should be twice the thickness of the skin may apply, although in some instances, this procedure may result in an excessive number of sutures being used, leading to impaired healing as a result of excessive tissue reaction.[15]

The tension applied when placing and tying skin sutures should be sufficient to appose the skin edges, but overtightening

of sutures can result in failure of the suture line. Suture tension is a summation of intrinsic and extrinsic forces. *Intrinsic tension* is the constricting effect within the suture loop, which, if excessive as a result of the suture being tied too tightly, causes strangulation of the blood supply to tissue within the loop of the suture. A higher degree of intrinsic tension can be generated with heavier suture material, and any postoperative swelling will increase the intrinsic tension of a suture. *Extrinsic tension* results from opposing forces exerted by the surrounding skin on the suture when drawing the skin edges together. Extrinsic tension is related to the size of the defect being sutured and to the amount of redundant or loose skin in the area.[21] Tension on sutures can lead to tissue necrosis by interfering with local blood supply, increasing edema, and decreasing tissue perfusion. The clinical result of this can include wound dehiscence, sloughing of tissue, visible scar formation, and delayed healing, which may have catastrophic consequences depending on the location of the suture line.

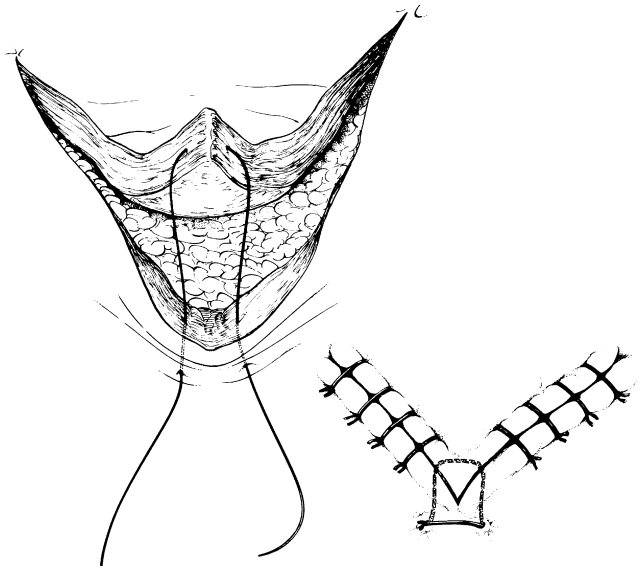

Figure 24-2. Corner suture used to minimize vascular compromise to the tip of the flap.

Basic Patterns

SUBCUTICULAR AND INTRADERMAL SUTURES

Subcuticular sutures are those placed in the subcutaneous tissue layer. They can be placed in a continuous or an interrupted pattern. Bites into the underlying soft tissue minimize the dead space. Subcuticular sutures reduce the tension between the wound margins prior to placement of skin sutures.[20] This pattern is inappropriate as a standalone closure pattern.

Intradermal sutures can be continuous or interrupted and provide excellent skin apposition and eliminate the need for percutaneous skin sutures in some instances. This can be advantageous in some patients, eliminating the need for suture removal. Other advantages are the elimination of suture tract sinuses and possible scarring associated with the use of skin sutures.

Simple interrupted sutures

Simple interrupted sutures (see Figure 16-7, *A*) can provide excellent tissue apposition if they are not placed too far back from the skin edge or pulled too tightly, both of which will cause inversion of the skin edges. Placement with slight eversion is preferred to inversion.[22] The ability to vary the width of their placement in irregularly shaped wounds and those with variable skin thickness facilitates better alignment of the skin edges than do continuous patterns. Tension across individual sutures can also be easily adjusted. Skin wounds closed with interrupted patterns have been shown to have greater tensile strength and less compromise of the microvasculature than those closed with simple continuous sutures.[23,24] If tension exists across the suture line, the attributes of simple interrupted sutures can be combined with other tension suture patterns.

Simple continuous sutures

As with any continuous pattern, knot failure or suture breakage results in breakdown of a large portion or all of the incision line. Continuous patterns (see Figure 16-7, *H*) are quickly placed, but it is not possible to vary the tension on the suture line to the same degree as with an interrupted pattern. Continuous patterns have been shown to result in increased edema and compromised circulation and to have a prolonging effect on the inflammatory phase of wound healing.[23,24] Although a simple continuous pattern has some advantages, the lack of precise skin apposition makes it less appropriate for use in plastic or reconstructive procedures.

Corner suture

Also called a three-point or half-buried mattress suture, the corner suture is used to secure the sharp intersecting point of a Y-shaped incision (Figure 24-2).[15] The intersecting apex of a Y-incision is predisposed to ischemia, and the design of this suture pattern is such that it will not further compromise the blood flow. The three-point suture can also be used in other situations in which the angle of the skin edge, when sutured, would predispose it to ischemia. The corner suture pattern begins like a routine horizontal mattress suture, but instead of penetrating the full thickness, only a partial-thickness bite is taken. The suture is then passed horizontally through the dermis at the point of the V and completed as it was started with a partial-thickness bite.

TENSION-RELIEVING PATTERNS

Tension along suture lines can result from attempting to close wounds where there has been loss of skin, swelling in the area, or loss of elasticity in the surrounding tissue of more chronic wounds.[25] Closing wounds under tension should always be performed with caution, but the relationship between the tension on sutures and the incidence of necrosis of skin flaps has been challenged in a study, which concluded that the vascular damage resulted primarily from the process of undermining the tissue, and that skin with a good blood supply could be closed under considerable tension without fear of necrosis.[26] Careful judgment is required when increasing stress on suture lines; however, clinical experience suggests that equine wounds can be closed under a reasonable amount of tension and, provided there is a good blood supply and the suture line is well supported by some form of coaptation afterwards, healing is not delayed. If the force required on individual sutures to appose the skin edges increases to the point where vascular compromise is becoming a threat, tension sutures can be used to minimize that risk. Tension sutures can be used either alone or in combination with appositional patterns such as simple interrupted sutures and they are

often used in conjunction with other skin-mobilization techniques such as undermining or release incisions.

Tension sutures can usually be removed within 7 to 10 days, depending on the skin tension and provided that the site can be bandaged for additional suture line support.

Mattress sutures

Mattress sutures are described as vertical (see Figure 16-7, *E*) or horizontal (see Figure 16-7, *G*), depending on their orientation to the skin edge. These patterns when placed well away from the skin edges can be used when there is mild to moderate tension, and both provide reasonable apposition but have a tendency to evert the skin edges. They are placed 2 to 4 cm away from the wound margin and prior to sutures used to appose the skin edges. The vertical pattern is stronger under tension than the horizontal pattern and, as with a simple interrupted suture, results in little if any compromise to the microcirculation.[27] Horizontal mattress sutures, because of their configuration, may result in ischemia of the tissue within its suture loop, which may compromise subsequent efforts, if necessary, to reconstruct the defect. The number of tension sutures used in a wound is wound dependent. Buttons, plastic or rubber tubing, or gauze can be used beneath the skin suture loop to distribute pressure and prevent the suture from cutting through the skin (see Figures 16-9, *B* and *C*). These are known as *quilled support*, *quilled*, or *stented sutures*.[27] Although quilled sutures are particularly useful on the body where pressure bandages cannot be used to support the suture line, care should be taken when they are used beneath bandages or casts because external pressure can cause additional skin damage.[28]

The corium vertical mattress pattern results in minimal trauma (see Figure 16-7, *F*). The suture penetrates the skin and exits at the wound level through the corium (dermis). On the opposite side of the skin defect to be closed, the suture is placed entirely in the corium, where it exits intradermally at the skin edges, penetrates the dermis again at the other side of the defect, and exits near the initial penetrating suture, where the knot is tied. This results in a cosmetically superior closure because the sutures exit on only one side of the defect, which ensures perfect alignment of the skin edges without inversion or eversion.[29]

Far-near-near-far suture

The far-near-near-far suture pattern (or its modified form, the near-far-far-near pattern) combines a tension suture, the *far* portion, and an appositional suture, the *near* portion, with the name denoting the order and relative distance the sequential suture bites are taken from the skin edge (see Figure 16-9, *D*). This pattern has a higher tensile strength than either a simple interrupted or a mattress pattern, but it has the disadvantage of requiring that a large amount of suture material be placed in the wound.[27,29]

Walking suture

Walking sutures have been described for closing skin defects in small animals, particularly in areas where the skin fits loosely, such as the trunk (see Figure 16-9, *E*).[29,30] For additional information on this technique, see Chapter 16.

Support for Suture Lines

Supplying adequate support for sutured wounds can make the difference between success and failure in reconstructive procedures. The method of choice is determined to some extent by the location of the lesion and the amount of tension on the suture line. In many areas, bandages may be used to support a suture line, immobilize adjacent skin and joints, minimize edema formation, and obliterate dead space.[31] Pressure bandages are frequently used to support suture lines; however, a subtle balance exists between providing adequate support of the suture line and causing interference with regional blood flow. As a result of absorption of moisture and compression of the material, pressure bandages constructed from cotton or linen materials soon lose their compressive effect and hence their support.[31] To maintain effectiveness, it is necessary either to change these bandages at frequent intervals or to apply tension with an elastic bandage. (A more in-depth discussion on this topic can be found in Chapter 17.) When dealing with repairs on the upper limb or body, the clinician is often limited to the use of stent bandages (tie-over bandages). Stent bandages can provide effective support of suture lines and help obliterate dead space, but they are less effective in preventing or minimizing edema formation (Figure 24-3).

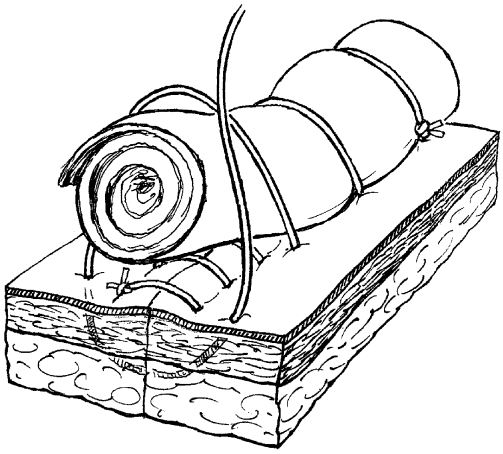

Figure 24-3. A stent bandage consists of rolled up sterile gauze sponges sutured with a large simple continuous suture pattern over an incision closed with simple interrupted sutures.

Cast or bandage removal is dictated by the amount of tissue mobilization and the anticipated tension on the sutured wound secondary to movement, swelling, and location when it is removed. In general, casts are removed between 2 and 3 weeks. Bandages, provided the dressing is clean and dry, are changed at 3- to 5-day intervals and maintained for 4 to 5 weeks.[32] Despite skin healing, tissue strength is only 20% of normal tissue at 3 weeks, 50% at 3 months, and can remain 20% to 30% weaker than the original tissue at 1 year (see Chapter 5). Prematurely removing the bandage or returning the horse to activity has resulted in failure of many wounds that were thought to be healed.

TENSION-RELIEVING AND SKIN-MOBILIZATION PROCEDURES

Tension on suture lines can result in discomfort for the animal, increased scarring, ischemia of the skin margin, and suture line breakdown with partial or complete wound dehiscence. As mentioned previously, suture line tension is influenced by the anatomic location of the lesion. On the lower limb, where there is essentially no redundant skin, excessive tension on suture

lines may create a tourniquet effect around the limb, leading to vascular compromise.[30] The consequences of tension across suture lines can be attenuated by using tension sutures, undermining the surrounding skin, or by using tension-relieving incisions or skin-mobilization techniques. These techniques may be used alone or in combination.

Skin-mobilization techniques allow many wounds with skin loss to be sutured closed rather than relying on contraction and epithelialization. Early wound coverage avoids complications associated with second-intention healing and results in a more rapid return to function. Although many of the reconstructive techniques that have been described for humans and small animals have obvious practical limitations in horses, certain techniques are applicable.

Undermining Skin

Undermining the skin edges around the wound or excision site prior to closure is the simplest tension-relieving procedure (Figure 24-4). Undermining is accomplished by either blunt or sharp dissection with careful attention to the blood and nerve supply of the given region. Blunt dissection has the advantage of minimizing damage to the cutaneous blood supply over sharp dissection. Opening the blades of scissors that have been inserted closed into fascial planes or using the handle of a scalpel in a back-and-forth motion are both accepted methods for bluntly undermining skin. Sharp dissection using a scalpel or scissors, however, is often necessary to separate the skin edge from the underlying tissue planes in chronic, fibrotic wounds. When sharp dissection is used there is an increase in bleeding, which may lead to hematoma formation. Placement of a drain prior to skin closure or a pressure bandage after closure may be necessary.

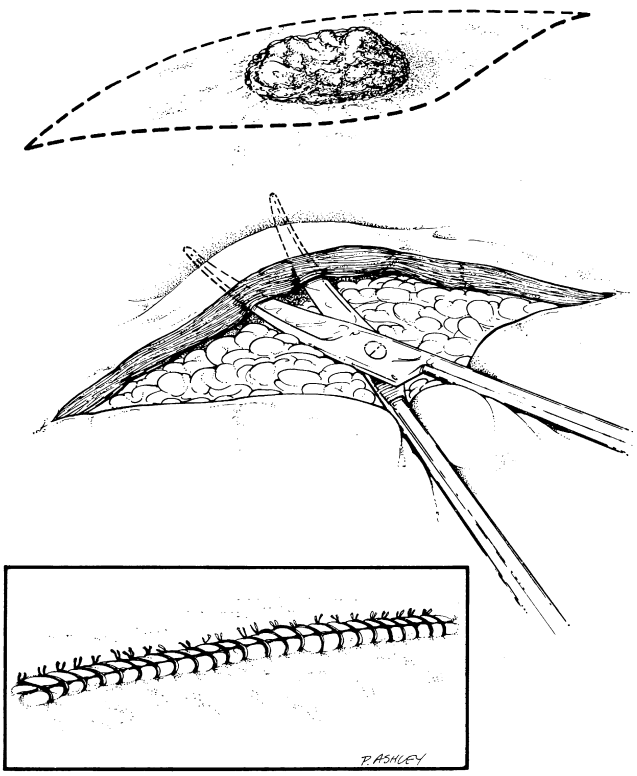

Figure 24-4. Fusiform excision. After excision, the skin is undermined to facilitate closure of the defect. Optimal length-to-width ratio of the fusiform defect is 4:1.

The depth at which skin is undermined depends on the vascular supply to the skin and the presence of superficial nerves in the particular area. Skin on the trunk should be elevated below the level of the panniculus muscle to preserve the small direct cutaneous vessels. On the distal limbs, where no panniculus muscle exists, the dissection plane should be as deep as possible between the subcutaneous tissue and the deep fascia.[21,29] Fascial planes are easy to identify where an elective incision has been made and primary closure is being used. In older wounds, however, because of scar tissue that develops as a result of the inflammatory process, these planes are not as readily identified until the dissection has been continued some distance from the skin edge. In these situations, it seems appropriate, from a clinical perspective, to begin the dissection at a level that approximates the original thickness of the skin.

The degree to which skin needs to be undermined can be estimated by drawing the skin edges together with towel forceps. As a rule, in a fresh wound, a distance equal to the width of the defect itself should be elevated on each side of the wound. If this is not sufficient, undermining can be extended half as much again. The extent to which skin can be undermined without significantly damaging the blood supply and causing necrosis has not been determined. In small animals, it is thought that undermining can be quite extensive without causing necrosis, provided there is limited interference with the blood supply. Clinical experience suggests the same is true for horses.[29,30,33] Used in conjunction with a mesh-expansion technique on the limbs of dogs, 360-degree undermining was not associated with any major complications.[34]

The benefits derived from undermining skin are the result of freeing the skin from its underlying subcutaneous attachments, which allows the surrounding skin to be drawn toward the defect and makes use of the elastic properties of the surrounding skin. The degree of benefit depends on the location of the wound and any other factors that alter the biomechanical properties of skin. In chronic wounds, as the process of wound healing proceeds, first the inflammatory edema and later the development of fibrous tissue will both lead to a loss of skin elasticity, which may necessitate undermining the adjacent skin more extensively to achieve the desired effect. Having an appreciation of the lines of maximal tension and extensibility in different regions of the body will allow the surgeon to take full advantage of the gains made by undermining.

Tissue Debulking

When performing delayed secondary closure or scar revision, removal of exuberant granulation tissue or fibrous tissue reduces the volume of the tissue in the wound, which allows closure under less tension. To determine the plane of dissection for débridement, the incision should extend beyond the perimeter of the wound into normal skin. The thickness of the normal skin can be used as a guide to determine the appropriate plane to undermine the skin adjacent to the wound site or scar. The granulation tissue or scar tissue within the wound site should then be removed until the normal subcutaneous tissue plane is encountered. When debulking a chronic wound, careful dissection is required to avoid inadvertent transection of vessels or nerves, trauma to tendons, and penetration of synovial structures.

Tension-Release Incisions

Tension-release incisions are longitudinal incisions made adjacent to the wound margin, which aid in advancing skin to cover the wound. When the tissue between the wound edge and the incision is undermined, the elevated skin acts as a bipedicle advancement flap. This technique is used to allow the movement of a limited amount of skin in those areas where simple undermining alone does not adequately relieve tension, yet the size of the defect to be closed does not justify more elaborate plastic procedures. A release incision can be made on either side of the wound or on both sides. When making a single release incision the incision should be placed at a distance of approximately the width of the wound away from the wound's edge over healthy tissue. When using two release incisions the placement of each incision is similar to that of a single incision. Release incisions are generally not closed but are allowed to heal by second intention. The wound that is created when using a single relief incision is similar in area to that of the original wound. When creating two release incisions the resultant size of each new wound is approximatley half of the original wound area, which is preferred over one release incision. Creation of tension release incision(s) is justified when it is necessary to provide skin coverage to a more vital area such as bone or tendon or ligament.

Mesh Expansion

Mesh expansion is a simple technique that when combined with undermining can increase the amount of skin available for mobilization and therefore wound coverage. The mesh incisions are created when the skin has been freed from attachments to the underlying fascia. The small incisions are made in staggered rows, parallel to the wound edge (Figure 24-5). Applying traction to the skin edges provides a good indication for the optimal location and orientation of the stab incisions to gain maximal relief of tension.[35] As a guideline, in fresh wounds, the distance between the individual stab incisions and between the adjacent rows should measure approximately 1 cm.[33] Placing either the rows or the incisions too closely should be avoided to prevent the possibility of the adjacent stab incisions becoming confluent or causing focal vascular compromise. The appropriate length of the stab incisions varies depending on the degree of elasticity and pliability of the undermined skin. In fresh wounds, more expansion can be obtained with smaller incisions, whereas for those wounds where the surrounding skin is thickened and fibrotic, longer incisions are required to achieve the same result. In some older wounds, the stab incisions do not readily open at the time of suturing, but clinical experience has shown that expansion does occur within a few hours postoperatively as a result of the viscoelastic nature of skin. Stress relaxation results in the undermined skin's becoming fatigued over time and in the stab incision's opening, which together result in reduced tension on the suture line.

The small mesh expansion wounds heal faster and more cosmetically than longer tension release incisions; however, they provide less skin relaxation than the larger release incisions. A combination of the methods of undermining, tension-release incisions, and mesh expansion can be used successfully to facilitate primary and delayed primary and secondary wound closures on the head, trunk, and limbs of horses.

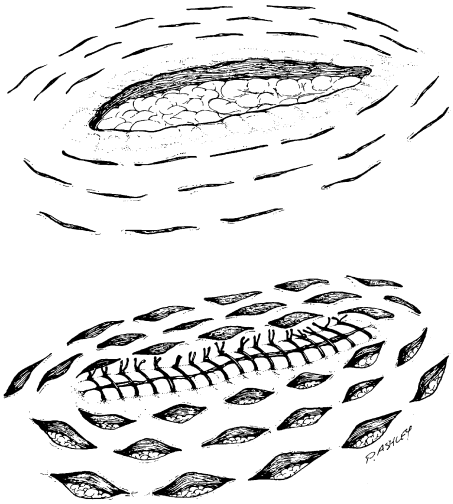

Figure 24-5. The mesh expansion method of closure. After undermining of the skin around the defect, two or three staggered rows of stab incisions are made parallel to the skin edges. After closure of the defect, the stab incisions gape open to provide both tension relief and drainage.

V-to-Y-Plasty and Y-to-V-Plasty

The V-to-Y-plasty technique for relieving tension requires a V-shaped incision with the point of the V directed away from the defect to be closed. When closure of the original defect has been accomplished, closure of the V incision is done by converting it to a Y (Figure 24-6). The longer the legs of the V, the greater will be the degree of tension relief; however, this method provides only a limited amount of skin movement and is not suitable for management of large defects.

This technique has been advocated for scar revision of the eyelid (see Chapter 56) and for relieving tension when closing elliptical defects.[28,29] Conversely the Y-to-V-plasty may be used if additional tension is required, such as for the surgical correction of an entropion.

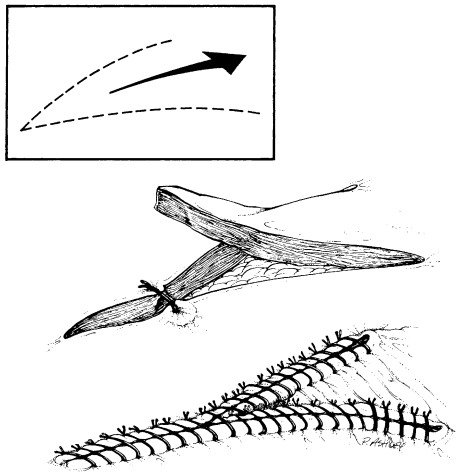

Figure 24-6. V-to-Y-plasty for tension relief. With this technique, tissue is mobilized in the direction of the arrow.

z-Plasty

Z-plasties can be used to relieve tension along a linear scar, to change the orientation of an incision line or a scar, or to relieve tension when closing a large defect.[13,29,36] These effects are achieved by recruiting loose tissue from the sides of the surgical site, and the success of the procedure depends on the presence of sufficient loose skin in the area to permit mobilization of tissue.[23,29] Where this situation does not exist, as in the lower limb of the horse, other procedures may be more suitable.

A Z-plasty represents a modification of a transposition flap. The basic Z-plasty is performed by making a Z-shaped incision with subsequent undermining and transposition of the two triangular portions of skin formed by the dissection (Figure 24-7). This technique results in a change in the orientation of the central limb of the Z and a gain in its length. The gain in length achieved by this procedure is in the direction of the original central limb—that is, before transposition occurs. Commonly, the Z is symmetric, with the three limbs of equal length and the same angle between the two arms and the central limb. An angle of 60 degrees is most frequently used, which results in a 75% gain in length. Varying the angles of the Z and the length of the arms influences the amount of elongation, and decreasing the angles results in a decreased gain in length. Maintaining a 60-degree angle and lengthening the limbs of the Z can achieve an increased gain in length; however, the greater the increase in length, the greater will be the resultant tension in the surrounding tissue. Using multiple small Z-plasties in the place of a single large procedure can minimize this problem.[21,29] Although the biomechanics and mathematics of Z-plasties have been examined extensively, this has been done using laboratory models, which are not influenced by the same forces as those found in living tissue.[37]

When Z-plasties are used to realign scars in humans, the limbs of the Z are oriented to follow the lines of minimal tension in the area, and the angles between the limbs of the Z vary according to the obliquity of the scar in relation to the lines of tension. If the procedure is to be used successfully for scar revision in horses, more information on the lines of tension and extensibility in the equine integument is needed.

In the horse, Z-plasties have been recommended as a relaxation procedure for closing elliptical defects and for revising scars involving the eyelids that have resulted in an acquired entropion.[38] A double Z-plasty was used to correct a stenotic naris in a filly following trauma.[39] Although other uses undoubtedly exist, the procedure does have some limitations and potential complications. The most common complication encountered with the use of a Z-plasty is ischemia and necrosis of the tips of the triangular skin flaps. The risk of this problem occurring can be reduced by making the base of the flap as broad as possible, and by minimizing tension on the suture line. Use of a modified three-point (half buried horizontal mattress) suture at the tips of the flaps is also recommended.

W-Plasty

W-plasties are designed to improve the cosmetic appearance of a scar. Scars that are at right angles to lines of maximal tension tend, over time, to widen and become cosmetically less acceptable. By using a W-plasty, such a scar is excised by making a series of opposing zigzag incisions in such a way that, when sutured, the incisions will interdigitate, with the resulting final suture line resembling a series of Ws. In this technique, the orientation of the single scar is changed from being at right angles to the lines of maximal tension to a series of connected smaller scars that are better aligned with the force of maximal tension and are thus not inclined to widen. Because this procedure involves the removal of tissue, with a subsequent increase in tension on the surrounding skin, and because it is primarily aimed at cosmetic improvement, careful consideration should be given to the need to undertake the surgery in the first place. If the technique is to be used, a template should be fashioned and the incision lines drawn carefully on the skin to ensure that the two opposing incisions are adequately aligned.

SKIN STRETCHING AND EXPANSION TECHNIQUES

Presuturing

Presuturing is based on the phenomenon that skin held in tension will gradually stretch. It is an ideal method to consider when elective procedures, such as skin biopsy, scar revision, or delayed wound closure, are being considered. It relies on the physiologic response of mechanical creep, which results in skin

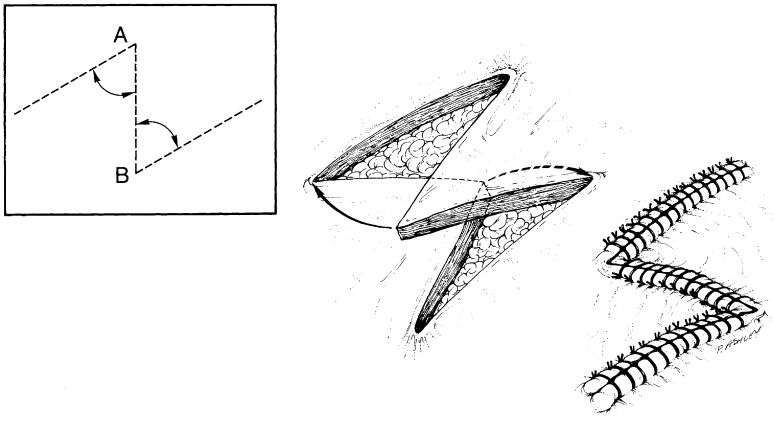

Figure 24-7. *Z*-plasty. The length of the central limb *(A to B)* is equal to the length of the two arms, and tissue movement occurs along the plane of the central limb. After closure, the orientation of the *Z* incision changes.

expansion and can be achieved when sutures are placed several hours prior to removal of a skin lesion. Using local anesthesia, sutures are placed to plicate skin over an area of planned excision.[40] The direction of suture placement is chosen according to the anticipated direction of primary closure. Wounds of the body and upper limb are generally the most amenable to presuturing. Large, nonabsorbable sutures (No. 1 or No. 2, polypropylene or nylon) are placed through the skin perpendicular and 2 to 6 cm to either side of the lesion. The sutures are then tightened to elevate and fold the skin over the lesion or wound. If presuturing is used in conjunction with tumor excision, the surgeon should be careful to place the sutures distant to the lesion to avoid iatrogenic seeding of tumor cells into healthy tissue.

The gain in tissue expansion persists for some time following removal of the preplaced sutures. This gain in tissue then facilitates closure of the wound site. In a pig model, the tension required to close a standardized wound was decreased by 40% when using this technique. Compared with simply undermining the surrounding skin, presuturing did result in some tissue gain and an initial decrease on closing tension, although this advantage diminished over time.[41] The advantages of presuturing diminish as edema and skin stiffness increase when sutures are left in place for too long. In the horse, when preplaced sutures were left in place for 24 to 30 hours, moderate edema resulted that was not seen when the sutures were removed after 4 to 8 hours.[42,43] Periods as short as 2½ hours have been shown to reap the benefits of presuturing.[40]

The original description of this procedure suggests that presuturing avoids the potential complications that can be associated with undermining.[40] However, the combination of presuturing and undermining may provide additional advantages.

Intraoperative Tissue Expansion

Intraoperative tissue expansion has been advocated as a means of decreasing incision closure tension.[44] Expansion can be obtained by techniques as simple as the placement of towel clamps and pulling the wound edges together for a short period of time prior to closure or the insertion of a Foley catheter in which the balloon is then inflated. Others have temporarily implanted balloon devices.[45] Variations in technique have been described ranging from tension being applied in three or four cycles of 3 to 5 minutes, to a single loading cycle applied for 20 minutes. Although expansion was initially thought to occur because of the viscoelastic property of creep, this explanation has been challenged.[46,47] Histologic studies fail to confirm the dermal changes associated with mechanical creep.[48] It is more likely that expansion results from the inherent elastic property of skin (extensibility), which is site dependent. [46,49-52] Although there are no published reports of using this technique in equine reconstructive surgery, there are sufficient reports of the potential benefits in other species to justify considering this procedure as part of a strategy to manage tension across a wound closure.

External Skin-Stretching Devices

Several external skin stretching devices are commercially available. These attach onto or into the normal skin on each side adjacent to the wound site or proposed incision and take advantage of the creep and stress-relaxation properties of skin. A maximum tension force of 3 kg/cm^2 can be safely applied across the wound to stretch the surrounding skin. Depending on the system used, tension can be gradually increased until this limit is reached.

The successful use of a relatively simple system using adherent skin pads and elastic connecting cables has been described in dogs.[53] The placement of the adherent pads relative to the skin edge can be varied according to the amount of skin recruitment required. The amount of tension was increased every 6 to 8 hours. The greatest gains in recruitment of surrounding skin appeared to be achieved 48 to 72 hours after application. The technique was reported as being well tolerated, and no biologic complications were encountered. Separation of the adhesive pads from the skin as tension was increased was the most common technical complication. Although the greatest gains in skin recruitment are seen between 48 and 72 hours, stretching can be achieved in as short as 20 to 30 minutes in wounds where the skin and subcutaneous tissues are normal. Interspersing periods of relaxation between periods of tension application results in greater elongation of tissues.

Elastomers

Silicone elastomer tissue expanders have been used in other species, but reports of their use in horses are limited.[54] Elastomers, which consist of a silicone pouch that can be gradually inflated percutaneously with sterile saline are available in various sizes and shapes to allow flexibility in placement and amount of tissue expansion. An elastomer with a base size 2½ times that of the defect that is to be reconstructed is selected and implanted below the skin adjacent to the lesion site. After the implant incision has healed, the pouch is expanded every 4 to 7 days through a dedicated self-sealing portal, thereby stretching the overlying skin. The optimal inflation pressure of the elastomer has not been determined in large animals. In a canine study, 20 to 40 mm Hg was initially used, but pressures approaching capillary pressure have been shown to be safe.[55] When sufficient skin expansion has been achieved, the elastomer is removed and the expanded tissue is undermined and used as a skin flap to cover the defect.

This procedure takes advantage of both mechanical and biological creep and can expand the area of the skin two- to threefold. The epidermis responds to the gradual inflation by an increase in mitotic activity and a net increase in epidermal tissue. The dermis thins in response to the elastomer expansion. However, skin flap thickness remains relatively the same because of the fibrous tissue response, which develops around the elastomer.[48] The initial thickening of the epidermis and thinning of the dermis seen immediately after expansion has been shown to return to normal 24 weeks after transfer of expanded skin in dogs, and similarly, the capsule that forms around the expander disappears.[56] However, this fibrous capsule results in an overall thickening of the raised flap and loss of elasticity of the expanded skin.[55] This increased stiffness may compromise the surgeon's ability to manipulate the flap in the reconstructive procedure. Removing the fibrous capsule may resolve this problem to some extent, and the effect of capsulectomy on the blood supply to the expanded skin has been investigated.[57] Although some controversy surrounds this issue, it appears that removing or incising the capsule to facilitate advancement of the flap does not critically affect the survival of the expanded tissue.[57]

The use of expanders may be of substantial benefit where limited skin is available for reconstructive procedures. Use in

dogs is well tolerated and has been associated with increases of 35.9% and 37.3% in the surface areas of skin on the antebrachium and crus following controlled expansion.[55,58] Skin flaps made from expanded skin are twice as likely to survive as those created from acutely raised skin.[59] This increased viability is attributed to similar effects seen in the delay phenomenon.[59,60] Despite increased survivability and the added benefits of presence of hair follicles, similarity of haircoat color of the donor skin to the surrounding area, the absence of a donor site defect, and the quality of the skin that is obtained, use of silastic elastomers in horses has been limited.

Complications include possible pain during saline distention, pressure necrosis of overlying skin, implant failure, wound dehiscence, and premature exposure of the expander necessitating its removal before adequate expansion had been achieved. Tissue expanders represent an additional dimension to the treatment and repair of skin defects in horses.

COSMETIC CLOSURE OF SKIN DEFECTS OF VARIOUS SHAPES

When undertaking scar revisions or the closure of traumatic wounds, the size of the lesion, the amount of redundant skin in the area, the elasticity of the surrounding skin, and the inherent lines of extensibility are all factors that must be considered during the planning process. Sound clinical judgment remains the cornerstone of making the required surgical decisions. Complex mathematical analyses have been developed to assess the optimal closure patterns of wounds with complex shapes, and these analyses may provide helpful information in the future.[61] The amount of skin that can be excised, the extent of undermining of the surrounding skin, the type of tension-relieving techniques used, the type of suture patterns to be applied, and postoperative support of the repair are other details that should be carefully contemplated when reconstructive or skin mobilization procedures are undertaken.

Fusiform Defects

Fusiform defects have sometimes been incorrectly referred to as elliptical defects; the latter do not have the tapered or spindle-shaped appearance of a fusiform excision and do not close as well.[10,29] Fusiform excisions can be used for elective scar revision, with the long axis of the defect being oriented parallel to the lines of skin tension (see Figure 24-4). A 3 : 1 or 4 : 1 length-to-width ratio will allow closure of the defect with a fairly even distribution of tension along the length of the suture line.[21,29] Shorter, broader defects result in uneven tension and in the formation of dog-ears at the end of the suture line.[62] In fusiform incisions, dog-ears can be prevented by tapering the ends of the excised portion of skin (described later). As with any reconstructive procedure, careful marking of the proposed incision facilitates excision of a piece of skin that has the optimal orientation and length-to-width ratio.

Triangular, Square, and Rectangular Defects

Where sufficient movable skin is present to permit closure, triangular defects should be closed from the points of the triangle toward the center, which will result in the formation of a Y-shaped suture line. There is a tendency for the skin at the center of the Y to develop ischemic necrosis. A half-buried horizontal mattress suture in a three-point closure (see Figure 24-2) can be used to secure this central point with minimal interference to the blood supply.[22,29]

Square and rectangular defects can also be closed by beginning to suture at the corners of the defect and closing toward the center.

V-Shaped Defects

V-shaped defects are fairly commonly encountered in veterinary medicine, and often part of the V-flap is lost or requires débridement prior to closure. After débridement, the resulting chevron-shaped defect can be closed with a Y-pattern in a fashion similar to that described for triangular defects. If the chevron-shaped defect is long and narrow, provided there is sufficient movable skin in the surrounding area, a fusiform incision could be made around it, which is then closed like a linear defect.

Circular Defects

Closure of circular defects commonly results in the formation of dog-ears, and several techniques have been described to prevent their occurrence. It is possible to close the defect without modifying its circular appearance by orienting the suture line along the relaxed skin lines of tension, followed by removal of any dog-ear as described later. A circle can be converted into either an X- or a Y-shape by tightening sutures placed at three or four points equidistant to each other around the circumference of the defect. The closure can then be completed, although this method also results in the formation of dog-ears.

The simplest method of facilitating closure of a circular defect is to excise two triangles on opposite sides of the circle, thereby creating a fusiform defect (see Figure 24-4). From a geometric point of view, the height of each triangle should be at least equal to the diameter of the circle; this will result in the removal of normal skin equivalent to 1½ times the area of the original defect.[63] The implications of removing this amount of normal skin must be carefully evaluated.

The double S-shaped incision with a bi-winged excision, the bow tie, and the combined V-incision are alternative methods of modifying circular defects and have been well described.[36] These methods are all designed to minimize scarring and dog-ear formation in human cosmetic surgery and are best applied to small circular defects.

Management of Skin Puckers (Dog-Ears)

Skin puckers or dog-ears often develop at the end of the suture line when closing oval or irregularly shaped defects or when using skin flaps as part of a reconstructive procedure. These dog-ears, if ignored, will flatten out to some extent over time and may be of little consequence. If the pucker is small and the cosmetic appearance is of limited importance, they can be managed by placing small sutures through half the thickness of the skin. In some locations, however, this conservative approach may result in an unsightly blemish. Because correction of dog-ears requires lengthening of the incision, it is worthwhile to assess the extent to which the cosmetic result will be compromised if the pucker is left alone.

To remove the puckered skin, the dog-ear can be stabilized with an appropriate instrument and removed by incising around the base, which results in a lengthening of the incision line

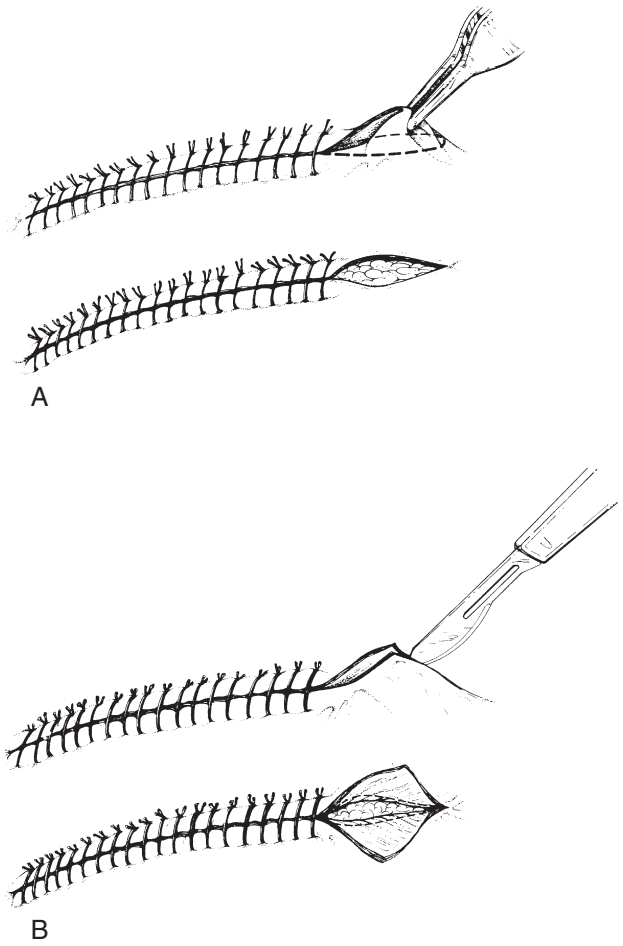

Figure 24-8. Methods for removal of dog-ears. **A,** The dog-ear is held securely, elevated and is excised level with the surrounding skin, leaving a small fusiform defect to close. **B,** The dog-ear is bisected to form two small triangular flaps, which are resected level with the skin surface.

(Figure 24-8, *A*). An alternative method is to close the incision until the dog-ear becomes well defined, and then to extend the initial incision through the middle of the dog-ear. This converts the pucker into two small triangular flaps of skin (Burow's triangles), which can be excised at their base (see Figure 24-8, *B*).

SKIN FLAPS

A skin flap or pedicle graft is a portion (or flap) of skin that, when created, can be moved from its original location to a second location on the body while, by virtue of its attachment (or pedicle), it maintains its vascular supply.[62] The survival of these grafts, unlike that of free skin grafts, is not dependent on successful revascularization from the recipient site. Pedicle grafts, because they have an attached blood supply, can be used to cover areas that, because of an inadequate blood supply, would be unsuitable for free skin grafts. When successful, pedicle grafts reduce healing time, minimize wound contraction and epithelialization, and provide an acceptable cosmetic result.[64] In contemplating the use of a skin flap, the clinician should evaluate the amount of loose skin in the area. It is preferable to be able to close the secondary defect that is created when the flap is raised, so sufficient skin must be available to be moved without producing excessive tension, either on the donor site or on the suture line at the new location. For this reason, large wounds on the distal limb may not be suitable candidates for a local skin flap, although some success with the use of advancement flaps and rotating flaps has been reported in treating wounds on the dorsal aspect of the tarsus and in the area of the metacarpophalangeal joint.[54,65,66] Pinching the adjacent skin into folds or pushing it toward the center of the primary defect can be used to assess availability of surrounding skin.

Flaps can be classified as local or distant, depending on the relationship of the donor site to the recipient site. Distant flaps usually involve either multiple surgical procedures or a degree of postoperative immobilization and patient compliance that makes them impractical in equine surgery. Local flaps (including rotation flaps, transposition flaps, and interpolating flaps) are usually one-stage procedures and can be simple advancement or rotating flaps. These types of flaps have been used successfully in the horse (discussed in more detail later).

Skin flaps can also be categorized as random or axial pattern flaps according to the nature of their vascular supply. Random pattern flaps, which do not have a defined vascular pattern, depend on the subdermal plexus for their survival and have been referred to as subdermal plexus flaps.[7,29] Axial pattern flaps, on the other hand, contain at least one major direct afferent and efferent cutaneous vessel and are usually named in accordance with that vessel. This enables a larger area of skin to be mobilized. In the dog, the omocervical, thoracodorsal, and caudal superficial epigastric flaps are well recognized and established axial pattern flaps. In horses, local random pattern flaps have greater potential use than axial pattern flaps.

Survival of a flap depends on the survival of its intrinsic vasculature. Random pattern flaps have traditionally been defined by the length-to-width ratio. Although the detailed differences in regional blood supply to the skin have not been studied in the horse, differences have been reported in other species, and those studies show that the optimal ratio for a flap varies with the location on the body. Length-to-width ratios from 1 : 1 to 3 : 1 for single-pedicle and 1.5 : 1 to 3 : 1 for bipedicle flaps have been reported in the veterinary literature. However, studies in dogs and pigs have shown that flaps of a standard length with similar vascularity survive regardless of the flap width.[67] In horses, a correlation of flap width to viable length in random pattern pedicle flaps of the trunk has been shown.[64] Length-to-width ratios of 1.5 : 1 and 3 : 1 have been used successfully on the limb and head, respectively.[54] The narrower the pedicle of the flap, the more maneuverable it will be, but the greater will be the chances of compromising its blood supply. On the other hand, a wide-based flap will have a good vascularity, but mobility, particularly rotational, is limited.

The *delay phenomenon* has been used to enhance the blood supply to the skin to increase the chances of flap survival. This two-stage technique involves incising and undermining the skin and subcutaneous tissue of the proposed flap and then leaving it sutured in its original location for a period of time. The incision may be on three adjacent sides of the flap or on two opposite sides, and undermining may extend to involve all or part of the flap. The most appropriate period of delay varies among species: in rabbits and pigs, 8 to 10 days is adequate, whereas circulation in single-pedicle flaps in dogs rose to 150% of normal in 3 weeks.[62,68] Although the mechanism by which flap survival improves using this technique is not well understood, both denervation and ischemia have been shown to play a role.

Both contribute, with a resultant increase in the number and diameter of the vessels as well as an increase in blood flow into the flap through its primary attachments.[62] Although this technique is not commonly used in equine reconstructive surgery, as the horizons of plastic surgery in the horse are advanced, specific studies are required to determine the most appropriate method and optimal time delay.

Tension applied to pedicle grafts has been shown to decrease blood supply and thus increase flap necrosis in pigs.[69] However, a study assessing the effect of tension on perfusion of axial and random pattern flaps in foals concluded that adequate perfusion was maintained in equine axial pattern flaps even when subjected to high tension.[70] Assessment of flap viability based on clinical criteria, such as temperature and color, is probably adequate. Other, more sophisticated techniques, such as radioisotope tests, histamine wheal, and fluorescein tests, have been described but are not routinely used.[21,29] It is debatable whether venous compromise or arterial compromise, or a combination of both, is of prime importance in flap necrosis; however, tension on the pedicle from stretching or over-rotating should be avoided to help prevent flap necrosis. Several methods for improving flap survival, in addition to the delay phenomenon, have been suggested; these include the use of vasodilators, massage, dimethyl sulfoxide, and hyperbaric oxygen, but all are of questionable clinical value and require further investigation before they can be recommended.[21,29]

Attention to the specific anatomy of local cutaneous vasculature is important in flap elevation. Flaps raised on the trunk should be elevated beneath the cutaneous musculature, whereas on the limb, dissection should be performed deep in the subcutaneous tissue. Careful design of the flap and good postoperative care greatly improve the success rate achieved. Planning should include determining which type of skin flap is to be used as well as mapping and marking the borders of the piece of skin to be elevated. This can be done using a paper towel or a cloth template of the defect to be covered. The flap should be slightly larger than the defect. Sharp corners, which may be prone to ischemia, should be avoided.

Advancement Flaps

Advancement flaps are random pattern flaps that can be of either the single or the bipedicle type. They have also been referred to as sliding flaps because there is no rotation of the elevated skin. A V-Y-plasty is an example of an advancement flap.

Simple bipedicle advancement flaps are performed either by making a single longitudinal incision on one side of the wound or by incising on each side of the defect. These incisions are made parallel to the wound edge to create skin flaps that are approximately the same width as the original defect. The bipedicle nature of this flap (Figure 24-9) provides two sources of blood supply to ensure survival of the mobilized portion of skin. The flaps and surrounding skin can be undermined and the initial defect closed. Depending on the nature of the surrounding skin, the new defects can be either closed or left to heal by contraction and epithelialization. As with many types of flaps, moving a single or bipedicle advancement flap may create some laxity in the adjacent skin. This can be managed by removing small triangular portions of skin called Burow's triangles, thereby preventing the formation of a dog-ear at the end of the suture line.

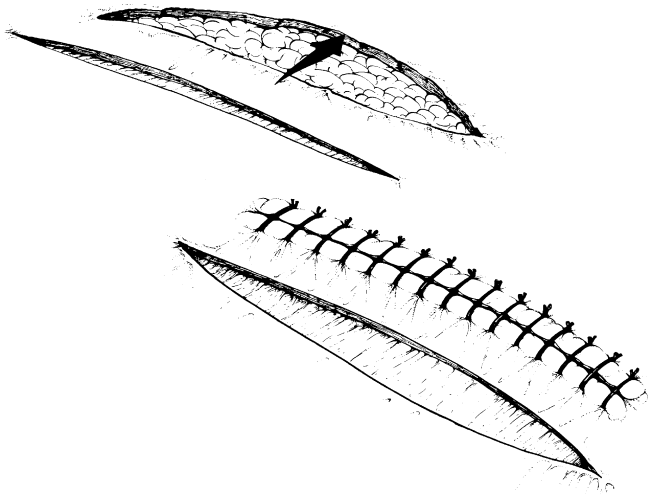

Figure 24-9. Simple bipedicle flap. This can be used with a single incision, as depicted here, or a second incision can be made on the opposite side of the primary defect. By using two relaxing incisions, it may be possible to close the secondary defects.

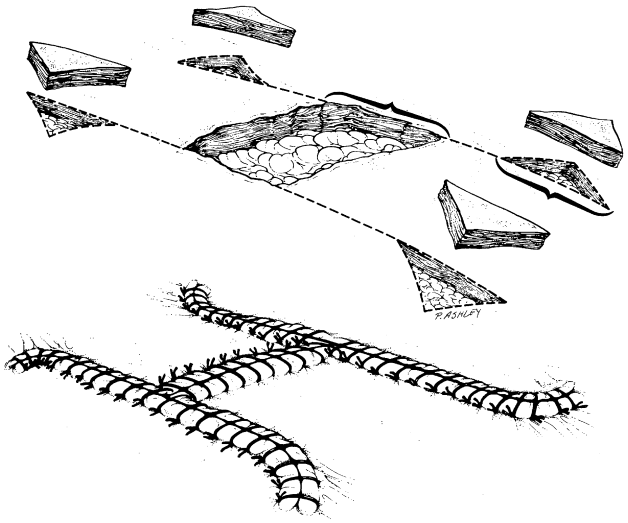

Figure 24-10. Sliding H-plasty. Burow's triangles are created and excised to prevent dog-ear formation after mobilization of the skin.

An H-plasty is a modification of a single-pedicle flap and is used to mobilize tissue during closure of a rectangular defect. Two single-pedicle flaps are used on opposite sides of the defect to advance the skin, and Burow's triangles are excised at the base of both pedicles to avoid dog-ear formation (Figure 24-10).

Rotating Flaps

Three types of rotating flaps are described: rotation, transposition, or interpolating flap. A *rotation flap* requires creation of a semicircular incision and moving the tissue laterally to cover the defect (Figure 24-11). A rectangular, single-pedicle flap that is created adjacent to a defect and subsequently rotated on its pedicle is called a *transposition flap* (Figure 24-12). These can be rotated up to 180 degrees, but increasing the amount of rotation has the effect of shortening the flap, which must be considered when planning the surgery. Moving a similar rectangular flap

Figure 24-11. Rotation flap. This pedicle flap is semicircular and can be used to cover small defects.

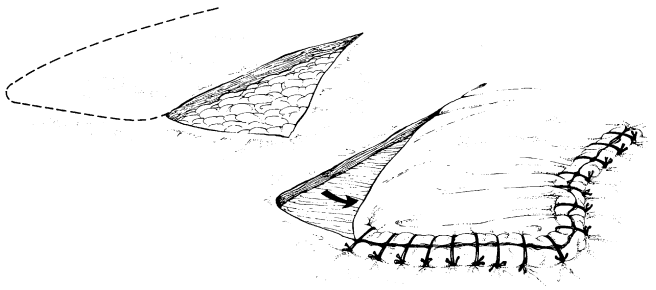

Figure 24-12. Transposition flap. This rectangular pedicle flap can be rotated up to 180 degrees to cover a defect.

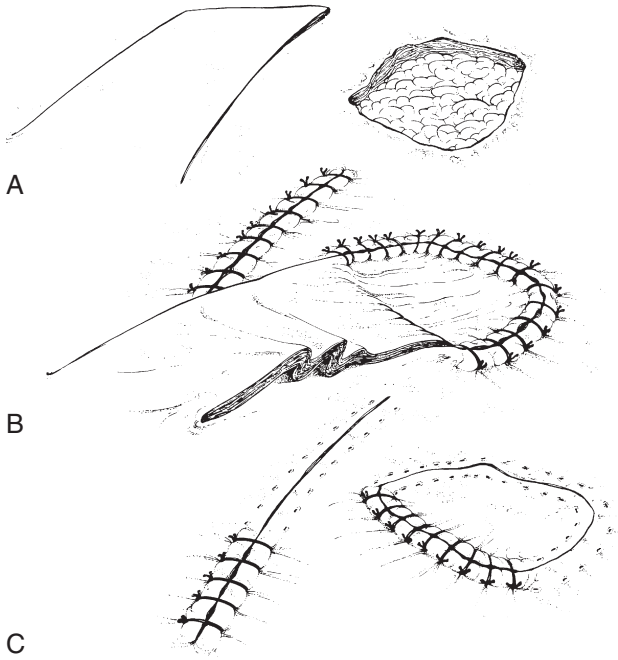

Figure 24-13. Interpolating flap. **A,** A pedicle flap is lifted from the skin adjacent to the defect. **B,** The flap bridges normal tissue to cover the defect. **C,** After the defect has healed, the pedicle is resected and the incised edges are sutured.

onto an immediately adjacent defect (i.e., the pedicle bridges an intact portion of the skin) creates an *interpolating flap* (Figure 24-13). The successful use of a rotating flap has been described in the management of a lesion on the craniolateral aspect of the tarsus of a horse.[65]

VASCULARIZED FREE TISSUE TRANSFERS

Vascularized free tissue transfers developed as a natural progression to axial pattern flaps with their well-defined arteriovenous supply. Microvascular techniques enable the skin/vessel unit to be transferred to remote sites and survive. An excised axial pattern graft can be reattached to its original perfusing vessel (orthotopic flap) or to vessels at a different location (heterotopic flap). Although the latter grafting technique is attractive as a useful technique in horses for the repair of limb wounds, successful protocols have remained currently elusive. Identified axial pattern flaps (based on dedicated direct cutaneous arteries) in the horse include those perfused by the caudal superficial epigastric artery, the medial saphenous artery, branches of the deep circumflex iliac artery, branches of the superficial temporal artery, dorsal and lateral nasal arteries, thoracodorsal artery, suprascapular artery, and linguofacial artery. Attempts to transfer a large axial pattern flap based on the deep circumflex iliac artery and vein, and a smaller one based on the saphenous artery and the medial saphenous vein, to distant defects in experimental horses have been unsuccessful.[8,71] In two separate studies, none of the heterotopically transferred flaps survived for longer than 4 to 6 days. The reasons for failure are not fully understood but may include poor perfusion as a result of vasospasm, a species tendency toward vascular thrombosis, or ischemia-reperfusion (IR) injury. Neutrophils are a significant source of the oxygen free radicals that mediate IR injury. A study to assess the role that IR injury plays in the failure of vascularized free tissue transfer in the horses showed no difference in neutrophil accumulation between control myocutaneous flaps and those subjected to a period of ischemia and reperfusion.[72]

Although the initial results are disappointing, further studies may resolve the difficulties encountered and make this technique a viable option in the future.

CHAPTER 25

Skin Grafting

James Schumacher

INDICATIONS FOR GRAFTING

The most common indication for applying a skin graft to a horse is a wound so large that it cannot heal by any other means, but the presence of any open wound that cannot be sutured is an invitation for grafting (Figure 25-1). The rapid healing achieved with a skin graft may make grafting the most economical choice for managing some wounds that cannot be sutured. A healed skin graft contains some epidermis, dermis, and some adnexa, including hair follicles, so it is likely to be more cosmetic and resilient than a wound healed primarily by epithelialization. Skin grafting should not be regarded as an option of last resort and should not be avoided because of fear of failure. Many techniques of skin grafting require little experience and only basic surgical equipment.

GRAFT CLASSIFICATION

The two basic types of skin grafts are the pedicle graft and the free graft.[1-3] A *pedicle* graft remains connected to the donor site, at least temporarily, by a vascular pedicle that sustains the graft, ensuring its viability. A pedicle graft is useful for covering a poorly vascularized wound, because the graft does not depend on the vascularity of the recipient site. The cosmetic appearance of wounds healed by application of a pedicle graft is good, because all components of skin are transferred. Cutaneous wounds of horses are rarely covered with a pedicle graft because the inelastic nature of equine skin makes mobilizing an adequate amount of skin for advancement difficult.[4] In humans and dogs, skin flaps that incorporate a direct cutaneous artery and vein (i.e., axial-pattern flaps) can be transferred to adjacent sites, or even to remote sites, by using microsurgical techniques to anastomose the flap's vessels to local recipient vessels.[5] Similar transfers in horses are unsuccessful, apparently because of reperfusion injury to the graft.[6,7]

A *free* skin graft is a piece of skin that has been completely separated from its local blood supply and transferred to a wound at another site, where it must establish new vascular connections to survive.[8,9] Free grafts can be categorized in several different ways, one of which is by their source. Most skin grafts applied to wounds of horses are *autografts* (or isografts), which are grafts transferred from one site to another on the same individual (Table 25-1).[10] The recipient of an autograft mounts no detrimental immune response against the graft because the recipient and donor are the same. Autografting is the most common and practical type of grafting of wounds of horses.

A graft transferred between different members of the same species is an *allograft* (or homograft), and a graft transferred from one species to another is a *xenograft* (or heterograft). The recipient of an allograft or xenograft mounts an immune response against the graft, causing the graft to be eventually rejected.[8,11] A second allograft from the same donor applied to the wound survives only a few days, but an allograft from a different donor survives for about the same time as the first allograft.[8] Because the immune mechanism is highly specific, an allograft from a different donor is not affected by circulating lymphocytes sensitized against the first allograft. Although allografts and xenografts are rarely applied to wounds of horses, these grafts are occasionally useful as a biological bandage.[12-14]

Free skin grafts can be categorized according to their thickness. Full-thickness grafts are composed of epidermis and the entire dermis; split-thickness (or partial-thickness) grafts are composed of epidermis and only a portion of the dermis. The percentage of dermis within the graft influences the graft's

Figure 25-1. A granulating wound on the fetlock of a horse. This wound is so extensive that it cannot heal by any means other than skin grafting.

TABLE 25-1. Graft Terminology*

Greek	Latin	Definition
Autograft	Isograft	A graft transferred from one site to another on the same individual
Allograft	Homograft	A graft transferred between different members of the same species
Xenograft	Heterograft	A graft transferred from a member of one species to a member of another species

*To avoid confusion, Greek and Latin prefixes that identify the source of the graft should not be used interchangeably in discussions.

Boykin JV, Molnar JA: Burn Scar and Skin Equivalents. p. 523. In Cohen IK, Diegelmann RF, Lindblad WJ, (eds): Wound Healing. Saunders, Philadelphia, 1992

acceptance, durability, and cosmesis at the recipient site. The thickness of dermis within the graft is directly proportional to the graft's durability and cosmesis but inversely proportional to the graft's ability to survive.

Full- or split-thickness free skin grafts can be applied to the surface of wounds as solid or meshed sheets, or they can be embedded in granulation tissue as pinch, punch, or tunnel grafts. Each method of free grafting has its merits and drawbacks, and the method selected depends on circumstances, such as the size and location of the wound, the necessity for cosmesis, the financial constraints imposed by the owner, the equipment available, and the expertise of the surgeon.

PHYSIOLOGY OF GRAFT ACCEPTANCE

Recipient Bed Characteristics

A prime requisite for free grafting is a recipient bed that is vascular and free of infection and devitalized tissue. A free graft cannot be expected to survive if placed on bone denuded of periosteum, tendon denuded of paratenon, or cartilage denuded of perichondrium, but practically any other tissue is capable of supporting a free graft.[15-18] Joint capsules, ligaments, and adipose tissue are capable of accepting a skin graft, but they do not accept a graft readily. Fresh surgically created wounds or fresh clean wounds caused by accident are vascular and free of infection and so readily accept a graft.[18,19] Granulating tissue is also capable of accepting a graft, although not as readily as is fresh tissue.[2,19,20] Granulation tissue healthy enough to allow epithelium to proliferate at its margin is generally healthy enough to accept a skin graft[18] (Figure 25-2).

Adherence

The graft is initially adhered to the recipient site by fibrin, which binds to collagen within the graft.[9,15,21,22] Vessels and fibroblasts invade the fibrin matrix by the fourth or fifth day, and the graft becomes firmly united to the recipient bed by around the 10th day.

Figure 25-2. Proliferating epithelium at the margin of a wound on the hip of a horse. Proliferating epithelium, represented by the pale ring around the edge of the wound, indicates that the wound is healthy enough to accept a skin graft.

Serum Imbibition (Plasmatic Circulation)

The newly applied graft is nourished by plasma-like fluid that it passively imbibes, by capillary action, into its open vessels, a process referred to as *plasmatic imbibition* or *plasmatic circulation*.[9,15,23] Oscillating movement of fluid into the vessels keeps the vessels open for revascularization. The graft becomes edematous and remains so until vascular connections to the graft are restored.

Revascularization

After about 48 hours, new capillaries generated in the recipient bed traverse the fibrin layer to anastomose with those in the graft, a process called *inosculation*.[9,15,23,24] Simultaneously, new capillaries from the recipient bed invade preexisting vessels within the graft, and others cut new vascular channels into the dermis (called *neovascularization*). The graft revascularizes between the fourth and fifth day after grafting, and reestablishment of circulation and lymphatic drainage brings about resolution of edema.[24]

Vascular bridging is a phenomenon that may enable a portion of the graft overlying a relatively avascular portion of the wound to revascularize.[17,25] With vascular bridging, capillaries enter the portion of the graft overlying the avascular portion of the wound from the relatively highly vascular aspects of the surrounding recipient bed to create a vascular bridge across the avascular portion of the wound. For vascular bridging to occur, the avascular area of the wound must be small, and the surrounding area must be highly vascular. Full-thickness grafts bridge avascular areas better than split-thickness grafts do, because collateral circulation within the dermis of a full-thickness graft is less interrupted than that within the dermis of a split-thickness graft.[25]

Organization (Organic Union)

The epidermis of the graft becomes hyperplastic after grafting and can double in thickness during the first 2 weeks.[18,26] The epidermis, especially that of a full-thickness graft, may die and slough in some areas, exposing pale dermis beneath it[26] (Figure 25-3). The exposed dermis may closely resemble granulation tissue, so a surgeon may remove the upper layer of the wound in preparation for a second graft, not realizing that a portion of the dermis has been accepted. Dermis can be differentiated from granulation tissue by its paler color. Exposed dermis becomes covered with epithelial cells that migrate from the hair follicles and the eccrine glands within the dermis.

Split-thickness skin grafts of humans usually begin to develop pigment about 4 weeks after grafting,[2,15,16] and the same is true of split-thickness grafts of horses.[26] Split-thickness grafts often remain scaly for several months, until the eccrine glands regenerate.[2,19,26] Split-thickness grafts of horses, no matter the thickness at which the grafts are harvested, are likely to be devoid of sweat glands,[27,28] and even full-thickness grafts of horses may be devoid of sweat glands.[27] Hair begins to appear in split-thickness grafts at between 4 and 6 weeks[26] and often grows to a greater than normal length, at least on grafts applied to limbs.[29,30] The growth of longer hairs may be related to a difference in temperature between the grafted limb and the donor site.

Reinnervation returns more rapidly, but to a lesser extent, in split-thickness grafts than in full-thickness grafts.[15,31] Sensation

Figure 25-3. Grafted wound of a horse. The epidermis has sloughed from all areas of the graft, exposing pale dermis beneath it. This wound contained enough dermis to allow rapid healing. (Courtesy Justin Perkins, BVetMed, University of London)

in split-thickness grafts of humans usually first appears between the seventh and ninth weeks but occasionally is present as early as the tenth day.[32] Sensation in split-thickness grafts remains incomplete and patchy. Regional nerves enter the base and margins of the graft and, by following vacated neurolemmal sheaths, reconstruct the innervation pattern of the grafted skin.[31] Humans sometimes suffer from hyperesthesia of the grafted wound,[16,31] and this may occur in horses also.

Graft Contraction

After being harvested, grafts immediately shrink because of recoil of the elastic fibers within the deep dermal layers.[18] This shrinkage is referred to as *primary contraction*. Primary contraction is greatest in full-thickness grafts and decreases as grafts become thinner. Full-thickness grafts from humans contract to nearly half their original size after being harvested. Split-thickness grafts that are about half the thickness of the whole skin contract to about three quarters of their original size, and grafts composed solely of epidermis do not shrink at all. The consequences of primary contraction are minor, because it is reversed when the graft is stretched and sutured or stapled to the recipient site.

Although grafts appear to contract after being accepted, this contraction is probably caused by contraction of the recipient bed, not by the graft itself.[18] Open wounds heal, at least in part, by contraction, which is brought about by the action of contractile fibroblasts, or myofibroblasts, within the wound.[18,33] Skin grafts inhibit wound contraction, to various extents, by accelerating the life cycle of the myofibroblasts within the wound.

The extent to which a skin graft is capable of inhibiting wound contraction is influenced by the relative thickness of the graft's dermis and the stage of healing of the recipient bed at the time of grafting.[18,33,34] The total percentage of the dermis grafted is more important than the absolute thickness of the skin graft in preventing wound contraction. Fresh or granulating wounds of humans and rats receiving a full-thickness graft tend to contract less than wounds receiving a split-thickness graft, even when the full-thickness graft is thinner than a split-thickness graft, indicating that physical or biochemical differences between the upper and lower portions of the dermis may strongly influence the effect of the skin graft on wound contraction.[33-35]

In a study on the effects of grafts on wound contraction in horses, fresh or granulating wounds to which a split-thickness graft was applied contracted at the same fractional rate as fresh or granulating wounds to which a full-thickness graft was applied.[36] The fractional rate of contraction of grafted fresh wounds, however, was less than that of grafted, granulating wounds.

Contraction of wounds of humans can sometimes lead to considerable cosmetic defects and to *contracture,* which is deformity of one or more joints caused by contraction of the wound.[8] Contraction of wounds of humans is sometimes intentionally inhibited by autografting or allografting to prevent cosmetic and functional defects caused by contracture.[2] Skin of horses is more mobile than that of humans and so is more capable of healing by contraction. Contraction of wounds of horses rarely, if ever, causes contracture of joints, so contraction of wounds of horses, before or after grafting, should be considered beneficial because it results in more rapid healing and smaller scars. If applied to a wound after contraction has commenced, skin grafts, regardless of whether they are full thickness or split thickness, appear to have little effect on inhibiting contraction in horses.[37] In one study, application of Meek micrografts (see "Modified Meek Grafting Technique," later) to naturally occurring wounds of horses stimulated, rather than inhibited, contraction of the wounds.[30]

GRAFT FAILURE

Reasons for graft failure include fluid accumulation beneath the graft, movement, and infection.[16,18,22,23,29] Grafts applied to horses fail most frequently because of infection.[38]

Fluid Accumulation

The graft must contact the wound intimately to prevent fluid from becoming interposed between the graft and the wound.[23] A hematoma, seroma, or exudate beneath the graft prevents fibrin from attaching the graft to the wound and acts as a barrier to the ingrowth of new vessels.[17,23] A graft can survive for only several days by imbibing nutrients from the hematoma or seroma, and if budding capillaries from the recipient bed are unable to traverse this barrier within this time, the graft expires. To avoid formation of a hematoma or seroma beneath a graft, grafting of a hemorrhagic wound should be delayed until hemorrhage has ceased.

Infection

Granulation tissue always has resident bacteria at its surface, but it contains abundant blood vessels and phagocytic cells that act as a partial barrier to bacterial invasion.[8,15,17,22,27,39] The wound becomes infected when the concentration of bacteria in the tissue exceeds the ability of humoral and cellular defenses to destroy the bacteria, and for most types of bacteria, this concentration seems to be about 10^5 organisms per gram of tissue.

Survival of a skin graft is better correlated to the concentration of bacteria in the recipient bed than to any other single factor.[40,41] If a wound is found, by quantitative bacterial analysis, to contain more than 10^5 bacteria per gram of tissue, the wound should not be grafted.

Because quantifying the concentration of bacteria in a wound is time-consuming and often impractical, at least for most veterinary surgeons, and because the concentration of bacteria in the wound is sometimes not as important as the *type* of bacteria,[22] the bacterial status of a wound to be grafted is usually assessed qualitatively. A wound that shows signs of inflammation, such as redness, swelling of the surrounding area, and formation of exudate, should be assumed to be infected. Bacteriologic culture of a wound that appears to be infected should precede grafting, and isolates should be tested for antimicrobial susceptibility. Unfortunately, even a wound that has no signs of inflammation and appears to be healthy may have more than 10^5 bacteria per gram of tissue.[41]

The concentration of some bacteria, most notably β-hemolytic streptococci and *Pseudomonas* spp, required to infect a wound is much less than 10^5 per gram of tissue.[22,42] β-Hemolytic streptococci produce proteolytic enzymes, including streptokinase and staphylokinase, that are destructive to both the graft and its recipient bed. These bacterial enzymes, and others, destabilize the fibrin network between the graft and the recipient wound by catalyzing the conversion of plasminogen to plasmin, which digests fibrin.[22,43] *Pseudomonas* species also critically weaken a graft's fibrinous attachment by producing elastase, which specifically degrades elastin in the dermis of the graft to which fibrin attaches.[22]

Inflammation

Granulating wounds on the distal portion of the limb of horses are inherently chronically inflamed,[44,45] which causes the granulation tissue to be poor in quality and to produce a moderate amount of exudate, factors that impair acceptance of a graft. Granulating wounds of ponies are less apt to be chronically inflamed,[45] and consequently, a graft applied to a granulating wound of a pony may be more likely to be accepted than would a graft applied to a granulating wound of a horse.

Motion

The graft must remain immobilized long enough to become vascularized. Shearing forces between the graft and the underlying recipient bed dislodge the fibrin seal, impairing plasmatic imbibition, inosculation, and capillary ingrowth. Shearing forces occur when the recipient wound is located in a highly mobile area, such as over a joint, or when the grafted area is inadequately immobilized. Fibrin glue has been used successfully to promote acceptance of skin grafts applied to wounds of human patients by increasing the strength of the attachment between the graft and the wound.[43] A trial using fibrin glue to attach skin grafts to wounds of horses, however, did not decrease the incidence of graft failure.[46]

GRAFTING TECHNIQUES

Preparation of the Recipient Site

Preparation of the recipient site is the most important contributor to survival of a free graft.[4] Factors to consider when determining if a wound is prepared sufficiently to accept a graft are the wound's vascularity and whether the wound appears to be infected.[15] Grafting should be delayed if the wound appears to have inadequate vascularity to support a free graft or if it appears to be infected or to have a higher than ordinary vulnerability for developing infection.

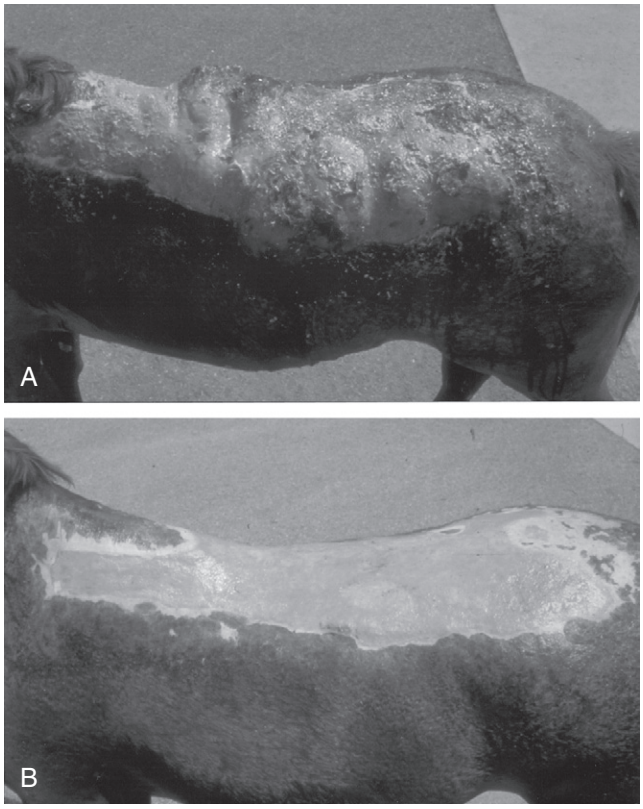

Figure 25-4. Burn wound on the back of a horse. **A,** The wound contained exuberant, relatively avascular granulation tissue that was excised to skin level, with the horse standing, in preparation for grafting. **B,** About 75% of a meshed, split-thickness skin graft, applied several days later, was accepted.

Highly vascular granulation tissue readily accepts a graft, but as the granulation tissue matures, its vascularity and ability to accept a graft diminish[42] (Figure 25-4). Fibrous, poorly vascularized granulation tissue, or granulation tissue plagued by unremitting infection, should be excised to a level below the margin of the wound to allow the wound to form fresh, vascular granulation tissue free of infection before a graft is applied.[29] Granulation tissue can usually be excised with the horse standing, because granulation tissue has no innervation.

Delaying grafting of a fresh wound for several days may decrease the time required for the graft to revascularize.[47] Sprouting capillaries capable of rapidly revascularizing the graft develop in the wound within 48 hours, so, by delaying grafting for 2 days after wounding, the time before the graft begins to revascularize (i.e., the phase of plasmatic imbibition) can be reduced by about one half. Wounds that are allowed several days to develop sprouting capillaries before being grafted are referred to as prepared wounds.

Although eliminating all bacteria from a wound is difficult, removing streptococci is relatively easy, because streptococci are nearly always susceptible to penicillin.[42,48,49] Occasionally, penicillin or other β-lactam antibiotics are ineffective in resolving a

Figure 25-5. A graft applied to a healthy-appearing, granulating wound on the dorsal aspect of a metacarpus was completely accepted, but a draining tract soon appeared in the healed wound. Drainage was caused by infection of bone beneath the wound and the development of a bone sequestrum.

streptococcal infection, because other resident bacteria, particularly staphylococci and gram-negative bacteria, produce β-lactamase, an enzyme that inactivates β-lactam antibiotics.[48] The efficacy of the β-lactam antibiotic against streptococci can be preserved if the β-lactam antibiotic administered is effective against β-lactamase–producing bacteria as well as streptococci. The activity of the β-lactam antibiotics can also be preserved by administering clavulanic acid, a potent inhibitor of β-lactamase, in conjunction with the β-lactam antibiotic.[48] Clavulanic acid has no therapeutic value when administered alone. Pseudomonads are usually sensitive to topically applied mafenide acetate, aminoglycosides, or polymyxin-B sulfate.[18,50]

Topical application of an antimicrobial drug to an infected, granulating wound is often more effective for eliminating infection than is systemic administration of the same antimicrobial drug, because systemically administered antimicrobial drugs often fail to reach therapeutic concentrations within granulation tissue.[15,51] Fibrin within granulation tissue appears to prevent adequate penetration of the antimicrobial drug.

Before a wound is grafted, it should be evaluated thoroughly for evidence of damage to synovial structures, ligamentous or tendinous tissue, or bone. Bone beneath slowly healing wounds or beneath wounds with draining tracts should be examined radiographically for evidence of a foreign body and for evidence of infection or sequestration of bone (Figure 25-5). Granulation tissue within chronic, slowly healing wounds, particularly those wounds that appear to be pruritic, should be examined histologically for the presence of larvae of the equine stomach worm *Habronema*. Some neoplasms, such as sarcoids or carcinomas, sometimes resemble granulation tissue.

Preparation of the recipient bed immediately before grafting should include clipping or shaving the skin around the wound. A surgical scrub solution can be used to cleanse the skin around the wound, but the wound itself should be cleansed only by rinsing it with physiologic saline solution or a balanced electrolyte solution. Contact between the wound and the detergent found in surgical scrub solutions increases the wound's susceptibility to infection.[52]

Preparation of the Donor Site

The area selected as the donor site depends on the technique of grafting selected and on whether the graft is to be harvested with the horse anesthetized or standing. Because harvesting skin creates a wound, the donor site, especially the donor site of a split-thickness graft, should be at an inconspicuous location.

Hair is removed from the donor site by clipping with a No. 40 clipper blade, by shaving, or by applying a chemical depilatory agent. Although chemical depilatory agents may irritate the donor skin, they have no clinically apparent detrimental effect on acceptance of grafts (my observation). When hair is removed completely from the surface of the donor site by shaving or by depilation, the graft should be marked in a way that ensures that when the graft is applied, the direction of its hair growth matches that of the skin surrounding the recipient site. The direction of hair growth on the graft remains visible when the donor site is clipped with a No. 40 clipper blade. After the donor site is scrubbed, it should be rinsed thoroughly with water or physiologic saline solution so that no residue detrimental to the graft, such as isopropyl alcohol, remains.

Full-Thickness Sheet Grafting

The site most suitable for procuring a full-thickness graft is the cranial pectoral region, where the skin is relatively mobile (Figure 25-6).[53,54] The graft can be removed, and the donor site sutured, with the horse anesthetized or with the horse standing and sedated after desensitizing the donor site with local anesthetic solution. If a sutured wound in this region should dehisce, healing occurs rapidly by contraction with little scarring. The scar is less obvious if the donor site spans the midline of the pectoral region.[54a] The graft should be cut slightly larger than the recipient site, even though the shrinkage caused by recoil of elastic fibers is largely reversed when the graft is stretched and fixed to the margin of the wound.[3,18]

Subcutaneous tissue attached to the undersurface of the graft acts as a barrier to plasmatic imbibition and ingrowth of new

Figure 25-6. Cranial pectoral area from which a full-thickness graft was obtained. The graft was obtained with the horse standing. The incision was closed with skin staples.

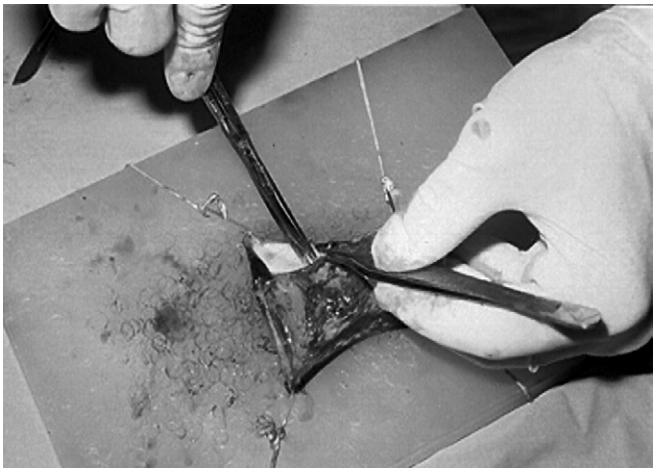

Figure 25-7. Removing fascia and fat from a full-thickness graft using sharp dissection. A scalpel blade can also be used.

vessels, so it must be removed to expose the dermis and its vasculature.[1,3,23] Subcutaneous tissue can also be excised from the graft as the graft is being excised, or it can be excised after stretching and fixing the graft, epidermal side down, to a sterile piece cardboard, Styrofoam, plastic sheet, or polypropylene block. Fascia and fat should be removed by sharp dissection, because scraping the subcutaneous tissue from the graft can injure the dermis and its vasculature (Figure 25-7). The graft should be attached to the recipient site with slight tension to keep the small dermal vessels open for inosculation.[55]

Full-thickness sheet grafting requires no sophisticated equipment for harvesting and can be performed with the horse standing. Full-thickness skin grafts resist trauma better than split-thickness skin grafts, and because they contain all the properties of the surrounding skin, full-thickness skin grafts provide the best cosmetic appearance and function of any type of free graft.[2,3,8,38,56] A full-thickness skin graft can be easily procured to cover a cutaneous defect created by excision of a cutaneous lesion and is particularly advantageous for treating horses undergoing removal of a cutaneous malignancy, such as a sarcoid, of the distal portion of a limb because closing the wound with a graft enables excision of a wide area of tissue surrounding the neoplasm, thereby decreasing the likelihood of recurrence of neoplasia.[57]

Full-thickness grafts are not accepted as readily as split-thickness grafts, because they have fewer exposed blood vessels than split-thickness grafts and because their requirement for nourishment is greater.[8,23,56,58] Circumstances for full-thickness grafting must be ideal, because blood vessels in a full-thickness graft that are available for diffusion of nutrients or for inosculation by vessels in the recipient wound are few in number and large in diameter. Although healthy, highly vascular granulation tissue is capable of accepting a full-thickness skin graft,[36] full-thickness grafting is usually reserved for fresh, uncontaminated wounds.[2,8,15,26,42] Desquamation of full-thickness grafts, even those applied to fresh wounds, has been reported to occur frequently after application to wounds of human patients[59] and to wounds of horses.[57] The entire epidermis may become necrotic and slough without adversely affecting the final appearance of the graft because re-epithelialization occurs from the dermal adnexa and from the epithelial edges of the wound (see Figure 25-3).[57,60]

A considerable disadvantage of full-thickness grafting of wounds of horses is the horse's lack of redundant donor skin. This disadvantage makes full-thickness grafting practical for covering only relatively small wounds, provided that the surgeon intends to suture the donor site after the graft is harvested. The largest elliptical graft that can usually be harvested from the cranial pectoral region of a horse of average size is about 8 cm (3 inches) at its widest point. A full-thickness graft can be used to cover a wound larger than the graft itself by meshing and expanding the graft, but full-thickness skin of horses is too thick to be easily meshed using some commercial meshgraft dermatomes, such as the Zimmer mechanical skin mesher (see "Meshing Sheet Grafts," later).

Split-Thickness Sheet Grafting

A split-thickness graft is composed of epidermis and a portion of the dermis. The thickness of a split-thickness graft is determined by the relative amount, rather than the absolute amount, of dermis included in the graft, because the thickness of the dermis varies between individuals and between regions.[2,27,29] To obtain a split-thickness graft, a portion of the dermis with its overlying epidermis is harvested with a free-hand knife, a drum dermatome, or a power-driven dermatome. Relatively inconspicuous donor sites for obtaining a split-thickness graft from horses are the ventral portion of the abdomen and the ventrolateral aspect of the thorax, caudal to the elbow.[53,61-63]

Hand Instruments

Scalpel blades, double-edged razor blades, and surgical straight razors are sometimes used to harvest small, split-thickness grafts from humans, but these types of dermatomes are of little use for harvesting skin grafts from horses, because they can be used to harvest only relatively small grafts and because their use requires considerable technical expertise to obtain a graft of consistent thickness.

Large grafts necessary to cover wounds of horses can be cut with a variety of knives designed specifically for harvesting skin. The Watson skin grafting knife, a modification of the

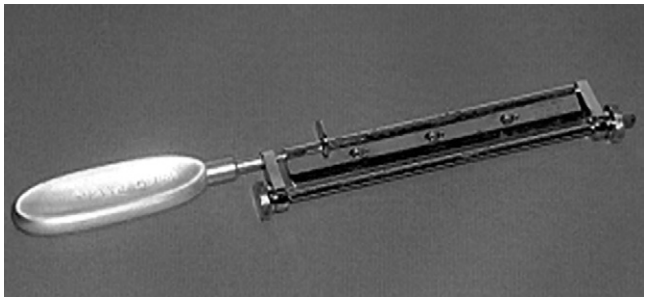

Figure 25-8. The Watson skin grafting knife. Using this dermatome, a surgeon can harvest a graft 100 mm (4 inches) wide. The knife uses disposable blades and is fitted with an adjustable roller in front of the blade to control the depth of the cut.

Braithwaite knife, can harvest a graft 100 mm (4 inches) wide, uses disposable blades, and is fitted with an adjustable roller in front of the blade to control the depth of the cut (Figure 25-8). Because the thickness of the graft is controlled by the adjustable roller, only a moderate amount of practice is required to develop the expertise necessary to achieve a uniform, split-thickness graft of the desired thickness. The position of the adjustable roller is controlled by a screw marked with calibrations at one end and a lock at the other. The thickness of graft represented by each calibration is learned by experience. The thickness of the graft depends not only on the position of the roller but also on the angle of incidence at which the skin is cut and on the pressure applied to the knife while cutting.[42] The heavier the pressure and the greater the angle of incidence, the thicker is the harvested skin.

Drum Dermatomes

A clinician with only minimal training can harvest a uniform section of skin with a drum dermatome.[2,15,23] The drum dermatome uses a knife that oscillates back and forth on a piston to precisely split the dermis of a section of skin that has been glued to the drum of the dermatome (Figure 25-9). The depth of cut is predetermined by the caliber of shims placed next to the blade.

The drum dermatome allows the surgeon to harvest a graft of the exact dimensions to fit the wound for which the graft is intended.[15] Using a template from the recipient site, glue is applied only to a similar area on the drum, so that as the drum is rotated, only that portion of skin that adheres to the drum is cut. The drum dermatome requires no external power source. It is considerably more expensive than a free-hand knife but not as expensive as power-driven dermatomes.[8] A major drawback to the use of the drum dermatome to harvest grafts for wounds of horses is that the length of the graft is limited by the circumference of the drum. An example of a drum dermatome is the Padgett Manual Dermatome (Z-PD-100R).

Power-Driven Dermatomes

Power-driven dermatomes use a rapidly oscillating blade, driven by an electric motor or gas turbine to harvest a split-thickness skin graft with predictable precision. The depth and width of cut can be adjusted precisely. Commonly used power-driven dermatomes are the Stryker electric dermatome and the Brown pneumatic or electric dermatome (Figure 25-10). The cutting

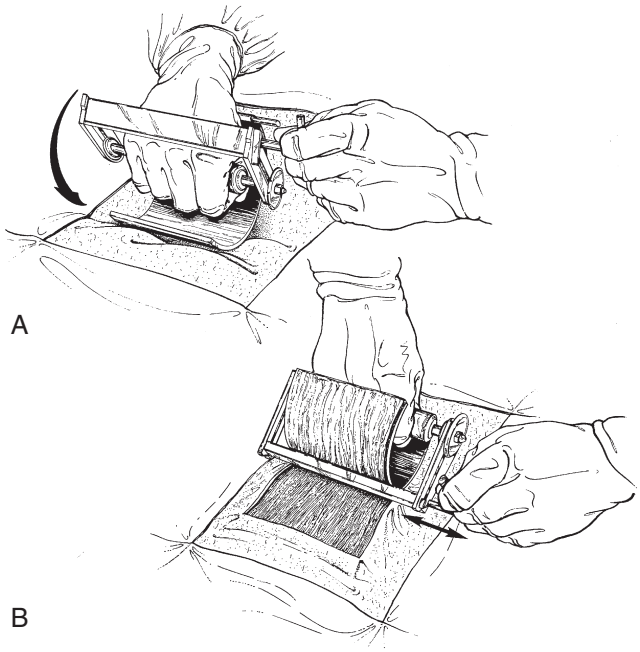

Figure 25-9. Harvesting a skin graft with a drum dermatome. **A,** Rotating the drum of a drum dermatome elevates skin to which it has been glued. **B,** The skin attached to the drum is cut at a precise depth with a knife that oscillates back and forth on a piston.

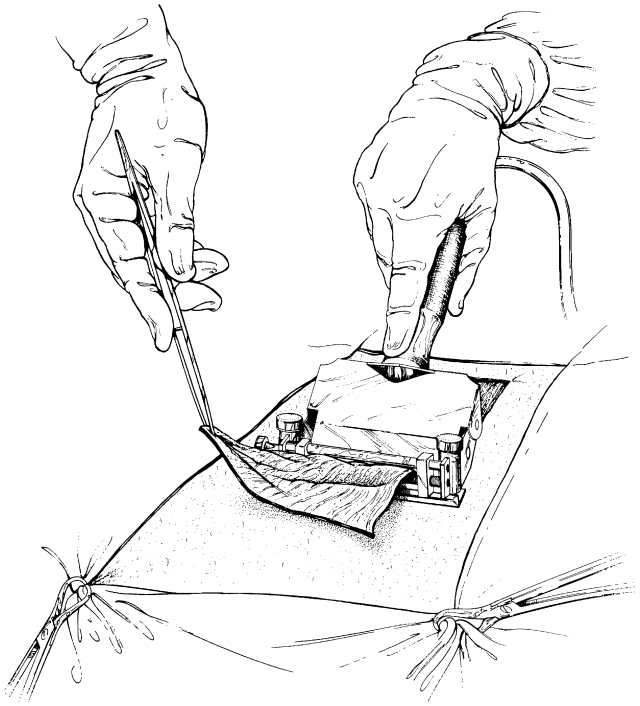

Figure 25-10. Harvesting a split-thickness skin graft with a pneumatic dermatome. Although they are expensive, power-driven dermatomes allow the cutting of very uniform grafts by minimally experienced operators.

head of a pneumatic dermatome oscillates more rapidly than that of an electric dermatome, making harvesting smoother.[23]

The Davol-Simon skin graft dermatome is a relatively inexpensive dermatome powered by a rechargeable handle, similar to the handle of an electric toothbrush.[17,18] A disposable, nonadjustable cutting head harvests a split-thickness skin graft 33 mm (1½ inches) wide and 0.38 mm (0.015 inch) thick. Grafts obtained with this skin graft dermatome are too thin to impart a cosmetic appearance to wounds of horses, but they may be useful for covering relatively small wounds when cosmetic appearance is not important.

Although a power-driven dermatome provides precision harvesting, the widest graft that can be harvested with many power dermatomes is only 76 mm (3 inches). A surface firmer than the ventral aspect of the abdomen, the least conspicuous donor site on the horse, is often necessary when harvesting with a power-driven dermatome. Although operating a power-driven dermatome requires only a minimum of experience, a power-driven dermatome requires skilled maintenance.[8] Because of their expense, power-driven dermatomes are found primarily only at large equine surgical referral centers.

An advantage of the free-hand knife over the power-driven dermatome is that consistently uniform grafts more than 100 mm wide (4 inches or greater) can be harvested using a free-hand knife. Grafts can be harvested from the ventral aspect of the abdomen with a free-hand knife, which is a difficult feat for a power-driven dermatome. A free-hand knife is far less expensive than a power-driven dermatome, requires less maintenance, has fewer parts to malfunction, and is easier to sterilize and to transport.

Technique of Harvesting a Split-Thickness Graft

A split-thickness skin graft can be harvested from any convex surface of the body, but the cosmetic appearance of the horse should be considered when selecting a donor site, because a split-thickness graft of acceptable durability and hair coverage cannot be obtained without creating a large epithelial scar at the donor site. Harvesting a split-thickness skin graft is painful to the horse and can be accomplished only when the horse is anesthetized.

To harvest skin from the ventral aspect of the horse's abdomen using a free-hand knife, the horse is positioned in lateral recumbency with its abdomen protruding beyond the edge of the table. The ventral portion of the abdomen must protrude over the edge of the table to accommodate the handle of the hand-held knife. The donor site is prepared for aseptic surgery, but draping is not necessary. Harvesting usually begins at the umbilicus and extends craniad. The donor site can be stabilized, if necessary, by assistants stretching the skin with towel clamps. The knife is applied to the skin at an acute angle of about 5 to 10 degrees, and the skin is cut using a regular sawing motion, concentrating on moving the blade back and forth, rather than pushing it forward (Figure 25-11). Lubricating the donor site with physiologic saline solution and the blade with a light coating of mineral oil reduces friction. Mineral oil does not adversely affect acceptance of the graft.[8,18] Slight, uniform tension should be applied to the cut end of the graft as the graft is harvested.

After several centimeters of graft have been cut, the graft and donor site should be inspected to ensure that the graft is the desired thickness before harvesting is continued. The thickness

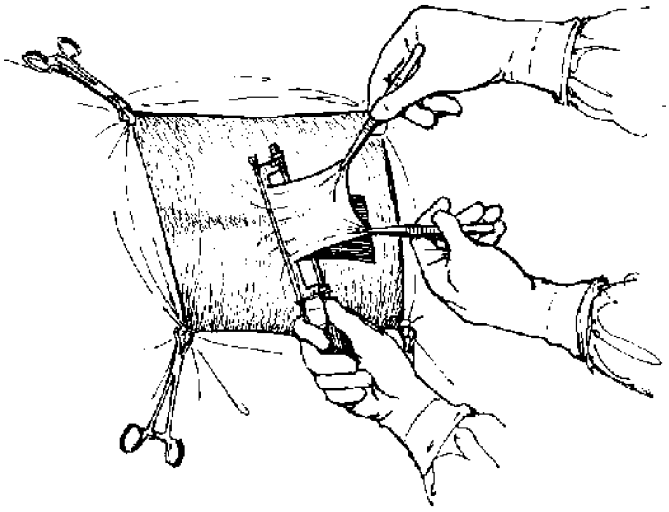

Figure 25-11. Harvesting split-thickness skin from the ventral aspect of the abdomen using a free-hand knife. The ventral portion of the abdomen must protrude over the edge of the table to accommodate the handle of the hand-held knife.

of the graft can be assessed subjectively by examining the graft for translucency and the donor site for the pattern of bleeding.[17,18] A shallow cut through the dermis produces a translucent graft and exposes many small bleeding vessels, whereas a deep cut produces a more opaque graft and exposes fewer but larger bleeding vessels. If subcutaneous fat is exposed, the graft is full-thickness and therefore much too thick. The depth of cut can be changed by repositioning the adjustable roller, by changing the pressure applied to the knife, or by raising or lowering the knife's angle of incidence. When the desired length of graft has been cut, the knife is tilted upward to sever the graft. If the graft is to be meshed and fully expanded, the length of graft should be considerably longer than the wound to which it is applied, because expanding the graft's width also shortens the graft's length.

The split-thickness graft is the most useful type of graft, because it can be used to cover defects too large to be covered by a full-thickness graft and because it survives more readily than does the full-thickness graft.[8,20,42,58] The cosmetic appearance of a wound healed by split-thickness skin grafting is inferior to that of a wound healed by full-thickness skin grafting, but it is superior to that of a wound healed by island grafting (see "Island Grafts," later). A split-thickness graft is less conveniently procured than a full-thickness graft because, to obtain a split-thickness graft, the horse must be anesthetized.

Meshing Sheet Grafts

A split-thickness or full-thickness sheet graft can be applied to a recipient bed as a solid or as a meshed sheet. A graft is meshed by uniformly fenestrating it manually with a scalpel blade or mechanically with a meshgraft dermatome. The primary reason for meshing a sheet graft is to allow the graft to uniformly cover a wound larger than the graft itself.[2,15,17,23,29,53,61-66] Grafts are also meshed to prevent serum, blood, or exudate from mechanically disrupting a newly applied graft from its delicate fibrinous and vascular attachments to the recipient bed. Fenestrations also enable a topically applied antimicrobial agent to contact a large

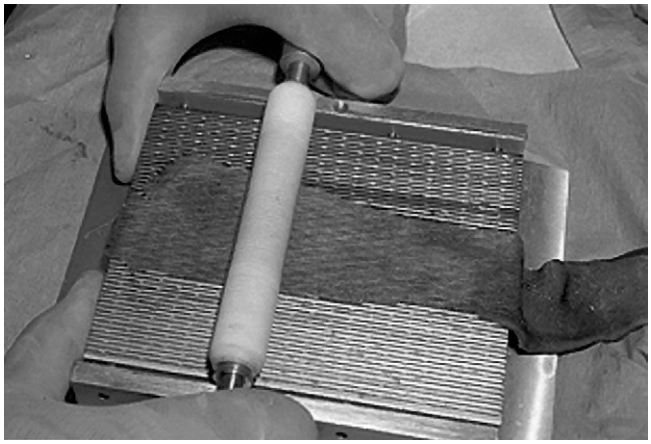

Figure 25-12. A Padgett mechanical skin mesher. The mesher consists of an aluminum block with staggered, parallel rows of blades and a Teflon rolling pin. The graft is positioned on the block, dermal side down, and pressed into the cutting blades with the rolling pin.

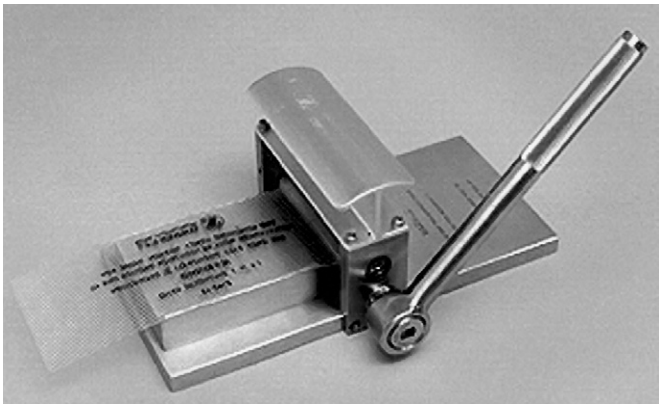

Figure 25-13. A Zimmer mechanical skin mesher. The mesher is capable of expanding the graft to many times its original area. The graft is positioned on a specially grooved plastic carrier, and the graft and carrier are fed through the mesh cutter by turning a hand crank.

portion of the recipient wound. A meshed graft conforms to an irregular surface better than does a nonmeshed graft, and its ability to expand allows it to better tolerate motion. Fenestrations in the graft fill with fibrin, which increases the graft's stability on the recipient bed.[38]

An example of a meshgraft dermatome is the Padgett mechanical skin mesher (Mesh Skin Graft Expander, No. Z-PD-170). This instrument consists of an aluminum block with staggered, parallel rows of blades and a Teflon rolling pin. The graft is positioned on the block, dermal side down, and pressed into the cutting blades, in the direction of the blades, with the rolling pin (Figure 25-12). The rolling pin should first be rolled lightly across the graft to secure the graft to the blades of the mesher and then firmly so that the blades pierce the graft. The staggered cuts produce a meshed pattern that allows the graft to be expanded to three times its original width.

The Zimmer mechanical skin mesher (Zimmer Meshgraft Dermatome) is a more elaborate and expensive meshing instrument, capable of expanding the graft to one and one-half, three, six, or nine times its original area. The graft is positioned dermal side down on a specially grooved plastic carrier selected according to the degree of expansion desired, and the graft and carrier are fed through the mesh cutter by turning a hand crank (Figure 25-13). The pattern engraved onto the plastic carrier determines the distance between cuts. The graft must be placed on the ridged surface of the carrier, because placing the graft on the smooth side of the carrier causes the graft to be shredded into spaghetti-like strips.

An important consideration when purchasing a meshgraft dermatome is the width of grafts routinely harvested with the skin-graft dermatome. Grafts up to 100 mm wide are harvested routinely with a free-hand skin graft knife, but a graft wider than 76 mm is difficult to mesh with a Zimmer mechanical skin mesher. Grafts up to about 110 mm wide can be fitted onto the cutting surface of the Padgett mechanical skin mesher. Although the Padgett mechanical skin mesher accommodates a graft only 13.5 cm (5.3 inches) long, a longer graft can be meshed in sections.

Full-thickness sheet grafts of horses are difficult to mesh on commercial meshing instruments and often must be meshed manually. Meshing a graft manually is tedious, especially if the graft is large or if it must be greatly expanded. The skin is fixed to a cutting board, such as sterile sheet of cardboard or Styrofoam, with the dermal side up, and after the subcutaneous fascia is removed staggered, parallel rows of incisions are created using a scalpel blade. The longer and the more numerous the incisions, the greater the expansion.

Figure 25-14. An expanded, meshed graft on the back of a foal. The graft has the appearance of chain-link fencing and uniformly exposes portions of the wound within the fenestrations. These exposed portions of the wound must heal by contraction and epithelialization.

An expanded, meshed graft has the appearance of chicken wire or chain-link fencing and uniformly exposes portions of the wound within the fenestrations (Figure 25-14). The amount of wound exposed within the fenestrations depends on the degree to which the graft is expanded. Portions of the wound covered by the graft heal primarily, but each portion of the wound exposed within the fenestrations must heal by contraction and epithelialization. The exposed portions of the wound epithelialize rapidly because of the enormous increase in the border of the graft from which epithelial cells migrate.[61,62] The epithelium that eventually covers the expanded fenestrations has no adnexa, causing the wound to heal with abundant, diamond-shaped epithelial scars. The more a graft is expanded at application, the more apparent are the diamond-shaped scars.[2,42,61,62] Greatly expanded grafts are difficult to apply, and

the greater the expansion, the longer the period of epithelialization. The size of the epithelial scars can be reduced by attaching the graft to the wound so that the fenestrations within the graft are parallel with the skin lines (i.e., parallel to the long axis of the limb).[63] The diamond-shaped epithelial scars within the grafted wound diminish in size as the grafted wound contracts.

Applying Sheet Grafts

Excess granulation tissue should be excised before the graft is harvested, to allow time for hemorrhage to stop before the graft is applied. Excising exuberant granulation tissue 24 hours in advance of grafting ensures hemostasis and provides time for budding capillaries to develop at the surface of the wound for rapid vascularization of the graft[47] (see "Preparation of the Recipient Site," earlier). If granulation tissue is not exuberant, the surface of the wound should be rubbed with a gauze sponge or gently scraped with a scalpel blade held 90 degrees to the wound, until serum exudes from the wound's surface.

The graft should be situated on the wound so that the direction of its hair growth conforms to that of the surrounding skin. A graft harvested with the horse anesthetized can be sutured or stapled to the wound's margin before the horse is allowed to recover from anesthesia. To avoid constant disturbance of the fibrin seal at the edge of the graft when securing the graft with sutures, the suture needle should pass from the graft to the surrounding skin, rather from the surrounding skin to the graft.[23] To suture or staple the graft to the wound's margin with the horse standing, the margin of the wound must first be desensitized using local or regional anesthesia. The graft can be fixed to the margin of the wound, with the horse standing, without using local or regional anesthesia, by overlapping and gluing the margin of the graft to the margin of the wound with cyanoacrylate glue (Superglue), provided that sufficient skin has been harvested to allow overlap of the graft (Figure 25-15). Applying the graft with the horse standing reduces the time of general anesthesia and eliminates the possibility of damage to the graft that may occur while the horse recovers from general anesthesia.

A graft need only be fixed to the wound's margin, because fibrin produced by the wound fixes the graft to the wound's surface within minutes after the graft is applied.[2,26] If the wound is large or is in an area that is difficult to immobilize, however, such as the dorsum of a fetlock, the graft can be further secured with simple interrupted sutures placed through the fenestrations in the meshed graft. To suture a graft to the bed of a fresh wound with the horse standing, the wound must first be desensitized with regional or local anesthesia. A graft can be sutured to granulation tissue with the horse standing without anesthesia because granulation tissue has no innervation (Figure 25-16). Sutures can be removed in 6 or 7 days when acceptance of the graft is certain. Catgut is convenient to use as a suture because it swells, causing the knot to loosen. If tied with a square knot, the suture can usually be removed by applying gentle traction to one end of the suture with a hemostat. Removing sutures in this fashion is easier than cutting the sutures.

Acceptance and Cosmesis

The thickness of a graft greatly influences its acceptance at the recipient wound.[8,17,20,23,27,28,58] The thinner the graft, the less

Figure 25-15. Attaching a graft to the margin of a wound, with the horse standing. The graft is attached by overlapping and attaching the margin of the graft to the margin of the wound with cyanoacrylate glue.

Figure 25-16. Suturing a graft to granulation tissue with the horse standing. Anesthesia is not necessary because granulation tissue has no innervation.

its metabolic demands and the less its demands for vascularity at the recipient bed. Blood vessels branch as they ascend the dermis, so the thinner the graft, the greater the number of exposed vessels. The greater the number of exposed vessels, the better the absorption of nutrients from the recipient wound and the more rapid revascularization from inosculation. The thinner the graft, the poorer its durability and cosmetic appearance.

Split-thickness grafts obtained from the hip, gaskin, or ventral aspect of the abdomen of horses that are 0.5 mm (0.020 inches) or less thick lack durability and have sparse or no hair coverage.[20] Split-thickness grafts harvested from these areas and from the ventrolateral aspect of the thorax that are between 0.63 mm (0.025 inches) and 0.76 mm (0.030 inch) thick have moderate to good piliation and good durability.[20,29] The thickness to which the graft should be harvested is a matter of judgment, because the thickness of the dermis varies between horses and between donor sites.[29] Although one of the aims of split-thickness grafting is to provide adequate piliation at both the donor and recipient sites, occasionally piliation is inadequate at either site.[56]

When donor skin is in short supply, such when a burn wound covers a large portion of the trunk, a "two-layer" technique of harvesting split-thickness grafts may provide sufficient skin to cover the wound. Using this technique, two thin split-thickness grafts are harvested from the same site. The first split-thickness graft is composed of the epidermis and a thin portion of the dermis. The second split-thickness graft, harvested from the same site, is composed only of dermis. Although the second is graft composed only of dermis, epithelialization proceeds from adnexa contained within to resurfaces the dermis.[67]

Island Grafts

An island graft is a small piece of full-thickness or split-thickness skin placed either into or onto a granulating wound.[68-70] Other names for this type of graft include implantation graft and seed graft.[3,4] Implanting island grafts into granulation tissue of horses, rather than applying them to the surface of the wound, avoids shearing forces between the graft and the bandage. The purpose of island grafting is to increase the area of epidermis from which epithelialization can proceed; consequently, wounds that receive island grafts heal primarily by epithelialization. Types of island grafts used to graft wounds of horses are the punch graft, the pinch graft, and the tunnel graft.

Punch Grafts

Punch grafts are small full-thickness plugs of skin that are harvested and implanted into granulation tissue using skin biopsy punches. Punch grafts can be taken directly from the horse or from an excised full-thickness sheet of skin.

Common donor sites for obtaining punch grafts directly from the horse are the ventrolateral aspect of the abdomen, the perineum, and the portion of the neck that lies beneath the mane. The donor site is clipped, scrubbed, and desensitized with a local anesthetic agent. The perineal area can be desensitized using caudal epidural anesthesia. Removing punch grafts directly from the horse with a skin biopsy punch creates small blemishes at the donor site (Figure 25-17). Therefore, the grafts should be harvested in a symmetrical pattern about 1 cm apart to improve cosmesis.[38] The small wounds created by the biopsy punch need not be closed, but suturing or stapling each wound may produce less-obvious blemishes.

Figure 25-17. Blemishes on a horse's neck created with a skin biopsy punch.

Subcutaneous fascia and fat should be sharply excised from each individual graft before it is implanted to facilitate plasmatic imbibition and re-vascularization.[71] Removing subcutaneous tissue from each small plug of skin is a tedious process. One method is to stretch the subcutaneous tissue between one thumb forceps grasping the top of the plug and another thumb forceps grasping the subcutaneous tissue. A second person excises the taut subcutaneous tissue from the dermis with scalpel blade. Another method is to excise subcutaneous tissue from the dermis while the cut disc remains attached to the horse. The biopsy punch is rotated until it penetrates the skin, and the graft is elevated, using thumb tissue forceps, to expose the attached subcutaneous tissue, which is excised from the dermis using a scalpel blade.[72]

Punch grafts can also be harvested from an elliptical, full-thickness sheet of skin, which is usually harvested from the cranial pectoral area, where the skin is relatively mobile.[1] A 10-cm–long by 4-cm–wide (4-inches–long by 1½-inches–wide) section of skin provides enough punch grafts to cover most wounds and allows easy primary closure of the donor site.[54] The section of skin is stretched and secured, epidermal side down, to a sterile piece of cardboard or Styrofoam or to a sterile polypropylene block. After all subcutaneous tissue is sharply excised from the section of skin, full-thickness plugs are cut from the skin using a 6- to 7-mm–diameter skin biopsy punch (Figure 25-18). The grafts are stored on a gauze sponge moistened with physiologic saline solution until they are implanted, and the wound created at the donor site is closed in one or two layers. Applying a stent bandage to the sutured wound decreases tension on the suture line.

Exuberant granulation tissue at the recipient site should be excised to the level of the margin of the wound 24 to 48 hours prior to grafting. The recipient holes in the granulation tissue should be created before the grafts are harvested to allow hemostasis to occur prior to implantation. The depth of the recipient holes should correspond to the thickness of the grafts to be inserted.[1] To avoid obscuring the wound with hemorrhage that occurs when the recipient holes are created, creation of the recipient holes should begin at the distal end and proceed proximad.[71] A cotton-tipped applicator inserted into

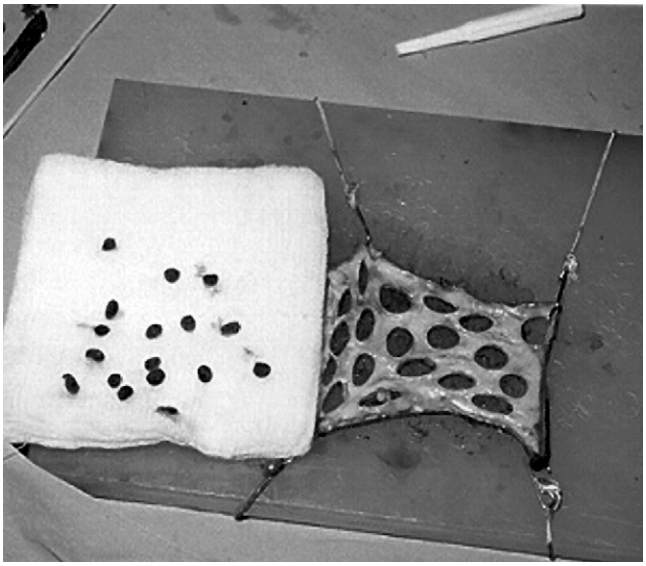

Figure 25-18. Punch grafts harvested from a full-thickness section of skin. The section of skin was obtained from the pectoral region. Full-thickness plugs are cut from the skin using a skin biopsy punch.

Figure 25-19. Cotton-tipped applicators inserted into recipient holes in a granulating wound. An applicator enables a hole to be located easily and prevents a blood clot from forming in the hole.

the recipient holes enables each hole to be located easily for insertion of a graft and prevents a blood clot from forming in the hole (Figure 25-19). Spraying the wound with phenylephrine before creating the recipient holes may improve visibility by decreasing hemorrhage. Creating the recipient holes hours in advance of implantation ensures a hemorrhage-free wound for grafting.[54] The holes should be placed about 6 mm (about ¼ inch) apart in a symmetrical pattern.[1]

The recipient holes are created with a slightly smaller biopsy punch than that used to harvest the grafts, to allow for contraction of the graft. For example, if the grafts are harvested with a 7-mm–diameter biopsy punch, the recipient holes should be

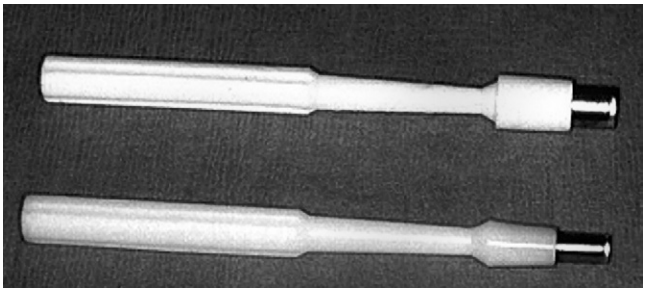

Figure 25-20. Skin biopsy punches used for harvesting punch grafts and for creating recipient holes. The recipient holes for punch grafts are created with a slightly smaller skin biopsy punch than that used to harvest the grafts. The larger punch is used to harvest punch grafts, and the smaller biopsy punch is used to create recipient holes.

created with a 5-mm biopsy punch (Figure 25-20). The grafts are inserted into recipient holes, and the grafted wound is covered with a non-adherent dressing and a bandage. Consideration can be given to the direction of the hair growth on the graft when the graft is inserted, but the cosmetic outcome may be little affected by properly orienting the direction of the hair.

The pigmented, superficial portions of the grafts frequently slough, exposing non-pigmented deeper layers. By 3 weeks, each plug of skin is surrounded by a red ring, which represents migrating epithelium.[1] Acceptance of the grafts is ensured if the grafts remain within the recipient hole.[38] Survival of 60% to 75% of the grafts is a realistic expectation.[54] The time required for the wound to completely epithelialize is inversely proportional to the amount of wound covered by viable plugs. Punch grafting requires no expensive or sophisticated equipment and little expertise, and the grafts are accepted into recipient beds that are unsuitable for sheet grafting.[1] Punch grafting can be performed with the horse standing, making this an inexpensive method of grafting wounds. Punch grafting is usually reserved for small wounds where cosmesis is not important. Wounds healed by punch grafting are covered primarily by an epithelial scar from which grow sparse tufts of divergent hair (Figure 25-21).

Pinch Grafts

Pinch grafts are small discs of skin, harvested by excising an elevated cone of skin, that are laid onto or implanted into granulation tissue.[26,49,55,68-70] The pinch graft is sometime referred to as a Reverdin graft.[70] The donor sites for obtaining pinch grafts from the horse are the same as described for punch grafts; small blemishes created at these donor sites are relatively inconspicuous. A disc of optimal size is approximately 3 mm in diameter, which approaches full thickness toward its center, but its thickness diminishes toward its periphery.[69]

Preparation of the donor site is identical to that described for punch grafts. A cone of skin is elevated using a tissue forceps, a suture needle, or a hypodermic needle with a bent point, and it is excised with a scalpel blade (Figure 25-22).[49,55,68-70] A No. 11 scalpel blade is most suited for excising the cone of skin. The grafts are stored on a gauze sponge moistened with physiologic saline solution until they are implanted.

The recipient site is prepared in the same way as for punch grafts. The recipient pockets can be created hours in advance of implantation to ensure a hemorrhage-free wound for grafting,

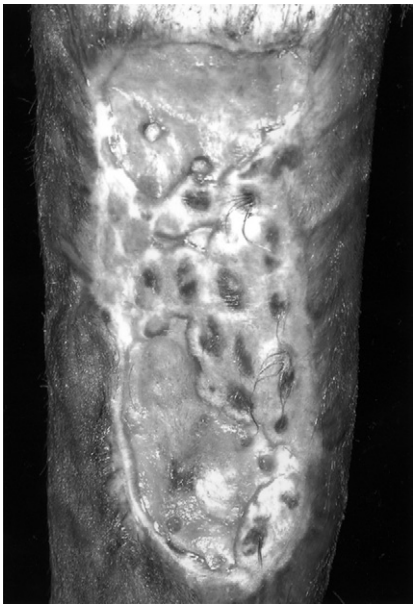

Figure 25-21. A nearly healed, punch-grafted wound. The nonpigmented tissue between the pigmented punch grafts is epithelium. This epithelium will eventually become pigmented.

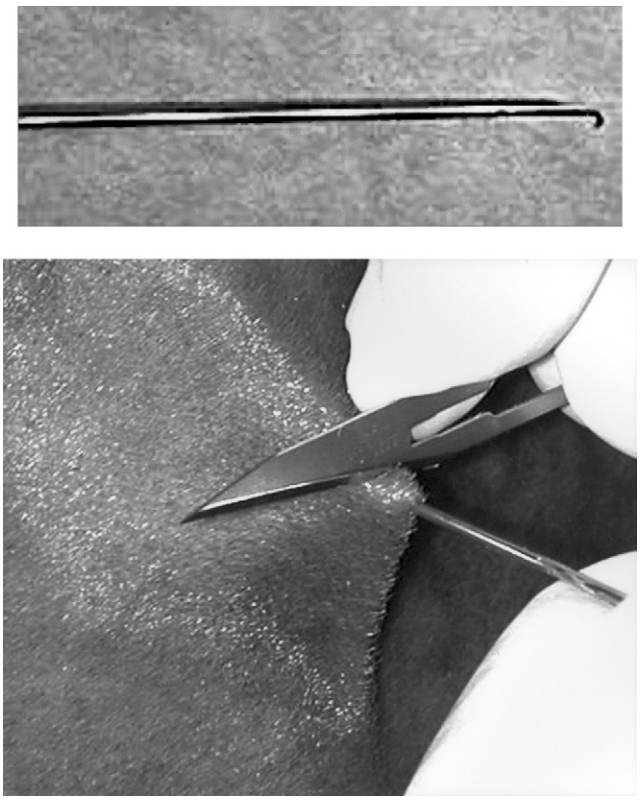

Figure 25-22. Harvesting a pinch graft. A cone of skin is elevated using a hypodermic needle with a bent point, and the elevated cone of skin is excised with a scalpel blade.

Figure 25-23. A wound covered with pinch grafts.

but locating the pockets after hemorrhage has ceased may be difficult.

To implant a graft, a No. 15 scalpel blade is stabbed into the granulation tissue of the recipient bed at an acute angle to create a shallow pocket into which the graft is inserted. Implantation should begin at the distal end and proceed proximad, because the pockets are obscured by hemorrhage after they are created. The grafts should be implanted about 3 to 5 mm apart.[69] Each graft is laid onto the wound, epidermal side up, proximal to the pocket, and slid into the pocket using a hypodermic needle, a straight suture needle, or the scalpel blade used to create the pocket. Consideration can be given to the direction of the hair growth on the graft when the graft is inserted, but the cosmetic outcome is little affected by properly orienting the direction of the hair. To speed implantation, three or more grafts can be laid onto the granulation tissue at once, each 15 to 20 mm (6 to 8 inches) proximal to its proposed site of implantation. Hydrostatic pressure prevents the grafts from falling from the wound. The surgeon creates a pocket distal to a graft and inserts the graft into the pocket using the same scalpel blade that was used to create the pocket. The surgeon can create and implant the pockets in rapid succession without looking away from the wound.

Wounds created at the donor site are left to heal by second intention or closed with a single suture or staple. The grafted wound is covered with a nonadherent dressing and a bandage.

The thin layer of granulation tissue covering each pinch graft usually sloughs between the first and second week after grafting.[69] Grafts initially appear as dark spots on the wound's surface (Figure 25-23), but frequently the superficial pigmented portion of the graft sloughs, causing the graft to appear as a white spot surrounded by pink granulation tissue. Within 3 weeks, each disc of skin is surrounded by a red ring, which represents migrating epithelium. Epithelium migrates from the margin of the wound, as well as from the margin of each graft, so that eventually the entire wound is covered with epithelium. Even under adverse conditions, one can expect at least 50% to 75% of the grafts to survive.[69]

Pinch grafting, like punch grafting, is a relatively inexpensive technique of grafting, because the procedure can be performed with the horse standing and because only basic instruments are required. Little expertise is necessary, and the grafts can survive in a granulation bed that is less than ideal.[3,68] Pinch grafting is tedious, however, and imparts a poor cosmetic appearance, because the wound is left covered by an epithelial scar from which grow sparse tufts of divergent hair.

Tunnel Grafts

Tunnel grafts are strips of split-thickness or full-thickness skin implanted into tunnels created in granulation tissue.[4,73,74] The grafts are exposed days later, when they have re-vascularized, by excising the overlying granulation tissue that forms the roof of the tunnel. Donor skin can be harvested from various sites on the horse, using various techniques, and implanted with the horse anesthetized or sedated.

Split-thickness or full-thickness strips of skin can be harvested conveniently from the portion of the neck that lies beneath the mane or the ventral aspect of the flank.[4,73,74] In preparation for harvesting strips of skin, linear wheals, 2 to 3 cm wide and slightly longer than the wound to be grafted, are created along the longitudinal axis of the donor site by subcutaneously injecting local anesthetic solution (or physiologic saline solution if the graft is to be harvested with the horse anesthetized).

A straight intestinal forceps is applied to the base of each wheal so that skin protrudes slightly above the jaws of the forceps.[4,73,74] If a strip of skin longer than the jaws of the forceps is required, two intestinal forceps are applied end-to-end to the base of the wheal. The thickness and width of the graft is determined by the amount of skin that protrudes above the jaws. The protruding skin is severed with a scalpel (Figure 25-24). If the excised strip of skin is full thickness, subcutaneous tissue should be removed from it to expose the dermis, and the wound at the donor site should be closed with staples or sutures. If the strip of skin is split thickness, the donor site can be closed or left open.

Full-thickness strips of skin can also be harvested from the neck or ventral portion of the abdomen by making a series of parallel incisions 2 mm apart.[74] Strips are excised, and subcutaneous tissue attached to the dermis is sharply excised. The donor sites are closed with sutures or staples. Split-thickness strips of skin can be cut from a split-thickness sheet of skin usually harvested from the ventral aspect of the abdomen or ventrolateral aspect of the thorax, using techniques previously described (see "Technique of Harvesting a Graft," earlier). The donor site of the split-thickness sheet graft heals by epithelialization.

To implant a strip of skin in the granulation bed, the end of a long, thin, rat-tooth alligator forceps is inserted into granulation tissue at the edge of the wound and advanced through the granulation tissue at a depth of about 5 or 6 mm until it emerges at the opposite margin of the wound.[4,74] One end of the graft is grasped in the jaws of the forceps, with the epidermis positioned toward the surface of the wound, and pulled through the tunnel. The grafts should be embedded at right angles to the convex surface of the wound to aid entry and exit of the forceps.[74] A wound that is not convex is more easily grafted if granulation tissue is allowed to proliferate so that it protrudes slightly above the margin of the wound.[4] The strips should be embedded about 2 cm apart.[74]

The strip of skin is embedded in two steps if the alligator forceps is not long enough to completely span the wound, or if the wound is too convex for the alligator forceps to completely span it.[4,73,74] In either case, the forceps is advanced through the granulation tissue as far as possible and exited, one end of the graft is grasped, and the forceps is pulled back through the tunnel, with the graft in tow (Figure 25-25). The

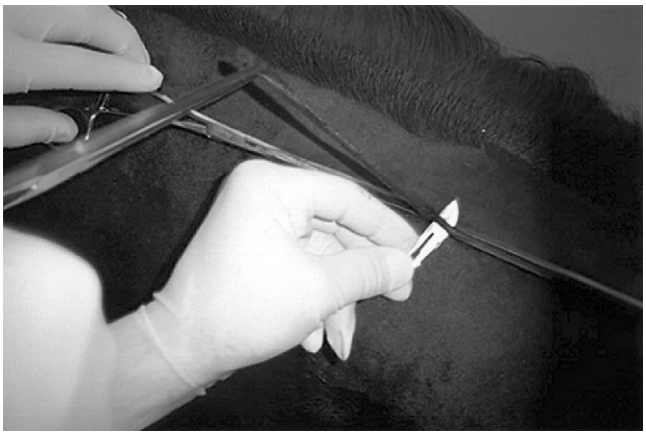

Figure 25-24. Harvesting a tunnel graft. One or two straight intestinal forceps are applied to the skin, so that skin protrudes slightly above the jaws of the forceps. The protruding skin is severed with a scalpel.

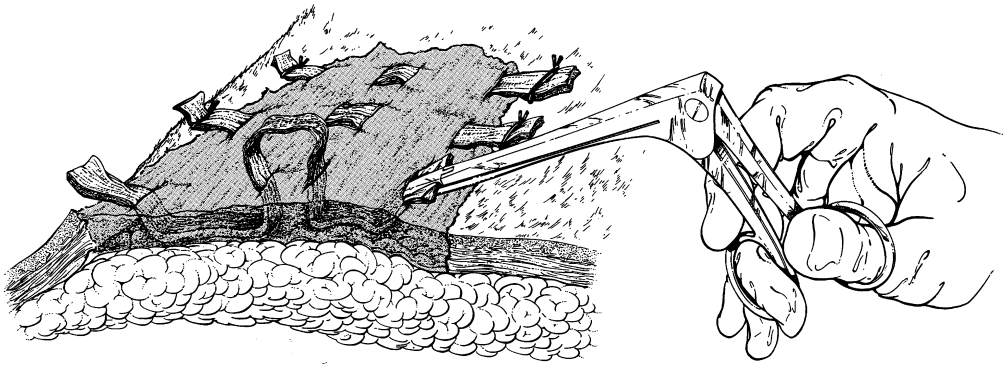

Figure 25-25. Implanting a tunnel graft using an alligator forceps. The strip of skin is embedded in two steps if the forceps is not long enough to completely span the wound.

end of the forceps is reinserted into the granulation bed at the opposite margin of the wound and advanced beneath the surface of the granulation tissue until it emerges at the site of exit of the graft. The end of the graft is grasped in the jaws of the forceps, and the forceps, with graft in tow, is pulled back through the second tunnel.

The graft can also be embedded by positioning the strip of skin onto a strip of adhesive tape, with the epidermis next to the tape.[73] The purpose of the adhesive tape is to prevent the edges of the strip from folding inward and to act as a guide when the grafts are later exposed. The tape should extend 5 cm beyond one end of the strip, and excess tape at this end is folded over the skin so that about 1 cm of the end of the strip is covered by tape. Excess tape along the graft's margin is trimmed with scissors. The tape-covered end of the graft is fitted through the eye of a 10- to 12-cm (4- to 5-inch) cutting needle with a flat curve, and the graft–tape composite is implanted by advancing the needle beneath the surface of the granulation bed. If the needle is not long enough to span the wound completely, or if the wound is too convex for the needle to completely span it, the needle is advanced beneath the bed as far as possible, exited, and reentered at the point of exit for a second bite. Another method of creating the strips of graft and tape is to lay a sheet of split- or full-thickness skin, epidermal side down, onto the sticky side of a similarly sized sheet of adhesive tape; strips of skin and tape are cut from this composite.[54]

The exposed ends of the embedded strips are attached to the margin of the wound with a suture, staple, or cyanoacrylate glue, and the wound is covered with a non-adherent dressing and a pressure wrap. Six to 10 days after grafting, the roof of each tunnel is removed, with the horse sedated or anesthetized, to expose the grafts, and if necessary, to remove adhesive tape.[4,73,74]

To remove the roof of a tunnel, a smooth, malleable probe is inserted into the tunnel superficial to the graft, and a V-shaped strip of granulation tissue is carefully excised over the probe with a scalpel blade to expose the graft. The roof of each tunnel can also be sawed off using a twisted doubled piece of fine wire threaded through the tunnel.[73] Accidentally removing a graft while attempting to expose it or failure to locate buried grafts can detract from the success of tunnel grafting.[74] These complications can best be avoided by applying a tourniquet proximal to the wound to enhance visibility or by exposing the grafts with the horse anesthetized. Placing the grafts closer than 2 cm apart may affect the viability of granulation tissue surrounding the grafts. About 60% to 80% acceptance of the strips can be expected.[73,74]

Tunnel grafting is recommended primarily for wounds located in areas where immobilizing other types of grafts would be difficult, such as the dorsal aspect of the hock.[73,74] Tunnel grafts are unaffected by movement in highly mobile areas, because the grafts are circumferentially encompassed and immobilized by granulation tissue. Tunnel grafting does not require expensive equipment and can be performed with the horse standing, but the technique requires the presence of a granulation bed, and aspects of this technique, especially removing the top of the tunnels, make tunnel grafting relatively tedious. The tedious job of removing the granulation tissue over the graft may not be necessary; however, if the graft is embedded so that only 1 to 1.5 mm of granulation tissue covers the graft. The shallow covering of granulation tissue sloughs, usually within a week, exposing the graft.

Modified Meek Grafting Technique

The modified Meek technique of skin grafting is a combination of island grafting and split-thickness sheet grafting.[30] Using this technique, 3-mm^2 islands of split-thickness skin, or micrografts, are applied to the surface of the wound. The technique is particularly useful for grafting large wounds because the donor skin can be expanded more with micrografts than with meshed sheet grafts.[75] This technique of grafting is particularly useful when the donor skin is in short supply, as may be the case for horses with extensive burns.

Meek micrografting equipment consists of a frame, a cutting block, and a pneumatic or hand-driven motor. A split-thickness section of skin of the desired thickness is harvested with the horse anesthetized (see "Split-Thickness Sheet Grafting," earlier) and the split-thickness graft is placed, dermal side down, onto a 42 × 42 mm cork plate and trimmed to the size of the plate. The cork plate, containing the graft, is placed onto a cork holder, which is placed in a cutting block (Figure 25-26). The cork, covered with graft, is then passed through a machine that contains 13 rotating, circular blades that cut the graft, but not the cork, into 14 3-mm wide strips (Figure 25-27). The cork and

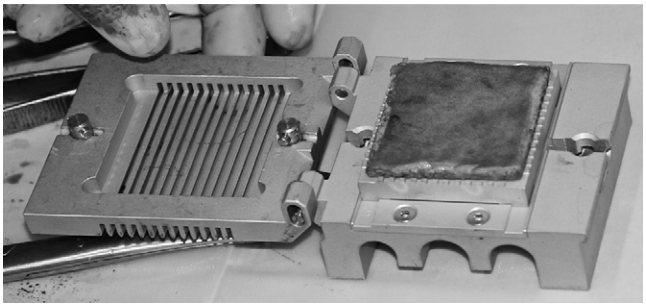

Figure 25-26. To obtain Meek micrografts, a split-thickness graft is placed with the dermal side down, on a cork template and trimmed exactly to fit the template. The cork template with graft is placed on a cork holder, which is then placed in the cutting block. (Courtesy Jacintha Wilmink, Woumarec, Wageningen, NL.)

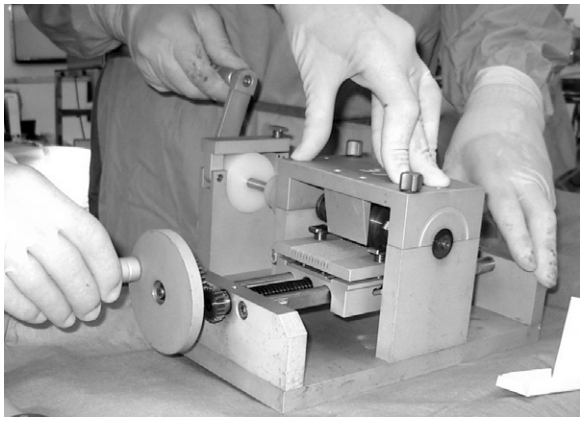

Figure 25-27. A Meek micrograft machine shown with a hand-drive (a machine with pneumatic motor for turning the knives is also available). The cutting block with the cork template and graft are passed through the Meek micrograft machine, which contains 13 circular knives that cut the graft into 14 3-mm wide strips. The cork holder is rotated 90 degrees and replaced onto the cutting block, and by passing it through the machine again, the strips of graft are cut into 196 (14 × 14) 3 × 3 mm micrografts. (Courtesy Jacintha Wilmink, Woumarec, Wageningen, NL.)

graft are rotated 90 degrees, replaced onto the cutting block, and again passed through the machine, which cuts the strips of graft into 196 (14 × 14) 3 × 3 mm grafts.

The epidermal surface of the graft is sprayed with an adhesive, which is allowed to dry until it becomes tacky. The cork plate, covered with graft, is pressed onto a pleated polyamide gauze backed by aluminum foil, which when unfolded expands the graft in a ratio of 1:3, 1:4, 1:6, or 1:9 (Figure 25-28). A pleated gauze with the smallest expansion ratio (1:3) is used for grafting most wounds of horses because most horses have an abundant amount of skin available for harvesting. The cork is carefully removed, leaving the postage stamp–sized islands of graft on the gauze. The pleats are unfolded, separating the grafts at a set uniform distance, by applying traction to all of its four sides (see Figure 25-28), and the supporting aluminum backing is peeled off and discarded, leaving the expanded gauze with the separated islands of graft. The expanded gauze to which the grafts are attached is trimmed appropriately, applied graft side down to the wound, and secured to the margin of the wound with staples or sutures (Figure 25-29). The grafted wound is covered with a bandage or a cast. The gauze can be removed after about 6 days, when the grafts have become attached to the wound.

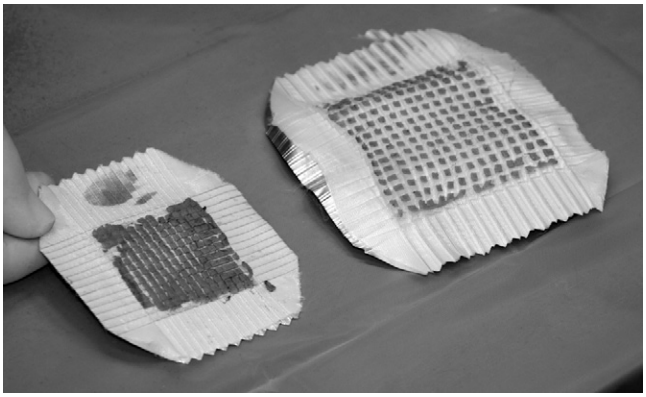

Figure 25-28. *Left,* The epidermal side of the Meek micrografts was sprayed with an adhesive, and the graft was glued to a prefolded pleated polyamide gauze (e.g., plissé), after which the cork template was removed. *Right,* The plissé was unfolded in two directions, separating the Meek micrografts at set uniform distances. (Courtesy Jacintha Wilmink, Woumarec, Wageningen, NL.)

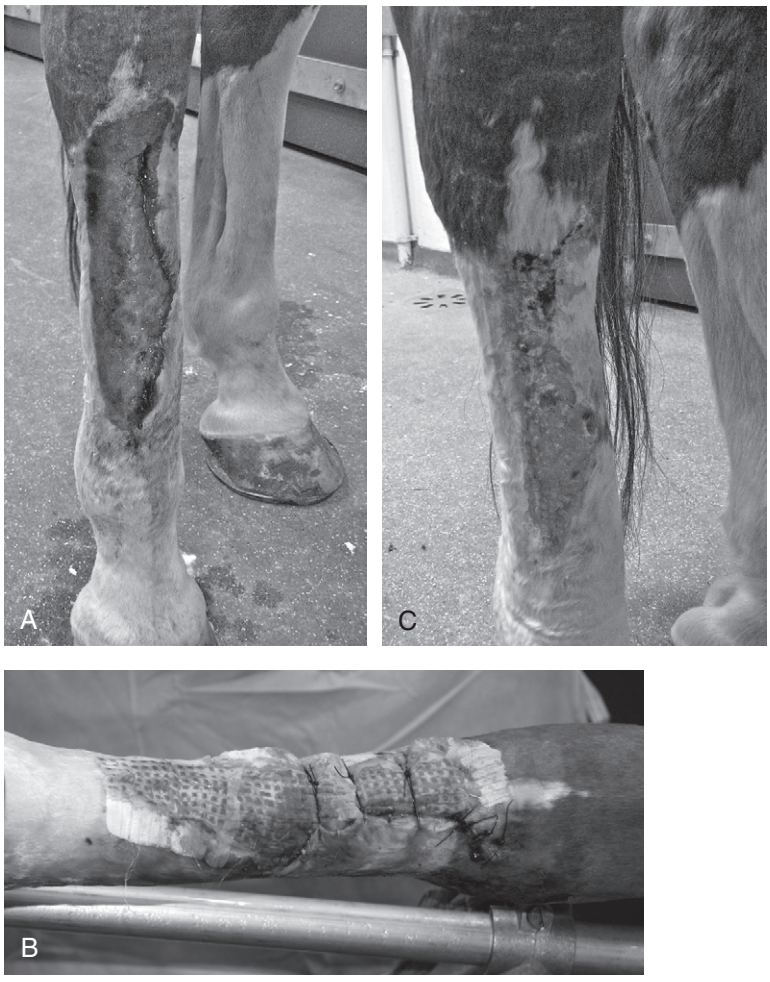

Figure 25-29. A, A large chronic wound at the time of admission. The horse was caught in a fence several weeks earlier and acquired a large loose skin flap on the medial side of the metatarsus; **B,** One month later grafting was performed on the prepared wound. The expanded gauze with Meek micrografts was applied to the wound, and the gauze was trimmed to the size of the wound and secured with staples and sutures. The loose skin flap that was retracted was mobilized and secured with three big sutures to the lateral wound margin; **C,** The same horse 1 month later. Nearly all micrografts are accepted, and the wound is almost healed. (Courtesy Jacintha Wilmink, Woumarec, Wageningen, NL.)

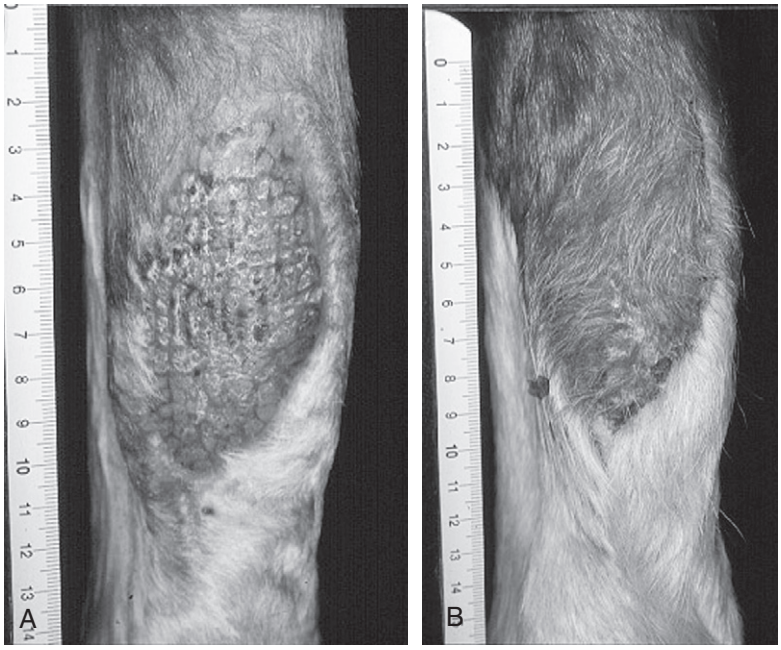

Figure 25-30. A, A nonhealing wound on the palmar aspect of a metatarsus is almost healed after receiving Meek micrografts 24 days earlier. The original square Meek micrografts from which epithelialization proceeds can still be seen. Only tiny areas remain to be epithelialized. **B,** Five months after grafting, the grafted site is covered with hair the same color as that at the donor site. The hair coat is somewhat sparser than the surroundings because the newly formed epithelium between the micrografts does not produce hair. (Courtesy Jacintha Wilmink, Woumarec, Wageningen, NL.)

As the wound contracts, the distance between the grafts decreases. Most wounds that receive Meek micrografts are healed within a month, regardless of the wound's size and location.[30] Hair growth is regular, but thinner and longer than normal (Figure 25-30).

The modified Meek technique of skin grafting provides uniform distribution of properly oriented islands of split-thickness skin. Detachment of one Meek micrograft, such as from infection or movement has no direct effect on surrounding micrografts because the micrografts are not connected to each other. Detachment of a portion of a sheet graft, on the other hand, may propagate into other areas of the graft, resulting in complete loss of the graft.[30,75,76] Meek micrografts are, therefore, more easily accepted by poor-quality wounds than are sheet grafts and can be applied with greater ease and in a higher concentration than can other types of island grafts, such as pinch, punch, or tunnel grafts. Acceptance of Meek micrografts in horses appears to be consistently better than what can be achieved using other techniques of skin grafting, and in one study, acceptance approached 95%.[30]

A disadvantage of the modified Meek micrografting technique over other methods of island grafting is that the horse must be anesthetized to harvest the split-thickness donor skin. Equipment to harvest the split-thickness skin and the micrografting machine are relatively expensive but no more so than much of the mechanized equipment available for harvesting and meshing sheet grafts.

AFTERCARE OF THE DONOR SITE

The donor site of a split-thickness graft retains a portion of the dermis and is comparable to a deep abrasion.[15,18,29] Blood and fibrin form a scab over the abrasion, and beneath this scab, epithelial cells from the wound's edge and epithelial cells produced by adnexa in the remaining dermis migrate to cover the surface of the abrasion. The wound at the donor site is usually covered by epithelium within 1 to 3 weeks, depending on the depth of the cut (Figure 25-31).[20,62] The new pink epithelium covering the donor site begins to develop pigment within a month after it forms, causing the epithelial scar to become black. The quantity of adnexa is greatest in the upper layers of the dermis, and consequently, healing of the donor site proceeds more quickly when a thin skin graft is harvested.[15,20] When grafts between 0.63 mm and 0.76 mm thick are harvested from the horse, the donor site heals with a noticeable epithelial scar.[20,61]

Figure 25-31. The donor site of a split-thickness graft 2 weeks after the graft was harvested. The donor site is nearly covered by epithelium. The new, pink epithelium will begin to develop pigment within a month, causing the epithelial scar to become black.

Pain caused by exposure of nerves at the donor site of a split-thickness graft can be reduced by bandaging the donor site,[15] but split-thickness grafts of horses are virtually always taken from an area that is difficult to bandage. Pain can be decreased by covering the donor site with fine-mesh gauze or a biological bandage, such as a stored allograft or xenograft (see "Allografts and Xenografts" and "Storage of Grafts," later). The gauze or biological bandage falls off when the donor site is completely

epithelialized. An uncovered donor site develops a scab, and this scab should not be removed. Any attempt to remove the scab is met with violent resistance from the horse, and its removal interferes with epithelialization that proceeds beneath it. An analgesic drug, such as phenylbutazone, should be administered before the graft is harvested and for at least several days after surgery.

AFTERCARE OF THE RECIPIENT SITE

The grafted wound should be covered with a sterile, nonadherent dressing, such as cotton nonadherent film dressing (Telfa Sterile Pads), rayon polyethylene dressing (Release), or petrolatum-impregnated gauze dressing (Adaptic). Petrolatum-impregnated gauze dressings can be prepared by steam-autoclaving a container filled with gauze sponges topped with a dollop of petrolatum. The petroleum impregnates the gauze as it melts. The wide weave of a gauze sponge, however, makes the sponge more likely to adhere to the grafted wound than would a commercially available petrolatum-impregnated gauze dressing with a close weave.

The primary dressing is secured to the grafted wound with sterile elastic, conforming, rolled gauze. If the grafted wound is in an area that is difficult to immobilize, such as the dorsal aspect of the hock, securing the primary dressing with staples[38] or with elastic adhesive tape, rather than rolled gauze, may help to decrease shearing forces between the graft and the bandage. The secondary layer of the bandage should be bulky, to decrease motion of the limb, and absorbent, to wick bacteria and destructive enzymes from the grafted wound. Immobilizing the limb with a cast is usually not necessary unless the grafted wound is located in a highly mobile area, such as the dorsum of the fetlock. A splint or a Robert Jones bandage applied to the limb usually immobilizes the grafted wound sufficiently.

The bandage should not be changed for 4 or 5 days after grafting, unless virulent nosocomial infections are a common problem in the hospital, because changing the bandage may disturb the graft's delicate attachment to the wound. If such infections are a common problem in the hospital, however, the bandage should be changed daily, or even twice daily, for at least 5 days. Changing the bandage daily allows exudate, which contains destructive enzymes, to be removed from the wound, and it allows application of an appropriate antimicrobial drug to the wound. Complete loss of a sheet graft, from infection or motion, later than 5 days after grafting is uncommon.[38] Streptococci or pseudomonads can quickly destroy a recently applied graft (Figure 25-32), so prompt recognition of infection and application of an appropriate antimicrobial drug to the grafted wound are necessary. Infection caused by a *Pseudomonas* species is characterized by the presence a bluish-green exudate on the surface of the wound and an odor similar to that of grape juice. Exudate that develops on a grafted wound should be cultured for bacterial growth, and isolates should be tested for antimicrobial susceptibility. Until the results are known, a broad-spectrum antimicrobial agent, effective against both β-hemolytic streptococcus and *Pseudomonas,* such as a combination of ticarcillin disodium and clavulanate potassium,[50] should be applied topically to the wound.

If the limb has been immobilized in a cast, and if nosocomial infection from streptococci or pseudomonads is a common problem in the hospital, an antimicrobial drug should be applied periodically to the wound through an infusion tube fixed to the grafted wound and exited through the top of the cast. A serviceable infusion tube can be prepared from silicone tubing by sealing its distal end and perforating it (with a 25-gauge needle) in multiple places along the portion that lies adjacent to the wound.

Figure 25-32. A recently applied graft destroyed by streptococcal infection.

Even a docile horse should be heavily sedated during the initial bandage changes to help avoid movement that may disturb the delicate vascular connections forming between the recipient bed and the graft. Adherence of the primary dressing to the grafted wound by fibrin that exudes through a meshed graft usually indicates that the graft is well adhered to the wound by a fibrin seal. Soaking the primary dressing with physiologic saline solution may ease removal of the dressing. The dressing should be removed by grasping it at one end and pulling it parallel to the wound; pulling the dressing perpendicular to the wound places more traction on the graft. If the primary dressing cannot be removed easily, it should be left in place.

Exuberant granulation tissue that inhibits epithelial migration may grow through the latticework of a meshed graft, especially if the graft was applied to the wound fully expanded. A corticosteroid applied to the grafted wound causes the exuberant granulation tissue within the graft to regress, allowing epithelial migration to proceed, even if at a slower than normal pace.[29,77-79]

Ideally, grafted wounds on limbs should be protected by a bandage until epithelialization is complete. If bandaging becomes impractical before epithelialization is complete, small, nonepithelialized areas within the grafted wound can be allowed to heal beneath a scab, which soon forms when the wound is left exposed.

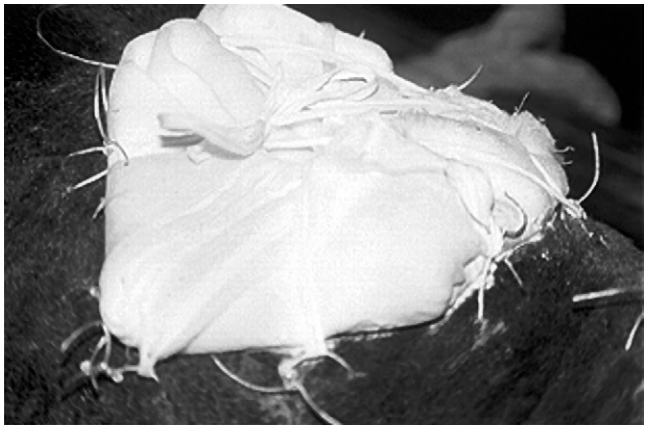

Figure 25-33. A stent bandage applied to a grafted wound on the back of a horse. A grafted wound in an area that is difficult to wrap can be protected with a stent bandage. To apply a stent bandage, the grafted wound is covered with a nonadherent dressing followed by a bolus of gauze. Long ends of interrupted sutures, preplaced around the margin of the grafted wound, are tied tightly over the bolus.

A grafted wound in an area that is difficult to wrap, such as the abdomen or thorax, can be protected with a "tie-over" bolus dressing, sometimes referred to as a stent bandage.[4,29,71] To apply a stent bandage, the grafted wound is covered with a nonadherent dressing followed by a bolus of gauze. Long ends of interrupted sutures, preplaced around the margin of the grafted wound, are tied tightly over the bolus (Figure 25-33).

Pressure on a graft from a bandage is not necessary for the graft to be accepted, so, for areas that are difficult to bandage or for wounds that are chronically plagued with infection, the grafted wound can be left uncovered.[2,23] "Open" grafting avoids shearing forces imposed by a bandage and avoids maceration of the graft by allowing constant drainage of exudate. To successfully employ open grafting, precautions, such as tying the horse or applying a neck cradle, must be taken to prevent the horse from disturbing the exposed graft.

Some horses probably suffer from hyperesthesia at the grafted wound, so when bandaging is discontinued, temporarily applying a neck cradle or tying the horse may be prudent to prevent the horse from mutilating its grafted wound. Drying and scaling of the healed donor and recipient sites of a split-thickness graft, caused by reduced concentration of eccrine glands, can be lessened by periodically applying an ointment containing lanolin until enough glands regenerate that scaling is no longer a problem.[8]

ALLOGRAFTS AND XENOGRAFTS

Cutaneous allografts (i.e., skin grafts taken from one animal and transplanted to another of the same species) or cutaneous xenografts (i.e., skin grafts taken from one animal and transplanted to another of a different species) can be used as a biological dressing on wounds of horses. Cutaneous allografts and xenografts, usually pigskin, have been used extensively since the middle of the 19th century to temporarily dress large wounds on humans. Although xenografts have been used to dress wounds of horses,[12,13,80,81] the use of cadaveric, cutaneous allografts to dress their wounds has only recently been investigated.[14] Viable cutaneous allografts can be obtained from refrigerated cadavers 24 hours or longer after death.[82] Allografts applied to wounds of horses seem to survive between 2 and 3 weeks, but the length of survival can be difficult to determine, because even when the superficial portion of the graft appears to be desiccated, the deeper portion of the graft may still be viable and attached to the recipient wound by strong vascular connections.

A cutaneous allograft or xenograft can be used to temporarily cover a wound if autografting is physically unfeasible or economically impractical. An allograft or xenograft encourages healing by promoting epithelialization and angiogenesis at the recipient bed.[83] The allograft or xenograft also retards formation of exuberant granulation tissue and acts as a bacterial barrier to protect the wound from infection.[12,80,82] A cutaneous allograft or xenograft revascularizes, and this vascularization may explain, at least in part, the ability of the cutaneous allograft or xenograft to resist infection.[11] Acceptance of a graft is not essential for bacterial destruction, however, because bacterial colonization decreases even beneath nonviable grafts, perhaps because the fibrin that forms between the graft and the wound enhances phagocytosis.[12,13,15,39,84] Adherence of an allograft or xenograft to a wound is a useful indicator that the wound is sufficiently healthy to accept an autograft.

The use of cutaneous porcine xenografting in humans arose from the need for a substitute for allografts as a biological dressing because of the short supply of cadaveric skin, but clinical comparisons in humans have shown that cutaneous porcine xenografts are inferior to cutaneous allografts.[11] Cutaneous porcine xenografts are more poorly adhered than allografts, allow higher bacterial counts in the wound, and cause a more intense immunological rejection.

STORAGE OF GRAFTS

Autografts or allografts can be applied successfully to wounds after being stored for several weeks at refrigeration temperature, in gauze that has been soaked in either physiologic saline solution or lactated Ringer's solution.[8,17,23] Skin can be stored in a refrigerator in a nutrient medium, such as McCoy's 5A Medium to which serum has been added, for much longer periods.[82,85-87]

McCoy's 5A Medium is a tissue-culture medium composed of a balanced electrolyte solution to which amino acids, vitamins, dextrose, and a pH indicator (phenol red) have been added. Adding vitamins, amino acids, dextrose, and serum to the electrolyte solution greatly extends the time that a graft can be stored. Skin from humans has been stored successfully in refrigerated nutrient media for 6 to 8 weeks.[82,85] Wounds of horses have been grafted using split-thickness skin grafts refrigerated at 4° C in a solution of McCoy's 5A Medium and horse serum for 3 weeks, with consistently successful results,[87] and wounds of some horses have been grafted successfully using skin stored for as long as 12 weeks.

The concentration of serum in the storage medium should be between 10% and 33%.[88] A concentration of serum greater than 33% stimulates the metabolic activity of the graft. Antigenic reaction of the serum to the graft is avoided by using a commercially available antibody-free serum (GG-Free Horse Serum), pooled homologous serum, or the horse's own serum.[85] The stored grafts should be allowed access to air.[82]

To prepare a meshed split-thickness skin graft for storage, the graft is laid on a sterile gauze swab or gauze dressing, with the epidermis of the graft next to the gauze. The gauze–graft

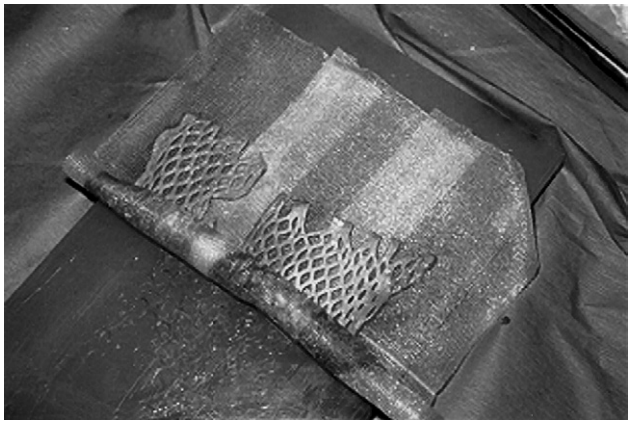

Figure 25-34. Preparing the graft for storage. The gauze–graft composite is rolled up, with the gauze to the outside of the roll.

Figure 25-35. Storing the graft. The gauze-graft composite is stored, in a refrigerator, in a sterile container containing McCoy's 5A Medium to which horse serum has been added.

composite is rolled up, with the gauze to the outside of the roll (Figure 25-34), and placed in a sterile container containing approximately 1 to 2.5 mL of the storage medium for each square centimeter of stored graft[85,88] (Figure 25-35). The storage medium should be examined occasionally for a color change brought about by a change in pH. A color change in the McCoy's 5A Medium from cherry-red to orange-yellow indicates excessive accumulation of catabolites and the need for immediate application of the graft or replacement of the medium. Only half of the volume of medium should be replaced, because total replacement affects the graft deleteriously.[85]

A split-thickness skin graft, harvested while the horse is anesthetized for treatment of a wound, such as removal of a bone sequestrum, can be stored until the wound's condition has improved enough to permit grafting.[23,89,90] A graft can be stored for delayed grafting of an excisional defect accompanied by excessive hemorrhage. Storing the graft, so that it can be applied with the horse standing, shortens the anesthetic period and eliminates the risk of the graft's being disturbed during recovery. A stored graft is often more readily accepted than a fresh graft, because grafts stored for 24 hours or more release anaerobic metabolites that stimulate rapid revascularization of the graft.[47,91] For this reason, a stored graft is sometimes referred to as a "prepared graft."

A stored graft is useful for covering a defect created when all or a portion of a primary graft sloughs, and for this reason, harvesting more skin than is required to cover a wound is often prudent, especially when grafting has a greater than usual possibility of failure. A stored graft not required for autografting can be used as a biological dressing for a wound of another horse, when circumstances permit.

CHAPTER
26 Management of Superficial Wounds

Dean A. Hendrickson

The skin is the largest organ in the body and is very adaptable to the environment. The main functions of the skin are to protect against wear and bacterial invasion, to aid in thermal regulation, and to prevent water loss.[1,2]

ANATOMY

The anatomy of the equine skin was first completely described by Talukdar and colleagues in 1972.[3] Using normal horses of ages 2 to 17 years, they collected skin from 49 different areas. The average skin thickness of the body skin was 3.8 mm, the skin near body openings 3.3 mm, and the skin at the main and tail 6.2 mm. Skin was thicker in older geldings than in younger horses and at the extensor surface of the legs than at the flexor surface of the legs. In general, the skin of the horse is thicker than that of swine, goats, and sheep; thinner than that of beef cattle; and similar in thickness to that of dairy cattle.[3]

The epidermis is composed of four layers: the stratum basale, stratum spinosum, stratum granulosum, and stratum corneum (Figure 26-1). The stratum corneum slows water loss and functions as a barrier to harmful substances. Other cells found in the epidermis include melanocytes for production of melanin, Merkel cells for mechanoreception of light touch, and Langerhans' cells to help fight infection by engulfing foreign material. The dermis is separated into two layers, the superficial papillary layer and the deep reticular layer, and it provides support for the epidermis. The dermis in the lumbar, sacral, and gluteal regions has a third layer of collagenous fibers. The dermis also contains a rich vascular network that supplies the skin with a continuous blood supply. The vascular system is very important in temperature regulation, access of nutrients to the skin, absorption of topical medications, delivery of systemic medications, and the healing of wounds (see Chapter 5). The main vascular supply comes from the subcutaneous area. In the thinner-skinned areas, and the hair angle is more acute. The hair follicles in the general skin areas where the hair length changes with the season are shorter than the hair follicles in the areas of mane and tail. In most cases, two sebaceous glands are associated with each hair follicle. The sweat glands are apocrine.[2,3] The hairs are surrounded by nerves that provide sensation by responding to pressure on the hair shaft. The primary nerve supply comes from the subcutaneous region.

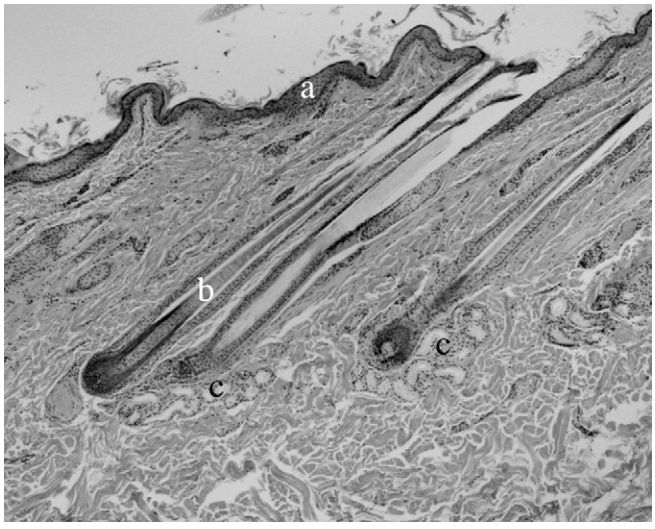

Figure 26-1. Photomicrograph of normal equine skin epidermis *(a)*, hair shaft and follicle *(b)*, and sweat glands *(c)*.

Cleavage lines (Langer's lines of tension, see Chapter 24) have been described in many species. The pattern is determined by placing an awl through the epidermis into the dermis and observing the orientation of the split or cleavage formed.[4] In a review, Rooney cites the work of Schouppe, who studied cleavage lines.[4,5] Schouppe found that horses had cleavage lines whose orientation was parallel to the predominant orientation of the collagen fibers. These cleavage lines changed very little between adult horses, and wounds that healed best were parallel to the cleavage lines. In general, the cleavage lines were parallel to the long axis of the legs, head, and torso, and perpendicular to the long axis of the neck and flank. This is different from the cleavage lines found in dogs, which look more like stripes on a tiger.[6] In my opinion, cleavage lines on horses more closely approximate those of dogs than was reported by Schouppe (see Figure 24-1). When possible, incision lines should be made parallel to the cleavage lines.

FIRST AID

Appropriate wound care is always a balance between improving the wound environment and harming the cells that are integral to the healing process. Consequently, the veterinarian must carefully weigh the benefits and the detriments of any particular action, not only for the immediate results but also for the long-term healing process. Additional information on first aid can be found in Chapter 73.

ASSESSMENT

Wound assessment is one of the most important steps in wound therapy. More repaired wounds fail because of improper preparation and assessment than because of improper therapy. Properly preparing the wound provides an accurate assessment of the wound and deeper structures. Wound preparation begins with placing the animal in a location and environment that will allow the clinician to best determine the status of the wound. If the environment is not adequate to perform all of the tasks in the following paragraphs, it may be a good idea to move the horse to a place where these procedures can be done more efficiently and easily. In general, the best option is to perform any lifesaving therapy at the site where the horse was injured, and then to transport the horse as quickly as possible to a location where definitive therapy can be performed.

INITIAL MANAGEMENT

Restraint and Analgesia

For the horse with a wound, many types of restraint are appropriate, from simply holding its head to general anesthesia. Before using sedation, the horse's systemic status should be determined. It is rare for a horse to lose enough blood to cause problems with sedation, but if this is the case, the horse may collapse because many commonly used sedative agents induce hypotension. Physical examination, blood work including packed cell volume, and skin turgor testing can help determine the systemic status of the horse and allow the clinician to decide if sedation is advisable (see Chapters 1 and 4). Alternatives to systemic sedation include manual restraint with a twitch and/or local anesthesia of the affected area. In many cases, local anesthetic agents provide the best opportunity to prepare and examine the affected area and to eventually treat the wound.[7]

Initial Preparation

After the horse has been restrained appropriately and the area has been desensitized with local anesthetic, the clinician decides whether to treat the wound under aseptic conditions or if a simple clean technique is adequate. Simple clean technique should always include the use of clean exam gloves. If there is a possibility of cross-contaminating a wound while preparing and exploring, aseptic technique should be used. The next step is to clip the hair over and around the wound site. To minimize the amount of clipped hair that gets into the wound, it can be covered with water-soluble, sterile, lubricating gel prior to clipping. It is best to put on a pair of sterile gloves, apply the gel onto the fingers, and rub the gel into place (Figure 26-2). This technique generally ensures that the gel will remain in contact with the wound bed. Some of the clipped hair is is trapped in the gel. At the end of clipping, the gel with the trapped hair can simply be rinsed from the wound with water or saline solution. Only when the entire wound area has been clipped and prepared can the clinician begin to fully appreciate the complexity of the wound. In many cases, the object(s) causing the wound, even seemingly insignificant ones, will have invaded synovial structures, and because accurate assessment was not made, appropriate aggressive therapy was not instituted, leading to the eventual euthanasia of the horse.

DÉBRIDEMENT

Débridement is an effective way to reduce the bacterial load within a wound and to minimize necrotic tissue. The benefits of débridement have been widely discussed in the field of human wound care.[8] Necrotic tissue and bacterial infection are major roadblocks to effective and cosmetic wound healing. The presence of foreign material reduces the number of bacteria necessary for infection by a factor of 10 (i.e., from 10^5 to 10^4 bacteria per gram of tissue). Débridement is used to alter the wound classification from infected to contaminated to clean contaminated to clean. Each type of débridement has positive and negative consequences for wound healing, and it is important to select the technique that provides the best benefit-to-detriment ratio. The most common types of débridement are sharp, mechanical, chemical, biological, and autolytic. Sharp and autolytic débridement should be used primarily in equine wound care. The other types of débridement tend to create more trauma to the wound bed, consequently increasing the healing time required.

Sharp Débridement

Sharp débridement is one of the least traumatic methods available to the equine clinician, yet it is often underutilized. The major drawback to sharp débridement is that when the tissue is removed, it cannot be put back, so it is wise to be conservative in the removal of tissue. If the margin between viable and nonviable tissue is not clear, it is often better to leave some tissue for removal at a later time if necessary. Many skin flaps, especially on the head, retain viability even though they are cool at presentation. Tools for sharp débridement include a scalpel, scissors, and lasers. Scalpel débridement is the least traumatic of these techniques (Figure 26-3), and it should be used

Figure 26-2. Application of sterile water-soluble gel to wound before clipping.

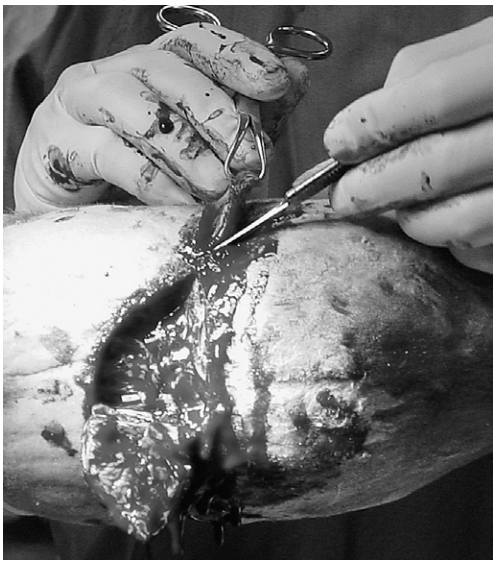

Figure 26-3. Sharp débridement of a wound on the dorsal and lateral aspect of the pastern region.

whenever possible in the initial wound treatment stages. Other types of sharp débridement play a more secondary role.

Mechanical Débridement

Mechanical débridement is more traumatic, and unfortunately it is probably the most commonly used method in the horse. It can be performed using woven gauze (Figure 26-4), lavage (Figure 26-5), wet-to-wet, or wet-to-dry dressings. Mechanical débridement can be a useful tool, and it can be beneficial in the healing process, but it can also be very traumatic. Often, when using gauze, too much pressure is applied and trauma to the wound bed ensues. Only gentle pressure should be used. If more aggressive débridement is necessary, sharp débridement should be selected. Woven gauze provides mechanical débridement characteristics superior to those of nonwoven gauze (Figure 26-6).

Lavage can be used successfully for mechanical débridement. It involves two critical components, the selection of a noncytotoxic cleansing solution and the delivery of that solution to the wound surface with appropriate pressure and volume to wash away the necrotic debris without pushing it further into the tissue planes of the wound.[9] The pressure should be between 10 and 15 pounds per square inch (psi). One way to achieve this pressure is to attach a 19-gauge needle or catheter to a 35-mL syringe.[10] Many devices are available. Showerheads are safer and more effective than single-jet lavage systems. Therefore, devices that produce high pressures (e.g., the WaterPik) should not be used. A simple gentle, low-pressure lavage system can be made by using a 16-gauge needle to punch four to eight holes in the cap of a 1-L bottle and then squeezing saline out (Figure 26-7, and see Figure 26-5).

The fluids most commonly used in veterinary medicine are dilute antiseptics. However, there is no evidence that dilute

Figure 26-5. Mechanical débridement with sterile saline.

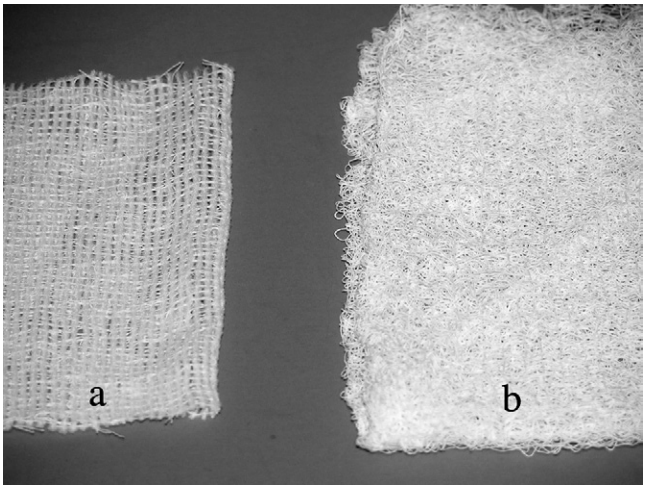

Figure 26-6. Nonwoven *(a)* and woven *(b)* gauze.

Figure 26-4. Mechanical débridement with woven gauze.

Figure 26-7. Saline bottle, with 16-gauge holes in the cap, used for lavage (see Figure 26-5).

antiseptics successfully kill bacteria when there is necrotic tissue in the wound. To achieve bacterial killing in necrotic tissue, high concentrations of antiseptic are necessary, and high concentrations have a negative effect on the cells necessary for wound healing. Antiseptics are best used around the wound but not in the wound.[11] Saline has been shown to be effective in reducing bacterial counts in an infected wound but to have no effect on wound healing in clean wounds.[12,13] In one study comparing saline solution and water in an infected wound in a rat model, saline solution reduced the bacterial counts by 81.6%, whereas tap water reduced bacterial counts by 82%.[14] However, work by Buffa and coworkers suggests that tap water is very toxic to fibroblasts.[15] In the presence of exudate, surfactant-based wound cleansers, such as Constant-Clens (Kendall/Covidien, Healthcare, Mansfield, MA), are more effective than saline or polyionic fluids.[10,16-18] In summary, the surgeon should avoid putting something in a wound that would not be tolerated in the eye or should not be consumed.[16,18] If wound infection is present, sharp débridement together with systemic antibiotics is necessary to rid the host of bacteria. Local antibiotics, either by intravenous or intraosseous perfusion or topical application, are also helpful.

Wet-to-wet or wet-to-dry dressings can be used for mechanical débridement. Wet-to-wet dressings are intended to stay wet, whereas the wet-to-dry dressings are intentionally designed to dry out between bandage changes. Wet-to-wet dressing may have to be remoistened up to six times a day. These dressings are much more effective at removing necrotic tissue than is mechanical débridement using gauze, while causing less damage to the fibroblasts and epithelial cells. However, it is very time consuming and is generally available only in an intensive care hospital environment. Wet-to-dry dressings are performed by moistening the primary dressing (the dressing against the wound bed) with saline while leaving the rest of the dressings dry. The concept is that the absorbent secondary dressing will pull the fluid from the primary dressing, pulling the wound exudate into the primary dressing also. Because it is difficult to keep the primary dressing moist unless a large amount of exudate is produced by the wound, the primary dressing often becomes dry between bandage changes. When the dried primary dressing is removed, it effectively débrides the wound bed, but this débridement is very nonselective. Thus, the usefulness of a wet-to-dry bandage is questionable. Primary dressings should never be allowed to become dry, as this reduces the effectiveness of autolytic débridement (see later) and leads to indiscriminate removal of epithelial cells and fibroblasts.

Chemical and Enzymatic Débridement

Chemical débridement has been used in many different forms in wound care. Dakin's solution, a diluted sodium hypochlorite (bleach) solution, was originally used during World War I. Other chemical agents include hydrogen peroxide, acetic acid, and, more recently, hypertonic saline. Chemical débridement is nonselective and should be reserved for very contaminated wounds. Hypertonic dressings provide an effective chemical débridement with minimal damage to the wound in the early stages of healing (see "Second-Intention Healing," later). While hypertonic saline débridement dressings are very effective in selected cases, sharp débridement is probably a better technique for removing large amounts of necrotic debris.

Enzymatic débridement involves placing enzymes directly onto the wound bed. The most commonly used enzymes are streptokinase/streptodornase, collagenase, DNase/fibrinolysin, papain/urea, and trypsin. Enzymatic débridement is limited when large amounts of necrotic tissue have to be removed and should be used only after an initial sharp débridement. For enzymatic débridement to be effective after a rigid eschar has formed, the eschar must first be scored with a scalpel blade.

Biological Débridement

Biological débridement has been used since antiquity by applying larvae of *Lucilia sericata* (greenbottle fly) into wounds. The Larvae digest only the necrotic tissue and pathogenic bacteria, leaving the healthy tissue unharmed. More recently, sterile medical grade larvae have been made avialable. The larvae provide rapid and relatively selective débridement. Unfortunately, there is often a problem with client compliance as there is a reluctance to allow the larvae to inhabit the wound. There is some evidence that secretions of the larvae may be able to be used for débridement, antibacterial effects, and promotion of angiogenesis.[19]

Autolytic Débridement

Autolytic débridement is the least traumatic of these techniques. It is achieved by leaving wound fluid (containing white blood cells and enzymes released from dead white blood cells) in contact with the wound bed. The white blood cells and enzymes affect only the dead and necrotic tissue, leaving healthy cells intact for wound healing. This can occur only in moist wounds (Figure 26-8). When wounds are allowed to dry, autolytic débridement is slowed significantly. Autolytic débridement

Figure 26-8. Wound undergoing autolytic débridement. This is a normal amount of exudate between bandage changes.

reduces the bacterial count by allowing access of white blood cells to the wound bed without causing continued trauma to the wound bed. However, sharp débridement should be performed before using autolytic débridement because the latter technique is ineffective in the presence of large volumes of necrotic material.

OPTIONS FOR WOUND CLOSURE

The options for wound closure can generally be categorized as primary closure, delayed primary closure, and second-intention healing. To choose the most appropriate technique, the stages and classification of wounds must be understood.

Stages of Wound Healing

There are four stages of wound healing: the inflammatory/cellular reaction stage, the débridement stage, the tissue formation/proliferation stage, and the maturation/remodeling stage. However, these stages overlap during the wound healing process (see Chapter 5). The duration and intensity of the inflammatory stage are generally determined by the extent of injury. For example, a surgical wound has a much shorter inflammatory stage than a severe degloving wound. The inflammatory stage is prolonged in the presence of necrotic debris, foreign material, or infection. The inflammatory stage should be reduced to the shortest duration possible. Extension of the inflammatory stage results in a delayed repair process.[8]

The débridement stage begins early in the inflammatory stage and is marked by migration of neutrophils and macrophages into the wound site. The white blood cells phagocytize bacteria and enzymatically remove necrotic tissue. The length of this stage depends on the size of the wound and the amount of necrotic debris present.

The tissue formation (or proliferation) stage involves fibroblast migration and proliferation as well as epithelialization of the wound. The fibroblasts migrate into the wound along the fibrin scaffold. They secrete the ground substance of the wound as well as the collagen that will eventually provide tensile strength in the wound. Granulation tissue, which is highly vascular and important in wound contraction, quickly becomes evident in a noninfected wound. Wound contraction is the process by which full-thickness skin is drawn together by specialized fibroblasts known as myofibroblasts, which are similar to smooth muscle cells. Myofibroblasts cause thinning of the surrounding skin as they pull the wound edges together. Wound contraction, which is most effective in areas with excess skin, stops when cells of the same type are brought together, or when skin tension equals the ability of the myofibroblasts to contract. Epithelialization, which is part of the repair phase of the wound and begins early in the wound-healing process, can be stopped with infection, drying of the wound surface, exuberant proliferation of granulation tissue, and repeated dressing changes.

The maturation stage of wound healing occurs when there is an equilibrium between collagen production and collagen destruction. It is during this stage that the collagen fibers are realigned along the lines of tension and when wound tensile strength increases. The number of fibroblasts is also reduced.

Wound Classification

Wounds are typically classified on the basis of degree of contamination. Clean wounds, usually seen only in surgical situations, are not infected and do not involve the respiratory, alimentary, or urogenital tract. Clean contaminated wounds, generally seen in surgical situations, involve the lumen of the respiratory, alimentary, or urogenital tract. Contaminated wounds are generally traumatic in nature and may have gross contamination and necrotic debris. Infected wounds generally involve large numbers of bacteria, inflammation, edema, and suppuration.[20] For additional details on infection, see Chapter 7.

Another wound classifciation technique is the color evaluation or RYB color code.[21] The concept is that if you evaluate the wound colors and the percentage of surface area of the different colors in the wound, healing progress can be better determined. The "R" refers to red, and indicates granulation tissue. The "Y" refers to yellow, and indicates purulent debris. The "B" refers to black, and indicates necrotic tissue. Some wound care specialists add a "P," which refers to pink and indicates epithelialization, and others will add a "G," which refers to green and indicates gangrenous tissue. The wounds are evaluated at each dressing change, and a "color" scale is determined. In general, as healthy wounds progress, the black and yellow colors decrease, and the amount of red and pink color increases. If a wound deteriorates, it will have proportionately more black and/or yellow. Infection should always be suspected if this occurs.

In summary, in the early stages of wound healing (i.e., in the inflammatory or débridement stage), wounds that are clean or clean contaminated are the best candidates for primary or delayed primary closure. Wounds that are in the later stages of healing or are contaminated or infected heal best by second intention.

BACTERIA IN WOUNDS

All wounds contain bacteria, but not all bacteria in wounds are cause for concern. Bacterial contamination describes the presence of bacteria in a wound without active multiplication or trauma to the host. Bacterial colonization indicates that the bacteria have attached to the tissue and are multiplying but are not necessarily causing trauma to the host. High numbers of bacteria in the absence of a host response may indicate an impaired immune response. Bacterial infection occurs when bacteria invade healthy tissue and actively multiply, overwhelming the host's immune response.[22] Frequent bandage changes have been implicated in an increase in bacterial numbers as the wound is left exposed to the environment during the dressing change.

Bacteriologic Assessment

Two methods of bacteriologic assessment used in equine practice are described: qualitative and quantitative. Qualitative assesssment involves determining the types of bacteria in the wound, coupled with sensitivity testing. These methods can guide the clinician in choosing antibiotics for treatment. Quantitative bacteriology is rarely performed in veterinary medicine, but it should be considered when a wound is not progressing as anticipated or when a skin graft fails. Bacterial counts greater

than 10^5 per gram of tissue generally indicate an active infection. The number of bacteria needed to produce an active infection is reduced if foreign material (e.g., suture, necrotic debris, a foreign body) is present, if the virulence of the bacteria is high, or if host resistance is decreased. Clinical observation is generally adequate for determining if a wound is infected. Signs such as discolored granulation tissue, edema in and around the wound, purulent exudate, odor, and lameness can indicate an infection. However, a wound can be infected without these overt signs. If infection is suspected, the wound should be cultured.

Technical Considerations in Contaminated Wound Closure

The three main strategies for preventing bacterial infection of wounds are effective wound cleansing and débridement (see "Débridement," earlier), appropriate use of advanced dressings and procedures for dressing changes (see "Second-Intention Healing," later), and appropriate use of topical antimicrobial agents.[9]

Antiseptic agents, in use since the 1800s, are effective against a broad range of gram-positive and gram-negative bacteria. However, they do not penetrate necrotic debris well and are unlikely to reduce bacterial populations deep in a wound bed.[10] Many investigators have looked at the use of antiseptic and antimicrobial agents in the wound.[23-29] In one study, the use of saline in combination with gauze was more effective in reducing bacterial numbers and encouraging wound healing than silver sulfadiazine or povidone-iodine.[28] In a review, Rodeheaver noted that the following antiseptics have been used in the false hope of killing bacteria without negatively affecting the wound bed: acetic acid, alcohols, aluminum salts, boric acid, chlorhexidine, formaldehyde, gentian violet, hexachlorophene, hydrogen peroxide, hypochlorite, iodine, povidone-iodine, Merthiolate, permanganate, and silver nitrate.[10] A recent paper concluded that practitioners should reconsider the ritualistic use of chlorhexidine of any concentration on open wounds until such time that research actually proves that the benefits outweigh the ill effects.[30] Although the evaluation of daily bathing with chlorhexidine to reduce the acquisition of methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci in human intensive care units has been shown to be beneficial,[31] it is clear that antiseptics should be reserved for use on the normal skin surrounding the wound and not on the wound bed itself.

Unlike antiseptics, topical antimicrobial agents provide efficacy against bacteria within the wound bed, and, depending on the vehicle, they have minimal negative side effects on wound healing. In one study in horses with experimentally created leg wounds, silver sulfadiazine used alone without wound dressings resulted in less formation of granulation tissue than wounds covered with pressure bandages.[32] Antiseptics cannot target specific bacteria, but topical antibiotics can. However, antimicrobial resistance has rendered some antimicrobials ineffective, so the use of systemic antibiotics alone has been advocated to control the appearance of resistant organisms. In some chronic infections, the blood supply to the surface is diminished, and topical antimicrobials are required. Antimicrobials should always be selected on the basis of culture and sensitivity or on the basis of a judgment on the most likely bacteria to be found in the wound. When possible, to reduce concerns about antibiotic resistance, the antimicrobial chosen for topical use should be one that is unlikely to be used systemically. Wound débridement is still the best way to reduce the bacterial count in wounds with necrotic debris, and it should be performed before either an antiseptic or a topical antimicrobial is used.

Systemic antibiotics should be used for chronic or acute wounds that have a large degree of trauma or are close to critical structures such as bones or joints. If possible, cultures and sensitivity test results should be obtained to determine an appropriate antibiotic. Triple antibiotic ointment has been shown to be one of the most effective topical antibiotics in wound healing. Nitrofurazone, at least in current vehicles, is quite toxic to wounds and cannot be recommended.

WOUND CLOSURE TECHNIQUES

After the wound has been successfully débrided, cleaned, and examined, the veterinarian needs to employ some method to achieve an epithelial covering. The options are suture closure, healing by second intention, skin grafting, or some combination of these to provide a continuous epithelial surface over the wound. The type of closure technique to use depends on what caused the wound, the time from injury, the degree of contamination, the extent of the injury, the potential dead space, and the veterinarian's surgical skills. The "golden period" of 6 hours from the wounding, after which the wound is considered to be infected, is no longer deemed correct, and it behooves the clinician to examine the wound carefully to determine which of the following techniques to use for wound closure. The primary goal is to have a functional and cosmetic end result.

Primary Closure

Primary closure is a technique whereby the wound is closed immediately and completely, using strict aseptic technique. This is the technique most likely to provide the best functional and cosmetic result. Unfortunately, primary closure is acceptable only in wounds with minimal tissue loss, minimal bacterial contamination, and minimal tension on the wound edges after closure.

Regardless of whether primary closure or delayed primary closure (see later) is performed, the wound needs to be cleaned and prepared for closure, because excess bacteria in the wound increase the possibility of wound dehiscence. There are many suturing techniques for wound closure (see Chapter 16) and many reviews of suture types for primary closure.[33-37] For areas of tension, complex suture patterns (such as the near-far-far-near, vertical mattress, and horizontal mattress patterns) provide more tension reduction than simple patterns such as a simple interrupted or simple continuous patterns (see Chapters 16 and 24). The near-far-far-near suture pattern (see Figure 24-4) is most satisfactory, as it provides apposition of the skin edge at the same time as tension relief. Additionally, the mattress patterns can be used with stents to reduce pull-through at the skin–suture interface (see Chapter 16). A large-diameter suture material should be used if tension exists. Small-diameter suture material can be used between tension-relieving sutures for tissue apposition and cosmetic purposes. The wound edges should be undermined whenever possible, preserving blood supply, to reduce tension on the closed wound.

When closing a wound, the management of dead space is very important. Failure to obliterate dead space can lead to the development of a hematoma or a seroma, providing an excellent medium for bacterial growth. One or a combination of four techniques can be used to manage dead space in a wound: suture, meshing the skin, passive or active drains, and pressure bandages. Each technique has benefits and risks that need to be weighed. Suture material, although very useful in wound closure, can also act as a foreign body. Excess suture use (too many sutures, a too-large diameter, or too many knots) can potentiate infection.[38] Consequently, the clinician should use the smallest-diameter suture material possible, monofilament, absorbable suture material, and only surgeon's knots (or interrupted sutures if absolutely necessary when the suture material must be buried). Good surgical technique also benefits the patient, as it reduces trauma to the wound site. If dead space cannot be managed by suture placement, meshing the skin (see Chapter 25) or suction drains (passive or closed) should be employed (see Chapter 17). However, drains not only allow evacuation of dead space but also can act as a conduit for bacteria to enter the wound. Drains should be left in place only as long as necessary to reduce the possibility of infection. Pressure bandages can and should be used whenever possible in addition to sutures, meshing, or drains, or sometime in place of them to reduce dead space. A properly applied bandage closes dead space without adding any foreign material. However, if a bandage is too tight, the blood supply to the wound may be compromised, leading to wound failure.

Delayed Primary Closure

In a delayed primary closure, the wound is initially treated openly to allow débridement and reduce bacterial contamination. Next, the wound is closed primarily. In some cases, only a portion of the wound can be completely closed (Figure 26-9). Delayed primary closure is reserved for wounds that have mild to moderate bacterial contamination, minimal tissue loss, and minimal tension on the wound edges after closure. Drains may be placed to evacuate fluid after closure. Delayed wound closure is very useful in the management of abdominal incisions after colonic rupture in humans.[39-41] These studies showed as much as a twofold increase in incisional infection with primary closure of contaminated abdominal wounds. Delayed primary closure after 3 to 5 days did not result in an increased hospital stay.

Figure 26-9. A chronic wound that has been débrided and partially closed with near-far-far-near sutures.

Wounds destined for delayed primary closure should be débrided and cleaned to reduce the bacterial burden. Hypertonic saline dressings (see "Second-Intention Healing," next), topical antimicrobials, and systemic antimicrobials can be very useful in treating wounds prior to closure.

Second-Intention Healing

Second-intention healing occurs when primary or delayed primary closure cannot be accomplished. In most cases, these wounds have gross contamination and moderate to severe tissue loss that would make closure difficult. They must heal completely through the process of contraction, granulation, and epithelialization.

In the relatively new concept of moist wound healing, the wound exudate is purposely left in contact with the wound bed. In 1962, George Winter showed that in both swine and humans, full-thickness skin wounds kept in a moist environment re-epithelialized in approximately 12 to 15 days, whereas similar wounds exposed to the air took 25 to 30 days to heal.[42,43] Moist wound healing resulted in wounds that were less inflamed, caused less itching, had less eschar formation, and were more likely to heal without scarring. However, the earliest reports of moist wound healing were by Bloom and Bull in the mid 1940s. Bloom, an army surgeon, sterilized cellophane to treat burn wounds at a World War II prisoner of war camp. His primary goal was to reduce the risk of bacteria entering the wound. Although the dressing reduced bacterial infection, unanticipated benefits included movement with less pain, and less plasma loss.[44] Bull and colleagues studied a transparent nylon that stopped bacterial and fluid penetration yet allowed wound exudate to escape from the dressing. Benefits included faster healing and fewer dressing changes.[45]

The concept behind moist wound healing is that the wound exudate provides the necessary cells and a substrate rich in enzymes, growth factors, and chemotactic factors; controls infection; and provides the best environment for healing. Enzymes come from the breakdown of white blood cells and metalloproteinases. Occlusive dressings keep the wound fluid in contact with the wound bed to encourage autolytic débridement. This in turn provides a good foundation for the rest of the wound-healing process. Local growth factors and cytokines (see Chapter 5) provide a stimulus for the fibroblasts, epithelial cells, and angiogenesis. Chemotactic factors stimulate more neutrophils and macrophages for continued bacterial control and débridement. A moist environment allows better migration of neutrophils and macrophages than a dry wound environment. It has also been shown that wound fluid, even without white blood cells, has some antimicrobial action.[46] Another benefit of occlusion is constant thermal regulation. Concerns with moist healing include bacterial colonization, folliculitis, and the possibility of trauma to periulcer borders. Although bacterial colonization is a concern, a wound that is not infected before occlusion is unlikely to become infected afterward. Another benefit of moist wound healing is that the reduced frequency of dressing changes means that the wound is less exposed to the environment, so it is less likely to become contaminated. Last but not least, moist wound healing is cost effective for the owner.

DRESSINGS, GROWTH FACTORS, AND DRUGS

The open wound changes as it heals, and different dressings provide better results when used during specific stages of the healing process.[47] Consequently, dressing manufacturers have developed many different dressings. Under the following headings, some of the more common dressings are described, and the wounds for which they are best used are mentioned. The ideal dressing keeps the wound bed moist, but not overly so, and the surrounding skin dry. The clinician needs to learn how to manage the amount of exudate present while making sure the wound does not dry out. Experience will quickly guide the use of the different dressing types. The dressings are described in the order a surgeon might use them when treating a wound.[48]

Hypertonic Saline Dressing

Most contaminated and infected wounds contain necrotic tissue and need some form of débridement. Hypertonic saline dressings (Curasalt, 20% hypertonic saline on a Kerlix gauze) have been designed for use on necrotic or heavily exuding wounds. They work by osmotic action to remove necrotic tissue and bacteria. However, they provide a nonselective chemical débridement and consequently need to be monitored carefully. Dressings need to be changed every 24 to 48 hours at the beginning of the treatment period to maintain the hypertonicity and thus the effectiveness. These dressings can be used effectively in most abscess situations. This dressing is available in a 15 × 15 cm (6 × 6 inch) loosely woven gauze and a 1.2 cm (½ -inch) cotton tape for packing small draining tracts. After the necrotic tissue or bacterial infection has been removed, another dressing type should be used.

Honey

Honey has been used in wound healing for centuries because of its ascribed bacteriocidal effects. Also, "growth factor–like" properties of honey have the capability to improve wound healing. In one study comparing honey and sugar, honey was noted to be more effective in reducing bacterial numbers and promoting wound healing.[49] The patients treated with honey were also in slightly less pain during dressing changes and when exercising. More recent research would indicate that Manuka honey from the nectar of the Manuka bush *(Leptospermum scoparium)* in New Zealand is superior at reducing bacterial numbers than are other types of honey.[50] When comparing Manuka honey to hydrogel in a prospective study, the honey group had increased incidence of healing, effective débridement, and lower incidence of infection than the control group.[51] Although the exact reasons for the benefits are unknown, simple hypertonicity does not appear to be the sole cause, especially in light of the previously mentioned study with Manuka honey.[49] There are no scientific reports on the use of honey in equine wounds.

Antimicrobial Dressings

Antimicrobial dressings have been designed to stop bacterial penetration into open as well as closed wounds. The agents are very effective against bacteria and minimally traumatic to the wound. A preferred dressing is called Kerlix AMD (Figure 26-10). The active agent is polyhexamethylene biguanide (PHMB), and it is available bound to Kerlix Super Sponge, Kerlix roll gauze, and other types of dressings. PHMB belongs to a class of cationic surface-active agents that have been used as preservatives in aqueous solutions and as disinfectants and antiseptics (e.g., in cosmetics, contact lens solutions, baby wipes, and pool sanitizers). Increased concentrations, when impregnated into fabric, have shown the capability to suppress microbial growth and penetration. Microbial death occurs by destabilization and disruption of the cytoplasmic membrane, resulting in leakage of macromolecular components. This response is irreversible, and the microbe cannot adapt or become resistant to the PHMB. These dressings are particularly useful in preventing bacterial infection in surgical incisions or where wounds are close to synovial structures and subsequent deep penetration of bacteria would be catastrophic. Although the dressings have been designed to prevent bacterial penetration, they have also been useful in reducing the bacterial load in the wound (Figure 26-11). As these dressings are dry, and made with woven gauze, they should be premoistened before being placed in a wound. They can also be used to cover surgically closed incisions. Silver has recently been impregnated into dressings as well, and they

Figure 26-12. Gel dressings (Kendall/Covidien). *a,* Curafil as an amorphous gel. *b,* Curafil as a gel-impregnated gauze dressing. *c,* Curagel, a gel pad.

can be used in a similar fashion. An *in vitro* evaluation of a silver chloride–coated nylon wound dressing against common equine wound pathogens identified an effective reduction in bacterial numbers.[52] The dressings should be changed every 3 to 7 days (the shorter times when used for open wounds and the longer times for surgically closed wounds). After the wound has been cleared of infection, the dressing should be replaced with one of the following dressings.

Hydrogels

Hydrogel dressings were designed to provide moisture to a wound that has dried out. Hydrogels are medical-grade gels composed of water, glycerin, and polymers. They conform to the wound, are nondrying, and provide a bacterial barrier and, eventually, a moist environment. They are available as amorphous gels, in gel-impregnated gauze, or in a mesh-reinforced pad (Figure 26-12). They are completely occlusive and provide an excellent environment for autolytic débridement, white blood cell migration, and thermal regulation, and they thus result in improved wound healing. The gel dressing should be changed every 4 to 7 days, depending on the amount of exudate. When the wound is moist, a different dressing should be used.

Calcium Alginate Dressings

Calcium alginate dressings are used primarily for the granulating phase of wound repair. They are made from alginate, a derivative of seaweed. The calcium in the dressing interacts with sodium in the wound, providing a wound exudate that stimulates myofibroblasts and epithelial cells and speeds wound homeostasis.[53] The calcium also modulates epithelial cell proliferation and migration. Alginate dressings come in nonwoven pads and rope dressings. They conform well to the wound, have excellent vertical wicking properties, and are designed for moderately to heavily exudative wounds. If a wound has a granulation tissue defect and does not have a moderate amount of exudate, the pad should be premoistened with saline before use. The dressings can be changed every 3 to 7 days, depending on the amount of exudate.

Topical Dressings: Collagens and Maltodextrins

Topical dressings such as collagens and maltodextrins are designed for use in the granulating stage of wound repair. They are hydrophilic and should maintain a moist wound bed. They are available in powder or gel form. If the wound does not have a lot of exudate, it is probably best to use the gel form to prevent drying out of the wound bed. Maltodextrins may provide nutrition to the wound bed.[54,55] As soon as adequate granulation tissue is present, a semi-occlusive foam dressing should be used.

Biological Dressings

Various substances have been used as biological dressings. These dressings are intended to provide a framework over which other cells migrate, and as a stimulant to those cells to form the tissue that is desired. Some of the more commonly used biological dressings include porcine small intestinal submucosa (SIS), porcine bladder basement membrane, equine amnion, and various skin products. The porcine small intestinal submucosa and bladder products are not rejected by the host as other xenografts are. From clinical experience, they appear to be best if they are kept moist. In one study, SIS dressing was applied to fresh and chronic wounds. Compared with similar wounds treated without SIS, exuberant granulation tissue was reduced and drainage was facilitated, which reduced wound exudation and improved epithelialization. Overall, wound healing was faster and costs for bandages and hospitalization were reduced.[56] Other studies have shown that the use of equine amnion reduces wound retraction and granulation tissue formation while improving epithelialization.[57] Amnion has been shown to be beneficial as a nonadherent dressing in skin grafting.[58]

Growth Factors

Growth factors (see Chapter 5) have become very popular in experimental studies of wound care. The benefit of platelet-derived growth factor (PDGF) in decreasing wound-healing times has been shown.[59,60] It acts as a chemotactic agent and mitogen for fibroblasts, smooth muscle cells, and inflammatory cells.

Other growth factors have been studied in horses to determine their effects on granulation tissue formation. In one study, it was determined that transforming growth factor-β (TGF-β) has a profibrotic function in wound healing, in that it seems to encourage formation of granulation tissue. It was also found to be more upregulated in limb wounds than in trunk wounds.[61] A human study has shown the benefit of leaving wound fluid in contact with the wound bed by stimulating fibroblast and endothelial cell growth.[62] Various cytokines have been found useful in treatment of experimentally infected wounds.[63] More studies need to be performed to look at different combinations of growth factors, used sequentially through the wound healing process to determine the true effectiveness of exogenous growth factors. The growth factors may be most useful in the granulating and epithelialization stages of wound healing and may be used in conjunction with other synthetic dressings.

Semiocclusive Foam Dressings

Semiocclusive foam dressings are designed for use on mildly exudative wounds (Figure 26-13). They are best used after the

Figure 26-13. Semiocclusive foam dressings. **A,** COPA (Kendall/Covidien), **B,** AMD Antimicrobial dressing (Kendall/Covidien).

wound has been cleaned up, necrotic debris has been removed, bacteria are brought to a count below that needed for infectivity, and healthy granulation tissue is present. The dressings should not be used in the presence of infection. Foam dressings provide a moist environment and thermal regulation that will enhance epithelialization while minimizing exuberant granulation tissue. Newer foam dressings have smaller pore sizes that reduce the chance of tissue growing into them, thereby reducing the chance of the dressing's adhering to the wound. Polyurethane layers prevent strikethrough while still allowing moisture-vapor transmission reducing skin maceration. It is also possible now to use a semiocclusive foam dressing impregnated with an antimicrobial (AMD Foam). It is best to surgically débride exuberant granulation tissue prior to applying a foam dressing. Nonadherent foam dressings have also been useful in skin grafting. They should be changed every 4 to 7 days, depending on the amount of exudate.

Negative Pressure Wound Therapy

Negative pressure (vacuum) wound therapy has been shown to be beneficial in both acute and chronic wound care. A foam dressing is cut to the shape of the wound, placed into the wound cavity, and covered with a transparent adhesive drape (see Figures 17-8 and 17-9). In horses, the skin should be prepared by clipping, shaving, degreasing with alcohol, and applying an adhesive spray. A small hole is made in the drape, and a rigid drain is inserted. The drain tube is attached to a vacuum canister. In one study on humans, it was shown that while the cost of negative pressure wound therapy is more expensive to begin with, it allowed a more rapid definitive therapy when compared to moist wound healing alone (average of 20 days less therapy). The hospitalization cost was approximately 60% less for the negative pressure group than the moist wound healing group.[64] While information in horses is limited, it would appear to be a valuable asset in a wound-healing regimen. Possible benefits include increased blood flow, increased angiogenesis, increased rate of granulation tissue formation, increased flap survival, and decreased bacterial number and edema formation.

Corticosteroids

Corticosteroids are commonly used in equine wound care to reduce the volume of, or to inhibit the formation of, exuberant granulation tissue. However, *in vitro* studies have shown that hydrocortisone upregulates plasminogen activator inhibitor-1 and downregulates plasminogen activators. The plasminogen activators play an important role in wound homeostasis. This change probably inhibits proteolytic matrix degradation and reepithelialization, which are both necessary for rapid and efficient wound repair.[65] Dexamethasone has been shown to interfere with the synthesis and degradation of types I and III collagen in rats. Type III collagen plays a major role in the induction of wound healing and is affected more dramatically by dexamethazone.[66] Triamcinolone has been shown to decrease vascular growth and consequently granulation tissue formation in rabbits. Topical administration was more severe in reducing angiogenesis than was systemic therapy. Testosterone has been shown to delay wound healing in mice.[67] Based on this information, steroids should not be used to inhibit excess granulation tissue formation. There are better ways to accomplish this, such as effective wound débridement and the use of moist wound healing principles.

Nonsteroidal Anti-Inflammatory Agents

Inflammation is an important part of the wound healing process. However, to achieve the most cosmetic and functional results, the inflammatory stage should be minimized.[8] At therapeutic doses, studies have shown that there are few deleterious effects of using anti-inflammatory drugs during wound healing.[68,69] In time, the selectivity of new antiprostaglandin drugs may provide better efficacy without potential side effects, which will make the use of these drugs even more beneficial.

Antiseptics

Generally, antiseptics should not be used in superficial wound. However recently octenidine dihydrochloride (Octenivet Solution, Schülke & Mayr GmbH, Norderstedt, Germany),

a cationic antiseptic belonging to the bispyridine class of chemicals and being effective against gram-positive and gram-negative bacteria[70] was introduced to the veterinary market in Europe. Effectiveness could be shown in oral hygiene by preventing plaque and gingivitis, as a whole body wash for MRSA decolonization,[71] and for skin disinfection of pre-mature newborn infants.[72] Currently, no veterinary literature is available but clinical studies are under way.

TETANUS PROPHYLAXIS

Tetanus, caused by *Clostridium tetani*, should be prevented if at all possible. Adequate protection can be achieved by vaccination, but therapy after infection is often unrewarding.[73,74] Although it has been shown that horses given an initial vaccination and a single booster should be protected for 5 years, it is probably better to have an annual booster.[74-76] This is especially true in horses with an uncertain vaccination history. Unvaccinated horses should receive both a tetanus toxoid and a tetanus antitoxin.

CHAPTER 27

Management of Deep and Chronic Wounds

Dean A. Hendrickson

The first part of this chapter is devoted to deeper wounds of the head, neck, thorax, abdomen, and extremities; and the second part discusses chronic wounds. Please see Chapters 5 and 26 for more in-depth information on specific wound-healing events.

DEEP WOUNDS

Wounds in different parts of the body heal at different rates and often produce disparate cosmetic results.[1,2] Wounds on the head, neck, and body often appear to heal better than wounds on the extremities. In a review on the topic, Knottenbelt discussed reduced vascularity in the extremities as a possible cause for prolonged wound healing there.[2] However, increased infection, increased inflammatory response, and reduced regional temperature are all involved in the equation as well.[3-5]

Head and Neck

The head and neck have an extensive vascular supply that provides nutrition, oxygen, and white blood cells to the wound for healing. There is good soft tissue support to most areas of the head and neck, which also provides a good basis for healing.[2,6] Unfortunately, many other important structures, such as the cranium, eyes, ears, sinuses, salivary ducts, nerves, and nares, can be involved in lacerations, and exploring them to ensure that nothing is missed requires a thorough knowledge of their anatomy. For example, one horse hit its head on a feeder, causing a laceration in front of the ear. At the initial presentation, the wound looked very superficial; however, a more thorough examination revealed that it involved the cranium and actually penetrated into the brain (Figure 27-1). Initially, the horse had no obvious neurologic signs indicating the puncture. Thus, a thorough and complete physical examination is necessary to adequately assess wounds to the head and neck. Often, horses with head wounds should be heavily sedated before wound preparation and exploration, unless neurologic signs are present.

Diagnostic aids for evaluating head and neck wounds include radiographs, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). Radiographs of the head can be difficult to evaluate because of all of the overlapping bones.[7] CT (Figure 27-2) and MRI provide excellent renderings of abnormalities, but they are expensive, not always available, and require general anesthesia. Therefore, if applied, surgical

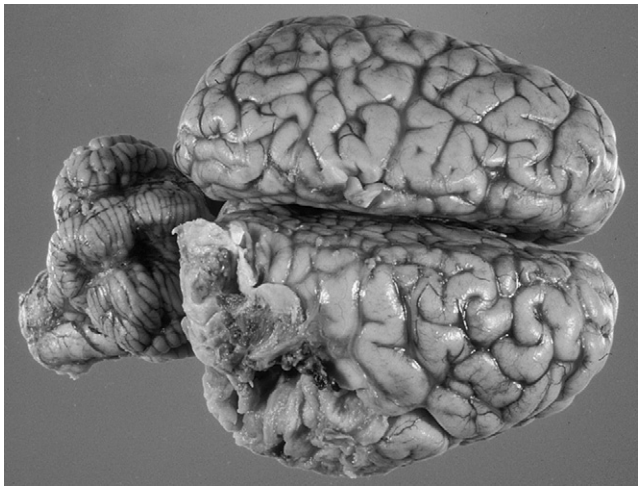

Figure 27-1. The brain of a horse with a penetrating injury to the head showing trauma to the right temporal lobe.

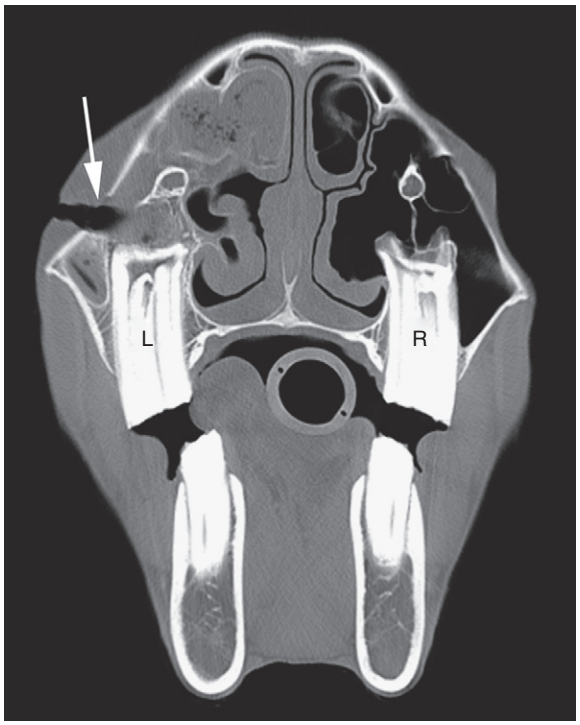

Figure 27-2. Computed tomography scan of a horse with trauma to the left maxillary sinus and subsequent filling of the sinus with blood. The *arrow* shows the entry wound.

wound management should follow the evaluation, if needed. Fortunately, good wound preparation and digital examination often provide enough information on the amount of bone involvement in a head laceration. Fractures should be considered whenever there is a laceration to the head. When cranial fractures are suspected, a thorough neurologic examination should be performed to help determine the extent of the laceration. If the cranium is involved, aggressive therapy should be instituted to reduce the possibility of bacterial penetration and eventual septic encephalitis.

Lacerations around the orbit should be examined to determine involvement of the bone and the globe of the eye (see Chapter 55). To avoid trauma to the cornea, special care is needed when cleaning around the eye. Chlorhexidine should not be used in this area.[8] If possible, lacerations around the eye should be closed primarily to reduce functional problems of the lids. Lacerations to the lids should be closed using small-diameter, absorbable suture material in many layers (see Chapter 56). Multiple layers using small-diameter suture materials provide more stability in areas of increased motion yet will not unnecessarily add to the foreign body volume of the wound. Orbit fractures can be treated using bone reconstruction plates (Figure 27-3) (see Chapter 102).

Figure 27-3. Intraoperative photograph of a horse with an orbital fracture repaired with a reconstruction plate.

Repair of ear lacerations can be particularly difficult because ears have considerable mobility. Their range of motion is nearly 270 degrees, and they are supported by cartilage. Ear lacerations, like eyelid lacerations, should be closed primarily whenever possible for the best cosmetic and functional results. Because of the location and blood supply of the ear, lacerations there are rarely too contaminated to close primarily, but sometimes the wounds are too old to hold sutures and must heal by second intention, with revision at a later date. General anesthesia should be used to repair ear lacerations for the best cosmetic result. Rolled gauze or radiographic film can be used as a support to minimize ear movement and improve healing. The gauze is placed inside the pinna and the pinna taped around the gauze. Some horses resent the gauze and shake their head. Placement of radiographic film on both the inner and outer portion of the pinna in combination with the introduction of mattress sutures through the films and the ear represents another option.

Lacerations that involve the frontal and maxillary sinuses may lead to bone sequestration and eventual fistula formation.[9] Prompt intervention can make the difference between a wound that can be closed primarily and one that requires multiple surgeries and wound revisions. Stable bone fragments should be elevated back into position, whereas loose fragments devoid of periosteal coverage should be removed. Rotational skin and periosteal flaps may be necessary to close defects in this area. If there is a large bone defect, the addition of a periosteal flap may

improve the possibility of bone formation in the area. Other dressings, such as ACell, have been suggested for use in this type of wound to encourage bone formation.

Mandibular lacerations can involve other structures, such as the salivary ducts or even the mandibular incisors. Depending on the cause of the laceration, evaluation of the ducts can be very difficult, especially if extensive trauma has occurred. When possible, the integrity of the duct should be confirmed by feeding the horse and observing salivary fluid loss. If transected ends of the parotid salivary duct can be visualized and anastomosed, the result will be better, but this is rarely achievable. If the ends cannot be anastomosed, ligating the salvary duct may be all that is necessary to stop salivary secretion because the gland will atrophy. Sometimes the salivary gland has to be chemically ablated.

Lacerations of the nares are common in equine practice. Successful reconstruction depends on thorough wound débridement, good case selection, and using multiple layers of suture closure to reduce the chance of incisional dehiscence. Fresh wounds are easiest to treat if there is not a large volume of tissue missing. When horses present with wounds that are 7 to 20 days old, the wounds should probably be allowed to heal by second intention and be reconstructed at a later date when they are more likely to hold sutures. In all cases of nares lacerations, multiple layers of closure are necessary for a successful closure.[10]

Thorax

Trauma or lacerations to the thorax can involve the ribs and/or can penetrate the pleural cavity and cause a pneumothorax. Consequently, the wounds must be carefully examined to be absolutely certain of the depth of penetration. The area should be clipped and aseptically prepared to allow a thorough examination of the site (see Chapter 26). Aseptic technique should be used for all thoracic wounds, because involvement of the pleura cannot be ruled out until after the manual examination. If the examination area is quiet, the surgeon may be able to hear air being sucked into the wound during inspiration. Thoracic auscultation should also be performed to help rule out pneumothorax. Radiography, ultrasonography, and thorocoscopy can be helpful adjuncts to the examination (Figure 27-4). If the wound has entered the pleural cavity, a chest tube should be placed to evacuate the air from the chest (see Chapter 48). If the surgeon cannot place a chest tube, the wound should be closed in as many layers as possible, bandaged, and then referred (see Chapter 48). As an alternative to a chest tube, a teat cannula can be attached to a 60-mL syringe with a three-way stopcock to remove air from the chest cavity. With time, it is possible to evacuate most of the air from the pleural cavity with this technique, but a suction pump is more efficient. The chest tube or the teat cannula should be placed in the upper third of the chest to enable removal of the largest volume of air. In case of pleural penetration, broad-spectrum antibiotics should be instituted. The wound care instituted should be appropriate for the stage of healing. Stent bandages can be used to cover the primary dressing. Thoracoscopy can serve as an aid to diagnose pleuritis secondary to thoracic lacerations (see Chapter 48).

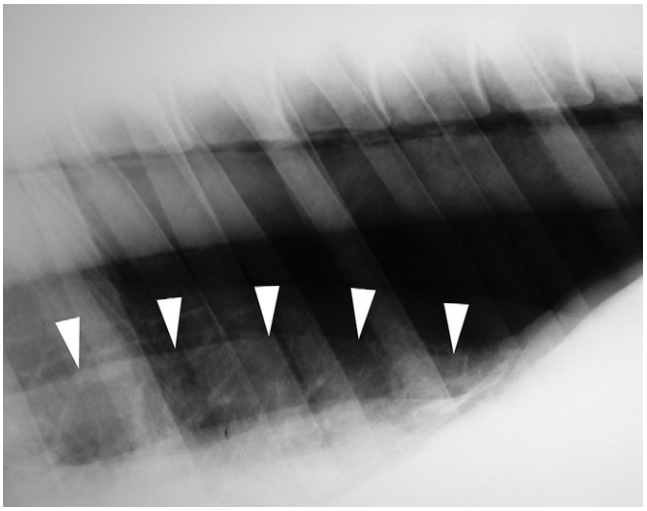

Figure 27-4. Lateral radiographic view of a horse with a thoracic injury and subsequent pneumothorax. Note the dorsal edge of lung outlined by *arrows.*

Abdomen

Lacerations to the abdominal wall offer a diagnostic challenge. The abdominal wall has numerous layers that vary depending on the location. The hair should be clipped, and aseptic technique should always be used on abdominal wounds until peritoneal penetration has been ruled out. If the entry point is small, it may be useful to enlarge the wound to better explore the deeper layers, and the horse may have to be sedated to allow thorough examination. The skin is generally more resistant to tearing than the fascial planes and muscles of the abdominal wall. All tissue planes should be examined for involvement. It is possible for the tissue planes to move, allowing overlap of the layers. An abdominocentesis may help, but in many cases, the cell counts and total protein are within normal limits. Confirmation of abdominal penetration may not be possible, so the veterinarian must carefully monitor the patient for signs of peritonitis after the wounding.

If the wound does not involve the peritoneal space, it should be débrided and closed in multiple layers if at all possible. A drain may be helpful in evacuating dead space. Wounds that have a large amount of tissue loss may be predisposed to herniation. However, it is not advisable to place a mesh in a contaminated wound. Therefore, the wound should be treated until healed, and then a mesh can be implanted to reduce the chance of hernia formation. Abdominal bandages can be useful to help support the body wall. The need for abdominal support may be minimal, but the bandage often reduces edema formation at the wound site and encourages more rapid wound healing. Broad-spectrum antibiotics are often indicated in abdominal wounds.

If peritoneal penetration has occurred, an abdominal bandage should be placed on the animal and broad-spectum antibiotics administered for transport to a surgical facility for an abdominal exploration. Whenever peritoneal penetration has occurred, it is possible that there has been trauma to the viscera. Abdominal lavage using copious amounts of polyionic fluid should be performed, and broad-spectrum antibiosis should be continued. Laparoscopic exploration should be considered to evaluate the peritoneal cavity (see Chapters 13 and 34). It is not possible to visualize all portions of the bowel, but it can be possible to evaluate the dorsal-most structures in a standing animal and the ventral-most structures in a dorsally

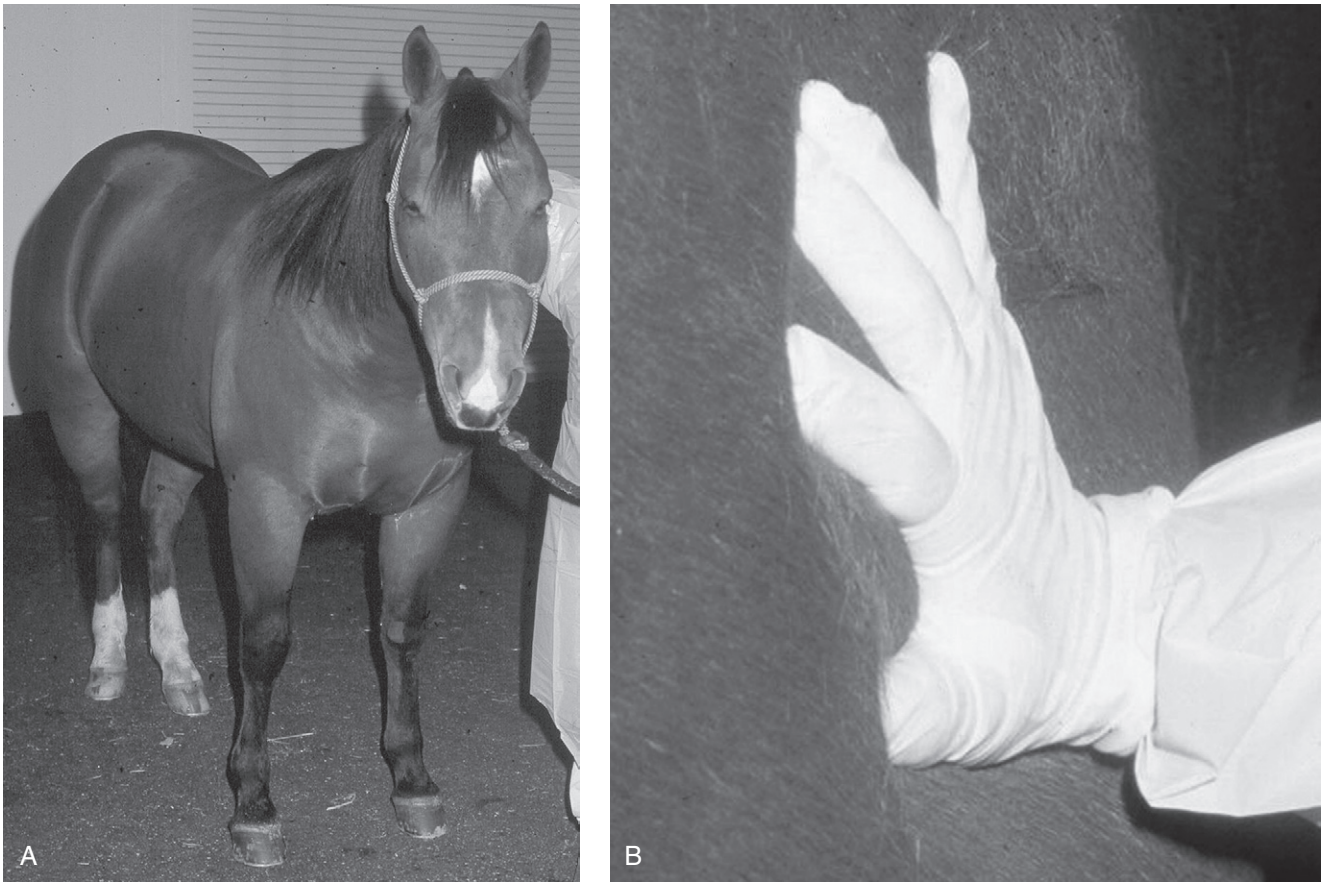

Figure 27-5. A, A horse with an axillary wound and subsequent subcutaneous emphysema. **B,** Close-up showing how the skin indents over the shoulder with manual pressure.

recumbent animal. Directed lavage can be very helpful in reducing the contamination of peritoneal penetration.

Extremities

Axillary Lacerations

Horses that present with lacerations of the axillary region often have subcutaneous emphysema (Figure 27-5). The emphysema is created when the horse moves its leg forward, opening the wound and filling it with air. When the horse moves forward and the leg is positioned caudal relative to its forward position, the air is trapped and forced into the surrounding tissues. In some cases, a pneumomediastinum occurs, which can lead to a pneumothorax.[11] The hair over these wounds should be clipped, and the wounds should be cleaned and débrided. Packing the wound is difficult, but it reduces the accumulation of air in the surrounding tissues. The best way to reduce subcutaneous air accumulation is to limit the movement of the horse. When the air has accumulated, it must be reabsorbed, and there is no efficient way to remove it. Calcium alginate dressings may encourage formation of granulation tissue, speeding the sealing of the wound.

Lacerations Involving Synovial Structures

Lacerations into synovial structures must be identified and aggressively treated as early as possible. The veterinarian must know the locations of the synovial structures—repeated and thorough reviews of equine anatomy are helpful. Whenever a laceration occurs that is close to one of these structures, synovial involvement must be determined. The best way to confirm the involvement of a synovial structure is to place a needle into the structure at a site distant from the wound and distend the structure with sterile saline (Figure 27-6). Strict aseptic technique is a prerequisite for this injection. If the wound involves a synovial structure, aggressive therapy, including lavage, intravenous antibiotics, local perfusion, and effective wound dressings, should be performed (see Chapter 83). Synovial structures should be closed primarily if the wound can be débrided and the synovial membrane apposed.

Heel Bulb Lacerations

Lacerations to the heel bulb area are common in equine practice and can involve anything from the skin to the coffin joint, so the structures involved must be identified. Synovial involvement of either the digital flexor tendon sheath or the coffin joint should be ruled out before treatment. If there is no synovial involvement, heel bulb lacerations are often best repaired using delayed primary closure. Because the foot is in contact with the ground, most heel bulb lacerations are very contaminated. Effective wound preparation, débridement, and treatment are critical (see Chapter 26). After the wound is cleaned, it can be sutured and a slipper cast applied.[12] The

Figure 27-6. The digital tendon sheath is filled with sterile saline solution to determine if communication exists with the laceration on the lateral aspect of the fetlock region.

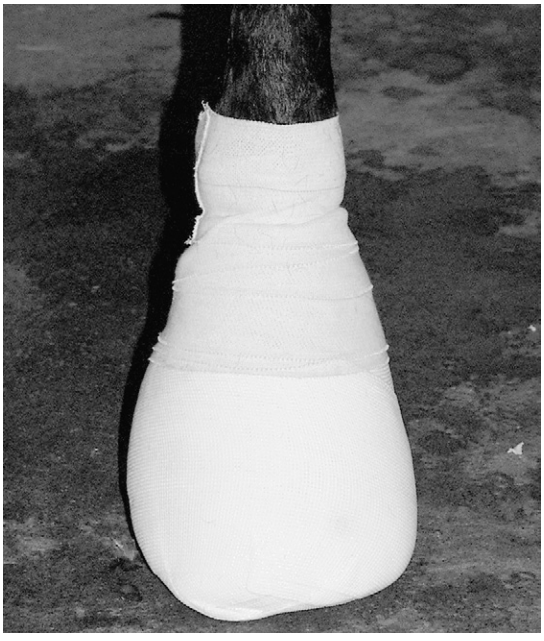

Figure 27-7. A horse in a slipper cast after reconstruction of a coronary band laceration. (See Chapter 17 for cast application.)

slipper cast reduces movement in the area and allows much more rapid and cosmetic healing (Figure 27-7). Additional information of the management of heel bulb wounds is found in Chapter 90.

CHRONIC WOUNDS

Chronic wound care can be challenging and demanding. In human medicine, "a chronic wound is a window to underlying disease. Each wound is a symptom of underlying infirmities that undermine the potential for healing."[13] The local wound environment is part of the larger milieu of the body, and chronic, nonhealing wounds can indicate a larger problem in the macroenvironment of the body.[13] Consequently, it is critical to examine the entire animal when a nonhealing or chronic wound is present. Chronic wounds in both people and horses are commonly found on the extremities. In people, they are often secondary to chronic metabolic diseases, whereas horses often have some type of underlying infection.

Much work has been done on the local wound environment of nonhealing wounds in humans. Studies have shown that wound fluid found in chronic wounds inhibits the growth of fibroblasts by affecting the cell cycle.[14,15] The negative effect of the wound fluid can be reversed by high temperatures. Tumor necrosis factor-α (TNF-α) may play a role in the reduction of fibroblast growth rates, whereas interleukin-1β (IL-1β) and transforming growth factor-β1 (TGF-β_1) do not significantly affect growth rates.[15] Other studies have shown an increase in fibroblast proliferation when these cells are exposed to wound fluid from chronic wounds.[16] Differences in experimental conditions may have caused the difference in results, which underscores the importance of further research into the effects of chronic wound fluid.

Another difference in wound fluid obtained from acute versus chronic wounds is in proteolytic activity. In acute wound fluids, the plasminogen activator system is active, and in chronic wound fluids, the urokinase-type plasminogen activator and urokinase-type plasminogen activator receptors are active.[17] Different proteins are expressed at different levels during the wound healing process. Heat shock protein, platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), and their receptors were increased in the wound within 24 hours of skin injury. The levels declined to normal levels by day 7 to day 14, coinciding with healing. The expression of these factors in chronic wounds was delayed or inhibited, suggesting that addition of these agents might improve wound healing in chronic wounds.[18]

Sarcoids are the most common cutaneous tumor in the horse. Frequently sarcoids develop at the location of previous wounds.[19] A study designed to look at the response of cells—isolated from sarcoids, granulation tissue, and normal dermal fibroblasts grown from primary cell cultures—to growth factors showed different morphologic features for each cell type. Sarcoid-derived and granulation tissue–derived cells grew more slowly than the normal dermal cells. When growth factors (epidermal growth factor, acidic fibroblast growth factor, and basic fibroblast growth factor) were added, the sarcoid-derived cells and normal cells were stimulated, but the granulation tissue–derived cells were inhibited. However, when TGF-β_1 was added, the granulation tissue–derived cells were not preferentially inhibited.[20] Continued research in wound healing should help to identify ways to change chronic wounds to acute wounds, thereby improving the healing response.

Chronic wounds often heal with a poor functional and cosmetic result. For the most functional and cosmetic healing, the best environment for wound healing should be provided early. The best way to treat a chronic wound is to not allow the wound to become chronic in the first place. Because this is not always possible, the surgeon is required to treat horses with chronic, nonhealing wounds.

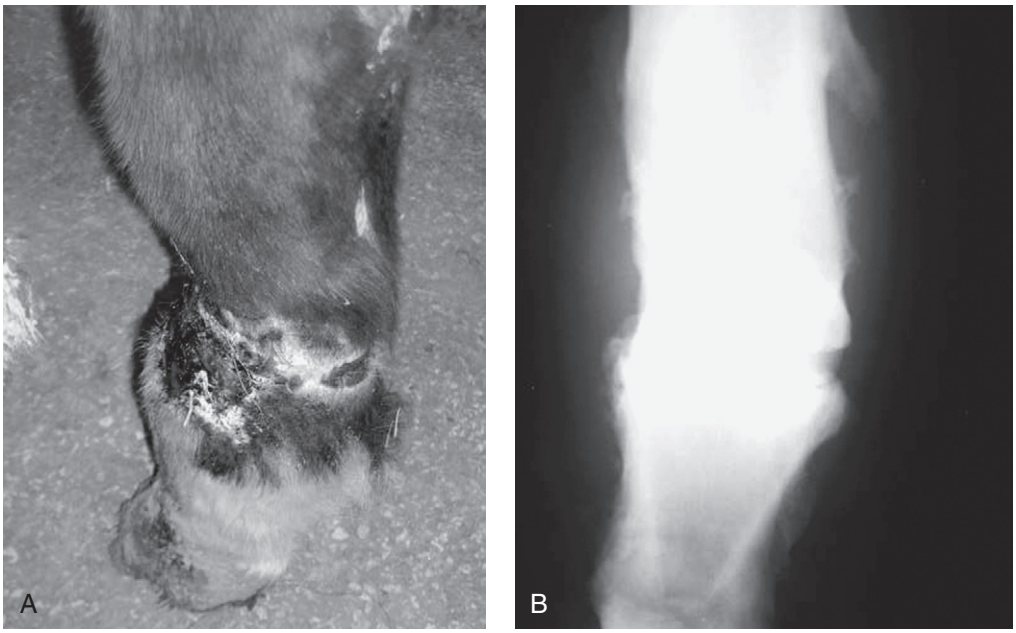

Figure 27-8. A, A chronic wound near the fetlock. **B,** Radiographic evidence of osteomyelitis and new bone production.

As with an acute wound, the first step in treating a chronic wound is to prepare the wound for examination (see Chapter 26). The examination generally starts with digital exploration. The wound should be explored for pieces of foreign material (e.g., bone, wood, metal, sand, suture material). In some cases, draining tracts are found that guide the exploration (see Chapter 28). In others, the foreign material is walled off and difficult to palpate. In those cases, ancillary methods such as radiography, ultrasonography, CT, or MRI can be useful. Radiography is best for bone and other radiodense objects. Ultrasonography can be very useful for radiolucent objects such as wood. CT and MRI may be very useful but cost is often prohibitive.

Infection should be suspected whenever a wound does not heal in the anticipated time frame. In a review of wound infection, Dow identified parameters that show the effect of chronic wound infection on wound healing.[21] He also identified the best ways to diagnose wound infection, the most common being by the clinical appearance of the wound. Inflammation, edematous granulation tissue, discolored granulation tissue, draining tracts in the granulation tissue, and odor are clinical signs that should increase suspicion of infection (Figure 27-8).

A second (and the absolute) way to determine infection in a wound is by bacterial culture. However, all wounds contain bacteria. A wound with a bacterial burden of 10^5 or 10^6 bacteria per gram of tissue is generally considered to be infected.[21] Quantitative bacteriology involves submitting a defined amount of tissue (at least a gram) for bacterial culture and calculating the number of bacteria per gram of tissue. This is rarely done in equine medicine, but it should be considered when wound healing does not progress as expected. Qualitative culture should be performed to determine the types of bacteria in the wound, and antibiotic sensitivity testing should be conducted to determine the most effective antibiotic. (See Chapter 26 for information on topical antibiotics, antiseptics, and systemic antibiotic therapy.) As mentioned repeatedly, adequate débridement and removal of foreign material represents the most important steps in reducing wound infection is.

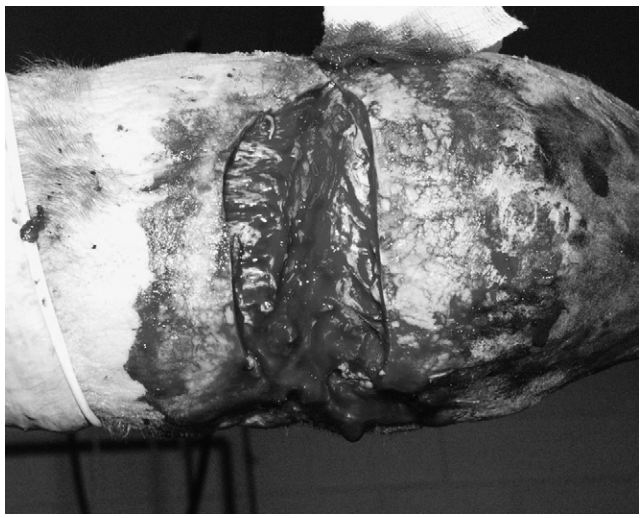

Figure 27-9. A chronic wound after débridement to encourage wound healing.

After examining and exploring the wound, the clinician decides the next step in wound care. In many cases, the wound needs to be "freshened" to stimulate it to heal. Surgical débridement, commonly used to accomplish this (Figure 27-9), can essentially turn a chronic wound into an acute wound.

Surgical débridement is a vital adjunct for wound care in humans with diabetic foot ulcers, and it is an important part of chronic wound therapy.[22,23] Any infected bone or tissue should be removed by the débridement, so that no foreign material is left behind.

As previously described, growth factors hold promise for wound healing. An understanding of the wound environment

is necessary before growth factors are routinely used.[24] Purified growth factors may be useful only in combination.

After surgical débridement, wound closure may be attempted (see Chapter 26). A benefit of working with a chronic wound is that the granulation and scar tissue often stretch the skin. After the scar tissue and granulation tissue are removed, there is ample skin to close the defect. In some cases, only a portion of the wound can be closed, and the rest is allowed to heal by second intention or skin grafting (see Figure 26-11). The skin within approximately 1 cm of the skin edge is usually not healthy enough to hold sutures, and it is often best to remove this tissue during wound débridement.

Sometimes, wounds do not respond in an anticipated fashion, and keloids or excess scar tissue results. Keloids are distinguished from hypertrophic scars in that keloids extend beyond the original wound and rarely regress.[25] The pathogenesis of keloid or hypertrophic scar formation is unknown, but it has been linked to an increased number of epidermal Langerhans' cells.[26] The epidermal immune barrier may play an important role in the development of hypertrophic scars, which have been noted to have increased blood flow in humans evaluated with laser Doppler.[27] In the normal wound healing process, the vasculature diminishes, allowing the completion of healing. Hypertrophic scars may represent an interruption in this healing process. Possibly, vasoconstrictive agents employed in the maturation stage of healing would reduce the proliferation of vasculature, which might inhibit hypertrophic scarring. In humans, there is a familial disposition to keloid formation. Steroid injection, surgical excision, radiation therapy, compression, and tension reduction have been used for treatment of keloids.[28,29] *In vitro* culturing of fibroblasts from keloids with the dietary compound quercetin (a flavonol) has shown some promise in inhibiting proliferation and contraction of the cells.[30]

CHAPTER
28 Management of Sinus Tracts and Fistulas

John A. Stick

Sinus tracts are distinct from fistulas, although the terms are often used interchangeably. A fistula is an abnormal passage or communication, usually between two internal organs or leading from an organ to the surface of the body.[1] Examples include communications between a tendon sheath and a joint (synovial fistula), from the intestine through the abdominal wall (enterocutaneous or parietal fistula), and between the mouth or esophagus and the surface of the body (orocutaneous or esophageal fistula).[2,3] A sinus tract, on the other hand, is defined as a cavity or channel. It may be normal (e.g., a venous sinus), or it may be a pathologic condition (e.g., an abnormal channel or fistula that permits the escape of pus through the skin).[1] In this chapter, the discussion is limited to the management of sinus tracts. Fistulas are described in chapters dealing with the specific affected anatomic organ or space.

ETIOLOGY

Chronic sinus tracts in horses commonly occur secondary to trauma and foreign bodies. Those involving the lower limbs are frequently associated with bone sequestra (Figure 28-1). Many of these become self-limiting, as the sequestrum undergoes natural débridement or will resolve immediately after sequestrectomy. However, chronic sinus tracts associated with foreign bodies have been described in many areas of the body and are sometimes quite difficult to resolve, especially if the foreign body is inert and not easily degraded by lysosomal enzymes released from white blood cells. Foreign bodies can be wood, metal, sand or small rocks, and even plastic.[4] Frequently, nonresorbable suture material results in a chronic sinus tract.[5]

Sharp foreign bodies have a tendency to migrate through tissues, especially when one end is blunt and the other is sharp, and can be found at some distance from the original site of entry. Examples of this include wood and metal foreign bodies with one blunt and one pointed end and can include surgical instruments.

DIAGNOSIS

Because foreign bodies are suspected at any time a chronic sinus tract is encountered, identification of the type of foreign body prior to surgery is always attempted. Foreign bodies are frequently noted as radiographic abnormalities on survey films, and, therefore survey films should always be taken. Metallic foreign bodies are easily identified this way. Other radiographic abnormalities include soft tissue swelling, thickening, gas densities, and soft tissue and periosteal reactions near bone, any of which may allow the foreign material to be located and identified.

Positive-contrast sinography is easily performed with water-soluble contrast medium (Figure 28-2). It is particularly useful for identifying of radiolucent foreign bodies, which frequently appear as space-occupying lesions in the center of the contrast

Figure 28-1. Radiograph of the carpal region of a horse that had a draining sinus tract just proximal to the carpus. Note the sequestrum on the distal radius.

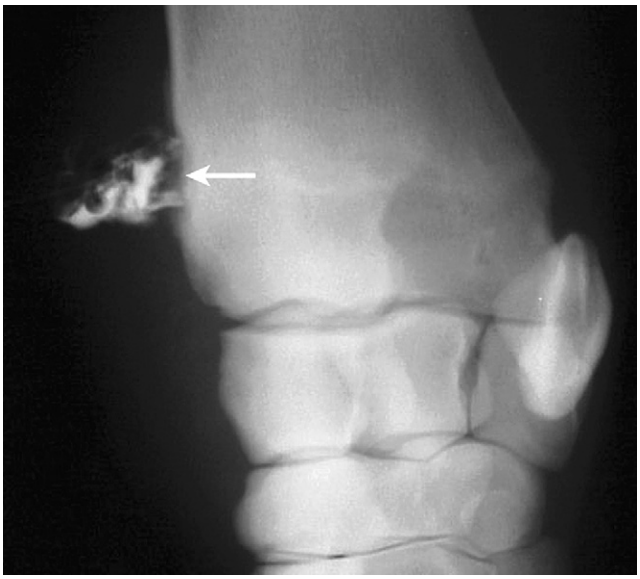

Figure 28-2. Positive-contrast sinography (performed on the horse shown in Figure 28-1) outlines the extent of a sinus tract. Note that the contrast material outlines the sequestrum *(white arrow).*

material. Ultrasonography is also useful in the diagnosis of foreign bodies such as wood, especially those embedded in muscle. Water-bath studies have shown that bone, wood, and large tendons all demonstrated acoustical shadowing in equine muscle.[6-8] Differences in hyperechogenicity and acoustical shadows help detect and identify a foreign body.

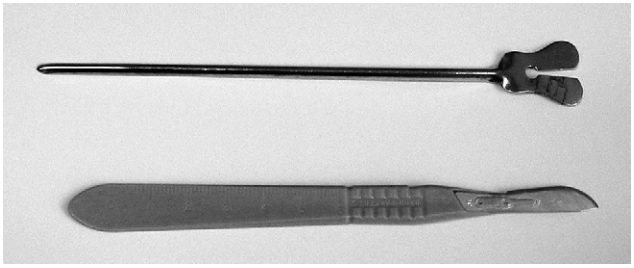

Figure 28-3. A groove director (next to a scalpel blade). When the scalpel blade is placed within the groove director with the point ventrad, the groove director guides the blade into the tract, and the incision can be made from the sinus tract outward. (See Figure 28-6.)

EXPLORATION

Extirpation of the foreign body is the treatment of choice for a chronic sinus tract. Exploration of the sinus is carried out with a malleable probe and a groove director (Figure 28-3). A malleable probe is used to determine the direction in which the exploration should occur (Figure 28-4), and a groove director allows sharp dissection of the superficial portion of the sinus tract, which can be opened rapidly without bypassing the tract. Frequently, sinus tracts travel at varying angles and need to be opened in several directions. Occasionally, they even need to be opened a fair distance from the opening in the skin.

After exploration with a malleable probe, the groove director is inserted through the opening in the skin and guided along the probe. The probe is removed and, with the point of a No. 10 scalpel blade placed in the groove, the tract is opened toward the skin (Figure 28-5).

This process is repeated if the tracts continue in other directions. When sinus tracts are quite deep, Weitlaner retractors are useful to hold open the incision. The tract itself usually has a dark purple membrane, which allows easy identification. Initial

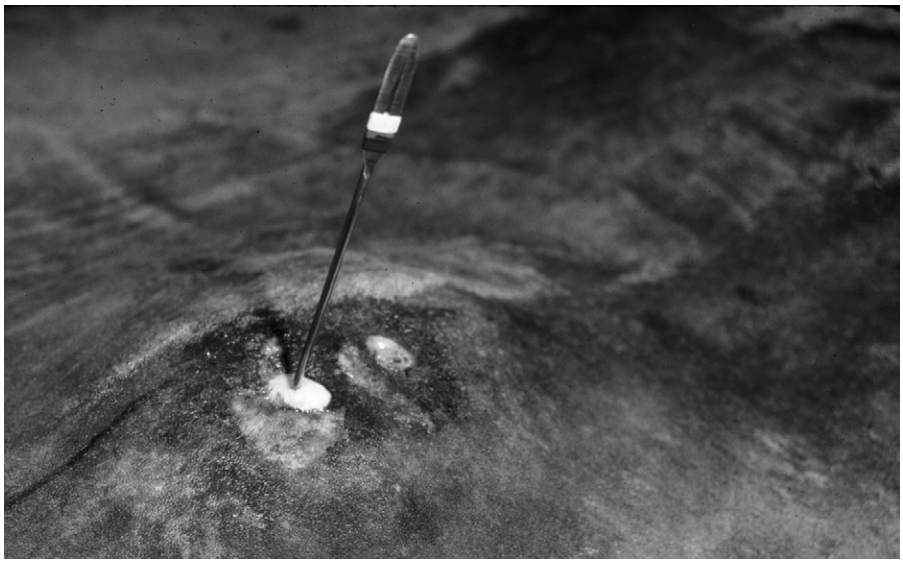

Figure 28-4. A malleable probe is inserted into one of the draining tracts in the ventral abdomen of a horse to localize the foreign body (nonabsorbable suture material in this case).

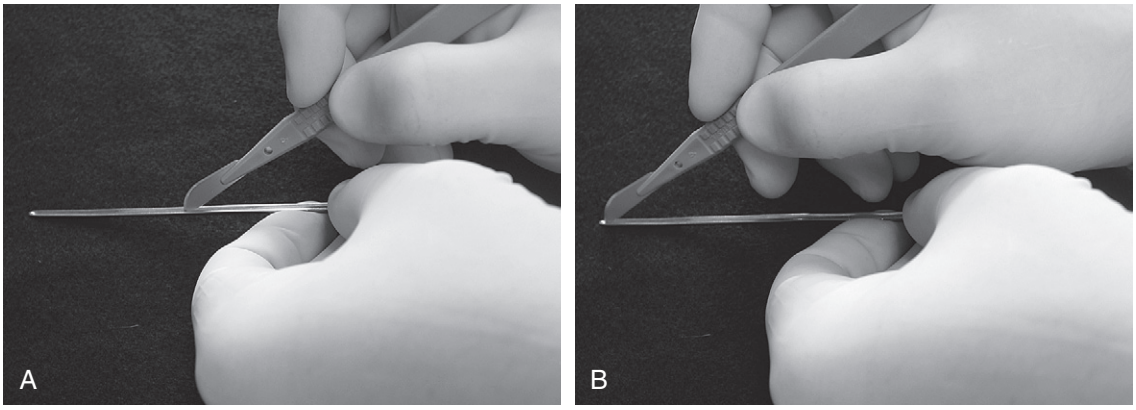

Figure 28-5. The groove director is inserted through the cloaca into the sinus tract. This is followed by sliding a No. 10 scalpel blade point in the groove of the tract **(A)** and opening toward the skin. As the scalpel blade reaches the end of the groove director, it has a stop **(B);** hence, the incision is not made beyond the extent of the end of the groove director.

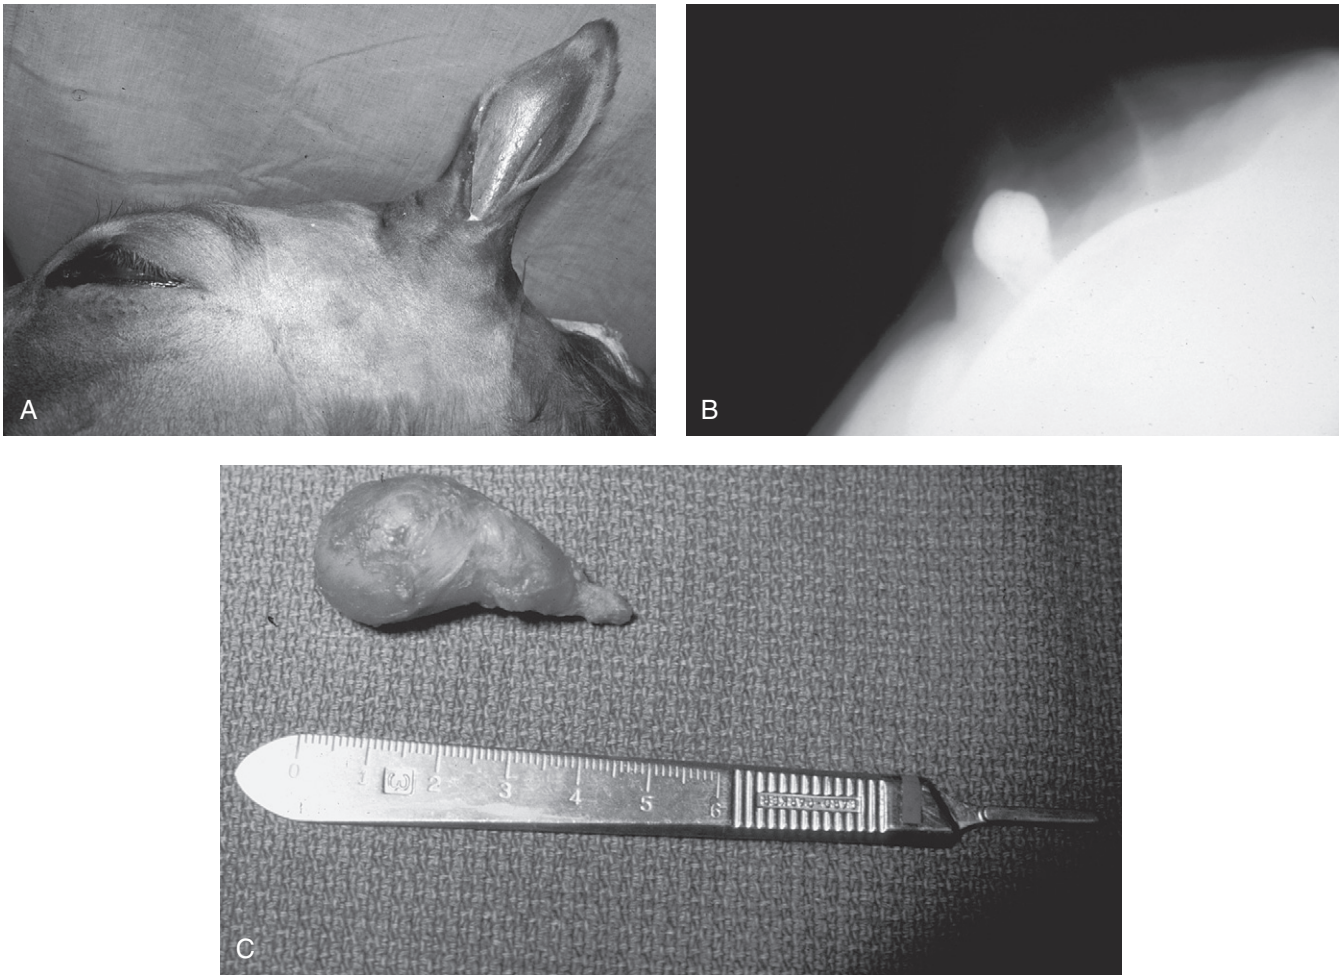

Figure 28-6. Sinus tracts located at the base of the ear usually indicate the presence of a conchal cyst. This can usually be palpated just cranial to the ear as an enlargement **(A),** radiographs confirm that it is a tooth **(B),** and the aberrant tooth with its cyst lining is removed in its entirety **(C).**

infusion of a vital dye such as Evan's blue further facilitates recognition of the tract during surgery, as it stains the tract lining dark blue.

After the foreign body has been identified and removed, all linings of the sinus tract should be curetted so that most of the bacterial contamination is removed and the sinus tract will stop draining. The membrane itself will produce purulent material for some time. The tract should be thoroughly flushed with sterile saline. Although much of the tract may be closed after this procedure, it is usually better to simply débride the cloaca rather than to close it.

SPECIAL CONSIDERATIONS

The location of the sinus tract may be an indication that the tract did not develop secondary to a foreign body. Any time a sinus tract develops on the head, a sinus infection or a dental problem should be suspected, especially if sinography outlines the tract to the apex of a tooth. A sinus tract opening found near the base of the ear is usually the result of a conchal cyst (ear tooth). This can easily be diagnosed with radiography (Figure 28-6). For details on surgical treatment of this condition, see Chapter 29. A sinus tract over the pole or the withers region may indicate the development of an infected bursa in this area (Figure 28-7). The former is called *pole evil* and the latter is

Figure 28-7. Any time a sinus tract develops along the withers, the condition of fistulous withers is suspected, and this can be confirmed radiographically. However, because this condition may be caused by a *Brucella* infection (zoonosis risk), cultures and a titer should be obtained prior to further diagnostic workup and treatment. (See Chapter 82 for more details on this condition.)

called *fistulous withers.* If either is the case, a blood sample should be taken to determine a *Brucella* titer, as brucellosis is a human health hazard.

COMPLICATIONS

Lacerations or incisions into large vessels, or even into internal organs, are possible when following a sinus tract. Therefore, caution is necessary when sinus tracts are deeply embedded in and around body cavities. Also, some sinus tracts contain more than one foreign body, especially if the foreign body is made of wood or nonabsorbable suture material. Other sinus tracts do not contain a foreign body, as it may have been absorbed or expulsed and the drainage comes from the sinus tract lining alone. Owners should be warned that recurrence is a possibility any time this exploration is attempted, and that, in fact, foreign bodies sometimes cannot be found. Another surgery may be necessary when a new cloaca forms from a new sinus tract.

CHAPTER 29

Skin Conditions Amenable to Surgery

Elizabeth A. Carr

The majority of equine skin diseases requiring a surgical consultation or surgical intervention are neoplastic in origin. Consequently, the major focus of this chapter is on neoplasms of the skin. The biological behavior, predisposing factors, diagnosis, prognosis, and treatment options are discussed. When available, comparative reviews of treatment protocols are included. The goal of this chapter is to provide information to assist the clinician in determining the best approach to treatment of a particular neoplastic condition. In addition, a handful of other skin conditions are reviewed. This is not an exhaustive review of all skin conditions but instead a review of the more common diseases, with an emphasis on those that are amenable to surgical resolution.

SARCOIDS

The equine sarcoid was first described by Jackson in 1936.[1] The most common tumor in horses worldwide, sarcoid is a cutaneous, fibroblastic neoplasm with a proliferative epithelial component.[1] Sarcoids are frequently classified histopathologically as benign tumors because of the morphologic characteristics of the fibroblasts and because many sarcoids are slow growing and cause little if any physical problems in the affected animal. This classification is misleading, however, and ignores the large number of sarcoid tumors whose clinical behavior can only be described as malignant.[2]

Sarcoids are subtyped, on the basis of clinical appearance, into occult, verrucous, nodular fibroblastic, ulcerative fibroblastic, mixed tumors, and malevolent. This classification correlates with their biological behavior (Figure 29-1). The most aggressive subtype consists of malevolent sarcoids, which infiltrate locally along fascial planes and vessels; grow rapidly, and have a high recurrence rate after excision.[2]

Sites of predilection vary with geographic location and include the face (muzzle, ears, and periocular region), distal limbs, neck or ventral abdomen, and areas of previous injury and scarring.[3] Location has been reported to affect prognosis, with sarcoids on the distal limb and periorbital region having a worse prognosis for resolution than sarcoids in other locations.

Epidemiology

The relationship between breed and risk for development of sarcoid was evaluated in a large number of horses admitted to the New York State College of Veterinary Medicine between 1975 and 1987.[4] Quarter Horses and related stock breeds were almost twice as likely to develop sarcoid as Thoroughbreds. Standardbred horses were less than half as likely to develop sarcoid as Thoroughbred horses. A direct genetic linkage has been reported between equine leukocyte antigens (ELA) and risk for equine sarcoid. ELA alleles A3 and W13 were strongly associated with risk for sarcoids in Thoroughbreds and Swiss, French, and Irish Warmblood horses.[5-7] The absence of the W13 allele in the Standardbred population may confer relative resistance to sarcoid. Interestingly, a familial predisposition has been reported in a herd in which all five descendants of a sarcoid-affected mare developed sarcoid, whereas none of the unrelated animals on the premises developed these tumors.[8]

Spontaneous malignancies that develop as a result of serial genetic mutations are more common in older animals. Sarcoids generally develop in younger individuals, suggesting a genetic

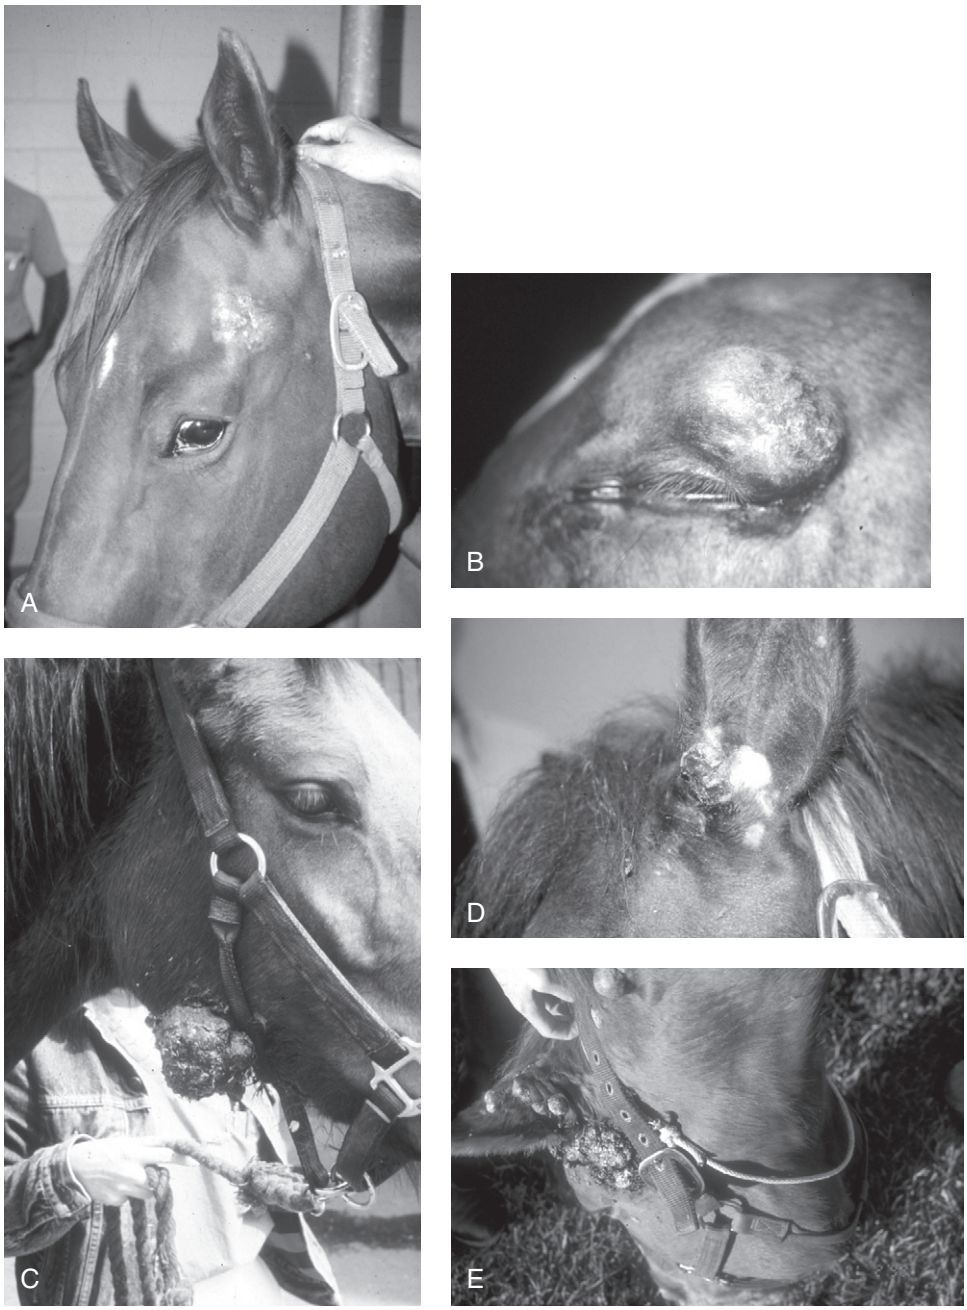

Figure 29-1. Subtypes of sarcoids. **A,** A verrucous sarcoid on the temporal region of the head. **B,** A subcutaneous fibroblastic sarcoid. **C,** An ulcerative fibroblastic sarcoid. **D,** A mixed form consisting of both verrucous and fibroblastic components. **E,** A horse with a malevolent sarcoid. The lesion had spread down the neck along lymphatic chains and to the retropharyngeal and parotid lymph nodes.

predisposition or an exogenous factor. Individuals with a genetic predisposition have an inherited gene defect that increases their susceptibility to further mutation. Consequently, these individuals develop tumors at a much earlier age. The genetic predisposition for and the age of onset of sarcoids suggest that both genetic factors and exogenous factors may play a role in development. A long-term epidemiologic study of a large herd of donkeys suggests the possibility of transmission of sarcoids between individuals housed in close contact.[9] In addition, an epizootic outbreak was reported in a small herd.[8] Incidence peaked in young horses over a 1-year period. Interestingly, only related, highly inbred animals were affected. A vector such as a fly may explain the predisposition for tumors to develop around the eye, distal limbs, and ventrum (common feeding locations for these insects).

A specific viral etiology was first proposed by Olsen and Cook.[10] While studying the transmissibility of cutaneous papillomas, they noted a striking similarity between equine sarcoid and experimental lesions induced by the injection of bovine wart extracts into the skin of individual horses. Several research groups have since confirmed the presence of bovine papillomavirus (BPV) DNA in nearly all equine sarcoid tissues examined.[11-20] Papillomaviruses play a role in oncogenic transformation in other species, but viral infection alone is not enough to trigger

transformation, as BPV DNA can be found in normal skin of sarcoid-affected horses.[20-22] Papillomavirus infection of an abnormal host (such as BPV infection in a horse) generally results in a nonproductive infection; consequently, no viral capsids are produced. Instead, the virus maintains its presence by production of several housekeeping genes, including two, *E5* and *E6*, known to be capable of transforming cells to malignancy. The production of one of these two transforming genes, *E5*, has been documented in a small number of sarcoids examined.[23] Expression of the viral E5 protein appeared to correlate with the grade of tumor malignancy. Furthermore, although viral DNA was detected in normal skin surrounding sarcoids, E5 protein expression was not. A triggering event such as trauma may be required to activate a latent viral state. This could be one explanation for the tendency for sarcoids to occur at the sites of previous injuries. Experimental inoculation of purified viral DNA has resulted in sarcoid-like tumors, but the majority of these lesions regress spontaneously.[24]

A viral role is strongly suggested by the finding of viral DNA and viral transforming proteins in all sarcoids examined. However, the mechanism of viral transformation is unclear. Given the genetic and breed predispositions, sarcoid occurrence is most likely the result of host, viral, and environmental factors.

Treatment

There are numerous articles regarding treatment of sarcoids. The number of treatment options reflects the variable success as well as the costs of certain treatments. Efficacy is difficult to critically assess; most early studies were not controlled and were based on a subset of cases sent to referral hospitals. Sarcoids commonly referred for treatment are usually more aggressive variants or tumors that have recurred after unsuccessful treatment. Sarcoids can transform to a more aggressive phenotype after incomplete or unsuccessful treatment and are then harder to resolve. In contrast to those tumors typically seen at referral centers, there is anecdotal evidence of a subset of sarcoids that remain quiescent and of others that undergo spontaneous regression.

Surgical Excision

Surgical excision without adjunctive therapy has been reported to be one of the least successful treatment options, having a recurrence rate of 15.8% to 82%.[3,25-27] The reason for this may in part be that tumor projects fronds of malignant cells into the surrounding "normal tissue."[28] Because these projections are infrequent, they are missed on histopathologic review, leading to an incorrect assumption of complete excision. In addition, the possibility exists that a viral agent may remain latent in the surrounding tissue.[20,21] Surgical trauma and the subsequent growth stimulation may trigger viral activation and expression of viral oncogenes. In a recent prospective trial, the detection of viral DNA at the surgical margin of an excised sarcoid correlated with an increased risk of recurrence.[21]

Laser Ablation

Laser ablation of tumors has been used to remove or debulk tumor mass.[25,29-32] Laser ablation causes less damage to the surrounding tissues and less spread of malignant cells to healthy regions than sharp surgical excision with mechanical tools. A large retrospective study evaluating CO_2 laser excision of 60 sarcoids documented an overall recurrence rate of 38%.[30] The use of laser ablation in conjunction with intralesional chemotherapy or other adjunctive therapy may improve overall success rates.

Cryotherapy

Cryotherapy (see Chapter 14) has historically been one of the most commonly used methods for treatment of equine sarcoid.[33-35] Success rates of 60% to 100% have been reported. However, a recent retrospective study evaluating treatment success in a large number of periorbital sarcoids reported a recurrence rate of 91% (9% success rate) in tumors treated by cryotherapy.[27] Longer follow-up time may explain the discrepancy in successful outcome. Cryotherapy has its greatest success with veterinarians who use it frequently and have experience with duration and depth of freeze, which are important for an effective response. Thermocouples can be used for more precise measurement of the tissue temperature and depth of freeze. In one report, the use of a three-treatment −30° C protocol was felt to be more effective than a two-treatment −20° C protocol, with an overall initial success rate of 68%.[33] With multiple repeat treatments, the success rate improved to 85% (85 tumors resolved of 100 retreated). Thirty-three of the 50 horses were cured of their sarcoids using a liquid nitrogen spray apparatus, although many required multiple treatments.[34] Three horses in this study had spontaneous regression of untreated tumors after cryotherapy of another lesion. This seems to indicate that destruction of one tumor can result in an immune response against other, distant sarcoids.

Hyperthermia

Hyperthermia has been reported to be successful in a small number of equine sarcoids, with spontaneous resolution of some of the nontreated tumors.[36] Differences in the metabolic rate of tumor cells compared with normal cells is thought to make the tumor cell more heat sensitive.

Radiotherapy

Radiotherapy using locally implanted iridium-192 has been reported to be successful in the treatment of sarcoids.[27,37-39] The recurrence rate was low, with 1-year tumor-free incidences of 94%, 87.5%, and 100%. Radiotherapy using a linear source of iridium-192 has been reported to have a 100% success rate in a small number of sarcoids.[40] All cases were reported to resolve after a single dose of radiation. Recurrence rate at 1 year was zero for all tumor types, but the number of cases actually followed for a full year was not reported. The 1-year progression-free survival was 86.6% in 62 sarcoids treated with iridium interstitial brachytherapy.[41] Treatment complications included hair and pigment loss as well as fibrosis, cataract formation, and corneal ulceration when treating periocular tumors. Radioactive gold-198 implants have been reported to have a high success rate for treatment of sarcoids—a rate similar to that for the other implant therapies.[42] Although reported success rates using radiation therapy are high, treatment is expensive, requires special equipment and housing, and is potentially hazardous. General anesthesia may be required to implant iridium needles or to deliver a radiation dose via a linear source. These limitations

make radiation therapy a difficult and infrequently used method of treatment and confine its use to referral centers.

Immunotherapy

Immunotherapy has been used to successfully treat sarcoids in several reports.[27,35,43-45] Several immunostimulants have been used, including *Mycobacterium* cell wall extracts, live whole-cell bacille Calmette-Guérin (BCG), and propionibacterial cell wall extracts. These products are thought to stimulate cell-mediated immunity, leading to recognition of tumor cell–specific antigens and subsequently to tumor cell destruction. Most immune stimulants require multiple intralesional injections with or without prior cytoreduction of the tumor mass. Success rates are high for smaller tumors, tumors located periorbitally, and fibroblastic tumors. Knottenbelt and Kelly reported a poorer success rate with occult or verrucous periorbital lesions and hypothesized that this was because of the inability to saturate the tumor bed effectively.[27] Multiple treatments are generally required. Local tissue swelling can be quite severe, and complications include death from anaphylactic shock, particularly after two or more injections.[45] Spontaneous regression of untreated tumors has also been reported with immunotherapy.[35] Recurrence rates vary from 0% to 40%, depending on the study and observation time.[27,35,43-45]

More specific immunotherapy in the form of *vaccination* has been used to treat equine sarcoids for decades with variable success. More recently, a vaccine consisting of tumor tissue was successfully used to treat 20 of 21 horses presenting with equine sarcoid, though multiple treatments were required in some cases.[46] Vaccination of sarcoid affected donkeys using a chimeric virus-like particle that expressed viral proteins had limited success.[47]

Intralesional Cisplatin

Intralesional cisplatin in an oily emulsion is reported to have an 87% 1-year relapse-free rate for sarcoids.[48] The repositol effect of the oily emulsion prevents significant systemic levels, avoiding systemic toxicity, and maintains effective tissue levels of the chemotherapeutic for prolonged periods of time.[48] Epinephrine can be added to the emulsion (1 : 1000, diluted 1 : 10). The resultant vasoconstriction prolongs tumor cell exposure to cisplatin. A dosage of 1 mg cisplatin per cubic centimeter of tumor mass, with a minimum of four treatments, is recommended. Cytoreduction to decrease the mass of the tumor is beneficial when treating large tumors. Intralesional cisplatin instituted at the time of surgical excision or debulking was not shown to affect wound healing.[49] The repositol effect of the oily emulsion is critical for treatment success. A 66% recurrence rate after cisplatin treatment was reported by Knottenbelt.[27] However, the concentration used was lower than that recommended by the original authors.[48]

Intralesional tumor necrosis factor (TNF) combined with a xanthate compound has also been used with success.[50]

Topical Application of Chemotherapeutics

Topical application of chemotherapeutic agents, including 5-fluorouracil (5-FU) and a series of compounded creams, AW3-LUDES and AW4-LUDES, have been reported to be successful in the resolution of sarcoids.[27,51,52] 5-FU had a resolution rate of 66% in 9 tumors treated daily for 15 days, but only small occult or verrucous sarcoids were chosen for this treatment protocol.[27] In the same report, the AW4-LUDES cream had a resolution rate of 35% (56 of 146 tumors treated) without complication. The authors reserved this treatment for small, previously untreated verrucous lesions. Six additional tumors resolved with the topical application of AW4-LUDES but had significant scarring after treatment. As with 5-FU, the authors recommend avoiding the use of these creams on tumors in close proximity to the eye. Topical application of a compounded cream containing bloodroot and zinc is anecdotally reported to be extremely effective in the treatment of equine sarcoid, but few controlled studies have been done. I evaluated one sarcoid-affected horse that was treated with this compound; in response to the compound, the tumor became very swollen and ulcerated and began to grow rapidly. More controlled studies evaluating the efficacy of bloodroot and zinc against different types of sarcoid tumors are needed.

Spontaneous regression of untreated tumors suggests that immune recognition plays a role in tumor resolution.[36] Anecdotal reports of successful vaccination therapy exist, but controlled studies are rare. In one report, successful resolution was achieved in 11 of 12 horses treated with an autogenous tumor vaccine.[53] A second vaccination protocol resulted in resolution of the one recurrence. All 12 cases had had no previous tumor treatment. A lower success rate was reported in horses with previously treated, recurrent sarcoids.

With large, aggressive, or multiple tumors, it is recommended that a combination of treatment modalities be employed. At the Veterinary Teaching Hospital at Michigan State University, surgical excision or laser ablation is commonly combined with intralesional chemotherapy or radiation therapy. Unfortunately, these combination treatment regimens are expensive and require a significant time commitment from the owner or caretaker of the patient.

SQUAMOUS CELL CARCINOMA

Epidemiology

Squamous cell carcinoma (SCC), a malignant, locally invasive neoplasia of squamous epithelial cells, is the second most common tumor in horses.[54,55] Although SCC can develop anywhere on the integument, sites of predilection include areas lacking pigmentation, poorly haired regions, and skin near mucocutaneous junctions. SCC is the most common neoplasm of the equine eye, conjunctiva, ocular adnexal structures, and external genitalia.[56] It has also been reported in the nasal cavity, paranasal sinuses, pharynx, larynx, and hoof capsule, and it should be considered in horses with chronic, refractory foot abscesses.[57-60] Ultraviolet light–induced damage is thought to predispose to SCC. Many tumors arise from precancerous lesions, including actinic keratosis, carcinoma *in situ*, squamous metaplasia of the penile epithelium, and irritant-induced chronic keratitis.[61,62] Proposed irritants include topically applied chemicals, smegma, and flies. SCC has been reported to develop in areas of chronic, poorly healing wounds and at sites of previous burn injury.[56,63,64] Breeds with poorly pigmented, pink-skinned areas, including Appaloosas and paint-colored horses, are more prone to develop SCC; 69% of all ocular SCC cases occur in individuals lacking periocular pigmentation.[65]It has been suggested that draft breeds have an increased incidence of SCC.[60]

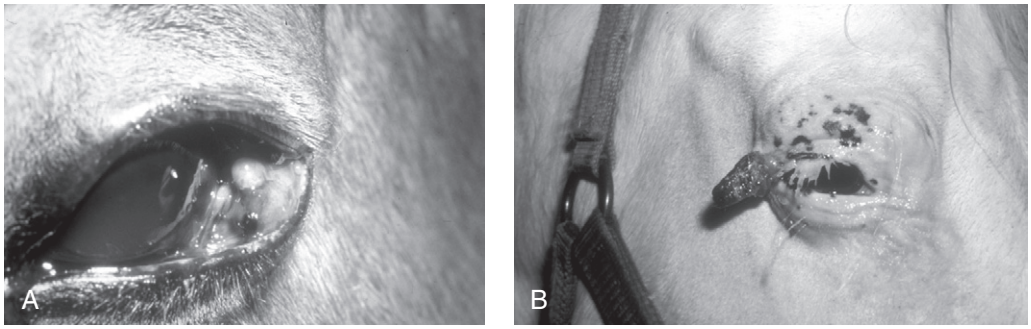

Figure 29-2. Squamous cell carcinoma. **A,** Ulcerative, proliferative lesion involving the conjunctiva of the eye in a bay Quarter Horse mare. **B,** Pedunculated lesion involving the margin of the upper eyelid in an Appaloosa mare.

Tumors are classified as ulcerative or proliferative and generally arise as solitary lesions. Ulcerative SCC may develop over time, with early lesions appearing as small nodules underlying normal-haired skin. Ulcerative lesions can be mistaken for nonhealing wounds and chronic granulation tissue, resulting in delayed treatment. Ocular lesions can begin as small ulcerative lesions on lid margins, or as keratitic plaques on the cornea, so SCC should be suspected whenever raised red lesions appear on the lid margins, sclera, or conjunctiva, particularly in unpigmented skin (Figure 29-2). Squamous cell carcinoma of the ocular structures can invade the orbit, calvarium, tear duct, and sinuses if left untreated. Proliferative pedunculated lesions on the penis often have a cauliflower-like appearance. SCC typically spreads to surrounding tissues and local lymph nodes, but distant metastasis is rare (see Chapter 60). Tumors with local or distant metastases or large, invasive tumors have a poor prognosis for cure.

Treatment

Surgical excision, radiation therapy, topical application of antimitotics, intralesional chemotherapy, cryotherapy, laser excision, hyperthermia, immunotherapy, and photodynamic therapy have all been successfully used to treat equine SCC.[42,48,66-80] Surgical excision alone should be reserved for small tumors and has a better overall success rate when combined with adjunctive therapies such as chemotherapy, cryotherapy, or radiation therapy.[49,66,67] Keratoplasty with or without adjunctive radiation therapy has been used successfully to treat corneal SCC.[68,69] Cryotherapy is reported to be most useful in small periocular lesions and lesions arising from the external genitalia. Larger lesions may benefit from surgical debulking prior to cryotherapy.[70,71] Frequent reexamination is recommended to monitor regrowth and may be the most important determinant of success. Failure to retreat small recurrences quickly may allow tumor regrowth and failure of the treatment protocol.

Irradiation

Several radiation modalities have been used to successfully treat SCC, including external beam radiotherapy, implanted radiation devices, and b-emitting wands. Strontium wands (b-radiation) can be used to treat small superficial plaques on the cornea, sclera, or conjunctiva.[72-74] Beta irradiation has a very short penetration depth, making it extremely useful for small corneal lesions; an 89% nonrecurrence rate was reported in one study.[73] Both radioactive implants and external beam therapy have been reported as successful in the treatment of SCC.[42,75-78] External beam therapy can be performed on an outpatient basis, whereas radiation implants require hospitalization and special housing during treatment protocols. Radiation therapy is generally limited to referral practices because of the licensure requirement, specialized equipment, and housing requirements.

Intralesional Chemotherapy

Intralesional chemotherapy is very effective in treating SCC, whether as an adjunctive treatment after surgical cytoreduction or as a sole treatment protocol.[48,49] Cisplatin binds directly to DNA and inhibits its synthesis in dividing cells. Mixing cisplatin in an oily emulsion creates a repositol effect, maintaining the drug in the local tissues for a prolonged period of time. Intralesional cisplatin in oily emulsion used with or without surgical cytoreduction has a 2-year local control rate of 89% for SCC. Overall success is better with SCC of the external genitalia than with periorbital SCC. Cosmetic results are generally excellent. Drawbacks include the multiple treatments needed, the expense, and potential exposure of the staff, but overall success rates are high.

Topical Chemotherapy

Topical 5-FU, with or without surgical débridement, has a reported success rate of 90% in the treatment of SCC of the male external genitalia.[78] In another small case series, three individuals with superficial SCC were successfully treated with repeated application of topical 5-FU.[79] Topical application was associated with local inflammation and swelling. The use of 5-FU as a sole treatment modality is best reserved for small superficial tumors.

Photodynamic therapy using a diode laser was used as an adjunct therapy in 9 horses (10 eyes) with periocular SCC following surgical debulking. Horses were tumor free for the duration of the study (25 to 698 months of follow-up).[80]

Successful treatment of a recurrent SCC of the lower lip using the nonsteroidal anti-inflammatory piroxicam is reported.[81] Nonsteroidal anti-inflammatory drugs inhibit cyclooxygenase (COX) enzymes that catalyze the conversion of arachidonic acid to prostaglandins. Overexpression of the COX-2 enzyme by neoplastic tissue has been reported.[82] Both the lower lip and metastatic lesions resolved with oral piroxicam therapy. No recurrence was reported at the 5-year follow-up. Successful treatment of periocular SCC using immunotherapy has also been reported, but case numbers are small.[83]

In a retrospective study of 43 horses with ocular SCC, nonrecurrence rates were 55.6% for surgical excision, 75% for radiation therapy, and 33.4% for cryotherapy, and combination therapy had a greater success rate than single-modality treatment.[66] In a retrospective study of 147 cases of ocular/adnexal SCC, factors that influenced survival included tumor location and size. Prior treatment modalities, the presence of multiple tumors, and treatment modality used at the time of examination did not influence survival.[84]

MELANOMA

Epidemiology

Equine melanoma is one of the most common skin tumors in horses. Histopathologic surveys report that melanomas account for 4% to 15% of all skin tumors.[62,85] The majority of melanomas occur in gray horses; breed predispositions are most likely caused by the incidence of the color gray within a breed. Virtually all gray horses will develop melanoma over time. In a population study of Lipizzan horses, less than 6% of horses 16 years of age or older were melanoma free.[86] Melanocytic tumors in gray horses are thought to arise because of a disturbance in melanin transfer from dermal melanocytes to follicular cells.[87] Progression from melanocyte accumulation to melanoma formation has been documented in melanoma-prone locations. Interestingly, sites of predilection are the first areas to show depigmentation changes (vitiligo) with aging.[88] There are four types of equine melanomas: melanocytic nevi, dermal melanomas, dermal melanomatosis, and malignant melanomas.[89] *Melanocytic nevi* are composed of larger pleomorphic melanocytes with an increased number of mitotic figures, binucleate cells, and variable cytoplasmic pigmentation. Melanocytic nevi are typically single or multiple discrete nodules and are found in similar frequency in both gray and nongray individuals.[89]

Dermal melanoma and melanomatosis appear benign on histopathologic examination and are composed of smaller, homogenous dendritic cells with condensed chromatin, dense pigmentation, and no visible mitosis. *Dermal melanomas* originate in the deeper dermis and are typically small singular or multiple nodules (Figure 29-3). *Dermal melanomatosis* is defined as confluent multiple large melanomas. The risk of dermal melanomatosis increases with age and its occurrence is associated with an increased risk of metastases.[86,89] True *malignant melanomas* are rare and are classified on the basis of the presence of both histopathologic and clinical characteristics of malignancy.[89] In one retrospective study, only 2 of 53 cases were classified as malignant. Both occurred in aged horses (older than 20 years), and both recurred within 10 months after surgical excision.[89] Malignant melanomas are frequently invasive and associated with a poor prognosis for complete resolution.[89-94]

Figure 29-3. Dermal melanomas on the ventral surface of the tail in a gray horse.

The majority of melanomas are located around the perineum and base of the tail, with lesions around the head (lips, eyes, parotid region) and other sites less frequently reported. Melanomas have also been reported in the foot, meninges, thorax, ocular structures, and abdominal cavity. These unusual locations appear to be associated with a poor prognosis.[89-96]

Treatment

Despite their histopathologic differences, dermal melanomas and melanocytic nevi have similar clinical characteristics, and surgical excision is curative in the majority of cases. Smaller lesions can be sharply excised; alternatively, the use of the CO_2 laser has been recommended.[97] The ability to cauterize the wound bed and control hemorrhage makes laser excision particularly useful in sites where primary closure cannot be achieved (e.g., the base of the tail).

Complete excision is difficult with larger lesions such as dermal melanomatosis, but surgical debulking can be palliative.[98] Oral cimetidine has been recommended to treat melanomas, particularly larger lesions and those exhibiting a rapid growth phase.[99-103] Cimetidine has antitumor activity and is a histamine receptor antagonist. Immunomodulation of lymphocyte activity via histamine receptor interaction is postulated to be a mechanism of antitumor activity. Reports of the effectiveness of cimetidine in the treatment of equine melanoma are variable. Response is reported to be the highest in tumors exhibiting a rapid growth phase; successful response was achieved using a dose of 2.5 mg/kg every 8 hours. The frequency of dosing may be the most critical factor in predicting clinical response. Treatment is recommended for 3 months, or for 3 weeks after cessation of tumor growth. Although a complete cure has rarely been reported, cimetidine may have some benefit in halting rapidly growing tumors and returning them to a more quiescent state.[98]

Additional treatments for equine melanoma include intralesional chemotherapy and cryotherapy. Successful treatment of smaller nodules has been reported using intralesional cisplatin, and this is beneficial in decreasing the size of larger tumors prior to surgical excision.[103,104]

A melanoma vaccine is available and has been reported to have some success.[105] Successful treatment of malignant melanoma using a cytokine-enhanced suicide gene therapy was recently reported. Repetitive treatments were performed and resolution of both treated and untreated tumors was reported with a tumor-free follow-up of 33 months.[106] The successful treatment of equine melanoma using intratumoral injections of human interleukin (IL)-12 has also been reported.[107]

In one study that examined melanomas in a population of gray horses, all patients exhibited normal quality of life regardless of tumor number and type.[86] Consequently, it is frequently suggested that melanomas be treated with benign neglect, because they are rarely the cause of significant disease in affected horses. However, with age, the risk of progression to dermal melanomatosis and metastases increases. Small nodules are

easily removed and rarely recur, but owners need to be informed that new tumors will quite likely develop over time. Although conservative management is reasonable in the majority of cases, more aggressive treatment, including early removal of smaller tumors, may decrease the risk of melanomatosis or metastases as the animal ages.

Malignant melanomas have a higher recurrence rate with simple excision. Combination therapy, including surgical debulking and intralesional chemotherapeutic injections, may offer palliation, but the prognosis for cure is poor.[88,92]

MAST CELL TUMORS

Epidemiology

Equine cutaneous mastocytosis (ECM) is less common in horses than in small animals.[108] The benign, solitary, nodular cutaneous form is the most common, although malignant ECM and congenital disseminated forms have been recognized.[109-111]It has been suggested that the benign nodular form is not a true neoplasia and is instead the result of an inflammatory reaction to dysplastic mast cells and recruited eosinophils.[112] The release of inflammatory products from accumulated eosinophils and mast cells results in necrosis, and later a granulomatous reaction develops with fibrosis and subsequent encapsulation of the nodule. The histopathologic findings of a necrotic focus, a granulomatous inflammatory response, and fibrosis surrounding well-differentiated mast cells differentiates equine cutaneous nodular mastocytosis from malignant ECM, which contains abnormal mast cells with increased nuclear-to-cytoplasmic ratios, anisokaryosis, and increased mitotic figures.[110]

Treatment

The majority of cutaneous nodular ECMs are successfully treated with wide surgical excision (margins of 1 cm or greater).[108] Reports of resolution after incomplete resection exist. Intralesional injection of glucocorticoids has also been used to successfully treat cutaneous nodular ECM. Malignant ECM is not responsive to surgical excision and is associated with a poor prognosis for cure.

LIPOMAS

Epidemiology

External lipomas are a relatively uncommon neoplasia in horses. Unlike mesenteric lipomas, they are principally found in young horses.[113-115] Subcutaneous lipomas are generally encapsulated, singular, nonpainful masses that are fluctuant to firm on palpation, although infiltrative lipomas have been reported in the horse.[113-115] Sites of occurrence include the limbs, thorax, abdominal wall, and eyelids. Histopathologic examination reveals encapsulated well-differentiated adipocytes. Infiltrative lipomas consist of similar cell types infiltrating surrounding muscle tissue.[116]

Treatment

Lipomas are generally encapsulated, slow-growing masses, and thus they are benign, clinically insignificant, and typically a cosmetic concern only. Surgical excision is reported to be curative in all cases; recurrence has not been reported even with incomplete excision of infiltrative or large lipomas.

CUTANEOUS HABRONEMIASIS

Epidemiology

Cutaneous habronemiasis is a proliferative ulcerative lesion produced by aberrant migration of the larvae of three endoparasites *(Habronema muscae, Habronema microstoma*, and *Draschia megastoma)* that inhabit the stomach of horses.[117] Eggs, shed in the feces of horses, hatch, and the larvae are ingested by maggots of the house fly, *Musca domestica*, or the stable fly, *Stomoxys calcitrans*. Third-stage infective larvae migrate to the head of the fly and are passed to the horse when the fly feeds on a warm, wet surface. The larvae are then swallowed by the horse and mature to adults in the stomach. The cutaneous form, also called summer sores, develops when larvae are attached to wound beds or aberrant moist surfaces, including the penis, prepuce, and ocular adnexa.[118,119] Lesions are most commonly seen on the penis, in cutaneous wounds, or around the eye. The proliferative, ulcerative, granulomatous lesions are thought to result from a hypersensitivity reaction to the larvae, and mild to severe pruritus may develop.[120]

Ophthalmic habronemiasis can develop in the conjunctiva or nasolacrimal ducts, resulting in third-eyelid granulomas or granulating ulcers below the medial canthus. Clinical signs include epiphora, chemosis, and photophobia. The presence of pale yellow granular material, or the finding of larvae on impression smears, may aid in the diagnosis. Histopathologic examination is recommended, because habronemiasis can develop secondary to an underlying neoplastic or infectious condition. The incidence of disease has declined dramatically since the development of ivermectin anthelmintics. Lesions occur principally in warm months and are associated with increased fly populations and poor manure collection.

Treatment

Lesions have been reported to resolve with onset of cooler weather.[119] Treatment is aimed at reducing the size of the lesions, resolving the inflammatory or allergic component, and preventing reinfestation.[119] Treatment with systemic ivermectin will kill migrating larvae but may not result in resolution of the lesion, because the dead parasite can continue to cause a severe inflammatory reaction. In some cases, oral ivermectin results in an increase in pruritus and self-trauma. Larger masses may require surgical cytoreduction. The intralesional injection of corticosteroid is recommended to decrease the allergic or inflammatory reaction to the larvae. Successful resolution using systemic corticosteroids alone has been reported.[120] Re-infestation can be prevented by application of topical organophosphates or by placing the wound under a bandage. Topical preparations that combine organophosphates, corticosteroids, dimethyl sulfoxide, and nitrofurazone have been used.[108,119] The ophthalmic form of habronemiasis can be treated with oral ivermectin, topical corticosteroid eye drops, and curettage. Careful assessment of the corneal integrity should be made prior to the use of ophthalmic corticosteroids.

PYTHIOSIS

Epidemiology

Pythiosis is a cutaneous disease caused by invasion of the organism *Pythium insidiosum*, a fungus-like oomycete.[121] The disease occurs principally in warm, tropical regions; the organism has

an aquatic life cycle and requires relatively warm temperatures for reproduction.[121] Pythiosis is commonly seen in the southern United States during the late summer and early fall. Horses are infected when invasion occurs through small wounds or skin breaks, typically in lakes, swamps, or flooded lands. Zoospores, released during reproduction, are attracted to organic debris and invade open wounds.[121] Characteristic lesions are ulcerative masses of granulation tissue. Rapid enlargement can occur, even within a matter of days. Pythiosis is often pruritic; sinus tracts are visible and often contain gritty, coral-like masses, called "kunker" or "leeches."[122] Kunker are made of necrotic vessels, inflammatory cells, and *Pythium hyphae.* Pythiosis occurs most commonly on the distal extremities and ventral body wall.[123] In chronic, untreated infections, invasion of deeper tissues, including bone, joints, tendon sheaths, and lymph nodes, can occur.[123-126] The diagnosis of pythiosis is made on the basis of the history and clinical signs, when the causative organism is found on culture or histopathologic examination.

Treatment

Surgical excision is the treatment of choice for pythiosis. If surgical excision is impossible because of the size or location of the lesion, the prognosis for resolution is poor. Systemic, topical, and intralesional antifungals have been used, but recurrence is common.[126]

Amphotericin B is administered intravenously at a dosage of 0.3 mg/kg diluted in 1 L of 5% dextrose.[127] The dose is increased by 0.1 mg/kg every third day until a maximal dosage of 0.8 to 0.9 mg/kg is achieved. Treatment can be continued daily for 30 days and then every other day until the horse is cured. Sodium iodide administered intravenously has been recommended as an adjunctive therapy.[126] A recent report showed improved *in vitro* susceptibility of 17 equine isolates using an antifungal in combination with terbinafine compared to antifungal agents alone.[128] Further work is needed to assess efficacy *in vivo*.

In addition, a topical dressing containing 50 mg amphotericin B, 10 mL sterile water, and 10 mL dimethyl sulfoxide is recommended.[125] Because amphotericin B is nephrotoxic, serum creatinine, urea nitrogen, hydration status, water consumption, and urine output should be closely monitored. Reported side effects of amphotericin B include depression, anorexia, pyrexia, and urticaria.

Immunotherapy using a vaccine made from fungal cultures is reportedly curative if administered early in the course of the disease.[129] In a study of 40 horses with pythiosis, 53% were cured with vaccination alone. Surgical cytoreduction combined with vaccination improved success rates if vaccination was performed within 2 weeks of surgical débridement.[129]

NODULAR NECROBIOSIS

Epidemiology

Nodular necrobiosis, also called collagenolytic granulomas or eosinophilic granulomas with collagen degeneration, is reported to be one of the most common skin diseases in horses.[130] The underlying etiology is unclear; insect hypersensitivity has been proposed, and the propensity for lesions to develop at pressure points (under the saddle region, in particular) suggests trauma may play a role.[131] Diagnosis is based on histopathologic findings of a granulomatous reaction containing eosinophils, lymphocytes, and histiocytes, with collagen degeneration.[132] Typical lesions are 0.5- to 1.0-cm subcutaneous nodules and are most commonly found on the withers and dorsum but can occur anywhere on the body. The differential diagnosis includes equine amyloidosis, foreign body granuloma, dermoid cysts, habronemiasis, equine sarcoid, and other neoplasia.

Treatment

Single asymptomatic lesions that are not a cosmetic concern can be left untreated. Single lesions can be surgically excised. Alternatively, intralesional injection of glucocorticoids such as triamcinolone acetonide (3 to 5 mg per lesion) or methylprednisolone acetate (5 to 10 mg per lesion) can be performed.[130] Lesions that are calcified can be difficult to inject and may require surgical excision.[108] Systemic corticosteroids have been recommended to treat multiple lesions—for example, prednisolone at 1 mg/kg orally, daily for 14 days, followed by 0.5 mg/kg orally for an additional 14 days. Lesions may recur and require multiple retreatments for resolution.

PAPILLOMATOSIS

Epidemiology

Papillomaviruses are very host- and tissue-specific and are the causative agents of the majority of warts seen in mammals. Equine papillomatosis and aural plaques are caused by equine papillomaviruses (EqPV).[133] Papillomaviruses infect the basal layer of the epidermis, resulting in an abnormal proliferation and hyperkeratosis of the epithelium. Clinical syndromes include aural plaques and juvenile papillomas (juvenile warts). Congenital neonatal papillomatosis was thought to be the result of *in utero* infection by papillomavirus; however, reports suggest that congenital papillomatosis is in reality a hamartomatous lesion and not a virus-induced growth.[134]Affected foals are born with a large wartlike lesion located anywhere on the integument.

Juvenile Papillomatosis

Juvenile papillomatosis most commonly occurs in young horses (6 months to 4 years), but older horses can be affected. Multiple small (5-mm) gray-pink, vegetative, cauliflower-like warts usually develop on the lips, muzzle, face, distal limbs, and external genitalia. Lesions can be spread by direct contact, contamination of the local environment, and vectors. Large numbers of infectious virus are shed in the superficial keratinocytes.

Aural Plaques

Aural plaques are raised, white or tan, smooth plaques arising on the internal surface of the pinnae (Figure 29-4). Fly irritation may exacerbate these lesions, making them crack and causing the horse discomfort. Equine papillomavirus DNA has been identified in both aural plaques and juvenile papillomas, but different viral subtypes are suspected.

Treatment

Congenital papillomas can be removed surgically or ligated and allowed to undergo necrosis. In the majority of cases, juvenile warts will spontaneously regress when immune recognition occurs. Immunologic compromise may result in failure to

regress; in these cases, surgical excision may be necessary. Vaccination using wart tissue has been recommended.[135] Alternative treatments include cryotherapy, intralesional chemotherapy, and radiofrequency hyperthermia.

Though historically treatment protocols for aural plaques have been unrewarding, the recently described use of topical imiquimod 5% cream resulted in resolution of aural plaques in 87.5% of horses. Duration of topical therapy was 1½ to 8 months.[136] In addition, successful resolution using laser ablation has been reported. The lesions are manually débrided with a dry gauze pad to remove keratinous debris, and then the lesions are lightly painted with the laser probe. Recurrence has not been reported.[137]

DENTIGEROUS CYSTS

Etiology

A dentigerous cyst is a congenital defect. It arises as a result of incomplete closure of the first branchial cleft during embryologic development. By definition, dentigerous cysts contain dental elements, such as enamel, dentin, and cementum.[130] The epidermal lining differentiates as does normal epidermis, and the cyst becomes nodular as it begins to fill with keratin. Lesions are usually asymptomatic. They may be present from birth, but they remain unnoticed until they enlarge.[138,139] They typically appear as a unilateral swelling at the base of the ear but can occur in other locations on the head and sinuses.[138-141] The secretory, cystic lining produces a mucoid fluid that may drain intermittently from the nodule. Diagnosis is frequently made on the basis of location, clinical history, and the presence of pale yellow, mucoid, cystic fluid.[141] Definitive diagnosis requires surgical excision and histopathologic examination.

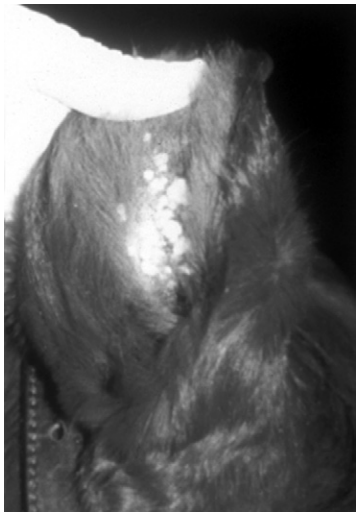

Figure 29-4. Typical appearance of aural plaques in the pinna.

Treatment

No treatment is required. However, if desired, surgical excision with complete extirpation of the cyst lining is necessary to prevent recurrence.[142] Preoperative radiographic evaluation is recommended to determine the location of dental material and the number of cysts, and prior to anesthesia, the extent of the cyst should be defined by careful palpation. The preparation and surgical scrub should include the pinnae to allow manipulation during surgery. The sinus tract, which is identified using a malleable probe (Figure 29-5), is opened and the neck of the cyst is sealed with a ligature prior to dissection. The plane of dissection should be as close to the wall of the cyst as possible to prevent damage to the auriculopalpebral nerve and auricular muscles, as well as to minimize hemorrhage. Distention of the cyst is aids in its identification and removal. The auricular muscles are small and can be difficult to visualize because of the aberrant connective tissue associated with the dentigerous cyst. Opening the cyst should be avoided at all cost; spillage can result in contamination of the incision site and result in infection, dehiscence, and excessive scarring. The dental tissue can vary in size from a small and easily removable tooth to large areas of enamel-covered bone. Careful excision using a chisel or drill is required in such cases to prevent damage to the cranium and brain.[140] Failure to remove all the dental tissue may result in dehiscence and refistulization. Auricular muscles and fascial

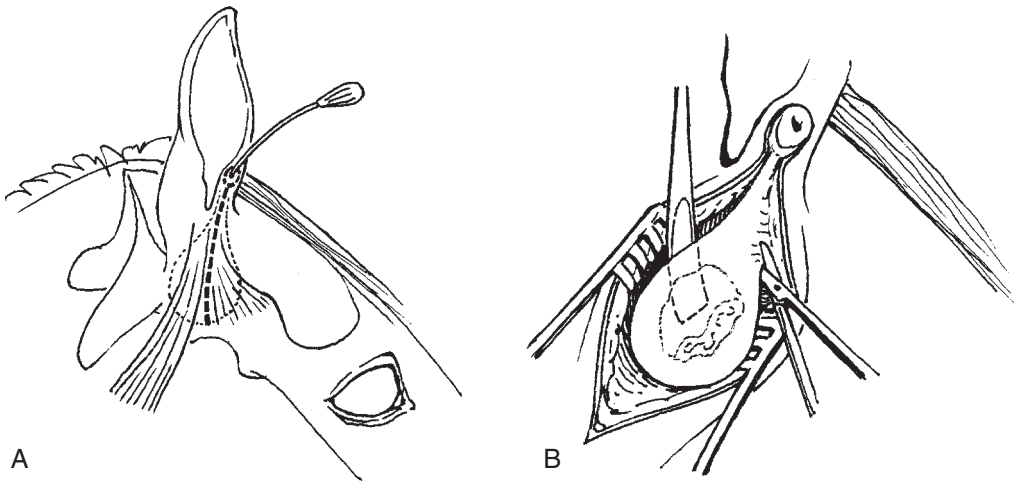

Figure 29-5. Dentigerous cyst. **A,** Identification of the sinus tract is made easier with a malleable probe inserted into the cloaca until it touches the dental material. **B,** After closure of the sinus tract, the cyst is removed intact. The dental material may need to be loosened with an elevator or an osteotome to complete cyst removal.

layers are apposed with 3-0 polydioxanone, and skin closure is routine. Postoperative antibiotics are not routinely indicated, although anti-inflammatory drugs are recommended, particularly when forceful extraction of dental tissue was required. In one report, an ectopic tooth was found compressing the cerebellum.[140]

CHAPTER
30

Oral Cavity and Salivary Glands

Padraic M. Dixon and Mathew P. Gerard

DENTISTRY

After almost a century of inactivity, equine dentistry has made rapid progress over the past 15 years, and equine dental disorders are now documented as one of the most common diseases recognized by U.S. practitioners.[1] Additionally, up to 10% of British equine practitioners' time is spent dealing with dental-related disorders.[2] This part of the chapter will concentrate on the many surgical aspects of this expanding field of practice, with other areas of equine dentistry adequately covered elsewhere. The modified Triadan system of dental nomenclature (Figure 30-1) is used in this chapter.

Examination of the Oral Cavity and Teeth

The equine incisors and canine teeth are readily examined in the unsedated horse. With the mouth closed, the rostral aspect of the mandible should be pushed sideways and the distance of lateral movement of the lower incisors in relation to their upper counterparts (e.g., 1 cm) before separation of the incisors (as the angled occlusal surfaces of opposing cheek teeth come into contact) can be measured. This measurement can be used to assess the angulation of the cheek tooth occlusal surfaces and can also detect the presence of major cheek tooth overgrowths

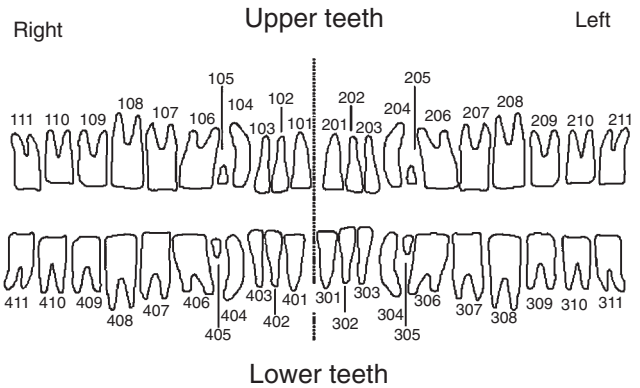

Figure 30-1. The modified Triadan system of equine dental nomenclature. To identify deciduous teeth, add 4 to the first number of its permanent successor. For example, the deciduous incisor 501 is replaced by permanent incisor 101.

that will suddenly block the lateral movement of the mandible.[3] This maneuver is easier to perform in sedated horses, as is examination of the oral cavity. There is great variation in the degree of separation of incisors that occurs during this maneuver in normal horses. However, some operators have arbitrarily determined that if a defined degree of incisor separation does not occur during the maneuver, it indicates the presence of overlong incisors. They then reduce the length of incisors until a normal degree of incisor separation occurs (i.e., "incisor bite alignment techniques"), sometimes exposing the incisor pulps during the reduction procedure. Because the cheek teeth have a surface area 10 to 15 times that of incisors and are composed of a harder type of enamel,[4] it is mechanically impossible for overlong incisors to keep the cheek teeth apart. However, after removal of large cheek tooth overgrowths, some horses may benefit from slight reduction of their incisors.

A combination of factors, including the limited angle of opening of the equine mouth (common to all herbivores), the rostral positioning of the lip commissures, and the length of the equine cheek teeth rows, make it very difficult to visually examine the cheek teeth, particularly in unsedated horses. Palpation through the cheeks may reveal food pocketing or major dental irregularities (such as a displaced or missing maxillary cheek tooth, or a large overgrowth of the rostral cheek teeth). Even if no such abnormalities are palpable, stimulation of a pain response during this palpation may indicate the presence of sharp overgrowths on the lateral aspect of the upper cheek teeth. A useful test for suspected cases of dental disease is to feed the (unsedated) horse a small amount of forage. Affected horses may not make the normal vigorous crunching sounds of mastication, may show restricted mandibular movements that may be confined to one side of the mouth, or may even quid (drop boluses of partially masticated forage) if a painful dental disease is present.

A detailed equine oral examination can only be performed using a full mouth speculum (gag), and every equine practitioner should have one (Figure 30-2). It is possible to perform a safe digital examination of the cheek teeth and oral cavity of most unsedated horses, but a more complete visual examination requires sedation, especially with painful disorders and in difficult horses. Food retained in the oral cavity should be removed by flushing the mouth using a large dental (dosing) syringe and water or a very dilute chlorhexidine solution. The

Figure 30-2. This horse is having a dental examination while being restrained in stocks equipped with an overhead extension to allow a dental head collar to be attached. Note the use of the Hausmann speculum and headlight for this examination.

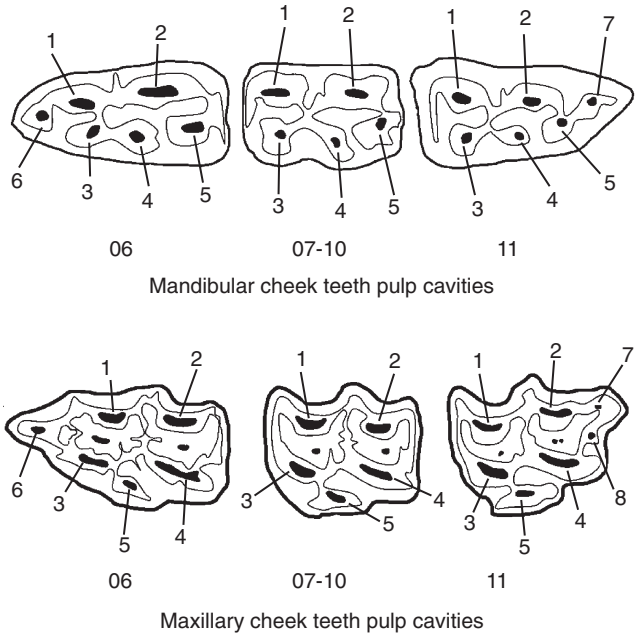

Figure 30-3. Identification of the individual pulp chambers of mature equine cheek teeth using a recently modified system of pulp nomenclature by du Toit et al.[3] The 06s *(left side of figure)* have six pulp horns. The 07s to 10s *(center of figure)* have five pulp horns. The 11s *(right side of figure)* have six or seven horns.

use of a strong headlight (a hand-held light is much less satisfactory), a dental probe or metal examination "basket" to displace the tongue, and an equine dental mirror (or a rigid dental endoscope, if available) allow full visual examination of the equine oral cavity.

Unless each tooth and the adjacent soft tissues (gums, cheeks, and tongue) are carefully visualized and palpated, major disorders, especially of the caudal mandibular cheek tooth and its periodontal membranes, can readily be missed. A long dental mirror or intraoral endoscope is essential to examine the gingival margins of the cheek teeth, especially on their buccal aspects, for the presence of periodontal disease and food impaction, and also to visualize the cheek teeth occlusal surfaces (e.g., to detect pulpar exposure and more fully assess dental fractures and infundibular caries). It is also useful to smell the oral cavity for halitosis, which usually indicates anaerobic infections, which are most commonly a result of periodontal food pocketing and infection, but halitosis is occasionally caused by advanced dental caries or cheek teeth fractures.

A very significant disorder, especially in the younger horse, is cheek tooth apical (the roots are often not yet even formed) abscessation. In most cases, little obvious change is visible on the clinical crown, except with some maxillary cheek tooth apical infections, where gross infundibular caries or sagittal fractures of the clinical crown may be present. However, close examination of the occlusal surface of the suspect cheek teeth with a dental mirror or endoscope, and probing the secondary dentine on the occlusal surface that overlies the five to seven pulps of the cheek tooth[5] (Figure 30-3) with a fine steel probe, will reveal pulpar exposure (i.e., dull, darker areas of the secondary dentine, with pitting and food pocketing into the pulp chamber) in 34% of infected mandibular[6] and 23% of infected maxillary teeth.[7] This finding can be of enormous value when other clinical findings and radiology are inconclusive in cases of apical infection. Occasionally, occlusal pulpar exposure in the absence of apical infection is found in older horses.[8]

Figure 30-4. This foal has a moderate degree of overjet, with the upper incisors protruding approximately 2 cm rostral to the lower incsors.

Disorders of the Incisors

Overjet and Overbite ("Parrot Mouth")

Many horses have some degree of what the older textbooks term mandibular brachygnathism ("parrot mouth," "overshot jaw"), referring to a rostral projection of the upper incisors beyond the lower incisors in a horizontal plane, which should correctly be termed "overjet" (Figure 30-4). However, in some of these cases,

Figure 30-5. This adult horse has a marked degree of overbite, with the upper incisors protruding rostral to the lower incisors and also lying rostral to them in the vertical plane.

there may not be shortness of the mandible. Instead, an overlong maxilla (maxillary prognathism) may be present. Both of these conditions induce cheek teeth wear disorders.[9] Consequently, a major significance of overjet is that affected horses commonly have overgrowths of the rostral aspects of 106 and 206 and of the caudal aspects of 311 and 411. In older horses with overjet, the reduced wear on upper incisors 101 and 201, in particular, may cause them to overgrow, and the upper incisors subsequently develop a convex occlusal surface, which has been termed a "smile." In more severe cases, the upper incisors, as well as projecting rostrally to the lower incisors in the horizontal plane, also grow down in front of the lower incisors in a vertical direction (i.e., overbite) (Figure 30-5), and this may prevent the small, normal amount of rostrocaudal mandibular movement that normally occurs in horses,[10] and it may even retard mandibular growth, thus exacerbating cheek teeth abnormalities.[11] Unless contact between opposing incisors is totally absent, overjet and overbite rarely cause the horse trouble in prehending food, as its mobile lips and tongue can compensate. However, this condition is esthetically undesirable, especially in show horses.

In affected foals, overjet can be corrected or partially corrected by use of an incisor orthodontic brace—that is, by placing steel wires (a tension band) around the upper incisors and fixing these wires around the 506 and 606 (or 507 and 607) to retard growth of the premaxilla and maxilla.[11,12] A newer technique involves passive extension of the rostral mandible following an osteotomy of both rami and implantation of a rachet fix device on each ramus (see Chapter 102). This surgery is best performed at around 3 months of age, but it can be of value in foals up to 8 months old. Under general anesthesia, a 1-cm horizontal stab incision is made in the skin of the cheeks, as dorsally as possible to avoid damaging branches of the dorsal buccal nerve, opposite the interdental spaces between the upper 06s and 07s, or between the 07s and 08s. A short Steinmann pin fitted to a Jacobs chuck (or a bone drill protected by a drill guide) can be pushed through the skin wound to puncture the cheeks and enter the oral cavity (Figure 30-6). Using a finger in the oral cavity for guidance, the point of the pin or drill is directed into the interdental (interproximal) space, as close to the gingival margin as possible, and it is subsequently forcibly

Figure 30-6. A bone drill and drill sleeve have been inserted through a horizontal stab incision in the skin and buccal muscles of this foal with overjet in order to drill between the deciduous cheek teeth for placement of a tension-band prosthesis.

Figure 30-7. A length of 1.25-mm stainless steel wire is being inserted through the cheek incision into the interdental space between the first and second cheek teeth (606 and 607).

pushed (while twisting) through this tight space and directed to exit at the medial (palatal) interdental space, again close to gingiva (at the border of the hard palate). The Steinmann pin is withdrawn and a 14-gauge needle inserted along its path, followed by insertion of a 1.25-mm diameter stainless steel wire of 60-cm (24-inch) length through the needle into the interdental space and into the oral cavity (Figure 30-7). Most of the wire is drawn into the oral cavity and pulled rostrally to the incisors. The needle is withdrawn.

The external free end of the wire is directed beside the initial part of the wire through the buccal incision into the oral cavity, taking great care not to entrap any soft tissue (possibly the buccal nerve) and not to creat acute bends in the wire. The second wire end is palpated as it penetrates the buccal mucosa,

again as close as possible to the lateral (buccal) gingival margin of the interdental space. This part of the wire is subsequently drawn into the oral cavity along the lateral aspect of the cheek teeth. As the last of the wire is pulled through the cheek incision, a kink will occur in it, and this area of weak wire should later be discarded.

The two free ends of the wire are withdrawn from the mouth, on either side of the cheek teeth, while making them even in length. While pulling them rostrally, the free ends are twisted back to the rostral border of the upper 06s, as dorsally as possible. The twisted wires are then placed over the labial (rostral) aspect of the incisors. This procedure is then repeated on the other side of the mouth, and the free ends of both pairs of wires are twisted tightly together, just below the gingival borders of the upper incisors (or interwoven between some incisors at the gingival level) and their ends are trimmed (Figure 30-8). The wire knot should be embedded in polymethyl methylacrylate (PMMA/acrylic) to prevent soft tissue trauma.

If an overbite is present in young foals, the tension from this orthodontic brace may well cause further caudoventral deviation of the upper incisors and premaxilla toward the rostral aspect of the lower incisors, and this would simply worsen the overbite, rather than retard premaxillary and maxillary bone growth. In such foals, a "biteplate" can additionally be fitted along with the orthodontic brace to promote indirect occlusion between the upper and lower incisors.[11,12] The biteplate can be fashioned from a perforated aluminium plate (2 to 4 mm thick) that is cut to fit the shape of the rostral aspect of the hard palate, extending caudad about 4 to 5 cm (approximately 2 inches) from the incisors.

Having fitted the brace as just described, the underlying hard palate is covered in Vaseline, and the biteplate, covered with soft acrylic, is placed on the hard palate. Additional acrylic should be placed beneath the caudal aspect of the biteplate, so that the sloped plate will tend to push the lower incisors more rostrally during prehension. Acrylic is now also used to join the biteplate to the wires of the brace (Figure 30-9), ensuring that the acrylic does not extend too high on the gingiva above the incisors, where it can form a sharp rim that can traumatize the lip mucosa. After a biteplate is fitted, foals may have trouble suckling.

Another option involves the fitting of PMMA only, without the aluminum plate, to the rostral part of the hard palate and wires pressed at strategic locations into the soft PMMA before it hardens. Once the PMMA is hard, the wires can be used to attach the PMMA plate to the adjacent teeth.

The biteplate may also hurt the mare's udder during suckling, causing her to temporarily prevent the foal from suckling. In such cases, the mare should be milked for a few days and the foal bottle-fed with her milk. If the foal is uncomfortable because of the brace, it should be given low doses of nonsteroidal anti-inflammatory drugs (NSAIDs) and anti–gastric ulcer medication, such as omeprazole. Some clinicians recommend that foals be weaned before fitting orthodontic braces with biteplates. Any overgrowths on the rostral aspects of the upper 06s and on the caudal aspects of the lower 08s should be rasped off, to promote free rostrocaudal mandibular movement.

Wires may break unilaterally or bilaterally and thus cause the biteplate to loosen; owners must be prepared for this extra work and expense. Consequently, the foal's mouth needs to be regularly inspected, and broken wires need to be replaced, usually under general anesthesia. The brace can be removed when the incisors are aligned or nearly so. With severe overjet or overbite, complete resolution will not be possible, but esthetically pleasing results, and certainly much reduction in the concurrent cheek teeth overgrowths, can be achieved. The ethics of these orthodontic procedures, especially in animals that may be used for breeding, are debatable, and some breed societies do not allow registration of horses that have been treated with this technique. This aspect should be discussed with the owners in detail before orthodontic wires and biteplates are applied.

Orthodontic treatment is not feasible in adult horses. Large overjet/overbite incisor overgrowths in adult horses should be reduced using power or manual instruments, in stages of about 5 mm every 6 months, to prevent pulpar exposure. To partially remove incisor overgrowths, it is best to sedate the horse and place a plastic pipe gag in the interdental space (circular metal gags, such as Swale's gag, can fracture cheek teeth, and rubber wedge gags promote constant chewing movements). Once the overgrown incisors have been reasonably reduced (maximum 5 mm at a time), they should be rasped level biannually, as

Figure 30-8. The twisted wires that are attached bilaterally to the cheek teeth have been interwoven between some incisors and then tightly joined together in front of the incisors, to retard premaxillary and maxillary growth.

Figure 30-9. This foal had marked overbite as well as overjet, and it has had a perforated aluminum biteplate embedded in acrylic, attached to the orthodontic brace. The still soft polymethyl methacrylate is being molded around the prosthetic wires *(arrows)* (untwisted in this case).

should concurrent cheek teeth overgrowths (see "Disorders of the Cheek Teeth," later in this chapter).

Underbite ("Sow Mouth")

Prognathism ("undershot jaw," "underbite") is rare in the horse, except in miniature horses, and is usually clinically insignificant unless there is a total lack of occlusion between the upper and lower incisors. Severely affected horses eventually develop a concave upper incisor occlusal surface, which has been termed a "frown," and may develop lower 06 and upper 11 overgrowths. Correction may be achieved using the same orthodontic procedures as discussed for the maxilla, with the orthodontic device being applied to the mandible, or by extension of the premaxilla/maxilla (see Chapter 102).

Retained Deciduous Incisors

Deciduous incisors, which normally lie rostral (i.e., labial) to their permanent counterparts, are occasionally retained beyond their normal time of shedding, and they will cause the permanent incisor to be displaced caudally (lingually), occasionally leading to permanent changes in the incisor occlusal surface. If retained incisors are very loose, they can be removed using small-animal dental extraction forceps or equine "wolf teeth" forceps. If more firmly attached, they should be extracted using a small-animal dental elevator under sedation and local anesthesia (by injecting 2 to 5 mL lidocaine, directed 2 to 4 cm caudally, into the ostium of the mental or infraorbital canal). If a permanent incisor does not erupt beneath its deciduous predecessor, little resorption of the deciduous reserve crown may occur, and up to 6 cm of the deciduous tooth may remain in the alveolus. In such cases, much of the rostral aspect of the alveolar wall of the retained incisor will have to be removed with a bone chisel in order to extract the retained incisor (Figure 30-10). Occasionally, a permanent incisor erupts *rostral* to the deciduous incisor, and great care must be taken in removing the deciduous incisor that is now positioned on the caudal (lingual) aspect of the permanent incisor.[13]

Figure 30-10. This horse has a large retained 702 (deciduous precursor of 302), and minimal resorption of its apex and reserve crown has occurred. A lingual (caudal) deviation of the permanent tooth is now present that would cause a permanent incisor malocclusion. About 5 cm of the rostral aspect of the alveolar wall of 702 was removed *(white arrows)*. The tooth was subsequently loosened with elevators and is now being extracted with incisor forceps.

Supernumerary Incisors

Supernumerary incisors are permanent teeth that are additional to the normal six permanent incisors on each arcade. They are usually morphologically identical to a normal permanent incisor, which helps differentiate them from retained deciduous incisors.[14] Supernumerary incisors may have long (more than 7 cm [3 inches]) reserve crowns that may be intimately related to the reserve crowns and roots of the normal permanent incisors, and consequently they are usually impossible to differentiate from normal incisors, both clinically and radiographically.[5,15] Consequently, extraction of supernumerary incisors (especially if multiple) is technically very difficult and also risks damaging the adjacent normal incisors. If they are grossly displaced rostrally (labially) and thus protrude submucosally, they are amenable to extraction, as described for a large retained deciduous incisor. As most supernumerary incisors cause few clinical problems, they are usually best left alone (except, perhaps, in show horses), with biannual rasping of any incisors that are not in occlusion to prevent overgrowths caused by their prolonged eruption.

Fractures of the Incisors

Fractures of the incisor teeth, and often of their supporting mandibular or premaxillary bones, can occur because of trauma (usually from kicks) and commonly result in exposure of the pulp (i.e., complicated dental fractures).[5,16] Idiopathic incisor fractures are rare, in contrast to the common presence of such fractures in equine cheek teeth. All young equine teeth (incisors and cheek teeth) have very wide apical foramina (root canal openings), along with a very large, vascular pulp, which can resist the infection, and more so the inflammation, that inevitably develops in orally exposed pulp.[17] Consequently, pulpar exposure, especially in younger horses, does not necessarily lead to the degree of pulpar inflammation that compresses its vascular supply (with subsequent pulpar ischemia and necrosis, and death of the tooth), as usually occurs with pulpar exposure in brachydont (e.g., human or canine) teeth. Horses with incisor fractures should receive tetanus prophylaxis and prolonged (7 to 10 days) antibiotic (e.g., trimethoprim/sulfadiazine) therapy.

A regional nerve block (mental or infraorbital nerve) followed by the removal of any loose dental fragments and débridement of any exposed pulp with a 16-gauge needle is of benefit as first aid, or as the main treatment if endodontic treatment is not possible. Pulpar bleeding can be controlled with pieces of compressed cotton wool held in a small hemostat (or by using dental paper points if available), and the exposed aspect of the pulp canal should be filled with a calcium hydroxide preparation that promotes reparative tertiary dentine formation.

If facilities are available, the preferred treatment involves endodontic management through the damaged occlusal aspect, which greatly increases the chances of saving the tooth. This usually consists of vital pulpotomy—that is, removal of devitalized pulp with a fine-pointed scalpel, control of hemorrhage from the underlying vital pulp with paper points or hemostatic agents, followed by sealing the healthy pulp with a calcium hydroxide preparation. Having sealed off the vital pulp, the remaining open pulp canal is prepared for filling by etching it for 1 minute with a phosphoric acid gel (to make the dental surface more porous to bond to dental restorative materials), which is then flushed away with water and air-dried. The pulp

canal (which may be undecut with a dental burr to help retain the restoration) is subsequently thinly coated with a bonding agent (Figure 30-11) and sealed, in layers if necessary, with a modern, composite restorative material (e.g., StarFill 2B dual-cure composite) (Figure 30-12).

In some young horses, the pulp becomes sealed off at the site of exposure by reparative (tertiary) dentine formation even without treatment, with the tooth remaining vital and continuing to erupt normally.[5] Treatment of premaxillary and mandibular fractures involving the incisors is discussed in Chapter 102.

Abnormalities of Incisor Wear

Incisor disorders include rectangular overgrowth of individual incisors ("steps") as a result of traumatic loss, or of maleruption (e.g., delayed eruption or displacement) of the opposing teeth, in addition to the previously noted incisor overgrowths occurring with overjet or underjet. Abnormal wear pattern of the occlusal and rostral aspects of the 01s and occasionally of the 02s occurs in crib biters. Another common abnormality of incisor wear is a tilted or slanted incisor occlusal surface, which is termed *slope mouth* or *slant mouth*. This defect is most commonly associated with a major unilateral abnormality of the cheek teeth that has caused a pronounced unilateral chewing action, thus causing uneven wear of the incisors.[5,18] The disorder of "wry nose" (campylorrhinus lateralis) can also cause this incisor defect as a result of incisor malocclusion (see Chapter 102). Such incisor overgrowths should be reduced in stages to prevent pulpar exposure, as previously described.

Figure 30-11. This horse is having endodontic treatment of its traumatically damaged incisors (402 and 403). Exposed necrotic pulp in 402 has been removed to the level of healthy pulp. The pulp cavitiy was sealed with calcium hydroxide paste, and the pulp canal above was acid-etched. A bonding agent is now being applied to the sealed pulp canal.

Figure 30-12. A modern, self-curing composite filler is being inserted into the prepared pulp cavity on top of the calcium hydroxide layer to further seal off the underlying vital pulp (same horse seen in Figure 30-11).

Disorders of the Canine Teeth (Triadan 04s)

Rarely, displaced canine teeth can interfere with the bit or injure oral soft tissues. The displaced aspects of such teeth should be partially ground down, taking care to avoid pulpar exposure that may cause pulpitis and possibly death of the tooth, which may not become evident until years later.[18] The sharp tips, or even most of the clinical crown of the canine teeth, are rasped off by some operators to allegedly prevent these teeth from lacerating the operator's hands during dental procedures and to prevent them from interfering with the bits. There is no objective evidence on the value of this procedure, and if pulpar injury occurs during this procedure, some horses develop painful pulpitis and later death of the tooth.

Rarely, canine teeth need to be extracted—for example, as a result of traumatic fracture or infection,[19] with the latter often being secondary to the recently described equine odontoclastic tooth resorption and hypercementosis (EOTRH) sydrome, which can also affect incisors.[20] Long-term unerupted canine teeth that are causing mucosal ulceration and bitting problems in horses older than 7 years can also be extracted if deep incision of the mucosa and underlying periosteum does not relieve the problem. Because of the great length of their unerupted crown (up to 7 cm long), extraction of uninfected canine teeth is difficult and should never be undertaken without good reason.[19] Following an appropriate nerve block in the standing sedated horse, extraction is performed by initially removing the vertical aspect of its lateral alveolar wall (Figures 30-13 and 30-14). A dental elevator is subsequently used to further loosen the canine tooth in the horizontal, more apical aspect of the alveolus, finally allowing complete extraction (Figure 30-15). It is a difficult procedure in firmly attached younger teeth, and the apical aspect of the canine tooth may fracture during extraction. In the absence of apical infection or EOTRH syndrome, up to one third of a healthy root (canine teeth are brachydont teeth) may be left in the alveolus without causing postoperative problems.

Disorders of "Wolf Teeth" (Triadan 05s)

Wolf teeth (Premolar 1, Triadan 05) are small vestigial teeth (usually 1 to 3 cm long) that are, without much critical evidence, blamed for many behavioral and bitting problems in horses, and therefore these teeth are frequently extracted. Wolf teeth most commonly develop in the maxilla, lying in front of the 06s and most are lost when the 06 deciduous cheek teeth is shed. If normally positioned and small, it is difficult to envisage how the upper wolf teeth can interfere with the bit. However, displaced, enlarged, fractured, or unerupted ("blind") wolf teeth with overlying painful or ulcerated mucosa may

Figure 30-13. This horse had a long-term bitting problem associated with a partially erupted canine tooth (204) that caused chronic painful ulceration of the overlying mucosa. After sedation and infraorbital nerve block, an incision is being made over the ventrolateral aspect of the 204 alveolus.

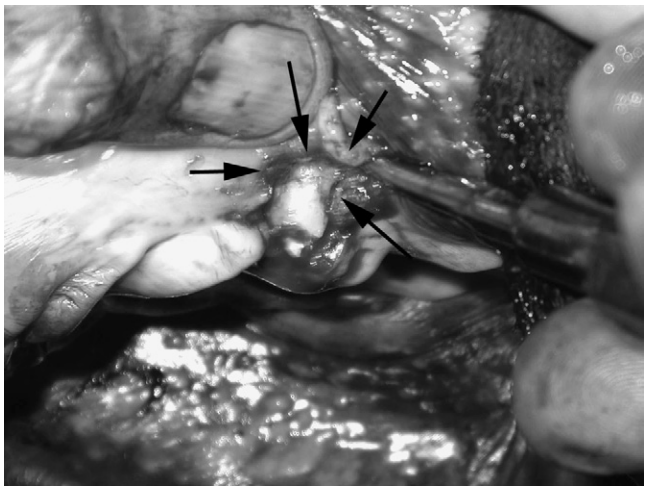

Figure 30-14. After retraction of the incised mucosa, the ventrolateral aspect of the alveolar wall of 204 has been removed with a dental elevator, revealing the vertical aspect of the crown of the problematic canine *(arrows)*.

Figure 30-15. Note the great length and the curvature of the canine tooth, which has been extracted intact. A Butler gag is being used.

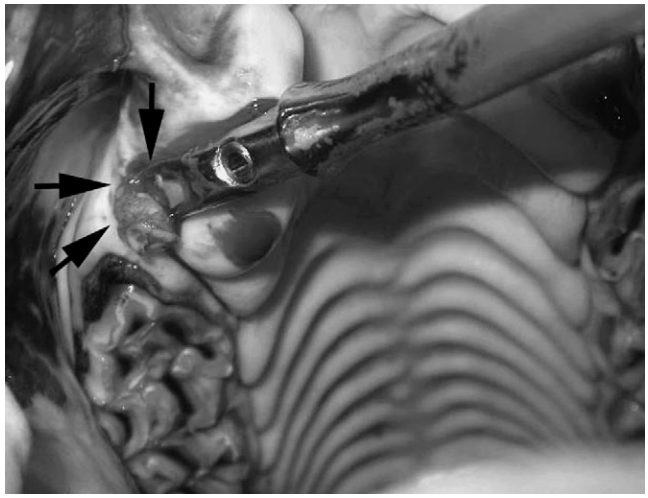

Figure 30-16. This large and rostromedially displaced "wolf tooth" (105) *(arrows)* has been loosened from its periodontal attachments with a Musgrave elevator. The intact, loosened tooth can now be readily extracted with forceps.

cause bitting problems. Such wolf teeth should be extracted, as should all mandibular wolf teeth, which invariably will contact a bit. Unless they are digitally loose (mainly in younger horses), wolf teeth should be extracted under sedation using subgingival local anesthesia or, preferably, infraorbital or mental nerve blocks.[19] The latter technique, which will anesthetize the more relevant sensory nerves deep in the periodontal ligament, is advised when extracting the more deeply embedded wolf teeth commonly found in older horses. These teeth often lie in a sclerotic alveolus.

A variety of specialized instruments (e.g., Burgess or Musgrave elevators) can be used to separate the gingiva around these teeth, and an elevator is subsequently inserted into different sites around the periodontal space to loosen the teeth (Figure 30-16), followed by forceps extraction when adequately loosened. Large (often unerupted) wolf teeth may have to be extracted through a mucosal incision, followed by loosening them from the underlying maxilla using an osteotome and mallet. In contrast, small mobile wolf teeth in younger horses may be readily extracted using forceps only. It is imperative to separate firmly attached wolf teeth from the alveolus and, most importantly, not to break them off above the alveolar level, where the protruding fragment often causes more oral discomfort than was present before the partial extraction. If the roots or adjacent apical parts of wolf teeth fracture below alveolar level during extraction, these alveoli usually heal over fully and so should be of little concern. The greater palatine artery can be lacerated during wolf tooth extraction, and local infection and tetanus can also develop after such procedures.

Disorders of the Cheek Teeth

Developmental Disorders of the Cheek Teeth

RETAINED DECIDUOUS CHEEK TEETH

Retention of the remnants of the deciduous cheek teeth ("caps") can occur in horses between 2 and 5 years of age. When loose, and especially partially retained by their gingival attachments, they may cause oral pain, and affected horses may show quidding, bitting problems, and occasionally, loss of appetite for a couple of days.[18] Such signs in this age group warrant a careful examination of the rostral three cheek teeth for evidence of loose deciduous cheek teeth. Loose caps should be removed using specialized cap extractors.

The prolonged retention of "caps" has been alleged to cause delayed eruption of permanent cheek teeth, and the development of large mandibular eruption cysts in 3- or 4-year-olds under the apices of the erupting permanent cheek teeth (07s and 08s),[21] but another study found no evidence of this relationship.[22] The presence of very enlarged eruption cysts, especially if unilateral, hot, or painful, should prompt a thorough oral and, if necessary, open-mouth radiographic examination for the presence of retained deciduous cheek teeth. Additionally, standard radiographic views to look for evidence of apical infection should be obtained. However, the practice of methodically removing deciduous teeth at set ages in horses results in the premature removal of some deciduous cheek teeth, causing pain to the horse and prematurely exposing the underdeveloped permanent counterparts lying below. In the upper cheek teeth, this leads to some loss of blood supply to the still-developing infundibular cementum, possibly leading to infundibular cemental hypoplasia (patent infundibulum) and thus predisposing the tooth to infundibular caries and possible apical infection or cheek teeth fracture later in life.

DIASTEMATA

The occlusal surfaces of all six cheek teeth are normally compressed closely together, and each cheek teeth row should function as a single grinding unit. This is achieved by the action of the angled rostral and caudal cheek teeth compressing the occlusal aspects of all six cheek teeth together.[17] Even with age, the progressively smaller reserve crowns usually remain tightly compressed at the occlusal surface (the cheek teeth taper in slightly from crown to apex). However, if a space, or diastema (plural diastemata), develop between the occlusal aspects of adjacent cheek teeth, clinical problems will occur.[22,23] Very severe clinical problems occur when these spaces are narrow (often only 2 mm wide) at the occlusal surface and wider (approximately 4 to 5 mm) at the gingival margin,[24] a condition termed *valve diastemata*.[25] In some cases, cheek teeth diastemata are caused by lack of sufficient angulation of the rostral (06s) and caudal cheek teeth (10s and 11s) to provide enough compression of the occlusal surface of the six cheek teeth. In other cases, diastemata occur with apparently normal cheek teeth angulation, suggesting that the dental buds have developed too far apart.[22,26,27] Individual diastemata can also be caused by displaced or supernumerary cheek teeth, or they may occur adjacent to overgrown cheek teeth (e.g., rostral to an overgrown lower 11 or caudal to an overgrown upper 06 that have been displaced caudally or rostrally, respectively, because of their focal overgrowths).

Food becomes impacted into these abnormal interdental spaces by the prolonged (up to 18 hours a day in some normal horses) grinding of tough forage (Figure 30-17), leading to progressively deeper and more painful packing of food into the sensitive periodontal spaces, which causes a secondary, malodorous periodontal infection. Diastemata can be recognized visually (with use of a dental mirror or intraoral endoscope) or by digitally detecting food fibers protruding between the affected teeth at the gingival level. In a longer-standing case, this food pocketing and periodontal disease may extend along the full width of affected teeth and extend deep into the mandible or maxilla, including into the maxillary sinuses.[28]

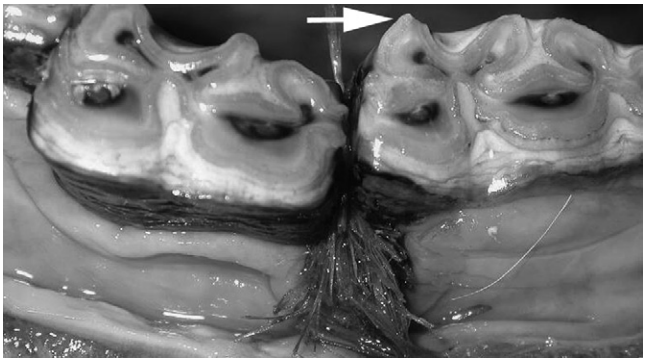

Figure 30-17. A diastema with deep interdental food pocketing is present between 410 and 411, both of which have slight medial displacement. A slight "steplike" overgrowth is also present on 411 *(arrow)*, which may have caused caudal displacement of this cheek tooth and so predisposed to the diastema.

Evaluation of the severity and numbers of diastemata can be difficult because the caudal mandibular cheek teeth are most commonly affected and the gingival margin of these teeth is hidden by the tongue. The use of oral endoscopy or intraoral mirrors, or obtaining 10- to 15-degree, latero-oblique radiographs with the horse's mouth open,[29,30] can be very helpful in assessing diastemata.

Treatment of cheek teeth diastemata can be difficult. Cleaning out the periodontal pockets manually (with specialised diastema forceps, dental picks, and long forceps) or with high-pressure pneumatic or water instruments, and filling the periodontal defects with antibiotics and plastic impression material is of value in some cases.[26] However in many cases, this treatment only gives temporary relief, unless the underlying mechanical predisposition to this food impaction is also treated. In younger horses with mild developmental diastemata where there is sufficient angulation of their cheek teeth (as judged radiographically), the abnormal spaces may close when further dental eruption occurs. Such horses should not have their diastemata mechanically widened. Many horses show severe clinical signs when fed hay and then improve greatly when out at grass in the summer. Likewise, feeding only a finely chopped (milled) diet, such as grass or alfalfa cubes (whose fiber length is too short to become entrapped in diastemata), often reduces or fully removes the clinical signs.

Currently, the best treatment for this disorder in mature horses appears to be to widen problematic diastemata—to about 4 to 6 mm wide on the occlusal surface—using a specialized diastema burr (such as, Powerfloat, D&B Enterprises, Inc., Calgary, Alberta, Canada).[27] Cases should be evaluated and selected for this treatment by careful oral examination, and also by use of open-mouth radiography in younger horses. Horses to be treated should be heavily sedated and the periodontal

pockets and diastemata cleared of food as described earlier, a procedure that usually causes much discomfort to horses. During diastemata widening, water should be sprayed over the cheek teeth being burred to prevent thermal pulpar damage and the site should be inspected frequently (e.g., at 5-second intervals) during the procedure to ensure the site of widening is correct and that adjacent pulp horns are not exposed. The pulp horns are closer to the caudal aspect of the cheek teeth, and therefore as much tooth as possible should be removed from the rostral aspect of the tooth positioned caudal to the diastema, to help prevent exposing dental pulp (Figure 30-18).[31] If painful diastemata are caused by a markedly displaced tooth (teeth), and diastema widening is found to be ineffective, extraction of the displaced tooth (teeth) will usually result in complete cessation of quidding, as food will not become trapped in a wider extraction space. Some young horses with severe, multiple diastemata and osteomyelitis of alveoli and supporting bones are very difficult to treat.

ROSTRAL POSITIONING OF THE MAXILLARY CHEEK TEETH ROWS

A common dental abnormality in horses is a rostral positioning of the maxillary cheek teeth rows relative to their mandibular counterparts, invariably occuring in conjunction with overjet/overbite ("parrot mouth"). This disorder eventually leads to the development of focal overgrowths of the rostral aspect of the upper 06s, which may cut the cheeks and interfere with the bit. If small, these overgrowths can be manually rasped level with a solid carbide float, but if they are large, a power tool is best to reduce them, in stages of about 5 mm every 3 to 6 months, to avoid pulpar exposure.

Similar overgrowths on the caudal aspect of 311 and 411 frequently go undetected and can lacerate the tongue, wear down the opposite cheek teeth (maxillary 11s) to gum level, and even penetrate the hard palate or lacerate the greater palatine artery. There is very little room between the occlusal surfaces of the caudal maxillary and mandibular cheek teeth, especially if large overgrowths are present on these teeth. Consequently, these overgrowths are best reduced using power tools, grinding them from their medial aspect if there is not enough room to reduce them from their occlusal surface, and then restoring the normal occlusal angle (i.e., have them sloping down in a lateral [buccal] direction). Molar cutters and percussion guillotines (which encircle this caudal hook) can fracture these teeth and cause pulpar exposure, especially in smaller breeds (e.g., Arabian horses and Welsh ponies) that have marked dorsal curvature (curve of Spee) of the caudal occlusal surface of their cheek teeth, which can be mistaken as dental overgrowths of the mandibular 11s. Such dental fracture and pulpar exposure may lead to apical infections or even to life-threatening cellulitis of the mandibular and pharyngeal areas.[32]

DISPLACEMENTS OF THE CHEEK TEETH

Most severe cases of equine (medial, lateral, rotatory) cheek teeth displacements, which usually involve the 09s and 10s, are developmental in nature and appear to be caused by overcrowding of the cheek teeth during eruption. This type of displacement is often marked and also may be present bilaterally.[22] Gross dental overgrowths later develop on areas of the displaced teeth and their opposite counterparts that are not in occlusal contact, causing soft tissue trauma. Additionally, painful food pocketing develops in diastemata that are invariably present on both sides of the displaced cheek teeth. This often causes severe and painful periodontal disease (Figure 30-19) and even osteomyelitis, sinusitis, or orosinus fistula formation. Acquired cheek teeth displacements (usually medial displacements of the lower 10s and 11s) can also develop in older horses and are usually associated with lesser degrees of cheek teeth displacement and overgrowth, but they still may cause painful diastemata.[22]

Abnormal protrusions or overgrowths on displaced cheek teeth should be removed, preferably with a power tool, and in stages to help prevent pulpar exposure. Painful diastemata can be widened with a diastema burr as described earlier, and this often alleviates periodontal pain and thus quidding. When a cheek tooth is very displaced and has advanced periodontal disease, the displaced tooth should be extracted, as noted earlier. This is readily performed *per os* in the sedated horse using cheek

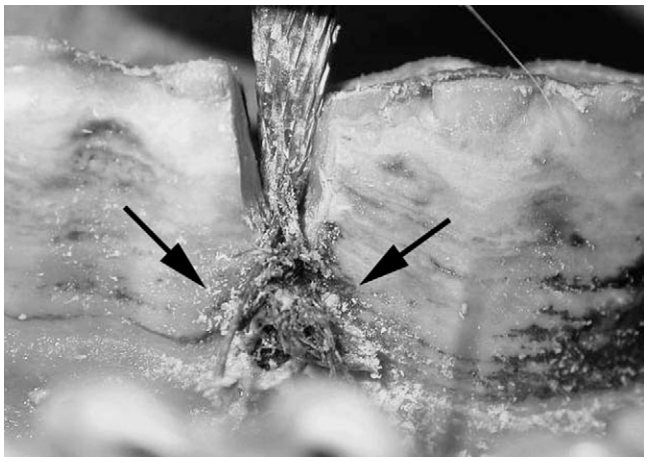

Figure 30-18. A diastema burr (Powerfloat, D&B Enterprises, Inc, Calgary, Alberta, Canada) is being used to widen the occlusal, interdental space in this specimen, which had diastema and food pocketing *(arrows)*. With valvelike diastemata, inserting the burr from the lateral and medial directions into the wider subocclusal space, followed by burring occlusally and caudally, is a more effective technique.

Figure 30-19. This mandible has a grossly laterally displaced cheek tooth that is probably developmental in origin. Because of its angulation, the displaced cheek tooth appears wider than its counterparts. Note the severe periodontal food pocketing in diastemata beside the displaced cheek tooth and to a lesser extent between other cheek tooth. Oral extraction of this displaced cheek tooth is indicated.

teeth extraction forceps (see later), and these horses usually cease quidding immediately following exodontia. Overgrowths on opposing cheek teeth should be reduced at 6-month intervals.

SUPERNUMERARY CHEEK TEETH

Supernumerary cheek teeth (i.e., the presence of more than six cheek teeth in a row) are common in horses, usually occurring at the caudal aspect of the maxillary, and less commonly the mandibular cheek teeth rows.[15,22,33] These may be large connated structures (i.e., formed from two to three fused, maldeveloped cheek teeth). Because they are sometimes large and irregularly shaped, or because of overcrowding of adjacent cheek teeth, abnormal spaces and subsequent periodontal food pocketing occurs between the supernumerary and adjacent teeth. This can result in pain and quidding and occasionally deeper infections.[15,22] Additionally, if the supernumerary teeth are present in just one row (i.e., are unopposed), they later form large overgrowths. If severe periodontal disease develops, particularly if associated with apical infection and sinusitis or an oro-sinus fistula,[28] the supernumerary cheek teeth should be extracted. Extraction should be performed *per os* if possible, as repulsion of the caudally positioned and also caudally angulated reserve crown and apex (apex likely to lie below the orbit) is technically very difficult. In the absence of periodontal disease, 6-monthly removal of overgrowths on supernumerary cheek teeth is required. Some of these caudal supernumerary cheek teeth (i.e., Triadan 12s) share an alveolus with the normal Triadan 11 or lie in a separate alveolus with poor periodontal attachments and can be orally extracted without too much difficulty.

Acquired Disorders of the Cheek Teeth

ACQUIRED OVERGROWTHS OF CHEEK TEETH

Feeding concentrates greatly alter the masticatory action of horses, causing them to chew with a more vertical rather than lateral mandibular action, and also for a much shorter time, than a horse that is only eating forage. This restricted lateral mandibular movement predisposes horses to develop overgrowths (initially of enamel) of their cheek teeth.[34] If these enamel overgrowths are neglected, the sharp enamel points eventually merge into a steeply angulated (e.g., 45 degrees versus the normal 10 to 30 degrees)[35] occlusal surface that is termed *shearmouth* or *scissor mouth*. A mechanical obstruction now additionally interferes with the normal side-to-side mandibular masticatory movements, rendering mastication even less efficient. Food stagnation and secondary periodontal disease also commonly develop, especially around the more caudal cheek teeth. In advanced cases of dental overgrowths, undulating irregularities of the occlusal surface of the cheek teeth rows in the rostrocaudal plane (i.e., "wavemouth") develop.

Some affected horses chew very slowly and make soft slurping sounds (instead of the normal vigorous crunching sounds) when chewing forage. Some affected horses use just one side of their mouth for chewing rather than alternating sides (and consequently develop a sloping incisor occlusal surface, called *slope mouth* or *slant mouth* as discussed earlier), or they may hold their head in an abnormal position during chewing. Affected horses may also have abnormal head carriage and bitting problems. The prime role in equine dental care is to prevent these major overgrowths from developing by routine oral examinations and effective teeth rasping.

TRAUMATIC DISORDERS OF THE CHEEK TEETH AND BARS OF THE MOUTH

In young horses, traumatic mandibular fractures often damage the long cheek teeth reserve crowns, which occupy much of this bone (see Chapter 102). In some cases of unilateral, nondisplaced mandibular fractures, conservative therapy (2 weeks of antibiotic administration and feeding a soft diet, such as soaked grass or alfalfa cubes for 2 to 3 months) is adequate, with the cheek teeth at the fracture site helping to stabilize the fracture, and the undamaged hemimandible acting as an effective splint. Traumatic fractures of maxillary cheek teeth are less common because of their anatomic position. Even if external sinus tracts develop after mandibular or maxillary fracture, it is worthwhile persevering with conservative therapy until radiographic changes (including the use of a metallic probe in any sinus tracts present) definitively confirm the presence of dental infection. Extraction of infected cheek teeth should be delayed for at least 3 months to allow mandibular or maxillary fracture healing to occur (see Chapter 102).

Bit-induced injuries to the dorsal aspect of the mandible at the interdental space ("bars of mouth") can occur as a result of very excessive bit force.[16,36] In most cases, a superficial periostitis or sequestration of the dorsal mandibular cortex will occur at this site. However, pathologic fractures of the mandible, mandibular osteomyelitis, and lower 06 cheek teeth infection can also occur.[16,36,37] These mandibular bone injuries should be assessed radiographically and sequestra removed under sedation (and mental nerve block if necessary). The horses should be ridden with a bitless bridle or hackamore for 4 to 6 weeks, and thereafter a wide rubber bit should be used with restraint. Exostoses (bone spurs) may develop at the sites of bitting injuries (especially on the caudal aspect of the lower bars of mouth).[38] However, some normal horses have a raised and variably sharp ridge at this site, and some also exhibit roughening of the mandibular cortex more laterally at the insertion of the buccinator muscles. Very large and irregular exostoses at this site may damage the overlying mucosa because of bit contact, and in doing so they cause permanent bitting problems. Large osseous protrusions can be removed under sedation and local nerve block or local infiltrative anesthesia, using an osteotome.[38]

IDIOPATHIC FRACTURES OF THE CHEEK TEETH

Idiopathic cheek teeth fractures (i.e., cheek teeth fractures in the absence of known trauma) are common in horses and mainly affect the upper cheek teeth.[37,39,40] Most commonly, "slab" fractures occur through the two lateral pulp cavities (pulp horns number 1 and 2) (Figure 30-20), usually of the upper 09s.[39] Less commonly, lower cheek teeth also suffer from such lateral sagittal fractures through pulp horns 1 and 2.[39] The maxillary cheek teeth slab fracture site usually becomes filled with fibrous food, thus laterally displacing the smaller lateral cheek teeth fragment into the cheeks, causing buccal lacerations with subsequent quidding and bitting problems. Spontaneous loss or extraction of the smaller, loose fragment with cheek teeth fragment forceps (Figure 30-21) usually resolves the clinical signs, even though radiographic and scintigraphic evidence of apical inflammation and alveolar remodeling often occur in these cases. Usually the two exposed pulp horns become effectively sealed off from the

Figure 30-20. Intraoral view of a horse with a lateral "slab" fracture of 208. The fracture site is filled with food that has slightly displaced the larger medial portion into the hard palate and markedly displaced the thin, lateral fragment *(arrows)* into the cheeks, where it has caused buccal ulceration *(arrowheads)*.

Figure 30-21. A lateral "slab" fracture of a maxillary cheek tooth that was readily removed with forceps. Gross caries on its medial aspect and destruction of its apical area *(arrowheads)* are evident.

fracture site with reparative dentine, and the remainder of the cheek teeth erupts normally.[40] Less commonly, apical infection and death of the tooth occurs and occlusal pulpar exposure can later be recognized in the remaining larger (medial) fragment. This remaining dead dental fragment will likely have to be removed within a year or so when it loosens or if it causes clinical signs of apical infection, such as sinusitis.[7]

Midline (sagittal) fractures of the maxillary cheek teeth occur less commonly than slab fractures, and the 09s are again most

Figure 30-22. This mandibular tooth had a sagittal fracture with subsequent food impaction and displacement. Both parts of the fractured (and now carious) cheek tooth were orally extracted with little difficulty (see extractor forceps marks on tooth).

commonly affected.[39,40] This type of fracture is believed to be secondary to advanced infundibular caries, with coalescence of two carious infundibula leading to mechanical weakening, followed by fracture of the cheek teeth. Infection of the underlying pulp and periapical aspect of the tooth commonly ensues. Maxillary sinusitis more commonly accompanies these midline sagittal cheek teeth fractures because the infection often spreads outside the alveolus. If clinical signs of apical infection occur, all parts of the fractured tooth should be extracted, *per os* if possible, even though the clinical crown is weakened.[41] This can best be performed by cleaning out the food in the fracture site and using cheek teeth extractors to close the two fragments together, followed by gently rocking the combined fragments until the tooth is loose. If much concurrent periodontal disease is present, extraction is usually easy (Figure 30-22).

Endoscopic assessment of the affected sinus for the presence of inspissated material, and its subsequent removal via sinoscopy or sinusotomy, is indicated.[42,43] Sinus lavage is adequate if sinusitis with liquid exudate is present. In the absence of clinical signs of apical infection, extraction of the looser fracture fragment (usually the lateral fragment) is sufficient to alleviate clinical signs such as quidding.[40] The remaining stable medial dental fragment should be reduced in height to prevent its medial displacement caused by normal masticatory forces. In the absence of apical infection, the retention of a large dental fragment is beneficial, because it prevents drifting of adjacent cheek teeth into its space, for a few years perhaps, and also decreases the development of major overgrowths (stepmouth) on the opposite cheek teeth.

FILLING OF CARIOUS INFUNDIBULA

An endodontic type of treatment has been used for treating deep caries of the infundibulum, in an attempt to prevent further infundibular decay and to structurally strengthen these cheek teeth. This treatment may prevent affected cheek teeth from fracturing and also prevent caries from extending into the pulp, which could lead to apical infection. After cleaning out

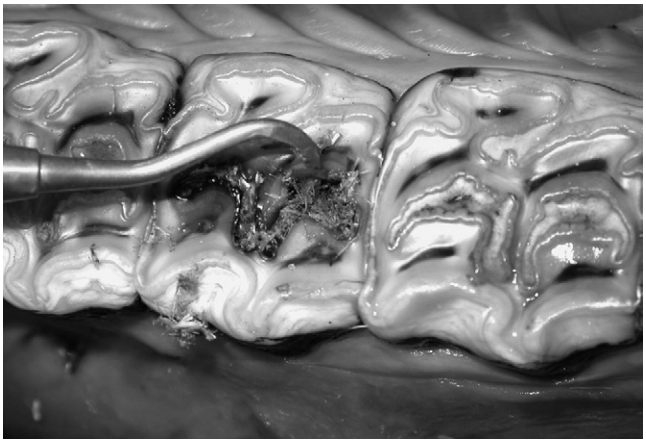

Figure 30-23. This maxillary cheek tooth specimen has impacted food in a carious (note dark infundibular enamel) infundibulum that is being removed with a dental pick.

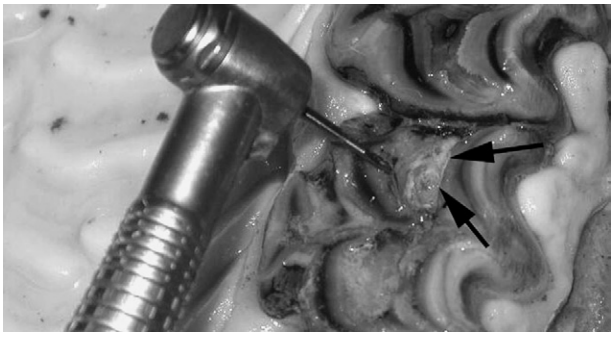

Figure 30-24. The carious infundibulum of Figure 30-23 has had all of the carious cementum and enamel removed with a high-speed dental drill *(arrows)*. The caudal infundibulum is filled with drill coolant water.

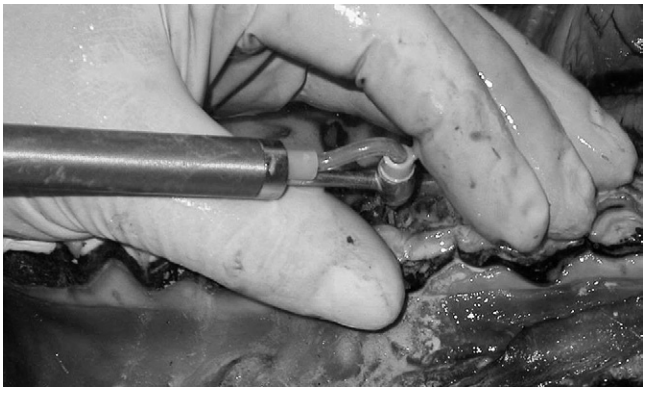

Figure 30-25. A high-pressure aerosol containing microfine aluminum powder (Equine Dental System, Pacific Equine Dental Institute, El Dorado Hills, CA) is being used to clean out a carious infundibulum in this specimen.

food material with a dental pick (Figure 30-23) or high-pressure aerosol or water lavage, the carious cementum in the infundibula is removed insofar as is technically possible using a dental drill (Figure 30-24) or by high-pressure aerosol abrasion with fine silica or aluminium powder (Figure 30-25).

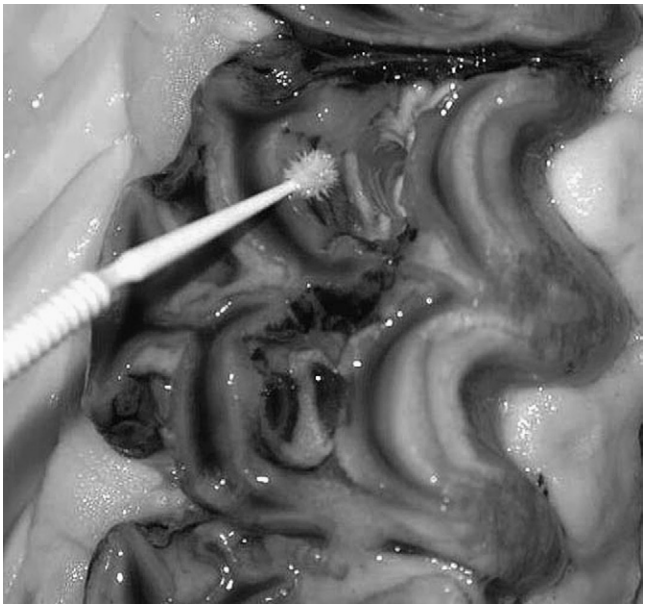

Figure 30-26. The cleaned infundibulum, which has also been acid-etched, washed, and dried, is now having bonding material applied with a flexible brush.

Figure 30-27. The prepared infundibulum has now been filled with a modern, self-curing, composite restorative material.

The cleaned infundibulum is flushed with sodium hypochlorite and acid-etched; then a bonding agent is applied (Figure 30-26) before it is filled in layers with a modern composite restorative material (Figure 30-27) as previously described (for incisor fractures). Because access to these carious infundibula (usually in the upper 09s) is difficult, it is not always possible to fully remove all carious cement (or enamel) and debris deep in the infundibula. Additionally, some infundibula have large dilated cemental defects deep (e.g., more than 5 cm) in the reserve crown that cannot by physically accessed from the occlusal surface.[44] Therefore it is unclear whether this therapy can always prevent extension of caries into the adjacent pulp or apex, but it should render the affected cheek teeth more mechanically sound and thus help prevent sagittal fractures.

Although encouraging anecdotal information is available, no objective data are yet available on the long-term value of this treatment.

DENTAL (ODONTOGENIC) TUMORS

Dental tumors are rare in horses, but when present they can mimic apical infections (i.e., with the presence of maxillary and mandibular swellings that later may become much larger than the swellings commonly associated with apical infections). Additionally, these swellings rarely develop sinus tracts, and they are usually firm and painless. Dental tumors include ameloblastomas, which are noncalcified epithelial tumors derived from the epithelium that forms enamel. A similar tumor, an ameloblastic odontoma, does induce calcification of adjacent mesenchymal tissues (and reciprocally of enamel epithelium) and so also contains dentine, cementum, and enamel. The appearance of these tumors can therefore vary from a noncalcified, polycystic, fibrous type of tumor to growths containing such tissues along with calcified dental tissues.

Dental tumors also include a variety of calcified tumors from dentinal tissues (odontoma) or cement (cementoma) or more commonly combinations of all three dental components (compound odontoma or, as noted earlier, ameloblastic odontoma).[45,46] Affected horses typically present with slowly growing, hard focal mandibular or maxillary masses that are usually very radiodense. The prognosis depends on their size and whether they are defined enough from the surrounding bones to allow complete surgical excision.[45-47]

CHEEK TEETH PERIAPICAL INFECTION

Apical (true roots may not even be formed at the time of infection) infections of cheek teeth may occur secondary to previously discussed abnormalities, including dental fractures or descending periodontal disease (e.g., beside a diastema). Additional proposed etiologies include bloodborne infection of pulp (or anachoresis), possibly predisposed to by vertical impaction of the rostral cheek teeth, which subsequently develops hyperemic, enlarged eruption cysts; and deep infundibular caries with extension of infection from the infundibulum into the pulp cavity (maxillary cheek teeth only).[48] Two studies have more clearly defined the causes of equine mandibular and maxillary cheek teeth apical infections.[5,6] The described equine cheek teeth pulp nomenclature[49] that has already been modified to improve its clarity[5] (see Figure 30-3) can be used to identify individual pulps in mature cheek teeth. Regardless of its etiology, if an apical infection (with death of pulp) has been present for many months, the secondary dentine normally worn away on the occlusal surface by mastication is not replaced and therefore occlusal pulpar exposure occurs over all pulp horns (Figure 30-28). Examination for pulpar exposure using a dental mirror or endoscope and a fine steel probe is simple and represents a currently underused but valuable clinical test for establishing dental viability (Figure 30-29).[50]

In the early stages, an anachoretic infection may remain confined to the apex, and all the pulp horns (or the common pulp in immature cheek teeth) may remain vital. At this early stage of infection, antibiotic treatment (e.g., 2 to 4 weeks of trimethoprim/sulfonamide) may be effective, but no factual data are available on the efficacy of such antimicrobial therapy. Surgical curettage of the affected apex has also been used with varying success, possibly having led to some failures that further compromised pulpar blood supply by damaging the apical vasculature.[48,51] In the later stages of apical infection, the common pulp or just some of the individual pulp horns may become necrotic. At this stage, dental extraction or possibly endodontic therapy is required.

Anachoretic apical infections occur mainly in younger horses, which have long reserve crowns and largely healthy periodontal membranes. Consequently, the infection cannot drain into the oral cavity via a periodontal route but instead spreads to the apical aspect of the alveolus and and from there to the adjacent supporting bones. Mandibular apical infections are invariably accompanied by unilateral, painful, ventral mandibular swellings that often develop external draining tracts. Infections of the

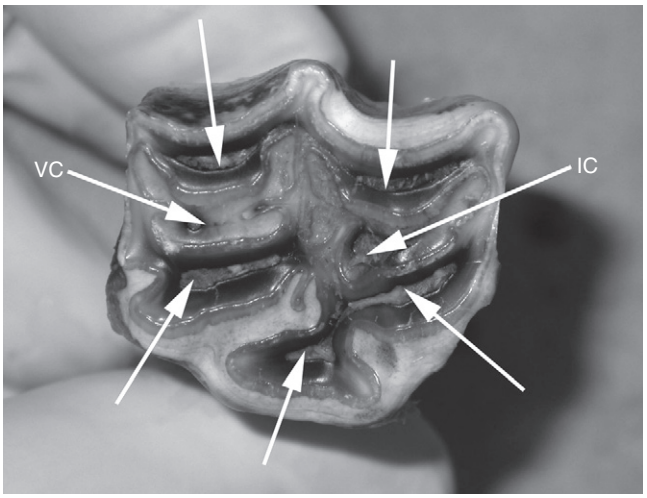

Figure 30-28. The occlusal surface of a cheek tooth extracted because of apical infection shows pulp exposure at all five pulps, all of which contain impacted food material *(arrows)*. One infundibulum contains a distinct vascular channel *(VC)*, and another one has localized clinically insignificant infundibular cemental caries *(IC)*.

Figure 30-29. The occlusal surface of this cheek tooth (06s have six pulp horns) has intact secondary dentine over five pulp cavities but has a pulp exposure over one (pulp horn five, with needle inserted). Some minor discoloration is present in both infundibula.

upper 06 and 07 (occasionally the 08) cheek teeth cause focal swellings of the rostral maxilla (rostrodorsal to the rostral aspect of the facial crest), which are almost pathognomonic for such dental infections. Some of these horses also develop an external sinus tract or, less commonly, a tract drains into the nasal cavity. Apical infections of the caudal three or four maxillary cheek teeth (08s to 11s) usually result in a secondary maxillary sinusitis, with a chronic, malodorous, unilateral nasal discharge, and marked facial swelling. External draining tracts are rare with this type of sinusitis. In older horses, apical infections commonly drain through the shorter periodontal membrane into the mouth, and therefore swellings of the supporting bones or sinus tract formation seldom occur.

A thorough clinical examination of suspect sinusitis cases should be performed, including an intraoral examination for evidence of abnormalities, such as cheek teeth fractures, gross infundibular caries, diastemata, deep periodontal disease, or occlusal pulpar exposure (see Figures 30-28 and 30-29). Radiographic evaluation of apical infection should include 45-degree ventrolateral-lateral oblique projections for imaging mandibular cheek teeth apices and 30-degree dorsolateral-lateral oblique projections for imaging maxillary cheek teeth apices. The interpretation of equine dental radiographs is often difficult because of the frequent presence of overlying anatomic structures and because of combinations of lucent areas (from demineralization of apices and adjacent alveoli) and radiodense areas (from apical hypercementosis, alveolar sclerosis, and surrounding soft tissue inflammation). Interpretation is especially problematic in early apical infections in young horses where radiolucent normal eruption cysts have many radiographic similarities to apical infections.[32] If a sinus tract is present, as often occurs with mandibular or rostral (06s to 08s) maxillary cheek teeth infections, it is essential to obtain radiographs with a metallic probe *in situ* to confirm the presence of apical infection (Figure 30-30). This procedure also provides surgical landmarks (helpful if the infected tooth is to be extracted by repulsion). Similarly, metallic markers (e.g., skin staples) should be placed over areas of maximal facial swelling to establish possible anatomical relationships between facial swellings and the underlying cheek teeth apices. When available, computed tomography imaging is the optimal technnique to allow these complex three-dimensional structures to be more fully assessed. Endoscopic examination of the sinuses (sinoscopy) is helpful, as it sometimes demonstrates normal alveoli and so indicates that the sinusitis present is not of dental origin. The goal of these examinations is to definitively confirm whether any of the cheek teeth are diseased and need to be extracted.

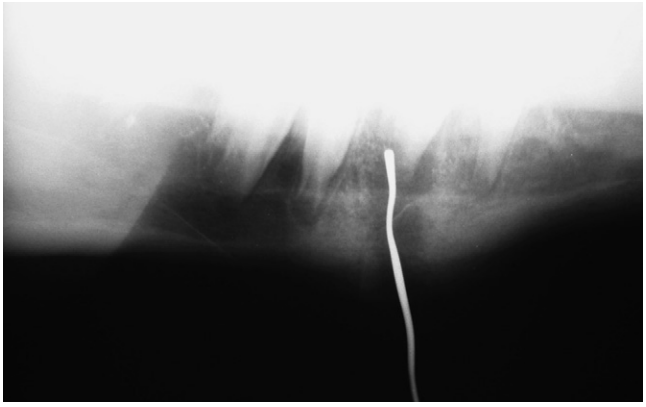

Figure 30-30. This radiograph shows an apically infected mandibular cheek tooth, with thickening of the underlying mandible, that also contains a lytic track leading to its caudal root. The caudal aspect of this root has been destroyed and is thickened more dorsally. The probe inserted up the sinus tract further confirms that infection is present in this cheek tooth.

When doubt exists about whether apical infection is present, scintigraphy may provide additional evidence. If any doubt still remains following all investigations, conservative therapy should be initiated—for example, a 2- to 4-week course of oral potentiated sulfonamides (possibly along with oral metronidazole therapy) for suspected mandibular infections and rostral (06 to 08) maxillary cheek teeth apical infections, and maxillary sinus lavage and similar antibiotic therapy for suspected caudal (09 to 11) maxillary cheek teeth apical infections. Failure to respond to this conservative therapy should prompt a further clinical and radiographic evaluation for the presence of apical infection. Serial radiographs of cases with dental sinusitis often later show definitive dental changes that were not present in earlier radiographs. Only when definite evidence of dental infection is present should dental extraction be considered.[19,48]

Treatment of Disorders of the Cheek Teeth

EXTRACTION OF CHEEK TEETH

Most cheek teeth apical infections occur in younger horses, and in these cases the infection is usually confined locally to the apical area, and great mechanical force is required to break down the remaining extensive, healthy periodontal membranes. Consequently, extraction of a long-crowned equine cheek tooth is a major surgical procedure with many possible immediate and delayed sequelae.[41] Oral extraction is the technique of choice for removal of most equine cheek teeth, as it can be performed in the standing horse, does not require surgery of the supporting bones, and greatly reduces postoperative complications compared to the repulsion or buccotomy technique.[41]

Oral extraction of cheek teeth

The availability of today's safe and effective sedatives and analgesics is a major reason for the revival of the oral extraction techniques. Most of the instrumentation has remained unchanged for over 100 years.[19,41,52,53]

A prerequisite for oral extraction of equine cheek teeth is excellent chemical restraint of the horse. This can be achieved by a combination of an α_2-adrenergic receptor and butorphanol (or morphine). A detomidine continuous-infusion technique has also been used successfully (loading doses of 4 mg IV of detomidine and 10 mg IV of butorphanol are given followed by 2 drops per second of a drip that contains 14 mg of detomidine in 250 mL of saline). Local anesthesia of the mandibular and infraorbital nerves can be used; for example, the upper 06s or 07s can be anesthetized by inserting a 5-cm, 21-gauge needle 3 to 4 cm caudad in the infraorbital canal and then slowly injecting 3 to 5 mL of lidocaine. The mandibular nerve, which is sensory to all mandibular teeth, can be anesthetized as it enters the mandibular canal on the medial aspect of the mandible. The mandibular foramen lies at the intersection of a vertical line at the caudal limit of the orbit with a line parallel to the occlusal surface of the cheek teeth. After subcutaneous local anesthetic infiltration and aseptic skin preparation, a 15-cm (6-inch), 18-gauge spinal needle is "walked" up the

periosteum of the medial aspect of the mandible and 20 to 30 mL of lidocaine is deposited at the site and 1 to 2 cm dorsocaudally to it.

With more difficulty, the maxillary branch of the trigeminal nerve can be anesthetized as it enters the caudal aspect of the infraorbital canal. After aseptic skin preparation, a 9-cm (3½-inch) spinal needle is inserted caudal to the highest point of the zygomatic arch and is then walked ventrorostromedially down the orbital aspect of the frontal bone to the caudoventral aspect of the orbit, where 20 to 30 mL of lidocaine is deposited. A simple, recently described technique to anesthetize the maxillary nerve (after aseptic skin preparation) is to insert a needle at right angles to the skin immediately ventral to the zygomatic process between the middle third and caudal third of the orbit. The needle is inserted 30 to 35 mm (3 to 3.5 cm) through the masseter muscle, and a change in consistency is detected as it enters the extraperiorbital fat body. The needle is advanced 15 to 20 mm (1.5 to 2 cm) further and 20 mL of local anesthetic is inserted.[54] It may take 20 minutes or so for the maxillary nerve to become anesthetized.

For oral cheek teeth extraction, the horse should be restrained in stocks with its head on a headstand or suspended in a dental head collar (see Figure 30-2). At least one assistant is needed to stabilize the head and help with the extraction. A good headlight is also required, especially when extracting caudal cheek teeth, to absolutely ensure that the correct cheek teeth are separated and that the correct tooth is subsequently correctly grasped with foceps and later extracted. In many horses, the medial (palatal) aspect of the maxillary cheek teeth contains very little exposed crown, with the gingival margin in some horses lying just a few millimeters below the occlusal surface. In such cases, a long-handled, pointed metal dental pick is used to detach the gingiva around the affected tooth to the level of the alveolar crest on the medial aspect of the tooth. This procedure normally exposes enough of the dental crown to allow cheek teeth extractors to be firmly applied on both the lateral and medial aspects of the tooth to be extracted.

A narrow-blade cheek teeth separator ("molar spreaders") can now be slowly inserted into the interdental spaces, first in front of and then caudal to the affected tooth (Figure 30-31). The separator should be kept in place for about 5 minutes to excessively stretch and therefore damage the periodontal ligaments. A series of cheek teeth separators with increasingly wider blades can then be used to further stretch the periodontal ligaments. When extracting an 07, separators should not be used between the 06 and 07 in case the (rostrally unsupported) 06 is excessively displaced rostrally and loosened. Separators must also be cautiously used when extracting caudal cheek teeth in horses with a marked curve of Spee, because the vertical blades of the separator will not fit into the nonvertical interdental spaces of such cheek teeth and may instead fracture them.[19,41]

A cheek teeth extractor is subsequently firmly attached to the crown of the diseased tooth and the cheek tooth is rocked in the horizontal plane, initially very gently (Figure 30-32). After a variable period (20 to 120 minutes), depending on the extent and health of the periodontal membranes, a "squelching" sound is heard. The tooth can now be more easily rocketed with the extractor, and foamy blood will appear at the gingival margin. The tooth usually becomes digitally loose as the squelching sounds increase. Only at this stage should a fulcrum be placed on the occlusal surface of the tooth rostral to the infected tooth. Vertical pressure is now exerted on the forceps, drawing the affected intact tooth from the alveolus. With caudal mandibular cheek teeth, it may be safer not to attempt elevation with a fulcrum, in case this vertical force fractures the obliquely positioned teeth. Instead, the tooth should be loosened digitally and extracted in a rostrodorsal direction using manual force (Figure 30-33). Unlike repulsed cheek teeth, the apices of extracted cheek teeth are virtually always intact (Figure 30-34).[41]

If no sinus tract or secondary sinusitis is present, the empty alveolus should be lavaged with saline, dried, and allowed to develop a blood clot (by gentle curettage if necessary) that will speed up alveolar healing. The alveolus can subsequently simply be filled with one or two cotton swabs (sponges) that contain metronidazole or another antibiotic (Figure 30-35), to prevent long fibrous food from being trapped in very deep alveoli before it granulates closed. In older horses with shallower alveoli (less than 5 cm deep), no alveolar packing is required. The alveolus should be checked 2 to 4 weeks later and the swab(s) removed if still present. The alveolus, if still patent, should now also be digitally palpated to detect roughened areas, which are usually

Figure 30-31. A narrow-blade, cheek tooth separator is being inserted between two cheek teeth in this specimen.

Figure 30-32. A Routeledge-type cheek tooth extractor applied to a mandibular cheek tooth (308), in the latter stages of dental extraction, when this cheek tooth has been elevated 2 to 3 cm into the oral cavity.

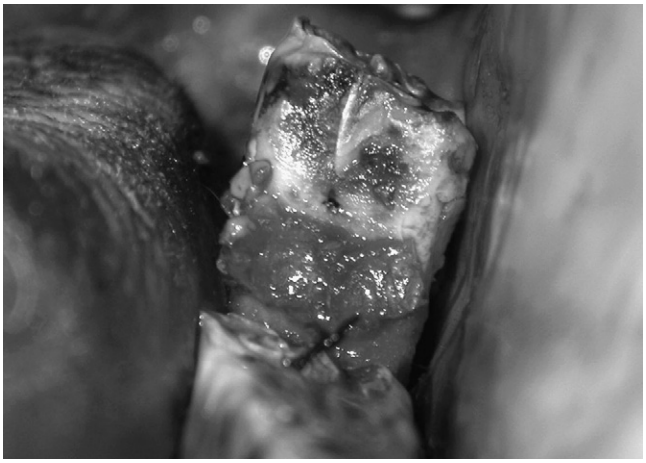

Figure 30-33. The final stages of oral cheek tooth extraction shows a mandibular cheek tooth that has been elevated into the oral cavity. It can be digitally removed at this stage.

Figure 30-34. The extracted mandibular cheek tooth (shown in Figures 30-31 to 30-33) has extensive, healthy periodontal covering over all of the reserve crown and apex, except at the tip of the thickened, infected root *(arrows)*.

caused by sequestration of conical areas of alveolar cortex. If detected, such loose alveolar fragments should be digitally removed or curetted. Specialized long-handled, right-angled alveolar curettes are necessary to effectively curette the more caudal alveoli. Alveoli that still have a deep, large lumen may have a swab replaced for a further 2 weeks before being similarly rechecked.

If an external sinus tract was present before extraction, the bone at the base of the tract can be gently curetted percutaneously, and the tract will usually spontaneously heal within a few days. If the sinus tracts are wide or if gross alveolar infection is present, it is advisable to seal off the oral aspect of the alveolus with dental wax or an acrylic plug and to irrigate the sinus tract with a dilute povidine-iodine solution for a couple of days.

Oral extraction of the cheek teeth can also be performed on horses with infection of the caudal maxillary cheek teeth, which

Figure 30-35. Surgical gauze, impregnated with antibiotics, is being inserted into a mandibular cheek tooth alveolus. It will be left in place for a couple of weeks to prevent impaction of food deep within the alveolus.

have a secondary sinusitis. If the apical aspect of the alveolus digitally feels intact after cheek teeth extraction (as is almost always the case), it can simply be packed with an antibiotic-impregnated swab, as described earlier. If the alveolus appears disrupted (very rare), an acrylic plug should be inserted between the two adjoining cheek teeth (as described later) to prevent the development of an oromaxillary fistula. In all cases of maxillary sinusitis caused by dental infections, a separate small (e.g., 10-mm diameter) portal should be made in the ipsilateral frontal sinus to allow sinoscopic assessment for the presence of inspissated pus that should be removed by transendoscopic techniques if possible, using biopsy forceps, baskets, and high pressure lavage. This procedure will require fenestration of the ventral conchal bulla (see Chapter 43) if the 08 or 09 cheek teeth are infected and concurrent rostral maxillary and ventral conchal sinus infection are consequently present.[42,43] Alternatively (but more invasively) inspissated pus can be removed by sinusotomy, preferably in the standing horse to reduce intraoperative hemorrhage. The sinoscopy portal described earlier should be used for postoperative lavage of the infected maxillary sinus twice daily, with 5 L of very dilute povidine-iodine or saline solution for about 7 days or until the lavage fluid is odorless and runs clear.

After successful oral extraction of cheek teeth by experienced surgeons, postoperative complications are rare (they occur in about 10% of cases) and are usually of a minor nature—for example, nonhealing alveoli caused by alveolar sequestra, or localized osteitis. Most can be resolved by digital sequestrum removal or alveolar curettage, using long-handled equine dental curettes and antibiotic therapy.[41,55]

Repulsion

The standard method for extracting equine cheek teeth in the late 19th and most of the 20th century has been cheek teeth repulsion under general anesthesia.[19,52] This procedure has the expense and the inherent risks for morbidity and mortality of equine general anesthesia, and it is also associated with a high level of postoperative complications. A surgical window (e.g., 2 cm in diameter) is made using a bone saw, trephine, or chisel adjacent to the infected apex. For mandibular cheek teeth

repulsion, this site is beneath the ventral mandible (Figures 30-36 and 30-37), and for repulsion of maxillary 06, 07, and occasionally 08 cheek teeth, it is on the dorsorostral aspect of the rostral maxillary bone. For the latter trephination, care must be taken to avoid the infraorbital canal and nerve. Larger (e.g., 5 to 6 cm^2) caudal maxillary bone flaps (hinged in a dorsal direction) can be used to perform a sinusotomy (see Chapter 43), and this is preferable to making a small sinus trephine opening for repulsion of the caudal maxillary cheek teeth. Such larger windows allow a visual and digital inspection of the apices of the 09 to 11 cheek teeth and subsequently their repulsion, if apical infection is confirmed. Infected apices lose the smooth, rounded, soft tissue–covered appearance of normal apices; rarely, sharp edges of exposed apical enamel or the edges of alveoli are palpable, and more commonly, local granulation tissue and mucosal inflammation are evident.

Intraoperative radiographs should always be obtained if there is any doubt about the site and the direction of placement of the repulsion punch (Figures 30-38 and 30-39). Radiographs should also be obtained after the repulsion, unless the surgeon is certain that the tooth has been fully removed. As wide a punch as possible should be used during repulsion, with offset punches most suitable for upper cheek teeth repulsion. Hammering a thin metal blade down the periodontal space, especially on the (flat) rostral and caudal cheek teeth margins, can greatly decrease the time and trauma necessary to repulse a cheek tooth.

After cheek teeth repulsion, it should be determined that the alveolus is free of dental or alveolar remnants by digitally and visually examining the extracted cheek teeth and by obtaining postoperative radiographs. The oral (occlusal) aspect of the alveolus should be thoroughly dried and sealed with a dental wax plug (after mandibular or rostral maxillary cheek teeth repulsions), or with an acrylic plug attached to the two adjacent cheek teeth (for caudal maxillary cheek teeth repulsions). The plugs should lie below the occlusal level; otherwise they will loosen quickly with the high continual forces of mastication. They should also not extend more than 3 to 4 cm into the alveolus, or they will delay alveolar healing and can be very

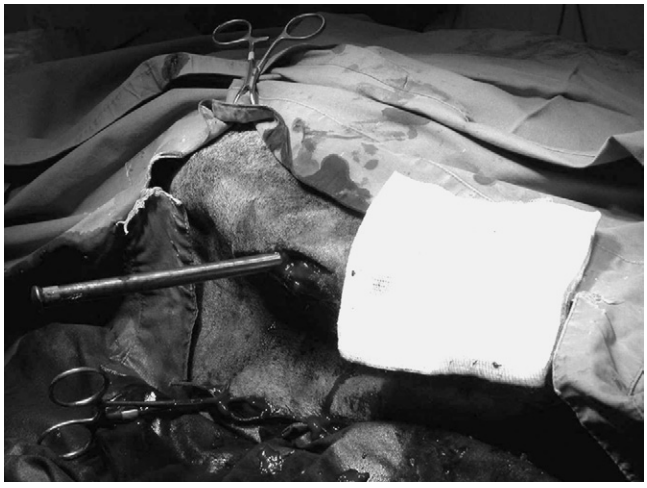

Figure 30-36. This horse is having a mandibular cheek tooth repulsed under general anesthesia. Note the steel punch in a ventral mandibular site.

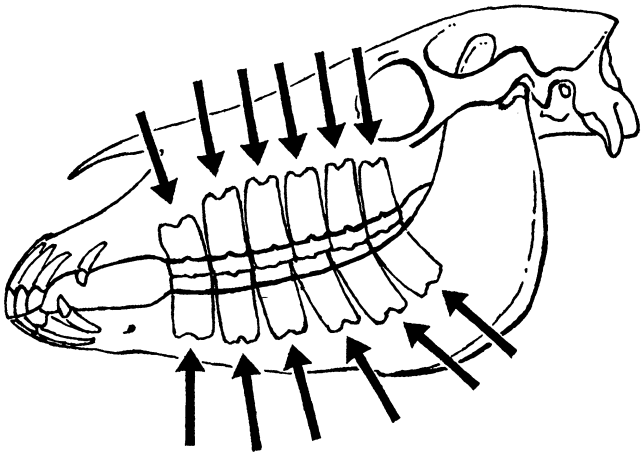

Figure 30-37. The direction of repulsion of the cheek tooth in a young horse.

Figure 30-38. Intraoperative radiography of a horse having a mandibular cheek tooth repulsed. This radiograph is being obtained to confirm punch positioning and angulation to prevent iatrogenic damage to adjacent cheek teeth.

Figure 30-39. This intraoperative radiograph shows the punch correctly positioned over the affected apex and also shows that it is facing in a suitable direction to effectively remove this (09) cheek tooth.

difficult to remove. The surgical site used for repulsion of rostral maxillary or mandibular cheek teeth should be left open and irrigated (e.g., with saline or a very dilute povidone-iodine solution) for a few days, especially if they remain purulent or malodorous. Broad-spectrum antibiotics and NSAIDs should also be administered for at least 3 days after dental repulsions.

Complications commonly occur after repulsion of apically infected cheek teeth from younger horses, because much mechanical damage occurs to the alveolar and supporting mandibular or maxillary bones by the high forces and often prolonged nature of cheek teeth repulsion.[55] These problems include nonhealing alveoli as a result of residual dental fragments or alveolar sequestra; localized osteomyelitis; oronasal, orofacial, and oromaxillary fistulae; chronically draining facial tracts; damage to adjacent teeth; and chronic sinusitis. Some bone sequestration may be delayed and will not be detectable until many weeks following repulsion. A number of studies have shown that between 32% and 70% of cases of equine dental repulsion require additional surgical and nonsurgical treatments, with most complications following maxillary cheek teeth repulsions (Figure 30-40).[48,56-58] Careful radiographic assessment for the presence of dental or bone sequestra, osteomyelitis, adjacent damaged or infected cheek teeth, and chronic sinusitis helps (in cases where such problems are detected) in the selection of an appropriate treatment modality, such as alveolar curettage, replacement of loose alveolar plugs, sinus lavage, and antibiotic therapy.[55]

REMOVAL OF THE LATERAL ALVEOLAR PLATE (LATERAL BUCCOTOMY TECHNIQUE)

A further technique for equine cheek teeth extraction that has been used for over 100 years involves the removal of the supporting bone lateral to the alveolus. It is most suitable for extraction of the rostral upper three cheek teeth, but it has been adapted for extraction of the rostral three mandibular cheek teeth by the buccotomy technique and also for the more caudal mandibular cheek teeth by dissection through the masseter muscles.[19,58-60]
