Very little is known so far about the photophysics of other porphyrin isomers. Room temperature measurements have been reported for toluene solutions of OEHPc **21** and OECp **20**. The fluorescence is stronger in the hemiporphycene derivative. The ratio of the quantum yields (0.09 in **21** vs. 0.03 in **20**) is very similar to the ratio of absorption coefficients for the transition to L_1 (see Table 6). Both compounds reveal high efficiency of triplet formation (0.9 and 0.6 for **20** and **21**, respectively). They also generate single oxygen, with a quantum yield of 0.48 for **20** and 0.58 for **21**.

A. Mechanism of Excited State Deactivation in Alkylated Porphycenes

Tetraalkyl substitution of porphycene at the β positions has very little influence on the photophysical properties. In contrast, *meso*-substitution has a dramatic effect. This was first observed by Levanon and coworkers, who studied the triplet formation in the parent porphycene and two *n*-propyl derivatives **10** and **11**.[167] At room temperature, comparable triplet yields were observed for all three compounds when triplet–triplet sensitization was used to produce the porphycene in the T_1 state. On the contrary, the triplet formation yield was negligible for the *meso*-derivative when the route to the triplet involved laser excitation followed by intersystem crossing. The triplet state was detectable at temperatures below 240 K. In order to interpret these results, the authors postulated the existence of a thermally activated singlet state lying about 1000 cm^{-1} above S_1. This state would be directly coupled to the ground state, thus providing an efficient channel for S_1 depopulation.

Further studies demonstrated that fluorescence of methyl and *n*-propyl *meso*-substituted porphycenes **29** and **11** can be enhanced not only by lowering the temperature but also by increasing the viscosity of the environment.[39] Actually, embedding the chromophore in a polymer sheet at 293 K is nearly as effective as lowering the temperature to 77 K. Comparison of the effect of temperature on the fluorescence intensity in the parent porphycene **2** and in 9,10,19,20-tetra-*n*-propylporphycene **11** is shown in Figure 24. The fluorescence of **2** is intense already at 293 K and increases only weakly at low temperatures. In contrast, the emission intensity of **11** increases dramatically, by more than two orders of magnitude in the temperature range between 293 and 77 K; this is accompanied by a corresponding increase in the fluorescence decay time. In fact, the emission decay for **11** and the tetramethyl analog **29** is biexponential, since both *trans* and *cis* tautomeric forms are present.

Similar behavior, namely large viscosity dependence of the fluorescence quantum yield and lifetime, was observed for β,β'-substituted octaalkyl derivatives. Again, the emission enhancement can be induced in two different ways: either by viscosity increase or by temperature decrease. An interesting observation is that, for the same solvent, both fluorescence quantum yields and lifetimes are about an order of magnitude higher for octaalkyl-substituted than for *meso*-substituted porphycenes.

Replacement of the two internal protons by deuterons leads to an increase in fluorescence intensity. At the same time, the activation barrier for the depopulation process remains the same for deuterated and nondeuterated derivatives. This can be seen from the same temperature dependence of the emission intensity presented in Figure 24 for both nondeuterated **11** and its deuterated derivative.

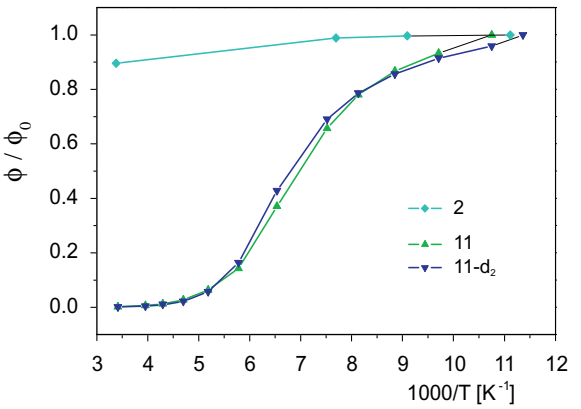

Figure 24. Relative changes of fluorescence quantum yield with temperature, measured for parent porphycene **2** and 9,10,19,20-tetra-*n*-propylporphycene **11**. The results are also presented for the doubly deuterated **11**.

Another observation relevant to the explanation of the depopulation mechanism was provided by comparison of photophysical properties of free-base and zinc octaethylporphycenes.[168] In the zinc derivative, the sum of fluorescence and intersystem crossing quantum yields was found to be close to unity. This was not the case for the free base, for which the value of this sum was very small and solvent-independent. Thus, the internal protons must play a role in the radiationless deactivation. Still, another factor must also be taken into account, responsible for the viscosity dependence. The latter suggests that a large amplitude motion is involved.

The model which was recently proposed to explain the photophysics of alkylated porphycenes[39] is based on the above experimental factors and on the results of calculations performed for three different tautomeric forms of porphycene. The calculations yielded an unusual result for the *cis*-2 form of porphycene (the forms **2b′** and **2b″** in Figure 8): in this tautomer, the state of lowest energy corresponds to an open shell configuration with strongly nonplanar geometry, whereas the planar, closed shell structure has a slightly higher energy. Since the *cis*-2 form is the least stable tautomer of porphycene, both energy levels are located in the vicinity of the first excited state of the *trans* (and *cis*-1) forms. In the correlation of the electronic states of the *trans* and *cis*-2 tautomers (Figure 25), the open shell states of the former must be correlated with the open shell states of the latter. The same is true of the closed shell states. Therefore, the correlation curves must cross along the curve describing the excited state *trans–cis*-2 tautomerization. Since the *cis*-2 structure was found to be strongly nonplanar, the hydrogen transfer coordinate involves not only the proton translocation but also twisting. The observed sensitivity to viscosity can thus be explained.

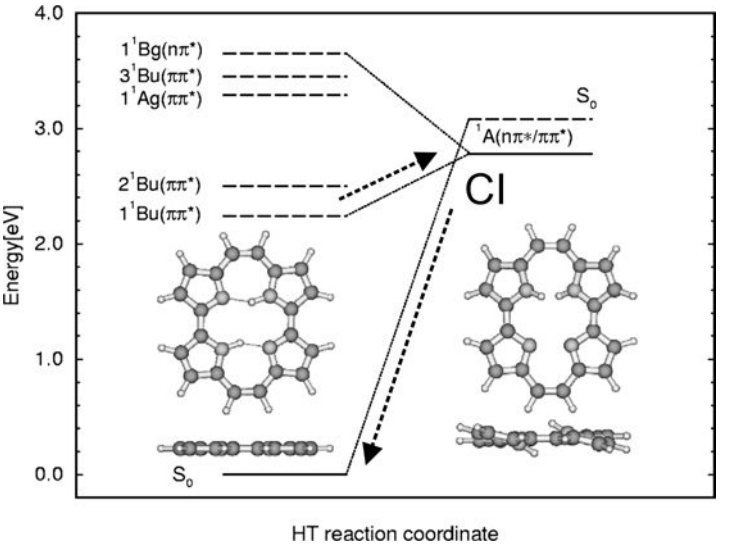

Figure 25. Correlation of the electronic states in the *trans* (left) and *cis*-2 tautomeric forms of parent porphycene. The arrows indicate the path of deactivation involving a conical intersection (CI). (Modified with permission from Ref. 39.)

Preliminary calculations indicate the existence of a conical intersection along the tautomerization coordinate, corresponding to a nonplanar structure, in which the two pyrrolic rings on which the protons reside in the *cis*-2 tautomer are twisted from the molecular plane. For testing the model, four porphycenes — **2**, **40**, **15**, and **29** — were selected as a representative series. In **2** and **40** the emission is strong, whereas for **15** and **29** the fluorescence quantum yield in nonviscous solutions is very low. A perfect correlation was obtained between the experimentally measured S_1 deactivation rate and the calculated difference between the lowest electronic state of *cis*-2 and the energy of the excited S_1 state of the *trans* tautomer. According to the model, this value is a measure of the activation barrier, i.e. the energy required to assume the geometry of the conical intersection. The calculated values increase in the order **29**, **15**, **40**, **2**. This is exactly the order of the experimentally determined S_1 deactivation rates. The model allows one to understand this ordering. If the deactivation were controlled only by nonplanarity, then the largest rate should be expected for the nonplanar octaalkyl derivatives. If, on the other hand, the process is governed by the tautomerization barrier, one should expect the most efficient depopulation in the *meso*-derivatives, which have the shortest, and therefore the strongest, intramolecular hydrogen bonds. The barrier to deactivation via tautomerization should be the largest in octaalkyl derivatives, which have the weakest hydrogen bonds. The fact that the two extreme cases, octaalkyl and *meso*-substituted derivatives, are depopulated most efficiently,

demonstrates that both hydrogen transfer and deviation from planarity contribute to the deactivation. A somewhat similar explanation had been proposed before to account for the lack of emission in strongly nonplanar dibenzoporphycenes.[159]

It remains to be seen whether the above model can be successfully extended to other porphycene derivatives, in particular those containing aryl substituents.

B. Relaxation from Higher Excited States

Picosecond time-resolved absorption and emission studies have been performed for several porphycenes isolated in cryogenic argon and nitrogen matrices.[157,158,160] The transient signals originating in the S_1 state were monitored as a function of time delay from the moment of excitation. An unusually long relaxation time was observed for parent porphycene excited into the Soret region. The relaxed S_1 state was observed only after a delay exceeding 100 ps. On the other hand, no spectral evolution was observed for direct excitation into S_1 (Figure 26). Similar behavior was observed for tetra-*tert*-butylporphycene **30**. On the other hand, the relaxation from higher excited states was found to be very fast for dibenzoporphycenes **84** and **99**. These differences were explained by the rigidity and planarity of the parent porphycene, as opposed to a flexible structure of the dibenzo derivatives. For the latter, the times of relaxation from higher excited states were compared for the chromophore embedded into an argon matrix at 27 K and the same chromophore in a glassy and liquid 2-methyltetrahydrofuran at 93 and 293 K, respectively. The same relaxation times, 9–13 ps, were observed for the glassy and liquid matrices, whereas for Ar the relaxation was significantly longer (16–20 ps).[157]

The dynamics of relaxation from the Soret states has also been studied at room temperature for *meso*-substituted porphycenes **11** and **29**, using a femtosecond fluorescence upconversion technique.[169] An extremely short time, about 50 fs, was determined for the relaxation of the B into the L states. This value is similar to, or even shorter than, the one observed for porphyrin, even though the separation between the Soret and Q bands is nearly twice as large in the case of porphycenes.

The electronic and vibrational relaxation processes occurring after excitation to S_2 were monitored for porphycene **2** in solution at 293 K.[170] The sequence of processes following the excitation includes intramolecular vibrational redistribution, S_2–S_1 internal conversion, and thermal equilibration via energy transfer to the solvent. The last process is the longest and takes about 16 ps in acetonitrile.

C. Triplet State Studies

In view of potential applications in photodynamic therapy, the properties of the triplet states of porphycenes have been intensively studied.[25,68,69,75,112,115,167,168,171–179]

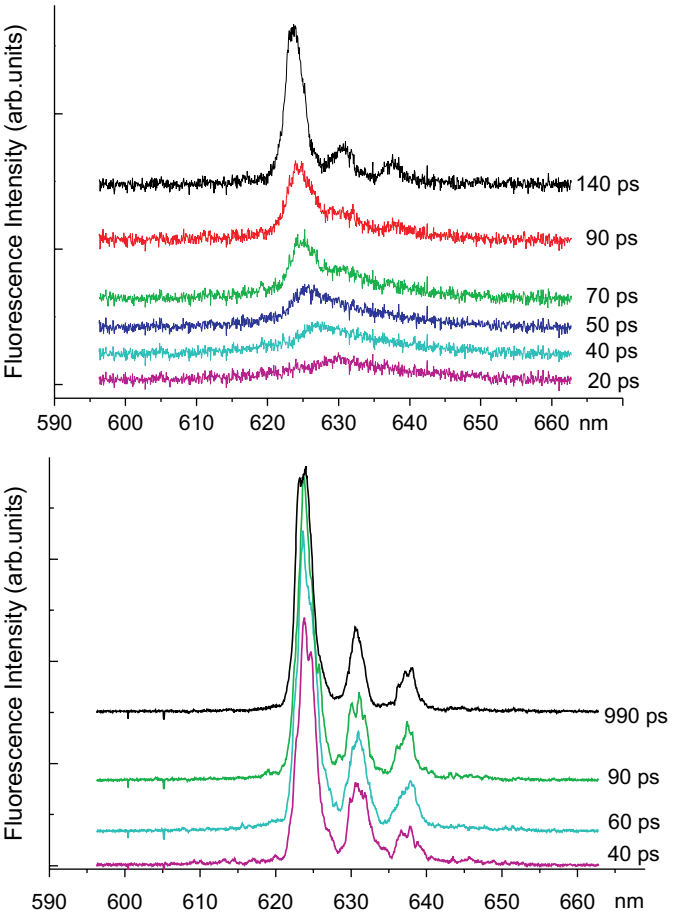

Figure 26. Time evolution of fluorescence spectra of 2 in a nitrogen matrix at 15 K. Bottom: excitation to S_1 (593 nm); top: excitation into the Soret band (355 nm). Time delay from the moment of excitation is indicated for each spectrum. (Modified with permission from Ref. 160.)

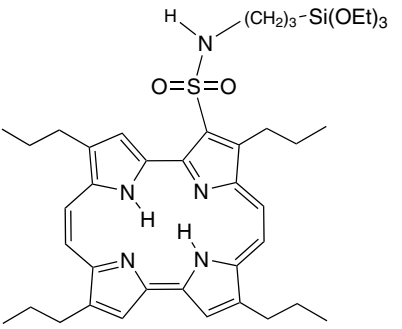
As can be inferred by comparing the data in Tables 8 and 9, the triplet state is populated less efficiently than in porphyrins. As a consequence, the efficiency of singlet oxygen generation by porphycenes should be lower. Fortunately, this is compensated for by the fact that porphycenes absorb much more strongly. Moreover, the triplet state usually generates singlet oxygen with a nearly 100% yield (Table 9). Thus, the average value for $^1O_2$ photosensitization, 0.3 ± 0.1, is very close to the usual triplet formation efficiency, which allows porphycenes to be called "excellent photosensitizers".[17] When one is considering practical applications, however, it is to be remembered that the predictions obtained on the basis of *in vitro* experiments may not always be transferable to living systems. This was



100

demonstrated in a paper by Baumer and coworkers, devoted to singlet oxygen generation by 9-acetoxy-2,7,12,17-tetrakis-(β-methoxyethyl)porphycene **64** in solution.[177] The results showed that, due to very different oxygen concentrations *in vitro* and *in vivo* (lower in the latter), the obtained quantum yield values may be very different in the two cases.

Photosensitizing properties of porphycenes can also be exploited in the solid state. In work by Hisaeda and coworkers,[179] a porphycene derivative **100** was covalently immobilized in a sol–gel silica film. Under irradiation with visible light, singlet oxygen was produced, which was then used for oxidation of 1,5-dihydroxynaphthalene. This procedure could be recycled.

Photoexcited triplet states of several porphycene derivatives have been studied by EPR, ENDOR, and electron spin echo techniques.[25,168,174–176] These measurements resulted in the determination of the zero-field splitting parameters D and E, as well as the hyperfine coupling tensor components. Comparison of the latter with the values calculated for *trans* and *cis* forms of parent porphycene indicated that the molecule exists in the *trans* form in the triplet state.[25]

Very little is known about the triplet state properties of the other porphyrin isomers. Magnetic, kinetic, and structural parameters were determined using time-resolved EPR for OECp **20** and OEHPc **21** in toluene and liquid crystal matrices.[180] For doubly protonated OECp, studied in benzene solutions, the values of the quantum yield of triplet formation and singlet oxygen generation have been determined (0.82 and 0.38, respectively).[181]

V. Tautomerism

A. Tautomerism in Porphyrins

The process of migration of two internal protons between the four nitrogen atoms which form the inner cavity of porphyrin has been studied since the early

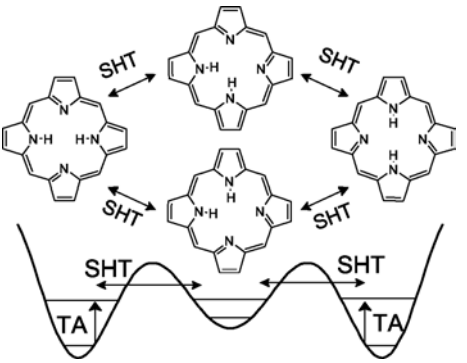


Figure 27. Scheme of stepwise tautomerization in porphyrin: TA — thermal activation; SHT — single hydrogen tunneling.

1970s.[182,183] The main issues considered are related to the stepwise vs. concerted mechanism of the reaction and the role of tunneling. After two decades of investigations, the tautomerization mechanism was established, based mainly on the NMR studies by Limbach and coworkers.[91–93] The reaction proceeds according to a stepwise mechanism, with thermal activation of a level isoenergetic with a transient *cis* tautomer intermediate. The second step involves single hydrogen tunneling through the potential barrier (Figure 27). The model is based on several experimental findings. The HH/DD isotope effect is very large, 17 at 273 K for parent porphyrin[92] and 29 for TPP,[91] whereas the HD/DD effect is much smaller (1.9 and 2.0, respectively). Such behavior is characteristic of a stepwise process which involves two consecutive hydrogen transfer steps via an intermediate. Large isotope effects (11 for **1** at 293 K) indicate tunneling, which is additionally corroborated by nonlinear Arrhenius plots. A remarkable observation is that for the parent porphyrin the tautomerization rate constants and isotope effects are the same for the liquid phase and polycrystalline environment. It was concluded that the liquid state degeneracy of two *trans* tautomers is maintained in the solid phase.[92] Finally, one should mention that the *cis* tautomeric intermediate, crucial for the mechanism, has never been experimentally observed in porphyrins.

The tautomerization occurs in porphyrin not only in the ground electronic state but also after photoexcitation.[184–186] This reaction proceeds even at liquid helium temperatures, in contrast to the dark process, which can be frozen at low temperatures. Such behavior enables photoorientation, i.e. achieving partial alignment of initially isotropic samples by irradiation with linearly polarized light. This methodology has been used for porphyrins isolated in rare-gas matrices.[94,95,187,188] Combining photoorientation with linear dichroism studies enabled polarization assignments for transitions observed in the electronic and IR absorption spectra, as well as detailed characterization of matrix site characteristics.[162,163] The mechanism of photoinduced tautomerization in porphyrin most probably involves a triplet state.[96,189]

B. Tautomerism in Porphycenes

1. *Coherent Double Hydrogen Tunneling in Isolated Molecules*

Quantum mechanics dictates the delocalization of wave functions in a system containing several energy minima separated by barriers, as long as the barriers are finite. Porphyrin and porphycene provide examples of such compounds: two chemically equivalent tautomers are separated by a potential barrier. For such a special, symmetric double minimum case, the two tautomers are equally probable, and the energy levels are split into doublets (Figure 28). Because of selection rules, only certain transitions between tunneling levels are allowed. For the S_0–S_1 electronic absorption or emission, these are the transitions labeled O_+^+ and O_-^- in Figure 28, involving either lower or upper tunneling levels in S_0 and S_1.

The value of the tunneling splitting depends on the mass of the tunneling particle, the distance it has to travel, and the effective tautomerization barrier. Naturally, these parameters should be strongly correlated with the molecular structure, in particular with the strength of the NH···N intramolecular hydrogen bonds. Shorter, more linear hydrogen bonds should yield lower barriers to tautomerization. One could therefore expect a smaller barrier for porphycene than for porphyrin, a prediction which was fully confirmed by calculations.[44,190] As a consequence, tunneling splittings in porphycene should be be larger than in porphyrin. Indeed, the fluorescence excitation spectrum of porphycene isolated

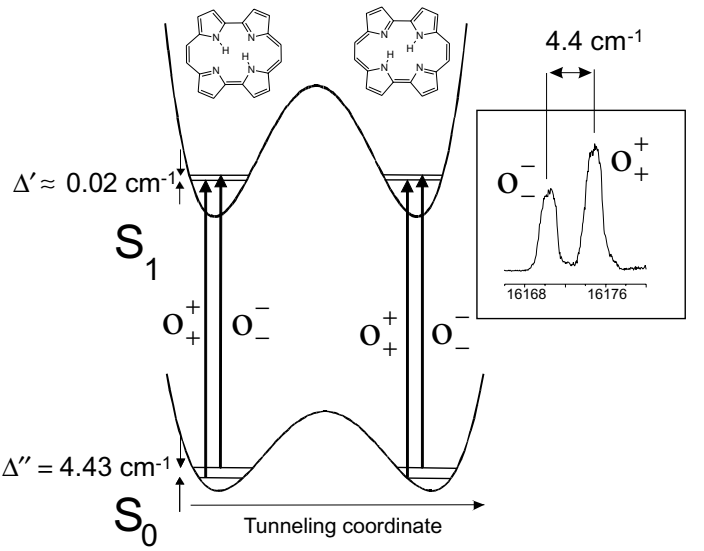

Figure 28. Tunneling splitting due to delocalization of internal protons in porphycene, and the allowed optical transitions between the ground and the lowest excited singlet state. Inset: The 0–0 region of the fluorescence excitation spectrum of porphycene isolated in a supersonic jet, revealing the tunneling splitting.[22]

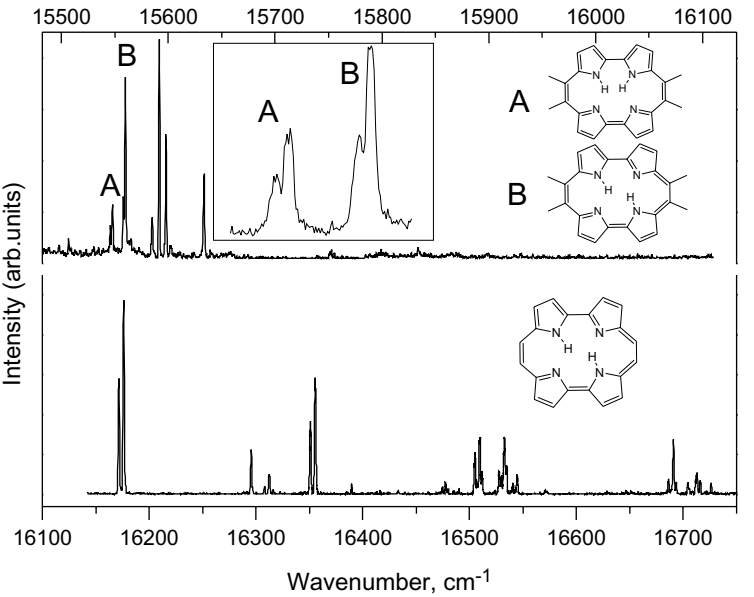

Figure 29. Fluorescence excitation spectra of parent porphycene (bottom) and of 9,10,19,20-tetramethylporphycene **29** (top) isolated in supersonic jets. The inset shows the expanded region of the 0–0 transitions for *cis* (A) and *trans* (B) tautomers of **29**. (Modified with permission from Ref. 30.)

in supersonic jets consists of doublets, separated by 4.4 cm^{-1} (Figures 28 and 29).[22] In contrast, the spectrum of supersonic-jet-isolated porphyrin reveals no splittings.[191]

The proof that the splittings are due to coherent double hydrogen tunneling was provided by experiments on porphycene with one ($Pc–d_1$) or two ($Pc–d_2$) internal protons substituted by deuterons. No splittings were observed under these conditions.

In general, the splittings observed in the spectra express the difference between ground and excited state tunneling splitting values. For a special case where the splitting is negligibly small in one of the states, the separation of the spectral lines becomes equal to the tunneling splitting in the other state involved in the monitored spectral transition. This is the case for porphycene, as revealed by the same values of doublet separation observed for the 0–0 transition and numerous vibronic peaks. Based on the red shifts observed in the spectra of $Pc–d_1$ and $Pc–d_2$, it was concluded that the observed 4.4 cm^{-1} separation of doublet components is practically due entirely to the splitting in the ground electronic state.[22] The finding of a much larger tunneling splitting in the ground electronic state than in the first excited singlet state was explained assuming that the molecule expands upon excitation. In particular, the

two NH···N distances become larger, which weakens the intramolecular hydrogen bonds and thus leads to an increase of the tautomerization barrier. This hypothesis has been confirmed by geometry optimization of electronically excited porphycene.

About a decade later, the conclusions reached on the basis of supersonic jet studies were confirmed and extended by an investigation of porphycene embedded in helium nanodroplets.[40] These studies, carried out at a lower (and, in contrast to the jet, well-defined) temperature of 0.37 K and with better spectral resolution yielded 4.43 cm^{-1} as the tunneling splitting value of the ground state vibrationless level. It was also possible to obtain the respective splitting for Pc–d_1; a value of 0.58 cm^{-1} has been measured. In addition, the value of the splitting in S_1 was estimated at 0.02 cm^{-1}.

Most spectacular were the results of fluorescence measurements, which yielded the tunneling splitting values for different vibrational levels of the electronic ground state. These values were found to depend crucially on the particular vibrational mode. Thus, for some vibrational levels, the splitting values were very close to the value observed for the 0–0 transition. For a 182 cm^{-1} a_g mode, the splitting was much higher — 12 cm^{-1}. On the contrary, for another a_g mode, 145 cm^{-1}, the splitting was found to be so small that it could not be experimentally resolved. It was thus demonstrated that the tunneling is mode-specific. In other words, tautomerization characteristics may be different for different vibrational levels. Some modes can promote the process by lowering the barrier, which is manifested by a larger tunneling splitting. Other vibrations may increase the barrier and thus decrease the splitting. Finally, there exist also "neutral" vibrations, which, when excited, do not change the effective barrier penetrated by the tunneling protons.

The forms of several low-frequency modes, including the "promoting" ($2a_g$), "hindering" ($1a_g$), and two "neutral" ones ($3a_g$ and $4a_g$), are presented in Figure 30. In accordance with chemical intuition, the neutral modes do not greatly affect the hydrogen bond parameters, whereas the others do that to a great extent. Especially instructive is the form of the promoting $2a_g$ mode. For this vibration, the nuclear motions simultaneously make both hydrogen bonds shorter and more linear. The smaller barrier for double hydrogen tunneling (and, in consequence, a larger tunneling splitting) is therefore easy to understand. The behavior of the hindering $1a_g$ mode is the opposite: this vibration results in weakening of the hydrogen bonds.

A detailed supersonic jet study was also performed for two *meso*-substituted porphycenes, **11** and **29**.[30] Since the X-ray and NMR data[71] indicate stronger hydrogen bonds, one could expect larger tunneling splitting values. Indeed, the values for the ground and the lowest excited singlet state were estimated at 15 cm^{-1} and 2 cm^{-1}, respectively. Most interestingly, the potential for tautomerization in **29** was found not to be symmetric, the reason being the coupling between the motion of the internal protons and the methyl substituents. The asymmetry is reversed upon excitation (Figure 31).

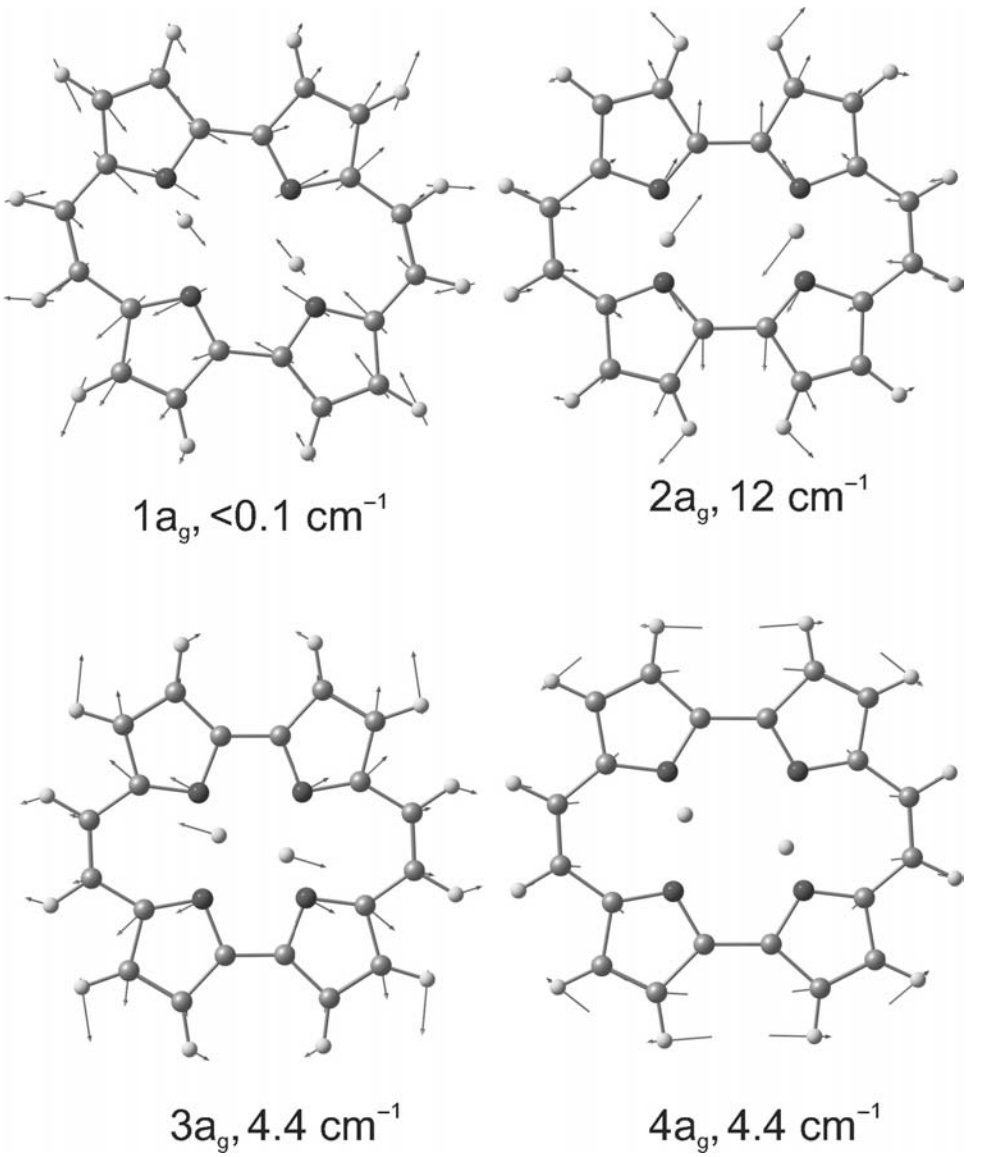

Figure 30. The forms of four lowest-frequency a_g modes of porphycene with the corresponding values of ground state tunneling splittings determined from fluorescence in helium nanodroplets at 0.37 K.[40]

These supersonic jet studies resulted in another valuable finding. The fluorescence excitation spectra of **11** and **29** exhibit a structure consisting of a doublet of doublets (features A and B in Figure 29). One of the doublets disappears upon cooling. In a singly or doubly deuterated derivative, features A and B consist of

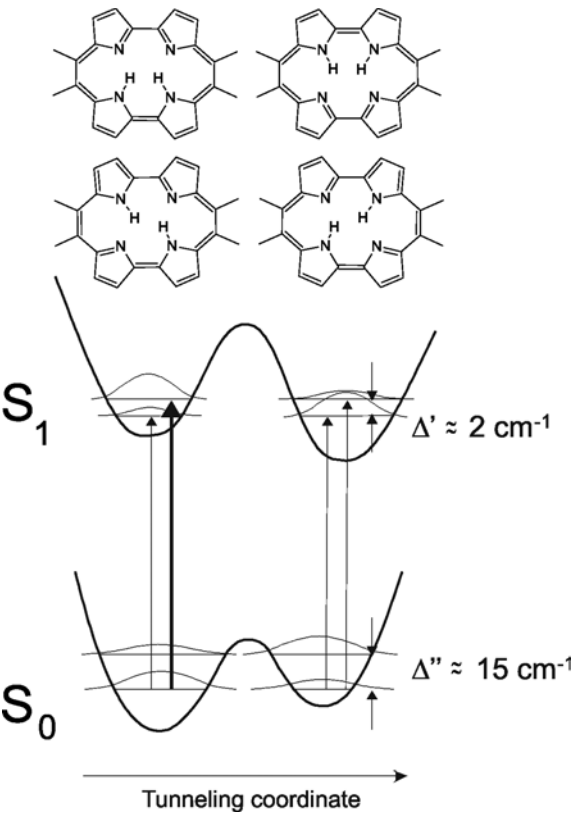

Figure 31. The shapes of potential energy curves governing tautomerization in 9,10,19,20-tetramethylporphycene **29**, with the estimated values of tunneling splitting in the S_0 and S_1 electronic states. (Modified with permission from Ref. 30.)

single lines. These findings were interpreted as an indication of the presence of both *cis* (feature A) and *trans* (feature B) tautomeric forms, each revealing similar tunneling splitting values in S_0 and S_1. The existence of both tautomeric forms was also confirmed for solutions, by observing doubly exponential fluorescence decays.[39] The calculations predict that the two tautomeric forms in **29** should have similar energies, differing by less than 1 kcal/mol. To the author's knowledge, this molecule is so far the only porphycene for which the presence of both *cis* and *trans* tautomeric forms has been reported.

Finally, the results of supersonic jet studies confirmed the existence of a rapid deactivation channel in electronically excited *meso*-alkylated porphycenes. As seen in Figure 29, the fluorescence excitation spectra are limited to a narrow range above the 0–0 transition — less than 200 cm^{-1}. Excitation with higher energy excess leads to the disappearance of fluorescence, indicating the

onset of an efficient radiationless process. According to the model discussed in Section IV.A, the deactivation efficiency should be related to the medium viscosity, extremely low for a supersonic jet. Therefore, the activation energy for this channel in the jet should be lower than that determined from solution studies. This is indeed the case, which provides yet another argument for the model which postulates that the radiationless deactivation of excited porphycenes proceeds along the pathway involving both hydrogen transfer and distortion from planarity.[39]

2. *Molecules in Condensed Phases*

a. *Ground state tautomerism in polycrystalline porphycene*

Early ^{15}N-CPMAS-NMR comparative studies of crystalline porphyrin and porphycene by Limbach and coworkers[18] showed a much larger tautomerization rate in the latter. The line shape analysis allowed one to determine tautomerization rates in porphyrin; they decrease from >30000 s^{-1} at 356 K to 500 s^{-1} at 244 K. For porphycene the rates were too fast to be determined, as no line broadening was detected, even at the lowest available temperature of 107 K. Four sharp lines were observed, indicating the presence of two nonequivalent asymmetric proton transfer systems. Two alternative explanations were proposed: (i) existence of two nonequivalent molecules in the crystal, each having access to two tautomeric states; (ii) equivalence of all the molecules in the crystal, each with four accessible tautomeric states. The nonequivalence of tautomers is due to crystal effects.

Further studies of porphycene enabled determination[24] of the rate constants from the analysis of longitudinal ^{15}N T_1 relaxation times in the temperature range 228–355 K. The tautomerization was found to occur on a nanosecond time scale. The temperature dependence of the rate pointed to the dominant role of tunneling across a barrier of about 8 kcal/mol. A concerted mechanism of tautomerization was suggested, based on strong coupling between the two hydrogen bonds.

Work from Limbach's group,[37] based on high-resolution ^{15}N and ^{2}H NMR spectroscopy and longitudinal relaxometry, yielded several unusual results. The tautomerization rates have been found to decrease sharply at higher temperatures. Above 225 K, the rate was reported to drop by four orders of magnitude. A phase transition was postulated to occur at this temperature. Another unexpected finding was the observation of the same rates of the HH and HD/DD tautomerism. The authors proposed that the reaction occurs in a concerted fashion at high temperatures and as a stepwise process at low temperatures. In the low-temperature region, non-Arrhenius behavior was observed for the DD transfer, indicative of tunneling. Finally, two nonequivalent molecules were detected in

the unit cell, corroborating the hypothesis proposed in the first NMR study on porphycene.[18]

b. *Studies using polarized spectroscopy techniques*

The measurements of fluorescence anisotropy of porphycene showed that the emission is partially depolarized.[19,20] An example is presented in Figure 32. When the molecule is excited into S_1, the anisotropy value is below 0.20 instead of 0.4, expected for parallel orientation of absorbing and emitting transition dipole moments. In turn, for excitation into S_2, the anisotropy is around 0, whereas, judging from the results of calculations, it should be close to –0.2, because the S_0–S_1 and S_0–S_2 transition moments are predicted to be nearly perpendicular.

These results can be understood by assuming a rapid *trans–trans* tautomerization in the excited state. The reaction changes the direction of each transition moment. Tautomerization is equivalent to the reflection of the transition moment in the vertical or horizontal plane perpendicular to the plane of the porphycene macrocycle (Figure 33). In a high-temperature regime, when the reaction occurs many times back and forth before the excited molecule emits a photon, the probabilities of emitting with a transition moment corresponding to that of the initially excited and that of the other tautomer are equal. The observed value of the anisotropy is related to the position of the transition moment in the molecular

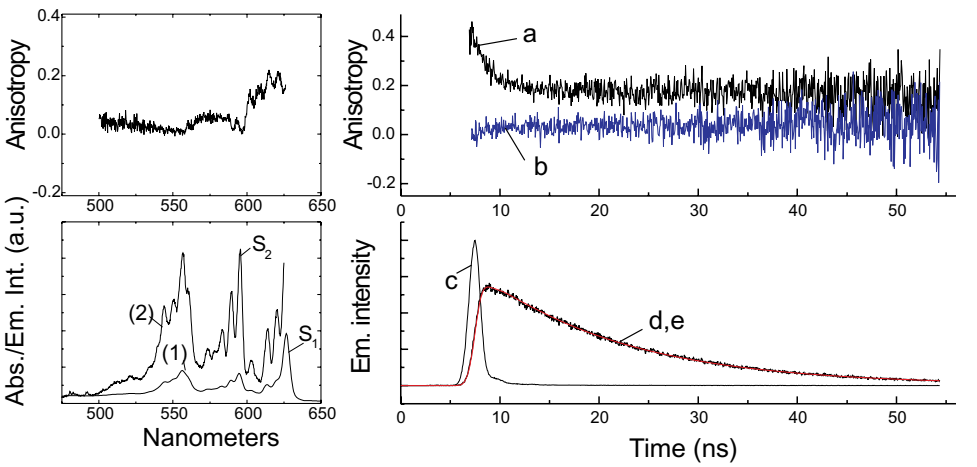

Figure 32. Porphycene in 1:1 methanol:ethanol glass at 97 K. Left — absorption (1) and fluorescence excitation (2); top — anisotropy of fluorescence excitation. Right — decay of anisotropy for excitation into S_1 (625 nm, a) and S_2 (590 nm, b); bottom — experimental (d) and fitted (e) fluorescence decay curve and the excitation profile (c). (Modified with permission from Ref. 32.)

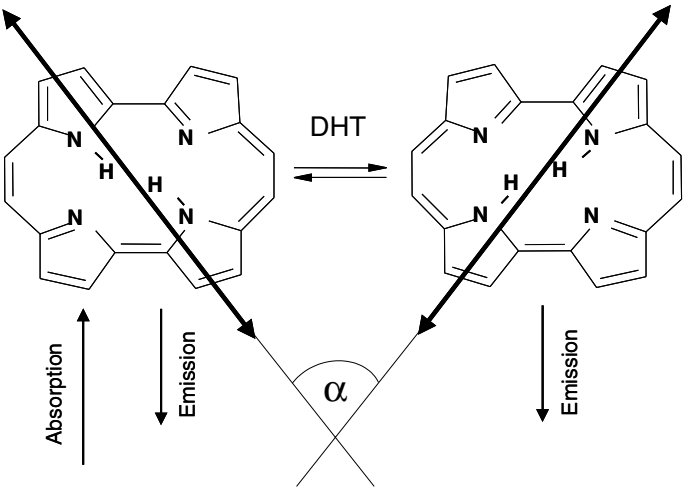

Figure 33. Change in the transition moment direction caused by double hydrogen transfer in porphycene. The structure on the left corresponds to the initially excited form.

plane. Therefore, it is possible to determine the transition moment directions, using fast excited state tautomerization as a tool. This has been performed for the parent porphycene.[20] Even though the symmetry of porphycene is C_{2h}, which allows any direction in the molecular plane, the directions of S_0–S_1 and S_0–S_2 transition moments resemble the situation in free-base porphyrin: the transition to S_1 is polarized approximately along the NH direction, and the transition to S_2 is nearly perpendicular to it. Initial anisotropy studies of OECp indicate similar behavior of the transition moments corresponding to two lowest excited singlet states.

The observation of depolarized fluorescence immediately shows that the dominant tautomeric structure corresponds to the *trans* tautomer, as the direction of the transition moments does not change during the *cis–cis* conversion. *Trans–cis* or *cis–trans* processes would lead to different values of the anisotropy than observed experimentally.

Comparative studies of four different porphycenes, **2**, **10**, **11**, and **15**, performed in *n*-propanol glass at 113 K revealed depolarized fluorescence for all but the last of these compounds. Thus, at this temperature, the reaction is too slow in **15** to occur within the excited state lifetime, about 10 ns. Octaethylporphycene **15** has the largest NH···N distance of all the studied porphycenes, and thus the weakest hydrogen bonding. This explains the lowest tautomerization rate for this molecule. As discussed later in this section, the difference in rates is dramatic, which is most probably due to the tunneling mechanism of hydrogen transfer in porphycenes.

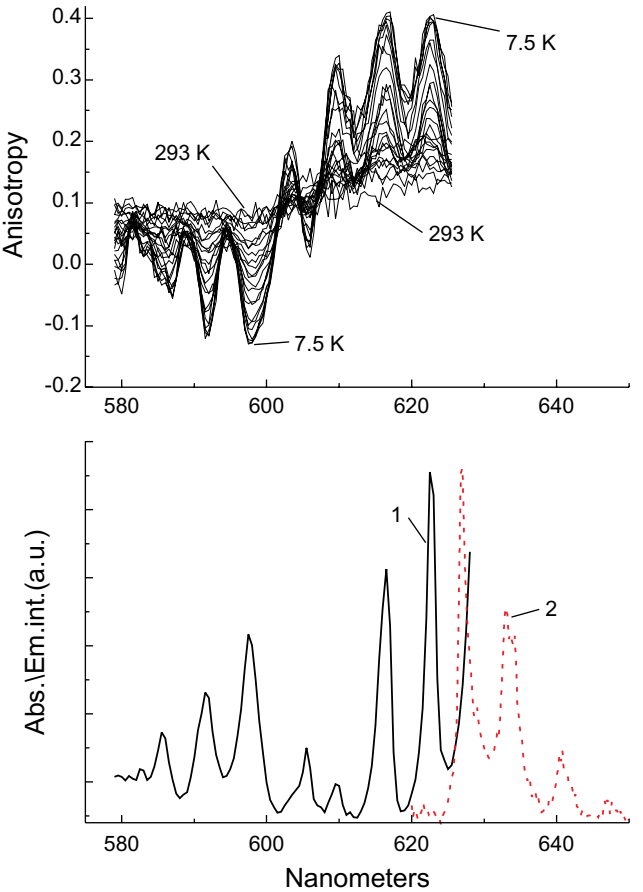

Figure 34. Top: Temperature dependence of the anisotropy of fluorescence excitation recorded between 293 and 7.5 K for porphycene embedded in a poly(vinyl butyral) matrix. Bottom: Fluorescence excitation (1) and fluorescence at 15 K. (Modified with permission from Ref. 32.)

A methodology has been developed[31,32] which enables determination of the excited state tautomerization rates from the analysis of absorption anisotropy, measured in both the stationary and time-resolved modes (see Figures 32 and 34). Studies of the temperature dependence of the anisotropy of porphycene fluorescence (Figure 34) resulted in an Arrhenius plot from which a surprisingly low activation energy, 0.55 kcal/mol, was extracted. This was interpreted as evidence of thermally activated double hydrogen tunneling. The value of the apparent tautomerization barrier is, within the experimental error, equal to the frequency of the $2a_g$, "promoting" mode, which was found to reveal the largest tunneling splitting for the chromophore isolated in helium nanodroplets (See Section V.B.1 and Figure 30).

The methodology was subsequently extended to transient absorption studies, or, more generally, to pump–probe experiments.[35,36] This approach allows determination of the rates not only for the electronically excited but also for the ground state. The rates in both states can be determined in one experiment by changing the pump/probe wavelengths.

Using this technique, the rates of double hydrogen transfer, in both S_0 and S_1, have been measured for porphycene **2** and four derivatives: **11**, **15**, **29**, and **30**.[36] The results are presented in Figure 35 and Table 11. The difference in the rates is striking: the values vary by over three orders of magnitude. The fastest reaction is observed in the two porphycenes in which the hydrogen bonding is the strongest, i.e. **11** and **29**. The slowest rate is obtained for **15**, a molecule with the largest NH···N distance. The values of the rates correlate nicely with ^{1}H chemical shifts, which thus can be treated as good indicators of intramolecular hydrogen bond strength. Other indices, i.e. the X-ray-determined or calculated NH···N, also work nicely

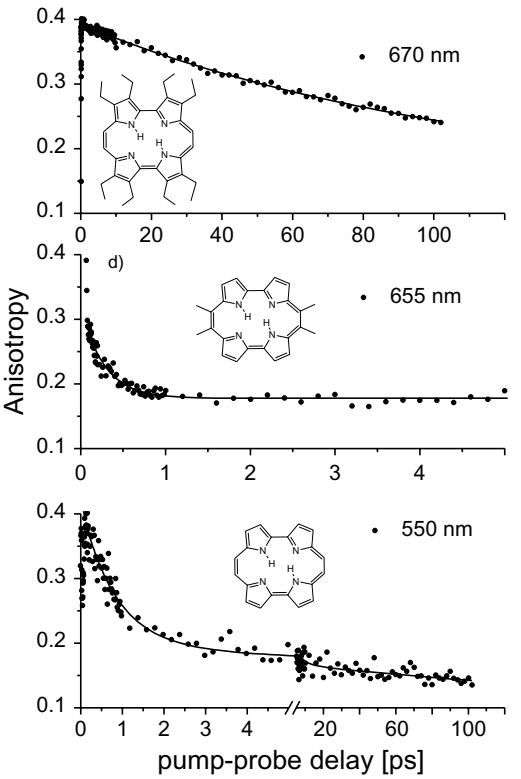

Figure 35. Time-resolved anisotropy of transient absorption measured at 293 K for **2**, **15**, and **29** in ethylene glycol. The wavelength of pump and probe pulses is indicated for each compound.

Table 11. The rates of tautomerization in five different porphycenes in the ground (k_0) and the lowest electronically excited singlet state (k_1), measured at 293 K in ethylene glycol solutions.[36]

	k_0 (s^{-1})	k_1 (s^{-1})
2	$5.8 \cdot 10^{11}$	$7.4 \cdot 10^{10}$
2-d_2[a]	$1.3 \cdot 10^{11}$	$1.5 \cdot 10^{10}$
30	$13.7 \cdot 10^{11}$	$2.0 \cdot 10^{11}$
30-d_2[a]	$1.7 \cdot 10^{11}$	$2.6 \cdot 10^{10}$
11	$\sim 10^{13}$	$1.9 \cdot 10^{12}$
29	$\sim 10^{13}$	$1.9 \cdot 10^{12}$
15	$\sim 10^{10}$	$\leq 10^{9}$

[a]Obtained from the isotope effects measured in O-deuterated ethanol or butanol.

when the corresponding values strongly differ, but fail for geometrically similar structures, like **2** and **30**, for which the tautomerization rates vary by a factor of 2–3. The fact that the change in NH···N separation from 2.53 Å in **11** to 2.80 Å in **15** results in rate constants differing by orders of magnitude provides another argument for the dominant contribution of the tunneling mechanism, even at room temperature.

In all the investigated porphycenes the reaction is slower in S_1, by approximately an order of magnitude, in agreement with the smaller tunneling splittings observed for the excited state.

The same pump and probe methodology was used to determine the rate of an intermolecular process — exchange of internal hydrogen atoms by deuterons provided by the solvent, deuterated alcohol.[35] The reaction, studied for **2** and **30**, turned out to be unusually slow; at 293 K, about 20 hours were required to complete the double deuteration. The kinetic evolution of Pc-d_0, Pc-d_1, and Pc-d_2 populations could be monitored separately for each tautomer (Figure 36). The same value was obtained for the rates of the first and the second deuteration.

The results obtained so far suggest a mechanism for tautomerization in porphycene which is presented in Figure 37, together with the corresponding scheme for porphyrin. As opposed to a stepwise mechanism for the latter, the double hydrogen transfer in porphycene occurs most probably in a concerted fashion. The barrier for the concerted transfer in **2** is significantly lower than in **1**. Moreover, it can be dynamically modulated by vibrational excitation. It is possible that exciting the 182 cm^{-1} promoting mode is sufficient for inducing a rapid tunneling. Remarkably, such energy excess is small with respect to the *cis–trans* energy difference, calculated as about 2 kcal/mol.

Tunneling of two internal hydrogen atoms in condensed phases has been demonstrated to occur at low temperatures by the studies of unsymmetrically

substituted acetoxyporphycene **45**.[23] In this molecule, two *trans* tautomers are no longer degenerate. Both forms can be observed in the absorption spectra, their $S_1(0–0)$ transitions differing by about 10 nm. Fluorescence, on the other hand, occurs preferentially from one form, indicating a nonsymmetrical excited state potential. Combined absorption/emission studies, carried out in a large temperature range, showed that the two forms interconvert in the ground electronic state even at temperatures below 20 K. The asymmetry of the potential in S_0 was estimated to be very small, but in S_1 the internal hydrogen atoms become localized (Figure 38).

c. *Tautomerization in the triplet state*

Studies of porphycene by time-resolved EPR, ENDOR, and electron spin echo techniques have been carried out in a large temperature range.[25,174–176] These investigations,

combined with calculations of triplet and singlet geometries, allowed establishing that porphycene exists in the *trans* form in the triplet state.[25] The calculations also indicated that the energy difference between *cis* and *trans* tautomers is larger in T_1 than in S_0 (21.6 vs. 11.25 kJ/mol, B3LYP/6-31G*). The inner cavity is expanded in T_1, the increase in the rectangle sides being about 0.6% with respect to S_0.

Investigations of parent porphycene in a toluene glassy matrix in the temperature range 4–100 K indicated the presence of two triplet state species;[176] only one form is observed at 4 K, whereas the population of the other increases with temperature. This was interpreted as evidence of triplet state tautomerism, with the maximum rate at 100 K estimated at $7 \cdot 10^8$ s^{-1}.

3. *Single Molecule Studies*

Fluorescence detection is one of the favorite techniques in single molecule spectroscopy. It is often coupled with use of polarized light. The fact that the transition moment direction in porphycene changes after tautomerization suggested a possibility of monitoring the double hydrogen transfer reaction in a single chromophore. This was achieved by analyzing spatial profiles of the emission excited with an appropriately polarized laser beam.[29] Figure 39 shows the spatial patterns

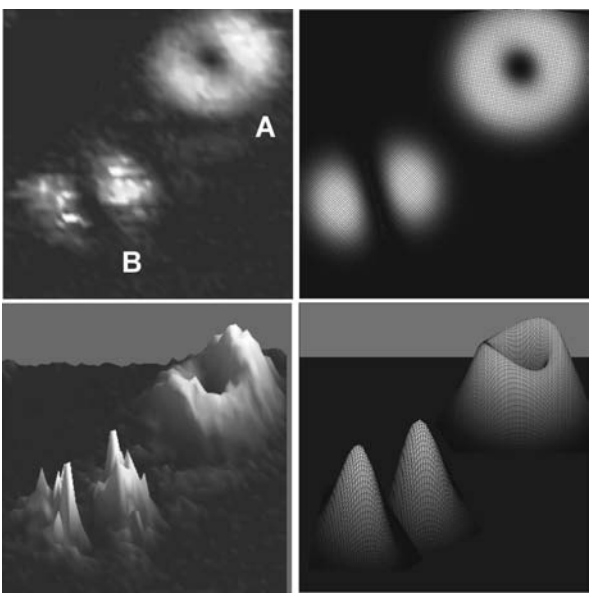

Figure 39. Left: Confocal image of two fluorescing porphycene molecules in PMMA matrix. Right: Simulated patterns. The lower pictures represent 3D plots of the same area as the upper ones. (Adapted with permission from Ref. 29.)

of the emission from two porphycene molecules embedded in poly(methyl methacrylate) film. Simulations demonstrate that a ring pattern cannot be obtained from a single emitting dipole. On the other hand, such a pattern is readily reconstructed assuming two transition dipoles forming an angle of 72°, in excellent agreement with the results obtained for bulk samples in stationary fluorescence[20] and, independently, transient absorption experiments.[36]

While the interpretation of the ring shape as being due to a "dual-dipole emitter" was straightforward, this was not the case with the double lobe pattern. It may be due to a dual emitter molecule which is oriented perpendicular to the surface plane or, alternatively, it may originate from molecules in which, for some reason, the tautomerization is hindered and which therefore emit "normally" as a single dipole. Although the latter case seems less probable, such a possibility had to be checked. The issue was resolved by comparing special patterns of the same single chromophore using two polarization modes, azimuthal and radial (Figure 40).[38] This analysis left no doubt that the emitting single chromophores contain two transition dipoles. Moreover, using two polarization modes of the exciting laser beam, it was possible to determine the 3D orientation of the chromophore in the polymer matrix. For molecules oriented perpendicular to the matrix support plane, such analysis allows one to differentiate the chromophores in which the two transition moments form similar angles with the sample surface from those in which one transition moment is approximately parallel and the other approximately perpendicular to the surface (molecules 2 and 3, respectively, in Figure 40).

So far, tautomerization at a single molecule level has been observed for four different porphycenes, namely **2**, **30**, the "mixed" derivative **40**, and the recently synthesized 2,7,12,17-tetratriphenylmethylporphycene **101**. Given the importance

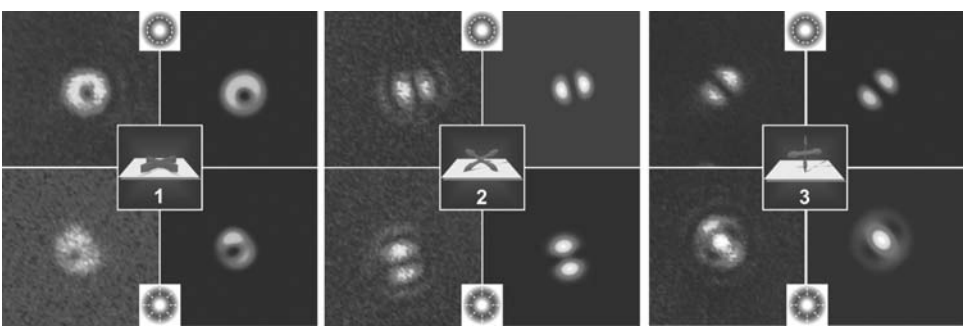

Figure 40. Confocal fluorescence images from single molecules of 2,7,12,17-tetra-*tert*-butylporphycene **30** excited by azimuthally (top) or radially (bottom) polarized laser beam. Left — experiment; right — simulation. The insets show the orientation of the transition moments with respect to the sample surface. (Adapted with permission from Ref. 38.)

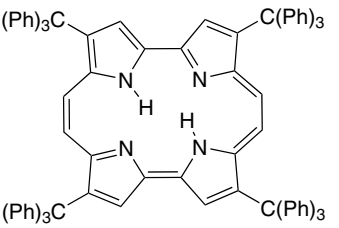

101

of porphycenes in photodynamic therapy and photodiagnostics, this methodology carries great potential for studying biological systems.

VI. Summary and Outlook

Structural, spectral, and photophysical studies of free-base porphycenes reveal important differences with regard to the corresponding characteristics of porphyrins. The rectangular shape of the inner core results in a shorter distance between the nitrogen atoms and, as a consequence, in stronger, more linear hydrogen bonds. This leads to dramatic consequences for the mechanism of tautomerization. All the results obtained so far indicate that, in contrast to the situation in porphyrins, the double hydrogen transfer in porphycenes occurs in a concerted fashion. The low energy barrier for tautomerization leads to tunneling splittings which can be readily detected and characterized quantitatively. Such investigations, carried out for cold, isolated molecules, have shown the mode specificity of the reaction. In turn, experiments in condensed phases based on techniques which use polarized light allow determination of reaction rates in both ground and excited electronic states. Porphycenes thus provide a rare opportunity of probing, for the same system, the characteristics of double hydrogen transfer occurring either in a coherent fashion or as a rate process. In addition, the potential energy barrier for the process can be readily modified by chemically "mild" substituents, such as alkyl groups. Using such procedures, it is possible to increase or decrease the energy barriers and to perturb the symmetry of the double minimum potential. All these factors make porphycenes role models for studying intramolecular hydrogen bonding and tautomerization, and, in particular, such aspects of these phenomena as cooperativity of hydrogen bonding and proton translocation, tunneling, and mode specificity. Those porphycenes which reveal ultrafast hydrogen transfer seem to be promising candidates for quantum control experiments.

Several experimental observations for porphycenes still await interpretation. The large difference in the values of tautomerization rates at room temperature obtained by NMR spectroscopy for polycrystalline porphycene and by optical

techniques for the same molecule in solutions and polymer films has not yet been explained. Interestingly, the two methods yielded similar values at low temperatures. Another finding to be elucidated is the lack of the NH stretching band in the IR spectrum, even though the calculations predict that this transition should be the strongest of all. Evidently, harmonic approximation is not a good model, and the appropriate description has to take into account coupling with other modes, as suggested by the results obtained for porphycene isolated in supersonic jets and helium nanodroplets.

The absorption characteristics of porphycenes, qualitatively similar to those of porphyrins, are quantitatively very different. Larger transition moments for both Q transitions result in stronger absorption and more intense emission. Still, triplet states are populated with reasonable intensities, and the quantum efficiency of singlet oxygen generation is very high. All these properties make porphycenes extremely attractive candidates for use in photodynamic therapy. Actually, comparison of photodynamic activity of several porphycenes, bearing two or four methoxyethyl side chains, with the properties of Photofrin (an FDA-approved, clinically used sensitizer), showed that porphycenes were 17–220 times more active.[16] Since the difference in the extinction coefficient is only about 10-fold, and the triplet formation efficiency may be lower in porphycenes, other factors, such as membrane solubility, must be critical and favorable for porphycenes.

Strong fluorescence makes porphycenes good candidates for cellular imaging. Even more important, perhaps, is the huge sensitivity of the emission intensity in several alkyl-substituted porphycenes to the viscosity of the environment. This property may allow better characterization of localization in the cell and monitoring of cellular metabolism. A procedure for monitoring viscosity in a cell based on chromophores which exhibit viscosity-dependent fluorescence has been proposed recently.[192,193]

Another promising application of porphyrin isomers to biological systems which is being intensively developed[194–205] is to replace the porphyrin moiety in hemoproteins by porphycene, hemiporphycene, and corrphycene derivatives (see Chapter 20, by Hayashi).

The investigations of isomers other than porphycenes are still in the early stage. However, some general comparisons are already possible. Porphycenes, being negative-hard chromophores, have definitely the strongest absorption and, in consequence, the largest radiative constants. Moreover, these characteristics should not vary strongly among different derivatives, though modification of transition energies by substitution is possible. These properties, along with good triplet yield, make porphycenes the best choice for photodynamic therapy sensitizers among all the porphyrin isomers synthesized so far. Of the remaining three isomers, **6** and **8** should be similar to porphycene, as they are also predicted to be strongly negative-hard chromophores.

The small sensitivity of spectral properties of porphycenes to internal perturbations — and even smaller to external perturbations — suggests little use in analytical/sensoring applications. Here, corrphycene, isoporphycene, and their derivatives have greater potential. As soft chromophores, they should be very sensitive even to minor structural perturbations, such as changes in tautomeric equilibria or in the properties of the environment. MCD seems to be a method of choice for monitoring such changes.

Regarding photophysical characteristics, alkyl-substituted porphycenes are quite promising, with their fluorescence greatly affected by the environment. The potential of other isomers is still unknown. Hopefully, these compounds will be the subject of more intensive studies in the years to come. Naturally, availability of cheap and expedient synthetic procedures is a limiting factor. Recent progress in the synthesis of porphycenes[57,72,206] allows an optimistic forecast.

VII. Acknowledgments

The author is indebted to the many colleagues who contributed to the results presented in this work: Michał Gil, Hubert Piwoński, Natalia Urbańska, Alexander Vdovin, Piotr Fita, Czesław Radzewicz, Oksana Pietraszkiewicz, Marek Pietraszkiewicz, Jerzy Sepioł, Yuriy Stepanenko, Alfred Meixner, Alkwin Slenczka, Bernhard Dick, Achim Hartschuh, Clemens Stupperich, Alexander Kyrychenko, Jacek Dobkowski, Paweł Borowicz, Grażyna Orzanowska, Sylwester Gawinkowski, Gabriela Wiosna-Sałyga, Andrzej Mordziński, and Alexander Starukhin. The author is especially grateful to Emanuel Vogel and Josef Michl, who stimulated his interest in porphycenes. The help of Oleksandr Shkurenko in searching the Cambridge Structural Database is greatly appreciated. This work was partially supported by the grant N204 3329 33 from the Polish Ministry of Science and Higher Education.

36 Recent Applications of Infrared Spectroscopy and Microscopy in Chemistry, Biology and Medicine

Petra Hellwig and Frédéric Melin

Institut de Chimie, UMR 7177, Laboratoire de Spectroscopie Vibrationnelle et Électrochimie des Biomolécules, Université de Strasbourg, 1, rue Blaise Pascal, 67000 Strasbourg, France

List of Abbreviations

4-AcPy	4-acetylpyridine
Arg	arginine
Asn	asparagine
Asp	aspartic acid
ATP	adenosine triphosphate

ATR	attenuated total reflexion
C*a*	α-pyrrolic carbon atoms
C*b*	β-pyrrolic carbon atoms
Cyt	cytochrome
C_n-cap (n = 2, 3)	phenyl-capped tetraphenylporphyrin with $-O(CH_2)_nOCO-$linkers between the cap and the porphyrin
C*m*	*meso* carbon atoms
CASSCF	complete active space self-consistent field
DFT	density functional theory
DFT-SQM	density functional theory with scaled quantum-mechanical force field
2D-IR	two-dimensional infrared
DMAP	4-dimethylaminopyridine
DNA	deoxyribonucleic acid
IR	infrared
FEL	free electron laser
FIR	far-infrared
fs	femtosecond
FTIR	Fourier-transformed infrared
Gln	glutamine
Glu	glutamic acid
Hb	hemoglobin
Im	imidazole
ISP	iron–sulfur protein
Mb	myoglobin
MIR	mid-infrared
MeIm	methylimidazole
Me_2Im	dimethylimidazole
Mepip	methylpiperidine
$NapC_2$-cap	phenyl-capped tetranaphtalenylporphyrin with $-O(CH_2)_2OCO-$linkers between the cap and the porphyrin
NIR	near-infrared
NRVS	nuclear resonance vibrational spectroscopy
OC_3OPor	phenyl-capped tetraphenylporphyrin with $-O(CH_2)_3O-$ linkers between the cap and the porphyrin
OD	optical density
OEP	octaethylporphyrin

Pc	phthalocyanine
MedPiv	medium tail pocket porphyrin
OBTPP	octabromotetraphenylporphyrin
PDT	photodynamic therapy
Pip	piperidine
Piv_2C_n (n = 8, 9, 10, 12)	hybrid basket handle porphyrin with n carbons in the strap
PocPiv	small tail pocket porphyrin
PPIX	protoporphyrin IX
PPIXMe	protoporphyrin IX dimethylester
Py	pyridine
SDS	sodium dodecyl sulfate
SEIRAS	surface-enhanced infrared absorption spectroscopy
SERS	surface-enhanced Raman scattering
SIR	synchrotron infrared emission
SOMO	singly occupied molecular orbital
TalPiv	large tail pocket porphyrin
TAP	*meso* tetra(*p*-anisyl)porphyrin
TCP	twin coronet porphyrin
TCP-py	twin coronet porphyrin with a covalently bound pyridine
TDCPP	*meso* tetra(2,6-dichlorophenyl)porphyrin
TD-DFT	time-dependent density functional theory
TDFPP	*meso* tetra(2,6-difluorophenyl)porphyrin
TD-THz	time-dependent terahertz
THz	terahertz
TMP	*meso* tetramesitylporphyrin
T(*p*-CF_3)PP	*meso* tetra(*p*-trifluoromethylphenyl)porphyrin
T(*p*-CN)PP	*meso* tetra (*p*-cyanophenyl)porphyrin
TPFPP	*meso* tetra(pentafluorophenyl)porphyrin
TPivPP	*meso* tetra($\alpha,\alpha,\alpha,\alpha$-*o*-pivalamidophenyl)porphyrin
T(*p*-OCF_3)PP	*meso* tetra(*p*-trifluoromethoxyphenyl)porphyrin
TPP	*meso* tetraphenylporphyrin
TTP	*meso* tetra(*p*-tolyl)porphyrin
δ	label of in-plane deformation vibrational modes
γ	label of out-of-plane deformation vibrational modes
ν	label of stretching vibrational modes

I. Introduction

Infrared spectroscopy is a versatile technique that can be used for all types of materials, including polymers, biological samples, individual molecules and tissues. Although the theory of infrared spectroscopy has been thoroughly worked out, its scientific basis is currently undergoing a boost, with the application of this analytical technique in biology and biomedicine and the development of new time- and space-resolved techniques in chemistry and biochemistry.

For many years infrared spectroscopy has been a popular technique for analyzing porphyrins and their derivatives.[1–13] The vibrational modes typically found are specific to the porphyrin ring,[4,14,15] its oxidation and spin states,[14,16,17] the central ion and, more importantly, its axial ligands[18–22] and hydrogen bonding environment or interaction.[23,24] Normal coordinate analysis and other theoretical approaches can be applied for detailed analysis. Together with Raman spectroscopy, the technique has developed to a point where it is a standard analytical method that accompanies synthesis and characterization of porphyrin compounds.[25–29] This is especially the case for the mid- and near-infrared spectral ranges, where low cost instruments are available.

Infrared spectroscopy is used to study reaction mechanisms and has been crucially employed in clarifying reaction intermediates within the catalytic cycle of enzymes and their models.[11,30–33] Combination with other techniques, including photo- or redox chemistry, has been realized. Infrared microscopy and infrared imaging have recently emerged, adding the possibility of studying spatial resolution of molecular ensembles, tissues or crystals. The development of the step scan technique and the evolution of laser spectroscopies allowed studies with a time resolution up to the femtosecond (fs) range. The unique combination of molecular level structural information and ultrafast time resolution was achieved by two-dimensional (2D) IR spectroscopies, giving previously inaccessible insight into rapid structural fluctuations, vibrational dynamics and solvent–solute interactions.[34–36] Synchrotron radiation for high resolution gas phase infrared spectroscopy was used in pioneering applications at MAXLab in Sweden[37] and LURE in France,[38] and new facilities have been developed at a number of synchrotrons, including SOLEIL (France), the Australian Synchrotron, IRIS and ANKA (Germany), and the Swiss Light Source. Synchrotron radiation provides an infrared source that is much brighter than conventional thermal sources. This type of light source is ideal for applications requiring high spatial resolution (i.e. spectromicroscopy) or high spectral resolution (<0.001 cm^{-1}).

In this chapter, an overview of recent developments in the area of infrared-light-based spectroscopies is given along with selected examples from the field of porphyrins and their derivatives. Some emphasis will be given to studies of

hemoproteins derived from the respiratory chain. After a summary of the well-established mid-infrared spectral properties of porphyrins and derivatives, we will focus on the emerging NIR and FIR studies as well as IR differential spectroscopy induced by variation of external parameters like the redox state or temperature.

II. Infrared Absorbance Spectra of Porphyrins and Related Compounds

Infrared spectroscopists distinguish three main spectral ranges: the near-infrared (NIR) extends close to the visible from 12,500 to 4000 cm^{-1} (800–2500 nm), the mid-infrared (MIR) from 4000 to 450 cm^{-1} and the far-infrared (FIR) from approximately 450 to 2 cm^{-1} (13.5–0.06 THz). Normal coordinate analysis has been carried out for porphyrins starting from an idealized D_{4h} symmetry, and then the symmetry constraints were relaxed to take into account the deviation from planarity of the macrocycle as well as the rotation of peripheral substituents.[39–42] In D_{4h} symmetry the planar porphyrin core has 71 in-plane vibrational modes, out of which 18 of E_u symmetry are IR-active, and 34 out-of-plane modes, out of which 6 of A_{2u} symmetry are IR-active. *Meso*- or β-substitution of the porphyrin core further increases the number of vibrational modes: the metallotetraphenylporphyrins (MTPPs), for instance, have 169 normal modes, out of which 27% can be characterized by IR spectroscopy. The planar core of phthalocyanines has 165 normal vibration modes, out of which 8 of A_{2u} and 28 of E_u symmetry are IR-active.[43]

A. The Mid-Infrared or Rock Salt Region

The MIR absorption of porphyrins has been described for the simplest porphyrin or substituted ones (such as tetraphenylporphyrin (TPP) and derivatives, octaethylporphyrin (OEP), protoporphyrin IX (PPIX) and hematoporphyrin IX, *N*-methyl porphyrins), a variety of their metal complexes (Mg(II), Mn(II) and Mn(III), Fe(II) and Fe(III), Co(II) and Co(III), Ni(II), Pd(II), Pt(II), Cu(II), Ag(II), Zn(II), Cd(II)) and with or without biologically relevant additional ligands (O_2, CO, NO, imidazoles).[1–13,18] In some cases, a complete quantum-chemistry-based analysis is also available.[40,41] Usually up to four regions can be distinguished in the spectra.[18,39,41,44] Between 500 and 810 cm^{-1} there mostly appear out-of-plane vibrations of the porphyrin (in particular pyrrole folding modes, deformations $\gamma(H_\beta)$) as well as the phenyl deformation bands in the *meso*-phenyl-substituted porphyrins. The second region extends approximately from 900 to 1350 cm^{-1} and encompasses mainly in-plane vibrations (coupled pyrrole breathing and deformation bands, pyrrole half-ring modes, C–H in-plane bending modes). Between 1400 and 1700 cm^{-1} there appear the coupled stretching modes of the =C–N, C=N and

C=C bonds of the porphyrin core and the phenyl substituents. At higher energy (above 3000 cm^{-1}) the weak stretching N–H and C–H bands of the pyrrole and methine bridges can be seen. In addition, the spectra of protoporphyrin IX and hematoporphyrin IX derivatives show the strong pH-dependent absorption peaks of the propionate carbonyl stretches between 1700 and 1750 cm^{-1} and the weaker antisymmetric and symmetric C–H alkyl stretching mode just below 3000 cm^{-1}. The C=C stretching bands of the vinyl substituents of protoporphyrin IX can be found at approximately 1640 cm^{-1}.

A similar analysis of the spectrum can be done for phthalocyanines (Pc): below 900 cm^{-1} are encountered mainly the γ(C–H) and ring out-of-plane ϕ_{C-C} deformations, whereas between 1000 and 1500 cm^{-1} can be found the in-plane C–H bending vibrations. The C=C pyrrole, isoindole and benzene as well as C=N stretching vibrations can usually be distinguished in the spectra, in the region between 1300 and 1600 cm^{-1}. Just above 3000 cm^{-1} can be seen the stretching C–H vibrations.[43,45,46]

Partially reduced metalloporphyrins, such as chlorins, display more complex spectra, due to their lower molecular symmetry. All the modes which were forbidden for porphyrins of D_{4h} symmetry become IR-active in the corresponding chlorins. A strong band in the region 1620–1640 cm^{-1}, attributed to a C_{α}–C_{meso} stretching vibration, seems to be characteristic of chlorins.[47,48]

Several rare-earth double- and triple-decker porphyrins, phthalocyanines or mixed porphyrins–phthalocyanines have also been characterized by IR spectroscopy.[49–51]

1. *Square Planar M(II) Porphyrins and Analogs: Metal-Sensitive Bands*

When studying different monomeric metalloporphyrins with several divalent metals by IR spectroscopy, Thomas and Martell,[18] Boucher and Katz,[7] Ogoshi and coworkers,[44] and Lavallee[1] identified several metal-sensitive bands. Some sharp absorption bands near 960, 980 and 1000 cm^{-1} in the MTPP derivatives and between 920 and 970 cm^{-1} in the protoporphyrin and hematoporphyrin IX dimethyl ester derivatives, and attributed to either an in-plane deformation mode or a C–H rocking mode, shifted to higher frequencies approximately in the order Pt > Pd > Co, Ni > Cu > Ag > Zn > Cd > Mg. This dependency was suggested to be correlated with the strength of the metal–nitrogen bond in these complexes and is consistent with the order of stability of the metalloporphyrins. The weak bands attributed to the C=C and C=N stretches between 1500 and 1700 cm^{-1} also showed some metal dependency in both their frequencies and intensities, especially in the case of nonsubstituted porphyrins, octaethylporphyrin and *N*-methyl tetraphenylporphyrin derivatives.

Metallophthalocyanines show three strong absorptions in the 1000–1200 cm^{-1} region, which are sensitive to the nature of the central metal.[45]

2. *Five- and Six-Coordinate M(II) Porphyrins: Axial Ligand Bands*

Most porphyrin derivatives have been designed and studied to model the active site of hemoproteins which contain iron porphyrins coordinated to one or two axial ligands. Biologically relevant ligands include imidazoles, thiols, O_2, CO, CN^- and NO. The infrared frequencies of the axial ligand after binding can be compared to their respective values for the free ligand, which usually gives valuable insight into the strength and mode of coordination of these ligands to the metalloporphyrin.

a. *Imidazoles*

Mono-imidazole and bis-imidazole ligated iron porphyrins, as models of naturally occurring histidine ligated hemoproteins, have been mainly examined by Raman resonance spectroscopy, and only a few IR studies are available. These ligands show several characteristic bands in the MIR domain, which were assigned for 4-MeIm, 1-MeIm and Im using H/D and $^{14}N/^{15}N$ exchange.[52] The δ(CH) and ring stretching modes have been localized between 1400 and 1500 cm^{-1}, and δ(NH) modes between 1200 and 1350 cm^{-1}. Two specific vibrational modes have also been observed for all these ligands between 1060 and 1100 cm^{-1} and attributed to coupled ν(C–C) and δ(CH) modes and coupled δ(CH) and δ(NH) vibrations. These latter bands are clearly identified in the spectra of bis-imidazole iron porphyrins (Fe(P)$(Im)_2$) as well as in cyt b_{559} of the photosystem II complex, which contains a heme coordinated to two histidines of two distinct transmembrane α-helices.

b. *Dioxygen*

In its free form dioxygen (O_2) is IR-inactive; however, it is possible to observe a $\nu(O_2)$ band in metalloporphyrins and metallophthalocyanines, due to a nonsymmetric binding, but the band is expected to be weak, and therefore quite difficult to identify in the spectra.[53] In addition, O_2 adducts are sometimes formed only at very low temperature, or are quite unstable, requiring special technology for isolation and spectroscopic characterization. For instance, most O_2 adducts of metallotetraphenylporphyrins and octaethylporphyrins without additional axial ligands were obtained by the "matrix isolation" method.[54–59]

The $\nu(O_2)$ frequency shows some dependency on the nature of the metal and the sixth axial ligand. Depending on the family of porphyrins, these effects are small (see in Table 1 the picket fence porphyrins TpivPP and the capped porphyrins) or more pronounced (see the TPP family), and therefore difficult to

Table 1. $\nu(^{16}O_2)$, $\nu(^{16}O^{18}O)$, $\nu(^{18}O_2)$ frequencies measured in cm^{-1} in some O_2 adducts of synthetic porphyrins and hemoproteins.

predict and explain.[67] However, the intensity of the $\nu(O_2)$ band, its frequency, and its behavior upon isotopic exchange are considered as good indicators of the mode of binding of the O_2 ligand in these complexes.[61,62] Co(TPP)(O_2) showed a high $\nu(O_2)$ frequency and two $\nu(^{16}O^{18}O)$ frequencies, which is consistent with a superoxide-like end-on mode of coordination (see Figure 1). For Mn(TPP)(O_2) a peroxide-like side-on coordination of O_2 was proposed from EPR studies.[68] This seems to be consistent with the significantly lower value of $\nu(O_2)$ frequency obtained for this complex. It was also suggested that the higher value of $\nu(O_2)$ frequency obtained for Fe(TPP)(O_2) and Fe(OEP)(O_2) could belong to an end-on complex, whereas the lower value could belong to a side-on complex.[58]

c. *Carbon monoxide*

Carbon monoxide (CO) is also a biologically important molecule, since it is produced by heme catabolism. CO binds stronger than O_2 to unprotected hemes, making even the natural level of CO in cells potentially lethal. Therefore nature has developed its own mechanisms for preventing poisoning of hemoproteins by CO.[69] In this connection, a wide diversity of carbonmonoxy iron porphyrin models Fe(P)(CO)(L) (with L an additional nitrogen ligand) have been studied both in solution and in the solid phase to find out the environmental factors controlling the discrimination between CO and O_2 in natural hemoproteins. CO in its free form has a strong absorption band at 2143 cm^{-1}, in a region of the MIR where porphyrins do not show any major absorption, thus making carbonmonoxy metalloporphyrins rather easy to characterize by IR. When it is ligated to a metalloporphyrin, the frequency of this band decreases dramatically, by as much as 220 cm^{-1} (see Table 2). The *d*-electron back-donation mechanism,[70,71] which is well verified in the case of unprotected hemes, allows correlation of the decrease in the ν(CO) frequency with the strength of the Fe–CO bond: the lower the ν(CO) frequency, the stronger the Fe–CO bond.

Table 2 shows that the carbonmonoxy iron metalloporphyrins studied so far exhibited a quite large range of ν(CO) frequencies. Within the same system, it is even possible sometimes to observe several ν(CO) frequencies corresponding to different binding conformations (see for instance the TPP complexes in the solid phase[72] or the carbonmonoxy myoglobin[84] and cytochrome *c* oxidase in Table 2). Such important differences are now thought to arise from secondary interactions between the CO molecule and its environment in the binding pocket of the porphyrin as well as electrostatic effects,[53,72] rather than just deviations from the linearity of the Fe–CO bond, as initially suggested. First, when one is comparing carbonmonoxy metalloporphyrins with different sixth axial ligands L in solution, it appears that this ligand exerts a *trans* effect on the CO ligand, decreasing the ν(CO) frequency in the order 4-acetylpyridine > pyridine > 1-methylimidazole > dimethylaminopyridine > alkyl thiol.[81] Therefore, the more electron-donating this ligand is, the larger the effect will be. However, a very interesting study by Scheidt *et al*. on TPP complexes with different imidazoles (see Table 2)[72] showed that in the solid phase, additional interactions such as hydrogen bondings between bound CO and neighboring imidazoles lead to large differences in the observed ν(CO) frequencies and one of the lowest ν(CO) frequencies observed to date. In contrast, the "twin coronet" porphyrins (TCPs) showed some of the highest ν(CO) frequencies observed so far in metalloporphyrins.[82] These high frequencies were correlated with the presence of polar residues (such as oxygen atoms) close to the oxygen atom of the CO molecule. Therefore proton donors in the binding pocket

Table 2. ν(CO) frequencies measured for some representative iron(II) synthetic porphyrins and hemoproteins.

seem to favor the $Fe^{\delta+}$=C=$O^{\delta-}$ resonance structure, whereas electron-rich residues favor the $Fe^{\delta-}$–C≡$O^{\delta+}$structure.

In strapped porphyrins such as the "basket handle porphyrins" and in "capped porphyrins," a higher ν(CO) frequency was observed for tighter structures (see the comparison between the "hybrid basket handle porphyrins" with respectively 8, 9, 10, 12 carbon atoms in the strap,[80] and the comparison between C_3-cap and C_2-cap

compounds[73]). In "pocket porphyrins,"[78] the situation is less clear since the ν(CO) frequency of Fe(MedPiv)(CO)(1-MeIm) is lower than that of both the more encumbered Fe(PocPiv)(CO)(1-MeIm) and less encumbered Fe(TalPiv)(CO)(1-MeIm) systems. A combination of steric and electronic interactions between the bound CO and the strap or the cap was invoked to explain all these observations. The high dependency of the ν(CO) frequency on the metal environment in these systems justifies why CO has long been used as a sensor of the binding pocket in both synthetic metalloproteins and hemoproteins.

d. *Cyanide*

The ligand cyanide (CN^-) has been used for a long time as a common inhibitor and ligand of the active site of hemoproteins, mainly with iron in its +III oxidation state. Reduction of the low spin (cyano) Fe(III) hemoproteins usually leads to the (cyano) Fe(II) hemoproteins. However, it is only recently that a (cyano) Fe(II) complex of a synthetic porphyrin has been prepared and characterized, i.e. $[Fe(TPP)(CN)]^-$, by Scheidt and coworkers in 2008.[86] Interestingly, this complex exhibited two strong CN stretching vibrations at 296 K: a major one at 2070 cm^{-1} and a minor one at 2105 cm^{-1}. For comparison, the CN stretching vibration appears at 2098 cm^{-1} in gaseous HCN.[87] With the help of temperature effects, the major band was attributed to a low spin Fe(II) compound whereas the minor band was attributed to a high spin Fe(II) compound.

e. *Nitric oxide*

Many iron nitrosyl metalloporphyrins have been studied, particularly as models of the nitrite reductase enzymes, such as the cytochrome *c* nitrite reductase, which converts nitrite NO_2^- into ammonia NH_3. These compounds belong to the $\{M–NO\}^7$ family of metal nitrosyl complexes[88] (as established by Enemark and Feltham[89]), where the superscript 7 is the sum of *d*-electrons on the metal and electrons in the π^* orbital of NO. Other metalloporphyrins, with cobalt(II) and manganese(II), are also able to bind and activate NO. The corresponding nitrosyl complexes are members of the $\{M–NO\}^8$ and $\{M–NO\}^6$ families, respectively. Bis-nitrosyl metalloporphyrins have been reported, by subsequent reaction at low temperature between a parent mono-nitrosyl porphyrin and excess NO.[90,91]

In its gaseous form, NO absorbs at 1876 cm^{-1}, and this wavenumber decreases upon coordination to a metalloporphyrin (Table 3).

Like the ν(CO) in carbonmonoxy metalloporphyrins, the ν(NO) frequency is highly dependent on the electronic environment of the porphyrin. The macrocycle basicity has a direct influence on its value, as observed when one is comparing the

Table 3. $\nu(^{14}NO)$ frequencies obtained for some synthetic porphyrins.

various substituted porphyrins studied. Adding electron-donating substituents on the porphyrin (such as alkyl groups)[92,96] increases the electronic density on the metal, which in turns decreases the NO bond strength through *d*-electron back-donation. In contrast, adding electron-withdrawing substituents (such as $–CF_3$, $–OCF_3$ and halides)[96,98] decreases the electronic density on the metal, which is then less prone to back-donation; therefore the ν(NO) appears at higher frequency. Linear relationships between the ν(NO) frequency and the first oxidation potential of the porphyrin (which is linked to the porphyrin ring basicity) were derived from some of these data.[92] The axial base exerts a *trans* effect on the NO ligand,[93,96] decreasing the ν(NO) frequency in the order alkyl alcohol > piperidine > imidazoles. The ν(NO) frequencies below 1700 cm^{-1}, obtained for the iron(II) and cobalt(II) complexes, are consistent with bent M–N–O geometries, whereas those

of the Mn(II) porphyrins are consistent with a quasi-linear M–N–O geometry.[88] The bis-nitrosyl Fe(TPP)$(NO)_2$ complex, isolated at 213 K, showed a main NO band nearly twice as intense as the corresponding band of the parent mono-nitrosyl Fe(TPP)(NO) compound, suggesting that the two NO ligands have nearly the same electronic structure.[91]

3. *M(II) and M(III) Porphyrins: Redox- and Spin-State-Sensitive Bands*

From the study of 20 hexacoordinated Fe(TPP)(L)(L′) complexes (L and L′ are two additional axial ligands),[14] two structure-sensitive bands were identified; one strongly spin-dependent at 1330–1350 cm^{-1}, called band I; and the other strongly oxidation-state-sensitive at 806–790 cm^{-1}, called band II. Band I was usually observed at 1349–1343 cm^{-1} for low spin iron TPP derivatives and 1341–1333 cm^{-1} for high spin complexes, and was only slightly sensitive to deuteration of the β-pyrrolic protons. Calculations showed that this band corresponds to a highly mixed mode labeled ν_{41} with both some stretching ($\nu(C_\alpha–C_{meso})$ + $\nu(C_{meso}$–phenyl) + ν(pyrrole half ring)) and in-plane deformation ($\delta(C_\beta–H)$) characters.[41] Band II appeared at higher wavenumbers for Fe(III) species than for Fe(II) species and showed a strong shift upon deuteration of the β-pyrrolic protons. It was assigned from calculations to out-of-plane deformation vibrations ($\gamma(C_\beta–H)$ and pyrrole folding, labeled γ_5).[41]

Other studies on biologically relevant porphyrins such as protoporphyrin IX[10] revealed two main redox-sensitive bands; one in the C=C and C=N stretching region at 1575–1525 cm^{-1} involving β carbon atoms and labeled ν_{38}, and the other in the in-plane-deformation region at 1280–1262 cm^{-1} involving *meso* carbon and hydrogen atoms and labeled δ_{42}. A redox-sensitive band similar to band II, in the out-of-plane deformation region but at slightly higher wavenumbers (830–848 cm^{-1}), was also observed for these porphyrins.[101] All these bands are clearly seen in the spectra of hemoproteins[10,102] and are therefore used as specific redox heme markers.

Some axial ligand bands described previously are also highly metal-redox-state-sensitive. Carbonmonoxy iron(III) porphyrins are unknown; however, mono- and bis-cyano iron(III) porphyrins abound,[103] and nitrosyl iron(III) porphyrins have been prepared.[88] Nitrosyl ferric porphyrins belong to the $\{M–NO\}^6$ series and their ν(NO), at significantly higher frequencies than that of the ferrous analogs (see Table 4), is consistent with quasi-linear M–N–O groups and a Fe(II)–NO^+ electronic structure, sometimes suggested for these complexes. Interestingly, a ν(NO) frequency at 1913 cm^{-1} was detected in the reaction of *Paracoccus pantotrophus* cytochrome cd_1 nitrite reductase with nitrite,[104] showing that a nitrosyl ferric heme intermediate is probably formed. The measured ν(CN)

frequencies are also higher for the low spin iron(III) than for the low spin iron(II) metalloporphyrins (see Table 4).

4. *Porphyrin π-Cation Radicals*

Oxidation of both synthetic metalloporphyrins and natural hemoproteins can occur either on the metal or on the macrocycle itself, and FTIR allows a clear and simple identification of the oxidation site. The π-cation radicals of TPP metalloporphyrins (Cu, Fe) exhibit a strong band in the region 1270–1295 cm^{-1},[106] assigned by Hu and Spiro to the ν_{41} mode (ν(pyrrole half ring)) using selective deuteration.[107] This mode had been discussed before as being a spin state marker of Fe(II) and Fe(III) TPP derivatives. The increase in intensity of the corresponding IR band, when removing one electron from the porphyrin, was explained by a good matching between the topology of the a_{2u} SOMO of $TPP^{\bullet+}$ and the vibrational phases of ν_{41}. In contrast, π-cation radicals of OEP metalloporphyrins (Cu, Ni) showed increased intensity of two bands between 1550 and 1600 cm^{-1},[106] attributed to C_α–C_{meso} asymmetric stretchings (ν_{37}) and C_β–C_β stretchings (ν_{38}).[107] In this case, the SOMO of the porphyrin radical cation is of a_{1u} symmetry and is topologically adapted to the eigenvectors of ν_{38}. The π-cation radical of the sterically crowded and therefore highly unplanar Cu(II) octaethyltetraphenylporphyrin was also studied by IR spectroscopy.[108] It showed an intensity enhancement of the ν_{41} mode as well, but shifted at higher energy (1355 cm^{-1}), which is a probable consequence of the conformational distorsions in this porphyrin.

From the studies of double-decker actinide and lanthanide phthalocyanines or mixed phthalocyanines–porphyrins, a similar marker band for oxidized phthalocyanines was identified at about 1310 cm^{-1}, and assigned to pyrrole stretching.[49,109,110]

These π-cation radical characteristic bands led to a better understanding of the electronic structure of neutral, oxidized and reduced rare-earth double-decker phthalocyanines, bis-porphyrins or mixed phthalocyanines–porphyrins. Since Pc, TPP and OEP show different marker bands, it was possible to determine where the electronic hole preferentially resides in these complexes. Homoleptic complexes usually showed a delocalization of the hole over the two equivalent macrocycles. However, in (TPP)Eu^{III}(OEP) for instance, the electronic hole was rather localized on the OEP ring, whereas in [(TPP)Ce^{IV}(Pc)]$^+$ the hole could be found on the phthalocyanine.[50,51,110,111]

B. Recent Developments in the Near-Infrared

The NIR is widely used in analytical chemistry, industry and biomedical research.[112,113] In the biomedical field, this technique has gained importance because NIR light penetrates superficial layers (skin, subcutaneous fat, skull, etc.) and is either absorbed by chromophores (oxy- and deoxyhemoglobin and myoglobin) or scattered within the tissue. So-called NIR spectroscopy is a noninvasive and relatively low-cost optical technique that is becoming widely used instrumentation for determining tissue O_2 saturation, changes in hemoglobin volume and, indirectly, brain/muscle blood flow and muscle O_2 consumption.[114–116] Tissue O_2 saturation represents a dynamic balance between O_2 supply and O_2 consumption in the small vessels, such as the capillary, arteriolar and venular bed. Quantitative measurements of blood flow *in vivo* are possible using NIRS and a light-absorbing tracer, which can be applied to evaluate, for example, circulatory responses to exercise and to assess tissue O_2 saturation. The venular O_2 saturation can be estimated with NIRS by applying venous occlusion and measuring changes in oxygenated hemoglobin versus total hemoglobin. These various measurements provide the opportunity to evaluate several important metabolic and circulatory patterns in localized regions of tissue and may be fruitful in the study of occupational syndromes and a variety of diseases. This technique was further developed for NIR-spectroscopic imaging[117,118] and for cancer research.[119–121] Furthermore, absorption bands in the NIR are important in different fields of biomedicine. Extended porphyrins and conjugated porphyrin dimers have been developed, based on their favorable photophysical properties and intracellular behavior. These molecules are suitable for photodynamic therapy (PDT) and similar modalities.[122–126]

In chemistry, several NIR spectroscopic features have been found to be useful for the characterization of porphyrins and hemoproteins.[127,128] For example, "band III" in porphyrins is a fine probe of the heme pocket conformation. This signal, positioned in the NIR at ~760 nm (~13,200 cm^{-1}), is observed only in the deoxygenated derivative of Hb and is attributed to a porphyrin-to-iron charge transfer

electronic transition. This signal is sensitive to heme pocket structural relaxations, and is thus called the "conformation band". Recent studies include the analysis of hemoglobin conformational variations.[129]

C. The Far-Infrared or THz Spectral Region

1. *Modes of a Collective Nature*

The FIR is of great importance due to the rich chemical and physical processes observable in this spectral range and therefore has seen a flurry of research activity.[130–134] The interest in this spectral range is based on the observation that the FIR contribution of a wide range of molecules is dominated by vibrations involving a substantial fraction of the atoms forming the molecule and motion associated with intermolecular hydrogen bond vibrations. Due to their collective nature, such modes are highly sensitive to the intra- and intermolecular structure and thus provide a unique fingerprint of the conformational state of the molecule and effects of its environment.

The interest in this spectral domain originated from the prediction of the collective structural vibrational modes for DNA and other large biological molecules first presented more than 30 years ago.[135] As a consequence, the inter- and intramolecular hydrogen bonding interaction can be characterized and interesting broad features are found for proteins,[136,137] or any system containing hydrogen bonding components such as water.[138] This signal strongly depends on the polarizability of the hydrogen bond.[139] Theoretical predictions indicate a noticeable role of the vibrational anharmonicity in the FIR spectral features.[140]

Any molecule with internal hydrogen bonding structures displays a large broad feature in the FIR/THz range that seems to include dense, overlapping normal modes (see Figure 2).[141–143] Whereas chemists attribute this continuum to the low frequency hydrogen bonding modes,[144] in physics this large signal is named the "boson peak."[145] In crystals, lattice modes are also involved in this spectral region. Since the study of this spectral range for larger molecules and especially for the THz range is very recent, only a few publications are available.

The development of new sources, as well as progress in the interpretation of the results, is very promising.[133,146–151] In addition to the use of synchrotron light sources, so-called free electron lasers (FELs) have been developed for the FIR. FELs allow the generation of electromagnetic radiation in a wide field of frequencies through the proper adjustment of the energy of an electron beam and the field configuration of a magnetic undulator passed by this beam. The energy obtained is significantly higher than from conventional sources.[137,152] FIR or THz spectroscopy is currently being promoted to become a routine technique for

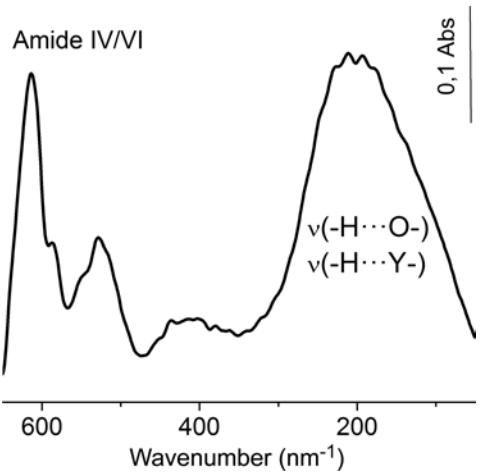

Figure 2. FIR spectrum of cytochrome *c* oxidase from *P. denitrificans,* including the amide region and the low frequency hydrogen bonding feature. Y represents any hydrogen bonding partner. In the spectra of large membrane proteins, the heme modes are less dominant. (Modified from Ref. 6.)

all-day use in science and industry. Quantitative studies show the potential of THz spectroscopy for the detection and identification of intermolecular hydrogen bonds in unknown mixture samples.[153,154]

An interesting example of an application, found in the field of porphyrin research, is the so-called heme "doming" mode. This motion seems to be significantly delocalized, so that distant sites respond to ligand interactions including oxygen binding on vibrational time scales. The delocalization has ramifications for understanding long range interactions in biomolecules, such as those that mediate cooperativity in allosteric proteins. In the spectral region below 300 cm^{-1}, the doming modes, the hydrogen bonding signatures and clearly defined signals of the metal–ligand vibrations are observed. Some examples are given below.

2. *Metal–Ligand Vibrations*

A classic application of the FIR involves the characterization of metal–ligand vibrations. In contrast to resonance Raman data, only a few infrared-spectroscopic reports are available for the FIR region; however, the analysis is often completed by a full theoretical study.[6,52,155,156] In the field of porphyrins, FIR spectra were published for Ni(TPP) using DFT-SQM calculations.[40] Paulat and coworkers presented infrared and resonance Raman spectra of different metalloporphyrin complexes (Fe, Mn and Co) with a Cl^- ligand, together with DFT calculations in the spectral range of 2000–300 cm^{-1}.[41] For Fe(TPP)Cl, a complete vibrational data set

was discussed. The use of FIR is again very important in the field, due to the development of THz spectroscopy and synchrotron-based infrared approaches.[6,8,155–157]

In a recent synchrotron-light-based study, FTIR absorbance data of different heme model compounds in the mid- and low-frequency regions were obtained from thin films of protoporphyrin IX, hemin, hematin, microperoxidase 11 and horse heart cytochrome *c*.[6] The porphyrin model compound data are dominated by ring motions; however, metal–ligand vibrations of noteworthy intensities are typically distinguishable, such as the Fe–Cl vibration at 345 cm^{-1} and the Fe–N vibrational mode at 378–390 cm^{-1}. The Fe–N vibration is especially important for the study of heme proteins, such as hemoglobin, myoglobin, or cytochrome *c* oxidase, where the iron–histidine bond is the only covalent bond between protein and the active site where oxygen binds. This vibration is a marker for changes in protein structure and dynamics.

Whereas the assignment of the Fe–N stretching motions between 250 and 200 cm^{-1} is well accepted for Raman spectra,[9,158] the position in the infrared data is under debate. This question was clarified by studying a model compound. The active site of oxygen-binding proteins was mimicked using the ferric protoporphyrin IX derivative hemin, coordinated to two imidazole molecules and embedded in sodium dodecyl sulfate (SDS) micelles.[155] The detergent simulated the hydrophobic cavity of heme proteins. Both infrared and Raman data are available for this compound.[155,159] The Fe–N motions were tentatively attributed to being involved in the asymmetric ν(Fe–N) vibration (378 cm^{-1}) and the ν(Fe–N) + δ(pyr *trans*) vibration (401 cm^{-1}). Paulat *et al.*[41] reported that the asymmetric Fe–N (N: imidazol-ligand) stretching vibration can be expected at 390 cm^{-1} and the ν(Fe–N) + δ(pyr *trans*) vibration at 402 cm^{-1}. Based on theoretical calculations, Mitchell and colleagues assigned the asymmetric ν(Fe–N) in spectra of Fe(III)(OEP)$(Im)_2$ to a signal at 386 cm^{-1}; the mode is coupled with the out-of-plane pyrrole tilting mode (pyr-tilt).[21] The signal would be expected around 350 cm^{-1} without the coupling of the modes. This assignment was recently confirmed.[156]

Within this context, the dynamics of a five-coordinate deoxymyoglobin model, Fe(TPP)(2-MeIm), is discussed in relation to the active site of the six-coordinate heme protein, carbonmonoxymyoglobin. The iron-imidazole stretching mode was identified at 226 cm^{-1} for the first time in a six-coordinate heme system.[8] The heme in-plane modes with large contributions from the ν_{42}, ν_{49}, ν_{50} and ν_{53} modes of the core porphyrin were identified. In general, the iron modes can be attributed to a coupling with the porphyrin core, the CO ligand, the imidazole ring and/or the phenyl rings. Other significant findings were the observation that vibrations of the porphyrin ring peripheral substituents are strongly coupled to the iron doming mode and that the Fe–C–O tilting and bending modes are related by a negative interaction force constant.[157]

In infrared spectra of proteins, the predominant features can be assigned in general to motions of the amide linkage. It was thus investigated whether or not metal–ligand vibrations could be depicted in the low frequency range. For cytochrome *c* and microperoxidase 11, the Fe–N vibration was seen at 380 cm^{-1}.[6] Microperoxidase is a cytochrome *c* site model with 11 attached amino acids, which is obtained on the basis of a trypsin digestion.[102] The most prominent signal in large proteins, however, is the large internal hydrogen bonding feature (see Figure 2). Ligands coordinated to heme sites in proteins have been extensively characterized in the MIR. Most of the ligands compete with oxygen or NO for their binding site. Based on the strong infrared absorption of these ligands, they have been established as probes for the active site of oxidases, sensors and transporters.[22,160,161] These experiments will be discussed together with reaction-induced FTIR spectroscopy.

D. Using the Effect of Temperature: T-Derivative Spectroscopy

Studies of the temperature dependence of IR spectra make it possible to compare the spectra in various phase states and to clarify the role of intermolecular forces.[19] Data are studied in all accessible temperature ranges. With the help of closed circle cryostats, temperatures down to 4 K can be obtained; however, nitrogen-cooled systems are often sufficient.[162–165] Measurements at low temperatures were also performed to trap reaction intermediates, including dioxygen adducts of heme model compounds in cryogenic matrixes[54,166,167] or unstable complexes.[168] For example, in oxygen carrier models (see Section II.A.2.b), the $\nu(O_2)$ frequency was found between 1100 and 1280 cm^{-1} for end-on ligation, and between 900 and 1000 cm^{-1} for side-on ligation.[58] Isotope labeling of the ligand is typically performed to confirm the assignments.

Temperature-derivative spectroscopy has proven to be a particularly powerful technique for studying protein–ligand interactions. Several ligand binding studies of porphyrins in proteins are known. Myoglobin, a ubiquitous mammalian oxygen storage heme protein, was the first protein with a structure determined by X-ray crystallography[169] and serves as a model system for heme–ligand interactions.[162,170] The most extensively studied form is the complex bound with CO, which is more stable than the protein complexed with the physiological O_2 ligand. A large photodissociation quantum yield and the high intensity of the ν(CO) vibration in the MIR spectral range made the mode accessible for extensive studies, the ligand being utilized as a local probe of structure function and dynamics[160,164,171,172] due to the high sensitivity of the ν(CO) to the heme environment, as discussed in Section II.A.2.c.

Among a large number of excellent studies, the temperature dependence of the slow geminate recombination of CO in oxygen transporters by Frauenfelder and

coworkers, and others, was crucial in initiating an understanding of the dynamics of conformational substates in proteins.[173,174] Barrier crossings associated with conformational changes of the protein-dissociated CO system were determined based on the temperature dependence of the vibrational motions. Geminate ligand rebinding of CO with myoglobin was found to be highly nonexponential at T < 200 K, giving evidence for the trapping of a large number of protein statistical substates at low temperature.[175,176] Measurements are started with a completely photodissociated sample at a temperature around 10 K, where rebinding is extremely slow on the experimental time scale. While linearly increasing the sample temperature with time, FTIR spectra are measured continuously. The absorbance difference spectra, involving information on the different substates, are then calculated from spectra at successive temperatures.

Temperature-dependent investigation of an infrared spectrum can be analyzed by the vibration involved in a signal. Although many of the absorption bands are combination modes, they can be roughly considered as stretching or bending modes. When H-bonding is present, it is more difficult to bend a bond and consequently the frequencies of the bending modes increase with H-bonding. H-bonding will weaken the intramolecular force constant and as a result it shifts the IR absorption of a stretching motion to lower frequency. At higher temperatures, H-bonding is weaker and the respective shifts can be induced. For coupled vibrations this does not always apply.

Temperature-dependent studies also aim to answer questions on the crucial role of H-bonds, since temperature has a large effect on H-bonding, which is both directional and cooperative. For many molecules, H-bonds are what often determine structure, and when extreme temperature disrupts the structure, the IR spectra change. This may be explained with the help of water, which is a liquid at room temperature. As the temperature increases, the motion of water increases, decreasing its H-bonding contribution and thereby changing the IR spectra. Because water H-bonding is temperature-dependent, any vibrational modes that are coupled directly or indirectly to water H-bonding will also be temperature-dependent. Temperature-dependent infrared spectroscopy can monitor such temperature-dependent H-bonding to study conformational changes, binding events or the nature of solvation.

The temperature dependence of a vibrational mode is a strong indication of the presence of H-bonds within a molecular structure, and the shifting of absorption peaks with decreasing temperature may be ascribed to the collective vibrational modes of the molecule. These effects are of special interest in the FIR, where the shift of vibrational peak frequencies with temperature may be used to probe the expansion of the H-bonding network of molecular ensembles or proteins.[23]

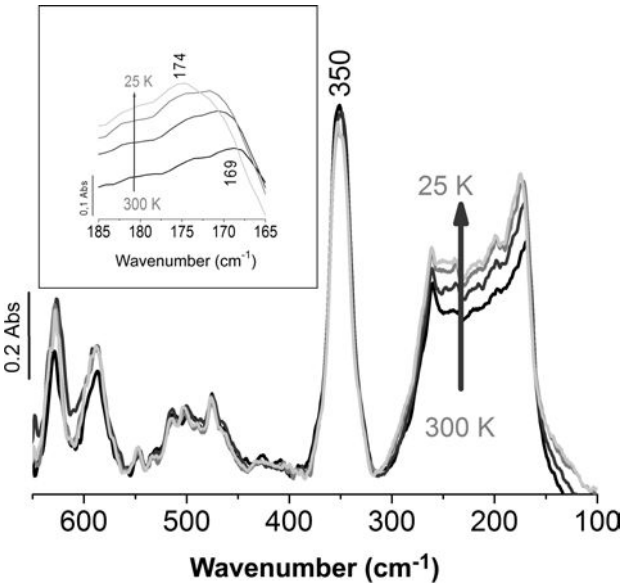

Figure 3. Absorbance spectra between 650 and 100 cm^{-1} of hemin Fe(III)(PPIX)Cl for the temperatures 300, 200, 100 and 25 K. The inset shows an enlarged view of the hydrogen bonding features. (Adapted from Ref. 155.)

Figure 3 shows the temperature dependence of the IR spectrum of hemin, an iron(III) porphyrin derived from red blood cells. Whereas the Fe–Cl vibration at 350 cm^{-1} does not show any noticeable shift,[155] the broad spectral feature between 300 and 100 cm^{-1} increases and up-shifts with temperature, indicating the internal strengthening of the H-bonding interaction, most likely taking place between the hemin propionate groups.

E. Using Pressure in Infrared Spectroscopy

1. *Pressure Dependence of Infrared Spectral Features*

The pressure dependence of vibrational modes is another parameter that can be used to probe signals in the MIR and FIR. Evidently, the samples need to be very stable and the effect should be reversible. Infrared spectroscopy under high pressure is technically challenging, due to the limited space in a pressure cell, such as a diamond anvil cell. Typically, pressures of up to GPa are applied. The signal that will be perturbed by the pressure needs to be sensitive to the local environment and to the orientation of the motion.

The pressure dependence of an infrared mode was used to assign the out-of-plane movement of Fe porphyrins, as described below.[177] Further pressure

dependence studies involve the manipulation of ligands bound to iron in porphyrin complexes and the decrease in the N–O stretching frequency with increasing pressure, which was studied for a nitrosyl complex of iron(II) tetraphenylporphyrin [FeTPP(NO)], for example.[178,179] The decrease in the N–O stretching frequency is based on the increase in the Fe–N–O angle. This kind of effect can be applied to study ligand binding.

2. *Assignment of Heme Doming Modes*

The dynamics of the heme prosthetic group and that of the surrounding group are directly coupled to the properties of the protein and thus its function. The dynamics was especially interesting for the formulation of the allosteric mechanism of hemoglobin, first suggested by Monod *et al.*[180] and put on a sterochemical basis by Perutz.[181] The two-state model was interpreted in terms of an equilibrium between two alternative structures: a tense one (T) with low oxygen affinity, constrained by salt bridges between the C-termini of the four subunits; and a relaxed one (R), lacking these bridges. The equilibrium was thought to be governed primarily by the positions of the iron atoms relative to the porphyrin: the iron is out-of-plane in five-coordinated, high-spin deoxyhemoglobin, and in-plane in six-coordinated, low-spin oxyhemoglobin. The spectral signature of these motions should be included in doming modes.

The optical excitation of six-coordinate hemes induces, via the transitions lying in the plane of the heme, the population of intrinsically short-lived excited states (hundreds of fs to a few ps).[182] These excited states have an antibonding character and can lead to dissociation of the Fe–ligand bond within tens of fs. Dissociation subsequently leads to a heme "doming" within 1 ps.[11] Interestingly, this translation motion of the heme core can be resilient, as observed spectroscopically.[143]

In an interesting synchrotron-light-based experimental and density functional approach, the "doming motion" that is found for the crucial out-of-plane movement of Fe porphyrins was probed. The pressure dependence of vibrational modes was used to identify the doming motion and other related normal modes.[177] A 20 cm^{-1} shift of the respective signal at 53 cm^{-1} could be induced by applying 0.24 GPa to a carbonmonoxy pyridine iron octaethylporphyrin complex. The respective data and the heme motion are shown in Figure 4.

Further theoretical and spectroscopic studies on these doming modes and the analysis of low-lying spin states of iron(II) porphyrin predicted the doming mode of porphyrin to be at 71 cm^{-1}, close to the 75 cm^{-1} frequency determined from coherent reaction dynamics in myoglobin.[17] In most approaches, however, it was not possible to make a definitive assignment, due to either lack of theoretical

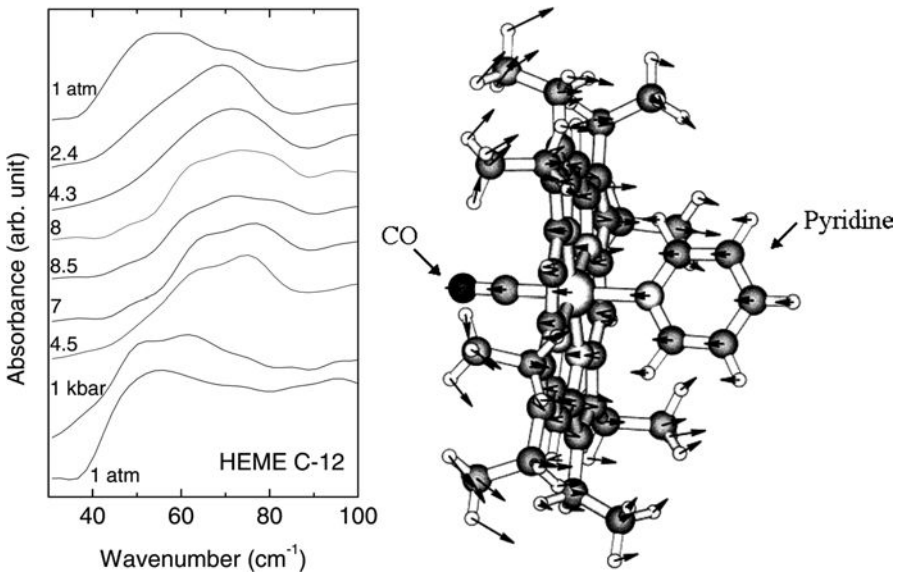

Figure 4. FIR absorption spectra of Fe(OEP)(CO)(Py) determined with the help of synchrotron light. The gasket and sample were ~500 μm thick, with a 500 μm diameter (*left*). The Fe(OEP)(CO)(Py) molecule shows atom displacements for the doming mode (*right*). The Fe atom is located between the CO and pyridine molecules. Nitrogen atoms are bonded to the Fe atom. calculations or incomplete experimental information such as intensity data or the use of pressure dependence.

F. Space-Resolved Techniques

1. *Infrared Microscopy and Imaging*

The combination of microscopic techniques and infrared spectroscopy has added the possibility of studying surfaces and tissues at molecular resolution and has led to infrared imaging.[183] Chemical, biochemical and biomedical information can be combined with spatial information. This has been one of the most important applications of vibrational spectroscopy to biomedically oriented research during the last decade.[184,185] Studies on living cells and tissue have emerged prominently in recent years. Infrared microscopy was realized for the MIR and the FIR, the latter being called THz imaging.

In chemistry and life sciences, FTIR imaging can be directly applied to the sample, for example to obtain the distribution of a certain compound in a sample. The identification of any compound with a clear vibrational marker is

possible within a large matrix.[186–188] Hemazoin-type porphyrin derivatives have been detected in biological cells, and candidates for photodynamic therapy were identified. NIR molecular imaging probes are being developed based on amphiphilic bisporphyrins and their Yb(III) complexes.[189] Furthermore, the contributions of the classic NIR vibrational markers in tissue, hemoglobin and myoglobin can be monitored.[190] Finally, infrared-fluorescent probes are increasingly important. Their wavelengths penetrate tissue well; therefore these probes are suitable for whole-body imaging.[191] In addition, combination with electrochemical techniques was reported, including the FTIR-microscopic study on self-assembled or immobilized heme layers on different types of electrodes.[192,193] Data of this type are typically obtained with a setup which includes a reflection element and, more recently, which is often coupled to synchrotron light sources.

2. *Working with Synchrotron Light*

The use of synchrotron light for infrared spectroscopy (SIR) and microscopy has dramatically increased during the past couple of years. Worldwide there are an increasing number of synchrotron infrared facilities.[194,195]

Flux for conventional and synchrotron infrared emission are almost equivalent but the opening angle of the edge radiation is narrower from the constant field of the bending magnet; the SIR is emitted into a narrow range of angles. The intensity profiles of the two types of emission at various wavelengths are different. The brightness advantage is thus not based on a higher power produced by the synchrotron, but on the fact that the effective source size is small; a synchrotron infrared source typically fills a 10–20 μm area. For studies below 200 cm^{-1}, synchrotron light is the "best" light source available. For low aperture settings also, the MIR shows a higher brightness.

Imaging has become one of the main applications of synchrotron-light-based infrared spectroscopies.[131,183,196–199] The high brilliance of the infrared light, however, is also of special interest to biochemists and chemists working with transmission techniques in the FIR.[155,177] New approaches include time-resolved measurements in combination with spatial resolution, such as TD–THz.

A recent development is the so-called nuclear resonance vibrational spectroscopy (NRVS), an emerging synchrotron-based approach.[13,200] NRVS achieves the ultimate limit of selectivity for a single atom in a complex molecule, because only the vibrational dynamics of the probe nucleus contribute to the measured signal. The NRVS signal is proportional to the mean square amplitude of the metal along the direction of the X-ray beam, and all modes involved will contribute to the measured spectrum.

III. Reaction-Induced FTIR Difference Spectroscopy

A. Motivation

By using reaction-induced FTIR difference spectroscopy, the reorganization of proteins upon the induced reaction can be monitored without contributions from the background. This technique can also be applied to smaller molecules or any other material. It became an especially important tool for the analysis of reaction mechanisms in enzymes and was essentially improved by spectroscopists working in the field of biochemistry and biophysics. Measurements in aqueous solutions have been made possible, in spite of the high absorptivity of water.[30,201] The first studies were presented by researchers working on bacteriorhodopsin,[202] and on photosynthesis.[10,203,204] Other applications followed.

The success of this approach is based on the possibility of monitoring the vibrational absorption bands of a single –COOH group, or any other residue, in a protein, which contains residues on the order of 10^3. The difficulties are obviously substantial. In practice, this amounts to being able to monitor absorption of about 10^{-5} OD in a background of about 1 OD, which requires very low random noise and drift (1 part in 10^{-6}). Data reported are thus typically obtained by cycling the reaction of interest and averaging a large number of scans and cycles. Several approaches have been used to obtain difference FTIR spectra. The goal in all cases is to maintain the sample at a constant concentration and path length, while perturbing the state of the sample in a way that is informative.

The analysis is based on the presence of specific vibrational marker modes of reactant, intermediate or product states. The outcome or kinetics of the induced reaction can then be interpreted by inspection of the transitions of these marker modes. Site-specific information is obtained for vibrational marker modes that involve nuclear motions of specific molecular side groups. When vibrational normal modes are involved in nuclear motions of extended parts of the molecules, a direct structural insight is usually not obtained. Isotopic substitution reveals the involvement of certain nuclei in the vibrational motions. When, in comparing the experimentally observed vibrational mode pattern with predictions from quantum-chemical calculations, a full correspondence is possible, the three-dimensional structure is derivable. Current quantum-chemical calculation routines, such as density functional theory (DFT), allow for the estimation of the electronic ground state structure of medium-sized molecules. For electronic excited states, including intermediate and product states, reliable results can be obtained with the *ab initio* complete active space self-consistent field (CASSCF) routine, albeit for mid-sized molecules not much larger than 20 atoms. New developments in numerical procedures, such as time-dependent density functional theory (TD-DFT), may prove beneficial in the estimation of larger molecular structures in electronic excited states.

A significant difficulty of the reaction-induced technique is thus the discrimination of individual contributions in the spectrum and their unequivocal assignment. A number of strategies were developed over the years, including the variation of external parameters like pH, pressure, temperature, specific and nonspecific isotope labeling, or, in the case of proteins, site-directed mutagenesis on crucial amino acids. In the following section some reaction-induced approaches are presented.

B. Electrochemically Induced FTIR Difference Spectroscopy

1. *Thin Layer Electrochemistry*

Porphyrin vibrational modes depend on the redox state of the central metal center. It was thus of interest to couple the spectroscopic experiments with electrochemical techniques. For *in situ* infrared-spectroscopic investigations of electrochemical reactions, a number of different techniques were developed. The first thin layer cells were reported in the 1970s[205,206] and that became a well-established tool for investigating porphyrins, phthalocyanines and their derivatives in different redox states.[109,207]

The development of electrochemical cells for infrared-spectroscopic measurements in aqueous solution was achieved in the 1990s. The basic design realized has not been significantly changed since then. It should be noted that implementation for infrared spectroscopy is considerably more complicated when it comes to measurements in aqueous solutions. Moss and colleagues have developed a cell that became successful for redox-induced FTIR-difference-spectroscopic studies on biological molecules in aqueous solution in transmission mode.[208] Fourier transform infrared spectra are obtained on the basis of thin layer electrochemistry of the protein at a modified gold grid electrode. The modification or functionalization of the surface is often done with the help of thiols that covalently bind to the electrode and thus protect the protein from irreversible adsorption onto the gold surface. This spectroelectrochemical thin layer cell allows fast, accurate and reproducible control of the redox situation of the protein. The resulting reduced minus-oxidized infrared difference spectra show the changes in the frequencies and intensities of molecular vibrations that arise from the redox-linked conformational change and coupled protonation changes. The concept of the transmission cell has not been significantly changed since then.

The thin layer electrochemical cell presented in Figure 5 (the path below 10 μm) was used to obtain full redox titration of large proteins. Detailed analysis of heme–heme interactions with cooperative systems, such as the hemes in the

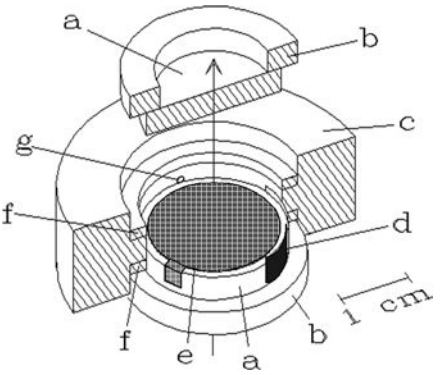

Figure 5. Scheme of a thin layer spectroelectrochemical cell adapted from Ref. 208. In detail: (a) IR window, CaF_2 for MIR, ZnSe for the lower frequency range[101] and diamond or Si for the FIR[52]; (b) plastic ring; (c) cell body; (d) Pt counterelectrode; (e) gold mesh, working electrode, not to scale; (f) rubber O-ring; (g) capillary connection to reference electrode.

bacterial reaction center in photosynthesis[209] or in the cytochrome *c* oxidase from the respiratory chain, was carried out.[210]

2. *Surface-Enhanced Infrared Absorption Spectroscopy*

Another possibility of working with samples that require aqueous solutions is a setup based on the reflection of the infrared light. Attenuated total reflection (ATR) FTIR spectroscopy devices have been successfully combined with electrochemistry.[211] The measurements are performed in reflection mode; therefore the working electrodes may be of any metal or of glassy carbon. Unfortunately, a large sample volume of 20 μL is needed.

A technical solution using a significantly lower sample volume was developed based on surface-enhanced approaches, where the sample is directly adsorbed onto the electrode surface (see Figure 6). This development is based on the seminal discovery of surface-enhanced Raman scattering (SERS) in the early 1970s, which opened up the field of surface-enhanced spectroscopies.[212] The phenomenon was subsequently observed at longer wavelengths and ultimately led to the realization of surface-enhanced infrared absorption spectroscopy (SEIRAS).[213] The practical and theoretical aspects of the phenomenon have more recently been described.[214,215] Characteristic of vibrational techniques, SERS and SEIRAS provide a wealth of molecular information on the level of a single chemical bond.

SERS and SEIRAS are complementary techniques, and each has its own advantages and disadvantages. SERS takes advantage of its enormous enhancement factor (on the order of 10^6–10^{12}). The strongest enhancement results from the

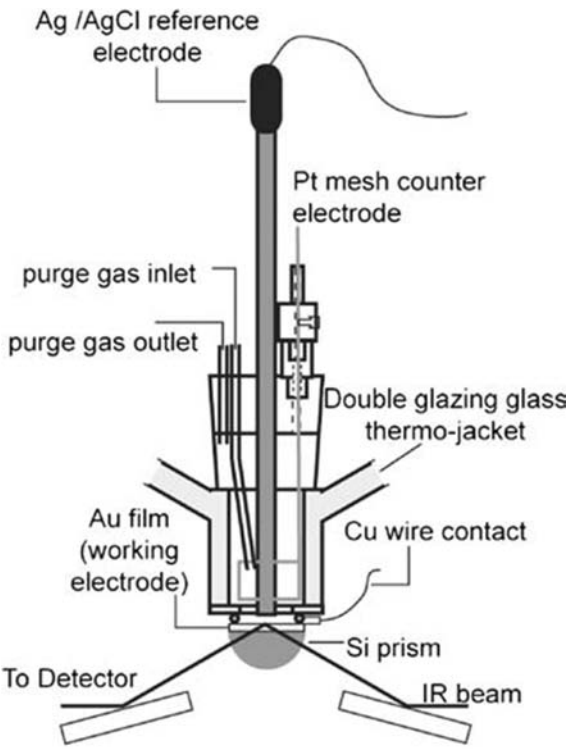

Figure 6. Cell developed for the study of immobilized proteins and other adsorbed species for the SEIRAS technique. (Reproduced with permission from Ref. 216; Copyright 2007, Springer-Verlag.)

resonance condition, if the biomolecule carries a chromophoric cofactor. The Raman signal is very weak and the fluorescence which often accompanies the phenomenon may render detection of the Raman spectrum difficult. Although this is not a problem with SEIRAS, the surface enhancement is modest (about 10–10^3). SEIRAS probes almost all bands of the adsorbed species as long as the vibrational mode includes a dipole component perpendicular to the surface (surface selection rule).[217] Although the enhancement factor of SEIRAS is smaller than that of SERS, the cross-section for infrared absorption is several orders of magnitude higher than the corresponding Raman cross-section. Thus, the weaker enhancement of SEIRAS may be sufficient for many applications.

A number of successful experiments using this technique have been reported.[218,219] Since the signal relay comprises only small amounts of monolayer molecules at the interfaces, measurement with a very small amount of the sample is possible.[216] Surface-enhanced vibrational spectroelectrochemistry constitutes a powerful approach to elucidating the reaction mechanisms and dynamics not only

of smaller molecules but also of immobilized redox proteins. In contrast to traditional electrochemical methods, the combination of SERS and SEIRA provides a direct and detailed molecular picture of all potential-dependent processes of the adsorbed species.

A profound knowledge of the molecular structure and dynamics of immobilized proteins and enzymes that can be obtained by these methods is a prerequisite for the rational design of bioelectronic devices of technological importance. In addition, surface-enhanced vibrational spectroscopies create new possibilities of studying complex biomimetic systems, thereby providing novel insight into fundamental biological processes.

Generally, the influence of electric fields on the various parameters that control electron- and proton-transfer reactions of soluble and membrane-bound proteins, like cytochrome *c*[220] and cytochrome *c* oxidase,[221] can now be studied. Electric fields of a magnitude comparable to those at the interfaces of biomembranes, i.e. the natural reaction environment, may have a substantial influence on redox potentials, protein structure, redox-linked conformational changes and orientation/reorientation of electrostatic complexes; therefore these studies demonstrate a functional role of the electric field effects *in vivo*.

C. Examples of Redox-Induced FTIR Difference Spectra

1. *Studies on Porphyrins and Small Hemoproteins*

Redox-induced FTIR difference spectroscopy was successfully applied for the characterization of the redox-sensitive vibrational modes of porphyrins and hemoproteins. Together with the redox-dependent transitions, signals from the reorganization of the direct environment upon electron transfer become available. These reorganizations may include protonation state changes or conformational movements. Cytochrome *c* and its derivatives are well characterized by the electrochemically induced FTIR-difference-spectroscopic approach.[16,208,222] Data analysis was possible due to several studies on model compounds. An often-used heme *c*-site model is the so-called microperoxidase, which is obtained by trypsic digestion of cytochrome *c*.[10,102] The number of amino acids still attached to the *c*-type heme is indicated by a number.

Figure 7 shows the reduced-minus-oxidized FTIR difference spectra for cytochrome *c* and for imidazole-microperoxidase-8.[10,102,222] In it the positive and negative signals correspond respectively to changes that occur upon reduction or oxidation. Generally, the data include all changes that happen upon the induced reaction. The structural changes are involved in the so-called amide I band, which is observed between 1700 and 1600 cm^{-1} and includes the ν(C=O) vibration of the polypeptide backbone in a hydrogen-bonding-dependent manner.

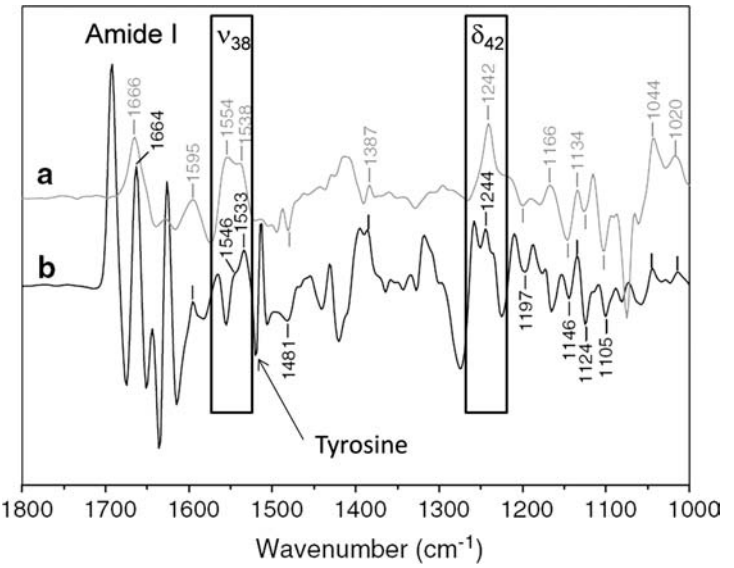

Figure 7. Reduced-minus-oxidized FTIR difference spectra of (a) an imidazole-microperoxidase-8 complex and (b) horse heart cytochrome *c*. (Modified from Ref. 102.)

Furthermore, the amide II signal seen from 1580 to 1520 cm^{-1} may provide information on structural rearrangements. Comparing the difference spectra of cytochrome *c* and the microperoxidase, strong differences can be noticed. This is based on the additional contributions from beta turns and beta sheet segments in the cytochrome *c* data. In addition, signals from amino acids contribute to the spectrum, such as signals characteristic of the protonation of a tyrosine residue at 1518 and 1500 cm^{-1}, a signal that arises in all known cytochrome *c* FTIR difference spectra.[208,222]

The redox-sensitive contribution of the hemes typically observed in the redox-induced difference spectra is the ν_{38} and δ_{42} vibrational modes at 1556–1533 cm^{-1} and 1244 cm^{-1}, respectively, the exact position depending on the type of heme in the protein.[10,102,210,223] The common redox-sensitive markers are summarized in Table 5. An additional heme marker can be found at around 840–830 cm^{-1}, a signal that includes the γ(CH) mode of the porphyrin ring.[101] Several other less intense vibrational modes are found at lower frequencies.

Similar thin layer cells were developed for studies on the nonhydrosoluble synthetic porphyrins in organic media.[224] Redox-induced FTIR difference spectroscopy was used in particular to determine where the removal or addition of an electron takes place, on either the metal or the porphyrin. Using the diagnostic band of π-cation radicals (Section II.A.4), it was for instance proven that the second oxidation of Fe(OEP)(NO) leads to the porphyrin π-cation radical $Fe(OEP^{\bullet})^{2+}$.[92,225–227]

Table 5. Typical redox-sensitive heme vibrations.[210]

Vibration and coupled vibration	Nomenclature	Typical spectral range (cm^{-1})
ν(C*a*C*m*) δ(C*a*C*m*H), δ(C*m*X)	ν_{37}	1560–1625
ν(C*b*C*b*) ν(C*a*C*m*), ν(NC*a*), ν(C*b*X), δ(C*b*X)	ν_{38}	1535–1570
ν(C*a*C*m*)^{sym} ν(NC*a*), ν(C*b*C*b*), ν(C*a*C*m*)	ν_{39}	1450–1490
ν(C*a*C*b*) δ(C*b*X), ν(NC*a*), δ(C*a*C*b*C*b*)	ν_{40}	1435–1450
ν(C*a*N) ν(C*a*C*b*), δ(C*b*X), δ(C*a*C*b*C*b*)	ν_{41}	1360–1395
δ(C*m*H) δ(C*b*X), ν(C*a*N), ν(C*a*C*b*)	δ_{42}	1220–1270

Since the 1980s, most studies describing the combination of electrochemistry with infrared spectroscopy have been carried out in the MIR range.[208,222] More recently, the use of the so-called fingerprint region in the lower frequency range and of the FIR region, which includes signals from metal–ligand vibrations, has started to evolve.[52,101]

2. *Studies on Enzymes from the Respiratory Chain*

Despite the difficulty of obtaining crystal structures from membrane proteins, several high resolution structures of enzymes from the respiratory chain are available. Crucial information like ligand and substrate dynamics, proton acceptor sites and cofactor coupling, however, is essentially obtained by spectroscopic techniques, often in combination with biochemical approaches, including site-directed mutagenesis or monoclonal antibody studies. X-ray crystallography is not sensitive to proton location, due to the weak electron density of the proton and the very high resolution that would be required. Most crystal structures of membrane proteins lack structural information on hydrogen atoms. In contrast, infrared spectroscopy is highly sensitive to the location of protons. In the following paragraphs, an overview of some interesting studies in this field will be presented.

a. *Identification of protonation sites in cytochrome* c *oxidase*

In the cellular respiration process, oxygen reduction is coupled to the formation of an electrochemical membrane proton gradient that drives ATP synthesis. The terminal heme/copper oxidases in the respiratory electron transfer chains reduce oxygen to water and efficiently couple electron and proton transfer.[228] Besides the four protons required for water formation, up to four protons are pumped across the membrane (termed "vectorial protons") by most terminal heme/copper oxidases to contribute to the electrochemical proton gradient. Four redox-active cofactors participate in the electron transfer within the cytochrome *c* oxidase. Cu_A represents

the first acceptor for electrons from cytochrome *c* that are subsequently transferred to heme *a*. Further electron transfer leads to the binuclear heme copper center (heme a_3 and Cu_B), where oxygen is bound and reduced. The crystal structures of several bacterial and mammalian oxidases give a clear view of the architecture of the enzyme active sites and confirm likely sites for the proton transport.[229,230]

Figure 8 shows the oxidized-minus-reduced FTIR difference spectrum of cytochrome *c* oxidase from *Paracoccus denitrificans*.[231] The positive and negative signals correspond respectively to changes that occur upon oxidation or reduction. The vibrational modes observed include redox-dependent changes of the hemes themselves, of the environment of the electron acceptors/donors, and of any coupled protonation or conformational change. In the amide I range (1680–1620 cm^{-1}), the differential signals indicate absorption changes arising from alterations of C=O groups from the polypeptide backbone. These difference signals can be related to subtle perturbations in the structure after the redox process.

In addition, contributions from the formyl group of hemes *a* and a_3, the heme propionates, and from individual amino acid side chains (Asn, Gln and Arg) are expected in this spectral region. In the spectral region from 1560 to 1520 cm^{-1} (the amide II range), essentially contributions from aromatic amino acid side chains and heme C=C groups are observed, as well as antisymmetric COO^- modes caused by protonation/deprotonation or perturbation of COO^- groups (Asp, Glu and heme

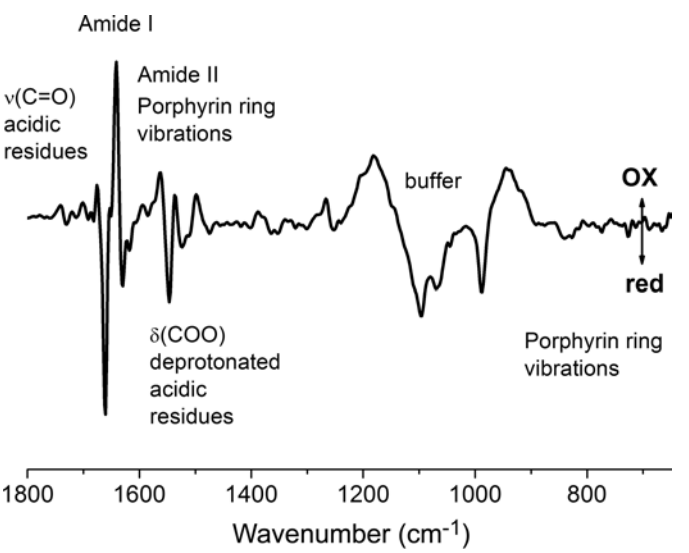

Figure 8. Oxidized-minus-reduced FTIR difference spectrum of the cytochrome *c* oxidase from *P. denitrificans* for the full potential step from –0.5 to 0.5 V versus a Ag/AgCl reference electrode. (Adapted from Ref. 210.)

propionate modes). At 1748 cm^{-1}, a positive signal, correlating with the oxidation of the enzyme, can be seen. In the spectral region above 1710 cm^{-1}, contributions from the ν(C=O) vibrational mode of protonated Asp and Glu side chains are expected exclusively.[232–234]

Some noteworthy differences have been described when comparing the spectra of the same enzyme found in different organisms, such as from the bacterium *Paracoccus denitrificans* and from bovine heart mitochondria.[235,236] This is interesting, since the two oxidases host the same heme centers, hemes *a* and a_3, with far-reaching similarities regarding their environment.[229,230] The same redox-dependent changes of the porphyrin ring, the formyl and vinyl substituent and the heme propionates are expected to manifest themselves in the spectra. The redox-dependent reorganization of an additional amino acid was suggested based on the crystal structure and can be depicted in the spectra together with the protonation reaction induced by the electron transfer.[235,237] The identification of the contribution of one individual amino acid clearly demonstrates the sensitivity of the reaction-induced FTIR-difference-spectroscopic technique. However, the explanation for this additional feature is under debate, since the existence of a third proton pathway was excluded for bacterial enzymes.[238]

Several studies have identified the contributions from individual amino acids within the enzyme. The possible function of individual amino acid side chains as proton acceptor/donor and thus their participation in the proton pathway have often been investigated by site-directed mutagenesis, which involves biochemical perturbation of the individual amino acids. The molecular processes concomitant with the redox reactions of a wild-type and mutant enzyme can be analyzed by combining protein electrochemistry and FTIR difference spectroscopy. Using these techniques the protonation state of glutamic acid 278 in the cytochrome *c* oxidase from *P. denitrificans* was assigned. This residue is the key proton transporter within the proton pump.[239,240] Analysis of the infrared signal was confirmed by groups working on the same enzyme from different organisms.[231,241]

Another way of obtaining information at the molecular level is isotope labeling. ^{13}C-isotope labeling was used to assign the protonation states of the heme propionates within the cytochrome *c* oxidase (see Figure 9). The structure of the heme environment is shown in Figure 10. This labeling was important for identification of the role of the heme propionates during the catalytic cycle. Based on crystallographic data it has been suggested that these propionate groups participate in proton translocation.[229]

Specific isotopic labeling provides an excellent tool for redox-FTIR investigations and avoids structural changes that can arise upon site-directed mutagenesis. A method for providing isotopically labeled cytochrome *c* oxidase was developed that guaranteed a very efficient and specific ^{13}C-enrichment at the carboxyl groups of the heme propionates. The protein obtained from these preparations had

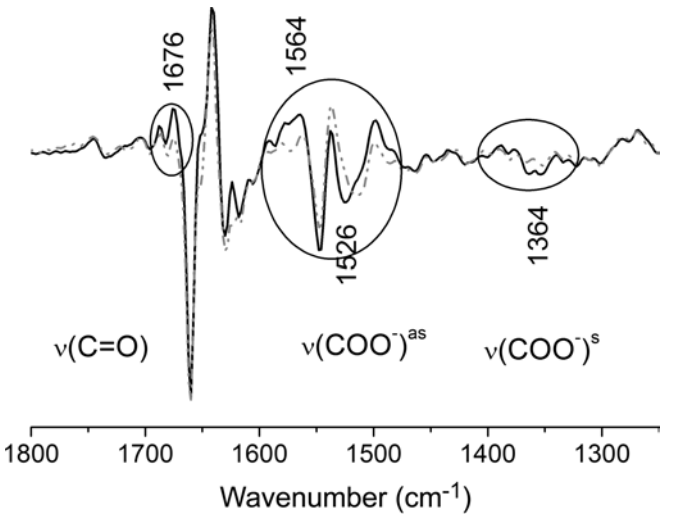

Figure 9. Oxidized-minus-reduced FTIR difference spectra of the cytochrome *c* oxidase from *P. denitrificans* as isolated (full line) and after ^{13}C labeling at the –COOH propionate functions of all hemes in the protein (dotted line). (Modified from Ref. 31.)

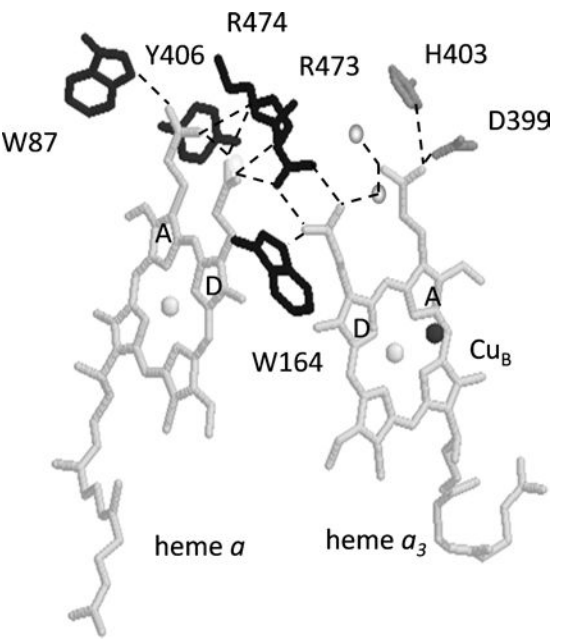

Figure 10. Structure of the heme environment in the cytochrome *c* oxidase from *P. denitrificans*. All amino acids within hydrogen bonding distance of the four heme propionates are shown. (Modified from Ref. 244.)

spectral characteristics and enzymatic activity identical to those of the wild type. The ^{13}C-labeled enzyme was used to identify the signals observed in electrochemically induced FTIR difference spectra of the cytochrome *c* oxidase and to assign their protonation states.[31,242]

Based on direct comparison between the "as-isolated form" of the protein and the oxidase, in which all COOH propionate functions were ^{13}C-labeled, the vibrational modes of heme propionates within a heme protein were distinguished for the first time. As seen in Figure 9, signals at 1570 cm^{-1} and in the 1546–1528 cm^{-1} range were assigned to antisymmetric COO^- modes. A signal at 1390 cm^{-1} was attributed to a symmetric COO^- mode of deprotonated heme propionates. The vibrational mode at 1676 cm^{-1} was attributed to a COOH mode of a protonated heme propionate.[31] The assignments were confirmed for a related oxidase by analogous experiments,[242] and the technique developed was used to clarify the analogous questions in other hemoproteins.[243]

To assign the individual vibrational modes within the spectrum of the full redox step to each of the specific heme propionates, additional experiments were necessary. First, an assignment of the individual heme was made with the help of infrared redox titrations on the basis of the respective redox potential.[210] In addition, site-directed mutagenesis was performed. The crystal structure[229] revealed that all four heme propionates had strong hydrogen bonding interactions with several amino acids (see Figure 10), and with parts of the protein backbone in close proximity.[244] The spectra of mutant proteins of the interacting amino acids have been accompanied by changes of the vibrational modes of the corresponding heme propionate. These changes are based on the variation of the hydrogen bonding toward the respective heme propionate. The respective experiments led to the conclusion that the ring D propionate of heme *a* acts as a proton acceptor upon reduction of cytochrome *c* oxidase, and none of the other three heme propionates seemed to be protonated upon reduction of the enzyme.[244] It was suggested that the ring D propionate of heme a_3 underwent significant conformational changes in its charged state, which might result in a change of the proton arrangement within the cluster of interacting residues and thus cause an increase in net protonation.[244]

b. *The bc_1 complex from the respiratory chain*

The cytochrome bc_1 complex (ubiquinol–cytochrome *c* oxidoreductase; complex III) is one of the fundamental components of the respiratory electron transfer chains located in the inner mitochondrial or bacterial cytoplasmic membranes.[245] The enzyme catalyzes the electron transfer from ubiquinol to cytochrome *c*; this electron transfer is coupled to translocation of protons across the membrane. All bc_1 complexes contain three catalytic subunits: cytochrome *b* with two *b*-type

hemes (hemes b_L and b_H), cytochrome c_1 with a covalently bound *c*-type heme and the Rieske iron–sulfur protein with a [2Fe–2S] cluster (ISP).

Figure 11 shows the different heme contributions that were obtained by addressing the redox step typical of each heme. Control experiments were performed in the visible spectral range, where the contribution typical of each

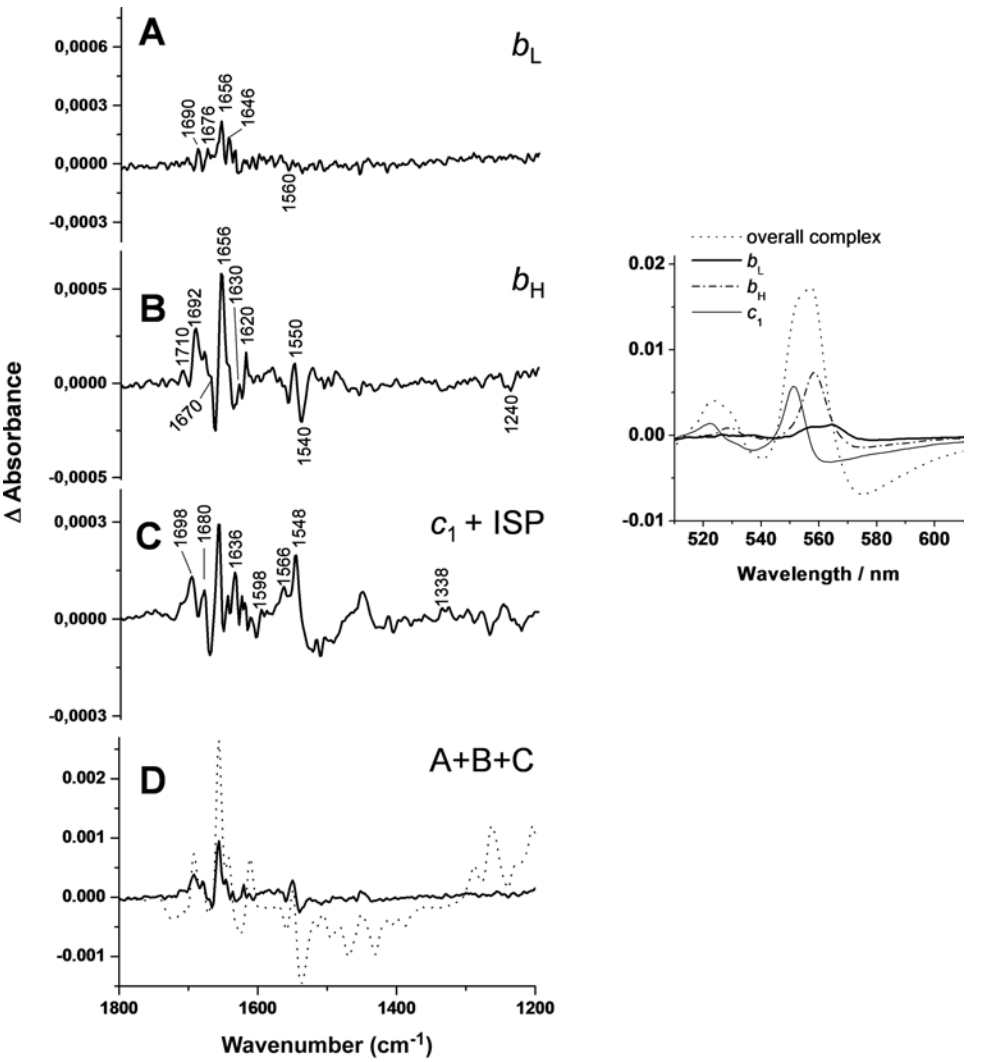

Figure 11. Oxidized-minus-reduced FTIR difference spectra of the individual hemes in the bc_1 complex from *P. denitrificans* (A: heme b_L; B: heme b_H, C: heme c_1 and Rieske Protein; D: comparison of the sum of the A–C spectra (bold line) with the spectrum of the overall complex (dotted line)). The potential steps were selected from the UV/visible titration of the individual hemes (see insert). (Modified from Ref. 248.)

heme type can be distinguished. Redox-induced FTIR difference spectra of the bc_1 complex have been studied by several groups.[211,246–248] The analysis of the contribution of each heme and the coupling of protonation changes to each transition was important for clarifying the interplay between different sites in the protein.

Redox-induced FTIR difference spectra include information on the protonation state of for example the amino acids or the heme propionates in an equilibrium situation. Time-resolved techniques have been developed that allow following the electron transfer and the coupled conformational changes or protonation reactions in "real" time.

D. Time-Resolved Techniques and Photoinduced Reactions

1. *Accessible Time Domains*

Chemistry occurs over a large range of time scales, most of which are accessible to infrared spectroscopy. Elementary steps in chemistry, such as the dynamical event of a chemical bond breaking or bond formation, appear to take place on femtosecond-to-picosecond time scales.[249] Examples of ultrafast chemistry are hydrogen and proton transfer, electron transfer, bond fissions and *cis–trans* isomerizations. Biomolecular reaction dynamics in liquid solutions are dominated by relatively slow mutual diffusion; typical time scales are on the order of nanoseconds. The dynamics of ultrafast condensed phase chemistry are determined not only by the potential energy surfaces of the reactant–product species, but the surrounding solvent also plays a major role in modulating the energy levels of reactants, intermediates and products, as well as the energy barriers separating these species. The outcome of chemical reactions is thus partially different from those for isolated reacting species. Photoinduced chemistry offers the opportunity to trigger the reaction dynamics at a well-defined point in time, and is thus often used for time-resolved approaches.

Rapid scan FTIR is used to study time-resolved motions, from a few milliseconds to seconds. The use of standard rapid scan FTIR spectroscopy is an experimentally accessible approach that allows a time resolution of 60 ms, if a 4.5 cm^{-1} resolution is chosen. Time-resolved FTIR difference spectroscopy experiments often use light-triggered reactions in proteins such as photoreceptors or photosynthetic pigments. The time scale of rapid scan FTIR, however, is also suitable for molecules that are not light-triggered using rapid mixing applications.

Step scan FTIR was developed for the characterization of the functionally important motions that take place in the time window from a few nanoseconds to a few milliseconds. The time-limiting step of the interferometer technique (FT) is the movement of the mirror; the highest velocity possible is the one used in the rapid scan approach. To obtain a higher time resolution, only a fraction of the

interferogram is measured in the step scan approach; this corresponds to a partial movement of the mirror. Then, as a function of the fractions of the interferogram measured, the reaction needs to be cycled to obtain the complete interferogram and consequently, after Fourier transformation, the full spectrum. Obviously, time-resolved step scan FTIR spectroscopy is technically challenging because it is sensitive to vibration and requires long measurement times for data averaging. Consequently, only a limited number of studies have been carried out using step scan FTIR spectroscopy. Step scan FTIR was first established to study the photoinduced reaction of bacteriorhodopsin,[250] and later to characterize the rebinding of CO to hemoglobin and cytochrome *c* oxidase in the nanosecond time range.[12,251]

Ultrafast infrared spectroscopy elucidates molecular structure evolution during ultrafast chemical reactions and represents an exquisite tool for following chemical reactions in real time after applying an optical trigger pulse. It is often used as a single wavelength technique or with short-pulsed laser systems, because the velocity of the mirror in an FT spectrometer limits time resolution (see step scan technique).

This technique is interesting to chemists and biochemists. Following vibrational marker modes in real time provides direct insight into the structural dynamics, as shown in studies on intramolecular hydrogen transfer, bimolecular proton transfer, electron transfer, hydrogen bonding during solvation dynamics, bond fission in organometallic compounds and heme proteins, *cis–trans* isomerization, and transformations in photochromic switch pairs. Femtosecond infrared spectroscopy monitors the site-specific interactions in hydrogen bonds. Furthermore, the conversion between excited electronic states can be followed for intramolecular electron transfer by inspection of the fingerprint IR-active vibrations, in conjunction with quantum-chemical calculations. Excess internal vibrational energy, generated either by optical excitation or by internal conversion from the electronic excited state to the ground state, is observable through transient frequency shifts of IR-active vibrations. An early example of picosecond infrared spectroscopy on excited state intramolecular hydrogen transfer was presented in 1986.[252] The method has mainly been employed on metallocarbonyl compounds[253] and heme proteins.[254–256] With the availability of sensitive MIR detector arrays, it is now possible to fully explore the potential of time-resolved vibrational spectroscopy to gain insight into transient molecular structures involved in chemical reaction pathways.

2. *Light-Induced FTIR Difference Spectroscopy*

a. *Ligand rebinding*

One of the most elementary photoinduced chemical processes is bond fission, where after absorption of a UV-vis photon one or several chemical bonds break

and the molecular fragments separate from each other. In most of the studies, the binding of the ligand or the rebinding of the photodissociated form is followed spectroscopically. Photodissociation is induced by lasers or white flash lamps. The measurements are performed for all temperature ranges and both rapid scan and step scan studies are known.

Groundbreaking work on photodissociation of small molecules using ultrafast UV-vis pump–probe techniques has been reported since the early days of ultrafast spectroscopy.[20,257] As mentioned in Section II.C.2, ligands like CO and CN^- that compete with oxygen for its binding site have been systematically used to analyze all types of oxidases and transporters.[22,160,161] The signal for the CO rebinding is typically found between 1980 and 1910 cm^{-1}.[171] The less-often-studied Fe–CO bending and stretching contributions are found in the FIR at about 574 cm^{-1} and 495 cm^{-1} for hemoproteins and porphyrin models.[258] Polarization-sensitive spectroscopy revealed the orientation of the CO or NO ligands in myoglobin or hemoglobin, either bound to the heme iron or released into the heme pockets. NO rebinding typically takes place in the ps range, in a phase that was suggested to reflect a barrier-less rebinding to the protein.

A number of proteins have been studied by time-resolved spectroscopies. They include NO binding proteins (signaling proteins), like NO synthase, Fix L, CooA or heme-based biological sensors.[172,259–263] Heme-based sensors presently constitute the majority of the proteins known to sense NO, O_2 and CO and to initiate the chemistry required to adapt to changes in their availability. They are found in a great variety of organisms throughout all the kingdoms of life. These signal transducers achieve their responses by coupling a regulatory heme-binding domain to a neighboring transmitter. The past several years have been witness to a staggering rate of advancement in the understanding of how organisms respond to changes in the availability of diatomic molecules that are toxic and/or crucial for survival. Infrared spectroscopy is thus used to characterize the ligand binding properties and, together with mutagenesis studies, defines crucial parameters of their sensoring ability.

b. *Ligand rebinding in cytochrome* c *oxidase*

The active site of the final acceptor of the respiratory chain, the cytochrome *c* oxidase, was structurally characterized in great detail using light-induced rebinding studies. In this enzyme, CO, CN^- and other ligands compete with oxygen for its binding site to the heme a_3–Cu_B binuclear center. As noted before, in contrast to oxygen these ligands give strong infrared bands, and thus represent excellent probes for spectroscopic investigations of cytochrome *c* oxidase.[264]

The negatively charged CN^- ligand was used to examine redox-linked conformational changes at the binuclear site.[265] Of the various possible ligands competing

with oxygen, CO was most extensively used to probe the environment of the binuclear center. It tightly binds to the reduced heme a_3/Cu_B center and can be photolyzed with a quantum yield close to 100%. Ultrafast kinetic studies on the photolysis of CO in the visible and MIR spectral range have provided insight into the primary molecular steps of photodissociation and rebinding.[266,267] In addition, the CO adduct of the cytochrome *c* oxidase has been studied with infrared spectroscopy at cryogenic temperatures.[85,164,268–270]

The thermodynamically favored binding site for CO is the iron of heme a_3. However, it was demonstrated that the binding of CO to heme a_3 proceeds via a CO adduct to Cu_B.[271] After photoexcitation of heme a_3, the Fe–CO bond is broken and CO is transferred to Cu_B, which is only 4.5 Å away from the heme a_3 center.[229] The stability of this intermediate depends on temperature and on CO concentration in the surrounding medium. At ambient and moderately low temperature, this Cu_B–CO adduct is in equilibrium with free CO in the bulk phase, whereas for the enzyme at temperatures below 140 K the Cu_B-bound CO can be trapped. Only transfer of CO within the binuclear center from heme a_3 to Cu_B after photoexcitation is observed.[272,273] The Cu_B binding site is relevant not only to CO but also to the physiological O_2 ligand.[274]

Figure 12 shows such a rebinding experiment for the fully reduced form of the cytochrome *c* oxidase. The positive signal seen corresponds to the Cu–CO vibrational modes and the negative signal to the Fe–CO vibrational modes. In each signal a number of conformers can be distinguished. Based on the analysis of the light-induced FTIR difference spectra on mutants of cytochrome *c* oxidases, the ligands of the Cu_B site and the surrounding loops were predicted, several years before the structure was determined by X-ray crystallography.[275,276]

CO bound to fully reduced cytochrome *c* oxidase exhibits two molecular conformations, termed the α- and the β-form, previously reported for the aa_3 oxidase from *R. sphaeroides*.[277] In wild-type cytochrome *c* oxidase from *P. denitrificans*, the α-form was attributed to signals at 1966/2063 cm^{-1} and the β-form to signals at 1952/2042 cm^{-1}.[85] The relative contribution of the conformers was found to be pH-dependent and suggested to originate from a residue with a pK value of 7.3 in the vicinity of the heme copper center.[277] This pH dependency is lost in mutants in the vicinity of the heme propionates for heme a_3, indicating that an interaction takes place between the active site and the propionates.[278]

Investigation of CO photolysis and rebinding to the fully reduced cytochrome *c* oxidase revealed that CO moves within the binding site and is released from the enzyme at higher temperature. Both CO rebinding at 268 K and at cryogenic temperature result in FTIR difference spectra that are similar with respect to the amide I, amide II and heme modes, but essentially differ due to the motional constraints of the CO molecule at low temperature. In the case of the mixed valence

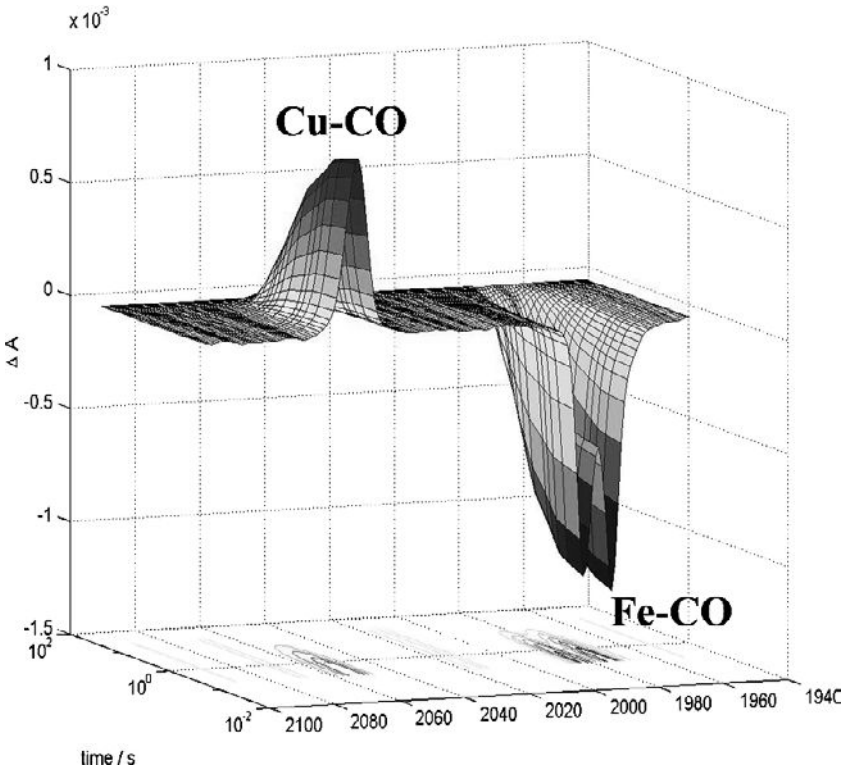

Figure 12. 3D plot of the CO rebinding to the fully reduced cytochrome *c* oxidase from *P. denitrificans* at 140 K. A. (Böhm and P. Hellwig, unpublished data; working conditions as described in Ref. 85.)

cytochrome *c* oxidase, photodissociation of CO initiates "reverse" electron transfer; proton release to the medium is coupled to this reaction.[279,280] Data obtained for the *P. denitrificans* cytochrome *c* oxidase clearly indicated that this reverse electron transfer causes changes at an acidic residue.[85,278] This is illustrated by a difference signal at 1746 cm^{-1}, which is shifted to 1740 cm^{-1} in ^2H_2O. The data obtained from a mutation, where glutamic acid 278 was replaced by a residue that does not contain the COOH function, show the absence of this signal and thus allow identification of this residue as being responsible for the signal. Taking into account the data of the electrostatic calculations,[281] the balance of evidence suggests the possible repositioning of the carboxylate proton in response to changes of the local electric fields rather than proton release, because proton release is still observed in a related mutant enzyme. At low temperature (below 270 K), rotations leading to a proton repositioning are most likely frozen, resulting in the absence of the signal assigned to the prominent glutamic acid 278.

FTIR-spectroscopic study of the CO rebinding is an established observable for the analysis of heme-Cu sites. In addition, the analysis of other heme-containing oxidases was successful, leading for example to the finding of a heme–heme binuclear center in the *bd* oxidase.[282] This type of oxidase is found in prokaryotes and is implicated in the survival of some bacteria, including pathogens, under conditions of low aeration. With a very high affinity for dioxygen (in the nM range), cytochrome *bd* not only couples respiration to the generation of a proton motive force, but also scavenges O_2.[283]

3. *Time-Resolved THz Spectroscopy*

Time domain THz (TD-THz) spectroscopy is a technique that is very promising for its unique time-resolved feature and its applications to dynamic and time-resolved processes. As mentioned above, contributions of metal–ligand vibrations and hydrogen bonding collective motions can be probed in the FIR region (<800 cm^{-1}) and these low frequency modes also involve contributions from water chains in the protein or any hydrogen bonding within the structure.[134,136,284] The spectroscopic characterization of low frequency signals may lead to an understanding of the protein dynamics that give rise to protein function, including ligand accommodation and electron and proton transfer.

TD-THz approaches probe the time-resolved reorganization of water within an induced reaction, such as in protein refolding.[132] The TD-THz technique is a pump–probe approach. The major components are a fs laser, a THz emitter source and a THz detector (FIR). A sample is excited in a desired spectral range and then monitored with a second laser system. Data on intermolecular forces, reaction dynamics or bond formation are accessible due to a fs time resolution. This technique has not yet been used to characterize hemoproteins or porphyrin derivative reactions and its citation here is meant to inspire the use of this promising technique.

4. *Two-Dimensional Infrared Spectroscopy*

a. *The approach*

Similarly, exciting developments have been seen in the field of two-dimensional infrared (2D-IR) spectroscopy; however, this technique has not yet been used for the characterization of the reactions of porphyrins and related compounds. This spectroscopic tool combines structural and ultrafast time resolution.[285] The idea is based on the transferability of the concepts of multidimensional nuclear magnetic resonance (NMR) spectroscopy to IR spectroscopy, which was postulated already

in the earliest publications on 2D-NMR. The first 2D-IR spectrum, however, was measured relatively recently.[286,287] Despite the fact that multidimensional optical techniques are analogs of their NMR counterparts, the time resolution is significantly improved: from ms in NMR to fs in IR.[288,289]

In 2D-IR spectroscopy, the response of complex molecules to sequences of fs infrared pulses is measured. A unique view of the structure, dynamics and fluctuating environments of molecules is provided, such as signatures of conformational and hydrogen-bonding fluctuations, protein folding and chemical exchange processes. Since vibrational spectra of large molecules are complex and congested, the use of a vibrational marker for 2D-IR is essential. A vibrational marker is a signal that should have a spectrally resolved transition in a part of the spectrum that is free of other transitions of the molecule and the solvent and at the same time should have a reasonably large extinction coefficient. Stretching modes with a large transition dipole, such as C=O, amide-I, amide-II, O–H and N–H, are often used in 2D-IR measurements. In addition, isotope labeling can be used to support the analysis. The interpretation is made on the basis of theoretical tools and simulation protocols, based on different approaches, including for example vibrational exciton Hamiltonians or united residue models.[289–291]

The study of metal carbonyls[292,293] demonstrated the unique ability of 2D-IR spectroscopy to resolve vibrational structure and dynamics in multimode systems. It was possible to resolve the transitions between vibrational energy levels, to determine the orientations and relative magnitude of the corresponding transition dipole moments, to measure the coupling between modes due to the anharmonicity of the potential, and finally to probe energy redistribution among the modes as well as energy relaxation to other degrees of freedom. In addition, valuable new information has been obtained on metal-to-ligand charge transfer processes, solvent–solute interactions and fluxionality. The technique is currently being advanced to allow the attribution of distances or bond connectivity patterns in molecules and reach the level of an analytical method.[294] Two examples are given below.

b. *OH stretching and H-bonding in water*

Water dynamics have been studied in detail, most recently using multidimensional nonlinear infrared spectroscopy to acquire structural and dynamical information on fs time scales.[295,296] Many of the unusual properties of liquid water are attributed to its unique structure, which is a random and fluctuating three-dimensional network of hydrogen bonds that link the highly polar water molecules. One of the most direct probes of the dynamics of this network is the infrared spectrum of the OH stretching vibration, which reflects the distribution of hydrogen-bonded

structures and the intermolecular forces controlling the structural dynamics of the liquid. Two-dimensional infrared photon echo and pump–probe studies of the OH stretching vibration provide a sensitive probe of the correlations and couplings in the hydrogen-bonded network of liquid water. Spectral diffusion and resonant energy transfer occur on a time scale much shorter than the average hydrogen bond lifetime of approximately 1 ps. The efficiency of energy redistribution within the hydrogen-bonded network means that liquid water essentially loses the memory of persistent correlations in its structure within 50 fs.[295,296]

c. *Estimating angles and distances between molecules*

One of the great strengths of NMR spectroscopy has been its ability to measure the coupling strength between nuclear spins and subsequently to deduce the distance between them. This capability stems from the relatively simple physics that determines the spin–spin coupling, in which distances interfere. It was shown that for systems in which electrical anharmonicity dominates, the coupling can be well described by the physics of multipole coupling, which corresponds approximately to the dipole–dipole coupling.[297] There are two types of anharmonicities intrinsic to a molecular system. The first of these comprises the lowest order anharmonic terms in a molecular potential energy surface, known as the mechanical anharmonicity. The second is the electrical anharmonicity, defined as the nonlinearity in a molecular electrical dipole moment.

Guo and coworkers analyzed the complex-forming molecular system, phenylacetylene and benzonitrile.[297] Here, the cross-peaks formed by dipolar couplings appear with the predicted strength and at the predicted locations in a 2D-IR spectrum. The polarization dependence of the cross-peaks can be used to deduce the angle between the molecules in question and thereby to estimate the distances between the two interacting modes via the intensities of the intermolecular cross-peaks. 2D-IR spectroscopy can be used to detect weakly interacting complexes and also to analyze their interaction geometry.

E. Perfusion-Induced Approaches; Stopped-Flow and Rapid Mixing

The combination of infrared spectroscopy with conventional mixing or stopped-flow technologies was recently achieved even for aqueous solutions. The main problem during development was the realization of the mixing procedure of the relatively concentrated sample solution with its reactant in an infrared cell with a path of about 50 μm or less. High pressure is needed to achieve instant mixing. The first prototype of a stopped-flow cell for aqueous solution was available in 1995.[298] The cell path was optimized down to 10 μm, allowing studies in the

MIR.[299] The applications of this technique include the characterization of active sites within proteins and their reactions[300,301] and the measurements on chemical and biochemical reactions in a time-resolved manner.[302–304] Typically, a 100 ms mixing time is needed; the reaction is then followed with the time limits of the respective FTIR apparatus. A stopped-flow mixing unit was recently presented combined with an infrared microscope; the setup added spatial information to the data.[305]

An alternative approach that was specifically developed for protein–substrate interaction is perfusion-induced FTIR difference spectroscopy. For example, studies on cytochrome *c* oxidase led to conclusions about oxygen reaction intermediates.[306,307] In order to monitor perfusion-induced difference spectra, it is necessary to create a stable protein layer on the ATR crystal. This can be achieved via direct immobilization or using the hydrophobic properties of some crystals. In the first studies presented, films from the cytochrome *c* oxidase from *Rhodobacter sphaeroides* and beef heart mitochondria were reconstituted with lipids and then adhered to the internal reflection element of the ATR device.[306] This procedure leads to samples with a quite low concentration, since the protein is "diluted" by the lipids. Interestingly, membrane proteins, when separated from the detergent molecules used for solubilization, can be directly applied on the crystal surface. The crystal surface then replaces the hydrophobic membrane. The success of this approach was unexpected, since membrane proteins tend to be extremely unstable; however, a fully functional protein was obtained.[307–309] The principle is evidently suited not only for membrane proteins. The immobilization of any molecule via hydrophobic interaction on the surface of the ATR crystal and subsequent study of the interaction with a partner is possible.

IV. Conclusion

Infrared spectroscopy is a technique that may provide data on the structure, function and dynamics of a molecule. The basic approach uses reaction- or structure-sensitive vibrational markers, such as redox, metal or π-cationic sensitive modes when one is working with porphyrins or hemes. Experimentally, several new approaches have emerged during the last few years, including reaction-induced approaches, ultrafast time-resolved techniques, 2D-IR, imaging and the use of synchrotron light as an infrared source, allowing in particular a better understanding of reaction mechanisms in hemoproteins or identification of protonation sites in proton-pumping enzymes. These recent techniques, mainly developed in the biomedical and biochemical fields, now offer promising applications, such as the real time study of chemical reactions by means of 2D-IR or TD-THz spectroscopy. Infrared spectroscopy is evidently a very

versatile technique, and the development of infrared-light-based techniques is surely far from being finished.

Contents

Preface

Although the porphyrin and tetrapyrrole research area was regarded as "fully matured" during the 20th century, as evidenced for example by the awarding of numerous Nobel Prizes to its principal researchers, new advances and accomplishments in the field still amaze us as editors. The area continues to blossom and to expand into new areas of science and applications that would probably never have occurred to our 20th century heroes. An earlier *Porphyrin Handbook* assembled the large amount of factual data that had been accumulated during the 20th century. Our new venture, the *Handbook of Porphyrin Science* takes a completely new look at our research area and comprehensively details the contemporary science now appearing in the scientific literature that would indeed have been hard to predict even 10 years ago. In particular, fundamentally new methodologies and potential commercial applications of the beautiful compounds that we all love are exemplified, fully recognizing the subtitle of the series — "with applications to chemistry, physics, materials science, engineering, biology and medicine".

The three of us have complementary expertise in physical chemistry, synthetic and bioorganic chemistry, and in synthetic and mechanistic organometallic chemistry; this has enabled us to cover the whole field of porphyrin science and applications, and to devise comprehensive volume and author content. As of the date of writing, between the three of us, we have published more than 1600 tetrapyrrole research articles, and hold 31 patents related to commercial applications of porphyrin science. So we do know our field, and this has enabled us to assemble a first-rate group of experts who have written comprehensive up-to-date chapters with accuracy and authority; we thank our authors for their cooperation and willingness to go along with our highly ambitious schedule for production of these volumes.

We look forward to comments from our readers, and to suggestions that might enable us to expand our basic interests and scientific coverage even further. Meanwhile, we hope that porphyrin researchers, old, new and of the future, will enjoy reading these volumes just as much as we enjoyed planning and, with the help of World Scientific Publishing Company, producing them from manuscript to published article, in a timely manner.

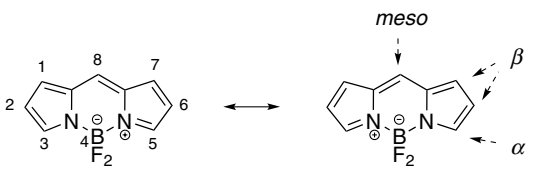
37 BODIPY® Dyes and Their Derivatives: Syntheses and Spectroscopic Properties

Aurore Loudet and Kevin Burgess

Department of Chemistry, Texas A&M University, P.O. Box 30012, College Station, Texas 77842, USA

I. Introduction

4,4-Difluoro-4-bora-3a,4a-diaza-*s*-indacene, or BODIPY® (hereafter abbreviated to BODIPY) dyes tend to be strongly UV-absorbing molecules that emit sharp fluorescence peaks with high quantum yields. They are relatively insensitive to the polarity and pH of their environment, and are reasonably stable to physiological conditions. Small modifications to their structures enable tuning of their fluorescence characteristics, hence these dyes are widely used to label proteins[1–5] and DNA.[6] However, potential applications of these dyes are so diverse that modifications to the BODIPY framework are desirable for many reasons.



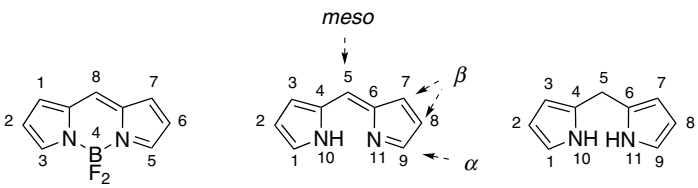
BODIPY dyes
small, intensely fluorescent systems

This chapter summarizes the basic chemistry and spectroscopic properties of common BODIPY-derivatives, and draws attention to ways in which interesting

probes could be prepared. Applications of BODIPYs as labelling reagents,[2,4,7–34] fluorescent switches,[35,36] chemosensors[37–74] and as laser dyes[75] may be interested in this review as a guide to synthesis and spectroscopic properties, but details on use of the dyes in those ways are not included here. Those seeking small amounts of commercially available dyes for labeling should also consult the Invitrogen (formerly Molecular Probes) catalog.[2,76] This chapter is based on a review that was published by us in 2007,[77] but has been updated to include pivotal recent developments in the area.

II. The BODIPY Core

The IUPAC numbering system for BODIPY dyes is different to that used for dipyrromethenes,[78] and this can lead to confusion. However, the terms α-, β-positions, and *meso*- are used in just the same way for both systems.



the "BODIPY core" | the "dipyrrin core" of dipyrromethenes | dipyrromethane core

A. Fundamental Properties

BODIPY dyes were first discovered in 1968 by Treibs and Kreuzer.[79] While the syntheses of many substituted BODIPYs have been reported since then, the preparation of the fully unsubstituted BODIPY **1** remained a challenge and has only recently been reported in the literature.[80,81] This is because of synthetic difficulties obtaining this compound related to the fact that the unsubstituted dipyrromethene core is sensitive to nucleophilic addition. Synthesis of the corresponding dipyrromethene precursor has been reported, but this compound is unstable and decomposes above −30 °C to −40 °C.[82] The symmetrical, dimethyl-substituted compound **2** has been prepared[83] and could be considered as a reference to which other simple alkylated BODIPYs can be compared. The symmetrically substituted systems **3** and **4** have apparently not been reported, reflecting synthetic limitations for even some simple BODIPY systems. However, the unsymmetrically substituted BODIPYs **5** and **6** have been prepared.[84] There are relatively minor differences in the reported UV-absorption maxima, fluorescence emission maxima, and quantum yields of these compounds, and these should not be

over-interpreted because small calibration errors are common in these types of experiments. However, when the symmetrically-, tetra-, hexa-, and hepta-alkylated systems **7**,[84,85] **8**, and **9** are included in the comparison then an unambiguous trend towards red-shifted absorption and emission maxima with increased substitution becomes apparent.

Alkylation or arylation at the *meso* position has no special effect on the absorption and emission wavelengths (compare **2** with **11**, and **7** with **12**) even

though this substitution position is structurally unique. However, the quantum yield of the *meso*-phenyl compound **11** is appreciably less than the more substituted analog **12**. Such differences are widely attributed to 1,7-substituents preventing free rotation of the phenyl group reducing loss of energy from the excited states via non-irradiative molecular motions. Consistent with this, introduction of *ortho*-substituents on the phenyl ring has been observed to increase quantum yields, and similar explanations have been invoked.

BODIPY derivatives in which aliphatic rings have been fused to the pyrrole fragments are perhaps more constrained than ones bearing acyclic aliphatic substituents. Nevertheless, the effects on their emission maxima are not always easily rationalized. Compound **13** has a shorter emission wavelength maximum than **9** even though both have three substituents on the pyrrole rings. On the other hand, **14** has only two such attachments, yet it has the longest wavelength fluorescence emission.

B. Syntheses of the Unsubstituted BODIPY 1

There are three recent reports on preparations of **1**.[80,81,86] In the first, BODIPY **1** was prepared by oxidation of the corresponding dipyrromethane.[87] As mentioned above, the dipyrromethene core is very unstable and must be stabilized rapidly after oxidation. Thus, the oxidation was carried out at −78 °C, under nitrogen for 1 hour. Upon completion of the oxidation, the dipyrromethene was reacted *in situ* with DBU and boron trifluoride diethyl etherate to form **1** in 5–10% (Chart 1).[80]

To avoid the oxidation step from the dipyrromethane to dipyrromethene, BODIPY **1** was prepared via the classical asymmetric synthesis route. Thus, condensation of 2-formylpyrrole and 1H-pyrrole, followed by complexation with boron afforded **1**. Although the synthesis is straightforward, the purification is quite extensive and laborious, yielding the target compound in low yield (8%). The author also reported that **1** exhibits a high photochemical (τ_{Fl} 7.2 ns) but low thermal stability, decomposing at temperature above 50 °C.[86]

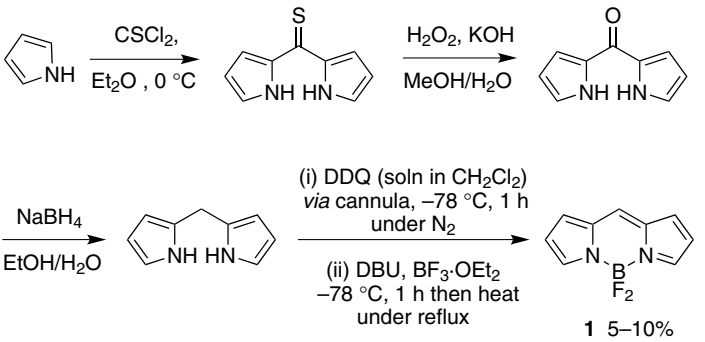

Chart 1.

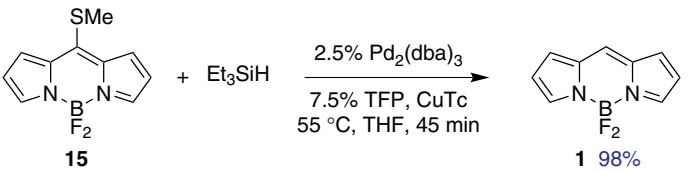

Chart 2.

Chart 2 describes a much more efficient route to **1** affording the target compound in 98% yield.[81] Compound **1** was obtained by reaction of 8-thiomethylBODIPY **15** (synthesis discussed later) with triethylsilane in the presence of a catalytic amount of Pd and a stoichiometric amount of copper(I) thienyl-2-carboxylate (CuTc) in THF at 55 °C for 45 min (Chart 2). BODIPY **1** emits brightly in both nonpolar and polar solvents (Φ ranges from 68 to 93% from nonpolar to polar solvents), and surprisingly was sparingly soluble in water. It is an air-stable, crystalline red solid with excellent bench-life. It is highly recommended to handle it in a well-ventilated fume hood since as a powder, since the authors noticed it causes rather strong nose, skin and throat irritation.

C. Syntheses of Substituted BODIPYs from Pyrroles and Acid Chlorides or Anhydrides

8-Substituted BODIPY® dyes **A** (i.e., ones with substituents in the *meso* position) tend to be relatively easy to prepare via condensation of acyl chlorides with pyrroles (Chart 3).[88,89] These transformations involve unstable dipyrromethene hydrochloride salt intermediates. The intermediate dipyrromethene hydrochlorides are easier to handle and purify as the number of substituents on the pyrrole

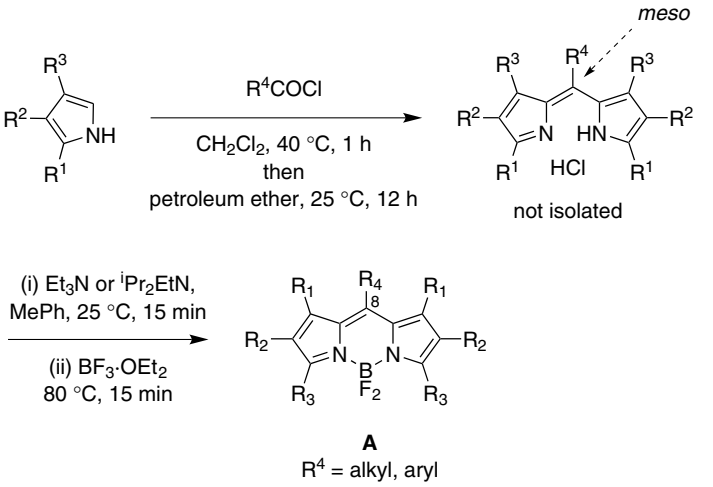

Chart 3.

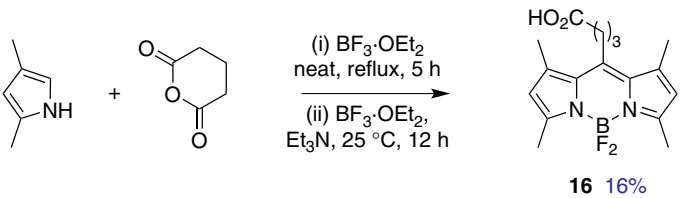

Chart 4.

increases but, even so, these are not generally isolated in syntheses of BODIPY dyes.

Other activated carboxylic acid derivatives could be used in place of acid chlorides in Chart 3. In the particular case of acid anhydrides, this concept has been reduced to practice. Chart 4 shows how the BODIPY derivative **16** was prepared from glutaric anhydride.[28] An attractive feature of this chemistry is that a free carboxylic acid is produced, and this may later be used to attach the probe to target molecules.

D. From Pyrroles and Aldehydes

Syntheses similar to those depicted in Charts 3 and 4 but which use aromatic aldehydes[5] (to the best of our knowledge, *aliphatic* aldehydes have not been reported in this reaction) require oxidation steps. The reagents for these oxidations can introduce experimental complications. Thus, in Chart 5 the oxidant used was

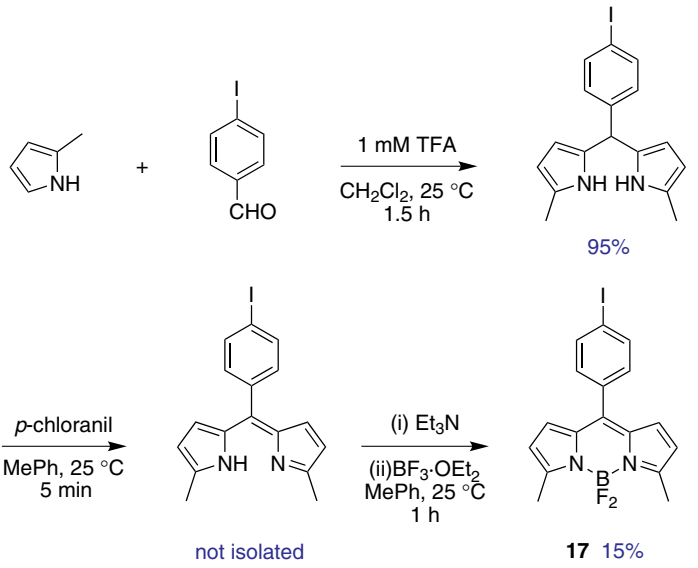

Chart 5.

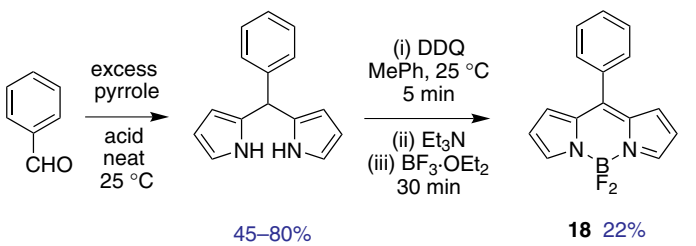

Chart 6.

p-chloranil and eventually the byproducts from this had to be removed (in fact, this was done after complexation with the boron).

α,β-Unsubstituted BODIPYs e.g. **18** can also be prepared from aldehydes using neat conditions.[5] The aldehyde is dissolved in excess pyrrole at room temperature, and the dipyrromethane intermediate (the reduced form of the dipyrromethene) was formed and isolated. The BODIPY dye was obtained after oxidation with DDQ and complexation with boron (Chart 6). Acid chlorides probably would be too reactive to use with pyrrole (since it is unsubstituted and more reactive) so this aldehyde-based approach is the method of choice.

Use of, for instance, halogenated benzaldehydes (or halogenated acid chlorides as above) provides compounds like **17** that can be further elaborated. In another example, systems **19** and **20** were prepared from benzaldehyde derivatives

that have long chain acid substituents. These probes were used to investigate dynamic effects in membranes.[16] Presumably *ortho*-substituents were included on the *meso*-aromatic group to restrict rotation of that ring and increase quantum yields.

The fact that a diverse set of aldehydes could be used to prepare *meso*-substituted BODIPYs provides a means to introduce more sophisticated functionalities for specialized purposes. For instance, 8-hydroxyquinoline-2-carboxaldehyde was used to prepare the Hg^{2+}-selective chromo- and fluoroionophore **21**.[51] This probe is highly fluorescent in the presence of transition-metal ions (Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}) and heavy-metal ions (Pb^{2+}, Cd^{2+}), but 5 equiv. of mercuric ions reduced its emission by more than 98% (the color of the solution also changed from light amber to red enabling the progress of the complexation event to be visualized). A 1:1 complex with Hg^{2+} is formed in which the dipyrromethene core of **21** adopts a nearly orthogonal conformation with the 8-hydroxyquinoline moiety because of the methyl groups in positions 1- and 7- on the BODIPY core. This particular arrangement displays the binding site of 8-hydroxyquinoline for complexation of metal ions. The shape of these BODIPY-based ligand is such that 2:1 L:M complexes are sterically disfavored.

Fluorescent pH probes **22**–**25** have been prepared from phenolic benzaldehydes (a case where the acid chloride approach would have raised chemoselectivity issues).[59] These compounds are weakly fluorescent in the phenolate form presumably due to charge transfer from the phenolate donor to the excited-state indacene moiety. The pKa of the different derivatives was tuned by varying the aromatic substituent.

It is unusual to use nonaromatic aldehydes to prepare BODIPY derivatives. In this sense the vinylic thioether probe **26** is exceptional. A catalytic amount of ytterbium (III) trifluoromethane sulfonamide was used to mediate the condensation process, the intermediate dipyrromethane was oxidized with DDQ, and complexation with boron trifluoride gave the product, though in very poor yield (Chart 7).[90] The fluorescence emission of compound **26** was red-shifted relative to dyes with a phenyl group at the *meso* position (e.g. **11**). Compound **27** has a sulfide in conjugation with the BODIPY core, just as **26** does. The fluorescence emission maximum of **26** is 26 nm red-shifted compared to **27**, indicating that electron donating groups in this position tend to have that effect.

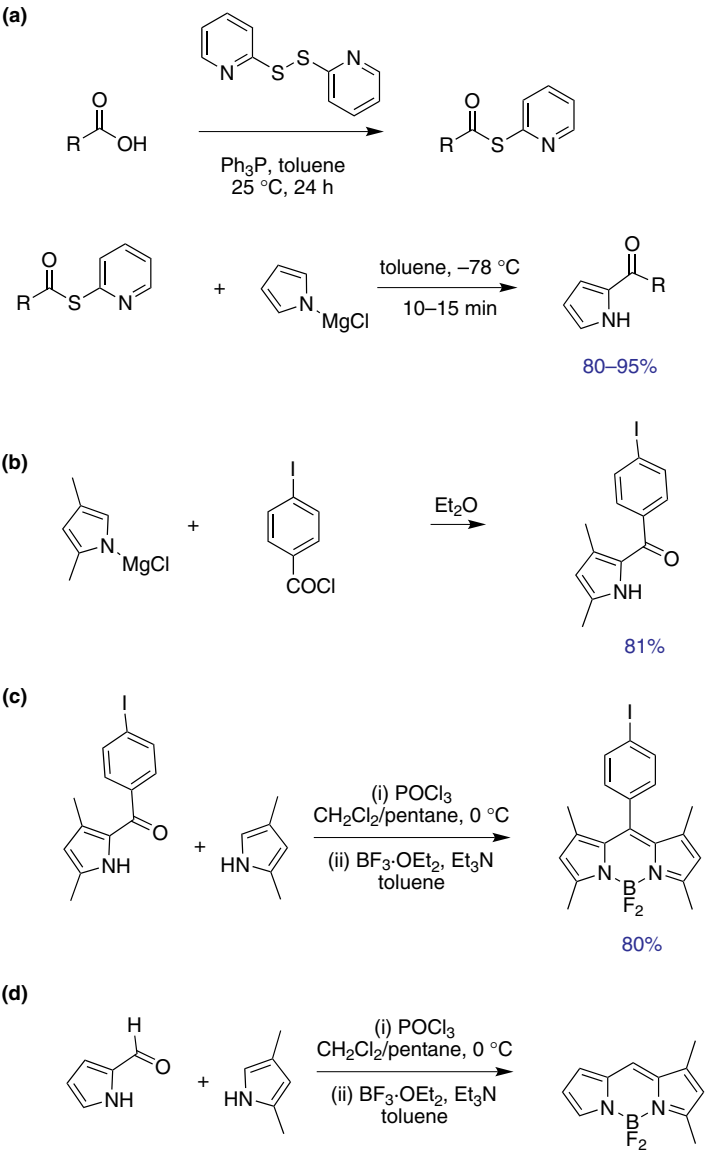
E. From Ketopyrroles Including Syntheses of Unsymmetrical BODIPYs

Condensations of pyrroles with acid chlorides or with benzaldehyde derivatives, as outlined above, are direct and convenient methods to access symmetrically substituted BODIPY dyes. However, another approach is required to form unsymmetrically substituted ones. Generally, this is achieved via preparations of ketopyrrole intermediates, followed by a Lewis acid mediated condensation of these with another pyrrole fragment.

Schemes 1a and b show reactions of magnesium anions of pyrroles with activated carboxylic acid derivatives to give the corresponding 2-ketopyrroles.[91,92] In part c, one such ketopyrrole is condensed with another pyrrole unit to give a BODIPY framework. That example gives a symmetrical product, but the method is particularly valuable for unsymmetrical ones, as in Scheme 1d.

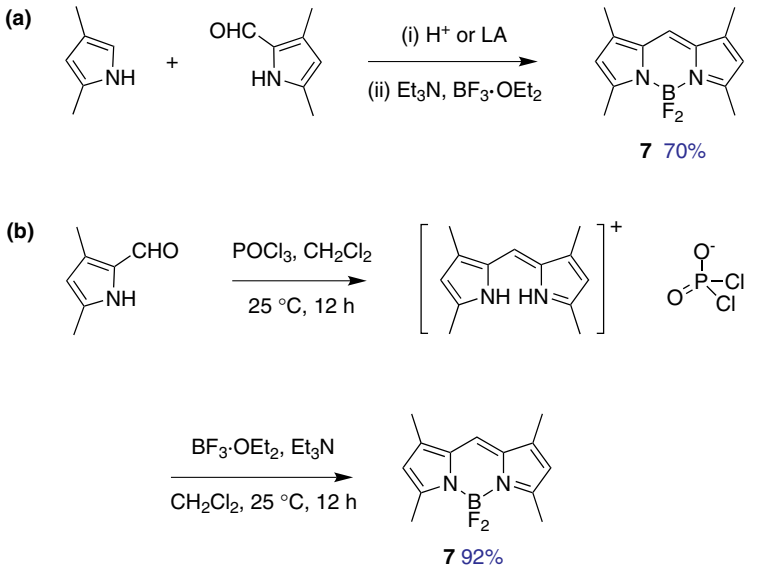
F. Synthesis of Symmetrical BODIPY from Pyrrole-2-Carbaldehyde

BODIPYs unsubstituted at the *meso* position are usually prepared by condensation of a pyrrole-2-carbaldehyde with a pyrrole. However, Burgess and coworkers have recently reported that similar BODIPY derivatives, without any substituents at the *meso* position, could easily be prepared from the aldehyde alone (Scheme 2).[93]



Scheme 1. (**a**) and (**b**) two different methods for production of ketopyrroles from magnesium derivatives of pyrrole, and application of these starting materials in the production of (**c**) symmetrical, and (**d**) unsymmetrical dyes.

Thus, a series of alkyl and aryl substituted BODIPYs i.e. probes **28–30** was prepared from the corresponding pyrrole-2-carbaldehyde and phosphorus oxychloride. The latter seems to be intimately involved in this reaction as the dipyrromethenium cation was not formed when other Lewis acid were used (TFA or $BF_3{\cdot}OEt_2$).



Scheme 2. (**a**) Conventional synthesis of tetramethyl-BODIPY **7**; (**b**) Preparation of tetramethyl-BODIPY **7** from the corresponding pyrrole-2-carbaldehyde and phosphorus oxychloride.

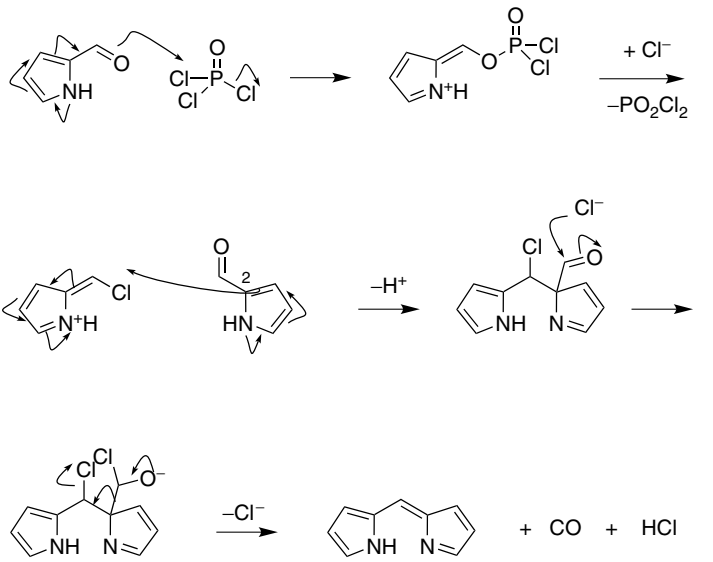

Figure 1. A possible mechanism for the formation of dipyrromethene from pyrrole-2-carbaldehyde and phosphorus oxychloride.

A possible mechanism is that $POCl_3$ reacts with pyrrole-2-carbaldehyde to give a vinylogous Vilsmeier-Haack reagent. Electrophilic attack from the C^2-atom of another pyrrole-2-carbaldehyde on to the vinylogous Vilsmeyer-Hack reagent then leads to the formation of the dipyrromethene (Figure 1). All the new BODIPY dyes prepared emit bright, sharp fluorescent signals. As various substituents were tolerated in the synthesis, probes that emit in the range 516–662 nm could be prepared.

III. Modifications to *meso*-Aromatic Substituents on the BODIPY Core

A. Introduction

The BODIPY core is robust enough to withstand a range of chemical transformations, and a variety of aromatic groups can be introduced at the *meso*-position for appropriately functionalized BODIPY dyes. Alternatively, dyes with special *meso*-groups can be produced via *in vivo* synthesis. These strategies have been used to produce several dyes for many different applications; just a few illustrative ones are shown in Figure 2. For instance, derivatives of this type have been formed as selective sensors of particular redox active molecules (**31**,[53] **32**,[56] **33**,[39] **34**,[94] **35**,[95] **36**[96] and **37**,[97] Figure 2a), pH probes (**38**[46] and **39**,[42] Figure 2b), metal-chelators

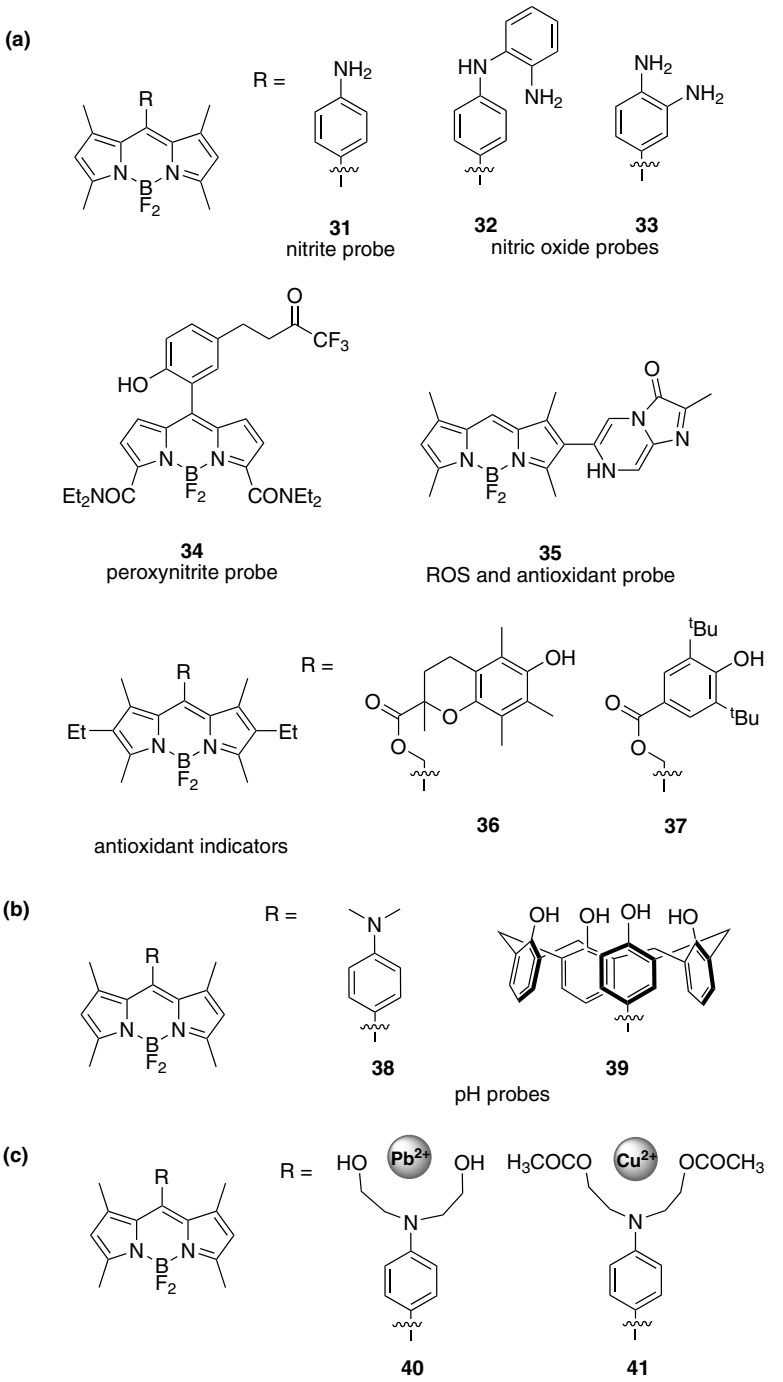

Figure 2. Selected BODIPYs with *meso*-modifications to give: (**a**) selective sensors of particular redox active molecules; (**b**) pH probes; (**c**) metal-chelators; (**d**) biomolecule conjugating groups; and (**e**) cyanide ions.

Figure 2. (*Continued*)

(**40**,[70] **41**,[70] **42**,[65] **43**,[58] **44**,[57] **45**,[44] **46**,[71] **47**,[69] **48**,[73] and **49**,[62] Figure 2c), as biomolecule conjugating groups (**50**,[40] **51**,[72] and **52**,[98] Figure 2d) and as sensor for cyanide ions (**53**,[99] Figure 2e).

Here we intend to restrict the discussion to the general concepts that influence the fluorescence properties of *meso*-modified BODIPY dyes; this review does not attempt to give a comprehensive list of all the compounds made. Without exception, the chemosensors operate by perturbing the reduction potential of the *meso*-substituent as illustrated in Figure 3a and b for the case of **36** and **37**, respectively. The next section discusses in more details the electronic effects of these perturbations on fluorescence.

B. Fluorescence Control via Photoinduced Electron Transfer

Transfer of electrons between nonplanar parts of fluorescent molecules modifies their fluorescence intensities.[100] This has been known for some time but Nagano, Ueno and coworkers have skillfully applied calculated orbital energy levels and experimentally determined electrochemical data to rationalize quantum yields. Their initial work with fluorescein derivatives,[101,102] was later expanded to encompass BODIPY systems as described here.[103]

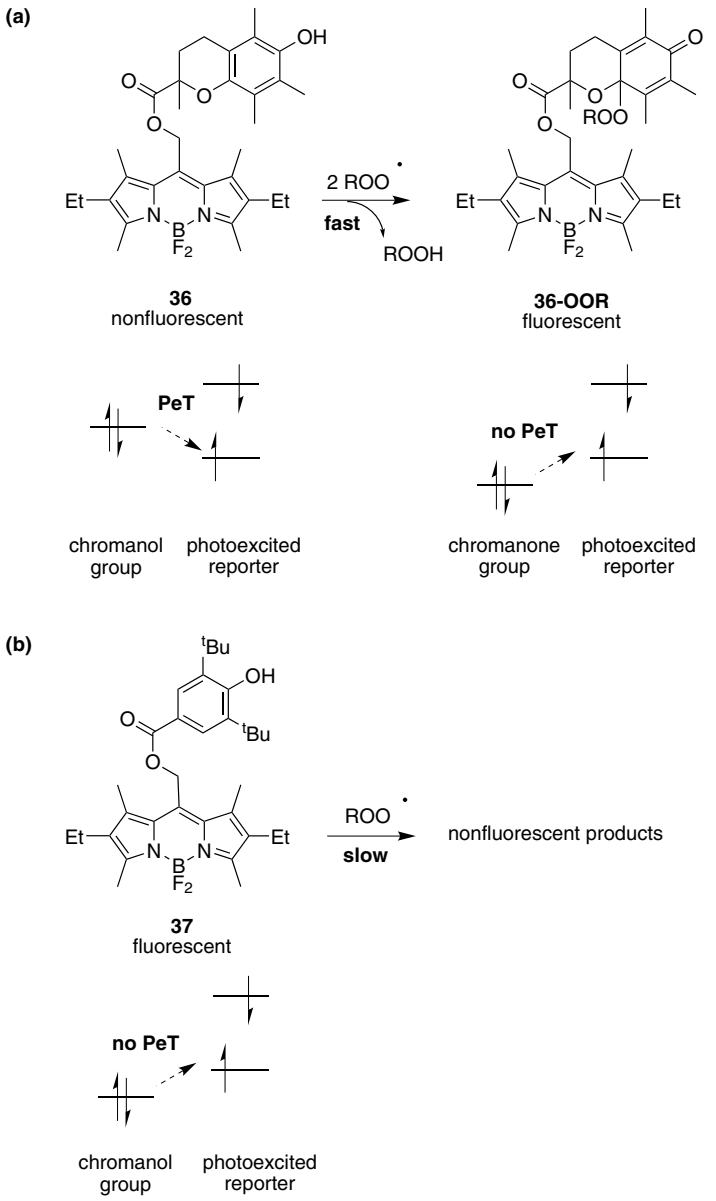

Figure 3. Off/on sensing mechanism for (**a**) **36**; and (**b**) **37** is controlled by PeT from the chromanol group.

Some nonplanar fluorescent molecules can be regarded as a highly fluorescent group with non- (or significantly less) fluorescent substituents (Figure 4a). Some such substituents, depending on their oxidation potentials relative to the excited state of the BODIPY core, can act as electron donors or acceptors. If electron

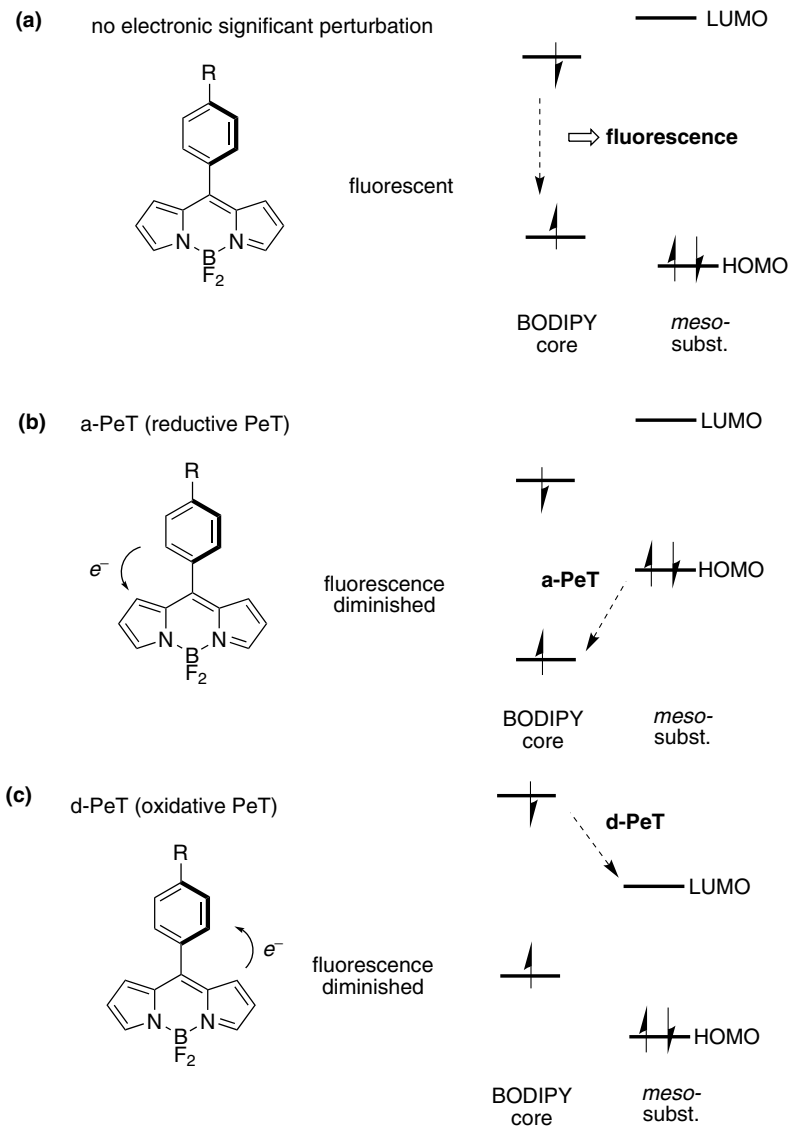

Figure 4. The *meso*-substituent provides: (**a**) no significant electronic perturbation; (**b**) electrons to the excited state; and, (**c**) a low lying LUMO to accept electrons from the excited state.

transfer occurs then the fluorescence is diminished when the fluorescent group in its excited state is reduced. In this situation, the fluorescent group is acting as an acceptor, consequently this may be called reductive-PeT or a-PeT ("a" for acceptor; Figure 4b). However, if the energy states are such that the excited state of the fluorescent group can donate electrons to the substituent LUMO then oxidative-PeT,

d-PeT, occurs ("d" for donor; Figure 4c). Indirectly, solvent polarity has an effect on this process. This is because photoexcitation and oxidation processes involve modification of ground state dipoles, and solvents may stabilize or destabilize these changes according to polarity.

The feasibility of electron transfer can be judged from the change in free energy (ΔG_{PeT}), as described by the Rehm-Weller equation[104]:

$$\Delta G_{PeT} = E_{1/2}\,(D^+/D) - E_{1/2}\,(A/A^-) - \Delta E_{00} - C$$

where

$E_{1/2}\,(D^+/D)$ = ground-state oxidation potential of the donor
$E_{1/2}\,(A/A^-)$ = ground-state reduction potential of the acceptor
ΔE_{00} = excitation energy
C = an electrostatic interaction term.

Nagano and coworkers applied these principles to the triazole-BODIPY derivative **55** (Figure 5) to develop a nitric oxide probe.[52] The low fluorescence of the diamine **54** was explained in terms of reductive PeT. When nitric oxide converts the diamine into the benzotriazole **55** then reductive PeT does *not* occur and fluorescence is observed. Scheme 3 outlines the synthesis of the probe and the oxidized product.

A refinement of these ideas was used to explain why the fluorescence for the compounds **55** decreased in the order **b** > **a** > **c** (Figure 6). This is because the nature of the substituent impacts the reduction potential of the BODIPY core in that order (**b** is the most negative).

Fluorescence of the $Zn^{2=}$ and NO_2^+ chemosensors **56**[54] and **57**[105] has been explained using reductive PeT concepts outlined above. Chelation or nitration makes the reduction potential of the *meso*-substituent more negative, PeT is switched-off, and the probes become fluorescent.

Strongly electron-withdrawing substituents on aromatic *meso*-substituents lower the LUMO of the aromatic system to the level where it might accept electrons from the orbital containing the promoted electron in the BODIPY core (Figure 4c). In such cases *oxidative* PeT comes into play. An illustration of this is the quantum yields of **58**–**60**.[105] For dye **60** oxidative PeT is diminished because the ketones lower the energy of the BODIPY orbital containing the promoted electron.

At least two weaknesses are associated with combining theoretical calculations and electrochemical data to rationalize quantum yields. First, the reduction potentials for the two components are calculated on isolated systems: the fact that they are attached to each other must perturb the actual orbital levels. Second,

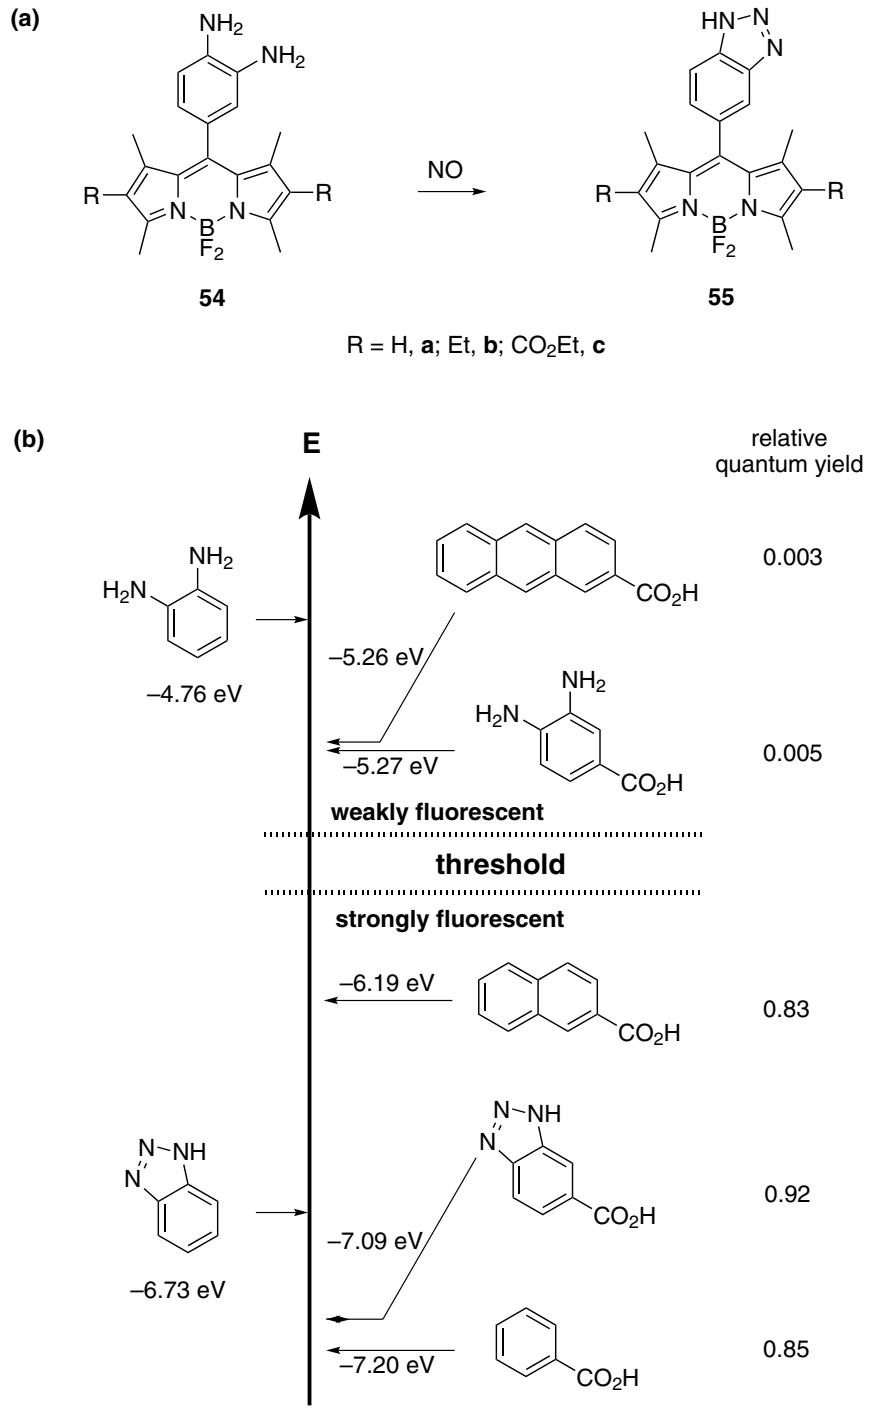

Figure 5. (**a**) Calculated HOMO energy levels of *meso*-substituents for BODIPY **54** and **55**; (**b**) Reductive PeT occurs above the threshold indicated.

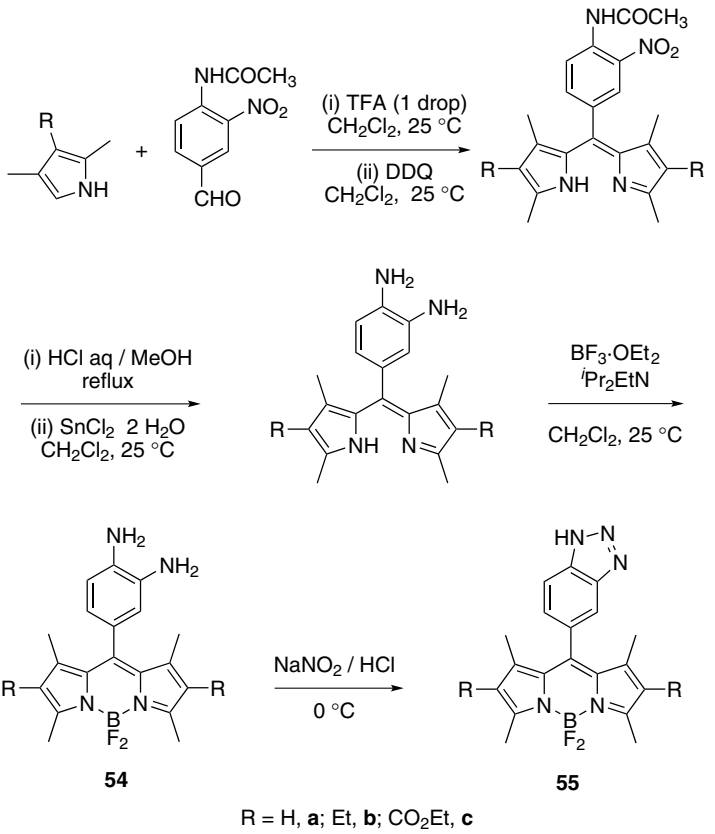

Scheme 3. Synthesis of diaminobenzene- and triazole- BODIPY derivatives **54** and **55.**

energies of excited states are notoriously difficult to calculate. Nevertheless, the approach emphasized by Nagano and coworkers helps dispel dogmas that surround fluorescent probes. For instance the assertion that nitro groups or heavy atom substituents always quench fluorescence is simply not true. The reality is that

they tend to do so but only if their orbital energy levels interact with the fluorescent chromophore in a way that facilitates PeT.

IV. BODIPYs with Heteroatom Substituents

A. From Electrophilic Substitution Reactions

Simple considerations of mesomeric structures reveal that 2- and 6-positions of the BODIPY core bear the least positive charge, so they should be most susceptible to electrophilic attack (Figure 7). However, there is no definitive study of regioselectivities in these reactions for BODIPYs without pyrrole substituents; almost invariably some of the other positions are blocked by substituents.

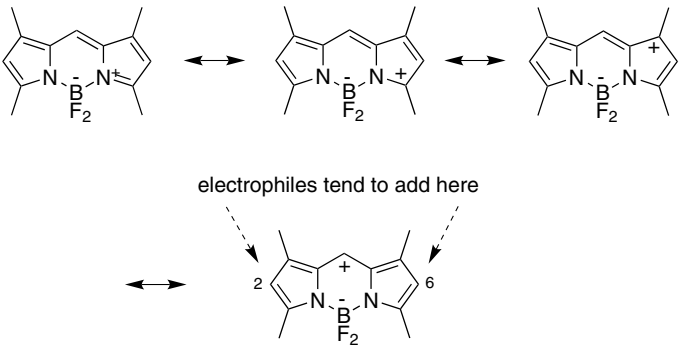

Figure 7. Electrophilic attack on tetramethyl-BODIPY.

1. *Nitration*

The 2,6-dinitro BODIPY dye **61** can be obtained via nitration with nitric acid at 0 °C (Chart 8). In this reaction, the fluorescence quantum yield of the product is much less than that of the starting material.[88,106–108] To the best of our knowledge, this is the only nitration of a BODIPY dye that has been reported in the literature.

2,6-Dinitro-BODIPY **62**[109] and **63**[110–114] have also been reported in the Japanese patent literature for applications as sensitizers and inks. We were unable

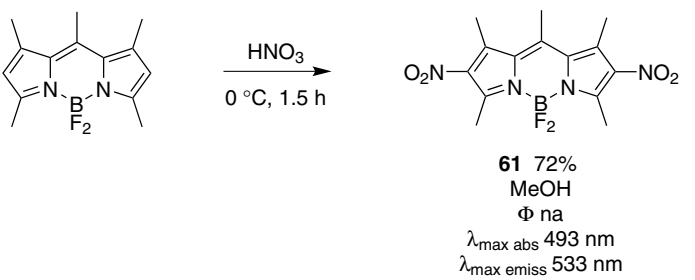

Chart 8.

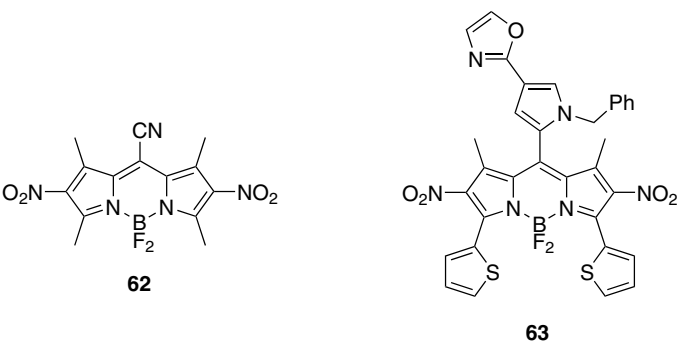

to find procedures for their syntheses and the corresponding spectroscopic data in these documents.

2. *Halogenation*

Bromination of the 1,3,5,7,8-pentamethyl-substituted BODIPY shown in Chart 9 gave the dibromination product **64**.[88,115] Predictably, introduction of bromo substituent onto the dipyrromethene core causes a significant red shift of both the UV-absorption and emission maxima, and it quenches the fluorescence quantum yield via the heavy atom effect.

2,6-Diiodo-tetramethyl BODIPY **65** was prepared as described in Chart 10.[116] Just as for the dibromo-BODIPY **64**, iodo-substituents cause significant red shift of the UV-absorption and fluorescence emission maxima, and decrease the fluorescence quantum yield via the heavy atom effect. Compound **65** is much more resistant to photobleaching than Rose Bengal; this is because the BODIPY core has a more positive oxidation potential than the xanthone unit of Rose Bengal. Compound **65** is an efficient photosensitizer.

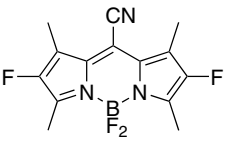
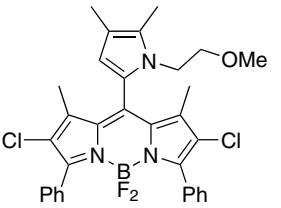
Rose Bengal

2,6-Difluoro- and 2,6-dichloro- BODIPY derivatives **66**[109] and **67**,[110–114] have been applied in electroluminescent devices and sensitizers. Their synthesis has not been reported.

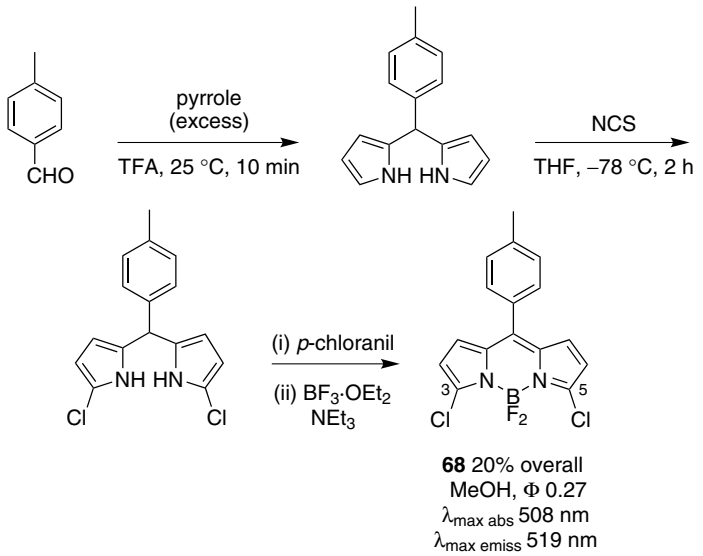


66



67

Chlorination of the unsubstituted dipyrromethane shown in Scheme 4 occurs preferentially at the α-positions. Thus the 3,5-dichloro BODIPY derivative **68**



Scheme 4. Preparation of 3,5-dichloro-BODIPY via chlorination of a dipyrromethane intermediate.

could be obtained after oxidation with *p*-chloranil and complexation with boron trifluoride etherate. Applications of such chlorinated materials as S_NAr electrophiles are described later in this chapter.

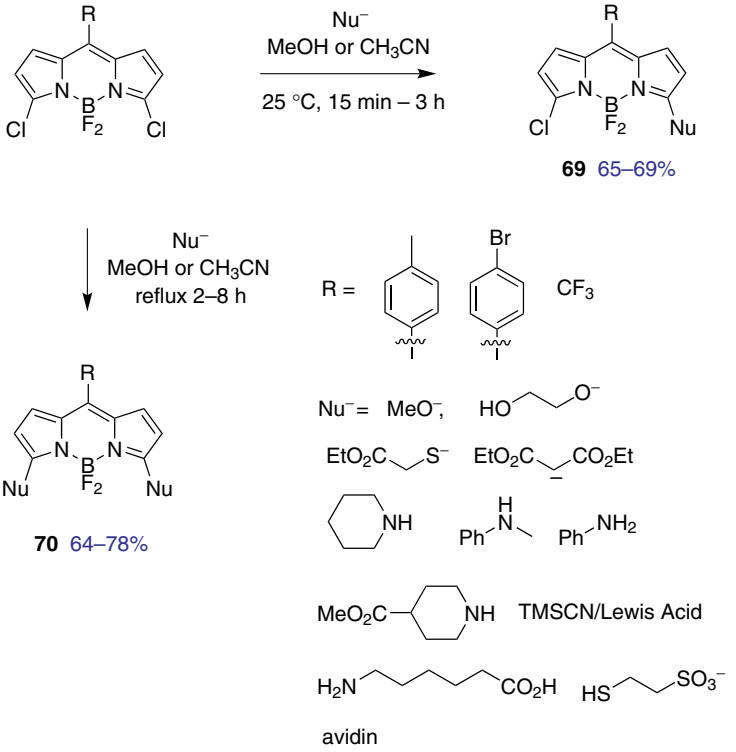
3. *Potential for Other Electrophilic Substitution Reactions*

BODIPY dyes are intrinsically electron rich, and the reactions shown above illustrate that they will react with electrophiles. It is therefore surprising that the reactions shown above represent the state-of-the-art in this area. There are very few sulfonation reactions (see Section V) despite the importance of water-soluble dyes; most of the sulfonated BODIPY compounds in the Invitrogen catalog (aka Molecular Probes) feature carboxylic acids with sulfonated leaving groups. There are no reports in the literature of some common electrophilic addition processes like Vilsmeier-Haack reactions on BODIPY substrates, but Burgess and coworkers have investigated this type of reaction, and the mono-formylated BODIPY dye could successfully be synthesized in excellent yield (unpublished results).

B. From Nucleophilic Attack on Halogenated BODIPYs

The most common approach to introduce substituents on the 3- and 5-positions of the BODIPY core involve *de novo* syntheses with appropriately substituted pyrroles, but an exciting recent development reaches the same goal via nucleophilic substitution on 3,5-dichloro-BODIPY such as **68**.[117–121] The nucleophiles used so far include alkoxides, amines, thioalkoxides, diethyl malonate anion, and cyanide. These reactions can be stopped at the mono-substitution stage or forced to the disubstitution product (Scheme 5) hence they are useful for access to asymmetric **69** and symmetric **70**, hetero-substituted BODIPY dyes, which would be difficult to obtain by other routes. When cyanide was used as nucleophile, displacement was achieved using Lewis acid activation of trimethylsilyl cyanide. Addition of tin tetrachloride gave selective substitution at the carbon atom, i.e., compound **71**, while boron trifluoride promoted displacement at both the carbon and boron atoms giving the corresponding tetracyanide derivative **72**. S_NAr reactions were successfully used to simultaneously change the BODIPY core structure, its fluorescent properties, and enhance its water solubility (compounds **73–75**). In addition, Burgess and coworkers showed that this process could be used to conjugate dyes to proteins, e.g., to give **76** and **77**.[119]

The spectroscopic effects of electron-donating groups attached to the BODIPY core for the compounds in Scheme 5 were studied. The 3- and 5-substituents had significant effects, shifting both the absorption and/or emission spectra, and



Scheme 5. BODIPY dyes via S_NAr reactions.

changing the fluorescence quantum yields. For example, introduction of an amino- or sulfur-centered nucleophiles results in a significant bathochromic shift (red shift) of both the absorption and emission.[117] Data were collected in methanol (Figure 8); the absorption and emission maxima were red-shifted in cyclohexane but otherwise it was quite similar to that for methanol (data not shown). The quantum yields varied widely with the nature of the nucleophiles and the degree of substitution. In general, mono-substituted dyes tend to have lower quantum yields than the bis-substituted ones. Interestingly, the water-soluble BODIPYs **73–75** have good to excellent quantum yields.

8-(ω-Haloalkyl)-BODIPY dyes **78** and **79** are useful starting materials. These are easily synthesized by condensation of a ω-haloacyl chloride with 3-ethyl-2,4-dimethyl pyrrole (Chart 11).[122]

Compounds **78** and **79** can be used as fluorescent electrophiles and can easily be functionalized by nucleophilic substitution reactions, giving compounds **B**.[49,122] Thus, cysteine-selective fluorescent label, fluorescent amino acids, chemosensors for metal ions[49] and fluorescent pH probes could be prepared.[123]

C. From Metal Mediated C-H Functionalization

Pyrroles can be functionalized via palladium-catalyzed activation reactions.[124–126] Burgess and coworkers applied the same strategy to synthesize novel BODIPY dyes via palladium-mediated C-H functionalization (Chart 12).[127] This route provides a direct way to extend the conjugation of the BODIPY core, without a halogenated or metalated intermediate prior to the coupling reaction. Highly fluorescent, mono- (**80**) or disubstituted (**81**) dyes can be obtained. A water-soluble, sulfonated BODIPY dye **80d** was also prepared via this route, but in low yield (2%).

The C-H functionalization process was also applied to α,β-unsaturated esters to form compounds **82** and **83**. Mono- and disubstituted products were obtained, but these do not correspond exactly because the alkene double bond was shifted out of conjugation with the BODIPY core.

Iridium-catalyzed direct borylation of aromatic compounds via C-H bond activation and the use of organoboranes with rhodium catalysis have been extensively explored for new types of C-C bond formation. Recently, Osuka and coworkers

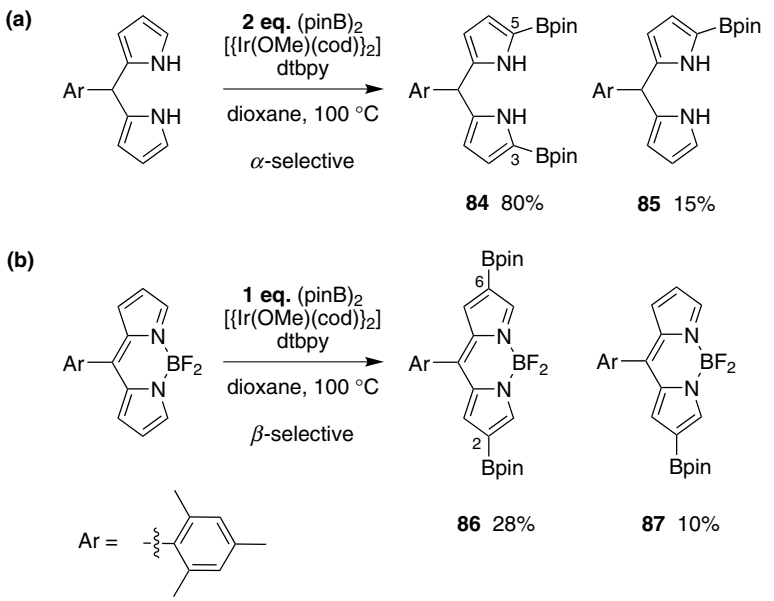
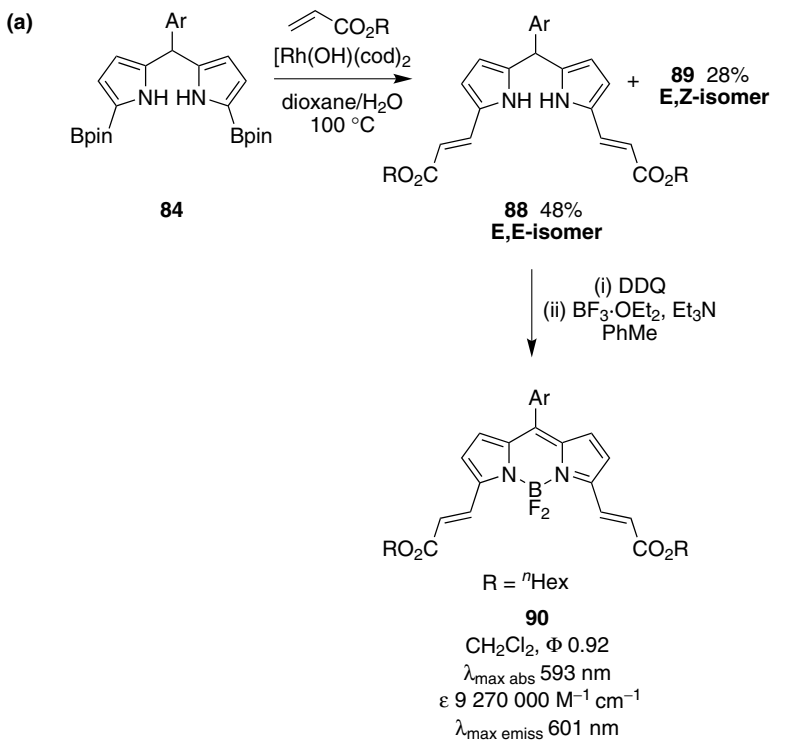


Scheme 6. Borylation of (**a**) *meso*-mesityldipyrromethane, and (**b**), *meso*-mesitylBODIPY.

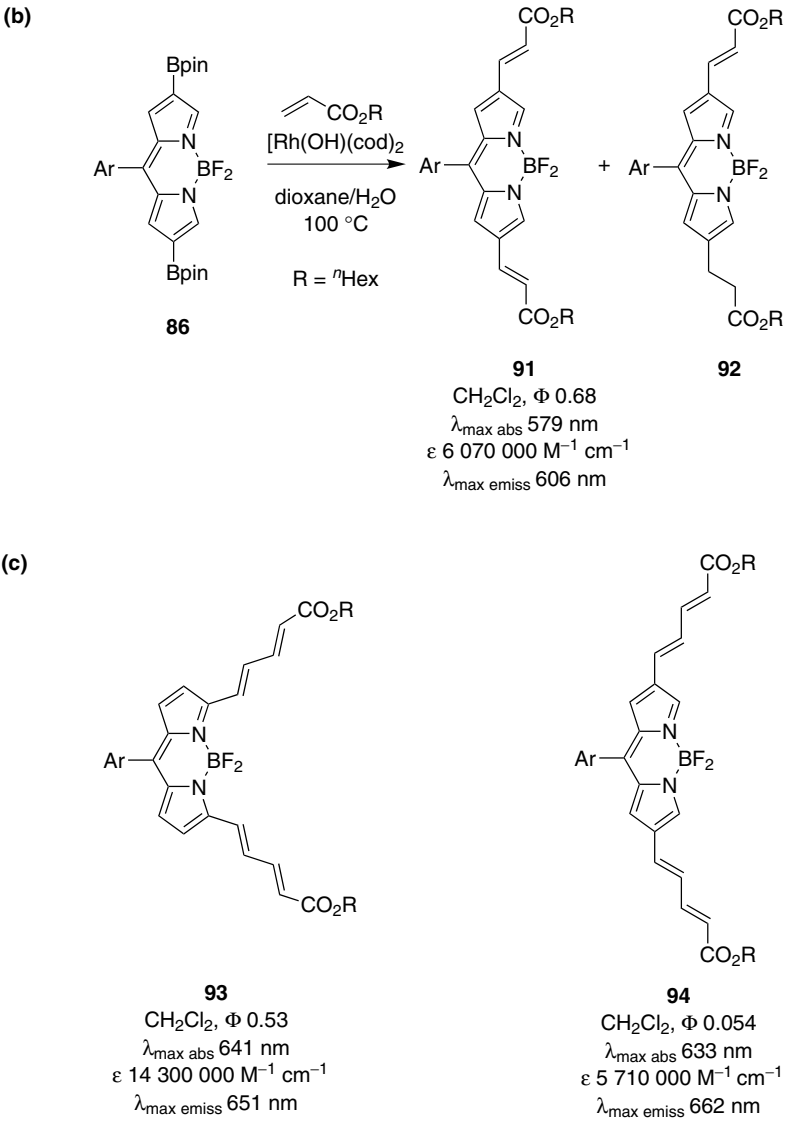
applied those novel metal-catalyzed methodologies to dipyrromethane and BODIPY dyes.[128] The BODIPY precursor was borylated regioselectively at the 3- and 5-positions (aka α positions), while the corresponding BODIPY reacted at the 2- and 6-positions (aka β positions) (Scheme 6). Borylation of the BODIPY occurred

in low yield probably because of the instability of the dye under the reaction conditions.

Rhodium-catalyzed Heck-type additions were used to prepare α- and β-functionalized BODIPY dyes from **84** and **87** (Scheme 7). Treatment of **84** with hexyl acrylate gave the desired 3,5-double addition products as a mixture of the *E*,*E*- and *E*,*Z*- isomers, **88** and **89**. Oxidation of **88** with DDQ, followed by complexation with boron afforded the corresponding BODIPY **90** (Scheme 7a). Under the same conditions, the BODIPY **86** gave the desired disubstituted product **91** along with some partially saturated compound **92** (Scheme 7b). α, β, γ, δ-Dienote functions were also introduced, but the corresponding products **93** and **94** were obtained in low yields. Photophysical properties of the new dyes were studied in CH_2Cl_2. A substantial red shift for both the absorption and emission was observed upon extending the conjugation of the system. The 3,5-substituted BODIPY dyes exhibit sharp fluorescence peaks, higher extinction coefficients and fluorescence quantum yields, relative to the 2,6- substituted BODIPY dyes **91**.



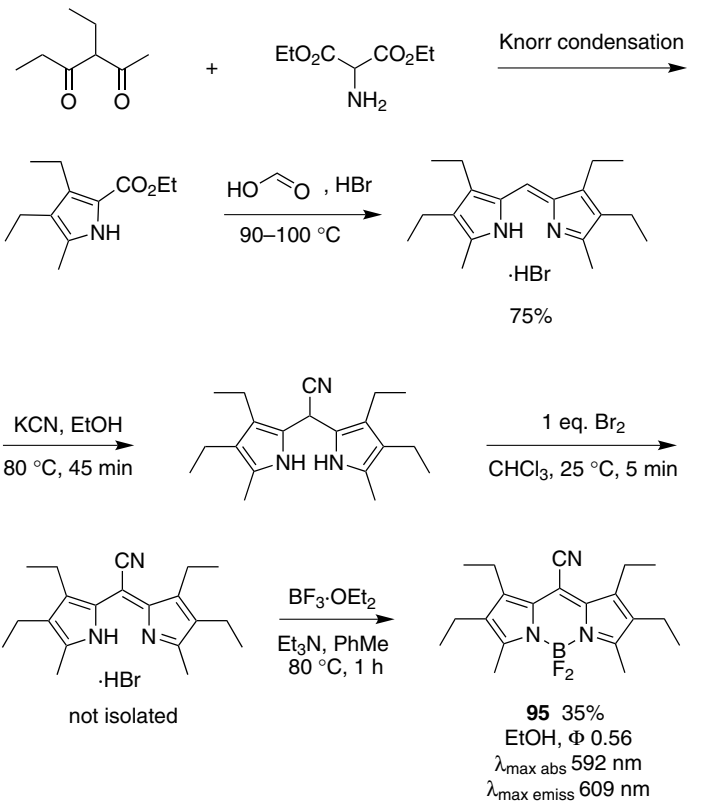
Scheme 7. Functionalization of: (**a)** the 3,5-borylated *meso*-mesityldipyrromethane **84**; and, (**b)** the 2,6-borylated *meso*-mesitylBODIPY **86**; and (**c**), the extended conjugated systems **93** and **94** formed via this approach.



Scheme 7. (*Continued*)

D. From Nucleophilic Attack at the *meso*-Position

BODIPY systems with a *meso*-cyanide substituent are special insofar as they fluoresce at significantly longer wavelengths than the unsubstituted systems.[129] Further, they can be accessed by direct addition of cyanide anion to the dipyrromethene core, followed by oxidation. The first synthetic route developed gave poor overall yields, mainly due to loss of material in forming the



Scheme 8. Cyanopyrromethene-BF_2 complexes via addition of cyanide.

dipyrromethene,[89] but an improved one was published by Boyer and coworkers (Scheme 8).[130] In that work, Knorr condensation of 3-ethylhexan-2,4-dione with diethyl aminomalonate give ethyl 3,4-diethyl-5-methylpyrrole-2-carboxylate. This pyrrole is then converted to the dipyrromethene hydrobromide via the presumed intermediacy of 2-methyl-3,4-diethylpyrrole and its condensation with the α-formyl derivative that is formed *in situ*.

Comparison of compound **95** with other *meso*-cyano BODIPYs (e.g. **96–99**) shows their fluorescence and absorption are about 60 nm red-shifted relative to simple alkyl-substituted BODIPYs. This large bathochromic shift seems attributable to a net stabilization of the BODIPY LUMO via interaction with the cyano group. The presence of the cyano group also significantly reduces the molecular extinction coefficient. Only in the case of **99** where the core bears two ester groups is this red-shift attenuated. Presumably in this case the esters reduce the electron density on the BODIPY core available for delocalization into the nitrile, and this affects the fluorescence emission wavelength.

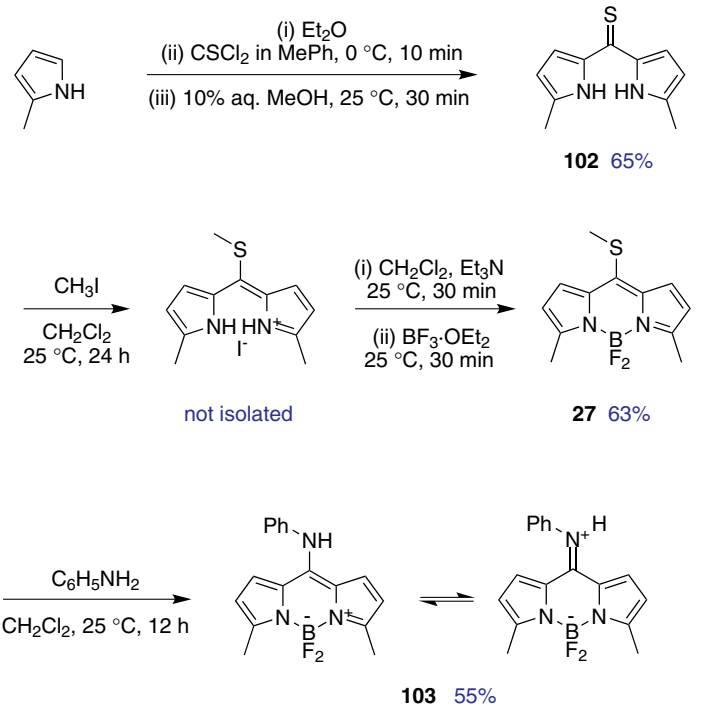
$\lambda_{max\ emiss}$ 552 nm

Red-shifted fluorescence associated with a cyano group is particular to the *meso*-position. 2,6-Dicyano BODIPY **100** has two cyano groups, neither occupies the *meso*-position, and fluorescence from this compound peaks at about the same wavelength as similar BODIPYs without nitrile substituents, e.g. **101** and **8**.[130] Similarly, substitution at the 2- and 6-positions with carboethoxy, acetamido, sulfonate anion, bromo or nitro groups do not produce any red shift.[89,130,131]

A synthesis of sulfur containing BODIPYs under mild conditions was recently achieved via reaction of thiophosgene with substituted pyrroles to give the corresponding thioketone **102**.[90] The latter can then react with various electrophiles to form the dipyrromethene intermediates that were combined with boron trifluoride in presence of base to afford the thio-BODIPY derivatives **27**. These *meso*-thioalkyl groups can be displaced by nucleophiles to give anilino-substituted BODIPY derivative **103** (Scheme 9, see also Chart 2). Amine adduct **103** was not



Scheme 9. Synthesis of sulfur- and anilino- BODIPY derivatives.

fluorescent, presumably because of electron transfer from the amine group to the BODIPY core in the excited state.

V. Water-Soluble BODIPY Dyes

A. From Electrophilic Substitution Reactions

Despite the practical value of *water-soluble* BODIPY dyes, very few have been reported. Up to 2008, only a few sulfonated BODIPY dyes had been reported. They were obtained from tetra-, or penta-substituted BODIPYs via treatment with chlorosulfonic acid, then subsequent neutralization with a base (e.g. Chart 13). Monosulfonated systems could be obtained when only one equivalent of chlorosulfonic acid was used. Introduction of the sulfonate groups did not change the absorption and emission spectra significantly relative to the unsulfonated dye. The sulfonated BODIPY dyes **104**–**107** are strongly fluorescent in water and/or methanol, and are claimed to have even better stability than the parent dyes.[88,132–137]

Burgess and coworkers recently developed sulfonation conditions to prepare various functionalized, mono- and bis-sulfonated BODIPY systems, e.g. **108**–**110**.[138]

BODIPY **108** is functionalized with an aryl iodide for elaboration via Pd-mediated couplings. Compound **109** has two chlorine atoms that could be replaced by S_NAr reactions. Probe **110** was designed with an acid functional group to facilitate activation and coupling to amines.

B. From Coupling or Substitution Reactions

So far, three different strategies have been explored to introduce water-soluble groups onto the hydrophobic BODIPY core: (i) S_NAr reaction at the 3-position of 3,5-dichloroBODIPY with 2-mercaptosulfonic acid (Section IV.B),[119] (ii) Heck-coupling in the 2- and 6-positions (Section IV.C)[127] and, (iii) electrophilic sulfonation with chlorosulfonic acid.[138] Only the last approach gives water-soluble BODIPYs in good yields without requiring prior functionalization of the BODIPY

core. Recently, Ziessel and coworkers reported two alternative strategies to introduce (poly)sulfonated groups onto the BODIPY core.[139] The first relies on a peptide coupling between α-sulfo-β-alanine and BODIPY **111** (obtained in two steps from the corresponding phenyliodo derivative via Pd-mediated carboalkoxylation, followed by saponification; Chart 14). The mild conditions (NMP-water, pH 8.5, 25 °C) involve in this amine/acid coupling allow the presence of

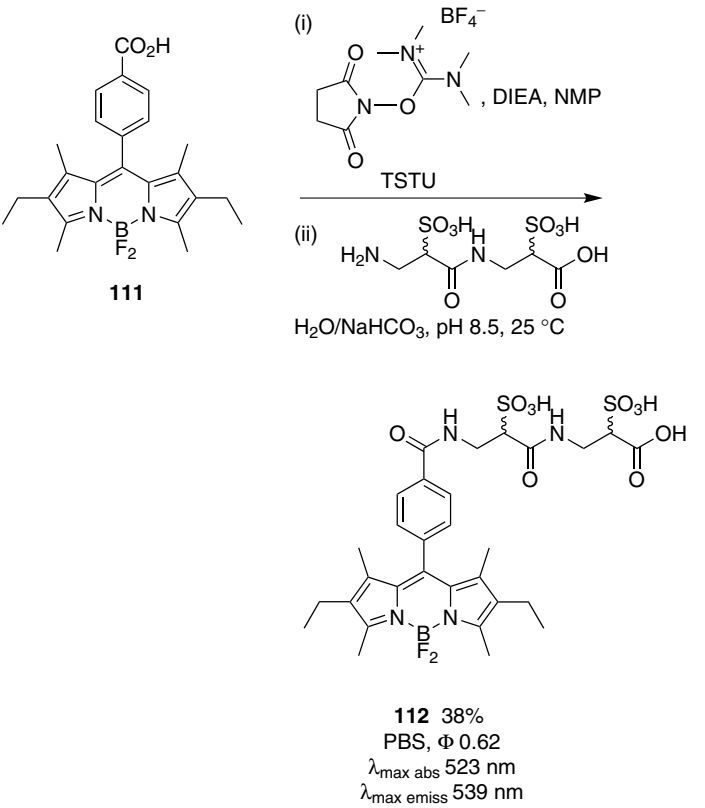

Chart 14.

additional sophisticated functional groups and provide hydrophilic fluorophores with a handle for conjugation to biomolecules.

Ziessel's second strategy to *water-soluble* BODIPYs is based on alkynylation at the 2,6-positions (Chart 15) and/or at the boron center (Chart 16) with 1-dimethylamino-2-propyne, followed by alkylation with propane sultone. Introduction of the hydrophilic linker at the 2- and 6-positions (dye **95**) resulted in a bathochromic shift in the emission spectra relative to dye **116**. BODIPY **116** shows two absorption maxima at 522 and 567 nm in PBS; the latter disappears in EtOH indicating aggregation of the dye in aqueous medium.

VI. Aryl-, Alkenyl-, Alkynyl-Substituted BODIPYs

A. *Meso* Aryl-, Alkenyl- and Alkynyl-Substituted BODIPYs

Meso-substituted BODIPY are usually prepared via condensation of an aryl aldehyde with a large excess of pyrrole under acid catalysis, oxidation with DDQ,

followed by complexation with BF_3 etherate. Although commonly used, this methodology has several disadvantages; for instance, it includes tedious purifications, synthesis of the aldehyde (if not commercially available), and some functional groups on the aryl aldehyde might be incompatible with acid, and DDQ oxidation.

Inspired by the work of Liebeskind[140] and Biellmann,[90] Peña-Cabrera and coworkers reported a novel, simple and efficient synthesis of *meso*-substituted BODIPY via Pd-catalyzed, Cu(I)-mediated cross-coupling of the 8-thiomethylBODIPY **117** with boronic acids under neutral conditions (Chart 17).[141] Both electron-rich and -poor aryl and alkenyl boronic acids reacted smoothly under the Liebeskind-Srogl coupling conditions. Bromo-aryl derivatives, e.g. compound **118**, could be prepared in good yield without further polymerization (via Suzuki-type reactions) as the Liebeskind-Srogl works in the absence of base. Bulky boronic acids did not compromise either the efficiency of the process as

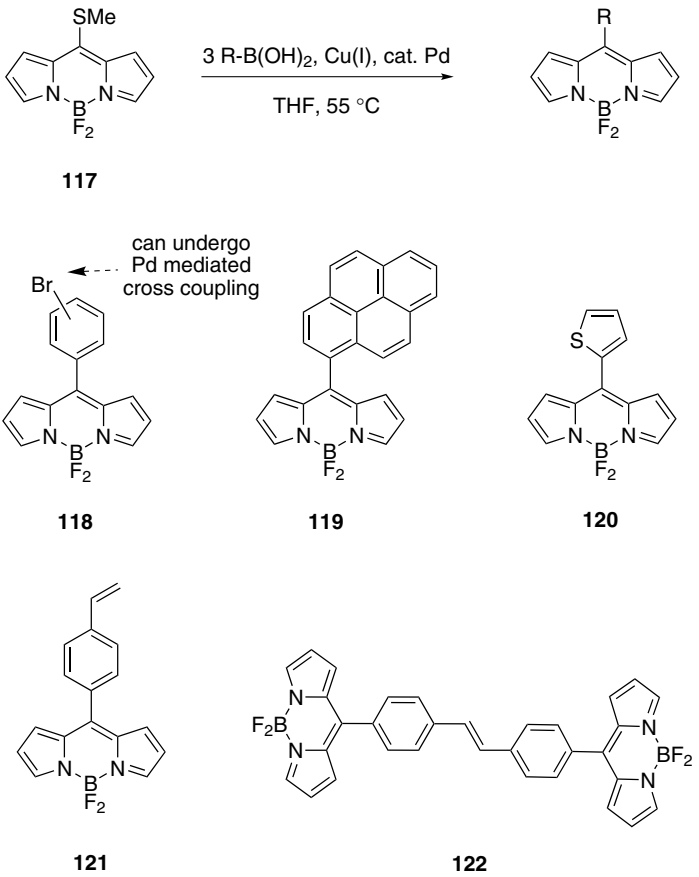

Chart 17.

BODIPY **119** could be prepared in 67% yield in 15 minutes. Heteroaryl boronic acids also showed excellent reactivity. This new route tolerates many functional groups allowing preparation of products that can be further elaborated. Compound **118** containing an aryl bromide can undergo Pd mediated cross coupling. BODIPY **122** was obtained from homometathesis of **121**. No spectroscopic data have been reported yet.

Until recently, there was only one *meso*-vinyl substituted BODIPY dye (compound **26**, Section II.D). Introduction of a vinyl unit at the *meso* position of BODIPY led to a bathochromic shift of the emission maxima, while the absorption did not change. Dyes **124**–**129**, synthesized from BODIPY **123**, illustrate a new series of dyes combining polymethine and dipyrromethene chromophoric fragments.[142] The methyl group of **123** is not highly reactive, but can undergo some condensation reactions. Thus, Vilsmeier-type formylation of **123** gave the disubstituted BODIPY **124**. The hemicyanine dye **126** was obtained by treating the monoformylated product **125** with aniline (Chart 18). BODIPY **124** shows good fluorescent properties. However, the derivatives **125** and **126** are nonfluorescent, presumably due to PeT quenching. Acidification of the solutions of **125** and **126** restores the fluorescence, but that of **125** disappears quickly, and irreversibly.[142]

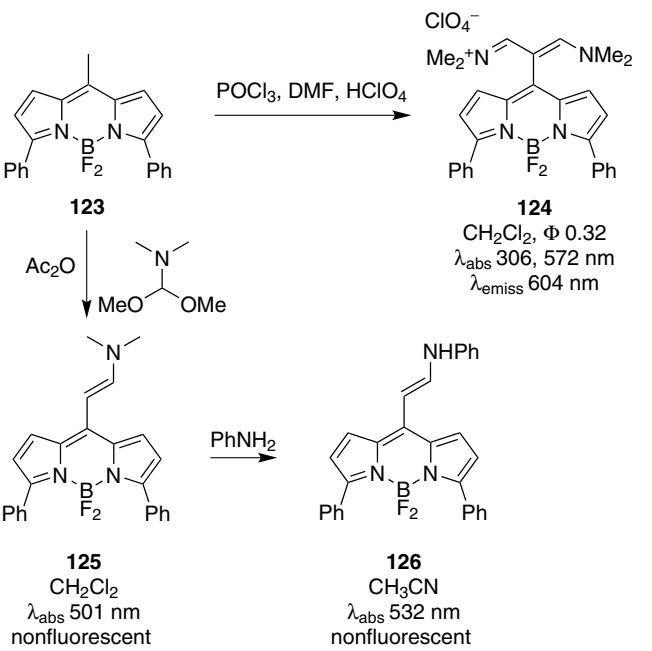

Chart 18.

BODIPY **123** reacts with more active phenyliminovinyl derivatives of heterocycles of low and medium basicity (e.g. 4-pyran, indoline, benz[*c,d*]indole, and benzothiazole) to form dyes such as **127–129** in good yields (Chart 19). Combination of **123** with 2-(phenyliminovinyl)quinoline led to the formation of **131** (Chart 20). The author postulates this may be due to the low electron-withdrawing ability of the BODIPY nucleus, which makes the betaine mesomeric form unfavorable. The contribution of the betaine mesomeric form increases with increasing electron-donating effect of the second terminal nucleus, whereas the stability of the boron complex decreases. Thus, the synthesis of symmetrical dyes such as **132** is difficult due to the formation of the unfavorable anionic form of the BODIPY nucleus.

The physical properties of new polymethine-substituted BODIPY dyes were studied in CH_2Cl_2 and DMF. The merocyanine nature of these dyes manifests itself in the existence of two absorption bands: a short-wavelength band characteristic of the BODIPY core and a more intense, long-wavelength band typical of the

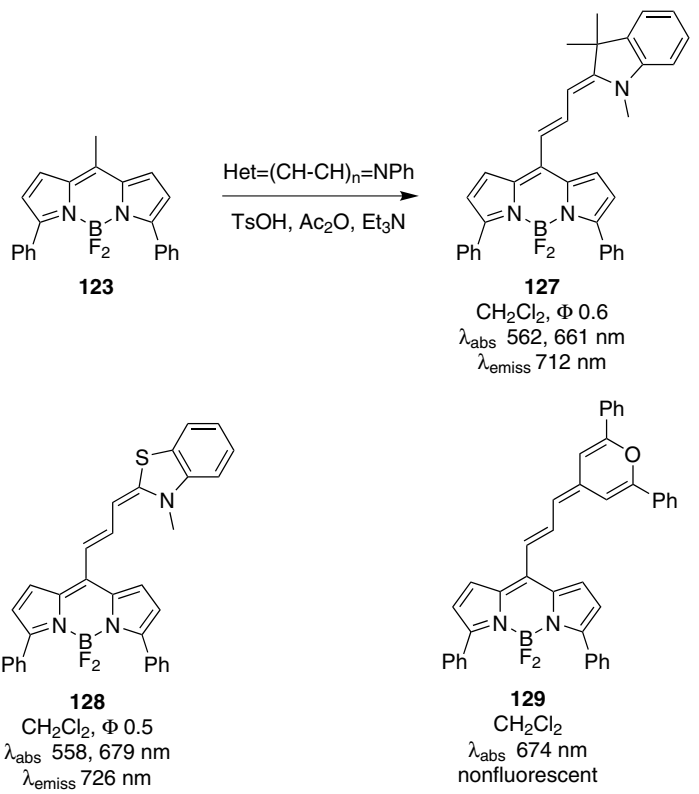

Chart 19.

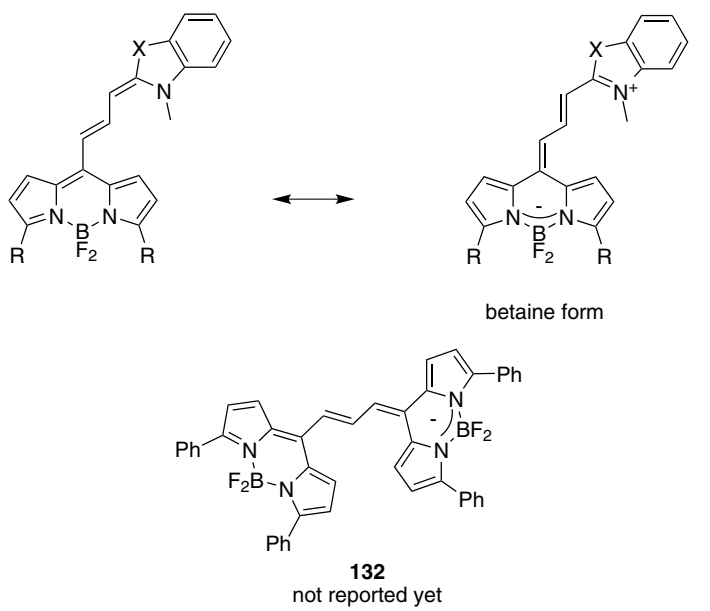
Chart 20.



132
not reported yet

polymethine fragment. Upon protonation, the long-wavelength absorption band completely disappears while the one corresponding to the BODIPY nucleus increases. Boradipyrromethenecyanines **127** and **128** are moderately fluorescent in CH_2Cl_2 ($\Phi \sim 0.5$–0.6), and are weakly fluorescent, particularly in polar solvents

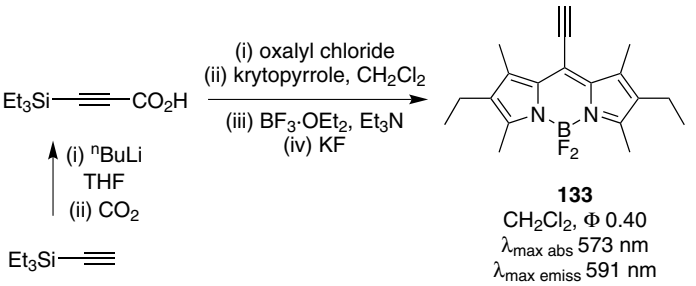


Chart 21.

($\Phi < 0.1$ in DMF). There is no fluorescence increase for these materials upon protonation.

Very few *meso*-alkynyl BODIPYs are known. As far as we are aware, the 8-ethynyl BODIPY **133** is the first one.[143] It was prepared by a classical route, involving condensation of 2,4-dimethyl-3-ethylpyrrole with triethylsilylacetylene acid (generated *in situ*), followed by complexation with BF_3 etherate, and deprotection of the silyl group with potassium fluoride (Chart 21). Compound **133** shows an intense absorption at 573 nm, red-shifted by 30 nm relative to the 8-methyl derivative due to extended conjugation.

B. 3,5-Aryl-Substituted BODIPYs from Aryl-Pyrroles

Aryl-substituted BODIPY dyes can be formed via condensation of the corresponding pyrroles with acyl chlorides.[144,145] The 2-aryl pyrroles used were prepared via Suzuki couplings[146] of *N*-*tert*-butoxycarbonyl-2-bromopyrrole (Chart 22); this was more convenient than starting with less accessible materials like 4-aryl-1-azidobutadienes[147] or a *N*-tosylarylimine.[148,149] Removal of the *N*-BOC protecting group under basic conditions gave the desired aryl pyrroles. These products were found to decompose on standing, rapidly under acidic conditions, and were therefore best formed immediately before use.

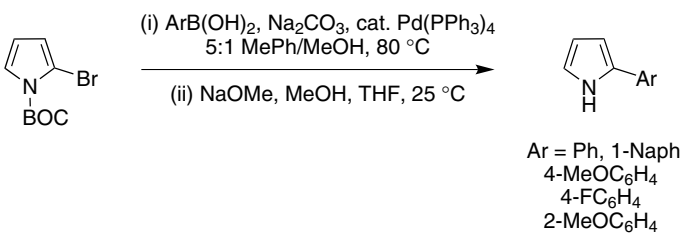

Chart 22.

3,5-Diaryl BODIPY dyes were obtained from the pyrroles shown above, via a one pot, two-step process featuring 4-iodobenzoyl chloride. The 3,5-aryl groups extend the conjugation of the BODIPY systems. Compared to the alkyl-substituted derivatives, e.g. **134** and **135** which have green, fluorescein-like emissions ($\lambda_{max\ emis}$ = 510 nm), both the absorption and emission maxima of 3,5-diaryl substituted BODIPYs **136–140** are shifted to longer wavelengths ($\lambda_{max\ emis}$ = 588–626 nm).[144,145] The *para*-electron-donating group of **138** gives a larger bathochromic shift and increased quantum yield, compared to the compound with that same substituents in the *ortho*-position **140**. Similarly, the extended aromatic substituent naphthalene of **137** red-shifted the emission maximum for this compound. However, the extinction coefficients for **136–140** were not markedly

increased relative to the alkyl systems **134** and **135** and their fluorescence quantum yields were significantly lower due to non-radiative loss of energy via rotation around the C-Ar bonds.[150]

Similarly to above, the polyphenylated BODIPYs **141–143** were prepared from the corresponding 2,4-diphenylpyrrole or 2,3,4-triphenylpyrrole prepared by Suzuki-Miyaura coupling of 2,3,4-tribromopyrrole with $PhB(OH)_2$ to study the effect of the peripheral phenyl groups on photophysical properties.[151] The peripheral phenyl groups of **141** and **143** are arranged in a propeller-like fashion in the solid state, as shown by X-rays analyses. In THF, the new BODIPY derivatives show strong absorption bands centered around 561–576 nm and fluorescence emission between 597–613 nm. Although, the emissions maxima for the new BODIPYs are close, significant differences were observed in their quantum yields. BODIPYs **29** and **141** have extremely high quantum yields, while dyes **142** and **143** are only moderate (20 and 30%). This marked difference is due to the phenyl ring at the *meso* position; the steric congestion around this group accelerates non-radiative internal conversion. Intense emissions for **142** and **143** were observed when the dyes (1%) were included in PMMA films. This is probably because rotation of the *meso*-phenyl ring is restricted in the solid state.

Fluorescence of some BODIPYs in solution can be reduced at elevated concentrations due to intermolecular π-stacking. BODIPY dyes can stack in two geometrically distinct forms: H- and J-dimers (Figure 9). The former is most likely a result of intramolecular dimerization, with the stacking of two BODIPY planes with almost parallel $S_0 \rightarrow S_1$ transition dipoles, and anti-parallel electric dipole moments. This dimer is practically non-fluorescent, and exhibits blue-shifted absorption relative to that of the monomer. The J-dimer, in which the $S_0 \rightarrow S_1$ transition dipoles are oriented in planes at 55°, is fluorescent and shows a red-shifted absorption relative to that of the monomer.[152–154]

Compound **144** was designed to sterically prevent dimers formation in solution.[155] Further, the hindered internal rotation of the mesityl rings reduces nonradiative relaxation of excited states, enhancing fluorescence quantum yields. Dyes such as **144** were prepared from mesityl aldehyde and the corresponding pyrrole **145**[156] (made via a Trofimov reaction).[149]

C. Knoevenagel Reactions with Benzaldehyde Derivatives to Give Alkenyl Systems

1. *3,5-Styryl-BODIPY Dyes*

3- and 5-Methyl BODIPY substituents are acidic enough to participate in Knoevenagel reactions. Thus, styryl-BODIPY derivatives can be obtained by condensation of 3,5-dimethyl-BODIPYs with aromatic aldehydes (Chart 23).[157,158] With *p*-dialkylaminobenzaldehyde the reaction can be restricted to one condensation (di(dimethylamino)styryl-substituted BODIPY dyes can be obtained with longer reaction time (7d)),[159] but 4-alkoxybenzaldehydes tend to give mixtures corresponding to one and two condensations.[160]

The condensation processes shown in Chart 23 provide BODIPY derivatives that have red-shifted fluorescence, and functional groups that can be used in sensors and molecular logic gates. UV-absorption spectra of compounds from one condensation (e.g. **148** and **149**) tend to reach maxima around 594 nm in MeOH, and their fluorescence emissions are similarly red-shifted. Both the absorption and, particularly, the fluorescence spectra are dependent upon solvent polarity.[161,162] The red shift is more pronounced in polar solvents indicating excitation of the dyes leads to more polarized excited states.

Structures **147**–**149** illustrate some effects of amino substituents in these styryl systems. When the amine is directly conjugated with the styryl group then a maximum red-shift is obtained, but when it is part of the *meso*-substituent then the bathochromic shift is less because this *meso* substituent is nonplanar. Quantum yields for these materials are only high when the amine is protonated disfavoring Intramolecular Charge Transfer (ICT) in the excited state.[157,162] Compound **149** is a metal sensor because complexation to ions alleviates ICT and increases its

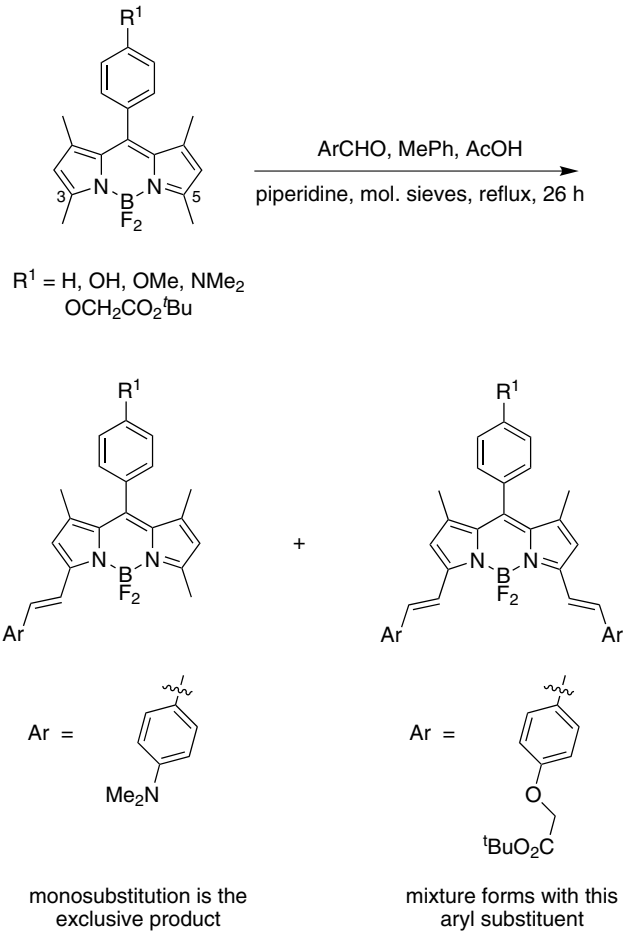

Chart 23.

quantum yield. Introduction of a second styryl group at the 5-position (compound not shown) red-shifts the UV and fluorescence maxima by almost 100 nm and 50 nm, respectively.[159]

BODIPYs **150** and **151** are ICT dyes; they display opposite spectral shifts upon protonation.[163] As expected, upon addition of acid (TFA), emission of **150** is significantly blue-shifted (from 753 to 630 nm) as the ICT donor group dimethylamino functionality is a considerably less effective electron donor when protonated. Conversely, **151** with acid gives a red-shifted absorption spectrum (from 620 to 660 nm).

Compound **152** can be called a molecular and logic gate for generation of singlet oxygen for photodynamic therapy.[164] The chemical inputs of the logic system are Na^+ and H^+ as the pH of tumor tissues is quite acidic, and the intracellular

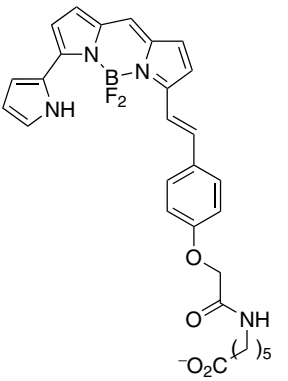
BODIPY 630/650

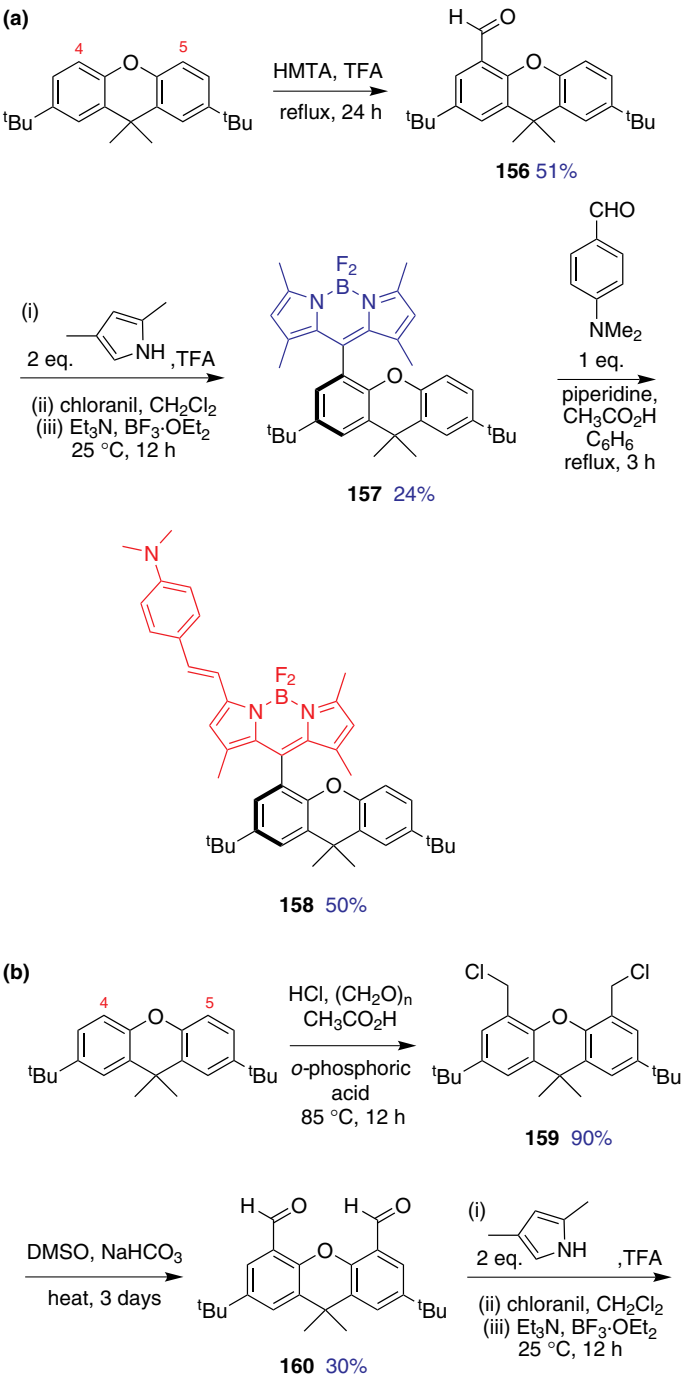


BODIPY 650/665

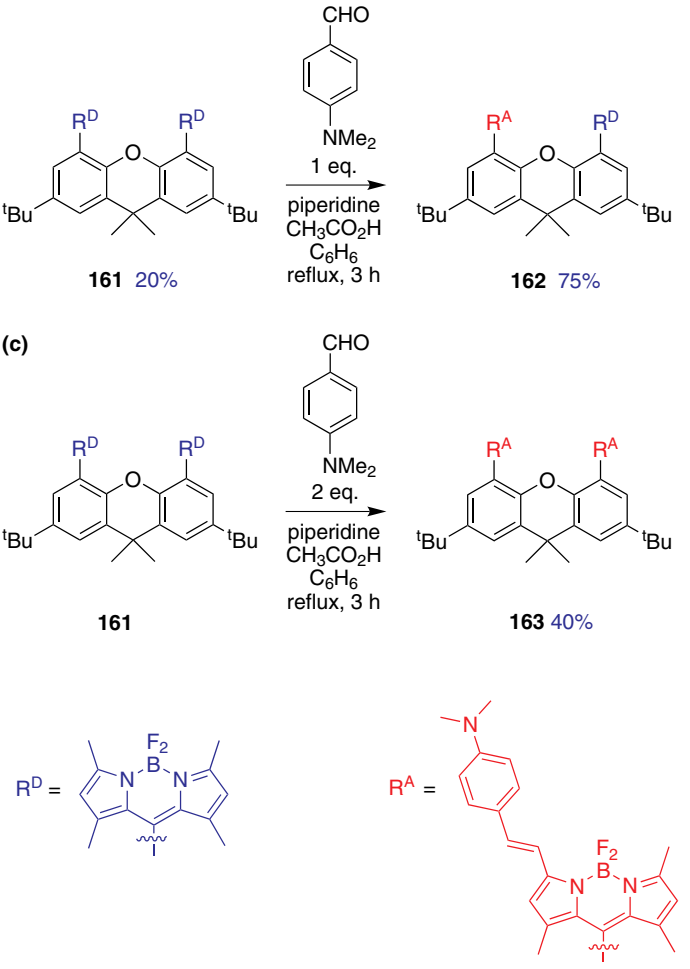
Although many new styryl BODIPYs have been synthesized, Invitrogen's BODIPY 630/650 and BODIPY 650/665 probes are the only two longest-wavelength amine-reactive BODIPY fluorophores commercially available to date.

Biomolecules labeled at relatively large BODIPY:protein ratios can have diminished fluorescence intensities due to interactions between the probes; the fluorescence can also be red-shifted for the same reason.[165] Small molecules containing two BODIPYs have been produced to test these types of effects. The first prepared were somewhat flexible being based on cyclohexane.[152,153] More recently, rigid ones with cofacial BODIPY dyes have been made and studied. Only one transition dipole moment is possible for these structures. The xanthane unit was chosen as a scaffold since it can be easily functionalized on its 4- and 5-positions. Aldehyde or bis-aldehyde functionalities on the xanthane (**156** or **160**, respectively) were used to construct the BODIPY units by condensation with 2,4-dimethylpyrrole. A 3-methyl substituent on the BODIPY was then reacted with *p*-dimethylaminobenzaldehyde to extend the conjugation (Scheme 10).[166]

Compound **161** has two cofacial BODIPY groups, and the UV absorption maximum of the BODIPY part is blue-shifted (to 478 nm, with a shoulder at 504 nm) relative to 1,3,5,7-tetramethyl-BODIPY **7** and the other control compound **157**. Compound **162**, which has one styryl-extended BODIPY and one tetramethyl-BODIPY substituent, has UV absorption peaks corresponding to both these substituents (455 nm and 575 nm). Upon excitation at 480 nm, the monochromophoric system **157** exhibits a very strong emission at 500 nm, while the fluorescence emission of the di-BODIPY system **161** is significantly quenched; it shows two peaks, one at 505 nm and a broader excimer-type emission at 590 nm. Efficient energy transfer from the donor (tetra-methyl BODIPY) to the acceptor (extended BODIPY) was observed for the system **162**. The cofacial chromophores are separated by approximately 4.5 Å, allowing both energy transfer and formation of an



Scheme 10. Syntheses of BODIPY dyes anchored on xanthene units to test self-quenching: (**a**) a system with one BODIPY dye; (**b**) a similar compound with two, where only one has extended conjugation; and, (**c**) another where both have extended conjugation.



Scheme 10. (*Continued*)

excimer-like state. Incidentally, system **162** acts as an energy transfer cassette; fluorescence emission could be observed at 650 nm from the extended BODIPY (acceptor) upon excitation of the other BODIPY (donor) at 480 nm. More discussion of energy transfer cassettes follows in Section 7.

2. *1,3,5,6-Tetrastyryl-BODIPY Dyes*

Mulliken-charge analysis on the core carbon atoms of tetramethyl-BODIPY **7** revealed that the methyl groups in positions 1 and 7 could be almost as acidic as the 3,5-methyls. Therefore BODIPY dye **164 c**arrying pyridinylethynyl substituents on the 2,6-positions could be condensed with *p*-anisaldehyde to form the

corresponding tetrastyryl BODIPY derivative **165c** (Chart 24). The styryl groups introduced by the Knoevenagel reaction were exclusively in the *trans (E)* configuration. The 2,6-dibromo derivative **164b** reacted as efficiently as the ethynyl-substituted derivatives. As expected, the 2,6-H BODIPY **164a** reacted slowly and, by stopping the reaction at different times, the mono-, di-, tri- and tetra-styryl derivatives could be obtained. The first methyls to react were exclusively the 3,5-methyls, and tri- and tetra-substituted products were obtained when the concentration of reactants was increased by removal of most of the solvent.[167]

With the exception of **165d**, the new tetrastyryl dyes absorb between 690 and 720 nm, and emit between 710–750 nm. They have large extinction coefficients, and their quantum yields are found to be moderate to high. Compound **165d** is a true near-IR dye, absorbing around 800 nm, and emiting near 837 nm; its quantum

yield tends to be decreased by the strong charge transfer and highly polar excited state.

D. From Palladium-Catalyzed Coupling Reactions at the 3- and 5-Positions

3,5-Dichloro BODIPY derivatives such as **68** have similar reactivities to heterocyclic imidoyl chlorides; this opens a new window for derivatization using transition-metal-catalyzed reactions. Thus, new 3-, 5-aryl, ethenylaryl and ethynylaryl compounds **166** and **167** were obtained via Stille, Suzuki, Heck and Sonogashira couplings (Chart 25).[168,169] The extended conjugation, and mono-/disubstitution patterns, of these dyes give dispersed fluorescence emission maxima within the series. Absorption maxima for the monosubstituted compounds **166** are blue-shifted by 20 nm to 50 nm relative to the disubstituted ones **167**. The largest red shift for both absorption and emission was observed for the styryl substituted derivatives. The dyes with ethenyl- or ethynyl-aryl substituents gave the highest quantum yields (**167c**, 0.92; **166d**, 0.98; and, **167d**, 1.00).[168] The mono-substituted BODIPY dyes can further be derivatized by nucleophilic substitution (see section above) or by another transition-metal-catalyzed coupling reaction to give unsymmetrically substituted probes.

Selectivity for mono-substitution via Pd mediated cross coupling, i.e., Sonogashira and Suzuki on compounds such as **68** is low, and the resulting products are hard to isolate in a pure form. Those problems could be overcome if mono-halogenated BODIPY dyes such as **168** were used. Such systems can be prepared from the corresponding 2-acyl-4-halo- and/or 2-acyl-5-halopyrroles via condensation with another pyrrole in presence of phosphorus oxychloride, followed by complexation with boron (Chart 26).[170] The *meso*-substituent of the BODIPY is introduced during the acylation (via Vilsmeier-Haack reaction) reaction of 2-halogenated pyrroles, allowing for a large number of substituents to be introduced. Furthermore, the spectroscopic properties of the resulting BODIPY can be easily tuned by careful selection of the pyrrole; the red-shifted BODIPY **169** was synthesized from the conformationally restricted 4,5-dihydro-1*H*-benzo[*g*]indole.

The mono-halogenated system **168** can then be further functionalized via Sonogashira or Suzuki cross coupling reactions to give BODIPY **170–172** (Chart 27). The new dyes are strongly fluorescent. Interestingly, the fluorescence quantum yield of the 2-alkynylated dye **170** decreases significantly with increasing solvent polarity (data not shown), while small variations are observed for the corresponding 3-alkynylated dye **171**. Moreover, the absorption maxima of the 3-alkynylated derivative is red-shifted relative to the 2-alkynyl isomer.

Chart 25.

As illustrated above, organometallic cross coupling reactions can extend the conjugation of the BODIPY core. However, such transformations are usually done in basic conditions and/or at high temperature that may cause partial decomposition of the BODIPY dyes. Furthermore, chemoselectivities are hard to control when several halides are present on the same molecule. On the other hand, Liebeskind-Srogl cross coupling is carried out under neutral conditions,[140] and is

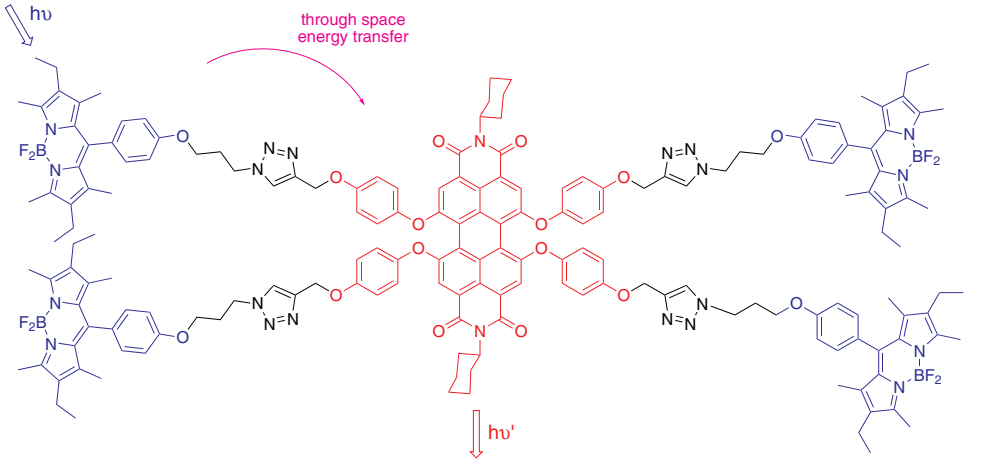
VII. Energy Transfer Cassettes

A. Through-Space Energy Transfer Cassettes

Two fluorescent entities may be joined in the same molecule to give a "cassette." One of these, the *donor*, may collect radiation efficiently at the excitation wavelength and pass this energy to the second fluorescent moiety that emits it at a longer wavelength. If the mechanism of energy transfer is through space then this system might be called a through-space energy transfer cassette. Energy transfer cassettes are typically used to artificially enhance the Stokes' shift of a probe. Ones featuring BODIPY dyes have been somewhat useful for DNA sequencing on a genomic scale[173] where four distinct fluorescent outputs are required, and usually only one excitation wavelength is used.

Through-space energy transfer efficiencies depend on several factors, including: (i) spectral overlap of the donor emission with the acceptor absorbance; (ii) distance between the donor and the acceptor; (iii) the orientation factors; and, (iv) the effectiveness of alternative de-excitation modes. Cassettes described in this section have no obvious way to transfer energy from donors to acceptors via bonds.

The dendritic light harvesting system **177** with four BODIPY donors and a perylenediimide (PDI) acceptor was constructed via click chemistry.[174] Its UV spectrum is equal to the sum of the donor and acceptor components indicating they are not electronically perturbing each other.[175] The extinction coefficients of **177** at 526 nm (BODIPY λ_{max}) and 582 nm (PDI λ_{max}) are 240 000 and 45 000 $M^{-1}cm^{-1}$, respectively, hence the donor absorption is huge simply because four BODIPY units are involved. No green fluorescence emission from BODIPY was observed



177

upon excitation at 526 nm, indicating efficient energy transfer (99%). Based on the energy transfer efficiency, the authors of this work calculated a Förster critical radius of 47 Å. An "antenna effect" (emission intensity at 618 nm when excited at 526 nm (BODIPY core) divided by that from excitation at 588 nm (at the PDI core)) gave approximately a 3.5-fold enhancement.

Most studies on energy transfer between porphyrins and other chromophores have focused on electron and energy transfer in the plane of the porphyrin. "Vertical" electron and energy transfer from axial ligands, on the other hand, have not been studied extensively but systems **178**–**181** were synthesized to study this phenomenon. An antimony porphyrin was chosen as the acceptor because this central metal can coordinate to ligands with oxygen, nitrogen, or sulfur atoms. Energy transfer from the excited singlet state of the BODIPY to the Sb(TPP) chromophore occurs for **178**, **179** and **181**. This happens with efficiencies in the 13–40% range, decreasing as the length of the methylene bridge increases. Little or no evidence was seen for quenching of the porphyrin excited singlet state by the BODIPY. This was true even when polar solvents were used and the donor and acceptor fragments would be expected to pack against each other. However, for system **180**, which differs from **178** only at the second axial ligand (phenoxy vs. methoxy), the excited singlet state of the Sb(TPP)-acceptor was quenched by the BODIPY and phenoxy ligands. The quenching by the phenoxy group occurs, at least in part, via a nonradiative electron-transfer process.[176]

Systems **182** and **183** are two novel BODIPY-silicon(IV) phthalocyanines (Pc) conjugates.[177] These only differ in their axial substituents; system **182** bears two BODIPY, while **183** has two mono-styryl BODIPY moieties. Upon excitation

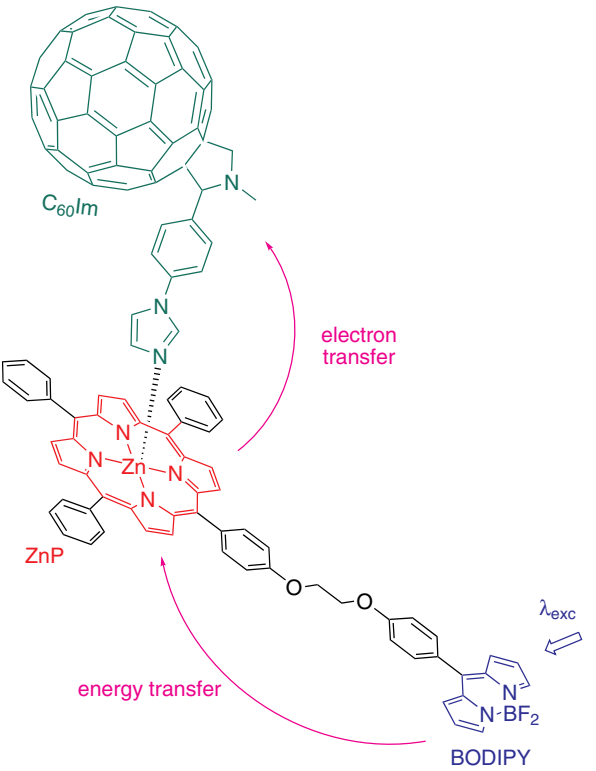
at 480 nm, efficient photoinduced energy-transfer (Φ_{ENT} 57%) from the excited BODIPY units to the phthalocyanine (Pc) core was observed for **182**. When the triad **182** was excited directly at the Pc core (615 nm), a strong emission band at 686 nm was observed suggesting that electron-transfer was not taking place to quench the excited Pc. The fluorescence quantum yield of the Pc emission was however significantly lower upon excitation at 480 nm relative to direct excitation of the Pc (Φ = 0.35 vs. 0.60). Surprisingly, upon excitation of the mono-styryl BODIPY units (530 nm) in **183**, a very weak emission band at 686 nm characteristic of the Pc core was observed, and the emission at 580 nm from the BODIPY moieties was also greatly reduced (Φ 0.003 vs. 0.78). This suggests that excitation energy transfer occurred from the initially excited mono-styryl BODIPY units to the Pc core, but, the fluorescence emission of the Pc is largely quenched, probably by an efficient electron-transfer process.

System **184** is another artificial light harvesting system with BODIPY dye donors, but here the energy is transferred to a zinc porphyrin (ZnP), then electron transfer occurs to a fullerene (C_{60}-Im) unit; thus the molecule was called a "supramolecular triad". The Zn-porphyrin connects to the fullerene component via metal to axial-ligand coordination. Both steps in the process were efficient.

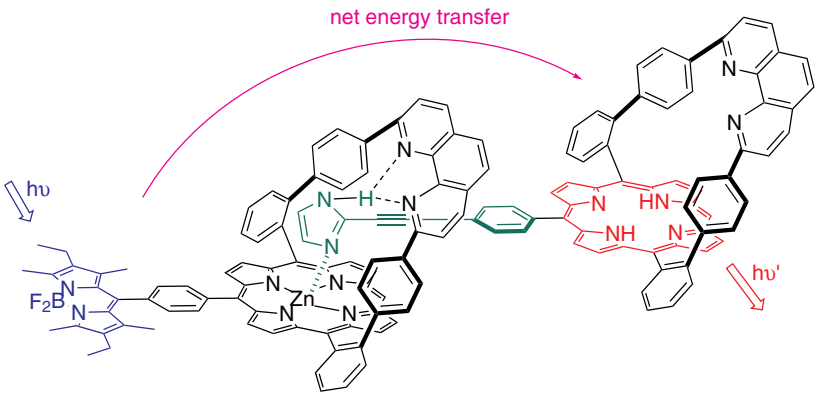


184

Overall, the system was said to mimic the "combined antenna-reaction center" in natural photosynthesis.[178]

Like **178**–**184**, complex **185** also features a donor and an acceptor system linked via axial coordination to a zinc porphyrin.[179] This self-assembling system is based on the exceptional affinity of phenanthroline-strapped zinc porphyrins for *N*-unsubstituted imidazoles.[180,181] Efficient net energy transfer (80%) was observed for excitation of the BODIPY at 495 nm and emission at the free porphyrin. Energy transfer from the excited ZnP-Im complex to the free porphyrin was calculated to be 85%.

Compound **186** was designed to be a molecular switch. It has two stable conformations governed by the bridged resorcin(4)arene scaffold.[182] In the absence of protons (or perhaps other guest cations) the molecule exists in a contracted geometry maximizing FRET (fluorescence resonance energy transfer) between the two BODIPY based probes. Decreased pH values switch the molecule to the expanded conformation and this is evident by the reduced energy transfer. An advantage of using BODIPY dyes in this study is their low sensitivity to pH changes.



185

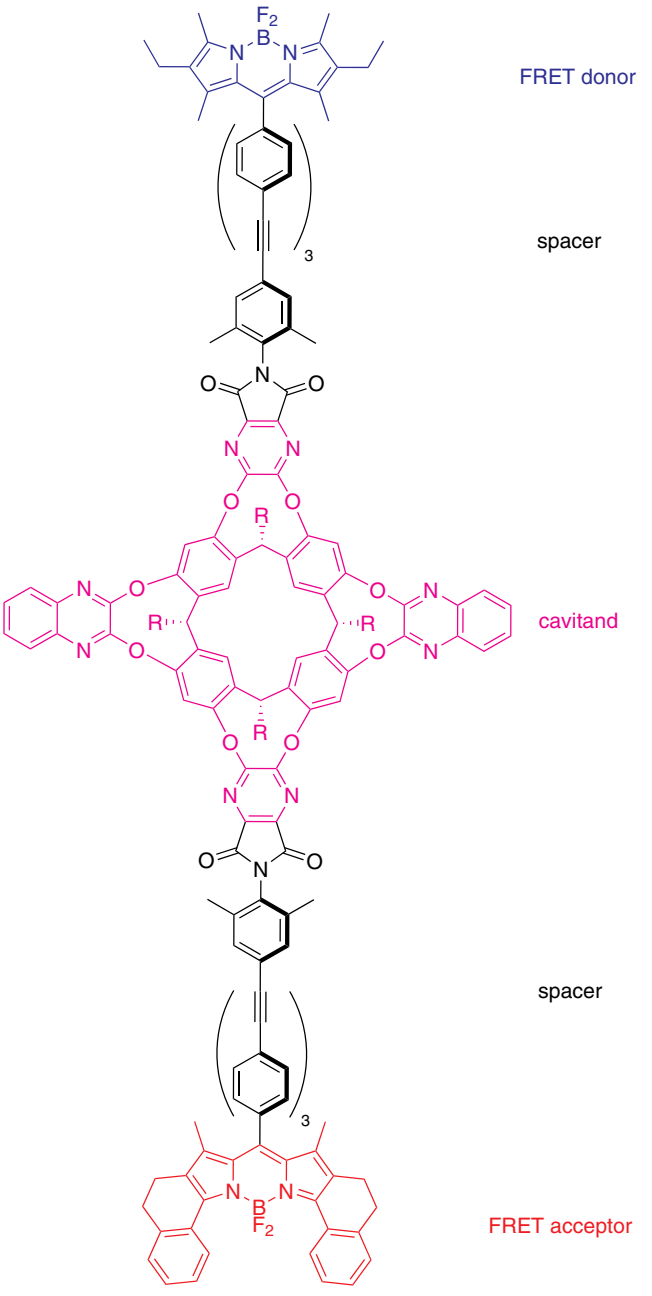
The UV spectrum of **186** displays three strong absorption bands assigned to the spacer (λ_{max} 332 nm), the donor (λ_{max} 529 nm) and the acceptor dye (λ_{max} 619 nm), respectively. Upon excitation at 490 nm, two emission bands at 542 nm (donor dye) and 630 nm (acceptor dye) are observed, in a ratio of the donor/acceptor fluorescence intensity of 45:55, indicating low FRET efficiency (possibly due to unfavorable orientations of the transition dipole moments, and/or to the dynamic behavior of the cavitand part). Upon addition of TFA, the emission from the acceptor is nearly completely quenched, whereas the donor fluorescence intensity doubles.

B. Through-Bond Energy Transfer Cassettes

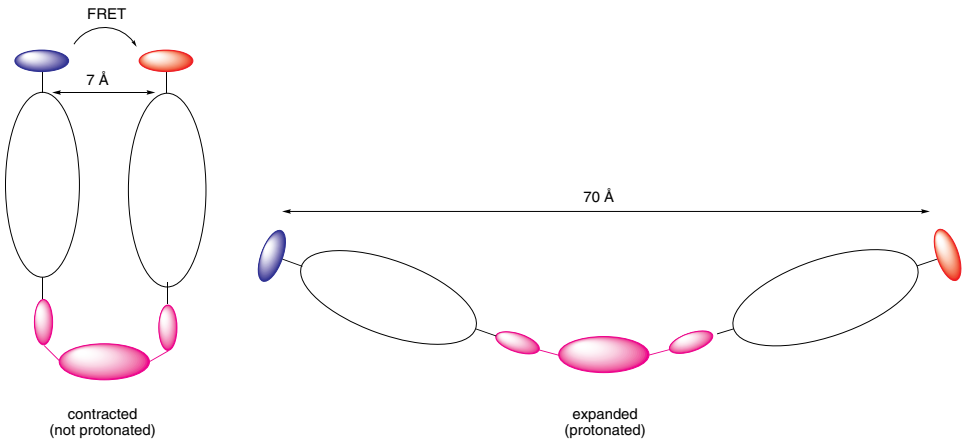
1. *Porphyrin-Based Systems as Models of Photosynthesis*

The prevalent mechanism of through-space energy transfer in most cassettes is likely to be via dipolar couplings, i.e. Förster energy transfer. The rate and efficiency of this is governed by, among other things, the overlap integral between the donor fluorescence and the acceptor absorbance.

If the donor and acceptor dyes are coupled to each other via a conjugated but twisted π-system then the prevalent mechanism of energy transfer is likely to be through bonds. Constraints on through-bond energy transfer are not well understood, but it appears there is no requirement for a good overlap integral. This is important in the design of fluorescent cassettes because, if this is true, there is no obvious limitation on the energy gap between the donor fluorescence and the acceptor absorbance, hence cassettes with huge "apparent Stokes' shifts" could be produced.



186
R = *n*-C_6H_{13}

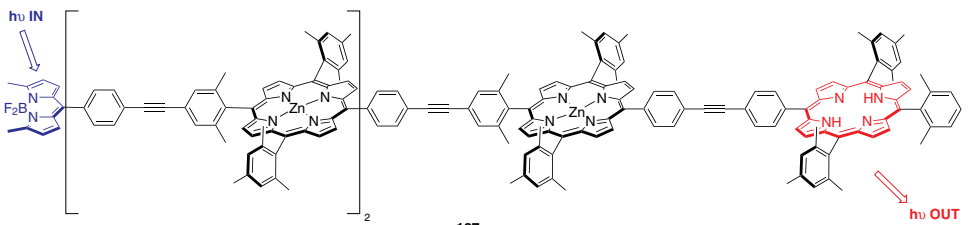


A pioneer of energy transfer systems featuring BODIPY donors was Lindsey who studied them in the context model porphyrin-based systems for photosynthesis.[183] He proposed that the rates and efficiencies of through-bond energy transfer are influenced by:

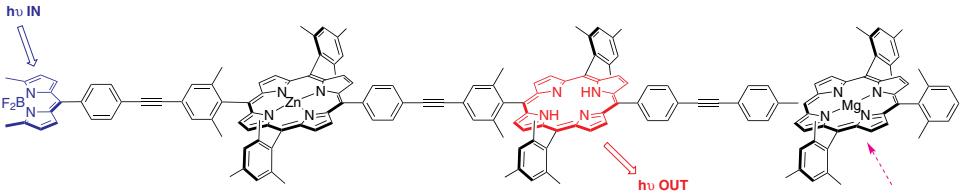
- steric interactions between the donor/acceptor wherein increased torsional constraints decrease rates and efficiencies of energy transfer;
- frontier orbital characteristics for the HOMO and LUMO; and, related to that,
- the site of attachment of the donor/acceptor to the linker and the nature of the linker.

Lindsey has described the through-bond energy transfer cassette **187** as a "linear molecular photonic wire". It features a BODIPY donor and a free base porphyrin acceptor. This donor-acceptor pair is separated by 90 Å. Efficient energy transfer (76%) from the donor to the acceptor was observed upon excitation at 485 nm (i.e., the donor $\lambda_{max\ abs}$).[184]

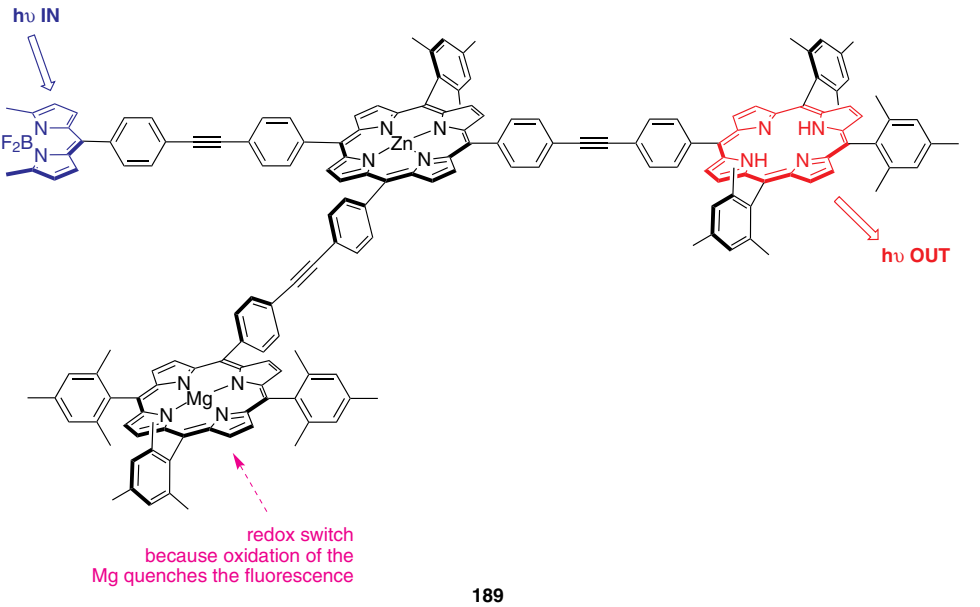
Systems **188** and **189** were described as "molecular optoelectronic linear- and T-gates", respectively. In these cassettes, the emission of the acceptor can be turned



187



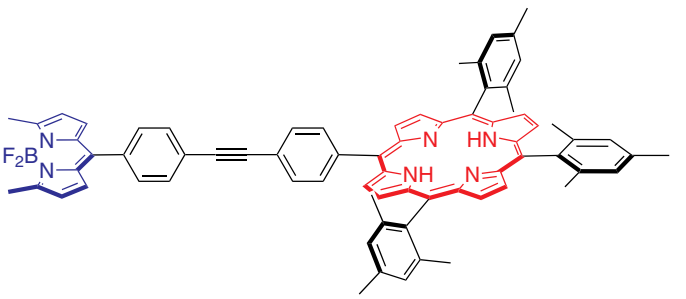
188



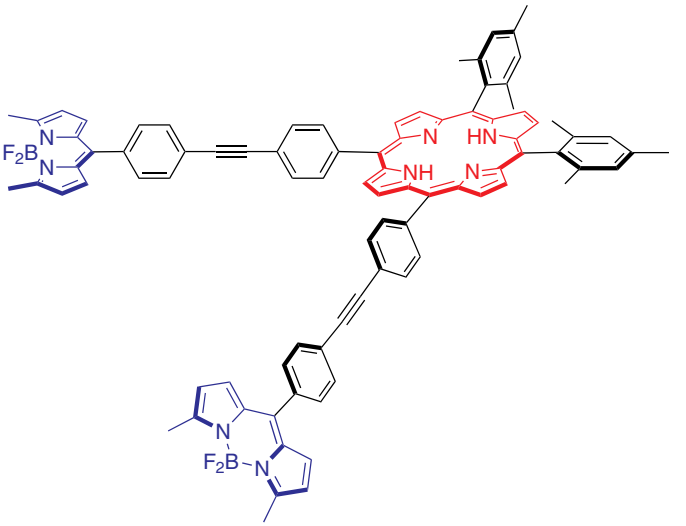
189

on or off via reduction or oxidation of the attached magnesioporphyrin; the latter in its oxidized state quenches fluorescence via ICT. For each cassette more than 80% of energy transfer was observed upon excitation of the BODIPY donor part.[185]

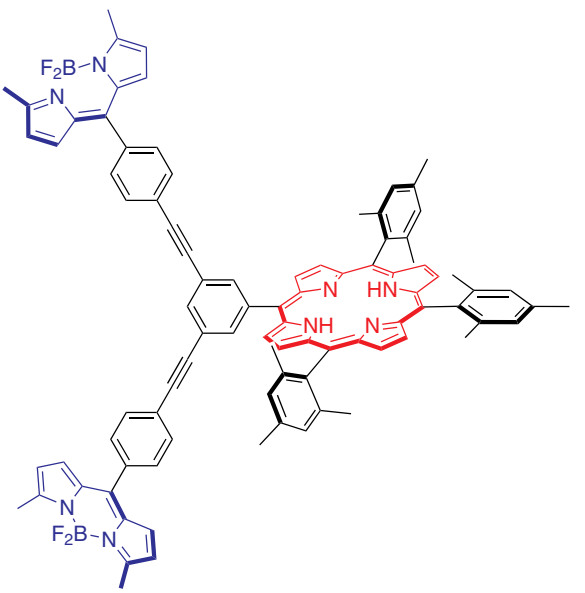
Compounds **190–193** are light-harvesting arrays featuring one, two, or eight BODIPY donors and one porphyrin acceptor. Increasing the number of BODIPY



190

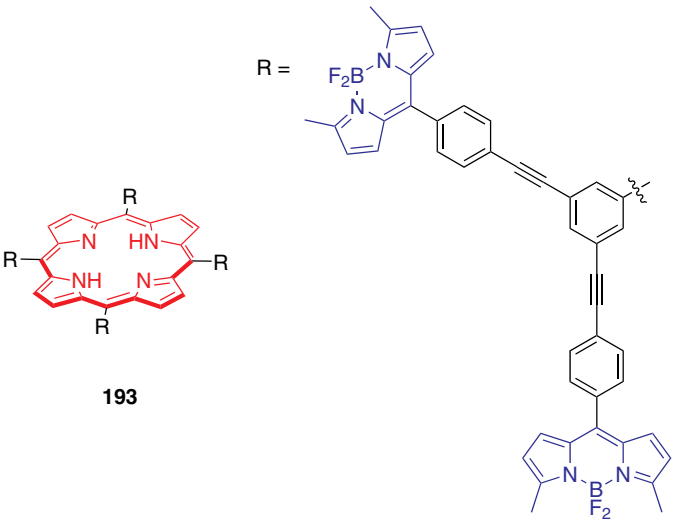


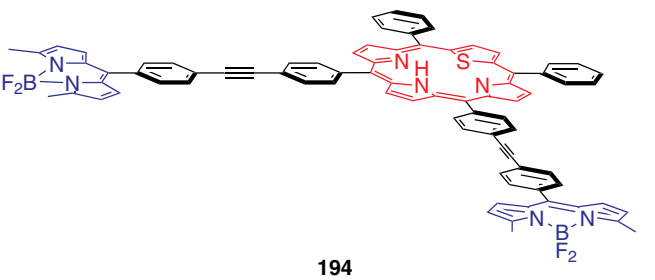
191

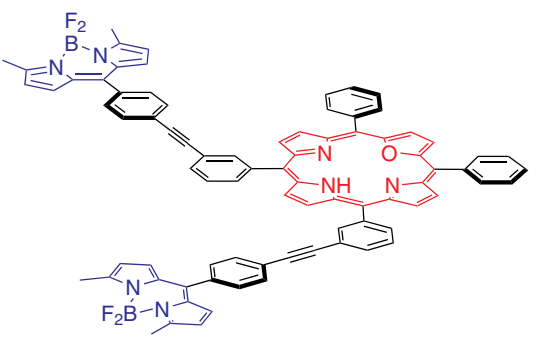


192

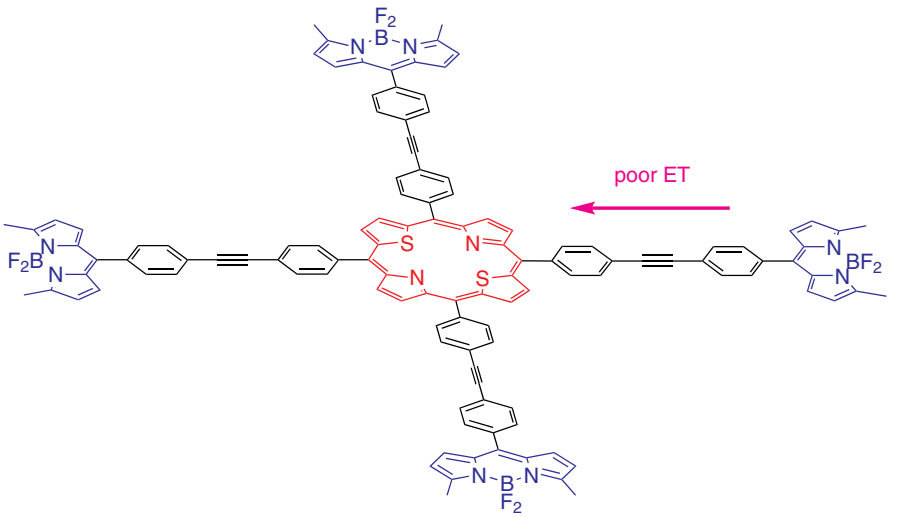
donors from one to eight only increases the relative absorption at 516 nm from 68 to 94% (of a BODIPY standard) for the free base porphyrins **190–193**, and from 91 to 99% for the Zn-porphyrin (not shown). Near quantitative energy transfer was observed for the systems containing one or two BODIPY units, but 80–90% energy transfer was observed for the system bearing eight BODIPY units.[186]



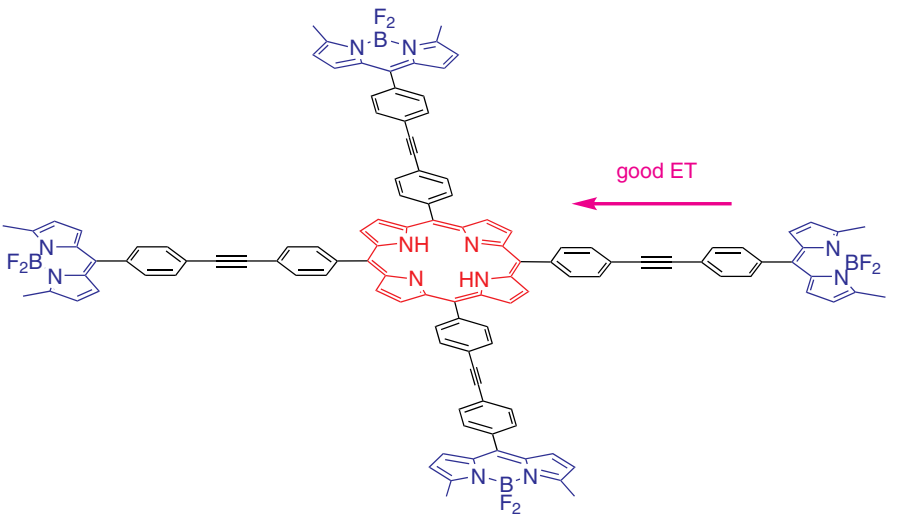




Cassettes **194** and **195** were synthesized from the corresponding thia- and oxo-porphyrins by Sonogashira couplings with 8-(4-iodophenyl)-BODIPY. Excitation of the BODIPY part at 485 nm gave weak emission from the BODIPY core and strong emissions from the porphyrin units, suggesting efficient energy



196

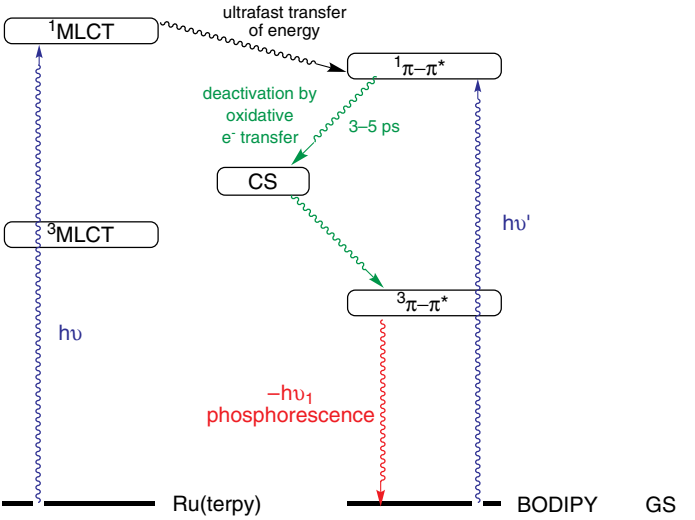


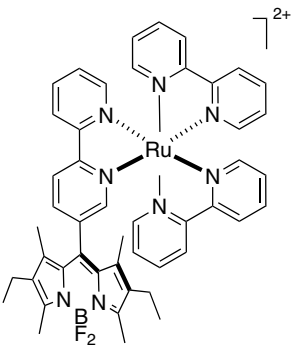
197

transfer. Direct comparison of the efficiencies of energy transfer is difficult because the separations and orientations of the donor and acceptor fragments are different.[187,188] Interestingly, the analogous system with two sulfurs, **196**, gave poor energy transfer (~ 11%) upon excitation at 485 nm,[189] whereas **197** which has a normal porphyrin core gave 97% energy transfer.[190]

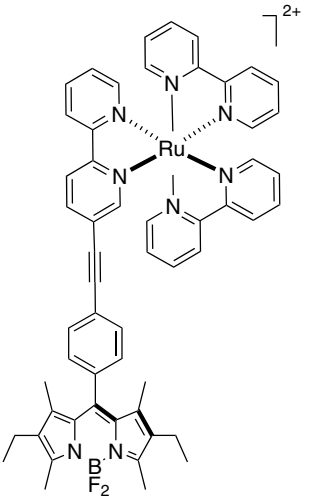
2. *Polypyridine Complexes Containing Accessory BODIPY Chromophores*

The dual-dye systems **198**–**205** featuring one or more BODIPY chromophores and a Ru(II) polypyridine complex have been synthesized as models for solar energy conversion and storage. The BODIPY chromophore was chosen for its strong fluorescence, whereas the Ru(II) polypyridine complex was chosen for its relatively intense and long-lived triplet metal-to-ligand charge transfer (MLCT) emission.

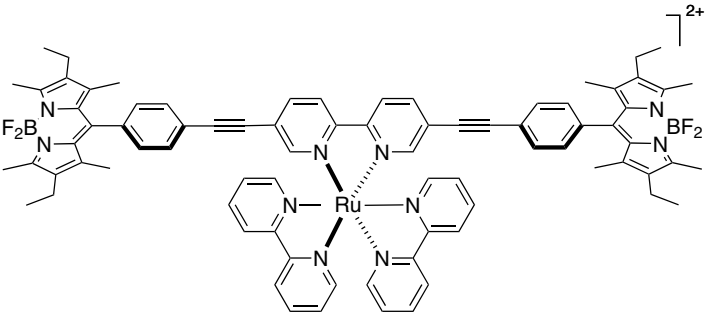




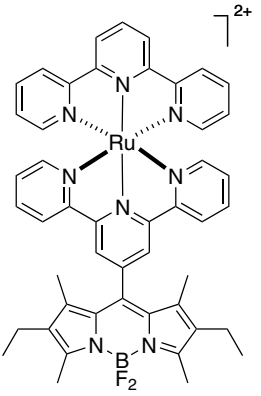
198



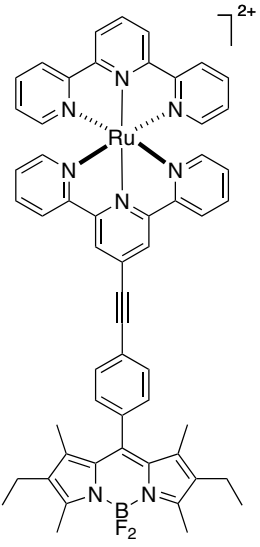
199



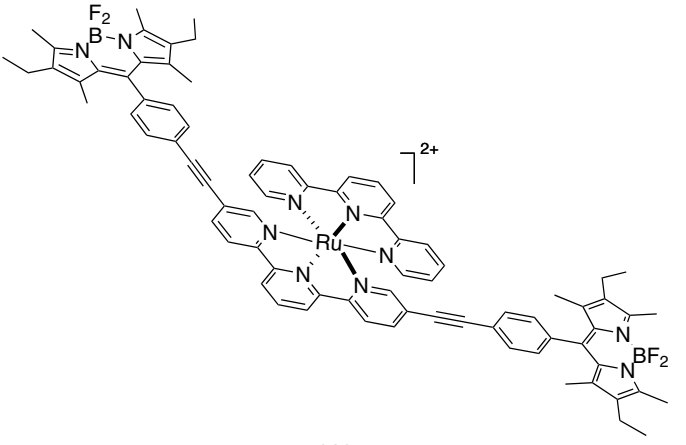
200



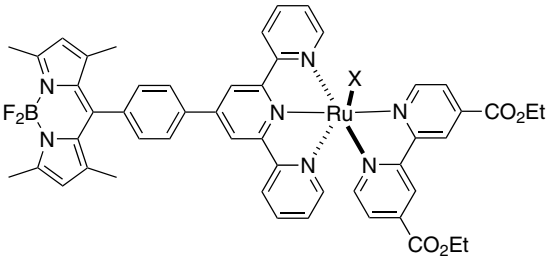
201



202



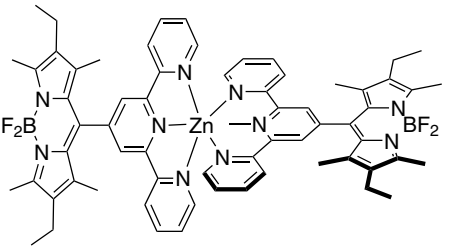
203



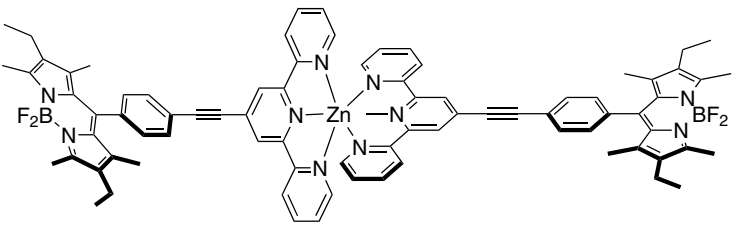
204 X = Cl
205 X = NCS

The pyridine based BODIPY dyes were synthesized by condensation of formylpyridine with 3-ethyl-2,4-dimethylpyrrole.[191–194] The new compounds exhibit intense absorption in the visible region, with a major sharp band at 523 nm (acetonitrile solution) assigned to the π–π^* transition for the dipyrromethene dye and a broader band of lower intensity between 450 and 500 nm. The free ligands are strongly fluorescent both in solution at room temperature and at 77 K in a rigid matrix, but no luminescence could be observed in solution for the Ru complexes, independently of the excitation wavelength. Nanosecond transient absorption spectra, however, revealed a relatively long-lived (ms time scale) excited state for all metal complexes. The latter was identified as the BODIPY-based triplet state, and is believed to be formed through a charge-separated level from the BODIPY-based $^1\pi$–π^* state. At 77 K, all the complexes studied except for **198**, exhibit the BODIPY-based fluorescence, although with a slightly shortened lifetime compared to the free ligands. However, the surprising finding was that **201**–**203** also exhibit a phosphorescence signal assigned to the BODIPY subunits (emission at 774 nm of 50 ms lifetime). This is the first report of phosphorescence for BODIPY based dyes. The authors propose that the phosphorescence is due to the presence of the heavy ruthenium metal, which facilitated intensity to be diverted into the BODIPY $^3\pi$–π^* state from the closely lying metal-based ^{3}MLCT level (for which luminescence decay is highly efficient at 77 K).[192,195,196] Phosphorescence from BODIPY units is certainly unusual. It only was observed here at 77 K for a system coupled with a ruthenium complex, and the efficiency of the process was not determined.

Compounds **204** and **205** combine ruthenium polypyridine units with BODIPY fragments. The BODIPY part ensures a high molar absorption coefficient of the system in the metal-to-ligand charge-transfer region (around 500 nm). The singlet excited states of **204** and **205** are strongly quenched by the presence of ruthenium: energy transfers to the Ru center with high efficiency (93% and 73% for **204** and **205**, respectively), where it is then dissipated via electron transfer and/or singlet to triplet intersystem crossing. The net effect of this arrangement is that these complexes are not fluorescent.[197]



206



207

Loss of fluorescence when BODIPY dyes are conjugated with metal complexes is common. For instance complexes **206** and **207** have greatly reduced fluorescence relative to the free ligands,[193,194] presumably due to intramolecular electron transfer.[193,198]

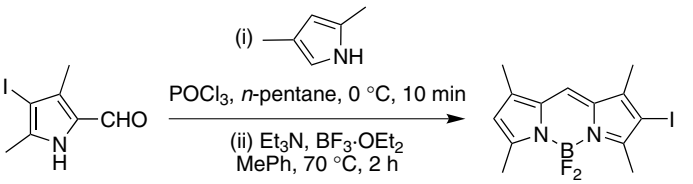
Other complexes, e.g. of platinum,[199] containing BODIPY-based ligands have been prepared, but without comment on their fluorescent properties. It is unlikely that such materials will be useful as probes.

3. *Relatively Compact Systems as Potential Probes in Biotechnology*

Porphyrin-based cassettes tend to be larger than is ideal for applications relating to labeling of biomolecules, but the through-bond energy transfer aspect could be useful for applications wherein one source is used and several different outputs must be observed simultaneously. Thus, there has been interest in making smaller through-bond energy transfer cassettes.

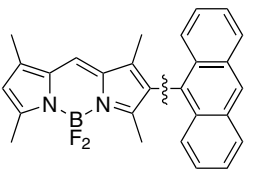
BODIPY-based cassettes featuring simple aromatic donors can be prepared from halogenated BODIPYs, e.g. **208** via palladium-mediated cross-coupling reactions.[200] Monoiodinated products can be quite useful for such syntheses. For instance, Chart 29 shows a typical stepwise BODIPY synthesis that was used for this.[200]

Fluorescence quantum yields of compounds **209–212** excited at the donor λ_{max} range from 0.02 to 0.75 (in chloroform). $S_1 \leftrightarrow S_0$ Transition moments of the two chromophores components for compound **213** are mutually perpendicular in all

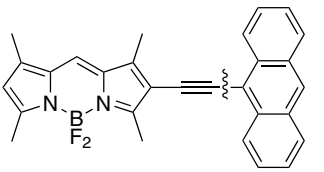


208 36%

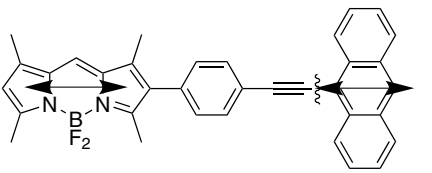
Chart 29.



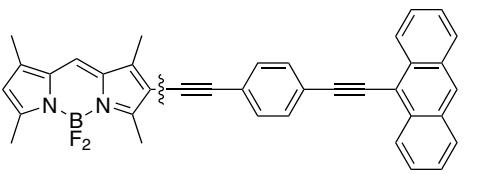
209



210



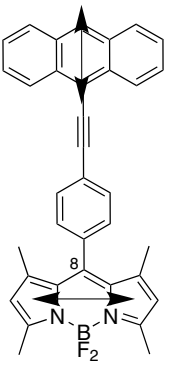
211



212

conformations. Fast energy transfer, of the order of 0.45 ± 0.08 ps, was observed for this compound. For **209**–**212**, the donor and acceptor $S_1 \leftrightarrow S_0$ transition moments are mutually coaxial with the linker in all conformations. The transfer rate for this set of compounds was *even faster* than for **213**, ~ 200 fs; in fact, this was too fast to be measured accurately.[201] Thus, it appears from this data that parallel and aligned transition moments are ideal for extremely fast energy transfer. The length of the linker in this series of compounds was also varied but not enough derivatives were made to arrive at conclusions relating this parameter with energy-transfer rates.

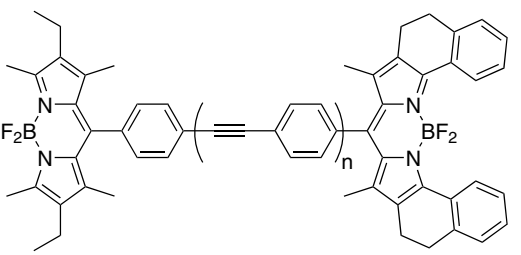
More recently, energy transfer cassettes like **213** have been prepared; these are similar except that the *meso*-donor group is one or two pyrene units linked with



213

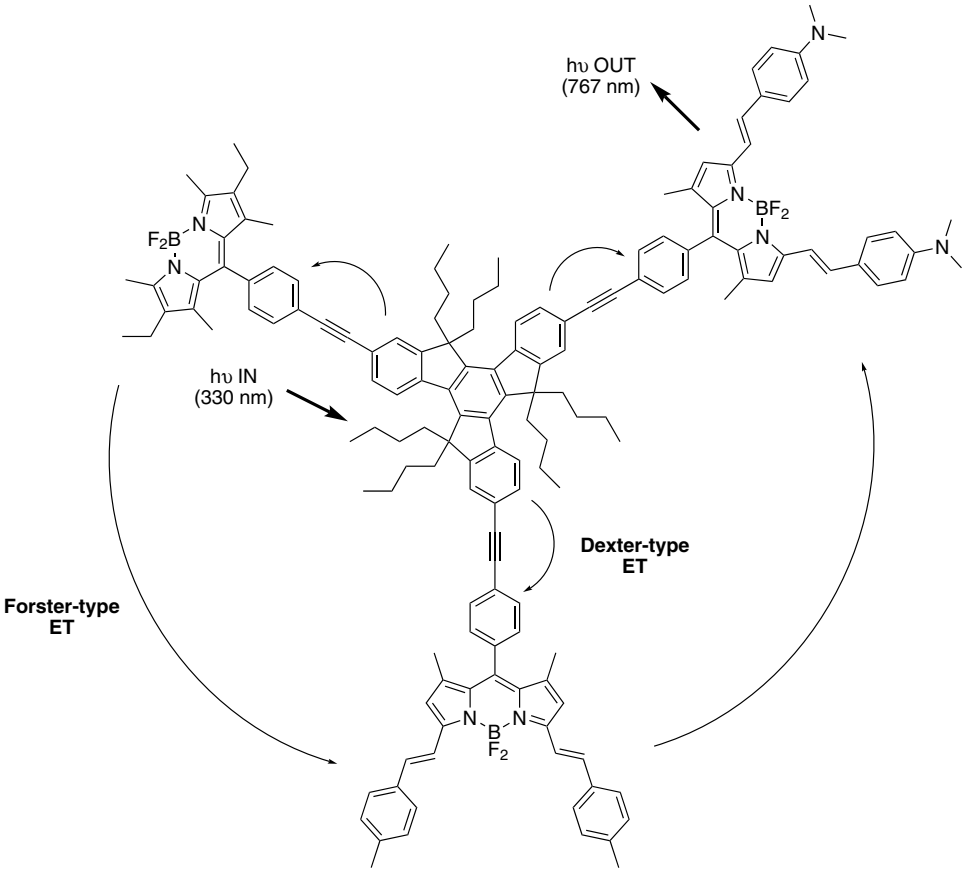
alkynes. It was shown that the energy transfer efficiency is reduced when alkyne units are added. Of course, use of conjugated pyrenes as the donor increases the UV absorption at shorter wavelengths and the λ_{max} for that donor-based band; the latter effect decreases the apparent Stokes' shift observed.[202]

Energy transfer cassettes like **214**–**216**, in which two BODIPY chromophores are linked via an acetylenic linker, have been prepared.[182] As the length of the linker increases, energy transfer efficiency decreases from about 98% to ~ 35%. These were described as FRET cassettes, but there is a strong possibility that some of the energy transfer takes place through bonds.



214–216
n = 1, 3, and 6 respectively

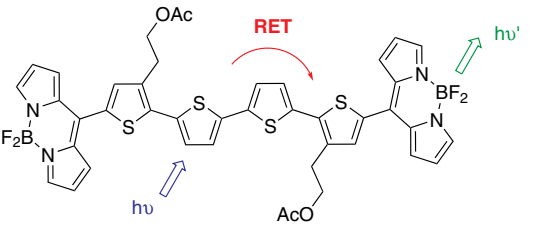
Compound **217** represents a novel star-shaped supramolecular multichromophoric system containing three different BODIPY dyes triangularly arranged around a truxene core.[203] The three BODIPY subunits used absorb at different wavelengths, allowing **217** to absorb a large fraction of UV and visible radiation. System **217** was prepared via Sonogashira couplings between the tri-iodo truxene and the corresponding ethynyl BODIPYs. At any excitation wavelength, the emission spectrum of **217** is dominated by a band at 767 nm, indicating that highly efficient and fast energy transfer processes occur within **217**. It is thought that both Dexter-type (from the truxene core to the peripheral BODIPYs) and Förster-type (between the peripheral BODIPYs subunits) mechanisms likely contribute to the overall energy transfer process.



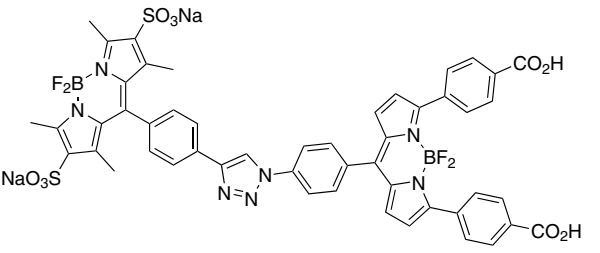
217

The oligothiophene-BODIPY-based donor–acceptor system **218** represents the first example of light-harvesting systems combining BODIPY and thiophenes. Efficient energy transfer was observed from the quaterthiophene to the BODIPY.[204]

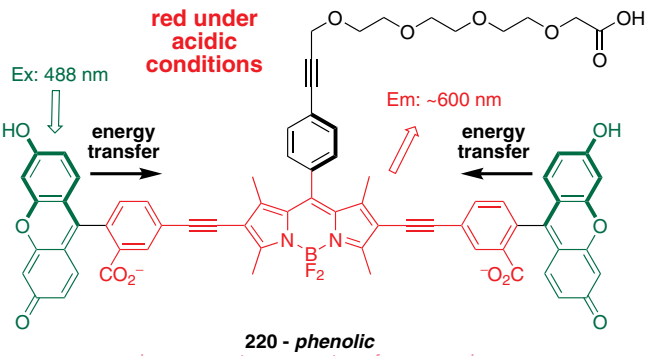
A restriction of FRET in observation of protein-protein interactions is that the emission from the donor must overlap with the absorbance of the acceptor. Compounds **209–218** are examples of "through-bond" energy transfer (TBET) cassettes in which the donor relays energy to an acceptor (or more) via twisted π-electron systems. However, these systems are very hydrophobic and have no handle to allow conjugation to biomolecules. *Water-soluble* probes **219–222** were recently reported by Burgess and coworkers.[172,205,206] These TBET cassettes were assembled via Pd-mediated cross coupling (**220**) or via copper-mediated alkyne/azide cycloadditions (**219** and **221–222**). Energy transfer in **220** is highly pH dependent. At pH < 6.0, energy transfer from the donor to the acceptor occurs efficiently and emission at around 600 nm i.e. from the acceptor is observed. In the phenolate form i.e. pH > 8.5, minimal energy transfer occurs and emission at



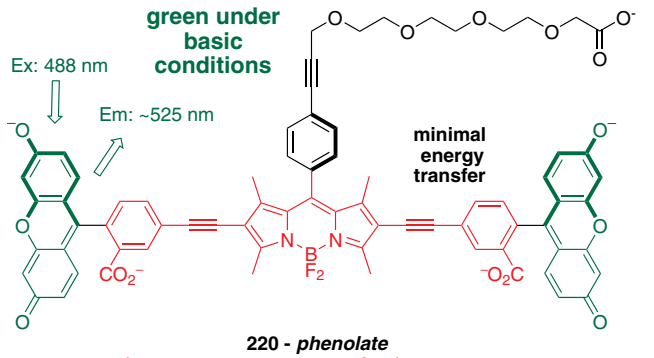
218



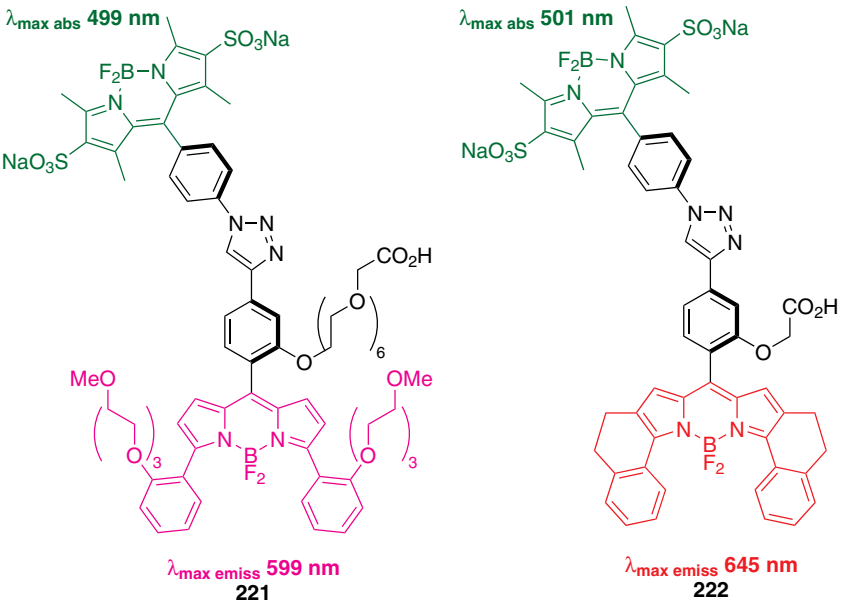
219



220 - *phenolic*
donor acceptor energy transfer occurs in
phenolic form pH < 6.0



220 - *phenolate*
donor acceptor energy transfer does not occur
for the phenolate pH > 6.5



around 525 nm (from the donor) is observed. Thus, this probe is a potentially useful ratiometric pH reporter. Indeed, **220**-BSA conjugate was synthesized and imported inside COS7 cells at 37 or 4 °C via Pep-1[207,208] to measure the pH of the endosomes and cytosol. The pH values of endosomes and cytosol, obtained from

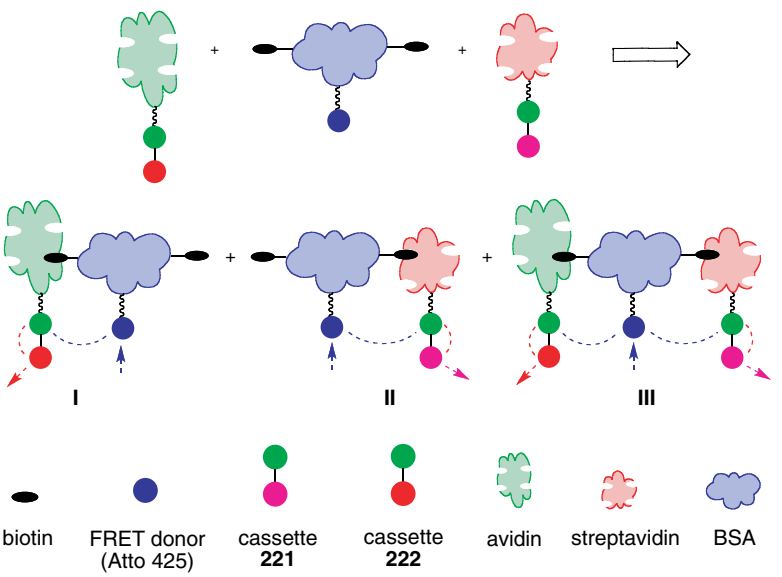


Figure 10. Protein–protein interactions can be monitored with through-bond energy transfer cassettes.

the red/green ratio, were 5.4 and 7.2, respectively; these data are consistent with those expected for such intracellular regions.

Cassettes **221** and **222** possess the same donor and differ only from their acceptor parts (**221** emits at ~ 600 nm, while **222** fluoresce at ~ 645 nm). These probes were used to monitor three-component interactions (via FRET and TBET) as illustrated in Figure 10. A FRET donor (Atto425 attached to BSA-biotin) was mixed with **221**-streptavidin and **222**-avidin conjugates, and the interactions between (strept)avidin and biotin were monitored by observing emissions from **221** and **222** upon excitation at 458 nm.[206] These cassettes allow increased dispersion of fluorescence emissions from a single excitation source.

VIII. BODIPY-Based Polymers

A. Poly(aryleneethynylene)s (PAEs) Co-Containing BODIPY (2,6-Positions)

Organic materials with large and fast nonlinear optical responses are promising for nonlinear devices. One parameter, two-photon absorption (TPA) is a very important third-order nonlinear optic (NLO) effect. Materials with large TPA cross-section are in great demand. In the last decade, many strategies have been developed to design molecules with large TPA cross-section, and it has been shown that conjugation length, molecular symmetry, strength of donor/acceptor groups, and molecular planarity affect TPA cross-section.[209,210]

Polymers **223**–**226** were synthesized under standard Sonogashira cross coupling conditions between the 2,6-diiodoBODIPY and the corresponding arylethynes, and their third-order nonlinear optical properties were studied.[211] The third-order nonlinear properties of these polymers increased with increasing amounts of BODIPY component, i.e. **223** exhibited the largest nonlinear absorption coefficient (β) and effective nonlinear refractive index (η). This indicates that the enhancement of third-order nonlinear optical response in the copolymers is not influenced by the conjugated phenylene motif, but is controlled mainly by the BODIPY component.

Akkaya and coworkers have reported the synthesis of the BODIPY oligomer **227** (via iterative Sonogashira coupling).[212] Decyloxy chains were incorporated on the *meso*-phenyl group of the parent BODIPY dye to keep the oligomer soluble as the chain was extended. As the number, n, of repeating units increases, both the absorption and emission maxima are red-shifted. These bright oligomers can be further elaborated by electrophilic aromatic substitution of the pyrrole moieties of the terminal BODIPYs.

The fluorescent conjugated copolymers **228a**–**c** were prepared by Pd catalyzed Suzuki polymerization of 9,9-dihexylfluorene-2,7-diboronic acid with each of three different 2,6-diiodo-substituted BODIPY monomers.[213] The copolymers absorb between 547–557 nm, and emit brightly (with quantum yield up to 0.85) between

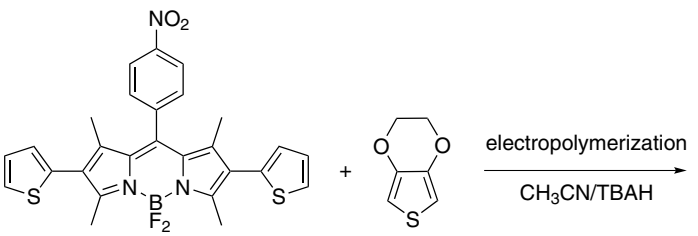
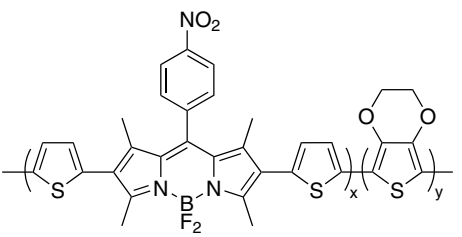
585–588 nm. Furthermore, no fluorescence from the fluorene moiety was observed in the copolymers, indicating efficient photoinduced energy transfer from the fluorene to the BODIPY. In addition, the copolymers display sensitive (and selective) fluorescent responses to fluoride and cyanide anions. Titration with chloride, bromide and iodide anions did not result in significant quenching of the fluorescence.

Polymer **231** was synthesized by electropolymerization of the 2.6-bis(thienyl) BODIPY **229** and compound **230** (3,4-ethyl-enedioxythiophene; EDOT) (Chart 30).[214] Polymer **231** represents a highly stable, environmentally robust electroactive material with well-defined quasi-reversible redox couple, and fast response time



229 **230**



231

Chart 30.

between redox states as well as high coloration efficiency. In addition, the copolymer film exhibited different electrochromic behavior, which can be adjusted by changing the polymerization potential.

B. BODIPY-Based Organoboron Polymer

Based on the work by Ziessel and coworkers, [215–217] Nagai and coworkers prepared the polymers **233 a–c** from monomer **232** via Sonogashira-Hagihara coupling.[218] The latter was prepared from the corresponding BODIPY and Grignard derivative. The Sonogashira-Hagihara coupling reaction of **232** with diynes proceeds via *p*-phenylene-ethynylene formation under mild conditions (Chart 31).

These new BODIPY-based poly(*p*-phenylene-ethynylene)s are highly luminescent and they can form particular or fibrillar nanostructures due to their rod-coil type structure; i.e. the rod and coil segments are a rigid π-conjugated polymer main chain and decyl group, respectively. Scanning electron microscopy (SEM) of

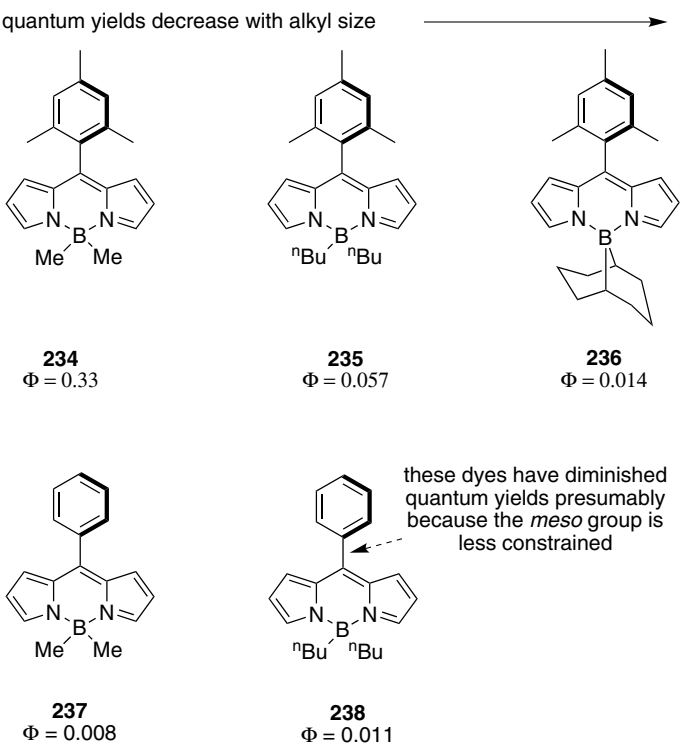
polymer **233a** revealed nm-sized particles and μm-sized fiber like structures, formed from aggregation of each particle. These fiber-like structures were less in **233b** and not observed in **233c**, suggesting that these architectures result from the steric factor of the substituents in the comonomer units. All polymers showed absorption maxima around 519 nm and emission brightly at around 532 nm.

IX. Substitution of Fluoride Atoms in the BF_2-Group

A. With Alkyl Groups

Some dialkyl-*B* BODIPY compounds have been prepared via reactions of the corresponding dipyrromethenes with bromodimethylborane, dibutylboron triflate, or 9-BBN triflate. Increased steric bulk at the boron atom along this series correlated with *decreased* fluorescence quantum yields. While the substituent at the *meso* position has no effect on the UV absorption and emission spectra, the fluorescence quantum yields strongly depend on the nature of the aryl group. Introduction of steric constraints on the aryl ring increases the quantum yield (compare **234** and **237**, **235** and **238**).[219]



234 $\Phi = 0.33$

235 $\Phi = 0.057$

236 $\Phi = 0.014$

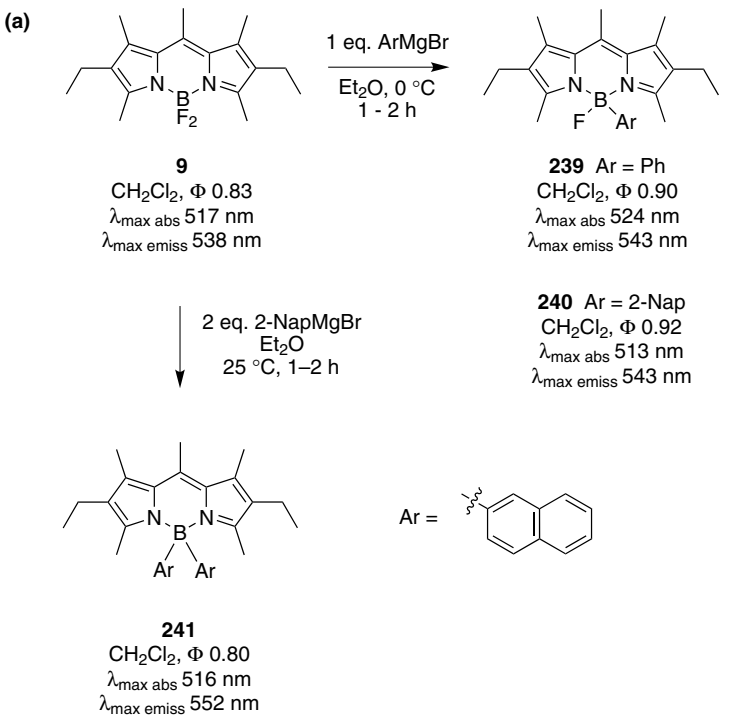
237 $\Phi = 0.008$

238 $\Phi = 0.011$

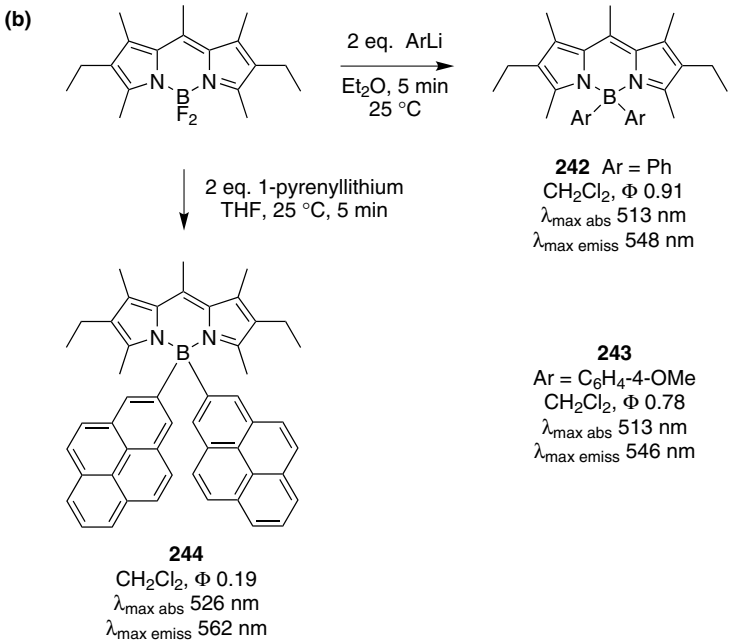
B. With Aryl Groups

Aryl Grignards can displace fluoride from the boron difluoride entity of BODIPY dyes. In Scheme 11a, at 0 °C, even with excess Grignard reagent, only the monosubstituted products **239** and **240** were obtained, but the disubstituted product **241** was formed by adding the Grignard reagent at room temperature. Reaction of aryl lithium reagents was much faster; these gave only the disubstituted products **242**–**244**, even when just one equivalent of anion was added (Scheme 11b).

The new dyes **239**–**244** are highly fluorescent in solution. While the absorption maximum of the BF_2 parent dye is relatively insensitive to the solvent polarity, the *B*-Ar BODIPYs tend to undergo small red-shifts in more polar solvents. The fluorescence emission maxima of **239**–**244** are also red-shifted relative to the parent BF_2 structures. Compared to the BF_2 parent dye, the Stokes' shift for the *B*-Ar derivatives **239**–**244** is also larger, and sensitive to the size of the aryl substituent. While the fluorescence quantum yield of the BF_2 parent dye is insensitive to the solvent polarity, a modest decrease is observed for **239**–**244** in more polar solvents like ethanol or acetonitrile. In these latter solvents, an increase in the rate of nonradiative decay for the *B*-Ar derivatives is observed. The origin of this



Scheme 11. Synthesis of *C*-BODIPYs using (**a**) aryl Grignard reagents; and, (**b**) aryl lithium reagents.



Scheme 11. (*Continued*)

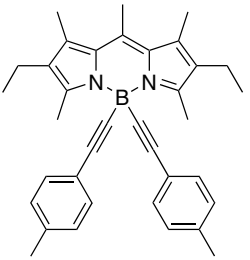
solvent dependence is thought to be a solvophobic effect in which the aryl substituents seek to minimize surface contact with more polar media.

UV absorbance by the aromatic substituents means that these compounds can be regarded as energy transfer cassettes, and when the *B*-Ar groups have good extinction coefficients then there may be some value in this aspect of their properties. The dipyrene system **244** absorbs in the range 230–317 nm corresponding to the $\pi \leftrightarrow \pi^*$ transition of the pyrene units, and emits exclusively (100% energy transfer) from the BODIPY part.[220] However, there is no immediate application of this effect.

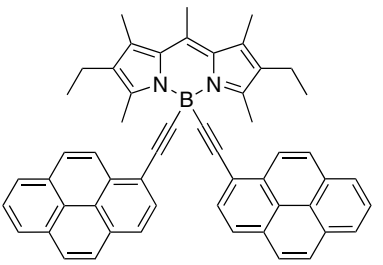
C. With Alkyne Groups

Acetylide anions are also good nucleophiles for the displacement of fluoride from the borondifluoride entity of BODIPY dyes. The pyrromethene dialkynyl borane complexes **245** and **246**, for instance, were synthesized from 4-lithioethynyltoluene and 1-lithioethynylpyrene, respectively.[215–217]

Adding groups to the boron atoms does not bring them into conjugation with the BODIPY core. Consistent with this, the absorption spectra of **245** and 2**46** have distinct BODIPY and ethynylaryl components. Upon excitation at 516 nm,



245
CH_2Cl_2, Φ 0.95
$\lambda_{max\ abs}$ 516 nm
$\lambda_{max\ emiss}$ 537 nm



246
CH_2Cl_2, Φ 0.94
$\lambda_{max\ abs}$ 371, 516 nm
$\lambda_{max\ emiss}$ 535 nm

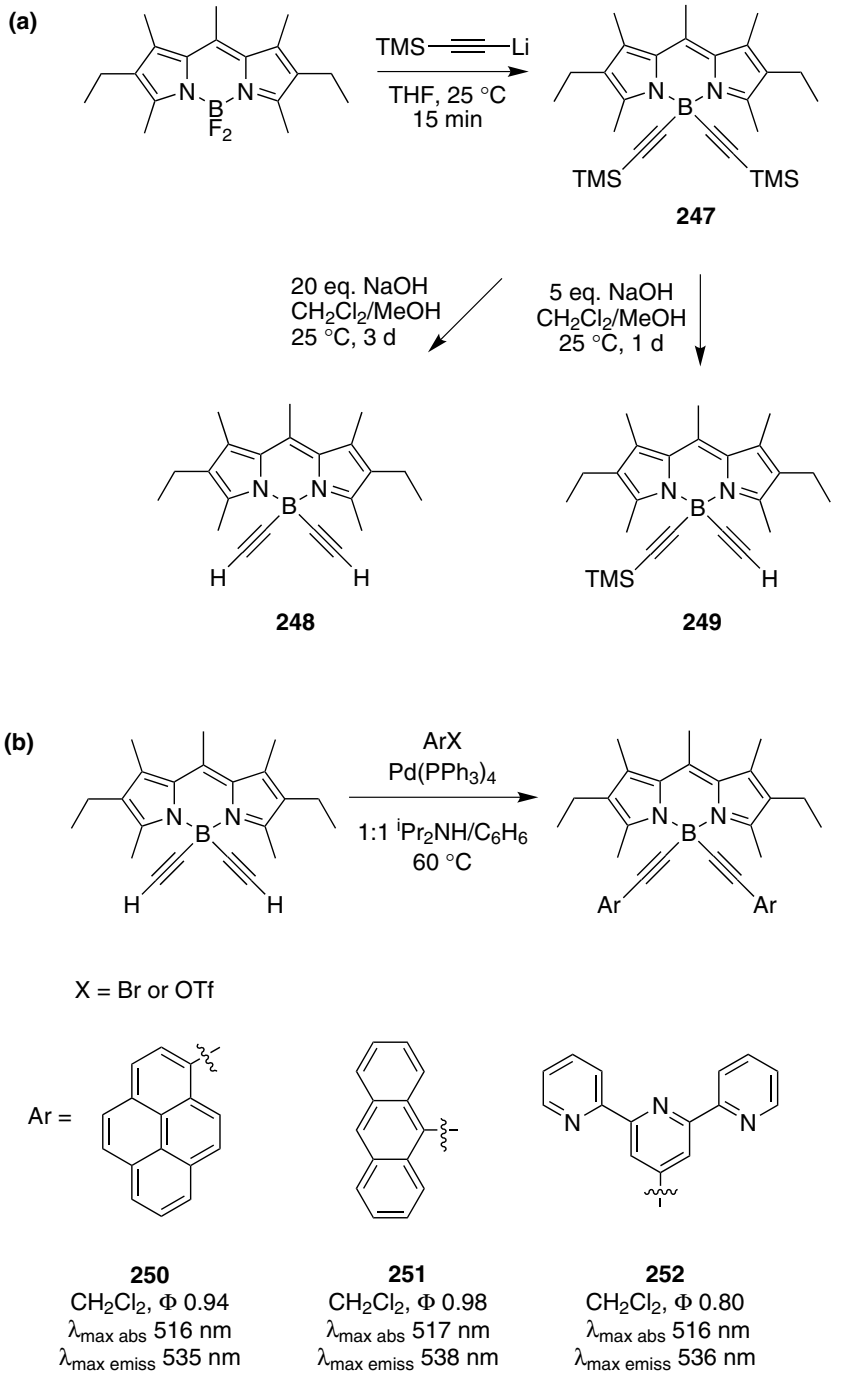
both **245** and **246** emit strongly, with high fluorescence quantum yield, in the region 535–540 nm. For **246**, excitation at 371 nm (pyrene absorption band) did not lead to emission from the pyrene but instead to emission characteristic of the indacene core, indicating an efficient energy transfer from the pyrene to the indacene moiety.[215,216,221]

It is possible to add trimethylsilylacetylide to displace fluoride from BODIPYs, then desilylate under basic conditions and Sonogashira couple to the terminal alkyne, e.g. **248** (Scheme 12). Whereas use of excess sodium hydroxide in the desilylation reaction affords the bis(ethynyl)BODIPY **248**, the monoprotected derivative **249** can be obtained using limited amounts of NaOH and shorter reaction times.[222,223] Access to the monoprotected derivative facilitates introduction of different *B*-alkynes substituents.[216]

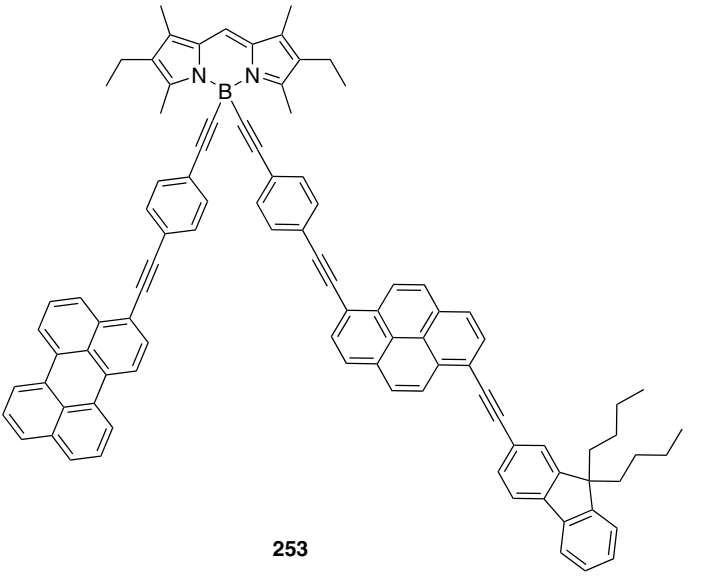
Compounds **250–251** can act as energy transfer cassettes, just like the *B*-aryl systems mentioned above. Irradiation of the donor (pyrene or anthracene) was observed to give only BODIPY emission, indicative of a near quantitative energy transfer. BODIPY **253** in which four different chromophores have been covalently linked together represents a more sophiscated cascade-type system.[224] Upon excitation in the pyrene and/or perylene region, efficient energy transfer occurs and emission from the BODIPY is observed.

Terminal alkynes like **249** and **256** can be oxidatively dimerized (Pd^{II} and CuI under aerobic conditions) to give butadiynes **254** and **257** (Scheme 13).[222] Deprotection of the product butadiyne **254** was very slow; for instance, only a mixture of monodeprotected **255a** and bisdeprotected **255b** was isolated after 6 days.[222]

Substitution of the fluoride ligands on boron by polyaryl-alkynide ligands was also performed on the near-IR dye **258**.[225,226] This allows the production of dyes with large virtual Stokes' shift by virtue of intramolecular energy transfer.[227]



Scheme 12. (**a**) Two-step synthesis of bis(ethynyl)BODIPY **248**, and the monoprotected analog **249**; and, (**b**) some examples of compounds that have been prepared via Sonogashira coupling of **213**.



253

Thus, the dialkyne intermediate **259** was obtained by reaction of **258** with the appropriate alkynyl-Grignard reagent. Subsequently, Sonogashira coupling with various ethynylarene derivatives afforded the systems **260**–**264**. All the new dyes exhibit UV absorption maxima at ca. 708 nm with a molar absorptivity of

~80 000 M^{-1} cm^{-1}. Higher energy absorption bands assigned to the pyrene, perylene, bis- and tri-pyridine were also observed near 350 and 450 nm. Upon excitation at 708 nm, a broad emission band at 750 nm, with quantum yields between 0.19 and 0.45 was observed in all cases. Fast energy transfer to the central dipyrromethene core was observed upon irradiation of the pyrene and perylene units in **263** and **264**, giving large virtual Stokes'shifts. The efficiency of the energy transfer for compounds **263** and **264** was estimated to 58% and 38%, respectively. Formation of aggregates was observed when the dyes were dissolved at concentrations higher than 10^{-7} M.

The same strategy, i.e. substitution of the fluoride with aryl-alkynides was applied to establish a tetrachromophoric cascade in dye **265**.[226] System **265**

contains three alkynylaryl energy donors, such as pyrene (D_1), perylene (D_2) and fluorene (D_3). As for **253**, selective irradiation in each absorbing subunit (D_1, D_2 or D_3) resulted in a single emission at ca. 750 nm, indicating efficient energy transfer over 25 Å to the BODIPY acceptor emitting.

D. With Alkoxide Groups

The first two *B*-methoxy BODIPYs prepared were **266**–**267**. These were made by reacting the corresponding BF_2 compound with sodium methoxide in methanol (Chart 32). The shape of the absorption and emission spectra were the same for the starting material **12** and the two products, suggesting the change in *B*-substituents had little effect on the electronic states of the boroindacene core. Interestingly, the monomethoxy- and dimethoxy-products were more water-soluble than the corresponding BF_2 compounds.[74]

The only other report of *B*-OR BODIPYs describes syntheses of systems **C** via treatment of the corresponding BODIPY with various alcohols in the presence of aluminum trichloride (Chart 33).[92] This study was more expansive than the first insofar as a more diverse set of alcohols were studied. Thus the alcohols used included simple alkoxy **268**–**270**, aryloxy **271**–**274**, and several diol-derived systems **275**–**278**. Across this series there were only minor changes in the absorbance

and emission spectra. The *dialkoxy*-BODIPYs **268–270** appear to have higher fluorescence quantum yields than the *diaryloxy*-ones **271–274**, and the systems binaphthol- and catechol-derived systems **275** and **276** have extremely poor quantum yields.

E. Boronium and Borenium BODIPY Cations

Due to their inherent fluorophilicity, organoboron compounds have often been used as fluoride sensors. However, in most cases, binding of fluoride anions with a neutral and/or cationic triarylborane to form the corresponding fluoroborate species results in a turn-off response both in the absorption and emission spectra of the borane; this limits the potential applications of the sensors. Therefore, boron-based fluoride sensors that give a turn-on response are becoming attracting. The BODIPY boronium cation [**280**-DMAP]$^+$, recently reported by Gabbai,[228] can be selectively and rapidly converted to the neutral BODIPY **280**-F in the presence of fluoride anions (Chart 34). Upon binding of the fluoride anion, the fluorescence intensity of the BODIPY increases by a factor of five, giving a response that can be easily detected with the naked eye. A 48% and 6% increase was observed upon addition of chloride and bromide anions to [**280**-DMAP]$^+$, respectively.

In similar work, Piers and coworkers reported the synthesis of the tricoordinate borenium cation **281**-F (Chart 35).[229] This compound is stable in a crystalline form, but decomposes readily (within 20–30 min) in a CD_2Cl_2 solution. Treatment of **281**-F with DIBAL-H gave the unprecedented borenium hydride cation, **282**-H, that was then easily converted to the corresponding boronium **283**-H by treatment with DMAP. Interestingly, compound **282**-H does not appear to promote hydroboration, as no reaction was observed upon treatment with phenylacetylene.

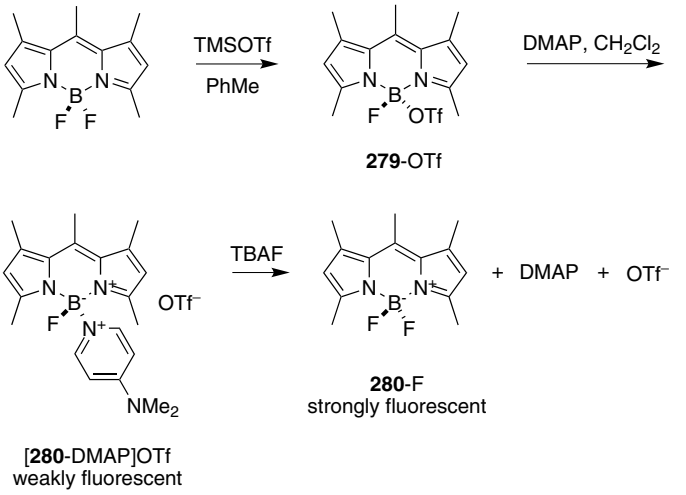

Chart 34.

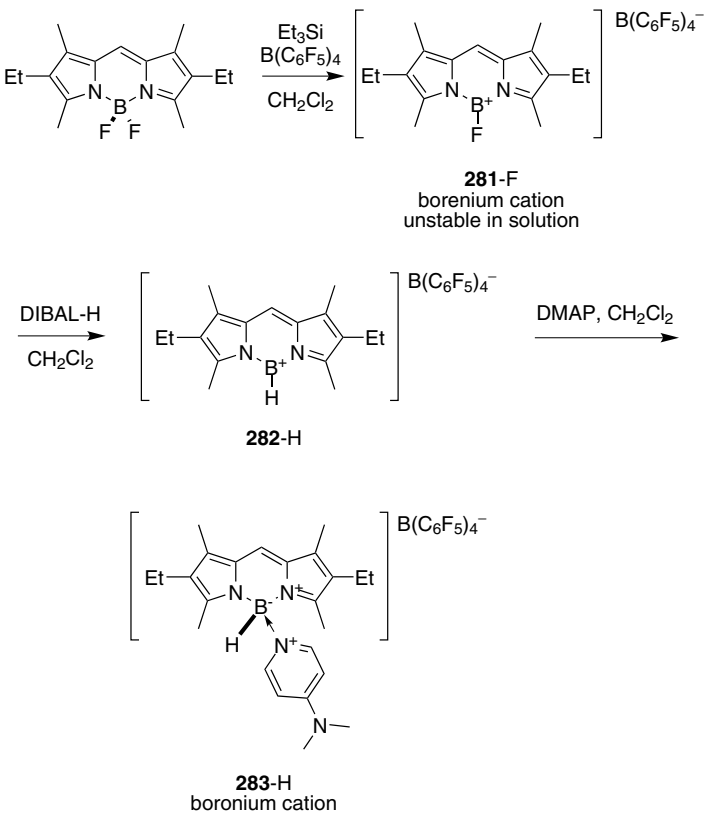

Chart 35.

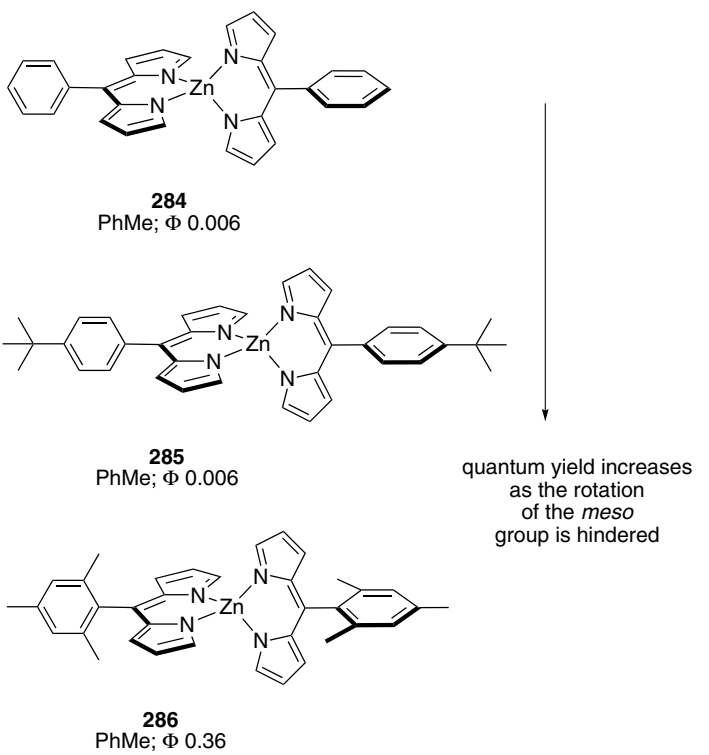
X. Use of Metals Other Than Boron

The BODIPY core features a boroindacene unit, so compounds where the boron has been substituted with other metals are, strictly speaking, beyond the scope of this review. However, there are a few dipyrromethene anion complexes of other metals that have highly fluorescent spectroscopic characteristics. These are covered here because they are clearly relevant as probes.

Free base dipyrrins react readily with a variety of metals salts to form the corresponding bis(dipyrrinato)-metal(II) or tris(dipyrrinato)-metal(III) complexes, but their fluorescence properties have rarely been studied and they have generally been regarded as non-fluorescent.[230–253] The first discussion of fluorescent properties for zinc complexes of the boraindacene fragment was in 2003.[254,255] The complexes were prepared either from treatment of a purified dipyrrin with zinc acetate, or, a two-step, one-flask approach involving oxidation of a dipyrromethane and complexation of the resulting crude dipyrrin with a $Zn(OAc)_2$ in presence of triethylamine. Complexes **284** and **285** are weakly fluorescent but **286** is a stronger emitter (it has a multinanosecond excited-state lifetime); thus free rotation of the *meso*-phenyl is again implicated as a major pathway for nonradiative relaxation to the ground state for **284** and **285**.



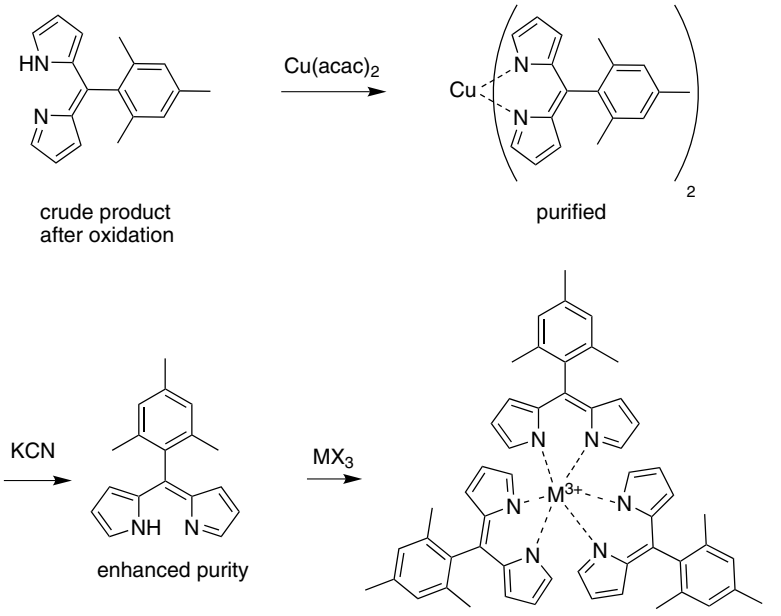


Chart 36.

Porphyrin or phthalocyanine complexes of group 13 metals can be fluorescent; this inspired syntheses of two new dipyrromethenes **287** and **288** from gallium(III) and indium(III), respectively (Chart 36). In hexanes, the new compounds fluoresce green light, with quantum yields of 0.024 and 0.074 for the gallium(III) and indium(III) complexes, respectively.[256]

"Nanoarchitectures" **289a–d** have been fabricated from Zn, Co, Ni, and Cu with dipyrromethene-based ligands, but are only strongly fluorescent with zinc.[257] The

fluorescence emission maxima of the zinc complexes in THF and in the solid state are around 510–515 nm and 532–543 nm, respectively. In acetonitrile, no emission was observed possibly because of aggregation of the particles. Fluorescence emission could be observed on a submicron scale for particles derived from Zn-bridged dipyrromethene oligomers; this is significant because quantum dots formed from clusters of inorganic compounds are considerably larger.

XI. BODIPY-Analogs with Extended Aromatic Conjugation

A. Restricted Systems

As mentioned previously, aryl-substituents on a BODIPY chromophore, e.g. in **136** and **137**, red-shift its absorption and emission spectra, but decrease its fluorescence intensity, presumably because of the free rotation of the aryl groups.[144,145] Consequently, more rigid systems like **290** and **291** where the aryl groups at position 3- and 5- are not freely rotating, were prepared and studied.[258]

These absorb and fluoresce more intensely at longer wavelengths, and their quantum yields are generally higher, with the exception of **291b**.

Derivatives **291** and **292** were obtained by condensation of 4-iodobenzoyl chloride with the corresponding pyrrole-based starting materials, which were prepared in several steps as described in Scheme 14. Most of the effort here is in the preparation of the pyrrole based starting materials. Part **a** of Scheme 14 shows

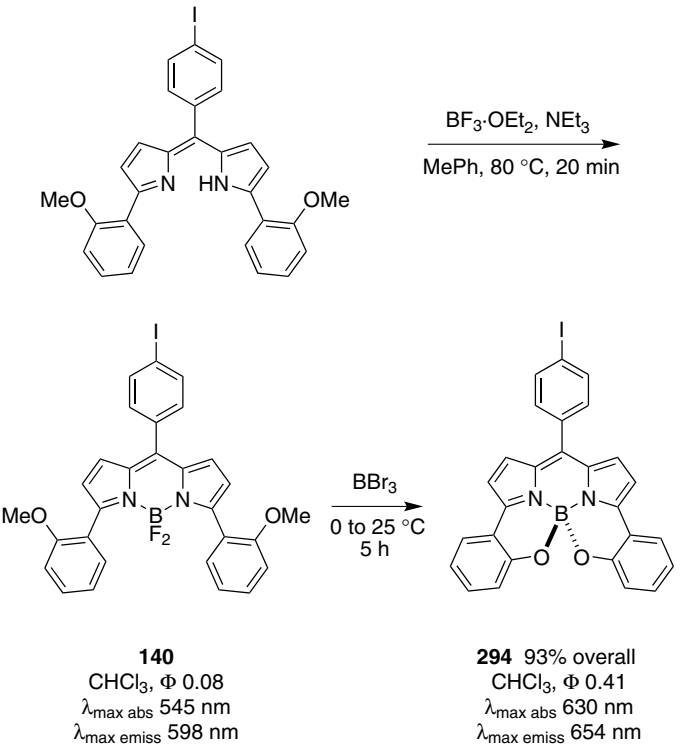
a route that featured intramolecular C-H activation by a nitrene, **b** involves a Trofimov reaction,[149] and **c** shows a classical condensation route.[259]

Oxidation of **291a** was attempted, but only the half-oxidized product **292** could be obtained; further treatment with excess DDQ at room temperature overnight gave no reaction (Scheme 15). Semi-empirical calculations showed that the activation energy required to form **293** was excessive compared with the half oxidized form **292** due to steric reasons. The physical properties of the mono-oxidized product were somewhat surprising. First, the maximum absorbance was not shifted to the red relative to **291a**, only the fluorescence emission was shifted to the red by 21 nm. Second, although the conjugation of the system was extended, the extinction coefficient was three times smaller than the reduced form of the dye **291a** (41000 vs. 126250 respectively); the quantum yield was also less than half that of **291a**.

2′-Methoxy substituents on α-aryl groups provide a special opportunity for syntheses of constrained BODIPY dyes. Thus **294**, wherein rotation around a



Scheme 16. Synthesis of a new NIR BODIPY dye.

C-Ar bond was prevented by B-O bond formation, was conveniently obtained by demethylation and intramolecular cyclization of **140** (Scheme 16).[260] Dye **294** has a red-shifted, sharper fluorescence emission than the BF_2 parent dye and its quantum yield is 5.5–6.0 times larger. This same approach has also been applied to aza-BODIPYs, e.g., Section XII.C.

Compound **296** could also be obtained directly from the dipyrrin ligand **295** by reaction with $B(OMe)_3$. Thus, a series of chiral Ar-BODIPY derivatives **297** was synthesized from reactions of **295** with arylboronic acids (Scheme 17).[261] The chiral boron center in these Ar-BODIPYs could be used for chiral recognition or for circularly polarized luminescence. The new BODIPYs derivatives **297a–c** show a strong absorption band at around 590 nm and an intense fluorescence centered around 615 nm with quantum yield of 0.63–0.68. As for compound **294**, the B-O linkage caused a red shift of both the absorption and emission.

Bright and long-wavelength emitting fluorophores, named Keio Fluors (KFL), **301** and **302**, based on BODIPY have recently been synthesized by Suzuki and coworkers.[262,263] These new probes were obtained from α-carboxylated furopyrrole **298** and α-formylated furopyrrole **299** in the presence of trifluoroactetic acid

	Ar	λ_{abs}	λ_{emis}	Φ

c	4-MeOPh	588	613	0.63

Scheme 17. Synthesis of chiral Ar-BODIPY dyes.

and trichlorophosphate (Scheme 19a). Preparation of the furopyrroles is described in Scheme 18. Briefly, furopyrrole 5-carboxylic acid **298** was synthesized by a Hemetsberger-Knittel reaction[264,265] on furan-2-carbaldehyde, and the furopyrrole **299** was obtained by α-formylation of the corresponding furopyrrole 5-carboxylic acid **298** (Scheme 18). Symmetrical and asymmetric KFLs can easily be synthesized (Scheme 19).

These new probes cover a wide spectral range from 542 nm to 738 nm. They exhibit high extinction coefficients (118 000–316 000 $M^{-1}cm^{-1}$), sharp emission spectra ($\Delta\lambda_{1/2}$ 16–30 nm) and high quantum yields, even in polar solvents (Φ 0.90–0.97 in EtOH). In addition, their absorption and emission profiles can be finely tuned through synthetic modifications. For example, both absorption and emission can be red-shifted by ca. + 40 nm via fusion of one furan ring gives (**5** vs. **301a**), fusion of two furan rings leads to ca. + 80 nm (**5** vs. **300a**), introduction of a phenyl ring gives ca. + 40 nm (**300a** vs. **304**), introduction of two phenyl rings gives ca. + 70 nm (**300a** vs. **300c**), attachment of one methoxy group in *ortho* or *para*-position of a phenyl ring leads to ca. + 20 nm (**300c** vs. **300b**, **300d**),

and introduction of an electron accepting group at the *meso* position gives ca. + 50 nm (**303** vs. **300b**).

B. Extended Aromatic Systems

1. *Di(iso)indomethene Dyes*

Aromatic ring-fused BODIPY derivatives, boron-di(iso)indomethene dyes **307** have been prepared via retro Diels-Alder reactions[266,267] featuring a norbornane-derived pyrrole (Scheme 20).[268] The spectroscopic data for the di(iso)indomethene derivatives **307** are shown below. The nature of the substituents at the *meso* position has no influence on the absorption and emission properties of the new dyes. The new di(iso)indomethene dyes display a red-shifted absorption compared to the bicyclic-BODIPY precursors **306**. The more expanded, conjugated, and rigid di(iso)indomethene BODIPY dyes **307** are also characterized by a significantly higher extinction coefficient relative to the bicyclic-BODIPY dyes **306**. Due to their rigid-fused system, which prevents a nonradiative deactivation of the excited state, bicyclic-BODIPY **306** and di(iso)indomethene BODIPY dyes **307** have small Stokes' shifts. The Stokes' shifts are, however, generally larger for bicyclic-BODIPY dyes **306** than for the di(iso)indomethene derivatives **307**. The absorption and emission spectra of bicyclic-BODIPY **306** and di(iso)indomethene BODIPY dyes **307** are independent of the solvent polarity. The fluorescence quantum yields of the bicyclic-BODIPY dyes **306** are much higher than the corresponding di(iso)indomethene BODIPY dyes **307**.

Other indomethene dyes including **258**[225] and **309–312**[225,269] have been prepared via a different route illustrated in Scheme 21. Substituted 2-acylacetophenones **308**, obtained by oxidation with lead(IV) acetate of the corresponding N-aroylhydrazones[270] formed by condensation of 2-hydroxyacetophenones and hydrazines, were condensed with ammonia to give the dibenzopyrromethene. These were treated with boron trifluoride to give the 3,4:3′,4′-dibenzopyrrometheneboron difluoride core (Scheme 21).

The new dyes **258** and **309–312**[225,269] exhibit very long wavelength absorption and emission bands, and are relatively stable to photobleaching.

2. *Dyes Based on Benz[c,d]indole*

Benz[*c,d*]indole and its derivatives have been used to form deeply colored dyes. Compound **313**, for instance, was obtained by condensation of

2-methylthiobenz[*c,d*]indolium iodide and 2-methylbenz[*c,d*]indolium iodide, followed by complexation with boron trifluoride etherate (Chart 37). Its fixed planar structure exhibits a sharp absorption band at 618 nm, and fluoresces at 625 nm.[271,272]

3. *Phenanthrene-Fused BODIPY Systems*

2H-Dibenzo[e,g]isoindole (or β-phenanthropyrrole) have also been used to prepare bright, near-IR dyes.[273] Compounds **316** for instance were prepared from ethylphenantro[9,10-*c*]-pyrrole-1-carboxylate **314** via 1-methylphenanthro [9,10-*c*]-pyrrole **315**, then condensation with aromatic aldehydes, oxidation with DDQ and complexation with boron (Chart 38). These new dyes display distorted, "propeller-like" conformations due to the steric hindrance between the *meso* substituent and the large phenanthrene groups. They absorb maximally

around 620 nm, and like for pyrrole or isoindole-BODIPY systems, they are insensitive to the solvent polarity, with the exception of **316d,** where the fluorescence is quenched due to fast charge transfer process from the *meso*-dialkylanilino substituent. Unlike BODIPYs, and because of their crowded structure, the nature of the substituent at the *meso* position can influence the electronic properties of dyes **316**: **316c** with the strongest acceptor (CN) shows the longest wavelength absorption and emission, while **316d** with the strongest donor (NMe_2) displays the shortest ones. Furthermore, despite their distorted, "propeller-like" conformations, these new dyes emit brightly (Φ > 0.9). Finally,

these new phenanthro-BODIPYs dyes are a promising platform to design more elaborated near-IR probes as their electronic properties can be finely tuned by changing the nature of the substituent at the *meso* position. Probe **316d** was used as a pH indicator for the acidic range.

4. *Porphyrin-Fused Systems*

Systems **318**–**320** have edge-shared porphyrin and BODIPY parts. They were synthesized from the formylated pyrroloporphyrin **317** via acid-catalyzed condensation with 2,4-dimethylpyrrole. Their UV spectra contain four quite intense bands in the 300–750 nm region, and do not resemble the sum of the spectra of tetraphenylporphyrin (TPP) and of BODIPY. Systems **318** and **320** emit respectively at 693 and 714 nm upon excitation over all the 240–700 nm region with low quantum yields, and **319** did not show any significant fluorescence.[3]

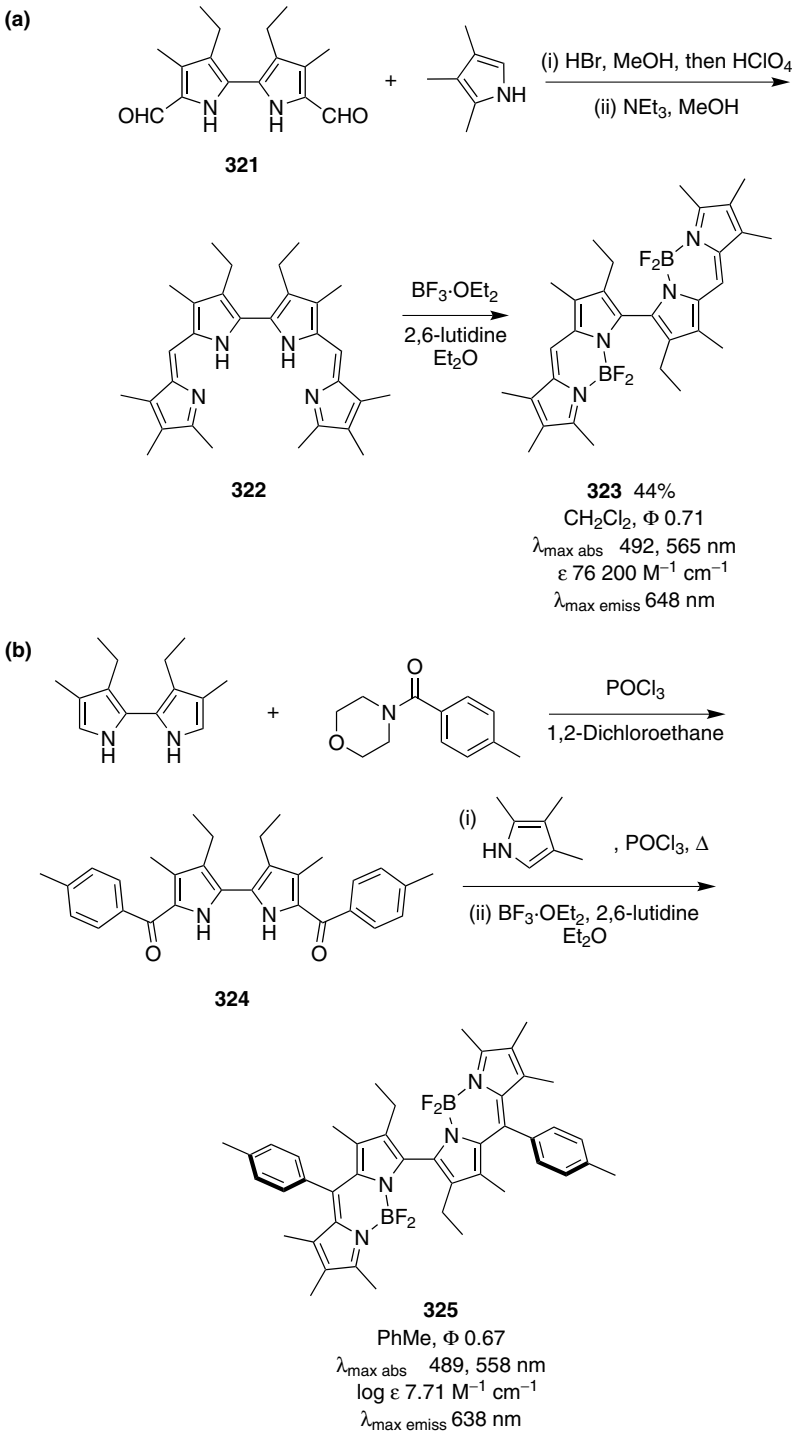
5. *Bis-BODIPYs Systems*

Meso-unsubstituted and *meso*-aryl-substituted bis-BODIPYs systems **323** and **325**, respectively, were prepared from their corresponding free-base ligands, i.e. **322** (Scheme 22).[274–276] Water-saturated diethyl ether was a preferred solvent



Scheme 22. Synthesis of (**a**) *meso*-unsubstituted and (**b**) *meso*-aryl-substituted bis-BODIPYs.

system for BF_2-coordination on dipyrrin ligands as it reduced the basicity of the fluoride anions and therefore limits side-reaction/decomposition processes, e.g., attack at the *meso*-position of both free ligands and bis-BODIPYs by basic fluoride anions formed *insitu* when the reaction was performed in CH_2Cl_2.

Unlike most classical BODIPYs, which are characterized by a single, strong absorption band at ca. 530 nm, an intense, narrow emission around 540 nm and a small Stokes' shift (200–400 cm^{-1}), these new dimeric chromophores display two major absorption bands with maxima at around 490 and 560 nm, an unstructured, broad emission and a remarkable large Stokes' shift (2200 cm^{-1}). Splitting of the absorption bands was assigned to exciton coupling; this was confirmed by the ratio between the integrated absorption spectra of the dimers and monomers being equal to 2. This exciton splitting had an intramolecular origin as no concentration effect (no aggregation) could be detected on the absorption parameters in the range 10^{-6}–10^{-4} M. No concentration effects could be observed on the luminescence either. Solvent polarity, however, had a significant effect on the luminescence quantum yield and the Stokes' shift. Increasing solvent polarity strongly reduced the luminescent quantum yield, especially on dimers without substituent at the *meso* position. Thus, bis-BODIPYs such as **323** could be used as polarity probes.

When compared to other dimeric BODIPY species, H-type nonluminescent dimers or J-type luminescent dimers, the data obtained for the bis-BODIPYs **323** or **325** were very similar to the one for J dimer, with the exception of the exciton splitting.

Furthermore, unlike BODIPYs, these new dyes exhibit a significant amount of singlet and triplet excited state with a fair ability to sensitize singlet oxygen.[274–276]

XII. Aza-BODIPY Dyes

A. Tetra-Aryl Systems

Synthesis of the azadipyrromethene chromophore **326** (without boron, but with aryl substituents) was first described in the 1940s.[277–279] This, as described below, is the framework for a very interesting set of dyes called the aza-BODIPYs. Two general methods to prepare these compounds were developed. In one, 2,4-diarylpyrroles were converted into their 5-nitroso derivatives, then condensed with a second molecule of pyrrole (Scheme 23a). Scheme 23b shows the second method, in which Michael addition products **D** from chalcones and nitromethane,[277] or cyanide **E**,[278,279] were reacted with formamide (or other ammonia-sources) to give the core **326**. In the first instance, these reactions were performed neat, i.e. without solvent. Soon after, it was realized that use of alcohol

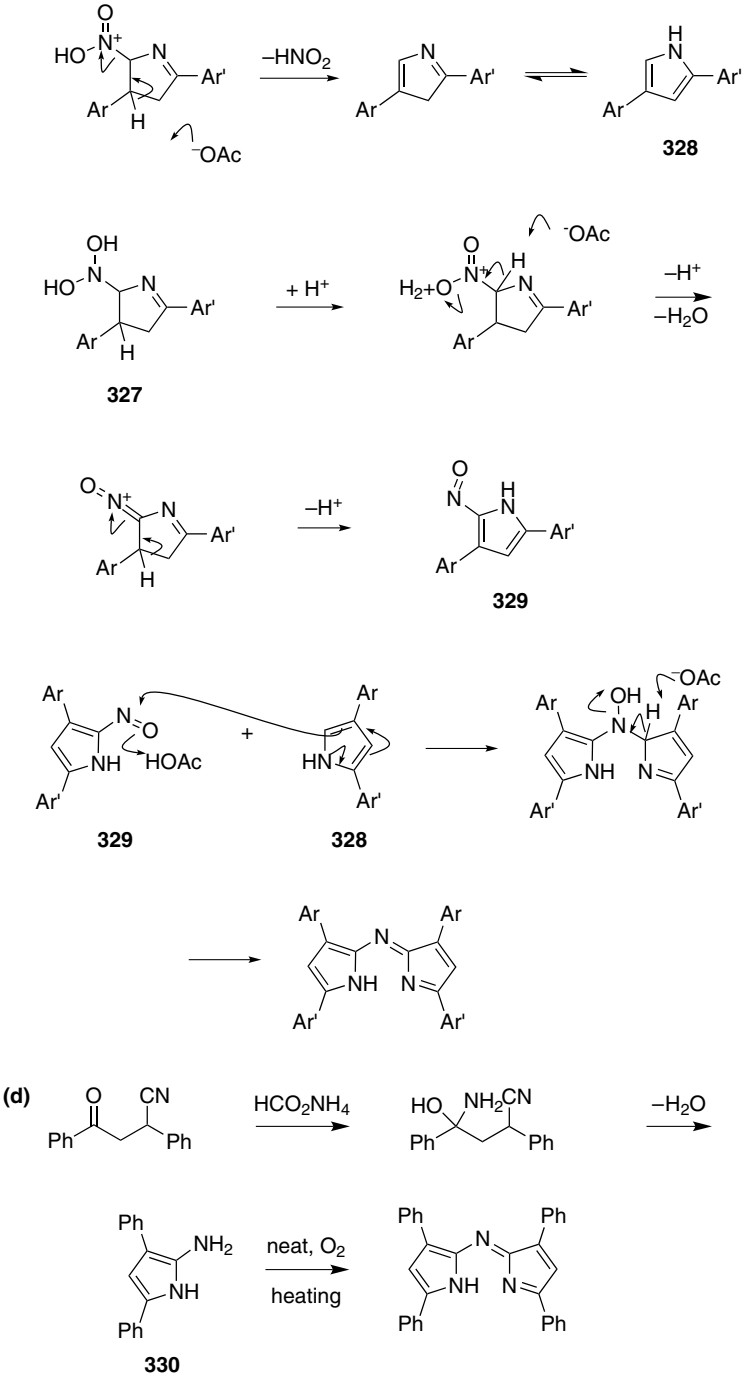
Scheme 23. Formation of azapyrromethene from (**a**) nitroso pyrrole; and (**b**) nitrobutyrophenones **D** and keto-nitrile **E**; (**c**) postulated mechanism for the formation of azapyrromethene from nitrobutyrophenones **D** and, (**d**) from keto-nitrile **E**.



Scheme 23. (*Continued*)

solvents usually causes the azadipyrromethenes to precipitate from the reaction mixture, thus enhancing the ease of isolation and yields. The postulated mechanism for formation of the azadipyrromethene core from the nitromethane adducts is shown in Scheme 23c. It proceeds via pyrrole **328**, which is nitrosylated *in situ* to give **329** that then condenses with another molecule of the pyrrole.

It is also possible to prepare the azadipyrromethene chromophore from cyanide Michael addition products **E** as described in Scheme 23d. Ammonium formate serves as a source of ammonia in the pyrrole-forming condensation step. The 2-amino pyrrole intermediates **330** readily convert to the azadipyrromethene core on heating in the air. Switching from acetate to formate in the dry melt process for the synthesis of **326** nearly doubled the yield to give approximately 50%.[279] Formation of this chromophore seems to be most facile when there are four phenyl substituents, but it is possible to obtain the diphenyl products **333** (below) by slight modification of the reaction conditions.[279]

The first reactions of azadipyrromethenes with boron electrophiles were reported in the early 90s (Scheme 24).[131,280] The aza-BODIPY **332** was made from the 3,5-tetraphenyl azapyrromethene **331** in that way. The less substituted aza-BODIPY **334** could not be obtained after treatment of the corresponding azadipyrromethene **333** with boron trifluoride[280]; however, this might have been an artifact of the particular conditions screened.

Beginning with research largely from O'Shea's group from 2002 onwards, there has been a resurgence of interest in aza-BODIPY dyes, resulting in syntheses of

dyes like **335**–**338**.[281–284] In this latest era of the field, the azadipyrromethene skeletons are still prepared from nitromethane adducts to the corresponding chalcone according to the route described in Scheme 23c but butanol, rather than methanol or solvent-free conditions, was the preferred medium.[282] The syntheses

were completed by adding $BF_3 \cdot OEt_2$ at room temperature; the intermediate azadipyrromethanes precipitated out in high purities and were not purified beyond washing with ethanol.[281,282]

UV absorption maxima of the tetraarylazadipyrromethene-BF_2 chelates strongly depend on the Ar-substituents. *para*-Electron donating groups on the 5-Ar substituents gives increased extinction coefficients and significant red-shifts in the $\lambda_{max\ abs}$ (149 nm for dimethylamino vs. H, *cf* **338** vs. **332**).[283] *para*-Substitution with an electron donating group on the 3-aryl ring has less impact, but still gives a bathochromic shift (*cf* **335** vs. **336**).[282]

The UV absorption maxima of the aza-BODIPY dyes are relatively insensitive to solvent polarity; only small blue-shifts tend to be observed (6–9 nm) when switching from toluene to ethanol. Their absorptions are sharp, with a full width at half-maximum height (fwhm) varying from 51 to 67 nm in aqueous solution with an emulsifier called Cremophor EL, and 47 to 57 nm in chloroform indicating that the dyes do not aggregate under those conditions. The extinction coefficients range from 75,000 to 85,000 M^{-1} cm^{-1}, which is much greater than substituted porphyrins (3000–5000 M^{-1} cm^{-1}) for instance. This strong absorbance is one of the factors that facilitate efficient singlet-oxygen generation, hence these molecules are potentially useful photosensitizers for photodynamic therapy.[285–288]

Fluorescence emission spectra of the aza-BODIPY dyes reported to date are also relatively insensitive to the solvent polarity. Compounds **332** and **335** to **337** have high fluorescence quantum yields. In the case of **337**, there is a bromine atom attached to the phenyl substituent, but no significant decrease in the quantum yield was observed.[282] On the other hand, introduction of bromine directly into the core of the dye, e.g. compounds **339** to **341** results in a significant decrease of the fluorescence quantum yields, indicating a larger heavy-atom effect and an increased singlet oxygen production.[282] A quantum yield was not reported for **338**, but the

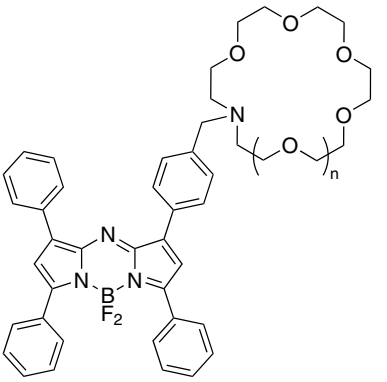
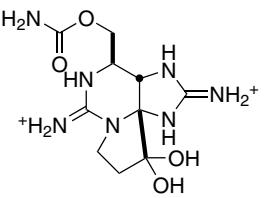
compound became much more fluorescent under acidic conditions due to variation in the internal charge transfer.[283] Upon addition of acid, the absorption band at 799 nm disappears and a new band at 738 nm appears indicating the monoprotonated form. The later disappears with addition of more acid, and a new band characteristic of the bis-protonated species appears at 643 nm.

Aza-BODIPY dyes mostly have been studied in the context of photodynamic therapy agents, but chemosensors have also been made from these compounds. Compound **342** is highly selective for mercuric ions that become chelated between the 2′-pyridyl groups.[289] Mercuric ion complexation red-shifts both the UV-absorption and fluorescence emission maxima. The dissociation constant was determined to be 5.4×10^{-6} M, with a 1:1 binding stoichiometry.

Compound **343** and **344** are photoinduced electron transfer crown ether chemosensors featuring aza-BODIPY chromophore[290]; they are used as visible sensors for the paralytic shellfish toxin Saxitoxin. Saxitoxin contains guanidine groups, and it is these functional groups that interact with the crown ether part of



343 n = 1
344 n = 4



Saxitoxin

these molecules. In the absence of Saxitoxin, PET from the crown ether to the fluorophore quenches the fluorescence. Upon complexation of the toxin, PET can no longer happen and fluorescence is turned on. At 1:1 toxin/crown stoichiometry, the fluorescence enhancement was over 100% for compound **343**. The average binding constant for **343** to Saxitoxin, 6.2×10^5 M^{-1}, was among the highest observed for any chemosensor of that toxin. Compound **344**, which has a larger crown ether bound the toxin less strongly (1.4×10^4 M^{-1}) and gave insignificant fluorescence enhancement. The putative PET mechanism in these systems involves π-stacking of one of the Saxitoxin's guanidiniums to the fluorophore.

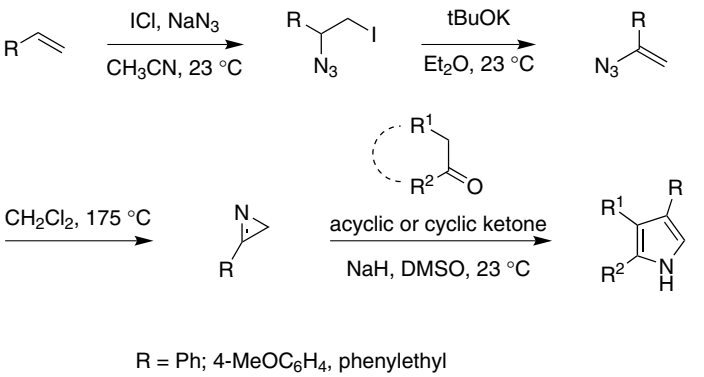
B. Extended Aza-BODIPY Systems

1. *Restricted Systems*

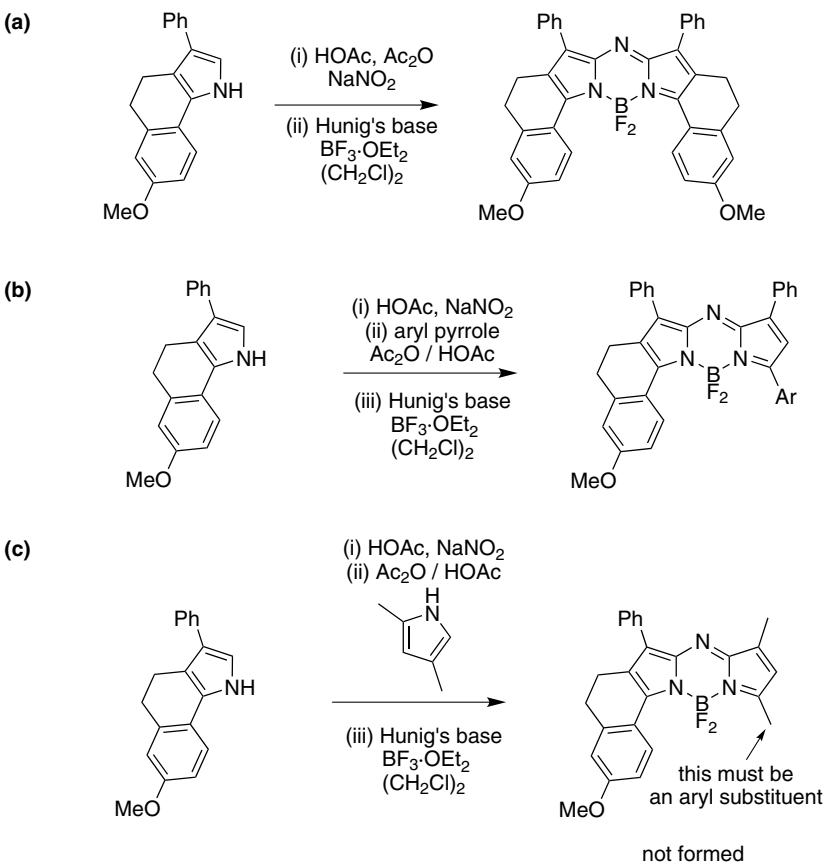
Strongly electron-donating groups, rigidifying structural modifications, and embellishments to extend the conjugation of the BODIPY dyes tend to red-shift their fluorescence emissions. Predictably then, similar modifications can be used to push the emission spectra of aza-BODIPY systems into the near-IR.

The "extended" aza-BODIPY systems **345**–**357** were synthesized from 2,4-diarylpyrroles. These starting materials were obtained in good overall yield over four steps from an alkene via (i) addition of iodo azide, (ii) dehydro-halogenation, (iii) pyrrolysis (azirine formation) and (iv) carbanion induced pyrrole formation as shown in Scheme 25.[291,292]

The conformationally restricted aza-BODIPY dyes were then prepared as shown in Scheme 26 via condensation of the pyrrole generated in Scheme 25 with a nitrosopyrrole generated *in situ*, followed by complexation with boron trifluoride. Attempts to condense 2,4-dimethylpyrrole with a nitrosated restricted



Scheme 25. Synthesis of cyclized/restricted 2,4-diarylpyrroles.



Scheme 26. Synthesis of (**a**), Symmetrical and (**b**), Asymmetrical Conformationally Restricted AzaBODIPY Dyes. (**c**) Reaction with 2-alkyl pyrrole does not yield to the desired product.

2,4-diarylpyrrole failed to give any product, suggesting that the 2-aryl substituent in the pyrrole is essential for the formation of these restricted aza-BODIPY dyes.

All the conformationally restricted systems **345–357** absorb over 650 nm. Dyes **345–347** with both sides incorporated in carbocyclic rings have narrow,

intense (high ε) absorption bands at long wavelengths. In comparison to the "non-constrained" tetraaryl-azaBODIPY **335**, there is a bathochromic shift of up to 52 nm and a concomitant halving of the fwhm (27 nm for **347** vs. 52 nm for **335**). The novel dyes were reported to possess excellent chemical and photostability. Furthermore, the fluorescence is insensitive to solvent polarity.[291,292]

There are also several details regarding the spectral properties of the dyes in this series. Substitution at the 3-position of the core does not affect the ε-value of the dyes (compare **345**–**347**). Introduction of electron-donating groups results in a small blue-shift and a slightly higher fluorescence quantum yield (**345** vs. **346**). Shorter λ_{abs}, lower ε, broader absorption band, and lower fluorescence quantum yield were associated with the sulfur-containing dye **348**. The dehydrogenated carbocyclic restricted ring in system **350** decreases its quantum yield relative to **345**. Aza-BODIPYs with only one side restricted have much lower extinction coefficients (**351**–**357** vs. **345**). The quantum yields of non-symmetric aza-BODIPY dyes are highly dependent on the substituents on the aromatic ring. Electron donating *para*-substituents give higher quantum yields (**351** and **352**), with shorter λ_{abs} indicating that the phenyl rings are twisted. *ortho*-Electron donating groups (e.g. in **353**) result in short λ_{abs}, low ε, and broad absorption bands, indicating that the phenyl rings in **353** are twisted. Unexpectedly shorter λ_{abs}, low ε, broader absorption bands and lower quantum yields were observed when two methoxy groups were present (**354** and **355**). The sharp and intense absorption, high quantum yield obtained in the special case of **356** wherein a 2-methoxy-1-naphthyl substituent is present indicates that the naphthyl ring is distorted so that electron transfer is suppressed.

2. *Dyes Based on Benz[c,d]indole*

Synthesis of compound **359** involves refluxing 2-benz[*c*,*d*]indolamine hydroiodide with 2-(methylthio)benz[*c*,*d*]indole-hydroiodide in 1,2-dichlorobenzene in presence of triethylamine gives the amine **358**. Subsequent treatment with boron trifluoride etherate affords the desired product **359** (Chart 39).[293]

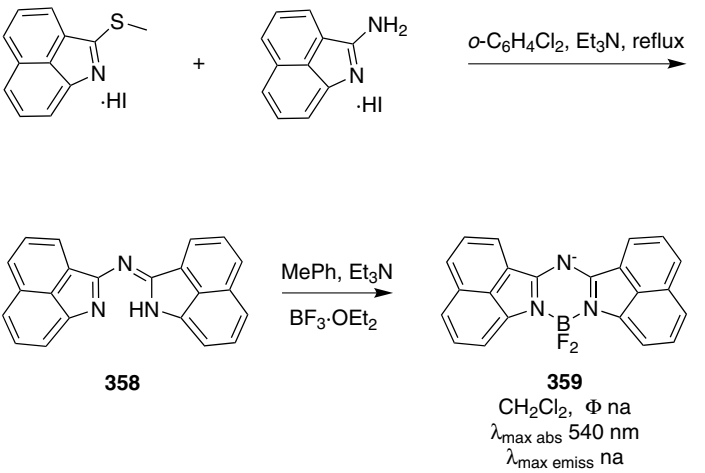

Chart 39.

While the benz[*c,d*]indole based BODIPY dye **313** displays a red-shifted absorption and fluorescence, the aza-BODIPY analog **359** shows a blue-shifted absorption at 540 nm. Unfortunately, no fluorescence properties have been reported.

C. Cyclized Aza-BODIPY Systems

As for BODIPYs, near-IR derivatives of aza-BODIPYs could be obtained via intramolecular B-O ring formation. Thus, systems like **361** were obtained via two complementary routes (Scheme 27).[294] Scheme 27a outlines the route developed for BODIPY by Burgess where upon treatment with boron tribromide, demethylation of the methoxy groups to the corresponding bisphenols occurs followed by spontaneous cyclization. Surprisingly, bromination of the pyrrole ring was also observed for **361b** leading to the products **361e** and **f**. When strong electron-donating groups were used in the *para*-position of the 3- and 5-aryl ring, e.g. **360c** and **d**, the desired product could be formed (as evidenced by UV) but not isolated, as they decomposed rapidly upon exposure to air. Thus, a complementary route (Scheme 27b) was developed by O'Shea and coworkers[294] to allow inclusion of strong electron donating substituent. Fluorophores **361g–h** were obtained in a one-pot BF_2 chelation and intramolecular phenolic oxygen-fluorine displacement from dipyromethene ligands **362g–h**.

As for BODIPY, restriction caused by the B-O bonds in **361** lead to bathochromic shifts for both the absorption (86 nm) and emission (56 nm) maxima and over a 7-fold increase in the quantum yield from 0.07 to 0.51 (**332** to **361a**). Interestingly,

	R	R'	X^1	X^2	λ_{abs}	λ_{emiss}	Φ

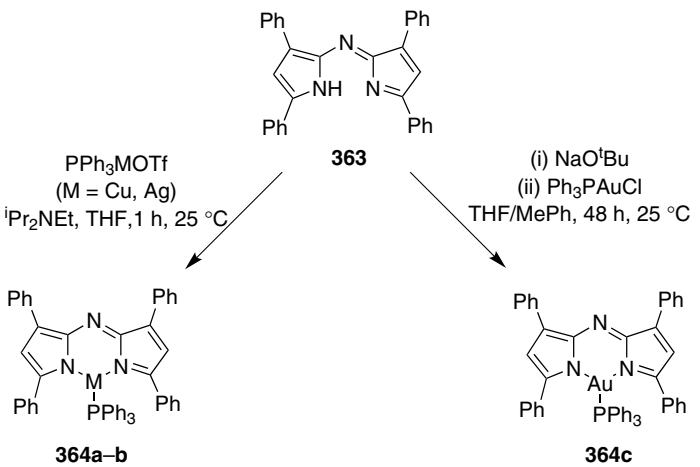
the tetrabromo derivative **361f** also has red-shifted absorption and emission maxima and introduction of bromines onto the pyrrole did not result in a significant quenching of fluorescence.

D. Other Metals

Tricoordinate Cu(I), Ag(I), and Au(I) complexes of the tetraphenylazadipyrromethene **363** have recently been described (Chart 40).[295] All complexes exhibit an intense absorption band centered around 600 nm. In the case of the silver based complex, the extinction coefficient is twice that of the copper ones. All complexes are weakly luminescent at room temperature (Φ = 0.0024–0.0039 compared to 0.0014 for **363**).

Aza-BODIPY complexes **365a–d** of Co(II), Ni(II), Cu(II) and Zn(II) were easily prepared from the aza-dipyrrin **332** by heating with the corresponding metal acetate salt in butanol (Chart 41). They all have 1:2 metal:ligand stoichiometries. The complexes absorb around 600 nm, with the exception of the Cu(II) one which shows a splitting with λ values of 566–640 nm, similar to the free ligand **332**



in $CHCl_3$

(λ_{abs} 593 nm), suggesting that the absorption is primarily ligand centered with band broadening upon metal chelation. In contrast to the BF_2 chelates, these complexes were non-fluorescent.[296]

XIII. Other Analogs of the BODIPYs

A. GFP-Chromophore Analogs

Compounds **371** were synthesized as mimics of the green fluorescent protein (GFP) fluorophore.[297] Synthetic analogues **H**–**K** of the GFP chromophore (**G**) have been prepared and studied, [298,299] but they fluoresce at shorter wavelengths and are not fluorescent primarily because of free rotation about the aryl-alkene bond (Figure 11). Steric and electronic factors prevent free rotation of the aryl substituents and isomerization of the alkene when the chromophore is encapsulated within the β-barrel protein structure; hence, the molecule is strongly fluorescent. To block free rotation around the aryl-alkene bond, inclusion of boron into compounds **370** to give compounds **371** was performed.

Synthesis of compounds **370** was first attempted following the known method, e.g. condensation of hippuric or aceturic acid derivatives with aldehydes

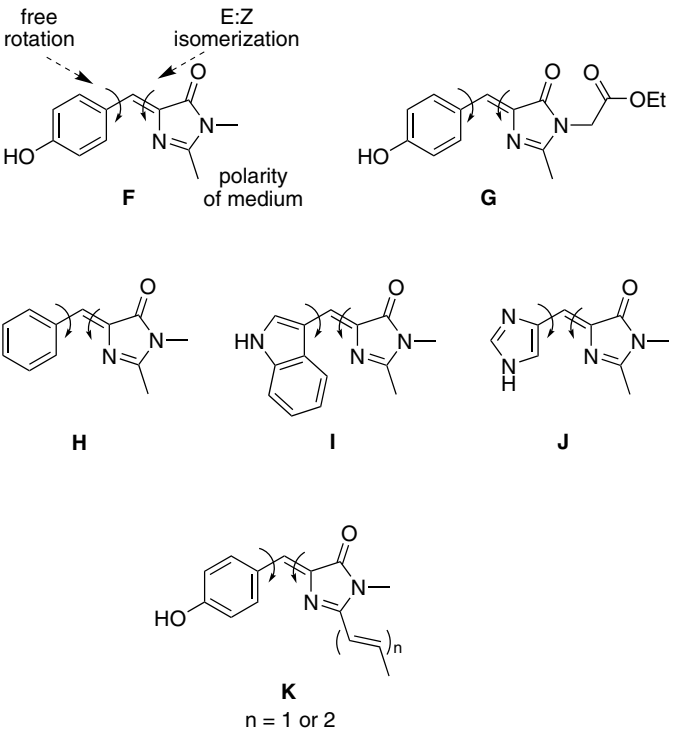

Figure 11. The GFP chromophore (**F**) and some synthetic analogues (**G–K**).

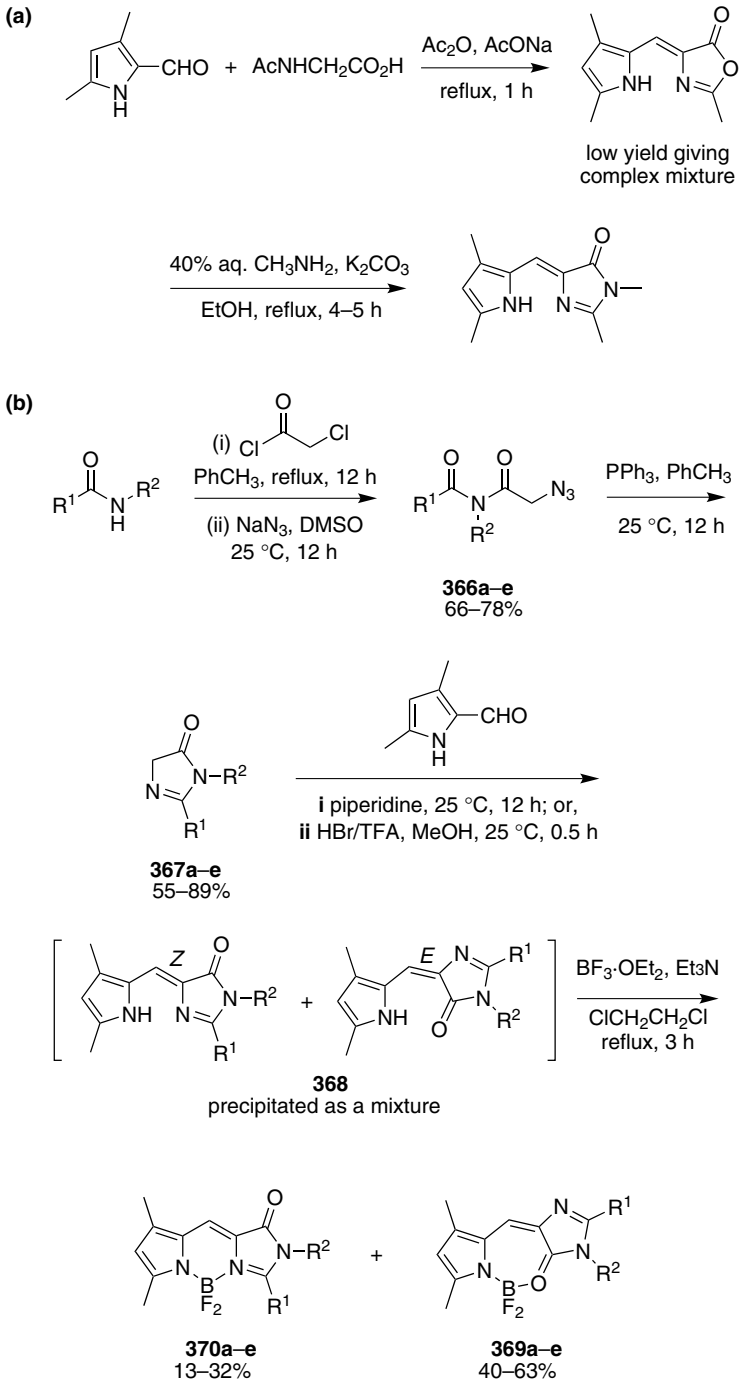
(Scheme 28a), but these conditions did not work well for pyrrole-2-carbaldehyde. Consequently, the targets compounds **370** were prepared via the route described in Scheme 28b. This new route involves preparation of an imidazolinone **367**, condensation of this with pyrrole-2-carbaldehyde to give compounds **368**, followed by addition of boron. In the last step, compound **368** isomerizes to form **369** and **370**. *E,Z*-Isomerization of compounds **368** did not significantly impact the syntheses of products **370** since the isomers interconvert in the chelation step. When *E*-**368c** (prepared via condensation mediated by HBr/TFA (condition ii in Scheme 28b)) was converted to the boron-containing products, both compounds **369c** and **370c** were formed, in a ca. 2:1 ratio, respectively. Similarly, when a 1:1 mixture of *E*-**368c** and *Z*-**368c** were treated with $BF_3{\cdot}OEt_2$, **369c** and **370c** were formed in a ratio of approximately 2:1. Therefore, it appears that formation of **370c** from **368c** is a stereorandom process.

Compounds **371** are neutral, uncharged, highly fluorescent molecules that absorb and emit around 520–530 nm. Addition of BF_2 to the open-chain intermediates **369** greatly increased the quantum yields of compounds **370** providing more evidence that GFP chromophores within the protein are highly fluorescent due to



Scheme 28. Synthesis of compounds **370** from (**a**), hippuric acid and pyrrole-2-carbaldehyde; (**b**) imidazolinone **367** and pyrrole-2-carbaldehydes.

the conformational locking within the β-barrel cocoon. The absorption and fluorescence maxima of **370a–e** are red-shifted by up to 20 nm in less polar media like CH_2Cl_2 (data not shown). Among the series, **370f** has the lowest fluorescence quantum yield, probably due to d-PeT. Compounds **370** can easily be sulfonated and modified to include a point of attachment to biomolecules while maintaining their strong fluorescence.

B. Fused Perylene Tetracarboxylic Diimide and BODIPY Analog

Perylene tetracarboxylic diimides (PDIs) are commonly modified by introducing side groups either to the imide nitrogen atoms or at the bay positions. Substitution at the imide nitrogen can improve their solubilities in organic solvents, while substituents at the bay positions can change their photophysical properties depending on their withdrawing or donating abilities and their steric hindrance. Electron donating groups can red-shift both the absorption and emission maxima, but induce a significant loss of fluorescence. To change the absorption and emission of PDIs without loss of fluorescence, compounds **374** an **375** were designed.[300] They combine PDI and BODIPY units. Compounds **374** and **375** were prepared from the corresponding PDIs **371** and **372** by condensation with 2-methylquinoline, followed by complexation with boron (Scheme 29).

The photophysical properties of the PDIs derivatives **373**–**375** were studied and compared to **376**. The new probes have good solubility in conventional organic solvents. Introduction of the quinoline unit resulted in a 6 and 11 nm red shift for the absorption maxima of **373a** and **b**, respectively, compared to **376**. The absorption maxima for **374** and **375** were further shifted to the red to 616 and 650 nm, respectively, upon complexation with boron. This is because coordination with boron has driven the quinoline to take a precisely coplanar conformation with PDI, therefore extending the conjugation of the aromatic system. Similarly, the

emission of **373a**–**b**, **374** and **375** were red-shifted relative to **376**. The fluorescence quantum yields and fluorescence lifetimes of **373a**–**b**, **374** and **375** are almost half of that of **376**. This might be caused by the increased flexibility of the molecule upon introduction of the quinoline, which induces mass nonradioactive decay.

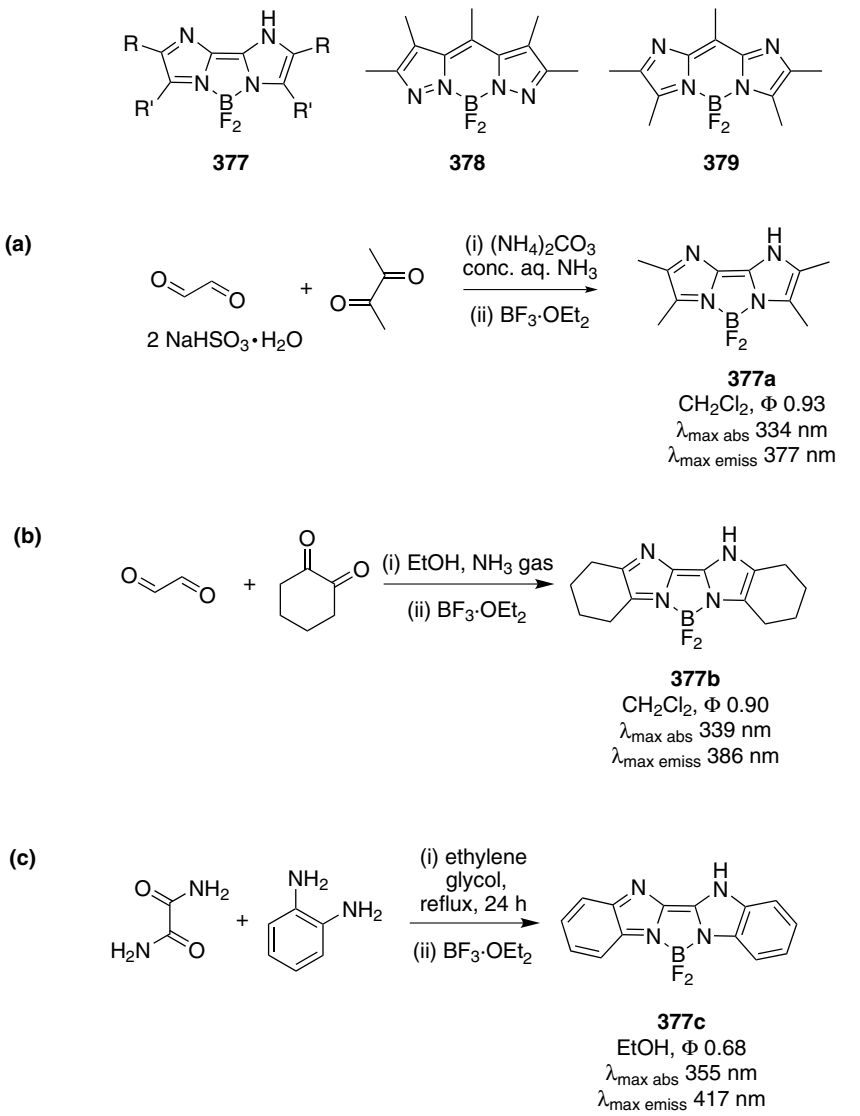
C. Biimidazol-2-yl-BF_2 Complexes

Biimidazol-2-yls difluoroborate complexes **377** have been obtained by: (i) reacting glyoxal bisulfite, 2,3-butanedione and concentrated aqueous NH_3 (Scheme 30a)[301,302]; (ii) condensation of 1,2-cyclohexanedione with 40% aqueous glyoxal in ethanol saturated with dry ammonia gas[302]; and, (iii) condensation of oxamide with *o*-phenylenediamine in refluxing ethylene glycol (Scheme 30c).[303,304] It would



Scheme 30. Synthesis of biimidazol-2-yls BF_2 complexes.

seem logical that similar dyes of the type **378** and **379** could be prepared, but attempts to do so have been reported as unsuccessful.[305]

The parent, non-*B*-coordinated heterocyclic systems for molecules **377** are not significantly fluorescent, but the BF_2 complexes display strong fluorescence. Predictably, red shifts for both the absorption and emission maxima, and increased extinction coefficients are observed with increased conjugation and rigidity.

D. Pyridine-Based Systems

The dipyridyl-2-yl-boron complexes **380–384** have been prepared from reactions of bipyridines with boron electrophiles.[306] They absorb between 302–322 nm, with the exception of the complex **383**, which absorbs at 371 nm. No fluorescence was detected for these complexes.

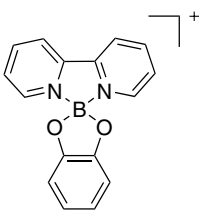
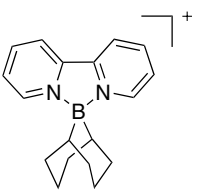
382



383



384

The pyridomethene-BF_2 complex **385** was synthesized as shown in Chart 42 from the 2,2′-dipyridylmethane by fusion with sodium borohydride.[307] The product shows a strong absorption at 468 nm, with a extinction coefficient of 17,783 $M^{-1}cm^{-1}$ in chloroform, but does not fluoresce.

The 10-azapyridomethene-BF_2 complex **386a** was obtained via condensation between dipyrid-2-ylamine and boron trifluoride.[280] Similarly, 10-azapyridomethene-$B(Et)_2$ **386b** was obtained by condensation with triethylboron (Chart 43). Complex **386a** absorbs at 382 nm (log ε = 4.47) in ethanol, and strongly fluoresces at 422 nm (Φ = 0.81).

Treatment of dipyrid-2-ylamine with methyl iodide gives the methyldipyrid-2-ylamine, which can be converted to the 10-methyl-10-azapyridomethene-BF_2 complex **387** by treatment with boron trifluoride. The homologous complex **388** was obtained by condensation between 2-amino-6-methylpyridine and 2-chloro-6-methylpyridine, and subsequent treatment with boron trifluoride. Both these complexes are fluorescent, but the neutral one, **388**, fluoresces at longer wavelength.

E. 2-Ketopyrrole Complexes

The 2-ketopyrrole complexes **389–393** were isolated as minor byproducts (less than 5%) in the synthesis of the corresponding BODIPY analogs.[308] The yield of **389–393** could be improved by increasing the amount of acid chloride used in the synthesis. 2-Ketopyrrole complexes are less conjugated than BODIPY dyes, hence their absorption, extinction coefficients and emission wavelengths are shorter/smaller. The Stokes' shifts for these compounds, however, are greater than for BODIPY systems (48 nm to 154 nm, *cf* approximately 10–15 nm for BODIPY dyes).

F. Azobenzene Derivatives

Azobenzenes are the most common chromophores in commercial dyes and, because of photoinduced isomerization, they are used as photoresponsive molecular switches. A consequence of facile photoisomerization is that quantum yields for these compounds are so low that fluorescence tends only to be observed in a rigid matrix at low temperature. A recent innovation in this field is fixation of the π-conjugate systems using boryl-entities to give the fluorescent compounds **394**–**396** (Chart 44).[309]

Azobenzene dyes **394** and **395** display a remarkable red shifted absorbance (386 nm and 439 nm, respectively) relative to unsubstituted (*E*)-azobenzene (λ = 315 nm). Irradiation of **394** and **395** with a super-high-pressure mercury lamp did not cause photoisomerization. The azobenzene derivative **396**, bearing a fluorinated substituent on the boron atom, showed almost no fluorescence. We speculate that this could be due to intramolecular charge transfer from the least electron rich aryl substituent into the excited state of the complexed azobenzene system.

G. Miscellaneous *N,N*-Bidentate Diphenyl Boron Chelates

Luminescent *N,N*-bidentate diphenylboron chelates **397**–**409**[310,311] have emission maxima that vary with the nature of the parent organic system. Limited information was provided regarding the spectroscopic properties of these molecules, but the data presented are interesting because some of the dyes have high quantum yields and/or fluorescence emissions around 600 nm. These systems perhaps warrant further attention.

A variety of methods were used to produce the parent heterocycles for the dyes shown above (Scheme 31). The 2-(2′-pyridyl)indole and 2-(2′-thiazolyl)indole based ligands were synthesized by a two-step Fischer synthesis (Scheme 31a

and b, respectively). Scheme 31c illustrates how a Negishi coupling[312] was used for the synthesis of the 2-(8′-quinolyl)indole or -azaindole. Treatment of the product heterocycles shown in Scheme 30 with triphenylboron (1:1 ratio) in toluene afforded the boron complexes **397**–**409** in good yields.

H. Boryl-Substituted Thienylthiazoles

Finally, there are compounds that are even less closely related to the BODIPY core, formed by intramolecular B-N coordination in *N*-heteroaromatic systems. This new concept is illustrated for the development of new electronic materials. The interaction between the Lewis acid (boron) and Lewis base (nitrogen) not only constrain the π-conjugated framework in a coplanar fashion, but also lower the LUMO level (Figure 12). Thus, (3-boryl-2-thienyl)-2-thiazole **410** was synthesized from (3-bromo-2-thienyl)-2-thiazole as shown in Scheme 32.[313]

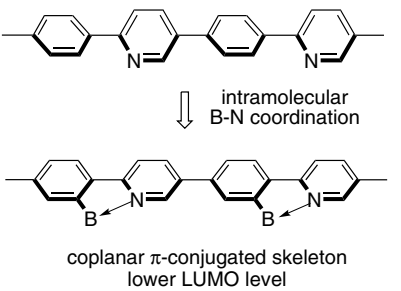

Figure 12. Intramolecular B-N Coordination of *N*-heteroaromatic systems.

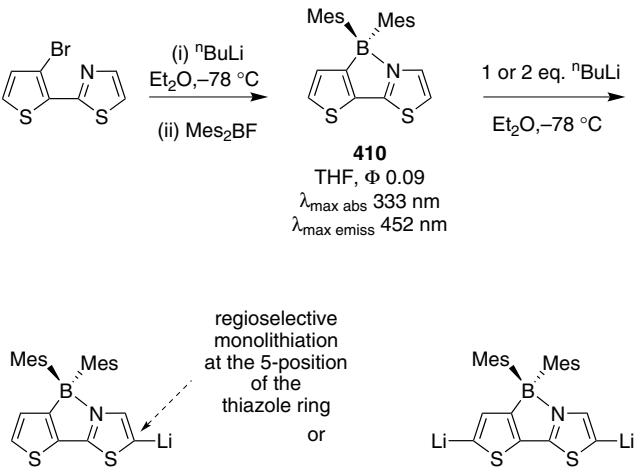
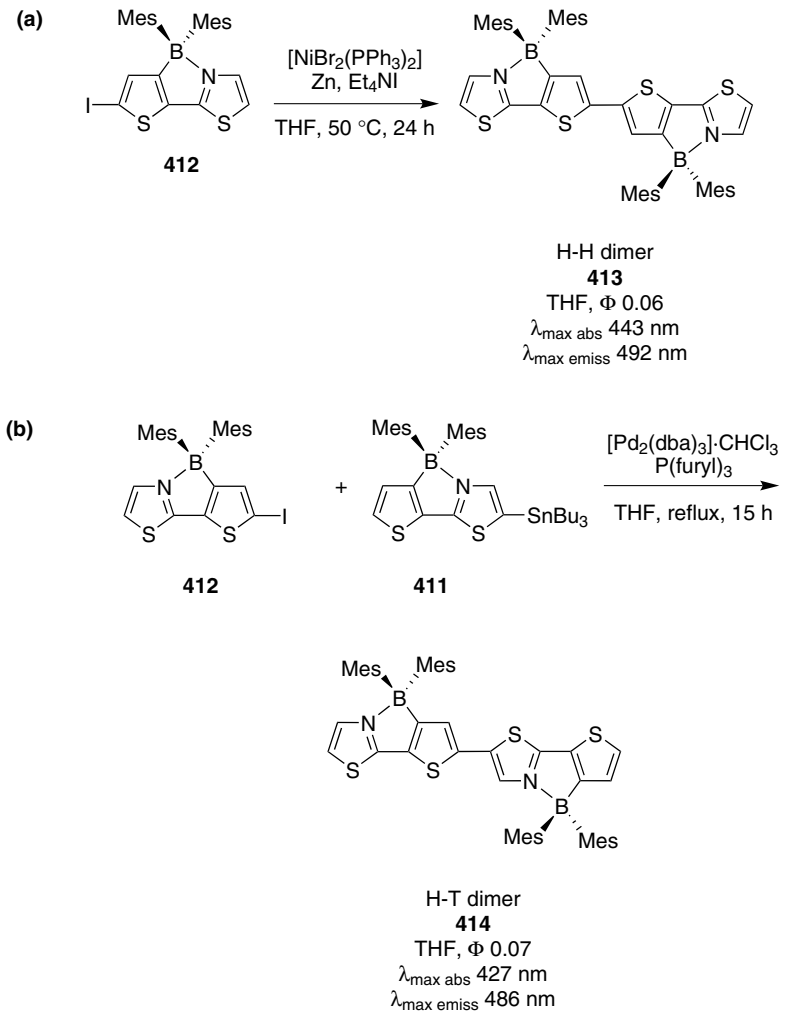


Scheme 32. Synthesis of the dimesityl-boryl substituted thienylthiazole **410**.

Compound **410** can easily be functionalized to the tin **411** or iodo **412** derivatives via the lithiated intermediates. Lithiation occurs regioselectively at the 5-position of the thiazole ring.

The corresponding tin and iodo derivatives can be used as building blocks in metal-catalyzed coupling reactions to prepare extended π-electron systems such as the head-to-head (H-H), head-to-tail (H-T), and tail-to-tail (T-T) dimers **413–415** (Scheme 33). The dimers display red-shifted absorption and emission relative to the monomer. The boryl-substituted thienylthiazoles **410** and **413–415** show weak fluorescence emission in the range 452–492 nm.[313]



Scheme 33. Synthesis of (**a**), head-to-head; (**b**), head-to-tail, and (**c**), tail-to-tail dimers.

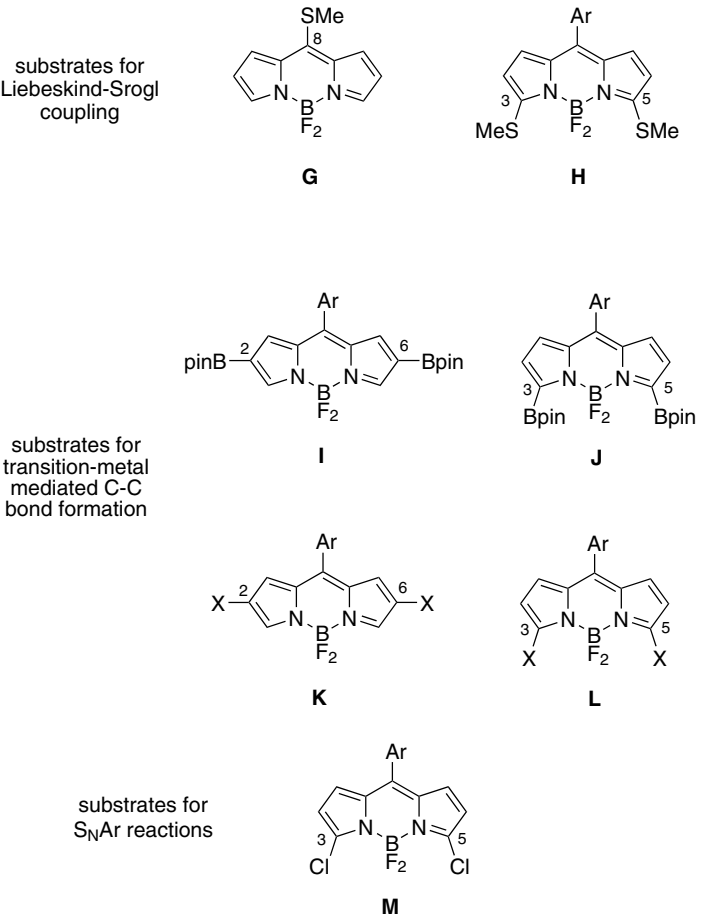
XIV. Conclusion

Modifications of the BODIPY core have reached an advanced stage of development, and there has been tremendous activity in the area even since our 2007 review.[77] The area of BODIPY-syntheses now resembles a jig-saw puzzle that is perhaps 95% complete, but with a few important pieces that have yet to be added. For instance, synthetic methods for BODIPY syntheses were previously dominated by condensation reactions of pyrroles with carboxylic acid or aldehyde derivatives. This situation has shifted markedly due to the emergence of some useful BODIPY synthons that can be elaborated to give dyes that would not be conveniently accessible via condensation processes. These key synthons include derivatives that have: *meso*-*S*-alkyl substituents **G**; 3,5-*S*-alkyl groups **H**; boronate esters **I** and **J**; and, 2,6- and 3,5-halogenated systems **K** and **L**, respectively; 3,5-dichloro substituents **M**. The halogenated systems, for instance, may be functionalized via S_NAr reactions, transition-metal mediated couplings, or directly attached to proteins.

Recent insights into the ways in which BODIPY dyes can react have also broadened the range of speciality dyes that can be prepared. Notable examples of this include modification of the BF_2 substituents, particularly by Ziessel and coworkers who have added many different *C*-substituents,[216,217,314] and cyclic systems incorporating the boron atom as illustrated by work from our laboratories.[315] Similarly, Akkaya's group[160,167] and others[157] have shown the value of Knoevanagel condensations of Me-substituted BODIPY dyes, particularly for syntheses of lipophilic probes that fluoresce in the near-IR region.

Access to near-IR fluorophores has been a long-standing objective in the field, particularly for applications in biotechnology. Significant contributions in this area come from incorporation of extended heterocyclic systems, one excellent example being the "Keio" fluors, e.g. **300h**[262,263] and another is the isoindole-based



systems **258**. O'Shea and coworkers have rejuvenated interest in the aza-BODIPY dyes, which are extremely interesting for the near-IR emission properties.

So, what are the remaining synthetic challenges in the area? Even though there have been some significant breakthroughs in syntheses of *water-soluble* BODIPY dyes (e.g. **104**, **110, 112** and **114**) all the one prepared so far tend to emit well below 600 nm. There is a significant demand in biotechnology for water-soluble dyes that fluoresce brilliantly in the near-IR region, and the BODIPY community had not yet addressed this issue directly. Similarly, there is an unmet need for conveniently accessible, water-soluble cassettes for multiplexing, i.e. that can be excited at one wavelength but fluoresce at conspicuously different wavelengths.

Short wavelength light has poor tissue permeability, may cause photodamage, and is easily swamped by background fluorescence. Conversely, two-photon methods enable of deeper imaging in tissue with minimal photodamage and induction of peripheral cell autofluorescence. However, only a few conventional

fluorescent dyes, such as rhodamines and fluorescein,[316] exhibit satisfactory two-photon cross-sections (TPAs) for practical applications. Efforts to design fluorophores with higher TPAs have not embraced BODIPYs systems as a means to generate probes with higher TPAs than endogenous compounds in cells.[317–323] A recent article by Qian[324] reports the novel long-wavelength BODIPY derivatives **416** and **417** which have considerable TPA cross-sections and strong red emissions. Efficient internal charge transfer processes and donor–acceptor arrangements are important in designing two-photon absorbing molecules. We envisage this could be an area of some interest in the next decade.

$\lambda_{max\ abs}$ 593 nm
$\lambda_{max\ emiss}$ 659 nm
$\lambda_{max\ emiss\ TPE}$ 687 nm
σ 60 GM

Compounds **418–419** are two more examples of BODIPY based systems in which the TPA properties have been studied. The TPA (σ) for these were found to be 48 and 75 GM at 990 nm, corresponding to about 2.4 and 3.7 times that of a reference compound **104** (σ = 20 GM at 920 nm).[318]

Materials research and some aspects of *in vivo* imaging might also motivate more interest in polymer systems based on, or incorporating BODIPY dyes. Several inroads into this type of research have already been made, but the contributions so far lack direct illustration of potential applications of these substances.

$\sigma_{at\ 990\ nm}$ 9 GM

This could be another area of interest. Similarly, dendritic systems such as **419**, seems to be at an early stage of development.

Finally, we envisage that research on BODIPY dyes is set to move into a second era. This will feature syntheses of tailor-made probes to explore issues in biotechnology and materials research that are more sophisticated than simple sensing applications. For instance, we can imagine specialized applications in genomics, directed *in vivo* diagnostics, and synthetic biology that may come to the fore.

38 Supramolecular Chemistry of Pyrrole-Based π-Conjugated Acyclic Anion Receptors

Hiromitsu Maeda

College of Pharmaceutical Sciences, Institute of Science and Engineering, Ritsumeikan University, Kusatsu 525-8577, Japan

PRESTO, Japan Science and Technology Agency (JST), Kawaguchi 332-0012, Japan

I. Introduction

Dimension-controlled organized structures consisting of organic molecules[1–7] have attracted considerable attention, due to their ability to act as potential soft materials[8] such as supramolecular gels[9–12] and liquid crystals.[13–15] Among a variety of noncovalent interactions to form supramolecular assemblies,[16] the electrostatic interaction is a fundamental interaction to form ionic pairs and salts of inorganic and organic species in solution as well as in the bulk (solid and liquid) states. Salts are used as utility materials in biotic systems and in industry. For example, some minerals are essential for life, whereas ionic liquids are used as nonvolatile utility solvents for various reactions. One of the advantages afforded by salts is the combination of numerous positive- and negative-charged species; this is a crucial factor for controlling their properties, such as stability, solubility, and conductivity. Furthermore, the structures and constituents of ionic species also play an important role in determining the properties of ion pairs. In the case of inorganic salts, the number of possible combinations is fairly large, but it is limited because there is less diversity in inorganic species. However, organic ionic species can afford various ion pairs and salts because of the varieties of organic molecules. One of the significant challenges to obtain utility salts consisting of organic ions is in the preparation of fairly stable charged organic species. The charge in organic molecules is usually delocalized and dispersed to several appropriate sites. Charged sites often behave as nucleophilic and electrophilic reaction sites for the corresponding cation and anion species. Based on this background, one of the most efficient strategies to prepare "organic ions" is to combine appropriate receptor molecules with inorganic ions such as spherical metal cations to halide anions. The combination of receptors and inorganic ions can afford a variety of fairly stable organic charged species as receptor–ion complexes.

Of the distinct charged species, cations and anions, the latter negative-charged ions are less "available" than cations. Metal coordination and electrostatic hydrogen bonding are efficient means by which organic molecules and related species can "capture" anions. Metal coordination, however, is often used to compensate for the positive charge(s) of metal cations so as to prevent them from yielding organic anionic species; in addition, the coordinated products are fairly stable because of the characteristic nature of the covalent bond. On the other hand, electrostatic hydrogen-bonding interactions that occur between anions and polarized hydrogen-bonding donor sites are useful for forming various receptor–anion

complexes that exhibit an anion exchange process in equilibrium. For example, in biotic systems, the ClC chloride channels catalyze the selective flow of Cl^- ions across cell membranes, thereby regulating electrical excitation in skeletal muscle and the flow of salt and water across epithelial barriers.[17,18] In 2002, MacKinnon and coworkers presented X-ray structures of two prokaryotic ClC Cl^- channels, wherein the antiparallel subunit defines a selectivity filter in which a Cl^- ion is stabilized by electrostatic interactions with α-helix dipoles and by chemical interaction with NH and OH sites.[19] The antibiotic ristocetin has been known to efficiently and selectively bind amino acid carboxylates.[20,21] At the same time, considerable efforts have been devoted to the development of artificial anion receptors and carriers, and various binding motifs have been synthesized in recent years.[22–37] Among the various artificial host molecules reported thus far, electronically neutral π-conjugated planar receptors form "planar anions" with spherical halide anions; negative-charged planar units are essential building units for supramolecular assemblies and functional materials by combination with appropriate countercations.

Among the building subunits of planar anion receptors, pyrrole is well-known as a π-conjugated aromatic heterocyclic molecule[38] present not only in biotic dyes such as heme and chlorophyll but also in artificial porphyrin derivatives.[39] In contrast to the relatively "inert" benzene, pyrrole has an excess of electrons (six) as compared to the number of atoms (five) in the framework. Therefore, pyrrole moieties are reactive and are stabilized by, for example, incorporation into aromatic macrocycles such as porphyrins or substitution by electron-withdrawing moieties. Pyrrole exhibits "duality" from its nitrogen moiety, which behaves both as a hydrogen-bonding acceptor or a metal coordination ligand due to the N site (Figure 1a) and as a hydrogen-bonding donor due to the NH site (Figure 1b). As the π-planes of the pyrrole unit also enable effective interactions that yield stacking assemblies and metal complexes as π-ligands (Figure 1c), pyrrole rings can act as potential building subunits forming supramolecular nanoscale structures. However, pyrrole rings are often observed as components of the preorganized macrocycles, porphyrins, and their analogs, wherein pyrrole N sites are located on the inside of fairly rigid closed rings and consequently cannot exhibit their potential as interaction sites. Therefore, new aspects of pyrrole rings can be revealed by the synthesis of new *acyclic* oligopyrrolic systems which form functional supramolecular materials and realize new properties and phenomena.

The pyrrole NH site acts as an efficient hydrogen-bonding donor. In fact, thus far, macrocycles consisting of pyrroles have been particularly attractive because they behave as essential binding units due to the presence of polarized NH sites, as seen in calixpyrroles (e.g. calix[4]pyrrole **1**)[40–43] and expanded porphyrins[44–47] including diprotonated sapphyrins (e.g. β-alkyl-substituted sapphyrin **2**)[48–50] and

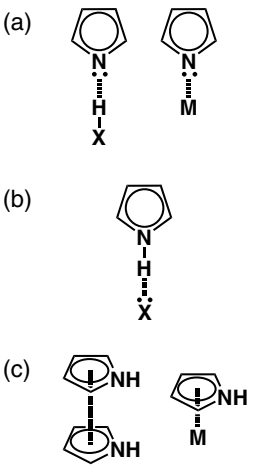

Figure 1. Possible interactions of pyrrole as (a) a hydrogen-bonding acceptor and a metal coordination site, (b) a hydrogen-bonding donor, and (c) a π-plane for stacking and metal coordination. The structures with an "aromatic circle" are used to represent various types of pyrrole units.

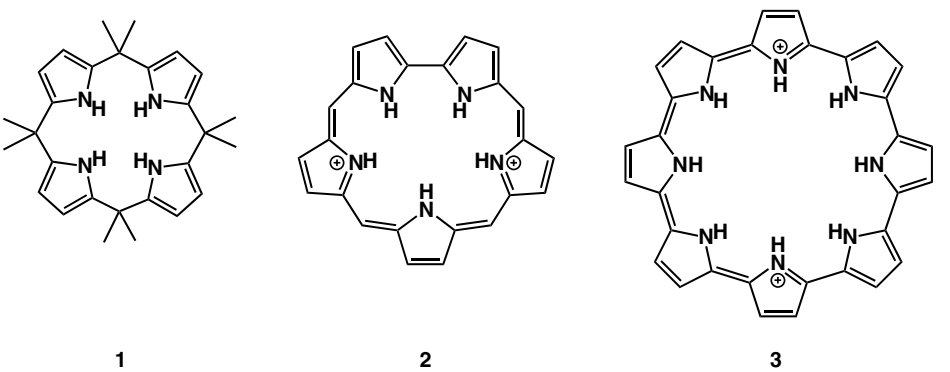

Figure 2. Representative cyclic oligopyrrole-based anion receptors: calix[4]pyrrole **1**, protonated sapphyrin **2**, and cyclooctapyrrole **3**. Expanded porphyrins **2** and **3** are represented as their skeleton forms.

cyclooligopyrroles (e.g. cyclooctapyrrole **3**)[51] (Figure 2). Multiple NH sites in the macrocycles cooperatively and efficiently bind a desired anion to form receptor–anion complexes. Although less extensively studied, acyclic pyrrole derivatives have potentially even greater advantages.[28,32,52,53] This is because they can form complexes with anions via the synthetic attachment of additional recognition units for hydrogen bonding, metal coordination, and van der Waals interaction, or simply because they easily form various macrocyclic systems. The receptors with

linear geometries are often required to change their conformation and to fit the volume and shape of the negatively charged species. Therefore, in the case of linear receptors, the essential factors that determine the binding affinities for guest species would be the existence of temporal preorganization along with other factors such as the strength of the induced effect required to polarize the association site(s) and the steric and electrostatic repulsions by the peripheral substituents. The balance between flexibility and rigidity is a key issue for controlling the anion-binding behavior of acyclic oligopyrroles — essentially, to form supramolecular structures with and without associated anions. The variety of linear oligopyrroles available may provide potential materials in the realm of supramolecular chemistry.

On the basis of the above chemistry, this chapter describes the behavior and properties of linear oligopyrrole systems as anion-binding receptors and the study of their supramolecular and materials chemistry which has recently been initiated. In sharp contrast to closed systems such as regular porphyrins, the characteristics of open-chain oligopyrroles that constitute the building subunits of supramolecular assemblies are significantly correlated with the nature of the pyrrole ring itself. As a postscript to this introductory section, acyclic receptors comprising indole moieties, which are "analogs" of pyrrole rings, are also fascinating and are being actively investigated; however, this chapter does not discuss the chemistry of indole-based anion receptors, because they were recently reviewed by Gale.[54]

II. Guanidinocarbonyl- and Amidopyrrole-Based Anion Receptors

The pyrrole ring itself acts as an anion receptor because of its polarized NH site (Figure 3). Obviously, it is not an efficient anion receptor in solution, wherein the binding constant (K_a) of 2,5-dimethylpyrrole for F^- in CD_2Cl_2 was estimated to be *ca*. 9 M^{-1},[40] due to the absence of supplementary interaction sites and cooperative binding sites of multiple pyrrole rings. However, pyrrole can form an anion complex in the crystal state; Gale and coworkers reported the first single-crystal X-ray structure of a pyrrole–anion complex, based on single crystals fabricated by the

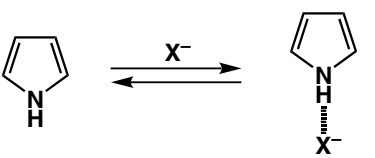

Figure 3. Anion-binding mode of pyrrole.

addition of a tetramethylammonium salt of Cl^- to pyrrole as a solvent.[55] Although anion-responsive monomeric pyrrole derivatives are interesting, this chapter focuses on the details of oligopyrrolic systems.

A. Guanidinocarbonylpyrrole-Based Anion Receptors

The representatives of "supplementary" interaction sites for pyrrole rings are guanidine and amide NH moieties; guanidine has positively charged and polarized NH sites,[35,56,57] whereas the amide NH is well-known as a polarized hydrogen-bonding donor site due to the neighboring carbonyl unit.[32,34] In 1999, Schmuck reported 2-(guanidinocarbonyl)pyrrole **4**, which shows the selective binding of *N*-acetyl-α-amino acid carboxylates in aqueous media (Figure 4a).[58] In DMSO-d_6, **4** associates with acetate ($CH_3CO_2^-$) with a binding constant (K_a) > 10^6 M^{-1}. Even in 40% water/DMSO-d_6, **4** binds $CH_3CO_2^-$ and *N*-acetyl-L-alanine carboxylate at 2790 and 770 M^{-1}, respectively. The corresponding phenylalanine carboxylate is bound much stronger (1700 M^{-1}) than the carboxylates including alanine, tryptophan (810 M^{-1}), and lysine (360 M^{-1}) because of effective π-stacking between the phenyl group of phenylalanine and the acylguanidinium unit of **4**.[58] On the basis of the carboxylate binding of guanidinocarbonylpyrrole derivatives, the receptors bearing a carboxylate unit would self-assemble to form dimer and oligomer structures. In fact, 5-(guanidinocarbonyl)-1*H*-pyrrole-2-carboxylate **5** (Figure 4b) is converted to an intermolecular self-assembled dimer, without the formation of dispersed oligomers, in DMSO. The dimer is very stable, as it shows the expected

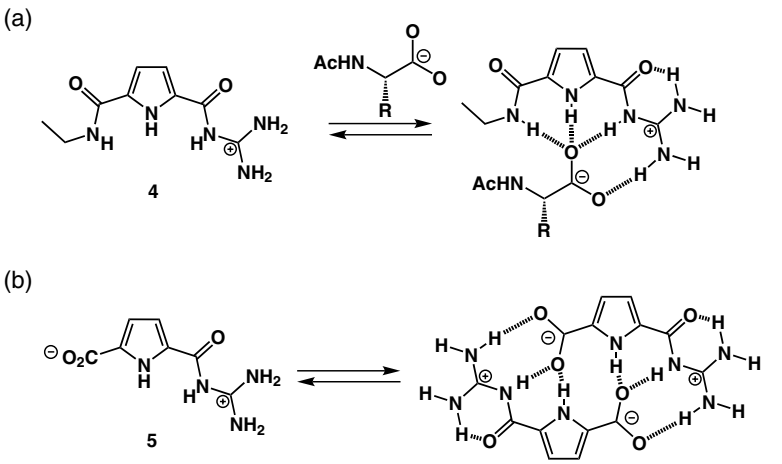

Figure 4. (a) Amino acid carboxylate binding of guanidinocarbonylpyrrole **4**[58]; (b) self-assembled dimerization of guanidinocarbonylpyrrole **5**.[59]

dimerization constant of *ca*. 10^{12} M^{-1}.[59] Schmuck summarized the various derivatives composed of the guanidinocarbonylpyrrole moiety in a review in 2006,[60] and therefore this section covers only oligopyrrolic systems bearing the guanidinocarbonyl moiety.

Schmuck *et al*. reported that self-assembled molecules formed with bispyrrole zwitterions bearing both carboxylate and guanidinium moieties (**6–8**, Figure 5a).[61,62] In DMSO, the zwitterion **6** forms a specifically folding monomer in which the carboxylate group on one end of the molecule interacts with the guanidinocarbonylpyrrole moiety on the other end (Figure 5b). In sharp contrast, the zwitterion **7**, which has a shorter spacer than **6**, cannot form such a folding structure. The concentration-independent behavior of **6** excludes the possibility of dimerization and higher oligomerization by self-assembly.[61] Another zwitterion, **8**, also forms a self-folding structure in methanol.[62]

Apart from zwitterions such as **6–8**, in DMSO-d_6 and DMSO-d_6/D_2O mixtures (0.5–50 mM), bis-zwitterion **9** (Figure 6a), which has a long oxyethylene spacer, exhibits the formation of a self-folding monomer and a self-assembled dimer in concentration-dependent equilibrium (Figure 6b). This is the first example of a homodimerization based solely on a hydrogen-bond-enforced ion pair formation, which leads to stable nanometer-sized discrete particles in DMSO–water mixtures

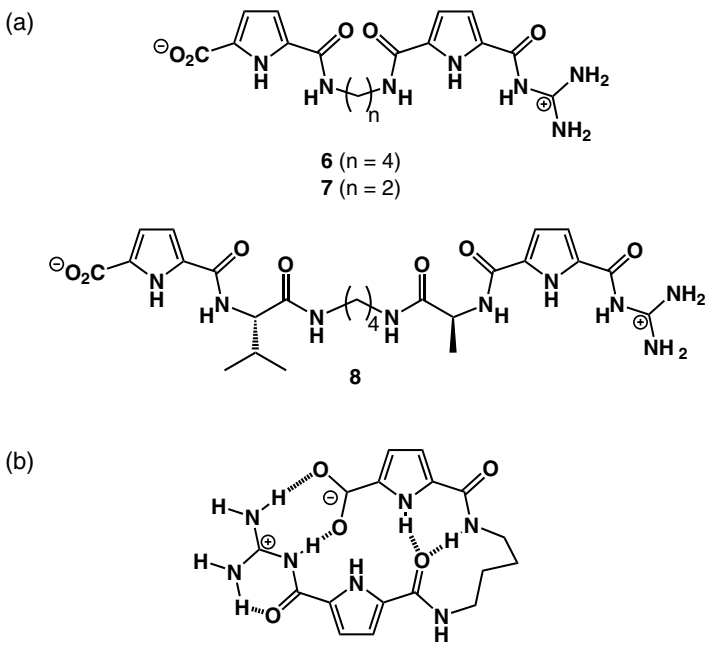

Figure 5. (a) Guanidinocarbonylpyrrole-based zwitterions **6–8**[61,62]; (b) self-folding mode of **6**.[61]

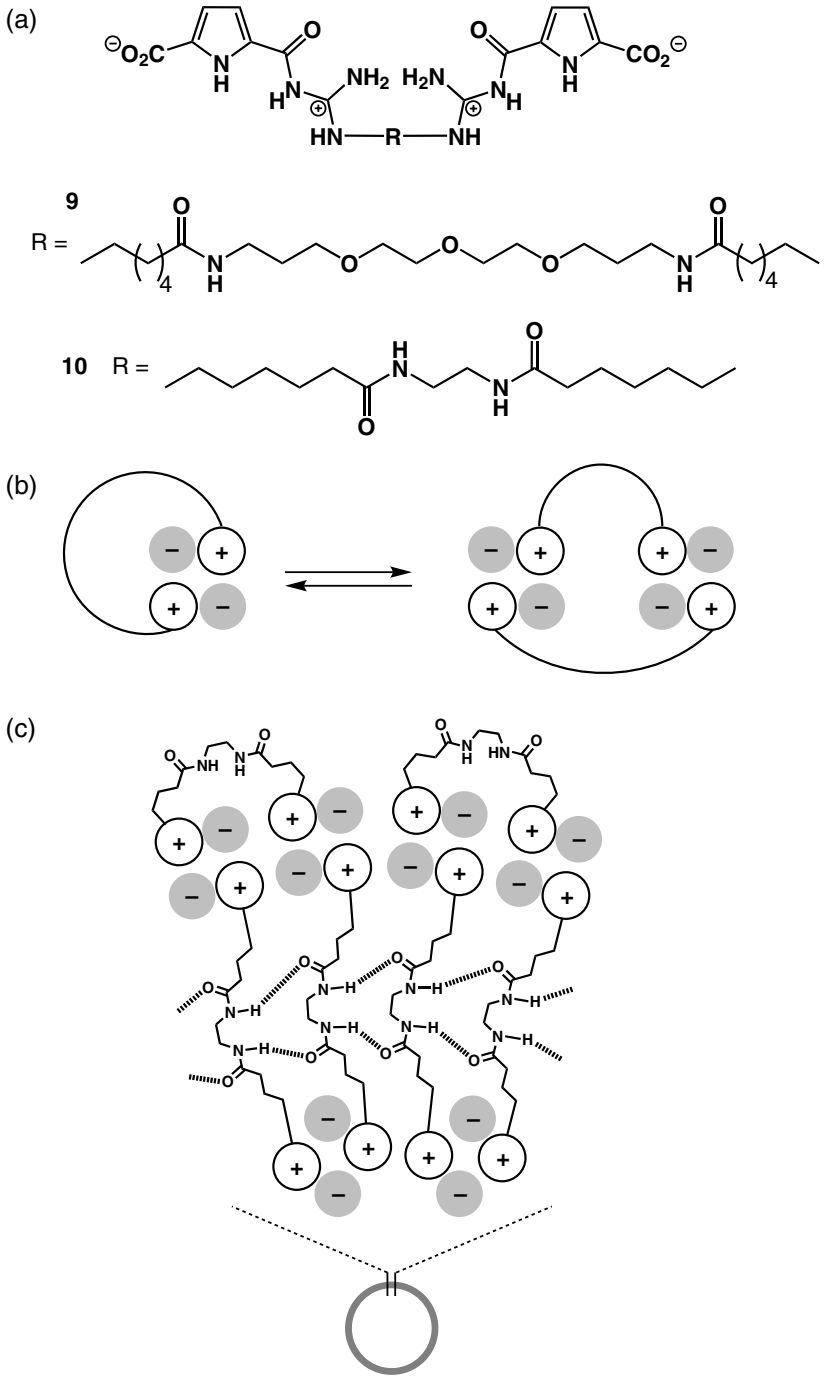

Figure 6. (a) Guanidinocarbonylpyrrole-based bis-zwitterions **9** and **10**[63,64]; (b) schematic representation of the self-folding monomer and self-assembled dimer of bis-zwitterions[63,64]; (c) schematic representation of self-assemblies to form vesicles.[64]

even without any structural bias within the molecule. The formation of nanometer-sized discrete particles by self-assembly was confirmed by DOSY NMR, FAB-MS, dynamic light scattering (DLS), and small-angle neutron scattering (SANS) studies.[63] Furthermore, in DMSO (0.5–50 mM), bis-zwitterion **10** (Figure 6a), wherein two charged binding sites are bridged by a bisamide lipophilic spacer, forms larger vesicular structures of *ca*. 150 nm under concentrated conditions (Figure 6c) along with a monomer and a dimer. The formation of larger aggregates is verified by atomic force microscopy (AFM) as well as DLS and SANS.[64]

One of the efficient binding motifs for guest species, especially trianions, is a tripodal host molecule based on 1,3,5-trisubstituted benzene.[65] Schmuck and Schwegmann also prepared a tripodal guanidinocarbonylpyrrole receptor **11** (Figure 7a), which binds trianionic species such as trimesic acid tricarboxylate and citrate with unprecedented high association constants of $>10^5$ M^{-1} in pure aqueous solutions.[66] This result suggests that the receptor **11** is one of the most efficient tricarboxylate receptors in aqueous media ($K_a = 3.4 \times 10^5$ and 1.6×10^5 M^{-1} for

(a)

trimesic acid tricarboxylate and citrate, respectively, as indicated by UV-visible spectral changes), because of the formation of an anion-binding complex like a "molecular flytrap," as elucidated from ^{1}H NMR and theoretical studies (Figure 7b).[66] Furthermore, Schmuck and Schwegmann used the tripodal receptor **11** as a "naked eye" sensor assembly for an indicator displacement assay with carboxyfluorescein for the selective detection of citrate.[67]

Zwitterionic guanidinocarbonylpyrrole can form supramolecular polymers[2,5] using additional metal coordination interactions.[68–70] Schmuck and coworkers reported the assembly behavior of terpyridyl-appended zwitterion **12** (Figure 8a)[71]; **12** dimerizes into hydrogen-bonding ion pairs in aqueous solution and, upon the addition of Fe(II), forms single-stranded supramolecular polymers in DMSO (Figure 8b). Polymerization by Fe(II) complexation was initially detected from DOSY NMR spectral changes and also from AFM; on a highly oriented pyrolytic graphite (HOPG) substrate, highly ordered molecular adlayers of individual polymer strands with a length of several hundred nanometers were observed.[71]

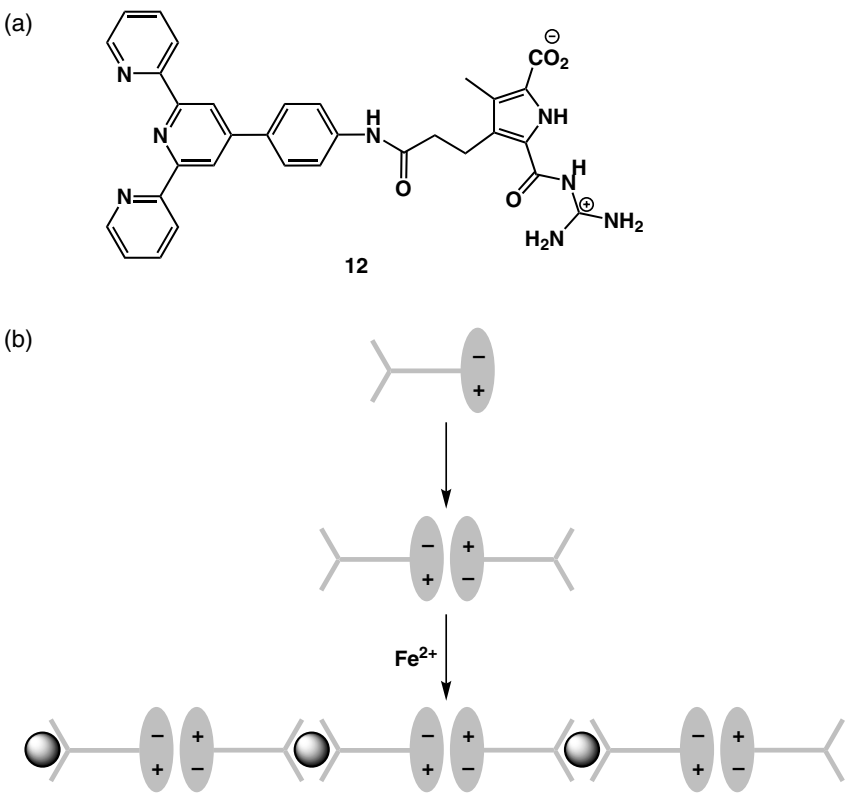

Figure 8. (a) Terpyridine-guanidinocarbonylpyrrole hybrid **12**[71]; (b) formation pathway for supramolecular polymers by self-assembled dimerization and metal coordination.[71]

B. Amidopyrrole-Based Anion Receptors

In 2001, Gale *et al*. reported 2,5-diamidopyrroles and 2-amidopyrroles (**13**–**16**, Figure 9a) as simple anion-binding receptors.[72,73] Amidopyrroles provide convergent binding sites (Figure 9b), which enable them to efficiently bind anions, especially oxoanions, in CD_3CN and 0.5% H_2O/DMSO. For example, **13** shows a K_a value of 2500 M^{-1} for benzoate in CD_3CN (Table 1).[72,73] Because Gale has summarized the various derivatives composed of the amidopyrrole moiety,[74] this section focuses mainly on the amidopyrrole-based oligopyrroles.

Gale *et al*. prepared phenylene-bridged amidopyrrole dimers **17** and **18** (Figure 10a), which have chlorine moieties at β positions to enhance the polarity of the pyrrole NH.[75] Crystals of **17** and **18**, which were obtained by slow evaporation of CH_3CN solutions in the presence of excess tetrabutylammonium fluoride (TBAF), exhibit the formation of interlocked chains of deprotonated **17** and **18**

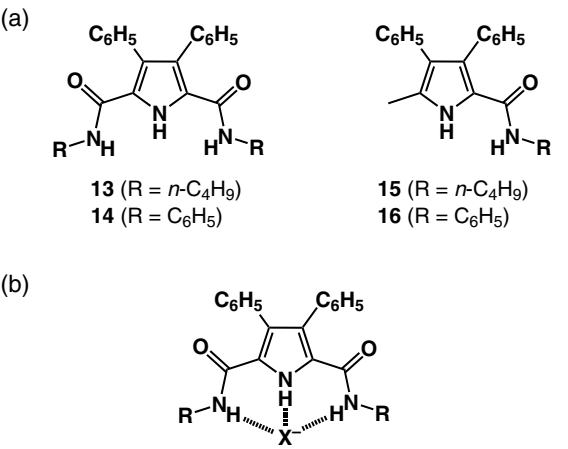

Figure 9. (a) Amidopyrroles **13**–**16**[72,73]; (b) anion-binding mode of amidopyrroles **13** and **14**.[72,73]

Table 1. Anion-binding constants (K_a, M^{-1}) of **13**–**15** upon the addition of anions as TBA salts in CD_3CN (**13** and **15**) and 0.5% H_2O/DMSO (**14**). Data taken from Refs. 72 and 73.

Anion	**13**	**14**	**15**
F^-	85	74	134
Cl^-	138	11	28
Br^-	<10	<10	<10
$H_2PO_4^-$	357	1450	89
$C_6H_5CO_2^-$	2500	560	202

anions via N–H···N hydrogen bonds (Figure 10b). In the solid state, the two half molecules are essentially planar, while the complete molecule is twisted such that the angle between the pyrrole rings is 61.79(5)°.[75] Furthermore, single-crystal X-ray analysis of the Cl^- complex of *p*-phenylene-bridged **18** as a TBA salt shows a [1 + 2]-type binding mode.[76] The molecular structures of protonated and Cl^- complexes were also supported by theoretical studies by Navakuhn and Ruangpornvisuti.[77,78]

Incorporation of additional pyrrole NH units to the monomeric amidopyrroles **13** and **14** would enhance the affinity of anion binding and modify the binding selectivity. Sessler *et al*. prepared amide-bridged tripyrrolyl derivative **19** (Figure 11a).[79] In the solid state, tripyrrolyl **19** forms intermolecular hydrogen bonds as elucidated from single-crystal X-ray analysis. In DMSO-d_6, **19** shows anion binding for $H_2PO_4^-$ and $C_6H_5CO_2^-$ with K_a values of 5500 and 10 300 M^{-1}, which are augmented compared to those of **14** (1450 and 560 M^{-1}, respectively), whereas **19** shows no binding behavior for Cl^-, Br^-, and HSO_4^-.[79] Sessler *et al*. also replaced the core pyrrole ring of **19** with pyridyl and phenyl moieties to afford

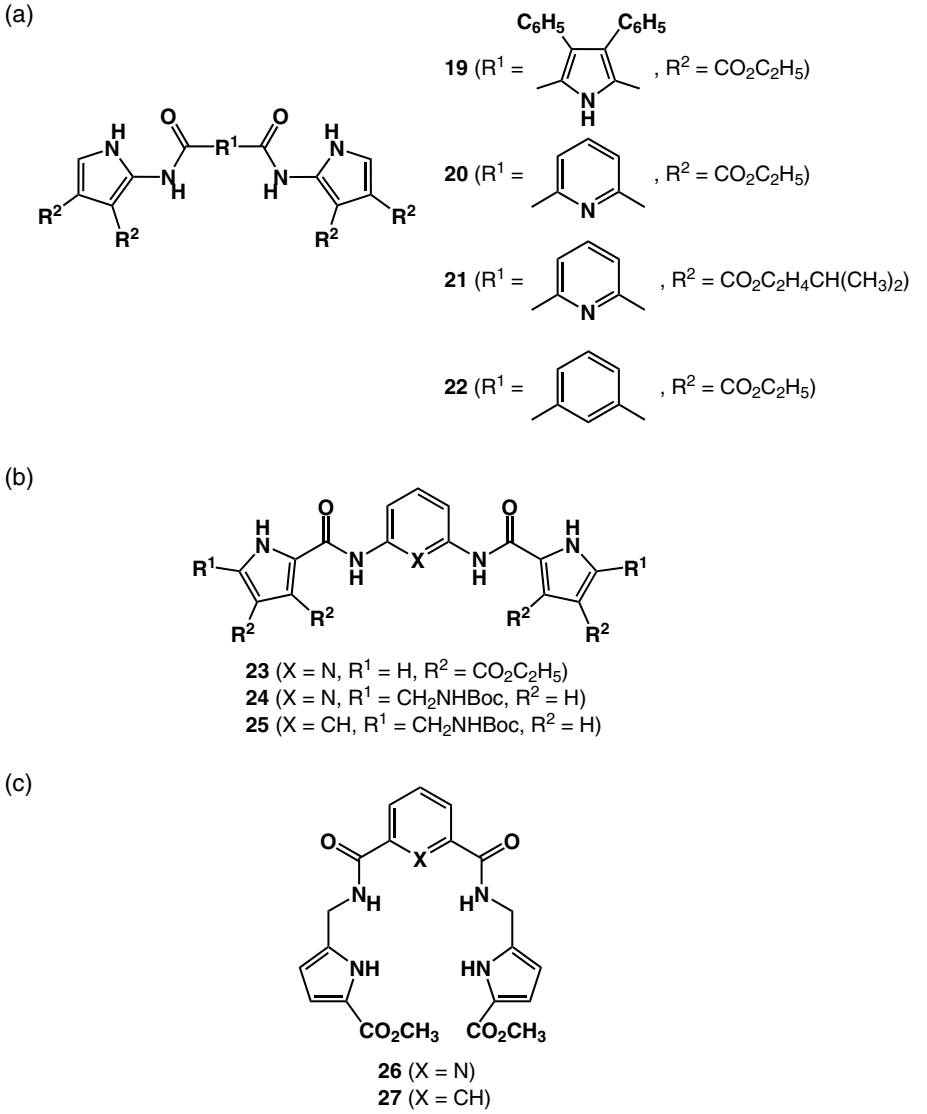

Figure 11. (a–c) Bisamidopyrrole-based anion receptors **19**–**27**.[79–81]

bispyrrole derivatives **20**–**22** (Figure 11b).[80] The solid-state structure of **20** shows a slightly distorted conformation with intramolecular hydrogen bonding, for example between the pyrrole-NH and amide-C=O. The bispyrroles **20**–**22** exhibit anion binding in nonpolar solvents such as CH_2ClCH_2Cl (Table 2), wherein **20** binds $CH_3CO_2^-$ ($K_a = 19\,000\ M^{-1}$), while these receptors show no interactions with Cl^- and Br^-. On the other hand, **23**, an isomeric form of **20** by changing the amide

linkages, binds Cl^- ($K_a = 805\ M^{-1}$) under similar conditions (Table 2).[80] Furthermore, Cheng and coworkers reported the similar receptors **24** and **25** as reference molecules of **26** and **27** (Figure 11c), which have sp^3 CH_2 moieties between pyrrole rings.[81] Among **24**–**27**, **26** binds anions more efficiently in DMSO-d_6, wherein K_a values for F^- are 102 (**24**), 73 (**25**), 1266 (**26**), and 138 (**27**) M^{-1}. In the cases of **24** and **25**, bulky Boc groups at the terminal positions inhibit the formation of U-type structures, which are appropriate for efficient anion binding (Table 3).[81]

In 2004, Cheng and coworkers prepared 1,2-pheylene-bridged bisamidopyrrole **28** (Figure 12), which, using intermolecular hydrogen bonding, forms a CH_3OH-assisted helical assembly in the crystal from CH_3OH/EtOAc and a knot-like dimer structure in the crystal from $CHCl_3$/DMSO or H_2O/DMSO.[82] In DMSO-d_6, **28** binds anions with K_a values of 320, <10, and 100 M^{-1} for F^-, Cl^-, and $H_2PO_4^-$, respectively.[82] Sun and coworkers modified the skeleton structure of **28** to provide the derivatives **29**–**33** from pyrrole-2-carbonyl chloride and various

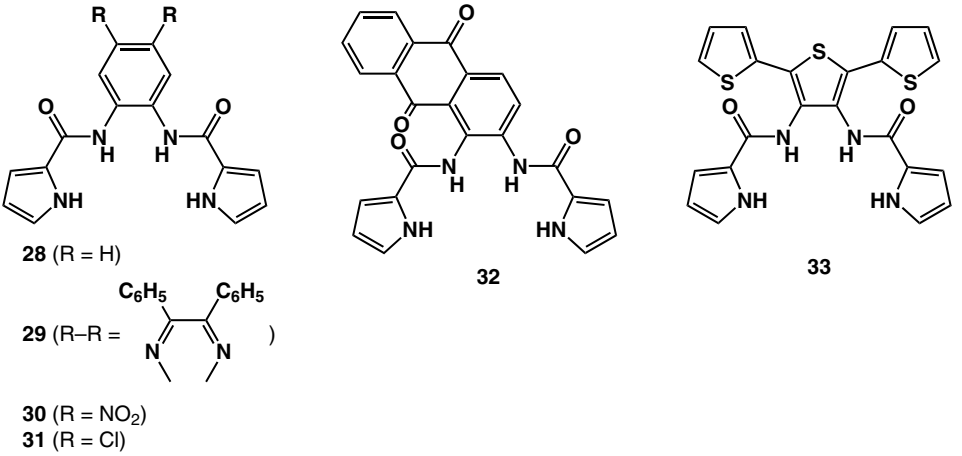

Figure 12. Bisamidopyrrole-based anion receptors **28**–**33**.[82–84]

diamino-substituted aryl units.[83] In CH_3CN/H_2O (9:1, v/v), both **29** and **30** respond to only CN^- among the 12 anions, including F^-, Cl^-, Br^-, I^-, NO_3^-, $CH_3CO_2^-$, $C_6H_5CO_2^-$, $HP_2O_7^{3-}$, $H_2PO_4^-$, HSO_4^-, and ClO_4^-. Upon addition of CN^-, the absorption bands of **29** at 291 and 378 nm decrease while three new bands at 299, 372, and 428 nm appear. Concomitantly, the fluorescence maximum at 425 nm is shifted to 554 nm. The binding constant for [1 + 2]-type stoichiometry was estimated as log $K = 5.91$.[83] Similarly, **30** shows absorption spectral changes with log $K = 9.20$. The colorimetric response of **30** to CN^- persists up to 50% water content. As seen in the ^1H NMR spectral changes of **30** in DMSO-d_6, formation of a CN^- adduct, a cyanohydrin, enables it to exhibit the sensing behavior to this anion. On the other hand, **29** shows an interaction between pyrrole moieties and CN^-.[83] A detailed examination of the receptors **29**–**33** for interaction with anions in CH_3CN or DMSO suggests efficient sensing behaviors for anions due to association, deprotonation, and cyanohydrin formation (Table 4).[84]

In 2007, Anzenbacher and coworkers demonstrated that the tripodal sensor molecules **34**–**37**, based on 1,3,5-triaminomethylbenzene (Figure 13), can bind and sense anions in hydrophilic polymer matrices, despite their inability to bind anions in water.[85] ^1H NMR titration suggests the formation of [1 + 1] complexes with C_3 symmetry. The anion-binding affinities of **35**–**37** follow the order of $H_2PO_4^- > HP_2O_7^{3-} > CH_3CO_2^- \gg Cl^- > Br^-$ due to the K_a (M^{-1}) range of 3.8–5.0 × 10^6 for F^-, 10–100 for Cl^-, 1.0–5.0 × 10^6 for $CH_3CO_2^-$, 2.3–5.0 × 10^6 for $H_2PO_4^-$, and 1.0–5.0 × 10^6 for $HP_2O_7^{3-}$ in DMSO. Less selectivity of these receptors **35**–**37** for anions compelled an examination of the possibility of sensor arrays including other anion receptors; the arrays detect the changes in the fluorescence intensity

Table 4. Equilibrium constants (K_a, K_d, and K_c,[a] M^{-1}) of **29**–**33** upon the addition of anions as TBA salts in CH_3CN (**29**, **30**, and **33**) or DMSO (**31** and **32**). Data taken from Ref. 84.

III. Dipyrrins and Their Analogs as Anion Receptors

A. Dipyrrin- and Dipyrromethane-Based Anion Receptors

Dipyrrins (dipyrromethenes) **38**, which are half-structures of porphyrins, are well-known as partial structures of bile pigments consisting of two pyrroles with an sp^2-*meso* position; they are essential π-conjugated bidentate monoanionic ligands for metal ions in natural and artificial systems.[86,87] Dipyrrins have only one pyrrole NH; therefore, the protonated form of dipyrrins can act as an anion receptor (Figure 14a). As observed in the pioneering work by Fischer and Orth, β-alkyl-substituted dipyrrins were prepared and were "stored" as hydrohalogenated salts[38]; however, there have been few examples of protonated dipyrrins as anion receptors, whose anion complexes are usually observed in solid-state structures. In 1978, Sheldrick and coworkers reported the first crystal structure of a protonated dipyrrin, which was characterized as a Br^- salt **39** (Figure 14b).[88] Sessler *et al*. demonstrated a similar anion complex as a Cl^- salt of protonated **40**[89]; in CH_3CN, the K_a values of **40** and **41**, which are protonated by HI, for Cl^- as a TBA salt are 8.8×10^5 and 3.0×10^5 M^{-1}, respectively, as determined from isothermal titration calorimetry (ITC) titrations (Figure 14c).[89] Dolphin and coworkers reported anion complexes of *meso*-aryl-substituted dipyrrin as protonated forms **42** and **43**.[90] Based on the conformation with two pyrrole rings facing the "outside," perfluorophenyl dipyrrin forms [2 + 1 (= receptors + anion)] complexes with dianion $ZnBr_4^{2-}$ and $ZnCl_4^{2-}$ (**42**) in the solid state, whereas the dipyrrin forms 1D supramolecular chain structure with Br^- (**43**) (Figure 14d). This is in sharp contrast to the cases of **39** and **40**, where two pyrrole NHs in the corresponding dipyrrin molecule cooperatively bind an anion.[90]

The flexibility observed in the pyrrole inversion upon protonation might be one of the reasons that the anion-binding chemistry of dipyrrins has not been well investigated. In contrast to dipyrrins, dipyrrinones such as **44**, where one of the pyrrole α positions is oxidized (Figure 15), can behave as neutral bidentate anion receptors. The dipyrrinone **44** binds anions with the binding constants (K_a) of 122, <10, 94, and 1680 M^{-1} for Cl^-, Br^-, NO_3^-, and HSO_4^-, respectively, in $CDCl_3$.[91] The preference for HSO_4^-, as compared to other anions, is due to the additional interaction of the amide-oxygen of **44** and protonic OH of the anion; this is also revealed by single-crystal X-ray analysis of **44**·HSO_4^-.[91]

Dipyrromethanes comprising two pyrrole rings bridged by an sp^3-*meso* carbon can be used as building units for π-conjugated porphyrin-related macrocycles

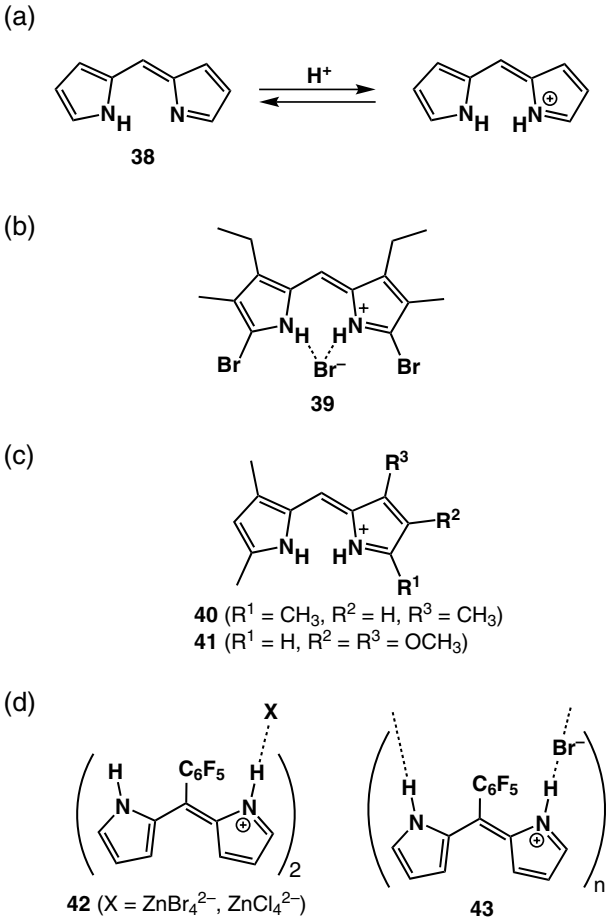

Figure 14. (a) Skeleton structure of dipyrrin (dipyrromethene) **38**; (b) first structure-solved Br^- complex of protonated dipyrrin **39**[88]; (c) protonated dipyrrins **40** and **41**[89]; (d) anion complexes of *meso*-perfluorophenyl dipyrrin in a protonated form (**42** and **43**).[90]

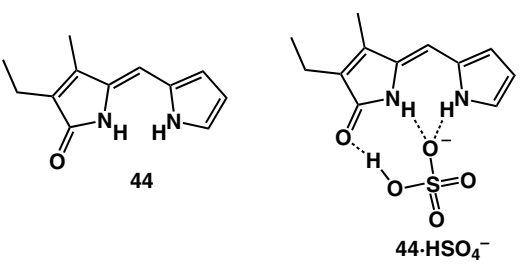

Figure 15. Dipyrrinone **44** and HSO_4^- complex.[91]

as well as dipyrrins, as discussed above. Dipyrromethanes can also be considered as half-structures of calix[4]pyrroles; from the weak cooperative interactions of pyrrole NH, due to the open-chain structures, the anion-binding properties of dipyrromethane seem fairly less significant. However, supplementary interaction sites would enhance the binding affinities for anions, as observed in the monopyrrolic anion receptor systems. Gale and coworkers reported the synthesis of 2,2-bisamidodipyrrolylmethanes: less stable **45** and **46** and relatively stable **47**–**49** and hemiamide derivative **50** (Figure 16).[92,93] Single-crystal X-ray analysis of **45**–**49** and hemiamide **50** reveals the formation of various hydrogen-bonding assemblies using pyrrole- and amide-NH sites and amide-CO moieties. Compounds **45**–**50** can bind, for example, F^- with K_a values of 8990, 7560, 124, 89, and 429 M^{-1}, respectively, in 5% H_2O/DMSO-d_6 and 1450 M^{-1} in 0.5% H_2O/DMSO-d_6 (Table 5).

$H_2PO_4^{-c}$	234	20	—	—	—	—

[a]No significant shift.
[b]An adequate fit could not be obtained.
[c]Measured in 25% water/DMSO-d_6.

Significantly, **45** shows F^- and $H_2PO_4^-$ binding (114 and 234 M^{-1}) even in the extremely competitive solvent mixture 25% H_2O/DMSO-d_6.[92,93] Efficient binding for $H_2PO_4^-$ is also supported by DFT geometry optimization to show that the receptor adopts a cleft conformation wherein the receptor binds to two oxygen atoms in $H_2PO_4^-$, each by hydrogen-bonding with the pyrrole- and amide-NH sites.[92,93]

Another strategy to enhance the binding affinities of dipyrromethanes is formation of charge transfer (CT) complexes. Jiang and coworkers examined the complexation between dipyrromethanes **51**–**55** (Figure 17a) and TCNQ in CH_3CN/H_2O (1:1, v/v)[94]; TCNQ complexes of **52**–**55** do not show any changes in color and absorption spectra from the addition of anions, whereas **51**·TCNQ can serve as a highly selective colorimetric sensor, from blue to pale purple, for anions, especially PO_4^{3-} and CO_3^{2-}. In this case, anion-binding and sensing motifs are quite different — presumably *meso*-hydroxymethyl units for binding and electron-rich properties, essential to formation of CT complexes, for sensing.[94] On the other hand, Sessler *et al*. examined the anion-binding properties of **52** in a nonpolar solvent without electron-deficient components[95]; the K_a values in CD_2Cl_2 are 2100, 110, 19, <10, <10, 310, 11, and <10 M^{-1} for F^-, Cl^-, Br^-, I^-, HSO_4^-, $H_2PO_4^-$, NO_3^-, and ClO_4^-.[95] Furthermore, the incorporation of bulky units at the *meso* position would hinder the rotational mobility of the pyrrole moieties and thus increase the stability of anion complexes. In fact, Mlinarić-Majerski and coworkers prepared adamantane-based dipyrromethanes **56**–**59** (Figure 17b), which show greater K_a values for anions (e.g. 80 M^{-1} for Cl^- with **56**) than *meso*-phenyldipyrromethane **60** (e.g. 22 M^{-1} for Cl^-) in $CDCl_3$.[96] F^- binding of, especially, "dimers" **57** and **59** includes slightly complicated [2 + 1], [1 + 1], and [1 + 2] modes (Table 6).[96] Attachment of a chromogenic moiety to dipyrromethane is another method for exhibiting anion sensing. Chauhan *et al*. prepared 1-arylazo-substituted dipyrromethanes (**61**–**64**, Figure 17c), which bind anions with K_a values of, for example, $>10^6$ M^{-1} for F^- with **64** in DMSO (Table 7).[97] Compound **64** shows a dramatic color change from orange to blue by F^- binding corresponding to the absorption changes from λ_{max} = 438 nm to λ_{max} = 575 nm.[97]

Denekamp, Suwinska, Eichen, and coworkers reported anion-binding behavior of simple tripyrrole molecule **65** (Figure 18).[98] Tripyrrolemethane **65** shows efficient [1 + 1] and [1 + 2] F^- binding in CD_3CN (K_1 = 41 000 M^{-1} and K_2 = 17 000 M^{-1}) and wet DMSO-d_6 (K_1 = 5000 M^{-1} and K_2 = 2000 M^{-1} in 0.25% D_2O/DMSO-d_6; K_1 = 1400 M^{-1} and K_2 = 1000 M^{-1} in 1% D_2O/DMSO-d_6; K_1 = 220 M^{-1} and K_2 = 200 M^{-1} in 5% D_2O/DMSO-d_6). Compound **65** exhibits [1 + 1] binding for $H_2PO_4^-$ with K_a values of 300, 60, <50, and <50 M^{-1} in CD_3CN, 0.25%, 1%, and 5% D_2O/DMSO-d_6. The addition of halide anions as TBA salts to **65** result in

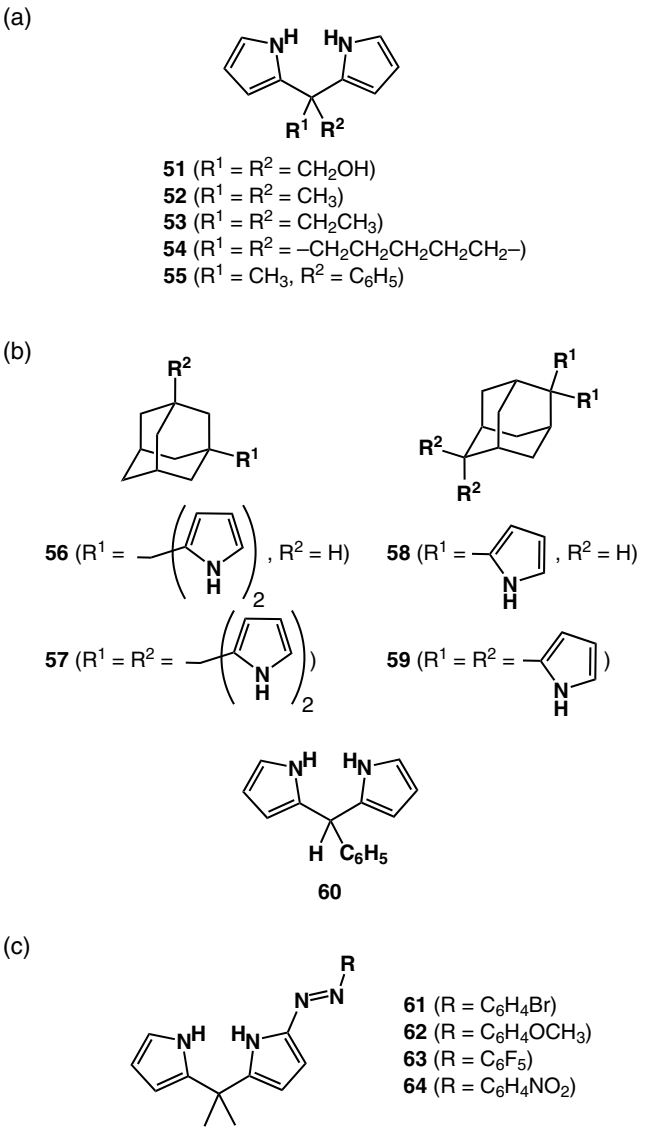

Figure 17. (a) *Meso*-disubstituted dipyrromethanes **51**–**55**[94,95]; (b) adamantane-based dipyrromethanes **56**–**59** and *meso*-phenyldipyrromethane **60** as a reference[96]; (c) 1-arylazo-substituted dipyrromethanes **61**–**64**.[97]

significantly smaller guest-induced shifts in the ^{1}H NMR spectra. Furthermore, single-crystal X-ray analysis of the Br^- complex of **65** reveals the formation of six crystallographically independent structures, some of which use the pyrrole β-CH site for Br^- binding.[98]

Table 6. Anion-binding constants (K_a, M^{-2}, M^{-1}, and M^{-2}, for 2:1, 1:1, and 1:2 binding) of **56–60** upon the addition of anions as TBA salts in $CDCl_3$ (F^-, Cl^-, Br^-, and $H_2PO_4^-$) and CD_3CN (HSO_4^-). Data taken from Ref. 96.

B. Dipyrrin- and Bipyrrole-Based π-Conjugated Systems

The anion-binding properties of a directly bridged bispyrrole, bipyrrole **66** (Figure 19a), were also examined by Sessler *et al.*[99] Bipyrrole **66** shows K_a values of 246, 4090, and 3650 M^{-1} for Cl^-, $C_6H_5CO_2^-$, and $CH_3CO_2^-$ by ITC (30 °C) and 53 and 35 M^{-1} for Br^- and HSO_4^- by ^1H NMR titrations (25 °C) in CH_3CN.[99] Also,

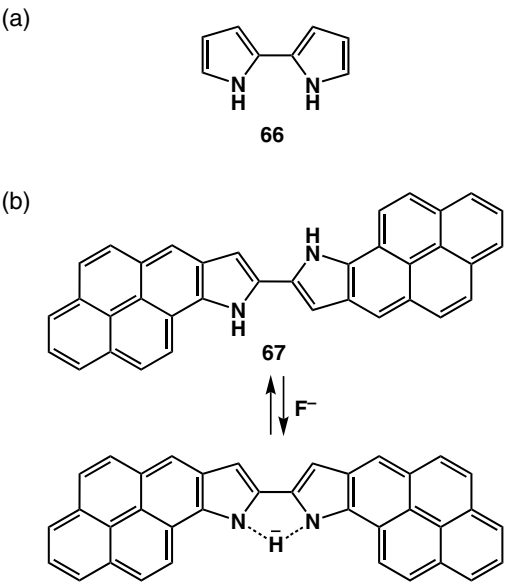

Figure 19. (a) Bipyrrole **66**[99]; (b) bispyrenopyrrole **67**.[100]

bis(pyreno[2,1-*b*]pyrrole) (**67**, Figure 19b), as one of the derivatives including π-fused "pyrrole" rings, displays excellent selectivity and sensitivity for detection of F^- in comparison with other anions such as Cl^-.[100] Excess F^- as a TBA salt deprotonates one of the pyrrole NH of **67** in DMSO, resulting in remarkable colorimetric and fluorescent changes in the visible region. ^{1}H NMR spectral changes using 2,2′-bisindole instead of **67** suggest that the *anti* form twisted conformation with and without the presence of 1 equivalent of F^- is transformed into *syn* conformation with presumably planar structure by deprotonation.[100]

One of the naturally occurring oligopyrroles is prodigiosin **68** (Figure 20a), which was first isolated from *Serratia marcescens* in 1929 and is characterized by a common pyrrolylpyrromethene skeleton consisting of dipyrrin and bipyrrole.[101] The prodigiosins and their analogs exhibit several biological activities. Kataoka and coworkers reported that prodigiosin acidified cellular organelles and vesicles by transporting HCl across membranes.[102,103] On the other hand, Sessler, Magda, and coworkers examined anion-binding properties of prodigiosin analogs **69–71** (Figure 20b)[89]; Cl^- binding constants (K_a) in CH_3CN using a TBA salt for **69–71** protonated by HI are 5.9×10^5, 1.1×10^5, and 1.1×10^5 M^{-1}, respectively, determined by ITC. The efficiency of Cl^- transport was determined by monitoring their efflux across a 200 nm liposome membrane as a function of time; the order of transport efficiency of prodigiosin analogs was found to be **69** > **70** > **71**. The order of anticancer activity *in vitro* was found to be similar: **69** > **70** > **71**.[89]

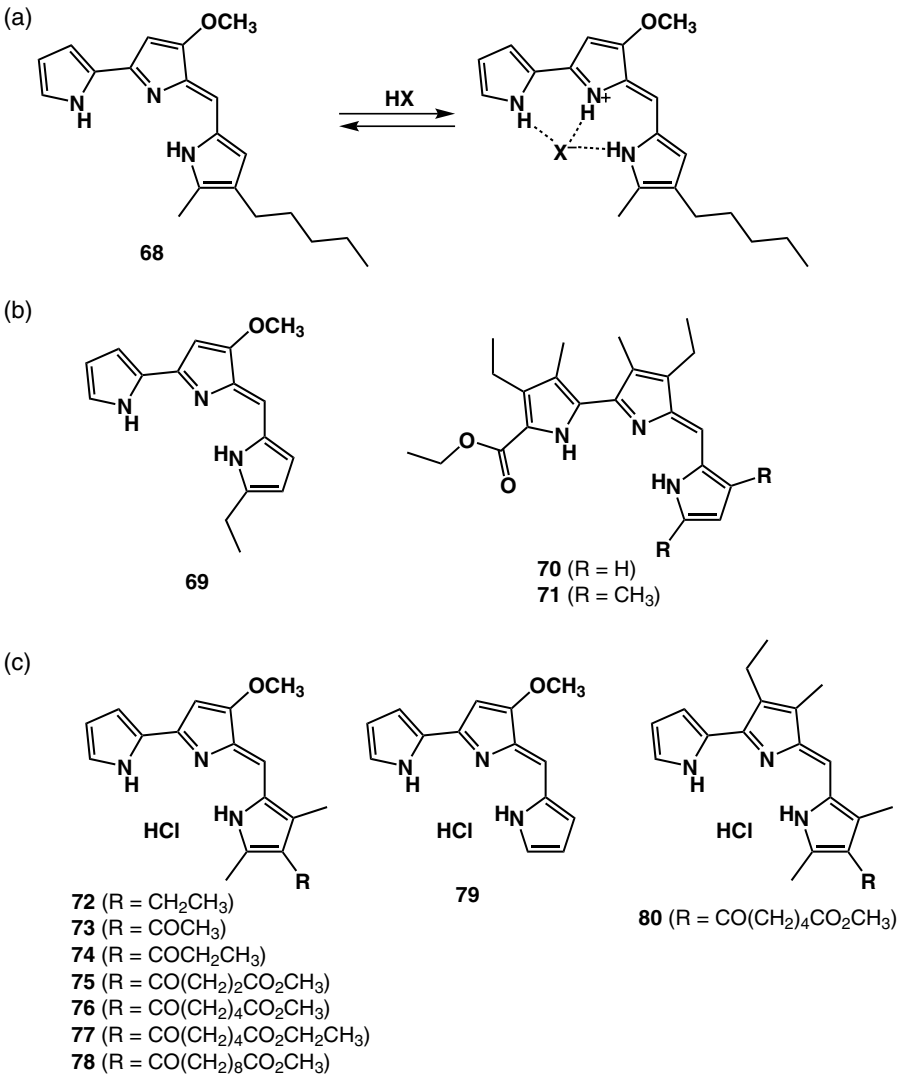

Figure 20. (a) Prodigiosin **68** and anion-binding mode[101,104]; (b, c) artificial prodigiosin derivatives **69**–**80** [protonated form in (c)].[89,105]

Seganish and Davis showed that prodigiosin **68** acts as a Cl^- carrier (H^+/Cl^- symporter) in phospholipid vesicles and demonstrated that **68** is able to exchange Cl^- for NO_3^- as an antiporter.[104] Furthermore, Thompson and coworkers prepared a series of prodigiosin derivatives **72**–**80** (Figure 20c) and demonstrated Cl^- transport through liposomal membranes.[105] The order of transport efficiency was found to be **72** ≥ **78**~**74** > **80**~**75**~**79** > **77** > **73** > **76**, with all prodigiosin analogs exhibiting significant Cl^- transport ability at relatively low ligand-to-lipid

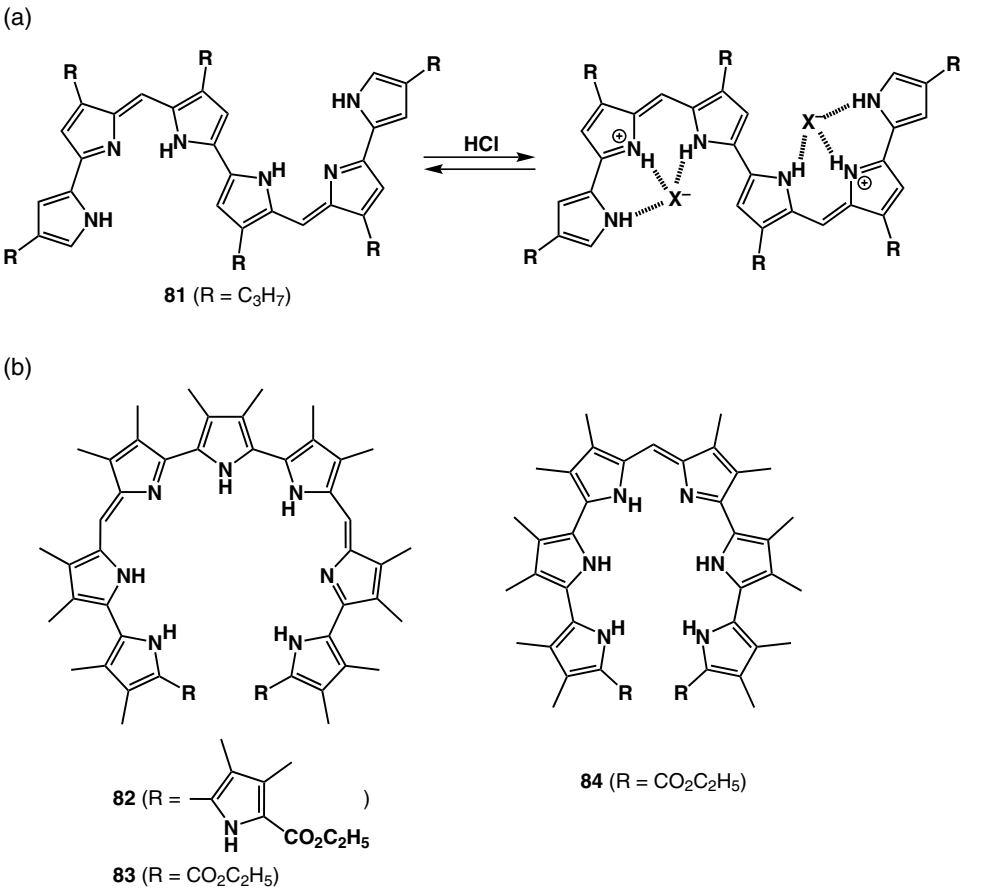

Figure 21. (a) Hexapyrrin **81** and anion-binding mode in protonated form[106]; (b) nona-, hepta-, and hexapyrrolic open-chain systems **82**–**84**.[107]

concentrations (0.1 mol % relative to lipid). Essentially, this result suggests that the prodigiosin core can be functionally altered without losing the ability to transport Cl^- across phospholipid membranes.[105]

As a π-conjugated pyrrole oligomer that has methine bridges and direct α–α linkages, hexapyrrolic "prodigiosin dimer" **81**, which is protonated by HCl, was reported by Sessler *et al*. (Figure 21a).[106] Single-crystal X-ray analysis of a Cl^- complex of the hexapyrrin **81** in protonated form reveals the formation of a fairly planar [1 + 2]-type complex with an S-shaped conformation. NOE experiments support the S-shaped conformation in the solution state.[106] Sessler and coworkers also prepared higher linear oligopyrroles **82**–**84** (Figure 21b), which show absorption maxima in the visible region like that of **81**.[107] The oligopyrroles **82**–**84** exhibit absorption spectral changes in the adduct forms with acetic acid.[107]

IV. Dipyrrolylquinoxalines and Related Aryl-Bridged Bispyrroles

A. Dipyrrolylquinoxalines

Among the open-chain pyrrole derivatives, 2,3-dipyrrol-2-ylquinoxaline (**85**, Figure 22a), a fluorescent dye directly connected to the pyrrole ring, was first synthesized by Oddo and Dainotti in 1911 by the acid-catalyzed condensation of 1,2-dipyrrol-2-ylethanedione (**86**, Figure 22b) and *o*-phenylenediamine,[108] and the process was much later refined by Behr *et al*.[109] Since the first synthesis, the anion-binding properties of dipyrrolylquinoxaline (DPQ) have not been investigated for a long time. In 1999, Sessler and coworkers found that DPQ **85** undergoes a change of color and quenching of emission in the presence of certain anions.[110] It contains two pyrrole NH groups that can function as anion-binding moieties and a built-in quinoxaline ring that might serve as a colorimetric receptor of anions. As illustrated in Figure 22a, this putative sensing system is expected to operate through a combination of electronic and conformational effects. DPQ **85** shows binding affinities (K_a), estimated from UV-visible absorption spectral changes upon the addition of anions, at 18 200, 50, and 60 M^{-1} for F^-, Cl^-, and $H_2PO_4^-$ as TBA salts in CH_2Cl_2, respectively, which are comparable to those of **86** at 23 000, 170, and <50 M^{-1}, respectively.[110] Even though DPQ is an electronically neutral acyclic oligopyrrole system, attachment of the electron-withdrawing quinoxaline moiety enhances the polarity of the pyrrole NH to efficiently bind anions.[110,111]

Replacement of the building blocks of DPQ **85** by other pyrrole and quinoxaline moieties affords the derivatives **87–93**, which possess various

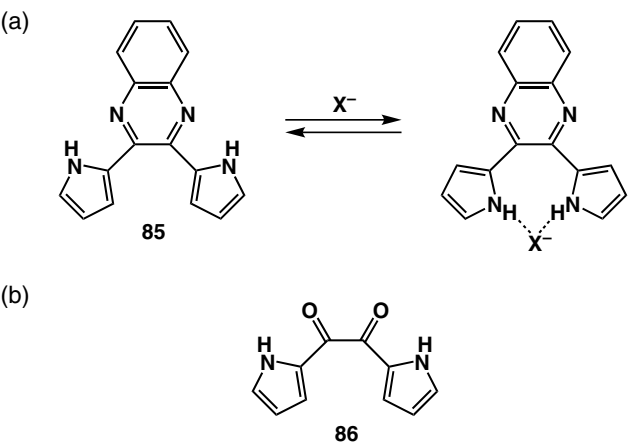

Figure 22. (a) Skeleton structure of dipyrrolylquinoxaline (DPQ) **85** and the anion-binding mode[110]; (b) 1,2-dipyrrol-2-ylethanedione **86**.[110]

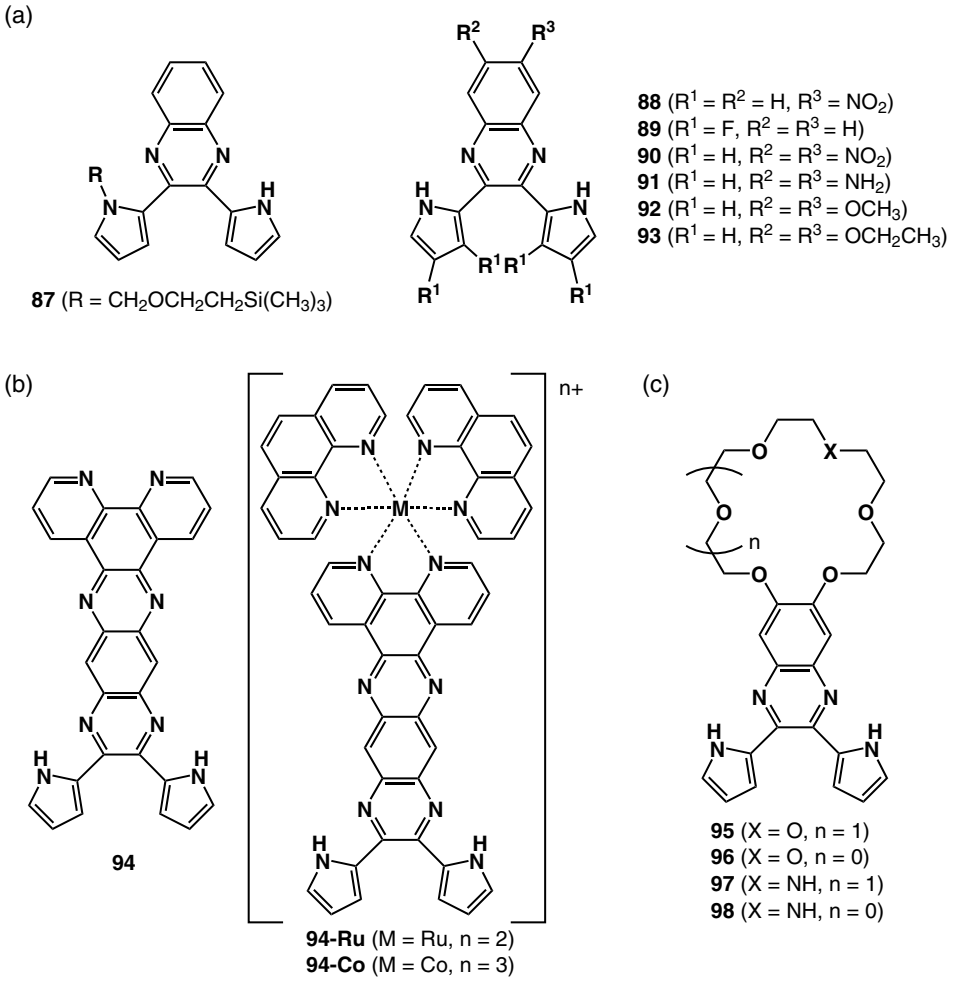

Figure 23. (a) DPQ derivatives **87**–**93**[110,112–114]; (b) phenanthroline-substituted DPQ **94** and metal complexes (**94-Ru**, **94-Co**)[113]; (c) crown-appended DPQs **95**–**98**.[114]

electron-withdrawing or electron-donating groups (Figure 23a).[110,112–114] For example, mono-N-substituted **87** shows smaller K_a values of 120, <50, and <50 M^{-1} for F^-, Cl^-, and $H_2PO_4^-$. 6-Nitroquinoxaline-containing **88** exhibits a higher K_a value (118 000 M^{-1} in CH_2Cl_2) for F^- and comparable values (50 and 65 M^{-1}) for Cl^- and $H_2PO_4^-$,[110] whereas 3,4-difluoropyrrole-substituted **89** shows higher anion binding (61 600, 180, and 17 300 M^{-1} for F^-, Cl^-, and $H_2PO_4^-$ in CH_2Cl_2) than **85**.[112] Diamino-substituted **91**, prepared from dinitro **90**, can be transformed into phenanthroline derivative **94** by condensation with 1,10-phenanthroline-5,6-diketone. Ru(II) and Co(III) complexes (**94-Ru**, **94-Co**) as ClO_4^- salts (Figure 23b)

Table 8. Anion-binding constants (K_a, M^{-1}) of **85**, **89**, **94**, **94-Ru**, and **94-Co** upon the addition of anions as TBA salts in DMSO. Data taken from Ref. 113.

Anion	**85**	**89**	**94**	**94-Ru**	**94-Co**
F^-	<100	59 000	440	12 000	54 000
Cl^-	ND[a]	ND[a]	ND[a]	10	20
$H_2PO_4^-$	ND[a]	5000	ND[a]	40	50

[a]Not determined.

show the higher K_a values for F^- (12 000 and 54 000 M^{-1} in DMSO) than **85** (<100 M^{-1}) and **94** (440 M^{-1}). The trend for the K_a values observed in **94**, **94-Ru**, and **94-Co** correlates with the increasing total charge of the receptor (Table 8). The redox properties of the metal complex can be used to detect the anion-binding behavior of **94-Co**[113]; differential pulse voltammetry (DPV) of **94-Co** in DMSO shows the reversible redox signal at 160 mV (vs. SHE) assignable to Co^{III}/Co^{II}, which disappears (or significantly shifts) by the addition of F^-. Addition of Cl^- and $H_2PO_4^-$ also shifts the higher reduction signals because of the "electron-donating" properties of bound anions.[113] As extended derivatives of dialkoxy-substituted **92** and **93**, "crowned" DPQs **95**–**98** (Figure 23c) were also reported.[114] Single-crystal X-ray structures of **92**, **95**, and **96** show the hydrogen-bonding molecular assemblies; in particular, the pyrrole NH sites of **92** and **96** form hydrogen bonds with methoxy- and crown-oxygen moieties. The cation-binding properties of **95**–**98** were examined, and a K^+-bridged dimer structure was also observed in the solid state of **96**. At present, although it has not yet been successful, the crown-substituted anion receptors are potential motifs for cooperatively binding cations and anions.[114]

The modification of pyrrole α positions also provides utility anion receptor molecules. Several α-formyl-substituted derivatives **99**–**101** (Figure 24a), prepared from **85**, **92**, and **93**, were converted to [2 + 2]-type Schiff base macrocycles **102**–**104** (Figure 24b) by condensation with 1,8-diaminoanthracene.[115] These macrocycles have two "pseudo" cavities; **102** exhibits homotropic positive allosteric effects for F^- and $H_2PO_4^-$ binding in CH_2Cl_2. The binding constants log K and the Hill coefficients are estimated to be 11.0 and 2.2 for F^- and 3.8 and 1.9 for $H_2PO_4^-$. This is the first example of an artificial allosteric system for $H_2PO_4^-$; once an anion is captured in one cavity, the other cavity "shrinks" to the point where its size is better-optimized for anion binding.[115] Furthermore, tetrapyrrole and hexapyrrole derivatives **105** and **106** (Figure 24c) were obtained by acid-catalyzed condensation of the biscarbinol form of **99** and **99** itself with excess pyrrole.[116] The receptors **105** and **106** have claw-like multiple binding NH sites; they show higher K_a values, 32 000, 550, and 4300 M^{-1} (**105**) and >1 000 000, 5800, and 300 000 M^{-1} (**106**) in CH_2Cl_2, for F^-, Cl^-, and $H_2PO_4^-$.[116]

Pyrazine analogs **107**–**112** (Figure 25a) were also prepared from dipyrrolyldiketone and diaminomalonitrile and subsequent formylation of **108** and **109**.[117] A similar synthetic protocol for **105** and **106** affords oligopyrrolic **110**–**112**; **112** shows higher K_a values for Cl^-, 48 000 M^{-1}, than **106**. The hexapyrrolic analogous receptors **106**

Table 9. Anion-binding constants (K_a, M^{-1}) of **106** and **112** upon the addition of anions as TBA salts in CH_2Cl_2. Data taken from Ref. 117.

Anion	**106**	**112**
Cl^-	5800	48 000
$H_2PO_4^-$	300 000	30 000
$CH_3CO_2^-$	46 000	175 000
oxalate	30 000	24 000
malonate	21 000	2100
succinate	53 000	2000[a]

[a]The equilibrium constant for the second binding for the [2 + 1] complex is 1.4 M^{-1}.

and **112** also efficiently bind dicarboxylates such as oxalate, malonate, and succinate as TBA salts in CH_2Cl_2 [e.g. 30 000 (**106**) and 24 000 (**112**) M^{-1} for oxalate] (Table 9).[117] In addition, Smanta and coworkers reported dipyrrolyl-substituted pyrido[2,3-*b*]pyrazine **113** (Figure 25b); the receptor **113**, which has both anion-binding and metal coordination sites, is responsive to F^- (4900 M^{-1} in CH_3CN) in the metal-free form.[118]

Formation of utility materials based on a DPQ structure has also been examined. In order to enhance and tune the fluorescence output, Anzenbacher and coworkers introduced aryl moieties at the 5- and 8-positions of the DPQ skeleton.[119,120] 5,8-Diaryl-substituted receptors **115**–**120** were prepared by Stille coupling or Suzuki coupling from dibromo derivative **114** (Figure 26a). The presence of 5,8-diaryl substituents results in both a dramatic increase in emission intensity

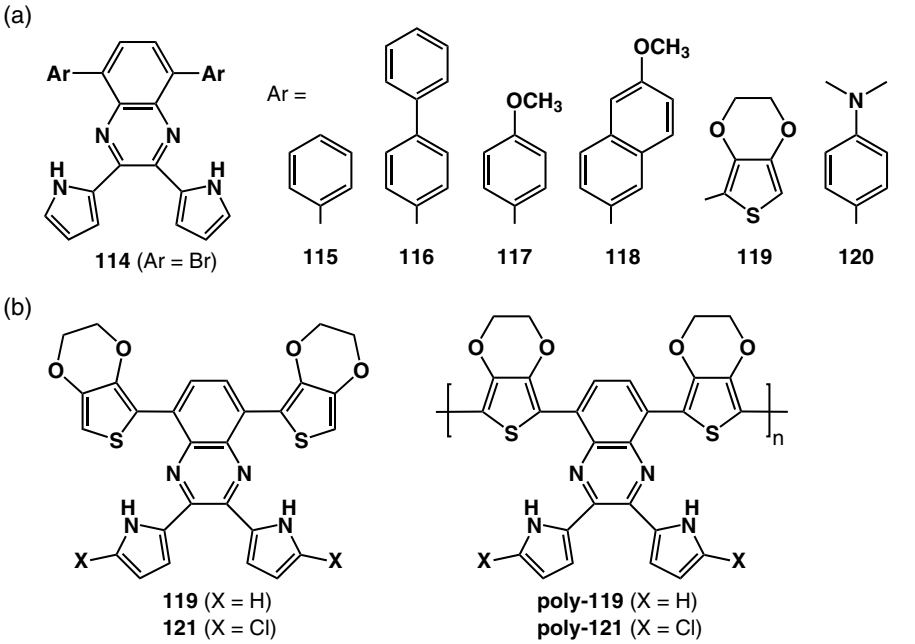

Figure 26. (a) 5,8-Dibromo- and 5,8-diaryl-substituted dipyrrolylquinoxalines **114–120**[119,120]; (b) thienyl-substituted dipyrrolylquinoxalines **119** and **121** and their polymers.[121]

Table 10. Anion-binding constants (K_a, M^{-1}) of **85** and **115–120** upon the addition of anions as TBA salts in CH_2Cl_2. Data taken from Refs. 119 and 120.

Anion	**85**	**115**	**116**	**117**	**118**	**119**	**120**
F^-	18 200	51 300	~12 200	24 700	10 200	25 600	27 500

and a shifted emission maximum compared to parent **85** (λ_{em} = 490 nm, Φ_F = 0.15 in CH_2Cl_2). That is to say, λ_{em} = 500 nm, Φ_F = 0.25 for **115**; λ_{em} = 506 nm, Φ_F = 0.38 for **116**; λ_{em} = 514 nm, Φ_F = 0.24 for **117**; λ_{em} = 520 nm, Φ_F = 0.13 for **118**; λ_{em} = 595 nm, Φ_F = 0.22 for **119**; and λ_{em} = 610 nm, Φ_F = 0.26 for **120**. The K_a values of **115–120** in CH_2Cl_2 are in the range of 10 200 (**118**) to 51 300 (**115**) M^{-1} for F^- and 24 300 (**118**) to 93 700 (**115**) M^{-1} for $HP_2O_7^{3-}$ (14 300 M^{-1} for **85**) (Table 10).[119,120] Significant changes in color and fluorescence emission are observed by the addition of F^- and $HP_2O_7^{3-}$. Therefore, polyurethane-embedded sensors exhibit color response in the presence of aqueous solutions of specific

Table 11. Anion-binding constants (K_a, M^{-1}) for **119** and **121** and apparent anion-binding constants (M^{-1}) for poly-**119** and poly-**121** upon the addition of anions as TBA salts in 0.1% H_2O/DMSO. Data taken from Ref. 121.

Anion	**119**	Poly-**119** [a]	**121**	Poly-**121**[a]
F^-	$>10^6$	48 000	$>10^6$	24 000
Cl^-	<100	<100	2000	<100
$HP_2O_7^{3-}$	$>10^6$	61 100	$>10^6$	11 000
$H_2PO_4^-$	<100	3800	$>10^6$	90 000

[a]Apparent binding constants were calculated with unknown concentration of the receptor in the material surface using the equation for 1:1 stoichiometry.

anions.[119,120] Furthermore, thienyl-substituted **119** and α-chloro **121** yielded conductive materials poly-**119** and poly-**121**, whose band gaps were estimated at 1.39 and 1.36 eV, respectively (Figure 26b).[121,122] Upon treatment with aqueous solutions of anions as TBA salts (the corresponding binding constants are summarized in Table 11), the sensor films resulted in gradual changes in the vis-NIR absorption spectra from $HP_2O_7^{3-}$ due to anion binding, which was also supported by the electrochemical quartz crystal microbalance (EQCM) method. Using sensing devices of poly-**121** with an interdigitated ITO electrode, the addition of anion ($HP_2O_7^{3-}$) results in dramatic changes in both visible-NIR spectra and drain current. The low level p-doping and a corresponding positive charge in the polymer results in a dramatic increase in the anion affinity.[121,122]

Pyrene-attached **122** and **123** (Figure 27a) exhibit fluorescence quenching through efficient binding for F^- and $HP_2O_7^{3-}$, 17 300 and 18 000 M^{-1} (**122**) and 19 600 and 29 500 M^{-1} (**123**), respectively, comparable to parent **85**.[123] The sensor **123** achieves signal amplification through effective excited state localization, whereas **122** shows Förster resonance energy transfer (FRET)–based light harvesting from the pyrene moieties to the DPQ moiety. Excitation of **122** at 320 nm, i.e. absorption of pyrene moieties, results in a ten-fold amplification of fluorescence compared to **85**. This means that **122** can be easily used for anion sensing for amounts that are ten times lower than **85**.[123] Anzenbacher *et al*. also reported that sensors **124** and **125** constitute a chromophore capable of undergoing an intensive change in color and a redox-active quinone moiety to generate strong colorimetric and electrochemical signals (Figure 27b).[124] According to UV-visible absorption spectral changes, **124** and **125** show efficient binding for F^- and $HP_2O_7^{3-}$, 482 200 and 316 000 M^{-1} (**124**) and 150 700 and 626 000 M^{-1} (**125**), respectively, in 0.5% H_2O/CH_3CN (Table 12). Electrochemical reduction waves of

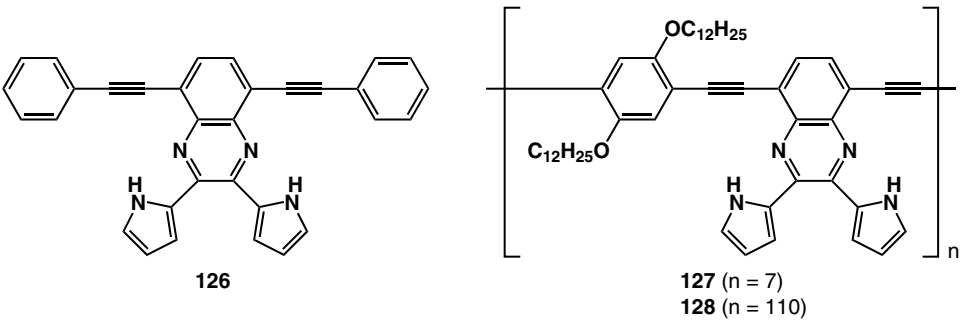
$C_6H_5CO_2^-$	100	400
Cl^-	<50	<50

124 and **125** in square wave voltammetry (SWV) show cathodic shifts because the electron-rich sensor–anion complex is difficult to reduce. Binding constants estimated from SWV show considerable agreement with those from UV-visible absorption spectral changes.[124] In addition, Anzenbacher and coworkers used



126 **127** (n = 7)
128 (n = 110)

Figure 28. Monomeric and polymeric forms of phenylethynyl-substituted dipyrrolylquinoxalines **126**–**128**.[127]

receptor **124** as one of the sensor molecules of the arrays detectable for anions in aqueous solutions.[125] Wong and coworkers also examined optical and electrochemical sensing for anion binding and conducted a theoretical study of **107** and **124**.[126]

Other extended and polymeric systems, **126**–**128** (Figure 28), have been reported by Sun and coworkers.[127] Monomer **126** exhibits F^- and $HP_2O_7^{3-}$ "binding" (2520 and 1440 M^{-1}), which are larger than those for CN^- (310 M^{-1}), $CH_3CO_2^-$ (50 M^{-1}), and other anions such as Cl^- and $H_2PO_4^-$ (<10 M^{-1}), in CH_2Cl_2; here, F^- and $HP_2O_7^{3-}$ are associated with a pyrrole NH while the other pyrrole NH is deprotonated under ambient conditions. The sensitivity of the DPQ-based chemosensor can be easily enhanced by incorporation into conjugated polymers **127** and **128**. The quenching constants derived from the Stern–Volmer plots, 16 800 (**126**), 70 200 (**127**), and 52 000 (**128**) M^{-1} for F^- and 11 200 (**126**), 49 300 (**127**), and 38 000 (**128**) M^{-1} for $HP_2O_7^{3-}$, respectively, demonstrated that the conjugated polymer with about ten repeating recognition sites is able to induce a substantial quenching effect with a 34-fold increase in the sensitivity as compared to the corresponding monomeric sensor.[127]

Other oligomer systems are achieved by incorporation into macrocycles such as **102**–**104**. Andrioletti and coworkers synthesized peralkyl-substituted DPQs **129**–**131**, which, however, cannot be converted to further modified derivatives.[128] Therefore, from the precursory diketone of **129**, tetrapyrrole derivatives **132** and **133**, similar to **104**, were obtained; **133** is a good starting material for macrocycles such as **134** and **135** (Figure 29). π-Conjugated **135** can be considered as a quinoxaline-bridged dipyrrin cyclic oligomer; single-crystal X-ray analysis of **135** shows a boat-like conformation with quinoxaline moieties almost facing each other, providing a rigid-wall cavity.[128]

On the other hand, Lee, Sessler, and coworkers reported DPQ-strapped calix[4]pyrrole **134**, which is prepared from **136** via dipyrromethane derivative

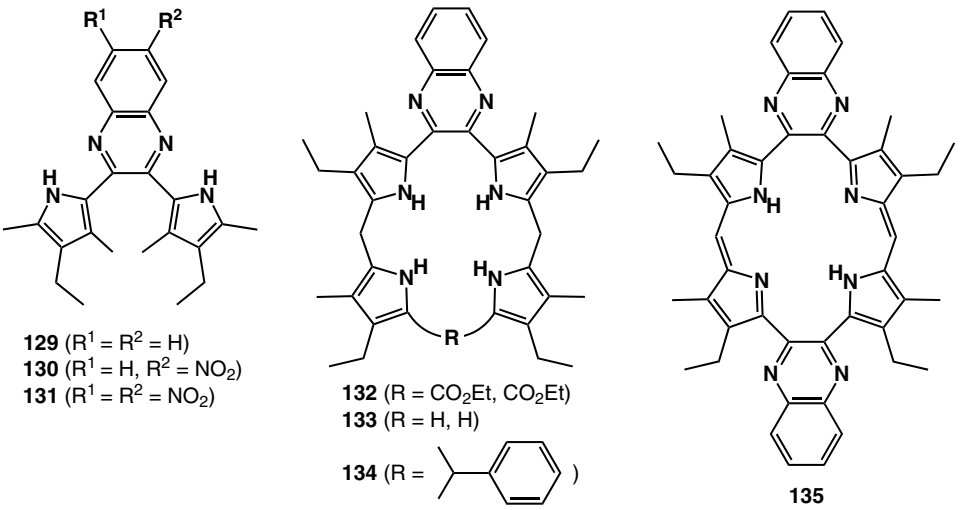


Figure 29. Alkyl-substituted DPQs **129**–**133** and macrocycles **134** and **135**.[128]

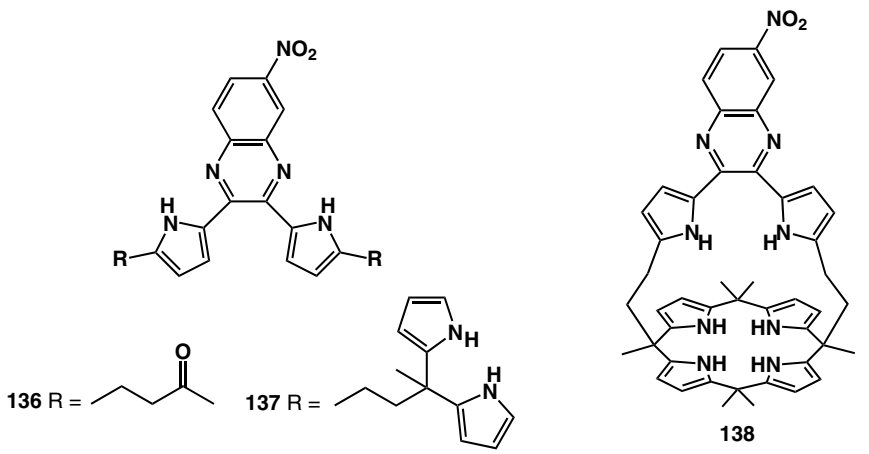

Figure 30. DPQ-calix[4]pyrrole hybrid **138** and starting **136** along with intermediate **137**.[129]

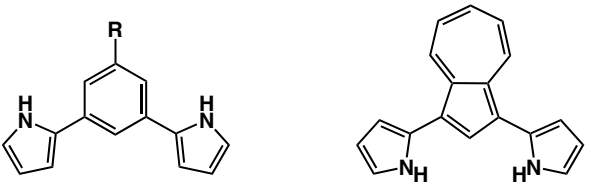
137 (Figure 30).[129] As seen from the ^{1}H NMR spectra (CD_3CN/DMSO-d_6 9:1, v/v) of **138**, with added TBAF, NH protons of the pyrroles on the strap, shifted from 5.99–5.96 to 5.57–5.54 ppm, do not interact with the added anions via simple NH–anion hydrogen bonds. This is derived from an anion–π interaction,[130,131] also supported by the downfield shifts of β-pyrrole CH from 6.54–6.49 and 5.80–5.74 to 6.85–6.80 and 5.92–5.90 ppm. ITC measurements (CD_3CN/DMSO-d_6 97:3, v/v) suggest multiple binding modes, [1 + 1] and [1 + 2], for F^- with K_a

values of 3.72×10^8 and 5.0×10^5 M^{-1}, and regular [1 + 1] binding for Cl^-, $CH_3CO_2^-$, and $H_2PO_4^-$ with K_a values of 1.94×10^4, 1.89×10^4, and 1.33×10^3 M^{-1}, respectively.[129]

B. Anion-Responsive Aryl-Bridged Bispyrroles

In addition to quinoxaline-bridged bispyrroles, there are several reports on aryl-bridged oligopyrroles that show anion binding. For example, 1,3-bis(pyrrol-2-yl)-benzenes **139–141** (Figure 31), which are an essential building unit of macrocycles, exhibit anion-binding behavior[95]; **139** shows K_a values at, for example, 2300, 4300, 1100, 190, 290, 1300, 280, and 32 M^{-1} for F^-, Cl^-, Br^-, I^-, HSO_4^-, $H_2PO_4^-$, NO_3^-, and ClO_4^-, respectively, estimated from ^1H NMR spectral changes in CD_2Cl_2. The K_a values are larger than those of dimethyldipyrromethane **52**, possibly because the bite angle present in **139** provides a better structural match to Cl^- (and likely most other anions).[95] Eichen and coworkers reported 1,3-dipyrrol-2-ylazulene **142** (Figure 31), which exhibits anion-binding properties for F^- (11 000 M^{-1}), Cl^- (110 M^{-1}), Br^- (100 M^{-1}), and I^- (50 M^{-1}) in CH_2Cl_2 and F^- (>1000 M^{-1}) in DMSO.[132] F^- enhances the fluorescence more than ten-fold in DMSO; this result presumably originates from the conformational changes from the fairly coplanar structure of core azulene and two pyrrole rings, elucidated by single-crystal X-ray analysis, to that with the partially disrupted π-conjugation between azulene and pyrroles.[132]

Sun, Hsu, Chow, and coworkers reported maleimide-bridged bispyrrole **143** (Figure 32a), which shows interaction with anions with K_a values of 18 500 and 36 300 M^{-1} for F^- and CN^- in CH_2Cl_2.[133] The significant fluorescence quenching and red-shift caused by F^- and CN^- are derived from deprotonation of a pyrrole NH.[133] Terpyrrole isomer **144** (Figure 32b), an analog of **143** and DPQs, was reported by Sessler and coworkers[134]; it shows color changes upon addition of anions such as F^- and $H_2PO_4^-$ in CH_2Cl_2. The K_a values of **144** are estimated as



139 (R = H)
140 (R = *t*-Bu)
141 (R = OC_6H_{13})

142

Figure 31. Aryl-bridged bispyrrole derivatives **139–142**.[95,132]

Figure 32. Pentacycle-bridged bispyrrole derivatives (a) **143**[133] and (b) **144**.[134]

182 000, 160, 60, and 17 500 M^{-1} for F^-, Cl^-, Br^-, and $H_2PO_4^-$, respectively, which are augmented compared to DPQ **85**.[134]

Metal-mediated changes to the preorganized conformation are observed in the metal complexes of bipyridine-bridged bispyrrole **145**.[135] Ru(II) and Rh(III) complexes **145-Ru** and **145-Rh** (Figure 33a) prepared by Sessler and coworkers, exhibit anion binding in DMSO, e.g. 7000, 370, and 104 000 M^{-1} for F^-, Cl^-, and $H_2PO_4^-$, respectively, in the case of **145-Ru** (Table 13). In particular, the K_a value for $H_2PO_4^-$ is *ca*. 2600-fold greater than for the DPQ-Ru(II) complex **94-Ru**. Higher affinities of triply charged **145-Rh** (870 M^{-1} for Cl^-) compared to **145-Ru** lead to precipitates upon $H_2PO_4^-$ binding. Single-crystal X-ray structures of Cl^- complexes of **145-Ru** and **145-Rh** elucidate C–H···Cl interactions (C···Cl: 3.65 and 3.59 Å on average for **145-Ru** and **145-Rh**) along with N–H···Cl interactions.[135] On the other hand, monomeric pyrrole building subunits can be incorporated into metal complexes by substitution of the metal ligand moiety. Gale and coworkers prepared Pt(II) complexes **146** and **147** (Figure 33b) from 3- and 4-(pyrrol-2-yl)pyridines.[136] The single-crystal X-ray structure of **146** as a BF_4^- salt elucidates the 1,2-alternate conformation and binding of two BF_4^- anions via N–H···F and C–H···F hydrogen bonds. The anion-binding behavior of **146** and **147** upon the addition of TBA salts in DMSO-d_6 reflects 1:1 stoichiometry except for $CH_3CO_2^-$ binding of **146** with K_2 (2400 M^{-1}) > K_1 (216 M^{-1}) (Table 14).[136] This

suggests that an allosteric effect is operating that preorganizes the second binding site upon complexation of the first equivalent of $CH_3CO_2^-$. In DMSO, compared to **147**, which binds anions using pyridyl *o*-CH sites and not pyrrole NH, **146** uses pyrrole β-CH and not NH to show large K_a values, e.g. 960 (**146**) and 216 (**147**) M^{-1} for Cl^- and 1115 (**146**) and <10 (**147**) M^{-1} for $CH_3SO_3^-$. In contrast to the binding mode in solution, **146** forms the $CH_3SO_3^-$ complex via an N–H···O hydrogen

Table 14. Anion-binding constants (K_a, M^{-1}) of **146** and **147** upon the addition of anions as TBA salts in DMSO-d_6. Data taken from Ref. 136.

bond; this result suggests that the hydrogen-bonding acceptor DMSO molecules drive the pyrrole rings to invert and face the "outside."[136]

C. Dipyrrolylpyrazoles Derived from Dipyrrolyldiketones

In 2005, Maeda and Kusunose found that the key starting molecule to afford utility acyclic oligopyrrole derivatives was 1,3-dipyrrolyl-1,3-propanedione (dipyrrolyldiketone) **148** (Figure 34),[137] which was first reported by Oddo and Dainotti in 1912[138] and was refined by Battersby and coworkers in 1984.[139] This diketone is an analog of the precursory diketone of DPQ. Dipyrrolyldiketone **148** can be obtained from pyrrole by treatment with malonyl chloride. Therefore, dipyrrolyldiketone derivatives can be prepared from the corresponding substituted pyrroles. On the basis of the "pyrrole library," thus far, Maeda and coworkers have synthesized various dipyrrolyldiketone derivatives.[137,140–148]

One type of molecule derived from dipyrrolyldiketones is the pyrazole-bridged bispyrrole; pyrazoles can interact electrostatically or via hydrogen bonds with anionic or polar substrates as partially or fully protonated forms. In accordance with the first example reported by Oddo and Dainotti,[138] dipyrrolylpyrazoles (DPPs, **149**–**153**, Figure 35a) were synthesized by Maeda *et al*. by the condensation of excess hydrazine monohydrate with the corresponding dipyrrolyldiketones in refluxing acetic acid for 3–4 days.[149] *N*-Methyl-substituted **154**–**156** were obtained similarly from diketones or from the methylation of the corresponding DPPs. Based on the anion-binding ability of the pyrrole NH sites as observed in **155** and **156** (K_a = 1600 and 28 000 M^{-1} for $CH_3CO_2^-$ in CH_2Cl_2, respectively), the

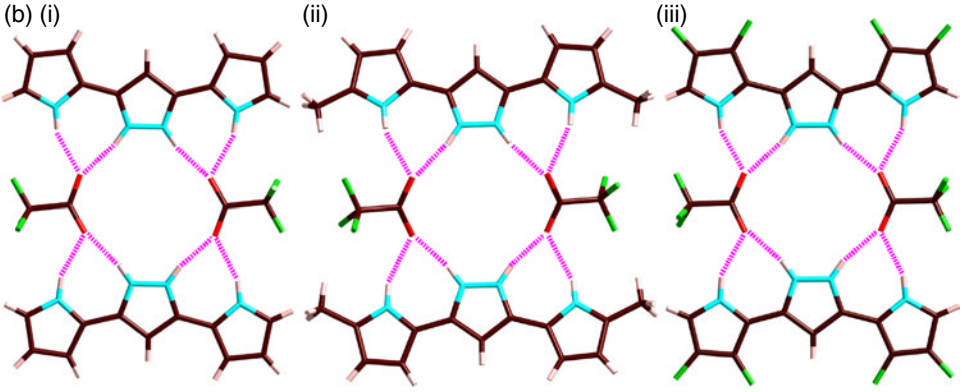

Figure 35. (a) Dipyrrolylpyrazoles **149**–**156**[149]; (b) solid-state [2 + 2] assemblies of (i) $\mathbf{149}_2$·TFA_2, (ii) $\mathbf{150}_2$·TFA_2, and (iii) $\mathbf{153}_2$·TFA_2.[149]

planar [2 + 2]-binding structures[150] with TFA were elucidated by single-crystal X-ray analyses of $\mathbf{149}_2$·TFA_2, $\mathbf{150}_2$·TFA_2, and $\mathbf{153}_2$·TFA_2 complexes (Figure 35b).[149] Complexation with an acid provides the planar geometry of DPP, which is required for the formation of micrometer- and nanometer-scale morphologies using intermolecular interactions such as π–π stacking. In fact, by casting the TFA complexes of DPP in CH_2Cl_2 on a silicon substrate, organized structures have been observed by SEM analysis. In sharp contrast to unsubstituted $\mathbf{149}_2$·TFA_2 and α-methyl $\mathbf{150}_2$·TFA_2, which yield crystalline objects, TFA complexes $\mathbf{150}_2$·TFA_2 and

151$_2$·TFA$_2$ with neopentyl and hexadecyl chains provide petal-like objects with widths of *ca*. 500 nm and assembled sheet structures with thicknesses <100 nm. Furthermore, β-fluorinated **153**$_2$·TFA$_2$ exhibits rod-like morphologies with widths of *ca*. 100–200 nm and small amounts of microcrystals.[149]

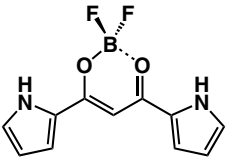
V. Boron Complexes of Dipyrrolyldiketones as Acyclic Anion Receptors with Planar Geometries

A. Synthesis and Properties of Boron Complexes of Dipyrrolyldiketones

Assemblies of π-conjugated molecules, mainly because of stacking interactions, are the basis of the dimension-controlled organized structures,[1–7] including soft materials. As π-conjugated molecules often have an optical absorption in the visible region, their assemblies behave as utility photonic and electronic materials. In addition, supramolecular assemblies comprising planar pyrrole-based anion receptors exhibit potential anion-responsive behavior and, under the appropriate conditions, form the functional organized structures comprising cations and anions, as described in the introduction. Therefore, initially, it is essential to design and synthesize promising fairly planar π-conjugated systems comprising pyrrole rings to efficiently bind anions.

As a candidate for a π-conjugated acyclic anion receptor to fabricate stacking structures, in 2005 Maeda and Kusunose reported the BF_2 complex **157** of dipyrrolyldiketone **148** (Figure 36).[137] Molecule **157** consists of two pyrrole rings and a boron-bridged 1,3-propanedione moiety. The pyrrole rings, which exist even in the acyclic structure, are stabilized by the neighboring electron-withdrawing carbonyl unit; therefore, the skeletal structure could be appropriate for various uses, such as sensors and materials. The absorption and emission maxima of receptor **157** are observed at 432 and 451 nm in CH_2Cl_2, respectively; these electronic properties of a single molecule could be applied to potential photonic and electronic materials such as supramolecular assemblies. The solid-state assembly of **157** is revealed by single-crystal X-ray analyses; planar **157**, wherein the pyrrole nitrogens are on opposite sides of the molecule as observed in solution, forms stacking structures with offset arrangement (Figure 37).[137,151] Observation of this stacking structure of parent **157** in the solid state is an impetus for supramolecular chemistry based on small molecules (*vide infra*).

The BF_2 complex **157** does not form a preorganized conformation, because the two pyrrole NH groups are not located at the appropriate positions for anion binding.[137] Upon the addition of anions, receptor **157** exhibits an inversion of the two pyrrole rings and binds anions using the pyrrole NH and bridging CH to form a planar receptor–anion complex (Figure 38). The BF_2 complex **157** can be considered



157

Figure 36. BF_2 complex of dipyrrolyldiketone **157**.[137]

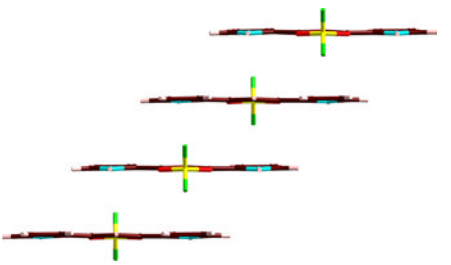


Figure 37. Solid-state molecular assembly of acyclic anion receptor **157**.

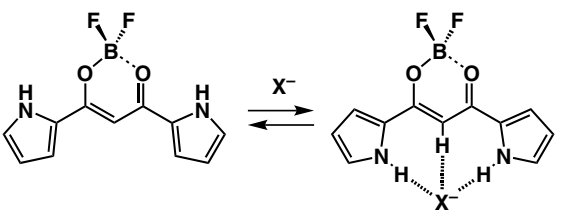

Figure 38. Anion-binding mode of BF_2 complex of dipyrrolyldiketone **157**.[137]

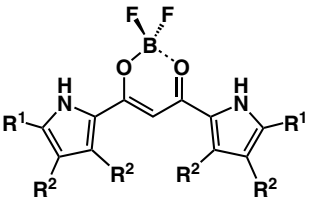
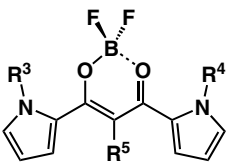
as a "molecular flipper" that enables space control between two planar states (free receptor and receptor–anion complex) by external chemical stimuli (anion). N–H···X^- and bridging C–H···X^- interactions are suggested from the ^{1}H NMR chemical shifts of other molecular flippers (instead of **157**, *vide infra*) upon the addition of anions as TBA salts. Furthermore, the discrete resonances of the two species — free receptor and anion complex — suggest that the equilibrium between these forms is too slow to be detected on the NMR time scale, possibly because of the requirement for pyrrole inversions to allow binding of the anion. The absorption and emission of **157** are adjusted by the addition of anions as TBA salts, suggesting its potential as a colorimetric anion sensor. UV-visible absorption spectral changes of **157** in CH_2Cl_2 by anion binding afford K_a values of 15 000,



158-n ($R^1 = C_nH_{2n+1}$ (n = 1–16), R^2 = H)
159 ($R^1 = CH_2C(CH_3)_3$, R^2 = H)
160 (R^1 = H, $R^2 = C_2H_5$)
161 (R^1 = H, $R^2 = CH_3$)
162 (R^1 = H, R^2 = F)



163 ($R^3 = R^4 = CH_3$, R^5 = H)
164 ($R^3 = CH_3$, $R^4 = R^5$ = H)
165 ($R^3 = R^4$ = H, $R^5 = C_2H_5$)

Figure 39. BF_2 complexes of dipyrrolyldiketones **158–165**.[140–142,144,146]

2100, 930 000, and 270 000 M^{-1} for Cl^-, Br^-, $CH_3CO_2^-$, and $H_2PO_4^-$, respectively.[137,144] Receptor **157** exhibits an efficient anion-binding property compared to DPQ **85**[110] and 1,3-bis(pyrrol-2-yl)benzene **139** (in CH_2ClCH_2Cl).[135]

On the basis of the library of pyrrole derivatives reported to date, the introduction of substituents to the receptor framework of **157** has yielded a variety of molecular flippers, **158–165** (Figure 39). Maeda *et al*. reported the α-alkyl-substituted receptors **158-n** and **159** from α-alkylpyrroles.[137,144] They also prepared β-alkyl- and β-fluorine-substituted receptors **160–162**, which can be considered as building blocks to form covalently linked oligomers due to the free α positions.[140,142,146] In addition, receptor molecules **163–165**, whose binding sites are (partially) protected, were also synthesized.[141] Furthermore, single-crystal X-ray analysis of some receptors revealed stacking structures similar to **157** (Figure 40). α-alkyl-substituted **158-1**,**4**,[144] **159**,[141] β-methyl-substituted **161**,[146] and β-fluorinated **162**[140] form 1D stacking structures, wherein core π-planes are partially overlapped, whereas α-ethyl-substituted **158-2** forms a dimer structure.[144] In contrast to these receptors, β-ethyl-substituted **160** shows no stacking structures and only N–H···F–B hydrogen-bonding interaction.[146] In the solid state, the interaction between NH and BF, which is essential for forming specific assembling modes such as the hydrogen-bonding dimer, is observed in other receptors, including parent **157**.

The anion-binding properties of the BF_2 complexes were examined from the UV-visible absorption spectral changes upon the addition of anions (Cl^-, Br^-, $CH_3CO_2^-$, $H_2PO_4^-$, and HSO_4^-) as TBA salts in CH_2Cl_2. The binding constants (K_a) of **157**, **158-16**, and **159–162** are summarized in Table 15[137,140,142,144,146]; enhanced values are obtained for unsubstituted **157** because of less sterical hindrance at the pyrrole α-positions and for β-fluorinated derivative **162** because of the polarized NH and CH binding sites. The K_a values of α-alkyl-substituted receptors **158-n** are

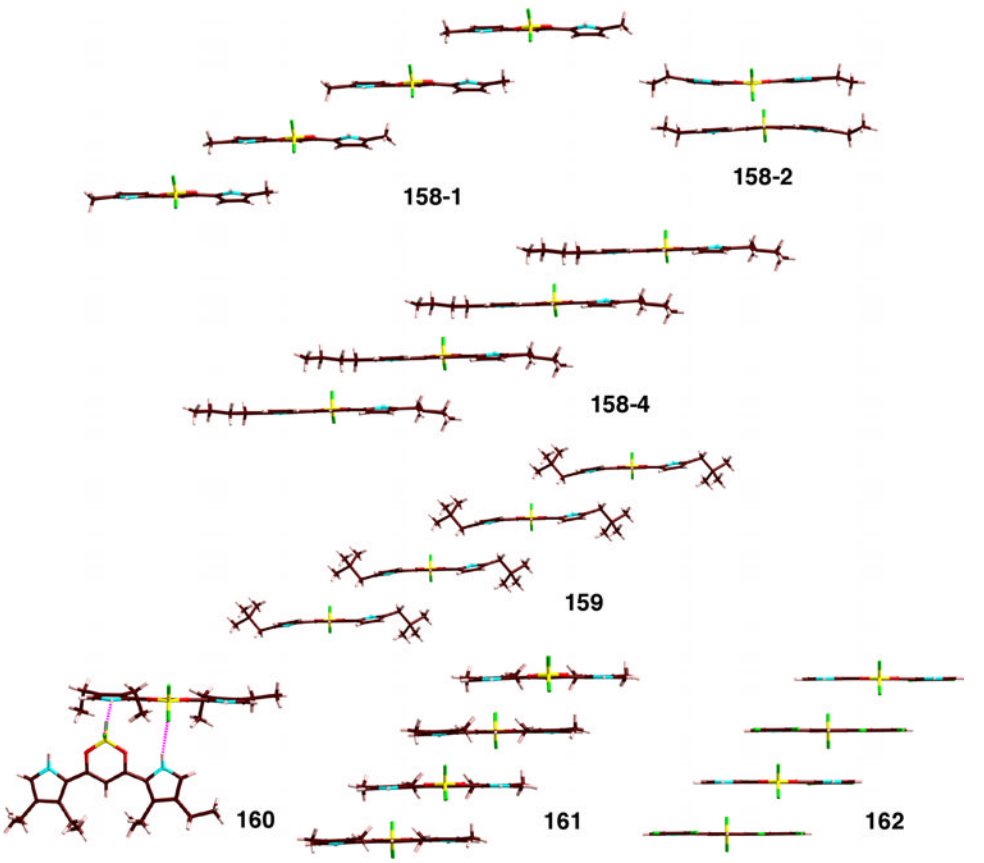


Figure 40. Selected solid-state molecular assemblies of acyclic anion receptors **158-1**,**2**,**4** and **159**–**162**.[137,140,142,144,146]

smaller in receptors with longer alkyl chains and their binding kinetics are also dependent on the alkyl chain lengths. All of the receptors **157**–**162** shown here except for **161** bind $CH_3CO_2^-$ more efficiently than the other anions. Upon the addition of $CH_3CO_2^-$ to **162** (2×10^{-3} M) in CD_2Cl_2 at −50 °C, both the NH and CH peaks (at 9.02 and 6.65 ppm, respectively) in ^{1}H NMR spectra disappear and new signals appear in the downfield region at 12.09 and 8.23 ppm, respectively. Similar downfield shifts are observed upon the addition of other anions to these acyclic receptors. The anion-binding behaviors of the "blocked" derivatives **163**–**165** suggest the essential role of the bridging CH site for anion binding.

The above observations, in which the anion-binding behavior of these acyclic receptors can be correlated with the effects of the peripheral substituents, can be explained from DFT calculations at the B3LYP/6-31G(d,p) level.[137,140,142,144,146] Consistent with experimental results such as from NMR analysis, molecular

Table 15. Anion-binding constants (K_a, M^{-1}) of **157**, **158-16**, and **159–162** upon the addition of anions as TBA salts in CH_2Cl_2. The values in the parentheses are the ratios to the K_a values of **157**. Data taken from Refs. 137, 140, 142, 144, and 146.

simulations for the receptors **157–162** have suggested that the most stable conformations of the free receptors with intramolecular interactions between pyrrole NH and oxygen (the left side structure for **157** in Figure 38) are unsuitable for anion recognition, and therefore pyrrole inversions are required to bind anions. The relative energies of the "preorganized" structures (the right side structure for **157** in Figure 38) of **157–162** compared to each stable conformation are estimated at 9.08, 9.10 (**158-8** as an example), 8.96, 4.98, 6.94, and 15.04 kcal/mol, respectively, suggesting that the β-alkyl-substituted receptors **160** and **161** show stronger preferred preorganized geometries than those of **157–159** and **162**. From the experimental and theoretical data, the affinities for anions can be determined from the following factors: (i) electronic effects of the peripheral substituents, (ii) steric effects of the α substituents, and (iii) relative stabilities of the preorganized conformation.

The solid-state structures of the receptor–anion complexes have also been revealed by single-crystal X-ray analyses (Figure 41).[137,140,144] The receptor–anion complexes are dispersed in good solvents and, in some cases, are crystallized in poor solvents such as hydrocarbons to give single crystals obtained by using TBA salts of anions. In the case of the Cl^- complex of unsubstituted **157**, for a 1:1 mixture of the receptor and TBACl, the CH proton and one of the two pyrrole NH protons are associated with the Cl^- anion. The other NH proton turns to the opposite side and binds to another Cl^- anion to form an anion-bridged 1D hydrogen-bonding infinite chain (Figure 41a).[137] The β-fluorinated **162** utilizes only the NH interaction site to form the supramolecular 1D chains bridged by Cl^-, possibly

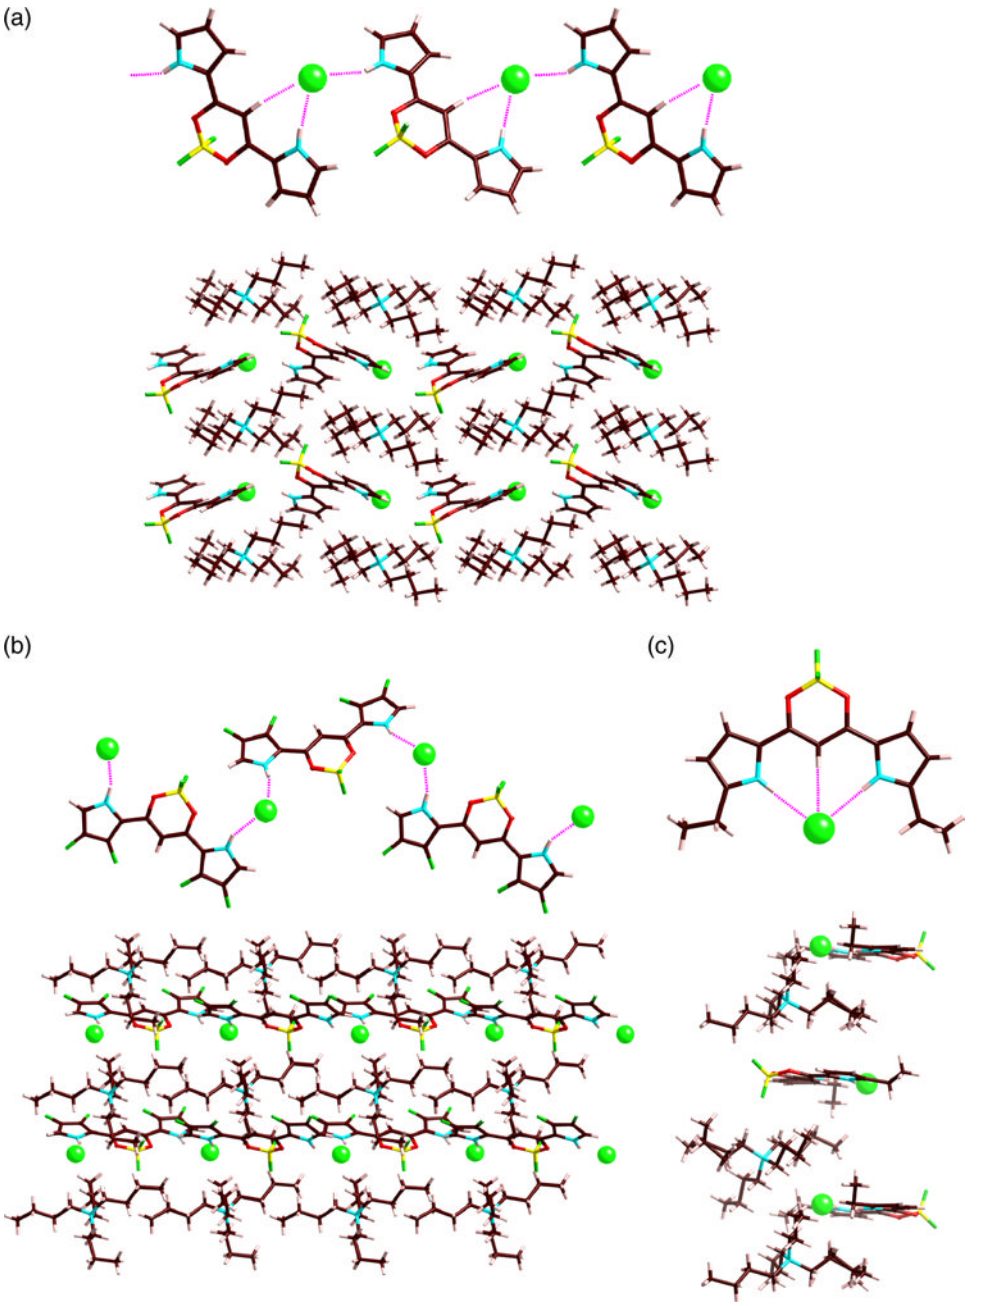

Figure 41. Solid-state chain structures or single-molecule and packing diagrams of receptor–anion complexes: (a) **157**·Cl^-, (b) **162**·Cl^-, (c) **158-2**·Cl^-. TBA cations are omitted for clarity in the top views.[137,140,144]

because of the more polarized NH as compared to NH sites of the β-H derivative (Figure 41b).[140] In both cases, countercations (TBA) are located between the 1D receptor–anion chains, quite different from the binding modes in the solution state, to form alternatively stacked structures. In contrast to the α-unsubstituted **157** and **162**, α-ethyl **158-2** has shown a similar binding mode, as observed in the solution state with the inversion of two pyrrole rings (Figure 41c).[144]

B. Aryl-Substituted Anion Receptors

In order to extend the π-conjugation of the molecular flippers for tunable electronic properties and stacking abilities, Maeda *et al*. attempted to synthesize α-aryl-substituted derivatives of dipyrrolyldiketone BF_2 complexes.[143] Initially, α-aryl-substituted **166–169** (Figure 42) were obtained from the α-aryl-substituted pyrroles, which were synthesized by cross-coupling reactions, via the corresponding α-aryl-substituted dipyrrolyldiketones. The absorption maxima (λ_{max}) of **166**, **167**, and **169** in CH_2Cl_2 appear at 500, 480, and 516 nm in CH_2Cl_2, respectively, which are red-shifted as compared to **157** (432 nm), **158-16** (457 nm), **159** (457 nm), **160** (452 nm), **161** (449 nm), and **162** (421 nm). Conversely, λ_{max} for **168** appears at 456 nm, which is blue-shifted by 46, 24, and 60 nm as compared to **166**, **167**, and **169**, respectively, as a result of the distortion of the aryl rings.[143]

Maeda and Eifuku also prepared the receptors bearing mono-alkoxy-substituted phenyl moieties **170–175** (Figure 43).[147] The UV-visible absorption maxima (λ_{max}) of **170**, **171**, and **172** in CH_2Cl_2 were observed at 513, 501, and 518 nm, respectively, suggesting that alkoxy substitution at the *ortho* and *para* positions affords a red-shift and that at the *meta* position has almost no effect in comparison with the λ_{max} value of α-phenyl **166** (500 nm), while the length of the alkoxy chains has almost no effect on the electronic state.[147]

Figure 43. Aryl-substituted derivatives **170–175**.[147]

Single-crystal X-ray analysis of α-aryl-substituted receptors also demonstrates the stacking structures (Figure 44).[143,147] Phenyl- **166** and *o*-tolyl-substituted **167** form stacking assemblies, wherein the slightly distorted aryl rings in **167** produce less effective stacking, whereas 2,6-dimethylphenyl-substituted **168** has shown no stacking structures because of steric hindrance. X-ray analysis of **169** shows one trimeric and two tetrameric stacking structures as the various slipped assemblies in the solid state.[143] Like **166** and **167**, methoxy-substituted **170–172** also form stacking structures: compared with **171** and **172**, *o*-methoxy **170** has edge-to-edge–like stacking assemblies. α-Aryl-substituted receptors **166**, **167**, **171**, and **172** form hydrogen-bonding dimers using N–H···F–B interactions. On the other hand, *o*-methoxy **170** shows intramolecular N–H···O hydrogen bonds as observed in solution, whereas 2,6-dimethyl **168** is not incorporated in the assemblies using hydrogen-bonding interactions.[147]

The synthetic route for **166–175** based on aryl-substituted pyrroles is useful but is applied to a limited number of the derivatives. Therefore, the design of more efficient routes is required in order to introduce various aryl rings to the molecular flippers. In fact, selective iodination at the α-pyrrole positions of β-ethyl-substituted **160** by treatment with 2.7 and 1.1 equivalents of *N*-iodosuccinimide (NIS) in CH_2Cl_2 has been found to be a key step toward affording mono- **176** and bis-iodinated derivative **177** as essential starting materials of the coupling reactions for various utility molecules and covalently linked oligomer systems.[152] Bromination by *N*-bromosuccinimide (NBS) gives complicated mixtures containing species with a bromo-substituent at the fairly reactive bridging carbon. Suzuki cross-coupling reaction of **176** and phenylboronic acid (1.2 equivalents) affords monophenyl-substituted **178**, while a similar procedure using bis-iodinated derivative **177** and phenylboronic acid (2.2 equivalents) affords bisphenyl derivative **179**.[152] Under similar conditions using the corresponding aryl boronic acids, the

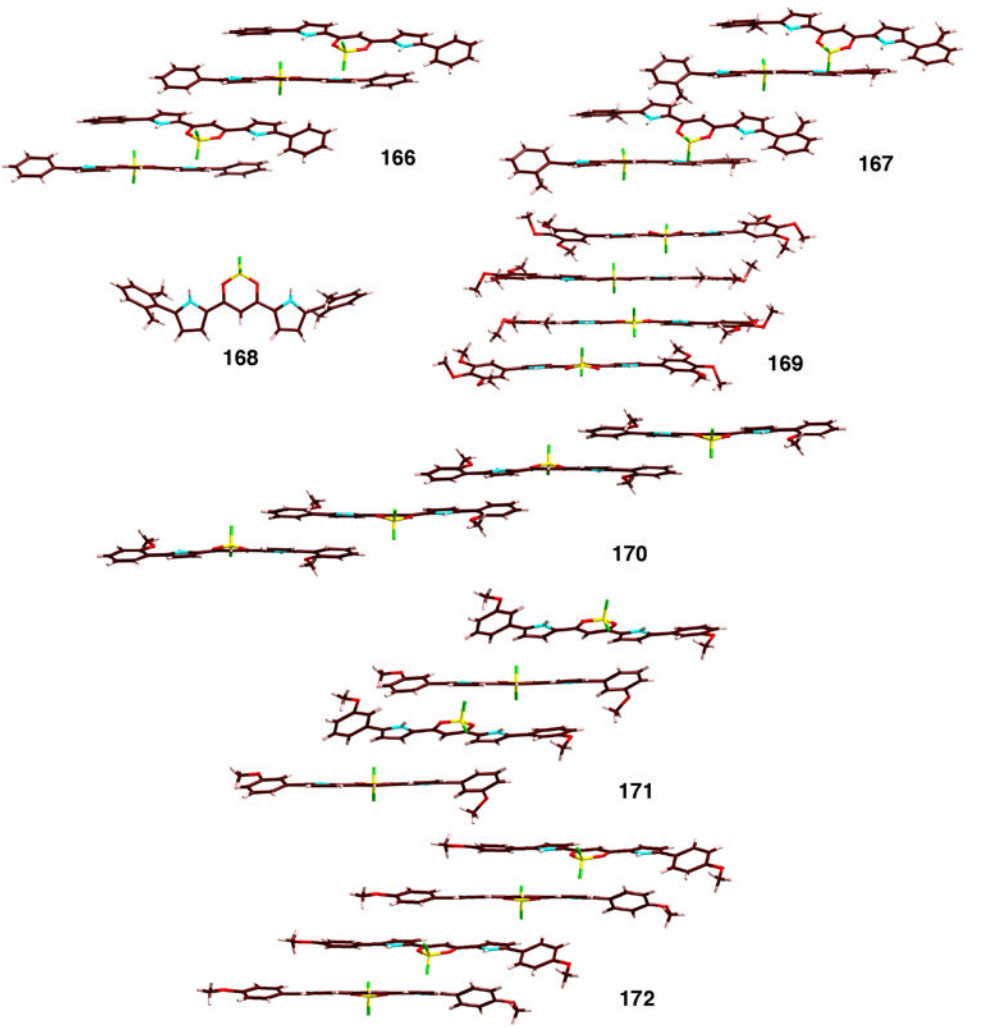

Figure 44. Solid-state molecular assemblies of acyclic anion receptors **168**–**172**. In the case of **169**, one of the three stacking modes is represented.[143,147]

bis-iodinated derivative **177** can be transformed into pyrrolyl-, furyl-, and thienyl-substituted derivatives **180**–**182** (Figure 45a).[153] Mono-iodinated **176** and bis-iodinated **177** are also converted to receptors **183**–**186** possessing a formyl functionality.[154] The covalently linked dimer **187** (Figure 45b) was synthesized by the coupling reaction of mono-iodinated **176** with 1,3-benzenediboronic acid bis(pinacol)ester (0.5 equivalents). Further iodination of phenylene-bridged dimer **187** affords bis-iodinated and mono-iodinated dimers (**188** and **189**).[152] The UV-visible absorption bands of **179**–**182** in CH_2Cl_2 are observed at 499, 551, 538,

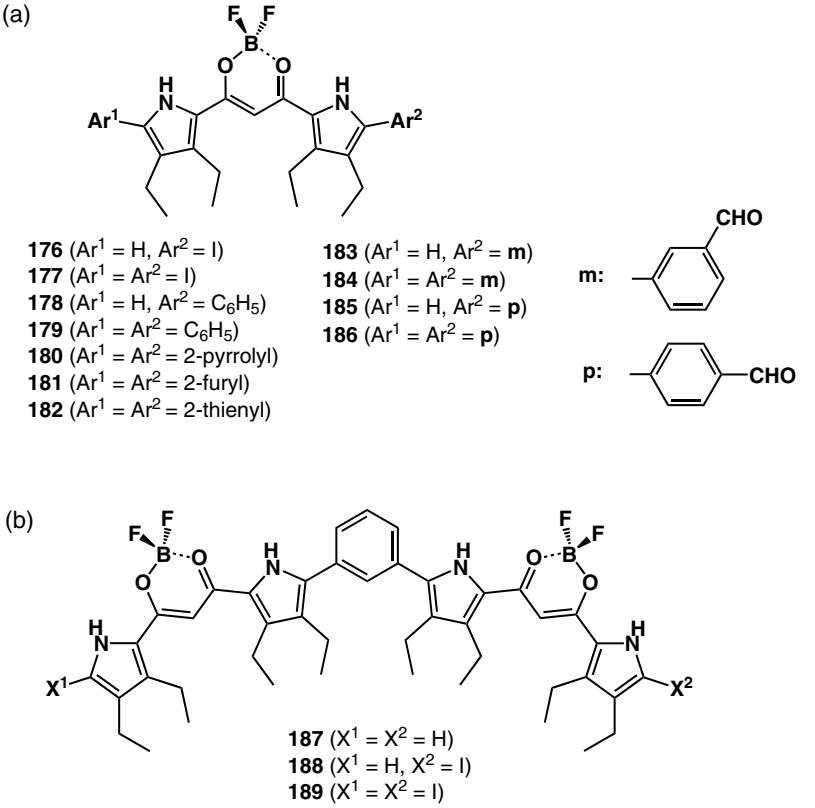

Figure 45. (a) Iodinated **176** and **177** and β-ethyl-substituted aryl-substituted receptors **178**–**186**[152–154]; (b) phenylene-bridged dimers **187**–**189**.[152]

and 527 nm, respectively, suggesting red-shifts that are comparable to that of α-unsubstituted **160** (451 nm).[152,153] Those of formyl-substituted **183**–**186** in CH_2Cl_2 are observed at 474, 495, 482, and 510 nm, respectively.[154] Dimer **187**, whose λ_{max} value is 489 nm due to the incomplete π-conjugation at the *meta*-phenylene linkage, and its iodinated derivatives can be potential subunits for forming anion-responsive oligomers.[152]

In the solid state, receptors **177** and **179**–**186** form stacked dimers or higher-stacked structures (Figure 46).[152–154] Compounds **177**, **179**–**182**, and **185** form the stacking dimers because of sterical β-ethyl-substituents, whereas formyl **183** and **184** exhibit a more tightly stacked structure comprising more than two units in these derivatives because of supporting van der Waals interactions between ethyl moieties and between ethyl units and the π-plane. In contrast, there are no stacked structures in **186**. In most structures, through intermolecular N–H···F–B hydrogen bonds, complicated 3D networks are formed along with stacking interactions. For

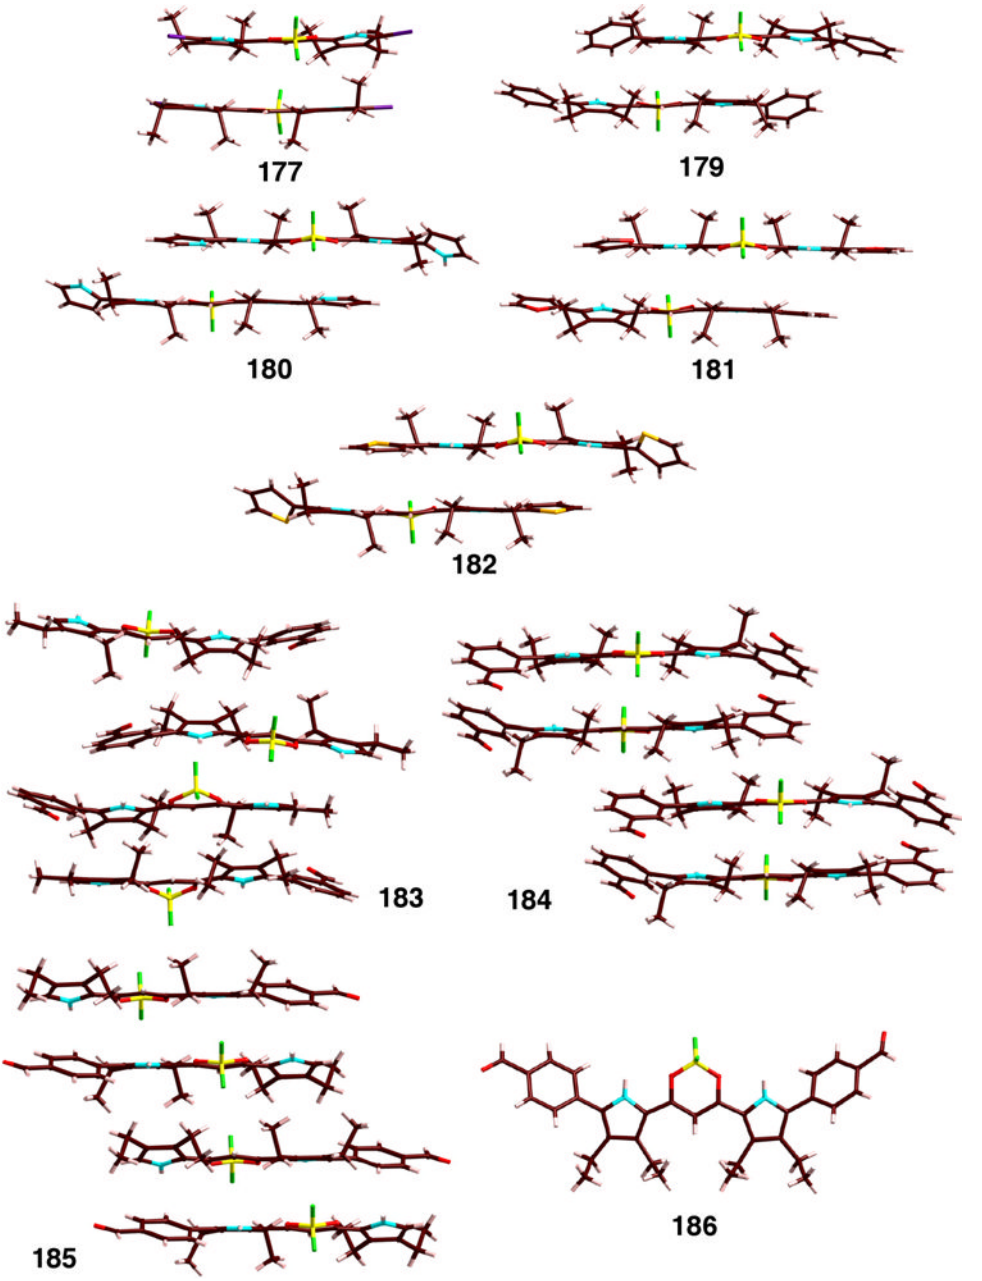

Figure 46. Solid-state molecular assemblies of acyclic anion receptors **177** and **179–186**.[152–154]

example, receptors **177** and **179–182** form dimeric structures using N–H···F and aryl-C(N)–H···F interactions,[152,153] while **183–186** fabricate more complicated hydrogen-bonding assemblies using the CHO moiety, along with pyrrole NH and BF units.[154] In these solid-state structures along with those of other receptors (Figures 40 and 44), the acyclic anion receptors exist as dispersed monomer forms in good solvents, while they form ordered 3D organized structures, i.e. crystals, in poor solvents.

The anion affinities of the β-unsubstituted α-aryl-substituted receptors and β-ethyl **179** were estimated from changes in the UV-visible absorption spectra in the presence of increasing concentrations of the respective anions (Table 16).[143,147,152] Compared to unsubstituted **157**,[142] α-phenyl **166** shows augmented K_a values, especially for halides (*ca.* 2.0- and 1.3-fold enhancement for Cl^- and Br^-, respectively), possibly due to pentacoordination (Figure 47), in contrast to oxoanion binding.[143] In contrast, doubly and totally *o*-C-blocked **167** and **168** exhibit K_a values less than those of **166** (*ca.* 1/10 and 1/30 for Cl^- binding), possibly due to sterical hindrance and electrostatic repulsion of the anions by the π-plane.[143] The K_a values of *meta*-substituted **171** and **172** and *para*-substituted **174** and **175** are almost comparable to those of **166**. There are no significant differences between methoxy- and octyloxy-substituted receptors. In contrast, the intramolecular hydrogen bonding in *ortho*-substituted **170** and **173** affords complicated binding modes with low affinities for anions; this result suggests that *ortho*-substituents can interfere with anion binding.[147] Furthermore, compared to **166**, β-ethyl **179** shows similar and smaller K_a values for oxoanions and halides, respectively.[152] ^{1}H NMR spectral changes of α-aryl-substituted receptors upon anion binding provide valuable insights into the binding behaviors of aryl-*o*-CH along with those of core pyrrole NH and bridging CH. For example, upon the addition of 1.5 equivalents of Cl^- as a TBA salt to a CD_2Cl_2 solution of **166** (1×10^{-3} M) at 20 °C, the signals due to **166** at 7.68 (*o*-CH), 9.73 (pyrrole NH), and 6.23 (bridging CH) ppm decreased in intensity with the concurrent appearance of new signals at 8.19, 12.27, and 9.04 ppm, respectively.[143] Furthermore, at lower temperatures with a small amount of Cl^-, a new NH signal between that of the free receptor and the [1 + 1] complex is attributed to the [2 + 1] binding complex $\mathbf{166}_2 \cdot Cl^-$. Formation of the [2 + 1] complex is also supported by DOSY NMR and electrospray ionization time-of-flight mass spectrometry (ESI-TOF-MS).[143] Furthermore, the signals of the aryl-substituted receptors and the pentacoordinated receptor–anion complexes can be observed independently, suggesting that a slow exchange takes place between these species on the NMR time scale. Rate constants k for the F^-, Cl^-, and Br^- binding of, for example, **166** using TBA salts in CH_2Cl_2 at 25 °C are estimated to be 7.2×10^4, 13.0×10^4, and 6.0×10^4 $M^{-1}s^{-1}$, respectively, by stopped-flow measurements. While the order of k ($Cl^- > Br^-$) is consistent with that of the binding

Table 16. Anion-binding constants (K_a, M^{-1}) of **166**–**168**, **171**, **172**, **174**, **175**, and **178** upon the addition of anions as TBA salts in CH_2Cl_2. The values in the parentheses are the ratios to the K_a value of unsubstituted **157**. Data taken from Refs. 143, 147, and 152.

constants (K_a), the more associated F^- (240 000 M^{-1}) exhibits an intermediate value between those of Cl^- and Br^-; this suggests that thermodynamic stability is not always correlated with the kinetic properties.[143]

The K_a values of β-ethyl-substituted **179–182** (Table 17) are determined from UV-visible absorption spectral changes induced by the addition of appropriate anions as TBA salts in $CHCl_3$ containing 0.5% EtOH, which suppresses the binding affinities because of the higher K_a values of **180** in CH_2Cl_2.[153] For example, pyrrolyl **180** shows considerably larger K_a values, $>10^6$ M^{-1} for Cl^-, $H_2PO_4^-$, and $CH_3CO_2^-$, than those of **179**, **181**, and **182** and α-unsubstituted **160** because of the presence of multiple polarized NH sites. Upon the addition of 1 equivalent of Cl^- to $CDCl_3$ solution of **180** (1×10^{-3} M) at 20 °C, the signals of the "inner" NH and "outer" (terminal) NH are shifted from 9.29 and 8.77 ppm to 11.04 and 11.16 ppm, respectively, suggesting that the anions are bound more tightly to the terminal pyrrole NH.[153] The anion-binding behavior of formyl-substituted **183–186** was

Table 18. Anion-binding constants (K_a, M^{-1}) of **183–186** upon the addition of anions as TBA salts in CH_2Cl_2. The values in the parentheses are the ratios to the K_a values of β-ethyl-substituted **160**. Data taken from Ref. 154.

Anion	**183**	**184**	**185**	**186**
Cl^-	13 000 (1.9)	27 000 (4.0)	20 000 (2.9)	65 000 (9.6)
Br^-	2000 (1.7)	2700 (2.3)	2200 (1.8)	3900 (3.3)
$CH_3CO_2^-$	120 000 (0.57)	200 000 (0.95)	250 000 (1.2)	320 000 (1.5)
$H_2PO_4^-$	9700 (0.11)	71 000 (0.78)	74 000 (0.81)	37 000 (0.41)
HSO_4^-	400 (0.33)	870 (0.73)	420 (0.35)	320 (0.27)

also examined from the UV-visible absorption spectral changes (Table 18).[154] In contrast to the smaller K_a values in accord with an increase in the number of phenyl-substituents in **160**, **178**, and **179** because of the steric hindrance between the α-phenyl and β-ethyl moieties, bisformyl-substituted receptor **184** exhibits augmented K_a values compared to those of the corresponding monoformyl **183**. On the other hand, receptor **186** shows larger K_a values for halide and $CH_3CO_2^-$ anions than that for **185**.[154] This tendency of anion-binding behavior in formylphenyl-substituted receptors **183–186** may be derived from the increased affinity of the *o*-CH sites due to the electron-withdrawing formyl moiety.[152,154]

Maeda *et al*. reported single-crystal X-ray structures of the anion complexes of α-aryl-substituted receptors, **166**·Cl^-, **169**·Cl^-, and **180**·Cl^-, which form penta-coordinated geometries as the building components of the electrostatically mediated, alternatively stacking structures consisting of "planar anions (receptor–anion complexes)" and tetra-alkylammonium cations (Figure 48).[143,153] Based on the "charge-by-charge" columnar structures, which are observed only in the crystal states as 3D organized structures at present, dimension-controlled organic salts can be fabricated by using planar anions under appropriate conditions.

C. Anion-Responsive Supramolecular Gels Consisting of Acyclic Anion Receptors

Modification at the periphery of the receptors makes it possible to stabilize the stacked structures not only in the solid state but also in the solution state; for example, the introduction of various additional interactive moieties at the α-aryl rings enables the formation of molecular assemblies as soft materials that exhibit

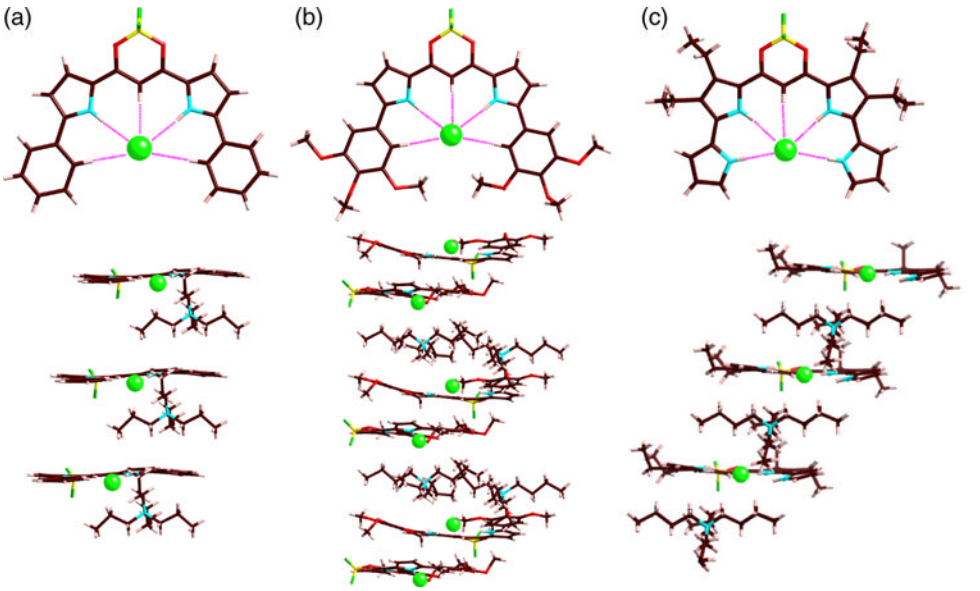

Figure 48. Solid-state single molecules and "charge-by-charge" assemblies of receptor–anion complexes: (a) **166**·Cl^-, (b) **169**·Cl^-, (c) **180**·Cl^-. Tetraalkylammonium cations are omitted for clarity in the top views.[143,153]

specific properties such as anion-responsive organized structures. Among the self-assembled oligomeric systems based on low-molecular-weight π-conjugated molecules, the gel materials — especially those susceptible to the influence of external stimuli — are of interest and play a crucial role as potential soft materials.[9–12,155,156] Supramolecular gels consist of nanoscale fibers, tubes, and sheets, formed by organized molecular assemblies. In contrast to physical stimuli, the structural modification of supramolecular gels under chemical control is very attractive because a large variety of potential additives are available.[157,158]

Maeda *et al*. prepared derivatives with aliphatic chains at the aryl rings (**190–192**, Figure 49) by procedures similar to those used for **166–175**.[143] These anion receptors **190–192** gelate octane (10 mg/mL); the transition temperatures between the gel and solution states are −8.5 (**190**), 4.5 (**191**), and 27.5 °C (**192**, Figure 50a), suggesting that the longer alkyl chains afford more stable gels. An octane gel of hexadecyloxy-substituted **192** (10 mg/mL) exhibits split absorption bands with absorption maxima at 525 and 555 nm along with a shoulder at 470 nm due to the formation of stacked structures; this is in contrast to the single peak at 493 nm exhibited in a diluted solution containing the dispersed monomers. The octane gel exhibits emission at 654 nm (excited at 470 nm), which is red-shifted as compared to that ($\lambda_{em} = 533$ nm; $\lambda_{ex} = 493$ nm) in the diluted condition (1×10^{-5} M).

191 (R = $OC_{12}H_{25}$)
192 (R = $OC_{16}H_{33}$)

Figure 49. BF_2 complexes **190**–**192** with 3,4,5-trialkoxy-substituted aryl rings.[143]

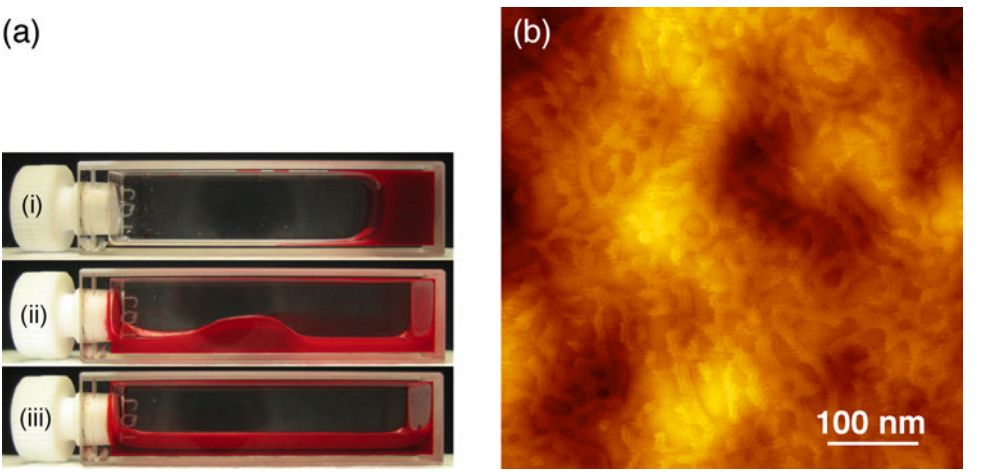

Figure 50. (a) Phase transition of **192** in octane (10 mg/mL) between solution and gel at (i) 25.0, (ii) 27.5, and (iii) 30.0 °C[143]; (b) AFM 2D image in a tapping mode of **192** (from octane gel) cast by spin-coating on a silicon substrate.[143]

Supramolecular organogel formation is achieved for the ordered structures based on the noncovalent interactions between the π-conjugated moieties and their substituents; this is supported by AFM (Figure 50b), SEM, and XRD observations.[143]

The addition of TBA salts of anions (10 equivalents) in the solid form to the fluorescent octane gel results in the transition to the solution state; the gels are gradually transformed into solutions beginning from areas close to where the solid salts have been added (Figure 51).[143] In this process, once the receptor (gelator) molecules in the gel bind to the anions, the counter TBA cations concertedly approach the receptor–anion complexes to form soluble ion pairs and afford the octane solution. These transitions in the case of the gel of **192** are quite distinct from the crystal states mentioned previously (e.g. **169**·Cl^-; Figure 48b), which are

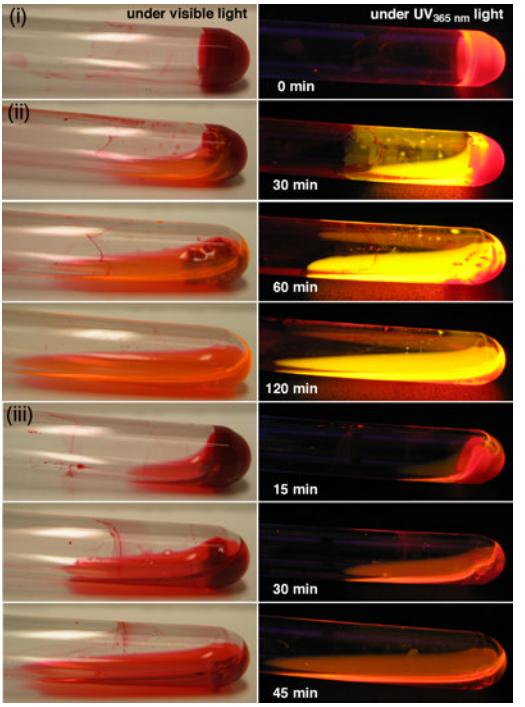

Figure 51. Transition of supramolecular organogel of **192** in octane (10 mg/mL, (i)) at 20 °C upon the addition of (ii) Cl^- (10 equiv.) and (iii) F^- (10 equiv.) added as solid TBA salts.[143]

due to the insolubility of the TBA salt of **169**·Cl^- in apolar hydrocarbon solvents. In contrast, the absorption and emission spectra of the gel from **192** that are changed by the addition of anions suggest that the transitions occur from the molecular assemblies to the dispersed monomeric states.[143,159]

The formyl group is well known to be transformed into an imine (Schiff base) moiety by treatment with a primary amine. Condensation of **183**–**186** with hexadecylamine or 3,4,5-trihexadecyloxyaniline and following reduction by $NaBH(OAc)_3$ afforded **193**–**200** (Figure 52).[154] In contrast to **192**, bis-substituted **198** and **200** in octane (10 mg/mL) appear to have fairly dispersed, and not gel-like, states at room temperature. When the solutions are cooled, **198** and **200** show opaque solutions below *ca.* 1 and *ca.* −10 °C, respectively, and form gel-like materials below *ca.* −10 and *ca.* −30 °C, respectively (Figure 53). The variable temperature (VT) UV-visible spectral changes in **198** at 1×10^{-3} M between 60 and −50 °C indicate the formation of stacked structures at lower temperatures. Formation of assembled structures is also supported by NMR analysis in octane-d_{18} and DLS. In these systems, connection of three π-conjugated moieties — a core π-plane and two side aryl units, by sp^3 methylene bridges provides supramolecular

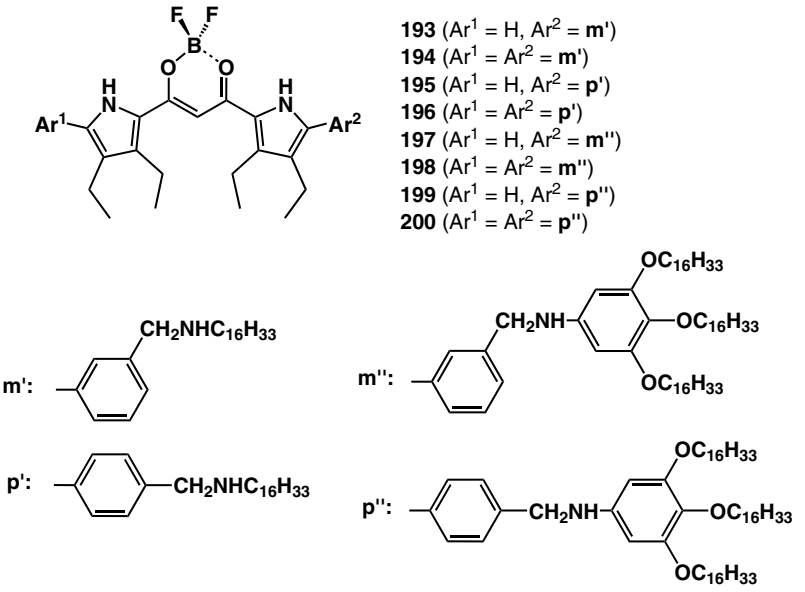

Figure 52. BF_2 complexes **193**–**200** derived from formyl-substituted receptor molecules.[154]

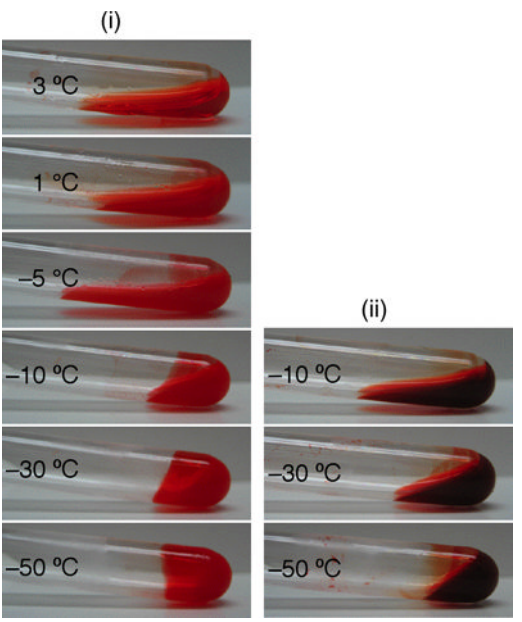

Figure 53. Photographs of the gel-like materials of (i) **198** and (ii) **200** in octane (10 mg/mL).[154]

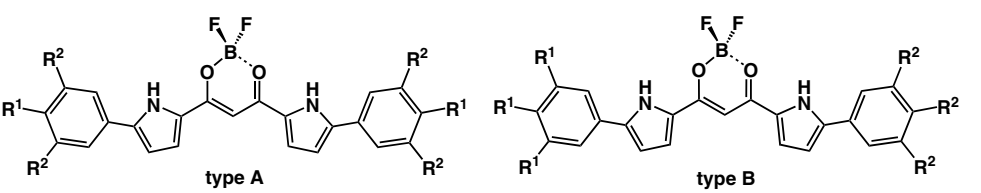
assemblies, which are not very rigid but yield soft materials by fairly ordered organization under the appropriate conditions. Furthermore, addition of 1 equivalent of Cl^- as a TBA salt can modulate the assembled structures, along with the optical and electronic properties.[154]

D. Solvent-Assisted Organized Structures from Amphiphilic Anion Receptors

Supramolecular assemblies in an aqueous solution are ubiquitous in biotic systems such as folded proteins, DNA double helices, and membranes consisting of lipid bilayers. These organized structures can be formed by using the interactions between hydrophobic moieties inside the assemblies and the association of hydrophilic sites with water molecules.[8,16] Organized structures that can be modulated by external stimuli provide versatile actuators activated in aqueous solutions and related solvents.[160–162] Maeda *et al*. synthesized the poly(ethylene glycol) (PEG)-substituted amphiphilic π-conjugated acyclic oligopyrroles (type A — **201**–**204**; type B — **205**–**208**; Figure 54) by procedures similar to those for **166**–**175** and **190**–**192**.[145] While amphiphiles **201**, **207**, and **208** exhibit precipitation in water, derivatives **202**–**206** are soluble in the same solvent, wherein their λ_{max} values are observed at 460, 496, 506, 462, and 481 nm (1×10^{-5} M), respectively, which are blue-shifted as compared to those in MeOH (498, 510, 512, 510, and 512 nm), suggesting the formation of H-aggregates in aqueous solutions. The fluorescence spectra of **202**–**206** in aqueous solutions are observed as the fluorescence of each monomer at 546, 571, 572, 672, and 671 nm with low-emission quantum yields (Φ_F, determined at λ_{ex} values that are equal to the respective λ_{max} values) of 0.01, 0.01, 0.09, 0.02, and 0.02, respectively, which are characteristic aspects of H-aggregates. The solid films cast from the aqueous solutions of **202**–**206** exhibit almost the same red-shifted UV-visible absorption profiles (λ_{max} = 526, 540, 530, 548, and 531 nm, respectively) as those cast from CH_2Cl_2 solutions;



201 (R^1 = TEG, R^2 = H)
202 (R^1 = H, R^2 = TEG)
203 (R^1 = R^2 = TEG)
204 (R^1 = R^2 = HEG)

205 (R^1 = OC_8H_{17}, R^2 = TEG)
206 (R^1 = OC_8H_{17}, R^2 = HEG)
207 (R^1 = $OC_{16}H_{33}$, R^2 = TEG)
208 (R^1 = $OC_{16}H_{33}$, R^2 = HEG)

Figure 54. Amphiphilic derivatives of acyclic anion receptors **201**–**208**.[145]

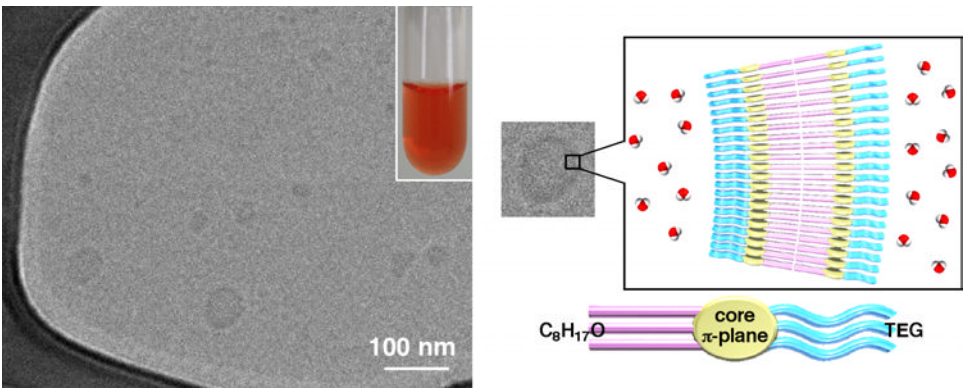


Figure 55. Image of cryo-TEM of **205** from an aqueous solution (1×10^{-5} M) without staining, photograph of the aqueous solution (1×10^{-4} M; inset), and possible assembling mode of **205** in vesicles.[145]

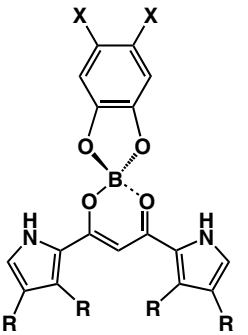
this result suggests that the removal of water molecules by slow evaporation at room temperature or by a freeze-drying process disrupts the H-aggregate formations, which are supported by water molecules, and instead forms other assembled structures (J-type aggregates).[145]

The morphologies of the transformed organized structures from the aqueous solutions were examined: only larger assemblies without specific shapes are observed by TEM analyses of the aqueous solutions (1×10^{-5} M) of **202–204** with $UO_2(OAc)_2$ staining, while under the same conditions **205** and **206** exhibit the formation of capsules, with diameters within the range of 50–150 nm, and cylindrical aggregates, respectively, as transformed objects from the removal of water molecules around the hydrophilic moieties.[145] Furthermore, cryo-TEM analysis of **205** (1×10^{-5} M) shows vesicular structures[163] with diameters of 30–80 nm (Figure 55), which are consistent with the result of the DLS measurements. The wall thickness (dark part) of capsules is estimated to be *ca*. 5 nm, indicating hydrophobic segments which consist of bilayers of amphiphilic molecules (*ca*. 3.9 nm from AM1 calculation). In contrast to the amphiphiles with only hydrophilic chains (type A), possibly **205** (type B) forms bilayers like biotic lipids by using hydrophobic interactions of the aliphatic chains and locates the hydrophilic TEG chains outside the layers to obtain water-soluble vesicles.[145]

E. Modifications around Boron Units of Acyclic Anion Receptors

The replacement of fluorine substituents in a boron moiety of molecular flippers by 1,2-diol units such as catechol derivatives enables the attachment of acyclic



209 (R = H, X = H)
210 (R = C_2H_5, X = H)
211 (R = H, X = NO_2)
212 (R = C_2H_5, X = NO_2)

Figure 56. Catechol-substituted boron complexes of dipyrrolyldiketones **209**–**212**.[164]

anion receptors to the π-conjugated "backbone." Maeda *et al*. synthesized catechol-substituted receptors **209**–**212** (Figure 56) from the corresponding dipyrrolyldiketones[137,142] by treatment with BCl_3 and then with excess catechol derivatives in refluxing CH_2Cl_2.[164] The UV-visible absorption spectra of "BO_2" complexes **209** and **210** in CH_2Cl_2 exhibit absorption maxima (λ_{max}) at 435 and 454 nm, respectively, which are red-shifted by 2–3 nm in comparison with the maxima of the corresponding BF_2 complexes: unsubstituted **157** (432 nm) and β-ethyl **160** (452 nm). Furthermore, compared with the high-intensity fluorescence of **160** at 471 nm (λ_{em} excited at 420 nm; emission quantum yield — $\Phi_F = 0.98$), the weak fluorescent emission of **210** observed at 474 nm (λ_{em} excited at 420 nm; $\Phi_F = 0.001$)[165] can be attributed to the quenching path of the intramolecular electron transfer involved in HOMO and HOMO–1, which are localized at the catechol moiety. The binding constants (K_a) of **210** (and the ratios to the K_a values of **160**) for anions in CH_2Cl_2 are 2300 (0.34) (Cl^-), 270 (0.23) (Br^-), 33 000 (0.10) ($CH_3CO_2^-$), 67 000 (0.74) ($H_2PO_4^-$), and 80 (0.07) (HSO_4^-) M^{-1} due to the electronegativity of catechol oxygens (**210**), which is lower than that of fluorines (**160**). The K_a values of **212** for anions are higher [46 000 (Cl^-), 5400 (Br^-), 1 300 000 ($CH_3CO_2^-$), 150 000 ($H_2PO_4^-$), and 2300 (HSO_4^-) M^{-1}] than those of **210** because of the electron-withdrawing effect of the nitro groups.[164]

The substitution at a boron unit by vicinal hydroxyl groups of various functional units enables the formation of covalently linked dimers. Maeda *et al*. prepared ditopic receptors **213** and **214** (Figure 57a) by the treatment of intermediate BCl_2 complexes with *p*-phenylene-bridged dicatechol.[164] These receptors are extended systems bridged by "spacer" moieties between the acyclic anion receptor; single-crystal X-ray analysis of **214** suggests that the two receptor units are oriented in the same direction so that a Π-shaped *syn* conformation is generated with an intramolecular B–B distance of 8.68–9.17 Å (Figure 57b). Because of the

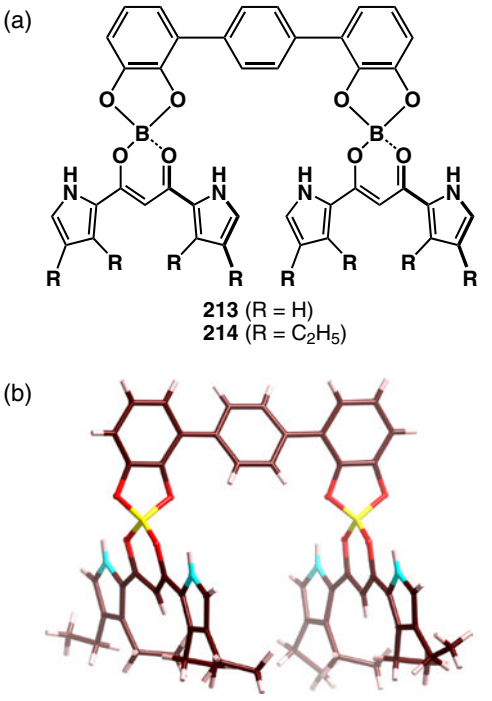


Figure 57. (a) Terphenyl-bridged dimers **213** and **214**[164]; (b) single-crystal X-ray structure of **214**.[164]

appropriate locations of the two receptor units, **214** has shown [1 + 1] binding for linear dicarboxylates [$^{-}O_2C(CH_2)_nCO_2^{-}$, $n = 2$–6]; the K_a values for succinate ($n = 2$), glutarate ($n = 3$), adipate ($n = 4$), pimelate ($n = 5$), and suberate ($n = 6$) as their TBA salt forms in CH_2Cl_2 are 19 000, 72 000, 810 000, 2 600 000, and 440 000 M^{-1}, respectively. This observation suggests that the distance between the receptor units (*ca.* 9 Å) is crucial in the determination of the selectivity of the dianions. In contrast to the α-linked oligomers,[152] the systems based on the BO_2 complexes behave as genuine multitopic receptors that can be incorporated in various macromolecules.[164,166]

VI. Summary

In this chapter, progress in the guest-binding and supramolecular chemistry of anion-responsive acyclic oligopyrroles has been described. Acyclic oligopyrrole systems are advantageous because they exhibit dynamic conformation changes and can be incorporated into various macromolecules and complexes as building subunits by means of covalent and noncovalent interactions such as metal coordination,

hydrogen bonding, and π–π stacking. The formation mechanisms and styles of nanoscale structures such as supramolecular assemblies depend on the molecular structures of the building subunits. Therefore, modifications to the receptor molecules result in versatile, unique organized architectures and stimulus-responsive soft materials with various utilities. Furthermore, anion binding by π-conjugated acyclic oligopyrroles is fascinating from the viewpoint of forming planar anionic species. The interaction of suitable negative-charged planar units with the appropriate cations will make it possible to form novel supramolecular assemblies and to tune and control the structures and properties of these materials, thereby making them practical. The use of appropriate molecular design and definitive synthetic procedures for the subunits will allow the formation of soft materials such as gels, liquid crystals, colloids, and micelles, consisting of both negative- and positive-charged species as the building components.

VII. Acknowledgments

The contribution from the Maeda group reported herein has been supported by Grants-in-Aid for Young Scientists (B) (Nos. 17750137, 19750122, 21750155) and Scientific Research in a Priority Area "Super-Hierarchical Structures" (Nos. 18039038, 19022036) from the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Izumi Science and Technology Foundation, Iketani Science Technology Foundation, Mitsubishi Chemical Corporation Fund, Kumagai Foundation for Science and Technology, Nissan Science Foundation, Saneyoshi Scholarship Foundation, Japan Securities Scholarship Foundation, Science and Technology Foundation of Japan, Shorai Foundation for Science and Technology, and Kao Foundation for Arts and Sciences, the matching fund subsidies for private universities from the MEXT (2003–2008 and 2009–2014), and the Ritsumeikan Global Innovation Research Organization (R-GIRO) project (2008–2013).

39 The Synthesis and Properties of Dipyrrins

Tabitha E. Wood, Md. Imam Uddin and Alison Thompson

Department of Chemistry, Dalhousie University, Halifax,
Nova Scotia, B3H 4J3, Canada

List of Abbreviations

Ac	acetyl
acac	acetylacetonato
bipy	2,2′-bipyridine
BODIPY	boron difluoride dipyrrinato
CAN	ammonium cerium(IV) nitrate
CDMT	2-chloro-4,6-dimethoxy-1,3,5-triazine
DAT	diaminotriazinyl
DCC	*N,N*′-dicyclohexylcarbodiimide
DDQ	2,3-dichloro-5,6-dicyano-1,4-benzoquinone
DIBAL-H	diisobutylaluminum hydride
DIEA	*N,N*-diisopropylethylamine
DMAP	*N,N*-dimethylaminopyridine
DMF	*N,N*-dimethylformamide
DMSO	dimethylsulfoxide
DTT	dithiothreitol
ESR	electron spin resonance
Et	ethyl
hfacac	hexafluoroacetylacetonato
HPLC	high performance liquid chromatography
*i*Pr	*iso*-propyl
IR	infrared
*m*CPBA	3-chloroperbenzoic acid
Me	methyl
MOF	metal-organic framework
*n*Bu	*n*-butyl
NMR	nuclear magnetic resonance
Ph	phenyl
salen	bis(salicylidene)ethylenediamine
p-TSA	*p*-toluenesulfonic acid
Tf	trifluoromethanesulfonyl
TFA	trifluoroacetic acid
THF	tetrahydrofuran

I. Dipyrrins

A. Nomenclature of Dipyrrins

In 1987 an IUPAC Commission established guidelines for the nomenclature of dipyrrins, and many other oligopyrrolic molecules.[1] The recommended numbering scheme for dipyrrins is shown in Figure 1. Occasionally the 1- and 9-positions are referred to as the α-positions, and the 5-position as the *meso*-position, which are terms borrowed from historic pyrrole and porphyrin nomenclature, respectively. Structural isomers of dipyrrins are named according to their connectivity, such as 2,2′-, 2,3′- and 3,3′-dipyrrins, although the actual usage of numbers to describe the connectivity in bis(dipyrrin)s is far from standardized.[2,3] 2,2′-Dipyrrins constitute the vast majority of structures being described when the generic term "dipyrrin" is used, and this convention will be followed in this chapter.

B. Syntheses of Dipyrrins

1. *Introduction*

Research interest regarding dipyrrins originated in experiments conducted by early twentieth century chemists who pursued extensive research on these compounds as intermediates in the synthesis of porphyrins. At this time, dipyrrins were commonly referred to as dipyrromethenes. A particularly important publication was Hans Fischer and Hans Orth's *Die Chemie Des Pyrrols*,[4] a compilation of physical data and preparative strategies for known dipyrrins (although many of them circuitous by today's standards) published in 1937. The required knowledge of techniques for the synthesis and handling of pyrrole derivatives towards the "messy and often ruinous manipulation"[5] of dipyrrins resulted in the relatively esoteric characterization of these compounds for many decades. After

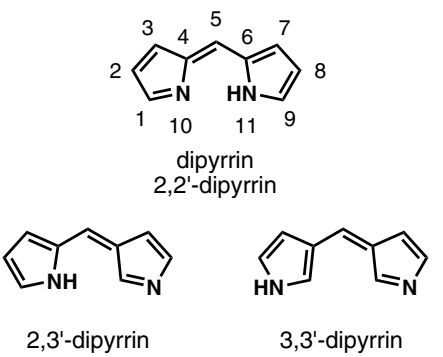

Figure 1. Dipyrrin numbering scheme.

languishing in relative obscurity, dipyrrins have now returned to the forefront of chemical research in the capacity of ligands that can be prepared from readily available reagents, and are often capable of forming crystalline charge-neutral complexes with desirable optical properties using an ever-growing variety of cations.

After a short history of the development of dipyrrin synthesis, Part I of this chapter describes the finite number of methods commonly used to synthesize dipyrrins. This is followed by a discussion of some of the physical properties of these molecules, as well as the applications that they have found. Part II focuses upon the synthesis, properties, and applications of cation-coordinated dipyrrinato complexes, which is where the majority of modern research interest seems to lie.

The aim of this chapter is to provide a brief summary of the historical background and current trends in the burgeoning field of dipyrrin and dipyrrinato complex research. The objective is therefore a representation of all modern dipyrrin research. A full appreciation of modern applications of dipyrrins is best achieved by reading this chapter in conjunction with Chapter 37 (by Burgess and Loudet) in the current volume in this Handbook on the synthesis and spectroscopic properties of BODIPY dyes, as well as Chapter 41 (by Broering) and Chapter 40 (by Balch and Garcia) concerning oligomeric dipyrrins and their dipyrrinato complexes.

Methods for the synthesis of dipyrrins vary according to the required symmetry in the product as well as the number and nature of substituents. The presence of a substituent in the 5-position is especially decisive with regard to a suitable synthetic strategy. Generally, methods that involve condensation of two different pyrrolic compounds are well-suited to the preparation of unsymmetric 5-unsubstituted dipyrrins. Conversely, methods involving the oxidation of dipyrromethanes, which are also known as 5,10-dihydrodipyrrins by IUPAC guidelines,[1] are more suited for the preparation of symmetric, especially 1,2,3,7,8,9-unsubstituted-5-substituted dipyrrins. Substituents on the skeleton of the dipyrrin generally reduce the possibility of oligomerization and increase the stability of the product to attack from a variety of nucleophiles.[6–10] The preparation of fully unsubstituted dipyrrin has been reported; however, the compound was unstable in solution above –40 °C due to its susceptibility to attack by both electrophiles and nucleophiles,[11] though it has also been known to be stable when isolated as its boron difluoride complex.[12,13] The preparation of 5-aryldipyrrins represents a shift in research interest from alkyl-substituted dipyrrins that are suitably disposed as precursors of naturally-occuring oligopyrroles towards dipyrrins that are capable of forming stable radical cations for optoelectrochemical applications.[14]

2. *Synthesis of Dipyrrins by Condensation of Pyrroles*

The procedures for synthesizing dipyrrins by the acid-catalyzed condensation of two pyrrole reagents have remained relatively unchanged from the time of Hans Fisher. In this class of reactions there are three general strategies, depending upon the nature of substitution about the target dipyrrin. The procedure for unsymmetric, 5-unsubstituted dipyrrins is described in the following section, that of symmetric, 5-unsubstituted dipyrrins in Section I.B.2.b and that of symmetric, 5-substituted dipyrrins in Section I.B.2.c.

a. *Unsymmetric 5-unsubstituted dipyrrins*

The acid-catalyzed condensation of a pyrrole-2-carboxaldehyde with a pyrrole that is unsubstituted in the 2-position yields a 5-unsubstituted dipyrrin[15] as shown in Figure 2, and is capable of providing unsymmetrically substituted products. Reports show that bacteria are capable of utilizing supplemented pyrrole-2-carboxaldehyde and 2-unsubstituted pyrrole substrates in the enzymatic synthesis of dipyrrin compounds using an analogous reaction.[16,17]

The choice of acid catalyst for this condensation is open to variation: hydrobromic acid is commonly used, as the corresponding hydrobromide salts of dipyrrins tend to be more crystalline than salts of many other anions,[4] but phosphorus(V) oxychloride has also seen usage.[18,19] In one report, the use of a 2,5-diunsubstituted pyrrole to prepare a 1-unsubstituted bis(dipyrrin) was made possible through the use of phosphorus(V) oxychloride when mineral acids failed.[20] Generally, the yield for this reaction is high, and is limited only by purification of the product from the reaction mixture, although this aspect is not to be assumed facile. Isolation is usually achieved by precipitation of the dipyrrin salts, as they are generally more stable than the free-base, especially in the case of 5-unsubstituted dipyrrins.[15] A limitation to this reaction is that low yields are obtained for dipyrrins prepared from 2-unsubstituted pyrroles with electron-withdrawing groups, resulting from competing self-condensation of the 5-formyl pyrrole with elimination of one carboxaldehyde group.[15] This can be avoided by planning the synthesis such that of the two pyrrole precursors, the less nucleophilic

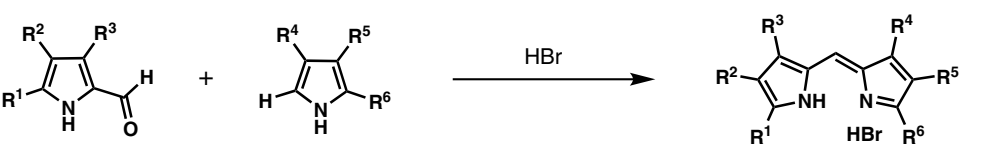

Figure 2. Synthesis of unsymmetric, 5-unsubstituted dipyrrins by acid-catalyzed condensation reactions.

pyrrole moiety bears the carboxaldehyde functional group. The 2-unsubstituted pyrrole reactant can be prepared *in situ* by decarboxylation of pyrrole-2-carboxylic acids in the presence of strong acid.[21,22]

b. *Symmetric 5-unsubstituted dipyrrins*

Symmetric dipyrrins that bear a hydrogen substituent at the 5-position can be prepared using two equivalents of a 2-unsubstituted pyrrole. This preparation generally involves combining the pyrrole reactant with a mixture of formic acid and a strong mineral acid, such as hydrobromic acid,[4] hydrochloric acid,[23] or perchloric acid,[24] or with a mixture of an orthoformate and trifluoroacetic acid,[25,26] as depicted in Figure 3. In the most popular variations of this method the 2-unsubstituted pyrrole is prepared *in situ* from a pyrrole bearing a functional group that can be eliminated under strongly acidic conditions, such as a carboxylic acid group, or a carboxylic ester (usually the ethyl ester). It has been shown that a moderate reaction temperature of 20 to 40 °C is critical for the preparation of the 2,8-di(carbethoxy)-substituted symmetric dipyrrin (**3** in Figure 4) using the *tert*-butyl ester derivative **1** as a precursor for *in situ* generation of the 2-unsubstituted pyrrole reagent.[26]

c. *Symmetric 5-substituted dipyrrins*

The condensation of two equivalents of a 2-unsubstituted pyrrole with an acid chloride,[27,28] as shown in Figure 5, provides a synthetic route to 5-substituted

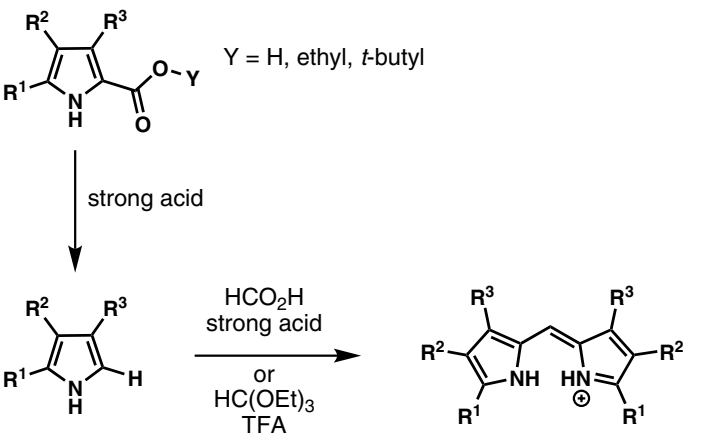

Figure 3. Synthesis of unsymmetric, 5-unsubstituted dipyrrins by acid-catalyzed condensation reactions.

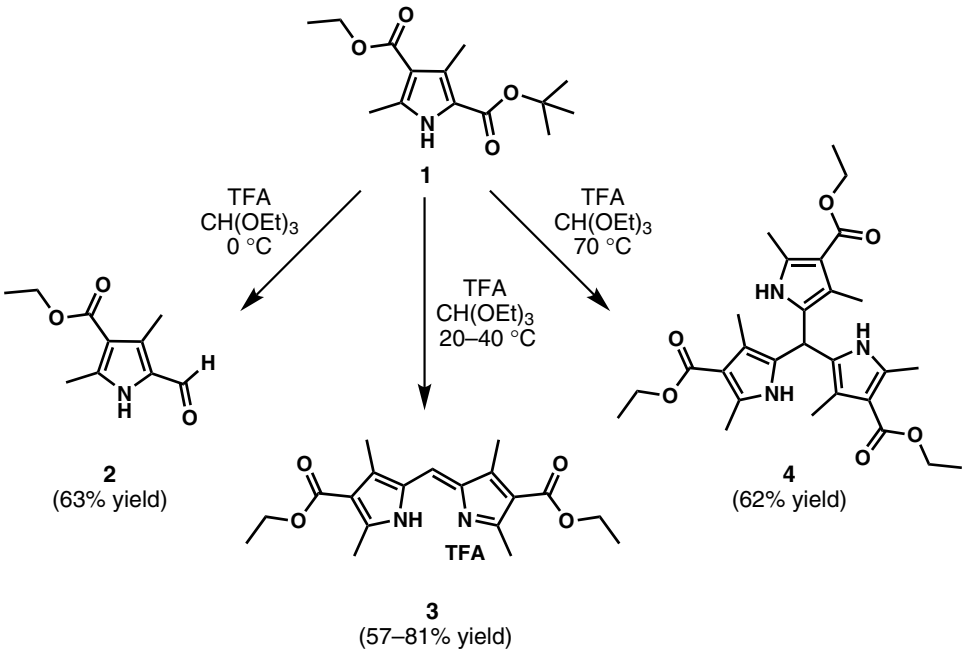

Figure 4. Temperature dependence for the condensation of *tert*-butyl 3,5-dimethyl-4-carbethoxypyrrole-2-carboxylate with triethylorthoformate.

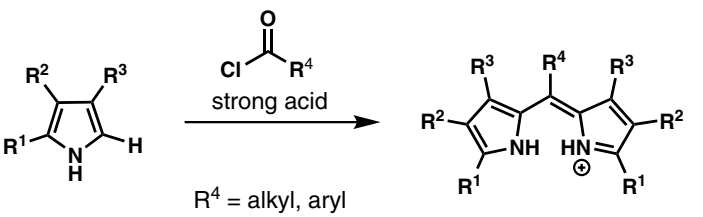

Figure 5. Synthesis of symmetric, 5-substituted dipyrrins by acid-catalyzed condensation reactions.

dipyrrins. Similar to the reaction with formic acid described in **b**, the 2-unsubstituted pyrrole may be prepared *in situ* from an appropriate precursor. It is reasonable to propose that these reactions proceed by a similar mechanism to that for the analogous reactions with formic acid, i.e. an acylated pyrrole intermediate is attacked by a second equivalent of the 2-unsubstituted pyrrole.[23] One report compares the preparation of a symmetric 5-aryldipyrrin by either the reaction of 4-iodobenzoyl chloride with an excess of 2-unsubstituted pyrrole, or the reaction of the 2-ketopyrrole product of 4-iodobenzoyl chloride and a 2-unsubstituted pyrrole, and a second equivalent of the 2-unsubstituted pyrrole in the presence of

phosphorous(V) oxychloride, and notes that the overall yield was higher for the two-step procedure.[29]

3. *Synthesis of Dipyrrins by Oxidation of Dipyrromethanes*

The preparation of 5-aryldipyrrins by the oxidation of dipyrromethanes (as outlined in Figure 6) has become a very popular synthetic route, though this method has thus far been less successful for the preparation of 5-alkyl and 5-unsubstituted dipyrrins.[30] This transformation can be effected using a variety of different oxidizing agents, the most popular of which is 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), although *p*-chloranil is occasionally seen when a more mild oxidizing agent is desired.[31,32] The dipyrrin products of this reaction are generally isolated in their free-base form, as 5-aryl dipyrrin bases are generally stable, unlike 5-unsubstituted dipyrrins. Chromatography and crystallization techniques are typically employed for the purification of free-base dipyrrins, and vacuum sublimation has been used to produce very pure samples.[33,34] One report details the isolation of dicyanovinyl-di(5-aryl)dipyrrins upon attempting to oxidize 5-(2,6-dichlorophenyl)dipyrromethane with DDQ, and fluoro-substituted derivatives behaved similarly.[35] Evidently the DDQ underwent an addition reaction with the pyrrolic moieties of the dipyrromethane. Treatment of the adducts under acidic or basic conditions promoted partial elimination and the creation of novel bis- and mono-dipyrrins bearing remnants of DDQ at the 2-positions of the dipyrrins.

Dipyrromethanes can be prepared from reactions analogous to those described earlier in this chapter for dipyrrins, with the *meso*-carbon precursor one oxidation state lower. For example, the acid-catalyzed reaction of a 2-acyl substituted pyrrole with a 2-unsubstituted pyrrole allows for the preparation of unsymmetrically substituted dipyrromethanes, and the reaction of two equivalents of a 2-unsubstituted pyrrole reagent with an aldehyde yields symmetric dipyrrolic products. Figure 7 shows a synthetic route to 5-unsubstituted dipyrromethanes involving the self-condensation of an appropriate pyrrole carbinyl cation precursor under acidic conditions[36] (e.g. Montmorillonite K-10 clay[37] or *p*-toluenesulfonic acid,[38] *p*-TSA), or

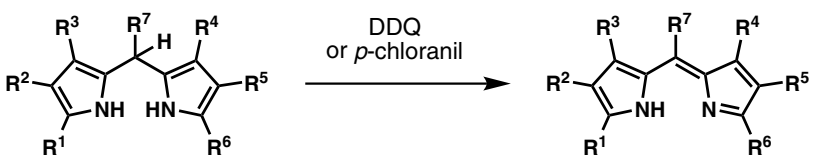

Figure 6. Synthesis of dipyrrins by oxidation of dipyrromethanes.

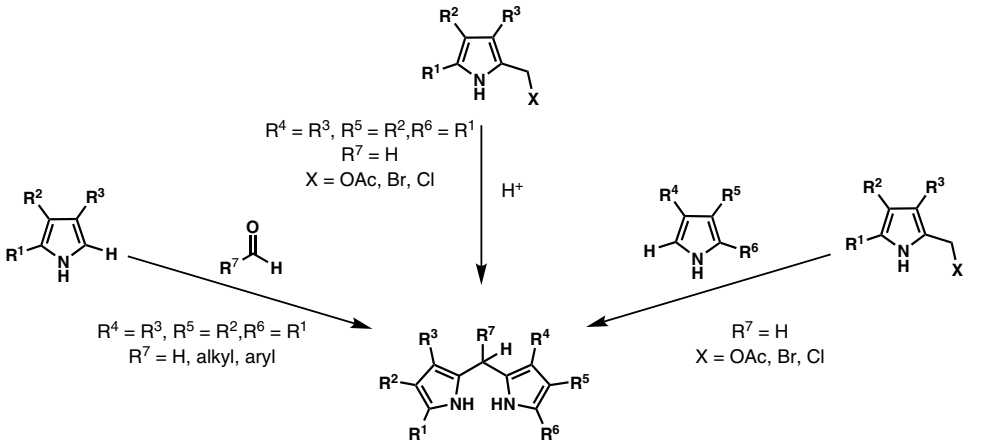

Figure 7. Synthesis of dipyrromethanes from condensation of pyrroles.

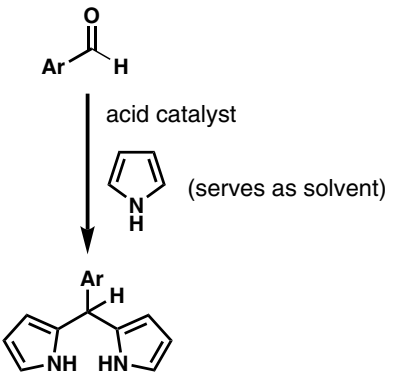

Figure 8. Synthesis of 5-substituted dipyrromethanes using excess pyrrole.

via the reaction of the same precursor species with a 2-unsubstituted pyrrole if unsymmetric dipyrromethanes are desired.[15]

One of the most important advances for opening the field of dipyrrin chemistry to researchers not specialized in the synthesis of pyrrole derivatives has been the development of procedures for preparing 5-aryldipyrrins from 5-aryldipyrromethanes, with pyrrole and an aromatic aldehyde, or the corresponding dimethyl acetal,[39] as starting materials.[40–46] Pyrrole is readily available commercially and can be purified by a non-rigorous distillation procedure, and the excess amount used in this reaction can be easily recycled. The optimal conditions for reactions of this type, shown in Figure 8, are highly generalizable: the reaction of an aromatic aldehyde with 100 equivalents of pyrrole in the presence of a mild

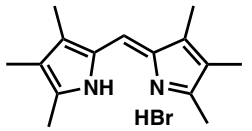
Lewis acid catalyst (such as $InCl_3$) at room temperature in the absence of air for a few hours. The dipyrromethane products are often isolated with high purity by chromatography or crystallization, with yields generally greater than 50%, and the reactions are scalable.[44] Methods for the preparation of dipyrromethanes that bear substituents on the pyrrole rings have also been developed. These procedures use only two equivalents of the precursor 2-unsubstituted pyrrole as oligomerization side-reactions are not as prominent.[32,47–52] Moreover, the use of 5-alkylthio-protected pyrroles precludes the use of excess pyrrole reagent by preventing oligomerization during dipyrromethane synthesis.[53]

C. Properties and Reactions of Dipyrrins

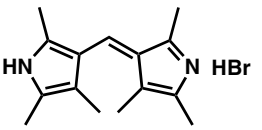
The Chemistry of Linear Oligopyrroles and Bile Pigments[24] describes some physical properties of dipyrrins (e.g. structure, solubility, NMR characteristics, fluorescence spectra, and light absorbance spectra). Thermal decomposition data, as well as solvation and light absorption characteristics, for dipyrrin and bis(dipyrrin) hydrobromide salts and dipyrrinato metal complexes have also been reported elsewhere.[2,3,54–57]

Dipyrrins as their free-bases are relatively strong bases.[15] Spectrophotometric titrations have been used to measure the pK_a of the N–H proton for a series of dipyrrins: electron-withdrawing and electron-donating effects of substituents were observed to have a definite effect upon the acidity of the dipyrrinato proton.[58] The solvolytic dissociation and deprotonation of dipyrrin hydrobromide salts by organic solvents such as DMSO, DMF, and pyridine (accelerated in dilute solution, $< 10^{-4}$ M) have been investigated, and these studies enabled the observation of a correlation between the proton affinity of a dipyrrin and its thermodynamic constant of complexation with zinc(II) ion.[3,56,57,59] The solvation effect upon the electronic absorption is less dramatic with solvents such as benzene, CCl_4, $CHCl_3$, CH_2Cl_2, and alcohols.[59]

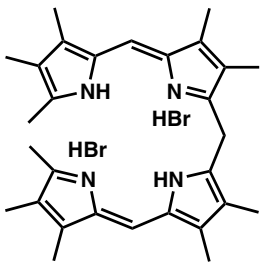
For this part of the discussion, 2,2′- and 3,3′-dipyrrins are referred to specifically by their numbering system, whereas in all other parts of this article the default term "dipyrrin" implies a 2,2′-dipyrrin as mentioned previously. The physical and chemical properties of 2,2′- and 3,3′-dipyrrins largely depend upon the effects of the substituents attached to the dipyrrin skeleton, as well as upon the nature of the linkage in the case of bis(dipyrrin)s. 2,2′-Dipyrrins often have physical and chemical behaviors distinct from those of 3,3′-dipyrrins (Figure 9), and the electronic absorption properties of a series of 2,2′- and 3,3′-dipyrrins and related bis(dipyrrin)s have been extensively studied and compared.[59] In particular, dipyrrin HBr salts behave as weak electrolytes, partially dissociating to the protonated dipyrrin and bromide ion in polar organic solvents. In polar aprotic solvents,



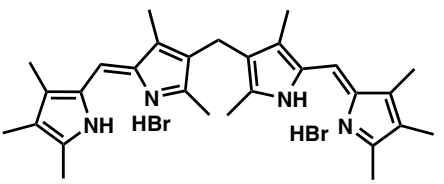
dipyrrin · HBr
ν_{N-H} 3415 cm^{-1}, δ_{N-H} 1601 cm^{-1}



3,3'-dipyrrin · HBr
ν_{N-H} 3415 cm^{-1}, δ_{N-H} 1618 cm^{-1}



1,1'-bis(dipyrrin) · HBr
ν_{N-H} 3417 cm^{-1}, δ_{N-H} 1609 cm^{-1}



2,2'-bis(dipyrrin) · HBr
ν_{N-H} 3480 cm^{-1}, δ_{N-H} 1611 cm^{-1}

Figure 9. 2,2′- and 3,3′-Dipyrrins and bis(dipyrrin)s.

the equilibrium moves further towards the ionic forms as the bromide anion is better solvated. Solvolytic dissociation of the salts to generate free-bases in solution occurs in polar protic solvents. Such electrolytic and/or solvolytic behavior can be detected using absorption spectroscopy through the presence of shoulders representing the protonated dipyrrin or free-base dipyrrin, respectively, and/or through the gradual transformation of spectra of salts into spectra of free-base dipyrrins in polar protic solvents. Comparatively, the HBr salts of 3,3′-dipyrrins and 3,3′-linked bis(dipyrrin)s are less stable than their 2,2′-analogs (i.e. dissociation occurs more readily for 3,3′-dipyrrins and 3,3′-bis(dipyrrin)s than for 2,2′-dipyrrins), and the decreased stability was estimated from the long wave shift of the N–H stretching vibration band in the IR spectra (Figure 9).[59] The dissymmetry and planarity of a 2,2′-dipyrrin was examined using an X-ray crystal structure of the corresponding HBr and carboxylate salts.[25] In contrast 3,3′-isomeric salts were found to be weakly distorted from planarity, resulting in considerable bathochromic shifts of the most intense bands in the electronic spectra.[59]

In studies relating to the antioxidant properties of dipyrrins and other oligopyrrolic compounds, a significant difference between isomeric dipyrrins was observed. The 2,2′-dipyrrin, which mimics the linkage of natural linear tetrapyrrolic compounds, was found to be an excellent antioxidant whereas the 3,3′-linked isomer was found to be inactive in this regard.[60] To be an effective antioxidant, it was found that the N–H group of the 2,2′-linked dipyrrins should

be unprotected: the *N*-methylated compounds were not active antioxidants.[61] Additionally, the antioxidant property was found to drop dramatically in methanol due to hydrogen bonding at the pyrrolic N–H. Further to the electronic properties of dipyrrins, some oxidation potentials of linear hexapyrroles and the guest recognition abilities of cyclic oligopyrroles including metal complexes of Cs^+, Rb^+, and K^+ have been reported.[62,63]

The types of substituents attached to the dipyrrin have significant effect on the physical and chemical properties of the dipyrrin, particularly with respect to stability and biological properties. It was observed that dipyrrins bearing alkyl and benzyl substituents at the *meso*-position, and thus possessing an allylic acidic proton, undergo base-promoted isomerization to give the corresponding dipyrrinylethane as shown in Figure 10.[64] As previously noted,[34,65] dipyrrins bearing aryl and heteroaryl substituents at the 5-position enjoy increased stability over their 5-unsubstituted analogs, thereby facilitating easier handling and storage of the former under aerobic conditions, even as their free-bases.

A pyrrole attached through its 2-position to a 2,2′-dipyrrin gives the skeleton of the prodigiosin class of natural products, some of which possess important biological properties such as anticancer, antimicrobial, and immunosuppressive properties.[66] Analogs of prodigiosin such as phenolic A-ring derivatives (Figure 11) structurally resemble 2-(2′-hydroxyphenyl)benzimidazole, and other related systems, that can exist in *syn*- and *anti*-enol conformational forms. The *syn*-enol undergoes photochemical tautomerization to the keto form, accompanied by a large Stokes-shifted fluorescence. Indeed, such tautomerization to the keto form occurs in the ground-state for the A-ring *o*-phenolic prodigiosin derivative shown in Figure 11, in polar, protic solvents. Such proton transfer demonstrates yet another route by which to alter the conjugation of the dipyrrolic moiety.[67] As part of studies to investigate the light vs. dark cytotoxicity of derivatives of prodigiosin, a buffered aqueous solution of an A-ring phenyl analog (Figure 11) was photoirradiated in the presence of thioglycolic acid. Mono-, di-, and tri- conjugates of the dipyrrin and the thiol were subsequently isolated, thus supporting the intermediacy of a dipyrrin-centered radical cation and providing a route to functionally elaborated dipyrrins.[68]

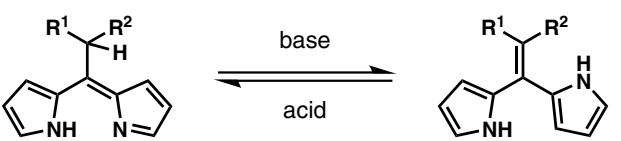


Figure 10. Tautomerization of dipyrrin bearing an allylic-H to the corresponding vinylic dipyrrole.

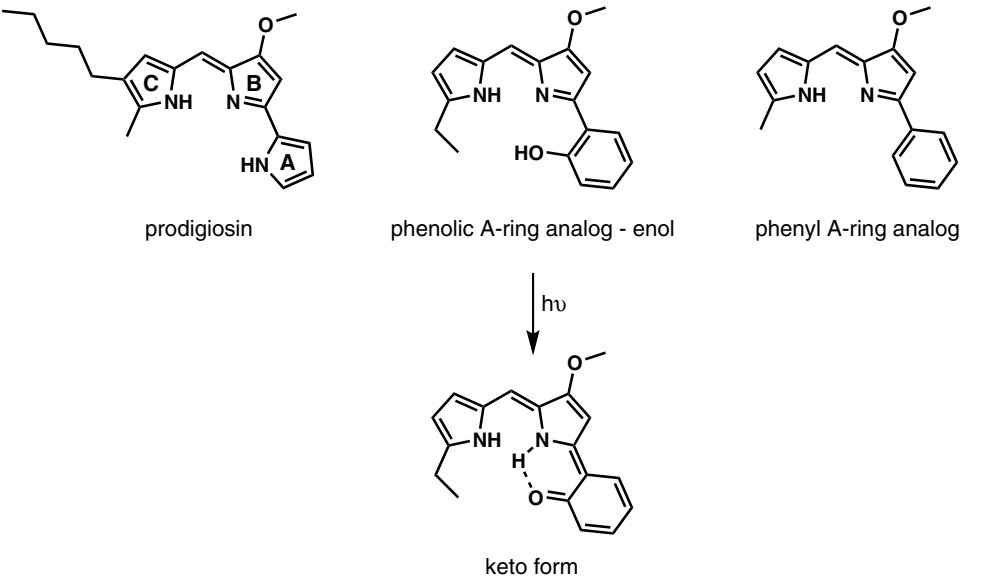

Figure 11. Dipyrrin-containing prodigiosin and two synthetic analogs.

The ^{15}N NMR chemical shifts for dipyrromethanes, dipyrrins, and dipyrrinato complexes have been found to be diagnostic of gross structure concerning the oxidation and complexation states of the dipyrrolic compounds, although such values do not reveal information about the effect that substituents might have upon the bonding environment of the nitrogen atom.[69] This general method has found use in reported ^{15}N chemical shifts of numerous pyrrolic compounds, with generally diagnostic values maintained.[64,70–73]

II. Dipyrrinato Complexes

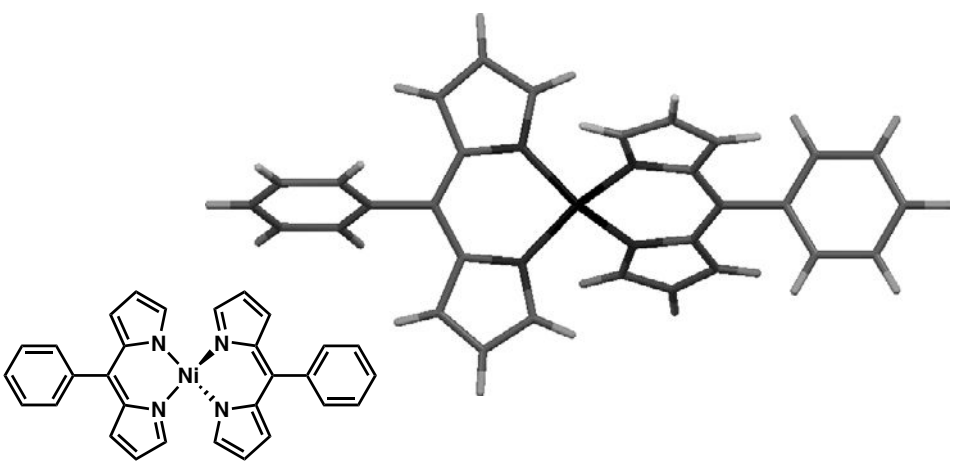
A. Syntheses of Dipyrrinato Complexes

Popular procedures employed for the synthesis of dipyrrinato metal complexes vary mostly in whether the dipyrrin ligand is isolated before complexation, or prepared *in situ*. Generally, dipyrrins prepared by the condensation of pyrrolic reagents are isolated before complexation, whereas the general procedure for the oxidation of dipyrromethanes to dipyrrins is amenable to one-pot dipyrrin formation and complexation. The complexes formed can be classified according to the nature of the cation complexed, whether the complex is homoleptic or heteroleptic, as well as whether the complex exists as a discrete molecular unit or as part of a supramolecular complex.

1. *Complexation Geometries*

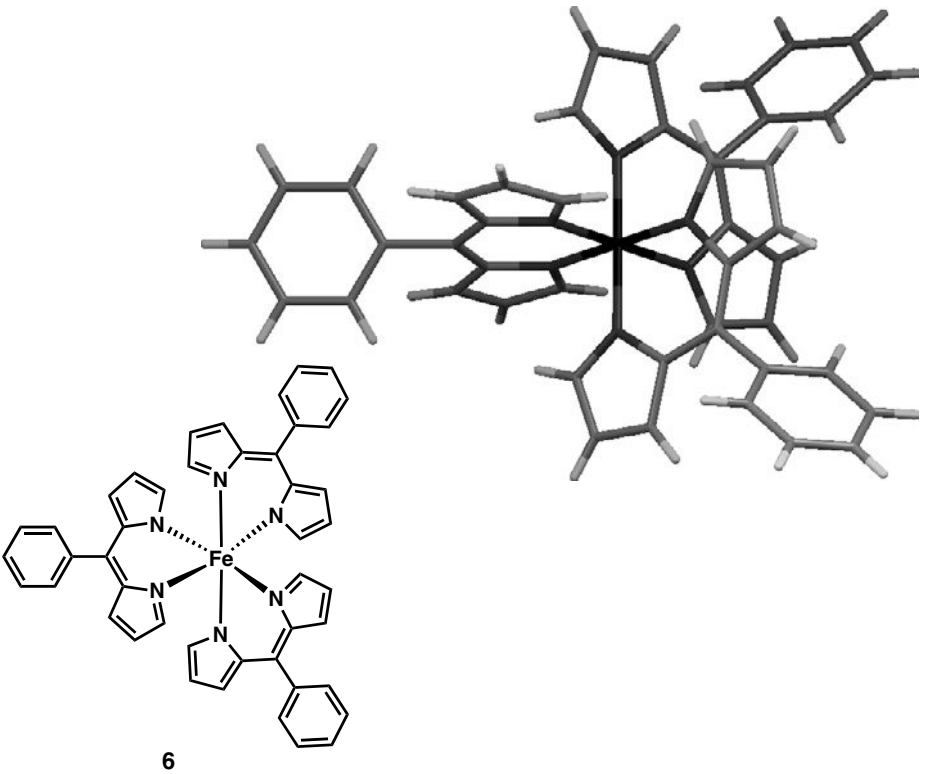
Dipyrrinato ligands bind cations in a chelating κ^2 manner in the vast majority of dipyrrinato complexes. As such, depending on the charge of the cation in the complex, ML, ML_2, and ML_3 dipyrrinato complexes are isolable. The coordination geometry of the metal center in these complexes is influenced not only by the nature of the metal ion, but also by steric interactions between substituents at the 1- and 9-positions of multiple ligands brought into close proximity by complex formation.[74] The vast majority of homoleptic ML_2 dipyrrinato complexes adopt tetrahedral, or distorted tetrahedral, coordination geometry. The distorted tetrahedral complex bis(5-phenyldipyrrinato) copper(II)[31] shows that interactions between 1- and 9-substituents as small as hydrogen atoms result in the preferential formation of non-square-planar coordination geometry about the complexed metal ion, although this is not the typical coordination geometry adopted by copper(II) complexes. Another interesting example is the diamagnetic low-spin complex bis(5-phenyldipyrrinato) nickel(II) (compound **5** in Figure 12).[31]

Octahedral coordination geometry is observed for ML_3 dipyrrinato complexes as seen for iron(III) tris(5-phenyldipyrrinato), compound **6** in Figure 13.[75] One report describes the auto-oxidation in air of an unstable tetrahedral bis(5-phenyldipyrrinato) cobalt(II) complex to the octahedral tris(5-phenyldipyrrinato) cobalt(III) complex, and observes that the same product could be prepared from



5

Figure 12. Tetrahedral coordination geometry in a nickel(II) dipyrrinato complex, adapted from Ref. 31.

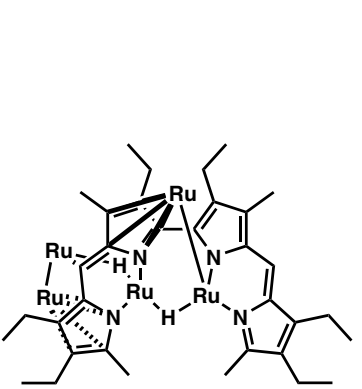


6

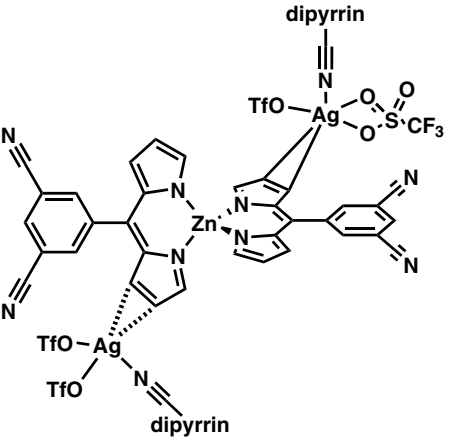
Figure 13. Octahedral coordination geometry in an iron(III) dipyrrinato complex, adapted from Ref. 76.

complexation of the dipyrrin ligand with an appropriate cobalt(III) salt.[76] In the ^{1}H NMR spectrum of the cobalt(III) complex, the relatively shielded chemical shift of the 1- and 9-hydrogen substituents is somewhat diagnostic for octahedral complex formation, as it results from these atoms being shielded by two adjacent aryl dipyrrinato systems.[76] Octahedral tris(dipyrrinato) complexes of iron(III), cobalt(III), gallium(III), and indium(III) have been extensively studied for use in the formation of metal-organic frameworks.[34,75,77–84]

Some exceptions to the κ^2 binding behavior of dipyrrinato ligands have been noted. The first example of a pyrrolic unit of a dipyrrin binding a metal ion in an η^5 manner, analogous to pyrrole in azaferrocene,[85] was reported by Bröring and coworkers (Figure 14).[86] It was demonstrated that the reaction of a bis(dipyrrin) with $Ru_3(CO)_{12}$ produced a ruthenium-dipyrrin cluster (**7**) in which one of the pyrrole rings was bound in an η^5 manner to a ruthenium ion. An example of a silver ion bound in an η^2 manner to one of the pyrrolic units in a dipyrrin complex (**8** in Figure 14) was reported by Hosseini and coworkers,[87] and was followed by the



7
$Ru_5H[b(dpme)](CO)_{11}$
(carbonyl ligands removed for clarity)



8

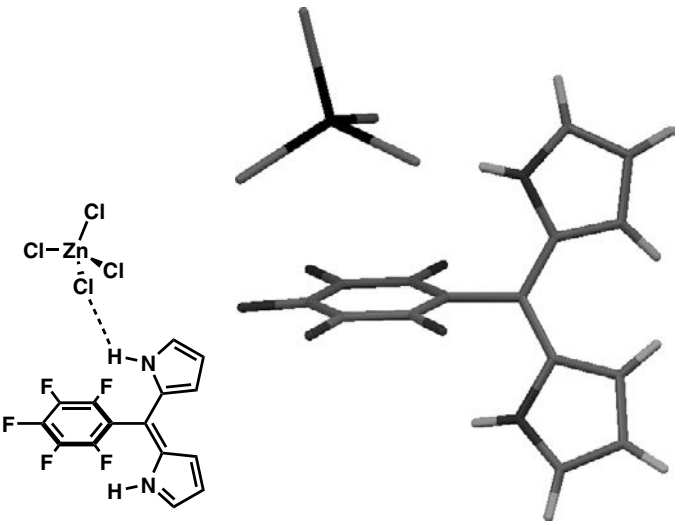
Figure 14. Example of η^5- and η^2-binding of dipyrrin, adapted from Refs. 86 and 87.

report of a related structure.[88] Indeed, the number of reports of complexes and macrocycles of dipyrrins involving coordination to silver has been increasing.

Although there are multiple conformations that dipyrrins can possibly adopt,[24,88] one conformation is observed in the vast majority of dipyrrinato complexes. Reported complexes of dipyrrins in which the pyrrolic units have adopted a conformation such that the nitrogen atoms are oriented in the same direction as the 5-substituent are very rare. One report presented solid state structures of dipyrrin complexes such as **9** in which protonated dipyrrins in an *E-syn* conformation formed supramolecular structures with tetrahalozinc anions (Figure 15).[89] A report has described the solid-state structure of a dimeric Ag(I) complex of 5-(4-cyanophenyl)dipyrrin in which the dipyrrin ligands adopt an *E-anti* conformation.[88]

2. *Scope of Metal Ions in Homoleptic Dipyrrinato Complexes*

The variety of metal ions with which dipyrrins are known to form isolable complexes is extensive. Upon deprotonation, the monoanionic dipyrrinato ligands generally form neutral homoleptic (bearing two or more identical ligands on a metal center) complexes. However, heteroleptic (bearing two or more different ligands on a metal center) complexes have also been observed. Dipyrrinato ligands are known to form homoleptic complexes with magnesium(II),[90] calcium(II),[91,92] chromium(III),[93] manganese(II),[91,94,95] manganese(III),[94] iron(II),[96] iron(III),[75,76,79–81,96] cobalt(II),[97–106] cobalt(III),[76,80–82,107] nickel(II),[31,91,92,97–99,101–106,108–110] copper(II),[30,31,54,55,78,79,84,90–92,97,98,101–106,108,111–113]



9

Figure 15. Rotation about the 5-position in dipyrrins, adapted from Ref. 89.

zinc(II),[30,31,54,55,82,91,97–99,101,102,105,106,108,114–119] gallium(III),[34,84] ruthenium(II),[120] rhodium(II),[121] palladium(II),[30,99,105,109,122] cadmium(II),[99,105] indium(III),[34,84] mercury(II),[99,105] thallium(I),[123] and thallium(III).[123] The synthesis of a lithium(I) dipyrrin complex was described in which the lithium ion was unsupported by coordinated solvent molecules in the solid-state structure,[119] and other lithium complexes were prepared and used *in situ*.[39,124]

3. *Dipyrrinato Complexes of Boron*

Chapter 37 in this volume is dedicated to a discussion of the syntheses and properties of boron difluoride complexes of dipyrrins (BODIPYs, Figure 16). Briefly, these extremely important fluorescent molecules were first reported in 1968.[125] Even in this earliest of reports the researchers described the intense fluorescence of complexes of this type and this has become recognized as their signature property. The effect of molecular structure upon the spectroscopic properties of boron difluoride dipyrrinato complexes has received a great deal of attention in the literature,[19,24,27–29,33,58,70,114,126–155] and continues to be a vibrant research theme.

4. *Heteroleptic Dipyrrinato Complexes*

Although the most commonly described dipyrrinato complexes are of a homoleptic nature, the isolation of heteroleptic complexes is becoming increasingly

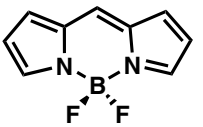


Figure 16. General structure of a boron difluoride dipyrrinato complex.

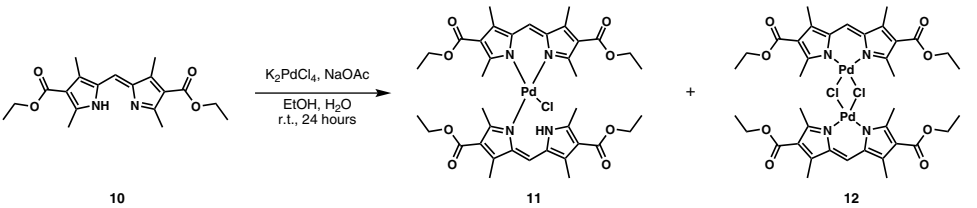

Figure 17. Formation of heteroleptic and bridged dimer palladium(II) dipyrrinato complexes.[99]

frequent. A variety of studies have shown heteroleptic complexes in solution as intermediates preceding the formation of homoleptic complexes.[56,156–159] Absorption spectroscopy solution studies of the complexation of copper(II) chloride or zinc(II) acetate with dipyrrin ligands have been reported to exhibit an isosbectic point, whereas those involving copper(II) acetate do not.[158] The somewhat broad absorption profile for the dipyrrinato unit, as well as overlapping signals for ligand, homoleptic, and heteroleptic complexes, creates a serious complication in the analysis of electronic absorption spectra corresponding to complexation reactions. With a number of heteroleptic species being possible along the reaction pathway, the clarifications afforded by ^{1}H NMR spectroscopy have made this a useful technique for detecting the presence of these species.[159]

One factor that may promote the formation of isolable heteroleptic dipyrrinato complexes is the resulting facilitation of a square planar coordination geometry about the complexed cation, while the steric requirements of 1- and 9-substituents force tetrahedral or octahedral coordination geometry in homoleptic complexes. Examples of this are the proposed products from the attempted formation of a homoleptic palladium(II) complex of dipyrrin **10**: the heteroleptic complex **11** and a bridged dimeric complex **12** (Figure 17).[99] The structure of heteroleptic **11** was later confirmed using X-ray analysis, with the dipyrrinato unit coordinated as a monoanionic bidentate ligand and the dipyrrin coordinated as a neutral unidentate ligand.[122] To date, there are very few reports of homoleptic palladium(II) dipyrrinato complexes.[30,160]

Complexation reaction conditions have been shown to affect the formation of heteroleptic dipyrrinato complexes. These variables include stoichiometry,[119] the

presence of non-dipyrrin species to coordinate with the metal ion,[22,73] the choice of solvent,[22] the ionic radius of the metal ion,[22] and the temperature utilized for the reaction. As an example, in the preparation of mercury(II) dipyrrinato complexes, the constitution of the product complex was shown to depend upon the salt used: mercury(II) nitrate gave a homoleptic dipyrrinato mercury(II) complex, while mercury(II) chloride gave a heteroleptic chlorodipyrrinato mercury(II) complex.[99] Similarly, it has been shown that conducting complexation reactions in DMF, a strongly coordinating solvent, promotes the formation of heteroleptic products.[22] Dipyrrinato lithium(I) complexes have been used successfully as starting materials in the preparation of several heteroleptic complexes.[39,119]

The scope of dipyrrinato complexation has recently been extended by reports of aluminum complexes of the N_2O_2 type, whereby dipyrrins substituted in the 1- and 9-positions with phenols, such as dipyrrin **13** in Figure 18, form tetradentate complexes, such as **14**, with aluminum(III).[161] The aluminum complexes are reminiscent of BODIPYs in that they are fluorescent. The addition of $ZnCl_2$ to the aluminum complexes results in a change of absorption properties with the concurrent formation of a heterometallic Al-dipyrrinato-Zn adduct, such as **15**, courtesy of the phenolic moieties binding to both aluminum and zinc.

Along a similar vein, a divalent tin complex has recently been reported.[124] In this example a lithium dipyrrinato complex was generated *in situ* by reacting a dipyrrin free-base with *n*-BuLi at −78 °C, followed by the addition of $SnCl_2$. The dipyrrinato-Sn-Cl species thus generated exhibited similar fluorescence properties to BODIPYs.[124]

Strongly-coordinating ligands, such as bidentate 2,2′-bipyridine (bipy),[120] *N,N′*-bis(salicylidene)ethylenediamine (salen),[88] acetylacetonato (acac),[162,163] or its hexafluoro-derivative (hfacac),[78] are frequently the ancilliary ligand in heteroleptic dipyrrinato metal complexes. Another feature that makes acac and hfacac excellent ancilliary ligands is the minimal steric encumbrance that they create near the metal center (unlike the 1- and 9-substituents of dipyrrins).[163] Thus,

mesityl (**13b**)

14a,b

15a,b

Figure 18. Formation of an aluminum(III) dipyrrinato complex.

heteroleptic dipyrrinato complexes of this type can accommodate square planar coordination geometry, such as for copper(II) and palladium(II).[99] Heteroleptic complexes of rhodium(I) have been reported to form upon the reaction of $[Rh(CO)_2Cl]_2$ with dipyrrins in the presence of sodium acetate[121] or potassium carbonate.[164] These complexes each contain a bidentane dipyrrinato ligand and two CO ligands. Heteroleptic iridium(III), ruthenium(III) and rhodium(III) dipyrrinato complexes have also been reported, with the latter two having been investigated as catalysts for transfer hydrogenolysis.[165,166] In a rare example of a heteroleptic complex in which the non-identical ligands are simply differently-substituted dipyrrins, the preparation of [5-(cyanophenyl)-1-methoxydipyrrinato]bis[5-(cyanophenyl)dipyrrinato] cobalt(III) complex was reported as a mixture with the homoleptic complex tris[5-(cyanophenyl)dipyrrinato] cobalt(III).[82]

In another example, heteroleptic zinc(II) halide complexes **17** were prepared from 5-(1-methylimidazol-2-yl)dipyrrin, **16**, by reaction with zinc halides and ammonia, while the homoleptic complex **18** could be prepared from zinc acetate (Figure 19).[73] The complexes **17** also serve as examples in which substituents on the dipyrrinato ligand coordinate with the complexed metal ion. This mode of chelation can result in the formation of discrete structures as in the case of the 5-(2-pyridyl)dipyrrinato zinc(II) halide dimeric complexes,[167] and monomeric

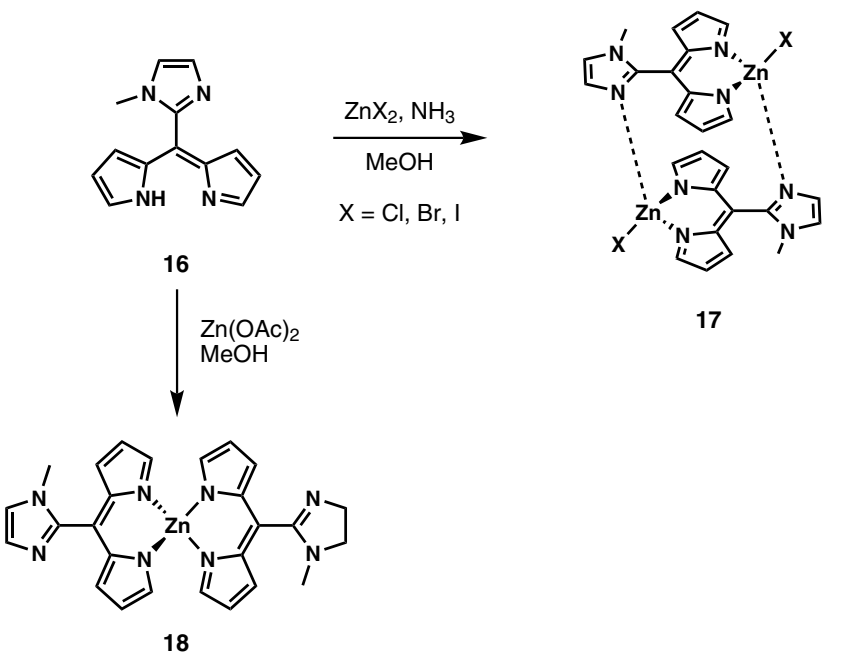

Figure 19. Formation of a discrete heteroleptic dipyrrinato complex.

nickel(II) and copper(II) diamidodipyrrinato complexes.[168] However, this may also result in the formation of vast coordination polymer networks.[169]

5. *Demetalation of Homoleptic Dipyrrinato Complexes*

Demetalation of dipyrrinato complexes can be achieved using several methods. Treatment of the homoleptic 5-phenyldipyrrinato zinc(II) complex with excess trifluoroacetic acid or methanolic hydrochloric acid was observed to result in incomplete demetalation,[30] which is somewhat surprising as many complexes are labile under acidic conditions. Dithiothreitol (DTT, threo-1,4-dimercapto-2,3-butanediol) has been used[30] to effect complete demetalation of a variety of dipyrrinato complexes when similar treatment with ethylene glycol proved unsatisfactory. As an alternative method for demetalation, reduction of the homoleptic 5-phenyldipyrrinato zinc(II) complex with sodium borohydride was shown to give the corresponding dipyrromethane,[30] akin to the well-documented reduction of dipyrrins to give dipyrromethanes.[170] The treatment of dipyrrinato rhodium(I) complexes with bromine or chlorine has been observed to result in demetalation of the complexes, generating the hydrobromide or hydrochloride salts, respectively, of the dipyrrin ligands.[121] Furthermore, the treatment of dimeric dipyrrinato copper(II) complexes with potassium cyanide resulted in complete demetalation.[79,84] This method of demetalation allowed for the preparation of gallium(III) and indium(III) dipyrrinato complexes (**22a**, **b** in Figure 20) that were not obtainable using standard one-pot procedures starting from dipyrromethanes.[84] As a consequence of reacting a copper(II) bis(dipyrrinato) complex with artemisinin, a 1,2,4-trioxane natural product, cleavage of the peroxidic O–O bond in the antimalarial compound was accompanied by concomitant cleavage of the Cu–N bonds and thus liberation of the metal and free-base/artemisinin adduct: the same effect was observed with iron(III) dipyrrinato complexes.[171]

6. *Supramolecular Dipyrrinato Metal Complexes*

The versatility of dipyrrins has made them a popular ligand in the design of supramolecular metal coordination complexes. Tetradentate bis(dipyrrin) ligands, in which two dipyrrin units are connected by a variable tether, have been shown to form an array of discrete supramolecular complexes whose interesting geometries can be controlled by factors such as the number of degrees of freedom and the location of the linking points of the tether unit. An outline of the nomenclature for bis(dipyrrin)s is shown in Figure 21, but the literature is rife with commonplace numbering for bis(dipyrrin)s. Dipyrrinato ligands that are substituted with

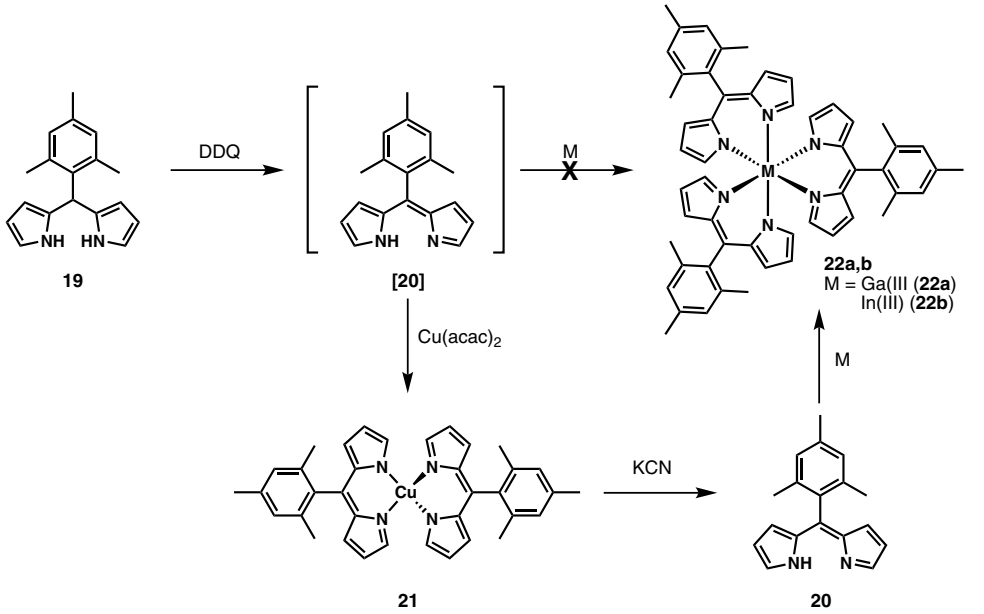

Figure 20. Demetalation of Cu(II) dipyrrinato metal complex using potassium cyanide.

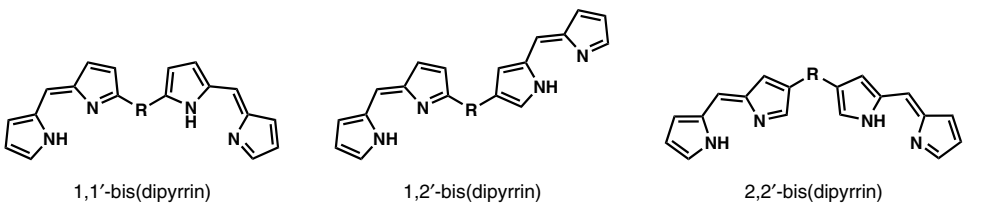

Figure 21. Bis(dipyrrin) numbering scheme.

metal-coordinating functional groups are finding utility in the formation of extended coordination polymers or metal-organic frameworks.

a. *Discrete helical complexes*

Metal ion complexation products of bis(dipyrrin)s adopt helicate (chiral) or mesocate (non-chiral) structures, arising from the approximately perpendicular arrangement of two bidentate dipyrrinato units to a single metal center as shown in Figure 22. Even in complexes with non-tetrahedral coordination geometries, the steric demands of the 1,9-positions of the dipyrrin force the two dipyrrinato units out of plane, creating a helical twist in the ligand backbone. It

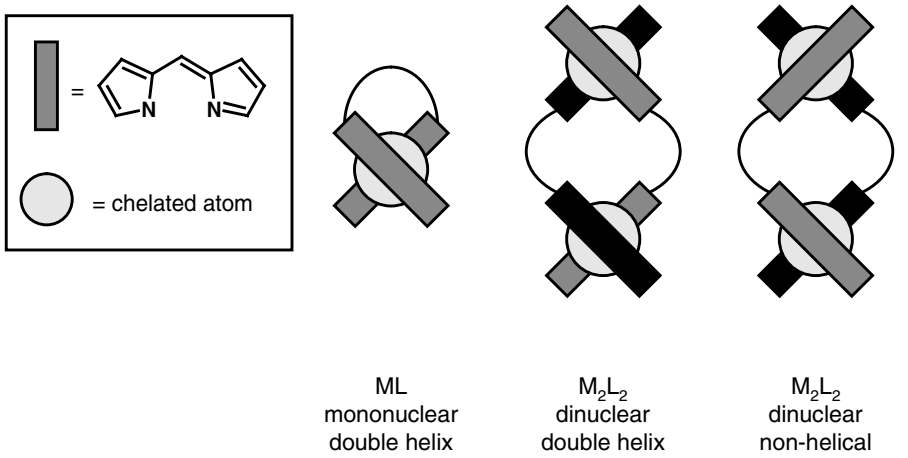

Figure 22. Helical conformation of metal complexes of bis(dipyrrin)s, adapted from Ref. 65.

has been demonstrated that these complexes can be formed stereoselectively,[21,172] as discussed in Section 8.

As with dipyrrins themselves, bis(dipyrrin)s were originally synthesized for the intended use as precursors in the preparation of macrocyclic tetrapyrroles,[173–189] and also of strapped porphyrins.[190] An account of the syntheses of palladium(II) complexes of 1,12-bis(dipyrrin)s was reported by Fisher and Stachel in 1939,[173] work that was reproduced 20 years later, showing that these complexes could be used to prepare oxacorrole palladium(II) complexes by oxidative cyclization.[174] Further investigations demonstrated the utility of nickel(II) complexes of bis(dipyrrin)s for the synthesis of tetrahydrocorrins and corroles.[182–186] It was during these studies that it was first noted how a combination of factors including reaction conditions, the nature of the coordinated metal ion, and the structure of the bis(dipyrrin) ligand affected the shape and size of the metal complex formed.[185,186,191,192]

As an example, bis(dipyrrin) ligand **23** (Figure 23) has been shown to form dimeric complexes **24a**, **b** when the metalation reactions were conducted in methanol with cobalt(II) or zinc(II) ions. However, monomeric complexes **25a**, **b** were formed with nickel(II) and copper(II) favoring the formation of mononuclear complexation products under these conditions.[191,192] A similar bis(dipyrrin) ligand had been shown to form monomeric complexation products with cobalt(II) when metalation was conducted in ethanol, but dimeric products when the reaction was conducted in methanol.[185,186] Triple-stranded helicates and mesocates (non-chiral) have been obtained using the same bis(dipyrrinato) ligand and cobalt(III) and iron(III), i.e. both forms isolated from the same reaction mixture.[193]

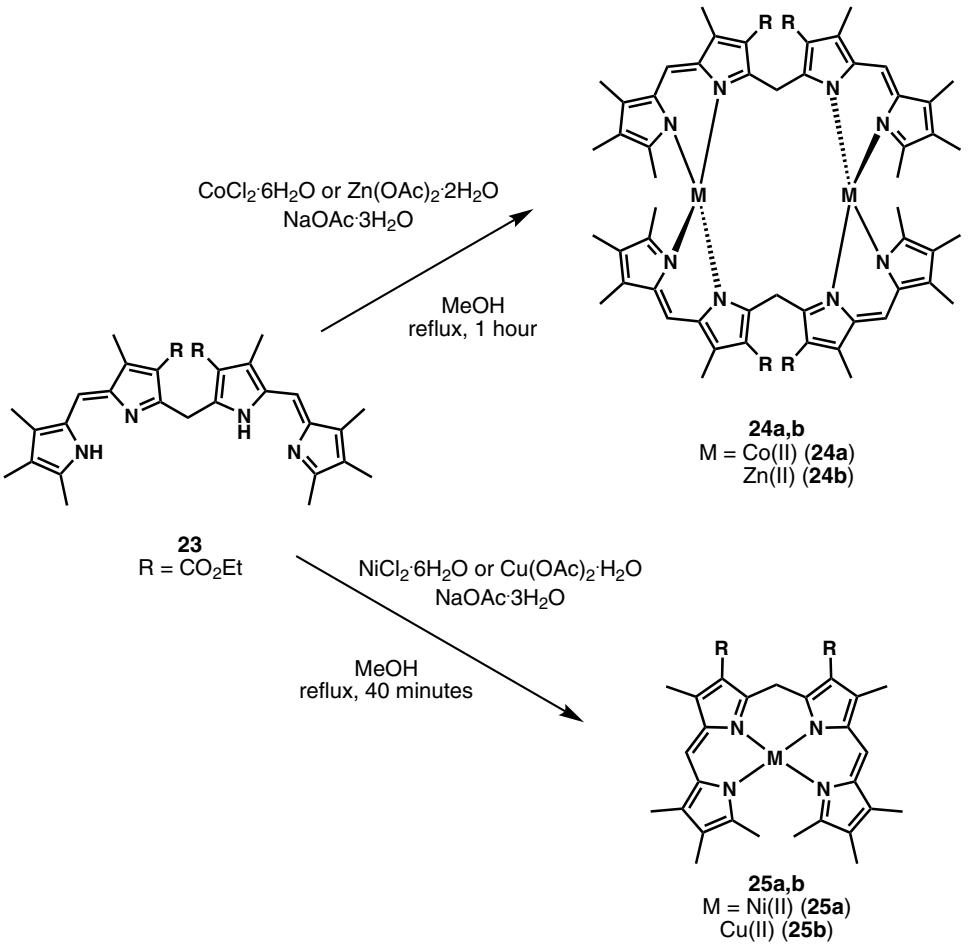

Figure 23. Dependence of bis(dipyrrin) complexation product upon reaction conditions.

It has further been shown that steric demands of the 1,9-substituents[20,194] affect the helicity of bis(dipyrrin) complexes, and that the points of connection between the two dipyrrin units, and the number of degrees of freedom in the tether, have an impact upon the metal-to-ligand ratio of the complexation products.[195–201] The demonstrated ability to influence the shape of bis(dipyrrin) metal complexes has created interest in their use to demonstrate metal-ion assisted self-assembly, and in their potential as supramolecular building blocks.[108,202] The solid state structures of a number of 1:1, and 2:2 metal ion-to-bis(dipyrrin) complexes have been reported, as well as the solid-state structures of a 3:3 zinc(II):1,1′-bis(dipyrrin) molecular triangle[196] and a zinc(II) 1,2′-bis(dipyrrinato) molecular rectangle.[203]

b. *Metal-organic frameworks (MOFs)*

Tris(dipyrrinato) iron(III), cobalt(III), indium(III), and gallium(III) complexes of 5-(4-pyridyl)dipyrrin self-assemble into heterobimetallic metal-organic frameworks[204] in the presence of silver(I) salts.[34,80,81] X-Ray crystallography reveals that each silver(I) ion is coordinated to three pyridyl ligands in the extended framework generating two dimensional (6,3) networks (Schläfli symbol 6^3, vertex symbol $6\cdot6\cdot6$) or three dimensional (10,3) networks (Schläfli symbol 10^3, vertex symbol $10_2\cdot10_4\cdot10_4$),[205] depending on the choice of silver salt (Figure 24).[34,81] MOFs prepared with AgOTf reliably formed three-dimensional (10,3) networks, whereas the use of $AgSbF_6$ produced two-dimensional (6,3) honeycomb-like networks. In the two-dimensional networks each silver(I) ion is coordinated to three different dipyrrinato complexes (through intermolecular interactions with substituents at the 5-position) and also coordinated by a solvent molecule (e.g. MeCN) rather than the SbF_6^- anion. On the other hand, the use of $AgPF_6$ gave two-dimensional networks with tris(dipyrrinato) iron(III) and cobalt(III) complexes and three-dimensional networks with tris(dipyrrinato) indium(III) and gallium(III) complexes. Networks prepared with salts of $AgBF_4$ reliably formed three-dimensional (10,3) networks with iron(III) or cobalt(III) complexes. The use of larger metalloligands such as cobalt(III) tris[5-(4-[pyridin-4-ethynyl]phenyl)dipyrrinato] and iron(III) tris[5-(4-quinolynyl)dipyrrinato] overrode the anion templating effect, and this is consistent with analogous organic systems.[34,81] Given their facile synthesis, the use of dipyrrinato ligands within such networks allows the possibility to tune optical, magnetic, and fluorescence properties within the framework, as well as to develop porous materials with interesting photophysical properties.

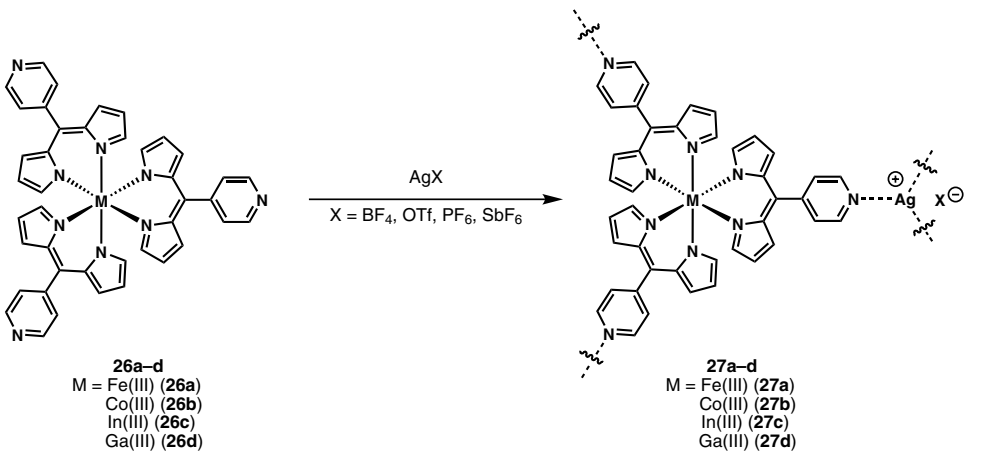

Figure 24. Synthesis of M(III)[5-(4-pyridyl)dipyrrinato]$_3$AgX metal-organic frameworks (MOFs).

Furthermore, the octahedral coordination geometry of central metal ions provides an opportunity to create homochiral extended solids.[81] Carboxylate-functionalized tris(dipyrrinato) *rac*-cobalt(III) complexes generated two-dimensional and three-dimensional MOFs with infinite and trinuclear zinc(II) secondary-building units.[77] However, under identical reaction conditions enantiopure metalloligands produced amorphous solids.[77]

Dipyrrins bearing suitable heterocyclic systems at the 5-position are also capable of non-covalent interactions such as hydrogen bonding (Figure 25) and metal coordination in the neutral and/or deprotonated forms.[87,88] This strategy for preparing extended networks of various types has seen extensive development, and now dipyrrins with additional coordinated functional groups at the 5-position are routinely used for the preparation of metallotectons, metallamacrocycles, and heterometallic MOFs.[81,88]

Tectons are molecular subunits that engage in multiple reliable directional intermolecular interactions as supramolecular synthons and can therefore serve as building blocks for the rational construction of crystals and material in the solid state. Enantiomerically pure and racemic cobalt(III) tris(dipyrrinato) complexes bearing three trigonally directed substituents such as aryl-CO_2H and diaminotriazinyl (DAT) groups in the 5-position, compounds **30a** and **b** in Figure 26, are able to generate molecular networks, building through hydrogen bonding within the metallotectons.[107,206] In essence, the complexed dipyrrinato units assemble via an

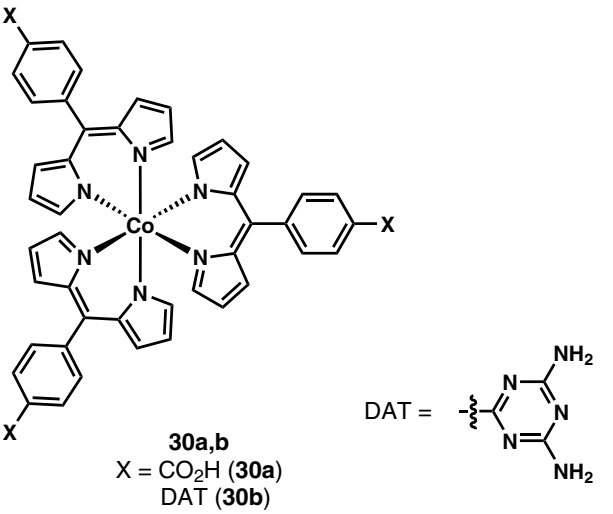

Figure 26. Intermolecular hydrogen bonding involving CO_2H and DAT groups in metallotectons.

additional mode of bonding, through intermolecular interactions such as hydrogen bonding at moieties peripheral to the dipyrrinato heterocyclic core. In general, but not always, crystalline complexes of the enantiomerically pure form pack less efficiently than their racemic counterparts, and the crystallization of racemic mixtures tends to produce racemic crystals rather than conglomerates of crystals composed of single enantiomers.[206] Metallotectons formed via the intermolecular interactions of carboxyl groups apparently prefer to adopt one-dimensional zig-zag chains through intertectonic hydrogen bonding, whereas those involving DAT groups are hydrogen bonded to three neighbors with each DAT group participating in four hydrogen bonds, and thus generating highly porous and robust networks.[107,206]

Mono- and dicyanophenyl substituted homo- and heteroleptic zinc(II) and copper(II) dipyrrinato metalloligands combined with silver salts to generate Ag(I)–C=C double bond interactions with one- and two-dimensional networks.[87] Interestingly, 5-(4-cyanophenyl)dipyrrin free-base **31** combined with $AgBF_4$ to generate metallamacrocycle **32**, whereas the heteroleptic (salen) Co(III) dipyrrinato **33** complex formed metallamacrocycle **34** with $Ag(SbF_6)$ after slow evaporation from benzene and benzene/acetonitrile respectively (Figure 27).[88] The average distance for Ag–C bonds in these complexes was within the usual range for η^1 and η^2 arene–silver complexes (2.39–2.63 Å), and the complex was determined to be unsymmetrical with one Ag–C contact longer than the other.[87,88]

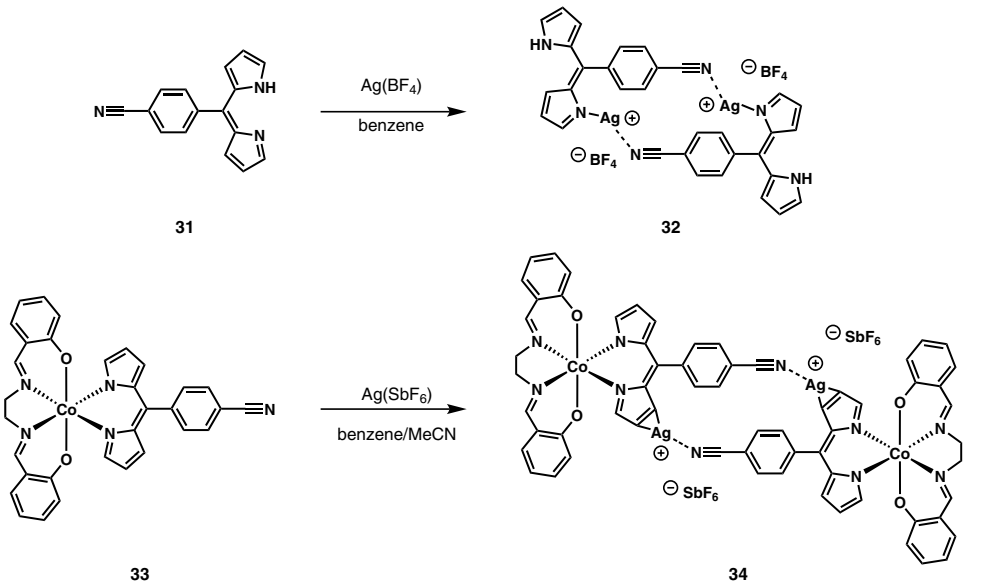

Figure 27. Formation of metallamacrocycles **32** and **34** using slow evaporation technique.[88]

Dipyrrins act as planar building blocks for self-assembled coordination oligomers in combination with various spacer units.[202] These interesting properties of dipyrrins make it possible to create well-defined micro- and nanometer-sized architectures of various shapes and sizes (Figure 28).[202,207] Another approach to linear short oligomeric chains of repeating dipyrrinato complexes involved the synthesis of a bis(dipyrrin) with one of the dipyrrin units complexed with BF_2.[208] Such capped bis(dipyrrin)s were then used as terminating units in oligomerization complexation reactions involving free-base bis(dipyrrin)s linked by an aryl group.

Dipyrrins with a catecholyl group attached to the 5-position (**35**) react with boron trichloride and produce self-assembled boron–dipyrrin macrocyclic oligomers of trimeric **36**, tetrameric **37**, and pentameric **38** nature (Figure 29).[137] The ^{11}B NMR spectrum of such oligomers showed a broad singlet at around 7.51 to 7.64 ppm, reflecting the formation of a tetrahedral boron complex with a 5-(catecholyl)dipyrrinato N_2O_2 ligand. Macrocycle **36**, having a cavity at the core of the molecule, can act as a supramolecular host with a binding site surrounded by oxygen atoms.[137] Thus, the introduction of K^+, Rb^+, and Cs^+ to complex **36** caused considerable spectral changes in the ^1H NMR spectra as a consequence of titration studies, and indicated the formation of 1:1 host:guest complexes. The Na^+ ion, with its ionic radius (0.97 Å) smaller than the radius of the cavity of complex **36** (1.4 Å), showed no interaction. The self-assembled square boron–dipyrrinato complex **37** generated one-dimensional channels filled with solvent molecules.[137]

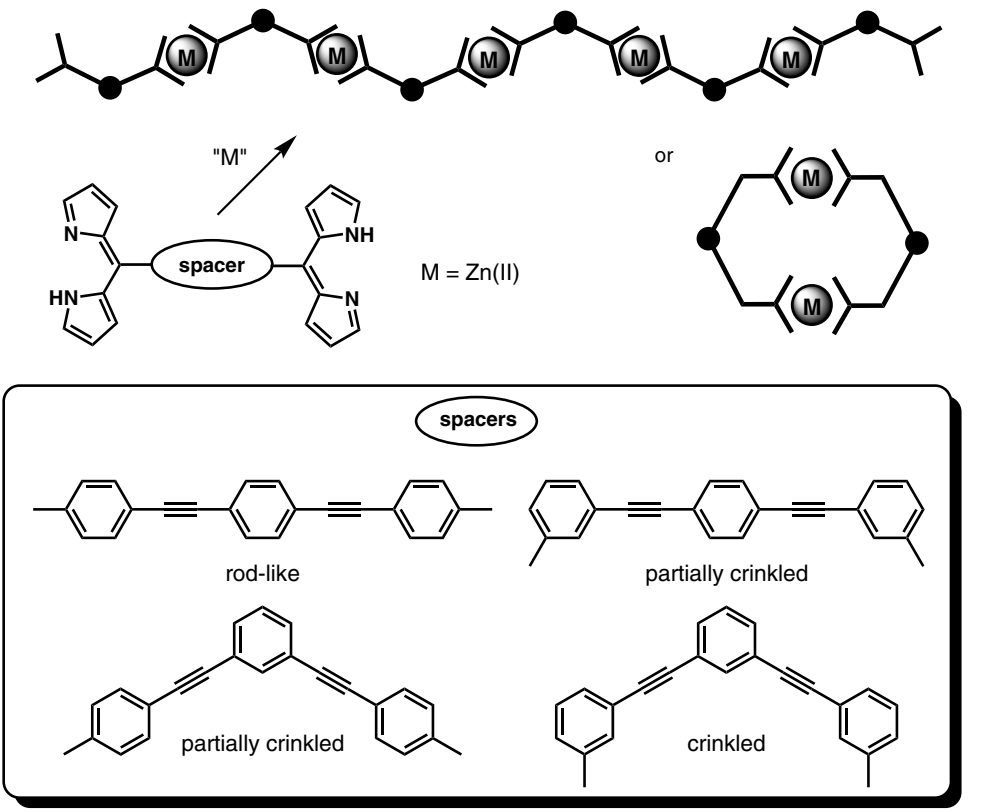

Figure 28. Formation of micro- and nanometer-sized architectures based on bis(dipyrrin)s with various spacer units, adapted from Ref. 207.

Heteroleptic dipyrrinato complexes have proven useful in the construction of extended networks and coordinative polymers. While homoleptic complexes of copper(II) were observed to form when 0.4 equivalents of copper(II) acetylacetonate was used in the complexation reaction,[113] heteroleptic complexes were more likely to be formed in the presence of stoichiometric, or excess, amounts of the metal salt, as expected. This coordination is responsible for the formation of many of the extended networks reported. For example, 5-(4-cyanophenyl)dipyrrin formed a discrete heteroleptic complex with copper(II) acetylacetonate but the 5-(4-pyridyl)dipyrrin heteroleptic complex formed a coordination polymer.

The discrete head-to-tail cyclic dimer **40** is formed upon reaction of one equivalent quantity of $Cu(hfacac)_2$ with two equivalents of 5-[3-(methylthio) phenyl]dipyrrin, formed *in situ* from the corresponding dipyrromethane (**39** in Figure 30).[78] The dimer is held together by two weak sulfur–copper(II) interactions between the thioether moiety of one dipyrrinato ligand and the copper(II)

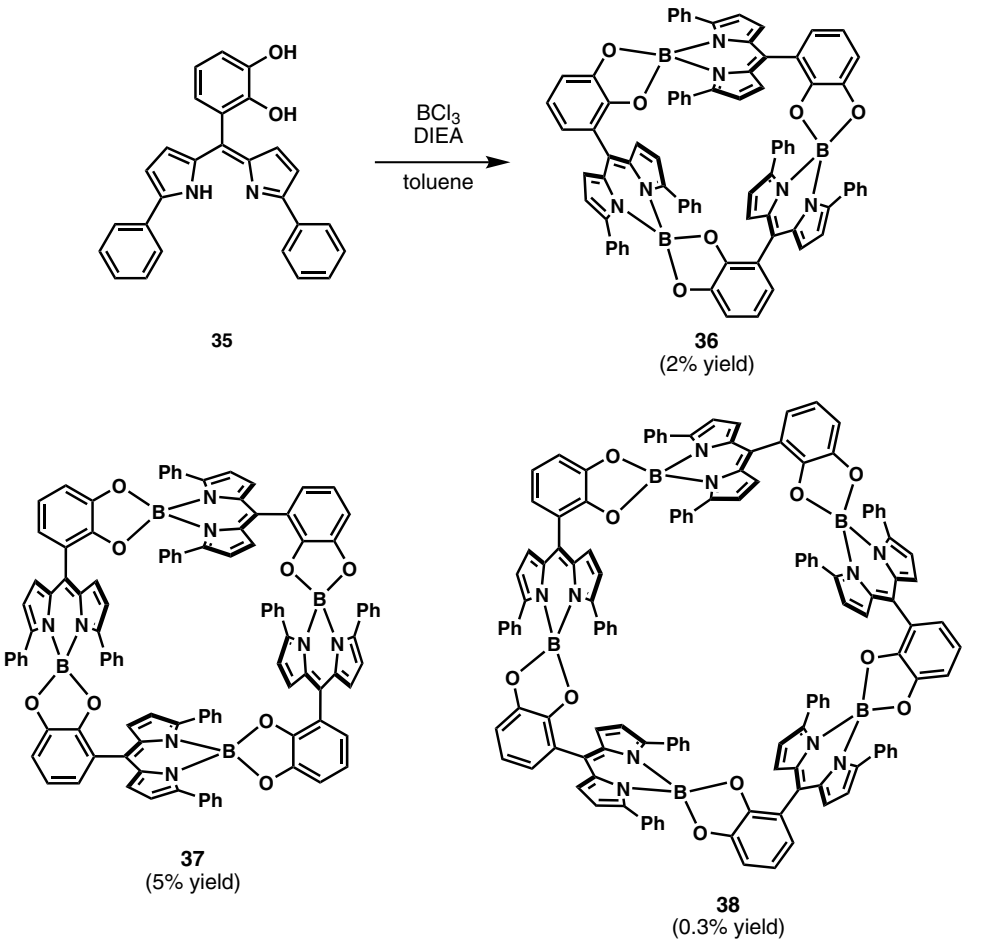

Figure 29. Synthesis of nano-porous materials based on boron–dipyrrin oligomers.[137]

center bound to the other dipyrrinato ligand. The isomeric dipyrrin **41** (Figure 30) gives extended helical copper(II) coordination polymers upon reaction with Cu(hfacac)$_2$, whereby the thioether moiety weakly binds to the axial position of a square pyramidal copper(II) center in a neighboring unit. The trifluoromethyl groups are oriented in the solid state with self-aggregation, reminiscent of phase-separation in fluoroalkanes. This interaction is extremely important to the stability of the polymer as complexation of copper(II) acetylacetonate with **41** gave a heteroleptic complex that decomposed during isolation to give the homoleptic dipyrrinato complex. Such disproportionation is common between solution and solid-state dipyrrin chemistry, and between pre- and post-work-up procedures.[159] Fluorine–fluorine interactions dominated the tendency of 5-quinolinyl substituted dipyrrins

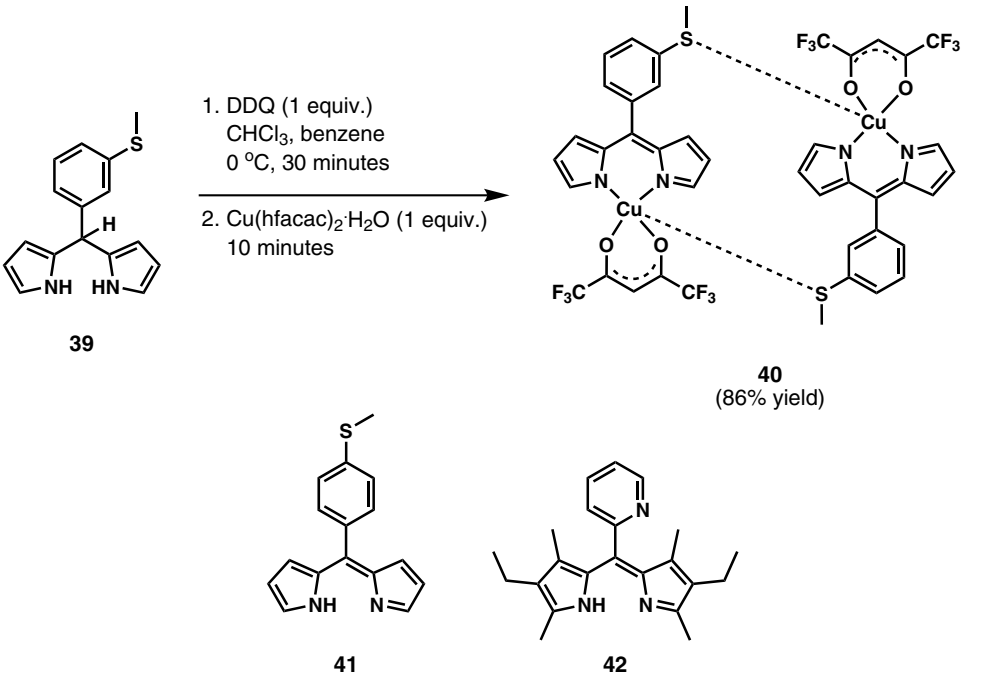

Figure 30. Heteroleptic head-to-tail copper(II) dipyrrinato(hfacac) complex dimer.[113]

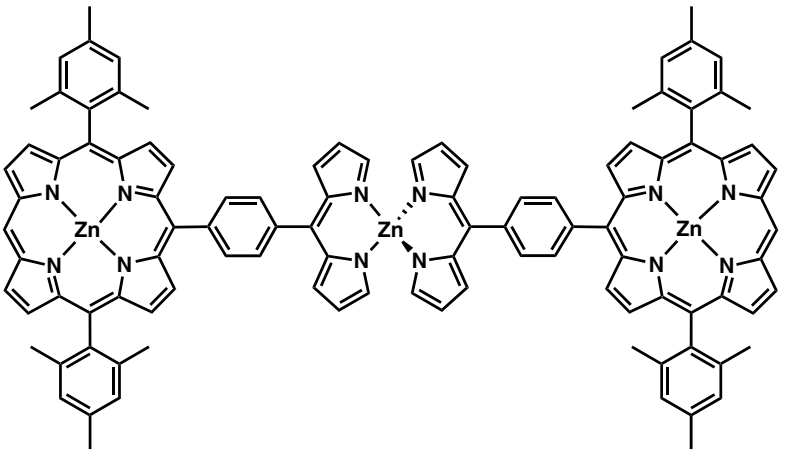
to self-assemble into extended heteroleptic coordination polymers.[209] Another discrete heteroleptic head-to-tail cyclic dimer, $Zn_2(dipyrrinato)_2Cl_2$, was formed when 5-pyridyl substituted dipyrrin (**42**) was reacted with zinc(II) chloride. The dimer was found to be held together by each tetrahedral zinc(II) being coordinated to one bidentate dipyrrinato ligand and the pyridyl moiety of the other dipyrrinato ligand.[167]

This work has been extended to include dipyrrins substituted in the 5-position by aryl rings with appended 4-methanoate, 4-amido, and 4-nitro groups, and the magnetic and thermal properties of complexes formed from such ligands have been studied.[210] Upon the formation of square-planar heteroleptic complexes containing copper(II), the amido and nitro groups enabled the formation of polymeric chains in the solid state through hydrogen bonding and coordinative contacts, respectively. The ester functional group was used to immobilize a dipyrrin onto Wang resin, and subsequent reaction with stoichiometric amounts of copper(II) acetylacetonate gave immobilized heteroleptic Zn(dipyrrinato)(acac) complexes. An interesting feature of such immobilized complexes lies in the ability of the swollen polymer to react reversibly with pyridine.

In the quest for efficient light-harvesting systems and linear arrays capable of efficiently transferring the energy from absorbed photons through multiple



43

Figure 31. Porphyrin–zinc(II) dipyrrinato–porphyrin light-harvesting triad.

chromophores, dipyrrins have been used as auxiliary pigments and linkers in multiporphyrin structures. Typically, porphyrins have strong absorption profiles in the blue region but weak absorption throughout the rest of the visible spectrum limits their potential usefulness in light-harvesting arrays.[30] The incorporation of auxiliary pigments that absorb in complementary regions has the potential to increase the efficiency of the light-harvesting array in porphyrin–zinc(II) dipyrrinato–porphyrin triads such as **43** in Figure 31.[30] In essence, the dipyrrinato metal complex links the two porphyrin units together and simultaneously provides essential light-collection capabilities.

Fluorescence studies have indicated efficient energy transfer from the dipyrrinato moiety to the porphyrin, making such triads promising leads in the quest for efficient light-harvesting systems.[30] The ready self-assembly of homoleptic dipyrrinato complexes, and thus the linking role of the unit, renders such complexes advantageous over boron difluoride dipyrrinato complexes despite the longer excited-state decay of the latter. However, it is interesting to note that triads linked via dimeric dipyrrinato zinc(II) complexes were found to be unstable to silica, and decomposition to the corresponding free-base ensued.[30] Furthermore, it was postulated from results of electrochemical studies that oxidation of both porphyrin–zinc(II) dipyrrinato–porphyrin triads and homoleptic dipyrrinato zinc(II) complexes leads to demetalation.[30] One approach[30] used to prepare such triads involved the Suzuki coupling of 5-(4-iodophenyl)dipyrrinato palladium(II) and a porphyrin appended with a boronic-ester at a *meso*-position. Analogous arrays involve boron difluoride dipyrrinato–porphyrin–boron difluoride dipyrrinato triads such as **45a** (Figure 32), or the corresponding rhodium(I) complex **45b**.[211]

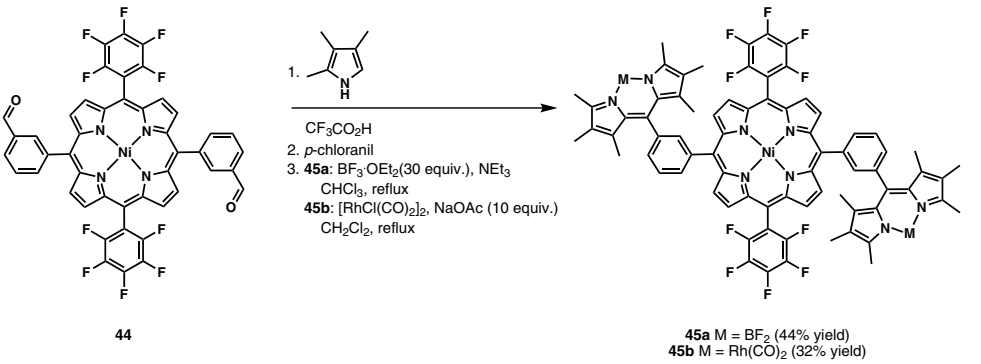


Figure 32. Dipyrrinato complex–porphyrin–dipyrrinato complex triad.[211]

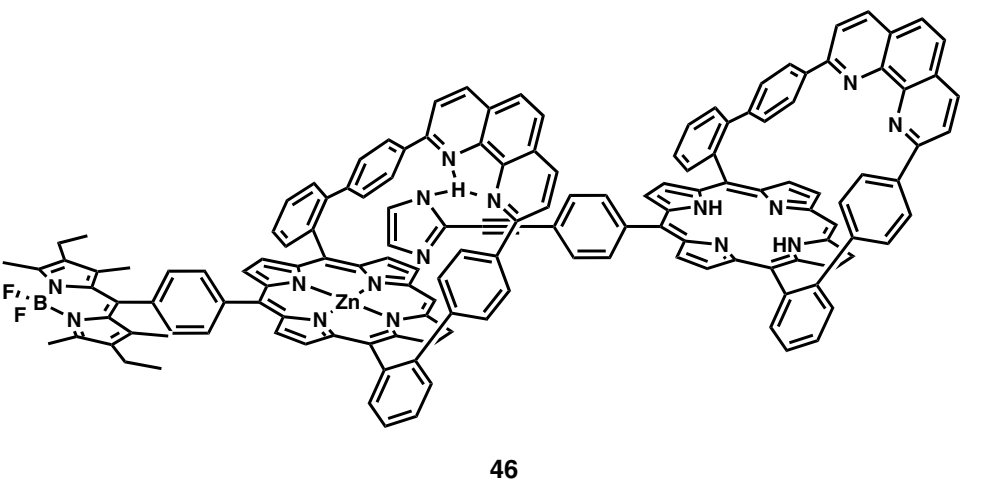

Figure 33. Boron difluoride dipyrrinato–porphyrin–porphyrin triad.[212]

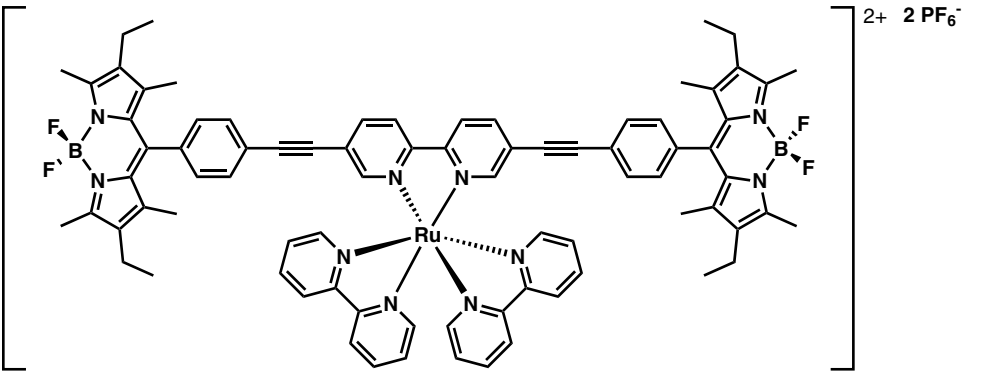
A system involving a boron difluoride dipyrrinato–porphyrin–porphyrin architecture, **46** in Figure 33, was reported as a suitable building block for incorporation into light-harvesting arrays designed as linear coordination polymers.[212] Self-assembly of this system resulted from the affinity of imidazole for zinc(II) porphyrins, and so an imidazole-appended porphyrin and a boron difluoride dipyrrinato complex-appended zinc(II) porphyrin strapped with a phenanthroline unit were brought into close proximity. The boron difluoride dipyrrinato moiety absorbs energy that efficiently migrates to the porphyrin units. This self-assembled approach to light-harvesting arrays presents an attractive synthetic alternative to the use of covalent bonds to link appropriate absorbers and emitters. During attempts to form corroles, a phlorin–dipyrrin conjugate was isolated as a low-yield



47

Figure 34. Boron difluoride dipyrrinato–ruthenium(II)tris(bipyridyl) multichromophoric system.

side-product from the condensation/oxidation of perfluorinated benzaldehyde and 5-mesityldipyrrin.[213]

Multichromophoric systems containing ruthenium(II) tris(bipyridyl) complexes and boron difluoride dipyrrinato units (Figure 34) allow electron-rich metal centers, effective energy absorbing dipyrrinato complexes and electron-accepting bipyridyl ligands to be united in a single structure (**47**).[169] The twisted nature of the structure, courtesy of methyl substituents on the dipyrrinato units, renders the dipyrrinato and bipyridyl chromophores non-planar and so conjugation of the two is prevented. In addition to efficient intercomponent energy transfer processes and rich reversible redox behavior, the complexes exhibit phosphorescence assigned to the boron difluoride dipyrrinato units. The latter is believed to be an effective decay process due to the presence of the heavy ruthenium(II) center surrounded by bipyridyl ligands.

7. *Chemical Manipulations of Dipyrrinato Complexes*

Chemical transformations to produce elaboration or diversification of dipyrrin structures are rarely performed using dipyrrins in their free-base or salt form.[82,154] Typically, these transformations are performed on the synthetic precursors to dipyrrins, or on dipyrrinato complexes. These compounds are frequently more stable and easier to isolate than the dipyrrin free-bases and salts. The complexes have an added advantage during purification, being generally less polar, more visible, and less prone to streaking during chromatography. Manipulations of functional groups on the 5-aryl substituents of dipyrrins are employed most frequently. This provides minimal disruption to the electronic environment of the binding unit of

the dipyrrinato ligand and capitalizes on the diversity of substituted aromatic aldehydes readily available for use in dipyrrin synthesis. There are an ever-increasing variety of reactions that are being performed using dipyrrinato complexes as substrates. The only apparent limitation is the requisite avoidance of strongly acidic and/or reductive conditions so as to prevent demetalation of the dipyrrinato complex, as discussed in Section II.A.5.

There are many examples of dipyrrinato complexes successfully used as reactants in metal-catalyzed cross-coupling reactions. One article describes the use of a boron difluoride dipyrrinato complex bearing an alkene attached by an alkyl tether as a successful substrate for an alkene cross-metathesis reaction catalyzed by Grubbs' second generation catalyst.[148] The Sonagashira reaction, or modifications thereof, has found particular success in application to coupling dipyrrinato complexes.[19,49,50,79,146,214–219] This reaction can be used to substitute both positions on the 5-aryl ring substituents and on the rings of the dipyrrin. Macromolecular light-harvesting arrays are commonly prepared by the coupling of boron difluoride dipyrrinato units with porphyrins by means of the Sonagashira reaction.[215,216] A cautionary note was provided in a report demonstrating that palladium-catalyzed Suzuki couplings are poisoned by free-base dipyrrins and zinc(II) and copper(II) complexes of dipyrrins, and this was attributed to the sequestration of palladium from the catalyst.[30] The corresponding palladium(II) dipyrrinato complex **48** is compatible with Suzuki coupling as shown in Figure 35, a method used for the synthesis of the porphyrin–zinc(II) dipyrrinato–porphyrin triad **50**.[30]

Dipyrrinato complexes have proven amenable to a variety of substitution reactions both via aromatic substitution at positions on the dipyrrin unit or otherwise on appended groups. The first reported substitution reaction of metal dipyrrinato complexes was the sulfonation of boron difluoride dipyrrinato complexes for the preparation of water-soluble fluorescent probes and laser dyes, as shown in Figure 36.[220,221] The increased nucleophilicity of the 2,8-positions over the 5-position of complex **51** results in selective substitution to give disulfonate **52** in acceptable yields. Recent investigations into the sulfonation of similar boron difluoride dipyrrinato complexes by this method noted that considerable experimentation was required to elucidate the optimal conditions for isolating high yields of pure sodium sulfonate salt products.[143]

In a rare example of a chemical transformation performed upon a free-base dipyrrin, as opposed to a dipyrrinato complex, 5-aryl-1,9-unsubstituted dipyrrins have been shown to undergo metal-mediated alkoxy monosubstitution using several different examples of alcohols.[82] The partially optimized reaction conditions showed that an oxidant, such as DDQ, was necessary for the alkoxy substitution to occur, and that product yields were highest when weakly- or noncoordinating solvents were employed.[82] In the presence of an oxidant, such as ammonium

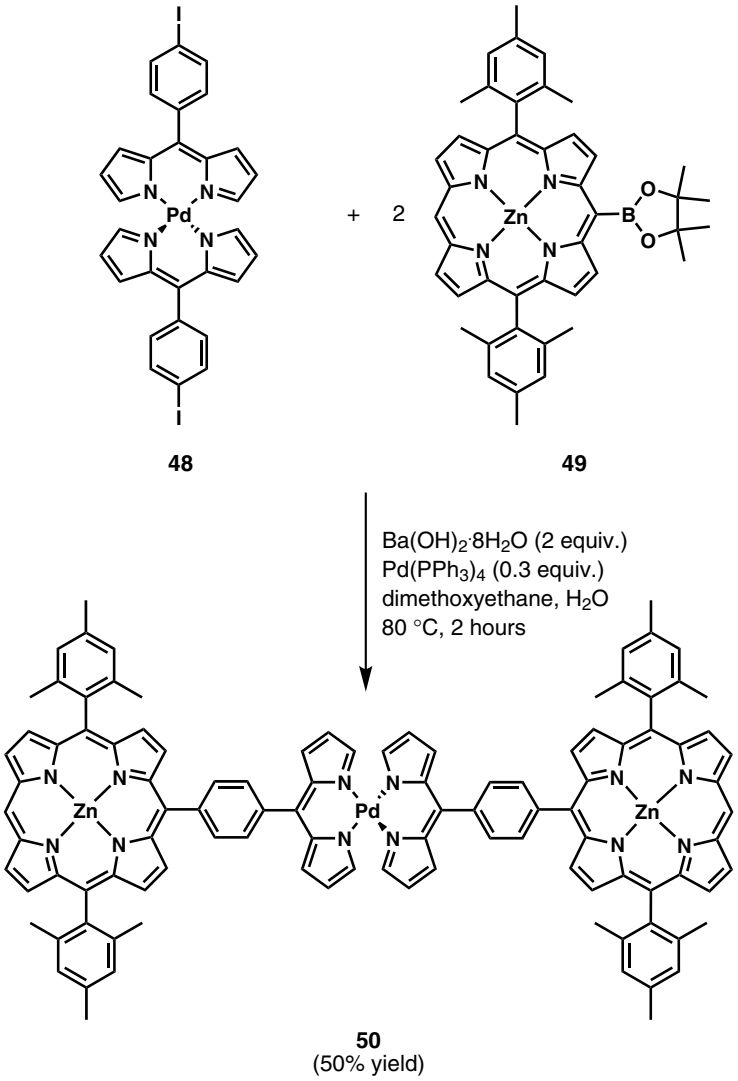


Figure 35. Suzuki cross-coupling reaction involving a palladium(II)dipyrrinato complex.[30]

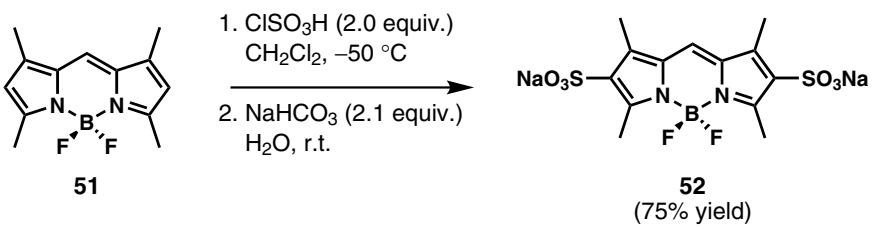

Figure 36. Sulfonation of dipyrrinato complex.

cerium(IV) nitrate (CAN), and a 2-unsubstituted pyrrole, a nickel(II) bis(dipyrrin) complex was found to undergo pyrrole exchange and pyrrylation at the newly formed 5-position.[20] Unsubstituted positions on the pyrrolic rings of boron difluoride dipyrrinato substrates have been successfully shown to undergo halogenation with bromine[153] and iodine.[222] However, 1,9-dichlorodipyrrinato complexes have previously been prepared from the corresponding dichlorodipyrromethane.[133] Additionally, a study demonstrating bromination reactions illustrated the regioselectivity of this reaction wherein the first equivalent of bromine yielded a tentatively assigned 1,9-dibromodipyrrinato complex, followed by the second and third equivalent adding at the 2,8-positions to yield a cleanly isolable tetrabromo product and a 1,2,3,7,8,9-hexabromodipyrrinato product, respectively.[153] These halogen-substituted dipyrrinato complexes can undergo subsequent substitution of the halogen substituents by nucleophiles such as cyanide, sulfides, and various amines.[133] A 5-thiomethyl-dipyrrinato boron difluoride complex, an example of an unusual 5-heteroatom-substituted dipyrrin, is known to undergo substitution of the thiomethyl substituent with aniline to yield the corresponding 5-anilino-dipyrrinato complex.[131] Based upon the absorbance spectrum and its non-fluorescence, the structure of this 5-aniline-substituted dipyrrinato ligand is thought to be more closely represented as an *N*-phenyl-dipyrrolic iminium species.[131]

Other examples of substitution reactions include those in which the derivatization transformation occurs at a substituent on the dipyrrin ring. Reports in the literature have described the esterification of a hydroxy substituent on a dipyrrinato complex with an acrylate group, for subsequent polymerization reactions,[223] and the substitution of the chlorine in a 5-chloromethyl-dipyrrinato complex with dipicolylamine to form a tertiary amine.[224] Motivated partly by the popularity of fluorescent biomarkers, it has been demonstrated that boron difluoride dipyrrinato complexes are compatible for use with the amide coupling reagent 2-chloro-4,6-dimethoxy-1,3,5-triazine (CDMT)[225] and carbodiimide reagents such as *N,N′*-dicyclohexylcarbodiimide (DCC).[132,226]

Manipulations of functional groups on 5-aryl substituents of complexed dipyrrinato ligands are also known: for example, hydroxy groups on 5-phenol substituted dipyrrins undergo alkylation.[154] Boron difluoride dipyrrinato complexes are amenable to tetrakis(triphenylphosphine) palladium(0)-mediated deprotection of allyl-protected hydroxy substituents on 5-aryl substituents.[145] The hydrogenation of the nitro-group of 5-(4-nitrophenyl)dipyrrin complexes to yield 5-(4-aminophenyl) dipyrrin complexes is a particularly useful transformation (Figure 37).[51,76,225] It has been demonstrated that primary amino groups present on 5-aryl substituents of dipyrrinato complexes can be transformed into azide groups[143] or, quantitatively, into isocyanate or isothiocyanate groups which can subsequently undergo transformations to give ureas and thioureas respectively by reaction with amines.[51,135]

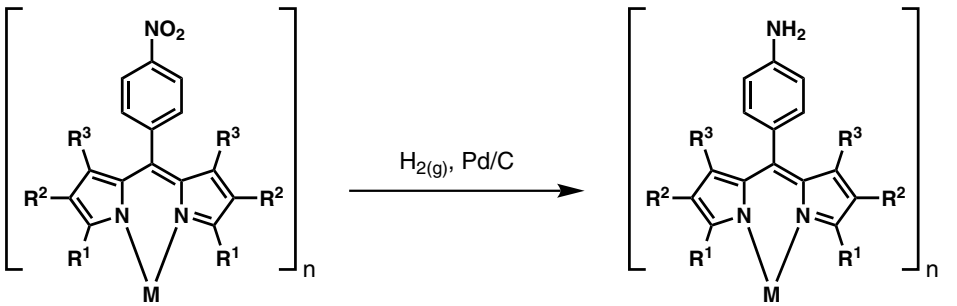

Figure 37. Derivatization of 5-substituted amino-aromatic dipyrrinato complexes.

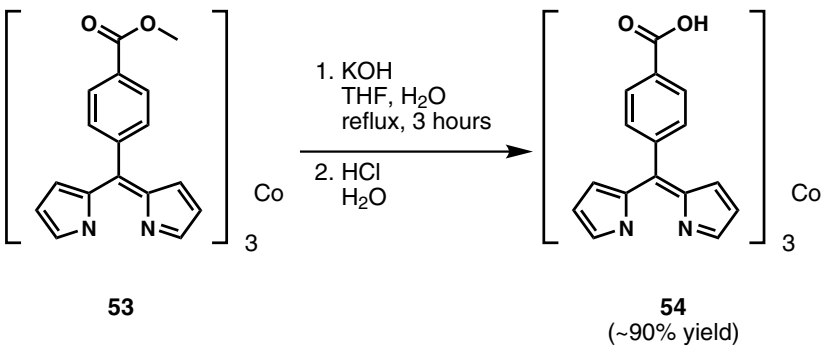

Figure 38. Derivatization of 5-substituted carboxy-aromatic dipyrrinato complexes.[76]

The azide products have been shown to successfully participate in copper-mediated azide–alkyne cycloaddition reactions, the so-called "click" reactions.[143,150] In addition, diamino-substituted 5-aryl substituents can be transformed into polyimine derivatives.[51]

In an interesting demonstration of the ability to perform manipulations of the functional groups present in dipyrrinato metal complexes, the methyl ester of **53** (Figure 38) was saponified and then reformed through a series of organic procedures.[76] Further functional group interconversions performed using the optically pure Δ and Λ enantiomers of cobalt(III) complex **54** showed that the carboxamide derivative could be dehydrated to give the cyano derivative, which could be transformed into the diaminotriazine derivative by reaction with dicyandiamide and potassium hydroxide without any loss of stereochemical purity throughout the procedures.[107]

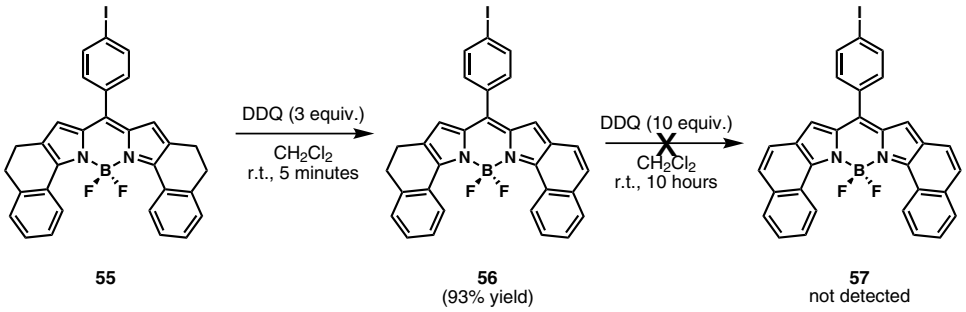

Figure 39. Dehydrogenation of dipyrrin substituents.[228]

Efforts to dehydrogenate rings attached to dipyrrins, in an attempt to increase conjugation to the dipyrrin rings, have not been very successful.[227,228] In one example, the attempted DDQ dehydrogenation of the methylene groups in compound **55** to prepare boron difluoride complex **57** resulted in **56**, in which only one side of **55** had undergone dehydrogenation (Figure 39).[228] Increasing the number of molar equivalents of DDQ failed to provide the desired product and increasing the temperature of the reaction resulted in decomposition of the starting material.[227] Computational modeling of the reaction revealed that the activation energy required to transform **56** to **57** was prohibitively high as a result of the strong steric interactions created between the hydrogen atoms of the aryl rings and the fluorine atoms when the dipyrrin ligand of the product is made planar upon dehydrogenation.[228] In a related example a symmetric dipyrrinato boron difluoride complex was reacted with 10 molar equivalents of DDQ in an attempt to dehydrogenate 1,2-butadiyl substituents and give a 1,2-butenyl product. However, an α-ketone derivative was the only product isolated.[227] This ketone product formed via a proposed mechanism of hydride abstraction, subsequent trapping of the carbocation with water, followed by oxidation.[227]

Oxidations of methyl groups on the dipyrrin rings of boron difluoride dipyrrinato complexes can be performed as shown in Figure 40.[223,227] In one example of this reaction, the 1-methyl group of the dipyrrinato complex **58** was oxidized to a formyl group using DDQ.[223] Hydrogenation of aldehyde **59**, catalyzed by palladium on activated charcoal, yielded the corresponding alcohol with the formation of two side-products: the formyldipyrromethane (with concomitant demetalation), and regenerated **58**.[223] Alternately, methyl substituents have been shown to undergo oxidation by lead(IV) tetra-acetate exemplified by the transformation of dipyrrinato complex **58** into **60**, a reaction traditionally used for the oxidation of α-methyl groups of pyrroles.[227]

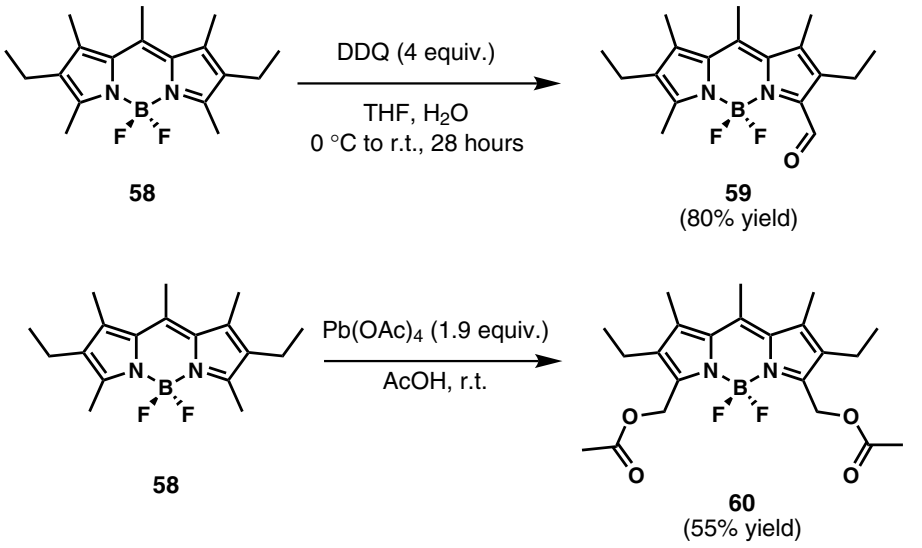

Figure 40. Examples of 1-methyl oxidations in dipyrrinato complexes.

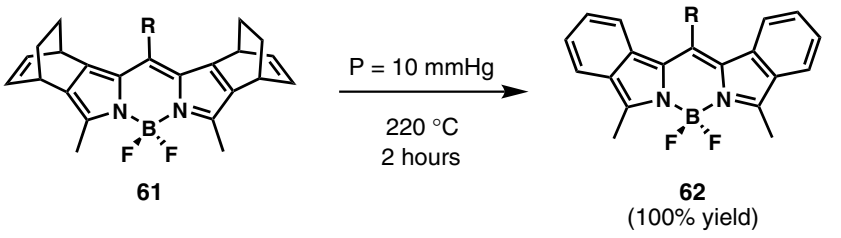

Figure 41. Retro Diels-Alder reaction performed upon a substituted boron difluoride dipyrrinato complex.

An examination of the sulfoxidation of 5-thienyldipyrrinato complexes showed a disparity between the boron difluoride complex in comparison to the corresponding iron(III), cobalt(III), nickel(II), and copper(II) complexes.[153] Under the conditions examined, namely titration to 100 equivalents of *m*CPBA in acetonitrile, a variety of boron difluoride derivatives cleanly undergo sulfoxidation of the 5-thienyl substituent. However, the iron(III), cobalt(III), and copper(II) complexes largely resist oxidation, while the nickel(II) complex undergoes extensive degradation, presumably due to oxidation of the metal center.[153]

A particularly unique example of the chemistry of dipyrrinato complexes is the retro Diels-Alder reaction to prepare the benzo-fused boron difluoride dipyrrinato product **62**, as shown in Figure 41.[229] The reactant dipyrrinato complex **61**

was prepared by condensing two equivalents of the corresponding tricyclic pyrrole precursor with one equivalent of an alkyl or aryl acid chloride. This was followed by boron complexation.[229]

Only a small fraction of the wealth of organic transformations is represented in this review of chemical reactions performed upon dipyrrinato complex substrates. There is much emphasis placed upon the manipulations of dipyrrinato complexes of boron difluoride in the literature. This undoubtedly stems from the great interest in modification of these complexes to fine-tune their optical properties, or to attach selective binding receptors. There remains a great opportunity to explore the potential diversity of chemical transformations of dipyrrinato complexes.

8. *Stereochemistry of Dipyrrinato Metal Complexes*

Due to their bidentate binding mode, dipyrrinato ligands have potential to form chiral homoleptic metal complexes with tetrahedral and octahedral coordination geometries. Tetrahedral homoleptic bis(dipyrrinato) complexes of unsymmetrical ligands are chiral as shown in Figure 42. Similarly, tetrahedral complexes of bis(dipyrrin) ligands (in which two dipyrrin units are attached by a linker) form *M* (left) and *P* (right) helical enantiomers. Octahedral homoleptic tris(dipyrrinato) complexes are propellor-shaped and therefore exhibit Λ and Δ chirality (Figure 42). Several

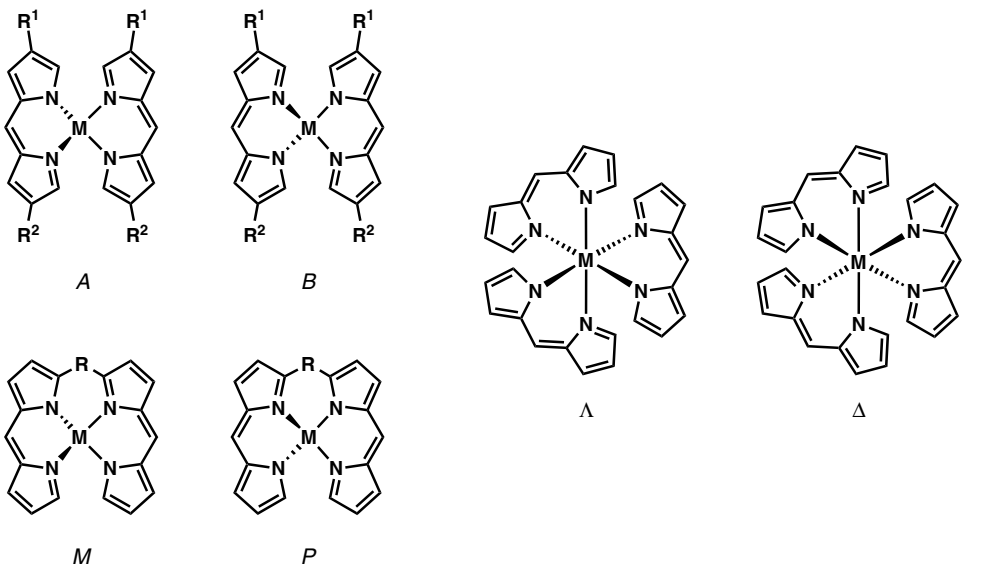

Figure 42. Chiral tetrahedral and octahedral dipyrrinato complexes.

studies have shown that optically pure dipyrrinato complexes are stable to racemization.[203] Enantiopure cobalt(III) tris(dipyrrinato) complexes were subjected to reaction conditions for further chemical manipulation of functional groups on the ligand with no observed loss of stereochemical purity.[107,172,230,231]

In the absence of any chiral influence the dipyrrinato metal complexes described above form as racemic mixtures of enantiomers. There has been a great deal of research interest focused on the preparation of optically pure dipyrrinato metal complexes either by resolving racemates, or by chiral templating and chiral induction during synthesis. Several examples have been reported of the successful resolution of *M* and *P* helical bis(dipyrrinato) complexes achieved using HPLC and a chiral stationary phase.[21,172,194,230] The precipitation of diastereomeric salts formed with (−)-cinchonidine has been demonstrated as a method to resolve the Λ and Δ enantiomers of tris[5-(4-carboxyphenyl)dipyrrinato] cobalt(III).[107]

High levels of stereoselectivity have been reported for the preparation of metal complexes of chiral-templated dipyrrinato ligands.[107] Characterization using HPLC, ^{1}H NMR spectroscopy, circular dichroism, and X-ray structure analysis supported the formation of a helical zinc(II) complex of a homochiral binol-linked bis(dipyrrinato) ligand with a diastereomeric ratio of > 99:1.[21,172] It has been shown that the stereoselectivity of the complexation process, as well as the ratio of ligand to metal ions, and the degree of helicity of the formed complex is influenced by structural features of the bis(dipyrrin) ligand such as the degrees of freedom provided by the linker group, and the points of connection, that is to say 2,2′- versus 3,3′-connection.[232] The use of chiral reagents to induce stereoselective dipyrrinato complex formation has shown some success.[21,194] In some examples distant point chiral auxiliaries substituted on a dipyrrinato ligand achieved small amounts of diastereoselectivity during zinc(II) complexation.[114,231,234] In another example, the use of copper(II) salts of either enantiopure *R*- or *S*-mandelic acid were shown to induce a modest degree of stereoselectivity in the formation of helical copper(II) complexes of dipyrrin-containing cyclooctapyrroles.[233] The same report demonstrated that diastereoselectivity for the formation of complexes of these cyclooctapyrroles from copper(II) chloride could be induced through the use of *R*-α-methylbenzylamine as an enantiopure base.[233] An interesting report described the preparation of metal-coordinated macrocycles from the phenylethynyl-linked bis(dipyrrin) ligand **63** as seen in Figure 43.[202] The space within the macrocycle cavity is large enough to allow rotation of the zinc(II) bis(dipyrrinato) units, resulting in the transition between chiral (ΔΔ- and ΛΛ-**64**) and achiral (*meso*) isomers.

Despite the popularity of BODIPY compounds, the synthesis of chiral boron difluoride dipyrrinato complexes is a relatively unexplored area of research.[155] Enantiopure atropisomeric binaphthyl auxiliaries attached through the 5-position

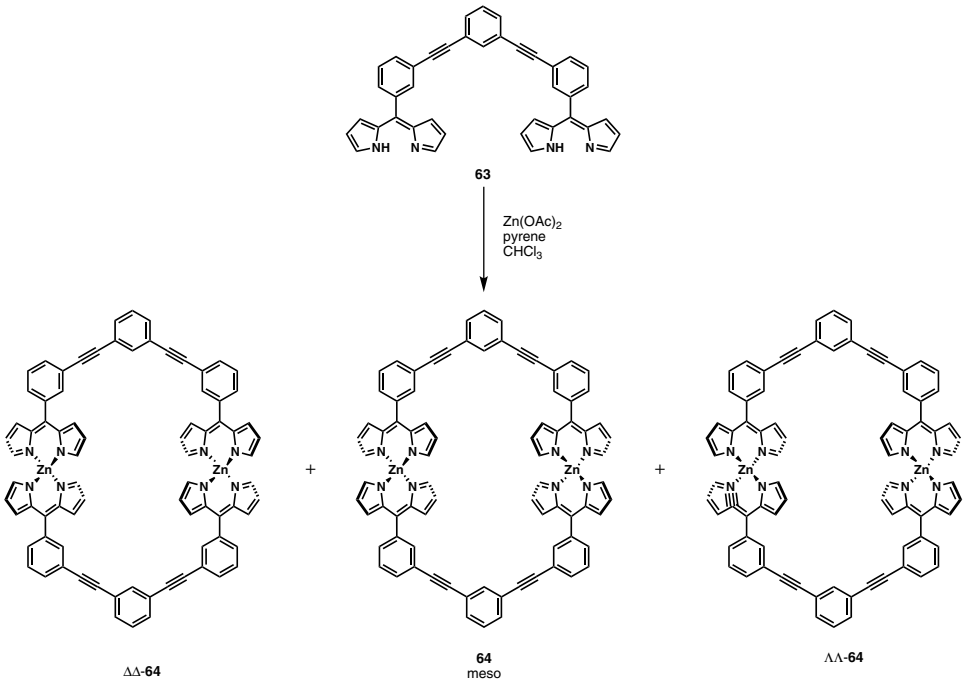

Figure 43. Preparation of achiral and chiral zinc(II) bis(dipyrrinato) complexes.

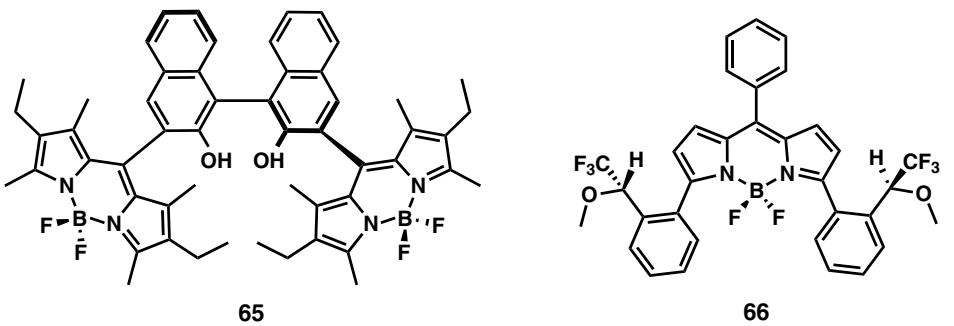

Figure 44. Chiral boron difluoride dipyrrinato complexes.

of the dipyrrinato ligand were the source of chirality in one boron difluoride complex, **65** in Figure 44.[236,237] Analysis of the rate of fluorescence quenching of the chiral boron difluoride dipyrrinato complex **65** by amines revealed differential quenching by enantiomers of chiral amines.[236,237] It was proposed that the observed differential quenching rates could be exploited for chiral discriminations. In another report regarding chiral boron difluoride dipyrrinato complexes such as **66**

in Figure 44, aryl substituents bearing a stereogenic center serve as the source of chirality at either the 5- or the 1,9-positions of the dipyrrinato ligand.[238]

B. Properties and Reactions of Dipyrrinato Complexes

The steric interactions between 1,9-substituents of dipyrrins,[99] even substituents as small as hydrogen atoms, were found to distort the geometry of coordination about the metal ions, as discussed in Section II.A.1. Even those metal(II) ions that usually prefer square planar coordination geometry were found to adopt pseudo-tetrahedral coordination geometry with dipyrrinato ligands.[239,240] These observations prompted the study of conductivities,[241] magnetic susceptibility,[94,96,102,105] ligand field parameters,[94,104,110] X-ray crystal structures,[92,105,122,239,240] and spectroscopic behavior from absorption spectra,[91,94,96,102–106,110,115,122] X-ray powder spectra,[102,106] IR spectra,[91,94,96,103,104,106,115] ^{1}H NMR spectra,[91,105,115,121,122,242] and ESR spectra[106,112] for a wide variety of dipyrrinato metal complexes, as previously summarized.[24]

The complexation of dipyrrinato ligands has recently been studied using absorption spectroscopy, calorimetry, and ^{1}H NMR spectroscopy. All revealed the intermediacy of heteroleptic dipyrrinato metal complexes in the complexation process to form homoleptic complexes as seen in Figure 45 and discussed in Section II.4.[159,243] Thermodynamic data such as equilibrium constants have been reported[55,157,244–246] for the complexation process, although the intermediate heteroleptic complexes were not accounted for in the calculations. More recent publications confirm the observation of the heteroleptic intermediates,[162,247] and reveal that the equilibria moves towards the formation of homoleptic dipyrrin complexes by alteration of factors such as basicity[243] and the coordination preferences of the metal salt anion.[162] For example, metal chlorides do not form heteroleptic dipyrrin complexes as readily as metal acetates, acetylacetonates or valinates.

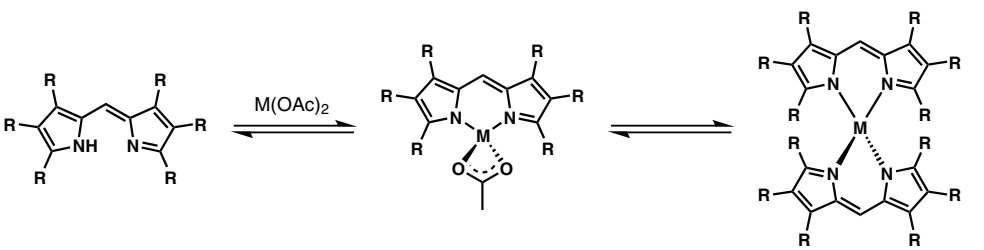

Figure 45. Formation of homoleptic dipyrrinato metal complexes through a heteroleptic intermediate.

1. *Fluorescent Dipyrrinato Metal Complexes*

Dipyrrinato complexes of BF_2 (BODIPYs) are strongly fluorescent, having a high fluorescence quantum yield, whereas the corresponding dipyrrin free-bases are generally not strongly fluorescent (with some exceptions). BODIPYs are currently in the midst of a substituent revival, with the fluoride substituents on the boron atom being replaced by a number of alternative substituents. The chemistry of BODIPYs is not extensively covered in the current chapter, but some select examples are included here as they exemplify the ability of the dipyrrinato ligand to support the boron atom as it is cajoled into compromising bonding environments. In one case,[70] a borenium cation was generated through mono-fluoride extraction of a BODIPY (**67** in Figure 46) using the triethylsilylium ion. The stabilization of the planar three-coordinate borenium ion usually requires a bulky ligand set, yet the dipyrrinato ligand and a single fluoro ligand were able to effect such stabilization in this case. A borenium hydride, **69**, was subsequently prepared via treatment with DIBAL-H, and the hydride was then converted into the corresponding tetrahedrally coordinated boronium ion, **70**, through treatment with DMAP. The incorporation of a dipyrrinato ligand into a sensor for fluoride ions through the use of boronium ions has also been reported, again exploiting the excellent capacity

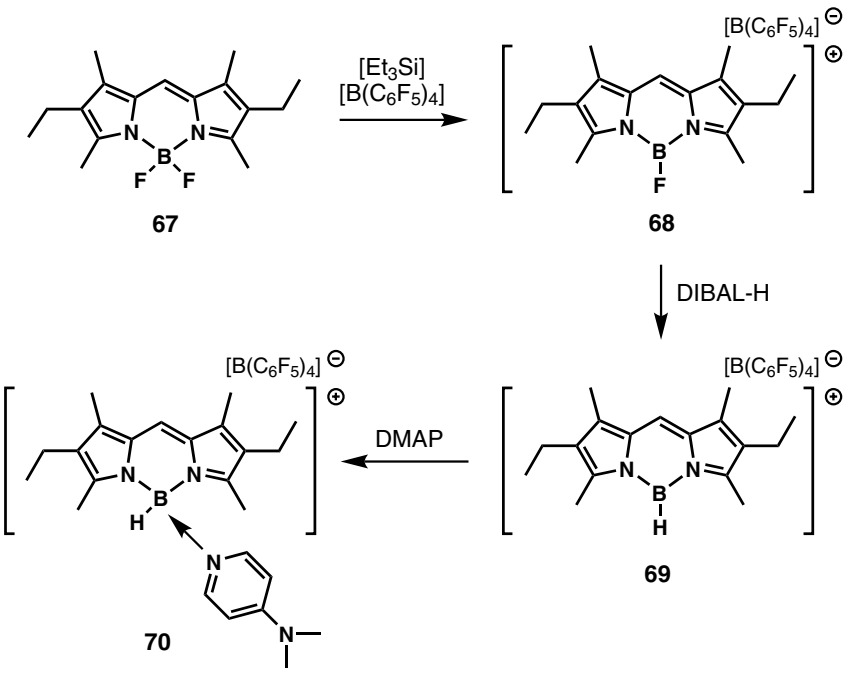

Figure 46. Generation of borenium cations from BODIPY dyes.[70]

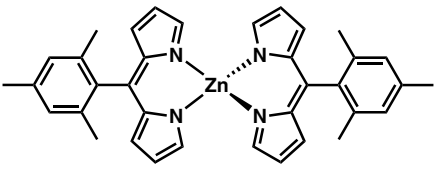
of the dipyrrinato ligand to support novel bonding environments for the boron atom.[249] Perfluoroaryl-substituted BODIPYs have also been reported, whereby the boron atom was coordinated to one or two perfluorophenyl groups or a perfluorodiphenyl moiety. Borenium ions were generated via fluoride abstraction from a complex with one perfluorophenyl and one fluoro substituent on the boron atom.[248]

Although it was traditionally believed that homoleptic dipyrrinato metal complexes were nonfluorescent, it was reported that the zinc(II) dipyrrinato complex **71** in Figure 47, bearing a mesityl substituent at the 5-position of the dipyrrinato unit, is highly fluorescent.[116] Furthermore, 5-phenyl and 5-(4-*tert*-butylphenyl) substitution results in very weak emitters, as seen for **72a** and **b**. Presumably the 2,6-methyl groups of the mesityl group within **71** prohibit internal rotation, and so dramatically enhance the excited-state lifetime of complexes involving 5-mesityldipyrrinato ligands. These types of emitting dipyrrinato complexes would be ideally suited to applications for which intense absorption and fluorescence attributes in the visible region are desirable. As dipyrrinato ligands facilitate self-assembly, they are also valuable synthetic linking tools for supramolecular chemistry applications (see Section II.A.6). Homoleptic gallium(III) and indium(III)



71
Fluorescence quantum yield (Φ_f) = 0.36 in toluene

analogs of **71** exhibit decreased levels of fluorescence.[84] Increased fluorescence as a result of inhibition of the rotation of an aryl group in the 5-position is also seen for a 5-(2-pyridyl)dipyrrinato ligand which forms a head-to-tail cyclic dimer, **73** in Figure 47, in the zinc(II) complex prepared using zinc(II) chloride.[167] The heteroleptic dimer contains two zinc(II) centers, two tridentate ligands and two coordinated chloride ions. The nitrogen atom of the pyridyl group satisfies tetrahedral zinc(II) coordination, and so rotation of the pyridyl group relative to the dipyrrinato unit is prohibited.

Bis-fullerenes coupled through a homoleptic dipyrrinato zinc motif have been reported.[250] In this case, dipyrrins appended with a substituent at the *meso*-position enabled the attachment of a fullerene. Coupling of such fullerene-appended dipyrrins via reaction with zinc(II) gave a bis(dipyrrinato) complex and thus brought together two fullerenes into the same molecule. The complex was studied for its fluoresence and energy-transfer properties, and was of special interest due to its two different constituent chromophores. A similar strategy using copper(II) was used to bring two 1,4-benzoquinine-containing triazoles into the same molecule.[251]

2. *Electrochemical Studies of Dipyrrinato Complexes*

Dipyrrins and their metal complexes exhibit intense ligand $\pi \rightarrow \pi^*$ transition afforded by electronic conjugation of the dipyrrinato system. Electrochemical studies of dipyrrinato complexes reveal consistent behavior for ligand-centered oxidations and reductions, although some variances due to molecular structure have been observed. The redox behavior of free-base dipyrrins is similar[128,230,252,253] to that of their protonated forms, although lower oxidation potentials are observed for the free-bases and this can be rationalized by the reduced electron availability in the protonated systems.[253] Of course, the electrochemical properties of dipyrrinato complexes also differ with respect to the nature and oxidation state of the complexed metal ion.[230,252,254] For dipyrrins with aryl substituents in the 5-position, the Hammett constants for the various aromatic substituents have been shown to directly correlate to the redox potentials of the corresponding nickel(II) dipyrrinato complex.[230]

Nickel(II),[230] copper(II),[252,254] and palladium(II)[254] complexes of 1,1′-bis(5-aryldipyrrin)s exhibit two reversible redox couples, although verification of the second reduction is sometimes limited by the electrolytic discharge limit.[230] Iron(III) complexes of 5-aryl dipyrrins display one quasi-reversible one-electron oxidation, with little variance upon the nature of aryl substituents at the 5-position.[75,79] The electronic absorptions for the heteroleptic iron complexes **74**, **75**, and **76** are observed in the range 460–518 nm, much like for their porphyrin congeners. Cyclic voltametry disclosed their fully reversible one electron $Fe^{III/II}$ redox

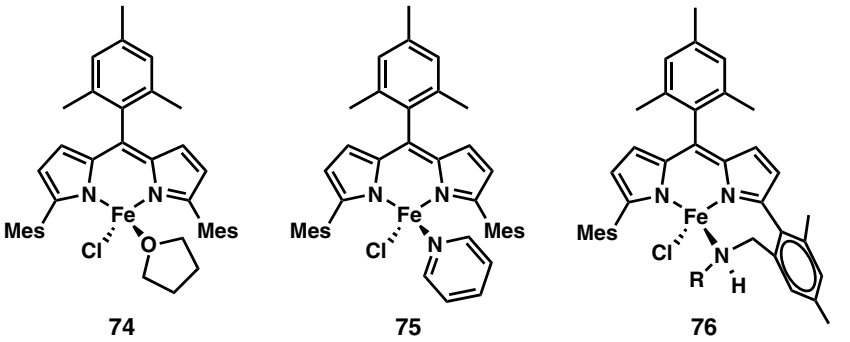

Figure 48. Heteroleptic iron–dipyrrinato complexes.

wave centered at –400 mV vs. an internal ferrocene reference (Figure 48).[39] The high-spin iron(II) dipyrrinato complexes **74** and **75** were reacted with organic azides ($R–N_3$) to expel nitrogen (N_2) and produce amination products (**76**), via C–H activation of a neighboring methyl group of an α-mesityl substituent, presumably induced by the Fe–dipyrrinato center.

Zinc(II) complexes of dipyrrins substituted with aryl groups at the 5-position undergo two highly irreversible one-electron oxidations,[30] the irreversibility having been attributed to demetalation of the complex upon formation of the mono- or dication.[30] The electrochemical behavior of BODIPYs[14,18,48,50,51,169,216,225,228,229,236,255–264] is often used to calculate HOMO–LUMO gaps for energy diagrams.[169,230] Generally, BODIPYs undergo one reversible one-electron oxidation, and one reversible one-electron reduction,[255] although scanning at more positive and negative potentials than are routinely used has revealed additional irreversible redox reactions.[256] Effecting increased conjugation by substitution with, for example, electron-donating groups has been found to stabilize the radical cation formed upon electrochemical oxidation and therefore make the oxidation potential of the corresponding substituted BODIPYs less positive. However, substitution with electron-withdrawing groups has been found to make the oxidation potential more positive.[49,51,145,169,259,260,265] Substituents with a higher HOMO energy level than the BODIPY unit diminish the fluorescence properties of BODIPYs (Figure 49).[145,152] Chemical modification of such substituents to give derivatives with a comparatively lower HOMO energy level would generate strongly fluorescent compounds. This strategy has been used as a probe for the detection of the oxidant hypochlorous acid (HOCl).[145]

The position at which groups conjugated to dipyrrins are situated has been shown to have little effect upon the redox potentials of BODIPYs.[18,265] For example, **77** and **78** (Figure 50) have essentially the same redox profile.[18] Some BODIPYs of dipyrrins substituted with pyridyl moieties at the 5-position have

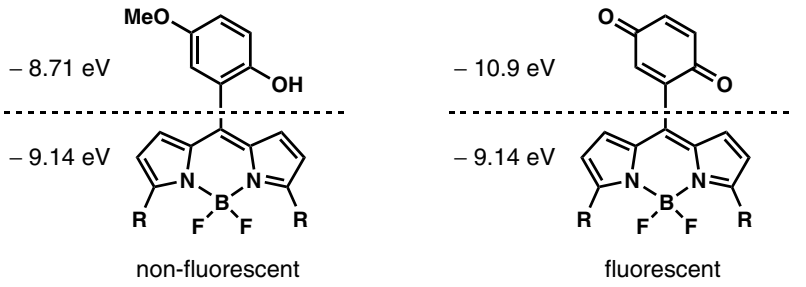

Figure 49. Dependence of fluorescence upon the HOMO energy levels of BODIPYs and their substituents, adapted from Ref. 145.

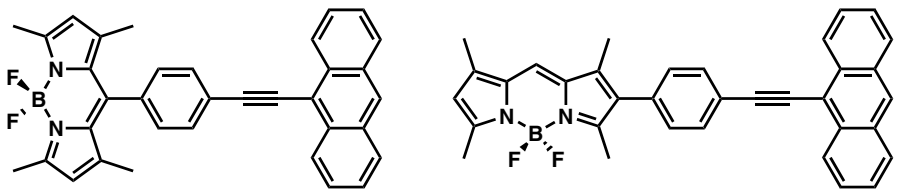

Figure 50. Differently substituted boron difluoride dipyrrinato complexes with similar redox behaviors.

been shown to possess electrochemical properties that are quite different to those of typical complexes in dichloromethane.[49] This observation, presumably due to reaction of the radical cation (formed upon oxidation) with the solvent, was found to be eliminated by recording the cyclic voltammograms in acetonitrile.[49] In compounds that contain more than one boron difluoride dipyrrinato unit, it has been observed that the two (or more) units undergo reduction at different potentials, indicating that the units are electronically isolated.[169,258]

III. Concluding Remarks

Dipyrrins and complexes thereof have interesting features to offer to many fields of research. The variable structure and functionalizations afforded by these molecules determine many useful biological, optical, electrochemical, and stereochemical properties. The increasing number of methods available for preparing increasingly diversely functionalized dipyrrins, and the expanding ability to characterize the properties of these molecules promise a dynamic and exciting future for dipyrrin research. Hopefully this chapter has provided a reference to where dipyrrin research has ventured in exploring the potential of these interesting and

adaptable molecules. Hopefully, it will also provide some new directions for exploration.

40 Coordination Chemistry of Verdohemes and Open-Chain Oligopyrrole Systems Involved in Heme Oxidation and Porphyrin Destruction

Alan L. Balch and Faye L. Bowles

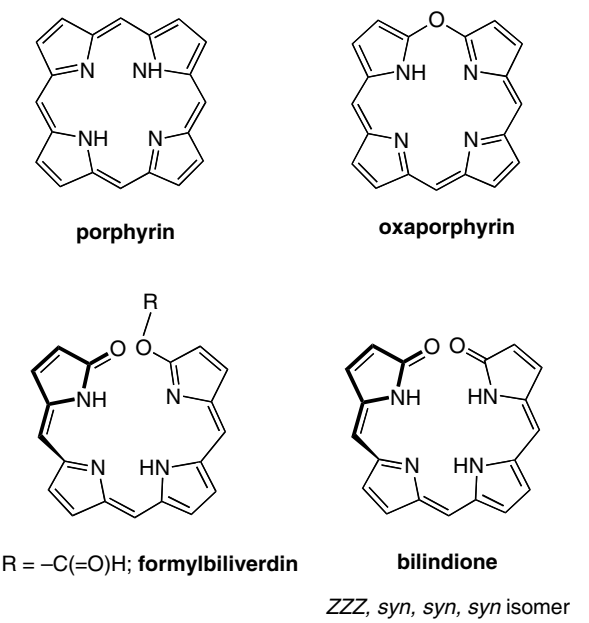
Department of Chemistry, University of California, Davis, California 95616, USA

List of Abbreviations

OEP	dianion of octaethylporphyrin
TPP	dianion of tetraphenylporphyrin
OEOP	monoanion of octaethyloxaporphyrin
OEPO	trianion of octaethyloxophlorin
OEB	trianion of ocatethylbilindione
py	pyridine

I. Introduction

This article focuses on the coordination chemistry of a closely related set of tetrapyrrole ligands whose fundamental skeletons are shown in Scheme 1. These tetrapyrrole ligands are formed during the process of heme destruction and this chapter will emphasize the interrelationships of these ligands as heme degradation products and as ligands that impart distinctive chemical and physical properties to their complexes. The well-known porphyrin macrocycle provides a nearly planar array of four nitrogen atoms and usually coordinates as a dianion through the loss of the two N–H protons. The oxaporphyrin macrocycle found in verdoheme has an oxygen atom replacing one of the *meso* carbon atoms and usually coordinates metal ions as a monoanion. The two open-chain tetrapyrroles shown in Scheme 1

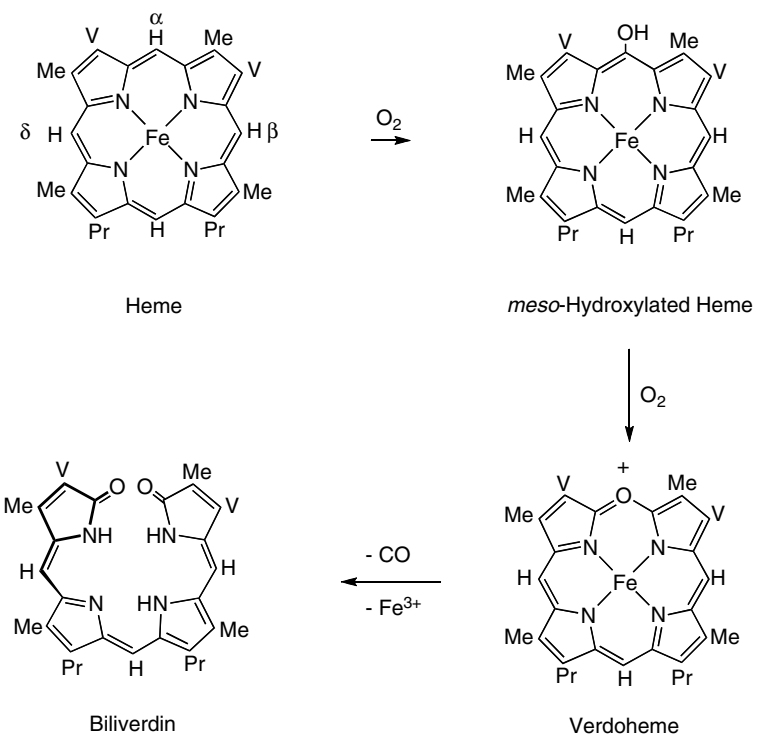


Scheme 1. Ring skeletons of tetrapyrrole ligands.

differ from the macrocycles in that they have helical structures that are produced in order to avoid contact of the terminal substitutents. The formylbiliverdin ligand coordinates as a dianion, while the bilindione ligand can lose three protons to form a trianion. There are a number of other open-ring tetrapyrrole ligands, such as the products of nucleophilic attack on verdohemes, that are related to the formylbiliverdin ligand and coordinate metal ions as a dianion. These different tetrapyrrole ligands are linked through a series of oxidation reactions of metalloporphyrins, as explained below.

A. Heme Catabolism

The enzyme heme oxygenase binds heme as the substrate and utilizes dioxygen to carry out a regiospecific opening of heme at the α-methine position, as shown in Scheme 2.[1–3] In the process, the α-methine carbon is converted to carbon monoxide, and iron is eventually released to give biliverdin as the final product. A second enzyme, biliverdin reductase, subsequently reduces biliverdin to bilirubin, the yellow pigment responsible for jaundice in humans. The regiospecificity of the



Scheme 2. Heme cleavage by heme oxygenase. Me, methyl; V, vinyl; Pr, propionate.

oxidation is introduced in the initial step of the process, which produces a *meso*-hydroxylated heme as a detectable intermediate in the reaction.[4] The coordination chemistry of *meso*-hydroxylated porphyrins or oxophlorins has been reviewed elsewhere.[5] A green heme, verdoheme, is a second intermediate that is formed during the heme-oxygenase-catalyzed oxidation.[6] The crystal structures of verdoheme bound to human heme oxygenase and to rat heme oxygenase 1 have been reported.[7,8]

B. Coupled Oxidation

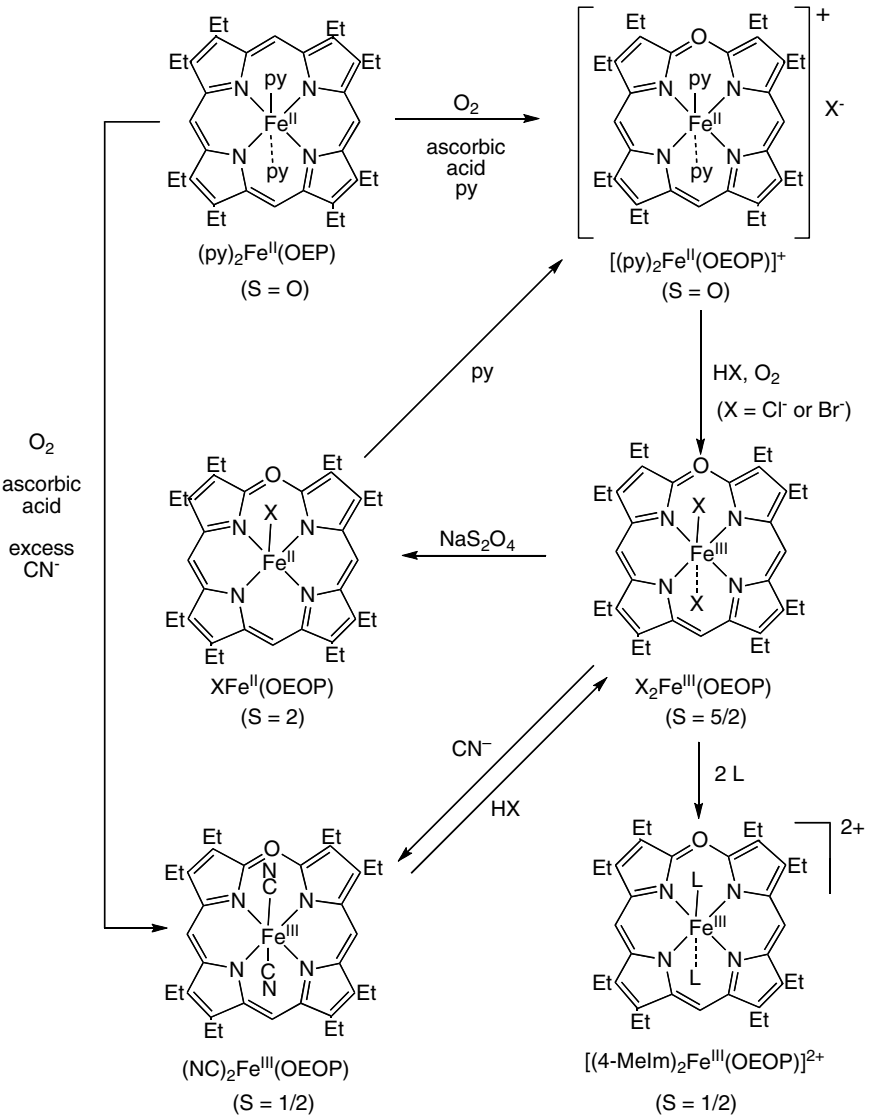
Heme and other iron porphyrins are also converted into biliverdin, carbon monoxide and free iron ion by the purely chemical process of coupled oxidation.[9] In this procedure, the iron porphyrin is subjected to aerial oxidation in solution in the presence of an excess of axial ligands (pyridine or cyanide ion) and a reducing agent (ascorbic acid or hydrazine).[10,11] This reaction also produces *meso*-hydroxylated heme and verdoheme as intermediates. However, coupled oxidation of unsymmetrical hemes does not induce the regiospecific opening of heme that is characteristic of the heme oxygenase reaction. Thus, it is the protein, not the porphyrin alone, that guides this hydroxylation step. Coupled oxidation can also be used to oxidize heme proteins.[12–14] This process also results in heme cleavage and the eventual release of biliverdin. Similar intermediates, *meso*-hydroxylated heme and verdoheme, are involved. Coupled oxidation of myoglobin and an active site variant of myoglobin results in cleavage that occurs exclusively at the α-*meso* carbon.[15]

Finally, we note that open-chain oligopyrroles are utilized as pigments in chemistry and biology.[16] As a particularly relevant example, zinc biliverdin complexes have been found to be pigments in the eggshells of birds.[17,18]

II. Verdohemes

A. Verdoheme Formation by Porphyrin Oxidation

Verdohemes are produced chemically by the process of coupled oxidation, as described above.[19,20] Scheme 3 summarizes the results of detailed studies of the verdoheme products from coupled oxidation of $(py)_2Fe^{II}(OEP)$ (py is pyridine and OEP is the dianion of octaethylporphyrin) in pyridine solution with hydrazine as the reducing agent.[21,22] As seen in this scheme, the iron center can undergo a set of reactions that include changes in the oxidation state, axial ligation, and spin state without disruption of the oxaporphyrin ring. The oxaporphyrin ring resembles a porphyrin. However, the oxaporphyrin ligand bears a 1– charge, whereas a corresponding



Scheme 3. Verdohemes produced by coupled oxidation.

porphyrin carries a 2– charge. The coupled oxidation of $(py)_2Fe^{II}(OEP)$ in the presence of pyridine results in the formation of green, diamagnetic $[(py)_2Fe^{II}(OEOP)](PF_6)$, which has been isolated as a somewhat air-sensitive solid. The structure of the cation, $[(py)_2Fe^{II}(OEOP)]^+$, is shown in Figure 1. The oxaporphyrin ligand is planar and the iron is six-coordinate. Treatment of $[(py)_2Fe^{II}(OEOP)](PF_6)$ with hydrochloric acid or hydrobromic acid in air results in the formation of paramagnetic $X_2Fe^{III}(OEOP)$ (X = Cl or Br). Structural studies by

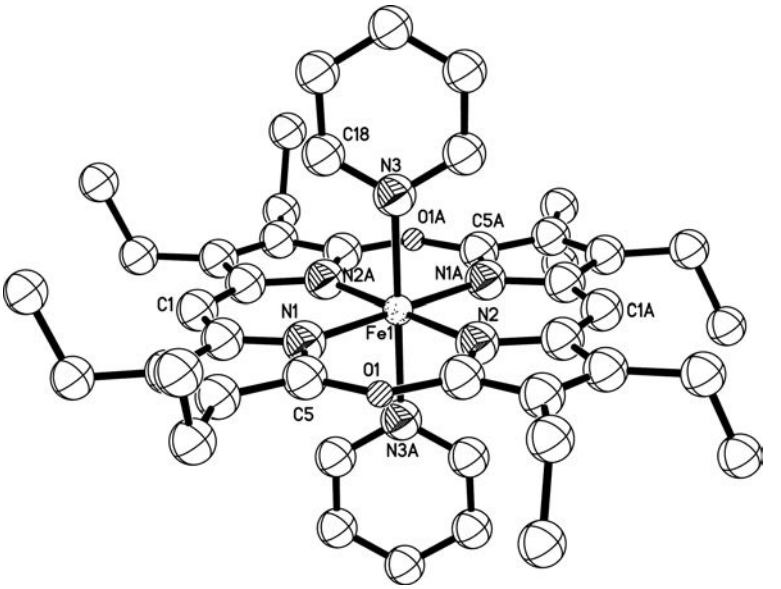


Figure 1. A drawing of $[(py)_2Fe^{II}(OEOP)]^+$ with uniform spherical atoms. Hydrogen atoms are not shown. As is usual with structures of oxaporphyrins, there is disorder in the position of the oxygen atom. The two sites labeled O1 and O1A are occupied equally by an oxygen atom and by a carbon atom. For clarity, the counter anion, $(PF_6)^-$, is not shown. Drawn from data in Balch, A. L.; Koerner, R.; Olmstead, M. M. *J. Chem. Soc., Chem. Commun.* **1995**, 873–874.

^{1}H NMR spectroscopy and X-ray crystallography reveal that the iron in $X_2Fe^{III}(OEOP)$ is six-coordinate and high-spin (S = 5/2). As seen in Figure 2, the iron in $Br_2Fe^{III}(OEOP)$ resides in the plane of the oxaporphyrin and is coordinated by two equivalent axial bromide ligands. Treatment of $X_2Fe^{III}(OEOP)$ with strong-field ligands, CN^- or 4-methylimidazole (4-MeIm), results in the substitution of the axial anionic ligands and the formation of low-spin, six-coordinate complexes, as seen in Scheme 3. Reduction of $X_2Fe^{III}(OEOP)$ with sodium dithionite yields air-sensitive $XFe^{II}(OEOP)$, whose oxidative chemistry is discussed in Section E. Paramagnetic $XFe^{II}(OEOP)$ contains a five-coordinate iron, which is also high-spin (S = 2). The structure of $ClFe^{II}(OEOP)$ as determined by single crystal X-ray diffraction is shown in Figure 3. The oxaporphyrin ligand is not planar but domed. The iron is 0.69 Å out of the porphyrin plane and bound to a single axial bromide ion. The average Fe–N distance increases from 1.964 Å in the iron(III) complex to 2.094 Å in the iron(II) complex. When $XFe^{II}(OEOP)$ is dissolved in pyridine, $[(py)_2Fe^{II}(OEOP)]Cl$ is produced.

Conducting the coupled oxidation of $Fe^{II}(OEP)$ in the presence of a large excess of potassium cyanide results in the formation of low-spin, six-coordinate

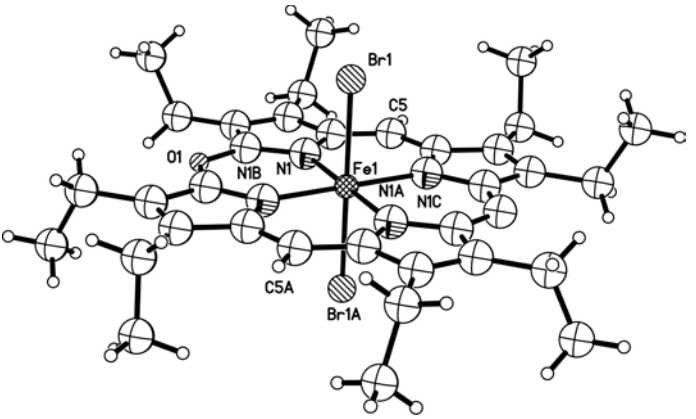

Figure 2. A drawing of Br_2Fe^{III}(OEOP) with uniform spherical atoms. There is disorder in the position of the oxygen atom but this is not shown. Drawn using data in Balch, A. L.; Grazynski, L. L.; Noll, B.; Olmstead, M. M.; Szterenberg, L. Safari, N. *J. Am. Chem. Soc.* **1993**, *115*, 1422–1429.

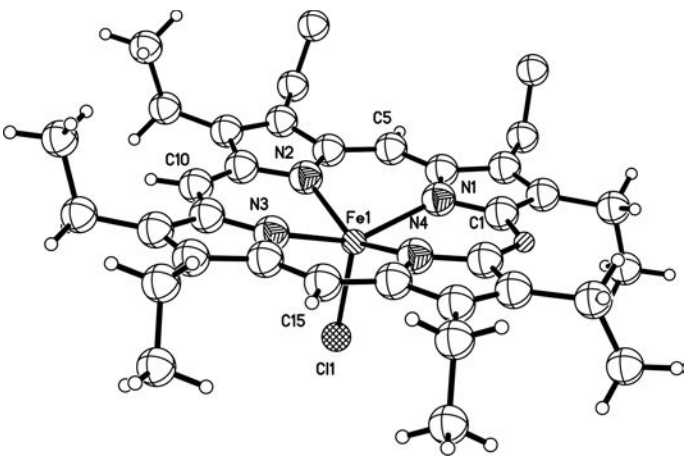

Figure 3. A drawing of $ClFe^{II}$(OEOP) with uniform spherical atoms. There is disorder in the position of the oxygen atom but this is not shown. Drawn utilizing data in Balch, A. L.; Grazynski, L. L.; Noll, B.; Olmstead, M. M.; Szterenberg, L.; Safari, N. *J. Am. Chem. Soc.* **1993**, *115*, 1422–1429.

$(NC)_2Fe^{III}$(OEOP), as seen in Scheme 3.[11] $(NC)_2Fe^{III}$(OEOP) can be reduced to air-sensitive $[(NC)_2Fe^{II}(OEOP)]^-$ by reaction with sodium dithionite.

The reaction of $[(py)_2Fe^{II}(OEOP)]Cl$ with an excess of ammonium hexafluorophosphate and hydrofluoric acid produces the high-spin, five-coordinate complex $(PF_6)Fe^{II}$(OEOP), which may be subsequently converted into

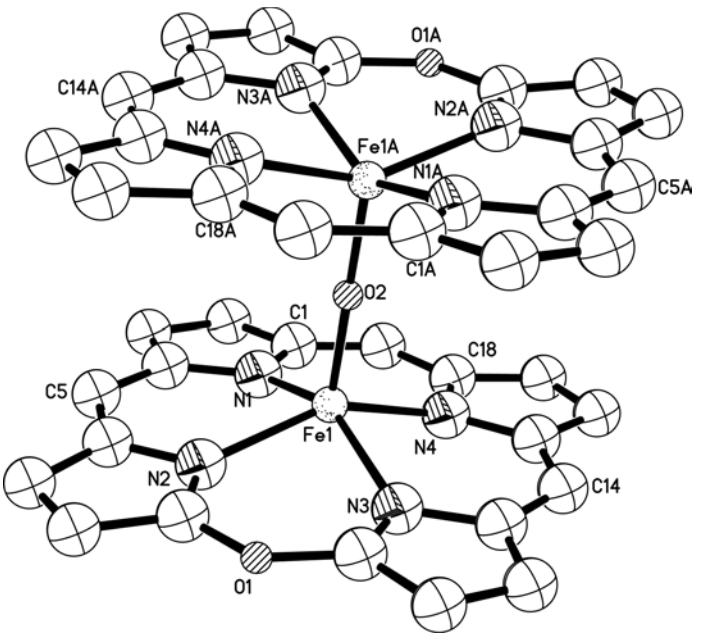

Figure 4. A drawing of the dication in the salt $[\mu\text{-O}\{Fe^{III}(OEOP)\}_2](PF_6)_2$ with uniform spherical atoms. For clarity the ethyl groups are not shown. Drawn from data in Khorasani-Motlagh, M.; Safari, N.; Noroozifar, M.; Saffari, J.; Biabani, M.; Reboucas, J. S.; Partick, B. *Inorg. Chem.* **2005**, *44*, 7762–7769.

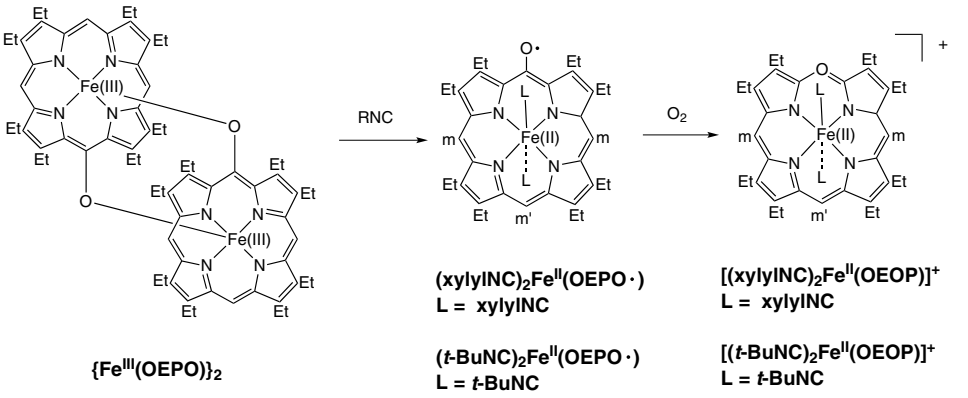
$[\mu\text{-O}\{Fe^{III}(OEOP)\}_2](PF_6)_2$ by reaction with dioxygen.[23–25] The structure of the dication in $[\mu\text{-O}\{Fe^{III}(OEOP)\}_2](PF_6)_2$ is shown in Figure 4. The dication $[\mu\text{-O}\{Fe^{III}(OEOP)\}_2]^{2+}$ is the analog of the well-known porphyrin μ-oxo-dimer, e.g. $(\mu\text{-O})\{Fe^{III}(OEP)\}_2$.[26]

Exposure of the novel dimer, $\{Fe^{III}(\mu\text{-OEPO})\}_2$, to dioxygen after the addition of an isocyanide (RNC), which may be xylyl isocyanide or *t*-butylisocyanide, offers a route to the formation of diamagnetic, six-coordinate $(RNC)_2Fe^{II}(OEOP)$, as shown in Scheme 4.[27] Crystallographic characterization of $(xylylNC)_2Fe^{II}(OEOP)$ indicates that the structure is similar to that of $[(py)_2Fe^{II}(OEOP)]^+$ (see Figure 1) and that the oxaporphyrin ring is planar.

Coupled oxidation has also been utilized with $Fe^{II}(TPP)$ (TPP is the dianion of tetraphenylporphyrin) as the substrate.[28] No evidence of the formation of verdohemes was reported in this reaction. However, several iron-free, open-chain tetrapyrroles were isolated as products.[28]

Although the coupled oxidation procedure is usually performed with iron porphyrins, it can be modified to utilize cobalt porphyrins as well. For example, it is possible to convert $Co^{II}(OEP)$ into a number of products including the verdohemes



Scheme 4. Verdoheme formation by oxidation of a *meso*-hydroxylated heme.

Cl_2Co^{III}(OEOP) and $[Co^{II}(OEOP)](PF_6)$ through oxidation, as shown in Scheme 5.[29,30] Treatment of Co^{II}(OEP) with air in pyridine did not produce evidence of the formation of the corresponding verdoheme or biliverdin, but by changing the solvent to an 8:1 ratio of dichloromethane:tetrahydrofuran and cooling it was possible to observe the formation of a green suspension from which the various products shown in Scheme 5 were obtained. The crystallographically determined structures of six-coordinate, diamagnetic Cl_2Co^{III}(OEOP) and four-coordinate, S = 1/2 $[Co^{II}(OEOP)]^+$ are shown in Figure 5.

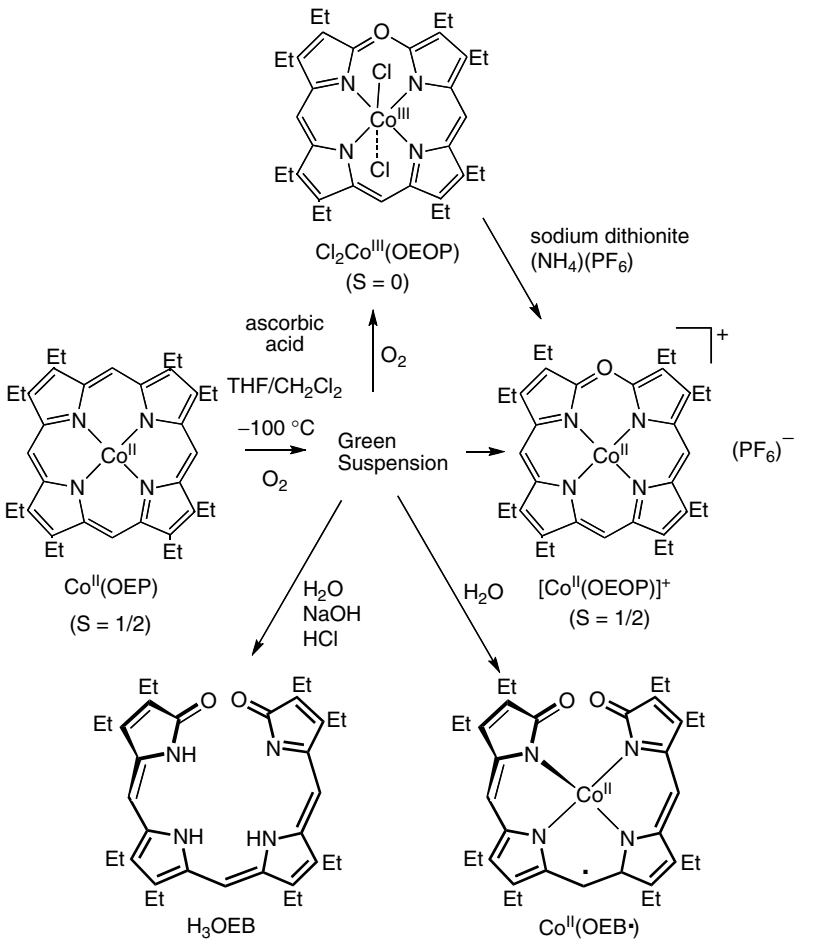
B. Verdoheme Formation by Dehydration of a Bilindione

Verdohemes can also be obtained by dehydration of the corresponding bilindione (biliverdin). Scheme 6 shows a prototypical reaction of this sort — the conversion of a bilindione to zinc verdoheme through reaction with a zinc(II) salt.[31] The structure of the product with a five-coordinate zinc ion and a slightly domed oxaporphyrin ligand is shown in Figure 6.

III. Open-Chain Tetrapyrroles from Ring Opening of Verdohemes

Verdohemes are subject to ring opening through the attack of external nucleophiles. This reaction has been widely employed to produce a variety of stable zinc(II) complexes with helical structures. These zinc(II) complexes are diamagnetic and readily characterized by UV-visible and ^{1}H NMR spectroscopy.

Addition of methoxide, methanethiolate, or dimethylamide to zinc verdoheme, $[Zn^{II}(OEOP)](O_2CCH_3)$, proceeds in a good yield to produce helical complexes of



Scheme 5. Coupled oxidation of Co^{II} (OEP).

the open-ring tetrapyrroles, as shown in Scheme 7.[32,33] Presumably, these ring-opening reactions proceed through nucleophilic attack on a carbon atom adjacent to the oxygen atom of the verdoheme. Each of the products, Zn^{II}(OEBOMe), Zn^{II}(OEBSMe), and Zn^{II}(OEBNMe_2), has been isolated and characterized by single crystal X-ray diffraction. Figures 7 and 8 show the structures of Zn^{II}(OEBOMe) and Zn^{II}(OEBNMe_2), respectively. The ligands in Zn^{II}(OEBOMe), Zn^{II}(OEBSMe), and Zn^{II}(OEBNMe_2) all adopt a helical geometry that is characteristic of the geometry of H_3OEB and many complexes of other open-chain tetrapyrrole ligands. In each complex, the four-coordinate zinc ion has a geometry that is best described as a flattened tetrahedron. Generally, the Zn–N distance to the pyrrole ring bearing the added nucleophile is the longest of the four Zn–N

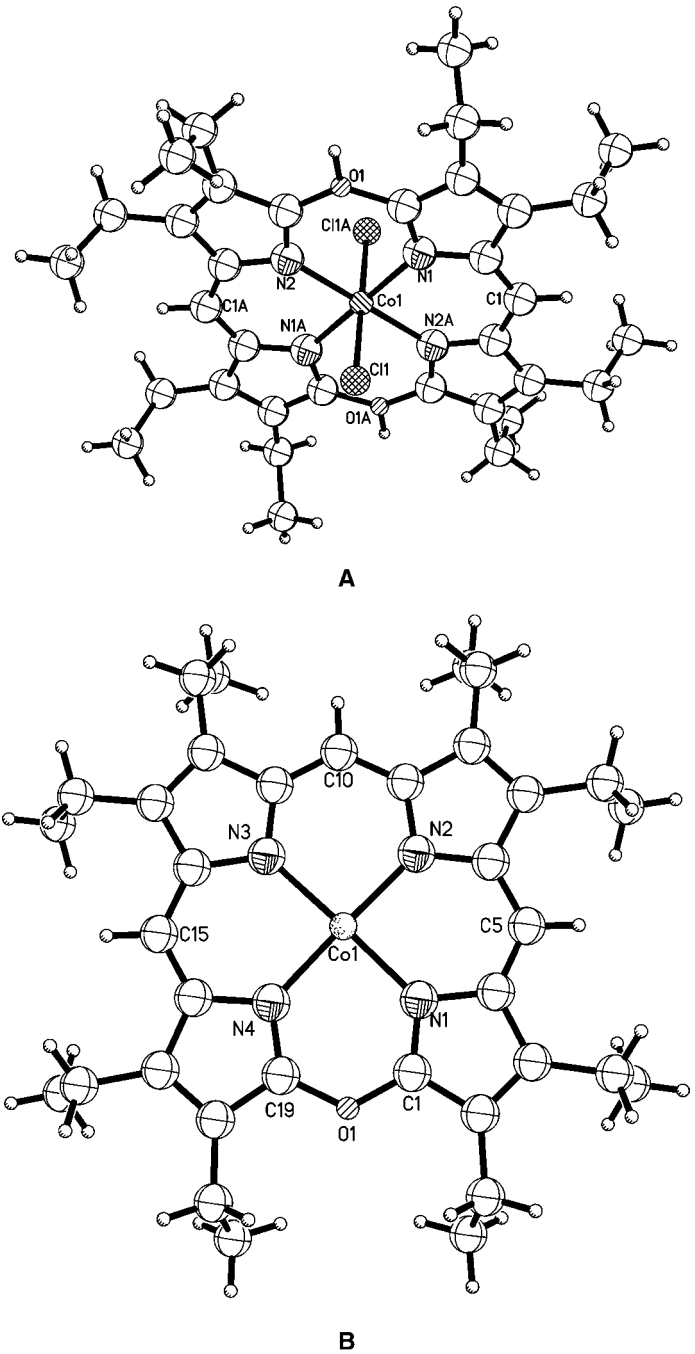


Figure 5. **A**, a drawing of Cl_2Co^{III}(OEOP) with uniform spherical atoms from data in Balch, A. L.; Mazzanti, M.; Olmstead, M. M. *J. Chem. Soc., Chem. Commun.* **1994**, 269–270. **B**, a drawing of the cation in the salt $[Co^{II}(OEOP)](PF_6)$ with uniform spherical atoms from data in Balch, A. L.; Mazzanti, M.; St. Claire, T.; Olmstead, M. M. *Inorg. Chem.* **1995**, *34*, 2194.

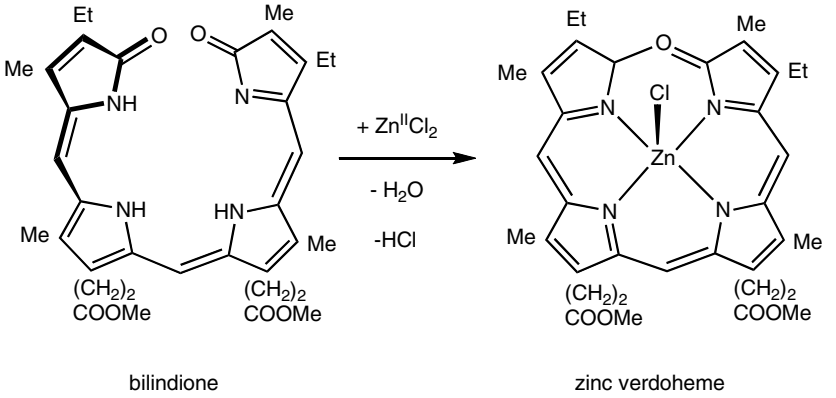

Scheme 6. Formation of a zinc verdoheme by dehydration of a bilindione.

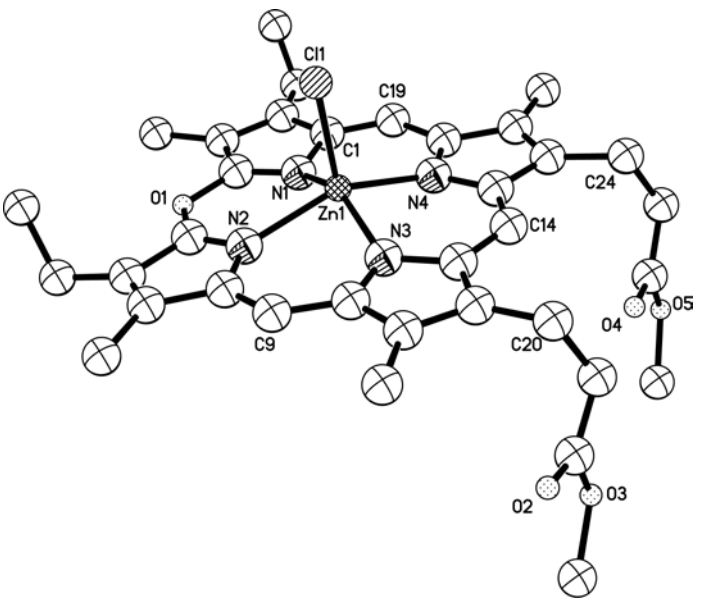

Figure 6. A drawing of chloro-(5-oxonia-mesoporphinato-dimethyl ester)-zinc(II) with uniform spherical atoms. Drawn using data from Fuhrhop, J.; Krüger, P.; Sheldrick, W. S. *Liebigs Ann. Chem.* **1977**, *3*, 339–359.

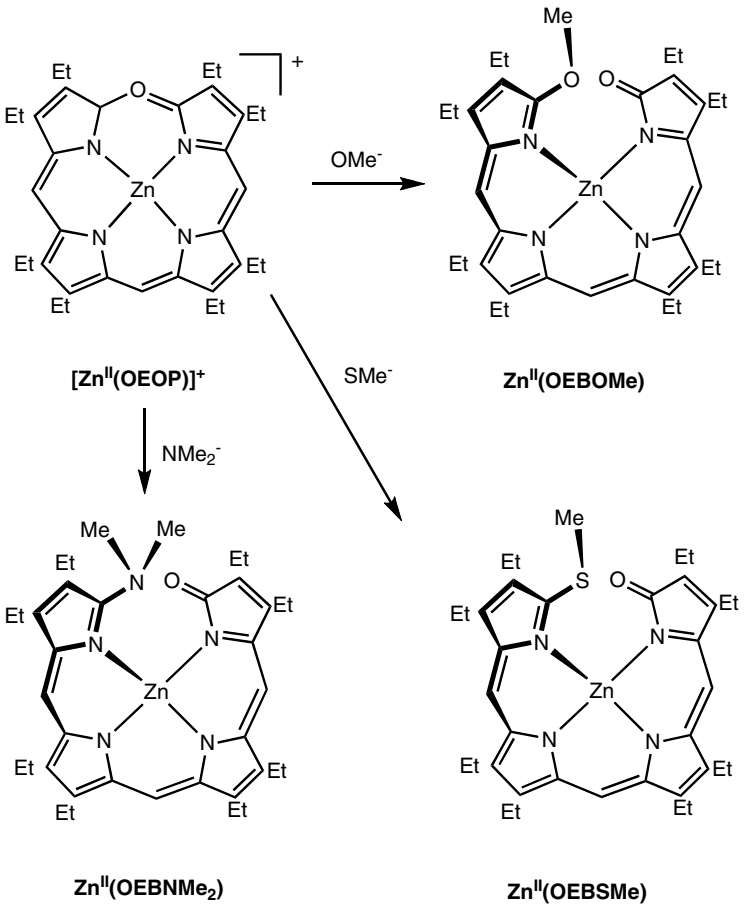
distances. For example, in $Zn^{II}(OEBNMe_2)$, the Zn–N(1) distance is 2.184(5) Å, which is the longest of the four Zn–N distances. The other Zn–N distances fall in the range 2.002(5)–2.022(5) Å and are slightly shorter than those found in zinc porphyrins, where the Zn–N distances fall in the range of 2.06–2.07 Å.[34] In $Zn^{II}(OEBNMe_2)$, the environment about N(5) of the dimethylamide group is planar.



Scheme 7. Reactivity of zinc verdoheme with nucleophiles.

The C–N(5)–C bond angles, C(1)–N(5)–C(37), 122.0 (6)°, C(1)–N(5)–C(38), 123.5 (6)°, and C(37)–N(5)–C(38), 114.4 (5)°, are near 120°, and the sum of these three angles is 359.9°. The dimethylamide unit is also nearly coplanar with the adjacent pyrrole ring. The dihedral angle between these two units is only 16.6°. The planarity of N(5) and the orientation of the dimethylamide unit suggest that conjugation within the tetrapyrrole ligand extends out into this functionality.

Computational studies have examined the mechanism of the addition of nucleophiles to zinc verdohemes.[35]

The addition of cyanide ion to $[Zn^{II}(OEOP)](O_2CCH_3)$ is a more complex process than that observed when methoxide, methanethiolate, or dimethylamide is added to the same zinc verdoheme. When cyanide reacts with $[Zn^{II}(OEOP)](O_2CCH_3)$, ring opening is accompanied by a degree of substitution at the *meso* positions, as seen in Scheme 8.[36] The reaction of cyanide with $[Zn^{II}(OEOP)]$

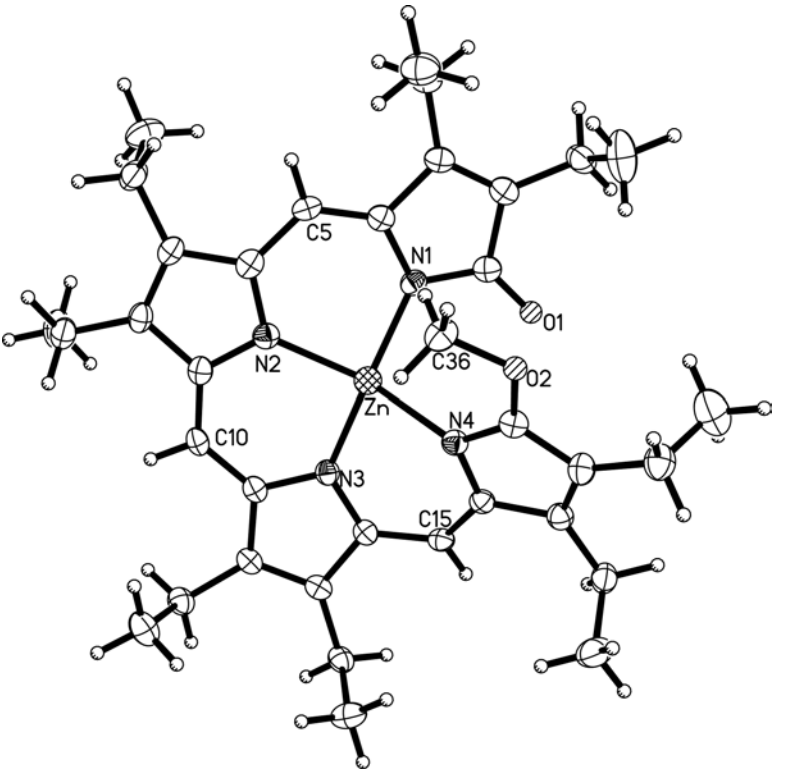


Figure 7. A drawing of Zn^{II}(OEBOMe) with 50% thermal ellipsoids. Drawn from data in Latos-Grazynski, L.; Johnson, J.; Attar, S.; Olmstead, M. M.; Balch, A. L. *Inorg. Chem.* **1998**, *37*, 4493–4499.

(O_2CCH_3) was challenging to control, and three products, H_2(OEB-15,19-$(CN)_2$), Zn^{II}(OEB-15,19-$(CN)_2$), and Zn^{II}(OEB-10,15,19-$(CN)_3$), have been isolated and identified crystallographically and spectroscopically, despite the fact that a clean separation of these products was difficult to accomplish. The reactions shown in Scheme 8 are somewhat reminiscent of the reaction of cyanide with H_3OEB, which also results in *meso* substitution and the formation of H_3OEB-10-CN.[37]

When Zn^{II}(OEB-15,19-$(CN)_2$) and Zn^{II}(OEB-10,15,19-$(CN)_3$) were crystallized from acetone/water, the unusual binuclear complexes μ-H_2O-{Zn^{II}(OEB-10,19-$(CN)_2$)}$_2$ and μ-H_2O-{Zn^{II}(OEB-10,15,19-$(CN)_3$)}$_2$ were obtained.[36] These complexes involve five-coordinate zinc ions rather than the four-coordinate zinc ions found in Zn^{II}(OEBOMe), Zn^{II}(OEBSMe), and Zn^{II}(OEBNMe_2) (see Scheme 7). The structure of μ-H_2O-{Zn^{II}(OEB-10,15,19-$(CN)_3$)}$_2$ is shown in Figure 9. Both μ-H_2O-{Zn^{II}(OEB-10,19-$(CN)_2$)}$_2$ and Zn^{II}(OEB-10,15,19-$(CN)_3$)

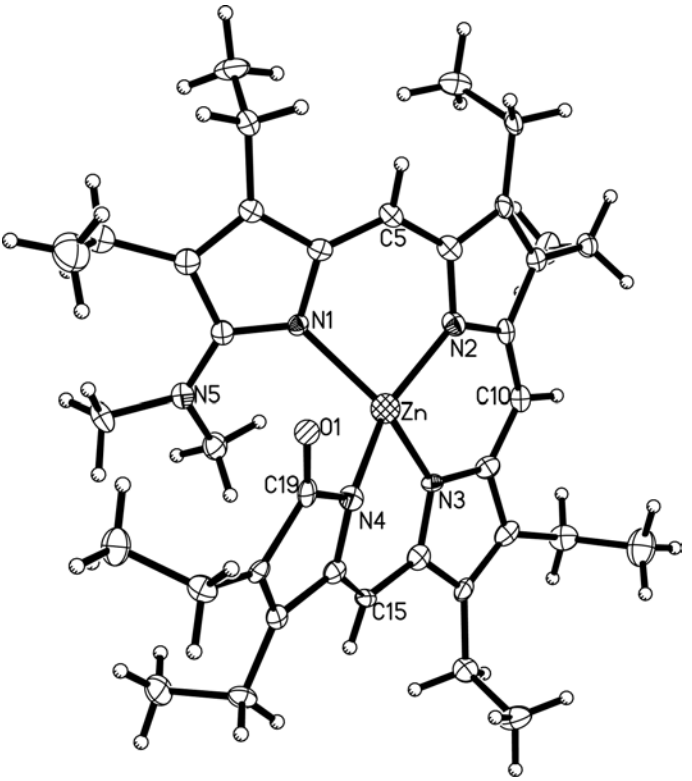

Figure 8. A drawing of $Zn^{II}(OEBNMe_2)$ with 50% thermal ellipsoids. Drawn with data from Johnson, J. A.; Olmstead, M. M.; Balch, A. L. *Inorg. Chem.* **1999**, *38*, 5379–5383.

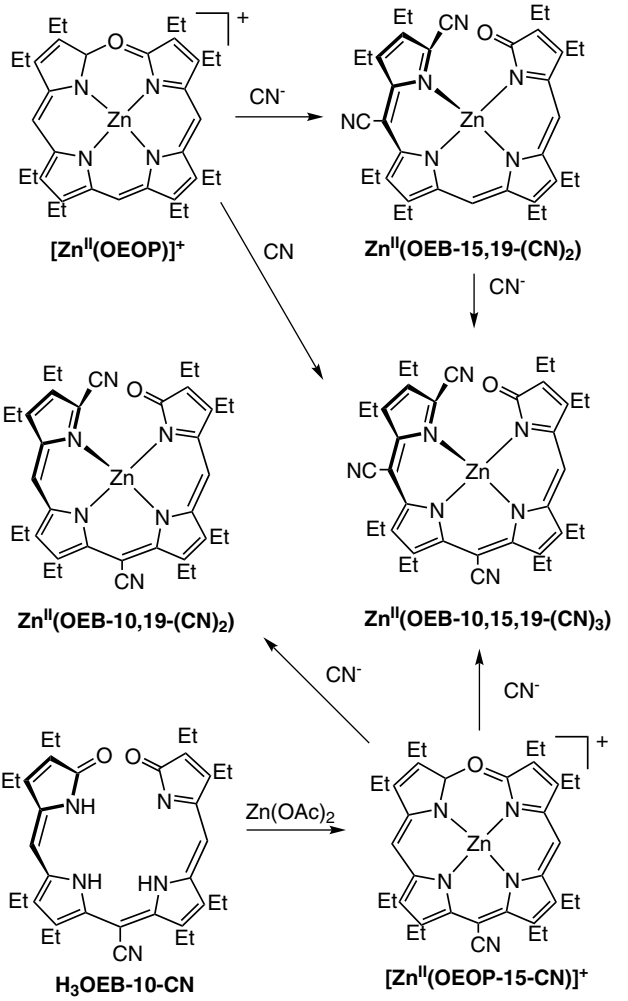
have helical structures in which the chirality of each tetrapyrrole is the same in any one molecule. A bridging water molecule, which is hydrogen-bonded to both tetrapyrrole ligands and coordinated to two zinc ions, serves as an effective linker to transfer the helical sense of one tetrapyrrole to the adjoining tetrapyrrole.

The chiral nature of the helical zinc complexes shown in Scheme 7 has been utilized in a number of studies of molecular recognition involving chiral molecules as axial ligands.[38–50]

IV. Biliverdin and Its Metal Complexes

A. Free Ligand

The conformational aspects of metal-free biliverdins have been reviewed.[50] Briefly, the *ZZZ*, *syn*, *syn*, *syn* isomer shown in Scheme 1 is the favored geometry, as demonstrated by computational studies and experimental studies.[51] Several biliverdins have been crystallized and their structures determined by X-ray



Scheme 8. Reactivity of zinc verdoheme with cyanide ion.

crystallography. Figure 10 shows the structure of an example.[52] Notice that the free ligand adopts a helical structure with the two terminal oxygen atoms separated by 3.4 Å. Several other bilindiones, including biliverdin dimethyl ester, have been examined by X-ray crystallography and shown to have very similar structures.[53,54]

Octaethylbiliverdin undergoes a two-electron oxidation to form $[H_2OEBox]^+$ when treated with diiodine, as shown in Scheme 9.[55] The oxidation product, a diamagnetic aquamarine cation, has been isolated as a triiodide salt and crystallized. The structure of the product reveals that the helical structure is retained after

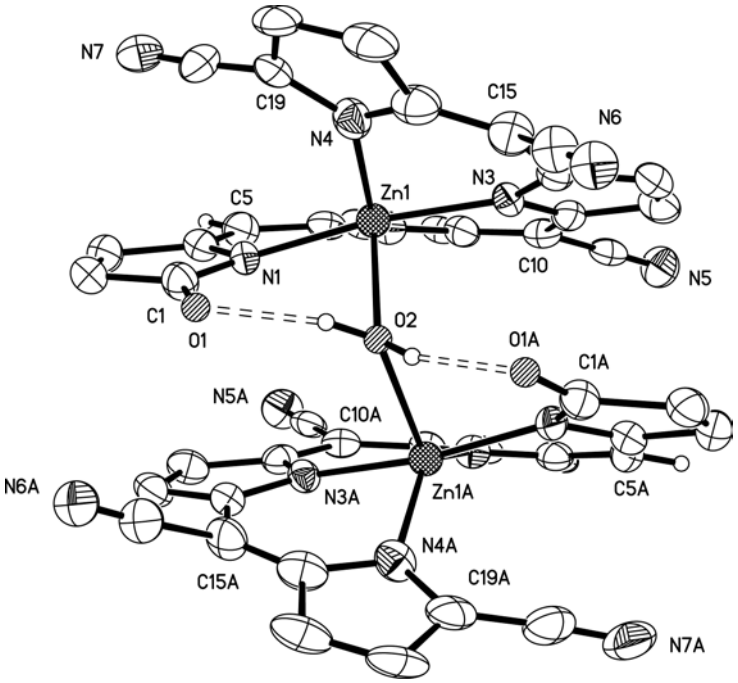


Figure 9. A drawing of μ-H_2O-{Zn^{II}(OEB-10,15,19-$(CN)_3$)}$_2$ with 50% thermal ellipsoids. For clarity the ethyl groups have been omitted. The dashed lines show the hydrogen bonding. Scheme 9. Two-electron oxidation of octaethylbilindione.

oxidation but the nonbonded O···O separation in the product (2.98 Å) is less than that in a bilindione (3.34 Å). A computational analysis of the oxidation product and its dimerization through hydrogen bonding is available.[56]

B. Dimeric Complexes; The Case of $\{Mn^{III}(\mu\text{-OEB})\}_2$

Treatment of H_3OEB with various metal salts, including manganese acetate, produced metal complexes with the general formula M(OEB),[57–59] but these early studies did not provide insight into the diverse physical and electronic structures of these complexes, which may exist as monomers or dimers. The manganese complex, which forms olive green solutions, has a dimeric structure, $\{Mn^{III}(\mu\text{-OEB})\}_2$, as shown in Figure 11.[60] The manganese ions are five-coordinate with bonds to the four nitrogen atoms of one OEB ligand, with the fifth bond supplied by the oxygen atom of the other OEB ligand. Each dimer has C_2 symmetry and is chiral, but the compound crystallized as a racemate in the space group *C*2/*c*, where an inversion center relates a pair of dimers. The dimer, $\{Mn^{III}(\mu\text{-OEB})\}_2$, dissolves in pyridine to form intensely green solutions from which crystals of monomeric, five-coordinate $(py)Mn^{III}(OEB)$ have been obtained.[60] The structure of $(py)Mn^{III}(OEB)$ is shown in Figure 12. The manganese ion in $(py)Mn^{III}(OEB)$ is five-coordinate, with the tetrapyrrole ligand assuming a helical arrangement. The manganese ion has a distorted trigonal prismatic coordination. The N(l)-Mn-N(3) unit with a bond angle of 177.1(2)° forms the axis, while the equatorial plane contains the pyrrole nitrogen atoms, N(2) and N(3), and the pyridine nitrogen atom, N(5).

The magnetic moments of these manganese complexes are indicative of the presence of high-spin Mn(III) (d^4) ions.[60] In pyridine solution, $(py)Mn^{III}(OEB)$ has a magnetic moment of 4.8(3) μ_β at 23 °C. In chloroform solution at 21 °C,

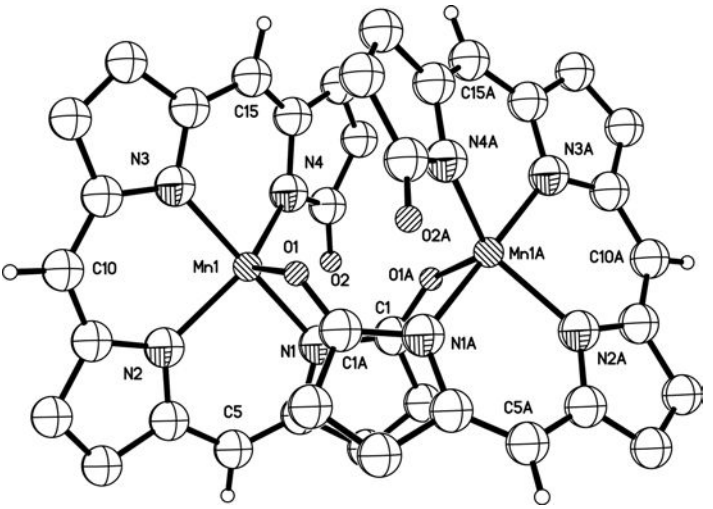

Figure 11. A drawing of $\{Mn^{III}(\mu\text{-OEB})\}_2$ with uniform spherical atoms. For clarity, all ethyl groups have been removed. Drawn from data in Balch, A. L.; Mazzanti, M.; Noll, B. C.; Olmstead, M. M. *J. Am. Chem. Soc.* **1994**, *116*, 9114–9122.

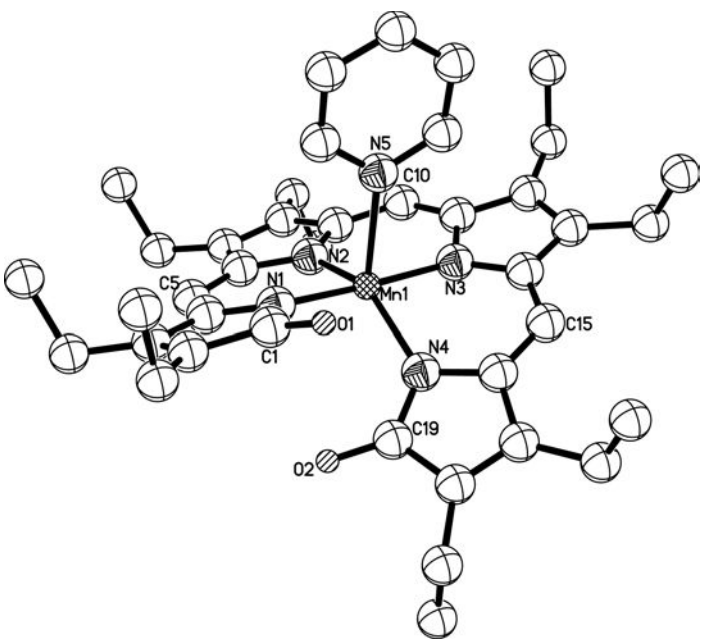

Figure 12. A drawing of (py)Mn^{III}(OEB) with uniform spherical atoms. Drawn with data from Balch, A. L.; Mazzanti, M.; Noll, B. C.; Olmstead, M. M. *J. Am. Chem. Soc.* **1994**, *116*, 9114–9122.

$\{Mn^{III}(\mu\text{-OEB})\}_2$ has a magnetic moment of 4.7(3) μ_β for each Mn ion, and this value is unchanged over the temperature range from −50 to +21 °C. Hence, it appears that any magnetic coupling between the two Mn(III) ions is small, as is expected since the nonbonded Mn–Mn distance is large, 4.430 (1) Å, and the covalent path between the two Mn(III) ions is long.[60] Due to the paramagnetic nature of the high-spin Mn(III) ions, no ^{1}H NMR spectrum could be detected for $(py)Mn^{III}(OEB)$ or $\{Mn^{III}(\mu\text{-OEB})\}_2$.

Solutions of either $\{Mn(\mu\text{-OEB})\}_2$ in chloroform or $(py)Mn^{III}(OEB)$ in pyridine are air-sensitive, but the products of oxidation have not been identified.[60] The biliverdin ligand system has also been utilized to develop a catalytic scavenger of superoxide that employs the Mn(III)/Mn(IV) redox couple.[61]

C. Monomeric Biliverdin Complexes, $M^{II}(OEB\bullet)$

A series of monomeric complexes are formed by reaction of H_3OEB with cobalt, nickel, palladium, or copper. Spectroscopic studies (*vide infra*) all point to the fact that these complexes involved an oxidized ligand radical, which requires them to be formulated as $M^{II}(OEB\bullet)$ rather than $M^{III}(OEB)$.

Crystals of the products — $Co^{II}(OEB\bullet)$,[60] $Ni^{II}(OEB\bullet)$,[59] $Pd^{II}(OEB\bullet)$,[62] and $Cu^{II}(OEB\bullet)$[63] — are isostructural. Figure 13 shows the structure of a representative example, $Pd^{II}(OEB\bullet)$. To prevent contact between the terminal oxygen atoms, the tetrapyrrole ligand assumes a helical geometry. The constraints of this arrangement require that the palladium ion should not have truly planar geometry. Thus, the PdN_4 unit shows the following deviations from planarity: Pd, 0.00; N(1), +0.22; N(2), –0.23 Å. Selected bond distances and angles for the set of $M^{II}(OEB\bullet)$ complexes are given in Table 1. These data show that cobalt, nickel, and copper complexes have similar bond distances while the palladium complex, as expected, has longer metal–nitrogen bond lengths. The C(1)–O(1) bond distances, which fall in the range of 1.20–1.25 Å, are consistent with the presence of a C=O group at the end of the ligand.

Evidence for the presence of ligand free radicals in this series comes from spectroscopic measurements that are also supported by computational studies.[64,65] Both $Ni^{II}(OEB\bullet)$ and $Pd^{II}(OEB\bullet)$ display EPR resonances that are indicative of ligand-based spins (g = 2.03 for Ni, 2.08 for Pd) and show only very broad, unassigned resonances in the 0–3 ppm region of the NMR spectrum.[62] In contrast, $Cu^{II}(OEB\bullet)$ does not produce an EPR spectrum, but shows a well-resolved ^{1}H NMR spectrum that extends from 135 to −90 ppm.[63] The eight methylene resonances (at 92, 87, 66, 48, 28, 20, 6, and −1 ppm) show linewidth variations with the resonances, with the largest hyperfine shifts showing the greatest linewidths. These variations result from local dipolar

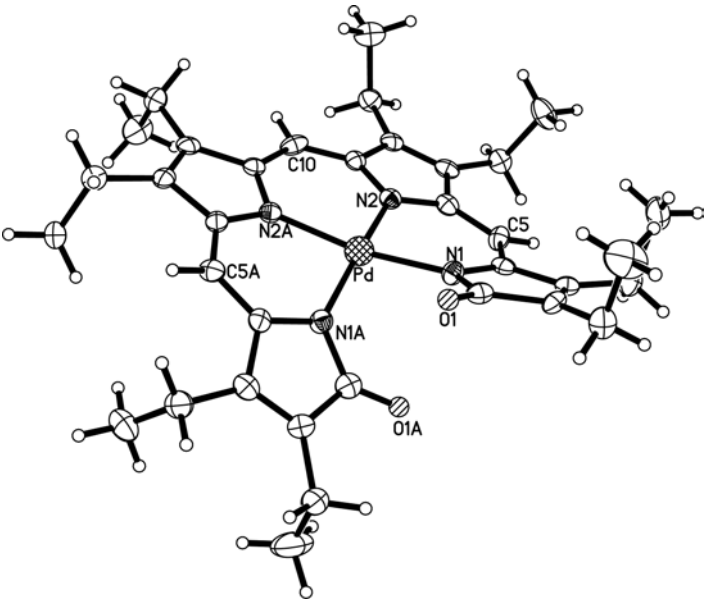

Figure 13. A drawing of Pd^{II}(OEB•) with 50% thermal ellipsoids. Co^{II}(OEB•), Ni^{II}(OEB•), and Cu^{II}(OEB•) have been crystallographically characterized and have similar structures. Drawn from data in Lord, P. A.; Olmstead, M. M.; Balch, A. L. *Inorg. Chem.* **2000**, *39*, 1128–1134.

Table 1. Selected bond distances and angles for M^{II}(OEB•).

	Co^{II}(OEB•)[a]	Ni^{II}(OEB•)[b]	Pd^{II}(OEB•)[c]	Cu^{II}(OEB•)[d]
Bond distances (Å)

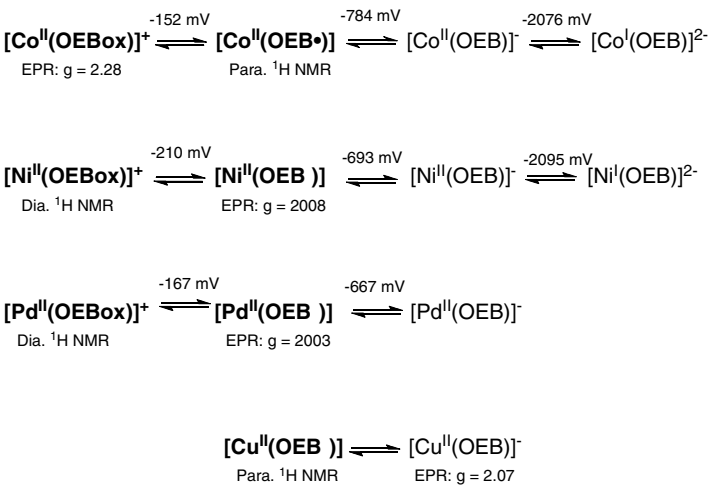
relaxation due to the delocalized spin density that resides on the tetrapyrrole ligand.

Co^{II}(OEB•), Ni^{II}(OEB•), Pd^{II}(OEB•), and Cu^{II}(OEB•) are members of four series of complexes that are related by reversible redox reactions. Scheme 10 summarizes relevant information. For palladium, the three-membered electron



Scheme 10. Redox reactions of monomeric M^{II} (OEB•). Key: **Boldface,** complex isolated and characterized by X-ray diffraction; EPR, solution *g* value given; Dia. ^{1}H NMR, diamagentic ^{1}H NMR spectrum; Para. ^{1}H NMR, paramagnetically broadened and shifted ^{1}H NMR spectrum analyzed. Above each redox process the average electrochemical E_p(ox) and E_p(red) are given in mV for a dichloromethane solution vs. ferrocene/ferrocinium.

transfer series involving $[Pd^{II}(OEBox)]^+$, $Pd^{II}(OEB•)$, and $[Pd^{II}(OEB)]^-$ has been characterized electrochemically, while for nickel the four compounds — $[Ni^{II}(OEBox)]^+$, $Ni^{II}(OEB•)$, $[Ni^{II}(OEB)]^-$, and $[Ni^{I}(OEB)]^{-2}$ — have been detected electrochemically.[62] The most highly oxidized members of these series have been isolated in the form of their diamagnetic tri-iodide salts. $[Ni^{II}(OEBox)]I_3$ and $[Pd^{II}(OEBox)]I_3$ have been characterized spectroscopically and by X-ray diffraction. Figure 14 shows the structure of $[Pd^{II}(OEBox)]I_3$. A compilation of relevant bond distances and angles for $[Ni^{II}(OEBox)]I_3$ and $[Pd^{II}(OEBox)]I_3$ and related compounds is given in Table 2. These two compounds are isomorphic and isostructural. Their structures again involve helical coordination of the open-chain tetrapyrrole ligand about the metal. The triiodide ion is not coordinated to the metal but sits over one of the *meso* carbon atoms of the tetrapyrrole. Reduction of $[M^{II}(OEBox)]I_3$ causes a slight elongation of the M–N bonds, as seen in the data in Tables 1 and 2.

$Co^{II}(OEB•)$ has a magnetic moment of 1.9 μ_β at 25 °C, which decreases with decreasing temperature so that it is 1.4 μ_β at −173 °C.[60] The ^{1}H NMR spectrum of $Co^{II}(OEB•)$ shows paramagnetically shifted resonances that do not obey the Curie law. Thus, the complex may be formulated as $Co^{II}(OEB•)$ with a reduced, paramagnetic cobalt(II) ion and an oxidized ligand, which is present as a coordinated radical. Temperature variations in the coupling between the two paramagnetic

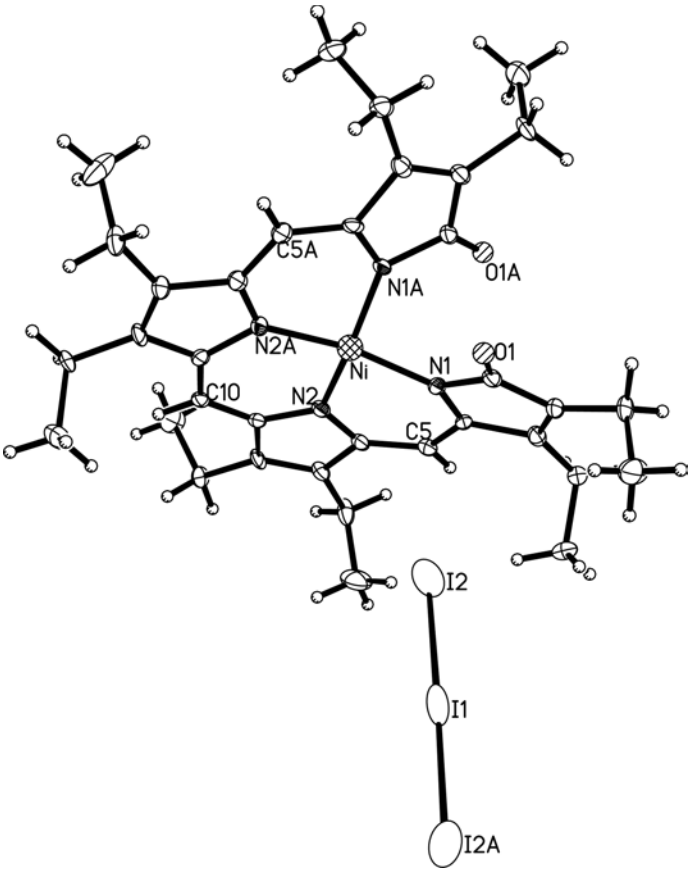


Figure 14. A drawing of both ions in the salt $[Pd^{II}(OEBox)]I_3$ with 50% thermal ellipsoids. $[Ni^{II}(OEBox)]I_3$ is isostructural. Drawn utilizing data in Lord, P. A.; Olmstead, M. M.; Balch, A. L. *Inorg. Chem.* **2000**, *39*, 1128–1134.

centers could produce the changes that are seen in the magnetic properties. Alternatively, there may be a thermal equilibrium between a diamagnetic $Co^{III}(OEBox)$ state and a paramagnetic $Co^{II}(OEB\bullet)$ state or there may be an equilibrium between a diamagnetic $Co^{III}(OEBox)$ state and a triplet $Co^{III}(OEBox)$ state. Cyclic voltammetry of $Co^{II}(OEB\bullet)$ shows that this complex is also part of a four-membered electron transfer series that includes $[Co^{II}(OEBox)]^+$, $Co^{II}(OEB\bullet)$, $[Co^{II}(OEB)]^-$, and $[Co^{I}(OEB)]^{-2}$.[66] Oxidation by diiodine produces $[Co^{II}(OEBox)]I_3$, which has been isolated and crystallized. The structure is shown in Figure 15. While one of the iodine atoms of the triiodide ion lies above the cobalt, the triiodide ion is disordered so that there are three different Co–I distances — 2.875(10), 2.818(4), and 2.798(14) Å — that are considerably longer than a typical Co–I_3 bond distance of 2.589 Å. Consequently, the triiodide ion is

only loosely associated with the cation. The NMR spectrum $[Co^{II}(OEBox)]I_3$ complex in dichloromethane solution indicates that the anion is dissociated and the cobalt ion is four-coordinate. The EPR spectrum of $[Co^{II}(OEBox)]I3$ (solution: g, 2.28; solid: g_1, 2.23; g_2, 2.42; and g_3, 2.01) and the magnetic moment of 1.8 μ_β indicate that it is a low-spin Co(II) complex.

Changes in the axial ligation of this cobalt complex can alter the electronic distribution between the metal and the ligand. Addition of pyridine to a sample of $[Co^{II}(OEBox)]I_3$ results in the formation of $[[(py)_2Co^{III}(OEB\bullet)]I_3$, as indicated by a marked alteration in the EPR spectrum.[67] In a frozen solution the new spectrum shows a sharp, slightly anisotropic signal ($g_{x,y}$ = 1.996, g_z = 2.018) near the free electron g value, with none of the cobalt hyperfine coupling that is seen for $[Co^{II}(OEBox)]I_3$. The salt $[(py)_2Co^{III}(OEB\bullet)]I_3$ has been isolated in crystalline form, and the cation has been shown to involve a six-coordinate cobalt ion with two axial pyridine ligands, as seen in Figure 16.

Solutions of $Cu^{II}(OEB\bullet)$ and $Co^{II}(OEB\bullet)$ are sensitive to air, which causes their conversion into tetrahedral complexes containing two monoanionic tetraethyl-propentdyopent (TEPD) ligands, as shown in Scheme 11.[63,68] In addition to forming $Co^{II}(TEPD)_2$ in a 40% yield, aerial oxidation of $Co(OEB\bullet)$ produces both carbon monoxide and carbon dioxide, which were detected by infrared-spectroscopic

analysis of the gases above the reaction mixture. This behavior has a certain analogy to the oxidation of porphyrins that leads to the formation of biliverdins with the release of carbon monoxide, as shown earlier in Scheme 2. The structure of $Co^{II}(TEPD)_2$ with nearly tetrahedral coordination of the cobalt ion is shown in Figure 17. $Cu^{II}(TEPD)_2$ has a very similar structure. In chloroform-*d* solution the magnetic susceptibility of $Co^{II}(TEPD)_2$ is 3.9 μ_β at 23 °C.[68] This value is consistent with the presence of high-spin (S = 3/2) cobalt(II) in the complex.

D. Dimeric Complexes Revisited; The Curious Case of $\{Pd_2(\mu\text{-OEB})\}_2$

In addition to forming $Pd^{II}(OEB\bullet)$, the reaction of palladium salts with H_3OEB can produce a novel, diamagnetic dimer, $\{Pd_2(\mu\text{-OEB})\}_2$, whose remarkable structure is shown in Figure 18.[69] $\{Pd_2(\mu\text{-OEB})\}_2$ consists of two helical $Pd^{II}(OEB)$ units that are joined through a $(Pd^{I}_2)^{2+}$ unit. The coordination geometry within the two $Pd^{II}(OEB)$ portions of the tetranuclear complex is similar to that in $Pd^{II}(OEB\bullet)$ (see Figure 13) and $[Pd^{II}(OEBox)]^+$ (see Figure 14). While complexes of the type $[Pd^{I}_2L_6]^{2+}$ (L is a neutral, two-electron donor) are a well-established part of palladium chemistry,[70] the environment of the central $(Pd^{I}_2)^{2+}$ unit which is suspended between the two $Pd^{II}(OEB)$ moieties has several novel features. Each palladium atom of the $(Pd^{I}_2)^{2+}$ unit is coordinated to an olefinic bond of one of the two $Pd^{II}(OEB)$ units. Such η^2 coordination of a transition metal center to the π system at one of the *meso* carbon atoms of the OEB ligand is unusual for the chemistry of porphyrins or open-chain tetrapyrroles. One nitrogen atom from each tetrapyrrole ligand is also coordinated to one of the palladium ions in the central $(Pd^{I}_2)^{2+}$ unit. Thus, N8 bridges Pd4 and Pd3, while N4 bridges Pd2 and Pd1. The Pd–N distances that involve the bridging nitrogen atoms [Pd1–N4, 2.082(9); Pd2–N4, 2.107(8); Pd3–N8, 2.091(8); Pd4–N8, 2.094(8) Å] are longer than the strictly terminal Pd–N distances [2.007(10), 2.051(8) Å]. Such bridging by pyrrole

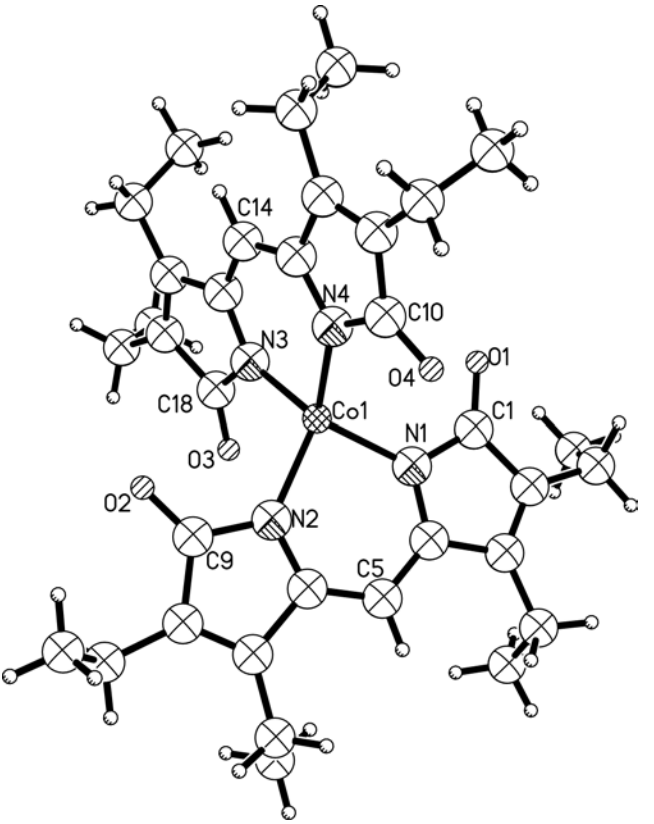

Figure 17. A drawing of $Co^{II}(TEPD)_2$ with uniform spherical atoms. Drawn with data from Koerner, R.; Olmstead, M. M.; Van Calcar, P. M.; Winkler, K.; Balch, A. L. *Inorg. Chem.* **1998**, *37*, 982–988.

nitrogen atoms in transition metal complexes of porphyrins and related tetrapyrroles is uncommon. The coordination of the $(Pd^{I}_2)^{2+}$ portion is completed by Pd–O bonds to each of the Pd^{II}(OEB) units.

$\{Pd_2(\mu\text{-OEB})\}_2$ undergoes several interesting reactions, as shown in Scheme 12.[71] Treatment of $\{Pd_2(\mu\text{-OEB})\}_2$ with pyridine results in the formation of Pd^{II}(OEB•), which has been described previously.[62] More remarkably, the reaction of diiodine with $\{Pd_2(\mu\text{-OEB})\}_2$ in pyridine solution produces the rearranged complex **1** (in Scheme 12), in which one of the *meso* carbon atoms of the ligand has been incorporated into one of the pyrrole rings to produce a pyridine-like ring and *trans*-$Pd(py)_2I_2$. This process of bilindione rearrangement and oxidation occurs as a direct consequence of the π-coordination of the palladium. The reaction results in the migration of a nitrogen atom from a pyrrole carbon atom to what was formerly a *meso* carbon atom to transform a former pyrrole ring into a

six-membered ring. Additionally, this process results in cleavage of the Pd–Pd and Pd–C bonds, oxidation of palladium, and introduction of an oxygen atom from water, but not necessarily in this particular sequence. The helical structure of **1** is shown in Figure 19. The overall structure is similar to the structures of Pd^{II}(OEB•) and $[Pd^{II}(OEBox)]^{+}$.

E. Iron Biliverdin Complexes

Iron biliverdin complexes play an integral role in the process of heme cleavage and have been detected as relatively stable intermediates in the enzymatic and purely chemical paths of heme oxidation. However, the formation of an iron biliverdin complex by direct metalation of a biliverdin has not been reported. Despite many attempts in the Balch laboratory, where many other metals have been coordinated to produce biliverdin metal complexes, direct metalation using iron salts has not been observed. In contrast, iron biliverdin and related complexes are available from oxidation of porphyrins and from verdohemes. The study of the reactions leading to the formation of iron biliverdin complexes has involved complementary studies in solution utilizing UV-visible spectroscopy and especially

^{1}H NMR spectroscopy and X-ray crystallographic studies of individual isolated compounds. Many of the compounds involved are paramagnetic; yet, clearly resolved ^{1}H NMR spectra have been obtained and analyzed for these compounds.

The coupled oxidation process generally produces a verdoheme in only ~40% yield and this low yield suggests that there are other products. Careful examination of the coupled oxidation of $(py)_2Fe^{II}(OEP)$ in pyridine solution resulted in the isolation of $[(py)_2Fe^{II}(OEOP)]Cl$ as a diamagnetic green solid in a 50% yield along with a previously unknown, paramagnetic iron complex that was identified as $\{Fe^{III}(\mu\text{-OEB})\}_2$ in a 32% yield.[72] $\{Fe^{III}(\mu\text{-OEB})\}_2$ was identified by a combination of ^{1}H NMR and X-ray crystallographic studies. Figure 20 shows the structure of the dimer. In this dimer, each iron is coordinated to four nitrogen atoms from one OEB trianion and an oxygen donor from another OEB ligand. The structure of $\{Fe^{III}(\mu\text{-OEB})\}_2$ is related to that of $\{Mn^{III}(\mu\text{-OEB})\}_2$, which was shown previously in Figure 11. For a dimer of this sort, a centrosymmetric (and hence achiral) dimer is formed when the two monomeric units that combine have opposite helicity (opposite chirality), as shown in Scheme 13. The initially reported data showed that $\{Fe^{III}(\mu\text{-OEB})\}_2$ has such a centrosymmetric structure.[72] However, if the two monomeric units that combine have the same helicity, then a chiral dimer with C_2 symmetry will form. Scheme 13 shows schematic diagrams of the enantiomeric pair of C_2 dimers for $\{M^{III}(\mu\text{-OEB})\}_2$. $\{Mn^{III}(\mu\text{-OEB})\}_2$ has the C_2 structure in the solid state.[60]

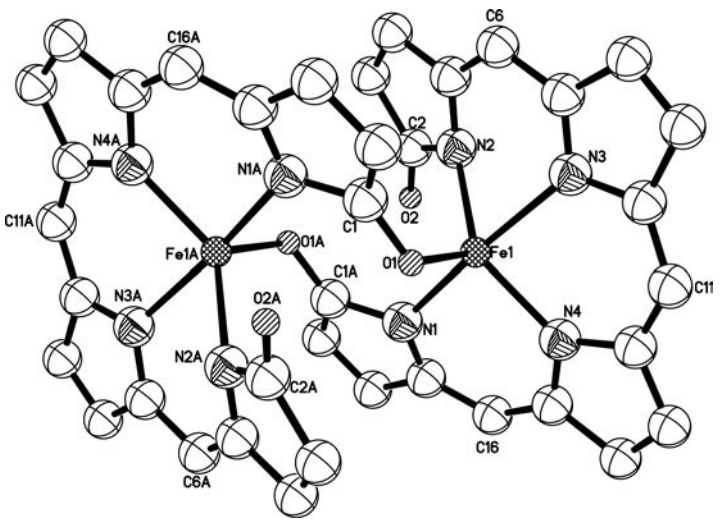

Figure 20. A drawing of $\{Fe^{III}(\mu\text{-OEB})\}_2$ with 50% thermal ellipsoids. For clarity the ethyl groups are not shown. Drawn using data from Balch, A. L.; Latos-Grazynski, L.; Noll, B. C.; Olmstead, M. M.; Safari, N. *J. Am. Chem. Soc.* **1993**, *115*, 9056–9061.

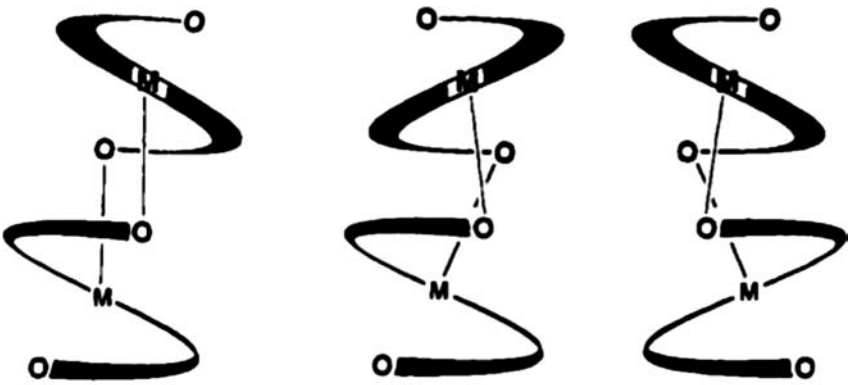
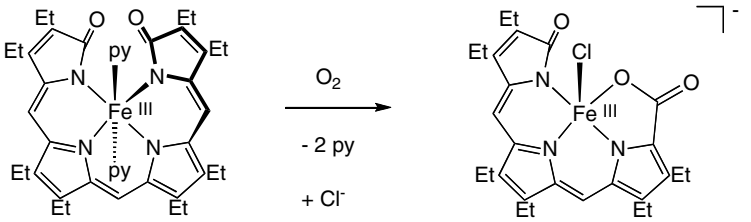


Scheme 13. Isomers of dimeric $\{M^{III}(OEB)\}_2$.

Treatment of $\{Fe^{III}(\mu\text{-OEB})\}_2$ with hydrochloric acid releases the blue bilindione H_3OEB in a 91% yield.[72] In pyridine-d_5 solution, ^1H NMR studies have shown that $\{Fe^{III}(\mu\text{-OEB})\}_2$ undergoes cleavage of the Fe–O bond when the dimer is dissolved in pyridine to form monomeric $(py)_2Fe^{III}(OEB)$. This process is reversible and is related to similar disruption of $\{Mn^{III}(\mu\text{-OEB})\}_2$ by coordination of pyridine. The ease with which $\{Fe^{III}(\mu\text{-OEB})\}_2$ undergoes loss of iron is one of its notable characteristics. Indeed, the crystal structure of $\{Fe^{III}(\mu\text{-OEB})\}_2$, shown in Figure 20, suffers from partial occupancy of the iron sites. The ease of loss of iron from $\{Fe^{III}(\mu\text{-OEB})\}_2$ and the difficulty of inserting iron into biliverdin may be an important consideration in the process of heme destruction.[72]

In pyridine solution, $(py)_2Fe^{III}(OEB)$ is air-sensitive, and upon exposure to the atmosphere it is converted into a tripyrrole, as shown in Scheme 14.[73] The oxidative process is apparently related to the previously discussed oxidation of $Cu^{II}(OEB\bullet)$ and $Co^{II}(OEB\bullet)$ by air, which results in oxidation of a *meso* C–H unit to produce complexes containing two dipyrrole ligands, as shown in Scheme 11.[63,68] Oxidation of $(py)_2Fe^{III}(OEB)$ seems to select one of the two equivalent C–H groups rather than the unique C–H group in the middle of the ligand. The structure of the product, $[ClFe^{III}(HETP)]^-$, is shown in Figure 21. The Fe–N distances in the two independent anions in the crystal are 1.990(7) [2.049(8)], 2.077(8) [2.077(9)], and 2.001(7) [2.001(6)] Å, and the Fe–Cl distances are 2.251(3) and [2.253(3)] Å. These distances are similar to those of five-coordinate iron(III) complexes such as $ClFe^{III}(OEP)$, which has an Fe–N distance of 2.073(8) Å and are Fe–Cl distance of 2.235(9) Å.[74]



Scheme 14. Oxidative formation of an iron tripyrrole complex.

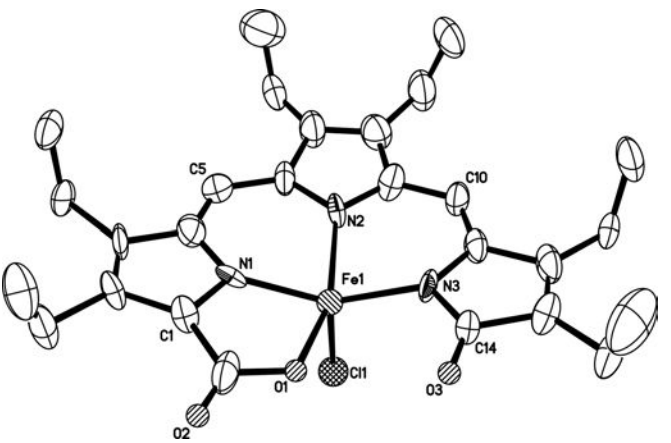


Figure 21. A drawing of the anion in (n-Bu_4N)[$ClFe^{III}$(HETP)] with 50% thermal ellipsoids. Drawn with data from Rath, S. P.; Olmstead, M. M. Latos-Grazynski, L.; Balch, A. L. *J. Am. Chem. Soc.* **2003**, *125*, 12678–12679.

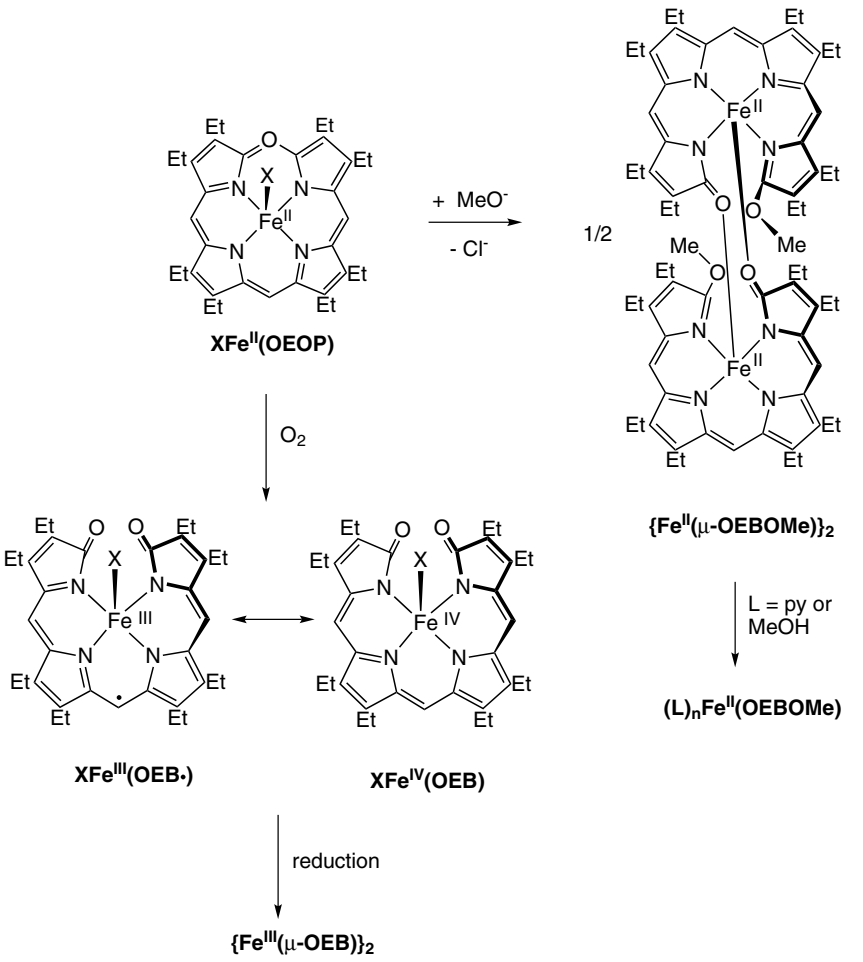
Related helical iron complexes have been obtained by various reactions of verdohemes, as shown in Scheme 15. For example, studies of the reaction of 5-oxaporphyrin iron complexes with methoxide ion were undertaken to provide models for the initial step in hydrolysis of verdohemes.[75,76] Treatment of both low-spin [$(py)_2Fe^{II}$(OEOP)]Cl and high-spin $ClFe^{II}$(OEOP) with the methoxide ion in either pyridine or methanol solution with careful exclusion of dioxygen caused ring opening and addition of methoxide to one end of the tetrapyrrole in reactions that are analogous to those of zinc verdohemes shown in Scheme 7. Black {Fe^{II}(μ-OEBOMe)}$_2$ was isolated in crystalline form from the reaction of $ClFe^{II}$(OEOP) with methoxide in methanol and studied by single-crystal X-ray diffraction. The structure of the dimer is shown in Figure 22. The molecule has a centrosymmetric, dimeric structure composed of two helical Fe(μ-OEBOMe) units with FeN_4



Scheme 15. Ring opening reactions of XFe^{II}(OEOP).

coordination that are connected by a pair of Fe–O bonds. Thus, each iron ion has approximately trigonal bipyramidal geometry. Black crystals of $\{Fe^{II}(\mu\text{-OEBOMe})\}_2$ dissolve in dichloromethane in the presence of methanol or pyridine to form high-spin $\{(MeOH)_nFe^{II}(OEBOMe)\}$ or $\{(py)_nFe^{II}(OEBOMe)\}$ (n = 1 or 2) through rupture of the Fe–O bonds in the dimer.[75] The electronic absorption spectra of these open-chain complexes show characteristic low-energy features at *ca.* 720 and 810 nm. At 23 °C, the paramagnetically shifted ^{1}H NMR spectrum of $\{Fe^{II}(\mu\text{-OEBOMe})\}_2$ shows a characteristic upfield methoxy resonance, 16 methylene resonances in the 47–5 ppm region, and *meso* resonances in the 51–29 ppm region. The temperature dependence of these spectra shows marked deviations from the Curie law that are consistent with a dimeric structure.

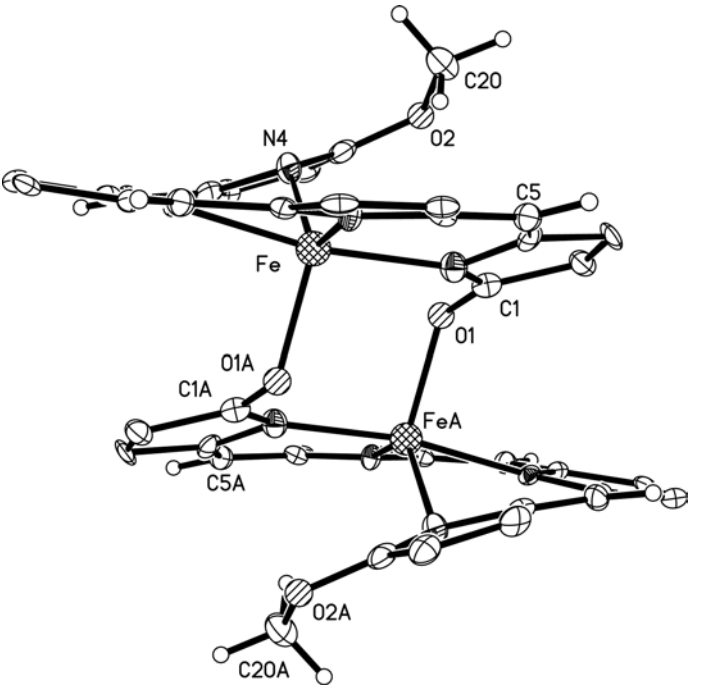


Figure 22. A drawing of $\{Fe^{II}(\mu\text{-OEBOMe})\}_2$ with 50% thermal ellipsoids. For clarity the ethyl groups are not shown. Drawn from data in Koerner, R.; Latos-Grazynski, L.; Balch, A. L. *J. Am. Chem. Soc.* **1998**, *120*, 9245–9255.

The process of hydrolysis of verdoheme and its conversion into biliverdin has also been the subject of some computational studies.[77,78]

High-spin, five-coordinate XFe^{II}(OEOP) (X = Cl or Br) is unusually reactive toward dioxygen. In contrast, the six-coordinate iron(III) verdoheme, Cl_2Fe^{III}(OEOP), is not affected by exposure to dioxygen. Treatment of a green solution of XFe^{II}(OEOP) (X = Cl or Br) with dioxygen results in the formation of a new paramagentic complex, which may be formulated as an iron(IV) complex [XFe^{IV}(OEB)] or as a complex with an oxidized ligand and iron(III) [XFe^{III}(OEB•)], in a matter of minutes, as seen in Scheme 15.[79] The reaction was initially monitored by ^{1}H NMR spectroscopy. The formation of XFe^{IV}(OEB)/XFe^{III}(OEB•) was signaled by the growth of eight new methylene resonances in the upfield −20 to −70 ppm region, with the other eight methylene resonances in the downfield region from 70 to 10 ppm and with dispersed *meso* proton resonances at 35, −28, and −167 ppm. XFe^{IV}(OEB)/XFe^{III}(OEB•) has been isolated in crystalline form and its structure has been determined by X-ray crystallography. Figure 23 shows the structure of this five-coordinate monomer, which has the iron bound to four pyrrole nitrogen atoms and the chloride ligand.[79] The tetrapyrrole ligand assumes the helical shape that is characteristic of the other

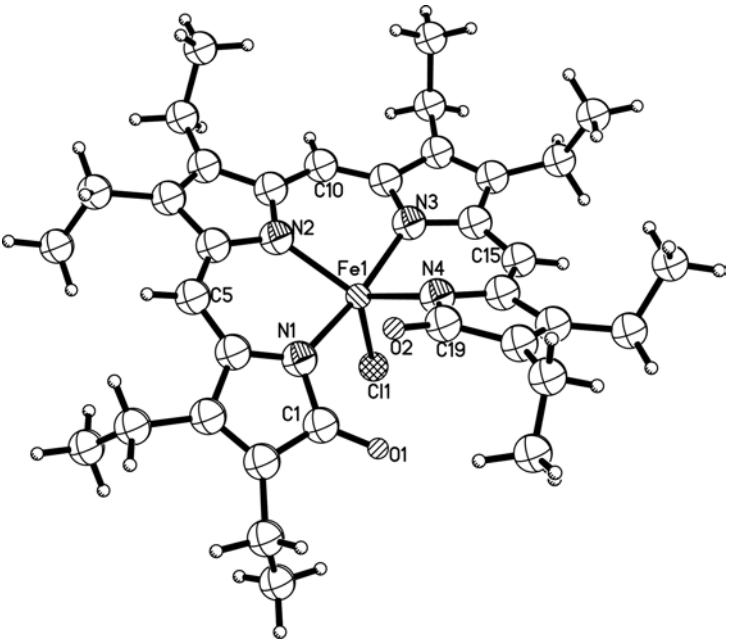

Figure 23. A drawing of Fe^{IV}(OEB)/Fe^{III}(OEB•) with uniform spherical atoms. Drawn with data from Nguyen, K.; Rath, S. P.; Grazynski, L. L.; Olmstead, M. M.; Balch, A. L. *J. Am. Chem. Soc.* **2004**, *126*, 6210–6211.

bilindione complexes described above. The Fe–N distances for the terminal pyrrole groups [Fe–N1, 2.018(2); Fe–N4, 2.016(2) Å] are somewhat shorter than those for the inner two pyrrole rings [Fe–N2, 2.049(2); Fe–N3, 2.070(2) Å]. For comparison, the Fe–N distances in high-spin, five-coordinate iron(III) porphyrins fall in the range of 2.06–2.09 Å.[80] The Fe–Cl distance, 2.2694(8) Å, is similar to those found in a number of five-coordinate iron(III) porphyrins.

The structure of rat heme oxygenase-1 with an iron biliverdin complex bound at the active site has been determined by single-crystal X-ray diffraction.[81] Figure 24 compares the structure of the synthetically prepared XFe^{IV}(OEB)/XFe^{III}(OEB•)[79] with that of the protein-bound iron biliverdin complex in the heme oxygenase.[81] The two structures show considerable similarity. Both utilize helical bilindione ligands with similar pitches. However, the protein structure involves an axial imidazole ligand from a histidine residue of the protein. The chloride ligand in synthetic XFe^{IV}(OEB)/XFe^{III}(OEB•) occupies a similar position. Unfortunately, there are no experimental data that definitively determine the oxidation state of the iron in the protein-bound iron biliverdin complex.

Pyridine solutions of $ClFe^{III}$(*meso*-NH_2-OEP) or $(py)_2Fe^{II}$(*meso*-NH_2-OEP) undergo oxidative ring opening when exposed to dioxygen, as shown in

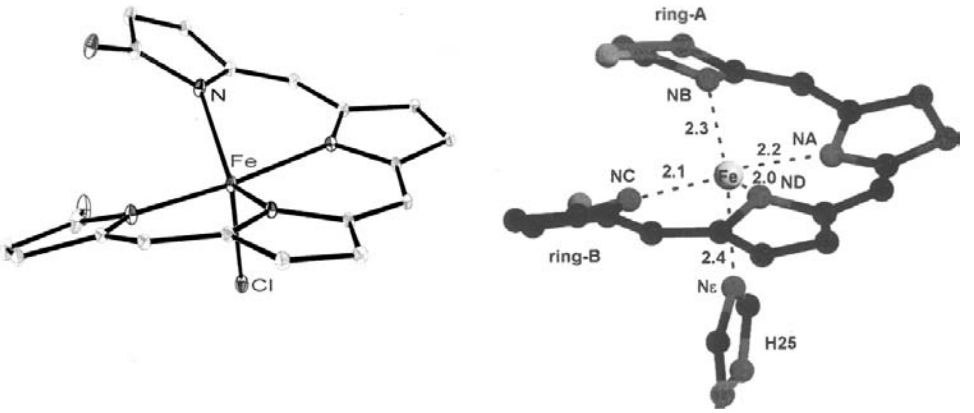

Figure 24. A comparison of the structure of Fe^{IV}(OEB)/Fe^{III}(OEB•) with that of rat heme oxygenase-1 bound iron biliverdin complex. Drawn using data from Nguyen, K.; Rath, S. P.; Grazynski, L. L.; Olmstead, M. M.; Balch, A. L. *J. Am. Chem. Soc.* **2004**, *126*, 6210-6211 and from Sugushima, M.; Sakamoto, H.; Higashimoto, Y.; Noguchi, M.; Fukuyama, K. *J. Biol. Chem.* **2003**, *278*, 32352–32358.

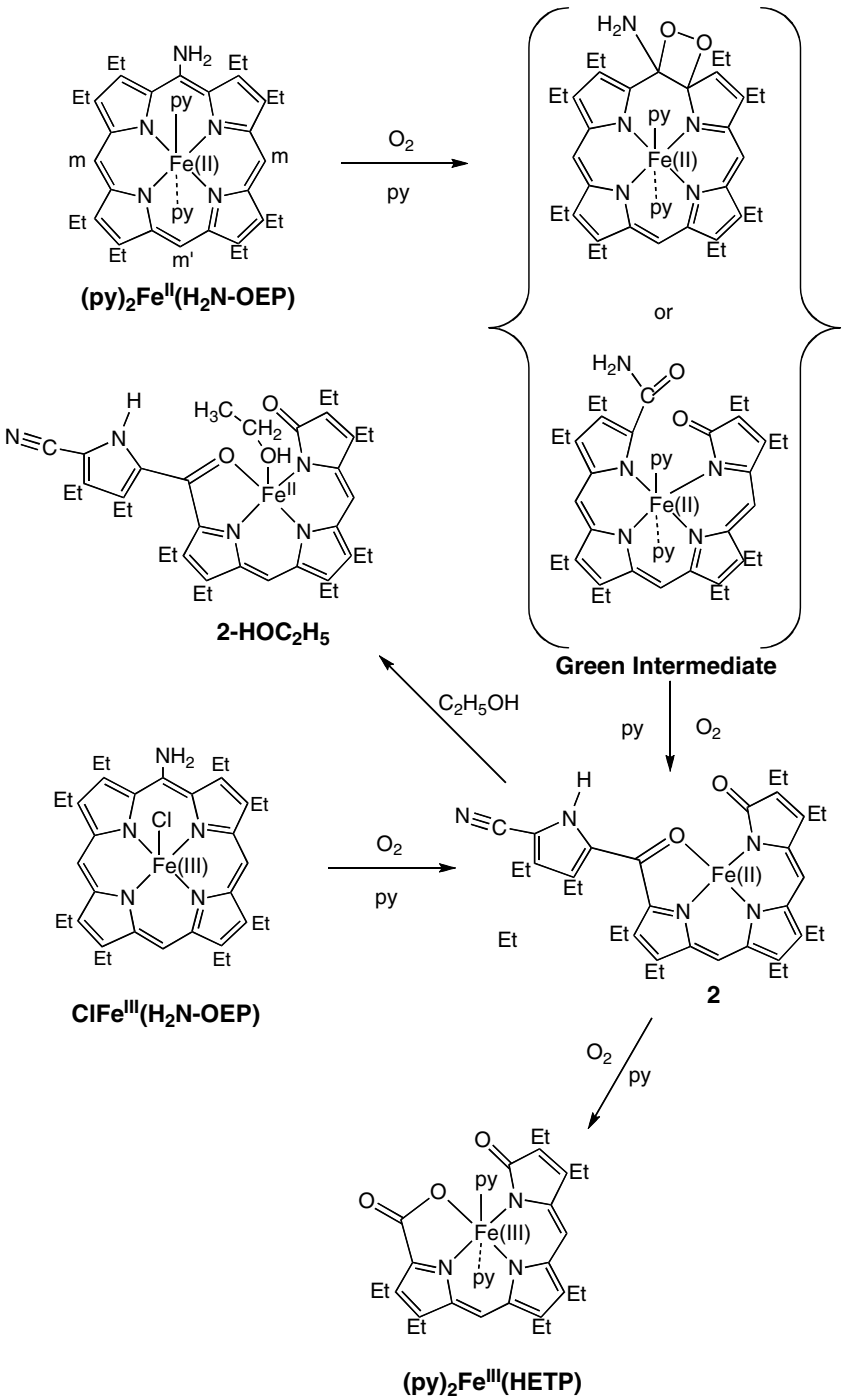
Scheme 16.[82,83] In pyridine-d_5 solutions of ClFe^{III}(*meso*-NH_2-OEP), there is a temperature-dependent equilibrium between the high-spin (S = 5/2), six-coordinate complex, {(py)ClFe^{III}(*meso*-NH_2-OEP)}, and the six-coordinate, low-spin [S = 1/2 with the less common $(d_{xz}d_{yz})^4(d_{xy})^1$ ground state] complex, [$(py)_2$Fe^{III}(*meso*-NH_2-OEP)]$^+$. Such pyridine solutions are air-sensitive, and the remarkable degradation reactions have been monitored by ^{1}H NMR spectroscopy. These studies revealed conversion of $(py)_2$Fe^{II}(*meso*-NH_2-OEP) into a green intermediate that was not isolated and then into a new open-chain tetrapyrrole complex **2** in Scheme 16, in which the original amino group and the attached *meso* carbon atom have been converted into a nitrile group. Additional oxidation at an adjacent *meso* carbon occurs to produce a ligand that binds iron by three pyrrole nitrogen atoms and the oxygen atom introduced at a *meso* carbon. This open-chain tetrapyrrole complex itself is sensitive to attack by dioxygen and is converted into a tripyrrole complex that is stable to further oxidation and has been isolated as set out earlier in Scheme 14. Compound **2** has been isolated with a molecule of ethanol acting as an axial ligand. The structure of **2**-ethanol is shown in Figure 25.

V. Metal Complexes of Formylbiliverdin and Related Tetrapyrroles

The coordination complexes of octaethylformylbiliverdin (H_2OEFB) are helical molecules that have much in common with the products of ring opening of verdohemes by nucleophiles. Transmetalation of Mg^{II}(OEFB), which can be



Scheme 16. Oxidation of $(py)_2Fe^{II}(H_2N\text{-}OEP)$.

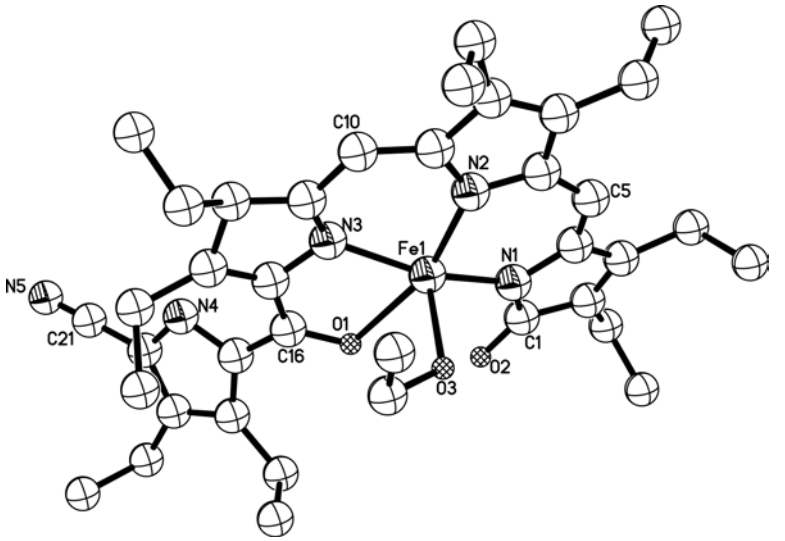


Figure 25. A drawing of the ring opened complex **2**-ethanol obtained by oxidation of $(py)_2$FeII(*meso*-NH2-OEP) with uniform spherical atoms. Notice that the pyrrole ring containing N4 is twisted out of the plane of the FeN_3O unit. Drawn with data from Kalish, H.; Lee, H. M.; Olmstead, M. M.; Grazynski, L. L.; Rath. S. P.; Balch, A. L. *J. Am. Chem. Soc.* **2003**, *125*, 4674–4675.

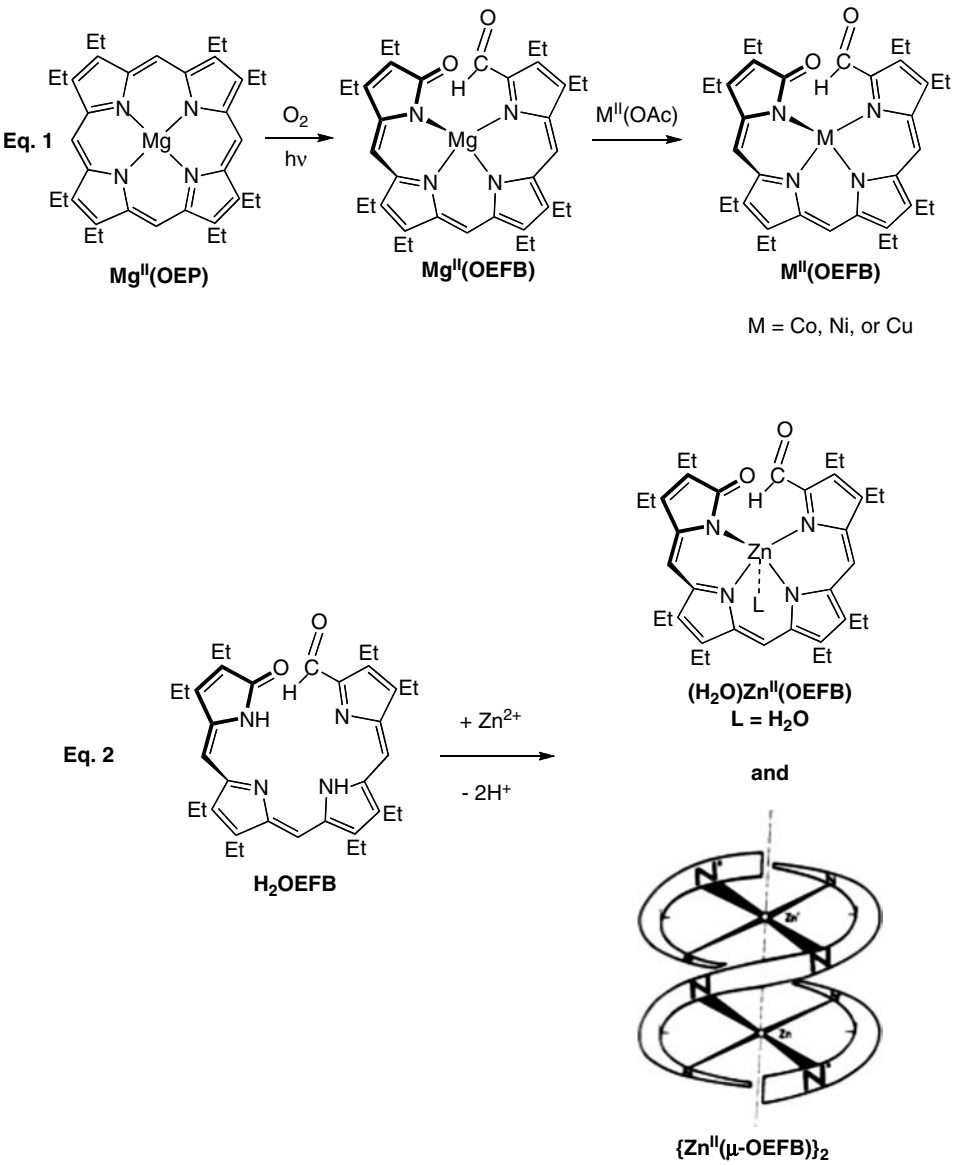
obtained by photooxidation of Mg^{II}(octaethylporphyrin) in air,[84] with a metal(II) acetate yielded the low-spin, monomeric complexes Cu^{II}(OEFB), Ni^{II}(OEFB), and Co^{II}(OEFB), as shown in Eq. 1 of Scheme 17.[85] Single crystal X-ray diffraction of Cu^{II}(OEFB) revealed that it consists of a four-coordinate copper(II) center that is bonded to the four nitrogen atoms of the tetrapyrrole ligand to produce a distorted planar coordination, as shown in Figure 26. The tetrapyrrole ligand has a helical geometry. The structure of the solid is complicated by the existence of three molecules in the asymmetric unit and C–H···O hydrogen bonding between pairs of these. Both Cu^{II}(OEFB) and Co^{II}(OEFB) can be converted to the verdoheme analogs, $[Cu^{II}(OEOP)]^+$ and $[Co^{II}(OEOP)]^+$, through oxidation with hydrogen peroxide. Additionally, $[Cu^{II}(OEOP)]^+$ was produced by heating a toluene solution Cu^{II}(OEFB) in the presence of trifluoroacetic acid under an atmosphere of dioxygen. Carbon monoxide is produced when Cu^{II}(OEFB) is converted to $[Cu^{II}(OEOP)]^+$ by either procedure. The product, $[Cu^{II}(OEOP)](PF_6)$, has been isolated and characterized by single-crystal X-ray diffraction. The cation has a planar, porphyrin-like structure. The ^{1}H NMR spectrum of diamagnetic Ni^{II}(OEFB) was shown to be consistent with the helical structure through the use of lanthanide and chiral lanthanide shift reagents. The EPR spectrum of Co^{II}(OEFB) shows that it forms a low-spin adduct with pyridine and that this adduct acts as a reversible dioxygen carrier.[84]



Scheme 17. Formation of formylbiliverdin complexes.

As shown in Eq. 2 of Scheme 17, introduction of Zn(II) into H_2OEFB resulted in the formation of two products: brown, monomeric, five-coordinate $(H_2O)Zn^{II}$(OEFB) and the unusual dimeric $\{Zn^{II}(\mu\text{-OEZB})\}_2$, which is green.[86,87] Both products were characterized by X-ray crystallography. The structure of brown $(H_2O)Zn^{II}$(OEFB) is similar to those of many of the other helical biliverdin-based complexes discussed

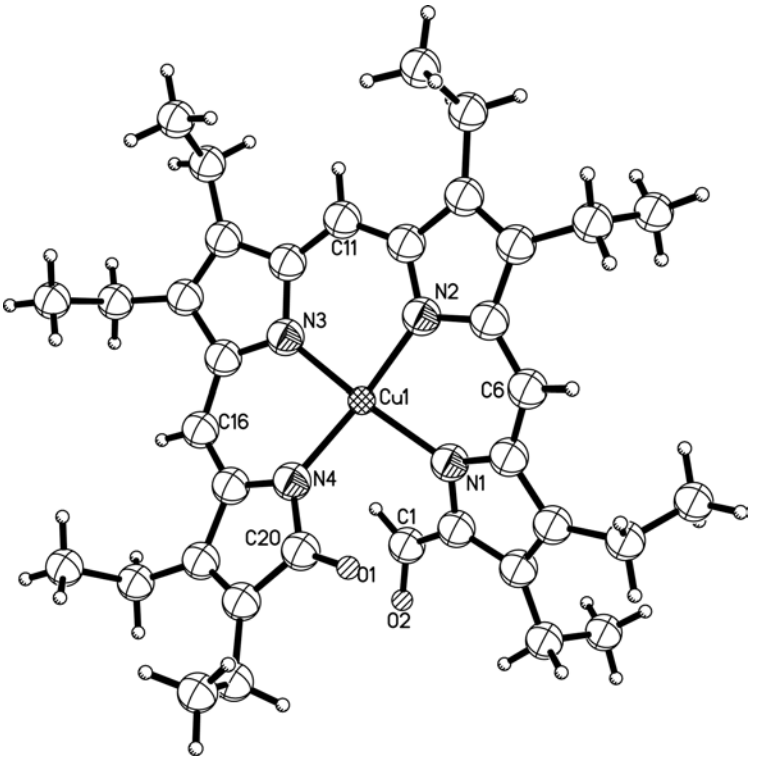


Figure 26. A drawing of Cu^{II}(OEFB) with 50% thermal ellipsoids. Drawn from data in Koerner, R.; Olmstead, M. M.; Ozarowski, A.; Phillips, S. L.; Van Calcar, P. M.; Winkler, K.; Balch, A. L. *J. Am. Chem. Soc.* **1998**, *120*, 1274–1284.

in this chapter, e.g. Cu^{II}(OEFB) shown in Figure 26. The structure of the green complex is unusual since it involves the formylbiliverdin ligands acting as bridging ligands with two nitrogen atoms of one ligand bound to one zinc ion, and the other two nitrogen atoms coordinated to a second zinc ion, as illustrated in schematic form in Scheme 17. The resulting molecule has a helical structure nature that is quite distinct from that of $\{Mn^{III}(\mu\text{-OEB})\}_2$ (shown in Figure 11) and $\{Fe^{III}(\mu\text{-OEB})\}_2$ (shown in Figure 20). In particular, the oxygen atoms of the OEB ligands do not coordinate the zinc ions. It was reported that the conversion of brown $(H_2O)Zn^{II}$(OEFB) into green $\{Zn^{II}(\mu\text{-OEFB})\}_2$ was promoted by acid, but the role of acid in this conversion is unclear.[86,87] This system might profit from further investigation, particularly since the crystallographic coordinates of $(H_2O)Zn^{II}$(OEFB) and green $\{Zn^{II}(\mu\text{-OEFB})\}_2$ are not in the Cambridge Crystallographic Database.

Open-chain tetrapyrrole ligands can also form dinuclear complexes. Photooxidation of magnesium tetraphenylporphyrin induces ring cleavage and the

Scheme 18. Formation of a dinuclear copper complex.

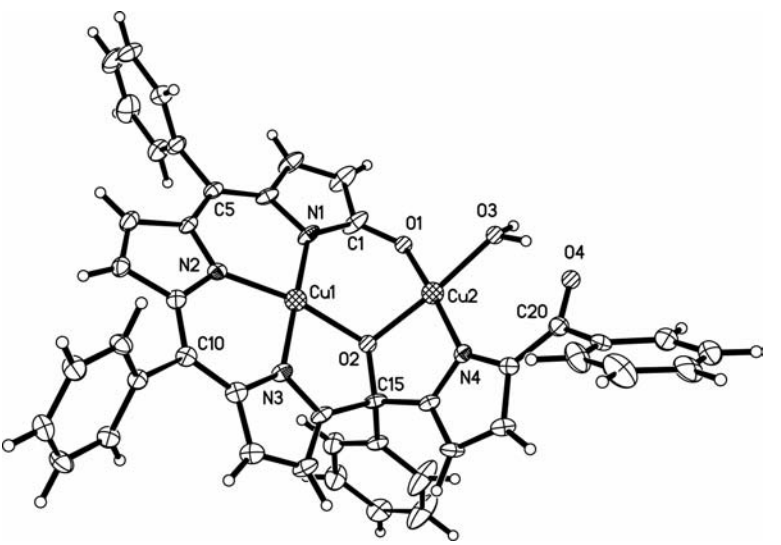

Figure 27. A drawing of Cu$^{II}_2$(TPKB-O)(H$_2$O)(THF) with 50% thermal ellipsoids. For clarity, the tetrahydrofuran molecule coordinated to Cu1 has not been shown. Drawn using data from Koerner, R.; Olmstead, M. M.; Ozarowski, A.; Balch, A. L. *Inorg. Chem.* **1999**, *38*, 3262–3263.

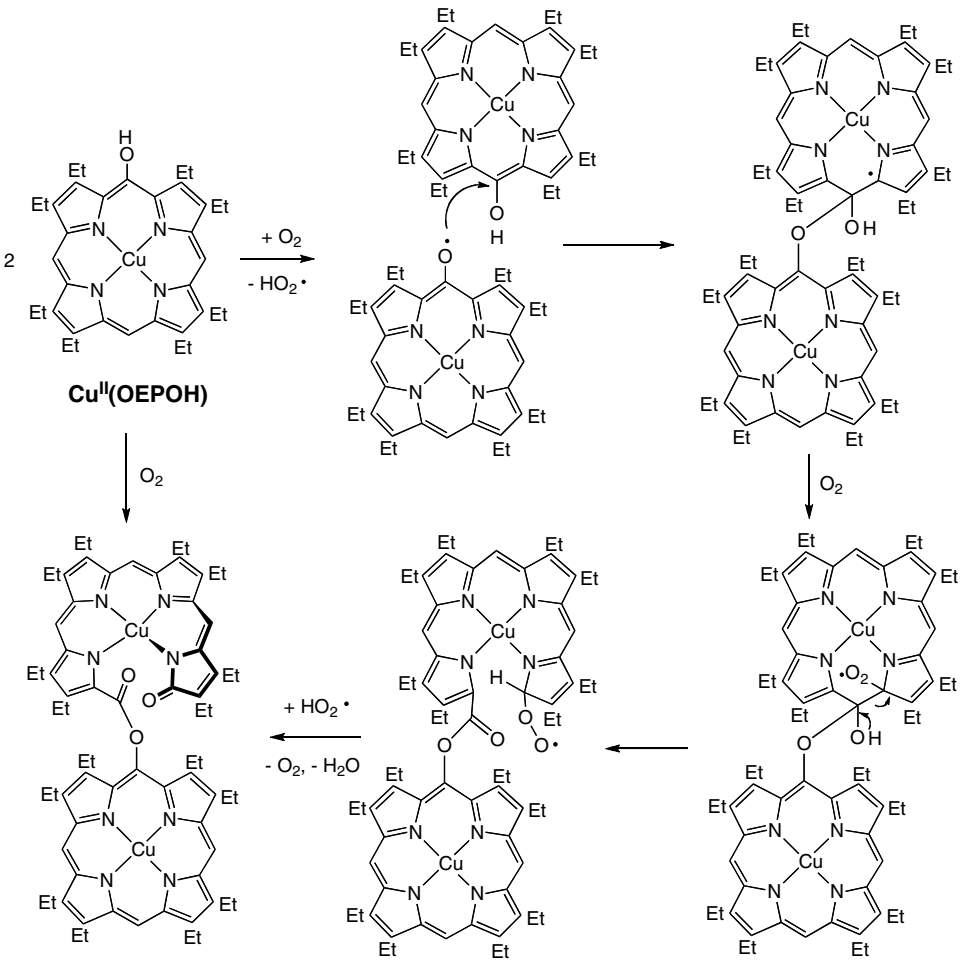
formation of magnesium tetraphenylketobiliverdin, Mg^{II}(TPKB),[88] which has been transmetalated with $Cu^{II}(OAc)_2 \cdot H_2O$ in methanol to produce two new complexes, brown–yellow Cu^{II}(TPKB) and blue Cu^{II}_2(TPKB-O)(H_2O)(THF), as shown in Scheme 18.[89] The yield of blue Cu^{II}_2(TPKB-O)(H_2O)(THF) was greatly improved by treating Cu^{II}(TPKB) with excess $Cu^{II}(OAc)_2 \bullet H_2O$ in boiling acetone for 18 h. This reaction occurs either under normal atmospheric conditions or under an atmosphere of purified dinitrogen. Thus, dioxygen is not necessary for the formation of Cu^{II}_2(TPKB-O)(H_2O)(THF). Figure 27 shows the structure of the dinuclear complex, Cu^{II}_2(TPKB-O)(H_2O)(THF).



Scheme 19. Formation of dinuclear {Cu^{II}(μ-OEPOC(O)OEB)Cu^{II}}.

VI. Some Other Interesting Open-Chain Complexes that Do Not Fit the Above Classification

As shown in Scheme 19, Cu^{II}(OEPOH) undergoes oxidation by dioxygen to form the novel dinuclear copper complex, {Cu^{II}(μ-OEPOC(O)OEB)Cu^{II}}, whose structure has been determined by X-ray crystallography.[90] Figure 28 shows a drawing of the neutral dinuclear complex. This remarkable compound is composed of a copper(II) *meso*-substituted porphyrin portion (with a planar CuN_4 unit) that is attached through an ester linkage to a helical copper(II) complex of an open-chain tetrapyrrole. The ring-opened portion must have been provided by oxidative cleavage of a second molecule of Cu^{II}(OEPOH). A speculative mechanism suggested for this process is shown on the right hand side of Scheme 19.

In related chemistry, oxidation of Ni^{II}(OEPNH$_2$) with ferric chloride in a mixture of chloroform and ethanol results in the formation of two products, as shown in Scheme 20.[91] The structure of one of these, Ni^{II}(OEB-CO_2Et), is shown in Figure 29. Ni^{II}(OEB-CO_2Et) has a helical structure that resembles those of many of the other biliverdin complexes discussed in this chapter. Despite the distortion from planarity of the nickel ion, the complex displays a conventional ^{1}H NMR spectrum.[91]

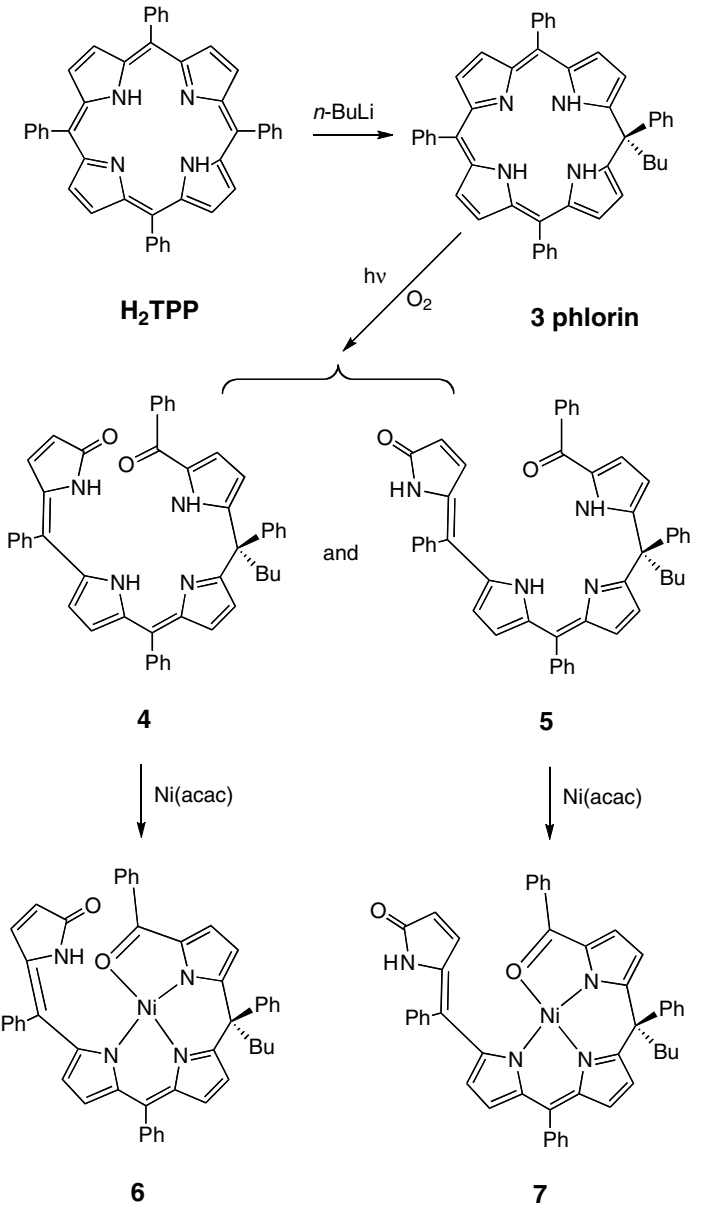
Some unusual open-chain tetrapyrrole complexes have been obtained by photooxidation of the phlorin complex **3** shown in Scheme 21.[92] The phlorin **3** was obtained by addition of *n*-butyl lithium to H_2TPP. Photooxidation of the phlorin **3** produced the open-ring compounds **4** and **5**. Treatment of **4** and **5** with $Ni^{II}(acetylacetonate)_2$



Scheme 21. Formation of phlorin-derived open-chain nickel complexes.

produced the four-coordinate nickel(II) complexes **6** and **7**, shown in Scheme 21. The structures of **6** and **7**, are shown in Figures 30 and 31, respectively. Despite the rather crowded nature of these complexes, the nickel ions in both compounds have a nearly planar geometry.

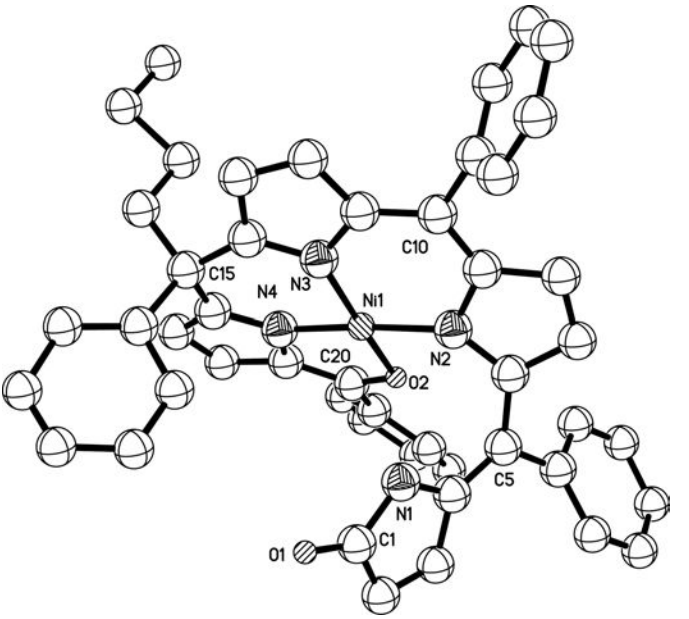


Figure 30. A drawing of **6**, (5,10,15,20-tetraphenyl-15-*n*-butylbiladiene-ab-1,20(21H)-dione-N,N′,N″,O)-nickel(II) with uniform spherical atoms. Hydrogen atoms were omitted. Drawn with data in Jeandon, C.; Krattinger, B.; Ruppert, R.; Callot, H. J. *Inorg. Chem.* **2001**, *40*, 3149–3153.

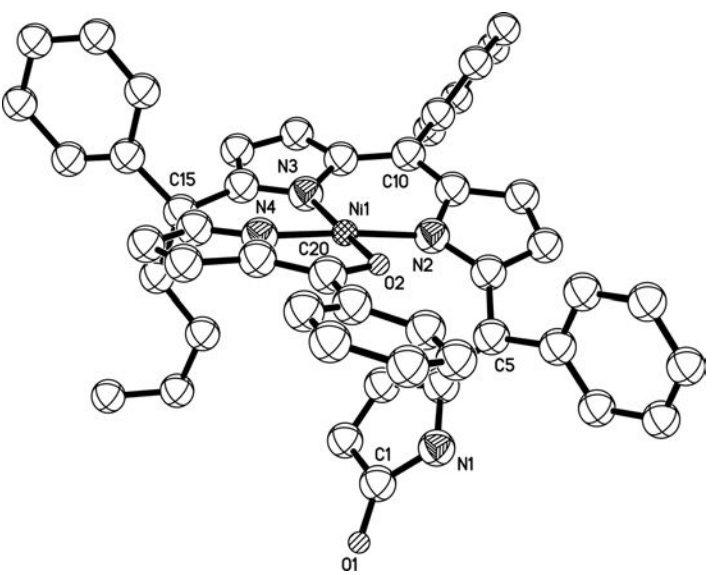

Figure 31. A drawing of **7**, (5,10,15,20-tetraphenyl-15-*n*-butylbiladiene-ab-1,20(21H)-dione-N,N′,N″,O)-nickel(II) with uniform spherical atoms. Hydrogen atoms were omitted. Drawn utilizing data from Jeandon, C.; Krattinger, B.; Ruppert, R.; Callot, H. J. *Inorg. Chem.* **2001**, *40*, 3149–3153.

VII. Conclusions

This article has reviewed the structural chemistry of verdohemes and open-chain oligopyrroles that are formed as the products of porphyrin degradation, generally by oxidative processes. The results have shown that the verdohemes usually have planar structures that are similar to the corresponding porphyrins. One rather characteristic aspect of the open-chain compounds and their metal complexes is the helical nature of their structures. Despite their nonplanarity, the complexes of bilindiones undergo facile, reversible redox reactions that are ligand-based. The chiral nature of the biliverdin chelates offers an interesting aspect that deserves further study. So far, the only explicit use of the chiral nature of these chelated complexes has employed axial ligand binding to the type of zinc complexes shown in Scheme 7 to selectively coordinate chiral ligands.[38–50]

I. Introduction

A. Introductory Remarks and Scope of This Chapter

The coordination chemistry of open-chain oligopyrroles has long been a heterogeneous and peripheral area of porphyrin chemistry.[1–3] In most of the early instances the description of open-chain tri- and tetrapyrrole coordination compounds appeared only within the context of tetrapyrrole synthesis or analysis, and systematic studies of such species in their own right were not to be found until Fuhrhop and coworkers worked on bilin analogs in the 1970s. Due to their ubiquitous occurrence in nature and their biological importance, linear oligopyrroles have mainly been studied as purely organic entities in biological dyes, or as intermediates in heme and corrin biosyntheses, degradation, and phytochrome formation.[4] Those aspects remain important issues of this chemistry. Nevertheless, some reports on the importance of transition metal complexes of such ligands have been known for quite some time. The peculiar lability of iron biliverdin complexes which occur as intermediates in the biological heme degradation process[5–10] was recognized early,[11,12] and the use of divalent zinc ions in the analysis of phytochromes belongs to the standard repertoire of today's photobiologists and biochemists.[13–15] A further example is the early development of an accurate and relatively simple method for the determination of bilirubin in urine based on the formation of a strong copper(II) complex with azobilirubin.[16,17] As can be seen from these examples, the linear tetrapyrroles clearly dominate the field compared with the tripyrroles. This is certainly due to the fact that even the better-known groups of tripyrrolic compounds, the biopyrrins[18] and the prodigiosens,[19–21] still await detailed studies as ligands in coordination compounds.

Besides the tri- and tetrapyrrolic derivatives, some related oligopyrroles with two or with more than four pyrrole moieties have been reported as ligands. Work on shorter dipyrrolic species, the so-called dipyrrins, has recently been

reviewed[22,23] and is the topic of another chapter in this volume.[24] Reports on metal or anion complexes of longer or of branched oligopyrroles are rather rare,[25–30] which may well relate to the restricted number of easily accessible or naturally occurring examples of this class.[31–45] Several types of hybrid (oligo)pyrrole/Schiff base ligands and some intriguing transition metal chelates thereof have also been described, often employing the molecular achitecture of the H_2(salen) ligand family.[46–55] The tripyrrolic compounds have also found mimics which have been introduced very successfully into modern coordination chemistry. These are the bis(arylimino)isoindoline [H(bai)] ligands related to the phthalocyanines, and most recently the bis(oxazolinyl)pyrroles [H(bop)], which show much promise in catalysis (Figure 1). This article will concentrate on tripyrrolic and longer chain entities, including the H(bai) and H(bop) ligand classes. Dipyrrins and salen-like pyrrole hybrid ligands, as well as the technically important polypyrrole, [56,57] are considered to be beyond the scope of this review.

B. Types of Open-Chain Tri- and Tetrapyrrolic Species

In principle, a plethora of different open-chain tri- and tetrapyrroles can be derived from a simple building system using pyrroles and several bridging units at either the pyrrolic α- or β-positions, although only a minor number of these have been prepared and studied to date.[58] As mentioned above, two classes of linear tripyrroles are naturally occurring. These are prodigiosin **1** and the related prodigiosenes; and two biopyrrins of the tripyrrindione type — biotripyrrin a **2** and the regioisomeric biotripyrrin b **3** (Figure 1). Prodigiosenes are red pigments which are produced from microorganisms such as *Streptomyces* or *Serratia*.[19,59,60] They are much-studied substances in medicine, as the natural and many synthetic derivatives show promise as immunosuppressive and as anticancer drugs.[61–69] Little is known with respect to the coordination properties of prodigiosenes. The biopyrrins have been isolated very early from urine and urate sediments, but their molecular structures were unknown for a long time.[70–75] Biotripyrrin a **2** as the more stable *endo*-vinyl isomer was identified first and initially named "uroerythrin". The elusive *exo*-vinyl isomer **3** was later found and named "biotripyrrin b".[18] Both species are products from the antioxidative action of biliverdin IXα (Figure 2), and their level in human urine is a medicinal indicator of stress and inflammation under a multitude of different conditions, like schizophrenia, depression, sepsis, heart failure, or after surgery.[76–91] The first synthetic tripyrrindiones were known prior to the structure elucidation of **2** and **3**,[92–95] and simple model systems like hexaethyl derivative **4** have been prepared.[96–99] Related degradation products of modified metal porphyrins with the tripyrrin-1-one framework **5** were detected under several nonbiological oxidative conditions, usually as

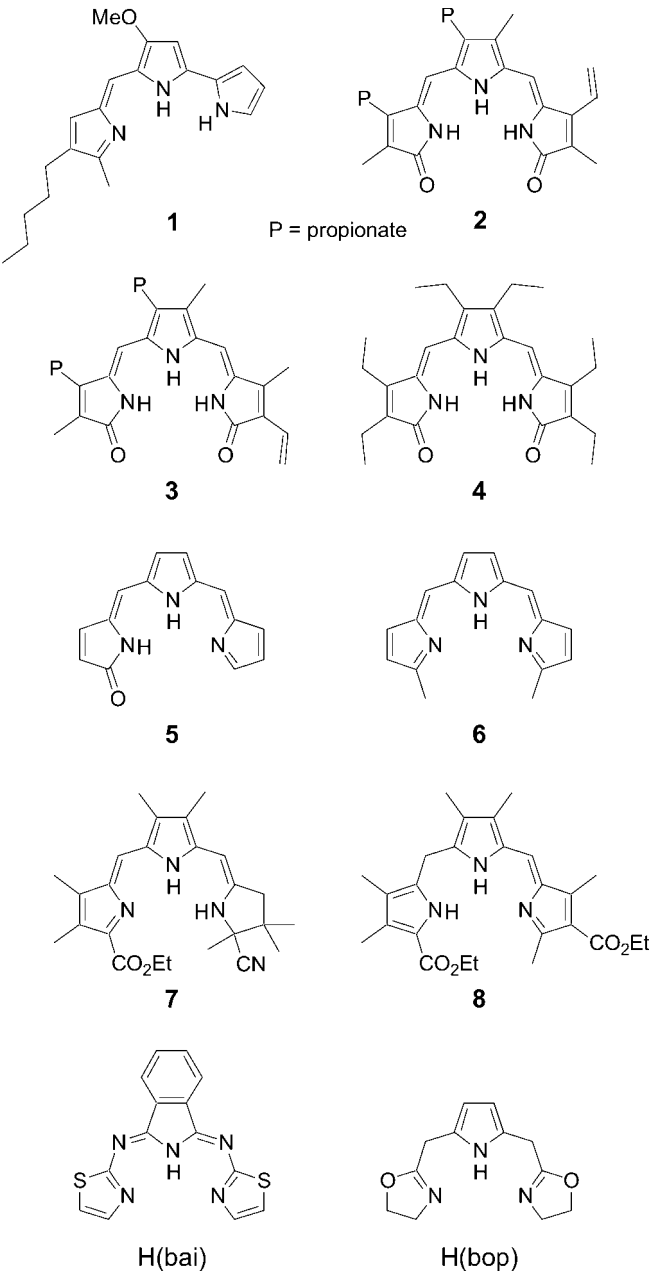

Figure 1. Selected examples for linear tripyrrolic ligands **1**–**8**, for bis(arylimino)isoindolines [H(bai)], and for bis(oxazolinyl)pyrroles [H(bop)].

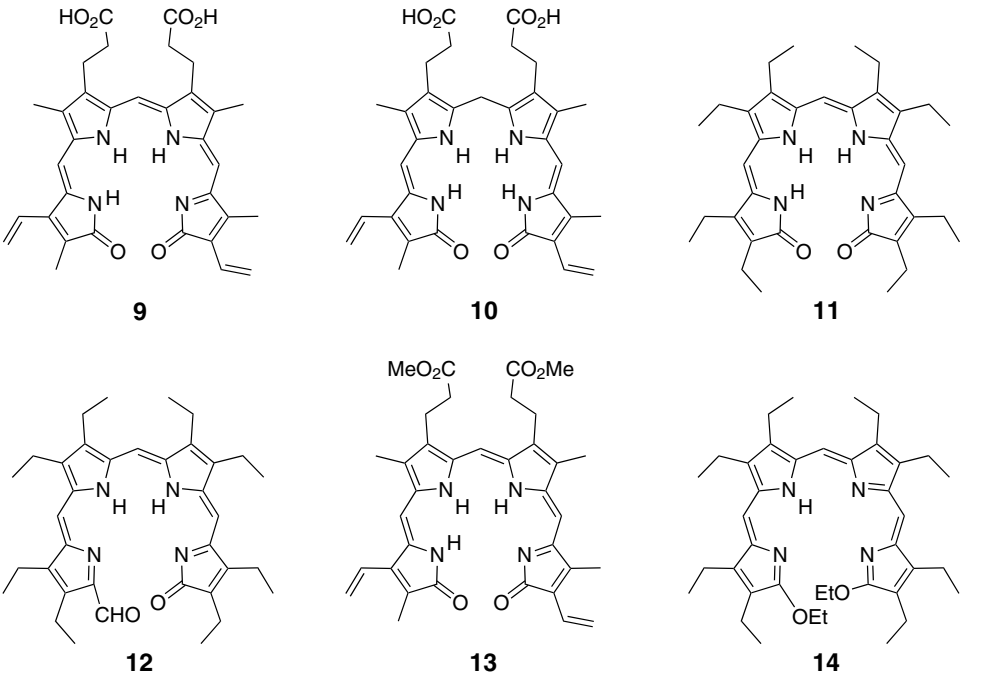

Figure 2. Some natural and artificial bilindione-type ligands: biliverdin-IXα **9**, bilirubin-IXα **10**, octaethylbilindione H_3(oeb) **11**, formyl-octaethylbilinone **12**, dimethyl biliverdin-IXα **13**, and diethoxybilatriene **14**.

metal complexes,[100–103] and several related species have been synthesized by design.[96–98,104–118] Finally, the synthetic alkyl- or alkoxy-substituted tripyrrins **6**,[98,117,119–123] the partially hydrogenated tripyrrin **7**,[124,125] and many tripyrrenes such as **8**[126–134] are known tripyrrolic ligands and belong to this class of compounds.

The natural linear tetrapyrroles comprise many intermediates in syntheses of biological porphyrin, chlorin, corrin, and phytochrome compounds, as well as of the respective degradation processes, of which only biliverdin IXα **9** and bilirubin IXα **10** have been studied as ligands in coordination compounds (Figure 2). Such oxoterminated species, the so-called bilindione-type ligands, provide several model ligands with simplified preparations and peripheral substitution such as **11** or **12**, or with protected carboxylate and/or terminal oxo groups such as **13**[135] and **14**, respectively. These model compounds overcome the typical drawbacks of the natural materials, i.e. solubility problems in nonaqueous solutions and formation of carboxylate salts in the presence of metal ions. Bilindiones have been employed as ligands in many studies of the biological importance of iron biliverdins, and a number of other applications of these chelate complexes have been made in the more recent past.

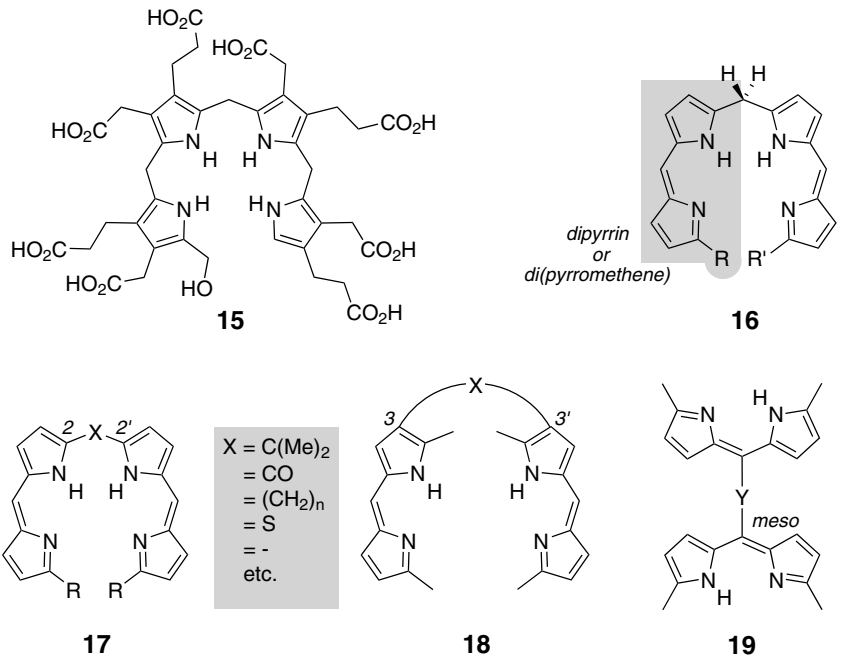

Figure 3. Examples for bilane and bis(dipyrrin)-type tetrapyrroles: preuroporphyrinogen **15**, methylenebis(dipyrrin) or *a,c*-biladiene **16**, 2,2′-bis(dipyrrin) **17**, 3,3′-bis(dipyrrin) **18**, and *meso*-bridged bis(dipyrrin) **19**.

The central tetrapyrrolic intermediate of heme biosynthesis is preuroporphyrinogen **15**, a typical bilane devoid of stabilization by electron-withdrawing groups at the terminal pyrrole rings.[136] The tetrapyrrolic core of this biomolecule is very reactive with respect to hydrolytic as well as oxidative processes, but may be stabilized through twofold dehydrogenation and formation of methylene-bridged bis(dipyrrin)s **16**, often called *a,c*-biladienes (Figure 3).[137,138] Artificial species derived from **16** may carry different residues (R and R′) at the terminal position which alter their reactivity, and the nature and position of the bridging unit may be changed to allow the construction of a large number of tetrapyrrolic bisdipyrrin ligands such as **17** or **18**. Coordination compounds of such engineered ligands have been used as precursors for the syntheses of many corrinoid and porphyrinoid compounds, and have found entry into the construction of supramolecular systems. Several examples of oligo(dipyrrin)s connected via the bridging methine group (C-6) **19** have been prepared and used in the latter field as well as in photochemistry. Other artificial tetrapyrroles containing one or no dipyrrin subunit are also well known,[139–147] but have only rarely been employed in coordination compounds to date.[148–150] Partly hydrogenated species, on the other hand,[151–153]

have been studied in much detail within the context of research toward the synthesis of cobalamins and hydroporphyrins.

II. Preparation of Open-Chain Oligopyrrole Ligands

A. Tripyrroles: Prodigiosenes and Related Species

The basic framework of prodigiosenes contains three pyrrole nuclei which are connected to each other via the α-positions, one pair directly and one pair with a methine bridge. Three general approaches are to be found in the scientific literature on prodigiosene syntheses. The retrosynthetic analysis leading to these three synthetic pathways, A–C, is shown in Figure 4. In most of the reported cases, the formation of the prodigiosene follows the biosynthesis of these molecules and proceeds by the acid condensation of a monoformyl bipyrrole with a pyrrole, as displayed on pathway A.[32] For simple alkyl-substituted derivatives, the alternative approach employing a bipyrrole and a formylpyrrole as in path B is advantageous, as the precursors are often easier available.[154] However, pathway C, i.e. the formation of the direct pyrrole–pyrrole bond in the final step is somewhat ponderous and has been used so far only for one partially hydrogenated derivative[140] and for the total synthesis of several natural species and their analogs. Since no reports on the coordinating properties of these latter species are available, this issue will not be discussed here, and only some key references for the structure elucidation and total

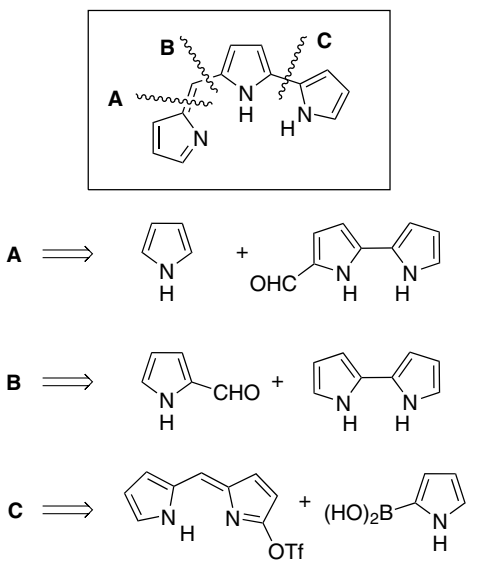

Figure 4. Retrosynthetic analysis of the prodigiosene chromophore.

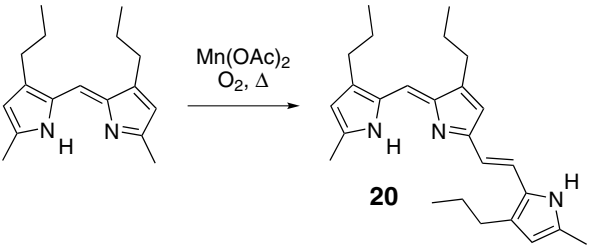

Figure 5. Formation of **20**.

syntheses of natural or biomimetic prodigiosenes are given here for the interested reader.[21,155–171] A vinylogous derivative, the tripyrrole **20**, has been described as the unexpected product of an unusual oxidation reaction of a tetraalkyldipyrrin.[172] No metal chelates of this novel species were reported (Figure 5).

B. Tripyrroles: Tripyrrinones, Tripyrrins, and Related Tripyrroles

The basic skeleton of the major group of linear tripyrrolic ligands contains two one-carbon bridges, thus preorganizing the three C_4N heterocycles for a meridional N,N,N coordination to a metal center. These ligands may be ordered by the functionalities occupying the α-terminal positions, and by the degree of hydrogenation, into the above-described groups. The major reaction leading to these compounds is the basic or acidic condensation of pyrrolic aldehydes. Symmetric tripyrrindiones such as **4** or **21** form under enforced basic conditions from a pyrrolic dialdehyde and two pyrridinone moieties, as depicted in Figure 6. The reaction is not complete, and significant amounts of dipyrrolic compounds **22** and **23** form as byproducts.[99] Symmetric tripyrrins **6** with some variation in their substitution have been described to form under strongly acidic conditions in boiling trifluoroacetic acid.[119–123] Again, one equivalent of a pyrrole dialdehyde is used in combination with two equivalents of an α-free pyrrole. These tripyrrins are stable as protonated moieties but decompose quickly in the presence of nucleophiles. The nucleophilic attack occurs presumably at the α-terminal positions, as the sterically protected *tert*-butyl derivative **24** can easily be obtained from its protonated form by the action of the base (Figure 6).[123] Unprotected tripyrrins may be obtained by the decomplexation reaction of nickel(II) tripyrrins with excess cyanide (see later in this section). In the neutral form, tripyrrins are much less prone to nucleophilic attack and consecutive decay, and may be used for coordination studies. These free base tripyrrins were fully characterized, while protonated species have only been incompletely analyzed by ^{1}H NMR spectroscopy (after condensation in deuterated trifluoroacetic acid) and by HRMS.[119]

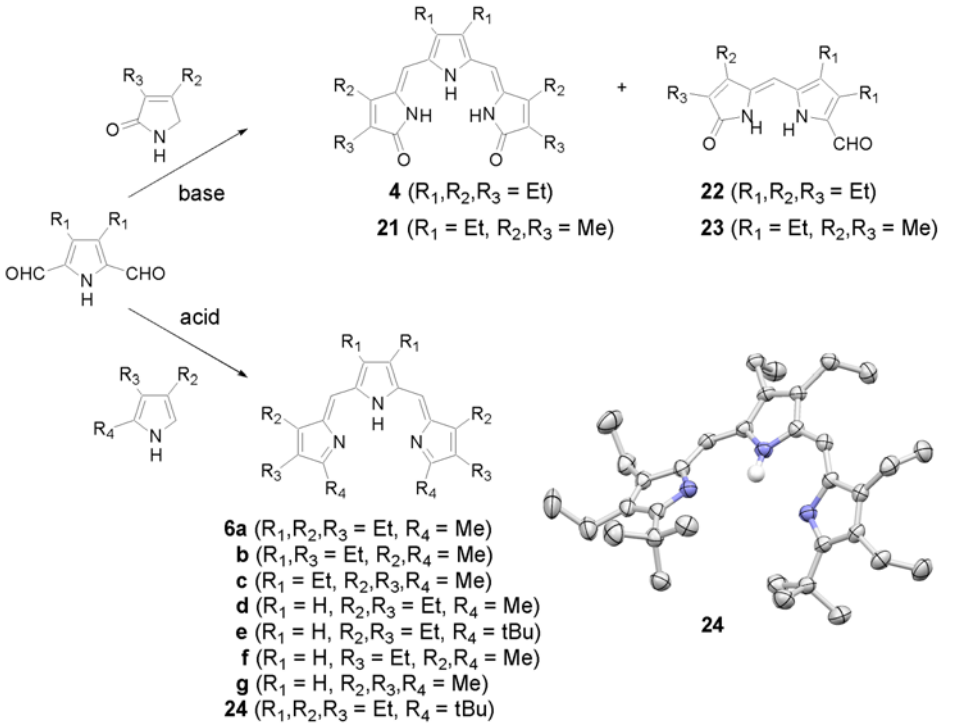

Figure 6. Stepwise condensation reactions for the preparation of symmetric tripyrrindiones and tripyrrins, and molecular structure of *tert*-butyl terminated tripyrrin **24** (crystallographic figure adapted from Ref. 123).

Tripyrrin-1-ones **25** with different terminal substituents R have been obtained by the basic condensation of a formylpyrrole with a hydrogen- or halogen-terminated dipyrrinone **26**, as shown in Figure 7.[98,105,110] Water-soluble sulfonic acid derivatives have also been obtained from hydrogen-terminated tripyrrin-1-ones by the action of sulfuric acid,[113] and unsymmetric tripyrrindiones such as **27** are readily available from the bromo-substituted tripyrrin-1-ones by hydrolysis with aqueous acetate.[97] In addition, the basic condensation is not restricted to pyrrolic aldehydes but allows the preparation of a number of analogs **28** by the use of different aromatic aldehydes (Figure 7).[107,109,173,174]

A related acidic condensation strategy using an unsymmetric dipyrromethane **29** and a formylpyrrole is the key to the synthesis of most of the known tripyrrenes **8** (Figure 8).[126–132] Tripyrrenes have rarely been described in coordination compounds and are mainly used as precursors for the synthesis of unsymmetrically substituted porphyrins or linear tetrapyrroles. An alternative approach has been described in the acidic condensation of a dipyrrinone **26** with an acetoxymethyl-activated pyrrole **30** to give the tripyrrene **31**.[134] Unsymmetric tripyrrin **7** was

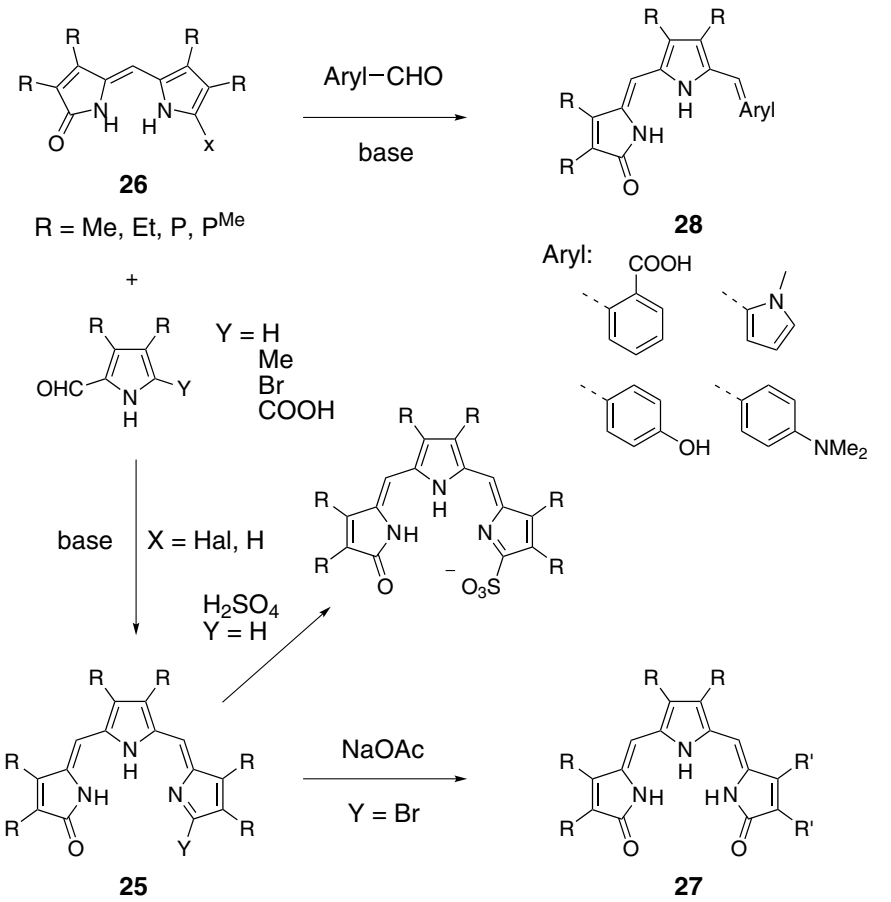

Figure 7. 2 + 1 Condensation reaction for the preparation of tripyrrin-1-ones and related derivatives.

prepared as a precursor for the synthesis of hydroporphyrins by a different strategy, employing the coupling of a dipyrrinthione **32** and the hydrogenated bromomethylpyrrole **33** and consecutive sulfur extrusion.[124,125]

Besides the condensation-reaction-based approaches described above, only little work is reported for tripyrroles using different strategies. The oxidative degradation of natural linear tetrapyrroles results *inter alia* in tripyrrolic products.[175] A multistep photooxidation of biliverdins and other bilatrienes in the presence of Tl(III) or Pb(IV) reagents has been found to produce mainly formyltripyrrin-1-ones,[106,108,111] and a different one-step strategy for the synthesis of these tripyrroles from bilatrienes has been communicated.[115] Bromination of α-methyldipyrrinone **34** also results in the formation of formyltripyrrin-1-one **35**, presumably via a bilatriene intermediate **36** (Figure 9).[112] A seemingly more

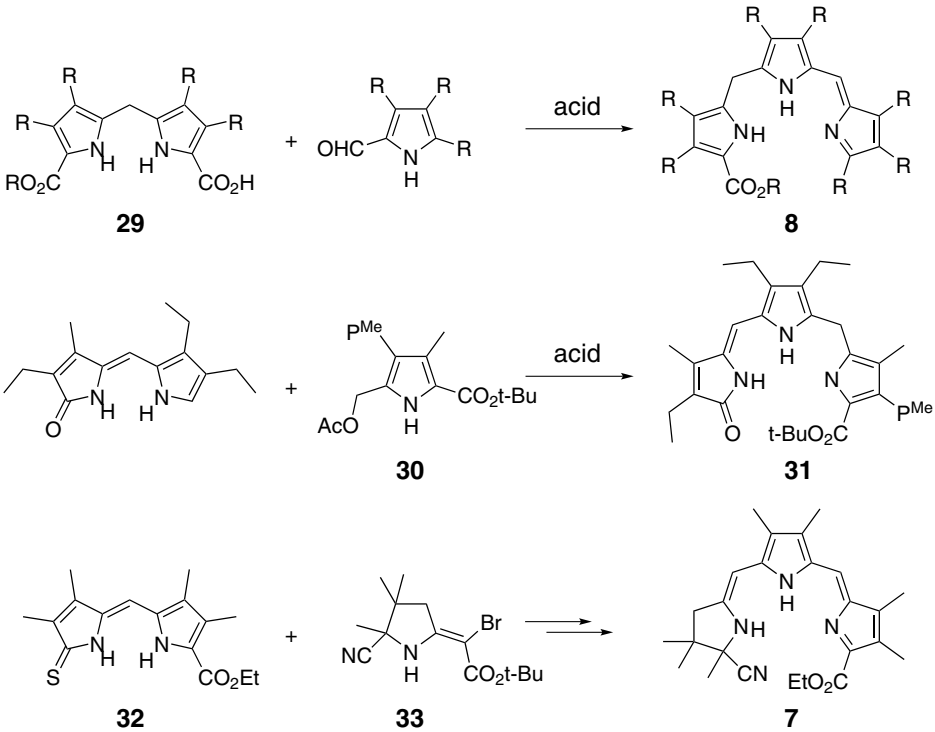

Figure 8. 2 + 1 Condensation reactions for the preparation of partly hydrogenated tripyrroles.

conventional approach to tripyrrins, the oxidative dehydrogenation of tripyrranes **37** and **40** under different conditions, has been reported by two groups (Figure 9).[117,118] No simple tripyrrins were isolated, but tripyrrin-1-ones **38** and **41**, along with methoxytripyrrin **39** and tripyrrin-2-one **42**, respectively, were obtained.

Finally, tripyrrolic compounds **43**–**46** have been isolated and characterized as byproducts from condensation reactions for the preparation of dipyrrins[96] and porphyrins (Figure 10).[116,133]

C. Tripyrroles: Bis(arylimino)isoindolines [H(bai)]

In the course of investigations into the reactivity and properties of heterocyclic amines, Linstead prepared the first bis(arylimino)isoindolines [H(bai)] in 1952.[173–175] The simple preparation and advantageous chemical stability of the H(bai) dyes have led to continual development of novel derivatives ever since. H(bai) ligands contain only one central pyrrole unit, but as their molecular

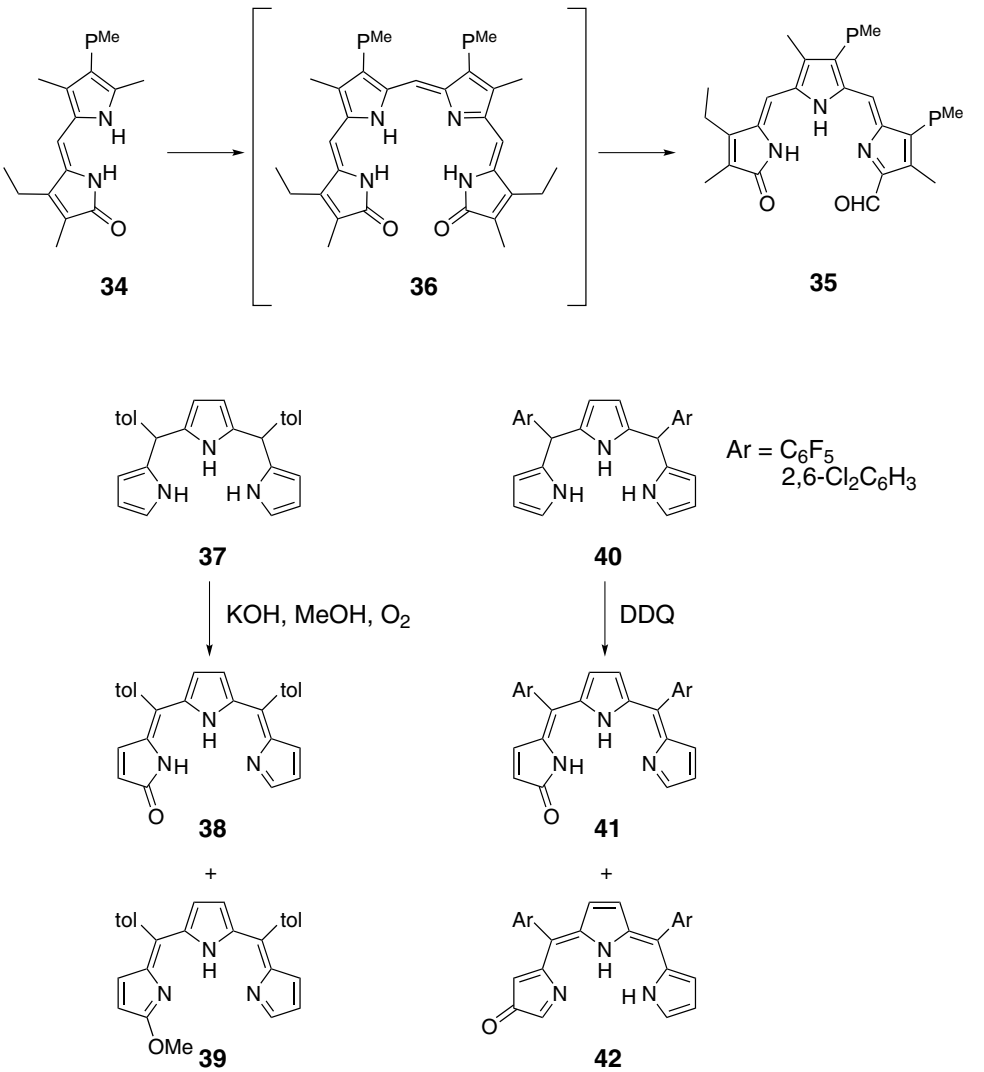

Figure 9. Selected oxidative transformations leading to tripyrrolic ligands.

framework and coordination properties are closely related to phthalocyanines and tripyrrins, respectively, they will be introduced in this section. Linstead's H(bai) synthesis is generally a condensation reaction of the 1,3-di-iminoisoindoline **47** and a heterocyclic amine in an alcoholic solvent, as generalized in Figure 11. In most cases, the heterocyclic endgroups consist of (substituted) pyridyl or thiazolyl moieties. Other terminal groups are possible; however, the investigation of such H(bai) dyes has mainly been driven so far by their optical properties, as these chromophores are bright yellow to red in color.[176–179] Another early investigation

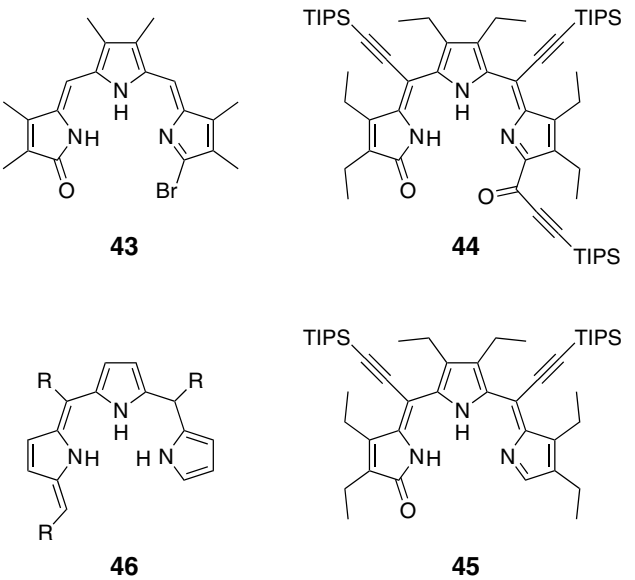

Figure 10. Tripyrroles as isolated byproducts from different condensation/oxidation reactions.

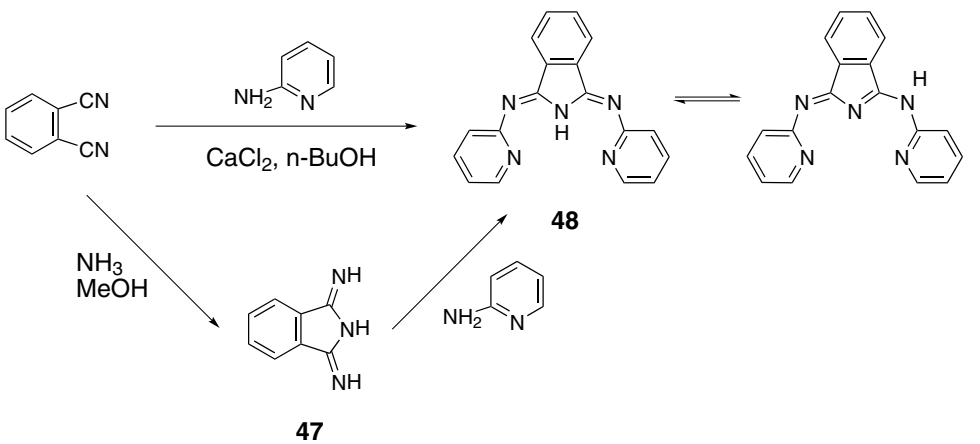

Figure 11. General preparation and tautomers of bis(pyridylimino)isoindoline **48** as an example for symmetric H(bai) ligands.

is the issue of N–H···N tautomeric forms which are present depending on the end groups.[180–185] In this context, several aryl- and alkyl-terminated H(bai) species as well as some monocondensation products have been prepared and studied.[186–188] The substitution of the imino groups of **47** proceeds in a stepwise manner,[173–175] and the role of the alcoholic solvent in the formation of acetale intermediates has

been assumed, similar to the synthesis of phthalocyanines. A broader use of H(bai) compounds as ligands for transition metal ions has been documented in the literature after the development of a one-step synthesis from phthalonitrile and amino heterocycles in the presence of a metal salt, by Siegl (Figure 11).[189–191] Depending on the cation, either the free base ligand (Ca^{2+}, Mg^{2+}) or the respective transition metal–bai complexes form under these usually forcing conditions, in varying yields. Although initally favored over the two-step synthesis, the one-step scheme has been found to be less economical in most reported studies.

H(bai) ligands have been prepared with a number of different end groups and substituents on both the central isoindoline and the terminal heterocycles.[192–202] Several chiral ligands have been prepared.[203,204] Figure 12 provides an overview of the reported derivatives relevant to coordination studies. For some bis(pyridylimino)isoindolines (bpi), functionalization strategies have been worked out, based on either nucleophilic aromatic substitution[190] or palladium-catalyzed coupling reactions.[195]

While several protocols for the preparation of symmetric H(bai) species are known, unsymmetric H(bai) ligands have so far been prepared mainly as mixtures.[186–188] On the base of known preparations of symmetrical H(bai)s, a two-step strategy and a mixed one-step synthesis with separation have recently been proposed and reported for the successful preparation of unsymmetric H(bai)s. In cases with one terminal phenyl and one terminal heteroaryl functionality, the two-step strategy was found advantageous due to tautomerization issues. The introduction of two different heterocycles, however, is usually accompanied by a significant amount of scrambling, so that a one-step process and control of the products by the stoichiometry of the heteroaromatic amines is favored.[205,206] Figure 13 shows the examples prepared to date.

D. Tripyrroles: Bis(oxazolinyl)pyrroles [H(bop)]

Oxazolines and their derivatives, in particular as part of the pybox family of ligands, have been attracting much attention in asymmetric catalysis. Transition metal complexes of the tridentate pybox manifold and of related meridional coordinating N,N,N and N,C,N donor ligands have been intensively studied and have found a wide range of applications. Bis(oxazolinyl) derivatives with a central pyrrole unit show a structurally tight relation to natural tripyrroles and will be discussed in this section. In general, two types of such bis(oxazolinyl)pyrroles [H(bop)] exist: one group with directly linked heterocycles, as in **54**[207,208]; and a second group with two dangling oxazolinyl groups connected via methylene bridges, as in **55**.[209,210] The latter group has a rigidified subgroup with twofold benzo annelation **56**.[211,212] All H(bop) derivatives have been prepared using

the same strategy by a two-step double condensation of a pyrrole dinitrile or di(carboxylic ester) derivative and an amino alcohol (Figure 14). Most derivatives have been prepared from chiral pool amino alcohols and are thus available as enantiomerically pure chiral ligands.

E. Tetrapyrroles: Model Ligands Prepared from Natural Biliverdin and Bilirubin

Chemically simplified bilin derivatives obtained from natural sources have been known for some time,[135,137,138,213,214] as three major drawbacks are associated with the use of natural biliverdin **9** and bilirubin **10** in chemical studies and, in particular, as ligands for coordination compounds. All three issues are correlated with the peripheral substitution of the tetrapyrrole core. The presence of two propionate side chains renders the natural bilines almost insoluble in most organic solvents and provides additional reactive sites for metal ions as well as for hydrogen bridging. This problem is usually overcome by the introduction of methyl or other alkyl esters, as shown for biliverdin derivative **13** in Figure 2. Additional reactivity stems from the vinyl substituents. Substitution by ethyl instead of the sensitive

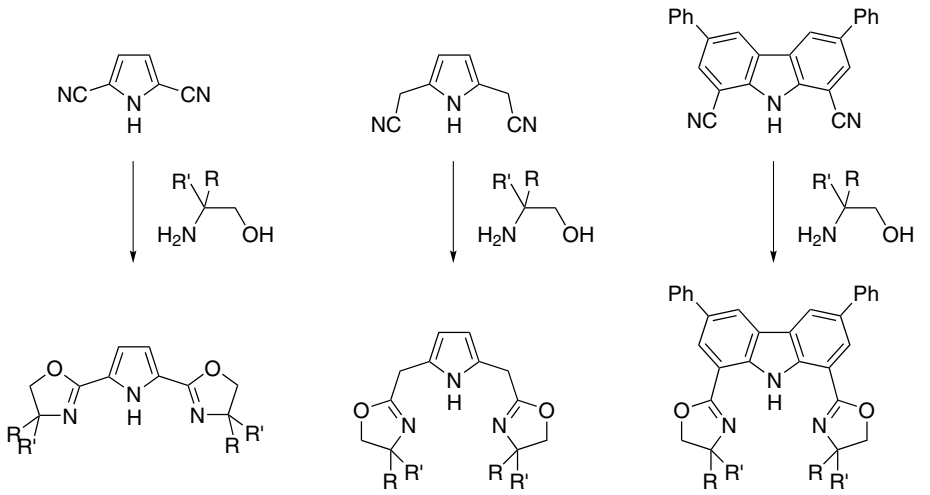

Figure 14. Preparation of the bis(oxazolinyl)pyrrole [H(bop)] ligands **54**–**56**.

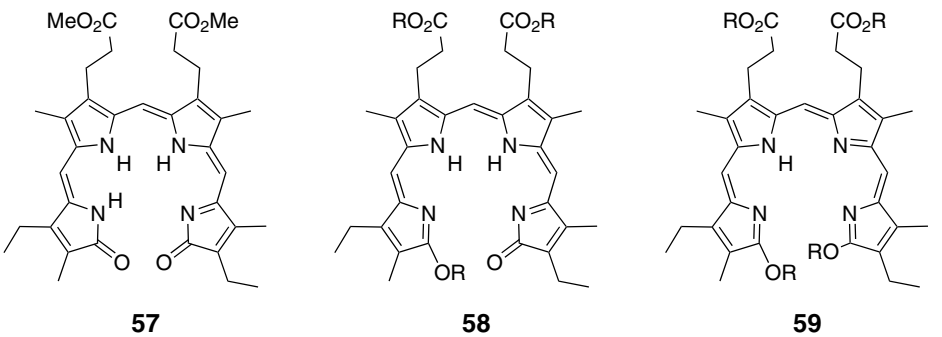

Figure 15. Mesobiliverdin dimethyl ester **57** and O-lactim-ethers derived therefrom.

vinyl groups results in the so-called *meso* forms, which are also of biological origin. These mesobilins are often used as the methyl- or ethyl-esters, thus directing the site of interaction with metal ions exclusively toward the porphyrinoid N_4 cavity (see **57** in Figure 15). The third problem is associated with the terminal oxo groups and relates to different tautomeric forms of the biological species. Figure 15 illustrates that this prototropic dynamic can result in three different protonation states for the same ligand. This ambiguity can be overcome by O-alkylation of one or both oxo groups, thus resulting in ligands **57**–**59** with distinct charges of (3-), (2-), and (1-) in the fully N–H deprotonated states.

F. Tetrapyrroles: Oxidative Ring-Opening of Tetrapyrrole Macrocycles

The naturally occurring degradation processes of heme and chlorophyll are initiated by oxidative ring-opening transformations. Biomimetic and chemical variations of such transformations have been developed and have led to the preparation of a number of different artificial tetrapyrroles. Two protocols — the coupled oxidation of iron porphyrins and the photooxidation of porphyrins and chlorins bound to magnesium, zinc, and other ions — dominate this approach and have also attracted scientific interest in their own right.

Many metal porphyrins undergo the coupled oxidation reaction to give *meso*-oxygenated porphyrinoids,[215] but only for iron porphyrins have the ring-opening and formation of open-chain tetrapyrrolic products been reported. The reaction occurs either under biomimetic conditions with dioxygen and ascorbic acid, or as a shunt reaction in the presence of hydrogen peroxide. Both variants require pyridine as solvent or cosolvent. Iron β-alkylporphyrins **60** (Figure 16) yield bilindiones **61** exclusively with loss of one *meso* carbon atom. For nonsymmetric derivatives, all possible regioisomers are formed in different ratios.[216] Iron complexes of *meso*-arylporphyrins **62** are less selective and react in two steps via a hydrated product **63**.[217,218] This intermediate can be dehydrated to form tetrapyrroles of the aroylbilinone type **64**. Bilindiones **65** form in a side reaction as minor byproducts. The absence of β-situated alkyl groups allows the rotation of the terminal C_4H_2NO unit(s), which results in the presence of conformational isomers **a** and **b** for **63**–**65** (Figure 16).

Photooxidative porphyrin cleavage occurs simply upon irradiation of a porphyrin in the presence of dioxygen. Porphyrins with magnesium, zinc, and cadmium central atoms have been employed mainly for this reaction; however, other metals such as copper, iron, nickel, or thallium may also be used.[219] Two differences are characteristic with respect to the coupled oxidation approach. First, all products are still in the metalated form except for iron derivatives, and free base porphyrins as well as an N-alkylated species have also been shown to undergo the reaction.[220] Second, no carbon atom is expelled during the reaction, so that formylbilinones or aroylbilinones are formed throughout. Mechanistic studies on magnesium tetraphenylporphyrin have shown that initially an intermediate with a four-membered C_2O_2 ring is formed, which then ring-opens to give the observed products (Figure 17).[221,222]

With *meso*-arylporphyrins as substrates, hydrated forms **63** and aroylbilinones **64** are the only products.[223–225] No regioisomers of **64** have been described in the product mixture. Coincidentally, the successive reaction of tetraphenylporphyrin with butyl lithium and O_2/hν has provided a *meso*-butylated aroylbiladienone with the same regiochemistry.[226]

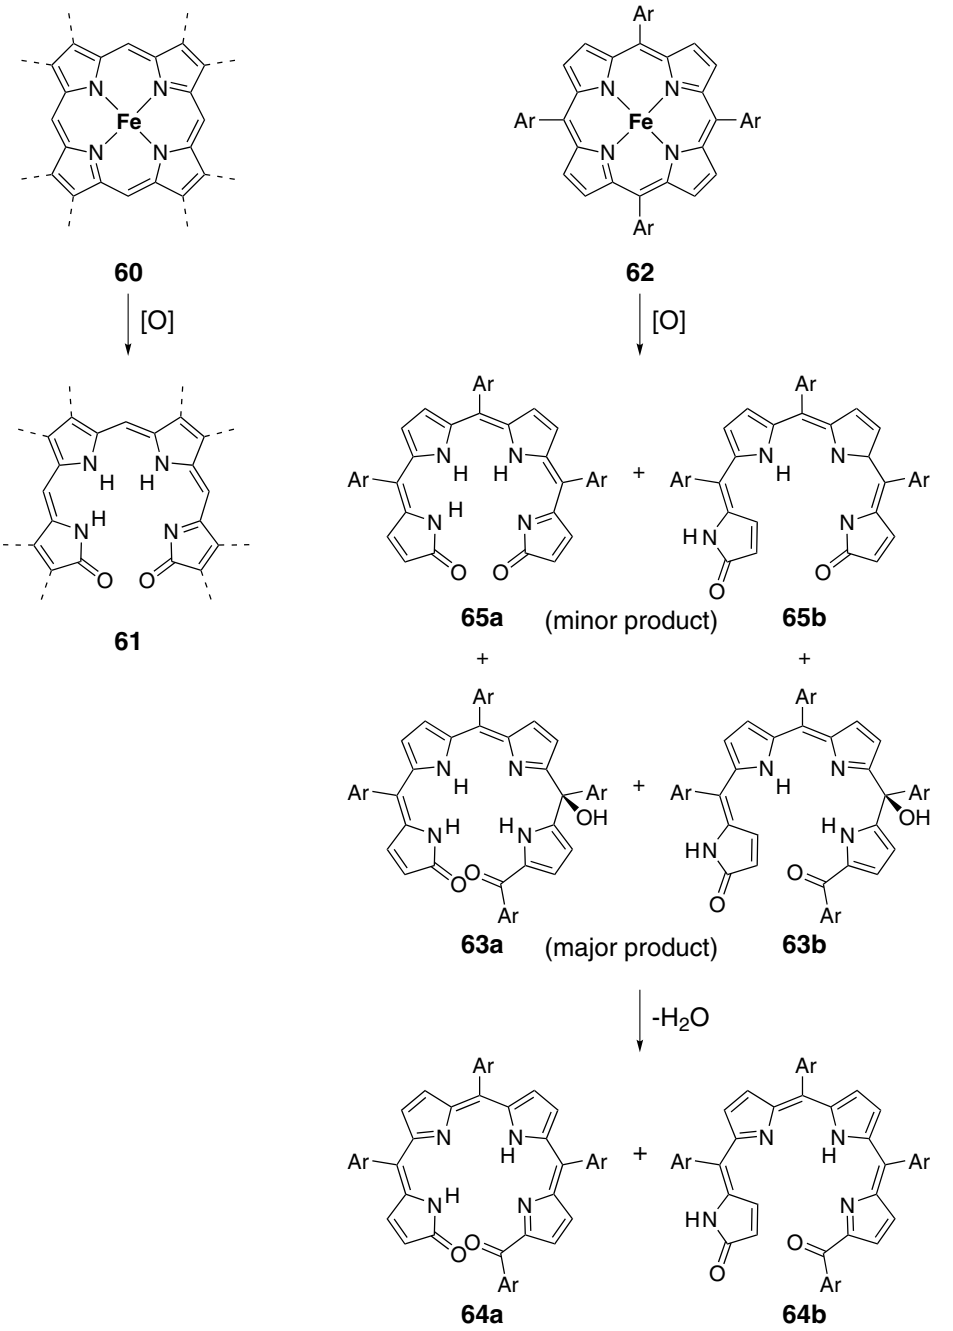

Figure 16. Coupled oxidation of iron porphyrins with β-alkyl- (left) and *meso*-aryl (right) substituents.

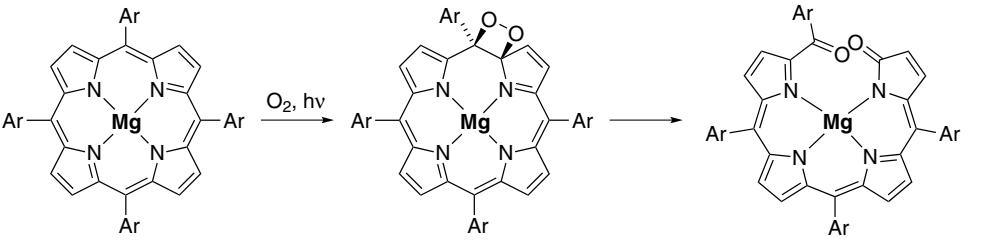

Figure 17. Proposed mechanism for the photooxidation of magnesium tetraphenylporphyrin.

β-Alkylporphyrins form exclusively formylbilinones such as **12** and no hydrated species.[219] The reaction shows a high degree of regioselectivity. In magnesium and zinc complexes of protoporphyrin IX dimethylester **66**, the oxygenation is directed to the position between the two vinylpyrrole moieties. Zinc, copper, and nickel complexes of the partially hydrogenated β-alkylporphyrin **67** (a chlorin) are exclusively opened next to the reduced five-membered ring.[219] For pheophorbide **68** an intriguing dependency of the site of oxygenation from the metal atom (zinc vs. cadmium) has been observed (Figure 18).[227,228] This reaction was also studied mechanistically.[229]

Some further oxygenation protocols leading to ring-opened tetrapyrroles and/or their corresponding metal chelates have been reported. A sterically encumbered octaalkyltetraphenylporphyrin has been successfully oxygenated by sodium nitrite/tfa or by *m*-CPBA/pyridine, resulting in the respective zinc, copper, or nickel chelates of the persubstituted aroylbilinone.[230] Trivalent thallium has occasionally been reported as a powerful oxidant for the ring-opening of chlorins, although overoxidation is a problem here.[231,232] Early work on vitamin B_{12} analogs revealed selective macrocycle opening with ozone,[233,234] and a monoarylcorrole was ring-opened at the direct pyrrole–pyrrole junction by molecular dioxygen to give a biliverdin analog.[235] This latter reaction has, however, not yet found practical application.

G. Tetrapyrroles: Coupling of Dipyrrolic Building Blocks

The coupling methodologies of oligopyrroles differ with respect to the precursor nuclearity and the desired bridges. Coupling reactions of two dipyrroles have been achieved by direct coupling, by coupling through a one-carbon bridge, and by coupling through different functionalized bridges, all using different methods. The direct linkage of dipyrroles on the more reactive α-positions of pyrroles was first observed in 1939 as a serendipitous finding during a debromination study on 1-bromo-9-methoxydipyrrin **71** with elemental zinc.[236] In the same year, the action

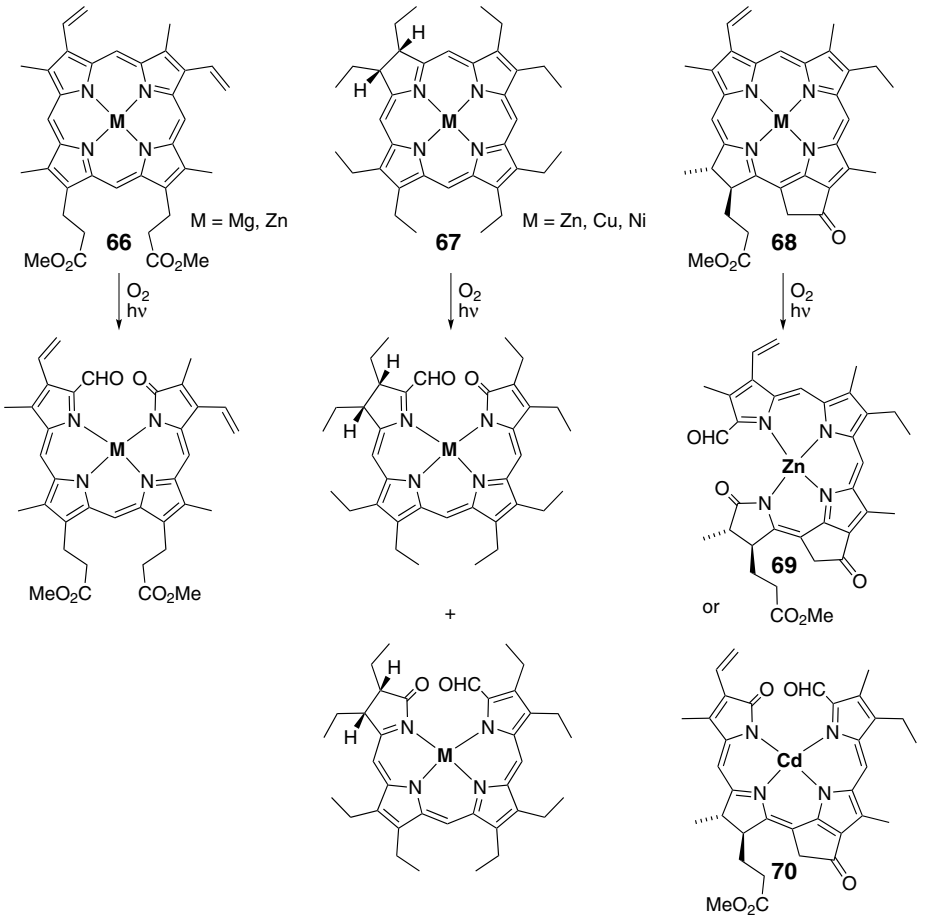

Figure 18. Photooxygenation of different β-alkylporphyrins and chlorins.

of lead(IV) acetate on a nonbrominated dipyrrinone **73** was found to result in the formation of a similar artificial tetrapyrrole, the so-called 2,2′-bidipyrrinone **74** (Figure 19).[237] Twenty years later, a similar reductive coupling of 1,9-dibromodipyrrins **75** with palladium on a solid support was observed[238] and further developed as a method for the preparation of a series of β-substituted 2,2′-bidipyrrins.[239] Three more decades later, the oxidative coupling of dipyrrinone **79** was investigated with a large number of oxidants, leading to products **80** and **81** in different oxidation states (Figure 19).[240]

Meso-aryl-2,2′-bidipyrrins are also available from dipyrrolic precursors. A first example, **82**, was found as a byproduct from a corrole-forming reaction and was structurally characterized.[241] A more directed approach uses the template action of divalent nickel to produce complexes **83**, from which the desired

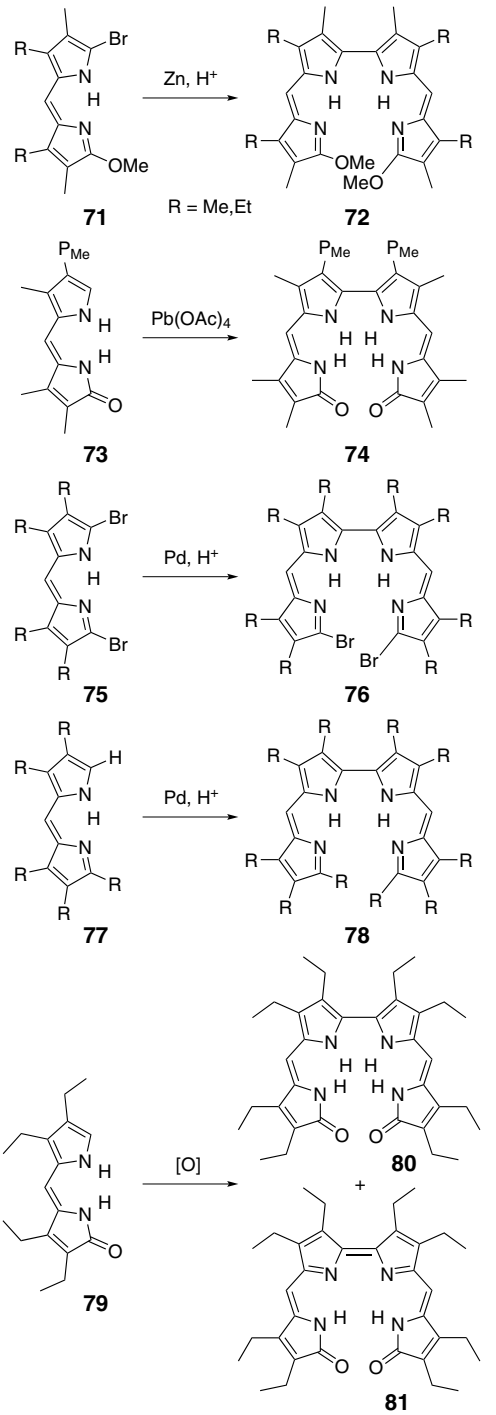

Figure 19. 2,2′-Bidipyrrins from direct couplings of dipyrrolic precursors.

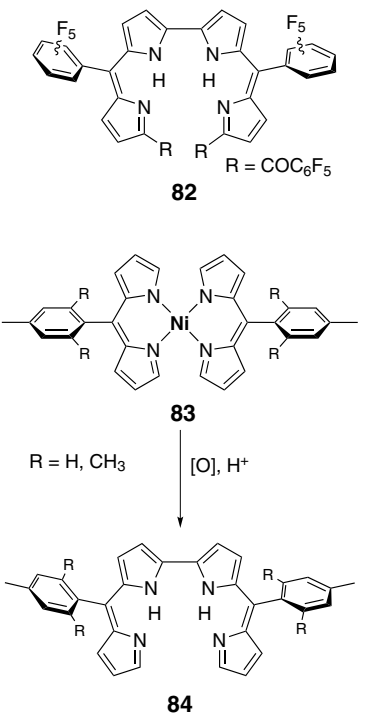

Figure 20. *Meso*-aryl-2,2′-bidipyrrins.

tetrapyrroles **84** could be obtained after oxidative coupling and hydrolytic release (Figure 20).[242]

The introduction of a central CH bridge during the coupling of dipyrrolic precursors has been achieved by the use of trialkylorthoformiate reagents under acidic conditions. Octaethylbilindione **11** has been prepared from the respective dipyrrinone by this method,[243] and chlorin **85** has been described earlier to form under similar conditions (Figure 21).[244] With careful choice of conditions the same reagent was successfully applied to the coupling of the sensitive 2,2′-bipyrrole to give bisnorbilin **86**.[143]

Octaalkylbilindione **88** has been prepared from methylated dipyrrinone **87** by direct oxidation with loss of one carbon atom. Two different protocols employing air and strong alkali[245] or chloranil[246] have been reported for this transformation (Figure 22).

In order to form unsymmetric derivatives and differentiate between the two dipyrrolic precursors, several coupling strategies leading to different types of C_1 bridges have been reported. Methylene bridges can be introduced by coupling a dipyrrole with a bromomethyl or chloromethyl group, e.g. **89**, and an unsubstituted derivative such as **90** under acidic conditions.[247,248] The introduction of a keto

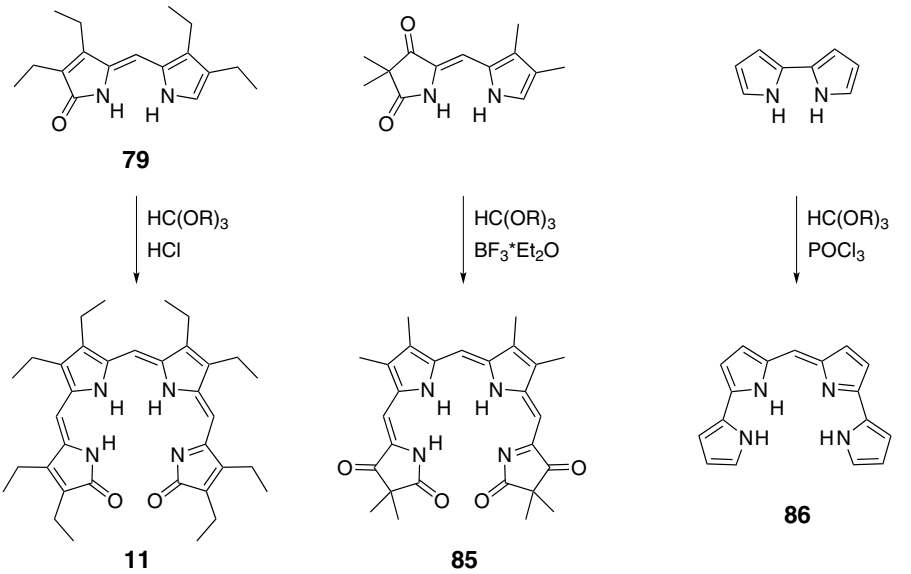

Figure 21. Application of trialkylorthoformiate as C_1-synthon for methine-bridged open-chain tetrapyrroles.

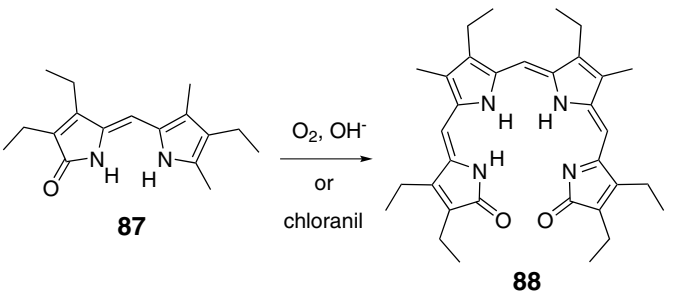

Figure 22. Direct oxidative coupling of α-methyldipyrrinone **87**.

bridge in **91** was achieved by using a dimethylamido terminal group under Vilsmeier conditions (Figure 23).[248]

The most frequently used and most widely applicable method for the coupling of dipyrroles is the acidic coupling of a dipyrrolic aldehyde **92** with an α-free dipyrrole **93** (Figure 24). This reaction typically results in the formation of a stable methine bridge. In many cases, the sensitive α-free dipyrrole is formed *in situ* from an acid labile precursor, especially from a carboxylic acid or *tert*-butyl ester **95** or **96**, respectively. The approach allows the construction of many symmetric and unsymmetric derivatives of the so-called *b*-bilene type **94**.[33,249–251]

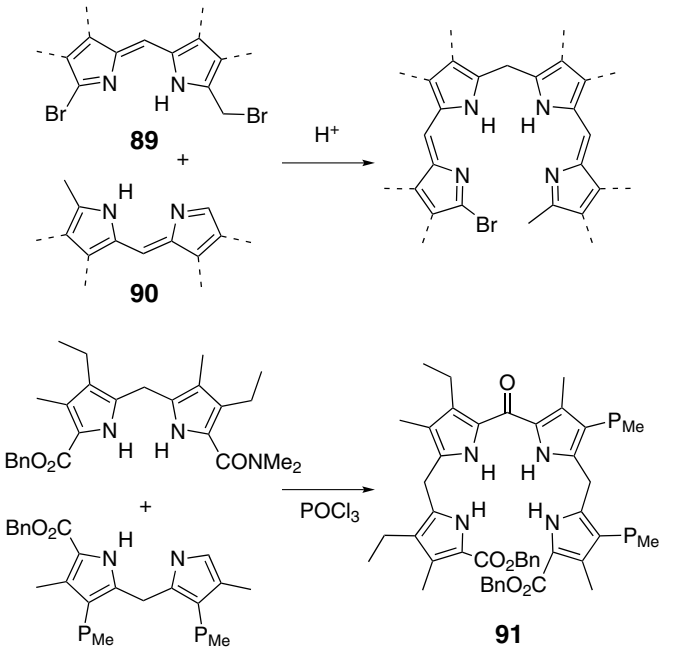

Figure 23. Examples of unsymmetric coupling of dipyrroles through methylene and keto bridges.

Ring-annelated species such as **97** have been accessed from suitable precursors,[252,253] as have been partially hydrogenated tetrapyrroles **98**[153] and **99**,[254] and several bipyrrole-containing species, such as **100**[139,141] or **101**[147] (Figure 24).

A special coupling strategy has been reported in the context of vitamin B_{12} synthesis. This approach couples two dipyrroles **102** and **103** carrying a cyanovinyl group and a lactim-ether, respectively, under alkaline conditions to give tetrapyrrole **104** (Figure 25).[151]

A series of artificial tetrapyrroles with a longer chain central bridge and an (often) extended π system has been prepared from dipyrrinone precursors **105** (Figure 26). Different reagents have been exploited in order to obtain the desired compounds.[255–259] For some of the species the presence of different stable oxidation states has been confirmed. BODIPYs (BOron DIPYrrins) **106** have been used as luminescent building blocks and introduced as functional units in a number of large molecule constructions (Figure 27).[23] Bis(dipyrrins) **107** with the dipyrroles connected to each other at the *meso* position via a large spacer have been built from dialdehyde **108** using the same synthetic strategy as for dipyrrins (Figure 28).[260] A similar approach was successfully applied to the preparation of "Pacman" biscorroles.[261]

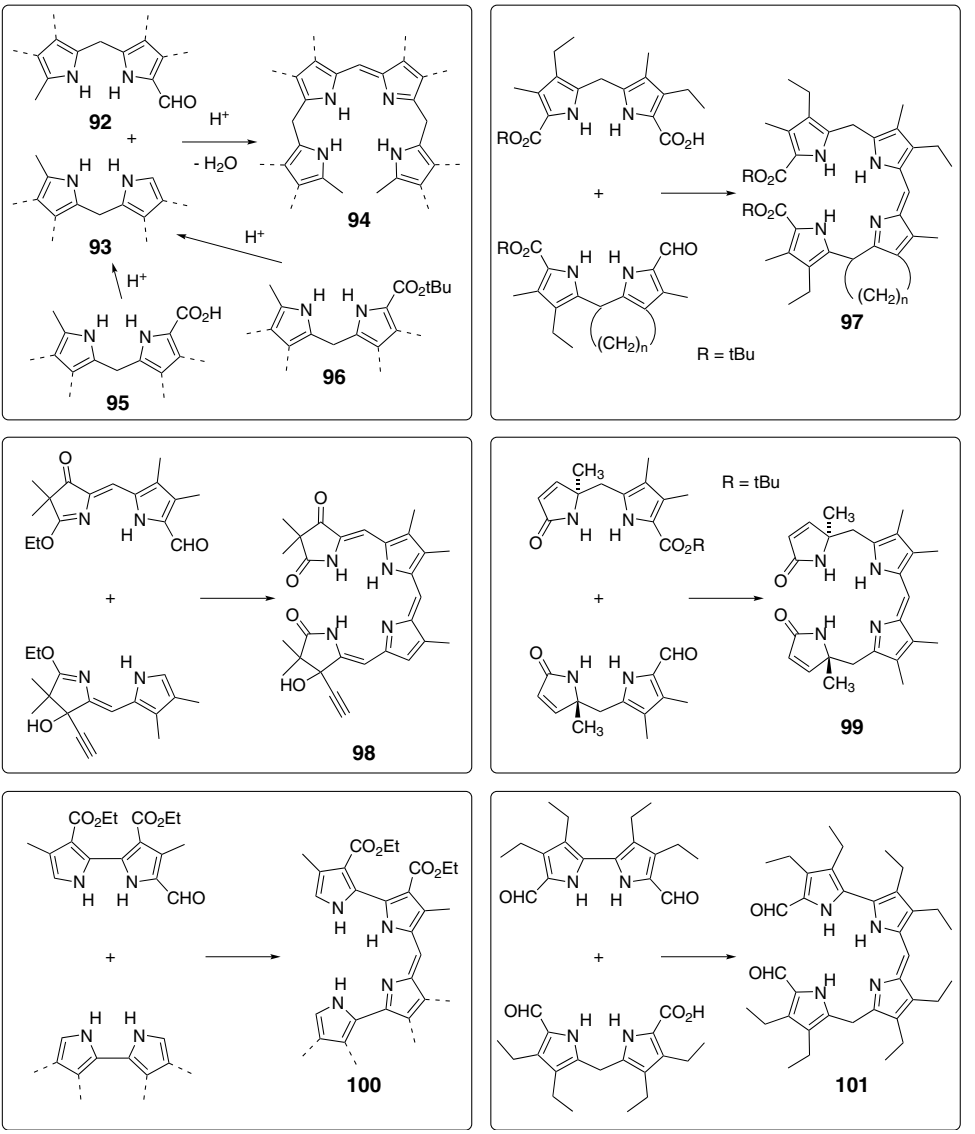

Figure 24. Overview of tetrapyrroles formed by the coupling of a dipyrrole aldehyde with an α-free dipyrrole or related precursor.

H. Tetrapyrroles: Coupling Two Pyrrole Units with a Dipyrrole

This is the most important method for preparing open-chain tetrapyrroles. The coupling of a dipyrrolic center to two pyrrole termini shows the largest number of applications in the literature and allows the construction of numerous variants of all important as well as many less usual tetrapyrrole architectures. The major

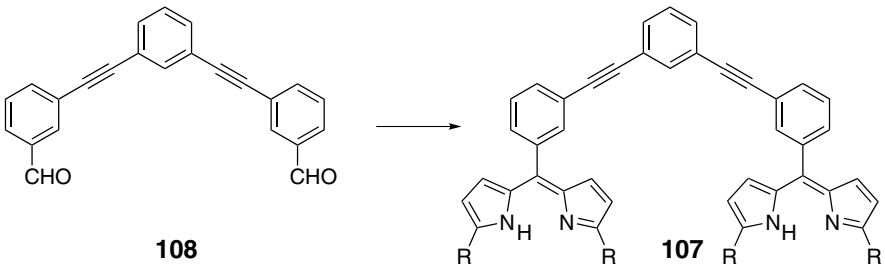

Figure 28. *Meso*-bridged bis(dipyrrin)s **107**.

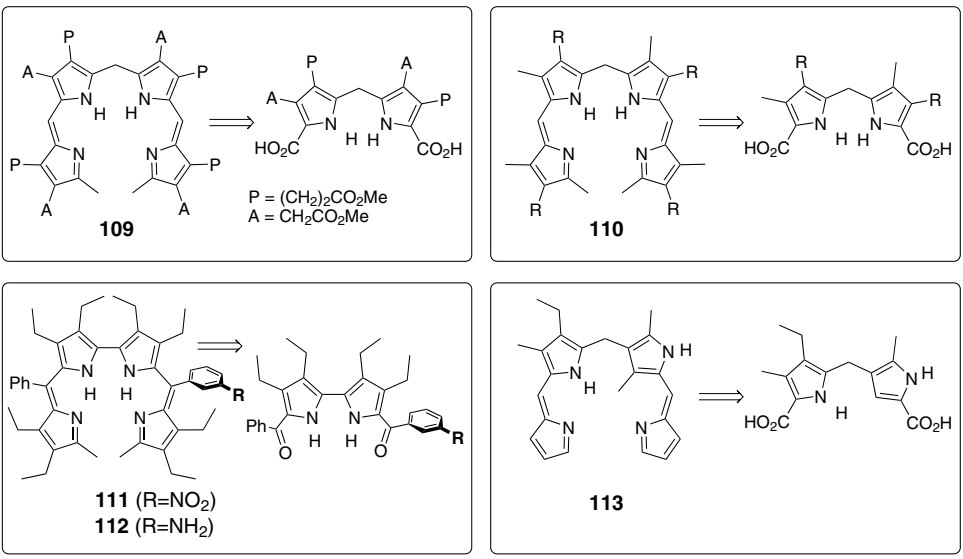

Figure 29. Unsymmetric tetrapyrroles from condensation reactions of one dipyrrolic and two pyrrolic units.

drawback of this approach is found in the necessity to produce C_2-symmetric products. In part, this symmetry constraint can be broken by the use of unsymmetric dipyrroles, as shown by several examples in the past (Figure 29).[129,262–264]

Usually, the coupling is achieved in one step through twofold condensation of an aldehyde with an unsubstituted pyrrole or with a carboxylate, as described above. The aldehyde function may be located on the pyrrolic or the dipyrrolic precursor; however, in some cases different yields have been reported. Only two cases employing different strategies have been described.[265,266] Many derivatives can be found in the literature which are best organized by the type of the central dipyrrole moiety.

2,2′-Bipyrroles have been used extensively as the central building block for tetrapyrroles, and the preparation of many simple alkyl-substituted

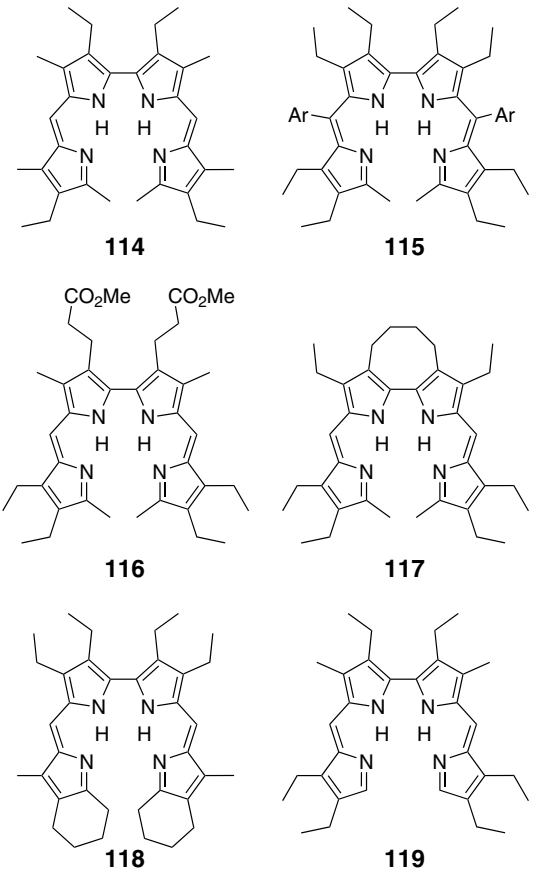

Figure 30. 2,2′-Bidipyrrins **114**–**119** prepared from 2,2′-bipyrrole dialdehydes or diketones.

2,2′-bidipyrrins **114** has been reported from this group of precursors.[27,263,267] Persubstituted derivatives with different *meso*-aryl groups **115** are available under forcing conditions,[263,267] and some functionalized species with biomimetic propionate side chains **116**[268] and with annelated carbocyclic rings **117** and **118**[269–271] are known (Figure 30). Bipyrroles undergo the double condensation reaction only if the keto function is localized at the dipyrrolic precursor. If the terminal positions are free, as in **119**,[270] particularly smooth reaction conditions have to be applied, and several byproducts form from oxidative scrambling reactions.[271]

Due to the biomimetic, bilirubin-like bridging pattern of the tetrapyrrolic products, the so-called *a*,*c*-biladienes, a central dipyrromethane unit, have most often been applied to open-chain tetrapyrrole preparations with this approach. Different alkyl, acetate, propionate, alkoxy, and carboxylic ester side chains are present at the β-positions of these derivatives, and hydrogen atoms,[273,275,281,284]

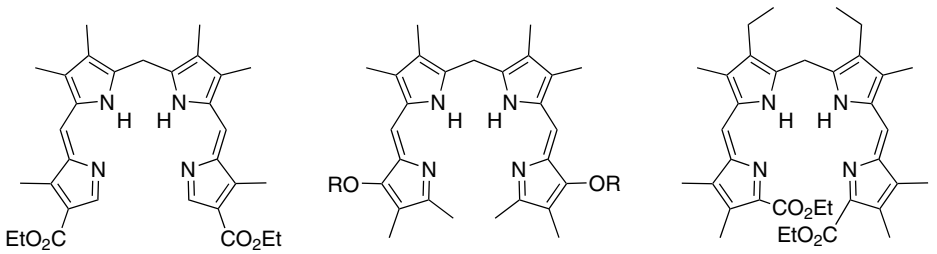

Figure 31. Typical *a,c*-biladienes with different terminal groups.

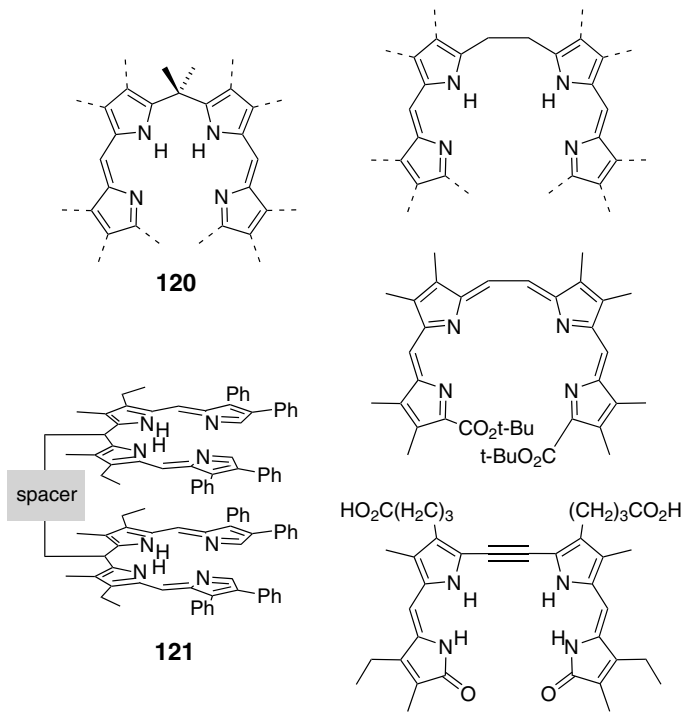

Figure 32. Preparation of *meso*-substituted *a,c*-biladienes **120** and **121**, and an overview of extended biladienes.

methyl groups,[32,128,272–274,276–280,283,284] or carboxylic esters[276,282,283] may be used as terminating entities, as shown in selected examples in Figure 31.

Two types of higher functionalized dipyrromethane building blocks have been described: *meso*,*meso*-dimethyl compounds **120**[239,285,286] and bridged bis-*a*,*c*-biladienes **121**[261] (Figure 32). Both species were prepared in excellent yields using the above methodology. Tetrapyrroles with other extended bridges have only occasionally been synthesized by this approach. In all known cases so far, dicarbon units in different oxidation states constitute the central bridge (Figure 32).[239,287–290]

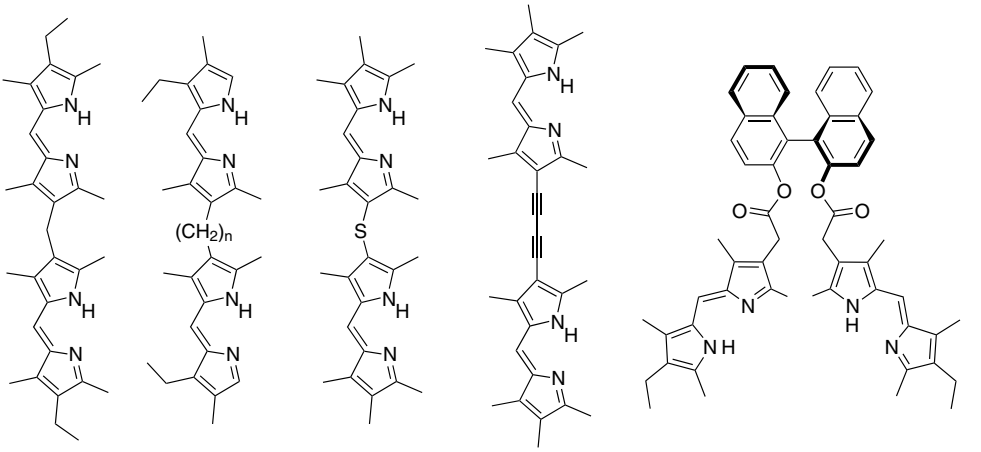

Figure 33. Typical examples for β-bridged bis(dipyrrins) **122**–**126**.

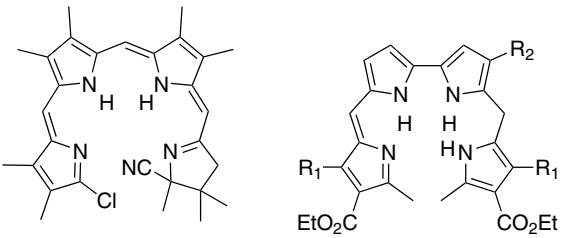
Unique to this approach is the preparation of tetrapyrroles with a central bridge between pyrrolic β-positions (Figure 33). Most studies use a methylene bridge at this position, as in **122**. Both possible options with the aldehyde located at the pyrrolic as well as the dipyrrolic unit have been successfully applied.[291–295] Some further reports deal with similar constructions using longer flexible alkane linkers (C_2–C_8) as found in **123**,[291,296,297] a sulfur bridge as in **124**,[28] or rigid diacetylenes such as **125**.[298] A chiral derivative **126** with the dipyrrins connected by a binaphthyl bridge has been reported.[299] These ligands are often referred to as bis(dipyrrins), as their coordination behavior is more reminiscent of the single dipyrrin subunits than of the bilins.

Functionality has occasionally been introduced with the terminal pyrrole moieties or by a posterior modification. Chiral tetrapyrroles were obtained by the use of enantiomerically pure pyrrole propionates.[300] An *a*,*c*-biladiene with two terminal nickel porphyrin moieties has been described.[40] Benzyl, acetyl, and propionyl substituents have been introduced at the terminal α-positions of *a*,*c*-biladienes as probes for a macrocyclization reaction to porphyrins.[301] Two oxidative protocols have been reported for the introduction of terminal formyl groups in fully substituted 2,2′-bidipyrrins.[302] None of these reports has, however, found any generalization in the preparation of tetrapyrroles to date.

I. Tetrapyrroles: Stepwise Coupling of Pyrrolic Precursors

Further developments in the preparation of unsymmetric open-chain tetrapyrroles have targeted the application of sequences that build the desired compounds from



127

Figure 34. Partially hydrogenated unsymmetric tetrapyrroles **127** and **128**.

single pyrroles in a linear strategy. Several of such approaches have been published, and in some cases relevant material for coordination studies has been reported. In most of the reports, unsymmetric *a*,*c*-biladienes have been prepared for templated macrocyclization studies to yield metal porphyrins.[130,132,301,303–305] In general, the applied method involves an orthogonal protecting group strategy in order to condense a dipyrrole with pyrrole A, and after deprotection with pyrrole B to form the desired product. A hydrogenated chlorin precursor **127** could be prepared by a similar approach,[152] and two early reports confirm the accessibility of a class of unsymmetric, *meso*-hydrogenated 2,2′-bidipyrrins **128** (Figure 34).[141,239]

III. Coordination Behavior and Complex Properties

A. Interaction of Prodigiosenes with Metal Ions

Despite the strong biomedical interest in the prodigiosene group of linear tripyrroles, little is known about the coordination properties of these entities. Early studies on an ethoxycarbonyl-terminated, partially hydrogenated ligand gave analytical data in agreement with a 2:1 complex **129** for Ni^{II} and a hydrolyzed 1:1 species with Cu^{II} **130**.[140] The hydrolysis occurred in the second case only, and the carboxylate anion was assumed to fill the coordination sphere of the copper ion (Figure 35). Several studies suggested a functional role of prodigiosenes as ligands by a measured reactivity such as ion transport[154] or nuclease activity,[150,306] in the presence of certain ions. Divalent copper appears to be the ion of choice in all these studies. Only recently have the first crystallographic analyses of prodigiosene copper and zinc chelates appeared in the literature and confirmed the suggested stoichiometries of the compounds.[307] While zinc(II) chelate **131** was found to reside in the expected tetrahedral arrangement and with two protonated, pendant pyrroles, copper(II) complex **132** contains a N,N,N-bound two-electron oxidized tripyrrole ligand, regioselectively hydrated at the dipyrrin α-position. This hydroxy group is believed to originate from the redox cycling of molecular

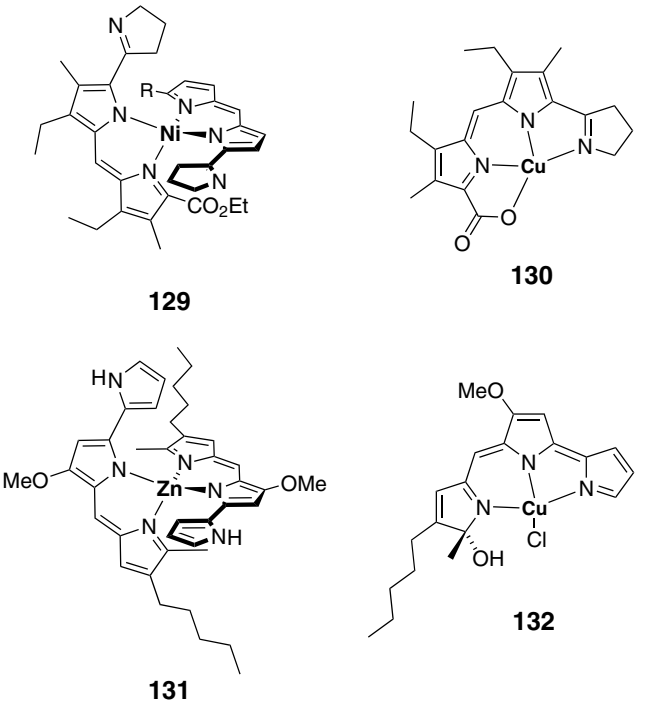


Figure 35. Metal complexes with prodigiosene ligands.

oxygen and Cu^{I} ions, producing hydrogen peroxide, with copper(I) being formed in an initial step by partial copper oxidation of the prodigiosene ligand. A similar Cu^{I}/O_2 driven redox cycling is presumably responsible for the DNA strand scission, i.e. nuclease activity, of this and related species.

B. Tripyrrinone and Tripyrrin Metal Chelates

Although natural tripyrroles with a tripyrrindione core, biopyrrins **3** and **4**, have been known to coordinate to ions, metal chelates of these or artificial tripyrrindiones have not yet been isolated. Some description of the optical properties of zinc and copper derivatives may be found in the literature,[98] but neither crystallographic nor analytical data have so far been reported. Copper and iron complexes of tripyrrin-1-ones **133**–**135** and **136** have been found occasionally as oxidative degradation products of metal chelates of N-confused porphyrin,[100,101] carbaporphyrin,[102] and *meso*-aminoporphyrin (Figure 36).[103] Copper chelates **133**–**135** were investigated in more detail with respect to the regiochemistry of the ring-opening,[103] and to demetalation/remetalation possibilities, and several examples of tripyrrin-1-one complexes with a N,N,N-bound zinc(II), nickel(II), palladium(II), and platinum(II)

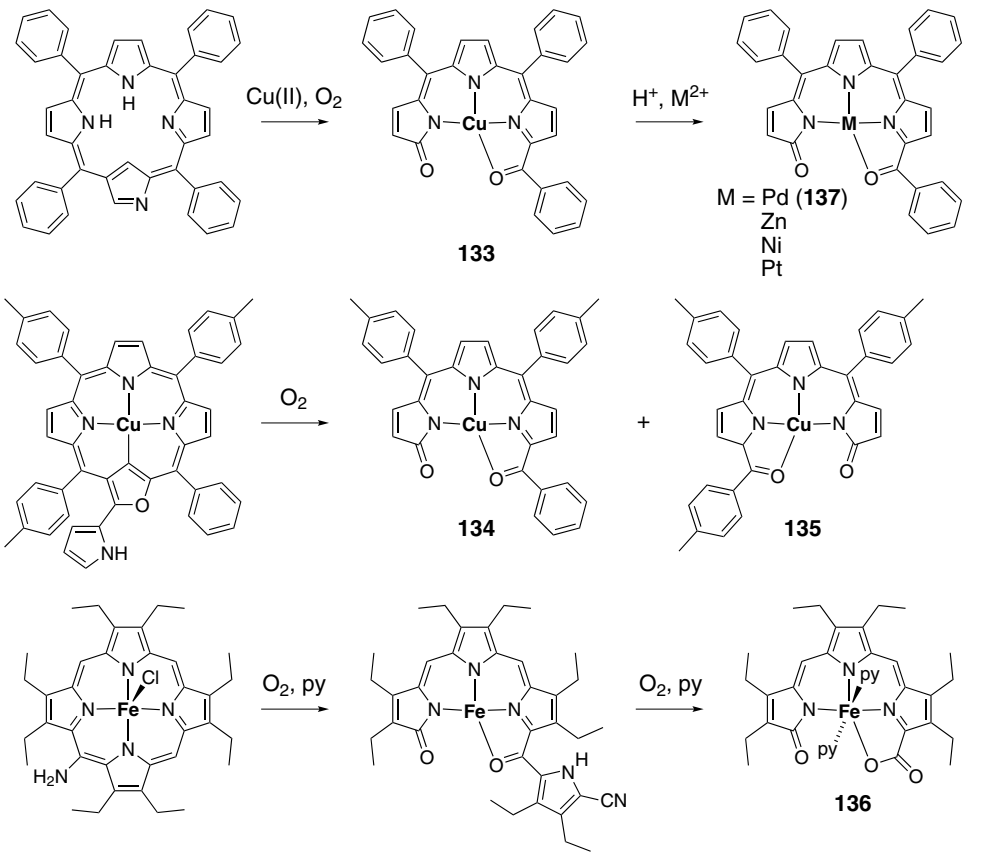

Figure 36. Oxidative degradation processes leading to metal tripyrrin-1-ones.

ion were obtained.[101] Structural characterization has been performed for the iron (see Section V.A), copper, and palladium derivatives. Another structural analysis is available for nickel chelate **138**, which was prepared from **44** (Figure 37).[116] The basic structures of **138** and the palladium example **137** deviate mainly by the different degrees of tripyrrole nonplanarity, which appears to be of sterical origin.

Tripyrrin-1-one carboxylic acids **139** have been found to form a variety of metal derivatives **140** which are insoluble in water (Figure 38).[92,93,95] Further work revealed two distinct groups of species. With iron(II), cobalt(II), rhodium(III), iridium(IV), nickel(II), palladium(II), platinum(II), copper(II), zinc(II), cadmium(II), mercury(II), tin(II), lead(II), and UO_2^{2+} ions, typical transition metal complexes were described, the transformation being accompanied by extensive changes in the IR and UV-visible spectra. NH_4^+, alkali, and alkali earth ions, on the other hand, react with **139** to give sparingly water-soluble compounds, for which a helical arrangement of several tripyrrinone acid molecules around the

metal ion was proposed.[104,105] No crystallographic analysis has been reported, and details of the aggregation process have not been unraveled. A UV-visible titration study later revealed L_1M_1 stoichiometries for transition metal and alkali metal chelates, and a L_2M_1 stoichiometry for the calcium(II) compound.[110]

The copper(II) and zinc(II) chelates **141**–**147** of several tripyrrin-1-ones with carboxylate, sulfonate, and/or alkyl substitution have been prepared by the extraction of the corresponding ions from aqueous solutions (Figure 39). The products have been described as rather labile, and in the case of copper were found to be very sensitive to oxidation by excess copper(II) and by air. The chelates show L_1M_1 stoichiometry and the expected structures for NH dideprotonated tripyrrin-1-one ligands chelating the metal ion in a N,N,N mode. For zinc derivative **148**, however, the tripyrrole is only monodeprotonated, and the lactam ring resides preferentially in the tautomeric hydroximino form. The pH dependence of this tautomeric equilibrium was determined by a spectrophotometric titration.[113] Such

tripyrrin-1-ones and related aryl-substituted dipyrrinones have also been studied in the context of their ability to function as ion transporters for a large number of metal cations.[308–311]

Tripyrrins with terminal alkyl substitution were studied in coordination compounds in some detail. Fully protonated tripyrrin moieties, as formed under the condensation conditions in neat trifluoroacetic acid, decompose very quickly in the presence of nucleophiles and base. The successful preparation of the first examples involved the divalent palladium, zinc, and copper derivatives, which with the corresponding acetate salts gave trifluoracetato complexes **149**–**154**, **167**–**170**, and **176**, **177** (Figure 40 and Table 1).[119–122] Ni(II) could be introduced by the same approach, but the intermediate nickel chelate required an exchange of the anionic ligand (presumably trifluoracetate) with a cyanate ion to give **186/187** in order to gain sufficient stability for the necessary chromatographic separation.[312,313] Nickel isocyanates may be cleanly demetalated using excess cyanide

and have been used as the only source of free base tripyrrin ligands. Remetalation with acetate salts of divalent manganese, iron, cobalt, and cadmium proceeds smoothly and allows access to metal tripyrrins **194**, **197**, **203/204**, and **206/207** as the acetato complexes.[314,315] The diversity of the metal tripyrrins described to date is mainly based on the large variety of axial ligands which may be introduced by simple extraction with an aqueous solution of the appropriate alkali salt.[122,314–316] By this means, halide, pseudohalide, and a variety of oxo anions have been introduced as coligands to metal tripyrrins. For palladium halide derivatives, two alternative routes for ligand exchange have been reported to give advantageous results. Iodopalladium tripyrrin **162** was made under Finkelstein conditions with sodium iodide in dichloromethane, and the chloro and bromo derivatives **160/161** were obtained using the corresponding trimethylsilylhalide at low temperature (Figure 40 and Table 1).[120] All these compounds contain metal ions only in the +2 oxidation state. Electrochemical data are available for a set of chloro complexes with Pd(II), Ni(II), Zn(II), Cu(II), and Co(II). Only copper ions may be reduced to the monovalent state within the tripyrrin environment. Spectroelectrochemical studies revealed exclusively ligand-centered oxidation and reduction steps for all other compounds.[317]

The tripyrrin molecule is formally derived from the macrocyclic parent porphyrin by the loss of one of the four C_4N rings. Chemically, however, the trpy ligand differs largely from the porphyrin with respect to ligand stability and the open *cis*-situated coordination site at the central ion. With regard to the meridional N,N,N coordination and the monoanionic nature, the tripyrrin ligand is closely

related to the class of pincer ligands. The major difference with the tripyrrin systems studied so far appears to be the presence of two terminal methyl moieties which shield the one coordination site situated in the N_3M plane of a given complex. Neutral palladium(II) complexes of such α,ω-dimethyltripyrrin ligands are typically characterized by the steric repulsion which is present between the anionic coligand (in particular the donor atom of that coligand) and the two methyl groups situated at the termini of the open-chain tripyrrole (methyl termini). The steric overcrowding at the open site of the linear tripyrrole leads to strained, nonplanar structures, and in one case even fluxional behavior has been observed, i.e. a dynamic interconversion process between two different nonplanar conformations **210**-I and **210**-II (Figure 41).[119–121,318] These two limiting conformations have so far been the only ones observed for neutral palladium tripyrrin species, and they have been named *strained pseudoplanar* and *helical*, in accordance with the corresponding tripyrrole conformation. In the pseudoplanar conformation, the Pd^{2+} ion is bound in an intermediate situation between distorted square-planar and distorted tetrahedral, while for the helical form a planar coordination of the

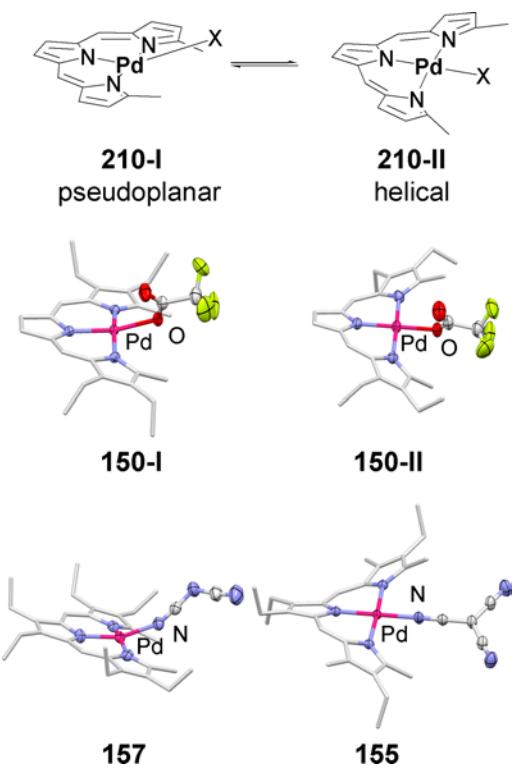

Figure 41. Structural aspects and dynamics of neutral palladium tripyrrins (crystallographic figures adapted from Refs. 120 and 316).

palladium(II) ion results. The pseudoplanar scenario is present in the majority of compounds,[120] while the helical form has mainly been observed with the trifluoracetato ligand. In addition, a linear coligand containing a small donor atom increases the chance to observe (trpy)Pd species in the helical conformation. The N-donor pseudohalides thiocyanate and tricyanomethanide have been used successfully for this purpose. The related dicyanamido ligand, on the other hand, produces palladium tripyrrins which reside exclusively in the pseudoplanar form.[316] The inner strain of palladium tripyrrins supports ligand exchange processes and has been used to prepare a variety of cationic derivatives (see Section IV.A).

In contrast to the situation with palladium, nickel(II) tripyrrins usually contain a high-spin-configurated d^8 ion in solution and in the solid state, with a structure described as unstrained pseudoplanar, as demonstrated for cyanato derivative **186** in Figure 42. The coordination environment of the nickel ion in these species is strongly distorted toward a tetrahedron.[312,313,319] The only known exceptions are cyano complexes **188** and **211**, in which low-spin nickel(II) ions are present. In both species strained pseudoplanar conformations with distorted square-planar coordination of the nickel ions are realized, regardless of the terminal or the bridging binding mode of the cyano ligand (Figure 42).[319] A typical probe for distinguishing between the strained and the unstrained pseudoplanar forms, besides the spin-state-dependent Ni–N distances, is the distance between the methyl termini of the tripyrrin ligands and the donor atoms of the coligand. For example, this distance is 3.406–3.503 Å for the unstrained cyanato derivative **186**, but only

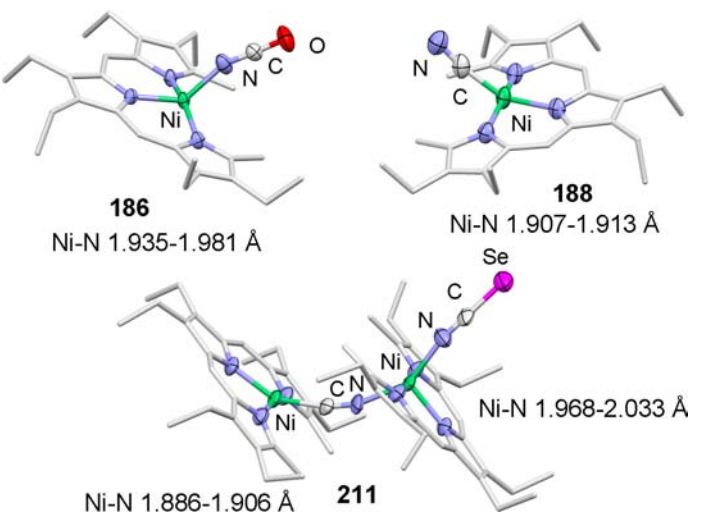

Figure 42. Structural aspects of high-spin and low-spin nickel(II) tripyrrins. (Adapted from Ref. 319.)

2.993–3.018 Å for the strained cyano complex **188**. Another marked difference in this regard is the finding that metal tripyrrins in the strained pseudoplanar conformation do not accept a fifth donor atom (for an exception see Section IV.A), while unstrained pseudoplanar examples readily bind to one, but not two, additional donor or solvent molecules, and form products with five-coordinate nickel. Thermodynamic data are available for the binding of pyridine N-oxide to a chloronickel tripyrrin.[312]

Four-coordinate complexes of the tripyrrin ligand with divalent cobalt, copper, and zinc centers also tend to form unstrained pseudoplanar molecules. Examples are the halide and pseudohalide species **173**, **180**, **184**, and **200**, summarized in Figure 43. As for the nickel chelates, these complexes tend to bind a

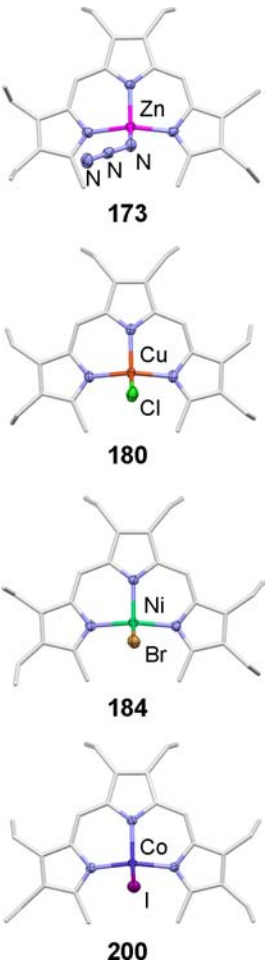

Figure 43. Four-coordinate tripyrrin (pseudo)halide complexes with different 3d metal centers. (Adapted from Refs. 122, 312 and 314.)

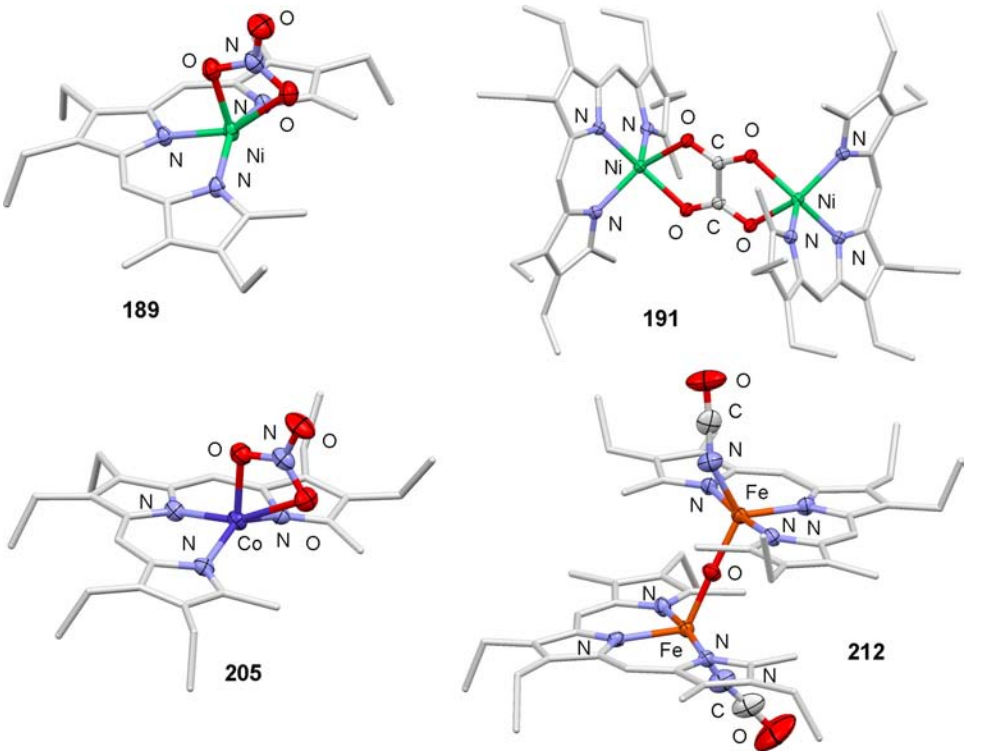

Figure 44. Metal tripyrrins of iron, cobalt, and nickel in different trigonal bipyramidal forms. (Adapted from Refs. 314 and 319.)

fifth donor atom. This tendency, however, is less pronounced for the smaller copper and zinc ions. If bidentate ligands such as nitrate, salicylate, oxalate, or acetate are employed, nickel and cobalt tripyrrins prefer a chelating η^2-coordination and formation of five-coordinate species with a strained trigonal pyramidal structure, as in **189**, **191**, and **205** (Figure 44). Linear or stretched polydentate ligands, on the other hand, yield 1D coordination polymers with the metal tripyrrin building block in an unstrained trigonal bipyramidal situation (see Section VIII.A).[121,122]

Attempts to crystallize simple iron or manganese tripyrrins have not been successful so far. These compounds are reported to be extremely sensitive with respect to dissociation as well as oxidation, so long-term crystallization attempts usually resulted in the decomposition of the material. In one instance, however, the slow crystallization of an iron tripyrrin with isocyanate coordination yielded a small amount of very sensitive dark violet crystals that were shown by XRD to consist of the μ-oxo derivative **212** (Figure 44). Compound **212** is so far the only

example of a metal tripyrrin with the metal in an oxidation state other than +2. Further spectroscopic data of **212** were not reported.[314]

Ligand exchange experiments on cadmium tripyrrins disclosed a marked tendency toward pentacoordination, which is achieved by the formation either of chelates or of 1D coordination polymers arising from the size of the central metal. The attempted introduction of chloro, iodo, or cyanato ligands, instead, led mainly to decomposed material, while the use of 1,1,1-trifluoracetylacetonate, salicylate, and acetate ligands resulted in stable, pentacoordinate, and monomeric complexes such as **208** or **209**, with the external ligand bound as a four- or six-membered O,O-chelate ring (Figure 45).[315] With the pseudohalogenido ligands thiocyanate, selenocyanate, and azide as well as with the weakly coordinating trifluoroacetate, 1D coordination polymers with a variety of chain structures were obtained (see Section VIII.A). Treatment with fluoride and other basic anions like hydroxide, phenoxide, or *tert*-butoxide does not result in the expected formation of the ligand exchange product or in the breakdown of the sensitive tripyrrolic ligand framework, but yields the sterically congested 2:1 product, bis(tripyrrinato)cadmium(II) **213**, as the only isolated compound in an almost quantitative yield. Compound **213** is the only tripyrrinate with a hexacoordinate metal center observed so far. The compound is very stable and was characterized by means of solution spectroscopy and single crystal X-ray diffraction (Figure 45). The result of the X-ray crystallographic analysis demonstrates the chiral nature of single molecules of **213** in the solid state. This chirality stems from the helical distortion of both tripyrrin ligands, which in turn is the structural answer to the presence of a steric constraint at the open face of this ligand. In solution, however, the compound was reported to racemize rapidly.[320]

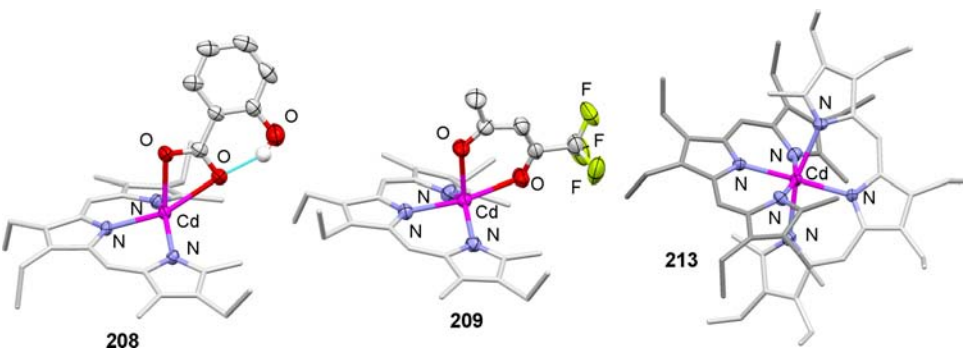

Figure 45. Examples of five- and six-coordinate cadmium tripyrrins **208**, **209**, and **213**. (Adapted from Refs. 315 and 320.)

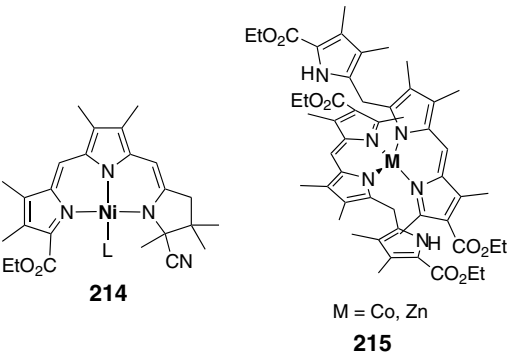

Figure 46. Coordination compounds of partially hydrogenated tripyrroles **7** and **8**.

A small number of reports have appeared concerning coordination compounds of other tripyrroles. Two types of partially hydrogenated tripyrrins were employed as ligands. Nickel(II) complex **214** (Figure 46) was reported to function as a stabilized storage form of the corresponding, highly sensitive free base tripyrrin **7**, which is used as an intermediate for the preparation of sophisticated, functionalized chlorins.[124,125] Tetrahedral cobalt(II) and zinc(II) complexes were prepared from *meso*-hydrogenated tripyrrene **8**, a precursor for unsymmetric porphyrins, and characterized in solution as the L_2M_1 species **215**.[128]

Several examples of tri- and tetrapyrrolic ligands with N,N,N,O coordination have been reported. This coordination is known for carbonyl, carboxylate, and sulfonate terminated tripyrrin-1-one complexes. Structural proof beyond these species has been obtained accidentally in those cases summarized in Figure 47. Nickel(II) salts react with biladien-5-ones to give tripyrrin chelates **216** and **217**.[321] Both compounds show evidence of an oxidative introduction of a hydroxo or methoxo group, respectively, during the metalation process, as seen above for the copper chelate of prodigiosene **132**. Metal chelates of a *meso*-alkylated tetrapyrrole were obtained, and two stereoisomers **218** and **219** were characterized.[226] A copper(II) complex of a *meso*-oxotripyrrin **220** forms from the tripyrrane precursor under oxidative conditions. Demetalation/remetalation allows the preparation of isostructural zinc(II) and cobalt(II) chelates of this new ligand.[114]

A hybrid dipyrrin/pyrrole/Schiff base ligand was observed as a square-planar nickel(II) complex **221** from an unexpected hydration/condensation sequence and was analyzed by structural means (Figure 48).[322]

C. Bis(arylimino)isoindoline Complexes

Middle and late transition metal ions as well as most noble metals have been employed in general studies concerning the preparation and properties of bai

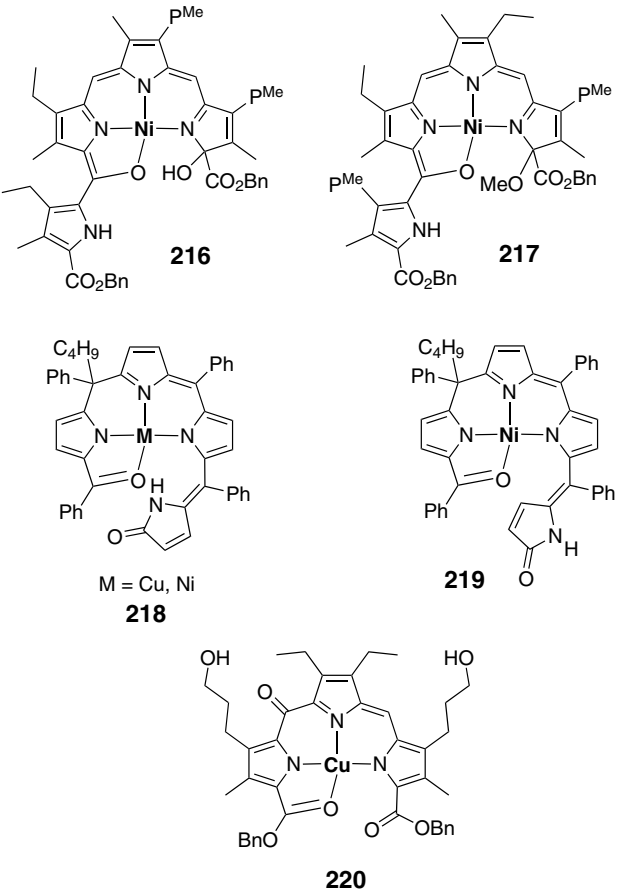

Figure 47. Coordination compounds of tri- and tetrapyrroles with N,N,N,O coordination.

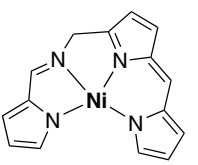

Figure 48. Unexpected formation of tripyrrole imine complex **221**.

complexes. Many of these studies are strongly focussed on an application such as catalysis or bioinorganic modeling. Most of the compounds described so far are of either the L_1M_1 or the L_2M_1 stoichiometry. The first metal chelates of unsubstituted parent ligand H(bpi) **48** were described by Elvidge and Linstead in 1952.[173]

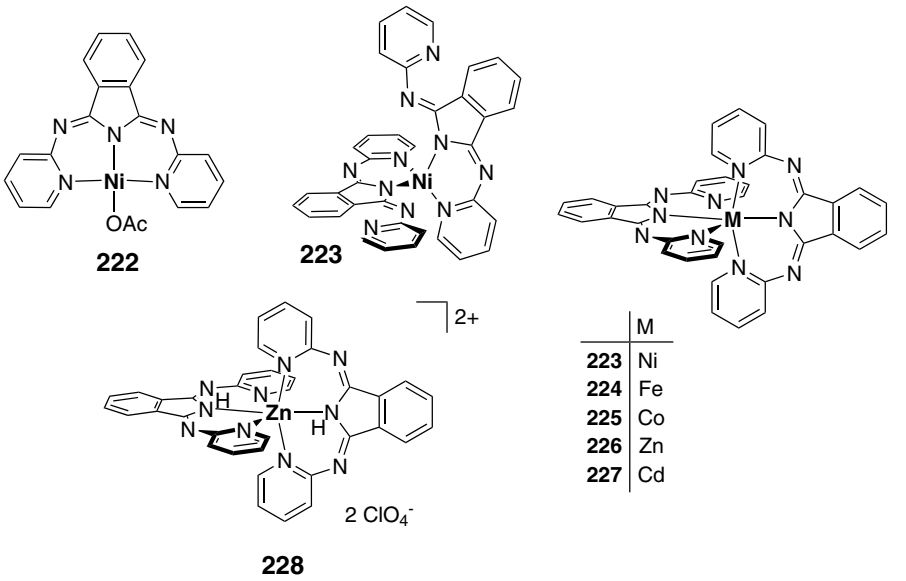

Figure 49. Early assignments of metal chelates **222**–**228** with the bpi and H(bpi) ligands.

Two species were obtained by the action of nickel(II) acetate on **48** and assigned to L_1M_1 and L_2M_1 compounds **222** and **223**, respectively, on the basis of analytical data. The tetracoordinate structure of **223** was later corrected in favor of the octahedral species (Figure 49).[184] In this second report about metal bai compounds, further L_2M_1 compounds [M = Fe(II), Co(II), Zn(II), and Cd(II)] **224**–**227** were discussed, and characterized by optical, magnetic, and analytical methods. At ambient temperature, octahedral coordination and high-spin configurations were found throughout the series, and double protonation was observed if perchlorate salts and no additional base were employed in the coordination of H(bpi) **48**. Results from optical and vibrational spectroscopy on these protonated complexes pointed to the presence of two NH groups per molecule. The location of these protons was first assumed at the central pyrrole nitrogen of the ligands, as depicted for **228** in Figure 49, since this is the most basic site of the bpi anion.[184] Later work provided crystallographic proof for the protonation of the bridging imino groups (see below).[323]

Detailed analyses of the electronic and magnetic structures of L_2M_1-type bpi complexes **223**–**225** and **229** with the divalent ions of nickel, iron, cobalt, and manganese, respectively, and of several simple alkylated bpi derivatives have been performed, and the room temperature susceptibility data as well as optical spectra of these series of compounds proved the presence of high-spin species throughout. Electrochemical data were provided for compounds with the 4-Mebpi ligand.[183]

Paramagnetic NMR spectra could be fully assigned on the basis of data obtained by high-field, high-resolution ^{2}H NMR experiments. $(bpi)_2Zn$ **226** was studied as a diamagnetic reference compound for corrections, and EPR data were obtained for cobalt derivative **225** (Figure 50 and Table 2). In addition, the first crystallographic analysis of a L_2M_1 bai chelate, $(3\text{-Mebpi})_2Mn$ **230**, was reported. The geometry about the metal center is a distorted octahedron. Because the two 3-methylpyridyl groups of a single bpi unit are unable to span the metal, their average *trans* angle is reduced from 180° to about 160°, and the planarity of the conjugated π system of **230** is lost in favor of a slightly helical conformation due to steric congestion.[324]

$(bpi)_2Fe$ **224** and a derivative (**244**) carrying a methyl group at the isoindoline backbone were later characterized structurally.[194,325] Both derivatives showed

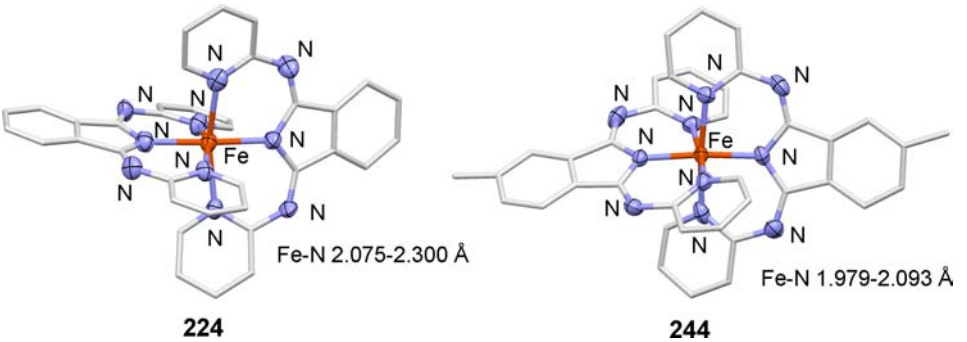

Figure 51. Molecular structures of $(bai)_2Fe$ compounds **224** and **244**. (Adapted from Refs. 194 and 325.)

iron–nitrogen bond lengths of about 2.0–2.3 Å, characteristic of high-spin Fe(II). A Mössbauer study on **224** confirmed this assignment (Figure 51).

Acetatonickel(II) complex **222** of the L_1M_1 type, already described in the first report of metal bai chelates, had been obtained again as a byproduct of $(bpi)_2Ni$ synthesis, and was characterized electronically as a high-spin species at ambient temperature.[184] Further L_1M_1 chelates **245**–**247** with the acetate coligand and M = Co(II), Cu(II), and Zn(II) have been described as isolated products from the template synthesis of bpi (Figure 52).[191] Ni(II), Co(II), and Cu(II) proved to be good template ions and gave good yields in this transformation, while for Zn(II) only 20% of the product could be obtained. Divalent nickel was also successfully used in the template syntheses of several other bai ligands from 2-amino-3-methylpyridine, 2-amino-4-methylpyridine, 2-amino-5-methylpyridine, 2-amino-5-chloropyridine, and 2-aminothiazole, but was unsuccessful with 2-amino-6-methylpyridine, 2-amino-4,6-dimethylpyridine, 2-amino-4-methylthiazole, aniline, 3-aminopyridine, 4-aminopyridine, and 2-aminopyrimidine. The diversity of metal bai complexes was further increased by the description of successful ligand exchange reactions of acetate against azide for the simple nickel and copper chelates **248** and **249**.[191] In later work, ligand exchange was undertaken on (bpi)Ni(OAc) **222**, and new halide, pseudohalide, and cyanamide compounds were reported as well-studied products. The latter cyanamides, such as **250**, were reported to contain a low-spin Ni(II) ion, which is easily solvated to form five-coordinate high-spin species (Figure 52). Thermodynamic parameters have been measured for this association process, and the results suggest that both electronic and steric factors play important roles in determining the stability of the solvated complexes.[326]

The chemistry of copper bai complexes was developed mainly in the context of bioinorganic mimicking of redox enzymes and of the interaction of Cu(I) with dioxygen. Acetato complex **251** was prepared from the components by a

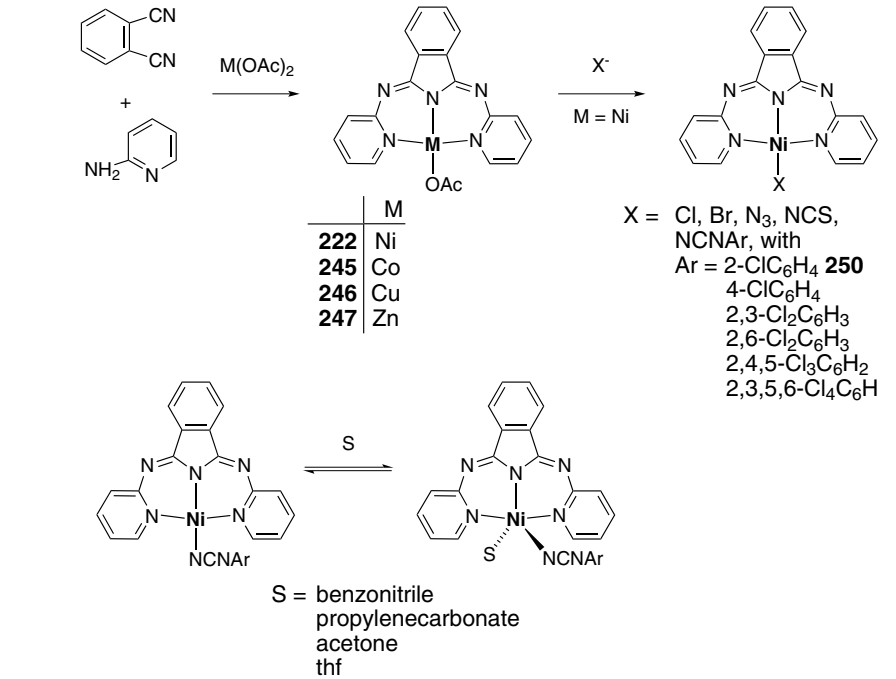

Figure 52. Template synthesis of acetato metal bai complexes, and ligand exchange chemistry on [(bpi)Ni(OAc)] **222**.

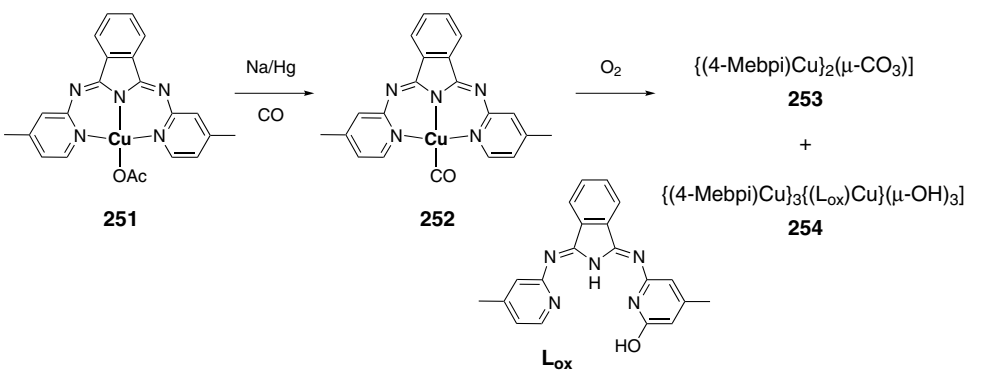

Figure 53. Cu(I)/O_2 reactivity in the 4-Mebpi system.

stoichiometric reaction, and gave carbonyl copper(I) species **252** upon reduction with sodium amalgam in the presence of CO (Figure 53). **252** reacts with dioxygen under the formation of two products: a carbonato-bridged dimer **253** and a tetranuclear hydroxo cluster **254** with the partially oxygenated bpi ligand.[327] Both products were identified by single-crystal analyses.

Two different bai-based model systems for galactose oxidase (GO), a fungal H_2O_2-producing enzyme, have been reported. A structural model **255** containing a distorted pentacoordinate copper(II) ion in a N_3O_2 ligand field was prepared from 5-Mebpi and a deprotonated dibenzoylmethane ligand. EPR analysis of a microcrystalline sample of this compound showed a dipolar spin coupling, which was explained by the formation of weakly associated dimers in the crystal lattice.[328] Acetato complex **251** with the 4-Mebpi ligand could be crystallized with one additional water ligand in a different five-coordinate N_3O_2 environment. This compound has been studied as a spectroscopic model of the GO active site with respect to the influence of cyanide and other anion binding on EPR and optical spectra.[329] For quercetin dioxygenase, another copper-dependent oxidoreductase, a functional model complex **256**, was reported.[330] Compound **256** formed upon treatment of mesitylcopper(I) with flavonol H(fla) in the presence of H(bpi) **48** as a diamagnetic complex, which on reaction with molecular oxygen underwent oxidative splitting of the C2–C3 bond of the pyranone ring of the flavonolate ligand to give the copper(I) chelate [(H(bpi))Cu(O-bs)] (O-bs = O-benzoylsalicylate) and carbon monoxide. The reaction of $[Cu(an)_4]ClO_4$ (an = acetonitrile), H(fla), and H(bpi) with dioxygen at room temperature affords the paramagnetic copper(II) complex $[(H(bpi))Cu(fla)]ClO_4$, and after elimination of $HClO_4$, [(bpi)Cu(fla)] **257** is formed. The latter undergoes cleavage of the pyranone ring upon oxygenation at 80 °C to give [(bpi)Cu(O-bs)] and carbon monoxide. [(bpi)Cu(fla)] and its perchloric acid adduct serve as good catalysts for the oxygenation of flavonol to O-benzoylsalicylic acid. Figure 54 provides an overview of the different oxygenase models.

More structural information on copper bai species is available through an acetato copper(II) complex with a benzoannelated ligand,[331] a chiral polysubstituted example,[203] and a twofold hydrated pentacoordinate cation as perchlorate.[332] Another, quite instructive study compares the conformation and catalytic performance of two simple acetato copper(II) complexes with a bpi- and a thiazole-based bti ligand, **258** and **259**, respectively (Figure 55).[196] Both species are selective catalysts for the allylic peroxidation of cyclohexene, with bpi derivative **258** showing the higher activity. Structurally, this derivative is characterized by a significant nonplanar distortion of the conjugated heterocyclic ligand framework, while bti derivative **259** is essentially planar, due to reduced steric encumbrance at the site of the anionic coligand. This effect is even more pronounced for bai ligands with terminal methyl substituents and has been observed in palladium complexes **260** and **261** (Figure 55).[199] However, whether an increased ligand exchange reactivity of bpi vs. bti complexes is accompanied by this increase in intramolecular strain has so far remained unexplored.

The conformational flexibility of bai ligands and their possible presence in protonated and deprotonated states have become particularly obvious in studies of

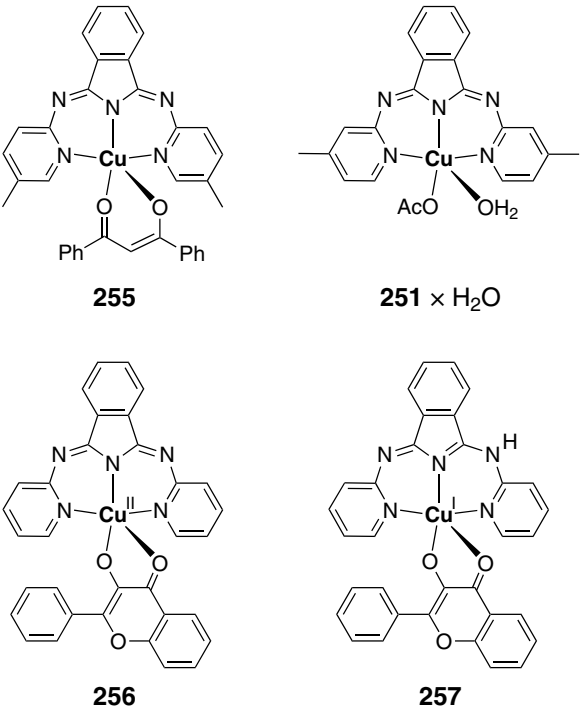

Figure 54. (bpi)Cu-based model compounds for different oxidoreductases.

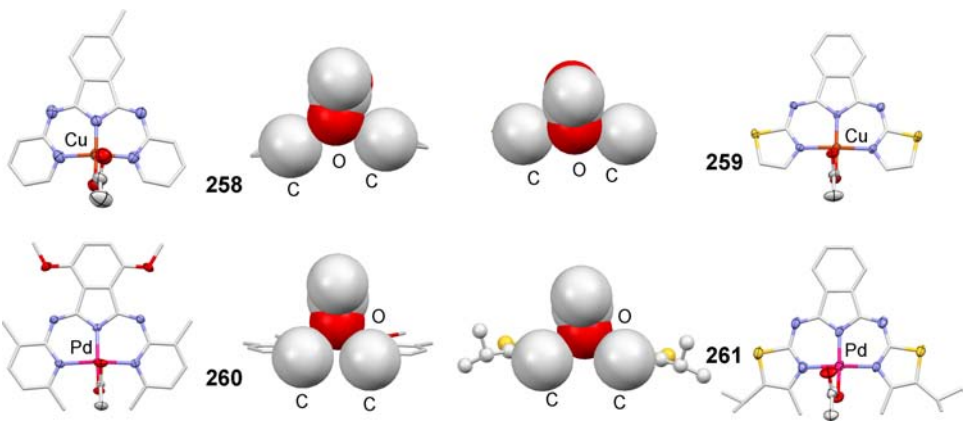

Figure 55. Conformative differences of [(bpi)Cu(OAc)] **258** and [(bti)Cu(OAc)] **259**, and of the methyl-terminated palladium analogs **260** and **261**. (Adapted from Refs. 196 and 199.)

zinc and cadmium chelates. The reaction of Cd(II) and Zn(II) perchlorates with H(4-Mebpi) produced series of L_2M_1-type complexes with zero, one, and two additional protons **262**–**267** (Figure 56).[323,332] Complexes (4-Mebpi)$_2$Cd **262**, (4-Mebpi)$_2$Zn **263**, and [(H(4-Mebpi)(4-Mebpi)Cd]ClO_4 **264** were characterized

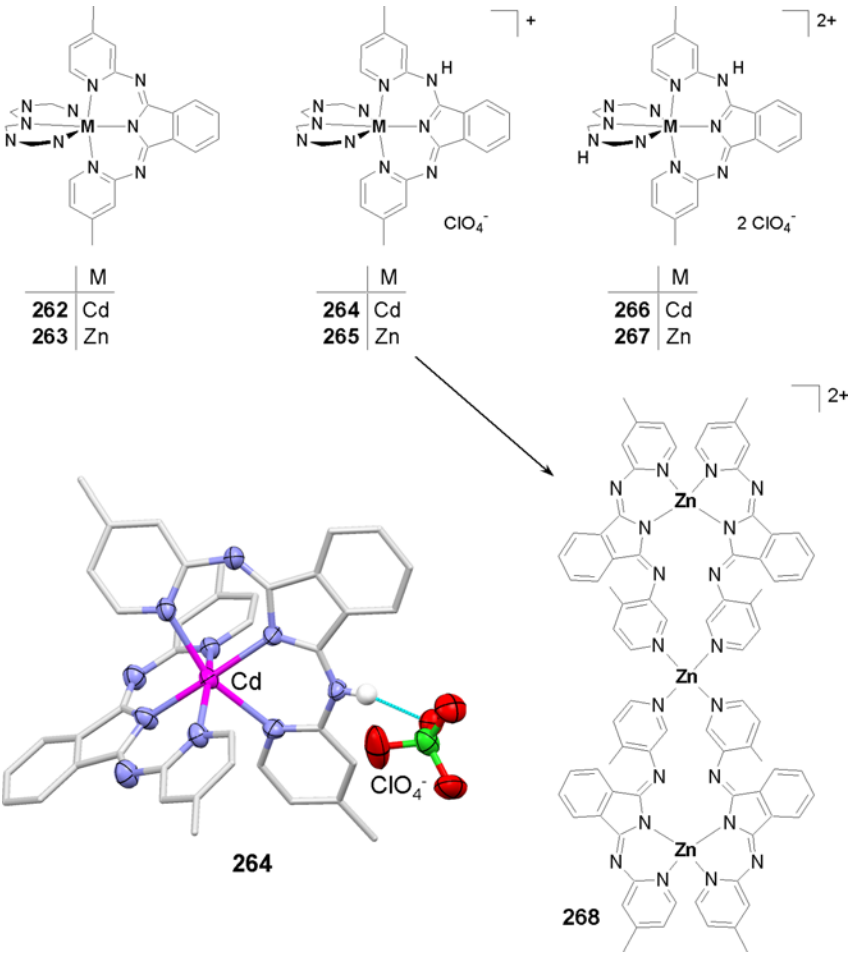

Figure 56. Structures and reactivity of zinc and cadmium chelates of 4-Mebpi in different protonation states. (Adapted from Ref. 323.)

crystallographically, with the additional proton of the latter being located at one of the bridging imino groups. Whereas $[(H(4\text{-Mebpi})(4\text{-Mebpi})Cd]ClO_4$ **264** is stable in solution, $[(H(4\text{-Mebpi})(4\text{-Mebpi})Zn]ClO_4$ **265** converts to the tetrahedrally coordinated, trinuclear complex $[(4\text{-Mebpi})_4Zn_3](ClO_4)_2$ **268** with a linear zinc backbone. All protonated complexes were reported to be tautomeric in solution because of the shuffling of the iminium protons between imine nitrogen atoms.

Besides the protonated $(4\text{-Mebpi})_2M_1$ complexes discussed above, the synthesis and structure of L_1M_1 complex $[(4\text{-Mebpi})Cd(NO_3)_2]$ **269** with a seven-coordinate cadmium ion have been reported (Figure 57).[180] As before, this compound is tautomeric in solution as the NH proton moves between the bridging

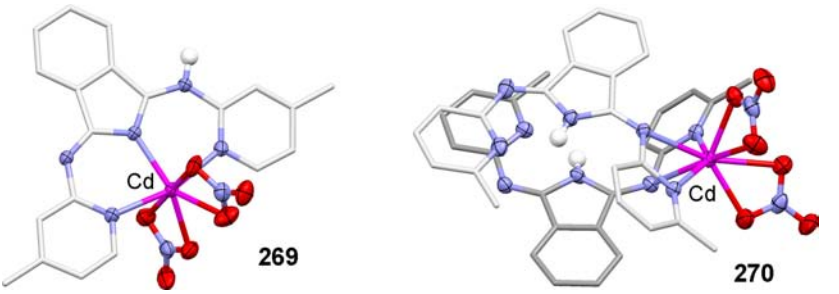

Figure 57. Cadmium H(bpi) chelates with high coordination numbers. (Adapted from Refs. 180 and 197.)

imine nitrogen atoms. If the sterically encumbered 6-Mebpi ligand is employed, cadmium and zinc atoms bind in a different N,N coordination mode using one bridging imine and one pyridine nitrogen atom. Cadmium(II) forms the eight-coordinate fluxional complex **270** with two protonated 6-Mebpi units and two chelating nitrate ligands, while in the presence of zinc(II) the ligand hydrolyzes with loss of one of the pyridylamine subunits.[197]

An extension of the chemistry of bai ligands was achieved by the advent of binucleating ligand **271**. Dinuclear species **272–275** were obtained by the reaction of **271** with mononuclear acetato metal(II) compounds of the 4-Mebpi ligand of manganese, iron, cobalt, and nickel (Figure 58). Magnetic, optical, and electrochemical investigations have revealed that the two metal ions in **272–275** are only very weakly coupled, and an application of these and related dinuclear or polynuclear compounds as multielectron catalysts was discussed.[183]

Dinuclear ruthenium complexes were prepared in which the metal atoms are bridged by bis(bpi) ligand **271** and terminated by 4-Mebpi.[182] Mixed valence (Ru(II)/Ru(III)) **276** and mixed metal complexes were prepared and their spectroscopical and electrochemical properties studied in the context of electron transfer mechanisms. Mononuclear ruthenium complex **277** was found to contain a protonated H(4-Mebpi) unit and three chloride anions as ligands, thus residing in the oxidation state +3 (Figure 59). This complex catalyzes the autoxidation and electrochemical oxidation of alcohols in basic alcoholic solution. The reaction is general, resulting in the oxidation of primary and secondary alcohols, with the principal products being aldehydes and ketones. More than 200 turnovers were observed in the oxidation of ethanol at the ambient temperature, with little or no loss of catalytic activity. Possible pathways for the catalytic autoxidation and electrochemical oxidation were discussed.[181]

Dinuclear molybdenum(II) complexes **278–288** with a variety of different bai ligands have been reported to form upon exchange of one of the acetato ligands

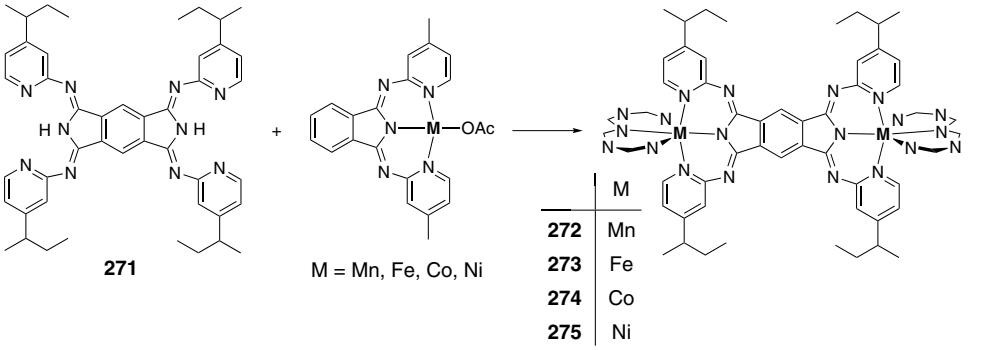

Figure 58. Preparation of homodinuclear bis(bpi) complexes **272**–**275**.

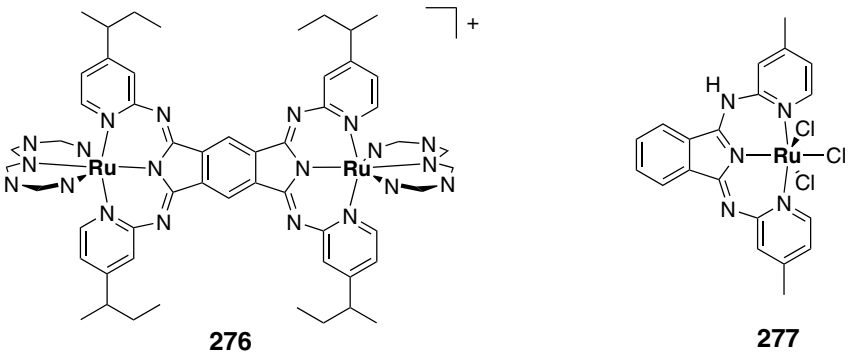

Figure 59. Dinuclear and mononuclear ruthenium complexes **276** and **277**.

from $Mo_2(OAc)_4$ with one deprotonated bai ligand.[333] The structure of the parent bpi compound **278** has been determined,[334] and it consists of a quadruply bonded dimolybdenum unit which is bound to three bridging acetates and one bridging bai ligand. The bai ligand is bound to one molybdenum by an imino nitrogen and to the other molybdenum by the isoindoline nitrogen and a pyridyl nitrogen. The pyridyl nitrogen is bound in a position approximately coaxial with the metal–metal bond (Figure 60). The Mo–Mo bond distance is 2.109 Å, and it has been found that the d–d* transition of the quadruple bond is influenced by the different heterocyclic end groups of the bai ligands in a complex fashion.[335]

Several studies concerning bai complexes with low-spin d^8 metal ions have been reported. Such ions tend to form square-planar or square-pyramidal coordination compounds for electronic reasons and are thus well suited for the preparation of L_1M_1-type species. Rhodium(I) **289**–**292** and iridium(I) complexes **293**–**297** have been reported with a variety of different bai ligands, mainly with the bpi framework (Figure 61).[185] Different neutral coligands have been used to

stabilize these compounds, with CO being the best choice in both cases. For rhodium(I) derivative **289** the oxidative addition of methyl iodide was studied. The expected product **298** undergoes insertion reactions to acyl complexes **299** and **300** upon addition of further CO, or $P(OMe)_3$, respectively.

Divalent palladium also forms neutral square-planar complexes with an anionic coligand occupying the fourth coordination site. Species with bpi- and bti-type ligands have been reported, and several crystallographic studies provided insight into metal–ligand interactions and crystal-packing phenomena.[195,199,204,336] Figure 62 presents selected examples **301**–**304** of such crystallographic analyses. For some of these palladium chelates, catalytic activity was reported in the hydrogenation of alkenes[195] and in C–C coupling reactions (see Section IV.C).

The cobalt-catalyzed oxidation of hydrocarbons by molecular oxygen represents one of the largest-scale applications of homogeneous catalysis and is widely used in industry, such as for the synthesis of adipic acid from cyclohexane. A significant increase in selectivity in the decomposition of cyclohexyl hydroperoxide to cyclohexanol and cyclohexanone in the presence of transition metal (particularly cobalt) complexes of bai derivatives was reported repeatedly in the patent literature[337–340] and set off significant activity in the field of bai-based oxidation catalyses that continues today. In the original reports it was stated that cobalt bpi catalysts are very active and long-lived, allowing cyclohexylhydroperoxide to be

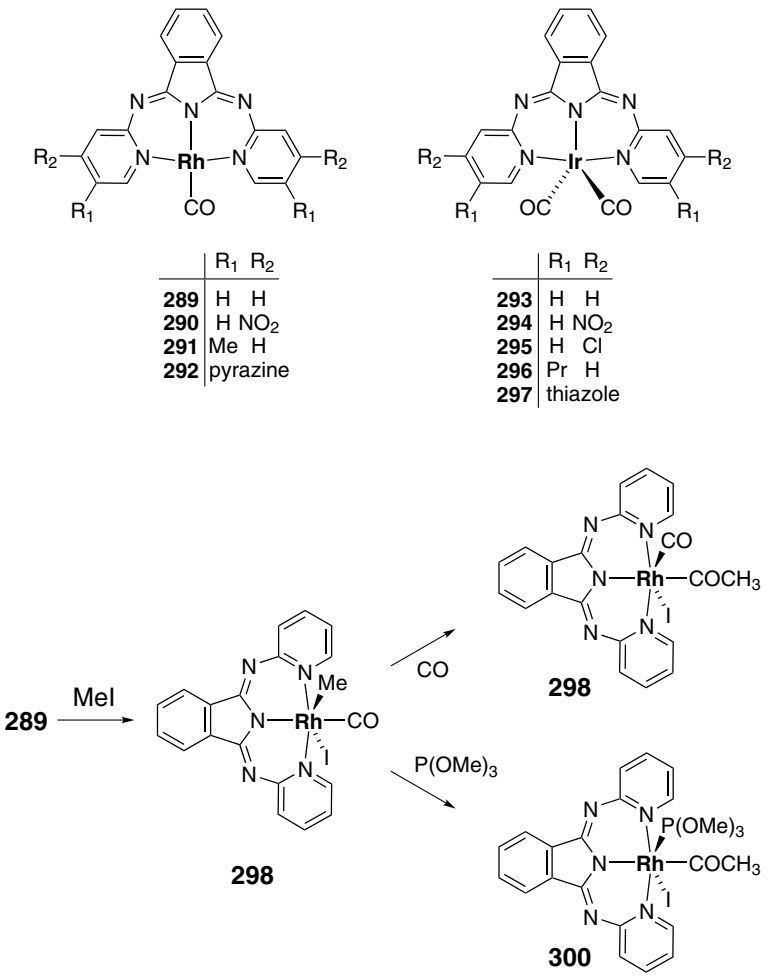

Figure 61. Chemistry of iridium and rhodium bai species.

converted in a selective, low-temperature process. The structure of one of the precatalysts, the L_2M_1 derivative [(3-Mebpi)$_2$Co], had been determined crystallographically. Under reaction conditions, it was assumed that the active form of the catalyst has lost one bpi ligand.[341] This assumption was later confirmed by the synthesis and characterization of active cobalt(III) alkylperoxide species (Figure 63 and Table 3).[194,342] An X-ray structure was obtained of one *tert*-butylperoxo derivative, **306**. This analysis revealed a distorted octahedral environment with a chelating carboxylate moiety and an apically bonded *tert*-butylperoxo group. The reactivity of cobalt(III) alkylperoxo complexes toward hydrocarbons was found to be dependent on their thermal decomposition rate, with bpi complexes being the most reactive. In addition, the activity of the cobalt bpi catalysts proved to

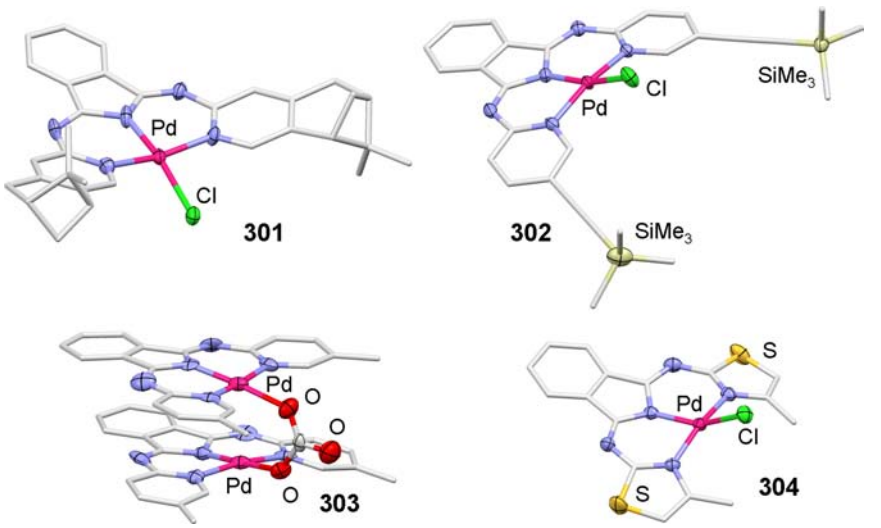

Figure 62. Selected molecular structures of neutral palladium bai complexes **301**–**304**. (Adapted from Refs. 195, 204, and 336.)

be essentially independent of the substitution pattern in the ligand. Saturated hydrocarbons are oxidized by Co(III) *tert*-butylperoxo complexes into alcohols, ketones, and *tert*-butylperoxo products. The hydroxylation reaction preferentially occurs at the more nucleophilic C–H bonds with extensive epimerization at the hydroxylated carbon atom. Hydrocarbons having labile allylic or benzylic C–H bonds react already at room temperature to give a large amount of allylic or benzylic *tert*-butyl peroxide. Olefins having no allylic hydrogen atom are

preferentially transformed into epoxides. The catalytic hydroxylation of alkanes by *tert*-BuOOH in the presence of cobalt(III) bpi complexes has the same characteristics as the stoichiometric reaction. The homolytic decomposition and reactivity of cobalt(III) alkylperoxo complexes were discussed in the context of the Haber–Weiss mechanism of alkyl hydroperoxide decomposition and of hydrocarbon hydroxylation by first-row transition metal peroxides. A photochemical variant of this reaction has also been worked out.[343] Figure 63 and Table 3 show typical cobalt(III) catalysts.

Besides their use in the technical process described here, achiral and chiral cobalt and iron bpi chelates such as **320**, **321**, and **322** (Figure 64) have most recently been investigated as useful and selective catalysts for the living radical

polymerization of acrylates,[202] the stereoselective cyclopropanation of alkenes, and the stereoselective hydrosilylation.[203] These results demonstrate the great potential of this group of complexes in modern catalysis research.

D. Complexes of Bis(oxazolinyl)pyrroles

Bis(oxazolinyl)pyrroles [H(bop)] are the most recent extension to the tripyrrin class of ligands in coordination chemistry. These ligands allow the relatively simple introduction of chirality at the terminal positions and are therefore particularly valuable in molecular catalysis. Three slightly different types of H(bop) ligands have been reported. Ligands **54a** and **54b** consist of a pyrrole center with two directly attached oxazoline moities, and have been studied in the coordination to divalent palladium. A dinuclear complex **323** was obtained from achiral ligand **54a**, demonstrating that for steric reasons only two of the three nitrogen donors can bind to the same metal ion (Figure 65).[207,208] As the dinuclear species forms a double-helical structure, the use of the chiral ligands (*R*,*R*)- and (*S*,*S*)-**54b** yields

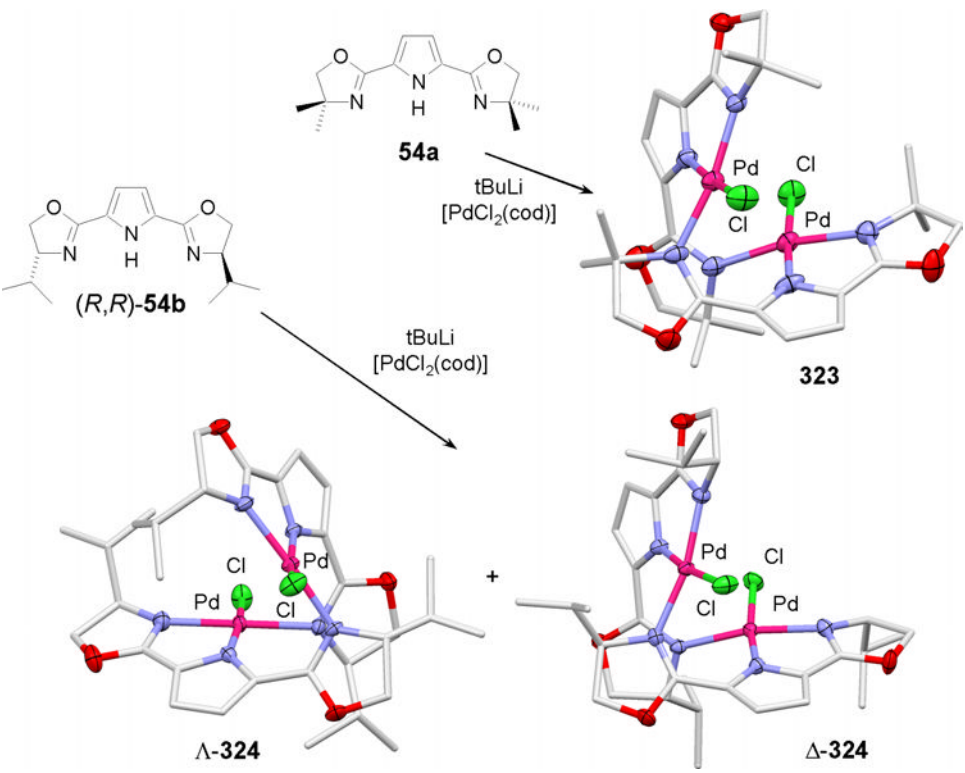

Figure 65. Molecular structures of dinuclear palladium complexes with achiral and chiral bop ligands (crystallographic figures adapted from Refs. 207 and 208).

mixtures of double-stranded helicate diastereomers **324** which have been separated and investigated in detail with respect to structure and dynamics. In addition, dinuclear complex **323** was found active in the catalytic Suzuki cross-coupling reaction (see Section IV.C).

H(bop) ligands **55**, which contain bridging methylene groups between the heterocyclic components, have been described as complexes with palladium, zinc, and rhodium. Chloro palladium(II) chelates **325** form from the respective ligand after deprotonation and treatment with [$PdCl_2$(cod)] in fair-to-acceptable yields. Peculiar dehydrogenation and formation of the complexes with conjugated ligands **326** has been observed in this system. The transformation occurs in the presence of oxygen or of excess palladium and is highly chemoselective. Crystallographic analyses of members of nonconjugated and of conjugated complexes confirm significant planarization and rigidification during this process (Figure 66).[209] If zinc is coordinated to **55a**, complex **327** with a conjugated ligand is formed immediately. Other than **326**, however, **327** is not an oxidized but rather a rearranged form of the original framework. A similar rearrangement was found in the palladium series.[344]

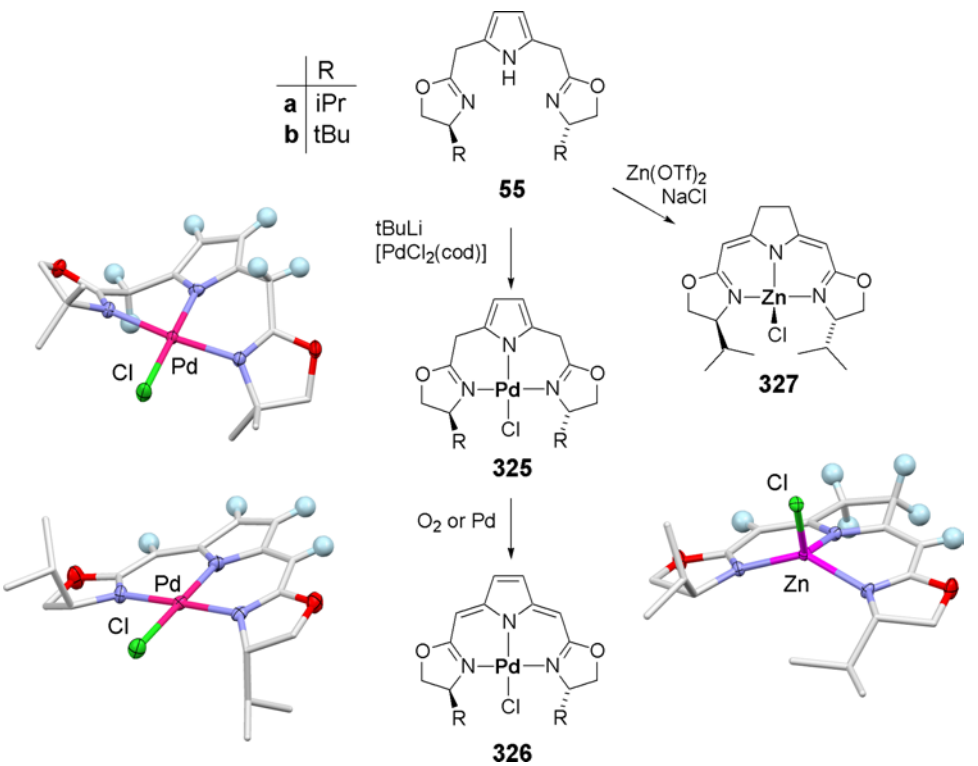

Figure 66. Planarization of palladium and zinc bop species (crystallographic figures adapted from Refs. 209 and 344).

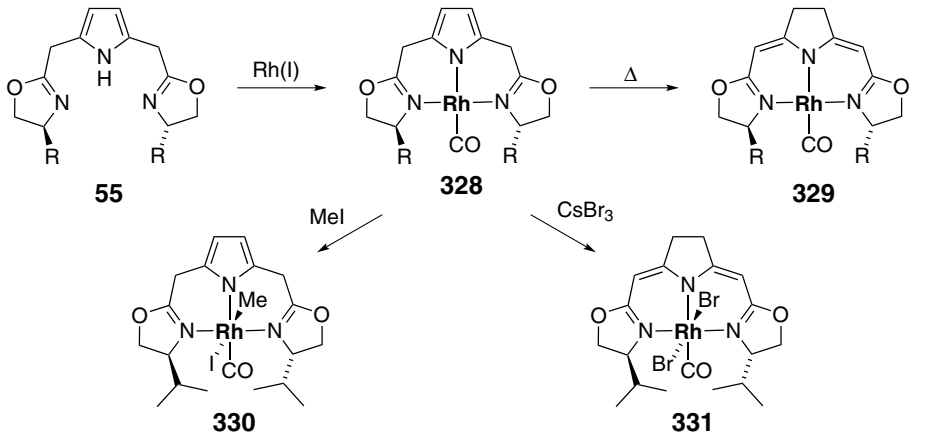

Figure 67. Chemistry of rhodium bop complexes.

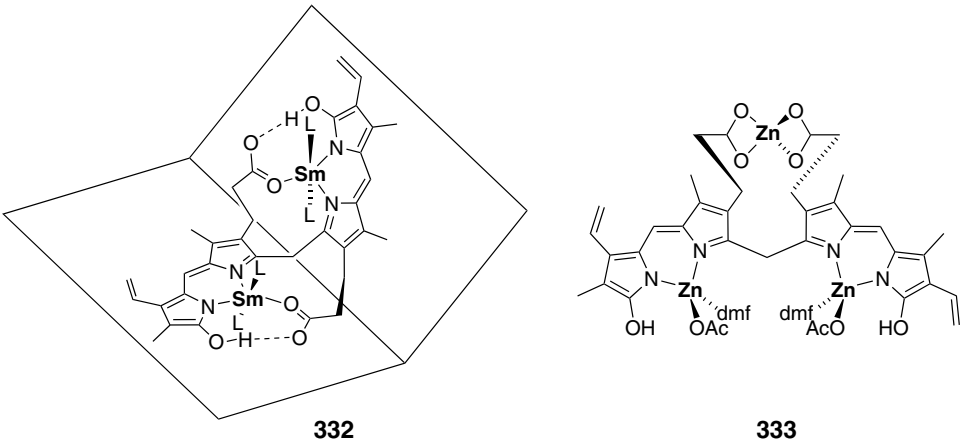
Rhodium(I) complexes **328** have been prepared analogously from deprotonated ligands and $[RhCl(CO)_2]_2$ or $[Rh(acac)(CO)_2]$, for a number of different derivatives (Figure 67). Upon heating the compounds at 100 °C in toluene over several hours, a rearrangement to isomeric species **329** occurs, similar to that described above for zinc complex **327**. Compound **328** (R = iPr) reacts with methyl iodide in the expected way by oxidative addition to rhodium(III) complex **330**. $CsBr_3$, on the other hand, converts **328** (R = iPr) into dibromo rhodium(III) compound **331** with a rearranged bop ligand.[210]

The third subgroup of H(bop) ligands are the chiral, twofold benzoannelated species **56** (Figure 14). With respect to the rigidity of the conjugated backbone, these ligands are closely related to the rearranged and even closer to the oxidized derivatives mentioned above. Pincer ligands **56** have so far been described only in the context of chromium-catalyzed asymmetric Nozaki–Hiyama allylation and related processes.[211,212,345]

E. Behavior of Bilirubin and Biliverdin Toward Metal Ions

A role of the natural bile pigments biliverdin **9** and bilirubin **10** in the secretion of trace metals was assumed early on the basis of changes in the optical spectra of medicinal preparations. Later on, numerous attempts to quantify the interactions of bile pigments with different transition metal ions and to clarify the unknown structures of these complexes were undertaken. Zn^{2+} was the first ion for which a distinct binding to bilirubin **10** and mesobilirubin in a biomimetic buffer was confirmed spectrophotometrically.[346] Many other di- and trivalent 3d and 4f cations also led to marked changes in the optical spectra under similar conditions.



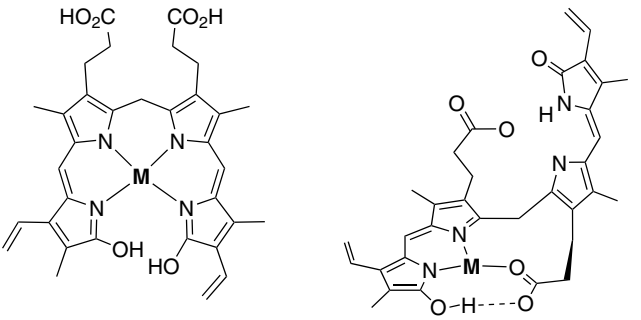
332 **333**

Figure 68. Assumed folded structures of dinuclear samarium complex of bilirubin **332** formed in protic media and trinuclear zinc species **333** formed in DMF solution.

However, the complexes formed were unstable in most cases.[347] Sm^{3+} was found to form a stable adduct with bilirubin **10**, and the first structural assignment of a L_1M_2 complex of this ion, **332** was deduced from the results of a spectrophotometric titration of **10** with samarium acetate (Figure 68).[348] Subsequently the 1:2 stoichiometry of **332** was confirmed and similar chelates with Zn^{2+}, Cd^{2+}, and Fe^{2+} ions were identified. Stability constants were obtained by spectrophotometric titrations, and a quite small stability window of around pH 8 was found to be a typical feature of these compounds.[349–352] In aprotic media, however, the interaction patterns are obviously different due to intramolecular hydrogen bridges of **332** and similar chelates, and bilirubin **10** has been found to form stable trinuclear species such as **333** with Zn^{2+}, Cd^{2+}, and Co^{2+} under these conditions (Figure 68).[353]

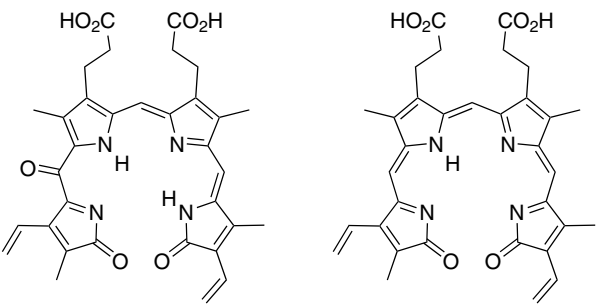
In a surface-confined state, however, the coordination behavior of bilirubin **10** differs markedly from the above findings. Raman studies of **10** absorbed on silver (SERS method) indicate the formation of L_1M_1 complexes in the presence of excess metal cations. In the case of the divalent Fe^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+} ions, bilirubin acts as a tetradentate nitrogen donor like in **334**, while for Ag^{+} and Au^{3+} an open conformation as in **335** and binding to only two nitrogen atoms is reported (Figure 69).[354,355]

In addition, the former species displays a pronounced sensitivity toward redox transformations, and in the copper case the reversible oxidation to a complex of biliverdin **9** was reported. Copper(II) was indeed found earlier to oxidize bilirubin **10** to biliverdin **9** in aqueous solution as well as in DMSO,[352] and a spectrophotometric titration of bilirubin **10** with the tetrachloroaurate anion also confirmed the initial formation of biliverdin **9**. Further addition of $[AuCl_4]^{-}$, however, resulted in



334 **335**

Figure 69. Assumed structures of mononuclear bilirubin complexes **334** and **335** on a silver surface.



336 **337**

Figure 70. Bilipurpurin **336** and biliviolin **337**.

a new spectral pattern which was assigned to a gold(III) complex of the oxygenated bilipurpurin **336** (Figure 70).[356] Bilipurpurin **336** and biliviolin **337** are the two most important natural degradation products of biliverdin **9** and bilirubin **10**, and have long been known to exist as metal-binding dyes in oxidized bile.[111,357,358]

Bile extracts show a characteristic fluorescence in the present of zinc cations. In 1934, Lemberg prepared the first pure zinc and copper complexes of biliverdin dimethyl ester **13** and proved that the zinc derivative is in fact not fluorescent under inert conditions.[359] Fluorescence occurs upon aerial oxidation of chelate **338** and has been assigned from the optical spectra to the 2 e^-, 2 H^+ oxidized biliviolin species **339** (Figure 71). This assignment was later confirmed by the preparation and investigation of model compounds.[111,358]

Metal complexes of biliverdin **9** itself were described rather late for Zn^{2+}, Cd^{2+}, and Cu^{2+} ions, and spectrophotometric titrations have confirmed the expected 1:1 stoichiometry in all cases.[352] Biliverdin dimethyl ester **13**, the corresponding diethyl

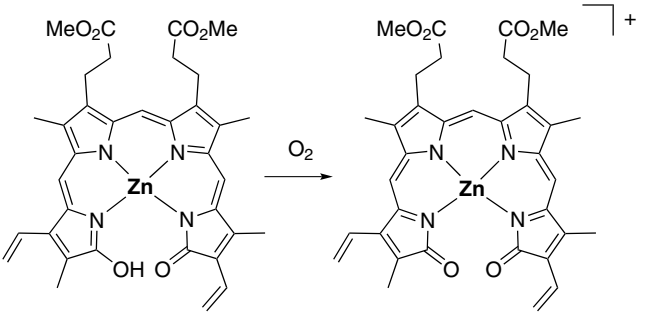


Figure 71. Aerial oxidation of zinc biliverdin dimethyl ester **338** to the fluorescent biliviolin complex **339**.

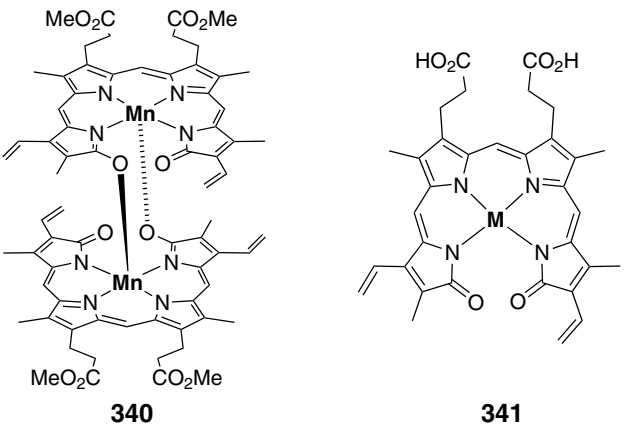

Figure 72. Di- and mononuclear complexes **340** and **341** of biliverdin ligands.

ester, and respective *meso* forms such as **57** were used instead in order to establish complexes of this ligand framework with the divalent transition metal ions Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}, and detailed studies of the electronic structures of these species have been reported. In addition to these investigations, a related O-lactim ether derivative was shown to be capable of coordinating to divalent copper and zinc ions.[214,360,361] Iron was found to form unstable material only under forcing conditions. While the metalated species with divalent metal ions are usually monomeric in solution, a dimeric structure is reported for the Mn^{3+} derivative **340** (Figure 72).[362,363] This compound has recently found application as a superoxide dismutase (SOD) mimetic. As the most recent additions, palladium and platinum complexes of biliverdin **9** were obtained and investigated by spectrophotometric

titrations. The compounds were assigned to species **341** with the metal ions in the oxidation state +3.[364,365] Results from model studies (*vide infra*), however, give rise to the assumption that these species are better understood as complexes of divalent metal ions with a biliverdin radical ligand.

F. Mononuclear Tetrapyrrole L_1M_1 Complexes and Associates

As described in the foregoing section, biliverdin and its carboxylic ester and lactim ether derivatives bind to transition metal ions to form complexes with a simple L_1M_1 composition. Structural information about complexes with this ligand framework was obtained from model studies using bilindione ligands such as octaethylbilindione [H_3(oeb)] **11** with simpler alkyl substituents. Bonnett and coworkers described the first transition metal chelates (manganese, cobalt, nickel, copper, and zinc) with this ligand (Figure 73). An iron derivative could not be obtained.[243,366,367] Nickel derivative [(oeb)Ni] **342** was characterized crystallographically and a more detailed investigation toward the electronic structure was performed. The oeb ligand was found to bind in a noninnocent, radical dianionic fashion to a nickel(II) ion, and only a minor contribution of a nickel(III) state was deduced from EPR spectra. The same conclusions had been drawn earlier by

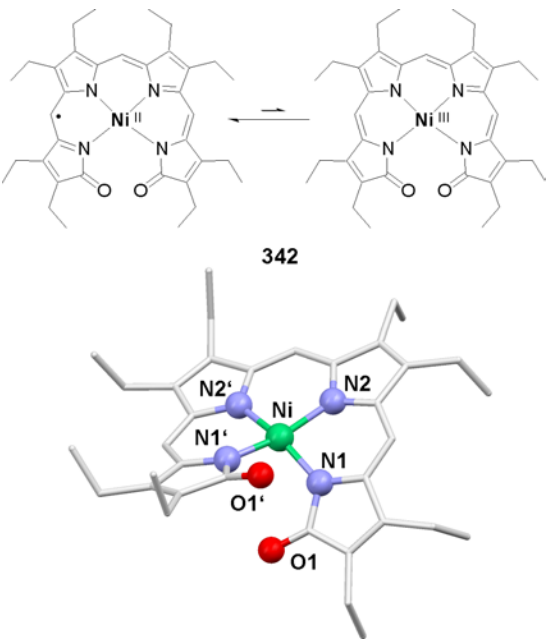

Figure 73. Assumed resonance structure and molecular structure of [(oeb)Ni] **342** (crystallographic figure adapted from Ref. 366).

Fuhrhop and coworkers based on spectroscopic investigations into related nickel complexes of mesobiliverdin diethylester and biliverdin diethylester.[361] An X-ray diffraction study on **342** revealed steric interactions between the terminal oxo groups and a helical distortion of the tetrapyrrole ligand. The nickel ion binds to the four nitrogen atoms in a slightly distorted square-planar fashion with small Ni–N distances of 1.875 and 1.897 Å, indicating a low-spin character of the metal ion. The radical character of the ligand, however, cannot be extracted from the structural parameters of the ligand backbone.

In later studies further transition metal complexes of oeb **11** and related bilindiones were investigated in more detail, mainly by the group of Balch.[10] Manganese derivatives usually contain an intact trianionic ligand and a five-coordinate, trivalent manganese ion, with the fifth coordination site being occupied either by the keto terminus of a second complex moiety **343** or by a solvent molecule (methanol, pyridine **344**). Several examples have been structurally characterized.[368,369] A manganese(II) complex **345** of a biliverdin ester had been described before to change its optical spectra with the pH of the solution. This observation was interpreted in terms of a conformational change of the ligand and of the metal binding, as depicted in Figure 74.[243]

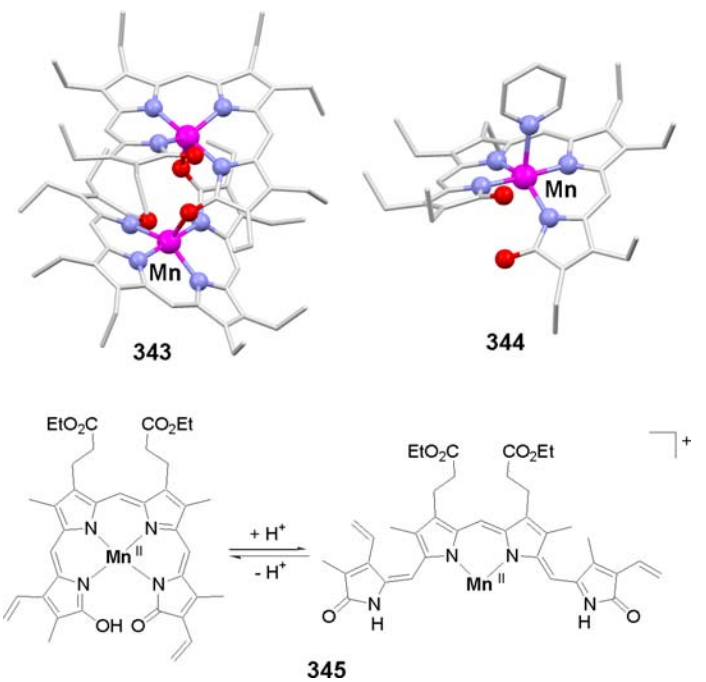

Figure 74. Structures and dynamics of manganese complexes **343**–**345** with bilindione ligands (crystallographic figures adapted from Refs. 368 and 369).

Several reports dealing with iron derivatives can be found in the literature, and the first isolated complexes have more recently been reinvestigated. The iron chemistry of open-chain tetrapyrrole ligands relates directly to the heme degradation process and poses a special challenge due to the sensitivity of the compounds. Section V discusses biological findings and the model chemistry of open-chain iron tetrapyrroles related to iron biliverdin IXα.

Cobalt complexes of oeb **11** have been prepared by careful hydrolysis of the respective verdoheme analogs, as shown in Figure 75.[368,370] The primary product [(oeb)Co] **346** displays a thermal spin equilibrium with a singlet ground state and a triplet excited state. These states have been assigned to the formulations *low-spin*-Co^{III}-oeb^{3-} and *low-spin*-Co^{II}-oeb^{2-}, respectively, the latter with the radical dianionic oeb ligand seen earlier in nickel complex **342**. The complex redox behavior of **346** has been investigated in some detail, and an oxidized species [(oeb)Co(I_3)] **347** with a two-electron-oxidized, monoanionic tetrapyrrole ligand (so-called oebOX) and a weakly bound triiodide ligand at the divalent cobalt atom

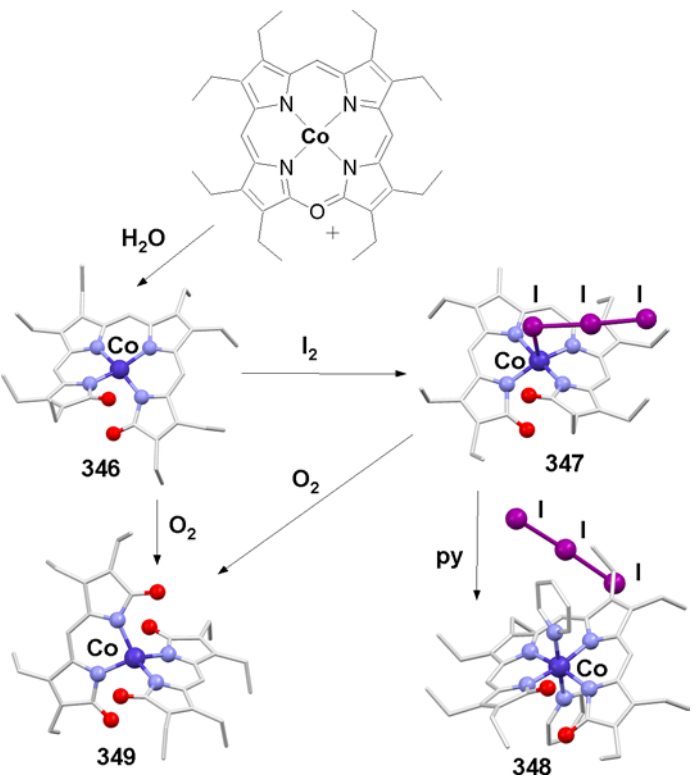

Figure 75. Structures and oxidation characteristics of oeb cobalt complexes (crystallographic figures adapted from Refs. 368 and 371–373).

was analyzed spectroscopically and crystallographically.[371] This ligand may be regarded as a model for biliviolin **337** (Figure 75). Compound **347** accepts two pyridine ligands to form the six-coordinate cobalt(III) complex **348** with the oeb radical dianion.[372] Oxidation of **346** or **347** in the presence of dioxygen leads to ligand degradation, and a cobalt complex with two propentdyopent ligands **349** was isolated as the final product.[373]

The identification of nickel(II)octaethylbilindione **342** as a compound with a radical ligand, which was discussed earlier, was confirmed by later work, and a similar electronic structure has been found for a related palladium derivative, **350**. As for cobalt chelate **346**, the nickel and palladium derivatives are easily oxidized and reduced at the ligand to form anionic $[(oeb)M]^-$ and cationic $[(oebOX)M]^+$ species. The latter are again stabilized by triiodide anions which are, however, not bound to the metal centers in these cases. Both of the species **351** (Ni) and **352** (Pd) form isostructural assemblies with the triiodide anion and were structurally investigated in the solid state (Figure 76).[374] No significant bond length or angle changes were found between the neutral and the cationic [(oeb)M] complexes of each metal ion, which points to ligand-centered redox processes.

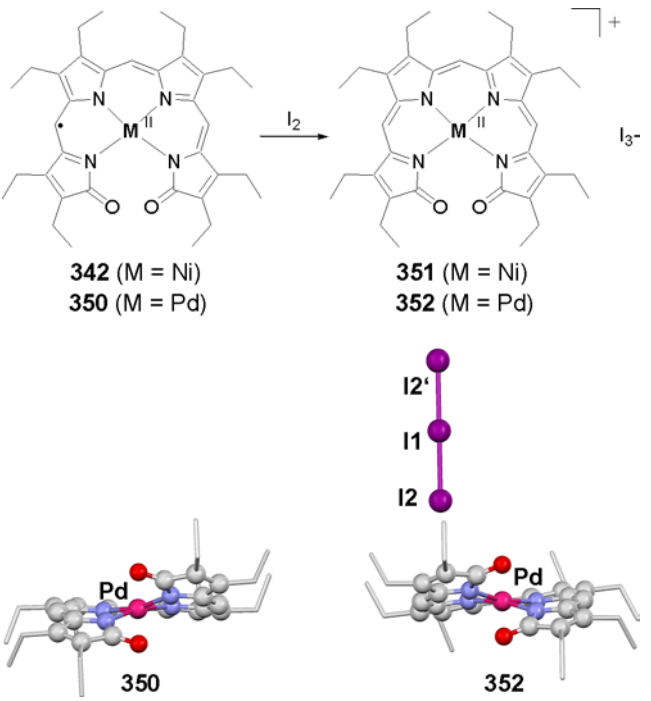

Figure 76. Iodine oxidation of nickel and palladium complexes of oeb **342** and **350**, and comparison of structures for palladium derivatives **350** and **352** (crystallographic figures adapted from Ref. 374).

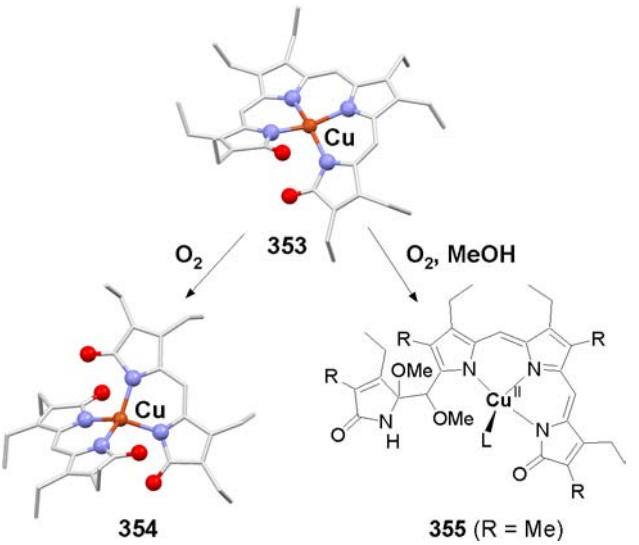

Figure 77. Structure and redox behavior of copper bilindiones (crystallographic figures adapted from Ref. 375).

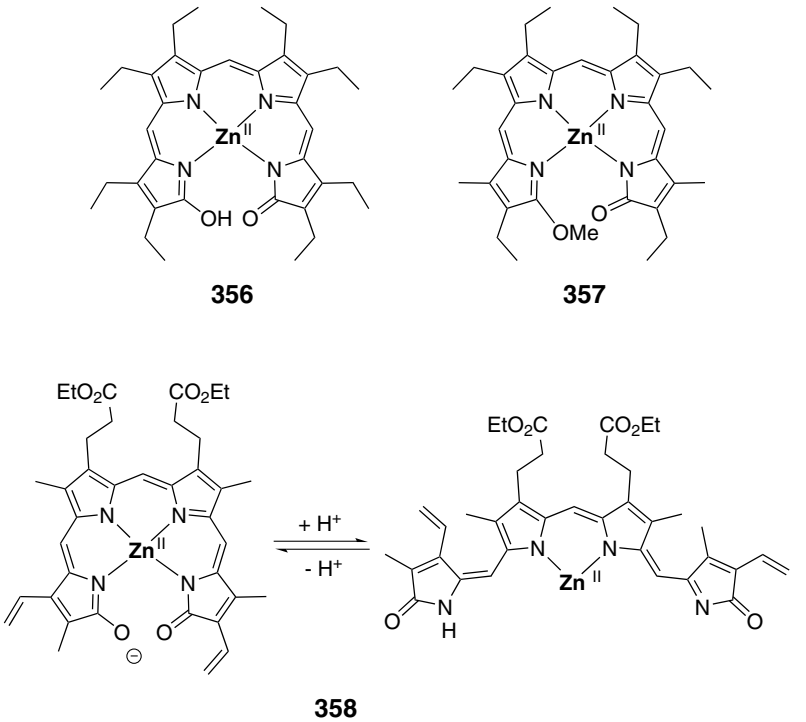
[(oeb)Cu] **353** also constitutes a complex with the bilindione radical dianion.[369,375] A similar tetraethyl-tetramethyl-substituted compound has been electro-oxidized and -reduced at the ligand, while an oxidation state of +2 was maintained at the copper atom.[376] Structural data of these species are, however, not available. In the presence of dioxygen, **353** forms propentdyopent derivative **354**,[375] while a twofold methoxylation at a terminal *meso* methine group of **355** was observed under slightly different conditions in methanol.[369] A similar dimethoxy derivative has been described to form upon controlled oxidation of a thallium(III) bilindione with dioxygen in methanolic solution.[106] Figure 77 summarizes the findings on copper bilindiones.

Zinc complexes such as **356** and **357** have been described with different octa-alkylbilindiones and with the corresponding monolactim ethers. Different from most of the known chelate complexes, the tetrapyrrole ligand of **356** binds in a nonradical and twofold deprotonated state. The third proton is believed to be situated in a hydrogen-bridging position between the terminal oxygen atoms. Therefore, monolactim ethers as in **357** are preferred for the coordination to zinc(II) and find broad application in this chemistry.[246,369] An early report describes pH-dependent changes in the optical spectra of a zinc(II) bilindione **358** and explains this feature by reversible formation of a zinc complex with an open and a closed tetrapyrrole ligand, similar to the findings described above for divalent manganese (Figure 78).[243] Two DFT studies have been reported on metal bilindione species, confirming the above findings that bilindione is a



356 **357** **358**

Figure 78. Typical structures and assumed dynamics of zinc bilindiones.

redox active ligand and exists in a radical form in simple Co, Ni, Pd, and Cu chelates.[377,378]

A large number of coordination compounds of open-chain tetrapyrroles have been obtained as products from the photooxidation or related oxygenation protocols of metalloporphyrinoids. The ligands of these products are terminated by one oxo and one formyl or aroyl group and thus serve as dianionic ligands. A non-innocent behavior or electronic ambiguity which is typical of bilindiones is unknown for metal chelates of this group, so that a discussion ordered after different originating porphyrinoids is more instructive in this case.

Zinc and magnesium chelates of the ring-opened formylbilinone from protoporphyrin IX dimethyl ester have been described.[219] Some preference has been found with respect to the site of the ring-opening, and the two isomers with the oxygenated termini opposite to the propionate side chains have been reported. The model system octaethylporphyrin has been used coordinated to a number of different divalent metal ions, and photooxidation of these complexes led to the formation of the respective metal octaethylformylbilinones (oefb) with magnesium(II), cobalt(II) **359**, nickel(II), copper(II) **360**, and zinc(II) **361** centers (Figure 79). The compounds have been carefully characterized, and their

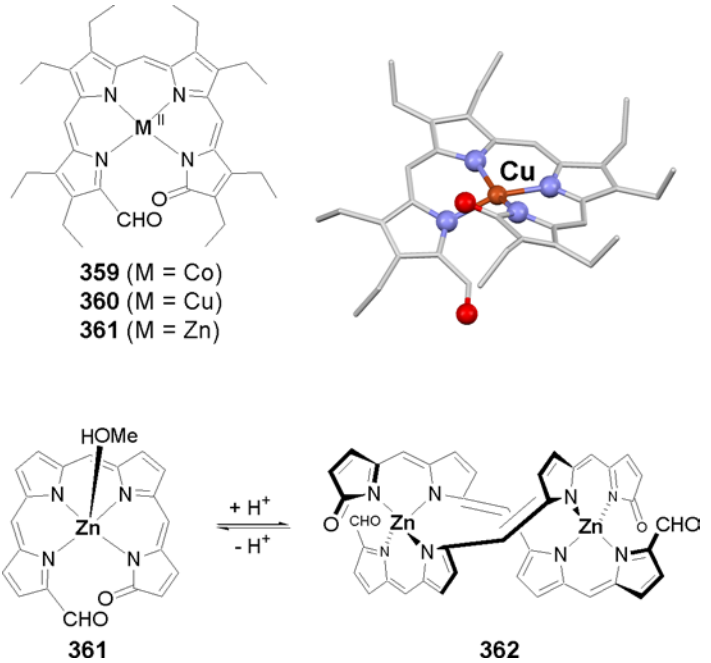


Figure 79. Selected metal octaethylformylbilinones [(oefb)M] (crystallographic figure adapted from Ref. 379).

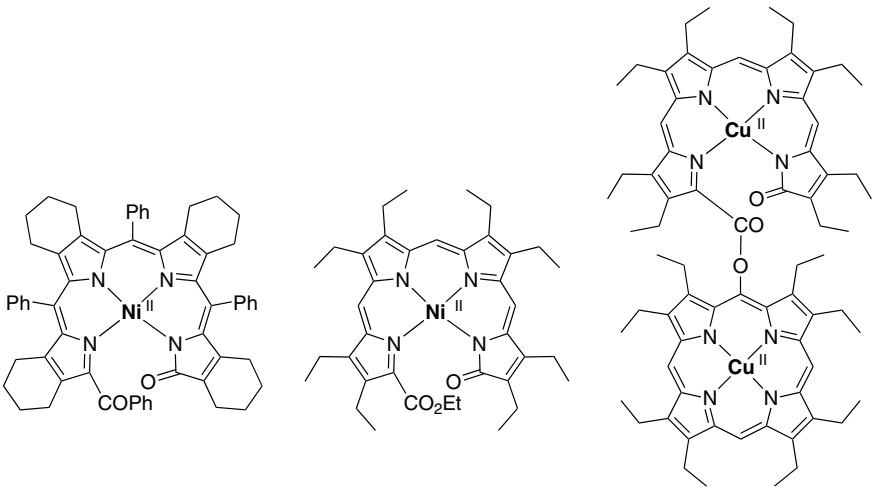
magnetism as well as their redox behavior has been studied. A structural characterization has been achieved for the copper and the zinc derivatives **360** and **361**.[219,243,379] The first preparation of an iron derivative of an open-chain tetrapyrrole ligand was also achieved by this route (Section IV). Some special observations have been made with the cobalt, copper, and zinc derivatives of oefb **359–361**. [(oefb)Co] **359** is capable of binding molecular dioxygen in pyridine solution in a reversible process. [(oefb)Cu] **360**, on the other hand, decarbonylates in the presence of dioxygen and yields a copper verdoheme analog.[379] The zinc chelate has been reported to change its optical spectra with pH. This feature was interpreted in terms of a reversible change of the ligand conformation and metal-binding mode, as shown above for zinc and manganese(II) chelates of bilindione ligands.[219] An X-ray diffraction study, however, proved that a pH-dependent dimerization/monomerization equilibrium between the forms **361** × MeOH and **362** is responsible for the observation (Figure 79).[380]

Metal chelates of carbonyl-terminated bilinones obtained by oxidizing metal porphyrinoids have occasionally been reported from other oxygenation protocols. Nickel and copper complexes of a dodecasubstituted porphyrin open to give benzoylbilinone derivatives **363** with mCPBA in pyridine.[230] The oxidative ring-opening of nickel *meso*-amino-octaethylporphyrin with iron(III) in alcoholic



363 **364** **365**

Figure 80. L_1M_1 chelates **363–365** of open-chain tetrapyrroles from alternative porphyrin ring-opening procedures.

solution results in the formation of ethoxycarbonylbilinone **364**.[381] In a similar way, the ring-opening of copper *meso*-hydroxy-octaethylporphyrin and its trifluoroacetate was reported to yield dinuclear complex **365** (Figure 80).[382] All these products were identified by X-ray crystallographic studies.

While the photooxidation protocol has been widely applied to β-substituted metalloporphyrins, the transfer of this method to tetraarylporphyrins and in particular to metal tetraphenylporphyrins [(tpp)M] has been reported in only a limited number of cases. [(tpp)Mg] opens photooxidatively to give the corresponding benzoylbilinone **366**. The magnesium ion is labile, and **366** was shown to undergo transmetalation with copper(II) to give copper chelate **367**.[383] If the metalloporphyrin is activated by nucleophilic addition of n-BuLi at a *meso* position, the subsequent photooxidative ring-opening occurs at a neighboring methine group in a regiospecific fashion. The products **218** and **219** from this transformation now employ the benzoyl oxgen atom as the fourth donor for the nickel(II) or copper(II) ion rather than the fourth N atom from the pendant pyrrolinone moiety (Figure 81).[226] This behavior is presumably a result of protonation and electroneutrality issues.

The zinc complex of tpp has been found to yield a hydrated product **368** after photooxidation which dimerizes by several hydrogen-bonding interactions, as shown in Figure 82.[384] Compound **368** is capable of reversibly losing a molecule of water under different conditions (heat, solvent change), and the first applications of the associated coordination, thermo- and solvato-chromic features of the

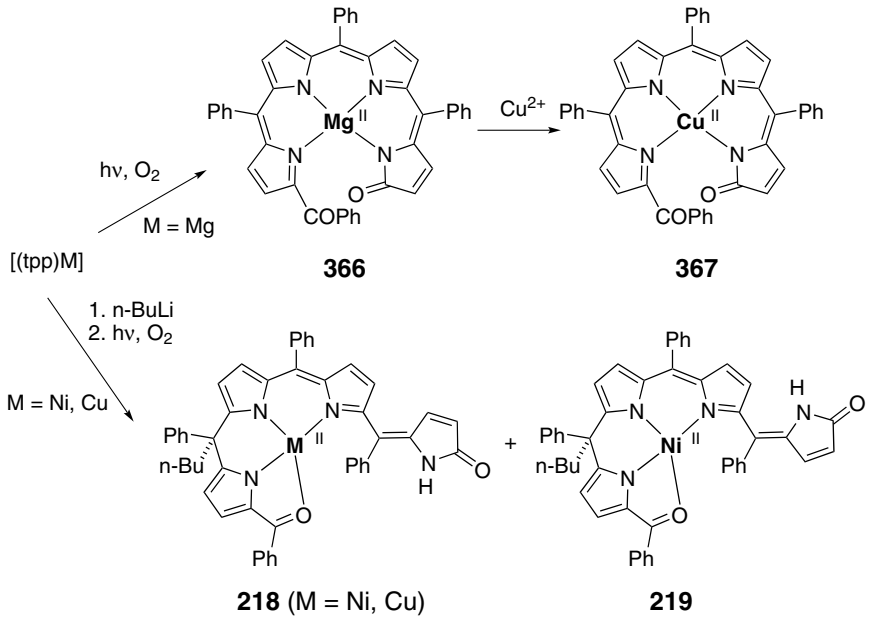


Figure 81. Formation of copper(II) and nickel(II) complexes of ring-opened tetraphenylporphyrins.

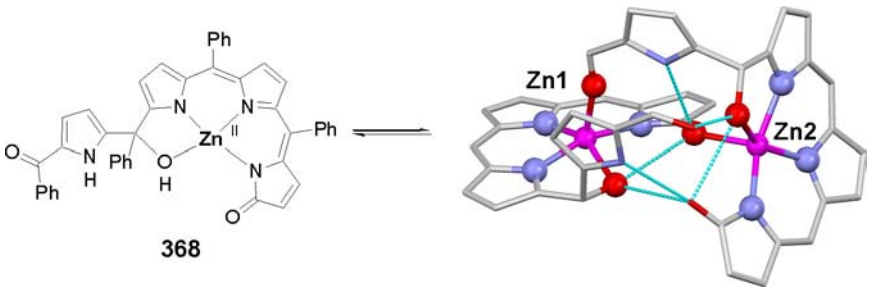

Figure 82. Hydrated zinc benzoylbilinone **368** in monomeric and dimeric form, with hydrogen-bonding network (aryl groups omitted for clarity; crystallographic figure adapted from Ref. 384).

compound as sensoric moments,[385] as well as its use as a conductivity switch,[386] have been reported.

Another group of metal complexes with open-chain tetrapyrrole ligands is available from the attack of different nucleophiles on verdoheme analogs. Verdoheme is an intermediate in the natural heme degradation process and differs from heme by the exchange of one *meso*-situated CH group with an O^+ function. The positive charge thus located at the porphyrin perimeter directs the attack of nucleophiles toward a position adjacent to the oxonium bridge. Consequently,

metalated bilinones with a heterofunctionality as the second terminus result after ring-opening. Mainly zinc(II) complexes have been reported so far from this approach. First examples were obtained by the nucleophilic attack of ammonia and of simple amines on zinc verdoheme dimethyl ester and on the corresponding *meso* form.[387,388] Products **369** are mixtures of two regioisomers, as expected from the unsymmetric substitution pattern of the starting material. A systematic exploration of the action of different O-, N-, and S- nucleophiles on zinc(II) and cobalt(II) complexes of an octaethyl-substituted ligand has been reported in a series of papers. Alkoxide addition results in the formation of monolactim ethers of zinc(II) and cobalt(II) bilinones.[389] A similar *S*-lactim ether and a dimethylamino derivative were obtained with zinc as the central ion.[390] Then again, cyanide addition to zinc derivative **370** did not produce a single product but rather a complex mixture of mono-, di- and trisubstituted species.[391] Some of the products could be isolated and characterized. Figure 83 summarizes results from these studies.

Occasionally, partially hydrogenated or reduced bilindione ligands related to the chlorins have been described as metal complexes. The examples known to date have, however, not been investigated in much detail, and structural information is absent. A stercobilin type ligand **371** has been shown by spectroscopic means to coordinate to copper and zinc ions in an unknown fashion.[392] The nickel and palladium complexes **372** of a threefold deprotonated tetraoxo derivative have been reported to reside in the metal(II)–ligand radical form.[243] Zinc and copper(II) chlorins have been ring-opened to hydrogenated formylbilinones **373**.[219] Zinc oxochlorin **374** loses the metal ion after thallium trifluoroacetate treatment with spontaneous oxidative ring-opening. A similar benzoannelated nickel chelate **375** yields methoxybilinone **376** if oxidized with the same reagent and further by a coupled oxidation with O_2 and ascorbate.[232] Figure 84 provides an overview of these investigations.

While oxo-terminated open-chain tetrapyrroles of the biliverdin type are characterized by a conjugated ligand backbone and thus by a certain conformational rigidity, the π-system of twofold methyl- or alkoxycarbonyl-terminated species is always discontinued at the central *b*-position, thus forming ligands composed of two methylene-linked and electronically decoupled dipyrrin subunits. The additional flexibility gained by this change in the framework results in the observation of coordination compounds in different binding modes and stoichiometries, similar to the chemistry of the bilirubin chromophore discussed above. Hydrogen-terminated *a*,*c*-biladienes tend to form macrocyclic metal corroles by oxidative ring closure reactions in the presence of transition metal ions. Dehydrogenated *a*,*b*,*c*-bilatrienes with methyl termini are also very reactive with respect to a variety of different electrocyclic ring closure transformations and cannot be obtained as metal chelates (see Section VII). *b*-Bilenes, on the other hand, react

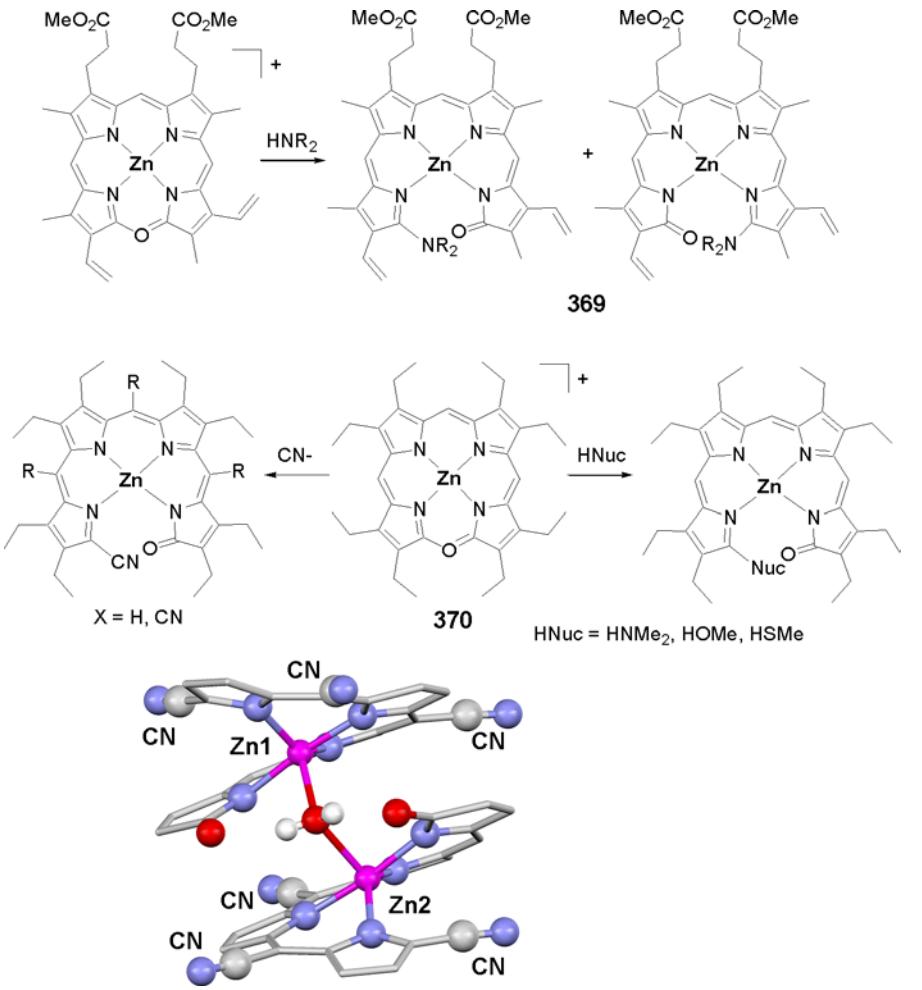

Figure 83. Products from addition/substitution reactions on zinc verdoheme analogs, and molecular structure of a water-bridged zinc bilinone dimer with several cyano groups (alkyl substituents omitted; crystallographic figure adapted from Ref. 391).

similarly to substituted dipyrrins in the presence of metals, and the formation of distorted tetrahedral zinc(II) and cobalt(II) chelates **377** in a L_2M_1 stoichiometry has been reported (Figure 85).[128,272]

a,*c*-Biladiene derivatives with methyl termini have occasionally been investigated as ligands in coordination compounds in order to study possible intermediates in the templated macrocyclization of such compounds to porphyrinoids under oxidizing conditions. The binding of one or two metal ions to *a*,*c*-biladienes in the stretched or in the coiled conformation, respectively, is mainly conducted by the coordinative preferences of the metal ion. The thermodynamics of the metalation

reaction and the influence of the metal ions on the stoichiometry of the products have been investigated in DMF solutions on decamethyl-*a*,*c*-biladiene for divalent ions of nickel, copper, zinc, cadmium, and mercury by a combined calorimetric and spectroscopic study.[393] Nickel(II) and copper(II) bind to these ligands in a L_1M_1 mode, while for zinc(II) and cobalt(II) L_2M_2 species have been reported[276,394] (see Section III.H for more examples). The twofold methylation of the central *b*-position, on the other hand, has no significant influence on the coordination properties of *a*,*c*-biladienes (Figure 86).[239]

Linear tetrapyrroles carrying a *meso*-situated oxo functionality at either the central or a side position have been employed occasionally in coordination studies. The readily accessible bilane precursors have been used and oxidized *in situ* to the respective biladienes before addition of the metal ion carrier. The divalent ions of cobalt, nickel, palladium, and copper form L_1M_1 complexes such as **379** and **380** with the expected N_4 coordination.[321,395] Exceptions are found for nickel chelate **216**, in which the metal binds to a side-oxygenized and hydrated biladiene ligand in a N_3O fashion, and for an analogous methanol solvate (Figure 87).[321]

Formally, the removal of the central methylene bridge of biladienes yields 2,2′-bidipyrrins, a nonnatural class of linear tetrapyrroles for which many coordination compounds have been reported. L_1M_1 complexes of these ligands are

Figure 88. Early metalated 2,2′-bidipyrrins of the L_1M_1 type.

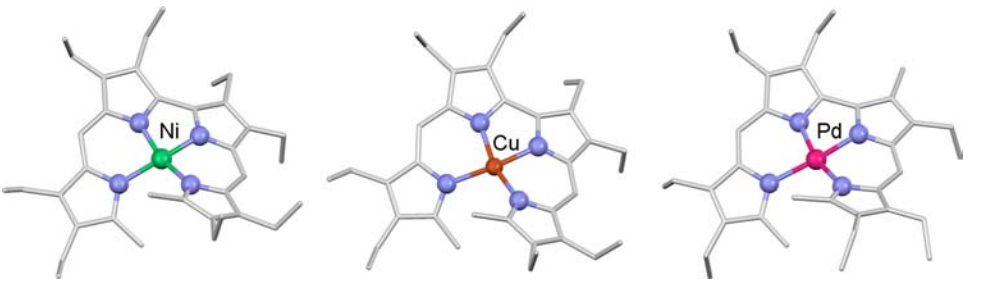

Figure 89. Molecular structures of nickel, palladium, and copper octaethyl-10,10′-dimethyl-2,2′-bidipyrrins. (Adapted from Refs. 396 and 397.)

less prone to oxidative macrocyclization reactions, because the termini of 2,2′-bidipyrrins in metal complexes are further apart from each other than in related *a*,*c*-biladiene chelates. Metalated 2,2′-bidipyrrins have a long history. The first examples were reported in the 1930s in the context of reduction experiments with halogenated dipyrrins.[236,238] Johnson and Price developed the chemistry of 2,2′-bidipyrrins systematically, with the goal of producing corroles from these tetrapyrroles by a metal-templated oxidative macrocyclization. Work from the Johnson group described a number of L_1M_1 coordination compounds with the divalent ions of nickel, palladium, and copper and with 2,2′-bidipyrrins carrying a range of different substituents and termini (Figure 88). A cyclization in the desired way, however, could not be realized.[239]

The first crystallographic investigations and the proof of stable, noninverting helical structures in solution were reported only during the 1990s. Methyl-terminated nickel, palladium, and copper chelates of symmetric and unsymmetric 2,2′-bidipyrrins with alkyl and mixed alkyl/aryl substitution were investigated and shown to display helical solid state structures throughout (Figure 89). The ethyl substituents of diamagnetic nickel and palladium chelates display diastereotopically split signals in solution ^{1}H NMR spectra up to 370 K, indicating static helices even for the large palladium ion. Spectroelectrochemical investigations have shown that two oxidation and two reduction processes occur. All processes are

purely ligand-centered and reversible, although some variation has been observed in the reduction steps of copper derivatives. Other than for *a*,*c*-biladienes, however, an electrochemical ring closure reaction within the group of methyl-terminated 2,2′-bidipyrrin chelates has not been observed.[271,396,397]

The molecular geometry of these simple 2,2′-bidipyrrin complexes has been fine-tuned by the choice of the termini as well as by additional carbocyclic substituents which serve as clamps and restrict intramolecular movement. H-terminated 2,2′-bidipyrrin complexes such as **381** are characterized by small helical distortions and a fast helix inversion in solution, while all alkyl-terminated dervatives investigated so far are rigid under the same conditions (Figure 90). *Tert*-Butyl groups at the terminal positions of a 2,2′-bidipyrrin have been reported to inhibit metal coordination entirely, so that neither L_1M_1 nor dinuclear L_1M_2 or L_2M_2 species were obtained from this tetrapyrrole.[243,270] Besides the obvious strain imposed by the *tert*-butyl substituents in the binding event, these groups seem to reduce the accessibility of the dipyrrin N-donor atoms and thus kinetically prevent the binding of metal ions. A similar stability or an enforced CH activation of the *tert*-butyl substituent has been reported for several related heterocyclic N-donor chelate ligands.[123,201,398–400] In a different approach, an eight-membered carbocycle has been employed as a central clamp. This restraint tears the terminal methyl groups apart from each other and thus results in a slight planarization of the overall structure. A palladium derivative of this ligand, **382**, has been reported.[269] As above, a precedent oligoheterocyclic species with a similar restraint is known.[401]

Complexes with ligand frameworks other than those of the *a*,*c*-biladienes and 2,2′-bidipyrrins have scarcely been reported to date. A copper complex of an

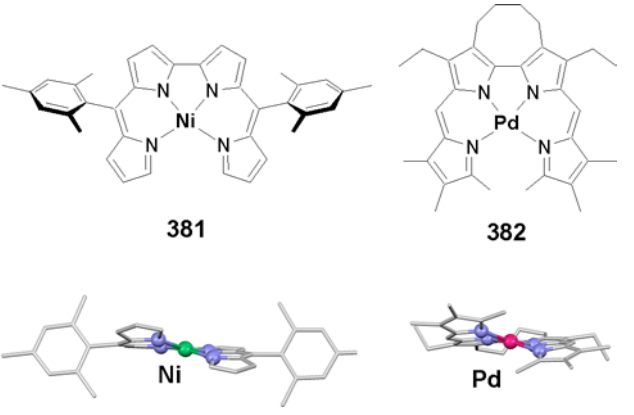

Figure 90. Helical distortions of the H-terminated nickel-2,2′-bidipyrrin complex **381** and the clamp-restrained palladium derivative **382** (end-on views; crystallographic figures adapted from Refs. 241 and 269).

ethylene-bridged bis(dipyrrin) has been mentioned,[239] as has been a zinc chelate of a partially hydrogenated *a*-norbilene.[140] Little spectroscopic evidence and no structural data are available for either species. A study concerning copper nuclease activity of the naturally occurring tetrapyrrole **383** in the presence of copper ions has appeared, but nothing is mentioned with respect to the coordination mode or stoichiometry of the active species.[150] A similar ligand framework, however, is present as a partial structure in palladium derivative **384**, the only structurally characterized metal complex of a hexapyrrolic ligand (Figure 91).[30]

Several transition metal chelates of strongly hydrogenated open-chain tetrapyrrolic ligands have been reported in the context of vitamin B_{12} research. A protocol for the reversible ring-opening and closure of some similar neutral $Co(CN)_2$ and positively charged Ni species yields open-chain derivatives **385** and **386** (Figure 92).[233,234] Divalent nickel provided a good template ion for the cyclization of another open-chain B_{12} precursor, **387**, and has been structurally characterized.[151,402] Yet another ligand framework is present in the Ni, Pd, and Pt complexes **388**, which were also structurally characterized and discussed in the context of the influence of the metal ion size on the magnitude of helical distortion.[403]

The helical molecular structure of all these mononuclear tetrapyrrole complexes and the issue of stereochemistry have been the topic of a number of different studies on open-chain tetrapyrrole coordination chemistry. The central question concerning the stability of the helical form and the rate of helix inversion has been discussed in several contributions. H-terminated 2,2′-bidipyrrin complexes of nickel and of trivalent iron (see Section V.B) have been shown by qualitative VT ^{1}H NMR studies to invert fast on the time scale of the NMR experiment, and no coalescence could be observed for these species. Alkyl-terminated derivatives, on the other hand, are rigid and show no dynamics up to the upper temperature limit of the experiment.[270,396,397] A nickel-2,2′-bidipyrrin with alkyl

and aryl substitution has been separated into its enantiomers chromatographically, and CD spectra were obtained from the chiral material.[396] Enantiopure material was subjected to prolonged heating in high-boiling solvents, but no signs of helix inversion have been found below the decomposition temperature. Stereoselective synthesis of a helical chiral metal complex with an open-chain tetrapyrrole ligand has been achieved by using a set of β-bridged bis(dipyrrin)s with a chiral binaphthyl-type strap such as **126**. Zinc chelates of such ligands, e.g. **389**, form enantiomerically pure with up to 99% ee, depending on the lengths and flexibility of the bridging linker (Figure 93).[299]

Conformational dynamics were studied in depth on zinc bilinone **357** and related species with different substituents at the pyrrole rings. A slow inversion of the helix was found by variable ^{1}H NMR spectroscopy at low temperature (223 K). The rate of the process can be lowered with the size of the terminal pyrrole substituents (reorganization effect). More interestingly, the inversion rate can also be accelerated by the addition of donor ligands, particularly amines and amino acid esters. Further quantitative investigations confirmed that this acceleration is catalytic in the external donor, and a kinetic model has been proposed (Figure 94). This finding is an important issue in the context of the use of such tetrapyrrole complexes as sensor molecules.[246,404]

Chiral discrimination has been observed to occur during the coordinative binding of chiral guests to dynamic zinc bilinone hosts such as **390**. Using amino acid esters or chiral aliphatic amines, the point chirality of the guest is effectively transferred to the helical chirality of the host in a diastereospecific way. The degree of chiral induction has been quantified by CD spectroscopy and depends largely on the nature and binding capability of the guest.[405,406] In addition, the choice of solvent was found to vary the efficiency of the chirality transfer in a predictable fashion.[407] Some covalent dimers and trimers of zinc bilinones, such as **391** (Figure 95), have been prepared and used in related binding studies. It has been found that the conformations of the monomeric forms tend to form homohelical structures upon binding of a small molecule. The synchronous alignment of the helices enhances the sensoric moment, i.e. the change in CD effect upon binding. Consequently, these compounds have been discussed in terms of model systems for allosteric binding of small N donor molecules.[408,409] In another

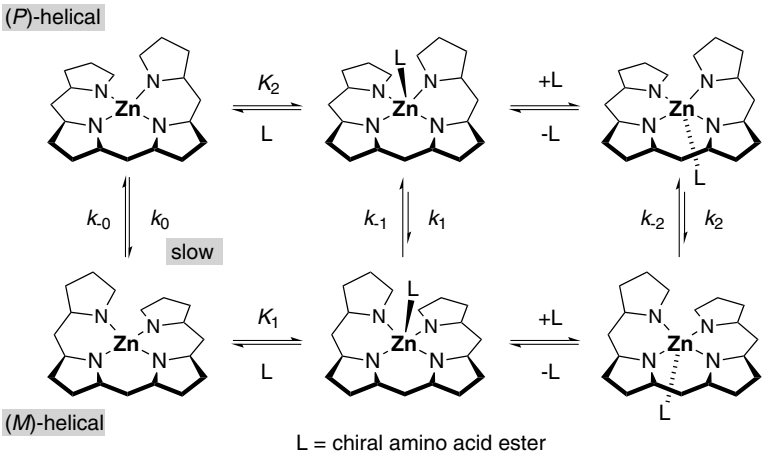

Figure 94. Schematic view of the kinetic model for the catalytic enhancement of the rate of helix inversion on zinc bilinone **390**.

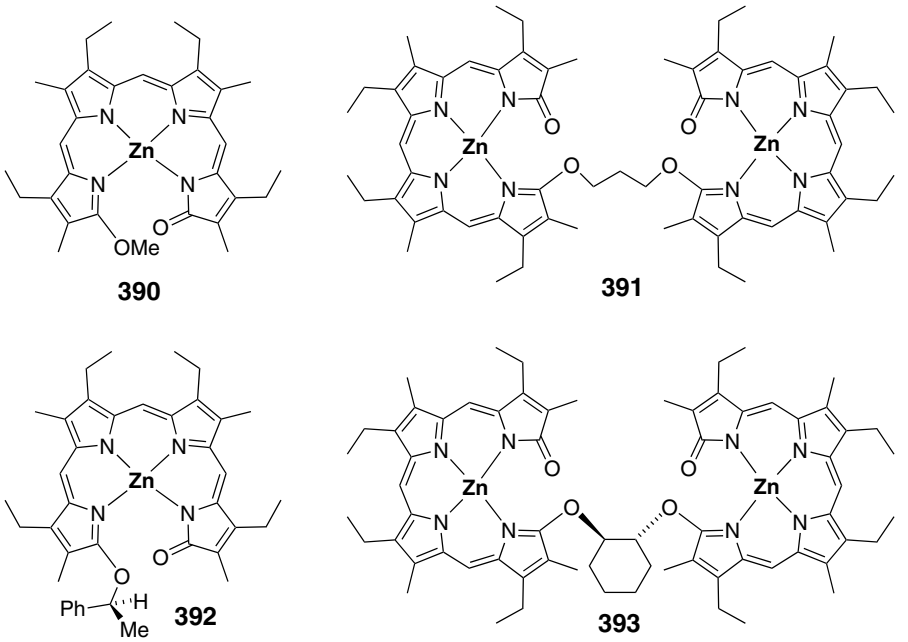

Figure 95. Monomeric and dimeric zinc bilinones **390**–**393** as dynamic multifunctional sensor molecules.

contribution, several chiral substituents were introduced as the alkoxy moiety of the zinc bilinone (e.g. **392** in Figure 95). The substituents were found to induce a significant chiral discrimination on the helical structure in solution.[410] The effect is even stronger if an allosteric enhancement is used,[411] and a number of compounds with chiral bridges between two zinc bilinone subunits, such as **393**, have been prepared and studied. These compounds have found applications in sensing and molecular recognition of the chirality of amino acid esters,[412,413] as well as in liquid crystals.[414]

G. Dinuclear Tetrapyrrole L_2M_2 Complexes

The capability of bilirubin to bind simultaneously to more than one metal cation has been discussed earlier, and related species have been reported for several artificial *a*,*c*-biladiene and 2,2′-bidipyrrin ligands, mainly with zinc ions.[236,273] As for the natural species, the coordination mode and structural details were speculative at the beginning, and a L_2Zn_2 binding mode has been proposed based on combustion and optical data. In-depth studies on the distinction between the L_1M_1 and the L_2M_2 binding modes were undertaken on an α,ω-dimethyl-*a*,*c*-biladiene derivative using vapor pressure osmometry, ligand field spectroscopy, NMR and powder

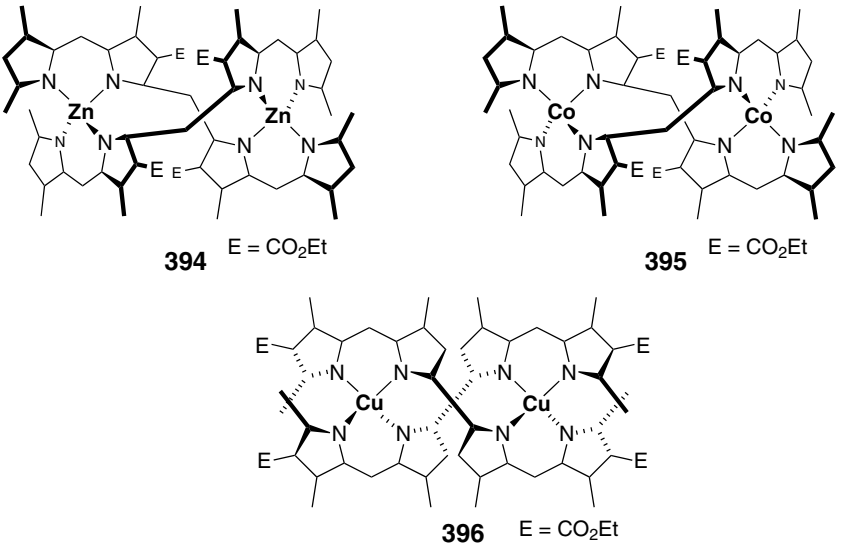

Figure 96. Early dinuclear L_2M_2 derivatives **394**–**396**.

X-ray diffraction techniques, and zinc and cobalt(II) dervatives **394** and **395** were found to exist in the L_2M_2 mode in solution as well as in the solid state.[277,394] At about the same time, copper ions were observed to bind to a 2,2′-bidipyrrin ligand in either a L_1Cu_1 or a L_2Cu_2 mode **396**, depending on the pH of the reaction mixture.[239] Similar 3D molecular structures were proposed for these compounds, as depicted in Figure 96.

A pH-dependent dynamic process similar to the findings on **396** has also been observed spectroscopically with manganese(II) and zinc complexes of bilindione ligands such as **345** or **358** (Figures 74 and 78). This dynamic, however, has not been interpreted in terms of dimer formation. Instead, a conformational change of the ligand and concomitant reduction of the coordination number is reportedly responsible.[214,219] The first single-crystal X-ray diffraction analysis on a dinuclear L_2M_2 species was reported in 1976 and proved the often-stated pH-dependent equilibrium of zinc bilins for formylbilinone complexes **361** and **362** (Figure 79).[380] During the last decade several single-crystal X-ray diffraction studies on dinuclear metal bilins have appeared in the scientific literature and have supported the general formation of a bis-helical conformation. Dimeric zinc decamethyl-*a*,*c*-biladiene **397** has been characterized crystallographically, and the two dipyrrin subunits of each tetrapyrrole ligand were found to reside in an almost orthogonal arrangement. This relaxed conformation results in a zinc···zinc distance of 4.38 Å (Figure 97).[415,416] A very similar, but less symmetric, molecular structure with a metal···metal distance of 4.33 Å has been observed for a cobalt(II) *a*,*c*-biladiene derivative **398**.[27] A dinuclear zinc

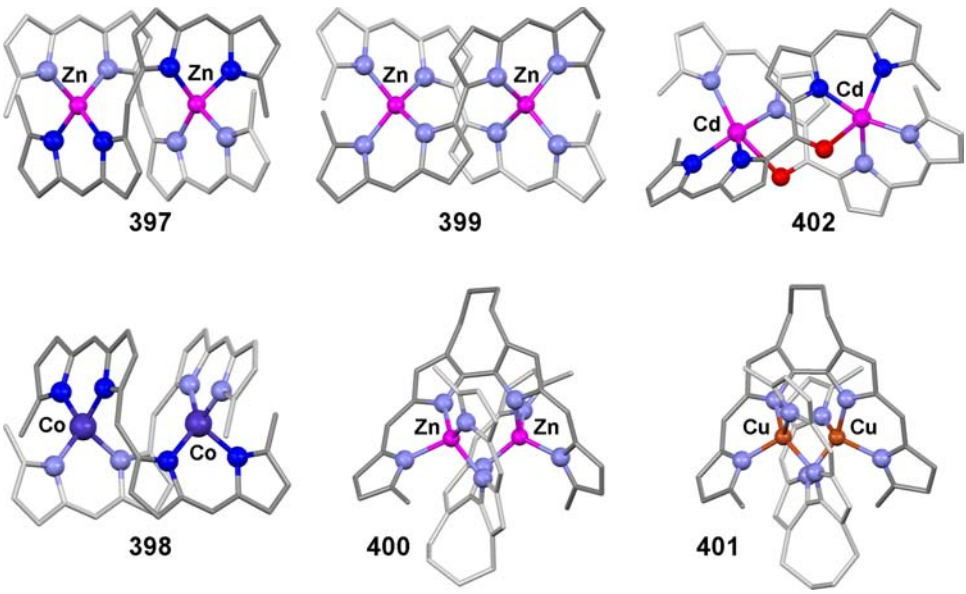

Figure 97. Molecular structures of dinuclear bis(dipyrrin) helicates **397**–**402** (peripheral substituents omitted; adapted from Refs. 27, 269, 395, and 415).

2,2′-bidipyrrin complex **399** with a smaller bridge between the dipyrrin subunits was found to crystallize in a stretched conformation with a zinc···zinc distance of 4.89 Å.[27] An annelated carbocyclic ring at the bipyrrolic unit of 2,2′-bidipyrrins serves as a clamp and results in reduced flexibility of the ligand. A zinc complex of such a ligand, **400**, has been reported to form a compressed helicate (zinc···zinc distance of 3.44 Å). This effect is even larger with the corresponding copper chelate **401**, where a copper···copper distance of only 3.01 Å has been found.[269] This value is below the van der Waals distance for copper but is still too large for covalent Cu–Cu bonding interactions. On the other hand, the introduction of a fifth donor atom such as in the 10-oxobiladienes can lead to stretched conformations. This has been demonstrated for cadmium chelate **402**, where pentacoordinate metal ions in a distance of 5.12 Å are present (Figure 97).[395]

While α-bridged bis(dipyrrin) ligands tend to form L_1M_1 complexes with most transition metal ions, β-bridged tetrapyrroles such as **122**–**126** (Figure 33) are much more prone to bind to two ions in either a L_1M_2 or a L_2M_2 fashion.[295] Attempts to develop tetrapyrrole-based helicates have therefore turned more recently to this latter group of ligands. In β-bridged (bis)dipyrrins, the two chelating dipyrrin units coordinate to the same or two different metals, depending on the size and flexibility of the bridge. As a rule, short- and medium-length bridges result in exclusive formation of dinuclear helicates while longer and more flexible

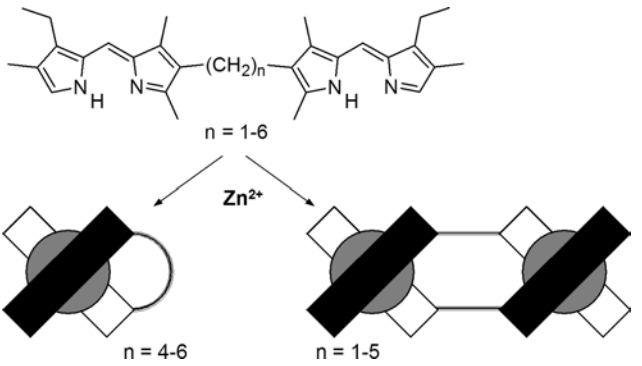

Figure 98. Formation of mono- and dinuclear coordination compounds from β-bridged bis(dipyrrin)s as a function of the lengths of the bridging unit.

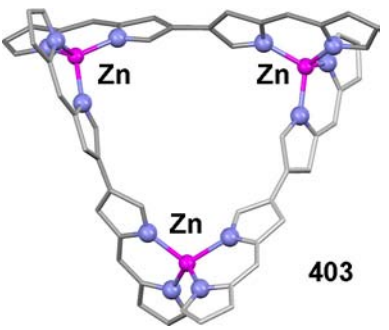

Figure 99. Molecular structure of trinuclear zinc chelate **403**. (Adapted from Ref. 417.)

bridges yield mixtures of mono- and dinuclear coordination compounds. These results were obtained in a study on zinc, copper(II), and cobalt(II) chelates, as sketched in Figure 98.[291] For binap-bridged ligands the aspect of flexibility has been found to be of major importance. Methylene derivative **126** forms a clean L_1M_1 compound **389**, while more rigid as well as a more flexible forms with zero and four CH_2 units in the bridges, respectively, produce mixtures of mono- and dinuclear species.[299] In the case of a directly connected 3,3′-bidipyrrin ligand (i.e. for $n = 0$ in Figure 98), a trinuclear species L_3Zn_3 **403** was reported (Figure 99).[417]

Methylene-bridged members have been employed in most of the reported coordination studies on β-bridged bis(dipyrrin)s, and crystallographic analyses were obtained on dinuclear nickel(II),[418] cobalt(II),[419] and zinc(II)[292,293,419] chelates such as **404**–**406** (Figure 100). In addition, optical and vibrational spectra have been recorded, and detailed TD-DFT calculations have been undertaken to elucidate the physicochemical properties of these new materials.[420] A triple helicate/mesocate system was described, and the zinc chelate **407** of an unsymmetric methylene

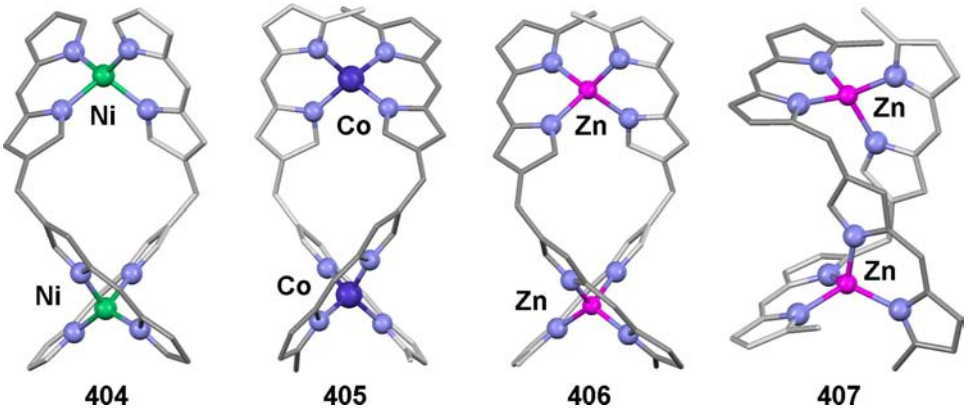

Figure 100. Results from X-ray crystallographic studies (peripheral substituents omitted) on dinuclear helicates with β- and α,β-bridged bis(dipyrrin) ligands **404**–**407**. (Adapted from Refs. 264, 292, 418 and 419.)

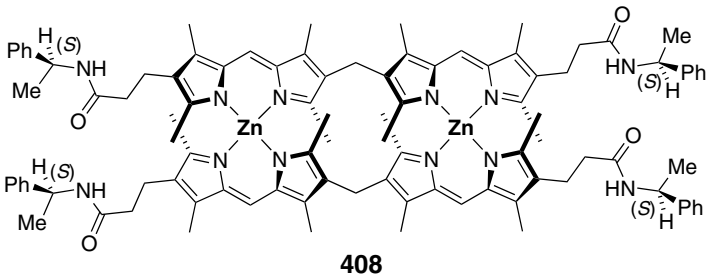
α,β-bridged ligand has been found to crystallize in only one of the two possible conformations.[264,421]

Two reports can be found in which bridges other than the simple saturated hydrocarbon have been used (Figure 33). A sulfur atom connected (bis)dipyrrin ligand **124** was used in the coordination to zinc ions.[28] The resulting complex displays a molecular structure similar to that of methylene derivative **406**. In another instance, several rigid bridges based on oligoacetylenes such as **125** were used and the tetrapyrroles coordinated to zinc and cobalt(II) ions.[298] Dimeric cobalt chelates similar to **405** result for bent bridges, and a trimeric zinc compound similar to **403** (Figure 99) has been found for linear ligand **125** (Figure 33). These elongated bridges leave hollows in the crystal lattice, thus giving hope for an application in supramolecular materials (see Section VIII).

Stereochemical aspects of the dinuclear helicates formed from zinc ions and methylene-bridged bis(dipyrrins) have been discussed in three contributions. The presence of helical chiral molecules in solution has been proven in one case by NMR spectroscopy using lanthanide shift reagents.[422] For a series of β-bridged bis(dipyrrin) ligands carrying chiral peripheral groups such as tetra-amide **408** (Figure 101), the diastereoselectivity of the helicate formation upon the addition with zinc ions was investigated,[300] and the stereochemical stability of the products was established in solution by separation using chiral HPLC.[423]

H. Oligonuclear Noble Metal Species

The coordination of tetrapyrrolic ligands to noble metal atoms may be expected to yield helical chiral porphyrinoids. Such derivatives would be intriguing



408

Figure 101. Stereochemically stable dinuclear double helicate **408**.

bioorganometallic compounds with perspectives in enantioselective catalysis, and several attempts to obtain species of this class have been undertaken in the past. The coordination chemistry of these metals, however, and in particular the observed coordination modes, have been found to differ largely from those of the 3d metals. With the exception of examples for divalent palladium and platinum, no simple noble metal compounds with N_4 coordination have so far been obtained, and even with palladium some unexpected behavior was reported.

Rhodium(I) and iridium(I) are well known to prefer square-planar coordination. Both ions have been employed in coordination studies with 2,2′-bidipyrrin ligands.[424–426] Mononuclear complexes HL_1M_1 and dinuclear species L_1M_2 have been observed and isolated. Figure 102 summarizes the formation and reactivity of rhodium and iridium 2,2′-bidipyrrin coordination compounds, and Figure 103 gives molecular structures of two examples of the L_1M_2 type.

Rhodium(I) and iridium(I) form mono- and dinuclear complexes with 2,2′-bidipyrrins in which the metal ions are always coordinated in a distorted square-planar geometry. Mononuclear HL_1M_1 species **409** of rhodium and iridium form exclusively upon the use of particular metal precursors, i.e. $[Rh(cod)Cl]_2$ and $[Ir(cod)OMe]_2$, respectively. If the combination of metal and anionic coligand is switched, i.e. if $[Rh(cod)OMe]_2$ and $[Ir(cod)Cl]_2$ are used, dinuclear species **410** are obtained as the only isolated products. No rationale has been provided so far for this peculiarity. The exchange of the cod ligands in **409** and **410** for two CO is generally possible and results in very robust dinuclear and very labile mononuclear products. Dinuclear rhodium carbonyl derivative **411a** may also be obtained directly by the use of $[Rh(CO)_2Cl]_2$ in the presence of a solid base. All dinuclear complexes with either cod or CO coligands, such as iridium derivative **411b**, display a *syn* conformation with short M···M contacts in solution and in the solid state (Figure 103).

Rhodium carbonyl complex **411a** has been used as starting material for ligand exchange studies with different monophosphanes and diphosphanes. Excess triphenylphosphine displaces the sterically less hindered CO ligand on both rhodium

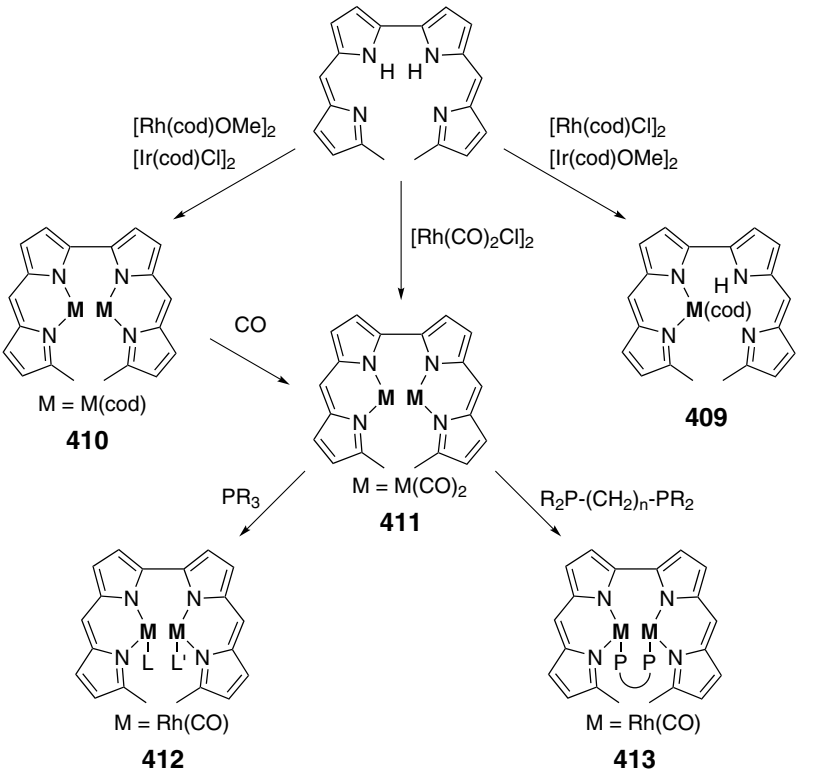


Figure 102. Rhodium and iridium complexes with 2,2′-bidipyrrin ligands.

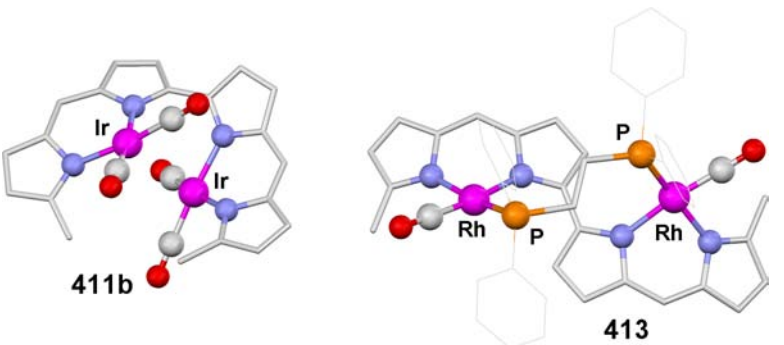

Figure 103. Molecular structures of dinuclear iridium and rhodium 2,2′-bidipyrrins **411b** and **413** in the *syn* and *anti* conformations. (Adapted from Refs. 425 and 426.)

atoms to give symmetric derivative **412**, while the more basic trimethylphosphane and tri-isopropylphosphane can only be used in stoichiometric amounts and form inseparable mixtures of derivatives of **412** with one and two phosphane ligands (Figure 102; L = PR_3, L′ = CO). 2D correlation NMR studies have confirmed a *syn*

conformation of the tetrapyrrole in all cases. If chelating diphosphanes such as dppm or dppe are employed, the tetrapyrrole switches to an *anti* conformation. As the X-ray crystallographic analysis on **413** shows, the 2,2′-bidipyrrin is now stretched out and the two rhodium atoms are bridged over the same side of the tetrapyrrole by the diphosphane clamp. Again, only the less hindered CO ligand has been exchanged. All attempts to form simple L_1M_1 species with N_4 coordination to monovalent or trivalent rhodium and iridium ions have failed so far, despite the fact that the transformation of L_1M_2 to L_1M_1 is well established in the chemistry of the related porphyrins.

While the compounds with rhodium and iridium ions still follow the general principles of the chemistry of these ions with porphyrinoid ligands, several other cases have been reported in which the coordination mode has been entirely unpredictable. One such case was observed during a study of the synthesis of copper complex **367** (Figure 81). In the presence of excess copper(II) ions and water this complex is hydrated at a *meso* position, and a second copper atom binds to the hydrated ligand to form the new dinuclear species with a Cu_2O_2 core. Upon crystallization, this dinuclear complex dimerizes via an additional, but weak, Cu_2O_2 interaction to give tetranuclear species **414** (Figure 104).[383] A similarly hydrated aroylbilinone ligand has been reported for a mononuclear zinc chelate. This species, however, dimerizes directly via multiple H-bonding interactions to give **368** (Figure 82).

Another tetranuclear cluster was observed as a byproduct during the synthesis of (oeb)Pd **350**. Mixed-valence species **415** contains two divalent and two monovalent palladium ions, the latter being connected to each other by a covalent

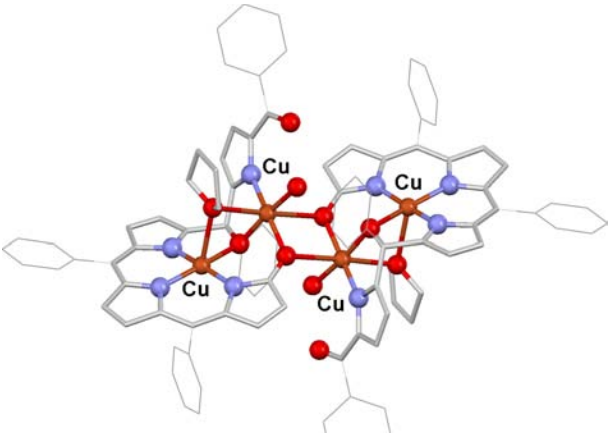

Figure 104. Molecular structures of tetranuclear dimer **414**. (Adapted from Ref. 383.)

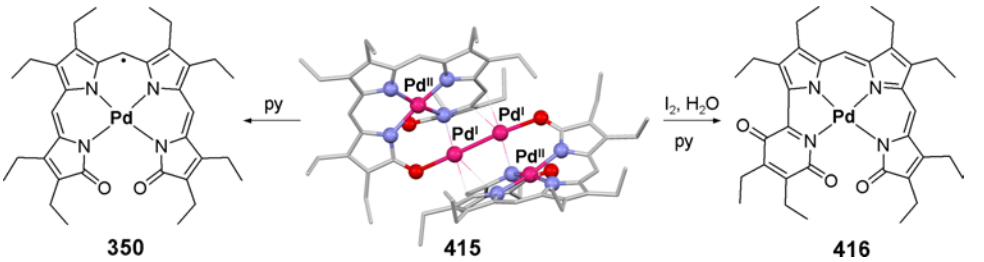

Figure 105. Structure and reactivity of tetranuclear palladium chelate **415** (crystallographic figure adapted from Ref. 427).

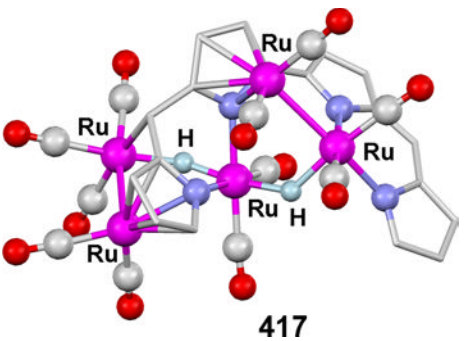

Figure 106. Molecular structure of pentanuclear ruthenium carbonyl cluster **417** (alkyl groups omitted; adapted from Ref. 429).

bond.[427] Compound **415** is remarkably stable and survives even chromatographic conditions, presumably because the $(Pd^{I})_2$ subunit is perfectly shielded by the two tetrapyrrole π systems. The reactivity of **415** was studied in some detail and revealed further peculiarities (Figure 105).[428] In the presence of pyridine, **415** was found to decompose with the formation of the radical palladium(II) oeb complex **350**. If iodine and water are present, however, the oeb tetrapyrrole framework undergoes an unprecedented rearrangement, yielding the novel palladium chelate **416**.

The coordination compound of a linear tetrapyrrole with the highest nuclearity has been isolated from the reaction of a 2,2′-bidipyrrin with $[Ru_3(CO)_{12}]$ in boiling toluene. After chromatographic workup a red compound was isolated in a 13% yield, which was identified by single-crystal X-ray diffraction as pentanuclear ruthenium carbonyl complex **417** (Figure 106).[429] As for Pd_4 derivative **415**, the remarkable stability of the cluster compound arises from an efficient shielding of the linear Ru_5H_2 core, which in this case is affected by the tetrapyrrole and the 11 CO coligands. Two features of **417** deserve special attention. First, this complex comprises three different types of metal–tetrapyrrole interactions, i.e. four

classical Ru–N coordinative bonds, two Ru–C_4N–η^5 bonds, and one organometallic Ru–C(sp^3) bond. In addition, the ruthenium atoms are in different formal oxidation states, i.e. 2 × Ru(0) at the ends and 3 × Ru(II) in the center. Second, the NH protons of the ligand have remained in the cluster framework as bridging hydride ligands. These hydrides were unambigously identified by NMR spectroscopy and confirm that NH activation processes occur during ruthenium complexation.

IV. Pincer-Like Palladium Complexes

A. Cationic Species

Cationic N donor chelate complexes and organometallics of divalent palladium have found many uses in academic as well as applied chemistry. Prominent examples are found in the polymerization or oligomerization of alkenes and in alkene/CO copolymerization reactions which are successfully catalyzed by activated palladium complexes with diimine or other N,N chelate ligands, and which yield a plethora of functional polymers with specialized and commercially interesting properties. In addition, many stoichiometric and catalytic C–C and C–E bond-forming and isomerization reactions and a vast number of C–H activation processes and cyclopalladation reactions have been investigated within this class of transition metal complexes, and several of these transformations have been proven valuable in the syntheses of small molecules. More fundamental studies, concerning e.g. functionalization strategies, ligand exchange processes, structure/reactivity correlations, fluxional behavior, or electron transfer issues, are also well documented in the scientific literature, particularly for cationic bipy, terpy, and pincer-type palladium(II) species. In the series of tripyrroles, cationic palladium complexes have become available with methyl-terminated tripyrrin and bti ligands. Transition metal complexes of α,ω-dimethyltripyrrin or bti ligands are characterized by the steric repulsion which is present between an anionic coligand (in particular the donor atom of that coligand) and the two methyl groups situated at the termini of the open-chain tripyrrole. The steric overcrowding at the open site of the linear tripyrrole leads to strained, nonplanar structures, as shown for some neutral derivatives above, and eases the formation of cationic species.

The formation of cationic palladium(II) tripyrrin complexes by salt metathesis of the respective trifluoroacetates **149** and **150** with different salts of weakly coordinating anions was reported.[430] With nonhydrolizable counterions, cationic mono- and dinuclear complexes **418**–**421** are observed, depending on the nature of the anion and the solvent (Figure 107). Mononuclear cations **420** and **421**, which are formed only with the BAr^F anion [= tetrakis(3,5-bis(trifluoromethyl)phenyl)boranate], were

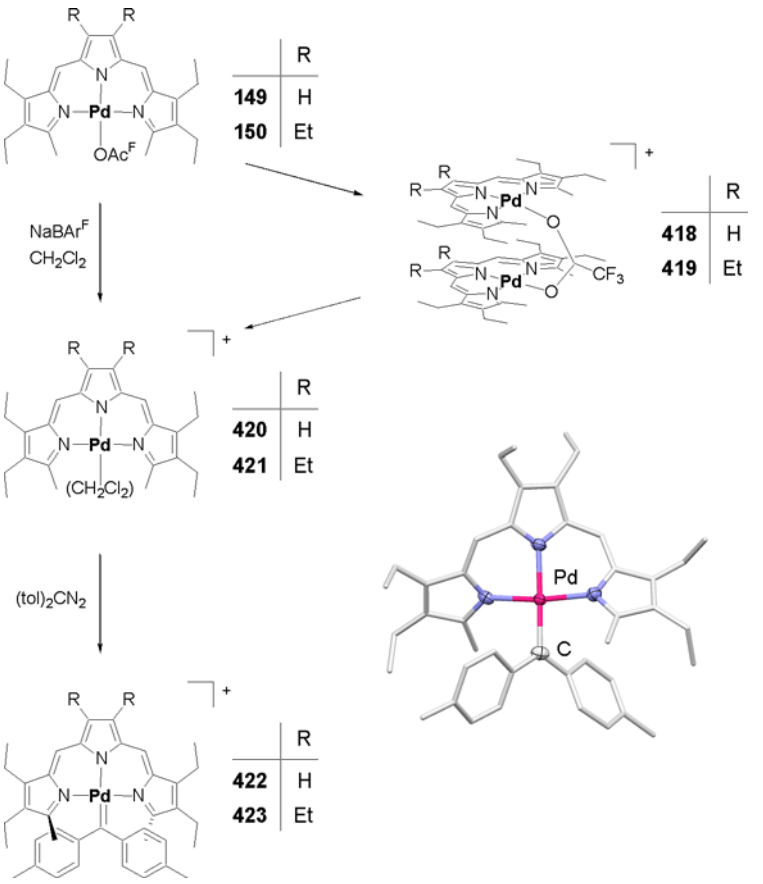

Figure 107. Salt metathesis and carbene complex formation on palladium tripyrrins (crystallographic figure adapted from Ref. 431).

assumed to carry a weakly bound molecule of dichloromethane at the fourth coordination site. When treated with diazoalkanes, these cations are sufficiently reactive to form carbene complexes **422** and **423** (Figure 107).[431] Coordination compounds of alkylidene ligands with the d^8 transition metal ions Rh(I) and Ir(I) have become available in recent years, and the structural and spectroscopic properties as well as reactivity patterns are known for several examples. In addition, a large and constantly growing number of Pd(II) and Pt(II) complexes of Fischer- and Arduengocarbenes have been reported in much detail. Surprisingly, though, Pd(II) complexes of non-heteroatom-stabilized carbene ligands have remained unknown so far, with the exception of **422** and **423**. Pd(II) carbenes have, however, been postulated as the reactive intermediates in the Pd(II)-catalyzed cyclopropanation of alkenes.

Four-coordinate Lewis base adducts with CH_3NC, *t*$BuNH_2$, PMe_3, PEt_3, and P*i*Pr_3 **424**–**432** have been prepared from mononuclear cations **420** and **421** and

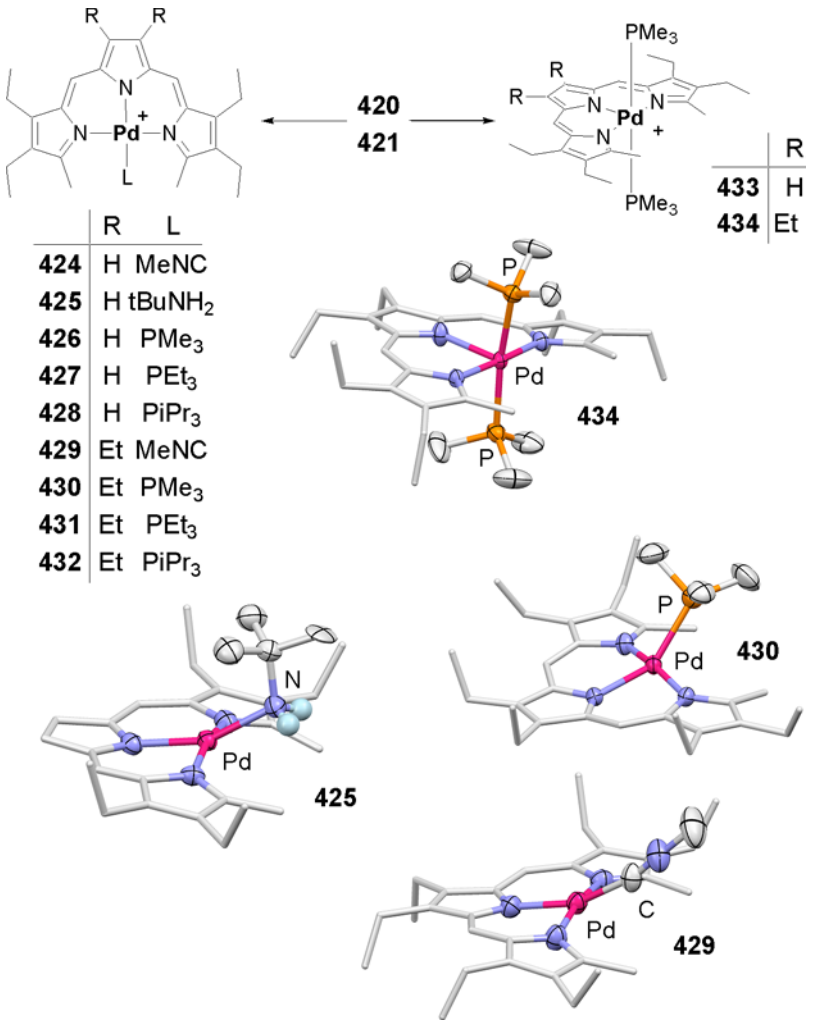

Figure 108. Molecular structures of four- and five-coordinate palladium tripyrrin complexes (crystallographic figures adapted from Refs. 430 and 432).

were analyzed by X-ray diffraction.[430] With two equivalents of PMe_3, five-coordinate 18 VE (valence electron) complexes **433** and **434** were obtained; these are stable in the solid and in solution (Figure 108).[432] The square-pyramidal coordination of **433** and **434** results in an unstrained molecular structure and in elongation of the apical Pd–N bond to about 2.3 Å. Pd(II) ions usually form very stable square-planar 16 VE complexes, due to a high-energy nonoccupied $4d(x^2–y^2)$ orbital. Ligand exchange reactions on these tetracoordinate complexes always proceed via an associative mechanism, with a square-pyramidal or trigonal-bipyramidal 18 VE species being the reactive intermediate. As shown

by electrochemical methods, anionic 18 VE complexes play a major role in all important palladium-catalyzed C–C coupling reactions. In the past, many such five-coordinate Pd(II) species have been characterized in the solid state by X-ray diffraction. In solution, however, these compounds are mainly dissociated, and only four-coordinate 16 VE species could be observed directly. Again, tripyrrin derivatives **433** and **434** are the only exceptions to this rule. In addition, the exclusive formation of a stable five-coordinate complex seems to be characteristic of the PMe_3 ligand and was observed also in a series of cationic cobalt tripyrrines.[433]

With one half equivalent of $NaBAr^F$, only every second trifluoracetato ligand of **149** and **150** is exchanged, and the system stabilizes in dimeric double-decker trifluoracetates **418** and **419** with attractive structures (Figure 109). From these, dichloromethane complexes **420** and **421** can be obtained simply by adding the remaining equivalents of the reagent.[430] bti palladium complexes, on the other hand, are less reactive, and always form the chlorobridged double-decker compound **435** from a neutral precursor, regardless of the stoichiometry of the reaction.[434] A cationic mononuclear palladium bti species has been obtained from this double-decker with acetonitrile and additional $NaBAr^F$, while harder O donor ligands failed in this reaction. The ultrasoft $TeMe_2$ ligand, on the other hand, was

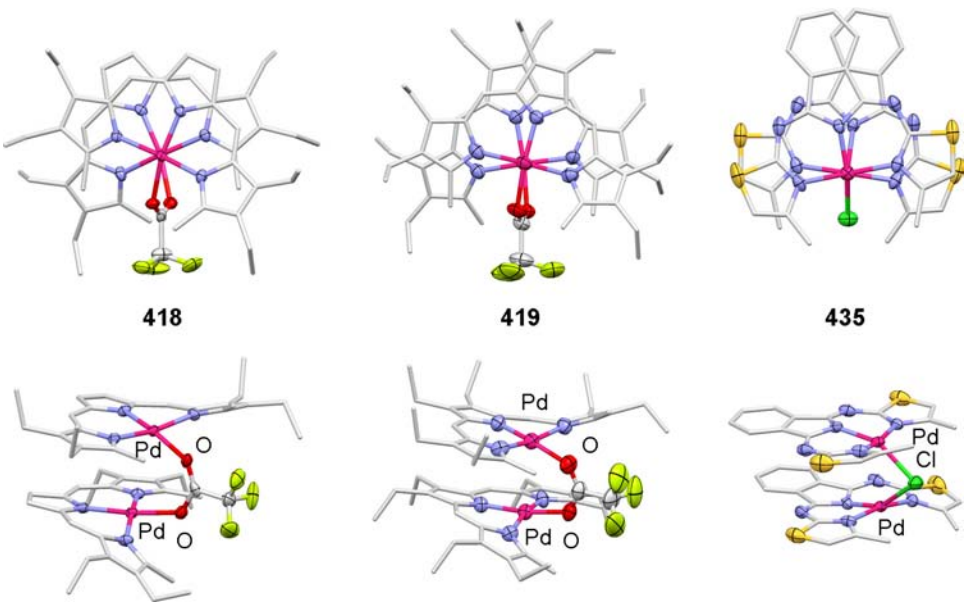

Figure 109. Selected representations from X-ray crystallographic analyses of cationic palladium tripyrrin and bti complexes with double-decker structures. (Adapted from Refs. 430 and 434).

reported to displace the bti ligand and form a cationic complex $[PdCl(TeMe_2)_3]^+$ under these conditions.[435]

B. Intramolecular CH Activation

Palladacycles constitute an important class of organometallic species. Despite their historical role in the development of organometallic chemistry, cyclometalated palladium(II) compounds have found entry in many different fields, such as organic synthesis, catalysis, and materials science. In addition, many of the nowadays-indispensable palladium-promoted organic transformations are considered to proceed via palladacyclic intermediates. A cyclopalladation reaction was reported to occur yielding square-planar 6-Mebpi complex **436**, in which a deprotonated isoindoline anion coordinates as a tridentate pyridinium C,N,N pincer ligand (Figure 110).[197] The finding is in contrast with the classical N,N,N coordination observed with sterically hindered bti ligands and indicates an increase in intramolecular strain in going from the bti or tripyrrin to the bpi ligand framework. The related reaction of H(6-Mebpi) with palladium acetate results in the high-yield formation of the cyclometalated and insoluble tetranuclear dimer **437**.[198] This latter transformation was monitored by ^{1}H NMR spectroscopy and was found to proceed stepwise via a classical Werner-type N,N,N chelate and a mononuclear cyclometalated C,N,N chelate species.

An H(4,6-Me_2bpi) ligand was studied in which the steric encumbrance of the N,N,N and the C,N,N coordination scenario is of comparable strength. Both of the forms **438** and **439** could be isolated and characterized crystallographically.[436] It was reported that the addition of a second equivalent of palladium acetate to **438** resulted in irreversible formation of cyclometalated dimer **439**. Further studies with bai ligands with different degrees of intramolecular strain gave classical Werner-type compounds **440**, **441**, and **442**. Neither unstrained complex **440** nor pyrazine derivative **442** could be triggered to bind a second Pd(II) ion, and it was concluded that the second metalation step supports the C–H activation but does not induce it. In addition, compound **441** showed that the reactivity of the system is not sufficient for C–C activation (Figure 111).[198]

These findings on cyclometalated palladium bai complexes led to the development of a strategy for the preparation of unsymmetric C,N,N pincer complexes by a stepwise condensation to bis(arylimino)isoindolines and successive cyclopalladation. Several new species from this class were prepared, characterized, and visualized by X-ray crystallographic analyses.[205] The simple phenylimino-substituted bai ligand H(phpi) reacts with palladium(II) acetate upon cyclopalladation to yield the expected complex **443**, but is subject to side reactions. As a product from one such side reaction, a dimetalated species **444** was detected

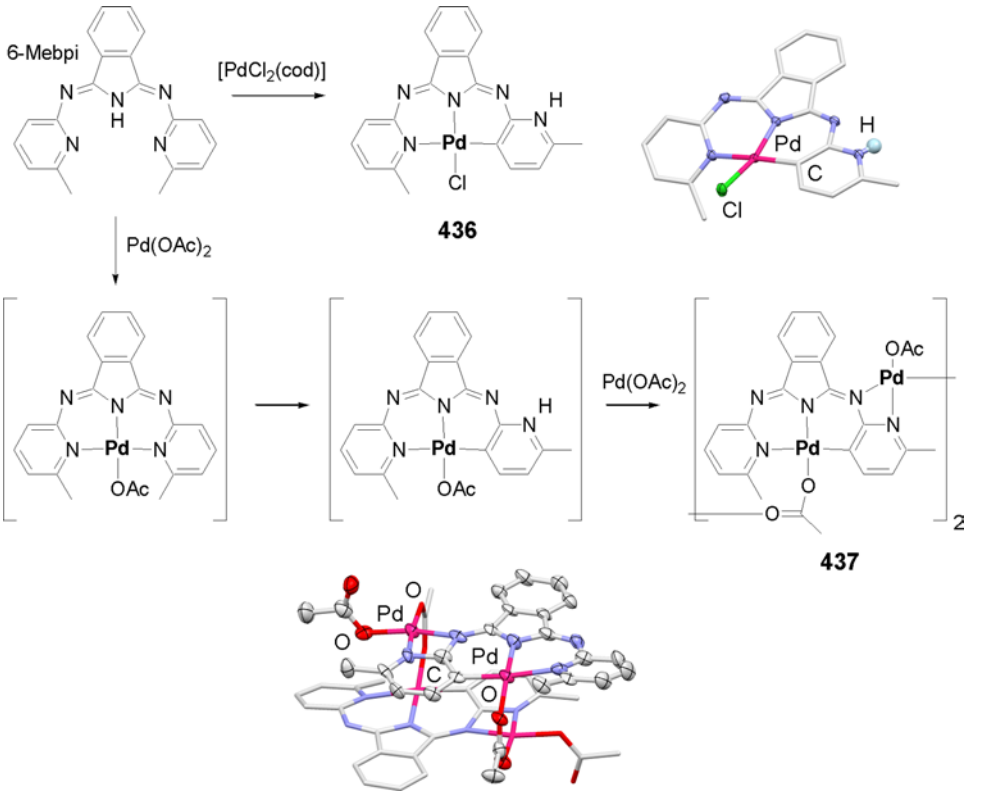

Figure 110. Cyclopalladation reactions with the H(6-Mebpi) ligand (crystallographic figures adapted from Refs. 197 and 198).

crystallographically. If the coordination site for a second palladium atom, i.e. the 2-position of the phenyl group, is substituted by methyl or even by iodo, the respective ligands H(2-tolti) and H(2-Iphti) react cleanly and produce the desired mononuclear products **445** and **446** in acceptable yields. In this system, the iodophenyl group is not attacked by palladium(II) acetate but can easily be used for oxidative addition to the zerovalent palladium precursor $[Pd(PPh_3)_4]$ to yield an *exo* complex **447** (Figure 112).

The use of a H(bti) ligand with methyl groups at terminal positions led to the Werner-type compound **304** only. When these methyl groups were exchanged for *tert*-butyl substituents, however, the reaction took a different course, and a new compound **448** with C(sp^3)–H-activated *tert*-butyl group and S-coordinated thiazole donor in the *cis*-position was isolated (Figure 113).[201] The reaction was carried out using three equivalents of palladium acetate and was reported to proceed smoothly in a range of different solvents (acetonitrile, toluene, methanol, dichloromethane, etc.) at ambient temperature without any detected side products.

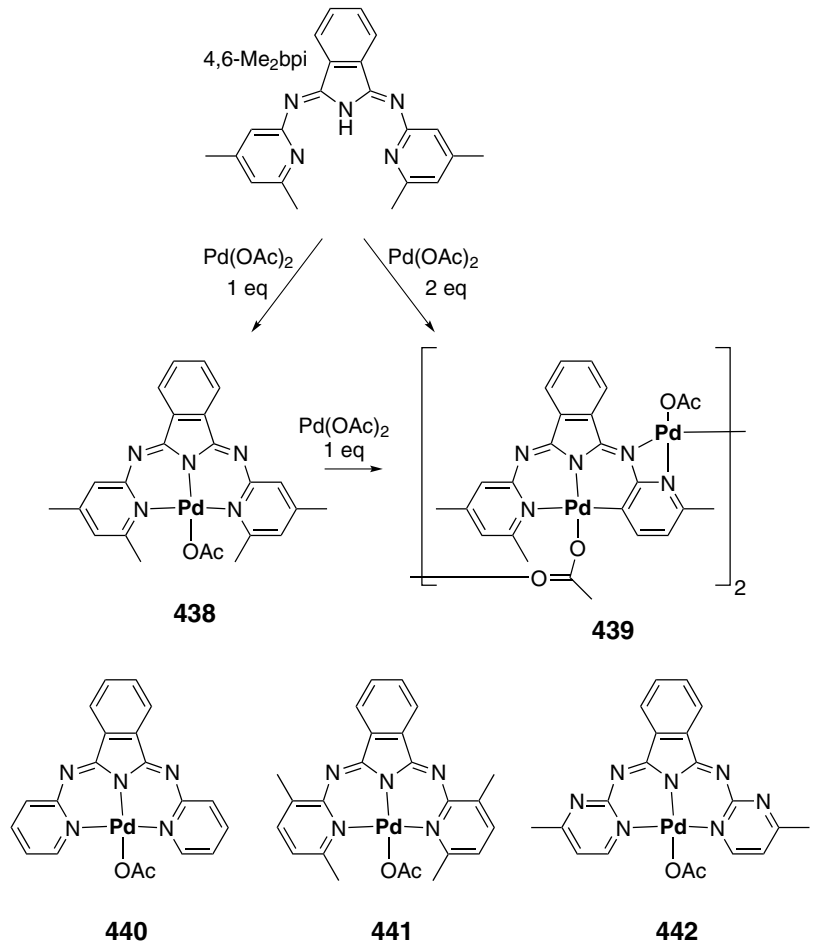

Figure 111. C–H activation and dimer formation studies on different bai ligands.

Both the C(sp^3)–H activation and the S(thiazole) coordination at palladium(II) are rare features in palladium chemistry. The thiazole was found to be bound only very weakly, and clean exchange of this donor with CO and pyridine to give **449** and **450**, respectively, has been observed.

C. Active Catalysts

Pincer complexes of palladium(II) are of general interest in the context of catalytic C–C coupling reactions. While so far no reports on catalytic properties of palladium chelates with "real" tripyrrole ligands have appeared, the more robust bai and bop systems have been the subjects of a number of reports. Compound **323**

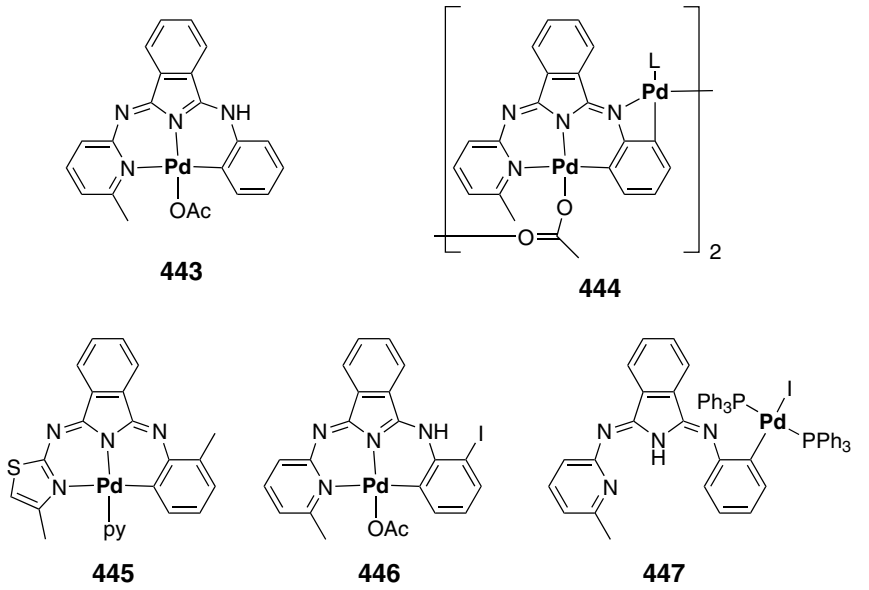

Figure 112. Cyclometalated palladium chelates **443**–**447** from unsymmetric bai ligands.

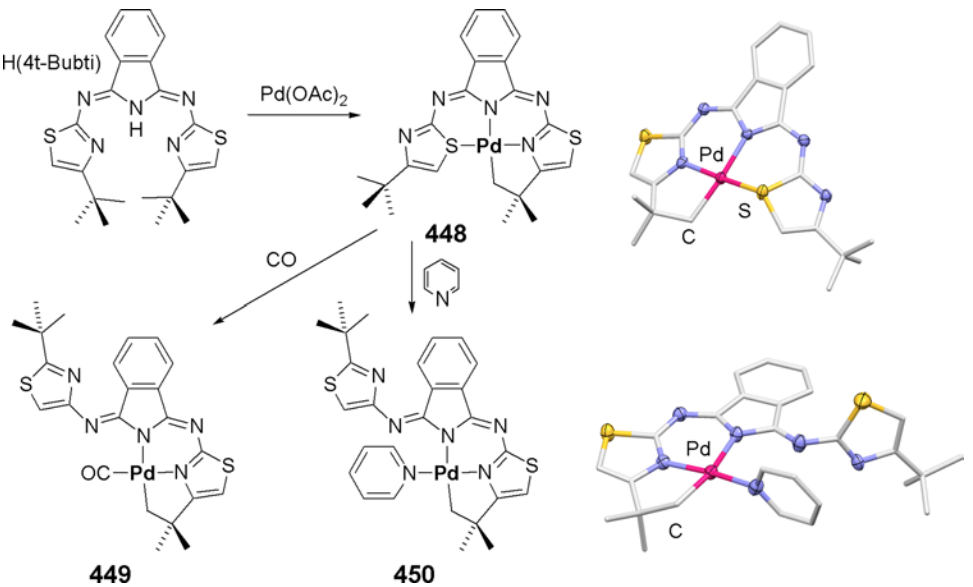

Figure 113. C(sp^3)–H activation and chemistry of hemilabile cyclometalated palladium bti **448** (crystallographic figures adapted from Ref. 201).

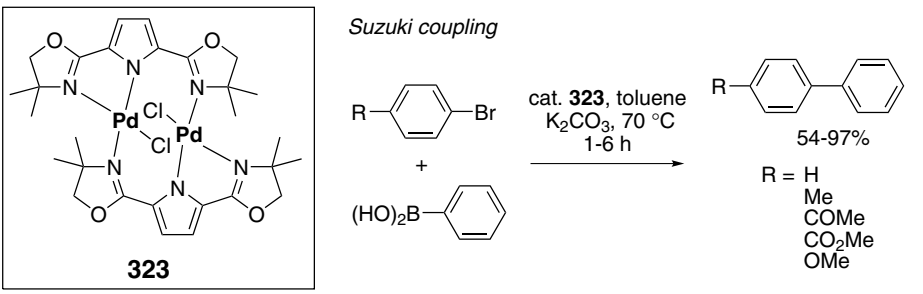

Figure 114. Catalytic performance of palladium bop dimer **323**.

was found to be a highly active catalyst in the Suzuki-type coupling of phenylboronic acid with aryl bromides at relatively moderate temperature (Figure 114). The new catalyst was found to be very stable under the conditions of the Suzuki coupling, and no palladium black was formed during the reaction. The catalytic reaction was followed by GC-MS, and 100% conversion was obtained with both activated and deactivated bromides after 1–6 hours. Decrease of the catalyst/substrate ratio to 10^{-5} still gave an 82% isolated yield of 4-bromoacetophenone and 54% 4-methoxyacetophenone after 4 hours, amounting to turnover numbers of 82,000 and 54,000, respectively. In contrast to the reactivity toward aryl bromides, the catalyst proved to possess only very low activity toward the corresponding chlorides, with the reaction effectively stopping after a few cycles at 110 °C.[437]

Compound **445** has been used as a precatalyst for Heck and Stille-type coupling reactions, as depicted in Figure 115. The catalytic performance was studied as a function of electronic and steric factors of the substrate. In the Heck reaction, the reactivity decreases as expected in the order iodoaryl > bromoaryl > chloroaryl, whereas an increase in steric repulsion has only a minor effect on the outcome of the reaction. The activity of **445** as a precatalyst is higher compared to palladium acetate, but does not reach the performance of some other palladium complexes that have been studied earlier. A similar picture is provided by the attempts to catalyze Stille coupling reactions. In this case, however, the influence of steric bulk was reported to be much more pronounced than for the Heck reaction. In all cases, the reaction mixtures turned dark upon heating, and the addition of mercury stopped the transformations immediately, indicating that the active species throughout is elemental palladium.[205]

The activity of **451** in the catalytic hydrogenation of C=C double bonds was tested for the reaction with styrene, 1-octene, and cyclohexene. As expected, the reaction proceeds fast for styrene and very slowly for the internal alkene, cyclohexene. A mechanistic scheme taking into account the possibility of imino N protonation during the cycle has been proposed (Figure 116). The stability of the palladium

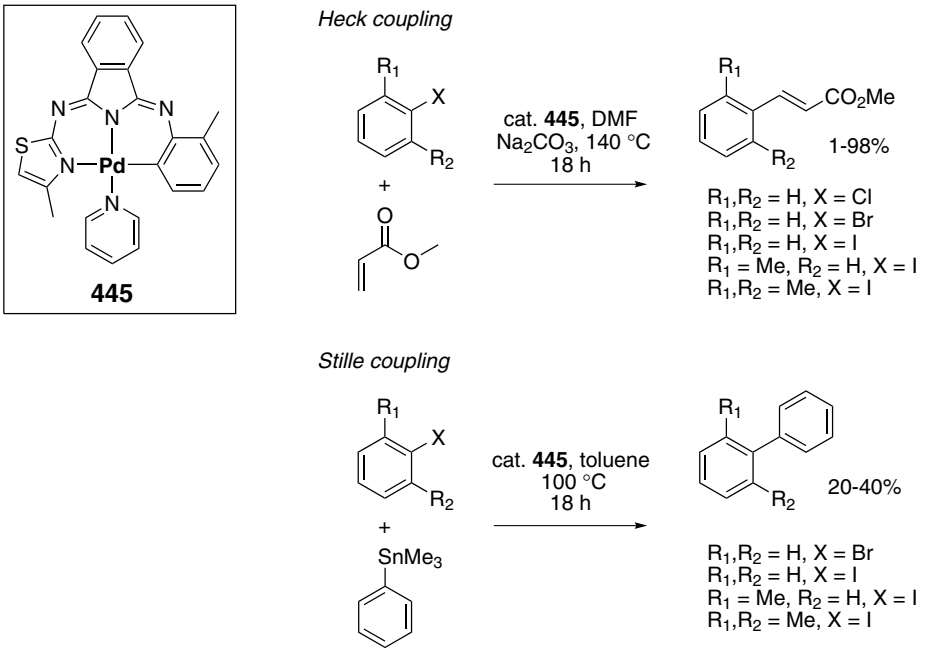

Figure 115. Catalytic performance of cyclometalated palladium bai **445**.

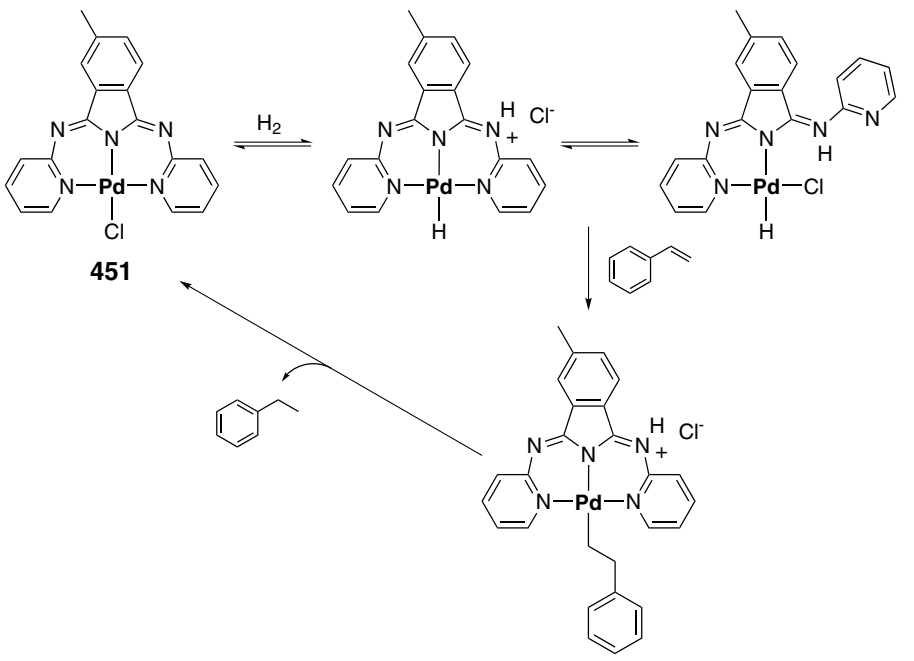

Figure 116. Mechanistic proposal for the catalytic hydrogenation of styrene by **451**.

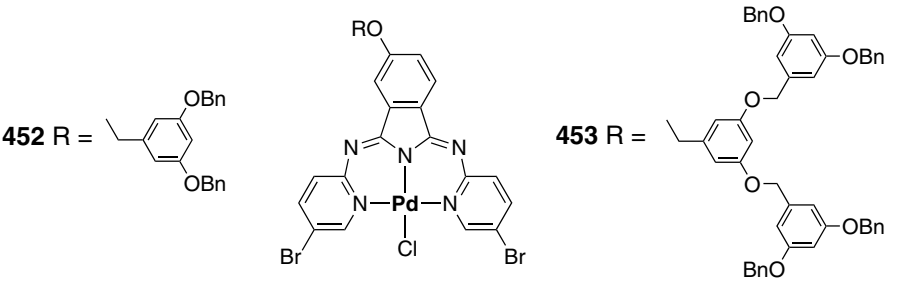

Figure 117. Dendritic palladium bpi hydrogenation catalysts **452** and **453**.

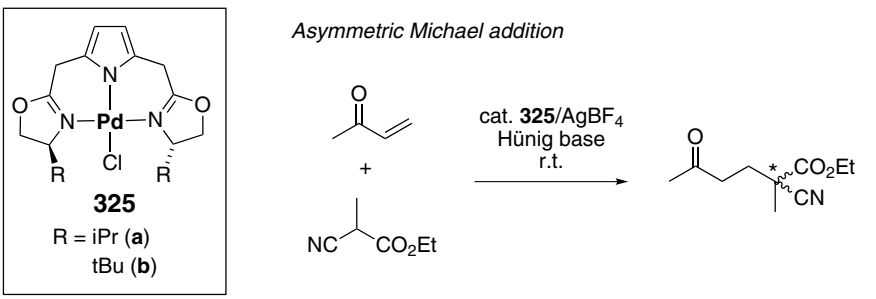

Figure 118. Asymmetric Michael addition catalyzed by chiral palladium bop complexes **325**.

complex, the reproducibility of the reaction kinetics, the different behavior toward the three olefins chosen as substrates, as well as the possibility of isolating the non-decomposed catalyst after several catalytic runs, provide circumstantial evidence for molecular catalysis with the bpi–palladium complexes in this case.[438]

Similar results were obtained with dendron-substituted complexes **452** and **453** (Figure 117).[439] A remarkable feature of these catalysts carrying dendritic wedges is the rapid isomerization of 1-octene to 2-octene, which for the second generation dendrimer catalyst **453** leads initially to an almost complete shift of the C=C double bond (> 80%) before the hydrogenation of the olefin(s) sets in.

Finally, bop complexes **325a** and **325b** were tested in catalytic asymmetric Michael addition of ethyl 2-cyanopropionate to methyl vinylketone (catalyst loading: 1 mol%) and were found to give maximum ee values of 43% and 21%, respectively, at low conversions (Figure 118).[209]

V. Biomimetic Iron Complexes

A. Intermediates and Products from Ring-Opening Reactions

Heme oxygenases (HOs) are a family of enzymes which catalyze the oxygen-dependent degradation of heme to biliverdin IX **9**, CO, and iron. Three molecules

of O_2 and seven reducing equivalents are required for this transformation. In mammals, HO has a key function in physiological heme metabolism, whereas in certain pathogenic bacteria it is used for iron uptake from heme obtained from the host. In contrast, in higher plants, cyanobacteria, and algae, HO functions in the biosynthesis of linear tetrapyrroles such as the phytochrome chromophore, or phycocyanobilin. More recently, an additional role of certain HOs in the production of CO as a neurotransmitter has been speculated on. This natural heme degradation process is still one of the major driving forces for linear tetrapyrrole research, in particular with respect to their coordination properties. The mechanism of the transformation of heme to biliverdin IXα **9** is complex and has been studied ever since the enzymatic nature of the reaction was unraveled in 1963. The current proposal for vertebrate HO action consists of three distinct oxygenation steps and is shown in Figure 119.[5,8,9] Several details of this scheme are, however, still a topic of lively debate.[440]

An iron biliverdin intermediate has been proposed as the direct precursor to biliverdin,[12] but all initial attempts to prepare such iron bilindione derivatives or related tetrapyrrole iron complexes failed because of the remarkable and unexpected instability of the products.[214,219] Recent protein crystallographic studies

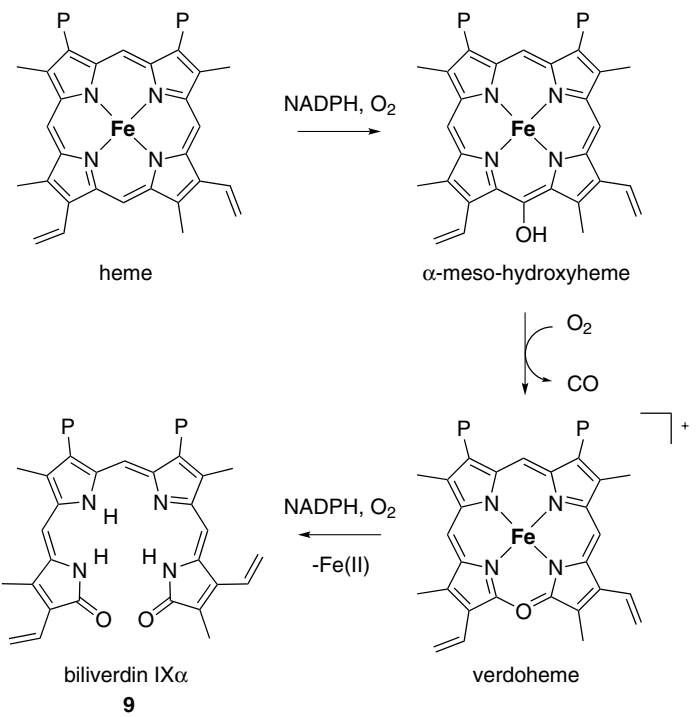

Figure 119. Distinct steps of HO action.

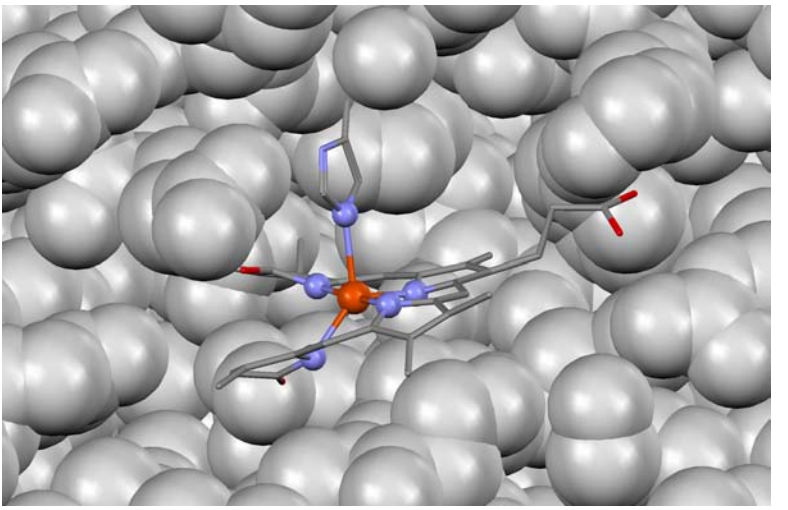

Figure 120. Iron biliverdin IXα embedded in the active site of rat HO-1 (PDB code 1J2C; adapted from Ref. 6).

have now established the presence of iron biliverdin IXα and free biliverdin IXα in the protein matrix at different stages of the reaction.[6,7] Details of these studies show the influence of the increase of required space for the ring-opened compounds upon the flexibility of the protein pocket and suggest a stepwise mechanism in which iron is released from the complex before dissociation of the biliverdin. An iron biliverdin moiety bound in the protein pocket of rat HO-1 is shown in Figure 120.

Whereas all attempts to prepare iron biliverdins directly by the coordination of iron to linear bilindiones or formylbilinones failed, the biomimetic oxidative ring-opening of a verdoheme analog was successful and led to the observation of iron bilin model compounds with the oeb ligand. Figure 121 summarizes the results obtained on products of iron(II) octaethylporphyrin **453**. Upon treatment of the intact porphyrin **453** with O_2 and a reductant (ascorbate, hydrazine) in pyridine, an immediate reaction to oxophlorin **454**[441] and a further reaction with concomitant CO extrusion to verdohemochrome **455** occur.[442] Compound **455** has been characterized as a diamagnetic, low-spin iron(II) complex. NMR investigations of the reaction mixture, however, indicated the presence of a paramagnetic contaminant which was identified as iron(III) bilindione complex **456**. If the pyridine-containing solvent is removed from solutions of **456** *in vacuo*, the compound is found to undergo a dimerization to bilindione complex **457**. Dimer **457** was the first-ever crystallographically characterized iron bilindione species.[442]

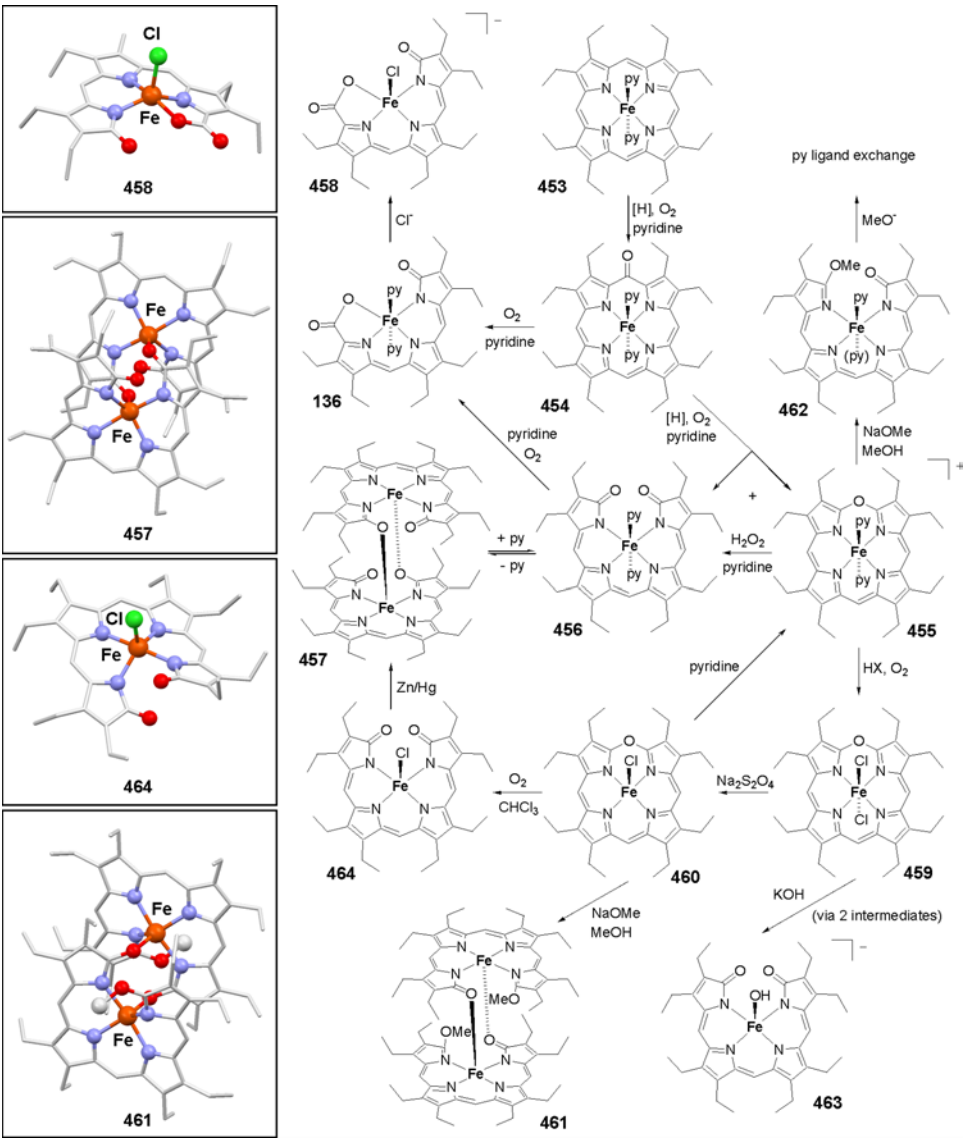

Figure 121. Reactivity scheme and structures of crystallographically characterized products of coupled oxidation processes starting from iron octaethylporphyrin **453** (crystallographic figures adapted from Refs. 442–444 and 446).

Iron(III) derivatives **456** and **457** turned out to be very labile and sensitive to O_2. The oxidative decomposition of **456** and **457** in the absence of excess reduction equivalents splits off one of the terminal pyrrole subunits and leads to tripyrrinone carboxylate species **136**.[443] Tripyrrinone **136** is also formed directly

from oxophlorin **454** under the same conditions. Upon exchange of the pyridine coligands with chloride anions, anionic iron chelate **458** formed, and was analyzed by means of X-ray crystallography.

When iron(II) verdohemochrome **455** was treated with O_2 in the presence of chloride or bromide anions, dichloroiron(III) verdohemochrome complex **459** or the corresponding bromo derivative was isolated. These iron(III) species were readily reduced, with loss of one halogen atom to chloro (or bromo) iron(II) derivative **460**.[444] Treatment of **460** with pyridine recovers the starting pyridine adduct **455**, while the addition of sodium methoxide in methanol yields an inert and insensitive Fe(II)–monolactim ether complex, which was isolated and crystallographically characterized as dimer **461**. The reaction of verdohemochrome **455** with sodium methoxide and of **459** with potassium hydroxide have been studied in more detail by proton NMR spectroscopy.[445] Compound **455** has been found to open its macrocycle upon treatment with the methoxide nucleophile to yield monolactim ether **462**, which is then subject to pyridine ligand exchange processes. Iron(III) derivative **459** reacts with the hydroxide ion via two intermediate steps (ligand exchange and deprotonation) to give anionic hydroxoiron(III) bilindione **463**. The exchange of chloro vs. hydroxo ligands at the iron center was reported to occur with a large change in the resonance spectra, indicating a change in the electronic fine structure of the compound during this process.

Finally, if chloroiron(II) verdohemochrome **460** is treated with dioxygen in chloroform solution, the macrocycle opens spontaneously to give oxidized bilindione chelate **464**.[446] Compound **464** is stable and insensitive to oxidation and was characterized crystallographically. Upon reduction with a zinc amalgam a new species is formed, which was isolated and analyzed as dimer **457**.

Apparently, the reactivity of the iron(II) porphyrin is markedly enhanced after the first oxygenation step to afford oxophlorin **454**. Further products then form, following different decomposition and ring-opening cascades, depending on the respective conditions. Oxophlorin **454** thus plays the role of the activated species in the decomposition processes, similar to α-*meso*-hydroxyheme in the natural HO-catalyzed reaction (Figure 119). The activation of the porphyrin macrocycle may also be achieved by the introduction of a *meso*-situated amino functionality, as in **465**. Under simple aerobic conditions, **465** cleaves its macrocycle with remarkable ease.[447] Detailed NMR investigations have led to a proposed pathway for this decomposition, as depicted in Figure 122. Tripyrrinone complex **136** was identified as the final product, and a tetrapyrrolic N_3O coordinated species **466** was trapped and analyzed crystallographically.[103]

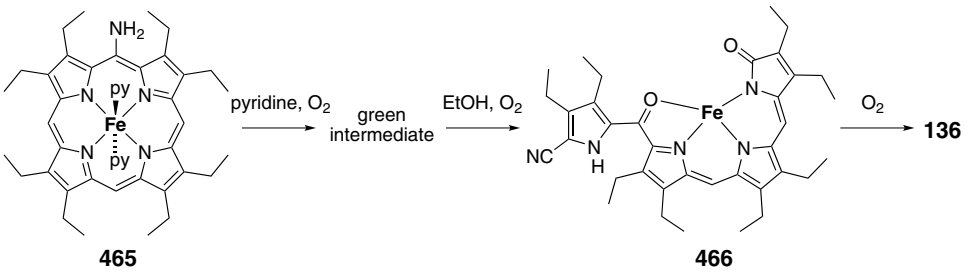

Figure 122. Intermediates of the aerobic ring cleavage of iron *meso*-aminoporphyrin **465**.

B. Direct Metalation of 2,2′-Bidipyrrins

Other than for the bilinones and related formylbilinones which cannot be metalated directly to give the iron chelate species, iron(III) complexes of hydrogen-terminated 2,2′-bidipyrrins were obtained from a metal insertion reaction, as shown in Figure 123. However, a successful preparation was achieved only if the ligand was prepared *in situ* from mono- and dipyrrolic components directly before the addition of a mixture of iron(II) and iron(III) precursors. This scheme was first developed for the synthesis of chloroiron derivative **467** of octaethyl-2,2′-bidipyrrin. In the reaction mixture, **467** is rather unstable and decomposes quickly in an aerobic and protic environment. The crucial point in the preparation turned out to be a quick crystallization step. As a clean compound and in the absence of protons and oxygen, **467** was reported to be a well-behaved complex which could be characterized in depth and employed in a number of reactivity studies. Anion exchange and introduction of the axial ion fluoride, bromide, and iodide ligands have been achieved using typical reagents and conditions for such transformations. The preparation of the complete series of halide complexes **467**–**470** is summarized in Figure 123.[448]

Results from single–crystal X-ray diffraction studies and powder diffraction data provide evidence for the presence of two crystal morphologies for the chloro, bromo, and iodo derivatives **467**, **469**, and **470**, respectively. In both forms, the molecules organize in weakly associated and slipped π-stacked dimers. These dimers, however, pack in either one (iodo complex **470**) or two orientations (chloro complex **467**), resulting in a triclinic or monoclinic crystal system, respectively, as depicted in Figure 124. Bromo derivative **469** was found to crystallize in either structure. Intriguingly, the molecular parameters of the FeN_4Br subunit differ significantly for these two isomorphs, as does the crystal density.[448,449] The different packing pattern thus appears to depend on the different steric requirements of the halide ligands.

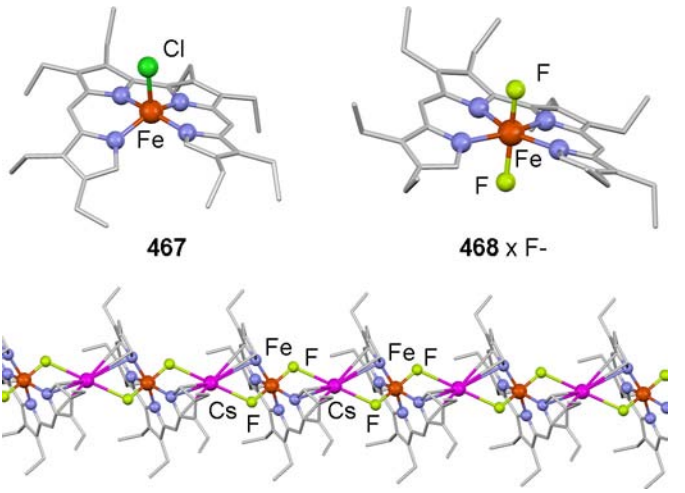

Figure 125. Selected molecular structures for mono- and polymeric iron 2,2′-bidipyrrin complexes. (Adapted from Ref. 448.)

The molecular structures of **467**, **469**, and **470** are very similar and are generally characterized by very short iron–nitrogen distances, in combination with elongated iron-halide bonds as compared to other iron porphyrinoids (Figure 125). Mössbauer and SQUID measurements performed on microcrystalline samples revealed the presence of an unexpected intermediate-spin ground state (S = 3/2) and a thermal excitation to a high-spin state (S = 5/2), and showed that the amount of high-spin admixture at a given temperature decreases with increasing size of the axial halide ligand. In solution, however, only a high-spin state (S = 5/2) can be observed for all species over the whole temperature range.

Fluoro derivative **468** was reported to be extremely sensitive to hydrolytic decomposition and could be crystallized only in the presence of excess reagent, i.e. CsF. Compound **468** forms 1D chains composed of Cs^+ ion-bridged anionic difluoroiron 2,2′-bidipyrrin moieties and some solvate molecules (Figure 125). The six-coordinate iron(III) atom in **468** × CsF now displays significantly elongated Fe–N bond lengths, and a Mössbauer analysis provided evidence for the expected high-spin ground state (S = 5/2). The compound slowly transforms in solution, as shown by ^{1}H NMR spectroscopy. This transformation yields a single new species with twice the number of resonance signals, and a comparison with the NMR spectra of the other halogen species **467**, **469**, and **470** indicated the dissociation of one of the fluoride anions and the formation of a pentacoordinate iron species.[448]

By treatment of the halogen derivatives with hydroxide ions, or simply by using a stronger base during the workup of the iron insertion step, μ-oxodiiron

474a (R^1,R^2,R^5 = Et, R^3,R^4 = Me)
474b (R^1,R^2,R^4 = Et, R^3,R^5 = Me)

Figure 126. Overview of known μ-oxo di(iron 2,2′-bidipyrrin) complexes **471**–**474**.

derivatives have been obtained.[450] These species are well known in porphyrin and salen chemistry but have not been observed so far with bilindione ligands. With respect to the sensitive halogen derivatives **467**–**470**, such oxo-bridged dinuclear chelates are reported to be less labile and allowed the preparation of alkyl-substituted iron 2,2′-bidipyrrins beyond the octaethyl derivative. The known examples **471**–**474** are summarized in Figure 126. All compounds are weakly paramagnetic at ambient temperature, as expected for dinuclear high-spin (S = 5/2) iron(III) complexes with antiferromagnetic exchange and an exchange coupling constant in the order of –120 cm^{-1} (for the spin Hamiltonian $\hat{\mathbf{H}} = -2J\hat{\mathbf{S}}_1 \times \hat{\mathbf{S}}_2$). Compounds **471**–**474** thus show behavior analogous to those of iron porphyrins and iron salens.

Figure 127 provides an overview of the structural complexity of the μ-oxo dimers of iron 2,2′-bidipyrrins.[450,451] The most intriguing structural details are the different relative arrangements of the two tetrapyrrole helices of each molecule. In all cases pockets of different size and shape are formed close to the briding oxygen atom. These pockets are filled with guests, either solvent molecules (dichloromethane, water, pyrrole) or an ethyl side chain of a neighboring complex molecule. In two cases a hydrogen bridge between the guest and the host-oxygen atom was observed. For such hydrogen-bridged species elongated Fe–O bonds and reduced Fe–O–Fe angles result.

Chloro compound **467** and oxo-bridged dimer **471** were studied to probe the possible influence of steric strain on the lability of the bound iron atom in linear tetrapyrrole complexes. In the presence of air, the iron chelates react stepwise with nucleophiles (methanol or imidazolate) at the tetrapyrrole terminal α,ω-positions, presumably through the hexacoordinate species $[Fe(bdp)MeOH)_2]^+$ and $[Fe(im)_2(bdp)]^-$, respectively. The successive increase of strain at these positions is

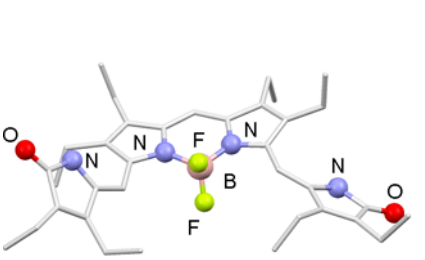
proposed to result in increasingly labile intermediates that spontaneously release the iron ion from the mono- or disubstituted tetrapyrrole ligands. In both cases, the respectively substituted free ligands **475**–**478** were isolated and characterized as the major products of the decomposition step (Figure 128).

VI. Fluorescent Boron Derivatives (OligoBODIPYs)

Boron dipyrrins (BODIPYs, also called boron dipyrromethenes or boraindacenes) constitute a class of boron chelates with a dipyrrin ligand (usually with a BF_2 subunit) that are currently attracting increased interest in many research areas owing to their advantageous photophysical properties.[23,452,453] BODIPYs are very versatile and have found use as light-stable functional dyes in a variety of different applications, such as laser dyes, fluorescence switches, or biomolecular labels. While many simple BODIPY derivatives are known and numerous compounds



479

Figure 129. BF_2 chelates of bilindione ligands **479** and **480** (crystallographic figure adapted from Ref. 367).

are even commercially available, only a limited number of BF_2 complexes with linear tetrapyrroles have been described so far. The first such complex was the difluoroboron derivative of octaethylbilindione ligand **479**, which forms as a strongly fluorescent species upon treatment of H_3oeb **11** with boron trifluoride etherate and triethylamine.[367] A crystallographic analysis was performed and revealed that the central dipyrrin unit of the tetrapyrrole ligand **479** is borylated (Figure 129). A series of other bilindiones as well as some partially hydrogenated species of the urobilin type have also been used in coordination studies with boron trifluoride.[254,454] These reports discuss the formation of two isomeric forms, one with a central BF_2 unit and one unsymmetric, in which one pyrrole and one lactam ring are coordinated. This new coordination mode leads to complete fluorescence quenching and has been enforced by the exchange of one NH vs. a NMe, O, or S functionality. Examples **480a**–**480d** are shown in Figure 129. As a useful property, these compounds show characteristic through-space ^{19}F–^{1}H couplings in the ^{1}H NMR spectra which have allowed analysis of different solution structures in some depth.

While bilindiones have been found to bind exclusively to one BF_2 unit, two such entities may be introduced into artificial linear tetrapyrroles of the 2,2′-bidipyrrin type. Species such as **481** (Figure 130) may also be regarded as covalent dimers of the basic BODIPY luminophore and have therefore been named BisBODIPYs. The solid state molecular structure of these dimers and the relative orientation of the subunits have been illustrated by several X-ray diffraction studies which showed that the BODIPY subunits of the molecules are conformationally restricted in a chiral, almost orthogonal arrangement.[455] Two of the fluorine atoms are found in close contact with each other and a ^{19}F NMR experiment has shown a characteristic through-space coupling between these atoms in solution. Further ^{19}F–^{1}H and ^{19}F–^{13}C through-space couplings are found

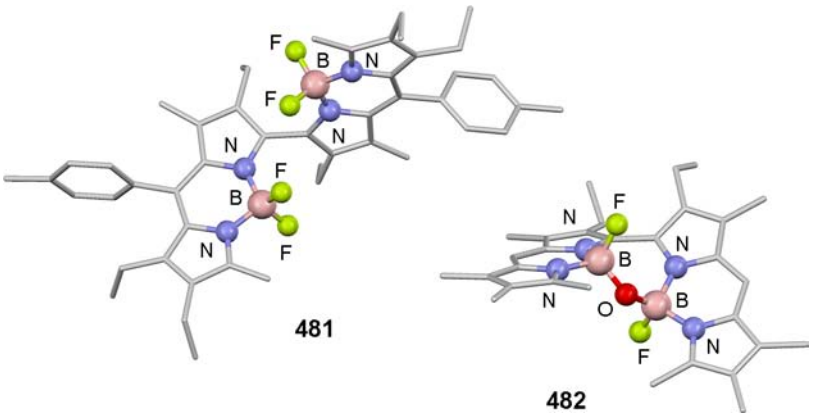

Figure 130. Molecular structures of BisBODIPY **481** and hydrolysis product **482** based on 2,2′-bidipyrrin ligands. (Adapted from Refs. 268 and 455.)

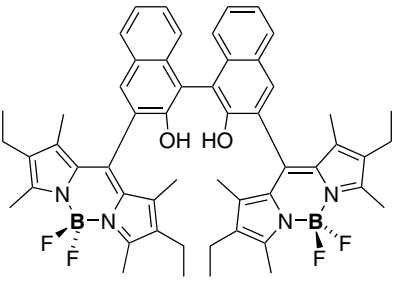
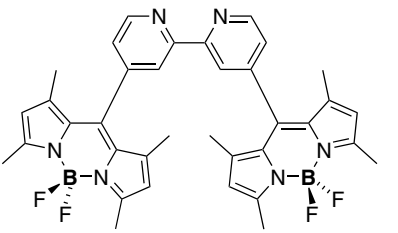
in other spectra and have been investigated in detail and used for a solution structure determination.[456,457] All BisBODIPYs exhibit a clear exciton splitting in the absorpiton spectra with maxima at about 490 and 560 nm, and are highly luminescent with an intense emission band at around 640 nm. The Stokes shift, which is the difference between the maximum of the lowest-energy absorption band and the maximum of the emission band, has a typical value of 5–15 nm for simple BODIPYs, whereas this value increases to 80 nm or more for the dimers, along with a slight decrease in fluorescence quantum yields and lifetimes. In addition, some triplet state is excited in the dimers while only singlet photophysics is known for simple BODIPYs.[458] A derivative with biomimetic di(methylpropionate) substitution has also been described. Hydrolysis of the ester groups does not, however, result in the desired dicarboxylate but in slow decomposition. The formation of an oxo-bridged species **482** as an early intermediate in this process has been made probable by a crystallographic study (Figure 130).[268]

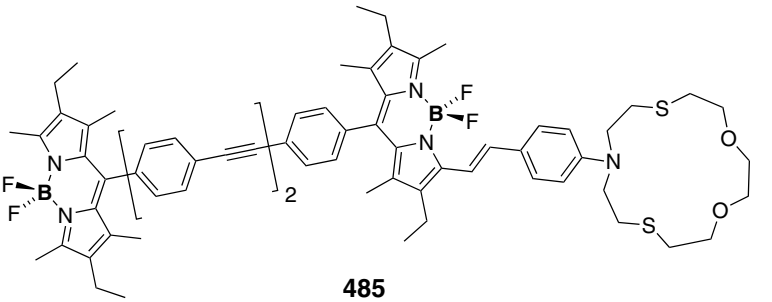
Dinuclear boron species with 2,2′-bidipyrrin ligands consist of electronically decoupled but exitonically correlated BODIPY units and may be regarded as intermediate between linear tetrapyrrolic and functionally bridged bis- and oligoBODIPY dyes. The latter class employs the robust BODIPY unit as a building block in different molecular architectures. The designed combination of two or more of these chromophors allows one to tune special properties for a number of topical fields of application, such as sensors, energy transfer, or light-emitting polymers. Bis(BODIPY)s on the basis of binaphthyl bridges **483** were developed as dyes for optoelectronics and have been investigated as chirality sensors.[459,460] A related architecture with a bridging 2,2′-bipyridine subunit **484** has been reported to act as a photometric sensor for metal cations.[461] BisBODIPY **485** contains a



483



484



485

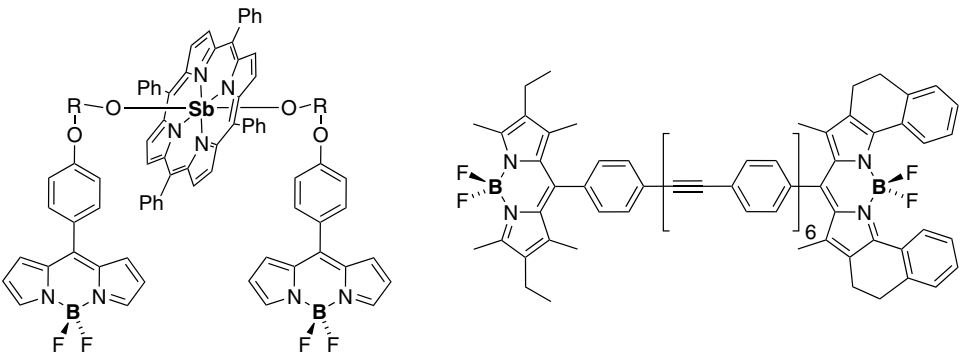
Figure 131. *Meso*-bridged BisBODIPY dyes **483–485** for sensor applications.

long and rigid di(phenylacetylene)-type linker and has been employed as a radiometric sensor for mercury.[462] Figure 131 gives selected examples for this class of tetrapyrroles.

The relatively simple preparation of monofunctionalized BODIPYs and their strong photoluminescence have led to different oligomeric architectures for the study of intramolecular energy transfer. Such compounds have often been called energy transfer cassettes and may be divided into two classes: through-space energy transfer cassettes[463–467] and through-bond energy transfer cassettes.[468–478] The former class has been used mainly in studies toward an understanding of the geometrical requirements for multiple dye antenna systems, while the latter class is currently discussed as being particularly valuable for applications in biosensing. Figure 132 summarizes examples from both groups of functional dyes.

Several studies describing the use of BODIPY units in the backbone of homo- and copolymers have appeared in the scientific literature. Poly(aryleneethynylene)s co-containing BODIPYs were synthesized and studied with respect to NLO properties.[479] Transition-metal-catalyzed polycondensation reactions were used to prepare similar homo- and copolymeric BODIPYs from a di-iodinated monomer. Depending on the bridging units, these polymers show very similar or slightly different photophysical properties with respect to the monomer, and the fluorescence quantum yields remain remarkably high upon polymerization.[480–483] Three

Through-space energy transfer cassettes



Through-bond energy transfer cassettes

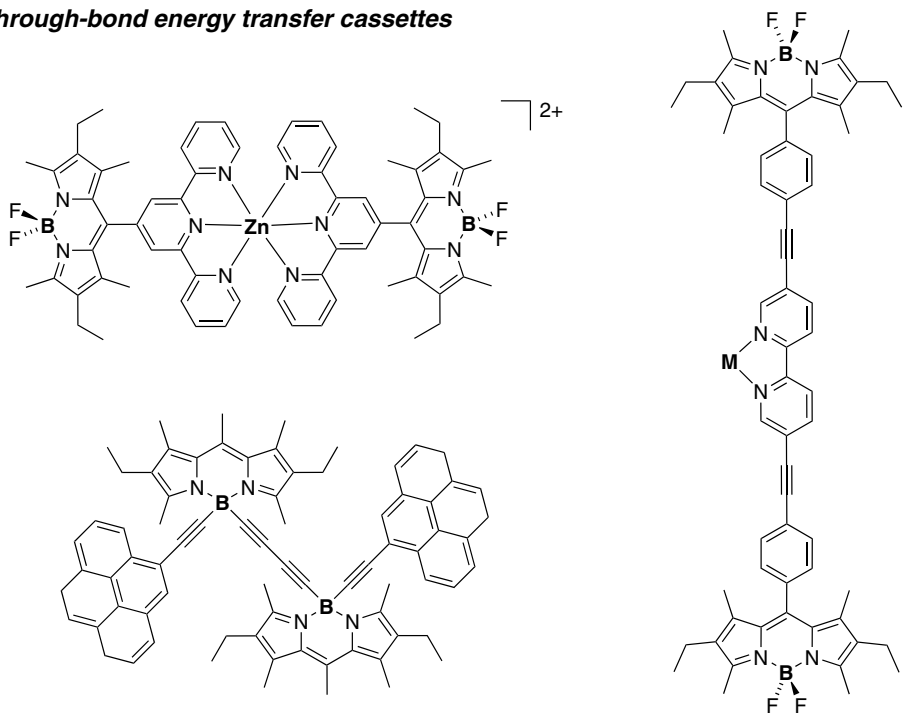


Figure 132. Selected examples for bis(BODIPY) dyes used in energy transfer studies.

examples of alternating fluorene and BODIPY-containing polymers were prepared under Suzuki conditions and studied for their optical properties. These polymers were found to display a sensitive fluorescent response to fluoride and cyanide anions, while no interaction with chloride, bromide, or iodide anions could be

monitored.[484] Copolymers of BODIPYs and dithiophene units have been prepared and were tested for application in OLEDs.[485,486] Polymers with BODIPY units as side chains have also been reported,[487,488] and one example of a polymer with the boron atom in the main chain is known.[489]

VII. Macrocyclization Reactions

A. To Give Porphyrins

The formation of porphyrins upon metal ion insertions in methyl-terminated linear tetrapyrroles was reported as early as 1961.[272] This transformation, which originally led to copper porphyrins, has found multifaceted interest as a highly variable and reliable preparative entry to tailor-made porphyrins, and the systematic exploration of the scope and limitations of tetrapyrrole cyclization to porphyrins has been documented in many publications over about 40 years. As a general view the macrocyclization way to porphyrins proceeds by either the *a*,*c*-biladiene route or the *b*-bilene route (Figure 133). The two approaches give equally good results and have been extensively reviewed in the past.[490–493] Therefore, only the basic concepts and findings will be summarized here.

The cyclization of β-substituted α,ω-dimethyl-*a*,*c*-biladienes and α,ω-dimethyl-*b*-bilenes occurs spontaneously at ambient temperature upon treatment with excess Cu(II) ions and air in solution.[33,129,132,249,266,494–498] For all simple tetrapyrrole precursors copper porphyrins form and may be demetalated in a second step to give the free base porphyrins. The second methyl group is generally lost during the reaction and does not remain in the product under standard conditions. Terminal alkylacetate, alkylpropionate, or benzyl groups have been employed, and several intermediates as well as rearrangement products could be isolated from these attempts.[301,499,500] Some of these compounds, **486–488**, are shown in Figure 134 and point to particular reaction pathways during the porphyrin formation process. The reaction is very smooth and allows the introduction

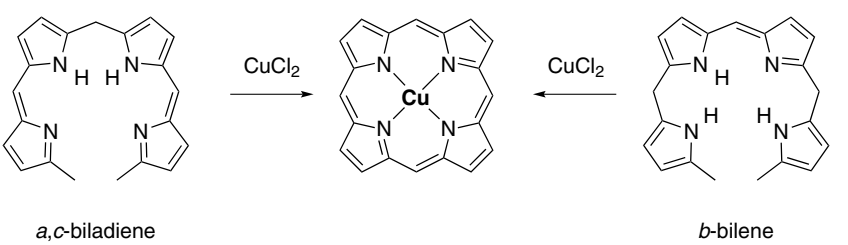

Figure 133. Schematic view of the *a,c*-biladiene and the *b*-bilene routes to copper porphyrins.

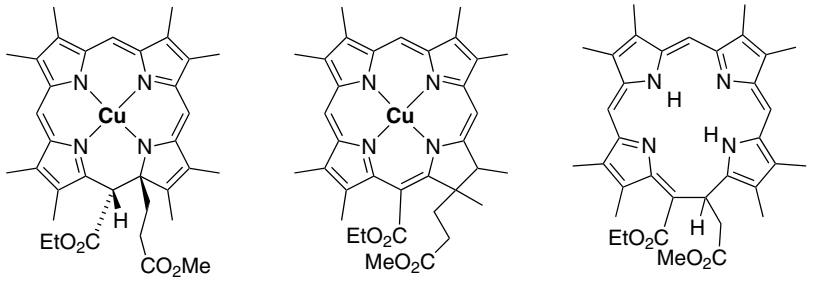

486 **487** **488**

Figure 134. Selected examples **486–488** of isolated intermediates and rearrangement products from the copper(II)-mediated ring closure of *a,c*-biladienes.

of a large number of different β-substituents and patterns. Only side chains with an increased sensitivity to oxidation processes such as vinyl groups may not be used. In addition, chlorin derivatives have been prepared from partially reduced precursors by this methodology.[252,501]

The course of the macrocyclization reaction depends strongly on the choice of the metal ion. Porphyrins form exclusively if copper(II) is used, while with nickel(II) only corrin-type products are isolated (see below). Trivalent ions of rhodium and chromium have been reported to perform well in the transformation to porphyrins, although for the latter the products do not contain a metal ion.[502,503] Oxidative conditions of any sort appear to be vital for a successful porphyrin synthesis. Remarkably, the ring closure of an α,ω-dimethyl-*a,c*-biladiene has been achieved without any metal ion present by electrochemical means.[504] This points to the role of the metal ion as a supporting template, which is not necessarily required.[505]

^{13}C isotope labeling studies have been undertaken in order to gain insight into the mechanism of the ring closure reaction.[506,507] The results prove that only one of the terminal methyl groups remains in the porphyrin as a *meso* methine moiety. From these studies and in agreement with the isolated intermediates from above, the mechanistic scheme in Figure 135 was proposed. In a first step a bilatriene **489** with a fully conjugated backbone forms upon oxidation of both *a,c*-biladiene and *b*-bilene precursors. The two routes thus meet very early in the reaction sequence, which explains the similar performance of the two linear tetrapyrroles. The bilatriene is proposed to exist in a helical conformation even without metal ion coordination. Such a templating action does not appear necessary but would certainly help to put the methyl termini in close contact. This bilatriene should also be very prone to one electron oxidation, and after deprotonation of the oxidized form an activated methylene-terminated π-system **490** is formed, which is proposed to undergo a fast electrocyclic ring closure. Further oxidation and dehydrogenation

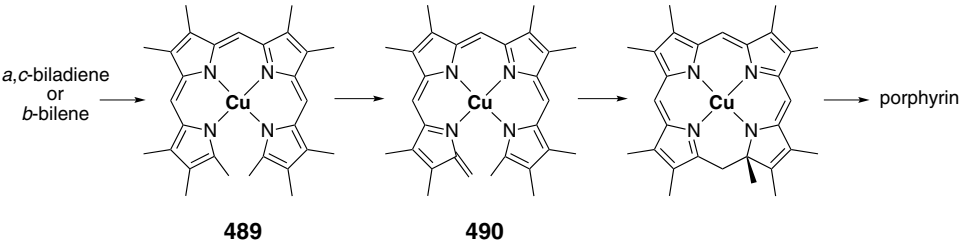

Figure 135. Mechanistic proposal for the formation of porphyrins from methyl terminated *a,c*-biladienes.

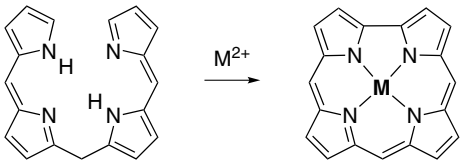
steps as well as a nucleophilic substitution at the pending methyl group finally result in the observed porphyrin.

B. To Give Corroles and Other Porphyrinoids with a Direct Pyrrole–Pyrrole Bond

Due to the unsymmetric C_{19} perimeter of the corrole macrocycle, there are generally two different linear tetrapyrroles which may serve as precursors for macrocyclization reactions to give this ligand: the methyl-terminated 2,2′-bidipyrrins and the hydrogen- or halogen-terminated *a*,*c*-biladienes. The first successful synthesis of a corrole followed the second route and used copper(II) ions as template and as oxidant.[273] As for the porphyrin synthesis, the choice of the metal ion is vital and dictates the outcome of the reaction. Nickel and palladium ions gave products with unclear constitution, while for copper, cobalt, and iron corroles **491** were obtained in good yields (Figure 136).[508,509] Cobalt corroles played a major role in the early development of this chemistry due to their relevance to potential vitamin B_{12} syntheses.

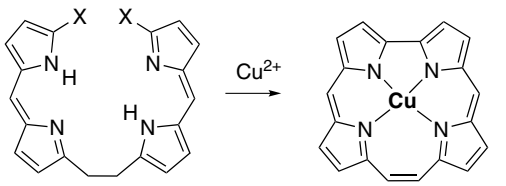
The strategy to form macrocycles by the oxidative formation of the direct pyrrole–pyrrole bond starting from a templated tetrapyrrole ligand has been reported as a successful strategy also for the syntheses of corrphycenes such as **492**. Two protocols are known to fulfill this task, both using copper(II) ions as the template and redox active reagent.[287,288] A macrocyclic nickel complex without a fully conjugated ligand backbone, 10,10′-dimethylisocorrole **493**, could be prepared by the same strategy (Figure 137).[285,286] This example indicates that electrocyclic reactions may be of lesser importance in this chemistry than is usually believed. All the above reactions proceed in minutes and at ambient temperature, and an open-chain metal complex or related intermediate could be isolated for any of the linear tetrapyrrole precursors.

Early attempts to prepare metal corroles from α,ω-dibromo-2,2′-bidipyrrin complexes and formaldehyde failed, and instead gave the first metal chelates of

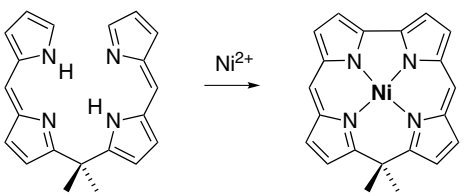


491

Figure 136. Formation of metal corrole **491** from *a,c*-biladienes.



492

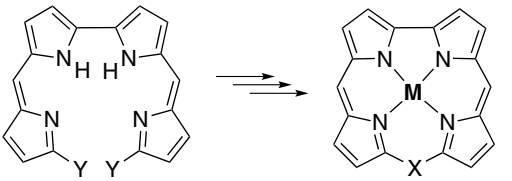


493

Figure 137. Formation of metal porphyrinoids **492** and **493** from 1,2-ethylene- and 2,2-propylene bridged bis(dipyrrin)s.

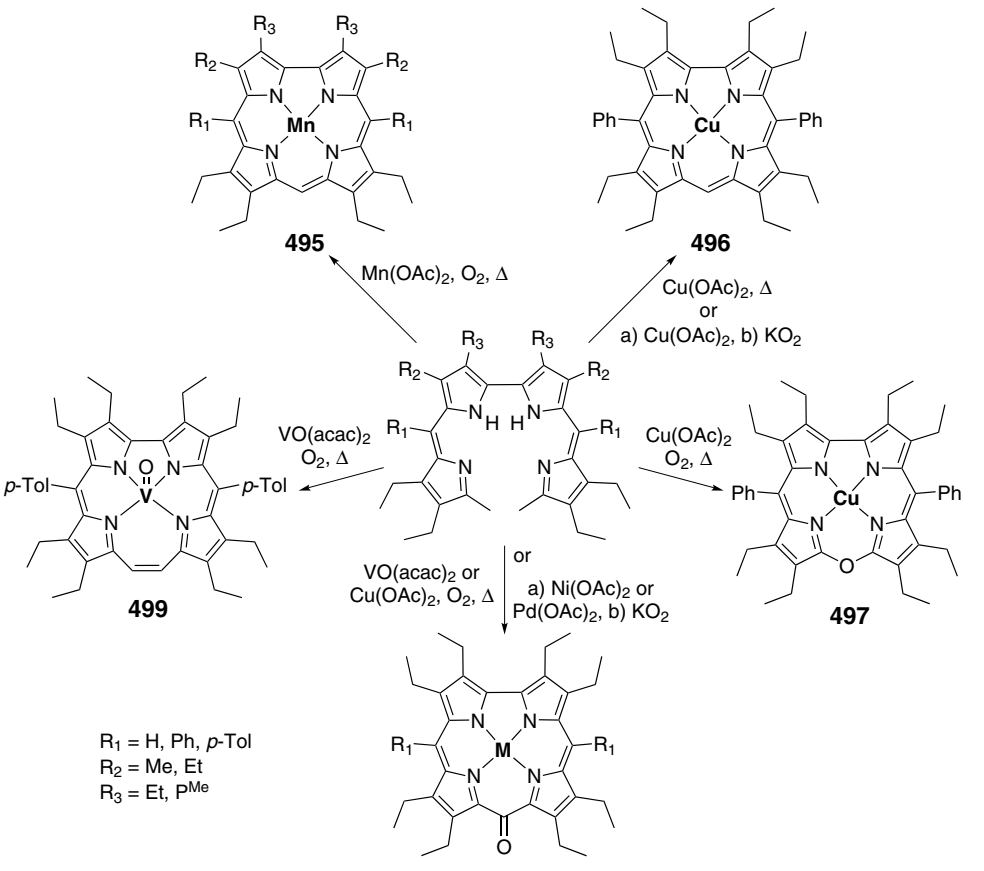
10-oxacorroles.[273,510] A study devoted to the preparation of related heterocorroles **494** succeeded in the syntheses of 10-oxa-, 10-aza-, and 10-thia-corroles, as shown in Figure 138. Treatment of α,ω-dimethyl-2,2′-bidipyrrins with divalent metal ions of zinc, copper, nickel, and palladium under the conditions used for the porphyrin synthesis from *a*,*c*-biladienes left the methyl termini untouched and yielded only the metal complexes of the linear tetrapyrroles.

The failure of metal corrole formation from methyl-terminated 2,2′-bidipyrrins was later related to the reaction conditions. Under more forcing conditions, i.e. at >150 °C and in the presence of air, manganese corroles **495** were obtained as the only nonpolymeric products (Figure 139).[511] Octa- and decasubstituted species form in yields of about 20% and were structurally characterized as the iodo manganese(IV) complexes.[512,513] The reaction has been applied also to the preparation of a biomimetic corrole with propionate substitution, albeit with a



494

Figure 138. Single- and multistep formation of metalated heterocorroles **494** from halogenated 2,2′-bidipyrrins.



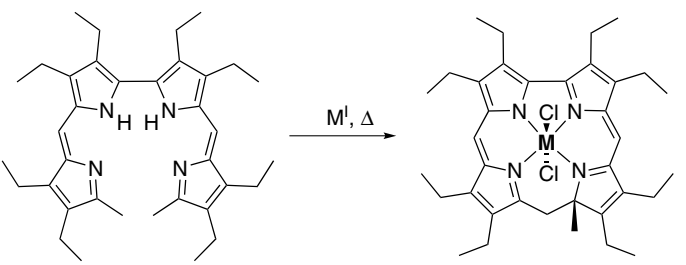
495 **496** **499** **497** **498**

Figure 139. Porphyrinoid macrocycles **495–499** obtained from α,ω-dimethyl-2,2′-bidipyrrins.

reduced yield.[268] Besides the manganese(II)/air system, copper(II) salts are also active in the formation of copper corroles **496** at elevated temperatures. Here, the absence of air is crucial; otherwise overoxidation products such as oxacorroles **497** and oxocorroles **498** form (Figure 139).[514] The superoxide anion may be used as an alternative oxidant at ambient temperature. The copper, nickel, and palladium complexes of the decasubstituted 2,2′-bidipyrrin react with superoxide to form copper corrole and nickel as well as palladium 10-oxocorrole **498**, respectively.[302] A 10-oxocorrole product also forms if vanadyl(IV) acetylacetonate is used as the templating agent at 150 °C in air. For this template, a second product was found and characterized structurally as vanadyl corrphycene **499**.[515] As both methyl carbon atoms are still present in **499**, this finding points to a difference in the reaction mechanism in terms of a twofold redox activation step for vanadium(IV).

The corrole formation from α,ω-dimethyl-2,2′-bidipyrrins was proposed to proceed via a mechanism similar to that accepted for the porphyrin formation discussed above. Other than in this case, however, a templating ion is necessary because 2,2′-bidipyrrins exist in a linear, stretched conformation and will not form macrocycles but rather polymers upon oxidation. In addition, the fully conjugated bidipyrrin chromophore is less prone to oxidation compared with the bilatriene moiety, so that higher temperatures or very strong oxidants are required to activate the tetrapyrrole. As for the porphyrin synthesis, the final step in the M/O_2-induced corrole-forming reaction is the loss of one of the methyl termini and aromatization of the tetrapyrrole. If rhodium or iridium ions are used as templates, this methyl group remains untouched and has been found in product complexes **500** (Figure 140).[424–426]

First attempts to form macrocycles from the hydrogen-terminated 2,2′-bidipyrrin complex **467** of iron have been reported (Figure 141). When **467** is treated with excess iodide in air, **470** is formed first by ligand exchange, followed by a slow oxidative ring closure to give norcorrole **501**. Compound **501** itself tends to dimerize and forms the mixed valence species **502** as the final,



500

Figure 140. Macrocyclic rhodium(III) and iridium(III) chelates **500** from 2,2′-bidipyrrins.

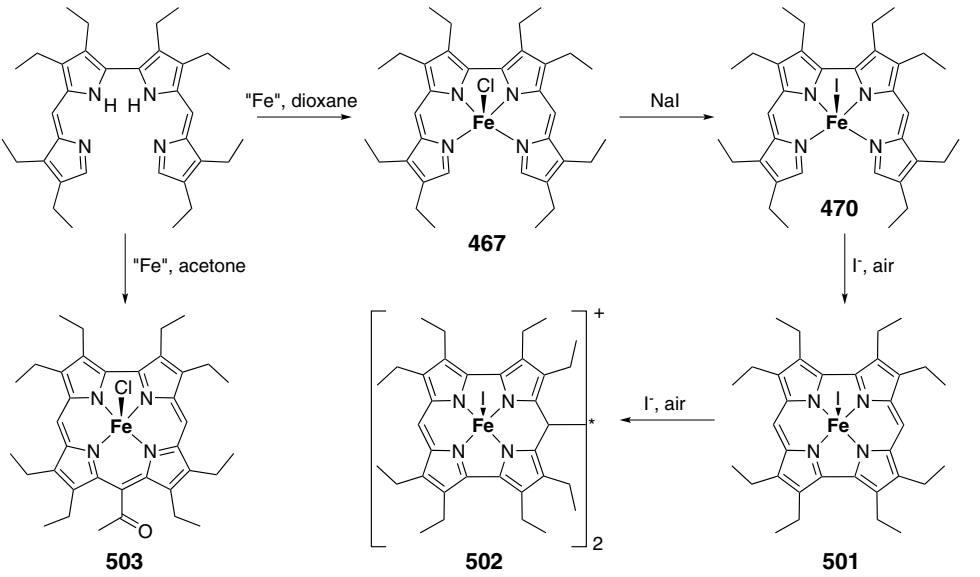


Figure 141. Macrocycle formation starting from iron 2,2′-bidipyrrin **467**.

crystallographically characterized product.[516] In a different example, 10-acetylcorrole complex **503** of iron was found if the iron insertion reaction of an *in-situ*-formed 2,2′-bidipyrrin was carried out in the presence of acetone. A multistep mechanistic scheme was proposed for this transformation; however, no proof has so far been given for it.[517]

Besides bilatriene- and bidipyrrin-based linear tetrapyrroles, a third class of tetrapyrroles, the bisnorbilins of basic structure **86** (Figure 21), have been reported to undergo metal-induced ring closure reactions to afford porphyrinoid products. Crucial to this reaction is the presence of one or two vinylogous aldehydes as terminal groups. As before, the employment of different metal ions results in the formation of different porphyrinoids, as depicted in Figure 142. Divalent copper and nickel ions transform monoformyl derivative **504** into formylisocorrole complexes of which copper derivative **506** could be isolated.[148] Palladium acetate instead induces a condensation to a rare porphyrinoid isomer, isoporphycene **507**. Similar metal isoporphycenes **508** with one additional formyl group form during the action of copper acetate, palladium acetate, or nickel acetate on disubstituted bisnorbilen **505**.[146,149]

C. To Give Corrins and Hydroporphyrins

One of the key transformations during the total synthesis of vitamin B_{12} is the ring closure to the corrin system, which was finally realized in the way shown for

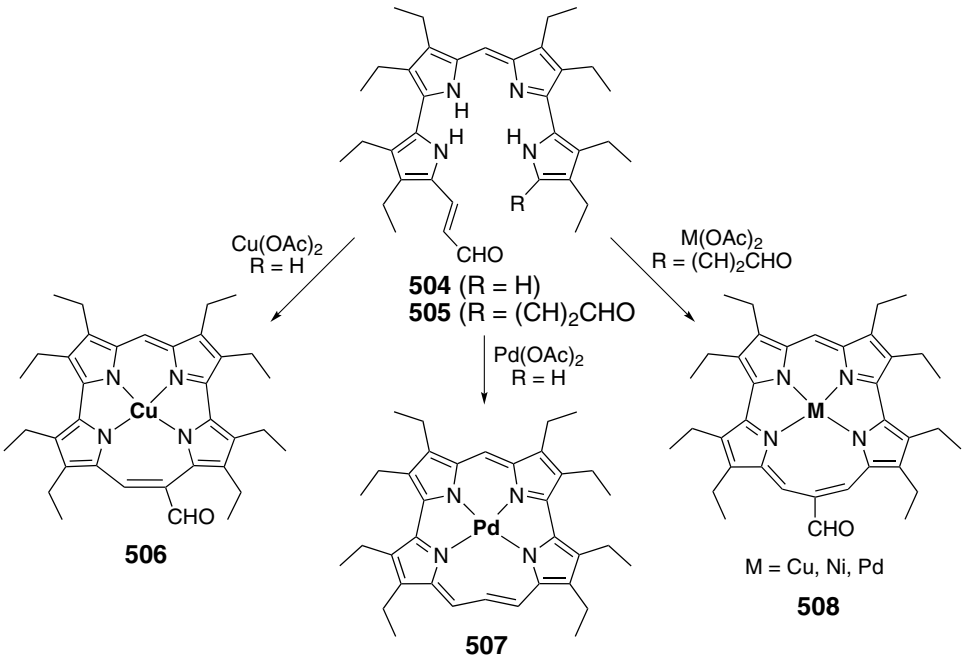

Figure 142. Bisnorbilin-originated macrocyclic complexes **504–508**.

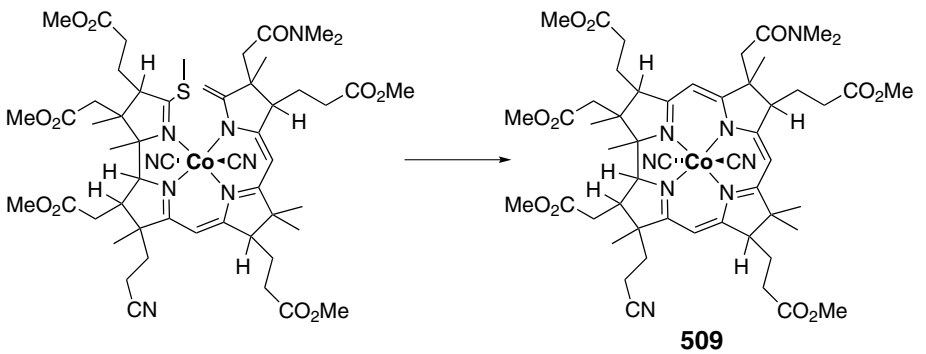

Figure 143. Cobalt-templated macrocyclization to bisnorcobyrinic acid **509**.

bisnorcobyrinic acid derivative **509** in Figure 143. As a biomimetic approach to this step, different ring closure alternatives starting from metal chelates of linear tetrapyrroles have been investigated in great detail. The employment of different metal ions and reaction conditions has allowed the preparation of the highly reduced macrocycle of vitamin B_{12} as well as of a wealth of related corrinoids with different degrees of reduction. The total synthesis of vitamin B_{12} including the many model studies performed during the process of it,[518–521] as well as a set of

model reactions starting from *a*,*c*-biladiene precursors, have been comprehensively and repeatedly reviewed,[492,493,522] and a summary of related work toward the preparation of hydroporphyrinoid systems has also appeared in the literature.[523]

The first strategy, similar to the successful approach described above, was to use an ethoxy instead of a methylthio derivative with the same regiochemistry. The ready cyclization of such a precursor had been demonstrated in a much-cited paper as early as 1964,[151] wherein the cationic nickel complex **387** of a reduced tetrapyrrole forms corrin **510** if treated under strongly alkaline conditions (Figure 144).

At about the same time, several reports of model studies on *b*-bilene- and *a*,*c*-biladiene-type tetrapyrroles started to influence the field. Most remarkably, the direct pyrrole–pyrrole junction was formed by this new approach, including the introduction of one or two stereocenters (Figure 145). Divalent nickel and cobalt ions served as template ions and allowed a straightforward and high-yield cyclization of mono- and dimethyl-terminated tetrapyrroles to give the corresponding corrins **511**–**513**.[274,276,283,494,524–526] The substituent pattern of the tetrapyrroles was widely varied, including such substituents as propionate and acetate esters or acids, or alkoxy groups, in order to find suitable derivatives which react selectively in later hydrogenation steps.[262,278–280,527,528] Most recently, this chemistry has been extended to benzopyrrolic species and zinc, copper, and lanthane template ions.[529] The

388

Figure 146. Photochemical ring closure of metal chelates **388**.

attempted hydrogenation chemistry, however, did not result in the desired products.[305,530] As a second transformation, methylations were attempted on a simple nickel bilin of this class, and the formation of a ring-opened product carrying one or two methyl substituents at the central *meso* position was reported.[531]

Apart from these drawbacks, a photochemical variation of this new ring closure strategy was successfully applied to partially reduced linear tetrapyrroles such as **388** (Figure 146).[532] Further research with similar systems was reported and revealed possibilities for exchange of the photochemical trigger with a redox step, with a proton-catalyzed reaction, or with a complex metalation/rearrangement process.[533–535] Different hydrocorrinoids were obtained from these studies. Furthermore, the isolation and characterization of a chlorin as a byproduct in one case led to the development of synthetic entries to hydroporphyrins.[152]

The templated macrocyclization reaction is not restricted to alkyl-terminated precursors and has been developed further toward alkoxy-terminated species. Such compounds can easily be obtained from natural bilirubin by simple peralkylation, and were cyclized to give the corresponding corrins with cobalt and nickel template ions.[213] A second important extension was found for ethoxycarbonyl-terminated *a*,*c*-biladienes. Unlike most alkyl- or hydrogen-terminated *a*,*c*-biladienes, helical complexes of ester-terminated linear tetrapyrroles can be obtained and isolated. Thus, besides nickel and cobalt derivatives, palladium and platinum chelates have been obtained and transformed into the corresponding macrocycles.[282,536,537] From this class of tetrapyrroles several β-hydroxylated and β-oxygenated derivatives related to the corrins were be obtained.[538]

VIII. Supramolecular Assemblies

A. Tripyrrin- and Bai-Based Coordination Polymers

Polymeric supramolecular assemblies of metalloporphyrins and metallophthalocyanines have had a significant impact in the field of metal-organic functional

materials. Well-established examples can be found, for example, in ferromagnetic and ferrimagnetic 1D coordination polymers of iron and manganese porphyrins with radical bridging ligands, or in π-stacked metallophthalocyanines which exhibit anisotropic electric conductivity after doping with iodine. The field of coordination polymers and metal-organic frameworks (MOFs) has seen a tremendous increase in research activity. Much of this research was motivated by crystal engineering and the preparative access to new functional materials with potential applications in gas storage (especially for dihydrogen) and drug delivery, and as single-chain magnets or conductors. These novel approaches have involved a number of porphyrin ligands so far, but artificial porphyrinoids have not been taken into account at all for this purpose. Two noteworthy exceptions to this rule can be found in the literature: the chemistry of coordination polymers from metalated dipyrrins and the chemistry of polymeric metallotripyrrins.[539,540]

The first indication of the formation of coordination polymers from tripyrrins came from a paramagnetic ^{1}H NMR study of homologous pseudohalide complexes of a nickeltripyrrin, **186**, **514**, and **515**. The spectral widths observed for the thio- and selenocyanate homologs **514** and **515** were markedly reduced with respect to NCO derivative **186**, while the line-broadening developed in the opposite direction. The signal pattern, however, appeared almost identical in all three spectra. Magnetic susceptibility measurements undertaken in dilute solutions by the Evans method indicated the expected temperature-independent behavior and magnetic moment for **186**, while for **514** a reduced magnetic moment in combination with an unexpected temperature dependence was found. These findings were attributed to the beginning of an oligomerization process of **514** and **515** in solution. The formation of coordination oligo- and polymers from thio- and selenocyanato derivatives of nickel tripyrrins was confirmed by the results of X-ray crystallographic work on **514** (Figure 147).[313] While isocyanato complex **186** crystallizes monomeric in an unstrained pseudoplanar geometry, the thiocyanate ligand in **514** is bound in a bridging μ(N,S) mode and connects the nickel tripyrrins to give one-dimensional strands with pentacoordinate nickel ions. The monomeric units are from an unstrained trigonal-bipyramidal geometry, which appears ideally suited for the formation of such chain structures. It was, however, noted that the Ni–N bond appears much stronger than the Ni–S bond according to structural parameters. A similar coordination mode of the $NCSe^-$ anion had been observed for **211**.

While the helical polymeric chains of **514** pack densely in the crystal lattice and leave little free space between the strands, the employment of other pseudohalide-bridging ligands results in the stabilization of functionalized inner surfaces. Dicyanamido and tricyanmethanido ligands, called dca and tcm, respectively, have been proven to be particularly useful in this regard. The treatment of

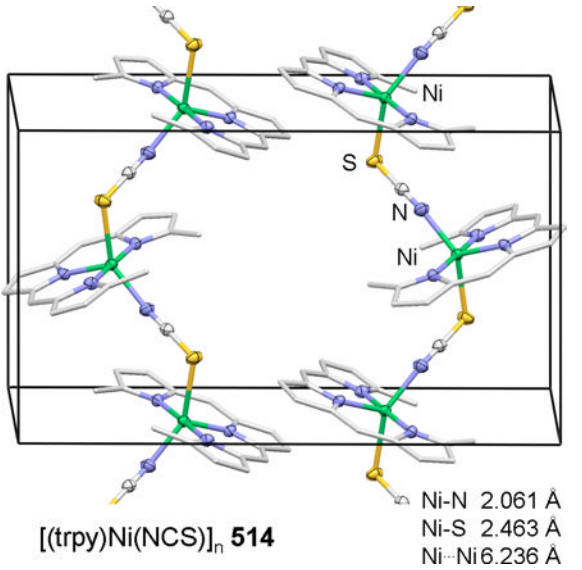

Figure 147. Crystallographic unit cell with strands of coordination polymer $[(trpy)NiNCS]_n$ **514** (β-ethyl groups omitted for clarity; adapted from Ref. 313).

cyanato derivative **187** with the sodium or potassium salt of either of these anions results in the immediate formation of a solid which can be filtered and washed to yield analytically clean material. Redissolution of the microcrystalline or amorphous material is possible in methanol, and careful crystallization yielded highly crystalline nickel(II)-based coordination polymers. Figure 148 presents two structurally distinct examples for a dicyanamido derivative **516** and a tricyanmethanido species **517**.[313] Both materials are characterized by functionalized inner surfaces, which differ from each other by both the functionalization and the dimensionality. The monomeric subunits of **516** and **517** show structural parameters typical of *high-spin* nickel(II) species. Unlike before, however, the binding between the nickel ion and the two external donors is of comparable strength. The dca and tcm bridges lead to large Ni···Ni separations of about 8.4 Å, and the tripyrrolic ligands of adjacent nickel tripyrrin subunits are separated by about 8 Å. The nickel tripyrrin planes in tricyanmethanido derivative **517** are arranged in a coplanar fashion and without any torsion, whereas in **516** a tilt of 10° and a torsion angle of 40° are observed. This difference can be explained by the steric influence of the third, noncoordinating cyano group of **517**. These rather small differences between the intrastrand structures of **516** and **517** markedly influence the relative arrangement of the pillars. The empty space between adjacent nickel tripyrrin planes in a single chain of **516** is partially filled by two nearby pillars that come very close and whose nickel tripyrrin units interdigitate at interstrand π–π

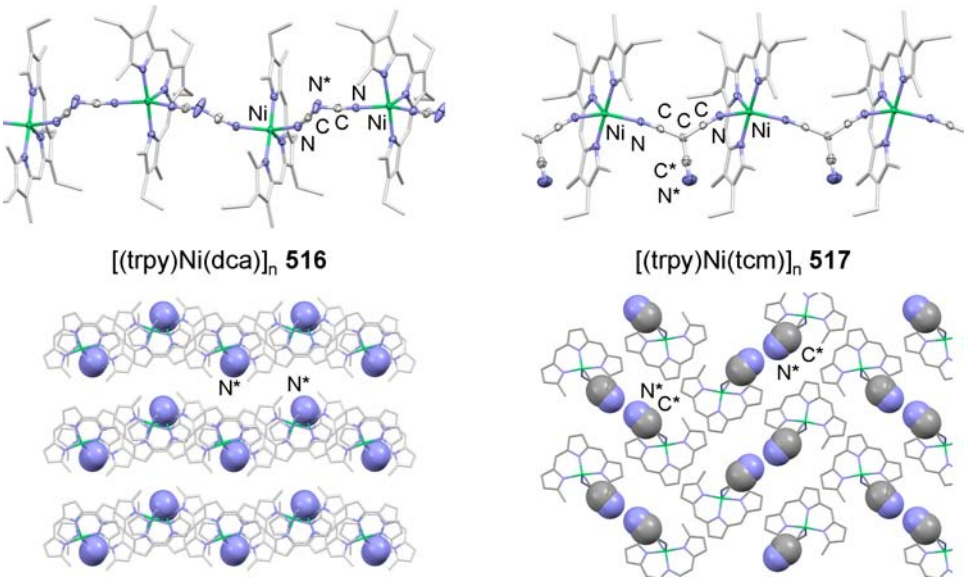

Figure 148. Organization of polymeric chains of tripyrrin nickel dca and tcm complexes **516** and **517**. (Adapted from Ref. 313.)

distances of about 3.4 Å. As the next pillars are significantly further away, a 2D-layered pillar structure results. Interestingly, the divalent central nitrogen atoms of the dicyanamido bridges are oriented toward the gaps between these layers, thus producing a functionalized cleft. Complex **517** instead forms a structure with almost isolated polymer chains in which six pillars arrange to form a trapezoid pore with dimensions of about 6.2 × 4.7 Å. The noncoordinated cyano group of two of these pillars points directly into this pore, resulting in functionalization of the pore with N···N distances of 5.8 Å. The potential of such arrangements in the field of anisotropic ion conductors is evident from Figure 148.

Hydrogen bridges are another bonding scheme found within the class of nickel-tripyrrin-based coordination polymers. The constitutionally most simple example was observed for the aqua complex of a chloro nickel tripyrrin **182** which forms 1D strands by H-bridges between the water ligand of one complex unit and the chloro ligand of an adjacent one.[319] Interestingly, the so-formed supramolecular structure is isostructural with the arrangement of isothiocyanate polymer **514** (Figure 149). A second, more complex example has been found during attempts to use cyanometalate anions as bridging ligands in a brick-and-mortar approach. Thus, a 2:1 mixture of **518** and sodium tetracyanonickelate crystallizes from a methanol/toluene mixture as the pentanuclear dication $[\{(trpy)Ni(MeOH)\}_4\{Ni(CN)_4\}]^{2+}$, which is connected to four adjacent $[Ni(CN)_4]^{2-}$ dianions via hydrogen bonds and forms a 3D coordination network in the crystal (Figure 149).[313]

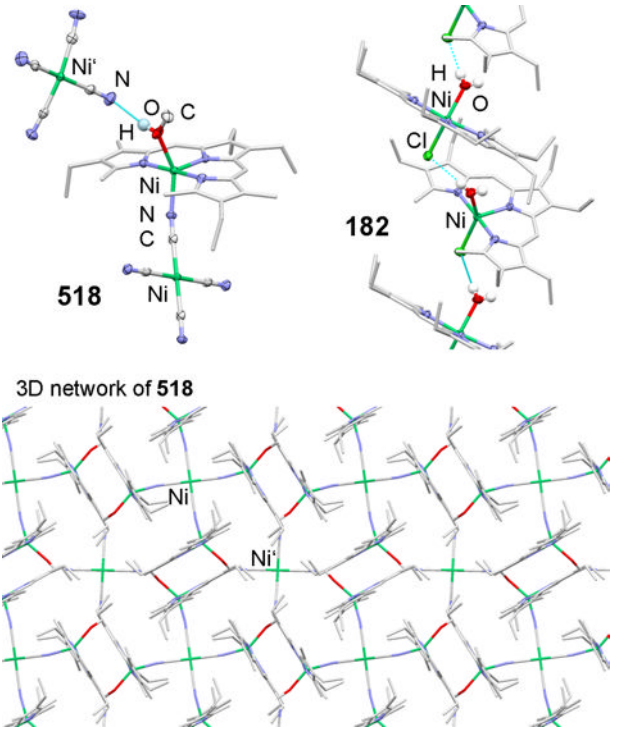

Figure 149. 1D and 3D nickel tripyrrin polymers of **182** and **518** with hydrogen bridges. (Adapted from Refs. 313 and 319.)

The approach using bidentate pseudohalides and cyanometalates — in particular, the favorable dicyanamide and tricyanmethanide anions — in combination with metal tripyrrin precursors was also investigated with other divalent metal ions. Zinc and copper ions show a tendency to form predominantly tetracoordinate species in the tripyrrin environment, in the unstrained pseudoplanar type, regardless of the external ligand (tricyanmethanido, dicyanamido, NCSe, N_3). UV-visible spectroscopic investigations, however, indicate some weak association of methanol in this solvent and the formation of pentacoordinate species from both transition metal ions. Coordination polymers have indeed been found by single-crystal X-ray diffraction in two cases: a dicyanamido derivative of zinc **519** and a heterodinuclear chain of a dicyanoargentate copper(II) species **520**. The spatial relation of the (trpy)M subunits and the arrangement of the polymeric chains in the crystal lattices are shown in Figure 150. The zinc ion in **519** is coordinated by five nitrogen atoms in a distorted trigonal-bipyramidal geometry with the two imino type donors of the trpy ligand occupying the apical positions. The (trpy)Zn fragment is almost planar with the zinc ion only 0.0007 Å above the tripyrrin N,N,N plane. The polymeric chain of **519** is formed by a torsionless and coplanar

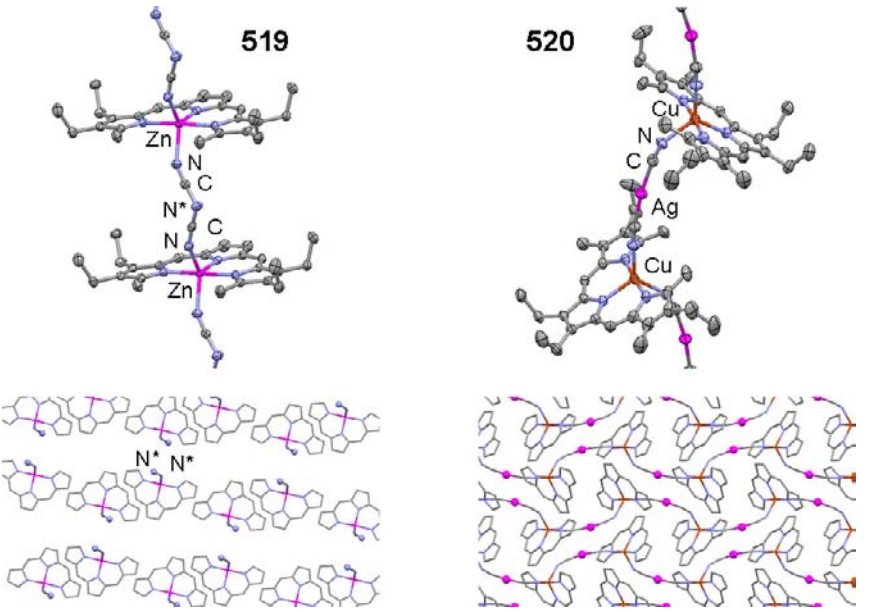

Figure 150. 1D coordination polymers of zinc and copper tripyrrins **519** and **520**. (Adapted from Ref. 122.)

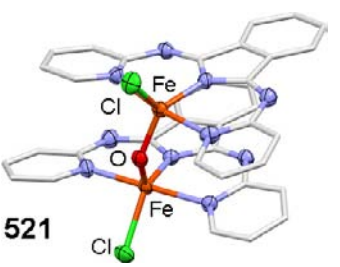
arrangement of the (trpy)Zn subunits. The dicyanamido ligand is μ-1,5-bridging two subunits in such a way that the central nitrogen atom appears turned to the side. The space which is formed between opposite (trpy)Zn plates is filled by adjacent polymeric columns, similar to that observed for dicyanamido nickel derivative **516**. The alkyl side chains of the (trpy)Zn subunits of the next two neighboring strands are interdigitating with the (trpy)Zn plates, thus forming layers of pillars, which show clefts in the crystal. Interestingly, and as indicated in Figure 150, the central nitrogen atoms of the dicyanamido bridges are localized on the surfaces of these clefts. The coordination environment of the copper(II) ion in polymeric **520** is very similar to that for zinc(II) in **519**. Five N donor atoms form a slightly distorted trigonal bipyramide around the copper center, and the out-of-plane deviation of the copper ion from the tripyrrin N,N,N plane is negligible at 0.0301 Å. The unsymmetric bridging mode of the $[Ag(CN)_2]^-$ ligand is documented in the unequal N–Cu–N angles of the triangular base, and in the difference of the Cu–N bond lengths of 2.085 and 2.149 Å. Each copper(II) ion has two intrachain Ag(I) neighbors within a distance of 5.064 and 5.242 Å. The dicyanargentato ligand is not linear but is slightly bent, and the two ends bind with different angles and lengths to the copper centers of the trpyCu units. Adjacent trpyCu planes of each copper(II) ion in **520** are arranged without torsion, but not in a

coplanar fashion. Different from **519**, the steric demand of the tripyrrin backbone of **520** thus leads to densely packed zigzag chains without open spaces.[122]

As described above, the advent of free-base tripyrrins has led to the availability of further metallotripyrrin subunits as potential monomers for supramolecular aggregates. Ethereal solutions of free-base tripyrrins were prepared by treatment of nickel isocyanate complexes [(trpy)Ni(NCO)] with excess cyanide. From these solutions sensitive metallotripyrrins with cobalt(II), iron(II), and manganese(II) ions [(trpy)MX] and with a choice of external ligands X could be obtained in pure, crystalline form. [(trpy)Fe(NCO)] undergoes a redox transformation to μ-oxoiron(III) species **212** upon crystallization, and was structurally characterized as such with an almost linear Fe–O–Fe subunit (Figure 44).[314] A very similar coordination and association has been described for dinuclear chloro iron(III) bpi derivative **521** (Figure 151), albeit with tilted Fe–O–Fe bonding.[541]

Donor association was studied by UV-visible spectroscopy employing different solvents, and showed that all manganese(II) and iron(II) species are very prone to the formation of pentacoordinate species, whereas the cobalt(II)-containing compounds have an intermediate tendency to do so. Nevertheless, complex fragments of all three metal ions form 1D coordination polymers with dicyanamido ligands, and were investigated by means of IR and SQUID measurements.

The introduction of the large cadmium(II) ion into the tripyrrin N,N,N coordination site was accomplished by the use of cadmium acetate as the metal precursor. Ligand exchange experiments using sodium salts of different anions disclose a marked tendency toward pentacoordination, which is achieved by the formation either of chelates or of 1D coordination polymers arising from the size of the central metal.[315] Thus, attempted introduction of chloro, iodo, or cyanato ligands leads mainly to decomposed material, while the use of 1,1,1-trifluoracetylacetonate, salicylate, and acetate ligands results in stable, pentacoordinate, and monomeric complexes. With the pseudohalogenido ligands thiocyanate, selenocyanate, and azide as well as with the weakly coordinating trifluoroacetate, trigonal bipyramidal species form as 1D coordination polymers



521

Figure 151. Molecular structure of μ-oxo-di[(bpi)chloroiron(III)] **521**. (Adapted from Ref. 541.)

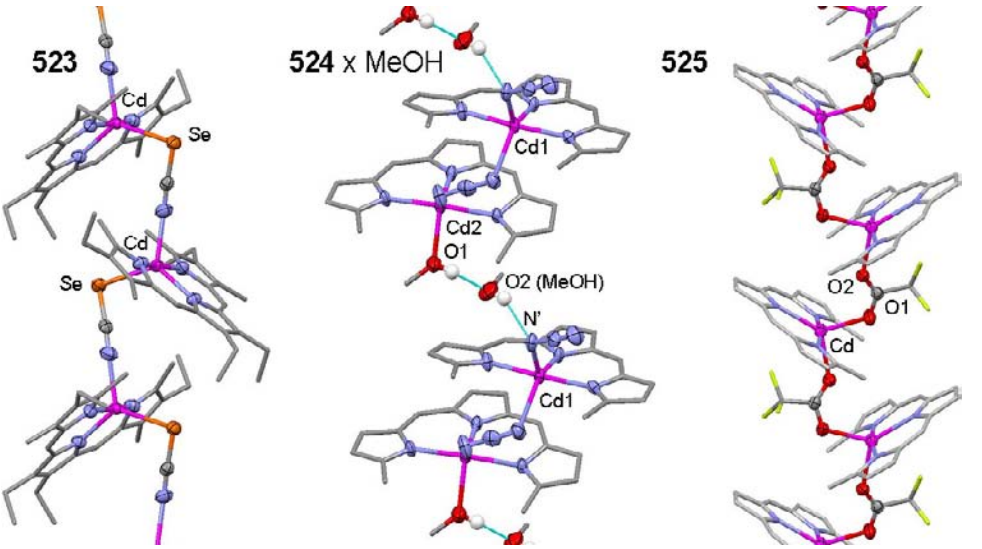


Figure 152. Different 1D chain structures of cadmium tripyrrin polymers with bridging selenocyanate **523**, azide **524**, and trifluoroacetate ligands **525**. (Adapted from Ref. 315.)

522–**525**, respectively, with a variety of chain structures (Figure 152). The most interesting compound in this series is azido derivative **524**, which is present in crystal as a coordinatively and hydrogen-bonded methanol adduct with a dimeric repeating subunit.

In addition to the tripyrrin-based aggregates, three examples of bai-based coordination polymers are found in the literature. The polymeric copper bti with acetate bridges crystallizes together with monomer **259**.[196] In contrast to the almost ideally planar four-coordinate structure of monomeric **259**, the copper atoms in the polymeric chains display fivefold coordination and a ligand polyhedron which is an intermediate form between a trigonal-bipyramidal and a square-pyramidal geometry. While the arrangement of the three heterocycles of the bti ligand remains almost planar, the acetato ligand is tilted out of this plane, therefore making space for the coordination of the second acetato oxygen atom of a neighboring coordination unit. Significantly, the Cu–O bond lengths of 2.08 and 2.23 Å are longer than in the square-planar monomer **259**, and indicate substantial intermolecular bonding, leading to the polymeric assembly (Figure 153). A related cobalt(II) bpi complex **526** aggregates as a coordination polymer in which each Co atom is coordinated by two bridging acetate groups and one bpi ligand (Co–O = 2.043, 2.022 Å). The polymeric nature of **526** was reported to be responsible for the low solubility of bpi cobalt acetato complexes in general.[202] The polymer chains of both bai-based polymers adopt folded structures similar to cadmium tripyrrin **525**, and as represented in Figure 153.

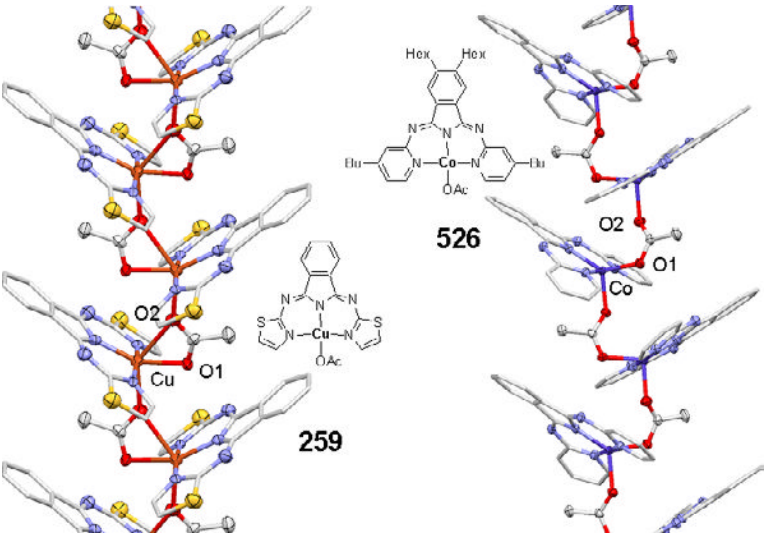

Figure 153. Polymeric acetato complexes of copper bti **259** and cobalt bpi **526** (crystallographic figures adapted from Refs. 196 and 202).

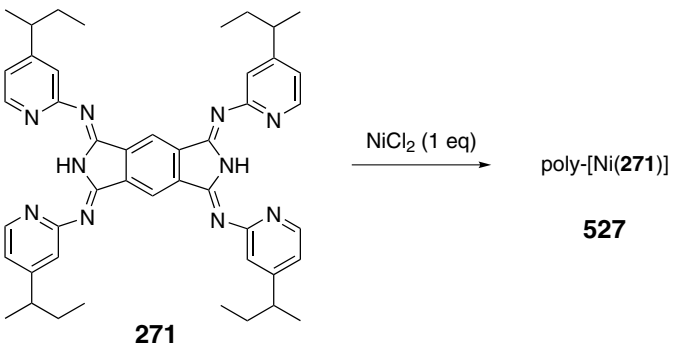

Figure 154. Coordination polymer **527**, formed from bischelating bpi ligand **271** and nickel(II).

A different approach to coordination polymers was briefly reported in one instance. The reaction of bischelating ligand **271** with nickel chloride in a 1:1 ratio results in the formation of a metal-organic polymer **527** (Figure 154).[192] Only the optical spectrum of this new coordination polymer was reported.

B. Bis(arylimino)isoindolines in Dendrimers

Many ligands and catalytically active metal complexes have been immobilized on the inside or outside of dendrimers. The aim of these research activities has been the development of catalysts which combine the advantages of homogeneous

catalysis (high activity and selectivity; directed catalyst design) with those of heterogeneous catalysts (e.g. facile catalyst separation and recycling). In principle, the position of the catalytic sites in high density at the periphery of dendritic macromolecules may significantly alter the activity and selectivity when compared with the respective mononuclear catalysts. Three approaches to organization of bpi ligands and palladium complexes by dendritic hosts have been reported. They differ generally by the type of the chemical linker and by the order of steps during the assembly of the supermolecules.

A successful approach to dendritic bpi ligands employed the highly efficient coupling of alkynyl linker units to carbosilane dendrimers and dendrons. The suitably functionalized bpi ligands **528a** and **528b** were prepared by nucleophilic substitution of 4-nitrophthalodinitrile with 4-butynol, followed by double condensation with 2-aminopyridines. Lithiation of **528a** with LDA and reaction with Si–Cl or Si–OTf (OTf = triflate) end groups in core or peripheral positions of dendritic carbosilanes gave *endo* or *exo* bpi functionalized dendrimers, respectively, such as **529** (Figure 155), **530** (Figure 156), and others.[542] All functional

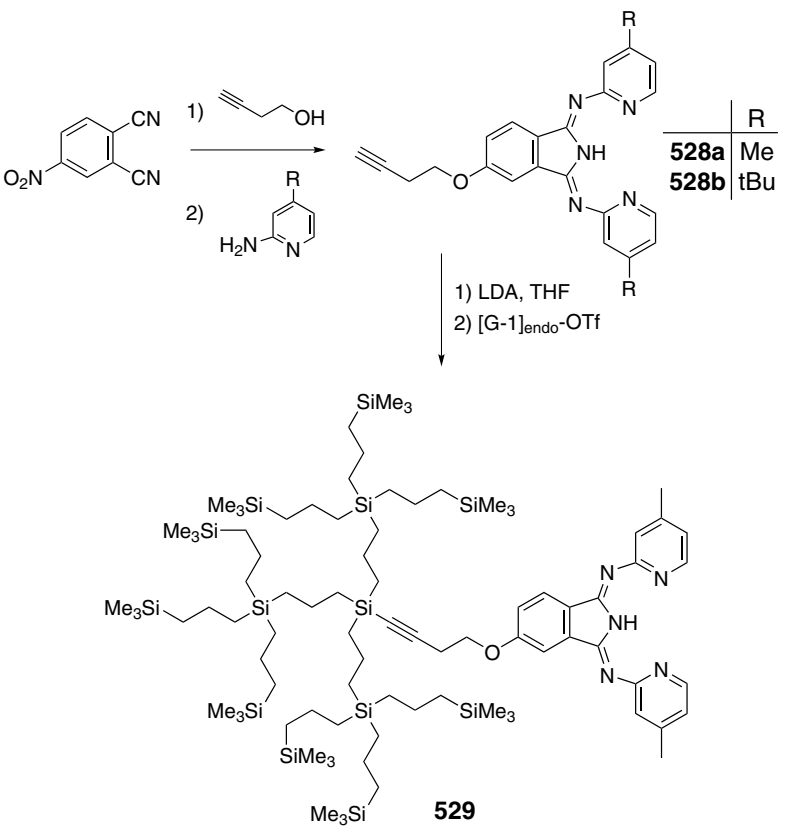

Figure 155. Preparation of alkinyl-bpi appended [G-1]-carbosilane dendrimer **529**.

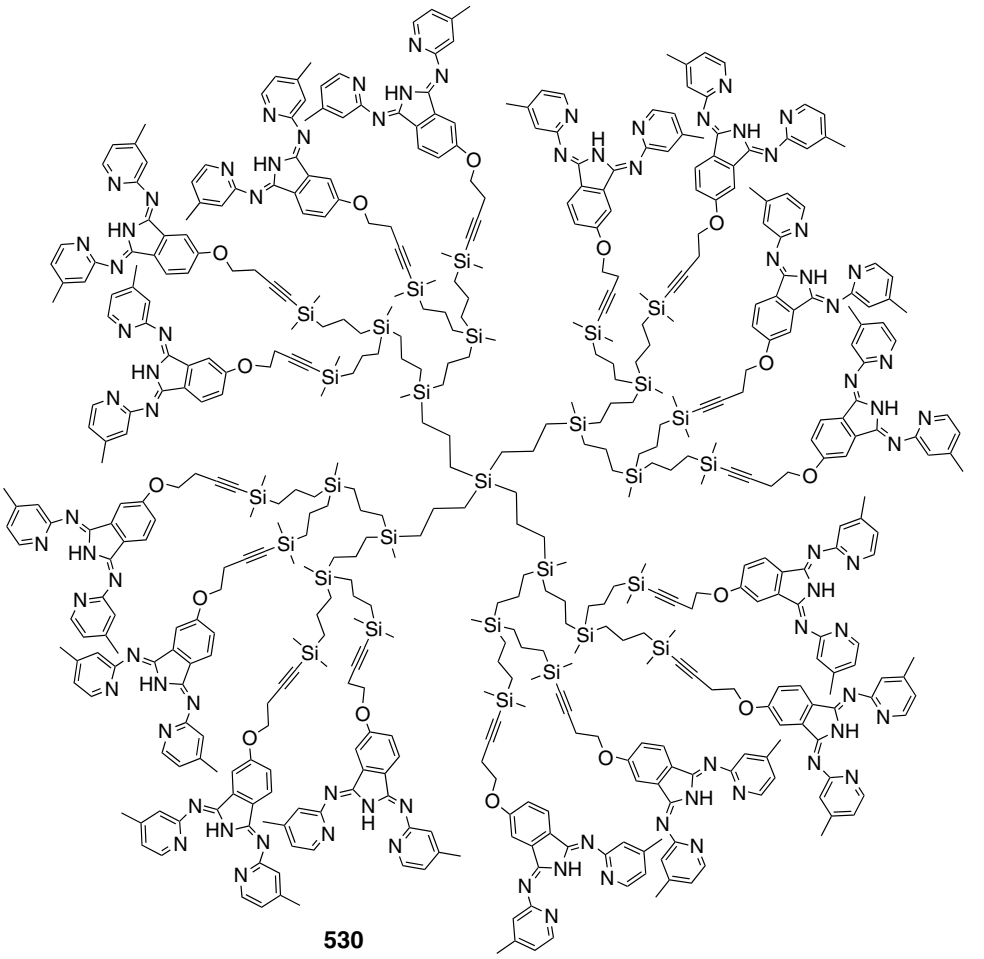

Figure 156. [G-2]-Carbosilane dendrimer **530** with 16 H(4-Mebpi) ligands.

dendrimers were metalated by reaction with $[(PhCN)_2PdCl_2]$ in dichloromethane to give the corresponding pallada-dendrimers.

A related alternative was reported using ethyleneglycol-modified bpi ligands for the immobilization in carbosilane dendrimers.[543] The fixation of the linker was again carried out at the stage of the phthalodinitrile precursor by nucleophilic *ipso*-substitution. Following the condensation with the aminopyridine, the ethylene-glycol-functionalized H(bpi) derivative **531** was treated with the zero-generation carbosilane dendrimer [G-0]4-exo-Cl **532** and yielded the functionalized dendrimer **533** (Figure 157). Palladium(II) was again successfully introduced by reaction of the ligands with $[(PhCN)_2PdCl_2]$ in benzene using triethylamine as auxiliary base.

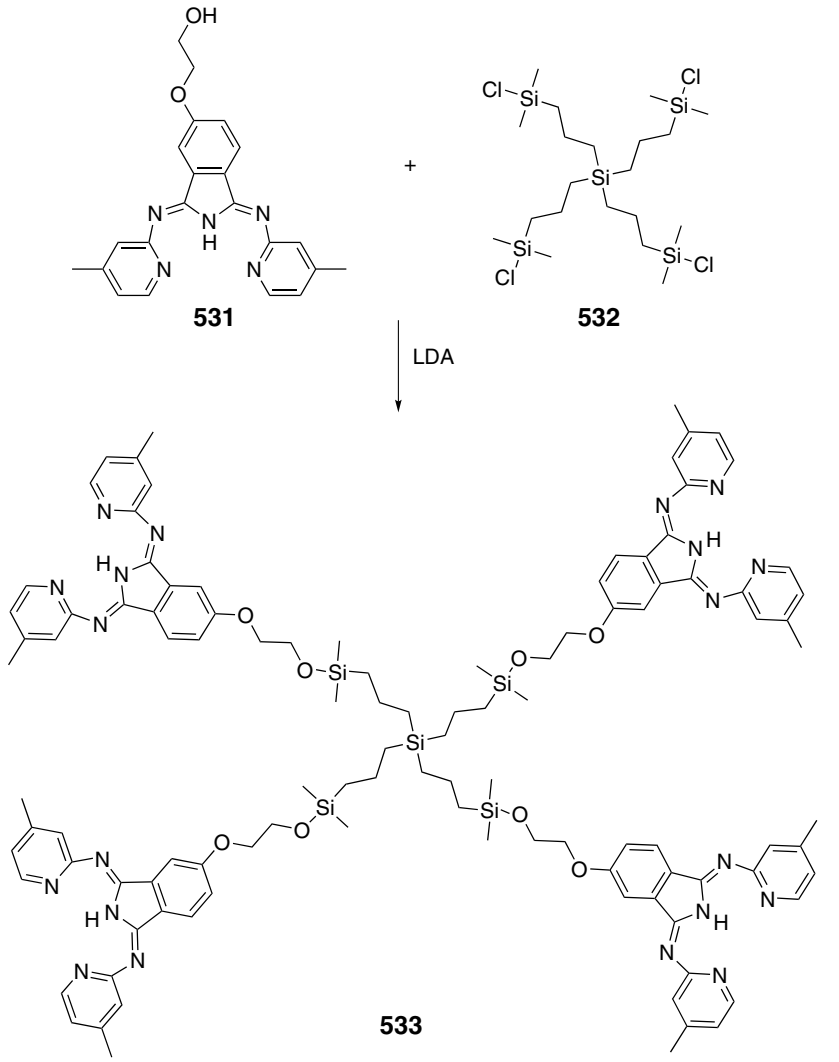

Figure 157. [G-0]-Carbosilane dendrimer with four bpi units by ethylene glycol linkage.

In the third report, polyether dendritic wedges — the so-called Fréchet wedges — were attached to bpi ligands, and the corresponding Pd(II) complexes were synthesized and studied as hydrogenation catalysts (see Section IV.C). The fixation of dendrons at the ligand framework was carried out at the stage of the phthalodinitrile precursor of the bpi ligands, again by nucleophilic substitution of 4-nitrophthalodinitrile, with the *in-situ*-generated alcoholates. The reaction of 1,3-dibenzyloxy-2-propanol [G-1] **534** and the coupling of Fréchet's first and second generation arylether dendrons [(3,5)-G-1]-OH **535**, [*t*-bu-(3,5)-G-1]-OH **536**, and

[(3,5)-G-2]-OH **537** gave the corresponding O-coupled phthalodinitrile derivatives **538**–**541**. The synthesis of bpi ligands **542**–**545** was then achieved in the last step by reaction with two molar equivalents of 2-amino-5-bromopyridine (Figure 158). All the ligands were cleanly metalated to give the corresponding palladium(II) complexes. In contrast to the unsubstituted complexes, the dendrimer-functionalized derivatives **452** and **453** hydrogenate styrene and 1-octene without decomposition (see Section IV.C), and catalyst **453**, carrying the second generation dendron, displayed sufficient stability to be isolated and reused several times.[439]

C. Tetrapyrroles in Supramolecular Assemblies

Attempts to use tetrapyrrolic entities for supramolecular engineering started with the finding of tetrapyrrole-based helicates and have been reported so far only for di- and trinuclear metal complexes of three different classes of bis(dipyrrin)s. A dinuclear copper helicate **401** with a sterically restricted 2,2′-bidipyrrin ligand was reported to pack in a peculiar fashion and form solvent

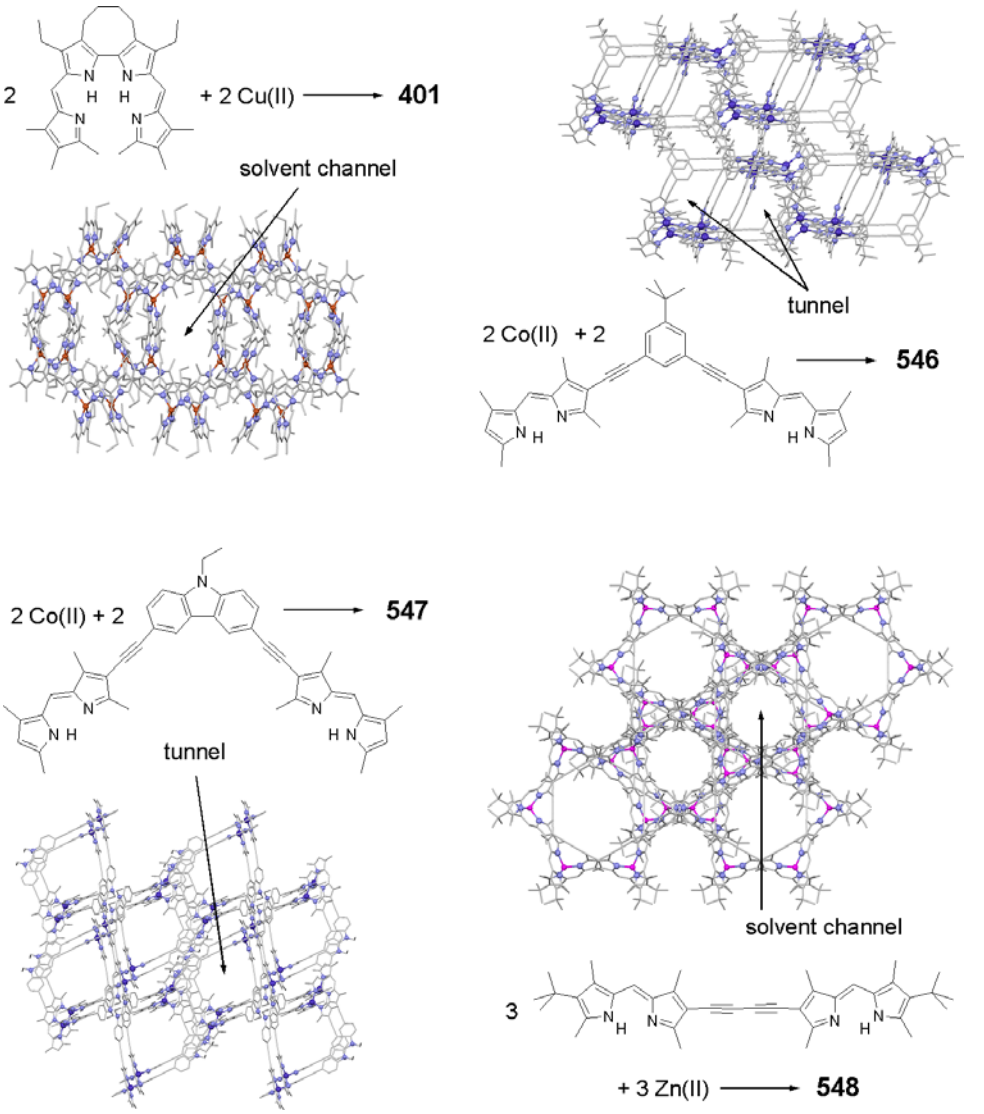

Figure 159. Di- and trinuclear tetrapyrrole species **401** and **546**–**548**, and selected views of their crystal structures (crystallographic figures adapted from Refs. 269 and 298).

channels in the crystalline state.[269] Di- and trinuclear zinc and cobalt chelates of expanded, β-bridged bis(dipyrrin)s **546**, **547**, and **548** show similar behavior and have been analyzed crystallographically in some detail. In these cases porous solids with tunnels or with solvent-filled channels result from the packing of molecules (Figure 159).[298]

A set of *meso*-bridged bis(dipyrrin)s with expanded bridges **107** and **549–551** has been prepared, and the metal complexes of these ligands were tested in supramolecular assemblies and nanostructures. A dinuclear zinc(II) chelate **552** was found to reside in either of two stereochemically distinct forms: a *rac* and a *meso* form. NMR analyses provide evidence for slow exchange of the stereochemistry by the independent rotation of each of the bis(dipyrrinato)zinc subunits

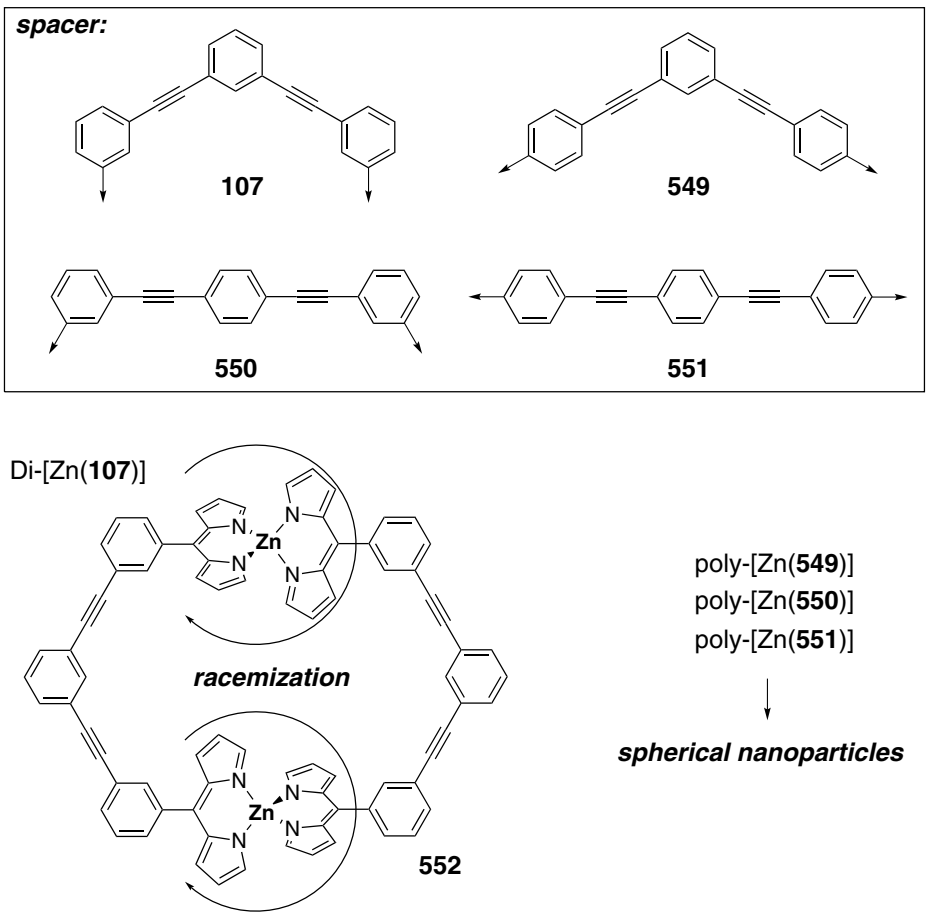

Figure 160. Molecular and supramolecular behavior of di- and polymeric zinc chelates of stretched tetrapyrroles.

within the nanoring.[260] For ligands with a more stretched architecture, such as **549–551**, the formation of spherical nanoparticles from 1D polymeric coordination compounds has been detected (Figure 160).[544] First coordination oligomers of this type have most recently been isolated by a statistic approach using a linking bis(dipyrrin) and an end group.[545] Albeit only little is known so far about such and other tetrapyrrole-based nanostructures, there seems to be much potential for controlling the fabrication and morphology of such nano-objects through this coordination chemistry approach in the future.

IX. Concluding Remarks

The coordination chemistry of linear open-chain tri- and tetrapyrrole ligands is currently developing into a very broad area ranging from biomedical and microbiological applications through synthetic improvements in macrocycle preparations and luminescent material for modern photophysics to catalysis and nanoscience. The basics of the coordination chemistry of such ligands are well-understood for the most important examples only — the tripyrrins, bais, bilins, and the bidipyrrins — but still not sufficiently developed for most of the many possible ligand architectures. Furthermore, most of the many linear tetrapyrroles known from preparative studies have not been or have only been little investigated within coordination compounds. This is particularly true for the natural tripyrroles and for tetrapyrroles designed using the bis(dipyrrin) concept. The possibilities still to open up in the field of linear oligopyrrole metal chelates leave much space for future work on stereochemically and electronically interesting species with unforeseen reactivity, and the opportunity to use these compounds in life science, materials, and nanotechnology will be the topic of interdisciplinary studies in the near future.

X. Acknowledgments

I thank Anne Scheja for her help in accessing obscure papers, and Dr. Klaus Harms for his support in mining crystallographic data.

Preface

Although the porphyrin and tetrapyrrole research area was regarded as "fully matured" during the 20th century, as evidenced for example by the awarding of numerous Nobel Prizes to its principal researchers, new advances and accomplishments in the field still amaze us as editors. The area continues to blossom and to expand into new areas of science and applications that would probably never have occurred to our 20th century heroes. An earlier *Porphyrin Handbook* assembled the large amount of factual data that had been accumulated during the 20th century. Our new venture, the *Handbook of Porphyrin Science* takes a completely new look at our research area and comprehensively details the contemporary science now appearing in the scientific literature that would indeed have been hard to predict even 10 years ago. In particular, fundamentally new methodologies and potential commercial applications of the beautiful compounds that we all love are exemplified, fully recognizing the subtitle of the series — "with applications to chemistry, physics, materials science, engineering, biology and medicine".

The three of us have complementary expertise in physical chemistry, synthetic and bioorganic chemistry, and in synthetic and mechanistic organometallic chemistry; this has enabled us to cover the whole field of porphyrin science and applications, and to devise comprehensive volume and author content. As of the date of writing, between the three of us, we have published more than 1600 tetrapyrrole research articles, and hold 31 patents related to commercial applications of porphyrin science. So we do know our field, and this has enabled us to assemble a first-rate group of experts who have written comprehensive up-to-date chapters with accuracy and authority; we thank our authors for their cooperation and willingness to go along with our highly ambitious schedule for production of these volumes.

We look forward to comments from our readers, and to suggestions that might enable us to expand our basic interests and scientific coverage even further. Meanwhile, we hope that porphyrin researchers, old, new and of the future, will enjoy reading these volumes just as much as we enjoyed planning and, with the help of World Scientific Publishing Company, producing them from manuscript to published article, in a timely manner.

I. Introduction

This chapter covers UV-vis absorption spectroscopic properties of phthalocyanines (Pcs) and related macrocycles, including tetraazaporphyrins (TAPs), naphthalocyanines (Ncs), and anthracocyanines (Acs). Pcs consist of four isoindole units, which are linked angularly by four *meso*-nitrogen bridges, leading to a macrocyclic aromatic molecule (Figure 1). Considering the aromatic skeleton of porphyrin as a reference, the replacement of four *meso*-carbons with nitrogen atoms generates a TAP. Therefore, Pcs, Ncs, and Acs are radially benzo-, naphtho-, and anthraco-ring-fused TAP analogs, respectively. Hereafter, the term "Pc" also includes these analogs. Since the chance discovery of an insoluble blue pigment in the early 20th century,[1] and the subsequent structural determination,[2,3] Pc-based dyestuffs, known today as phthalocyanine blue or phthalocyanine green, have been widely employed as robust coloring materials. In the late 20th century, the application of Pcs expanded into various advanced materials, such as dyes for read-write optical media, photosensitizers for photodynamic therapy (PDT), photovoltaic devices, and so forth.[4–18] These sophisticated molecular functionalities are ascribed to the versatile electronic structures of Pcs and as a consequence, Pcs have established a firm position as high-tech materials today.

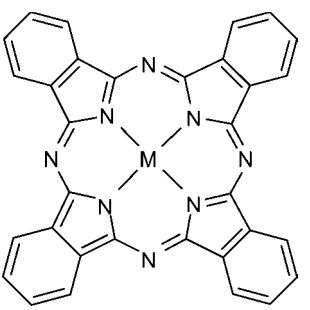

Figure 1. Molecular geometry of a metalloPc. M represents the central element.

More recently, chemists have been able to synthesize more complicated and more controlled Pc derivatives, thanks to the development of advanced synthetic strategies and purification techniques, leading to rapid progress of this academic field over the past decade. UV-vis absorption is one of the most important properties of Pc derivatives, because the spectral shape of an absorption spectrum is closely related to the molecular and electronic structure of the compound. It should also be noted that absorption spectroscopy is routinely used by chemists working in relevant fields, so that they can check their reactions quickly when synthesizing novel Pc derivatives. From this point of view, electronic absorption spectroscopy in Pc chemistry is equivalent to NMR and IR spectroscopy in general organic synthesis, since the appearance of the expected absorption signals provide a very powerful first evidence for formation of the Pc skeletons.

Figure 2 depicts the absorption spectrum of ZnPc in pyridine as an example of the typical spectral pattern of metalloPcs. The sharp, intense band observed in the lowest energy region (674 nm) is an *x*/*y*-polarized π–π^* transition, referred to as the Q band. The broad band in the 300–400 nm region consists of more than one component, including B_1 and B_2 bands, and is referred to as the Soret region.[19] Several less-intense components observed at the foot of the Q band are considered to be of vibronic origin.[20] Vapor phase absorption spectra of typical metalloPcs exhibit additional three-band components in the 200–300 nm region, which are referred to as N, L, and C bands in the order of increasing energy.[21] The characteristics of the B and N bands are sensitive to the central metal, and it is suggested that MLCT and LMCT transitions are involved in this spectral region.[22]

Figure 3 compares the absorption spectra of octaethyl-substituted NiTAP (solid line) and MgTAP (dashed line) in hexane.[23] Intense single Q bands appear at 590 and 596 nm for the nickel and magnesium complexes, respectively, while the near

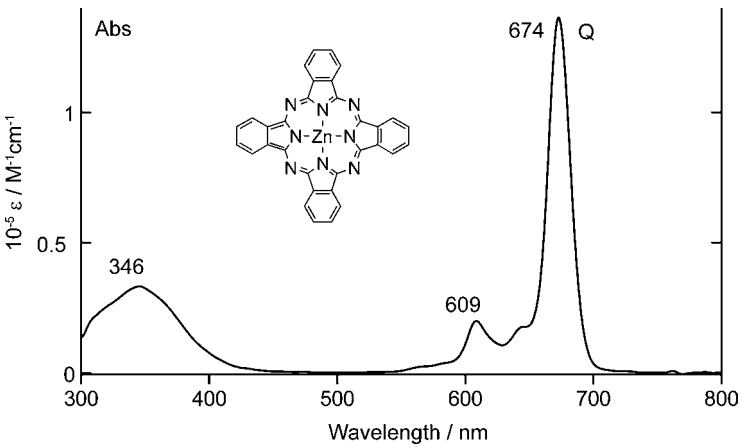

Figure 2. Absorption spectrum of ZnPc in pyridine.

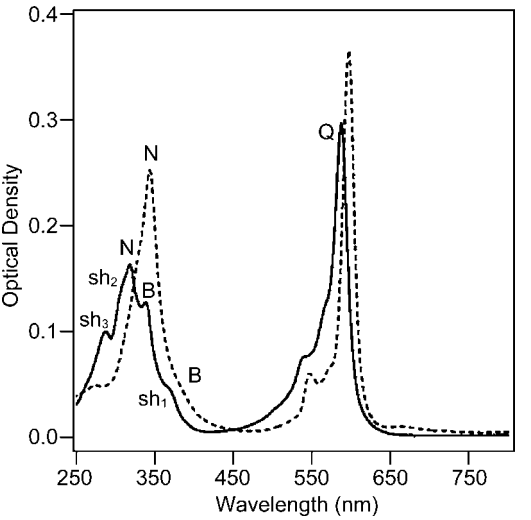

Figure 3. Absorption spectra of octaethyl-substituted NiTAP (solid line) and MgTAP (dashed line) in hexane at room temperature. Redrawn with permission from Rosa, A.; Ricciardi, G.; Baerends, E. J.; van Gisbergen, S. J. A. *J. Phys. Chem. A* **2001**, *105*, 3311–3327. Copyright 2001 American Chemical Society.

UV region shows different spectral shapes. More structure is seen in the near UV region for the nickel complex compared to the magnesium complex. Although not shown, the magnetic circular dichroism (MCD) signal corresponding to the Q band is a derivative-shaped Faraday A term, indicating that the Q band arises from a transition to an orbitrally degenerate excited state. Although the general absorption features of Pcs can be well-described by Gouterman's four-orbital model, various structural parameters such as the central metal and macrocyclic substituents affect the band energy and even the constituents of the observed bands. In this chapter, therefore, we have collected UV-vis absorption data of previously reported Pcs and related analogs, and summarize their spectral characteristics with respect to the molecular structures, central metals, and macrocyclic substituents.

As a general introduction, the theoretical background of the absorption spectral properties of Pcs is described in the first section, followed by a summary of their spectral characteristics. Pcs are classified with respect to their central metal (group), and the way in which the central metal affects the absorption spectral properties is discussed in detail. The relationship between the aromatic skeletal structures and the spectral features, as well as substituent effects will also be included. Although we will not go into detail in this chapter, MCD spectroscopy gives more information on the electronic structures of Pcs than absorption spectroscopy, and therefore, some conclusions based on results from MCD spectroscopy will also be cited where necessary. At the end of this chapter, comprehensive absorption data of the known Pc derivatives are compiled (Tables 1–13), which may assist the reader in designing and/or

characterizing new Pc derivatives during the course of their research. The abbreviations and nomenclatures used in these tables will be explained in the corresponding section. Details of the spectral properties of ring-oxidized or -reduced Pc species are omitted in this chapter, since this was covered in an earlier publication.[24] Finally, the authors would like to inform the reader that several excellent publications and review articles regarding the absorption properties of Pc derivatives are already available. In particular, a Russian book published in 1989 by Luk'yanets is all-inclusive and well-categorized, and was probably the only comprehensive database of absorption data for Pc compounds at that time.[25] The fundamental chemistry of Pcs, including their spectroscopic properties, has been reviewed by Lever.[20] Stillman and Nyokong gave a detailed account of the spectral properties of Pcs in 1989.[26] Detailed discussion on mono-, di-, and triazaporphyrin derivatives is omitted from this chapter, since the properties of these compounds have already been summarized.[27]

II. Basic Theoretical Description of the Absorption Properties of Phthalocyanines

Since the central element of neutral Pcs is formally divalent, the Pc skeleton can be regarded as a dianion. Typical metalloPcs with D_{4h} symmetry have an unsplit lowest-energy band (Q band) in the visible region (*ca.* 650–700 nm) and less-intense B bands in the 300–500 nm region (Soret region). Although charge transfer (CT) transitions are also relevant for metalloPcs having unsaturated transition metal ions at the center, most of the observed absorption bands in the UV-vis region can be ascribed to π–π* transitions. Therefore, a "particle on a ring" model, which often appears in basic quantum chemistry textbooks, is probably the simplest way to describe the electronic structures of Pcs. Historically, porphyrins took the lead in theoretical studies on the electronic structures and optical transitions of this type of macrocyclic molecule. Simpson assumed an 18-membered cyclic polyene having 18 π electrons, which means that the symmetry of the wavefunctions of the HOMO and LUMO are $e^{\pm i4\theta}$ and $e^{\pm i5\theta}$, respectively.[28] Assuming this model, one-electron transitions from the HOMO to LUMO generate four states with the symmetries of $e^{\pm i\theta}$ and $e^{\pm i9\theta}$. The former two states are allowed, and correspond to the Soret band of porphyrins, while the latter are forbidden, being consistent with the weak Q band of porphyrins. This model, however, is unable to sufficiently explain the energy difference between the Soret and Q bands (Figure 4a). Meanwhile, Platt and coworkers obtained porphyrin π-MOs using an LCAO technique.[29] On the basis of this model, the degeneracy of the HOMO obtained by Simpson's model is lifted due to symmetry lowering from the cyclic polyene to the D_{4h} porphyrin skeleton, to give two occupied MOs with a_{1u} and a_{2u} symmetries. The LUMO remains degenerate and has e_{g_x} and e_{g_y} symmetries. Although Platt's model is superior in terms of the energy difference between the Soret

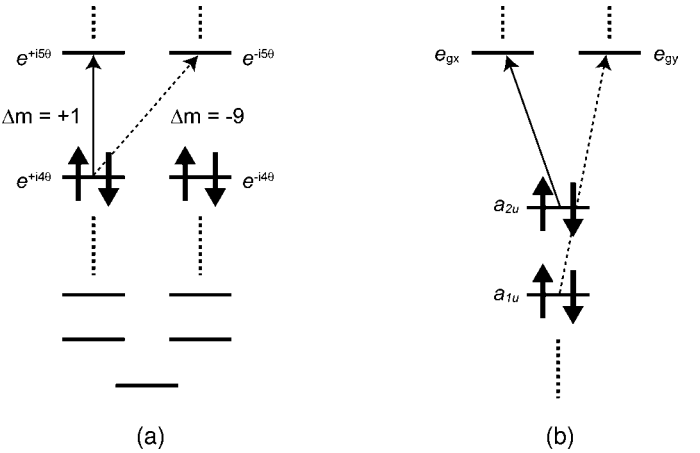

Figure 4. Early MO models of a porphyrin proposed by (a) Simpson[28] and (b) Platt and coworkers.[29]

and Q bands, it does not explain the observed intensity differences (Figure 4b). Therefore, it was necessary to combine these two models in order to understand the absorption spectra of porphyrin. In 1959, Gouterman demonstrated how Simpson's model is related to the LCAO MOs. This model is referred to today as "Gouterman's four-orbital model."[30] Gouterman's four-orbital model states that the two lowest singlet excited states, S_1 and S_2, of D_{4h} porphyrins consist mainly of a linear combination of the $^1(a_{2u}e_g)$ and $^1(a_{1u}e_g)$ configurations, where a_{2u}, a_{1u}, and e_g correspond to the HOMO, HOMO-1, and LUMO of porphyrin, respectively. In other words, one-electron excited states having the same symmetry possibly interact with each other. The degree of this type of configurational interaction depends on the relative energy difference of the related two one-electron excited states, i.e. two degenerate excited states with the same symmetry can interact most significantly. This relationship can be formulated for *y* polarized states as:

$$\left|S_{1y}\right\rangle \equiv \left|Q_y\right\rangle \equiv -\sin\nu\left|B_y^0\right\rangle + \cos\nu\left|Q_y^o\right\rangle, \tag{1}$$

$$\left|S_{2y}\right\rangle \equiv \left|B_y\right\rangle \equiv \cos\nu\left|B_y^0\right\rangle + \sin\nu\left|Q_y^o\right\rangle, \tag{2}$$

where $\left|B_y^0\right\rangle$ and $\left|Q_y^0\right\rangle$ are defined respectively as:

$$\left|B_y^0\right\rangle \equiv 2^{-\frac{1}{2}}\left[^1(a_{2u}e_{gy}) + {}^1(a_{1u}e_{gx})\right], \tag{3}$$

$$\left|Q_y^0\right\rangle \equiv 2^{-\frac{1}{2}}\left[^1(a_{2u}e_{gy}) - {}^1(a_{1u}e_{gx})\right]. \tag{4}$$

Readers should consult the original paper for the definition of tan 2ν.[30] In the case of porphyrin, $2\nu \leq 1$ due to the accidental degeneracy of the a_{1u} and a_{2u} orbitals, and $|Q_y\rangle$ and $|B_y\rangle$ can be approximated as:

$$|Q_y\rangle = |Q_y^0\rangle - \nu|B_y^0\rangle, \tag{5}$$

$$|B_y\rangle = |B_y^0\rangle + \nu|Q_y^0\rangle. \tag{6}$$

As a consequence, the corresponding transition energies E and dipole strengths q for the Q and B bands are:

$$\begin{aligned} E_Q &= \frac{1}{2}\left[E(a_{1u}e_{gx}) + E(a_{2u}e_{gy})\right] - (1+2\nu^2)\int (a_{1u}e_{gx})\mathbf{H}(a_{2u}e_{gy})dv, \\ q_Q^2 &= (\nu R - r)^2, \end{aligned} \tag{7}$$

and

$$\begin{aligned} E_B &= \frac{1}{2}\left[E(a_{1u}e_{gx}) + E(a_{2u}e_{gy})\right] + (1+2\nu^2)\int (a_{1u}e_{gx})\mathbf{H}(a_{2u}e_{gy})dv, \\ q_B^2 &= R^2 - \nu^2 R^2 + 2\nu Rr, \end{aligned} \tag{8}$$

respectively, where R and r are defined as:

$$\begin{aligned} R^2 &\equiv \frac{1}{2}\left(\langle a_{1u}e_{gx}|\mathbf{r}|S_0\rangle + \langle a_{2u}e_{gy}|\mathbf{r}|S_0\rangle\right)^2, \\ r^2 &\equiv \frac{1}{2}\left(\langle a_{1u}e_{gx}|\mathbf{r}|S_0\rangle - \langle a_{2u}e_{gy}|\mathbf{r}|S_0\rangle\right)^2. \end{aligned} \tag{9}$$

Since $\langle a_{1u}e_{gx}|\mathbf{r}|S_0\rangle \approx \langle a_{2u}e_{gy}|\mathbf{r}|S_0\rangle$, $R^2 \geq r^2$. Therefore, much smaller transition moments for the Q band than the B band of porphyrin are expected, which is consistent with the experimental results.

Gouterman confirmed the validity of these formulas by plotting oscillator strength vs. Q-band energy for various metallotetraphenylporphyrins. Figure 5 shows the agreement of experiment with the theoretical relationships, supporting the validity of Gouterman's four orbital model.[31] When the accidental degeneracy of the a_{1u} and a_{2u} orbitals is lifted, largely by changing the molecular structure, ν is no longer much less than 1. In this case, the Q transitions gain intensity, and the Q–B energy separation increases. Figure 6 shows the four frontier orbitals and their energies for TAP, calculated by ZINDO. Unlike porphyrin, the a_{2u} orbital (HOMO–1) is largely stabilized, and the accidental

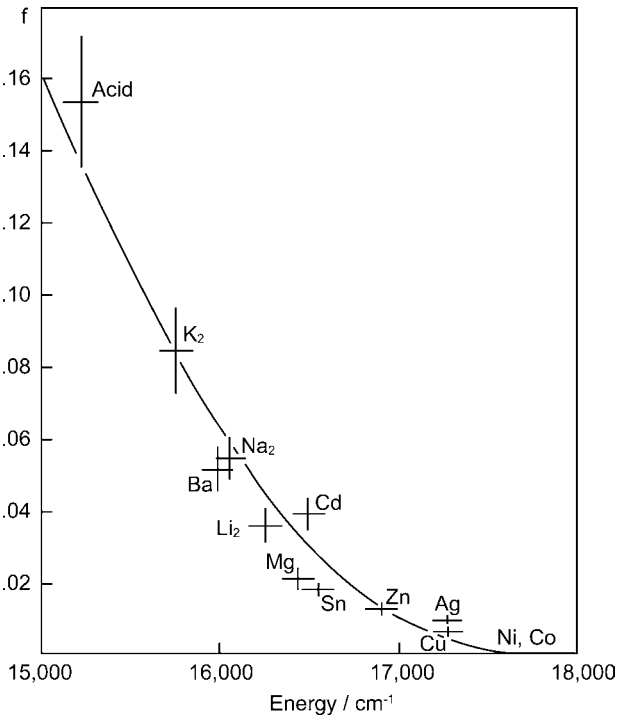

Figure 5. Oscillator strength vs. energy of Q(0–0) band in metallotetraphenylporphyrins. The line is theoretical. Redrawn from Gouterman, M. *J. Mol. Spectrosc.* **1961**, *6*, 138–163. Copyright 1961, with permission from Elsevier.[31]

degeneracy between the a_{1u} and a_{2u} orbitals is lost. The a_{1u} orbital has anti-nodes at the diagonal *meso*-atoms, while the a_{2u} orbital has significant MO amplitude on these four atoms. The large MO amplitude (electron density) at the electronegative atoms leads to stabilization of the corresponding MOs. Therefore, replacement of the four *meso*-carbons with nitrogen atoms, to give the TAP skeleton, results in the stabilization of the a_{2u} (HOMO−1) orbital relative to the a_{1u} orbital (HOMO). As a consequence, the interaction between the $^1(a_{1u}e_g)$ and $^1(a_{2u}e_g)$ configurations calculated for TAPs is not as significant as it is for the porphyrins. In the case of the Q transition of TAPs calculated by the Pariser-Parr-Pople (PPP)-SCF-MO method, the $^1(a_{1u}e_g)$ configuration accounts for *ca.* 72%, while only 57% of the HOMO–LUMO transition contributes to the Q transition for porphyrin.[32] The Q band also becomes purer, the larger the molecule, so that the $^1(a_{1u}e_g)$ configuration accounts for *ca.* 72, 87, 91, and 92% for TAP, Pc, Nc, and Ac, respectively.[32] These results justify Gouterman's four-orbital model for the Q bands, although it is known that higher-lying excited states are necessary to correctly describe the Soret region.

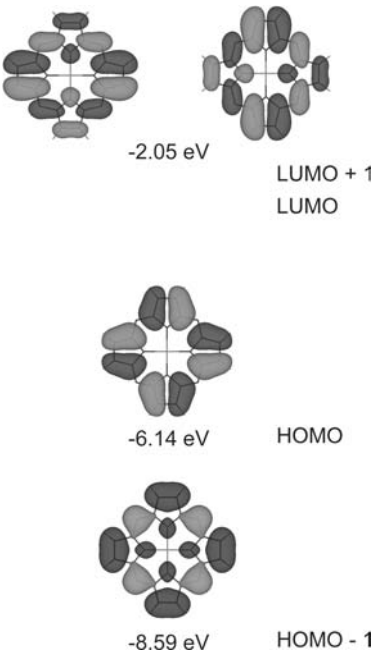

Figure 6. Four frontier MOs of ZnTAP calculated within the framework of the ZINDO method.

Higher-level calculations are able to estimate the effect of non-π electrons such as d electrons and lone pairs on the nitrogen atoms, which are ignored for the Gouterman model. Figure 7 shows energy level schemes for MgTAP, ZnTAP, and NiTAP obtained using DFT calculations (refer to Ref. 22 for details of the calculations). The hatched lines (the $4a_{2u}$, $1a_{1u}$, and $5e_g$ orbitals) indicate that these are the four Gouterman orbitals. The metal 3d orbitals and N_b lone pair orbitals are indicated by heavy lines and dashed lines, respectively. From the calculated results based on the TDDFT method, the Q transition (1^1E_u state) of NiTAP consists of 84% of $1a_{1u} \rightarrow 5e_g$ and 14% of $4a_{2u} \rightarrow 5e_g$ configurations, supporting Gouterman's interpretations (see Table 4 in Ref. 22). Although Gouterman's second-lowest transition corresponds to the $4a_{2u} \rightarrow 5e_g$ configuration-dominated transition, an additional two transitions (2^1E_u and 3^1E_u states) are predicted in between the so-called Q and B transitions, which consist of almost pure $2b_{2u} \rightarrow 5e_g$ and $3a_{2u} \rightarrow 5e_g$ configurations, respectively. Since the transition to the 3^1E_u state is predicted to be very low in intensity, the shoulder denoted as sh_1 in Figure 3 arises mainly from a transition to 2^1E_u. Contrary to the Gouterman model, the next-lowest state (4^1E_u), assigned as the B transition, contains only 38% of the $4a_{2u} \rightarrow 5e_g$ configuration, and instead $4e_g(d\pi) \rightarrow 2b_{1u}(\pi^*)$ and $12e_u(N_b(1one\ pair) \rightarrow 7_{1g}(d\sigma^*)$ configurations account for 44 and 14%, respectively, showing

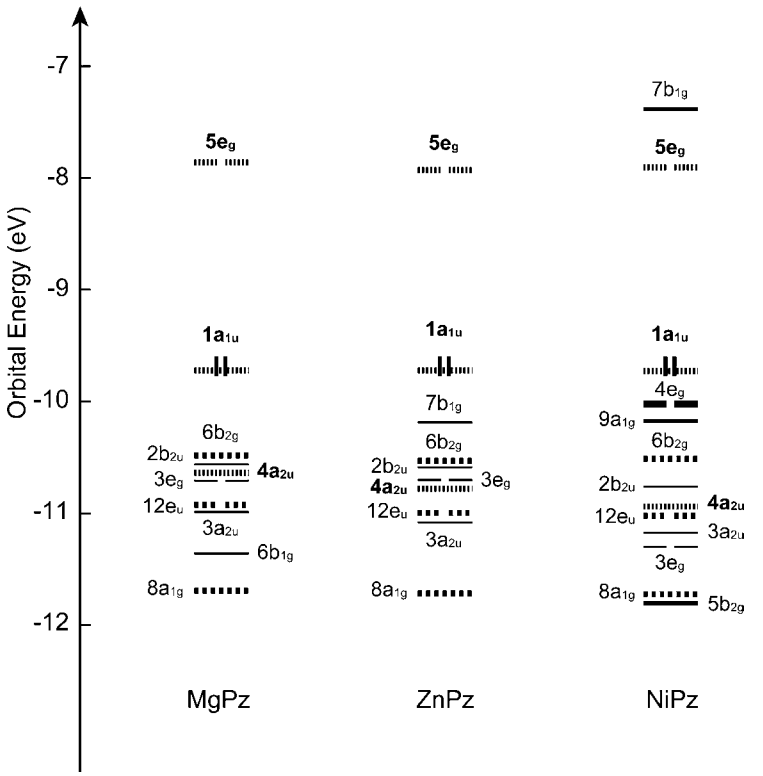

Figure 7. Energy level scheme for MgTAP, ZnTAP and NiTAP. Double occupancy is indicated for the HOMO only. The hatched lines, i.e. $4a_{2u}$, $1a_{1u}$, and $5e_g$ orbitals, indicate that these are the four Gouterman orbitals. The metal 3d orbitals and the N_b lone pair orbitals are indicated with heavy lines and dashed lines, respectively. Redrawn from Baerends, E. J.; Ricciardi, G.; Rosa, A.; van Gisbergen, S. J. A. *Coord. Chem. Rev.* **2002**, *230*, 5–27. Copyright 2002, with permission from Elsevier.

that the presence of MLCT and LMCT transitions cannot be ignored for interpretation of the bands in the near UV region for NiTAPs. The other combinations of these configurations generate an additional two excited states, 5^1E_u and 6^1E_u, of which the latter is assigned to the N transition. In the case of MgTAP and ZnTAP, metal-centered orbitals contribute less significantly to the absorption spectra (see Tables 4 and 5 in Ref. 22). As a result, fewer structures are seen in the absorption spectrum in the near UV region for octaethyl-substituted MgTAP (Figure 3). On the other hand, the $3a_{2u} \rightarrow 5e_g$ configuration is responsible for the B and N transitions in addition to Gouterman's configurations ($4a_{2u} \rightarrow 5e_g$ and 1 $a_{1u} \rightarrow 5e_g$), since ring deformations caused in the magnesium and zinc complexes increase the $4a_{2u}$ orbital energy. The same type of calculations for NiPc has been conducted by the same group, which clarified that the B band of NiPc can no longer be described

in terms of the four-orbital model.[23] In the B band region, seven excited states are predicted, of which the 4^1E_u, 7^1E_u, and 8^1E_u states have large oscillator strengths (see Table 5 in Ref. 23). These are of π–π^* origin, and the 4^1E_u, and 7^1E_u, and 8^1E_u states are assigned to B_1 and B_2 bands, respectively. MLCT and LMCT transitions are involved in the higher-lying excited states.

III. Absorption Spectra of Pcs

A. H_2Pc and HPc

Unsubstituted H_2Pc is sparingly soluble in most organic solvents, while the solubility increases remarkably for substituted H_2Pcs such as tetra-*tert*-butyl H_2Pc. Therefore, vapor-phase[21,33] or matrix-isolated[34–36] absorption spectra were reported in the early papers. Unsubstituted H_2Pc shows split Q band components at *ca.* 693 and 656 nm in $CHCl_3$, CCl_4, and DMF.[37–39] This splitting has been interpreted as due to the diagonally occupying two protons on the pyrrolic nitrogens reducing the molecular symmetry from D_{4h} to D_{2h}, thus lifting the degeneracy of the LUMO. Clear band splitting is not observed for the Soret region at room temperature. Although the solvent dependence of the Q band positions is small, the addition of a strong base to the solution causes deprotonation, to give an unsplit Q band. Whalley reported a coalesced Q band for H_2Pc dissolved in pyridine, suggesting that the two central protons of H_2Pc have some acidity, and are removed from the Pc skeleton in basic media.[40] Figure 8 shows the spectral changes in the Q-band region during the addition of NaOH/EtOH to a solution of H_2Pc in $PhCCl_3$. The initial spectrum exhibits two clear Q-band components, having approximately equal intensity (A). Upon addition of the base, these bands begin to coalesce to a single absorption band (B and C). It is claimed that the two central protons are replaced by sodium cations.[41] The spectral envelope for tetra-*tert*-butyl H_2Pc is practically identical with that of the unsubstituted derivative, as shown in Figure 9.[42] The lower energy Q band position depends slightly on the solvent, ranging from 694 to 703 nm. As a general trend, the Q bands shift to the red in the order of alkanes < oxygen-containing solvents < aromatic hydrocarbons < nitrogen-containing solvents < 1-chloronaphthalene.

The Q-band splitting energy is related to the Q-band energy, and the splitting decreases with increasing size of the aromatic skeleton. Figure 10 depicts the absorption spectra of tetra-*tert*-butyl H_2TAP, Pc, Nc, and Ac (from top to bottom).[43–45] The splitting reaches almost 2000 cm^{-1} for H_2TAP, and decreases to 733 cm^{-1} for H_2Pc. In the case of H_2Nc and H_2Ac, no splitting of the Q band is observed experimentally, although a small splitting can be observed for H_2Ac having a Q band above 950 nm if the conditions permit, as illustrated in Figure 11.[46]

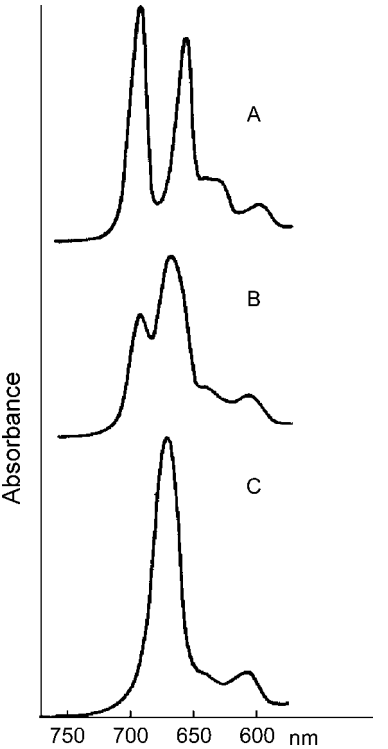

Figure 8. Q-band region of absorption spectra of H_2Pc. A: H_2Pc in $PhCCl_3$, B and C: after addition of NaOH/EtOH solution. Redrawn from Ledson, D. L.; Twigg, M. V. *Inorg. Chim. Acta* **1975**, *13*, 43–46. Copyright 1975, with permission from Elsevier.

A solvent dependency of the splitting energy is also observed for tetra-*tert*-butyl H_2Nc.[47] In *n*-octane, the Q band appears at 778 and 760 nm, while these coalesce to single absorption at 784 nm in $CHCl_3$. According to group theory, a molecule with D_{2h} symmetry has no degenerate excited states. Therefore, it is conceivable that the observed single absorption arises from two energetically-close merged bands. MCD spectroscopy also supports this assignment. In addition, this type of decrease of the splitting energy with respect to the Q-band energy is observed not only for aromatic ring-expanded series but also for Pcs having different substituents.[48]

Low symmetry H_2Pcs can have two tautomers depending on the location of the two central protons. Drobizhev *et al.* observed the two-photon induced photo-tautomerization of a mono-benzo-fused H_2Pc derivative.[49] As depicted in Figure 12, the sample film shows two strong, narrow absorption peaks at 706 and 753 nm at 77 K (T_1), indicating that the T_1 tautomer is the more stable of the two possible structures. A similar tautomerism was also observed by using resonant one-photon

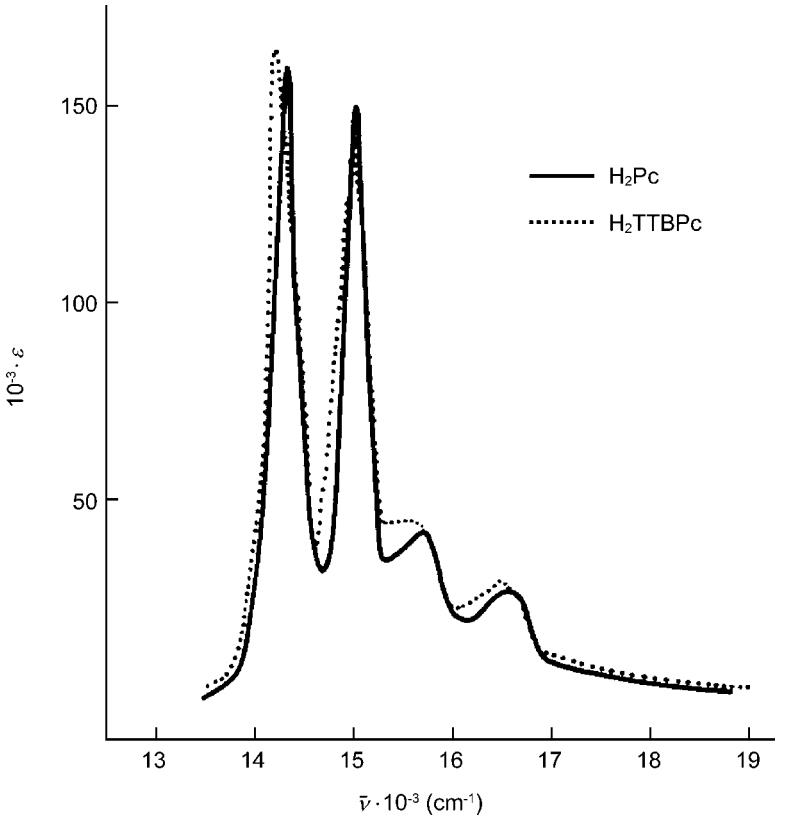

Figure 9. Q-band region of absorption spectra of H_2Pc (solid line) and tetra-*tert*-butyl H_2Pc (dotted line) in 1-chloronaphthalene. Redrawn from Jerwin, K.; Wasgestian, F. *Spectrochim. Acta A* **1984**, *40*, 159–163. Copyright 1984, with permission from Elsevier.

excitation.[50] The absorption spectral shapes of tautomeric isomers of low-symmetry H_2TAP derivatives were assigned by the combined use of MCD spectroscopy and MO calculations (Figure 13).[51] The spectral shapes of $1H_2$ and $3H_2$ in Figure 13 resemble that of the summation of T_1 and T_2 of Ref. 49 (Figure 12), indicating that the observed spectra arise from a mixture of the two tautomers. The MCD spectra show dispersion-type pseudo A-terms corresponding to the bands at 653 and 671 nm for $1H_2$ and $3H_2$, respectively. The calculations predict that these originate from $1H_2Y$ and $3H_2Y$, respectively. On the other hand, band peaks at 701 and 598 nm for $1H_2$, and 709 and 611 nm for $3H_2$ can be assigned to two split Q components, since oppositely-signed MCD signals were observed for these two coupled peaks. The calculations show that these spectra arise from $1H_2X$ and $3H_2X$, respectively. Since the two possible tautomeric structures are identical for $2AdH_2$, only one chemical species likely contributes to the spectrum. In the case of

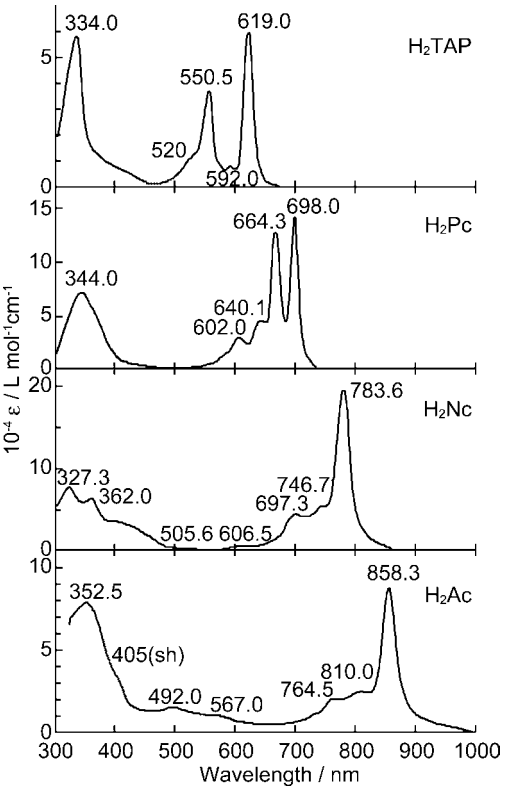

Figure 10. Absorption spectra of tetra-*tert*-butyl H_2TAP, H_2Pc, H_2Nc, and H_2Ac (from top to bottom) in pyridine. Redrawn from Kobayashi, N.; Nakajima, S.; Ogata, H.; Fukuda, T. *Chem. Eur. J.* **2004**, *10*, 6294–6312.

$2OpH_2$, spectral data suggest that only one of the possible two isomers, i.e. $2OpH_2X$, is likely to be present. These observations imply that the stability and equilibrium constants of tautomers depend significantly on the molecular structure.

Figure 14 gives another example of spectral observations demonstrating tautomeric isomers.[52] The thiophene-fused derivative shows three distinct bands in the Q-band region (Figure 14, top), indicating that the spectrum arises from a mixture of two tautomers. Similar spectral shapes were also reported for other thiophene-fused H_2Pcs.[53,54] On the other hand, absorption spectra of the dimethyl acetylenedicarboxylate adduct, and the derivative obtained therefrom (Figure 14, middle and bottom, respectively) appear to originate from one chemical species.

Sugimoto and coworkers prepared the stable free radical of Pc (HPc) by the reaction of Li_2Pc with iodine in acetone.[55] HPc is a dark brown solid, and is almost insoluble in most organic solvents. Figure 15 shows the reflectance spectra of LiPc, HPc, and Li_2Pc from top to bottom (see the subsequent section for LiPc and

Li_2Pc).[55] It can be seen from the spectra that new bands appear at 440 and 490 nm compared to Li_2Pc, in addition to broad band in the 550–800 nm region.

B. Group 1: Li_2Pc, LiHPc, LiPc, Na_2Pc and K_2Pc

Similar to metal-free Pcs, alkali metal Pcs can have two metal cations in the central cavity, since alkali metals are monovalent. The solubility of unsubstituted Li_2Pc in alcohols and acetone is much greater than that of H_2Pc.[56] However, an unsplit Q band is reported for Li_2Pc in acetone, where the absorption spectrum of Li_2Pc is similar to that of typical metalloPcs rather than H_2Pc.[20,57] Stillman and Thomson measured the absorption spectra of Li_2Pc dissolved in DMSO in the absence and presence of NaCN, and reported that unsplit Q bands appear at 15 350 cm^{-1} (651 nm) and

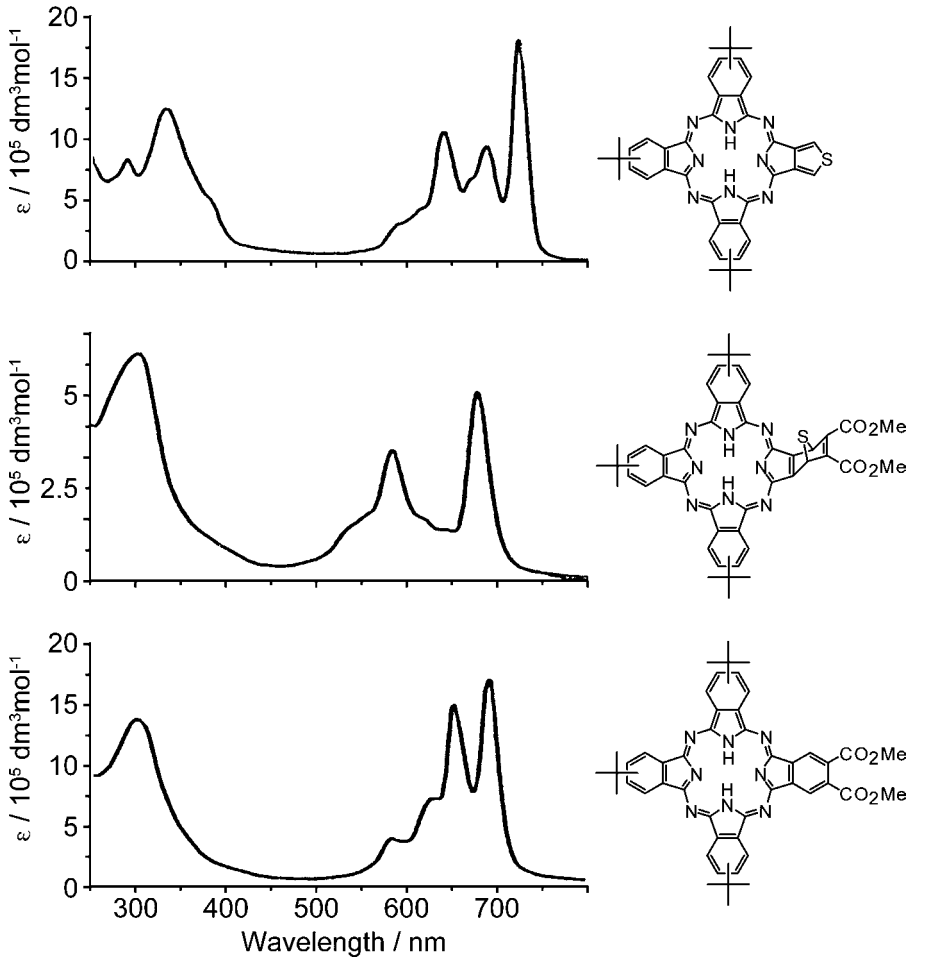

Figure 14. Absorption spectra of tribenzo[*b, g, l*]thiopheno[3,4-*q*]porphyrazine (top), its dimethyl acetylenedicarboxylate adduct (middle), and substituted tribenzo[*b, g, l*]porphyrazine (bottom). 15 340 cm^{-1} (652 nm), respectively.[58] By combining the results of absorption and MCD spectroscopy, they commented that the lithium ions do not occupy the center of the ring in the same manner as protons. However, the MCD spectra discard the possibility that the lithium ions are not occupying the ring center. As a consequence, they concluded that in DMSO, Li_2Pc contains only one lithium ion in the center of the ring, or that two lithium ions are disposed, to preserve an axis of symmetry perpendicular to the D_{4h} ring plane. The absorption spectrum of Li_2Nc is very similar to that of Li_2Pc in shape, except that the Q band shifts to the red by *ca.* 80 nm.[59] A larger

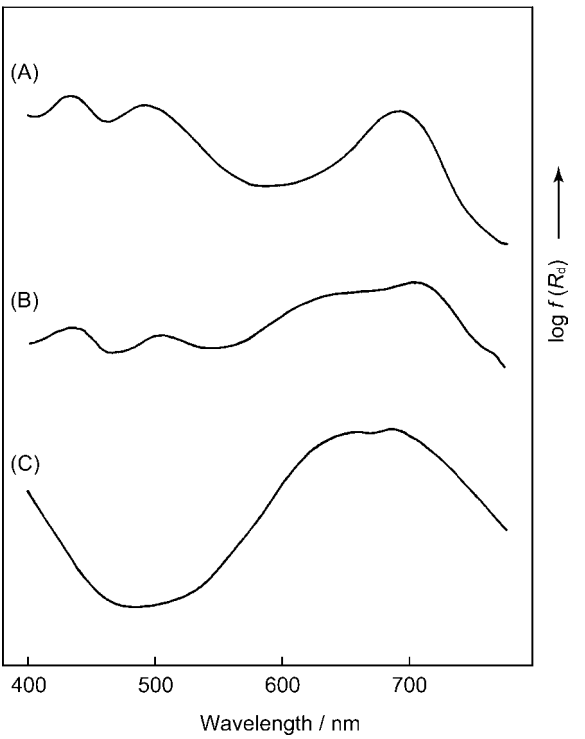

Figure 15. Reflectance spectra of LiPc (A), HPc (B), and Li_2Pc (C). Sugimoto, H.; Higashi, T.; Mori, M. *J. Chem. Soc. Chem. Commun.* **1983**, 622–623. Redrawn by permission of The Royal Society of Chemistry.

absorption coefficient is observed for the Q band of Li_2Nc (*ca.* 375 000 $M^{-1}cm^{-1}$) compared to Li_2Pc (*ca.* 150 000 $M^{-1}cm^{-1}$) in acetone. Li_2Pc is readily demetallated by protic solvents. Upon addition of a small amount of distilled water (pH = *ca.* 6) to a solution of Li_2Pc in weakly coordinating solvents (DMA or DMSO), the initial Q band at 658 nm collapses, while new bands appear at *ca.* 655 and 685 nm. These two bands diminish further, to give a single new Q band at 664 nm within 2 hours, suggesting that the solvent molecules are protonated and act as axial ligands above and below the Pc plane.[60] Upon heating this solution, the spectrum changes into that typical of H_2Pc with D_{2h} symmetry, with split Q bands at 685 and 658 nm being observed. The lithium-hydrogen complex, LiHPc, is formed by the reaction of excess of phthalonitrile with lithium amyloxide.[56] LiHPc is expected to be also formed as an intermediate during the demetalation process of Li_2Pc. On the other hand, LiHPc yields Li_2Pc on treatment with lithium amyloxide. LiHPc exhibits an unsplit Q band at 667 nm in pyridine, indicating that both the lithium cation and proton are eliminated, and presumably the observed spectrum arises from the Pc

dianion.[61] Homborg prepared several lithium Pc derivatives, including (tetraalkylammonium)LiPc, AgLiPc, and CuLiPc.[62] The absorption spectrum of (tri-*n*-dodecylbutyl)-ammonium LiPc in CH_2Cl_2 showing an unsplit intense principal band at 14 990 cm^{-1} (667 nm) is practically identical to that of LiHPc in pyridine, suggesting presumably that the observed spectra arise from $LiPc^-$ or Pc^{2-} species (not shown).[61,62] The double decomposition of (tri-*n*-dodecylbutyl)-ammonium LiPc with either a cuprous or silver complex in nonpolar aprotic solvents yields CuLiPc and AgLiPc, respectively, of which the former exhibits absorption peaks at 678, 648, and 610 nm in KBr at 10 K. In contrast, AgLiPc shows band peaks at 812, 482, and 435 nm in addition to the normal peaks at 672, 645, and 607 nm in KBr, indicating that the ring-oxidized species is involved in the spectrum.[63]

Mono-lithiated Pcs (LiPcs) and Ncs (LiNcs) are prepared by electrochemical oxidation or air oxidation of the corresponding di-lithiated complex.[64–73] Figure 16 shows the absorption spectra of LiPc (dashed line) and its aggregate (solid line) in 1-chloronaphthalene.[59] In Ref. 59, the authors claimed that the peaks at 945 and 693 nm for LiPc can be assigned to the aggregate form, since these disappear at low concentration, although this assignment is debatable. Substituted LiPc derivatives have also been prepared in a similar manner to the unsubstituted derivative. Figure 17 depicts the absorption spectra of α-OBu-substituted LiNc (solid line) and the corresponding H_2Nc (dashed line) in THF.[73] While H_2Nc exhibits a strong Q band at 865 nm, the LiNc derivative shows peaks at 1005, 857, 705, and 449 nm. These spectral features are similar to those observed for unsubstituted LiNc in various solvents.[70] Substituted LiPc derivatives also show similar spectral characteristics.[69]

Ledson and Twigg claimed that the chemical species generated by the addition of an NaOH/EtOH solution to H_2Pc in $PhCCl_3$ is Na_2Pc (Figure 8c). However,

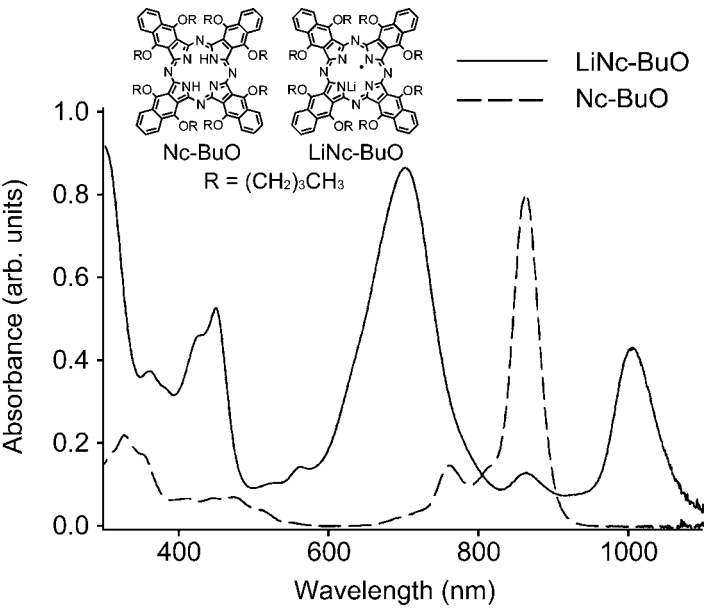

Figure 17. Absorption spectra of α-OBu substituted LiNc (solid line) and the corresponding H_2Nc derivative (dashed line) in THF. Pandian, R. P.; Kim, Y. I.; Woodward, P. M.; Zweier, J. L.; Manoharan, P. T.; Kuppusamy, P. *J. Mater. Chem.* **2006**, *16*, 3609–3618. Redrawn by permission of The Royal Society of Chemistry.

there is no evidence proving that the spectrum shown in Figure 8c really arises from Na_2Pc rather than the Pc dianion (Pc^{2-}).

Reaction of potassium amyloxide and phthalonitrile gives K_2Pc.[74] Crystals of K_2Pc(DMF)$_4$, K_2Pc(diglyme)$_2$, and K_2Pc(18-crown-6)$_2$ were grown from K_2Pc in DMF, in benzene containing excess 18-crown-6, or hot diglyme, respectively, and their X-ray structures solved.[75,76] The potassium cations are located out of the Pc plane, with the K–K axis being practically coincident with the principal axis of the Pc skeleton. K_2Pc in DMF shows an unsplit Q band at 667 nm.[75] The crystal structures of KPc have also been solved.[77]

C. Group 2: BePc, MgPc, CaPc and BaPc

Information on BePc is very limited, because particular caution is required due to the highly toxic nature of beryllium.[57,74,78–80] BePc dihydrate exhibiting a Q band at 692 nm in 1-chloronaphthalene has been reported,[57] although a recent study by Kubiak *et al.* has clarified from thermogravimetric measurements that anhydrous BePc is readily hydrated in moist air to give the monohydrate, BePc(H_2O), rather than the dihydrate.[80]

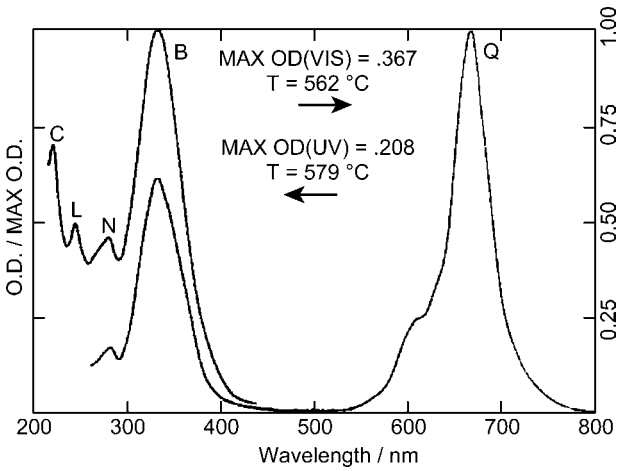

Figure 18. Vapor-phase absorption spectrum of MgPc. Redrawn from Edwards, L.; Gouterman, M. *J. Mol. Spectrosc.* **1970**, *33*, 292–310. Copyright 1970, with permission from Elsevier.

MgPc is an ideal species for investigating the optical absorption properties of metalloPcs, because MO mixing between the central metal and Pc ligand is negligible. Edward and Gouterman reported a vapor phase absorption spectrum, exhibiting the Q and B bands at 666 and 332 nm, respectively, in addition to N, L, and C bands in the 200–300 nm region (Figure 18).[21] Unsubstituted MgPc has a high solubility in various organic solvents, especially in N- or O-donor solvents, making possible the spectroscopic study of the unsubstituted species.[20,81] MgPc is able to coordinate two axial ligands, and Janczak reported the crystal structure of $MgPc(H_2O)$.[82] The Q-band energy depends little on the axial ligands. Thus, the Q bands of MgPc, $MgPc(im)_2$, $MgPc(meim)_2$, $MgPc(py)_2$, $MgPc(mepy)_2$, and $MgPc(CN^-)_2$ in CH_2Cl_2 appear at 670, 672, 672, 671, 671, and 671 nm, respectively, where im = imidazole, meim = methylimidazole, and mepy = 4-methylpyridine.[83] Figure 19 depicts the absorption spectrum of $MgPc(py)_2$ in pyridine.[84] The spectrum is similar in shape to that recorded in the vapor phase (Figure 18), although more well-resolved vibronic bands can be recognized to lie at higher energy to the Q band in pyridine. According to the band deconvolution analysis of the absorption and MCD spectral data performed by Stillman and coworkers (Figure 20), five degenerate transitions are identified for $MgPc(im)_2$ in CH_2Cl_2 at 672, 364, 339, 282, and 248 nm, which are assigned as the Q, B, N, L, and C transitions, respectively.[83]

A theoretical interpretation of the absorption spectrum of MgTAP based on TDDFT calculations has already been described earlier.[22] Ishikawa *et al.* performed *ab initio* calculations of the excited states of MgPc based on the HF/CIS/6-31G

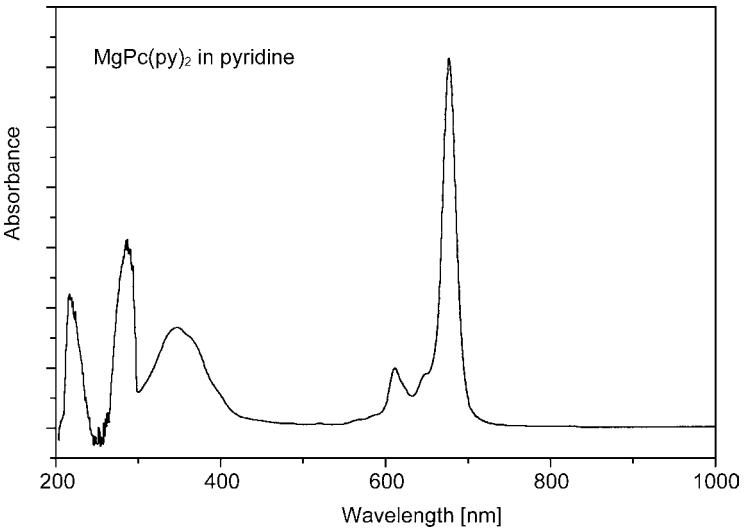

Figure 19. Absorption spectrum of $MgPc(py)_2$ in pyridine. Redrawn from Janczak, J.; Kubiak, R. *Polyhedron* **2002**, *21*, 265–274. Copyright 2002, with permission from Elsevier.

level.[85] The lowest state, assigned as the Q band ($1E_u$), is accounted for by 92% of the $2a_{1u} \rightarrow 6e_g$ (HOMO $\rightarrow$ LUMO) transition, while the $3E_u$ and $4E_u$ states are predicted at 5.36 and 5.74 eV with an oscillator strength (f) of 2.40 and 0.85, and therefore are assigned as the B_1 and B_2 transitions, respectively. In addition to these three excited states, another excited state having E_u symmetry ($2E_u$) with $f =$ 0.0054 is also predicted between the Q and B_1 transitions, which consists of 52% of $3b_{2u} \rightarrow 6e_g$ (HOMO–2 $\rightarrow$ LUMO) and 21% of $4a_{2u} \rightarrow 6e_g$ (HOMO–7 $\rightarrow$ LUMO) configurations.

MgPc films are known to have several polymorphic phases, which arise from different molecular stacking arrangements. The α-phase obtained by vacuum deposition has an optical absorption maximum at around 695 nm, while the x_1-phase prepared by thermal or solvent treatment of the α-phase has a stronger absorption peak at 830 nm (Figure 21).[86,87] Mizuguchi and coworkers has succeeded in growing two kinds of six-coordinate MgPc crystal, namely $MgPc/(H_2O)_2$(*N*-methyl-2-pyrrolidone)$_2$ and MgPc/(2-methoxyethanol)$_2$, and clarified that the former crystals exhibit a near-IR absorption around 830 nm.[88] By using the X-ray data for these crystals, the origin of the near-IR absorption is discussed in terms of exciton coupling.

CaPc was obtained by either the reaction of calcium oxide or ethoxide with phthalonitrile, or double decomposition between Li_2Pc and $CaCl_2$, and was reported to have a dull green color.[56,74] However, the absorption properties of CaPc have not been reported to date. Although BaPc is formed similarly by using baryta and phthalonitrile, no absorption data is available.[74]

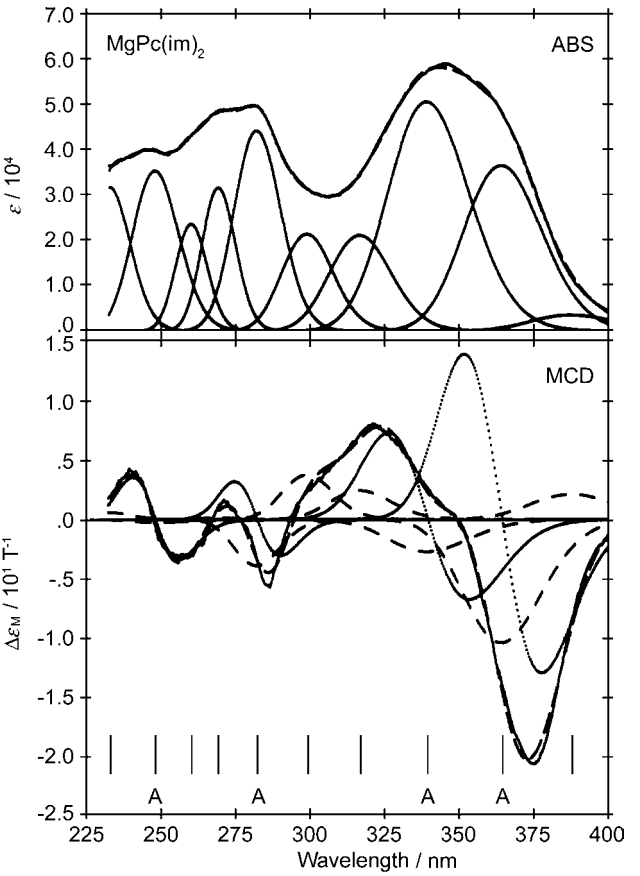

Figure 20. Results of band analysis for $MgPc(im)_2$ in CH_2Cl_2 for the UV region. The fitted data are shown by the dashed lines, and the experimental data by the solid line. Each Gaussian component is also shown, as well as the corresponding MCD signals. The vertical lines labeled 'A' correspond to the band centers of Faraday A terms. Redrawn with permission from Ough, E.; Nyokong, T.; Creber, K. A. M.; Stillman, M. J. *Inorg. Chem.* **1988**, *27*, 2724–2732. Copyright 1988 American Chemical Society.

D. Group 3: ScPc, $ScPc_2$, YPc_2 and Y_2Pc_3

Lapkina *et al.* prepared monomeric tetra(15-crown-5)phthalocyaninato(acetate) scandium, and reported that the absorption spectrum of this complex in $CHCl_3$ shows a Q band at 697 nm accompanied by a shoulder at *ca.* 680 nm.[89] The addition of 3 vol.% MeOH to the $CHCl_3$ solution results in a hypsochromic shift of the Q-band maximum to 681 nm. The absorption spectral shapes of the corresponding sandwich dimers, namely neutral $[Sc(R_4Pc)_2]^0$ and its reduced form $[Sc(R_4Pc)_2]^-$, are typical of those seen for lanthanide double-decker Pcs, and practically identical with those of unsubstituted $[ScPc_2]^0$ and $[ScPc_2]^-$,

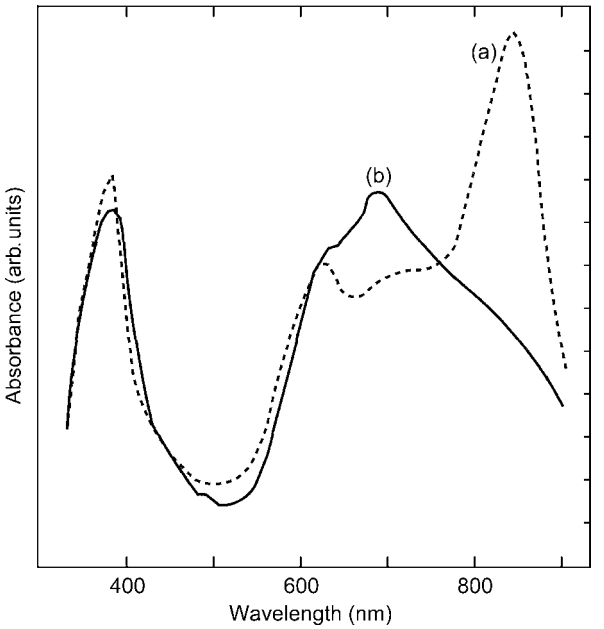

Figure 21. Absorption spectra of a MgPc film: curve (a), as-prepared; curve (b), after heat-treatment at 250 °C for 1 hour under vacuum. Redrawn from Kubota, H. G.; Muto, J.; Itoh, K. M. *J. Mater. Sci. Lett.* **1996**, *15*, 1475–1477 with kind permission from Springer Science and Business Media.

respectively.[90] Figure 22 shows the spectral changes observed in the course of the reduction of $[Sc(R_4Pc)_2]^0$ with hydrazine monohydrate in $CHCl_3$ to yield $[Sc(R_4Pc)_2]^-$.[89] The neutral form shows bands at 661, 466, and 365 nm in addition to bands at 919 and 1210 nm (not shown), which are characteristic of radical sandwich lanthanide diphthalocyanines. The most intense band at 661 nm is an analog of the prominent π–π^* transition (Q band). The band at 1210 nm has been assigned to an intervalence charge transfer transition. It is known that this band position depends largely on the metal ions. Upon addition of hydrazine monohydrate to give the anionic form, these bands lose their intensity, and instead, new bands at 724 and 619 nm appear. The intervalence transition that is prominent for the neutral species is absent for the reduced form. The crystal structure of a ($^nBu_4N$) complex of $[ScPc_2]^-$ with an orthorhombic unit cell indicates that the scandium ion is eight-coordinated by the eight isoindole nitrogen atoms in square antiprismatic coordination polyhedra. The rotational conformation of the two Pc moieties is staggered, and each Pc ring has a saddle-type deformation.[90]

Although the number of examples is limited, double- and triple-decker type yttrium Pcs, namely PcYPc (or YPc_2) and PcYPcYPc (or Y_2Pc_3), have also been

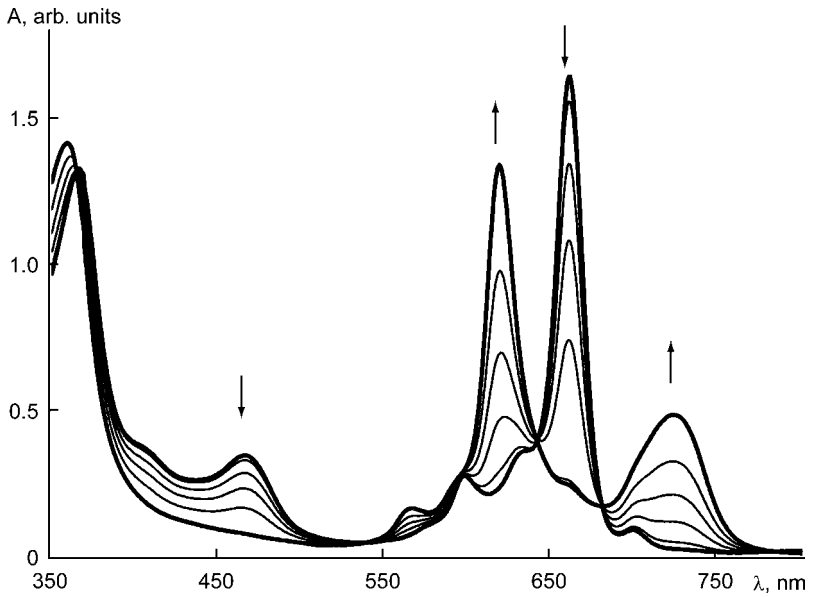

Figure 22. Spectrophotometric titration of a solution of $[Sc(R_4Pc)_2]^0$ in $CHCl_3$ with N_2H_4–H_2O to $[Sc(R_4Pc)_2]^-$. Redrawn from Lapkina, L. A.; Sakharov, S. G.; Konstantinov, N. Y.; Larchenko, V. E.; Gorbunova, Y. G.; Tsivadze, A. Y. *Russ. J. Inorg. Chem.* **2007**, *52*, 1758–1768 with kind permission from Springer Science and Business Media.

reported. In general, the closer the ring-to-ring separation, the stronger the π–π interactions are expected to be. The smaller ionic radius of yttrium compared to most of the lanthanide ions results in sandwich-type Pc dimer and trimer complexes containing yttrium ion(s) exhibiting profound effects of the π–π interactions on their absorption properties. Figure 23 depicts the absorption of $[Y(Pc)_2]^-$ (reduced form, top) and $[Y(Pc)_2]^0$ (neutral form, bottom) in CH_2Cl_2.[91] The latter shows bands at 663 (15 080 cm^{-1}), 598 (16 710 cm^{-1}), and 458 nm (21 810 cm^{-1}) in the visible region, and 1538 (6500 cm^{-1}), 1395 (7110 cm^{-1}), and 916 nm (10 950 cm^{-1}) in the near-IR region in $CHCl_3$.[92] The near-IR bands are blue-shifted compared to the corresponding lanthanide complexes such as $[Eu(Pc)_2]^0$ and $[Gd(Pc)_2]^0$, indicating a larger π–π interaction between the two Pc rings due to the smaller ionic radius of yttrium.[92] The reduced form has bands at 14 470 (691 nm) and 16 050 cm^{-1} (623 nm), of which the former is slightly blue-shifted compared to the corresponding scandium complex (724 nm), while the latter band appears at an approximately identical position (619 nm). The crystal structure of the ($^nBu_4N$) complex of $[YPc_2]^-$ is isostructural with that of $[ScPc_2]^-$.[90] The triple-decker, Pc_3Y_2, is synthesized from *o*-phthalonitrile and yttrium(III) acetate hexahydrate.[93] Figure 24 shows the spectral changes observed during the preparation of Pc_3Y_2. An absorption band which can be assigned as a monophthalocyanine

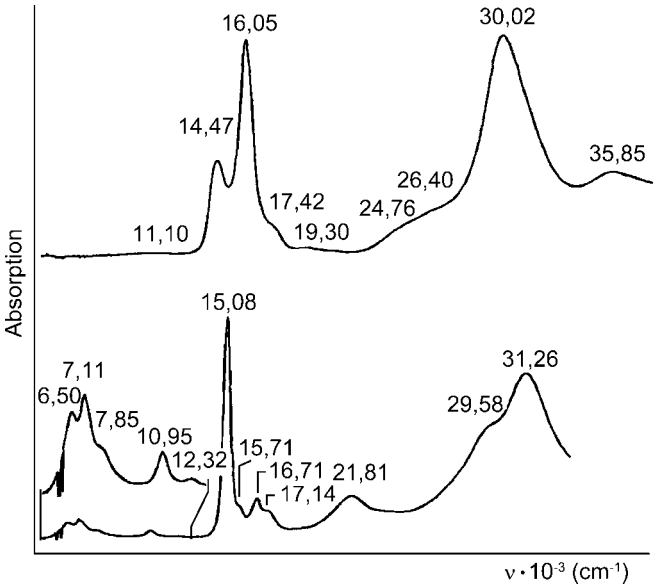

Figure 23. Absorption spectra of $[Y(Pc)_2]^-$ (top) and $[Y(Pc)_2]^0$ (bottom) in CH_2Cl_2. Redrawn from Ostendorp, G.; Homborg, H. *Z. Anorg. Allg. Chem.* **1996**, *622*, 1358–1364.

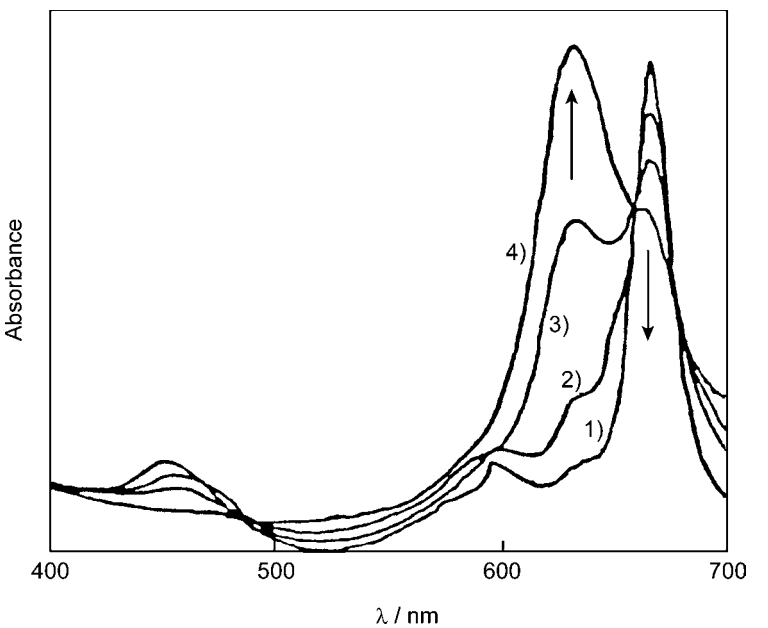

Figure 24. Spectral changes observed during the reaction of *o*-phthalonitrile and $Y^{III}(OAc)_3$ monohydrate at *ca.* 230 °C. Kasuga, K.; Ando, M.; Morimoto, H.; Isa, M. *Chem. Lett.* **1986**, 1095–1098. Redrawn by permission of The Chemical Society of Japan.

complex first appears at 665 nm (1), subsequently followed by the appearance of a band characteristic of the radical double-decker Pc_2 at 460 nm (2). After continuing the heating for several hours, the band at 665 nm shifts to 633 nm, which is assigned to Pc_3Y_2 (3 and 4).[93] The spectrum of Pc_3Y_2 is similar to that of $[YPc_2]^-$, with the Q band appearing at 633 nm and an accompanying weak band on the longer wavelength side (705 nm). Kasuga *et al.* observed that the Q-band position shifts to shorter wavelength with decreasing ionic radius for a series of Pc_3M_3 complexes, where M is Nd, Gd, Er, Y, and Lu.[93] On the other hand, the longer-wavelength band shifts to longer wavelength with decreasing ionic radius, being different from that observed for $[MPc_2]^-$ type complexes. The spectral properties of sandwich-type Pc dimers and trimers are interpreted in more detail in the subsequent section.

E. Complexes of the Lanthanide Elements

Although some monomer Pcs containing a lanthanide(III) ion (Ln^{III}) as the central metal have been synthesized and their absorption properties reported, these are more or less similar to the corresponding Pcs containing other central metals. However, as described briefly in the previous section, the absorption properties of double- and triple-decker Pc dimers and trimers are quite different from those of the original Pc monomers. Therefore, sandwich-type Pc dimers and trimers dominate the chemistry of Ln^{III}Pcs. In this section, the origin of the absorption bands of these sandwich-type complexes is interpreted on the basis of a series of studies by Ishikawa *et al.*[94] Double-decker Pc dimers are generally able to have three different oxidation states: a reduced form ($[Ln^{III}(Pc)_2]^-$), a neutral form ($[Ln^{III}(Pc)_2]^0$), and an oxidized form $[Ln^{III}(Pc)_2]^+$. Figure 25 shows absorption (top) and MCD (bottom) spectra of $[Lu^{III}(Pc)_2]^-$ (reduced form) in CH_2Cl_2/MeOH (4:1 v/v).[95] In this case, the formal charge of both Pc rings is 2–. Clear splitting of the Q-band is observed, of which the lower energy component has a smaller relative intensity. The maximum in the B band region shifts to higher energy compared to the typical Pc monomer, and shoulder-like weak bands appear in between the Q and B regions. The Q and B components both show an *A* term in the MCD spectrum, indicating that all of the excited states remain doubly degenerate. The simplest interpretations of what occurs on the interaction of two chromophores are based on the exciton-coupling theory, which predicts a hypsochromic shift of the Q band for a face-to-face dimer conformation.[96] However, the exciton model fails to explain the appearance of the lower energy Q-component. Ishikawa *et al.* took the electronic configuration of charge transfer (CT) between the Pc rings into consideration, and successfully interpreted the observed spectra theoretically.

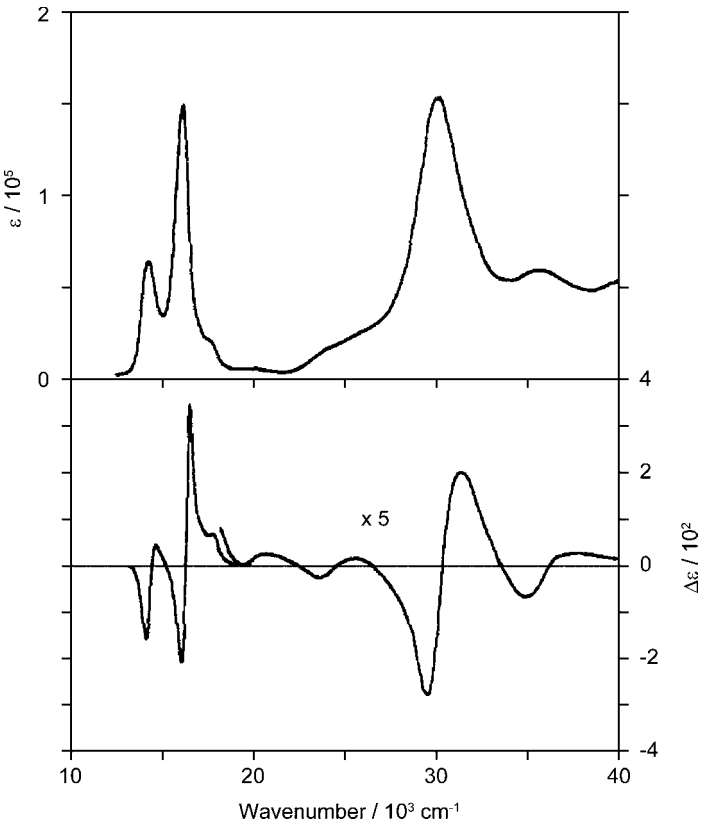

Figure 25. Absorption (top) and MCD (bottom) spectra of $[Lu(Pc)_2]^-$. Redrawn with permission from Ishikawa, N.; Ohno, O.; Kaizu, Y.; Kobayashi, H. *J. Phys. Chem.* **1992**, *96*, 8832–8839. Copyright 1992 American Chemical Society.

Let $|G\rangle = |\cdots a\bar{a}\cdots b\bar{b}|$ be the wavefunction for the ground state in accordance with Ishikawa's notation, and define the two constituting Pc rings as A and B. Local excitation (LE) within a Pc ring can be expressed as:

$$|\mathrm{LE^A}\rangle = |^1(j \leftarrow a)_\mathrm{A}\rangle = \frac{\{|\cdots j\bar{a}\cdots b\bar{b}| - |\cdots \bar{j}a\cdots b\bar{b}|\}}{\sqrt{2}}, \tag{10}$$

$$|\mathrm{LE^B}\rangle = |^1(k \leftarrow b)_\mathrm{B}\rangle = \frac{\{|\cdots a\bar{a}\cdots k\bar{b}| - |\cdots a\bar{a}\cdots \bar{k}b|\}}{\sqrt{2}}, \tag{11}$$

where the HOMOs and LUMOs of Pc(A) and Pc(B) are denoted as *a* and *b*, and *j* and *k*, respectively. These excitations take place only within each Pc ring, and no inter-Pc-ring excitation (charge transfer) is considered. The interaction

of these two configurations generates two new excited states (EC, exciton states):

$$\left|\mathrm{EC}^{+}\right\rangle = \frac{\left\{\left|\mathrm{LE}^{\mathrm{A}}\right\rangle + \left|\mathrm{LE}^{\mathrm{B}}\right\rangle\right\}}{\sqrt{2}}, \tag{12}$$

$$\left|\mathrm{EC}^{-}\right\rangle = \frac{\left\{\left|\mathrm{LE}^{\mathrm{A}}\right\rangle - \left|\mathrm{LE}^{\mathrm{B}}\right\rangle\right\}}{\sqrt{2}}, \tag{13}$$

of these, the former is allowed, while the latter is forbidden. As a consequence, a blue shift of the Q band is expected on the basis of the exciton model. Next, the charge transfer configuration (a one-electron excitation from one Pc ring to another) can be written as:

$$\left|\mathrm{CT}^{\mathrm{B}\leftarrow\mathrm{A}}\right\rangle = \left|{}^{1}(k \leftarrow a)_{\mathrm{B}\leftarrow\mathrm{A}}\right\rangle = \frac{\left\{\left|\cdots k\bar{a}\cdots b\bar{b}\right| - \left|\cdots \bar{k}a\cdots b\bar{b}\right|\right\}}{\sqrt{2}}, \tag{14}$$

$$\left|\mathrm{CT}^{\mathrm{A}\leftarrow\mathrm{B}}\right\rangle = \left|{}^{1}(j \leftarrow b)_{\mathrm{A}\leftarrow\mathrm{B}}\right\rangle = \frac{\left\{\left|\cdots a\bar{a}\cdots j\bar{b}\right| - \left|\cdots a\bar{a}\cdots \bar{j}b\right|\right\}}{\sqrt{2}}. \tag{15}$$

The interaction of these also yields two new excited states (CR, charge resonance states):

$$\left|\mathrm{CR}^{+}\right\rangle = \frac{\left\{\left|\mathrm{CT}^{\mathrm{B}\leftarrow\mathrm{A}}\right\rangle + \left|\mathrm{CT}^{\mathrm{A}\leftarrow\mathrm{B}}\right\rangle\right\}}{\sqrt{2}}, \tag{16}$$

$$\left|\mathrm{CR}^{-}\right\rangle = \frac{\left\{\left|\mathrm{CT}^{\mathrm{B}\leftarrow\mathrm{A}}\right\rangle - \left|\mathrm{CT}^{\mathrm{A}\leftarrow\mathrm{B}}\right\rangle\right\}}{\sqrt{2}}, \tag{17}$$

where both of these states are forbidden unless the orbitals of Pc(A) and Pc(B) overlap. However, the allowed $\left|\mathrm{EC}^{+}\right\rangle$ state possibly mixes with the $\left|\mathrm{CR}^{+}\right\rangle$ state, since these two configurations have identical irreducible representation along with a nonzero interaction between them. As a consequence of these discussions, the higher-energy bands in both Q and B band regions can be assigned to $\left|\mathrm{EC}^{+}\right\rangle$ states, and the lower-energy bands to $\left|\mathrm{CR}^{+}\right\rangle$ states. Quantum chemical calculations performed by Ishikawa *et al.* indicate that the lowest allowed excited state is $1\mathrm{E}_1$, in which the most dominant component is a charge resonance configuration, written as:

$$\left|6\mathrm{e}_{\mathrm{g}} \leftarrow 2\mathrm{a}_{1\mathrm{u}}\mathrm{CT}^{+}\right\rangle = \frac{\left\{\left|6\mathrm{e}_{\mathrm{g}}^{\mathrm{B}} \leftarrow 2\mathrm{a}_{1\mathrm{u}}^{\mathrm{A}}\right\rangle - \left|6\mathrm{e}_{\mathrm{g}}^{\mathrm{A}} \leftarrow 2\mathrm{a}_{1\mathrm{u}}^{\mathrm{B}}\right\rangle\right\}}{\sqrt{2}}. \tag{18}$$

The second allowed excited state is $2E_1$, in which the most dominant component is an exciton type configuration, written as:

$$\left|6e_g \leftarrow 2a_{1u}EC^+\right\rangle = \frac{\left\{\left|6e_g^A \leftarrow 2a_{1u}^A\right\rangle + \left|6e_g^B \leftarrow 2a_{1u}^B\right\rangle\right\}}{\sqrt{2}}. \tag{19}$$

Therefore, the two observed Q bands (14 000 and 16 000 cm^{-1}) can be safely assigned to $1E_1$ and $2E_1$, respectively. See the original papers for the corresponding MO-based interpretations.[94,95] It is known that the splitting of the Q band becomes smaller with increasing ionic radius of the Ln^{III} ion, in other words, with increasing ring-to-ring distance. Calculations conducted by varying the interplanar distances show that the energy of the CR configuration shifts rapidly to higher energy with increasing interplanar distance. The observed spectral shifts are consistently in agreement with the calculated results. For example, the relatively large splitting of the Q band observed for $[Y^{III}(Pc)_2]^-$ is consistent with the small ionic radius of Y^{III}.

The absorption characteristics of triple-decker Pc trimers can be interpreted in a similar manner, since the formal charge of all the Pc rings is 2–. Figure 26 shows absorption (top) and MCD (bottom) spectra of [PcLu(Crown-substituted Pc)LuPc] in $CHCl_3$.[97] Two distinct bands (Q bands) are observed at 15 800 and 14 000 cm^{-1} similarly to $[Lu^{III}(Pc)_2]^-$, although the relative intensity of the lower energy band is considerably weaker than the other band, compared to the dimer species. Dispersion-type MCD A terms appear, corresponding to both of these bands, indicating that the bands are associated with doubly degenerate states. Two shoulders (10 500 and 12 000 cm^{-1}) are detected on the lower energy side of these bands, although the intensities are very weak. In the near-IR region, a broad band is observed at 7400 cm^{-1}. Therefore, at least five bands exist on the lower energy side of the Q band. In the B-band region, a broad band at 30 300 cm^{-1} along with a shoulder at 27 000 cm^{-1} are reported. Similarly to the dimer case, three locally excited configurations are written as:

$$\left|LE^A\right\rangle = \left|{}^1(j \leftarrow a)_A\right\rangle, \quad \left|LE^B\right\rangle = \left|{}^1(k \leftarrow b)_B\right\rangle, \quad \left|LE^C\right\rangle = \left|{}^1(l \leftarrow c)_C\right\rangle.$$

By neglecting the interaction between Pc(A) and Pc(C), three diagonalized EC states are obtained as follows:

$$\left|EC^{+-+}\right\rangle = \frac{1}{\sqrt{2}}\left|LE^A\right\rangle - \frac{1}{\sqrt{2}}\left|LE^B\right\rangle + \frac{1}{\sqrt{2}}\left|LE^C\right\rangle, \tag{20}$$

$$\left|EC^{+-}\right\rangle = \frac{1}{\sqrt{2}}\left|LE^A\right\rangle - \frac{1}{\sqrt{2}}\left|LE^C\right\rangle, \tag{21}$$

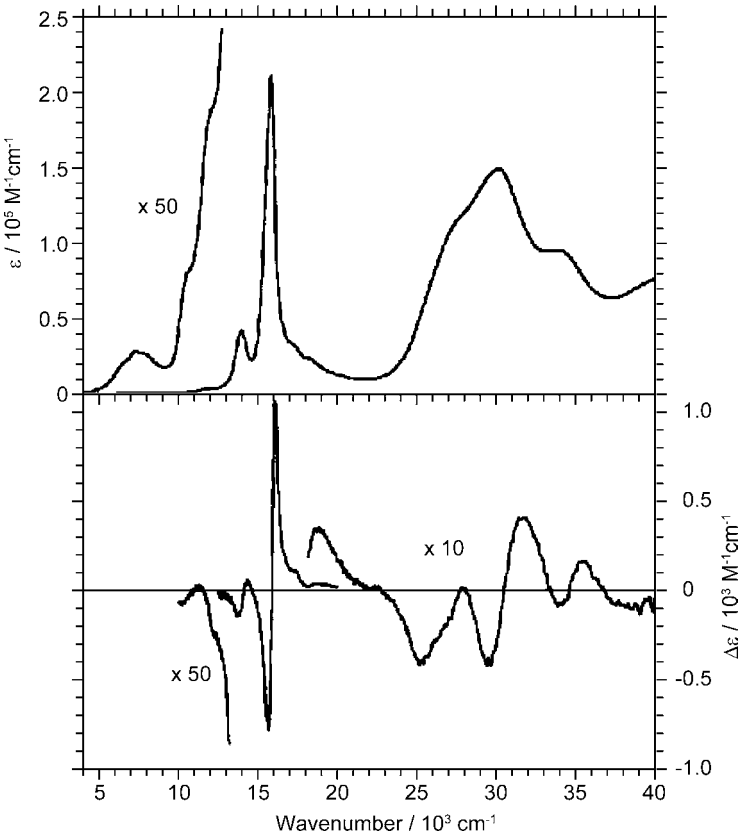

Figure 26. Absorption (top) and MCD (bottom) spectra of [PcLu(Crown-Pc)LuPc] in $CHCl_3$. Redrawn from Ishikawa, N.; Kaizu, Y. *Chem. Phys. Lett.* **1994**, *228*, 625–632. Copyright 1994, with permission from Elsevier.

$$\left|\mathrm{EC}^{+++}\right\rangle = \frac{1}{2}\left|\mathrm{LE}^{\mathrm{A}}\right\rangle + \frac{1}{\sqrt{2}}\left|\mathrm{LE}^{\mathrm{B}}\right\rangle + \frac{1}{2}\left|\mathrm{LE}^{\mathrm{C}}\right\rangle. \tag{22}$$

Under D_{4h} symmetry, only $|EC^{+-+}\rangle$ and $|EC^{+++}\rangle$ are allowed, and a much smaller transition dipole moment is expected for the former configuration (*ca.* 1/34). There are six possible charge transfers, and the possible allowed resonance states obtained therefrom are:

$$\left|\mathrm{CR}^{\mathrm{A}\rightarrow\mathrm{B}\leftarrow\mathrm{C}}\right\rangle = \frac{\left\{\left|\mathrm{CT}^{\mathrm{B}\leftarrow\mathrm{A}}\right\rangle + \left|\mathrm{CT}^{\mathrm{B}\leftarrow\mathrm{C}}\right\rangle\right\}}{\sqrt{2}}, \tag{23}$$

$$\left|\mathrm{CR}^{\mathrm{A}\leftrightarrow\mathrm{C}}\right\rangle = \frac{\left\{\left|\mathrm{CT}^{\mathrm{C}\leftarrow\mathrm{A}}\right\rangle + \left|\mathrm{CT}^{\mathrm{A}\leftarrow\mathrm{C}}\right\rangle\right\}}{\sqrt{2}}, \tag{24}$$

$$|\mathrm{CR}^{\mathrm{A}\leftarrow\mathrm{B}\rightarrow\mathrm{C}}\rangle = \frac{\{|\mathrm{CT}^{\mathrm{A}\leftarrow\mathrm{B}}\rangle + |\mathrm{CT}^{\mathrm{C}\leftarrow\mathrm{B}}\rangle\}}{\sqrt{2}}, \tag{25}$$

These CR configurations belong to the same irreducible representation as $|\mathrm{EC}^{+-+}\rangle$ and $|\mathrm{EC}^{+++}\rangle$, meaning that they can borrow transition intensity from the exciton coupling states. As a consequence, two EC type and three CR type bands are expected in the Q-band region of triple-decker Pc complexes. The most intense band at 15 800 cm^{-1} is safely assigned to the $|\mathrm{EC}^{+++}\rangle$ state. Ishikawa *et al.* pointed out that the second intense band at 14 000 cm^{-1} is not the $|\mathrm{EC}^{+-+}\rangle$ state, but can be assigned to one of the allowed charge resonance states, since the splitting energy between these two bands (1800 cm^{-1}) is much smaller than that expected for EC type splitting (*ca.* 6000–9000 cm^{-1}).[97] Therefore, the three weak bands in the 7000–12 000 cm^{-1} region are assigned to the $|\mathrm{EC}^{+--}\rangle$ state and two of the three allowed CR states. This description of the electronic states of the triple-decker Pc trimer are fully supported also by the results of quantum chemical CI calculations.

The absorption properties of neutral double-decker Pc complexes ($[\mathrm{Ln}^{\mathrm{III}}(\mathrm{Pc})_2]^0$) and the oxidized form ($[\mathrm{Ln}^{\mathrm{III}}(\mathrm{Pc})_2]^+$) are quite different from the reduced form shown above. Figure 27 compares the absorption of $[\mathrm{Lu}(\mathrm{Pc})_2]^0$ (broken line) and $[\mathrm{Lu}(\mathrm{Pc})_2]^+$ (solid line). The neutral form (broken line) shows absorption bands at 7000, 11 000, 15 200, and 22 000 cm^{-1} along with broad bands at around 30 000 cm^{-1}. Although this spectral shape resembles a superposition of the typical metalloPc monomer ($\mathrm{M}^{\mathrm{II}}\mathrm{Pc}^{2-}$, 15 200 and 30 000 cm^{-1}) and its π-radical cation ($\mathrm{M}^{\mathrm{II}}\mathrm{Pc}^{\bullet-}$, 11 000 and

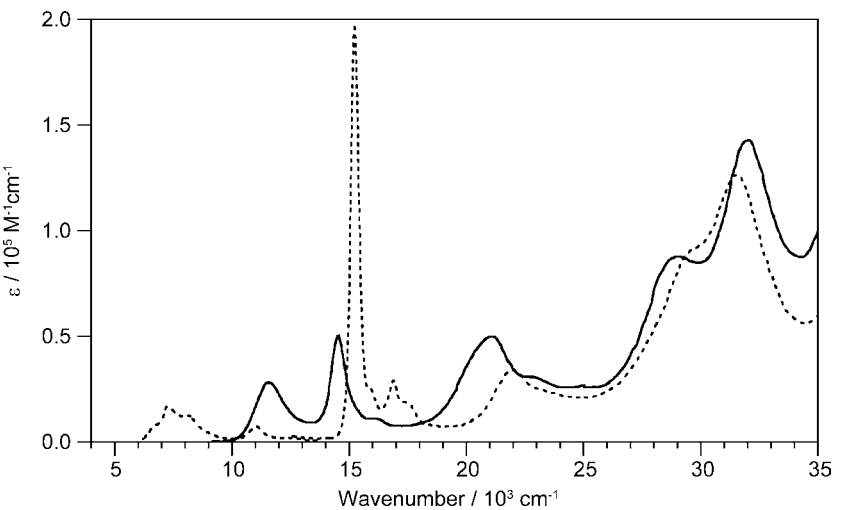

Figure 27. Absorption spectra of $[\mathrm{Lu}(\mathrm{Pc})_2]^0$ (broken line) and $[\mathrm{Lu}(\mathrm{Pc})_2]^+$ (solid line) in CH_2Cl_2. Redrawn from Ishikawa, N.; Kaizu, Y. *J. Porphyrin Phthalocyanines* **1999**, *3*, 514–521.

22 000 cm^{-1}), the band at 7000 cm^{-1} is unassignable to these. This feature, together with the results of NMR, ENDOR, and resonance Raman spectroscopy, suggests that the hole is delocalized over the two Pc rings for the neutral form.[98,99] A comparative study of the spectra of $[Lu(Pc)_2]^0$, $[LuPcNc]^0$, and $[Lu(Nc)_2]^0$ demonstrated that the spectral shapes of the hetero-dimer, $[LuPcNc]^0$, are neither identical to Pc nor Nc, i.e. the hole is not localized on one of the two Pc rings.[100] Upon oxidation of the neutral form, the Q band at 15 200 cm^{-1} shifts to lower energy by 700 cm^{-1} and decreases in intensity (Figure 27, solid line). The MCD signal corresponding to this band is a dispersion type A-term. The band at *ca.* 22 000 cm^{-1} shifts by 1000 cm^{-1} to 21 000 cm^{-1}. The NIR band at 7000 cm^{-1} disappears upon oxidation, and a new band accompanied by an MCD B-term appears at 11 500 cm^{-1}. Readers should refer to the original papers for further details and theoretical treatment of the spectral characteristics of the electron-deficient oxidized species.[94,101,102]

The electronic absorption spectra of $[Ln^{III}(Pc)_2]^-$, where Ln = Y, Pr, Nd, Sm–Lu, are compared in Figure 28. Each spectrum consists of a single Soret band

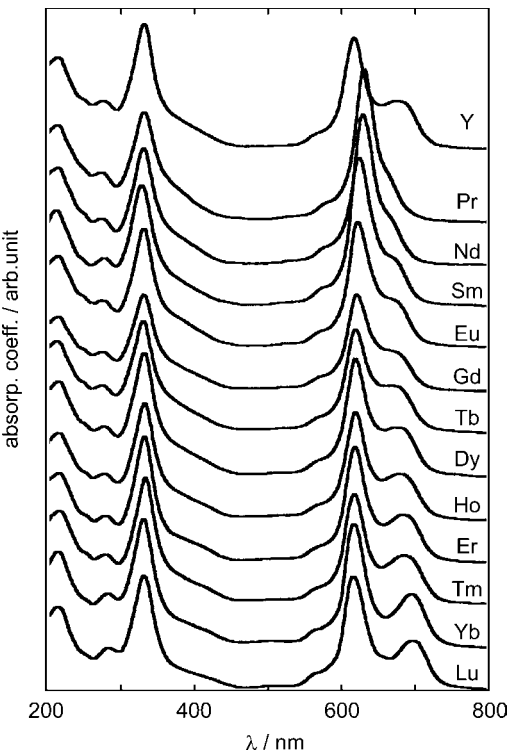

Figure 28. Electronic absorption spectra of a series of $[Ln^{III}(Pc)_2]^-$ complexes in $CHCl_3$. Redrawn from Kobayashi, N. *Coord. Chem. Rev.* **2002**, *227*, 129–152 with permission.

(*ca.* 300–350 nm) and one or two split Q bands. The extent of the Q-band splitting increases with decreasing ionic radius of the Ln^{III} ions, reflecting the extent of the π–π interaction between the two Pc rings. The splitting increases much more rapidly than anticipated from the variation of the radius, if exciton interactions only are taken into consideration. As described above, a rapid increase of electronic interactions via overlapping orbitals with decreasing Pc–Pc distance rationalizes the experimental results. The absorption spectra of $[Ln(Pc)_2]^0$ are different from those of neutral species, as shown in Figure 29. The spectra show intense bands at *ca.* 15 000 and 31 000 cm^{-1}, which shift to higher energy with decreasing Ln^{III}

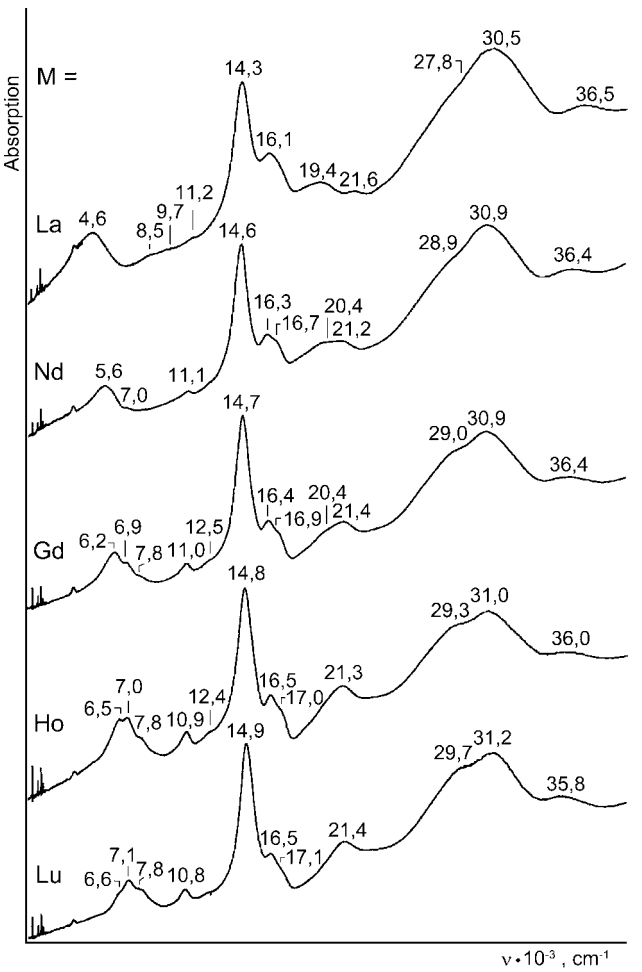

Figure 29. Electronic absorption spectra of $[Ln(Pc)_2]^0$ in KBr, where Ln = La, Nd, Gd, Ho, and Lu. Redrawn from Ostendorp, G.; Homborg, H. *Z. Anorg. Allg. Chem.* **1996**, *622*, 1222–1230.

radius. The bands have some similarity to those observed for monomer Pc^{2-}, while the bands at *ca.* 11 000 and 22 000 cm^{-1} are characteristic of a Pc^{-} π-radical, although it has been clarified that the hole is delocalized over two Pc rings as described above. The band at *ca.* 11 000 cm^{-1} shifts to lower energy with decreasing Ln^{III} radius. The NIR bands observed in the 4000–9000 cm^{-1} region show a distinct dependency on the metal size.[103] These bands are now assigned to an electronic transition from a bonding orbital constructed from the HOMO of each Pc ring to a half-occupied antibonding orbital.

A series of tetra-*tert*-butyl Nc Ln^{III} sandwich dimers has been reported.[104,105] Similar to the Pc series, both radical and reduced forms have been prepared. The main Q bands of the radical form (767–799 nm) and the π-radical anion band (593–648 nm) shift to the red with increasing metal size, while the B band region (328–334 nm) remains relatively unshifted (Figure 30).[106] A similar trend was also

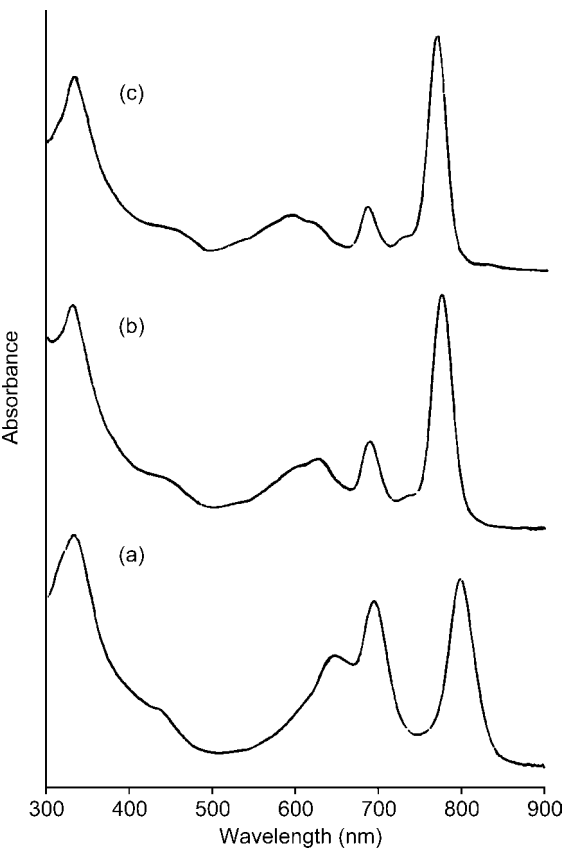

Figure 30. Absorption spectra of the radical form of (a) La[Nc(*tert*-Bu)$_4$]$_2$, (b) Eu[Nc(*tert*-Bu)$_4$]$_2$, and (c) Er[Nc(*tert*-Bu)$_4$]$_2$ in $CHCl_3$/EtOH = 1:1 (v/v). observed for the broad NIR band (1818–2346 nm, not shown). The band assignments appear to be the same as with the Pcs. In the reduced form, the Q band generally splits into two, to give an intense blue-shifted band (715–729 nm) and a weak band (782–821). Figure 31 depicts some examples of the reduced Nc dimer. The B-band region (328–333 nm) is virtually unshifted compared to the corresponding neutral form. The Q band of alkylthiosubstituted 2,3-Nc differs from that of tetra-*tert*-butyl 2,3-Nc in shape, but the spectral shape is similar in the other regions.[104]

F. Complexes of the Actinide Elements

A very limited number of actinide Pcs has been reported to date because of the radioactivity of the actinide elements. Guilard *et al.* reported the absorption

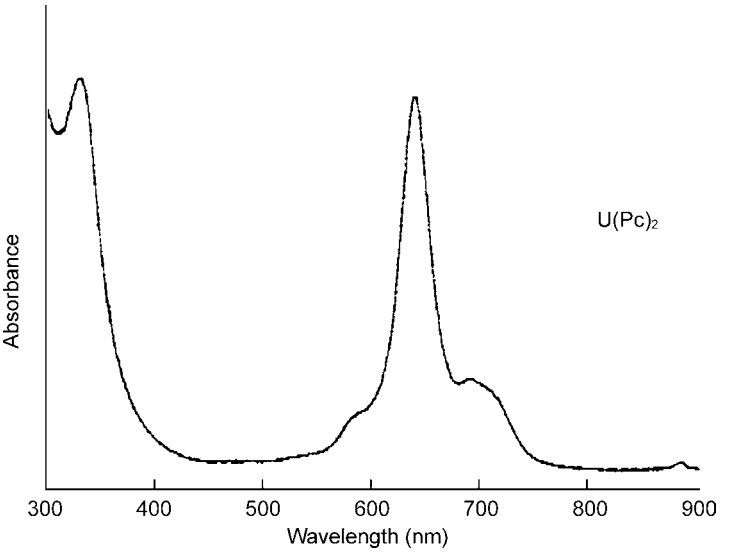

Figure 32. Absorption spectrum of UPc_2 in CH_2Cl_2. Redrawn with permission from Kadish, K. M.; Moninot, G.; Hu, Y.; Dubois, D.; Ibnlfassi, A.; Barbe, J. M.; Guilard, R. *J. Am. Chem. Soc.* **1993**, *115*, 8153–8166. Copyright 1993 American Chemical Society.

properties of $Th^{IV}Pc(acac)_2$ and $U^{IV}Pc(acac)_2$, where acac = acetyl acetonato.[107] The absorption spectra of these are similar to typical metalloPcs in shape, with the Q band appearing at 684 and 689 nm, respectively, in PhCN containing 0.2 M TBAP. Double-decker dimers have been reported for thorium,[108] protoactinium,[109,110] uranium,[108,111] neptunium,[112] and americium[113] complexes. PuPc appears in Ref. 108. No actinide-containing Nc sandwich has been reported. Figure 32 shows the absorption spectrum of $U(Pc)_2$ in CH_2Cl_2. The Soret band is located at 332 nm, which is blue shifted with respect to the corresponding band of $UPc(acac)_2$ (351 nm).[107] In the Q-band region, the intense band at 638 nm is accompanied by weaker bands positioned on both sides (593 and 700 nm).

The reaction of phthalonitrile with UO_2Cl_2 yields macrocyclic uranyl complexes, in which the UO_2 moiety is surrounded by five isoindole units linked by *meso*-nitrogen atoms, namely superphthalocyanine (superPc).[114–116] Only uranium is known to give this superPc structure up to the present date. The lowest-energy transition is red-shifted compared to typical metalloPcs. The unsubstituted superPc shows absorption bands at 912, 810 (shoulder), and 420 nm in toluene, while the pentamethyl-substituted congener has bands at 922, 810 (shoulder), and 420 nm (Figure 33).[114] Basic quantum chemical calculations within the framework of SCF-CI-PPP method indicate that superPc possesses a singly-degenerate HOMO and an essentially doubly-degenerate LUMO, similar to

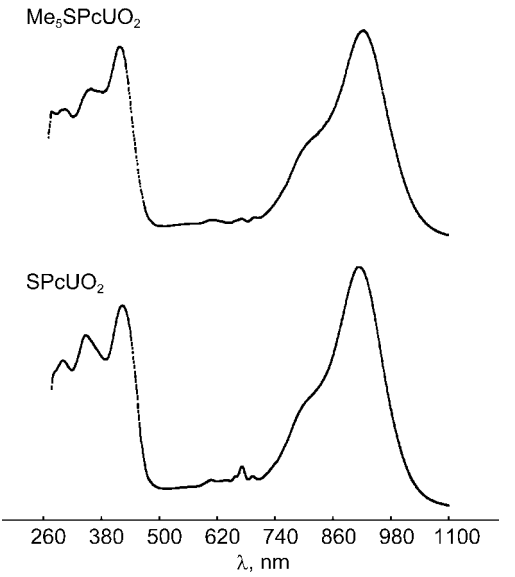

Figure 33. Absorption spectra of superPcs, with (top) and without (bottom) five methyl groups as peripheral substituents in benzene. Weak signals in the 620–740 nm region are due to trace amounts of metal-free Pcs. Redrawn with permission from Marks, T. J.; Stojakovic, D. R. *J. Am. Chem. Soc.* **1978**, *100*, 1695–1705. Copyright 1978 American Chemical Society.

metalloPcs.[115] Therefore, the bands located at 912 nm can be assigned to a π–π^* origin.

G. Group 4: TiPc, ZrPc, $ZrPc_2$ and HfPc

$Ti^{III}Pc$ and $Ti^{IV}Pc$ have been reported, of which only the latter has been the subject of an absorption study. Although TiPc described in Ref. 117 was handled as if it were a Ti^{II} complex, the description is ambiguous. Figure 34 shows the absorption spectra of TiOPc in 1-chloronaphthalene at various temperatures.[118] The spectra are typical in shape, with a Q band at *ca.* 699 nm, and show a slight hypsochromic shift accompanied with a reduction in intensity with increasing temperature. The Ti=O bond exhibits reactivity towards bidentate ligands such as catechol and its derivatives, to give axially-substituted TiPcs.[119] Barthel and Hanack investigated the effect of axial modification, and demonstrated that any effects are very limited.[120] $Ti(Pc)_2$ obtained by the reaction of $TiCl_2Pc$ and Na_2Pc has a unique structure.[121] The two Pc planes are 'stapled' by two carbon–carbon σ bonds, and accordingly, the Pc chromophore no longer exists in the resultant compounds (no absorption above 500 nm).

Cherian and Menon reported optical data of vacuum-deposited $TiCl_2Pc$ thin films (Figure 35).[122] The Q and B bands appear at 712 and 365 nm, respectively,

remaining unchanged by the annealing process. The solid-state absorption spectra of TiOPc differ significantly from those in solvent, and also depend on the crystal system. Despite the importance of solid-state Pcs, however, the analysis of solid-state spectra has been less than satisfactory until recently. Figure 36 (top right)

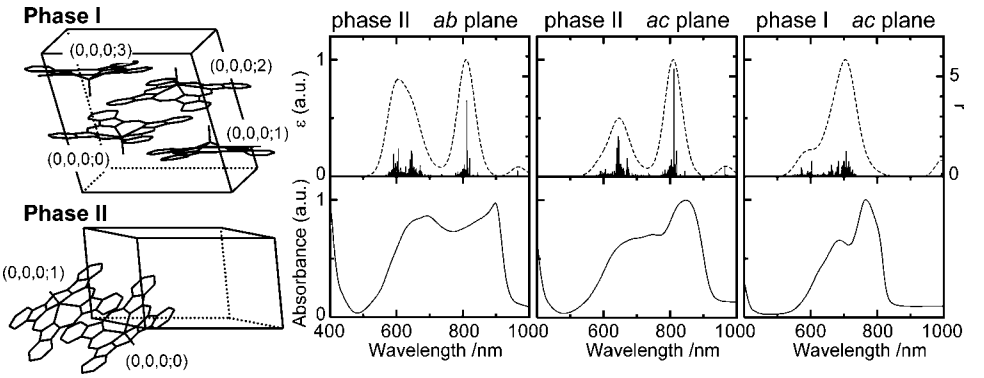

Figure 36. Calculated (broken line) and experimental (solid line) absorption spectra when the incident light direction is perpendicular to the crystallographic *ab* plane of phase II (top left), *ac* plane of phase II (top middle), and *ac* plane of phase I (top right) with molecular structures in the unit cell of phase I (top left) and phase II (bottom left). Solid bars in the calculated spectra denote the products of oscillator strengths and coefficients of CT configurations, ρ. Redrawn with permission from Nakai, K.; Ishii, K.; Kobayashi, N.; Yonehara, H.; Pac, C. *J. Phys. Chem. B* **2003**, *107*, 9749–9755. Copyright 2003 American Chemical Society.

depicts the calculated solid-state absorption spectra of TiOPc, in which exciton and charge-transfer (CT) interactions, and molecular distortions are taken into consideration.[123] The results reproduce fairly well the experimental results (bottom right), where the characteristics of phase dependence, dependence on the incident light direction, and the absorption profiles are rationalized. Readers should consult the original paper for the calculation details.[123] The calculations also clarified that the large red shift and high CT character originate from large exciton interactions and large intermolecular resonance integrals, respectively. In addition, it has been revealed that the photoconductive properties correlate well with the intermolecular resonance integrals. These considerations are important for investigating applications of the Pcs.

As a result of the large ionic radius and high valent nature of zirconium (Zr^{IV}), the metal center of ZrPc is located out of the Pc plane, and ZrPcs are able to have a variety of axial substituents. Figure 37 shows the absorption spectrum of ZrPc possessing two octanoato ($C_7H_{15}COO$) groups as axial substituents in DMSO.[124] The spectrum is similar in shape to a general metalloPc, with no additional bands being observed. The Q band at 688 nm is barely sensitive to the axial substituents, and the Q-band positions for the chloro adduct ($ZrCl_2Pc$) and β-diketonate adducts are observed at 688 and 682–692 nm, respectively.[124–126] Tomachynski *et al.* reported that the shape of the spectrum does not change dramatically in various solvents, with only a small shift of the Q-band position being observed. The lowest value of molar extinction coefficient is observed in DMSO, while the largest

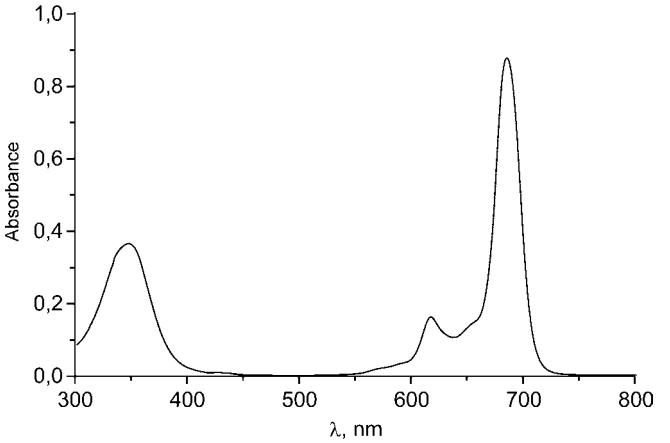

Figure 37. Absorption spectrum of ZrPc possessing two $C_7H_{15}COO$ groups as axial substituents in DMSO. Redrawn from Tretyakova, I. N.; Chernii, V. Y.; Tomachynski, L. A.; Volkov, S. V. *Dyes Pigments* **2007**, *75*, 67–72. Copyright 2007, with permission from Elsevier.

value is estimated in toluene. The double-decker form, $Zr(Pc)_2$, is also possible. Since the zirconium center is tetravalent, unlike the tervalent state of lanthanide ions, the neutral form can be described as Pc(2–)ZrPc(2–). Therefore, the absorption properties of neutral $Zr(Pc)_2$ resemble those of $Sn(Pc)_2$ rather than $[Ln(Pc)_2]^0$.[127] Figure 38 illustrates the absorption spectra of $Zr(Pc)_2$ (1), and its one-electron (2) and two-electron (3) electro-oxidized species.[128] The figure clearly demonstrates that the neutral, oxidized, and double-oxidized forms correspond to the reduced, neutral, and oxidized forms of the lanthanide congeners. Silver *et al.* also investigated the electrochromic behavior of $Zr(Pc)_2$.[127]

The spectroscopic behavior of HfPcs is very similar to ZrPc.[124–127] The Q-band position of $HfCl_2Pc$ is reported to be at 684 and 688 nm in DMSO and toluene, respectively.[124]

H. Group 5: VPc, NbPc and TaPc

Similar to TiOPc, vanadium(IV) (V^{IV}) is the stable oxidation state for VPc, and as a result, vanadyl (V=O) Pc complexes have been the most commonly studied. The crystal structure of VIPc is also available, although the absorption properties are absent.[129] The crystal structures of VOPc indicate that the molecule takes a dome-type deviated form, to give C_{4v} molecular symmetry.[130,131] Kobayashi *et al.* reported that Q bands of tetra-*tert*-butyl VOTAP, VOPc, and VONc were observed at 594.0, 698.0, and 809.6 nm, respectively, and that the dipole strength increases in this order.[43] Compared to the corresponding copper derivatives, the Q band of

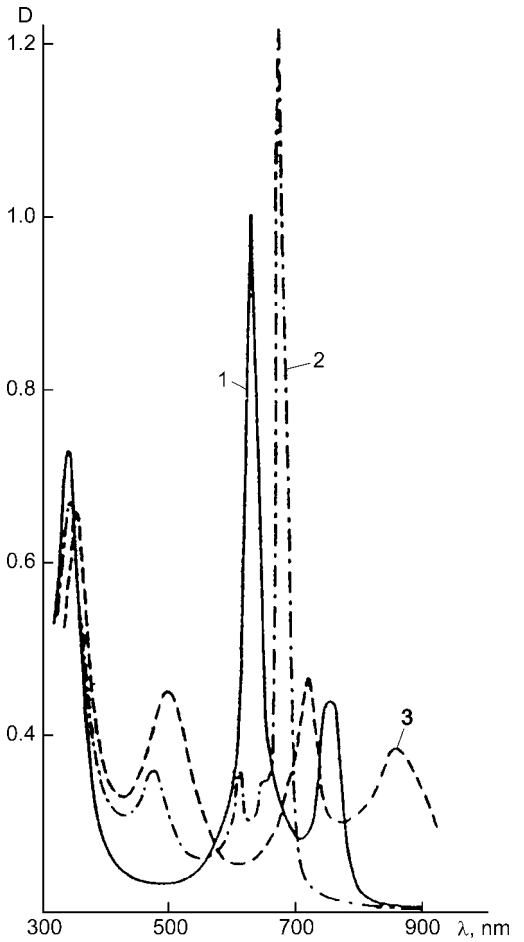

Figure 38. Absorption spectra of $[Zr(Pc)_2]$ (1), and its one-electron (2) and two-electron (3) electro-oxidized species in *o*-dichlorobenzene containing 0.2 M TBAP. Redrawn from Tomilova, L. G.; Ovchinnikova, N. A.; Lukyanets, E. A. *Zh. Obshch. Khim.* **1987**, *57*, 2100–2104.

the VO complexes lies at longer wavelength, with an intensity which is always lower. Huang and Sharp mentioned that any peculiarities of the electronic properties of VOPc compared with other Pcs are related to the axial ligand and the unpaired electron of the vanadyl ion.[132] Unsubstituted VOPc shows absorption peaks at 700.8 and 630 nm, with a shoulder at 670 nm in 1-chloronaphthalene, while a slight blue shift is observed in CH_2Cl_2.[132] Figure 39 shows the absorption data of $VOPcF_{16}$ in (a) acetone and (b) benzene.[133] The acetone solution of the complex exhibits a Q band at 640 nm, while the Q band appears at 709 nm in benzene. Polar solvents such as DMF, pyridine, and CH_2Cl_2 also give a Q-band

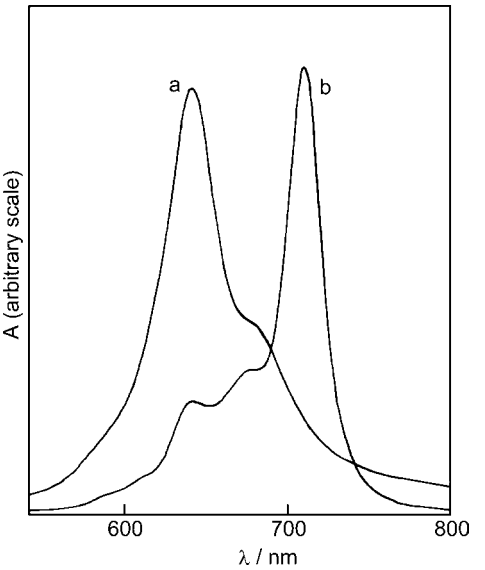

Figure 39. Absorption spectra of $VOPcF_{16}$ in acetone (a) and benzene (b). Redrawn from Handa, M.; Suzuki, A.; Shoji, S.; Kasuga, K.; Sogabe, K. *Inorg. Chim. Acta* **1995**, *230*, 41–44. Copyright 1995, with permission from Elsevier.

position of *ca.* 640 nm. On the other hand, the Q-band appears at 709 nm in non-polar solvents such as *o*-DCB. Tetra-*tert*-butyl VOPc does not exhibit such a strong solvent dependence. The band at 709 nm originates from the monomer species, while the band at *ca.* 640 nm can be ascribed to the dimer species. The ESR data also support these assignments.[133] The Q band of α-$(SC_5H_{11})_8$ substituted VOPc appears beyond 830 nm (830, 834, 841, and 850 nm in toluene, THF, $CHCl_3$, and CH_2Cl_2, respectively).[134]

In the case of niobium, $Nb^{IV}Pc$ and $Nb^{V}Pc$ are possible and, accordingly, $NbPcCl_2$ and $NbPcCl_3$ have been synthesized.[135] Various derivatives are obtained by elimination of the chlorides in $NbPcCl_2$ in the presence of nucleophiles, to yield Nb^{IV}(cat)Pc, Nb^{IV}(oxal)Pc, $Nb^{IV}(SO_4)$Pc, $Nb^{IV}Cl_2$IPc, and Nb^{V}(cat)IPc, where cat = catecolato and oxal = oxalato.[135] $NbCl_2Pc$ shows absorption bands at 690 (Q band), 625, 340, and 272 nm in CH_2Cl_2 (Figure 40, dotted line).[136] Niobium shows some similarities to titanium regarding Pc formation. The structure of $Nb(Pc)_2$ is isostructural, and the two Pc planes are "stapled" by two carbon–carbon σ bonds. The resultant compound exhibits no absorption above 500 nm (Figure 40).[136–139]

$Ta^{V}Cl_3Pc$ was synthesized by Gingl and Strähle,[140,141] and the absorption spectrum was reported recently.[142] Due to the large ionic radius of Ta^{V}, the three axial ligands take on *cis* conformations. The Q and B bands appear at 697 and 342 nm

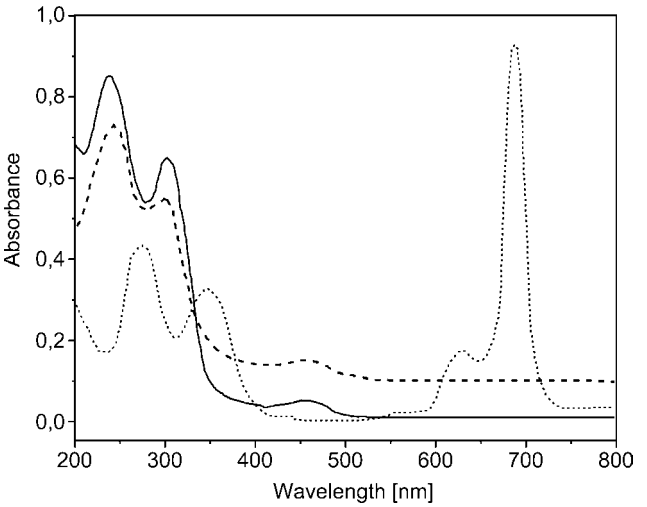

Figure 40. UV-vis spectra in CH_2Cl_2 solution of $[NbPc_2]IBr_2$ (solid line), $[NbPc_2]IBr_2 \cdot I_2$ (dashed line) and $NbPcCl_2$ (dotted line). Redrawn from Janczak, J.; Kubiak, R. *Polyhedron* **2003**, *22*, 313–322. Copyright 2003, with permission from Elsevier.

in $CHCl_3$, respectively (Figure 41). Although the crystal structures of $^{cis}[Ta^{V}F_4Pc]^-$ and $^{cis}[Ta^{IV}F_3Pc]^-$ have also been reported, their absorption data are not given.[143]

I. Group 6: CrPc, MoPc and WPc

The Cr^{II} and Cr^{III} Pc complexes have been isolated. The absorption spectra are typical in that the most intense band is in the visible region at 670–690 nm, with

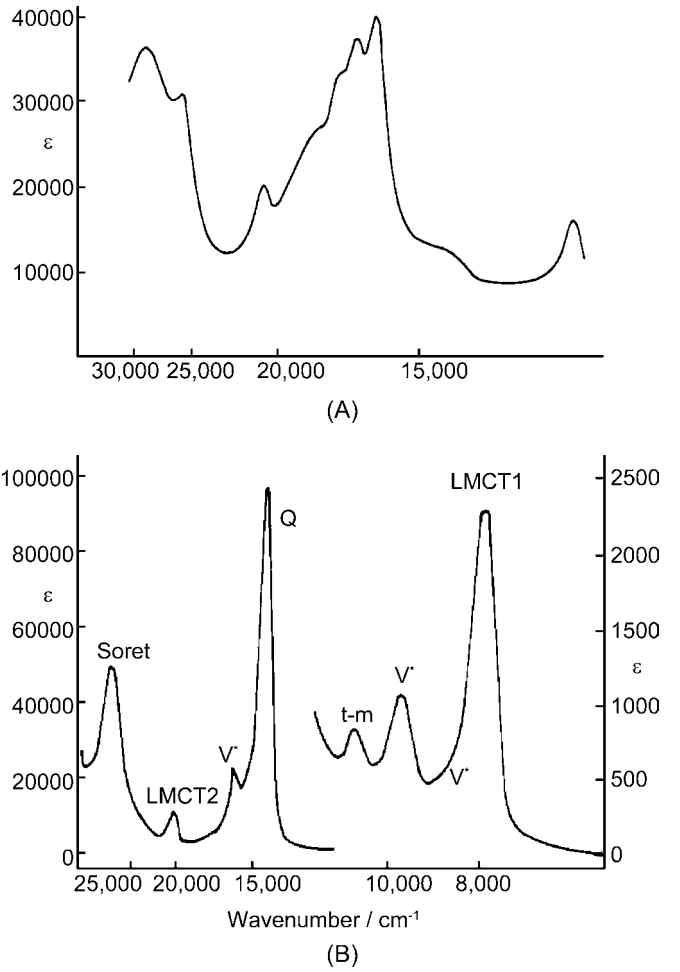

Figure 42. Electronic spectra of electrochemically-prepared tetrasulfonato $Cr^{II}Pc$ in DMF (A) and Na_3(tetrasulfonato)$Cr^{III}Pc$ (B). Redrawn with permission from Lever, A. B. P.; Pickens, S. R.; Minor, P. C.; Licoccia, S.; Ramaswamy, B. S.; Magnell, K. *J. Am. Chem. Soc.* **1981**, *103*, 6800–6806. Copyright 1981 American Chemical Society.

the second most intense band at 330–350 nm. For example, $Cr^{II}Pc(py)_2$ shows band peaks at 687, 632, 560, 525, 500, and 345 nm in pyridine, while $Cu^{III}PcOH$ exhibits peaks at 689, 621, 502, and 347 nm in methanol.[144] The spectra of tetrasulfonato $Cr^{II}Pc$ (A) and Na_3(tetrasulfonato)$Cr^{III}Pc$ (B) are shown in Figure 42.[145] Additional absorption bands are observed both in the near-IR region and at energies lying between the Soret and Q bands. The Cr^{III} species has a hole in the $e_g(d_\pi)$ orbital. The bands at 7900 and 20 080 cm^{-1}, designated as LMCT1 and LMCT2 in Figure 42B respectively, are assigned to $a_{1u}(\pi) \rightarrow e_g(d_\pi)$ and $a_{2u}(\pi) \rightarrow e_g(d_\pi)$

transitions, respectively, by careful analysis of the redox potentials of the compound. Since the a_{1u} orbital has a node at the chelating nitrogen atoms, the orbital overlap associated with the LMCT1 is small. As a consequence, LMCT1 is expected theoretically to be less intense than LMCT2, which is consistent with the experimental result. In the case of the Cr^{II} species, the LMCT1 transition (11 850 cm^{-1}) is remarkably intense compared with the Cr^{III} complex, while the Q band lies at a high energy (16 300 cm^{-1}) and is weak. Lever *et al.* mentioned that it seems probable there is extensive mixing between the Q and LMCT1 transitions in the Cr^{II} species, because they lie fairly close together, producing both the blue shift of the Q band and the unusual intensity distribution.[145] It is conceivable that the band at 19 650 cm^{-1} might be assigned to the $a_{2u}(\pi) \rightarrow a_{1g}(d_{z^2})$ transition (LMCT3). It is possible for the Cr^{III} complex to yield a μ-oxo dimer species, CrPc–O–CrPc, by the reaction of tetra-*tert*-butyl $CrCl_2HPc$ with 2 N NaOH in benzene.[146] The resulting compound shows absorption peaks at 629, 495, and 340 nm in toluene.

MoPc,[147] MoOPc,[148] MoO_2Pc,[149] and $MoClPc_2$[150] were reported in the early studies. The structure of MoOPc is similar to that of VOPc, and the molybdenum coordination is square pyramidal, where the molybdenum atom is located 69 pm above the plane generated from the four coordinating nitrogens.[151,152] The nature of the oxidation state of molybdenum in MoOPc had been the subject of discussion, and the oxidation state of molybdenum in MoOPc prepared from the reaction of phthalonitrile and molybdenum trichloride was shown to be +5 from ESR study,[153] while the reaction of ammonium molybdate and phthalonitrile was reported to give $Mo^{IV}OPc$.[152] The absorption spectrum of $Mo^{IV}OPc$ in 1,2,4-trichlorobenzene shows a prominent peak at 703 nm and a weaker peak at 643 nm, while VOPc exhibits the corresponding peaks at 700 and 630 nm.[152] Successive washing of MoOPc with 0.1 N NaOH, water, and acetone yields $Mo^{V}O(OH)Pc$.[154] Figure 43 shows the Q-band region absorption data of $Mo^{V}O(OH)Pc$ (c) and its electro-oxidized or reduced species (a and b, respectively). The initial state (Mo^{V}) exhibits a Q band at 700 nm. Upon oxidation/reduction, the Q band shifts to longer/shorter wavelength without any reduction in intensity, which are assigned to the Mo^{VI} and Mo^{IV} species, respectively.[154,155] Nitrido-MoPc complexes, namely MoNPcs, have also been also successfully synthesized.[156,157] The Q band of octa-β-alkyl-substituted MoNPc appears at 709–716 nm in toluene.[156] Gorsch and Homborg reported the absorption properties of a $(MoPc)_2$ dimer having a Mo–Mo direct bond (Figure 44).[158]

The number of reports on WPc is very limited.[156,157,159–161] Tungsten has an oxidation state of +5 in WCl_3Pc[159] and W(O)OH(PcCl).[161] The maximum of the Q band for W(O)OH(PcCl) is at 730 nm. The nitride complex, WNPc, shows a red shift of the Q-band maximum to 751.0 nm in 1-chloronaphthalene. In this case, the

Figure 43. Q band is broadened and shows two shoulders at 699.5 and 673.5 nm.[156] The substituted derivatives, WN(*tert*-Bu_4Pc) and WN((C_5H_{11})$_8$Pc), show broad Q bands at 745.0 and 770.5 nm in toluene, respectively.[156]

J. Group 7: MnPc, TcPc, RePc and $RePc_2$

The manganese ion in MnPc exists in several stable oxidation states, ranging from Mn^{I} to Mn^{IV} depending on the number and nature of the axial ligand, while the transition energies also depend on both the metal oxidation state and spin state. Figure 45 shows the absorption spectrum of $Mn^{II}Pc$ dissolved in pyridine.[162] $Mn^{II}Pc$ is considered to have fifth and sixth ligands in a coordinating solvent, and thus the spectrum shown in Figure 45 arises from the dipyridinated Pc species, $Mn^{II}Pc(py)_2$, which was confirmed also by X-ray crystallography.[163] In addition to the intense principal band at 660 nm, the spectrum is characterized by a less intense absorption in the 800–900 nm region. Furthermore, several bands in the 500–600 nm region are characteristic of MnPc, which do not appear for metalloPcs containing a main-group metal such as magnesium and zinc. Elvidge and Lever,[164] and Rutter and McQueen[165] reported that the main absorption band appears respectively at 712.5 and 620 nm. However, Engelsma *et al.* confirmed that these bands originate from oxidized species.[162] Of the possible ground states for a d_5 ion (Mn^{II}) in a D_{4h} crystal field, the $^4A_{2g}$ [166–170] and ^4E_g [171] states have been suggested for the ground state of $Mn^{II}Pc$. Williamson *et al.* measured the absorption and MCD spectra of $Mn^{II}Pc$ isolated in an Ar matrix, and concluded that the obtained data are consistent with a $^4E_g(e_g^3\, b_{2g}\, a_{1g})$ ground state term.[172] Figure 46 shows absorption (bottom) and MCD (top) spectra of Ar-matrix-isolated $Mn^{II}Pc$ obtained at *ca.* 5 K. Compared to the spectrum shown in Figure 45, the bands observed for the matrix-isolated

$Mn^{II}Pc$ are sharper, and some additional bands which are not seen in Figure 45 can be recognized. The strong MCD signals seen in Figure 46 indicate the presence of Faraday C terms based on ground-state degeneracy, which is confirmed by the saturation measurements. The MCD signals corresponding to the bands at *ca.* 11 600, 16 500, and 20 000 cm^{-1} are pairs of oppositely-signed C terms (bisignated C terms, solid arrows in Figure 46), while the dashed arrows at *ca.* 15 000, 22 500, and 28 200 cm^{-1} indicate that these are assigned as single-signed C terms. Given that the ground state is $^4A_{2g}(b_{2g}^2\ e_g^2\ a_{1g})$, the only *x*,*y*-polarized spin-allowed transitions are of the type $^4A_{2g} \rightarrow {}^4E_u$. The ^{4}Eu excited terms are split by first-order spin-orbit (SO) interactions into four Kramers doublets, each of which is split further by an externally applied magnetic field. See Figure 4 in Ref. 172, where an energy level diagram for the transitions $^4A_{2g}(b_{2g}^2\ e_g(d_\pi)^2\ a_{1g}) \rightarrow {}^4E_u(b_{2g}^2\ e_g\ a_{1g}\ b_{1u}(\pi^*))$ designated as MLCT2 by Lever *et al.* is shown as an example.[145] In this case, at very low temperature, bisignated MCD C terms with a sign which is negative at lower energy and positive at higher energy are expected. Similarly, bisignated C terms are expected for the other $^4A_{2g} \rightarrow {}^4E_u$ transitions including LMCT1 ($a_{1u}(\pi) \rightarrow e_g(d_\pi)$), although the MCD signal observed at 15 000 cm^{-1} is apparently single-singed and therefore inconsistent with this assumption. In the case of $^4E_g(e_g^3\ a_{1g}\ b_{2g})$ as the ground state, the MLCT2 excitation corresponds to $^4E_g \rightarrow {}^4A_{1u}$, $^4A_{2u}$, $^4B_{1u}$, and $^4B_{2u}$ (see Figure 5 in Ref. 172). At the low-temperature limit in this case, $^4E_g \rightarrow {}^4A_{1u}$ and $^4A_{2u}$ transitions are expected to be associated with

negative C terms, and $^4E_g \rightarrow {}^4B_{1u}$ and $^4B_{2u}$ transitions to be associated with positive C terms, while weak bisignated C terms are expected for $\pi \rightarrow \pi^*$ excitations due to small interactions between the π-skeleton and metal orbitals. Since these theoretical expectations are fully consistent with the experimental data, the ground state of $Mn^{II}Pc$ is determined to be ^4E_g ($e_g^3\ b_{2g}\ a_{1g}$). As a consequence, LMCT1 ($a_{1u}(\pi) \rightarrow e_g(d\pi)$) and LMCT2 ($a_{2u}(\pi) \rightarrow e_g(d_\pi)$), giving rise to $^4B_{2u}$ and $^4B_{1u}$ terms, respectively, are assigned as the bands at *ca.* 15 000 and 28 200 cm^{-1}, since positive-signed C terms are expected for these transitions. The weak bisignated C term at *ca.* 16 500 cm^{-1} implies that the corresponding absorption band originates from π–π^* transitions, namely the Q band. In the case of MLCT2 ($e_g(d_\pi) \rightarrow b_{1u}(\pi^*)$), four transitions, of which two corresponding to $^4B_{1u}$ and $^4B_{2u}$ terms show positive C terms, and the other two corresponding to $^4A_{1u}$ and $^4A_{2u}$ show negative C terms, are expected. Therefore, the bands at *ca.* 11 600 and 20 000 cm^{-1} can be assigned to these, of which the former band contains two overlapping transitions. DFT study also predicts that the ground state of unligated $Mn^{II}Pc$ is ^4E_g.[173] For the six-coordinated adducts with two pyridine ligands, an intermediate-spin state was assigned experimentally,[163] which, however, has been doubted theoretically.[173] According to the DFT calculations, the axial coordinations raise the energy of the d_{z^2}-orbital. Therefore, $Mn^{II}Pc(py)_2$ adopts a low-spin $^2A_{1g}$ ($a_{1g}^1\ b_{3g}^2\ b_{2g}^2 = d_{xy}^1\ d_\pi^4$) state.

In the case of $Mn^{III}Pc$ derivatives (high-spin d^4 species), LMCT transitions corresponding to the $a_{1u}(HOMO) \rightarrow e_g(d_\pi)$ and $a_{2u}(HOMO–1) \rightarrow e_g(d_\pi)$ transitions are observed in the near infrared (*ca.* 7600 cm^{-1}) and visible (*ca.* 20 100 cm^{-1}) regions, respectively (Figure 47).[145] The weaker bands observed between the Q and lower energy LMCT bands were assigned as either vibronic or trip-multiplet transitions by Lever *et al.* When charge-transfer (CT) transitions lie close to either the Q or B bands, quite significant changes take place in the bandwidth, band energy, and band intensity. Thus, the Q band of MnPc is often observed in a lower energy region compared to other metalloPcs, since configuration interactions between the π–π^* and CT one-electron transitions lowers the Q band energy. The Leznoff and Nyokong groups described some substituted $Mn^{III}Pc$ derivatives, such as $Mn^{III}Pc$ substituted by hexadecaalkoxy groups, and $Mn^{II}Pc$ having eight alkylthio groups.[174,175] Since the Q band of these compounds appears beyond the visible region (for example, $Mn^{III}Pc(SC_5H_{11})_8(OAc)$ shows a Q band at 893 nm in CH_2Cl_2), contributions of the Q band to the "color" of the compounds are less significant. Instead, the color appearance is affected by the LMCT transition observed between 450 and 650 nm. As a result, $Mn^{III}Pc$ derivatives with electron-donating substituents are brown or red in color. The spectra of $Mn^{IV}Pc$ species have been rarely reported. Mbambisa *et al.* generated the $Mn^{IV}Pc(2–)$ species electrochemically, and observed the lowest energy band at 920 nm in CH_2Cl_2 containing

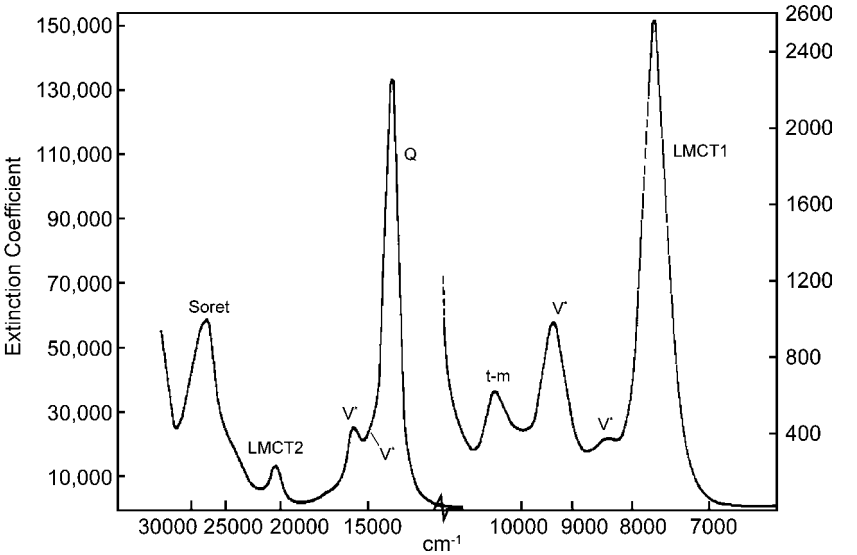

Figure 47. Absorption spectrum of (*tert*-Bu)$_4$Mn^{III}Pc(OAc) in DMF. Redrawn with permission from Lever, A. B. P.; Pickens, S. R.; Minor, P. C.; Licoccia, S.; Ramaswamy, B. S.; Magnell, K. *J. Am. Chem. Soc.* **1981**, *103*, 6800–6806. Copyright 1981 American Chemical Society.

0.1 M $TBABF_4$.[175] The Mn^VPc analog was first achieved by employing the triazacorrole (corrolazine) skeleton as a Mn^V-oxo complex, which shows moderately intense bands at 634 and 418 nm.[176]

Yoshihara *et al.* concluded that the oxidation state of the technetium ion in TcPc obtained using a recoil implantation technique is +4.[177] Synthesis of a Tc^V complex was also reported as nitrido-Tc^VPc.[178] El-Tamer *et al.* prepared ^{99m}TcPc tetrasulfonate, and illustrated its blue color using a picture.[179] However, no detailed absorption study is available on TcPc.

Soluble RePcs were first reported by Ziener *et al.*[180,181] The absorption spectrum of (*tert*-Bu)$_4$ReNPc and (*tert*-Bu)$_4$ReO(OEt)Pc exhibits band maxima at 698 and 363 nm, and 726 and 368 nm, respectively, in CH_2Cl_2. The μ-oxo dimer, [(*tert*-Bu)$_4$ReO(OEt)Pc]$_2$O, exhibits a Q band at 688 nm, which is blue-shifted by *ca.* 40 nm relative to the monomeric species. In addition, the dimer species shows a small band at 747 nm in CH_2Cl_2.[181] The BBr_3 adduct of the nitride complex, (*tert*-Bu)$_4$ReN(BBr_3)Pc, shows a Q band red-shifted from 698 to 725 nm due to the electron-withdrawing effect of the BBr_3 group.[102] Frick *et al.* claimed that [(*tert*-Bu)$_4$Re(O)Pc]$_2$ forms a rhenium–rhenium bond. Figure 48 compares the absorption spectra of [(*tert*-Bu)$_4$Re(O)Pc]$_2$ (top) and [(C_5H_{11})$_8$Re(O)Pc]$_2$O in chloroform or as a KBr pellet.[156] The Q band of [(*tert*-Bu)$_4$Re(O)Pc]$_2$ is blue-shifted (652.5 nm in $CHCl_3$) relative to (*tert*-Bu)$_4$ReNPc (698 nm in CH_2Cl_2),

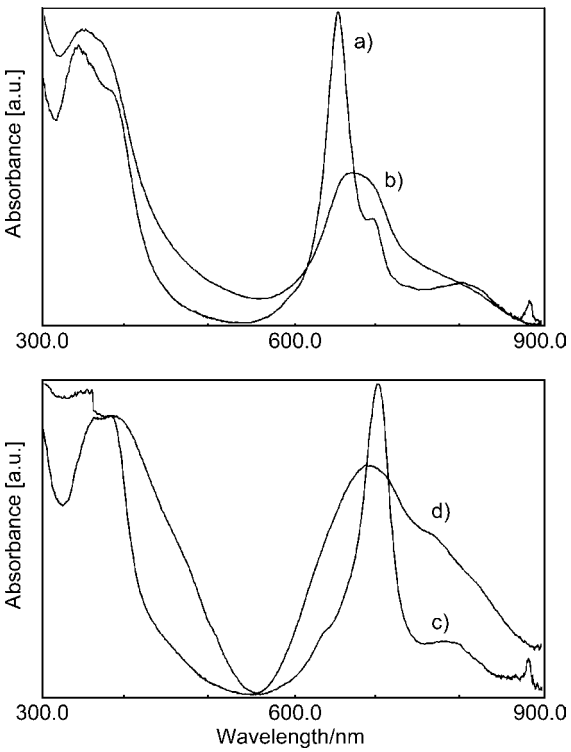

Figure 48. Absorption spectra of [(*tert*-Bu)$_4$Re(O)Pc]$_2$ (top) and [(C$_5$H$_{11}$)$_8$Re(O)Pc]$_2$O (bottom) in chloroform (a and c) and as a KBr pellet (b and d). Redrawn from Frick, K.; Verma, S.; Sundermeyer, J.; Hanack, M. *Eur. J. Inorg. Chem.* **2000**, 1025–1030.

while that of [(C$_5$H$_{11}$)$_8$Re(O)Pc]$_2$O (701.5 nm in $CHCl_3$) is approximately identical, indicating that larger exciton type π–π interactions are involved for [(*tert*-Bu)$_4$Re(O)Pc]$_2$ due to the closer ring-to-ring distance. The weak bands in the longer wavelength region of the Q band are also indicative of the formation of a face-to-face dimer structure as described in Section E. Figure 49 exhibits another example of the absorption data of (RePc)$_2$, having a rhenium–rhenium bond whose structure has been unambiguously determined by crystallography.[182] The spectrum reveals the principal absorptions at 15 800 (Q region), 29 500/33 100 (B1/B2 region), and 36 600 cm^{-1} (N region). On the other hand, the dissolved complex shows a splitting of the Q region into two strong bands of comparable intensity at 14 100 and 16 500 cm^{-1} (Figure 49b). The band at 8950 cm^{-1} for the monomer species (Figure 49c) was assigned as a trip-doublet transition, resulting from spin–spin coupling of the triplet state of the Pc ligand with the $^2T_{2g}$ ground state of low-spin Re^{II} which is assumed to have a pseudo-O$_h$ symmetry.[182,183]

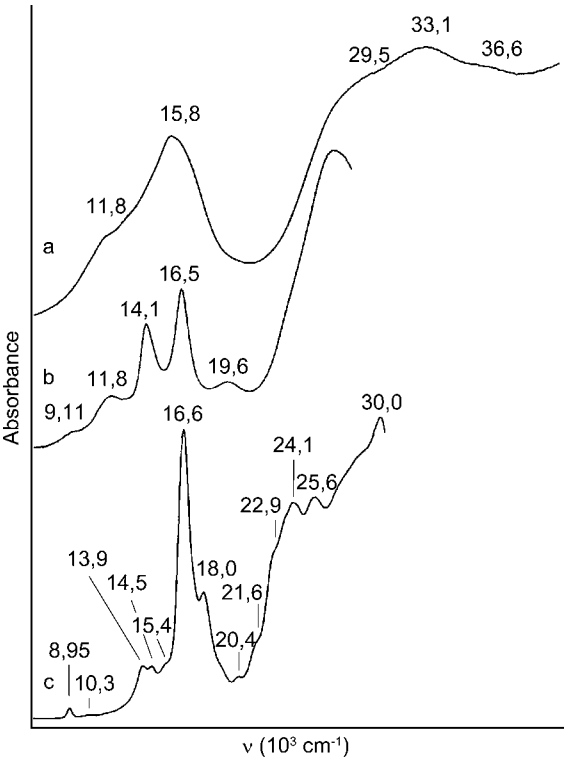

Figure 49. Absorption spectra of $(RePc)_2$ dispersed in a KBr pellet (a), $(RePc)_2$ dissolved in 1-chloronaphthalene (b), and $^{trans}[Re(PPh_3)_2Pc]$ dissolved in pyridine (c). Redrawn from Göldner, M.; Hückstädt, H.; Murray, K. S.; Moubaraki, B.; Homborg, H. *Z. Anorg. Allg. Chem.* **1998**, *624*, 288–294.

K. Group 8: FePc, RuPc and OsPc

The oxidation state of the iron ion in FePc can vary from Fe^{I} to Fe^{IV}, depending on the number and the nature of the axial ligands. Edwards and Gouterman compared the absorption data of $Fe^{II}Pc$, both in vapor-phase and in DMSO, and found that a large blue shift was observed in the Q band on going from vapor (676 nm) to DMSO (655.5 nm), indicating that the principal species in DMSO differs from that in vapor.[21] A large number of bisaxially coordinated low-spin $Fe^{II}Pcs$ has been studied.[184–203] Dale estimated the effect of axial ligands on the absorption spectrum of $Fe^{II}L_2Pc$, where L represents a ligand at one of the axial positions.[200] Figure 50 depicts the absorption spectra of $Fe^{II}Pc$, $Fe^{II}(py)_2Pc$, $Fe^{II}(NH_3)_2Pc$, and $Fe^{II}(CN)_2Pc$ in DMSO (from top to bottom). In the presence of axial ligands, the magnitudes of the resultant shifts in the absorption bands appear to be related to the σ-donor strength of the axial ligands. The spectrum of $Fe^{II}(py)_2Pc$ is similar to that of

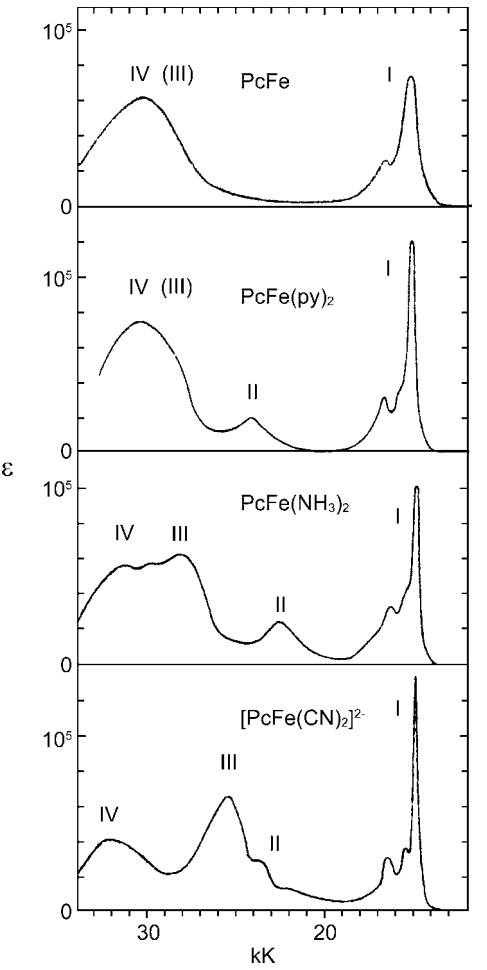

Figure 50. Absorption spectra of $Fe^{II}Pc$, $Fe^{II}Pc(py)_2$, $Fe^{II}Pc(NH_3)_2$, and $Fe^{II}Pc(CN)_2$ in DMSO (from top to bottom). Dale, B. W. *Trans. Faraday Soc.* **1969**, *65*, 331–339. Redrawn by permission of The Royal Society of Chemistry.

$Fe^{II}Pc$, although an additional band at 24 100 cm^{-1} is recognized. A small shoulder on the low-energy side of the band at 30 300 cm^{-1} is also characteristic. In the case of $Fe^{II}(NH_3)_2Pc$, the band at *ca.* 30 000 cm^{-1} splits into at least two components. A similar trend was also observed for $Fe^{II}(im)_2Pc$, $Fe^{II}(n\text{-}Bu)_2Pc$, and $Fe^{II}(pip)_2Pc$ (not shown). In the case of $Fe^{II}(CN)_2Pc$, two, clearly separated bands are observed in the UV region. The bands labeled as I in Figure 50 (Q band) vary by less than 400 cm^{-1}. On the other hand, the bands labeled as II–IV deviate progressively from $Fe^{II}Pc$ as the π-donor strength of the axial ligands is increased. Dale tentatively assigned band II to a CT transition, and later, Stillman and Thomson

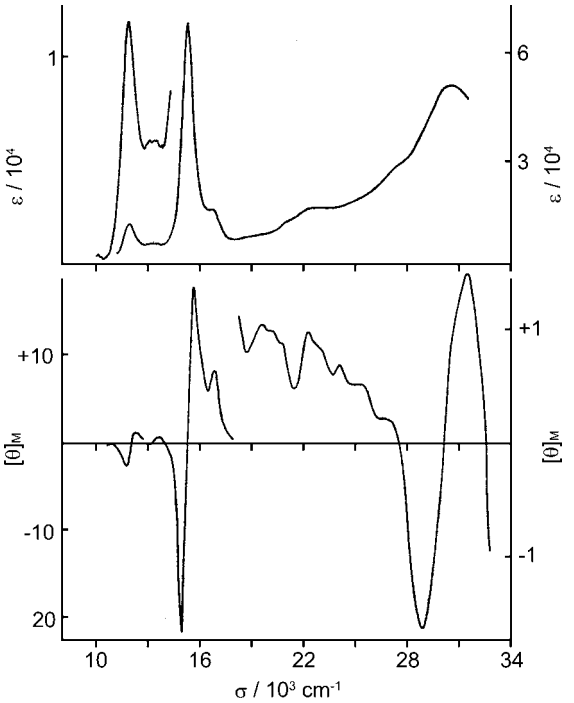

Figure 51. Absorption (top) and MCD (bottom) spectra of $Fe^{II}Pc$ in *o*-DCB. Stillman, M. J.; Thomson, A. J. *J. Chem. Soc. Faraday Trans. 2* **1974**, *70*, 790–804. Redrawn by permission of The Royal Society of Chemistry.

claimed that this assignment is not overturned by the MCD data.[204] However, it has been claimed that the spectrum of $Fe^{II}(CN)_2Pc$ has a resemblance to that of $Co^{III}(CN)_2Pc$ which is devoid of CT transitions.[204] See the following section and Figure 63 on $Co^{III}(CN)_2Pc$. In a weekly coordinating solvent, $Fe^{II}Pc$ exhibits a new absorption band close to 12 000 cm^{-1}, which is absent in the spectra shown in Figure 50, while the corresponding MCD signal is a dispersion type A-term, as depicted in Figure 51. Stillman and Thomson proposed that a satisfactory interpretation of these results can be obtained if a spin state other than S = 0 is assumed for the iron ion, and concluded that the ground state of $Fe^{II}Pc$ in *o*-DCB is $^3A_{2g}$.[204] In this case, the e_g orbitals must be the highest occupied d-orbitals, and the transition $^3A_{2g} \rightarrow {}^3E_u$ is expected to give rise to the lowest energy band. Of the two possible excited configurations, $(e_g b_{1u})$ and $(e_g b_{2u})$, the latter possibly corresponds to the lowest-energy band.[145,204] Nemykin *et al.* prepared a series of $Fe^{II}L_2Pcs$, and demonstrated that the experimental MLCT band positions are well-correlated with the theoretical results obtained by a semi-empirical AM1 method and the cone angle concept.[201] Ough and Stillman classified the axial ligands into three groups

on the basis of the spectral features, according to the σ donor and π acceptor strengths, i.e. (1) strong σ donors and weak π acceptors, (2) strong σ and π donors, and (3) weak σ donors and strong π acceptors. The authors performed a detailed analysis of the absorption and MCD spectra of the corresponding $Fe^{II}L_2Pc$ species.[202] Accordingly, (1) an increase of the σ donor strength of the axial ligands decreases the energy of the degenerate transitions; (2) an increase of the π acceptor strength of the axial ligand decreases the separation between the B1-B2 and MLCT1-MLCT2 transitions; and (3) an increase of the π donor strength of the axial ligands increases the separation between the B1–B2 and MLCT1–MLCT2 transitions. Fukuda *et al.* demonstrated that a highly-deformed 1,4,8,11,15,18,22, 25-octaphenyl $Fe(py)_2Pc$ with a saddle-type D_{2d} aromatic symmetry shows broad absorption bands of medium intensity on the lower energy side of the Q band.[205] These bands have been assigned to MLCT transitions which are forbidden for normal planar $Fe^{II}Pcs$ with D_{4h} symmetry. Hanack *et al.* compared the absorption spectra of tetra-*tert*-butyl $Fe^{II}L_2Pc$, $Fe^{II}L_2Nc$, and $Fe^{II}L_2Ac$, where L = Me_2PhNC (Figure 52).[206] The spectra show a bathochromic shift of the Q band with linear annulation of the benzene units (658, 751, and 829 nm for Pc, Nc, and Ac, respectively), and the absorption coefficients of the Q bands increase on going from Pc to Ac. A series of bisaxially substituted FeNcs have also been synthesized by the same group.[207]

Lever and Wilshire reported the absorption spectrum of $(py)Fe^{I}Pc(2-)$ in py/LiCl (Figure 53).[208] The observation that the spectral envelope is quite different from that of normal metalloPcs indicates that the Fe^{I} ion interacts significantly with the π-system. The observed band peak positions are 30 615, 26 572sh, 19 405,

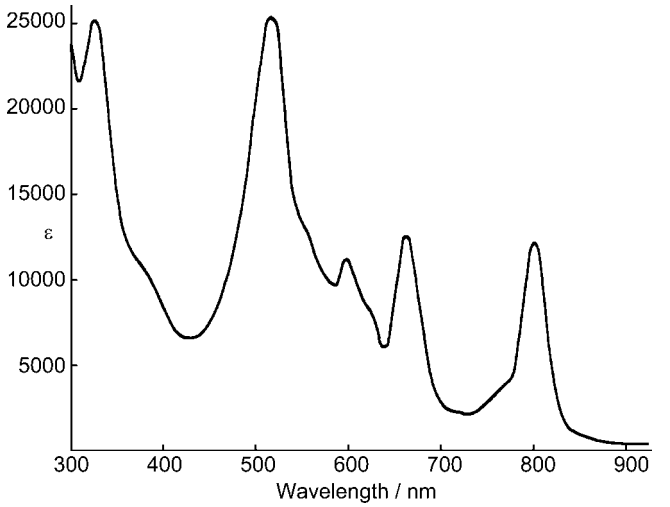

Figure 53. Absorption spectrum of (py)Fe^{I}Pc(–2) in py/LiCl. Redrawn with permission from Lever, A. B. P.; Wilshire, J. P. *Inorg. Chem.* **1978**, *17*, 1145–1151. Copyright 1978 American Chemical Society.

16 800, 16 250sh, 15 130, 13 890sh, and 12 480 cm^{-1}. The authors also claimed that $Fe^{II}Pc$ in *N,N*-dimethylacetamide containing LiCl is oxidized by air (oxygen), to give the stable Fe^{III} complex. Kennedy *et al.* reported a detailed investigation of the spectral properties of a range of six- and five-coordinated $Fe^{III}Pcs$.[209] Anionic six-coordinate species, B^+–[$Fe^{III}L_2$(Pc(2–))]$^-$ (B^+ = bulky cation; L = OH^-, OPh^-, NCO^-, NCS^-, N_3^-, CN^-), display low-spin d^5 characteristics. The absorption spectra of these species (Figure 54, part a top, and part b a–c) can be distinguished from those of five-coordinate complexes (Figure 54, part a c–f). The six-coordinate species show a Q band at *ca.* 690 nm with a weak band at *ca.* 775 nm, while the Q band of the five-coordinate species appears at *ca.* 660 nm with shoulders on each side at *ca.* 590 and 710 nm. Weak LMCT bands are also observed at 465 and 840 nm. The Q band at *ca.* 660 nm indicates that the complex has a high-spin d^5 configuration. Kobayashi *et al.* reported that the spin state of iron in 1,2,8,9,15,16,22,23-octadecyloxycarbonyl $Fe^{III}Pc$ dissolved in CH_2Cl_2 or $CHCl_3$ changes from a high-spin to a low-spin state by the addition of tetrabutylammonium chloride and/or bromide (Figure 55).[210] In the absence of an electrolyte, the complex exhibits peaks at 817, 738, 650, and 337 nm. When tetrabutylammonium chloride is added, the spectrum changes with a set of isosbestic points, and the final spectrum shows new peaks at 690, 617, 552, 410, and 329 nm, which corresponds to a change of the electronic configuration from the high-spin to low-spin state. Reports on $Fe^{IV}Pc$ species are limited.[211,212] Bottomley *et al.* observed spectral changes obtained during the electrolysis of a μ-nitrido FePc dimer, $(FePc)_2N$, in pyridine (Figure 56).[212] The neutral

complex is considered to have an $Fe^{III1/2}$–$Fe^{III1/2}$ (or Fe^{IV}–Fe^{III}) mixed valence state, and the spectrum before electrolysis shows a strong band at 626 nm, with two shoulders at 573 and 658 nm. After electrolysis at an applied potential of +0.300 V vs. SCE, the final spectrum shows a prominent band at 637 nm, with two shoulders at 578 and 677 nm. The authors assigned this species as $(Fe^{IV}Pc)_2N$. A similar experiment was also performed for a μ-oxo FePc dimer, $(FePc)_2O$, in pyridine (Figure 57).[211] The initial spectrum shows an intense band at 622 nm and two shoulders at 569 and 653 nm, while the intense band shifts to 652 nm in addition to new shoulders appearing at 624 and 692 nm after electrolysis at +0.59 V vs. SCE. The generated species is speculated to be an Fe^{IV}–Fe^{III} complex.

The synthesis, properties, and applications of RuPcs have been reviewed by Rawling and McDonagh.[213] The absorption properties of RuPcs are relatively sensitive to axial ligands. Although nitrogen-containing aromatic heterocycles, amines, and phosphanes appear not to have a significant effect on the Soret band, the coordination of a carbonyl ligand (CO) leads to a profound hypsochromic shift of the Soret band, along with a significant increase in the molar

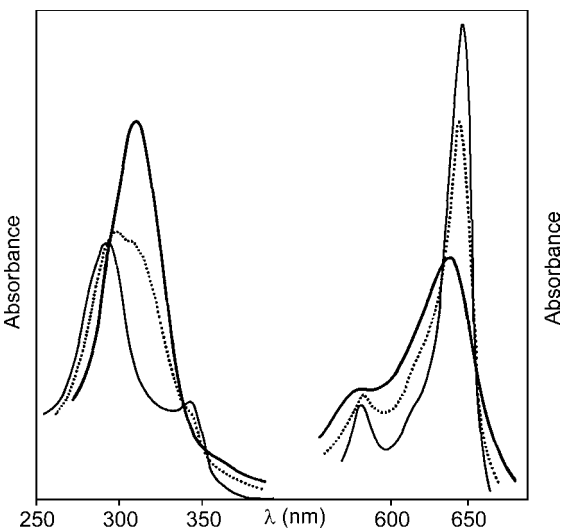

Figure 58. Visible spectral changes during photolysis of Ru(4-Mepy)(CO)Pc in CH_3CN (thin solid line), to give $Ru(CH_3CN)_2Pc$ (thick solid line). Redrawn with permission from Dolphin, D.; James, B. R.; Murray, A. J.; Thornback, J. R. *Can. J. Chem.* **1980**, *58*, 1125–1132.

extinction coefficient of the Q band.[214–216] A variety of RuL_2Pc complexes have been prepared by photolysis of RuL'(CO)Pc complexes in the presence of excess L, where L represents pyridine derivatives, imidazole, DMF, DMSO, and acetonitrile.[214,217] Figure 58 shows the spectral changes seen during photolysis of Ru(4-Mepy)(CO)Pc in CH_3CN to give $Ru(CH_3CN)_2Pc$. The mono carbonyl complexes, Ru(py)(CO)Pc, Ru(4-Mepy)(CO)Pc, Ru(4-*tert*-Bupy)(CO)Pc, Ru(dmf)(CO)Pc, and Ru(dmso)(CO)Pc, show an intense, sharp Q band in the 637–645 nm region, which is characteristic of typical metalloPcs. Absorption

bands in the 340–380 nm region are also distinctive for this type of complexes. Upon photolysis, the Q band shifts slightly to the blue, broadens, and loses the intensity. Thus, the molar extinction coefficient of $Ru(CH_3CN)_2Pc$ is half as large as that of the monocarbonyl complexes. Although the absorption band in the 340–380 nm region disappears for $Ru(CH_3CN)_2Pc$, further photolysis in pyridine, to give $Ru(py)_2Pc$, generates an absorption band at *ca.* 370 nm again.[214] Tetra-15-crown-5 appended $Ru^{II}Pc$ also shows a similar spectral trend.[216] Gutierrez observed that $Ru^{II}(CO)(py)Pc$ exhibits splitting of the Q band in a glassy matrix at 5 K, which is likely to be attributed to the polar electronic influence of solvents on the microenvironment around the complex.[218] Stuzhin *et al.* reported a series of $Ru^{II}L_2(OPTAP)$ complexes, where OPTAP = octaphenyl TAP (Figure 59).[219] For the N-base adducts (L = NH_3, pyridine (py), pyrazine (pyz), and *s*-tetrazine (tz)), the decrease of the σ-donor and increase of the π-acceptor properties of the axial ligands leads to a slight hypsochromic

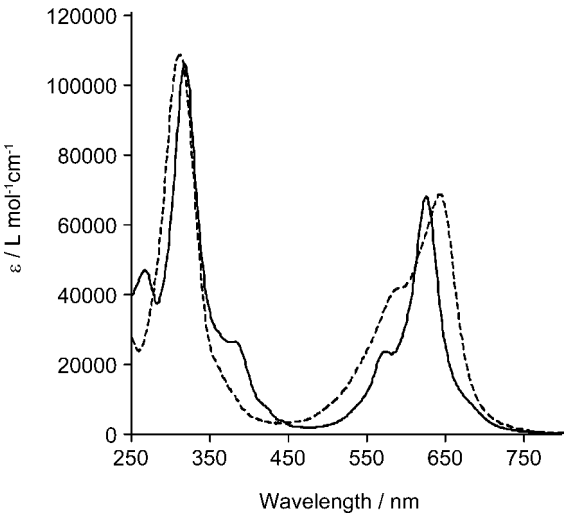

Figure 60. Absorption spectra of tetra-*tert*-butyl $Ru^{II}Pc$ having either 4-(*N,N*-dimethylamino) pyridine (solid line) or 4-nitropyridine (dashed line) as axial ligands in CH_2Cl_2. Redrawn with permission from Rawling, T.; Xiao, H.; Lee, S. T.; Colbran, S. B.; McDonagh, A. M. *Inorg. Chem.* **2007**, *46*, 2805–2813. Copyright 2007 American Chemical Society.

shift of the $\pi \rightarrow \pi^*$ transitions. In particular, the Q, B, and L bands for $Ru(NH_3)_2$(OPTAP) are shifted to lower energy because of the pure σ-donor properties of NH_3. In the case of isocyanides (*tert*-BuNC and *p*-diisocyanodurole (did)) as axial ligands, the B band is shifted considerably to the red, while the Q band remains at the same position, similarly to py, pyz,, and tz adducts. The origin of these observations is attributed to the strong π-accepting and σ-donating properties of isocyanides. Medium-intensity absorption bands between the Q and B bands are assigned to CT transitions.[220] The CT band of $Ru(NH_3)_2$(OPTAP) appears at 513 nm, since coordinated NH_3 ligands have only σ-donor properties. In the case of π-accepting ligands, the CT band shifts to the blue in the order L = py (473 nm), pyz (458 nm), and tz (423 nm). However, the assignments of these CT transitions have not been fully understood. Rawling *et al.* compared the effects of the electron-donating/withdrawing properties of axial substituents. Figure 60 shows the absorption spectra of tetra-*tert*-butyl $Ru^{II}Pc$ having either 4-(*N,N*-dimethylamino)pyridine (solid line) or 4-nitropyridine (dashed line) as axial ligands.[221] The spectrum of the electron donating 4-(*N,N*-dimethylamino)pyridine complex shows Q and Soret bands at 626 and 318 nm, respectively, in CH_2Cl_2, while these bands shift to 645 (Q) and 318 nm (Soret) for the 4-nitropyridine adduct. A dimeric RuPc, in which two ruthenium atoms are bonded directly, has also been proposed,[222–224] and the absorption data have been reported.[222]

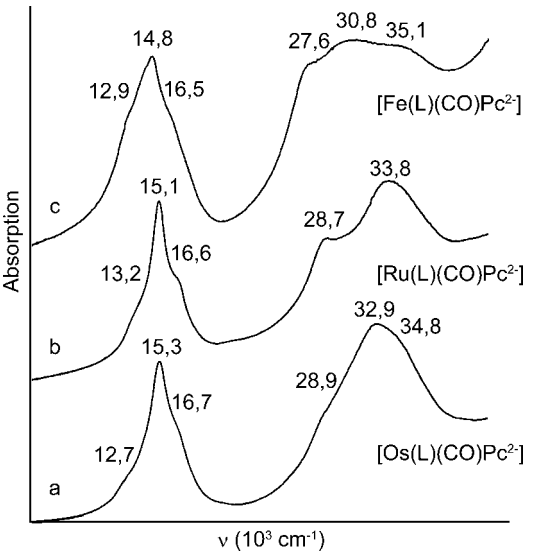

Figure 61. Absorption spectra of M(L)(CO)Pc in a KBr pellet. (a) M = Os, L = THF, (b) M = Ru, L = H_2O, (c) M = Fe, L = CH_3OH. Redrawn from Weidemann, M.; Homborg, H. *Z. Anorg. Allg. Chem.* **1996**, *622*, 2095–2098.

Several OsPc complexes have been described in the literature, although spectroscopic investigations of these are limited.[217,225–237] However, the spectroscopic properties of OsPcs have a general resemblance to those of RuPcs. $Os^{II}(py)_2Pc$ exhibits absorption bands at 616, 563, 369, and 308 nm in chloroform, while the corresponding bands of $Ru(py)_2Pc$ appear at 625, 573, 377, and 313 nm, respectively.[214,229] Of these, the bands at 377 and 369 nm for the ruthenium and osmium complexes, respectively, have been assigned to CT transitions between the metal and axial ligands.[200] The corresponding transition for $Fe(4\text{-pic})_2Pc$ is observed at 410 nm. Figure 61 compares absorption spectra of M(L)(CO)Pc, where M = Os, Ru, and Fe.[235] A bathochromic shift of the Q band is observed in the order Fe (14.8 kcm^{-1}), Ru (15.1 kcm^{-1}), and Os (15.3 kcm^{-1}) complexes, and all of these exhibit shoulders on both sides of the Q band. The Soret region shows different spectral shapes. The iron complex shows a featureless spectrum in this region, while the ruthenium and osmium complexes have prominent band components at 33.8 and 32.9 kcm^{-1}, respectively. Additional bands are observed in the lower-energy region of the Soret region, implying the presence of CT transitions. However, it is claimed that the presence of CT transitions for OsPc is not readily confirmed.[235] Hanack and Vermehren reported that the Q and Soret bands of $Os(dmso)_2Pc \cdot dmso$, $Os(pyz)_2Pc$, and $Os(\textit{tert}\text{-}BuNC)_2Pc$ are shifted to shorter wavelength compared with the corresponding ruthenium complexes.[229]

L. Group 9: CoPc, RhPc and IrPc

The oxidation state of the cobalt ion in CoPc can vary from Co^{I} to Co^{III}. Unsubstituted Co^{II}Pc shows absorption peaks at 658, 597, and 332 nm in pyridine, while slight red shifts are observed for tetra-*tert*-butyl Co^{II}Pc (662, 600, and 330 nm).[238] Kobayashi *et al.* compared the absorption data of tetra-*tert*-butyl Co^{II}TAP, Co^{II}Pc, Co^{II}Nc, and Co^{II}Ac (Figure 62, solid lines).[43] The Q band shifts to longer wavelength, but with an extent diminishing with increasing size of ligand. The Q bands appear at 579, 672, 759, and 839 nm for Co^{II}TAP, Co^{II}Pc, Co^{II}Nc, and Co^{II}Ac, respectively. In Figure 62, the spectra of the corresponding first reduction products are also drawn using dotted lines. The Q band of the Co^{I} species always appears in the longer wavelength region compared with the corresponding Co^{II}

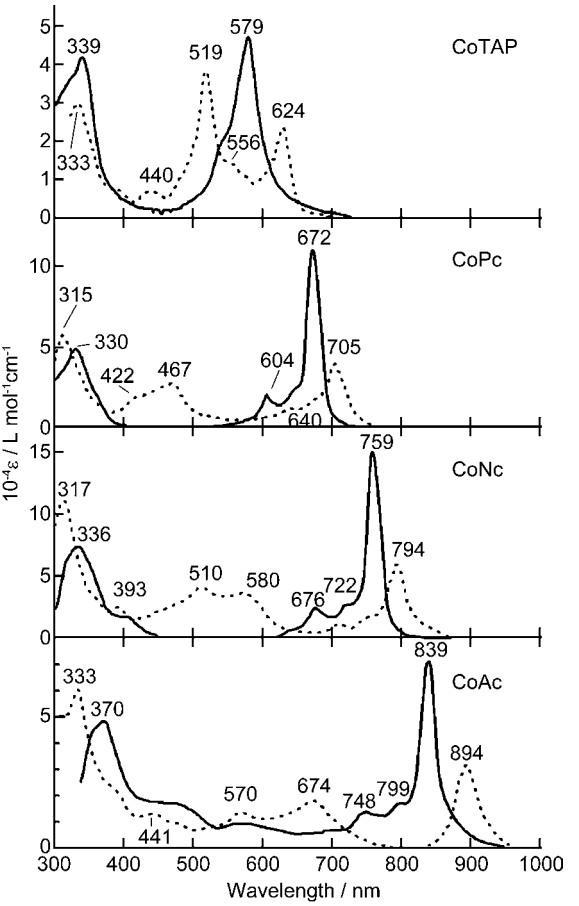

Figure 62. Electronic absorption data of Co^{II} (solid lines) and electrochemically-reduced Co^{I} complexes of tetra-*tert*-butyl TAP, Pc, Nc, and Ac (from top to bottom) in *o*-DCB. Redrawn from Kobayashi, N.; Nakajima, S.; Ogata, H.; Fukuda, T. *Chem. Eur. J.* **2004**, *10*, 6294–6312.

species. It is known that the Q band shifts to longer wavelength with concomitant decrease in intensity upon reduction of $Co^{II}Pc$ to form $Co^{I}Pc$. A new absorption band thus developed between the Q and B bands in the 400–500 nm region is assigned to the MLCT transition from $e_g(d_\pi)$ to ligand b_{1u} and b_{2u} orbitals.[204,239–242] Similar behavior is observed on reduction of all the complexes in Figure 62 (dotted lines). The energy differences of the two MLCT peaks in each species (422 and 467 nm for CoPc, 510 and 580 nm for CoNc, and 570 and 674 nm for CoAc) increases with molecular size on going from CoPc (2280 cm^{-1}), to CoNc (2380 cm^{-1}), and further to CoAc (2710 cm^{-1}), indicating an increased energy difference between the ligand b_{1u} and b_{2u} orbitals in this order. Assuming that the energy of the $e_g(d_\pi)$ orbital is insensitive to the size of the ligand, then the longer-wavelength shift of the MLCT bands with increasing molecular size indicates that the energy difference between the cobalt $e_g(d_\pi)$ and ligand b_{1u} and b_{2u} orbitals becomes smaller the larger the ligand. In the case of CoTAP, two prominent bands appear upon reduction (519 and 624 nm), of which the former appears to be an MLCT transition. However, the assignments of these bands have not been fully understood. Stillman and Thomson performed an MCD experiment on chemically-reduced $Co^{I}Pc$ in DMSO, and observed more than one *A* term between the Q and Soret region, confirming the assignments of the MLCT transitions.[204] Addition of cyanide (CN^-) to a DMSO solution of $Co^{II}Pc$ generates $Co^{III}(CN)_2Pc$ (Figure 63).[204] The high-energy region of the spectra (19 000- cm^{-1}) contains at least three identifiable bands, and thus the spectral envelope is more complex in shape than that of $Co^{II}Pc$. The bands at *ca.* 22.5 kcm^{-1} are extra bands compared with $Zn^{II}(CN)_2Pc$ (not shown), so that these are likely to be CT bands. However, the only allowed CT transition is the $a_{2u} \rightarrow a_{1g}$ LMCT transition, which cannot give rise to an MCD *A* term. As a consequence, the extra band cannot be assigned as LMCT. It is suggested that all the bands in the near UV region arise from excited configurations of the Pc ring as a plausible alternative.[204] Nombona and Nyokong obtained spectral changes during the generation of electrochemically-oxidized α-tetraphenylthio- or β-tetraphenylthio-substituted $Co^{II}Pcs$.[243] The Co^{II} complexes have a Q band at 695 and 673 nm for the α and β derivatives, respectively. The oxidation results in a bathochromic shift of the Q band (709 and 686 nm for the α and β derivatives, respectively) with an increase in intensity.

$Rh^{II}(py)_2Pc$ exhibits absorption peaks at 661, 633, 598, 371, and 327 nm in DMF.[244] In contrast, a hypsochromic shift of these bands is observed for the Rh^{III} complex. Here, $Rh^{III}ClPc$ shows absorption peaks at 654, 625, 590, 341, and 280 nm in chloroform, which does not change significantly when the rhodium center is coordinated to pyridine, 4,4′-bipyridine, 1,4-diazabicyclo[2,2,2]octane (dabco), and 2-methylpyrazine (mepyz).[245] In addition, the chloride ligand has a small effect on the absorption energies, where the iodo congener, $Rh^{III}IPc$, shows

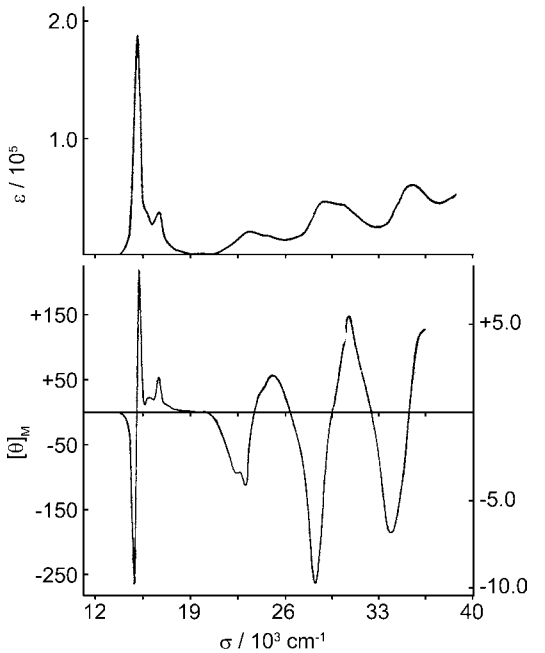

Figure 63. Absorption (top) and MCD (bottom) spectra of $Co^{III}(CN)_2Pc$. Stillman, M. J.; Thomson, A. J. *J. Chem. Soc. Faraday Trans. 2* **1974**, *70*, 790–804. Redrawn by permission of The Royal Society of Chemistry.

absorption peaks at 656, 632, 593, 573, and 556 nm in 1-chloronaphthalene.[246] Therefore, the effect of the oxidation state of rhodium on the absorption bands is opposite to that observed for CoPc. The spectra of Rh^{III} complexes are typical in shape of metalloPcs (Figure 64a). The absorption spectrum of $(^nBu_4N)[Rh^IPc^{2-}]$ in isopropanol indicates that the Q band of this complex is shifted slightly to longer wavelength compared with the Rh^{III} species (Figure 64c).[247] It is proposed that the intense band at *ca.* 40 000 cm^{-1} can be assigned to MLCT transitions. Gaffo *et al.* observed a pronounced, partially-reversible quenching of the Q-band absorption when an LB film of the RhPc complex is exposed to chlorine gas.[248] Balkus *et al.* reported absorption data of RhPc encapsulated in zeolites.[249] Photolysis of octaethyl Rh(Me)TAP in benzene ($\lambda > 350$ nm) results in the formation of $[(\text{octaethyl TAP})Rh]_2$, which has a direct Rh–Rh bond. The spectroscopic changes occurring during the photolysis are shown in Figure 65 (top).[250] Dissolution of $[(\text{octaethyl TAP})Rh]_2$ in pyridine gives a new species which shows a weak band at 750 nm (Figure 65, bottom). The generated species is proposed to be a π anion radical, i.e. $[(\text{octaethyl } Rh^{III}(py)_2TAP)]^{\bullet}$.

Several references are available on IrPc, although few of these include any absorption study.[246,247,251–260] $Ir^{III}ClPc$ exhibits absorption peaks at 648, 625, 586,

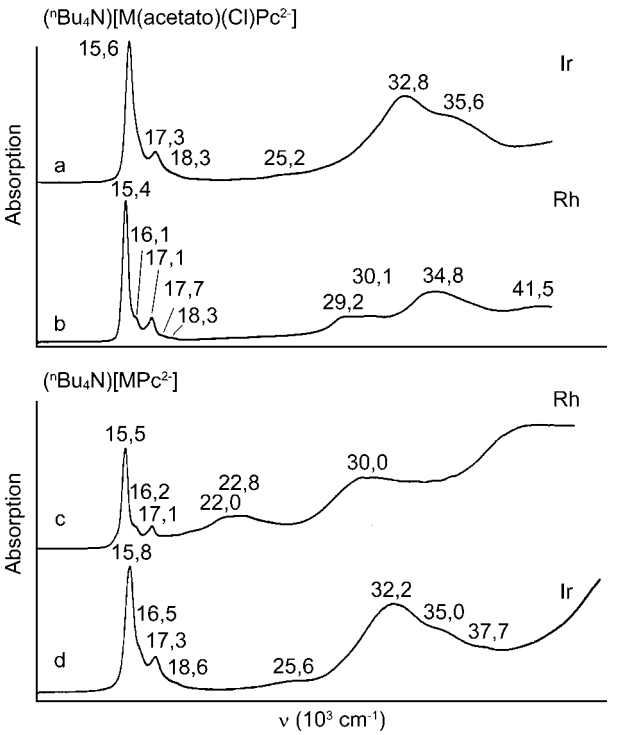

Figure 64. Absorption spectra of (^{n}Bu$_4$N)[M^{III}(acetate)(Cl)Pc^{2-}] in CH_2Cl_2 [M = Ir (a) and Rh (b)], and (^{n}Bu$_4$N)[M^{I}Pc^{2-}] in isopropanol [M = Rh (c) and Ir (d)]. Redrawn from Hückstädt, H.; Homborg, H. *Z. Anorg. Allg. Chem.* **1998**, *624*, 715–720 and Hückstädt, H.; Homborg, H. *Z. Anorg. Allg. Chem.* **1998**, *624*, 980–986.

567, 553, and 390 nm in 1-chloronaphthalene.[246] Examples of absorption spectra of Ir^{III} and Ir^I complexes are shown in Figures 64a and d, respectively.[247,258]

M. Group 10: NiPc, PdPc and PtPc

The spectral properties of NiPcs are, in a sense, featureless because no significant metal-ligand interactions, nor any axial ligands are expected. The first oxidation and reduction couples of general NiPc are ligand-centered. Unsubstituted Ni^{II}Pc shows absorption peaks at 651, 594, 327.5, 235, and 210 nm [Q, Q(1–0), B, L, and C band, respectively, Figure 66].[21] Fielding and MacKay observed weak bands at *ca.* 6400 cm^{-1} (1560 nm) for a crystalline thin film of NiPc, which they assigned to the d–d transition.[261] These bands, however, disappear in vapor-phase and solution spectra. Lever *et al.* commented that no LMCT transitions from the a_{1u} or a_{2u} levels of Pc are permitted, and no absorption other than the π–π^* transitions are observed at energies below the Soret band.[145] Indeed, although recent DFT

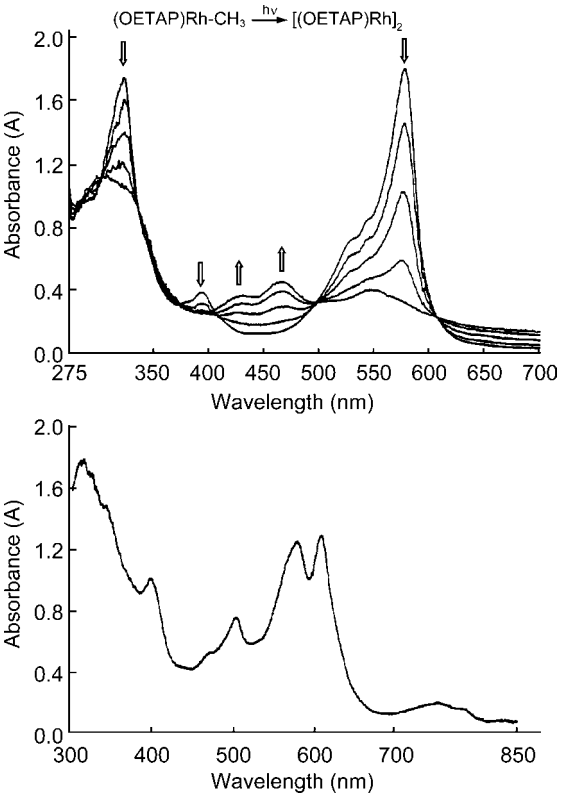

Figure 65. UV-vis spectral changes during the photolysis of octaethyl Rh(Me)TAP in benzene, to form [(octaethyl TAP)Rh]$_2$ (top), and absorption spectrum of a solution resulting from dissolving [(octaethyl TAP)Rh]$_2$ in pyridine at 295 K (bottom). Redrawn with permission from Ni, Y. P.; Fitzgerald, J. P.; Carroll, P.; Wayland, B. B. *Inorg. Chem.* **1994**, *33*, 2029–2035. Copyright 1994 American Chemical Society.

calculations predict that the $b_{1g}(d_{x^2-y^2})$ orbital lies at an energy below the $e_g(\pi^*)$ orbital,[262] no absorption bands have been observed in the corresponding region due to the symmetry-forbidden nature of the transition ($a_{1u}(\pi) \rightarrow b_{1g}(d_{x^2-y^2})$). The normalized Q-band region absorption spectra of NiPc (670 nm), NiNc (770 nm), α-octabutoxy NiPc (740 nm), and α-octabutoxy NiNc (845 nm) in 1-chloronaphthalene are shown in Figure 67.[262] The spectra show a red shift of the Q band upon substitution with either benzoannulation or octabutoxy. Since these two effects are both operative and independent, the Q band of α-octabutoxy NiNc is red-shifted by *ca.* 170 nm relative to that of NiPc. In addition, α-butoxy substitution of both the Pc and Nc rings also induces a substantial broadening of the Q bands.

PdPc exhibits absorption peaks at 660, 635, 595, 575, 560, 440, 420 nm in 1-chloronaphthalene. Figure 68 shows the absorption spectra of octaphenyl PdAc

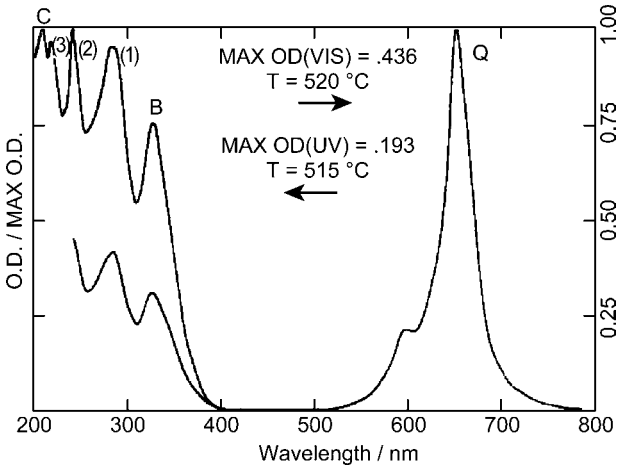

Figure 66. Vapor-phase absorption spectrum of NiPc. Redrawn from Edwards, L.; Gouterman, M. *J. Mol. Spectrosc.* **1970**, *33*, 292–310. Copyright 1970, with permission from Elsevier.

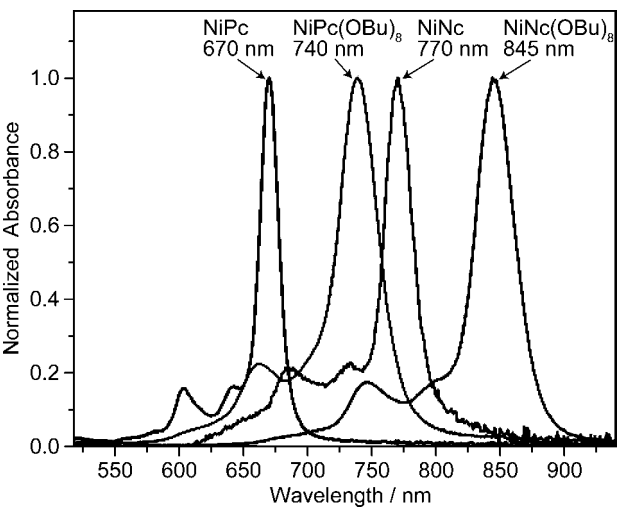

Figure 67. Normalized Q-band region absorption spectra of NiPc (670 nm), NiNc (770 nm), α-octabutoxy NiPc (740 nm), and α-octabutoxy NiNc (845 nm) in 1-chloronaphthalene at room temperature. Redrawn with permission from Soldatova, A. V.; Kim, J.; Peng, X. H.; Rosa, A.; Ricciardi, G.; Kenney, M. E.; Rodgers, M. A. J. *Inorg. Chem.* **2007**, *46*, 2080–2093. Copyright 2007 American Chemical Society.

(compound 1 in the figure) and its *trans*-annular endoperoxide (compound 2 in the figure) in benzene.[263,264] The photooxygenation of 1 in the presence of molecular oxygen generates 2. The spectral changes observed in the course of the photooxygenation unambiguously proved that the newly generated compound has an

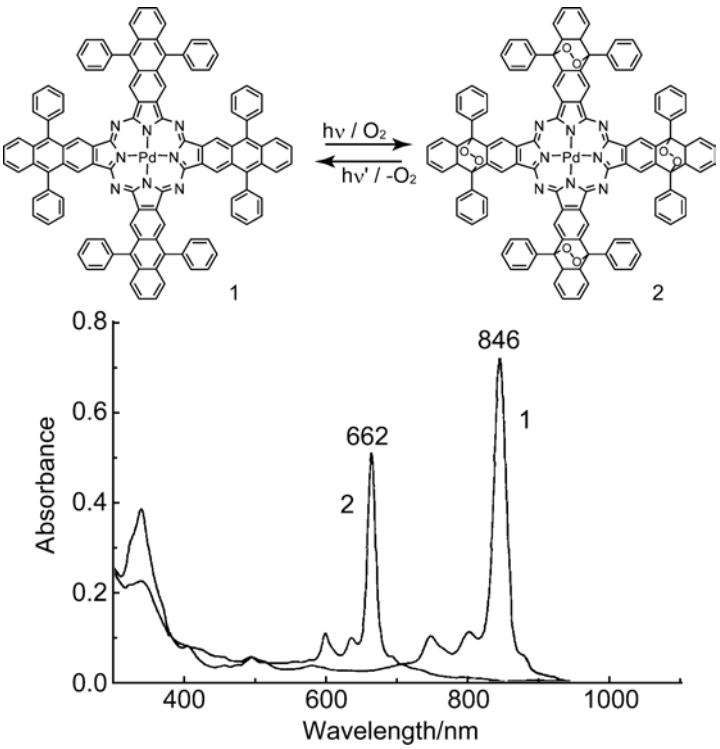

Figure 68. Absorption spectrum of octaphenyl PdAc in benzene. Redrawn from Freyer, W.; Flatau, S. *Tetrahedron Lett.* **1996**, *37*, 5083–5086. Copyright 1996, with permission from Elsevier.

aromatic structure identical to Pc. The Q band at 846 nm for 1 disappears during the photooxygenation, and a new band at 662 nm is generated instead. Excitation of the photoproduct 2 into higher excited electronic states by UV-laser light results in the release of molecular oxygen and the regeneration of the starting molecule 1. Miwa *et al.* synthesized a series of low-symmetry PdPc derivatives, and confirmed that the absorption spectra are analogous in shape with those of the corresponding zinc complexes (not shown).[265] The splitting energy of the Q band is also similar to that of the corresponding zinc derivatives, although the Q band shifts by 300–400 cm^{-1} to higher energy relative to the zinc complexes. This blue shift of the Q band is attributed to destabilization of the LUMO by interaction between the LUMO of the ligand and the dπ orbital of the palladium ion. The Soret bands of the palladium complexes (*ca.* 300–360 nm) also shift to the higher energy side. In addition, broad absorption bands are observed between the Soret and Q bands (400–500 nm). Presumably, this absorption can be assigned to an MLCT transition (d$\pi \rightarrow \pi^*$), because the corresponding MCD spectrum shows intense dispersion-type signals in this region.

Similarly to NiPc, the platinum in PtPc takes on a tetra-coordinated square planer structure. Therefore, PtPc is a four-coordinated planar complex, and thus no axial ligands are involved. In 1-chloronaphthalene, $Pt^{II}Pc$ shows absorption peaks at 650, 625, 586, 567, 550, and 455 nm. Spectroscopic studies on PtPc have been reported by Brown *et al.*[266]

N. Group 11: CuPc, AgPc and AuPc

$Cu^{II}Pc$ is the most common CuPc, and it has not been possible to isolate a Cu^{I} derivative.[267] Gardberg *et al.* reported the crystal structures of singly and doubly oxidized CuPc derivatives, $CuPc(ReO_4)$ and $CuPc(ReO_4)_2$, and demonstrated that both of these are compounds of Cu^{II}.[268] There have been very limited reports on the absorption data of unsubstituted $Cu^{II}Pc$, since it is sparingly soluble in most solvents. The best solvent for unsubstituted CuPc is probably 1-chloronaphthalene, although it is reported that CuPc forms light-scattering microcrystals at concentrations as low as 1×10^{-5} mol dm^{-3} even in this solvent.[58,269] Unsubstituted CuPc, shows absorption bands at 657.5 (Q), 600 (Q(0–1)), 325 (B), 276 (N), 240.5 (L), and 218 (C) nm in the vapor-phase (Figure 69),[21] and at 678, 648, 611, 588, 567, 526, 510 nm in 1-chloronaphthalene.[40,270] In a series of tetra-*tert*-butyl CuTAP, CuPc, and CuNc, the Q band shifts from 583 nm (CuTAP), to 676 nm (CuPc), and to 771 nm (CuNc).[43] No LMCT transitions are permitted from a_{1u} or a_{2u}. However, Schott reported a near-infrared absorption band for CuPc crystals, as shown in Figure 70.[271] At least nine bands can be recognized in the 800–1100 nm

region, of which the band at *ca.* 1080 nm is the most intense. Lever *et al.* also succeeded in observing the corresponding absorption for tetrasulfonato CuPc in DMSO (not shown).[145] It is likely that these bands originate from trip-multiplet transitions, since no other options are available in this region. The absorption peaks of hexadecachloro CuPc (Pigment Green 7) in H_2SO_4 differ, depending on the reference. The reported values are 854, 813, 768, 469, and 350 nm in Ref. 272, 860, 815, 730, and 490 nm in Ref. 273, and 861, 816, 770, 729, 656, 584, and 465 nm in Ref. 274.

Barrett *et al.* synthesized a Pc complex containing one silver ion, which is soluble in 1-chloronaphthalene, but tends to decompose in the boiling solvent, with the formation of phthalocyanine and metallic silver.[56] However, they could not determine whether the structure of the complex is $Ag^{II}Pc$ or $Ag^{I}HPc$. It is known that the corresponding porphyrins are compounds of Ag^{II}.[275] Anderson *et al.* reported that this complex shows absorption bands at 675, 642.5, 605, 580, and 560 nm in 1-chloronaphthalene.[57] ESR studies performed by Kholmogorov and Glebovsky implied that the oxidation state of the silver is 1,[276,277] while MacCragh and Koski concluded that the oxidation state of the silver is 2.[278] The synthesis and spectroscopy of tetraneopentoxy $Ag^{II}Pc$ ($TNAg^{II}Pc$) have been reported.[279–281] Figure 71 shows the spectroelectrochemistry of $TNAg^{II}Pc$. Stepwise, controlled-potential first oxidation of a solution of the complex results in the spectroscopic changes shown in Figure 71 (top). The initial spectrum shows absorption peaks at 685, 618, 386, and 356 nm, with isosbestic points observed at 703, 557, and 395 nm in the course of the oxidation. The final spectrum, showing absorption bands at 722, 647, 424, and 361 nm, is consistent with that of a metalloPc(2–) species and not an oxidized Pc(1–) species. Therefore, the observed spectral changes can be ascribed to the oxidation of the metal from Ag^{II} to Ag^{III}, to give $[Ag^{III}TNPc(2–)]^{+}$. Both the Q and Soret bands

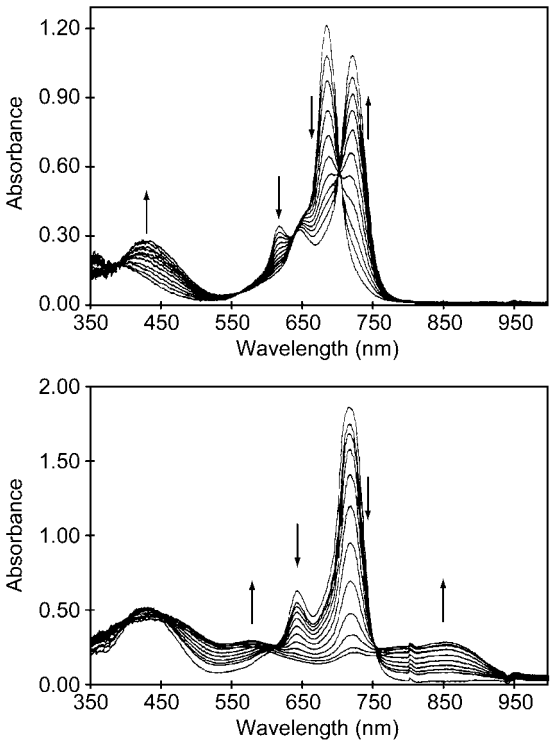

Figure 71. Stepwise, controlled-potential spectroelectrochemistry: (top) TNAg^{II}Pc in *o*-DCB solution, showing the development of [Ag^{III}Pc(2–)]$^{+}$ as the potential is stepped through the first oxidation wave from 0.55 to 0.9 V vs. SCE; (bottom) electrochemically generated [Ag^{III}Pc(2–)]$^{+}$ in *o*-DCB showing the development of the π radical cation [Ag^{III}Pc(1–)]$^{2+}$ as the potential is stepped through the second oxidation wave from 1.10 to 1.40 V vs. SCE. Copyright 1990 American Chemical Society.

shift to longer wavelength by *ca.* 40 nm for the Ag^{III} species compared with the Ag^{II} species. The spectral changes associated with the second oxidation potential, to exhibit absorption bands at 854, 721, 649, 574, and 439 nm (Figure 71, bottom) is characteristic of the formation of a radical Pc(1–) species.

MacCragh and Koski reported that Au^{II}Pc shows absorption peaks at 662, 633, 601, and 348 nm,[282] although it is still questionable whether gold Pc is a truly divalent gold complex or a tervalent complex.

O. Group 12: ZnPc, CdPc, Cd_2Pc_3 and HgPc

The Zn^{II} ion has a d^{10} configuration, so LMCT and d–d transitions should not appear in the UV-vis region. Therefore, Zn^{II}Pc is free from CT transitions, and is

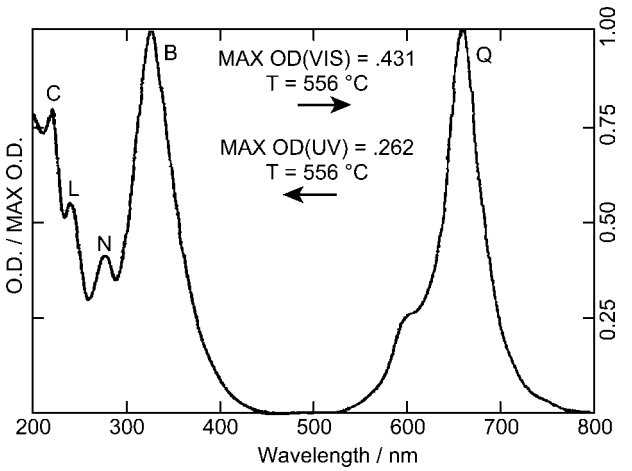

Figure 72. Vapor-phase absorption spectrum of ZnPc. Redrawn from Edwards, L.; Gouterman, M. *J. Mol. Spectrosc.* **1970**, *33*, 292–310. Copyright 1970, with permission from Elsevier.

well-suited for a spectroscopic study of the Pc ligand. Unsubstituted ZnPc shows absorption bands at 661 (Q), 600 (Q(0–1)), 326.5 (B), 276 (N), 240 (L), and 220 (C) nm in the vapor-phase (Figure 72),[21,33] at 680, 649, 616, 587.5, and 565 nm in 1-chloronaphthalene,[57] and at 672, 646, 607, and 347.5 nm in pyridine.[40] In coordinating solvents, a solvent molecule coordinates at the axial position of the zinc atom,[283] so that the actual species in pyridine solution is Zn^{II}(py)Pc.[284] Bajema *et al.* measured the absorption spectra of a matrix-isolated ZnPc at liquid hydrogen temperature by using argon, krypton, xenon, methane, nitrogen, and sulfur hexafluoride.[34] It was observed that the width of the absorption lines increases in the order of Ar < CH_4 < Kr < Xe < N_2 < SF_6. The absorption and MCD spectra of Zn^{II}Pc in DMSO with and without added cyanide (CN^-) are shown in Figure 73.[204] The band at *ca.* 29 kcm^{-1} in DMSO splits into two upon addition of CN^-. Nyokong *et al.* performed a band deconvolution analysis of both the MCD and absorption data for ZnPc and its π-cation-radical species,[19] of which the latter is omitted here, since another chapter of this handbook describes this species in detail.[24] Figure 74 shows the absorption and MCD spectra of Zn(CN^-)Pc in the Q-band (left) and B-band (right) regions. The MCD signal corresponding to the Q band at *ca.* 15 000 cm^{-1} (670 nm) is a Faraday A-term, reflecting the degenerated states of the Q band. On the other hand, the vibronic bands in the 15 200–17 500 cm^{-1} region give Faraday B type MCD signals, unlike the case for porphyrins. In the B-band region (23 000–38 000 cm^{-1}), three MCD A-terms are deconvoluted at 25 874, 30 213, and 36 505 cm^{-1}, which can be assigned to the B, N, and L bands, respectively. Coordination of imidazole instead of cyanide to the zinc changes the shape of the

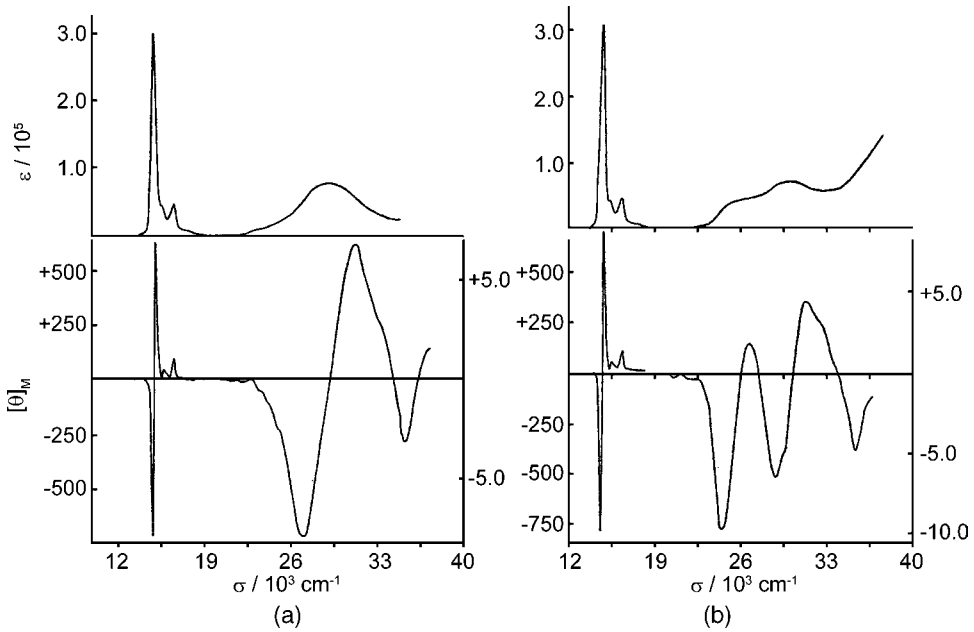

Figure 73. Absorption (top) and MCD (bottom) spectra of $Zn^{II}Pc$ in (a) DMSO and (b) DMSO plus NaCN. Stillman, M. J.; Thomson, A. J. *J. Chem. Soc. Faraday Trans. 2* **1974**, *70*, 790–804. Redrawn by permission of The Royal Society of Chemistry.

spectra slightly (not shown). In this case, the B-band region contains at least four MCD A-term components, which are deconvoluted at 27 150, 29 780, 35 440, and 40 650 cm^{-1}. These are assigned to the B, N, L, and C bands, respectively. Moment analysis of MCD data can estimate the value of the angular momentum associated with the photo-excitations. It has been proposed that the value of the angular momentum of the metalloPc is always less than that of the pure Pc ring, since the empty $1e_g(\pi^*)$ orbitals of the Pc can interact with the metal orbitals, reducing the value of angular momentum.[285] Nyokong *et al.* reported that the angular momentum of the ZnPc species follows the trend $Zn(CN^-)Pc > Zn(py)Pc > Zn(im)Pc$, and commented that the observed results can be rationalized on the basis of the effects of the π-acceptor and σ-donor strengths of the axial ligand.[19] The CN^- ion as an axial ligand is a good π acceptor, so that it lowers the energy of the metal d orbitals, which results in an increase in the angular momentum. On the other hand, imidazole is a strong σ donor, leading to a decrease in the angular momentum. Since pyridine is a weaker σ donor than imidazole, Zn(py)Pc gives an intermediate result. VanCott *et al.* measured the MCD and absorption spectra of ZnPc isolated in an argon matrix over the range 14 700–74 000 cm^{-1}.[35] The matrix spectra show sharper bands and much more structure than the gas-phase, thin-film, or

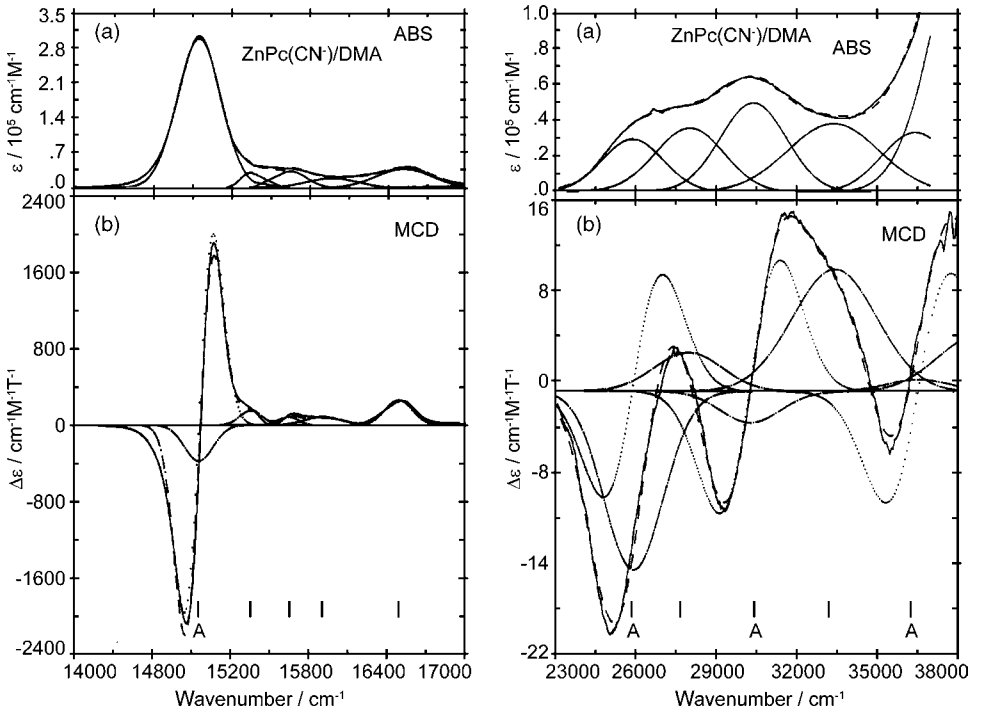

Figure 74. Band deconvolution analysis for ZnPc with added CN^- ligand in dimethylacetamide for the Q-band (left) and B-band (right) region: (a) absorption experimental data (solid line) and fitted result (dashed line) together with the deconvoluted individual bands; (b) MCD experimental data (solid line) and fitted result (dashed line) together with the individual *A* and *B* terms. solution spectra. Figure 75 (top left) shows the Q(0–0)-region absorption and MCD spectra of ZnPc/Ar at *ca.* 5 K. At least 12 peaks and shoulders are observed in the absorption data in this region, each of which is associated with a maximum or minimum in the MCD. Interestingly, the individual MCD signals correspond to Faraday B-terms. This is due presumably to the existence of a crystal-field-stabilized Jahn-Teller effect, resulting in the splitting of a doubly degenerate excited state, to give rise to a pair of B terms of opposite sign but equal magnitude. The spectra of the other energy region are also summarized in Figure 75. Readers should see Ref. 35 for a detailed discussion.

There are very few reports on CdPcs in the literature.[74,286–293] α-Octa-*n*-hexyl CdPc exhibits a Q band at 708 nm in hexane, which is characteristic of a metalloPc substituted with alkyl chains at the α-positions (Figure 76, lower).[288,289] Recently, Chambrier *et al.* have reported the first example of a di-cadmium tris-Pc triple-decker sandwich complex, which shows absorption peaks at 867, 718, 646, 599,

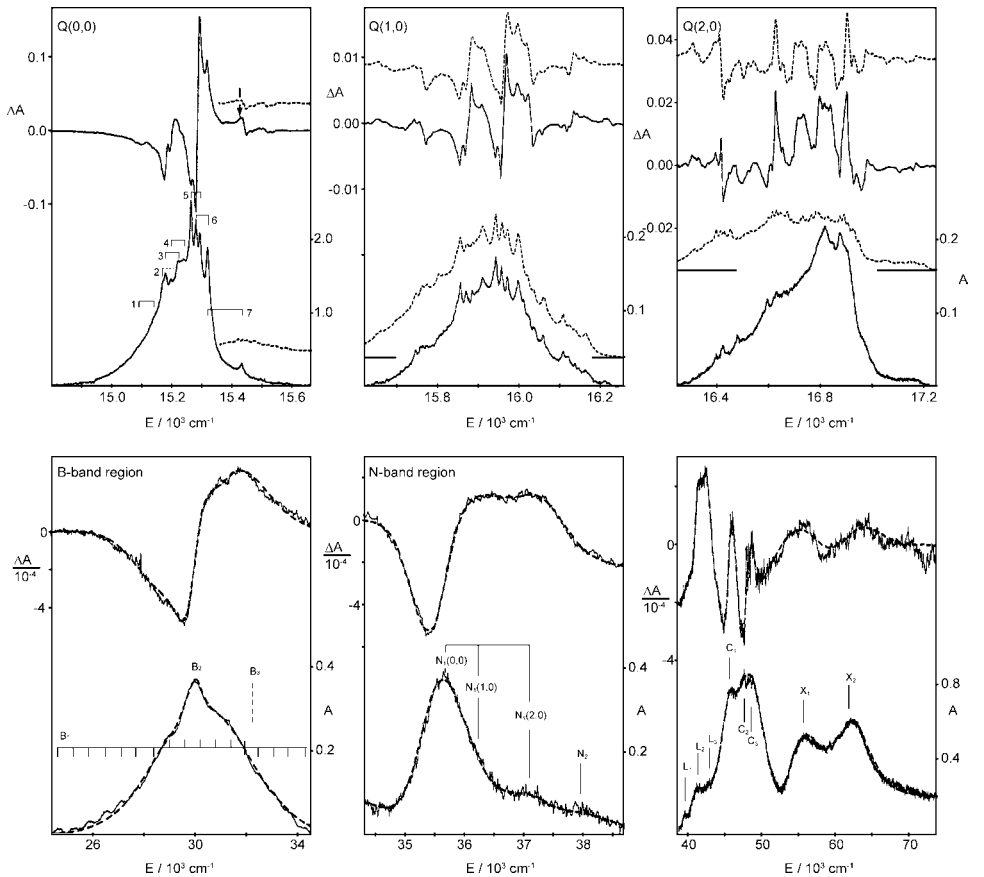

Figure 75. MCD (upper curve) and absorption spectra (lower curves) of ZnPc/Ar in the region of the Q(0,0) (top left), Q(1,0) (top center), Q(2,0) (top right), B-band (bottom left), N-band (bottom center), and vacuum ultraviolet (bottom right) envelope at *ca.* 5 K. *A* is absorbance and Δ*A* is the MCD per tesla. and 483 nm in hexane (Figure 76, upper).[288,289] The relative intensities of some of these bands vary somewhat in other solvents.

Phthalocyaninatobis(methylmercury), $(CH_3Hg^{I})_2Pc$, and $Hg^{II}Pc$ have been reported,[56,286,294,295] of which the former shows absorption peaks at 721, 654, 440, 342, and 285 nm.[294]

P. Group 13: B-subPc, AlPc, GaPc, InPc and TlPc

In 1972, Meller and Ossko serendipitously found that reactions of phthalonitrile with boron complexes such as BBr_3, BCl_3, and $PhBCl_2$ yielded macrocyclic

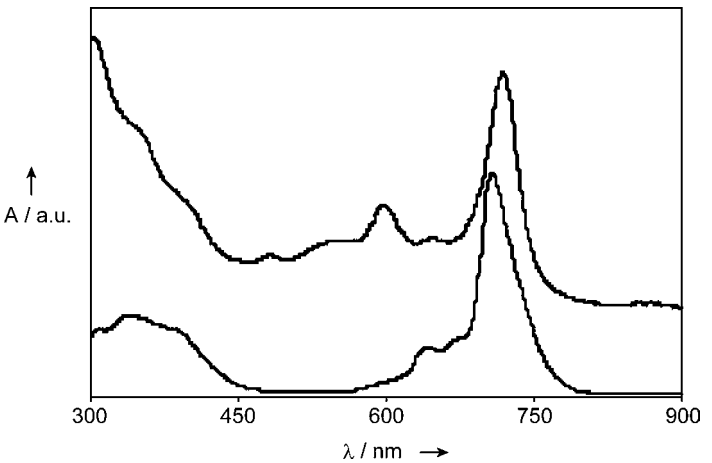

Figure 76. Absorption spectra of α-octa-*n*-hexyl CdPc (below) and the Cd_2Pc_3 type triple decker complex obtained therefrom (above) in hexane. Chambrier, I.; Hughes, D. L.; Swarts, J. C.; Isare, B.; Cook, M. J. *Chem. Commun.* **2006**, 3504–3506. Redrawn by permission of The Royal Society of Chemistry.

boron complexes, in which the boron is surrounded by three isoindole units linked by meso-nitrogen atoms, named subphthalocyanine (subPc).[296] There is a comprehensive review on subPcs by Torres and coworkers.[297] The boron atom in subPc has one axial ligand, and BBr-subPc and BCl-subPc show axial reactivity with nucleophiles, to yield axially-substituted subPcs. The corresponding boron Pc complex has not been reported to date. The absorption spectra of subPcs resemble that of typical metalloPcs in shape, irrespective of the ring contraction from the 18π-system of Pcs to the 14π-system, and the resultant cone-shaped aromatic ring deformation. The Q band generally appears at *ca.* 560–590 nm, while another band containing more than one transition is also observed in the Soret region. Compared with the Q band positions of the corresponding cyclic tetramers, namely TAPs, Pcs, and Ncs, the Q bands of subPcs shift to the blue by *ca.* 170–180, 120–130, and 100–120 nm, respectively. In addition, the molar extinction coefficients (ε) are smaller than those of the corresponding tetramers.[298] Figure 77 (dotted line) shows the absorption spectrum of BCl-subPc in $CHCl_3$.[299] An intense Q band appears at 565 nm, which is accompanied by an associated vibronic band at *ca.* 520 nm. In the Soret region, a peak at 305 nm was observed.[300] BF- and tri-*tert*-butyl BBr-subPcs exhibit Q bands at 570 and 567 nm, respectively.[296] BPh-subPc obtained from the reaction of phthalonitrile with triphenylboron (BPh_3) in the presence of DBU in naphthalene shows a Q band at 566 nm in toluene.[301] Thus, the effect of the axial ligand on the Q band position is relatively small. There are several reports on subazaporphyrins

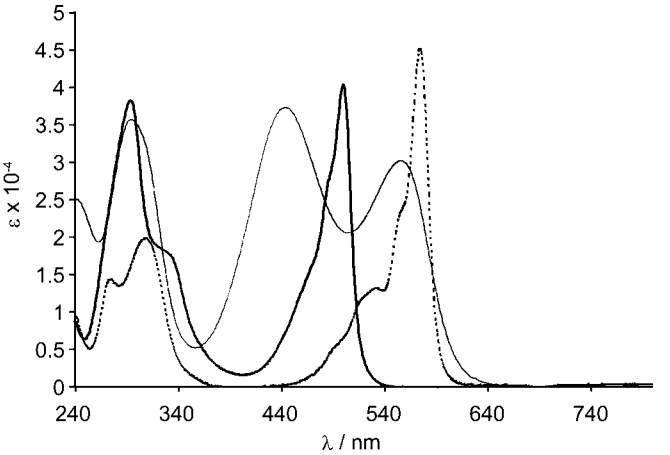

Figure 77. Absorption spectra of BCl-subPc (dotted line), BCl-(*n*-Pr)$_6$subAP (thick line), and BCl-($SC_{18}H_{37}$)subAP in $CHCl_3$. Redrawn from Rodríguez-Morgade, M. S.; Esperanza, S.; Torres, T.; Barberá, J. *Chem. Eur. J.* **2004**, *11*, 354–360.

(subAPs). Hanack mentioned that hexa-*p-tert*-butylphenyl BCl-subAP shows an absorption peak at 378 nm in toluene,[301] while Kobayashi tentatively assigned the Q band of a BBr-subAP derivative in $CHCl_3$ prepared from 1-(1,2,2-tricyanoethenyl)-2-trifluoromethylbenzne at 411 nm.[302] Torres and coworkers isolated a series of subAP derivatives. Figure 77 compares the absorption spectra of BCl-subPc (dotted line), BCl-(*n*-Pr)$_6$subAP (thick line), and BCl-($SC_{18}H_{37}$)subAP in $CHCl_3$.[299] The Q-band region of the former two complexes are very similar in shape. BCl-(*n*-Pr)$_6$subAP shows absorption peaks at 501 and 295 nm corresponding to the Q and Soret bands, respectively. On the other hand, the spectrum of BCl-($SC_{18}H_{37}$)subAP has a different shape to that of the other two derivatives, exhibiting a peak in the Soret region (298 nm) in addition to two broad bands at 444 and 559 nm. The band at 444 nm was assigned to $n \rightarrow \pi^*$ transitions from the peripheral sulfur lone-pair electrons to a π^* orbital of the macrocycle, while the band at 559 nm was assigned as the Q transitions. The peripheral thioalkyl groups shift the Q band to the red by *ca.* 60 nm. The same group also reported that fluoro subAP derivatives, namely BF-subAPs, exhibit a Q band in the *ca.* 500–570 nm region, depending on the peripheral substituents, although the introduction of a fluorine atom into the axial position itself has no significant effect on the Q band position.[303] The first X-ray structure of a subAP derivative was reported for BOH-Et$_6$subAP, which shows a Q band at 496 nm in hexane.[304] A comparative study of a series of ring-expanded subPc analogs clearly indicates a tendency for both the Soret and Q bands to shift to longer wavelengths and increase in intensity with increasing size of the π-system. Thus, the Q band

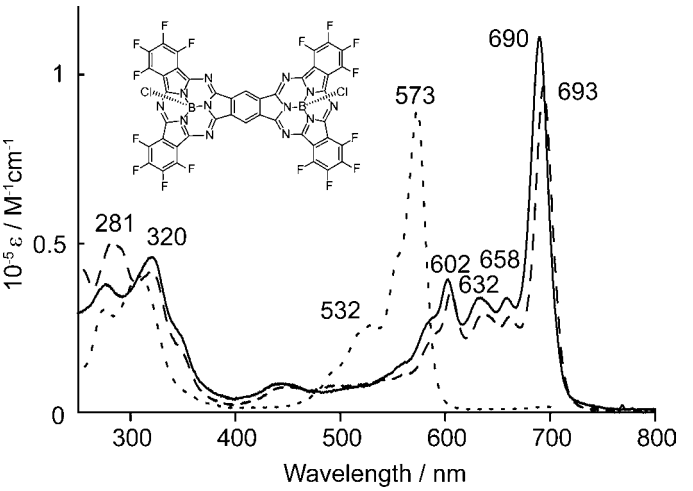

Figure 78. Absorption spectra of *cis* (solid line) and *trans* (dashed line) forms of dimeric BCl-F_{16}subPc in $CHCl_3$. The spectrum of the monomeric form, BCl-F_{12}subPc is also shown as a reference (dotted line). Redrawn from Fukuda, T.; Stork, J. R.; Potucek, R. J.; Olmstead, M. M.; Noll, B. C.; Kobayashi, N.; Durfee, W. S. *Angew. Chem. Int. Ed.* **2002**, *41*, 2565–2568.

of subnaphthalocyanines (subNcs) appears at 650 and 667 nm, for BPh-subNc and BBr-subNc, respectively.[298,301,302]

A binuclear subPc dimer which shares a central benzene ring was first prepared as a mixture of *cis* and *trans* isomers by Kobayashi in 1991.[305] A decade later, two groups have succeeded independently in separating these two isomers by using the fluoro-substituted dimer.[306,307] As shown in Figure 78, the absorption bands of the dimer species in the visible region are shifted to the red by *ca.* 120 nm and have more structure compared to the monomer species, BCl-F_{12}subPc, indicating an extension of the π-system. Both *cis* and *trans* isomers show similar-shaped spectra, although the Q band of the *trans* isomer appears at longer wavelength compared to the *cis* isomer, by *ca.* 3–4 nm, while the absorbance on the shorter-wavelength side of the Soret band is higher for the *trans* isomer.[307] As an extension, trinuclear subPc trimers have also been synthesized, and their absorption spectra reported.[308] The Q band of a μ-oxo dimer, (tri-*tert*-butyl subPc)$_2$O, shifts to the blue, while the position of the Soret band is virtually unchanged. The blue-shift of the Q band is explained on the basis of an exciton interaction.[302,309] On the other hand, Torres and coworkers claimed that the shape of the absorption spectrum of a subPc dimer having a direct B–B linkage is practically identical to that of the monomer species.[310]

AlPcs are of interest because of their possible application in the area of photodynamic therapy (PDT). The aluminum ion in AlPc is generally trivalent, and thus

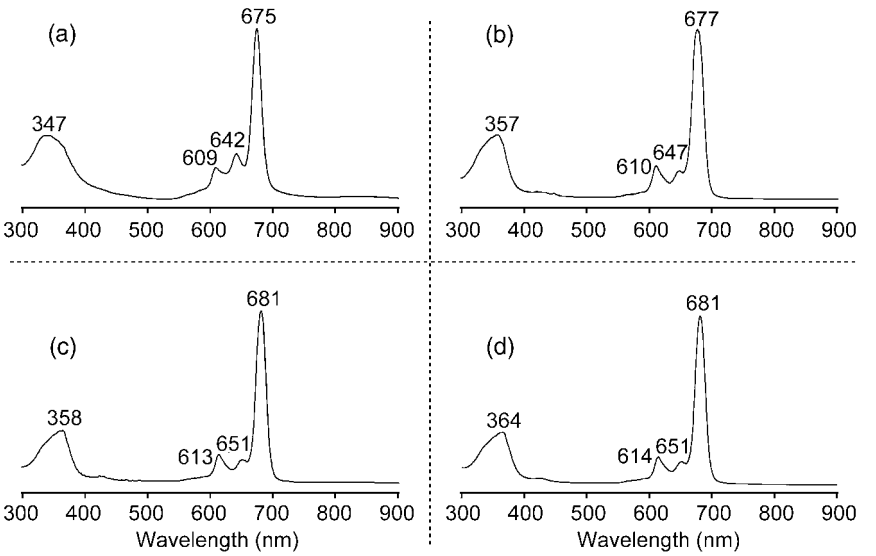

Figure 79. Absorption spectra of AlPcCl in (a) THF, (b) DMF, (c) DMSO, and (d) pyridine. Redrawn with permission from Ou, Z. P.; Shen, J.; Kadish, K. M. *Inorg. Chem.* **2006**, *45*, 9569–9579. Copyright 2006 American Chemical Society.

neutral AlPc has an axial ligand. As intuitively expected, and empirically and theoretically supported, the structure of typical $Al^{III}LPc$ takes on a dome-shaped C_{4v} symmetry.[311] Unsubstituted AlClPc and Al(OH)Pc show band peaks at 691, 665, 622, 597 and 576 nm in 1-chloronaphthalene, and 672 nm in DMF, respectively.[57,312] AlBrPc and AlIPc are also known.[313] The axial ligand can be replaced with various alcohols. For example, tri-*n*-hexylsiloxy-substituted AlPc is obtained by reacting tri-*n*-hexylchlorosilane with Al(OH)Pc, and has absorption band peaks appearing at 672, 638, 606, and 345 nm in THF.[314] Homborg and Murray isolated a $[AlF_2Pc]^{2-}$ species by treatment of AlClPc in dichloromethane with TBAF·$3H_2O$, which is subject to hydrolysis, to give $[(AlFPc)_2O]^{2-}$.[315] Figure 79 depicts the absorption spectra of AlClPc in THF, DMF, DMSO, and pyridine.[316] The spectral envelopes are typical of "normal" Pcs. An intense Q band appears at 675–681 nm depending on the solvent, accompanied by two additional bands between 609 and 651 nm. The B band is located in the 347–364 nm region. There is a correlation between the band energies and donor number of the solvent, where the B and Q bands shift bathochromically and show an increase in molar extinction coefficients (ε) upon changing from the low-donor THF to high-donor pyridine. Electrochemical study revealed that AlClPc(solvent) is the effective species. Addition of TBAF·$3H_2O$ to a THF solution of AlClPc produces a three-step spectral change, of which the first step (0–0.35 equivalent of F^-) can be attributed to the formation of the μ-oxo dimer, $(AlPc)_2O$.

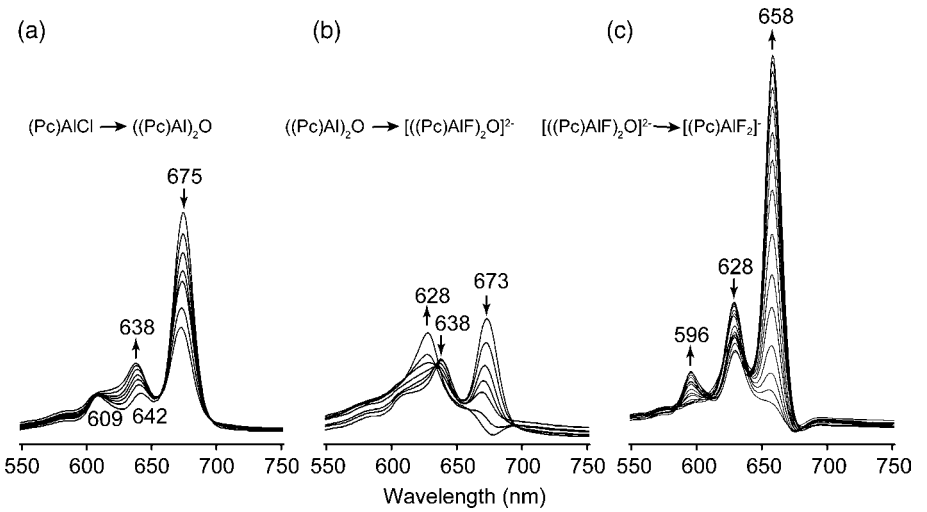

Figure 80. Spectroscopically monitored titration of AlPcCl with TBAF·3H_2O in THF: (a) first step (0–0.35 equiv of F^-), (b) second step (0.35–5.2 equiv of F^-), and (c) third step (5.2–86.4 equiv of F^-). Redrawn with permission from Ou, Z. P.; Shen, J.; Kadish, K. M. *Inorg. Chem.* **2006**, *45*, 9569–9579. Copyright 2006 American Chemical Society.

Accordingly, the initial Q band at 675 nm decreases in intensity and shifts slightly to the blue (673 nm) during the titration, while a new band appears at 638 nm. Further addition of TBAF·3H_2O (0.35–5.2 equivalent of F^-) causes the disappearance of the band at 673 nm, and the appearance of a single, new band at 628 nm, suggesting the formation of the $[(AlFPc)_2O]^{2-}$ species. The final step (5.2–86.4 equivalent of F^-) generates the six-coordinate fluoride complex, $[AlF_2Pc]^{2-}$, which is monitored by the appearance of an intense Q band at 658 nm (Figure 80). The spectrum of $[AlF_2Pc]^{2-}$ is similar to that of ZnPc and MgPc in shape. Similar spectral changes are also observed for a TBAOH titration, although there is no spectral evidence for the formation of a μ-oxo dimer nor six-coordinate $[Al(OH)_2Pc]^{2-}$. In the original paper, it was concluded that the final spectrum, exhibiting bands at 668, 638, and 601 nm, in a TBACN titration arises from Al(CN)Pc(THF). Reinot *et al.* described that the Q-band of AlPc splits into two components.[317] Although the formation of a dimer species and the presence of coordinated water molecules are possible reasons for the observed Q-band splitting, TDDFT calculations demonstrated that the origin of the splitting is largely related to a change in the N–C bonds caused by interaction between the surroundings and the molecule.[318] Reduction of AlClPc with 1.1 equivalents of Na/Hg in THF yields the stable radical $AlPc(THF)_2$, whose absorption peak appears at 649 nm.[319]

Similar to AlPcs, the gallium ion in GaPc is generally trivalent, and chlorogallium (GaCl) derivatives are the most common. No CT transitions are expected

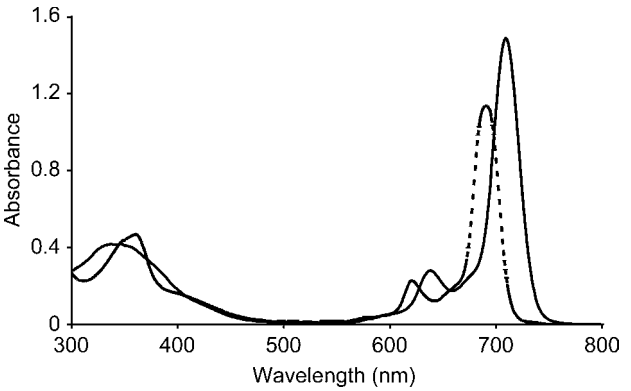

Figure 81. Absorption spectra of α-tetra-phenoxy GaClPc (solid line) and β-tetra-phenoxy GaClPc (dashed line) in DMSO. Redrawn from Durmuş, M.; Nyokong, T. *Tetrahedron* **2007**, *63*, 1385–1394. Copyright 2007, with permission from Elsevier.

for complexes of this category. Nyokong and coworkers have developed a variety of GaPc derivatives in anticipation of the application of these complexes to PDT,[320–324] while Hanack and coworkers are interested in GaPcs as optical limiting (OL) materials.[325–330] Unsubstituted Ga^{III}ClPc exhibits a Q band at 680, 678, and 677 nm in DMSO, DMF, and THF, respectively.[321] Figure 81 shows the absorption spectra of α-tetraphenoxy Ga^{III}ClPc (solid line) and β-tetraphenoxy Ga^{III}ClPc (dashed line) in DMSO.[323] The spectra have the general shape of metalloPcs, showing Q bands at 712 nm (α-derivative) and 691 nm (β-derivative). The α-substituted derivative has its Q band at slightly longer wavelength compared to the β-substituted derivative. In addition, some differences in spectral shape are observed in the 300–400 nm region between the α and β derivatives. Interestingly, the Q band of β-octaphenoxy GaClPc occurs at 687 nm in DMSO, which is an even shorter wavelength than that of the β-tetraphenoxy derivative (691 nm).[321] Figure 82 compares the absorption spectra of tetra-*tert*-butyl GaClPc (dashed line) and tetra-*tert*-butyl Ga(*p*-trifluoromethylphenyl)Pc (solid line).[326] As shown in the figure, both spectra resemble each other in shape, in particular, in the Q-band region, indicating that the electronic structure of Ga^{III}Pc is relatively independent of the axial ligand. The Q band position is not significantly changed by μ-oxo dimerization. For example, tetra-*tert*-butyl GaClPc and [tetra-*tert*-butyl GaPc]$_2$O show Q bands at 693 and 692 nm in toluene, respectively.[329,331]

The indium ion in InPc is also trivalent,[322,323,325,329,332–345] and the absorption properties of InPcs resemble those of GaPcs. The Q band of tetra-*tert*-butyl InClPc appears at 695 nm in toluene, while α-octathiohexyl InClPc extends to 836 nm in THF.[338] The axial chloride ligand can be replaced with an aryl or alkyl group by employing a Grignard reaction.[333] Figure 83 demonstrates how the absorption

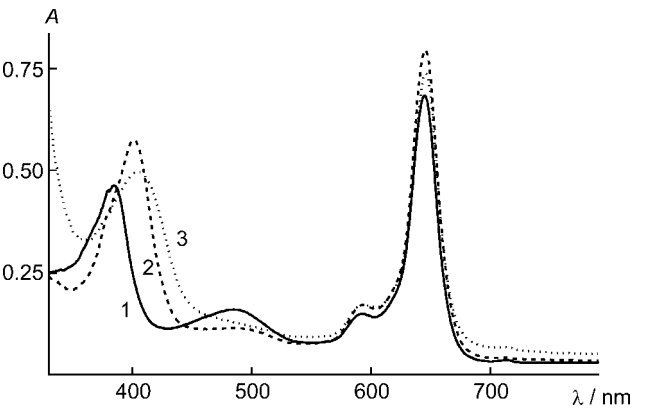

Figure 83. Absorption spectra of octaphenyl InClTAP (1), InPhTAP (2), and In(*n*-Bu)TAP (3) in benzene. Redrawn from Mal'chugina, O. V.; Stuzhin, P. A. *Russ. Chem. B* **2002**, *51*, 2261–2267 with kind permission from Springer Science and Business Media.

spectra of octaphenyl In(L)TAP differs in shape, depending on the axial ligand, where L = Cl, Ph, or *n*-Bu.[333] The main differences in the spectrum occur in the B band region, while the position of the Q band remains virtually unchanged (645 nm). The Q band can be assigned as the $a_{1u} \rightarrow e_g$ transitions. Since the a_{1u} orbital has zero coefficients at the coordinated pyrrole nitrogen atoms, the a_{1u} orbital does not influence the Q band position significantly. The formation of the μ-oxo dimer leads to a small blue shift of the Q band and a red shift of the

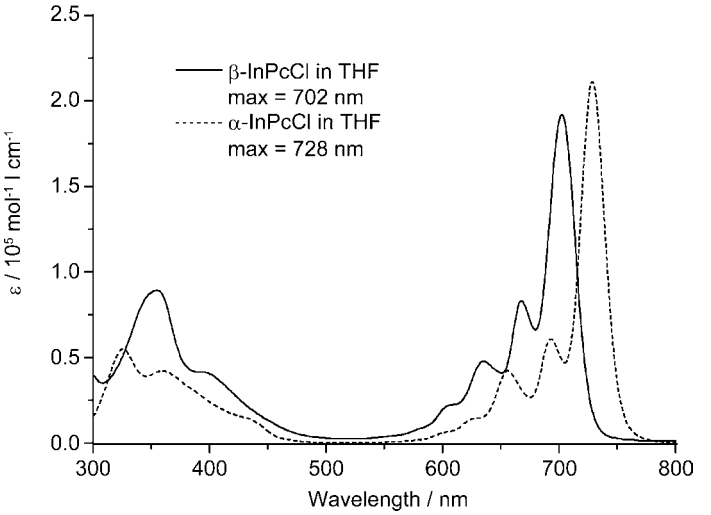

Figure 84. Absorption spectra of α-tetraalkoxy InClPc and β-tetraalkoxy InClPc in THF. The alkoxy group is $-OCH_2CH(CH_2CH_3)_2$. Redrawn from Wang, S. Q.; Gan, Q.; Zhang, Y. F.; Li, S. Y.; Xu, H. J.; Yang, G. Q. *ChemPhysChem* **2006**, *7*, 935–941.

B band.[325] The axially bridged In–In Pc dimer, namely [tetra-*tert*-butyl InPc]$_2$·2tmed (tmed = *N,N,N′,N′*-tetramethylethylenediamine), was first reported by Hanack and coworkers.[346] Spectroscopic studies clarified that the dimerization does not greatly affect the spectral profile, so that the main differences between the spectral features of the monomer and dimer are associated with changes of the molar extinction coefficients due to the different number of absorbing Pc rings per molecular unit.[341] Figure 84 compares the absorption spectra of tetra α- or β-alkoxy InClPcs as an example of representative absorption shapes of InPcs.

Barrett *et al.* reported that double-decomposition reactions between Li_2Pc and thallium hydroxide gave a bright green precipitate, presumably the TlPc complex.[56] However, no further spectroscopic investigations on TlPcs are found in the literature.

Q. Group 14: SiPc, GePc, SnPc, $SnPc_2$ and PbPc

SiPcs have two axial ligands above and below the Pc plane. Only the tetravalent species, $Si^{IV}Pc$, is known to date. Optical data for SiPcs are normal in shape, and are similar to that of MgPc (Figure 85, dashed line).[347,348] $SiCl_2Pc$ exhibits a Q band at 699 nm in pyridine, which is shifted to 671 nm when the two axial ligands are replaced with two hydroxyl groups. The axial ligands can be readily replaced with various substituents. For example, axial substitution by two $OSiMe_3$ groups

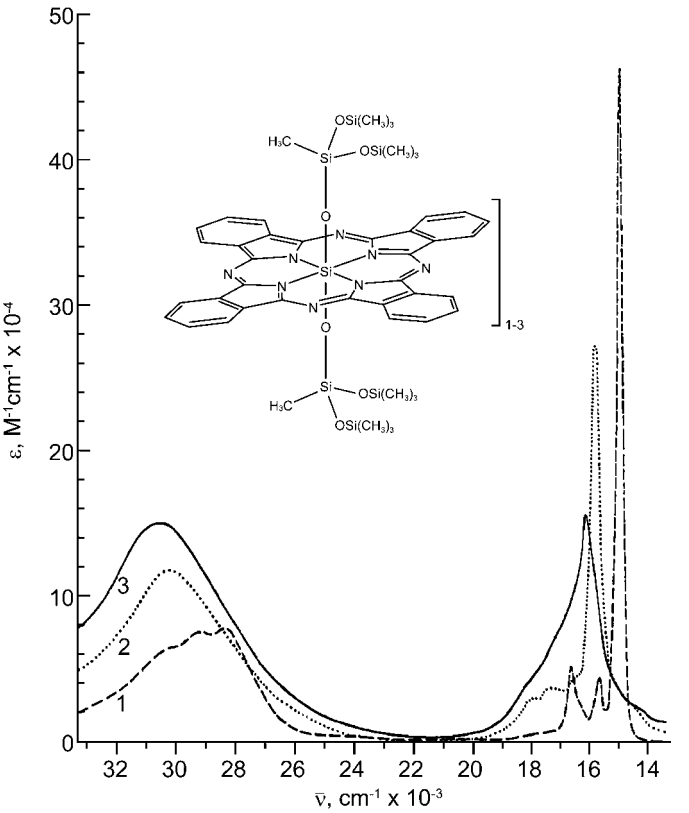

Figure 85. Absorption spectra of silicon Pc monomer (dashed line) and μ-oxo dimer (dotted line) and trimer (solid line). The axial ligands are $OSi(CH_3)(OSi(CH_3)_3)_2$. Redrawn with permission from Kane, A. R.; Sullivan, J. F.; Kenny, D. H.; Kenney, M. E. *Inorg. Chem.* **1970**, *9*, 1445–1448. Copyright 1970 American Chemical Society.

is achieved by reacting $SiPc(OH)_2$ with $(Me_3Si)_2NH$ in dry pyridine.[349] The resultant $SiPc(OSiMe_3)_2$ shows a Q band at 667 nm in benzene. Treatment of $SiPcCl_2$ with primary Grignard reagents in the dark gives the corresponding diorgano Pc derivatives, $SiPcR_2$.[350] A similar procedure using monoorgano-monochloro precursors, $SiPcR^1Cl$, gives unsymmetrical organo SiPcs, $SiPcR^1R^2$. The Q band of $SiPc(C_8H_{17})_2$ appears at 783 nm in cyclohexane. In the case of the bis(alkylcarboxylato)-substituted complex, $SiPc(OCOC_8H_{17})$, the Q band appears at 697 nm in $CHCl_3$. These examples indicate that the Q band position of SiPcs is relatively sensitive to their axial substituents. Thermal reaction of $SiPc(OH)_2$ yields a dimer, trimer, and oligomers having siloxane bonds. As shown in Figure 85, the spectral envelope is sensitive to the number of Pc rings per molecule. A blue shift of the Q and B bands with increasing chain length was observed, which was mainly attributed to exciton interactions between the constituted Pc rings. Thus, the Q band at

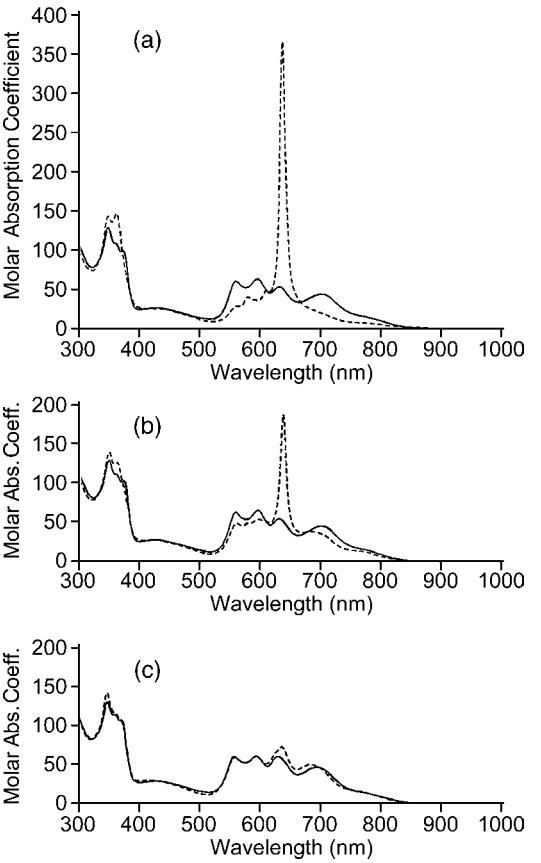

Figure 86. Absorption spectra of (a) $[(H_{17}C_8O)_8SiPc(OSiMe_2\text{-}tert\text{-}Bu)_2]_2O$, (b) $[(3,7\text{-}Me_2\text{-}C_8H_{15}O)_8SiPc(OSiMe_2\text{-}tert\text{-}Bu)_2]_2O$, and (c) $[(2\text{-}Et\text{-}C_6H_{12}O)_8SiPc(OSiMe_2\text{-}tert\text{-}Bu)_2]_2O$ in benzene (dashed lines) and CH_2Cl_2 (solid lines) at 25 °C. Redrawn with permission from Kleinwächter, J.; Hanack, M. *J. Am. Chem. Soc.* **1997**, *119*, 10684–10695. Copyright 1997 American Chemical Society.

15 040 cm^{-1} (665 nm) for the monomer shifts to 15 880 cm^{-1} (630 nm), 16 180 cm^{-1} (618 nm), and 16 270 cm^{-1} (615 nm) for dimer, trimer, and tetramer, respectively.[347] Kleinwächter and Hanack reported that the torsion angle between adjacent Pc rings in μ-oxo SiPcs depends on the choice of peripheral substituents.[351] Figure 86 demonstrates the solvatochromic behavior of octaalkoxy-substituted μ-oxo SiPc dimers. The spectra recorded in CH_2Cl_2 are quite different from those of typical metalloPcs, with all the dimer species showing a multiply split Q-band comprising at least five transitions between 500 and 900 nm in CH_2Cl_2 (Figure 86, solid lines). Nonaromatic solvents such as acetone, diethyl ether, THF, $CDCl_3$, and *n*-hexane also give similar results. In contrast, the spectral envelopes depend on the peripheral substituents (R) when recorded in benzene. When R = OC_8H_{17}, a

sharp Q band appears at 639 nm with accompanying tails on both sides (Figure 86a, dashed line), while no such clear Q band can be observed even in benzene when R = 2-Et-OC_6H_{12} (Figure 86c, dashed line). An intermediate result was obtained when R = 3,7-Me_2-OC_8H_{15} (Figure 86b, dashed line). The authors in Ref. 351 concluded that the torsion angle between the two Pc rings is *ca.* 20–30° in nonaromatic solvents. On the other hand, the species which gives a sharp Q band has a fully staggered or eclipsed conformation. Absorption data on silicon triazacorrole and silicon tetrabenzotriazacorrole have been reported independently by the Hanack and Kobayashi groups.[352–355]

The chemistry of GePcs is analogous to that of the SiPcs. $Ge^{IV}Cl_2Pc$ is synthesized by the reaction of germanium tetrachloride with H_2Pc,[356] 1,3-diiminoisoindoline,[357] or phthalonitrile.[358] The axial ligands can be replaced with dihydroxy and further by diphenoxy groups, to give $Ge^{IV}(OH)_2Pc$ and $Ge^{IV}(OPh)_2Pc$, respectively.[356] Unsubstituted $Ge(OH)_2Pc$ exhibits absorption peaks at 676, 645, 607, 415, 358, and 315 nm in pyridine.[358] $Ge(OSi(n\text{-}C_6H_{13})_2Pc$ shows a Q band at 673.7 nm (14 843 cm^{-1}) in toluene, which is red-shifted by *ca.* 120 cm^{-1} compared to the corresponding silicon derivative.[359] Figure 87 compares the absorption spectra of $Si(OH)_2Pc$ (dashed line), $Ge(OH)_2Pc$ (dotted line), and $Sn(OH)_2Pc$ (solid line) in pyridine.[358] The Q band shifts to the red in the order of SiPc → GePc → SnPc, which is attributed to the decrease in electronegativity of the central metal in this order. Lower electronegativity causes

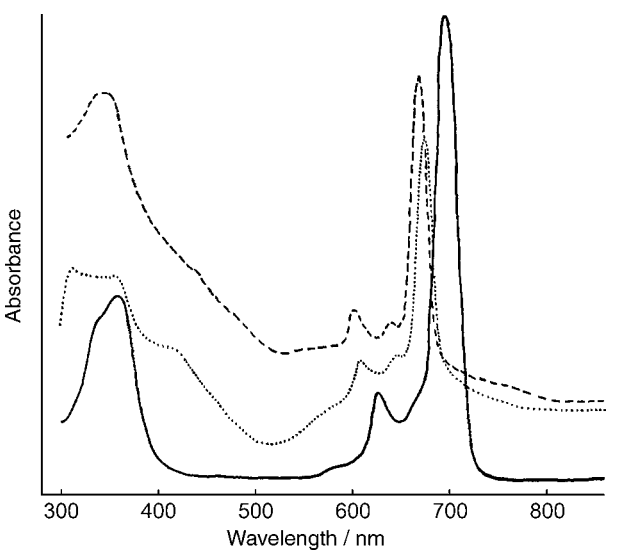

Figure 87. Absorption spectra of $Si(OH)_2Pc$ (dashed line), $Ge(OH)_2Pc$ (dotted line), and $Sn(OH)_2Pc$ (solid line) in pyridine. Redrawn with permission from Dirk, C. W.; Inabe, T.; Schoch, K. F.; Marks, T. J. *J. Am. Chem. Soc.* **1983**, *105*, 1539–1550. Copyright 1983 American Chemical Society.

a shift of charge on the metal onto the Pc ring, and as a consequence, the $a_{2u}(\pi)$ orbital increases in energy. GePcs are also able to form μ-oxo dimer, trimer, and oligomers, which show the same trend in spectral envelope shape as the silicon congeners. $\{[(CH_3)_3SiO]_2(CH_3)SiO\}(Ge^{IV}PcO)_2\{Si(CH_3)[OSi(CH_3)_3]_2\}$ exhibits a Q transition at 15 840 cm^{-1}, while the Q band of the corresponding monomer species appears at 14 970 cm^{-1}.[347,360] Hohol and Urban synthesized μ-oxo GePc polymers, $[GePcO]_n$, by irradiating a solution of $GeCl_2Pc$ with ultrasonic energy in the presence of a germanium chalcogenide.[357] Figure 88 shows the absorption spectral changes during the sonication of $GeCl_2Pc$. With increasing sonication time, a hypsochromic shift of the Q band from 690 to 640 nm is observed, demonstrating a general tendency observed for μ-oxo oligomerization of Pc derivatives.[357] Stover *et al.* reported that a reduction reaction of $Ge^{IV}Cl_2Pc$ with either $NaBH_4$ or $SnCl_2$ yielded $Ge^{II}Pc$.[361] This complex

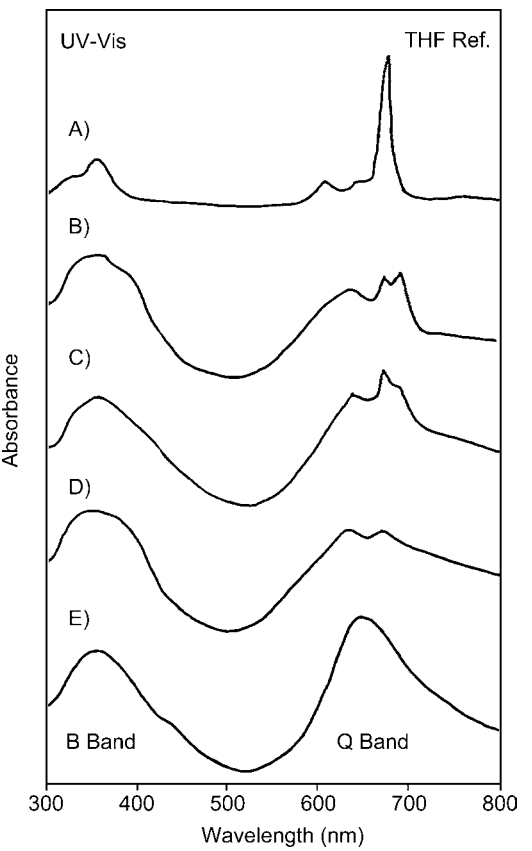

Figure 88. Absorption spectral changes of $GeCl_2Pc$ during the course of sonication in the presence of sodium telluride, for periods of: A, 0 minutes; B, 15 minutes; C, 30 minutes; D, 60 minutes; and E, 120 minutes. Figure 89. Absorption spectra of metalloid TBC derivatives in isopropyl alcohol. Redrawn with permission from Fujiki, M.; Tabei, H.; Isa, K. *J. Am. Chem. Soc.* **1986**, *108*, 1532–1536. Copyright 1986 American Chemical Society.

shows intense absorption bands at 445 and 330 nm, together with a shoulder at 415 nm in pyridine, in addition to intense bands and shoulders at 655, 602sh nm. However, the compound was later shown instead to be germanium triazatetrabenzocorrole hydroxide, Ge(OH)TBC.[362] Figure 89 exemplifies the absorption spectra of gallium, aluminum, germanium, and silicon complexes of the TBC derivatives. Recently, Cissell *et al.* reinvestigated the synthesis of $Ge^{II}Pc$, and reported that the reaction of $GeCl_2$(dioxane) with $K_2Pc(DMF)_4$ in THF gives a new germanium complex, which has a complicated-shaped absorption spectrum, suggesting that it has a 20-π electronic configuration, i.e. $Ge^{IV}Pc(4–)$, (Figure 90, black line).[363] After exposure to air, the complex shows clear Q-like bands in the 600–700 nm region (Figure 90, gray line).

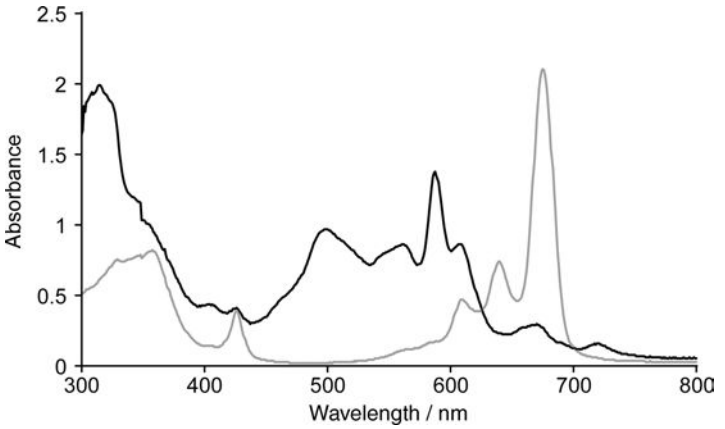

Figure 90. Absorption spectra of $Ge(py)_2Pc$ in pyridine (black line) and spectrum of the same sample in pyridine after exposure to air (gray line). Redrawn with permission from Cissell, J. A.; Vaid, T. P.; DiPasquale, A. G.; Rheingold, A. L. *Inorg. Chem.* **2007**, *46*, 7713–7715. Copyright 2007 American Chemical Society.

$Sn^{II}Pc$ and $Sn^{IV}Pc$ species have been reported to date, and their X-ray structures are also available.[364,365] $Sn^{IV}Cl_2Pc$ shows absorption peaks at 690, 625, and 270 nm in the vapor phase, with a spectral window in the 400–600 nm region (Figure 91).[21] $Sn^{IV}(OH)_2Pc$ and $Sn^{II}Pc$ exhibit absorption bands at 696, 665, 626, 360, and 340 nm in pyridine,[358] and at 682 and 359 nm in ethanol,[366] respectively. Similarly to SiPc and GePc, a hypsochromic shift of the Q transition is observed on formation of the μ-oxo oligomers, although the shift is quite small (695 nm for $[SnPcO]_n$, and 696 nm for the monomer).[358] A series of homo- and hetero- μ-oxo dimers, namely Si–O–Si, Si–O–Ge, and Si–O–Sn complexes, show a bathochromic shift of the Q band in this order.[359] Nyokong and coworkers have reported the spectroscopic properties of some substituted SnPc derivatives.[367–369] Sn^{IV} also forms a double-decker-type binuclear $Sn^{IV}Pc_2$.[40,74,370–372] X-ray crystallography clarified that the two Pc moieties are rotated by 42° with respect to each other.[371] Since the tin center is tetravalent, unlike the tervalent state of lanthanide ions, the neutral form can be described as Pc(2–)SnPc(2–). Therefore, the absorption properties of neutral $Sn(Pc)_2$ resemble those of $Zr(Pc)_2$ rather than $[Ln(Pc)_2]^0$. Figure 92 shows the absorption and MCD spectra of $Sn^{IV}Pc_2$.[372] A splitting of the Q band is observed, of which the lower energy component has a smaller intensity. The B band also shows a notable blue shift compared to the monomer species, with a longer wavelength tail extending to *ca.* 22 kcm^{-1}. The MCD spectrum shows dispersion type A-terms for the Q and B bands, indicating degenerate excited states corresponding to these bands. Importantly, A-terms are observed for both of the split Q bands. As described above (Section E), the exciton theory is insufficient to fully understand

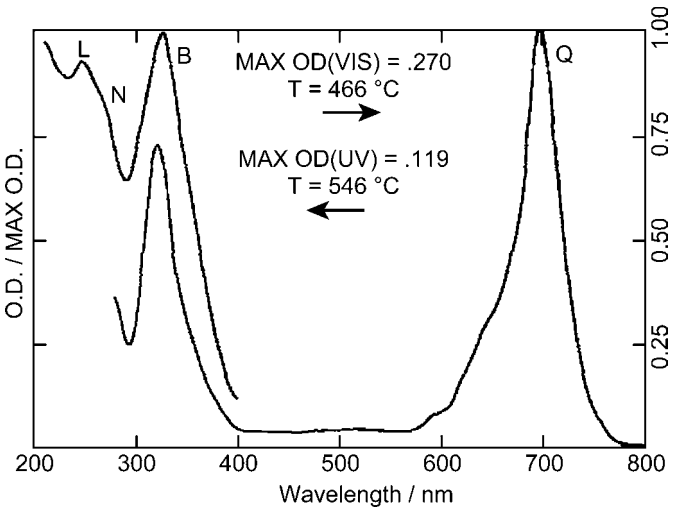

Figure 91. Vapor-phase absorption spectrum of $Sn^{IV}Cl_2Pc$. Redrawn from Edwards, L.; Gouterman, M. *J. Mol. Spectrosc.* **1970**, *33*, 292–310. Copyright 1970, with permission from Elsevier.

Redrawn with permission from Ohno, O.; Ishikawa, N.; Matsuzawa, H.; Kaizu, Y.; Kobayashi, H. *J. Phys. Chem.* **1989**, *93*, 1713–1718. Copyright 1989 American Chemical Society.

these spectral features, and the inclusion of charge resonance terms is inevitably necessary to theoretically reproduce the experimental results.

In the case of PbPc complexes, only $Pb^{II}Pc$ species have been isolated. X-ray crystallography clarified that the Pc ring in PbPc adopts a shuttlecock conformation, with the lead ion located above the convex side and displaced by 0.906 Å (monoclinic and tetragonal forms) or *ca.* 1.28 Å (triclinic form) from the mean-plane of the four pyrrole nitrogen atoms.[373–375] Unsubstituted PbPc shows absorption peaks at 698 (Q), 640 (Q(1–0)), 332.5 (B), 280 (N), 245 (L), and 207.5 (C) nm in the vapor phase (Figure 93).[21] Figure 94 shows the absorption spectrum of α-tetrapentoxy PbPc in $CHCl_3$.[376] The spectrum has a shape typical of metalloPcs for the B and Q band regions, with the B and Q bands appearing at 333 and 751 nm, respectively, as unsplit single bands. The authors in Ref. 376 assigned the weak absorption band at around 431–437 nm as an n-π^* transition due to the presence of the alkoxy groups. However, this assignment remains a matter of debate, because even unsubstituted PbPc shows similar spectral envelopes in this region (Figure 93). In addition, other substituted PbPc complexes, such as thioalkyl–,[338] phenyl–,[377] and nitro-substituted[378–380] derivatives, also exhibit weak absorption bands in this region, indicating that the band is inherent in PbPcs rather than originating from substituents. Zhang *et al.* performed time-dependent DFT calculations in order to calculate the electronic absorption spectra of metalloPcs of group 14, by employing a combination of the B3LYP functional and the LANL2DZ basis set.[381] According to their results, the band in the 400–500 nm region consists mainly of the HOMO–1 → LUMO transition, in which the HOMO–1 orbital of PbPc is mainly composed of the

d_{z^2} orbital of the lead with some subsidiary contribution from the p_z orbital of the nitrogen atoms, i.e. the band in this region has an MLCT character. Yaraşir *et al.* performed spectroelectrochemistry of octapropyl PbTAP, which revealed that the complex is demetalated during the controlled potential coulometry measurement after the first reduction couple of the complex (not shown).[382]

R. Group 15: PPc, AsPc, SbPc, BiPc, $BiPc_2$ and Bi_2Pc_3

In 1981, Gouterman *et al.* reported the synthesis of $P^{III}Pc$ and $P^{IV}Pc$ by the reaction of H_2Pc with py-PBr_3, and commented that the absorption spectrum of $P^{III}Pc$ shows an unusual sharp band at 442 nm.[366,383] However, Fujiki *et al.* pointed out later that the "$P^{III}Pc$" species is in fact a tetrabenzotriazacorrole (TBC) complex, P^{V}=O(TBC).[362] Figure 95 shows the absorption spectra of unsubstituted P^{V}=O(TBC) in pyridine (solid line) and in trifluoroacetic acid (TFA, dashed line).[384] In pyridine, at least five components can be recognized in the Q-band region, while a marked bathochromic shift is observed in TFA compared to pyridine. The sharp, intense bands at *ca.* 440 nm are characteristic features of the spectrum in pyridine. These spectral characteristics have similarities to those reported by Gouterman *et al.*[383] and to other references on TBC.[362,385–387] Examples of authentic phosphorus Pcs are rare.[384,388,389] The ionic $P^{V}Pc$ species, $[P^{V}(OH)_2Pc]^{+}(OH)^{-}$, shows a typical UV-vis absorption spectrum unlike TBC (669, 640, 602, 353 nm in pyridine). Upon addition of HCl to the complex dissolved in DMF, a bathochromic shift of the Q band is observed (not shown), which is presumably due to the formation of the $[P^{V}(OH)(OH_2)]^{2+}$ species.[384]

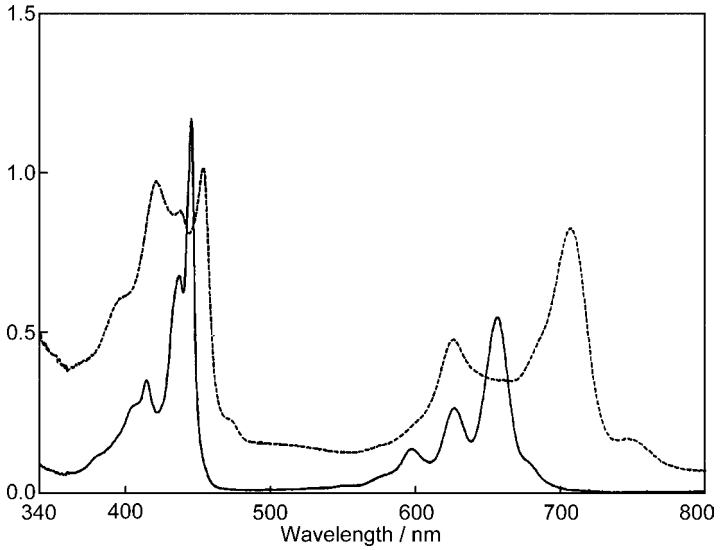

Figure 95. Absorption spectra of unsubstituted P^{V}=O(TBC) in pyridine (solid line) and in trifluoroacetic acid (dashed line). Redrawn from Li, J. Z.; Subramanian, L. R.; Hanack, M. *Eur. J. Org. Chem.* **1998**, 2759–2767.

Very few AsPc complexes have been described in the literature.[165,390–393] $As^{III}ClPc$ shows absorption bands at 580 and 340 nm in DMF.[165,366]

In analogy to PPcs, both Sb^{III} and Sb^{V} species are available for SbPcs. The low-valent $[Sb^{III}Pc]^{+}F^{-}$ can be easily converted to the high-valent species, $[Sb^{V}(OH)_2Pc]^{+}F^{-}$, by treatment of the low-valent complex with stoichiometric amounts of 30% hydrogen peroxide.[394] Figure 96 shows the absorption spectra of $[Sb^{III}Pc]^{+}F^{-}$ (top) and $[Sb^{V}(OH)_2Pc]^{+}F^{-}$ (bottom) in ethanol. In the case of the Sb^{III} complex, two prominent bands in the 300–500 nm region are assigned to the B and MLCT bands. In contrast, no MLCT transitions can be recognized for the Sb^{V} complex, indicating that all of the transitions are attributed to π–π^* transitions. Therefore, the absorption spectrum of the Sb^{V} species is typical in shape to that of metalloPcs. The Q band of the Sb^{III} complex appears at 729 nm, while that of the corresponding Sb^{V} complex is observed at 699 nm. The counter anions exert little effect on the absorption properties.[395] In contrast, the axial ligands have a moderate effect on the absorption spectra. Thus, the Q band of tetra-*tert*-butyl $[Sb^{V}L_2Pc]^{+}$ appears at 723.5, 739, and 742 nm in CH_2Cl_2 for L = OH, Cl, and Br species, respectively.[396] Isago reported that an unusual red shift of the Q band in nonaqueous media was observed for tetra-*tert*-butyl $[Sb^{III}Pc]^{+}$.[397]

A series of $Bi^{III}PcX$ complexes, where X = Cl^{-}, Br^{-}, I^{-}, and NO_3^{-}, were prepared by Isago and Kagaya.[398] The spectra of these are insensitive to X, and are

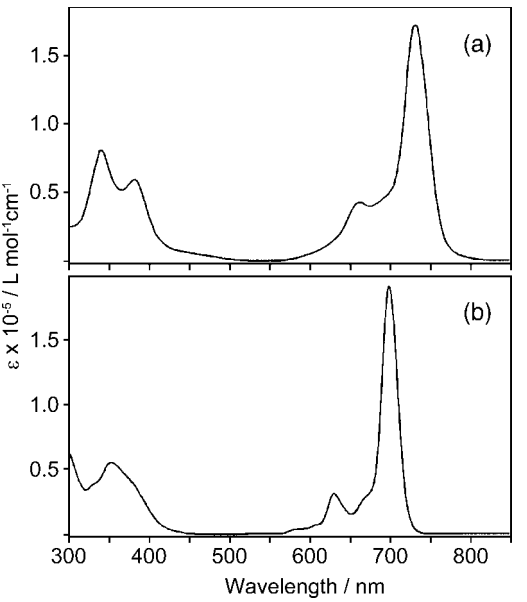

Figure 96. Absorption spectra of (a) $[Sb^{III}Pc]^+F^-$ and (b) $[Sb^{V}(OH)_2Pc]^+F^-$ in ethanol. Redrawn with permission from Knör, G. *Inorg. Chem.* **1996**, *35*, 7916–7918. Copyright 1996 American Chemical Society.

virtually identical to each other in shape. Thus, the band peaks are observed at 716.0, 645.0, 415sh, and 343.0 nm, and at 716.0, 645.0, 415sh, and 344.0 nm, and at 715.5, 645.0, 415sh, and 343.0 nm, and at 716.0, 645.0, 415sh, and 343.0 nm for X = Cl^-, Br^-, I^-, and NO_3^-, respectively in DMSO, indicating the ionic nature of the $Bi^{III}PcX$ species. The absorption spectrum of $Bi^{III}PcCl$ is displayed in Figure 97. The spectrum is characteristic of typical metalloPcs. The band at *ca.* 415 nm can be assigned to an MLCT band arising from a transition from the $a_{2u}(6p_z)$ orbital of the bismuth(III) to the $e_g(\pi^*)$ orbital of the Pc moiety. Double-decker[399,400] and triple-decker[401,402] BiPc complexes, namely $BiPc_2$ and Bi_2Pc_3, respectively, are also available. The reduced form of the dimer, $[BiPc(2-)_2]^-$ (Figure 98a), shows a spectral shape typical of this type of complex.[399] Two split Q bands appear at 13.33 and 15.59 kcm^{-1}, of which the latter is the exciton-dominated component. In the case of the neutral form (Figure 98b), the spectrum is also typical in shape of this type of complex. A sharp, most intense band was observed at 14.54 kcm^{-1} accompanied by two vibronic bands at 15.16 and 16.06 kcm^{-1}. The band at 21.01 kcm^{-1}, as well as a series of weak bands in the near-IR region, is indicative of the presence of the Pc radical moiety. Figure 99 shows the absorption spectra of Bi_2Pc_3.[402] The spectra in pyridine (a) and DMSO (c) are similar in shape, while that in DMF (b) is shifted hypsochromically by *ca.* 43 nm. In pyridine, two Q components lie at 718 and 644 nm, of which the former is

more intense, being in disagreement with the spectra of Ln_2Pc_3 and In_2Pc_3.[403] The crystal structure of (1,24-bicyclophthalocyaninato)bismuth(III) was reported in 2001. As a result of disruption of the aromatic π-system, this complex shows no absorption bands in the Q-band region (not shown).[404]

IV. Collective Absorption Data Tables

The remainder of the chapter is devoted to a collective database of the absorption data for hitherto reported Pc and its derivatives and analogs. Abbreviations used throughout the database are summarized in List of Abbreviations. In this database, the covered compounds are grouped into 13 categories (13 tables). Since units used to represent transition energy vary from one paper to another, only the first transition energy of each compound is accompanied by the unit. Moreover, molar extinction coefficients or relative intensities are given in parentheses if available. Band shoulders are denoted using "sh." Thus, an example of the method of representing transition energies and intensities is: 698 nm (lg ε 5.21), 665sh, 638 (4.62), etc…

Table 1 summarizes the absorption data of unsubstituted Pcs. Central metal, solvent, transition energy and intensity, remarks, and reference number are given from the left column to the right. Since Table 1 treats unsubstituted species, no further structural information appears in this table.

Table 2 summarizes the absorption data of α- and/or β-substituted Pcs. Some of the so-called "low symmetry Pcs" are also included in this table.

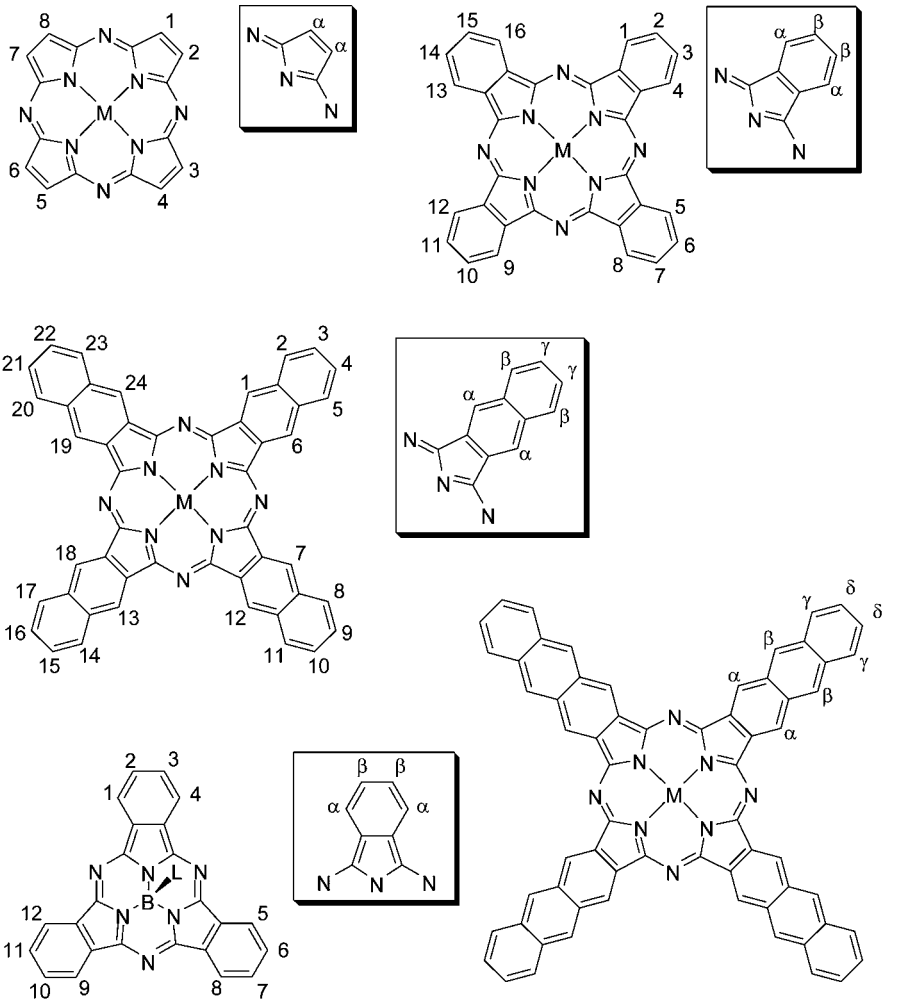

Figure 100. Numbering system, showing the positions of the substituents employed throughout the following absorption database in order to specify molecular structures.

Structures are represented by using the numbering system shown in Figure 100. For example, "R_2, R_3 = Me" and "R_2 = Me" stand for "2,3-bismethyl Pc" and "2-monomethyl Pc," respectively. If identical substituents are introduced into the four benzene rings around the Pc core, α and/or β symbols are used in order to simplify the notation. Thus, "$\alpha\alpha$ = Me", "$\beta\beta$ = Me" and "$\alpha\alpha\beta\beta$ = Me" are equivalent to "R_1, R_4, R_5, R_8, R_9, R_{12}, R_{13}, R_{16} = Me" and "R_2, R_3, R_6, R_7, R_{10},

R_{11}, R_{14}, R_{15} = Me", and "R_1, R_2, R_3 R_4, R_5, R_6, R_7 R_8, R_9, R_{10}, R_{11}, R_{12}, R_{13}, R_{14}, R_{15}, R_{16} = Me" respectively. Moreover, "α = Me" and "β = Me" stand for "R_1, $R_5(R_8)$, $R_9(R_{12})$, $R_{13}(R_{16})$ = Me" and "R_2, $R_6(R_7)$, $R_{10}(R_{11})$, $R_{14}(R_{15})$ = Me", respectively. Therefore, these two notations imply that the sample is a mixture of the possible structural isomers. The notation "$\alpha\beta$ = Me" is ambiguous because two structures, namely "R_1, R_2, … = Me" and "R_1, R_3, … = Me", are possible. In this case, for example, "$\alpha\beta$ (R_1, R_2) = Me" is used to specify the molecular structure. If different substituents are introduced at the two α or β positions and the sample contains structural isomers, "$\alpha\alpha'$ = Me, Et" and "$\beta\beta'$ = Me, Et" are used. Molecular structures are given directly in the table for more complex molecules.

Table 3 summarizes the absorption data of TAPs and mono-, di-, or triazaporphyrin analogs. The numbering system is shown in Figure 100. Thus, "α = Me" and "$\alpha\alpha$ = Me" correspond to "R_1, $R_3(R_4)$, $R_5(R_6)$, $R_7(R_8)$ = Me" and "R_1, R_2, R_3, R_4, R_5, R_6, R_7, R_8 = Me", respectively.

Table 4 summarizes the absorption data of Nc, Ac, and other ring-expanded Pc analogs. The numbering system is used to represent the structures of Ncs, as shown in Figure 100. The other skeletal structures are directly drawn in the table.

Table 5 summarizes the absorption data of sub- and super-Pcs. For subPcs, the axial ligand is denoted as L unless otherwise specified. The numbering system is shown in Figure 100.

Table 6 summarizes the absorption data of Pc analogs containing heteroatoms inside the aromatic skeleton. This category includes pyrazinoporphyrazines.

Table 7 summarizes the absorption data of Pc derivatives having crown-ether or related macrocycle units.

Table 8 summarizes the absorption data of tetraazachlorin derivatives.

Table 9 summarizes the absorption data of triazacorrole derivatives. The numbering system used is shown in the table.

Table 10 summarizes the absorption data of double decker and triple decker type Pc derivatives. This category includes hetero dimers consisting of Pc and porphyrin rings.

Table 11 summarizes the absorption data of dimers and oligomers. Sandwich-type structures are not included in this table, which appear in Table 10.

Table 12 summarizes the absorption data of Pc analogs containing triazole units.

Table 13 summarizes the absorption data of Pc polymers.

Table 1. UV-vis absorption data of unsubstituted Pcs.

M	Solvent	Transition Energy (Intensity)	Remark	Ref.
