Preface

Although the porphyrin and tetrapyrrole research area was regarded as "fully matured" during the 20th century, as evidenced for example by the awarding of numerous Nobel Prizes to its principal researchers, new advances and accomplishments in the field still amaze us as editors. The area continues to blossom and to expand into new areas of science and applications that would probably never have occurred to our 20th century heroes. An earlier *Porphyrin Handbook* assembled the large amount of factual data that had been accumulated during the 20th century. Our new venture, the *Handbook of Porphyrin Science* takes a completely new look at our research area and comprehensively details the contemporary science now appearing in the scientific literature that would indeed have been hard to predict even 10 years ago. In particular, fundamentally new methodologies and potential commercial applications of the beautiful compounds that we all love are exemplified, fully recognizing the subtitle of the series — "with applications to chemistry, physics, materials science, engineering, biology and medicine".

The three of us have complementary expertise in physical chemistry, synthetic and bioorganic chemistry, and in synthetic and mechanistic organometallic chemistry; this has enabled us to cover the whole field of porphyrin science and applications, and to devise comprehensive volume and author content. As of the date of writing, between the three of us, we have published more than 1600 tetrapyrrole research articles, and hold 31 patents related to commercial applications of porphyrin science. So we do know our field, and this has enabled us to assemble a first-rate group of experts who have written comprehensive up-to-date chapters with accuracy and authority; we thank our authors for their cooperation and willingness to go along with our highly ambitious schedule for production of these volumes.

We look forward to comments from our readers, and to suggestions that might enable us to expand our basic interests and scientific coverage even further. Meanwhile, we hope that porphyrin researchers, old, new and of the future, will enjoy reading these volumes just as much as we enjoyed planning and, with the help of World Scientific Publishing Company, producing them from manuscript to published article, in a timely manner.

43 Metalloporphyrin-Catalyzed Asymmetric Atom/Group Transfer Reactions

Joshua V. Ruppel,* Kimberly B. Fields,* Nicole L. Snyder† and X. Peter Zhang*

*Department of Chemistry, University of South Florida, Tampa, FL 33620, USA
†Department of Chemistry, Hamilton College, Clinton, NY 13323, USA

I. Introduction

Metalloporphyrins have been shown to catalyze many fundamental and practically important chemical transformations in biological systems and in the chemical laboratory. The most notable examples have been accomplished using metalloporphyrin complexes inspired by biology. These complexes have been used to perform atom/group transfer reactions including oxene, nitrene, and carbene transfers, which in turn have provided chemists with direct access to complex and functionally diverse compounds from abundant and inexpensive alkenes and alkanes.

In an effort to improve the catalytic ability and specificity of these "synthetic enzymes", researchers have focused on the synthesis of "designed" complexes that are based on well-defined biological/chemical scaffolds. These complexes, which incorporate chiral peripheries into the metalloporphyrin framework, have provided researchers with scaffolds to directly manipulate the stereoselectivity of the reaction system. Three methodologies for synthesizing these derivatives have been developed: (1) porphyrins formed through the classical condensation of chiral aldehydes with pyrrole; (2) porphyrins formed through substitution of amino- and hydroxyl-substituted tetraphenylporphyrins with chiral building blocks; and (3) bridging of the enantiotropic faces of prochiral porphyrins to afford a chiral environment. The porphyrins prepared by these three methods have provided important information regarding the type of chiral environment required to induce enantioselectivity when used as catalysts. The trends indicate that the more rigid the chiral environment, the greater the catalytic stability and the slower the intramolecular decomposition. This in turn provides for a longer catalytic lifetime and higher turnover numbers (TON). On the other hand, more flexible substituents are more vulnerable to degradation, such as oxidation of the porphyrin periphery, and produce products with decreased enantioselectivity.

The chiral units' proximity to the active center constitutes an important observable trend. Chiral units that are far away provide less chiral induction as the approach of the incoming substrate is not substantially affected by the peripheral chiral environment. On the other hand, chiral units that are too close to the metal center often suffer from decomposition as the chiral environment itself becomes the substrate and is then compromised.

Chiral proximity also plays a role in the enantioselectivity observed with substrates of different sizes and shapes, although the specific requirements are not always as well defined or easy to define. This constraint has led some research groups to incorporate a modular design with steric environments that can be systematically modified to best suit each type of substrate.

The modification and design of porphyrin ligands to create chiral environments has led to a diverse array of catalysts. To categorize these chiral ligands, the

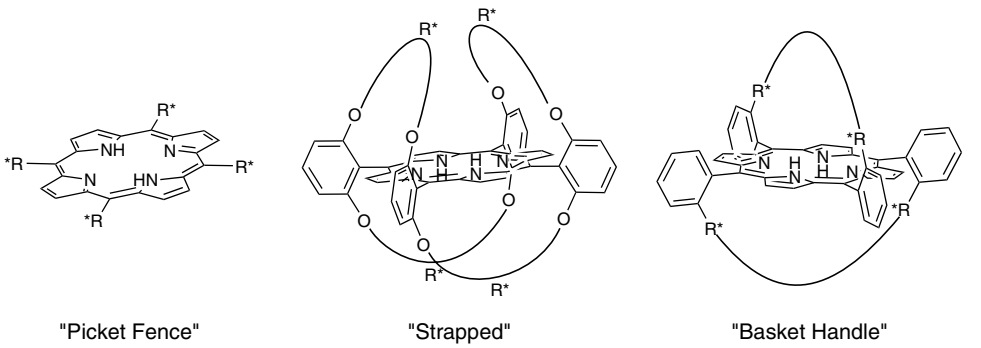

Figure 1. Examples of "picket fence", "strapped", and "basket handle" type porphyrin scaffolds.[1]

classification system outlined by Collman and coworkers in 1993 will be used.[1] In this system, chiral porphyrins (Por*) are categorized by class: "picket fence", "strapped", and "basket handle" (Figure 1).

The picket fence class contains porphyrin ligands with chiral units (R*) around the perimeter of the porphyrin ring, but without connections between adjacent or opposite functionalities. Chiral groups can be connected directly to the *meso*- or *beta*-positions or attached to the *meso*-aryl positions in a wide range of orientations.

The strapped and basket handle classes are categorized by the positions of the chiral units bridged around the porphyrin perimeter above and below the porphyrin plane. The major difference between the two classes is the orientation of the chiral bridge. Chiral bridges that connect adjacent positions (e.g., the 5,10-positions) are considered strapped. Chiral bridges connecting opposite positions (e.g., the 10,20-positions) are categorized as basket handle.

This chapter will review the major advancements in asymmetric atom/group transfer reactions utilizing metalloporphyrin catalysts, specifically the asymmetric epoxidation, cyclopropanation, and aziridination of alkenes. Several reports of various forms of C–H functionalization will also be discussed. These works will be organized by ligand class and the literature covers the period through July 2009.

II. Epoxidation

Early work on epoxidation was developed out of studies on cytochrome P-450, a heme-containing monooxygenase, which catalyzes the incorporation of oxygen from molecular dioxygen into organic substrates.[2] Simple mimics based on iron, manganese, chromium, and ruthenium metalloporphyrin frameworks have been

developed to convert alkenes, alkanes, and aromatic hydrocarbons into valuable commodity chemicals in a controlled and selective fashion.[3] A variety of oxidants have been employed for these systems; including molecular dioxygen, hydroperoxides, peroxyacids, NaOCl, N_2O, and iodosylbenzene (PhIO) and its derivatives.[3] These oxidants have been used to produce high-valent metal intermediates in an effort to replace existing auto-oxidation technologies[4] allowing for stereocontrol of the products.

In 1976, Ullrich and coworkers demonstrated that cytochrome P-450 could catalyze oxygenation reactions through an alternate pathway known as the "peroxide shunt".[5] This pathway allows for the use of exogenous oxygen sources such as PhIO which opened the door to the exploration of alternative oxidants. The mechanistic aspects of these processes will not be covered in this chapter, as they have been extensively addressed by others.[6–8]

Following Ullrich, Groves and coworkers showed that a number of single-oxygen donors, including hydroperoxides, peroxy acids, and PhIO could be used with metalloporphyrin enzyme mimics to perform oxygen transfer in a manner similar to the fully reconstituted enzyme system.[9,10] For example, the combination of 5,10,15,20-tetraphenylporphinatoiron(III) chloride [Fe(TPP)Cl], and PhIO was used to transfer oxygen to alkenes and alkanes to form epoxides and hydroxides, respectively. Groves and coworkers established that there were dramatic differences in both yield and selectivity between porphyrins with peripheral variations, suggesting that the ligand environment was as intimately involved in the oxygen transfer step as the transition metal ion. Their work provided a foundation for tuning the selectivity and reactivity of metalloporphyrin catalysts through alteration of the porphyrin periphery.[11] Subsequent work by Lindsay-Smith and coworkers illustrated the importance of having a sterically bulky porphyrin periphery to interrupt μ-oxo dimer formation while leaving the metal center open to the approach of the olefin into the active site.[12]

Although the capability of these metalloporphyrins to mimic the oxo-transferase ability of cytochrome P-450 using nonbiological oxidants was impressive, initial catalysts suffered from rapid decomposition of the macrocycle, particularly for porphyrins with open *meso*-positions.[3] Groves and coworkers typically reported TONs for epoxidation and hydroxylation of approximately 10 or less, prompting research into the production of catalysts with greater stability.[13] As a result, electron-withdrawing groups were incorporated onto the macrocycle to increase the stability of the porphyrin. Continued efforts by Chang and Ebina[14] and then later by Traylor and coworkers[15] eventually produced metalloporphyrin catalysts that were capable of effectively epoxidizing alkenes in up to 10,000 TON.

Additional insight for improving metalloporphyrin catalysis was provided by studies on metallosalens, close relatives of porphyrins. The salen architecture offers the advantage of two chiral sp^3-hybridized carbons at the periphery within close proximity to the active metal center.[1] Salens have been shown to be highly effective catalysts for asymmetric epoxidation. In addition to the use of iodosylarenes, the effective use of more practical, inexpensive, oxidants such as sodium hypochlorite (bleach) and molecular dioxygen have made these catalysts especially appealing.[16–27]

Several salens capable of providing greater than 90% enantiomeric excess of *cis*-substituted alkenes have been reported in the literature.[18,28] The major drawback of these complexes is based on the susceptibility of the catalyst to oxidative decomposition. As a consequence, metallosalens typically have low TON (<40). However, the degradation products are generally inactive, thus the products of the reaction remain uncompromised.[1] The development of a catalytic asymmetric epoxidation system that could match the selectivities of the reported salen systems with the stability and high TON typically reported for metalloporphyrin-catalyzed epoxidation systems would combine the best attributes of both systems to produce the "ideal" epoxidation catalyst.

This section will cover metalloporphyrin-catalyzed epoxidation reactions and, more specifically, investigations into the enantioselectivity of the products generated by these catalysts with a detailed overview of the major contributions to this field.

A. Chiral Picket Fence Porphyrins

Groves and Myers published the first metalloporphyrin-catalyzed asymmetric epoxidation system in 1983.[10] Utilizing a similar scaffold developed by Collman and coworkers for investigating the binding of molecular oxygen to ferrous porphyrinates,[29] Groves and Myers synthesized an $\alpha,\beta,\alpha,\beta$-atropisomer with chiral moieties directed toward the iron metal center (Figure 2). The resulting chiral iron porphyrin contained identical chiral faces, each consisting of two chiral groups. They evaluated the ability of this picket fence porphyrin **1** to epoxidize styrene using PhIO and found that styrene oxide was produced in 65% yield with a moderate enantioselectivity of 31% ee (entry 1, Table 1). The $\alpha,\alpha,\beta,\beta$-isomer **2** and the $\alpha,\alpha,\alpha,\alpha$-$\mu$-oxo-dimer **3** generated racemic products when evaluated under the same conditions (entries 2–3, Table 1).

These results prompted the use of a binaphthyl chiral appendage using the same porphyrin scaffold (Figure 3) in the hopes of generating a relatively large and rigid chiral cavity around the iron center. The resulting chiral porphyrin **4** was

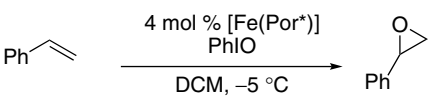
Table 1. Asymmetric epoxidation catalyzed by atropic isomers of [Fe(HydPP)Cl].[10]



Entry[a]	[Fe(Por*)][b]	Yield (%)[c]	ee (%)
1	[Fe(**1**)Cl]	65	31(*R*)
2	[Fe(**2**)Cl]	99	0
3	[Fe(**3**)]$_2$O	93	0

[a] Reactions were performed using 4 mol % of [Fe(Por*)] with 1 equiv. of PhIO as oxidant and 3 equiv. of styrene in DCM. Over a period of 3 hours the oxidant was added at an average temperature of –5 °C and was stirred for an additional 45 mins; [b] See Figure 2; [c] Based upon consumed PhIO.

evaluated for epoxidation using iodosylmesitylene as the oxidant and as little as 0.625 mol % catalyst loading. The epoxidation of styrene, along with other olefins, proceeded in moderate yields (58–75%) and enantioselectivity (15–51% ee) (Table 2). However, Groves and Myers noted the activity of the metalloporphyrin diminished after 100 catalytic cycles. Presumably, the oxidation of the porphyrin

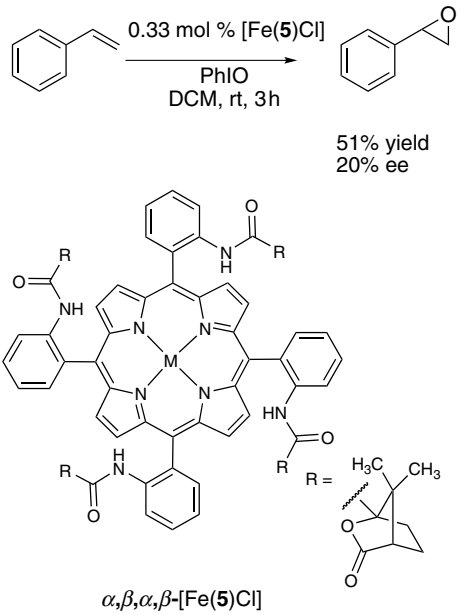
led to unfavorable changes in either the conformation or the electronic properties of the catalyst.

Several years after Groves and Myers seminal work on metalloporphyrin-catalyzed epoxidation, Paolesse and coworkers synthesized chiral porphyrin **5** containing camphanylamido groups on the *ortho*-positions of the *meso*-aryl groups (Scheme 1).[30] The subsequent catalyst [Fe(**5**)Cl] was used to generate



Scheme 1.[30]

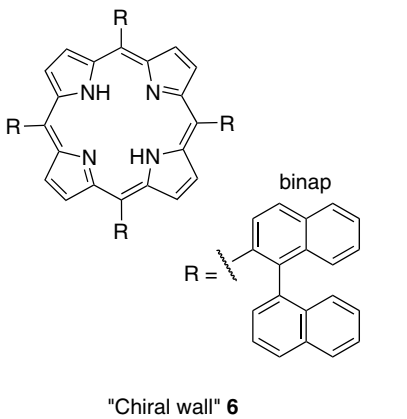


Figure 4. "Chiral wall" porphyrin.[31]

styrene oxide from styrene (5 equivalents) in moderate yields and 20% ee at room temperature in the presence of PhIO.

The binaphthyl group was also used as the chiral moiety by O'Malley and Kodadek in an effort to address catalytic stability.[31] Using the manganese complex of what they termed the "chiral wall" (**6**, Figure 4), the epoxidation of styrene and

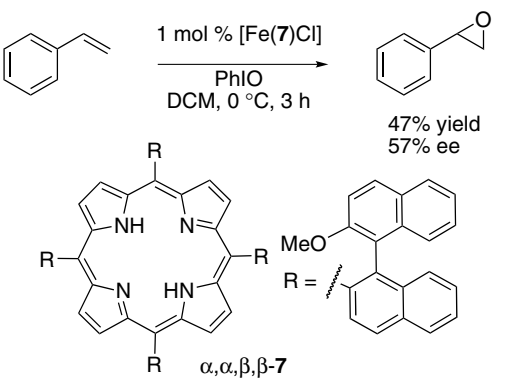

Scheme 2.[32]

several styrene derivatives was accomplished with moderate enantioselectivity (15–40% ee) using hypochlorite and only 0.03 mol % of catalyst to produce the corresponding styrene oxides (Table 3). "Chiral wall" porphyrin **6** was also shown to be quite stable, inducing the same enantioselectivities after several hundred catalytic turnovers (Table 3).

Several years after Kodadek's first report of the "chiral wall" catalyst, Salvadori and coworkers published results based on iron and manganese complexes of a similar ligand **7** (Scheme 2) for epoxidation.[32] The atropisomers of porphyrin **7** were prepared and evaluated for their ability to epoxidize styrene in an asymmetric fashion. Overall, the iron complex of the $\alpha,\alpha,\beta,\beta$-atropisomer [Fe(**7**)Cl] was found to provide the highest asymmetric induction (Scheme 2). It is also worth noting the differences in selectivities produced when different metals were

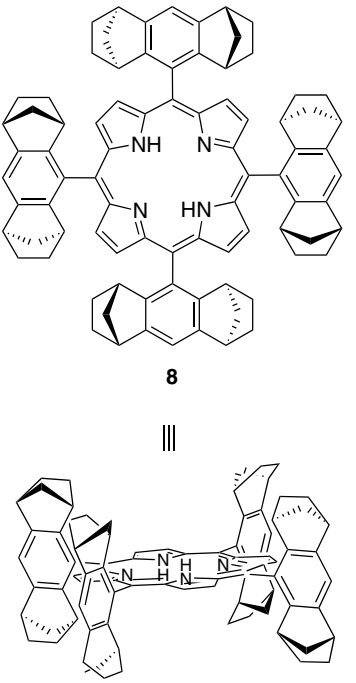

Figure 5. Halterman's D_4-symmetric porphyrin.[33]

used with $\alpha,\beta,\alpha,\beta$-porphyrin **7**: the resulting enantioselectivities of the manganese and iron complexes were 8 and 48% ee, respectively.

In 1991, Halterman and Jan published the synthesis and evaluation of a D_4-symmetric porphyrin **8** (Figure 5).[33] The Halterman porphyrin **8** has become one of the most investigated porphyrin-based catalyst not only for epoxidation but also for other atom/group transfer reactions that will be discussed later in this chapter. Halterman and coworkers reported the use of [Mn(**8**)Cl] with 4-*tert*-butylpyridine as an axial ligand for the epoxidation of styrene derivatives with Clorox® bleach.[34] Under these reaction conditions, high yields and moderate to good enantioselectivities were observed within hours (Table 4). Halterman and coworkers also reported the synthesis and evaluation of several derivatives of **8**. However, the reactivity and selectivity of these systems were either comparable to or lower than the manganese complex of **8**.[35]

One of the remarkable features of this reaction is the use of excess oxidant without adverse side reactions. In most oxidation systems, the oxidant is used as the limiting reagent and a large excess of substrate is used to consume the oxidant quickly to avoid poisoning the catalyst. Using commercially available Clorox® bleach, this catalyst performed well when a 3% sodium hypochlorite

aqueous/DCM medium was employed in the presence of as little as 0.05 mol % of catalyst loading.

The use of the Mn(III) chloride complex of the Halterman porphyrin **8** was further studied by Chang and coworkers using Oxone® ($KHSO_5$) and *cis*-β-methylstyrene.[36] In their work, various axial ligands were employed to evaluate the potential *trans* effect on the yield and selectivity of the catalytic epoxidation reaction (Table 5). Although not as effective as Halterman's original catalytic system (entry 4, Table 4), a significant increase in enantiomeric excess was observed when DMAP was employed as the axial ligand (entry 13, Table 5).

Epoxidation employing [Ru(**8**)$(O)_2$] was first investigated by Che and coworkers for the stoichiometric epoxidation of styrene.[37] Moderate yields and enantioselectivities were obtained using styrene as the substrate (Scheme 3). The authors also reported the epoxidation reaction under catalytic conditions with dioxygen as the oxidant (8 atm), generating the desired product with low TON (10) and moderate enantioselectivity (70% ee) (Scheme 3). The authors commented that higher TON and enantioselectivity should be accessible with the optimization of these reaction conditions.

In a separate report, Che and coworkers explored the effects of solvent on the catalytic process with [Ru(**8**)(CO)].[38] The epoxidation of styrene derivatives in either benzene or dichloromethane using [Ru(**8**)(CO)] and PhIO was found to have little effect on the enantioselectivity of the catalytic process (entries 1 and 2, Table 6). Che and coworkers went on to evaluate both

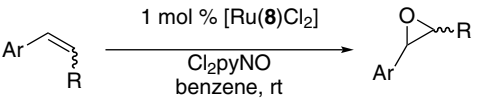
[Ru(**8**)(CO)] and [Ru(**8**)$(O)_2$] as catalysts for the epoxidation of styrene derivatives (Table 6). The [Ru(**8**)(CO)] was found to be slightly more selective than [Ru(**8**)$(O)_2$] (entries 2 and 3, Table 6), although this trend was not observed with all styrene derivatives.

In their continued effort to develop ruthenium complexes of the Halterman porphyrin **8**, Che and coworkers published the synthesis and evaluation of [Ru(**8**)Cl_2] in 2001.[39] For these reactions, 2,6-dichloropyridine-*N*-oxide (Cl_2pyNO) was used as oxidant with 1 mol % catalyst in benzene to generate moderate yields and enantioselectivities with high TON, typically greater than 800 (Table 7). This system was shown to be capable of catalyzing a wide range of substrates, including mono- and di-substituted olefins, having various steric and electronic properties (Table 7). To evaluate the stability of this catalytic system, [Ru(**8**)Cl_2] was reused in four consecutive runs, and it was observed that product conversion diminished with each consecutive run. Through characterization and the analysis of the catalyst after the reaction, it was determined that a new Ru(CO) complex, generated *in situ*, was suspected to be responsible for the decreased efficiency of the catalyst.

Another strategy employed to increase the catalytic turnover was the incorporation of the ruthenium porphyrin complex into sol-gel to produce a heterogeneous

Table 7. Asymmetric epoxidation of olefins catalyzed by [Ru(**8**)Cl_2].[39]



Entry[a]	Substrate	Time (h)	Yield (%)[b]	TON	ee (%)

7		16	95 (18)	220	16

[a] Reactions were performed using 1 mol % of catalyst, 1 equiv. of substrate, and 1.1 equiv. of oxidant in benzene at room temperature; [b] Yields are based upon the amount of alkene consumed in the reaction. The value in parenthesis represents conversion of substrate.

matrix. Remarkably, the use of these immobilized catalysts not only increased the TON to more than 10,000 in some cases, but the observed selectivity was comparable to the homogenous catalytic system. This approach was further expanded in a later report by Che and coworkers through the use of mesoporous silica gel, generating TON in excess of 13,000 with comparable enantioselectivities.[40]

The [Ru(**8**)(CO)] complex was also evaluated by Berkessel and Frauenkrom for the epoxidation of olefins with 2,6-dichloropyridine-*N*-oxide.[41] [Ru(**8**)(CO)] proved to be an effective catalyst under the reported conditions, providing good to moderate yields and moderate enantioselectivities for the epoxidation of dihydronapthalene and styrene derivatives. As shown in Table 8, aliphatic and more hindered olefins were ineffective substrates for catalysis using this system.

Berkessel and coworkers published catalytic studies of ruthenium complexes of a variety of Halterman porphyrin derivatives in 2003.[42] Building on the complexes previously reported by Halterman's group,[43] they modified the *para*-position of the *meso*-aryl group by introducing various groups (Figure 6). The use of an electron-withdrawing trifluoromethyl group afforded a very effective catalyst when Cl_2pyNO was employed. This modification led to improved yields and enantioselectivities with a respectable turnover frequency (Table 9). Berkessel speculated that the electron-withdrawing trifluoromethyl group disfavored the oxidative poisoning/destruction of the catalyst by stabilizing the macrocycle.

Table 8. Asymmetric epoxidation of olefins catalyzed by [Ru(**8**)CO].[41]

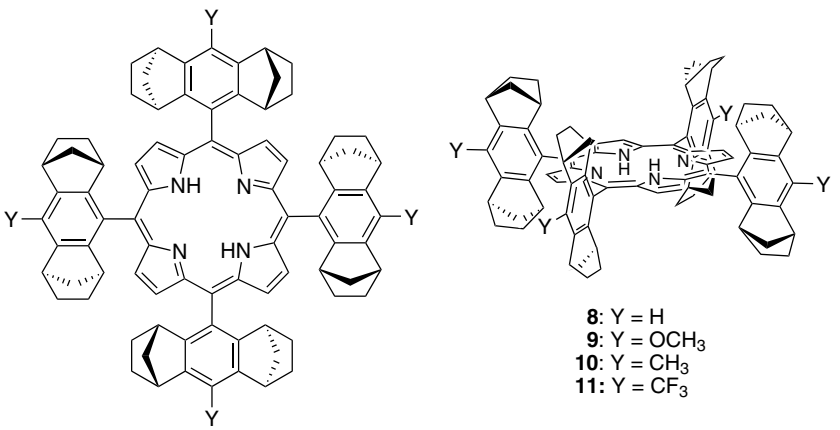

Figure 6. Halterman porphyrin **8** and its derivatives.[42]

Che and coworkers followed up on their previous catalytic work on ruthenium Halterman complexes by developing a molybdenum complex of **8**.[44] [Mo(**8**)(O)(OMe)] was used with *tert*-butylhydrogen peroxide (TBHP) for the epoxidation of aromatic alkenes. Although this molybdenum catalyst was fairly unique, the results as a whole provided low TON (4) and poor enantioselectivity (16% ee) (Scheme 4).

In 1997, Kodadek and coworkers reported the synthesis and catalytic activity of a new derivative of the D_4-symmetric Halterman porphyrin, **12** (Figure 7).[45] The manganese complex of **12** was used for the asymmetric epoxidation of a variety of olefins, including aliphatic olefins (Table 10). Moderate enantioselectivities and high TON were reported.

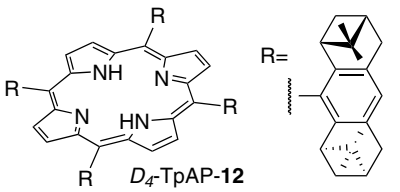

Figure 7. Kodadek's Halterman-like D_4-symmetric porphyrin.[45]

Higuchi and coworkers developed a D_4-symmetric chiral porphyrin **13** (Figure 8) related to Halterman porphyrin **8**.[46] The Fe(III) bromide complex of chiral porphyrin **13** was prepared and evaluated for the epoxidation of various aromatic olefins in the presence of PhIO. The results from this investigation are shown in Table 11. While the yields and enantiomeric excess are generally moderate, the selectivity ranged from 8% ee for *trans*-β-methylstyrene to 78% ee for

3-nitrostyrene (Table 11). As expected, when the substrate was increased from 10 equivalents to 60 equivalents, it was shown that the TON increased nearly ten-fold from 68 to 638 for the epoxidation of styrene. The authors attributed this to decreased poisoning of the catalyst by the oxidant.

The increase in enantioselectivity obtained for the epoxidation of electron-deficient styrene derivatives using the D_4-symmetric iron porphyrin complex [Fe(**13**)Br] led Higuchi and coworkers to further examine the electronic properties of this catalyst.[47] They were able to synthesize derivatives of **13** in which the *para*-position of the *meso*-aryl group was substituted with electron-donating or electron-withdrawing groups (Figure 8) to determine the effect of substitution on asymmetric induction. As presented in Table 12, no significant differences in enantioselectivity were observed; however, a slight trend of increased enantioselectivity was noted with the incorporation of electron-withdrawing substituents on the porphyrin.

Momenteau and coworkers developed a protocol for the preparation of iron and manganese glycosylated porphyrins (Figure 9) as catalysts for the epoxidation of olefins.[48] The atropisomers of these porphyrins were prepared and used to epoxidize

4-chlorostyrene in the presence of PhIO. Moderate yields and enantioselectivities were reported using the Fe(III) chloride complex of the $\alpha,\beta,\alpha,\beta$-atropisomer which was shown to be the most effective catalyst (Scheme 5).

In a later report, Momenteau focused on 2-chloro, 6-glycosylated manganese porphyrins (Figure 10).[49] These glycosylated porphyrins were assessed using 4-chlorostyrene as the olefin substrate as in their previous work. Both PhIO and H_2O_2 were shown to be suitable for catalysis with [Mn(**21**–**23**)Cl] (Table 13). Although the manganese system was not as effective as the [Fe(**18**)Cl]-based system (Scheme 5) with respect to yield or enantioselectivity, the catalyst proved to be relatively more robust, yielding slightly higher TON.

Momenteau and coworkers continued to develop new glycosylated porphyrins via the incorporation of larger sugar units onto the *meta*-position of the *meso*-aryl

[a] Performed for 30 min at room temperature with ~0.1 mol % catalyst 1.0 equiv. of oxidant, 2.5 equiv. of substrate, and 1.5 equiv. of 4-methylpyridine; [b] See Figures 10 and 11 for structures.

group, as shown in Figure 11.[50] Manganese complexes of these porphyrins, along with those presented earlier, were employed as catalyst to determine the efficacy of each complex in catalyzing the epoxidation of 4-chlorostyrene in the presence PhIO. The results, shown in Table 14, demonstrate that the sugar residues need to be in closer proximity to the metal center to induce asymmetry.

"Chiroporphyrins" **27**, developed by Marchon and coworkers, are porphyrins containing chiral cyclopropyl ester and amide moieties attached directly to the *meso*-positions of the porphyrin in an $\alpha,\beta,\alpha,\beta$-arrangement (Figure 12).[51] The manganese complexes of **27** were evaluated for their catalytic ability to epoxidize 1,2-dihydronaphthalene in the presence of the axial ligand pyridine. The results

revealed that when the *meso*-positions were functionalized with large cyclopropylamide groups, the catalyst afforded the corresponding epoxides with the highest enantioselectivities (Table 15).

With the success of their first generation of "chiroporphyrins", Marchon and coworkers envisioned using electron-withdrawing groups to enhance the activity of the catalytic system.[52] Their efforts led to the preparation of second generation "chiroporphyrins" with pentafluorophenyl groups occupying the 5,15-*meso*-positions of the porphyrin ring, and chiral cyclopropyl groups occupying the remaining 10,20-*meso*-positions (Figure 13). In most cases, these porphyrins were able to completely epoxidize the substrate in an hour or less (Scheme 6). Unfortunately, the enantioselectivities were generally lower in comparison to the first generation "chiroporphyrin" system.

Smith and Reginato developed chiral picket fence porphyrins (A_4-**31**, A_3B-**32**, A_2B_2-**33**, Figure 14) containing chiral ether moieties on the *ortho*-positions of the *meso*-aryl groups of the porphyrins.[53] The Fe(III) chloride complexes of A_4-**31** and A_2B_2-**33** were both evaluated for the epoxidation of styrene with PhIO in dichloromethane. The use of the more bulky [Fe(A_4-**31**)Cl] resulted in lower yields, as expected; the use of the [Fe(A_2B_2-**33**)Cl] provided a quantitative yield with similar enantioselectivity as compared to the A_4-complex **31** (Scheme 7). For the [Fe(A_2B_2-**33**)Cl]-catalyzed reaction, it was shown that lowering the temperature

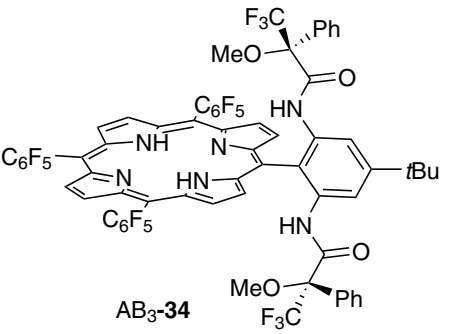
to 0 °C increased the enantioselectivity slightly without sacrificing yield. Although the porphyrin catalysts designed for this particular study were only moderately effective in inducing enantioselectivity, the results provided "proof of concept" that rigid and bulky chiral groups could be used to produce more effective catalysts.



AB_3-**34**

Figure 15. Chiral picket fence porphyrin derived from Mosher's chiral amide.[55]

Prior to Smith and Reginato's work with chiral porphyrin ligands **31**–**33**, Rose and coworkers prepared a series of chiral porphyrins using Mosher's amide as the chiral moiety on the *ortho*-positions of the *meso*-aryl ring.[54] Among the different complexes examined for catalytic epoxidation, the Fe(III) bromide complex of AB_3-**34**, shown in Figure 15, gave the highest enantiomeric excess, albeit very low (6% ee).[55]

The research groups of Hevesi and Quici also developed porphyrins with chiral moieties on the *meso*-positions.[56,57] Although catalysts **35** and **36** (Figure 16) produced moderate yields and low enantioselectivities for epoxidation of styrene (Scheme 8), [Mn(**36**)Cl] exhibited respectable TON (195) for the reaction.

In an effort to mimic the chiral environment of the cytochrome P-450 enzyme, Ohkatsu and coworkers attached peptide chains to the *meso*-positions of the porphyrins using a modular approach, allowing them to tune the steric and electronic properties of the ligand environment to enhance asymmetric induction.[58] Epoxidation reactions of styrene with PhIO were initially performed using porphyrin derivatives containing three peptide chains (Figure 17). It was shown that varying the nature of the amino acid residues resulted in changes in yield and selectivity. For example, when γ-benzyl-L-glutamate (γ-BLG) was used in place of L-phenylalanine (L-Phe), the yield increased 15%; however, enantioselectivity decreased dramatically from 60% ee to 11% ee (Scheme 9). It was noted that lengthening the average peptide chain (n) decreased the yield of the epoxidation reaction as a result of increased hindrance. Several other biomimetic porphyrins with various side chains and compositions were also prepared. However, they provided no significant improvement in yield or enantioselectivity.

B. Chiral Strapped Porphyrins

Naruta and coworkers developed one of the first examples of chiral strapped porphyrins incorporating binaphthyl groups for use in asymmetric epoxidation (Figure 18).[59,60] The binaphthyl group, which was used to bridge adjacent *meso*-aryl groups through an ether linkage, effectively blocked one face of the catalytic site thus establishing a sterically bulky chiral environment near the metal center. The use of the binaphthyl bridge is similar to the work discussed previously by

Groves and Myers[10] in 1983. These porphyrins, known as "twin-coronet" porphyrins, are classified by the arrangement of the "straps", which can be in either an eclipsed or staggered orientation, resulting in the generation of two unique ligand environments (Figure 18).

The difference in selectivity resulting from the two different conformations is showcased by the epoxidation of 2-nitrostyrene (Scheme 10). Based on an initial screening, the eclipsed [Fe(**39**)Cl] was further evaluated for the epoxidation of styrenes with PhIO (Table 16). Good enantioselectivities were observed for

electron-poor styrene derivatives (entries 2–7, Table 16). Conversely, the more electron-rich substrates displayed lower enantioselectivities (entries 8 and 9, Table 16).

Naruta and coworkers continued their investigations with iron binaphthyl strapped porphyrin [Fe(**39**)Cl] and compared it to [Mn(**39**)Cl] for the epoxidation of styrene and its electron-deficient derivatives.[61] Differences in reactivity and selectivity between the manganese and iron complexes were observed for the epoxidation of *cis*-β-methylstyrene (entries 8–9, Table 17). It was shown that enantioselectivities could be marginally improved in select cases by the use of axial ligands and the electron-deficient oxidant iodosyl(pentafluorobenzene), C_6F_5IO.

Naruta and coworkers continued to develop "twin-coronet" porphyrins by producing bitetralin-strapped variations **41** and **42** (Figure 18).[60,62,63] The iron complexes of both the eclipsed **41** and staggered **42** forms were evaluated for the epoxidation of styrene with PhIO. The activity of the bitetralin-strapped version of the "twin-coronet" porphyrin correlated well with the binaphthyl-strapped version (Table 18). Additionally, the eclipsed and staggered Fe(III)Cl complexes of **41** and **42** were evaluated for the epoxidation of styrenes with PhIO; again the eclipsed version **41** was shown to be a better catalyst (entries 1 and 2, Table 18). The improved enantioselectivity generated with electron-poor styrene derivatives is highlighted by the 96% ee obtained with the use of 3,5-dinitrostyrene as substrate (entry 6, Table 18).

Collman, Rose, and coworkers developed porphyrins analogous to Naruta's binaphthyl-strapped "twin-coronet" ligands.[64,65] The main difference between the two systems is the chiral bridge. Collman's catalysts are linked to the porphyrin via an amide linkage on the *ortho*-positions of the *meso*-aryl-groups, while Naruta's catalysts are linked through an ether linkage. The amide linkage provided for an open, accessible face (Figure 19) yielding higher reaction rates with a variety of olefin substrates, while decreasing oxidative poisoning of the catalyst (Table 19). For example, epoxidation of styrene with Collman's catalyst showed exceptional rate and stability with a TOF (turn over frequency) = 40/min and up to 5,500 turnovers. In addition, the amide linkage produced a more rigid structure, providing enantiomeric excesses of up to 83% for styrene (entry 1, Table 19).

Collman and coworkers observed an interesting change in enantioselectivity during the course of epoxidation catalyzed by [Fe(**43**)Cl]. They noted that the enantioselectivity increased initially but eventually decreased over the course of the reaction. Investigations into the cause for this observed phenomenon led to the discovery of the iron complex of a new porphyrin **44**, which was generated *in situ* from the oxidation of **43** (Figure 19), as a more selective catalyst. It was rationalized that the initial rise in enantioselectivity was attributed to the generation of **44**, and that subsequent decrease in enantioselectivity occurred as a result of the over oxidation of **44** to a less selective catalyst.

In a separate report, Roschmann and coworkers used Collman's catalyst for the epoxidation of allylic alcohols.[66] This report is especially noteworthy since it was the first example using porphyrins as catalysts for the asymmetric epoxidation

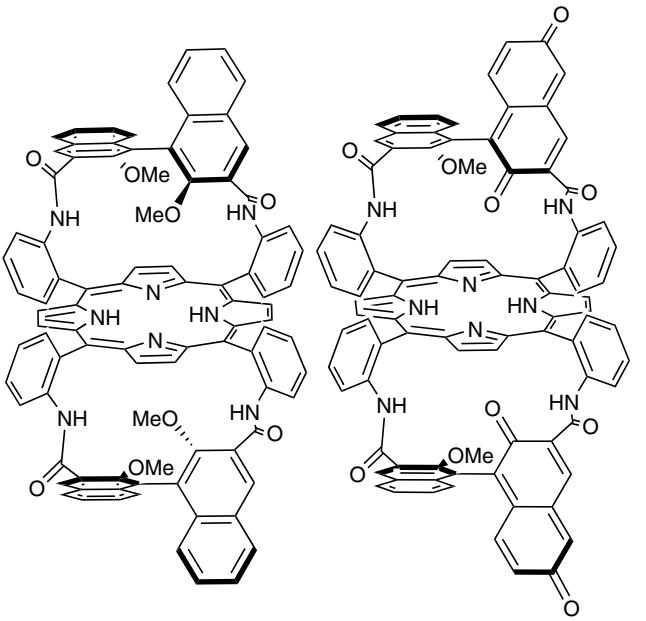

Figure 19. Binaphthyl-derived catalysts by Collman and Rose.[64,65]

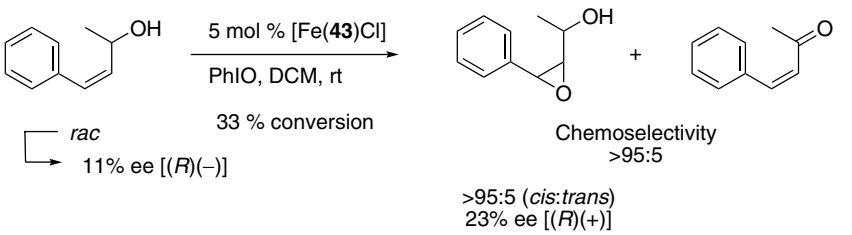
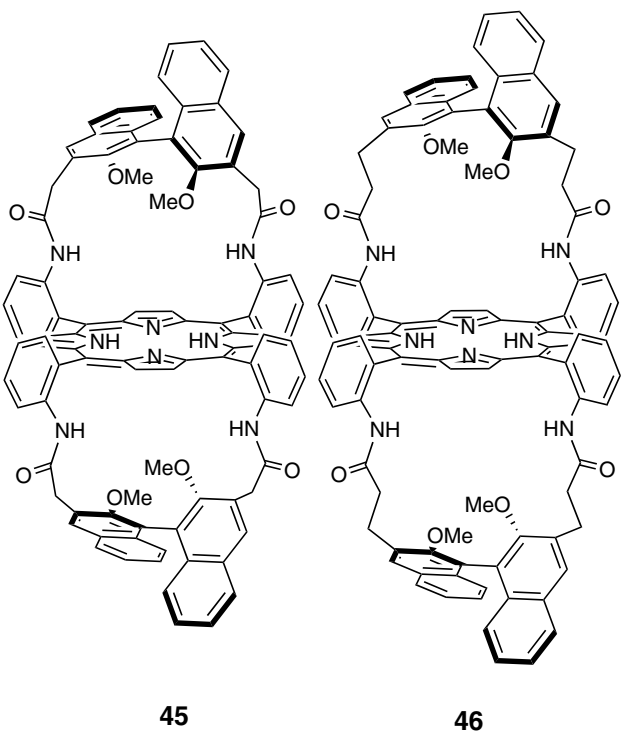
of allylic alcohols. Previous work in this area focused almost exclusively on the use of established catalytic systems, such as the Sharpless system.[67–69]

Using the reaction conditions shown in Scheme 11, racemic allylic alcohols were subjected to catalytic oxidation with PhIO. The resulting epoxides were



Scheme 11.[66]



45 **46**

Figure 20. Rose's modified Collman catalyst.[70]

formed (33% conversion) in excellent diastereoselectivity and with modest enantioselectivity. The resolution of the allylic alcohol provided an enantiomeric purity of 11% ee. Other allylic olefins were examined using this system and similar results were obtained. The oxidation of allylic alcohols into α,β-unsaturated ketones was the only side reaction reported under the reaction conditions.

Rose and coworkers attempted to induce higher levels of enantioselectivity by extending the linkage on Collman's catalyst **43** to produce catalysts **45** and **46** with a flexible chiral pocket in close proximity to the metal center (Figure 20).[70]

[a] Reactions were performed with 1 mol % of catalyst, 1 equiv. of oxidant, and 10 equiv. of substrate in DCM at –5 °C.

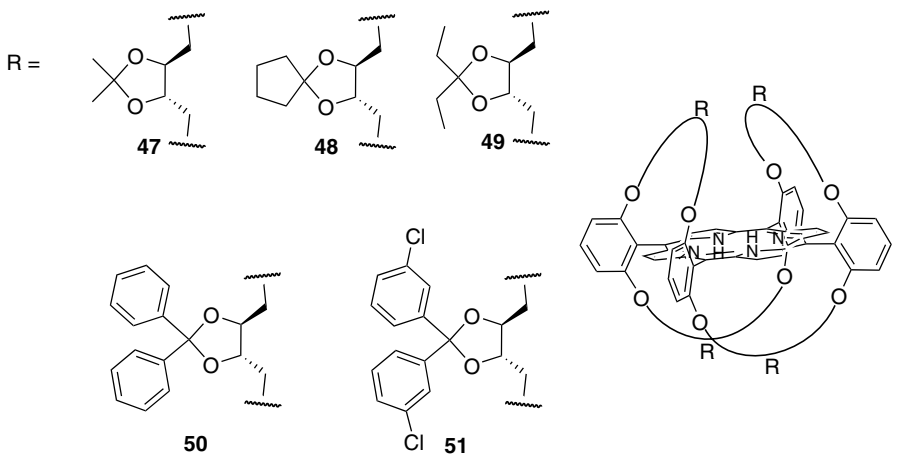

Figure 21. Homochiral threitol-strapped porphyrins.[72–76]

The iron chloride complex of **45** was used with PhIO to epoxidize several styrene derivatives (Table 20). The reported 96% yield and 97% ee for styrene is among the highest reported values for styrene epoxidation; not only for the Collman type catalysts, but also for any metalloporphyrin-based epoxidation system. In 2009, Ren and coworkers also examined the iron complexes of **45** and **46**, generating results similar to those communicated by Collman and Rose.[71]

Gross and coworkers also developed a series of porphyrin ligands based on the design of "twin-coronet" porphyrins.[72,73] Threitol derivatives were appended to adjacent *ortho*-aryl positions into an eclipsed orientation to produce the strapped ligands shown in Figure 21. Manganese, iron, and ruthenium complexes of these porphyrins were evaluated for their ability to serve as asymmetric catalysts in the

epoxidation of styrene (Scheme 12). In general, the Fe(III) chloride complex of **47** generated higher yields and enantiomeric excesses in comparison to the analogous magnesium and ruthenium derivatives.

Further exploration and development of the threitol-derived strapped homochiral porphyrin ligand system by Gross and coworkers led to the observation that lower reaction temperatures and higher catalyst loading could provide significant improvements over their previous system (Table 21).[74,75] An additional

development was the use of the ruthenium oxo complex [Ru(**51**)$(O)_2$] (Figure 21), which contains an electron-withdrawing chlorine atom on the aryl group. In many cases, the use of [Ru(**51**)$(O)_2$] resulted in increased enantioselectivities and TON (Table 22).

In addition to their report on catalytic olefin epoxidation by ruthenium complexes of the Halterman porphyrin **8,** Che and coworkers studied catalytic reactions of ruthenium complexes of **48** and **49** (Figure 21), which are derivatives of Gross's homochiral porphyrin **47**.[76] The complexes [Ru(**48**)$(O)_2$] and [Ru(**49**)$(O)_2$] were evaluated for the stoichiometric epoxidation of styrene, generating moderate enantioselectivities (Scheme 13).

Following their successful use of picket fence chiroporphyrin ligands, Marchon and coworkers synthesized a new strapped porphyrin variation consisting of different length cyclopropane moieties (Figure 22).[77] The manganese complexes of these new "bridled chiroporphyrins" were employed for the catalytic

adjacent aryl positions (Figure 23).[78] This ligand system is similar to the threitol-strapped ligand derivatives reported by Gross and coworkers (Figure 21). [Ru(**54**)(O)$_2$] was able to reach an average TON greater than 200 for the epoxidation of several of the olefins in this study (Table 24). Unfortunately, the enantioselectivity

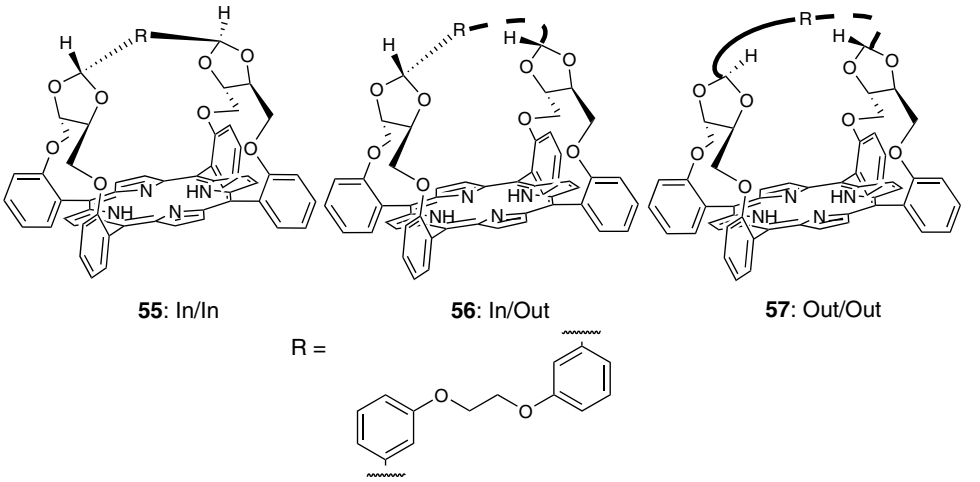

Figure 24. Threitol-strapped porphyrin.[79,80]

induced by these catalysts did not compare favorably with Gross's system (Tables 21 and 24).[72–75]

Collman and coworkers synthesized single-faced threitol-strapped porphyrins containing a bridge across the porphyrin plane connecting the two chiral moieties (**55**–**57**, Figure 24).[79,80] This system is analogous to basket handle porphyrin ligands, which will be discussed later in this chapter. The open-faced structure of porphyrins **55**–**57** (Figure 24) required an adequate axial ligand to block the achiral face of the catalyst from playing a role in the epoxidation process. The bulky 1,5-dicyclohexylimidazole (DiCyIm) was identified as a suitable axial ligand. The Mn(III) chloride complex of **57**, [Mn(**57**)Cl], was used as a catalyst for the epoxidation of several aromatic olefins in the presence of DiCyIm (Table 25). [Mn(**57**)Cl] was shown to be capable of epoxidation of a range of olefin substrates, including an example of an aliphatic olefin. Good yields and enantioselectivities were generally obtained.

Boitrel and coworkers synthesized and evaluated a series of Fe(III) chloride complexes of porphyrins as catalysts for asymmetric epoxidation. The ligand systems produced (including picket fence, strapped, and basket handle porphyrins) all contained chiral proline units, which served as chiral auxiliaries (Figure 25). The Fe(III) chloride complexes of these ligands were tested for their ability to epoxidize 4-chlorostyrene and 1,2-dihydronaphthalene.[81,82] The enantioselectivity of these reactions is summarized in Table 26. The only catalyst which displayed enhanced enantiomeric performance for both 4-chlorostyrene and 1,2-dihydronaphthalene was $\alpha,\alpha,\beta,\beta$-**61** (entry 7, Table 26).

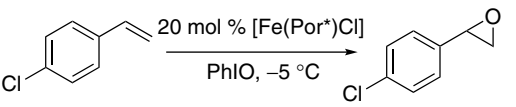
C. Chiral Basket Handle Porphyrins

Mansuy and coworkers reported the first example of a basket handle porphyrin for the epoxidation of 4-chlorostyrene (**64**, Figure 26).[83] The rigid chiral environment was inspired by the desire to mimic the active site of cytochrome P-450. In the course of the development of **64**, precursors **62** and **63** (picket fence type ligands)

Table 27. Comparison of picket fence and basket handle porphyrins as catalysts for the asymmetric epoxidation of 4-chlorostyrene.[83]



Entry[a]	Por*	Yield (%)	ee (%)
1	**62**	60	12 (*S*)
2	**63**	45	21 (*S*)
3	**64**	35	50 (*R*)

[a] Reactions were performed with 20 mol % of catalyst, 1 equiv. of oxidant, and 300 equiv. of substrate in DCM at –5 °C in a 1:1 ratio of DCM and benzene for 3 h.

were also evaluated for the epoxidation of 4-chlorostyrene (Table 27). In general, the iron basket handle porphyrin [Fe(**64**)Cl] was shown to be a superior catalyst in terms of selectivity when compared to the picket fence complexes [Fe(**62**)Cl] and [Fe(**63**)Cl]. However, it is noted that this system required high catalyst loadings (20 mol %) and generated only modest yields (35–50%) and enantioselectivities (12–50% ee).

Groves and Viski developed a basket handle derivative of their picket fence porphyrin using a binaphthyl bridge as shown in Figure 27.[84] Iron and manganese complexes of **65** were used as catalysts for the epoxidation of a number of different olefins (Table 28). This system was shown to be suitable for a range of aromatic and aliphatic olefins, generating low to moderate enantioselectivities. The low enantioselectivities reported were believed to result from the oxidative poisoning of the catalyst over the course of the reaction.[85] In the case of bulky substrates such as *cis*-β-methylstyrene, good asymmetric induction was achieved with the iron complex [Fe(**65**)Cl] (entry 6, Table 28).

Collman and coworkers also synthesized a basket handle porphyrin using binaphthyl groups. The iron complex of the "binap-capped" porphyrin **66**, shown in Figure 28, was used for the asymmetric epoxidation of mono- and di-substituted aromatic olefins to generate epoxides with moderate yields and enantioselectivities (Table 29).[86]

Inspired by the metalloenzyme cytochrome P-450, Inoue and coworkers synthesized a series of basket handle porphyrin ligands with optical antipodes, as shown in Figure 29. The iron complexes of these ligands were prepared and used as catalysts for the epoxidation of aromatic olefins as shown in Table 30.[87,88] Various axial ligands were used to coordinate to the open face of the porphyrin in

an effort to prevent the generation of racemic products. As anticipated, both enantiomers of catalyst **67** gave similar results with opposite senses of asymmetric induction (entries 1–2, Table 30). The omission of the requisite axial ligand led to an increase in the overall product yield, but with a significant drop in enantiomeric excess as shown in entry 3 (Table 30).

III. Cyclopropanation

Metal-catalyzed cyclopropanation of olefins with diazo reagents has attracted interest due to the fundamental and practical importance of the resulting cyclopropyl units.[89–92] Cyclopropane rings are recurrent motifs in biologically important molecules and can serve as versatile precursors in organic synthesis.[93–96] Currently,

the metal-mediated decomposition of diazo reagents in the presence of olefins constitutes the most direct route to the synthesis of cyclopropanes. This approach provides the advantage of using achiral reagents with the induction of chirality occurring as a direct result of the chiral environment of the catalysts. Prior to the development of catalytic systems capable of decomposing diazo reagents, the Simmons–Smith reaction was the predominant method for cyclopropanation,[91] and chiral starting materials or chiral auxiliaries were required for asymmetric induction.

In the last 20 years, a number of metal-mediated asymmetric cyclopropanation systems incorporating copper, ruthenium, cobalt, rhodium, and various ligands have been developed.[97–104] Copper bisoxazoline and dirhodium complexes are examples of some of the more general and selective catalysts that have been prepared. For example, Doyle's use of dirhodium carboxamides as catalysts for the general and selective asymmetric intramolecular cyclopropanation with diazo reagents has achieved broad use in the chemical literature.[103–110]

Among the wide variety of catalytic systems, metalloporphyrin-based ligand designs are unique, owing to their excellent selectivities and high catalytic TON. Metalloporphyrins were first used as catalysts for cyclopropanation by Callot and coworkers.[111,112] Their initial reports on rhodium-catalyzed cyclopropanation were significantly expanded by Kodadek and coworkers.[113–119] Woo and coworkers showed that osmium porphyrins could also catalyze the cyclopropanation of alkenes, although with less efficiency.[120] Subsequently, Kodadek, Woo, and coworkers jointly reported that iron porphyrins were effective catalysts for the shape-selective and stereoselective cyclopropanation of alkenes.[121] These early works paved a solid foundation for the subsequent development of highly diastereoselective and enantioselective catalysts.

In the following sections, the asymmetric cyclopropanation of alkenes using metalloporphyrins will be discussed. This section will follow the same general outline as the epoxidation section. The robust Halterman porphyrin **8**, examined in various systems for the epoxidation of alkenes, has historically been one of the most widely studied chiral porphyrin ligands for cyclopropanation. More recently, the development of Co(II) complexes of a new family of D_2-symmetric chiral porphyrins capable of high levels of stereocontrol over an expansive substrate scope has broadened the use of metalloporphyrin-based catalysts for asymmetric cyclopropanation.

A. Chiral Picket Fence Porphyrins

Inspired by the previous reports of Doyle[105,106,110] and Callot[111,112] who used rhodium complexes for the cyclopropanation of olefins, O'Malley and Kodadek employed their "chiral wall" porphyrin (**6**, Figure 4, Section II.A) as a ligand for rhodium-catalyzed asymmetric cyclopropanation.[116,117,119] Based on Callot's work, they

believed that the use of the bulky "chiral wall" ligand would favor *cis* cyclopropane isomers, which are normally the minor products in most catalytic cyclopropanations. As anticipated, the *cis*-isomer was generated when the Rh(III) iodide complex of **6** was employed for the asymmetric cyclopropanation of styrene, *cis*-β-methylstyrene, and allyl benzene in the presence of ethyl diazoacetate (EDA). The TON for this catalytic system were outstanding with up to 4,500 TON obtained for the cyclopropanation of *cis*-β-methylstyrene. In all the cases examined, the *cis* isomer was favored over the *trans*, although the *trans* product exhibited significantly higher enantioselectivity (Table 31).

Kodadek and O'Malley designed and synthesized a new chiral porphyrin, termed the "chiral fortress" (**70**, Figure 30), incorporating bulkier aromatic rings

Table 31. Asymmetric cyclopropanation of olefins catalyzed by [Rh(**6**)I].[117,119]

in an effort to enhance the formation of the *cis*-cyclopropanated products.[116] The rhodium complex of **70**, [Rh(**70**)I], was shown to be an active catalyst for the cyclopropanation of olefins. In comparison to the "chiral wall", [Rh(**6**)I], the *cis*:*trans* ratio was only slightly improved for styrene, and a decrease in diastereoselectivity was observed for all other substrates (Table 32). It was concluded that the active site was too sterically encumbered to induce similar levels of selectivity in comparison to the "chiral wall".

In 1997, Simonneaux and coworkers reported the successful use of ruthenium porphyrins such as [Ru(**71**)$(O)_2$] (Scheme 14) for the asymmetric cyclopropanation of olefins with EDA.[122] Previous studies using this system reported complex mixtures of products, with EDA dimerization identified as the major product of the reaction. The introduction of EDA over several hours minimized the formation of these side products and produced the desired cyclopropane derivatives with good diastereoselectivity albeit low enantioselectivity (Scheme 14). This technique ultimately proved useful for most rhodium, iron, and ruthenium systems.

Che and coworkers expanded their previous work on Halterman complexes by using ruthenium complexes, [Ru(**8**)(CO)] and [Ru(**8**)(CPh_2)] (Figure 5, Section II.A), as catalysts for the cyclopropanation of styrene derivatives with diazo reagents (Tables 33 and 34).[123,124] Overall, the [Ru(**8**)(CO)] complex generated higher yields and greater diastereo- and enantioselectivities over a range of aromatic olefins in comparison to [Ru(**8**)(CPh_2)]. In addition, the catalytic efficiency of both of these complexes were shown to be outstanding, providing TONs greater than 1,200.

[a] Reactions were performed with 0.05 mol % of catalyst, 1 equiv. of EDA, and 5 equiv. of substrate in DCM at room temperature for 20 h.

The ruthenium carbonyl complex of the Halterman porphyrin, [Ru(**8**)(CO)], was also examined as a potential catalyst for intramolecular cyclopropanation to produce valuable cyclopropyl fused ring products (Table 35). Although the yields and enantioselectivities reported for these cyclopropanes are low to moderate, this represents one of the first reports of asymmetric intramolecular cyclopropanation catalyzed by a ruthenium porphyrin complex.

Che and coworkers investigated ruthenium and rhodium complexes of the Halterman porphyrin **8** for both inter- and intramolecular asymmetric cyclopropanation.[125] As presented in Tables 36 and 37, for both inter- and intramolecular cyclopropanation systems, [Ru(**8**)(CO)] generated higher diastereo- and enantioselectivities. Despite using catalysts with the same ligand environment, an "enantiomeric switch" was observed for one of the substrates when the rhodium metal was exchanged with ruthenium (entry 4, Table 37). These results led to the assumption that these two metal complexes cyclopropanate via different mechanistic pathways, generating the two different enantiomers.

Che and coworkers also reported the use of ruthenium complex [Ru(**8**)(CO)] encapsulated in mesoporous molecular sieves for intramolecular cyclopropanation.[40] Although only one example was reported (Scheme 15), the catalytic system generated a respectable enantioselectivity (85% ee) and could be reused up to four times. The results from this heterogeneous system were comparable to the corresponding homogenous system (Table 37).

Iron complex [Fe(**8**)Cl] was also reported by Che and coworkers for asymmetric cyclopropanation with ethyl diazoacetate. The diastereo- and enantioselectivities reported were similar to those of the aforementioned rhodium and ruthenium complexes (Table 38).[126] However, the iron complex produced the cyclopropanes with lower TON in comparison to the ruthenium complex (Tables 38 and 33). Further investigation of the iron-catalyzed system showed that the use of nitrogen-based axial ligands could improve the diastereo- and enantioselectivity across a range of substrates as shown in Table 39. However, the use of an axial ligand resulted in even lower TON as shown in Table 39.

Berkessel and coworkers evaluated ruthenium complexes of the Halterman porphyrin **8** and its derivatives **9–11** (Figure 6, Section II.A)[42] as catalysts for the cyclopropanation of aromatic olefins using the slow addition method for the introduction of EDA (Table 40). Excellent diastereoselectivities and high enantioselectivities were observed with all ligand derivatives when styrene was used as the substrate (entries 1–5, Table 40). Results showed that the derivatization of the *para*-phenyl position of the *meso*-aryl group with electron-donating or -withdrawing groups did not have a pronounced effect on the diastereo- and enantioselectivity in comparison to the metal complexes of the Halterman porphyrin.

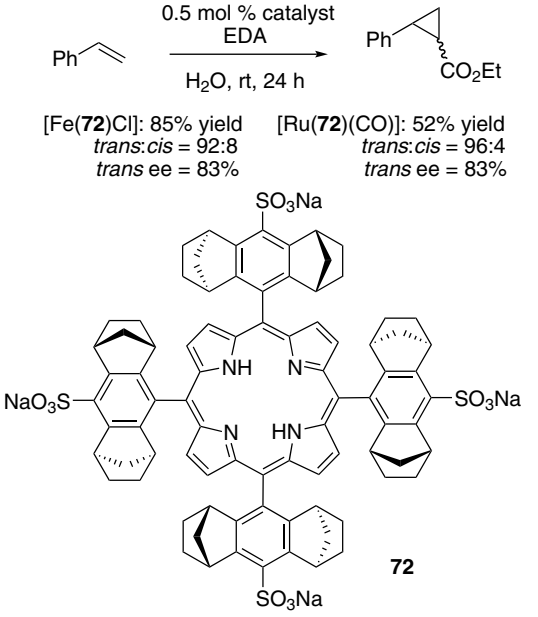
[a] Reactions were performed with 0.1 mol % of catalyst, 1 equiv. of substrate, and 1 equiv. of EDA in DCE at 0 °C. Diazo was added by means of a syringe pump over 2 h; [b] See Figure 6 for structures; [c] [Ru(**8**)PF_3] used as catalyst.



Scheme 16.[127]

Simonneaux and coworkers reported the synthesis of a water-soluble Halterman porphyrin derivative (**72**, Scheme 16) and the use of its iron and ruthenium complexes for the cyclopropanation of styrene with EDA.[127] While both [Fe(**72**)Cl] and [Ru(**72**)(CO)] catalysts displayed very similar diastereo- and enantioselectivities, the iron complex provided superior yields (Scheme 16). It was also noted that the iron complex was recyclable up to four times, with no significant decrease in enantioselectivity while retaining excellent diastereoselectivity. However, the enantioselectivity and yield of the cyclopropanated product generated by the ruthenium complex decreased significantly after the first cycle.

Continued development by Simonneaux and coworkers led to the introduction of heterogeneous catalytic systems for olefin cyclopropanation, and in 2005 they introduced the use of a heterogeneous polymer-supported Halterman porphyrin system as a catalyst for the cyclopropanation of olefins (Figure 31). Iron and ruthenium complexes of the Halterman porphyrin **8** were incorporated into the backbone of the polymer-based system,[128] and the use of an alternative diazo reagent, trifluorodiazoethane (Table 41), was employed for the first time.[129] The diastereoselectivities reported for this polymer-supported system were excellent, however, the yield and enantioselectivity were only moderate.

Following their use of trifluorodiazoethane, Simmonneaux and coworkers explored bulkier diazo reagents for asymmetric cyclopropanation. For example,

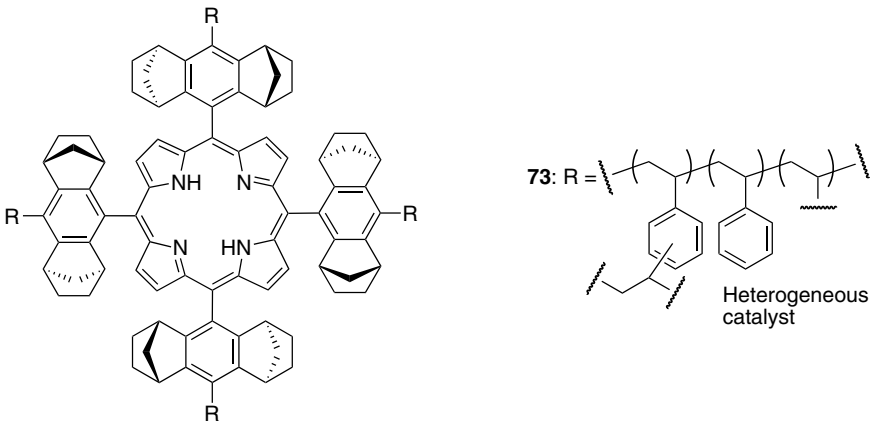


Figure 31. Polymer-supported Halterman ligand.[128]

3	[Fe(**73**)Cl]	52	97:3	56
4	[Ru(**73**)(CO)]	33	99:1	61

[a] Reactions were performed with 0.5 mol % catalyst, 1 equiv. of diazo, and 5 equiv. of substrate in DCM at room temperature for 2 h.

the diazo reagent 2,6-di-*tert*-butyl-4-methylphenyl diazoacetate (Scheme 17) was employed in the cyclopropanation of styrene by [Ru(**8**)(CO)].[130] Although excellent diastereoselectivity was achieved with this system, the yield and enantioselectivity was relatively low. The authors speculated that the low yield and enantioselective outcome was a consequence of the formation of a stable carbene intermediate. Acquisition of a crystal structure of the carbene intermediate supported this claim.

Further studies on the expansion of diazo substrate scope led Simonneaux and coworkers to the use of the ruthenium Halterman complex for the asymmetric cyclopropanation of styrene with diisopropyl diazomethylphosphonate (DAMP).[131] The results, shown in Table 42, demonstrate that excellent diastereo- and

enantioselectivities as well as high product yields could be achieved with this diazo reagent.

Simonneaux and coworkers also reported the design and synthesis of a new porphyrin ligand. The incorporation of a mixture of two types of rigid, bulky groups onto the meso positions of the porphyrin ring generated porphyrin ligands **74**–**76**, as shown in Figure 32. The ruthenium complexes of these Halterman-like porphyrins, bearing 1–4 chiral appendages (with 4 chiral appendages being the Halterman porphyrin **8**) were employed as catalysts for the cyclopropanation of styrene with EDA and DAMP (Table 43). Catalyst [Ru(**74**)(CO)] bearing three chiral groups displayed high levels of asymmetric induction, while ligands [Ru(**75**)(CO)] and [Ru(**76**)(CO)] having only one and two chiral groups, respectively, led to a significant reduction.

In 2006, Cenini and coworkers reported the use of porphyrin **77** for the ruthenium-catalyzed cyclopropanation of α-methylstyrene with EDA (Scheme 18).[132] In comparison to the Halterman porphyrin-based catalysts, this system produced

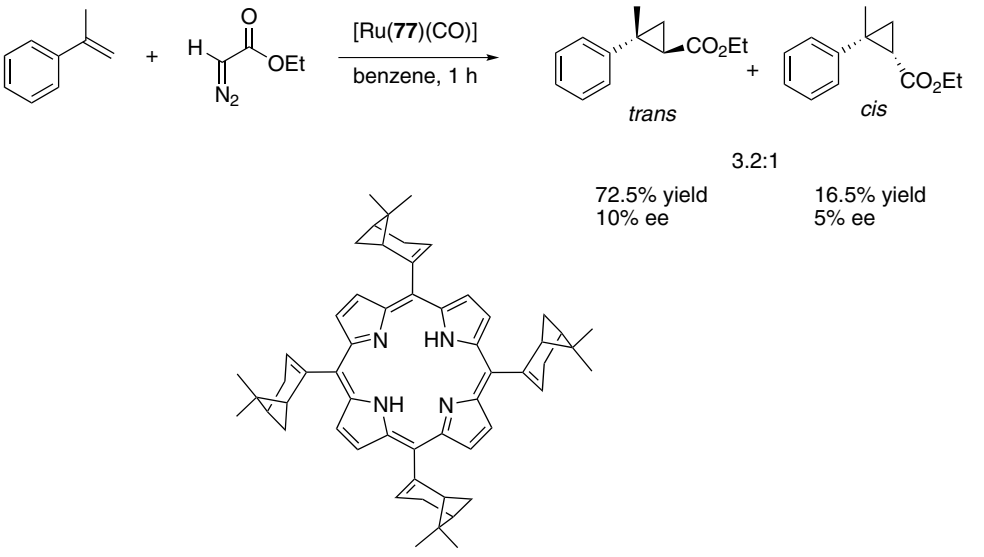
significantly lower selectivities. In the same report, a cobalt complex of **77** was used for the cyclopropanation of styrene with EDA. It was shown that [Co(**77**)] generated slightly greater diastereoselectivities (*trans*:*cis* = 4.4:1) than the ruthenium-catalyzed system. The enantioselectivities of the products generated from this cobalt-catalyzed system were not reported.



77

Scheme 18.[132]

Independently, Zhang and coworkers also reported some of the first examples of cobalt porphyrin-catalyzed asymmetric cyclopropanations.[133,134] One of the distinct advantages of using cobalt over the existing metal-catalyzed systems was that the slow addition of the diazo reagent was no longer required to inhibit dimer formation.

In the initial report by Zhang and coworkers, cobalt complexes of several chiral porphyrins (**78**–**82**, Figure 33) were prepared and evaluated for the asymmetric cyclopropanation of styrene with EDA (Table 44). Their initial results demonstrated that chiral groups directed toward the metal-center, as with complex **82**, provided the highest selectivities. Continued development of porphyrin ligand systems with chiral groups in close proximity to the metal center led to improved selectivities in Co(II)-catalyzed asymmetric cyclopropanation.

Based on this work, Zhang and coworkers designed and synthesized a series of D_2-symmetric chiral porphyrins for use in cobalt-catalyzed cyclopropanation (Figure 34).[135,136] One notable feature of these systems is the modular design of the porphyrin ligand. The synthetic strategy reported by Zhang and coworkers allows for the direct installation of select chiral amides using a palladium-catalyzed cross-coupling approach between brominated porphyrins and chiral amides. Through selection of the appropriate chiral groups, each of the four diastereomers of the cyclopropanated product could be accessed with excellent enantioselectivity (Scheme 19).

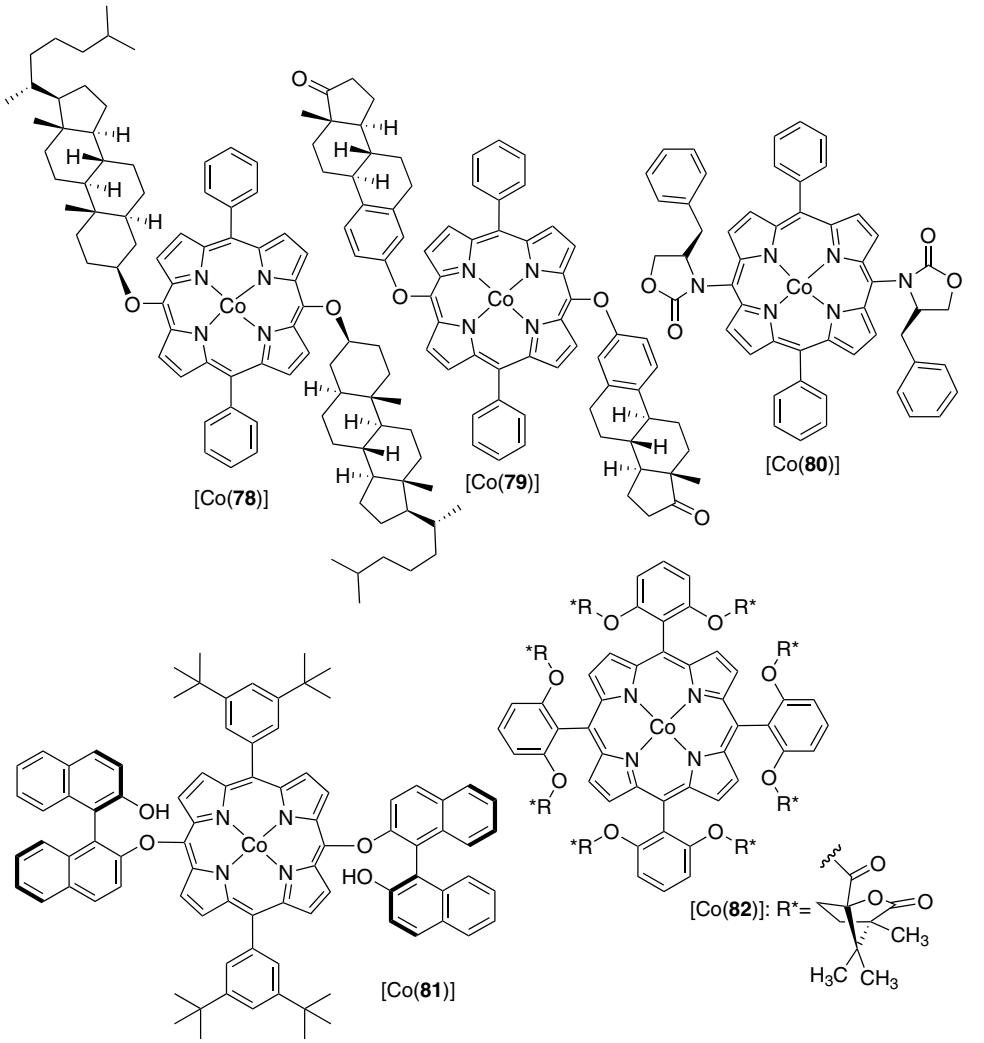


Figure 33. Chiral cobalt porphyrin complexes.[133,134]

The resulting chiral porphyrins (selected examples are shown in Table 45) were evaluated for the cobalt-catalyzed cyclopropanation of styrene with EDA and *tert*-butyl diazoacetate (*t*-BDA). Axial ligands, such as 4-*N*,*N*-dimethylaminopyridine (DMAP), were found to significantly increase diastereo- and enantioselectivity without diminishing the yields (entries 1 and 5, Table 45). Further improvements were achieved by lowering the reaction temperature (entries 8 and 9, Table 45). Given the low cost of cobalt, the "one-pot" process practicality, yield and enantioselectivity, chiral cobalt complexes

presented themselves as desirable alternatives to other cyclopropanation systems.[137]

Zhang and coworkers continued to focus their attention on increasing the substrate scope of their cobalt-based system (Table 46).[138] The cobalt D_2-symmetric porphyrin **87** was shown to be a suitable catalyst for the asymmetric cyclopropanation of aromatic olefins (entries 1–5, Table 46). However, the most notable feature of this catalytic system was its ability to cyclopropanate electron-deficient olefins, normally shown to be inactive in other cyclopropanation systems (entries 7–10, Table 46).[138]

In 2008, Zhang and coworkers reported the use of diazosulfones as diazo reagents for cobalt-catalyzed cyclopropanation.[139] During the course of this study, it was discovered that a new porphyrin ligand would be required to obtain high enantioselectivities (Figure 35). The results, shown in Table 47, demonstrated that the porphyrin complexes examined in the previous cyclopropanation system (**87**–**88**) did not produce adequate levels of enantioselectivity. Subsequently, ligands **89** and **92** were designed and synthesized in an effort to increase the rigidity and polarity of the chiral environment, thereby enhancing enantioselectivity. The more sterically demanding ligand **92** of the "group of six" (Figure 35) was shown to be the best for supporting cobalt-catalyzed cyclopropanation with diazosulfones (entry 7, Table 47).

With the cobalt complex of ligand **92** identified as the catalyst of choice, the substrate scope was examined (Table 48). Results showed that cobalt-catalyzed

cyclopropanation reactions with diazosulfones could be applied to a broad range of olefins, including aromatic and electron-deficient olefins, to generate the desired products with high levels of diastereo- and enantioselectivity.

The use of succinimidyl diazoacetate as a carbene source was examined by Zhang and coworkers for the cobalt-catalyzed cyclopropanation of both aromatic and electron-deficient olefins (Table 49).[140] Both ligands **87** and **90** from the "group of six" (Figure 35) provided excellent diastereo- and enantioselectivities. Although the yields associated with the cyclopropanation of electron-deficient olefins were diminished in this system, the stereoselectivities were still very high. The products of these reactions, cyclopropyl succinimidyl

B. Chiral Strapped Porphyrins

In 1998, Simonneaux and coworkers described the use of threitol-strapped ligand **47** (Figure 21), previously reported by Gross and coworkers for epoxidation[72,73] (Section II.B), for the ruthenium-catalyzed asymmetric cyclopropanation of aromatic olefins. The ruthenium complex [Ru(**47**)(CO)] was used with ethyl diazoacetate to generate cyclopropane products with excellent yields and moderate diastereo- and enantioselectivities (Table 52).[143]

In 2003, Simonneaux and coworkers reported on their work with threitol-strapped ruthenium catalysts for the cyclopropanation of styrene with diisopropyl diazomethylphosphonate (DAMP) as the carbene source.[144] The yield and diastereoselectivities (Scheme 20) produced with [Ru(**47**)(CO)] in the presence

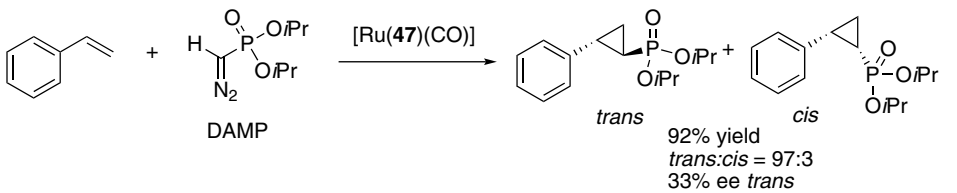

Scheme 20.[144]

The research groups of Rose and Cenini collaboratively developed an asymmetric cyclopropanation system utilizing cobalt complexes of the binaphthyl-strapped porphyrins **45** and **46** (Figure 20 in Section II.B).[145] These porphyrin complexes, first developed by Collman and Rose for asymmetric epoxidation, were evaluated for cobalt-catalyzed cyclopropanation of various styrene derivatives using EDA (Table 53). Although the yields were consistently excellent across a range of substrates, the diastereo- and enantioselectivities reported were not as high as the cobalt-catalyzed cyclopropanation systems developed by Zhang and coworkers.[135]

In 2002, Rose, Woo, and coworkers published a report using the Halterman porphyrin derivative **12** and Collman's bis-binaphthyl strapped ligand **43** for the Fe(II)-catalyzed asymmetric cyclopropanation of styrene with EDA.[146] The Fe(II) complex of the Halterman porphyrin derivative, [Fe(**12**)], generated excellent yields and diastereoselectivities. However, it afforded only a modest 45% ee (Scheme 21). The Fe(III) bis-binaphthyl strapped complex, [Fe(**43**)], showed decreased selectivities.

IV. Aziridination

The fundamental and practical significance of aziridine derivatives in chemistry and biology has stimulated intensive research into their synthesis.[147–151] Among the most important routes for the preparation of aziridines, the metal-catalyzed aziridination of alkenes with nitrene sources has received significant attention as this method provides direct access to the desired products.

Despite the success of metalloporphyrins in other atom/group transfer reactions, their use in asymmetric aziridination has been limited.[152–155] Early important efforts in the development of asymmetric aziridination systems by Evans and Jacobsen were based on non-metalloporphyrin systems.[156,157] More recently, several research groups have made significant progress in the development of metalloporphyrin complexes capable of performing asymmetric aziridination. For example, Che and coworkers used manganese and ruthenium Halterman complexes for the asymmetric aziridination of a number of different olefins. In addition, Zhang and coworkers used cobalt complexes of their D_2-symmetric porphyrin catalysts for the aziridination of olefins using azides as nitrene sources. Finally, Marchon and coworkers employed the manganese complex of the "chiroporphyrin" ligand **27a** developed previously for epoxidation and cyclopropanation for use in asymmetric aziridination.

Traditionally, aziridination systems relied heavily on hypervalent iodine species, such as PhI=NTs and its derivatives.[158–163] Current investigations in the field have focused on the development of alternative nitrene sources, such as the *in-situ* generation of iminoiodane derivatives and azides.[164–172]

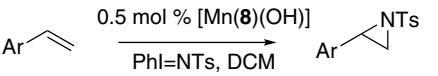
This section will review the current efforts in metalloporphyrin-catalyzed asymmetric aziridination, including recent developments concerning the use of new nitrene sources. As in previous sections, the reaction system will be categorized by the type of porphyrin ligand.

A. Chiral Picket Fence Porphyrins

Che and coworkers investigated the catalytic asymmetric aziridination of olefins by the manganese complex of the Halterman porphyrin **8**, [Mn(**8**)(OH)], using PhI=NTs as nitrene source.[173] Moderate yields and enantioselectivities were achieved with the manganese-catalyzed system, and modest TONs were reported (Table 54).

In a later report, Che and coworkers compared the ruthenium and manganese complexes of the Halterman porphyrin **8** (Table 55).[174] In the case of styrene, the manganese complex generated selectivity superior to that of its ruthenium counterpart (entries 1 and 2, Table 55). Comparisons between entries 3 and 4 in Table 55

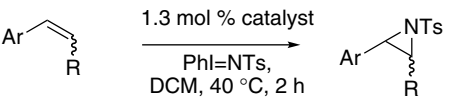
Table 54. Asymmetric aziridination with PhI=NTs catalyzed by [Mn(**8**)(OH)].[173]



Entry[a]	Substrate	Yield (%)	TON	ee (%)
1	Styrene	71	130	49
2[b]	Styrene	73	142	55
3	4-Methylstyrene	66	132	44
4	4-Chlorostyrene	43	86	45
5	3-Chlorostyrene	49	98	49
6	2-Bromostyrene	44	88	62

[a] Reactions were performed with 0.5 mol % of catalyst, 20 equiv. of substrate, and 1 equiv. of PhI=NTs in DCM at 40 °C for 2 h; [b] 4-Phenylpyridine-*N*-oxide as additive.

Table 55. Asymmetric aziridination of aromatic olefins catalyzed by ruthenium and manganese complexes of **8**.[174]



Entry[a]	Substrate	Catalyst	Yield (%)[b]	ee (%)
1	Styrene	[Mn(**8**)(OH)]	78 (99)	47
2	Styrene	[Ru(**8**)(CO)]	84 (71)	21
3	4-Methylstyrene	[Mn(**8**)(OH)]	76 (99)	44
4	4-Chlorostyrene	[Mn(**8**)(OH)]	93 (99)	50
5	2-Vinylnaphthalene	[Mn(**8**)(OH)]	94 (99)	56
6	Indene	[Ru(**8**)(CO)]	73 (99)	11

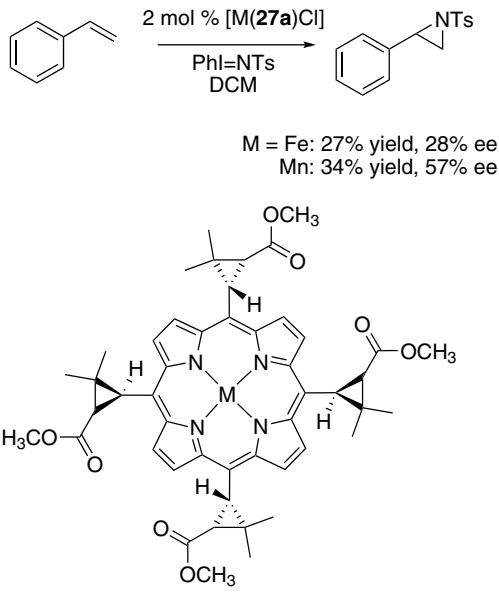
[a] Reactions were performed with 1.3 mol % of catalyst, 1 equiv. of substrate, and 3 equiv. of PhI=NTs in DCM at 40 °C for 2 h; [b] Yields are based upon the amount of alkene consumed in the reaction. The number in parenthesis represents conversion of substrate.

and those in Table 54 demonstrate that an improvement in yield could be achieved with higher catalyst loadings without sacrificing enantioselectivity.

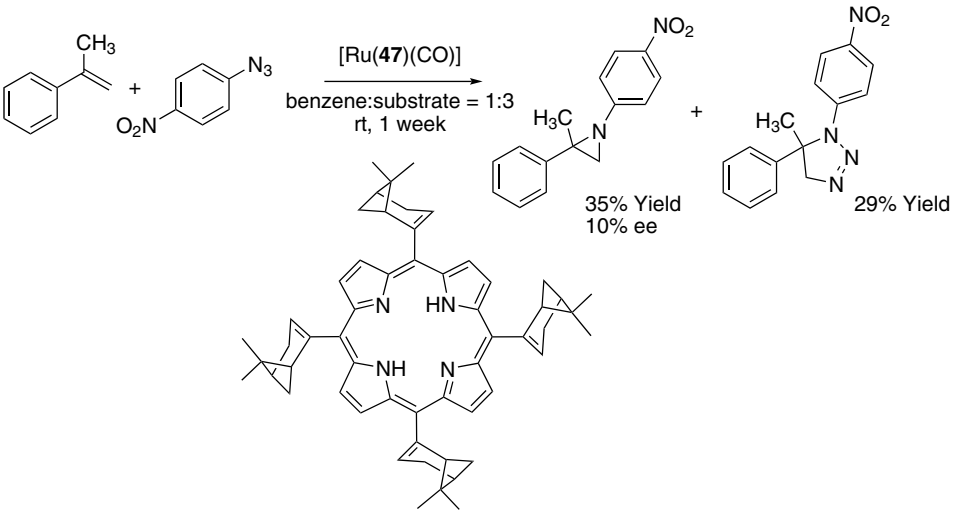
Marchon and coworkers employed iron and manganese complexes of "chiroporphyrin" **27a** for the aziridination of aromatic olefins with PhI=NTs.[175] They reported that [Mn(**27a**)Cl] produced higher yields and greater enantioselectivities than [Fe(**27a**)Cl] when styrene was employed as a substrate (Scheme 22).

In their 2006 report on the use of the ruthenium complex of **77** for cyclopropanation using EDA, Cenini and coworkers also communicated the first report of the ruthenium porphyrin-catalyzed aziridination of olefins using aryl azides (Scheme 23).[132] They observed the formation of the aziridine product in low yield and enantioselectivity with the corresponding triazoline produced as the major side product.

The success of the D_2-symmetric chiral porphyrins developed for asymmetric cyclopropanation encouraged Zhang and coworkers to continue investigating other atom/group transfer reactions, including aziridination.[176] Their research focused not only on using the "group of six" porphyrins (Figure 35, Section III.A) as ligands for cobalt-catalyzed aziridination, but also on the use of nitrene sources other than hypervalent iodine reagents. They reported the use of diphenylphosphoryl azide (DPPA) for the asymmetric aziridination of aromatic olefins (Table 56).

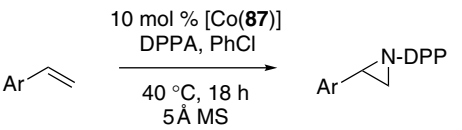


Scheme 22.[175]



Scheme 23.[132]

Table 56. Asymmetric aziridination of aromatic olefins with DPPA catalyzed by [Co(**87**)].[176]



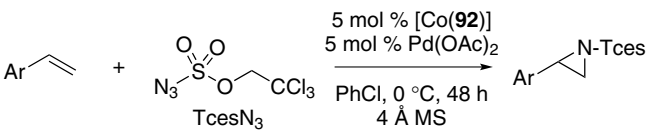
Entry[a]	Substrate	Yield (%)	ee (%)
1	Styrene	88	37
2	4-Methylstyrene	58	37
3	4-*tert*-Butylstyrene	77	53
4	4-Bromostyrene	65	28
5	4-Chlorostyrene	64	6
6	4-Trifluoromethylstyrene	64	44
7	3-Nitrostyrene	58	46

[a] Reactions were performed with 10 mol % of catalyst, 5 equiv. of substrate, and 1 equiv. of DPPA in PhCl at 40 °C for 18 h in the presence of 5 Å MS.

While their early attempt at cobalt-catalyzed asymmetric aziridination produced modest yields and enantioselectivities, their report is significant in that it presents one of the first uses of diphenylphosphoryl azide (DPPA) for asymmetric aziridination.

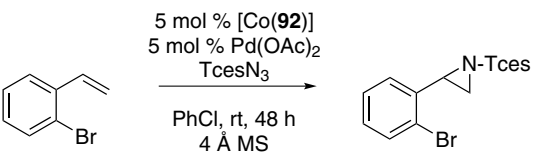
In their continued efforts to develop nitrene sources other than PhI=NTs and its derivatives, Zhang and coworkers synthesized and explored trichloroethoxysulfonyl

Table 57. Asymmetric aziridination of olefins with $TcesN_3$ catalyzed by [Co(**92**)].[177]



Entry[a]	Substrate	Yield (%)	ee (%)
1	Styrene	91	94
2[b]	Styrene	69	94
3	4-Methylstyrene	89	90
4	4-Chlorostyrene	93	91
5	4-Trifluoromethylstyrene	88	81
6	3-Nitrostyrene	82	88
7[c]	α-Methylstyrene	48	80
8[d]	Allylbenzene	42	91

[a] Reactions were performed with 5 mol % of catalyst, 5 equiv. of substrate, and 1 equiv. of $TcesN_3$ in PhCl at 0 °C for 48 h in the presence of 4 Å MS; [b] Without $Pd(OAc)_2$; [c] rt; [d] 24 h without $Pd(OAc)_2$.



first cycle: 95% yield, 96% ee
second cycle: 89% yield, 94% ee
third cycle: 81% yield, 94% ee

Scheme 24.[177]

azide, $TcesN_3$.[177] The cobalt complex of the D_2-symmetric porphyrin **92** generated excellent yields and enantioselectivities for asymmetric aziridination of both aromatic and aliphatic olefins with $TcesN_3$ (Table 57). The importance of $Pd(OAc)_2$ as a co-catalyst was noted. The addition of sub-stoichiometric amounts of $Pd(OAc)_2$ improved yield without affecting the asymmetric induction (entries 1–2, Table 57). This effect is attributed to the potential activation of the olefin by $Pd(OAc)_2$ as a π-electrophilic Lewis acid.

The [Co(**92**)] catalyst was also demonstrated to be recyclable in the catalytic system. The cobalt catalyst could be precipitated onto molecular sieves with the addition of hexanes. After being filtered and dried, it was reused in subsequent reactions without significant loss of enantioselectivity over at least three cycles (Scheme 24).

V. Carbon–Hydrogen Bond Functionalization

Carbon–hydrogen bond functionalization via atom/group transfers represents a direct way to convert hydrocarbons into valuable intermediates.[52,154,178–184] This section will examine several examples of asymmetric carbon–hydrogen bond functionalization reactions, encompassing hydroxylation and amination, in addition to the analogous oxidation reactions including sulfoxidation and carbene insertion into thiols. Asymmetric catalytic systems that have been developed using chiral porphyrin catalysts, which were discussed previously in this chapter, will be briefly highlighted in these applications.

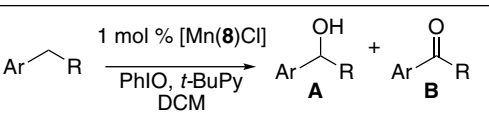
A. Chiral Picket Fence Porphyrins

1. *Hydroxylation*

In 1997, Halterman and coworkers reported on the use of the manganese complex of porphyrin **8**, [Mn(**8**)Cl], for the asymmetric hydroxylation of hydrocarbons.[34] Although reactions with ethylbenzene (entry 1, Table 58) gave rise to products in low yield and with poor enantioselectivity, reactions with indan and tetrahydronaphthalene resulted in improved yields and higher enantioselectivities (entries 2–3, Table 58). The authors noted that the reactions needed to be carefully monitored, as longer reaction times resulted in over-oxidation and the formation of a ketone side product.

The ruthenium complex of the Halterman porphyrin **8**, [Ru(**8**)(CO)], was also used by Che and coworkers in 1999 for asymmetric hydroxylation.[76,185] The use of the ruthenium carbonyl complex led to significant improvements in enantioselectivity when compared to the [Mn(**8**)Cl] prepared by Halterman. The ruthenium oxide complex [Ru(**8**)$(O)_2$] was also shown to be capable of performing hydroxylation under stoichiometric conditions, although with lower yield and enantioselectivities in comparison to [Ru(**8**)(CO)] (entries 1 and 2, Table 59).

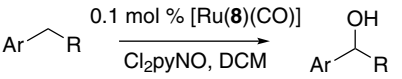
Table 58. Asymmetric benzylic hydroxylation catalyzed by [Mn(**8**)Cl].[34]



Entry[a]	Substrate	Time	Yield (%)	ee (%)	**A**:**B**
1	Ethylbenzene	16 h	27	9	1:1
2	Indan	20 m	50	53	5:1
3	Tetrahydronaphthalene	40 m	39	44	3:1
4	2-Ethylnaphthalene	14 h	24	40	2:1

[a] Reactions were performed using 1 mol % of catalyst, 10 equiv. of substrate, and 1 equiv. of PhIO with 20 mol % of *t*-BuPy as additive in DCM.

Table 59. Asymmetric benzylic hydroxylation catalyzed by [Ru(**8**)(CO)].[76,185]



Entry[a]	Substrate	Time	Yield (%)[b]	ee (%)
1	Ethylbenzene	12	62 (13)	72
2[c]	Ethylbenzene	12	30	37
3	4-Ethyltoluene	30	72 (20)	76
4	1-Bromo-4-ethylbenzene	8	63 (14)	74
5	4-Ethylanisole	8	65 (15)	62
6	2-Ethylnaphthalene	20	62 (15)	75
7	Indan	6	65 (54)	12
8	Tetrahydronaphthalene	2	60 (42)	12

[a] Reactions were performed using 0.1 mol % of catalyst, 1 equiv. of substrate, and 1.1 equiv. of Cl_2pyNO as oxidant in benzene; [b] Yields are based upon the amount of alkene consumed in the reaction. The number in parenthesis represents conversion of substrate; [c] [Ru(**8**)$(O)_2$] used under stoichiometric condtitons.

Table 60. Asymmetric sulfoxidation catalyzed by [Mn(**8**)Cl].[34]

Entry[a]	Substrate	Yield A (%)	ee (%, A)	**A**:**B**
1	Thioanisole	93	55	44:1
2	Ethyl phenyl sulfide	82	42	13:1
3	2-Bromothioanisole	99	68	>95:1
4	4-Bromothioanisole	98	59	34:1
5	4-Methoxythioanisole	99	40	44:1
6	Thiochroman-4-one	99	47	>95:1

[a] Reactions were performed using 0.5 mol % of catalyst, 2 equiv. of substrate, and 1 equiv. of PhIO in DCM.

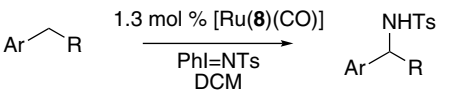
2. *Sulfoxidation*

In conjunction with their previous reports on epoxidation and hydroxylation using porphyrin **8**, Halterman and coworkers reported sulfoxidation of prochiral aromatic aryl alkyl sulfides.[34] Using the manganese complex [Mn(**8**)Cl], they demonstrated that the sulfoxide products **A** could be generated in high yields with moderate enantioselectivities (Table 60). Similar to the work on hydroxylation, minimal amounts of over-oxidized sulfone side products **B** were produced.

3. *Amination*

During the course of their study on the asymmetric aziridination of olefins with metal complexes of **8**, Che and coworkers reported the asymmetric amination of hydrocarbons.[174] The ruthenium complex [Ru(**8**)(CO)] was explored for catalytic amination of various benzylic substrates with PhI=NTs. Moderate to low enantioselectivities were produced (Table 61). Improvements were achieved through the *in-situ* generation of the nitrene from a sulfonyl amide in the presence of $PhI(OAc)_2$ (Table 62). These systems were able to achieve moderate enantioselectivities

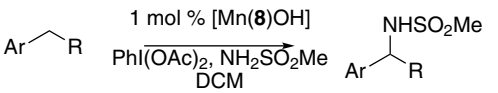
Table 61. Asymmetric amination of benzylic hydrocarbons catalyzed by [Ru(**8**)(CO)].[174]



Entry[a]	Substrate	Yield (%)	ee (%)
1	4-Ethylanisole	82 (29)	22
2	Indan	92 (32)	3
3	Tetrahydronaphthalene	85 (22)	28
4	2-Ethylnaphthalene	84 (23)	47

[a] Reactions were performed using 1.3 mol % of catalyst, 2 equiv. of PhI=NTs, and 1 equiv. of substrate in DCM at 40 °C for 2 h; [b] Yields are based upon the amount of alkene consumed in the reaction. The number in parenthesis represents conversion of substrate.

Table 62. Asymmetric amination of benzylic hydrocarbons with *in-situ* generation of nitrene source catalyzed by [Mn(**8**)(OH)].[174]



Entry[a]	Substrate	Yield (%)[b]	ee (%)
1	4-Ethylanisole	84 (26)	50
2	Tetrahydronaphthalene	84 (22)	46
3	2-Ethylnaphthalene	92 (21)	56
4[c]	2-Ethylnaphthalene	90 (34)	40

[a] Reactions were performed using 1 mol % of catalyst, 1 equiv. of $PhI(OAc)_2$, 1.25 equiv. of sulfonyl amide, and 1.5 equiv. of substrate in DCM at 40 °C for 2 h; [b] Yields are based upon the amount of alkene consumed in the reaction. The number in parenthesis represents conversion of substrate; [c] Catalyzed by [Ru(**8**)(CO)].

across a variety of benzylic substrates. It was also shown that [Mn(**8**)OH] was able to induce a higher level of asymmetry than the ruthenium complex [Ru(**8**)(CO)] (entries 3 and 4, Table 62).

B. Chiral-Strapped Porphyrins

1. *Hydroxylation*

In 1999, Gross and coworkers reported the use of the threitol-strapped porphyrin **51** (Figure 21) for the ruthenium-catalyzed hydroxylation of a racemic tertiary alkane.[75] The desired hydroxylation product was generated in 38% enantiomeric excess (Scheme 25). The result is remarkable since the asymmetric induction relies on the differentiation of the similar methyl and ethyl groups on the substrate by the active site of the catalyst (Scheme 25).

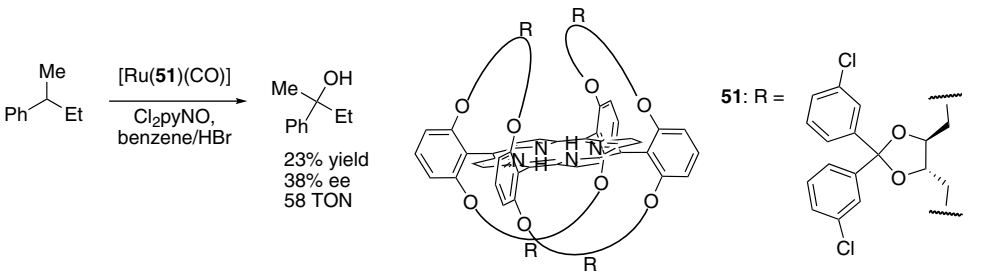
2. *Carbene Insertion*

In addition to using porphyrin ligand **47** for the ruthenium-catalyzed asymmetric cyclopropanation of olefins with EDA, Simonneaux and coworkers reported the ability of the catalyst to perform carbene insertion with thiols.[143] Although high yields were generated with this system, the resulting asymmetric induction was low (Scheme 26).

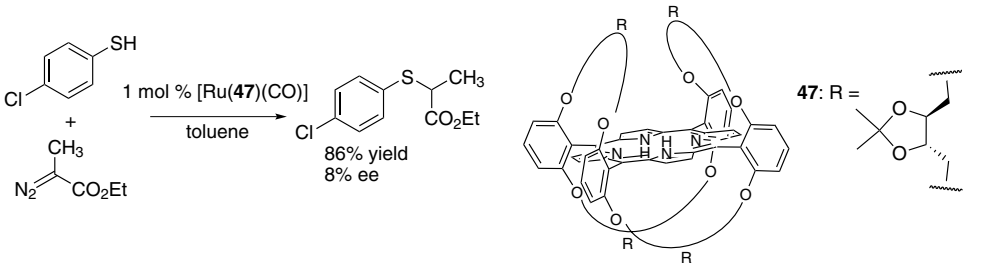
C. Chiral Basket Handle Porphyrins

1. *Hydroxylation*

Groves and coworkers employed both iron and manganese complexes of "vaulted" binaphthylporphyrin **65** (Figure 27) for studying the catalytic hydroxylation of hydrocarbons.[84] Several substrates were screened for hydroxylation with



Scheme 25.[75]



Scheme 26.[143]

Table 63. Asymmetric sulfoxidation catalyzed by iron and manganese complexes of ligand **65**.[84]

		[Fe(**65**)Cl]			[Mn(**65**)(Cl)]		
Entry[a]	Substrate	Yield (%)	ee (%)	A:B	Yield (%)	ee (%)	**A**:**B**
1	Ethylbenzene	40	40	2.3:1	77	26	1:3:1
2	1-Phenylpropane	32	44	5.0:1	98	16	1:4:1
3	Indan	72	54	7.2:1	82	18	4:5:1
4	Tetrahydronaphthalene	47	72	20.2:1	46	12	1:3:1

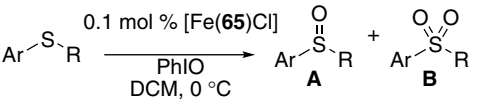
[a] Reactions were performed with 1 mol % of catalyst, 1 equiv. of PhIO, and 10 equiv. of substrate in DCM at 0 °C.

[Fe(**65**)Cl] and [Mn(**65**)Cl] as catalysts (Table 63). Although the yields generated by the manganese complex were typically higher, the iron-catalyzed system gave higher enantioselectivities. In addition to the desired hydroxylation products, ketones were observed as the side products, even in the presence of a tenfold excess of substrate.

2. *Sulfoxidation*

The iron complex of "vaulted" binaphthyl porphyrin **65** was also used by Groves and coworkers for asymmetric sulfoxidation of aryl sulfides.[84] Similar to the results by Halterman with [Mn(**8**)Cl] (Table 60), it was shown that the [Fe(**65**)Cl]-based sulfoxidation process could successfully generate the desired sulfoxide products **A** in good yields, but low enantioselectivities and with sulfones **B** as the over-oxidation side products (Table 64).

Table 64. Asymmetric sulfoxidation catalyzed by [Fe(**65**)Cl].[84]



Entry[a]	Substrate	Yield (%)	ee (%)	**A**:**B**
1	Thioanisole	84	24	8.2:1
2	Ethyl phenyl sulfide	73	42	7.9:1

4	4-Bromothioanisole	88	20	7.5:1
5	4-Methoxythioanisole	70	14	6.2:1
6	Thiochroman-4-one	67	28	8.9:1

[a] Reactions were performed using 0.5 mol % of catalyst, 1 equiv. of substrate, and 10 equiv. of PhIO in DCM at 0 °C.

VI. Conclusions

The use of chiral porphyrin ligands for asymmetric atom/group transfer reactions has significantly evolved since the first report by Groves and Myers in 1983. Various metal complexes of chiral porphyrins have been used for catalytic asymmetric epoxidation, cyclopropanation, aziridination, and in several reports of carbon–hydrogen bond functionalizations. The greatest efforts have been focused on the development of metalloporphyrin catalysts for asymmetric epoxidation. Much of the research in this area has been devoted to the synthesis and evaluation of metal complexes of Halterman porphyrin **8**. Catalytic systems based on this robust porphyrin have been shown to be capable of achieving several thousand TON for some catalytic processes. Complexes of Collman's binap-strapped porphyrins **43**–**44**, including its derivatives **45**–**46** prepared by Rose, have been demonstrated with the highest enantioselectivities for metalloporphyrin-catalyzed asymmetric epoxidation reactions.

The successes of both the Halterman porphyrin and Collman's binap-strapped porphyrins emphasize a balanced need for open access and steric hindrance of catalyst's active site where the approach of substrates and subsequent reactions take place. The desired balance of the two factors in these successful metalloporphyrin-catalyzed epoxidation processes has allowed for facilitation of reaction rates and reduction of catalyst degradation while reaching high selectivities.

Research activities on metalloporphyrin-catalyzed asymmetric cyclopropanation were also dominated by the use of metal complexes of Halterman porphyrin **8**. Similar to the development of metalloporphyrin-based asymmetric epoxidation, various metal complexes of the Halterman porphyrin have been employed as catalysts for asymmetric cyclopropanation. High diastereoselectivity and enantioselectivity,

along with high TON, have been achieved for some asymmetric cyclopropanation processes. The recent development of Co(II) complexes of the D_2-symmetic chiral porphyrins **87–92** by Zhang and coworkers has provided some of the most selective and practical cyclopropanation catalytic systems. These Co(II)-catalyzed cyclopropanation systems have been demonstrated to be effective for a wide range of alkene substrates and with different types of diazo reagents, providing the desired cyclopropane products in high yields with excellent diastereoselectivities and enantioselectivities.

The development of metalloporphyrin-catalyzed asymmetric aziridination has lagged behind in comparison to epoxidation and cyclopropanation reactions. Many of the same catalytic systems employed for asymmetric cyclopropanation have been extended to asymmetric aziridination. Although this direction of efforts have been further advanced by the recent publications from the research groups of Che, Zhang, and others, many challenging issues remain to be solved in the development of catalytic systems for asymmetric aziridination.

The demonstrated examples of asymmetric carbon–hydrogen bond functionalization processes, developed in conjunction with other atom/group transfer reactions, are another indication of the catalytic versatility of metalloporphyrin-based catalysts. Further development for these more challenging catalytic transformations is one of the most important on-going objectives in asymmetric catalysis by metalloporphyrins.

Finally, the diverse porphyrin ligand systems already developed and the great amount of progress achieved in epoxidation and cyclopropanation reactions ensure that the continued development of metalloporphyrin-based asymmetric atom/group transfer processes will remain an active goal for researchers around the world in the years to come.

VII. Acknowledgments

This chapter contains a number of contributions from our own research group. We would like to thank all of our coworkers and collaborators for their valuable contributions. We would also like to acknowledge the National Science Foundation, the American Chemical Society, and the University of South Florida for financial support.

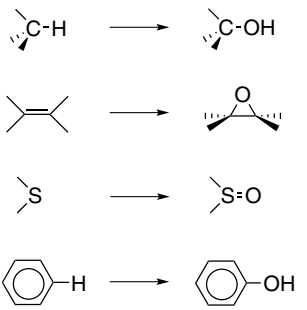
I. Introduction

Cytochromes P450 (CYP 450s) are a superfamily of cysteine thiolate-ligated heme enzymes that catalyze the transfer of one oxygen atom from molecular oxygen into a wide variety of biological substrates (S), whereby the second oxygen



Scheme 1. Reactions catalyzed by CYP 450 enzymes.

atom is reduced by two electrons and two protons to a water molecule (Eq. 1).[1–7] They are therefore mono-oxygenase enzymes, as only one oxygen atom from molecular oxygen is incorporated into substrates. CYP 450s are widespread in nature and perform a vast array of oxidative transformation reactions of endogenous and exogenous molecules.[8–10] The most-often-encountered oxidation reactions by CYP 450s are the hydroxylation of saturated hydrocarbons, the epoxidation of olefins, the oxidation of heteroatoms, the oxidation of aromatic compounds, and heteroatom dealkylation (Scheme 1).[11–15] CYP 450s have a range of different functions in biosystems, varying from the biosynthesis of antibiotics in prokaryotes and hormones in eukaryotes to the biodegradation of drugs and xenobiotics.[16]

$$S + O_2 + 2e^- + 2H^+ \xrightarrow{\text{(Cytochrome P450)}} SO + H_2O \qquad (1)$$

Due to their versatility and efficiency in performing complicated hydroxylation reactions in regio- and stereoselective ways, they have attracted much attention in the communities of biological, bioinorganic, and oxidation chemistry. Moreover, templates of the active site have been created and investigated as biomimetics to gain insight into the fundamental properties of the CYP 450's active center. Most recently, computational chemists have become interested in CYP 450,[17–20] and the combination of experimental and computational studies with native and mutant enzymes and biomimetic complexes has given insights into the critical components of the CYP 450's active site. In this chapter, we will focus on biomimetic and computational research while paying special attention to reaction mechanisms of substrate monoxygenation by CYP 450.

The first X-ray crystal structure of CYP 450 was reported by Poulos and coworkers in 1985: the soluble bacterial CYP 450_{cam} isolated from the bacterium *Pseudomonas putida*.[21] Since then, many more crystal structures of catalytic cycle intermediates have been detected and characterized and, as a result, a

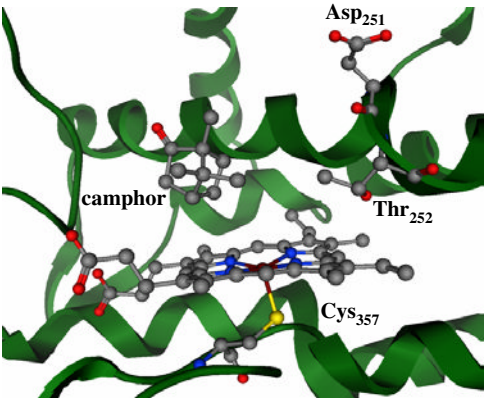


Figure 1. Active site structure of CYP 450 as taken from the 1DZ9 pdb file,[24] with key amino acids and substrate (camphor) highlighted.

protein databank[22] search on "P450" gives well over 300 different structures of various CYP 450 isozymes. These enzymes show considerable homology and all contain a central heme group, where the catalysis takes place. CYP 450 enzymes consist of a single polypeptide chain containing a heme *b* group (iron protoporphyrin IX) linked to a cysteine (Cys) amino acid via the axial ligand of the metal.[23] Figure 1 gives the active site structure of a typical CYP 450 isozyme, namely CYP 450_{cam}, as taken from the 1DZ9 protein databank structure.[24] This is a bacterial CYP 450 that regioselectively hydroxylates camphor at the C^5 position and is one of the most extensively studied CYP 450s.[25,26] The heme *b* group is bound to the protein via an iron-cysteinate bond that is deeply embedded in the hydrophobic interior of the enzyme to accommodate hydrophobic substrates, and the proximal Cys amino acid forms hydrogen bonds with neighboring amide protons of three amino acids,[27] which is believed to play a significant role in modulating the catalytic activity of CYP 450.[28–33] Indeed, the name "cytochrome P450" is derived from the fact that a red-shifted strong Soret band (high-energy π–π^* transition of the porphyrin ring) appears at 450 nm when CO binds to ferrous heme (Fe^{II}–CO), which is caused by the strong electron-donating character of the cysteinate proximal ligand.[34–36]

Since activation of inert C–H bonds is a holy grail of chemistry, mechanistic details of dioxygen activation and oxygen transfer reactions by CYP 450 have been intensively investigated in enzymes and biomimetic iron porphyrin complexes over the past four decades, thereby proposing the catalytic cycle of CYP 450 (Figure 2).[1–20,37,38] Recently, theoretical chemistry, and especially density functional theory (DFT) and quantum mechanics/molecular mechanics (QM/MM) techniques, have provided important clues to understanding structures, spin states,

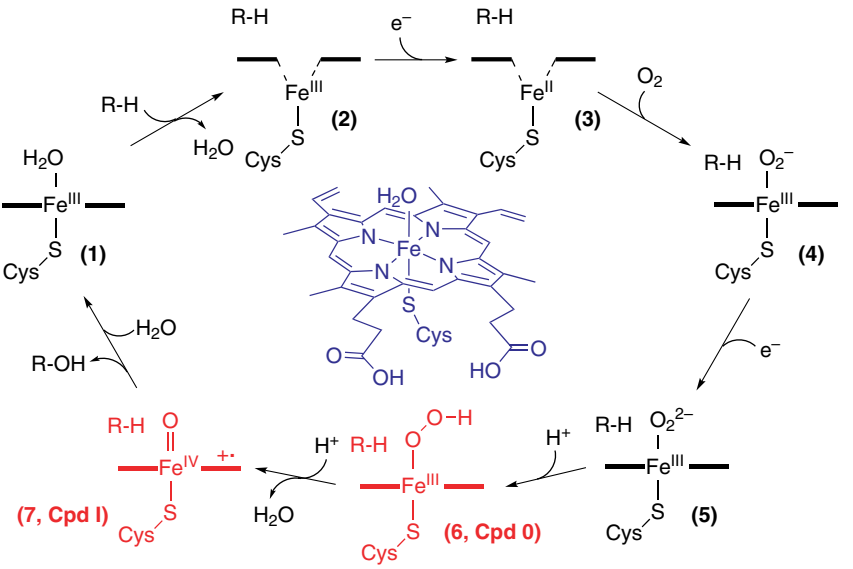

Figure 2. Proposed catalytic cycle of CYP 450.[14] Iron(III) protoporphyrin IX with a cysteinate as an axial ligand is shown in the center, and the two key intermediates, Cpd I and Cpd 0, are highlighted in red.

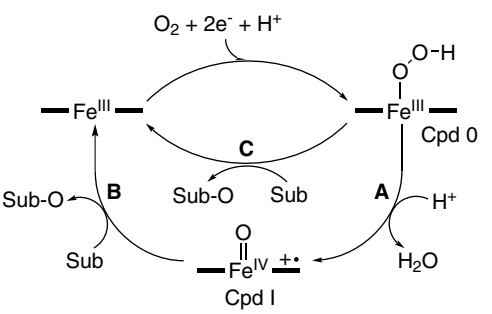
and chemical and physical properties of the unstable intermediates involved in the enzymatic and biomimetic oxidation reactions.[17–20,39] Since the topic of this review is not about the catalytic cycle of CYP 450 but is focused more on the reactivities of active oxidants in oxygenation reactions, only a bird's eye view of the overall catalytic reaction cycle is given and the interested reader is referred to the various detailed reviews of the catalytic cycle of CYP 450 enzymes.[17–20,39]

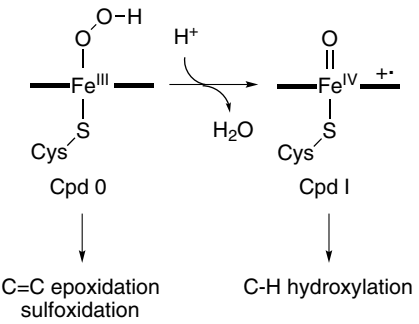
The catalytic cycle starts from the resting, substrate-free state, **1**, where CYP 450 contains a six-coordinate low-spin ferric state with water as the displaceable distal ligand (Figure 2). The binding of substrate into the substrate-binding pocket triggers a spin state crossing from low spin to high spin,[40] whereby the distal water molecule is expelled and a five-coordinate high-spin ferric state, **2**, is generated. In many CYP 450 isozymes, substrates bind in a very-tight-binding pocket where they are locked in position through electrostatic and hydrogen bonding interactions.[41] DFT and QM/MM calculations on model complexes indeed confirmed a different spin state ordering for **1** and **2**.[42–44] This spin state change triggers an electron transfer process from the reductase domain to reduce the ferric complex to a ferrous complex, **3**.[40] Dioxygen then binds to the ferrous heme to form the ferric-superoxo heme (Fe^{III}–O_2^-), **4**. Addition of the second electron to **4**, which is presumed to be the rate-limiting step in the catalytic cycle,[45] yields a ferric-peroxo species (Fe^{III}–O_2^{2-}), **5**, which is then protonated to

give a ferric-hydroperoxo complex, **6**, also known as compound 0 (Cpd 0). Recently, the ferric-peroxo and ferric-hydroperoxo intermediates were generated by radiolytic cryoreduction of the ferric-superoxo of CYP 450_{cam}, **4**, with gradual temperature annealing and characterized by EPR, ENDOR, and UV-vis spectroscopies.[24,46–48] The delivery of the second proton in the catalytic cycle onto the ferric-hydroperoxo species, **6**, results in heterolytic O–O bond cleavage to release a water molecule and generate a putative iron(IV)-oxo porphyrin π-cation radical intermediate, **7**, which is equivalent to compound I (Cpd I) of horseradish peroxidase (HRP). Although the intermediate **7** is believed to be the most likely candidate for the reactive species of CYP 450 that hydroxylates unactivated hydrocarbons, the characterization of the intermediate has not been successful, probably due to its high reactivity. Schlichting and coworkers reported that the ferric superoxo of CYP 450_{cam}, **4**, was converted by X-ray irradiation at cryogenic temperature into an intermediate that would be consistent with an iron(IV)-oxo species.[24] In different studies, the oxidation of CYP 450 by *m*-chloroperbenzoic acid (*m*-CPBA) generated intermediates with UV-vis spectral features characteristic of an iron(IV)-oxo porphyrin π-cation radical, **7**.[49,50] The final step of the CYP 450 reaction cycle is the transfer of an oxygen atom from **7** to the substrate to give the alcohol product, followed by the regeneration of the resting, water-bound state, **1**.

The catalytic cycle shown in Figure 2 is the consensus mechanism[2,3,5] for dioxygen activation by CYP 450. Among the short-lived intermediates in the catalytic cycle, the nature of active oxidants which are responsible for oxygen atom transfer to organic substrates attracted much attention in the bioinorganic and biological chemistry communities. It has been believed for a long time that iron(IV)-oxo porphyrin π-cation radicals, Cpd I, are generated via O–O bond heterolysis of ferric-hydroperoxo porphyrins, Cpd 0, and are the active oxidants that effect the oxygenation of organic substrates (Scheme 2, pathways A and B). Although Cpd I



Scheme 2. Two intermediates, Cpd 0 and Cpd I, proposed[51] in the catalytic oxygenation of organic substrates by CYP 450.



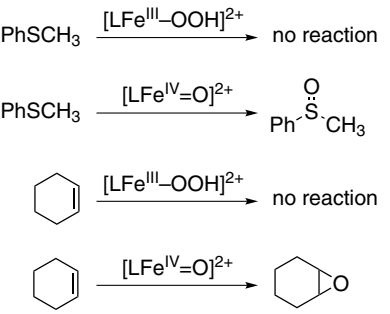
Scheme 3. Two-oxidant hypothesis of substrate monoxygenation by the CYP 450s.

has been poorly characterized in enzymatic reactions, probably due to high reactivity and instability in nature, a number of synthetic iron(IV)-oxo porphyrin π-cation radicals have been prepared and investigated in various oxygenation reactions, including alkane hydroxylation and olefin epoxidation.[14,15] Thus, there is no doubt that Cpd I is a strong oxidant capable of oxygenating various organic substrates. However, the nature of the active oxidant was thrown into doubt by site-directed mutagenesis studies that implicated the participation of Cpd 0 as a second electrophilic oxidant in substrate monoxygenation reactions, such as oxygenation of alkanes, olefins, sulfides, and *N*,*N*-dialkylanilines (Scheme 3).[51,52] The primary evidence for the second electrophilic oxidant derives from site-directed mutagenesis studies, in which different products and/or product distributions were observed in the reactions of CYP 450 and their mutants.[53–56] Thus, studies using so-called radical-clock substrates which distinguish between radical and cationic mechanisms implicated an ultrashort lifetime indicative of two active oxidants in the reaction mechanism.[52] Site-directed mutations were done that disrupted the proton relay machinery and supposedly blocked formation of Cpd I by termination of the catalytic cycle at Cpd 0. The key amino acids assigned to the proton transfer mechanisms in CYP 450_{cam} include the alcohol side-chain of Thr_{252} and the carboxylic acid group of Asp_{251} (see Figure 1). Indeed, the Thr252Ala mutation significantly decreased the activity of the enzyme and led to a substantial increase of decoupling whereby the ferric-hydroperoxo was converted into ferric-hydrogen peroxide and no hydroxylation took place.[57] Further studies showed that although the activity of the Thr252Ala mutant had sharply decreased toward aliphatic hydroxylation reactions, in fact double bond epoxidation reactions still proceeded and, in cases where epoxidation and hydroxylation mechanisms were competitive, a regioselectivity switch was observed.[53–56,58] Based on these studies, a two-oxidant scenario was hypothesized[51] wherein Cpd I is the oxidant for aliphatic hydroxylation reactions whereas Cpd 0 is responsible for double bond epoxidation (Scheme 3).

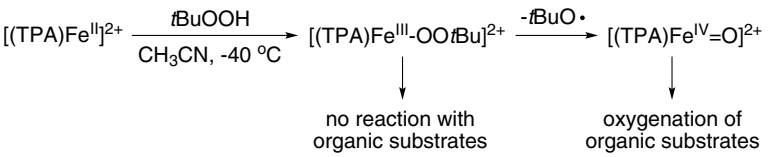
The two-oxidant hypothesis has created extensive discussion as a viable hypothesis, but was questioned by computational and biomimetic studies.[59–62] In particular, computational studies using DFT and combined QM/MM[59–62] have resulted in an alternative, namely the two-state reactivity (TSR) scenario,[19,63] wherein one oxidant, i.e. the iron(IV)-oxo heme π-cation radical (or Cpd I), is the active oxidant and reacts with substrates on several close-lying spin state surfaces. Later in this chapter a more detailed explanation of the TSR principle will be given. Biomimetic studies support the TSR scenario and have ruled out the ferric hydroperoxo as a potential oxidant of aliphatic and aromatic hydroxylation and sulfoxidation reactions.[64] Thus, *in situ* generated nonheme iron(III)-hydroperoxo complexes did not show any activity in nucleophilic and electrophilic reaction mechanisms, such as olefin epoxidation and sulfoxidation. The results derived from the direct reactivity studies of nonheme iron(III)-hydroperoxo intermediates imply that Cpd 0 is unlikely to be an oxidant of C=C epoxidation and sulfoxidation reactions as proposed by the two-oxidant model, and the experimental product distributions, therefore, originate from another oxidant.

To further ascertain that Cpd 0 is an unlikely oxidant, DFT and QM/MM calculations focused on the proton transfer step that converts Cpd 0 into Cpd I. These studies implicated that Cpd 0 and Cpd I are close in energy.[65–69] Recent QM/MM studies[69] showed that active site mutations, such as Thr252Ala, can give rise to extra water molecules in the substrate-binding pocket that promote distal protonation of Cpd 0 leading to hydrogen peroxide products (called uncoupling) rather than the formation of Cpd I. The intricate shape and size of the substrate-binding pocket and the availability of proton donors and acceptors, therefore, influence the protonation steps in the catalytic cycle and determine whether Cpd I or hydrogen peroxide is formed.

DFT calculations on the relative activity of ferryl-oxo versus ferric-hydroperoxo in C=C double bond epoxidation[59,60] found little evidence of activity of Cpd 0 and as such contradicted the experimental two-oxidant hypothesis. These studies used small model complexes and ignored the protein surroundings of enzymes. Nevertheless, as discussed above, the work was supported by experimental biomimetic studies on substrate epoxidation and hydroxylation by synthetic iron(IV)-oxo complexes versus their iron(III)-hydroperoxo analogs.[64] Thus, the sulfoxidation and epoxidation reactions of three different ferric-hydroperoxo oxidants, namely $[(N4Py)Fe^{III}(OOH)]^{2+}$, $[(Bn\text{-}tpen)Fe^{III}(OOH)]^{2+}$, and $[(TPA)Fe^{III}(OOH)]^{2+}$, with N4Py = *N*,*N*-bis(2-pyridylmethyl)-*N*-bis(2-pyridyl)-methylamine, Bn-tpen = *N*-benzyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine and TPA = tris(2-pyridylmethyl)amine, were investigated in electrophilic and nucleophilic reactions. No reaction was observed between these ferric-hydroperoxo complexes and either thioanisole or cyclohexene (Scheme 4), thus supporting the DFT calculations.



Scheme 4. Reactivities of nonheme $[LFe^{III}–OOH]^{2+}$ and $[LFe^{IV}=O]^{2+}$ complexes, where L = N4Py, Bn-tpen or TPA, in the oxidation of sulfides and olefins.

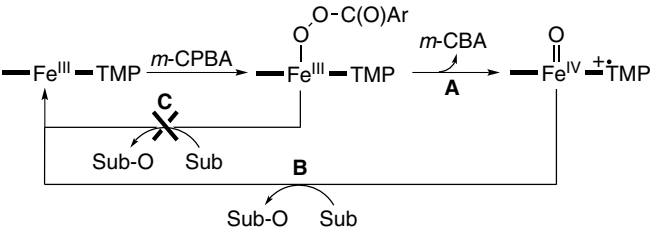


Scheme 5. Nonheme iron(III)-alkylperoxo and iron(IV)-oxo complexes in oxygenation reactions.

In addition to the lack of electrophilic oxidation by ferric-hydroperoxo, activity with respect to nucleophilic deformylation was not detected either.[64] By contrast, the analogous iron(IV)-oxo complexes reacted efficiently with olefins and sulfides to give epoxide and sulfoxide products.[64]

Similarly, reactivity and spectroscopic studies of a mononuclear nonheme iron(III)-alkylperoxo complex, $[(TPA)Fe^{III}(OOtBu)]^{2+}$ (*t*BuOOH = *tert*-butyl hydroperoxide), revealed that this intermediate is not capable of oxygenating substrates either and that a high-valent iron(IV)-oxo intermediate, $[(TPA)Fe^{IV}(O)]^{2+}$, which is generated via O–O bond homolysis of the $[(TPA)Fe^{III}(OOtBu)]^{2+}$ species,[70] is the active oxidant that effects the oxygenation of organic substrates, such as sulfides, olefins, and alcohols (Scheme 5).[71] These experimental results are strongly supported by DFT calculations, in which the energy barrier for the O–O bond activation of Fe(III)-OOR species is lower than that for the direct oxygen atom transfer from the intermediate to organic substrates.[71]

More recently, Woggon, van Eldik, and coworkers provided spectroscopic evidence for the formation of reactive intermediates, such as $(Porp)^{+\bullet}$ Fe^{IV}=O, and the involvement of the intermediate in oxygen atom transfer to substrates, such as *cis*-stilbene, in the reaction of an RSO_3^--substituted iron(III) porphyrin complex and *m*-CPBA.[72] In addition to the spectroscopic evidence for the formation of the



Scheme 6. High-valent iron(IV)-oxo porphyrin π-cation radical as an active oxidant in the oxygenation of organic substrates by Fe(TMP)Cl and *m*-CPBA.

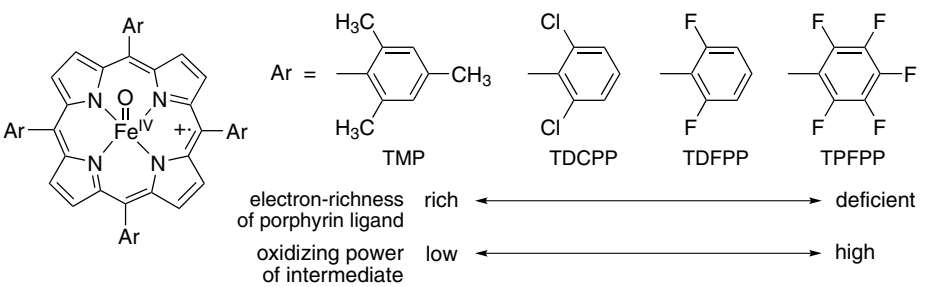
iron(IV)-oxo porphyrin intermediate, rate constants for the formation and decay of intermediates formed in the catalytic reaction of the iron porphyrin complex and *m*-CPBA and for the oxygen atom transfer to the substrate were determined by using low-temperature rapid-scan stopped-flow techniques. Similarly, Nam and coworkers have provided strong evidence that a high-valent iron(IV)-oxo porphyrin π-cation radical is an active oxidant in the catalytic oxygenation of organic substrates by an iron(III) porphyrin complex and *m*-CPBA, whereas an iron(III)-oxidant porphyrin adduct is a sluggish oxidant in iron porphyrin model reactions.[73] In the study, the authors determined rate constants for the oxygenation of various substrates by $[(TMP)^{+\bullet}Fe^{IV}=O]^+$ (TMP = *meso*-tetramesitylporphyrin). Then, the reaction of Fe(TMP)Cl with *m*-CPBA was carried out in the presence of the substrates under catalytic reaction conditions. The formation of $[(TMP)^{+\bullet}Fe^{IV}=O]^+$ was observed, followed by the disappearance of the intermediate with rates identical to those observed in the reaction of $[(TMP)^{+\bullet}Fe^{IV}=O]^+$ and substrates under stoichiometric conditions. These results demonstrated that $[(TMP)^{+\bullet}Fe^{IV}=O]^+$, which is formed via O–O bond heterolysis of Fe^{III}(Porp)(*m*-CPBA) (Scheme 6, pathway A),[74,75] is an active oxidant that is responsible for the oxygenation of organic substrates at low and room temperatures (Scheme 6, pathway B). The results further implied that an iron(III) porphyrin-oxidant adduct, Fe^{III}(Porp)(*m*-CPBA), is a sluggish oxidant in oxygenation reactions (Scheme 6, pathway C).

II. Iron(IV)-Oxo Porphyrin π-Cation Radical Complexes

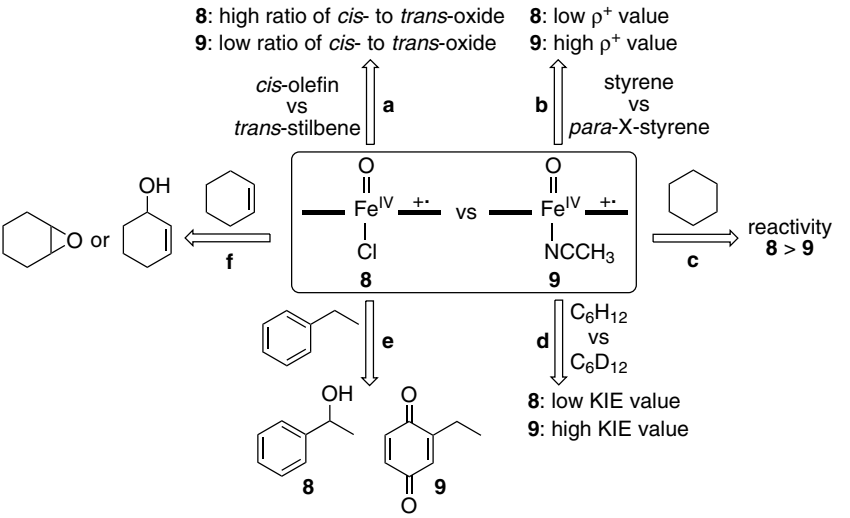
"High-valent iron-oxo porphyrins" is a description that refers to iron complexes with porphyrin ligands in which the oxidation state of the iron ion is higher than +3 and contains a terminal oxo group bound to the metal center. The first synthetic iron(IV)-oxo porphyrin π-cation radical complex, $[(TMP)^{+\bullet}Fe^{IV}=O]^+$, was reported by Groves and coworkers after reacting Fe(TMP)Cl with *m*-CPBA in a CH_2Cl_2/CH_3OH mixture at −78 °C.[76] The formation of $[(TMP)^{+\bullet}Fe^{IV}=O]^+$ occurs via O–O bond cleavage of the (TMP)Fe^{III}–OOC(O)Ar intermediate, as shown in

Scheme 6, pathway A.[74,75] The green species, formulated as $[(TMP)^{+\bullet}Fe^{IV}=O]^{+}$, was characterized by various spectroscopic techniques, such as UV-vis,[76] ^{1}H NMR,[76,77] EPR,[77] Mössbauer,[77,78] resonance Raman,[77,79] magnetic circular dichroism,[80] and EXAFS spectroscopies.[81] The $[(TMP)^{+\bullet}Fe^{IV}=O]^{+}$ complex was also prepared using other oxidants, such as ozone,[82] dimethyldioxirane,[83] and iodosylbenzene.[84] Since then, a number of iron(IV)-oxo porphyrin complexes have been synthesized with porphyrin ligands bearing electron-donating and -withdrawing substituents on the porphyrin ligand. The reactivities of the iron porphyrins were then investigated in various oxidation reactions under catalytic or stoichiometric conditions, to understand the electronic effect of porphyrin ligands on the chemical properties of the iron-oxo intermediates.[85–87] As electron-deficient iron(III) porphyrin complexes are better catalysts in catalytic oxygenation reactions,[85–87] iron(IV)-oxo porphyrin π-cation radicals bearing electron-deficient porphyrin ligands show high reactivities in hydrocarbon oxygenation.[88] This result indicates that the electronic nature of porphyrin ligands is an important factor that controls the oxidizing power of iron(IV)-oxo porphyrin π-cation radicals, and that iron-oxo species with electron-deficient porphyrins are more powerful oxidants in the electrophilic oxidation of organic substrates (Scheme 7).

Since the thiolate axial ligand in CYP 450 is believed to play a significant role in dioxygen activation and oxygen atom transfer reactions,[28–33,89,90] the effects of axial ligands bound *trans* to the iron-oxo moiety have also been investigated in various oxygenation reactions with iron(IV)-oxo porphyrin π-cation radical complexes bearing different axial ligands.[91–96] Gross and Nimri reported a pronounced axial ligand effect on the epoxidation of olefins by $(TMP)^{+\bullet}Fe^{IV}(O)(X)$, in which $(TMP)^{+\bullet}Fe^{IV}(O)(X)$ complexes bearing ligating anionic ligands (X = F^{-}, Cl^{-}, $CH_3CO_2^{-}$) showed a greater reactivity than those bearing nonligating anions (X = $CF_3SO_3^{-}$ and ClO_4^{-}) in the epoxidation of styrenes.[82] Subsequently, Nam and coworkers demonstrated that iron(IV)-oxo porphyrin π-cation radicals bearing



Scheme 7. Porphyrin ligand effect on the oxidizing power of iron(IV)-oxo porphyrin π-cation radicals in oxygenation reactions.[14,85]



Scheme 8. Axial ligand effects on the reactivities of iron(IV)-oxo porphyrin π-cation radicals.[97]

different axial ligands such as chloride and acetonitrile, $(TPFPP)^{+\bullet}Fe^{IV}(O)(Cl)$ (**8**) and $(TPFPP)^{+\bullet}Fe^{IV}(O)(NCCH_3)$ (**9**) [TPFPP = *meso*-tetrakis(pentafluorophenyl) porphyrin] (Scheme 8), exhibit diverse reactivity patterns, such as in the selectivity of *cis*- versus *trans*-olefins (reaction *a*) and of styrene versus *para*-substituted styrenes (reaction *b*) in olefin epoxidation, the oxidizing power in alkane C–H activation (reaction *c*), the kinetic isotope effect (reaction *d*), the regioselectivity of aromatic ring oxidation versus C–H hydroxylation in ethylbenzene (reaction *e*) and of C=C epoxidation versus C–H hydroxylation (reaction *f*) in olefin oxygenation.[14,97] These results indicated that the axial ligands control not only the oxidizing power of the iron-oxo moiety but also the stereo- and regioselectivity change in substrate oxygenation reactions. The results further demonstrated that iron(IV)-oxo porphyrin π-cation radicals can exhibit diverse reactivity patterns under different circumstances, suggesting that one oxidant, not multiple oxidants, is involved in oxygenation reactions.[53–56] Very recently, theoretical calculations provided plausible explanations for the role of axial ligands in the change of the regioselectivity of aliphatic versus aromatic hydroxylation in ethylbenzene hydroxylation (reaction *e*)[98]; the change of the regioselectivity is proposed as a result of differences in orbital interactions between the axial ligand and the iron-oxo porphyrin system.

The effects of axial ligands on the reactivities of iron(IV)-oxo porphyrin π-cation radicals have also been studied with $[(TMP)^{+\bullet}Fe^{IV}(O)(para\text{-Y-PyO})]^{+}$ bearing *para*-substituted pyridine *N*-oxides (*para*-Y-PyO, Y = OCH_3, CH_3, H, Cl) as axial ligands in various oxygenation reactions, such as olefin epoxidation,

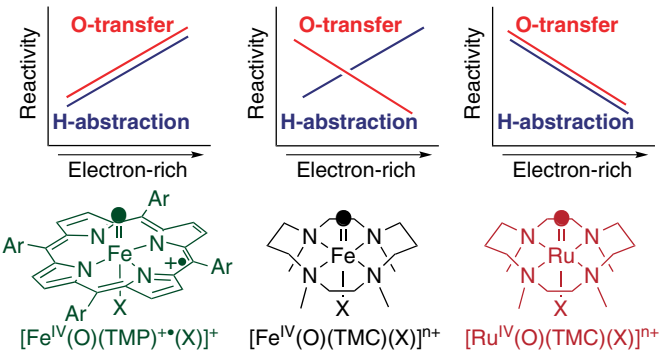


Figure 3. Schematic drawings showing the axial ligand effects on the reactivities of $[Fe(IV)(O)(TMP)^{+\bullet}(PyO)]^{+}$ (left), $[Fe(IV)(O)(TMC)(X)]^{n+}$ (middle), and $[Ru(IV)(O)(TMC)(X)]^{n+}$ (right) in oxo-transfer (red line) and H-atom abstraction (blue line) reactions.[99]

aromatic hydroxylation, alcohol oxidation, and alkane hydroxylation.[99] In all of the reactions, the reactivities of the iron-oxo porphyrin intermediate were found to depend on the axial ligands, giving negative Hammett ρ values of $-1.4 \sim -2.7$ when the reaction rates were plotted against σ_ρ of the substituents of *para*-Y-PyO. These results, as well as previous ones on the effect of anionic ligands,[82,97] show that iron(IV)-oxo porphyrin π-cation radicals bearing electron-donating axial ligands are more reactive in both oxo-transfer and hydrogen-atom abstraction reactions (Figure 3, left). Since iron(IV)-oxo porphyrin π-cation radicals are electrophilic species, the observed negative Hammett ρ values are counterintuitive. Thus, theoretical calculations of anionic and neutral ligands were attempted to elucidate the counterintuitive experimental findings.[99] In the case of anionic ligands, as the ligand becomes a better electron donor, it strengthens the FeO–H bond and enhances thereby H-abstraction activity. In addition, it weakens the Fe=O bond and encourages thereby oxo-transfer reactivity. Both are Bell–Evans–Polanyi effects.[100–102] However, in a series of neutral ligands like *para*-Y-PyO, there is a relatively weak trend that appears to originate in two-state reactivity (TSR).[19] This combination of experimental and theoretical studies provided rationales that shed light on the factors that control the reactivity patterns of iron(IV)-oxo porphyrin π-cation radicals in oxidation reactions either by TSR or by basicity of the iron-oxo reagent.[99]

As shown in Figure 3, the axial ligand effects have also been investigated systematically in nonheme iron(IV)- and ruthenium(IV)-oxo systems.[103–106] For example, the reactivity of a nonheme iron(IV)-oxo complex bearing different axial ligands, $[Fe(IV)(O)(TMC)(X)]^{n+}$ (TMC = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane; X = CH_3CN, $CF_3CO_2^-$, N_3^-, and RS^-), in oxo-transfer to PPh_3 and hydrogen atom abstraction from phenol O–H and alkylaromatic C–H bonds is

affected by the nature of anionic axial ligands (X^-) in opposite ways, depending on the reaction types (Figure 3, middle).[103,104] As can be seen in Figure 3 (middle), oxo-transfer reactivity correlates with the electrophilicity of the nonheme iron(IV) complex and is enhanced by the electron-withdrawing ligand, whereas H-atom abstraction reactivity follows an opposite trend and is enhanced by the electron-donating ligand. This dichotomy was theoretically interpreted based on the fact that nonheme iron(IV)-oxo reagents possess two close-lying spin states: a ground state with a triplet spin state (T) and a low-lying quintet spin state (Q).[104] As such, the inverted reactivity in H-atom abstraction was ascribed to the increased contribution of the more reactive quintet state (such as blending of the triplet and quintet states or faster spin crossover for the better donor ligand).[103,105,106] By contrast, in the analogous Ru(IV)-oxo complexes, $[Ru(IV)(O)(TMC)(X)]^{n+}$ (Figure 3, right), where the ground state is triplet and the quintet state is high-lying, it was observed that both reaction types were enhanced by electron-withdrawing ligands, in line with the increased electrophilicity of the Ru(IV)-oxo reagent.[106] Hence, the electrophilic reactivity trend in the nonheme Ru(IV)-oxo complexes was shown to be an outcome of a single-spin-state reactivity, which is quite different from the nonheme iron-oxo reagent that proceeds via TSR.[20,103,105]

Since the electron-donating property of the axial-thiolate ligand in CYP 450 is believed to be responsible for the strong oxidizing power of CYP 450 in the activation of C–H bonds,[28,89,90] continued extensive research is in progress to elucidate the axial ligand effects on the chemical and physical properties of iron(IV)-oxo intermediates in heme enzymes and the biomimetic heme and nonheme iron-oxo complexes.

III. Theoretical Modeling of CYP 450 Properties and Reactivities in Oxygenation Reactions

In recent years computational chemistry resources have improved significantly, and nowadays relatively large chemical systems (up to about 200 atoms) can be calculated with relative accuracy. As a consequence of that, there has been a substantial increase in computational studies focused on biomimetic and enzymatic systems. Many of these theoretical studies investigated the structure and function of heme enzymes. In this work, we will restrict ourselves to heme-based monoxygenase enzymes and biomimetics, and in particular focus on the mechanisms of substrate activation by their active oxidant.

As described in detail above, CYP 450s are heme-based monoxygenases that react with substrates efficiently. The reactions catalyzed by them include aliphatic C–H hydroxylation, C=C double bond epoxidation, aromatic C–H hydroxylation, sulfoxidation, dehydrogenation, and *N*-dealkylation.[5,11–13] In many substrates,

therefore, competing reaction mechanisms are possible, with multiple products formed; thus, the nature of the environment in the active site, such as the substrate-binding topology, plays in many cases a key role in determining the regioselectivity of a reaction.[11–13] By using combined experimental and theoretical modeling, mechanisms have been established for most of these reactions, which we will discuss in the following. Before discussing the reactivity patterns of CYP 450s in detail, let us first examine the active oxidant and its electronic properties and how these have an effect on its reactivity patterns.

There are many closely related heme enzymes, such as peroxidases and catalases, which have different functions and properties. Although their active site shows similarities to CYP 450s, including an iron(IV)-oxo species in the catalytic cycle, we will not look at these systems in depth. Studies on the mechanism and function of peroxidases and catalases have been reviewed elsewhere and therefore will not be dealt with in great detail here.[108–110]

A. Compound I

It is generally accepted that compound I (Cpd I) is the active species of CYP 450 that performs substrate monoxygenation, although there have been suggestions of alternative oxidants such as Cpd 0, which we will discuss later in this work. Cpd I of CYP 450 is elusive, but indirect experimental evidence through product distributions, kinetic isotope effects, and low-pressure mass-spectrometric studies has shown an iron(IV)-oxo porphyrin cation radical species to be the most likely candidate.[49,50,111] Further extensive theoretical modeling has made predictions on its electronic and spectroscopic properties, and confirmed it to be the most likely oxidant of CYP 450 enzymes. In this subsection we will describe the electronic properties of Cpd I and in particular the effect of the ligands on its chemical properties. Studies have been reported of many different Cpd I analogs, which essentially differ in the nature of the axial ligand used. To highlight the axial ligand used in the model, we will designate it in parentheses after Cpd I, i.e. Cpd I(SH^-) is a Cpd I mimic with SH^- in the axial ligand position.

Figure 4 displays the high-lying occupied and low-lying virtual molecular orbitals of [Fe^{IV}=O($Por^{+\bullet}$)Cl] or Cpd I(Cl^-), whereby the heme is abbreviated to iron(II) protoporphyrin IX and all side chains replaced by hydrogen atoms. Replacement of the axial ligand with another anionic ligand gives molecular orbitals with very similar shapes and energies. In this system the axial ligand is chloride, which is isoelectronic to thiolate (SH^-) and has been shown to produce similar electronic properties and molecular orbitals.[112] Experimental studies on biomimetic iron(IV)-oxo porphyrin complexes usually have trimethylphenyl or related groups on the *meso*-position (see Scheme 7).[14,15,104,113–115] Recent DFT

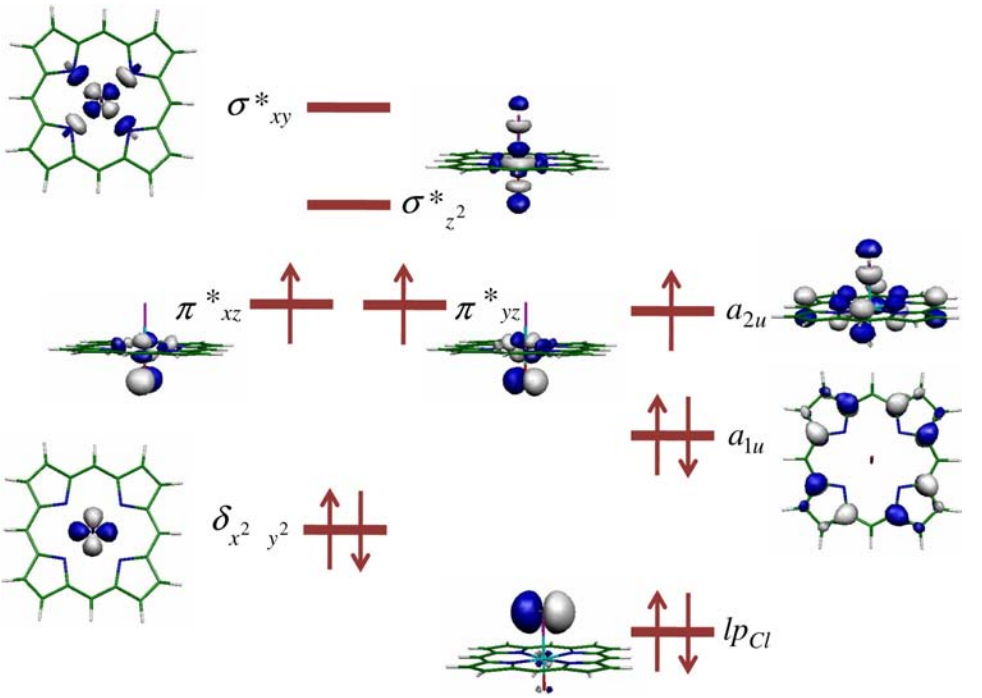

Figure 4. High-lying occupied and low-lying virtual orbitals of Cpd I(Cl^-).

studies with 2,6-dichlorophenyl groups on the four *meso*-positions of the porphyrin (TDCPP) implicated no change in the orbital occupation due to *meso*-substitution.[116] Although the stretch vibration for the Fe–O bond (ν_{Fe-O}) is decreased by 8 cm^{-1} upon addition of *meso*-substituents, as a matter of fact the bond distances are the same with respect to the unsubstituted porphyrin. However, the charge of the *meso*-carbon decreases from $Q = 0.21$ for the unsubstituted porphyrin to $Q = 0.09$ for TDCPP, which affects substrate binding.

The key molecular orbitals of Cpd I are divided into a set of metal-based 3*d* orbitals (left-hand side of Figure 4) and some high-lying heme- and ligand-based orbitals (right-hand side of Figure 4).[19,117,118] The metal 3*d*-type orbitals split into a nonbonding orbital (δ_{x2-y2}), a set of π^*_{FeO} orbitals (π^*_{xz} and π^*_{yz}) and a pair of σ^* orbitals (σ^*_{xy} and σ^*_{z2}). The lowest-lying of those is the nonbonding δ_{x2-y2} orbital, which, due to the symmetry in the heme ligand, cannot form favorable orbital interactions and is doubly occupied in Cpd I. Higher in energy are the two π^*_{FeO} antibonding orbitals built from $3d_{xz,yz}$ atomic orbitals on Fe with $2p_{x,y}$ on oxygen π^*_{xz} and π^*_{yz}, which are singly occupied in Cpd I. Two virtual metal-type orbitals in Cpd I are for the σ^* interactions of the metal with the porphyrin macrocycle (σ^*_{xy}) and for the metal with its distal and axial ligands (σ^*_{z2}). Thus, due to the

occupation of the metal 3*d*-type orbitals with four electrons, the oxidation state is Fe(IV) in Cpd I. The heme ligand has many π^*-type orbitals, and two of them are shown in Figure 4, namely the ones that in D_{4h} symmetry have the labels a_{1u} and a_{2u}.[117,119–122] The former is doubly occupied in Cpd I and although the a_{2u} orbital is expected at an energy similar to that for the a_{1u} orbital, in fact in Cpd I it is much higher in energy due to mixing of the a_{2u} orbital with a π orbital on the axial ligand.[123,124] Thus, the a_{2u} orbital is a mixed a_{2u} and π_{Cl} orbital in Cpd I(Cl^-) and is raised in energy, and as a consequence is also singly occupied.[119] Thiolate ligation has a similar effect, and also mixing of the a_{2u} and π_S orbital destabilizes the singly occupied orbital, although it is considerably smaller in peroxidase Cpd I models where an imidazole (ImH) group of a neutral histidine ligand binds to the axial position. Due to the fact that the a_{2u} and π^*_{FeO} orbitals are close in energy and the electrons in them interact little, Cpd I can exist in an overall quartet spin state or an overall doublet spin state, both with occupation $\delta_{x2-y2}^2\ \pi^*_{xz}{}^1\ \pi^*_{yz}{}^1\ a_{1u}{}^2\ a_{2u}{}^1$. As will be described in the next subsection, these two spin states will create TSR patterns on competing spin state surfaces.[63]

In many of the valence and virtual orbitals in Cpd I, the ligand *trans* to the oxo group, i.e. the axial ligand, plays a key role that determines its stability and electrophilicity.[125,126] For instance, the a_{2u} orbital mixes strongly with a lone-pair orbital on the axial ligand and hence is destabilized. As a consequence of these ligand interactions, the energies of the valence orbitals and also the optimized geometries vary, depending on the chosen model. Figure 5 depicts a selection of optimized geometries of different Cpd I systems with a variable axial ligand: Cpd

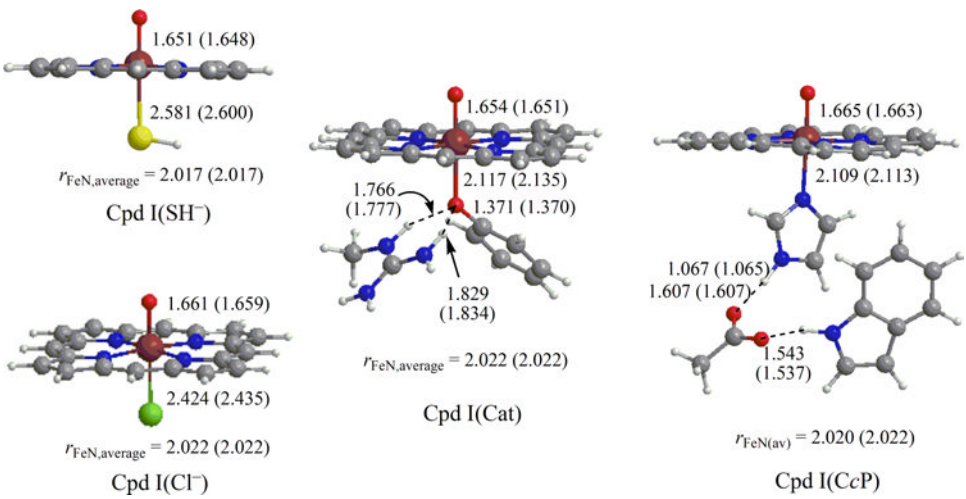

Figure 5. Optimized geometries of Cpd I models of P450, catalase, cytochrome *c* peroxidase, and a biomimetic iron(IV)-oxo porphyrin cation radical. Data taken from Refs. 127–131.

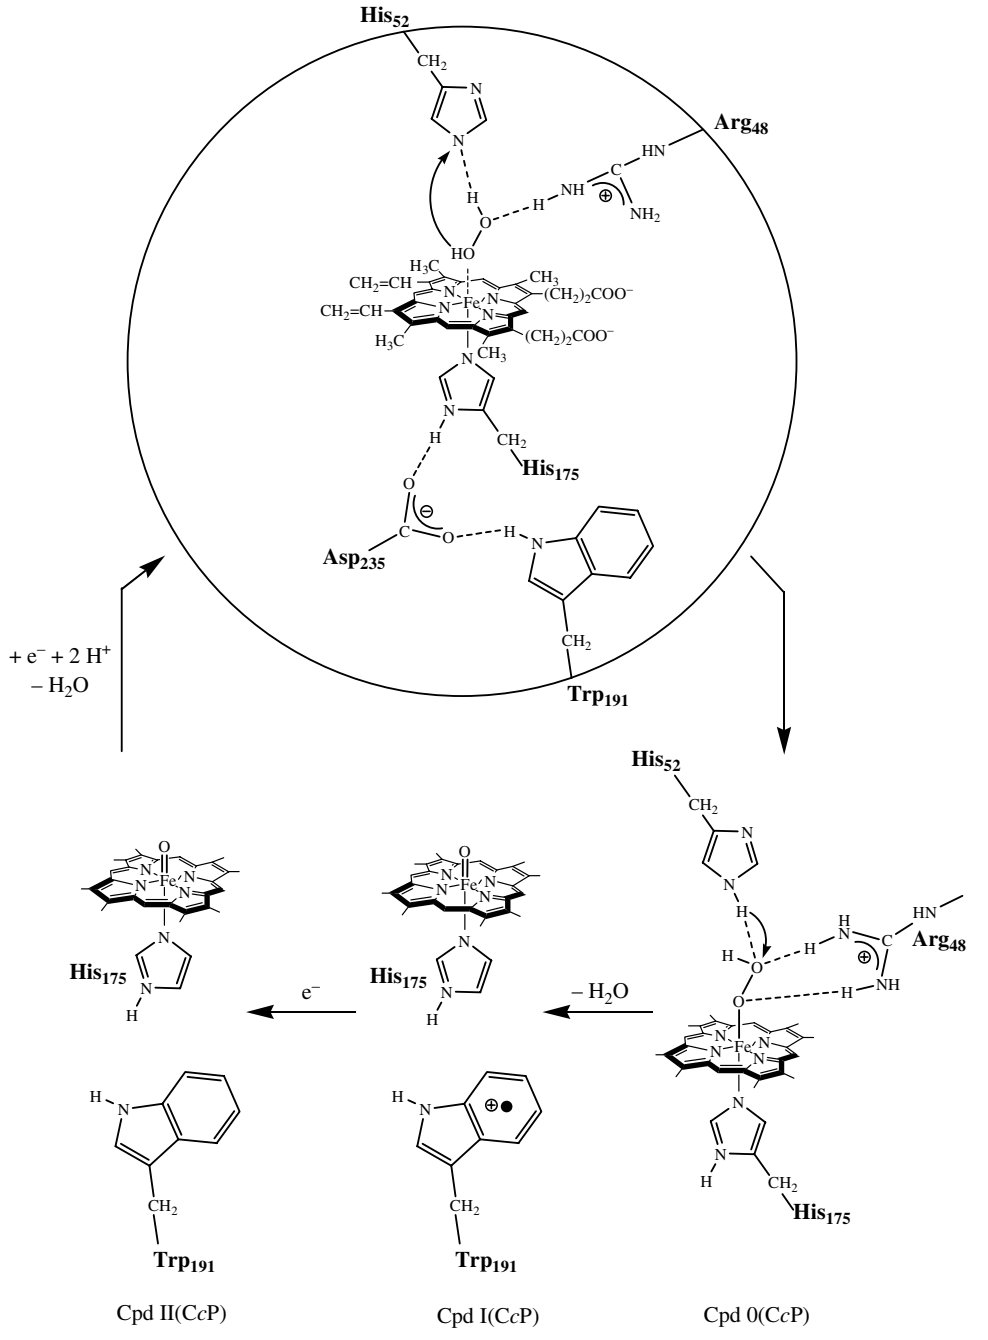
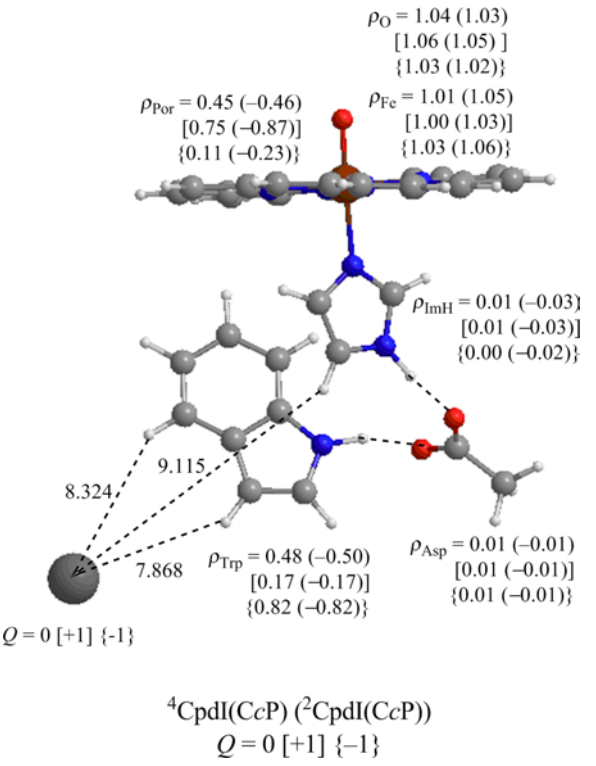
I(SH^-),[127] Cpd I(Cl^-),[112] Cpd I(Cat),[128] and Cpd I(C*c*P).[129–131] The latter two structures are mimics of the iron(IV)-oxo species of catalase and cytochrome *c* peroxidase (C*c*P) enzymes. In catalase a tyrosinate ligand binds in the axial ligand position that is held by hydrogen-bonding interactions with an arginine residue. In peroxidases, such as C*c*P, an axial histidine binds to the metal, which is involved in a triad of hydrogen-bonding interactions with a neighboring aspartic acid side chain that bridges also with a tryptophan group. This unique system has a tryptophan radical rather than a heme-based radical; however, addition of a point charge ($Q = +1$) at a distance of about 8 Å from the tryptophan group in the K^+ binding loop changed the system to a porphyrin radical instead.[129–132] Optimized geometries give only minor differences in the strength of the Fe–O bond, so that it does not appear to matter whether a neutral or anionic ligand binds to the metal in the axial position. This does not change when the axial ligand is replaced by one of the many other axial ligands tested so far.

The catalytic cycle of peroxidase enzymes is shown in Scheme 9 with C*c*P as an example. Thus, in C*c*P the heme is bound to an axial histidine residue (of His_{175}) that is part of a hydrogen-bonded triad with the acetic acid group of Asp_{235} and a proton from Trp_{191}. On the distal side several proton sources can be found, namely His_{52} and Arg_{48}. Hydrogen peroxide binds to the distal side, and the imidazole group of His_{52} abstracts one of its protons to give an Fe(III)-hydroperoxo species, i.e. Cpd 0. A subsequent proton transfer gives water and an Fe(IV)-oxo species, similarly to the catalytic cycle of CYP 450 shown above. This species abstracts an electron to give Cpd II, which is involved in the further reduction of the oxo group to a water molecule.

A closely related enzyme with a very similar active site to C*c*P is ascorbate peroxidase (APX), but despite its close resemblance to C*c*P in Cpd I(APX) the porphyrin is a cation radical and the tryptophan group in the axial binding site is neutral.[133] Further studies on the difference between Cpd I(APX) and Cpd I(C*c*P) with QM/MM methods revealed that the induced electric field due to the protein is responsible for the difference in orbital occupation: the electron affinity of the tryptophan and heme groups are influenced by perturbations of the protein and change Cpd I from [Fe^{IV}=O(Por)His---$Trp^{+\bullet}$] in C*c*P to [Fe^{IV}=O($Por^{+\bullet}$)His---Trp] in APX.[134] Indeed, DFT calculations on an active site model of Cpd I(C*c*P) with an additional point charge in the K^+ binding position gave a dramatic change in orbital occupation and hence electron distributions (Scheme 10).[128] Thus, without the point charge the group spin densities indicate a mixture between porphyrin cation radical and tryptophan radical, as also highlighted by Siegbahn and coworkers in earlier studies.[134] However, a positive charge in the K^+ binding site position changed the group spin densities and created a situation with a porphyrin cation radical and a closed shell tryptophan ($Por^{+\bullet}$ Trp). By contrast, the opposite



Scheme 9. Catalytic cycle of peroxidases, such as C*c*P.



Scheme 10. Group spin densities of Cpd I(C*c*P) in the gas phase and with a point charge added.

was found with a negative point charge, where a tryptophan radical was created (Por Trp$^{\bullet}$). These studies support experimental work[135,136] and have confirmed a strong electronic change to the active species upon the addition of a point charge at a distance of almost 10 Å from the heme.

The differences in chemical properties between CYP 450s, heme peroxidases, and catalases were assigned to the axial ligand bound to the iron-heme, which is a cysteinate residue in CYP 450s, a histidine in peroxidases and a phenolate group of a tyrosine residue in catalases.[134,137] It was reasoned that cysteinate prompts a push effect of electrons, whereas histidine withdraws electrons from the active center and thereby changes the electronegativity of the iron(IV)-oxo oxidant. Quantum-chemical calculations have established two factors contributing to the push or pull effect of the axial ligand: (1) a quantum-chemical factor (ΔE_{QM}) due to orbital mixing between ligand and metal, and (2) an electric field effect (ΔE_{field}) from electrostatic interactions between the negatively charged ligand and the metal.[31] Figure 6 displays the estimated values of ΔE_{QM} and ΔE_{field}

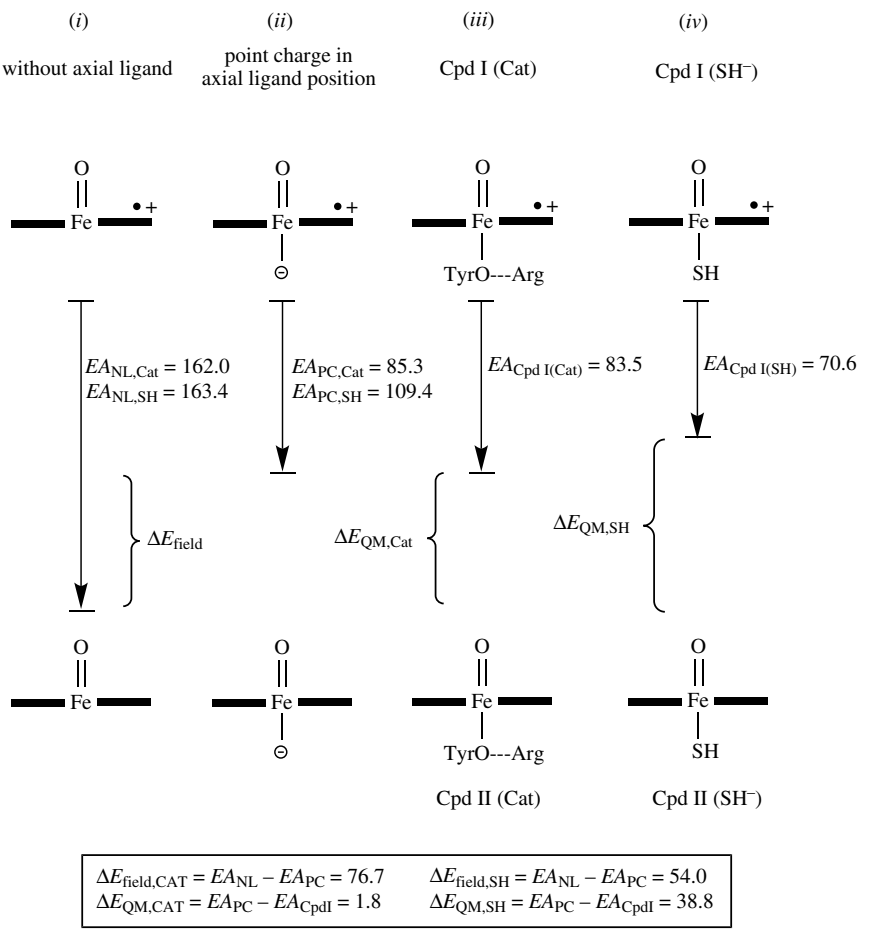


Figure 6. Quantum-chemical estimate of the push effect of anionic ligands on the iron(IV)-oxo moiety as calculated for Cpd I(Cat) and Cpd I(SH⁻), with values in kcal mol^{-1}.

for Cpd I(SH⁻) and Cpd I(Cat).[31,138] The electron affinity of Cpd I ($EA_{\text{Cpd I}}$) is calculated for Cpd I(SH⁻) and Cpd I(Cat). Subsequently, the ligand is removed from both systems and a single-point calculation of Cpd I and Cpd II provides EA_{NL}, the electron affinity of the iron(IV)-oxo porphyrin complex without ligand. Finally, the axial ligand of Cpd I and of Cpd II are replaced by a point charge, and single-point calculations give EA_{PC}. Subsequently, using the calculated values of EA_{NL}, EA_{PC}, and $EA_{\text{Cpd I}}$, the contributions of the field effect (ΔE_{field}) and the QM effect (ΔE_{QM}) are estimated (Figure 6). As follows, in Cpd I(Cat) the dominant contribution is the field effect, primarily because the distance between the ligand and the metal is small: $r_{\text{Fe–OPh}} = 2.117$ Å in ^{4}Cpd I(Cat), while $r_{\text{Fe–SH}} = 2.581$ Å in Cpd I(SH⁻). On the other hand, Cpd I(SH⁻) has a much larger QM effect due

to mixing of the a_{2u} orbital with a π_S orbital, which is much less when a tyrosinate group binds in the axial ligand position. As a consequence of the differences in ΔE_{field} and ΔE_{QM} between Cpd I(Cat) and Cpd I(SH^-), there is a 14.3 kcal mol^{-1} larger push effect in the thiolate ligated system, which will affect the electrophilicity of the oxo group.

DFT calculations on Cpd I(SH^-) that took environmental effects into consideration, such as a dielectric constant or hydrogen-bonding interactions toward the thiolate by additional ammonia molecules in the model, showed a shift of group spin densities away from the thiolate ligand onto the porphyrin macrocycle, as indicated in Figure 7.[124,139] Thus, the a_{2u} orbital is described as a mixture of two valence bond (VB) states, |a⟩ and |b⟩; |a⟩ reflects an Fe^{IV}=O(Por)($SH^{\bullet}$) configuration, whereas |b⟩ is an Fe^{IV}=O($Por^{+\bullet}$)(SH^-) state. Environmental effects, such as through

hydrogen-bonding interactions, change the charge of the thiolate ligand and make the system more[b)]-like.

To establish the electronic configuration of Cpd I of CYP 450 in its native environment, QM/MM calculations were performed on the complete enzyme with the active site in the QM region and the rest of the protein with solvent in the MM layer.[140] Figure 7(b) displays results of comparative QM/MM and gas phase DFT calculations on CYP 450_{cam} with three different Cpd I models deviating in the description of the axial ligand (SR) ranging from the smallest system SH^- via SCH_3^- to a full description of cysteinate and its neighboring peptide groups (SR_3). Only results for the quartet spin state structures are given in Figure 7(b), since the doublet spin data follow the same trends. The optimized geometries are all very much alike and the only differences obtained concern the Fe–S distance which is somewhat elongated in the gas phase models. The group spin densities give dramatic changes from a dominant thiolate-based radical in the gas phase to a porphyrin radical in an enzyme-mimicked environment. For the description of Cpd I of CYP 450, it is important, therefore, to take environmental perturbations into consideration since the gas phase distorts the orbital contributions. Further QM/MM calculations of Harvey and coworkers[141] on a selection of Cpd I structures of various CYP 450 isoforms showed only minor fluctuations in the electronic description of Cpd I, so that the actual size and shape of the protein are expected to have only minor effects.

B. Two-State Reactivity

As discussed above, the iron(IV)-oxo oxidant has close-lying doublet and quartet spin states with the same orbital occupation. Reaction mechanisms with substrates, as a consequence, proceed on both spin state surfaces, but not necessarily with the same barriers.[14–16,63] This has led to the experimental suggestion that two oxidants are active in the reaction mechanism, although it may be these two spin states that masquerade as two different oxidants. Figure 8 shows the potential energy profile of a typical TSR reaction starting from Cpd I(SH^-) for the aliphatic hydroxylation of propene. In the past this mechanism was shown for a range of different substrates irrespective of the axial ligand.[142–147] Thus, Cpd I is a chameleonic oxidant that behaves as multiple oxidizing species, but in fact is the same oxidant in a different spin state.[19] As a matter of fact, this appears a common phenomenon in bioinorganic chemistry that CYP 450s share with mononuclear nonheme iron(IV)-oxo complexes.[148–150]

Generally, hydroxylation reactions proceed with an initial hydrogen abstraction barrier ($\mathbf{TS}_H$) to form an iron-hydroxo complex ($\mathbf{I}_H$). Subsequently, a radical rebound step via a rebound transition state ($\mathbf{TS}_{reb}$) gives alcohol product complexes ($\mathbf{P}_H$).

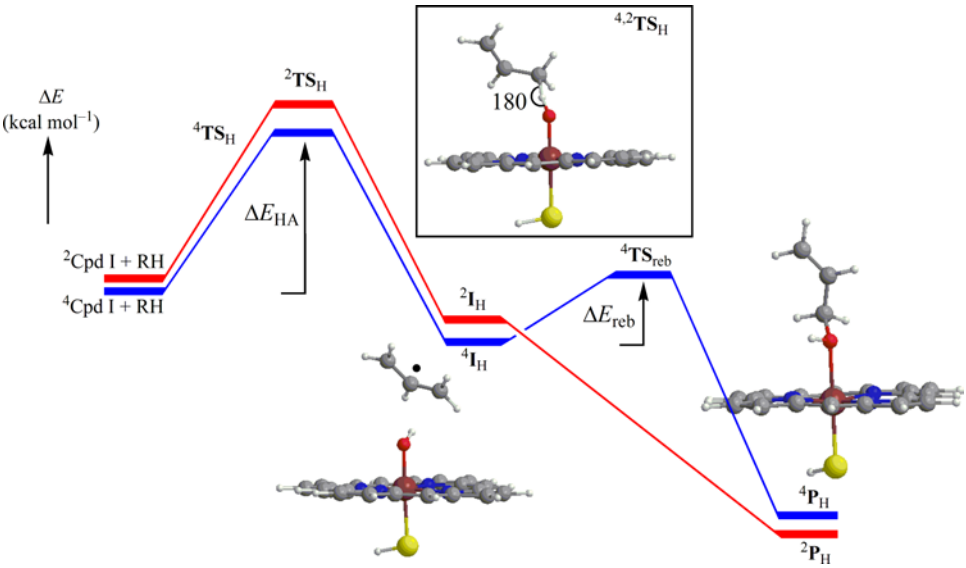

Figure 8. TSR potential energy profile for propene hydroxylation by Cpd I(SH^-).

On the doublet and quartet spin state surfaces, usually similar aliphatic hydrogen abstraction barriers and energies are encountered due to the same electron transfer processes in the reaction, namely electron donation into the a_{2u} orbital. As a result, $^4\mathbf{I}_H$ and $^2\mathbf{I}_H$ have the same orbital occupation, namely $\delta_{x2-y2}{}^2\,\pi^*_{xz}{}^1\,\pi^*_{yz}{}^1\,a_{1u}{}^2\,a_{2u}{}^2\,\phi_R{}^1$, and hence are degenerate. The radical rebound step, by contrast, undergoes different electron transfer processes. Namely, in the low spin state an electron is transferred from the substrate into the π^*_{xz} orbital, whereas in the high spin state it moves into a higher-lying σ^*_{z2} orbital.[151] Consequently, the high-spin process encounters a significant rebound barrier, whereas on the low-spin surface a virtually barrierless transition leads to alcohol products. The difference in rebound barrier between the high-spin and low-spin surfaces influences rearrangement reactions and product distributions. For instance, it was shown, using *trans*-2-phenylmethylcyclopropane as a radical-clock substrate, that rearrangement reactions are possible only on the quartet spin state surface and not on the doublet one, which influences product distributions as well as kinetic isotope effects.[152,153] There are cases where one of the two spin state surfaces is stabilized with respect to the other so that single-state reactivity (SSR) is encountered instead. Thus, aromatic hydroxylation generally proceeds on a dominant low-spin surface, whereas sulfoxidation does so on a high-spin surface. In the following subsections, therefore, we will discuss the various substrate monoxygenation reactions separately and discuss the differences and comparisons.

C. Aliphatic C–H Activation by Cpd I of CYP 450

As shown in the previous subsection, Cpd I reacts with aliphatic substrates via an initial hydrogen abstraction reaction, leading to a radical intermediate followed by a radical rebound of the hydroxyl group to the substrate rest group to form alcohol products. Thermodynamically, the hydrogen abstraction from substrate RH by Cpd I or [Fe^{IV}=O($Por^{+\bullet}$)L], with L the axial ligand to form the intermediate complex $\mathbf{I}_H$, has an exothermicity (ΔH_{HA}) dependent on the energies of reactants and products in Eq. 2.

$$[Fe^{IV}=O(Por^{+\bullet})L] + RH \rightarrow [Fe^{IV}(OH)(Por)L] + R^{\bullet} + \Delta H_{HA}. \quad (2)$$

The reaction enthalpy (ΔH_{HA}) for reaction 2 can be described as a function of the bond dissociation energy (BDE) of the C–H bond of the substrate and the BDE_{O-H} for the O–H bond of [Fe^{IV}(OH)(Por)L] through combination of Eqs. 2 and 3 to get Eq. 4.

$$RH \rightarrow R^{\bullet} + H^{\bullet} + BDE_{C-H}, \quad (3)$$

$$\Delta H_{HA} = BDE_{C-H} - BDE_{O-H}. \quad (4)$$

Since all hydrogen atom abstraction reactions using Cpd I(SH^-) have the same BDE_{O-H}, this means that the reaction exothermicity for formation of the intermediate complexes ($^{4,2}\mathbf{I}$) in Figure 8 should correlate linearly with BDE_{C-H} for a series of substrates RH. This correlation is shown in Figure 9 and indeed fits a straight line in agreement with Eq. 4. The standard deviation displayed in that figure is

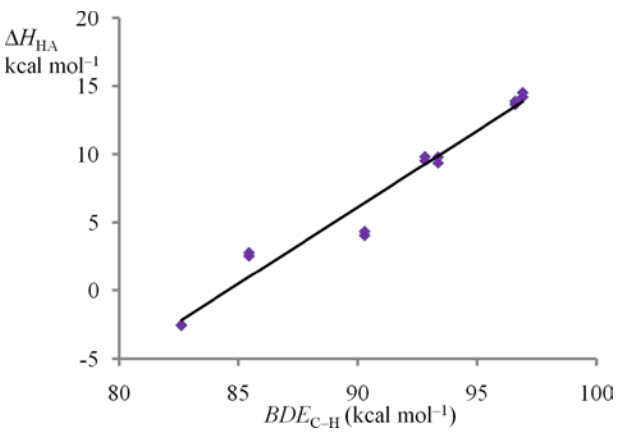

Figure 9. Correlation of the reaction energy of hydrogen abstraction (ΔH_{HA}) with BDE_{C-H}.

small and shows that the reproducibility of DFT calculations is quite good. Moreover, it appears that DFT-calculated exothermicities are within an error of a few kcal mol^{-1}. This is much smaller than the systematic error generally reported for DFT calculations of 3–5 kcal mol^{-1} with respect to experimentally determined enthalpies.[154–156]

The hydrogen abstraction mechanism has been further generalized by a valence bond (VB) curve crossing diagram, as shown in Figure 10.[147] Thus, the reaction starts on the bottom left of the figure with the reactant geometry, where the critical VB electrons are highlighted with dots. Thus, the Fe–O bond in Cpd I is described by the pairs of $\pi_{xz,yz}$ and $\pi^*_{xz,yz}$ molecular orbitals. The bonding pair is doubly occupied, whereas the antibonding pair has two unpaired electrons spread out over the iron(IV)-oxo group due to single occupation of two π^*_{FeO} orbitals, and hence six dots are drawn next to the Fe–O bond. In addition, Cpd I has a heme cation radical due to single occupation of the a_{2u} molecular orbital. The reaction finishes with the alcohol product complexes shown on the bottom right of the figure in red, which is the result of two-electron oxidation of our reactant species and transfer of one electron into the heme (a_{2u}) and one in a π^* orbital to give the metal oxidation state Fe(III). A VB curve crossing diagram is constructed by drawing a line from the reactant geometry, which has wave function Ψ_r, and connecting it to the product geometry with excited state wave function Ψ_p*. Similarly, starting from the product complexes with wave function Ψ_p,

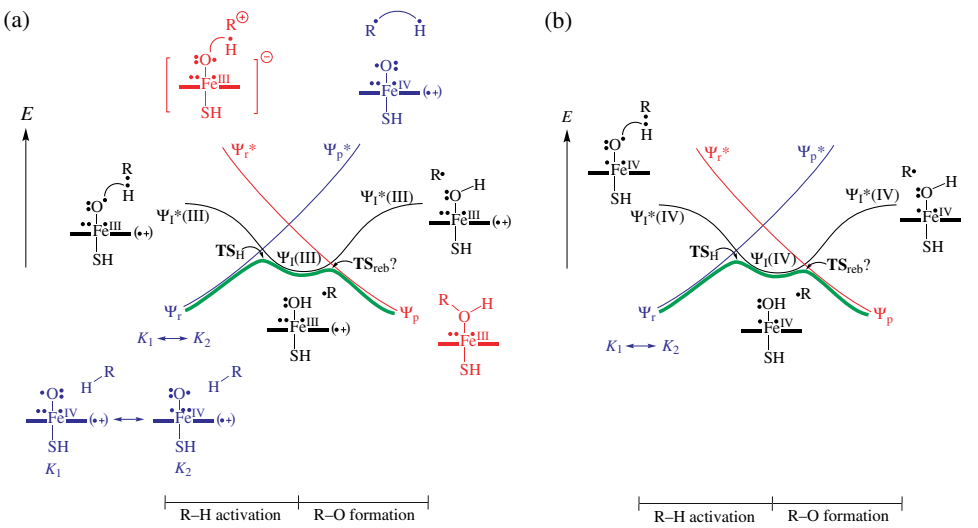

Figure 10. VB curve crossing model for the hydroxylation reaction of RH by Cpd I via an $Fe^{III}(Por^{+\bullet})(OH)$ intermediate [part (a)] or an $Fe^{IV}(Por)(OH)$ intermediate [part (b)]. Reproduced with permission from the American Chemical Society.[147]

a connection is made with the reactants via Ψ_r*. Thus, in Ψ_r* the system has the reactant geometry but the electronic configuration of the products, while for Ψ_p* it is the other way around. Crossing of these two VB curves will give rise to an avoided crossing and consequently a transition state for the reaction. Thus, a concerted reaction mechanism, such as ethylbenzene hydroxylation by iodosylbenzene, has only one barrier through the mixing of reactant and product curves.[157] However, in CYP 450 a third curve for the intermediate wave function bisects the reactant and product wave functions to give rise to two avoided crossings: one for hydrogen abstraction and one for radical rebound. This intermediate curve has either the metal in the oxidation state Fe(IV) together with a closed-shell heme, i.e. [Fe^{IV}(OH)(Por)L---R$^{\bullet}$], or the metal in the oxidation state Fe(III) combined with a cation radical on the heme to give [Fe^{III}(OH)($Por^{+\bullet}$)L---R$^{\bullet}$]. These two intermediate wave functions are identified with Ψ_I(IV) and Ψ_I(III), respectively, and give rise to the two distinctive radical intermediates in the reaction mechanism. Figure 10(a) displays the VB curve crossing mechanism that passes the Fe(III) intermediate, while the one passing the Fe(IV) intermediate is shown in Figure 10(b). Generally, gas-phase DFT calculations predict the Fe(IV) intermediates to be the lowest-lying,[146,158] but QM/MM seems to lower the Fe(III) intermediates.[140] Therefore, the relative ordering of the Fe(IV) and Fe(III) intermediates is dependent on polarized effects from, for example, the protein surroundings or through hydrogen-bonding interactions, and leads to multistate reactivity (MSR) patterns.

The intermediate curve crosses the reactant wave function and gives rise to an avoided crossing and hence a hydrogen abstraction transition state. This barrier leads to the corresponding radical intermediate but past the intermediate the wave function crosses the product wave function to give rise to a second avoided crossing and the radical rebound barrier. Thus, the VB curve crossing model explains why the reaction is stepwise via a radical intermediate. In VB terms, the hydrogen abstraction barrier ($\Delta E_H^{\ddagger}$) can be written in terms of the height of the crossing point (ΔE_c) minus the resonance energy (B):

$$\Delta E_H^{\ddagger} = \Delta E_c - B. \tag{5}$$

It was shown that the height of the crossing, in fact, is a fraction (f) of the promotion gap (G_H).[159] Since the electronic difference between the reactant configuration and the excited intermediate wave function (Ψ_I) is based on the singlet-to-triplet excitation energy of the C–H bond, this implies that the promotion gap is actually proportional to the strength of the C–H bond, i.e. the bond dissociation energy of the C–H bond (BDE_{C-H}), Eq. 6. In addition, the promotion gap contains electron transfer energies which for the Fe(IV) wave function reflect the energy

transfer from π^*_{OO} into the a_{2u} orbital, while for Fe(III) the electron transfer is into the π^*_{xz} orbital.

$$\Delta E_H^{\ddagger} = fG_H - B \propto \mathrm{BDE}_{CH}. \quad (6)$$

Indeed, DFT calculations of a series of hydrogen abstraction barriers by Cpd I(SH^-) and Cpd I(SCH_3^-) gave a linear correlation with BDE_{C-H}; one of these correlations is shown in Figure 11.[146,160] Further correction to the trend with resonance energy stabilization of the transition state structures gave the C–H bond strength D_{C-H}, which correlates perfectly with the barrier heights of C–H abstraction of nine aliphatic C–H bonds. Olsen and coworkers calculated 24 hydrogen abstraction barriers by Cpd I(SCH_3^-) and found correlations similar to those given

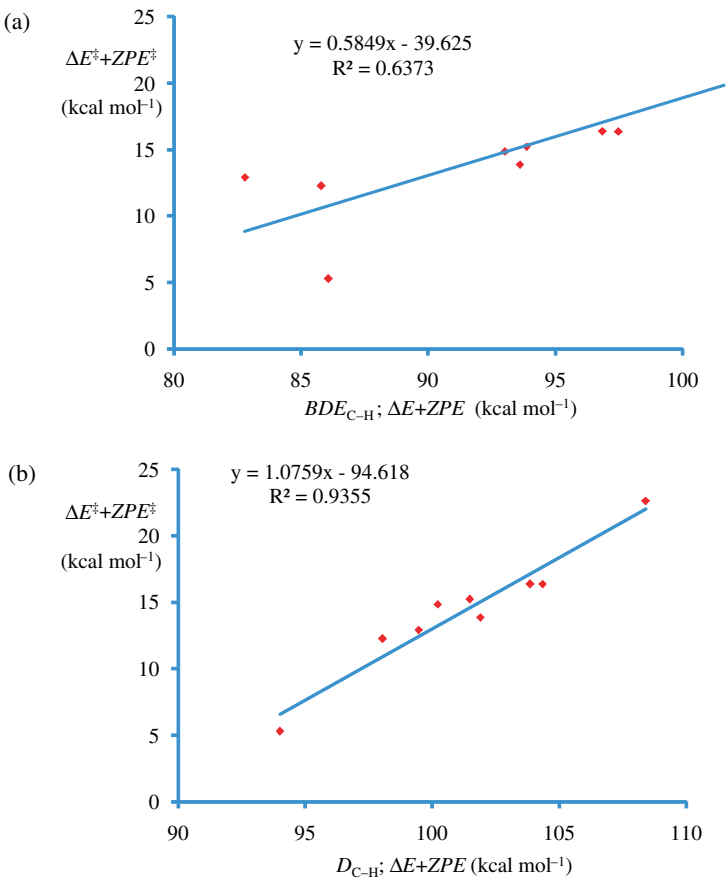

Figure 11. Correlation of the hydrogen abstraction barriers for a series of substrates with BDE_{C-H} and with D_{C-H}; data taken from Ref. 147.

in Figure 11.[160] In their paper the resonance energy is labeled "frozen BDE" and addition of this factor improves the correlation significantly. These studies confirm and rationalize experimental correlations of the logarithm of the rate constant with BDE as found for several mononuclear metal-oxo complexes.[161–164]

The subsequent step in the aliphatic hydroxylation mechanism is the radical rebound step which leads to alcohol product complexes. The general reaction for this is described by Eq. 7 for the process starting from the Fe(IV) intermediate, and by Eq. 8 for the Fe(III) intermediate. The reaction exothermicities for this reaction are ΔH_{rebIV} and ΔH_{rebIII}, respectively. Obviously, the two reactions lead to the same products, so that the overall exothermicity from Cpd I(L) and RH to form [Fe^{III}(Por)] and ROH products is identical.

$$[Fe^{IV}(OH)(Por)L] + R^{\bullet} \rightarrow [Fe^{III}(Por)] + ROH + \Delta H_{\text{rebIV}}, \quad (7)$$

$$[Fe^{III}(OH)(Por^{+\bullet})L] + R^{\bullet} \rightarrow [Fe^{III}(Por)] + ROH + \Delta H_{\text{rebIII}}. \quad (8)$$

The reaction energies given in Eqs. 7 and 8 reflect the OH transfer energies from the iron-porphyrin complexes to the radical R. Using the definition of the hydroxyl affinity (BDE_{C-OH}) as defined in Eq. 9, the reaction enthalpy for Eqs. 7 and 8 can be described in terms of differences in hydroxyl affinity between [Fe^{III}(Por)] and $R^{\bullet}$, as shown in Eqs. 10 and 11.

$$ROH \rightarrow R^{\bullet} + OH^{\bullet} + BDE_{C-OH}, \quad (9)$$

$$\Delta H_{\text{rebIV}} = BDE_{FeIV-OH} - BDE_{C-OH}, \quad (10)$$

$$\Delta H_{\text{rebIII}} = BDE_{FeIII-OH} - BDE_{C-OH}. \quad (11)$$

The overall reaction enthalpy (ΔH_r) for the reaction starting from Cpd I and substrate (RH) to give alcohol products and an Fe^{III}-porphyrin complex is therefore the sum of Eqs. 4 and 10 as given in Eq. 12:

$$\Delta H_r = \Delta H_{\text{HAIV}} + \Delta H_{\text{rebIV}} = BDE_{C-H} - BDE_{O-H} + BDE_{FeIV-OH} - BDE_{C-OH}. \quad (12)$$

For the radical rebound step, a VB curve crossing diagram was designed to explain the differences in rebound barriers between the high-spin and low-spin surfaces, as well as between the Fe^{IV} and Fe^{III} states. Figure 12 shows the VB curve crossing diagrams starting from [Fe^{IV}(OH)(Por)SH---$R^{\bullet}$], i.e. ^{4,2}**I**(IV).

As described in Eq. 6, the hydrogen abstraction barrier height ($\Delta E_H^{\ddagger}$) correlates with the excitation energy from the ground state wave function to the excitation

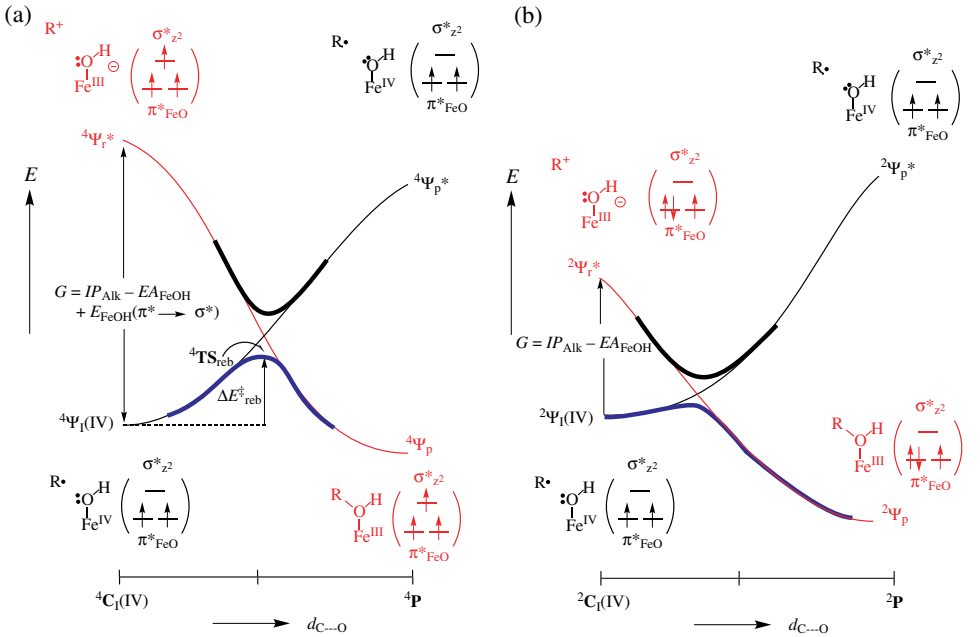

Figure 12. Rebound VB model in the high-spin (a) and low-spin (b) pathways, starting from the intermediate complexes in the Fe(IV) oxidation state. Reproduced with permission from the American Chemical Society.[147]

state wave function, G_H. The same is true for the radical rebound barrier ($\Delta E_{reb}^{\ddagger}$), which is proportional to the excitation energy from the ground state to the excitation state in the intermediate geometry, i.e. excitation from $^{4,2}\Psi_I(IV)$ to $^{4,2}\Psi_r^*$ for the Fe(IV)-type intermediates ^{4,2}**I**(IV) and from $^{4,2}\Psi_I(III)$ to $^{4,2}\Psi_r^*$ for the Fe(III)-type intermediates ^{4,2}**I**(III). Thus, ^{2}**I**(IV) has electronic configuration $\delta^2\ \pi^*_{xz}{}^1\ \pi^*_{yz}{}^1\ a_{2u}{}^2\ \phi_R{}^1$, whereas for the product complex ^{2}**P** and hence also $^2\Psi_r^*$ the configuration is $\delta^2\ \pi^*_{xz}{}^2\ \pi^*_{yz}{}^1\ a_{2u}{}^2$. In other words, the excitation energy involves ionizing the substrate rest group and reduction of the iron-hydroxo complex with one electron (EA_{FeIVOH}). The low-spin barrier will, therefore, correlate with the difference between the ionization potential of R (IP_R) and EA_{FeIVOH}:

$$\Delta E_{reb,LS}^{\ddagger} \propto IP_R - EA_{FeIVOH}. \tag{13}$$

The electron affinity of the iron-hydroxo complex leads to electron donation into the π^*_{xz} orbital to give ^{2}[Fe^{III}(OH)(Por)L]; however, excitation from $^4\Psi_I(IV)$ to $^4\Psi_r^*$ gives a quartet spin iron-hydroxo complex with occupation $\pi^*_{xz}{}^1\ \pi^*_{yz}{}^1\ \sigma^*_{z2}{}^1$. As a consequence of this, the excitation energy from $^4\Psi_I(IV)$ to $^4\Psi_r^*$ is larger than the difference between IP_R and $EA_{Fe}IV_{OH}$ by the excitation energy (E_{FeOH}) of an

electron from π^*_{xz} to σ^*_{z2}, (Eq. 14). This is the reason why a low-spin rebound is generally barrierless or small, whereas in high spin significant barriers are encountered that can cause reorganization of the radical leading to stereochemical scrambling or formation of by-products.

$$\Delta E_{\text{reb,HS}}^{\ddagger} \propto IP_{\text{R}} - EA_{\text{FeIVOH}} + E_{\text{FeOH}}(\pi^*_{xz} \rightarrow \sigma^*_{z2}). \quad (14)$$

In summary, electron transfer mechanisms, orbital occupations, and thermodynamic data explain why aliphatic hydroxylation reactions are stepwise via TSR scenarios on competing doublet and quartet spin state surfaces. Indeed, all calculated aliphatic hydroxylation reactions have so far been shown to proceed via the general mechanism shown in Figures 8 and 10. In the last few paragraphs of this subsection we will give some examples of aliphatic hydroxylation reactions studied by theoretical methods.

The first hydrogen abstraction reactions by CYP 450 model systems studied with DFT methods used methane as a substrate.[142,165,166] However, in the past 10 years, more realistic substrates have also been studied. Special emphasis always has been on camphor hydroxylation by CYP 450_{cam}, since it is the natural substrate hydroxylation reaction of this CYP 450 isozyme. Moreover, several crystal structures are available for this CYP 450 enzyme.[24,26] Initial studies used DFT methods, but later on complete enzyme studies with the QM/MM technique were reported.[145,167] Essentially, all these studies predict the same mechanistic trends that are described by the fundamental rules in this section: an initial hydrogen atom abstraction followed by a radical rebound. The regioselectivity of C^5 hydroxylation from camphor is determined by the substrate-binding site, where camphor is tightly bound and only the C^5 position approaches the heme close enough to enable hydroxylation.

Table 1 summarizes substrate hydroxylation reactions calculated with DFT or QM/MM methods for Cpd I(L).[112,133,147,160,168–181] Essentially, all calculations support the general mechanism shown in Figure 8, with a rate-determining hydrogen atom abstraction leading to an iron-hydroxo species that rebinds to the radical to give alcohol product complexes. Occasionally, however, the rebound step is replaced by *N*-dealkylation or dehydrogenation, but also in these cases the hydrogen atom abstraction is rate-determining. On average the low-spin states are below the high-spin ones by 0.9 ± 1.3 kcal mol^{-1}, irrespective of the axial ligand used. Clearly, substrate hydroxylation is a TSR phenomenon with competing spin state surfaces and reaction barriers. The close energy between $^4\mathbf{TS}_{\text{H}}$ and $^2\mathbf{TS}_{\text{H}}$ is evident from the electron transfer processes shown in Figure 10, where most substrates lead to an intermediate with the metal in the oxidation state Fe(IV). The only exceptions to this are methane hydroxylation which leads

[a]Methyl group hydroxylation
[b]Cyclopropane ring hydroxylation
[c]QM/MM result

to an Fe(III) intermediate and substrate hydroxylation studied with QM/MM methods on enzymatic systems.

Three substrates (methane, propene, and cyclohexane) have been studied with a range of different Cpd I species with variable axial ligands. Thus, a phenolate ligand (PhO^-) as appears in catalase, for instance, destabilizes hydrogen abstraction barriers by a couple of kcal mol^{-1} with respect to Cpd I(SH^-), and therefore catalase is not a likely oxidant of hydroxylation reactions.[138,170] The theoretical studies on the effect of an imidazole ligand mimicking peroxidases such as horseradish peroxidase (HRP) or cytochrome *c* peroxidase (C*c*P) give conflicting results. Methane hydroxylation by an HRP mimic gave increased barrier heights with respect to those found for Cpd I(SH^-),[170] whereas in propene hydroxylation the opposite trend was observed.[168] Studies on propene hydroxylation by Cpd I of C*c*P using the model shown above in Figure 5, which includes the hydrogen-bonded axial triad, predicted sluggish activity of substrate hydroxylation reactions.[131] This is because Cpd I(C*c*P) is essentially [Fe^{IV}=O(Por)L---$Trp^{+\bullet}$] and has no heme cation radical, like all other Cpd I species. As a consequence the electron transfer processes take place over a larger distance and the barriers are higher. Recent experimental studies on biomimetic iron(IV)-oxo porphyrin complexes with imidazole, 2-methylimidazole, and 3-fluoro-4-nitrophenolate as axial ligands showed increased cyclooctene epoxidation rate constants for imidazole and phenolate ligated complexes as compared with a chloride axial ligand.[182] However, the nature of the oxidant in all these cases is Fe^{IV}=O($Por^{+\bullet}$)L with single occupation of the a_{2u} orbital.

Cyclohexane hydroxylation was studied with four different Cpd I(L) models, where L = OH^-, CH_3COO^-, Cl^-, and $CF_3SO_3^-$, as well as with a range of *para*-substituted pyridine *N*-oxides as axial ligand.[99,172] Thus, the hydrogen abstraction barrier of cyclohexane hydroxylation by Cpd I(L) was found to correlate linearly with both the electron affinity of Cpd I(L) and the Fe–O distance in the transition states. Moreover, calculations of second-order perturbation stabilization interaction energies between the transition state and reactants showed an increase with enhanced electron-donating ability of the oxidant. Therefore, the electron-donating ability of anionic axial ligands in iron(IV)-oxo complexes controls aliphatic hydroxylation reactions. The studies with *para*-substituted pyridine *N*-oxides as axial ligands showed that as the ligand becomes a better electron donor the FeO–H bond is strengthened and the Fe=O bond weakened to give more efficient hydrogen abstraction.

So far, all these DFT and QM/MM calculations have resulted from a hydrogen atom abstraction; however, technically, a hydride transfer is also possible as the first reaction step. As shown recently by Nam, Fukuzumi, and coworkers,[183,184] iron(IV)-oxo porphyrins are able to react with substrates with weak C–H bonds

via an initial hydride abstraction (Eq. 15), with exothermicity ΔH_{HT}, rather than the commonly observed hydrogen atom transfer:

$$[Fe^{IV}{=}O(Por^{+\bullet})L] + RH \rightarrow [Fe^{III}(OH)(Por)L]^{-} + R^{+} + \Delta H_{HT}. \quad (15)$$

In analogy with Eqs. 3 and 4, the exothermicity of Eq. 15 is written as a function of the hydride affinity of Cpd I ($HA_{Cpd\ I}$), the bond dissociation energy of the C–H bond in RH (BDE_{C-H}, Eq. 3), the ionization potential of the radical rest group R (IP_R), and the electron affinity of a hydrogen atom (EA_H):

$$\Delta H_{HT} = HA_{Cpd\ I} - BDE_{C-H} + IP_R - EA_H. \quad (16)$$

In the case where hydride transfer is a much more exothermic process than hydrogen atom abstraction by Cpd I, $\Delta H_{HT} > \Delta H_{HA}$, which can be rewritten by combining Eqs. 4 and 16:

$$HA_{Cpd\ I} - BDE_{O-H} > EA_H - IP_R. \quad (17)$$

Since the difference in energy between the hydride transfer and the hydrogen atom abstraction energies is roughly the difference between EA_H and $EA_{Fe}IV_{OH}$, this means that if $IP_R < EA_{Fe}IV_{OH}$ the hydride transfer is more exothermic, whereas the hydrogen atom transfer is more exothermic for $IP_R > EA_{Fe}IV_{OH}$. Most substrate rest groups have substantially larger ionization potentials than $EA_{Fe}IV_{OH}$; however, cofactor analogs such as 10-methyl-9,10-dihydroacridine ($AcrH_2$) have a very low ionization potential and as a consequence react via hydride transfer abstraction instead of the normal hydrogen atom abstraction.[185]

DFT studies of the reaction of Cpd I(Cl^-) with $AcrH_2$ predicted a hydride transfer mechanism via very low barriers ($^{4,2}\mathbf{TS}_{H,cat}$) of 5.6 and 6.1 kcal mol^{-1} for the quartet and doublet spin state surfaces, respectively (Figure 13).[185] These barriers are much lower than the hydrogen abstraction barriers of most substrates shown in Table 1. Moreover, an alternative hydrogen atom abstraction (via $^{4}\mathbf{TS}_{H,rad}$) was calculated and found to be higher in energy by 5.5 kcal mol^{-1}. The inset of Figure 13 shows the alternative hydroxylation mechanism starting from the one-electron reduced complex of Cpd I, namely compound II or Cpd II(Cl^-). This oxidant reacts with $AcrH_2$ via significantly higher barriers; furthermore, the reaction proceeds via hydrogen atom abstraction rather than hydride transfer. These calculations, therefore, show that Cpd II(Cl^-) is a possible oxidant of weak C–H bonds, but will not be as efficient and reactive as Cpd I(Cl^-), which can react via an alternative hydride transfer mechanism. The difference in energy between the hydrogen atom abstraction barriers by Cpd I and Cpd II in Figure 13

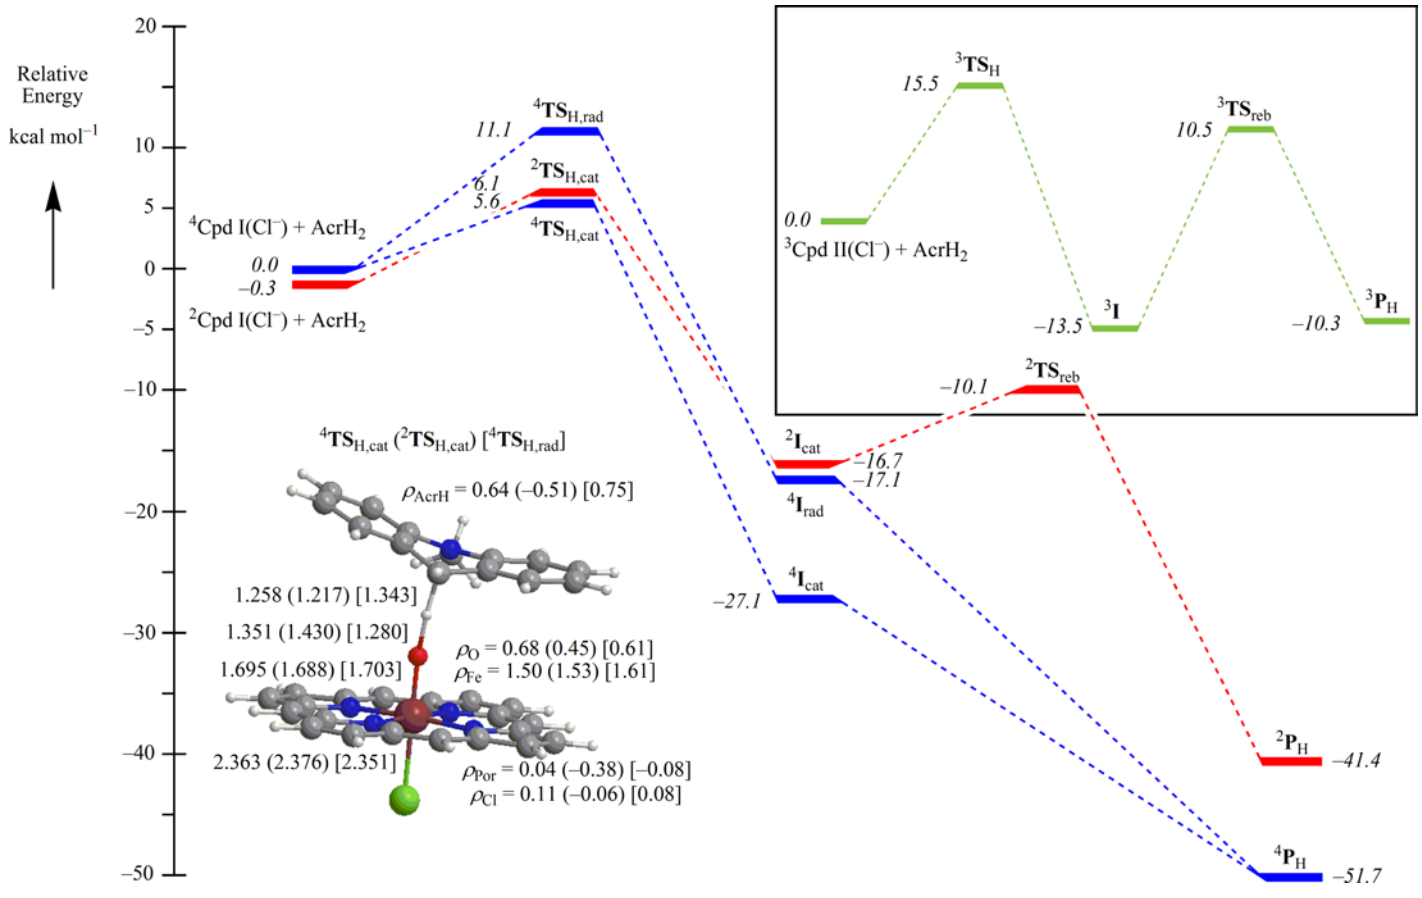

Figure 13. Potential energy profile of $AcrH_2$ hydroxylation by Cpd I(Cl^-) and Cpd II(Cl^-) as calculated by DFT. Energies are in kcal mol^{-1} relative to isolated reactants. Also shown are optimized geometries with group spin densities and bond lengths (in angstroms) of the hydrogen and hydride transfer transition states for Cpd I(Cl^-).

is 4.4 kcal mol^{-1}, which is close to the QM/MM difference of camphor hydroxylation by Cpd I and Cpd II of P450$_{cam}$.[186] This implies that the protein environment has little effect on the relative barriers and will not favor Cpd II over Cpd I. Although ^{4,2}**TS**$_{H,cat}$ appear to be transition states for a hydride transfer, in fact, looking at the group spin densities reveals that the hydride transfer is actually an initial hydrogen atom abstraction followed by a fast electron transfer prior to formation of the intermediate complex.

D. Aliphatic Hydroxylation Mechanisms with Byproduct Formation

The lifetime of the intermediate complexes (^{4,2}**I**) in the reaction mechanisms determines whether a substrate can undergo skeletal rearrangement and produce rearranged products. Experimentally, Ortiz de Montellano and Stearns[187] used bicyclo[2.1.0]pentane as a substrate to determine the lifetime of the radicals, i.e. ^{4,2}**I** in Figure 8. They measured the product ratio of un-rearranged (*U*) to rearranged (*R*) products, as well as the free radical rearrangement constant k_r (Figure 14). These studies established the lifetime of the radical: $\tau = 50$ ps. For a series of radical clock substrates, however,[53–56] it was shown that the lifetime of the radical is not realistic and the results pointed to carbocationic intermediates instead. Thus, it was suggested that radicals are not present and presumably two oxidants were active in the reaction mixture, which were assigned as ferric-hydroperoxo (Cpd 0) and Cpd I. To prove that these radical clock results are obtained through TSR patterns, a set of calculations on radical clock substrates, namely *trans*-2-phenyl-methylcyclopropane and *trans*-2-phenyl-isopropylcyclopropane, with Cpd I(SH$^-$) models were performed, and the highlights of those results are shown in Figure 15.[152,153,188]

Cpd I(SH$^-$) reacts with *trans*-2-phenylmethylcyclopropane via an initial and rate-determining hydrogen abstraction to give radical intermediates (^{4,2}**I**$_U$), as

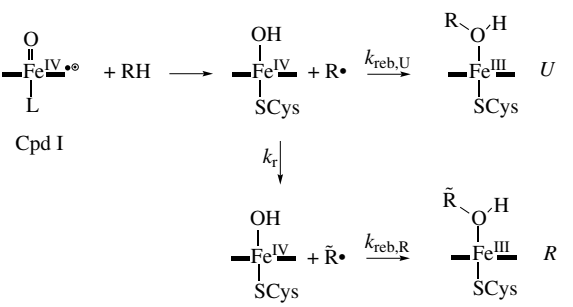

Figure 14. Reaction mechanism for formation of rearranged (*R*) and un-rearranged (*U*) products in the reaction of RH with Cpd I.

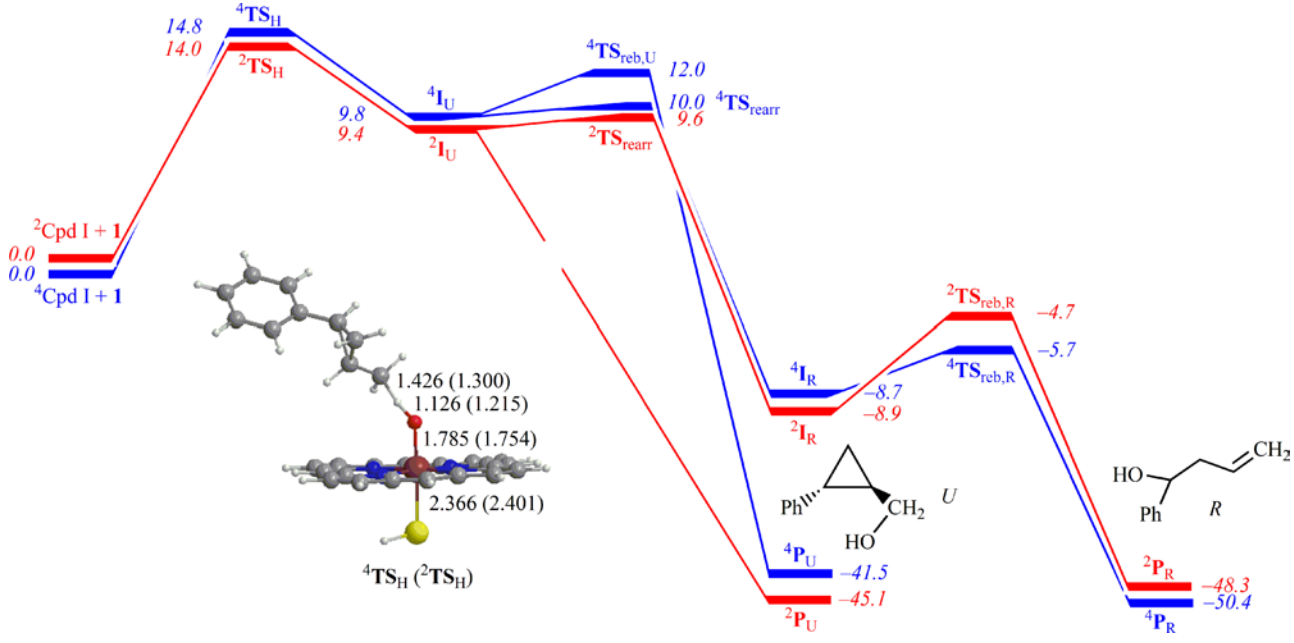

Figure 15. DFT-calculated reaction mechanism of *trans*-2-phenylmethylcyclopropane activation by Cpd I(SH^-) leading to un-rearranged (*U*) and rearranged (*R*) products. Energies in kcal mol^{-1}, with ZPE included taken from Ref. 153 and optimized geometries of hydrogen abstraction transition states from Ref. 147, with bond lengths in angstroms.

expected from the TSR discussion above. From these un-rearranged intermediates, the potential energy surface bifurcates, whereby one mechanism leads to a direct radical rebound and the formation of un-rearranged products ($^{4,2}\mathbf{P}_U$), whereas the alternative mechanism provides radical rearrangement via a barrier $^{4,2}\mathbf{TS}_{rearr}$ to give a rearranged radical intermediate ($^{4,2}\mathbf{I}_R$). A final rebound barrier from rearranged intermediates gives rearranged product complexes ($^{4,2}\mathbf{P}_R$). As follows from Figure 15, the rebound barrier of the un-rearranged intermediate on the doublet spin state is negligible, whereas a small barrier leads to rearranged intermediates, so that dominant un-rearranged products may be expected. On the other hand, on the quartet spin state surface, the rebound barrier of the un-rearranged intermediate is significant (2.2 kcal mol^{-1}), whereas the rearrangement costs only a few tenths of a kcal mol^{-1}, which implies that on the quartet spin state rearrangement will be the preferred mechanism. Accordingly, the product isotope effect (PIE) observed from the ratio of un-rearranged to rearranged products is in fact proportional to the kinetic isotope effect (KIE) ratio of the low-spin and high-spin structures (Eq. 18). Indeed, calculated PIE values were in excellent agreement with experimentally determined PIE data and hence proved the existence of a TSR scenario[153]:

$$\mathrm{PIE}(\mathbf{P}_U/\mathbf{P}_R) = \mathrm{KIE}_{LS}/\mathrm{KIE}_{HS}. \quad (18)$$

Subsequent studies tested the activity of Cpd 0 and ferric-hydrogen peroxide (Fe^{III}–H_2O_2) as possible oxidants of *trans*-2-phenylmethylcyclopropane.[189] These C–H hydroxylation barriers by Cpd 0 and Fe^{III}–H_2O_2 are 9.9 and 3.6 kcal mol^{-1} higher in energy than those obtained for Cpd I(SH^-) with environmental effects included. Moreover, the bond dissociation energy of the Fe–O bond in Fe^{III}–H_2O_2 is much lower in energy than the hydrogen abstraction barrier, so that predominant uncoupling reactions leading to free H_2O_2 are expected rather than C–H hydroxylation. In Cpd 0, the Fe–O bond is sufficiently strong and much higher in energy than the homolytic O–O bond breakage energy. Despite this, little C–H hydroxylation is expected from the Cpd 0 mechanism, due to a lower-lying barrier leading to *meso*-hydroxylation instead. These studies, therefore, have given theoretical evidence that neither Cpd 0 nor Fe^{III}–H_2O_2 can act as an alternative oxidant in C–H hydroxylation reactions in P450 enzymes.

Cpd I of CYP 450 enzymes often regioselectively hydroxylates a specific C–H bond of a substrate, such as the C^5 position in camphor by CYP 450_{cam}, whereby the substrate-binding topology determines the reactivity patterns. In many cases, therefore, gas phase DFT calculations on model complexes are insufficient to ascertain these regioselectivity preferences, and advanced methods such as QM/MM on the complete enzyme are required. In some cases,

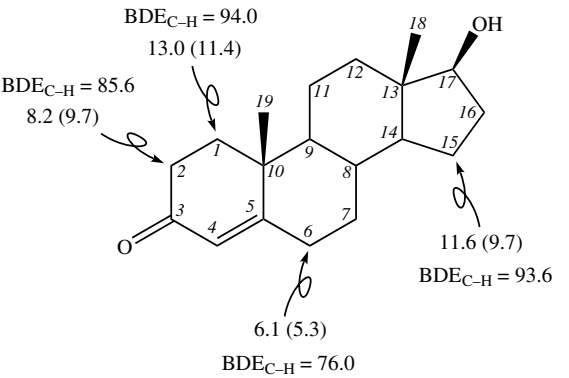

Figure 16. Testosterone hydroxylation at the β1, β2, β6, and β15 positions as calculated with DFT. Barriers and BDE$_{C-H}$ values are in kcal mol^{-1}, with low-spin data in parentheses.

however, the substrate-binding pocket is large and the regioselectivity is simply determined by the relative strengths of the available C–H bonds in the substrate. For instance, testosterone hydroxylation by CYP 450 can take place on many different positions, and experimentally determined product distributions yielded hydroxylated products at the β1, β2, β6, and β15 positions of testosterone (Figure 16). Gas phase DFT calculations[177] using a Cpd I(SH^-) oxidant on the hydroxylation of these four C–H bonds of testosterone showed that the product distributions and experimental rate constants correlate with the calculated hydrogen abstraction barrier heights and consequently with the strength of the C–H bond of the substrate.

Finally, a not-uncommon byproduct in aliphatic hydroxylation reactions is dehydrogenation of the substrate to give alkenes. Studies of C–H hydroxylation of the antiepileptic drug valproic acid by CYP 450 enzymes showed dehydrogenase-oxidase activity that originated from the same precursor as substrate monoxygenation, possibly an iron(IV)-oxo species.[190] Several studies, so far, have focused on substrate dehydrogenation by CYP 450 model complexes.[116,188] Figure 17 gives the general reaction scheme of competitive hydroxylation and dehydrogenation of a substrate $R_2CH_2CH_2R_1$, which may be a cycloalkane, with definitions of the reaction enthalpy of each individual step. Both investigations confirmed an initial and rate-determining hydrogen atom abstraction to form an iron-hydroxo complex. The reaction enthalpy $\Delta H_{r,1}$ for this is as described in Eq. 4 and will depend on the relative BDE values of the O–H and C–H bonds, i.e. $\Delta H_{r,1} = \Delta H_{HA}$. The intermediate rebound of the radical gives alcohol products with exothermicity $\Delta H_{r,2}$, i.e. $\Delta H_{r,2} = \Delta H_{rebIV}$ (Eq. 10). Instead of a radical rebound (Eqs. 7 and 8), a second hydrogen abstraction can form an Fe(III)–H_2O complex with a nearby alkene.

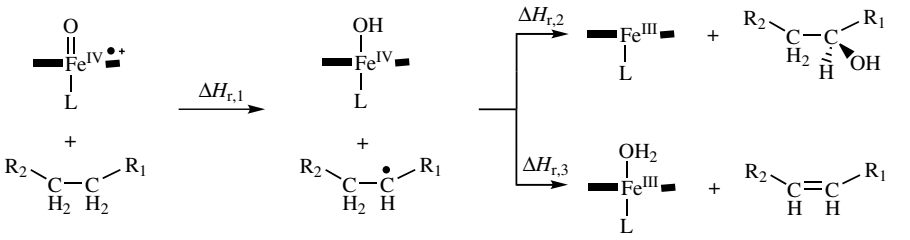

Figure 17. Reaction mechanism leading to substrate hydroxylation and dehydrogenation.

Table 2. DFT-calculated reaction enthalpies and BDE values (in kcal mol^{-1}) of selected substrates.

Substrate	BDE_{C-H}	$\Delta H_{r,1}$	BDE_{rad}	$\Delta H_{r,3}$	BDE_{C-OH}	$\Delta H_{r,2}$
ethane	96.2	9.5	36.7	–34.0	85.8	–55.5
trans-butane	92.6	5.9	33.5	–37.3	85.4	–55.2
cyclohexane	93.0	6.4	33.6	–37.2	85.8	–55.6
cyclohexene	77.7	–9.0	47.5	–23.3	69.1	–38.9
cyclohexadiene	69.0	–17.6	21.8	–49.0	59.7	–29.5

The reaction enthalpy $\Delta H_{r,3}$ for dehydrogenation of the radical, as with Eq. 4 is equal to the difference in bond dissociation energy of an O–H bond in [Fe^{III}–H_2O(Por)L] (designated BDE_{FeHO-H}) and the C–H bond of the radical complex (BDE_{rad}):

$$\Delta H_{r,3} = BDE_{rad} - BDE_{FeHO-H}. \quad (19)$$

To test the regioselectivity preference for a series of substrates, we did DFT calculations to obtain the reaction exothermicities $\Delta H_{r,1}$, $\Delta H_{r,2}$, and $\Delta H_{r,3}$ from BDE values; see Table 2.[116] As follows from the table, the C–H abstraction reaction exothermicity correlates linearly with the strength of the C–H bond, in agreement with the trend depicted in Figure 11. The dehydrogenation exothermicity is more or less constant for aliphatic hydrocarbons and sharply decreases for cyclohexadiene as the result of formation of resonance-stabilized benzene. An opposite trend is observed for the OH rebound to the radical, which is found to be constant and highly exothermic for aliphatic hydrocarbons and is less exothermic for cyclohexene and even more so for cyclohexadiene. As a consequence, the most exothermic reaction for cyclohexadiene is dehydrogenation rather than hydroxylation, which will be the preferred mechanism for all other substrates.

E. Aromatic C–H Activation by Cpd I of CYP 450

Aromatic hydroxylation deserves special attention, since its mechanism deviates significantly from aliphatic hydroxylation, described extensively above. As a matter of fact, aromatic hydroxylation does not start with an initial hydrogen abstraction, but with a C–O bond activation to give either a cationic or radicalar intermediate ($\mathbf{I}_{cat}$ or $\mathbf{I}_{rad}$). Figure 18 displays the aromatic hydroxylation of ethylbenzene by Cpd I(Cl^-).[173] The mechanism observed for aromatic hydroxylation of benzene and toluene by Cpd I(SH^-),[191,192] and benzene by Cpd I(SCH_3^-),[193–195] as well as that for ethylbenzene hydroxylation by Cpd I($NCCH_3$),[98] are the same as the mechanism shown in Figure 18. Moreover, combined experimental and theoretical studies using a nonheme iron(IV)-oxo oxidant showed the same mechanism for nonheme complexes, so that it appears to be universal.[196] The radical intermediate has the same orbital occupation as the aliphatic hydroxylation intermediate, namely $\delta_{x2-y2}^2\ \pi^*_{xz}{}^1\ \pi^*_{yz}{}^1\ a_{2u}{}^2\ \phi_R{}^1$, and hence the metal is in the oxidation state Fe(IV) and the substrate radical is smeared out over five neighboring carbon atoms of the substrate. This delocalized radical has a low ionization potential and, as a result of this, there is also a close-lying cationic intermediate with occupation $\delta_{x2-y2}{}^2\ \pi^*_{xz}{}^2\ \pi^*_{yz}{}^1\ a_{2u}{}^2\ \phi_R{}^0$ in the doublet spin state and $\delta_{x2-y2}{}^2\ \pi^*_{xz}{}^1\ \pi^*_{yz}{}^1\ \sigma^*_{z2}{}^1\ a_{2u}{}^2\ \phi_R{}^0$ in the quartet spin state; both have the metal in oxidation state Fe(III). The latter state is not shown in Figure 18 since it is higher in energy than the radical intermediate $^4\mathbf{I}_{rad}$. In the low spin state the ordering of the cationic and radical intermediates is reversed with a cationic ground state. From the intermediate complexes a proton shuttle takes place to one of the pyrrole nitrogen atoms of the porphyrin ring to form the proton transfer intermediate ($^{4,2}\mathbf{PT}$), which brings the aromaticity back into the substrate ring and consequently is an extremely exothermic process. Indeed, this process has been observed for iron(IV)-oxo porphyrin complexes as well as for nonheme iron(IV)-oxo oxidants.[196] From $^2\mathbf{I}_{cat}$, the proton shuttle to the heme is essentially barrierless, since the two structures have the same electronic configuration, whereas the process from the radical intermediates encounters a significant barrier ($\mathbf{TS}_{PT}$). Geometrically, the porphyrin ring is distorted in $^{4,2}\mathbf{PT}$ and one pyrrole ring bends downward due to protonation. A subsequent proton transfer to the oxo group gives *p*-ethylphenol products ($^{4,2}\mathbf{P}_{phenol}$) via negligible rebound barriers ($\mathbf{TS}_{reb}$). Alternatively, the proton can rebound to the *ortho*-carbon position to form 4-ethylcyclohexa-2,4-dienone ($^{4,2}\mathbf{P}_{keton}$) via a rearrangement barrier ($\mathbf{TS}_{rearr}$). This rearrangement barrier is considerable (>10 kcal mol^{-1}), so that the dominant products will be phenols rather than ketones. Furthermore, the mechanism shown in Figure 18 explains the experimentally detected "NIH" shift, which is the migration of protons from the hydroxylation site to the adjacent carbon atom.[197] Thus, crossing of $^{4,2}\mathbf{TS}_{rearr}$ from the proton

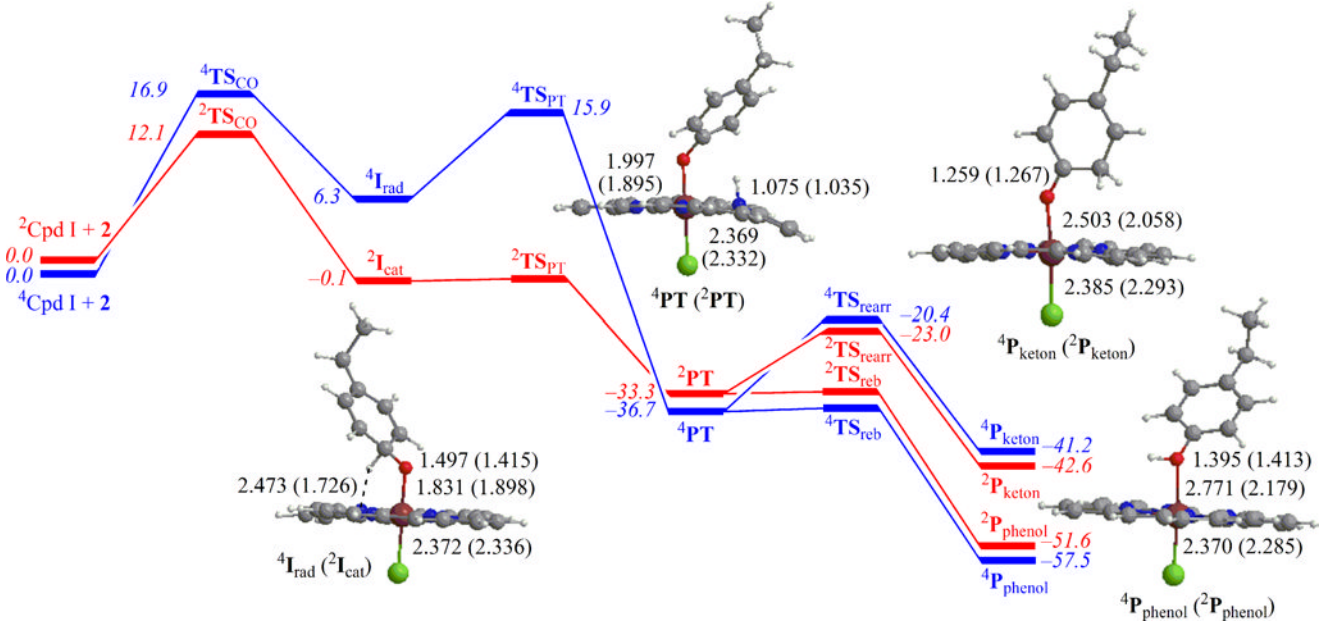

Figure 18. Aromatic hydroxylation of ethylbenzene by Cpd I(Cl^-) leading to phenol and ketone product complexes. All energies are in kcal mol^{-1} relative to isolated reactants, and bond lengths are in angstroms.

transfer intermediates gives cyclohexadienone products where one hydrogen atom has shifted to an adjacent carbon atom, in agreement with the NIH shift. Additionally, these studies prove that phenol and cyclohexadienone products originate from the same intermediate ($^2\mathbf{I}_{cat}$), which is of the cationic type. In contrast to aliphatic hydroxylation (discussed above), aromatic hydroxylation appears via single-state reactivity (SSR) on a dominant low-spin pathway, whereas the competing high-spin pathway has much higher barriers due to much less stable cationic intermediates. In addition to the mechanism shown in Figure 18, the process from $^2\mathbf{I}_{cat}$ also can lead to epoxide product complexes via a ring closure transition state ($\mathbf{TS}_{rc}$). This barrier in the case of benzene hydroxylation is much higher in energy than the proton shuttle barrier to form $^{4,2}\mathbf{PT}$.

As follows from the energy diagram in Figure 18 for ethylbenzene hydroxylation by Cpd I(Cl^-), the rate-determining step in the reaction is the C–O bond activation. Moreover, the reaction takes place on a dominant low-spin surface due to the difference in stability between $^4\mathbf{I}_{cat}$ and $^2\mathbf{I}_{cat}$. Since no hydrogen atoms migrate in the rate-determining step in the aromatic hydroxylation reaction, there is also no kinetic isotope effect for replacement of hydrogen atoms in the substrate by deuterium atoms. DFT studies of ethylbenzene-h_{10} and ethylbenzene-d_{10} hydroxylation by Cpd I(Cl^-) showed competing mechanisms via aromatic and aliphatic hydroxylation, whereby ethylbenzene-h_{10} gave dominant aliphatic hydroxylation, and the fully deuterated substrate aromatic hydroxylation.[173]

F. C=C Epoxidation by Cpd I of CYP 450

CYP 450s as well as biomimetic iron(IV)-oxo porphyrin complexes are known to catalyze C=C double bond epoxidation reactions very efficiently.[1,19,20] As a consequence many theoretical studies have been devoted to this process, as well as processes leading to byproducts of double bond epoxidation by Cpd I(SH^-).[60,143,144,158,198–201] As with the hydrogen abstraction reactions described above, C=C epoxidation proceeds by a stepwise mechanism via a radical intermediate. Thus, an initial C–C bond activation via barrier $^{4,2}\mathbf{TS}_E$ leads to formation of a C–O bond between oxo and substrate groups whereby the other carbon atom of the double bond remains as a radical center ($^{4,2}\mathbf{I}_E$). This radical attacks the oxo group and leads via a ring closure barrier ($\mathbf{TS}_{rc}$) to epoxide products. Figure 19 displays the calculated potential energy profiles of ethene, propene, and styrene epoxidation by Cpd I(SH^-), taken from Refs. 144, 198, and 201. The reactions proceed via TSR patterns on competing doublet and quartet spin states, where the doublet surface is essentially concerted, whereas the quartet spin intermediate has a significant lifetime due to the existence of a ring closure barrier. The rate-determining barrier, therefore, is the initial C–O bond activation via $^{4,2}\mathbf{TS}_E$ and is the lowest for styrene,

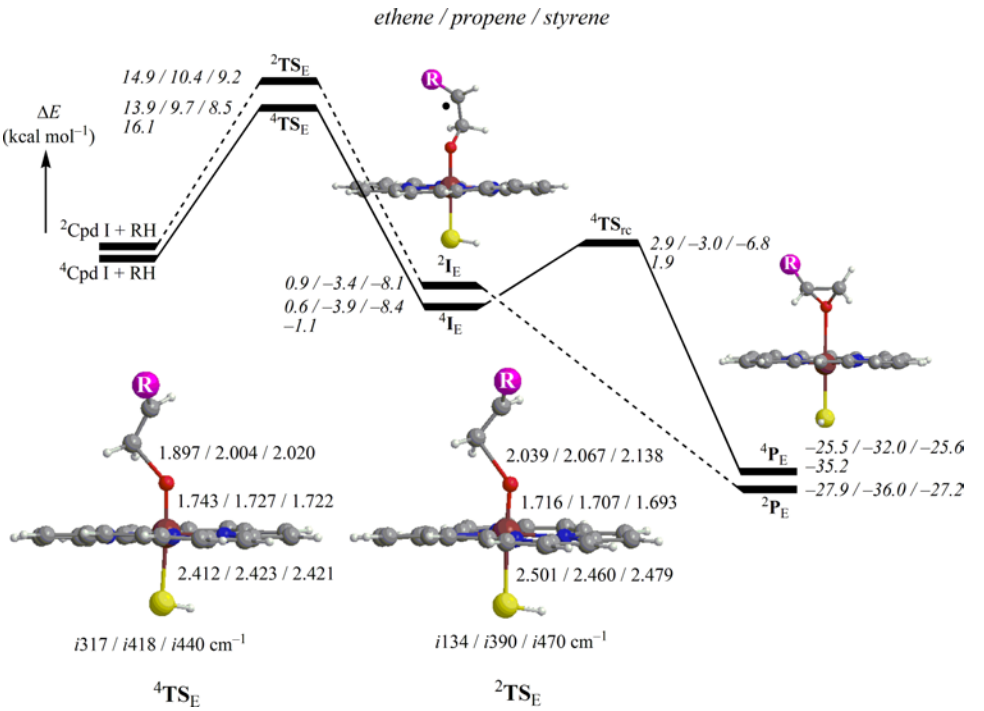

Figure 19. Potential energy profile of substrate (RH) epoxidation by CpdI(SH⁻). Energies are in kcal mol⁻¹ relative to isolated reactants in the quartet spin state. Also shown are optimized geometries of the rate-determining transition states for ethene, propene, and styrene epoxidation. The first line with data is taken from Refs. 144, 198, and 201 for ethene, propene, and styrene epoxidation, whereas the second line gives ethene epoxidation data for the quartet spin state from Ref. 60. The styrene data contain zero-point energies.

as expected from experimental observations. The calculated free energy of activation of styrene epoxidation by this CYP 450 model complex[201] of $\Delta G^{\ddagger}$ = 20.9 kcal mol^{-1} is in line with biochemical studies of CYP 450 enzymes that estimated a barrier of 24–25 kcal mol^{-1}.[52] The differences in barrier height lead to small differences in transition state geometries (Figure 19), where the lowest barriers correspond to early transition states with long C–O and short C–C and Fe–O distances.

Experimental studies on CYP 450$_{cam}$ and its T252A mutant showed that in the mutant C–H hydroxylation reactions were hampered, but not in the C=C epoxidation reactions.[51,52] It was concluded that this was due to the participation of two active oxidants in the reaction mixture, where Cpd I performs C–H hydroxylation reactions and Cpd 0 alkene epoxidation. To test this hypothesis, DFT calculations on competitive epoxidation of ethene by Cpd 0 and Cpd I were made.[59,60] However, DFT studies showed Cpd 0 to be a sluggish oxidant that reacts with alkenes via high reaction barriers, whereas the complementary reaction with Cpd I

encounters much lower barriers. Experimental studies on the reactivity differences of the iron(IV)-oxo porphyrin cation radical versus ferric-alkylperoxo with respect to C–H hydroxylation and epoxidation confirmed that Cpd 0 is a sluggish oxidant unable to compete with Cpd I.[64]

Finally, alkene epoxidation reactions in some cases produce byproducts; for instance, in enzymatic systems terminal olefins are known to give so-called suicidal complexes, which are dead-end products that destroy the activity of the enzyme.[202,203] In addition, byproducts have been reported as being due to stereochemical scrambling and hydrogen migration to form aldehydes. DFT calculations[158,200] established mechanisms for the formation of suicidal complexes ($^4\mathbf{P}_S$) and aldehyde ($^4\mathbf{P}_A$) byproducts, (Figure 20). Thus, both products originate from the intermediate ($\mathbf{I}_E$) in the epoxidation reaction mechanism and the amount of byproduct formation is therefore dependent on the lifetime of this complex. In the low-spin state the ring closure barrier to epoxide products is negligible, so that $^2\mathbf{I}_E$ (Figure 19) will have a very short lifetime. By contrast, a finite barrier for ring closure is found on the high-spin surface, which implies that $^4\mathbf{I}_E$ will have a finite lifetime during which rearrangement can occur. Hence, a manifestation of TSR, is the fact that byproducts are possible only on the high-spin surface and not on the low-spin surface since this is a pseudoconcerted reaction for C–H hydroxylation as well as epoxidation.

The intermediate complex $^4\mathbf{I}_E$(IV) is a radical intermediate with orbital occupation $\delta_{x2-y2}{}^2\,\pi^*_{xz}{}^1\,\pi^*_{yz}{}^1\,\phi_{St}{}^1$ and connects to the epoxide product complex $^4\mathbf{P}_E$ with configuration $\delta_{x2-y2}{}^2\,\pi^*_{xz}{}^1\,\pi^*_{yz}{}^1\,\sigma^*_{z2}{}^1$ via a ring closure transition state. It can react to form the suicidal complex ($^4\mathbf{P}_S$) through an attack of the radical on one of the nitrogen atoms of the porphyrin ring, whereby an N–C bond is formed and one of the pyrrole rings is lifted out of the plane of the heme. However, $^4\mathbf{P}_S$ has electronic configuration $\delta_{x2-y2}{}^2\,\pi^*_{xz}{}^1\,\pi^*_{yz}{}^1$, $\sigma^*_{xy}{}^1$, and a lower-lying mechanism for its formation from $^4\mathbf{I}_E$ is possible through an internal electron transfer and the formation of a cationic complex $^4\mathbf{I}_{cat}(xy)$ with configuration $\delta_{x2-y2}{}^2\,\pi^*_{xz}{}^1\,\pi^*_{yz}{}^1\,\sigma^*_{xy}{}^1$ that connects without barrier to the suicidal complex. The alternative cationic complex $^4\mathbf{I}_{cat}(z^2)$ with configuration $\delta_{x2-y2}{}^2\,\pi^*_{xz}{}^1\,\pi^*_{yz}{}^1\,\sigma^*_{z2}{}^1$ connects without barrier to the aldehyde product complex. The lifetime of the radical intermediates, i.e. either $^4\mathbf{I}_E$(IV) or $^4\mathbf{I}_E$(III), determines the amount of rearrangement to byproducts. Especially, mechanisms passing Fe(III) intermediates have high rebound barriers (as discussed above with VB curve crossing diagrams) and consequently are prone to the formation of suicidal inactivation and aldehyde byproducts.

G. Sulfoxidation by Cpd I of CYP 450

The final reaction catalyzed by CYP 450 enzymes and biomimetics that has received considerable attention is alkylsulfide sulfoxidation (Figure 21).[204–207] In

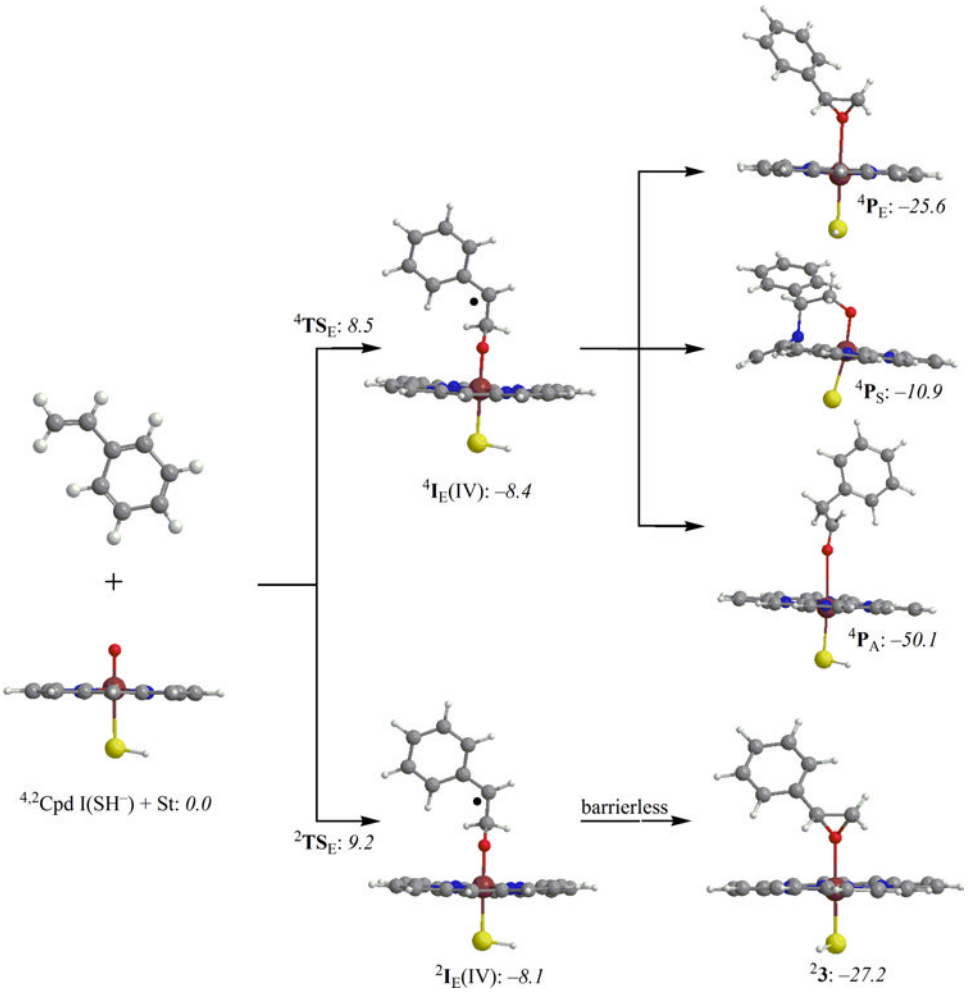

Figure 20. Double bond activation mechanisms of styrene (St) by Cpd I(SH^{-}) leading to products and byproducts. Energies are in kcal mol^{-1} relative to isolated reactants.

contrast to aliphatic and aromatic hydroxylation and C=C epoxidation reactions, this reaction is stepwise via a single transition state for the S–O bond formation (**TS**$_{SO}$), whereby two electrons are transferred from substrate to heme. These electron transfer processes are different in the doublet and quartet spin states, and hence considerably different barrier heights on the two spin state surfaces are encountered. In the low spin state the electron transfers are into the a_{2u} and π^*_{xz} orbitals, whereas in the high spin state they are into the a_{2u} and σ^*_{z2} molecular orbitals. As a consequence of these differences, the substrate attacks from the top in the quartet spin state to align the substrate with the σ^*_{z2} orbital, whereas the substrate attacks from the side in the doublet spin state for ideal overlap with

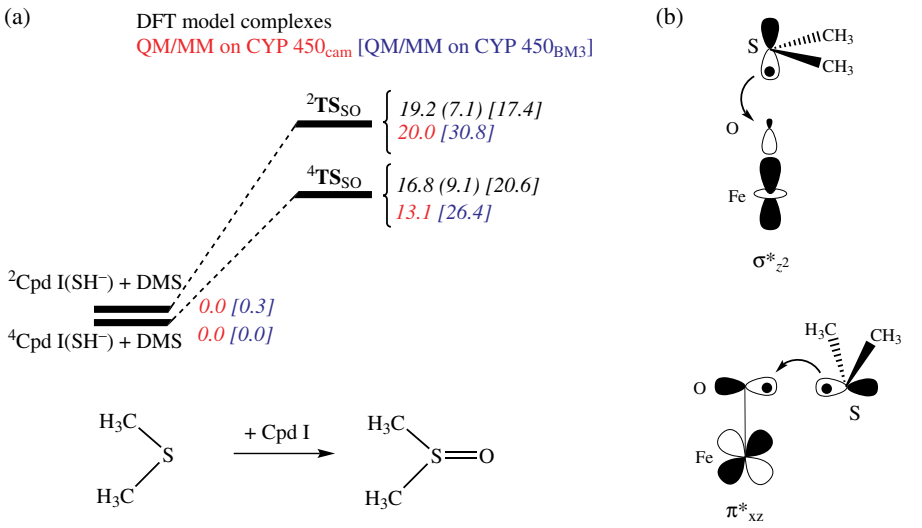

Figure 21. (a) DFT- and QM/MM-calculated sulfoxidation barriers of dimethylsulfide (DMS) by CYP 450 Cpd I models. The top line represents energies (in kcal mol^{-1}) from DFT model complexes of Cpd I(SH^-) or Cpd I(SCH_3^-) from Refs. 204, 207, and 206. The bottom line shows QM/MM-calculated energies of CYP 450_{cam} (in red) and CYP 450_{BM3} (in blue) from Ref. 62. (b) Electron transfer mechanisms in the high-spin (top) and low-spin (bottom) states.

the π^*_{xz} orbital. Due to these differences, the energy gap between ^{4}**TS**$_{SO}$ and ^{2}**TS**$_{SO}$ is considerable in some cases (6.9 kcal mol^{-1} for CYP 450_{cam}), but the DFT model complexes predict an energy gap of 2–3 kcal mol^{-1} although the ordering is reversed in Ref. 204. Nevertheless, all calculations give SSR patterns with preference for one spin state over the other; in three studies the quartet spin mechanism is the lowest, while in the remaining two studies the doublet spin is rate-determining. Clearly, more work is needed to establish what spin state is crucial for P450 sulfoxidation reactions.

IV. Conclusions

In the past two decades, significant understanding of the mechanistic functions of enzyme catalysis on a heme center has been achieved. These studies were focused on important and vital human heme enzymes such as CYP 450s which are involved in key metabolic and biosynthetic reactions, including drug metabolism and the biosynthesis of hormones. Different approaches have been used, ranging from enzymatic studies to experimental work on synthetic models (biomimetics) and, most recently, computational studies. The research has resulted in major breakthroughs in the understanding of the enzymatic processes. This

chapter has shown that the interplay of experimental and computational techniques on biomimetic models leads to advanced understanding of reaction mechanisms of iron-porphyrin complexes, which are correlated with enzymatic systems.

In this chapter, studies using biomimetic and computational methods have been reviewed. First of all, these studies established what the active oxidant of CYP 450 enzymes is. Many potential oxidants were tested, including Cpd 0 and Cpd II, but so far the iron(IV)-oxo porphyrin cation radical or Cpd I has been found to be the most efficient oxidant of substrate monoxygenation reactions. Alternative oxidants, such as the iron(III)-hydroperoxo complex, were tested and found to be poor oxidants of substrate epoxidation and sulfoxidation reactions. In principle, the reduced form of Cpd I, i.e. Cpd II, is able to react with substrates via hydrogen atom abstraction reactions and either dehydrogenate or hydroxylate substrates. Combined biomimetic and density functional studies showed that although Cpd II and its analogs can abstract hydrogen atoms from weak C–H bonds, its hydrogen abstraction barriers are much higher than those for Cpd I, especially in cases where a hydride abstraction is possible.

Further studies have shown how the intricate interplay of the ligands on the metal-oxo center influences the oxidative properties of the active species. Thus, an axial ligand induces either a push or a pull effect on the metal center and thereby changes the oxygen transfer ability of the oxidant. This ligand effect is attributed to two factors: a quantum-mechanical effect due to orbital interactions between the metal and the ligand, and an electric field effect due to charge–charge interactions between the ligand and the metal. These contributions are dependent on the nature of the axial ligand and determine the electrophilicity of the oxo group. In addition, Cpd I exists in close-lying doublet and quartet spin states with the same orbital occupation, and hence reactions on two spin state surfaces result, which has been termed “two-state reactivity” (TSR). As a consequence of TSR, there are barriers on two spin state surfaces and sometimes even different mechanisms on the doublet and quartet spin state surfaces. This makes interpretation of experimental data difficult, especially rate constants and product distributions.

The CYP 450 enzymes are versatile oxidants that catalyze a range of different reactions, including aliphatic and aromatic hydroxylation, dehydrogenation, epoxidation, sulfoxidation, etc. Most of these mechanisms have been studied with biomimetic and computational methods. General reaction schemes have been derived and factors that influence mechanisms are being identified. Nevertheless, the biomimetic and computational studies have shown that subtle changes to the models influence mechanisms, barriers, and product distributions, so that a universal mechanism is still lacking.

So what are the key questions that remain in the studies of CYP 450 and biomimetic analogs? First of all, there are still issues regarding the exact effects of the nature of the axial ligand and the porphyrin ring and its substituents. Why is it that with some biomimetic systems there is a regioselectivity preference for aromatic over aliphatic hydroxylation, whereas it is reversed with an alternative model? Furthermore, how does the protein environment influence the reaction mechanisms and regioselectivities? What happens if we replace the metal? The goal for the future will be to create biosynthetic systems of CYP 450 enzymes that have higher efficiency and turnover and regioselectively and stereospecifically monoxygenase substrates. Combination of experimental biomimetic and computational studies may provide the right tools for achieving this goal.

45 On the Significance of Phthalocyanines in Solar Cells

M. Victoria Martínez-Díaz and Tomás Torres

Departamento de Química Orgánica,
Universidad Autónoma de Madrid, 28049-Madrid, Spain

List of Abbreviations

BCP	bathocuproine
BHJ	bulk heterojunction
CHENO	3α, 7α-dihydroxy-5β-cholic acid
D–A	donor–acceptor
DOTs	dendritic oligothiophenes
DSSCs	dye-sensitized solar cells
EBL	exciton blocking layer
EQE	external quantum efficiency
ERDS	energy relay dyes
IPCE	incident photon to current efficiency
ITO	indium tin oxide
MDMO-PPV	poly[2-methoxy-5-(3′,7′-dimethyloctyloxy)-1,4-phenylenevinylene]
Ncs	naphthalocyanines
OPVs	organic photovoltaics
PCBM	[6,6]-phenyl-C_{61}-butyric acid methyl ester
$PC_{71}BM$	phenyl-C_{71}-butyric acid methyl ester
Pcs	phthalocyanines
PEDOT:PSS	mixture of poly(3,4-ethylenedioxythiophene) and poly(styrenesulfonate)
P3HT	poly(3-hexylthiophene)
PPVs	poly(para-phenylenevinylenes)
PTs	polythiophenes
PTCBI	3,4,9,10-perylenetetracarboxylic bis(benzimidazole)
PyFs	pyrrolidinofullerenes
SubNcs	subnaphthalocyanines
SubPcs	subphthalocyanines
SWNTs	single walled carbon nanotubes

I. Introduction

During the last few decades, phthalocyanines (Pcs)[1–4] have found applications in different fields of technology. As a matter of fact, they have been successfully incorporated as active components of semiconductor and electrochromic devices, information storage systems and liquid crystal color displays, among others. More recently, they have received particular attention at the research level as building blocks for the construction of molecular materials due to their outstanding electronic and optical characteristics.[5–7] Numerous properties arise from their

electronic delocalization, which makes them valuable in different areas of science and technology.

Solar energy technologies are emerging as one of the most promising options for necessary sustainable energy production. In this connection, photosynthesis is the unavoidable example to be followed; it relies on the simple fact that sunlight constitutes the initial energy source of a complicated chain of events that take place in the photosynthetic process in living things. The ultimate goal, therefore, is to design and assemble artificial systems which can efficiently harvest, convert and store sunlight, replicating the natural analogs.[8–11] This is the reason why, during the last few decades, the development of artificial photosynthetic systems mimicking the natural process of solar energy conversion and the exploitation of molecular devices have attracted a great deal of interest.[12–17]

Porphyrinoids are typically employed as components of such photovoltaic and artificial photosynthetic devices.[18–30] However, synthetic porphyrin analogs such as phthalocyanines have the advantage, as photon harvesters, of exhibiting very high extinction coefficients in a wavelength range that extends to around 700 nm, where the maximum of the solar photon flux occurs.[31] Consequently, Pcs have emerged as excellent light-harvesting antennas for incorporation into donor–acceptor systems, mainly in connection with fullerenes as an acceptor moiety.[32–53] This overview is divided into two parts. The first is devoted to pure organic solar cells and the second to organic–inorganic hybrid or dye-sensitized solar cells.

II. Phthalocyanines in Organic Solar Cells

Organic materials, both small molecules and π-conjugated polymers, are real alternatives to silicon-based solar cells. In particular, they offer easy processing in thin films, by either vacuum evaporation or solution cast technologies, and the possibility of being adapted lo large-area substrates of complex shape.[54–63] Furthermore, organic thin films may show high optical absorption coefficients, which make them good chromophores for optoelectronic applications. Among organic molecules, semiconducting conjugated polymers — particularly poly(*para*-phenylenevinylenes) or PPVs and polythiophenes (PTs) — and fullerene derivatives have played a special role.[64,65]

In organic photovoltaic (OPV) devices, light absorption leads to the formation of excitons rather than free electron–hole pairs. Efficient exciton dissociation occurs under strong electric fields or at the interface between two materials of different electron affinities, i.e. donor–acceptor (D–A) interfaces. This concept has been extensively applied to the fabrication of organic D–A bilayer devices, commonly by vacuum deposition of the molecular components. The efficiency of OPV devices depends on the absorption efficiency of incident photons, which can be

simply increased by using thicker photoactive layers.[66] However, only excitons generated close to the D–A interface will generate free carriers, limiting the J_{sc} and the overall power conversion efficiencies. In order to improve the fraction of photogenerated excitons that diffuse to the D–A interface, the so-called bulk heterojunction (BHJ) solar cell configuration was proposed instead, in which an interpenetrating network of the donor and acceptor materials is used as a single active layer, thereby maximizing the interfacial area between donor and acceptors. The most effective BHJ organic solar cells currently reach power conversion efficiencies up to 6%, employing semiconducting conjugated polymer–fullerene composites as the active layer.[67–75]

A number of approaches have been explored for the optimization of organic solar cell,[76] starting from a better understanding of the mechanism of operation. It has been shown that the optimization of the solar cells is influenced by many different parameters, among which are fine-tuning of the electronic properties of the donor and acceptor components, active layer absorption properties, efficiency of the interfacial charge transfer process, and transport of the charges in the respective phases to the electrodes.

A common strategy for implementing these devices is to employ materials with a strong absorption in the red and near-infrared part of the solar spectrum, to harvest the photons where the maximal flux is located (approximately 700 nm). Despite significant progress in the synthesis of low-band-gap polymers capable of absorbing a broad range of solar photons in which alternating electron-rich and electron-poor units define the polymer backbone, only a few examples have achieved power conversion efficiencies comparable with those of devices fabricated from P3HT.[77–85] On the other hand, substitution of the typical acceptor component PCBM by the C_{70} derivative, with a significantly stronger absorption across the visible region, led to an improvement in the performance of a variety of polymer solar cells.[73,86]

Alternative routes would consist in introducing either on the polymer or in the acceptor counter-partner "colored" antenna groups, or just blending the polymer with small dye molecules or quantum dots. When one is selecting the chromophore, it is crucial to consider that its energy levels should lie between those of the polymer and the acceptor in order to avoid charge trapping on the dye.

Until very recently, solution-processable OPVs have always been related to soluble conjugated polymers because of their ability to form uniform films upon spin-coating. Solution-processable small molecule semiconductors have been proposed as new donor materials in BHJ solar cells as alternatives to conjugated polymers.[87–92] They offer some specific advantages, such as reproducible synthesis and easier purification, since they are intrinsically monodisperse. Moreover, molecular organic materials exhibit, in general, better charge transport properties

than polymeric semiconductors because they are more likely to exhibit long range order. However, they may lack the necessary viscosity for film casting and often present a poor solid state miscibility with the acceptor material. Until very recently, published results were quite poor.[87,93]

Together with fullerene derivatives, phthalocyanines are among the benchmark materials for photovoltaic heterojunctions based on small molecules. They exhibit very high extinction coefficients — typically higher than 100,000 $M^{-1}cm^{-1}$ at the Q band absorption (*ca*. 650–700 nm). In addition to their outstanding optical properties, Pcs have excellent thermal stability and a rich redox chemistry, which can be modulated by chemical synthesis.[1–6] Thus, it is possible to tune the physicochemical properties of synthetic phthalocyanines through introduction of specific substituents or central metals. Moreover, they exhibit a self-organization tendency which is reflected in high charge carrier mobility values. Usually Pcs play the double role of donor component and antenna. All of these properties make them especially suitable for integration into photovoltaic devices, as will be described in this review.

Unsubstituted Pcs possess remarkable limited solubility and a strong tendency to aggregate in most organic solvents, which makes it difficult to apply solution-processing techniques for the fabrication of solar cells. For this reason, phthalocyanine thin films are typically prepared via vapor deposition. Most of the success of phthalocyanines in the field of organic photovoltaics is based on unsubstituted Pc thin films incorporated as active layers in different types of architecture devices.

In contrast, chemically elaborate Pcs (including those with peripheral substituents to increase solubility in organic solvents or electroactive units to favor intramolecular photoinduced processes) are usually not stable for the application of high vacuum vapor deposition techniques. In these cases, photovoltaic device fabrication requires solution-processing techniques. Efficient solar cells based on solution-processed phthalocyanines are still scarce but have started to appear in the literature, as will be discussed in the following pages. Even rarer are the cases where efficient solar cells incorporate Pcs together with semiconducting polymers.

Depending on the production process, heterojunctions (both planar and bulk heterojunction solar cells) can be differentiated in vapor-deposited and solution-processed solar cells. However, mixtures of the two techniques are currently used in the preparation of single- and multilayered heterojunction solar cells. For the sake of schematizing the present overview, we have classified Pc-based organic solar cells into two types: (a) heterojunctions of any type in which phthalocyanines (or Pc analogs) have been processed by vapor deposition and (b) Pc-based organic solar cells in which these macrocycles have been solution-processed to be incorporated into the active film.

A. Incorporation of Phthalocyanines into Organic Photovoltaic Devices by Vapor Deposition

Pcs have been used in molecular organic solar cells since the first report by Tang in 1986.[94] In fact, a two-layer thin film photovoltaic cell was fabricated by vacuum evaporation of CuPc (donor) and the perylene derivative PTCBI (acceptor) (Figure 1), achieving a power conversion efficiency of *ca*. 1% under simulated AM2 illumination.

1. *Introduction of Exciton-Blocking Layers*

Device performance was significantly improved up to 2.4% by introduction of a large band gap (3 eV) and, hence, transparent exciton-blocking layer (EBL) of bathocuproine (BCP) between the photoactive organic layers and the metal cathode (Figure 2).[95] Inserting such a layer prevents damage of the active layer due to cathode evaporation and prohibits excitons from diffusing toward the Al electrode, where they would otherwise be quenched. Since the EBL provides a spacer between the photoactive region and the cathode, the optical intensity at the D–A interface is increased, thereby raising the light absorption efficiency.

2. *Hybrid Planar–Mixed Molecular Heterojunctions*

The device modification proposed by Hiramoto *et al.* in 1991 consisted in employing a three-layered organic solar cell with a photoactive interlayer of codeposited dyes, namely metal-free phthalocyanine and the perylene derivative PTCBI,

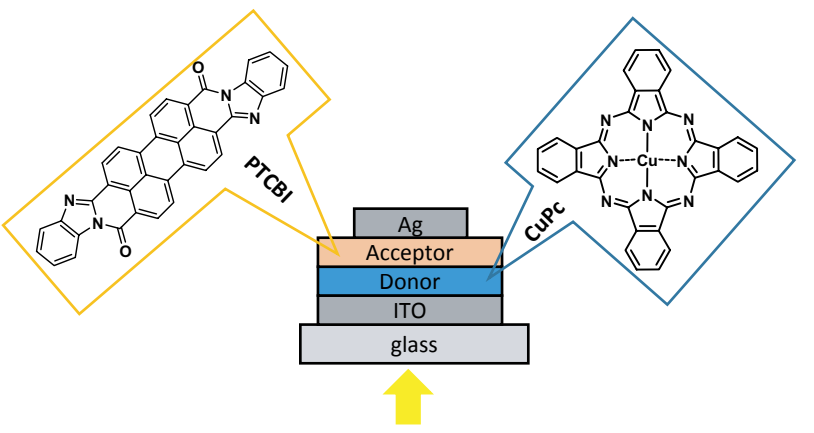

Figure 1. Planar donor–acceptor heterojunction made of CuPc and a perylene derivative.

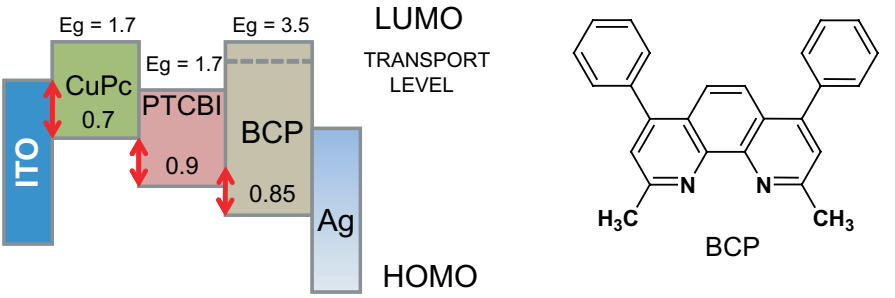

Figure 2. Energy level diagram of ITO/CuPc/PTCBI/BCP/Ag OPV cells, taken from Ref. 95.

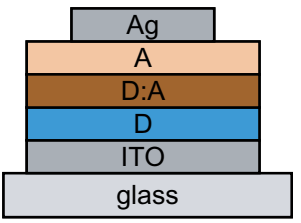

Figure 3. Schematic representation of hybrid planar–mixed molecular heterojunction (PM-HJ) devices.

between pristine donor and acceptor material layers (Figure 3).[96] This device architecture can be considered as a hybrid combination of planar and bulk heterojunction structures. However, the advantage of this configuration was not realized by the authors, due to the use of excessively thick layers.

The substitution of the acceptor material PTCBI with fullerene C_{60} by Forrest and coworkers in 2001 led to a substantial improvement in the cell efficiency (up to 3.6% when a BCP exciton-blocking layer was also employed).[97] The results were justified considering the longer exciton diffusion length of C_{60} (77 Å), which results in an enhanced transport of photogenerated carriers due to the spherical shape of the C_{60} molecules, in contrast to the planar perylene derivative.

Device implementation, namely fabrication of a hybrid planar–mixed heterojunction (PM–HJ) solar cell consisting of a 1:1 (by weight) mixed layer of CuPc and C_{60} sandwiched between a homogeneous layer of CuPc and C_{60} [ITO/CuPc/CuPc:C_{60}/C_{60}/BCP/Ag], gave rise to efficiencies up to 5% under 1–4 suns of simulated AM1.5G solar illumination.[98] The use of very thin layers turned out to be crucial for facilitating the diffusion of excitons across the entire heterojunction to the nearby D–A interface.

3. *Structural Modifications in the Phthalocyanines*

Other unsubstituted metallophthalocyanines, such as TiOPc and $(RuPc)_2$, have been incorporated in phototovoltaic devices[99–102] by high vacuum evaporation techniques, although the most relevant results were found with CuPc and ZnPc.[103–105]

Of special interest are metallophthalocyanines with strong absorption in the near IR. Among them, aluminum phthalocyanine chloride (AlPcCl) and tin phthalocyanine dichloride ($SnPcCl_2$) have attracted much attention. In addition to the work functions of the electrodes, most reports suggest that the V_{oc} value depends on the energy difference between the lowest unoccupied molecular orbital (LUMO) energy of the acceptor and the highest occupied molecular orbital (HOMO) energy of the donor.[106,107] As predicted on the bases of its HOMO energy (Figure 4), AlPcCl cells showed significantly higher open-circuit voltages than CuPc ones and therefore higher conversion efficiencies under the same experimental conditions (almost twice the values).[108,109] In addition, both AlPcCl and $SnPcCl_2$ extend the solar cell photoresponse into the near-IR region (between 755 and 1000 nm).[110] It seems that the main drawback of these long-wavelength absorbing-materials-based solar cells are the low open-circuit voltages obtained due to their small energy gaps and high dark currents. Recently, Forrest and coworkers have reported the benefit of incorporating an electron-blocking layer between the donor layer and the anode contact, which can help to reduce the dark current and subsequently increase the photovoltaic cell efficiency.[111] Thus, it was shown how the dark current of $SnPcCl_2/C_{60}$ heterojunction solar cells is decreased by two orders of magnitude compared to cells lacking the blocking layers, reaching overall efficiencies of 2.1% at 1 sun.

Among the phthalocyanines analogs, the boron chlorosubphthalocyanine derivative (SubPcCl) has been selected as a promising strongly absorbing donor material for C_{60}-based solar cells owing to its lower oxidation potential, which results in an increase of the V_{oc} as a consequence of a larger difference between

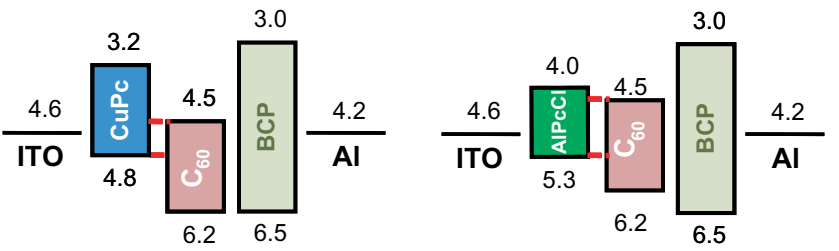

Figure 4. Schematic energy band diagrams of CuPc/C_{60}- and AlPc/C_{60}-based planar heterojunctions modified from Ref. 108.

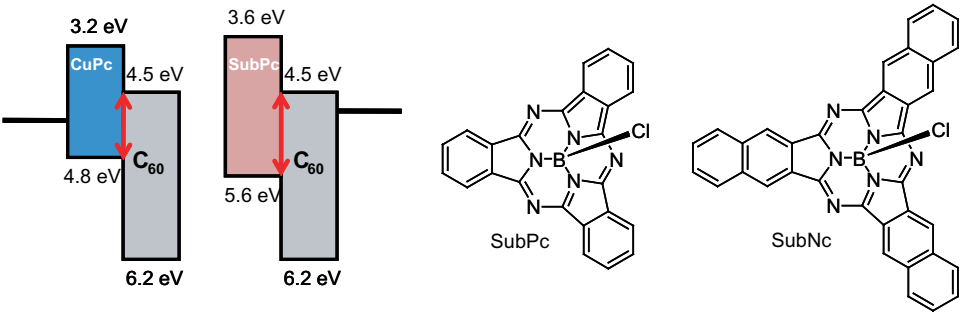

Figure 5. (a) Schematic energy level diagrams of CuPc/C_{60} and SubPc/C_{60} planar heterojunctions modified from Ref. 112. (b) Molecular structures of SubPc and SubNc macrocycles.

the LUMO of the acceptor and the HOMO of the donor (Figure 5).[112] Thus, it has been described that a double-heterostructure SubPc/C_{60} thin film solar cell has a more-than-doubled V_{oc} compared to a conventional CuPc/C_{60} cell under 1 sun AM1.5G simulated illumination. Power efficiencies of either 3% or 2.5% under 1 sun have been measured using SubPcCl or SubNcCl films, respectively, in combination with C_{60} in a planar bilayer donor/aceptor heterojunction.[113,114]

Very rarely, Pcs bearing electron-withdrawing substituents such as fluoro, namely $CuF_{16}Pc$, have played the role of acceptors blended with typical *p*-type materials, such as *p*-sexiphenyl.[115] However, the scope of Pcs as acceptor components has not been sufficiently studied yet.

In the same way, only very recently have perfluorinated SubPcs been employed as acceptors in bilayer organic solar cells in which unsubstituted SubPc played the expected role of donor material. Power conversion efficiencies of 0.96% and a remarkably high open-circuit voltage (as high as 940 mV) were achieved in devices with the following structure: ITO (100 nm)/SubPcCl (13 nm)/F_{12}SubPcF (33 nm)/BCP (10 nm)/Al (80 nm) under 1 sun simulated solar illumination.[116]

4. *Bilayer Heterojunctions Fabricated Using Two Different Processing Techniques*

Bilayer heterojunctions can also be fabricated using solution-processing techniques.[117] An innovative approach was proposed by Sariciftci and coworkers which consisted in donor–acceptor "diffused" bilayer solar cells formed by deposition of solutions of pyrrolidinofullerenes (PyFs) bearing chelating pyridyl groups on vacuum-evaporated films of ZnPc (Figure 6). The idea

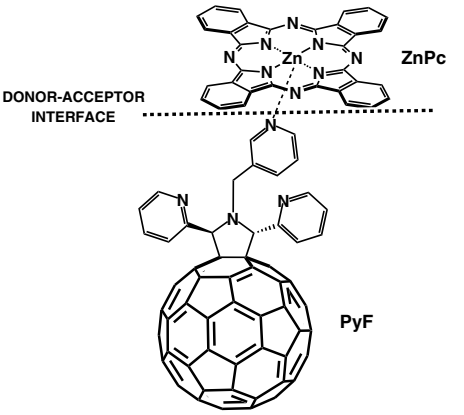

Figure 6. Py–Zn interaction at the donor–acceptor interface (from Ref. 118).

consisted in taking advantage of the coordination between the pyridyl groups attached to the fullerene component and the Zn(II) metal in the Pc cavity that would take place at the interface between the donor and the acceptor, thus facilitating the photoinduced charge separation process step. The devices exhibited conversion efficiencies of up to 1.5% under 100 nmW/cm^2 simulated AM1.5 illumination. Reference cells based on nonchelating fullerene derivatives (namely PCBM) as acceptor yielded significantly lower power conversion efficiencies (0.4–0.6%).[118]

5. *Tandem Solar Cells*

The number of photons that can be absorbed and collected in a single cell is limited by the maximum thickness of the active layer in regard to its transport properties. One way to bypass this limitation consists in tandem solar cells, which are stacks of different cells connected in series by a transparent intermediate layer. This layer ensures the recombination of electrons coming from one cell with the holes coming from the other cell in such a way that the resulting V_{oc} should be the sum of the single cells.[119] However, the overall efficiency is limited by the J_{sc}, which is the lowest of the individual cells. Highly efficient (η = 5.7%) tandem photovoltaic cells have been published by Forrest and coworkers by stacking two CuPc/C_{60} hybrid PM–HJs in series.[120]

Tandem solar cells have also been proposed as an alternative solution for overcoming the mismatch between the absorption spectra of the materials and the terrestrial solar spectrum which limits the efficiency of the photovoltaic devices.[121] In this case, each connected cell contains different active layers

which absorb in different spectral regions. Tandem solar cells based on the combination of P3HT:PCBM and CuPc/C_{60} subcells have been reported.[121–124] By using a highly transparent, high-work-function WO_3 layer as part of the interconnecting system for the two subcells, stacked devices with power conversion efficiencies as high as 4.6% are claimed.[124] The efficiency of the stacked devices is close to the sum of the efficiencies of the individual subcells. Organic connecting layers are highly desirable for simplifying the fabrication process (by lowering the sublimation temperature) and optimizing the cell performance. Namely, 3 nm each of $SnPcCl_2$ and F_{16}CuPc layers have recently been used for joining two identical ZnPc/C_{60} subcells with a hybrid planar–mixed heterostructure device configuration, shown in Figure 7.[125] Doubling of the V_{oc} was achieved for the tandem cell, whereas the overall efficiency increased from 1.11% of the single cell to 1.46%, showing that these Pc layers behave as good effective recombination centers for the electrons and holes photogenerated in the front and the back cell by a tunnel mechanism. The concept could be extended to tandem cells with different active layers wherein device performance is expected to be further increased.

To overcome the inherent problems of tandem solar cells — namely, the intercellular layer used to connect the subcells will reflect and absorb some light and hence will decrease the amount of transmitted light, new device architectures are being explored. Simple devices have been fabricated by spin-casting a P3HT:PCBM blend onto an evaporated thin layer of CuPc (Figure 8). In this way, two simultaneous bilayer heterojunctions are formed, achieving a power efficiency (2.79%) which is nearly the sum of those of the individual CuPc/PCBM and P3HT/PCBM cells with much less complex device architecture.[126] Optimization of these cells gave power conversion efficiency as high as 4.13%.[127]

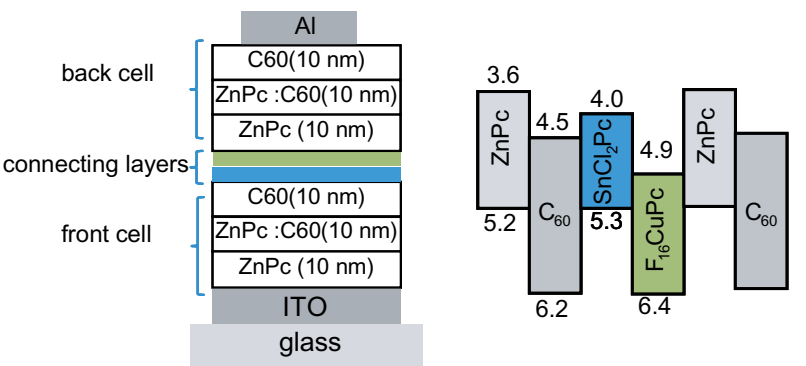

Figure 7. Device architecture and energy level diagram of tandem ZnPc/C_{60} cells incorporating thin $SnCl_2$Pc and F_{16}CuPc connecting layers, modified from Ref. 125.

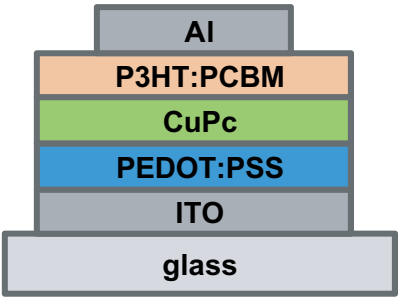

Figure 8. Device architecture of a P3HT:PCBM/CuPc bilayer heterojunction, modified from Ref. 126.

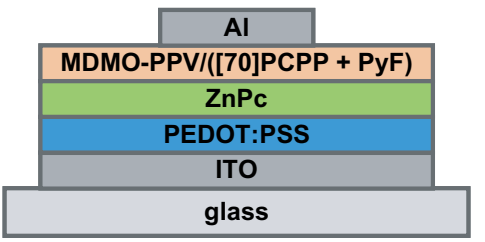

Figure 9. Multicomponent device mixture of bulk and bilayer heterojunctions, modified from Ref. 118.

Similarly, multicomponent devices made of spin-coated MDMO-PPV/[70]PCPP blends and bilayer ZnPc/PyF cells (Figure 9) yielded photovoltaic devices that showed power conversion efficiencies of up to 2.1%.[118]

Alternatively, OPV device performance enhancement can be based on the incorporation of absorbing dopants, aimed at extending the sensitivity of the device across the absorption of the three components. Absorbing dopants such as rubrene, $SnPcCl_2$ and SubPcCl have been tested independently as a second donor in well-established CuPc/C_{60} solar cells.[128–132] In all cases a remarkable enhancement of the power conversion efficiency has been observed as a consequence of the simultaneous formation of D_1/C_{60} and D_2/C_{60} nanoheterojunctions and/or the extended light-harvesting efficiency.

Another promising strategy consists in coupling an "antenna system" — which will not take part in the charge generation and transport steps but will donate the energy from photons absorbed in the blue and green spectral ranges — to the red absorbing solar cell materials.[133] The application of luminescent concentrators in organic solar cells based on ZnPc and C_{60} has been reported[134] wherein a photocurrent density increase from about 8.5 up to 10 mA/cm^2 was observed compared to a single solar cell of equal active area.

B. Incorporation of Phthalocyanines into Organic Photovoltaic Devices by Solution Processing

Solution process fabrication involving spin-coating techniques has attracted much attention, because they are suitable for producing low-cost large-area devices at ambient temperature and pressure. Moreover, these techniques are applicable to flexible devices.

Solution-processed Pc-based bulk heterojunction solar cells are rarely reported and almost ineffective.[135,136] In one report, the PV properties of cells containing soluble discotic liquid crystalline phthalocyanines and C_{60} as an active layer were discussed.[137] Highly ordered structures were obtained by thermal annealing of spin-coated thin films. However, efficiencies were only up to 0.08%.

Recently, bulk heterojunction devices made by spin-coating a blend containing rare earth phthalocyaninato double or triple deckers as electron donors and a perylenedi-imide derivative as electron acceptor have been published (Figure 10). These Pc derivatives offer unique optical electronic and optical properties, including a broad absorption which extends from the UV range to the near-IR, large exciton delocalization and high carrier mobility. The best cells (conversion efficiency of 1.3% under AM 1.5 solar illumination) were fabricated using a triple-decker Pc derivative and incorporating TiO_2 layers between the active layer and the electrodes.[138]

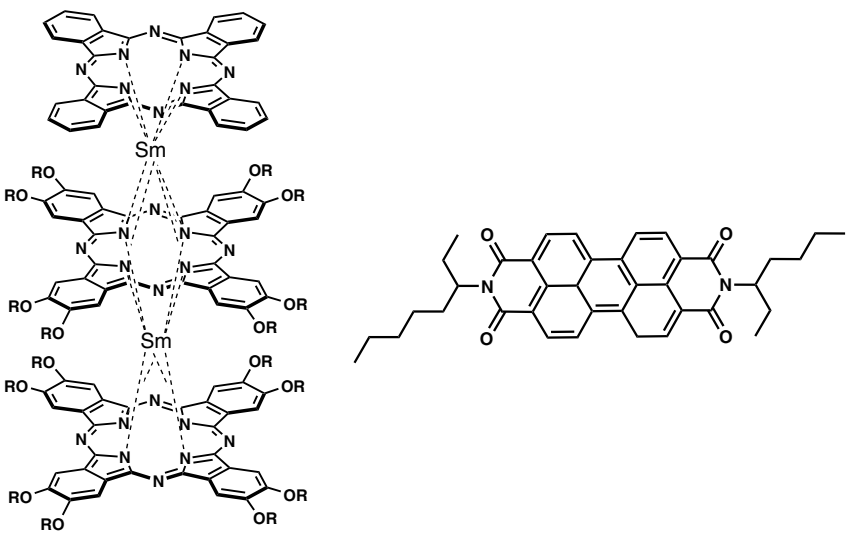

Figure 10. Molecular structures of the phthalocyaninato triple decker and perylenebisimide derivative active layer components of solar cells, described in Ref. 138.

In contrast with unsubstituted Pcs, the nonplanar structure of unsubstituted phthalocyanine boron analogs, so-called subnaphthalocyanine (SubNcCl) (Figure 5b), provides this macrocycle with distinctive physical properties such as high solubility and low tendency to aggregate, which makes feasible the fabrication of thin films via solution-processing techniques. A remarkable 1.5% power conversion efficiency has recently been reported by Frechet *et al.* with a planar heterojunction device made of a subnaphthalocyanine donor layer prepared by solution casting and a vapor-deposited C_{60} film.[139]

In addition, well-defined multilayered structures are difficult to construct using solvent-casting deposition techniques. New solution process techniques such as the layer-by-layer deposition method allow the fabrication of ultrathin films with a multilayered structure in the direction normal to the substrate and control of the thickness of each functional layer with nanometer precision.[140] This technique is based on the electrostatic adsorption of oppositely charged materials such as polycations or polyanions, and charged small molecules. Solution-processed thin film organic solar cells were developed by spin-coating deposition of a C_{60} film on top of PDDA/CuPcTS (tetrasodium tetrasulfonate CuPc derivative) films constructed by the layer-by-layer technique (Figure 11).[141] Although the reported efficiencies were very low compared with conventional CuPc-based solar cells fabricated by vacuum deposition, the approach seems useful for constructing solution-processed organic solar cells with a controlled multilayered structure.

In the field of OPVs, tandem solar cells have been shown to be the most successful option for catching as many photons of different energies as possible by connecting two cells in series whose active layers present complementary absorption. In any case, these multilayered devices are quite sophisticated. Ideally, simpler efficient solution-processed devices made of a single bulk heterojunction

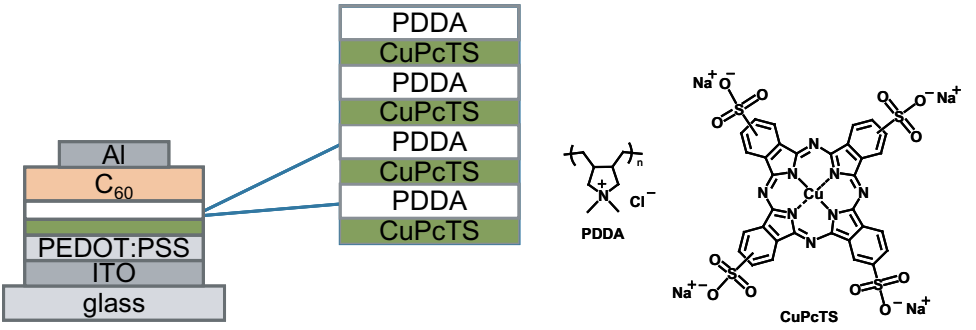

Figure 11. Molecular structures of the components PDDA and CuPcTS and device architecture, modified from Ref. 141.

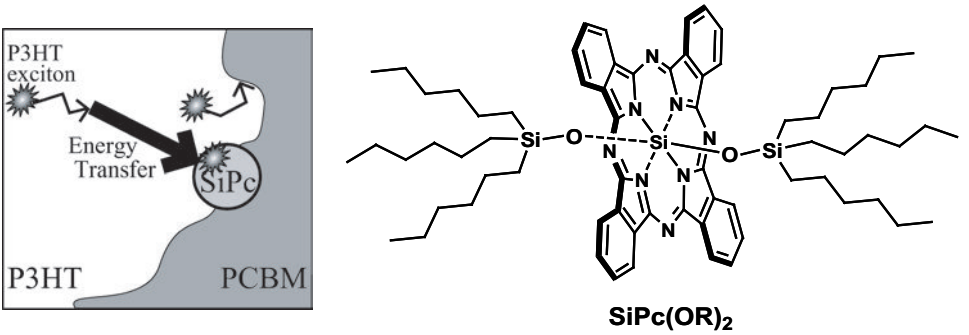

Figure 12. Schematic representation of a dye-sensitized P3HT/PCBM solar cell, taken from Ref. 145.

active layer consisting of a panchromatic mixture of donor and acceptors would be desired. Commonly, a dye molecule is introduced as the third component in a polymer/fullerene BHJ. Since mixing different active donor and acceptor molecules usually leads to phase segregation problems, this method rarely improves the device performance.[142–144] However, the introduction of a silicon phthalocyanine derivative [$SiPc(OR)_2$] as the third component in a P3HT/PCBM blend led to a substantial enhancement of the J_{sc} and hence the conversion efficiency by 20% compared with a P3HT/PCBM device.[145] To explain these results, the authors suggested a double role of the $SiPc(OR)_2$ molecule, as a light-harvesting photosensitizer and an energy funnel for the P3HT exciton, which implies that energy transfer from the P3HT to the $SiPc(OR)_2$ molecules is occurring at the P3HT/PCBM interface (Figure 12). The key point for this success is related to the use of a Pc dye molecule with a much-reduced tendency to form aggregates due to the axial substituents.

Covalent linkage of the active components has been proposed as a way to improve OPV performance avoiding phase segregation. Many Pc-based covalent donor–acceptor systems, like Pc–C_{60} dyads[32–53] (see one example in Figure 13), Pc-based polymers[146,147] and SWNT–Pc conjugates,[148–150] have been proposed as materials for photovoltaics but only a few of them have been tested in solar cells, although results are still very poor.[147,150,151]

The ZnPc–C_{60} dyad was used as a dye to improve the photocurrent around its maximum absorption (*ca.* 700 nm) as a third component in MDMO-PPV:PCBM cells.[152] Although a good matching of the device photocurrent spectrum and the solar emission spectrum is obtained, a reduction in the short-circuit current is observed, indicative of charge transfer problems.

The introduction of Pc–C_{60} dyad H_2Pc–C_{60}ee as a spin-coated film in a bilayer cell made of P3HT and C_{60} (or PTCDI) (Figure 14) leads to an enhancement in the

power conversion efficiency (between one- and-a-half and three times compared with the corresponding reference systems), as a consequence of an increase of the V_{oc}.[153] In other words, the dyad produces two different junctions in the cell (P3HT/dyad, and dyad/C_{60} or PTCDI) contributing to a more efficient charge transport toward the electrodes. Photoinduced electron transfer should take place in the

dyad layer, and subsequently the P3HT or acceptor layer would act as antenna and secondary electron donor, providing electron or holes to the dyad.

A promising approach would consist in the incorporation of relatively stable supramolecular systems in bulk heterojunctions. The great potential of RuPcs as platforms for the preparation of multifunctional materials has been proven.[154–158] Some examples of robust Pc assemblies have been reported based on the strong coordination of one or two pyridine axial ligands to the central Ru atom. Moreover, the strongly coordinated axial ligands dramatically decrease the natural tendency of Pcs to form aggregates and increase their solubility in organic solvents, which allow the processing of the molecules by spin-casting techniques.

Tetra-*tert*-butylRu(II)Pc has been self-assembled to different pyridine-functionalized chromophores, such as squaraines and dendritic oligothiophenes (DOTs) (Figure 15), yielding stable supramolecular systems[159] with enhanced light-harvesting ability. Furthermore, they have been incorporated into solution-processed BHJ cells blended with the suitable PCBM soluble acceptor. In particular, good efficiencies of up to 1.6% (when blended with $PC_{71}BM$ as acceptor) have been obtained for the DOT–RuPc hybrid molecules.

III. Phthalocyanines as Sensitizers of Dye-Sensitized Solar Cells

In the search for efficient, stable and low-cost alternatives to well-established but expensive silicon-based solar cells, dye-sensitized solar cells (DSSCs), mainly developed by the group of Grätzel, have been shown to be the most promising candidates.[160–163] In these devices, photons are collected by *organic dye* molecules which cover a layer of a wide-band-gap semiconducting material like *mesoporous* TiO_2. Anatase is a cheap material which can be processed in transparent flexible films which offer a huge interfacial area and high electron mobility. The third important component is the *redox electrolyte*, which interpenetrates the TiO_2 layer. Excitation of the dye leads to injection of electrons from the dye-excited state to the conduction band of the TiO_2 (Figure 16). The ground state of the dye is regenerated through reduction by the electrolyte (usually I^-/I_3^-) (Figure 16). The dyes employed should fulfill a number of requirements. The necessity of anchoring functions for attaching the dye to the semiconductor surface has been demonstrated. In particular, carboxylate groups have shown very good electronic coupling between the π^* orbital of the electronically excited complex and the 3d orbitals of the TiO_2 film. The LUMO level of the dye must be sufficiently high in energy for efficient charge injection in the TiO_2, and the HOMO level should allow efficient regeneration of the oxidized dye by the electrolyte. In contrast, the

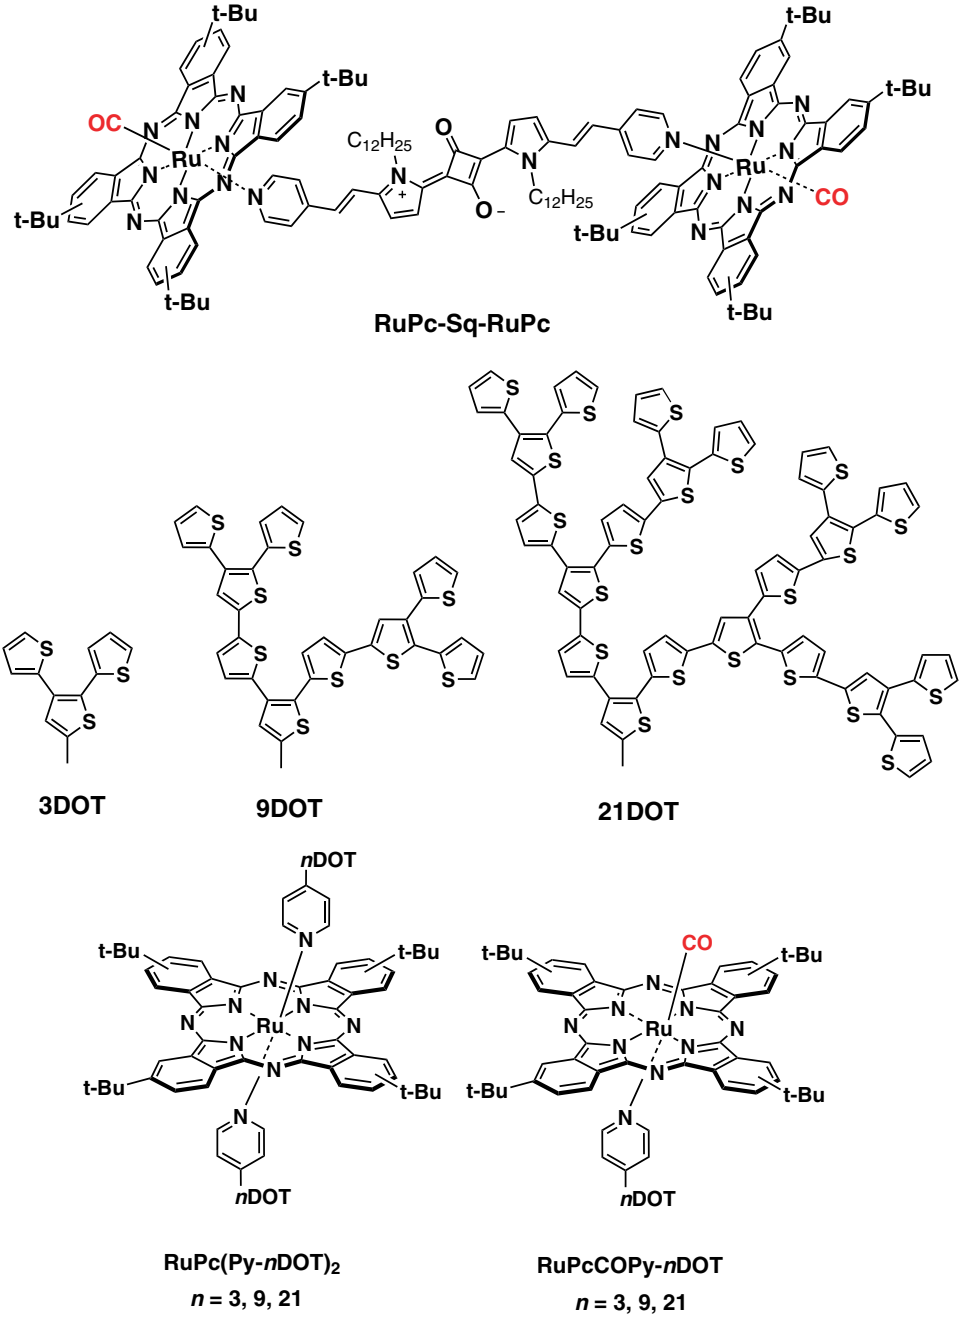

Figure 15. Molecular structures of multichromophoric Ru(II)Pc-based systems employed in BHJs, described in Refs. 158 and 159.

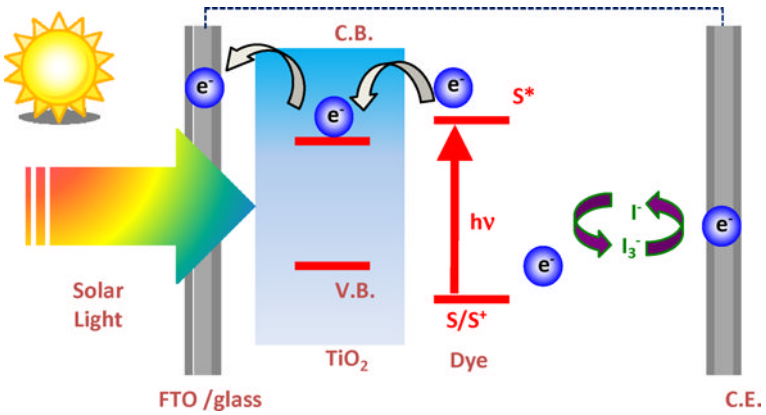

Figure 16. Schematic representation of fundamental processes in a DSSC.

redox mediator should not bind the semiconductor surface, since it should shuttle between the TiO_2 surface and the counterelectrode.

Energy conversion efficiencies of up to 11%, under AM 1.5 irradiation and small active solar cell area (0.2 cm^2), have been obtained using Ru-polypyridyl dyes, but commercial applications require further improvements in efficiency and stability. Despite extensive work in the development of dyes[164–168] for DSSCs, not very impressive progress has been reported. Improvement of the device performance has been limited by the light-harvesting capability of the state-of-the-art dyes, which lack strong absorption in the red/near-infrared region where the solar flux of photons is maximum. Dyes which have a high molar extinction coefficient in this spectral region would allow the preparation of thinner devices, minimizing charge recombination during the transport of charges to the electrode.[169]

A. Structural Optimization of Phthalocyanines

Pcs are also attractive sensitizers for DSSCs due to their intense red absorbance and robustness, as mentioned in Section II. Moreover, depending on the central metal and the peripheral substituents, they have appropriate redox properties for sensitization of the TiO_2 films and dye regeneration by the I^-/I_3^- electrolyte.

For a long time the applications of Pc dyes in DSSCs have been restricted due to problems associated with aggregation of the dye on the metal oxide surface, resulting in rapid deactivation of the dye-excited state and low sensitizing efficiency. Introduction of the required anchoring carboxy groups at the peripheral positions of Pcs usually leads to additional problems concerning poor solubility and aggregate formation.

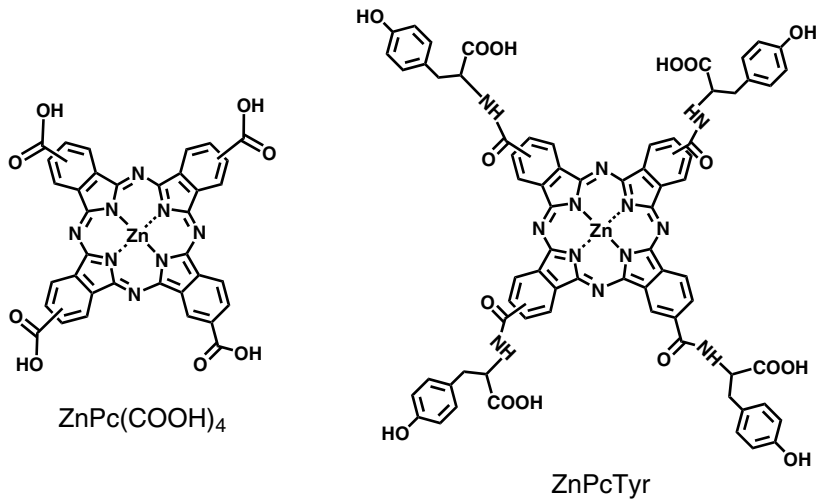

Figure 17. Molecular structures of tetracarboxy-ZnPcs tested in DSSCs.[170,175]

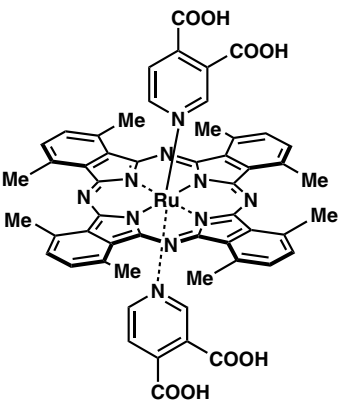
Efficient near-IR sensitization of nanocrystalline TiO_2 films by carboxy-zinc(II) and aluminum(III) phthalocyanines was first described by Grätzel, Wöhrle and coworkers in 1999.[170] Electron injection from the excited state of $ZnPc(COOH)_4$ (Figure 17) into the conduction band of TiO_2 was quite efficient in the near-IR region, displaying a maximum around 700 nm, where 45% of the photocurrent yield was obtained. The overall device efficiency was close to 1% under full AM 1.5 solar light.

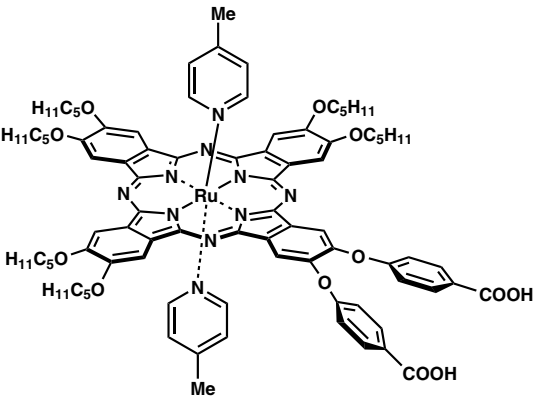
The data were obtained employing CHENO and 4-*tert*-butylpyridine additives, which helped to reduce the inherent aggregation problem. While the role of the 4-*tert*-butylpyridine can be easily explained by weak axial coordination to the Zn(II) metal ion, the role of the cholic acid was not clear. In this work it was also shown that structural Pc modifications such as replacement of Zn(II) by Al(III)OH, or introduction of carboxyphenoxy substituents, lead to poorer efficiencies. Similar results were obtained with ZnPcs containing sulfonic acid groups, offering a new way for anchoring the Pc dye to the TiO_2.[171–174]

A few years later, solar cells based on ZnPcTyr-coated nanostructure TiO_2 electrodes were reported by Sun, Sundstrom and coworkers.[175] Introduction of peripheral bulky carboxy-containing tyrosine units (Figure 17) made the dye ethanol-soluble and considerably decreased its aggregation on the surface. However, monochromatic IPCE values of only 24% at 690 nm were achieved, while the overall conversion efficiency remained moderate (*ca*. 0.54%); it was, however, one of the best results reported at that time.

Introduction of axial ligands is by far the best way to avoid the natural behavior of Pcs toward aggregation. This strategy implies the incorporation of



$RuPc[Py(COOH)_2]_2$



$RuPc(COOH)_2(PyMe)_2$

Figure 18. Molecular structures of carboxy-Ru(II)Pcs tested in DSSCs.[176,178]

metals able to form penta- or hexacoordinated complexes, such as Si(IV), Ti(IV) and Ru(II).

As early as 1998, $RuPc[Py(COOH)_2]_2$ (Figure 18) anchored to nanocrystalline TiO_2 films through axial pyridine 3,4-dicarboxylic acid ligands was already reported as an efficient near-IR sensitizer for photovoltaic injection cells.[176] Strikingly high photocurrent yields exceeding 60% in the near-IR region were obtained, demonstrating that efficient coupling of the dye-excited state to the conduction band could occur through space without involving the anchoring group. Other examples of RuPc bearing carboxylic groups, such as $RuPc(COOH)_2(PyMe)_2$ (Figure 18), came later,[177,178] but the results never went over 0.5% overall efficiencies.

Tetra-*tert*-butyl-substituted Pcs exhibit a good compromise between good solubility and reduced aggregation tendency. The Ti(IV)Pc derivative TiPc(COOH) bearing a carboxycatechol bidentate axial ligand (Figure 19) was efficiently anchored to nanocrystalline TiO_2 without the need for coadsorbents to prevent macrocycle aggregation.[179] However, photocurrent generation in the macrocycle Q band region was quite low, accounting for an inefficient electron injection from the LUMO level, which is close in energy to the TiO_2 conduction band.

Considering the rich electrochemistry of RuPcs, whose oxidation potential can be slightly tuned by changing the substituents at the pyridine axial ligands,[180] and in order to gain more insights into the possibilities of RuPcs as sentitizers of TiO_2, a family of tetra(*tert*-butyl)-RuPcs (RuPcA) bearing two different axial pyridine ligands were prepared by Torres and coworkers (Figure 19).[181] One ligand, 4-carboxypyridine, would play the role of the anchoring group and the

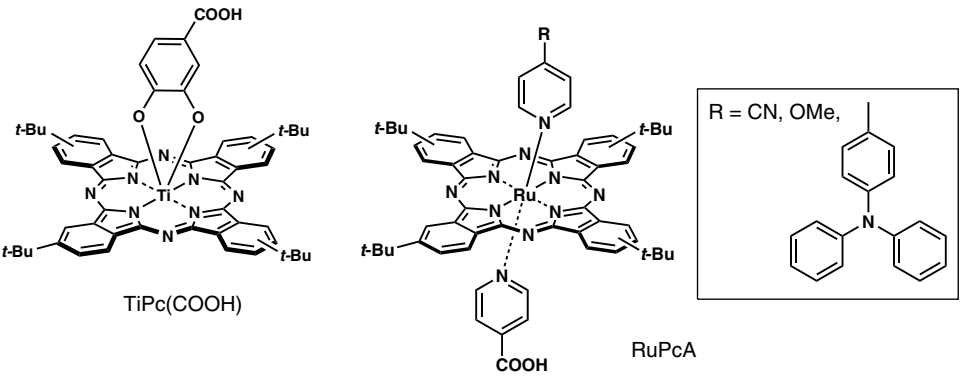


Figure 19. Molecular structures of tetra-*tert*-butyl-substituted TiPcs and RuPcs bearing carboxy groups at the axial ligand tested as TiO_2 film sensitizers, in Refs. 179 and 181.

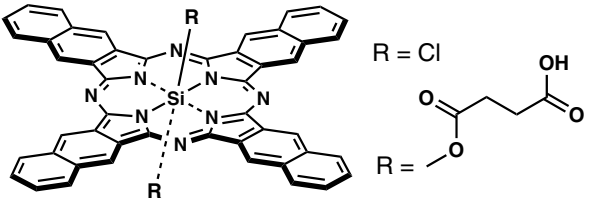

Figure 20. Silicon naphthalocyanine dyes tested in DSSCs.[182]

second one, bearing either an electron-withdrawing (e.g. CN) or an electron-donating (e.g. OMe, triphenylamine) substituent, can serve to modulate the electronic properties of the phthalocyanine. In DSSCs with suitable electrolytes, RuPcA were capable of efficient photocurrent generation, showing absorbed-photon-to-current efficiencies of up to 45%.

Very recently, silicon naphthalocyanine dyes (Figure 20) have been attached through the axial position to TiO_2 nanostructured photoelectrodes.[182] Si–O–Ti linkage resulted in being much more effective than the classical carboxy–TiO_2 interaction due to the high reactivity of $SiNcCl_2$ toward Si–O formation. Promising photovoltaic results were obtained, reaching a maximum IPCE of *ca.* 17% at 790 nm.

A major step forward for the application of Pcs in many fields, including DSSCs, came from the preparation of unsymmetrically functionalized, A_3B-type derivatives.[183] The introduction of *tert*-butyl groups at three of the isoindole units, leaving the fourth one for attaching the anchoring group, allowed the preparation of highly soluble carboxy–Zn(II)Pc derivatives PCH001 and TT-1 (Figure 21),

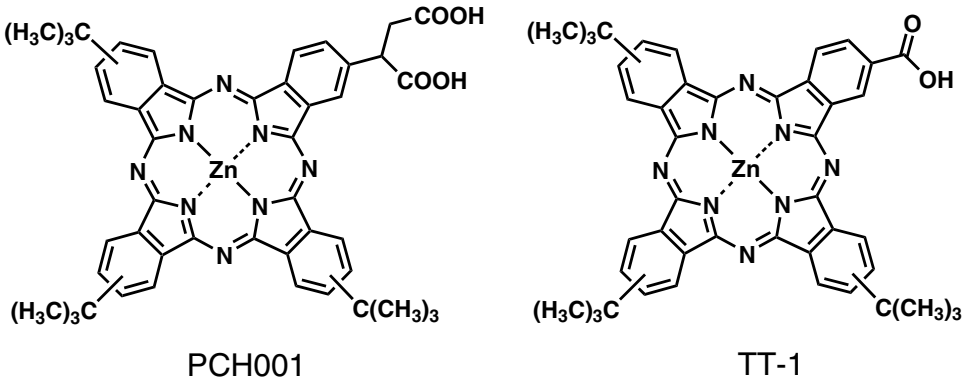

Figure 21. Molecular structures of unsymmetrically substituted carboxy–Zn(II)Pcs PCH001 and TT-1, reported in Refs. 184 and 185.

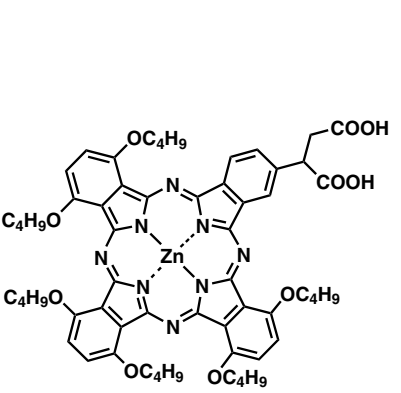
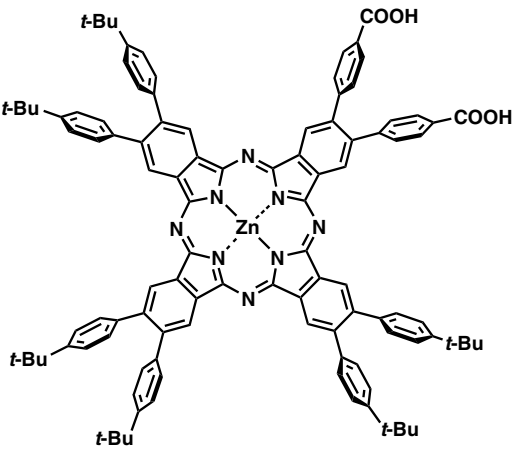
which had a low tendency toward aggregation.[184,185] In particular, TT-1 possesses a highly desirable "push–pull" structure with the carboxy group directly attached to the macrocycle, thus facilitating charge transfer from the LUMO orbital of the dye to the Ti 3d orbital and, therefore, optimizing the device performance to get overall efficiencies above 3.5% at 1 sun. This value, and the IPCE at the maximum absorption of the Q band of 80%, represented the best results ever reported for a PC–TiO_2 dye-sensitized solar cell.

Optimization of the dye component of the cell usually requires a systematic structural modification. In the case of phthalocyanine dyes, two approaches have been reported:

(1) *Peripheral modification* and preparation of new derivatives as single isomers with an enhanced *push–pull* character. Tri-*tert*-butyl-substituted Pcs PCH001 and TT-1 are, in fact, a mixture of regioisomers. However, by employing 3,6- or 4,5-disubstituted phthalonitrile precursors, this symmetry problem can be solved. Indeed, hexa-α-butoxy derivatives of PCH001 have been reported by Giribabu *et al.*[186] Neverthesless, when the new sensitizer PCH003 (Figure 22) was tested in DSSCs and compared with the parent molecule PCH001, the overall efficiency went down to *ca.* 1%, without any rational explanation. On the other hand, carboxy–ZnPc ZnPc($tBuC_6H_5$)$_6$($COOH$)$_2$ (Figure 22) bearing six bulky *t*-butylphenyl groups at the peripheral β position were also considered as sensitizers.[187] However, the corresponding cells displayed only 0.57% of conversion efficiency and 4.9% of IPCE at the Q band wavelength. It was demonstrated that, indeed, aggregation of Pcs was almost suppressed by introduction of the *t*-butylphenyl groups. However, the disappointing low



PCH003



$ZnPc(tBuC_6H_5)_6(COOH)_2$

Figure 22. Molecular structures of ZnPcs PCH003 and $ZnPc(tBuC_6H_5)_6(COOH)_2$, described in Refs. 186 and 187.

device efficiencies were attributed to the inefficient coupling between the dye and the conduction band of TiO_2. Also remarkable is the absence of photocurrent response when the free-base derivative was employed, due to its low excited singlet state [the oxidation potential of the free base is 330 mV more positive than that of the Zn(II) derivative, whereas the HOMO–LUMO gaps remain similar].

(2) A different approach en route to dye optimization has been reported by Torres and coworkers.[188,189] TT-1 derivatives bearing different π-conjugated and non-conjugated linkers between the carboxy group and the Pc macrocycle have been systematically checked in DSSCs and compared with TT-1 sensitizers (Figure 23). This work has shown the influence of the location of the carboxy anchoring group on the device performance. A modification of the linker groups within the series TT1–TT5, TT-14 and TT-20 allows not only a variable distance between the dye and the photosensitized nanocrystalline TiO_2, but also a distinct orientation of the dye molecular plane with regard to the semiconductor surface which modifies the orbital coupling between the dyes and the semiconductor. In particular, a remarkable influence on the electron injection and the recombination steps has been demonstrated. Table 1 summarizes the photovoltaic results obtained. Under standard solar simulation conditions, TT2 and TT4 derivatives gave the poorest performance. As previously stated by Nazeeruddin *et al.*,[170] the IPCE values drop dramatically when the carboxy anchoring group is separated from the Pc by insulating alkoxy or

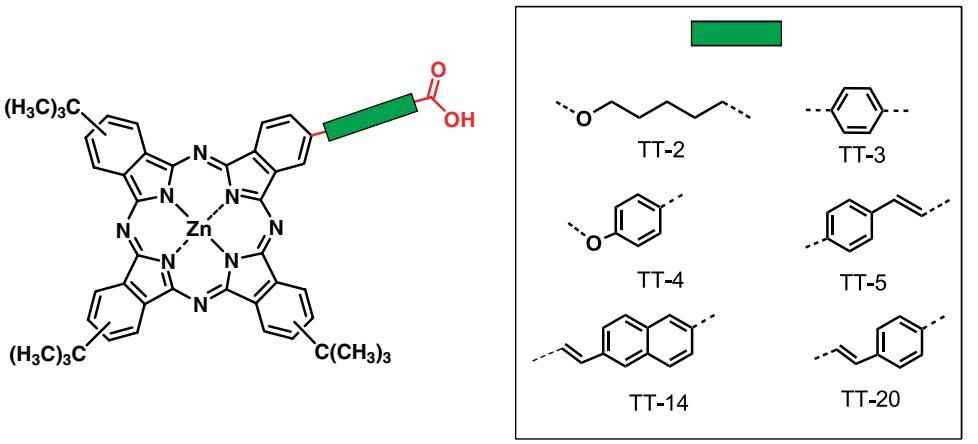


Figure 23. Molecular structures of TT-1 derivatives bearing different spacers between the macrocycle and the carboxylic anchoring group.[188,189]

Table 1. Comparative photovoltaic data[188,189] of tri-*tert*-butyl carboxy–PcZn dyes bearing different spacers between the Pc and the carboxy group.

Sensitizer	J_{sc} (mA/cm^2)	V_{oc} (mV)	η (%)
TT-1	7.6	617	3.52
TT-2	0.9	550	0.4
TT-3	4.8	610	2.20
TT-4	1.44	611	0.67
TT-5	6.8	613	3.10
TT-14	5.36	579	2.20
TT-20	4.36	587	1.87

aryloxy spacers. In constrast, rigid π-conjugated bridges do not interrupt electronic coupling between the Pc and the semiconductor surface, giving such derivatives (TT-3, TT-14 and TT-20) average power conversion efficiencies of 2%.

As in porphyrin derivatives,[190] conjugation of the carboxy anchoring group through an ethenyl spacer to the dye leads to superior photovoltaic responses in DSSCs. Thus, the TT-5 derivative, bearing a π-conjugated vinylenephenylene spacer, showed higher performance than the TT-20 derivative, which presents an opposite arrangement of the ethenyl and phenylene groups. In spite of this, the better results obtained with TT-1 suggest that the anchoring group should remain as close as possible to the chromophore so as to maximize the coupling between the Pc and the TiO_2.

The preparation of novel Pcs with better performance as DSSC sensitizers deserves much additional work. A hard synthetic effort is being developed in this connection, since there is convincing evidence that Pcs, among the plethora of red-light-absorbing molecules, can make a crucial contribution to the improvement of the current devices.

B. Insights into the Interfacial Electron Transfer Dynamics

After many years of research, numerous dyes have been tried and none have surpassed the best Ru–Bpy complexes.[160–169] In fact, the DSSC is a complicated system which is not yet fully understood. Besides systemic dye modification, new design rules are needed to guide new proposals focused on minimizing loss mechanisms and improving light harvesting. A better understanding of the physicochemical processes which underlie the function of DSSCs would also contribute to the optimization of these devices. In particular, there is a growing interest in studying the influence of dye structure on the interfacial electron transfer kinetics.[191] It can be said that "optimum" device performance will be observed when the recombination dynamics are as slow as possible while electron injection is sufficiently fast to compete with excited state decay.

As described above, upon excitation of the chromophore from its ground state to an excited state that is resonant with the TiO_2 conduction band, the electron is injected into the semiconductor surface. Electron injection is related to an efficient coupling between the dye and the TiO_2 conducting band. It can be monitored by following the formation of the corresponding electron transfer species. In the case of carboxy-substituted Zn(II)Pcs, it has been found that electron injection is very efficient (quantum yields higher than 90%) and very fast (around 200 ps). However, the question to answer is whether such a time scale of electron injection is necessary for achieving efficient DSSC function. It has been shown that efficient electron injection can also occur in systems where the dynamics are remarkably slower (up to three orders of magnitude). Ru(II) derivatives RuPcA (see Figure 29) exhibit electron injection rate constants of hundred of ns, and lower APCE values than Zn(II) derivatives.[181] The reason for the slow injection dynamics is that injection occurs more efficiently from the RuPcs triplet state. In other words, the relaxation of the singlet to the triplet excited state by intersystem crossing is faster (100 ps) than electron injection from the singlet excited state (600 ps to 30 ns). The long lifetime of this T_1 state (200 ns) enables electron injection into TiO_2 to be slow, in competition with the T_1 decay to the ground state.

Following efficient injection, the electron has to diffuse into the bulk and simultaneously relax to the bottom of the TiO_2 conduction band. If the relaxation inside the conduction band occurs faster than delocalization into the bulk, the electron

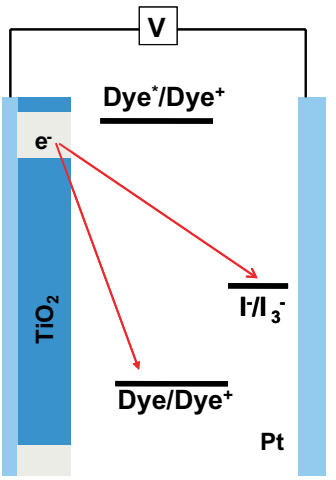

Figure 24. Schematic diagram representing recombination to the dye and dark current (recombination to the electrolyte) in a DSSC.

can be trapped at the surface. Since the electron is attracted by the positive charge remaining on the dye after injection, it can back-transfer and recombine with the hole of the chromophore ground state, thus short-circuiting the cell. By accepting the surface electron, the electrolyte can also short-circuit the cell.

From early studies it was already stated that very fast recombination to the dye (see Figure 24) was most likely responsible for the lower performance of Pc-sensitized solar cells[175] compared with highly efficient N3-sensitized TiO_2 films. Introduction of secondary donor groups could help to retard interfacial back electron transfer. However, this strategy was never reported.

O'Regan *et al.* have proposed that the bottleneck in Pc-sensitized cell performance could be related to the increased recombination rates to the I_2/I_3^- electrolyte, thus decreasing the resulting output voltage.[192] In fact, it was found that recombination is *ca.* 100 times faster for RuPc-sensitized cells than for the ones made of the N719 dye. This phenomenon, which it is claimed to be extrapolated to other organic dyes with an accessible aromatic surface, was rationalized considering that the reduction of iodine to tri-iodide could be mediated by the dye, through binding to the iodine, and therefore help to increase the iodine local concentration near the TiO_2 surface.

C. The Role of Coadsorbents

Coadsorbents are typically transparent compounds or ions which absorb together with the dye on the mesoporous semiconductor surface. They are used because

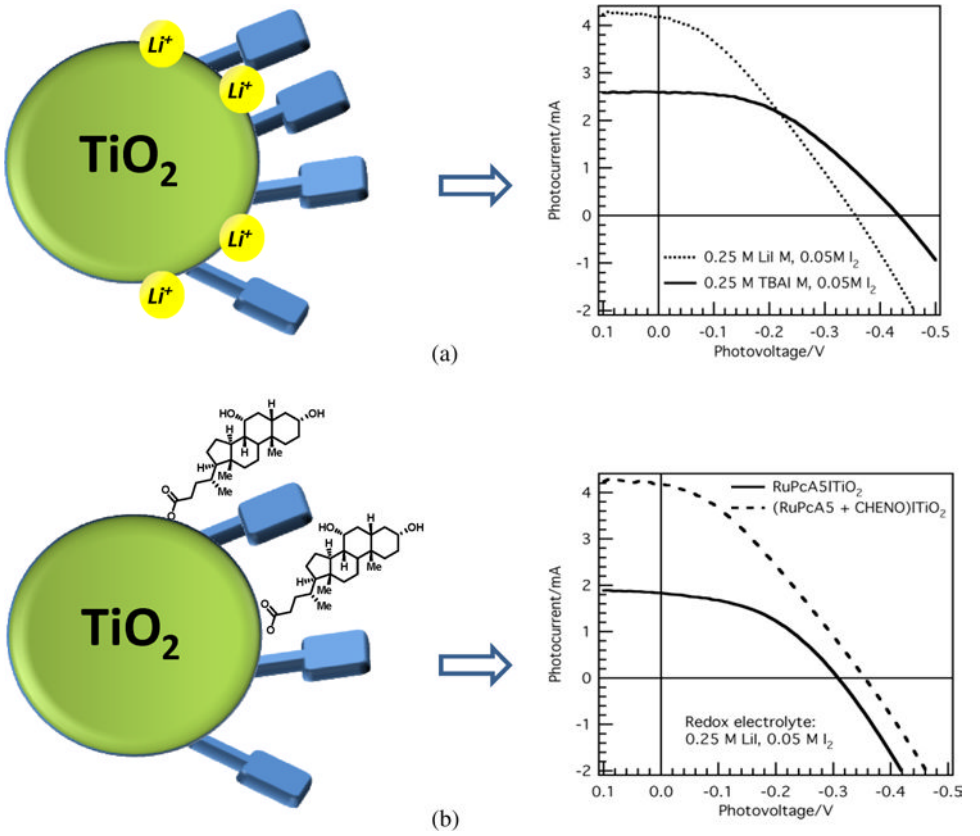

Figure 25. Schematic representation of a TiO_2 nanoparticle coated with both sensitizer and typical coadsorbents: (a) Li^+ and (b) CHENO. On the right side is represented how these coadsorbents affect the solar cell parameters (taken from Ref. 194).

their presence substantially improves the cell efficiency. However, the reason for this beneficial effect is not always well understood and their use is often empirical. Li^+ and CHENO are the most popular coabsorbents employed in DSSCs.

Li^+ cation acts directly on the TiO_2 surface, charging it positively. Its presence usually lowers the conduction band edge of TiO_2, therefore accelerating the electron injection and increasing the photocurrent in the device, although with concomitant decrease in photovoltage (see Figure 25a).

On the other hand, CHENO (see Figure 25b) bears a carboxylic acid functional group that allows its strong binding to the TiO_2 surface, in competition with the dye molecules. The addition of CHENO produced a remarkable increase in the photocurrent and to a lesser extent the photovoltage (Figure 25b). The increase in the photovoltage is usually attributed to the effect of CHENO breaking dye

aggregates.[167] In other cases, the beneficial effect of CHENO has been related to a decrease in recombination in the injected electrons with the redox electrolyte.[193]

Morandeira *et al.* have studied in detail the effect of these two coadsorbents on the device performance and photophysics of RuPcA-sensitized solar cells.[194] In the case of RuPcs the formation of aggregates is completely hindered by the presence of axial ligands. Indeed, the authors demonstrated that CHENO is not affecting the electron injection quantum yield, but the cation–TiO_2 (e^-) recombination and regeneration dynamics. In particular, the slower recombination of the dye cations with the TiO_2 electrons and the faster regeneration of the dye cations by the electrolyte are the reason claimed to be responsible for the enhanced photocurrent observed in the presence of CHENO coadsorbent molecules. A tentative explanation for that effect could be the change in the dye orientation induced by the presence of CHENO on the semiconductor surface, increasing the hole–electron distance. Anyway, the results suggest that the CHENO effect on DSSCs is more complex (and more beneficial) than what was previously assumed.

D. The Cosensitization Strategy

The possibility of combining different dyes with complementary absorbing spectra to achieve panchromatic sensitization of the TiO_2 films and increase device efficiency has always been a challenge in this field. Many "molecular cocktails" have been tried with limited success, due to the typical decrease in the sensitizing efficiency of the individual dyes upon mixing them.[195–201]

Pcs offer an optical window in the visible region that makes these molecules very appealing components of cosensitizer blends. $RuPc[Py(COOH)_2]_2$ (see Figure 18) was used together with Ru-bipyridyl dye N3 in a sophisticated device architecture which consisted in the deposition of a secondary Al_2O_3 layer between the N3-coated TiO_2 nanoparticles and the RuPc layer.[202] This approach avoided competition between the two dyes for absorption sites, and resulted in an interfacial electron transfer cascade in which the hole moved from the inner dye, closer to the TiO_2 surface, to the outer dye, thus retarding the interfacial charge recombination dynamics.

More recently, efficient cosensitized DSSCs have been prepared using the previously reported organic dyes, JK2 and TT-1 (see Figure 21). The photoresponse of the molecular cocktail was higher than those of the single dye-sensitized devices (Figure 26). The overall device efficiency, one day after the preparation of the device, was 7.74%.[181] The key point for this success was rationalized to be related to the high extinction coefficients of the dyes, which allow using low dye concentrations to achieve efficient absorption and therefore leave sufficient space on the TiO_2 surface to attach a second dye with a complementary absorption spectrum.[203]

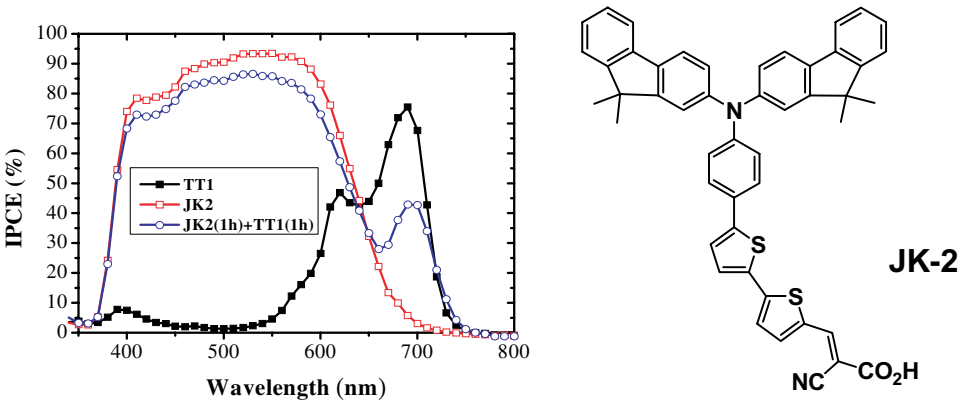

Figure 26. Molecular structure of JK2 dye and IPCE versus wavelength representation of the "TT-1/JK-2 molecular cocktail" in comparison with those of the individual cells, from Ref. 185.

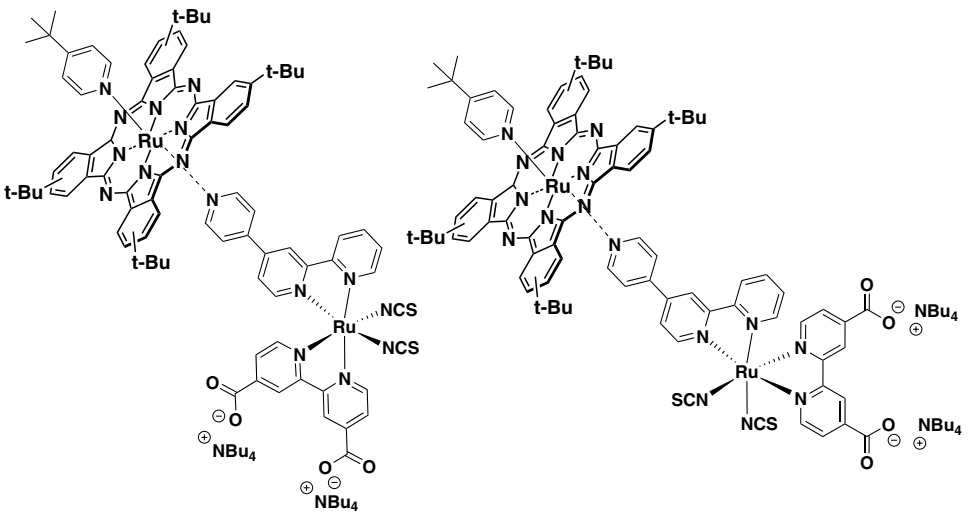

Figure 27. Molecular structures of the RuPc–Rubis(bipyrididyl) dyads tested in DSSCs.[204]

The cosensitization strategy possesses an obvious serious constraint concerning the number of sites on the titania surface that are available for dye attachment. Beyond that, it can be envisaged that molecular or covalent or supramolecular dyads constituted by two complementary absorbing dyes would positively contribute to the panchromatic sensitization of the TiO_2 films, avoiding the competition between the dyes for the binding sites in the TiO_2, since only one of the chromophoric units would bear the anchoring group to attach the whole molecule to the surface.[204] Up to now, only one example of a supramolecular dyad containing both RuPc and Ru bis(bipyridyl) chromophores (Figure 27) has been

published.[205] Unfortunately, solar cell efficiencies were not improved when compared with the reference N716 Ru bis(pipyridyl) dye. However, photocurrent generation *per molecule* was superior in the case of dyads. Indeed, the increased molecular size of the dyads is believed to be responsible for a concurrent decrease in dye coverage and DSSC performance.

A new concept for increasing light harvesting in DSSCs using energy relay dyes (ERDs) as cosensitizers has been proposed by Hardin *et al.*[206] In particular, a 26% increase in power conversion efficiency was achieved by incorporating an unattached highly luminescent PTCDI chromophore inside the liquid electrolyte in a TT-1 (see Figure 21) sensitized solar cell (Figure 28). The improvement in the device performance is attributed to the increase in the short-circuit photocurrent caused by an increase in the EQE in the 400–600 nm region, while the open-circuit voltage remained almost unchanged.

New sensitizers are being tested in DSSCs such as inorganic semiconducting materials that are so-called *quantum dots*. They possess ideal properties such as tunable band gaps. However, both quantum-dot-sensitized solar cells have shown lower efficiencies than initially expected, due to difficulties in finding appropriate redox couples and resolving stability issues.

Hybrid-sensitized solid cells combining PbS or CdS quantum dots with a near-IR-absorbing TT-1 have also been described. In this case, the TT-1 chromophore is added over the quantum-dot-deposited layer to strengthen the light-harvesting capabilities into the near-IR region.[207] Although the photocurrent decreased somewhat in the visible range compared to the original signal from PbS, photocurrents in the near-IR range increased at around 690 nm, where TT-1 dye absorbs strongly. A positive coctkail effect was obtained from a combination of CdS and sensitizer.

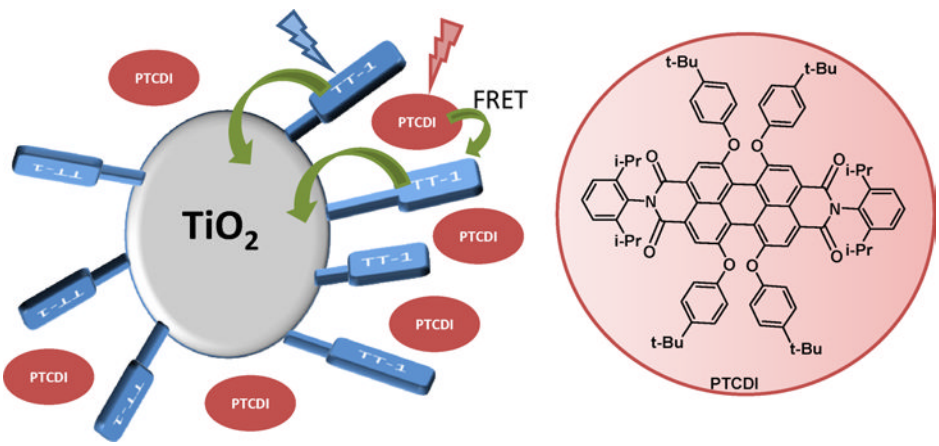

Figure 28. Schematic representation of a DSSC with energy relay dyes, reported in Ref. 206.

IV. Summary and Conclusions

Phthalocyanines, which possess intense absorption in the UV/blue and the red/near-IR region spectral regions, are materials especially suitable for integration in photovoltaic devices. In order to accomplish this function, specific requirements must be met, like collection of light energy, separation of charges, an appropriate active layer morphology that ensures charge migration, and stability, among others. Pcs usually play the double role of donor component and antenna.

Phthalocyanines are among the benchmark materials for photovoltaic heterojunctions based on small molecules. Thus, most of the success of Pcs in the organic photovoltaic field is based on unsubstituted Pc evaporated thin films incorporated as the active layer in different types of architecture devices; in this case efficiencies of *ca*. 6% have been reached. The use of Pc analogs in this area, like subphthalocyanines, is also very promising.

On the other hand, efficient solar cells based on solution-processed phthalocyanines are still scarce. The incorporation of phthalocyanines into polymeric photovoltaic devices is typically performed in blends together with semiconducting polymers and, usually, acceptor molecules such as fullerenes, obtaining only moderate (near 2%) efficiencies. Further developments using small molecules instead of polymers, or blends of conducting polymers and n-type Pcs instead of fullerenes, are worth of much attention.

The morphological problems of the so-called bulk heterojunctions have suggested the preparation of intrinsically bipolar materials, in which the donor and acceptor photoactive units are covalently linked within the same molecule, including the so-called "double-cable" approach with Pcs pending of conducting polymers. However, the efficiencies found in Pc-based solar cells fabricated exclusively with this kind of electroactive materials are still very low, and the field deserves further research.

On the other side, phthalocyanines are suitable to be applied as sensitizer dyes in dye-sensitized solar cells. DSSCs based on mesoporous TiO_2 have been an attractive alternative to the purely organic devices because of their huge interfacial area and high electron mobility in mesoporous titania. The efficiency of DSSCs has been limited by the low optical absorbance in the red/near-IR region of the dyes commonly used, such as ruthenium bipyridyl, as well as their low extinction coefficient. This is one of the points on which "colored" Pcs can be really useful in this area.

The applications of Pc dyes in DSSCs have been restricted due to problems associated with aggregation of the dye on the metal oxide surface, resulting in

rapid deactivation of the dye-excited state and low sensitizing efficiency. Recent development of red-absorbing Pc-based sensitizers with no dye aggregation on the TiO_2 surface has allowed efficient sensitization. Moreover, the modification of the spacer between the Pc core and the anchoring moiety has allowed not only a variable distance between the dye and the photosensitized nanocrystalline TiO_2, but also a distinct orientation of the dye molecular plane with regard to the semiconductor surface. Both axial and peripheral attachments of the Pc to the semiconductor have been shown to be effective, particularly the latter. Thus, efficient electron injection of a zinc phthalocyanine (TT-1), which yields 80% IPCE at 690 nm and an excellent efficiency (*ca.* 4%) under standard illumination conditions, have been described. Moreover, there has been illustrated the possibility of combining efficiently two dyes with complementary spectra and obtaining higher efficiencies, which could not be achieved separately by each of them, by taking advantage of the optical properties of the zinc phthalocyanine.

Very recently, a new design has been described, where high-energy photons are absorbed by an energy relay dye, unattached to the titania, which undergoes Förster resonant energy transfer to a Pc-sensitizing dye (TT-1). This novel architecture allows for broader spectral absorption and an increase in dye loading, and relaxes the design requirements for the phthalocyanine. This system offers a viable pathway for developing more efficient DSSCs.

The design of more efficient Pc-based sensitizers and their application to cosensitized and tandem solar cells, consisting of complementary absorbing dyes, energy relay dyes or "quantum dots," represent the trend in this area. The ultimate potential of Pcs for solar cell development can be hard to quantify, thus making predictions about the future very difficult. The results achieved to date, however, reveal that phthalocyanines must be considered seriously as photoactive components for future organic photovoltaic devices.

V. Acknowledgments

Funding from MEC and MICINN (CTQ2008-00418/BQU, CONSOLIDER-INGENIO 2010 CDS2007-00010 Nanociencia Molecular, FOTOMOL, PSE-120000-2009-008, PLE2009-0070), ESF-MEC (MAT2006-28180-E, SOHYDS), EU (Solar-N-type, MRTN-CT-2006-035533, ROBUST DSC, FP7-Energy-2007-1-RTD, No. 212792), COST Action D35 and CAM (MADRISOLAR, S2009/PPQ/1533) is gratefully acknowledged. We would also like to thank all coworkers and collaborators (Guldi, Durrant, Grätzel, Nazeeruddin and Palomares, among others) who have performed with us exciting research in the field of Pc-based organic photovoltaics.

I. Introduction

The food we eat and the fossil fuels we use are products of photosynthesis, which is the process that converts solar energy to chemical energy. The overwhelming part of our energy supply comes from the chemical energy which has been stored in the fossil fuels over several billions of years. The world's energy consumption rate of fossil fuels is expected to increase further in the next few decades, due to increase in demand from the developing countries. The rapid consumption of fossil fuels has caused unacceptable environmental problems such as greenhouse effects, which

are predicted to have disastrous climatic consequences.[1–3] Thus, renewable and clean energy resources are definitely required in order to maintain the quality of human life as well as the environment of the earth.[1–3] One of the most attractive strategies to stop global warming is the development of artificial systems that mimic natural photosynthesis in the conversion and storage of solar energy.[4–8]

Energy from sunlight is first captured by photosynthetic π-pigments such as chlorophylls and carotenoids, which cover a wide spectral range of solar irradiation.[9–11] The captured light energy is transferred to chlorophylls that are in a special protein environment where the actual energy conversion event starts via electron transfer processes.[9–11] Pigments and proteins involved in this actual primary electron transfer event together are called the reaction center.[9–11] A large number of π-pigment molecules (100–5000), collectively referred to as antennas, harvest light and transfer the light energy to the same reaction center.[9–11] The purpose of such antenna molecules is to maintain a high rate of electron transfer in the reaction center, even at lower light intensities.[9–11] The importance and the complexity of energy transfer and electron transfer processes in the photosynthetic reaction center have prompted the design and preparation of a variety of donor–acceptor covalently and noncovalently linked ensembles, including dyads, triads, tetrads and pentads, which are able to mimic the energy-transfer and electron transfer processes in the photosynthetic reaction center.[12–24]

This chapter presents an overview of development on artificial photosynthetic reaction center models using porphyrins, phthalocyanines and related maclocycles by focusing on a deeper understanding of the function of the photosynthetic reaction center and also applications of the functional models to develop low cost and efficient organic solar cells. First, a rational design of the photosynthetic reaction center models is described, based on the Marcus theory of electron transfer.[25,26] Then, the difference in the photoinduced electron transfer properties depending on the type of porphyrins (planar vs. nonpolar porphyrins and monomeric vs. dimeric porphyrins) is clarified in light of Marcus' theory. A variety of photosynthetic reaction center models composed of porphyrins or phthalocyanines linked with electron donors and acceptors by covalent and noncovalent bonding have been developed, including multicomponent systems, which undergo efficient charge separation, electron or hole migration and slow charge recombination. Finally, supramolecular porphyrin assemblies with electron donors and acceptors have been applied to develop porphyrin solar cells.

II. Rational Design of Photosynthetic Reaction Center Models

Rational design of the photosynthetic reaction center has been made possible based on the Marcus theory of electron transfer.[25,26] According to the theory, the

rate constant of nonadiabatic intramolecular electron transfer (k_{ET}) in an electron donor–acceptor-linked molecule at the fixed distance between the donor and acceptor moieties is given by Eq. (1)

$$k_{ET} = \left(\frac{4\pi^3}{h^2 \lambda k_B T}\right)^{\frac{1}{2}} V^2 \exp\left[-\frac{(\Delta G_{ET} + \lambda)^2}{4\lambda k_B T}\right], \quad (1)$$

where V is the electronic coupling matrix element, h is Planck's constant, T is the absolute temperature, ΔG_{ET} is the free energy change of electron transfer, and λ is the reorganization energy of electron transfer, which is the energy required to structurally reorganize the electron donor and acceptor and their solvation spheres upon electron transfer. According to Eq. 1, the logarithm of the rate constant (log k_{ET}) of electron transfer in an electron donor–acceptor dyad (D–A) in Figure 1a is given as a parabolic function of the driving force of electron transfer ($-\Delta G_{ET}$), as shown in Figure 1b. The parabolic dependence of log k_{ET} on $-\Delta G_{ET}$ is determined by two factors: one is the electronic coupling matrix element V, which determines the maximum k_{ET} value, and the other is the reorganization energy (λ). When the magnitude of the driving force of electron transfer becomes the same as the reorganization energy ($-\Delta G_{ET} \sim \lambda$), the k_{ET} value reaches a maximum, which is determined by the magnitude of electronic coupling (V) between the donor and

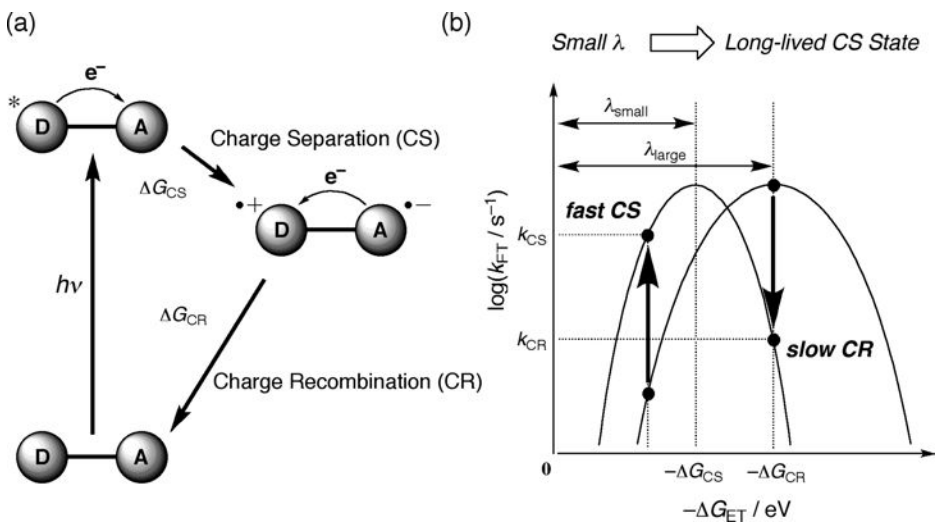

Figure 1. (a) Energy diagram of photoinduced electron transfer of an electron donor–acceptor dyad with photoexcitation of the donor moiety. (b) Driving force dependence of log k_{ET} of the CS and CR processes with different λ values.

acceptor moiety (Figure 1b). In the highly exothermic region of the parabola ($-\Delta G_{ET} > \lambda$), an increase in the driving force results in a decrease in the electron transfer rate. This highly exergonic range is generally referred to as the Marcus inverted region.[25–31] The smaller the reorganization energy, the faster the forward photoinduced charge separation (CS) process of an electron donor–acceptor dyad (D–A), but the charge recombination (CR) process becomes slower when the CR driving force ($-\Delta G_{CR}$) is larger than the reorganization energy (λ) of electron transfer, as shown in Figure 1b.

III. Planar vs. Nonplanar Porphyrins

Porphyrins normally have a planar π-core, which enables efficient electron transfer, because the uptake or release of electrons from porphyrins usually results in minimal structural change upon electron transfer.[31] Introduction of bulky substituents on a porphyrin macrocycle affords nonplanar conformations of porphyrins. For example, synthetic dodecaphenylporphyrin (H_2DPP), which contains a phenyl group at each β-pyrrole and *meso* position of the porphyrin macrocycle, adopts a saddle-shaped nonplanar conformation.[32–35] The doubly protonated porphyrin dication (H_4DPP^{2+}) is readily obtained due to the distortion and H_4DPP^{2+} can act as an electron acceptor.[36] How conformational distortions of the porphyrin ring affect the rates of intermolecular electron transfer reduction of diprotonated porphyrins in solution has been examined using a series of nonplanar porphyrins, hydrochloride salts of saddle-distorted dodecaphenylporphyrin ($[H_4DPP]Cl_2$), tetrakis(2,4,6-trimethylphenyl)porphyrin ($[H_4TMP]Cl_2$), tetraphenylporphyrin ($[H_4TPP]Cl_2$), and octaphenylporphyrin ($[H_4OPP]Cl_2$), in comparison with that of a planar porphyrin, (acetonitrile-κN)-(tetrakis(pentafluorophenyl)porphyrinato) zinc(II) ([Zn(F_{20}TPP)(MeCN)]), as electron acceptors.[35] The optimized structures of $[H_4DPP]Cl_2$, $[H_4OPP]Cl_2$, $[H_4TPP]Cl_2$, and $[H_4TMP]Cl_2$ exist in saddle-distorted structures — whereas [Zn(F_{20}TPP)(MeCN)] is planar, as shown in Figure 2[36] — together with the optimized structures of the one-electron-reduced species.[35]

The rate constants for photoinduced electron transfer from a series of analogous electron donors (ferrocene derivatives) to the triplet excited states of noplanar diprotonated porphyrins and planar [Zn(F_{20}TPP)(MeCN)] were determined by laser flash photolysis measurements.[35] The driving force dependence of the logarithm of the rate constants of the photoinduced electron transfer ($\log k_{et}$) is shown in Figure 3.[35] Intermolecular photoinduced electron transfer from an electron donor (D) to $^3\{[H_4DPP]Cl_2\}^*$ occurs as shown in Scheme 1, where k_{12} and k_{21} are the diffusion rate constant and the dissociation rate constant in the encounter

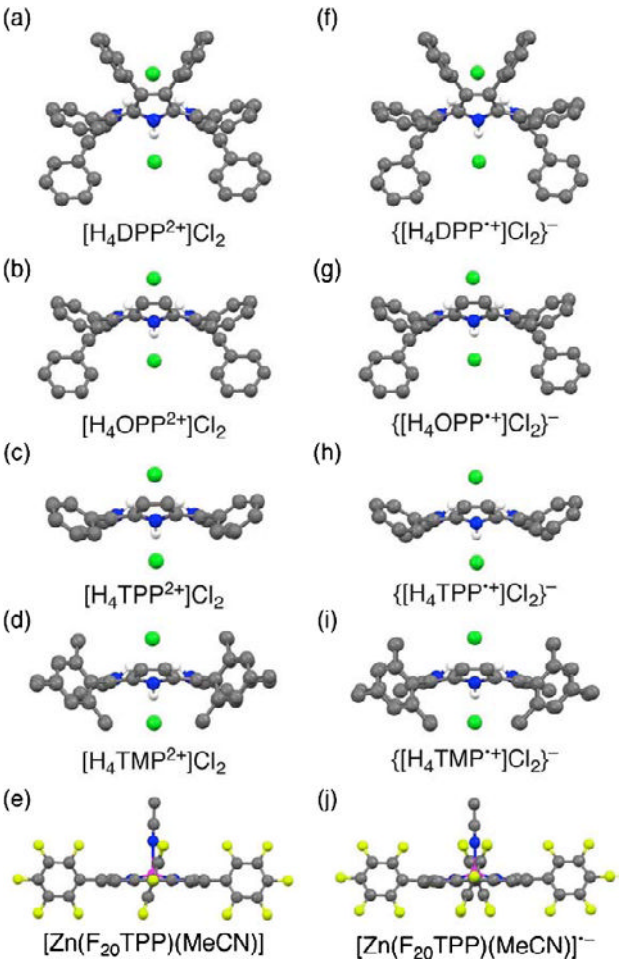

Figure 2. Optimized structures of (a) $[H_4DPP^{2+}]Cl_2$, (b) $[H_4OPP^{2+}]Cl_2$, (c) $[H_4TPP^{2+}]Cl_2$, (d) $[H_4TMP^{2+}]Cl_2$, (e) $[Zn(F_{20}TPP)(MeCN)]$, (f) $\{[H_4DPP^{\bullet+}]Cl_2\}^-$, (g) $\{[H_4OPP^{\bullet+}]Cl_2\}^-$, (h) $\{[H_4TPP^{\bullet+}]Cl_2\}^-$, (i) $\{[H_4TMP^{\bullet+}]Cl_2\}^-$, and (j) $[Zn(F_{20}TPP)(MeCN)]^{\bullet-}$ obtained by DFT calculations at the B3LYP/3-21G level of theory (adapted from Ref. 35). Hydrogen atoms of phenyl groups are omitted for clarity.

complex, respectively, and k_{ET} is the first-order rate constant of electron transfer in the encounter complex.[37]

The observed second-order rate constant of electron transfer (k_{et}) is given by Eq. 2. The dependence of k_{ET} on the driving force of electron transfer ($-\Delta G_{et}$) for

$$k_{et} = \frac{k_{ET}k_{12}}{k_{21} + k_{ET}} \tag{2}$$

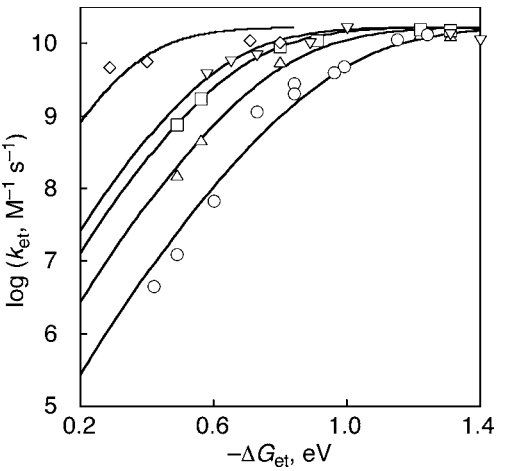

Figure 3. Driving force dependence of log k_{et} for electron transfer from electron donors to $^3\{[H_4DPP]Cl_2\}^*$ (○) and $^3[Zn(F_{20}TPP)(MeCN)]^*$ (◇) in MeCN at 298 K and $^3\{[H_4OPP]Cl_2\}^*$ (Δ), $^3\{[H_4TPP]Cl_2\}^*$ (□) and $^3\{[H_4TMP]Cl_2\}^*$ (▽) in MeCN containing *ca.* 30 equivalents of HCl at 298 K, and the fit of the curve based on the Marcus theory of electron transfer (Eq. 3) is shown by the solid line with λ = 1.69, 1.45, 1.29, 1.21, and 0.84 eV. (Adapted from Ref. 35.)

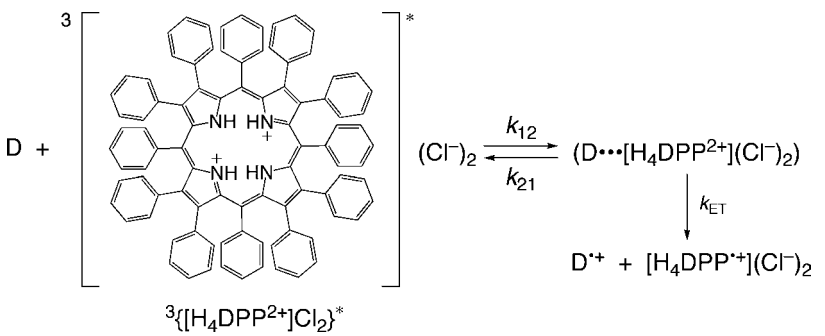

Scheme 1.

adiabatic outer-sphere electron transfer is given by Eq. 3,

$$k_{et} = \frac{k_{12} Z \exp\left[-\left(\frac{\lambda}{4}\right)\left(1+\frac{\Delta G_{et}}{\lambda}\right)^2 \Big/ k_B T\right]}{k_{12} + Z \exp\left[-\left(\frac{\lambda}{4}\right)\left(1+\frac{\Delta G_{et}}{\lambda}\right)^2 \Big/ k_B T\right]}, \quad (3)$$

where Z [= $(k_BT/h)(k_{12}/k_{21})$] is the collision frequency, which is taken as 1×10^{11} M^{-1} s^{-1}.[37,38] The k_{12} values is the diffusion rate constant in MeCN, which is

taken to be 2.0×10^{10} M^{-1} s^{-1}.[37] The driving force dependence of the log k_{et} values of photoinduced electron transfer from electron donors to $^3\{[H_4DPP]Cl_2\}^*$, $^3\{[H_4OPP]Cl_2\}^*$, $^3\{[H_4TPP]Cl_2\}^*$, and $[Zn(F_{20}TPP)(MeCN)]$ is well fitted by solid lines with the λ values of 1.69, 1.45, 1.29, and 0.84 eV, respectively.[35] Thus, the λ value becomes smaller as the porphyrin macrocycle becomes more planar.

A more quantitative analysis has been made by adopting root-mean-square out-of-plane displacement (ΔRMS), which is defined in Eq. 4,[39]

$$\Delta\mathrm{RMS} = \sqrt{\frac{1}{24}\sum_{i=1}^{24}\delta_i^2}, \tag{4}$$

where δ_i is the orthogonal displacement of atom *i* in the macrocycle from the mean plane. There is a good linear correlation between the λ and ΔRMS values, as shown in Figure 4.[35] The linear correlation between reorganization energy and distortion of the porphyrin ring (ΔRMS) indicates that the distortion governs the intramolecular term of the reorganization energy (λ_i) and the larger distortion gives rise to the larger λ_i, because the solvent term of reorganization energy may be the same. The differences in ΔRMS values of porphyrin dications before and after electron transfer are approximately the same, whereas the difference in the distance of hydrogen bonding among the pyrrole N–H protons and the chloride anions (N–H···Cl^-) becomes larger, with increase in ΔRMS values.[35] This suggests that the elongation of the hydrogen bond is the main factor in the increase of λ_i.

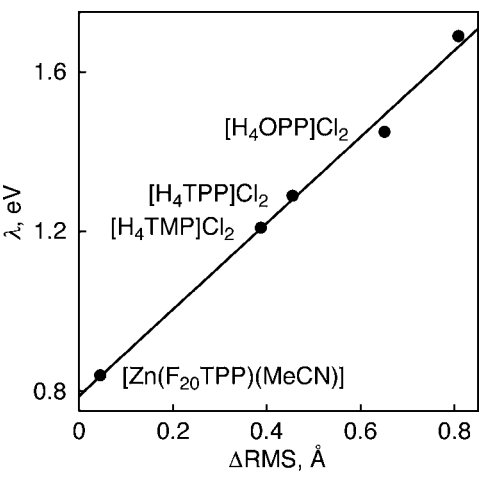

Figure 4. A relationship between λ values in photoinduced electron transfer reduction of diprotonated porphyrin dications in MeCN and root-mean-square out-of-plane displacements (ΔRMS). (Adapted from Ref. 35.)

This observation is similar to that in the oxidation of metalloporphyrins, which exhibit large reorganization energies due to the large changes in coordination bond lengths around metal centers before and after electron transfer.[40] The clarification of electron transfer properties of nonplanar vs. planar porphyrins provides invaluable information for utilizing their novel functions based on the saddle distortion of the porphyrin core, as will be discussed later.

IV. Monomer vs. Dimer Porphyrins

As described in the Introduction, a bacteriochlorophyll dimer, the so-called special pair, plays a pivotal role in initiating efficient multistep electron transfer reactions among photosynthetic pigments to attain the long-lived charge-separated state with a nearly 100% quantum yield.[9–11] High-resolution X-ray crystallographic studies have revealed that the mean plane distance of the bacteriochlorophylls in the special pair is around 3.5 Å.[41–43] Thus, it seems evident that a strong π–π interaction exists between the two macrocycles of the special pair, in particular when the special pair is oxidized to the radical cation. π-electron delocalization between discrete π-systems is well recognized in aromatic dimer radical cations which exhibit new charge resonance absorption bands in the electronic spectra and doubling of hyperfine splitting in the ESR spectra.[44–46] Porphyrins, which have similar macrocyclic frameworks to chlorophylls, are also known to form π-complexes with the radical cation to afford the dimer radical cations, the so-called "mixed valence" radical cations.[47,48] Extensive efforts have so far been devoted to mimicking the dimer structure and the redox properties of the special pair so as to understand the important role of the special pair in the photosynthetic reaction center.[49–55] In particular, the effects of π–π interaction in porphyrin dimer radical cations on the electron transfer dynamics of porphyrin dimers have been clarified in relation to the important role of the special pair in the photoinduced electron transfer dynamics in the photosynthetic reaction center, as described below.[55]

The intramolecular π–π interaction and the dynamics of photoinduced electron transfer reactions of porphyrin dimers were examined using cofacial porphyrin dimers linked with different spacers in comparison with a reference monomer porphyrin in Figure 5.[55] The mean plane distances between porphyrin rings of (DPB)Zn_2 and (DPO)Zn_2 are 3.8 Å and *ca.* 7.8 Å, respectively.[56,57] (DPOx)Zn_2 has a slipped conformation, because the porphyrin rings are linked by a flexible spacer, diphenyl oxide.[58]

The intramolecular π–π interaction in the one-electron oxidized species of (DPB)Zn_2, (DPOx)Zn, and (DPO)Zn_2 is recognized in Figures 6a–d, which show the cyclic voltammograms of ($Et_4Me_4Ph_1P$)Zn, (DPB)Zn_2, (DPOx)Zn_2, and

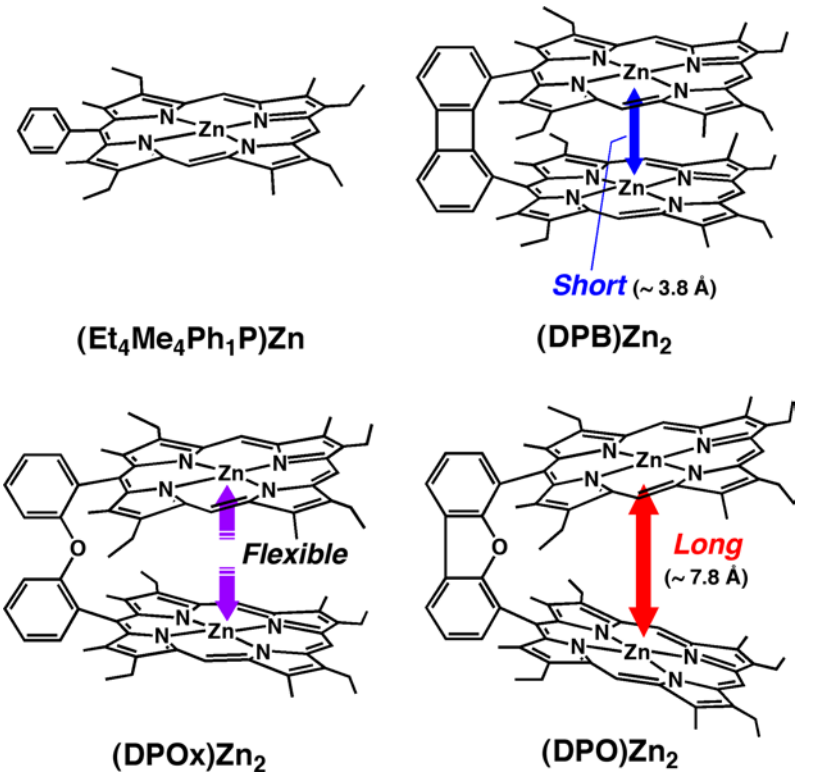

Figure 5. Chemical structures of zinc porphyrin monomer and dimers.

$(DPO)Zn_2$, respectively.[55] The oxidation process of $(DPB)Zn_2$ is split into four discrete one-electron steps. The first oxidation potential of $(DPB)Zn_2$ (0.58 V vs. SCE) is lower by 0.14 V than that of the reference porphyrin, $(Et_4Me_4Ph_1P)Zn$. This indicates that $(DPB)Zn_2^{\bullet+}$ is more stabilized than $(Et_4Me_4Ph_1P)Zn^{\bullet+}$ due to the π–π interaction between porphyrin rings. The second, third, and fourth oxidation potentials of $(DPB)Zn_2$ are higher than those of $(Et_4Me_4Ph_1P)Zn$, because the electrostatic repulsion becomes dominant rather than the attractive interaction. Such electrochemical oxidation of cofacial porphyrin dimers results in the geometrical change from the closed form of $(DPB)Zn_2^{\bullet+}$ to the open form of $(DPB)Zn_2^{2+}$.[51] Similar redox behavior is observed for the porphyrin dimer bearing a flexible spacer [$(DPOx)Zn_2$] (Figure 6c).[55] In the case of $(DPO)Zn_2$, the broadening of the redox wave suggests the existence of the weak interaction between porphyrins (Figure 6d).[55] A similar negative shift of the first oxidation potential of the natural special pair extracted from plants is observed as compared to the monomer counterpart.[59] Thus, the redox behavior of the porphyrin dimers, in particular $(DPB)Zn_2$, resembles that of the natural special pair in the photosynthetic reaction center.

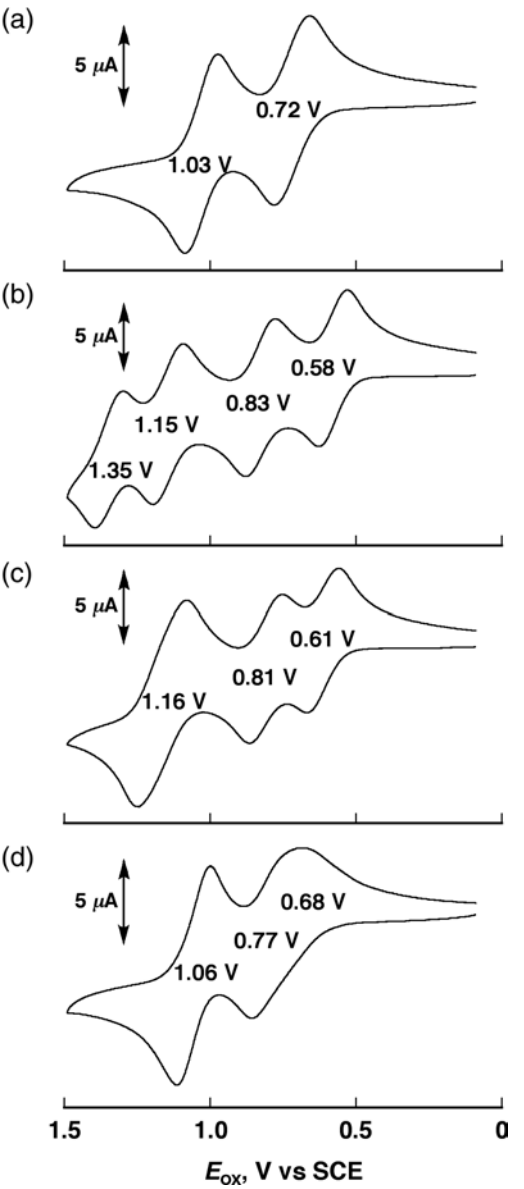

Figure 6. Cyclic voltammograms (0.1 V s^{-1}) of (a) $(Et_4Me_4Ph_1P)Zn$, (b) $(DPB)Zn_2$, (c) $(DPOx)Zn_2$, and (d) $(DPO)Zn_2$ at 1 mM in CH_2Cl_2 containing 0.1 M $TBAPF_6$. (Adapted from Ref. 55.)

New charge resonance absorption bands are observed in the vis-NIR spectral titration of cofacial porphyrin dimers with a one-electron oxidant $[Ru(bpy)_3]^{3+}$ (bpy = 2,2′-bipyridine), as shown in Figure 7.[55] Such charge resonance absorption bands in the NIR region are explained as the absorptions corresponding to the

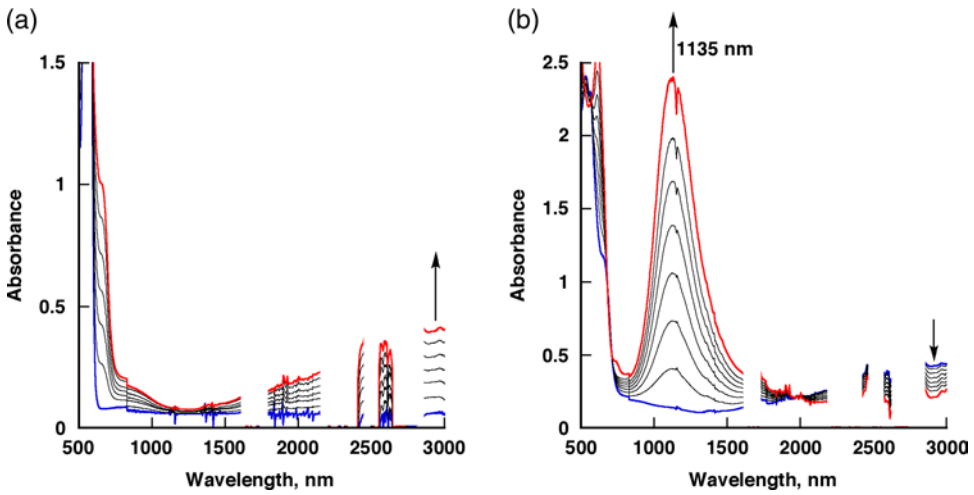

Figure 7. Vis-NIR spectral changes upon addition of $[Ru(bpy)_3]^{3+}$ ((a) 0–2.0×10^{-4} M; (b) 2.0×10^{-4} to 4.0×10^{-4} M) to a CH_2Cl_2 solution of $(DPB)Zn_2$ (2.0×10^{-4} M) at 298 K. The vibrational absorption due to the solvent is cut off. (Adapted from Ref. 55.)

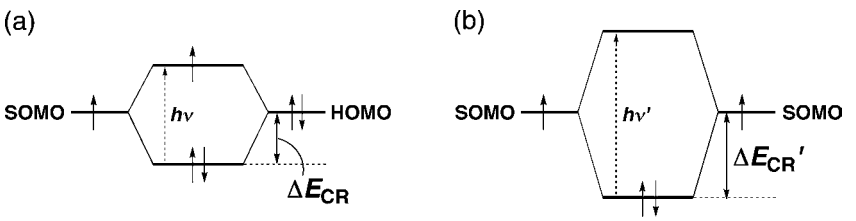

Figure 8. Molecular orbital diagrams for (a) the dimer radical cation and (b) the radical cation dimer.

electronic transition ($h\nu$) from the bonding to the antibonding π-orbital of the π-dimer radical cation (Figure 8a) and that of the π-radical cation dimer (Figure 8b).[55] Charge resonance absorption bands are also observed for the intermolecular formation of the π-dimer porphyrin radical cation and π-radical porphyrin cation.[60,61] The π-dimer radical cation $(DPB)Zn_2^{\bullet+}$ is stabilized by ΔE_{CR} due to π-bond formation between the porphyrin ring and the radical.[55] The π-radical cation dimer $(DPB)Zn_2^{2+}$ also gains bonding interactions between the porphyrin rings, and hence is stabilized by $\Delta E_{CR}'$.[55] The $\Delta E_{CR}'$ value of the dimer radical cation is larger than the ΔE_{CR} value of the radical cation dimer because of the lack of an electron in the antibonding π-orbital.[55] The larger $\Delta E_{CR}'$ value results in the blue shift of the absorption maximum of the radical cation dimer as compared to the dimer radical cation in Figure 7a.[55] The electrostatic repulsion in doubly charged dimeric units destabilizes $(DPB)Zn_2^{2+}$, leading to the higher oxidation potential as compared to

the first oxidation potential of $(Et_4Me_4Ph_1P)Zn$.[55] The ΔE_{CR} value estimated from the absorption maximum ($\lambda_{max} \cong 3000$ nm) is *ca.* 0.20 eV, which is consistent with the negative shift of the first oxidation potential of $(DPB)Zn_2$ (0.14 eV).[55] Similar spectral changes in the NIR region are observed when the other cofacial porphyrin dimers are oxidized by $[Ru(bpy)_3]^{3+}$.[55] The ΔE_{CR} value increases in the order $(DPO)Zn_2$ < $(DPOx)Zn_2$ < $(DPB)Zn_2$ as the mean plane distance between porphyrin rings decreases. In contrast to the case of the dimers, there is little change in the NIR region when $(Et_4Me_4Ph_1P)Zn$ is oxidized by $[Ru(bpy)_3]^{3+}$ under the same conditions.[55]

The photoinduced electron transfer dynamics of cofacial porphyrin dimers were compared with those of the reference porphyrin monomer using nitrobenzene derivatives and a series of benzoquinone compounds as electron acceptors.[55] The rate constants (k_{et}) of electron transfer from the triplet excited states of cofacial porphyrin dimers and the reference porphyrin monomer to electron acceptors were determined by laser flash photolysis measurements.[55] The k_{et} value increases with the degree of the interactions between porphyrin rings as mentioned above, i.e. $(DPO)Zn_2 < (DPOx)Zn_2 < (DPB)Zn_2$.[55] The k_{et} values of the porphyrin dimers are always larger than those of the monomer, $(Et_4Me_4Ph_1P)Zn$. The driving force of electron transfer from $^3(DPB)Zn_2^*$ to each acceptor is larger than that of $^3(Et_4Me_4Ph_1P)Zn^*$ by 0.10 eV, due to the stabilization of $(DPB)Zn_2^{\bullet+}$.[55]

As shown in Figure 9, the driving force dependence of log k_{et} cannot be fitted with one averaged λ value (Eq. 3) and the λ values of both monomer and dimers rise with increase in the driving force of photoinduced electron transfer.[55] Such an increase in the λ value may result from the elongation of the mean distances

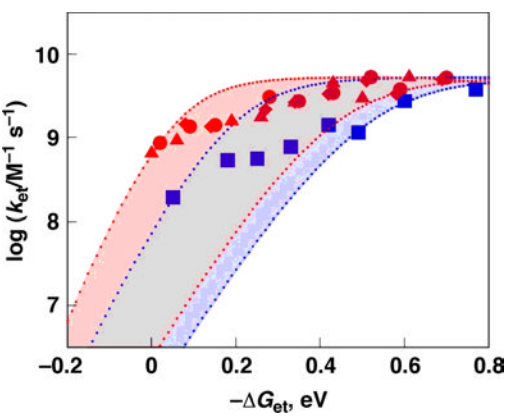

Figure 9. Dependence of log k_{et} on $-\Delta G_{et}$ for electron transfer from $(DPB)Zn_2$ (red circle), $(DPOx)Zn_2$ (red diamond), $(DPO)Zn_2$ (red triangle), and $(Et_4Me_4Ph_1P)Zn$ (blue square) to various acceptors in PhCN at 298 K. The dotted lines are calculated by the Marcus equation, with $\lambda = 0.50$, 1.10 eV (red), and 0.74–1.21 eV (blue), respectively. (Adapted from Ref. 55.)

between the porphyrin (donor) and acceptor molecules with increase in the driving force of photoinduced electron transfer, because the distances (R_{DA}) between donor and acceptor molecules are inversely proportional to the solvent reorganization energy (λ_s) in accordance with Eq. 5,

$$\lambda_s = \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{2r_D}+\frac{1}{2r_A}-\frac{1}{R_{DA}}\right)\left(\frac{1}{\varepsilon_{op}}-\frac{1}{\varepsilon_s}\right), \tag{5}$$

where e is electric charge, ε_0 is the electric constant, r_D and r_A are the ionic radii of the donor and the acceptor, and ε_{op} and ε_s are the optical and static dielectric constants of the solvent, respectively.[38,62,63]

Figure 10 shows the driving force dependence of the λ values of the dimer and monomer porphyrins, which were determined from the k_{et} values using Eq. 3.[55] The λ values of all of the porphyrins increase linearly with increase in the driving force of photoinduced electron transfer. Because the λ values of $(DPB)Zn_2$ and $(DPOx)Zn_2$ are consistently smaller than those of $(Et_4Me_4Ph_1P)Zn$ by *ca.* 0.19 eV irrespective of the difference in the driving force of electron transfer (Figure 10), the difference in the total reorganization energy (λ) between the dimer and the monomer is attributed mainly to the smaller λ_s values of the porphyrin dimers as compared to the monomer.[55] The smaller λ value of the porphyrin dimer results in the acceleration of the forward photoinduced electron transfer but the deceleration of the back electron transfer.[55] The acceleration of the photoinduced electron

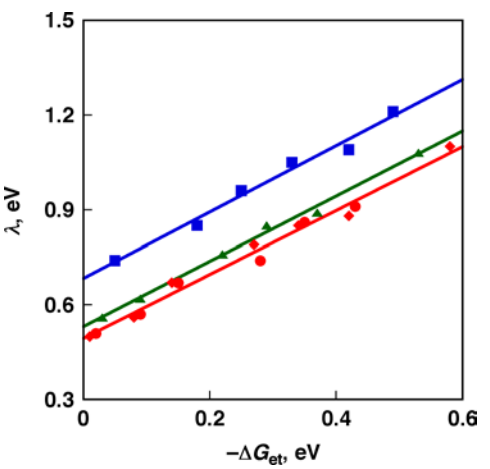

Figure 10. Driving force ($-\Delta G_{et}$) dependence of λ for electron transfer from $(DPB)Zn_2$ (red circle), $(DPOx)Zn_2$ (red diamond), $(DPO)Zn_2$ (green triangle), and $(Et_4Me_4Ph_1P)Zn$ (blue square) to various acceptors in PhCN at 298 K. (Adapted from Ref. 55.)

transfer and the deceleration of the back electron transfer of the porphyrin dimers are the key factors in attaining the high efficiency of the energy conversion in the photosynthetic reaction center, where the special pair (chlorophyll dimer) plays the essential role. The minimum λ value of $(DPOx)Zn_2$ (0.50 eV) is fairly close to the reported value of the electron transfer reaction in the π-complex between a cofacial free-base porphyrin dimer and a sandwiched acridinium ion (0.54 eV).[12c] This is the first example that shows a systematic distance dependence of the λ values depending on the driving force of photoinduced electron transfer and also a clear difference in the λ values between the dimeric and monomeric systems.

V. Charge Separation Using Chlorophyll Analogs

Chlorophyll that participates in photosynthesis is a chlorin pigment, which is a dihydro-compound structurally similar to porphyrins; it is produced through the same biosynthetic pathway as other porphyrin pigments, such as heme. The number of reduced double bonds in the pyrrole rings is zero in the case of porphyrins, one in the case of chlorins and two (diagonal to each other) in the case of bacteriochlorins. The one-electron oxidation potential decreases with increasing peripheral saturation.[64,65] Such a change in the oxidation potential results in a drastic difference in terms of the photodynamics of electron donor–acceptor-linked dyads in which zinc and free-base chlorins and porphyrins in Figure 11 act as electron donors and C_{60} acts as an electron acceptor, as described below.[65,66]

Laser photoexcitation of a deoxygenated PhCN solution containing the zinc chlorine–C_{60} dyad (ZnCh–C_{60}) affords a transient absorption spectrum with maxima

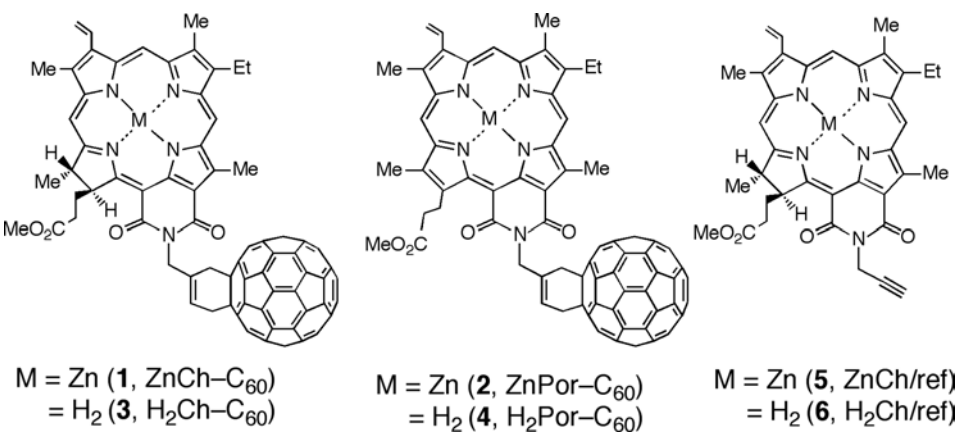

Figure 11. Zinc and free-base chlorin–C_{60}, zinc and free-base porphyrin–C_{60}, and the reference compounds without C_{60}.

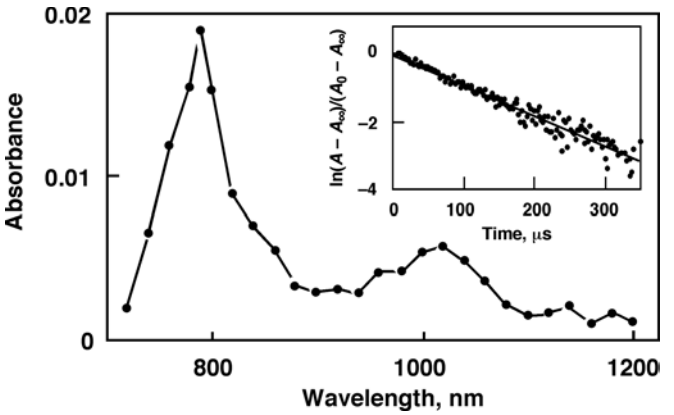

Figure 12. Transient absorption spectra of **1** in deaerated PhCN at 298 K at 0.1 μs after laser excitation at 355 nm. Inset: First-order decay plot of absorbance at 790 nm. (Adapted from Ref. 66.)

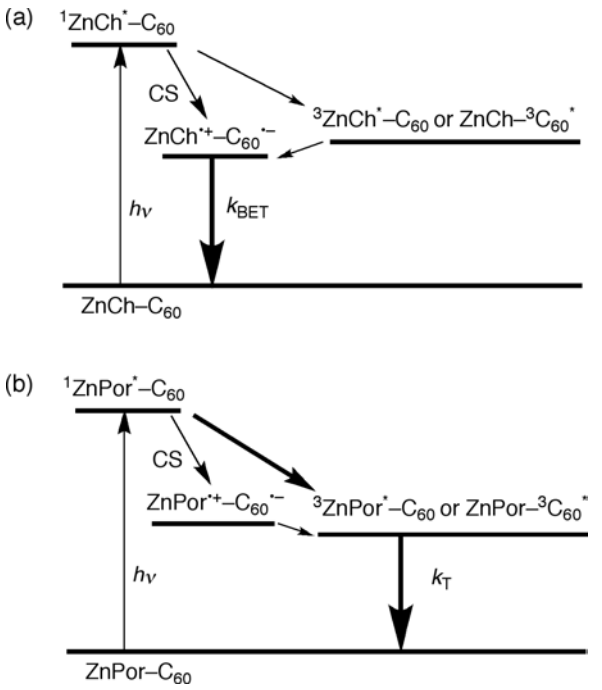
at 790 and 1020 nm, as shown in Figure 12.[66] The absorption band at 790 nm is assigned to the radical cation of the ZnCh moiety, and the absorption band at 1020 nm is a diagnostic marker of the monofunctionalized fullerene radical anion.[67]

The reference chlorin compound **5** shows a fluorescence band at 690 nm with a quantum yield (Φ) of 0.10, whereas the fluorescence emission is significantly quenched in **1** (Φ = 0.002 in PhCN) due to electron transfer from the singlet excited state of **1** to C_{60}.[66] The driving force of photoinduced electron transfer from the singlet excited state of **1** to C_{60} in PhCN is determined to be 0.47 eV from the one-electron oxidation potential of **1** and the excitation energy (S_1 = 1.80 eV) of the ZnCh moiety and the one-electron reduction potential of the C_{60} moiety in **1**.[66] The charge-separated (CS) state ($ZnCh^{\bullet+}$–$C_{60}^{\bullet-}$) is lower in energy (1.33 eV) than both the triplet excited state of C_{60} (1.45 eV)[68] and ZnCh (1.36–1.45 eV).[66] Thus, photoinduced electron transfer from the singlet excited state of ZnCh ($^1ZnCh^*$) to the C_{60} moiety of **1** occurs to produce the CS state, in competition with the intersystem crossing to $^3ZnCh^*$ and energy transfer to produce ZnCh–$^1C_{60}^*$ and ZnCh–$^3C_{60}^*$, as shown in Scheme 2a.[66] Electron transfer from $^3ZnCh^*$ to C_{60} also results in the formation of the CS state.[66]

The CS state detected in Figure 12 decays via back electron transfer (BET) to the ground state rather than to the triplet excited state.[66] The BET rate was determined from the disappearance of the absorption band at 790 nm due to the CS state and the decay of the absorption band obeys first-order kinetics (inset of Figure 12).[66] The k_{BET} value is determined to be 9.1×10^3 s^{-1}.[66]

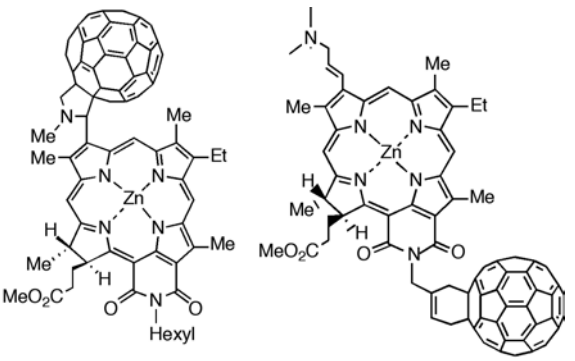
In contrast to the case of ZnCh–C_{60} (**1**), no transient formation of $C_{60}^{\bullet-}$ at 1020 nm was detected for any other dyad in Figure 11 (**2**–**4**).[66] In each case, only the



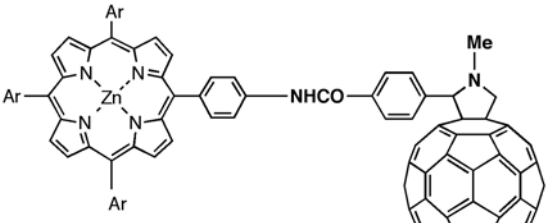
Scheme 2.

triplet–triplet absorption due to chlorin or porphyrin moiety was observed due to the higher energies of the CS state as compared to the triplet excited states (Scheme 2b).[66] This demonstrates the importance of the use of a chlorin chromophore with a zinc ion instead of a fully conjugated porphyrin system to obtain the long-lived CS state.

Photoexcitation of the free-base bacteriochlorin–C_{60} dyad with the same short methylene linkage leads to formation of the radical ion pair, which decays quickly to the triplet excited state of the bacteriochlorin moiety.[69] Figure 13 shows the driving force dependence of the intramolecular electron transfer rate constants (CS and BET) of zinc chlorin–C_{60} and zinc porphyrin–C_{60} dyads with different edge-to-edge distances (R_{ee}), which corresponds to the shortest distance between two molecules. In contrast to the case of **2** in Figure 11, the CS state energy of zinc porphyrin–C_{60} (**9**: 1.38 eV) in Figure 13 is lower than the energy of the triplet excited state of C_{60}.[70] The best fit of Eq. 1 provides and $\lambda = 0.51$ eV and $V = 7.8$ cm^{-1} for zinc chlorin–C_{60} (**8**: $R_{ee} = 5.9$ Å), and $\lambda = 0.66$ eV and $V = 3.9$ cm^{-1} for zinc porphyrin–C_{60} with a longer amide spacer (**9**: $R_{ee} = 11.9$ Å).[69] A directly linked ZnCh–C_{60} dyad which has an extremely short donor–acceptor distance (**7**: $R_{ee} = 2.6$ Å) affords the smallest reorganization energy ($\lambda = 0.42$ eV).[71] The smaller λ value with the shorter R_{ee} value may result from the smaller solvent reorganization energy of electron transfer, according to Eq. 5. On the other hand, the V value in Eq. 1 increases with decrease in the R_{ee}



7: R_{ee} = 2.6 Å **8: R_{ee} = 5.9 Å**



9: R_{ee} = 11.9 Å

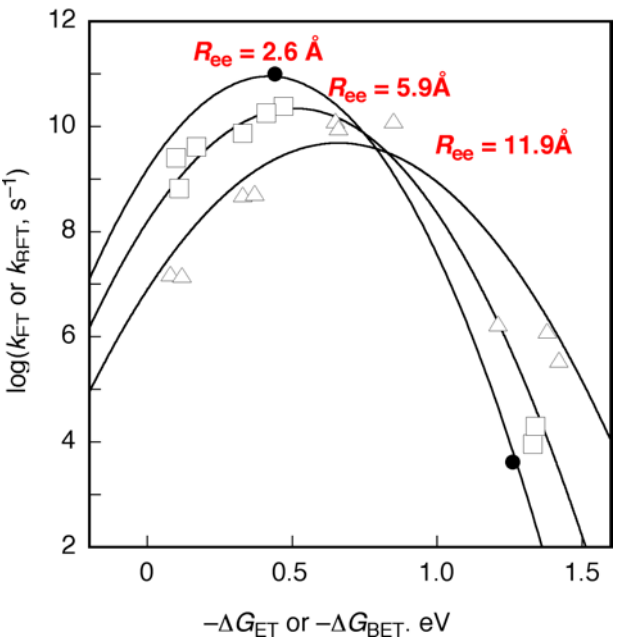


Figure 13. Driving force dependence of log k_{ET} and log k_{BET} for photoinduced electron transfer in zinc chlorine–, zinc porphyrin–fullerene dyads in PhCN linked with different spacers [edge-to-edge distances (R_{ee}) are 2.5, 5.9, and 11.9 Å]. (Adapted from Refs. 69–71.)

value due to the larger orbital overlap between the donor and acceptor moieties. The lifetime of the CS state of the ZnCh–C_{60} dyad (**7**) with the shortest donor–acceptor distance (R_{ee} = 2.6 Å) is determined to be 230 μs at 298 K, which is the longest CS lifetime in the series of dyads shown in Figure 13.[71] The temperature dependence of the decay rate constant (k_{BET}) was examined in PhCN solution observed by laser flash photolysis (25–65 °C) and also in frozen PhCN observed by the ESR signal decay (−150 to −100 °C).[71] The CS lifetime at −150 °C is determined to be as long as 120 s.[71]

A zinc imidazoporphyrin–C_{60} dyad [ZnImP–C_{60} (**10**)] with a short linkage (Figure 14a) also affords a long-lived CS state in PhCN with a lifetime of 330 μs at 278 K.[72] In nonpolar solvents, the CS state of donor–acceptor-linked systems becomes higher in energy than the triplet excited state of the donor or acceptor moiety when charge recombination results in formation of the triplet excited state rather than the ground state.[73] However, a zinc porphyrin–Au(III) porphyrin dyad with a short spacer [ZnPQ–$AuPQ^+$ (**11**) in Figure 14b] affords the long-lived CS state in a nonpolar solvent such as cyclohexane.[73] The introduction of quinoxaline into the porphyrin ring in **11** results in a lowering of the electron transfer state energy, which becomes lower than the energies of the triplet excited states of ZnPQ (1.32 eV) and $AuPQ^+$ (1.64 eV).[74] In this case, photoinduced electron transfer occurs from the singlet excited state of the ZnPQ ($^1ZnPQ^*$) to the metal center of the $AuPQ^+$ moiety to produce $ZnPQ^{\bullet+}$–$Au^{II}PQ$, which has the lifetime of 10 μs in cyclohexane.[74] The observed long lifetime of $ZnPQ^{\bullet+}$–$Au^{II}PQ$ results from a small reorganization energy for the metal-centered electron transfer of $AuPQ^+$ in nonpolar solvents due to the small change in solvation upon the electron transfer as compared with that in polar solvents.[74] The long-lived $ZnPQ^{\bullet+}$–$Au^{II}PQ$ was detected by EPR in toluene at 143 K, as shown in Figure 15. The broad signal with the hyperfine interaction with ^{197}Au (I = 3/2, A_1 = 180 G, A_2 = 14 G) at g_1 = 2.182, g_2 = 2.043, and g_3 = 1.979 clearly indicates that the site of electron transfer is the Au metal rather than the porphyrin ligand.[75–77]

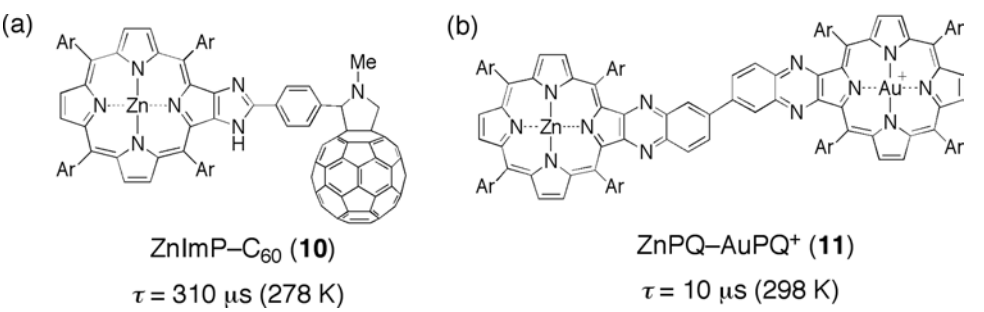

Figure 14. (a) A zinc imidazoporphyrin–C_{60} dyad (**10**: ZnImP–C_{60}); (b) a zinc porphyrin–Au(III) porphyrin dyad (**11**: ZnPQ–$AuPQ^+$). The CS lifetimes are given together.

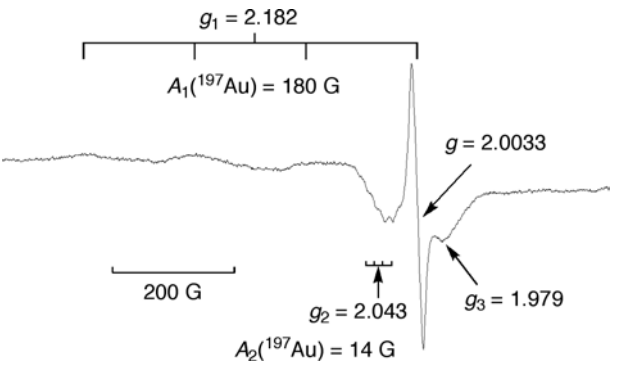

Figure 15. EPR spectrum observed under photoirradiation of a toluene solution of **11** at 143 K. (Adapted from Ref. 74.)

In a polar solvent such as PhCN, no CS state could be seen, but instead only the triplet–triplet absorption due to ^{3}ZnPQ*–AuPQ$^+$ was observed.[78] The absence of an observable CS state of **11** in the polar solvent PhCN may result from the much slower photoinduced electron transfer due to the large reorganization energy as compared with that in nonpolar solvents, allowing an efficient intersystem crossing process in **11** to produce the triplet excited state ^{3}ZnPQ*–AuPQ$^+$.[74,78]

A dodecafluorosubphthalocyanine [SubPc(F)$_{12}$] can also be used as an excellent electron acceptor unit, which is connected to the zinc porphyrin (ZnP) ring with three covalently linked triphenylamine entities at the *meso* position (Figure 16).[79]

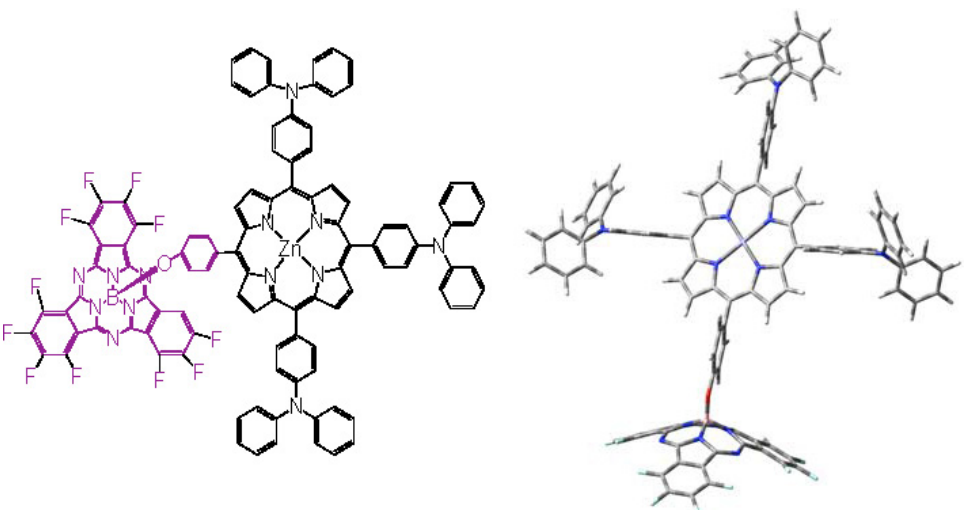

Figure 16. Molecular and optimized structure of ZnP(TPA)$_3$–SubPc(F)$_{12}$ (**12**). (Adapted from Ref. 79.)

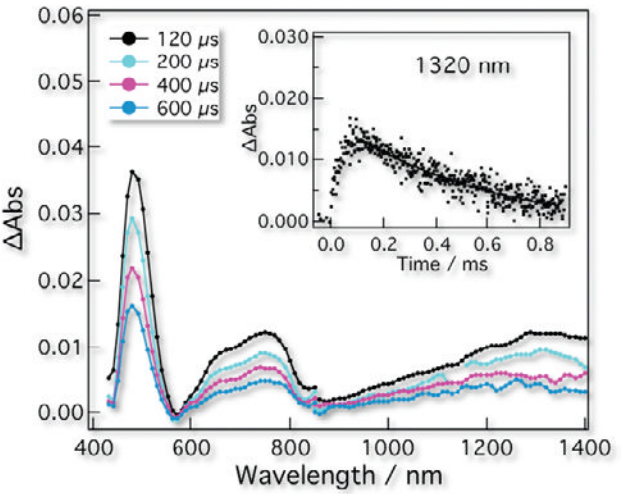

Figure 17. Nanosecond transient spectra obtained by 430 nm laser excitation of **12** in PhCN. (Adapted from Ref. 79.)

The conically shaped subphthalocyanines (SubPc) with their three *N*-fused units arranged around a central boron atom and π-electron aromatic core with their curved structures exhibit different photophysical and photochemical properties compared to their higher homologs, the phthalocyanines.[80–83] SubPcs act as electron acceptors for the photoactive assemblies.[84–86] The energy level of the CS state is below the triplet states of either of the donor and acceptor entities.[79] The CS state $[ZnP(TPA)_3^{\bullet+}–SubPc(F)_{12}^{\bullet-}]$ in PhCN is still alive at long time scales, reaching 2 milliseconds, as shown in Figure 17.[79] The absorption due to the $ZnP(TPA)_3$ radical cation in the near-IR region at 1320 nm in the figure serves as a diagnostic probe for identifying the CS state of **12**, allowing an accurate analysis of the intramolecular electron transfer dynamics without the interference of triplet absorption bands that have absorptions in the visible region.[79] The quantum yield of the CS state of **12** was determined to be 29%.[79] The time profile at 1320 nm shows a slow rise within 50 μs, followed by extremely slow decay.[79]

The rate of the slow rise was estimated at $5.3 \times 10^5\ s^{-1}$ and was referred to the rate of the CS process via $^3ZnP^*$.[79] However, the slow decay is due to the CR process of the radical ion pair with a triplet spin character, estimated at $1.7 \times 10^3\ s^{-1}$ ($\tau = 588\ \mu s$), which implies a significant increase in the triplet CS lifetime as compared to the singlet CS lifetime under the same conditions.[79]

Another example of formation of a long-lived CS state in a nonpolar solvent is tribasic corrole–C_{60} dyads (**13** and **14**), shown in Figure 18.[87] Corroles, which were first reported in 1965,[88] possess the skeleton of the corrin macrocycle (found in vitamin B_{12}) with only three *meso*-carbons between the four pyrrole rings.

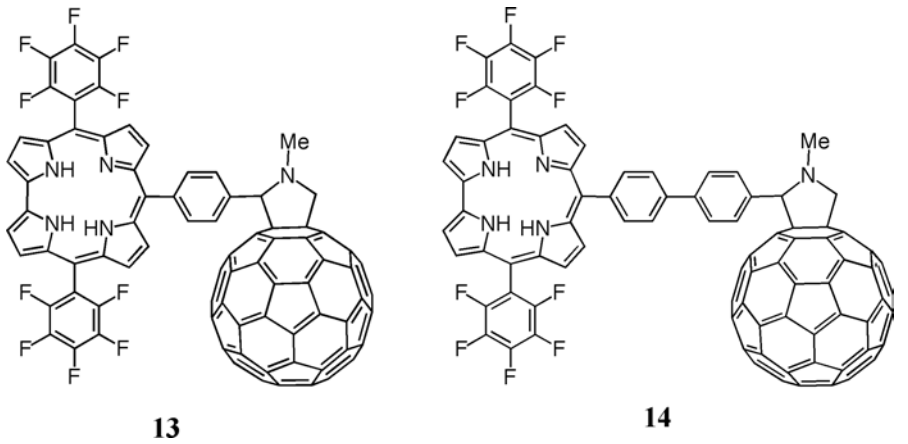

Figure 18. Molecular structures of corrole–C_{60} dyads (**13** and **14**).

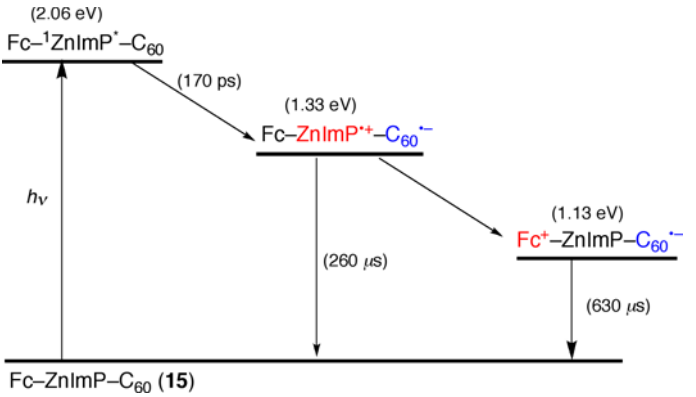
Recent synthetic breakthroughs have made this macrocycle readily available.[89,90] When compared with porphyrins, these tribasic aromatic macrocycles exhibit excellent properties, including lower oxidation potentials, higher fluorescence quantum yields, larger Stokes shifts, and more intense absorption of red light.[91–94] The donor corrole entity, due to the facile oxidation compared to the traditionally used porphyrin analogs, yielded higher exothermicity for the photoinduced charge separation process. Consequently, efficient charge separation of corrole–C_{60} dyads (**13** and **14**) was observed from the time-resolved emission, and femto- and nanosecond laser flash photolysis measurements.[87] Because of the appropriate positioning of the energy levels of the CS state with respect to the triplet energy level and small reorganization energies of electron transfer in nonpolar solvents, the CS state with the lifetime of the order of a few microseconds was attained in nonpolar solvents.[87]

VI. Multistep Photoinduced Electron Transfer

Extensive efforts have been devoted to attaining a long distance charge separation via multistep photoinduced electron transfer, mimicking the natural photosynthetic reaction center.[95–100] A ferrocene unit was attached to ZnImP–C_{60} in Figure 14 to synthesize a triad (**15**: Fc–ZnImP–C_{60}).[101] Photoinduced electron transfer from ZnImP to C_{60} is followed by electron transfer to afford the final CS state (Fc^{+}–ZnImP–$C_{60}^{\bullet-}$), which has a much longer lifetime (630 μs) than the dyad ($ZnImP^{\bullet+}$–$C_{60}^{\bullet-}$: 230 μs) in PhCN at 298 K.[101] The energy diagram of photoinduced electron transfer of **15** is summarized in Scheme 3 with the lifetime of each transient species.[101] The CS lifetime (630 μs) of **15** is much longer than the



Scheme 3.

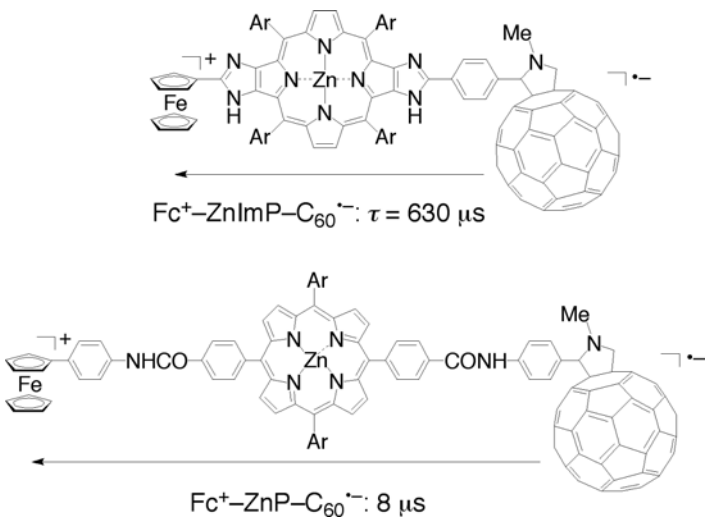


Figure 19. Comparison of the CS lifetime (τ) between Fc$^+$–ZnImP–$C_{60}^{•-}$ and Fc$^+$–ZnP–$C_{60}^{•-}$.

lifetime (8 μs) of a similar triad connected by a longer amide linkage, Fc–ZnP–C_{60} (**16**) in Figure 19.[101]

The longer CS lifetime of Fc$^+$–ZnImP–$C_{60}^{•-}$ is suggested to arise from partial cancelation of two effects: the rate reduction stemming from the smaller solvent reorganization energy with a shorter donor–acceptor distance (Eq. 5), and the rate enhancement due to increased coupling V which arises from the orbital delocalization.[101]

A ferrocene–zinc porphyrin–C_{60} triad (**16**) was further extended to a ferrocene–zinc porphyrin–free-base porphyrin–C_{60} tetrad [**17**: Fc–ZnP–H_2P–C_{60}; Figure 20a].[102]

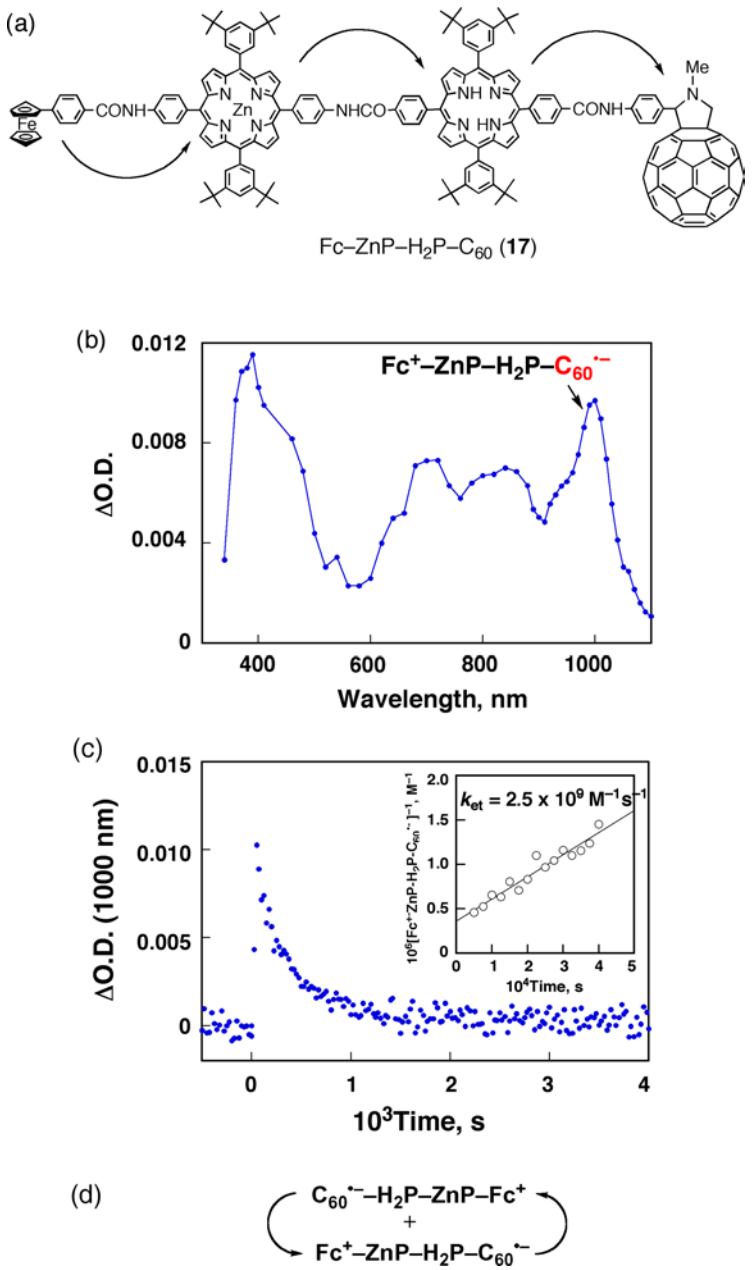

Figure 20. (a) The direction of photoinduced electron transfer in a Fc–ZnP–H_2P–C_{60} tetrad (**17**). (b) Differential absorption spectra obtained upon nanosecond flash photolysis (532 nm) of 7.2×10^{-6} M solutions of **17** in nitrogen-saturated PhCN with a time delay of 50 ns at 298 K. (c) The time profile of absorbance at 1000 nm obtained by nanosecond time-resolved absorption spectra of Fc–ZnP–H_2P–C_{60} (3.6×10^{-6} M) in argon-saturated DMF excited at 532 nm at 298 K. Inset: Second-order plot derived from the absorption change at 1000 nm. (d) Bimolecular back electron transfer between the CS state molecules. (Adapted from Ref. 102.)

Nanosecond transient absorption measurements of **17** reveal unambiguously the $C_{60}^{\bullet-}$ fingerprint (*ca.* 1000 nm), which matches quite reasonably that known for the π-radical anion of an *N*-methylfulleropyrrolidine (Figure 20b).[67,103] The transient absorption spectrum of **17** is virtually the same as that of Fc^{+}–ZnP–$C_{60}^{\bullet-}$ and Fc^{+}–H_2P–$C_{60}^{\bullet-}$.[70,104] The total quantum yields ($\Phi_{CS(total)}$) for the CS state of **17** were determined to be 0.20 (THF), 0.24 (PhCN), and 0.17 (DMF).[102] The relatively low quantum yields (0.17–0.24) result from the competition of charge shift from Fc–ZnP–$H_2P^{\bullet+}$–$C_{60}^{\bullet-}$ (1.63 eV) to Fc–$ZnP^{\bullet+}$–H_2P–$C_{60}^{\bullet-}$ (1.34 eV) versus the decay of Fc–ZnP–$H_2P^{\bullet+}$–$C_{60}^{\bullet-}$ to the triplet states of the free-base porphyrin (1.40 eV) and the C_{60} (1.50 eV).[102] In fact, the absorption due to $^3H_2P^*$ and $^3C_{60}^*$ (600–900 nm)[105] is observed together with that of Fc^{+}–ZnP–H_2P–$C_{60}^{\bullet-}$ in Figure 20b.[102]

The time profiles at 1000 nm due to the CS state of **17** obey second-order kinetics, rather than first-order kinetics, as shown in Figure 20c.[102] From the best fits, intermolecular ET dynamics were calculated that are nearly diffusion-controlled (PhCN: 5.4×10^9 M^{-1} s^{-1}; DMF: 2.5×10^9 M^{-1} s^{-1}).[102] The second-order rate law suggests that the intramolecular charge recombination in Fc^{+}–ZnP–H_2P–$C_{60}^{\bullet-}$ is too slow to compete with the diffusion-limited intermolecular charge recombination (Figure 20d). Thus, the rate of intramolecular charge recombination in Fc^{+}–ZnP–H_2P–$C_{60}^{\bullet-}$ was determined by electron paramagnetic resonance (EPR) measurements in a frozen matrix at variable temperatures using a low concentration in PhCN (1.0×10^{-5} M) under irradiation to stop the diffusion.[102] The EPR spectrum (Figure 21a) under irradiation at 203 K shows a characteristic broad signal attributable to $C_{60}^{\bullet-}$ (g = 2.0004).[67] As shown in Figure 21b, the EPR signal grows in immediately upon turning on the irradiation of **17** and upon turning off the irradiation source, the EPR signal decays, obeying first-order kinetics to afford a rate constant of 3.0 s^{-1} (Figure 21c) for the intramolecular CR process (k_{CR}). Only small temperature dependence of k_{CR} (2.6–3.0 s^{-1}) was observed upon varying the temperature between 163 and 203 K.[102] The lifetime of the CS state of **17** was determined to be 0.4 s, which is comparable to the lifetimes (~1 s) of the CS state in the bacterial photosynthetic reaction centers.[9–11,106]

The driving force dependence of the electron transfer rate constants (k_{ET}) of the dyad (**9**), triad (**16**), and tetrad (**17**) for CS and CR processes is shown in Figure 22, where log k_{ET} is plotted against the driving force ($-\Delta G_{ET}$).[102] The lines in the figure represent the best fit to Eq. 1 (**9**: λ = 0.66 eV, V = 3.9 cm^{-1}; **16**: λ = 1.09 eV, V = 0.019 cm^{-1}; **17**: λ = 1.32 eV, V = 0.00017 cm^{-1}).[102] The λ value increases, whereas the V value decreases with increasing edge-to-edge distance in the order of the dyad (R_{ee} = 11.9 Å), the triad (R_{ee} = 30.3 Å), and the tetrad (R_{ee} = 48.9 Å). In the case of the dyad, the CR rate in $ZnP^{\bullet+}$–$C_{60}^{\bullet-}$ in the Marcus inverted region is much slower than the CS rate constants from both the singlet and triplet excited states in the Marcus normal region (Figure 22). This enables a subsequent

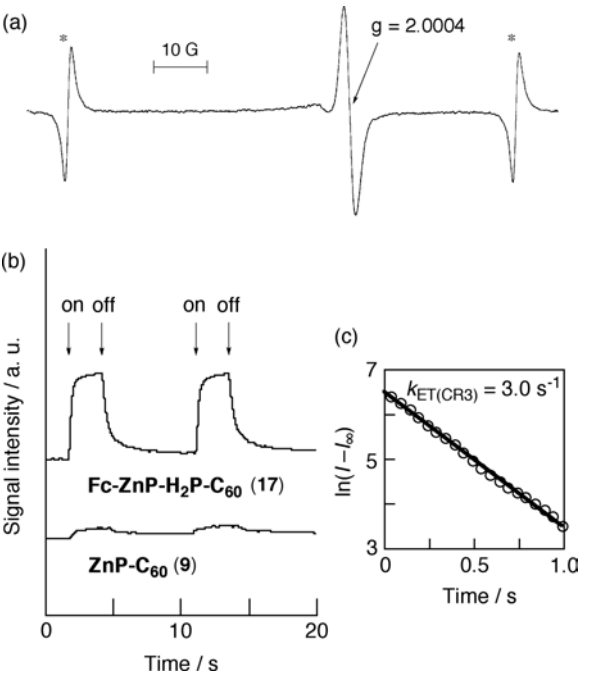

Figure 21. (a) ESR spectrum of **17** (1.0×10^{-5} M) in a frozen deaerated PhCN solution observed at 203 K under irradiation of UV-vis light from a high-pressure Hg lamp (* denotes a Mn marker). (b) Signal intensity response of **17** (1.0×10^{-5} M, top) and 9 (1.0×10^{-5} M, bottom) in a frozen deaerated PhCN solution at the maximum of the ESR signal intensity due to the $C_{60}^{\bullet-}$. (c) First-order plot for the decay of the ESR signal intensity (I) in **17** ($k_{ET(CR3)} = 3.0\ s^{-1}$). (Adapted from Ref. 102.)

electron transfer from Fc to $ZnP^{\bullet+}$ in the triad ($Fc–ZnP^{\bullet+}–C_{60}^{\bullet-}$) to produce the final CS state, $Fc^{+}–ZnP–C_{60}^{\bullet+}$, in competition with the back electron transfer in the initial CS states. In the case of the tetrad (**17**), the multistep electron transfer processes afford the final CS state, $Fc^{+}–ZnP–H_2P–C_{60}^{\bullet-}$, in which charges are separated at a long distance ($R_{ee} = 48.9$ Å).[102] The lifetime of the resulting CS state at such a long distance in a frozen PhCN becomes as long as 0.4 s (*vide supra*).[102] It should be noted that the CS lifetime is temperature-independent, since the CR process is at the Marcus top region (Figure 22).[102]

The maximum k_{ET} value (k_{ETmax}) of each Marcus plot in Figure 22 is correlated with the edge-to-edge distance (R_{ee}), separating the radical ions, according to Eq. 6,

$$\ln k_{ETmax} = \ln\left(\frac{2\pi^{3/2}V_0^2}{h(\lambda k_B)^{1/2}}\right) - \beta R_{ee}, \tag{6}$$

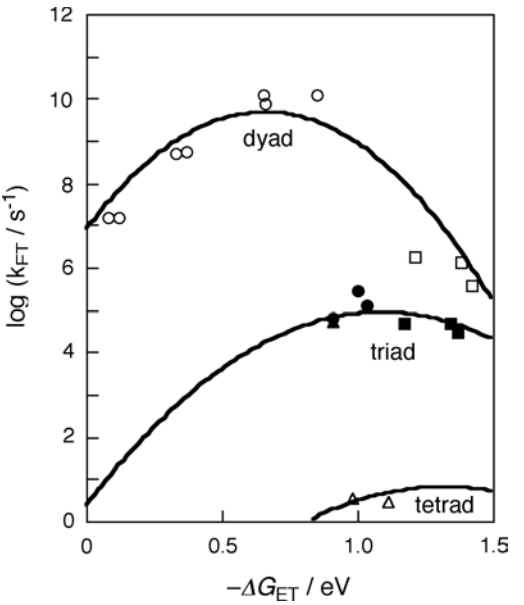

Figure 22. Driving force ($-\Delta G_{ET}$) dependence of intramolecular electron transfer rate constants (k_{ET}) in a dyad **9** (CS: white circles; CR: white squares), a triad **16** (black circles), and a tetrad **17** (white triangles). The data of other triads, Fc–H_2P–C_{60} (black triangles) and ZnP–H_2P–C_{60} (black squares), are also included. (Adapted from Ref. 102.)

where V_0 refers to the maximal electronic coupling element, while β is the decay coefficient factor (damping factor), which depends primarily on the nature of the bridging molecule.[102] From the linear plot of ln k_{ETmax} vs. R_{ee} in Figure 23, the β value is determined to be 0.60 Å^{-1}. This β value is located within the boundaries of nonadiabatic electron transfer reactions for saturated hydrocarbon bridges (0.8–1.0 Å^{-1}) and unsaturated phenylene bridges (0.4 Å^{-1}).[107]

The quantum yield for the final CS state was improved from 0.24 for Fc–ZnP–H_2P–C_{60} (**17**) in PhCN to 0.34 for Fc–ZnP–ZnP–C_{60} (**18**).[108] In addition, the CS lifetime was elongated to 1.3 s in DMF at 298 K.[107] This is by far the largest value ever reported for *intra*molecular charge recombination in synthetic donor–acceptor systems, including porphyrin–fullerene-linked systems. Substitution of the metal-free tetraphenylporphyrin chromophore (H_2P) by the corresponding zinc analog (ZnP) raises the excited state energy of the chromophore from 1.89 eV to 2.04 eV, and also lowers the one-electron oxidation potential of the electron donor by nearly 300 mV.[108] As a consequence of these two effects, the driving force of the charge separation is markedly increased, ensuring better efficiency.

The quantum yield for the CS state was further improved by employing a ferrocene-*meso*, *meso*-linked porphyrin trimer–fullerene pentad (**19**: Fc–$(ZnP)_3$–C_{60})

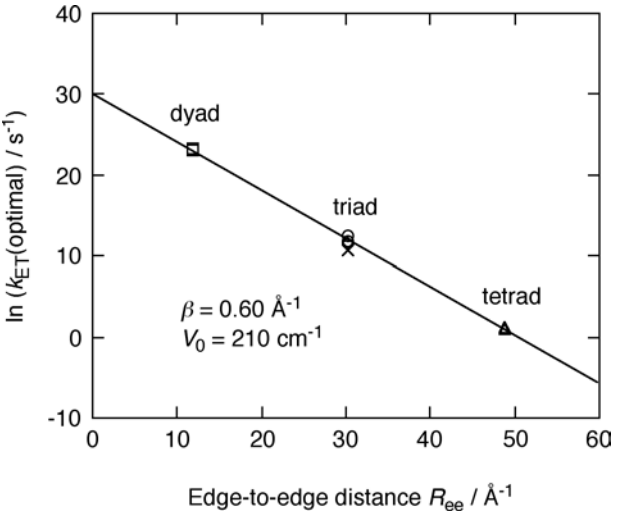

Figure 23. Edge-to-edge distance (R_{ee}) dependence of optimal electron transfer rate constants ($\ln[k_{ET}(\text{optimal})/s^{-1}]$) in **9** (square), **16** (circle), Fc–H_2P–C_{60} triad (diamond), ZnP–H_2P–C_{60} triad (cross), and **17** (triangle). The line represents the best fit to Eq. 1 ($\beta = 0.60$ Å^{-1}, $V_0 = 210$ cm^{-1}). (Adapted from Ref. 102.)

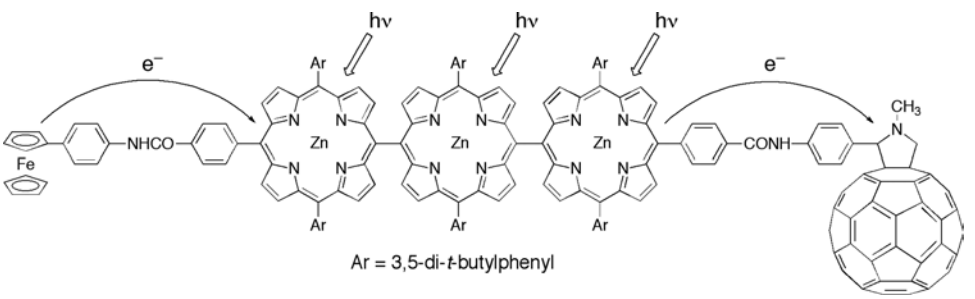

Figure 24. The direction of photoinduced electron transfer in a ferrocene-*meso,meso*-linked porphyrin trimer–fullerene pentad (**19**: Fc–$(ZnP)_3$–C_{60}). (Adapted from Ref. 109.)

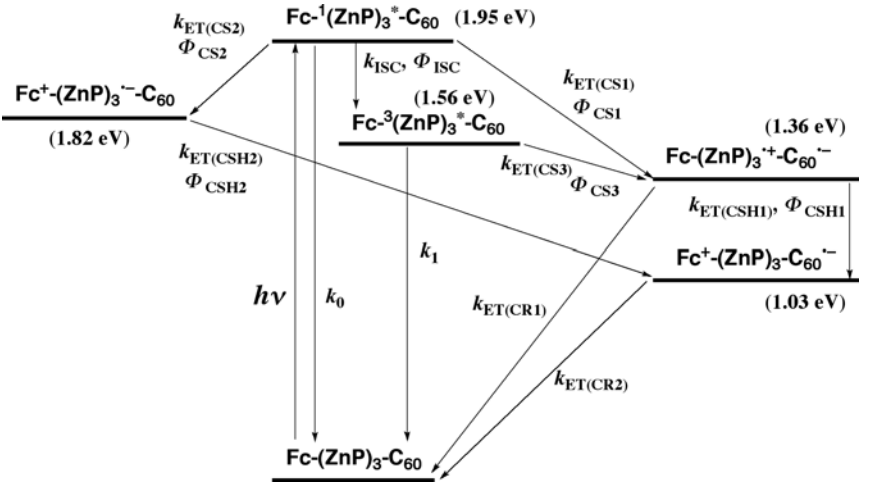
in Figure 24.[109] Photoirradiation of **19** results in photoinduced electron transfer from both the singlet and triplet excited states of the porphyrin trimer [$^1(ZnP)_3^*$, $^3(ZnP)_3^*$] to the C_{60} moiety to produce the porphyrin trimer radical cation–C_{60} radical anion pair, Fc–$(ZnP)_3^{\bullet+}$–$C_{60}^{\bullet-}$.[109] The energy levels in PhCN are shown in Scheme 4.[109] Because a ferrocene unit is tethered at the end of $(ZnP)_3$–C_{60}, the pentad undergoes multistep photoinduced electron transfer, i.e. Fc–$^1(ZnP)_3^*$–C_{60} (1.95 eV) → Fc–$(ZnP)_3^{\bullet+}$–$C_{60}^{\bullet+}$ (1.36 eV) → Fc$^+$–$(ZnP)_3$–$C_{60}^{\bullet-}$ (1.03 eV) in PhCN (Scheme 4).[109]



Scheme 4.

The time profiles at 1000 nm due to the final CS state of **19** also obey second-order kinetics in solution, because the bimolecular CR is predominant over the intramolecular CR.[109] When the diffusion was stopped in a frozen PhCN at 163 K, the ESR signal due to the CS state observed upon photoirradiation of **19** exhibited a slow and nearly seconds-lasting decay, which was best-fitted by first-order kinetics yielding a rate constant of 2.9 s^{-1} for the intramolecular CR process ($k_{ET(CR2)}$).[109] The CS lifetime of **19** was determined to be 0.53 s in frozen DMF at 163 K.[109] This CS lifetime is also comparable with the lifetime (~1 s) of the final CS state in the bacteria photosynthetic reaction centers.[106] The efficient formation of the final CS state with a high quantum yield (Φ = 0.83) has been achieved in the present pentad system.[109] Such excellent performance of **19** can be rationalized by the efficient charge separation because of the small reorganization energy of electron transfer and retarded charge recombination through the *meso*,*meso*-linked porphyrin trimer.[109]

Compared with the porphyrins described above, phthalocyanines (Pcs) emerge as attractive molecular building blocks for the artificial photosynthetic systems, in which they function as antennas with a wider absorbing range of the solar spectrum, where porphyrins fail to exhibit appreciable absorption.[110–112] Generally, Pcs undergo intermolecular π–π stacking interactions between the planar faces of the macrocycles, even at low concentration, giving rise to dimerization or aggregation which results in fluorescence quenching and low solubility. In contrast, axially substituted silicon Pcs have gained great attention because they do not aggregate due to their special structural features.[113–116] The integration of silicon Pc with two units of different electron acceptors, 1,4,5,8-naphthalenediimide

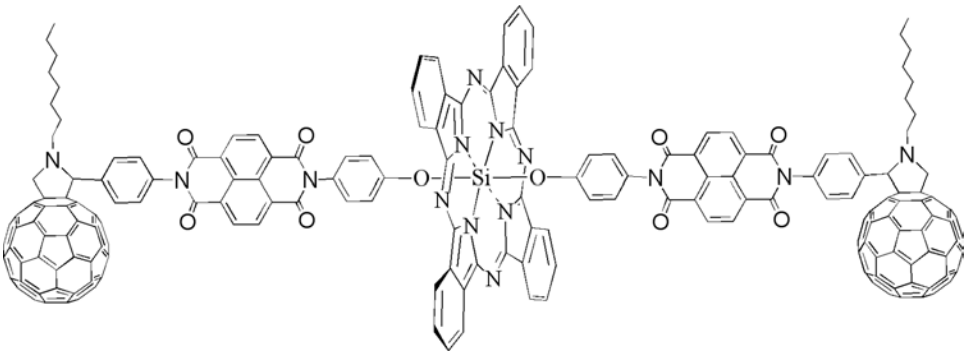


Figure 25. Silicon phthalocyanine linked with two units of different electron acceptors, 1,4,5,8-naphthalenediimide (NDI) and C_{60}, through the axial position (**20**: SiPc–$(NDI)_2$–$(C_{60})_2$). (Adapted from Ref. 117.)

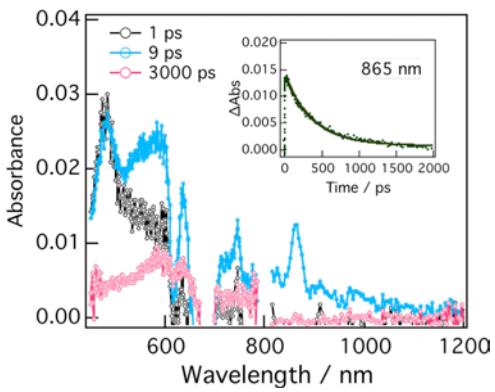

Figure 26. Femtosecond transient absorption spectra of **20** in deaerated PhCN after laser excitation at 380 nm. (Adapted from Ref. 117).

(NDI) and C_{60}, was made possible through the axial position to form the SiPc–$(NDI)_2$–$(C_{60})_2$ pentad (**20**) in Figure 25.[117] The pentad serves as light harvesting architecture with good spectral coverage in the visible and NIR regions. The planar NDI has the higher energy excited state than SiPc and C_{60}, as well as the lower one-electron reduction potential. Upon photoirradiation of a deaerated PhCN solution containing **20**, the characteristic absorption bands due to $SiPc^{\bullet+}$ (λ_{max} = 865 nm)[115] and $NDI^{\bullet-}$ (λ_{max} = 714 nm)[118] were observed as shown in Figure 26, where a weak absorption in the NIR region due to $C_{60}^{\bullet-}$ was also observed.[117] This indicates that an electron shifts from the $NDI^{\bullet-}$ to the adjoining C_{60} to generate $SiPc^{\bullet+}$–$(NDI)_2$–$(C_{60})_2^{\bullet-}$. The rate constants of CS and CR processes were determined be 3.0×10^{11} and 1.0×10^{9} s^{-1}, respectively.[117] The high k_{CS}/k_{CR} ratio

indicated the usefulness of **20** as a light-harvesting system. However, the decay of the CS state in deaerated PhCN affords the triplet excited state, SiPc–$(NDI)_2$–$^3(C_{60})_2^*$, which is converted to the lower triplet excited state, $^3SiPc^*$–$(NDI)_2$–$(C_{60})_2$, which decays to the ground state with a rate constant of 1.4×10^4 s^{-1}.[117]

VII. Supramolecular Porphyrin Complexes

In contrast to photosynthetic reaction center models in which each component is covalently bonded to the other (*vide supra*), each component of the photosynthetic reaction center is located at the required position by noncovalent bonding in the protein matrix to optimize the charge separation efficiency.[9–11] The use of noncovalent bonding situations such as metal–ligand coordination, electrostatic interaction, and hydrogen bonding provides simpler but more elegant ways to construct electron donor–acceptor ensembles mimicking the efficient biological electron transfer systems.[119–125] In particular, π–π interaction is one of the most important noncovalent binding methods because of its important role in biological systems such as π-stacking of double-strand DNA.[126–128] The acridinium ion is suitable as a component of an artificial photosynthetic reaction center because of the small reorganization energy (λ) of electron transfer,[129] which results in fast photoinduced electron transfer but extremely slow back electron transfer.[130,131]

A cofacial free-base bisporphyrin (H_4DPOx), which is regarded as a model compound of a bacteriochlorophyll dimer [$(BChl)_2$], forms a relatively strong π-complex with acridinium perchlorate ($AcH^+ClO_4^-$) in PhCN (**21** in Figure 27).[132]

The formation constant (K) of the H_4DPOx–AcH^+ complex is determined to be 97000 ± 1000 M^{-1} from spectral titration in PhCN, indicating relatively strong complex formation.[132] The π-complex formation is confirmed by ^{1}H NMR, in which signals due to both H_4DPOx and AcH^+ exhibit upfield shifts upon complexation.[132] The one-electron oxidation potential of H_4DPOx (E_{ox}) is shifted from 0.58 V in the absence of AcH^+ to 0.71 V by the insertion of AcH^+, because the bisporphyrin becomes more difficult to oxidize due to the repulsion of positive charges between the porphyrin radical cation and AcH^+.[132] The one-electron reduction potential of AcH^+ was also shifted from –0.46 V in the absence of the bisporphyrin to –0.57 V in the presence of the bisporphyrin due to complex formation.[132] As a result, the free energy change of electron transfer to form the ET state is changed from 1.04 eV to 1.28 eV in the π-complex (**21**).

Photoinduced electron transfer from the singlet excited state of H_4DPOx ($^1H_4DPOx^*$) to the AcH^+ moiety occurred efficiently in **21** to form the electron transfer state ($H_4DPOx^{\bullet+}$–$AcH^{\bullet}$), as indicated by the transient absorption spectra of a PhCN solution containing both H_4DPOx and AcH^+ observed upon laser excitation in Figure 28a.[132] The strong absorption in the range from 450 nm to 540 nm

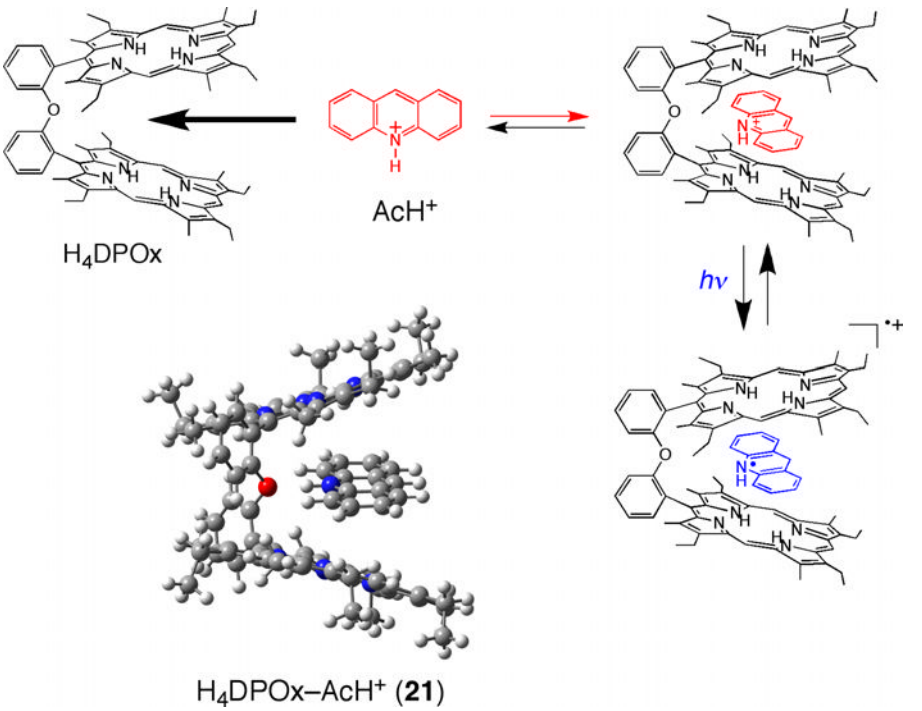

Figure 27. Formation of an electron transfer state of a π-complex of acridinium ion (AcH^+) inserted between porphyrin rings of a cofacial bisporphyrin (**21**: $H_4DPOx–AcH^+$). (Adapted from Ref. 132.)

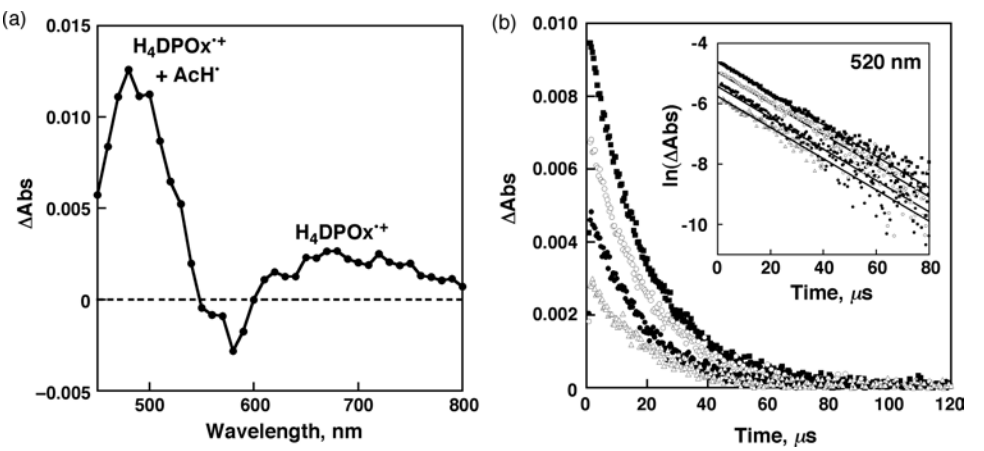

Figure 28. (a) Transient absorption spectrum of H_4DPOx (3.4×10^{-5} M) in the presence of AcH^+ (3.3×10^{-4} M) in deaerated PhCN at 273 K taken at 20 μs after laser excitation at 520 nm. (b) Time profiles of the absorption at 520 nm of $H_4DPOx^{\bullet+}$–$AcH^{\bullet}$ obtained with different laser intensities (1.5, 1.9, 2.1, and 3.8 mJ/pulse) in deaerated PhCN at 298 K. Inset: First-order plots. (Adapted from Ref. 132.)

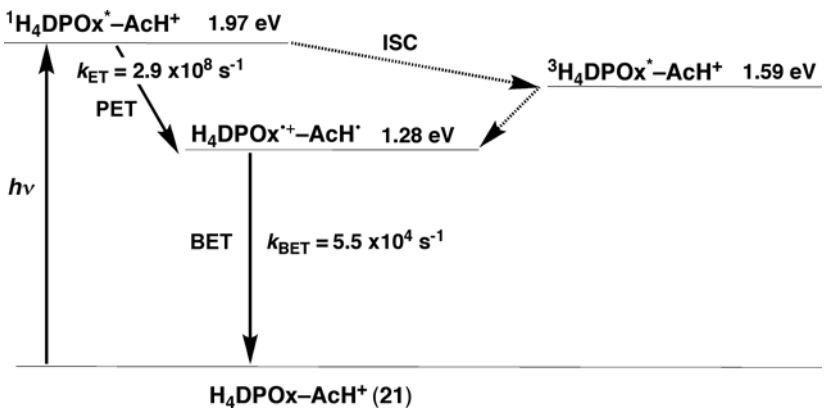
is ascribed to $AcH^{\bullet}$,[129,130,133] and the transient absorption in the range from 620 nm to 800 nm is ascribed to $H_4DPOx^{\bullet+}$.[132] The decay time profiles of the absorption at 520 nm with the different laser intensities are shown in Figure 28b, where the first-order plots afford good linear correlations with the same slope, irrespective of the different laser intensities.[132] Such a first-order decay with the same slope strongly indicates that the back electron transfer from $AcH^{\bullet}$ to $H_4DPOx^{\bullet+}$ occurs in **21** and that no bimolecular decay is involved. The lifetime of the electron transfer state is determined to be 18 μs at 298 K ($k_{BET} = 5.5 \times 10^4$ s^{-1}).[132] The quantum yield of the electron transfer state is determined to be as high as 90%.[132] The electron transfer state lifetime exhibited large temperature dependence.[132] As a result, a remarkably long-lived electron transfer state has been attained at low temperature, and virtually no decay of the electron transfer state was observed at 77 K.[132]

The energy diagram of **21** is summarized in Scheme 5.[132] The rate constant (k_{ET}) of electron transfer from the singlet excited state of H_4DPOx ($^1H_4DPOx^*$) to AcH^+ in **21** was determined by time-resolved fluorescence measurements to be 2.9×10^8 s^{-1}.[132] The energy level of the electron transfer state of **21** (1.28 eV) is lower than that of the triplet states of H_4DPOx (1.59 eV) and AcH^+ (2.01 eV).[132,134] In addition to the π–π interaction described above, the axial coordination of pyridine compounds to the metal center of metalloporphyrins has been utilized to construct multiporphyrin assemblies as light-harvesting units by self-organization of Zn(II) porphyrins.[135–137] The axial coordination of pyridine was combined by complex formation of ammonium cation with crown ether to construct a biomimetic model of the bacterial "special pair", as shown in Figure 29.[138] A supramolecular complex (**22**) was formed between a cofacial zinc Pc dimer linked by complexation of four bis crown ether units with potassium ion, and a fullerene derivative functionalized with a pyridine coordinating entity and an alkyl ammonium cation entity for two-point binding.[138]



Scheme 5.

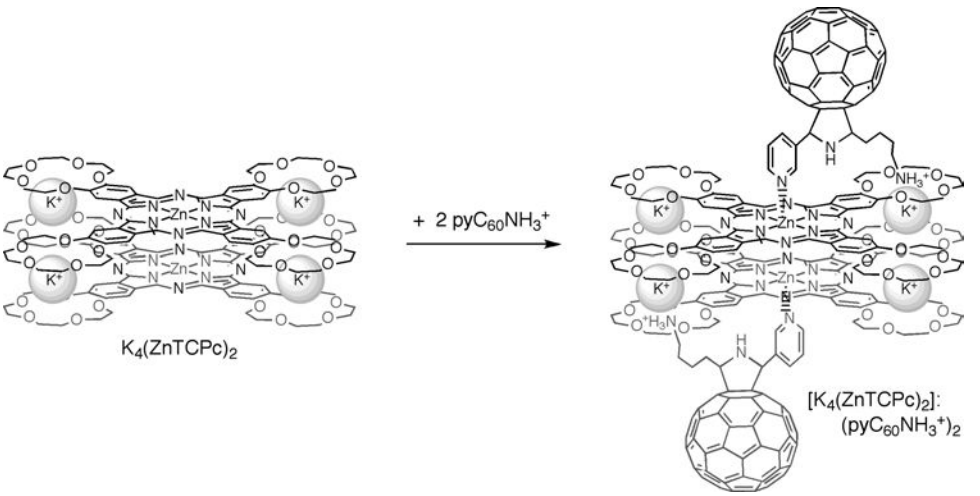


Figure 29. A supramolecular $K_4[ZnTCPc]_2$:$(pyC_{60}NH_3^+)_2$ conjugate (**22**). (Adapted from Ref. 138.)

Potassium-ion-induced dimerization of 4,5,4′,5′,4″,5″,4‴,5‴-tetrakis (1,4,7,10,13-pentaoxa-tridecamethylene)phthalocyanine zinc(II) (ZnTCPc) to afford the $K_4[ZnTCPc]_2$ dimer has been well established.[139–143] The K^+ ion is sandwiched between two 15-crown-5 entities from two different Pcs due to the size differences.[138] Then, the $K_4[ZnTCPc]_2$ dimer was allowed to interact with fullerene functionalized with a pyridine coordinating entity and an alkyl ammonium cation entity (Figure 29).[138] The calculated structure of **22** (Figure 30) revealed that the pyridine coordinates to the zinc center while the alkyl ammonium ion forms a complex with one of the crown ether entities without destroying the K^+-sandwich dimer via a "two-point" binding motif.[144–146] Utilization of such well-defined multiple modes of binding in a controlled fashion results in the formation of biomimetic supramolecular donor–acceptor conjugates.[138]

The photoexcitation of supramolecular $K_4[ZnTCPc]_2$–fullerene complex (**22**) affords a charge-separated state with a much longer lifetime (6.7 μs) as compared with the corresponding zinc porphyrin supramolecular complex (50 ns).[146] Such a drastically increased lifetime of the CS state in **22**, as compared to the corresponding porphyrin dimer complex, may result from a smaller reorganization energy of electron transfer for the more π-expanded Pc macrocycle relative to the porphyrin macrocycle.[138]

In order to further enhance the strength of axial coordination in Zn(II) macrocyclic compounds, the Lewis acidity of the Zn(II) center should be increased. The Lewis acidity of the Zn(II) center can be enhanced by macrocyclic ring distortion, which enforces lone pairs of nitrogen atoms in the pyrrole moieties to point out of

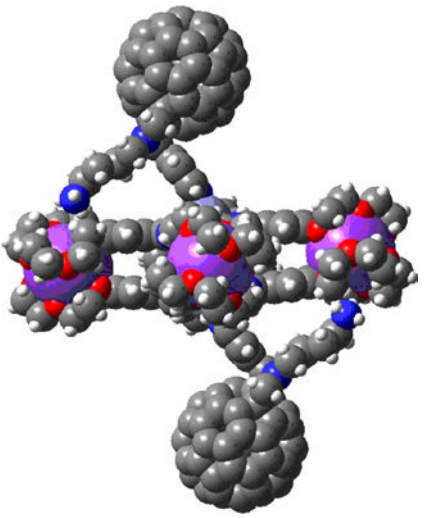

Figure 30. B3LYP/3-21G(*) optimized structure of the supramolecular $K_4[ZnTCPc]_2$:$(pyC_{60}NH_3^+)_2$ conjugate (**22**). The countercations and anions are omitted for clarity. (Adapted from Ref. 138.)

plane.[147] This misdirection of the lone pairs can weaken the interaction between the Zn(II) center and the nitrogen lone pairs to enhance the Lewis acidity of the Zn(II) center. Thus, the more the porphyrin ring is distorted as reflected on a larger ΔRMS value (see Figure 4), the stronger becomes the Lewis acidity of the Zn(II) to enhance the axial coordination bond strength with a base. The Zn(II) complexes of TPP^{2-} (tetraphenylporphyrin dianion) OPP^{2-} (octaphenylporphyrin dianion) and DPP^{2-} (dodecaphenylporphyrin dianion) showed different degrees of distortion of the porphyrin rings.[148–150] Among them, the DPP^{2-} ligand exhibited the largest nonplanarity as a saddle distortion and the largest displacement of the Zn(II) ion from the porphyrin mean plane.[147]

A saddle-distorted H_2DPP has also enabled facile protonation to give a stable diprotonated species, H_4DPP^{2+}, which can form intermolecular hydrogen bonds with electron donors.[151–154] The H_4DPP^{2+} can be combined with a nonplanar Zn(II) complex of saddle-distorted octaphenylphthalocyanine (H_2OPPc)[155,156] using pyridine-4-carboxylate (4-$PyCOO^-$) which can connect the Zn(OPPc) donor and the H_4DPP^{2+} acceptor by coordination bond and hydrogen bond.[157] The reaction of $[H_4DPP](4\text{-}PyCOO)_2$ with Zn(OPPc) in toluene gave a novel supramolecular assembly, $[(H_4DPP)\{Zn(OPPc)(\kappa^1\text{-}N\text{-}4\text{-}PyCOO)\}_2]$ (**23**).[157] The crystal structure is shown in Figure 31a.[156] The assembly contains one saddle-distorted H_4DPP^{2+} and two saddle-distorted Zn(OPPc) linked by two 4-$PyCOO^-$ anions (the components are shown in Figure 31b).[157] The bridging 4-$PyCOO^-$ coordinates to the Zn(II)

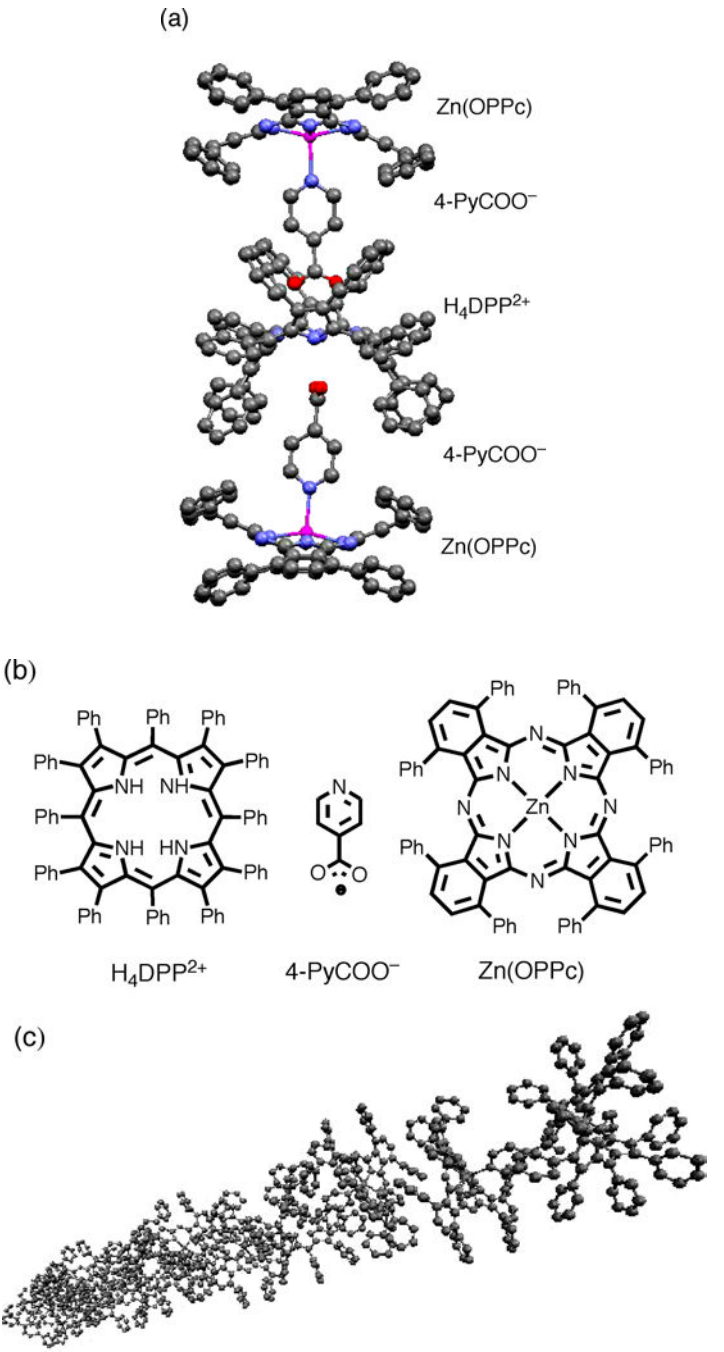

Figure 31. (a) Crystal structure of $[(H_4DPP)\{Zn(OPPc)(\kappa^1\text{-}N\text{-}4\text{-}PyCOO)\}_2]$ (**23**): purple — zinc; red — oxygen; blue — nitrogen; light gray — carbon. (Adapted from Ref. 157.)

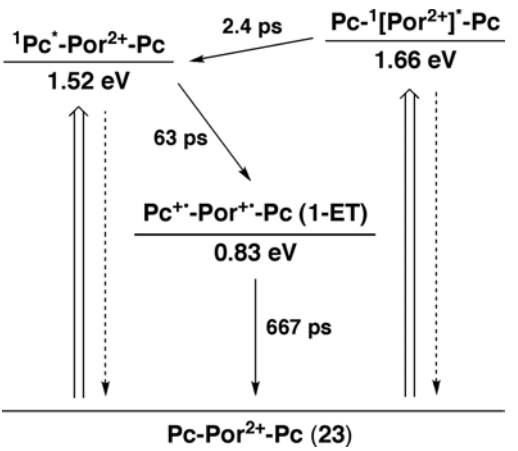
center of ZnOPPc through the axial coordination of pyridine nitrogen. It should be noted that there is two-point hydrogen bonding between H_4DPP^{2+} and 4-$PyCOO^-$ to connect the Zn(OPPc) units to the H_4DPP^{2+} moiety. The interatomic distances for those hydrogen bonds are in the range of 2.631(9)–2.725(7) Å, which suggests that hydrogen bonding is fairly strong.[157] The coordination of the pyridine linker is strong enough due to the remarkable saddle distortion of the $OPPc^{2-}$ ligand. The bond lengths of Zn1-N9 and Zn2-N18 are 2.117(3) and 2.140(3) Å, respectively, which are comparable with that found in [Zn(OPPc)(py)].[155,156] The crystal packing of **23** exhibits a one-dimensional nanowire structure (Figure 31c) by intermolecular π–π interactions of peripheral phenyl groups of the OPPc ligand.[157]

The supramolecular assembly in Figure 31 is stable enough in solution to maintain its structure, because ^{1}H diffusion-ordered spectroscopy (1H DOSY) in $CDCl_3$ allowed one to estimate its molecular volume (4849 $Å^3$), which was consistent with that (5096 $Å^3$) calculated on the basis of the crystal structure.[157] The stability of the supramolecular assembly in solution originates not only from the strong two-point hydrogen bonding between positively charged H_4DPP^{2+} and negatively charged 4-$PyCOO^-$ but also from the strengthened coordination of the nitrogen in 4-$PyCOO^-$ to the Zn(II) center with enhanced Lewis acidity within the saddle-distorted $OPPc^{2-}$ ligand.[157]

The energy diagram of the photoinduced electron transfer processes in **23** is shown in Scheme 6.[157] Femtosecond laser flash photolysis measurements revealed the photodynamics of **23** in PhCN.[157] Photoexcitation at 410 nm affords the singlet excited states of both H_4DPP^{2+} and Zn(OPPc) units ($^1[Por^{2+}]^*$ and $^1Pc^*$).[157] The singlet excited state of the porphyrin (Por) unit (1.66 eV) undergoes fast intra-supramolecular energy transfer with the rate constant of 4.2×10^{12} s^{-1}, which is comparable to that of



Scheme 6.

intramolecular energy transfer observed for a covalently linked ZnPor–ZnPc dyad.[158] This is followed by intra-supramolecular electron transfer from $^1Pc^*$ to Por^{2+} to give the electron transfer state at the energy level of 0.83 eV with the rate constant of 1.5×10^9 s^{-1}.[157] No energy transfer from the singlet excited state of $[H_4DPP](4\text{-}PyCOO)_2$ to Zn(OPPc) has occurred in **23**.[157] The electron transfer state has a lifetime of 667 ps, which is much longer than that observed in a covalently linked Zn (porphyrin)–Sn(phthalocyanine) dyad reported by Odobel and coworkers.[159]

The accessibility, stability, and reliability of multiporphyrin donor–acceptor systems can be further improved by using the stronger axial coordination in saddle-distorted Sn(IV) porphyrins with μ_3-O-centered and carboxylato-bridged trinulcear Ru^{III} clusters, as shown in Figure 32,[160] where the Sn(IV) ion, which is

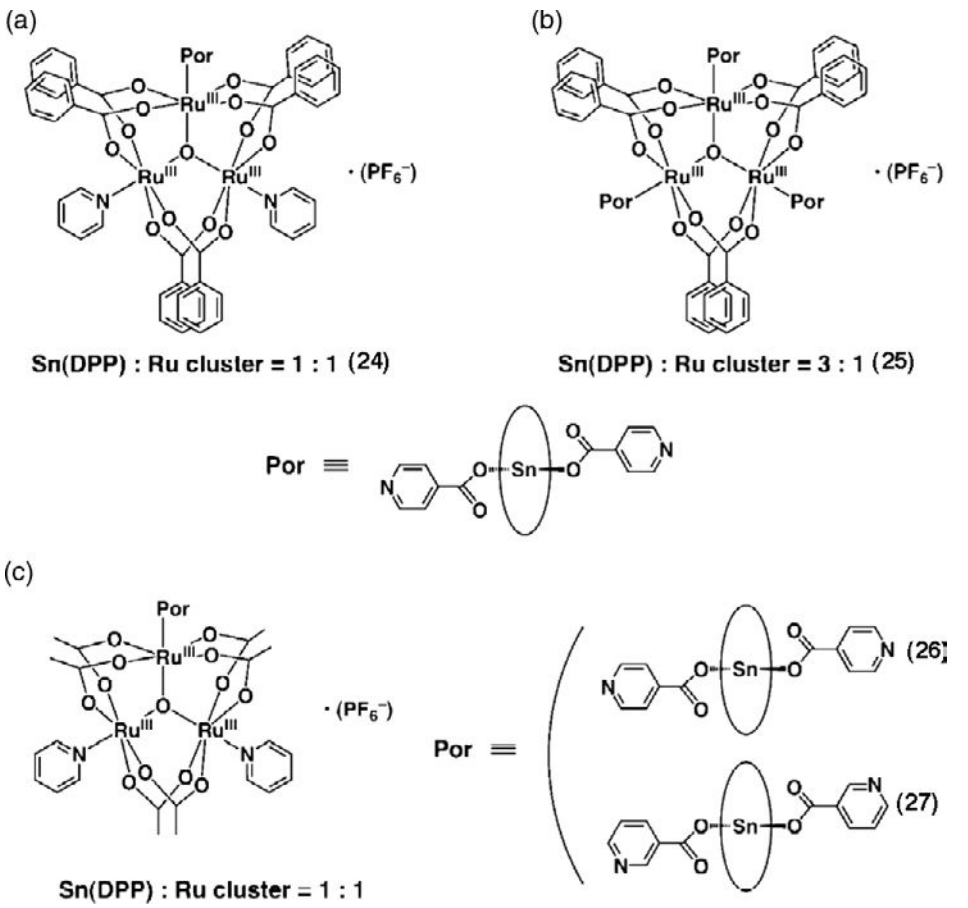


Figure 32. Schematic description of structures of conglomerates composed of Sn-DPP and Ru clusters: (a) a 1:1 complex (**24**), (b) a 3:1 complex (**25**), (c) 1:1 complexes (**26**, **27**). (Adapted from Ref. 160.)

a hard Lewis acid, binds with a hard base such as carboxylate oxygen to form a stable coordination bond with electron acceptors.[160] As electron acceptor, μ_3-oxo-centered and carboxylato-bridged trinuclear ruthenium clusters, $[Ru_3(\mu_3\text{-}O)(OC(O)R)_6L_3]^{n+}$, were employed due to their small structural change in the course of redox reactions for smaller reorganization energies.[161–164] The conglomerates are stable in solution, as demonstrated by ^{1}H NMR and ESI-MS spectroscopies.[160] This stability stems from the saddle distortion of the DPP^{2-} ligand to enhance the Lewis acidity of the Sn(IV) center, which strengthens the axial coordination of the linker.[160]

The conglomerates exhibited three reversible redox waves, as shown in Figure 33, where the Ru cluster moieties showed one reversible reduction wave due to $Ru^{III}{}_3/Ru^{II}Ru^{III}{}_2$ redox couples (0.03 V for **7**; 0.11 V for **25**) and one reversible oxidation wave ascribed to $Ru^{III}{}_3/Ru^{III}{}_2Ru^{IV}$ redox couples (1.06 V for **7**; 1.06 V for **25**).[160] The Sn(DPP) moieties exhibited reversible reduction waves (–0.91 V for **24**; –0.90 V for **25**) due to the Sn(DPP)/Sn($DPP^{\bullet-}$) redox couples and the oxidation waves ascribed to the Sn(DPP)/Sn($DPP^{\bullet+}$) redox couples (1.06 V for **24**; 1.06 V for **25**), which are overlapped with the oxidation waves of Ru cluster moieties in the case of **24** and **25**.[160]

The fast intramolecular photoinduced electron transfer from the Sn(DPP) unit to the trinuclear Ru^{III} cluster affording the electron transfer state [Sn($DPP^{\bullet+}$)–$Ru^{II}Ru^{III}{}_2$] was observed by femtosecond laser flash photolysis measurements.[160] The electron transfer state of the conglomerates showed lifetimes ranging from 98 ps to 405 ps, depending on the clusters and linkers employed.[160] The electron

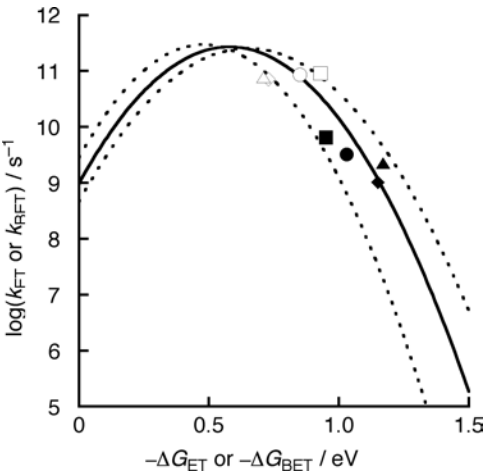

Figure 34. Driving force dependence of log k_{ET} (closed marks) or k_{BET} (open marks) for intramolecular electron transfer of conglomerates in PhCN at 298 K; **24** (circle), **25** (square), **26** (triangle), and **27** (rhombus). The fit of the curve based on the Marcus theory of electron transfer (Eq. 1) is shown by the solid line with $\lambda = 0.58$ eV and $V = 28.2$ cm^{-1} and the dotted lines with $\lambda = 0.50$ and 0.66 eV and $V = 28.2$ cm^{-1}, respectively. (Adapted from Ref. 160.)

transfer state decays via back electron transfer to recover the ground state, Sn(DPP)–Ru^{III}_3.[160] The lifetimes of the electron transfer states are determined from the back electron transfer rate constants to be 305 ps for **7**, 154 ps for **25**, 446 ps for **26**, and 98 ps for **27**, respectively.[160] The driving force dependence of log(k_{ET} or k_{BET}) for photoinduced electron transfer and back electron transfer is shown in Figure 34.[160] The fitting of the results to Eq. 1 afforded the reorganization energy of $\lambda = 0.58$ eV and $V = 28.2$ cm^{-1}, as shown (as the solid line) in Figure 34.[160] Both the rate constants of photoinduced electron transfer and back electron transfer in the conglomerates fall in the Marcus inverted region. This is a rare case in which both electron transfer and back electron transfer rates are located in the Marcus inverted region due to the small reorganization energy of electron transfer.[165] This reorganization energy of electron transfer is relatively small in comparison with other related dyads, giving rise to CS or electron transfer states.[4-6,14,15]

VIII. Porphyrin–Nanocarbon Composites

Formation of nanoscale donor–acceptor ensembles is also made possible by π–π interaction between multiporphyrin compounds such as the porphyrin–peptide hexadecamer [$P(H_2P)_{16}$][166,167] and single-walled carbon nanotubes (SWNTs), as shown in Figure 35.[168] The novel and unique electronic properties of SWNTs make them excellent candidates for next-generation nanoelectronic applications.[169–172]

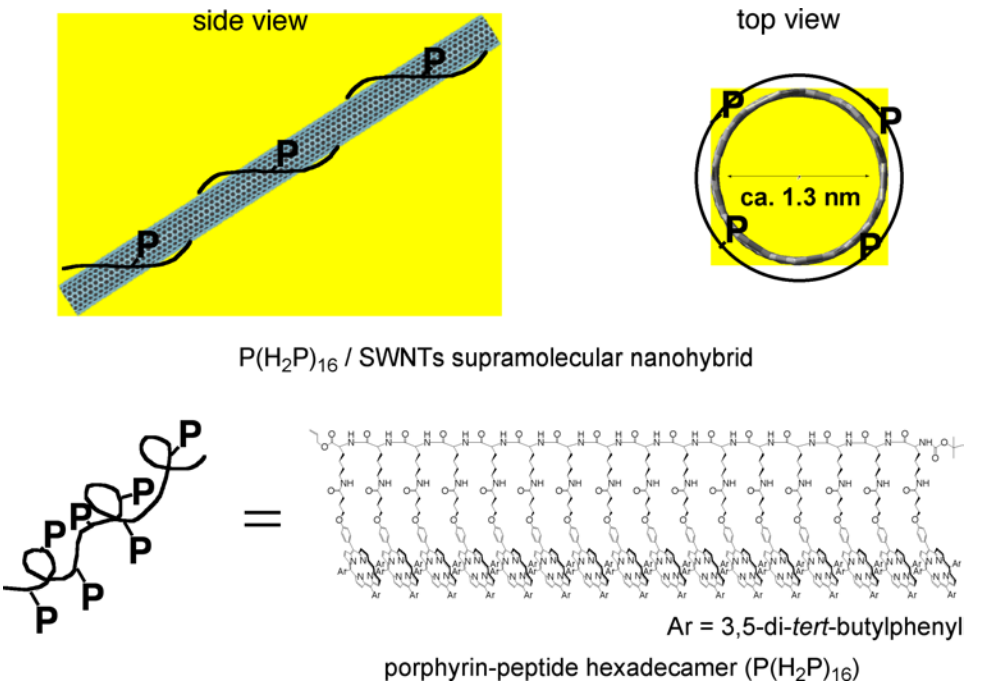

Figure 35. Formation of a supramolecular complex (**28**) between porphyrin–peptide hexadecamer [$P(H_2P)_{16}$] and single-walled carbon nanotube (SWNTs). (Adapted from Ref. 168.)

Supramolecular formation occurs through π–π interaction between porphyrins and nanotubes together with wrapping of the peptidic backbone in $P(H_2P)_{16}$.[168] This makes it possible to extract the large-diameter nanotubes (*ca.* 1.3 nm) as revealed by ultraviolet–visible–near-infrared and Raman spectroscopy as well as high-resolution transmission electron microscopy, as shown in Figure 36, where only an individual nanotube with a diameter below 2 nm and individual nanotubes with small-diameter bundles are observed.[168]

Laser photoexcitation of $P(H_2P)_{16}$/SWNTs nanohybrid (**28**) in DMF results in appearance of a transient absorption at 450 nm together with a broad absorption band in the 500–800 nm region, which exhibits a number of bleaching bands (Figure 37a).[168] Taking into account the fact that the bleaching bands agree with the absorption bands due to **28** (inset of Figure 37a) and no transient absorption was observed upon photoexcitation of $P(H_2P)_{16}$, the observed transient absorption spectrum was assigned to the CS state of **28**, which was produced by photoinduced electron transfer from the excited states of $P(H_2P)_{16}$ to SWNTs.[168] The decay of the CS state of **28** obeyed first-order kinetics with the same slope irrespective of any difference in the laser intensities, as shown in Figure 37b.[168] The same slope, irrespective of difference in the laser intensities in Figure 37b, strongly indicates

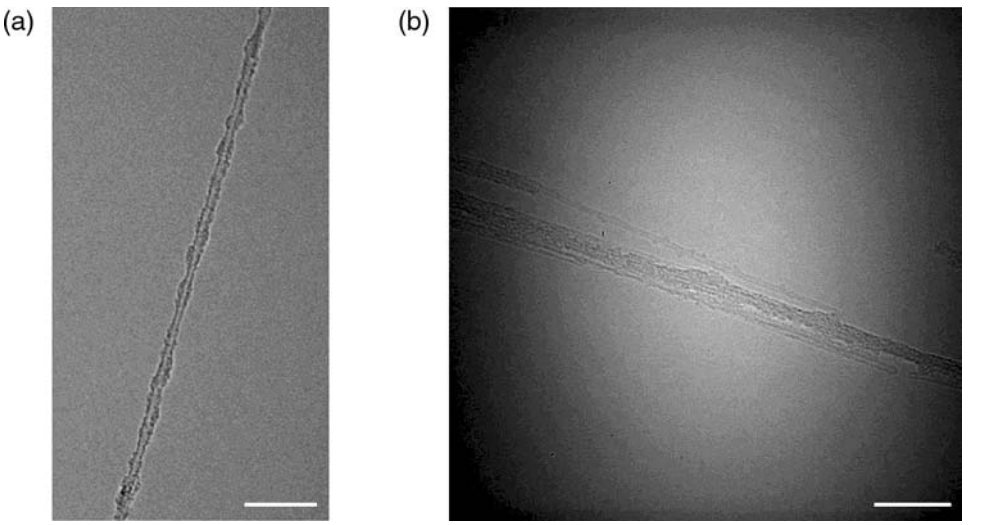

Figure 36. HRTEM images of **28** (scale bar = 20 nm): (a) an individual nanotube and (b) individual nanotubes with small-diameter bundles. (Adapted from Ref. 168.)

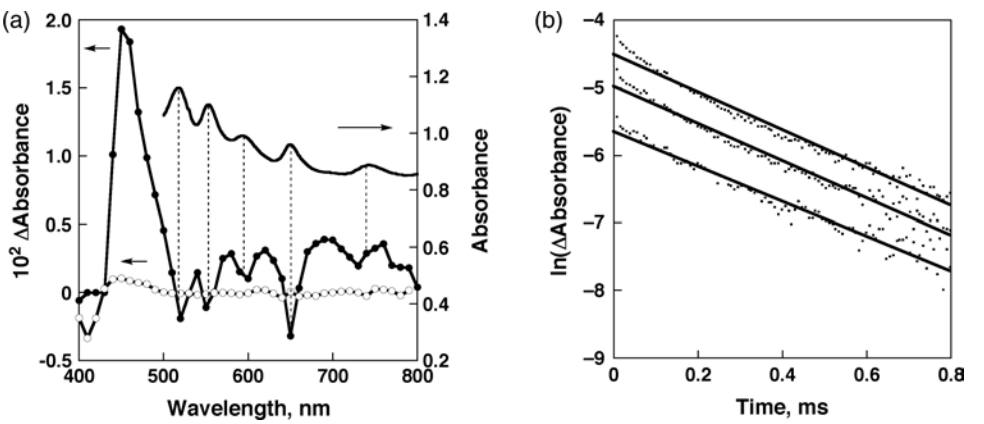

Figure 37. (a) Transient absorption spectra of **28** (solid line with black circles) and $P(H_2P)_{16}$ (solid line with white circles) in DMF at 298 K taken at 6 μs after laser excitation at 440 and 427 nm, respectively. that the decay of the porphyrin radical cation results from the back electron transfer from the reduced SWNTs to the porphyrin radical cation in the supramolecular complex.[168] The CS lifetime is determined to be 370 μs, which is significantly shorter than the reported triplet lifetimes of porphyrin–peptide oligomers.[167] Formation of such nanohybrids affording the long-lived CS state of **28** opens up a new strategy for the extraction of large-diameter SWNTs without destruction of

the π-conjugated system within SWNTs and the development of efficient light energy conversion devices.

Although SWCNTs exhibit excellent chemical and physical properties,[173–177] the fine control of the size (i.e. length) of SWCNTs is a great challenge for solubilization and construction of nanoscale architectures and devices. The control of the diameter and size of carbon nanotubes has recently been made possible using cup-stacked carbon nanotubes (CSCNTs) that consist of truncated conical graphene layers with a hollow tubular morphology, composed of cup-shaped carbon units with diameters ranging from 50 to 150 nm and lengths of up to 200 μm.[178–180] In addition, the availability of reactive edges on the outer and inner surfaces of cup-shaped carbons to chemical functionalization or surface modification will open up new ways to utilize them in electronic, catalytic, and photovoltaic applications.[181] CSCNTs were efficiently destacked by the electron transfer reduction with sodium naphthalenide to produce individual cup-shaped carbons with controlled diameter and size, as shown in Figures 38a and b.[182] Addition of 1-iodododecane to reduced cup-shaped carbons leads to functionalized cup-shaped carbons (**29**), which are stable in air and highly dispersible in nonpolar solvents for long time periods (Figure 38c).[182] Photoinduced electron transfer reduction of CSCNTs with dimeric 1-benzyl-1,4-dhihydronicotinamide also results in the highly dispersible cup-shaped nanocarbons with size homogeneity.[183]

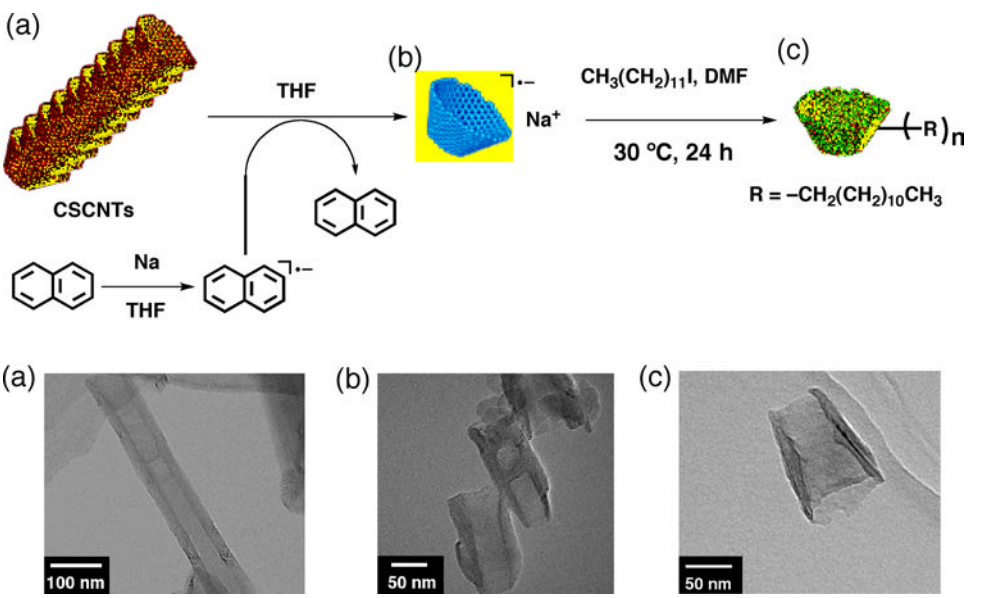

Figure 38. Electron transfer reduction of (a) cup-stacked carbon nanotubes (CSCNTs) to prepare (b) reduced CSCNTs and (c) docecylated CSCNTs (**29**) with controlled diameter and size, with their TEM images. (Adapted from Ref. 182.)

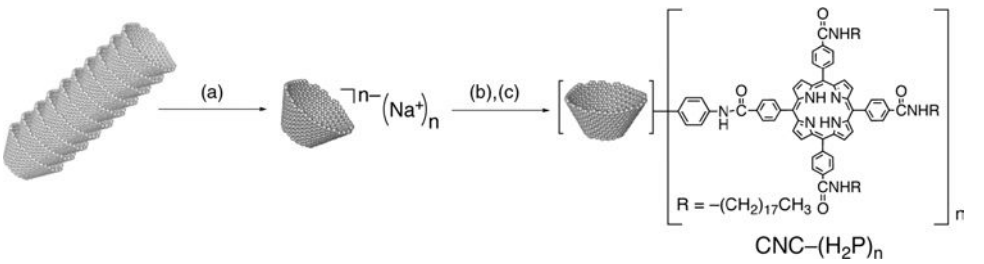

Figure 39. Synthesis of the porphyrin-functionalized cup-shaped nanocarbons (**30**: CNC–$(H_2P)_n$). Reagents and conditions: (a) naphthalene (Na), THF, r.t., 24 h; (b) 4-iodoaniline, DMF, 30 °C, 24 h; (c) porphyrin–COCl, pyridine, DMF, 120 °C, 72 h. (Adapted from Ref. 184.)

The cup-shaped nanocarbons generated by the electron transfer reduction of CSCNTs can be readily functionalized with porphyrins for use as light-capturing chromophores.[184] The general procedure for the synthesis of the porphyrin-functionalized cup-shaped nanocarbons [CNC–$(H_2P)_n$] (**30**) consists of two steps, as shown in Figure 39.[184] The first step involves cup-shaped nanocarbons functionalized with aniline as the precursor for functionalization with porphyrins. In the second step, the aniline-functionalized nanocarbons react with the porphyrin derivatives to construct the nanohybrids.[184] The resulting donor–acceptor nanohybrid (**30**) has been well characterized by thermogravimetric analysis (TGA), Raman and IR spectroscopy, transmission electron microscopy, elemental analysis, and ultraviolet–visible–near-infrared (UV–vis–NIR) spectroscopy.[184] The weight of porphyrins attached to the cup-shaped nanocarbons was determined to be 20% by the TGA and elemental analysis.[184] This corresponds to one functional group per 640 carbon atoms of the nanocup framework for **30** on average.[184] This result was supported by the elemental analysis that indicated a chemical formula of $C_{640}H_{55}(C_{108}H_{145}N_8O_4)$, from which the amount of porphyrins grafted to the cup-shaped carbons was determined to be 21.0%.[184] The structure of the cup-shaped nanocarbons of **30** was revealed by the TEM image in Figure 40, which shows the independently cup-shaped nanocarbon with a well-controlled diameter (*ca*. 50 nm) and size (*ca*. 100 nm).[184]

Laser photoexcitation of **30** in DMF results in appearance of the transient absorption, as shown in Figure 41a (solid line with open circles).[184] The triplet–triplet absorption of ref-H_2P (Figure 41b) exhibits quite different features as compared to **30** [see the near-infrared region (600–800 nm) as well as the peak top positions].[184] Thus, the observed transient absorption spectrum is assigned to the CS state of **30**, which is produced by photoinduced electron transfer from the singlet excited states of H_2P to cup-shaped nanocarbons in the nanohybrid. The formation of the CS state was also detected by electron spin resonance (ESR)

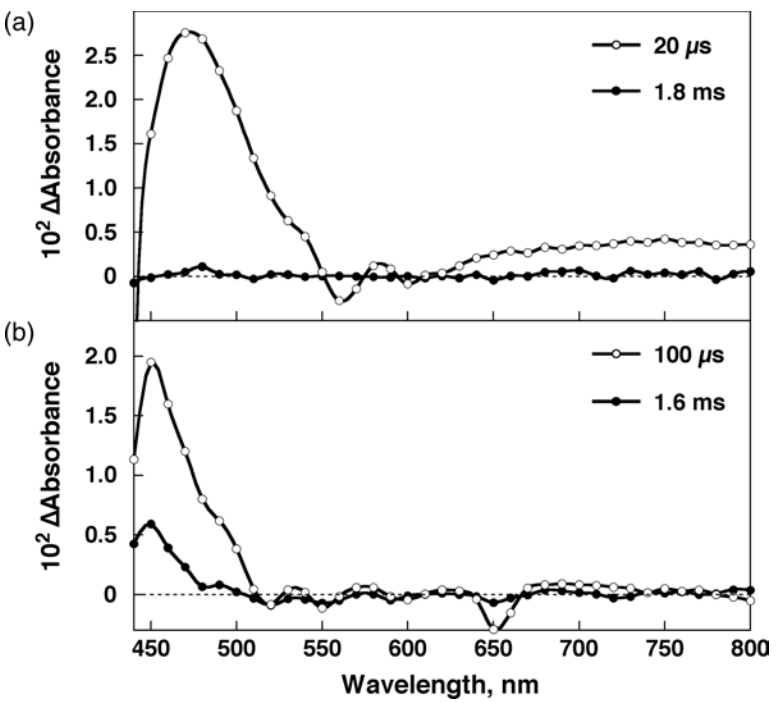

Figure 41. Transient absorption spectra of (a) CNC–$(H_2P)_n$ in deaerated DMF at 298 K taken at 20 μs (solid line with open circles) and 1.8 ms (solid line with black circles) after laser excitation at 426 nm and (b) ref-H_2P in deaerated DMF at 298 K taken at 100 μs (solid line with open circles) and 1.6 ms (solid line with black circles) after laser excitation at 426 nm. (Adapted from Ref. 184.)

measurements under photoirradiation of **30** with a high-pressure mercury lamp in frozen DMF at 153 K.[184]

The CS state detected in Figure 41a decayed obeying clean first-order kinetics.[184] Thus, the decay process is ascribed to intramolecular back electron transfer in the nanohybrid rather than intermolecular back electron transfer between $H_2P^{\bullet+}$ and $CNC^{\bullet-}$ produced by photoinduced electron transfer. The CS lifetime of **30** is determined from the first-order plots to be 0.64 ± 0.01 ms, which is the longest lifetime ever reported for electron-donor-attached nanocarbon materials. Such a long CS lifetime may result from the efficient electron migration in the cup-shaped nanocarbons following the charge separation.[184]

Nanocarbon structures can be obtained using only synthetic porphyrins which form aggregates in the form of fibers, nanorods, and nanotubes.[185–187] Robust porphyrin nanotubes can be prepared by ionic self-assembly of two oppositely charged porphyrins in aqueous solution.[187] The nanotubes are composed entirely of porphyrins and electrostatic, van der Waals, hydrogen bonding, axial coordination, and other weak intermolecular interactions, which typically contribute to the formation of porphyrin aggregates, and enhance the structural stability of these nanostructures.[187]

When $[H_4DPP_2]Cl_2$ is employed as a building block, this compound acts as a starting material to form a variety of novel porphyrin nanochannel (PNC) structures, in which various electron donors are incorporated.[188,189] In the presence of hydroquinone derivatives, the starting PNC (PNC-water) underwent guest exchange from the water molecules to a series of guest molecules in the course of recrystallization.[188] The crystal structure of the PNC including hydroquinone (**31**: PNC-H_2Q) was determined as shown in Figure 42.[188] The structure of the skeleton unit is the same as that of PNC-water and the water molecules are just replaced by hydroquinone.[188] The hydroquinone molecule was included due to intermolecular π–π interactions with H_4DPP^{2+}.[188] Hydrogen bonding was found for the hydroxyl groups of hydroquinone with the nitrogen atoms of the acetonitrile molecules in the skeleton units in the distance of 2.85 Å.[188] This hydrogen bonding fixes the configuration of the two hydrogens of the hydroxyl groups to be *trans* PNC compounds.[187] In the case of benzoquinone derivatives, which are two-electron oxidized species of corresponding hydroquinones, no inclusion was observed for those molecules under the same conditions.[188] These results indicate that electron-donating molecules are included selectively.[188] When tetrabromohydroquinone (H_2QBr_4) was employed as a guest molecule, however, it was not included in the PNC.[188] This indicates that steric factors are also important in the inclusion process of PNC-guest formation.[188]

The photodynamics of **31** is shown in Scheme 7.[188] The photoirradiation of **31** affords the singlet excited state of the porphyrin dication, $^1(H_4DPP^{2+})^*$, which

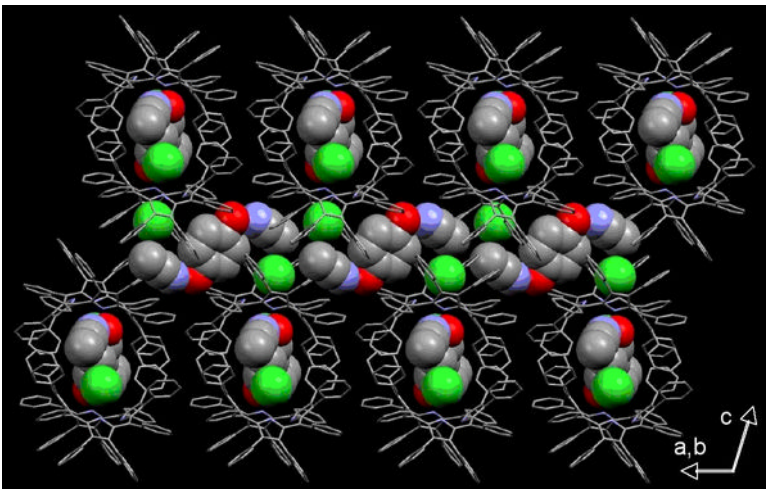

Figure 42. Crystal structure of PNC-H_2Q (**31**). The H_4DPP^{2+} unit is drawn with a wire frame. Carbon — gray; Oxygen — red; nitrogen — blue; chloride — light green. (Adapted from Ref. 188.)

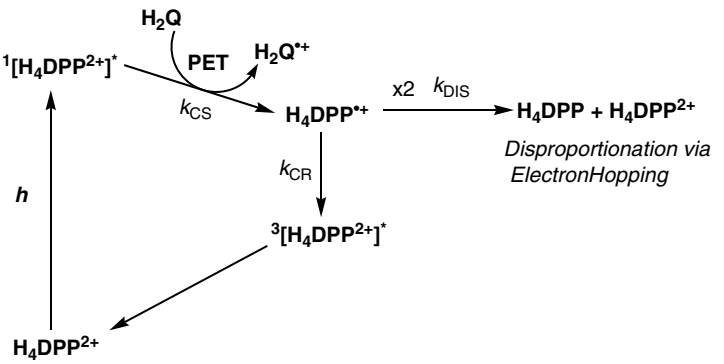

Scheme 7.

accepts one electron from the guest molecule, hydroquinone, to give the corresponding radical cation. The reduced radical cation of $H_4DPP^{\bullet+}$ undergoes fast disproportionation based on electron hopping in the solid state due to close contacts with other H_4DPP^{2+} via intermolecular π–π interactions to give the original H_4DPP^{2+} and the two-electron reduced species of H_4DPP (Scheme 7).[188] In addition, $H_4DPP^{\bullet+}$ undergoes back electron transfer (charge recombination) to form $^3(H_4DPP^{2+})^*$, the energy of which is lower than that of the electron transfer state. The photoinduced electron transfer process from guest donor molecules to $^1(H_4DPP^{2+})^*$ occurs much more efficiently than the intersystem crossing to give the

triplet state, $^3(H_4DPP^{2+})^*$, due to close and secure contact and inevitable intermolecular interactions with the guest molecules in the PNC.[188] Thus, the PNC provides an excellent opportunity to construct and develop porphyrin-based photofunctional materials.[188]

Supramolecular porphyrin nanochannels (PNCs), including tetrathiafulvalene (TTF) acting as a strong electron-donating guest in the inner space, were also prepared with the hydrochloride salt of dodecaphenylporphyrin ($[H_4DPP]Cl_2$) by self-assembly based on intermolecular π–π interactions, as shown in the crystal structure of the TTF-included PNC (**32**: PNC-TTF) in Figure 43.[189] Intermolecular π–π interaction was also recognized among peripheral phenyl groups of the porphyrin, mainly in the direction of the crystallographic *c* axis to form a column structure.[189] Photoinduced electron transfer from TTF to $^1(H_4DPP^{2+})^*$ occurred to afford the electron transfer state, $TTF^{\bullet+}$ and $H_4DPP^{\bullet+}$ in PNC.[189]

A single crystal ($0.87 \times 0.23 \times 0.10$ mm^3) of **32** exhibited photoconductivity upon photoirradiation at 633 nm with a He–Ne laser (5 mW) and the photocurrent was 0.7 nA at an electrical field strength of 3.5×10^4 V cm^{-1}.[189] The photocurrent showed direction dependence toward the crystallographic *c* axis.[189] This indicates that the main electron conduction path of the photocurrent is the π–π interactions among phenyl groups to facilitate electron hopping.[189]

In the case of a cyclic porphyrin dimer (Ni_2-CPD_{Py}) linked by butadiyne moieties bearing 4-pyridyl groups (Figure 44a),[190] Ni_2-CPD_{Py} acts as an electron donor to form a 1:1 inclusion π-complex with an electron acceptor C_{60} (**33**: $C_{60}\subset Ni_2$-CPD_{Py}).[191] The titration in solution indicated that Ni_2-CPD_{Py} included C_{60} to give a

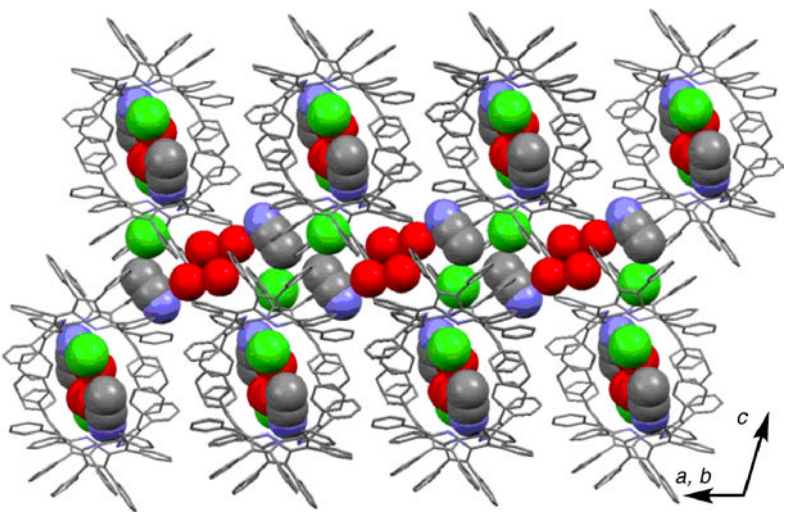

Figure 43. The crystal structure of PNC-TTF (**32**). (Adapted from Ref. 189.)

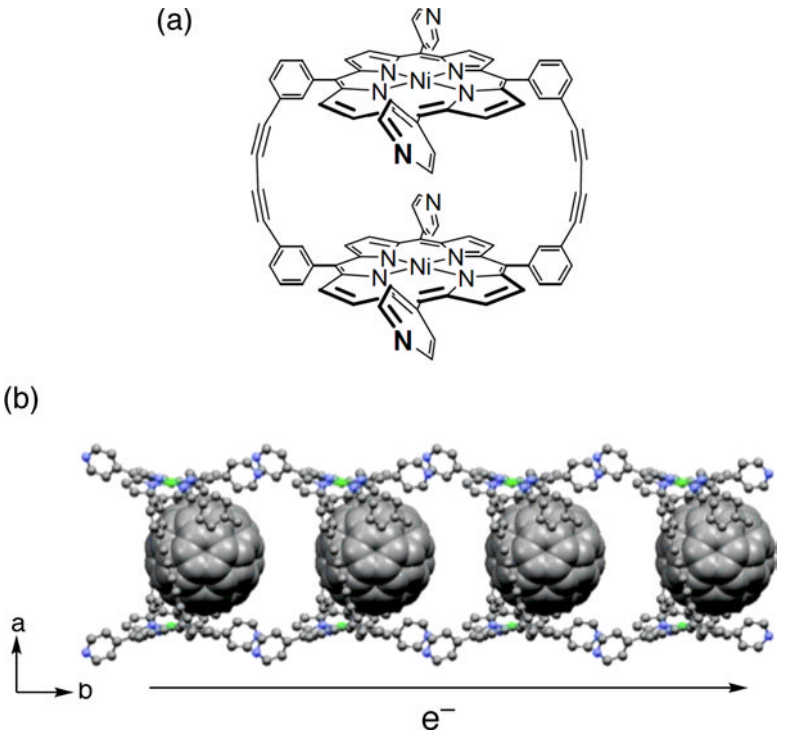

Figure 44. (a) Chemical structure of Ni_2-CPD_{Py}. (b) Crystal structures of tubular assemblies of C_{60}⊂Ni_2-CPD_{Py} (**33**). Hydrogen atoms are omitted for clarity. (Adapted from Ref. 191.)

1:1 inclusion complex (**33**) with an association constant (K) of 2.0×10^5 M^{-1}.[191] X-ray crystallography confirmed the 1:1 inclusion complex of C_{60} with Ni_2-CPD_{Py} (Figure 44b).[191] A nanosized tubular assembly is observed in the crystal packing of **33**. The tubular structure along the crystallographic b axis is formed by self-assembly through two kinds of cooperative noncovalent interactions between Ni_2-CPD_{Py} molecules.[191] One is a pair of complementary C–H···N hydrogen bonding interactions between the pyrrole β-CH and the nitrogen atoms of the pyridyl groups.[191] The other noncovalent interaction is a weak π–π interaction between the pyridyl groups.[191] In the crystal structure of **33**, a porphyrin nanotube is formed by the self-assembly of Ni_2-CPD_{Py}. Ni_2-CPD_{Py} molecules link together through non-classical C–H···N hydrogen bonds and π–π interactions of the pyridyl groups along the crystallographic b axis.[191] The included C_{60} molecules are linearly arranged in the nanotube to afford a supramolecular peapod. The charge carrier mobility of the single crystal of **33** was determined by flash photolysis time-resolved microwave conductivity (FP-TRMC) measurements. It has an anisotropic high electron mobility ($\Sigma\mu = 0.72$ cm^2 V^{-1} s^{-1}) along the linear array of C_{60}

(crystallographic *b* axis).[191] Such a high electron mobility in **33** suggests that supramolecular complexes of self-assembled porphyrin nanotubes and fullerenes provide promising materials for photovoltaic applications.

IX. Porphyrin Solar Cells

The important role of porphyrin derivatives combined with electron donors and acceptors in mimicking light harvesting and photoinduced electron transfer in the photosynthesis described above suggests that porphyrin molecules could serve as potential photosensitizers in dye-sensitized solar cells as well as electron donors in bulk heterojunction solar cell application.[192–198]

The PNC-TTF supramolecules in Figure 43 have been utilized to prepare porphyrin supramolecular solar cells.[188] Schematic description of the solar cell using an OTE/SnO_2/PNC-TTF anode is shown in Figure 45.[189] The PNC crystals-deposited films were prepared by the drop-cast method.[189] Photoelectrochemical measurements were carried out in a standard two-compartment cell consisting of a working electrode and a Pt wire gauze counterelectrode in the electrolyte (0.5 M LiI and 0.01 M I_2) in MeCN.[189] The incident photon-to-current efficiency (IPCE) values at various excitation wavelengths were determined from Eq. 7,[195]

$$\text{IPCE}\ (\%) = \frac{\frac{I_{SC}}{I_{inc}}}{\frac{1240}{\lambda}} \times 100, \tag{7}$$

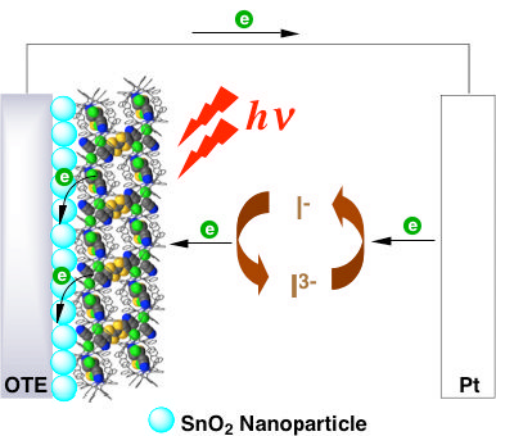

Figure 45. A schematic description of a photoelectrochemical cell using an OTE/SnO_2/PNC-TTF anode.

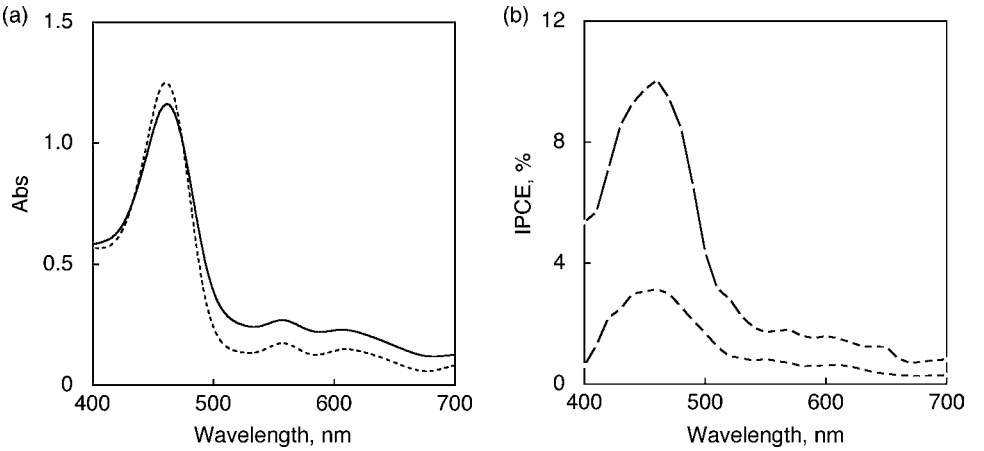

Figure 46. (a) Absorption spectra of OTE/SnO_2/PNC-TTF (solid line) and OTE/SnO_2/PNC-water (dotted line); (b) IPCE plots for OTE/SnO_2/PNC-TTF (circle) and OTE/SnO_2/PNC-water (square). (Adapted from Ref. 189.)

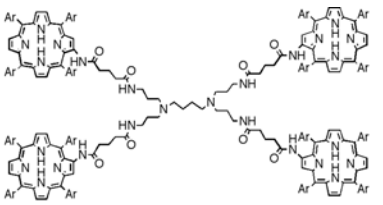
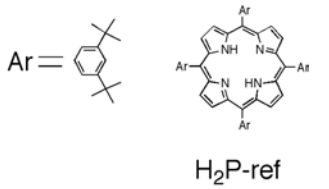
where I_{inc} is the incident light intensity (W cm^{-2}) and λ is the excitation wavelength (nm). The action spectra of both the OTE/SnO_2/PNC-TTF and the OTE/SnO_2/PNC-water electrodes are shown in Figure 46.[189] The close match in the absorption and action spectra indicates that the singlet excited state of $[H_4DPP]Cl_2$ is responsible for the photocurrent generation. Photoinduced electron transfer from TTF to $^1\{[H_4DPP]Cl_2\}^*$ followed by intermolecular electron hopping results in enhancement of photocurrent generation, because the maximum IPCE value (10.1%) for the OTE/SnO_2/PNC-TTF is more than three times higher than that for the OTE/SnO_2/PNC-water (3.1%).[189]

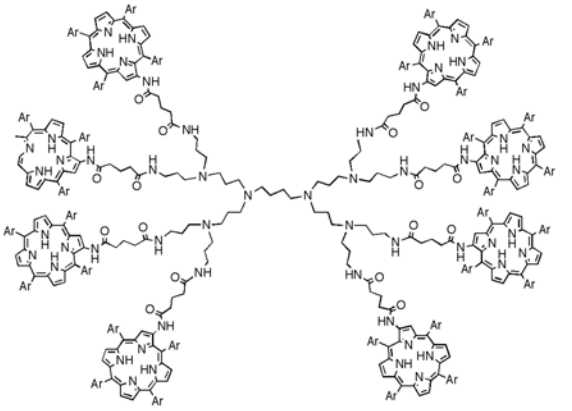
A combination of porphyrin dendrimers (chromophores and electron donor) and fullerenes (electron acceptor) is expected to result in enhanced light-harvesting efficiency of chromophores throughout the solar spectrum. Thus, a new type of solar cell has been constructed using molecular clusters of porphyrin dendrimer (donor) and fullerene (acceptor) dye units assembled on SnO_2 electrodes, which have high charge separation efficiency as well as efficient hole and electron transport.[199,200] The porphyrin dendrimers [D_nP_n; n = 4 (**34**), 8 (**35**), 16 (**36**)] are shown in Figure 47 together with the reference porphyrin compound (H_2P-ref).[199,200] Porphyrin dendrimers (D_nP_n) form supramolecular complexes with C_{60} in toluene and they are clustered in an acetonitrile/toluene mixed solvent system.[199,200] Then, the clusters are attached on nanostructured SnO_2 electrodes by an electrophoretic deposition method to afford the modified electrodes [denoted as OTE/SnO_2/$(D_nP_n+C_{60})_m$ (n = 4, 8, 16)].[199,200] The photoelectrochemical measurements were performed with a standard two-electrode system consisting of a



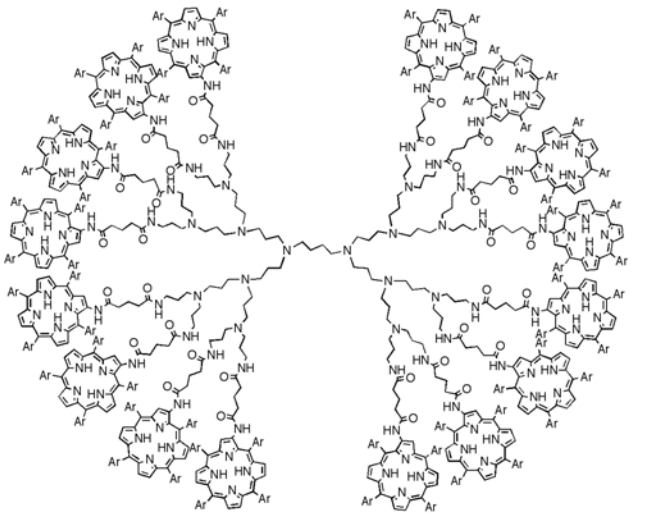
D_4P_4 (**34**)



H_2P-ref



D_8P_8 (**35**)



$D_{16}P_{16}$ (**36**)

Figure 47. Porphyrin dendrimers (**34**–**36**) and the reference compound employed for construction of organic solar cells composed of multiporphyrin/C_{60} supramolecular assemblies. (Adapted from Refs. 199 and 200.)

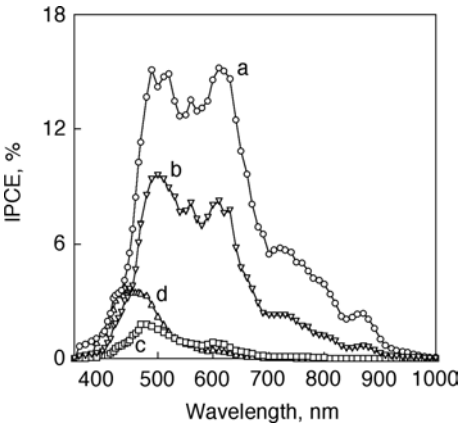


Figure 48. Photocurrent action spectra (IPCE vs. wavelength) of OTE/SnO_2/$(D_nP_n+C_{60})_m$ systems [(a) $n = 4$ (**34**); (b) $n = 8$ (**35**); (c) $n = 16$ (**36**)], (d) OTE/SnO_2/$(H_2P\text{-ref}+C_{60})_m$ and [D_4P_4] = 0.048 mM, [D_8P_8] = 0.024 mM, [$D_{16}P_{16}$] = 0.012 mM and [H_2P-ref] = 0.19 mM; [C_{60}] = 0.31 mM in MeCN/toluene = 3/1. (Adapted from Ref. 200.)

working electrode and a Pt wire gauze electrode in 0.5 M NaI and 0.01 M I_2 in air-saturated MeCN.[199,200] Figure 48 shows the wavelength dependence of the IPCE of the OTE/SnO_2/$(D_nP_n+C_{60})_m$ system and the reference system (OTE/SnO_2/$(H_2P\text{-ref}+C_{60})_m$) at a constant concentration ratio of porphyrin to C_{60}.[200] The OTE/SnO_2/$(D_4P_4+C_{60})_m$ system has the maximum IPCE value of 15% as well as the broad photoresponse, which extends well into the infrared (up to 1000 nm).[200]

Comparison of the photoelectrochemical properties between the OTE/SnO_2/$(D_4P_4+C_{60})_m$ system and the reference system indicates that the composite clusters of porphyrin dendrimers with C_{60} exhibit remarkable enhancement in photoelectrochemical performance due to the effective π–π interaction between porphyrins and fullerenes in the interpenetrating structure of the supramolecular clusters as compared with the reference system.[200] The broad long-wavelength absorption in the NIR region is diagnostic of the charge transfer absorption band due to the π-complex formed between the porphyrin and C_{60}, because similar charge transfer interactions leading to extended absorption have been observed for porphyrin–C_{60} dyads linked in close proximity.[201,202] The IPCE value decreases with increase in the number of dendrimer generation, and the OTE/SnO_2/$(D_{16}P_{16}+C_{60})_m$ system has even smaller IPCE values compared with the reference system [OTE/SnO_2/$(H_2P\text{-ref}+C_{60})_m$] (Figure 48).[200] In the case of $D_{16}P_{16}$ (**36**), the space between porphyrin rings may be too small for the interaction with C_{60}. This indicates that the distance between two porphyrin rings is also an essential factor in forming such a supramolecular complex.

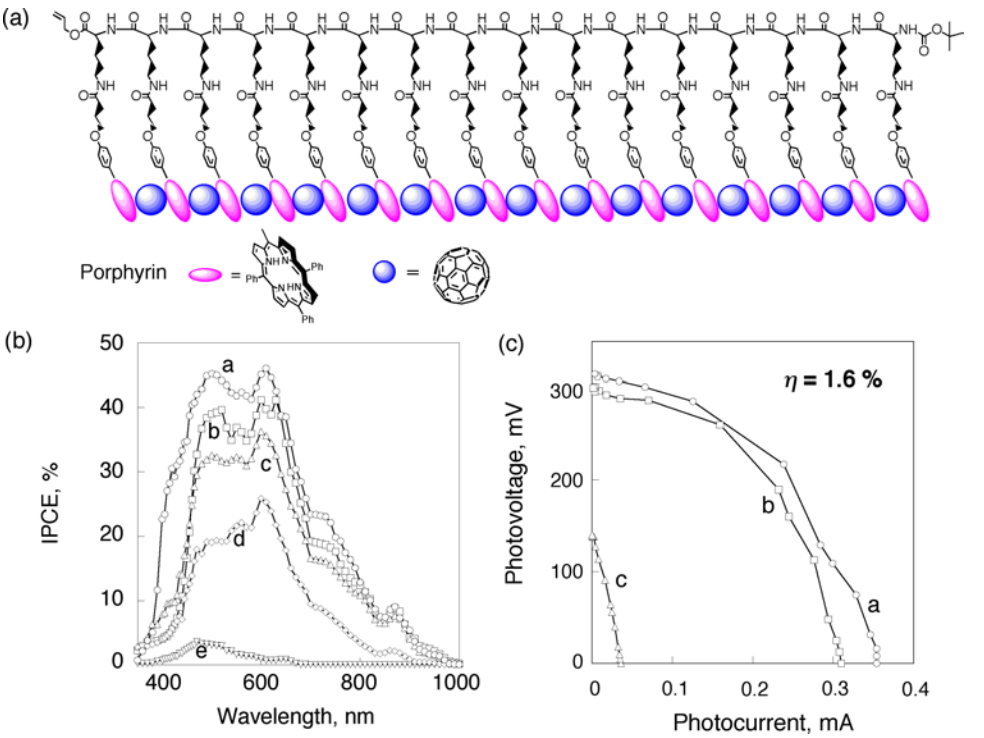

Figure 49. (a) Supramolecular complex between porphyrin–peptide hexadecamer $[P(H_2P)_{16}]$ (**41**) and C_{60}. (b) The photocurrent action spectra (IPCE vs. wavelength) of (a) (**41**+$C_{60})_m$, (b) (**40**+$C_{60})_m$, (c) (**39**+$C_{60})_m$, (d) (**38**+$C_{60})_m$, and (e) (**37**+$C_{60})_m$ modified OTE/SnO_2 electrodes under short circuit conditions. (c) Current–voltage characteristics of (a) OTE/SnO_2/(**41**+$C_{60})_m$, (b) OTE/SnO_2/(**40**+$C_{60})_m$, and (c) OTE/SnO_2/(**37**+$C_{60})_m$. (Adapted from Ref. 204.)

Porphyrin oligomers with a polypeptidic backbone, shown in Figure 49, are flexible enough to accommodate C_{60} between the porphyrin units.[203,204] The organization of $P(H_2P)_n$ and C_{60} composite clusters onto an optically transparent electrode (OTE) of a nanostructured SnO_2 electrode (denoted as OTE/SnO_2/$(P(H_2P)_n+C_{60})_m$ [n = 1 (**37**), 2 (**38**), 4 (**39**), 8 (**40**), 16 (**41**)]) was performed as the case of porphyrin dendrimers (*vide supra*). The IPCE value of OTE/SnO_2/$(P(H_2P)_n+C_{60})_m$ (n = 1, 2, 4, 8, 16) exhibits a remarkable rise with increase in the number of porphyrins in a polypeptide unit, as shown in Figure 49(b).[204] The OTE/SnO_2/$(P(H_2P)_{16}+C_{60})_m$ system has the maximum IPCE value of 48% at 600 nm as well as a broad photoresponse extending into the infrared region (up to 1000 nm).[204] This indicates that efficient photoinduced electron transfer occurs from the excited state of the porphyrin unit to C_{60} in the supramolecular complex with increase in the number of porphyrins in a polypeptide unit. Such an effective

light energy conversion is largely ascribed to the polypeptide structure which controls the three-dimensional organization between porphyrin and C_{60}.

The current–voltage (*I/V*) characteristics of OTE/SnO_2/(**41**+C_{60})$_m$, OTE/SnO_2/(**40**+C_{60})$_m$, and OTE/SnO_2/(**37**+C_{60})$_m$ electrodes are shown in Figure 49(c).[204] The (**41**+C_{60})$_m$ system has a fill factor (FF) of 0.47, an open circuit voltage (V_{oc}) of 320 mV, a short circuit current density (I_{sc}) of 0.36 mA cm^{-2}, and the overall power conversion efficiency (η) of 1.6% at input power of 3.4 mW cm^{-2}.[204] The *I/V* characteristics of the OTE/SnO_2/(**41**+C_{60})$_m$ system is remarkably enhanced (more than 40 times) as compared with the OTE/SnO_2/(**37**+C_{60})$_m$ electrode under the same experimental conditions.[204]

Supramolecular porphyrin solar cells have also been constructed using porphyrin-alkanethiolate monolayer protected-gold nanoclusters and C_{60} by clustering with gold nanoparticles and the electrophoretic deposition on SnO_2 electrodes to attain the power conversion efficiency of 1.5%.[205,206] Thus, supramolecular approaches between porphyrins and fullerenes provide a promising perspective for the development of efficient organic solar cells.

X. Concluding Remarks

As demonstrated in this chapter, porphyrins and phthalocyanines exhibit excellent photoinduced energy transfer and electron transfer properties with electron donors and acceptors, efficiently mimicking the functions in natural photosynthesis. The small reorganization energies of electron transfer of these functional π-compounds are essential for the design of artificial photosynthetic systems with fast charge separation but extremely slow charge recombination, which can be successfully applied to construct efficient light energy conversion systems such as photovoltaic devices. In particular, three-dimensional steric control in the supramolecular complexes of porphyrins and phthalocyanines with electron donors and acceptors contributes to efficient charge separation as well as hole and electron migration. Further improvement of energy transfer and electron transfer properties of photosynthetic reaction center models composed of porphyrins and phthalocyanines will certainly provide promising perspectives for the development of efficient light energy conversion systems.

XI. Acknowledgments

The author gratefully acknowledges the contributions of his collaborators and coworkers who are mentioned in the references. He also thanks the Ministry of Education, Culture, Sports, Science and Technology, Japan, and KOSEF/MEST through a WCU (R31-2008-000-10010-0) project for continuous support.

List of Abbreviations

AFM	atomic force microscopy
BDMD	boron-doped microcrystalline diamond
BDND	boron-doped nanocrystalline diamond
BE	binding energy
CcO	cytochrome c oxidase
CMOS	complementary metal oxide semiconductor
CNT	carbon nanotube
Cyt c	cytochrome c
o-DCB	o-dichlorobenzene
DDQ	dichlorodicyanobenzoquinone
DMF	dimethylformamide
DIPEA	N,N-diisopropylethylamine
DRAM	dynamic random access memory
EDC	N-(3-dimethylaminopropyl)-N″-ethylcarbodiimide
EMOS	electrolyte molecule oxide silicon
EMS	electrolyte molecule silicon
FTIR	Fourier transform infrared
HOBt	1-hydroxybenzotriazole
IR	infrared
ITO	indium tin oxide
MBJC	molecular break junction
MC	macrocycle
MWCNT	multi-walled carbon nanotube
MOS	metal oxide silicon
Nc	naphthalocyanine
NMR	nuclear magnetic resonance
OEP	octaethylporphyrin
OLED	organic light-emitting diode
P	porphyrin
Pc	phthalocyanine
PDMS	polydimethylsiloxane
RAM	random access memory
SAM	self-assembled monolayer
SC	semiconductor
STM	scanning tunneling microscopy
SWCNT	single-walled carbon nanotube
TD	triple-decker
TEM	transmission electron microscopy

THF	tetrahydrofuran
TPP	tetraphenylporphyrin
Tyr	tyrosine
UV	ultraviolet
vis	visible
VdW	van der Waals
XPS	X-ray photoelectron spectroscopy

I. Introduction

For several decades chemists have invented methods for grafting porphyrins and phthalocyanines onto the surfaces of organic or inorganic solids using strong covalent bonds, with the view of designing novel materials such as supported homogeneous catalysts or chemically modified electrodes. In a related field, basic studies on the transfer of electrons between an electrical conductor and a surface-anchored molecule, and on the effect of light on this process, have induced the development of chemical methods for anchoring species such as metalloporphyrins on gold and other metal electrodes. Concurrent to these investigations, potential applications in the fields of photoinduced electron transfer, biomimetic models of the photosynthetic special pair, and photovoltaic cells have been proposed.

The need for ultimate miniaturization in microelectronics, combined with the emergence of molecular electronics, have led to the idea of coupling redox-active molecules, such as porphyrins and phthalocyanines, to the surface of silicon and to carbon nanotubes, with the view of designing novel devices with improved performance such as OLEDs, transistors, and memories. With the continuous increase in the density of silicon-based electronic devices (the Moore law), the process scaling in semiconductor technology will soon reach physical and technical limits preventing miniaturization below about 10 nm. Molecular electronics seeks to bring an answer to that problem by implementing new technologies in which one or a few molecules will function as switches, connections, and other logic or memory devices.[1]

With these considerations in mind, in this chapter we review the current methods used for anchoring porphyrins and phthalocyanines to the surface of conductors and semiconductors that are of current or potential use in microelectronics technology. This review successively addresses the functionalization of gold, silicon, carbon nanotubes, and oxide surfaces. For each material the basic chemical reactions of common use are first summarized. This overview of the field is followed by a collection of concise reports that are meant to illustrate the current state of the art. Even though the collection of examples is selective, the authors

have tried to be exhaustive in their coverage of the literature and in the list of references. Inclusion of experimental details in some examples has been made when these were deemed pertinent. A short final section summarizes a few innovative technologies and concepts in hybrid silicon/molecular electronics. The authors hope that this concise review may help the emergence of novel ideas and processes combining molecular chemistry and microelectronics.

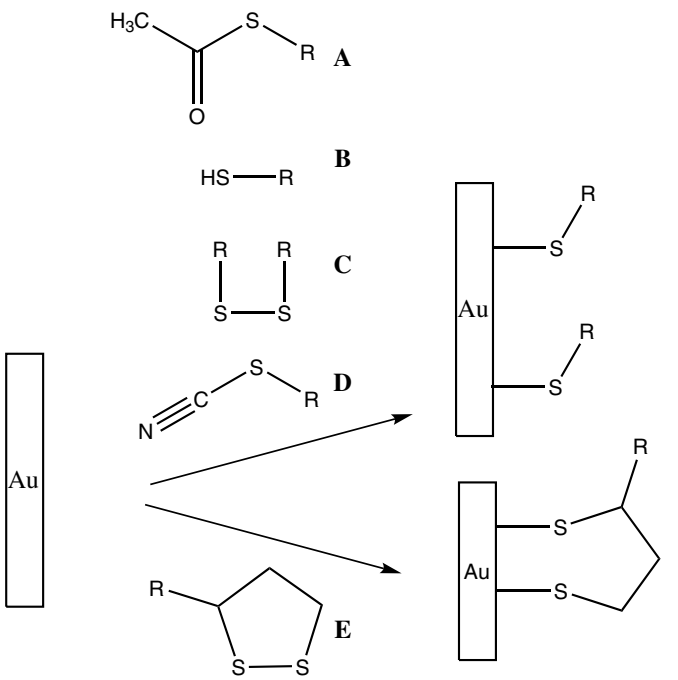
II. Surface Functionalization of Gold

A. Overview

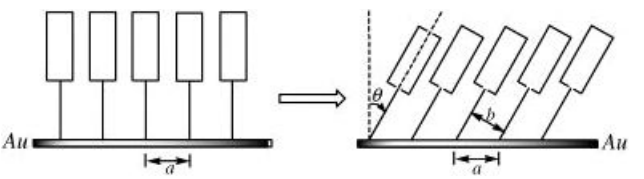
Sulfur has a strong affinity for gold. The spontaneous adsorption of sulfur-containing compounds on gold affords self-assembled monolayers (SAMs) that are well organized and homogeneous,[2] and it provides an efficient method for integrating molecules to electronic components. The modified Au surfaces are ideally suited to basic studies of molecular packing and orientation, surface-molecule coupling or charge-transfer.[3]

Bonding probably involves a (RS^-)–Au(I) species obtained by oxidative addition of the S–H bond to Au(0). One of the most commonly used techniques to generate this Au–S bond is to expose the gold surface to a thiol (B in Scheme 1).[2–4] Disulfide compounds (C and E in Scheme 1) are also used. The C type yields a SAM similar to that obtained with a thiol, but the E type yields a SAM with two Au–S bonds as anchors, which confers a more robust surface-bound system. During SAM formation thiol molecules can be oxidized to disulfides but also to other species. In order to avoid the formation of these parasitic derivatives other types of sulfur-containing species have been investigated, such as thioacetate and thiocyanates (A and D in Scheme 1). Metalloporphyrins and phthalocyanines have been immobilized on Au using thiol, disulfide or thioacetate derivatives. The thiocyanate route has been worked out to provide an alternative to harsh deprotection conditions that are not always compatible with molecular endurance.[5,6] To our knowledge this chemistry has not yet been tested on pyrrolic macrocycles.

To form a dense and well-ordered SAM experimental parameters such as reaction time, temperature, thiol concentration, and substrate roughness have to be taken into account. The grafting process can be divided into two steps: a fast initial adsorption (Scheme 2, left) and a subsequent slow reorganization (Scheme 2, right).[4,7] The initial step can be compared to a diffusion-controlled Langmuir adsorption. The thiol concentration has a strong impact, and a concentration in the mM range is commonly used in order for this step to be completed in minutes. The kinetics also depends on the reactivity of the thiol molecule, i.e. on the electron density on sulfur. The following step is a “packing step”: the molecules develop



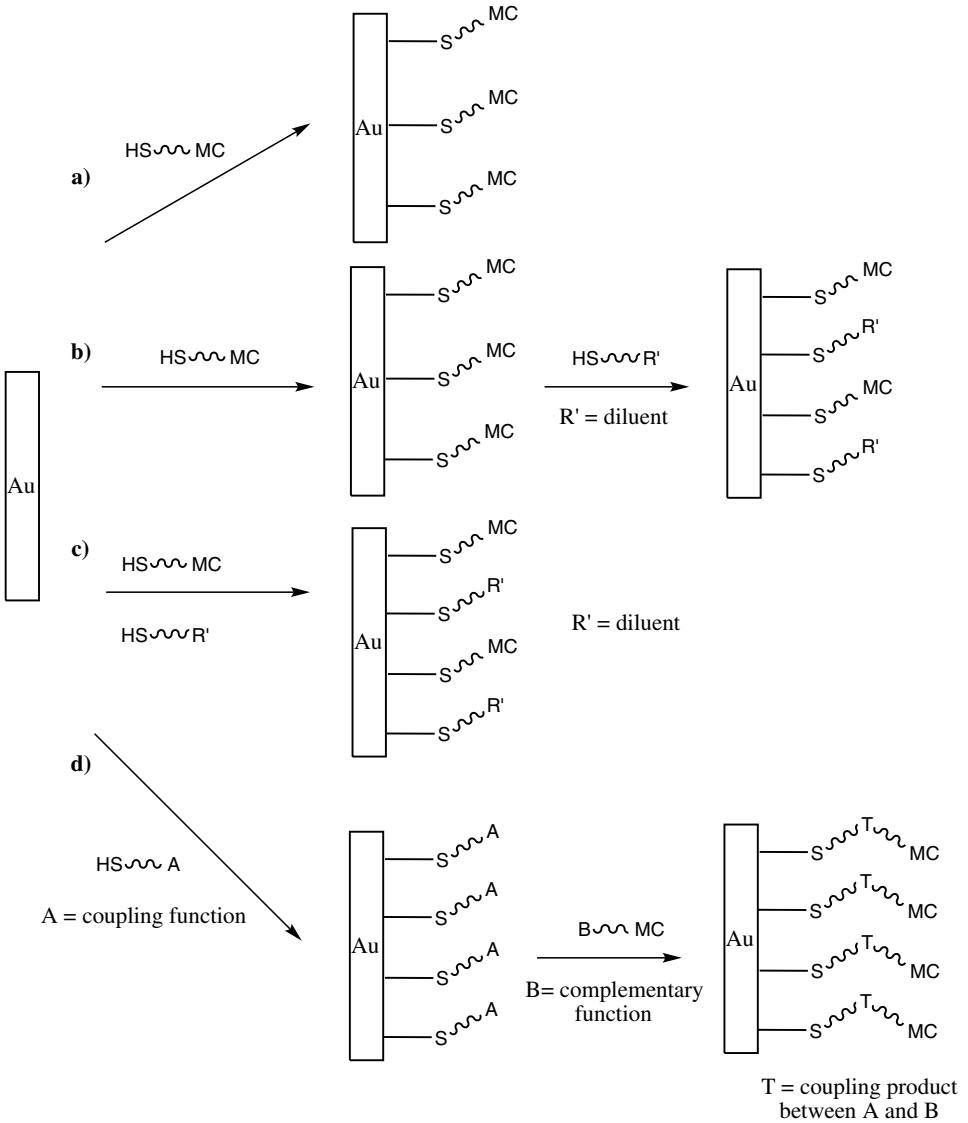
Scheme 1. Immobilization of sulfur compounds on the surface of gold.



Scheme 2. Successive steps in the formation of a porphyrin SAM on gold. *a* is the S–S distance, *b* the chain-to-chain distance, and θ the tilt-angle. (Adapted from Ref. 7.)

inter-molecular interactions (VdW, π–π stacking, dipole–dipole, etc.) leading to a well-packed and ordered monolayer. This step can require hours to be completed.[8] A generally successful method is to dip a clean Au substrate in an ethanol solution of thiol at a mM concentration- for ~10–20 hours at room temperature.

Optimal surface coverage and ordering of the SAM result from maximized attractive lateral interactions between thiol molecules, and these interactions can be restricted by steric crowding leading to lower SAM quality. In order to obtain a good quality SAM with specifically chosen molecular units protruding from the surface, a sequential grafting can be performed, or the diluent technique can be used. For the first method a spacer thiol is immobilized and in a subsequent step

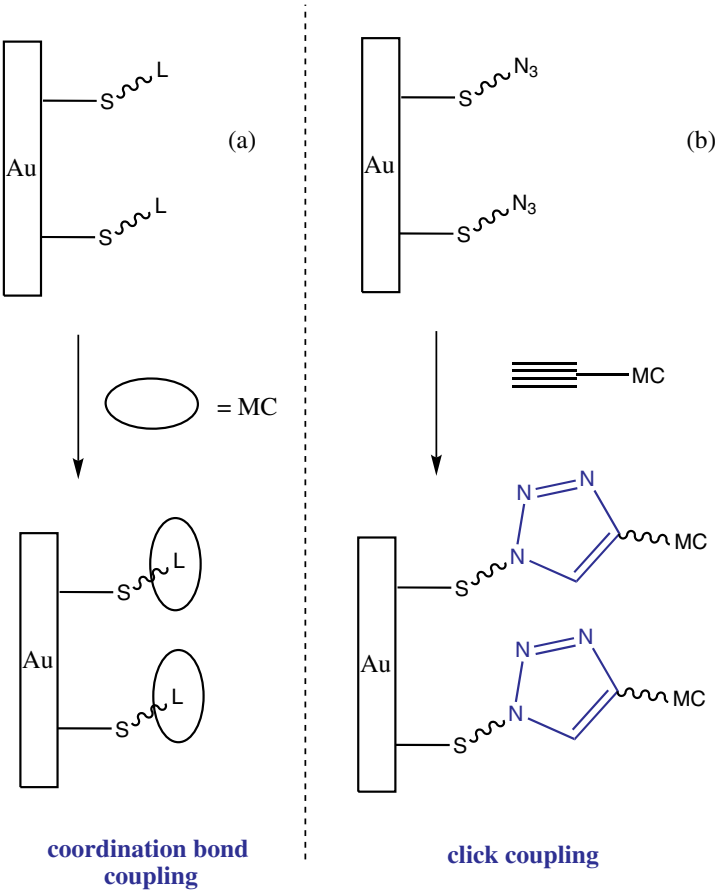


Scheme 3. Methods used for anchoring porphyrin and phthalocyanine macrocycles on gold. (a) Single-step adsorption; (b) diluent post-immobilization; (c) co-adsorption procedure; (d) sequential grafting (MC = macrocycle).

the molecule of interest is coupled to this spacer ad-layer (Scheme 3d). The molecules will therefore react within the limits of their coulombic repulsion and steric crowding. The diluent technique involves the co-adsorption of the molecule of interest along with an alkylthiol that should be co-immobilized on the surface (Scheme 3c).[9] This co-adsorption can sometimes lead to monolayers with

nonreproducible properties, resulting from segregation into islands of the different thiol compounds. To avoid such problems a post-adsorption of the diluent thiol is sometimes performed (Scheme 3b). In such cases the monolayer interstices are filled by the diluent forming a tighter monolayer that displays the expected properties.

Sequential grafting has been investigated for a variety of compounds. Spacer molecules bearing terminal amine or carboxylic acid functions have been immobilized on Au and further reacted with carboxylic acid or alcohol and amine derivatives to yield an ester or amide coupling link between the spacer and the compound of interest. In the case of pyrrolic macrocycles, such ester and amide coupling links are less common, and spacers bearing terminal end groups that are able to coordinate to the metal center have been used. In such cases the coupling link is a coordination bond (Scheme 4a). Another method involves the immobilization of a



Scheme 4. Coupling methods used to sequentially immobilize tetrapyrrolic macrocycles on gold via (a) a coordination bond or (b) a cycloaddition.

spacer bearing a terminal azide function that is able to undergo click-coupling via 1,3-Huisgen cycloaddition with a macrocycle possessing a C–C triple bond. The coupling link obtained is a triazole (Scheme 4b).

B. Selected Examples

1. *Direct Immobilization of the Macrocycle*

a. *TPP derivatives*

Tetraphenylporphyrin (TPP) derivatives such as (**1**) and (**2**) have been immobilized on Au via the use of a thiol substituent (Figure 1).[10] These porphyrins are obtained from an aldehyde bearing a protected thiol function. Metalation is accomplished prior to the alkaline deprotection step, but in some cases metal insertion can be performed post-assembly.[11] The SAM is obtained by dipping the gold substrate in a chloroform solution of the thiol at a concentration around 1 μM.

This method has been used to study the charge-transfer between the TPP derivative and the Au surface through the SAM.[12] Modification of the surface has been evidenced by measuring the contact angle of water for a bare gold surface and a functionalized surface (Figure 2). The modified surface is more hydrophobic as the measured contact angle is larger.

Disulfide porphyrin derivatives have been prepared to allow their subsequent immobilization on Au.[13] Here the porphyrin SAM was prepared by dipping the

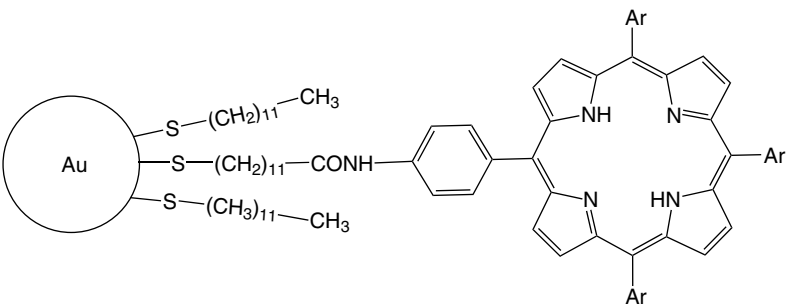

Figure 3. Schematic view of a SAM resulting from the diluent co-adsorption procedure on a gold nanocluster.

gold electrode in a porphyrin solution (50 mM in chloroform) for 12 hours at room temperature. The SAM was characterized electrochemically giving access to the surface coverage in redox compound. A coverage of 150 pmol.cm^{-2} was reached for a Mn porphyrin monolayer, and the surface concentration for porphyrin rings oriented perpendicular is estimated to be 330 pmol.cm^{-2}, and that of porphyrins oriented flat to be 70 pmol.cm^{-2}. Thus a tilted orientation of the porphyrins was proposed.

Several studies illustrate the diluent co-adsorption procedure for the formation of a packed monolayer (Figure 3).[14–17]

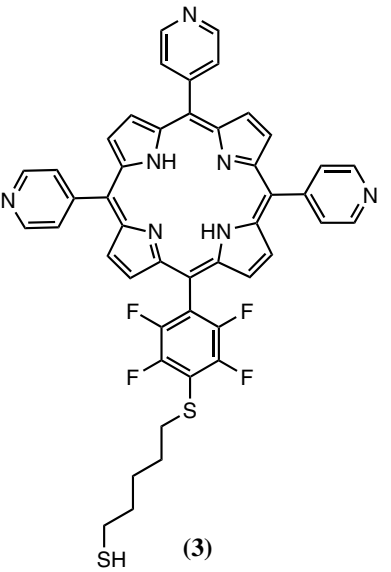

Figure 4. A tripyridylporphyrin with a terminal thiol.

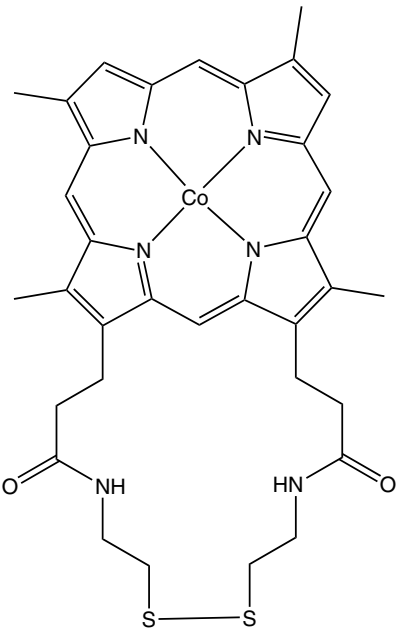
Tripyridylporphyrins such as (**3**) (Figure 4) have been immobilized on Au via a phenylthiol anchoring group.[18] In this case the diluent SAM was prepared first, and the thiol macrocycle was then adsorbed in the remaining molecular interstices. The Au film was dipped in a 1 mM solution of diluent (*n*-dodecanethiol) dissolved in ethanol for 24 hours. After copious rinsing with ethanol, the functionalized surface was soaked for 5 days in a 0.5 mM solution of porphyrin thiol dissolved in dichloromethane. This step is longer in order to increase the chances of filling the holes with the porphyrin compound. STM analysis showed that this interchange of the immobilization steps leads to deposition of single porphyrins, or of assemblies of 3 to 5 porphyrins, at the edges of the diluent SAM defects. The resulting SAM is able in principle to coordinate and assemble additional porphyrin layers.

The thiol anchoring group is often protected in order to avoid side reactions or decomposition during macrocycle synthesis, and also to prevent possible coordination of the thiol to the metal center. Studies have been conducted on various protecting groups [S-cyano, S-(*N*-ethylcarbamoyl), S-acetyl, S-(9-anthrylmethyl), S-(2,4-dinitrophenyl), S-pivaloyl] and showed that most of them survive porphyrin formation and metalation with zinc.[19] However only three groups, i.e. S-cyano, S-(*N*-ethylcarbamoyl), and S-acetyl, can be cleaved *in situ* upon exposure to Au thus allowing binding to this surface.

Deuteroporphyrin complexes (Co, Fe) such as (**4**) (Figure 5) bearing a disulfide anchoring substituent linking two adjacent β positions have been immobilized



(4)

Figure 5. A deuteroporphyrin derivative with a disulfide anchoring unit.

on Au, leading to two S–Au bonds per porphyrin complex.[20] The SAM was formed by simply immersing the Au sample in a 2 mM solution of porphyrin derivative dissolved in ethanol for 24 hours at 4 °C. Ellipsometry and cyclic voltammetry studies confirmed the immobilization of the porphyrin on the surface and suggested that the SAM formed is robust. These SAMs have been used for catalytic electrochemical reduction of O_2 to H_2O_2 or H_2O.

b. *Modulation of the linker between the surface and the macrocycle*

Electrochemical studies of various porphyrin SAMs obtained with different spacer lengths suggested that the surface concentration of electroactive species is higher when a longer spacer is used.[13,14] This points to a higher stability of the SAM with long chains that develop more important lateral interactions than those with short chains. It was also observed that the electron-transfer rate decreases with increasing surface coverage and with increasing distance between the redox centre and the surface.

Bocian, Lindsey and coworkers have conducted an extensive study of the effects of linker length and nature (conjugated or not) using a large library of porphyrin compounds immobilized on Au (Figure 6).[21]

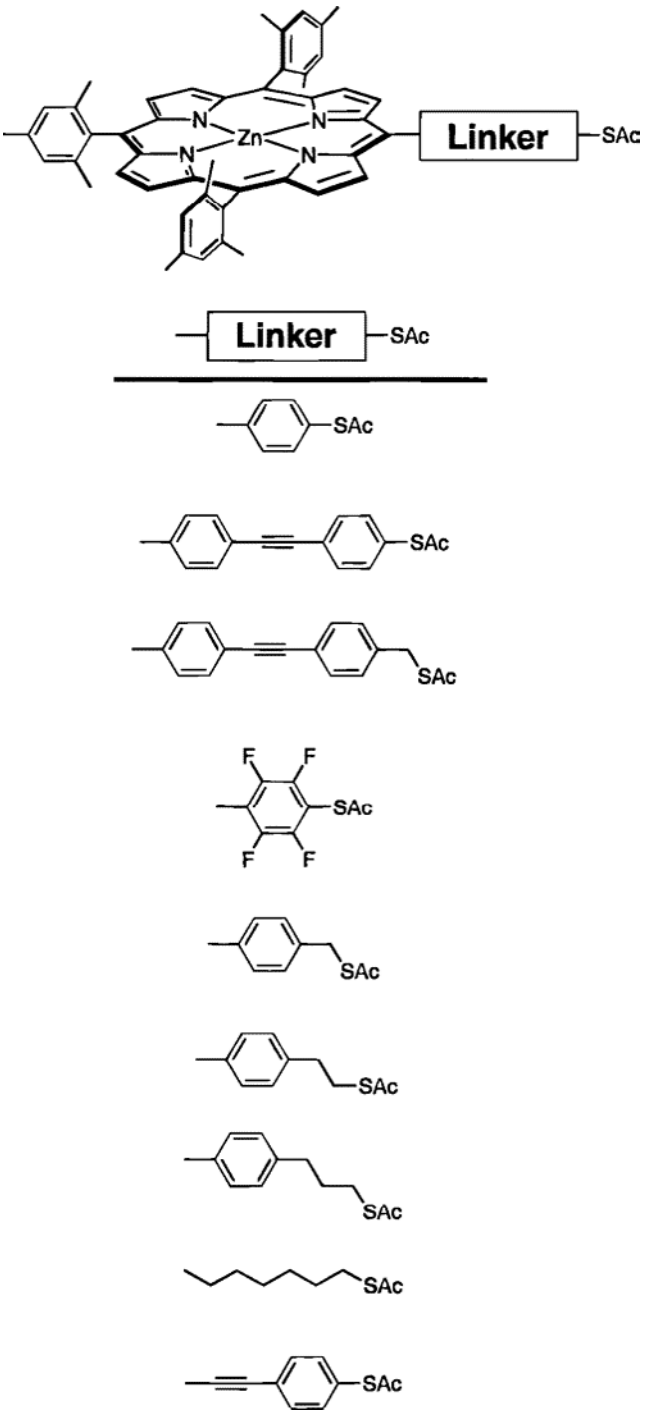


Figure 6. Various porphyrin-linker-thiol derivatives investigated for molecular-based information storage. (Adapted from Ref. 21.)

To perform these studies a specific 75-micron wide Au band substrate was prepared via e-beam evaporation on a glass slide covered with Cr. A 3 mm deep PDMS well was deposited on the Au band. Then the SAM was formed on the Au area at the bottom of the well by filling it with a 1 mM solution of porphyrin in absolute ethanol at room temperature for 30 minutes. Using this experimental setup the rate of electron-transfer (k°) for oxidation and the rate of charge dissipation $\tau_{1/2}$ (i.e. the charge retention half-time once the potential is switched off) were determined by electrochemical measurements.[22] Overall the k° values for most of these SAMs lie in the 10^4 to 10^5 s^{-1} range. Among the methylene containing linker SAMs, it was shown that the longer the alkyl chain, the slower will be the electron-transfer. Moreover the k° values are higher for fully conjugated than for aliphatic linkers. For the fully conjugated linkers, adding a phenyl ring between the macrocycle and the C–C triple bond decreases the value of k°. This is presumably due to a loss of conjugation between the macrocycle and the perpendicular phenyl substituent. The fastest electron transfer is obtained when the *meso* position is directly linked to the C–C triple bond of a conjugated linker. For a conjugated linker, an additional methylene group next to the sulfur anchor results in slower electron transfer, due to the breaking of the conjugation. The charge dissipation remains on average six times slower than the electron transfer. Opposite trends are observed for the rates of electron transfer and charge dissipation: if charge-transfer is fast, the charge retention time will be low, and *vice versa*. When a long aliphatic linker is used, the resulting SAMs exhibit the highest charge retention time. Both parameters decrease with increasing surface coverage. This was explained by hampered solvent/counterions diffusion and space-charge effects. For each linker used a different surface coverage was reached (surface crowding, tilt angle, molecular orientation) so this interdependence between surface coverage and k° or $\tau_{1/2}$ can screen the linker effect.

The influence of the electron abstraction site (metal center for Fe–P, or porphyrin ring for Zn–P) has been studied (Figure 7).[23] For ring-centered electron-transfer

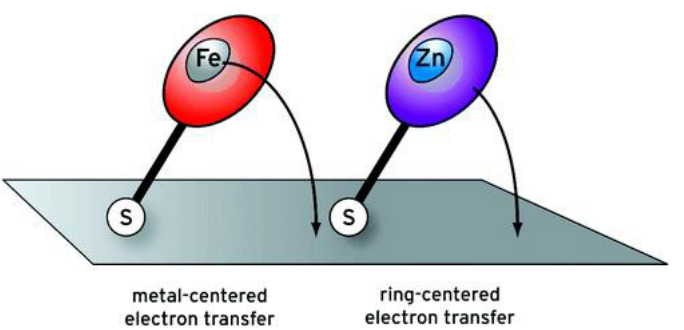

Figure 7. Schematic view of (*left*) metal-centered and (*right*) ring-centered electron transfer in porphyrin monolayers on gold. (Adapted from Ref. 23.)

the value of k^0 is 10 to 40 times higher than for the metal-centered case. This has been assigned to the delocalized nature of the molecular orbitals involved and to their proximity to the surface, compared to a d-orbital localized on the metal center.

c. *Multi-linkage between the surface and the macrocycle*

i. Two or four S containing *meso* substituents

Varying the number of anchoring groups has been investigated as a potential means of controlling the macrocycle orientation (parallel or perpendicular) relative to the Au surface, as well as the electron transfer rate (Figure 8).[24–29]

ii. Tripodal anchoring groups

A rigid aryl tripod based on a tris[4-(*S*-acetylthiomethyl)phenyl]-derivatized methane was constructed on a tetraarylporphyrin (Figure 9), in order to enforce perpendicular orientation of the macrocycle relative to the Au electrode.[30] Tests have been conducted on porphyrins, phthalocyanines, triple-decker (TD) and ferrocene-porphyrin systems. Electrochemical responses recorded for the tripod SAMs are more stable over time than when monopodal units are used. Therefore

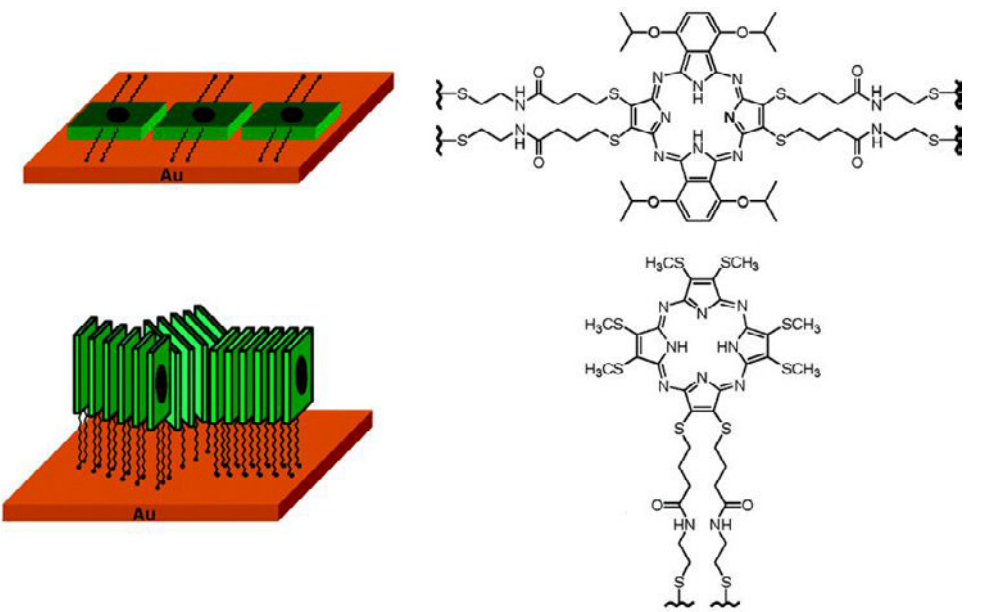

Figure 8. Schematic views of the expected SAM orientations of porphyrazines possessing two or four anchoring units. (Adapted from Ref. 25.)

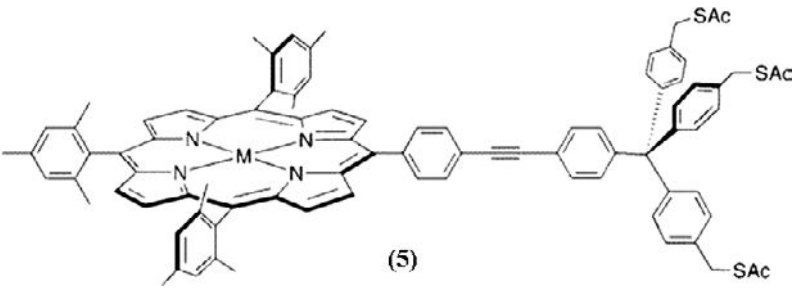

Figure 9. Substitution by a tripod is expected to allow anchoring of the porphyrin redox-active unit in upright position on gold. (Adapted from Ref. 31.)

these tripods lead to more robust SAMs with k° and $\tau_{1/2}$ parameters similar to those observed for monopodal SAMs.[31]

d. *Immobilization of complex porphyrin systems*

Porphyrin-ferrocene conjugates with a thioacetate anchoring unit on the macrocycle have been synthesized.[32] On the resulting SAM the ferrocene unit is positioned away from the gold surface, and the distance between the macrocycle and the ferrocene unit can be tuned by modifying the nature of the linker (Figure 10a). In related systems the ferrocene units are positioned on both sides of the macrocycle (Figure 10b). Electrochemical studies confirmed SAM formation on Au and they showed three oxidation waves: one for the ferrocene unit and two for the porphyrin core. These systems give access to larger numbers of redox states and various values of $k^\circ/\tau_{1/2}$ parameters that could be interesting for the design of molecular memory devices.

In similar systems such as (**6**) and (**7**) (Figure 11), a redox unit such as ferrocene[33] or a quinone[34] is placed between the porphyrin core and the surface, giving well-packed SAMs with high surface coverage which exhibit interesting photoinduced electron transfer properties.

In a search of good molecular candidates for multibit information storage, molecules with multiple redox states have been prepared, such as linear porphyrin dimers (**8**) (Figure 12), trimers[35,36] and triple-deckers.[37,38] SAM formation on Au was successful. For the porphyrin dimer SAMs the oxidation potentials are sufficiently resolved to identify individual states, whereas for trimers the waves overlap. Moreover the *meso–meso* linkage is not really stable upon oxidation of the porphyrin macrocycle. Other studies have been conducted with a linker added between the two porphyrins.[36]

Triple-decker (TD) systems such as (**9**) in which two Eu centers are sandwiched between three porphyrins and/or phthalocyanines (Figure 13) have

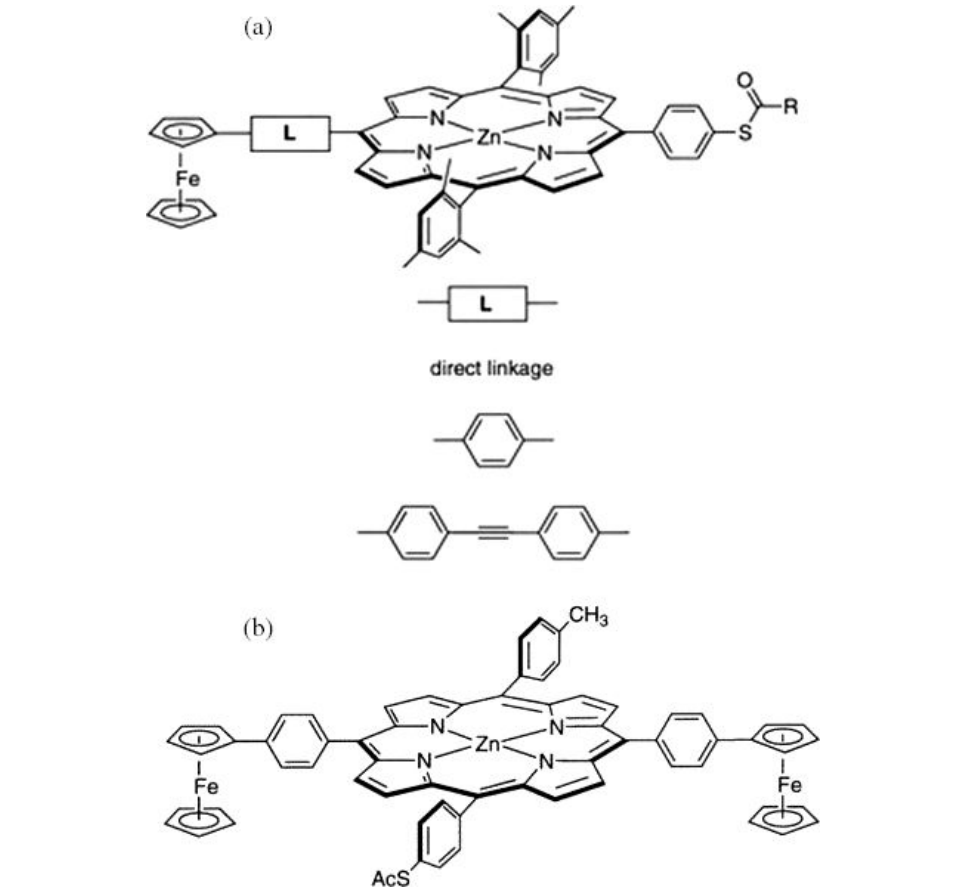

Figure 10. Structures of porphyrin-ferrocene conjugates synthesized for multibit information storage. (Adapted from Ref. 32.)

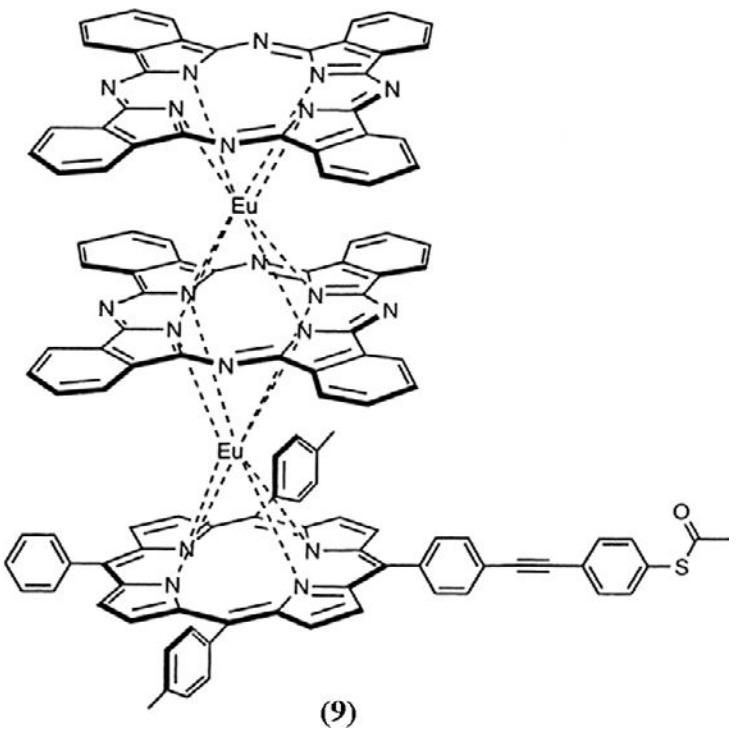

Figure 13. Structure of a typical triple-decker complex that has been immobilized on Au. (Adapted from Ref. 37.)

been synthesized.[37,38] A thioacetate anchoring unit is placed on the porphyrin of the TD.

A "pacman" structure (**10**) composed of two co-facial porphyrins linked by their available *meso* position with an aromatic bridge has been immobilized on Au

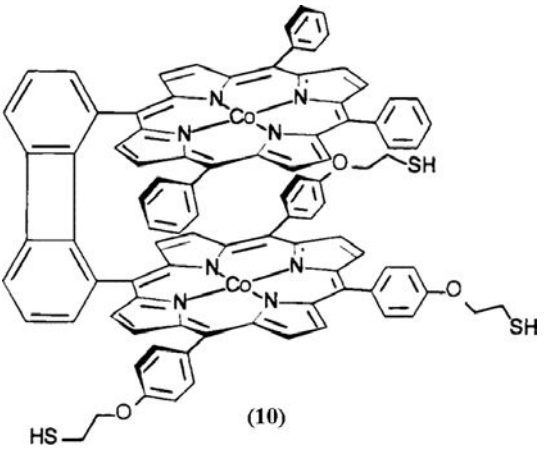

Figure 14. A thiolated bis(cobalt) cofacial diporphyrin used as a catalyst for the electrochemical reduction of dioxygen. It is a 4-electron reduction catalyst producing water when adsorbed on graphite. When chemisorbed on a gold electrode surface, the same catalyst exhibits the activity of only a two-electron catalyst, producing hydrogen peroxide. (Adapted from Ref. 39.)

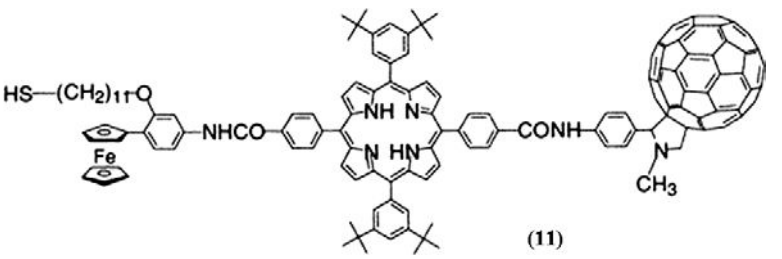

Figure 15. Structure of a ferrocene-porphyrin-fullerene triad used as a SAM on gold for light harvesting and photocurrent generation by gold electrodes. (Adapted from Ref. 40.)

(Figure 14).[39] On this structure only one of the two porphyrins bear three thiol anchoring functions in order to immobilize the structure parallel to the Au surface.

Ferrocene-porphyrin-fullerene conjugates with a thiol function such as (**11**) have been prepared (Figure 15) in a study dedicated to the understanding of photosynthetic energy and electron transfer on a gold surface.[40] Mixed SAMs of such system and boron-dipyrrin have been obtained by dipping the gold substrate in a 10 μM solution of both systems in various molar ratios and dissolved in CH_2Cl_2 for about 20 hours. Electrochemical and photochemical studies showed that a cascade of photoinduced energy transfer and multistep electron transfer takes place giving rise to photocurrent output with a high quantum yield (50 ± 8%).

2. *Sequential Immobilization of the Macrocycle*

Sequential grafting allows the benefit of a well-packed and ordered underlayer to be combined with the presence of sterically crowded species such as porphyrin macrocycles.

a. *Coordination bond coupling*

An appealing procedure is the immobilization of a bi-functional spacer possessing a terminal end group such as a pyridine or imidazole that can act as a ligand of the metalloporphyrin compound, or that can be transformed into a potential ligand (Figure 16).[41] Co-immobilization of a diluent thiol is required to accommodate the bulky macrocyclic species on the Au surface. Two distinct methods, labelled

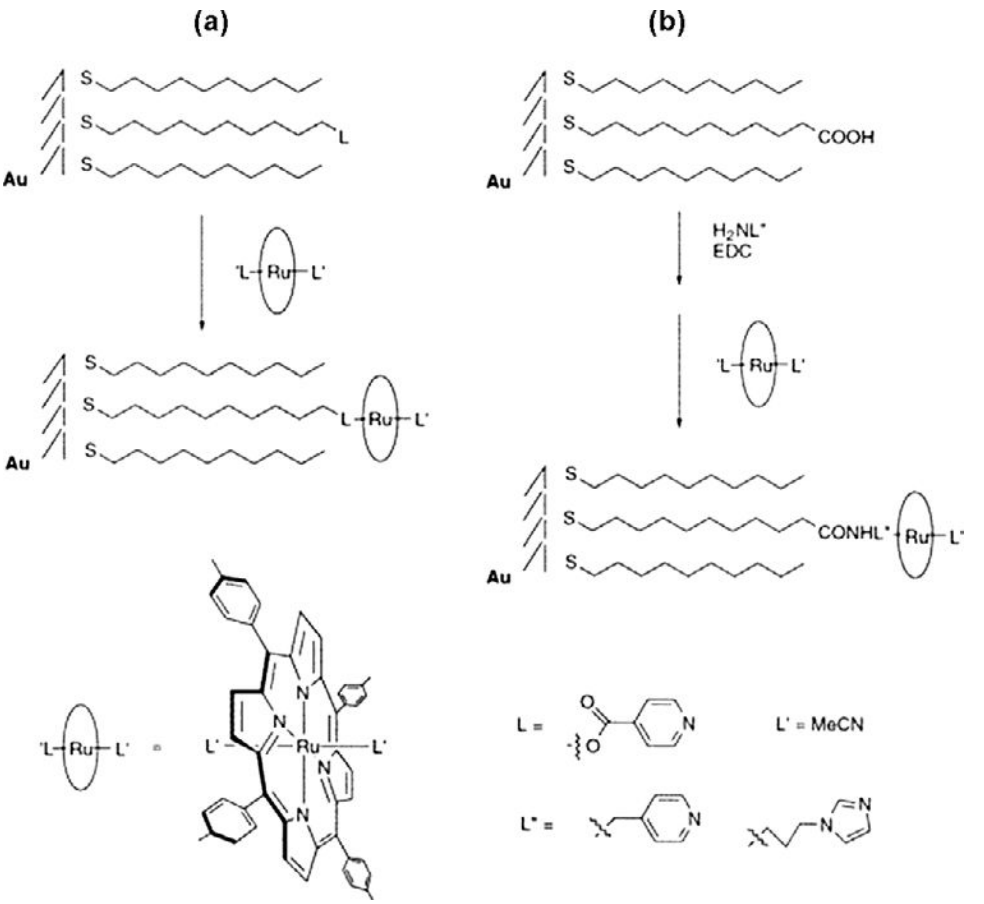

Figure 16. Modular formation on gold of monolayer assemblies containing axially ligated metalloporphyrins. (Adapted from Ref. 41.)

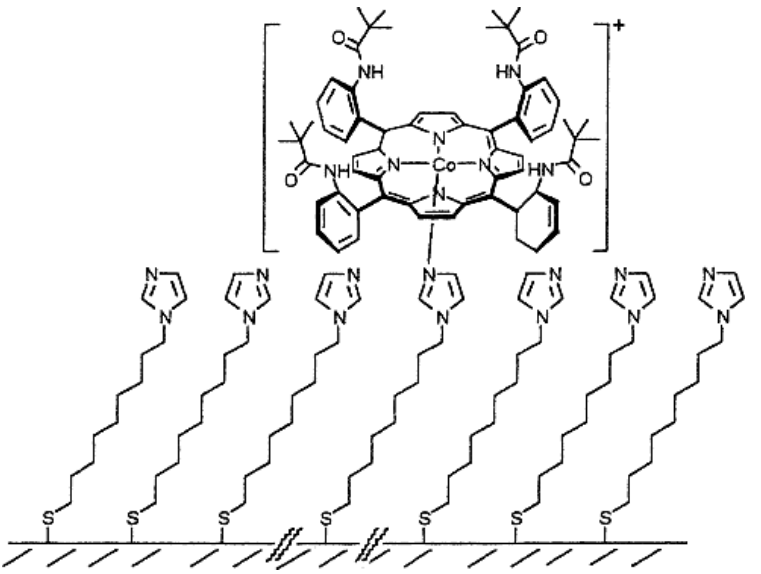

Figure 17. Self-assembled monolayers of 1-(10-mercaptodecyl)imidazole on gold electrodes used to bind cobalt "picket fence" porphyrin to the electrode surface. The binding involves coordination of the cobalt(III) center of the porphyrin to the pendant imidazole groups in the monolayer coating. (Adapted from Ref. 45.)

(a) and (b) in Figure 16, have been used to form a RuTPP SAM. To ease the chemical process the diluent is chosen so as to be slightly shorter than the bi-functional spacer to give access to the reactive function. The monolayers formed are quite stable. Both the Ru and macrocycle oxidation waves are visible in the cyclic voltammogram. Such procedures could be used for the growth of an array of different layers of metalloporphyrins.[42]

Various TPP and OEP derivatives have been similarly immobilized on Au using a pre-assembled pyridine SAM.[43,44]

The axial ligation immobilization technique has been used to form a SAM of a Co "picket fence" porphyrin (Figure 17).[45] The spacer used exhibits an imidazole end group that can coordinate to the metal center of the porphyrin. Cyclic voltammetry studies indicated good cycling stability.

Phosphorous TPP derivatives have been immobilized using a related method but the coordination to the thiol spacer via its terminal alcohol function was performed prior to SAM formation (Figure 18).[46]

b. *Click coupling*

The Huisgen 1,3-cycloaddition also known as the "click" reaction is a convenient and high-yielding process now used in numerous fields of chemistry and materials

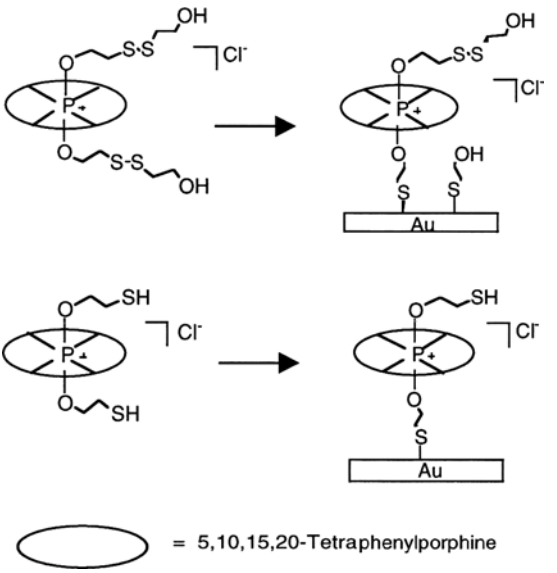

Figure 18. SAM formation on gold by a phosphorus TPP derivative via coordination of a thiol-containing axial ligand. (Adapted from Ref. 46.)

design.[47,48] It is also used to immobilize various species,[49–53] such as pyrrolic macrocycles on Au by sequential grafting. A Cu(I)-catalyzed click reaction was used to immobilize ferrocene and also porphyrins on Au (Figure 19).[9,54] In the first step a diluent and a bi-functional spacer — bearing a N_3 terminal end group — were co-adsorbed on the electrode surface. Each azide group then reacted with an acetylenic porphyrin derivative in the steric limit. Chidsey and coworkers investigated the impact of the resulting triazole linkage on the electron transfer between the surface and redox center. They showed that this linkage has the same electronic behaviour as an ester group. The electron transfer rate can be tuned by varying the nature and the length of the spacer. This prototypical N_3-functionalized surface seems to be a very interesting scaffold for the immobilization of porphyrins and other compounds on Au, and it has been adapted to other surfaces. Moreover, the electrochemically controlled reduction of the Cu(II) catalyst gives access to site selective functionalization.[55,56]

In a landmark study cytochrome *c* oxidase (C*c*O) models have been immobilized on Au using the same click procedure (Figure 20).[57,58] The C*c*O model reproduces the coordination environment and relative locations of Fe_{a3}, Cu_B, and Tyr_{244}. Various control experiments were performed by immobilizing models without the Cu centre or without the phenol which mimicks the Tyr group. By tuning the

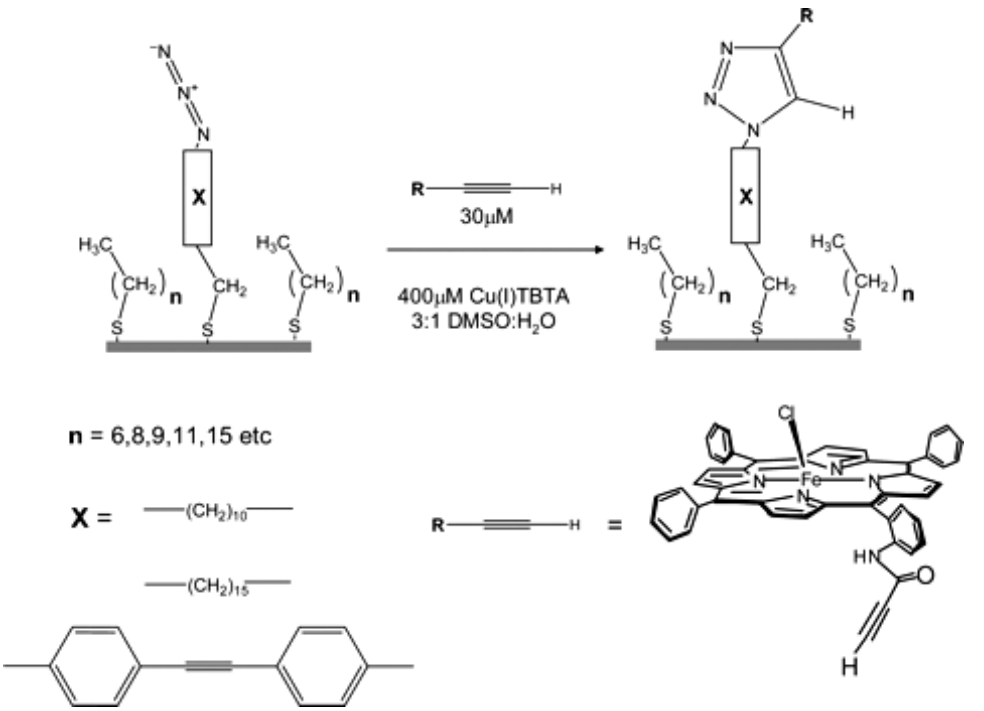

Figure 19. Scheme depicting the formation on gold electrodes of mixed monolayers coupled to redox species via Cu(I)-catalyzed azide-acetylene cycloaddition. The modular nature of the approach facilitates studies by allowing the diluent thiol, the nature of the tunneling bridge, X, and the redox species, R, to be independently varied. (Adapted from Ref. 56.)

spacer/diluent length and nature, the slow electron transfer occurring in the enzyme could be mimicked, and its significance in the efficiency of the four-electron reduction of O_2 catalyzed by C*c*O was delineated.

III. Surface Functionalization of Silicon

A. Overview

For molecular electronics the most appealing substrate is silicon as it has been used in the industry for years and because Si–O (~108 kcal.mol^{-1}) or Si–C (~76 kcal.mol^{-1}) bonds are stronger than the Au–S bond (~45 kcal.mol^{-1}).[59] The most commonly used techniques for silicon surface modification are the hydrosilylation reaction[60,61] and the grafting of aryldiazonium species[62] leading to Si–C surface bonds (Figure 21c–e). Another technique that has been used for porphyrin immobilization is the surface substitution reaction with hydroxyl anchoring units leading to Si–O surface bonds (Figure 21a).[59,63,64]

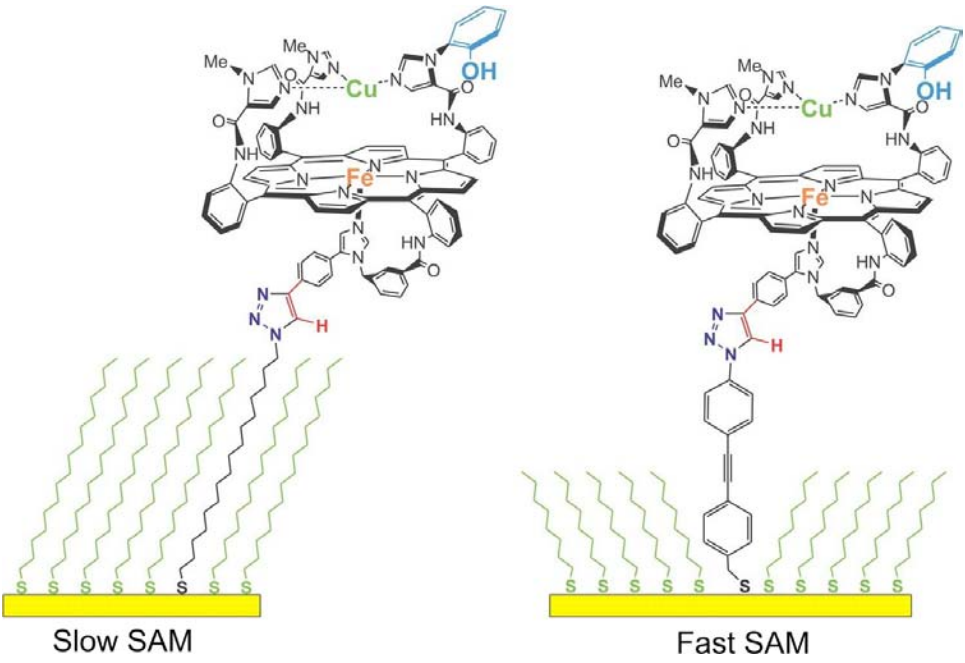

Figure 20. A functional model of cytochrome *c* oxidase active site covalently attached onto self-assembled monolayer-coated gold electrodes. When the electron transfer rate was made rate limiting via a slow SAM (left), both copper and phenol were required to enhance selective reduction of oxygen to water. (Adapted from Ref. 57.)

Alcohols can be immobilized on a Si substrate after an appropriate surface treatment[63,64]: hydrogenation by HF and/or halogenation by Cl_2 or PCl_5. The substitution reaction is often a "neat-grafting" procedure performed without any solvent or additional chemical. Thus liquid compounds are good candidates or else highly concentrated solutions (~ 0.1 M) are required. A reaction time of about 14 hours and a temperature of ~ 60–70 °C are necessary to obtain a good quality monolayer. This reaction has also been used to immobilize alcohols on porous Si.[65] This Si–O linkage can also be obtained by reaction of an aldehyde with the hydrogenated silicon surface,[66] which can be photoinitiated. To our knowledge this technique has been used to immobilize ferrocene[67] but not metalloporphyrins or phthalocyanines.

These procedures are useful but it seems that the Si–O bond is less stable than the Si–C bond when it comes to ageing and chemical resistance.[68] So in a number of studies the carbosilane linkage has been favoured. This linkage can be obtained by two methods: hydrosilylation or aryldiazonium addition. In the first method, the reagents are the hydrogenated Si surface and a compound bearing an unsaturation. The reaction is known to proceed through a radical mechanism (Figure 22).

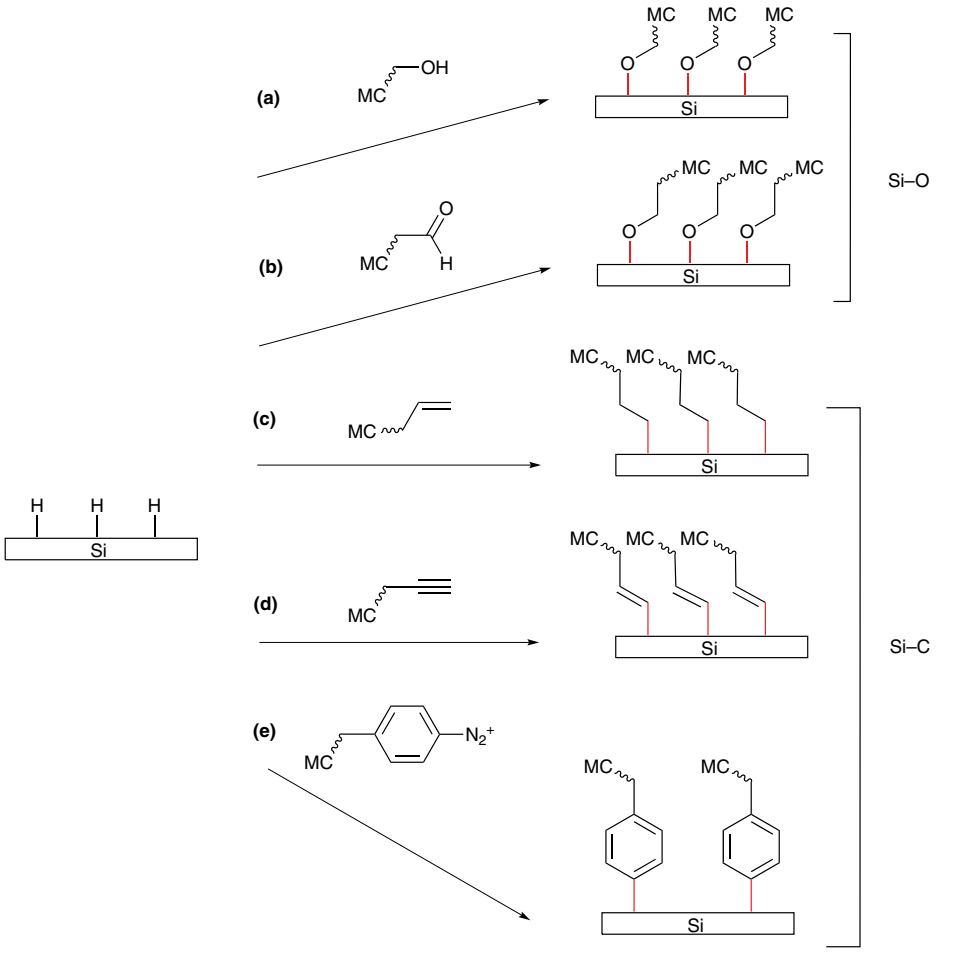

Figure 21. Methods used for anchoring porphyrin and phthalocyanine macrocycles on silicon by (a, b) Si–O or (c–e) Si–C bonds.

Si-centered radicals are formed upon cleavage of Si–H dangling bonds. A Si radical abstracts an H from the unsaturated molecule leading to a C• radical and a Si–C bond. In turn this C• abstracts an H from an adjacent surface Si–H group leaving another surface radical that will then propagate the reaction. The radical initiation can be obtained by electrochemical, chemical, thermal or by photochemical methods.

Figure 23 depicts the hydrosilylation of a C–C triple bond. In that case, different linkage types can be obtained: either the unsaturated site reacts with the adjacent Si–H site creating a cyclic linkage, or it does not react further and only abstracts an H from the adjacent Si–H site. This linkage diversity is hard to characterize.

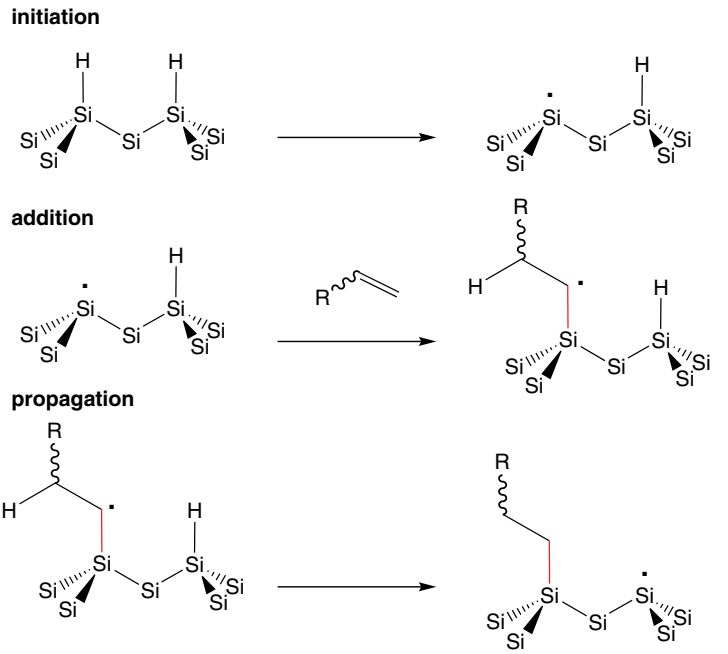

Figure 22. Radical mechanism of alkene hydrosilylation on the surface of hydrogenated silicon.

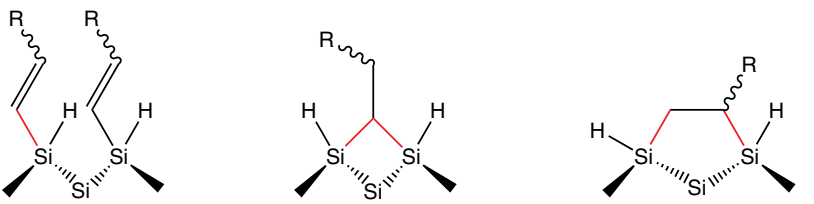

Figure 23. Various types of surface species obtained upon hydrosilylation of an alkyne by hydrogenated silicon.

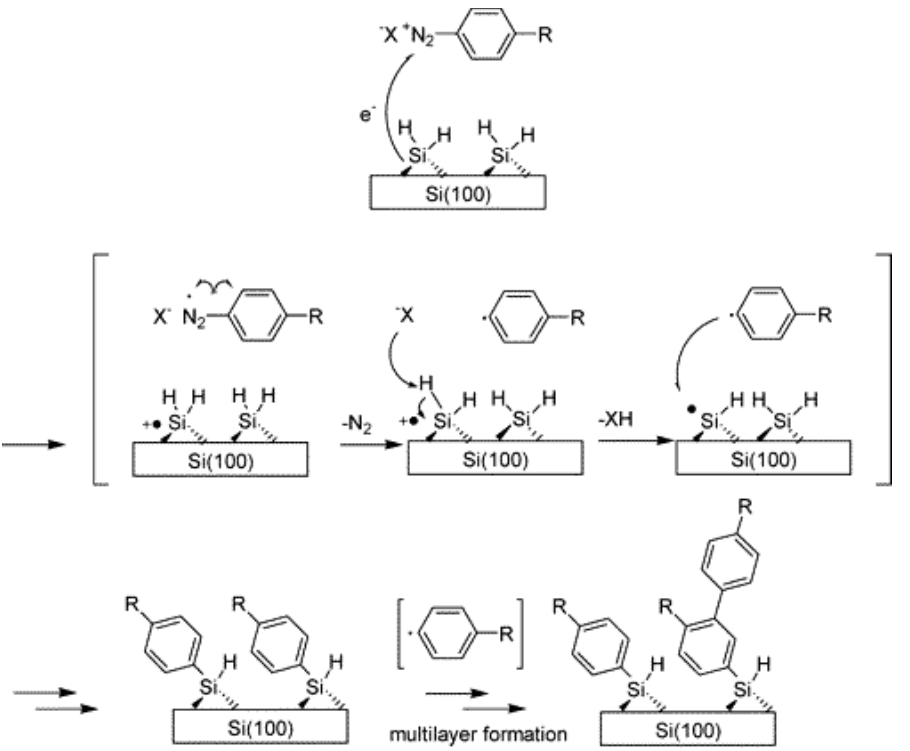
The nature of the Si atomic plane has a strong impact on the type of Si–C bond, its tilt angles, and surface coverage. The Si–H site on Si(100) is a dihydride species with a Si–H bond angle of ~45° which is somewhat maintained in the resulting Si–C bond. The tilt angle also depends on the nature and volume of the immobilized molecule. In contrast, the Si–H site on Si(111) is a monohydride so the resulting alkyl chains are much less tilted, and higher surface coverage can be reached with this substrate.

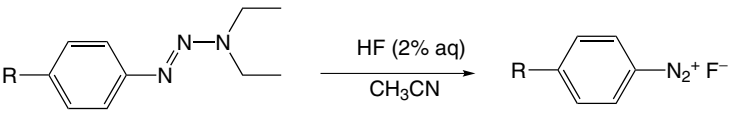
Prior to surface grafting, the Si sample is dipped in an acidic fluoride solution in order to etch the SiO_2 layer and leave a Si–H reactive surface. For Si(100) HF

solutions (10%) are commonly used, whereas for Si(111) NH_4F solutions are necessary. Such hydrogenated surfaces can be easily re-oxidized if left in air; thus most reactions are performed under inert atmosphere in Schlenk-like apparatus or in a glove box. The experimental conditions of the hydrosilylation reaction depend on the starting material. If it is a liquid available in large quantities a "neat-grafting" procedure is performed: the substrate is covered with a small volume of compound and heated above 110 °C. For photochemical initiation a drop of compound is placed on the substrate. If the starting material is a solid, or if it is available in small quantities, it is dissolved in a high-boiling solvent like mesitylene or xylene. The substrate is dipped in the solution and the temperature is raised above 110 °C.

The second method leading to Si–C bonding is the aryldiazonium reaction with reductive Si–H surface.[62] This reaction involves an aryldiazonium salt that is reduced chemically or electrochemically to an aryl radical that subsequently abstracts an hydrogen atom from a Si–H site (Scheme 5). Once the aryl monolayer is formed it can be attacked by aryl radicals in solution yielding multi-layers. Tuning of the film thickness by controlling the applied current has been attempted.



Scheme 5. Mechanism of the reaction of aryldiazonium salts with hydrogenated Si(100) surface. (Adapted from Ref. 69.)



Scheme 6. *In situ* generation of aryldiazonium salt from an aryldiethyltriazene.

The hydrated Si surface is very reductive, and the diazonium function can also be spontaneously reduced by the Si surface, but in such cases only low thickness films are obtained.

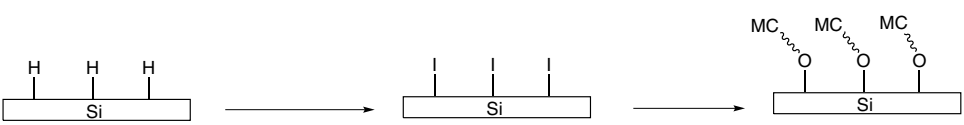
Another route to obtain surface generation of aryl radicals has been explored. Replacement of sensitive aryldiazonium salts by stable aryldiethyltriazenes as starting compounds has been successfully investigated (Scheme 6).[69] This method is appealing because the charged species is generated *in situ*.

B. Selected Examples

1. *Si–O Bonding of the Macrocycle*

Zn and free base TPP derivatives have been immobilized on Si(100) and Si(111)[70] by reaction of a hydroxyl substituent with a pre-treated Si-I surface (Scheme 7). Preliminary iodination was performed by exposing a hydrogenated Si(111) sample in a Schlenk-tube to a CH_2Cl_2 solution of I_2 for 30 minutes at room temperature under N_2. This Si sample was then transferred to a stoppered tube containing a solution of 0.05–1 mM of porphyrin dissolved in THF for 2 hours at 373 K. XPS and AFM characterization confirmed that the grafting was successful. The XPS data showed that partial demetalation is observed.

Bocian, Lindsey and coworkers have studied porphyrins and triple-decker structures possessing hydroxyl anchoring units (Figure 24).[59,71] The usual room temperature attachment of hydroxyl species onto a Si–H surface apparently did not yield good quality SAMs. Increasing the temperature to 170 °C did not significantly enhance monolayer quality. So another strategy was followed with the periodical deposition of microdrops of porphyrin solution onto the heated Si–H surface over 3 hours. More ordered SAMs were obtained but their quality was not



Scheme 7. Immobilization of hydroxyl containing porphyrins via iodination of the silicon surface.

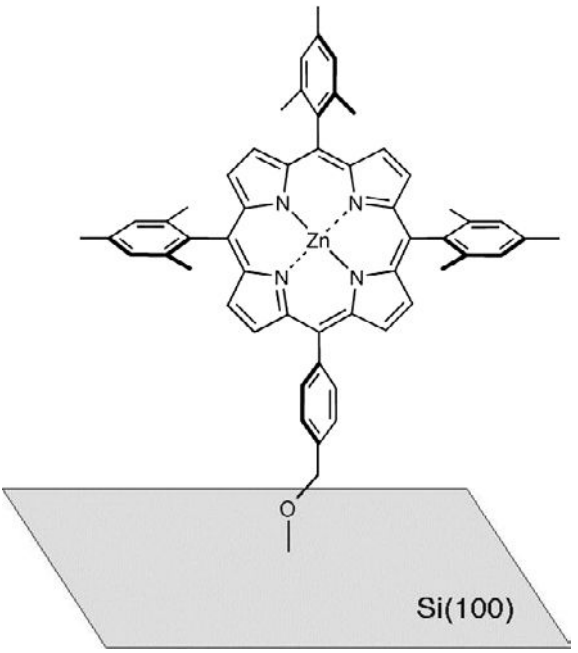


Figure 24. A typical porphyrin species tethered on silicon through a Si–O bond. (Adapted from Ref. 71.)

sufficient to record reproducible cyclic voltammetry data. Therefore the hydride surface was first iodized by dipping a Si–H sample in a saturated solution of I_2 in anhydrous $CHCl_3$. The macrocycle monolayer was obtained by placing on the Si–I surface microdrops (ca. 2 μL) of porphyrins in benzonitrile (10 mM) containing 1% pyridine. This base catalyzes the surface reaction and traps the HI formed during the reaction. One drop was deposited every 20 minutes over 3 hours while the substrate was heated to 165 °C. This drop deposition coupled to the heat control procedure yielded Si surfaces with the highest surface coverage. It was found that the modulation of the deposition time or the co-adsorption of a diluent can have an impact on the surface coverage. The success of the protocols was confirmed by electrochemical analyses. The surface coverage reached for the porphyrin macrocycles was in the 10^{-11} mol.cm^{-2} range. Good values of the k° and $\tau_{1/2}$ were obtained, similar to those obtained for modified Au surfaces, and they decrease with increasing surface coverage.[59]

Thiol- and selenol-containing porphyrins have been immobilized as monolayers on Si substrates via Si–S or Si–Se linkages.[72] The immobilization technique is adapted from the previously described baking procedure. The rate of electron transfer through the corresponding porphyrin monolayers does not depend on the nature of the group VI atom. The spacer nature and length have an impact on the

orientation and surface coverage, which in turn affect the monolayer electronic properties.

2. *Si–C Bonding of the Macrocycle*

a. *Hydrosilylation reaction*

Co and free base metalloporphyrins bearing four alkyne substituents have been immobilized on Si(100) and Si(111).[70] The immobilization was performed by dipping the Si substrates in a 4 mM solution of macrocycle dissolved in THF, for 24 hours at 373 K. A base was added to avoid demetalation. SAM formation was confirmed by XPS analysis. Tabulation of bonding energies (BE) for the porphyrin N1s and C1s revealed differences for free base porphyrins and metalloporphyrins. For free bases two values of ΔBE are found at 113 and 115 eV, consistent with two electronically inequivalent nitrogen atoms. Upon complexation, the Ns become equivalent and a single value is observed at 114 eV.

Two other hydrosilylation-related procedures (baking and sublimation) have been proposed for solid porphyrin compounds that are temperature resistant but unavailable in large quantities.[61,73] These techniques require high temperatures but only short reaction times (minutes). The porphyrin compound is placed on the substrate as a drop of solution, and it is baked at 400 °C, or it is sublimed onto a heated (400 °C) Si surface. In this case no solvent is required. Characterization of surfaces obtained after both types of treatment revealed the formation of porphyrin SAMs, and the electroactivity of the film was confirmed. This procedure is quite versatile as a variety of grafting substituents (ethynyl, vinyl, allyl, formyl, hydroxyl, acetylthio, acetylseleno, bromomethyl, bromo and iodo) have been tested, and good quality monolayers have been obtained. It seems that a polymerization is taking place on the surface and that covalent Si–C linkages are formed.

Two porphyrin derivatives bearing multiple allyl substituents (Figure 25) have been immobilized on Si via two anchoring units at two β-positions of the porphyrin core (**12**) or using a specific "tripodal" anchoring unit (**13**).[61,74] In both cases organosilane linkages are obtained. The tripod immobilization yielded monolayers displaying quite high retention time for the first porphyrinic oxidation state (ranging from 10 to 200 s depending on surface coverage). The baking procedure applied to the immobilization of these species can lead to high surface coverages (10^{-11} mol.cm^{-2} to 2×10^{-10} mol.cm^{-2}). It was suggested that the restricted motion of the linker arm between the surface and the macrocycle can explain this high coverage. The very robust and dense monolayers obtained with this compound prompted Bocian, Lindsey and coworkers to use it as a "starting block" for the

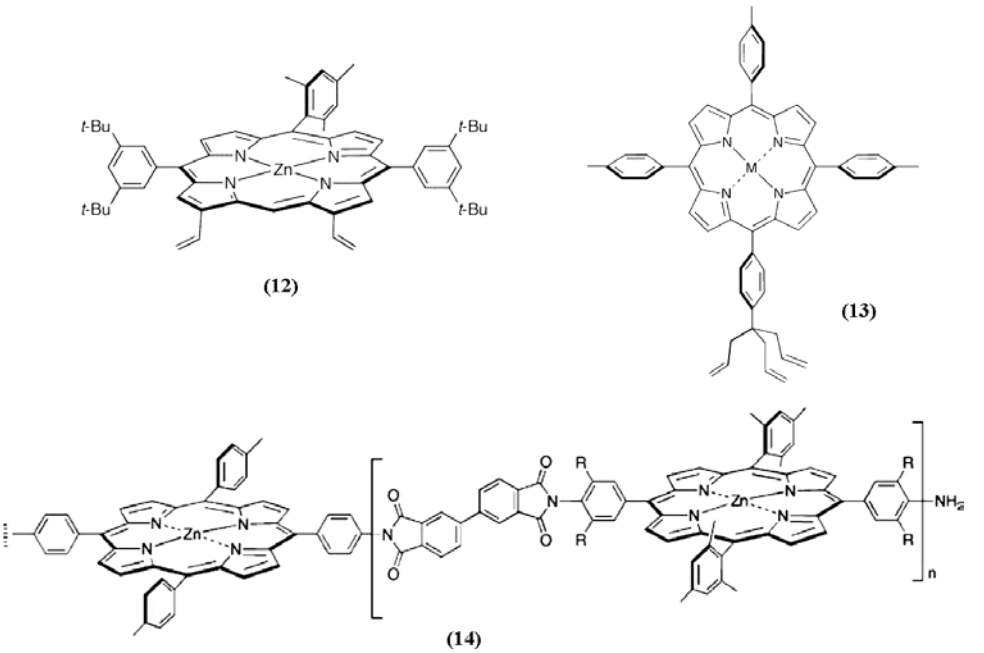

Figure 25. Porphyrins bearing two anchoring units in β-positions (**12**), an allylic tripod unit (**13**) and a "multad" immobilized on Si (**14**). (Adapted from Refs. 61, 74 and 75.)

sequential immobilization of porphyrinic "multads" (**13**).[75] These monolayers of porphyrin oligomers allowed higher storage capacities to be reached (Figure 25).

b. *Diazonium salt reaction*

Syntheses of porphyrins bearing an aryldiethyltriazene unit such as (**15**) have been performed and the resulting compounds were reacted with a Si surface (Figure 26a).[76] With these functional groups the difficult isolation of the diazonium salt is avoided. Immobilization was achieved by immersing the Si sample in a solution of porphyrins dissolved in a 1% HF/CH_3CN solution, which converted the aryldiethyltriazene to an aryldiazonium species that in turn reacted *in situ* with the Si–H surface. For compounds that are insoluble in this mixture, another method has been devised. The Si surface was passivated with HF and then immersed in a CH_3CN solution containing the porphyrin and a small amount of HBF_4 that generates the aryldiazonium salt. The concentration of the solution (0.1 to 0.5 mM) and the immersion time (10 to 120 minutes) can be tuned to obtain samples with various thicknesses. Smooth films of up to 80 nm can be conveniently obtained (Figure 26b).

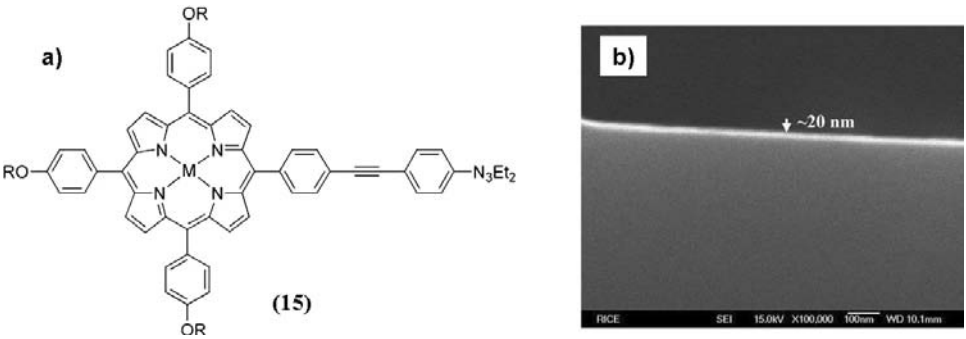

Figure 26. (a) Porphyrin bearing an aryldiethyltriazene substituent; (b) a SEM image of a film with an ellipsometric thickness of about 20 nm obtained with *in situ* aryldiazonium conversion conditions. (Adapted from Ref. 76.)

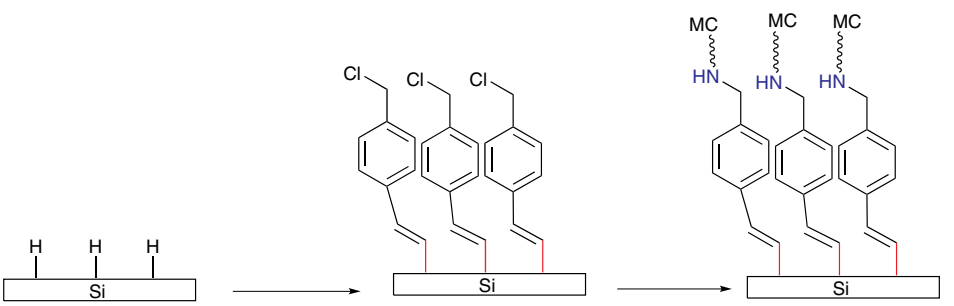
3. *Sequential Grafting*

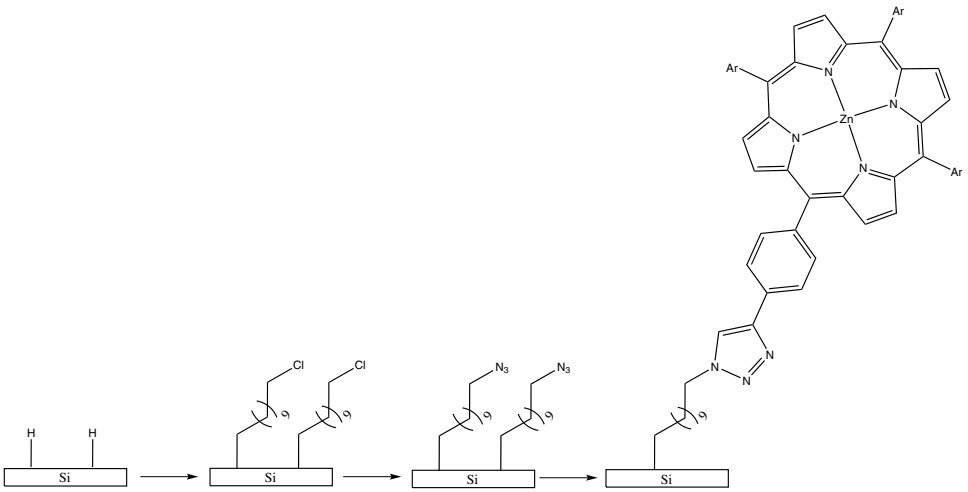
Sequential grafting provides an efficient procedure for immobilization of sensitive compounds on silicon.[77] A robust bi-functional spacer is first immobilized using one of the techniques described earlier, and the coupling to the molecule of interest can then take place.

Cu, Co and Zn porphyrins have been immobilized on Si(100) and Si(111).[70] Two different types of grafting have been tested: one with a pre-treated Si–I surface and another with a pre-functionalized Si substrate bearing a chloromethyl end group (Scheme 8).

Click-chemistry based grafting has also been adapted to Si surface modification.[78–83] This technique has been used to immobilize ferrocene and porphyrins on Si(100).[84,85] Delapierre and coworkers immobilized porphyrins bearing a single C–C triple bond on a phenyl substituent onto a functionalized Si substrate with



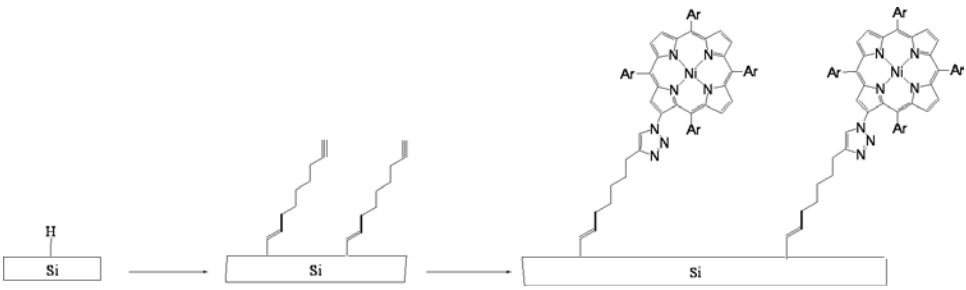
Scheme 8. Sequential immobilization of porphyrin macrocycles on Si using a chlorinated spacer.



Scheme 9. Immobilization of a zinc tetraphenylporphyrin complex on Si by successive hydrosilylation, substitution, and click cycloaddition on a *meso* phenyl position.

azide functional groups protruding from the surface.[84] Immobilization takes place in three steps (Scheme 9). Chloro-undecene is first anchored on the surface by dipping the Si sample in a mesitylene solution (10% vol.) for 2 hours at reflux. The second step is the substitution of the Cl atom by the N_3 function by immersion of the previously modified Si sample in a saturated solution of NaN_3 in DMF at 80 °C for 18 hours under argon. The final step consists in dipping the sample for 24 hours at room temperature in a dichloromethane solution containing porphyrin (1 mM) and CuI (0.1 mM) and DIPEA (1 mM) to catalyze the cycloaddition reaction. Each functionalization step was monitored and confirmed by IR, ellipsometry and XPS. Electrochemical studies showed that tuning the linker length has an impact on the electron-transfer rate between Si and the porphyrin, which is slower with longer alkyl linkers.

This study has been extended to porphyrins bearing an azide substituent on a β-position and a Si modified sample with C–C triple bond protruding from the surface (Scheme 10).[85] In the first step, the alkyne-containing compound is immobilized on the Si–H substrate by dipping the hydrogenated sample in pure nonadiyne for 12 hours at 140 °C. The presence on the IR spectra of the signal of the alkyne unreacted unsaturation coupled with ellipsometric data show that only one end of the nonadiyne has reacted with the surface. Then the modified surface is coupled to the porphyrin by dipping the Si sample in a dry DMF solution of porphyrin also containing $CuSO_4$ and ascorbic acid to catalyze the cycloaddition reaction. AFM, ellipsometry, XPS and electrochemical studies showed that the monolayer formation via β-linking was successful. The surface coverage obtained



Scheme 10. Immobilization of a nickel tetraphenylporphyrin complex on Si by successive hydrosilylation, substitution and click cycloaddition on a β pyrrole position. (Adapted from Ref. 85.)

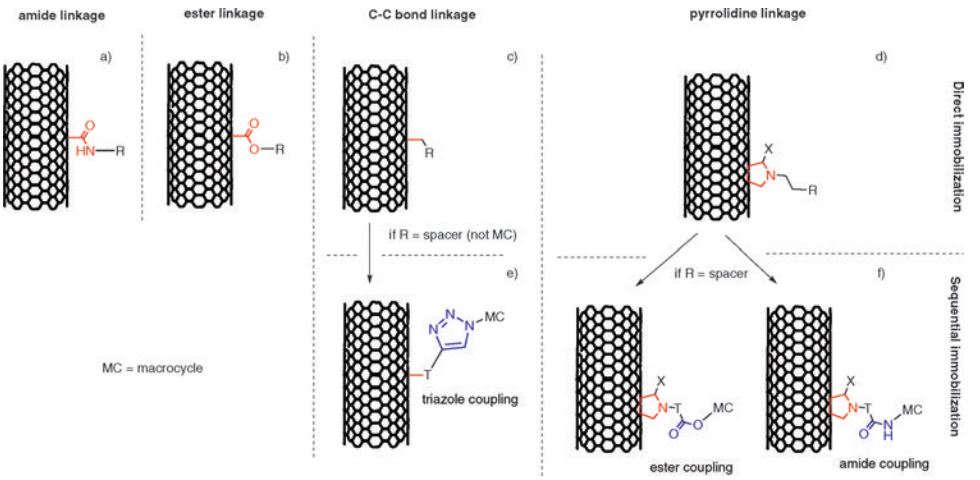
was 6×10^{-11} mol.cm^{-2}. No demetalation of the porphyrin was observed. It is noteworthy that the XPS signature of the triazole ring is very specific and can be used to confirm the surface cycloaddition reaction.

IV. Functionalization of Carbon Nanotubes and Surfaces

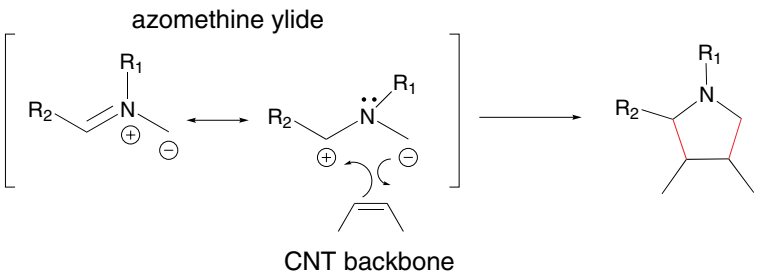
A. Overview

Carbon nanotubes (CNT) have been investigated as basic building blocks for electronic or photovoltaic devices. Their coupling to molecular species should allow the tuning of the properties of the resulting assembly and therefore lead to applications.[86] Porphyrins and phthalocyanines are among the molecules that have been immobilized on these substrates.[87] The anticipated applications lie mainly in the design of photoactive materials. The use of these hybrid systems in the electrocatalysis of reactions such as oxygen and hydrogen peroxide reduction, nitric oxide oxidation, oxidation of thiols and other pollutants has also been proposed.[88] A few molecular electronics applications have also been put forward.

Two different immobilization approaches, covalent[89,90] and noncovalent, have been suggested. Among the covalent procedures,[91] the most commonly used to modify CNTs with pyrrolic macrocycles are (Scheme 11): (1) amide or ester formation with the pending CO_2H functions, (2) reaction of aryldiazonium species with the CNT π-conjugated network,[92] and (3) 1,3-cycloaddition between an azomethine ylide and the CNT π-conjugated network (Prato reaction), yielding a pyrrolidine (Scheme 12).[89] In some cases, the macrocycle is immobilized in more than one step. The CNT surface is first decorated with a spacer using the aryldiazonium or the 1,3-cycloaddition reactions. In the following step the terminal end group of the spacer is reacted with the corresponding function on the macrocycle. Here again this coupling between the macrocycle and the spacer often uses an ester



Scheme 11. Methods used for anchoring porphyrin and phthalocyanine macrocycles on carbon nanotubes by (a–d) direct and (e, f) sequential immobilization.



Scheme 12. Reaction of an azomethine ylide with the CNT backbone.

or amide coupling link. But this link can also be a triazole when the spacer bears a C–C triple bond end group and the macrocycle possesses an azide function.

CNTs are very sensitive to surface perturbation, and covalent grafting is not always the chosen technique as it can lead to an important change of the CNT properties. Alternatively a molecule — most often a functionalized pyrene — is chosen to interact with the CNT by π–π interactions. This noncovalent linkage is called the pyrene linkage. A second set of intermolecular interactions is used in order to immobilize the macrocycle on the decorated CNT (Figure 27). Pyrene and macrocycle units have been synthesized so as to possess two complementary functions that are able to "recognize" each other. The intermolecular interactions that could be used are numerous, and they include hydrogen bonding, coordination bonding, electrostatic interactions, etc. Sometimes the assembly is strengthened by using more than one type of interactions.

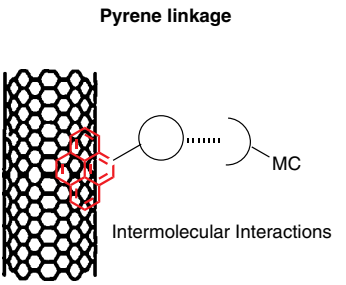


Figure 27. Noncovalent CNT surface modification involving pyrene interaction.

In the following section a few selected examples of phthalocyanines or porphyrins immobilized on CNT using one of these techniques are presented. Graphene and diamond substrates will also be briefly mentioned as the anchoring chemistry involved is very similar.

B. Selected Examples

1. *Covalent Linkage Between CNT and Macrocycle*

a. *Amide linkage with oxidized CNT*

Phthalocyanines have been coupled to CNTs to study the optical properties of the assembly.[93] After a purification step the single walled CNT (SWCNT) is oxidized in concentrated H_2SO_4/HNO_3 mixtures in order to produce carboxylic acid functions on the edges and on the defect sites of the CNT sidewalls. These functions were converted into acid chloride after reflux in $SOCl_2$. In parallel an aminophthalocyanine derivative was synthesized. This compound also bears hydrophobic groups to enhance the solubility of the final system. An amide formation reaction is then conducted between the Pc derivative and the acid chloride functionalized SWCNT in toluene in the presence of NEt_3. Due to poor solubility the system could not be characterized by NMR, however the UV-vis spectra of a dispersion of these species in $CHCl_3$ showed the broad absorption of the Pc core Q-bands. These bands are shifted towards the red indicating an electronic interaction with the SWCNT. Comparative IR analyses of KBr disks containing only CNT, Pc and the Pc-SWCNT system also confirmed the surface modification of the CNT. Electron-transfer processes within the system have been studied.

b. *Ester linkage with oxidized CNT*

Porphyrins have been covalently immobilized on CNT using an ester linkage.[94] Hydroxylated TPP derivatives were reacted with the pendant carboxylic functions of oxidized CNT. TPP derivatives possessing three hydrophobic C_{16} substituents and two linker lengths — between the OH group and the phenyl substituent — have been

tested. In this case, the ester formation was a solvent-free reaction: both CNT and porphyrin were put in contact in the solid state and stirred vigorously at 105 °C under N_2 for 24 hours. After a specific cleaning procedure, the systems were characterized by ^{1}H NMR and FTIR spectroscopies. The systems are soluble and the ^{1}H NMR spectra show the porphyrin signals with broader peaks that are consistent with the reduced mobility of immobilized species. In the IR spectra recorded in solution the signal of the C=O stretch of the ester linkage is clearly visible at 1734 cm^{-1} and 1730 cm^{-1}. TEM images showed CNT encapsulated by soft material that can be correlated to the porphyrin layer. The UV-vis and fluorescence data showed the predominant influence of the porphyrin properties, but the quantum yield analysis revealed the impact of the coupling between the molecules and the CNT, as the fluorescence quantum yield is reduced by 70% compared with the isolated porphyrin. This decrease can be explained by the intramolecular fluorescence quenching associated to the photoinduced electron transfer from the porphyrin to the nanotube. It was suggested that the linker length could have an impact on the molecular orientation at the nanotube surface leading to electron transfer modification. For a short linker no fluorescence quenching was observed. These results pave the way to the design of new nanometric photoactive material that could compete with dye-functionalized nanoparticles.

In a related procedure,[95] the acid chloride functions generated on CNTs were reacted with the hydroxylated porphyrin in toluene in presence of NEt_3 at 100 °C for 24 hours. FTIR analysis showed the presence of porphyrins on the nanotubes (Figure 28). The Soret band of the porphyrins around 450 nm was observed on the UV-vis spectra. For SWCNT even the Q bands were visible whereas for the multi-walled CNT (MWCNT) the absorption of the nanowire predominates and masks them. Upon excitation at 550 nm, the spectra recorded for a solution of porphyrin-nanowire system shows a ~95–100% quenching of the emission bands at 650 and 725 nm. This observation also suggests an intra-system electron-transfer process in this case.

c. *C–C Bond linkage between CNT and macrocycle*

i. Direct immobilization

The following example involves the immobilization of porphyrins on CNT using aryldiazonium chemistry and the formation of a C–C bond between the macrocycle and the nanowire.[96] For this surface modification procedure, prior oxidation of the CNT is not required. The purified SWNT are sonicated in o-dichlorobenzene (ODB) for 4 hours and an amino-TPP solution in acetonitrile is added. Then the reducing agent — isoamylnitrite — is added to the mixture that is stirred in the dark at 70 °C for 48 hours. Reduction of the *in situ* generated diazonium salt, followed by N_2 release, generates an aryl radical that reacts readily with the SWNT surface (Scheme 13) over a period of 48 hours. The final system was washed in DMF. The functionalization was confirmed by FTIR and UV-vis analysis.

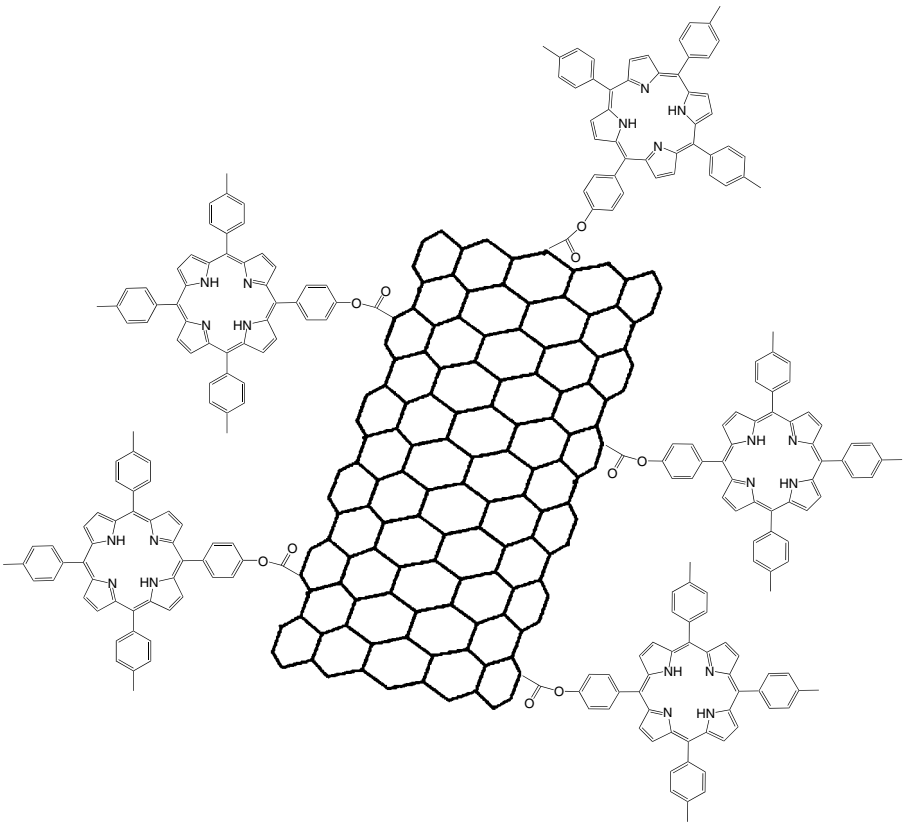

Figure 28. Porphyrins immobilized on SWNT by ester formation mediate photoinduced electron transfer. (Adapted from Ref. 95.)

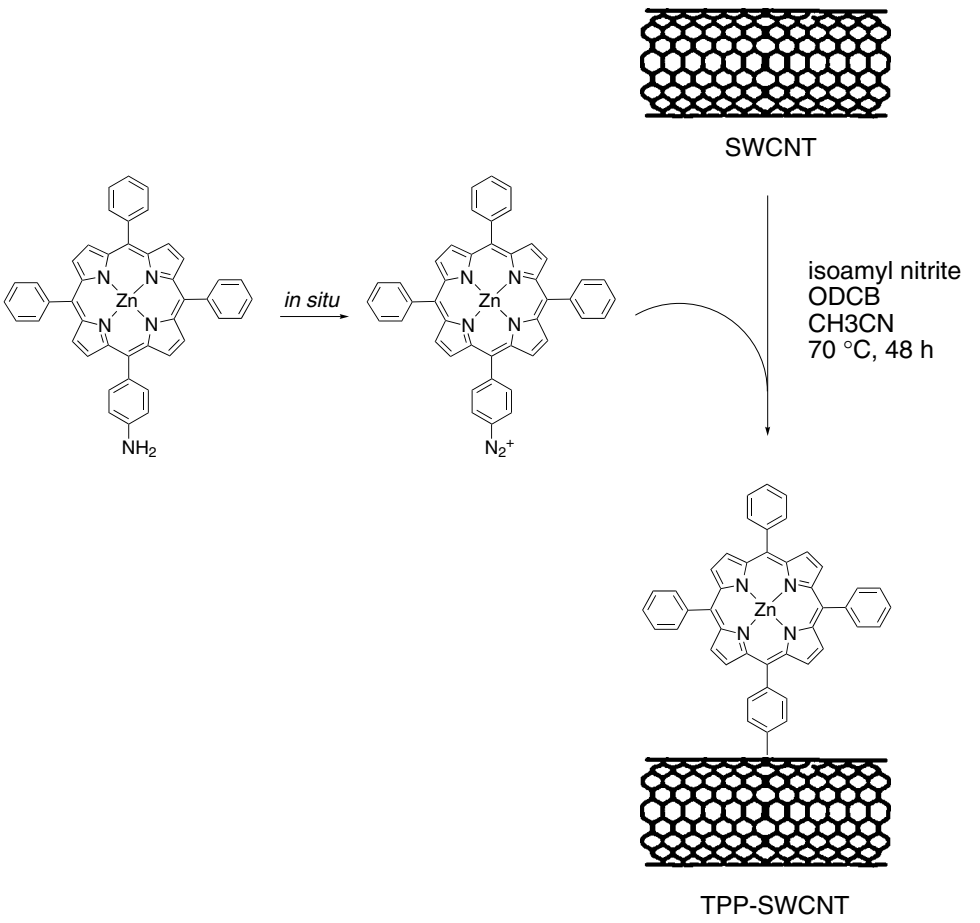
Thermogravimetric analysis showed that the porphyrin surface coverage is higher than 28%. UV-visible and fluorescence analyses showed that there is an important charge transfer between the molecule and the nanotube by a rapid through-bond mechanism: the Soret band is shifted and fluorescence is quenched by 97%.

The effect of the chemical link between the nanotube and porphyrins has been investigated by comparing the optical properties of assemblies obtained by ester formation, amide formation and diazonium salt reaction (Figure 29).[97] Upon excitation of the porphyrin at the Soret wavelength, an important fluorescence quenching is observed: for the C–C linker and TPP-SWNT system a 97% quenching is recorded for the fluorescence emission at 651 nm and 717 nm. For the amide linker and TPP-SWNT system a 25% quenching is observed. For the even shorter ester axial linkage almost no fluorescence quenching occurs. The length of the linker has a similar impact on the system properties. It is interesting to note that this aryldiazonium reaction takes place between an aminoporphyrin derivative and a CNT, whereas a Si surface is inert under the same conditions.[76]



Scheme 13. Anchoring porphyrin on CNT by *in situ* formation of an aryldiazonium salt.

ii. Click coupling

Phthalocyanine compounds have been immobilized on SWCNT using a method based on the high yielding and mild click-chemistry cycloaddition described in the preceding sections.[98–101] In a typical study,[102] a C–C bond linkage is first formed between the CNT and the spacer, and in a subsequent step a triazole coupling link is produced between the spacer end group and a phthalocyanine. The chosen anchor molecule — 4-(trimethylsilyl)ethynylaniline — is converted into a diazonium salt and then linked to the SWCNTs. The alkyne substituent is then deprotected and reacted with an azide-functionalized phthalocyanine (Figure 30).

The click reaction was performed in NMP at 70 °C for 48 hours in presence of $CuSO_4$ and sodium ascorbate. A polar solvent such as NMP was used to enhance the rate and yield of the reaction and to allow the solubilization of the

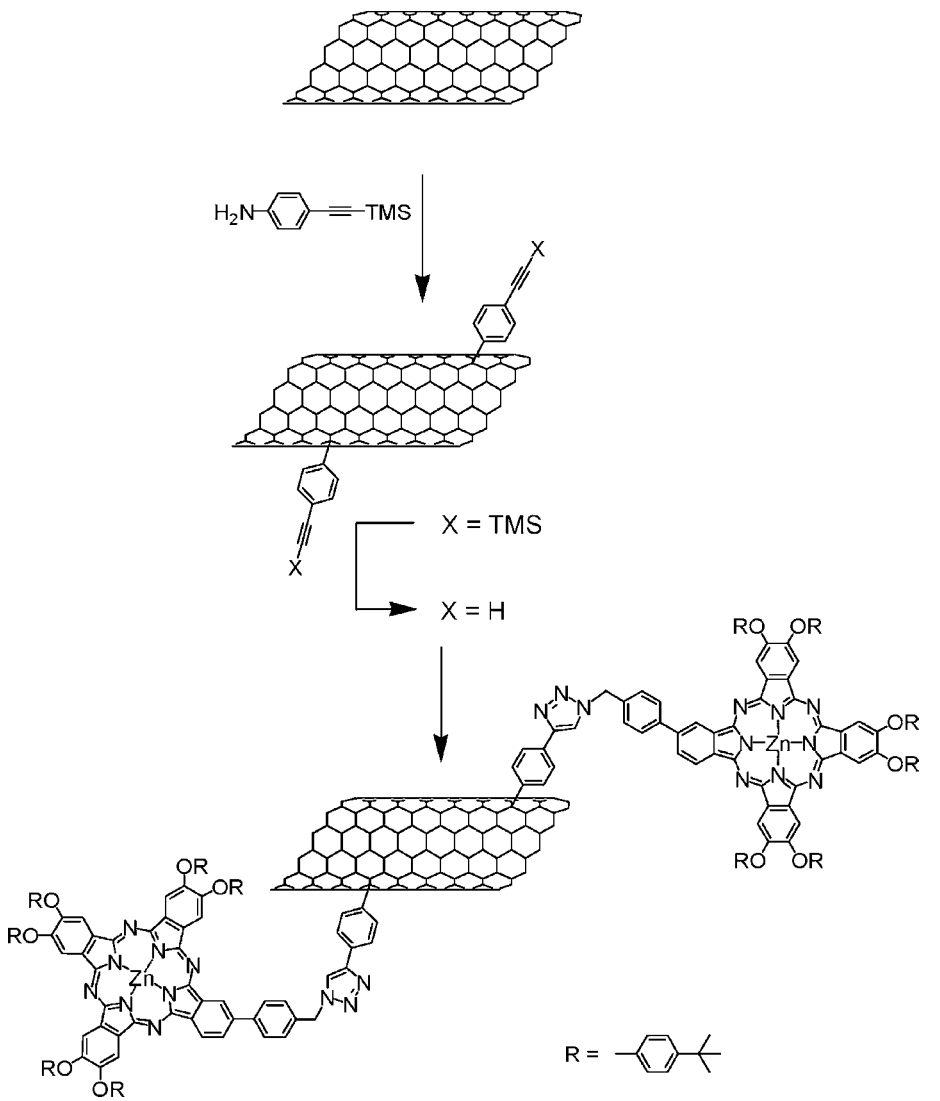

Figure 30. Phthalocyanine immobilization on SWNT via a click-chemistry based procedure. (Adapted from Ref. 102.)

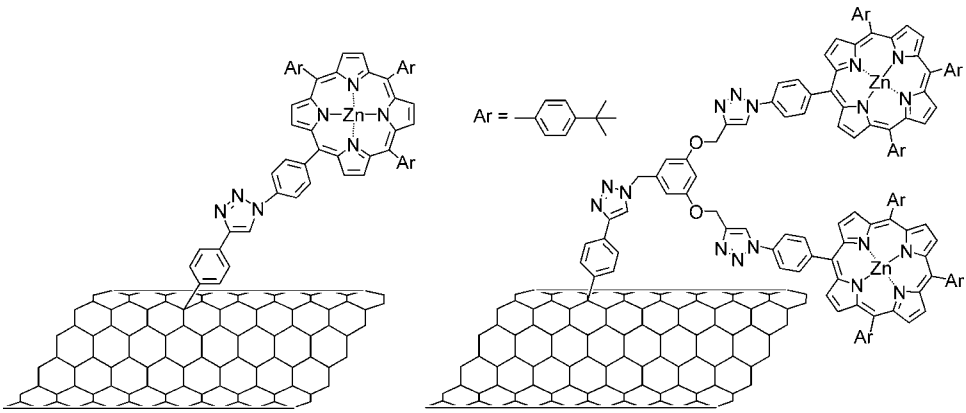

Figure 31. Porphyrin immobilization on SWNT via a click-chemistry based procedure. (Adapted from Ref. 107.)

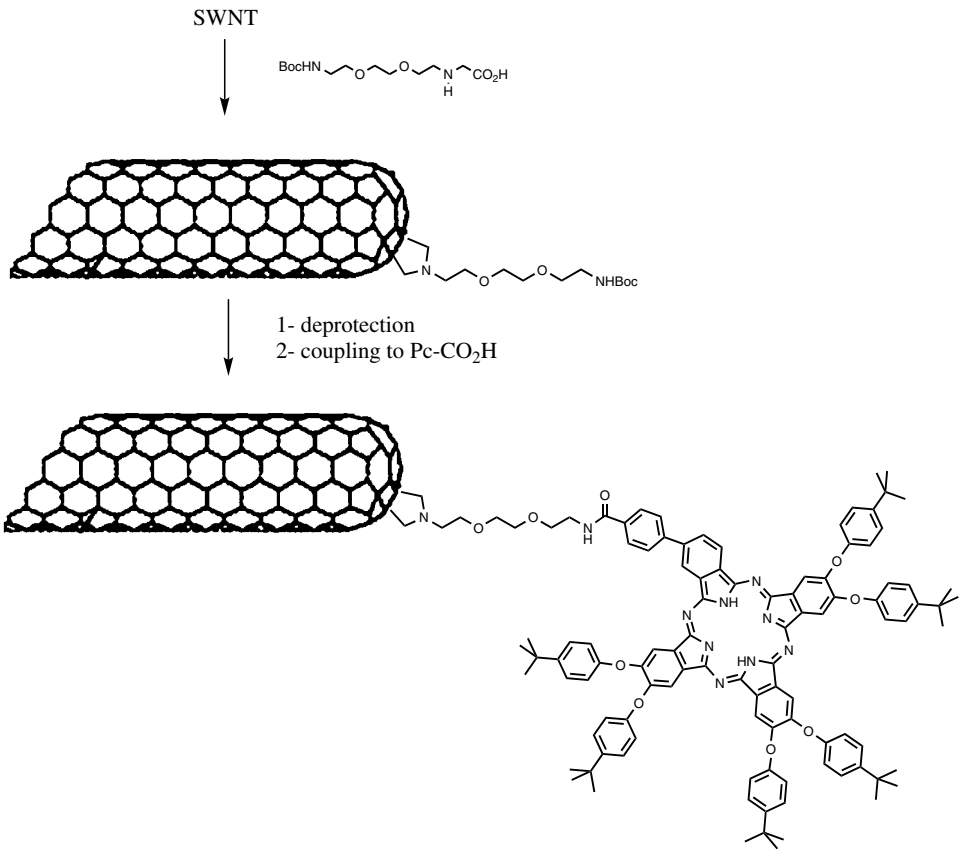
phthalocyanines. It was shown that metallic nanotubes display higher surface coverage, which was explained by the higher reactivity of these substrates towards aryldiazonium derivatives. Phthalocyanine immobilization was confirmed by UV-vis and Raman spectroscopy, and by thermogravimetry. Photovoltaic properties have been investigated using a photoelectrochemical cell. The system was deposited on an ITO substrate. An electrolytic solution of 0.1 M Na_3PO_4 in presence of ascorbic acid (to avoid Pc photooxidation) was used along with a three electrode set-up consisting of the ITO modified electrode, a Pt wire and a Ag/AgCl electrode. The photocurrent yield reached values as high as 17%.

The 1,3-Huisgen cycloaddition has already been widely used to prepare dendrimeric materials.[103–105] Azido porphyrins[106] have been immobilized on CNT using anchoring dendrons designed to react by the Huisgen cycloaddition (Figure 31).[107,108] The advantage of using a dendron is to increase the amount of porphyrin material linked to the nanometric species while limiting the disruption of π-conjugation by a large number of surface covalent bonds.

d. *Pyrrolidine linkage between CNT and a spacer unit*

i. Amide coupling of the spacer to the macrocycle

The previously described procedures yielded poorly soluble or totally insoluble systems. Another procedure leading to enhanced solubilities has been investigated.[109] This procedure had been used previously on nonpyrrolic macrocycles.[110] It is based on the Prato reaction, i.e. the 1,3-dipolar cycloaddition that occurs between an azomethine ylide and the CNT yielding a pyrrolidine linkage (Scheme 14). Immobilization of a spacer compound by a pyrrolidine linkage is followed by amide coupling to a specifically synthesized Pc compound. In the



Scheme 14. Phthalocyanine immobilization on SWCNT by a Prato reaction and amide formation. (Adapted from Ref. 109.)

first step, the SWNT are placed in a mixture of a N-protected aminoacid and paraformaldehyde that react *in situ* to yield the reactive azomethine ylide. The N-protecting group was cleaved by bubbling HCl in DMF. The Pc bearing an acid carboxylic function was then reacted with the SWNT-$NH_3^+Cl^-$ nanotube modified system in the presence of *N*-(3-dimethylaminopropyl)-*N*′′-ethylcarbodiimide (EDC), 1-hydroxybenzotriazole (HOBt) in ethyldiisopropylamine. Thermogravimetric analysis revealed a 43% Pc surface coverage. The system solubility was sufficient to conduct photophysical studies. Absorption spectra were recorded in THF, and immobilization was further confirmed by a small emission band around 700 nm.

A similar grafting technique involving a pyrrolidine linkage between the CNT and a dendrimeric anchor compound was performed and the system was further reacted with a porphyrin derivative (Figure 32).[108] The first anchor was immobilized

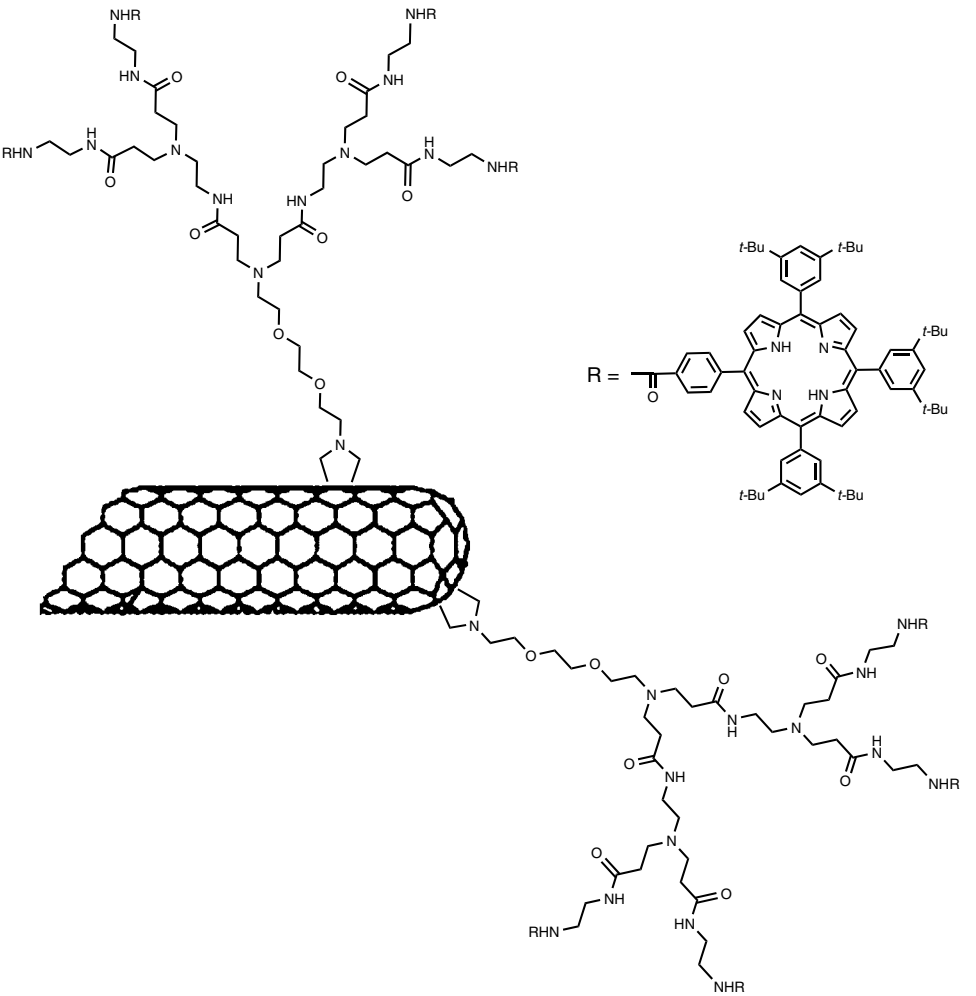


Figure 32. Porphyrin immobilization on SWNT via a dendronic approach. (Adapted from Ref. 108.)

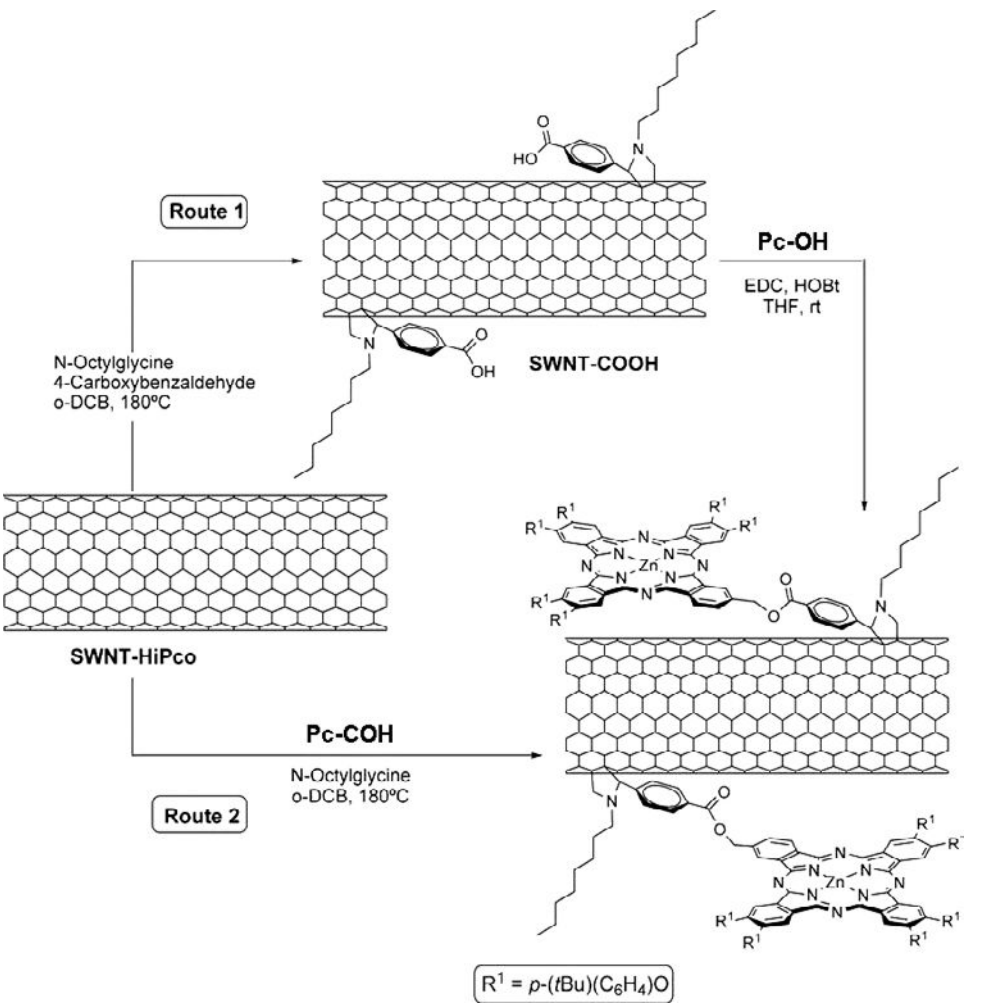
using the procedure just described. Then the SWNT-$NH_3^+Cl^-$ was reacted with methyl acrylate in methanol for 3 days at 80 °C. After washing and filtration the ester functions were reacted with ethylenediamine providing a dendron with two terminal amines. To obtain the second generation dendron the previous one was further reacted with methyl acrylate followed by another ester formation reaction with ethylenediamine. Then the final four amines were coupled to TPP derivatives possessing carboxylic acid functions. The overall method allowed an increase of the surface coverage in the redox compound while limiting the π-conjugation system disruption. AFM imaging showed that the diameter of the SWCNT increases

upon porphyrin grafting. Thermogravimetric analysis indicated the presence of two porphyrins per dendrimer. The photoactivity of the hybrid systems has been studied.

ii. Ester coupling of the spacer to the macrocycle

The Prato reaction can also be used to immobilize phthalocyanines in one or two steps (Scheme 15).[111] For the first procedure a phthalocyanine aldehyde derivative is required, whereas for the sequential grafting the pyrrolidine linkage is first



Scheme 15. Phthalocyanine immobilization on CNT by single-step and two-step grafting procedures. (Adapted from Ref. 111.)

obtained and the acid carboxylic end group of the spacer is then reacted with the hydroxyphthalocyanine. For the direct immobilization *N*-octylglycine and the Pc aldehyde derivative are mixed in o-DCB at 130 °C for 5 days yielding the Pc-functionalized SWNT. For the sequential grafting, the first step is the functionalization of the SWNT with a spacer bearing carboxylic acid functions. This reaction is performed in o-DCB with *N*-octylglycine and carboxybenzaldehyde at 180 °C for 5 days. The following step is the ester coupling between the Pc derivative and the CO_2H functions at room temperature for 4 days in THF using HOBt and EDC as coupling agents. Both procedures yielded Pc-CNT systems. With the sequential grafting higher Pc surface coverage is reached: 30% by weight compared to 20% by weight for the direct immobilization. In both methods *N*-octylglycine was used to facilitate the cycloaddition and impart higher solubilities.

2. *Noncovalent Linkage Between CNT and Macrocycle: π–π Interactions*

Studies have shown that tuning the length of the tether can influence the quenching behavior of the system. The nature of this tether is also important as the use of a C–C linker between an aromatic substituent and the nanotube leads to almost complete fluorescence quenching. In order to tune the system properties while keeping the nanotube as defect-free as possible, noncovalent functionalization procedures have been developed. The aromatic character of porphyrin and phthalocyanine derivatives has already been exploited to develop intermolecular interactions with CNT. Thus oligomers or polymers of porphyrins and sapphyrins have been immobilized irreversibly on the SWNT surface.[112–114]

An usual functionalization procedure involves the synthesis of a compound of interest bearing a pyrene "foot" that is able to interact via strong π–π interactions with the CNT backbone. In a few cases the pyrene compound bears a substituent that can act as a coordinating ligand,[115] or it bears a positive charge that interacts with negatively charged carboxylate function of the macrocyclic derivative.[116,117]

a. *Coordination bond coupling*

A pyrene bearing an imidazole moiety was immobilized on the SWNT surface (Figure 33). Then Zn–Pc and Zn–P were coordinated to the as-modified nanotubes. The presence of the macrocycle was confirmed by TEM imaging, UV-vis-NIR spectroscopy and electrochemical methods. Fluorescence quenching was also observed confirming the interaction between the macrocycle and the SWNT. Photoexcitation of the system resulted in the one-electron oxidation of the macrocycle (donor unit) and the simultaneous SWNT reduction (acceptor unit).

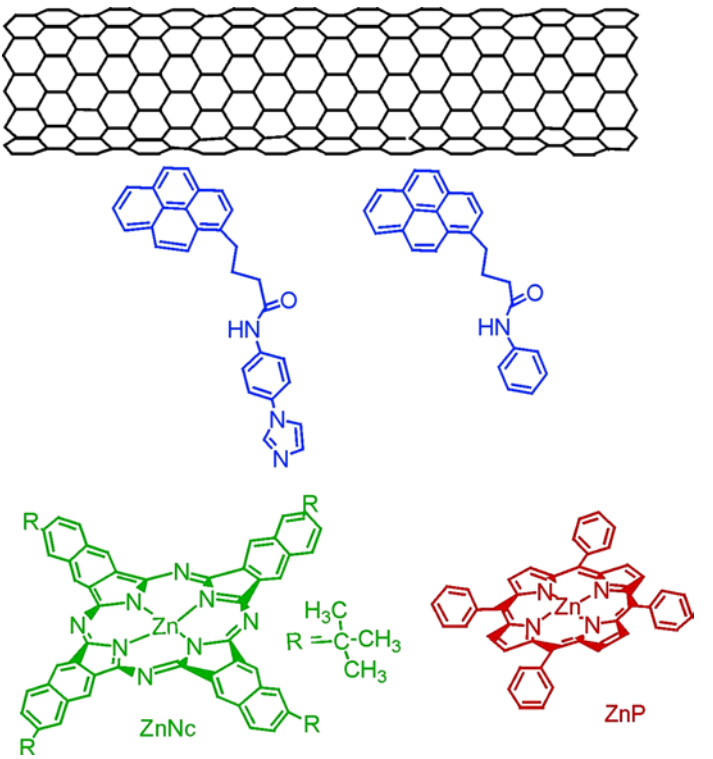


Figure 33. Representation of P and Nc immobilized on a CNT through coordination bond to a pyridino- or imidazolo-modified pyrene unit. (Adapted from Ref. 115.)

b. *Electrostatic coupling*

A positively charged pyrene has been designed so as to interact via electrostatic interactions with a negatively charged porphyrin (ZnP^{8-}).[116] To obtain the pyrene linkage 1-(trimethylammoniumacetyl)pyrene ($pyrene^{+}$) was dissolved in H_2O and water-soluble SWNT were added to the medium. The suspension was stirred overnight and then cleaned to afford the $pyrene^{+}$-SWNT system. The positively charged ammonium head group was used as an electrostatic anchor to bind the 8 anionic carboxylic groups of the zinc complex (ZnP^{8-}) (Figure 34). The modified SWNTs were dipped in dilute $Zn–P^{8-}$ solution and the success of the electrostatic immobilization was confirmed by TEM analysis and absorption spectroscopy.

c. *Crown ether-cation coupling*

Using the same pyrene foot as anchor for immobilization on the CNT, the electrostatic interactions can be replaced by crown ether-alkylammonium cation interactions to immobilize the porphyrin on the pyrene foot (Figure 35).[118] Mono- or

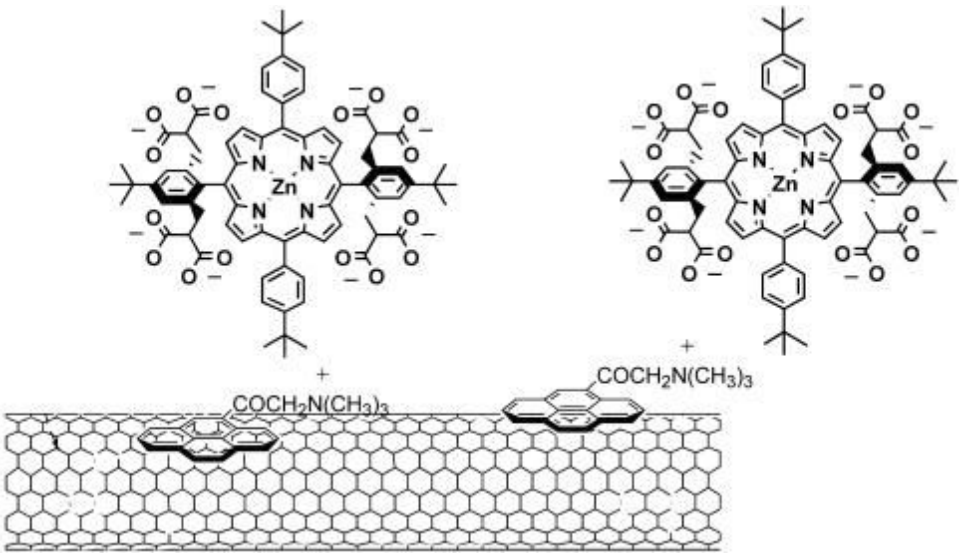

Figure 34. Porphyrin immobilization on a CNT through electrostatic coupling between positively charged pyrene units and negatively charged porphyrin substituents. (Adapted from Ref. 116.)

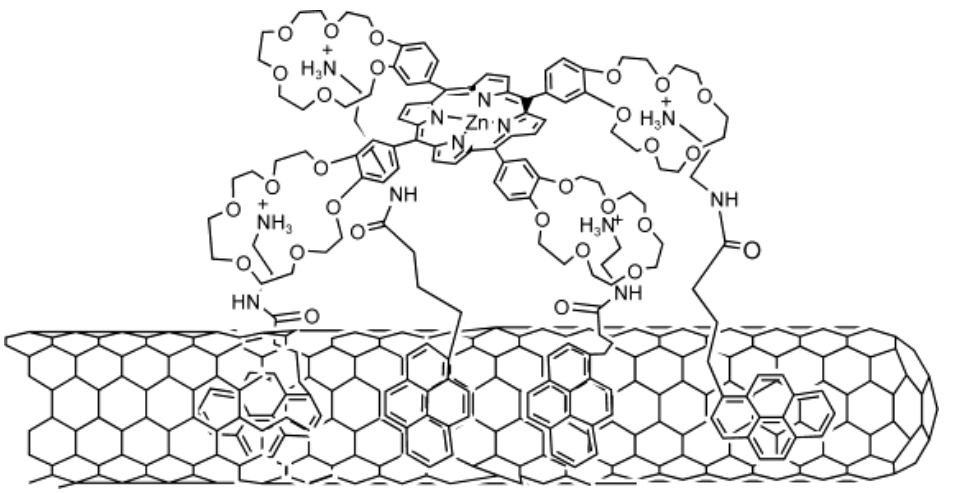

Figure 35. Porphyrin immobilization on a CNT through noncovalent interactions between ammonium cation modified pyrene unit and crown ether-substituted porphyrin derivative. (Adapted from Ref. 118.)

tetra- substituted porphyrins have been used and porphyrins with different arms between the aromatic ring and the crown ether have also been synthesized. The pyrene-SWNT system was formed upon stirring the CNT and pyrene in dry DMF at room temperature for 48 hours. The porphyrin interaction was characterized by

analyzing the photochemical properties of the systems, by TEM imaging and by electrochemistry. The porphyrins with four crown ether groups have been shown to interact more strongly with the SWNT.

3. *Graphene Functionalization via Amide Linkage*

Phthalocyanine and porphyrin deposition on graphite have been investigated for several decades[119]; however, it is only in the early 2000s that porphyrins have been covalently immobilized on graphene.[120,121] This material exists mainly as graphene oxide possessing various oxygen containing functional groups. These groups are reactive towards the amino groups of a porphyrin derivative. Thus, an amide linkage binds the porphyrin to the graphene layer (Figure 36). The success of this reaction has been confirmed by FTIR, UV-visible absorption and TEM analysis. Porphyrin grafting makes the system more soluble and processable and it affords a material with interesting optical properties.

As for the oxidized CNT, the carboxylic acid functions of graphene oxide can be converted to acid chloride by the use of $SOCl_2$ (Scheme 16).[122] These functions react in a second step with an aminoporphyrin also yielding a porphyrin linked to the graphene via an amide linkage.

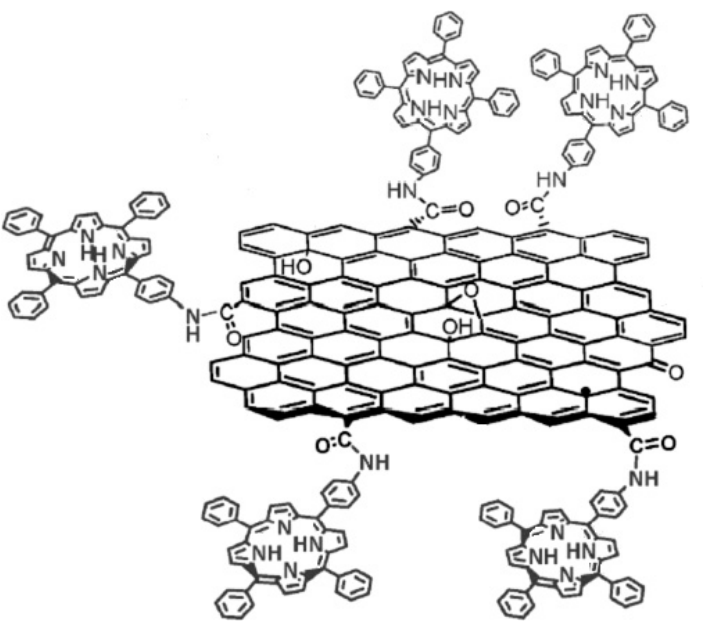

Figure 36. Porphyrins immobilization on graphene by ester formation with pendant acid carboxylic functions. (Adapted from Ref. 121.)

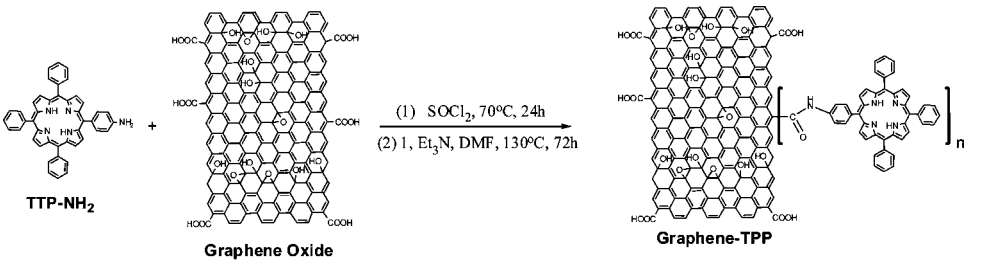
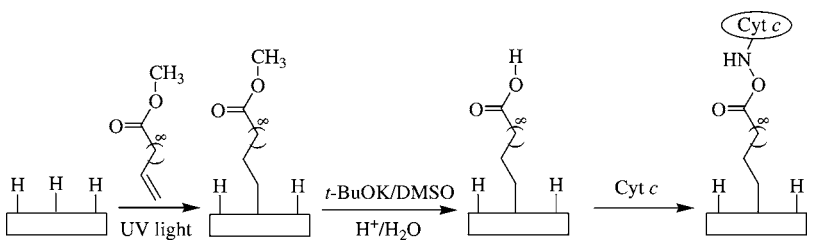


Scheme 16. Porphyrin immobilization on graphene by amide formation. (Adapted from Ref. 122.)

4. *Diamond Functionalization via C–C Linkage and Amide Coupling*

Investigations have been directed toward diamond surface modification. The reactions involved are comparable with those used to modify CNT.[123] Aryldiazonium grafting remains a convenient method to functionalize this material.[124] A cycloaddition between an allylic compound and the C backbone is also commonly used. Due to its compatibility with water diamond is a very attractive surface for functionalization with biomolecules.[125,126]

Cytochrome *c* has been covalently immobilized on a modified diamond electrode (Scheme 17) by amide coupling.[127] The electrode was boron-doped in order to decrease the material resistivity and to allow better electrical detection. The diamond was subjected to a hydrogen plasma for 45 minutes at 700 °C to produce a hydrogen-terminated surface that was then reacted with undecylenic acid methyl ester under photoirradiation. After a hydrolysis step, the amine function of cytochrome *c* was coupled to the immobilized carboxylic acid functions. Electrochemical analysis of the system showed the characteristic response of the cytochrome *c*, with a proportional trend between scan rate and current intensity confirming a surface-confined redox process. The surface coverage determined was ~1.2×10^{-11} mol.cm^{-2}. This study also showed that the electron-transfer between the redox species and the



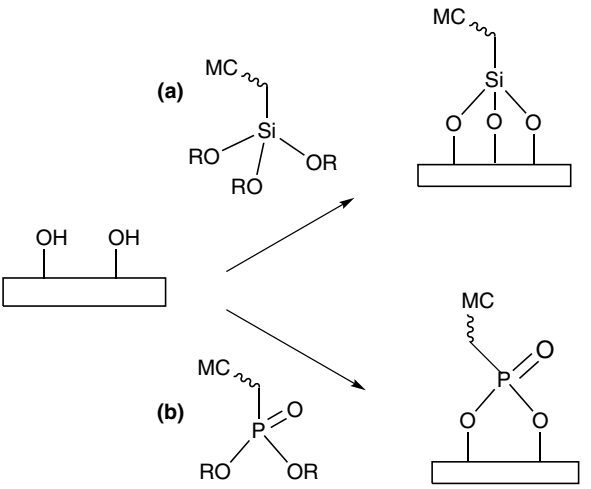
Scheme 17. Immobilization of cytochrome *c* on diamond following a sequential grafting procedure. (Adapted from Ref. 127.)

boron-doped nanocrystalline diamond (BDND) electrode is faster than with the boron-doped microcrystalline diamond (BDMD). The system also showed a good response toward the catalytic reduction of H_2O_2. This study showed that the coupling between a biological compound and a diamond electrode can lead to very sensitive electrochemical detection along with a stable response over time. Such hybrid systems could be of importance for the study of many proteins.

V. Functionalization of Oxide Surfaces

A. Overview

The most widely used technique to covalently immobilize compounds on oxide surfaces such as SiO_2, glass, TiO_2, or ITO is the silanization process, in which organosilanes possessing trialkoxysilane or trichlorosilane anchoring units are reacted with the oxide surface (Scheme 18a). The presence of water at the substrate interface seems to be mandatory for the reaction to proceed; it allows the initial hydrolysis of the reagent leaving silanol head groups which form hydrogen bonds to the protruding OH group of the substrate and with adjacent molecules. The subsequent step is a condensation releasing H_2O, forming a polymeric ad-layer of polysiloxane covalently immobilized on the surface. The coverage density and monolayer quality are improved if the solid substrate exhibits a large number of protruding silanol groups.[128] This is achieved by dipping the substrate in an acidic mixture (piranha) or by exposing the substrate to an oxygen plasma. These steps both clean the substrate and yield a hydrophilic surface that is prone to the deposition of water catalyst. The



Scheme 18. Schematic representation of the linkage between a hydroxylated surface and (a) a triethoxylsilane or (b) a phosphonic acid.

monolayer quality depends on factors such as the nature of silane and solvent, temperature and reaction time.[128] Another popular technique uses phosphonic acid anchoring units that are reacted with surface hydroxyl groups (Scheme 18b).

B. Selected Examples

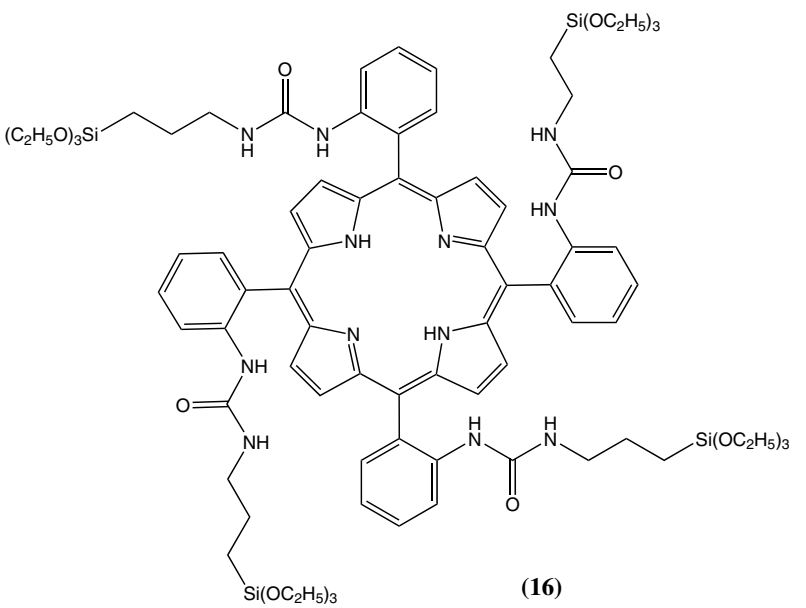
1. *Silanization*

a. *Direct immobilization*

Figure 37 shows a fluorescent free base porphyrin (**16**) that has been immobilized on a silica xerogel matrix.[129] Despite the chemical bonding between the molecule and the silica template no fluorescence quenching was observed.

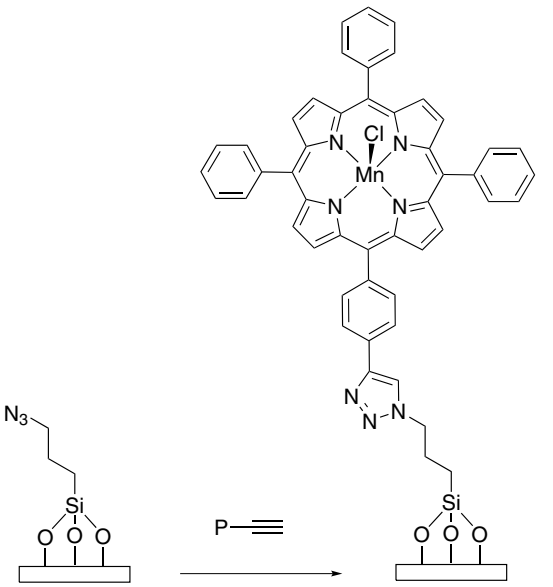
b. *Sequential immobilization*

The click-chemistry based sequential grafting procedure has been used to derivatize silica.[130,131] Porphyrins bearing one or four C–C triple bonds were reacted with azide-functionalized SiO_2 nanoparticles for application in epoxidation catalysis (Scheme 19). The multiple anchors led to a low porphyrin coverage as the flat macrocycle lies parallel to the surface. This is an advantage as the distance between active centers remains sufficiently large to minimize interporphyrin electron-transfer and bleaching. However turnover numbers are low.



(16)

Figure 37. A porphyrin bearing four triethoxysilane anchoring units for parallel immobilization on the oxidized Si surface. (Adapted from Ref. 129.)

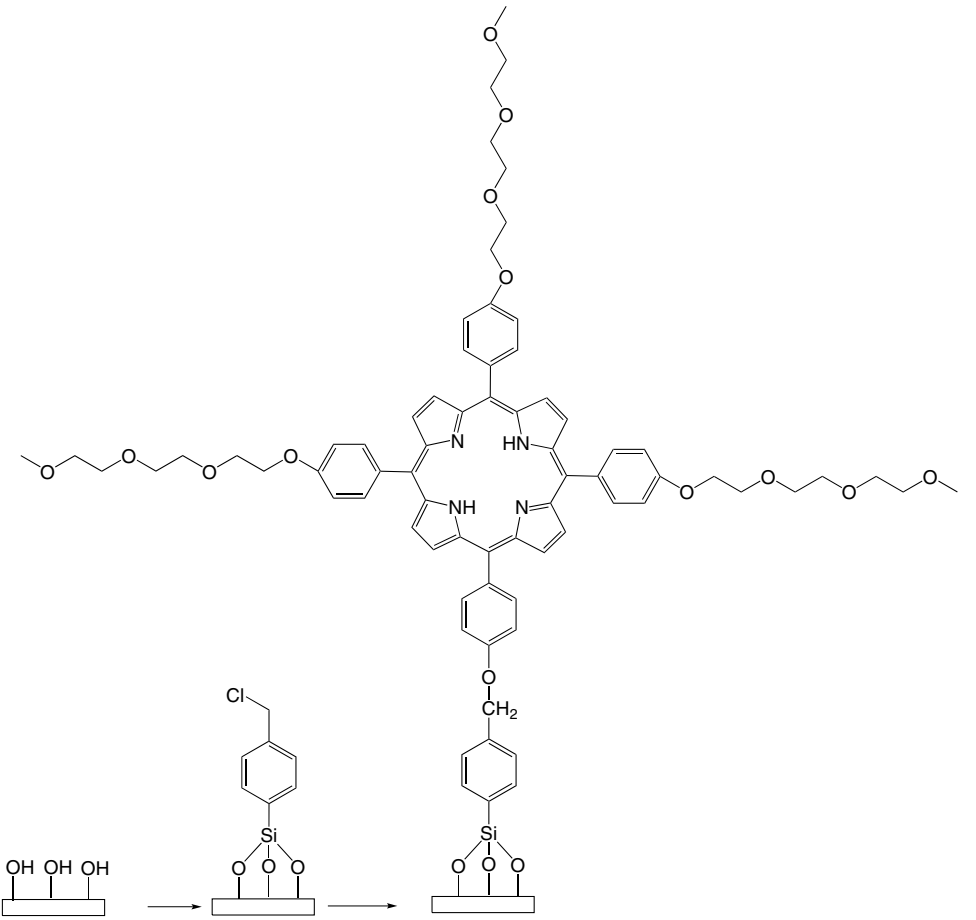


Scheme 19. Combination of alkoxysilane and click chemistries for the sequential immobilization of TPP derivatives on SiO_2 nanoparticules.

A porphyrin derivative has been immobilized on SiO_2 in two steps for acidic pH sensing applications (Scheme 20).[132] The compound used has one hydroxyl group for coupling to a spacer, and three 3-methoxy-3-(oxyethylene) *meso*-substituents to improve hydrophilicity. In the first step, a trichlorosilane coupling agent (CA) was grafted onto the surface by dipping the previously oxidised Si substrate in a 1:100 (v:v) solution of CA in hexane for 20 minutes at room temperature. Then the CA modified sample was immersed in a 5×10^{-3} mol.L^{-1} porphyrin solution in THF for 48 hours at 60 °C. This immobilization method was successful and yielded monolayers with 1.91×10^{13} molecules.cm^{-2} surface coverage. With this modified silica indicator pH can be monitored optically via changes of the Soret band of the porphyrin upon protonation.

The same protocol was used to immobilize a porphyrin bearing one hydroxyl unit for attachment to a modified silica sample and three aryl meso substituents possessing long alkyl chains.[133] This silica material-derivatized free base porphyrin monolayer has been tested as an optical gas sensor for NO_2 detection. Sensitivity to NO_2 is only observed with TPP derivatives, and not with OEP monolayers.

ITO electrodes have been modified with porphyrins using another sequential grafting procedure. A silanization reaction between the hydroxylated surface and a trimethoxysilane coupling agent is followed by amide formation between the terminal



Scheme 20. Representation of the sequential process used to immobilize porphyrins on silica.

amine function of the CA and carboxylic acid porphyrins.[134] SAMs of porphyrins with or without tert-butyl groups (R = H or t-Bu in Figure 38) have been obtained. Photo- and electro-chemical analyses of the monolayers showed that interactions between porphyrins are more important for the nonsterically hindered species. The good quality of the porphyrin SAMs gives access to long-lived excited singlet state apparently similar to those of the antenna function of photosystem I in cyanobacteria, opening the field to the construction of artificial light harvesting systems.

2. *Phosphonate Linkage*

Bocian, Lindsey and coworkers have prepared porphyrin derivatives (**17**) and (**18**) possessing protected phosphonic acid anchoring units (Figure 39).[135,136]

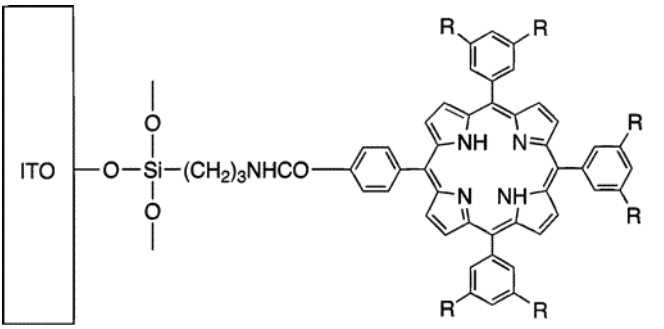


Figure 38. Self-assembled monolayers of porphyrins on ITO. (Adapted from Ref. 134.)

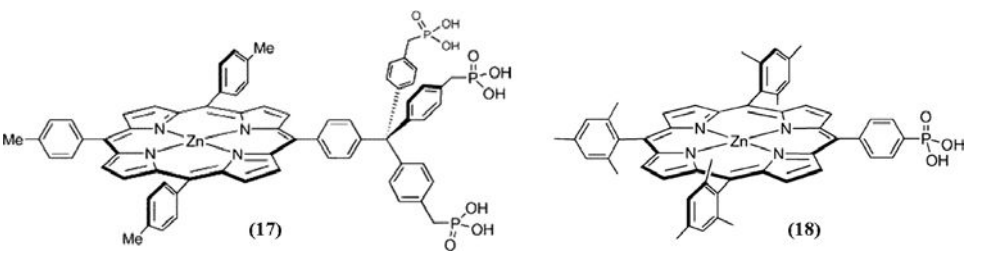

Figure 39. Porphyrin compounds bearing tripod- or mono-phosphonic acid anchoring units. (Adapted from Refs. 135 and 136.)

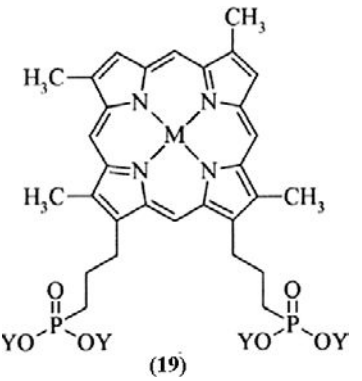
The di-*tert*butyloxyphosphoryl protected phosphonic acid is stable under the conditions of the coupling reaction, metallation, and DDQ oxidation; and the deprotection step does not lead to demetalation. The monolayer is formed by the baking method. Eight drops of a DMF porphyrin solution were deposited on the SiO_2 sample. Between each drop deposition, the sample is heated at 170 °C for 10 minutes. Electrochemical studies were conducted on these modified surfaces as the SiO_2 layer is thin and grown on a highly doped Si sample. The conducting samples thus obtained showed electrochemical characteristics consistent with the presence of robust monolayers.

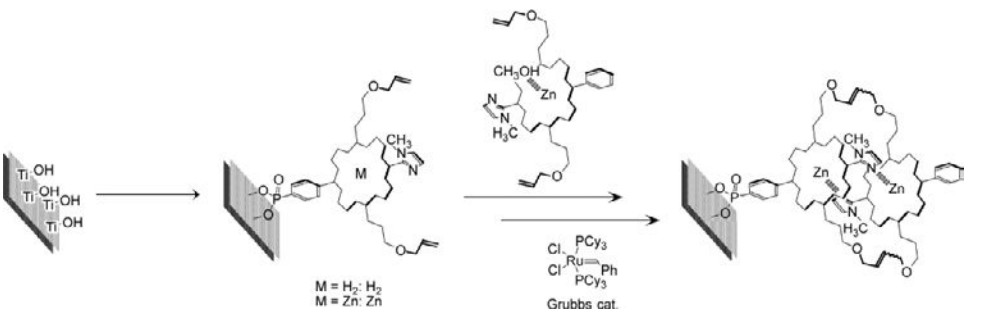
Deutero-porphyrin derivatives bearing phosphonate residues such as (**19**) have been synthesized for immobilization on TiO_2 (Figure 40).[137] Co porphyrin monolayers seemed to be sensitive toward detection of organohalogen compounds.

Slipped co-facial Zn porphyrins have been immobilized on a titanium-modified ITO anode using a phosphonic acid anchoring unit (Scheme 21).[138] These compounds have been investigated as special-pair mimic porphyrin assemblies. In the first step, a porphyrin bearing a phosphonate anchor and two terminal olefin groups was grafted on ITO. Pair formation with another Zn porphyrin was achieved in a second step by Zn-imidazole coordination followed by ring-closure



(19)

Figure 40. Deuteroporphyrin with phosphonate anchoring units for immobilization on TiO_2. (Adapted from Ref. 137.)



Scheme 21. Immobilization of a porphyrinic dimer on ITO with a phosphonic acid anchoring unit. (Adapted from Ref. 138.)

metathesis. These special-pair mimics exhibited efficient charge injection from the S_2 photoexcited state. High photocurrents were generated upon photoirradiation of the system in aqueous media containing hydroquinone.

Phosphonate coordination to Zr(IV) centers has been used to form multilayers of porphyrins on solid surfaces.[139–141] While this chemistry is useful for Langmuir-Blodgett film formation, it does not fit within the scope of a review devoted to surface functionalization.

VI. Innovative Technologies and Concepts in Hybrid Electronics

A. Overview

Porphyrins have been physically deposited on semiconductors for the design of hybrid devices based on their photoredox properties, such as light-sensitive Si- or

CNT-based transistors or optoelectronic memories.[142–145] Physical deposition methods are relatively simple to carry out, but they do not provide a controllable pathway for electrons at the interface between the bulk substrate and surface molecular materials. In contrast, chemical anchoring methods, such as those reviewed in the preceding paragraphs, afford strong coupling of the SAM molecular orbitals to the conduction and valence bands of the substrate, which in turn dictates the charge transport properties of the final device and warrants some reproducibility. Chemical approaches for hybrid silicon-molecular electronics have been reviewed.[146–150]

Porphyrin macrocycles and their metal complexes are regarded as key building blocks for this type of technology, as they remain robust under high-temperature processing steps and operating conditions. They also exhibit several redox states that are useful for multibit information storage, and they remain stable over a very large number of operational cycles.[71]

B. Selected Examples

1. *Molecular Capacitor Memory Cell*

Several libraries of specifically designed metalloporphyrins with various linker lengths and anchoring units have been constructed by Bocian, Lindsey and coworkers for the design of hybrid silicon memory devices. Electrochemical studies were first performed to determine values of the k° and $\tau_{1/2}$ parameters that can be linked to values of write/erase voltage and information retention time, respectively.[22,151] Information is stored as a charge in the redox monolayer. For capacitive electrochemical cell devices, a potential is applied between the reference/counter electrode and the porphyrin-decorated metal substrate (Figure 41). Once the voltage is high enough electrons flow from the molecule to the substrate and the molecule is oxidized. When the voltage is switched off, the molecule returns

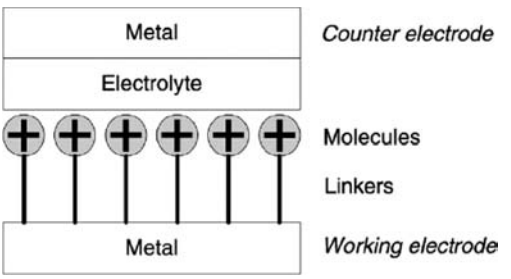


Figure 41. A typical example of molecular capacitor structure designed by Bocian, Misra and coworkers. (Adapted from Ref. 158.)

to its neutral state more or less rapidly. Initial studies were performed on capacitive cells based on metal electrodes.[152] In 2003, the substrate was switched to silicon in the design of so-called EMS (electrolyte molecule silicon) and EMOS (electrolyte molecule oxide silicon) structures.[153–155] The role of the tunnel oxide and of its thickness has been studied. The porphyrin monolayer showed good thermal stability (about 1 hour at 400 °C) and was stable upon continuous read-write cycling (10^{12} cycles).[71]

These results prompted the development of DRAM architectures (dynamic random access memory) using this hybrid technology by a startup company, ZettaCore, founded in 1999 for that purpose.[156] In brief, molecular capacitor cells offer several competitive advantages relative to the current DRAMs.[157] Self-assembly of the charge-carrying units in a single, uniform, dense monolayer, and higher charge density than in a conventional capacitor hold the key to increasing the density of DRAM in a cost-effective manner. Moreover, switching from a deep capacitor trench in conventional architectures to a flat electrochemical cell in the so-called ZettaRAM molecular capacitor is economically appealing. This will reduce the volume of the memory components on the chip, and also the lithography costs inherent to the engineering of capacitor trenches with a high aspect ratio (Figure 42). The ZettaRAM has the added benefit of being a low-power memory system.[158]

Following a similar strategy, De Salvo and coworkers have described novel types of capacitive cells in which metalloporphyrins are anchored to Si by

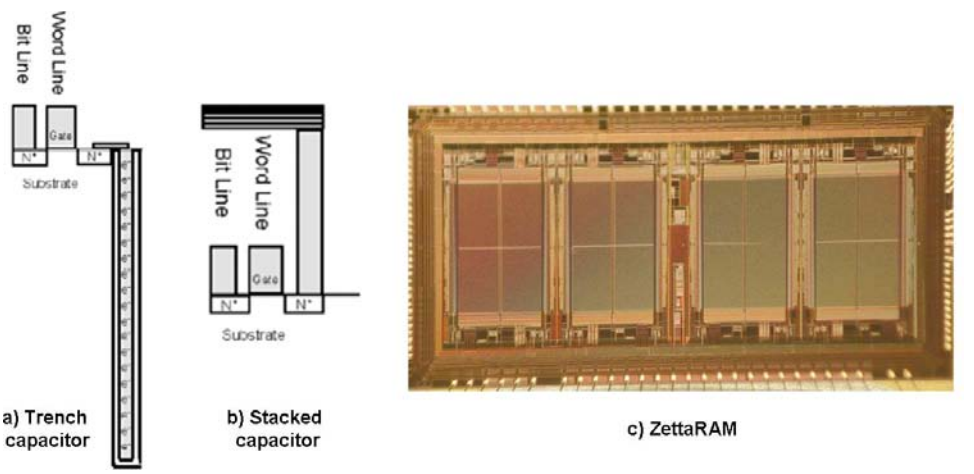

Figure 42. Examples of (a) trench and (b) stacked cell geometries for the DRAM capacitor, and (c) a photomicrograph of 1 MBit ZettaCore hybrid CMOS/molecular DRAM. (Adapted from Ref. 157.)

hydrosilylation, either in a single step or followed by a click cycloaddition.[159,160] Their potential in the design of advanced memory devices has been described,[161] and it has been highlighted in the International Technology Roadmap for Semiconductors (2009 edition).[162]

2. *Hybrid CMOS Transistor Memory*

Hybrid devices inspired from transistor and flash memory structures have been designed (Figure 43a).[163] The cell is made of a n-Si bulk with highly doped implanted p-Si source (S) and drain (D) regions. Between the S and D lies the channel above which a thin layer of SiO_2 tunnel oxide is deposited. The molecules are immobilized on the oxide layer via their phosphonate anchoring units, and this charging/discharging zone mimics the floating gate of flash memories. An electrolyte solution (or an ionic liquid) is then deposited and a metal top gate electrode is positioned in contact with the electrolyte.[164,165] All-solid pseudo-MOS hybrid silicon/molecular cells have been described (Figure 43b).[166,167]

3. *Hybrid Nanowire Transistor Memory*

An advanced memory structure obtained by immobilization of a Co porphyrin on an InO_2 nanowire linking two source and drain metallic dices (Figure 44a) has been described.[168] The procedure used to immobilize the porphyrin on the nanowire presumably generates a In–S bond. The I/V curve of the device was recorded upon

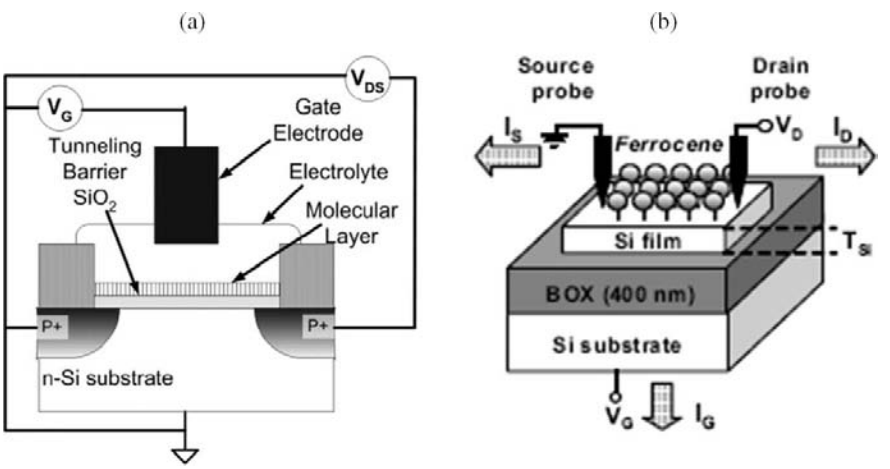

Figure 43. (a) Schematic view of a hybrid CMOS structure with a SiO_2 tunnel oxide layer. Adapted from Ref. 163. (b) An all solid pseudo-MOS device functionalized with ferrocene molecules. (Adapted from Ref. 167.)

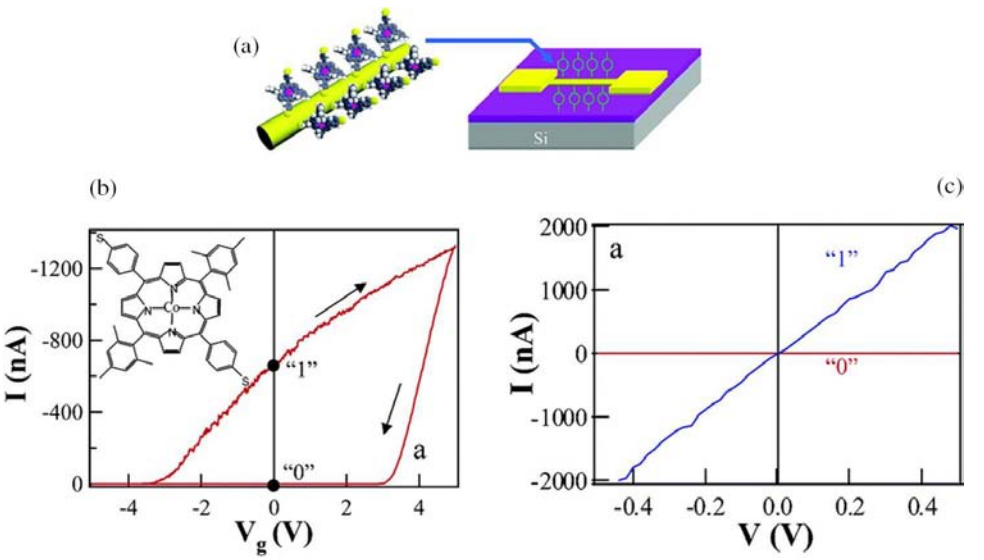

Figure 44. (a) Schematic view of a InO_2 nanowire transistor modified with a Co porphyrin SAM; (b) I/V_G characteristic recorded for this devices and (c) I/V_{DS} profile with $V_G = -0.1$ V after a write and a erase cycle leading to a "on-1" state and a "off-0" state. (Adapted from Ref. 168.)

sweeping the gate voltage (–5 V to 5 V) and recording the current in the nanowire with source-drain voltage set at 0.1 V. An important hysteresis was observed (Figure 44b). The memory states were probed by applying a positive (5 V) or a negative (–5 V) gate voltage to the Si (back gate), then the gate voltage was grounded and the memory state was identified by recording the conductance of the device through the nanowire (Figure 44c). In one case, the conductance of the nanowire varies linearly with V_{DS} and in the other case the conductance remains equal to 0. These two states correspond to an "on" and an "off" state. From the change of threshold voltage when the molecule are charged or discharged the number of electrons exchanged can be estimated (3 e^- per nm length of nanowire). The retention time was 41 seconds at room temperature, and could be increased up to hours by decreasing the temperature. The device also seemed stable upon write/erase cycling.

Similar measurements have been performed with a free base porphyrin rather than with a Co complex, and no hysteresis has been observed. This has been tentatively explained by the different natures of the oxidation sites — delocalized porphyrin orbitals in the second case vs. localized metal d orbitals in the first.

4. *Molecular Break-Junction Device*

Molecular break junctions are devices with a structure dedicated to mono-molecular electronics. A nanogap electrode is fabricated and presumably filled with a single

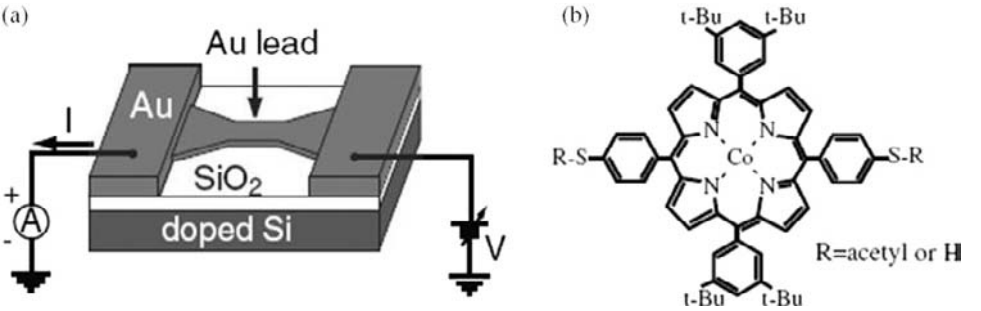

Figure 45. (a) Schematic view of the experimental setup used to study a molecular break junction on gold. The nanoscale break in the Au lead is not shown. (b) Chemical structure of molecule used to fill the nanogap. (Adapted from Ref. 169.)

molecule. A trans-A_2B_2 CoTPP derivative bearing two protected thiol anchoring units has been placed in a gold nanogap electrode (Figure 45).[169] Electron transport through the molecule has been studied.

VII. Conclusion

The wealth of chemical functionalization methods summarized in the preceding sections may lead one to consider that anchoring any porphyrin or phthalocyanine complex on any type of conductor or semiconductor is technically possible at this time. In this field again porphyrin compounds have the edge, due to their easy synthesis and derivatization. Sequential methods using the surface immobilization of a spacer and the subsequent coupling of an active molecule, such as those based on click chemistry, appear to be a major breakthrough for the anchoring of chemically or thermally sensitive molecules. A number of significant results have emerged which are of enormous interest in the design of molecular electronic devices. Due to their high stability in various redox states, porphyrin and phthalocyanine complexes faithfully play their role of charge storage sites which proves useful for information storage. Electron transport kinetics between the conductor (or semiconductor) substrate and the anchored molecule can be adjusted by changing the nature of the charge storage site (central metal or macrocyclic ring), and it can be finely tuned by modifying the nature (conjugated or not) and length of the linker. Such versatility may prove interesting for emerging technologies.

The development of hybrid silicon-molecular technologies thus seems foreseeable, but it may not be expected in the near future. A major hurdle lies in the inherent incompatibility of molecular chemistry with the techniques used for the elaboration of silicon chips. Clean room operations such as silicon etching and metal deposition require the exclusion of any possible source of contamination,

and molecular compounds and organic solvents clearly are potential contaminants. In this respect it is worth noting that in the few hybrid technologies developed so far (for the Zettaram memory cell), the anchoring of porphyrin and the steps involving molecular chemistry are conducted in the ultimate phase of the fabrication process. It will be interesting to watch the success met by this innovative product, and to see if its competitive advantages are recognized by the market.

In the meantime, molecular memory will still be viewed as a long term research goal. The knowledge base for molecular electronics obviously needs further fundamental work, which is currently under way in many laboratories all over the world.[162]

48 Bioinspired Catalysts with B_{12} Enzyme Functions

Yoshio Hisaeda and Hisashi Shimakoshi

Department of Chemistry and Biochemistry,
Graduate School of Engineering, Kyushu University,
Fukuoka 819-0395, Japan

List of Abbreviations

AB	arsenobatetaine
As_2O_3	arsenic trioxide
BDHC	1,19-dimethyl-AD-didehydrocorrin
CFC-113	1,1,2-trichloro-1,2,2-trifluoroethane
CFC-113a	1,1,1-trichloro-2,2,2-trifluoroethane
CH_3-H_4folate	N^5-methyltetrahydrofolate
Cob(II)7C_1ester	heptamethyl cobyrinate
Cob(II)7C_3ester	heptapropyl cobyrinate
1,2-DCE	1,2-dichoroethene
DDAB	didodecyldimethylammonium bromide
DDD	1,1-dichloro-2,2-bis(4-chlorophenyl)ethane
DDE	1,1-dichloro-2,2-bis(4-chlorophenyl)ethylene
DDMS	1,1′-(2-chloroethylidene)-bis(4-chlorobenzene)
DDMU	1-chloro-2,2-bis(4-chlorophenyl)ethylene
DDNU	1,1′-(ethenylidene)-bis(4-chlorobenzene)
DDO	1,1′-(ethylidene)-bis(4-chlorobenzene)
DDT	1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane
DH	dimethylglyoximato
DMA	dimethylarsinic acid
DTT	dithiothreitol
ECA	ethyl chloroacetate
GSH	glutathione
HSA	human serum albumin
HCB	hexachlorobenzene
HCH	hexachlorocyclohexane
H_2salen	*N*,*N*′-ethylenebis(salicylideneamine)

MMA	monomethylarsonous acid
PCB	pentachlorobenzene
PCE	tetrachloroethene
PFOS	perfluorooctane sulfonate
SCE	saturated calomel electrode
SHE	standard hydrogen electrode
TMAO	trimethylarsine oxide
TCE	trichloroethene
TCPP	5,10,15,20-tetrakis(4-carboxyphenyl)porphyrin
$TsOCH_3$	methyl tosylate
TTDB	2,3-dichloro-1,1,4,4-tetrakis(4-chlorophenyl)but-2-ene

I. Introduction

A. Enzymic Reactions

Vitamin B_{12} is a term found in health and nourishment studies, and has the chemical name of cyanocobalamin. However, this name is typically used for a cobalamin derivative. Vitamin B_{12} derivative denotes the cobalamin family that will be discussed in this chapter. Vitamin B_{12} derivatives consist of a cobalt atom coordinated with the tetrapyrrole ring system (corrin ring) and also linked to a heterocyclic base, 5,6-dimethylbenzimidazole, as shown in Figure 1. The corrin ring is similar to that in porphyrins, which are found in heme, chlorophyll, or cytochromes, but also different from porphyrin in that it is highly reduced and is missing one carbon atom from the carbon macro-ring. The porphyrin is a dianionic ligand; on the other hand, the corrin ring is a monoanionic ligand. Therefore, the corrin ring can stabilize the low oxidation states of the central cobalt.

Two coenzymatically active forms of vitamin B_{12} exist, i.e. adenosylcobalamin and methylcobalamin, as shown in Figure 1. The B_{12}-dependent enzymes catalyze various molecular transformations, for example, the rearrangement reactions as typified by the conversion of methylmalonyl-CoA to succinyl-CoA, the methylation reaction as in the synthesis of methionine, and the dehalogenation reaction of perchloroethylene, all as shown in Figure 2. These B_{12}-dependent enzymic reactions have been reviewed in the literature.[1–5] These reactions are very interesting from the viewpoint of organic synthesis. In this chapter, the biomimetic and bioinspired catalytic reactions with vitamin B_{12} enzyme functions are summarized.

B. B_{12} Model Complexes

Various cobalt complexes have been synthesized as model complexes of vitamin B_{12}.[6] However, all of these complexes cannot be qualified as favorable

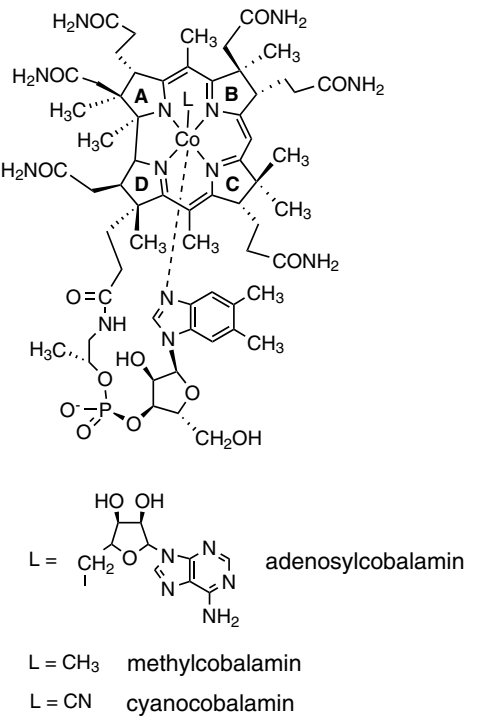

Figure 1. Structure of vitamin B_{12} derivatives.

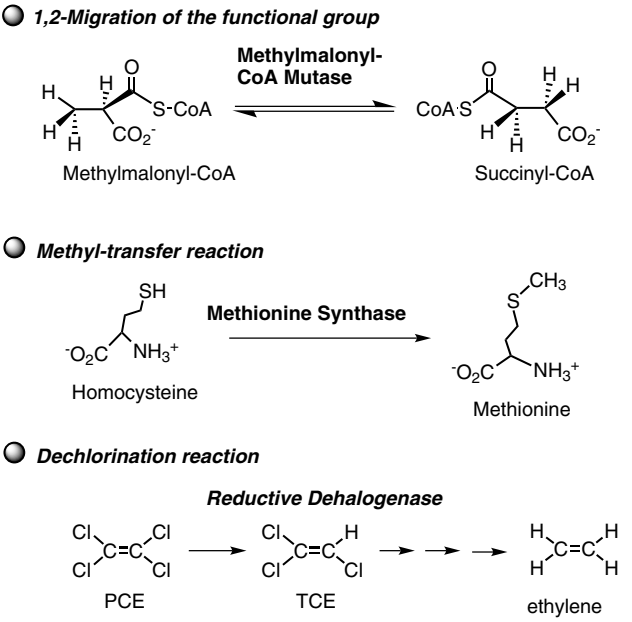

Figure 2. B_{12}-dependent enzymic reactions.

model complexes using the following criteria. (i) The redox behavior of the central cobalt, which is mainly controlled by the basicity of an equatorial ligand, must be similar to that for the naturally occurring B_{12}. (ii) The electronic properties must be equivalent to those of the natural B_{12}, which are provided by the corrin ring with eight double bonds and a direct bond between the rings A and D. (iii) The steric effects, which are caused by a methyl moiety and a hydrogen atom at the C(1) and C(19) positions in the corrin ring, respectively, may be important for the reactivity of the central cobalt.

The cobalt complexes have been extensively used not only as B_{12} models, but also as novel catalysts for organic syntheses by taking advantage of the high nucleophilicity of their univalent cobalt species. Typical model complexes are shown in Figure 3. However, most of these complexes cannot be used as functional simulations of B_{12}-dependent enzymes. For example, cobaloxime [bis(dimethylglyoximato)cobalt], [$Co(DH)_2$], which is readily prepared and frequently utilized, is capable of forming the cobalt–carbon bond with various ligands in the same manner as observed for the vitamin B_{12} derivative.[7] Nevertheless, this cobalt complex is not considered to be a good model since its redox behavior is different from that of B_{12}.[8] A cobalt complex of 1,19-dimethyl-AD-didehydrocorrin, [Co(BDHC)], has additional double bonds at the peripheral sites and an extra angular methyl group compared to the parent corrinoid.[9] This complex was found to be analogous to corrinoids on the basis of its electronic properties, but failed to simulate the reactions mediated by B_{12} because of the significant steric repulsion effect exerted by the angular methyl groups. As for the diimine-dioxime complex, [Co(DO)(DOH)pn], though this complex has a very simple structure compared to natural vitamin B_{12}, it shows redox behavior analogous to that of B_{12} with respect to the central cobalt.[10,11]

The naturally occurring apoproteins, which provide relevant reaction sites for B_{12}, are considered to perform additional important roles that lead to the desolvation and close association of reacting species. Based on this, the catalytic activity of B_{12} in hydrophobic microenvironments in order to simulate the catalytic functions of holoenzymes has shown some interesting characteristics. Under such circumstances, hydrophobic vitamin B_{12} derivatives (lipophilic derivatives), which have ester groups in place of the peripheral amide moieties of natural vitamin B_{12}, were reported.[12,13]

C. Construction of Artificial Enzymes

Naturally occurring holoenzymes are typical supramolecules composed of a specific apoprotein and an additional cofactor, such as a coenzyme or metal ions. Some artificial enzyme systems with organic/inorganic hybrid nanomaterials have

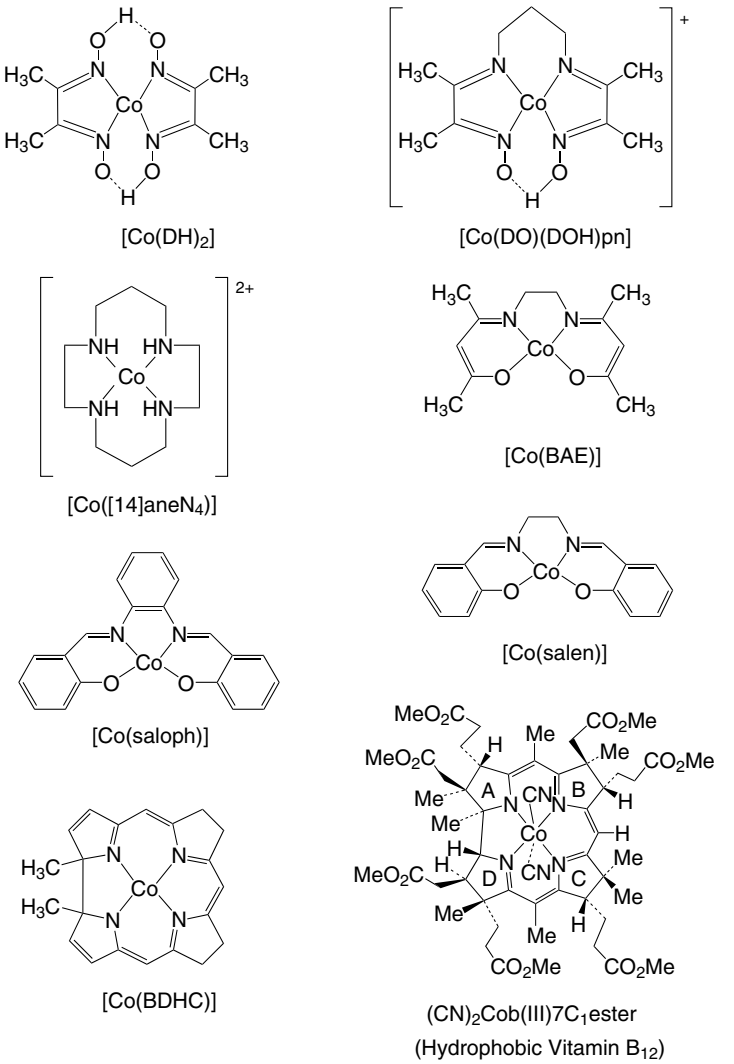

Figure 3. B_{12} derivative and model complexes.

been reported, as shown in Figure 4. One example is a vesicle-type artificial enzyme composed of peptide lipids and hydrophobic vitamin B_{12}.[14] The second example is a silica gel bearing vitamin B_{12} derivatives, formed by the sol-gel method.[15] The third is an organic/inorganic hybrid nanomaterial, i.e. human serum albumin (HSA) containing vitamin B_{12} derivatives.[16] The fourth example is a titanium dioxide–B_{12} hybrid system.[17] The electrochemical catalytic system and above

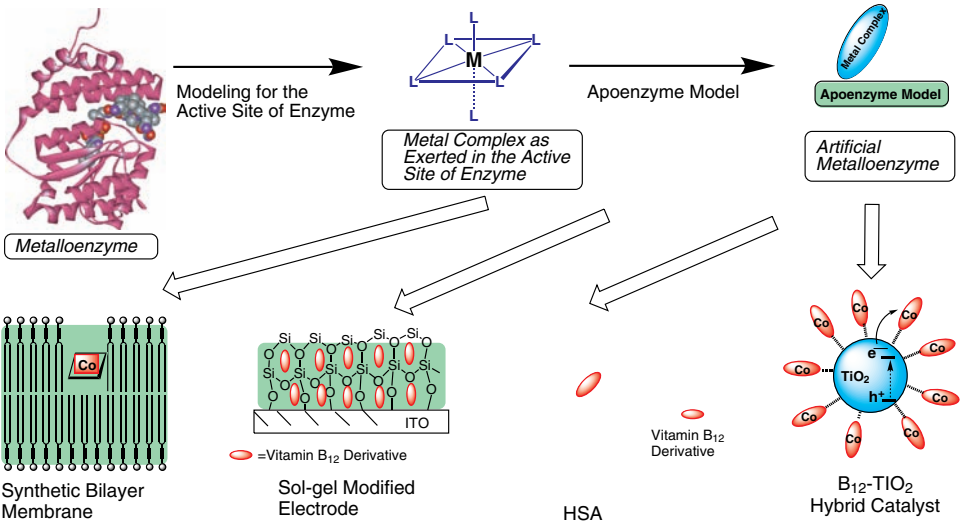

Figure 4. Artificial enzymes with organic/inorganic hybrid nanomaterials (adapted from Ref. 16).

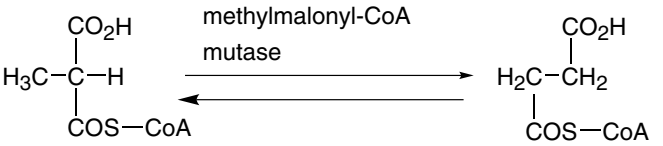
artificial enzyme systems are very useful for various molecular transformations. The catalytic simulations of B_{12} enzymes with bioinspired systems are summarized in this chapter.

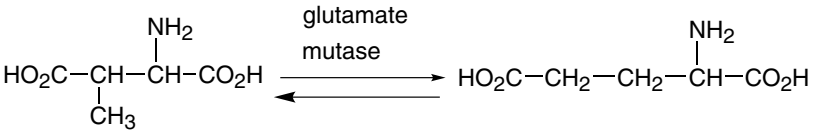
II. Bioinspired 1,2-Migration Reactions

The rearrangement reactions involve the intramolecular exchange of a functional group (X) and a hydrogen atom between neighboring carbon atoms [refer to Eq. 1].[18,19] These reactions have attracted much attention because of their novel nature from the viewpoints of organic and organometallic chemistry. Carbon-skeleton rearrangement reactions, mediated by methylmalonyl-CoA mutase, glutamate mutase, and α-methyleneglutarate mutase are shown in Eqs. 2–4.

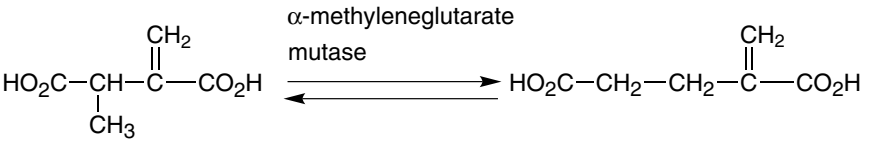
(1)



(2)



(3)

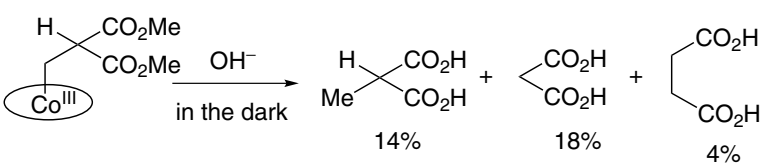


(4)

A. 1,2-Migration of Functional Groups on Cobalt Complexes

In B_{12} model reactions from the 1970s and 1980s, vitamin B_{12} derivatives or their model complexes are reduced to a super-nucleophilic Co(I) species, and alkylated complexes with the Co–C bond were obtained by reaction with the corresponding alkyl halide as the substrate. The products from the alkylated complex obtained by photolysis or thermolysis were then analyzed. Some typical and interesting reaction examples were shown as follows.

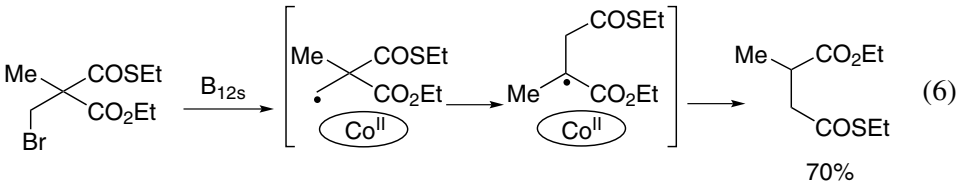
Dowd and Shapiro reported that the methylmalonate-bound cobalamin was prepared and the 1,2-migration product was obtained by the thermal cleavage of the Co–C bond at low yield as shown by Eq. 5.[20]



(5)

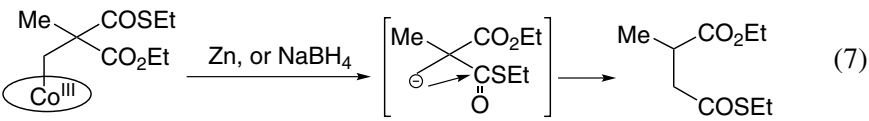
Scott and Kang reported that methylmalonyl monothiolate-bound cobalamin was prepared by the reaction between B_{12s} [Co(I) species of cobalamin] and the brominated substrate, and then the thioester-migrated product was obtained as the majority, as shown by Eq. 6.[21] This reaction is interesting from the viewpoint of

the migrating group, which is the thioester not the carboxylic ester. This tendency is similar to the enzymic reaction of methylmalonyl-CoA mutase.



(6)

Schrauzer and coworkers also reported the reaction of the methylmalonyl monothiolate-bound cobalamin that was investigated under reduced reaction conditions, and proposed a rearrangement mechanism with an anionic intermediate as shown in Eq. 7.[22] The reaction mechanism was not different from that for the enzymic reaction, but this report showed that the 1,2-migration reaction proceeded effectively via an anionic intermediate.



(7)

These reactions are interesting as pioneer model reactions for B_{12}-dependent enzymic reactions.

B. Electrochemical 1,2-Migration of Functional Groups

1. *Catalytic Simulation of Methylmalonyl-CoA Mutase*

The redox behavior of vitamin B_{12} derivatives was investigated in organic solvents, and a Co(I) species as a super-nucleophile is readily formed by electrochemical reduction.[23] On the basis of the redox behavior, the electrochemical catalytic cycles were established as shown in Figure 5. An alkylated complex, generated by the reaction of the Co(I) species and an alkyl halide, is generally decomposed by photolysis or electrolysis to afford reduction and/or rearrangement products.[24–26] One example using the hydrophobic vitamin B_{12}, [Cob(II)7C_1ester] ClO_4 (see Figure 6), is shown.

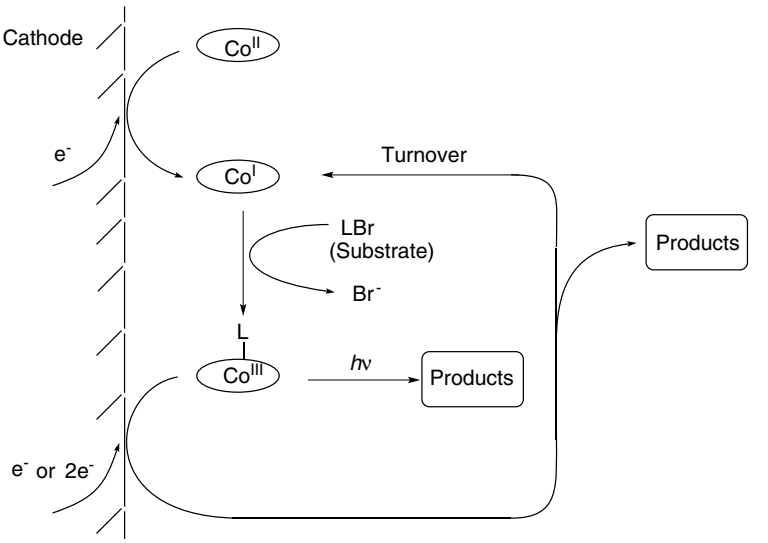


Figure 5. Electrochemical reactions mediated by B_{12} model complex.

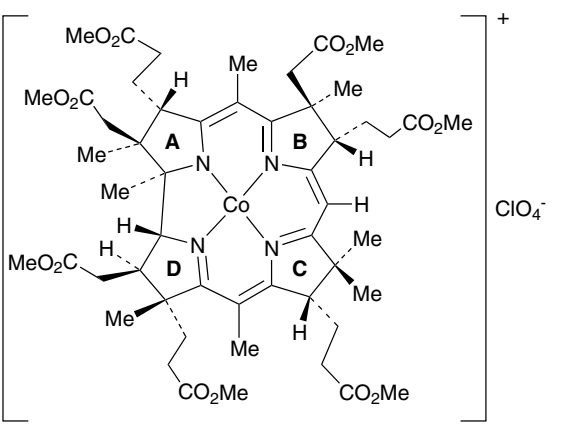

Figure 6. Structure of hydrophobic vitmain B_{12}, [Cob(II)7C_1ester]ClO_4.

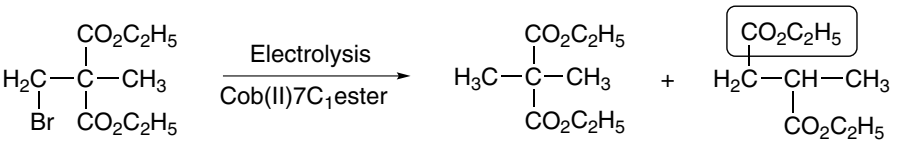
2,2-Bis(ethoxycarbonyl)-1-bromopropane has been adopted as a model substrate for methylmalonyl-CoA mutase. The redox behavior of [Cob(II)7C_1ester]ClO_4 in DMF containing the substrate was examined by cyclic voltammetry. The redox potential for the Co(II)/Co(I) couple was observed to be −0.59 V vs. SCE in the presence of the substrate. An irreversible reduction peak was observed at *ca.* −1.3 V vs. SCE and assigned to the formation of the one-electron reduction intermediate of the alkylated complex, which was generated by the reaction between the Co(I) species

and the substrate. In addition, the second irreversible reduction peak was observed at *ca.* −1.8 V vs. SCE. This peak was assigned to the formation of the two-electron reduction intermediate of the alkylated complex. This redox behavior indicates that different intermediates will be formed at −1.0 V, −1.5 V, and −2.0 V vs. SCE.

Electrolysis of the substrate was carried out after the addition of a catalytic amount of [Cob(II)7C_1ester]ClO_4 in DMF under various conditions (refer to Eq. 8).[26] The catalysis was quite efficient at −2.0 V vs. SCE as reflected in the yields of the rearrangement product.



(8)

1) -1.0 V vs. SCE (hv)	10%	trace
2) -1.5 V vs. SCE	30%	trace
3) -1.5 V vs. SCE (AcOH)	17%	43%
4) -2.0 V vs. SCE	15%	80%

Reaction mechanisms involved in the controlled-potential electrolysis have been investigated by various spectroscopic methods.[25,26] The results are consistent with the overall feature of the electrolysis shown in Figure 7. At −1.0 V vs. SCE, the divalent cobalt complex is first converted into the corresponding univalent cobalt species by electrochemical reduction. The alkylated complex is subsequently formed by reaction of the super-nucleophilic Co(I) species with the alkyl halide. The complex is then decomposed by visible light to give the Co(II) species and the alkyl radical, and the latter abstracts a hydrogen atom to afford the simple reduction product. At −1.5 V vs. SCE, the alkylated complex is further reduced to form the one-electron reduction intermediate in the dark. The electronic structure of the intermediate seems to be represented by two canonical forms. A proton attack on the β-carbon of the substrate induces the carbon-skeleton rearrangement, followed by the cobalt–carbon bond cleavage. On the other hand, the one-electron reduction intermediate is spontaneously decomposed to the Co(I) chelate and the alkyl radical in the absence of an efficient proton source. The reduction product is mainly derived from the alkyl radical by rapid abstraction of a hydrogen atom. At −2.0 V vs. SCE, the alkylated complex is converted into the two-electron reduction intermediate in the dark. This intermediate is decomposed to the Co(I) chelate and an anionic species, and the rearrangement product is obtained from the latter. Since the identical radical species, which is produced by the reaction of the present substrate with tributyltin hydride or by photolysis of the

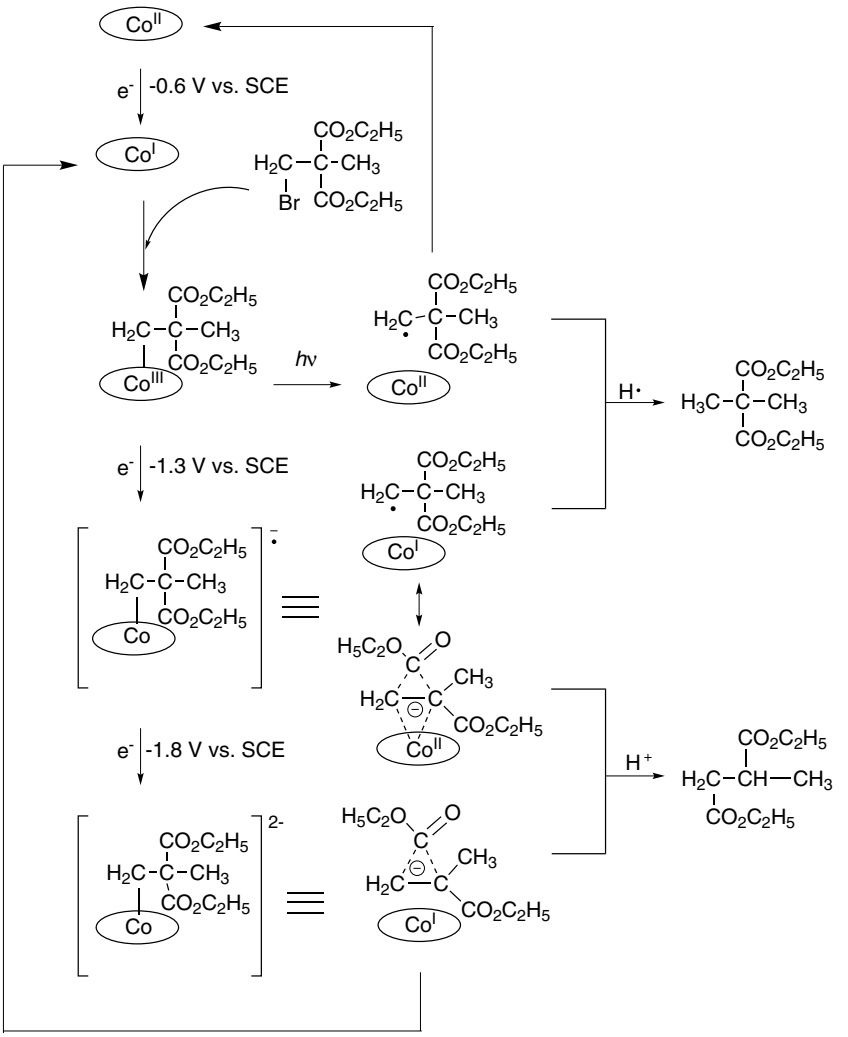


Figure 7. Overall electrochemical catalytic reactions mediated by hydrophobic vitamin B_{12} (adapted from Ref. 26).

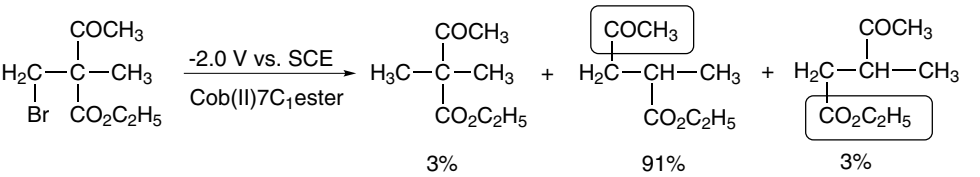
present substrate bound to cobaloxime, does not undergo the rearrangement reaction,[27] both of the anionic reduction intermediates given in Figure 7 are the primary sources for the rearrangement product.

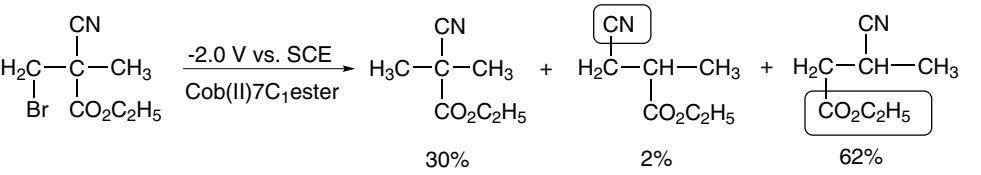
2. *Catalytic 1,2-Migration of Functional Groups*

In order to further characterize the catalytic proficiency of the hydrophobic vitamin B_{12} and to clarify the migratory aptitude of functional groups in the electrochemical rearrangement reaction, several kinds of substrates were also

used.[26] These substrates and the corresponding products are summarized in Eqs. 9 and 10. Substrates with two electron-withdrawing groups on the β-carbon atom tend to give the corresponding rearrangement products that are derived from the individual migration of the groups. Based on these results, the apparent migratory aptitude of electron-withdrawing groups decreases in the following sequence: COR > CO_2R > CN. Both steric bulkiness and the electronic character of the migrating groups are responsible for this tendency.

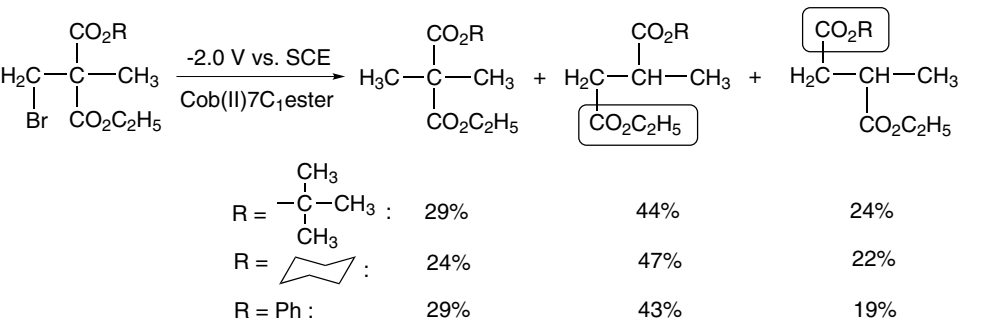


(9)



(10)

The steric effect in the carbon-skeleton rearrangement catalyzed by [Cob(II)7C_1ester]ClO_4 was investigated under the same conditions.[28] The controlled-potential electrolyses of alkyl halides having two carboxylic ester groups of different bulkiness on the same carbon atom were carried out in DMF (see Eq. 11). As for the correlation between the bulkiness of an ester group and migratory aptitude, a smaller ester group tends to migrate to the adjacent carbon atom more readily than a larger one. This steric effect is determined by the stereo-electronic effect.

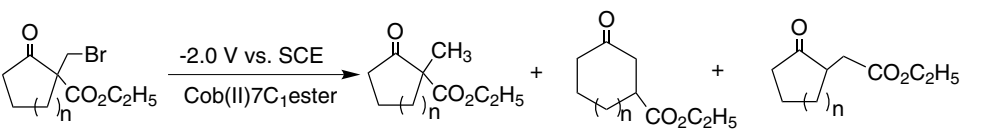


(11)

3. *Ring-Expansion Reactions*

Although naturally occurring B_{12}-dependent enzymes do not catalyze ring-expansion reactions, such reactions are mediated by vitamin B_{12} model complexes under electrochemical conditions. The ring-expansion of cyclic α-(bromomethyl)-β-keto esters by one carbon unit has been examined extensively by generating radical species with Bu_3SnH.[29–32] Torii and coworkers investigated the ring-expansion reactions of 2-alkyl-2-(bromomethyl)cycloalkanones, which have 5- and 6-membered rings, mediated by cobaloxime in methanol by constant-current electrolysis under irradiation with visible light.[33] Other ring-expansion reactions can be applied to vitamin B_{12} derivatives. [Cob(II)7C_1ester]ClO_4 was utilized to catalyze ring-expansion reactions under controlled-potential electrolysis conditions.

The electrolyses of alkyl halides with a cyclic ketone (5-, 6-, 7-, and 8-membered rings) and an ester group were carried out in DMF in the presence of [Cob(II)7C_1ester]ClO_4 at –2.0 V vs. SCE (see Eq. 12).[34] A simply reduced product, a ring-expanded product, and an ester-migrated product were reported. The major product was a ring-expansion product for all the substrates. The following facts became obvious based on these data: (i) The ring-expansion reactions are effectively catalyzed by the hydrophobic vitamin B_{12}. (ii) As for the reactivity of the substrates, an alicyclic ketone with a larger ring size (8-membered one) is less reactive than those with the smaller ring sizes (5-, 6-, and 7-membered). The formation of an alkylated complex with the substrate ($n = 4$) seems to be less favorable relative to that with other substrates due to steric reasons. (iii) As for the product selectivity, the major products are the ring-expanded ones for all substrates. Even when numbered substrates ($n = 2$ and 4) are used, ester-migrated products are obtained to some extent. Since the 6-membered ring is structurally stable, the 5-membered substrate ($n = 1$) readily afforded the ring-expansion product. On the other hand, the molar ratios of the nonexpanded products vs. the ring-expansion product are much higher for reactions with the 6-membered substrate ($n = 2$) than those for the other reactions.



n = 1 (5-membered ring)	1.5%	43%	0%
n = 2 (6-membered ring)	14%	49%	12%
n = 3 (7-membered ring)	3%	44%	trace
n = 4 (8-membered ring)	2%	21%	4%

(12)

C. Artificial Enzymes Composed of Apoenzyme Model and B_{12} Model Complexes

Various cobalt complexes have been synthesized as model complexes of B_{12}.[35] The naturally occurring apoproteins, which provide relevant reaction sites for vitamin B_{12}, are considered to perform additional important roles that lead to the desolvation and close association of the reacting species.[36,37] Based on this concept, the activity of B_{12} in hydrophobic microenvironments has been studied in order to simulate the catalytic functions of holoenzymes.

One interesting example is a cyclophane-type B_{12} artificial enzyme that is constructed with a combination of an octopus cyclophane and a hydrophobic vitamin B_{12} (Figure 8).[27,38–41] The hydrophobic vitamin B_{12} is noncovalently incorporated into the octopus cyclophane in a 1:1 molar ratio by a hydrophobic interaction. The vesicle-type B_{12} artificial enzyme has also been reported as another example.[42–46] This artificial B_{12} enzyme is noncovalently constructed with a combination of a single-walled bilayer vesicle composed of $N^{+}C_5Ala2C_{16}$ and

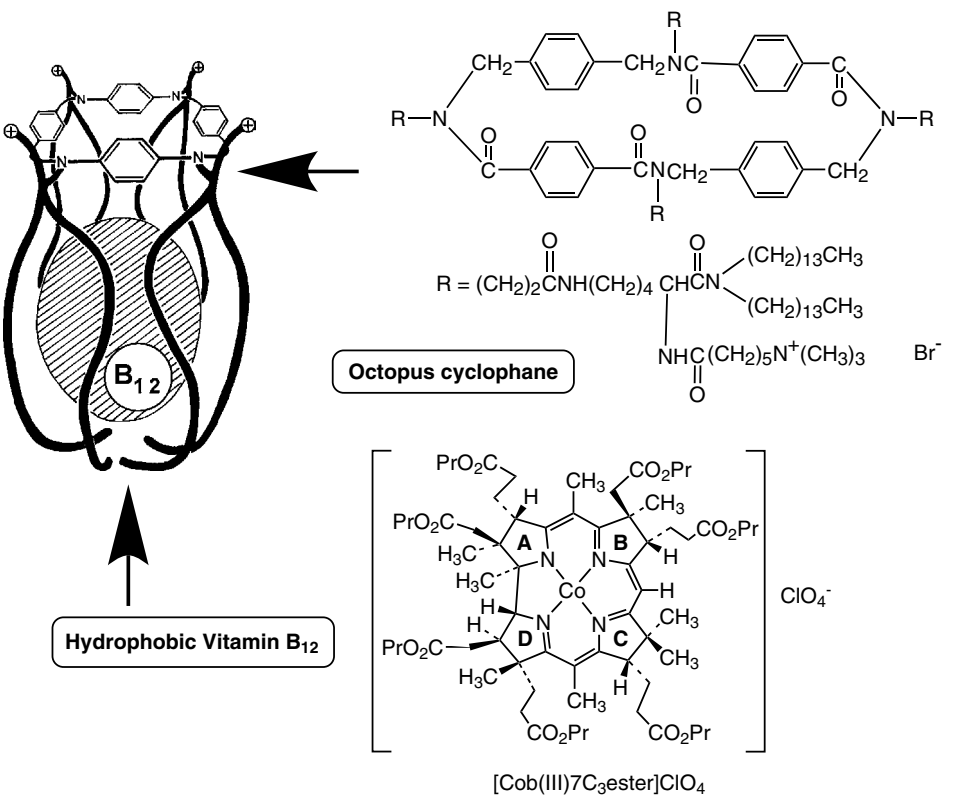


Figure 8. Cyclophane-type B_{12} artificial enzyme.

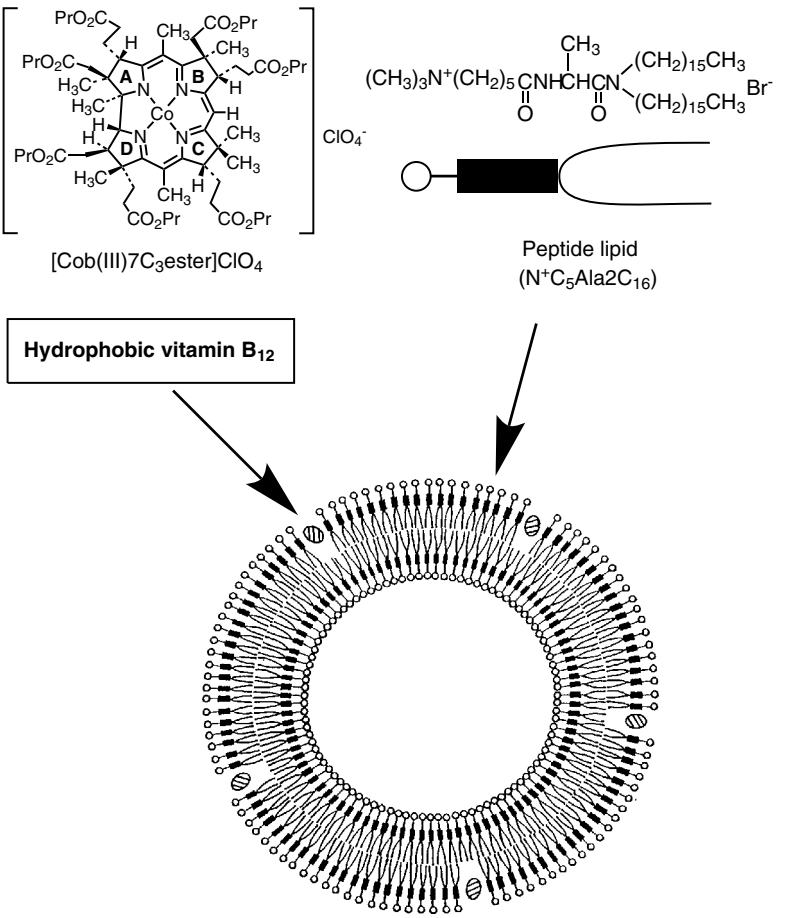

Figure 9. Vesicle-type B_{12} artificial enzyme.

the hydrophobic vitamin B_{12} (Figure 9). The morphological stability of the synthetic bilayer vesicle is not perturbed by the noncovalent incorporation of the hydrophobic vitamin B_{12}.[14,44] The model reactions of methylmalonyl-CoA mutase and glutamate mutase using artificial enzymes are outlined in the following section.

1. *Methylmalonyl-CoA Mutase-like Reactions*

Methylmalonyl-CoA mutase catalyzes the interconversion of methylmalonyl-CoA and succinyl-CoA. A characteristic aspect of the substrate, methylmalonyl-CoA, is that it has two electron-withdrawing groups on the same carbon atom. Successful model reactions have been reported in some papers.[27,44] The electrochemical

1,2-migration reactions proceed via anionic intermediates as described earlier. On the other hand, 1,2-migration reactions proceed via radical intermediates in artificial enzymes such as the cyclophane- and vesicle-type. Substrate species were bound to the hydrophobic vitamin B_{12} at one axial site of the nuclear cobalt, and the resulting alkylated complexes were noncovalently fixed in the bilayer membrane domain in aqueous media and then irradiated with visible light, resulting in the homolytic cleavage of the Co–C bond. Some typical experimental results are shown in Eqs. 13–16 and compared with the data obtained for the reactions in homogeneous solution. The apparent migratory aptitude of the electron-withdrawing groups was observed to increase as follows: CN ≈ $CO_2C_2H_5$ < $COCH_3$. The rearrangement reactions, which are slow in homogeneous solution, readily proceed in the vesicle by the cage effect of the apoenzyme model. Such microenvironmental effects provided by the bilayer membrane become more pronounced when the hydrophobic vitamin B_{12} is covalently bound to the lipid species.[47–51] A simpler artificial vitamin B_{12} holoenzyme has been constructed by combination of a bilayer membrane and a simple B_{12} model complex using the same procedure.[52,53]

(16)

The above reactions are stoichiometric rather than catalytic, even though the substrate species undergoes isomerization. In order to improve this situation, an effective process for activation of the substrates was coupled with the catalytic mediator composed of [Cob(II)7C_3ester]ClO_4 and the N^+C_5Ala2C_{16} vesicle.[44] An appropriate amount of [Cob(II)7C_3ester]ClO_4 and a large excess of vanadium trichloride were dissolved in an aqueous medium containing the N^+C_5Ala2C_{16} vesicle and an appropriate excess of the substrate. The solution was irradiated with visible light under aerobic conditions. The overall reaction cycle is shown in Figure 10. A substrate is activated by vanadium(III) ions and molecular oxygen,[54–57] and the resulting radical species undergoes coupling with [Cob(II)7C_3ester]$^+$ to afford the corresponding alkylated complex. The alkylated complex is subjected to homolytic cleavage to give the original substrate and the isomerized products, the former being subjected to catalysis. Similar reactions occur in the cyclophane-type artificial enzyme.[39,39]

The following aspects became apparent from these investigations. (i) A combination of vanadium trichloride and atmospheric oxygen abstracts a hydrogen atom from the terminal methyl group of a substrate species to

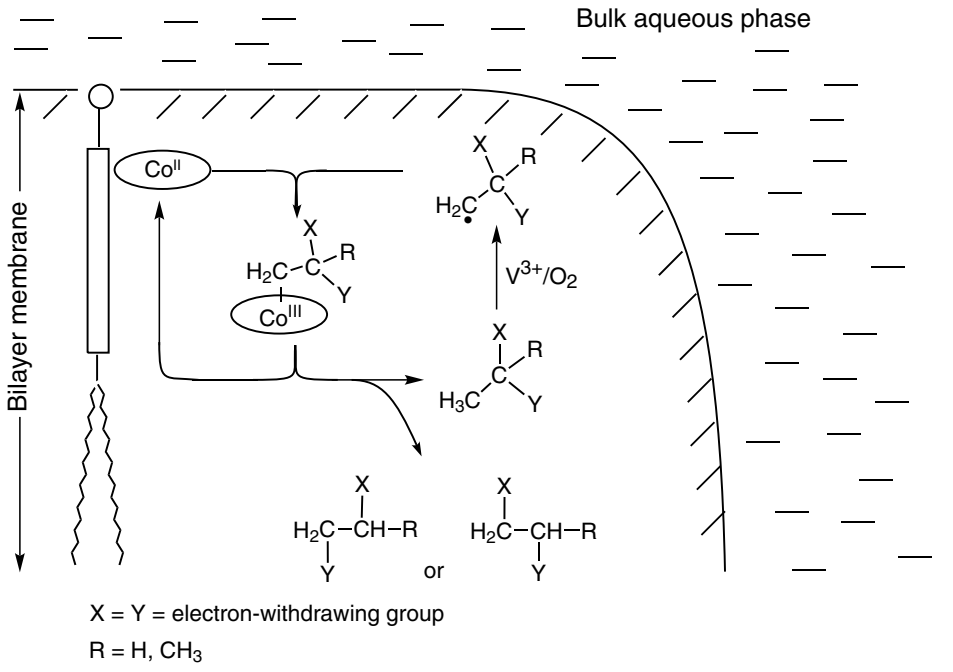

Figure 10. 1,2-Migration reactions activated by V^{3+}/O_2 in vesicle-type B_{12} artificial enzyme (adapted from Ref. 44).

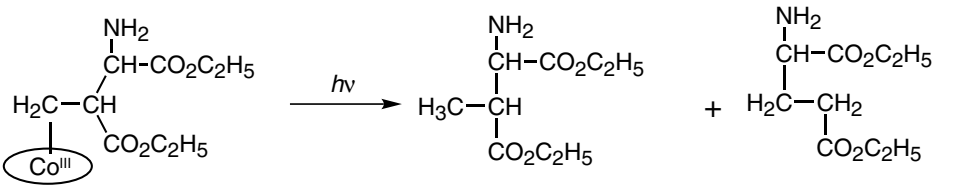
form the corresponding radical species, which then undergoes a reaction with $[Cob(II)7C_3ester]^+$ to form the Co–C bond. (ii) Since both suppression of the molecular motion and desolvation effects operate on the chemical species incorporated into the bilayer vesicle, $[Cob(II)7C_3ester]^+$ and the substrate radical, which are produced by homolytic cleavage of the Co–C bond upon photolysis, must form a tight pair. Under such conditions, the nuclear cobalt promotes the 1,2-migration of the electron-withdrawing groups. This artificial holoenzyme is expected to be applied to other nonenzymatic reactions that undergo similar reaction mechanisms.[44]

2. *Glutamate Mutase-like Reactions*

Glutamate mutase mediates the interconversion of methylaspartic acid and glutamic acid. A model reaction with the apoenzyme functions has been reported.[43,45] Diethyl methylaspartate was bound to the hydrophobic vitamin B_{12}, and the resulting alkylated complex underwent homolytic cleavage of the Co–C bond upon

irradiation with visible light. It is apparent from Eq. 17 that the isomerization reaction takes place only in the apoenzyme models.



Methanol	83%	0%

Vesicle	66%	14%
Cyclophane	68%	15%

(17)

The overall reaction sequence mediated by the artificial glutamate mutase in the single-walled bilayer vesicle is illustrated in Figure 11; a substrate bound to a hydrophobic vitamin B_{12} undergoes the homolytic Co–C bond cleavage upon irradiation with visible light, the generated substrate radical is converted into the product radical, and the product radical abstracts a hydrogen atom from its vicinity to produce the final product.

Which functional group preferentially migrates to the neighboring carbon atom, the glycyl group or the carboxylic ester, in a reaction mediated by the artificial glutamate mutase? It became clear by utilizing a deuterated substrate that the glycyl group predominantly migrates in a similar manner as observed for the corresponding enzymic reaction, as shown in Eq. 18.[46] Dowd and coworkers observed that the β-methylaspartate-glutamate rearrangement readily took place via formation of a ketimine Schiff base derivative of diethyl β-methylaspartate, as mediated by vitamin B_{12}. Based on these results, they suggested the possible formation of

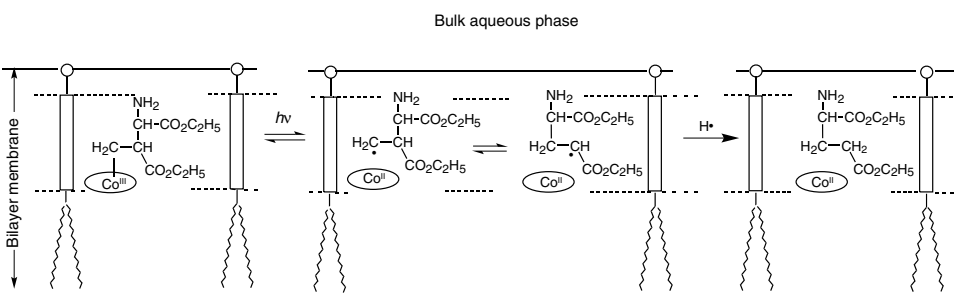

Figure 11. Overall reaction sequence in artificial glutamate mutase.

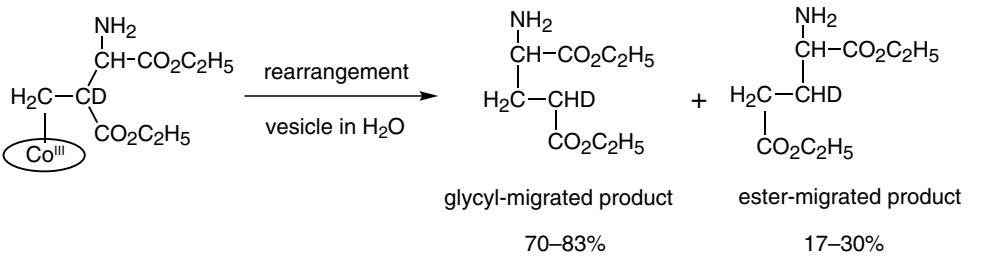
such a Schiff base intermediate in the corresponding enzymic reaction.[58,59] However, the glycyl group can migrate without the Schiff base formation in the apoenzyme model, though the yield is relatively low under the stated conditions.



(18)

3. *Other Carbon-Skeleton Rearrangement Reactions*

Even though naturally occurring B_{12}-dependent enzymes do not catalyze ring-expansion reactions, such reactions are mediated by artificial enzymes under experimental conditions comparable to those applied in the abovementioned reactions. The reactions shown by Eqs. 19 and 20 were carried out in various media under anaerobic irradiation by visible light. The products, 2-methyl-1,3-cyclopentanedione (simple reduction product), 1,4-cyclohexanedione (ring-expansion product), 3-methyl-2-pyrrolidinone (simple reduction product) and 2-piperidinone (ring-expansion product), were obtained. These results indicated that the conversions of the 5-membered ring compounds into the corresponding 6-membered products take place much more favorably in the vesicle or the octopus cyclophane, relative to those in methanol and benzene.[38,60]

III. Bioinspired Methyl Transfer Reactions

The methyl transfer reaction in methionine synthase catalyzed methylation at the sulfur of homocysteine using a methyl group from N^5-methyltetrahydrofolate (CH_3-H_4folate), which leads to tetrahydrofolate and methionine.[2] This reaction is also very interesting from the viewpoint of organic synthesis.

A. Methyl Transfer to Alkylthiols

The cobalamin-dependent methionine synthase that catalyzed the above methyl transfer reaction is one major role for the B_{12} coenzyme as shown in Figure 12. The cobalamin cofactor plays an integral role in methyl transfer, accepting methyl groups from CH_3-H_4folate and donating them to the homocysteine. During catalytic turnover, the cofactor cycles between the methylcobalamin and cob(I)alamin forms, alternately demethylated by homocysteine and remethylated by CH_3-H_4folate.[61]

It is difficult to achieve an efficient methyl transfer cycle under nonenzymatic conditions. Therefore, in model studies the methyl transfer cycle was often divided into two parts: the first half-reaction involving the methyl transfer from CH_3-H_4folate to cob(I)alamin, and the second half-reaction involving the methyl transfer from methylcob(III)alamin to homocysteine.[62] Zn^{2+} ions have been considered by many researchers to be the essential cofactor in this enzymic reaction.[63–65]

For the complete methyl transfer cycle, Keese, Darbre and coworkers in a pioneering study, reported that the methylated vitamin B_{12} derivatives involve the model methyl transfer reactions from methylamines to 1-hexanethiol in the presence of Zn and $ZnCl_2$ in refluxing ethanol.[66] They found that the methyl

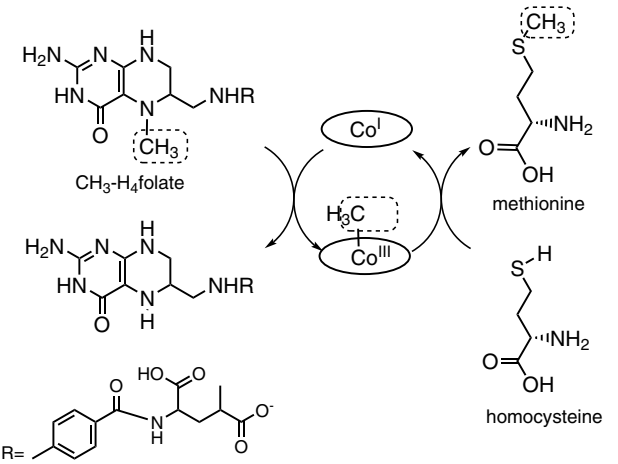

Figure 12. Catalytic cycle of methionine synthase.

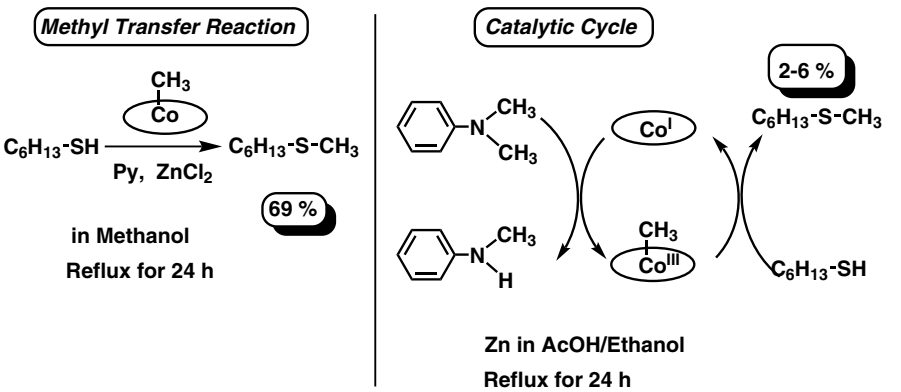

Figure 13. Model reaction of methionine synthase.

transfer reaction from methyl heptamethyl cobyrinate to 1-hexanethiol occurs in the presence of pyridine and $ZnCl_2$ in a 69% yield. They then used *N,N*-dimethylaniline as the methyl source, and constructed the catalytic cycle as shown in Figure 13. The methyl group first transfers to the Co(I) species from *N,N*-dimethylaniline to form methyl heptamethyl cobyrinate, and then it transfers to 1-hexanethiol. The authors carried out this reaction in the presence of Zn powder in acetic acid/ethanol under reflux conditions. The total yield of the hexyl methyl sulfide was about 6% based on the vitamin B_{12} derivative. The low yield may be attributed to the activity conflict between the methyl donor and methyl acceptor in the same environment, especially under neutral conditions.

A catalytic methyl transfer reaction from methyl tosylate ($TsOCH_3$) to 1-octanethiol mediated by heptamethyl cobyrinate perchlorate, [Cob(II)7C_1ester]ClO_4, was reported using an electrochemical method with a sacrificial Zn electrode as shown in Figure 14.[67] The catalytic methyl transfer reaction effectively proceeded under continuous controlled-potential electrolysis at −1.0 V vs. Ag/AgCl at 50 °C in the dark with a carbon-felt cathode and a sacrificial Zn-plate anode. Turnover behavior was observed for the first time under nonenzymatic conditions. During the electrolysis, Zn^{2+} ions from the sacrificial zinc plate anode played essential roles in the catalytic cycle. The mechanism for such methyl transfer reactions, as shown in Figure 15, was clarified by product analysis, electronic spectroscopy and ESR spin-trapping experiments, as well as cyclic voltammetry.[68] The formation

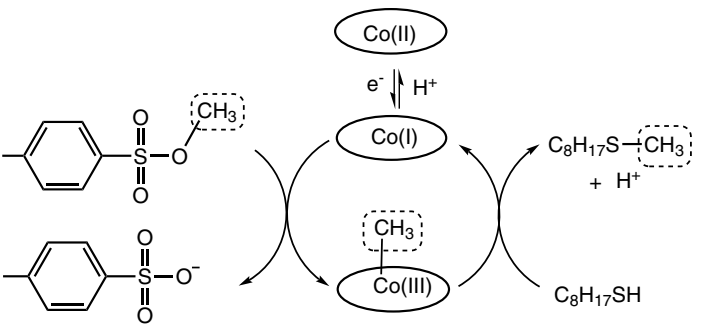

Figure 14. Methyl transfer cycle from methyl tosylate to 1-octanethiol catalyzed by B_{12} model complex (adapted from Ref. 67).

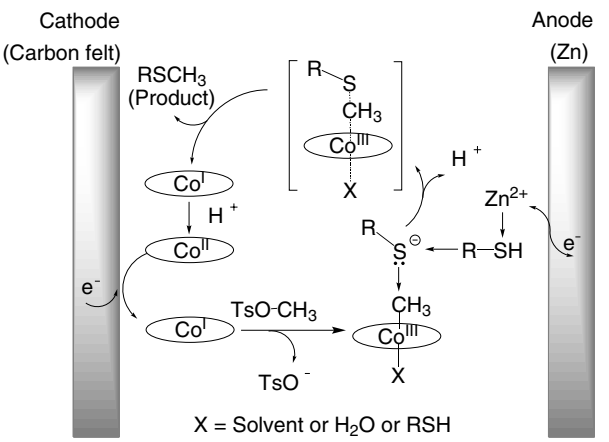

Figure 15. Mechanism of electrochemical methyl transfer reaction catalyzed by B_{12} model complex (adapted from Ref. 68).

and cleavage of the CH_3–Co bond is the indispensable intermediate during the catalytic methyl transfer reaction. Continuous electrolysis at −1.0 V vs. Ag/AgCl in the presence of $TsOCH_3$ insured a continuous Co(I) species, which facilitated the formation of the CH_3–Co intermediate by the reaction with methyl tosylate. Under thermodynamic conditions, with the help of Zn^{2+} and the interaction between the CH_3–Co bond and the activated 1-octanethiol, the CH_3–Co bond was cleaved, resulting in the methyl group transferred to the 1-octanethiol to form the methylated product. The Co(I) species formed may react with the proton from 1-octanethiol to form the Co(II) species. The catalyst will then be activated to the Co(I) species under electrochemical conditions.

B. Methyl Transfer to Inorganic Arsenics

Inorganic arsenic has caused serious chronic diseases through environmental pollution.[69] However, some methylated arsenic compounds, especially trimethylarsine oxide (TMAO) and arsenobatetaine (AB), have much lower toxicities than arsenic trioxide (As_2O_3). The acute toxicity of AB, as determined from animal experiments, is approximately one three-hundredth of that of arsenic trioxide.[70] Meanwhile, in marine ecosystems, inorganic arsenicals are biologically methylated through the food chain, which involves a methyltransferase and a reductase.[71–73] An interesting application of the methyl transfer reaction with vitamin B_{12} to the detoxification system for inorganic arsenic has been reported. A new synthetic pathway was designed for the transformation of arsenic trioxide into arsenobatetaine via trimethylarsine oxide, as shown in Figure 16.[74,75] It is a new and selective detoxification method for inorganic arsenic, which is the biomimetic methylation of arsenic trioxide (As_2O_3) to give trimethylarsine oxide (TMAO).

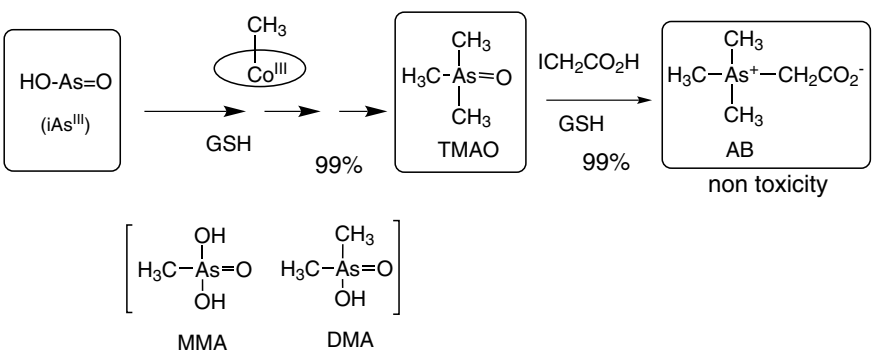

Figure 16. Methylation and detoxification of inorganic arsinic by methylated vitamin B_{12} derivative.

The methylation reaction of As_2O_3 was performed at 37 °C for 24 hours in an aqueous buffer solution using methyl heptamethyl cobyrinate as the methyl donor, in the presence of glutathione (GSH).[75] More than 98% of the arsenic trioxide (As_2O_3) was methylated to monomethylarsonous acid (MMA) 56%, dimethylarsinic acid (DMA) 41% and TMAO 1.4%. The generation of TMAO was not observed when methylcobalamin was used as the methyl donor under the same conditions.[76–78] Such activation may partly contribute to the interaction of GSH and the methylated hydrophobic vitamin B_{12}, which was observed by electronic spectroscopy. When such a methylation was performed at 100 °C in an aqueous buffer solution for 2 hours in the presence of glutathione with methyl cobyrinic acid as the methyl donor, the arsenic trioxide (As_2O_3) was almost quantitatively methylated to TMAO (99%).[74] This is the first report of the selective conversion of arsenic trioxide into TMAO using an artificial cofactor.

TMAO was quantitatively converted into AB in the presence of GSH and iodoacetic acid in an aqueous buffer solution at 37 °C.[74] The vitamin B_{12} derivatives and the GSH that are used in this detoxification method are safe and environmentally friendly materials. This method for the detoxification of inorganic arsenics could be used for the prevention of poisoning by inorganic arsenical compounds that are present in well water, which has been a widespread cause of chronic poisoning by arsenic.

IV. Bioinspired Dehalogenation Reactions

Vitamin B_{12}-dependent enzymes catalyze various molecular transformations that are of particular interest from the viewpoint of organometallic and catalytic chemistry. One of the most significant properties of the corrinoid compound (B_{12}) is the high nucleophilicity toward several organic halides to form an alkylated complex via dehalogenation. Much attention has been focused on such reductive dehalogenation reactions because of their potential application for the treatment of halogenated solvent wastes as well as for environmental remedial methods.[79] Within the past few decades, it has been demonstrated that certain bacteria can use tetrachloroethene as an electron acceptor by reducing it to *cis*-dichloroethene via trichloroethene and H_2 as an electron donor for energy conservation (dehalorespiration) (Figure 17).[80–83] Reductive dehalogenase isolated from the anaerobic bacteria contains the corrinoid compound as a cofactor.[84,85] Thus, the substantial ability of the corrinoid compound (B_{12}) to accomplish reductive dehalogenation prompted many researchers to investigate the catalysis of B_{12} for the degradation of various organic halides. Furthermore, efforts to clarify a mechanism for reductive dehalogenation of polychloroethylene in an enzymatic process have been reported using several model systems.[86–97] This

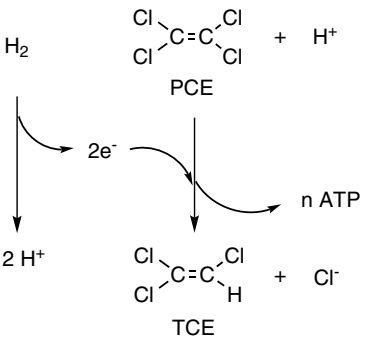

Figure 17. Scheme of dehalorespiration with H_2 as electron donor and tetrachloroethene as electron acceptor.

section highlights the catalytic dechlorination of chlorinated organic compounds by B_{12} and its models.

A. Reduction of Organic Halides by B_{12} Derivatives

In an early study, the reaction of the Co(I) state of B_{12} (vitamin B_{12s}) with various alkyl halides was investigated by kinetic experiments using sodium borohydride as the reducing reagent.[98,99] The nucleophilicity of vitamin B_{12s} was evaluated using Pearson's nucleophilic reactivity constants, n_{CH_3I} (Table 1).[100] Vitamin B_{12s} was recognized as a powerful nucleophile. Thus, the reductive dechlorinations of chlorinated organic molecules catalyzed by B_{12} derivatives were achieved using various chemical reductants. The catalytic and stoichometric reactions of two insecticides, mirex (1,1a,2,2,3,3a,4,5,5a,5b,6-dodecachlorooctahydro-1,3,4-metheno-1*H*-cyclobuta-[cd]pentalene) and kepone (1,1a,3,3a,5,5a,5b,6-decachlorooctahydro-1,3,4-methano-2*H*-cyclobuta[cd]pentalen-2-one) were conducted using vitamin B_{12s} in the presence of some reductants (either $NaBH_4$, 1-thioglycerol, 2,3-dimercaptopropanol, or

acetoin in alkali) (Figure 18).[101] A titanium(III) citrate was commonly used as the water-soluble reductant for the B_{12} activation. Chlorinated methanes, chlorinated ethylenes and ethanes, such as carbon tetrachloride, chloroform, dichloromethane, chloromethane, tetrachloroethylene, trichloroethylene, *cis*-dichloroethylene, *trans*-dichloroethylene, 1,1-dichloroethylene, vinyl chloride, trichlorofluoroethane, hexachloroethane, pentachloroethane, 1,1,1,2-tetrachloroethane, 1,1,2,2-tetrachloroethane, and 1,1,1-trichloroethane were dechlorinated to the corresponding alkanes and alkenes, catalyzed by cyanocobalamin (vitamin B_{12}) (Figure 19).[102–111] Toxaphene, a complex organochlorine pesticide mixture formed by the chlorination of camphene, was also dechlorinated by dicyanocobinamide and cyanocobalamin (Figure 20).[112] The most persistent metabolite in the environmental sample of toxaphene, 2-exo,3-endo,6-exo,8,8,10-hexachlorobornane, was also transformed. Reductive dechlorination of α-,β-,δ-,γ-hexachlorocyclohexane (HCH) isomers by

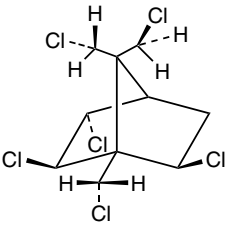

Figure 20. Structure of 2-*exo*, 3-*endo*, 6-*exo*, 8,9,10-hexachlorobornane.

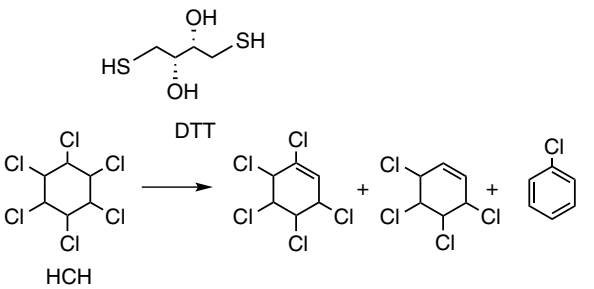

Figure 21. Dechlorination of hexachlorocyclohexane (HCH) by hydroxocobalamin/DTT system.

hydroxocobalamin was carried out in the presence of titanium(III) citrate (–0.48 V vs. SHE, pH above 7.3) and dithiothreitol (DTT) (–0.33 V vs. SHE, pH 7).[113,114] The reaction profiles for the dechlorination of HCH were dependent on the reductant. When DTT was used as the external electron source, α- and γ-HCH were transformed into pentachlorocyclohexane, tetrachlorocyclohexane, and chlorobenzene, whereas chlorobenzene was detected in all the HCH dechlorination systems together with small amounts of pentachlorocyclohexane and tetrachlorocyclohexane when titanium(III) citrate was used as the reductant (Figure 21).

The reductive dechlorination using the DTT/cyanocobalamin system was also applied to the degradation of carbon tetrachloride.[115] The Co(II) form of B_{12} (vitamin B_{12r}) was expected to be the predominant cobalt species that reacts with the organic halide, while cob(I)alamin (vitamin B_{12s}) did not participate in the reaction since DTT is a weak reductant. Therefore, the one-electron reduction of vitamin B_{12} followed by atom transfer to form the cobalt-trichloromethyl intermediate was proposed for the dechlorination mechanism (Figure 22).

As a thiol reductant, cysteine (–0.21 V vs. SHE, pH 7) was used for the carbon tetrachloride transformation mediated by cyanocobalamin.[116] The Co(II) form of B_{12} (vitamin B_{12r}) exhibited little reactivity toward carbon tetrachloride in the

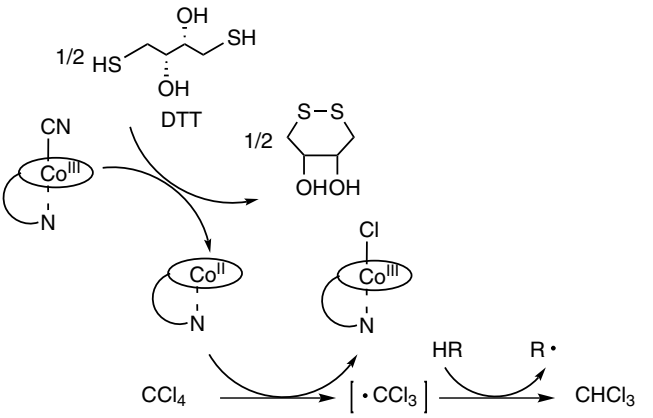

Figure 22. Proposed mechanism of CCl_4 reduction to $CHCl_3$ in the B_{12}-DTT system (adapted from Ref. 115).

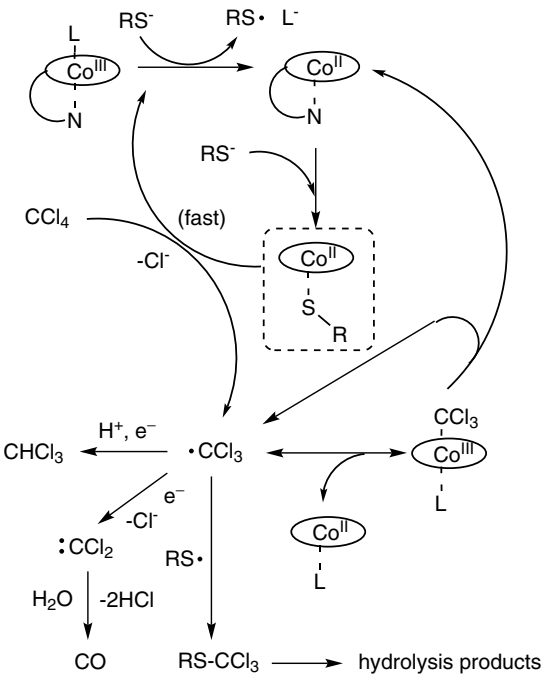

Figure 23. Hypothesized reaction scheme for CCl_4 transformation by B_{12} in cysteine solution (adapted from Ref. 116).

absence of cysteine, and the reactive B_{12} species was hypothesized to be the pentacoordinated Co(II)-cysteinate complex (Figure 23).

Dehalogenation of fluorinated organic compounds was also achieved by the B_{12} catalyst. Reductive defluorination of perfluorooctane sulfonate (PFOS)

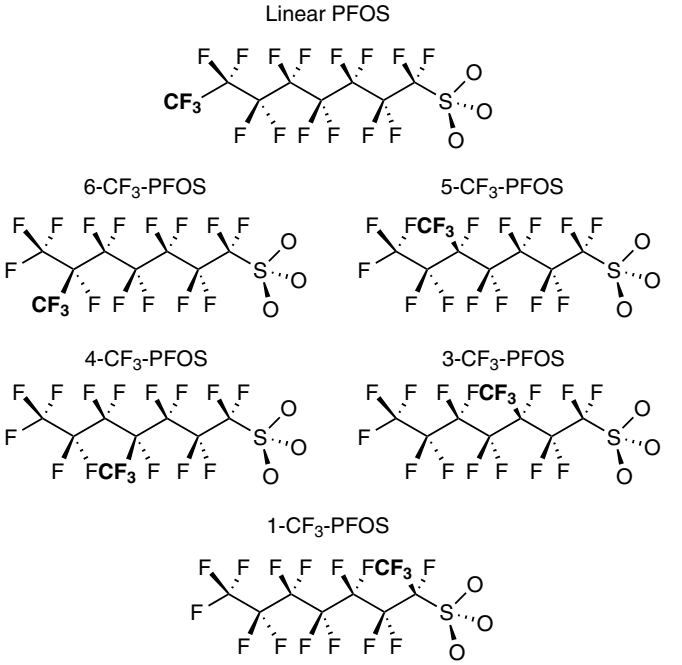

Figure 24. Structure of linear perfluorooctane sulfonate (PFOS) and branched isomers (6-CF_3-PFOS, 5-CF_3-PFOS, 4-CF_3-PFOS, 3-CF_3-PFOS, and 1-CF_3-PFOS).

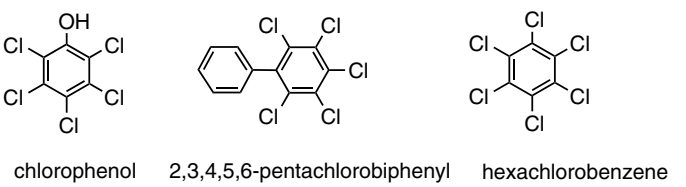

Figure 25. Structure of chlorophenol, 2,3,4,5,6-pentachlorobiphenyl, and hexachlorobenzene.

(Figure 24) was carried out using cyanocobalamin (vitamin B_{12}) as the catalyst and titanium(III) citrate as the bulk reductant in an anoxic aqueous solution at 70 °C and pH 9.[117] Partial defluorination of technical PFOS and PFOS branched isomers proceeded in seven days, with 18% and 71% fluoride releases, respectively.

Removal of the chlorine from the aromatic ring in chlorophenols,[118,119] 2,3,4,5,6-pentachlorobiphenyl[120,121] and hexachlorobenzene[121] were investigated by vitamin B_{12}/titanium(III) citrate or using the DTT system (Figure 25). Reductive dechlorination of such chlorinated benzenes by the B_{12} catalyst

proceed several days to weeks. For example, an approximately 10% chlorine removal for 2,3,4,5,6-pentachlorobiphenyl was observed for 36 days in aqueous condition at 20 °C.

Due to environmental concerns, zero valent metals were used as the reducing reagent for the B_{12} activation since a heterogeneous metal is easy to remove after the reaction.[122] Iron does not have enough reducing potential for Co(I) generation, while zinc efficiently reduced vitamin B_{12} to form the Co(I) species, as confirmed by UV-visible spectroscopy. The vitamin B_{12} and zinc combination system significantly enhances the reaction rates for both the PCE and TCE dechlorination compared with those for the metal only.

B. Electrocatalytic Reduction of Organic Halides by B_{12} Derivatives

Vitamin B_{12} derivatives are electrochemically active, and the Co(I) form of B_{12} is produced at the cathode in various media, such as DMF, DMSO, CH_3CN, alcohols, and aqueous solutions.[23,123] *In situ* generated Co(I) species in an electrolyte solution reacts with organic halides by dehalogenation. Ethylene dibromide, a suspected human carcinogen, was reduced to form an alkene at glassy carbon electrodes in a surfactant-stabilized emulsion using an electrocatalytic cycle involving vitamin B_{12} (Eqs. 21–25).[124,125] The catalysis of the Co(I) form of B_{12} saved an overpotential of 0.84 V compared to the direct reduction of ethylene dibromide. The intermediate (β-bromoalkyl)cobalamin (Eq. 21) was predicted but was kinetically invisible on the time scale under the investigated experimental conditions. Reductive dehalogenation of α-haloacetic acids to give acetic acid was achieved by vitamin B_{12s} during electrolysis at −0.9~−1.1 V vs. SCE in acetonitrile/water (1:1), pH 3 phosphate buffer.[126] Analysis by cyclic voltammetry showed the formation of a reduced organic product at the formal potential of Co(II)/Co(I). The organocobalt intermediate was also not observed in the reaction due to the carboxylic acid group that reductively destabilized the alkylated complex. In this way, the Co(I) species also formally acts as a powerful reductant toward these substrates.

$$Co(II) + e \longrightarrow Co(I) \tag{21}$$

$$Co(I) + CH_2BrCH_2Br \longrightarrow [BrCo(III)CH_2CH_2Br] \tag{22}$$

$$\longrightarrow Co(II) + \cdot CH_2CH_2Br + Br^- \tag{23}$$

$$Co(I) + \cdot CH_2CH_2Br \longrightarrow Co(II) + CH_2CH_2Br^- \tag{24}$$

$$CH_2CH_2Br^- \longrightarrow CH_2{=}CH_2 + Br^- \tag{25}$$

The electrolysis of 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (DDT) in the presence of corrinoid compound, heptamethyl cobyrinate perchlorate, was also reported.[127] Among the chlorinated organic compounds, DDT is characterized by a pronounced insecticidal property and has been used worldwide despite its known hazardous effects on human health and wildlife. DDT was catalytically dechlorinated by B_{12} to form 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane (DDD), 1,1-dichloro-2,2-bis(4-chlorophenyl)ethylene (DDE), 1-chloro-2,2-bis(4-chlorophenyl)ethylene (DDMU), and (*E*/*Z*) 2,3-dichloro-1,1,4,4-tetrakis(4-chlorophenyl) but-2-ene (TTDB) in DMF containing tetra-*n*-butylammonium perchlorate (Figure 26). A photosensitive intermediate having a Co–C bond formed during the electrolysis was identified by electronic spectroscopy.

A voltammetric study of the electrocatalytic reduction of vicinal dibromoalkanes, (*trans*-1,2-dibromocyclohexane, 1,2-dibromobutane) in ionic liquid media of cyanocobalamin (vitamin B_{12}) was reported.[128] Cyanocobalamin was hard to dissolve in a dry ionic liquid, but was dissolved in an ionic liquid (butyl-3-methylimidazolium trifluoromethanesulfonate) containing water (5–20% v/v). In contrast, the corrinoid compound, heptamethyl cobyrinate perchlorate, was soluble in the dry ionic liquid. Interestingly, enhancement for reactivity of the Co(I) form of B_{12} toward DDT in the ionic liquid, 1-butyl-3-methylimidazolium

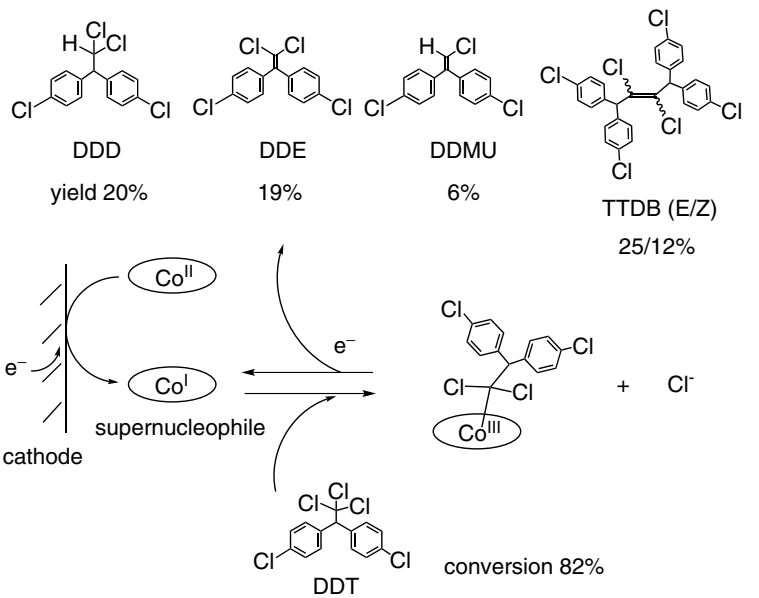

Figure 26. Dechlorination of DDT catalyzed by heptamethyl cobyrinate perchlorate under electrochemical conditions in DMF (adapted from Ref. 127).

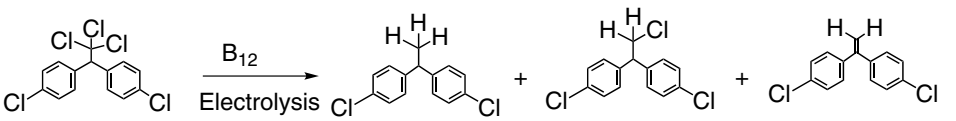
tetrafluoroborate, was reported.[129] More highly dechlorinated products, 1,1′-(2-chloroethylidene)-bis(4-chlorobenzene) (DDMS), 1,1′-(ethenylidene)-bis(4-chlorobenzene) (DDNU), and 1,1′-(ethylidene)-bis(4-chlorobenzene) (DDO) were produced under electrolysis in an ionic liquid in the presence of the B_{12} catalyst compared to the result in DMF mentioned above (Eq. 26). The enhanced reactivity of the B_{12}-ionic liquid system over the B_{12}-DMF system for the electrolysis of DDT was explained by an application of the Hughes-Ingold predictions of solvent polarity effects on reaction rates.[130] Two neutral reactants, the Co(I) form of B_{12} and an organic halide, react to form charged products via a charge-separated activated complex in the polar ionic liquid, which decreases the $\Delta G^{\ddagger}$ value, resulting in an increase in the reaction rate. The solvent polarity parameter, the E_T^N value of the ionic liquid, is greater than that of DMF.[131]



DDT → DDO 44% + DDMS 27% + DDNU trace (26)

The mechanism for the dechlorination of an organic chloride by B_{12} under electrochemical conditions was investigated by cyclic voltammetry.[132] Using chloroacetonitrile as an example, the crucial step in the catalytic process was elucidated as the proton transfer decomposition of the alkylcobalt(II) complex, which was formed by the reduction of the alkylcobalt(III) complex in DMF with the addition of an acid. Furthermore, it was pointed out that the reduction step of the alkylcobalt(III) complex was affected by the axial ligand, such as the chloride ion derived from the substrate (Figure 27). The stronger this ligand is, the more negative the potential required for this step which influences the catalytic process.

C. Photocatalytic Reduction of Organic Halides by B_{12} Derivatives

A photoredox compound was utilized for the activation of B_{12} to form a Co(I) species by irradiation with light. An inorganic complex, $[Ru(bpy)_3]Cl_2$ (where bpy is 2,2′-bipyridine) is widely used as a photosensitizer due to its ability to mediate electron transfer.[133–136] In the case of the B_{12} catalytic system, the

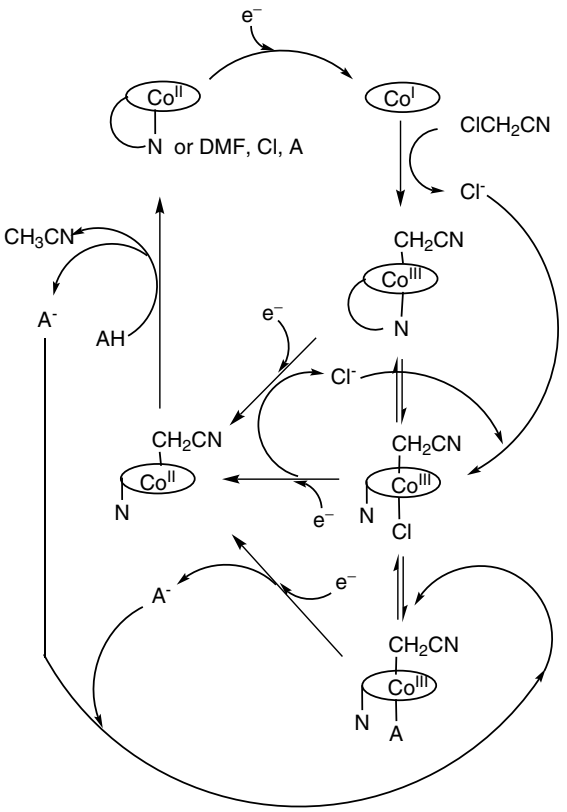


Figure 27. Proposed mechanism for dechlorination of organic chloride by B_{12} under electrochemical conditions (adapted from Ref. 132).

combined use of cyanocobalamin (vitamin B_{12}) and $[Ru(bpy)_3]Cl_2$ was first reported for the photochemical reduction of carbon dioxide and water by visible light irradiation.[137] Application of this combination for the dehalogenation of organic halides was also reported. The mono-dechlorination of DDT effectively proceeded using a heptamethyl cobyrinate perchlorate catalyst in the presence of $[Ru(bpy)_3]Cl_2$ by irradiation with visible light (Figure 28). The formation of the reactive Co(I) form of B_{12} was confirmed by the ESR spectral change in this system.[138,139]

Titanium oxide (TiO_2) was also utilized as the photosensitizer to mediate the electron transfer toward B_{12} (Figure 29). It is well known that TiO_2 generates an electron-hole pair under band gap excitation by UV light irradiation.[140–142] The conductive band electron for TiO_2 ($E_{red} = -0.5$ V vs. NHE in neutral aqueous solution) could reduce the B_{12} derivatives to form Co(I) species. A corrinoid compound having seven carboxylic acid groups, cobyrinic acid, was immobilized on TiO_2,

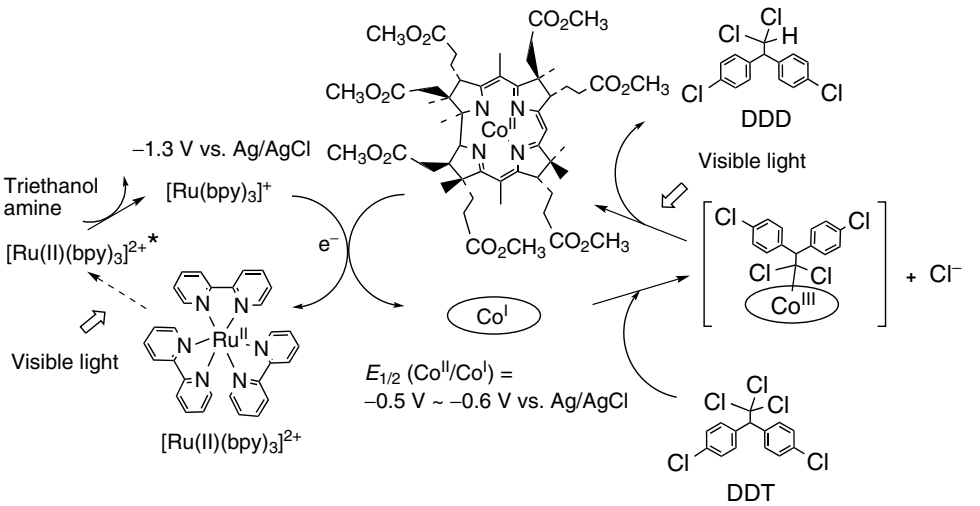

Figure 28. Strategy for photosensitized system for B_{12} catalysis (adapted from Ref. 138).

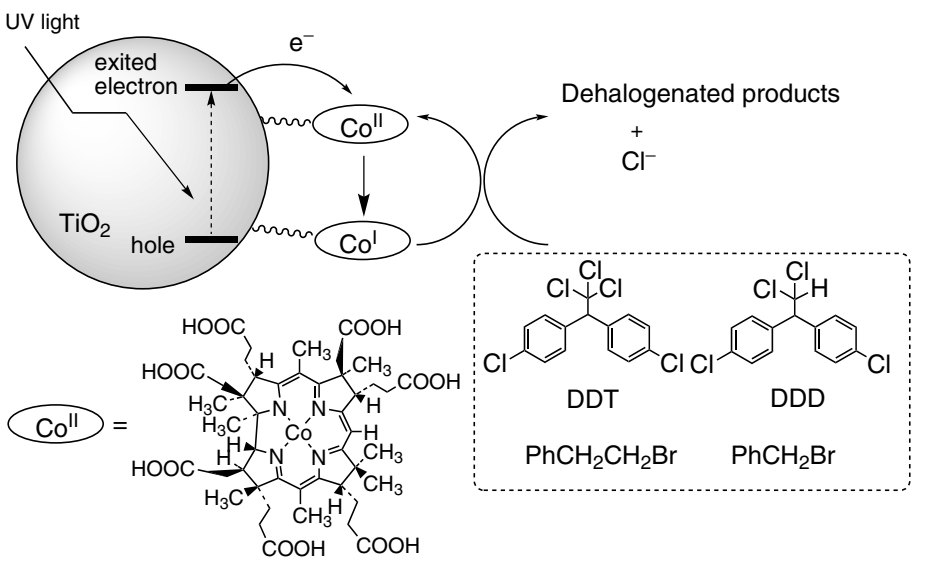

Figure 29. B_{12}-TiO_2 hybrid catalyst.

and the immobilized B_{12} was then reduced to the Co(I) state by irradiation with UV light (365 nm). The B_{12}–TiO_2 hybrid catalyst effectively dehalogenated various organic halides, such as DDT, DDD, and phenethyl bromide.[143] The powder type of B_{12}–TiO_2 hybrid catalyst can be immobilized on a glass plate. By irradiation

with UV light (365 nm), the immobilized catalyst (hybrid glass) shows efficient reactivity for the dechlorination of PCE to TCE and 1,2-DCE (*E*/*Z*) with product yields of 43% and 1/1%, respectively.[144]

D. Dechlorination of Organic Halides by Other Cobalt Complexes

Cobalt complexes, except for the corrinoid compound, have been synthesized and utilized for catalytic reactions. Tetradentate chelate compounds, such as porphyrin, phthalocyanine, cobaloxime, and H_2salen, where H_2salen is *N*,*N*′-ethylenebis(salicylideneamine), were extensively studied. The characteristics of each catalyst such as the stability, solubility, and redox potential of the cobalt center were dependent on each complex. The electrogenerated cobalt(I) salen was widely used for the dechlorination of various organic chlorides, such as ethyl chloroacetate (ECA),[145] 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113),[146] 1,1,1-trichloro-2,2,2-trifluoroethane (CFC-113a),[147] DDT,[148] hexachlorobenzene (HCB),[149] and pentachlorobenzene (PCB).[150] As for the photocatalytic system, cobalt(II) tetrasulfonatophthalocyanine[151] and cobalt(III) *meso*-tetra-(4-carboxyphenyl)porphyrin chloride[152] (Figure 30) were combined with TiO_2 for the reductive dechlorination of bromoform, carbon tetrachloride, and chloroform. The catalytic dechlorination

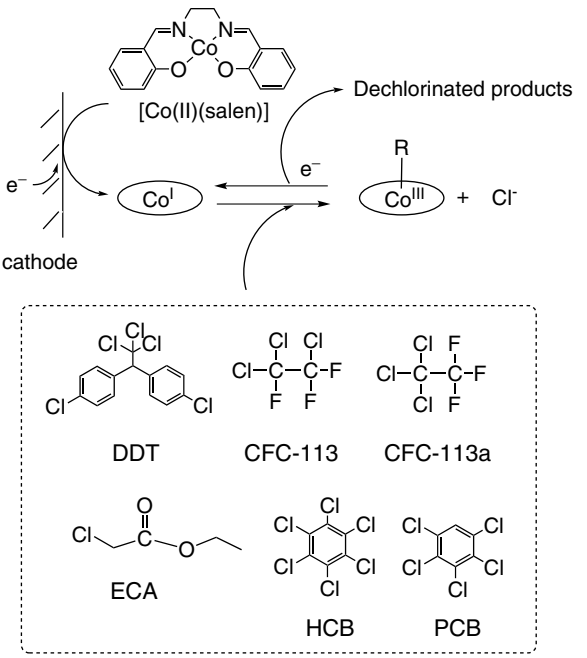

Figure 30. Electrolysis of various chlorinated organic compounds with [Co(II)(salen)].

of PCE and TCE by 5,10,15,20-tetrakis(4-carboxyphenyl)porphyrin cobalt [(TCPP)Co] with titanium(III) citrate as the bulk reductant was reported.[153] The bimolecular rate constants for the chlorinated ethylenes (PCE, TCE, *cis*-DCE, and *trans*-DCE) with the Co(I) form of (TCPP)Co and vitamin B_{12} were compared. The values of (TCPP)Co are 5.6 and 14 times for PCE and TCE, respectively, over B_{12}.

V. Bioinspired Immobilized Catalysts

A. B_{12} Modified Electrodes

Immobilized catalysts are generally considered to have many advantages: only a small amount is needed, they are usable in various media, and the products and catalyst can be easily separated. The catalyst can also be recovered and recycled, reducing waste significantly.[154] Various materials such as metals, polymers, clays, silica, and zeolite have been used as supports for the catalyst. Each support has different functions that are dependent on their properties. Among them, the electronic conductivity of the support is of importance and some materials were used as electrodes. Modified electrodes are a result of purposeful modification of a conductive substrate to produce an electrode suited for a particular function and they have properties which are different from those of the unmodified substrate. Therefore, modification of the electrode surface with a metal complex was developed as a good catalyst for electro-organic reactions.[155] This section highlights the studies of the B_{12} immobilized catalyst, and especially B_{12} modified electrodes for electro-organic reactions. The electro-catalytic utilities of the immobilized B_{12} result from the ready availability of the active Co(I) species by electron transfer from the electrode.

B. Noncovalently Bound B_{12} Modified Electrodes

The adsorption of a catalyst to an electrode surface has been known to modify the electrochemical behavior of the substrate. Zagal and coworkers have found that vitamin B_{12} (cyanocobalamine) strongly adsorbs on pyrolytic graphite.[156–158] The resulting vitamin B_{12} modified electrode catalyzed the oxidations of cysteine and glutathione and the reduction of cystine, while the bare electrodes are completely inert.

Vitamin B_{12} hexacarboxylate 8-aminocob(III)yrinic acid *c*-lactam [$B_{12}(COOH)_6$] was used to incorporate a catalytic activity into insoluble liquid crystal films of a cationic surfactant on carbon electrodes (Figure 31).[159] Didodecyldimethylammonium bromide (DDAB) films loaded with the vitamin B_{12} derivative catalyzed

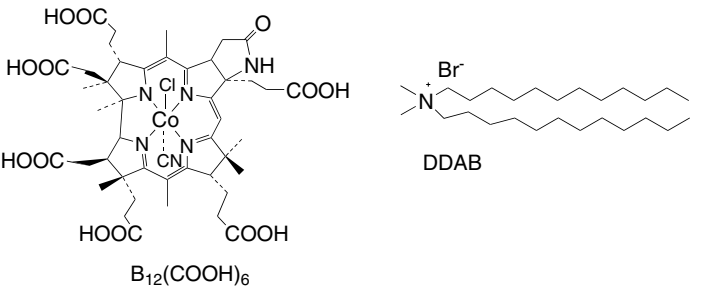

Figure 31. Structure of vitamin B_{12} hexacarboxylate ($B_{12}(COOH)_6$) and didodecyldimethylammonium bromide (DDAB).

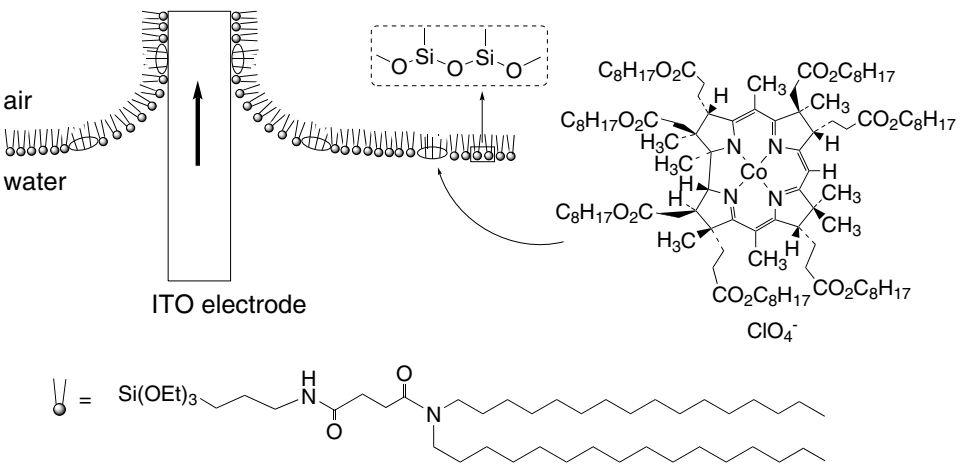

Figure 32. Illustration of B_{12}/LB film modified electrode.

the reductions of trichloroacetic acid and 1,2-dibromoethane at potentials of the Co(I) formation.

The corrinoid compound having seven long alkyl chains, heptaoctylcobyrinate perchlorate, was incorporated in a monolayer of an organosilane amphiphile, and the monolayer was transferred to an indium tin oxide (ITO) electrode as an X-type Langmuir-Blodgett (LB) film (Figure 32).[160] The redox behavior of the modified electrode was investigated by cyclic voltammetry, and the reversible Co(II)/Co(I) redox couple was observed at −0.65 V vs. Ag/AgCl in an aqueous solution. However the application of this modified electrode for electroorganic reactions was not reported.

A B_{12} modified electrode using sol-gel techniques was reported (Figure 33).[15] A hydrophobic heptapropyl cobyrinate perchlorate was readily trapped on an ITO

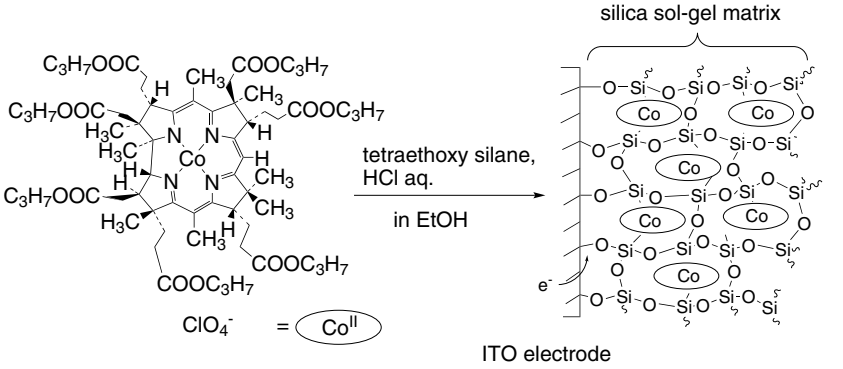

Figure 33. A sol-gel modified electrode containing the trapped B_{12} derivative (adapted from Ref. 15).

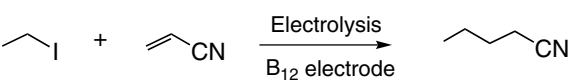
electrode by a sol-gel reaction. The complex was physically retained in a silica gel film formed on an ITO electrode. The electrolysis of benzyl bromide was performed at −1.20 V vs. Ag/AgCl by irradiation with visible light using the modified electrode to form bibenzyl and toluene.

C. Polymer-coated B_{12} Modified Electrodes

A surface modification of the carbon electrodes by polymers consisting of epoxy resins and a B_{12} derivative has been reported (Figure 34).[161] The polymeric monomer, Araldite CT-200 and the B_{12} derivative having a 3,5-diaminobenzoyl moiety at its peripheral site were co-polymerized onto an oxidized glassy carbon electrode surface at 373 K. The structure of the modified electrode was estimated to be a cross-linked polymer. Polymer-modified electrodes with large specific surfaces have been used in electroorganic synthesis. The synthesis of valeronitrile by the reductive cross-coupling of ethyl iodide and acrylonitrile effectively proceeded using the modified electrode (Eq. 27). This B_{12} modified carbon electrode was also used as an electrochemical sensor for alkylating agents, i.e. organic halides.[162] The oxidative addition



(27)

of an organic halide from dilute solutions to the immobilized Co(I) species of the B_{12} derivative yielded a surface-confined alkylated complex. The same modified electrode was applied to various electroorganic reactions as a functional simulation of the cobalamin-dependent enzymic reaction.[163] The

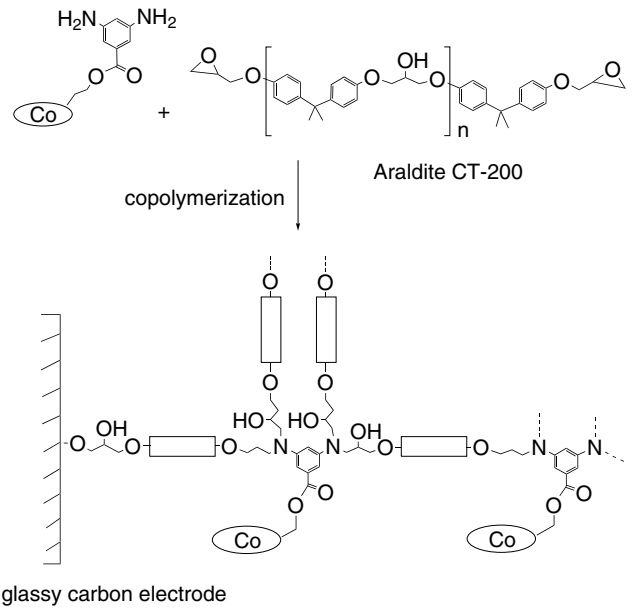


Figure 34. Polymerization by thermal curing of the B_{12} derivative and the diepoxide (Araldite) on basal plane pyrolytic graphite electrodes (adapted from Ref. 161).

carbon-skeleton rearrangement reactions of organic halides efficiently proceeded using the polymer-coated B_{12} modified electrode (Eqs. 28–30). The polymer matrix may provide an efficient microenvironmental effect on the rearrangement reaction catalyzed by B_{12}.

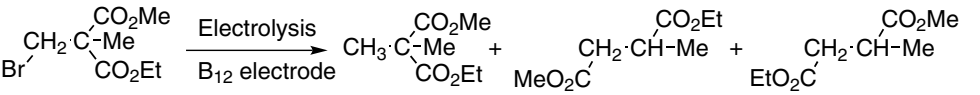
(29)



(30)

Another type of polymer-coated electrode was prepared.[164–167] Poly-*L*-lysine was covalently linked to carbon electrodes, and an amide linkage from polylysine to the B_{12} derivative was efficiently formed (Figure 35). The modified electrode showed a reversible electron transfer for the Co(II)/Co(I) couple. The electrocatalytic activities for various molecular transformations were conducted in microemulsions as the reaction medium (Eqs. 31 and 32).

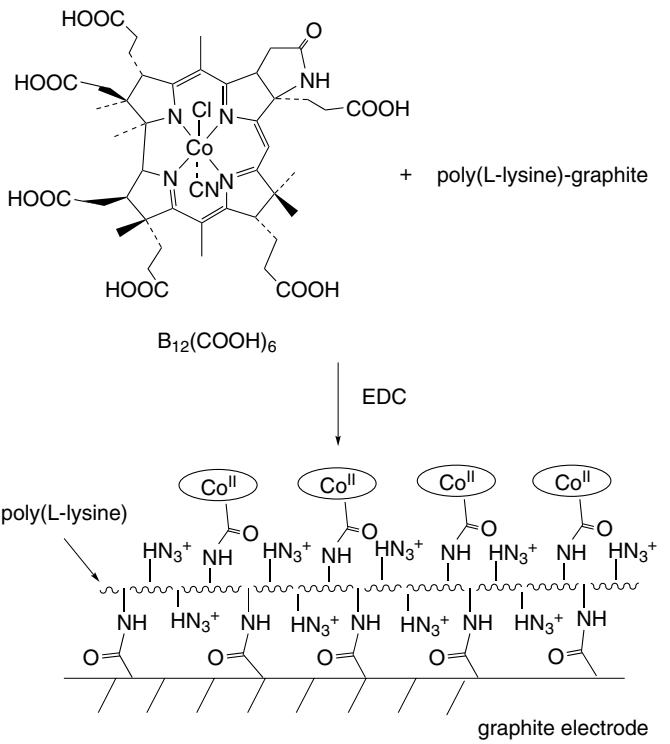


Figure 35. Illustration of preparation of vitamin B_{12} hexacarboxylate-poly(L-lysine) [$B_{12}(COOH)_6$-PLL] network on graphite electrode (adapted from Ref. 167).

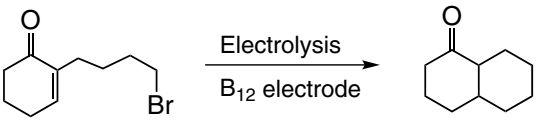
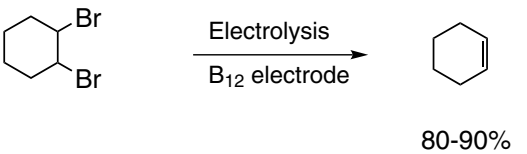


(31)



(32)

The electrochemical polymerization of a B_{12} derivative containing a pyrrole group in a peripheral alkyl chain on a platinum electrode surface has been reported (Figure 36).[168–170] The dissolved oxygen reduction reaction was chosen to obtain preliminary information about the catalytic activity of the B_{12}-containing polymer-modified electrodes. However, the application of this modified electrode for electroorganic reactions was not reported.

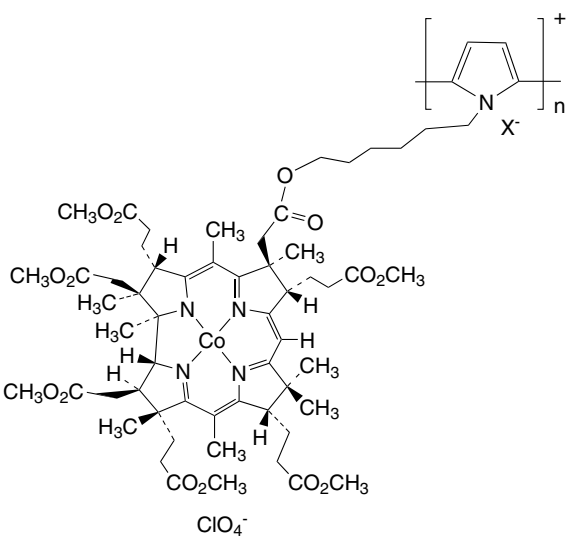


Figure 36. Polypyrrole branched B_{12}.

D. Covalently Bound B_{12} Modified Electrodes

The direct modification of the electrode surface with catalyst species provided some advantages compared to those of the previously described matrix-assisted modified electrodes. The predominant utility is facilitating the electron transfer from the electrode to the catalyst and easy access of the substrate to the bound catalyst. Synthesis of a B_{12} derivative having a trimethoxysilyl group at the peripheral position was reported (Figure 37).[171] This complex was easily immobilized onto an oxidized platinum electrode surface, and the immobilized complex exhibited a definitive Co(II)/Co(I) redox couple. The Co(I) species formed on the electrode surface reacts with phenethyl bromide to form styrene by irradiation with visible light and have a turnover number of over 6,000 for an hour.

A monolayer type B_{12} modified electrode was prepared using the self-assembly technique. A B_{12} disulfide derivative was spontaneously adsorbed onto the gold surface (Figure 38).[172] The modified electrode showed electrocatalytic activity for the reduction of dissolved oxygen. However, the application of this modified electrode for electroorganic reactions was not reported.

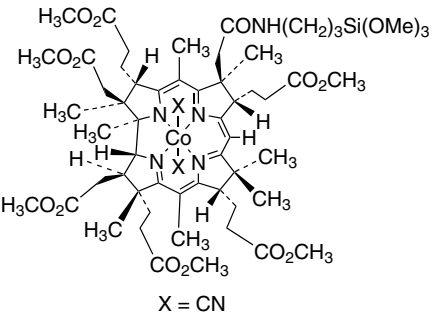

Figure 37. Structure of B_{12} derivative having a trimethoxysilyl group.

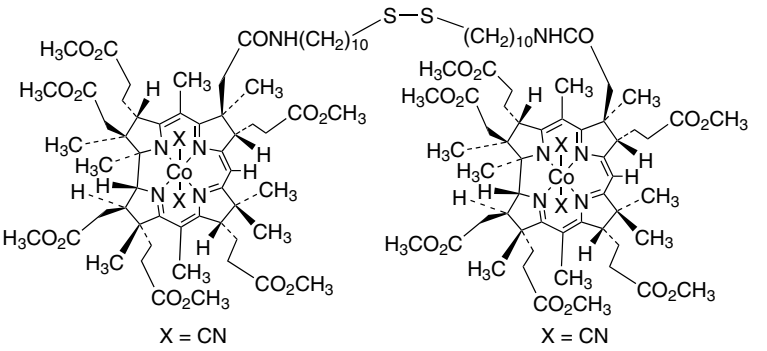

Figure 38. Structure of B_{12} disulfide derivative.

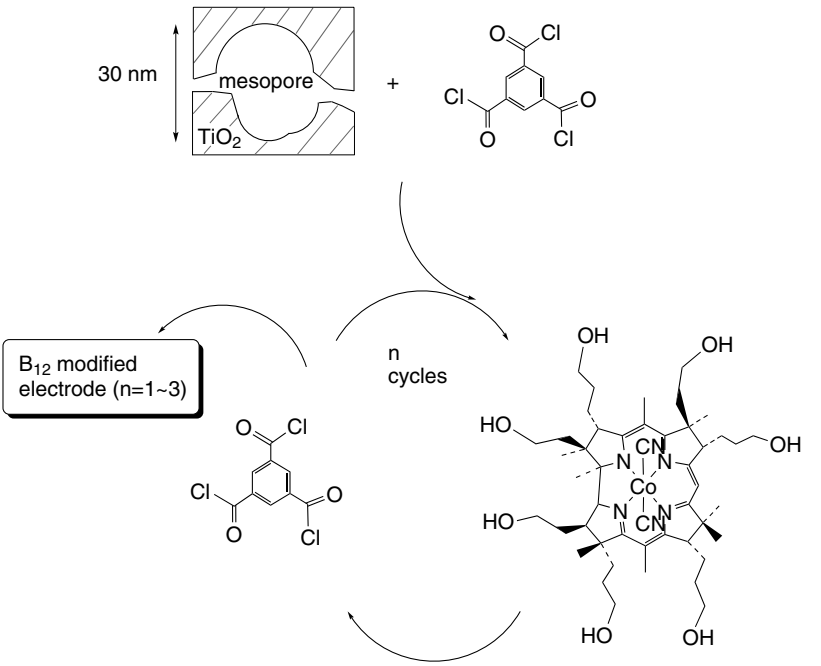

Figure 39. Preparation of B_{12}-modified electrode by cascade type surface modification of mesoporous TiO_2 electrodes (adapted from Ref. 174).

A mesoporous TiO_2 was also used as an electrode. A vitamin B_{12} hexacarboxylate, namely 8-aminocob(III)yrinic acid *c*-lactam ($B_{12}(COOH)_6$), was chemisorbed on a nanocrystalline TiO_2 electrode to form a B_{12} modified electrode.[173] The modified electrode was active for the debromination of dibromocyclohexane and the stereoselective cyclization of 2-(4-bromobutyl)-2-cyclohexen-1-one to 1-decalone in a microemulsion (Eqs. 31 and 32). Binding of the B_{12} catalyst to the TiO_2 electrode enhanced the electron-transfer rates and catalytic efficiency though about 70% of the B_{12} catalyst was desorbed from the TiO_2 electrodes during the reaction. A cross-linking of the B_{12} catalyst on the pore walls of a mesoporous TiO_2 electrode was achieved, based on a solid phase supported synthesis, to obtain a highly stable modified electrode (Figure 39).[174] The modified electrodes showed high electrocatalytic reactivity for the dehalogenation of vicinal dihalides (dibromoethane and *trans*-dibromocyclohexane).

E. B_{12} Immobilized Polymers

The use of a soluble polymer as catalyst support may be applicable as an advantageous alternative to conventional solid-phase supports. A soluble polymer

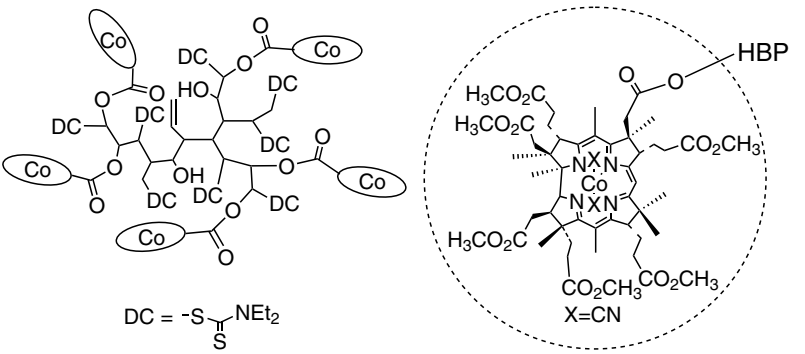

Figure 40. Structure of B_{12}-hyperbranched polymer (HBP).

support provides homogeneous reaction conditions that do not depress the access of the substrate. A hyperbranched polymer is one of the dendric polymers that are synthesized via a one-step polymerization reaction in an inexpensive and easy way, and it has various advantages when compared to dendrimers, which are synthesized via multiple-step polymerizations.[175] The B_{12}-hyperbranched polymers were synthesized and characterized by UV-visible and NMR spectroscopy as well as DLS (Figure 40).[176,177] The spherical shape of the hybrid polymer was observed by TEM. The hybrid polymer exhibits catalysis for the dehalogenation of phenethyl bromide to form ethylbenzene and 2,3-diphenylbutane by irradiation with UV light at room temperature.

VI. Other Bioinspired Reactions

A. Asymmetric Reactions

One of the fascinating functions of naturally occurring vitamin B_{12} is its potential as a chiral catalyst for asymmetric synthesis, since B_{12} creates a chiral reaction site provided by a corrin ring and peripheral substituents. B_{12} catalyzes asymmetric reduction of α,β-unsaturated carbonyl derivatives (esters and amides) in aqueous acetic acid in presence of zinc (Eq. 33).[178,179] Both cyanocobalamin and heptamethyl dicyanocobyrinate produce the (*S*)-isomer as product. Enantiometric excesses depended on the applied reaction conditions. The alkylated complex formed by *Re*-face attack of a Co(I) to substrate was considered as an intermediate, and subsequent reductive cleavage of cobalt–carbon bond afforded the (*S*)-configuration product in varying enantiometric excesses.[180] Schrauzer and coworkers investigated the asymmetric alkylation of cob(II)alamin with D/L-alanine in the presence of V^{3+} and oxygen radicals, and obtained the alanine-bound cobalamin with a 12% e.e. of the D-alanine-bound complex, as shown in Eq. 34.[54]

Ogoshi and coworkers studied the alkylation of cob(I)alamin with prochiral 1-acetyl-1-alkylcyclopropanes that induced an asymmetric center in the resulting alkyl ligands, as shown in Eq. 35, and found a 24% e.e. for X=Ac and Y=Et, and a 33% e.e. for X=Ac and Y=CH_2Ph.[181] Golding and coworkers carried out the alkylation of cob(I)alamin with *tert*-butyloxirane and methyloxirane as shown in Eq. 36, preferentially affording the (*R*)-alkyl-bound products in 62% and 50% e.e., respectively.[182,183] Bonhôte and Scheffold reported the asymmetric isomerization of 1,2-epoxycyclopentane to give (*R*)-2-cyclopenten-1-ol via the formation of the corresponding alkylated cobalamin, in 62% e.e.[184] Achiral epoxides and *N*-aziridines are isomerized to optically active allylic alcohols and *N*-acyl-allylamines by the hydroxocobalamin hydrochloride (vitamin B_{12a})/Zn/NH_4Cl system (Eqs. 37 and 38).[185,186] Using this system, an optically active cyclopenta[b] furan was obtained for prostaglandin synthesis.[187] Murakami and coworkers have investigated the enantioselective alkylation of hydrophobic vitamin B_{12} derivatives, which bear a chiral binaphthyl moiety, with various racemic 3-bromo-2-methylpropionic esters in methanol, and *S*-enantioselectivity with as high as 65% e.e. was observed regardless of the chiral nature of the binaphthyl moiety.[188,189] The higher *S*-enantiomer selectivity with hydrophobic vitamin B_{12} derivative has been reported as follows. The controlled-potential electrolysis of racemic ethyl 3-bromo-2-methoxy-2-phenylpropionate was carried out at −1.8 V vs. SCE in DMF, as mediated by hydrophobic vitamin B_{12} derivatives to afford ethyl 2-methoxy-2-phenylpropionate and ethyl 2-methoxy-3-phenylpropionate in the dark as shown in Eq. 39.[190] The best enantiomeric excess is 87% for the [Cob(II)7C_1ester]ClO_4.

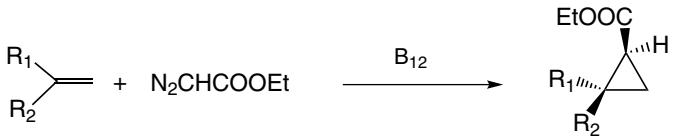
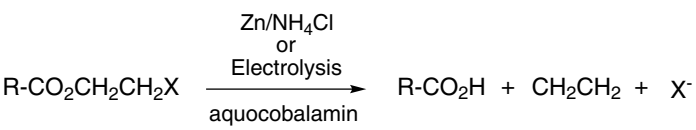
The enantioselective cyclopropanation of alkenes with ethyl diazoacetate was carried out in the presence of B_{12} (Eq. 40).[191] Among the cobalamin derivatives (cyanocobalamin, methylcobalamin, adenosylcobalamin, hydroxocobalamin hydrochloride), hydroxocobalamin hydrochloride (vitamin B_{12a}) exhibited the most effective catalysis for a variety of alkenes, which afforded the *cis*-dominant cyclopropanes in excellent yields and moderate enantioselectivities.



(40)

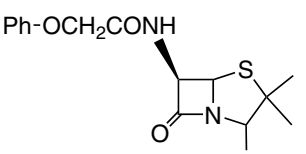
B. Other Reactions

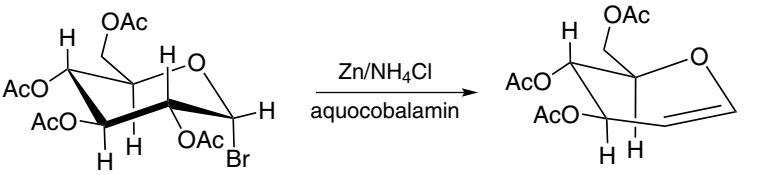
Reductive removal of β-haloethyl protecting groups from acids was conducted using vitamin B_{12} and vitamin B_{12} model compounds.[192] The catalytically active Co(I) species formed by electrolysis or treatment with zinc reacts with β-chloroethyl or β-bromoethyl esters to form alkylated Co(III) intermediates and the subsequent cleavage of the cobalt–carbon bond to produce the corresponding acids and ethylene (Eq. 41). Such a reductive elimination was used for the synthesis of glycols (unsaturated sugars) (Eq. 42).[193] The tetra- or triacetyl-1-bromosugar was converted to the tri- or diacetyl sugars by the vitamin B_{12}/zinc system in neutral media, MeOH.



(41)

R = C_6H_5, *p*-CH_3-C_6H_5-NH- X = Cl, Br





(42)

Reductive acylation of activated olefins with anhydrides was catalyzed by vitamin B_{12a}. 4-Oxo-aldehydes, ketones, esters, and nitriles were synthesized from the corresponding carboxylic anhydrides and activated olefins (Eq. 43).[194] The nucleophilic Co(I) form of B_{12} reacted with carboxylic anhydrides and other acyl derivatives to form Co(III) acyl compounds.[195] Photolysis or electrolysis of the cobalt–carbon bond provided the final product in the presence of an activated olefin.

$$(R^1CO)_2O + R^3HC{=}CR^2Z \xrightarrow[\text{vitamin } B_{12a}]{\text{Electrolysis, } h\nu} (R^1CO)R^3HC\text{-}CHR^2Z + R^1COO^- \quad (43)$$

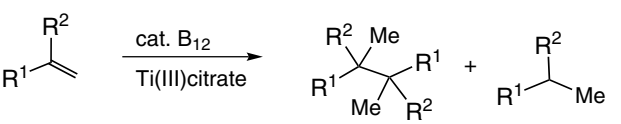
R^3 = H, CH_3

A unique reductive dimerization of arylalkenes catalyzed by the B_{12}/Zn or Ti(III) citrate system was reported in an environmentally benign solvent (ethanol/water).[196] Mono- and 1,1-disubstituted alkenes regioselectively provided the corresponding dimers along with some reduced product (Eq. 44), and dienes containing one aryl alkene afforded an intramolecular cyclized product (Eqs. 45 and 46). This reaction expands to the intramolecular cyclization reaction of N-substituted pyrroles and α-alkylstyrenes (Eqs. 47 and 48).[197]



(44)

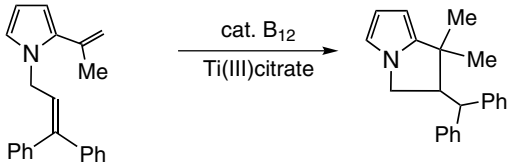
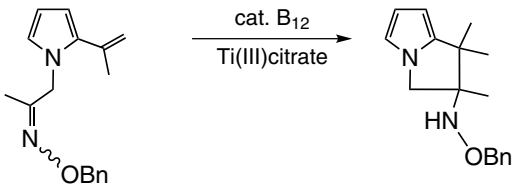
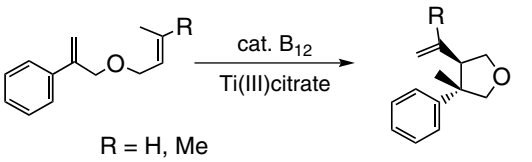
(45)



(46)



(47)



(48)

The photoreduction of CO_2 to CO catalyzed by a corrinoid compound, such as cyanocobalamin, hydroxocobalamin, and cobinamide, was carried out in acetonitrile/methanol solutions containing *p*-terphenyl and triethylamine as a photosensitizer and a sacrificial reductant, respectively.[198] The catalytic efficiency of the cobalt complexes for the photochemical production ($\lambda \geq 300$ nm) of CO and H_2 were compared for the corrinoid compounds and cobalt tetra-*m*-tolylporphyrin. The corrinoid compounds had higher product formation rates and yields than those of the porphyrin complex.

The photochemical catalytic reaction was also reported using the binuclear $Ru(bpy)_3$-B_{12} system. A radical-type cyclization of methyl 1-(3-bromopropyl)-4-oxocyclohexa-2,5-diene-1-carboxylate to the corresponding indene derivative was

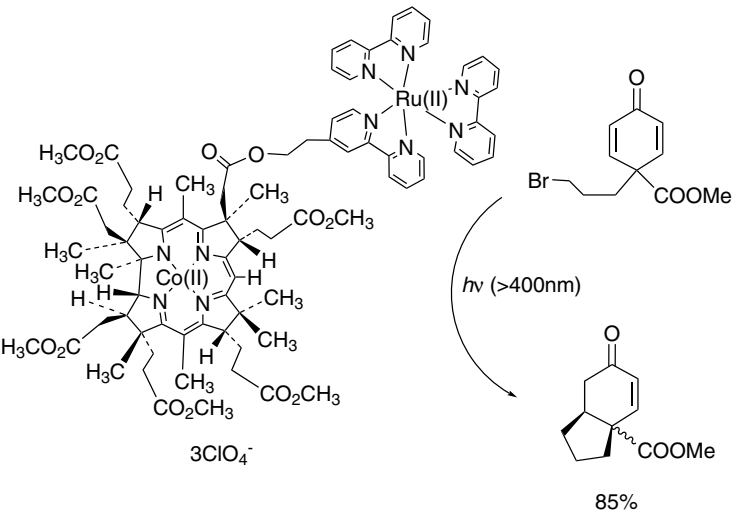


Figure 41. Photochemical catalytic reaction catalyzed by binuclear Ru(bpy)$_3$-B$_{12}$ system.

conducted using the photoredox-photocatalyst in the presence of triethanolamine (Figure 41).[199]

VII. Conclusions

The catalytic simulations, model reactions, and application reactions of B_{12} enzymes with bioinspired systems have been summarized in this chapter. Various cobalt complexes which act as B_{12} models exhibit a variety of wonderful reactivities. Hybrid catalysts composed of synthesized metal complexes and nano-space materials, which are similar to the active center of the B_{12} enzyme, enabled various molecular transformations, including environmental-friendly organic synthesis reactions and degradation reactions of organic halide pollutants by electroorganic or photochemical reactions. Combining the benefits of natural enzymes and engineering methods, this will allow the development of a new catalyst system that will exceed biological reactions. The development of bioinspired catalysts will play an important role in the next generation of science and technology.
