Handbook of Porphyrin Science

with Applications to Chemistry, Physics, Materials Science, Engineering, Biology and Medicine

Volume 6

NMR and EPR Techniques

Karl M. Kadish ▪ Kevin M. Smith ▪ Roger Guilard

Editors

World Scientific

How to go to your page

This eBook contains five volumes, beginning with Volume 6. Each volume has its own page numbering scheme, consisting of a volume number and a page number, separated by a hyphen.

For example, to go to page 5 of Volume 6, type v6-5 in the “page #” box at the top of the screen and click “Go.” To go to page 5 of Volume 8, type v8-5 in the "page #" box… and so forth.

Contents

Preface

Although the porphyrin and tetrapyrrole research area was regarded as "fully matured" during the 20th century, as evidenced for example by the awarding of numerous Nobel Prizes to its principal researchers, new advances and accomplishments in the field still amaze us as editors. The area continues to blossom and to expand into new areas of science and applications that would probably never have occurred to our 20th century heroes. An earlier *Porphyrin Handbook* assembled the large amount of factual data that had been accumulated during the 20th century. Our new venture, the *Handbook of Porphyrin Science* takes a completely new look at our research area and comprehensively details the contemporary science now appearing in the scientific literature that would indeed have been hard to predict even 10 years ago. In particular, fundamentally new methodologies and potential commercial applications of the beautiful compounds that we all love are exemplified, fully recognizing the subtitle of the series — "with applications to chemistry, physics, materials science, engineering, biology and medicine".

The three of us have complementary expertise in physical chemistry, synthetic and bioorganic chemistry, and in synthetic and mechanistic organometallic chemistry; this has enabled us to cover the whole field of porphyrin science and applications, and to devise comprehensive volume and author content. As of the date of writing, between the three of us, we have published more than 1600 tetrapyrrole research articles, and hold 31 patents related to commercial applications of porphyrin science. So we do know our field, and this has enabled us to assemble a first-rate group of experts who have written comprehensive up-to-date chapters with accuracy and authority; we thank our authors for their cooperation and willingness to go along with our highly ambitious schedule for production of these volumes.

We look forward to comments from our readers, and to suggestions that might enable us to expand our basic interests and scientific coverage even further. Meanwhile, we hope that porphyrin researchers, old, new and of the future, will enjoy reading these volumes just as much as we enjoyed planning and, with the help of World Scientific Publishing Company, producing them from manuscript to published article, in a timely manner.

29 NMR and EPR Spectroscopy of Paramagnetic Metalloporphyrins and Heme Proteins

F. Ann Walker

Department of Chemistry and Biochemistry, University of Arizona, 1306 E. University B1, Tucson, AZ 85721-0041, USA

I. Introduction and Background

Magnetic resonance techniques, both nuclear magnetic resonance (NMR) and electron paramagnetic resonance (EPR) spectroscopies are excellent techniques for investigating the structure, bonding, dynamics, electron configurations and magnetism of transition metal complexes, and this certainly includes metalloporphyrins. Of course, EPR techniques can only be used when there are odd numbers of unpaired electrons present, either on the metal itself or in some cases, on the ligand(s). The most common number of unpaired electrons present in systems which are studied by EPR spectroscopy is one, although five is another fairly common number, and three is also possible. The development of pulsed EPR techniques, which make possible the study of all magnetic nuclei that are within 3–5 Å of the site of the unpaired electron (usually the metal, although there are an increasing number of cases of macrocycle π-cation or π-anion radicals that have been studied). The types of magnetic resonance techniques, both those belonging to the EPR and to the NMR family, that are commonly used to study metalloporphyrin complexes are summarized and briefly described in Table 1. Although the results of pulsed EPR experiments are mentioned, where appropriate, the experiments and the detailed description of the results is beyond the scope of this chapter. Some of these may be found in a review published in *Inorganic Chemistry*.[1]

While EPR spectroscopy requires the complex to have at least one unpaired electron or multiple unpaired electrons, NMR techniques can be utilized whether the complex is diamagnetic or paramagnetic, and a large number of the metallic elements and/or their compounds have paramagnetic states ($S \geq 1/2$). In fact, a number of the transition metals have several oxidation states that are reasonably stable and can be studied by NMR spectroscopy, and for a given oxidation state there are often several different spin states that are possible. However, not all of these oxidation/spin state possibilities have the "proper" relaxation properties to be easily studied by NMR spectroscopy, as we will discuss later in Section II.B. This author has been involved in the writing of the previous chapters on NMR of paramagnetic metalloporphyrins,[2–4] and within the 30 year time span covered up to the present, some of the systems previously thought to be impossible to study by NMR spectroscopy have been reported, including chromium(III), manganese(IV), copper(II) and silver(II) porphyrins. In most of these cases it has been ^{2}H NMR spectroscopic investigations, where the chemical shifts are extremely similar to those of the corresponding ^{1}H complexes, but the linewidths of the resonances can be as much as a factor of 42 sharper, which have made possible the detection of signals previously thought to be entirely too broad to observe. Discussion of such systems will be found in Sections II.B.2, IV.B.7 and IV.H.1, IV.H.3.

Table 1. Common NMR and EPR experiments used for investigating paramagnetic metalloporphyrins.

NMR experiment	Information Obtained
1D ^{1}H, ^{2}H or ^{13}C	Chemical shift → isotropic or paramagnetic shift → mechanism of spin delocalization; from temperature dependence → information about excited states.
1D NOE difference spectroscopy	Proximity of one type of proton to another, up to a distance of about 5 Å. A spectrum is obtained in which a particular resonance is irradiated. Then a reference, off-resonance irradiation dataset is acquired and the reference is subtracted from the first. The irradiated peak appears as a strong negative peak, and those peaks that are due to protons in close proximity appear as either weak negative or positive peaks, depending on the size of the molecule.
1D saturation transfer difference spectroscopy (also called STD)	Identifies resonances that are involved in chemical exchange. The experiment is the same as that used for 1D NOE difference spectroscopy. Both irradiated peak and that (those) connected to it by chemical exchange are of negative phase if the reference spectrum is subtracted from each peak irradiated.
2D COSY; TOCSY	Correlation SpectroscopY; Total Correlation SpectroscopY. J-coupling information is obtained; helps identify components of a spin system such as an ethyl or propionate group.
2D HETCOR; HMQC	HETeronuclear CORrelation spectroscopy, a ^{13}C-detected 2D heteronuclear experiment; Heteronuclear Multiple Quantum Correlation spectroscopy, a ^{1}H-detected heteronuclear 2D experiment. C-H J-coupling information is obtained in both cases; both identify which proton(s) are bound to which carbon. HMQC has a much higher signal-to-noise (at least a factor of 4) ratio than HETCOR.
2D HMBC	Heteronuclear Multiple Bond Correlation spectroscopy, a modification of the HMQC experiment which allows detection of long-range H-C J-couplings. Very useful for assigning the spectra of unsymmetrical metalloporphyrins.
2D NOESY; EXSY; ROESY	Nuclear Overhauser and Exchange SpectroscopY (sensitive to both through-space (NOE) and chemical exchange processes; NOEs may be zero for intermediate-sized molecules, i.e., many metalloporphyrins); Exchange SpectroscopY (the same experiment), which identifies protons in chemical exchange with each other; Rotating frame Overhauser and Exchange SpectroscopY (also sensitive to both through-space and chemical exchange, but shows NOEs the opposite phase and chemical exchange peaks the same phase as the diagonal, no matter what the size of the molecule).
Continuous wave EPR	g-values → orbital of the unpaired electron; superhyperfine couplings, **a** or **A**, due to nuclei that are strongly coupled to the unpaired electron.

(*Continued*)

Table 1. (*Continued*)

NMR Experiment	Information Obtained
ESEEM	Electron Spin Echo Envelope Modulation → signals due to all nuclei that are so weakly coupled to the unpaired electron that they show no superhyperfine couplings in the continuous wave EPR spectrum. Magnetic field (g-value → dependence of the intensity and frequency of "double quantum" proton peaks near twice the Larmor frequency → orientation of the g-tensor; similar analysis of the ^{14}N and/or ^{2}H peaks also provides very useful bonding and structural information. Intensities of ESEEM peaks are usually readily fit quantitatively to theoretical models.
HYSCORE	2D Hyperfine Sublevel CORrElation spectroscopy: A two dimensional ESEEM experiment, $\pi/2 - \tau - \pi/2 - T_1 - T_2 - \pi/2 - \tau -$ echo, in which correlation is produced between nuclear frequencies in the spin manifolds for an electronic transition. In a HYSCORE experiment, the time between the second $\pi/2$ and π pulse is varied in one dimension and the time between the π and third $\pi/2$ pulse is varied in a second dimension. A two- dimensional FT gives the 2D spectra which can be analyzed in terms of the frequencies of the nuclei involved. As in an ESEEM experiment, the peaks observed are essentially an NMR spectrum of nuclei that are coupled to the electron. However, the 2D technique allows one to separate overlapping peaks. Peaks appearing in the upper right and lower left quadrants typically arise from nuclei in which the hyperfine coupling is less than the Larmor frequency. They appear at the Larmor frequency of the nucleus, separated by the hyperfine coupling. Peaks from nuclei in which the hyperfine interaction is greater than the Larmor frequency of the nucleus appear in the upper left and lower right quadrants. The HYSCORE spectrum can become very complicated for nuclei with a spin I greater than 1/2, with many peaks arising from the additional complication of addition nuclear Zeeman and quadrupole levels. Even with the complexity of the spectra, HYSCORE on complicated systems with multiple nuclei can make ESEEM spectra that would be difficult or impossible to interpret much more manageable.

NMR spectroscopy is particularly valuable for studying paramagnetic metalloporphyrins because the unpaired electrons "illuminate" the heme or other metalloporphyrin center by causing paramagnetic shifts of the protons (or carbons) of the macrocycle, the axial ligand(s) of the metal and, in the case of heme proteins, nearby protein residues, that are exquisitely sensitive to heme substituents, axial ligand effects such as histidine imidazole N–H hydrogen-bonding[5,6] or deprotonation,[5] axial ligand plane orientation,[5,7,8] methionine-SCH_3 chirality,[9] and cyanide

off-axis tilting (in protein complexes such as cyanometmyoglobin),[10,11] as well as the effect of nonbonded protein substituents,[5,12] on the electronic state of the heme. The chemical shifts of the heme macrocycle of heme proteins, also known as paramagnetic or hyperfine shifts if the metal is paramagnetic, are extremely sensitive to all of these factors, as well as to others that will be enumerated in later sections of this chapter, and much can be learned by carrying out a detailed study of a paramagnetic heme protein. Because of this extreme sensitivity, it is sometimes difficult to determine the relative importance of all the factors that might affect the chemical shifts. For this reason, a number of investigators have carried out detailed NMR investigations of appropriately designed model hemes or other metal tetrapyrroles having relatively high molecular symmetry (as compared to naturally-occurring hemes), in order to probe the importance of such factors as substituent effects, electronic asymmetry due to unsymmetrical substitution, axial ligand basicity and steric effects, axial ligand plane orientation, thermodynamics and kinetics of axial ligand binding, exchange and rotation, and hydrogen-bonding effects of these ligands on the NMR spectra of metalloporphyrins. The results of a large number of these investigations have been summarized previously in at least a dozen important chapters or books.[2–5,13–20] However, the focus in all but four of these[2–4,15] has been on heme proteins, where the metal ion was either iron(II) or iron(III). For that reason, this chapter will focus on the proton (and deuteron) NMR spectroscopy of metalloporphyrins of all known oxidation and spin states that have occurred since the literature search for the publication of the previous chapters in *The Porphyrins*[2] and *The Porphyrin Handbook*,[4] with only occasional detailed recapitulation of earlier topics at points where a background must be built up before the recent work can be discussed. The ^{13}C chemical shifts of a number of metalloporphyrins and heme proteins, and occasionally, the ^{19}F chemical shifts will also be discussed. Parts of this chapter will cover some of the same topics as *The Porphyrin Handbook* chapter[4] published about ten years ago, which is necessary for completeness. The NMR spectra of the heme centers of heme proteins will be discussed where the results of NMR studies of paramagnetic metalloporphyrins have direct relevance to interpretations of the heme protein data, or vice versa. In particular, a section on NMR spectroscopy of the nitrophorins and heme oxygenases, and a brief update on other heme proteins, is included (Section IV.A.10).

A. Structures and Electron Configurations of Metalloporphyrins

Structural formulas **1**–**3** show the general structures of porphyrins. The structures of closely related ring systems, including chlorins, isobacteriochlorins, dioxoisobacteriochlorins and corroles are shown in Structures **4**–**7**. Examples of the substituents present on commonly investigated metal macrocycles are summarized in

Tables 2–5. Porphyrin macrocycles can be classified as derivatives of natural porphyrins, of which deuteroporphyrin IX is considered the parent. The arrangement of the peripheral substituents of natural porphyrin derivatives is shown in Structure **1**, with the 1–8 and α–δ numbering system used in much of the NMR literature, and the nature of the variable substituents, the common names of the macrocycle and the symbols used in this chapter, are listed in Table 2. For cases in which the propionic acid side chains in Structure **1** are esterified, for example, as dimethyl esters, the symbol will have DME appended to the abbreviation. Two

types of synthetic porphyrins, those having either *meso* or β-pyrrole substituents, are shown in Structures **2** and **3**, respectively, and common substituents, IUPAC numbering system, ligand names and abbreviations are given in Tables 3 and 4, respectively.

Chlorins, isobacteriochlorins, 2,7-dioxoisobacteriochlorins and corrole macrocycles are shown in Structures **4**–**7**, respectively, and examples of high symmetry macrocycles of each type, with common substituents, ligand names and abbreviations are summarized in Table 5. Chang and coworkers have been instrumental in proving the structures of several of the so-called "green hemes", including heme d (actually a chlorin, 5,6-dihydroxy protochlorin IX[21]) and heme d_1 (actually a porphinedione or 2,7-dioxoisobacteriochlorin[22]). Other related ring structures that are involved in the stepwise oxidation of the heme to verdoheme and beyond are shown in Structures **8**–**13**, including 5-hydroxyporphyrins (oxophlorins), Structures **8**, oxaporphyrins (verdohemes), Structures **9**, azaporphyrins, **10**, formylbiliverdins, **11**, dioxodipyrromethanes, **12** and dialkyldipyrromethanes, **13**. The structures of other related macrocycles, including etioporphycene, porphyrazines (*meso*-tetraazaporphyrins), phthalocyanines and texaphyrin, are shown in Structures **14**–**17**, respectively. An example of how saturated β-pyrrole bonds can create an optically active macrocycle is shown in Structure **18** for the 5-coordinate high-spin state of chloroiron *trans*,*trans*-octaethylchlorin.

Coordination numbers possible for synthetic and natural metalloporphyrins include 4-coordinate (no axial ligands), 5-coordinate (one axial ligand), 6-coordinate (two axial ligands) and 7- to 9-coordinate (one bidentate ligand and up to three monodentate ligands, as observed for certain lanthanide porphyrins) geometries. The number of axial ligands, and their nature, have dramatic influences on the spin state, optical spectra, EPR g-values and in some cases superhyperfine coupling constants, NMR paramagnetic shifts, Mössbauer isomer shifts, quadrupole splittings and hyperfine coupling constants, as well as reduction potentials and reactivity towards reagents such as molecular oxygen, carbon monoxide, nitric oxide, alkyl halides, alkenes, alkynes and many others.

The molecular and electronic structures of metalloporphyrins may, in certain cases, depend on solvent, anion and degree of aggregation. Deuterated solvents are almost invariably used, except when deuterated porphyrin ^2H signals are being observed. Some solvents, including water (D_2O), dimethylsulfoxide (DMSO-d_6), dimethylformamide (DMF-d_7), methanol (CD_3OD), pyridine-d_5, and tetrahydrofuran (THF-d_8) may coordinate to the metal, or may simply change the dielectric constant of the medium, if strongly-binded ligands are separately provided for the metalloporphyrin. Water and alcohols can also be hydrogen-bond donors to the axial ligands. Chlorinated hydrocarbons, including chloroform ($CDCl_3$), methylene chloride (CD_2Cl_2) and dichloroethane ($C_2D_4Cl_2$), are typically good at dissolving metalloporphyrins, although they may contain traces of acid (DCl) that could react with the metalloporphyrin. Aromatic hydrocarbons, such as toluene-d_8, can interact with the π-system of the porphyrin, both to help dissolve the complex and also to change the π-acidity or -basicity of the macrocycle, as in the case of Co^{II} porphyrins. Carbon disulfide, CS_2, is also good at dissolving uncharged porphyrins. Anions can stabilize either high-spin states (halides, alkoxy, aryloxy, polyoxo anions) or low-spin states (cyanide, aryl, alkyl anions) if they remain coordinated to the metalloporphyrin when dissolved in the chosen solvent.

The known or suspected oxidation states of iron porphyrins, the most commonly studied metalloporphyrins, range from Fe^{I} (d^7) to (possibly) Fe^{V} (d^3). Among these, the possible spin states include high-, intermediate- and low-spin states of Fe^{II} (d^6) and Fe^{III} (d^5), high- and low-spin Fe^{I} (d^7) and Fe^{IV} (d^4), although there have been no reports of high-spin Fe^{I} or high-spin Fe^{IV}. In comparison, for the metals of the first transition series on either side of iron, cobalt porphyrins, both Co^{II} (d^7) and Co^{III} (d^6) complexes have been studied, with reports of both high- and low-spin Co^{II} complexes as a function of porphyrin substituents, but only low-spin (diamagnetic) Co^{III} porphyrins. For manganese porphyrins, Mn^{II} (d^5), Mn^{III} (d^4), Mn^{IV} (d^3), and possibly Mn^{V} (d^2), the latter two as oxomanganese(IV) and oxomanganese(V), have been studied by NMR spectroscopy; Mn^{II} exhibits only the high-spin state while Mn^{III} exhibits both high- and low-spin states, and the two highest oxidation states both appear to be high-spin. Chromium porphyrins have been studied as Cr^{II} (d^4) and Cr^{III} (d^3), the latter of which has extremely broad lines. Although nickel macrocycle complexes are known for Ni^{I} (d^9), Ni^{II} (d^8) and Ni^{III} (d^7), only the Ni^{II} (d^8) systems have been studied by NMR spectroscopy; the 5- and 6-coordinate complexes are paramagnetic, while the 4-coordinate complexes are diamagnetic. Copper porphyrins are known only as Cu^{II} (d^9), which have very broad lines. For most of these metals, the corrole ring is said to stabilize a higher apparent metal oxidation state than do the porphyrin or reduced porphyrin rings, although it often turns out that the electron is missing from the macrocycle rather than the metal. The only diamagnetic members of the extensive series of possible oxidation and spin states are low-spin d^6 6- (and sometimes 5-) coordinate Fe^{II}, Ru^{II}, Os^{II}, 6-coordinate Co^{III}, Rh^{III}, and 4-coordinate Ni^{II}, Pd^{II} and Pt^{II}. The NMR spectra observed for representative examples of each of the possible oxidation and spin states will be discussed in Section IV.

II. Principles

A. Proton Chemical Shifts

The chemical shifts which are observed for protons in paramagnetic molecules are the result of a combination of diamagnetic and paramagnetic contributions. These contributions are additive:

$$\delta_{obs} = \delta_{dia} + \delta_{para}. \quad (1)$$

The diamagnetic contribution, δ_{dia}, is the chemical shift which would have been observed if the molecule had no unpaired electron(s). It is directly evaluated by

recording the NMR spectrum of an appropriate diamagnetic analog of the molecule of interest, usually one containing a diamagnetic metal such as Zn(II), Ni(II), or Cd(II). The metal-free (free base) porphyrin, H_2P is sometimes used if no diamagnetic metal complex is available; the chemical shifts of the protons of a metal-free porphyrin are usually within ~0.2 ppm of those of a diamagnetic metal complex.

The paramagnetic contribution, δ_{para}, is often called the hyperfine shift, δ_{hf}, since it arises from the hyperfine interaction (scalar coupling) of an unpaired electron with the proton nucleus of interest, or the isotropic shift, δ_{iso}, since it is typically observed for molecules or ions in homogeneous solution, where electron spin relaxation and molecular rotation are both generally rapid, and thus yield an isotropic spectrum. The paramagnetic shift consists of two terms, the contact and the pseudocontact (or electron-nuclear dipolar) contributions:

$$\delta_{para} = \delta_{iso} = \delta_{hf} = \delta_{obs} - \delta_{dia} = \delta_{con} + \delta_{pc}. \quad (2)$$

The contact (δ_{con}) and pseudocontact (δ_{pc}) terms arise because spin delocalization from the unpaired electron, usually located on the metal ion, to the protons at the periphery of the molecule, can occur either through chemical bonds or through space (or a combination of the two, as in the case of high- and low-spin Fe^{III} porphyrins, see also Sections IV.A.6 and IV.A.8). The sign convention which will be used throughout this chapter is the one commonly used by all chemists: δ_{obs} is positive if the resonance is at higher frequency (lower shielding) than that of tetramethylsilane (TMS), and negative if the resonance is at lower frequency (higher shielding) than that of TMS. Hence, δ_{para} is positive when the resonance is at lower, and negative when it is at higher shielding than that of the diamagnetic reference compound. This is the reverse of the sign convention that was used in the earlier literature for paramagnetic complexes, including several of the earlier reviews.[2,13] The signs of all contact and pseudocontact (dipolar) shifts reported in earlier publications have been changed herein to conform to the now-accepted sign convention.

1. *Contact Shifts*

Contact shifts of protons, deuteriums, carbons and other nuclei in paramagnetic molecules originate from scalar coupling between electron spins and individual nuclei. In the most general case, the contact shift depends on the principal components of the electronic g-tensor of the paramagnetic center (g_{ii}), the magnetic susceptibility tensor of the molecule (χ_{ii}) and the Fermi hyperfine (contact) coupling

constant (A_h) for coupling the spin of the electron to the spin of the nucleus of interest:[23]

$$\delta_{con} = \left[\frac{A_h}{3\gamma_N \hbar \mu_B}\right]\left[\frac{\chi_{xx}}{g_{xx}} + \frac{\chi_{yy}}{g_{yy}} + \frac{\chi_{zz}}{g_{zz}}\right], \tag{3}$$

where μ_B is the Bohr magneton, χ_{ii} are the molecular magnetic susceptibilities, and g_{ii} are the g-values along each of the principal axes of the molecule. If a single spin state with an isotropic g-tensor is populated, and to the extent that the Curie law is valid, Eq. 3 reduces to a simpler form that is usually applicable to metalloporphyrins:[24,25]

$$\delta_{con} = \frac{A_h \langle g \rangle \mu_B S(S+1)}{3\gamma_N \hbar kT}, \tag{4}$$

where S is the total electron spin quantum number, $\langle g \rangle$ is the average (isotropic) g-value, μ_B is the Bohr magneton, γ_N is the magnetogyric ratio of the nucleus in question, and T is the absolute temperature. Thus, in simple, well-behaved systems, contact shifts are expected to vary linearly with 1/T and to extrapolate to zero at infinite temperature (1/T = 0). However, in cases where a thermally-accessible excited state exists, as is typically the case with low-spin Fe^{III} porphyrins and heme proteins, as well as many other cases, the contact shifts may not extrapolate to zero at infinite temperature, and an expanded form of the Curie law must be employed,[25] as will be discussed later in Section II.A.3.

The interpretation of the contact contributions to the paramagnetiic shifts of protons or deuteriums of paramagnetic molecules in terms of the covalency of metal-ligand bonds relies to a large extent on the McConnell equation:[26]

$$A_H = \frac{Q\rho_C}{2S}, \tag{5}$$

where A_H is the hyperfine coupling constant for each individual proton, Q is a constant for a given type of proton and ρ_C is the unpaired spin density of the electron at the carbon to which the proton is attached; the same holds for deuterium nuclei, which have almost identically the same chemical shifts, contact shifts and pseudocontact shifts as protons. For the case of spin delocalization to a π orbital on the carbon, $Q_H = -63$ MHz, and the contact shifts are negative (to lower frequency or higher shielding). If the proton directly bound to a carbon which has spin density in a π orbital is replaced by a methyl or other aliphatic group, Q_{CH2R} is positive and somewhat variable, because it depends on the rate of rotation

(or preferred orientation, if rotation is slow) of the methyl or other aliphatic group; values of +70 to +75 MHz have been used.[27,28] For alkyl groups larger than CH_3, preferred orientations are the rule, and Q can vary from nearly zero to +100 MHz, but follows the general expression:

$$A_{CH_2R} = \frac{Q_{CH_2R}\rho_C}{2S} = \frac{(B_0 + B_2 \cos^2 \varphi)\rho_C}{2S}, \quad (6)$$

where B_0 and B_2 are positive numbers, and φ is the angle between the C–C–H plane and the p_z orbital axis on the aromatic carbon. B_2 is usually small, and, since $\cos^2\varphi$ is positive for all angles φ, Q_{CH_2R} is always positive. Therefore, if π spin delocalization occurs to a particular carbon atom, a proton directly bound to that carbon will have a contact shift to lower frequency (higher shielding, δ_{con} negative), while replacement of the proton at that carbon position with a methyl or other aliphatic group will produce a contact shift to higher frequency (lower shielding, δ_{con} positive). Such reversal in the sign of paramagnetic shifts for H and CH_3 or CH_2R or CHR_2 at a given position is a clear sign of dominance of the paramagnetic shifts by π spin delocalization, as will be seen in many parts of this chapter. For spin delocalization to a σ-symmetry orbital on the carbon, Q is positive and depends on the number of σ bonds through which the spin is delocalized. For the electron in the 1s orbital of the hydrogen atom, A_H is 1419 MHz, a positive quantity.[29] For protons attached to carbons in metalloporphyrins, where metal electrons are delocalized through either σ or π orbitals of the carbons, the amount of spin density at a given proton on the periphery of the molecule is miniscule in comparison to the hydrogen atom, and is not directly comparable to 1419 MHz because the hydrogens in chemical compounds are involved in chemical bonds.

For σ spin delocalization to protons connected to a carbon framework, Q is also positive, and the spin density, ρ_C, is attenuated sharply as the number of σ bonds between the unpaired electron and the proton increases. In any case, the positive sign of Q means that the contact shifts are positive (to high frequency or low shielding) when σ spin delocalization occurs to the carbon to which the proton is attached. Thus, if the contact contribution to the paramagnetic shifts of protons in molecules such as metalloporphyrins can be separated from the pseudocontact (dipolar) contribution, the pattern of shifts to lower and higher frequencies, as directly-bound protons are replaced by methyl groups at the same symmetry positions on the ring, for example, readily reveals the mechanism(s) of spin delocalization to each symmetry position. This will be discussed further after the pseudocontact (dipolar) shift has been introduced, and after the general strategies for separation of the contact and pseudocontact contributions to the paramagnetic shift have been summarized.

2. *Pseudocontact (Dipolar) Shifts*

a. *Pseudocontact shifts of metalloporphyrin substituents*

The electron-nuclear dipolar contribution to the paramagnetic shift is now usually called the pseudocontact contribution. This is actually a misnomer, since the electron-nuclear dipolar shift contains no contribution from scalar coupling of the electron spin with the spin of the nucleus of interest, that is, no Fermi contact term. Rather, the electron-nuclear dipolar shift results from through-space dipolar coupling of the electronic and nuclear magnetic moments which arise from either the magnetic anisotropy of the metal ion or from zero-field contributions (in cases where the total spin of the ion is greater than one-half). Nevertheless, the use of the term "pseudocontact" to describe the dipolar shift is well entrenched in the literature of heme proteins, as well as throughout the high-resolution NMR community, and we will thus use this term throughout this chapter. However, one must be aware of the fact that it represents the through-space dipolar interaction between the unpaired electron(s) and the nucleus of interest, which should more correctly be called the dipolar shift. In fact, in Section II.A.2.c later, "dipolar couplings" in which a protein (that often includes a metal with one or more unpaired electron) is discussed, these are dipolar couplings between ^{1}H and ^{15}N nuclei. For nuclei other than protons, ligand-centered pseudocontact (dipolar) shifts may also arise from unpaired spin density in π-orbitals,[23,24] but this is not the case for protons. For pseudocontact shifts of protons by S > 1/2 metal atoms or ions it can be shown that

$$\delta_{pc} = \frac{N_A}{24\pi}\left\{\frac{[2\chi_{zz} - (\chi_{xx} + \chi_{yy})](3\cos^2\theta - 1)}{r^3} + \frac{3[\chi_{xx} + \chi_{yy})](\sin^2\theta\cos 2\Omega)}{r^3}\right\}, \quad (7)$$

where N_A is Avogadro's number, χ_{ii} are the principal components of the molecular magnetic susceptibility tensor in SI units (note that $\chi(SI) = (4\pi \times 10^{-7})\chi(cgs\ emu)$), θ is the angle between the proton-metal vector and the z molecular axis, r is the length of this vector, and Ω is the angle between the projection of this vector on the xy plane and the x axis.[24,30,31] The terms $(3\cos^2\theta - 1)/r^3$ and $(\sin^2\theta\cos 2\Omega)/r^3$ are typically known as the axial and rhombic geometric factors, G_{ax} and G_{rh}, respectively, and the terms in Eq. 7 to which they belong are often called the axial and rhombic contributions to the pseudocontact shift, respectively. Axial geometric factors for protons at the β-pyrrole and *meso* positions (Structures **2** and **3**, $R_1 - R_8$ and $R_\alpha - R_\delta$, respectively) of the commonly utilized model hemes, tetraphenylporphinatoiron, (TPP)Fe, octaethylporphinatoiron, (OEP)Fe[2,4] and tetramesitylporphyrinatoiron, (TMP)Fe[32–34] have been calculated from X-ray crystallographic data for the low-spin iron(III) complexes, and are presented in Table 6

Table 6. Axial geometric factors for iron(III) porphyrinates which have planar and ruffled cores.

for both iron(III) porphyrins with planar cores and those with ruffled cores (represented by (TMP)Fe^{III} with pyridine or hindered imidazole ligands). It is interesting to note that the pyrrole-H and mesityl *p*-CH_3 groups are not much affected by ruffling of the porphyrin ring, while the mesityl *o*-CH_3 and *m*-H groups have two geometric factors each, and the values of these depend somewhat on the degree of ruffling of the porphyrin ring. Pyridine 2,6-H and 3,5-H geometric factors for ruffled porphyrin complexes are somewhat larger than those reported earlier for planar porphyrin complexes, presumably because of the slightly shorter $Fe–N_{ax}$ bond lengths in the former complexes. Although these geometric factors have been obtained for low-spin iron(III) porphyrins, they are usually applicable to other metalloporphyrins unless M–L bond lengths are significantly different.

If the complex of interest has only one thermally-populated spin multiplet with effective spin S,[25,30] then:

$$\chi_{ii} = \left\{ \frac{\mu_0 (\mu_B)^2 S(S+1)}{3kT} \right\} g_{ii}{}^2, \tag{8}$$

where μ_0 is the permeability of free space and μ_B is the Bohr magneton (note that $\chi(SI) = (4\pi \times 10^{-7})\chi(cgs\ emu)$), and Eq. 8 can be simplified to

$$\delta_{pc} = \left\{ \frac{\mu_0 (\mu_B)^2 S(S+1)}{72\pi kTr_3} \right\} \times \left\{ [2g_{zz}{}^2 - (g_{xx}{}^2 + g_{yy}{}^2)](3\cos^2\theta - 1) + 3(g_{xx}{}^2 - g_{yy}{}^2)(\sin^2\theta \cos 2\Omega) \right\}. \tag{9}$$

This equation is the form that is often used for calculation of the pseudocontact contribution to the paramagnetic shift. However, Horrocks and Greenberg[30] showed some 35 years ago that second-order Zeeman (SOZ) contributions to the magnetic susceptibilities of heme systems range from ~3% (cytochrome b_5) to ~10% (cytochrome *c*) to 25% (metmyoglobin cyanide) of those of the first-order Zeeman (FOZ) effect (Curie behavior), and are of opposite sign for cytochrome *c* and metmyoglobin cyanide, but of the same sign for cytochrome b_5. Furthermore, excited electronic states of the metal ion that are thermally populated to varying extents as a function of temperature can lead to non-Curie behavior (nonzero intercepts at 1/T = 0).[25,31] As will be shown in Section II.A.3, this can lead, in the limit, to a reversal in the temperature dependence of the paramagnetic shifts of a complex over a broad temperature range of study. Thus, g-values cannot be used to quantitatively calculate the pseudocontact contributions to the paramagnetic shifts in very many cases, although the fact that they are usually the only magnetic anisotropy data available often makes it very tempting to use them. At the worst,

they at least give important *qualitative* information as to the importance of the pseudocontact contribution to the paramagnetic shift, and for that reason the EPR g-values of representative metalloporphyrins will be summarized in the sections following.

For heme proteins, *magnetic susceptibility anisotropies* can be calculated from Eq. 7 by fitting the protein side chain and backbone chemical shifts that cannot arise from the contact shift, but this is usually not possible for simple metalloporphyrins because of the difficulty of separating the contact and pseudocontact contributions for nuclei that are not many bonds away from the metal. (Examples of the determination of magnetic susceptibility anisotropies are discussed below in the following section.) However, Eq. 9 is sometimes useful for estimating the sizes of the pseudocontact shifts in two complexes for protons at the same molecular positions, when these complexes have different g-values (although note that different g-values lead to different sizes of deviations, as mentioned in the previous paragraph). Thus, if the size of a pseudocontact shift is known for one complex from some independent means, and if the g-values of both complexes are known, the pseudocontact shift of the second complex may be estimated by scaling it by the ratio of the g_{ii}^2 factors for the axial and rhombic terms by using Eq. 9. Examples of the use of such procedures are presented in Sections III.B.2 and III.B.3.

For pseudocontact shifts of metal complexes having S > 1/2, where the g-tensor is sometimes totally symmetric, magnetic anisotropy can still be present if the zero-field splitting, D, is large. In this case, Kurland and McGarvey[23] have shown that the pseudocontact contribution to the paramagnetic shift exhibits a $1/T^2$ dependence. The simplified equation for S = 5/2 is:

$$\delta_{pc} = -\left\{\frac{28\mu_0 \langle g \rangle^2 (\mu_B)^2 D}{36\pi k^2 T^2 r^3}\right\}\{3\cos^2\theta - 1\}, \qquad (10)$$

where μ_0 is the permeability of free space = $4\pi \cdot 10^{-7}[T \cdot m \cdot A^{-1}]$. (Note that a useful SI-unit equivalence for calculation purposes is $J = m^2 \cdot T \cdot A$.) The classic case of high-spin iron(III) porphyrins, where D-values range from 5.6 cm^{-1} (F^-) to 11 cm^{-1} (Cl^-) to 16.4 cm^{-1} (I^-),[35] yields curved Curie plots that result from a contact term that is linear in 1/T (Eq. 4) and a pseudocontact term that results from Eq. 10, with dependence on $1/T^2$.[2,4,36]

b. *Measurement of magnetic susceptibility anisotropies of ferriheme proteins*

Two examples of the determination of magnetic susceptibility anisotropies for proteins, in both cases for metmyoglobin are, first for the S = 1/2 cyanide complex

of sperm whale metmyoglobin, where Emerson and La Mar experimentally determined the paramagnetic pseudocontact shifts for noncoordinated amino acid side-chain protons in the heme pocket of sperm whale cyanometmyoglobin[10] and used them to determine, in solution, the orientation of the principal axes for the paramagnetic susceptibility tensor relative to the heme iron molecular coordinates.[11] The determination was made by a least-squares search for the unique Euler rotation angles which convert the geometric factors in the molecular (crystal) coordinates to ones that correctly predict each of 41 pseudocontact shifts measured[11] by using the magnetic anisotropies computed previously by Horrocks and Greenberg.[30] An excellent fit to experimental shifts was obtained, which also provided predictions that allowed subsequent new assignments to be made. The magnetic axes are oriented so that the z axis is tipped ~15° from the heme normal toward the heme 6-*meso*-H and coincides approximately with the characterized FeCO tilt axis in the isostructural MbCO complex.[37] The FeCO and FeCN units are isostructural, and so the authors proposed that the dominant protein constraint that tips the magnetic z axis from the heme normal was the tilt of the FeCN by steric interactions with the distal residues. The rhombic magnetic axes were found to align closely with the projection of the proximal His imidazole plane on the heme, which confirmed that the His–Fe bonding provided the protein constraint that orients the in-plane anisotropy.[11] (This worked well for cyanometmyoglobin because the histidine imidazole plane is aligned very close to one of the N_P–Fe–N_P axes; a different relationship would hold if the imidazole plane were aligned along the α,γ or β,δ *meso* directions, as in cytochromes *c* and nitrophorins, as discussed later in Section II.C.3.)

In this work[11] the actual axial and rhombic magnetic susceptibility anisotropies, $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$, were not reported. However, La Mar and coworkers returned to cyanometmyoglobin later and determined not only the orientations of the magnetic susceptibility axes, but also the anisotropies;[38] the resulting axial, $\Delta\chi_{ax} = (2.48 \pm 0.30) \times 10^{-8}$ m^3mol^{-1}, and rhombic anisotropy, $\Delta\chi_{rh} = -(0.58 \pm 0.03) \times 10^{-8}$ m^3mol^{-1} were found at 25 °C.[38] These values agree well with the theoretical estimates of Horrocks and Greenberg ($\Delta\chi_{ax} = 2.24 \times 10^{-8}$ m^3mol^{-1}, $\Delta\chi_{rh} = -0.60 \times 10^{-8}$ m^3mol^{-1}).[31] (The values calculated from the First Order Zeeman (FOZ) term only, i.e., the squares of the g-values (Eq. 9), which, for met-MbCN are 3.45, 1.89, and 0.72[39] are as follows: $\Delta\chi_{ax} = 3.90 \times 10^{-8}$ m^3mol^{-1}, $\Delta\chi_{rh} = -1.21 \times 10^{-8}$ m^3mol^{-1} at 25 °C, both of which are considerably larger than the measured values (~30–35% for $\Delta\chi_{ax}$; a factor of two for $\Delta\chi_{rh}$). Thus as reported previously,[30,31] using the g-values may overemphasize both the axial and rhombic anisotropy.)

The axial magnetic anisotropies of ferric cyanide heme complexes are expected to be larger than those of bis-histidine or His-imidazole complexes, because the g-values for the latter are not so widely different from each other, as

in the case of the cyanide complexes, with their large values of g_{max}, as mentioned above. For example, the nitrophorin-imidazole complexes, which have g-values identical to those of cytochromes b_5 (3.02, 2.25, 1.46)[143] have axial and rhombic anisotropies calculated therefrom of $\Delta\chi_{ax} = 2.18 \times 10^{-8}$ m^3mol^{-1}, and $\Delta\chi_{rh} = -1.20 \times 10^{-8}$ m^3mol^{-1} at 25 °C. Although these values may be larger than would be found by actual measurement,[38] the axial and rhombic magnetic anisotropies are not much different whether only the FOZ term or the FOZ + SOZ terms are used, according to Horrocks and Greenberg.[30,31] The $\Delta\chi_{rh}$ obtained from the g-values of $[TPPFe(ImH)_2]^+$, as a function of axial ligand plane angle of the (parallel) imidazole ligand planes, was used for the angle plot shown in Figure 11, and thus the pseudocontact contribution may be somewhat over-estimated, although for bis-imidazole-coordinated hemins, probably not by much.

In the NMR study of La Mar *et al.*,[38] quantitative determination of the magnetic anisotropies as a function of temperature allowed the quantitative separation of contact and pseudocontact shifts for the iron ligands.[38] The heme contact shifts reflect the expected dominant π spin density at the pyrrole positions, but the *meso*-protons were said to exhibit low-field contact shifts indicative of unpaired spin in a σ orbital. It was felt that such delocalized σ spin density could arise from either deformation of the heme from planarity or the loss of σ/π separation for the d_{xz} and d_{yz} orbitals when the major magnetic axis is tilted strongly from the heme normal, as is experimentally observed.[38] The observed anomalous temperature dependences of the heme methyl and axial His ring contact shifts, as well as that of the rhombic anisotropy, are all consistent with thermal population of the excited orbital state[38] (Section II.C.3).

The use of paramagnetism-based constraints for solution structure refinement has also been described for a high spin iron(III)-containing protein (metmyoglobin).[40] Metmyoglobin is known to have an axial water, and thus this was a study of a 6-coordinate high-spin ferriheme protein. It was considered a particularly challenging system due to the unfavorably high ratio between its magnetic susceptibility and its magnetic anisotropy, coupled with relatively long electron spin relaxation times.[40] The cross-correlation between internuclear dipole–dipole interactions and the time average of the electronic magnetic moment (Curie spin) was measured for 61 backbone NH nuclear pairs and used as structural constraint.[40] The magnetic anisotropy tensor parameters calculated after refinement using the energy-minimized average structure were found to be $\Delta\chi_{ax} = -(1.51 \pm 0.18) \times 10^{-8}$ m^3mol^{-1} and $\Delta\chi_{rh} = (1.02 \pm 0.18) \times 10^{-8}$ m^3mol^{-1}.[40] The average structure has a backbone RMSD from the X-ray structure of 0.70 Å.[40] Thus, the 6-coordinate, high-spin aqua complex of metmyoglobin is much less anisotropic than the low-spin cyanide complex discussed above, but with opposite signs of the anisotropies to those of the cyanide complex.

Pseudocontact shifts can also be useful in providing structural restraints in solid-state NMR spectroscopy of microcrystalline proteins that contain paramagnetic metal ions, and have been used to study the matrix metalloproteinase, MMP-12, containing cobalt(II).[41,42]

c. *Residual dipolar couplings of proteins for structure determination*

The dipole–dipole interaction between magnetic nuclei, the leading term of which is described in Eq. 11, is actually the basis of the nuclear Overhauser effect (NOE):

$$H_{\mathrm{Dij}} = -\left[\frac{\gamma_{\mathrm{i}}\gamma_{\mathrm{j}}\mathrm{h}}{2\pi^2\mathrm{r}^3}\right] < \left[\frac{3\cos^2\theta - 1}{2}\right] > \mathrm{I}_{\mathrm{zi}}\mathrm{I}_{\mathrm{zj}}, \tag{11}$$

where the γ values are the magnetogyric ratios for the nuclei i and j, h is Planck's constant, r is the distance between the nuclei, θ is the angle between the internuclear vector and the applied magnetic field, and the I_z are the spin operators for the two nuclei. In principle, the interaction would manifest itself as a splitting of NMR resonances into doublets. When nuclear pairs are directly bonded, as in a ^{1}H–^{15}N amide pair, for example, the interaction would add to the scalar coupling normally seen in nondecoupled high-resolution NMR spectra. Variations in scalar couplings due to dipolar effects are not normally observed in high-resolution spectra because of motional averaging denoted by the brackets in Eq. 11. All motions occurring on time scales short compared to the reciprocal of the dipolar interaction in Hz ($< 10^{-3}$ seconds for ^{1}H–^{15}N and r = 1 Å) contribute to the averaging, including molecular tumbling in solution.

For diamagnetic molecules at moderate field strengths, molecules have little preference in orientation, the tumbling samples a nearly isotropic distribution, and the term inside the bracket goes to zero. If, however, a molecule has a preference in orientation, an average interaction would persist, and the splitting of resonances would vary from their nominal scalar couplings by an amount that depends on the angle θ for each N–H bond vector. Actually, most molecules have preferred orientations in the presence of a magnetic field, because most have anisotropic magnetic susceptibility tensors, χ. Different orientations result in induced magnetic moments of different sizes, and the energies of interactions of these moments with the magnetic field are different. It is clear in Eq. 11 that measurement of residual dipolar couplings can provide powerful structural constraints through their relationship to the angle θ and the internuclear distance r. The effects of averaging simply need to be separated. When many interactions exist within the same molecule, and they are averaged by the same motions, this separation is possible. The

conditions for structural application are therefore well defined: large anisotropy of susceptibility, large magnetic field, and numerous interactions, preferably ones where either r or θ is known.[43]

In 1995, it was shown by Prestegard and coworkers that the dipolar contributions to the splitting of ^{15}N resonances of ^{1}H–^{15}N amide pairs in multidimensional high-field NMR spectra of field-oriented cyanometmyoglobin could be measured.[43] The splittings appeared as small field-dependent perturbations of normal scalar couplings, usually of the order of up to ±2–3 Hz. The paramagnetic protein was found to tend to align to a small extent with the magnetic field vector of a high-field spectrometer, in this first case a 750 MHz NMR spectrometer, so that the dipolar contributions to the ^{1}H,^{15}N amide couplings were not completely averaged. More than 90 resonances were assigned to specific sequential sites in the protein. A specially designed two-dimensional HSQC experiment was used to collect data at 750 MHz, from which splittings of the ^{15}N resonance in the indirect dimension could be measured (coupling-enhanced HSQC). The sequence is based on a gradient-enhanced water-flip-back-HSQC,[44] but incorporates an extra ^{15}N 180° pulse during t_1 evolution. The pulse was simultaneous with the usual 180° ^{1}H pulse, but both were positioned accordion-style to allow pure dipolar splitting evolution for half the period and chemical shift plus dipolar splitting evolution for the other half the period. This sequence scaled chemical shift dispersion so that a smaller spectral width and longer evolution time could be used. For the 750 MHz data set, 200 complex t_1 points were collected with a total t_2 acquisition time of 182 ms. The total experiment time was 14 hours, with a recycling rate of 0.5 s^{-1}.[43] While most variations are small compared to the typical ^{15}N line width, they are measurably different. Splittings range from 96 to 90 Hz. If scalar couplings alone were responsible for the splitting, nearly all pairs would be split by 94 ± 1 Hz. The splittings are also field dependent ($\propto B_0^2$), and thus the dipolar contributions should increase by a factor of 2.25 in going from 500 to 750 MHz,[43] and a additional factor of 1.44 on going from 750 MHz to currently-available high-field systems (900 MHz). This field dependence can be exploited to allow separation of the scalar and dipolar contributions to the observed splitting. The dipolar contributions could be correlated with predictions based on the known susceptibility and known structure of the protein. The implication of these residual dipolar couplings was that they could be used as an additional source of information for protein structure determination in solution. The same methods have been utilized more recently for study of methemoglobin[45] and a number of other systems.[46–50]

Since the first report for cyanometmyoglobin,[43] a number of ways of increasing the alignment of the paramagnetic molecule with the magnetic field of the NMR spectrometer have been developed; most of these rely on crowding the molecules of interest with large substances such as bicelles, phage particles or liquid

crystals, all of which themselves tend to align with a magnetic field. In many of these cases no paramagnetic metal is necessary. Residual dipolar couplings of ±10 Hz can be achieved by adjusting the concentration of bicelles in the mixture, for example, or by changing their axis of alignment by adding a paramagnetic metal that will bind to the bicelles. In addition, means of attaching a paramagnetic metal site, usually housing a lanthanide ion with multiple unpaired electrons[51,52] or several lanthanide ions,[53] to the protein of interest, have been developed, which make it possible to apply the technique of partial alignment of any protein with the strong magnetic field of a high-field NMR spectrometer (750–900 MHz), so that residual dipolar couplings can be measured and used as an additional kind of restraint to allow structure determination of larger and larger proteins.[54] Applications not only to proteins, but also nucleic acids and carbohydrates are envisioned,[54] and a number of these have already been published.[55–78]

3. *Temperature Dependence of Contact and Pseudocontact Shifts*

The temperature dependence of the paramagnetic shifts of paramagnetic complexes in general has often been explained as following the Curie law:[2–4,13]

$$\delta_{iso} \propto \frac{C}{T}, \tag{12}$$

where C is a combination of all the terms present in Eqs. 4 and 9, except in those cases for which the pseudocontact shift obeys Eq. 10. This is approximately true, despite the discussion of the pseudocontact shifts of high-spin metalloporphyrins, which exhibit T^{-2} dependence (Eq. 10). However, as described previously elsewhere,[25] in many cases there are excited states that are within 1–3 kT or so of the ground state, and hence paramagnetic complexes with such a thermally-accessible excited state do not follow the simple Curie law, but rather an expanded Curie law that takes into account the excited state:[25]

$$\delta_n^{con} = \left(\frac{F}{T}\right)\left\{\frac{W_1 C_{n1}{}^2 + W_2 C_{n2}{}^2 e^{-\Delta E/kT}}{W_1 + W_2 e^{-\Delta E/kT}}\right\}, \tag{13}$$

where δ_n^{con} is the contact shift of each proton or carbon of interest, F is the Curie factor that relates the contact shift to the orbital coefficients, T is the absolute temperature, W_1 and W_2 are the weighting factors for the ground and excited state orbitals (equal if the spin multiplicities of ground and excited states are the same), C_{n1} and C_{n2} are the orbital coefficients for position n in the ground and excited states (in the ground state the values of C_{n1} and C_{n2} should be similar to those of the McConnell equation, ρ_C, of Eqs. 5 and 6, unless ΔE is small), respectively, ΔE

is the energy separation between ground and excited states, k is the Boltzmann constant. Several model ferrihemes and ferriheme proteins,[25,79] including a Mo^V-appended $[(TPP)Fe(NMeIm)_2]^+$ complex,[80] for which one axial ligand is prevented from rotating by the bulky 2,3-Mo^V complex, have been analyzed in this manner, as will be discussed below. The values of ΔE range from very small for nonhindered unsymmetrically-substituted $(TPP)Fe^{III}$ derivatives[25] to 160 cm^{-1} for the Mo^V-appended $[(TPP)Fe(NMeIm)_2]^+$ complex,[25,80] 400–700 cm^{-1} for cytochrome b_5,[25,81] and 500 cm^{-1} for *Aplysia* cyanometmyoglobin.[25,82] In these cases ΔE values represent the difference in energy between the two 3e(π) orbitals (see Figure 2) of the heme, and hence also the ΔE between the d_{xz} and d_{yz} orbitals of low-spin iron(III), Figure 1. Another case that has been analyzed in terms of the expanded Curie law of Eq. 13 involves the so-called spin-admixed S = 3/2–5/2 or 5/2–3/2 states of ferric tetraphenylporphyrin perchlorates, where either the 5/2 or 3/2 state is the ground state,[83] as discussed in Section IV.A.**7**, and shown in Figure 27. Therefore, from NMR spectra one not only learns about the electronic ground state, but also, frequently, the first excited electronic state of the complex. The temperature-dependence fitting program TDF for Windows, written by Dr. Nikolai Shokhirev, can be downloaded from the World Wide Web,[84] saved in a directory and

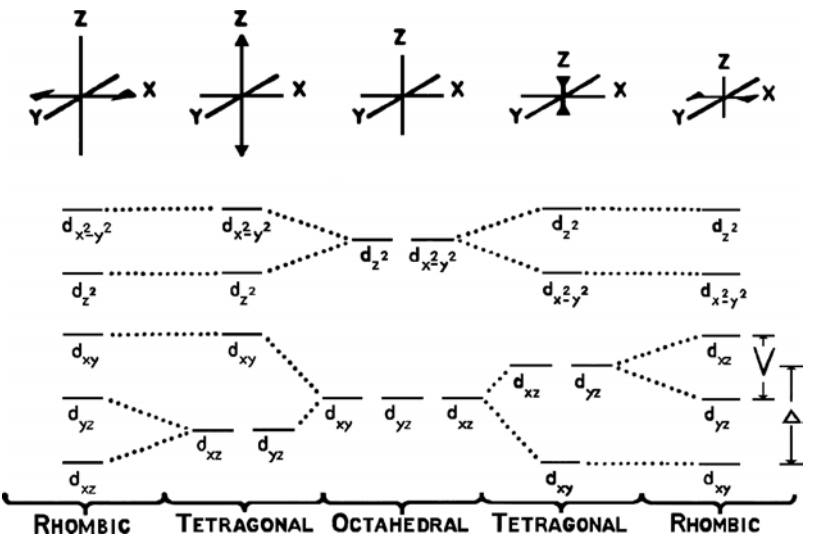

Figure 1. Possible lowering of symmetry of the d-orbitals from octahedral symmetry (center) to either tetragonal or rhombic symmetry. The porphyrin ring itself creates a tetragonal splitting, while planar axial ligands and/or macrocycle asymmetry create a rhombic splitting pattern. One of the two patterns on either side of the central octahedral pattern typically occurs for most metal porphyrinates. Reprinted from Walker, F. A. *Coord. Chem. Rev.* **1999**, *185–186*, 471–534 with permission from Elsevier.

unzipped for use. Assuming that the temperature dependence of the paramagnetic shifts can be fit by either Eq. 4 + 9 (the Curie law), 4 + 10 (Curie law + $1/T^2$ term) or Eq. 13, the system may be considered to be well-behaved, so as to lead to the possibility of separating the contact and pseudocontact contributions to the paramagnetic shift. Detailed approaches to this separation will be presented in Section III.B, after further consideration of the mechanisms of spin delocalization that comprise the contact term.

B. Nuclear Relaxation and Linewidths

In this section the focus will be on relaxation mechanisms[85] that affect only T_2, that is, chemical exchange effects, as well as those that affect both T_1 and T_2.

1. *Chemical Exchange Line Broadening and EXSY Cross Peaks*

Line broadening effects on 1D NMR spectra that result from chemical exchange have been discussed in depth elsewhere.[2,4,86,87] Dynamic processes that can be conveniently monitored are those whose rates are comparable to the chemical shift differences, $\nu_A - \nu_B$, in frequency units, between the exchanging sites A and B.[2,4,86,87] Paramagnetism often permits the resolution of magnetically nonequivalent environments that could not be resolved in a comparable diamagnetic system. In addition, since paramagnetism leads to such a large, nonlinear expansion in the chemical shift range, the chemical shift differences between exchanging environments are likely to be much larger, which permits the characterization of much faster dynamic processes by line broadening techniques. Two-dimensional NMR techniques based on the NOESY(EXSY) or ROESY experiments[88] permit the measurement of much slower rates of chemical exchange, at temperatures where line broadening is not even apparent. An example of such a study of a chemical exchange process is the case where the unsymmetrical axial ligands of $[(TMP)Fe(2\text{-}MeImH)_2]^+$ create four pyrrole-H, four *o*-CH_3, four *m*-H and two *p*-CH_3 environments that are then connected in matrices of cross peaks by chemical exchange as the axial 2-methylimidazole ligands rotate. From the intensity of the cross peaks, the rates of axial ligand rotation could be measured.[89] The rates of axial ligand rotation in the slow exchange regime could also be measured by saturation transfer[90] and by T_2 relaxation times,[91] the latter technique being useable over the same temperature range as the older line broadening techniques. Not only the paramagnetic low-spin iron(III) complexes could be studied by the 2D NMR technique, but also their diamagnetic cobalt(III) and iron(II) analogs.[89,92] This system will be considered in greater detail in Section IV.A.8.

2. *Proton T_1 and T_2 Relaxation Times, as Controlled by Electron Spin Relaxation Times, T_{1e}*

All of these relaxation times have important consequences with respect to whether or not the resonances of interest will be detectable or not.

a. *Electron spin relaxation times, T_{1e} or τ_s*

In the case of an example system which has electron spin S = 1/2, the electron spin relaxation time T_{1e} (sometimes also called τ_s) must be very short compared to the inverse of the electron-nuclear hyperfine coupling constant of the nuclei of our metalloporphyrin complex, $T_{1e} \leq (A/h)^{-1}$, and there are additional factors that make it typically necessary that it be much shorter than that.[93] Organic free radicals, including porphyrin π-cation radicals or their metal complexes, typically have T_{1e}s of 10^{-5} to 10^{-7} seconds, which is too long to achieve this averaging, while metal complexes may have T_{1e}s that range from 10^{-7} to 10^{-13} seconds.[93] Metals that have the longest T_{1e}s include VO^{2+}, Cu^{2+}, Mn^{2+} and Gd^{3+},[93] and to our knowledge, no proton NMR spectra (other than those of phenyl ring substituents of TPP derivatives[2,4]) of these metalloporphyrins have been reported to date, although the ^2H resonances of Cu^{II} porphyrins can be detected by ^2H NMR spectroscopy, as discussed in Section IV.H.1 and shown in Figure 80. Some of these ions have electron configurations that are either d^1 or d^9, for which there are no low-lying excited states to which the ground state is connected by spin-orbit coupling (as is the case of low-spin d^5 and d^7), and thus long T_{1e}s, well-resolved EPR spectra and poorly-resolved NMR spectra, or else, for S > 1/2 systems such as manganese(II), gadolinium(III), and to a lesser extent chromium(III) and manganese(IV), the zero-field splitting constants are small, which leads to long T_{1e}s,[94] well-resolved EPR spectra and poorly-resolved NMR spectra; again, ^2H NMR spectroscopy of appropriately deuterium-labeled complexes makes detection of resonances possible in a number of cases, as discussed below in Sections IV.E and H.3.

On the other hand, high-spin iron(III) and manganese(III) have large zero-field splittings[94] and give well-resolved NMR spectra. It is sometimes possible to extend the range of T_{1e}s over which resonances can be detected, for example for chromium(III) porphyrins, by substituting the protons in the complex of interest with deuterium atoms, which gives a theoretical factor of up to approximately 42 sharpening of the resonances, as discussed in more detail in Section II.D.2.

b. *Nuclear spin-lattice relaxation times, T_1*

The spin-lattice or longitudinal relaxation time of the protons of the metalloporphyrin complex under investigation is typically abbreviated T_1. T_1s are

typically measured by the Inversion-Recovery experiment, as described in various textbooks.[95–99] T_1s must be measured before any 2D NMR experiments are attempted, and typically in a protein having a paramagnetic metal center there is a very wide range of proton T_1s, from those farthest away and thus unaffected by the unpaired electron(s) (500 ms – 1 second if the solution has not been de-gassed with Ar or N_2) to shorter than 3 ms for protons bound to the direct ligands of high-spin iron(III). Although both contact and pseudocontact relaxation effects may be present, the most common situation is that pseudocontact relaxation dominates, especially for nuclei that are not directly connected to the metal through π bonds. Such pseudocontact relaxation results from dipolar coupling between the electron spin of the metal and the nuclear spin of the protons of interest within a given molecule, which is not averaged to zero by rapid rotation of the molecule. Usually, the inverse relaxation times, or relaxation rates, $R_1 = T_1^{-1}$, are proportional to τ_c/r^6, where τ_c is the rotational correlation time of the molecule. A more detailed look at the dependence of R_1 on molecular correlation time, however, shows that the dependence is actually given by:

$$R_1 = T_1^{-1} = \left(\frac{2}{15}\right)\left(\frac{\mu_0}{4\pi}\right)\left[\frac{g_N{}^2(\mu_N)^2\langle g\rangle^2(\mu_B)^2 S(S+1)}{\hbar^2 r^6}\right] \times\left[\frac{7\tau_c}{\left(1+\omega_S{}^2\tau_c{}^2\right)}+\frac{3\tau_c}{\left(1+\omega_I{}^2\tau_c{}^2\right)}\right], \quad (14)$$

where μ_0 is the permeability of free space, g_N is the nuclear g-value, μ_N is the nuclear Bohr magneton (also symbolized as β_N), $\langle g\rangle$ is the average electronic g-value of the metal complex, μ_B is the electron Bohr magneton (also symbolized as β in some of the EPR literature), S is the electron spin of the metal complex, r is the distance between the electron and the nucleus of interest, ω_I is the nuclear Larmor frequency and ω_S is the Larmor frequency of the electron.[93] Of course, there may be an added contact contribution to the R_1s of Eq. 14, especially for protons very near the metal.

For high-spin metals with zero-field splittings, it has been shown that although the exact equation governing T_{1e} differs for the various metal ions being considered,[94] the electron spin relaxation rate for a given metal ion can always be expressed as:

$$T_{1e}{}^{-1} \propto D^2 f(\tau_c), \quad (15)$$

where D is the zero-field splitting constant and τ_c is the rotational correlation time. Thus, linewidths (LW) for high-spin metal complexes should be given by:

$$LW \propto D^{-2}. \tag{16}$$

This relationship holds best for Fe^{III} porphyrinates, where linewidths decrease in the order $N_3^- > Cl^- > Br^- > I^-$.[94] Thus, Fajer and coworkers[100] and the author's coworkers[101] have used this fact to choose I^- as the best anion to produce the sharpest lines for high-spin Fe^{III} chlorins, oxochlorins and dioxoisobacteriochlorins.

Importantly, in connection with the basic $\tau_c r^{-6}$ dependence of R_1 is that the resonances of protons closest to the metal center typically have the shortest T_1s and thus their connectivities are hardest to detect in 2D NMR experiments. Because τ_c depends on solvent viscosity and temperature, changes in any of these factors may make significant changes in the T_1s of the protons, and may thus determine whether 2D cross peaks may be detected or not.

The excellent resolution of the ^1H NMR spectra of dicyanoiron(III) complexes of 2,4-disubstituted deuteroporphyrins was used by La Mar and coworkers to investigate in detail the proton pseudocontact relaxation by delocalized spin density.[102] If only the unpaired electrons on the metal contribute, nuclear relaxation of protons in low-spin iron(III) porphyrins by T_1 and T_2 processes should be given by:

$$R_1 = T_1^{-1} = 6Kr^{-6}T_{1e}, \tag{17}$$

$$R_2 = T_2^{-1} = 7Kr^{-6}T_{1e} + \left(\frac{1}{3}\right)S(S+1)A_h{}^2T_{1e}. \tag{18}$$

where $K = (1/15)\gamma_H{}^2\langle g\rangle^2(\mu_B)^2S(S+1)$.[102] This should mean that the T_1s of all ring CH_3 should be the same, since r^{-6} is identical for all ring CH_3. However, there is a marked difference in the T_1s of the four methyl groups of natural hemin derivatives that increases as the spread of the methyl resonances increases; the methyl with the largest paramagnetic shift has the shortest T_1.[102] These results were explained in terms of a sum of metal-centered pseudocontact relaxation and the pseudocontact relaxation by the delocalized spin density, ρ_C, in the aromatic carbon to which the methyl group is attached, which yields a modification of Eq. 17:

$$R_1 = T_1^{-1} = 6K[R_M{}^{-6} + \rho_C{}^2R_L{}^{-6}]T_{1e}, \tag{19}$$

where R_M is the distance from the metal center to the proton of interest, and R_L is the distance from the aromatic carbon to the proton. The quantity ρ_C is proportional to

the observed contact shift, as described by Eqs. 4 and 5. Thus, in line with the predictions of Eq. 19, a linear relationship was observed between the observed T_1^{-1} and $(\delta_{con})^2$. From the intercept, assuming $R_M = 6.15$ Å, T_{1e} was determined to be 1.8×10^{-12} seconds, and independent of the basicity of the porphyrins in these model compounds.[102] The slope of this line indicates that $R_M^{-6} = \rho_C^2 R_L^{-6}$ for a contact shift of −19 ppm. Assuming R_L ~1.9 Å, this yields $\rho_C = 0.03$. Thus, 0.03 of an unpaired electron in a carbon p orbital causes paramagnetic pseudocontact relaxation of the appended methyl proton of a magnitude comparable to that from the iron center,[102] and pseudocontact relaxation from both ligand-centered and metal-centered spin density must be considered in analyzing heme methyl T_1s, not only in model complexes, but also in heme proteins.

Ligand-centered pseudocontact relaxation is probably a contributor to the short T_1s of the pyrrole-H of TPP complexes of low-spin iron(III) and the *meso*-H of OEP and natural porphyrin complexes of high-spin iron(III), since R_L ~1.08 Å. This could make the ligand-centered pseudocontact relaxation term 33 times larger for a pyrrole-H than a pyrrole-CH_3 with the same magnitude contact shift. The difference in T_1s observed for low-spin iron(III) complexes of β-pyrrole-substituted porphyrins such as OEP and the natural porphyrins[102] as compared to those of TPP and other *meso*-substituted porphyrins are approximately of this magnitude.[3] However, another possible contribution to the short T_1s of the protons of imidazole and pyridine complexes of $(TPP)Fe^{III}$ could be the rapid modulation of the chemical shifts of the pyrrole-H in complexes where planar axial ligands rotate synchronously or asynchronously at a rate comparable to the energy separation of the $3e(\pi)$ orbitals.[103] This energy separation can be approximated as that between the d_{xz} and d_{yz} orbitals, as calculated from the EPR g-values (Section IV.A.8.a). This energy separation is of the order of up to 540–800 cm^{-1}, depending on the value chosen for the spin-orbit coupling constant,[2,4] (see Section IV.A.8.a). This energy separation translates to a ΔE of up to $1.6–2.4 \times 10^{13}$ s^{-1}. In comparison, the energy barrier to rotation of nonhindered imidazoles on $(TPP)Fe^{III}$ has been estimated as 3.3 kJ/mol for synchronous and 5.4 kJ/mol for asynchronous rotation.[90] These barriers lead to calculated rate constants of 1.6×10^{12} s^{-1} for synchronous rotation and 7.2×10^{11} s^{-1} for asynchronous rotation of ligands. The fact that the rate constant for synchronous rotation of axial ligands is within a factor of ten of the energy separation of the $3e(\pi)$ orbitals suggests that this mechanism of shortening of the T_1 and T_2 relaxation times is probably very important for low-spin $(TPP)Fe^{III}$ complexes. In support of this, TPP-related ferriheme complexes that have axial ligands that are "fixed" in orientation (i.e., that are rotating slowly on the NMR timescale) have much longer T_1s (up to 50 ms)[80,103] than do simple, unhindered $[(TPP)Fe^{III}L_2]$ complexes (9 ms or shorter).[104]

c. *Nuclear spin–spin relaxation times, T_2*

When chemical exchange is absent, spin–spin proton or transverse relaxation time in a paramagnetic metal complex is T_2, for which the inverse (R_2) is also often proportional to τ_c/r^6 if pseudocontact relaxation dominates. But the more detailed dependence on correlation time τ_c has a different relationship involving nuclear and electronic Larmor frequencies:

$$R_2 = T_2^{-1} = \left(\frac{1}{15}\right)\left(\frac{\mu_0}{4\pi}\right)\left[\frac{g_N{}^2(\mu_N)^2\langle g\rangle^2(\mu_B)^2 S(S+1)}{\hbar^2 r^6}\right] \times\left[\frac{13\tau_c}{1+\omega_S{}^2\tau_c{}^2}+\frac{3\tau_c}{1+\omega_I{}^2\tau_c{}^2}+4\tau_c\right], \quad (20)$$

where all terms have the same definitions as in Eq. 14. Of course, there may be added to Eq. 20 a contact contribution,[93] especially for protons very close to the metal, and in addition, there may be an additional term, especially for metals which have multiple unpaired electrons, due to Curie relaxation. This term is another type of pseudocontact relaxation which is proportional to $B_o{}^2S^2(S+1)^2\tau_c/T_2r^6$,[35] where B_o is the magnetic field, and is thus most noticeable at very high magnetic fields for large values of S. [It has not been possible to detect it for low-spin iron(III) porphyrins at 500 MHz.[103]] Most metalloporphyrins are not in the extreme narrowing limit at most common NMR frequencies and in most solvents, and so T_2 is usually shorter than T_1. For cases in which there is sizable magnetic anisotropy, linewidths become broader due to this factor, which shortens the electronic T_{1e} (Section II.B.2.a). Sternlicht first derived the expression for the nuclear relaxation rate for complexes possessing magnetic anisotropy:[105]

$$R_2 = T_2^{-1} = \left[\frac{2\gamma_N(\mu_B)^2 S(S+1)}{3r^6}\right]\left[\langle g\rangle^2 + g_{\|}{}^2\cos^2\theta + g_{\perp}{}^2\sin^2\theta\right]\tau_c, \quad (21)$$

where $\langle g\rangle^2$ is the square of the average g-value, r is the proton-metal distance, θ is the angle between the z-axis and the vector r, and all other quantities have their usual definitions. Thus, if $g_{\|}$ is aligned along the z-axis of the complex, as is usually the case, and only the pyrrole-H, for which $\theta = 90°$, are considered, the lines will be broadened in proportion to the size of $\langle g\rangle^2 + g_{\perp}{}^2$. This relationship provides an alternate means of accounting for the linewidths

of the pyrrole-H resonances of $[(TPP)FeL_2]^{+/-}$ complexes for L = CN^- as compared to ImH, discussed in the section above (where the g-values are 0.83 and 1.96, respectively, based on the g-values listed in Table 12), but may not account for the linewidths of low-spin cobalt(II) porphyrins, discussed in Section IV.C.1.

C. Spin Density and Bonding: Mechanisms of Spin Delocalization

Unpaired electrons of 3d metalloporphyrins of various oxidation and spin states are expected to be mainly localized either on the metal or on the porphyrin ring. If the unpaired electron is largely localized on the metal, it is expected to be located in one or more of the metal d-orbitals, while if it is localized on the porphyrin ring, it is expected to be found in either the HOMO (for metalloporphyrin π-cation radicals, $[(P^{-\bullet})M]^+$) or the LUMOs (for π-anion radicals, $[(P^{3-\bullet})M]^-$, or dianions, $[(P^{4-\bullet})M]^{2-}$). For metalloporphyrins in which the unpaired electron is located in one or more of the d-orbitals, spin delocalization can occur through either σ or π orbitals. In the latter case, the spin transfer can arise through either ligand-to-metal (L $\rightarrow$ M) spin transfer (the usual situation), which involves overlap of a filled π orbital with a half-filled d_π orbital, or rarely, by metal-to-ligand (M $\rightarrow$ L) spin transfer or "back-bonding", which involves overlap of an empty π orbital with a half-filled d_π orbital. Thus, an understanding of the symmetry properties and relative energies of the metal and porphyrin orbitals will be of value in understanding the possible mechanisms of spin delocalization to the protons on the periphery of the porphyrin ring.

1. *The Metal Ion*

The relative energies of the five d-orbitals are generally expected to be as shown in one of the sections of Figure 1, although individual variations in these relative energies are observed and are discussed in Section IV. The relative energies of the d-orbitals, beginning in the center of Figure 1, of an ideally octahedral complex (O_h point group) is shown, but it is not expected that the porphyrin will (probably ever) have the same ligand field as the axial ligands. Therefore, we descend to tetragonal symmetry by going to the right or the left of the center of the diagram, to the right if the axial ligands are of stronger field than the porphyrin ring, to the left if they are of weaker field; typically "stronger field" or "weaker field" is controlled by π-donor and π-acceptor properties of the axial ligands. Strong π-donor ligands (highly basic pyridines such as 4-dimethylaminopyridine or almost any imidazole) typically shift the system to the right side tetragonal section of the diagram, whereas strong π-acceptor ligands (cyanide ion, organic isocyanides,

low-basicity pyridines) typically shift the system to the left side tetragonal section of the diagram. Whether the electrons will be paired (low-spin) or unpaired (high-spin) depends on the splitting between the three lower-energy d-orbitals and the two higher-energy d-orbitals, which typically depends on the σ-donor strength of the axial ligands, and/or on whether the coordination number is five rather than six. Whether the orbitals are further split to rhombic symmetry depends on the nature of the axial ligands and their orientations (planar, in parallel, but not perpendicular planes) and on the electron configuration of the metal.

Metalloporphyrins which have been successfully studied by NMR spectroscopy are listed in Table 7. For many of these the metal may be either high-spin, in some cases intermediate-spin, or low-spin. Thus, metalloporphyrins have a rich variety of potential electron configurations. The valence electrons are almost invariably located in the 3d orbitals of the metal, except in the relatively rare cases of true π-cation radicals of $PFe^{II}(NO)$, $PRu^{II}(CO)$ or one-electron oxidized cobalt(III) porphyrins or related macrocycles or of π-cation radicals of bromoiron(III) oxophlorins,[106] but probably not the supposed π-cation radicals of iron(II) complexes of reduced hemes bound to organic isonitrile ligands,[107] which are more likely low-spin iron(III) complexes of the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state. In 4-, 5- and 6-coordinate metalloporphyrins, the d-orbitals consist of three general symmetry types: (1) The σ-symmetry orbitals that interact with the porphyrin nitrogens and with axial ligands (strictly speaking, in the idealized D_{4h} symmetry of 4- and 6-coordinate metalloporphyrins, these orbitals are of a_1 (d_{z^2}) and b_1 ($d_{x^2-y^2}$) symmetry, but in any case, they are engaged in σ-bonding interactions only); (2) the d_π orbitals, d_{xz} and d_{yz}, which can engage in π-bonding with filled (the common situation) or empty (uncommon) π-symmetry orbitals of the porphyrin ring as well as the axial ligands; and (3) the d_{xy} orbital, which is nonbonding, both in relation to the porphyrin ring and the axial ligands, at least when the porphyrin ring is planar. However, it becomes capable of π-bonding if the porphyrin ring is ruffled, as discussed in Section II.C.2, or if the metal is 5-coordinate and significantly out of the plane of the bonding nitrogens of the porphyrin or other macrocycle, as discussed in Sections II.C.4 and IV.A.6.b,c.

2. *The Porphyrin Ring*

Both 4- and 6-coordinate metalloporphyrins have effective D_{4h} symmetry, if the effects of planar axial ligands and potentially unsymmetrically-placed porphyrin substituents are neglected. Each porphyrin nitrogen supplies a σ-symmetry lone pair that points directly toward the porphyrin nitrogens along the *x*, *-x*, *y* and *-y* axes, and a single π-symmetry p-orbital that is perpendicular to the plane of the porphyrin ring, the p_z orbital of the bonding nitrogen. Not only does the bonding nitrogen have an available π-symmetry p_z orbital, but so do each of the C_α, C_β and

Table 7. Oxidation and spin states of metalloporphyrins for which NMR spectra have been reported.

Metal	Oxidation state	Spin state	Electron configuration
Cr	II	S = 2 High-spin	$(d_{xy})^1(d_{xz},d_{yz})^2(d_{z}2)^1$

[a]For the lanthanides, S is not a good quantum number.

C_m carbons of the porphyrin skeleton. Earlier[108–112] and recent workers[113–116] have developed more-or-less sophisticated molecular orbital treatments of the porphyrin ring and related macrocycles. In each of these treatments, π molecular orbitals are constructed based on the symmetry properties of the idealized D_{4h}-symmetry porphyrin ring. Hückel MO treatments are qualitatively useful if exact energy separations are not needed.[117] A program has been developed which utilizes the Huckel MO treatment and allows visualization of the molecular orbitals of the porphyrin and related macrocycles, and is available on the Web.[118] The 24 p_z orbitals of the porphine macrocycle are thus combined to produce 24 molecular orbitals (2 a_{1u}, 4 a_{2u}, 3 b_{1u}, 3 b_{2u}, and 6 e_g sets), 13 of which are filled by the 26 p_z electrons of the 24 atoms of the porphyrin nucleus. Although the theories differ in detail, all agree that the frontier and near-frontier orbitals are, in order of increasing energy, $3e(\pi) < 1a_{1u}(\pi) \sim 3a_{2u}(\pi) < 4e(\pi^*)$, using the notation of Longuet-Higgins, *et al*.[108] The $3e(\pi)$, $1a_{1u}(\pi)$ and $3a_{2u}(\pi)$ orbitals are filled, while the $4e(\pi^*)$ orbitals are empty. All theories agree further that the latter are the LUMOs of the porphyrin ring, while the HOMO(s) may be either $1a_{1u}(\pi)$, $3a_{2u}(\pi)$, or the d_{xy} or $d\pi$ orbitals, depending on the oxidation state of the metal, the porphyrin and degree of reduction of the macrocycle (chlorins and isobacteriochlorins), substituents[119] and the axial ligand(s) present. The symmetry properties and electron distributions predicted are shown in Figure 2, left and right, which have been calculated using the program MPorphW.[118] The two pictures show the electron density distributions observed if the nodal planes of the π-symmetry orbitals are placed along the porphyrin nitrogens, as usually shown (Figure 2, left), or along the *meso* positions, an equivalently correct representation (Figure 2, right). As will be shown below, the orbitals of Figure 2 left, are similar to those of the chlorin ring, while those of Figure 2 right, are similar to those of most other macrocycles.

There is at least one case where the metal d_{xy} orbital of a d^1 metalloporphyrin lies lower in energy than the highest-energy filled porphyrin orbital, and thus gives rise to a non-Aufbau filling of the orbitals. This is the case of the V^{IV}=O porphyrin complexes of both OEP and TPP, as well as the phthalocyanine complex (Pc).[120] The EPR spectra of these complexes are indeed those of the $(d_{xy})^1$ metal-based electron configuration,[121,122] yet one-electron oxidation removes an electron from the porphyrin ligand rather than from the $b_2(d_{xy})$ orbital,[123] and one-electron reduction places an electron into an empty porphyrin-based orbital rather than with the single electron in the b_2 (d_{xy}) orbital.[124] Similar behavior has been observed for oxoiron(IV) porphyrinates.[125] These observations have been interpreted in the past to mean that the valence porphyrin orbitals are very close in energy to the metal-based orbitals.

To determine the relative energies and nature of the positive ion states of VO(OEP) in the gas phase, the valence photoelectron spectra of this and related porphyrin and phthalocyanine molecules have been collected.[120] The photoelectron

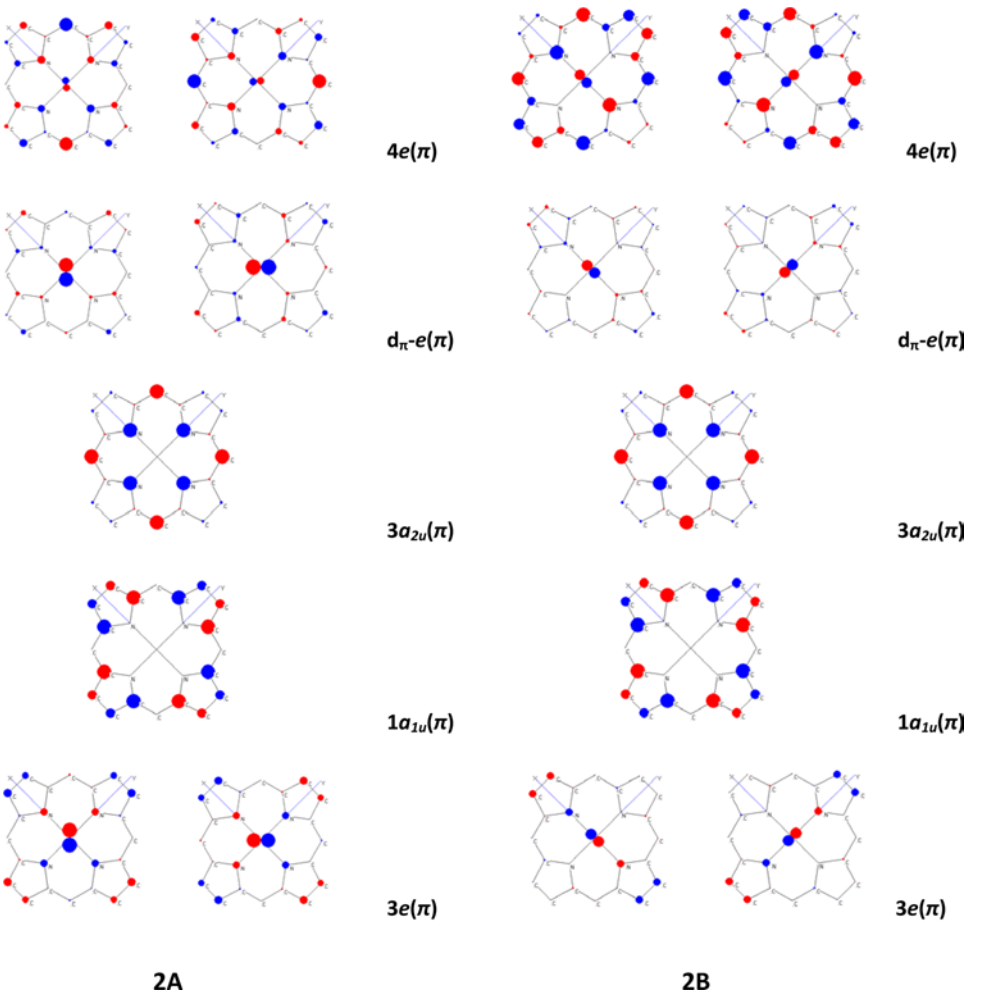

Figure 2. Frontier molecular orbitals of the porphyrin ring, including the mainly metal d_π–e(π) combination orbitals that are usually the HOMOs and/or SOMOs of a metalloporphyrin. Two equivalent representations of the orbitals are shown, with nodes through the nitrogens (left) or the *meso* positions (right). In practice, when axial ligands are also bound to the metal, nodes could be placed at any arbitrary angle in between these two, as long as the nodes of the two orbitals are at right angles to each other. The actual positions of the nodes will depend upon the orientation of planar axial ligand(s).[8] The relative sizes of the circles at each atom represent the relative orbital electron density coefficients, C_i^2, which should be closely related to spin density coefficients, ρ_C. Calculated using the program MPorphW.[118]

spectra show that the lowest energy ionization of VO(OEP) and of vanadyl phthalocyanine, VO(Pc), in the gas phase is from a filled ligand-based orbital, as found for the oxidation of VO(OEP) in condensed phases.[123] The photoelectron spectra also show the unusual result that ionization from the singly occupied metal d

orbital of these molecules requires considerably more energy (at least 1 eV) than ionization from the $3a_{2u}(\pi)$ and $1a_{1u}(\pi)$ doubly occupied porphyrin orbitals, and that the energies associated with high-spin stabilization are extremely small. These observations imply a non-Aufbau occupation of the molecular orbitals. Electronic structure calculations indicate that this non-Aufbau behavior is strongly favored by the electron–electron repulsion energies, regardless of electron relaxation energies with ionization, correlation energies, exchange energies, or other contributions. The large energy associated with this non-Aufbau behavior of vanadyl porphyrins suggests that such behavior may be important in the chemistry of other metalloporphyrins, certainly those of the +4 state for first-row transition metals, and the fundamental basis for this behavior may have important implications for the most stable states of other molecules.[120]

In spite of the non-Aufbau filling of the orbitals of vanadium(IV)[120] and iron(IV)[125] porphyrins, for the vast majority of cases of first-row transition metals in the +2 and +3 oxidation states the d_{xy} and d_π orbitals are believed to lie at similar or perhaps higher energy than the porphyrin or related macrocycle HOMO, and thus the d_π-$e(\pi)$ combined orbital set has been included in Figure 2, just above the $1a_{1u}(\pi)$ and $3a_{2u}(\pi)$ orbitals, in addition to the $3e(\pi)$ porphyrin-only orbitals, which are lower in energy than $1a_{1u}(\pi)$ and $3a_{2u}(\pi)$. The d_π-$e(\pi)$ set of Figure 2 are approximately 75% metal in character, and the orbital coefficients depicted are very similar in ratio to those of the porphyrin-based $3e(\pi)$ orbitals.

For electronic absorption spectra, excitations from $1a_{1u}(\pi)$ and $3a_{2u}(\pi)$ to $4e(\pi^*)$ give rise to the so-called α, β and Soret bands in the visible spectra[109–112] while excitations from $1a_{1u}(\pi)$ and $3a_{2u}(\pi)$ to d_π-$e(\pi)$ give rise to the near infrared charge transfer transitions that have been studied for heme models and proteins by MCD spectroscopy.[126,127] Porphyrin π-cation radicals $[H_2P^{\bullet}]^+$, or their metal(II)-bound counterparts, $[M^{II}P^{-\bullet}]^+$ have either $a_{2u}(\pi)$ or $a_{1u}(\pi)$ unpaired electrons, depending on whether they do or do not have *meso* substituents, respectively,[128] although this can change with the oxidation state and coordination number of the metal and other factors.[128] However, although either the $1a_{1u}(\pi)$ or $3a_{2u}(\pi)$ orbital is typically the HOMO of the porphyrin ring itself (excluding the largely metal-based d_π-$e(\pi)$ orbitals), neither of these orbitals have the proper symmetry to overlap with the d_π orbitals of the metal if the porphyrin ring is planar. In this case, only the $3e(\pi)$, which are lower in energy than either $1a_{1u}(\pi)$ or $3a_{2u}(\pi)$, and can form the depicted d_π–$e(\pi)$ hybrids, and the $4e(\pi^*)$ orbitals, which are higher in energy than either $1a_{1u}(\pi)$ or $3a_{2u}(\pi)$, have the proper symmetry for overlap with the metal d_π orbitals. The $4e(\pi^*)$ orbitals were earlier believed to interact strongly with the d_π orbitals in 5-coordinate Fe^{II}, Fe^{III} and Ni^{II} porphyrin complexes.[2–7] However, as will be shown later in Sections II.C.3 and IV.A.4.a(i), there is no longer any evidence that the $4e(\pi^*)$ orbitals are involved in spin delocalization in any of the metalloporphyrin

complexes to be discussed, even though they have proper symmetry to interact with the d_π orbitals via M $\rightarrow$ P π bonding. Since the 3e(π) orbitals are filled, the type of overlap interaction that can occur between them and the metal d_π orbitals is P $\rightarrow$ M (or, more generally, L $\rightarrow$ M) π bonding. Clearly, the only way in which this type of bonding interaction can lead to spin delocalization from metal to porphyrin π system is if the metal d_π orbitals are partially, but not completely, filled. Thus, spin delocalization via interaction between the filled 3e(π) orbitals and the metal d_π orbitals can occur only if the metal electron configuration is (d_{xz},d_{yz}).[1–3]

In cases where the porphyrin ring is strongly ruffled, the p_z orbitals of the porphyrin nitrogens are twisted away from the normal to the mean porphyrin plane, and thus have components of the p_z orbitals of the nitrogens that lie in the mean (xy) plane of the macrocycle. These components of the "twisted" p_z orbitals have the proper symmetry to interact with the metal d_{xy} orbital, as shown in Figures 3[129] and 4c,[130] and an interaction such as that shown presumes that the energies of the metal and interacting porphyrin orbitals are quite similar, unlike the case for the vanadyl porphyrin discussed above. Consistent with this presumption, while V^{IV}=O porphyrins have no distortion of the porphyrin ring other than a slight doming that places the metal somewhat above the plane of the four nitrogens in the direction of the oxo group, low-spin Fe^{III} porphyrins having two π-acceptor axial ligands such as *t*-BuNC, are strongly ruffled, even though the axial ligands are small. The porphyrin orbital that has proper symmetry to interact with the metal d_{xy} orbital in this case is the $3a_{2u}(\pi)$ orbital,[129] Figure 2. (Such a porphyrin-metal d_{xy}-$a_{2u}(\pi)$ combined orbital has not been depicted in Figure 2, but it would presumably lie above the d_π-e(π) set of the left or right sides of Figure 1, respectively.)

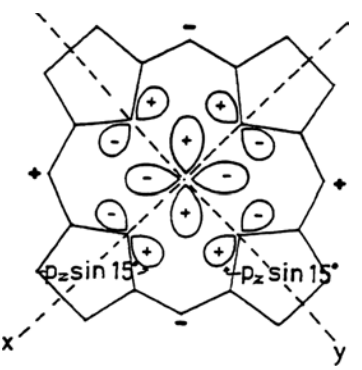

Figure 3. Possible interactions of the d_{xy} orbital with the porphyrin nitrogens in the case of strong S_4 ruffling. The remaining nitrogen p_z projections have proper symmetry to allow delocalization via the $a_{2u}(\pi)$ porphyrin orbital. Modified from Safo, M. K.; Walker, F. A.; Raitsimring, A. M.; Walters, W. P.; Dolata, D. P.; Debrunner, P. G.; Scheidt, W. R. *J. Am. Chem. Soc.* **1994**, *116*, 7760–7770, with permission from the American Chemical Society.

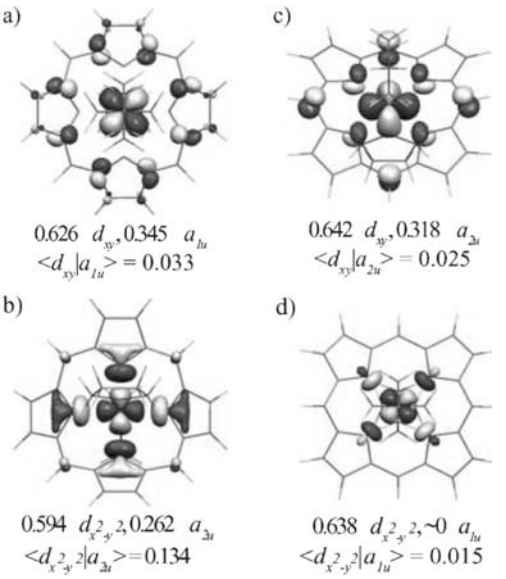

Figure 4. Molecular orbitals based on spin-restricted calculations which depict the bonding interactions between **(a)** d_{xy} and $1a_{1u}(\pi)$ and **(b)** $d_x2_{-y}2$ and $3a_{2u}(\pi)$ for saddled porphyrins, and the bonding interactions between **(c)** d_{xy} and $3a_{2u}(\pi)$ and **(d)** $d_{x^2-y^2}$ and $1a_{1u}(\pi)$ for ruffled porphyrins. The corresponding orbital contributions and the effective orbital overlap in space are also shown under each molecular orbital. Reprinted from Cheng, R.-J.; Wang, Y.-K.; Chen, P.-Y.; Han, Y.-P.; Chang, C.-C. *Chem. Commun.* **2005**, 1312–1314, with permission of the Royal Society of Chemistry.

A ruffled conformation of a metalloporphyrin also allows an additional nontraditional interaction between a metal d-orbital and a porphyrin π orbital: In a ruffled conformation the $d_{x^2-y^2}$ orbital can interact with the porphyrin $1a_{1u}(\pi)$ orbital; these interactions are shown in Figure 4d. As a result of such a ruffled conformation, a metalloporphyrin with an unpaired electron in the d_{xy} orbital would be expected to have spin delocalization to the porphyrin $3a_{2u}(\pi)$ orbital, while one with an unpaired electron in the $d_{x^2-y^2}$ orbital would be expected to have spin delocalization to the porphyrin $1a_{1u}(\pi)$ orbital. Conversely, if a metalloporphyrin is highly saddled, the interactions of these two orbitals with the two aforementioned π orbitals is reversed; in this case, as shown in Figure 4a, when the porphyrin is saddled, the d_{xy} orbital has proper symmetry to interact with the $1a_{1u}(\pi)$ orbital, and delocalization from d_{xy} to $1a_{1u}$ is allowed, while as shown in Figure 4b, the $d_{x^2-y^2}$ orbital has proper symmetry to interact with the $3a_{2u}(\pi)$ orbital and delocalization from $d_{x^2-y^2}$ to $3a_{2u}(\pi)$ is allowed. The d_{xy}-$1a_{1u}(\pi)$ interaction is clearly important in the case of the bis-*t*-BuNC complex of $OETPPFe^{III}$ discussed in Section IV.A.8.c.

If the unpaired electron is mainly localized in a porphyrin π-symmetry orbital, rather than in a metal d-orbital, as would be the case for PFe^{II} π-cation radicals,

then the system is described as a metalloporphyrin π-cation or -anion radical. The electron configuration of π-cation radicals, $[M^{II}(P^{-\bullet})]^+$, is typically either $(1a_{1u})^1$ or $(3a_{2u})^1$, since one or the other of these orbitals is typically the HOMO of the porphyrin π system. In the case of the $(3a_{2u})^1$ π-cation radical, confusion can arise as to whether the electron is mainly porphyrin-based or mainly metal-based with a half-filled d_{xy} orbital. (Simple Hückel MO theory, assuming a flat porphyrin ring, is not able to show this interaction.) Both NMR and EPR spectroscopy are useful for differentiating between these two, for the NMR spectra of porphyrin-based radicals usually have very large spin density at the *meso*-carbons, and EPR spectra of porphyrin-based radicals are extremely sharp (unless the metal has unpaired d-electrons, as for $[Fe^{IV}{=}O\ P^{-\bullet}]$ Compound I centers discussed in Section IV.A.13), with both $g_{\|}$ and $g_{\perp}$ being slightly greater than 2.0 and ranging from 2.001 to 2.003, while for metal-based low-spin d^5 configuration $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state systems $g_{\|}$ is less than 2.0 while $g_{\perp}$ is greater than about 2.2 in most cases,[131] as discussed further in Section IV.A.8.c (see, however, Ref. 132). π-Anion radicals typically have the electron configuration $(4e)^1$, and dianions $(4e)^2$, and again have g-values ranging from 2.001 to 2.003.

In the case of chlorins (dihydroporphyrins), Structure **4**, the chemical reduction of one pyrrole ring reduces the symmetry of the molecule, and thus removes the degeneracy of the $3e(\pi)$ and $4e(\pi^*)$ orbitals. Hückel molecular orbital calculations[118,133] predict the electron density pattern and nodal properties shown in Figure 5 for the corresponding chlorin π orbitals. An important feature of these modified orbitals is the fact that the former $1a_{1u}(\pi)$ orbital, in the chlorin case of Figure 5 denoted A_{-1}, has the proper symmetry at the nitrogens of rings II and IV to allow overlap with a d_π orbital, d_{xz} in the coordinate system shown.[133] This has important consequences for the pattern of spin delocalization observed for both high- and low-spin iron(III) complexes of chlorins, discussed in Sections IV.A.6.c and IV.A.8.i, respectively. Similar modifications of the electron density distribution and symmetry properties of the A,B-tetrahydroporphyrins, better known as isobacteriochlorins, Structure **5**, and dioxoisobacteriochlorins related to heme d_1,[22] Structure **6**, are also expected. The electron density pattern and nodal properties of the corresponding orbitals of isobacteriochlorins calculated with the program MPorphW,[118] are shown in Figure 6. In each case of lower than four-fold symmetry, the orbitals are labeled A (antisymmetric with respect to the two-fold axis) or S (symmetric with respect to the twofold axis), and are numbered 1, −1 and −2, depending on whether they are empty, highest filled or next-highest filled, respectively. The d_π-$e(\pi)$ type orbitals are labeled $d–A_{-2}$ and $d–S_{-2}$ in each MO diagram. However, the electron density pattern for the bacteriochlorins, which have *trans*-saturated pyrrole rings, and their relatives, the *trans*-dioxobacteriochlorins, both of which have a 2-fold rotation axis

Calculated using the program MPorphW.[118]

perpendicular to the plane of the macrocycle, have higher symmetry, and do not show the mixing of the $1a_{1u}(\pi)$ and d_{xz} orbital.

The corrole ring system (Structure **7**) is closely related to the porphyrins, and they also have frontier orbitals corresponding to those of the above-mentioned ring systems. These orbitals of the corrole ring, calculated with the program MPorphW,[118] are shown in Figure 7, where it is interesting to note that the energies of the S_{-1} and d-S_{-2} and d-A_{-2} orbitals are inverted. Perhaps this helps to explain the ease of removal of one π electron from the corrole ring, which will be discussed in Section IV for the Fe, Co, Ni, Mn and Cu corroles.

3. *The Effect of Axial Ligand Plane Orientation on the Combined Contact and Pseudocontact Shifts of Low-Spin Ferriheme Proteins and Synthetic Hemins with Hindered Axial Ligand Rotation*

Low-spin ferriheme complexes with the electron configuration $(d_{xy})^2(d_{xz},d_{yz})^3$, or any other system which has one or two unpaired electrons in the d_π orbitals, and also has one or two axial ligands with a π-symmetry lone pair of electrons that can act as a π-donor to the metal (in addition to the σ-symmetry lone pair), may be able to control the electron density distribution at the heme β- and *meso*-carbons. This should be evident from the two sets of molecular orbitals for the porphyrin ring shown in Figures 2A and B, where the p-orbitals in the center of Figure 2A are shown with their nodal planes along the N–Fe–N axes of the porphyrin at 90° angles to each other, while the p-orbitals in the center of Figure 2B are shown with their nodal planes along the C_{meso}–C_{meso} positions, also at 90° angles to each other for the two orbitals. These p-orbitals in fact represent the π-symmetry lone pair of electrons provided by a ligand, and the implication is that a π-donor ligand can determine the orientation of the nodal plane of the half-filled metal d_π orbital, and consequently, the particular $3e(\pi)$ orbital of the porphyrin used for porphyrin $\rightarrow$ metal π donation and hence spin delocalization to the porphyrin ring. As also stated in the caption of Figure 2, nodes could be placed at any arbitrary angle in between these two, as long as the nodes of the two orbitals are at right angles to each other. The actual positions of the nodes will depend on the orientation of planar axial ligand(s).[8] The relative sizes of the circles at each atom represent the relative orbital electron density coefficients, C_i^2, which should be closely related to the relative spin density coefficients, ρ_C, and thus the contact shift at each atom, discussed in Section II.A.1, Eqs. 3–6. For a system having the *x*- and *y*-axes of the heme oriented as shown in Figure 8, the dependence of the contact shift on the orientation of the nodal plane of the axial ligand should change as shown in Figure 9.

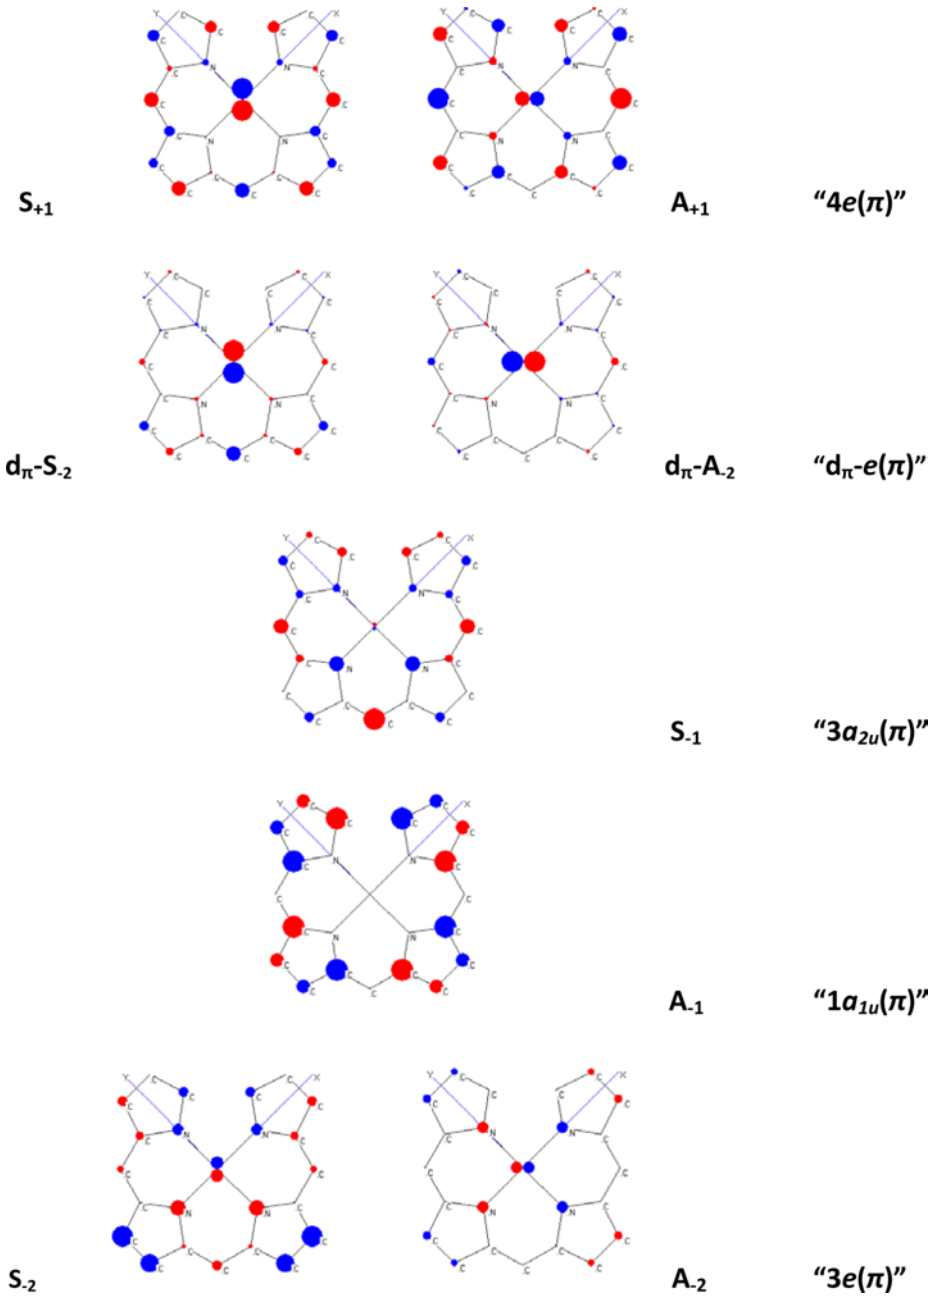

Figure 7. Frontier molecular orbitals of the corrole ring, including the mainly metal d_π–e(π) combination orbitals that are usually the HOMOs and/or SOMOs of a metalloporphyrin. The relative sizes of the circles at each atom represent the relative orbital electron density coefficients, C_i^2, which should be closely related to spin density coefficients, ρ_C. Note that although there is no line connecting the directly-bonded pyrrole rings, the calculations were done assuming a bond. Calculated using the program MPorphW.[118]

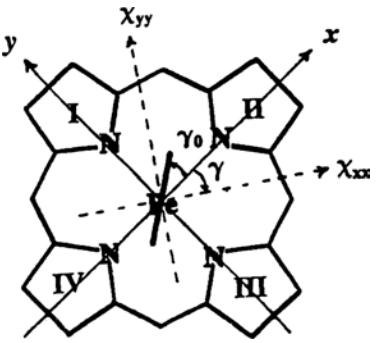

Figure 8. Heme ring with definition of axes (right-hand coordinate system) and axial ligand rotation angle, γ_0, and position of the magnetic axis χ_{xx} if counterrotation by an angle γ takes place. If the axial ligand plane is aligned along the *x* axis of the heme group, as shown, then the expectation is that the minimum magnetic susceptibility tensor component, χ_{xx}, will be aligned coincident with the axial ligand plane, along the molecular *x* axis. As the ligand rotates counterclockwise, χ_{xx} rotates in a clockwise direction in the majority of cases. Reprinted from Shokhirev, N. V.; Walker, F. A. *J. Am. Chem. Soc.* **1998**, *120,* 981–990, with permission from the American Chemical Society.

It has also been shown that as the angle of the nodal plane of the axial ligand rotates, the angle of the χ_{xx} and χ_{yy} tensors (as well as g_{xx} and g_{yy}) should change in the opposite direction, as shown in Figure 8, according to the principle of the counter-rotation of the g(χ)-tensor.[134] In ESEEM (Electron Spin Echo Envelope Modulation) spectroscopic studies of certain model ferriheme complexes it became clear that while the orientation of g_{zz} is the same for all complexes studied (pyrazole,[135] 3-aminopyrazole,[136] 4-dimethylaminopyridine[137] and imidazole[137] complexes of model hemes, and the histamine complex of the heme protein nitrophorin 1,[138] as well as the imidazole complex of iron(III) octaethylchlorin[139]), the orientations of g_{xx} and g_{yy} differ in a manner that suggests that as the axial ligands rotate counterclockwise by an angle γ_0 from being eclipsed with the porphyrinate nitrogens, g_{xx} and g_{yy} rotate clockwise by an angle $\gamma = -\gamma_0$, as diagrammed in Figure 8. It was also possible to demonstrate theoretically that this should be the case for most ferriheme systems.[140] Hence, when the (parallel) axial ligands lie over the porphyrin nitrogens, their nodal planes are aligned along g_{xx}, while when they lie over the porphyrin *meso* positions, their nodal planes are aligned along g_{yy}. This finding has considerable importance for NMR studies of ferriheme proteins, and counter-rotation of the g-tensor with rotation of axial ligands away from the porphyrin nitrogen axes can now be expected to occur in almost all cases.[7,137] Therefore, the dependence of the pseudocontact shift on the orientation of the nodal plane of the axial ligand should change as shown in Figure 10, where the magnetic anisotropy has been calculated from the g-values, Eq. 9. As can be

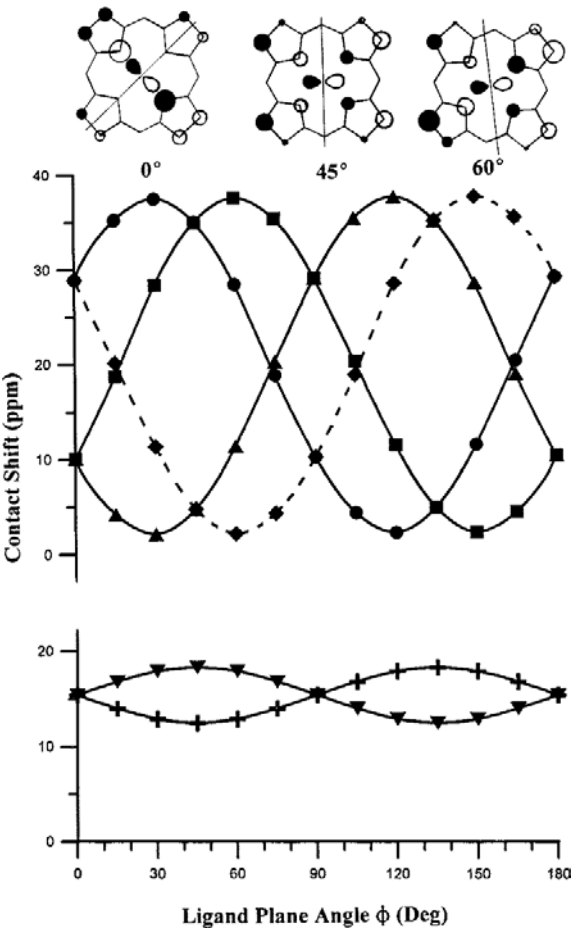

Figure 9. Plot of the dependence of the contact shifts of a symmetrical hemin on the orientation of a planar axial ligand (or two parallel axial ligands). Pictures of the spin density distribution for key angles (0°, 45°, 60°) are shown in the *inserts*. The plot is general, as if for octamethylhemin; in reality, the two α-protons of the 6,7 positions of naturally occurring hemins will have different contact shifts, because of the particular dihedral angle of each of the α-CH_2 protons of the propionates, and the 2,4-positions of protohemin will have different contact shifts, because of the presence of vinyl groups. The 2,6-positions of the symmetrical hemin are represented by a *dashed line*. • β-alkyl positions 1 and 5; ◇ β-alkyl positions 2 and 6; ▲ β-alkyl positions 3 and 7; ■ β-alkyl positions 4 and 8; ▼ α and γ *meso*-H; + β and δ *meso*-H. Reprinted from Shokhirev, N. V.; Walker, F. A. *J. Biol. Inorg. Chem.* **1998**, *3*, 581–594, with permission from Elsevier Publishing Company.

seen, for the imidazole-coordinated hemes whose contact and pseudocontact shift data were used in these calculations,[8] the contact shift is by for the most important at the β-pyrrole positions, while the pseudocontact shift is most important at the *meso* positions.

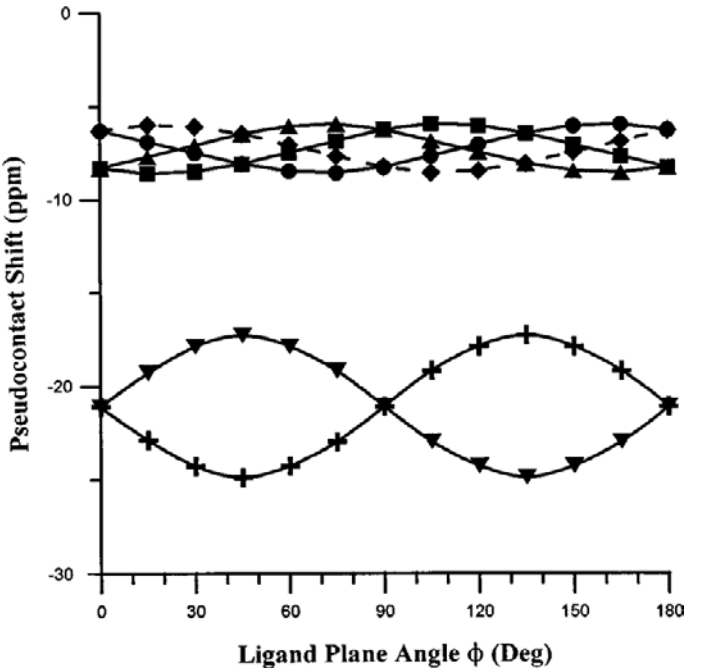

Figure 10. Plot of the dependence of the dipolar (pseudocontact) shift on the orientation of a planar axial ligand (or two parallel axial ligands). Again, the plot is general, as if for octamethylhemin. Counter-rotation of the in-plane **g**-tensor with rotation of the axial ligands was assumed.[88] • β-alkyl positions 1 and 5; ♦ β-alkyl positions 2 and 6; ▲ β-alkyl positions 3 and 7; ▪ β-alkyl positions 4 and 8; ▼ α and γ *meso*-H; + β and γ *meso*-H. The 2,6 positions are represented by a *dashed line*. Reprinted from Shokhirev, N. V.; Walker, F. A. *J. Biol. Inorg. Chem.* **1998**, *3*, 581–594, with permission from Elsevier Publishing Company.

The combination of the contact and pseudocontact contributions to the paramagnetic shift as a function of the angle of the axial ligand, γ, Figure 8 is as shown in Figure 11, when allowance is made for the substituent effect of the vinyl groups (which shifts the 1-Me and 3-Me to somewhat less positive chemical shifts than otherwise expected).[8] This angular dependence has been found to apply to a large number of ferriheme proteins,[8,141–150] as well as to the mono-Mo^{IV}=O-substituted derivative of $[TPPFe(NMeIm)_2]^+$ (Figure 14) and a number of other model heme systems. A program is available on the internet that calculates the relative heme methyl shifts.[151] Other similar methods, which emphasize only the contact interaction, have also been developed,[152–154] but have been used only in equation form. A variation of this angle plot, for high-spin iron(III) porphyrins,[141] shown in Figure 60 below, which is 90° shifted from that shown in Figure 11, and is also available.[151] The reasons for the 90° shift are discussed in Section IV.A.10.a(i).

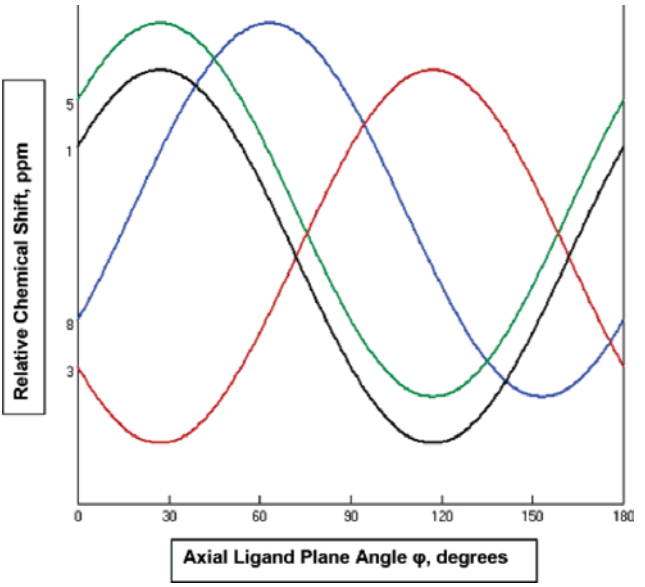

Figure 11. Relative chemical shifts of the heme methyls vs. ligand plane angle or effective ligand plane angle if two planar ligands are present, as calculated for low-spin ferrihemes. 4. *Mechanisms of Spin Delocalization through Chemical Bonds, and Strategies for Separation of Contact and Pseudocontact Shifts*

In Section II.A.1, it was mentioned that the McConnell Eqs. 5 and 6 and the opposite sign of Q for spin density in π and σ carbon orbitals make it possible for spin delocalization through the σ and π systems to be differentiated. Thus, all paramagnetic shifts of protons that are connected to the unpaired electron only by σ bonds should be in the same direction, whether the proton is directly attached to a conjugated π system or is separated by one or more saturated C–C bonds. On the other hand, if π delocalization mechanisms are involved, the same theory predicts that the sign of the contact shift of the proton bound to the carbon atom that is part of the π system will be opposite to that of a proton that is separated by a saturated C–C bond (Section I.A.1). Thus, π spin delocalization is characterized by a reversal in the sign of the paramagnetic shift when a proton that is directly attached to a carbon which is part of a π system is replaced by an aliphatic group such as $–CH_3$ or $–CH_2–$. Therefore, by judicious choice of model hemes, such as those shown in Structure **2**, with $R_2 – R_{18}$ = H and $R_5 – R_{20}$ = phenyl or alkyl, as contrasted to Structure **3**, with $R_2 – R_{18}$ = alkyl and $R_5 – R_{20}$ = H, it has been possible to assign the mechanism of spin delocalization to the β-pyrrole and *meso* positions

of the porphyrin ring for a number of oxidation and spin states of a number of metalloporphyrins.[2,4]

Some generalizations can be made as to the relative importance of the contact and pseudocontact contributions by analysis of the pattern of paramagnetic shifts for a newly-discovered spin or oxidation state of a metalloporphyrin. For example, if the sign of the paramagnetic shift reverses when protons directly bound to the aromatic carbons of the macrocycle or the axial ligands are replaced by methyl or other alkyl groups, then it may be assumed that the π contact contribution dominates the paramagnetic shift at that position. If so, then the nodal properties of the porphyrin or axial ligand π orbital involved may allow one to evaluate the residual pseudocontact contribution to the paramagnetic shift. For example, in low-spin iron(III) porphyrins having a $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, the paramagnetic shifts at the β-pyrrole positions (Structure **3**, $R_2 - R_{18}$) reverse in sign when –H is replaced by $-CH_2CH_3$, while those at the *meso* positions (Structure **2**, $R_5 - R_{20}$) are small and shifted to lower shielding for both –H and $-CH_2R$. Thus, it was concluded that the contact contribution results from π-symmetry spin delocalization which involves the $3e(\pi)$ orbitals of the porphyrin, since these orbitals have nodes at the *meso* ($R_5 - R_{20}$) positions, while the $4e(\pi^*)$ orbitals have much larger coefficients for the wave functions of the *meso* carbons than for those of the β-pyrrole carbons,[108] as shown in Figure 2. Thus, any observed paramagnetic shifts of *meso* substituents were assumed to be caused by the pseudocontact contribution. In tetraphenylporphyrin complexes such as $[(TPP)Fe(NMeIm)_2]^+$, the phenyl *ortho*-, *meta*- and *para*-H paramagnetic shifts were found to be directly proportional to the calculated geometric factors for those protons. Thus, scaling the *ortho*- or *meta*-H paramagnetic shifts by the ratio of the axial geometric factors for those protons to the axial geometric factor for the β-pyrrole protons allowed estimation of the axial pseudocontact contribution to the paramagnetic shift of the β-pyrrole protons.[2,4] The same procedure was found to be less successfully applicable to other axial ligand complexes of $(TPP)Fe^{III}$, as will be discussed in Section IV.A.8, because alternation in the sign of the *meso*-phenyl-H paramagnetic shifts (*o*-, *p*-H of opposite sign to *m*-H) indicated the existence of significant π contact contribution to the paramagnetic shifts of those protons, in the order imidazoles < cyanide < pyridines.[2,4] Such alternation in sign (for low-spin iron(III) porphyrins) is now usually taken as an indication of the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, with significant delocalization that involve the $3a_{2u}(\pi)$ orbital, as is the case for $[(TPP)Fe(t\text{-}BuNC)_2]^+$.[155]

Whenever the $d_{x^2-y^2}$ orbital is half occupied it has been found that there is a large σ contact contribution to the paramagnetic shifts of the β-pyrrole protons; this provides a major difference in the pattern of spin delocalization of high-spin iron(III) (d^5) and manganese(III) (d^4) porphyrins.[2,4] Such a σ contact contribution

can be readily recognized by its attenuation as aliphatic carbons are inserted between the porphyrin ring and the protons. The presence of large σ spin density at the pyrrole positions does not rule out the possibility of large π spin density at the *meso* positions, if the d_π orbitals of a 6-coordinate high-spin metal center contain at least one unpaired electron, or if the metal is 5-coordinate and located out of the mean plane of the porphyrin, in which case an unpaired electron in the d_{z^2} orbital can directly overlap with the porphyrin $3a_{2u}(\pi)$ orbital to allow large π spin delocalization to the *meso* carbons (see Section IV.A.4.a(i));[156] high-spin iron(II) and -(III) and nickel(II) porphyrins exhibit such a pattern of contact shifts, plus a much smaller pseudocontact shift term in the case of the iron complexes that is readily separable from the contact contribution because it varies according to $1/T^2$,[2,4] Eq. 10. It should be noted that this d_{z^2}–$3a_{2u}(\pi)$ interaction for 5-coordinate high-spin d^6 and d^5 iron porphyrins now replaces the earlier explanation of π spin density at the *meso*-carbons of 5-coordinate metalloporphyrins with a half-filled d_{z^2} orbital, that of mixing of the filled $3e(\pi)$ orbitals with the empty $4e(\pi^*)$ orbitals, so that there is currently no need to invoke the participation of the $4e(\pi^*)$ orbitals in spin delocalization in these systems.[156] Comparison of 5- and 6-coordinate high-spin iron(III) porphyrins and related macrocycles indicates a large σ spin density at the *meso* as well as β-pyrrole positions of the 6-coordinate complexes, but σ spin density only at the β-pyrrole, but π spin density at the *meso* positions for 5-coordinate complexes, as discussed in Section IV.A.6.b,c.

Cases for which the pseudocontact contribution dominates the paramagnetic shifts are readily recognized by the direct proportionality of the paramagnetic shifts to the geometric factors of the protons of interest. Several examples of this situation are the paramagnetic shifts of the phenyl protons of $[(TPP)Fe(R\text{-}Im)_2]^+$ complexes, as discussed in Section IV.A.8.b, the π-cation radicals of iron(III) porphyrins, as discussed in Section IV.A.11, and of cobalt(II) porphyrins, as discussed in Section IV.C.1.

D. Methods of Assignment of the ^{1}H NMR Spectra of Paramagnetic Metalloporphyrins

1. *Substitution of H by CH_3 or Other Substituent*

The original assignment of pyrrole-H, *meso*-H, *o*-, *m*-, and *p*-phenyl-H of symmetrically-substituted model hemes was made by this method,[2,4] and it needs no further elaboration. Balch and Renner[157] used it to assign the phenyl resonances of the ferryl porphyrin complexes, $[(TPP)Fe^{IV}{=}O]$, discussed in Section IV.A.13, and the author's group used it for assigning and interpreting

the nature of the β-pyrrole and *meso* resonance shifts of iron(III) corrolate π-cation radicals.[114,158,159]

2. *Deuteration of Specific Groups*

Methods have been developed by Smith, Goff, Dolphin, Strauss, and others, for specifically deuterating certain positions of both naturally-occurring and synthetic porphyrins or metalloporphyrins, as summarized in detail previously.[3] Although ^{2}H NMR investigation of deuterium-labeled diacetyldeuterohemin incorporated into sperm whale myoglobin was reported early,[160] Goff and coworkers[161–164] and, more recently, Balch and coworkers,[165] have repeatedly demonstrated the utility of ^{2}H NMR spectroscopy for assignment, and indeed, detection of resonances in model hemes. As pointed out, the linewidths of ^{2}H resonances, in Hz, could be narrowed by as much as $(\gamma_D/\gamma_H)^2$; that is, to 1/42 the line widths of the ^{1}H signals,[161] although experimentally, the pyrrole-H and pyrrole-D linewidths of [(TPP)FeCl] differ by only a factor of 10 (280 Hz and 28 Hz, respectively). The *o*-D of [(d_{20}-TPP)FeCl] are much sharper than the *o*-H of [(TPP)FeCl], and the *m*-D occur as a singlet, due to averaging of the two *m*-D environments of this 5-coordinate complex on the shorter time scale (lower frequency) of deuterium NMR.[161] Godziela and Goff utilized the increased sharpness of ^{2}H resonances to detect the pyrrole-D resonance of [(pyrrole-d_8-TPP)Cu^{II}] (1150 Hz wide at half-height) and *meso*-D resonance of [(d^4-OEP)Cu^{II}] which are totally undetectable in the protonated analogs,[164] and Li and Goff utilized this increased sharpness of ^{2}H resonances of the $-CD_3$ and $-C_2D_5$ groups, and wider spectral bandwidth (in terms of ppm available for ^{2}H to detect the α-D of iron(III) alkyl complexes,[163] which were previously undetected.[166] Karlin and coworkers have used pyrrole-deuterated TPP derivatives to good advantage to assign the pyrrole resonances of their cytochrome c oxidase models, as discussed in Section IV.A.4.a(iii). Chromium(III) porphyrins, whose ^{1}H resonances are very poorly resolved,[94] show well-resolved ^{2}H resonances for the pyrrole-D (−16.7 ppm at 24 °C) and phenoxide-D of [(TPP)Cr(OPh)],[165] as shown in Figure 12.

Specifically methyl-deuterated hemins were employed by La Mar, Smith and coworkers[167–169] to assign the methyl resonances of model hemes and heme proteins, and the author's group have used them to assign the heme methyl resonances of nitrophorins 1 and 4.[143,170] Strauss and coworkers[171] and Balch *et al.*[165] have used both ^{1}H and ^{2}H NMR spectroscopy in a complementary fashion to show that the signals that disappear from the ^{1}H spectrum upon deuteration are the only ones that appear in the ^{2}H spectrum. In many cases it is now possible to use 2D ^{1}H NMR techniques to carry out these assignments, if T_1 and T_2 relaxation times are long enough, as discussed in Section II.D.5.

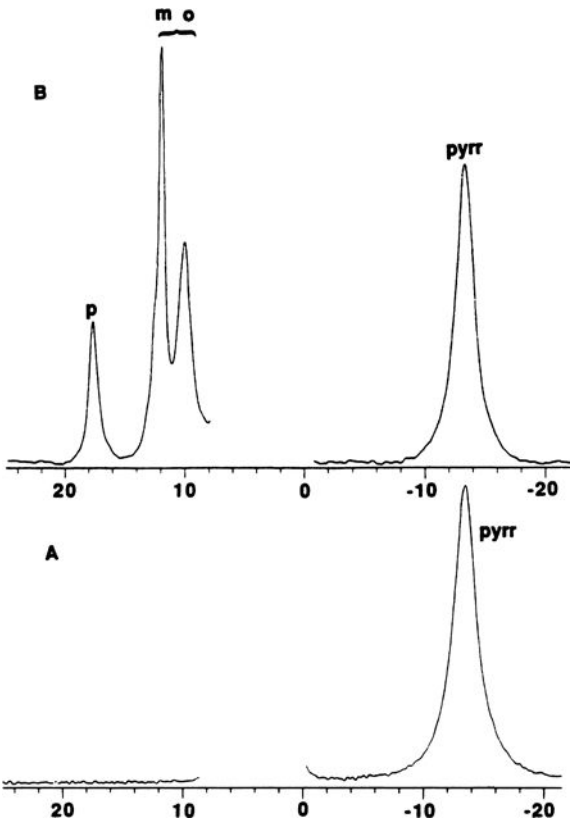

Figure 12. 46.0 MHz ^{2}H NMR spectra of (A) [(d_8-TPP)Cr^{III}(OPh)(THF)] and (B) [(d_8-TPP)Cr^{III}(OPh-d_5)(THF)] in THF solution at 24 °C, with chemical shift scale in ppm. Resonance assignments: pyrr, pyrrole deuterons; *o, m, p = ortho, meta, para* deuterons of the phenoxy ligand. Reprinted from Balch, A. L.; Latos-Grażyński, L.; Noll, B. C.; Olmstead, M. M.; Zovinka, E. P. *Inorg. Chem.* **1992**, *31*, 1148–1151, with permission from the American Chemical Society.

3. *2D ^{13}C Natural Abundance HMQC Spectra and Specific or Complete ^{13}C Labeling of Protohemin for the Assignment of Heme Resonances in Proteins*

A method that can be used by all researchers who have access to an inverse heteronuclear broadband or ^{13}C (^{1}H detect) probe is the $^{1}H\{^{13}C\}$-HMQC experiment. This allows correlation of the ^{13}C and ^{1}H chemical shifts of heme substituents and is especially useful for paramagnetic heme proteins, where some heme resonances are invariably buried under the protein resonance envelope,[141–146,172–179] but the author's group has also used it to investigate the chloroiron(III) corrolate π-radicals, [$Fe^{III}Cl(Corr)^{2-\bullet}$],[159] which are neutrally-charged species, as discussed

further in Section IV.A.11.e. Turner has used this method to aid the assignment of heme proteins since 1995,[173–179] and it is particularly useful for the bis-histidine bound tetra-heme cytochromes c_3.[173,179] We have also found these spectra to be very helpful in identifying and confirming the ^{1}H chemical shifts of heme and nearby protein substituents whose resonances may or may not be resolved outside the protein resonance envelope. By using the information obtained from the HMQC spectra the author's group has been able to assign most, if not all, of the heme substituent resonances of the axial ligand complexes of the nitrophorins,[141–145] and an example spectrum is shown in Figure 64. These heme resonances are fairly easy to assign because of their unique ^{1}H,^{13}C shifts. Model heme complexes have also been assigned with the aid of ^{1}H{^{13}C}-HMQC spectra,[228] as shown below in Figure 15. The unique shifts are a result of a combination of the contact, pseudocontact and diamagnetic contributions to the chemical shifts of both nuclei,[172] which shift these cross peaks well outside the normal ranges observed for the two nuclei in diamagnetic compounds, and thus make them easy to recognize and assign.

To observe these ^{1}H,^{13}C cross peaks in the HMQC spectrum of a low-spin Fe(III) heme protein requires at least a 1 mM concentration (2 mM is preferable) of ferriheme protein at ^{13}C natural abundance, and requires an approximate 24-hour experiment time. Any modern NMR spectrometer equipped with an inverse (^{1}H observe) ^{13}C or broadband probe can be used, and 500 MHz as the ^{1}H Larmor frequency is certainly sufficient for all systems that have been investigated thus far. All of the ^{1}H{^{13}C}-HMQC spectra presented in the author's group papers have been recorded at 500 MHz. Since inverse ^{13}C or inverse broadband probes are common on modern spectrometers, the use of this experiment is strongly recommended to find the heme ^{1}H resonances which are obscured by the protein resonances, and to then look for these resonances in the WEFT-NOESY spectra of the proteins, to permit complete assignment of the heme resonances. Protein side chains that are close to the heme iron, especially the histidine ligand β-CH_2 and α-CH cross peaks, as well as methyl-, methylene- and aromatic-containing side chains of amino acids that are within ~4 Å of Fe also have unusual ^{1}H,^{13}C chemical shifts because of the pseudocontact interaction, and can then be followed in the NOESY spectra to assign the side chains of those amino acids.

Another method for assigning heme resonances that relies on correlations to the ^{13}C chemical shifts of the heme has been used by Rivera and coworkers to prepare specifically ^{13}C-labeled heme precursors, δ-aminolevulinic acid molecules labeled at one of the four carbons of that molecule.[180] The first committed precursor in the biosynthetic pathway to heme and other tetrapyrrole synthesis is δ-aminolevulinic acid (ALA), as shown in Figure 13.[181] Condensation of two molecules of ALA results in porphobilinogen (PBG), the building block of tetrapyrrole synthesis, Figure 13.[182] Subsequently, four molecules of PBG are initially condensed head-to-tail to form the hydroxymethyl bilane (HMB) intermediate.

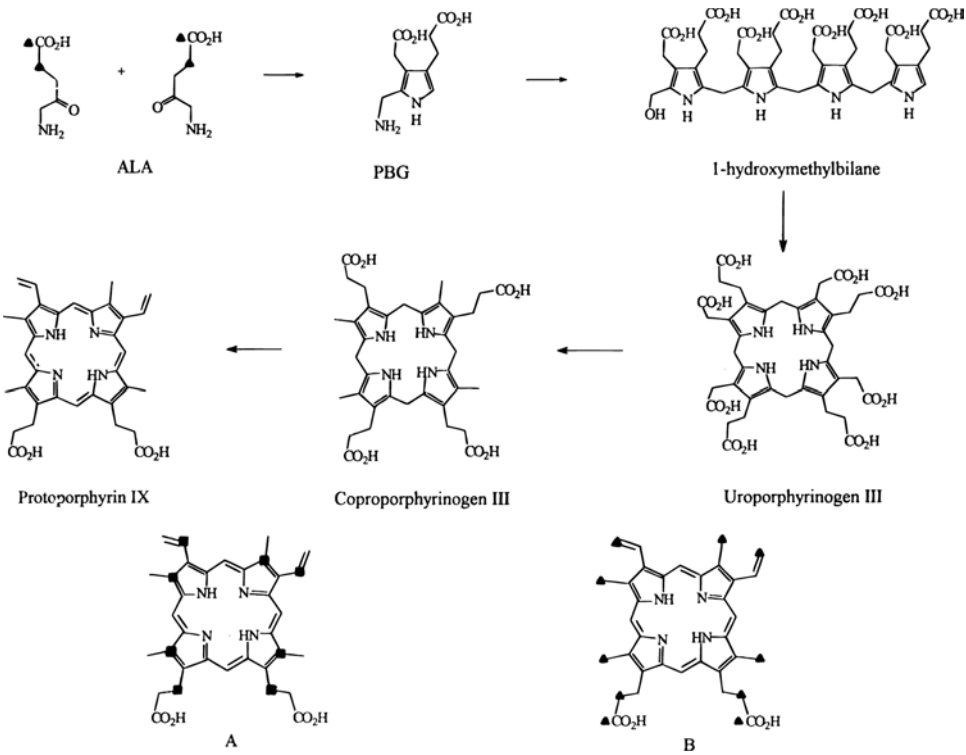

Figure 13. Schematic representation of the heme biosynthetic pathway in which δ-aminolevulinic acid is the first committed precursor. The introduction of iron into protoporphyrin IX, which is catalyzed by ferrochelatase, is not shown in the scheme. When [3-^{13}C]-δ-ALA is used as heme precursor, heme labeled at positions denoted by ■ in structure A is obtained. When [1,2-^{13}C]-δ-ALA is used as heme precursor, heme labeled at positions denoted by ▲ in structure B is obtained. Reprinted from Rodriguez-Marañón, M. J.; Qiu, F.; Stark, R. E.; White, S. P.; Zhang, X.; Foundling, S. I.; Rodriguez, V.; Schilling, III, C. L.; Bunce, R. A.; Rivera, M. *Biochemistry* **1996**, *35*, 16378–16390, with permission from the American Chemical Society.

This intermediate is cyclized to uroporphyrinogen III (uro'gen III) with rearrangement of ring D, as shown in Figure 13. The next step on the route to heme is the decarboxylation of the four acetate groups in uro'gen III by a single enzyme, uroporphyrinogen decarboxylase, to produce coproporphyrinogen III (copro'gen III, Figure 13). This step is followed by oxidative decarboxylation of propionates in pyrrole rings A and B of copro'gen III to give protoporphyrinogen IX. These decarboxylations are again carried out by a single enzyme, copro'gen oxidase, and involve the removal of six hydrogen atoms, one from each of the *meso* positions and two from nitrogen atoms. The last step in the biosynthesis of heme is the insertion of Fe^{2+} into the macrocycle by the enzyme ferrochelatase, which is not included in Figure 13. The many details of porphyrin biosynthesis can be found in

the reviews cited here[181–184] and in references therein, which describe the careful and elegant work carried out in the course of approximately two decades that led to the elucidation of the biosynthesis of heme, chlorophylls and vitamin B_{12}. It has been found that the expression of the genes for several heme proteins in *E. coli* leads to the induction of heme synthesis, and that if the desired ^{13}C-labeled δ-aminolevulinic acid is provided in the bacterial growth medium, the heme will be labeled[180,185] at the positions shown in Figure 13 for 1,2-[186] as compared to 3-^{13}C-labeled ALA.[180] Usually it is necessary to use minimal media to insure that the bacteria will not synthesize their own (unlabeled) ALA.[185] Totally labeled ^{13}C-ALA is commercially available, and has been used to label all carbons of protohemin in proteins.[186] 3-^{13}C-labeled ALA is also commercially available (Cambridge Isotope Laboratories for both). Methods for synthesis of the ^{13}C labeled isomers of δ-aminolevulinic acid that are not available commercially have been developed,[187] and thus specifically ^{13}C-labeled hemes can be synthesized and used for NMR investigations. Specific ^{1}H/^{13}C/^{13}C experiments have been developed,[188,189] and used to completely assign the ^{13}C heme resonances of rat outer mitochondrial membrane (OM) cytochrome b_5.[190] It is also very useful for assigning particular heme resonances, as shown in a very readable article in *Inorganic Chemistry*,[191] where the *meso*-carbon resonances of high-spin wild-type sperm whale-Mb (known to be 6-coordinate with a water bound to the sixth position of iron(III)), and its H64V mutant (known to be a 5-coordinate complex), were used to illustrate how specifically ^{13}C-labeled hemins can be used to assign the *meso*-carbon chemical shifts, and thus the coordination number of the high-spin heme. This methodology was then used to determine that a recently-discovered ferriheme protein from *Shigella dysenteriae* (ShuT) is 5-coordinate.[191]

4. *Saturation Transfer NMR Experiments*

Wüthrich and coworkers used these methods in 1980 to assign the heme resonances of ferricytochrome b_5 which was in chemical exchange with ferrocytochrome b_5, the heme resonances of which had been assigned by NOE techniques.[192] However, for hemes and metalloporphyrins in general outside the proteins, it was earlier thought that electron exchange may be sufficiently rapid so that in many cases separate resonances from the reduced and oxidized metal states of the complexes are not observed.[193–196] We have not found this to be generally true for model hemes at proton frequencies of 300 MHz or higher for either electron exchange or ligand exchange. We have thus used saturation transfer to assign resonances of the high-spin complexes of both model hemes and heme proteins, for which the low-spin resonances have been assigned by mainly 2D NMR techniques.[115,141–146] In the case of other types of chemical exchange, for example,

ligand exchange[197,198] or ligand rotation,[90] saturation transfer provides an effective means of assigning proton resonances of groups that are interchanged by means of the chemical exchange process, and also of estimating the rates of the process (with a cautionary note about possible contributions from spin diffusion).[90]

The most common current presentation of saturation transfer spectra is as difference spectra, called by some STD spectra, where an off-resonance saturation control spectrum is subtracted from each of the on-resonance saturation transfer spectra to give a large negative-pointing peak for each high-spin resonance which is irradiated, and a small negative-pointing peak for the low-spin resonance to which it is linked by saturation transfer, as shown in Figure 36 for assignment of part of the resonances of trans-OECFeCl, and Figure 59 for assignment of the heme resonances of high-spin NP2.

5. *NOE Difference Spectroscopy*

La Mar and coworkers[19,199–203] have used this technique extensively to assign the resonances of the heme group in ferriheme proteins; it is much more easily applied to large molecules, such as proteins, than to small, such as model hemes, since the large size of the proteins insures that the NOE will be negative. On the other hand, for model hemes in liquids of low viscosity, the rotational correlation time, τ_c, is in the intermediate motion limit,[203] such that the predicted steady-state NOE enhancement, though negative at low temperatures (−70 °C or lower in $CDCl_3$ or CD_2Cl_2), is small. This was earlier thought to be the reason that steady-state NOEs were sometimes not observed for model hemes,[203] although Barbush and Dixon[204] showed that the dicyanoiron(III) complex of protohemin gave small NOEs (1% negative) in DMSO-d_6 at 30 °C. Thus, the more serious limitation is that paramagnetic relaxation undermines the NOE.[205] However, if paramagnetic relaxation is independent of motion, as has been found to be the case, then it is possible to recover the NOE by slowing down the rate of molecular reorientation for both low-spin iron(III)[206] and high-spin iron(III) complexes.[133] Few model hemes are soluble in highly viscous solvents other than ethylene glycol or supercooled DMSO, and this may limit the application of NOE difference spectroscopy to model hemes. However, we have found that in general, at room temperature in CD_2Cl_2 or $CDCl_3$, positive steady-state NOEs of metalloporphyrins can be readily detected by NOE difference spectroscopy,[115,207] which is more successful than NOESY experiments, which depend on transient NOEs. At temperatures of −70 °C and below, negative steady-state NOEs of metalloporphyrins of the size of metal TPPs in these same solvents can be readily detected by NOE difference spectroscopy.[115,159,204] The case of a Mo^V-appended (TPP)Fe^{III} bis-N-methylimidazole complex, where two NOEs were detected at −58 °C in CD_2Cl_2,[80] is discussed in

the next Section II.D.6, and shown in Figure 17b; however, this is very close to the temperature where the sign of the NOE changes from positive to negative, which makes the NOEs very weak.

6. *Two-Dimensional NMR Techniques*

In addition to the natural-abundance $^{1}H\{^{13}C\}$-HMQC experiment discussed earlier in Section II.D.3, both ^{1}H-^{1}H scalar couplings and through-space NOEs can be detected for paramagnetic complexes under favorable circumstances. In terms of scalar-coupled systems, COSY (homonuclear correlation spectroscopy),[203,208–214] TOCSY (Total Correlation SpectroscopY, the rotating frame analog of COSY), HETCOR (heteronuclear correlation spectroscopy),[215,216] HMQC (heteronuclear multiple quantum correlation)[141–145,159,172–179] and HMBC[217] (heteronuclear multiple bond correlation) spectra of paramagnetic iron porphyrins have been reported. The success of these experiments is strongly limited by the short T_2 relaxation times of most paramagnetic complexes. For bis-N-methylimidazole complexes of iron(III) tetraphenylporphyrins, typical T_2s of the pyrrole-H are 8–9 ms,[209] or shorter,[104] while for dicyano and monocyano, monoimidazole complexes of β-pyrrole substituted iron(III) porphyrins, T_2s are usually much longer (T_2s for the ring CH_3s of (cyano)(imidazole)protohemin IX are 36–40 ms, and those of the *meso*-H are 21–32 ms),[218] as discussed in Section II.B.2.b. Short T_2 relaxation times can lead to significant cancellation of the antiphase components when J is small, and may prevent detection of cross-peak intensity.[219] However, on the positive side, the fact that T_2s are short for paramagnetic complexes means that the experiments can be run much faster than for diamagnetic compounds, since it makes no sense to acquire data over more than about 1.5–2T_2. In fact, if the acquisition time in t_2 is much longer than 2 × (longest T_2), significant cross peak intensity is lost.[209]

Because of the need to keep the acquisition time, A_t, short, of necessity the digital resolution of 2D NMR experiments for paramagnetic compounds decreases, since $A_t = N/F$, where N is the total number of real data points in the t_2 dimension and F is the spectral bandwidth. Likewise, acquiring many blank data blocks in the t_1 dimension only adds to the total experiment time, so the number of t_1 blocks typically acquired for model hemes with very short T_2s may be 256, 128 or even 64, yielding even poorer digital resolution in the t_1 dimension. However, this is often not a problem because of the large dispersion of the signals of many paramagnetic complexes. The apparent digital resolution can be improved by zero-filling one or more times in either or both dimensions. DQF-COSY experiments often give better resolution than magnitude COSY experiments.[212] An example of a magnitude COSY spectrum, that of $[(OEOP)Fe^{III}(CN)_2]$,[220] is shown in Figure 14.

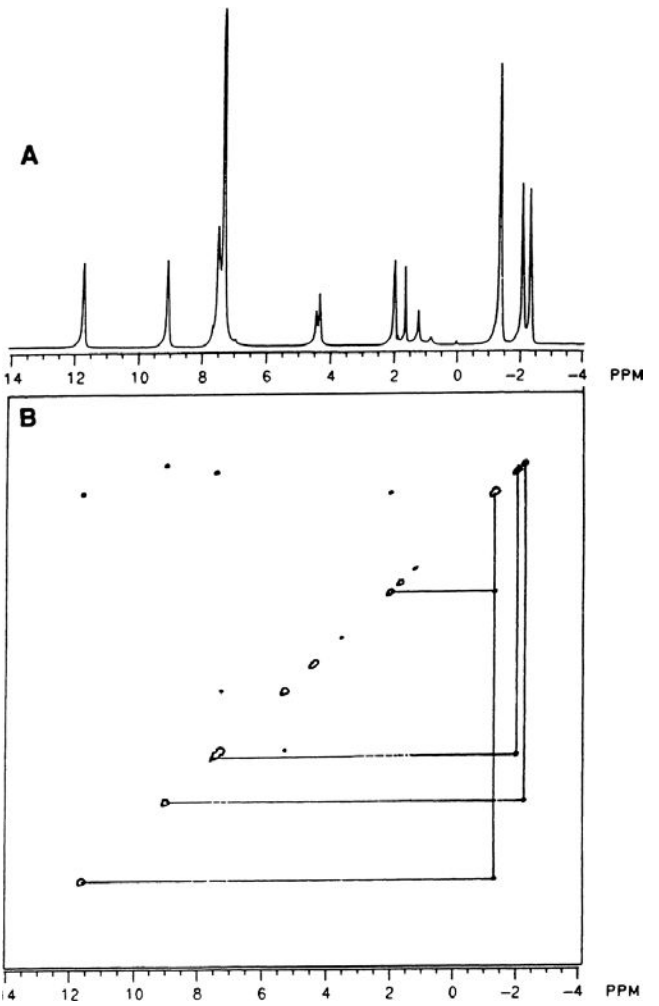

Figure 14. (A) ^{1}H NMR 1D and (B) M-COSY spectrum of $[(OEOP)Fe^{III}(CN)_2]$ in $CDCl_3$ at 20 °C. Reprinted from Gregson, A. K. *Inorg. Chem.* **1981**, *20,* 81–87, with permission from the American Chemical Society.

There have been reported fewer examples of heteronuclear correlation spectra of paramagnetic iron porphyrins, but the ^{13}C–^{1}H heteronuclear correlation (HETCOR) map of dicyanoprotohemin IX has been reported,[221] as has that of *Geleorhinus japonicus* (shark) metcyanomyoglobin.[215] Timkovich has reported the relayed $^{1}H\{^{13}C\}$ scalar correlation spectrum (HMQC) and the long-range ^{1}H–^{13}C scalar correlation (heteronuclear multiple-bond correlation, or HMBC) spectrum of dicyanoprotohemin IX,[216] Banci *et al*. have reported the $^{1}H\{^{13}C\}$ HMQC spectra of the bis-(imidazole) complex of protohemin IX, as well as metmyoglobin

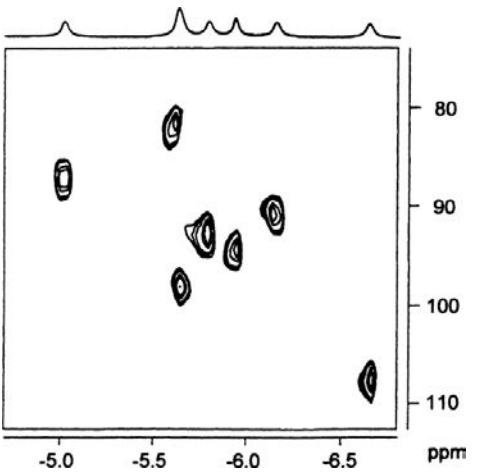

Figure 15. The pyrrole region of the 300MHz ^{1}H-^{13}C HMQC spectrum of $[(2\text{-Cl-TPP})Fe^{III}(CN)_2]^-$ in methanol-d_4 at 294 K. Reprinted from Wojaczynski, J.; Latos-Grażyński, L.; Hrycyk, W.; Pacholska, E.; Rachlewicz, K.; Sżterenberg, L. *Inorg. cyanide and ferricytochrome b_5,[222] and Latos-Grażyński and coworkers[223] have reported the $^{1}H\{^{13}C\}$ HMQC spectrum of a monopyrrole substituted TPP derivative, $[(2\text{-Cl-TPP})Fe(CN)_2]^-$. Part of the 2D map of the latter complex is shown in Figure 15. As mentioned above in Section II.D.3, the natural-abundance $^{1}H\{^{13}C\}$-HMQC experiment is very helpful in the assignment of heme resonances within proteins, although only low-spin ferriheme proteins can be studied. Skidmore and Simonis have shown that the HMBC correlations of the α-C and β-H of an unsymmetrically phenyl-substituted derivative of $[(TPP)Fe(NMeIm)_2]^+$ could be observed, despite the short T_1s and T_2s of the protons.[217]

2D Spectra using the NOESY/EXSY (Nuclear Overhauser enhancement and chemical Exchange SpectroscopY) and ROESY (Rotating frame Overhauser and chemical Exchange SpectroscopY) techniques can also be valuable in obtaining dynamic and three-dimensional structural information concerning model hemes. The observation of NOESY cross peaks depends on the mixing time, τ_m, being of the order of the T_1 relaxation times of the protons between which an NOE is expected.[104] Since the T_1s of protons of paramagnetic iron porphyrins can be 8–9 ms or shorter, and decrease as the temperature is lowered[104,224] (in comparison, T_1s of ring CH_3s of dicyanoprotohemin IX are in the range of 150–190 ms[102]), it is important to find experimental conditions that will maximize the lengths of the T_1s. Degassing the sample with argon can lengthen the T_1s by 1–3 ms,[104] which can make the difference between an unsuccessful and a successful experiment in some cases. Latos-Grażyński and coworkers[223] have used a combination of COSY

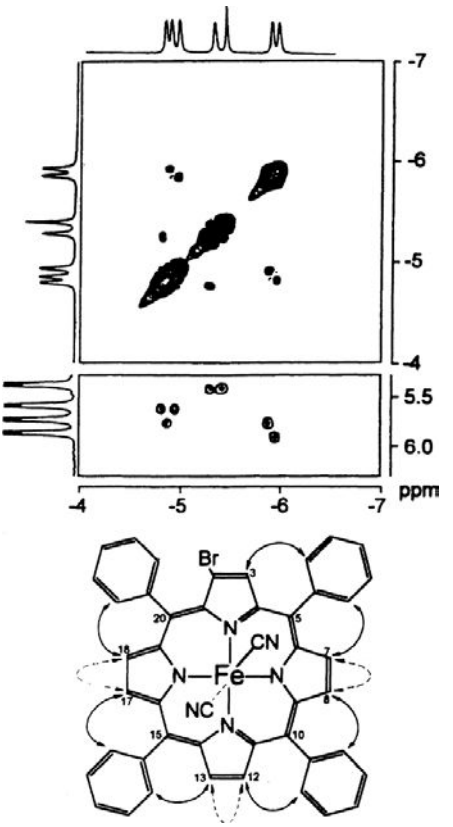

Figure 16. 2D ^{1}H NMR spectra of $[(2\text{-Br-TPP})Fe^{III}(CN)_2]^-$ in methanol-d_4 at 293 K. The upper box presents the COSY map of the pyrrole region, while the lower one shows a fragment of the NOESY spectrum with cross-peaks derived from contacts of *o*-phenyl and pyrrole protons. These contacts are indicated by solid arrows in the molecular scheme. Dashed arrows correspond to COSY cross- peaks. Two *ortho* protons on each phenyl ring are equivalent. Reprinted from Wojaczynski, J.; Latos-Grażyński, L.; Hrycyk, W.; Pacholska, E.; Rachlewicz, K.; Szterenberg, L. *Inorg. Chem.* **1996**, *35*, 6861–6872, with permission from the American Chemical Society.

and NOESY spectra to assign the pyrrole-H resonances of $[(2\text{-Br-TPP})Fe(CN)_2]^-$, as demonstrated in Figure 16. The author's research group has used NOESY spectra acquired at several (low) temperatures to measure the rate constants for chemical exchange due to axial ligand rotation[89] and to investigate the three-dimensional structure (at −74 °C) of $[(TMP)Fe(2MeImH)_2]^+$ in CD_2Cl_2.[104] Chemical exchange is evidenced by cross peaks between all protons of a given type whose magnetic environments are interchanged by the chemical exchange process,[89] as is discussed further in Section IV.A.8.l, whereas at very low temperatures, only the true NOE cross peaks are observed.[104] From the rotating frame NOE cross peaks of the

ROESY spectrum, the low-temperature, three-dimensional structure of the complex was deduced,[225] as discussed in Section IV.A.8.b(iii). In another example, a combination of chemical exchange and NOE cross peaks are observed for mono-*o*-phenyl substituted derivatives of $[(TPP)Fe(NMeIm)_2]^+$ due to hindered rotation of one of the axial ligands.[226]

Mixed success appears to have been experienced with rotating frame experiments using paramagnetic complexes. TOCSY spectra of $[(OETPP)Fe(NMeIm)_2]^+$ have readily been obtained;[214] here the T_1s and T_2s of the α-CH_2 protons of the ethyl groups are much longer than those of the pyrrole-H of the TPP derivatives. ROESY spectra provide an excellent method for distinguishing cross peaks resulting from NOEs (ROEs) and chemical exchange in model hemes.[225,227] However, in one case cross peaks observed in the NOESY experiment were not seen in the ROESY map.[227] A combination of COSY and NOE difference spectra, together with proton T_1s, were utilized to totally assign the pyrrole-H resonances of an unsymmetrically substituted low-spin iron(III) porphyrin having a bulky oxomolybdenum(V) substituent bound to the 2,3-phenyl positions of one phenyl ring, as shown in Figure 17 for $[((2,3\text{-MoOL})TTP)Fe(NMeIm)_2]^+$.[80] Scalar couplings between resonances 2,6 and 4,8 are seen in the COSY spectrum, Figure 18, left panel. NOE difference spectra showed that peaks 2 and 4 were in close proximity, Figure 18, right panel. These assignments for the long-T_1 and -T_2 protons led to two possible assignments of peaks 2, 4, 6 and 8; peaks 1, 3, 5 and 7, however, could be unambiguously assigned to protons h, a, g and b, respectively, on the basis of their short T_1s and T_2s, leading to the two possible assignments of the eight pyrrole-H resonances shown in Figure 18. Since the sharper half of the pyrrole-H resonances observed are correlated either by scalar or by pseudocontact coupling, it is clear that the observed eight pyrrole-H resonances must arise from a single molecular species and not from multiple species with different structures; the broader half of the resonances arise from the four pyrrole-H that are closest to the Mo(V) center.

Earlier COSY and NOESY studies of other unsymmetrically substituted derivatives of $[(TPP)Fe(NMeIm)_2]^+$ which showed the existence of two sets of COSY cross peaks and two different sets of NOESY cross peaks that appeared to allow the complete assignment of the four pyrrole-H resonances observed for these complexes[211] was later shown not to have any NOESY cross peaks, when phase-sensitive NOESY experiments were utilized,[103] and it was also shown in the latter work that the short T_1s of the protons (9 ms) for the distance over which the NOE would have to be transferred from one pyrrole ring to the adjacent one (5.4 Å) precludes detection of NOESY cross peaks for these complexes,[103] as well as for $[(TMP)Fe(2MeImH)_2]^+$, where T_1s are much longer (35 ms). (The steady-state NOE difference spectra used for the Mo-appended $(TPP)Fe^{III}$ complex of

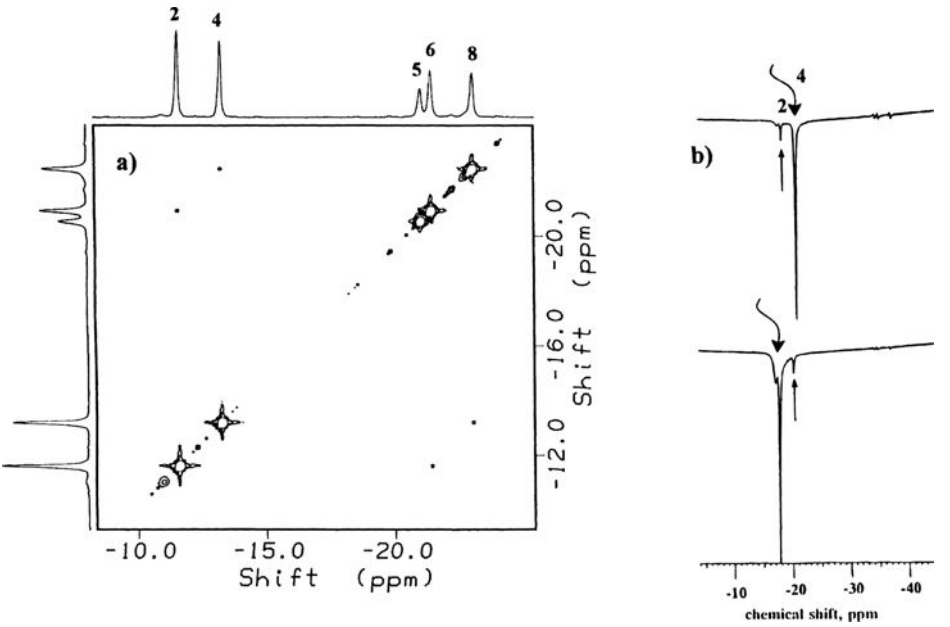

Figure 17. Left: 500MHz COSY map of the pyrrole-H region of [((2,3-MoOL)TTP)$Fe^{III}(NMeIm)_2]^+$ at 300 K. Note the cross peaks between resonances 2 and 6 and resonances 4 and 8, which indicate in each case that the pair of pyrrole protons are scalar coupled and are therefore in the same pyrrole ring. Figure 17, right panel[80] can detect much smaller NOEs than can the NOESY experiment, where transient NOEs are measured.) The magnitude NOESY experiments utilized in the earlier work produced cross peaks that were consistent with the expected shape of the π orbital utilized for spin delocalization,[211] but probably resulted from overlap of ridges in the magnitude NOESY spectra.

III. Spectral Analysis

A. Resolution and Assignment

The facility with which well-resolved ^1H (and ^{13}C) NMR spectra of paramagnetic metalloporphyrins can be obtained depends completely on the nature of the metal ion and its oxidation and spin states. Narrow lines are observed under the condition $T_{1e} \leq (A/h)^{-1}$ (see Section II.B.2.a), and in fact, $T_{1e} \leq \tau_c$.[2,4] As mentioned

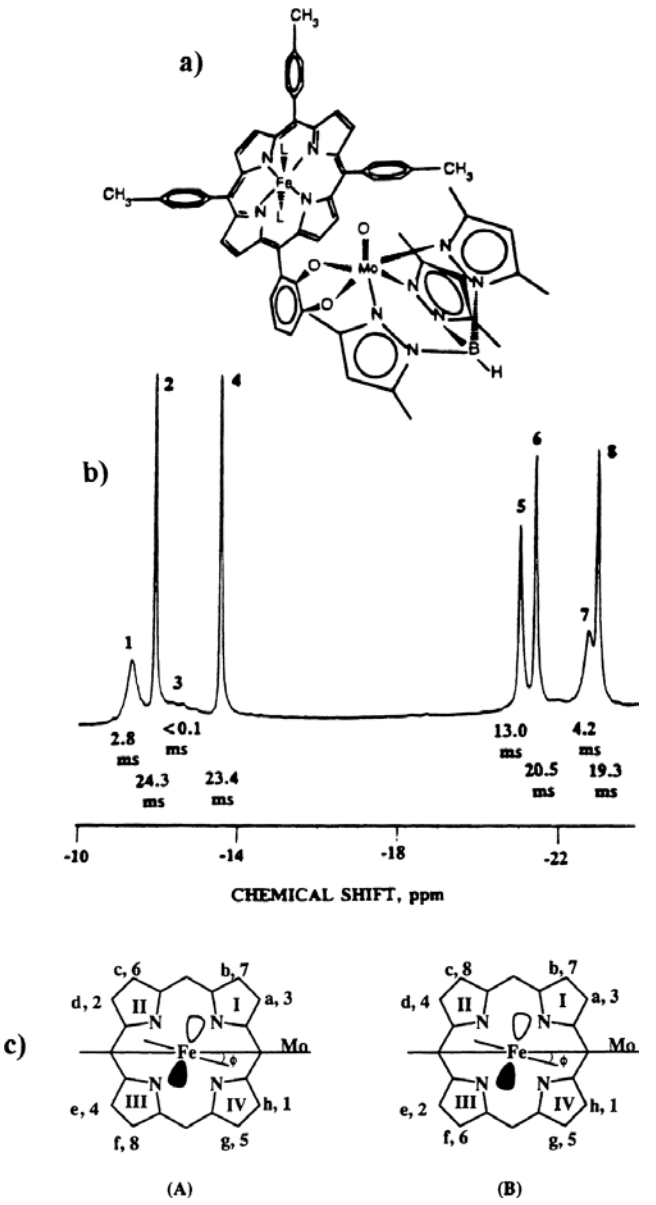

Figure 18. (a) Structure, (b) 500 MHz 1D spectrum of the pyrrole protons of [((2,3-MoOL)TTP)$Fe^{III}(NMeIm)_2]^+$ at 296 K in CD_2Cl_2. Peak numbering increases in order from lower to higher shielding. This is, not coincidentally, the order of increasing contact shifts of the pyrrole protons. (c) Two possible assignments of the pyrrole resonances of [((2,3-MoOL)TTP)$Fe(NMeIm)_2]^+$. Part A shows the assignment most consistent with the isotropic shifts of the protons H_c, H_d, H_e and H_f. Reprinted from Basu, P.; Shokhirev, N. V.; Enemark, J. H.; Walker, F. A. *J. Am. Chem. Soc.* **1995**, *117*, 9042–9055, with permission from the American Chemical Society.

above, VO^{2+}, Cu^{2+}, Mn^{2+} and Gd^{3+} do not satisfy this condition and have few if any resolved resonances for any of their complexes. Cu^{2+}, with T_{1e} values $> 10^{-9}$ seconds, comes the closest to violating this rule, especially in cases where it forms dimeric complexes,[228] but there are no reports of the ^1H NMR spectra of copper(II) porphyrins. However, as mentioned above, Godziela and Goff have observed the pyrrole-D resonance of [(d_8-TPP)Cu], as well as the deuterium resonances of [(d_{20}-OEP)Cu] and the silver(II) analog.[164] The 1150-Hz linewidth of the ^2H signal from the pyrrole-D resonance of [(d_8-TPP)Cu] (see Figure 80) would predict a linewidth of up to 48.3 kHz for the corresponding ^1H resonance of the protonated analog, which explains the fact that no such ^1H resonance has been detected. Chromium(III) porphyrins, with T_{1e} values $> 5 \times 10^{-10}$ seconds, give extremely broad ^1H spectra, but much better resolved ^2H spectra,[165] as shown in Figure 12. The linewidth of the ^2H resonance of the pyrrole-deuterons is about 125 Hz, which represents a major decrease over the greater than 3 kHz (undetectable) linewidth of the ^1H resonance of (TPP)CrCl,[94] and the difference between detectable and nondetectable signals. ^1H linewidths of up to 250–300 Hz are observed for high-spin iron(III) and manganese(III) porphyrins, but the larger range of shifts for the iron(III) porphyrins make it much easier to assign the spectra than for the manganese(III) analogs.

Most probably one of the simplest low-spin iron(III) porphyrin proton NMR spectra is that of $[(TPP)Fe(NMeIm)_2]^+$, shown in Figure 19. All resonances are well-resolved at 300 MHz, much better so than the original 100 MHz spectrum of the same complex shown in Figure 4 of Ref. 2. In comparison, the spectrum of the $[(mono\text{-}m\text{-}nitro, tris\text{-}m\text{-}fluoro\text{-}TPP)Fe(NMeIm)_2]^+$ complex, Figure 20a, shows four inequivalent pyrrole-H resonances and several kinds of phenyl resonances, yet is fairly easy to assign, except for an ambiguity in the assignment of the pyrrole-H resonances in the separate pyrrole rings; COSY spectra allow the pairs of resonances within a given pyrrole ring to be assigned, but the relationship of the two pyrrole rings to each other has not been determined, despite earlier belief to the contrary.[211] Using predictions of the shape of the π orbital used for spin delocalization, the ambiguity can be reduced to twofold, as was done for the $[(2,3\text{-MoOL})(TPP)Fe(NMeIm)_2]^+$ complex[80] shown in Figure 18.

Yet another unsymmetrically-substituted low-spin $(TPP)Fe^{III}$ derivative is that demonstrated by the mono-β-pyrrole-substituted complexes prepared and studied by Latos-Grażyński and coworkers.[223] In these cases there are seven unique β-pyrrole resonances, whose chemical shifts change with the nature of the substituent, as shown for a series of substituents in Figure 41. Even a single deuterium substituent lifts the degeneracy of the pyrrole-H resonances, as demonstrated in the inset of Figure 41. By comparison of Figures 20 and 21 the wide range of spreads of the pyrrole-H resonances are seen, yet their basic relatedness to the simple

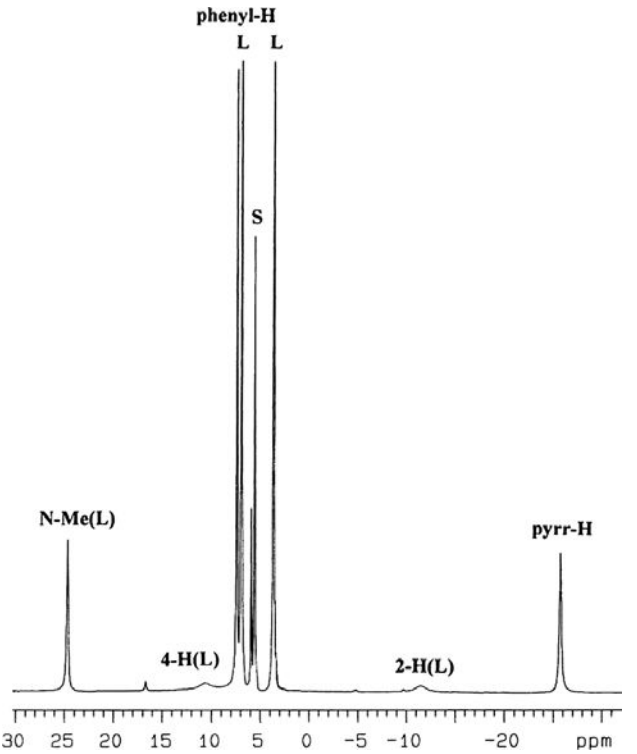

Figure 19. 300 MHz 1D NMR spectrum of $[(TPP)Fe^{III}(NMeIm)_2]^+$ recorded in CD_2Cl_2 at −45 °C. S = solvent, L = free ligand. (T. K. Shokhireva, unpublished work.)

spectrum of $[(TPP)Fe(NMeIm)_2]^+$, Figure 20, is evident. Similar relatedness in the face of increased complexity can be observed between the ^1H NMR spectrum of $[(OEP)Fe(NMeIm)_2]^+$ and an unsymmetrical derivative of this complex, $[(E_6A_2P)Fe(NMeIm)_2]^+$, where E = ethyl and A = diethylcarboxamide,[210] Figure 22. Natural porphyrin complexes of low-spin iron(III) have been studied for many years. A classic example of these spectra is shown in Figure 22, where the methyl regions of a series of 2,4-disubstituted deuteroporphyrinatoiron(III) bis-(cyanide) complexes[168] are shown.

^1H NMR spectra of high-spin iron(III) complexes of [(TPP)FeCl] and [(OEP)FeCl] in $CDCl_3$ and DMSO-d_6 are shown in Figure 23. As is evident, the pyrrole-H and pyrrole-CH_2 chemical shifts of the two porphyrinates have the same signs but the magnitude of the CH_2 shift is much smaller. The change in solvent from $CDCl_3$ to DMSO-d_6 does not greatly affect the chemical shifts of the pyrrole position resonances, but the *meso*-H resonance shifts approximately 100 ppm to higher frequency in the coordinating solvent. This will be considered in greater detail in Sections IV.A.6.a and IV.A.6.b.

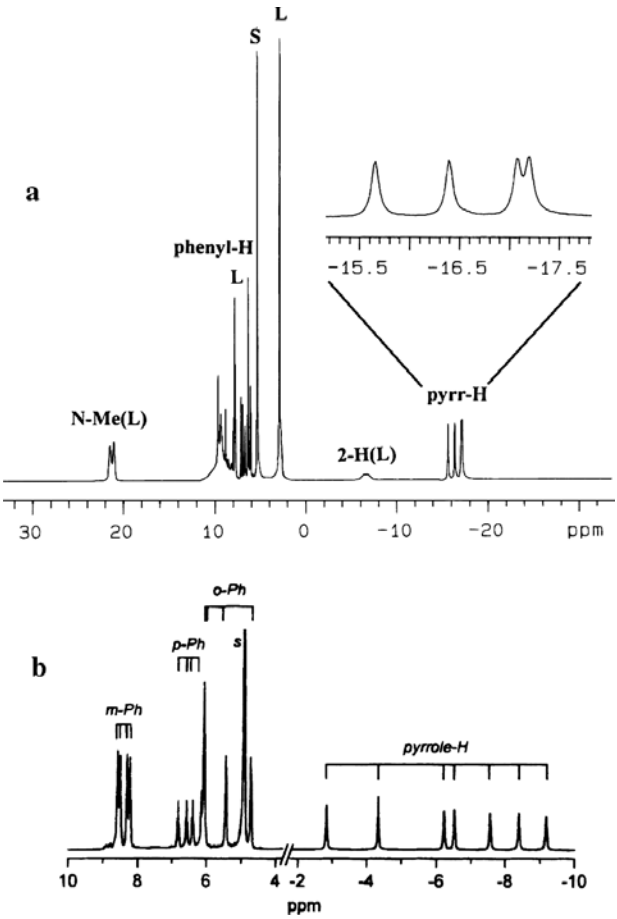

Figure 20. (a) 300MHz 1D NMR spectrum of $[((m\text{-}NO_2)_1(m\text{-}F)_3TPP)Fe^{III}(NMeIm)_2]^+$ recorded in CD_2Cl_2 at 290 K. S = solvent, L = free ligand. Note the two N-Me signals from ligands coordinated on the same and opposite sides to the *m*-NO_2. The coordinated ligand 2-H is also broadened by this inequivalence. (T. K. Shokhireva, unpublished work.) b) 300 MHz 1D ^1H NMR spectrum of $[(2\text{-}CN\text{-}TPPFe^{III}(CN)_2]^-$ in methanol-d_4 at 293 K. Reprinted from Wojaczyński, J.; Latos-Grażyński, L.; Hrycyk, W.; Pacholska, E.; Rachlewicz, K.; Szterenberg, L. *Inorg. Chem.* **1996**, *35*, 6861–6872, with permission from the American Chemical Society.

Similarly to chromium(III) porphyrins, d^3 manganese(IV) porphyrins have quite broad ^1H resonances, which are much better resolved as the deuterium-substituted analogs, when observed by ^2H NMR spectroscopy. As is shown in Figure 24, the pyrrole-D resonance of the TMP complex of oxomanganese(IV) is more than twice as broad as that of the corresponding complex of chloromanganese(III).[229] However, the observed pyrrole-D shifts are relatively similar, as will be discussed further in Sections IV.E.2 and IV.E.7, because of the major

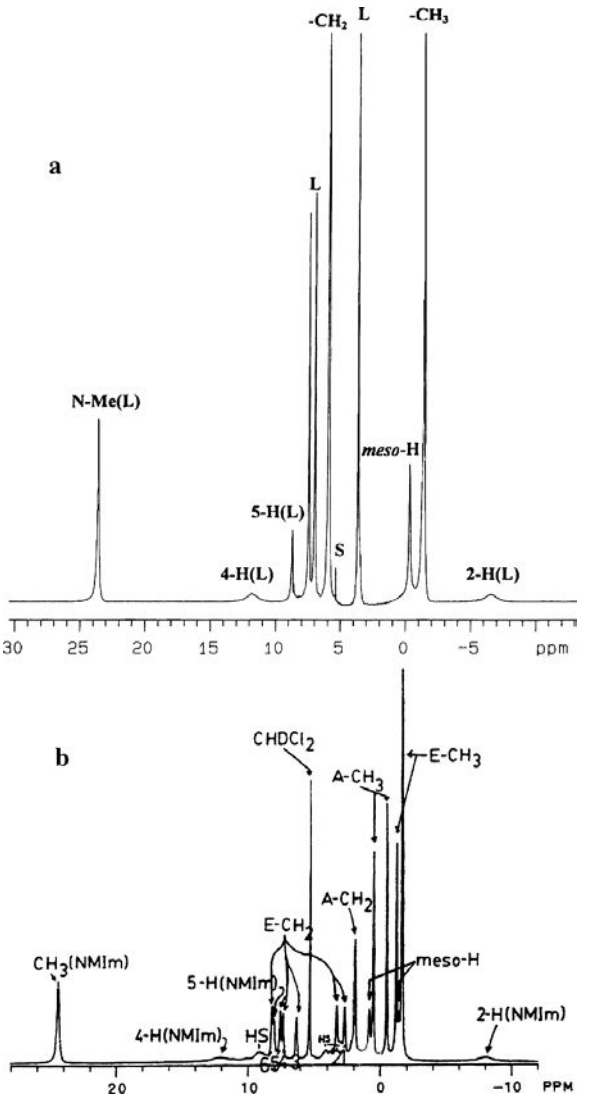

Figure 21. (a) 300 MHz 1D ^{1}H NMR spectrum of $[(OEP)Fe^{III}(NMeIm)_2]^+$ in CD_2Cl_2 at –45 °C. S = solvent, L = free ligand. (T. K. Shokhireva, unpublished work.) (b) 300 MHz 1D ^{1}H NMR spectrum of $[(E_6A_2P)Fe^{III}(NMeIm)_2]^+$ in CD_2Cl_2 at –45 °C. The broad peaks marked HS are due to the presence of a small amount of the high-spin complex, $[(E_6A_2P)FeCl]$. Modified from Isaac, M. F.; Simonis, U.; Lin, Q.; Suffian, D. J.;Wilson, D. L.; Walker, F. A. *Inorg. Chem.* **1993**, *32*, 4030–4041, with permission from the American Chemical Society.

importance of π delocalization involving the two d_π unpaired electrons present in both oxidation states.

Even though most cobalt(II) porphyrins are low-spin and have rather broad ^{1}H resonances with relatively small shifts that are largely pseudocontact in origin

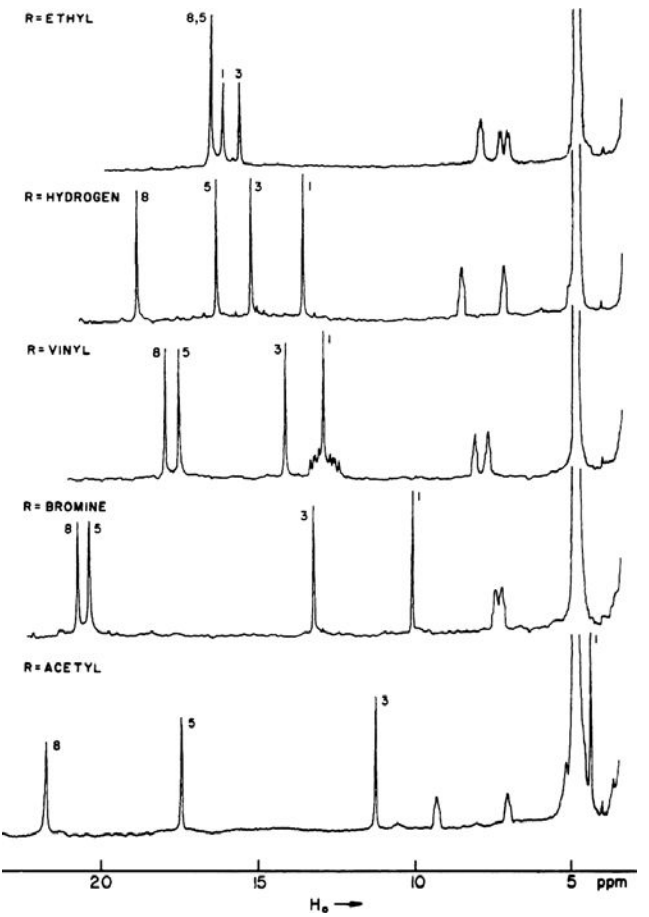

Figure 22. ^{1}H NMR spectra of the methyl regions of $[(2,4\text{-}R_2\text{deuteroporphyrin})Fe^{III}(CN)_2]^-$ in methanol-d_4 at 25 °C for R = ethyl, hydrogen, vinyl, bromine and acetyl. The methyls were assigned by ^{2}H substitution. Reprinted from La Mar, G. N.; Viscio, D. B.; Smith, K. M.; Caughey, W. S.; Smith, M. L. *J. Am. Chem. Soc.* **1978**, *100*, 8085–8092, with permission from the American Chemical Society.

(paramagnetic shifts of up to +19 ppm for the *meso*-H of the OEP complex at 35 °C), the ^{1}H NMR spectra of the chlorocobalt(II) N-methylporphyrin complexes of TPP and OEP,[230] shown in Figure 25, are those of high-spin cobalt(II) centers, and are quite a bit sharper. The lower symmetry of the N-methylporphyrin ligand creates many more resonances for each complex.

B. Analysis of Shifts

Both contact and pseudocontact shifts vary in their relative and absolute contributions to the paramagnetic shifts of the protons on the periphery of the porphyrin

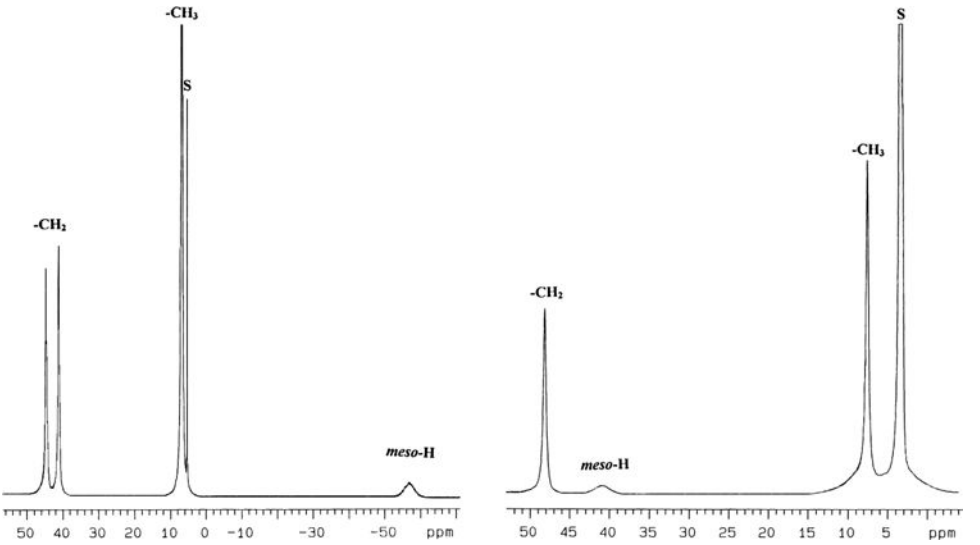

Figure 23. Left: 300 MHz 1D ^{1}H NMR spectrum of HS [(OEP)FeCl] in CD_2Cl_2, and right: DMSO-d_6 at 294 K. (T. K. Shokhireva, unpublished work.)

and axial ligands, depending on the electron configuration and magnetic anisotropy of the metal ion involved. Some knowledge of the magnetic properties and possible electron configurations of the particular system is required in order to begin the process of separating these two terms. Usually it is desired to gain insight into the contact contribution to the paramagnetic shifts, in order to determine what orbital or orbitals is/are used for spin delocalization. In order to do this the pseudocontact contribution to the paramagnetic shifts must be determined and subtracted. The approaches employed depend on the type of magnetic data available. For many electron configurations and spin states, EPR data are available to determine whether or not there is magnetic anisotropy or zero-field splitting that could give rise to a pseudocontact shift. Crystallographic data are available for a number of metalloporphyrins that allow calculation of the axial geometric factors, $(3\cos^2\theta-1)/r^3$, which are part of Eqs. 9 and 10. These axial geometric factors can then be used in one of three ways to separate out the pseudocontact contribution to the paramagnetic shift: (1) *analysis of curvature in the Curie plot*, (2) *empirical methods that rely on a comparison of predicted and computed relative pseudocontact shifts*, and (3) *use of EPR g-values with Eq. 9*. The rhombic geometric factors may be needed in some cases, but in general the rhombic contribution to the pseudocontact shift averages to zero for metalloporphyrins in homogeneous solution, where any nonhindered axial ligands are rotating extremely rapidly. The same is definitely not true of heme proteins, where axial ligands are usually fixed in position, often by hydrogen-bonds and crowding of protein side chains.

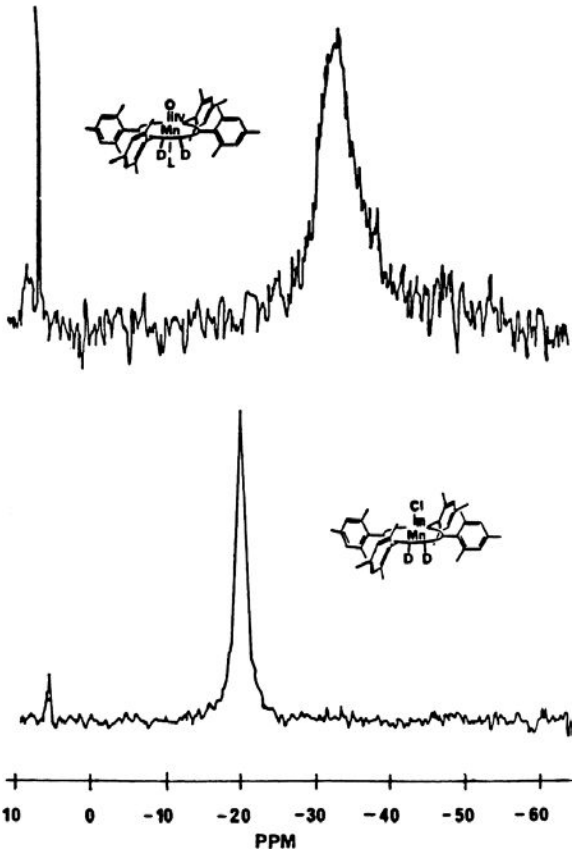

Figure 24. ^{2}H NMR spectra of [(d_8-TMP)Mn^{IV}(O)] (top) and [(d_8-TMP)Mn^{III}Cl] (bottom) in CH_2Cl_2 at –40 °C. The resonance at 5.2 ppm is $CHDCl_2$. Reprinted from Groves, J. T.; Stern, M. 1. *Curvature in the Curie Plot over the Temperature Range of the Measurement*

When one begins a study of a paramagnetic metalloporphyrin it is important to obtain the temperature dependence of the paramagnetic shifts of the metal complex over as wide a temperature range as possible. For complexes in which axial ligands are bound to the metal, this generally means going to very low temperatures, since axial ligand dissociation may be expected to become significant at or above ambient temperatures for most metalloporphyrins except those of cobalt(III). The mechanism of ligand exchange is generally dissociative,[231] and the intermediate in the ligand exchange processes may be of a different spin state, such as the case of low-spin iron(III), in which the

5-coordinate intermediate is high-spin. The presence of a small amount of this high-spin mono-ligand intermediate can shift the NMR resonances of the low-spin bis-ligand complex in the direction of those of the high-spin intermediate, and thus cause deviations from the expected temperature dependences based on Curie law (Eq. 11) or expanded Curie law (Eq. 13). Hence, the temperature dependence must be free of such chemical exchange due to ligand dissociation, which generally means working at low (sometimes very low) temperatures. Deuterated solvents typically used for obtaining Curie plots over wide temperature ranges include methylene chloride (mp –97 °C, bp 40 °C), chloroform (mp –64 °C, bp 61 °C), dimethylformamide (mp –61 °C, bp 153 °C), methanol (mp –98 °C, bp 65 °C) or toluene (mp –93 °C, bp 111 °C). Curie plots will typically show whether there is some unusual magnetic behavior of the system. Such unusual magnetic behavior includes: nonzero intercepts due to SOZ and/or excited state contributions to the pseudocontact shifts,[25,30] curvature due to hindered rotation of substituent groups, and curvature due to zero-field splitting contributions to the pseudocontact shift, Eq. 10, as described previously.[2,4]

a. *Zero-field splitting contributions to the pseudocontact shift*

In Section II.A.2 it was shown that zero-field splitting contributions can be separated if the temperature dependence [*over the range of temperatures at which the NMR spectra were measured*] follows a general expression

$$\delta_{iso} = \alpha T^{-1} + \varepsilon T^{-2}, \tag{22}$$

where $\alpha = g\mu_B AS(S+1)/18\gamma_H\hbar k$, $\varepsilon = -(28g^2(\mu_B)^2 D/9\gamma_N{}^2 k^2 r^3)(3\cos^2\theta - 1)$, and D is the zero-field splitting parameter. This has been used previously for separating the contact and pseudocontact contributions to the paramagnetic shifts of high-spin iron(III) porphyrins,[2,4,36] and Latos-Grażyński and coworkers have used it in the study of high-spin nickel(II) porphyrins that have sizeable zero-field splittings,[230] Section IV.F.

b. *Nonzero intercepts of the Curie plot*

Should the Curie plot for all proton resonances of the molecule appear to be linear over the temperature range of the measurements, but the intercepts of the paramagnetic shifts be nonzero, it is likely that there are significant SOZ contributions to the pseudocontact shifts,[30] and/or there is a significant temperature-dependent contribution from an excited state with a different pattern of spin delocalization than that of the ground state,[25] as discussed in Section II.A.3, Eq. 13. Some knowledge as to what types of excited states may be involved is necessary in order to analyze the temperature dependence. For example, if the ground state has a low-spin state (for example, S = 0 or S = 1/2) while the excited state has a higher-spin state (for example, S = 1 or S = 3/2 or 5/2, respectively), the proper weighting factors W_1 and W_2 must be used in Eq. 13. Various scenarios can tried using the program TDFw, available on the World Wide Web.[84] Examples of the use of Eq. 13 for analysis of the temperature dependence of a low-spin $TPPFe^{III}$ complex and of two intermediate spin [$((2,6\text{-}X_2)_4TPP)FeOClO_3$] complexes are shown in Figures 26 and 27, respectively. The only difficulty in using this treatment to separate the pseudocontact and contact shifts is that it assumes that the two have the same temperature dependence, and that the ground and excited state contributions are related in a particular way to the orientation of the nodal plane of the e(π) orbital of low-spin iron(III) for the ground and excited states. It was first thought that this would be a problem, because although the rhombic contribution to the magnetic anisotropy of Eq. 9 is expected to change sign between the ground and excited states, it was believed that the axial contribution to Eq. 9 would not. However, it has since been shown that for low-spin iron(III) the axial pseudocontact shift is opposite in sign for the excited state than it is for the ground state, because the

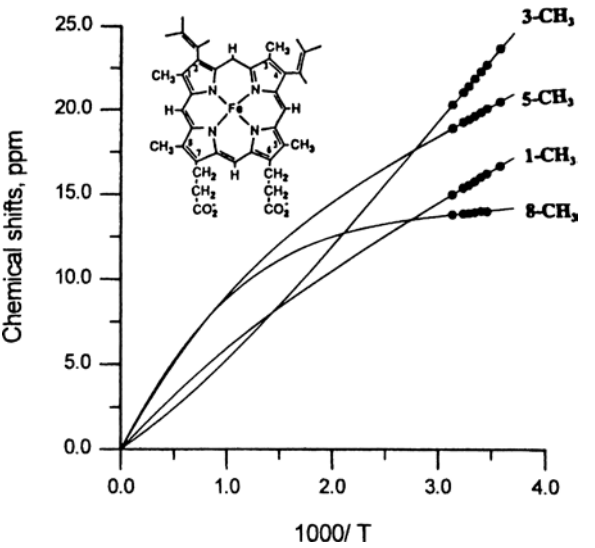

Figure 26. Plot of the fit of Eq. 13 to the calculated contact shifts of the pyrrole-H for [(2,3-MoL)TTPFe^{III}(NMeIm)$_2$]$^+$. The value of ΔE obtained from this fit is 211 ± 25 cm^{-1}, an intermediate value that is smaller than V/λ. Spin density coefficients obtained from this fit are, for the ground state, (c) 0.164, (d) 0.0059, (e) 0.0049, (f) 0.0158, (g) 0.0156 and (h) 0.0046, while for the excited state they are (c) 0.0141, (d) 0.0212, (e) 0.0199, (f) 0.0120, (g) 0.0114 and (h) 0.0195. These values compare reasonably with the magnitudes of those obtained from simple Hückel calculations. Reprinted from Shokhirev, N. V.; Walker, F. A. *J. Phys. Chem.* **1995**, *99*, 17795–17804, with permission from the American Chemical Society.

g-values of the excited state are opposite in magnitude than they are for the ground state.[172] This actually simplifies the fitting of data to Eq. 13, but it provides no means of separating the contact and pseudocontact shifts.

2. *Empirical Methods*

Usefulness of these approaches depends on it being possible to demonstrate relatively unambiguously that the shift(s) for some functional group(s) are either totally pseudocontact or totally contact in origin. In either case, it is then possible to assess the magnitude of the pseudocontact shift at all other positions of interest in the complex. This analysis depends on the fact that the relative pseudocontact shifts for nonequivalent protons in a complex are determined solely by the relative geometric factors.[2,4,23,24] Hence, in an axial case,

$$(\delta_{pc})_i : (\delta_{pc})_j : (\ldots) = \left[\frac{3\cos^2\theta_i - 1}{r_i^3}\right] : \left[\frac{3\cos^2\theta_j - 1}{r_j^3}\right] : [\ldots]. \qquad (23)$$

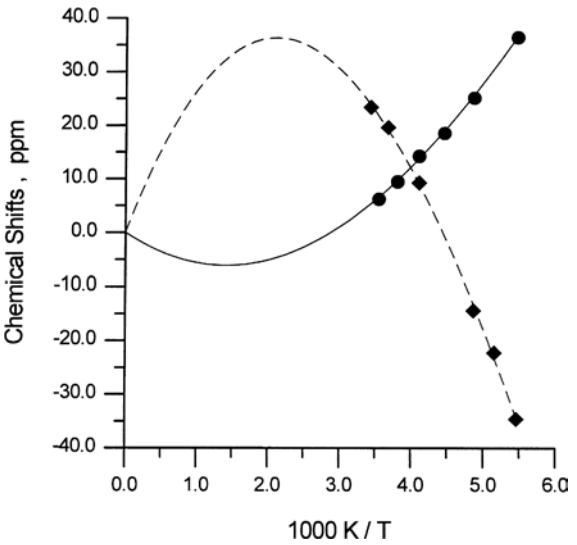

Figure 27. Plot of the fit of Eq. 13 to two spin-admixed $[(2,6\text{-}X_2)_4TPPFe^{III}OClO_3]$ complexes, where the filled circles are for X = F and the filled diamonds for X = Br. In the former case, the S = 5/2 state is the ground state, while for the latter, the S = 3/2 state is the ground state. Reprinted from Nesset, M. J. M.; Cai, S.; Shokhireva, T. K.; Shokhirev, N. V.; Jacobson, S. E.; Jayaraj, K.; Gold, A.; Walker, F. A. *Inorg. Chem.* **2000**, *39*, 532–540, with permission of the American Chemical Society.

If a certain set of protons exhibits relative shifts that are inconsistent with a pattern expected from spin delocalization, but are in quantitative or semiquantitative agreement with relative computed geometric factors, then the paramagnetic shifts may be assumed to be wholly pseudocontact in origin for these positions, for it is extremely unlikely that contact shifts would scale exactly parallel to the pseudocontact shifts. The known pseudocontact shifts for these positions then permit the determination of the pseudocontact contributions to all other shifts for the complex using the ratios of the geometric factors. Examples of a case where this works well and another where it does not, and it is thus possible to use this analysis to show that the shifts are largely or totally contact in origin, are shown in Figure 28. Both involve the phenyl protons of (TPP)Fe complexes. Plotting the observed paramagnetic shifts of the phenyl protons vs. the calculated geometric factors calculated for the *o*-H, *m*-H and *p*-H (Figure 28, left) yields a linear correlation for $[(RTPP)Fe^{II}]$, indicating essentially 100% pseudocontact contribution to the phenyl-H shifts,[232] but for $[TPPFe(t\text{-}BuNC)_2]^+$ (Figure 28, right) the observed shifts deviate significantly in opposite directions for the *o,p*-H and the *m*-H, which indicates that in the latter case the shifts are largely, if not completely, contact in origin.[155] Calculation

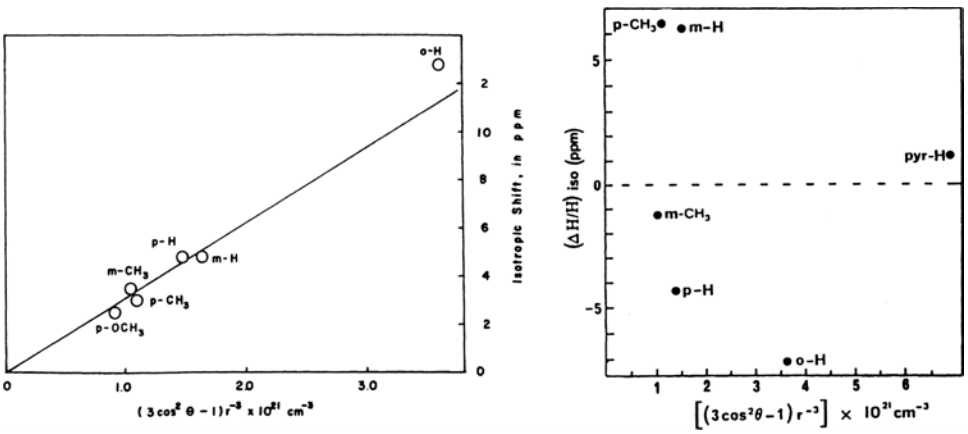

Figure 28. Left: Plot of the isotropic shifts for *meso*-aryl substituents in [(RTPP)Fe^{II}] in benzene-d_6 at 25 °C vs the calculated geometric factor, $\langle(3\cos^2\theta - 1)/r^3\rangle$, showing all aryl resonances close to the theoretical line. of the pseudocontact contribution to the pyrrole-H shifts of the bis-(imidazole) or (amino ester) complexes showed that the pseudocontact shift is a minor part of the paramagnetic shift at the pyrrole-H position, thus showing that there is a large contact shift at the β-pyrrole positions for the bis-(imidazole) and -(amino ester) complexes of low-spin iron(III) porphyrins. However, the bis-isocyanide complex of (TPP)Fe^{III} has a totally different pattern of shifts, with vanishingly small pseudocontact shifts at all hydrogen positions, but very large contact shifts at the phenyl-H positions and only a very small (positive) contact shift at the pyrrole-H position. This indicates that these two complexes use different porphyrin (and metal d) orbitals for spin delocalization, as will be discussed in greater detail below. Cobalt(II) porphyrins were earlier shown to have mainly pseudocontact shifts of the phenyl-H, as well as the pyrrole-H positions.[2,4,233] In contrast, manganese(III) porphyrins were shown to have predominantly π contact shifts at both the *meso*-aryl and pyrrole-H positions.[2,4,234] High-spin nickel(II) complexes have very small g-anisotropy, but sizeable zero-field splittings, which produce measurable pseudocontact shifts at the pyrrole positions, which can be separated from the contact shifts by use of Eq. 22, as discussed in Section IV.F.

3. *g-Tensor Anisotropy*

When two complexes have similar geometries but different EPR g-values, the g-values measured at low temperatures (4–77 K) can be used to calculate the axial ($g_{\parallel}^2$–$g_{\perp}^2$), and if necessary, the rhombic g anisotropies (g_{xx}^2–g_{yy}^2). If the sizes of the pseudocontact shifts are known for one of the complexes, those of the other can be estimated by scaling the pseudocontact shifts of the known complex by the ratios of the known g anisotropies of the two, according to Eq. 9. Such procedures have been used previously with good success for low-spin iron(III) porphyrins, $[(RTPP)Fe(ImH)_2]^+$,[2,4] but not for $(RTPP)Co^{II}$ complexes, where axial solvation at both ambient temperatures and 77 K strongly decreases the g-anisotropy measured from polycrystalline samples. Temperature-dependent axial solvation is the case for these cobalt(II) porphyrins.[2,4] For low-spin ferriheme proteins, the g-tensor anisotropy factoring method was used to estimate the pseudocontact shifts of metmyoglobins-cyanide and related molecules, and of cytochromes *c*.[8]

IV. Effect of Metal Ion and Spin State on Bonding

The large majority of NMR studies of paramagnetic metalloporphyrins have involved iron porphyrins of various oxidation and spin states. Thus, this section will begin with a study of iron porphyrins and will then be expanded to the other paramagnetic metalloporphyrins of the transition and lanthanide series.

A. Iron Porphyrins

The types of M-P bonding interactions and the ranges and signs of paramagnetic shifts found for iron porphyrins and the heme proteins are very dependent on oxidation state and spin state of the metal. In fact, the spectra are so characteristically similar within each class of iron(III) porphyrin complexes alone (high-spin, oxo-bridged dimers, intermediate-spin, low-spin with two different electron configurations), and so different between classes, that NMR spectroscopy is a valuable diagnostic tool for determining the nature of the axial ligands and spin state in a newly prepared iron(III) porphyrin complex. The same is also true for iron(II), iron(I) and iron(IV) porphyrin complexes, and thus each of these will be considered individually.

1. *Iron(I) Porphyrins*

Although iron(I) porphyrin complexes are known, only a few of them, such as the low-spin d^7 bis-(pyridine) iron(I) complex of a *meso*-alkoxyporphyrin which bears

an –OR group in one of the *meso* positions,[235] and low-spin d^7 iron(I) complexes of tetraphenylporphyrin, etioporphyrin and octaethylporphyrin[236] have been investigated by either proton or deuterium NMR spectroscopy, and there have been no new reports of their investigation in the past ten years. Proton or deuterium NMR spectra of the iron(I) species are of diagnostic value for determining the ground state of the metal ion, since characteristic positive paramagnetic shifts for certain resonances have been observed. For (tetraphenylporphyrinato)iron(I) the pyrrole-^{2}H signal is observed at about +29 ppm, and the *meso*-D signal of (etioporphyrinato)iron(I) and (octaethylporphyrinato)iron(I) at +14.5 ppm.[236] Pseudocontact shifts are relatively small. Hence, the pyrrole-^{2}H experiences predominantly a contact shift. Based on magnetic measurements and EPR studies of these complexes ($g_\perp = 2.28$ and $g_\parallel = 1.93$ for $[(TPP)Fe]^-$ and $g_\perp = 2.24$ and $g_\parallel = 1.92$ for $[(OEP)Fe]^-$, respectively, with $g_\perp > g_\parallel$,[236,237]) a spin state of S = 1/2 is widely accepted, with the unpaired electron residing in the d_{z^2} orbital, by analogy to cobalt(II) porphyrins.[238]

2. *Diamagnetic Iron(II) Porphyrins*

Ferrous porphyrin complexes are biologically relevant since they are active site analogs of the oxygen transport and storage proteins, hemoglobin and myoglobin. However, synthetic iron(II) porphyrins are easily oxidized, and thus proper care is needed to handle them. The resonance shifts observed in the NMR spectra of the diamagnetic complexes can be used as a convenient reference for determining the magnitude and the direction of the paramagnetic shifts in structurally related paramagnetic complexes.[2-4]

a. *Six-coordinate diamagnetic complexes*

Proton NMR spectra of 6-coordinate ferrous porphyrin complexes show proton resonances in the diamagnetic region. The pyrrole proton signals are shifted to slightly lower shielding by the large ring current effect of the porphyrin macrocycle and are observed at or near 9 ppm. The phenyl proton resonances in this and other complexes are found at 7 to 8 ppm, whereas the resonances of the axial ligands are shifted to high shielding as a consequence of the large ring current of the macrocycle. More extensive discussion of the diamagnetic 6-coordinate iron(II) porphyrin NMR spectra is provided elsewhere.[3,239] Diamagnetic iron(II) complexes derived from chelated protohemes, in which a coordinating imidazole ligand is provided by an alkyl imidazole attached to one or both of the heme propionates (see Figure 42) and in which CO represents the sixth ligand[240] provide examples of 6-coordinate heme models related to natural porphyrins. The porphyrin ring current affects the signals of these complexes in a characteristic

way: *meso*-protons are deshielded (9.7 ppm), vinyl protons are found at 6 to 8 ppm, and side chain protons are strongly shielded.

Several diamagnetic 6-coordinate ruthenium(II) porphyrins have been investigated by ^{1}H NMR spectroscopy, and their chemical shifts are included in Table 8, together with the shifts of other diamagnetic metalloporphyrins that may serve as convenient diamagnetic references for calculating the paramagnetic shifts of paramagnetic metalloporphyrins.

Despite the common belief that only one 2-substituted imidazole will bind to iron(II) porphyrins, and that such complexes are excellent models for T-state hemoglobins, the bis-1,2-dimethylimidazole complex of (TMP)Fe^{II} has been prepared and investigated by X-ray crystallography,[32] magnetic Mössbauer spectroscopy at 4.2 K[241] and by proton NMR spectroscopy in d_8-toluene at −70 to −90 °C.[92] Both of the latter techniques confirm that the complex is diamagnetic, but it has unique spectral parameters because of the strong ruffling of the porphyrinate ring that must occur in order for these sterically hindered ligands to bind to Fe^{II}. The NOESY spectrum of [(TMP)Fe^{II}(1,2-Me$_2$Im)$_2$] at −80 °C is very similar to that of [(TMP)Co^{III}(1,2-Me$_2$Im)$_2$]$^+$ at room temperature,[92] as shown in Figure 29. This similarity in the 2D spectra confirms the similarity in molecular structure of these two complexes, as well as their structural similarity to the highly ruffled paramagnetic iron(III) analog.[32,227] Multinuclear (^{13}C, ^{17}O, ^{57}Fe) NMR studies of diamagnetic carbonmonoxy heme proteins and synthetic model compounds have also been reported.[242]

Compounds with modified ring systems such as the *meso*-oxidized derivative of octaethylporphyrin, OEOP, which as the iron complex is a green pigment known as an iron *meso*-oxaporphyrin or verdoheme, Structure **9**, are low-spin iron(II) diamagnetic centers when bound to two pyridine axial ligands.[220] Their high-spin 5-coordinate halide counterparts are discussed in Section IV.A.4.b(vi).

b. *Five-coordinate diamagnetic complexes*

Chemical shift values of 5-coordinate iron(II) porphyrin complexes are very similar to those observed for the 6-coordinate complexes. Examples of 5-coordinate species are iron(II) alkyl complexes of *meso*-tetraphenylporphyrin, such as [(TPP)Fe($CH_2CH_2CH_3$)]$^-$ and [(TPP)Fe(CH_2CH_3)]$^-$.[243,244] Resonances for the σ-alkyl hydrogens are shielded by the ring current effect of the macrocycle.

3. *Intermediate-Spin Iron(II) Porphyrins: Observed Shifts and the Mechanism of Spin Delocalization*

Four-coordinate ferrous porphyrins have an intermediate spin state (S = 1). Some of these have been studied by various physical methods, and three possible ground

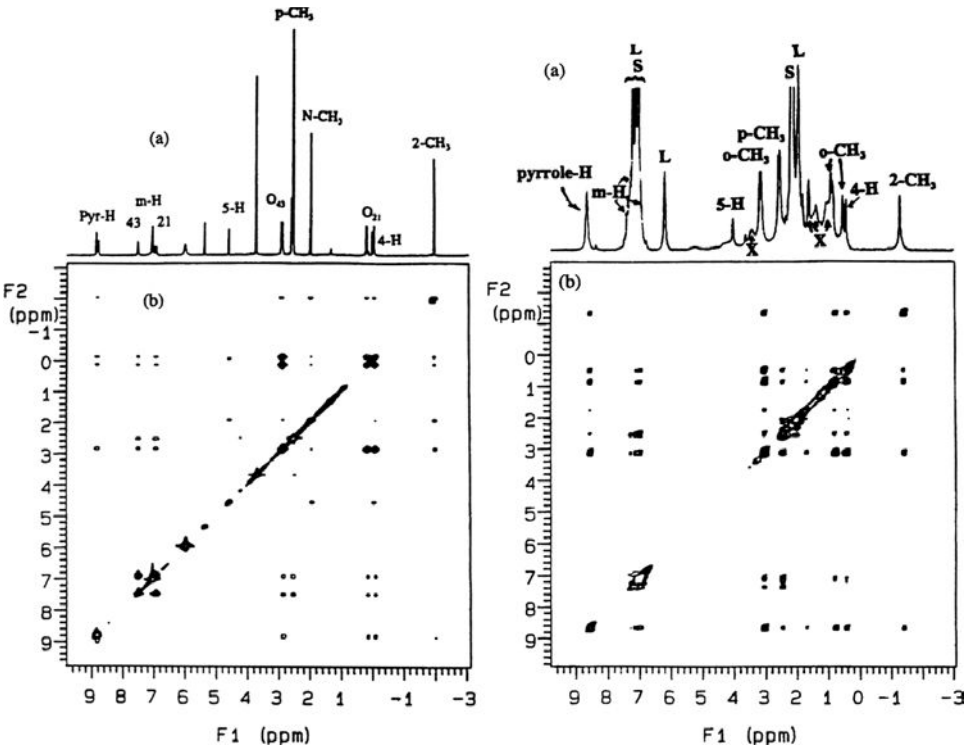

Figure 29. Left: (a) 1D 300 MHz ^{1}H NMR spectrum of $[(TMP)Co^{III}(1,2\text{-}Me_2Im)_2]^+$ in CD_2Cl_2 at +21 °C, showing the four separate *o*-CH_3 resonances observed for this complex, which are in slow exchange on the NMR time scale. (b) 2D phase-sensitive NOESY/EXSY spectrum, recorded at the same temperature with a mixing time of 700 ms, showing chemical exchange (multiple contours) and NOE (single circles) cross peaks. The peaks at 2.5, 3.7, 6.0 and 7.0 ppm are due to excess 1,2-Me_2Im in the solution, and the peak at 5.3 ppm is due to $CDHCl_2$. Right: (a) 1D 300 MHz ^{1}H NMR spectrum of $[(TMP)Fe^{II}(1,2\text{-}Me_2Im)_2]$ in toluene-d_8, recorded at −90 °C. (b) Phase-sensitive ^{1}H NOESY/EXSY spectrum recorded at the same temperature with a mixing time of 500 ms, showing both chemical exchange and NOE cross peaks. Note the similar pattern of *o*-CH_3 resonances for the Co^{III} (left) and Fe^{II} (right) complexes. In addition to the major peaks of the complex, intense resonances due to solvent (S), free ligand (L) and several unknown impurities (X) are marked; none of these show cross peaks in the 2D spectrum. Reprinted from Polam, J. R.; Shokhireva, T. Kh.; Raffii, K.; Simonis, U.; Walker, F. A. *Inorg. Chim. Acta* **1997**, *263*, 109–117, with permission from Elsevier Publishing Company.

states, each consistent with certain physical properties, have been proposed: $^3A_{2g}$ $(d_{xy})^2(d_{z^2})^2(d_{xz},d_{yz})^2$; ^3E_g $(d_{xy})^2(d_{z^2})^1(d_{xz},d_{yz})^3$; and $^3B_{2g}$ $(d_{xy})^1(d_{z^2})^1(d_{xz},d_{yz})^4$.[245] Most proton NMR studies of a variety of planar, 4-coordinate iron(II) complexes of synthetic porphyrin macrocycles favor the $^3A_{2g}$ ground state.[232,245–248] These complexes are generally synthesized in situ in benzene-d_6, toluene-d_8[246–248] or dichloromethane-d_2,[249,250] by reduction of the corresponding iron(III) porphyrins

using either the chromous, aqueous dithionite, the zinc amalgam, or sodium borohydride[251,252] reduction techniques. Representative ^{1}H NMR spectra of [(TPP)Fe] and the iron(II) complexes of deuteroporphyrin IX and protoporphyrin IX are shown in Figures 30 and 31, respectively. Large paramagnetic shifts are observed, as summarized in Table 9.

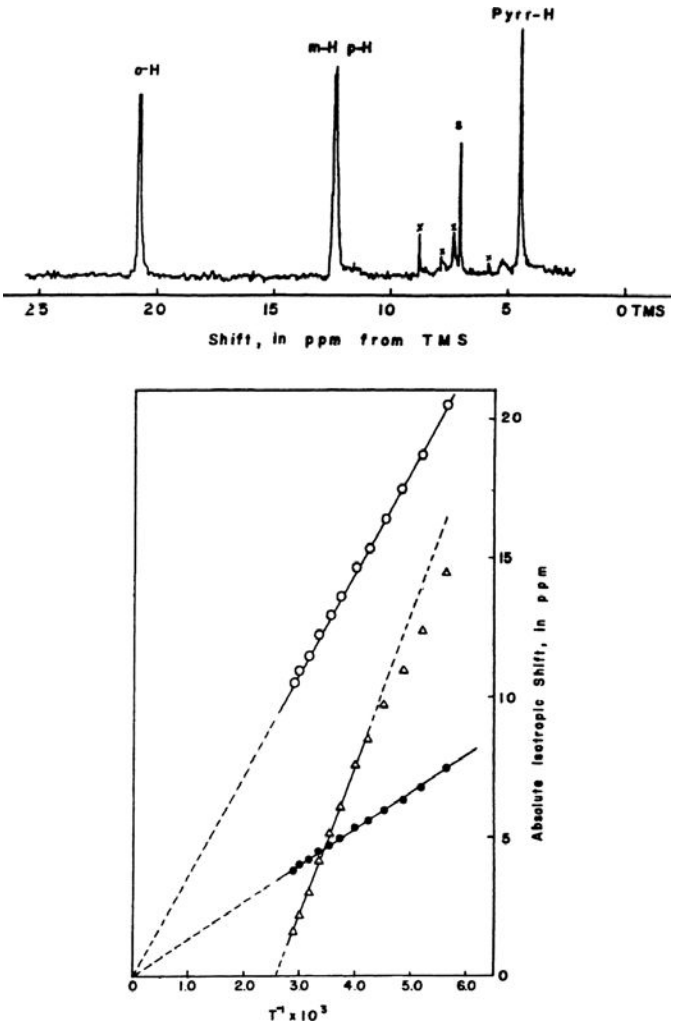

Figure 30. Top: 1D ^{1}H NMR of 0.25 mM [(TPP)Fe^{II}] in benzene-d_6 at 25 °C. The *m*-H/*p*-H clearly split apart at low temperatures to yield the resolved resonances. The *o*-H exhibits a ~8Hz doublet due to the *m*-H. S = solvent, C_6D_5H, and X = impurity. Bottom: Curie plot for the spectrum shown above. The paramagnetic shifts of the TPP, RTPP and OEP iron(II) complexes have been analyzed and discussed in detail elsewhere,[2–4,246] and can be summarized as follows: Except for the pyrrole protons, all proton resonances are significantly shifted to lower shielding, as seen in Figures 30 and 31. Such a bias of shifts in one direction indicates that at least a major portion of the paramagnetic shifts is a result of the pseudocontact interaction, a result expected, since the 4-coordinate iron(II) molecules are highly magnetically anisotropic.[246] For the synthetic (tetraarylporphinato)iron(II) derivatives the phenyl-H resonances are essentially totally pseudocontact in nature,[232] as demonstrated in Figure 28, left panel. These dominant pseudocontact shifts result from large magnetic anisotropies, $\chi_{\parallel} > \chi_{\perp}$. The paramagnetic shifts for the pyrrole protons of these complexes are found to be small and negative, which suggests that these shifts arise from both contact and pseudocontact contributions which have opposite signs. Negative pyrrole-H paramagnetic shifts are associated with the absence of spin in the $d_{x^2-y^2}$ orbital and at least one unpaired electron in the d_{xz} or d_{yz} orbital.[2,4] The π contact shift requires unpaired spin in d_{xz} and d_{yz} and strongly supports the $^3A_{2g}$ ground state configuration, $(d_{xy})^2(d_{z^2})^2(d_{xz},d_{yz})^2$.[246] The iron(II) complexes of the natural porphyrins also

exhibit large paramagnetic shifts at low concentrations; at higher concentrations they tend to aggregate.[246,247]

X-ray crystal structures and NMR studies of (OEP)Fe^{II} and the chlorin complex, (OEC)Fe^{II} were reported, by Strauss and coworkers, as a function of temperature.[248] In the solid state, the chlorin macrocycle is significantly S_4 ruffled, while the parent porphyrin macrocycle is nearly planar. Large paramagnetic shifts with significant pseudocontact contributions were observed for (OEP)Fe^{II}, as shown in Figure 32, which were analyzed as described earlier by Goff and La Mar.[246] However, the paramagnetic shifts of (OEC)Fe^{II} could only be fit to straight lines with large nonzero intercepts.[248] The unusual intercepts of the linear plots of the resonances of the (OEC)Fe^{II} complex were suggested to result from a large temperature-independent paramagnetism.[248] These unusual intercepts are more likely caused by a thermally-accessible excited state which has a different electron configuration and thus a very different pattern of spin delocalization via the contact interaction,[25] as demonstrated by the solid lines of Figure 33. A likely candidate for this excited state is the ^3E_g state, with $d_{xy}^2d_{z^2}^1d_{xz}^2d_{yz}^1$ electron

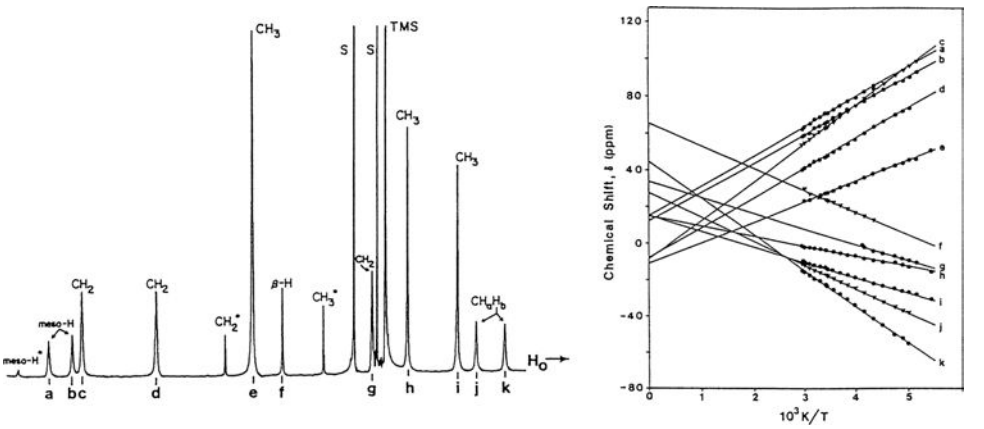

Figure 32. Left: 100 MHz ^{1}H NMR spectrum of [(OEC)Fe^{II}] in toluene-d_8 at 6 °C. Signal assignments are indicated (S = solvent). The resonances marked with asterisks are due to [(OEP)Fe^{II}]. configuration which would thus remove the possibility of spin delocalization to S_{-2} and cause an apparent increased weighting of the A_{-2} orbital as the temperature is increased.

These results can be explained by using the theory of McGarvey,[245] which explains the pseudocontact and contact shifts for 4-coordinated ferrous complexes for the general case of nonaxial symmetry. $^3A_{2g}$ appears to be the ground state for all intermediate spin iron(II) porphyrins, for which the ground state is spin-orbit coupled to the ^3E_g excited state at a particular energy, 600 cm^{-1} for [(OEC)Fe^{II}] and [(OEP)Fe^{II}], and 1000 cm^{-1} for [(TPP)Fe^{II}]. With addition of the contact shift consequences of an excited state in which d_{xz} is filled (that is, the E_g excited state, Figure 33, solid line), the contact shifts are more clearly understood.

The NMR spectrum of 4-coordinate 2,7,12,17-tetra-*n*-propylporphycene, (TPrPc)Fe^{II}, Structure **14**, in toluene-d_8 at 293 K has been reported to have pyrrole-H resonances at −37.52 ppm, *meso*-H at +71.56 ppm, and α-CH_2 at +27.47 ppm.[253] These chemical shifts are consistent with an S = 1 ground electronic state.

4. *Five-Coordinate High-Spin Iron(II) Porphyrins: Observed Shifts and the Mechanism of Spin Delocalization*

Five-coordinate high-spin ferrous porphyrin complexes with imidazole or pyridine as axial ligand have been of interest because they represent not only direct models of the oxygen transport and storage proteins deoxyhemoglobin and deoxymyoglobin, but they are also fairly good models of the reduced states of cytochrome P450 and chloroperoxidase, in which the single axial ligand is a cysteine thiolate. NMR investigations have been reported for a number of these models, as will be described below. Models of the heme a_3/Cu_B center of cytochromes *c* oxidase, C*c*O, and of the heme/nonheme centers of the C*c*O-like nitrite reductases, NORs, are also discussed in this section, although many of these models start with no or unknown fifth ligand.

a. *Models of deoxyhemoglobin and deoxymyoglobin*

High-spin ferrous complexes can be obtained by addition of a moderate excess of a 2-substituted imidazole or a pyridine to the corresponding 4-coordinated intermediate-spin iron(II) derivatives at ambient temperatures.[246] The paramagnetic shifts of the pyrrole-H in the TPP complexes are positive, and those of the phenyl protons are negative, with typical paramagnetic shifts of +43.5 ppm for the pyrrole-H and −1.0 to −1.5 ppm for the *o*-, *m*-, and *p*-phenyl protons. For 5-coordinate (OEP)Fe^{II} complexes, paramagnetic shifts of −7.0 ppm (chemical shift ~+4 ppm) for the *meso*-H and +8.5 ppm for the pyrrole-α-CH_2 protons have been reported.[246]

The paramagnetic shifts of a number of natural and synthetic high-spin iron(II) porphyrinate complexes are listed in Table 10. The phenyl-H paramagnetic shifts of high-spin (TPP)Fe^{II} are small and negative (Table 10), which suggests that the high-spin complexes exhibit only very small magnetic anistropy.[246] The predominant contribution at the β-pyrrole positions must therefore be contact in origin. The pyrrole-H and α-CH_2 paramagnetic shifts are positive (to higher frequency) (Table 10), which is indicative of primarily σ spin delocalization. The small negative *meso*-H shifts suggest only moderate π delocalization to the *meso* positions. This contact shift pattern, with dominance of σ-spin transfer to the pyrrole positions, is characteristic of an unpaired electron in the $d_{x^2-y^2}$ orbital, which leads to a ground state of $(d_{xy})^2(d_{xz},d_{yz})^2(d_{z^2})^1(d_{x^2-y^2})^1$ for the high-spin ferrous ion.

Moderate π delocalization to the *meso* position was until recently considered indicative of interaction of the partially filled d_π orbitals with e-symmetry porphyrin π orbitals, because while the $3e(\pi)$ orbitals have nodes at the *meso* positions, the d_π orbitals were earlier believed to "encourage" mixing of the $3e(\pi)$ with the $4e(\pi^*)$ orbitals, thereby introducing some π electron density to the *meso* positions, as indicated in Figure 2. However, more recently it has been shown that for 5-coordinate complexes, the out-of- plane position of the iron allows the half-filled d_{z^2} orbital to directly overlap with the $3a_{2u}(\pi)$ orbital to permit π spin density to be delocalized to the *meso* carbons, as shown in Figure 34. This possibility arises solely because the metal is out of the plane of the macrocycle.[156] Thus, at the present time, there is no evidence that the $4e(\pi^*)$ orbitals are involved at all in the spin delocalization of high- or intermediate-spin Fe^{II} or Fe^{III} porphyrinates.[156] This mechanism of spin delocalization is possible for all 5-coordinate iron porphyrinates which have a half-occupied d_{z^2} orbital, and hence 5-coordinate high-spin Fe^{II} and Fe^{III} and intermediate-spin Fe^{II} and Fe^{III} should all show spin density at the *meso*-carbons via this d_{z^2}–$3a_{2u}(\pi)$ spin delocalization mechanism.[156] This mechanism should also apply to high-spin 5-coordinate nickel(II) porphyrins, as is found to be the case (Section IV.F).

Other models of deoxyhemoglobin and deoxymyoglobin involved so-called tailed picket fence porphyrins[254] and pocket porphyrins,[255] in which the axial imidazole ligand that coordinates to the metal ion is covalently linked to the porphyrin. For the tailed picket fence porphinatoiron(II) complexes, four pyrrole-H peaks were observed in the ^1H NMR spectra, centered at a chemical shift of +56 ppm (paramagnetic shift +47.5 ppm).[254,255] This paramagnetic shift is similar to those of other high-spin iron(II) porphyrinates.[246] The pyrrole-H peaks shift with temperature according to the Curie law, and at −5 °C and below new sets of resonances between +10 and −10 ppm appear, which indicated disproportionation of two molecules of the 5-coordinate, high-spin iron(II) complex to yield one 4-coordinate, intermediate-spin iron(II) complex and one diamagnetic, 6-coordinate, low-spin iron(II) complex by intermolecular sharing of axial ligands.[254]

b. *Models for the reduced states of cytochrome P450 and chloroperoxidase*

Five-coordinate mercaptide (thiolate) complexes of iron(II) in which the porphyrin is derived from substituted and unsubstituted tetraphenylporphyrins or from octaethylporphyrin, deuteroporphyrin, protoporphyrin IX dimethyl ester or etioporphyrin I, and the mercaptide moiety from *n*-butyl-, *n*-propyl and ethyl mercaptide (thiolate) (BuS^-, PrS^-, EtS^-), can be obtained by chromous acetylacetonate reduction of the corresponding iron(III) chloride complexes.[256] The α-CH_2 shifts for the alkyl thiolate ligands of the model compounds are very large and appear at around +250 ppm, whereas the signals for the β-CH_2 protons are located at around −2 ppm for the TPP complexes and at −5 to −7 ppm for the natural derivatives.[257] Based on this assignment, the methylene protons for the axial cysteinate of ferrous cytochrome $P450_{CAM}$ and ferrous chloroperoxidase were found to resonate at +279 ppm and +200 ppm, respectively.[256] As summarized in Table 10, the pyrrole protons of the TPP complexes have chemical shifts of +59 to +64 ppm, whereas the phenyl-H have fairly small shifts (*o*-H: 8–10 ppm, *m*-H: 8–9 ppm, *p*-H at 8 ppm). The ring $-CH_2$ protons for the octaethylporphyrin and etioporphyrin complexes resonate at around +11 and +15 ppm, whereas the *meso*-H chemical shift is −0.3 to −0.4 ppm.[256,257] The *meso*-H paramagnetic shifts to negative ppm can only be explained by π spin delocalization, again via $3a_{2u} \rightarrow d_{z^2}$ π donation.[156] Nevertheless, the paramagnetic shifts of at least 250 ppm for the methylene resonances of the coordinated thiolate ligand support a very efficient σ spin delocalization to this ligand.[257]

c. *Models for the heme a_3-Cu_B and heme-nonheme Fe centers of cytochrome oxidase and NO reductase*

Since the two classes of enzymes, cytochrome *c* oxidases (C*c*O) and some of the bacterial nitric oxide reductases (NOR), have very similar architectures for the three metal sites in the subunit that actually does the reduction, they are frequently grouped together into a large enzyme superfamily.[258] A very brief synopsis of the

architectures of the two classes of enzymes is that in both classes there is one heme that is bis-His-coordinated (which could be a heme *a*, *b* or *c*), while the other heme (which could be an *a*, *b*, *o* or *d*) in the C*c*Os is mono-His-coordinated, with the open site very close to the so-called Cu_B center, which is coordinated to three His, one of which is covalently linked to a carbon of the aromatic side chain of Tyr, but in the (bacterial-only) NORs there is (usually) a nonheme Fe center in place of the Cu_B center. CcOs use 4 electrons and 4 protons to reduce O_2 to 2 H_2O, while NORs use 2 electrons and 2 protons to reduce 2 NO to N_2O and H_2O.[259,260] There are also a number of other types of bacterial NORs,[259] including one type that that is a cytochrome P450 enzyme.[261] Each is the/a terminal reductase of their respective respiratory chains.

Two groups have been active in the field of cytochrome oxidase (C*c*O) models during the past ten years, those of Collman and Karlin; not surprisingly, both groups have also branched into modeling NOR. Every paper of Karlin's has the NMR spectra of the (usually) paramagnetic complexes produced and studied therein, while only a few papers of Collman have NMR spectra, and those that do are usually of the diamagnetic precursors that contain no metal. In part this is because of the generally higher molecular symmetry of the models of Karlin; Collman's models tend to have very low molecular symmetry, which means that nearly every proton is unique. Thus, although many papers have been published by Collman and coworkers, those which have an NMR or EPR component are mainly the ones discussed herein.

Several designs have been created by Collman and coworkers, including a number that could be called tailed tri-picket fence porphyrins which knit the three pickets that do not provide a ligand to the iron in the porphyrin ring into a 3-coordinate site that will bind copper, usually to three imidazoles. Designs based on a triazacyclononane, three N- or C-substituted imidazole "pickets",[262] or a single "picket" with three imidazole ligands based on a trisimidazolylmethane or — methanol,[263] with the other two pickets providing protection of the bimetallic center, have been tried. The preparation of all of these models has required monumental synthetic efforts by the members of the group.[262,263] The same three types were shown in pictures in 2001.[264]

In 2002, a paper on binuclear Fe/Cu models for C*c*O was published in which the "picket" that carries the imidazole that binds to Fe on the proximal side carries a *p*-CF_3-phenyl group bound to the 5-carbon of the imidazole ring (the carbon adjacent to the nitrogen that is part of the "picket").[265] This CF_3 group is said to be a useful analytical tool. The ^{19}F NMR spectrum of the Fe/Cu complex shows that the diamagnetic $Fe^{II}CO$ site exists as a mixture of at least three product isomers with very closely spaced ^{19}F chemical shifts of –63.4 ppm vs. $CF_3SO_3^-$ in DMF-d_7.[265] No variable temperature studies are mentioned, nor any explanation

provided for the at least three isomers; the copper center was presumed to be Cu^{I}. A ^{1}H NMR spectrum of the Fe^{II}–CO complex (under N_2) and the presumed bis-CO complex (under CO) shows shifts of the 4-H(Im) of the three distal imidazole-containing pickets (2:1 by symmetry) that are consistent with binding of CO to Cu^{I} as well as Fe^{II} under these conditions.[266] A Zn/Cu complex was also prepared, which gave a Cu^{II} EPR signal having $g_{\|} = 2.28$, $g_{\perp} = 2.07$, $A_{\|} = 175$ G, $A_{\perp} = 13$ G and $A_N(g_{\perp}) = 15$ G.[266]

Another paper, this one on distal metal effects in cobalt porphyrins related to C*c*O, was also published in 2002.[266] This paper used the tri-distal-imidazole-picket-containing porphyrin, with the fourth picket also ending in an imidazole that binds to the cobalt on the proximal side. ^{1}H NMR spectra (9–4 ppm) of the metal-free, Fe^{II}–CO, and Co^{III}–X are shown; these are low-symmetry complexes so most protons show individual resonances, most of which are not assigned. Three EPR figures are shown of the Co–O_2 complex, both in the absence and presence of Cu.[266] The spectra and the idea were based on this author's 1985 paper on the Co–O_2 complex of mono-*ortho*-acetamidophenyl-TPP, which showed hindered rotation of O_2 because of hydrogen-bonding to the N-H of the *ortho*-acetamide.[267] Resonance Raman spectra of the $^{16}O_2$ and $^{18}O_2$ complexes are also shown.[266] Later, a study of water-soluble Co^{II} porphyrins and their O_2 complexes, with similar EPR spectra, were shown.[266] Collman and coworkers have also used electrochemical methods to study the catalytic reaction of models of C*c*O with O_2.[269–272]

In a paper published in 2003 on spectroscopic evidence for a heme-superoxide/Cu(I) intermediate in a functional model of C*c*O it was reported that the NMR resonances between 9 and 10 ppm in this either high-spin or intermediate spin Fe^{II}/Cu^{I} complex are the pyrrole-H resonances, which then move to 8.2–8.4 ppm on binding O_2.[273] However, as mentioned above, the pyrrole-H for a high-spin, 5-coordinate Fe^{II} complex are in the range of +43 to +52 ppm at ambient temperatures (Table 10), and there are no resonances in the +9 to +10 ppm region. This table was taken from the chapter in *The Porphyrins*,[2] and thus these chemical shifts have been known since before 1979. For intermediate-spin Fe^{II} (assuming that the MeCN-d_3/THF-d_8 solvent produced the intermediate-spin state) the pyrrole-H resonances are at −4 to −5 ppm (Table 9), while the *o*-H of the phenyl rings are in the +11 ppm region (for the picket fence porphyrin). Thus, it is not clear what the ligation of this complex was before O_2 was added, or, in fact, afterwards; it would have been wise to have looked for resonances over the range of ± 50 ppm in order to be certain that the complex was properly characterized. Later, the same group showed the results of a single-turnover reaction in a related C*c*O model, this one having a phenoxyl group attached at the 2-carbon of the phenoxyl to the 5-carbon of one imidazole of the three used to bind the copper on the distal

side of the iron porphyrin (this is a methyl-substituted phenoxyl, with the methyl *para* to the OH).[274] An EPR spectrum is shown, which is said to be that of a phenoxyl radical, but the scale over which it was recorded was from 2600 to 4000 G. A phenoxyl radical should have hyperfine splitting from the remaining three CH phenyl ring positions, and the entire spectrum should be quite sharp and extend over not more than 20–40 G at the very most, whereas the top to bottom of the derivative shape shown covers a magnetic field range of at least 80 G. In short, the EPR spectrum looks much more like that of a Cu^{II} complex. A similar EPR spectrum was shown in the *Science* paper on this complex.[272]

A later model of NOR, with Fe both in the porphyrin ring and in the 3-imidazole site, reacts with NO to give first an EPR signal of a S = 3/2 nonheme Fe–NO center (at −80 °C), which, upon warming, changes to a S = 1/2 heme Fe–NO center (at up to 25 °C).[275] A later model of C*c*O, again with the 3-imidazole site, this time containing copper, binds to azide to produce either a $Cu^{I}/Fe^{III}–N_3$ low-spin complex with EPR g-values of 2.75, 2.22 and ~1.87 (calc) or a $Cu^{II}/Fe–N_3$ complex.[276]

Karlin has used what he calls F_8TPPFe^{II}, or $[(2,6\text{-}F_2)_4TPPFe^{II}]$, as his heme model and either "untethered" $TMPACu^{I}(MeCN)$ (TMPA = tris-(2-pyridylmethylamine),[277–279] a tetra-coordinating ligand to Cu^{I} or MePY2 (bis-(2-pyridylethyl)methylamine,[280] a tri-coordinating ligand) or a "tethered" form with two 2-pyridyl groups unchanged and the third making a connection through the 6-position (later also the 5-isomer) of that pyridyl ring to the *ortho* position of one phenyl group on the porphyrin, called ^{6}L, which are tetra-coordinating,[281,282] and other designs which are tri-coordinating[283] ligands to Cu^{I}. These designs give either 4-fold ("untethered" or 2-fold ("tethered") symmetry of the porphyrin system, which is very useful for NMR studies. In 1999 they reacted the $Fe^{II}…Cu^{I}$ complex of ^{6}L with O_2 and observed the $Fe^{III}–OO–Cu^{II}$ intermediate and the $Fe^{III}–O–Cu^{II}$ final product,[281] which were characterized by UV-vis and ^{1}H or ^{2}H (for the d_8-pyrrole complex) NMR spectroscopy at 193 K in acetone. The starting complex gave pyrrole-H resonances at +90 to +80 ppm, the μ-peroxo-bridged intermediate complex gave extremely broad pyrrole-H resonances in the same region, plus very broad pyridyl resonances at −78 ppm, and the final μ-oxo-bridged complex gave 3–4 very broad pyrrole-H resonances in the +90–100 ppm region and very broad pyridyl-H resonances at −64 ppm.[281] These chemical shifts were said to be a result of antiferromagnetic coupling to yield a S = 2 spin state. A full study of the "untethered" $(F_8TPPFe)^{II}$ + $(MePY2)Cu^{I}$ and its reaction with O_2 published the same year[284] confirmed this spin state by the Evans method[376,377] and also showed much sharper ^{1}H NMR resonances because of the higher symmetry; for the μ-oxo-bridged complex at 297 K the pyrrole-H signal was at +67.7 ppm, CH_2–PY at +23.4, +18.9 ppm, pyridyl-H at +1.2, −2.7, −23.5, −37.2 ppm, CH_2-N at −87.7, −155.4 ppm, and CH_3–N at −189.4 ppm.[284] Protonation of the

oxo bridge was also investigated, and the pK_a for that protonation was found to be 16.7–17.6 in CH_3CN or 9.6 ± 2 in water.[284] Later the "untethered" $(F_8TPP)Fe^{II}$ + $(TMPA)Cu^{I}$ + O_2 system was studied and both the μ-peroxo and μ-oxo-bridged complexes were characterized by ^1H NMR spectroscopy at −40 °C in CD_3CN (pyrrole-H +68 and +83 ppm, Py-H −11, −20, and −28 ppm, respectively).[285] Cyanide-bridged complexes were also investigated and shown to have a pyrrole-H resonance at 170 ppm for the 1:1 complex and 160 ppm for the 1Fe:2Cu complex.[286]

In a study in 2001, Karlin and coworkers investigated the reversible dioxygen addition to F_8TPPFe^{II}, where the porphyrin was deuterated on the pyrrole positions.[287] At 193 K the pyrrole-D resonance in THF solvent moved from +93 ppm (+56 ppm at RT, consistent with high-spin Fe^{II}) to +8.9 ppm upon oxygenation to form **2**, the superoxide complex of F_8TPPFe^{III}. On warming this sample to RT and then cooling to 193 K to observe the ^2H NMR yielded complete conversion to $(F_8TPP\text{-}d_8)Fe^{III}$–OH ($\delta_{pyrr}$ = +125 ppm, 193 K).[287] That **2** was not the μ-peroxo dimer, PFe^{III}–OO–$Fe^{III}P$, was clear because La Mar, Balch and coworkers have shown this species to have δ_{pyrr} = +15–17 ppm, as is discussed below in Section IV.A.6.a. ^{19}F NMR chemical shifts for $(F_8TPP)Fe^{II}$, $(THF)(F_8TPP)Fe^{III}$–O_2^- and $(F_8TPP)Fe^{III}$–OH, all at 193 K in THF, are −116, −111, −113 (1:1), and −83 (1:2:1) ppm, respectively.[287] In CH_2Cl_2 the chemical shift of (F_8TPPFe^{II}) at 293 K were quite different, +4.9 ppm, which shifts to −3 ppm at 193 K, because it is intermediate spin (S = 1) Fe^{II}, Table 9; the ^2H chemical shift for $[(F_8TPP)Fe]_2$–O_2^{2-} at 193 K is +17.5 ppm.[287] Treatment of the μ-peroxo dimer with a Lewis base such as NMeIm or *p*-diethylaminopyridine yielded (B)$(F_8TPP)Fe^{IV}$=O, δ_{pyrr} = +3.5 ppm at 193 K.[287] All of these chemical shifts are consistent with those reported by other workers in the field, as discussed in Sections IV.A.3, IV.A.6.a and IV.A.12.b. The ^{19}F chemical shifts in CH_2Cl_2 were also reported. Thermodynamic and kinetic parameters were determined in EtCN and THF solvents.[287]

Similar investigations of the TMPA-tethered $(F_6TPP)Fe^{II}$ complex called $(^6L)Fe^{II}$ the following year, without copper bound,[282] showed very similar UV-vis and ^1H, ^{19}F NMR spectra for the O_2 adduct and its final breakdown product, the Fe^{III}–OH complex, at room temperature, but in the absence of O_2 the pyrrole-H resonances in CD_2Cl_2 were at +45.0, +46.4, +47.9 and +48.4 ppm, and similar chemical shifts in acetone-d_6 and acetonitrile-d_3, and there were also resonances of the pyridyl ligands at both +24.4 (to +20.6) and −12.9 (to −8.2) ppm in CD_2Cl_2 (and the other two solvents), which was again explained by the binding of one of the pyridyl ligands to Fe^{II} (with dynamic equilibrium among two of the three pyridyl ligands).[282] However, in THF-d_8 the pyrrole-H resonances were at +52.8, +54.0, +57.7, +58.4 ppm at room temperature, and the pyrrole-D resonances of the deuterated analog were at +95 and +79 ppm (1:1, both broad) at 193 K in THF,

which suggested that at low temperatures THF was able to successfully compete for one Fe^{II} coordination site. The pyrrole-D resonance of the O_2 complex was at 8.9 ppm and of the –OH complex was at +121 ppm, both at 193 K,[282] as observed for the $(F_8TPP)Fe^{II/III}$ compounds[287] discussed above. In CH_2Cl_2 the ^2H resonances were at +43 to +46 ppm for (^{6}L-d_8)Fe^{II} complex (again indicating 5-, not 4-coordinate as for the parent $(F_8TPP)Fe^{II}$) at 293 K, a single broad resonance at 75 ppm at 193 K for the same species, 9.3 ppm for the O_2 complex, 17.0 ppm for the μ-peroxo dimer, which appeared to rearrange to the Fe^{III}–O_2^- monomer in the presence of high concentrations of O_2, and +122 ppm for the Fe^{III}–OH final decomposition compound.[282]

Addition of CO to the "empty" (^{6}L)Fe^{II} and its (^{5}L)Fe^{II} counterpart (^{6}L has the pyridyl of TMPA linked to the 6-position of the pyridine ring, while ^{5}L has it linked to the 5-position) gave Fe–CO complexes with ν_{CO} at 1976 and 1978 cm^{-1}, respectively, and ^{13}CO chemical shifts of 207.0, 207.1 (~1:1) and 206.8, 207.0 (minor) ppm, respectively, in THF-d_8.[288] For the Cu^I-bound complexes, these values for Fe–CO binding were shifted only slightly (ν_{CO} at 1971 and 1973 cm^{-1}; δ_{13CO} at 207.0 (minor), 208.1 ppm for the 6L isomer and 206.8 (minor), 207.4 ppm for the ^{5}L isomer). (The two values are believed to be for the "outside" and "inside" binding CO isomers.) For Cu^I–CO binding, using TMPA-Cu^I as the standard, ν_{CO} was at 2091 cm^{-1} in THF, δ_{13CO} at 180.3 ppm; for the Fe^{II}…Cu^I complexes, ν_{CO} was at 2093 cm^{-1} for the ^{6}L complex and 2091 cm^{-1} for the ^{5}L complex, δ_{13CO} at 178.2 and 172.4 ppm for ^{6}L and ^{5}L, respectively. ^2H NMR pyrrole shifts for the Cu^I-loaded (^{6}L)Fe^{II} and (^{5}L)Fe^{II} complexes were +54.2, +56.7 (broad) ppm in the absence and +8.8–8.9 ppm in the presence of CO for ^{6}L and +54.0–58.8 (1:1:1:1) and 8.7–8.8 ppm, respectively, for ^{5}L. These are believed to be bis-CO complexes.

A variation on this ligand system was also created in which one pyridyl ligand was replaced by an imidazole ligand, which was further bound to a phenol.[289] Upon oxygenation of this Cu^I ligand complex a superoxo complex formed which rapidly reacted with the starting Cu^I complex to form a Cu^{II}–O_2–Cu^{II} dimer.[289] With $(F_8TPP)Fe^{II}$ a μ-peroxo dimer was formed, as shown by ^1H and ^2H NMR spectroscopy. It was shown that a stable heme-peroxo-copper species can be generated even in the presence of an imidazole-phenol group in close proximity.[289]

Tridentate Cu^I ligands have also been studied in their binding to Cu^I and its diatomic ligand complexes.[290] It was again shown that the O_2 complex generates the peroxo-bridged (S = 2) complex with the Cu ligand being a bis-pyridyl, monotertiary aliphatic amine. Reactivity with CO and PPh_3 was also studied.[290]

$(F_8TPP)Fe^{II}$ + $(TMPA)Cu^I$ + O_2 generated a dimeric μ-peroxo complex which was characterized by X-ray crystallography. The Fe–O–Cu bond angle was nearly linear (171.6°) with the distance between Fe and Cu being 3.58 Å. The

pyrrole-H resonance is at +40.6 ppm (293 K), and protonated –OH bridged complex at 110 ppm.[290]

The ligand architecture of the "tethered" complexes was studied in 2007. It was found that the relatively low ν(O–O) frequencies observed in the 3-coordinate Cu ligand complexes suports a μ–η^2–η^2-peroxo ligation to both iron and Cu.[292] There is no reaction between (F_8TPP)Fe^{III}–O_2^{2-})–Cu^{II}(TMPA) and CO, as observed for (^{6}L)Fe^{III}–O_2^{2-}–Cu^{II}. Rather, the complex behaves more like it has tridentate chelation to Cu, as though the bridging pyridyl ligand is no longer coordinated. This result suggested that the bonding at the metal-peroxide core in the latter complex was weaker than in the TMPA complex. Overall, the (F_8TPP)Fe^{III}–O_2^{2-}–Cu^{II} complex appeared to be the most stable heme-peroxo-copper complex studied.[292] In another paper in 2007, the (F_8TPP)Fe^{III}–O_2–Cu^{II}(TMPA) complex were further characterized by resonance Raman, ^{1}H NMR, Mössbauer and UV-vis spectroscopies.[293] This work was summarized in a review article.[294]

Finally, this group has investigated heme-nonheme diiron complexes as models of the active site of NOR. A crystal structure of the ^{6}Lfe–O–FeCl complex was solved, where Cl^- is a sixth ligand of the nonheme Fe^{III}.[295] The complex is found to have S = 0 by SQUID susceptometry (J = –114.82 cm^{-1}). In spite of that the ^{1}H NMR spectra show pyrrole-H chemical shifts of about +15–16 ppm and pyridyl-H chemical shifts of +10–15 ppm, and larger shifts for the TMPA-CH_2 protons (+24, +27 ppm). Mössbauer data are also reported.[295] The O_2, CO and NO adducts of this complex were reported the following year. RR spectroscopy showed that NO reacted with the complex to produce a dinitrosyl complex, with ν_{NO}(nonheme) = 1798 cm^{-1} and ν_{NO}(heme) = 1689 cm^{-1}.[295] A later study of a Fe^{II}…Cu^{I} model showed that ^{6}LFe(NO) (without Cu-loading) gave a typical Fe^{II}–NO EPR spectrum, the Fe^{III}–Cu^{II} fully oxidized complex gave a high-spin Fe^{III} (g = 6) signal and a typical axial Cu^{II} signal, while the reaction of NO with this complex appears to give Fe^{II}–NO with a fairly similar EPR signal + N_2O, i.e., a reaction of 3 NO molecules with this bimetallic complex.[296] A bis-NO-bound iron porphyrin complex is believed to be an intermediate. Further elaboration of this system has been published recently,[297] in which reductive coupling of NO that fits the stoichiometric reaction:

$$2\ \bullet NO(g) + Fe^{II} + Cu^{I} + 2\ H^+ \rightarrow N_2O(g) + Fe^{III} + Cu^{II} + H_2O. \qquad (24)$$

This reaction is equivalent to one enzyme turnover. As part of this work, the authors showed that the Cu^{II} product has a "reverse" axial EPR signal, i.e., with $g_\perp > g_\parallel$.[297] This occurs when Cu^{II} has a trigonal bipyramidal structure where the axial ligands have higher ligand field than do the equatorial ligands, which thus places the d_{z^2} orbital highest in energy and yields an EPR signal with $g_\perp \sim 2.22$, $g_\parallel \sim 2.02$, $A_\perp \sim 105$ G, $A_\parallel \sim 71$ G.[297,298]

d. *Hydroxide or fluoride complexes*

In addition to thiolate ligands, other anions such as hydroxide or fluoride can also coordinate to ferrous tetraphenylporphyrin or etioporphyrin complexes. Characteristic ^{1}H NMR shifts reveal that the resulting fluoride or hydroxide complexes $[(TPP)Fe(OH)]^-$, $[(TPP)FeF]^-$, $[(Etio)Fe(OH)]^-$, $[(Etio)FeF]^-$ are 5-coordinate and high-spin.[299,300] The positive pyrrole-H shifts in the TPP complexes (+32.8 and +30.3 ppm for the hydroxide and fluoride complexes, respectively) and the positive ring methyl and methylene shifts in the OEP complexes again indicate mainly σ spin delocalization.[299,300] The pyrrole-H resonances of $[(TPP)Fe(OH)]^-$ and $[(TPP)FeF]^-$ are less deshielded than those in other 5-coordinate complexes. This bias to smaller paramagnetic shifts reflects the importance of π spin delocalization in the porphyrin ring. Such π spin density at the pyrrole carbon positions results in a partial cancellation of the proton shifts at those positions due to σ delocalization.[300] The methyl and methylene proton signals in $[(Etio)Fe(OH)]^-$ and $[(Etio)FeF]^-$ appear at low shielding (CH_3, +18.3 ppm, CH_2, +14.9, +12.5 ppm; CH_3, masked, CH_2, +13.0, +14.0 ppm, respectively) and resemble those in other high-spin iron(II) complexes, which is consistent with σ spin delocalization from the singly occupied $d_{x^2-y^2}$ orbital. The *meso*-H resonances are at −12.0 ppm and −10.5 ppm, respectively, which implies that π spin delocalization to the *meso* positions is important.[156]

e. *N-Alkyl (aryl) porphyrin complexes*

N-substituted porphyrins, such as N-alkyl and N-aryl porphyrins are models for cytochrome P450 heme alkylation. These derivatives are known to be formed as inactivation products of hepatic cytochrome P450 by a variety of molecules, including simple alkenes, such as ethylene.[301–303] N-alkylporphyrins have been identified as metabolic products of drugs produced by animal liver cytochromes P450.[302] To model certain aspects of these mechanisms, iron(II) monohalide complexes of N-substituted porphyrin complexes such as N-methyltetraphenylporphyrin, *N*-methyloctaethylporphyrin[304] or [N-(2-phenyl-2-oxoethyl) tetraphenylporphyrin],[303] and iron (II) complexes containing a metallacycle[302] were structurally characterized. A paramagnetic shift pattern characteristic of paramagnetic compounds and consistent with the C_s symmetry of the complexes,[304] is observed in the NMR spectra of these complexes. The N-methyl, N-aryl or N-alkyl resonances are observed in a unique window of +60 to +160 ppm, and reflect a σ spin transfer mechanism.[304] Two of the four pyrrole protons are shifted to the +25 to +60 ppm region (the other two are observed at slightly higher shielding than TMS), the pyrrole CH_2 protons appear in the spectral region of +5 to +35 ppm, and the

meso-H are at −9.5 ppm. The phenyl-H resonances, with one set of phenyl groups which exhibits negative *o*-H and *p*-H paramagnetic shifts and positive *m*-H shifts of essentially the same magnitude, is consistent with π spin delocalization at the *meso* positions,[156] and argues strongly for negligible axial anisotropy for two phenyl rings, and thus for the entire complex. Since the pseudocontact shifts are negligible, the pyrrole-H paramagnetic shifts are thus predominantly contact in origin and reflect the effect of the lowered symmetry. Addition of imidazole ligands to the ferrous halide complexes of N-methyltetraphenyl- and N-methyloctaethylporphyrin results in the formation of the corresponding 5-coordinate imidazole complexes in which imidazole replaces the axial halide ligand. The overall porphyrin resonance pattern and the peak width in these adducts are retained.[304]

f. *Nitrene complexes*

It was proposed that the iron complexes found upon metabolic oxidation of 1,1-dialkylhydrazines by hepatic cytochrome P450 might involve an iron-nitrene bond.[305] Therefore, (porphinato)iron-nitrene complexes were investigated. High-spin, ferrous nitrene complexes, in which the nitrene moiety is inserted into the iron-porphyrin pyrrole nitrogen bond, were synthesized by reaction of (tetraaryl-porphinato)iron(II) complexes with the free nitrene NNC_9H_{18} at −80 °C. ^{1}H NMR data favor the well-defined high-spin ferrous (S = 2) state, with a resonance pattern that parallels that of the thiolate complexes discussed above in Section IV.A.4.a(ii).

g. *Verdoheme analogs: Iron(II) complexes of octaethyloxaporphyrin, OEOP*

In 1930 Warburg and Negelein created a green pigment from heme that they called verdoheme.[306] This pigment was investigated further by Lemberg[307] and Fischer.[308] Much later, Jackson and coworkers[309] showed that a *meso*-oxaporphyrin derivative can be created by oxidation of iron(III) octaethylporphyrin in pyridine by dioxygen in the presence of a reducing agent (hydrazine or ascorbic acid). This macrocycle is called octaethyloxaporphyrin, or verdoheme, OEOP, Structure **9**, a monoanionic ligand in this resonance structure. Balch and coworkers investigated this reaction by NMR spectroscopy.[220] Treatment of diamagnetic $[(OEOP)Fe^{II}(Py)_2]^+$ with HCl yields the 5-coordinate [(OEOP)FeCl]. The ethyl CH_2 resonances extend from +7 to +31 ppm, and adjacent resonances belong to individual CH_2 groups (peaks 1,2; 3,4; 5,6; and 7,8).[220] However, the assignment of the four ethyl groups to the four symmetry-related positions on the OEOP macrocycle has not been reported. The three *meso*-H have chemical shifts of +16 and +29.5 ppm (intensities 2:1,

respectively). Such positive chemical shifts suggest significant σ delocalization to the *meso* positions, since the $d_{x^2-y^2}$ orbital is half-filled. The reaction of iron verdohemes with phenylmagnesium bromide to form paramagnetic iron-phenyl complexes has also been reported.[310]

h. *"N-confused" or "N-inverted" iron(II) porphyrins and related N-modified macrocycle complexes*

If one pyrrole ring is "inverted" so that it binds to porphyrin *meso*-carbons through the 2- and 4-carbons of that individual pyrrole ring, a 2-aza-21-carbaporphyrin is created, where the 21-CH is pointing directly at the iron.[311,312] The $Fe^{II}Br$ complex of this porphyrin, (*H*CTPP*H*)$Fe^{II}Br$, is 5-coordinate and high-spin, with β-pyrrole resonances which reflect the combination of σ and π spin density expected (+45 (1), +44 (2), +38 (2) ppm, and β-NH at −7.5 ppm, 298 K).[313] The uniquely large paramagnetic shift of the inner H(21) (812 ppm, 298 K) indicates a Fe^{II}-{C(21)-H} agostic interaction.[313] Addition of I_2 or Br_2 to a solution of (*H*CTPP*H*)$Fe^{II}Br$ in the absence of O_2 results in 1-electron oxidation to yield [(*H*CTPP*H*)$Fe^{III}Br]^+$, which has pyrrole-H resonances at +115.2, +112.9, +107.9, +91.5, +50.7, +35.9, and −32.8 ppm and the 2-NH at −31.2 ppm.[314] If instead the (*H*CTPP*H*)$Fe^{II}Br$ complex is oxidized by 1-electron with O_2, accompanied by deprotonation of the C(21)H fragment and formation of an Fe–C(21) bond, an intermediate-spin, 5-coordinate iron(III) complex, (*H*CTPP)$Fe^{III}Br$, is formed which has pyrrole-H resonances at +7.2, −10.6, −19.2, −20.6, −23.2, −24.9 and −43.2 ppm, and 2–NH at −76.6 ppm.[314] In the subsequent step of oxidation an O atom is inserted into the preformed Fe^{III}–C(21) bond to produce [(CTPP*O*)$Fe^{III}Br]^-$, which is a high-spin Fe^{III} center (pyrrole-H resonances at +106.3, +82.2, +69.4, +68.5, +53.5, +48.1 and +37.5 ppm).[314] Protonation at the 2–N atom produces (*H*CTPP*O*)FeBr, which has pyrrole-H resonances at +117.3, +80.0, +76.8, +69.1, +59.1, +31.3 and +29.3 ppm, and 2–NH at −25.0 ppm. Structures of the two latter complexes were also obtained.[314] A similar study of the iron complexes of the N-methylated and C-methylated and the C- and N-dimethylated versions of this CTPP ligand has also been reported.[315]

Another N-confused macrocycle was created in the pyriporphyrin family, by linking a 3,5-disubstituted pyridine ring in place of a pyrrole ring, with the pyridine nitrogen facing outward.[316,317] This is formally called 8,11,18,21-tetraaryl-3-aza-*m*-benziporphyrin, (PyP*H*)H, a monoanionic macrocycle with a CH pointing toward the center of the macrocycle ring. The iron(II) complex of this macrocycle[316] has similar reactivity and ^1H chemical shifts to those of the N-confused porphyrin macrocycle discussed in the preceding paragraph, and the benziporphyrins discussed below.

As a variation on the theme of different donor atoms to Fe^{II}, the 5,10,15,20-tetraphenyl-21-*N*-pyriporphyrin ligand (derived from a 2,6-substituted pyridine) was

created and its Fe^{III} complex studied briefly.[318] The numbering system of the pyridine ring in this compound is that the 2,4-H are adjacent to the link to the *meso*-carbons and the 3-H is *para* to the pyridine nitrogen. The Zn^{II} complex has been characterized structurally, and the NMR spectrum of the high-spin dichloroiron(III) and low-spin dicyanoiron(III) complexes have been reported at ambient temperature.[318] For the pyrrole-H and 2,4-H of the high-spin dichloro complex, the ^1H resonances are at +86, +80, +74 and +60 ppm, but not assigned, with the 3-H of the pyridine ring being at +30 ppm. For the same resonances of the low-spin dicyano complex, there are pyrrole-H at +16, +6.5 and +5 ppm, 2,4-H at −3 ppm, and 3-H at +10.5 ppm.[318] This pattern of shifts for the pyrrole-H resonances of the dicyanoiron(III) complex strongly suggests that it has a $(d_{xz},d_{yz})^4(d_{xy})^1$ electronic ground state, and it is likely that the angles expected for the pyridine 6-membered ring atoms as compared to the pyrrole 5-membered ring atoms would encourage ruffling of the macrocycle.

As another variation on the theme of different donor atoms to Fe^{II}, the 5,10,15,20-tetraphenyl-21-oxaporphyrin ligand (derived from furan) was created and its Fe^{II} and Fe^{III} complexes studied.[319,320] The Fe^{III} complexes are more stable,[319] except for the cyanide complex in the presence of excess cyanide, and are discussed in Section IV.A.6.c(V). The Fe^{III} complexes can be reduced to Fe^{II} with moderate reducing agents, and $(OTPP)Fe^{II}Cl$ is 5-coordinate and high-spin, with pyrrole-H resonances at +39.3, +29.5 and −6.4 ppm and the furan β-H at +33.2 ppm at 295 K.[319] The autoreduced cyanide complex, $[(OTPP)Fe^{II}(CN)_2]^-$, is diamagnetic, with furan β-H at 8.56 ppm and pyrrole-H at 8.40, 8.35, and 8.06 ppm.[319] Titration of either $(OTPP)Fe^{III}Cl_2$ or $(OTPP)Fe^{II}Cl$ with *n*-BuLi in toluene-d_8 at 205 K resulted in the formation of $(OTPP)Fe^{II}(CH_2CH_2CH_2CH_3)$.[319] This compound decomposes by hemolytic cleavage of the Fe–C bond to produce $(OTPP)Fe^{I}$, which is a low-spin d^7 complex (d_{z^2} unpaired electron), at least at low temperatures, with g-values of 2.234, 2.032 and 1.990.[319] This complex exhibited pyrrole-H resonances at +156.2, +126.5 and +76.3 ppm and furan resonance at +161.4 ppm at 273 K;[319] these are unprecedentedly large pyrrole-H shifts for iron(I) porphyrins[319] (Section IV.A.1), and this author thinks may suggest that the spin state may be high-spin d^7 at ambient temperatures. Later studies of the reactions of the Fe^{II} oxaporphyrins with phenylmagnesium bromide showed that two σ-aryl groups could bind to form an anionic complex.[320] Oxidation of that complex with Br_2 produced the mono-phenyl, mono-Br six-coordinate complex.[320]

5. *Possible Iron(II) Porphyrin π-Cation Radicals*

The first step of *meso*-oxidation of the porphyrin ring places a hydroxyl group at one *meso* position, Structure **8**, which can then be deprotonated to yield a trianion, which is usually written as a ketonic oxygen, as also shown in Structure **8**, or, if oxidized by

one electron, a single bonded oxygen with a radical at that *meso*-carbon, with two deprotonated nitrogens. Morishima *et al*.[321] reported the NMR spectrum of the one-electron oxidized complex of deprotonated mono-(*meso*-OH-OEP)Fe^{II}, recorded either in pyridine-d_5 or in pyridine/methanol/HC1 solution, which showed two resonances at −154 and −111 ppm which were assigned to the *meso*-protons based on deuterium labeling.[321] An unusual non-Curie temperature-dependence was found for all resonances. The explanation provided was that the iron(II) oxophlorin radical was thermally admixed between nearly degenerate $b_2(\pi)$ and $a_2(\pi)$ (Figure 2) radical states. As the temperature is increased, the $a_2(\pi)$ (Figure 2) contribution of the radical state was believed to become greater, thereby allowing an increase in spin density at the β-pyrrole carbon atoms. However, based in part on their EPR spectra,[321] as discussed in more detail in Section IV.A.8.f and shown in Figure 51, most of which have axial spectra, and all with g-values too different from 2.00 to be carbon/nitrogen-based radicals, these bis-(pyridine) complexes of iron oxophlorins are clearly low-spin iron(III) oxophlorin complexes which have the less-common $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, with a d_{xy}-based unpaired electron rather than a porphyrin π-based unpaired electron.[131] The anomalous temperature dependence is likely the result of thermal excitation to a low-lying $(d_{xz},d_{yz})^3(d_{xy})^2$ excited state.[131] Further discussion of this and related low-spin iron(III) complexes with the unpaired electron in the d_{xy} orbital will be presented in Sections IV.A.8.a, IV.A.8.c and IV.A.8.e.

The preparation and investigation of iron(II) nitrosyl π-cation radicals of octaethylchlorin and octaethylisobacteriochlorin, as models for reaction intermediates of nitrite reductase were also reported by Morishima and coworkers.[322] The π-cation radicals had well-resolved hyperfine-shifted NMR resonances that were characteristic of an $a_2(\pi)$-type radical state of the iron(II) chlorin (see Figure 5), because of the extremely large positive shifts of the 7,8-H of the chlorin (+190 ppm). Likewise, the 2,3,7,8-deuterium signals of the multiple isomers of the isobacteriochlorin complex were observed between +150 and +260 ppm, while the *meso*-D signals were observed at +35 to +37 ppm (5-D), +18 to +22 ppm (10,20-D) and +87 to +89 ppm (15-D).[322] Non-Curie behavior of the deuterium resonances was interpreted in terms of a valence isomerization involving the $(ON)Fe^{II}$ chlorin π-cation radical and the Fe^{II}–NO^+ chlorin complex. This valence isomerization was also observed in the presence of imidazole.[322]

6. *High-Spin Iron(III) Porphyrins: Observed Shifts and the Mechanism of Spin Delocalization*

a. *Five-coordinate, monomeric iron(III) porphyrin complexes*

^{1}H NMR spectra of simple high-spin, 5-coordinate halide complexes of synthetic and natural porphyrins have been reported and discussed in detail.[2,4] In these

complexes, the metal is significantly out of the plane, and thus gives rise to two *o*-H and *m*-H signals for TPP derivatives and two α-CH_2 resonances for OEP and *meso*-alkyl porphyrin complexes. High-spin iron(III) (S = 5/2) has a ^6A ground state, for which the g-tensor is isotropic. However, relatively large splittings of the zero-field Kramers' doublets, ±1/2, ±3/2, ±5/2, give rise to pseudocontact shifts that are proportional to D/T^2, according to Eq. 10 (Section IV.A.2), and D-values estimated from analysis of the Curie plots are similar to those measured from far-infrared magnetic resonance measurements of (DPDME)FeX.[35] The solution proton NMR spectra of a number of monomeric, 5-coordinate, high-spin iron(III) porphyrins have been reported,[161,323–339] including those having X^- = OH^-, OR^-, OO^{2-}, ROO^-, N_3^-, RC_2^-, NCS^-, $RCOO^-$, NO_3^-, $OTeF_5^-$, SO_4^{2-}, HSO_4^-, RSO_3^-, WS_4^{2-}, (triazolate)$^-$ and (tetrazolate)$^-$. Of these, the NO_3^- complex is known to have the anion binding in a bidentate fashion to iron(III) in the solid state,[336] and both it and the RSO_3^- complexes (as well as the [((TPP)Fe)$_2$SO$_4$] dimer discussed in part d of this section) are believed to have bidentate anions in solution, based on the similarity of their pyrrole-H paramagnetic shifts at 299 K (+72.5, +72.9 ppm, respectively), as compared to monodentate Cl^-, RO^- and $RCOO^-$ (78–80 ppm).[336] (Carboxylates bind to iron(III) porphyrins as monodentate ligands.[335]) Zero-field splitting constants, D, have been estimated for some of these anions, and the order of increase in D appears to be $N_3^- < NCS^- < Cl^- \sim OTeF_5^- \sim N_4C(CH_3)^- < N_4C(C_6H_5)^-$.[329,337] The ions NCS^-, Cl^-, Br^- and I^- in [(TPP)FeX] have D = 5.1, 6.0, 12.5 and 13.5 cm^{-1}, respectively,[333,334] and OH^- in (TMP)FeOH has D = 8.9 cm^{-1}.[323]

The contact shifts of the 5-coordinate high-spin Fe^{III} complexes are large at both pyrrole and *meso* positions, but the mechanism of spin delocalization differs at these two sites. The contact shifts at the β-pyrrole positions are to lower shielding for both pyrrole-H (δ_{con} ~ +61 to +68 ppm at 29 °C) and pyrrole-α-CH_2 (δ_{con} ~ +30, +34 ppm), indicating that spin is delocalized from high-spin iron(III) to these positions through the σ-bond framework of the porphyrin. Such large σ spin delocalization is observed only in metalloporphyrins in which the $d_{x^2-y^2}$ orbital of the metal is half-occupied,[2,4] and is an important signature of half-occupancy of this orbital. In contrast, at the *meso* positions, the contact shifts are to higher shielding for *meso*-H (δ_{con} = −80 ppm at 29 °C) and to lower shielding for *meso*-α-CH_2 (δ_{con} ~+50 ppm).[2,4] This reversal in sign of the contact shift is a clear indication of spin delocalization through π orbitals to the *meso* positions. Since each d-orbital of high-spin iron(III) is half occupied, it is clearly possible that both σ and π spin delocalization can occur. Of the π-symmetry frontier orbitals of the porphyrin that have proper symmetry to overlap with metal orbitals (Figure 2) in these 5-coordinate high-spin Fe^{III} complexes where the metal is out-of-the-plane of the porphyrin nitrogens, it is the $3a_{2u}(\pi)$ orbital that interacts with the metal d_{z^2} orbital via

porphyrin → metal π donation (Figure 34) to permit π spin density to be delocalized to the *meso*-carbons.[156] This mechanism is different than discussed previously,[2,4] in which it was believed that the 4e(π*) orbitals, which have large wave function coefficients at the *meso* positions (Figure 5), allowed π-back-bonding from the d_{xz} and d_{yz} orbitals as the mechanism of spin delocalization.[2,4] The small π spin density at the β-pyrrole carbons of the $3a_{2u}(\pi)$ orbital, which interacts with the d_{z^2} orbital, and the larger π spin density expected at those positions for the 3e(π) orbitals, which can interact with the half-filled d_{xz},d_{yz} orbitals, suggest that the large positive shifts observed for the pyrrole-H are actually the balance of a much larger positive shift due to σ-delocalization and a negative shift due to π-delocalization. This becomes even more clear when the proton NMR spectra of reduced hemes such as iron(III) chlorins, isobacteriochlorins, and dioxoisobacteriochlorins, as well as the numerous macrocycles created by coupled oxidation of hemes are considered, Sections IV.A.6.c(i)–(vii).

Recent additions to the findings from NMR spectroscopic studies of the halide complexes of iron(III) porphyrins includes those arising from the study of the dodecasubstituted porphyrins, especially the octaalkyltetraphenylporphyrins. These complexes have been shown to be at least partially S = 5/2,3/2 spin-admixed complexes, and are thus discussed below in Section IV.A.7.

Notable among these 5-coordinate, monomeric, high-spin iron(III) complexes is the hydroxide complex, because of the difficulty encountered in preventing its well-known hydrolysis to form the μ-oxo dimer:

$$2\ (P)FeOH \leftrightarrows (P)Fe\text{-}O\text{-}Fe(P) + H_2O. \qquad (25)$$

This problem was solved by using tetraphenylporphyrin ligands having *o,o′*-substituents on the phenyl rings, such as $-CH_3$ (TMP), $-OCH_3$ ($(2,4,6\text{-}(OCH_3)_3)_4TPP$),[323] or halogens (–F or –Cl),[326] very bulky *m,m′*-substituents such as *t*-butyl,[324] or by use of superstructured porphyrins such as "basket-handle"[340] or "picket fence"[341] or related water-soluble "picket fence" derivatives.[342] The equilibrium represented by Eq. 25 was utilized to develop a possible pH-sensitive contrast agent for MRI.[343] It, and the additional equilibria between the diaqua and hydroxide complexes, have been studied for the water-soluble tetraphenylporphinesulfonate[344] and tetrakis-(tetrafluorotri-methylaminophenyl) porphyrin[327] complexes of iron(III), and for naturally-derived hemins in aqueous detergent micelles.[345–347] It is also worth noting that while the 5-coordinate hydroxide complex of synthetic iron(III) porphyrinates is high-spin, the 6-coordinate hydroxide complexes of ferriheme proteins are often low-spin, and in some cases mixed low- and intermediate-spin.[19] This subject is discussed in Sections IV.A.10.a(ii) and IV.A.10.b.

The peroxide complex, $[(TPP)FeO_2]^-$, was prepared from $[(TPP)Fe^{II}]$ and superoxide, O_2^-,[161] and is an example of the facile redox that takes place between iron(II) and dioxygen and its redox active reduced derivatives, superoxide and peroxide. The NMR spectrum is clearly diagnostic of a high-spin iron(III) porphyrin.

Formation of $(P)Fe^{III}OO$-*t*-Bu from $(P)Fe^{II}$ and t-BuOOH requires working at very low temperatures (−70 °C), to prevent thermal decomposition to $(P)Fe^{IV}O$ and *t*-BuO•:

$$[(TMP)Fe^{II}] + t\text{-Bu-OOH} \rightarrow [(TMP)Fe^{III}\text{-OO-}t\text{-Bu}] + \text{side products}, \quad (26)$$

$$[(TMP)Fe^{III}\text{-OO-}t\text{-Bu}] \rightarrow [(TMP)Fe^{IV}{=}O] + t\text{-BuO}\bullet, \quad (27)$$

followed by further reactions. Decomposition is catalyzed by bases, such as *N*-methyl-imidazole.[331] The chemical and NMR properties of the $(Fe^{IV}{=}O)^{2+}$ unit will be discussed in Section IV.A.12. The pyrrole-H shifts of the 5-coordinate OH^-, *t*-Bu-O^-, and *t*-Bu-OO^- complexes of $(TMP)Fe^{III}$ at −70 °C (+116.4, +122, +114 ppm, respectively)[331] suggest that OH^- and *t*-Bu-OO^- have similar values of the zero-field splitting constant D, while that for *t*-BuO^- may be larger. The smaller (and similar) value of the zero-field splitting constant for OH^- and *t*-Bu-OO^- are interesting in light of the use of the OH^- complex of hemin-bound heme oxygenase as a model for the HOO^- complex of that enzyme, discussed in Section IV.A.10.b.

Latos-Grażyński and coworkers have investigated the effect of a single β-pyrrole substituent on [(TPP)FeCl] on the pattern of pyrrole-H resonances.[223] The single pyrrole-H resonance of [(TPP)FeCl] at about +80 ppm at 293 K is split into up to seven resonances, in which the 3-H (the proton in the same pyrrole ring, next to the substituent) has the most extreme shift: to lower shielding if the substituent is electron-withdrawing (+104 ppm for 2-NO_2), and to higher shielding if it is electron-donating (+49 ppm for 2-$NHCH_3$), while the remaining six pyrrole-H signals are spread around +80 ppm,[223] as shown in Figure 35.

Introduction of a single *meso* substituent into $ClFe^{III}$(OEP) results in significant changes in the geometric and/or spectroscopic properties of this complex.[348] The mono-*meso*-substituted iron(III) complexes $ClFe^{III}$(*meso*-X-OEP), where X = Ph−, *n*-Bu−, MeO−, Cl−, NC−, HC(O)−, and O_2N−, were isolated and characterized by their UV/vis and paramagnetically-shifted ^1H NMR spectra. The structures of both $ClFe^{III}$(*meso*-Ph-OEP) and $ClFe^{III}$(*meso*-NC-OEP) were determined by X-ray crystallography. Both molecules have five-coordinate structures typical for high-spin (S = 5/2) iron(III) complexes. However, the porphyrins themselves no longer have the domed shape seen in $ClFe^{III}$(OEP), and the N_4 coordination

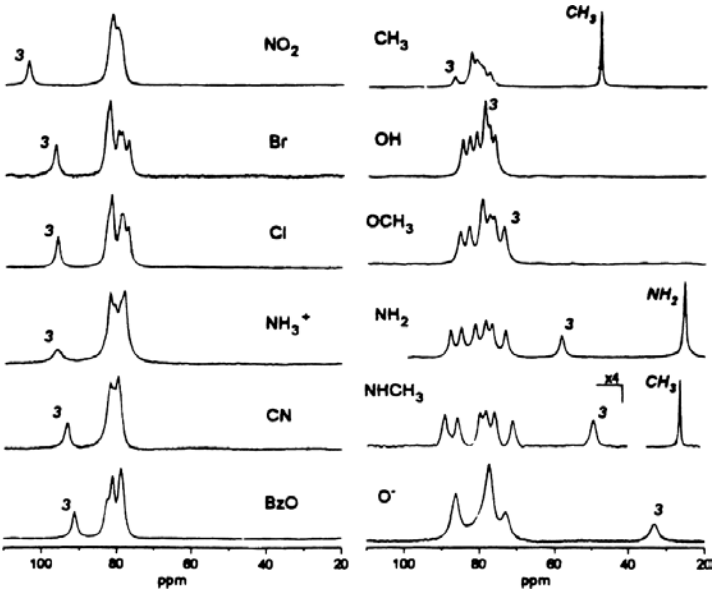

Figure 35. 300 MHz ^{1}H NMR spectra of the pyrrole-H region of a series of high-spin [(2-X-TPP)Fe^{III}Y] complexes in $CDCl_3$ at 293 K. The respective X substituents are shown on each trace. Y = Cl for all complexes except Y = OH for [(2-O-TPPFe^{III}(OH)]$^-$. The 3-pyrrole-H resonance is labeled in each case by 3. Reprinted from Wojaczyński, J.; Latos-Grażyński, L.; Hrycyk, W.; Pacholska, E.; Rachlewicz, K.; Szterenberg, L. *Inorg. Chem.* **1996**, *35*, 6861–6872, with permission from the American Chemical Society.

environment possesses a slight rectangular distortion. These high-spin, mono-*meso*-substituted iron(III) complexes display ^{1}H NMR spectra in chloroform-d solution which indicate that the conformational changes seen in the solid-state structures are altered by normal molecular motion to produce spectra consistent with C_s molecular symmetry. The CH_2 resonances at 298 K (at +43.7 and +41.6 ppm for OEPFeCl) were spread over the region +47.3 to +35.1 ppm for the *n*-butyl-substituted complex and +43.7 to +36.3 ppm for the methoxy-substituted complex, with all other complexes having resonances within these ranges. The *meso*-H resonance(s) (at −55.5 ppm for OEPFeCl) are at −57.9 (*cis*) and −74.3 (*trans*) ppm for the *n*-butyl-substituted complex and −63 (*cis*) and −75 (*trans*) ppm for the methoxy-substituted complex, but different chemical shifts for the phenyl (−65.9 (*cis*) and −58.5 (*trans*) ppm), chloro (−63.7 (*cis*) and −60.7 (*trans*) ppm), cyano (−39.8 (*cis*) and −25.3 (*trans*) ppm) and nitro (−57.3 (*cis*) and −44.4 (*trans*) ppm),[348] which perhaps reflects variable out-of-plane distances for Fe^{III} among these complexes.[156]

Iron(II) N-methylporphyrin complexes are readily oxidized to 5-coordinate high-spin iron(III) N-methylporphyrin halide cations.[349] At −50 °C in $CDCl_3$, [(MeTPP)FeCl]. has pyrrole-H chemical shifts of +128, +92, +70 ppm; the β-pyrrole

chemical shift of the N-methylpyrrole unit was found to be at 2.4 ppm using [(d_8-MeTPP)FeCl]$^+$ and detection by ^{2}H NMR spectroscopy.[349] The three remaining pyrrole rings appear to have similar average amounts of spin delocalization as those of [(TPP)FeCl]; only the modified pyrrole ring suffers sharply decreased spin transfer. The four *m*-H resonances of the N-MeTPP ligand have an almost identical average observed shift to the two of [(TPP)FeCl] at the same temperature.[349] The linewidths, Δ, of the proton resonances of the chloride and bromide complexes differ in proportion to the zero-field splitting parameter, D ($\Delta \propto D^{-2}$), with $\Delta_{Br} > \Delta_{Cl}$, as for the [(TPP)FeX] analogs.[94] The chemical shifts for [(MeOEP)FeCl]$^+$ and [(OEP)FeCl] show similar features, apart from the large asymmetry in spin delocalization caused by N-methylation.[349]

Although it had been known for more than 25 years in 1999 that alkyl groups of 5-coordinate porphyrin complexes such as OEPFeCl are diastereotopic,[350–352] Nakamura and coworkers conducted a detailed study of the coalescence of the CH_2 groups of Et, Pr and the methyl groups of *i*-Pr groups of *meso*-tetraalkyl porphyrinatoiron(III) chloride and determined the activation free energies of each.[353] The coalescence temperatures determined (−72, −60, −62 °C) are specific to the NMR frequency used (300 MHz in their case),[353] and the free energies calculated do not represent a barrier to rotation of the group, but rather a 1-point measurement of the temperature at which rotation of the alkyl group becomes fast enough to average the chemical shifts of the diastereotopic protons on the NMR timescale at 300 MHz — or the temperature at which the rate of chloride exchange averages the environments of the diastereotopic protons.[351,352] In any case, it is not a meaningful result.

The etioporphycene (Structure **14**) complex of chloroiron(III) has the bridging 9,10,19,20-"vinyl"-H at −12 ppm, the 3,6,13,16-CH_3 resonance at +79 ppm and the two α-CH_2 resonances at +37 and +24 ppm at 298 K in $CDCl_3$.[354] The iron(III)X complexes of 2,7,12,17-tetra-*n*-propylporphycene,[355] with X = PhO^-, Cl^-, Br^-, I^-, and ClO_4^-, demonstrate pyrrole-H shifts that depend strongly on anion (+65.3, +28.5, −7.8, −49.4 and −77.1 ppm, respectively, in CD_2Cl_2 at 294 K). The behavior of the chloroiron complex of etioporphycene[354] and the phenolatoiron complex of TPrPc[355] are very similar to that observed for 5-coordinate chloroiron porphyrins discussed above, but the halide and perchlorate complexes of TPrPc exhibit progressively greater spin-admixture, to the point where the perchlorate complex is quite pure S = 3/2.[355] The phenyl compound of etioporphycene appears to be low-spin d^5,[354] and will be discussed in Section IV.A.8.h.

b. *Six-coordinate monomeric high-spin iron(III) porphyrin complexes*

When ligands of medium coordinative ability with counterions that bind weakly are present, iron(III) porphyrins form high-spin, 6-coordinate complexes. This is

the case for [(TPP)FeI] in 1:3 mixed $CDCl_3/CD_2Cl_2$ solutions with added DMSO.[356] The concentration dependence of both [(TPP)FeI] and DMSO on the formation of the complex confirmed that the stoichiometry of the complex was 2 DMSO:1 Fe^{III}. The paramagnetic shift of the pyrrole-H of $[(TPP)Fe(DMSO)_2]^+I^-$ in 3:1 CD_2Cl_2:$CDCl_3$ at −72 °C is ~101 ppm, as compared to ~121 ppm for the 5-coordinate [(TPP)FeI] parent.[356] Dimethylformamide, DMF, also coordinates to [(TPP)FeI] to form 6-coordinate complexes.[195,356,357] Strongly electron-withdrawing 2,4-substituents of natural porphyrins induce a ring methyl paramagnetic shift spread similar to that observed in met-aquamyoglobins, which suggested to the authors of that work that the in-plane asymmetry in high-spin ferriheme proteins may arise from peripheral heme-apoprotein interactions.[357] However, this author suggests that it is more likely that the methyl shift spread observed for the proteins is strongly influenced by the orientation of the nodal plane of the axial (proximal) ligand such as a His-imidazole plane, via π-donation from the filled π orbital of the axial ligand to one of the half-filled d_π orbitals of high-spin iron(III), which, in turn, may decrease the amount of Fe → P π spin delocalization into the porphyrin ring involving that orbital. This hypothesis is supported by the patterns of heme methyl shifts for the resting (HS Fe^{III}) and met-cyano (LS Fe^{III}) states of horseradish peroxidase (HRP), which have heme methyl shifts in the order 5 > 1 > 8 > 3[358] and 8 > 3 > 5 > 1,[359] respectively (Figure 60 as compared to Figure 11). The reversal of the two pairs of almost oppositely-related methyl shifts is consistent with the fact that the histidine ligand lies close to the N_I–Fe–N_{III} vector of the protoporphyrin IX ring for HRP, so that for the high-spin iron(III) state, the d_{xz} unpaired electron, which can be delocalized to the histidine imidazole ring, is not as available to produce π spin delocalization to the 3e(π) orbital that has large electron density at the 1,2 and 5,6 positions of the heme[141] as is the other 3e(π) orbital, that has large electron density at the 3,4 and 7,8 positions of the heme and can interact with the d_{yz} unpaired electron to produce larger contact shifts at those positions. In contrast, for the low-spin state there is only one unpaired electron, so the 3,4 and 7,8 positions of the heme feel the majority of the spin density, even though some spin density is delocalized to the histidine ring. We have used this principle to explain the relative heme methyl shifts in high-spin Fe^{III} heme proteins,[141] as shown in Figure 60.

A major difference in the ^1H NMR spectra of 5- and 6-coordinate high-spin iron(III) porphyrins is the *reversal in sign of the paramagnetic shift for the meso-H*, as shown in Figure 24 and Table 10. This reversal was noted in 1979 for derivatives of natural hemins in DMSO-d_6.[357] The 90–95 ppm shift of the *meso*-H resonance to higher frequency, from about −55 to +40 ppm as the iron goes from 5- to 6-coordination, and presumably from out-of-plane to in-plane,

begged for an explanation at the time of the writing of the first *Porphyrin Handbook* chapter.[4] This question was answered by Cheng *et al.*,[156] who showed that the unpaired electron in the d_{z^2} orbital of 5-coordinate, but not 6-coordinate, high-spin Fe^{III} had the proper symmetry to overlap with the $3a_{2u}(\pi)$ filled porphyrin orbital, thus allowing P → Fe π donation and major spin delocalization to the *meso* positions of the heme. Thus the positive shift of pyrrole-CH_3 and α-CH_2 for 6- as compared to 5-coordinate Fe^{III} indicates that the 6-coordinate complexes have decreased π-delocalization to the β-pyrrole and *meso* positions of the porphyrinate ring because of the loss of the delocalization to the $3a_{2u}(\pi)$. This point is important in comparing the *meso*-H shifts of porphyrins, chlorins and isobacteriochlorins,[171] Table 11, discussed in the next subsection. The comparison of the size of the pyrrole–H and $–CH_2$ paramagnetic shifts of 5- and 6-coordinate high-spin (OEP)Fe^{III} and (TPP)Fe^{III}, as well as the pyrrole-H and $–CH_3$ paramagnetic shifts of the corresponding deuterohemin complex provide additional details: The pyrrole-H shifts are ~20% smaller and the pyrrole–CH_2 and $–CH_3$ shifts ~20% larger in the 6- than the 5-coordinate complexes, which indicates a smaller π contribution to the paramagnetic shifts at the β-pyrrole positions of the 6- than the 5-coordinate complexes.[357] The chemical shifts are totally consistent with lack of involvement of the $3a_{2u}(\pi)$ orbital in the 6-coordinate complexes, and there is thus no need to postulate a change in the energy of the d_π orbitals of high-spin iron(III) between the 5- and 6-coordinate complexes.[357] Comparison of 5- and 6-coordinate high-spin natural hemin derivatives suggests that some redistribution in spin density occurs among the β-pyrrole substituents upon change in coordination. Hence, upon reconstitution of heme proteins with deuterohemin, the relative pyrrole–H and $–CH_3$ shifts may serve as a useful indicator of the state of occupation of the sixth site in high-spin hemoproteins (+66, +46 ppm, respectively, 5-coordinate; +55, +64 ppm, respectively, 6-coordinate; –22, +15 ppm, respectively, low-spin).[356]

A 6-coordinate high-spin iron(III) porphyrin complex is produced if [(TPP)FeF] is reacted with hydrated tetrabutylammonium fluoride ($Bu_4NF•3H_2O$) in dichloromethane[360]: The bis-fluoride anionic complex, $[(TPP)FeF_2]^-$, is stable ($K_f = 4 \times 10^3\ M^{-1}$ at 25 °C), and is characterized by larger pyrrole-H (+85.8 ppm as compared to +72 ppm for the bis-DMSO complex discussed above) and *o,p*-phenyl-H paramagnetic shifts and slightly smaller *m*-phenyl-H paramagnetic shifts. Lack of splitting of the *o*- and *m*-phenyl signals of $[(TPP)FeF_2]^-$ supports the assumption of diaxial fluoride coordination with the metal in the plane of the porphyrin.[360,361] Greater linewidths of the ^1H signals of $[(TPP)FeF_2]^-$ suggest that the bis-fluoride complex has a smaller zero-field splitting constant D than the mono-fluoride complex discussed above.

Table 11. Isotropic shifts of five- and six-coordinate high-spin iron(III) porphyrins, chlorins and isobacteriochlorins.[a–c]

c. *Monomeric complexes of reduced or oxidized ferrihemes*

i. Iron(III) sulfhemins

Iron(III) complexes of several naturally-occurring chlorins have been investigated by ^{1}H NMR spectroscopy, including the bis-DMSO complex of the stable green sulfhemin prosthetic group extracted from sulfmyoglobin,[133,362] and that of (pyropheophorbide a)iron(III).[208,301] The positive *meso*-H paramagnetic shifts suggest 6-coordinate, bis-(DMSO) complexes in each case. Three of the ring CH_3s of sulfhemin C exhibit essentially unperturbed contact shifts relative to hemin, with only the 3-CH_3 (on the saturated ring) having a sharply attenuated shift, which thus identified the saturated ring as II[133] in the nomenclature of Structure 1; see also Structure **4** and Figure 5. For [(pyropheophorbide a)iron(III)], large paramagnetic shifts for the 1, 3, and 5-CH_3 groups, and relatively small shift for the 8-CH_3 is consistent with the saturated ring being IV[208,301] in the nomenclature of Structure 1; see also Structure 4 and Figure 5. The patterns observed are consistent with those observed for complexes of (OEC)Fe^{III},[301] discussed below.

ii. Iron(III) octaethyl- and tetraphenylchlorin

The symmetry properties of the former d_π–3e(π) (d-S_{-2} and d-A_{-2}, Figure 5) orbitals on going from the porphyrin to the chlorin, Figures 2 and 5, respectively, as well as the change in symmetry of the formerly $a_{1u}(\pi)$ orbital, the A_{-1} orbital of Figure 5, such that it can overlap with the d_{xz} orbital of the metal,[133] have important effects on the NMR spectra of high-spin iron(III) chlorins. With two chiral carbons, *trans*-(OEC)FeCl has two enantiomers that are mirror images of each other (Structure **18**). These two enantiomers have exactly the same NMR spectrum, and thus it is not necessary (and would not be possible) to separate them. The ^{1}H spectrum of high-spin *trans*-(OEC)FeCl (and its $OTeF_5^-$ and NCS^- anion counterparts) and tetraphenylchlorin (TPC) (X = Cl^-, $OTeF_5^-$) were reported and compared to those of the corresponding OEP and TPP complexes.[363] The assignments of the *meso* protons were made by selective deuteration.[363] Unlike its bis(ligand) complexes discussed in Section IV.A.8.i, (OEC)FeCl does not have C_2 symmetry. Thus, there should be a total of 16 different CH_2 resonances (12 from pyrrole-CH_2 groups and 4 from the pyrroline-CH_2 groups) from the eight ethyl groups, two different pyrroline protons, and four different *meso* protons, as reported previously.[363] Thus, the claim of slow or no interconversion between supposed ruffled conformations of *trans*-(OEC)FeCl,[364] as evidenced by the presence of four *meso*-H signals, relied on the misconception that the 5,20 and 10,15 *meso*-H could interconvert via ring inversion of the macrocycle when in a nonplanar conformation. In contrast, the observation of only two *meso*-H signals for

(*cis*-3,4-dihydroxyoctaethylchlorinato) iron(III) chloride at room temperature, which split into four resonances at low temperatures,[364] is indeed indicative of macrocycle inversion of this nonplanar chlorin.

Although the types of protons of (OEC)FeCl were assigned previously,[363] the full resonance assignments for high-spin (OEC)FeCl were obtained in the author's laboratory by using saturation transfer difference (STD) techniques,[115] as shown in Figure 36. To conduct the STD experiments, an NMR sample containing a mixture of (OEC)FeCl and its low-spin complex, [(OEC)Fe(4-Me_2NPy)$_2$]Cl, was made by adding less axial ligand to the solution of (OEC)FeCl than necessary to fully form the bis(ligand) complex (4-Me_2NPy:(OEC)FeCl = 1:1). Only the ^{1}H NMR resonances of (OEC)FeCl and [(OEC)Fe(4-Me_2NPy)$_2$]$^+$ were observed in this sample, and thus no mono(ligand) complex was present, because of its relative instability, which clearly causes it to disproportionate to the HS chloride and LS bis(ligand) complexes. The saturation transfer experiments were carried out on this mixture. Irradiation of the pyrrole-CH_2 peaks of the high-spin (OEC)FeCl form and observation of the saturation transfer to the corresponding peaks of the low-spin species, which had already been assigned (see Section IV.A.8.i), which arise from chemical exchange between the two, when recorded as a difference spectrum, allow the peaks of (OEC)FeCl to be assigned. The control spectrum (Figure 36a) shows the assignments derived for all the CH_2 groups and pyrroline protons from the experiments shown in Figure 36b–o, except for two peaks from the pyrroline-2,3-CH_2 protons, which are under or very close to the envelope of resonances of the low-spin [(OEC)Fe(4-Me_2-NPy)$_2$]Cl.[115] The saturation transfer difference experiments which led to the assignments of the four *meso* protons[115] are consistent with the assignments in the literature obtained by selective deuteration of the chlorin ring, and are thus not shown herein.

An interesting finding in the saturation transfer experiments shown in Figure 36 was that when any resonance from one of the pyrrole-CH_2 groups is irradiated, besides the chemical exchange signal from the corresponding low-spin species, there was another negative-phase signal observed from the high-spin form of (OEC)FeCl. This ST resonance was from the chemical exchange between two CH_2 protons in two different but symmetry-related (such as positions 12,13 or 7,18 or 8,17) ethyl groups. This chemical exchange arises from the binding, loss, and rebinding of chloride ion on the opposite side of the chlorin ring in the process of exchange with the 4-Me_2NPy ligands. For example, for one of the two CH_2 protons at position 8, if the chloride ion leaves when 4-Me_2NPy binds, a different Cl^- can bind to the metal center on the opposite side when 4-Me_2NPy leaves, and this proton will thereby have its chemical environment changed to that of a CH_2 proton at position 17 by virtue of the enantiomeric relationship shown in Structure 18. This process only occurs in the mixture of (OEC)FeCl and [(OEC)Fe(4-Me_2NPy)$_2$]Cl,

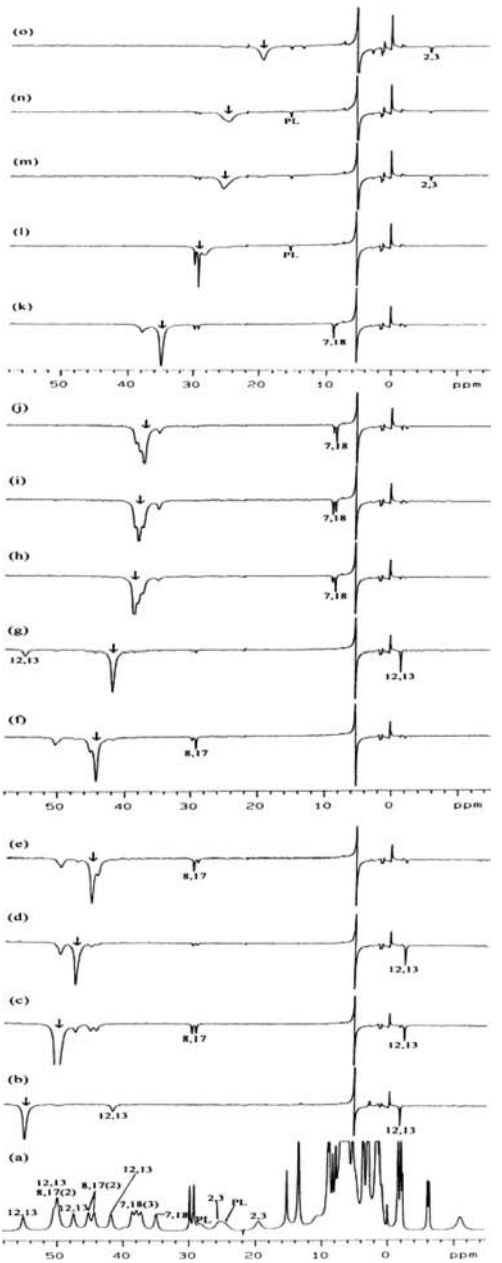

Figure 36. Bottom (a): ^{1}H NMR spectrum of high-spin (OEC)FeCl in CD_2Cl_2 at 30 °C. Above, (b-j): 1D saturation transfer difference spectra of the same complex in solution with enough pyridine-d5 to complex about 10% of the complex. An arrow shows the resonance irradiated in each STD spectrum and the negative-pointing low-spin resonance to which it correlates is numbered. Some NOEs are also observed (positive phase). Five additional STD spectra can be seen in the Supporting Information of the publication. Reprinted from the Supporting Information, Figure S8, of Cai, S.; Lichtenberger, D. L.; Walker, F. A. *Inorg. Chem.* **2005**, *44*, 1890–1903, with permission from the American Chemical Society.

among all ligand complexes studied.[115] (NMeIm and HIm bind too tightly and exchange too slowly to produce saturation transfer signals, while pyridine and 4-CNPy do not bind tightly enough and exchange too rapidly to allow resolved high-spin resonances to be observed.)[115] As a result, chemical exchange signals were observed between two symmetry-related CH_2 groups of the 4-Me_2NPy-containing sample. This chemical exchange was also observed in the NOESY/EXSY spectrum of the mixture of (OEC)FeCl and [(OEC)Fe(4-Me_2NPy)$_2$]Cl.[115] Since there are a total of 10 pyrrole-CH_2 peaks in the paramagnetically-shifted region from 36 to 56 ppm, 5 pairs of cross-peaks should be and are observed (the 2,3-CH_2 resonances are not present in this spectral region).[115]

Interestingly, in the NOESY/EXSY spectrum, only chemical exchange between the CH_2 protons of the high-spin (OEC)FeCl is observed.[115] Chemical exchange between (OEC)FeCl and [(OEC)Fe(4-Me_2NPy)$_2$]Cl was not observed in the NOESY/EXSY spectrum because of the large difference in the relaxation rates of these two species.[115] Thus, it is clear that if one wants to observe the chemical exchange or NOE between a rapidly and a slowly relaxing resonance, the steady-state experiment is a much better choice than the NOESY/EXSY experiment. By irradiating the rapidly-relaxing peak and observing the change of the slowly-relaxing peak, one can avoid the disadvantage of the NOESY experiment, the decrease of the signal during the t_1 increment and mixing time due to the fast relaxation rate of the fast-relaxing species.

The (TPC)FeCl complex pyrrole-H and pyrroline-H resonances, first reported by Strauss and coworkers,[363] were assigned, again by STD spectroscopy from the [(TPC)Fe(4-NMe_2Py)$_2$]$^+$Cl$^-$ complex.[365] In this case there are no chiral carbons. The pyrrole-H resonances are found at +86 (7,18), +77 (12,13), and +66 (8,17) ppm, while the pyrroline-H are found at −2 ppm. As is apparent, the various types of pyrrole protons in the TPC complexes and the various types of pyrrole methylene protons in the OEC complexes exhibit a large range of paramagnetic shifts ($\Delta\delta$ ~30 ppm at 300 K). For both TPC anion complexes, two pyrrole-H resonances are at higher shielding and one is at lower shielding than the pyrrole-H resonance for the TPP homologue, while for the OEC complexes the mirror image of this pattern is observed: Two sets of four pyrrole CH_2 resonances are at lower shielding and one set of four is at higher shielding than the average pyrrole CH_2 resonance for the OEP homologues. However, it should also be noted that the average pyrrole-α-CH_2 shift is larger for the chlorin (+42 ppm) than the porphyrin (+39.8 ppm), although this does not change the higher/lower frequency shift pattern by very much. This reversal in pattern on going from the TPC complexes to the OEC complexes is almost certainly due to the π component of the contact shift at the β-pyrrole position for the two types of complexes. These results suggest that the amount of spin density distributed from the iron atom to the protons in the pyrrole

groups of the macrocycle is nearly the same for 5-coordinate high-spin iron(III) porphyrins and chlorins, but is distributed quite asymmetrically among the various pyrrole positions in the chlorin complexes.[363]

The differential rate of substitution of deuterium at the two chemically different types of *meso*-H positions of OECFeCl under acidic and basic conditions,[171,366,367] as mentioned above, allowed assignment of the two types of *meso*-H; the absolute assignment of the four was achieved by saturation transfer.[115] For the 5-coordinate chloroiron(III) complex, the two *meso*-H adjacent to the reduced ring have a much larger negative paramagnetic shift, and hence a larger π contact shift, than those farther away from it (and much more negative than the *meso*-H paramagnetic shift of (OEP)FeCl as well),[171] which suggests that the S_{-1} orbital, the analog of the $3a_{2u}(\pi)$ orbital of the corresponding porphyrin, (compare Figures 2 and 5), is heavily involved in this π spin delocalization via delocalization of the d_{z^2} unpaired electron in this 5-coordinate chlorin complex.[156] But at the same time, utilizing the "antisymmetric" d_π electron, additional π spin delocalization from the A_{-1} orbital, which is the analog of the $1a_{1u}(\pi)$ orbital of the corresponding porphyrin (compare Figures 2 and 5, can also contribute spin density to the two *meso* positions closest to the pyrroline ring. Thus both the A_{-1} and S_{-1} MOs can contribute, via separate unpaired electrons and separate π molecular orbitals, to the large spin density at those positions. The *meso* positions closest to the saturated pyrrole ring are also those that exchange protons more rapidly with deuterium under acid conditions,[171] and are thus most electron-rich, which is consistent with the relative molecular orbital coefficients of A_{-1}. In contrast, for the 6-coordinate high-spin iron(III) OEC complex, the paramagnetic shift of the two *meso*-H adjacent to the pyrroline ring is only slightly smaller than that of the other two. In addition, both types of *meso*-H of the 6-coordinate complex have less positive paramagnetic shifts than the corresponding OEP complex, which is consistent with the loss of delocalization via the d_{z^2} unpaired electron to the S_{-1} orbital in this 6-coordinate complex.[156]

Peroxoiron(III) chlorin complexes have been prepared from $(OEC)Fe^{III}$ and $(TMC)Fe^{III}$ plus two equivalents of superoxide anion.[368] These complexes exhibit rhombic high-spin EPR spectra, with two resolved g-values of about 9 and 4.2. The NMR spectrum of the $(TMC)Fe^{III}(O_2^{2-})$ complex at −25 °C in acetonitrile showed three pyrrole-H resonances at +79, +72 and +67 ppm and the pyrroline resonance at −62 ppm. The *meta*-H of the mesityl rings is found at 7 ppm.[368]

iii. Two iron(III) octaethylisobacteriochlorin isomers

Iron(III) five- and six-coordinate complexes of both *trans-trans-trans* (*ttt*) and *trans-cis-trans* (*tct*) octaethylisobacteriochlorin, OEiBC, Structure **5**, have also

been investigated.[171] A number of resonances were assigned by means of deuterium substitution, with utilization of both ^{1}H and ^{2}H NMR spectroscopy, as described in Section II.D.2. For the 6-coordinate complexes of both isomers, the spread of the observed shifts of the pyrrole-α-CH_2 is larger for both isomers (*ttt*, $\Delta\delta$ = +54.9; *tct*, +56.2 ppm) than it is for the 5-coordinate complexes (*ttt*, $\Delta\delta$ = +35.5; *tct*, +33.7 ppm). Again, for the 5-coordinate complexes, the out-of-plane position of iron(III) and its anion makes each pyrrole and pyrroline proton magnetically unique in the *ttt* isomer, and those plus the *meso*-H unique in the *tct* isomer. The larger spread of pyrrole-α-CH_2 resonances for 6- vs. 5-coordinate complexes is also mirrored in the pyrroline α-CH_2 and –H resonances (see Table 11).

In the case of the 5-coordinate complexes, the *meso*-H resonances are all at very negative chemical shift, indicating large π spin delocalization to the *meso* positions because of the d_{z^2}-S_{-1} interaction[156] and the d_{xz}-A_{-1} interaction (Figure 5). The large spread (*ttt*, $\Delta\delta$ = 77.8; *tct*, 95.7 ppm) indicates π contact shifts in the order 5 >> 10,20 > 15. This is the opposite order from that observed for the rate of base-catalyzed *meso*-H exchange for deuterium in the metal-free (OEiBC)H_2 isomers,[171] and is thus the same as the order of decreasing electron density at the *meso* positions in each isomer. Thus, the π contact shift pattern at the *meso* positions is indicative of spin delocalization via filled π orbitals, that is, iBC $\rightarrow$ Fe π donation, probably mainly from the formerly $3a_{2u}(\pi)$ orbital of the porphyrin, denoted S_{-1} for the isobacteriochlorin, Figure 6, to the d_{z^2} orbital.[156]

Paramagnetic shifts of the *meso*-H in 6-coordinate DMSO adducts of the two isomers are quite different from those of the 5-coordinate complexes just discussed; as for the chlorin and porphyrin complexes, the sign reverses, indicating a dominance of σ spin delocalization at the *meso*, as well as the pyrrole positions, because of the allowed overlap between the $3a_{2u}(\pi)$-like orbital and the half-filled d_{z^2} metal orbital when the metal is out of the plane of the porphyrin nitrogens.[156] In addition, the spread of the *meso*-H resonances decreases on going from 5- to 6-coordination to 33.5 (*ttt*) and 29.1 (*tct*) ppm. More importantly, the order of the resonances changes, such that the minor π spin delocalization that occurs at the *meso* positions of the 6-coordinate complexes decreases in the order 5 > 15 > 10,20. This pattern is indicative of weak π delocalization via the filled S_{-1} π orbital of a ruffled macrocycle, that is, weak iBC $\rightarrow$ Fe π back-bonding, in addition to a large σ spin delocalization to all macrocycle positions.

iv. An iron(III) monooxochlorin complex

(Monooxooctaethylchlorinato)-iron(III) chloride, (oxo-OEC)FeCl, has been investigated by X-ray crystallography and by1D ^{1}H NMR spectroscopy.[207] The structure shows the iron to be 0.46 Å out of the 24-atom mean plane and 0.25 Å

out of the plane of the four nitrogens.[207] More recently, the CH_2 resonances of (oxo-OEC)FeI, which has much sharper NMR resonances, were assigned by saturation transfer from the $[(\text{oxo-OEC})\text{Fe}(2\text{MeImH})_2]^+\text{I}^-$ complex.[101] (oxo-OEC)FeCl has no C_2 axis, and thus there are 15 unique CH_2 resonances, which range in chemical shift from +69 to +46 ppm at 25 °C.[101] There are also four unique *meso*-H resonances, at −46, −51, −77, and −81 ppm.[101] The temperature dependence is as expected from Eq. 22.[101]

v. Two iron(III) dioxooctaethylisobacteriochlorin complexes

The ^{1}H NMR spectrum of a chloroiron(III) 3,7-dioxooctaethylisobacteriochlorin derived from OEP in CD_2Cl_2[100] shows a very similar pattern of chemical shifts for the *meso*-H, in this case indicating contact shifts in the order 5 > 20 > 10 > 15, with a spread of 69 ppm (Table 11). The spread of the pyrrole-α-CH_2 resonances is 36.7 ppm, with an average chemical shift of +49.4 ppm and that for the pyrroline α-CH_2 resonances is 3.5 ppm, with an average chemical shift of +19.6 ppm. Yang *et al*. attempted to make more detailed assignments of this complex, but were only able to separate the most highly-shifted CH_2 resonances into three groups, *a*, *b* and *c*, with assignments from 68.5 to 47 ppm of *a*, *b*, *a*, *c*, *b* and *c*.[101] Further assignments were not possible because of the lack of NOE interactions that could be detected. Except for the small spread of the pyrroline-α-CH_2 resonances, which is consistent with the structure of this reduced heme, the pattern is very similar to that of the [(OEiBC)FeCl] isomers reported by Sullivan *et al*.,[171] Table 11. Both groups who have studied the NMR spectra of the 3,7-dioxooctaethylisobacteriochlorin complex have used the iodide salt,[100,101] which has the sharpest ^{1}H resonances of all the halides.[94]

The trans-dioxoisobacteriochlorin complex, 2,12-dioxo-octaethylisobacteriochlorin complex, (2,12-dioxo-OEiBCFeI), was very easy to assign from the NOESY spectrum, based on cross peaks from 7,17 to 7,17, 8,18 to 7,17, 3,13 to 3,13 and 3,13 to 3,13-CH_2 protons. Thus, the CH_2 assignments are 7,17 > 8,18 > 8,18, 7,17 > 3,13 > 3,13 ≥ 3,13 > 3,13.[101] The 3,13-CH_2s are in the saturated rings. Thus, the largest spin density is at the 7,8 and 17,18 positions of the macrocycle, the aromatic pyrrole rings.[101]

vi. The iron(III) complex of tetraphenyl-21-oxaporphyrin

The 6-coordinate complex, $(\text{OTPP})\text{Fe}^{\text{III}}\text{Cl}_2$, which has one furan ring in place of a pyrrole ring, is a typical high-spin iron(III) complex, with pyrrole-H resonances at +86.2, +67.9 and +66.3 ppm and the furan β-H at +47.7 ppm.[319] This complex can undergo 1-electron reduction to $(\text{OTPP})\text{Fe}^{\text{II}}\text{Cl}$,[319] as discussed earlier in

Section IV.A.4.a(vii). It can also react with 2 equivalents of cyanide to produce $(OTPP)Fe^{III}(CN)_2$, which has pyrrole-H resonances at −16.2, −24.6 and −40.5 ppm and the furan β-H at −5.4 ppm.[319] In the presence of excess cyanide it is autoreduced to $[(OTPP)Fe^{II}(CN)_2]^-$, as was also discussed in Section IV.A.4.a(vii).

vii. The high-spin iron(III) complexes of mono-*meso*-octaethyloxaporphyrin and mono-*meso*-octaethylazaporphyrin

As was shown in Section IV.A.4.a(vi), oxidation of (OEP)FeCl in pyridine by O_2 in the presence of a reducing agent ("coupled oxidation") produces the *meso*-oxa derivative known as $[(OEOP)Fe^{II}Cl]$,[220] ring Structure **9**. One-electron oxidation of this complex in the presence of excess chloride ion produces $[(OEOP)Fe^{III}Cl_2]$, whose NMR spectrum in $CDCl_3$ at −60 °C shows four CH_2 resonances between +45 and +90 ppm, and two *meso*-H at +60 and +73 ppm (intensity 2:1, respectively). At 297 K these four resonances are found between +35 to +60 ppm.[369] As for the 6-coordinate iron(III) isobacteriochlorin complexes discussed earlier in Section IV.A.6.c(ii), this pattern suggests spin delocalization via the former $3a_{2u}(\pi)$ orbital of the porphyrin, that is, S_{-1} of Figure 6, in addition to a large σ-delocalization to all macrocycle positions.

Treatment of $Cl_2Fe^{III}(OEOP)$ in CD_2Cl_2 with a 1.0 M solution of KOD yields three intermediates with a total range of methylene resonances from +80 to −65 ppm.[369] These have been sorted out to identify the intermediates, first $[Cl_2Fe(OEBOH)]^-$, which has nine methylene resonances between +16.4 and +8.6 ppm and seven more strongly shielded methylene resonances from 0.2 to −11.5 ppm; second, the anion-substituted complex of the same open macrocycle, with one Cl^- replaced by OH^-; and third, the diketo form, which has only one OH^- ligand, [(HO)Fe(OEBO)].[369] The mixed anion intermediate has eight methylene resonances in the +10 to +65 ppm region and another eight in the −20 to −70 ppm region of the spectrum, which show COSY cross peaks between adjacent methylene resonances throughout most of the spectrum (1–2, 3–4, 5–6, and 7–8, but some variation in the remaining eight, with 9–10, 11–12, 13–15, 14–16). It is likely that this wide range of chemical shifts is indicative of radical character in the OEBO complex, but this has not been fully elucidated. The diketo [(HO)Fe(OEBO)] intermediate also exhibits individual methylene resonances, 13 of which are resolved outside the crowded diamagnetic region and ranges in chemical shift from +47 to 0 ppm; the two *meso*-H resonances are at +77 (1) and −7 (2) ppm.[369]

When $[(OEOP)Fe^{II}(Py)_2]Cl$ is treated with ammonia, followed by sulfuric acid and finally HCl, the complex $[(OEAP)Fe^{III}Cl]$ or $[(HOEAP)Fe^{III}Cl_2]$ is obtained if an excess of HCl is used.[370] The 5- and 6-coordinate high-spin iron(III) centers have rather different NMR spectra, with the eight ethyl CH_2 resonances of the 5-coordinate

complex lying between +39 and +50 ppm and the *meso*-H lying at about −18 and −26 ppm (intensities 1:2, respectively) at 23 °C.[370] In contrast, the four ethyl CH_2 resonances of the 6-coordinate dichloro complex lie between about +62 and +90 ppm while the *meso*-H lie at about +23 and +46 ppm (intensities 1:2, respectively) at −78 °C, and the *meso*-N–H proton is at about −46 ppm.[370] When the chloride anions are exchanged for nitrate and the complex is dissolved in DMSO-d_6, the four CH_2 resonances lie between +29 and +32 ppm at 23 °C, while only one *meso*-H resonance is observed, at +36 ppm.[370] These findings for the 6-coordinate complexes are also consistent with a combination of σ and π spin delocalization, as for the 6-coordinate iron(III) isobacteriochlorins and [(OEOP)$Fe^{III}Cl_2$] discussed in Section IV.A.6.c(ii) and the previous paragraph, respectively.

d. *Bridged dimeric complexes of high-spin iron(III) porphyrins and chlorins*

Several of the properties of μ-oxo dimers of iron(III) porphyrins, formed by hydrolysis of the hydroxide complex (Eq. 25) or by reaction of molecular oxygen with iron(II) porphyrins (Eq. 26), have been investigated, including their ^1H and ^{13}C NMR spectra, infrared and Raman spectra, Mössbauer spectra, magnetic susceptibilities and crystal and molecular spectra. These linear (P)Fe–O–Fe(P) units are antiferromagnetically coupled dimers of high-spin iron(III), although attempts to measure the coupling constant, −2J, from the temperature dependence of the magnetic susceptibility or NMR paramagnetic shifts have yielded a range of values.[2,4,371] Magnetic susceptibility results for [((TPP)Fe)$_2$O] in the solid state give −2J = 271 cm^{-1},[372] while values of 258 cm^{-1},[373] and 312 cm^{-1},[374] have been obtained from ^1H and ^{13}C NMR results, respectively. Calculation of −2J from the temperature dependence of the NMR spectra of these complexes is complicated by the possibility of pseudocontact, ZFS and contact contributions to the paramagnetic shifts.[2,4] In any case, the paramagnetic shifts of the protons of these (P)Fe–O–Fe(P) dimers are significantly different from those of the high-spin iron(III) monomers,[2,4] with all resonances occurring between +7 and +14 ppm at 320 K. Similar NMR spectra are observed for the reduced porphyrin analog, [((TPC)Fe)$_2$O], with the addition of two signals from the two types of protons in the pyrroline ring in the 2–4 ppm region.[373] The tetraphenylchlorin complex has a very similar derived value of −2J (265 cm^{-1}). The shift to lower frequency of the pyrroline protons suggests either (1) a sizable π contact shift to higher shielding, which possibly arises from spin delocalization via the $a_{1u}(\pi)$ counterpart of the porphyrin ring, that is, the A^{-1} orbital of Figure 5, or (2) a large rhombic component to the paramagnetic shift, as previously discussed for monomeric, 4-coordinate S = 1 complexes of the reduced hemes (OEC)Fe, (TPC)Fe and (TPiBC)Fe.[248]

The preparation of a series of mixed metal μ-oxo dimers of the type (P)Fe–O–Cr(P′) from (P)Fe^{II} and (P′)Cr=O hve been reported.[375] Their ^{1}H NMR spectra are characterized by resonances of the (P)Fe in the positions found for the symmetrical (P)Fe–O–Fe(P) dimer, and a resonance at +38 ppm due to the pyrrole-H of the chromium porphyrin unit. The peak at ~13 ppm was not present when (OEP)Fe^{II} was used as the iron starting material instead of (TPP)Fe^{II},[375] which confirms that this resonance is due to the pyrrole-H of the iron unit. The temperature dependence of the magnetic susceptibility of the mixed-metal dimer leads to its formulation as antiferromagnetically coupled Fe^{III} (S = 5/2) and Cr^{III} (S = 3/2), which yields S′ = 1, with −2J ~260–300 cm^{-1} and D_{Fe} and g_{Fe} ranging from 3.8 to 4.9 cm^{-1} and 1.98–2.05, respectively, if it is assumed $D_{Cr} \sim -1$ cm^{-1}.[375] Similar binuclear μ-oxo dimers can be made in which the iron complex is the phthalocyanine.[375]

An intermediate in the oxidation of 4-coordinate iron(II) porphyrins to the (P)Fe–O–Fe(P) μ-oxo dimer via Eqs. 28a–c:

$$\underset{A}{(P)Fe^{II}} + O_2 \rightarrow \underset{B}{(P)FeO_2}, \tag{28a}$$

$$\underset{B}{(P)FeO_2} + \underset{A}{(P)Fe^{II}} \rightarrow \underset{C}{(P)Fe^{III}–OO–Fe^{III}(P)} \rightarrow 2\underset{D}{(P)Fe^{IV}=O}, \tag{28b}$$

$$\underset{D}{(P)Fe^{IV}=O} + \underset{A}{(P)Fe^{II}} \rightarrow \underset{E}{(P)Fe^{III}–O–Fe^{III}(P)}, \tag{28c}$$

the μ-peroxo dimer, C, of tetra-(*m*-tolyl)porphinatoiron(III), has been detected by NMR spectroscopy at low temperatures.[378] The μ-peroxo complex, C, has a larger paramagnetic shift for the pyrrole-H at all temperatures, and has an antiferromagnetic coupling constant, −2J, that is about 30% smaller than that for the μ-oxo dimer, E, and the magnetic moment[376,677] decreases from 2.6 μ_B at −50 °C to about 2.2 μ_B at −80 °C, both consistent with weaker antiferromagnetic coupling in the μ-peroxo complex.[378]

Addition of dioxygen to 2,7,12,17-tetra-*n*-propylporphycene, (TPrPc)Fe^{II}, produces its μ-peroxo dimer, which has a pyrrole-H chemical shift of +17.99 ppm in d_8-toluene at 173 K and shows distinct nonCurie temperature dependence because of strong antiferromagnetic coupling.[253] It is stable at 203 K but converts to the μ-oxo dimer at higher temperatures. When the μ-peroxo dimer is reacted with nitrogen bases (pyridine-d_5, NMeIm) it forms the ferryl complex, B(TPrPc)Fe^{IV}=O, which has pyrrole-H at −1.32 ppm, *meso*-H at +11.80 ppm at 223 K; it reacts with triphenylphosphine to produce triphenylphosphine oxide.[253]

Related reactions of 4-coordinate (P)Fe^{II} complexes with *p*-benzoquinone and its derivatives yield hydroquinone dianion bridged iron(III) porphyrin dimers that are characterized by very small antiferromagnetic coupling constants, –2J ~7.2–31 cm^{-1}.[379] Accordingly, the ^1H NMR spectra of these complexes are fairly characteristic of high-spin iron(III) monomeric complexes, with the pyrrole-H resonance at +62–74 ppm at 23 °C.[380] However, the Curie plots show the opposite type of curvature from that of simple monomeric high-spin iron(III) complexes, due to the (small) antiferromagnetic coupling between the iron(III) centers in these dimers.

Several μ-nitrido dimers have been reported, including [(TPP)Fe–N–Fe(TPP)],[381] [(Pc)Fe–N–Fe(Pc)],[382] mixed porphyrin-phthalocyanine complexes such as [(TPP)Fe–N–Fe(Pc)],[383] all of which involve formally Fe^{III}–Fe^{IV} paramagnetic centers, in which each iron is said to behave as though it is +3.5, that is, a delocalized single unpaired electron. This contrasts with the Fe–Ru analog dimers, which behave as Fe^{IV}–Ru^{III} centers.[384] For the di-iron compounds, a single unpaired electron could result from antiferromagnetic coupling of high-spin iron(III) (S = 5/2) and high-spin iron(IV) (S = 2), intermediate-spin iron(III) (S = 3/2) and intermediate-spin iron(IV) (S = 1), or low-spin iron(III) (S = 1/2) and low-spin iron(IV) (S = 0), although the precedent of the μ-oxo dimer of iron(III) porphyrins would suggest that these 5-coordinate centers should be high-spin. In any event, neither the high-spin/high-spin nor intermediate-spin/intermediate-spin antiferromagnetically coupled cases could allow a delocalized electron, for transfer of one electron from iron(III) to iron(IV) would create a different spin state, and the corresponding Fe^{III}–Fe^{IV} μ-nitrido dimer of the iron cyclams has localized valences.[385] The mixed-valence Mn–Fe d^8 systems behave as Mn^{IV}–Fe^{III} and are formally diamagnetic.[386] One-electron oxidation of [(TPP)Mn–N–Fe(Pc)] produces the Mn^{IV}–Fe^{IV} oxidation state, and the oxidized dimers can coordinate pyridine to form mono- and bis-(pyridine) adducts. Up to six additional electrons can be removed from the (IV)–(IV) dimer. The complexes have been characterized by electrochemical techniques, EPR, Mössbauer and resonance Raman spectroscopy,[386] but not by NMR spectroscopy.

Dimeric dinegative oxoanion SO_4^{2-} and CrO_4^{2-}, $[((P)Fe)_2XO_4]$ complexes have been shown to have both ^1H and ^{13}C NMR resonances that are sharp and at very similar paramagnetic shifts to those of monomeric, high-spin iron(III) complexes,[336,387] which suggests that antiferromagnetic coupling is very weak or nonexistant in these dimeric complexes. Very small deviations from Curie behavior were noted, suggesting that zero-field splitting of high-spin iron(III) is very small; this fact and the slightly smaller pyrrole-H paramagnetic shifts of $[((TPP)Fe)_2(SO_4)]$, suggest that the sulfate anion may be acting as a bidentate chelating ligand to each iron(III).

High-spin iron(III) oxophlorins readily dimerize intermolecularly when in the *meso*-hydroxyporphyrin resonance form,[388] Structure **8**. In these 5-coordinate

high-spin iron(III) dimeric centers, antiferromagnetic coupling is very weak and the ^{1}H NMR shift pattern is similar to those of the monomeric chloro- or bromoiron(III) complexes discussed in Section IV.A.6.c(v). The eight ethyl-CH_2 resonances lie between +18 and +39 ppm and show significant differences in T_1s and T_2s depending on their distances from the other iron(III) center, while the *meso*-H resonances are observed at −28 and −98 ppm (intensities 2:1, respectively) in $CDCl_3$ at 28 °C,[388] as observed for other 5-coordinate high-spin iron(III) macrocycles discussed above.

A type of intermolecular dimer formation has also been observed for the unsymmetrically substituted 5-(2-hydroxyphenyl)-10,15,20-tritolylporphyrin complex of iron(III), in which the *o*-OH functions of one molecule are deprotonated and bind as PhO^- ligands to the Fe(III) of a second molecule, which in turn binds its deprotonated *o*-OH function to the iron(III) of the first. Despite this intramolecular dimeric structure, the proton NMR spectra reveal pyrrole-H signals in the +80 ppm region at 25 °C, which is diagnostic of an isolated high-spin iron(III) center, and the magnetic moments in solution[376,377] ($6.0 \pm 0.2\ \mu_B$) and solid-state ($5.91 \pm 0.05\ \mu_B$) match the spin-only value for high-spin iron(III), thus indicating that antiferromagnetic coupling is extremely small.[328]

Several covalently linked di-iron(III) diporphyrins, linked through an alkyl chain to the *ortho*-OH of a single phenyl ring on each porphyrin, have been reported by Wolowiec and Latos-Grażyński, who have also studied the cyanide coordination of them.[389] High-spin complexes in which each iron is coordinated to one cyanide, a bridging low-spin tricyano complex, plus a low-spin tetracyano complex are observed. The NMR spectrum of the tricyano complex that includes a μ-cyano bridge shows evidence of at least 16 pyrrole-H resonances between −12 and −19 ppm at 293 K in $CDCl_3$. This is believed to be due to the unsymmetrical nature of the μ-cyano bridge.[389] Oligomerization of the iron(III), gallium(III) and manganese(III) complexes of (2-hydroxyphenyl)triphenylporphyrin creates head-to-tail trimeric complexes that have been characterized by X-ray crystallography and by NMR spectroscopy.[390–392] The unique 3-H resonances of the iron(III) trimer occur at −90, −95 and −99 ppm for the different stereoisomers, while the other pyrrole-H resonances occur in the +62–81 ppm range.[390,392] The diamagnetic gallium(III) trimer has the 3-H resonances at 1.82, 2.18 and 2.82 ppm.[391] Mixed-metal trimers have also been prepared and characterized by NMR spectroscopy.[392]

7. *Intermediate-Spin Iron(III) Porphyrins: Observed Shifts and the Mechanism of Spin Delocalization*

When weakly-coordinating anionic axial ligands such as ClO_4^-,[15,393–400] $CF_3SO_3^-$,[374] SbF_6^-,[400–402] and $C(CN)_3^-$[374,403] or two weakly-basic pyridine ligands (in the case of β-pyrrole alkyl-substituted porphyrins such as OEP and etioporphyrin, EP), such

as 3-chloropyridine[404] and 3,5-dichloropyridine;[400,405] are present, iron(III) porphyrins exhibit a broad derivative-shaped EPR feature near g = 4[374,397,400,405] and NMR spectra that show anti-Curie behavior.[15,334,396,406] Many of these spectral features are similar to those of the cytochromes *c′*, including the EPR,[400,407,408] near-IR MCD,[400,409,410] Mössbauer[395,402,405,411] and resonance Raman[412,413] spectra, and the NMR spectra of *Chromatium vinosum* cytochrome *c′*, but not those of *Rhodospirillum rubrum*, *Rhodospirillum molischianum* and *Rhodopseudomonas palustris*.[414] Thus, it may be that *C. vinosum* cytochrome *c′* is the anomaly among this type of cytochromes *c*. Interestingly, it is the *C. vinosum* protein that has been studied most frequently by other spectroscopic techniques. The cytochromes *c′* are known to contain 5-coordinate heme *c*, with no distal residues present that are capable of hydrogen-bonding to endogenous ligands.[415,416] Moss and Maltempo have proposed the existence of an intermediate-spin (S = 3/2) state with a quantum-mechanical admixture of the more common high-spin (S = 5/2) state for the protein.[411,417,418] This differs from a simple S = 3/2 → S = 5/2 equilibrium, in that the EPR and Mössbauer features are unique, rather than simply a superposition of the expected spectra of the two spin states, and the ground state is composed of contributions from each state.[406]

The dramatic anti-Curie dependence of the pyrrole-H resonance of [(TPP)FeOClO$_3$] from about −20 ppm at −45 °C to +20 ppm at +54 °C[396] is a now-familiar hallmark of the ^{1}H NMR spectra of spin-admixed S = 3/2,5/2 model heme species. Smaller shifts in the *meso*-H (~ 0 to about −9 ppm) and pyrrole-α-CH$_2$ (−40 to about −33 ppm from −40 to +50 °C) resonances are observed for [(OEP)FeOClO$_3$].[334,374,396] At low temperatures, the S = 3/2 contribution to the spin-admixed state increases,which leads to depopulation of the $d_{x^2-y^2}$ orbital of the S = 5/2 state, and thus decreases the large σ contact shift contribution so characteristic of simple high-spin 5- and 6-coordinate iron(III) porphyrins (Section IV.A.6.a and IV.A.6.b). The NMR spectra have been fit to a model based on a d-orbital splitting pattern modified from the tetragonal pattern on the right side of Figure 1, with the energies of d_{z^2} and $d_{x^2-y^2}$ reversed,[406] where $\Delta = E_{x^2-y^2} - E_{xy} = 34{,}100$ cm^{-1}, $\delta_1 = E_{xz,yz} - E_{xy} = 2{,}500$ cm^{-1}, $\delta_2 = E_{x^2-y^2} - E_{z^2} = 25{,}000$ cm^{-1} and $g_\parallel = 2.0$, and the best values of $\zeta = 200$ cm^{-1}, $g_\perp = 4.77$, with the ground state wave function composed of 61% $^4A_2$ and 39% $^6A_1$ for [TPPFeOClO$_3$], and $\zeta = 120$ cm^{-1}, $g_\perp = 4.39$, with the ground state wave function composed of 80% $^4A_2$ and 20% $^6A_1$ for [(OEP)FeOClO$_3$].

Weak-field anions tend to stabilize the S = 3/2 ground state of the spin-admixed 3/2,5/2 systems, increasing in the order $CF_3CO_2^- \sim CF_3SO_3^- < C(CN)_3^- < ClO_4^-$ for (TPP)Fe^{III} [374] and $CF_3SO_3^- < C(CN)_3^- \sim ClO_4^- < SbF_6^-$ for (OEP)Fe^{III}.[374,400] The low-basicity ligand, 3,5-dichloropyridine, appears to stabilize the S = 3/2 ground state in [(OEP)Fe(3,5-Cl$_2$Py)$_2$]$^+$ about as well as ClO_4^- or SbF_6^-.[400] For *para*-substituted derivatives of [(TPP)FeOClO$_3$], the S = 5/2 contribution increases in

the order *p*-OCH_3 < *p*-H < *p*-Cl < *p*-CF_3,[399] so electron-donating substituents on the phenyl rings favor the S = 3/2 ground state, where the $d_{x^2-y^2}$ orbital is depopulated. Consistent with this, the 2,4,6-trimethoxy derivative, [((2,4,6-$(OCH_3)_3)_4$TPP)$FeOClO_3$] has the most negative reported chemical shift of the pyrrole-H (−30.6 ppm),[398] and thus appears to be the "purest" S = 3/2 complex. However, the temperature dependence of the paramagnetic shifts has not been reported. The shift to higher frequency (δ_{obs} positive) of the *m*-phenyl-H indicates a pseudocontact contribution of positive sign, consistent with the EPR parameters ($g_\perp > g_\parallel$) obtained for [(TPP)$FeOClO_3$].[406]

A series of perchloratoiron(III) complexes of four 2,6- and one 2,4,6-phenyl substituted tetraphenylporphyrin ligands have been investigated as a function of temperature by ^{1}H NMR spectroscopy.[83] The 2,6-phenyl substituents consisted of –H, –F, –Cl, and –Br, and the 2,4,6-phenyl substituents were $-CH_3$. A wide range of temperature dependences, ranging from negative slopes with very large positive 1/T = 0 intercepts (Cl ~ Br > CH_3 > H) to positive slope with very large negative 1/T = 0 intercept (F), were observed, as shown in Figure 37. The NMR results were combined with EPR spectroscopic data, theoretical calculations and curve fitting procedures to arrive at a consistent overview of the variety of temperature

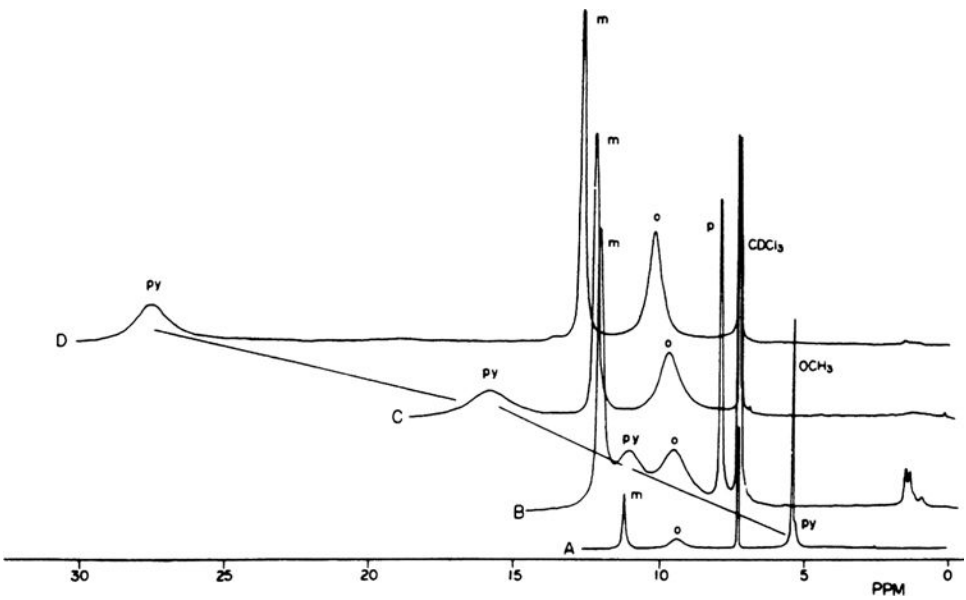

Figure 37. 250 MHz ^{1}H NMR spectrum of 4-substituted phenyl derivatives of [(TPP)$Fe^{III}OClO_3$]: (A) 4-OCH_3; (B) H; (C) 4-Cl; (D) 4-CF_3. Proton designations: *o, ortho*-H; *m, meta*-H; *p, para*-H; py, pyrrole-H. Solutions are ~2mM in $CDCl_3$ at 29 °C. Reprinted from Toney, G. E.; Gold, A.; Savrin, J.; ter Haar, L. W.; Sangaiah, R.; Hatfield, W. E. *Inorg. Chem.* **1984**, *23*, 4350–4352, with permission from the American Chemical Society.

dependent behaviors observed. This overview relies on the premise that in addition to the ground state, one (or more) thermally accessible excited states are populated to varying degrees over the temperature range of the NMR and EPR measurements. If only one excited state is considered, the analysis is consistent with the ground state being S = 3/2 (or largely S = 3/2) and the excited state being the high-spin state (S = 5/2) for all of the complexes except for [{$(2,6\text{-}F_2)_4$TPP}$FeOClO_3$], where the high-spin state (or largely S = 5/2) is the ground state and the intermediate-spin state (S = 3/2) is the excited state.[83] This is another example (see also Ref. 419) of *ortho*-phenyl substituents having opposite electronic effects to those of the *meta*- and *para*-phenyl counterparts.

The dodecasubstituted porphyrin macrocycles octaethyl- and octamethyltetraphenylporphyrin (OETPP and OMTPP, respectively),[420,421] and to a lesser extent tetra-(β,β'-tetramethylene) tetraphenylporphyrin (TC_6TPP),[421] are prevented from being planar macrocycles because of steric interference between the β-substituents and the phenyl rings. OETPPFeCl and OMTPPFeCl have highly saddled conformations with only a small ruffling contribution, with two opposite pyrrole rings having their β-carbons significantly above the plane of the four nitrogens, and the other two pyrrole rings having their β-carbons significantly below that plane, 1.15(11)[420,422] and 1.05(10)[420] Å, respectively. These distortions are less extreme for TC_6TPPFeCl, which also shows significantly more mixing of saddling and ruffling (Normal-coordinate Structure Decomposition (NSD) calculations for (TC_6TPP)FeCl resulted in the following lowest energy modes: B_{2u}(sad) = 1.9985, B_{1u}(ruff) = 1.3508, a small domed component, A_{2u}(dome) = 0.1457, and close to zero values for all the others).[421] The kinetics of nonplanar ring inversion for all three of these complexes, as well as $TC_6TPPFeONO_2$ have been studied by ^{1}H NMR spectroscopy,[420,421] as discussed later in Section IV.A.8.e. In all cases the Fe^{III} is out-of-plane with respect to the porphyrin nitrogens (0.43, 0.51[420] and 0.530(1)[421] Å, respectively). Unlike "flat" (Por)FeCl complexes, the ^{1}H NMR ($\delta(CH_2)_{av}$ ~ 35 ppm at ambient temperatures, curved Curie plots) and EPR ($g_\perp$ ~ 5.2–5.8, $g_\parallel$ = 2) spectra and magnetic susceptibility (μ_{eff} = 4.8–5.2 μ_B) of all three complexes show evidence of being of S = 3/2,5/2 spin-admixed iron complexes.[420,421] The nitrate complex, $TC_6TPPFeONO_2$, was found to have the metal less out-of-plane of the four nitrogens [0.359(1) Å], and to have a correspondingly higher fraction of S = 3/2 character (about 20%, as compared to 2.7% for the chloride complex).[420]

The highly ruffled intermediate-spin [(TEtPrP)Fe$(THF)_2$]$^+$ has been shown to adopt a novel $(d_{xz},d_{yz})^3(d_{xy})^1(d_{z^2})^1$ ground state, while the highly saddled porphyrin [(OETPP)Fe$(THF)_2$]$^+$ has a conventional $(d_{xy})^2(d_{xz},d_{yz})^3(d_{z^2})^1$ ground state, on the basis of the difference in *meso*-^{13}C chemical shifts (+104 vs. −244 ppm, respectively).[423] The same trend holds for the 5-coordinate perchlorate complexes

(+342 vs. –47 ppm, respectively).[423] The halide complexes of the highly ruffled F, Cl^- and Br^- complexes are high-spin, while the I^- complex adopts an admixed S = 5/2,3/2 state.[424] In contrast, the OETPPFeX complex, wher X = I, is a pure intermediate spin complex, on the basis of the *meso*-^{13}C chemical shifts.[424] Another study showed that weak donor ligands such as pyridine-N-oxide, DMSO, DMF, MeOH, THF, 2-MeTHF and dioxane create either high- or intermediate-spin iron centers depending on the structure of the porphyrin ring (TPP (flat), TiPrP (ruffled), and OETPP (saddled)). Again, *meso*-^{13}C chemical shifts were used to reach these conclusions.[425,426] The same 5-coordinate geometries can also be achieved with various 2-substituted imidazoles, and these complexes are also intermediate-spin or spin-admixed.[427]

Five-coordinate halide-ligated complexes of iron(III) porphycene and corphycene have been prepared and studied by X-ray crystallography, Mössbauer, ^1H NMR and EPR spectroscopy and SQUID magnetometry. It was found that the etioporphycene-iodide complex exhibits a mainly S = 3/2 spin state with a small amount of S = 5/2 admixture. In contrast, all of the other halide complexes of both macrocycles show the reverse, a mainly S = 5/2 spin state with a small amount of S = 3/2 admixture.[428]

Bis-ethanol complexes of iron(III) *meso*-tetrachiroporphyrinatoiron(III) (derived from (1R)-cis-caronaldehyde acid methyl ester and pyrrole), and abbreviated $(TMCP)Fe^{III}$, were formed by the reaction of the chloroiron(III) complex with $AgClO_4$ in $EtOH/CHCl_3$.[429] The crystal structures of two distinct products were obtained and found to be $[(TMCP)Fe^{III}(EtOH)_2]\ ClO_4$ and $[(TMCP)Fe^{III}(EtOH)(H_2O)]ClO_4$. Fe-O distances were long (2.173(5) – 2.272(4) Å).[429] The magnetic moment ($\mu_{eff} = 3.8\ \mu_B$), Mössbauer spectrum ($\delta = 0.35(1)$ mm s^{-1}, $\Delta E_Q = 3.79(1)$ mm s^{-1}), and EPR spectrum at 80 K ($g_\perp = 4.0$, $g_\parallel = 2.00$) were all consistent with a nearly pure S = 3/2 ($^4A_2$) ground state with very little rhombic distortion.[429] The NMR spectrum in $CDCl_3$ — EtOH showed the pyrrole-H at about –30 ppm, which is consistent with depopulation of the $d_{x^2-y^2}$ orbital;[429] no temperature of this measurement is given.

Calculations of Mössbauer and NMR data for various S = 3/2 and spin-admixed iron porphyrin complexes, covering four-, five-, and six-coordinate states and three commonly seen porphyrin conformations: planar, ruffled, and saddled have been carried out.[430] Most of the results provided reasonable comparison to experimental data.

8. *Low-Spin Iron(III) Porphyrins*

The low-spin iron(III) porphyrins have always been of major interest, and continue to be so, both because of the richness of information that can be obtained

about the nature of the orbital of the unpaired electron (this richness is aided by the good-to-excellent resolution of the spectra), and because of the relevance of this spin state to a variety of heme proteins (the ferricytochromes *a*, *b*, *c*, *d*, *f* and *o*, the cyanomet forms of the dioxygen-carrying proteins myoglobin and hemoglobin, the cyanide complexes of a number of peroxidases and other related heme oxidases and monooxygenases).

For a number of years it was accepted that low-spin iron(III) hemes have a $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, with spin delocalization via P → Fe π donation from the filled 3e(π) porphyrin orbitals to the single hole in the d_{xz},d_{yz} set, which leads to π contact shifts being observed at the β-pyrrole positions and no π contact shifts at the *meso* positions.[2,4] In addition, it has been shown that pseudocontact shifts, at least at the β-pyrrole carbons, are much smaller than contact shifts for this electron configuration, and a factoring method was developed, based on the axial geometric factors $((3\cos^2\theta - 1)/r^3)$ of the protons at various locations around the heme and the supposition that there was no contact shift at the *meso* positions (Refs. 2, 4, and references therein), as discussed in Sections II.C and D. This method was found to work well for bis-(imidazole) complexes of iron(III) porphyrins, but somewhat less well for dicyano and bis-(pyridine) complexes, in that order.[2–4] The reason for the increasing failure of the supposition that there was no contact shift at the *meso* positions was variously ascribed to "polarization" of the σ electronic system by the π-symmetry unpaired electron and increased π-bonding interactions of the porphyrin ring with the metal due to weaker σ-bonding from axial ligands to iron(III).[2,4] New results from a number of laboratories, discussed below, clarify this situation to show the importance of delocalization from the filled $3a_{2u}(\pi)$ orbital into the half-empty d_{xy} orbital in ruffled ferriheme complexes which are bound to strong π-acceptor ligands such as alkyl or aryl isocyanides. The $3a_{2u}(\pi)$ orbital has very large electron density at the *meso* carbons (Figure 2), but very small electron density at the β-pyrrole carbons. For other ligand complexes that also have ruffled conformations, there can be partial mixing of a d_{xy} component into a largely $(d_{xz},d_{yz})^3$ electron configuration, but the very large electron density at the *meso* carbons (Figure 2) means that even a small amount of d_{xy} mixing can increase the spin density at the *meso* carbons rather dramatically.

Although the pseudocontact shifts at the β-pyrrole carbons of low-spin ferrihemes are relatively small, it is desirable to calculate them according to Eq. 7, and to do so it is necessary to know the principal values of the magnetic susceptibility tensor, χ_{ii}. Furthermore, the pseudocontact shifts at the *meso*-carbons of low-spin ferrihemes are much larger than the contact shifts, as shown in Figures 9 and 10. However, these principal values of the magnetic susceptibility tensor are usually not available, especially for model hemes. Hence, the principal values of the g-tensor, g_{ii}, which are often readily available from EPR spectroscopy or a combination of

EPR and magnetic Mössbauer spectroscopies,[131,431] are used (Eq. 9), with the cautionary notes concerning the importance of the SOZ contribution presented in Section II.A. Thus, the g-values of a large range of complexes have been measured, and a representative group of these is presented in Table 12, where the axial g-anisotropy factor, $[g_{zz}^2 - (1/2)\,(g_{xx}^2 + g_{yy}^2)]$ or $g_{\|}^2 - g_{\perp}^2$, which is proportional to the axial pseudocontact shift, and the rhombic g-anisotropy factor, $g_{xx}^2 - g_{yy}^2$, which is proportional to the rhombic pseudocontact shift (see Section II.A.2), as well as the Δ/λ and V/Δ d-orbital splitting parameters and percent d_{xy} character of the orbital of the unpaired electron, discussed below, are also included. It can be seen from the data of Table 12 that the axial anisotropy increases in the order ImH < CN^-, and that the axial anisotropy of pyridine complexes depends strongly on the particular pyridine and the particular porphyrin. It is clear from the calculated axial anisotropies based on EPR g-values that the pseudocontact contribution to the paramagnetic shift should increase in the order ImH < CN^- < Py, for all but the least basic pyridines, but this is not usually observed.[2,4] In fact, the pseudocontact contribution usually decreases, while the contact contribution to the paramagnetic shift of *meso* substituents increases. This point is related to a change in the electronic ground state from $(d_{xy})^2(d_{xz},d_{yz})^3$ to $(d_{xz},d_{yz})^4(d_{xy})^1$, and will be discussed further below. For the time being, one should note that not only have bis-(imidazole), dicyano and bis-(pyridine) complexes of iron(III) porphyrins been studied, but also bis-(isonitrile), bis-(ammine), bis-(amino ester), bis-(phosphine), and mixed imidazole-imidazole, imidazole-imidazolate, imidazole-pyridine, pyridine-cyanide, imidazole-cyanide, imidazole-phosphine and a number of other mixed-ligand complexes. Each of these combinations has special features that will be discussed separately. First, the g-values of low-spin iron(III) porphyrins will be discussed, including those which have the historically common $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration, those which clearly have the increasingly recognized $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration, as well as those for which it is not clear what the electron configuration is.

a. *Griffith's three-orbital theory and experimental EPR data for low-spin iron(III) porphyrins and related macrocycles*

Extensive investigations of the molecular structures, EPR and NMR spectra, and in some cases Mössbauer spectra of well-defined low-spin ferriheme model compounds with imidazoles, high-basicity pyridines, pyrazoles, cyanide ions or organic isocyanides as the axial ligands have provided conclusive evidence of the existence of two different types of $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state complexes, one of which is characterized by single-feature EPR signals[431,432] known as "large g_{max}" or HALS (highly-anisotropic low-spin) signals (Figure 38a) that are only observed

Table 12. The g-values of selected low-spin iron(III) porphyrins and ferriheme proteins.

Table 12. (*Continued*)

[a]Unless otherwise indicated, calculations using g_1, g_2, and g_3 assume $g_1 = g_{zz}$, $g_2 = g_{yy}$, $g_3 = g_{xx}$

[b]$(g_{||}^2 - g_{\perp}^2) = [g_{zz}^2 + (1/2)(g_{xx}^2 + g_{yy}^2)]$, the axial magnetic anisotropy term in Eq. 9.

[c]$(g_{xx}^2 - g_{yy}^2)$ is the rhombic magnetic anisotropy term in Eq. 9.

[d]The tetragonal splitting of the d-orbitals. Calculated from Eq. 32.

[e]The rhombic splitting of the d-orbitals. Calculated from Eq. 31.

[f]Calculated from Eqs. 29, 30.

[g]$\%d_{xy} = 100c^2$.

[h]Watson and Walker, unpublished data.

[i]Unknown; $|g_{xx}^2 + g_{yy}^2|$ expected to be small.

[j]Calculated from $g_{zz}^2 + g_{yy}^2 + g_{xx}^2 = 16$.[453]

[k]Calculated assuming the same assignment of g-values as that given in a). Leads to $V/\Delta > 2/3$, and indicates an "improper" axis system.[448]

[l]Axis system known (by ESEEM investigations) to be that defined in a).

[m]Only a high spin signal observed; either complex did not form, or else it is high spin.

[n]Calculated assuming $g_1 = -g_{xx}$, $g_2 = g_{yy}$, $g_3 = -g_{zz}$. Gives rise to small V/Δ, which suggests a "proper" axis system.[448]

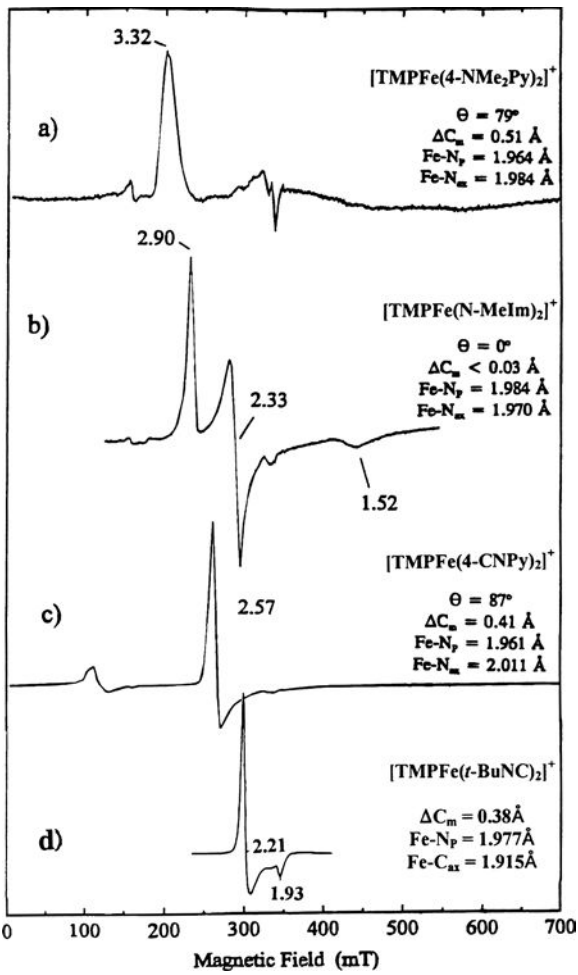

Figure 38. Typical types of EPR spectra exhibited by low-spin ferriheme complexes. (a) "large g_{max}," as in the case of $[(TMP)Fe(4\text{-}NMe_2Py)_2]^+$; b) normal rhombic, as in the case of $[(TMP)Fe(NMeIm)_2]^+$; (c) axial, with large difference between $g_{\|}$ and $g_{\perp}$, as in the case of $[(TMP)Fe(4\text{-}CNPy)_2]^+$; d) axial, with small difference between $g_{\|}$ and $g_{\perp}$, as in the case of $[(TMP)Fe(t\text{-}BuNC)_2]^+$. Relative orientation of the axial ligands is given in each case by θ. Both Fe-N(porphyrin) and Fe-axial ligand bond lengths are given, as well as the deviation of the *meso*-carbons from the mean plane of the porphyrin ring, ΔC_m, a measure of ruffling. In (a)–(c), minor impurity signals are also observed. Reprinted from Walker, F. A. *Coord. Chem. Revs.* **1999**, *185-186*, 471–534, with permission from Elsevier Publishing Company.

at very low temperatures (4–20 K), while the other of which is characterized by well-resolved rhombic EPR signals (Figure 38b) that are usually observed at temperatures up to 77 K. EPR signals of the former type had been observed for a number of poorly-characterized low-spin ferriheme centers in membrane-bound proteins, particularly those of the *b* hemes of mitochondrial Complex III,[433,434]

which are now known to have bis-histidine coordination.[435–439] Correlated structural and EPR studies have provided proof that the "large g_{max}" EPR signal is indicative of near-degeneracy of d_{xz} and d_{yz}.[431,432,434] For complexes with planar axial ligands, near-degeneracy correlates with perpendicular alignment of these ligands.[32–34,131,431,440]

The other type of $(d_{xy})^2(d_{xz},d_{yz})^3$ ground-state complexes, which has well-resolved rhombic EPR signals (Figure 38b), and includes all of the cytochromes b_5,[441] mitochondrial cytochrome *a*,[442] and methemoglobin-imidazole,[443] among many other heme proteins, some of whose EPR parameters are summarized in Table 12, are found to have parallel or near-parallel alignment of the planar axial ligands and marked difference in energy between d_{xz} and d_{yz}. Rhombic EPR spectra and the data derived from them were previously analyzed by Blumberg and Peisach using their "Truth Diagrams" to predict the axial ligands of each ferriheme protein center that gave rise to such a spectrum.[444–447] More recently, Taylor,[448] and later a number of other workers,[449–451] have discovered EPR spectra that are nearly or strictly axial, and have provided evidence that such spectra are indicative of the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration, in which g_{zz} is the smallest, rather than the largest g-value, as shown in Figures 38c, and d.

The theory developed by Griffith for low-spin ferriheme complexes assumed that the $d_{x^2-y^2}$ and d_{z^2} (σ-bonding) orbitals were very high in energy and thus did not mix with the other three d-orbitals, and thus were not involved in determining the g-values of complexes of this spin state.[452,453] Therefore, he developed a 3-orbital model for the g-values of low-spin ferrihemes. This approach was much later developed by Taylor[448] to provide expressions that allowed calculating the relative energies of the d_{yz}, d_{xz} and d_{xy} from the g-values. The wave functions of the lowest-energy Kramers doublet are given by:

$$\begin{aligned} |+\rangle &= a|d_{yz}^{+}\rangle - ib|d_{xz}^{+}\rangle - c|d_{xy}^{-}\rangle, \\ |-\rangle &= -a|d_{yz}^{-}\rangle - ib|d_{xz}^{-}\rangle - c|d_{xy}^{+}\rangle, \end{aligned} \tag{29}$$

and the normalization condition

$$a^2 + b^2 + c^2 = 1.000, \tag{30}$$

should hold. The three former t_{2g} orbitals are thus mixed by spin-orbit coupling; the three g-values are then given in terms of the mixing coefficients *a*, *b* and *c* as:[448]

$$g_{xx} = 2[a^2 - (b + c)^2]; \quad g_{yy} = 2[(a + c)^2 - b^2]; \quad g_{zz} = 2[(a + b)^2 - c^2]. \tag{31}$$

Thus, the experimental g-values of low-spin iron(III) complexes can be used to calculate the orbital mixing coefficients, and thereby provide information as to the individual d-orbital character of the orbital of the unpaired electron. In some cases two of the g-values must be measured by single crystal EPR spectroscopy,[440,454–457] or estimated from Mössbauer spectra at 4.2 K in the presence of an applied magnetic field.[33,431,458] Taylor[448] showed that the g-values could also be utilized to calculate the energy separation of the three formerly t_{2g} orbitals:

$$\frac{V}{\lambda} = \frac{E_{yz} - E_{xz}}{\lambda} = \frac{g_{xx}}{g_{zz} + g_{yy}} + \frac{g_{yy}}{g_{zz} - g_{xx}}, \tag{32}$$

$$\begin{aligned} \frac{\Delta}{\lambda} &= \frac{E_{yz} - E_{xy}}{\lambda} - \frac{V}{2\lambda}, \\ &= \frac{g_{xx}}{g_{zz} + g_{yy}} + \frac{g_{zz}}{g_{yy} - g_{xx}} - \frac{V}{2\lambda}, \end{aligned} \tag{33}$$

where V is the energy difference between the d_{xz} and d_{yz} orbitals, Δ is the energy difference between the d_{xy} and the average of the d_{xz} and d_{yz} orbitals, and λ is the spin-orbit coupling constant, whose value is 460 cm^{-1} for the free ferric ion[459] and somewhat smaller for fairly covalent iron(III) complexes such as the ferriheme centers of interest here.[460] The results of such calculations indicate that the parallel orientation is lower in energy for those cases in which the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^3$.[431]

One complication in using Eqs. 32 and 33 to determine the energy separations of d_{xy}, d_{xz}, and d_{yz} is that EPR measurements allow calculation of the magnitude, but not the sign, of the g-values of the paramagnetic center. Common use of the expressions derived by Taylor[448] usually assumes that the product of the three g-values, $g_{xx}g_{yy}g_{zz}$, is positive, as has been shown for several heme proteins by Münck, Huynh and coworkers.[461] Furthermore, Taylor showed that $g_{zz} + g_{yy} - g_{xx}$ must be positive.[448] These two conditions, along with Eq. 31, limit the possible choices of signs for the measured g-values. Most workers have also assumed that:

$$g_{xx}^2 + g_{yy}^2 + g_{zz}^2 = 16. \tag{34}$$

This expression allows the third g-value to be estimated in cases in which g-strain precludes its direct measurement,[462] as has been done for many of the "large g_{max}" centers listed in Table 12. However, while this limit appears to hold for systems having fairly pure $(d_{xy})^2(d_{xz},d_{yz})^3$ ground states, it has been shown that for systems having fairly pure $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, the sum of the squares of the g-values

has been reported to be as small as 13.1–13.5 for bis-(isocyanide) complexes,[449,463] and could be as small as 12, in the limit of no spin-orbit mixing of d_{xy} with the two d_π orbitals.[129,449,463]

The EPR parameters for a number of low-spin ferriheme models and proteins having "large g_{max}", normal rhombic and near-axial types of spectra are included in Table 12. Based on the orbital mixing coefficients, *a*, *b* and *c*, the orbital of the unpaired electron in all of the cases presented in Table 12 is a mixture of contributions from the three formerly t_{2g} orbitals. In particular, for the bis-isonitrile complexes of (TPP)Fe^{III}, the unpaired electron is largely in the d_{xy} orbital (and thus Δ/λ is negative),[449] but small amounts (0.4% each) of the d_{xz} and d_{yz} orbitals are mixed into the orbital of the unpaired electron. As is evident, high-basicity pyridine and imidazole complexes of iron(III) porphyrinates have been shown to be good models,[33,431] of the bis-(histidine)-coordinated cytochromes a, b and c that are involved in electron transfer in a large number of organisms, including cytochromes b_5,[444,464] and c_3,[465,466] as well as the membrane-bound cytochromes b recently shown to have bis-(histidine) coordination, including the two b hemes of mitochondrial "Complex III" (also known as ubiquinone-cytochrome c oxidoreductase)[434–439] and those of chloroplast cytochrome b_6.[467–470] The g-values of all of these complexes clearly indicate that the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^3$, and all have $g_{zz} > g_{yy} > g_{xx}$.[434]

For some years it was common practice to assign the largest g-value to the direction of the heme normal, on the basis of results of studies of several proteins, including single crystal EPR data for cytochrome *c*,[471] methemoglobin cyanide[443] and several model hemes.[440,455] On the basis of Griffith's theory[452,453] and Taylor's formulation,[448] this assignment was consistent with the d_{yz} orbital being the major contributor to the orbital of the unpaired electron, that is, a~1. However, Taylor showed that this sometimes leads to larger calculated energy separations between d_{xz} and d_{yz} (V/λ) than between their average and the lowest-energy d_{xz} orbital (Δ/λ), a situation that he described as an "Improper Axis System."[448] In such cases, he suggested, by permutation of the assignment of g-values one could arrive at calculated ligand field energy differences that obeyed the expected relationship $V/\lambda < 2/3$. This permutation typically led to a change in the major contributor to the orbital of the unpaired electron from (d_{xz},d_{yz}) to d_{xy}, that is, c~1, and indicated that d_{xy} was higher in energy than d_{xz} and d_{yz}, and thus yielded the "novel" electron configuration $(d_{xz},d_{yz})^4(d_{xy})^1$. Examples of systems, for which this permutation of the assignment of g-values was found to be necessary, included the bis-imidazole complex of octaethyl- and tetraphenylchloriniron(III),[448] the bis-(4-cyanopyridine),[129] -(*t*-butylisocyanide)[463] and –(2,6-xylylisocyanide)[449] complexes of (TPP)Fe^{III} and the bis-pyridine complex of $((C_3F_7)_4P)Fe^{III}$,[132] although the latter has g-values extremely close to those of a free radical, and thus may be a low-spin d^6 Fe^{II} center coordinated to a porphyrin π-cation radical, $P^{-\bullet}$.

Another type of complex that also appears to have this electronic ground state is that derived from *meso*-hydroxyoctaethylporphyrinatoiron(III) either by formation of the benzoyloxy esters[321] or by simple deprotonation of the hydroxy group to form the macrocycle known as an oxophlorin, OEPO, Structure **8**.[321,472–475] The NMR spectra of [OEPOFe(Py)$_2$] in $CDCl_3$ show four methylene resonances with chemical shifts that range from +33 to −2 ppm and *meso*-H resonances at −110 (2) and −153 (1) ppm. The EPR spectrum is axial with $g_\perp = 2.30$, $g_\parallel = 1.76$, and the sum of the squares of the g-values = 13.68,[472] rather than 16 Eq. 33. The authors suggested possible electron configurations of [(Py)$_2$Fe^{II}(OEPO$^{\bullet}$)] or [(Py)$_2$Fe^{III}(OEPO^{-})].[472] They later described it as the latter, although they have also said it can be described by any of three canonical structures, the third being [(Py)$_2$Fe^{I}(OEPO^{+})].[475] This system is discussed further in Section IV.A.8.f.

The preparation and characterization of bis-imidazole and bis-pyridine complexes of octamethyltetraphenylporphyrinatoiron(III), OMTPPFe^{III}, octaethyltetraphenylporphyrinatoiron(III), OETPPFe^{III}, and tetra-β,β'-tetramethylenetetraphenylporphyrinatoiron(III), TC_6TPPFe^{III}, have been reported: *paral*-[FeOMTPP(NMeIm)$_2$]Cl, *perp*-[FeOMTPP(NMeIm)$_2$]Cl, [FeOETPP(NMeIm)$_2$]Cl, [FeTC_6TPP(NMeIm)$_2$]Cl, [FeOMTPP(4-Me$_2$NPy)$_2$]Cl, and [FeOMTPP(2-MeImH)$_2$]Cl.[476] Crystal structure analysis shows that *paral*-[FeOMTPP(NMeIm)$_2$]Cl has its axial ligands in close to parallel orientation (dihedral angle = 19.5°), while *perp*-[FeOMTPP(NMeIm)$_2$]Cl has the axial imidazole ligand planes oriented at 90° to each other and 29° away from the closest N_P–Fe–N_P axis. [FeOETPP(NMeIm)$_2$]Cl has its axial ligands close to perpendicular orientation (dihedral angle = 73.1°). In all three cases the porphyrin core adopts relatively purely saddled geometry.[476] The [FeTC_6TPP(NMeIm)$_2$]Cl complex is the most planar and has the highest contribution of a ruffled component in the overall saddled structure compared to all other complexes in this study. (The estimated numerical contribution of saddled and ruffled components is 0.68:0.32, respectively.) Axial ligand planes are perpendicular to each other and 15.3° away from the closest N_P–Fe–N_P axis. The Fe–N_P bond is the longest in the series because [FeTC_6TPP(NMeIm)$_2$]Cl has the least distorted porphyrin core. In addition to these three complexes, two crystalline forms each of [FeOMTPP(4-Me$_2$NPy)$_2$]Cl and [FeOMTPP(2MeImH)$_2$]Cl were obtained. In all four of these cases the axial planes are in nearly perpendicular planes in spite of quite different geometries of the porphyrin cores (from purely saddled to saddled with 30% ruffling). The EPR spectral type correlates with the geometry of the OMTPP, OETPP and TC_6TPP complexes.[476] For the *paral*-[FeOMTPP(NMeIm)$_2$]Cl, a rhombic signal with g = 2.71, 2.51, 1.54 is consistent with nearly parallel axial ligand orientation. For all other complexes of this study, "large g_{max}" signals are observed ($g_{max} = 3.61 – 3.27$), as are observed for nearly perpendicular ligand plane arrangement. On the basis of this and previous work, the change from "large g_{max}"

to normal rhombic EPR signal occurs between axial ligand plane dihedral angles of 70° and 30°.[476] Additional complexes were prepared, including two imidazole, N-benzylimidazole, and N-methylimidazole complexes, [(OETPP)Fe(ImH)$_2$]Cl, [(OETPP)Fe(NBzIm)$_2$]Cl, and [(OETPP)Fe(NMeIm)$_2$]Cl.[477] Despite large variation in axial ligand size and major saddling of the porphyrin core, the unit cell parameters for all complexes are very similar; each structure has the same basic motif, with large voids formed by the extended porphyrin framework (filled by ordered or disordered axial ligands and disordered solvent), which allows differently sized ligands to fit within the same cell dimensions.[477] Each porphyrin core adopts a saddled conformation with $|\Delta C_\beta|$ = 1.13–1.15 Å. The dihedral angles between axial ligand planes, $\Delta\varphi$, are far from being either ideal parallel or perpendicular: 30.1°, 57.2° for [(OETPP)Fe(ImH)$_2$]Cl (molecules **1** and **2**), 56.8° for [(OETPP)Fe(NBzIm)$_2$]Cl, and 16.0°, 44.6°, 59.6°, and 88.1° for [(OETPP)Fe (NMeIm)$_2$]Cl, which has disordered axial ligands.[477]

Among the complexes of this study,[477] an axial ligand $\Delta\varphi$ of 56.8° is found to be the largest "parallel" angle (as defined by the observation of a normal rhombic or Type II, Figure 38, EPR signal[131] (N-BzIm, g = 3.08, 2.19, 1.31)), while 57.2° is found to be the smallest "perpendicular" $\Delta\varphi$ (as defined by the observation of a "large g_{max}" or Type I EPR signal (ImH, g_{max} = 3.24)). From the results of this and previous studies,[476,478] it appears that the size of the largest g for Types I and II[131] complexes varies continuously, with no break between the two,[477] as shown in Figure 39. While the switch in EPR signal type, from Type II to Type I,[131] appears to be very sharp in this study,[477] this may be somewhat artificial based on limited numbers of examples and the required saddle distortion of the (OETPP)Fe^{III} complexes. However, in comparison to several proteins with dihedral angles near 60° and Type II EPR spectra,[131] it was concluded that the switch in EPR signal type occurs near 57° ± 3–5°.[477]

Bis-pyridine complexes where the pyridine ligand ranges in basicity from 3,4-dimethylpyridine to 4-acetylpyridine have axial EPR spectra with $g_\perp$ in the range of 2.31 to 2.20 and $g_\parallel$ in the range of 1.73 to 1.90, respectively, as shown in Figure 51B, and were originally interpreted as being π-cation radicals of the iron(II) macrocycle.[321] However, these g-values deviate much too much from 2.0 to represent porphyrin-based unpaired electrons. As discussed in Section IV.A.8.c, there is obviously quite a bit of porphyrin $a_{2u}(\pi)$ character to the delocalized unpaired electron density, but based on the g-values (and the NMR spectra discussed below) the electron configuration of the 6-coordinate oxophlorin complexes is low-spin iron(III) with a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state. For the chlorin and isobacteriochlorin complexes the EPR spectra are rhombic with close spacing of the two largest g-values, while in all of the porphyrin complexes of this ground state the EPR spectra are axial (Table 12). There are however, a number of cases for which V/Δ has

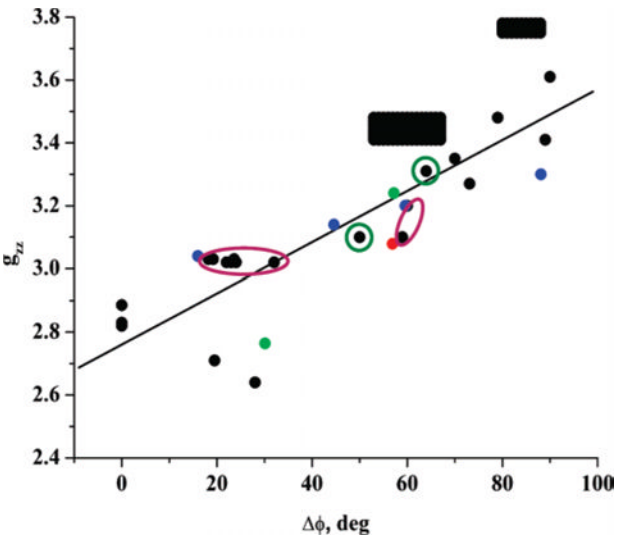

Figure 39. Correlation of the largest *g* value with the dihedral angle between axial ligand planes. Symbols: black, structures and *g* values reported previously are generally from Table 13 except for the points in color: red, N-benzylimidazole complex, 100% $\Delta\varphi = 56.8°$; green, HIm complex, 50% $\Delta\varphi = 30.1°$, 50% $\Delta\varphi = 57.2°$; blue, N-methylimidazole complex, 32% 16.0°, 45% 44.6°, 10% 59.6°, 13% 88.1°. The two points represented as black rectangles, centered at 60° and 84°, represent the range of *g* values and the average current histidine imidazole plane dihedral angles of the b_H and b_L hemes, respectively, of 10 recent structures of Complex III from a wide range of species, with the deviations from the averages for each shown by the width and height of the two rectangles. Proteins other than Complex III cytochromes *b* are enclosed in ovals or circles, purple for water-soluble proteins and green for membrane-bound proteins. Reprinted from Yatsunyk, L. A.; Dawson, A.; Carducci, M. D.; Nichol, G. S.; Walker, F. A. *Inorg. Chem.* **2006**, *45*, 5417–5428, with permission from the American Chemical Society.

been shown to be greater than two-thirds in systems that are unequivocally $(d_{xy})^2(d_{xz},d_{yz})^3$ ground states,[135,136,479,480] especially when the properties of the NMR spectra, discussed later in Section IV.A.8.b are considered. This calls into question the validity of the "Proper Axis System" rule,[448] and clarifies the fact that low-spin iron(III) chlorins, when bound to most nitrogen heterocycles *do not* have $(d_{xz},d_{yz})^4(d_{xy})^1$ ground states, but rather have $(d_{xy})^2(d_{xz},d_{yz})^3$ ground states, even though $V/\Delta > 2/3$.[138]

A part of the inconsistency between EPR and NMR results in such cases is that there are a number of systems which have a different electronic ground state at low temperatures, at which EPR studies are typically done, than they do at ambient temperatures, at which NMR studies are typically done. Such a case was shown to be that of the *t*-butylperoxide adduct of [TPPFe(OCH_3)],[481] which was unequivocally shown by pulsed EPR spectroscopy to have a $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic

ground state at 4.2 K, but a thermal equilibrium between the $(d_{xy})^2(d_{xz},d_{yz})^3$ and $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configurations by NMR spectroscopy at 178 K that became almost pure $(d_{xz},d_{yz})^4(d_{xy})^1$ at higher temperatures. The temperature dependence of the ^{13}C chemical shift of the *meso*-^{13}C of the TPP ligand of $[TPPFe(OCH_3)(OO^tBu)]^-$ was followed between 178 and 231 K in toluene-d_8, and was found to reverse chemical shift directions at about 195 K.[481] Above that temperature the ^{13}C chemical shift of the *meso*-^{13}C of the TPP exhibits anti-Curie temperature dependence. However, *the temperature dependence cannot be fit by assuming a thermally-accessible excited state*.[481] Rather, *it can only be fit by assuming a thermodynamic equilibrium between a planar heme conformation with an electron configuration* $(d_{xy})^2(d_{xz},d_{yz})^3$ *that is stable at very low temperatures* (at which the pulsed EPR spectral investigations were performed), *and a ruffled heme conformation with an electron configuration* $(d_{xz},d_{yz})^4(d_{xy})^1$ *that is stable at ambient temperatures*[481] (at which the NMR spectral investigations were performed). There are undoubtedly a number of other such examples that have not as yet been investigated carefully.

Iron(III) chlorin complexes, such as $[(TPC)Fe(ImH)_2]^+$,[483] have been particularly problematic in defining their electronic ground state. On the basis of his "Proper Axis System" rule Taylor assigned the electronic ground state of $[(TPC)Fe(ImH)_2]^+$ and $[(OEC)Fe(ImH)_2]^+$ to be $(d_{xz},d_{yz})^4(d_{xy})^1$,[448] with g_{zz} thus being the smallest g-value. This has been accepted by all those who have since studied iron(III) chlorins. However, the author's research group found that ESEEM and ENDOR data obtained at 4.2 K are consistent with g_{zz} being the largest g-value,[139] and the NMR data to be discussed below, obtained over the temperature range −90 to +30 °C, are consistent with the $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, with g_{zz} being the largest g-value.[115,482] Interestingly, the magnitudes of the three g-values of the chlorin complex $[(OEC)Fe(ImH)_2]^+$ (2.51, 2.37, 1.71)[135] are very similar to those of $[(TPP)Fe(PzH)_2]^+$ (2.64, 2.36, 1.71),[135] and the ground state of the former is the same as that of the latter.[139]

There are therefore two quite distinct, limiting ground states for low-spin iron(III) porphyrinates that give rise to three different types of EPR spectra: (1) the generally observed $(d_{xy})^2(d_{xz},d_{yz})^3$ state, for which $g_{zz} > g_{yy} > g_{xx}$, and for which the EPR spectra may be either rhombic or "large g_{max}" in appearance, depending on the relative orientation of planar axial ligands, and (2) the $(d_{xz}, d_{yz})^4(d_{xy})^1$ state, for which $g_{xx} \sim g_{yy} > g_{zz}$, where the d_{xz},d_{yz} pair are degenerate, or nearly so, and below the d_{xy} orbital in energy. For symmetrical porphyrinate rings, this latter electronic state leads to an axial EPR spectrum, with $2.6 \geq g_\perp > 2 > g_\parallel$,[129,132,449,463] and $g_\parallel$ may not be resolved due to g-strain. Equations 28–32 can be utilized to determine the energy differences among the three orbitals, and will be found to have the order shown in Figure 2, left-hand side. For this electron configuration, Eq. 33 does not

hold, but rather, the sum of the squares of the g-values is markedly less than 16, though usually larger than 13. It is becoming increasingly clear that the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state is not as uncommon or "unusual" as might have been thought, although not all workers have recognized their systems as being low-spin iron(III) complexes of the "unusual" ground state, rather than low-spin d^6 iron(II) π-cation radicals.

b. *NMR studies of low-spin iron(III) porphyrins having the $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state*

Bis-imidazole and -high-basicity pyridine complexes of synthetic and natural ferrihemes are the epitome of the $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state, as has been seen earlier on the basis of their EPR spectra. The ~1.9% d_{xy} character of the orbital of the unpaired electron (Table 12) via spin-orbit coupling is not readily noticed. Thus, spin delocalization is observed almost entirely to the pyrrole-H positions and only to an extremely small extent to the *meso* positions, consistent with P $\rightarrow$ Fe π delocalization via the 3e(π) filled orbitals of the porphyrin,[2,4] Figure 2. In addition, there can be pseudocontact shifts of the *meso*-H of approximately −6 ppm for synthetic and natural ferrihemes, and much more variable pseudocontact shifts for ferriheme proteins (Figure 10).

Paramagnetic shifts of the protons of the porphyrin, and their separation into contact and pseudocontact contributions, of the bis-imidazole complexes of iron(III) with symmetrical synthetic porphyrins such as tetraphenylporphyrin (TPP), 5,10,15,20-tetra-(*n*-propyl)porphyrin (T-*n*-PrP) and octaethylporphyrin (OEP), as well as a number of natural porphyrins, and the nature of spin delocalization to the imidazole ligand, have been reviewed.[2,3,41] The proton NMR spectra of $[(TPP)Fe(NMeIm)_2]^+$ and $[(OEP)Fe(NMeIm)_2]^+$ are presented earlier in this chapter in Figures 19 and 21a, respectively. There have been a number of investigations of (1) the effect of porphyrin substituents on the pattern of spin delocalization, (2) the effect of imidazole deprotonation on the pattern and extent of spin delocalization, and (3) the effect of imidazole plane orientation on the paramagnetic shifts of porphyrin protons, each of which were reviewed in detail in 1993.[3] Therefore, each of those topics will be summarized only briefly.

i. Effect of porphyrin substituents on the pattern of spin delocalization

The effect of porphyrin substituents was first studied by La Mar, Caughey and coworkers on the bis-cyanide complexes of a number of naturally-derived ferrihemes.[2,4,168,169] These NMR studies showed that the spread of the heme methyl resonances is strongly dependent on the nature of the 2,4-substituents of the heme,

Structure **1**, in a manner that may now be interpreted as being a function of both the electron density distribution in each of the 3e(π) orbitals as modified by the electronic effects of the substituents,[211] and the energy separation between the two.[25] Since then, a number of studies of bis-cyanide complexes of naturally-occurring and synthetic ferrihemes have shown that in certain cases the ground state of the low-spin iron(III) is not purely $(d_{xy})^2(d_{xz},d_{yz})^3$, as will be discussed further in Section IV.A.8.d, but this complication was not present in the original study. This early study is a benchmark in our understanding of the effect of substituents on the pattern of spin delocalization in the porphyrin ring of low-spin iron(III) porphyrins. The methyl chemical shifts of a representative series of these complexes were shown above in Figure 22. Recently it has been shown that in addition to using pseudocontact shifts in the solution structure determination of low spin ferriheme proteins, the contact shifts of propionate α-protons can also be used as further structural constraints, with the propionates of rat cytochrome b_5 having been refined in this way.[484]

The pattern of paramagnetic shifts of unsymmetrically phenyl-substituted derivatives of $[(TPP)Fe(NMeIm)_2]^+$ has been reviewed in detail elsewhere.[3] Examples of the spectra of such complexes are shown above in Figures 17 and 20a. Series of mono-*meso*-substituted TPPs have been synthesized and investigated by NMR spectroscopy.[419,485,486] It was found that for unsymmetrically substituted TPPs of the type $[((X)_1(Y)_3TPP)Fe(NMeIm)_2]^+$, where X and Y are located in the *meta*- or *para*-position of its respective phenyl ring, the pyrrole-H resonance, centered at about ~−16 ppm at 33 °C for the parent compound, $[(TPP)Fe(NMeIm)_2]^+$, is split into either three signals of intensity 1:1:2 (or four signals of equal intensity, where the two signals with largest negative chemical shift are very close together) if X is more electron-withdrawing than Y or 2:1:1 (or four signals of equal intensity having the two signals with least negative paramagnetic shift very close to each other) if X is more electron-donating than Y. However, for mono-*ortho*-X or 2,6-X_2 (Y = *p*-OCH_3) derivatives, the pattern is that expected for an electron-donating substituent, even when X is a halogen,[419] as shown in Figure 40. The apparently anomalous behavior of *ortho*-substituents was hypothesized to be due to direct overlap of the electron cloud of the halogen with that of the π system of the porphyrin ring.[419] Vangberg and Ghosh[487] have reported density functional calculations that support this hypothesis.

The EPR g-values of all of the unsymmetrically substituted $(TPP)Fe^{III}$ complexes are essentially identical,[488] so the variation in the spread of the pyrrole-H resonances must be largely due to a change in the contact contribution as the difference in electron-donating/withdrawing properties of the phenyl substituents increases, which suggests redistribution of the spin density in response to the difference in electronic effects of the substituents.

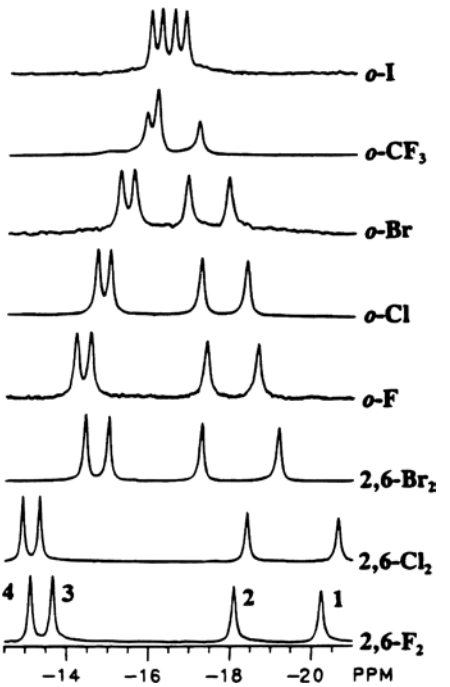

Figure 40. ^{1}H NMR spectra of the pyrrole-H resonances of the low-spin iron(III) complexes [((*o*-X)- or (2,6-X_2))(*p*-OCH_3)$_3$TPP)Fe(NMeIm)$_2$]$^+$ in $CDCl_3$ at 33 °C. Reprinted from Koerner, R.; wright, J. L.; Nesset, M. J. M.; Ding, X. D.; Aubrecht, K.; Watson, R.; Barber, R. A.; Tipton, A. R.; Norvell, C. J.; Mink, L. M.; Simonis, U.; Walker, F. A. *Inorg. Chem.* **1998**, *37*, 733–745, with permission from the American Chemical Society.

Both high- and low-spin ferriheme derivatives of (TPP)Fe^{III} in which there is a single substituent on one of the β-pyrrole positions, the 2-position, have been prepared and investigated by Latos-Grażyński and coworkers.[223] For the low-spin bis-cyanide complexes in methanol-d_4, a wide range of patterns of pyrrole-H resonances for the remaining seven pyrrole protons was observed, as shown in Figure 41. The insert is that of the pyrrole-H resonances of the 2-deuterium complex, which show that even the very small change in substituent, from H to D, breaks the symmetry of the remaining pyrrole-H resonances and creates a measurable substituent effect, particularly for the 3-H. In some cases it was possible to assign all pyrrole-H resonances using NOESY techniques, as shown in Figure 16. Both the patterns and the average chemical shift of the pyrrole-H resonances vary significantly, and in no case are the average shifts of the pyrrole-H indicative of a pure $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state (−7 to −2 ppm at 293 K),[223] in spite of a possible contribution of hydrogen-bond donation from the solvent to the coordinated cyanide.[488] Thus, although a detailed analysis of the pseudocontact (small) and

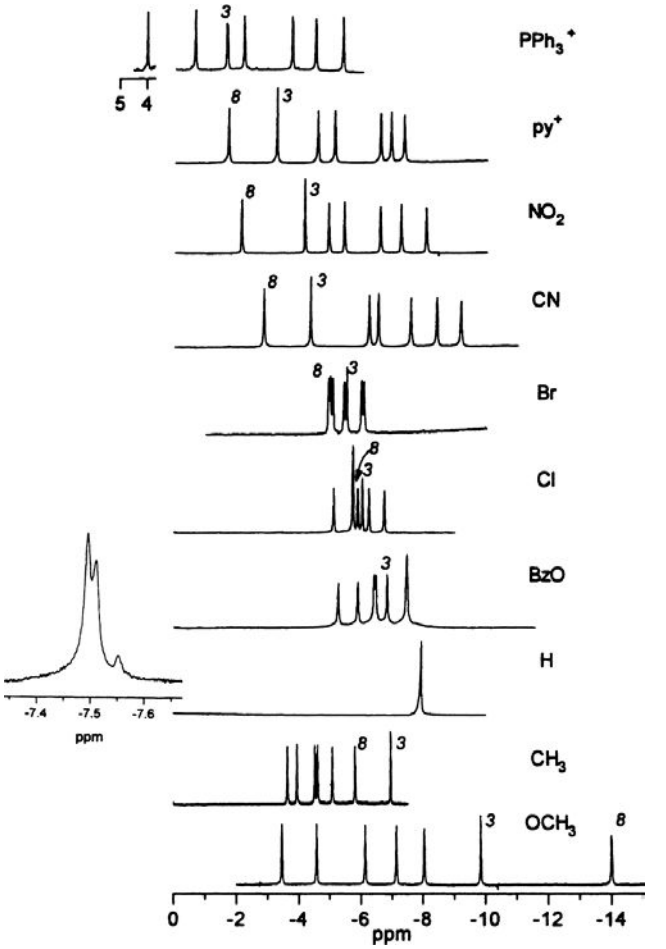

Figure 41. 300 MHz ^{1}H NMR spectra of the pyrrole region of a series of low-spin [(2-X-TPP)$Fe^{III}(CN)_2$]$^-$ complexes in methanol-d_4 at 293 K. X substituents are marked on each trace. The most characteristic 3-H and 8-H pyrrole resonances are labeled by 3 and 8, respectively. The X = D pyrrole-H pattern is shown in the insert to the left of the other spectra. Reprinted from Wojaczyński, J.; Latos-Grażyński, L.; Hrycyk, W.; Pacholska, E.; Rachlewicz, K.; Szterenberg, L. *Inorg. Chem.* **1996**, *35*, 6861–6872, with permission from the American Chemical Society.

contact (large) contributions to the paramagnetic shifts of the pyrrole-H was attempted, the situation is probably even more complicated than thought, because of some contribution of the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration as a thermally-accessible excited state, a situation that will be discussed further in Section IV.A.8.d, where the effect of single *meso*-substitution on the chemical shifts of [OEPFe$(CN)_2$]$^-$ complexes[348] is also discussed. The temperature dependences of these spectra, however, have not been reported.

ii. The shifts of coordinated imidazole ligands and the effect of imidazole deprotonation on the pattern and extent of spin delocalization

(a) *Neutral imidazole ligands*

Paramagnetic shifts of the protons of the imidazole ligands of $[(TPP)Fe(R\text{-}Im)_2]^+$, and their separation into contact and pseudocontact contributions, have been reported.[2,4,489] The pseudocontact shifts of all imidazole protons are positive (to low shielding), while the contact contributions are negative at all ring positions. Since the time of the original study it has been found that the imidazole ligand shifts are consistent with delocalization into the filled π orbital that has large density on the bonding nitrogen.[490] Hence, imidazoles interact with low-spin iron(III) as π donors, and the mechanism of spin delocalization is Im $\rightarrow$ Fe π bonding. This orbital has large π electron density at the 2-position and very small π electron density at the 4- and 5-position. For low-spin iron(III) porphyrins which have a $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state, the pseudocontact contribution to the paramagnetic shift is positive at all axial proton positions. Thus the positive shifts of the imidazole 4-H and 5-H are indicative of mainly pseudocontact shifts at those positions, while the negative shift of the 2-H is the balance of a positive pseudocontact shift and a negative contact shift caused by large π delocalization at that position. The same conclusion (L $\rightarrow$ Fe π bonding) has been reached concerning the interaction of strongly basic pyridines with low-spin iron(III), while weakly basic pyridines are found to act as π acceptors toward low-spin iron(III).[34,491]

It is found that two N–CH_3 and two 2-H signals of the imidazole moiety are well resolved when one phenyl ring has an *ortho*- or *meta*-substituent in the unsymmetrically phenyl-substituted derivatives of $[(TPP)Fe(NMeIm)_2]^+$ discussed in Section IV.A.8.b(ii).[80,226,419,486] Thus, the NMeIm ligands on the two sides of the porphyrin plane have different contact and/or pseudocontact shifts. These differences may be due to different contributions of the two ligands to the orientation of the nodal plane of the complex, which would be expected to affect both the contact and pseudocontact contributions to the paramagnetic shifts of the protons of the two ligands.[8] However, if the ligands are rotating very fast on the NMR timescale, then the two ligands cannot contribute to the orientation of the nodal plane of the 3e(π) orbital used for spin delocalization. In this case the differences in chemical shift of the two N–Me groups must be the result of different Fe–N bond lengths for the two ligands, which result from a nonplanar conformation of the porphyrin ring which results from the unsymmetrically-placed substituents, Usually, if one of those substituents is at an *ortho*-phenyl position, there will be a ruffling distortion to remove steric hindrance between this *ortho*-substituent and the rotating axial ligand. That ruffling distortion will contribute to strengthening the bond between the iron and the axial ligand on the same side of the plane as the

ortho-substituent, and weakening the bond between the iron and the axial ligand on the opposite side of the plane.

(b) *Imidazolate ligands*

Deprotonation of the coordinated imidazole ligands of $[(TPP)Fe(ImH)_2]^+$ results in large shifts in the resonances of the protoporphyrin and imidazole ring protons to lower frequency,[490] and a concommitant decrease in the g-anisotropy of the complex (Table 12). Thus, the pseudocontact contributions to the paramagnetic shifts of imidazolate ligand protons are decreased in magnitude as compared to those of the neutral ligands.[490] The contact contribution is decreased to somewhat over half that observed for the neutral ligand at H-4′ and approximately doubled at the H-5′ position of the ring, which suggests that deprotonation of the imidazole leads to an increase in the strength of L $\rightarrow$ Fe π donation.[490] The increased value of Δ/λ (Table 12) is consistent with this conclusion.

iii. Effect of imidazole plane orientation on the paramagnetic shifts of low-spin iron(III) porphyrins

For some time it has been known that the orientation of planar axial ligands is significant in producing the large spread of the methyl resonances of the protoporphyrin ring of heme proteins,[2–5,8,13,16,141–150] as is discussed earlier in Section II.C.3. A number of investigations of model hemes have been carried out aimed at testing this hypothesis.[80,226,492–495] Since the barrier to rotation of axial ligands in model hemes is very low,[89–92,496] a number of systems that involve covalent attachment of one or both axial ligands have been investigated.[488,492–494] However, such covalent attachment often leads to lower symmetry than desired.[488,492] Nevertheless, the importance of axial ligand plane orientation was clearly demonstrated by the fact that eight ring-CH_3 resonances were observed for the diastereomeric mixture of two coordination isomers of the dichelated protohemin monocyanides of Traylor and Berzinis, with a total spread of 17.1 ppm in DMSO-d_6 at ambient temperature,[492] as shown in Figure 42. Although two isomers are present, this approaches the known spread of the –CH_3 resonances in heme proteins (for example, 11.5 ppm for cyanoferricytochrome *c*,[497] 22.3 ppm for sperm whale cyanometmyoglobin,[10] and 27.1 ppm for HRPCN[498]), where axial ligands are held in particular orientations by the protein. (And as it turns out, the two outer CH_3 signals, 17.1 ppm apart, are in fact from the same isomer, as discussed below.)

2D NMR techniques have been used by this research group to assign a number of the resonances of the two isomers of Traylor and Berzinis' dichelated protohemin cyanide complexes.[499] As shown in Figure 43, NOESY/EXSY spectra at room temperature have shown that the methyl resonances of the two geometrical

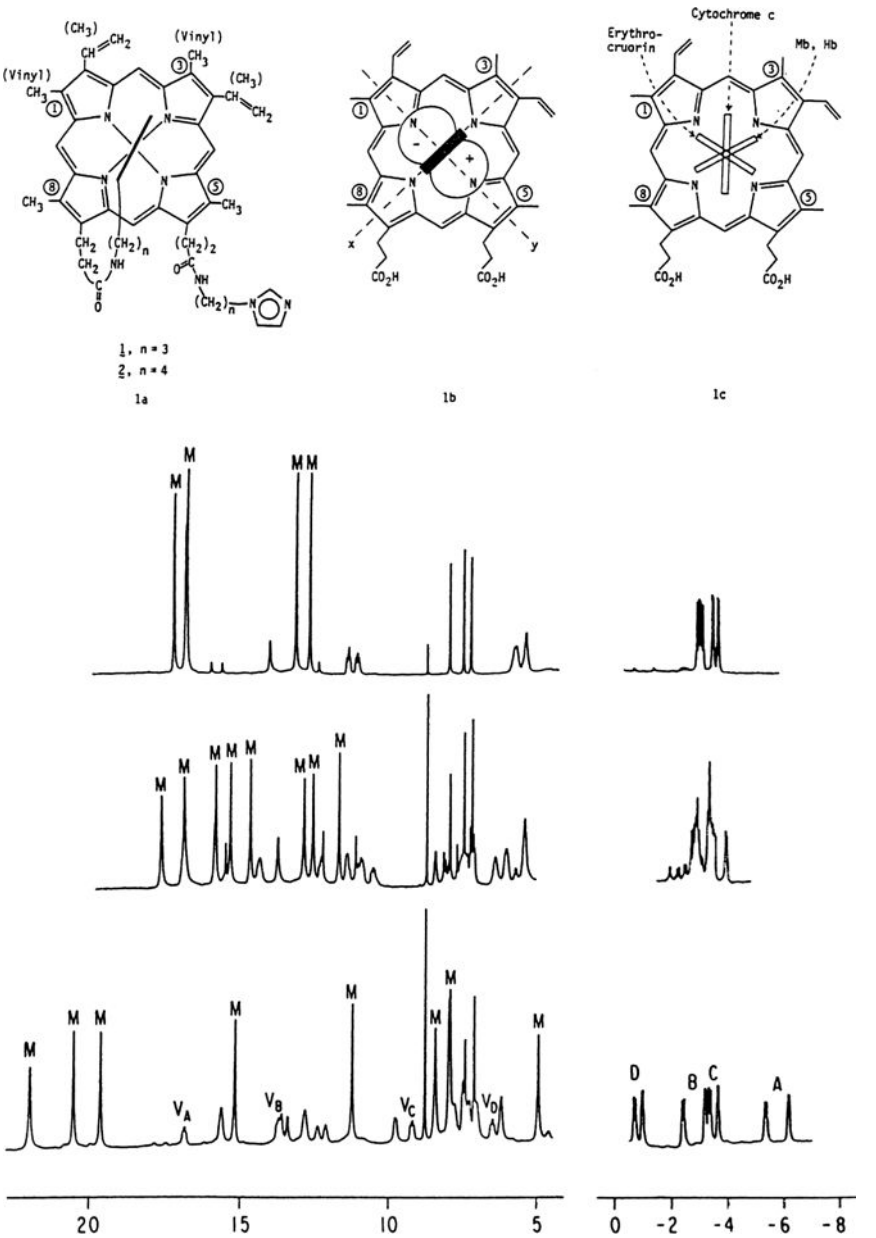

Figure 42. Top: (1a) Structures of one of the four diastereomeric isomers of the dichelated protohemin monocyanide complexes of Traylor and Berzinis; (1b) interaction of the imidazole p orbital with the d_{yz} orbital of the metal; (1c) orientation of axial imidazole planes in three heme proteins. Bottom: NMR spectra of cyanide complexes of the hemins 1 (lower trace), 2 (middle trace), and the complex with two freely rotating N-methylimidazole ligands (upper trace). Methyl group resonances are identified as M, and vinyl group resonances are identified as VA, VB, VC and VD (α-H), and A, B, C, D (β-CH_2). Reprinted from Traylor, T. G.; Berzinis, A. P. *J. Am. Chem. Soc.* **1980**, *102*, 2844–2846, with permission from the American Chemical Society.

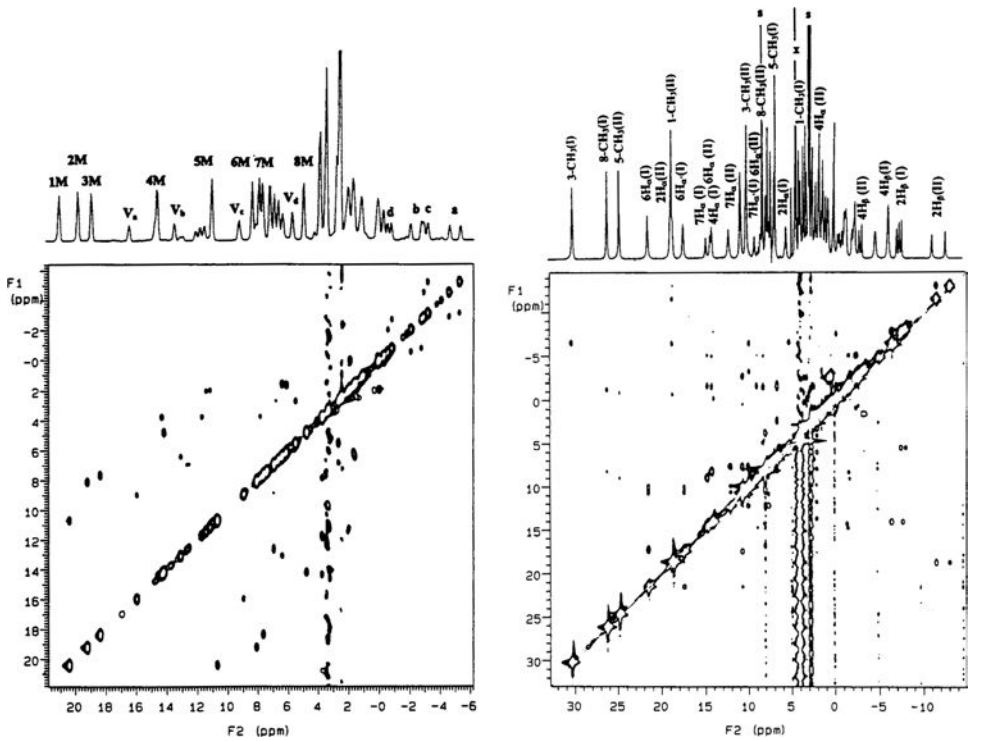

Figure 43. Left: 1D and NOESY/EXSY spectrum of the dichelated protohemin cyanide isomers recorded at 300 MHz in DMSO-d_6 at 35 °C. Note the strong chemical exchange cross peaks that result from exchange of the 6- and 7-imidazole groups and thus link the resonances of one isomer to their partners in the other isomer. As is evident, heme methyl resonances are linked 1M ↔ 5M, 2 ↔ 6, 3 ↔ 7, and 4 ↔ 8 by chemical exchange. Right: 1D and 2D NOESY and COSY spectra of **1** at -57 °C in DMF-d_7. The COSY spectrum (below the diagonal) shows the connectivities between α-H and β-H within each vinyl group. The NOESY spectrum (above the diagonal) shows NOEs between 3-CH_3-(**I**) (30.2 ppm) and 4H-β_t(**I**) (–6.4 ppm); 5-CH_3(**II**) (18.4 ppm) and 6Hα'(**II**) (9.0 ppm); 1-CH_3(**II**) (18.6 ppm) and 2H-β_t(**II**) (–11.5 ppm); 3-CH_3(**II**) (9.9 ppm) and 4H-β_t(**II**) (–3.1 ppm); 8-CH_3(**I**) (26.1 ppm) and 7Hα'(**I**) (8.1 ppm). Reprinted from Minniear, A. B.; Shokhireva, T. Kh.; Walker, F. A. *Inorg. Chem.* **1999**, *38*, 5856–5859, with permission from the American Chemical Society.

isomers are related by chemical exchange in pairs 1 ↔ 5, 2 ↔ 6, 3 ↔ 7 and 4 ↔ 8. DQF-COSY spectra allow assignment of vinyl and propionate resonances, and NOESY spectra recorded at −57 °C allow assignment of the 1- and 3-methyl resonances by NOEs to the 2- and 4-vinyls, respectively. The assignment of methyl resonances, from large to small chemical shift, is 3(**A**), 5(**B**), 8(**A**), 1(**B**), 3(**B**), 5(**A**), 8(**B**), 1(**A**), where **B** represents the isomer shown in Figure 42 top 1a.[492] Thus, isomer **A** has methyl order 3 > 8 ≥ 5 > 1 and is responsible for the 17.1 ppm spread of the heme methyl resonances, while isomer **B** has methyl group order

5 > 1 ≥ 3 > 8 and has a 12.5 ppm spread of its methyl resonances. The ligand of isomer **B** is actually rotated about 10° clockwise (rather than counterclockwise, as shown) from the N_{II}–N_{IV} axis of Figure 42 top 1a, and that of isomer **A** is rotated about 10° counterclockwise from the N_{I}–N_{III} axis of the 6-imidazole bound isomer. Thus, the methyl shifts are approximately those predicted by the angles 100° (**A**) and 170° (**B**) of Figure 11.

The tetramesitylporphyrin complex, $[(TMP)Fe(2MeImH)_2]^+$, proton NMR spectrum exhibits four pyrrole-H, four *ortho*-CH_3, four *meta*-H and two *para*-CH_3 resonances at temperatures below −30 °C, even though the porphyrin is symmetrically substituted[104,496] as shown in Figure 44. The multiplicity of porphyrin resonances was explained in terms of fixed orientations of the 2-methylimidazole ligands at low temperatures.[496] It has been shown by NOESY techniques at very low temperatures that the observed NOEs are consistent with the axial ligands lying over the *meso* positions of the porphyrin ring in perpendicular planes, with only two pyrrole-H giving rise to NOE cross peaks.[104] A complete assignment of the NMR spectrum was achieved from ROESY spectra of the complex,[225] as demonstrated in Figure 45. Such orientations of the hindered 2MeImH ligands are

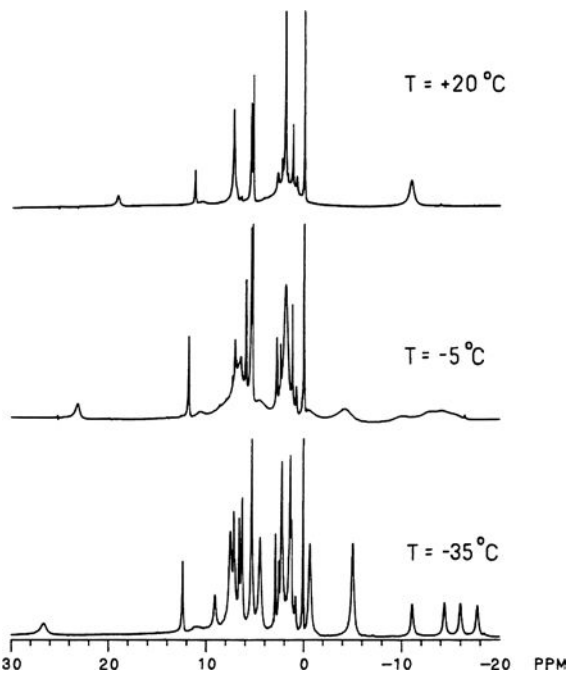

Figure 44. Temperature dependence of the 300 MHz 1D ^{1}H NMR spectrum of $[(TMP)Fe^{III}(2MeImH)_2]^+$. Reprinted with permission from the Ph.D. dissertation of K. I. Momot, University of Arizona, 1998.

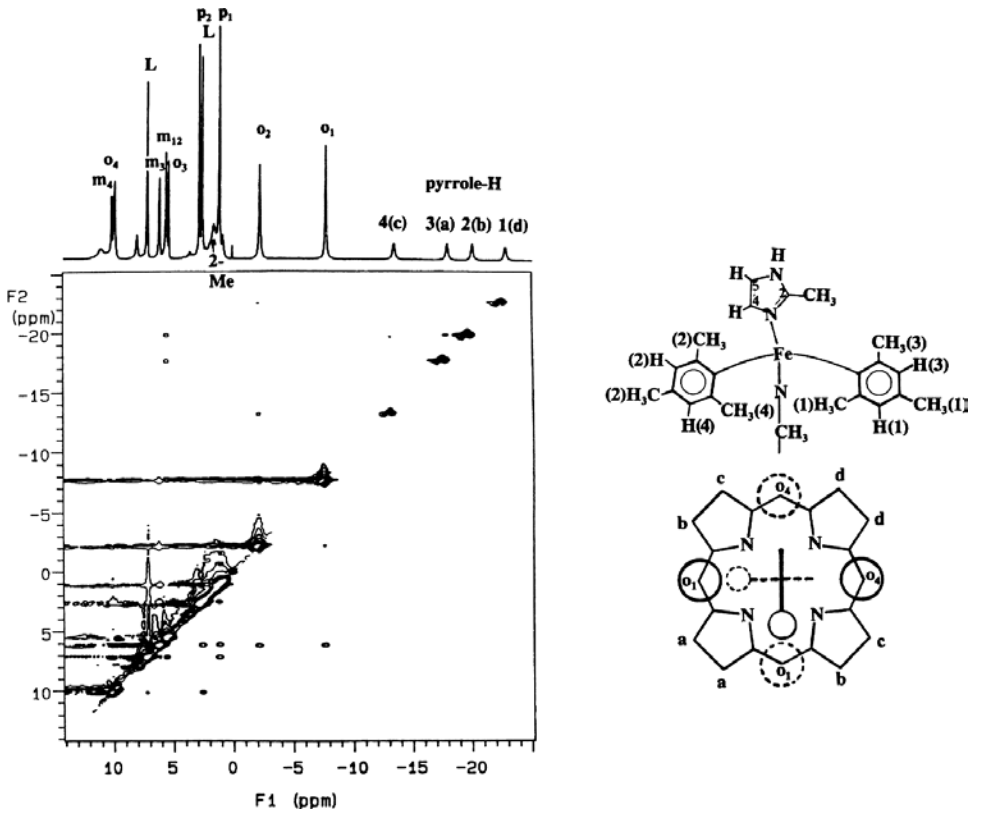

Figure 45. Left: 300 MHz ROESY spectrum of $[(TMP)Fe^{III}(2MeImH)_2]^+$ in CD_2Cl_2 at –75 °C. A much deeper contour, necessary to observe the weak ROEs between pyrrole-H(2) and -(4) and between pyrrole-H and *ortho*-CH_3 resonances, is shown in the half of the ROESY spectrum above the diagonal. Chemical exchange cross peaks are the same phase as the diagonal and are shown in multi-contour dark lines, while ROE cross-peaks are the opposite phase to the diagonal and are shown in single circles. Right: Assignment of the resonances on the basis of the ROESY spectrum. The assignment of mesityl protons is shown in the top structure and of mesityl and ligand 2-CH_3 groups in relation to pyrrole-H in the bottom structure. Reprinted from Shokhireva, T. K.; Nesset, M. J. M.; Walker, F. A. *Inorg. Chim. Acta* **1998**, *272*, 204–210, with permission from Elsevier Publishing Company.

expected in order that the Fe–N_{ax} bond lengths are short enough to allow the complex to be low-spin, and have been confirmed by the X-ray crystal structure for $[(TMP)Fe(1,2\text{-}Me_2Im)_2]^+Cl^-$.[32] Thus, the porphyrin ring is not sensitive to the symmetry of the axial ligands unless their substituents require that they bind to the metal in a tilted manner, off the axis normal to the plane of the porphyrin ring.

Nakamura and Groves first reported the coalescence behavior of the pyrrole-H, *o*-CH_3, *p*-CH_3, and *m*-H resonances of $[(TMP)Fe(2MeImH)_2]^+$ as the temperature is lowered from room temperature to –48 °C[496] (Figure 44). They correctly

ascribed this behavior to a slowing of axial ligand rotation as the temperature is lowered, and calculated activation parameters from complete line shape analysis of the two *p*-CH_3 signals of the TMP ligand. For the rotation of 2MeImH ($\Delta H^{\ddagger} = 54 \pm 2$ kJ/mol; $\Delta S^{\ddagger} = +16 \pm 7$ J/K-mol) and 1,2-Me_2Im ($\Delta H^{\ddagger} = 52 \pm 3$ kJ/mol; $\Delta S^{\ddagger} = +22 \pm 15$ J/K-mol).[496] Although their proposed structure of the low-temperature complex, in which ligand rotation is hindered, was later modified on the basis of NOESY investigations of this system[104] and the X-ray crystal structure of the bis-1,2-dimethylimidazole complex,[32] the activation parameters clearly describe the barriers to rotation of the two 2-substituted imidazoles. These barriers are considerably lower than those for axial ligand exchange,[583] discussed in Section IV.A.8.l, and clearly represent a totally different kinetic process.

The rates of ligand rotation have been measured by EXSY (see definition: Table 1) techniques for $[(TMP)FeL_2]^+$ and $[((2,6\text{-}X_2)_4TPP)FeL_2]^+$, where L = 2MeImH and X = Cl and Br,[89] for $[(TMP)CoL_2]^+$, where L = 2MeImH and 1,2-Me_2Im[89,92] and for $[(TMP)Fe^{II}L_2]$, where L = 1,2-Me_2Im.[92] Saturation transfer[90] and T_2 measurements,[91] and molecular mechanics calculations[90] have also been done for $[(TMP)FeL_2]^+$, where L = 2MeImH. Each of these systems represents a case of a four-site chemical exchange process having a single rate constant. The volume intensities of the cross- and diagonal peaks in the ROESY spectra, such as those shown in Figure 29 for the diamagnetic cobalt(III) and iron(II) complexes, can be used to calculate the rate constant at each temperature, using expressions derived from simple expansion of the expressions of Ernst, Bodenhausen and Wokaun[500] from two- to four-site exchange. For systems having four such sites, there are three possible patterns of weak and strong cross-peaks that can be obtained, depending on the sequential relationship of the chemical shifts and the spatial relationships of the four sites, as shown in Figure 46. The pyrrole-H resonances of $[TMPFe(2MeImH)_2]^+$ exhibit the pattern shown in Figure 46b, while the *o*-CH_3 resonances of the same complex exhibit the pattern shown in Figure 46c and the *o*-CH_3 resonances of the cobalt(III) analog exhibit the pattern shown in Figure 46d.

The rates of ligand rotation measured by saturation transfer difference spectra yielded somewhat higher values of the activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (59 kJ/mol and +41 J/molK, respectively)[90] than did the DNMR, EXSY or T_2 methods (54 and +16;[496] 41 and +3;[83] 48 and −10,[91] respectively, where all entropies of activation are within experimental error of zero). It is likely that spin diffusion occurs during the long irradiation times required for the saturation transfer experiments, which alters the intensities of the apparent saturation transfer peaks,[91] and thus this method is probably not the best for measuring rates of ligand rotation (and possibly other processes as well).

Other axial ligands rotate much more rapidly on all of the metal centers studied than do hindered imidazoles. The $[(TMP)Co(4\text{-}NMe_2Py)_2]^+$ complex shows

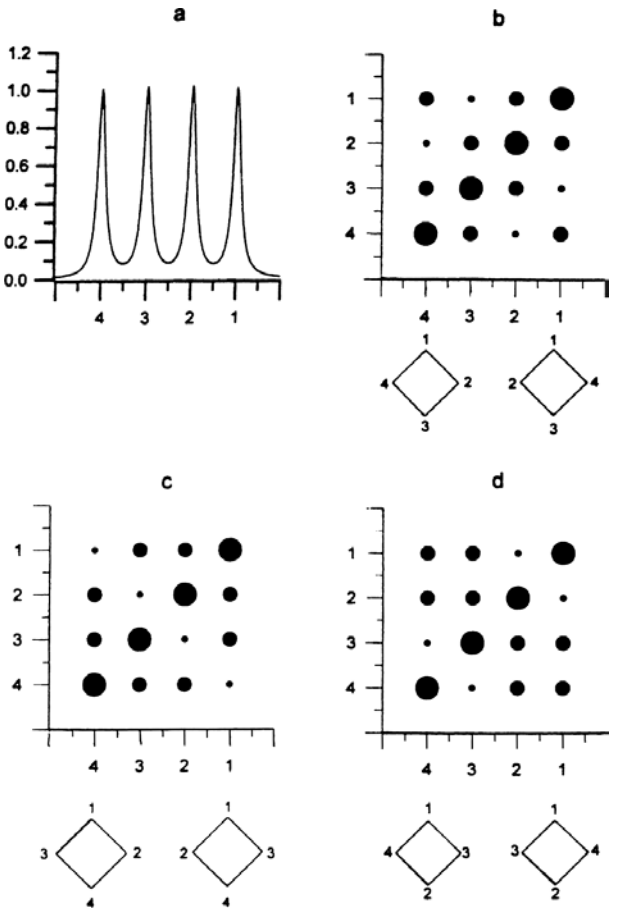

Figure 46. Computer simulation of the four-site chemical exchange process for four equally-separated exchanging peaks 1-4 observed in the 1D NMR spectrum, together with the three different possible 2D EXSY patterns that result from the possible spatial locations of the protons that give rise to the four resonances. Note that in each case there are four relatively weak cross-peaks and eight much stronger cross-peaks. These patterns result from "first-order" and "second-order" cross-peaks that depend on the spatial relationship between the exchanging protons and thus which protons can exchange upon one (or more) step(s) of chemical exchange. Reprinted from Shokhirev, N. V.; Shokhireva, T. Kh.; Polam, J. R.; Watson, C. T.; Raffii, K.; Simonis, U.; Walker, F. A. *J. Phys. Chem. A* **1997**, *101*, 2778–2886, with permission from the American Chemical Society.

broadening of the *o*-CH_3 resonance at 300 MHz at –90 °C that is indicative of a slowing of the rate of 4-NMe_2Py rotation and thus the creation at lower temperatures of two different types of mesityl *o*-CH_3 groups.[92] It is not possible to cool the solution to a low enough temperature to go through coalescence and see the two *o*-CH_3 resonances, at least at 300 MHz. Using line-broadening expressions in the fast-exchange regime,[86,87] and assuming what the final difference in frequency, $\Delta\nu$,

would be for the two *o*-CH_3 resonances, it was possible to estimate the rate constants over the temperature range 188–228 K and to determine the activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for this complex. The latter are 26 kJ/mol and −60 J/K-mol for the bis-(4-NMe_2Py) complex,[92] as compared to 48 kJ/mol and −62 J/K-mol for the bis-(2MeImH) complex and 44 kJ/mol and −84 J/K-mol for the bis-(1,2-Me_2Im) complex.[89] The reason for the very negative values of $\Delta S^{\ddagger}$ for the cobalt(III) complexes, as compared to the near-zero values for the corresponding iron(III) complexes, is not known, but may have to do with solvation differences arising from the difference in anion used (BF_4^- for cobalt(III), ClO_4^- for iron(III)).[89] The extrapolated rate constant for rotation of 4-NMe_2Py ligands at 298 K on (TMP)Co^{III} is at least 1.1×10^6 s^{-1}, as compared to 5.1 s^{-1} for 1,2-Me_2Im on the same metal,[92] a factor of at least 2×10^5 increase for the substituted pyridine. Since ligand rotation is much faster for (TMP)Fe^{III} complexes than for (TMP)Co^{III} (at least a factor of 700 times faster at 298 K),[89] it is not surprising that it has not been possible to obtain evidence of slowed rotation of pyridines or nonhindered imidazoles on low-spin iron(III) porphyrinates over the temperature ranges accessible in common NMR solvents. As for (TMP)Fe^{II}, estimation of a rate constant of ligand rotation for the bis-(1,2-Me_2Im) complex at −80 °C from the intensity of the EXSY cross peaks (Figure 29) of about 1 s^{-1}, and assumption of similar $\Delta H^{\ddagger}$ to those of the corresponding (TMP)Fe^{III} and (TMP)Co^{III} systems, suggests that the rate constant at 298 K could be of the order of 2×10^4 s^{-1}, similar to that of the iron(III) complex.[92]

It was reported by Nakamura that the same multiplicity of pyrrole-H, *o*-CH_3, *m*-H and *p*-CH_3 resonances were observed for the corresponding 2-methylbenzimidazole complex,[501] although the paramagnetic shifts of the TMP protons, their anti-Curie behavior, and the single observed EPR feature at g = 2.6 are all consistent with a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state having thermal occupancy of the $(d_{xy})^2(d_{xz},d_{yz})^3$ excited state, discussed in Section IV.A.8.c.

iv. Bis-ammine, amino ester and phosphine complexes

Though it has been reported that iron(III) porphyrins undergo autoreduction in the presence of aliphatic amines[502] and phosphines,[503] several workers have succeeded in obtaining the proton NMR spectra of several of these complexes. Kim and Goff found that although aliphatic amines caused autoreduction, the bis-ammonia complex was stable.[504] The NMR spectrum of $[(TPP)Fe(NH_3)_2]^+$ $SO_3CF_3^-$, recorded in CD_2Cl_2 at 25 °C is clearly indicative of a low-spin iron(III) complex with the "normal" $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, with pyrrole-H resonance at −21 ppm and phenyl resonances close to their diamagnetic positions. An interesting feature of the spectrum is the extremely large positive paramagnetic shift of the ammonia protons (+240.6 ppm). The Curie plots are linear for all protons of the TPP ligand, indicating a simple

electronic ground state. The EPR spectrum, recorded at 5.2 K, has a "large g_{max}" signal at g = 3.75, nearly the limit for low-spin iron(III), which indicates that there is very little, if any, rhombic splitting of d_{xz} and d_{yz}.[504] This is the expected situation for axial ligands that have no planes of symmetry and no π-bonding orbitals.

Simonneaux and coworkers have more recently reported the synthesis and characterization of low-spin bis-amino ester (the amino group of the carboxy-esterified amino acid) iron(III) porphyrin and chlorin complexes.[505,506] By using several esters of valine and leucine, they were able to prevent the autoreduction of the $(TPP)Fe^{III}$ center. The bis-(amino ester) complexes thus formed are partial models of cytochrome *f*, which has the N-terminal amino group coordinated to the heme, as well as a histidine imidazole.[507] The porphyrin complexes are typical $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state complexes with the pyrrole-H resonance at −23.0 ppm at 293 K and "large g_{max}" EPR signals at g_{zz} = 3.56–3.57, as well as a zero-crossing derivative feature at g_{yy} = 1.77–1.76.[505] The nonzero intercepts of the Curie plot suggest that the $(d_{xz},d_{yz})^4(d_{xy})^1$ excited state is thermally accessible.[505] The tetraphenylchloriniron(III) complex has a rhombic EPR spectrum, with g-values of 2.70, 2.33, and 1.61.[506]

The bis-(trimethylphosphine) complex, $[(TPP)Fe(PMe_3)_2]ClO_4$ shows a similar NMR spectrum;[508] the pyrrole-H resonance is observed at −19.6 ppm in CD_2Cl_2 at 20 °C. In this case, however, the PMe_3 methyl-H have an paramagnetic shift of −2.4 ppm, and a derived contact shift of −13.3 ppm. The opposite sign of the contact shift, as compared to that of the bis-(NH_3) complex discussed above, is consistent with the fact that although NH_3 can act only as a σ-donor, PMe_3 can act both as a σ-donor and a π-acceptor, the latter due to the presence of the empty 3d orbitals. Clearly, this π-acceptor character has a very large effect on the observed paramagnetic shift of the axial ligand protons. The EPR g-values reported in this work are g = 2.687, 2.088 and 1.680, from measurements at 140 K.[508] However, at 8 K the only signal found present by the author of this chapter is a "large g_{max}" signal at g = 3.5 (Table 12). Based on this latter spectrum, the effective pseudocontact contribution to the paramagnetic shift at 20 °C is negative at all TPP positions, and the ground state appears to be essentially pure $(d_{xy})^2(d_{xz},d_{yz})^3$. The mixed ligand PMe_3-NMeIm complex was also reported,[509] and has been used as a model for PMe_3-bound heme proteins, as discussed by Simonneaux.[510] The synthesis and characterization of the bis-dimethylphenylphosphine complex of tetraphenylchlorinatoiron(III) and –(II) has also been reported.[511]

v. Mixed-ligand complexes

Numerous ^1H NMR spectra of mixed-ligand complexes have been reported, including (N-RIm)(2MeImH),[493,494] (NMeIm)(R-Py),[512] (R-Py)(R′-Py),[512] (ImH)(Im^-),[490]

(ImH)(CN^-),[490] (2MeImH)(CN^-),[513] (Im^-)(CN^-),[490] (NMeIm)(CN^-),[514,515] (R-Py)(CN^-),[512] (ImH)(OR^-),[331] (Py)($C{\equiv}CR^-$),[330] (NMeIm)(PMe_3),[508,509] (Py)(PMe_3),[508] (ImH)(p-$NO_2C_6H_4O^-$)[331] and (NMeIm)(R^-) and (Py)(R^-) (R^- = aryl, alkyl or carbanion).[516] Most of these are direct models for the cyanide[5,16] or phosphine[517,518] complexes of a number of heme proteins. The mixed-ligand complexes involving R^- will be discussed in Section IV.A.8.d.

Mixed hindered/nonhindered imidazole ligation of (TPP)Fe^{III} produces a pyrrole-H paramagnetic shift (−13.0 ppm for (2MeImH)(NMeIm) at 34 °C) that is intermediate to those of the two symmetrical bis-imidazole complexes (−11.8 ppm for bis-(2MeImH); −16.5 ppm bis-(NMeIm),[494] while covalent attachment of the nonhindered imidazole to the TPP ligand produces a large spread of the pyrrole-H resonances.[493,494]

Complexes of (TPP)Fe^{III} with mixed phosphine-nitrogen donor axial ligands have very similar pyrrole-H shifts to those of the bis-L complexes: At 20 °C for (NMeIm)(PMe_3), δ_{iso} = −27.3 ppm as compared to −27.8 ppm for $(PMe_3)_2$,[508,509] and −26.4 ppm for $(NMeIm)_2$.[486] However, while for (Py)(PMe_3) at 20 °C, δ_{iso} = −28.8 ppm, δ_{iso} is about −21 ppm for the bis-(pyridine) complex.[519] Thus, it would appear that the phosphine ligand stabilizes the "normal" $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state of the mixed-ligand complex containing pyridine, as compared to the mixed $(d_{xz},d_{yz})^4(d_{xy})^1/(d_{xy})^2(d_{xz},d_{yz})^3$ ground state of the bis-(pyridine) complex. (See Section IV.A.8.d.) The PMe_3 complexes of myoglobin and hemoglobin have one and two methyl-H resonances from the coordinated phosphine, respectively, which may suggest some difference in the α and β heme distal environments of hemoglobin. Each of these PMe_3 methyl resonances have different paramagnetic shifts, suggesting some difference in either steric or electronic factors at the heme center of these proteins when bound to the phosphine;[517] permutation of the ring-CH_3 resonance order (Structure 1) for met-Mb(PMe_3) (5 > 8 > 1 > 3) as compared to met-Mb(CN), met-Mb(N_3) and met-Mb(Im) (5 > 1 > 8 > 3) (Structure **1**) suggests a possible steric factor of the phosphine ligand.[518]

c. *Observed shifts and the mechanism of spin delocalization for the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state*

Of the "pure" $(d_{xz},d_{yz})^4(d_{xy})^1$ systems having EPR g-values near 2.0 that have also been studied by NMR spectroscopy, the first report was for that of [(TPP)Fe(*t*-BuNC)$_2$]$^+$.[155] The ^{1}H NMR resonances, with pyrrole-H resonance at +10 ppm at 298 K was shown to follow the Curie law. The solution magnetic susceptibility of the complex was measured by the Evans method,[376,377] which also clearly showed that this was a S = 1/2 paramagnetic complex.[155] Strong alternation in the direction of the *meso*-phenyl-H shifts (Figure 28) suggested large π spin density at the

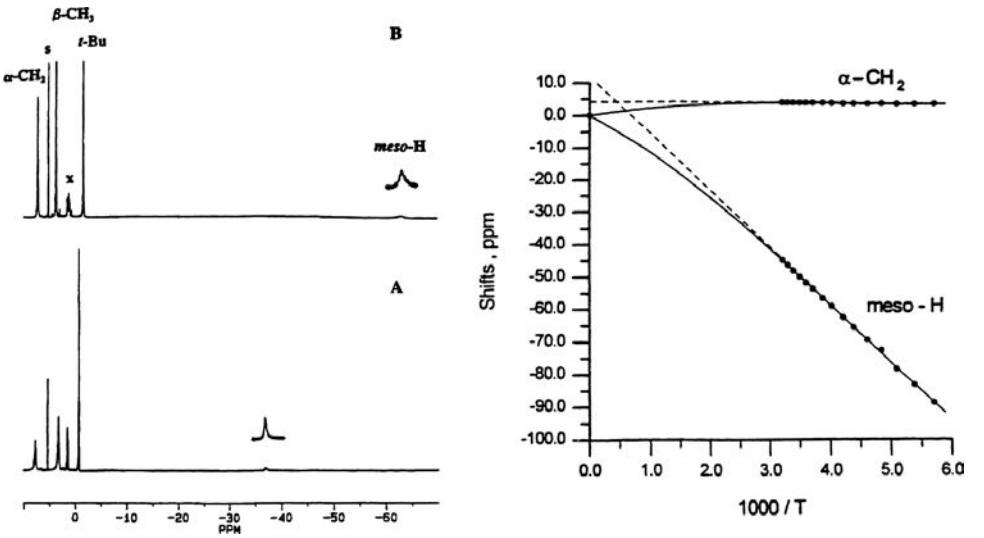

Figure 47. Left: 300 MHz 1D ^{1}H NMR spectrum of $[(OEP)Fe^{III}(t\text{-BuNC})_2]^+$ in CD_2Cl_2 recorded at (A) 303 K and (B) 195 K. Assignments of the resonances are given in (B). Right: Curie plot of the *meso*-H and α-CH_2 resonances of $[(OEP)Fe(t\text{-BuNC})_2]^+$. The dashed lines show the linear dependence, while the solid lines show the temperature dependence expected on the basis of a thermally-accessible excited state with $\Delta E = 296$ cm^{-1}. The derived orbital coefficients for the ground and excited state orbitals are 0.0332 and 0.0084 for the *meso*-H and 0.0004 and 0.0116 for the α-C to which the α-CH_2 are attached, respectively. The *meso*-H orbital coefficients are approximately one-quarter and twice those expected for the $3a_{2u}(\pi)$ and $3e(\pi)$ orbitals, respectively, on the basis of simple Hückel calculations. The β-C orbital coefficients obtained from the temperature dependence of the α-CH_2 resonance are in the right relative size order for those expected for the β-pyrrole carbons for those two orbitals ($\rho_C = 0.004$ and 0.051, respectively). Reprinted from Walker, F. A.; Nasri, H.; Turowska-Tyrk, I.; Mohanrao, K.; Watson, C. T.; Shokhirev, N. V.; Debrunner, P. G.; Scheidt, W. R. *J. Am. Chem. Soc.* **1996**, *118*, 12109–12118, with permission from the American Chemical Society.

meso positions.[155] A later NMR, EPR and magnetic Mössbauer study showed that for $[(OEP)Fe(t\text{-BuNC})_2]^+$, there is very small π delocalization to the β-pyrrole positions, as evidenced by only a 0.5 ppm shift to lower shielding of the α-CH_2 resonances, while there is very large π spin delocalization to the *meso*-H positions of $[(OEP)Fe(t\text{-BuNC})_2]^+$,[463] as shown in Figure 47, where the *meso*-H resonance is at −37 ppm at 30 °C, −63 ppm at −78 °C and −80 ppm at −98 °C. There is some σ spin delocalization to the β-pyrrole positions, for the TPP analog has observed pyrrole-H shifts of about 10 ppm, which amounts to about a 1 ppm shift to lower shielding. The Curie plot for $[(OEP)Fe(t\text{-BuNC})_2]^+$ is also shown in Figure 47, where it can be seen that there is a thermally-accessible excited state.[25] In this case the ΔE is the energy difference between the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state and the $(d_{xz},d_{yz})^3(d_{xy})^2$ excited state. For $[(OEP)Fe(t\text{-BuNC})_2]^+$, this ΔE is 296 cm^{-1}.[463] For

the related substituted $[(TPP)Fe(2,6\text{-xylylisocyanide})_2]^+$ complexes, it is difficult to estimate ΔE from NMR data.[449] The report of the EPR spectrum of the bis-pyridine complex of $((C_3F_7)_4PFe^{III}$, where $\sum g^2 = 12.53$,[132] unfortunately did not include the NMR spectrum. This spectrum would allow unambiguous assigment of the location of the unpaired electron (metal or porphyrin π).

The bis-(*tert*-butylisocyanide) complexes of three dodecasubstituted iron porphyrinates (OETPP, OMTPP; and TC_6TPP) have been prepared and studied by EPR and ^1H NMR spectroscopy.[520] From the results it has been found that the ground states of the bis-(*t*-BuNC) complexes of OETPP, OMTPP, and TC_6TPP are mainly (99.1–99.4%) $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configurations, with an excited state lying 700 cm^{-1} to higher energy for the OMTPP complex, and probably at lower and higher energies, respectively, for the OETPP and TC_6TPP complexes.[520] In the ^1H NMR spectra the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configurations of all three complexes are indicated by the large and positive *meso*-phenyl-H shift differences, $\delta_m-\delta_o$ and $\delta_m-\delta_p$, and close to the diamagnetic shifts of groups (CH_3 or CH_2) directly attached to the β-carbons. However, in comparison to *meso*-only substituted porphyrinates such as $[FeTPP(t\text{-BuNC})_2]ClO_4$, the *meso*-phenyl shift differences are much smaller, especially for the OETPP complex.[520] 2D NOESY spectra show that the flexibility of the porphyrin core decreases with increasing nonplanar distortion in the order $TC_6TPP > OMTPP > OETPP$ and in the same order the stability of the binding to *t*-BuNC ligands decreases.[520] The structures of two crystalline forms of $[FeOMTPP(t\text{-BuNC})_2]ClO_4$ were determined by X-ray crystallography. Both structures showed purely saddled porphyrin cores and somewhat off-axis binding of the isocyanide ligands.[520]

Although no structure of the corresponding $[FeOETPP(t\text{-BuNC})_2]ClO_4$ complex was determined, it is clear that it is more purely and more rigidly saddled than the corresponding OMTPP complex. Thus, as mentioned above in Section II.C.2 and shown in Figure 4a, in a saddled porphyrin conformation, the d_{xy} orbital has proper symmetry to interact with the $1a_{1u}(\pi)$ porphyrin orbital,[130] which has nodes at the *meso*-carbons and very small electron density at the β-pyrrole carbons. The fact that the OETPP complex does have at least small π delocalization to the *meso*-carbons suggests that there are ruffling modes that can be activated to some extent in this basically purely saddled iron porphyrinate; however, the lower stability of this complex than that of the OMTPP complex suggests that neither ruffling modes nor delocalization via the $1a_{1u}(\pi)$ orbital are favored by low-spin iron(III) when bound to isocyanide ligands. To our knowledge, this is the first example of a porphyrin complex with a purely saddled conformation that adopts the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state. All structurally-characterized complexes of this electron configuration reported previously are ruffled. Therefore, it was concluded that a ruffled geometry stabilizes the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, but is not necessary for its

existence.[520] It should be added that if a ruffled geometry is not possible, a saddled geometry can also allow delocalization of a d_{xy} unpaired electron via the $1a_{1u}(\pi)$ orbital,[130] although less enthusiastically. Overall we can say that putting bulky groups on the *meso*-carbons of a porphyrin certainly encourages ruffling and the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state.[451]

By substituting the four phenyl rings of OETPP with 3,5-bis(trifluoromethyl) groups, Nakamura and coworkers were able to turn the bis-*t*-BuNC complex into a $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state system.[521] The bis-*t*-BuNC complex of octaethylmonoazaporphyriniron(III) also appears to have a $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state.[522]

d. *The mixed ground state behavior of bis-cyanide complexes of low-spin ferrihemes: Observed shifts and the mechanism of spin delocalization*

The cyanide ligand has been used for both model hemes and heme proteins for many reasons: (1) CN^- enforces the low-spin state for most iron(III) systems; (2) it is not a planar ligand and hence does not create in-plane magnetic anisotropy (unless it binds in a bent Fe–C–N fashion); (3) CN^- is small and can enter the heme pocket of most heme proteins; (4) it may (or may not) be a good mimic of other ligands (O_2, CO, NO) that bind to heme proteins; (5) since it binds more readily to iron(III) than to iron(II), CN^- produces a coordination geometry, in a paramagnetic state of iron, that is relevant to many active sites of heme proteins (the paramagnetism "illuminates" the heme in the NMR spectrum of the protein); and finally, and most importantly, (6) the NMR spectra of dicyanohemin complexes are well resolved, since the lines are quite narrow, due to very rapid electron spin relaxation times and long proton T_1s and T_2s. (Both T_1s and T_2s are much longer for dicyano and monocyano, monoimidazole than for bis-imidazole complexes of most, if not all, iron(III) porphyrins,[102,218] as discussed in Section II.B.2.) This excellent resolution, combined with the availability of high-field NMR spectrometers, has made it possible to identify a number of iron porphyrins in coals and to assess their degree of carbonification,[523–525] to allow detection of very long-range isotope shifts in β-vinyl deuterated derivatives of dicyanoprotohemin IX,[526] and to allow a variety of heteronuclear 2D NMR experiments to be carried out on dicyanoprotohemin IX.[216,222] Dicyano and (cyano)(pyridine) complexes of natural hemins have also been studied in aqueous detergent micelles.[527,528]

The NMR spectra of the bis-cyanide complexes of a number of naturally-derived ferrihemes were, as mentioned above, reported before 1979,[2,168,169] the spectra of some of which are shown in Figure 22. These NMR studies showed that the spread of the heme methyl resonances is strongly dependent on the nature of the 2,4-substituents of the heme,[168,169] Structure **1**. There was, even in 1979, some

indication that the *meso*-H of these bis-cyanide complexes were exposed to more spin density than were those of the corresponding bis-(imidazole) complexes. Nevertheless, the "large g_{max}" EPR spectrum of $[(PP)Fe(CN)_2]^-$[443] indicated that this was clearly a $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state system. Simple $[(TPP)Fe(CN)_2]^-$ complexes have also been studied by NMR spectroscopy,[514] but with no evidence of "anomalous" contact shifts for the resonances, aside from a small alternation in the direction of the phenyl-H shifts. However, since then it has been shown that the bis-(cyanide) complexes of *meso*-substituted iron(III) porphyrinates having alkyl substituents of increasing size ($H < CH_3 < C_2H_5 <$ *i*-Pr),[450,529] *meso*-tetrachiroporphyrinatoiron(III) derived from (1R)-cis-caronaldehyde acid methyl ester and pyrrole,[530] *meso*-tetracyclohexylporphyrinatoiron(III),[531] quinoxalinotetraphenylporphyrinatoiron(III),[532] tetramesitylporphyrinatoiron(III)[533] and even mono-(*ortho*-substituted) derivatives of (TPP)Fe^{III}[419] show varying degrees of shift of the pyrrole-H resonances toward the limiting +10.82 ppm value indicative of the purest $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state reported thus far.[531] These more recent results have been interpreted as demonstrating the extremely low energy barrier to ruffling of the porphyrinate ring, as well as the interconnection (and perhaps continuum) between the $(d_{xy})^2(d_{xz},d_{yz})^3$ and $(d_{xz},d_{yz})^4(d_{xy})^1$ ferriheme complexes. The bis-2-methylimidazole complex of tetrakis-(*meso*-isopropyl)porphyrinatoiron(III) and the bis-1,2-dimethylimidazole complex of tetrakis-(*meso*-cyclohexyl)porphyrinatoiron(III) are other cases where NMR spectra indicative of the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state are observed, with four pyrrole-H resonances at 3.2, 4.3, 7.4 and 7.8 ppm at −35 °C for the *meso*-isopropyl derivative,[513,534,535] and 11.1, 10.6, 7.6 and 6.2 ppm at −20 °C for the *meso*-cyclohexyl derivative,[531] respectively. Presumably, the bulky *meso*-isopropyl and –cyclohexyl groups encourage the porphyrin to ruffle even more than does a *meso*-phenyl or –mesityl group, which hence stabilizes the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state.

However, all of these solution studies are in contradiction to the solid state studies (X-ray crystallography, EPR and Mössbauer spectroscopies reported by Scheidt *et al.*,[536] who find that in the solid state, whether the heme is ruffled or not, the ground electron configuration is always $(d_{xy})^2(d_{xz})^2(d_{yz})^1$, with the energy gap between d_{xz} and d_{yz} being quite small ($\leq$ ~600 cm^{-1}) and variable. For bis-cyanide derivatives, the two limiting ground states can be close in energy, and there is not a single structural feature that assures that bis-cyanoiron(III) porphyrinates will not have the $(d_{xy})^2(d_{xz})^2(d_{yz})^1$ ground configuration. Small perturbations of the bis-cyanoiron(III) porphyrinate systems may be sufficient to tip them into the alternate $(d_{xz},d_{yz})(d_{xy})^1$ state, but these require a solution state.[536]

Introduction of a single *meso* substituent into $K[(NC)_2Fe(OEP)]$ results in significant changes in the spectroscopic (and probably geometric, although no structures are available) properties of these complexes.[348] In methanol solution in the

presence of excess potassium cyanide, the low-spin six-coordinate complexes $K[(NC)_2Fe^{III}$(*meso*-R-OEP)], where R = Ph–, *n*-Bu–, MeO–, Cl–, NC–, HC(O)– and O_2N–. The ^1H NMR spectra of these show that electron-donating substituents produce a relocation of the *meso*-proton chemical shifts to higher shielding, with observed shifts from +3.32 ppm for $[OEPFe(CN)_2]^-$ to +5.50 (*cis*), +3.10 (*trans*) ppm for the formyl-substituted complex and −3.50 (*cis*), −10.31 (*trans*) ppm for the chloro-, −7.49 (*cis*), −10.74 (*trans*) ppm for the methoxy-, and −10.46 (*cis*), −17.15 (*trans*) ppm for the *n*-butyl-substituted complex.[348] This relocation was interpreted in terms of increased contribution from the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground electronic state as the *meso* substituent becomes more electron donating,[348] and suggests that electron-donating substituents may encourage ruffling of the porphyrin ring.

As has been pointed out elsewhere,[131] a correlation between the degree of ruffling of low-spin iron(III) porphyrinates whose structures have been reported and their electronic ground states can be made: If the average deviation of the *meso*-carbons, ΔC_m, is 0.55 Å or greater, the electronic ground state is $(d_{xz},d_{yz})^4(d_{xy})^1$, while if it is smaller than 0.51 Å the electronic ground state is $(d_{xy})^2(d_{xz},d_{yz})^3$. The single anomaly in this correlation is the bis-1,2-Me_2Im complex of $(TMP)Fe^{III}$, which has the largest value of ΔC_m, 0.72 Å,[32] but whose EPR spectral type is intermediate between that of a "large g_{max}" and that of an axial system.[533] The g_{max} value of 3.02 is much smaller than those of most other bis-(hindered imidazole) complexes (3.3 and greater, Table 12) but larger than any of the axial $(d_{xz},d_{yz})^4(d_{xy})^1$ species (2.6 and smaller, Table 12). In fact, the EPR signal for this complex is very broad, as was also observed earlier for the $(TMP)Fe^{III}$ complex with 3-chloropyridine,[34] which was also considered to be very close to the crossover point of the two electronic ground states. Thus, the $[(TMP)Fe(1,2\text{-}Me_2Im)_2]^+$ complex is seen as being "frustrated" by having strong π donor ligands that strongly favor the $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, but a very ruffled porphyrinate ring that strongly favors the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, and hence having some features of each electronic ground state. For the one octaethylporphyrinatoiron(III) complex having the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, the value of ΔC_m, is 0.38 Å,[463] which suggests that this β-pyrrole substituted, tetra-*meso*-H porphyrinate, the most similar to the naturally occurring ferriheme centers, switches to the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state at far lower degrees of ruffling than do the tetraphenylporphyrinates. No structures of *meso*-alkyl porphyrinato-iron(III)-bis-ligand complexes having $(d_{xz},d_{yz})^4(d_{xy})^1$ ground states have yet been reported; it would certainly be interesting to compare the structures of the series of bis-(cyanide) complexes reported by Nakamura *et al.*[529] and those of Latos-Grażyński *et al.*[530,532] The impression, based on NMR results, however, is that *meso*-substituted porphyrinates ruffle very readily, and are probably much more ruffled than the octaethylporphyrinate and the naturally-occurring

porphyrinates. Analysis of the distortions observed for the heme centers of a number of heme proteins[537,538] and structural studies of nickel(II) *meso*-(*t*-butyl)porphyrins[539] appear to bear this out. In contrast, the structures of *meso*-ethynylphenyl- and *meso*-diethynylphenylporphyrins are not ruffled,[540] and their bis-cyanide complexes have pyrrole-H shifts of −14 ppm for the symmetrical tetra-*meso*-(ethynylphenyl) porphyriniron(III) complex, or somewhat less for mixed-*meso*-substituted porphyrins at 298 K.[540]

The bis-cyanide complex of octaethyloxaporphyriniron(III) has an EPR spectrum that could be consistent with either ground state (g-values of 2.4, 2.2 and 1.8), but the NMR spectrum is clearly consistent with the $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, with α-CH_2 resonances ranging from +12 to +2 ppm and *meso*-H resonances at +4.5 ppm.[541] Consistent with this ground state, the crystal structure shows a planar porphyrin ring. The rhombic EPR signal of this bis-(cyanide) complex must arise from the asymmetry of the macrocycle.

e. *The mixed ground state behavior of bis-(pyridine) complexes of low-spin ferrihemes: Observed shift trends and the mechanism of spin delocalization*

The early work on the bis-pyridine complexes of Fe^{III} β-alkyl porphyrins such as $[(OEP)Fe(R\text{-}Py)_2]^+$, where R-Py = substituted pyridine, has been reviewed elsewhere.[2–4] A model that explains the paramagnetic shifts and solution magnetic susceptibilities of the $[(OEP)Fe(R\text{-}Py)_2]^+$ complexes was developed that includes contributions from the ^2E, $^6A_1(5/2)$, $^6A_1(3/2)$, $^4A_2(3/2)$ and $^2B_2(1/2)$ states.[542] For $[(OEP)Fe(3\text{-}ClPy)_2]^+$ at 320 K the percent contribution of each of these components to the E″ ground state is calculated to be 77%, 1%, 10%, 8% and 3%, respectively. The first and second excited states, both E′, are composed mainly of $^6A_1(1/2)$ and $^2E(1/2)$; hence, magnetic moments of these complexes may not rise above 4.5 μ_B, even though the ground state is not S = 3/2.[542] Interestingly, two different spin states (S = 3/2 and an S = 1/2 ↔ 5/2 equilibrium) have been observed for $[(OEP)Fe(3\text{-}ClPy)_2]^+$ in the crystalline state, depending on the relative and absolute orientations of the 3-chloropyridine ligands: When the φ angles are near 45° (ligands lying over the *meso* positions) and the ligands are in perpendicular planes, the complex was found to have a spin equilibrium,[543] while when the φ angles are small (ligands lying nearly over the porphyrin nitrogens) and the ligands are in nearly parallel planes, the spin state of the complex was found to be S = 3/2.[544,545] $[(OEP)Fe(3\text{-}CNPy)_2]^+$ also crystallizes as a S = 3/2 ground state complex with the axial ligands in parallel planes over the porphyrin nitrogens.[546] Certainly, all orientations are expected to be observed in solution, where axial ligands are expected to rotate rapidly over the temperature ranges investigated; hence

the solution magnetic susceptibility and NMR results[542,547] and the X-ray crystallographic and solid state magnetic susceptibility, EPR and Mössbauer results[543–546] are all consistent with the fact that low-basicity pyridine complexes of the type $[(OEP)Fe(R\text{-}Py)_2]^+$, as well as those of the natural porphyrins,[547] are very close to the magnetic triple point of S = 1/2, 3/2 and 5/2.[542] However, in the case of the basic pyridine complex, $[(OEP)Fe(4\text{-}NMe_2Py)_2]^+$, the S = 1/2 state alone, with a pure $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, is stabilized at all temperatures,[2,4,33] as it is for all bis-(imidazole) complexes.

Compared with the complex spin state behavior of β-alkylsubstituted porphyrins discussed above, all known bis-(pyridine) complexes of Fe^{III} tetraphenylporphyrins are low-spin.[2,4,34,491,519] Nevertheless, their behavior is not as simple as that of the corresponding bis-(imidazole) complexes. While it has been found in all cases that the pyrrole-H resonance shifts to lower shielding as the basicity of the pyridine decreases,[2,4,34,491,519] all TPP complexes not having *ortho*-phenyl substituents show Curie behavior, albeit with very small temperature dependence for $[(TPP)Fe(4\text{-}CNPy)_2]^+$,[519] while TPP derivatives which have *ortho*-phenyl substituents, such as $[(TMP)Fe(R\text{-}Py)_2]^+$,[34,491] exhibit anti-Curie behavior when R-Py is a low-basicity pyridine (3-CNPy, 4-CNPy). The *meta*-phenyl-H paramagnetic shift also increases dramatically as the basicity of the pyridine decreases, so that for low-basicity pyridines it is no longer possible to assume that the *meso*-phenyl-H paramagnetic shifts are totally due to the pseudocontact contribution.[491] The shift of the pyrrole-H resonance to lower shielding and the increasing contact shift of the *meta*-phenyl-H of the TMP, the anti-Curie behavior of the weakly basic pyridine complexes, and the change in the size (and sign) of the pseudocontact contribution to the paramagnetic shift are indicative of a progressive change in the ground state of these low-spin iron(III) complexes. For $(TMP)Fe^{III}$ complexes with pyridines of decreasing basicity, the pyrrole-H resonance position at −80 °C shifts from −30.9 ppm ($4\text{-}NMe_2Py$) to +2.1 ppm (4-CNPy).[34,491] The latter is clearly not a $(d_{xy})^2(d_{xz},d_{yz})^3$, but rather a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state complex. Because the shift is a smooth function of the pK_a of the conjugate acid of the pyridine ligand, it is difficult to say where the $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration ends and the $(d_{xz},d_{yz})^4(d_{xy})^1$ begins, partly because the energy separation between the two electronic ground states decreases as one moves from the right to the left extreme of the orbital diagram of Figure 1, and so both states are populated thermally as a function of the particular ligand and the temperature. Curie plots of the whole series of pyridine ligand complexes create a family of lines of decreasing negative slope to increasing positive slope as one goes from $[(TMP)Fe(4\text{-}NMe_2Py)_2]^+$ to $[(TMP)Fe(4\text{-}CNPy)_2]^+$.[491]

When axial imidazole or pyridine ligands are bound to low-spin iron(III) porphyrins in perpendicular planes, as discussed above, only one resolved EPR

feature, the "large g_{max}" signal discussed above, is observed.[33,34,431,458] The other two g-values are not resolved, probably due to g-strain, but they can be estimated by single crystal EPR techniques[440] or by magnetic Mössbauer spectroscopy at 4.2 K.[33,431,458] The g-values available are included in Table 12. The g_{max} values of nine bis-R-pyridine complexes of (TMP)Fe^{III} decrease in size from 3.48 to 2.53 as the pK_a of the conjugate acid of the pyridine decreases from 9.7 (4-NMe_2Py) to 1.1 (4-CNPy), with the type of EPR spectrum changing from "large g_{max}", with $g_{max} = g_{zz}$ in the former case, to an axial signal, with $g_{max} = g_{xx} = g_{yy}$ in the latter.[34] Structures of seven of these complexes have been reported.[32–34] In all of these complexes the axial ligands are in perpendicular planes lying over the *meso* positions of the porphyrin ring, with strong ruffling of the porphyrin core in order to reduce steric crowding between the *o*–CH_3 groups and the pyridine ligands, as shown in Figure 48. This strong ruffling produces two oblong "cavities" at right angles to each other, one above and one below the plane of the porphyrin ring, which hold the axial ligands in perpendicular planes over the *meso* positions. The EPR spectrum of $[(TPP)Fe(4\text{-}CNPy)_2]^+$ is also axial in both frozen solution and the solid state, and the X-ray crystal structure shows that the axial ligands are also in perpendicular planes lying over the *meso* positions, with a strongly ruffled porphinato core, even though there are no *ortho*-phenyl substituents.[129] The axial EPR spectra, with $g_\perp > g_\parallel$, Table 12, are indicative of a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state.[129] MCD studies of

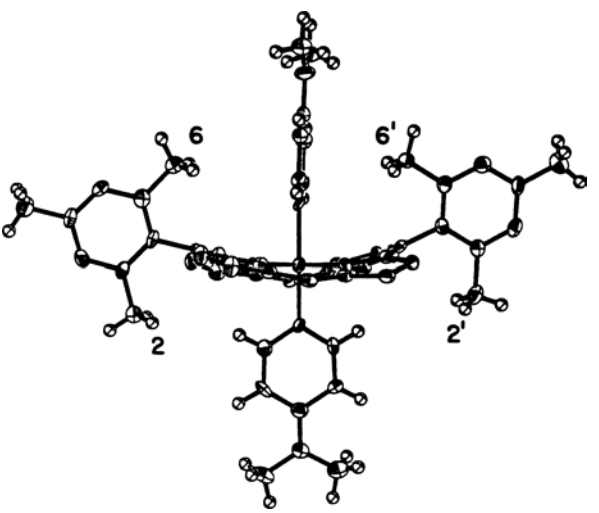

Figure 48. ORTEP diagram showing the arrangement of the effectively coplanar mesityl rings and the axial ligands of $[(TMP)Fe^{III}(4\text{-}NMe_2Py)_2]^+$. Hydrogen atoms have been drawn artificially small, and two of the mesityl rings have been deleted to improve clarity. Reprinted from Safo, M. K.; Gupta, G. P.; Walker, F. A.; Scheidt, W. R. *J. Am. Chem. Soc.* **1991**, *113*, 5497–5510, with permission from the American Chemical Society.

the TMP analog are also consistent with the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state.[127] Thus, low-basicity pyridines stabilize the less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ electronic ground state for low-spin iron(III), though not as strongly as do isonitrile ligands.[155]

A change in ground state of low-spin iron(III) from the usual $(d_{xy})^2(d_{xz},d_{yz})^3$ to the "unusual" $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration occurs smoothly through the series of pyridine complexes of both (TPP)Fe^{III} [514] and (TMP)Fe^{III},[34,491] but the trend is much more pronounced for the TMP complexes, which made it apparent that this change in the ground state was the reason for the $pK_a(BH^+)$ dependence of the paramagnetic shifts in both cases. This $pK_a(BH^+)$ dependence is due to profound effects of the electron configuration of the metal on both the pseudocontact and contact contributions to the paramagnetic shift. For the pseudocontact shift, a change in sign of the axial magnetic anisotropy term (Eqs. 7 and 9) occurs at some $pK_a(BH^+)$ between that of 4-dimethylaminopyridine and 3-cyanopyridine,[491] since the former complex has $g_{zz} > g_{yy} > g_{xx}$[33] while the latter has $g_{xx} = g_{yy} > g_{zz}$.[34] However, the actual anisotropies in homogeneous solution at −80 °C appear to be smaller than those calculated from the g-values (Eq. 9) as a result of thermal population of the "other" electron configuration. If the axial g-anisotropies derived from the g-values of Table 12 are compared to those estimated from the NMR shifts of model low-spin ferrihemes it becomes evident that g-values measured at 77 K and below may not be good indicators of the actual magnetic anisotropy of the complexes at the temperatures of the NMR measurements (183 K and above), and that in many cases the actual magnetic anisotropy may be of opposite sign from that predicted by the g-values measured at very low temperatures (Table 12).

The bis-4-dimethylaminopyridine, bis-1-methylimidazole, bis-cyanide,[548] and bis-4-cyanopyridine[549] complexes of iron(III) octamethyltetraphenylporphyrin, (OMTPP)Fe^{III}, octaethyltetraphenylporphyrin, (OETPP)Fe^{III}, its perfluorinated phenyl analog, (F_{20}OETPP)Fe^{III}, and tetra-(β,β'-tetramethylene)tetraphenylporphyrin, (TC_6TPP)Fe^{III}, have been prepared and characterized by ^{1}H NMR spectroscopy. Complete spectral assignments have been made using 1D and 2D techniques. The temperature dependences of the proton resonances of the complexes show significant deviations from simple Curie behavior and evidence of ligand exchange, ligand rotation, and porphyrin ring inversion at ambient temperatures. At temperatures below the point where dynamics effects contribute, the temperature dependences of the proton chemical shifts of the complexes could be fit to an expanded version of the Curie law (Eq. 12) using the temperature-dependent fitting program developed in this laboratory.[25,84] The results show that, although the ground state differs for various axial ligand complexes and is usually fully consistent with that observed by EPR spectroscopy at 4.2 K, the excited state often has S = 3/2 (or S = 5/2 in the cases where the ground state has S = 3/2). The EPR spectra (4.2 K) of bis-4-dimethylaminopyridine and bis-1-methylimidazole

complexes show "large g_{max}" signals with g_{max} = 3.20 and 3.12, respectively, and the latter also shows a normal rhombic EPR signal, indicating the presence of low-spin (LS) $(d_{xy})^2(d_{xz},d_{yz})^3$ ground states for both. The bis-cyanide complex also yields a large g_{max} EPR spectrum with g = 3.49 and other features that could suggest that some molecules have the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state. All of these complexes have been characterized by X-ray crystallography.[476,477,549]

For the bis-4-CNPy complexes, the magnetic resonance data depend on the porphyrin macrocycle, as first reported by Nakamura *et al*.[550] An axial EPR signal is observed ($g_\perp$ = 2.49, $g_\parallel$ = 1.6) in frozen solutions of both [FeOMTPP(4-CNPy)$_2$]ClO_4 and [FeTC$_6$TPP(4-CNPy)$_2$]ClO_4 at 4.2 K, which is indicative of the low spin (S = 1/2), $(d_{yz},d_{xz})^4(d_{xy})^1$ electronic ground state for these two complexes.[549] However, in CD_2Cl_2 at 183 K the CH_2 chemical shift of [FeTC$_6$TPP(4-CNPy)$_2$]ClO_4 is +6.8 ppm, which indicates the same spin state as seen in the EPR spectrum, while the CH_3 chemical shift of [FeOMTPP(4-CNPy)$_2$]ClO_4 is +31.4 ppm, which indicates that the latter complex has a higher spin state, identified as S = 3/2.[549] At 273 K the same two chemical shifts are 51.3 and 65.4 ppm, which indicates that both of these complexes have spin states S = 3/2 at ambient temperatures.[549] In contrast, the EPR spectra of [FeOETPP(4-CNPy)$_2$]ClO_4 at 4.2 K are typical of the S = 3/2 state, with g-values of 5.21, 4.25, and 2.07, in agreement with Nakamura *et al*.[550] However, distinct from previous conclusions, large negative phenyl-H shift differences δ_m–δ_o and δ_m–δ_p in the ^{1}H NMR spectra indicate significant negative spin density at the *meso*-carbons, and the larger than expected positive CH_2 shifts (+66.1, +14.8 ppm at 183 K, +45.7, +14.0 ppm at 273 K) are also consistent with a significant population of the S = 2 Fe^{II}, S = 1/2 porphyrin π-radical state, with antiferromagnetic coupling between the metal and porphyrin unpaired electrons.[549] This is the first example of this type of porphyrin-to-metal electron transfer to produce a partial or complete porphyrinate radical state, with antiferromagnetic coupling between metal and macrocycle unpaired electrons in an iron porphyrinate.

The dynamics of porphyrin ring inversion of a number of iron(III) complexes of octamethyltetraphenylporphyrin, (OMTPP)Fe^{III}; octaethyltetraphenylporphyrin, (OETPP)Fe^{III}; octaethyltetra(perfluorophenyl)porphyrin, (F_{20}OETPP)Fe^{III}; and tetra-β,β-tetramethylenetetraphenylporphyrin, (TC$_6$TPP)Fe^{III}, having either one (Cl^-, ClO_4^-) or two [4-(dimethylamino)pyridine, 4-Me$_2$NPy; 4-cyanopyridine, 4-CNPy, N-methylimidazole, NMeIm; tert-butylisocyanide, *t*-BuNC; or cyanide, CN^-] axial ligands were characterized by 1D dynamic NMR (DNMR) and 2D ^{1}H NOESY/EXSY spectroscopies as a function of temperature.[421,549,551] An example of the compounds studied and the types of spectra analyzed is shown in Figure 49, where it can be seen that some compounds could be studied both above and below the coalescence temperature, using fast-exchange techniques in the higher

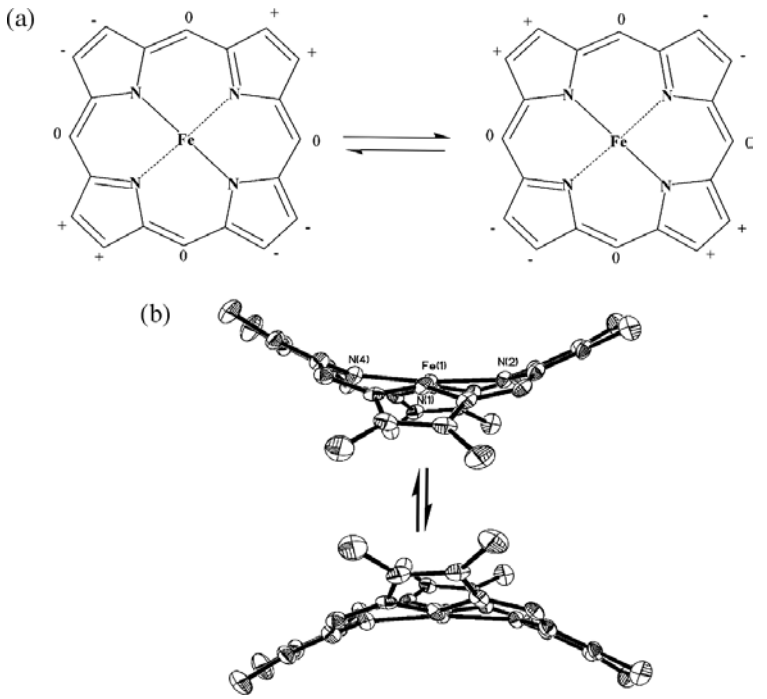

Figure 49. *Top*: Representation of the macrocycle inversion process for the saddle structure of a dodecasubstituted metalloporphyrin: (a) Displacements of the atoms with respect to the porphyrin mean plane are shown as + above the plane, — below the plane, and 0 in the plane; (b) ring inversion approximated using the ORTEP plot generated from the crystal structure of [FeOMTPP(2-MeImH)$_2$]Cl (phenyl ring and axial ligands have been omitted for clarity); ring inversion results in exchange between methyl (for OMTPP) or methylene (for OETPP, F_{20}OETPP, and TC_6TPP) protons.[551] *Middle*: Stacked ^{1}H 300 MHz NMR spectra (low shielding region only) that show broadening of the methyl signal in (OMTPP)FeCl with decreasing temperature.[551] The intensities of all resonances are on a common scale. Reprinted from Yatsunyk, L. A.; Ogura, H.; Walker, F. A. *Inorg. Chem.* **2005**, *44*, 2867–2881, with permission from the American Chemical Society. *Bottom*: 300 MHz ^{1}H NMR spectrum of (OMTPP)FeCl and the lower-shielding part of the NOESY/EXSY spectrum at –80 °C, with 5-ms mixing time; * represents impurities.[548] Reprinted from Yatsunyk, L. A.; Shokhirev, N. V.; Walker, F. A. *Inorg. Chem.* **2005**, *44*, 2848–2866, with permission from the American Chemical Society.

temperature region and 2D NOESY/EXSY (slow-exchange) techniques in the lower temperature region. The activation parameters, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta G^{\ddagger}_{298}$, and the extrapolated rate constants at 298 K for three chloride, one perchlorate, and three bis-(4-Me_2NPy) complexes as well as [FeOETPP(NMeIm)$_2$]Cl, [FeOETPP(*t*-BuNC)$_2$]ClO_4, and Na[FeOETPP(CN)$_2$] have been determined. The results indicate that there is a wide range of flexibility for the porphyrin core (k_{ex}^{298} = 10–10^7 s^{-1}) that decreases in the order TC_6TPP > OMTPP > F_{20}OETPP ≥ OETPP,

which correlates with increasing porphyrin nonplanarity.[551] To determine the effect of axial ligands, the free energy of activation, Eyring plots were constructed and $\Delta G^{\ddagger}_{298}$ for $OETPPFe^{III}$ and $OMTPPFe^{III}$ bis-ligated complexes were calculated for the complexes with 4-Me_2NPy, NMeIm, or 4-CNPy (~59 kJ mol^{-1}), and for complexes with small cylindrical ligands (*t*-BuNC and CN^-) (~37 kJ mol^{-1}), as well as the S = 3/2, 5/2 spin-admixed chloroiron(III) complexes, as shown in Figure 50. These data suggest that the $\Delta G^{\ddagger}_{298}$ for planar ligand rotation is roughly 20–25 kJ mol^{-1}.[551]

f. *The mixed ground state behavior of bis-(pyridine) complexes of low-spin iron(III) complexes of oxophlorins and meso-amino porphyrins*

The bis-(pyridine) complexes (pyridines of a range of basicities) of the deprotonated *meso*-hydroxyoctaethylporphyrinatoiron(III), also called the oxophlorin complex, where the oxoplorin ligand is OEPO, formally $OEPO^{3-}$, Structure **8**, the bis-(N-methylimidazole) and bis-(imidazole) complexes, as well as the bis-(pyridine) or cyanide, pyridine complexes of the same iron(III) macrocycle all show two *meso*-H resonances (ratios 2:1) at very negative chemical shifts.[321,472,473,552] (The oxophlorin derived from protoheme is an intermediate in the oxidation of

heme to verdoheme by the enzyme heme oxygenase.[220]) The methylene and methyl resonances of both [$(Py)_2$FeOEPO] and [$(Py)_2$FeEtioPO] were assigned by 1D NOE difference spectroscopy; for the former, the methylene resonances were found at +30 (2-CH_2), +15 (3-CH_2), +4.7 (4-CH_2) and −3 (1-CH_2) ppm, and, as mentioned above, the *meso*-H were found at −110 and −153 ppm,[475] assignments that indicate major spin delocalization to an orbital with $a_{2u}(\pi)$-like symmetry.

Three resonance structures of the macrocyclic OEPO complex, which involve Fe^{III}, Fe^{II}, or Fe^{I} have been considered,[475] as mentioned in Section IV.A.8.a. To clarify the electron configuration, the electronic and geometric structures of $(Py)_2Fe^{III}$(OEPO), $(ImH)_2Fe^{III}$(OEPO)•2THF, and $(ImH)_2Fe^{III}$(OEPO)•1.6$CHCl_3$ have been examined by single-crystal X-ray diffraction, measurement of magnetic moments as a function of temperature, and by EPR and NMR spectroscopy.[553] The results clearly show that both complexes exist in the Fe^{III} oxophlorin trianion form rather than the Fe^{II} oxophlorin radical form previously established for (2,6-xylylNC)$_2Fe^{II}$(OEPO$^{\bullet}$).[554] In the solid state from 10 to 300 K, [$(Py)_2Fe^{III}$(OEPO)] exists in the high-spin (S = 5/2) state with the axial ligands in parallel planes, a planar porphyrin, and long axial Fe–N distances.[553] However, in solution it exists predominantly in a low-spin (S = 1/2) form. In contrast, the structures of $(ImH)_2Fe^{III}$(OEPO)•2THF and $(ImH)_2Fe^{III}$(OEPO)•1.6$CHCl_3$ consist of porphyrins with a severe ruffled distortion, axial ligands in nearly perpendicular planes, and relatively short axial Fe–N distances. The crystallographic, magnetic, EPR, and NMR results all indicate that $(ImH)_2Fe^{III}$(OEPO) exists in the low-spin Fe^{III} form in both the solid state and in solution.[553] The *meso*-H resonances of the bis-ImH complex were found at −25 ppm, which suggests a $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration, but their temperature dependence is curved; the EPR spectrum at 4 K is rhombic, with g-values 2.72, 2.27 and 1.64.[553] These facts can be rationalized if the electron configuration at 4 K is $(d_{xy})^2(d_{xz},d_{yz})^3$, while that at ambient temperature is $(d_{xz},d_{yz})^4(d_{xy})^1$; whether this change is the result of a temperature-dependent equilibrium between the two, as found for the [TPPFe(OCH_3)(OO-^{t}Bu)]$^-$ case[481] discussed in Section IV.A.8.a, or a thermally-accessible excited state, is not clear. The bis-cyanide complex was also investigated and formulated as $[(CN)_2Fe^{III}(OEPO)]^{2-}$.[473]

[$(Py)_2Fe^{III}$OEPO$^-$] ↔ [$(Py)_2Fe^{II}$(OEPO$^{\bullet}$)] reacts with NO in the strict absence of O_2 to produce a dimer, $[(Py)(NO)Fe^{II}(OEPO)]_2$,[555] which has a 15-*meso*-15-*meso* bond. Its ^{1}H NMR spectrum at −10 °C has eight equally intense methylene resonances with chemical shifts of 18.9, 8.4, 4.3, 2.0, 1.6, 1.2, −1.6, and −4.8 ppm and two *meso*-H resonances at −95.9 and −148.2 ppm; the −148.2 ppm *meso*-H is at the bridging carbon. The reaction can be reversed upon purging with N_2.[555] The crystal structure of the dimer has been obtained and shows that the Fe–N–O unit is bent (138°), as expected for this $\{FeNO\}^7$ center.[555]

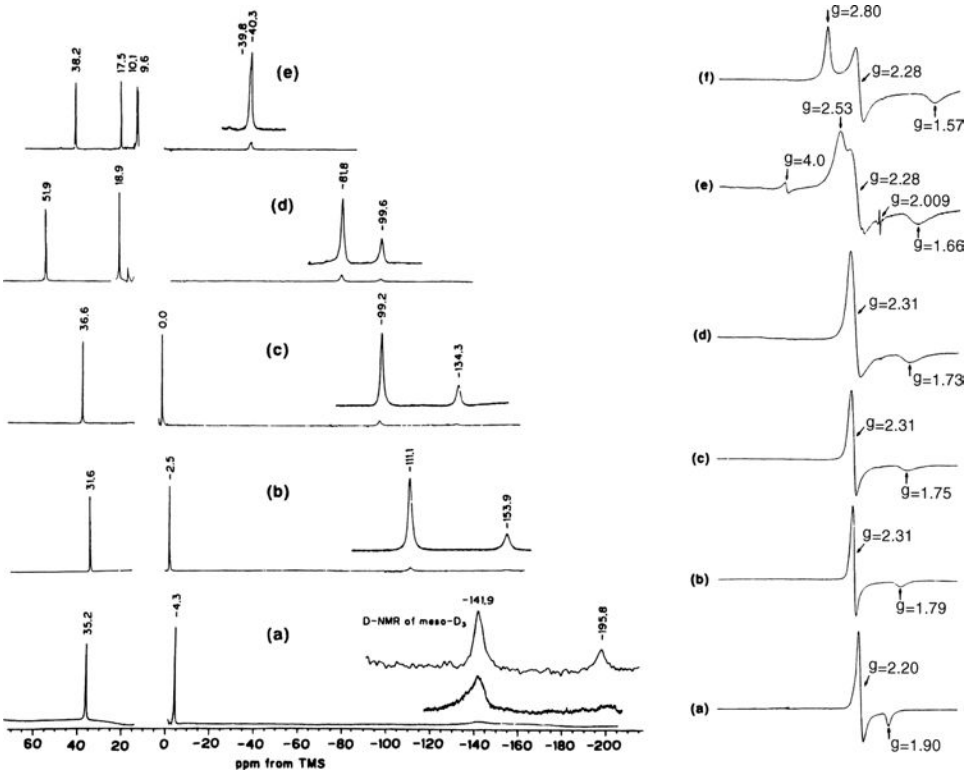

Figure 51. Left: ^{1}H NMR spectra of [(OEPO)Fe^{III}(R-Py)$_2$] measured in the ligand as solvent: (a) 4-acetylpyridine; (b) pyridine-d_5; (c) 4-methylpyridine; (d) 3,4- dimethylpyridine; (e) N-methylimidazole. Sharp signals are due to observable α-CH_2 (additional signals buried in the diamagnetic region), while insets of broad signals represent the *meso*-H. Note the decreasing meso-H shifts as the basicity of the ligands decreases. Right: EPR spectra of the same complexes measured at 77 K. (f) is [OEPOAc)Fe^{III}(ImH)$_2$] in CH_2Cl_2. Note the shift from rhombic to axial spectra and the decrease in g-anisotropy as the basicity of the ligands decreases. Reprinted from Morishima, I.; Fujii, H.; Shiro, Y. *J. Am. Chem. Soc.* **1986**, *108*, 3858–3860, with permission from the American Chemical Society.

Chemical shifts of the *meso*-H resonances of a series of [(R-Py)$_2$FeOEPO] complexes decrease as the basicity of the axial ligand increases and range from –141.9, –195.8 ppm (4-AcPy) to –81.8, –99.6 ppm (3,4-Me$_2$Py) to –40.3, –39.8 ppm (NMeIm),[321] and –118, –152 ppm (bis-pyridine) and –70, –90 ppm (Py, CN^-),[472–475] as shown in Figure 51. The bis-(hydrazine) adduct has *meso*-H shifts of –39 and –44 ppm.[552]) This is another interesting case of the degree of $a_{2u}(\pi)$ character decreasing as the basicity of the axial ligand increases, as observed previously also for the pyridine complexes of (TMP)Fe^{III},[34,491] and as discussed in Section IV.A.8.d above. As discussed earlier in Section IV.A.8.a, the EPR spectra also change in concert with the NMR spectra, such that the 4-AcPy complex has the axial spectrum with

the smallest difference between $g_\perp$ and $g_\parallel$, while 3,4-Me_2Py has the largest difference, and the NMeIm and ImH complexes have rhombic signals, as shown in Figure 51, right hand side. Clearly the oxophlorin ring system has a much greater tendency to have the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state than does the porphyrin ring, with a given axial ligand, yet the trend is still the same as for the (TMP)Fe^{III} system with pyridines of increasing basicity.[34,491] These oxophlorin-based complexes were originally assigned to be $[(OEPO^{-\bullet})Fe^{II}]^+$ π-cation radical electronic structures.[321] However, neither the EPR g-values, Figure 51, right, (which deviate too much from 2.0 to represent porphyrin-based unpaired electrons), nor the sharpness of the *meso*-H NMR signals, Figure 51, left, (which do, however, become broader with lower-basicity pyridine ligands),[321] are consistent with the unpaired electron being localized in the porphyrin π orbitals, because organic radicals in the absence of any other source of unpaired electrons (such as the $[(P^{-\bullet})Fe^{II}NO]^+$ complexes reported by Morishima and coworkers[322]) have extremely broad to undetectable NMR signals, because of their short electron spin relaxation times. Nevertheless, the large, negative *meso*-H shifts for the 4-acetylpyridine complex of octaethyloxophloriniron(III)[472,473] could represent up to 72% occupation of the $a_{2u}(\pi)$ orbital by the unpaired electron, while the *meso*-H shift of the [(OEP)Fe(*t*-BuNC)$_2$]$^+$ complex represents much less (only about 27%) occupation of that orbital, if simple Hückel calculations[211] are at all meaningful. Thus, this series of varying basicity pyridine complexes of octaethyloxophloriniron(III) may represent the closest approach to a smooth transition from a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state to a porphyrin-based $3a_{2u}(\pi)$ unpaired electron-low-spin iron(II) electron configuration found thus far. These systems should be compared to the $[(OEP^{-\bullet})Ru(CO)Br)]$ and $[(OEP^{-\bullet})Ru(CO)]^+$ ClO_4^- complexes discussed in Section IV.B later, where there is a clear shift from the ruthenium(III) to ruthenium(II) π-radical states, with relatively small differences in chemical shifts — at least of the pyrrole substituents.

Treatment of the bis-pyridine complexes of a series of mono-*meso*-substituted iron(II) derivatives of octaethylporphyrin, where the *meso*-substituent is NO_2, CN, HC(O), Cl, OMe, phenyl, or *n*-butyl, with hydrogen peroxide in the strict absence of dioxygen in d_5-pyridine at −30 °C yielded stable oxophlorin derivatives, as long as the samples were protected from exposure to dioxygen.[556] These reactions yielded mixtures of three possible oxygenation products, $[(Py)_2Fe$(*cis-meso*-R-OEPO)], $[(Py)_2Fe$(*trans-meso*-R-OEPO)], and $[(Py)_2Fe$(OEPO)]. The yield of $[(Py)_2Fe$(OEPO)], which results from replacement of the unique *meso* substituent, as a function of the identity of the *meso* substituent, decrease in the order NO_2 > HC(O) ~ CN ~ Cl > OMe > Ph, Bu, which suggests that the species responsible for attack on the porphyrin periphery is nucleophilic in nature. The ^{1}H NMR spectra of the products show methylene resonances in the +25 ppm region, but with

quite a wide variation in the separation between the *cis* resonances (largest for formyl (+16, +24 ppm), smallest for methoxy (+25 to +26 ppm)). The *meso*-H resonances were found in the −125 to −225 ppm region, with the *trans* isomer's *meso*-H resonance generally being at lower shielding than the two widely-spaced *cis* isomer *meso*-H resonances.[556] A mechanism involving isoporphyrin formation through attack of hydroxide ion on a cationic iron porphyrin with an oxidized porphyrin ring is suggested.[556] The identity of the unique *meso* functionality also affects the regiospecificity of substitution when the unique *meso* group is retained. Although random attack at the two different *meso* sites is expected to yield a *cis*/*trans* product ratio of 2, the observed ratios vary in the following order: cyano, 5.0; chloro, 3.2; formyl, 2.6; methoxy, 1.9; phenyl, 1.4.[556]

Pyridine solutions of $ClFe^{III}$(*meso*-NH_2-OEP) undergo oxidative ring opening when exposed to dioxygen.[557] The high-spin iron(III) complex, $ClFe^{III}$(*meso*-NH_2-OEP), was isolated and characterized by X-ray crystallography. In the solid state, it has a five-coordinate structure typical for a high-spin (S = 5/2) iron(III) complex. In $CDCl_3$ the ^1H NMR spectrum of $ClFe^{III}$(*meso*-NH_2-OEP) is characteristic of a high-spin, five-coordinate complex which is unreactive toward dioxygen. However, in pyridine-d_5 solution a temperature-dependent equilibrium exists between the high-spin (S = 5/2), six-coordinate complex, {(Py)$ClFe^{III}$(*meso*-NH_2-OEP)}, and the six-coordinate, low spin (S = 1/2 with the less-common $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state) complex, $[(Py)_2Fe^{III}$(*meso*-NH_2-OEP)$]^+$. Such pyridine solutions are air-sensitive, and the remarkable degradation has been monitored by ^1H NMR spectroscopy.[557] These studies reveal a stepwise conversion of $ClFe^{III}$(*meso*-NH_2-OEP) into an open-chain tetrapyrrole complex in which the original amino group and the attached *meso*-carbon atom have been converted into a nitrile group.[557] Additional oxidation at an adjacent *meso* carbon occurs to produce a ligand that binds iron by three pyrrole nitrogen atoms and the oxygen atom introduced at a *meso* carbon. This open-chain tetrapyrrole complex itself is sensitive to attack by dioxygen and is converted into a tripyrrole complex that is stable to further oxidation and has been isolated[557] and investigated by NMR spectroscopy.[558] The process of oxidation of the iron(III) complex, $ClFe^{III}$(*meso*-NH_2-OEP), has been compared with that of the iron(II) complex, $(Py)_2Fe^{II}$(*meso*-NH_2-OEP);[559] both converge to form identical products.

g. *Low-spin Fe^{III} complexes of meso–meso-linked 5,5′-bis(10,15,20-triphenylporphyrin)*

The ^1H NMR spectra of iron(III) complexes of dimeric 5,5′-bis-(10,15,20-triphenylporphyrin) [$(TrPPH_2)_2$], 5,5′-bis(10,15,20-tris(*p*-methoxyphenyl)porphyrin) [$(Tr(p\text{-MeOP})PH_2)_2$], and hybrid $(TrPPH_2)(Tr(p\text{-MeOP})PH_2)$ and the respective

monomeric 5,10,15-triphenylporphyrin ($TrPPH_2$) and 5,10,15-tris(*p*-methoxyphenyl) porphyrin [Tr(*p*-MeOP)PH_2] were investigated in order to investigate the impact of a direct *meso–meso* linkage on the electronic structure of corresponding high- and low-spin iron(III) porphyrins.[560] The following species, covering the representative spin/oxidation states, have been investigated: $(TrPP)_2(Fe^{III}Cl)_2$ (high spin); $[(TrPP)_2(Fe^{III}(CN)_2)_2]^{2-}$ (low spin); $[(TrPP)_2(Fe^{III}Cl)_2]$+ (high-spin iron(III), diporphyrin radical); $[(TrPP^{-\bullet})_2(Fe^{III}Cl)_2]^{2+}$ (high-spin iron(III), diradical of diporphyrin). The iron(III) diporphyrins $(TrPP)_2(Fe^{III}Cl)_2$, $[(TrPP)_2(Fe^{III}(CN)_2)_2]^{2-}$, $\{[(TrPP)Fe^{III}(CN)_2][(Tr(p\text{-}MeOP)P)Fe^{III}(CN)_2]\}^{2-}$, and $[(TrPP)_2(Fe^{III}Cl)_2]^{2+}$ revealed the same ^{1}H NMR features which have been typically encountered in the spectra of the relevant monomeric complexes. Thus magnetic interactions between the two subunits via the skeleton appear to be minor. This is consistent with the structures, in which the two porphyrin planes are perpendicular to each other. The characteristic broadening and/or paramagnetic shifts of 3-H and 7-H resonances were determined and are diagnostic features of the *meso–meso* linkage. One-electron, ligand-based oxidation of $(TrPP)_2(Fe^{III}Cl)_2$ to produce $[(TrPP)_2(Fe^{III}Cl)_2]^+$ was observed with the unpaired electron delocalized over both macrocycles.[560]

h. *Five-coordinate low-spin iron(III) porphyrins and a porphycene*

Publications on the NMR spectra of a number of low-spin iron(III) complexes bound to one alkyl, aryl or silyl axial ligand have appeared;[166,516,561–563] the chemical shifts of typical examples are presented in Table 13. The group IV anions are expected to be extremely strong σ-donors, and indeed, they are able to stabilize both low-spin iron(II)[243] and low-spin iron(III) in a 5-coordinate state, except when four or five electronegative fluorine atoms are present on the aryl ring, in which case the 5-coordinate complexes are high-spin.[564] For the low-spin complexes, porphyrin β-pyrrole-H and $-CH_2$ shifts are indicative of the "normal" $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, with spin delocalization via P $\rightarrow$ Fe π bonding.[516] The α-H of alkyl groups had not been detected under any condition until Li and Goff[163] reported the ^{2}H NMR spectra of [(d_8-TPP)Fe(CD_3)] and [(d_8-TPP)Fe(C_2D_5)] in toluene at 25 °C, recorded over a very large spectral width at 55 MHz: For the CD_3 group, δ_{obs} = 532 ppm, and for the C_2D_5 group, δ_{obs} for the CD_2 group is 562 ppm, with the CD_3 signal of the ethyl group at −117 ppm. These are the largest chemical shifts reported thus far for iron porphyrins; the low frequency of the ^{2}H nucleus makes possible the use of spectral bandwidths that correspond to such a large number of ppm. Widths of the α-CD_3 and $-CD_2$ resonances are reasonably narrow, 80 and 115 Hz, respectively, in both THF and toluene.[163] In light of the expected narrowing of deuterium resonances of up to a factor of 42 over those of protons at the same molecule positions (Section II.D.2), it is not surprising that $-CH_3$ and

[a]R = alkyl, aryl or silyl ligand.

α-CH_2 signals have not been detected. It has been possible to separate the β-H and more distant proton paramagnetic shifts of the 1-adamantane complex, [(TTP)Fe(1-adamantane)], into contact and pseudocontact contributions.[563] Contact shifts within the 1-adamantane group (as well as other alkyl groups) are negative, since the unpaired electron of low-spin iron(III) is in a π-symmetry orbital, while the spin must be delocalized to the alkyl group via σ-delocalization. It was noted, however, that whereas the β-methyl resonances of the ethyl, isopropyl,

and *tert*-butyl groups have characteristic resonances at about –115 ppm (at 20 °C), the β-methylene groups of *n*-propyl, *n*-butyl, 1-adamantane, and 4-camphor appear at least 50 ppm to lower shielding than these, due to the importance of the $\cos^2\varphi$ term in Eq. 6.[563] The much smaller shift of the silyl methyl protons,[565] Table 13, seems to suggest the possibility of competing σ and π delocalization mechanisms for this heavier coneger of the *tert*-butyl anion. For aryl anions bound to iron(III), the alternating sign pattern of aryl-H contact shifts (Table 13) is indicative of mainly π spin delocalization to the aryl group.[516] Addition of *N*-methylimidazole or pyridine to either 5-coordinate low-spin or high-spin iron(III) porphyrins produces low-spin mixed-ligand complexes, in which the paramagnetic shifts of the phenyl-H or alkyl groups bound to iron are decreased,[516] probably due to decreased $R^- \rightarrow Fe$ σ (and, in the case of R^- = aryl, π as well) delocalization from the R group to the metal. Thus, the effect of adding a sixth ligand, which decreases the contact shifts of the aryl-H, suggests that the aryl anion acts as either a strong σ donor or a π donor, rather than a π acceptor toward low-spin iron(III). However, the planar nature of the aryl ligand is not sufficient to produce a resolved rhombic EPR spectrum for [(TTP)Fe(C_6H_5)]; instead, a "large g_{max}" signal at g = 3.54 is observed, with a broad feature at about g ~ 1.7,[331] indicating near-degeneracy of d_{xz} and d_{yz}, probably due to the strong σ-donor nature of the aryl ligand. Addition of pyridine shifts this signal to g = 3.86 and the broad feature to higher field (lower g-value).[331] Comparison of the ^{1}H chemical shifts of the phenyl and 2,3,5,6-tetrafluorophenyl complexes of both (OEP)Fe^{III} and ((*p*-CF_3)$_4$TPP)Fe^{III} with d_5-pyridine reveals a shift to higher frequency in approximate proportion to the geometric factors for all porphyrin resonances as the electronegative fluorine atoms are substituted onto the phenyl ring; the 4-H of that ring shifts to lower frequency by about the same geometric factor proportion,[564] a clear indication that the major difference in the paramagnetic shifts is due to the pseudocontact contribution. Thus, it appears that the magnetic anisotropy of the low-spin 6-coordinate complexes [(OEP)Fe(C_6F_4H)(Py)] and [((p-CF_3)$_4$TPP)Fe(C_6F_4H)(Py)], as well as the perfluorophenyl analogs, is considerably smaller than that of the phenyl complexes. The EPR spectra of these 6-coordinate, low-spin fluorophenyl complexes have not been reported.

A report of NMR studies on an iron(III) phenyl etioporphycene (Structure **14**) has appeared.[354] The 3,6,13,16-CH_3 resonance is at +11.5 ppm while the α-CH_2 resonances are at 8 and 3.3 ppm and the 9,10,19,20-"vinyl"-H are at +6.7 ppm, and the phenyl-H are at –5.5 (*o*,*p*-H) and +3.7 (*m*-H) ppm. The pattern of shifts is similar to that of the corresponding [(OEP)Fe(C_6H_5)],[561] although the aryl-H shifts are much smaller in magnitude for the porphycene complex, and the alkyl shifts are somewhat smaller.[354] The EPR spectra of the phenyliron(III) porphycene complex and its pyridine adduct have been reported: The g-values are 2.29, 2.27 and

1.94 for the 5-coordinate and considerably more anisotropic for the pyridine adduct. The above-quoted g-values are consistent with the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, a very different result than obtained for the TTP analog, which has a "large g_{max}" EPR signal at g = 3.54 and a broad feature at g ~ 1.7.[563] A pure $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state should have very small paramagnetic shifts and Curie plot intercepts of zero, whereas the phenyliron(III) etioporphycene has negative intercepts for all types of protons.[354] This suggests that there is a thermally-accessible $(d_{xy})^2(d_{xz},d_{yz})^3$ excited state, as has been found for many other $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state systems discussed above.

i. *Low-spin iron(III) complexes of reduced hemes*

A number of investigations of the NMR spectra of the dicyano complexes of two reduced hemes have been reported.[133,206,207,566–568] The structure of sulfhemin isomer C, extracted from sulfmyomoglobin cyanide, was determined by NMR techniques,[133,566–568] and shown to be reduced at pyrrole ring II, Structure **1**. Reduction of the porphyrin ring to the chlorin changes the symmetries and molecular orbital coefficients of the frontier orbitals,[133] as shown in Figure 5. The pattern of paramagnetic shifts of this prosthetic group is indicative of delocalization not only from L $\rightarrow$ Fe π donation from the filled A_{-2} orbital of the chlorin (the modification of one of the 3e(π) orbitals of the porphyrin ring), but also from the filled A_{-1} orbital of the chlorin, which, unlike the $1a_{1u}$ orbital of the porphyrin, has proper symmetry to overlap with the d_{xz} orbital of the metal. The NMR spectra of all three of the modified hemin complexes have been observed and assigned as the metmyoglobin cyanide complexes.[362,569] Similar investigation of the dicyanoiron(III) complex of a chlorophyll a derivative, pyropheophorbide a methyl ester, in which it is ring D or IV, Structure **1**, that is reduced, and a fifth ring is present that bridges positions 13 and 15, yielded total assignment of the ^{1}H NMR spectrum of this "green heme" complex, as well as the corresponding bis-(imidazole) complex.[206] Later, the assignments were confirmed by 2D NMR techniques.[208] Again, the pattern of paramagnetic shifts was explained in terms of spin delocalization via L $\rightarrow$ Fe π donation from the A_{-2} and A_{-1} filled π orbitals of the chlorin (Figure 5).[206]

The NMR and EPR spectra of a series of pyridine complexes $[(OEC)Fe(L)_2]^+$ (L = 4-Me_2NPy, Py, and 4-CNPy) have been investigated.[115] The EPR spectra at 4.2 K suggest that with a decrease of the donor strength of the axial ligands, the complexes change their ground state from $(d_{xy})^2(d_{xz},d_{yz})^3$ to $(d_{xz},d_{yz})^4(d_{xy})^1$. The NMR data from 303 to 183 K show that at any temperature within this range the chemical shifts of pyrrole-8,17-CH_2 protons increase with a decrease in the donor strength of the axial ligands. The complete peak assignments of the $[(OEC)Fe(L)_2]^+$ complexes of this study have been made from COSY and NOE

difference experiments.[115] The pyrrole-8,17-CH_2 and pyrroline protons show large chemical shifts (hence indicating large π spin density on the adjacent carbons which are part of the π system), while pyrrole-12,13-CH_2 and -7,18-CH_2 protons show much smaller chemical shifts, as predicted by the spin densities obtained from molecular orbital calculations, both Hückel and DFT; the DFT calculations additionally show close energy spacing of the highest five filled orbitals [of the Fe(II) complex] and strong mixing of metal and chlorin character in these orbitals that is sensitive to the donor strength of the axial substituents.[115] The EPR spectra of the bis-ImH and -4-NMe_2Py complexes are rhombic, with g-values of 2.54, 2.39, 1.72 and 2.85, 2.47, 1.85, respectively, while those of the bis-Py and –4–CNPy complexes have only one resolved feature, at $g_\perp$ = 2.47 and 2.37, respectively; the bis-*t*-BuNC complex, however, has a rhombic EPR signal, with g-values of 2.32, 2.18, 1.93,[115] which are consistent with the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration in a complex where the macrocycle does not have 4-fold symmetry.

The pattern of chemical shifts of the pyrrole-CH_2 protons of [(OEC)Fe(*t*-BuNC)$_2$]$^+$ looks somewhat like that of [(OEC)Fe(4-Me_2NPy)$_2$]$^+$, while the chemical shifts of the *meso*-protons are qualitatively similar to those of [(OEP)Fe(*t*-BuNC)$_2$]$^+$. The temperature dependence of the chemical shifts of [(OEC)Fe(*t*-BuNC)$_2$]$^+$ shows that it has a mixed $(d_{xz},d_{yz})^4(d_{xy})^1$ and $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration that cannot be resolved by temperature-dependent fitting of the proton chemical shifts, with a S = 5/2 excited state that lies somewhat more than 2 kT at room temperature above the ground state; the observed pattern of chemical shifts is the approximate average of those expected for the two S = 1/2 electronic configurations, which involve the a-symmetry SOMO of a planar chlorin ring with the unpaired electron predominantly in the d_{yz} orbital and the b-symmetry SOMO of a ruffled chlorin ring with the unpaired electron predominantly in the d_{xy} orbital.[115] A rapid interconversion between the two, with calculated vibrational frequency of 22 cm^{-1}, explains the observed pattern of chemical shifts, while a favoring of the ruffled conformation explains the negative chemical shift (and thus the negative spin density at the α-pyrroline ring carbons), of the pyrroline-H of [TPCFe(*t*-BuNC)$_2$]$^+CF_3SO_3^-$.[570]

Thus, although most of the chlorins studied thus far by ^{1}H NMR spectroscopy clearly have $(d_{xy})^2(d_{xz},d_{yz})^3$ ground states when bound to imidazoles or high-basicity pyridines (despite their g-values, Table 12), when bound to strong π-acceptor ligands, they, like their porphyrin analogs, do have $(d_{xz},d_{yz})^4(d_{xy})^1$ ground states.

The NMR and EPR spectra of two bis-imidazole and three bis-pyridine complexes of tetraphenylchlorinatoiron(III), (TPC)Fe(L)$_2^+$ (L = Im-d_4, 2MeImH, 4-Me_2NPy, Py, and 4-CNPy), have been investigated.[365] The full resonance assignments of the [(TPC)Fe(L)$_2$]$^+$ complexes of this study have been made from correlation spectroscopy (COSY) and nuclear Overhauser enhancement spectroscopy

(NOESY) experiments and Amsterdam density functional (ADF) calculations. Unlike the $[(OEC)Fe(L)_2]^+$ complexes reported previously,[115] the NMR data for the $[(TPC)Fe(L)_2]^+$ complexes of this study indicate that the ground state is S = 1/2 for each bis-ligand complex, whereas a higher spin state was present at NMR temperatures for the Py and 4-CNPy complexes of $(OEC)Fe^{III}$. The pyrrole-8,17 and pyrroline-H of all $[(TPC)Fe(L)_2]^+$ show large magnitude chemical shifts (hence indicating large spin density on the adjacent carbons that are part of the π system), while pyrrole-12,13-CH_2 and −7,18-CH_2 protons show much smaller chemical shifts, as predicted by the spin densities obtained from ADF calculations.[365] The magnitude of the chemical shifts decreases with decreasing donor ability of the substituted pyridine ligands, with the nonhindered imidazole ligand having slightly larger magnitude chemical shifts than the most basic pyridine, even though its basicity is significantly lower (4-Me_2NPyH^+ $pK_a = 9.7$, H_2Im^+, $pK_a = 6.65$ (adjusted for the statistical factor of two protons)). The temperature dependence of the chemical shifts of all but the 4-Me_2NPy bis-ligand complexes studied over the temperature range of the NMR investigations shows that they have mixed $(d_{xy})^2(d_{xz},d_{yz})^3/(d_{xz},d_{yz})^4(d_{xy})^1$ electron configurations that cannot be resolved by temperature-dependent fitting of the proton chemical shifts, with an S = 3/2 excited state in each case that in most cases lies at more than kT at room temperature above the ground state.[365] The observed pattern of chemical shifts of the 4-CNPy complex and analysis of the temperature dependence indicate that it has a pure $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state and that it is ruffled, because ruffling mixes the $a_{2u}(\pi)$-like orbital of the chlorin into the singly occupied molecular orbital (SOMO). This mixing accounts for the negative chemical shift of the pyrroline-H (−6.5 ppm at −40 °C) and thus the negative spin density at the pyrroline-α-carbons, but the mixing is not to the same extent as observed for $[(TPC)Fe(t\text{-}BuNC)_2]^+$, whose pyrroline-H chemical shift is −36 ppm at 25 °C.[570] As mentioned above, peak assignments for high-spin (TPC)FeCl have been made by saturation transfer techniques that depend on chemical exchange between this complex and its bis-4-Me_2NPy adduct.[365]

A series of low-spin six-coordinate (tetraphenylchlorinato)iron(III) complexes $[Fe(TPC)(L)_2]^+$ (L = NMeIm, CN^-, 4-CNPy, and *t*-BuNC) which have their *meso*-carbons labeled with ^{13}C have been prepared, and their ^{13}C NMR spectra have been examined to aid in interpreting the electronic structure. These complexes were all found to exist as the mixture of the two isomers, with $(d_{xy})^2(d_{xz},d_{yz})^3$ and $(d_{xz},d_{yz})^4(d_{xy})^1$ ground states. The contribution of the $(d_{xz},d_{yz})^4(d_{xy})^1$ isomer increased as the axial ligand changes from NMeIm, to CN^- (in CD_2Cl_2 solution), CN^- (in CD_3OD solution), and 4-CNPy, and then to *t*-BuNC as revealed by the *meso*- and pyrroline-carbon chemical shifts; the *meso*-carbon signals at +146 and −19 ppm in $[Fe(TPC)(NMeIm)_2]^+$ shifted to +763 and +700 ppm in $[Fe(TPC)(t\text{-}BuNC)_2]^+$.[571] In the case of the CN^- complex, the population of the $(d_{xz},d_{yz})^4(d_{xy})^1$

isomer increased to a great extent when the solvent was changed from CD_2Cl_2 to CD_3OD. This result is ascribed to the stabilization of the d_{xz} and d_{yz} orbitals of iron(III) caused by hydrogen bonding between methanol and the coordinated cyanide ligand.[571] Comparison of the *meso*-^{13}C NMR data of the TPC complexes with those of the TPP, OEP, and OEC complexes revealed that the populations of the $(d_{xz},d_{yz})^4(d_{xy})^1$ isomer in TPC complexes are much larger than those in the corresponding TPP, OEC, and OEP complexes carrying the same axial ligands.[571]

Sirohemin is an iron(III) isobacteriochlorin that is found in sulfite and assimilatory nitrite reductases.[572] The dicyanoiron(III) complex of the extracted macrocycle has been studied by NMR spectroscopy,[573] where it was shown that the 13- and 17- α-CH_2 protons of the propionates of the two fully aromatic pyrrole rings have resonances in the +13.7 to +10.3 ppm region, while the 12- and 18-CH_2 resonances of the acetate groups of the same two pyrrole rings lie in the +7.0–5.2 ppm region at 15 °C in D_2O, pH 6.0. The 2- and 7- methyls of the saturated pyrrole rings are found in the diamagnetic region at 3.2 and 0.6 ppm, and the four *meso*-H resonances occur at −5.1, −26.3, −30.4 and −58.1 ppm.[573] The basis for assignment of these *meso*-H resonances to the 5, 10, 15 and 20 positions[573] is not clear, for it does not follow the symmetry of the molecule, and thus the expected spin densities at the *meso* positions. Only COSY spectra have been reported, and not NOESY spectra, which would have allowed unambiguous assignment of all (or at least most) of the resonances. The large negative *meso*-H shifts are indicative of $3a_{2u}$-type L → Fe spin delocalization of the unpaired electron for the ground state, consistent with a $(d_{xz},d_{yz})^4(d_{xy})^1$ electronic ground state. Consistent with this, an axial EPR signal is observed at low temperatures (15–20 K) with g-values of 2.37 and 1.78.[573] The shifts of the *meso*-H resonances to high shielding compared to the spin densities calculated from the simple Hückel program, MPorphW,[118,211] suggest an assignment 15 < 5 < 10,20, but this should be confirmed on the basis of NOESY spectra. The 13 and 17 α-CH_2 resonances exhibit anti-Curie behavior, suggesting that the $(d_{xz},d_{yz})^3(d_{xy})^2$ excited state is thermally accessible. Based on the anti-Curie behavior of the 13,17-α-CH_2 resonances but the "Curie" behavior of the *meso*-H, the excited state orbital is probably the former 3e(π) orbital having a node through the 5,15 *meso* carbons. The sirohemin bis-cyanide complex of the sulfite reductase protein has very similar NMR spectra, and the sulfite and nitrite complexes of the sirohemin-containing protein are fairly similar as well.[573] Thus, the electronic ground states of this low-spin iron(III) isobacteriochlorin and the chlorins discussed at the beginning of this section are different, and it thus appears that all reduced hemes cannot be classified as having the same electronic ground state, but rather only the isobacteriochlorins (and possibly also dioxoisobacteriochlorins) have the less-common $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state as the dicyano complexes.

j. *Low-spin iron(III) complexes of N-alkylporphyrins*

Enzymatic turnover of cytochrome P450 enzymes causes formation of N-substituted porphyrins; they are also formed by the reaction of substituted hydrazines with heme proteins. Their formation results in the inactivation of the proteins involved.[574,575] N-substituted porphyrins are also inhibitors of the enzymes ferrochelatase and heme oxygenase.[576] Their iron(II) complexes are surprisingly stable to oxidation in air,[577] but upon oxidation with halogens or the thianthrene π-cation radical they form high-spin iron(III) complexes, which readily bind axial ligands such as cyanide or imidazoles.[578] The NMR spectra of iron(III) complexes of both N-methyl-tetra-(*p*-tolyl) porphyrin (N-MeTTP) and *N*-methyl-tetramesitylporphyrin (N-MeTMP) complexes having one or two cyanide, and two imidazole or 5-methylimidazole ligands show the effects of the lowered symmetry of the porphyrin: Three of the four pyrrole-H resonances of [(N-MeTMP)Fe$(CN)_2$] occur at very high shielding. In the case of the bis-(5-MeImH) or the bis-ImH complex, six of the eight pyrrole-H resonances are resolved, indicating the effect of the N-methyl group on hindering the rotation of at least the 5-MeImH ligand on the same side of the porphyrin plane.[578] Two-dimensional NMR methods would allow assignment of the observed pyrrole-H resonances and identification of the two that occur in the 0–7 ppm region and are obscured by the presence of excess ligand, as well as investigation of possible kinetic processes involving ligand rotation in this system.

k. *Thermodynamics of axial ligation of iron(III) porphyrins*

Previous reports[2,489] have shown that the equilibrium constants for ligand addition to the axial positions of iron(III) porphyrins can be readily measured by observing the relative intensity of peaks due to known proton types within the starting material, [(P)FeX], and product, [(P)Fe(X)(L)] or [(P)FeL_2]$^+X^-$, if the rate of ligand exchange is slow on the NMR time scale. The intermediate complex, [(P)Fe(X)(L)], can be either 6-coordinate, as implied by the parentheses and brackets, or 5-coordinate, as a tight ion pair, [{(P)FeL}$^+X^-$], and is often not detected by UV-visible spectroscopy.[579,580] However, NMR spectroscopic investigations at temperatures above 25 °C indicate conclusively that it is present in measureable concentrations in many cases.[2,231,489] Ligands for which binding constants to either tetraarylporphinatoiron(III) or protohemin have been measured by NMR techniques include imidazoles,[197,198,489,581–583] cyanide,[581] and pyridine/water.[345] In $CDCl_3$ it was found that NMR measurement of the overall binding constants, β_2, for addition of two substituted imidazole (RIm) ligands to a series of tetraphenylporphinatoiron(III) halides yielded values of β_2 similar to those measured by

UV-visible spectroscopy.[579] Only the overall binding constant, β_2, could be measured by NMR spectroscopy at 25 °C and below.[489] A more detailed summary of this work has been presented previously.[3]

l. *Kinetics of axial ligand exchange*

Investigations of the dynamics of axial ligand exchange in the low-spin iron(III) complex $[(TPP)Fe(NMeIm)_2]^+Cl^-$ in $CDCl_3$ by observing line broadening of the coordinated NMeIm N-methyl peak as a function of temperature were first reported by La Mar and Walker.[231] It was established that even in the presence of excess ligand, ligand exchange proceeds by a dissociative mechanism which involves a 5-coordinate $(P)FeL^+X^-$ transition state:

$$[(P)FeL_2]^+ \leftrightarrows [[(P)FeL]^+]^\ddagger + L \quad k_1, \tag{35}$$

$$[[(P)FeL]^+]^\ddagger + L^* \leftrightarrows [(P)FeLL^*]^+ \quad \text{rapid.} \tag{36}$$

These studies were extended by Satterlee et al. to characterize the axial lability of various imidazoles and pyridines in bis-ligated low-spin ferric complexes of synthetic porphyrins, including tetraphenyl- and tetra-*n*-propylporphyrins.[583] Typical activation parameters determined in this study are $\Delta H^\ddagger$ = 17–20 Kcal/mol (71–84 kJ/mol), $\Delta S^\ddagger$ = 15–19 eu (63–79 J/K-mol). More recently it has been shown by a combination of saturation transfer, line width analysis and line shape analysis in the intermediate exchange rate region that, as for the TPP complexes, ligand exchange in sterically more hindered (tetramesitylporphinato)iron(III) complexes is also dissociative.[197,198] Dissociation rates of axially coordinated imidazoles measured for TPP and TMP complexes reveal that the axial lability of coordinated imidazoles increases with increasing steric bulk of the base; that is, 2-methylimidazole complexes have larger dissociation rate constants than the corresponding *N*-methylimidazole species. The increased lability is believed to be due to the steric repulsion between the alkyl substituent in the 2-position of the imidazole ring and the porphyrin macrocycle. Overall it was determined that TPP complexes are more labile than TMP counterparts. However, the stability of the TMP complexes is invariably greater than their TPP counterparts, as discussed in Section IV.A.8.k. In fact, the rate constants are inversely proportional to the equilibrium constants, β_2,[198] which suggests that this reaction indeed proceeds as described by Eqs. 35 and 36, and that $\beta_2/K_2 = k_f/k_r$, where $k_r = k_1$.

Kinetics of ligand exchange on cobalt(III) porphyrins have been studied by saturation transfer techniques at high temperatures and compared to those of the corresponding iron(III) porphyrins, where the ligands were all 1-alkyl, 2-alkyl or

1,2-dialkylimidazoles.[584] It was found that 2-alkylimidazoles (Me, Et, i-Pr) exchange 24–40 times more rapidly than NMeIm, and 1,2-Me_2Im exchanges 1400 times more rapidly than NMeIm for (TPP)Co^{III} and 40–200 (Me, Et, i-Pr) and 200 times more rapidly than NMeIm for (TPP)Fe^{III} at 90 °C. In comparison, the rates of ligand exchange on TMPCo^{III} were found to be slower and much more similar to each other for all ligands studied (0.074 vs. 0.2 s^{-1} for NMeIm, 0.38 vs. 8.2 s^{-1} for 2MeImH and 0.011 vs. 280 s^{-1} for 1,2-Me_2Im). Similarly, the rates of ligand exchange on TMPFe^{III} were found to be slower than those for TPPFe^{III} (0.71×10^4 vs. 6.8×10^4 s^{-1} for NMeIm, 1.7×10^4 vs. 160×10^4 for 2MeImH and 5.2×10^4 vs. 1200×10^4 s^{-1} for 1,2-Me_2Im). The reason for the slower rates of ligand exchange for the TMP complexes was suggested to be the attractive interaction between the *ortho*-methyls and the imidazole π system, or the lowered repulsion between ligand atoms and the porphyrin ring in the ruffled, perpendicularly-oriented axial ligand complexes of 2-alkylimidazoles.[584] The latter is undoubtedly the most important reason.

9. *Electron Exchange Between Low-Spin Iron(III) and Low-Spin Iron(II) Porphyrins*

Heme protein electron self-exchange has been studied by NMR spectroscopy since 1965, when Kowalsky first discovered the line broadening in mixed ferro-/ferri-samples of horse heart cytochrome *c*, which was not present in samples of the pure ferro- or ferri- protein.[585] The electron self-exchange reaction can be written as:

$$\underset{\mathrm{L}}{\overset{\mathrm{L}}{\mathrm{Fe}^{*\mathrm{III}}}} + \underset{\mathrm{L}}{\overset{\mathrm{L}}{\mathrm{Fe}^{\mathrm{II}}}} \leftrightarrows \underset{\mathrm{L}}{\overset{\mathrm{L}}{\mathrm{Fe}^{*\mathrm{II}}}} + \underset{\mathrm{L}}{\overset{\mathrm{L}}{\mathrm{Fe}^{\mathrm{III}}}}, \tag{37}$$

where the hemes were inside the cytochrome *c* protein. Kowalsky estimated the rate of electron exchange as ~5×10^4 $M^{-1}s^{-1}$ at pH 6.6, ~25 °C.[585] Gupta, Koenig and Redfield followed up on this report in 1972 with NMR studies on mixed solutions of the two oxidation states of cytochrome *c*.[586] They found that the rate of exchange of oxidation states by electron transfer was sensitive to the conformation of the protein molecules, and that the electron transfer process *in vitro* arose from binary collisions. At low ionic strengths, the rate was found to be affected by the electrostatic charge on the protein molecules.[586] Wüthrich and coworkers used this method to measure the self-exchange rate for *Pseudomonas aeruginosa* cytochrome c_{551} as 1.2×10^7 $M^{-1}s^{-1}$ at pH 7.0, 42 °C in 1976,[587] and of *Euglena gracilis* cytochrome c_{552} as 5×10^4 at pH 7.0, 29 °C in 1977.[588]

Thereafter the rates of electron exchange between several ferro- and ferricytochromes *c* and *b* were studied in more detail by Dixon and coworkers.[589–591] Electron self-exchange was measured by measurement of NMR linewidths and chemical shifts for cytochromes c_{551} from *Pseudomonas aeruginosa* and *Pseudomonas stutzeri*.[589] The rate for *P. aeruginosa* cytochrome c_{551} was found to be 1.2×10^7 $M^{-1}s^{-1}$ at 40 °C in 50 mM phosphate at pH 7. For *P. stutzeri* under the same conditions the rate was found to be 4×10^7 $M^{-1}s^{-1}$.[589] The electron-transfer self-exchange rate constant of trypsin-solubilized bovine liver microsomal cytochrome b_5 was also investigated as a function of temperature and ionic strength. Calculations based on ^{1}H NMR spectra acquired using the inversion-recovery method determined this rate constant to be 2.6×10^3 $M^{-1}s^{-1}$ at pH 7.0, $\mu = 0.1$ M (sodium phosphate), 25 °C, with $AH^{\ddagger} = 5.5$ kcal mol^{-1} and $AS^{\ddagger} = -23$ eu. The rate constant increases with ionic strength, and reaches a value of 4.5×10^4 $M^{-1}s^{-1}$ at $\mu = 1.5$ M. Analysis of the data in terms of Marcus theory gives a reorganization energy, λ, in the range 0.9–1.3 eV mol^{-1}.[591] Finally, the ionic strength dependence of the electron self-exchange rate constants of cytochromes *c*, c_{551}, and b_5 were measured and analyzed[590] in terms of a monopole-dipole formalism.[592] The self-exchange rate constants, extrapolated to infinite ionic strength, of horse heart cytochrome *c*, *Pseudomonas aeruginosa* cytochrome c_{551}, and bovine cytochrome b_5 were found to be 5.1×10^5, 2×10^7, and 3.7×10^5 $M^{-1}s^{-1}$, respectively, at 27, 40 and 25 °C, respectively; cytochrome *c* showed almost no ionic strength dependence, while the other two proteins showed strong ionic strength dependence below 0.2 M, with the rate of change decreasing from 0.2 M up to 1.6 M, the highest ionic strength investigated.[590] The control of electron transfer by the size and shape of the protein was investigated using a model which accounted for the distance of the heme from each of the surface atoms of the protein. These calculations indicated that the difference between the electrostatically corrected self-exchange rate constants of cytochromes *c* and c_{551} is due only in part to the different sizes (103 vs., 72 amino acids, respectively) and heme exposures of the two proteins.[590]

The role of the protein in controlling the rate of electron transfer between two cytochrome molecules which differ only in the oxidation state of the iron, is generally believed to involve electron transfer through the heme edges exposed to the solvent. The role of the protein in this process could best be assessed by investigating the factors that control electron transfer in hemes themselves; that is, the electron self-exchange rate constants between two hemes free in solution needed to be determined (Eq. 37). Dixon and coworkers employed NMR line broadening methods to determine electron self-exchange rate constants in a variety of heme model compounds with the goal of establishing how changes in porphyrin or axial ligand structure and in macrocycle saturation affect the exchange

rates.[196,593–595] The electron self-exchange rates for various bis-N-methylimidazole complexes of iron porphyrins determined at −21 °C in CD_2Cl_2 are found to range from 8.1×10^7 $M^{-1}s^{-1}$ for the TPP complex to 5.3×10^7 $M^{-1}s^{-1}$ for the 3-MeTPP derivative and do not vary in a regular fashion with increase of steric crowding on the periphery of the porphyrin macrocycle. The total range was less than a factor of 2. Similar rate constants were measured for systems with sterically bulky imidazole ligands, such as N-butylimidazole, which suggests that increasing the steric bulk at either the heme site or on the axial ligand has almost no effect on the rate constants of electron exchange. Changes in the degree of saturation of the macrocycle also affect the rate constants in a minor way. Similar rate constant values were obtained for both the OEP and the octaethylisobacteriochlorin complexes, thus indicating little effect of the macrocycle on the electron transfer rate, perhaps due to counterbalancing effects in either the inner or outer sphere reorganization and orbital occupation.[595]

This conclusion was also drawn from the analysis of the rate constants for the dicyano derivatives, $[(TPP)Fe^{III/II}(CN)_2]^{2-}$, for which rate constants ranging from 1.0×10^7 to 5.8×10^7 $M^{-1}s^{-1}$ at 37 °C in deuterated dimethyl sulfoxide solution were obtained.[196] The value of the rate constant obtained for the heme undecapeptide derived from cytochrome *c* proteolysis (1.3×10^7 $M^{-1}s^{-1}$) is comparable to those of other model compounds[195] and indicates that the rate constants for model hemes are approximately a factor of 10 larger than those found in cytochromes with 80–90 amino acids. This also argues that the heme exposure to the solvent seems not to be a major factor that controls the rate constants for electron self exchange in cytochromes. However, complexes with axial imidazoles bearing NH groups have self-exchange rate constants which are a factor of 2–3 smaller than those with N-alkyl imidazole substituents, which indicates that hydrogen bonding or complete deprotonation of the axial imidazole nitrogen atom may play an important role in controlling electron transfer rates.[595]

10. *^{1}H and ^{13}C NMR Spectroscopy of High- and Low-Spin Ferriheme Proteins: The Nitrophorins and Heme Oxygenases*

a. *NMR spectroscopy of the nitrophorins*

Several species of blood-sucking insects, including the Amazon river-based kissing bug, *Rhodnius prolixus*,[596–599] and the common bedbug, *Cimex lectularius*,[600,601] have developed the strategy of causing vasodilation by injecting the NO-transporting heme proteins known as nitrophorins (NP) into the tissues and capillaries of their victims. On rise in pH from ~5–6 in the salivary glands of the insect to ~7.3–7.5 upon injection of the saliva into the victim's tissues, and the dilution of the protein, NO

dissociates. This NO can pass through cell walls to reach the capillaries, and thereby allow their dilation. At the same time, in the case of the *Rhodnius* NPs, the insect's bite triggers release of histamine by the victim's mast cells and platelets.[602,625] This histamine readily binds to the distal heme site of the nitrophorins. Both of these actions permit the insect to remain on the victim for a longer period of time to obtain a sufficient blood meal before detection. One of the nitrophorins, NP2, has an additional activity which helps the insect obtain its blood meal, that of binding with coagulation factors IX (fIX) and IXa (fIXa).[603] The health concerns raised by the insect bites are discussed in detail elsewhere.[604–610]

It was discovered very early in the study of the nitrophorins that the heme-NO complex found in the salivary glands of the *Rhodnius* NPs is EPR silent,[597] as shown in Figure 52. The homogenate of the salivary gland pairs of 100 insects exhibited a small g = 6 signal, which grew larger when argon gas was equilibrated with the sample for extensive periods of time, and disappeared when NO gas was

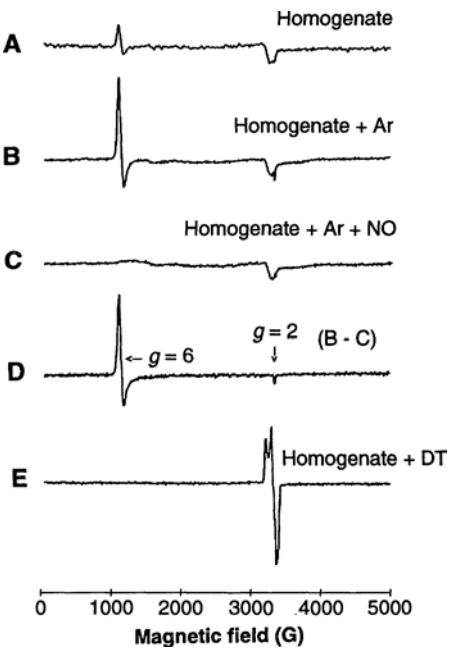

Figure 52. EPR spectra of 100 pairs of *Rhodnius* salivary glands obtained in 125 μL of PBS (A) before argon equilibration; (B) after equilibration in an argon atmosphere for 4 hours; and (C) after equilibration of (B) with NO for 2 min. (E) is the homogenate as in (A) treated with dithionite (DT) to reduce Fe(III) to Fe(II). All spectra are presented on the same scale except (E), which is shown reduced 3x in amplitude. Reprinted with permission from Ribeiro, J. M. C.; Hazzard, J. M. H.; Nussenzveig, R. H.; Champagne, D. E.; Walker, F. A. *Science* **1993**, *260,* 539–541 with permission from the American Association for the Advancement of Science.

subsequently equilibrated with the sample. Subtraction of the EPR spectrum of the NO-added sample from that of the argon-equilibrated sample yielded an axial EPR spectrum with g-values of 6.0 and 2.0, which is characteristic of 5-coordinate, high-spin ferriheme centers having histidine as the sixth ligand (Figure 52D). Thus, the NO-bound NP sample was EPR silent, as expected for a $\{FeNO\}^6$ center in the nomenclature of Feltham and Enemark,[611] in which the number of metal electrons plus the π^* electron of NO are counted. In the absence of NO, the heme center was clearly high-spin Fe(III). In order to obtain the typical EPR spectrum known for heme-NO samples[612] it was necessary to pre-reduce the untreated sample with dithionite and then to equilibrate this dithionite-treated sample with NO, as shown in Figure 52E. The observed EPR spectrum of the resulting sample is that of a 6-coordinate $\{FeNO\}^7$ center, where the sixth ligand is a nitrogen donor,[612] in this case a histidine. The NPs are unique among heme proteins in having stable $\{FeNO\}^6$ centers. This is the result of having a number of negatively-charged protein side chains at physiological pH within 8–16 Å of Fe, all but one of which help to stabilize the formal positive charge on iron(III).[613] As a result of the stabilization of the iron(III)-NO state, the dissociation constants for NO release are in the nM to μM range,[614] a very appropriate size of K_d for biological systems, rather than the pM range of the more typical iron(II)-NO K_ds,[615] which would prevent the NO from being utilized by the insect to help obtain a sufficient blood meal. Interestingly, the iron(II)-NO K_ds of the nitrophorins are even smaller than those (fM range).[614]

In common with the *Rhodnius* nitrophorins, the *Cimex* nitrophorin (*c*NP) was also found to bind one molecule of NO to the stable iron(III) form of the protein to form an EPR-silent $\{FeNO\}^6$ center.[601] However, in contrast to the *Rhodnius* NPs, in the absence of NO the EPR spectrum of the *Cimex* NP is rhombic, with g-values of 7.25, 4.75, and 1.90, which are typical of the high-spin iron(III) form of cytochromes P450.[616] This EPR spectrum thus indicated that in *c*NP the ferriheme is bound to a cysteine ligand. Also in contrast to the *Rhodnius* NPs, when the *c*NP is exposed to high concentrations of NO, two molecules of NO can bind, one to the one-electron-reduced iron(II) form to produce a $\{FeNO\}^7$ center whose EPR spectrum showed that the center was a 5-coordinate heme-NO complex,[612] i.e., that the iron(II) heme had lost its cysteine ligand.[601] The other NO was shown in the crystal structure to be bound to the cysteine, to form a thionitrosyl, SNO.[601] The conclusions which were based the EPR spectra, that the ferriheme center in the absence of NO was bound to a cysteine thiolate, and that the $\{FeNO\}^7$ center was 5-coordinate, with a bent Fe–N–O bond, were also confirmed by the structure of *c*NP in the absence and presence of two molecules of NO.[601] It is probable that the two-NO-bound form is not physiologically relevant, but it is interesting that it can form when the crystals are soaked in mother liquor containing NO. Because

the *c*NP protein has a mass of 30 kD and is thus not that easy to study by multinuclear, multidimensional protein NMR spectroscopy, and because initial characterization of it by 1D ^{1}H NMR spectroscopy revealed that only two heme resonances were exposed outside the spectral envelope of the protein, it will not be discussed further in this chapter.

For further investigation of the *Rhodnius* NPs, a cDNA library was produced from the salivary glands, and the gene for the most abundant nitrophorin, NP1, was cloned[599] and expressed.[617] The genes for NP2, NP3 and NP4 were later also cloned, sequenced, and found to be similar in sequence to NP1.[618] Two additional nitrophorins, designated NP5 and NP6,[619] were later detected in the five nymphal stages of development. The cDNA of another nitrophorin, designated NP7, was found in fifth instar nymphs.[620] The N-terminal sequence of NP5 is very similar to that of NP4 and that of NP6 is very similar to those of NP2 and NP3.[621] The sequences of the four NPs found in the adult insect, plus NP7, are shown in Figure 53, where it can be seen that there are a number of conserved features in the protein sequence, including the four cysteines, the His 59(57)(60), the Leu 123(122)(125) and Leu133(132)(135). NP7 is very different in sequence from NP1–NP4. It shows most similarity to NP2 and NP3 (63 and 64% identity, respectively). NP1 and NP4 are 91% identical in sequence, while NP2 and NP3 have 78% sequence identity. Many residues conserved in NP1–4 are very different in NP7, such that the sequence identity among the five proteins is only 32% (39% among NP1–4). NP7 has different properties than the other *Rhodnius* nitrophorins, in that it binds to anionic phospholipid membranes.[620] Its pI is 9.21,[622] which is much higher than

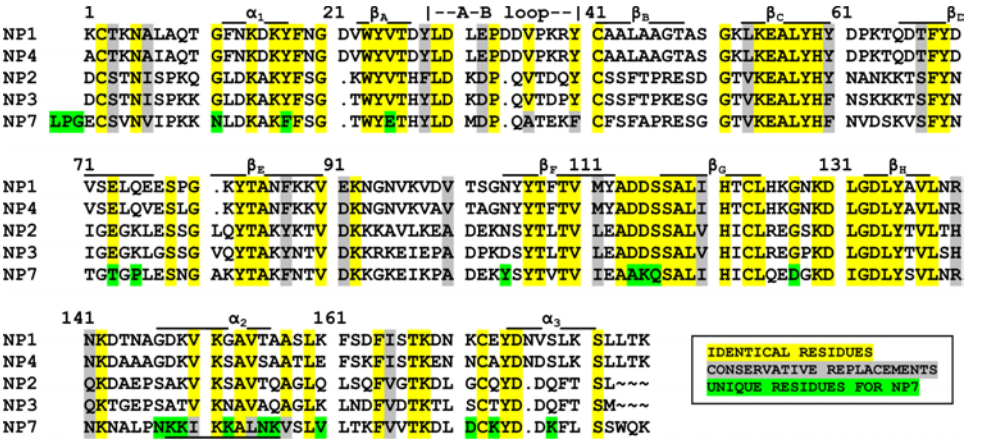

Figure 53. Sequences of five of the nitrophorins from *Rhodnius prolixus,* arranged to show sequence identities within the two groups; NP7 has greatest homology to NP2 and NP3. Helices and β sheet strands are labeled α and β, respectively. Definition of secondary structure is based on the structure of NP4.

those of the others (NP1–4 pI 7.97, 7.53, 6.94, 7.75, respectively[599]), so that if it were present in the saliva of the adult insects, from which NP1–4 were separated on a mono-P chromatofocusing column on an FPLC with triethanolamine HCl buffer at pH 8.4, it would have been missed. NP7 has been partially characterized[622–624] and is under further study in the laboratory of Dr. Markus Knipp at the Max-Planck-Institute for Bioinorganic Chemistry, Mülheim, Germany.

The *Rhodnius* NPs have a molecular mass of about 20 kDa. Crystallographic data show that the tertiary structure of the NPs is that of a β-barrel with a histidine residue that serves as the proximal ligand to the heme.[604] The 3-dimensional structures of various ligand complexes of recombinant NP1,[625,626] NP4[627–632] and NP2[633,634] by X-ray crystallography show that the protein fold of the nitrophorins belongs to a diverse class of proteins called lipocalins,[635,636] a family of relatively small secreted proteins that typically bind small, principally hydrophobic molecules such as pheromones,[637–639] retinol,[640,641] prostaglandins,[640,642] retinoic acid,[643] and biliverdin.[640,644–647] The structures of the cyanide and histamine complexes of NP1 and the NO complex of NP4 are shown in Figure 54. The ferriheme *b* molecule is bound to the protein via the imidazole nitrogen of His59 in NP1 and NP4 (His57 in NP2, NP3, and His60 in NP7). The immediate heme distal ligand-binding pocket is hydrophobic, although there are several glutamate and aspartate amino acid side chains at a somewhat greater distance (Figure 54). To date, these are the only known heme proteins with the heme inside a β-barrel.

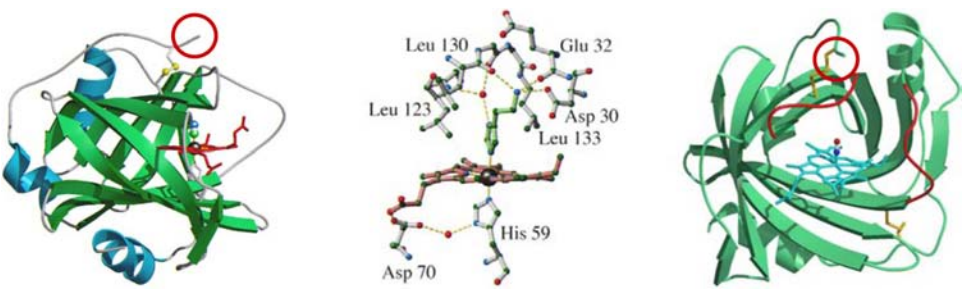

Figure 54. Left: Ribbon structure of NP1-CN,[620] with the A-B loop shown unstructured, sticking out in front of the heme propionate (PDB file 3NP1). Center: Heme binding site of NP1-histamine.[620] Note the proximity of Asp-30 and Glu-32 to the heme center (PDB file (1NP1). Reprinted from Weichsel, A.; Andersen, J. F.; Champagne, D. E.; Walker, F. A.; Montfort, W. R. *Nature Struct. Biol.* **1998**, *5*, 304–309 with permission from *Nature*. Right: Ribbon structure of NP4-NO,[623] showing the closed form of the A-B and G-H loops (red) and the N-terminal amino group above and adjacent to the C2-C122 disulfide bond (red). The two loops are well-resolved in this structure (PDB file 1ERX). Reprinted from Weichsel, A.; Andersen, J. F.; Roberts, S. A.; Montfort, W. R. *Nat. Struc. Biol.* **2000**, *7*, 551–554, with permission from *Nature*.

As is clearly shown in Figure 54 right, the structure of NP4-NO, now at 0.85 Å resolution, shows the heme to be highly nonplanar; this nonplanarity is largely a result of ruffling deformation of the heme. Among the structures of the nitrophorins now available (of NP1, NP2 and NP4), it is found that NP2 structures are most ruffled, with the average deviation of the *meso*-carbons, ΔC_m, being much larger for NP2 than for NP4 ligand complexes with NO, CN^-, ImH, Hm, NH_3, and even for the HS H_2O complex (50.8 vs. 30.3; 40.8 vs. 31.0; 27.0 vs. 15.0; 40.5 vs. 19.5; 39.8 vs. 22.7; 46.3 vs. 25.5, respectively, in 0.01 Å). Thus, the degree of ruffling of the various ligand complexes differs, yet the pattern of ΔC_m significantly larger for NP2 than for NP4 is preserved throughout. Probably the reason for this is the shorter length of both β-strand A and the A-B loop for NP2 (and NP3) than for NP4 (and NP1), Figure 53. The reason for some ruffling of the heme in all NPs is clear from the structure of apo-NP2, discussed below in Section IV.A.10.a(vii), where it is found that when heme is inserted into the apoprotein, the β-barrel must stretch horizontally in order for heme to bind, and the heme itself must also distort in order to fit within the β-barrel. As will be discussed below, the ruffling of the nitrophorin heme leads to several properties of the NPs that are not seen for other heme proteins.

We have made over 80 mutants of the nitrophorins, some of which will be discussed below. Goodin and coworkers have also made at least one mutant of NP1, the H57C mutant.[648] This mutant was characterized by UV-vis, resonance Raman, and room temperature MCD spectroscopies, and by X-ray crystallography. There is some evidence from low temperature measurements (MCD) that the cysteine binds weakly to Fe, although in the structures obtained, imidazole is able to replace the Cys and bind to both the proximal and the distal sites.[648] Histamine also can bind to the distal site, as it does in the native proteins,[648] NP1, NP2 and NP4 (PDB files 1NP1, unsubmitted, and 1IKE, respectively). NMR spectroscopy would be the best way to determine if the Cys ligand actually binds to heme iron at ambient temperatures.

NMR spectroscopy has played an important role in the characterization of the *Rhodnius* nitrophorins.[141–146,170,613,622–624,649] The proteins are stable in the ferriheme state (which is stabilized by the presence of multiple carboxylate side chains, nine for NP2 at distances of 7.99 to 18.45 Å from iron[613]), either as the high-spin (S = 5/2) aqua complex which is present in the absence of added ligand, or the low-spin (S = 1/2) form which is present in the presence of added electron-pair donor ligands such as histamine and various imidazoles or cyanide ion. The diamagnetic Fe^{III}–NO complex is also stable enough for NMR study, and considerable NMR data have been collected, although none are published at present.

The first report, in 1999, of the ^1H NMR spectrum of the imidazole complex of NP1, purified from the insect salivary glands,[626] was acquired from a sample

obtained by purification of approximately 5000 gland pairs of protein (of which NP1 was the major component, 50% of the nitrophorin fraction, 25% of the total protein present). This sample showed two possible protohemin methyl resonances, at +25.3 ppm and +13.0 ppm.[626] Additional experiments, however, showed that the +13.0 ppm resonance was the result of the accidental superposition of three 1-proton resonances at pH* 7.0 (pH* indicates the value measured with a pH meter and glass electrode, without correction for the deuterium isotope effect). When recombinant protein was available, after 1998, it was possible to investigate more highly purified protein samples.[141–146,170] Soon thereafter it was found that as is the case for the protein sequences (Figure 53), the rates of NO release also fall into two groups, with NP1 and NP4 having much larger k_ds than NP2 and NP3.[614]

i. NMR investigations of the high-spin forms of the nitrophorins from *Rhodnius prolixus*

The result of the first studies of the high-spin recombinant proteins, however, was highly disappointing for NP1 and NP4, because there were many overlapping heme resonances in the +70 to +30 ppm region,[170] as shown in Figure 55. High-spin NP2, however, showed paramagnetically-shifted heme substituent resonances that could be interpreted as having relative peak areas of 6:3:4:1:1:1:1:1.[141] As shown in Figure 55, there were also three small resonances, which were only about 1/8th of the intensity of the peaks of area 3, at +69, +68 and +56 ppm (and a fourth expected heme methyl resonance later shown to be at about +51 to +53 ppm which overlapped with the more intense resonances),[141,142] which were later shown to be the result of a minor (**A**) heme orientation.[170] The three small peaks were at first not assigned[141,142] because the crystal structure of NP2–NH_3 had definitively shown only one heme orientation.[633] However, it soon became clear, by following the intensities of the heme resonances as a function of time following addition of hemin, that either the crystals used for determining the structure of NP2–NH_3[633] contained only the major (**B**) heme orientation (presumably because the protein molecules containing the minor (**A**) heme orientation did not crystallize with the major (**B**) form), or else X-ray crystallography was unable to detect the minor (12–13% **A**) heme orientation (Figure 56).

Heme orientation in the nitrophorins has been defined in terms of the view of the heme from the distal pocket side, with the proximal His57 of NP2 being behind the plane of the heme. Viewed in this way, the major heme orientation for NP2 is **B**, with counterclockwise numbering of the heme substituents, as shown in Figure 56B. As has been known for many years, heme *b*-containing proteins may contain either one heme orientation exclusively, or, more frequently, both heme

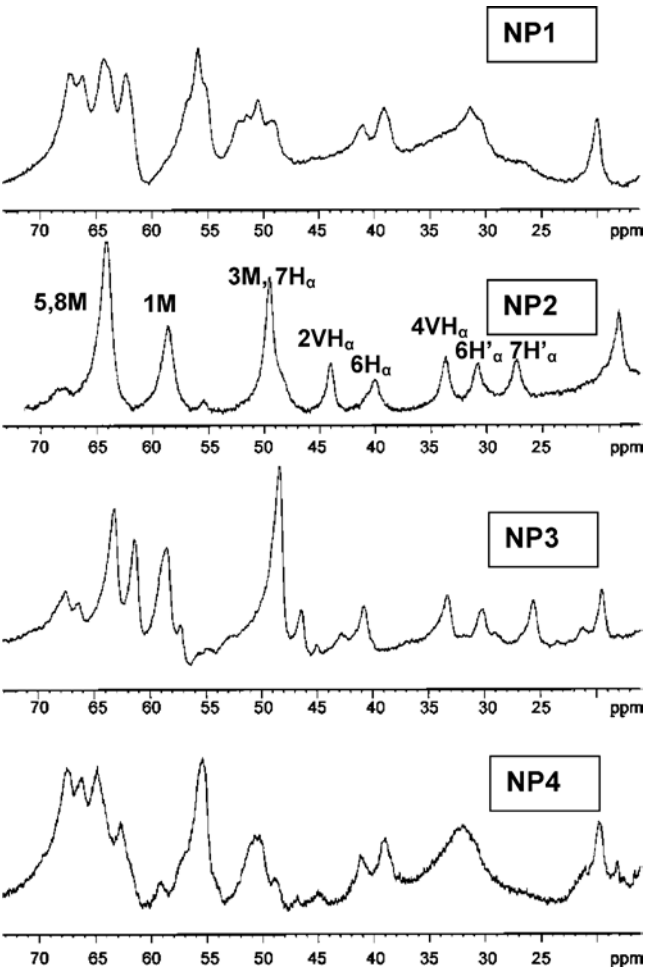

Figure 55. 1D ^{1}H NMR spectra of the high-frequency (16–73 ppm) region of the four NPs in the absence of added ligand at 25 °C, recorded at 500 MHz. The more intense resonances in the 55–68 ppm region for NP1 and NP4 and in the 49–67 ppm region for NP2 and NP3 are those of the eight heme methyls of the two heme rotational isomeric proteins (Figure 51). Resonance assignments given for NP2 were reported previously.[141] Reprinted from Shokhireva, T. Kh.; Smith, K. M.; Berry, R. E.; Shokhirev, N. V.; Balfour, C.; Zhang, H.; Walker, F. A. *Inorg. Chem.* **2007**, *46*, 170–178, with permission from the American Chemical Society.

orientations, with one or the other (**A** or **B**) being predominant, as first reported by La Mar and coworkers for the methemoglobins from the insect *Chironomus thummi thummi*[650] and sperm whale metmyoglobin.[651] The ratio of the two heme orientations, **A** and **B**, is the result of thermodynamic equilibrium between the two that depends on the steric requirements of the 2,4-vinyl substituents of the protohemin molecule in the particular protein's heme binding pocket (Figure 56).

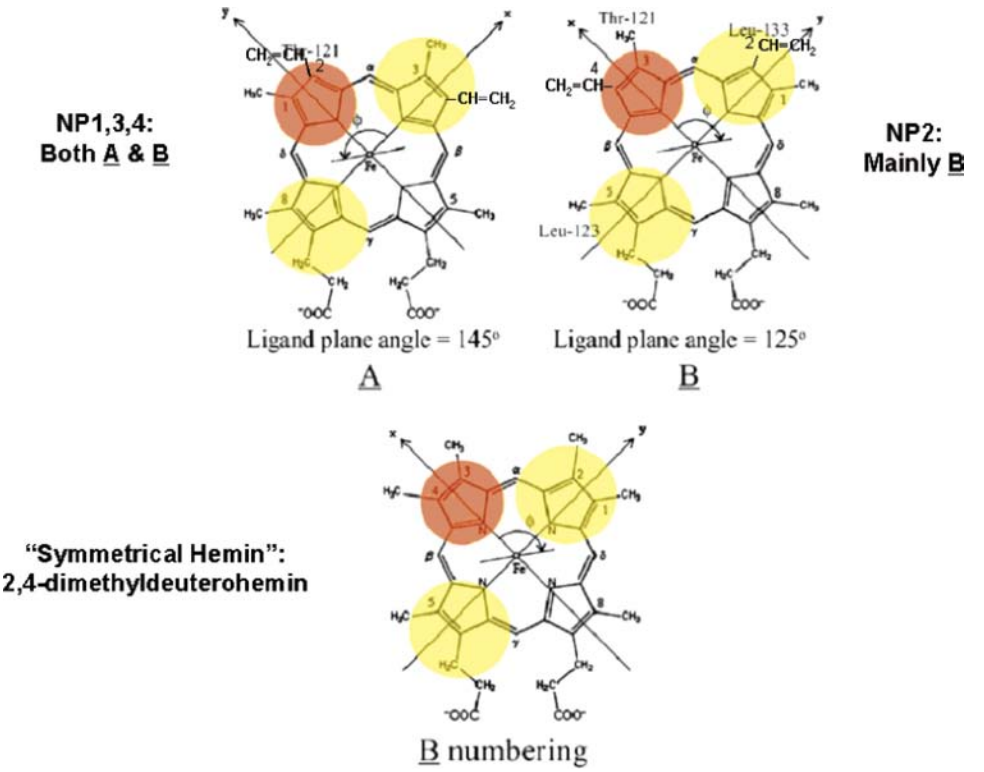

Figure 56. Top: **A** and **B**: the two isomers that result when protohemin IX is inserted into the heme pocket of a protein, with the circles showing the location of specific distal side chains for the nitrophorins. The orange circle represents the side chain of Thr121 for NP1 and NP4, Ile120 for NP2 and NP3, while the yellow circles represent the side chains of Leu123 and Leu133 for NP1 and NP4, Leu122 and Leu132 for NP2 and NP3. The proximal His59 (NP1, NP4) or His57 (NP2, NP3) is behind the plane of the heme. The equilibrium **A**:**B** ratio for each of the wild-type recombinant proteins is 1:1 (NP1, NP4), 1:8 (NP2), and 1:4 (NP3); mutation of Thr121 of NP1 to Ile changes the equilibrium **A**:**B** ratio to 1:8.[170] Bottom: 2,4-dimethyldeuterohemin, herein called the "symmetrical hemin". By convention, methyl numbering according to the **A** isomer is used for the symmetrical hemin. Reprinted from Shokhireva, T. Kh.; Smith, K. M.; Berry, R. E.; Shokhirev, N. V.; Balfour, C.; Zhang, H.; Walker, F. A. *Inorg. Chem.* **2007**, *46*, 170–178, with permission from the American Chemical Society.

[For a dramatic example of how a single residue can affect the heme orientation, see the story of NP7, NP7(E27V,Q) and NP2(V24E).[145,623,624]]

To prove unambiguously that the reason for the poorly-resolved spectra of NP1 and NP4 was nearly equal abundance of heme orientations **A** and **B**, the four NPs were also reconstituted with 2,4-dimethyldeuterohemin, the so-called "symmetrical hemin," also shown in Figure 56, which greatly simplified the spectra of all four nitrophorins;[170] more detailed studies of these high-spin symmetrical hemin complexes and some of their mutants were carried out,[170] as shown in

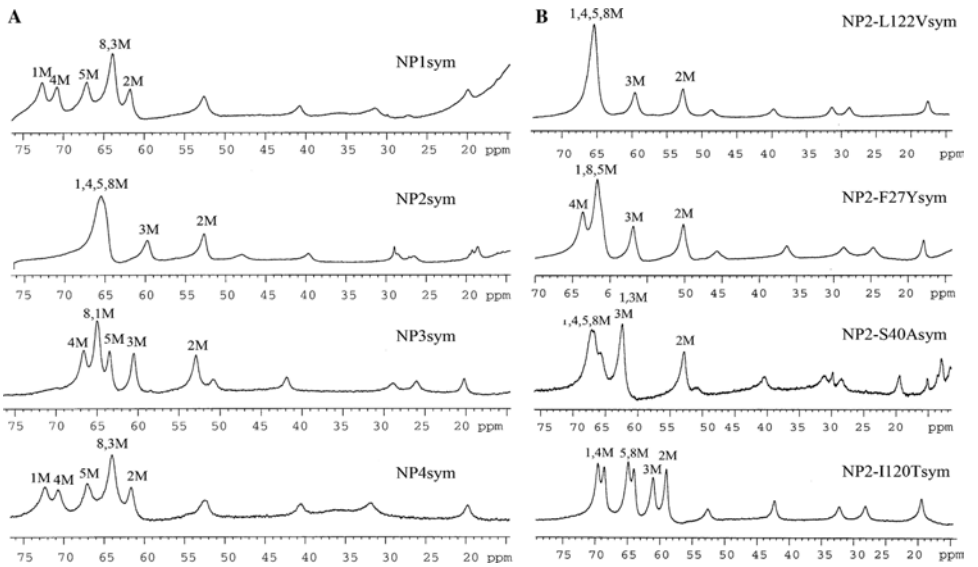

Figure 57. ^{1}H 1D NMR spectra of high-spin complexes of NP1sym–NP4sym (a) and the NP2sym mutants L122V, F27Y, S40A, and I120T (b) with symmetrical heme, all at 25 °C, pH* 7.0, recorded at 500 MHz. The NP2 sample used in spectra (a) and the NP2–S40A sample used in spectra (b) both have small amounts of a low-spin species present (a result of an adventitious ligand introduced during expression or purification), but this does not affect the chemical shifts of the high-spin complexes. Reprinted from Shokhireva, T. Kh.; Shokhirev, N. V.; Berry, R. E.; Zhang, H.; Walker, F. A. *J. Biol. Inorg. Chem.* **2008**, *13*, 941–959, with permission from Elsevier Publishing Company.

Figure 57 for NP1–NP4 and several mutants of NP2. However, it is now clear that there is a further contribution to the poorly-resolved spectra for NP1 and NP4 shown in Figure 55, and that is dynamics of the heme seating. This dynamics was clearly evident in the NOESY/EXSY spectra of the L44F mutant of NP1, as shown in Figure 58, where the EXSY cross peaks between two sets of heme methyl resonances for each heme orientation were evident; the positions of these cross peaks suggest a rotation about the H59 imidazole-Fe bond of approximately 10°.[144] The same type of broadened heme substituent resonances are present in the 1D spectrum of wild-type NP1, although the change in heme seating appears to be smaller and is more difficult to analyze in the wild-type protein case.[652]

The heme methyl resonances of high-spin NP2 were assigned by saturation transfer difference from the already-assigned low-spin complex with N-methylimidazole,[141] as shown in Figure 59, while the heme methyl resonances of high-spin NP1 and NP4 were assigned with the help of specifically deuterium-labeled isomers of protohemin provided by Professor Kevin M. Smith, the 5-CD_3, 5,8-$(CD_3)_2$, and 1,3-$(CD_3)_2$ isomers.[170] This latter method was used for many years by

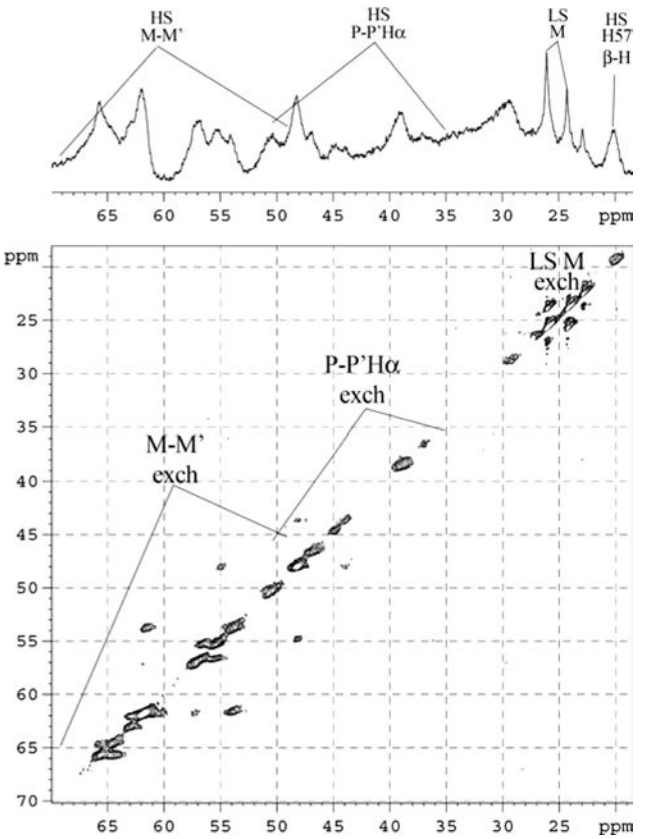

Figure 58. Water-eliminated Fourier transform (WEFT) nuclear Overhauser enhancement spectroscopy (NOESY) spectrum of the NP1(L44F)-ImH complex for the protohemin-containing protein at 35 °C, pH 7.0, recorded at 500 MHz. The sample contains both high-spin and low-spin forms of the mutant protein. The NMR spectrum shows both **A** and **B** orientations of the protohemin and chemical exchange between two high-spin forms for both **A** and **B** isomers, with different nodal plane orientations (**A′**, **B′**). At the same time, the low-spin complex shows chemical exchange (**A**–**A′**) for 3Me. Note that there are no exchange spectroscopy (EXSY) peaks between the high-spin and low-spin complexes. The frequency difference (approximately $1.4–2 \times 10^4$ Hz) between the high- and low-spin species, which are additionally in chemical exchange with each other, is much larger than the inverse mixing time of the NOESY experiment (33–100 Hz), while the off rate for ligand exchange for histamine is of the order of 5.6×10^{-2} s^{-1}, and even if it is a factor of 100 faster for N-methylimidazole (NMeIm), it would be much too slow to allow ligand exchange between low- and high-spin forms of the protein on the time scale of the NOESY experiments. Reprinted from Shokhireva, T. Kh.; Shokhirev, N. V.; Berry, R. E.; Zhang, H.; Walker, F. A. *J. Biol. Inorg. Chem.* **2008**, *13*, 941–959, with permission from Elsevier Publishing Company.

La Mar, Smith, and their coworkers to assign the heme resonances of many ferriheme proteins, as summarized in Ref. 19.

Wüthrich and Keller used the saturation transfer method very early to assign the heme resonances of ferricytochrome b_5 using the assignments already made

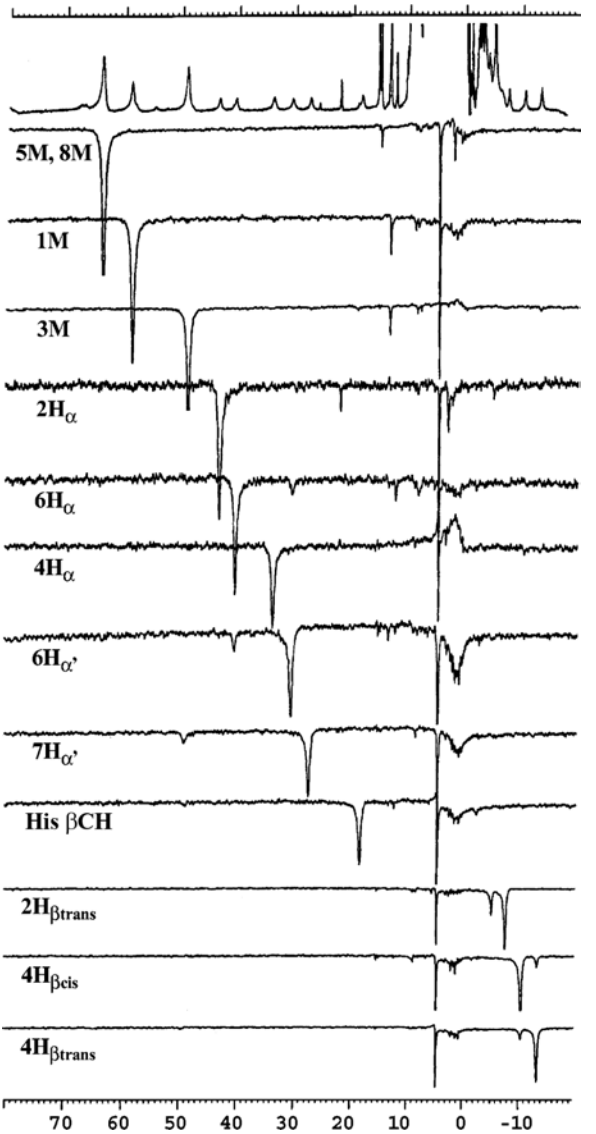

Figure 59. 1D ^{1}H saturation transfer difference spectra (STD) of a mixture of NP2 and the NP2-NMeIm complex at 37 °C and pH* 7.0, recorded at 500 MHz. Reprinted from Shokhireva, T. Kh.; Shokhirev, N. V.; Walker, F. A. *Biochemistry* **2003**, *42*, 679–693, with permission from the American Chemical Society.

for ferrocytochrome b_5,[192] and we have used it to assign the resonances of high-spin NP2 from the already-assigned resonances of the NMeIm complex of NP2.[141] The order of the heme methyl chemical shifts for the high-spin NP2 major **B** heme orientation is 5 = 8 > 1 > 3, while for the **A** heme orientation it is 8 > 5 > 1 > 3,

and the ratio **A**:**B** = 1:8.[170] For NP1,[170] NP3[146] and NP4[170] the order for the **A** isomer is also 8 > 5 > 1 > 3 while the order for the **B** isomer is 5 > 8 > 1 > 3 in all cases; the ratio **A**:**B** = 1:1,[170] 1:4,[141] 1.1:1,[170] respectively, as compared to 1:8 for NP2.[170] The orientation of the His59(57) imidazole plane could be predicted for each of these by using the angle plot specific for high-spin ferrihemes shown in Figure 60,[141] which is rotated by 90° from that of the low-spin ferrihemes,[8] which was discussed earlier in Section IV.A.8.b(iii), Figure 11.

An important property of the nitrophorins is the behavior of the mobile loops that form the opening to the heme distal pocket, the A–B and G–H loops. These are shown in red in the ribbon diagram of NP4-NO at pH 5.6, Figure 54, right. At this low pH, for the NO complex, the loops are well-ordered and there are hydrogen-bonds from several side chains of the A–B loop to side chains or backbone atoms of the G-H loop, so as to "close the door" to the heme pocket entrance.[627] This closed loop conformation is shown best by NP4 when bound to NO, as well as to some other ligands at low pH.[629–631] In contrast, structures solved at high pH (usually 7.5), including that of NP1-CN shown in Figure 54, left, have poorly-ordered loops that give rise to very diffuse electron density, because of the presence of multiple conformations of those loops; in the best-case scenarios, one or two open loop conformations can be modeled.[629–631] The change in loop conformation for NP4 as a function of pH has been used to develop models for the role of loop conformation in determining the rate of NO release from the nitrophorins.[629–631,653–655]

However, while for NP4 the first residue of the recombinant protein is Ala1,[627] as is true for native NP4 as well,[656] recombinant NP1, NP2 and NP3 carry the Met0 which results from the start codon of the recombinant gene. These three native nitrophorins have as their first amino acid one that has a charged side chain, Lys1, Asp1, and Asp1, respectively,[656] and while the native proteins are produced by cleavage of a leader sequence whose role is believed to be to allow export of the proteins to the salivary glands, the recombinant proteins were first produced by simply deleting the leader gene sequence and placing the start codon immediately before the codon for the first amino acid. *E. coli* has a methionine aminopeptidase (MAP) that cleaves methionine from newly-synthesized proteins which have a hydrophobic amino acid as the first amino acid of the mature protein sequence, but this MAP does not have activity to cleave Met0 from a protein whose first amino acid has a charged side chain. Therefore, recombinant NP1 produced from this gene has sequence M0K1C2…,[625] and NP2 and NP3 have sequence M0D1C2....[633] In the structure of NP2-NH_3 (PDB file 1EUO) it was clear that the side chain of M0 prevented the A–B loop from attaining its closed loop conformation. Thus, the NP2(D1A) gene was prepared and that mutant protein was expressed and studied in detail.[649] It was found that there were significant

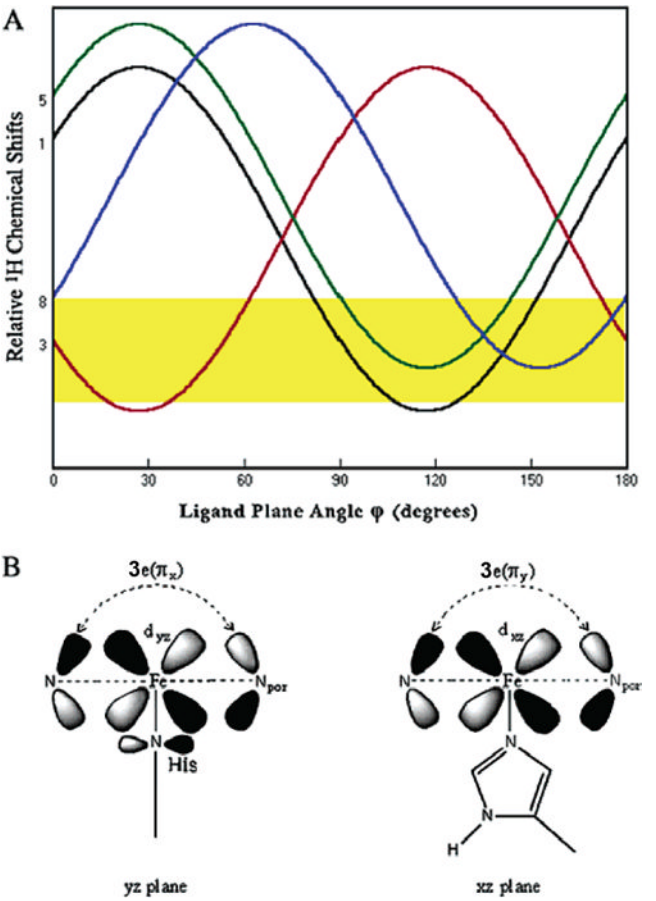

Figure 60. (A) Dependence of heme methyl shifts on the axial ligand nodal plane orientation angle φ for high-spin ferrihemes.[141] The angle φ is defined in Figure 51. No chemical shifts are provided on this modified plot, which is thus generically applicable to any high- or low-spin histidine-ligated heme protein, although the approximate end of the protein diamagnetic resonance envelope appropriate for low-spin ferrihemes is marked; for high-spin iron(III) proteins, the observed methyl shift pattern is that of the angle that is 90° shifted from the axial ligand plane orientation.[151] (B) Iron d_{xz} and d_{yz}, axial ligand π filled orbital on the binding nitrogen, and porphyrin $3e(\pi_x)$ and $3e(\pi_y)$ orbital interactions for high-spin ferrihemes. The transfer of spin density from the d_{yz} orbital of Fe to the histidine π orbital occurs by His $\rightarrow$ d_{yz} π donation, while the transfer of spin density from the d_{xz} orbital of Fe occurs by porphyrin $\rightarrow$ d_{xz} orbital by $3e(\pi_y)$ π donation. Therefore, the $3e(\pi_y)$ orbital obtains greater spin density than does the $3e(\pi_x)$ orbital, and therefore gives rise to the 90° shift in the angle plot shown. This mechanism is modified from that discussed in Ref. 141 because of the finding that the $4e(\pi^*)$ orbitals are not involved in spin delocalization.[156] Although H_2O is bound weakly to the sixth position of the high-spin nitrophorins, it is not expected to interact unequally with the d_{xz} and d_{yz} orbitals of the metal. Modified from Shokhireva, T. Kh.; Shokhirev, N. V.; Walker, F. A. *Biochemistry* **2003**, *42*, 679–693, with permission from the American Chemical Society.

differences between that point mutant protein and the wild-type, M0-containing protein: (1) While the equilibrium ratio of heme orientations **A** and **B** for the M0-containing protein was 1:8 (Figure 57), for NP2(D1A) **A**:**B** = 1:22 at equilibrium.[649] (2) While the $t_{1/2}$ for heme **A**:**B** equilibration of NP2(M0D1) was ~2 hours, that for NP2(D1A) was ~42 hours.[649] (3) Once ligand was added to NP2(D1A) there was no further **A** ⇆ **B** equilibration over periods of weeks. For NP2(M0D1) ligand complexes there was slow equilibration over periods of weeks.[649] (4) At pH 5.5 the midpoint potential of NP2(D1A) was about 30 mV more negative than that of NP2(M0D1) in the absence of added axial ligand (−318 vs. −287 mV), while at pH 7.5 the difference was only about half as great (−325 vs. −310 mV);[649] the axial ligand complexes (NO, Hm, ImH) in general had almost identical E_ms at pH 5.5 (NO: 48 vs. 49 mV; Hm: −408 vs. −410 mV; ImH: −400 vs. −423 mV, respectively), but at pH 7.5 the differences were in general greater (NO: −20 vs. +8 mV; Hm: −440 vs. −474 mV; ImH: −453 vs. −454 mV).[649] (5) In spite of these differences, the K_ds at pH 7.5 were identical for NP2(D1A) and NP2(M0D1) (K_d = 5.0 nM (NO), 10.0 nM (Hm), 40 nM (ImH)).[649] (6) The rate constants for Hm binding and release (k_{on}, k_{off}, respectively) were a factor of 2.5–5 larger for NP2(M0D1) than for NP2(D1A) (5×10^6, 2×10^6 $M^{-1}s^{-1}$; 0.056, 0.011 s^{-1}, respectively).[649] (7) The crystal structure of NP2(D1A)-NH_3 (PDB file 2EU7) showed that the A–B and G–H loops were much more closed, albeit not as closed as those of NP4-NO at low pH (PDB file 1ERX). However, what were very similar between the two proteins were the chemical shifts of the high-spin ferriheme resonances, as well as their NMeIm complexes,[649] which thus indicates that the interaction between the heme substituents and the protein, as well as the His57 orientation, were relatively unchanged by the D1A mutation and A–B loop conformation change. Since the publication of that work, a soluble expression system with export of the protein to the periplasm of *E. coli*, together with cleavage of the export sequence to leave D1 as the first amino acid has been successfully engineered,[657] and future NMR studies will use native NP2. The same soluble expression system has been achieved for NP1, and could in principle be achieved for NP3;[657] however, NP4 still requires its original recombinant gene, which begins with the start codon, immediately before the codon for A1, and the original purification of the apoprotein inclusion bodies obtained during expression[627] to obtain native NP4(A1).

ii. pH titration of the high-spin nitrophorins from *Rhodnius prolixus*

As shown in Figure 23 and discussed in Section IV.A.6.b earlier, the *meso*-H resonance of $OEPFe^{III}$ in DMSO, where the iron(III) porphyrin is 6-coordinate with two DMSO molecules bound axially, is observed at about +41 ppm at ambient

temperature. For symmetrical hemin-reconstituted nitrophorins, occasionally it is possible to see at least some of the broad *meso*-H resonances in the 33–45 ppm region of the ^{1}H NMR spectra of the high-spin proteins, as is evident in the NP1sym and NP4sym spectra[144] of Figure 57A, but usually these resonances are too broad to be observed. Based on the best-case examples and analogy to most other high-spin ferriheme proteins that have one protein-provided axial ligand (except peroxidases),[19] we have assumed that all four of the *Rhodnius* NPs of the adult insect have a water molecule bound on the distal side of the heme. In support of this, we have done pH titrations for NP2 and NP3 and found that they behave quite differently.[146]

What has been known for a long time about ferriheme proteins is that if they have only one protein-provided ligand, in the absence of added exogenous ligands, the aqua complex deprotonates at some basic pH to leave a hydroxide bound to Fe^{III} — or, a 5-coordinate ferriheme center without a bound water molecule reacts with hydroxide to produce a 6-coordinate ferriheme center. The reactions for metmyoglobin have been described as follows:[19]

$$\text{metMbH}_2\text{O} + \text{OH}^- \leftrightarrows \text{metMbOH} + \text{H}_2\text{O}, \tag{38a}$$

$$\text{metMb} + \text{OH}^- \leftrightarrows \text{metMbOH}. \tag{38b}$$

For ferroheme proteins it is not so common to have a water bound to Fe^{II} at low pH, and thus reaction (38b) may be more common for Fe^{II} than for Fe^{III}. As pointed out previously,[19] the hydroxide complex may exist as an equilibrium mixture of S = 5/2 and S = 1/2 spin states, with characteristic temperature dependence for the equilibrium. This point, and inclusion of an S = 3/2 possibility as well, becomes quite important for the heme oxygenases (HOs),[658,659] discussed later in Section IV.A.10.b.

For NP2 this water/hydroxide has a pK_a of about 10.5, and the spin state changes cleanly from S = 5/2 to S = 1/2,[144] as shown in Figures 61c and d, where the growing resonances of the high-pH form (the hydroxide complex) are clearly in the expected chemical shift range for a low-spin complex, with a compressed chemical shift scale which is indicative of the $(d_{xz},d_{yz})^4(d_{xy})^1$ electronic ground state (see next section) (19.0 (3M), 13.0 (5M), 10.7 (8M), 6.5 (1M) at 30 °C).[146] As can be seen, beyond the half-titration point the high-spin resonances become increasingly broadened, so that at pH = 10.99 most features of the high-spin ^{1}H NMR spectrum are too broad to interpret (Figure 61e), yet the low-spin resonances are still quite sharp.[146] This signifies that the rate of deprotonation of the HS form is approaching the difference in frequency between the HS and LS resonances, $(\nu_{HS(5M)}-\nu_{LS(5M)})$, which is about 25.5 kHz at 500 MHz and 30 °C for 5M,

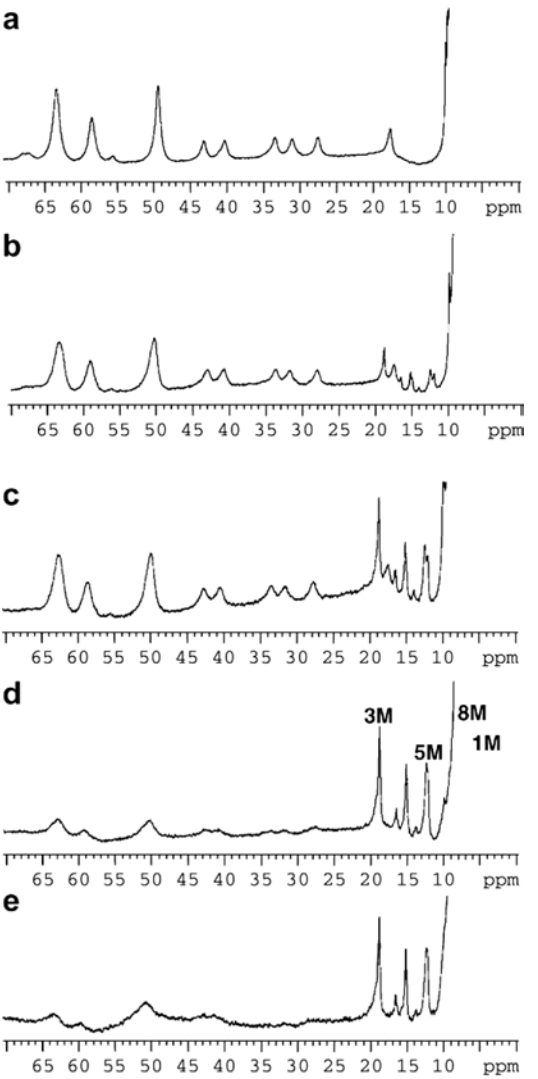

Figure 61. pH titration of NP2 in the absence of added axial ligand, recorded at 500 MHz, 25 °C. pH* values (uncorrected for the deuterium isotope effect) are (a) 7.10, (b) 9.90, (c) 10.30, (d) 10.86, (e) 10.99, (f) plot of pH dependence vs. fraction of hydroxo complex formed (from the relative intensities of the 3Me resonance of the high-spin aquo and the hydroxo complexes). From these data the pK_a of the water molecule bound to NP2 is estimated to be 10.5 (uncorrected for the deuterium isotope effect). Note that spectrum (e) shows the beginning of observable kinetic averaging of the NMR signals of the high-spin aquo and the hydroxo complexes that is quite far advanced at pH* 9.6 for NP3.[146] Methyl resonance assignments for the hydroxo complex[146] are marked on (d). Reprinted from Shokhireva, T. Kh.; Berry, R. E.; Zhang, H.; Shokhirev, N. V.; Walker, F. A. *Inorg. Chim. Acta* **2008**, *361*, 925–940, with permission from Elsevier Publishing Company.

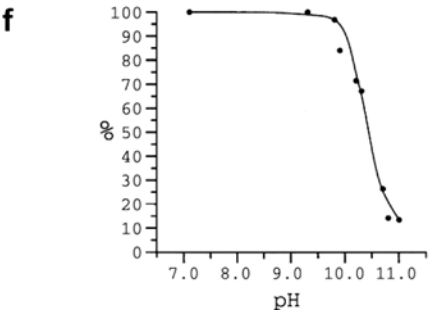

Figure 61. (*Continued*)

26.7 kHz for 8M, or that the rate constant for deprotonation is on the order of $2.6–2.7 \times 10^4$ s^{-1}.

However, for NP3 the same titration does not give well-resolved resonances of the hydroxide complex, but rather the high-spin aqua complex is in chemical exchange with the hydroxide complex on the NMR timescale, and resonances of both are broad and poorly resolved above pH 8.[146] Thus the results are not as clear, beyond the fact that 3M is the methyl resonance having the largest chemical shift for NP3–OH, as for NP2–OH[146] (Figure 61). A rough estimate of the pK_a of NP3–OH is ~9.9–10.[146] It is surprising that the rate of proton exchange is so different for the two proteins, when both the aqua and hydroxide complexes have very similar chemical shifts of the heme resonances. The calculated isoelectric points[660] of NP2 and NP3 are similar (6.1 and 6.5, respectively), and thus probably cannot explain the difference in the rate of proton exchange. Additional examples of deprotonation of the water bound to high-spin ferriheme proteins will be discussed in the section on heme oxygenases (Section IV.A.10.b).

iii. NMR investigations of the low-spin forms of the nitrophorins from *Rhodnius prolixus,* and comparison to other heme proteins

The low-spin (S = 1/2) complexes of the nitrophorins of interest to their biological functions of NO-binding and release and histamine binding include the histamine (Hm) complexes, their simpler models, the imidazole (ImH) complexes, other imidazole complexes (N-methylimidazole, NMeIm, and 2-methylimidazole, 2MeImH), which may be less stable and thus good candidates for saturation transfer studies aimed at assigning the hyperfine-shifted heme resonances of the high-spin complexes, and the cyanide (CN^-) complexes, which have been used as paramagnetic models for the diamagnetic NO complexes.[143–146] All of these have been studied in detail for all four of the major nitrophorins of the adult insect[141–146] and for a number of their mutants, and most have been studied for NP7 and several

of its mutants.[145,623,624] Most of the exogenous ligand complexes of the NPs are extremely stable, with binding constants for ImH and Hm both being 10^8 M^{-1} or larger (K_ds < 100 μM) at pH 7.5,[613] and that for cyanide estimated to be of the order of 10^{12} M^{-1} (K_d ~1 pM) at pH 7.5.[613] The binding constants for NMeIm and 2MeImH are several orders of magnitude smaller than those for ImH and Hm.[661]

In 1998, Shokhirev and Walker showed that the methyl and *meso*-H resonances of low-spin ferriheme proteins are strongly affected by the orientation of the plane of one or possibly both axial ligands, because the orientation of that plane determines the nodal plane orientation of the 3e(π) orbital that is involved in spin delocalization from low-spin iron(III) by Por $\rightarrow$ Fe π donation, and the angular dependence of the pseudocontact contribution to the paramagnetic shifts.[8] Thus, as the planar axial ligand is rotated to a certain angle in a particular ferriheme protein, as defined by Figure 8, so also is the nodal plane of the 3e(π) orbital rotated by simple rehybridization of the two Hückel orbitals, combined with the change in the angle of the pseudocontact contribution,[140,211] as discussed above in Section II.C.3 and shown in Figures 9–11. This concept was shown to apply to a large number of ferriheme proteins[8] and many more[141–150] since that original publication. A program called Shift Patterns[151] was developed for plotting methyl and *meso*-H chemical shifts as a function of ligand plane angle in a general way that is independent of the effect of ligand donor strength (that is, the pattern of relative spacings is used, rather than exact chemical shifts). By use of this program, it is possible to determine the orientation of the nodal plane of the heme 3e(π) orbital utilized for spin delocalization, if the heme methyl order has been assigned, by using the relative spacings of the resonances, with an accuracy in most cases to ±2–3°. Several systems for which this program did not predict the correct relative chemical shifts, for example *N. europae* cytochrome c_{552},[662] were later shown to have an unusual heme methyl chemical shift order (5 > 8 > 3 > 1) and a highly compressed chemical shift range because of dynamic flipping of the methionine ligand's methyl group on the NMR timescale, which has the effect of averaging the chemical shifts of the heme substitutents for the two possible nodal plane orientations of the methionine ligand.[663–666]

The NP2-ImH complex has been studied at pH* 7.0,[141–143,145] 5.5[145,624] and 4.0.[145] As can be seen in the 1D spectrum at these three pH* values shown in Figure 62, besides the major **B** orientation and minor **A** orientation, the 1D ^{1}H NMR spectrum at pH* 5.5 exhibits an extra set of three hyperfine-shifted resonances between 24 and 22 ppm which increased remarkably in intensity on lowering the pH* to 4.0. Peaks were assigned from the pH* 5.5[624] and the pH* 4.0[145] WEFT-NOESY spectra (Figure 63) and from the pH* 5.5[624] and pH* 4.0 ^{1}H{^{13}C}-HMQC spectra.[145] For the major **B** heme orientation of NP2, the order of heme methyl chemical shifts is the same from pH* 7.0 to 4.0, 3 > 5 > 1 > 8.[145] From the angle plot (Figure 11),[8,151] we can see that although the chemical shifts of the heme

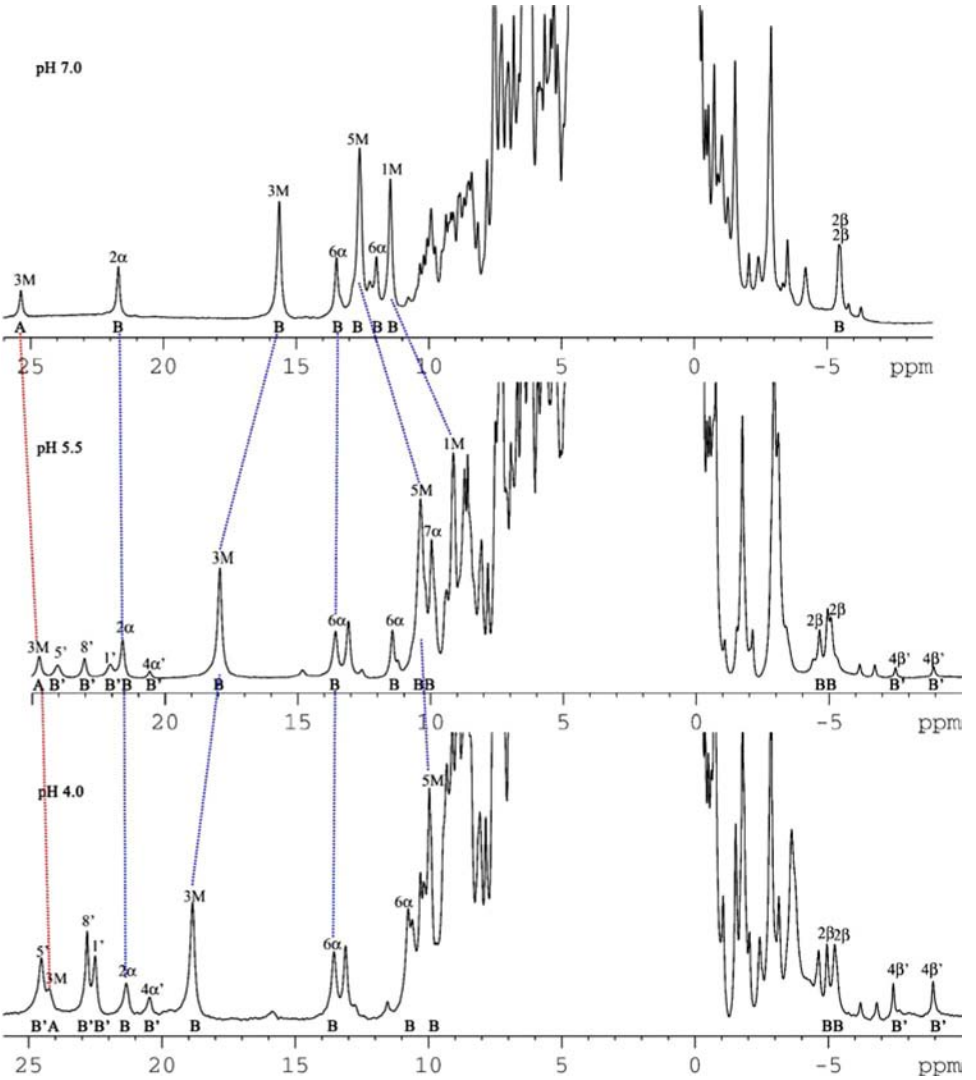

Figure 62. 1D ^{1}H NMR spectra of the hyperfine-shifted resonances of NP2-ImH at pH* 7.0 (top), pH* 5.5 (middle), pH* 4.0 (bottom), recorded at 25 °C at 600 MHz. Lines showing the variation in chemical shift of heme resonances of **A** (red) and **B** (blue) are displayed. Reprinted from Yang, F.; Knipp, M.; Berry, R. E.; Shokhireva, T. K.; Zhang, H.; Walker, F. A. *J. Biol. Inorg. Chem.* **2009**, *14*, 1077–1095, with permission from Elsevier Publishing Company.

methyls change quite a bit, the effective ligand nodal plane angle varies by only a few degrees, in the range of 150–154°; this angle represents the orientation of the exogenous ImH ligand for the **B** heme orientation, while for the **A** orientation the angle is believed to be 116–120°, although because of chemical exchange, not enough resonances of the **A** heme orientation of NP2-ImH have been observed to

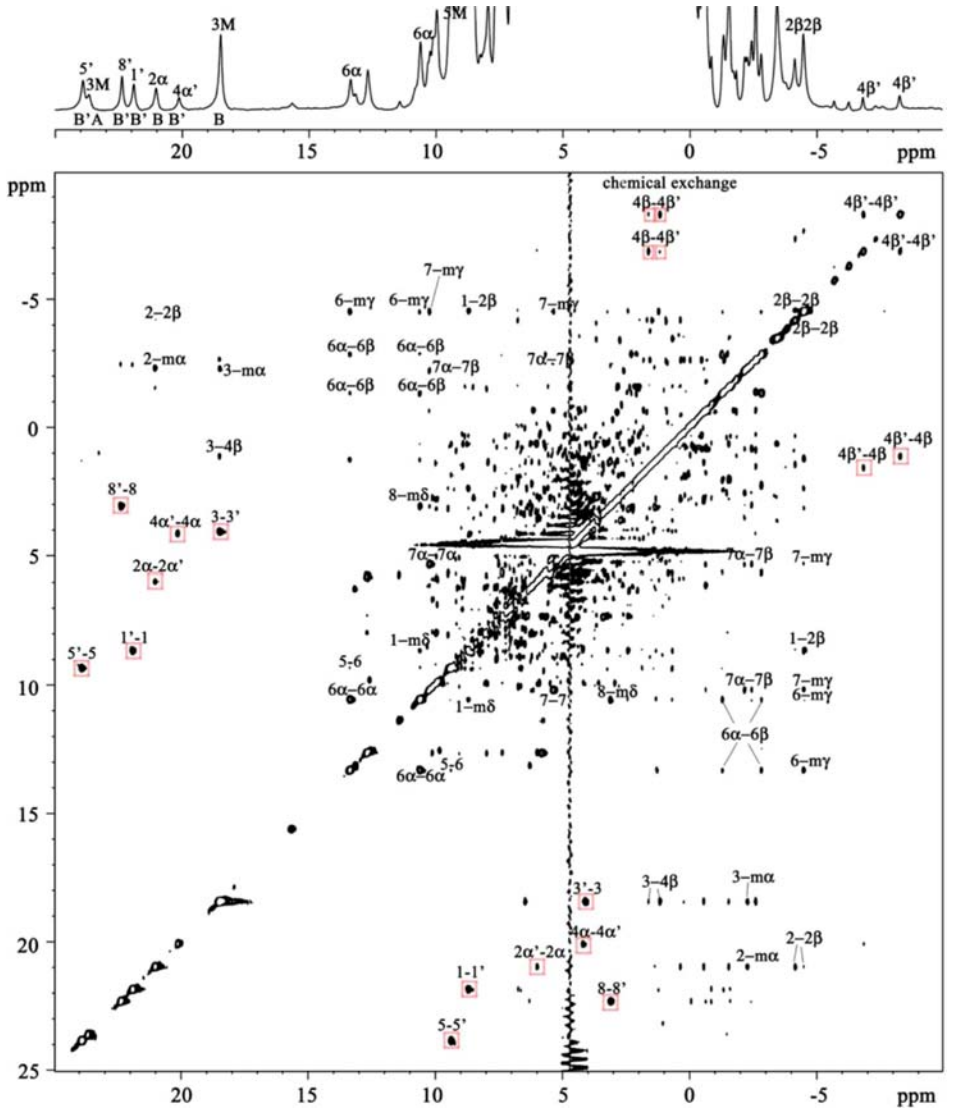

Figure 63. 1D ^{1}H and WEFT-NOESY/EXSY NMR spectra of NP2-ImH in D_2O, buffered with 30 mM Na_2DPO_4/acetic acid-d_4 (pH* 4.0), recorded at 33 °C and 600 MHz. There are both chemical exchange cross peaks between **B′** and **B** (red boxed), and NOESY cross peaks for **B**. Reprinted from Yang, F.; Knipp, M.; Berry, R. E.; Shokhireva, T. K.; Zhang, H.; Walker, F. A. *J. Biol. Inorg. Chem.* **2009**, *14*, 1077–1095, with permission from Elsevier Publishing Company.

define the angle well. Thus, the heme methyl chemical shifts change rapidly with the small changes in axial ligand orientation over this angle range.

Chemical exchange was observed in the NOESY/EXSY spectra of NP2-ImH at pH* 5.5[624] and 4.0[145] between the additional signals and the 5M, 1M, 8M and

3M resonances of the **B** orientation, which shows that these resonances are caused by an additional species with **B** heme orientation, which we have called **B′**. The methyl resonances of **B′** are easily assigned from the chemical exchange cross peaks between **B′** and **B** from the NOESY (EXSY) spectrum (Figure 63). In contrast to the methyl resonance order 3 > 5 > 1 > 8 obtained for **B**, **B′** exhibits the order 5 > 8 > 1 > 3 at both pH* 5.5[624] and pH* 4.0.[145] The effective nodal plane angle of **B′** (~42°) is about 110° different from that of **B** (~152°).[145] Since the proximal His imidazole plane orientation is about 135° from the heme axis defined by the line connecting N_{II} and N_{IV}[633,634] (Figure 8), it is obvious that the effective nodal plane angle obtained from the angle plot is dominated by the exogenous ligand ImH for NP2, as was observed previously at pH* 7.0,[141] and within 5° (156.9°) of the angle observed in the crystal structure (PDB file 1PEE).Thus the ImH plane in isomer **B** is nearly parallel (a difference in angle of ~17°) to the His57 imidazole plane, while in isomer **B′** the ImH plane is nearly perpendicular to the His imidazole plane (a difference of ~93°). Therefore, for simplicity, we can describe the two isomers as having parallel (**B**) and perpendicular (**B′**) ImH plane orientation.

Although a perpendicular orientation of the ImH ligand of NP2-ImH was not observed in our previous study of wt NP2 at pH* 7.0,[141] the **B′** orientation was seen for the symmetrical hemin complex, NP2sym-NMeIm,[146] and for the protohemin NP2 L → V mutants at pH* 7.0: NP2(L122V)-ImH, NP2(L132V)-ImH, and NP2(L122V, L132V)-ImH,[142] as well as for the other three major NPs of the adult insect, both for the protohemin[143,144] and the symmetrical hemin[146] complexes. However, for NP7-ImH, only the **A** heme orientation has been observed, and there is no chemical exchange, probably because of the crowding in the heme-binding pocket due to the presence of E27.[145,623,624]

Both Leu122 and Leu132 point from the β-strands above the heme pocket toward the distal side of the heme (Figure 54, center), and at the time of publication of the first study of the single and double Leu → Val mutants[142] it was believed that the perpendicular ImH orientation was permitted by the shorter Val side chain, which was able to create enough space in the distal pocket to allow ImH ligand rotation. It is now clear that it was only an accident of fate that the perpendicular orientation of ImH, **B′**, with chemical exchange between **B′** and **B** for wt NP2-ImH was not observed at pH 7.0, and that the reason for the existence of the perpendicular ImH orientation is the presence of a minor ruffled conformation of the heme, which cannot accommodate the parallel ImH ligand, but can allow binding of ImH in the perpendicular orientation; dissociation and re-binding of ImH, all within the distal pocket, are thus required in the exchange reaction.[143–145]

By measuring the NOESY/EXSY cross peak and diagonal peak intensities of wt NP2-ImH at low pH, the rate constants and equilibrium constant of interchange between **B′** and **B** can be calculated by use of the program “Two Site Exchange of

NMR Lines" developed in this laboratory.[667] From the results of this calculation, the equilibrium constant K_{eq} for the reaction **B′** ⇆ **B** at pH* 5.5 is larger (8.0) than that at pH* 4.0 (3.4). This is also easily seen from the 1D ^{1}H NMR spectra (Figure 62), that the peaks from **B′** at pH* 4.0 are relatively more intense than are those at pH* 5.5. The NOESY/EXSY spectra at different temperatures and different mixing times show that as the temperature decreases, the **B′** orientation is more favored.[145] Thus, at low temperature the ImH ligand has more tendency to be perpendicular to the His57 imidazole plane than at room temperature. The rate constants for the reaction **B′** ⇆ **B** (k_f, k_r = 8 and 1 s^{-1} at pH 5.5; 6.7 and 1.9 s^{-1} at pH 4.0, respectively, both at 33 °C)[145] also show that different mixing times in the EXSY experiments give the same rate constant, and thus confirm that both the rate and equilibrium constants are independent of mixing time.[145] NOESY/EXSY spectra of wild-type (wt) NP2–ImH and its L122V and L132V distal pocket single mutants and the L122V,L132V double mutant also exhibit chemical exchange cross peaks.[142] The rate of interconversion of the two forms at pH 7.5 could be estimated from the NOESY/EXSY diagonal and cross peak intensities (k_f ~ 54 s^{-1}, k_r ~ 0.5 s^{-1}, $K_{eq} = k_f/k_r$ = 100 or larger),[142] where the major **B** ImH orientation angle is somewhat larger than that found for the wt NP2–ImH complex (168–170°).[141] NMR spectroscopic investigations of the more sterically-demanding 2-methylimidazole ligand (2MeImH) showed that it binds to all three distal pocket mutants to create low-spin six-coordinate Fe^{III} complexes which have the protein-provided H57-imidazole and the distal 2MeImH in nearly perpendicular planes; it also binds to the wt protein in the presence of higher concentrations of 2MeImH, but yields a different ligand plane orientation (about 20° different) than is present in any of the three distal pocket mutants.[142] The crystal structure of the double mutant-ImH complex shows an approximately perpendicular angle which is different than any of those observed in solution (φ = 19.5°, $\Delta\varphi$ = 69.1°, PDB file 1PM1), and is highly ruffled, although not as ruffled as the wild-type (ΔC_m = 38.8 in 0.01Å).[634] In contrast, the orientation angle φ determined for the ImH of the **B′** species in solution is 56°. While both of these give similar dihedral angles to the H57 plane ($\Delta\varphi$ = 69° vs. 74°, since in both cases the dihedral angle less than 90° is measured), the orientation of the ImH ligand for the **B′** species is different by about 36° in solution from its orientation in the solid state.

The relevance of the **B′** ⇆ **B** exchange processes, whose rates can be measured by NOESY/EXSY techniques,[142,145] to the kinetics of NO release from the nitrophorins[668,669] is that **B′** ⇆ **B** exchange clearly involves loss of the ligand, but not loss from the distal pocket, followed by its re-binding in a different orientation. As shown above, the rate constant for ImH orientation change from **B** to **B′** for NP2 (L122V,L132V) at pH 5.5, is k_r ~ 0.5 s^{-1} at pH 7.5,[142] whereas the rate of NO loss from the binding pocket of wild-type NP2 has been measured at pH 8.0

as k_{off} ~ 0.12 s^{-1},[668] and at pH 7.5 as 0.16 s^{-1}.[669] Although NO is a much smaller ligand, and thus might be expected to have a faster rate of dissociation than ImH, the wild-type NP2 pocket is much more crowded than is that for the L → V double mutant.[634] And also, crystal structures of the NO complexes of NP2 and NP4 have shown that the A-B and G-H loops are in the closed conformation, whereas crystal structures of the ImH complexes of both NPs have shown that the A-B and G-H loops are fairly open.[628–634] In addition, in the **B/B′** case, it is likely that the ImH ligand does not completely leave the protein, but simply slides away from the binding site and then slides back in, in a different orientation (it cannot simply rotate through an angle of ~90° because of the bulky Leu122 and Leu132 side chains, Figure 54, center). The k_r values for **B/B′** kinetics of wild-type NP2-ImH at low pH (k_r ~ 1.9 s^{-1} at pH 4.0 and 1 s^{-1} at pH 5.5)[145] are considerably larger than k_r for the **B/B′** kinetics of ImH orientation change of the NP2 L → V double mutant,[142] but k_r (as well as the fraction of **B′**) decreases with increasing pH, which is consistent with the fact that the kinetics are not observed by EXSY techniques at pH 7.0,[141–143,145] and also suggests that at pH 7.5,[669] the rate of NO dissociation and ImH reorientation are rather similar.

The NMR spectra of NP2-histamine (Hm) have been studied by NMR spectroscopy at three different pH* values (6.5, 5.5, 4.5). The assignments at each pH* value were derived from WEFT-NOESY and $^1H\{^{13}C\}$-HMQC spectra.[145] The major **B** orientation at pH* 6.5 is 3 > 5 > 1 > 8, with 3,5,1-methyls very similar in chemical shift, but 8M is far from the other three and falls in the diamagnetic region.[145] From the angle plot (Figure 11), it can be seen that the effective ligand nodal plane orientation is 156–157°, which is similar to that for the ImH complex. Chemical exchange between the major **B** Hm imidazole plane orientation, which is fairly close to parallel to H57 ($\Delta\varphi = 37.6°$ from the unpublished X-ray structure of NP2(D1A)-Hm,[634] $\Delta\varphi$ = 22° from the NMR chemical shifts of the heme methyls[145]), and a very small amount of **B′** Hm orientation at pH* 5.5 and 4.5, which has the Hm imidazole plane nearly perpendicular (84°) to that of H57.[145] The intensities of the NOESY/EXSY cross peaks were too small to allow accurate measurement of the rate and equilibrium constants.[145] It is clear that the larger size of Hm as compared to its simple model, ImH, limits the ability Hm to bind in a perpendicular orientation. It is also very clear that the orientation of the Hm ligand cannot change by such a large amount unless the ligand leaves the distal binding pocket and then re-enters in a different orientation.

In Figure 64 the $^1H\{^{13}C\}$-HMQC spectra of NP2-Hm at pH* 6.5 is shown; the $^1H,^{13}C$ cross peaks of all heme substituents, except for 4Vα and the *meso*-CH, are clearly observed for the **B** heme isomer; they are fairly easy to assign because of their unique $^1H,^{13}C$ shifts.[145] These unique shifts are a result of a combination of the contact, pseudocontact and ring current contributions to the chemical shifts

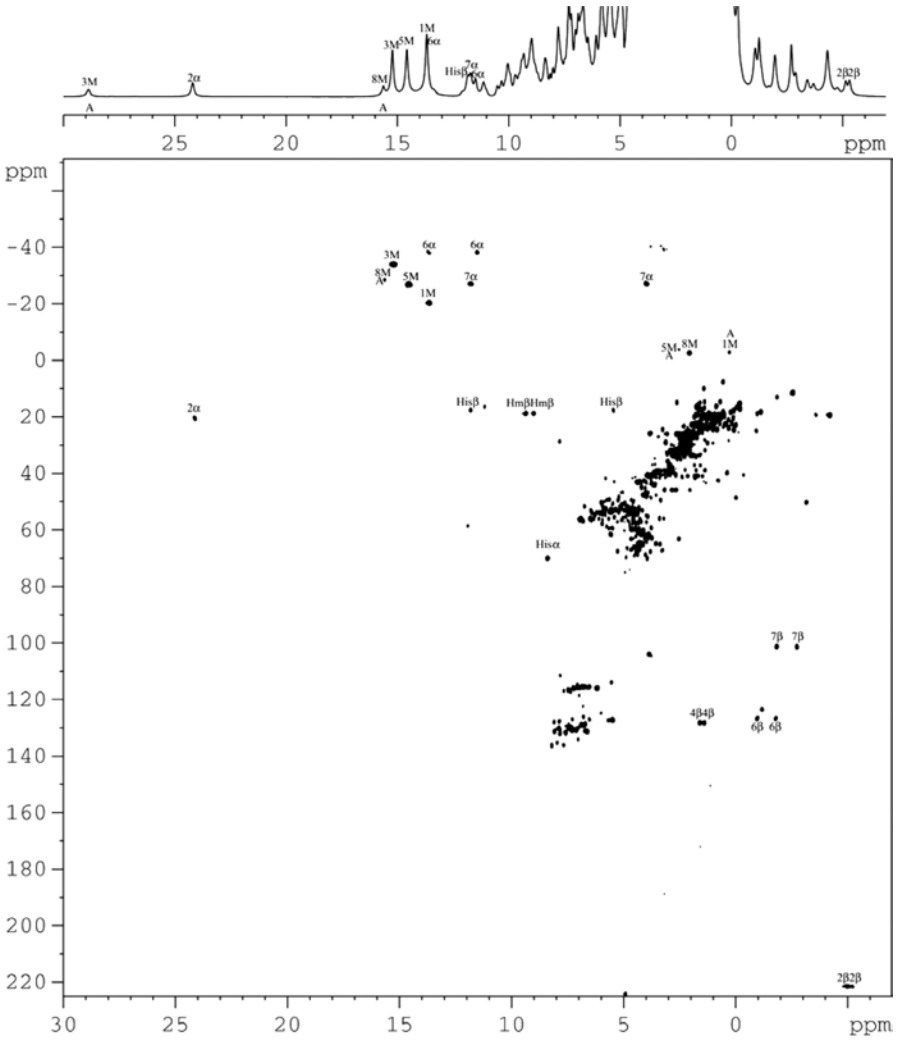

Figure 64. 1D ^{1}H and ^{1}H-^{13}C HMQC spectra of NP2–Hm in D_2O, buffered with 30 mM Na_2DPO_4/acetic acid-d_4 (pH* 6.5), recorded at 35 °C and 500 MHz. Reprinted from Yang, F.; Knipp, M.; Berry, R. E.; Shokhireva, T. K.; Zhang, H.; Walker, F. A. *J. Biol. Inorg. Chem.* **2009**, *14*, 1077–1095, with permission from Elsevier Publishing Company.

of both nuclei,[172] which shift these cross peaks well outside the normal ranges observed for the two nuclei in diamagnetic compounds, and thus make them easy to recognize and assign. The β-vinyl and α- and β-propionate C-H cross peaks can be spotted because pairs of protons have cross peaks to the same carbon. ^{1}H resonances of the 2- and 4α and $-\beta$ vinyl resonances are confirmed by their NOESY cross peaks, as are also the 6- and 7α and β propionate resonances,[145] Figure 64.

Other CH_2 groups that are easily recognized are those of His57 β-CH_2, ^{13}C chemical shift +17.6 ppm, ^1H chemical shifts +11.8 and +5.3 ppm for the **B** heme orientation, and in addition, the cross peaks from the histamine β-CH_2 group (adjacent to the imidazole ring) are also observed, ^{13}C chemical shift +18.7 ppm, ^1H chemical shifts +9.4 and +9.0 ppm. The ^1H His57 β-CH_2 chemical shifts are also confirmed by the NOESY spectra.[145,670] Additional ^1H,^{13}C cross peaks from protein methyls of I120, L122 and L132, which are close to the heme are also seen, with ^{13}C chemical shifts of 10–30 ppm and ^1H chemical shifts of 0 to −5 ppm.[670] There is a rough linear correlation between ^1H and ^{13}C shifts of the heme methyls that helps in the assignment of the heme methyl resonances and the electronic ground state of the ferriheme center.[671] This correlation is based on the contributions to the contact, pseudocontact and ring current shifts of heme substituents.[172]

With regard to the minor **A** isomer, the heme methyl ^1H,^{13}C cross peaks, except for that of 3M, are also observed in Figure 64. The ^1H,^{13}C cross peak for the most hyperfine-shifted methyl resonance is often not observed because it is broader than the other three methyl resonances, as expected from its larger ^1H chemical shift and thus larger expected spin density on its β-pyrrole carbon.[8] In addition, when chemical exchange is involved, as for the wild-type NP2-ImH complex $^1H\{^{13}C\}$-HMQC spectrum at low pH*, not all heme substituent cross peaks are observed, even for the major **B** isomer (6α, 7α, 2α and 4α are not observed).[145]

The wt NP2-CN complex has been investigated at four different pH values, pH* 7.0, 6.5, 5.5 and 4.5. 1D ^1H NMR spectra at pH* 6.5 and 4.5 are shown in Figure 65. Since CN^- is cylindrical, an exogenous ligand plane cannot be discussed in this case. However, as shown previously,[143–145] the nonplanarity of the heme still creates a ruffling nodal plane α for isomer **A** of around 157–159°, and for isomer **B** of around 108–112°. The orientation of this ruffling nodal plane, as determined from the NMR data agrees well with one of the two ruffling nodal planes seen from the crystal structure, that which is near the nitrogen and center of the pyrrole ring I and III for the **B** heme isomer or II and IV for the **A** heme isomer, which are just clockwise to the positions of Leu132 and Leu122 above the mean plane of the heme,[143] Figure 56. In contrast, for isomer **B′** this nodal plane α is around 19°, which is 90° from the just-discussed ruffling nodal plane, and the methyl order is 1 > 5 > 3 > 8. The methyl order for the **B** isomer is 3 > 8 > 1 > 5 at all three pH values, as we have seen for NP–CN complexes at pH 7.0.[143] The fact that 1M has larger chemical shift than 5M has previously been explained by the large degree of ruffling of the heme and somewhat off-axis binding of the cyanide.[143] The methyl order for the **A** isomer is characterized by 3M having similar chemical shift to 5M, and 1M having similar chemical shift to 8M (Figure 11).

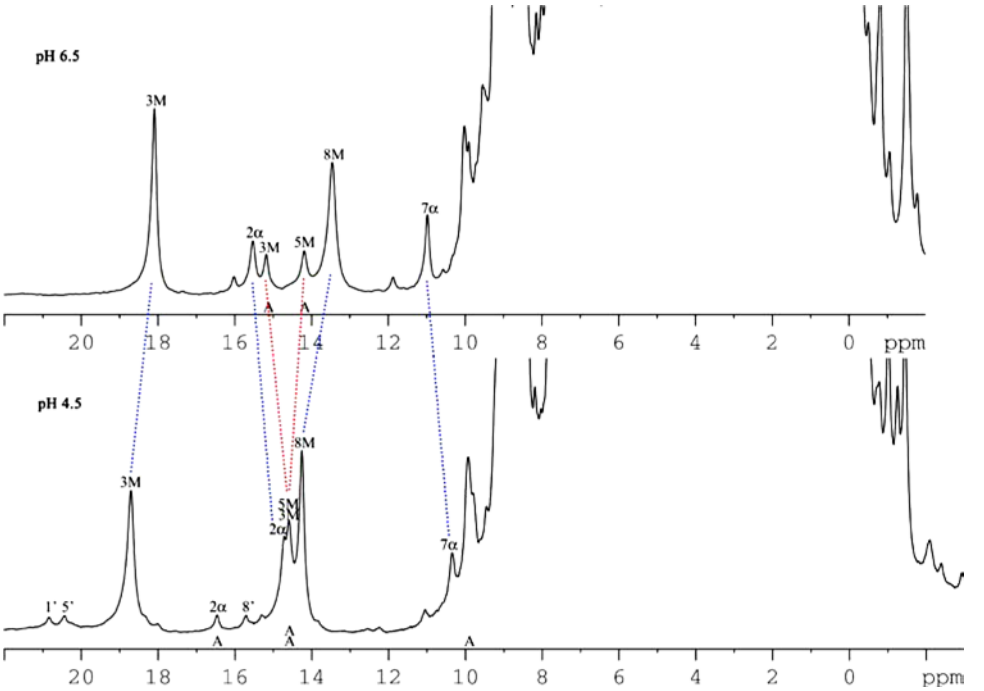

Figure 65. 1D ^{1}H NMR spectra of the hyperfine-shifted resonances of NP2-CN at pH* 6.5 (top) and pH* 4.5 (bottom), recorded at 35 °C at 500 or 600 MHz. Lines showing the variation in chemical shift of heme resonances of **A** (red) and **B** (blue) are displayed. Reprinted from Yang, F.; Knipp, M.; Berry, R. E.; Shokhireva, T. K.; Zhang, H.; Walker, F. A. *J. Biol. Inorg. Chem.* **2009**, *14*, 1077–1095, with permission from Elsevier Publishing Company.

All methyl orders for **A**, **B** and **B′** isomers are different from those of the ImH and Hm complexes.[145] In the ^{1}H{^{13}C}-HMQC spectrum the ^{1}H,^{13}C cross peaks for all heme substituents except the *meso*-CH are observed; His57 β-CH_2 cross peaks are also not seen.[145]

As for the case of the ImH and Hm complexes, resonances from a **B′** species are observed as the pH* is lowered. Although they are very weak in the 1D spectra, the **B′–B** exchange cross peaks for the methyl resonances are relatively strong in the NOESY/EXSY spectra. And by comparing the 1D spectra at pH* 6.5 and pH* 4.5 (Figure 65), the **B′** methyl peaks are relatively stronger at pH* 4.5; thus the trend is the same as seen for the ImH and Hm complexes. Since cyanide is a cylindrical anion and has no ligand plane, the **B′** isomer does not arise from distal ligand rotation, but from dynamic changes in heme symmetry, as concluded previously.[143–145] It is already known that the NP2-CN complex is very ruffled (PDB file 2HYS[143]), and as concluded previously[143–145] the **B′** species is a different ruffled form, with different orientation of the ruffling ridges. Although not observed

in the solid state, protein dynamics in solution at ambient temperatures allow the minor ruffled form to occur transiently on the NMR timescale.

iv. Heme ruffling of the nitrophorins and comparison to other heme proteins

This summary of the NMR spectra of the low-spin ImH, Hm and CN^- complexes of the nitrophorins shows that they are uniquely different from most other ferriheme proteins. Both heme orientations are observed,[142–146,170] except in the case of NP7,[622–624] and there are two orientations of planar axial ligands (ImH, Hm) observed for the major (**B**) heme isomer, which are in chemical exchange on the NMR timescale with each other at lower pH* for NP2,[145] but at all pH values for the other three major NPs.[143,144,146] The cyanide complexes also show chemical exchange, which helps to explain its nature for all ligands studied: A dynamic change in ruffling which is active on the NMR timescale.[143–146] To our knowledge there has been no report of such ruffling dynamics for any other class of ferriheme protein, although the reason is fairly obvious: No other class of heme proteins has such ruffled ferriheme centers as do the *Rhodnius* NPs. This high degree of ruffling is believed to contribute to the very negative midpoint potentials of these proteins, which stabilizes the iron(III) state which can release NO with nM to μM K_ds, whereas the iron(II) state would have pM to fM K_ds.[142,613] One of the effects of this ruffling that has been investigated recently, the average and the spread of the heme methyl resonances,[143,146] will be discussed in the following paragraphs. As these proteins are studied further, additional aspects of the effects of this ruffling will undoubtedly come to light.

In comparison to the nitrophorins, most of the ferriheme proteins for whose cyanide complexes the ^{1}H NMR spectra have been reported are those of myoglobins, hemoglobins, and peroxidases,[8,19,672–674] almost all of which have the histidine imidazole plane aligned along one or the other of the N_P–Fe–N_P axes (Figure 8, φ ~0 or ~90°). Such alignment of the imidazole plane "discourages" ruffling of the heme, whereas the orientation of H57(59) over the β,δ-*meso* carbons, as in the *Rhodnius* nitrophorins, "encourages" ruffling. In addition, the two leucine residues in the distal pocket (L123 and L133 for NP1[625] and NP4,[629] L122 and L132 for NP2[633] and NP3) that are in van der Waals contact with the heme and are believed to further encourage the heme to ruffle, with important consequences in terms of the stability of the Fe^{III}–NO oxidation state.[605,606] Ruffling of a ferriheme tends to stabilize the d_{xz} and d_{yz} orbitals of the iron and, in the limit, leads to a change in the electron configuration of low-spin iron(III) from the more common $(d_{xy})^2(d_{xz},d_{yz})^3$ to the less common $(d_{xz},d_{yz})^4(d_{xy})^1$ configuration[129] discussed in Section IV.A.8.c. This change in electron configuration brings about major

changes in the g-values measured by EPR spectroscopy, as well as major decreases in the proton chemical shifts of the β-pyrrole substituent resonances of the ferriheme. Both of these effects are aided by overlap between the half-filled d_{xy} orbital of iron and the porphyrin $3a_{2u}(\pi)$ molecular orbital.[129] This orbital has large spin density at the nitrogens and *meso*-carbons and very small spin density at the β-pyrrole carbons, Figures 2 and 3. Ruffling of the heme has important functional consequences for the nitric oxide complexes for which the cyanide complex is a model, in that strong ruffling of the heme should help to maintain the $Fe^{III}(d_{xz},d_{yz})^4(d_{xy})^1$–NO• electron configuration rather than the $Fe^{II}(d_{xz},d_{yz})^4(d_{xy})^2$–$NO^+$ electron configuration, which thus helps to facilitate NO release.[605,606]

Thus, as concluded previously,[143] the spread of the heme methyl proton resonances of monocyano ferriheme proteins should be a measure of the degree of d_{xy} character of the metal unpaired electron and thus also of the degree of ruffling of the heme. In Table 14 are summarized the heme methyl proton chemical shifts for a number of ferriheme-cyanide complexes of heme proteins, including the three nitrophorins for which crystal structures are available. As is apparent, there are two classes of ferriheme-cyanide complexes: those which have a spread of the heme methyl resonances of 19.1–29.3 ppm and those which have a spread of 7.2–14.7 ppm. The group with the larger spread of heme methyl resonances includes most of the metmyoglobin cyanides, except for those of *Aplysia* and *Dolabella*, the hemoglobins of *Scapharca* and human, but not lower organism hemoglobins, *Pseudomonas aeruginosa* hemin-containing heme oxygenase-CN in both the normal and alternate seatings, but not human or *Corynebacterium diphtheria* hemin-containing heme oxygenase cyanides. By this criterion of large spread of the heme methyl resonances, we would expect these ferriheme-cyanide proteins to have planar hemes and pure $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configurations in aqueous solution at ambient temperatures. On the other hand, *Aplysia*[675] and *Dolabella*[676] metmyoglobin cyanides, *Scapharca*[677] and human[676] hemoglobin cyanides, human[678] and *Corynebacterium diphtheria* hemin-containing heme oxygenase cyanide,[678] M80A cytochrome *c* cyanide,[679] microperoxidase-8-cyanide,[680] and horse cytochrome *c* cyanide[681] probably all have at least somewhat ruffled hemes, as do the *Rhodnius* nitrophorins.[625–634] In support of this statement, the structure of ferric *Aplysia limacina* Mb,[682] its CN^-, N_3^-, SCN^-, F^-, and imidazole complexes,[683] and several mutants where the mutated group is not near the heme binding pocket,[684] as well as the *Scapharca inaequivalis* tetrameric HbII–CO[685] all show that the histidine imidazole plane is aligned closer to the *meso–meso* axis than to the N–Fe–N axis. And although the heme is modeled as being planar in these crystal structures, it is very likely that in solution a low-energy vibration can take the heme from a planar conformation to a ruffled or possibly a saddled one. Human metHbCN dimer has the His-imidazole plane closer to the N–Fe–N axis

Table 14. Methyl proton shift patterns for histidine/cyanide-coordinated ferriheme proteins.

Protein	His-imidazole plane angle (°)	Methyl shift order	Methyl shifts (ppm)	Spread (ppm)	Average shift (ppm)	Ref.

than these,[686] but the angles are still far from the N–Fe–N axis as compared to sperm whale, horse, or elephant Mb. The near-*meso–meso* orientation of the His-imidazole plane in each of these cases would "encourage" the ruffled conformation, and thus the NMR observation of very small spread of the heme methyl resonances of the cyanide complexes is consistent with a ruffled heme macrocycle at room temperature.

Ruffling seems to inevitably lead to at least some degree of contribution from the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration.[129] Even for model hemes with sterically bulky imidazole ligands, for which the EPR spectra are of the "large g_{max}" type (Section IV.A.8.a), the average β-pyrrole–H or $-CH_3$ chemical shift magnitude at a given temperature is invariably smaller than for those bound to non-bulky imidazole ligands (−17 vs. −10 ppm for $[TPPFe(NMeIm)_2]^+$ and $[TMPFe(2MeImH)_2]^+$, respectively, both at 300 K, although there may be a small effect of hydrogen-bonding in the latter case). Notably, as just discussed for those ferriheme protein cyanides for which structures are available, and as based on the order of heme methyl resonances for the other members of the latter group of proteins, all have histidine imidazole planes oriented near either the β,δ- or the α,γ-*meso*-carbons, which "encourages" ruffling.[129] The degree of d_{xy} unpaired electron contribution does not have to be major, and in most cases is not major, for all of the members of this second group of ferriheme cyanides have larger spreads of the methyl resonances than does protohemin bis-cyanide in DMSO-d_6 (6.3 ppm spread, Table 14),[204] where there is no ligand plane. But an increase in the degree of d_{xy} character has the effect of yielding a much smaller *spread* of the heme methyl resonances, and a smaller *average heme methyl chemical shift* than the first group, and thus suggests that the hemes of these complexes are quite ruffled.

Interestingly, the EPR spectra of the nitrophorin-cyanide complexes are very similar to that of metMbCN, which indicates that at 4.2 K the electron configuration of both complexes is pure $(d_{xy})^2(d_{xz},d_{yz})^3$. This means that the NP1-CN electron configuration must change with temperature. A similar change in electron configuration with temperature was observed for a model of heme oxygenase, $[TPPFe(OCH_3)(t\text{-BuOO})]^-$, which also exhibited a $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration with a planar heme at 4.2 K but a $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration with a ruffled heme at ambient temperature,[481] as discussed above in Section IV.A.8.a.

v. Nitrite reductase activity of nitrophorin 7

He and Knipp have recently shown that NP7 reacts with sodium nitrite at pH 7.5 to produce NP7-NO and other products.[687] Resonance Raman spectroscopy was used to prove that the product was indeed NP7-NO.[687] The NP-NO complex is indeed EPR silent, and the ^1H NMR spectrum of the NP2 product is identical to

NP2-NO.[688] By quantitating the products using the Griess reaction,[689] the stoichiometry of the reaction was shown to be:

$$3\ NO_2^- + 2\ H^+ \rightarrow 2\ NO + NO_3^- + H_2O. \quad (39)$$

The nitrophorin, as a Fe^{III} protein, is simply a catalyst of this reaction, and does not itself undergo redox. This is a different reaction with nitrite than that of myoglobin and other Fe^{II} heme proteins, in which the protein is oxidized to Fe^{III},[690,691] and the oxidized (met) forms do not react with nitrite.[692,693]

vi. Dimerization of NP4

Of the four major nitrophorins in the adult *Rhodnius* insect, NP4 is by far the best for X-ray crystallography because it crystallizes in only one space group (C2) and yields structures of very high resolution (0.85 Å for NP4-NH_3 at pH 7.4, PDB file 1X8P, 0.97 Å for NP4-NO at pH 5.6, PDB file 1YWB). All structures of NP4 and its ligand complexes have four molecules per unit cell, and each is a monomer; there are no major interactions between one molecule and another. However, at NMR concentrations (1 mM, 50 mM acetate buffer at pH 5.5), NP4 is a dimer, and it remains mainly so to well above pH 7.5 at 1 mM concentration.[694] In fact, dimer formation at pH 5.0 provides an excellent method for purifying NP4, by size-exclusion chromatography.[694] NP4 containing the symmetrical hemin (Figure 56) is most useful for studies of the monomer-dimer equilibrium by $^1H\{^{15}N\}$-HSQC.

If histamine is added to NP4, the dimer dissociates, with each monomer having histamine bound to the distal side of the Fe^{III} heme; the apoprotein is also monomeric.[694] However, both high-spin NP4 and the NP4-NO complex are dimeric. One particular mutant of holo-NP4, the D30A mutant is, however, monomeric at all pH values in the absence of added ligand. In the wild-type protein, the histamine complex has a hydrogen-bond between the histamine $-NH_3^+$ side chain and D30. Thus, it is believed that D30 and a heme carboxylate are involved in this dimerization, but it is not yet clear what other groups may be involved.[694] NP2 has the analogous aspartate, D29, but does not dimerize, either as the wild-type (M0-containing) or as the native form (D1 as first residue, with no M0). NP1 also contains D30 and is 90% identical in sequence to NP4, but perhaps because it contains M0 (see Section IV.A.10.a(i) earlier), NP1 wild-type does not dimerize. However, newly-prepared native NP1, with K1 as the first residue and no M0, does dimerize, and in all respects behaves very similarly to NP4,[694] except for being a less stable dimer.

Several years ago a paper was published by Ambrus and coworkers,[695] on work done at the University of Arizona during the time when we were actively

studying the NP4 dimer, including by mass spectrometry. This study showed that NP4 dimerized, and that in the gas phase, as detected by mass spectrometry, (studied in the same MS facility as we were using), it formed up to octomers.[695] The DOESY NMR spectra of dimeric NP4 in solution were investigated, but it was remarked by the authors that the solvent HOD resonance was much broader than expected, and the authors did not understand why.[695] Ambrus had admitted to this author several years prior to that publication that he did not understand what the word "paramagnetic" meant; presumably he has never learned.

vii. NMR spectroscopy of apo-nitrophorin 2

NP2 in the absence of heme has been studied by multidimensional NMR spectroscopy at pH 6.5.[696] An NP2 sample with an N-terminus having residues GSHM before the D1 residue that begins the native protein sequence was used for this study. These residues were left following cleavage of an *N*-terminal His_6-tag that aided the purification of the doubly-labeled protein.[696] All but a few $^{1}H,^{15}N$ cross peaks (~8) in the $^{1}H\{^{15}N\}$-HSQC spectrum were assigned and the 3-dimensional structure was solved, first by using only the N–H and Cα-H NOEs, and later using a multitude of side-chain NOEs as well.[696] Refinement of the solution structure[696] shows it to be almost identical to that of the holoprotein obtained by X-ray crystallography,[633] as well as to apo-NP4, which was also solved by X-ray crystallography at pH 5.6.[697] The paper describing this structure provides little detail about the structure, other than "removal of the heme from NP4 has very little effect on (the protein's) structure: The heme binding cavity remains open and loops near the cavity entrance respond to lower pH in the same manner as the intact protein,"[697] meaning that the A-B and G-H loops form the closed loop conformation. Diffuse electron density was also found within the β-barrel, which the authors hypothesized resulted from one or more buffer or cryoprotectant molecules.[697]

The overall similarity of the calculated NMR structure of apoNP2 to the structure of the NP2 holoprotein[633] is remarkable. However, the packing of the β-barrel itself is not entirely identical; the insertion of the heme results in a widening of the the β-barrel opening in the holoprotein parallel to the plane of the macrocycle, by outward displacement of the D and E β-strands by ~1.4 Å. The ability of the extensively H-bonded β-barrel core to undergo such an expansion is somewhat counterintuitive, considering the rigidity that might be expected for this protein fold. However, H/D exchange rates, measured with SOFAST-HMQC[698] for the backbone amides, indicate that the backbone of the β-barrel core opposite to the side that faces the α2 helix is fully accessible to the solvent, and thus must possess significant structural plasticity. The "roof" of the heme cavity undergoes important structural rearrangements on heme binding. Steric clashes between heme and the

L132 side chain result in upward displacement of the H-strand, while downward rearrangement of the G β-strand brings the L122 side-chain into close contact with the heme, presumably by displacing water molecules from the heme cavity of the apoprotein as heme binds. It is noteworthy that both of these residues are conserved among all NPs.

The H/D exchange lifetimes indicate that the residues that show the slowest H/D exchange rates are localized on the α2 helix and F, G, H and A strands of the β-barrel. The slow exchange rates are indicative of the presence of a compact hydrophobic core involving the FGHA part of the β-barrel with the opposing side of the barrel exhibiting a higher degree of plasticity. Higher plasticity may account for the fact that the heme ruffling (and therefore its E_m) is insensitive to the bulkiness of the hydrophobic side chain residues located in that part of the protein. However, the steric requirements of the residues located in the rigid part of the β-barrel do disrupt the planarity of the heme, and undoubtedly modulate its E_m significantly. The rigidity of the β-barrel fold makes it uniquely suited for heme proteins such as the NO-carrying/releasing NP proteins, where a very strong electrochemical stabilization of the oxidized metal center is required. Mainly α-helical proteins cannot exert such pressure on the heme, and thus have flat hemes with much higher E_ms, meaning that Fe^{III} is much more easily reduced to Fe^{II} when the heme is flat. Thus, for release of NO with nM K_ds, the ruffled heme thus helps maintain the Fe^{III} oxidation state.

The $^1H\{^{15}N\}$-HSQC spectrum of the high-spin protohemin-containing holo-NP2 aqua complex showed doubling of a significant number of resonances because of the **A**:**B** disorder of the protohemin (1:8 at equilibrium[170]). Therefore the symmetrical hemin, Figure 56, with the GSHM0D1 N-terminus present, was used for detailed studies. Nearly complete assignment of the backbone spin-systems of the ligand-free high-spin holo-NP2 was obtained.[696] Not including the prolines and N-terminal GSHM sequence, the following were not observed in the 3D triple-resonance experiments and thus were not assigned: Y38, C39, S40, L55, Y56, H57, F66, I120, L122, L129, and L132. Backbone amide groups of all of these are located within 10 Å of the S = 5/2 metal center in the crystal structure (2A3F), and are thus expected to be broadened significantly. The holoprotein shows significantly greater dispersion of $^1H\{^{15}N\}$-HSQC resonances, due to pseudocontact shifts and the macrocycle ring current.[696] As a result, it was possible to obtain all assignments from HNCACB/CBCA(CO)NH and HNCA/HN(CO)CA experiments alone.[696] Further study of the structure and especially the dynamics of NP2 over multiple time scales is ongoing, but, based on the information about the role of extra residues at the N-terminus gained from the study of NP2(D1A) discussed above in Section IV.A.10.a(i), by using a construct which has the native N-terminus, and a C-terminus His_6-tag to allow rapid purification of small isotopically labeled protein samples.[699]

b. *NMR spectroscopy of the hemin-containing heme oxygenases*

Heme oxygenases (HOs) are found in organisms as simple as bacteria and as complex as humans. They are also found in plants, where they are soluble enzymes in which the product biliverdin is a starting point for the construction of linear, light-sensing tetrapyrrole pigments.[700] The heme oxygenase proteins bind hemin, which is then both the active site of the enzyme, as well as its substrate. A histidine is the heme ligand, and there is no distal His. The oxygenase mechanism is believed to involve a ferric hydroperoxide intermediate, as discussed below, rather than the ferryl Compound I species common to cytochromes P450.[701] The heme ring is cleaved at the *meso*-α-carbon in the case of animals, in a reaction that requires three molecules of O_2, seven electrons and nine protons,[702] and produces inorganic iron, carbon monoxide and a tetrapyrrole, biliverdin, which is subsequently reduced to bilirubin; both biliverdin and bilirubin are powerful antioxidants. Pathogenic bacteria such as *Pseudomonas aeruginosa* (*Pa*), *Corynebacterium diphtheriae* (*Cd*) and *Neisseriae meningitidis* (*Nm*) use their heme oxygenase enzymes to "mine" iron from their hosts, and the HOs of these organisms are not necessarily regioselective for the α-*meso*-carbon; for example *Pa*-HO (sometimes called PigA) produces 70% δ-, 30% β-biliverdin,[147] while wild-type *Cd*-HO (sometimes called HmuO) produces 100% α-biliverdin,[148,703] as does *Nm*-HO (sometimes called HemO).[704]

For humans there are two well-characterized isoforms of heme oxygenase, HO-1 and HO-2.[705,706] HO-1 is an inducible isoform, 33 kDa, that is expressed in response to stress (oxidative stress, hypoxia, heavy metals, cytokines, etc.). HO-2 is the constituitive isoform, 36 kDa, which is expressed under homeostatic conditions, and carries an extra ~20 amino acids at the N-terminus. Both human HOs have a C-terminal hydrophobic tail (~25 amino acids), which can be cleaved,[705] that binds them to microsomes, and both HO-1 and HO-2 are ubiquitously expressed and catalytically active. The X-ray crystal structures of human,[707–712] rat[713–717] and four bacterial (*Nm*,[718,718] *Cd*,[720] *Pa*,[721] and *Synechocystis sp.* PCC 6803[722]) HOs have been reported. An example structure, that of *Pa*-HO, is shown in Figure 66. As can be seen, the protein is highly helical, with the heme sandwiched between helices I,II and VII,VIII. The distal helix VII,VIII is very tightly packed against the O_2-binding site of the heme, and a Gly residue is believed to be very important to the activity of the enzyme, as discussed below. In mammals the transfer of electrons from NADPH to the enzyme is mediated by cytochrome P450 reductase,[723] while *Pa*-HO has a NADPH-binding, FAD-containing ferredoxin reductase, *Pa*-FPR, which shuttles the electrons to *Pa*-HO.[724] A small ferredoxin, *Pa*-Bfd, that can incorporate a $[2Fe\text{-}2S]^{2+/1+}$ center, had earlier been thought to shuttle the electrons from *Pa*-FPR to *Pa*-HO, but that was found not to be the case;

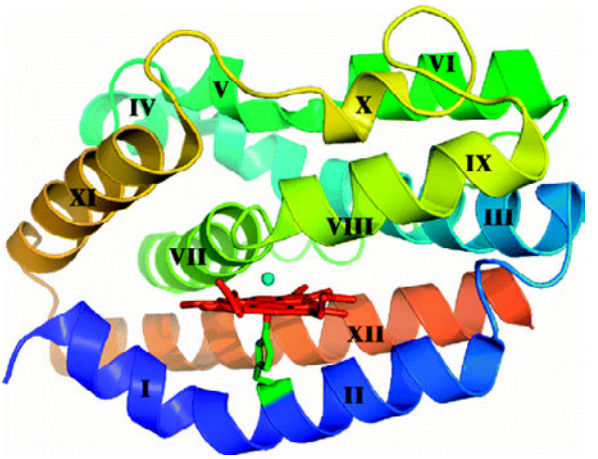

Figure 66. Structure of *Pa*-HO in its ferric resting state (PDB file: 1SK7) illustrating the α-helical fold, the positioning of the heme, and the axial coordination by a His-imidazole and water ligands. The heme is "sandwiched between the proximal helices (I and II) and the distal helices (VII and VIII). The loop between the two distal helices is typically referred to as the helix kink. Reprinted from Rodriguez, J. C.; Zeng, Y.; Wilks, A.; Rivera, M. *J. Am. Chem. Soc.* **2007**, *129*, 11730–11742, with permission from the American Chemical Society.

Pa-FPR does the job alone.[724] It is interesting that both the mammalian and the bacterial (at least in *P. aeruginosa*) HO enzymes get their electrons from flavin-containing reductases. More recently it was discovered that the mobilization of iron from bacterioferritin B requires the binding of apo-Bfd, and to date it appears that Bfd does not function as a normal electron-transfer ferredoxin, despite the fact that one can assemble a 2Fe,2S cluster in its fold.[725]

NMR spectroscopy has been used by the groups of both La Mar and Rivera to study the bacterial HOs, while La Mar initially and even recently has studied mammalian, and most often the human HO-1. The La Mar papers are technically extremely detailed and do not lend themselves to being presented as figures in a review article. In spite of that, the work is extremely well done. La Mar and his group do not begin by assigning the $^{1}H\{^{15}N\}$-HSQC spectrum and work outward to the side chains, but rather begin with the side chains that are affected by the presence of the paramagnetic heme.[678] If the structure of the protein is not available, they use the NOESY and TOCSY spectra of the low-spin cyanoferrihemin state to assign the side chain resonances of all residues which interact with the substituents of the hemin, and use the expected pseudocontact shifts to refine the assignment of these residues, and their exact placement.[678] From this point they will go back to the high-spin and apoprotein states and look at the NOESY and TOCSY spectra of the apoprotein and see which resonances are "bleached" by binding of the paramagnetic heme, based on the protein sequence, side chain type

(usually focusing on the aromatic resonances), and assign these in light of the assignments for the low-spin cyanoferihemin state. If the structure of the protein is available, they proceed in the same general way, but use the protein structure to choose the side chains on which to focus, and again use the expected pseudocontact shifts to refine the placement of these residues.[727] The Rivera papers tend to utilize newer multidimensional NMR methods, which include those for complete assignment of the protein sequence, the side chains, and their dynamics, methods that capitalize on isotopic labeling of the heme or of the polypeptide.

NMR spectroscopy has been used to study HOs for three main purposes: (a) To investigate propionate-polypeptide interactions, which, to a large extent, seat the heme in the pocket and determine regioselectivity (in their absence the heme is free to undergo large-amplitude in-plane motions, which appears to be a property so far unique to HOs); (b) to investigate the heme electronic structure and its possible implications in heme catabolism; and (c) to investigate dynamic-reactivity relationships, including those which involve water molecules in the distal pocket. Each of these topics will be covered in turn in the bacterial HO section.

i. NMR study of high- and low-spin mammalian heme oxygenases

The first paper from the La Mar group, on recombinant rat HO, appeared in 1994,[726] and is referenced in the Porphyrin Handbook chapter.[19] The labeling of the spectra in Figures 2 and 3 of that work does not agree with the captions given, but can be interpreted by studying the spectra in the Porphyrin Handbook chapter.[19] It was reported that rat HO-1 had ~1:1 heme heterogeneity (later refined as 55:45%[678]) and an "unusual hemin electronic structure that is characterized by large differences in delocalized spin density for the two positions within a given pyrrole, rather than the more conventional large differences between adjacent pyrroles."[726] This "unusual" hemin electronic structure was caused by the fact that the axial histidine was aligned close to two of the *meso* carbons (β,δ) rather than along the heme nitrogens (Figure 11), as had been the case for the myoglobins and hemoglobins that had been studied earlier by this group. The pattern was recognized as being similar to one published previously for model hemes having one unique substituent on one phenyl ring of the $[TPPFe(NMeIm)_2]^+$ (where one relatively electron-donating substituent leads to choice of the former $3e(\pi)$ orbital with node passing through the two *meso*-C which do not contain that unique substituent as the orbital preferred for spin delocalization, Figure 2, left, Figures 18 and 40),[211] but was believed by the authors to be due to "a perturbation of the heme by the protein matrix," one that might "activate the heme for attack at the α-*meso* position."[726] The heme heterogeneity did not affect the α-*meso* selectivity of human HO-1.[726]

In 1998 the second publication by La Mar and coworkers appeared, the first on recombinant human HO-1, hereafter called hHO-1, in which 2D NMR studies of substrate-free hHO-1 (apo-hHO-1) were reported.[678] This paper is also referenced in the Porphyrin Handbook chapter.[19] A cluster of nine mobile aromatic residues whose signals were largely "bleached" on binding high-spin hemin reappear at different chemical shifts in the low-spin cyanide-inhibited hHO-hemin complex.[678] There was also heme heterogeneity for hHO-1, but the ratio of the two heme orientations was about 3:1 (later refined to 3.5:1[727]) after adding "excess cyanide" and equilibrating for 2–3 days.[678] (Interestingly, the nitrophorins NP2 and NP3, which have heme **A**:**B** orientations significantly different from 1:1,[143,146] do not equilibrate the two heme orientations over time periods of weeks to months after addition of even a single equivalent of cyanide or other strong-field ligand. This is in agreement with the difference in protein fold of the two classes of proteins, and also suggests that the heme binding constant to hHO-1 is much smaller than that to the NPs, which is consistent with the function of each of these proteins.)

Resonance assignments allowed placement of the aromatic clusters into proximal, distal or peripheral positions over specific pyrrole rings, based on dipolar (NOE) contacts and/or relaxation effects. The three aromatic clusters were located, one on the proximal side adjacent to the axial His, and the other two peripheral and distal to the pyrrole I/II junction, the site of heme oxidation.[678] The heme methyl NOE contacts, when compared to those of globins or peroxidases, were judged to reflect an "open" pocket, where hemin binds in the preformed aromatic cluster of hHO with pyrrole rings I and II and parts of pyrrole ring IV buried in the protein, with pyrrole ring III largely exposed to the solvent, and with the proximal side oriented toward the protein surface and the distal site toward the protein interior.[678] A distal labile proton was located, which was found to serve as the H-bond donor to cyanide, and was felt to likely be the origin of the spectroscopically-detected pK_a of ~7.6 in the hHO-hemin complex, and was felt to probably arise from the same distal residue that serves as the H-bond donor to the activated O_2. The distal base was identified as a Tyr.[678]

Three years later, in 2001, after the crystal structure of hHO-1 had appeared,[707] the Tyr was identified as two Tyr, Y58 and Y137, both on the distal side of the heme binding pocket.[727] It was found, by identifying unique protein resonances by using the crystal structure information, that the major heme isomer was the opposite one to that shown in the crystal structure, and a distal four-ring aromatic cluster had moved 1–2 Å closer to the heme, which allowed for stronger H-bonds from the two Tyr.[727] The Fe-CN orientation showed a ~20° tilt of the distal ligand from the heme normal in the direction of the *α-meso* position, which suggested that the close placement of the distal helix over the heme exerted control of sterospecificity

by both blocking access to the β, γ, and δ-*meso* positions and by tilting the axial ligand, i.e., a proposed peroxide, toward the α-*meso* position.[727] The same group then used the symmetrical hemin (Figure 56), 2,4-dimethyldeuterohemin, to further characterize the heme binding site of hHO-1.[728] A unique distal network was found that involves particularly strong hydrogen-bonds, as well as inter-aromatic contacts. It was proposed that this network stabilized the position of the catalytically critical distal helix Asp-140 carboxylate.[728] Most of the residues of the distal helix (Y134 to L147) and a number of others were assigned. G143 had the largest observed N–H, CαH1 and CαH2 shifts, and the pseudocontact contribution could not be modeled without off-axis binding of the cyanide ligand.[728] Later the same year a study of eight strong hydrogen-bonds from immobilized water molecules within the strong distal H-bonding network of cyanide-inhibited hHO were detected by NMR spectroscopy.[729] It was demonstrated that significant magnetization transfer from the bulk water signal to these eight labile protons did not result from chemical exchange, but rather from direct nuclear Overhauser effect, due to the dipolar interaction of these labile protons with "ordered" water molecules.[729] The enzyme labile-proton-to-water-proton distances were estimated as ~3 Å. It was proposed that the role of the strong H-bonding network was to immobilize numerous water molecules which both stabilize the activated hydroperoxy species and also funnel protons to the active site.[729]

A study of "substrate-free" human heme oxygenase (apo-hHO-1) published in 2004[730] identified five conserved secondary structural elements and detected highly characteristic dipolar or H-bond interactions among these elements to confirm a strongly-conserved folding topology of helices C–H relative to that of substrate complexes in either solution or crystals. Correction of the chemical shifts for paramagnetic and porphyrin ring current influences in the paramagnetic substrate complex revealed that the strength of all but one of the relatively robust H-bonds was conserved in apo-hHO, and that similar ordered water molecules were located near these H-bond donors, as in the substrate-bound complexes.[730] The unique and significant weakening of the Y58-OH H-bond to the catalytically critical D140 carboxylate in apo-hHO was suggested to arise from removal of the axial H-bond acceptor ligand rather than the loss of substrate. The interhelical positions of the conserved strong H-bonds were seen to argue for a structural role in maintaining a conserved structure for helices C–H on loss of substrate.[730] While it was found that the structure and H-bond network were largely conserved upon loss of substrate, the variably increased rate of NH lability dictated a significant loss of dynamic stability in the conserved structure, particularly near the distal helix F.[730]

Although there are three additional papers on the topic of hHO-1 published after 2004, they seem to be aimed at goals related to the bacterial proteins, and will

therefore be discussed below, together with the bacterial HOs studied by the La Mar group.

ii. NMR studies of bacterial heme oxygenases

Meanwhile, Rivera began his NMR investigations of heme proteins on outer mitochondrial membrane cytochrome b_5 (OMb_5) in 1996,[186] following publication of the method used for preparing ^{13}C-labeled heme by expressing this protein in ^{13}C medium the year before,[180] and discussed earlier in Section II.D.3, Figure 13. The 1996 paper was a study of the role played by the propionates of OMb_5 in the electrostatic binding to cytochrome *c*.[186] Although the role of OMb_5 was unknown when the gene for the rat protein was synthesized and the protein investigated in the early 1990s,[731–733] it is now known that cytochromes *c* and OMb_5 are redox partners in the intermembrane space of mitochondria of at least three eukaryotes (rat, mouse, human).[734] In addition, OMb_5 has been shown to be the electron donor to mitochondrial amidoxime reducing component, mARC, a newly-identified molybdoenzyme in the outer mitochondrial membrane;[735,736] OMb_5 in this case is reduced by a mP450 reductase.[735,737,738]

For the study of cytochrome *c*/OMb_5 interactions, titrations of three ^{13}C-hemin-containing OMb_5 isomers, where the three were prepared from 1-^{13}C-ALA, 3-^{13}C-ALA and (1,2-^{13}C)$_2$-ALA (Figure 13), with horse cyt *c* showed clearly that only the heme propionate located on the exposed heme edge of OMb_5 participates in formation of this electrostatic complex. It was also shown that the stoichiometry of the complex is 1:1, and it has a conditional binding constant of 3.8×10^4 M^{-1} at $\mu = 0.02$ M.[186] As part of this work, the X-ray crystal structure of OMb_5 was solved at 2.7 Å and was shown to be almost identical to that of bovine microsomal cytochrome b_5, when compared at medium resolution.[186] Follow-ups to this study included complete isomer-specific ^{1}H and ^{13}C NMR assignments of the heme resonances of rat liver OMb$_5$,[190] which exists as a 1:1 ratio of the two heme orientations. For this study a variety of NMR experiments were used, including HMBC, INADEQUATE, and the more commonly used HMQC, NOESY and COSY experiments,[190] and a new experiment, called INEPT-INADEQUATE.[188,189] This experiment was created because assignments that would normally be performed with the aid of HMBC experiments in diamagnetic molecules proved difficult in the active site of a paramagnetic heme protein where $T_2^{-1} > {}^2J_{CH}$. To circumvent this problem, a new method was presented to selectively detect ^{1}H in ^1H_n–^{13}C–^{13}C fragments biosynthetically introduced into the active sites of heme proteins.[189] The pulse sequence combines well-known building blocks such as INEPT to transfer ^{1}H spin magnetization to bonded ^{13}C nuclei, followed by INADEQUATE to generate ^{13}C–^{13}C double-quantum coherence that is selected with

pulsed field gradients, and finally reverse-INEPT to transfer the magnetization back to ^{1}H nuclei for subsequent observation.[189] This $^{1}H_{n}$–^{13}C–^{13}C edited experiment took advantage of the relatively large values of $^{1}J_{CH}$ and $^{1}J_{CC}$, which avoid the long interpulse delays in HMBC that compromise the detectability of rapidly-relaxing nuclei. The potential applicability of the pulse sequence was first demonstrated by its contribution to the unambiguous assignment of the carbonyl carbons in the heme propionates of ferricytochrome b_5,[189] and then to the complete ^{1}H and ^{13}C assignment of both hemin isomers of ferriheme OMb_5.[190]

Additional directions in the study of OMb_5 involved probing the differences between rat liver OMb$_5$ and bovine microsomal cytoderome b_5[739] and comparing the large difference in plasticity of the two proteins,[740] but the observation that most related to future studies of heme oxygenases was the fact that the H63M mutant of OMb_5, which was prepared for a totally different purpose, when purified by ion exchange chromatography in air, became green in color.[741] Further study showed that the protein contained a product of coupled oxidation of heme, verdoheme.[741] Later study of the H39V mutant of OMb_5,[742] which could catalyze oxidation of heme to biliverdin in the presence of hydrazine and O_2, provided the important insight that catalase (an enzyme that disproportionates 2 H_2O_2 to H_2O and O_2) did not inhibit formation of biliverdin by this OMb_5 mutant, and thus no free H_2O_2 was produced.[742] However, the H63V mutant under the same conditions led to formation of verdoheme, but was completely inhibited by catalase, and only *meso*-hydroxyheme was produced under those conditions.[742] These findings illustrated the subtle but important mechanistic differences between the coupled oxidation reaction, where exogenous H_2O_2 reacts with a ferrous heme site to produce hydroxyheme, and heme oxygenation, where a ferric hydroperoxide moiety hydroxylates the heme to hydroxyheme (Section IV.A.6.c(vii)).

(a) *Heme propionate-polypeptide interactions dictate regioselectivity in HOs*

By this time, Rivera was well into the study of *Pa*-HO, in collaboration with Wilks and coworkers.[147] *Pa*-HO is an interesting bacterial heme oxygenase, in that it is not specific for oxidation at the *α-meso* position, but rather at the *β*- and *δ-meso* positions (30% and 70%, respectively[147]). Since *Pseudomonas aeruginosa* only uses the heme to obtain iron, it does not matter where the heme ring is attacked. In a paper published in 2002,[147] Rivera used specifically ^{13}C-labeled ALAs to produce specifically ^{13}C-labeled hemes in OMb_5, which could then be extracted and inserted into apo-*Pa*-HO (Figure 13, Section II.D.3). Using these labeled-heme-HOs it was possible to study the heme resonances by ^{1}H and ^{13}C NMR and resonance Raman spectroscopy.[147] Whereas the rR spectra indicated that the heme-iron ligation in *Pa*-HO is homologous to that observed in previously studied *α*-hydroxylating

HOs, the NMR studies suggested that the heme in this enzyme is seated in a manner that is distinct from that observed for all α-hydroxylating HOs for which structures were available (hHO-1 and *Nm*-HO at that time). It was found that the heme of *Pa*-HO is rotated in-plane by ~110°, so that the δ-*meso*-C of the major orientational isomer is located within the HO-fold in close to the same place where the α-hydroxylating enzymes typically place the α-*meso*-C.[147] The unusual heme seating displayed by *Pa*-HO, which was elucidated solely on the basis of ^{1}H and ^{13}C NMR spectroscopic studies, was later confirmed by X-ray crystallography.[721] The unusual heme seating places the heme propionates so that they point in the direction of the solvent-exposed heme edge. This orientation appears to originate mainly from the absence of stabilizing interactions between the polypeptide and the heme propionates,[147] which in hHO-1 and *Nm*-HO involve Lys16 and Tyr134, and Lys16 and Tyr112, respectively; the corresponding residues in *Pa*-HO are Asn19 and Phe117.

In agreement with this, preparation of the N19K/F117Y double mutant of *Pa*-HO produced a protein which showed a mixture of two distinct heme seatings, one of which was identical to that of wild-type *Pa*-HO, while the other had the alternative heme seating that was rotated by ~110°, and is very similar to the heme seating in h-HO-1 and *Nm*-HO.[147] Chemical exchange was observed between protein molecules having the two heme seatings for both heme orientational isomers, as shown in the EXSY spectrum of Figure 67, and thus the change in heme seating is active on the NMR timescale.[147] The authors proved that it was the heme that was moving, rather than the axial histidine imidazole plane, by finding an NOE from one of the γ-Me of Val33 to 1M and 3′M of the heme. The products of the *Pa*-HO double mutant were α- (55%), β- (10%) and δ-biliverdin (35%).[147]

In 2004, Rivera, Wilks and coworkers investigated the regioselectivity of the Arg-177 mutants of *Corynebacterium diphtheriae* heme oxygenase as a consequence of in-plane heme disorder.[743] This study was prompted by the report that R183E and R183D mutants of rat HO-1 produce approximately 30% δ-biliverdin.[744] Two plausible mechanisms were proposed to explain the observations. (a) Electrostatic repulsion between E183 (D183) and one of the heme propionates forces the heme to rotate, thereby placing the δ-*meso* carbon in a position that is susceptible to oxidation, or (b) rearrangement of the distal pocket structure is triggered by the formation of an H-bond between E183 (D183) and K179.[744] A change in the pK_a for the Fe^{III}–H_2O to Fe^{III}–OH transition of the mutants was interpreted as being consistent with rearrangement of the H-bond network in the distal pocket. The large similarities between the high-frequency portion of the ^{1}H NMR spectra corresponding to the wild-type and R183E and R183D mutants were interpreted to indicate that the heme in the mutants is not rotated to a significant extent.[744]

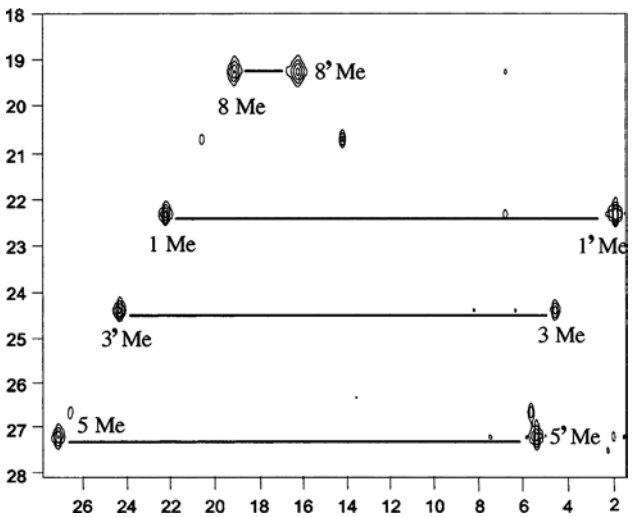

Figure 67. EXSY spectrum of the double mutant of *Pa*-HO-CN. The heme methyl resonance arising from the wild-type and alternative heme seatings are labeled as 1, 3, 5, 8 and 1′, 3′, 5′, 8′, respectively, recorded at 10 °C. Reprinted from Caignan, G. A.; Deshmukh, R.; Wilks, A.; Zeng, Y.; Huang, H.; Moënne-Loccoz, P.; Bunce, R. A.; Eastman, M. A.; Rivera, M. *J. Am. Chem. Soc.* **2002**, *124*, 14879–14892, with permission from the American Chemical Society.

Rivera, Wilks and coworkers re-examined this issue by studying the corresponding R177 mutants in HO from *Corynebacterium diphtheriae*, *Cd*-HO.[743] The replacement of R177 with E or D results in the formation of approximately 55% α- and 45% δ-biliverdin, whereas the R177A mutant retains α-regioselectivity. In addition, the K13N/Y130F/R177A triple mutant catalyzed the formation of 60% δ-, and 40% α-biliverdin, while single mutants K13N and Y130F did not appreciably change the regioselectivity of the reaction.[743] The pK_a of the Fe^{III}–H_2O to Fe^{III}–OH transition in wild-type *Cd*-HO is 9.1, and those of the R177E, R177D, R177A and K13N/Y130F/R177A mutants are 9.4, 9.5. 9.2 and 8.0, respectively. Thus, no obvious correlation exists between the changes in *pK*a and the altered regioselectivity. NMR spectroscopic studies conducted with the R177D and R177E mutants of *Cd*-HO revealed the presence of three heme isomers: A major (*M*) and a minor (*m*) heme orientational isomer related by a 180° rotation about the α–γ *meso* axis and an alternative seating (*m*′) which is related to *m* by an 85° in-plane rotation of the macrocycle.[743] The in-plane rotation of *m* to acquire conformation *m*′ is triggered by electrostatic repulsion between the side chains of D or E at position 177 and heme propionate-6. As a consequence, the δ-*meso* carbon in *m*′ is placed in the position occupied by the α-*meso* carbon in *m*, where it is susceptible to hydroxylation and subsequent formation of δ-biliverdin.[743]

In 2005, Rivera and Wilks and coworkers also investigated a chimera prepared from heme oxygenases from *Pa* and *Nm*, where *Nm*-HO was used, but with a chimeric piece of *Pa*-HO, in which the 107–142 distal helix part of *Nm*-HO was replaced by residues 112–147 of *Pa*-HO to produce *Nm*-HOch.[745] Electronic absorption spectra, resonance Raman and FTIR spectroscopic studies confirm that the orientation and hydrogen-bonding properties of the proximal His ligand are not significantly altered in the chimera relative to those of the wild-type proteins. The catalytic turnover of the *Nm*-HOch-heme complex yields almost exclusively α-biliverdin and a small but reproducible amount of δ-biliverdin.[745] NMR spectroscopic studies revealed that the altered regioselectivity to the chimeric protein likely stems from a dynamic equilibrium between two alternate in-plane conformations of the heme (in-plane heme disorder). Replacement of Lys16 with Ala and Met31 with Lys in the chimeric protein in an effort to tune key polypeptide-heme propionate contacts largely stabilized the in-plane conformer which was conducive to δ-*meso* hydroxylation.[745]

In 2006, La Mar and coworkers produced a triple mutant of hHO-1 that was designed to make it behave like the *Pa*-HO studied by Rivera, Wilks and coworkers in 2002. This triple mutant was K18E/E29K/R183E.[746] Mutation of Glu29 to Lys, which places a positive charge where it can interact with a heme carboxyl if the heme rotates ~90°, causes a slight loss of regiospecificity, but combined with the R183E and K18E mutations results primarily in β/δ-*meso* oxidation of the heme under all conditions.[746] NMR analysis of heme binding to the triple mutant confirmed rotation of the heme in the active site. Kinetic studies demonstrated that mutations of Arg183 greatly impair the rate of the P450 reductase-dependent reaction, in accord with the earlier finding that Arg183 is involved in binding of the reductase to hHO-1, but has little effect on the ascorbate reaction. Mutations of Asp140 and Tyr58 that disrupt the active site hydrogen-bonding network impair catalytic rates, but do not influence the oxidation regiochemistry.[746] The results indicated both that the oxidation regiochemistry is largely controlled by ionic interactions of the heme propionate groups with the protein, and that shifts in regiospecificity involve rotation of the heme about an axis perpendicular to the heme plane,[746] both of which were in agreement with the original report of Rivera and Wilks and coworkers in 2002[147] and their subsequent investigations of the R177E mutant of *Cd*-HO in 2004[743] and the *Nm*-HO-*Cd*-HO chimera in 2005.[745] Later analysis of the symmetrical hemin (Figure 56) complex of this mutant again showed that the protein contacts for the major solution isomers of both substrates dictate ~90° in-plane clockwise rotation relative to that seen in the wt *Nm*-HO.[747] The conventional interpretation of the pattern of substrate methyl hyperfine shifts, however, indicated substrate rotations of only ~50°. This paradox was resolved by demonstrating that the axial His25 imidazole ring also rotated counterclockwise

with respect to the protein matrix in the mutant relative to that in wild-type *Nm*-HO.[747] The axial His25 CβH hyperfine shifts were shown to serve as independent probes of the imidazole plane orientation relative to the protein matrix. It was stated that the pattern of heme methyl hyperfine shifts cannot be used alone to determine the in-plane orientation of the substrate as it relates to the stereospecificity of heme cleavage, without explicit consideration of the orientation of the axial His imidazole plane relative to the protein matrix.[747] This is obvious, as shown by Rivera and coworkers on wild-type *Pa*-HO-CN, where they found an NOE between heme methyls 1 (major) and 3′ (minor) and a methyl of the protein at –0.75 ppm, which was tentatively assigned as a γ-Me of Val33;[147] if this is true, then the His ligand has not changed its orientation, but rather the heme has rotated by ~110°.

In 2006, La Mar and coworkers also characterized the spontaneous "aging" of *Nm*-HO via cleavage of the C-terminus in contact with the substrate.[748] 2D NMR characterization of the cyanide-inhibited substrate complex showed that the C-terminal interactions between Arg208/His209 and the exposed pyrrole of the protohemin substrate in the "native" *Nm*-HO complex is lost in the "aging". Mass spectrometry and N-terminal sequencing of wild-type and "aged" *Nm*-HO reveal that the "aging process involves cleavage of the Arg208;His209 dipeptide."[748] The construction of the double deletion mutant without these two amino acids, and its NMR comparison as both the resting state substrate complex and its cyanide-inhibited complex with the "aged" *Nm*-HO reveal that cleavage of this C-terminal dipeptide is the only modification that takes place during the aging. Comparison with cyanide ligand binding constants reveal a factor of ~1.7 greater CN^- affinity in the native than the "aged" *Nm*-HO.[748] The rate of protohemin degradation and its stereoselectivity are unaffected by the C-terminal truncation. However, the free α-biliverdin yield in the presence of desferrioxamine is significantly increased in the "aged" *Nm*-HO and its deletion mutant relative to wild-type, which argues for a role of the *Nm*-HO C-terminus in modulating product release.[748] The facile cleavage of Arg208/His209 in the resting state complex, with a half-life of ~24 hours at 25 °C, suggested that previous characterization of *Nm*-HO may have been carried out on mixtures of native and "aged" NM-HO, which may account for the "lost" C-terminal residues in the crystal structure.[748] A follow-up on this study was published later the same year, in which the symmetrical hemin was used instead of protohemin.[749] The His207 from the C-terminus was found to interact with the substrate $1CH_3$, as opposed to the $8CH_3$ in the protohemin complex. The different mode of interaction of H207 with the alternate substrates was attributed to the 2-vinyl group of protohemin sterically interfering with the optimal orientation of the proximal helix Asp27 carboxylate that serves as acceptor to the strong H-bond by the peptide of His207.[749] The symmetrical hemin (Figure 56) complex

aged in a manner similar to that of protohemin, with mass spectrometry and N-terminal sequencing indicating that the Arg208/His209 dipeptide is cleaved in that case as well.[749] The symmetrical hemin complex of wild-type *Nm*-HO populates an equilibrium isomer stabilized in low phosphate concentration for which the axial His imidazole ring is rotated by ~20° from that in the wild-type. The His ring reorientation is attributed to Asp24 serving as the H-bond acceptor to the His207 peptide NH, rather than to the His23 ring $N_{\delta}H$, as in the crystals.[749]

(b) *NMR studies of heme electronic structure and its potential implications to the mechanism of heme oxidation*

In 2003, Rivera, Wilks and their coworkers published a second paper on *Pa*-HO, in which they studied the hydroxide complex as a model for the hydroperoxide complex, the activated form of the enzyme which attacks its own *meso*-carbon.[658] A ^{1}H titration similar to that shown in Figure 61 yielded an approximate pK_a of the water bound to the heme of *wt Pa*-HO of ~9.6 by this author's rough estimate; there was no remaining sign of high-spin resonances at pH 10.3.[658] The chemical shifts of the three exposed methyl groups of the major (70%) form of *Pa*-HO observed outside the diamagnetic envelope were about 23, 17 and 14 ppm at 25 °C,[658] which are considerably larger than in the NP2 case (19, 15 and 13 ppm, also at 25 °C).[146] However, the orientation of the imidazole plane of the His ligand is about 90–110° different for the two proteins, which would lead to a larger average heme methyl chemical shift for *Pa*-HO as compared to NP2 at a given temperature, assuming both of them are low-spin.[8] The ^{1}H chemical shifts of this *Pa*-HO-OH complex, however, were smaller than those of the cyanide complex of *Pa*-HO, (pH 7.4–10.0).[658]

To study the system further, ^{13}C labeling of the heme was done, in which 5-^{13}C-ALA was used to produce *meso*- and α-pyrrole ^{13}C-labeled heme, and 4-^{13}C-ALA was used to produce α- and β-pyrrole ^{13}C-labeled heme.[658] Analysis of the heme core carbon resonances revealed that the coordination of hydroxide in the distal site of the enzyme resulted in the formation of at least three populations of Fe^{III}–OH complexes with distinct electron configurations and probable nonplanar ring distortions that are in slow exchange relative to the NMR timescale.[658] The authors showed that the orbital of the unpaired electron makes a dramatic difference in the core carbon atoms of the heme, most of which (except for the *meso*-C) do not have protons attached, and thus had not previously been probed. The ^{13}C resonances of these core atoms have totally different chemical shifts, both absolute and relative, for the three electron configurations found to be important in this study,[658] as shown in Figure 68. The most abundant population (~88% at 37 °C) exhibited a spin crossover between S = 1/2 and S = 3/2 spin states (2/3 and 1/3 contribution, respectively, at 37 °C), and the two less abundant populations exhibited

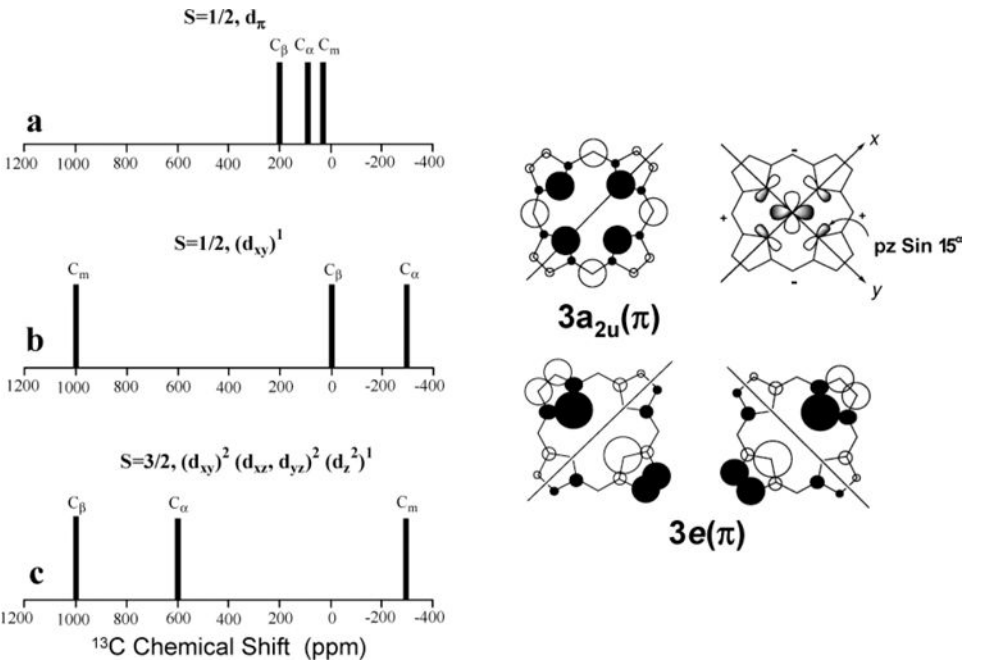

Figure 68. Left: Typical porphyrin core carbon chemical shifts for (a) Fe^{III}-porphyrinates with S = 1/2, d_π electron configuration, (b) Fe^{III}-porphyrinates with the S = 1/2, $(d_{xy})^1$ electron configuration, and (c) Fe^{III}-porphyrinates with the S = 3/2, $(d_{xy})^2(d_{xz},d_{yz})^2(d_z2)^1$ electron configuration. Right: Schematic representation (adapted from Ref. 84) of the $3a_{2u}(\pi)$ and $3e(\pi)$ porphyrin orbitals. The relative sizes of the circles at each atom are proportional to the calculated electron density. The possible interactions between the d_{xy} orbital and the porphyrin nitrogens of a ruffled porphyrin which allow spin delocalization into the $3a_{2u}(\pi)$ orbital are shown schematically next to this orbital. Reprinted from Caignan, G. A.; Deshmukh, R.; Zheng, Y.; Wilks, A.; Bunce, R. A.; Rivera, M. *J. Am. Chem. Soc.* **2003**, *125*, 11842–11852, with permission from the American Chemical Society.

pure S = 3/2 (~10% at 37 °C) and S = 1/2, $(d_{xy})^1$ (~2% at 37 °C) electron configurations, as shown in Figure 69. The major species shows strong temperature dependence of the Cα and Cβ resonances, from ~400 ppm at 37 °C to ~250 ppm at 0 °C, which is opposite the direction expected for Curie behavior, and suggests that the S = 1/2 d_π contribution to the spin-crossover species increases as the temperature is lowered.[658] In line with the work of others on model hemes,[423–429] the interconversion between these species at higher temperatures was believed to be facilitated by the interconversion among various nonplanar conformations of the porphyrin ring.[658] It was proposed that the highly organized network of water molecules in the distal pocket of heme oxygenase, by virtue of donating a hydrogen bond to the coordinated hydroxide ligand, lowers its ligand field strength and thereby increases the field strength of the porphyrin (equatorial) ligand, which

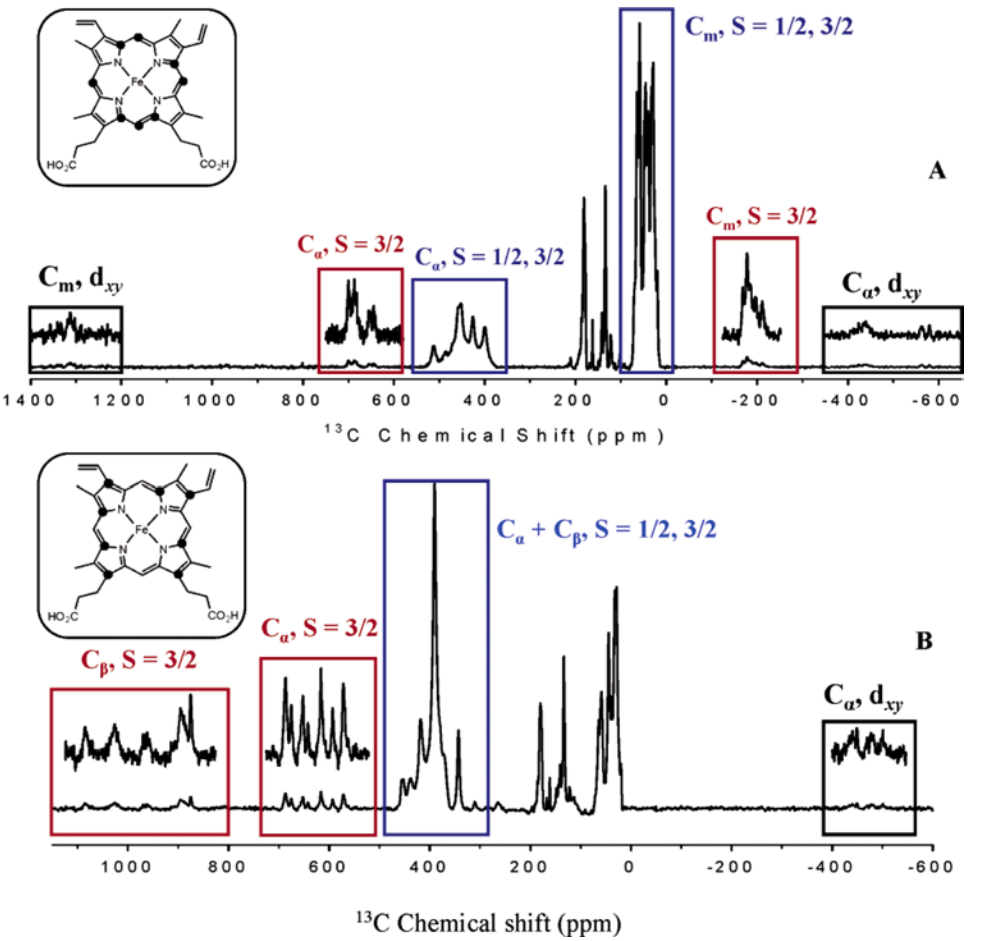

Figure 69. ^{13}C NMR spectra (37 °C) of *Pa*-HO-OH (pH* = 10.3) reconstituted with heme labeled at the C_α and C_m (A) and C_α and C_β carbons (B). Peaks corresponding to the populations exhibiting the S = 1/2,3/2 spin state crossover are highlighted by blue boxes, and peaks corresponding to the population with the S = 3/2 spin state are highlighted by red boxes. Reprinted from Caignan, G. A.; Deshmukh, R.; Zheng, Y.; Wilks, A.; Bunce, R. A.; Rivera, M. *J. Am. Chem. Soc.* **2003**, *125*, 11842–11852, with permission from the American Chemical Society.

results in nonplanar deformations of the macrocycle.[658] This tendency to deform from planarity, which is imparted by the ligand field strength of the coordinated OH^-, is likely reinforced by the flexibility of the distal pocket in HO.[658] The authors suggested that if the ligand field strength of coordinated OOH^- in heme oxygenase is modulated in a similar manner, the resultant large spin density at the *meso* carbons and nonplanar deformation of the porphyrin ring may prime the macrocycle to actively participate in its own hydroxylation.[658] This work will be

discussed further below, after discussion of a paper by La Mar and coworkers[659] that misquoted the results of this study[658] in the abstract of that paper.

In 2006, the La Mar group published a paper in which the 2003 paper of Rivera and coworkers on the hydroxide complex of *Pa*-HO[658] was attacked, first in the abstract of the 2006 paper.[659] Instead of the *Pa*-HO complex, La Mar and coworkers used the *Nm*-HO complex, and their abstract says in part, "The available [pseudocontact] shifts allowed the quantitation of both the orientation and anisotropy of the paramagnetic susceptibility tensor [of *Nm*–HO–OH]. The resulting positive sign, and reduced magnitude of the axial anisotropy relative to the cyanide complex, dictate that the orbital ground state is the conventional "d_π" $(d_{xy})^2(d_{xz},d_{yz})^3$); and not the unusual "$d_{xy}$" ($d_{xz}^2d_{yz}^2d_{xy}$) orbital ground state reported for the hydroxide complex of the homologous heme oxygenase (HO) from *Pseudomonas aeruginosa*[658] and proposed as a signature of the HO distal cavity."[659] There are several factual errors in these two sentences:

(1) Rivera *et al*. did *not* report that the "d_{xy}" electron configuration was the orbital ground state of *Pa*-HO–OH, but rather, as summarized above, they reported that there were at least three species present in the solution, *the major one of which (88% at 37 °C) had a mixed spin state of S = 3/2 (1/3) and S = 1/2 (2/3) d_π, the latter of which became more important as the temperature was lowered*;[658] a pure S = 3/2 ground state species was found to account for 10%; and *the d_{xy} ground state species was reported to comprise 2% at 37 °C.*[658]

(2) Rivera *et al*. did not propose "the d_{xy} ground state as a signature of the HO distal cavity." They did propose that at higher temperatures, such as 37 °C, the heme was able to access a number of nonplanar conformations, and that as the temperature was decreased the heme ring became less flexible and more rigidly planar.[658] They also *mentioned* the model heme paper on the *t*-butylperoxide, methoxide complex of $TPPFe^{III}$,[481] discussed earlier in Section IV.A.8.a. This author was one of the coauthors (with Rivera) of that paper, which clearly showed, by pulsed EPR spectroscopy *at 4.2 K, that the electronic ground state was purely $(d_{xy})^2(d_{xz},d_{yz})^3$, a conventional d_π electronic ground state, yet at room temperature the ^{13}C-meso-carbon shift was very large, which suggested at least some population of a $(d_{xz},d_{yz})^4(d_{xy})^1$ electronic ground state*. By fitting the temperature dependence of the ^{13}C chemical shift over the temperature range of the liquid state of the solvent (CD_2Cl_2) it was also shown that *the two were connected, not as ground and excited state configurations, but as a chemical equilibrium, probably between a planar porphyrin conformation that was stable at low temperatures, and a ruffled porphyrin conformation which became populated at higher temperatures by dynamic changes in porphyrin conformation*.[481] For some reason this paper has raised

the ire of several research groups,[659,750] who certainly did not read it carefully; in addition, some simply ignored it[751] because of what others[659,750] had said (incorrectly) about it. In the comments in the abstract of the 2006 La Mar group paper being discussed,[659] much of the ire expressed toward Rivera actually came from the mistaken convolution of the 2003 paper on *Pa*-HO[658] and the incorrectly-perceived conclusions of the model heme paper.[481]

(3) *Pa*-HO and *Nm*–HO are *not* homologous proteins, unless one believes that protein fold is the only thing important. Even so, they are only 37% identical in sequence;[752] *Nm*-HO is 26% identical in sequence with hHO-1,[753] while *Pa*-HO is only about 14% identical in sequence with hHO-1.[752,753]

(4) *Pa*-HO has a pK_a of the water molecule bound to Fe of about 9.6,[658] whereas *Nm*-HO has a pK_a of at least 10.3[659] (both of these values have been estimated by this author from the titration spectra shown in the two publications[658,659]). This could make it more difficult to obtain 2D NMR spectra of the completely deprotonated form of the *Nm*-HO protein, and the authors mention strong chemical exchange cross peaks in their NOESY(EXSY) spectra of *Nm*-HO-OH.[659] This was not a problem in the *Pa*-HO-OH study, in part because ^{13}C spectra (1D) were recorded, where, because of the much larger chemical shift differences for ^{13}C, the system is not in chemical exchange on the NMR time scale.

(5) La Mar and coworkers mention that the temperature dependence of the heme methyl shifts of Nm-HO-OH do not behave the Curie law, with "weak Curie behavior for 3M (apparent intercept at $T^{-1} = 0$ of 19 ppm) and weak anti-Curie behavior for the 8M peak (apparent intercept at $T^{-1} = 0$ of 30 ppm)."[659] This strongly indicates that spin states in addition to S = 1/2 are involved. The chemical shifts of the heme methyl protons alone, presented in both papers,[659,658] are rather different for the two proteins, but only three of each were assigned. They are in the order 3 > 8 > 5 > 1 for *Nm*-HO–OH, with chemical shifts of about 20, 19, and 13 ppm;[659] based on the angle plot it is likely that 1M is at about 10 ppm, which would mean that the spread of the resonances is about 10 ppm and the average about 15.5 ppm. Those for *Pa*-HO–OH are somewhat larger (methyl shifts from 24 to about 12 ppm, spread of 12–12.5 ppm, average shift of ~16.6 ppm),[658] as expected for the larger average chemical shift of the *Pa*-HO–OH protein due to the difference in histidine imidazole plane orientation.[8] Thus, it is probable that the heme methyl chemical shifts of the two HO–OH complexes are indicative of the same spin state or mixture of spin states, although not necessarily in the same percentages.

The *Pa*-HO–OH shifts are, however, much smaller than those of all of the metMb–OH complexes whose chemical shifts have been reported previously,

which range from nearly 40 to 20 ppm.[754–759] All of these hydroxide complexes have small spreads of the four heme methyl resonances (10.5–12.1 ppm), and large average heme methyl shifts (35.3–33.1 ppm), with T. *akamusi* metHbV–OH having the smallest spread (10 ppm) and the smallest average shift (25.9 ppm). The order of heme methyl resonances for the metMb–OH and one metHb–OH complexes ($5 \geq 8 > 3 > 1$ for most) does not match any prediction of the angle plot that is based on a low-spin $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration (Figure 11). The large sizes of the methyl shifts and their order thus suggest strongly that the spin state is not S = 1/2 for metMb–OH complexes, a conclusion that had been implied in the section of Ref. 19 which discussed the hydroxide complexes. In line with the findings of Rivera and coworkers, based on ^{13}C chemical shifts of the heme substituent resonances of *Pa*-HO–OH,[658] we suspect that metMb–OH complexes are mixed S = 3/2,1/2 spin state complexes with considerably more S = 3/2 character than exhibited by *Pa*-HO–OH.

In 2005, Rivera and Wilks and coworkers investigated the azide complexes of *Pa*-HO and *Nm*-HO by ^1H and ^{13}C NMR spectroscopy.[149] These complexes were shown to exist as an equilibrium mixture of two populations, one exhibiting an S = 1/2 $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration and planar heme and a second with a novel S = 3/2, $(d_{xz},d_{yz})^3(d_{xy})^1(d_{z^2})^1$ spin state and likely nonplanar heme.[149] At physiologically relevant temperatures, the equilibrium is shifted in the direction of the population exhibiting the novel S = 3/2 electron configuration and nonplanar heme, whereas at temperatures approaching the freezing point of water, the equilibrium is shifted in the direction of the population with the S = 1/2 d_π electronic structure and planar heme. These findings indicate that the microenvironment of the distal pocket in heme oxygenase is unique among heme-containing proteins, in that it lowers the σ-donating (field strength) ability of the distal ligand and, therefore, promotes the attainment of heme electronic structures thus far only observed in heme oxygenase.[149] When the field strength of the distal ligand is slightly lower than that of azide, such as OH^-,[658] the corresponding complex exists as a mixture of populations with likely nonplanar hemes and electronic structures that place significant spin density at the *meso* positions. The ease with which these unusual heme electronic structures are attained by heme oxygenase is likely related to activation of *meso*-carbon reactivity which, in turn, facilitates hydroxylation of a *meso*-carbon by the obligatory ferric hydroperoxide intermediate.[149]

Also in 2005, Rivera, Wilks and coworkers used 5-^{13}C-ALA to synthesize a combination *meso*- and α-labeled heme (Figure 13) and used it to reconstitute apo-*Nm*-HO, to investigate the nature of the verdoheme oxidation product that is formed by α-*meso* oxidation.[760] The ^{13}C NMR data indicated that the ferrous verdoheme complex of *Nm*-HO is six-coordinate and diamagnetic, with a proximal

His and distal hydroxide as axial ligands. The coordination number and spin state of the verdoheme-HO complex are in stark contrast to the 5-coordinate and paramagnetic nature of the heme-HO complex, and heme centers in general.

Several years later, in 2009, La Mar and coworkers used the hHO-1 azide complex[761] to attack Rivera and coworkers a second time. They claimed that the spin state of the azide complex was pure S = 1/2, and that 2D ^{1}H NMR assignments of the substrate and substrate-contact (protein) residue signals revealed a pattern of substrate methyl contact shifts that placed the lone iron π-spin in the d_{xz} orbital, rather than the d_{yz} orbital found in the cyanide complex. They reported that comparison of iron spin relaxivity, magnetic anisotropy, and magnetic susceptibilities argued for a low-spin, $(d_{xy})^2(d_{xz},d_{yz})^3$, ground state in both azide and cyanide complexes.[761] The switch from singly-occupied d_{yz} for the cyanide to d_{xz} for the azide complex of hHO was shown to be consistent with the orbital hole determined for the azide π-plane in the latter complex, which is ~90° in-plane rotated from that of the imidazole π-plane.[761] The induction of the altered orbital ground state in the azide relative to the cyanide hHO complex, as well as the mean low-field bias of methyl hyperfine shifts and their paramagnetic relaxivity relative to those in globins, indicated to the authors that azide exerts a stronger ligand field in hHO than in the globins, or that the distal H-bonding to azide is weaker in hHO than in globins.[761]

The two problems with these conclusions are (1) the assumption that everything that *Pa*-HO and *Nm*-HO do is identical to what hHO-1 does and thus the spin states of the three must of necessity be the same, and (2) the assumption[761] that the azide complex of hHO-1 is low-spin. Both Rivera and coworkers[149] and La Mar and coworkers[761] found orders of heme methyls that are not consistent with the low-spin state for a relatively flat hemin molecule, that is, 5M having a smaller chemical shift than 1M, whereas it should be the reverse.[8] The protohemin complexes of *Pa*-HO and *Nm*-HO could be ruffled enough to give rise to the ruffling-caused reversal of this order that has been observed for the nitrophorins,[143] but it could also be, as Rivera and coworkers concluded for this complex, that the spin state is not pure S = 1/2. For the protohemin complex studied by Rivera *et al.*,[149] this reversal is a very likely sign that the spin state that gives rise to the heme methyl chemical shifts is not actually that of a single low-spin state, but rather of some sort of hybrid or average with a state of different spin multiplicity. For the symmetrical hemin complex (Figure 56) studied by La Mar and coworkers, the 5M and 1M groups within the same complex should have the same chemical shift,[761] no matter what the orientation of the ligand orbitals are, unless there is some sort of serious protein-caused distortion of the heme that affects one and not the other of these heme methyls, which has not been shown in the crystal structures. Yet for the symmetrical hemin hHO-1 complex, 1M > 5M by about 0.7 ppm,

whereas for the cyanide complex, 5M > 1M by about 0.8 ppm.[761] Therefore, it is very likely that Rivera is correct that the ground state of the azide complex is not pure S = 1/2, and that a S = 3/2 component is involved.

(c) *NMR spectroscopic studies of dynamic reactivity relationships*

In 2006, Rivera and coworkers investigated the azide and cyanide-inhibited complexes of *Pa*-HO.[762] The azide complex was chosen for study because this ligand has lower ligand field strengthZ than cyanide, and it appears to have readily-available nonplanar heme macrocycle conformations, and also because of the bent conformation of the Fe–NNN unit, which was expected to be similar in angle to that of the Fe–OOH unit, and because the crystal structure of the azide complex of rat HO-1 appears to have a hydrogen-bond between conserved the Gly143 amide N-H (Gly 125 in *Pa*-HO) and the coordinating nitrogen of the azide ligand.[714] This hydrogen-bond is not possible for the approximately linear cyanide ligand, both because of its geometry and because there is no lone pair of electrons on the coordinating atom, a carbon in that case. The cyanide complex was chosen for study because it clearly has the $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration, which is strongly expected to favor a rigid, flat heme macrocycle.[762]

Nearly complete backbone assignments (>93%) for both complexes, of all nonproline residues were assigned, with the majority of the nonassigned residues corresponding to the first 10 amino terminal residues. Resonances strongly affected by heme iron paramagnetism were assigned with the aid of selective amino acid labeling and experiments tailored to detect fast relaxing signals, whereas the rest of the polypeptide was assigned using conventional three-dimensional NMR experiments.[762] Amide chemical shift assignments were used to monitor the rate of exchange of backbone protons in H/D exchange experiments, and the protection factors for each peptide bond were calculated, as shown in the plots in Figure 70. The polypeptide in the *Pa*-HO-N_3 complex was found to be significantly less prone to H/D exchange than the polypeptide in *Pa*-HO-CN, which was interpreted to indicate that *Pa*-HO-N_3 is conformationally less flexible than *Pa*-HO-CN.[762] The differences in protection factors (protection from H/D exchange, as calculated from the rate constants for H/D exchange using the procedures described by Englander[763]) extend to regions of the protein remote from the heme iron and distal ligand. When the differences in protection factors are mapped onto the X-ray crystal structure of *Pa*-HO, the pattern observed suggests that the distinct chemical properties imparted by the coordination of azide as compared to cyanide to the heme iron are transmitted to the polypeptide by a network of structural water molecules that extend from the active site to the surface of the enzyme,[762] as had been studied for hHO-1 by La Mar and coworkers.[678,728–730] While the ^{1}H amide resonance of Gly125 was too broad to detect, the corresponding ^{15}N resonance was

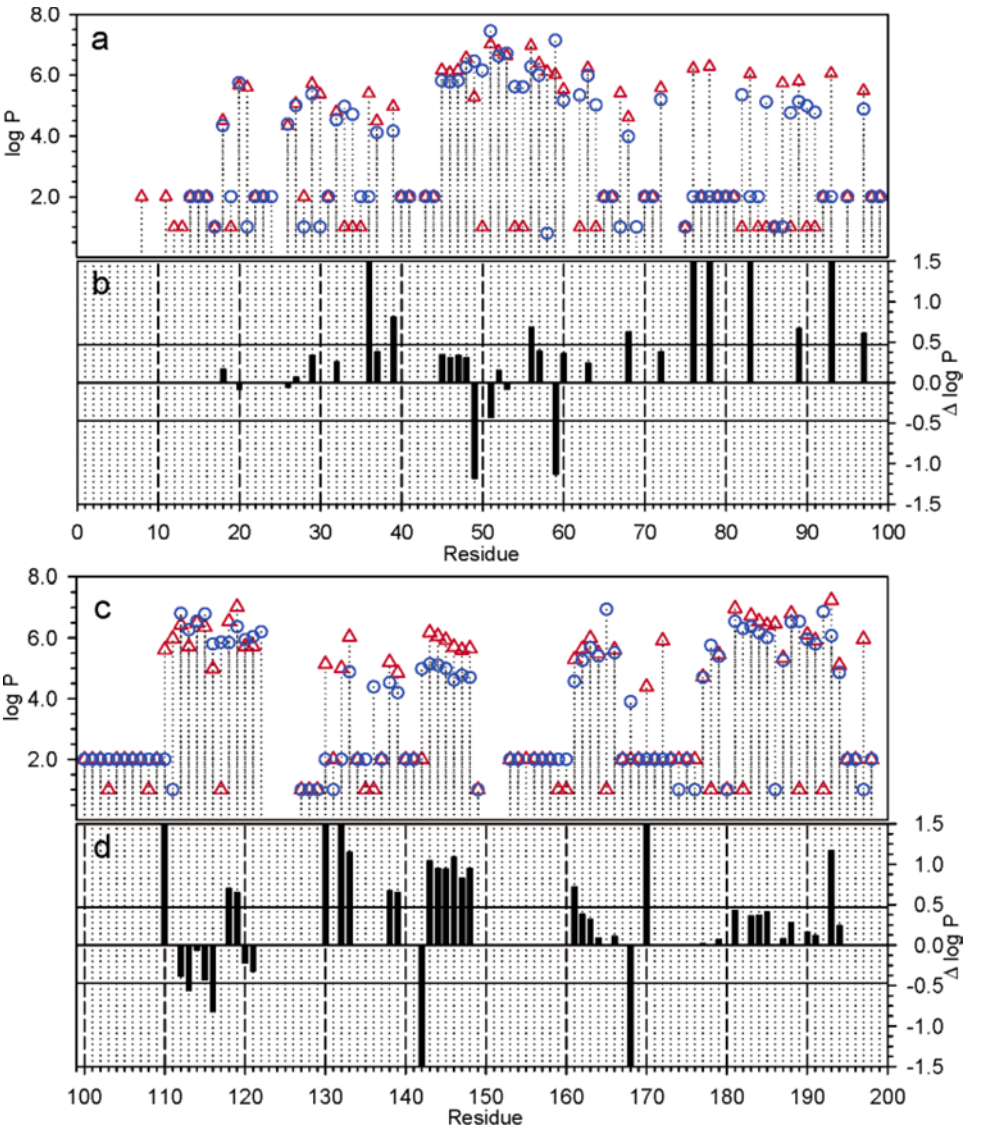

Figure 70. (a and c) Per residue protection factors obtained from amide H/D exchange experiments with *pa*-HO–N_3 (red triangles) and *Pa*-HO–CN (blue circles). A value of log $P = 2$ was arbitrarily given to residues exhibiting exchange rates too fast to be measured, and a value of log $P = 1$ was given to residues not included in the analysis due to either peak overlap or lack of assignments. (b and d) Per residue differences in protection factors ($\Delta\log P = \log P_{azide} - \log P_{cyanide}$) between the *Pa*-HO–$N_3$ and *Pa*-HO–CN. The average difference of all residues is indicated by the horizontal line. Bars reaching the maximum vertical scale ($\Delta\log P = 1.5$) correspond to residues exhibiting exchange rates measurable in *Pa*-HO–N_3 but too fast to measure in the *Pa*-HO–CN (not included in the computation of the average difference). Reprinted from Rodriguez, J. C.; Wilks, A.; Rivera, M. *Biochemistry* **2006**, *45*, 4578–4592, with permission from the American Chemical Society.

found to exhibit a large shift to lower shielding, large linewidth, steep temperature dependence, and a larger than usual shift to higher shielding of the deuterium isotope effect.[762] These properties indicated unpaired spin delocalization from the heme iron to the Gly ^{15}N atom via formation of a hydrogen-bond between the coordinated azide nitrogen and the Gly125 N–H.[762] Thus, this study provided the first clear comparison of the dynamic properties of a heme protein bound to two different axial ligands, and it showed major differences between the two ligand complexes of *Pa*-HO in terms of their H/D exchange rates.

In 2007, Rivera and coworkers presented a detailed look at the hydrogen-bonding network in *Pa*-HO by multidimensional NMR spectroscopy. Relaxation-compensated Carr-Purcell-Meiboom-Gill (rc-CPMG) NMR experiments were used to investigate the μs to ms motions in *Pa*-HO in its ferric state, inhibited by CN^- or N_3^-, and in its ferrous state, inhibited by CO.[764] Comparative analysis of the data from the three forms indicated that the nature of the coordinated distal ligand affects the μs-ms conformational freedom of the polypeptide in regions of the enzyme not only close to, but also far removed from the heme iron and distal ligand sites, as shown in Figure 71. Interpretation of the dynamic information in the context of the crystal structure of resting state *Pa*-HO showed that residues involved in the network of structural hydrogen-bonded waters characteristic of HOs undergo μs-ms motions in *Pa*-HO–CN (Figure 71a), which was studied as a model of the highly paramagnetic S = 5/2 resting form.[764] In comparison, similar motions are suppressed in the *Pa*-HO–CO (Figure 71d) and *Pa*-HO–N_3 (Figure 71b) complexes, which were studied as mimics of the obligatory oxyferrous and ferric-hydroperoxide intermediates, respectively, in the catalytic cycle of heme degradation.[764] These findings suggested that in addition to proton delivery to the nascent Fe^{III}–OO^- intermediate during catalysis, the hydrogen-bonding network serves two additional roles (i) to propagate the electronic state (reactive state) in each of the distinct steps of the catalytic cycle to key, but remote, sections of the polypeptide, via small rearrangements in the network of hydrogen-bonds and (ii) to modulate the conformational freedom of the enzyme, which thus allows it to adapt to the demanding changes in axial coordination state and substrate transformations that take place during the catalytic cycle.[764] This idea was probed by disrupting the H-bonding network in *Pa*-HO by replacing R80 with L. NMR spectroscopic studies conducted with R80L-*Pa*-HO-N_3 (Figure 71c) and R80-L-*Pa*-HO-CO (not shown) revealed that the mutant exhibited nearly global conformational disorder, which is absent in the equivalent complexes of the wild type enzyme.[764] As shown in Figure 72, the crystal structure of Pa-HO highlights the roles of R80, along with E52 and E56, in stabilizing the network of hydrogen-bonding waters in the distal pocket of *Pa*-HO. The "chaotic" disorder in the R80L mutant is likely related to its significantly lower efficiency in hydroxylating heme in the presence of H_2O_2, relative to the wild-type enzyme.[764] This work has given us an entirely

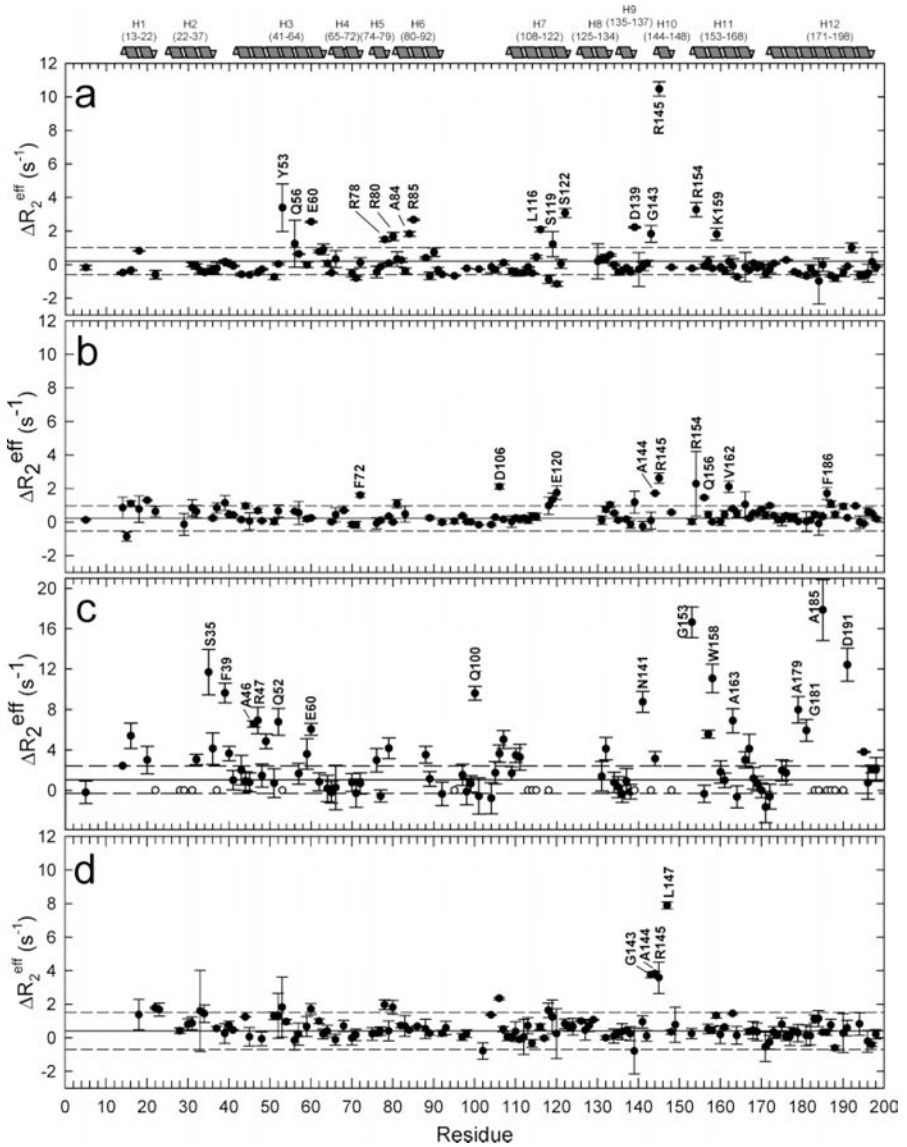

Figure 71. Per residue effect of axial ligand coordination on the backbone ^{15}N relaxation dispersion $\Delta R_2^{eff}(\nu_{CPMG})$ of *Pa*-HO axially coordinated with (a) CN^-, (b) N_3^-, and (d) CO. The per residue plot in (c) shows values of $\Delta R_2^{eff}(\nu_{CPMG})$ obtained for the R80L-*Pa*-HO mutant coordinated with N_3^-, which was prepared with the aim of disrupting the hydrogen-bonding network in *Pa*-HO. The horizontal line represents the average error obtained from two measurements, and the horizontal segmented lines represent 3 standard deviations above and below the average. Residues with $\Delta R_2^{eff}(\nu_{CPMG})$ values more positive than the segmented line representing 3 standard deviations above the mean are considered to be in conformational exchange in the μs–ms time regime sampled by the (constant time) ct-CPMG experiments utilized in these investigations. new view of heme oxygenases, and one would expect that further studies of the dynamics of various forms of these interesting proteins will be presented in the future.

As indicated by the preceding paragraphs, the dynamics of HO are tightly coupled to the structured waters in the distal pocket of this enzyme. La Mar and coworkers recognized the importance of the structured waters near the heme iron of HOs and have studied the distal water network for a number of years.[678,728–730] In 2003 when La Mar moved into the field of bacterial heme oxygenases with a collaboration with Ikeda-Saito on *Corynebacterium diphtheriae*,[765] before the crystal structure of that enzyme had been reported, he and his coworkers used the human HO (hHO) complex as a homology model. It was demonstrated that not only the spatial contacts among residues and between residues and heme, but also the magnetic axes that can be related to the direction and magnitude of the steric tilt of the Fe–CN unit are strongly conserved in the two HO complexes.[765] The results indicated that very similar contributions of steric blockage of several *meso* positions and steric tilt of the attacking ligand were operative. A distal hydrogen-bonding network that involved numerous very strong H-bonds and immoblized water molecules was identified in *Cd*-HO that is analogous to that previously identified in hHO.[728] The NMR results were completely consistent with the crystal structure of the *Nm*-HO substrate complex. The H-bond network/ordered water

molecules are proposed to orient the distal water molecule near the catalytically key Asp136 (Asp140 in hHO-1) that stabilizes the hydroperoxy intermediate.[765] The dynamic stability of this H-bond network in *Cd*-HO was found to be significantly greater than in hHO, and was suggested to account for the lower catalytic rate in bacterial HO compared with mammalian HO.[765]

The next year, 2004, La Mar and coworkers began a study of *Nm*-HO.[766] This enzyme exhibits less sequence homology to mammalian HO (25%) than does *Cd*-HO (35%). Solution ^{1}H NMR spectroscopy was utilized to define the active site molecular and electronic structure of the cyanide-inhibited, substrate bound complex for comparison with those provided by several crystal structures.[766] Extensive assignments by solely ^{1}H NMR 2D methods revealed a structure that was very strongly conserved with respect to the crystal structure, although H/D exchange indicated dynamically much more stable distal and proximal helices than those for other HOs. Several residues found with alternate orientations in crystal structures of water- and NO-ligated complexes were shown to occupy positions found solely in the NO complex,[719] which confirmed that there may be structural accommodations in response to ligating the substrate complex with a bent, diatomic, H-bond-acceptor ligand.[766] The observed pseudocontact shifts of the cyanide complex allowed the determination of the magnetic axes that showed that the Fe–CN unit is tilted ~10° toward the *α-meso* position, which thereby was thought might facilitate the *α*-stereoselectivity of the enzyme.[766] Numerous labile protons with larger than usual low-shielding bias were identified, and, in common with the other HO complexes, shown to participate in an extended, distal side H-bond network. This H-bond network appeared to order several water molecules, most, but not all, of which have been detected crystallographically.[766] A series of three C-terminal residues, His207-Arg208-His209, are not detected in crystal structures. However, ^{1}H NMR spectroscopy finds two residues, His207 and likely Arg208, in contact with pyrrole ring D,[766] which in crystal structures is exposed to solvent. The nature of the NOEs led the authors to propose a H-bond between the proximally-oriented His207 ring and the carboxylate of Asp27, and a salt-bridge between the terminus of Arg208 and the reoriented 7-propionyl carboxylate.[766] While numerous ordered water molecules are found near both propionates in the crystal structure, they found much larger water NOEs to the 6- than the 7-propionate, which suggested that water molecules near the 7-propionate had been expelled from the cavity by the insertion of Arg208 into the distal pocket.[766] The conversion of the 7-propionate link from the N-terminal region (Lys16) to the C-terminal region (Arg208) in the ligated substrate complex was found to both close the heme cavity more tightly, and was thought to facilitate product exit, the rate-limiting step in the enzyme activity.[766]

In 2005, La Mar and coworkers studied the high-spin iron(III) complex of *Nm*-HO,[767] to assess the prospects for definitive assignment of hyperfine-shifted

and — relaxed residue protons and the interpretation of those shifts in terms of the anisotropy and orientation of the paramagnetic susceptibility tensor, χ. 1D/2D ^{1}H NMR data, together with analyses of paramagnetic relaxation and a preliminary estimate of the magnetic anisotropy, revealed a χ that was anisotropic and oriented along the Fe-His bond vector.[767] Together with T^{-2} dependence of the shifts, $\Delta\chi_{ax}$ yields a zero-field splitting constant, $D = 9.1\ cm^{-1}$, which is expected to serve as a very sensitive probe of H-bond interactions between the iron-ligated water and a series of distal ordered water molecules that are implicated in the mechanism of HO action.[767] The side chains, Gln49 and His53, which are involved in the stabilization of catalytically relevant water molecules, were found to exhibit orientations rotated by 180° about the β-γ bonds in solution relative to those in the crystal.[767] The H-bond donor strengths of Gln49 and His53 were found to respond appropriately to H-bond donor (water) versus H-bond acceptor (cyanide) ion ligands. Very slow NH exchange for the N-terminal portion of the distal helix suggested that an intrinsically "unstable" distal helix may be valid only for the C-terminal portion.[767]

In 2006, La Mar and coworkers[768] described the study of the hydrogen-bonding of ligated water in ferric, high-spin, resting-state *Nm*-HO. Several hemes were utilized that had electron-withdrawing substituents on the hemin periphery. It was found that the pattern of ^{1}H NMR-detected pseudocontact shifts due to the paramagnetic anisotropy of the high-spin Fe^{III} center is strongly conserved among the complexes, with the magnitude of pseudocontact shifts or magnetic anisotropy $\Delta\chi_{ax}$ ($\propto D/T^2$, Eq. 10) increasing in the order 2,4-substituent formyl < vinyl < methyl.[768] The unique changes in the axial field strength implied by the variable zero-field splitting were found to be in accord with expectations for the axial water serving as a stronger H-bond donor in the order of hemin substituents formyl > vinyl > methyl. It was found that Gln49 and His53, ~10 Å from the iron, sensed the change in the ligated water H-bonding to the three nonligated, ordered water molecules that link the two side chains to the iron ligand.[768]

c. *NMR spectroscopy of miscellaneous other heme proteins*

Since publication of the chapter on Nuclear Magnetic Resonance of Hemoproteins in 2000 by La Mar, Satterlee and de Ropp[19] and the chapter on Solution Structures of Hemoproteins in the same volume,[20] there have been some developments on NMR spectroscopy of heme proteins not covered above that should be mentioned, at least briefly. A study of the solution NMR determination of the seating(s) of mono-*meso*-nitro-etioheme-1 in myoglobin has been published and the implications for steric constraints to meso position access in heme degradation by coupled oxidation discussed.[769] This study is distantly related to the HO systems discussed above. A further study of axial interactions of the proximal and distal His in the

cyanomet complexes of the isolated chains and of the 65 kDa intact tetramer of human hemoglobin A was published,[770] as were two papers on the H42A mutant (distal His) of horseradish peroxidase, one on the high-spin ferric form[771] and one on the low-spin ferric cyanide complex[772] and also a study of the electronic structure and magnetic properties of the high-spin ferrous heme in deoxymyoglobin from *Aplysia limacina*.[773] Solution NMR characterization of the equilibrium heme orientational disorder and its functional consequences in the bis-His-coordinated mouse Neuroglobin was reported,[674] although it was later shown that the orientation of the two His ligands is somewhat different in solution[774] than in the crystalline state.[775–777] A study of the bis-His-coordinated human cytoglobin has also been reported.[778] A review of the study by NMR spectroscopy of the mechanisms of electron transfer in heme proteins and models of them has been published, which covers not only iron porphyrin and heme protein self-exchange, but also multiheme intraprotein and interprotein electron transfer.[779] Cytochromes b_5,[780–786] b_{562},[787–790] mitochondrial *c*,[791–795] folding of cytochromes *c*,[796–802] yeast *c*,[803,804] bacterial *c*,[805–813] Mn peroxidase and its models,[814–816] cytochrome *c* complexing with cytochrome b_5,[817,818] Cu_A of cytochrome oxidase,[819] cytochrome *f* complexing with plastocyanin,[820] a heme chaperone[821] and a hemophore[822–824] have been studied by multidimensional NMR spectroscopy, and the ^{1}H NMR spectra of cytochrome *c* in a micellar environment have been investigated.[825,826]

Finally, the hemophore HasAp from *Pseudomonas aeruginosa*, from the heme acquisition system of that organism, which is secreted as a 205-residue-long protein which is subsequently cleaved at the C-terminal to produce mainly a 184-residue-long truncated protein that scavenges heme[827] has been characterized in the crystalline state by X-ray crystallography and in solution by NMR spectroscopy.[828] The X-ray crystal structure of truncated HasAp revealed a polypeptide with $\alpha\beta$ fold and a ferriheme coordinated axially by His32 and Tyr75, with the side chain of His83 poised to accept a hydrogen bond from the Tyr75 phenolic acid group.[828] NMR investigations conducted with full-length HasAp showed that the carboxyl-terminal tail (21 residues) is disordered and conformationally flexible.[828] NMR spectroscopic investigations aimed at studying a complex between apo-HasAp and human methemoglobin were stymied by the rapid heme capture by the hemophore. In an effort to circumvent this problem, NMR spectroscopy was used to monitor the titration of ^{15}N-labeled holo-HasAp with hemoglobin.[828] These studies allowed identification of a specific area on the surface of truncated HasAp, which encompasses the axial ligand His32 loop, that serves as a transient site of interaction with hemoglobin, for which it appeared that a putative encounter complex between apo-HasAp and hemoglobin exists that leads to efficient hemoglobin-heme capture by the hemophore.[828] Similar experiments conducted with full-length ^{15}N-labeled holo-HasAp and hemoglobin revealed a

transient interaction in full-length HasAp similar to that observed in the truncated hemophore.[828] The spectral perturbations observed while these interactions were being investigated, however, are weaker than those observed for the interaction between hemoglobin and truncated HasAp, which suggested that the disordered tail in the full-length HasAp must be proteolyzed in the extracellular milieu to make HasAp a more efficient hemophore.[828]

11. *Iron(III) Macrocycle π-Cation Radicals*

Single-electron oxidation of iron(III) porphyrins may lead to either iron(III) porphyrin π-cation radicals or iron(IV) porphyrins, depending on the axial ligation of the metal and the reaction conditions. In this section, the systems that have been formulated as iron(III) porphyrin π-cation radicals, and in the next section, the iron(IV) porphyrins will be considered. Note that a so-called "metalloporphyrin π-cation radical" is actually a metal ion in some positive oxidation state, M^{n+}, where n is 2 or larger, bound to a porphyrin π-anion radical, $P^{-\bullet}$. Since a porphyrin typically binds to a metal as a −2 anion (because the two protons on the nitrogens of the free-base prophyrins, H_2P, have been removed), removal of one electron from the porphyrin π system to produce the π-radical yields as mononegative, or π-anion radical. If the change on the metal is +2 or higher, then the entire unit, $[MP^{-\bullet}]^{n+}$ is cationic. This the term "porphyrin π-cation radical" is a misnomer. It is only a *cation* because it is bound to a metal of charge +2 or higher!

Considering the three different spin states observed for iron(III) porphyrins, it is not surprising to find that all three have been observed for the one-electron ring-oxidized complexes. Some high-spin, monomeric iron(III) porphyrins give rise to antiferromagnetically coupled S = 2 species;[829–831] others give rise to a noninteracting S = 5/2, S = 1/2 species;[831] spin-admixed S = 3/2,5/2 iron(III) porphyrin complexes give rise to spin-admixed π-cation radical species of either S = 5/2, 3/2[374] or S = 3/2,5/2[832] ground state; and low-spin iron(III) porphyrins give rise to low-spin iron(III) porphyrin π-cation radical species.[833] Although this work was reported previously,[4] it is summarized here for completeness.

a. *High-spin iron(III) porphyrin π-cation radicals*

Anodic oxidation of [(TPP)FeCl] in the presence of perchlorate or hexafluoroantimonate salts, or chemical oxidation with an iron(III) porphyrin π-cation radical of higher oxidation potential, produces a S = 5/2,S = 1/2 antiferromagnetically coupled (effectively $S_{tot} = 2$) 5-coordinate $[(TPP^{-\bullet})Fe^{III}Cl]^+$ π-cation radical[831] which has its pyrrole-H resonance at +66.1 ppm (compared to +79.4 ppm for [(TPP)FeCl]) and its phenyl-H at +37.6, +34.4 (*ortho*), −12.4 (*meta*) and +29.5 ppm (*para*) (compared to −6, 13.3, 12.2, and 6.35 ppm, respectively, for the parent) at 26 °C in CD_2Cl_2.[834] The

large, alternating shifts of the phenyl-H are indicative of large π spin density at the *meso* positions, which suggests that the electron has been removed from the $3a_{2u}(\pi)$ orbital, Figures 2 and 3. However, the sign of the shifts, δ_o positive, δ_m negative, is the opposite of that usually seen for metalloporphyrin π-cation radicals when there is large π spin density seen the *meso*-phenyl positions,[374] as is expected when the porphyrin radical spin is antiferromagnetically coupled to the metal spins. The Curie plots are linear, but the *o*-H has a very large, negative intercept. The X-ray crystal structure of [(TTP)FeCl]SbF_6 consists of isolated 5-coordinate $[(TPP)FeCl]^+$ units, in which the porphyrin macrocycle is strongly S_4 saddled.[831]

In comparison, the NMR spectrum of [(OEP)FeCl]ClO_4 shows relatively small shifts of the pyrrole-α-CH_2 to lower frequency (δ_{obs} = +30.5, +29.6 ppm at 20 °C, as compared to +43.1, +39.5 ppm at 30 °C for the parent) and a large shift of the *meso*-H to lower shielding (δ_{obs} = −18 ppm at 20 °C, compared to −54 ppm at 30 °C for [(OEP)FeCl]), which suggested to the authors that in this case the electron is removed from the $1a_{1u}$ orbital,[834] Figure 2.

π-Cation radicals of (P)Fe–O–Fe(P) species, the μ-oxo dimers of iron(III) porphyrins, are convenient chemical oxidants of the chloroiron porphyrins,[834] and they are interesting species in their own right. Those in which P = TPP or one of its derivatives also have larger phenyl-H paramagnetic shifts than the parent complexes, again with alternating signs, suggesting the same $(a_{2u})^1$ ground state for the metalloporphyrin π-cation radical, in this case delocalized over the two porphyrin rings; the pyrrole-H paramagnetic shift is affected much less (usually δ_{obs} decreases by ~1 ppm). The dication of the μ-oxo dimer can also be prepared, and exhibits attenuated paramagnetic shifts as compared to the monocation.[834]

Several groups have studied the neutrally-charged μ-nitrido dimer of (TPP)Fe, $[((TPP)Fe)_2N]$.[403,835] It is isoelectronic with the iron porphyrin π-cation radical of the μ-oxo dimers discussed above, but has rather different ^{1}H NMR spectra. Whereas $[((TPP)Fe)_2O]^+$ has resonances at 12.3 (pyrr-H), 1.3 (*o*-H), 11.7 (*m*-H) and 3.2 ppm (*p*-H), $[((TPP)Fe)_2N]$ has broad, overlapping resonances at 8.6, 8.3 and 7.6 ppm,[403,835] which suggests that its description as a delocalized system which has two $Fe^{3.5+}$ may be better than considering it to be a delocalized diiron porphyrin π-cation radical. If one-electron oxidation is carried out with I_2/Ag^+, a species with a much sharper NMR spectrum, with resonances at 8.32 (pyrr-H), 7.85 and 7.64 ppm (phenyl-H) is produced. This complex is believed to consist of Fe^{IV}–N^{-III}–Fe^{IV}.[835] Very small temperature dependence over the range +26 to −55 °C suggests that the metals are strongly antiferromagnetically coupled. The complex has a magnetic moment[376,377] of less than 1.8 μ_B at room temperature. Unlike $[((TPP)Fe)_2O]^+$ or $[((TPP)Fe)_2O]^{2+}$, both of which autoreduce in the presence of pyridine, $[((TPP)Fe)_2N]^+$ readily coordinates one or two pyridine ligands; stepwise addition can be observed by monitoring the pyridine *o*-H resonances at −1.26 ppm (1:1) and −1.46 ppm (2:1).[835]

b. *Spin-admixed and intermediate-spin iron(III) porphyrin π-cation radicals*

Electrochemical one-electron oxidation of $[(TPP)Fe(ROH)_2]ClO_4$, where ROH is water or ethanol, in the presence of perchlorate salts, produces the neutrally-charged complex $[(TPP^{-\bullet})Fe(OClO_3)_2]$, a 6-coordinate complex described as a S = 5/2, S = 1/2, non-interacting high-spin species because of its room temperature magnetic moment in the solid state (μ_{eff} = 6.5 ± 0.2 μB).[831] Its NMR spectrum at 25 °C in CD_2Cl_2 revealed paramagnetic shifts of +22.6 (pyrr-H), −27.1 (*o*-H), +27 (*m*-H), −20.6 ppm (*p*-H), suggesting a π-radical of a_{2u} type. However, investigation of this system in CH_2Cl_2 in the presence of electrolyte as a function of temperature, utilizing pyrrole- and phenyl-deuterated TPPs to eliminate the resonances of the large amount of tetra-(*n*-propyl)-ammonium perchlorate electrolyte present, revealed that although the pyrrole-D resonance shifts to higher shielding as the temperature is lowered, the Curie plots are not linear.[374] Rather, they have very steep slopes and very negative intercepts, and are curved at higher temperatures, which indicates that in this spin-admixed state, the ground state is largely S = 5/2.[374] The solution magnetic moment,[376,377] 4.8 ± 0.4 μ_B, is much lower than that observed in the solid state,[831] which suggests antiferromagnetic coupling of the metal and porphyrin spins.

The complexity of the behavior of iron(III) porphyrin π-radicals, and those of tetra-mesitylporphyrin in particular, is demonstrated by the properties of $[(TMP^{-\bullet})Fe(OClO_3)_2]$ in various solvents.[832] This π-radical of iron(III) was prepared by oxidation of $[(TMP)FeOClO_3]$ with ferric perchlorate, isolation and then dissolution in CD_2Cl_2. The temperature dependent behavior is the opposite that observed for $[(TPP)Fe(OClO_3)_2]$ in CH_2Cl_2, with the pyrrole-H resonance at very high shielding at low temperatures (δ_{iso} negative) and at low shielding at higher temperatures (δ_{iso} positive).[832] These results indicate that in the case of the TMP complex, the S = 3/2 ground state is greatly favored over the spin admixed 3/2,5/2 or 5/2,3/2 ground states. Treatment of the latter iron(III) porphyrin π-radical complex with two equivalents of sodium methoxide produced the electron configuration isomer, the d^4 iron(IV) porphyrin complex,[832] discussed in Section IV.A.12.

As an illustration of the chemical reactivity of these iron(III) porphyrin π-radicals, $[(TPP^{-\bullet})Fe(OClO_3)_2]$ reacts with the nucleophiles nitrite ion or triphenylphosphine to produce the mono-β-substituted iron(III) porphyrins.[836] The products were isolated as the 6-coordinate dichloride complexes, $[((2\text{-}NO_2)TPP^{-\bullet})FeCl_2]$ and $[((2\text{-}PPh_3)TPP^{-\bullet})FeCl_2]$, respectively; the latter was characterized by X-ray crystallography and ^{1}H NMR spectroscopy in CD_2Cl_2 for the bis-imidazole complexes.[836] Similar reaction of the π-radical of $(TPP)Fe^{III}$ with pyridine produces the (2-pyridiniumtetraphenylporphyrin)iron(III) bis-(pyridine) complex, as

well as an unstable 5-pyridiniumylisotetraphenylporphyrinato)iron(III) and its 5,10-dipyridiniumyltetraphenylporphodimethene)iron(III) complex.[837]

c. *Low-spin iron(III) porphyrin π-cation radicals*

Though complexes of the type $[(P)Fe(ImH)_2]^+$ could not be electrochemically oxidized to π-cation radicals, titration of the high-spin $[((p\text{-}OCH_3)_4TPP^{-\bullet})FeCl]ClO_4$ in CD_2Cl_2 with imidazole at −38 °C produced a transient complex whose pyrrole-H, *o*-H and *m*-H resonances were at −32.7, −236.3, and +24.8 ppm, respectively.[833] When the sample was warmed to room temperature, immediate autoreduction to the iron(III) porphyrin occurred. The temperature dependence of the pyrrole-H resonance of the transient radical was reasonably linear, and the deviation of the extrapolated shift at 1/T = 0 from the diamagnetic position was no greater than observed for low-spin $[(TPP)Fe(ImH)_2]^+$.[833] The alternating pattern of phenyl-H shifts suggests large π spin delocalization to the *meso* positions, indicative of a $3a_{2u}$ ground state for the radical; however, the sign of the shifts, δ_o negative, δ_m positive, is the reverse of that observed for the parent $[(TPP)FeCl]ClO_4$ complexes discussed above, which suggests a difference in the coupling of metal and porphyrin spins, possibly a switch from antiferromagnetic to ferromagnetic coupling, as in the case of the iron corroles discussed in Section IV.A.11.e. The high-spin radical complex appears to be the exception,[833] as discussed above. For the corresponding low-spin etioporphyrin complex, the ring α-CH_2 and −CH_3 resonances were at +50.4 and +133.1 ppm at −51 °C; the *meso*-H signal could not be detected.[833]

d. *Iron(III) π-cation radicals of oxophlorins*

Balch and coworkers oxidized the iron(III) oxophlorin (*meso*-hydroxyporphyrin) dimer complex of octaethylporphyrin, $[Fe^{III}(OEPO)]_2$ discussed in Section IV.A.6.c(vi) above, with Br_2 to yield two new, highly-oxidized complexes, $BrFe^{III}(OEPO\bullet)$ and $Br_2Fe^{III}(OEPOx)$ (where OEPO• and OEPOx are the octaethyloxophlorin dianion radical and the oxidized octaethyloxophlorin monoanion, respectively), in which the experimental data (especially ^1H NMR spectra) suggest that it is the ligand rather than the iron that undergoes oxidation. $BrFe^{III}(OEPO\bullet)$ has been characterized crystallographically, as well as by magnetic susceptibility (μ_{eff} = 4.9(2) μ_B at 23 °C), and NMR spectroscopy (*meso*-H resonances at extremely low shielding, +344 (1) and +232 (2) ppm, four CH_2 resonances at about +60 ppm, two near 0 ppm, and two at about −10 ppm at 24 °C), as shown in Figure 73, bottom.[106] The authors recognized these data to be indicative of a nominally 3^- anionic macrocycle which was actually a 2^- anion and hence

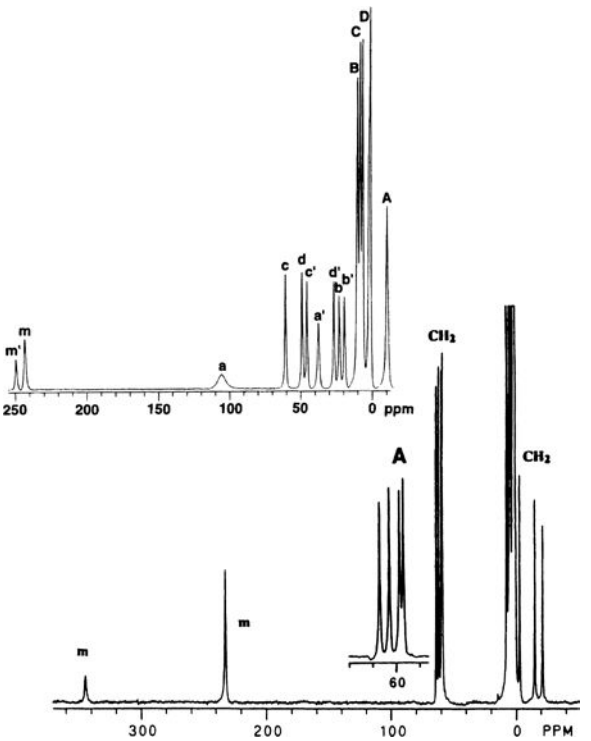

Figure 73. Top: 300 MHz ^{1}H NMR spectrum of $[((OEPO)Fe)_2]^+$ in $CDCl_3$ at 25 °C. Resonance assignments are made on the basis of the dimeric structure. Methylene resonances are identified by lower-case letters a-d′ while methyl resonances have been denoted by capital letters A-D. Cross peaks in the M-COSY spectrum (not shown) connect resonances in ethyl groups as follows: b,b′,B; c,c′,C; d,d′,D. Reprinted from Balch, A. L.; Latos-Grażyński, L.; St. Claire, T. N. *Inorg. Chem.* **1995**, *34*, 1395–1401, with permission from the American Chemical Society. Bottom: 300 MHz ^{1}H NMR spectrum of $[(OEPO^{2-\bullet})Fe^{III}Br]$ in $CDCl_3$ at 24 °C. Inset A shows an expansion of the methylene resonances at about 60 ppm. Reprinted from Balch, A. L.; Latos-Grażyński, L.; Noll, B. C.; Szterenberg, L.; Zovinka, E. P. *J. Am. Chem. Soc.* **1993**, *115*, 11846–11854, with permission from the American Chemical Society.

an iron macrocycle π-radical with the electron mainly located on the oxygen atom, which was antiferromagnetically coupled to high-spin Fe^{III}, and they suggested the $3a_{2u}(\pi)$-type orbital of the macrocycle as the half-filled orbital, Figure 7. Thus, this is an antiferromagnetically-coupled S = 5/2 Fe^{III}, S = 1/2 $OEPO^{2-\bullet}$ complex.[106] These results were very helpful to the author and her coworkers in explaining the ^{1}H NMR spectrum of the chloroiron(III) corroles as antiferromagnetically-coupled S = 3/2 Fe^{III}, S = 1/2 $Corr^{2-\bullet}$ complexes, discussed later in Section IV.A.11.e.

The two-electron oxidized octaethyloxophlorin complex, $[(OEPOx^{1-})FeBr_2]$, has both NMR and EPR spectra indicative of high-spin iron(III), indicating that the macrocycle has no unpaired electrons. The EPR g-values are 5.9 and 2.0, with

superhyperfine coupling on the $g_{\|}$ feature due to the two axial bromide ions. The NMR spectrum has four equally intense $-CH_2$ resonances in the +60 and +30 ppm region, plus two broad *meso*-H resonances at +34 and +21 ppm (intensities 1:2, respectively), a pattern typical of 6-coordinate high-spin iron(III) porphyrins, Section IV.A.6.b. The magnetic moment is 5.8 ± 2 μ_B.[106] The infrared spectrum shows a ketonic function at 1734 cm^{-1}, which indicates that the macrocycle has been oxidized. The self-dimer of iron(III) octaethyloxophlorin, where each iron is coordinated to the oxo group of the other oxophlorin ring, undergoes one-electron oxidation with silver perchlorate to give an iron macrocycle π-radical in which the single unpaired electron is delocalized over the two macrocycles.[838,839] The *meso*-H resonances are found at +250 and +243 ppm (intensities 1:2, respectively), while broad CH_2 resonances due to the ethyl groups closest to the oxo group and thus to the iron(III) of the other macrocycle are found at +106 and +37 ppm and sharper CH_2 resonances are found at +62 to +20 ppm, as shown in Figure 73, top. Like the monomeric $OEPO^{-\bullet}$ radical discussed above, the very large positive shifts of the *meso*-H resonances are indicative of an a_{2u}-type radical which is antiferromagnetically coupled to the high-spin iron(III) centers. Consistent with this, the magnetic moment is 4.8 μ_B per metal.[838]

e. *Iron(III) corrole π-radicals*

As discussed earlier, the corrole macrocycle (Structure **6**) lacks one *meso*-C and one double bond, as compared to the porphyrin. It is thus a −3-charged macrocycle and as such may either stabilize higher oxidation states of first-row transition metals or be more readily oxidized to a metal macrocycle π-radical itself. Although the slightly smaller ring size might suggest stabilization of the higher oxidation state of the metal, the more common situation is that a π-radical of the metal corrole ring is stabilized, as pointed out in Section II.C.2 and Figure 7. For a time it was believed that the chloroiron complex of octaethylcorrole (OECorr or Et_8Corr), as well as the μ-oxo dimer of the same iron macrocycle, were examples of iron(IV) corrolate complexes.[840] However, the ^{1}H NMR spectra of the chloroiron complexes of octamethylcorrole (OMCorr or Me_8Corr) show methyl signals at +40, +31, +18 and +16.6 ppm and *meso*-H at +175 and +166 ppm (intensities 1:2, respectively),[158,841] which are more indicative of the pattern observed for the chloroiron(III) octaethyloxophlorin neutrally charged π-radical[106] discussed earlier in Section IV.A.11.d and shown in Figure 73. The chloroiron 7,13-dimethylhexaethylcorrole gives a methyl signal at +18 ppm and six $-CH_2$ resonances between +40 and −10 ppm and *meso*-H resonances at +187 and +174 ppm (intensities 1:2, respectively) at −60 °C.[158] The magnetic moment (Evans method)[376,377] is 3.0 μ_B, which indicates a formal spin state S = 1. Thus, it was concluded that the iron is

intermediate spin (S = 3/2), and the corrolate radical is antiferromagnetically coupled to the metal, $Fe^{III}Corr^{2-\bullet}$.[158] In contrast, Gross and coworkers have stated repeatedly, without convincing scientific reasoning, that the electron configuration is S = 1 $Fe^{IV}Corr^{3-}$.[842–846] Additional studies of the chloroiron corrolates has shown conclusively that these are all S = 3/2 $Fe^{III}Corr^{2-\bullet}$ systems.[1,114,847–851] The triphenylcorrolatoiron chloride complex was studied by Mössbauer as well as NMR spectroscopy, and more recently by X-ray absorption spectroscopy.[852] While Mössbauer spectroscopy was unable to clearly differentiate the two possible electron configurations,[114,851] NMR spectroscopy clearly shows that phenyl-H resonances of chloroiron triphenylcorrolates (*o*-H +23–25 ppm, *m*-H −2.5 to −3.5 ppm; *p*-H +17 to +19 ppm) mirror those of the *meso*-H in showing large π spin delocalization to the *meso* positions, which is consistent with a π-radical being present in these metal complexes.[114,847,848–850] Calculations have been extremely important in explaining the spin coupling.[114,851,852]

Unlike the chloroiron corrolates, the phenyliron corrolate complex is best formulated as S = 1 $Fe^{IV}Corr^{3-}$, but again with negative spin density at all nitrogens and *meso*-carbons of the macrocycle, yet with the net spin density on the corrolate ring being virtually zero; the phenyl carbanion carbon has relatively large negative spin density of −0.15 and the iron +2.05. On the basis of all of the results, it was concluded that in both the chloroiron and phenyliron complexes the corrolate ring is noninnocent, in the chloroiron complex to a much larger extent than in the phenyliron complex.[114,852]

When treated with imidazole, the chloroiron hexaethyldimethylcorrole complex, [(7,13-Me_2Et_6Corr)FeCl], produces a new set of small peaks due to an imidazole complex, presumably the mono-(imidazole) complex. Increasing the concentration of imidazole increases the intensity of these peaks and creates another new set of peaks, but it is not possible to fully form the bis-(imidazole) complex at ambient temperatures. Cooling the sample to −60 °C in the presence of more than two equivalents of imidazole causes the disappearance of all signals except those of the bis-imidazole complex, whose methyl and $-CH_2$ resonances are found at +44, +14, −5.7 and −10 ppm, and *meso*-H at −93 and −107 ppm (intensities 2:1, respectively).[158] The large negative shifts of the *meso*-H suggest that in this low-spin complex the metal and corrole radical electrons are ferromagnetically coupled. In frozen CD_2Cl_2 at 4.2 K the EPR spectrum of this complex is that of a typical rhombic low-spin iron(III) complex, with g-values of 2.58, 2.21 and 1.82, and no evidence of the corrole radical spin.[158] In agreement with this, the magnetic moment at −60 °C is 1.7 μ_B.[158] This suggests that the complex forms a dimer in which the corrole radicals are spin paired and thus EPR silent. Similar behavior was observed earlier for the one-electron oxidized form of vanadyl octaethylporphyrin.[123]

Cyanide complex formation of (7,13-dimethyl-2,3,8,12,17,18-hexaethylcorrolato)iron chloride, [(7,13-Me_2Et_6Corr)FeCl], in dimethylformamide, DMF-d_7, was studied by ^{1}H NMR spectroscopy.[853] It was found that a bis-cyanide complex forms initially, in which the electron configuration is that of a low-spin Fe^{III} corrolate(2–•) π-radical,[853] a neutrally-charged radical. This complex is not stable, and is readily reduced by an excess of cyanide in the solution. The reduction occurs at the corrole ring instead of on the iron center, to give the monocyanide complex of the low-spin Fe^{III} corrolate(3–), [(7,13-Me_2Et_6Corr)FeCN]$^-$.[853] Thus, this is a case where an axial ligand serves as a reducing agent of the macrocycle, and not of the metal.[854]

The bis-pyridine complex of the $Fe^{III}Corr^{3-}$ state is a typical low-spin Fe^{III} complex, which has also been studied by X-ray absorption spectroscopy.[854] Monopyridine complexes of the 1-electron-reduced Fe(III) corroles have also been studied.[840]

One-electron oxidation of the iron(III) corrole π-radicals is discussed in Section IV.A.13.

12. *Iron(IV) Porphyrins*

Three types of iron(IV) porphyrin complexes have been studied by ^{1}H, and in some cases, ^{2}H NMR spectroscopy. All of of these complexes have spin state S = 1: The low-spin d^4 complex [(TPP)Fe(OCH_3)$_2$] mentioned in Section IV.A.11.a,[832] the deep red, 5-coordinate ferryl, $(Fe^{IV}=O)^{2+}$ complexes[855] and the 6-coordinate adducts of these ferryl complexes, the (B)$(Fe^{IV}=O)^{2+}$ complexes,[855–857] and the iron(IV) phenyl complex.[157] The pattern of spin delocalization observed in each of these systems is unique, as summarized in Table 15, despite the similar magnetic

Table 15. Chemical shifts of representative high-valent iron porphyrin species.

		Chemical shift, ppm				
Compound	T, °C	Pyrr-H	*o*-CH_3	*m*-H	*p*-CH_3	Ref.
[(TMP)Fe(OCH_3)$_2$]	–78	–37.5	2.4	7.72	2.86	832
[(TMP)FeO]	–70	8.4	3.3	6.4, 6.0	2.6	855

moments. The ferryl and iron(IV) phenyl cases have direct application to active states in heme proteins.

a. *Six-coordinate, bis-methoxide iron(IV) porphyrins*

As discussed earlier (Section IV.A.11.a), Groves and coworkers[832] have reported the valence isomerization of the iron(III) porphyrin π-radical in the presence of methoxide:

$$\underset{Fe^{III}P^{-\bullet}}{[(TMP)Fe(OClO_3)_2]} + 2\ CH_3O^- \leftrightarrows \underset{Fe^{IV}P^{2-}}{[(TMP)Fe(OCH_3)_2]} + 2\ ClO_4^-. \quad (40)$$

This species is characterized by relatively large π contact shifts to the β-pyrrole positions (−37.5 ppm at −78 °C in CD_2Cl_2/5% methanol-d_4), and relatively small, if any, shifts at the *meso* positions,[832] thus implicating the 3e(π) orbitals in spin delocalization. Wolowiec and Latos-Grażyński have produced this species by reaction of dimethyldioxirane with deuterated dichloromethane/methanol (4:1).[858] The ferryl π-cation radical, $[(TMP^{-\bullet})Fe{=}O(CD_3OD)]^+$ was also produced in this medium by warming the sample from 203 to 233 K for 15 min.[858] This species is unstable in basic solution.

b. *Five- and six-coordinate ferryl, $(Fe{=}O)^{2+}$, porphyrin complexes*

Ferryl complexes have been implicated in the reaction mechanisms of peroxidases and cytochromes P450. For horseradish peroxidase, two intermediates are spectroscopically detectable.[859] Compound I, formed on addition of peroxide to the resting iron(III) form of the enzyme, is a green species that is formally two oxidation levels higher than the resting state, and is widely believed to consist of an $(Fe^{IV}{=}O)^{2+}$ unit complexed to a porphyrin π-anion radical to yield $[Fe^{IV}{=}O\ P^{-\bullet}]^+$. NMR investigations of such complexes are discussed in Section IV.A.13. Compound II, which is red, and is obtained upon one-electron reduction of Compound I, also possesses a $(Fe^{IV}{=}O)^{2+}$ unit, in this case complexed to a normal porphyrin dianion.

Model hemes containing the ferryl unit have been prepared and investigated by ^{1}H NMR spectroscopy at low temperatures by Balch and La Mar and coworkers.[332,855,857,860] The ferryl species have been produced by thermal decomposition (at −30 °C) of the μ-peroxo dimer of $(P)Fe^{III}$, formed from reaction of 2 $(P)Fe^{II}$ with molecular oxygen at −70 °C, Eqs. 41 and 42,[855] by base catalyzed cleavage of the μ-peroxo dimer at similar low temperatures:[855–857]

$$\underset{Fe^{III}\text{-}O_2{}^{2-}Fe^{III}}{(P)Fe\text{-}OO\text{-}Fe(P)} + 2\ B \leftrightarrows 2\ \underset{(B)(Fe^{IV}{=}O),}{(B)(P)Fe{=}O}, \quad (41)$$

where reaction (41) is the same as the second part of reaction (27b), or by base catalyzed cleavage of (P)Fe(OOCHR$_2$) complexes:[332]

$$(P)Fe(OOCHR_2) + B \leftrightarrows (B)(P)Fe^{IV}{=}O + \bullet OCHR_2 \downarrow (P)Fe^{III}OH + O{=}CR_2 + B. \qquad (42)$$

Both the 5- and 6-coordinate ferryl porphyrin complexes have very small observed shifts of all resonances, as summarized in Table 15. Nevertheless, the Curie plots for all resonances are strictly linear, and the observed shifts extrapolate to close to the diamagnetic positions for each type of proton.[855] Investigation of 6-coordinate (imidazole or pyridine) adducts of synthetic ferryl porphyrins and ferryl myoglobin led to detection of broad, weak axial imidazole (histidine) resonances at −11 and −16 ppm in ferryl myoglobin at 35 °C.[860] Analysis of the hyperfine shifts of the axial ligands are consistent with imidazole → Fe π donation similar to that seen in low-spin iron(III) complexes with two imidazolate or one imidazolate and one cyanide ligand,[490] although the contact shifts are much smaller in the iron(IV) complexes.[860] For axial pyridine complexes, the dominant π bonding leads to spin polarization effects by the d_π spin, which leads to contact shift patterns very similar to those reported for low-spin iron(III) porphyrin bis-(pyridine) complexes,[519] but much smaller than those reported for the iron(IV) complexes.[860] These results indicate that the coordinated ligand is located trans to a strongly π-donating oxo ligand, where there is significant spin delocalization from the d_{xz},d_{yz} orbitals to the π_x and π_y orbitals of oxygen by this π donation in both the model compounds and ferryl myoglobin.[860] The small observed shifts are entirely consistent with theoretical calculations,[861,862] which indicate substantial π interaction between iron and oxygen orbitals and effective localization of unpaired spin density within the $(Fe^{IV}{=}O)^{2+}$ unit, a significant amount of which may be localized on the oxygen, which is in line with the reactivity of this group.[863,864]

c. *Five-coordinate iron(IV) phenyl porphyrins*

Single-electron oxidation of phenyliron(III) tetraarylporphyrin complexes with bromine in chloroform at −60 °C produces deep red solutions whose ^{1}H and ^{2}H NMR spectra indicate that they are the corresponding iron(IV) complexes.[157] As summarized in Table 15, the pyrrole-H are found at −60 to −70 ppm, while porphyrin aryl chemical shifts are almost exclusively pseudocontact in nature. The iron phenyl resonances at ~ −300 ppm (*o*-H), −50 to −75 ppm (*m*-H), −43 ppm (*m*-CH_3), ~ −100 ppm (*p*-H) and +112 ppm (*p*-CH_3),[157] indicative of large π spin delocalization to the phenyl ring. However, the nonalternation in sign for the

meta-phenyl-H paramagnetic shift and nonreversal in sign on substitution of CH_3 at the *meta* position suggests some degree of σ spin delocalization to the phenyl ring. In comparison to the phenyl iron(III) porphyrin complexes discussed in Section IV.A.8.f, except for the *meta*-phenyl position, the chemical shift pattern is similar for the two oxidation states, except that the shifts of the Fe(IV) phenyl complexes (Table 15) are larger than those for the iron(III) phenyl complexes (Table 15). This may not be surprising when one considers the electron configurations of the two: For the low-spin aryl iron(III) porphyrins, the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^3$, with one π-symmetry unpaired electron, while for the low-spin aryl iron(IV) porphyrins, the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^2$, with two π-symmetry unpaired electrons. However, it should be noted that because of symmetry considerations, only one of the d_π electrons can be delocalized to the aryl group. The aryl iron(IV) porphyrins are thermally unstable, and upon warming convert cleanly to N-phenylporphyrin complexes of iron(II) by reductive elimination.[157] Phenyl migration, which produces a green pigment, is known to occur under aerobic conditions in protein systems such as cytochrome P450, catalase, hemoglobin or myoglobin. The phenyl heme is produced by attack of aryl hydrazines in the presence of oxygen,[575,865] and probably goes through a phenyl iron(IV) intermediate. These N-arylporphyrin complexes of iron are readily demetalated, which leads to destruction of function of the heme protein.

d. *Comparison of iron(IV) porphyrins and iron(III) porphyrin π-radicals*

Balch and Renner[157] concluded that axial ligands play a major role in determining the electronic distribution within highly oxidized iron porphyrins. It has been found that an oxo ligand, a phenyl ligand or two methoxy ligands favor the iron(IV) porphyrin dianion structure, while two halide ions, imidazole or perchlorate ligands produce the iron(III) porphyrin π-radical monoanion electronic structure. The ability of the iron π unpaired electron to interact with the axial ligand(s) appears to make a major contribution to these differences.

13. *Iron(IV) Porphyrin π-Radicals*

In Section IV.A.12.b it was mentioned that the green Compound I species observed in peroxidase enzymes, which contains an iron porphyrin that is two oxidation levels above $(P)Fe^{III}$, consists of a ferryl porphyrin radical, $[(P^{-\bullet})(Fe^{IV}{=}O)^{2+}]^+$. The ferryl unit, complexed to a porphyrin π-anion radical, is a transient and very reactive species (either in the enzymes or in model hemes) and can readily insert the oxygen atom into many C–H bonds.[863,864] Horseradish peroxidase Compound I, in

which the heme iron is bound to a histidine imidazole ligand, was first assigned as an a_{2u} radical, while catalase Compound I, in which the heme iron is also bound to a histidine imidazole ligand, was believed to be an a_{1u} radical.[866,867] It was later shown that all of these heme Compound I states, including those of the cytochromes P450,[864] have a_{1u} radicals which are weakly antiferromagnetically coupled to S = 1 Fe^{IV}=O and give EPR signals near g_{eff} = 2,[868–876] although the breadth of the signal and its symmetrical shape suggests a mixture of weakly antiferromagnetic and weakly ferromagnetic coupling.[872] Compounds I of cytochromes P450 are much less stable than those of peroxidases and catalases, and in many cases cannot even be trapped by freeze-quench EPR experiments, although their decomposition products to Fe^{IV}=O protein radicals have been trapped in a few cases.[877–879] They have also been trapped in stopped-flow experiments. Chloroperoxidase, in which the heme is bound to a cysteine thiolate ligand, has a Compound I with a radical that is fairly strongly antiferromagnetically coupled to S = 1 Fe^{IV}=O, which thus gives S_{eff} = 1/2 and g-values of 1.64, 1.73 and 2.00.[880]

In contrast, different EPR spectra have been reported for the Compound I of *Micrococcus lysodeikticus* catalase[881] and that of ascorbate peroxidase,[882] which suggest *ferromagnetic* coupling of the S = 1/2 radical and the Fe^{IV}=O to yield a S_{eff} = 3/2 state. The Compound I form of these enzymes also show a S_{eff} = 3/2 state with EPR g-values of ~4 and ~2, although there are two subtypes, one which has a rhombic signal (g_{eff} = 4.5, 3.5, 1.98), and the other axial ($g_{\perp eff}$ ~3.4–3.3, $g_{\parallel eff}$ ~2). The catalase-peroxidases (KatGs) of a number of bacteria,[883–885] most importantly *Mycobacterium tuberculosis*,[886–888] show both catalase and peroxidase activity, and this enzyme activates the currently best drug against this disease, the pro-drug isoniazid. In fact, these examples are part of a continuum of spectra observed for Compounds I, which range from a g = 2 signal with extremely broad wings, indicative of antiferromagnetic coupling of radical and Fe^{IV} electrons, to rhombic and axial signals indicative of weak ferromagnetic coupling of these electrons; a good example of the range of signals observed thus far is shown in Figure 26 of the chapter on structure-function relationships in heme peroxidises in this series,[889] which includes the Compounds I of HRP, isoforms I and III of turnip peroxidases,[890] a KatG mutant,[888] ascorbate peroxidase,[882] and a model heme complex discussed below. It should be noted that most peroxidases, and particularly the KatGs, have more than the usual number of tyrosines and tryptophans in the protein sequence, and some of these that are near the heme center provide sites from which the ferryl porphyrin π-cation radical can capture an electron (more often Trp),[885,888,890] which gives a ferryl porphyrin-protein radical state, $[PFe^{III}=O](Trp^{\bullet})^{+}$ for example, and protein radical EPR signals may be observed, or they may show variable coupling to the S = 1, PFe^{IV}=O center, depending on the distance of the

protein radical from the PFe^{IV}=O center. This state may be the actual one that allows substrate oxidation, if there is no substrate binding site near the heme.[885,888–891]

No less that four research groups have investigated the NMR spectra of model complexes of this reactive species,[332,360,892–902] and Nanthakumar and Goff[897] have stabilized an iron(IV) porphyrin radical in the absence of the oxo group by using fluoro substituents on the TPP phenyl rings. Weiss, Gold and coworkers[897–901] have also generated oxoferrylporphyrin radicals by *m*-chloroperbenzoic acid oxidation of the chloro- and trifluoromethanesulfonato complexes of [(TMP)Fe^{III}] and the trifluoromethanesulfonato complex of tetra-(2,6-dichlorophenyl) porphinatoiron(III), [$((2,6\text{-}Cl_2)_4$TPP)Fe^{III}]. The ferryl porphyrin π-cation radical, [$(TMP^{-\bullet})(Fe{=}O)(CD_3OD)]^+$ can also be produced by reaction of dimethyldioxirane with [(TMP)$FeOClO_3$] in deuterated methylene chloride/methanol (4:1) at 203 K followed by warming the sample to 233 K for 15 min.[858] This species was found to be unstable in basic solution. The EPR and Mössbauer spectra of all of these species were found to be those of $[Fe^{IV}{=}O\ Por^{-\bullet}]^+$ in which the porphyrin π-radical was an $a_{2u}(\pi)$ type, not $a_{1u}(\pi)$, and fairly strongly ferromagnetically coupled to the $S = 1$ Fe=O center, rather than antiferromagnetically coupled, as found for the HRP-containing heme enzyme systems.[874–880] Only in the case of a crowded porphyrin with β-tetramethyl,tetraaryl substitution has the $a_{1u}(\pi)$ radical state, with weak ferromagnetic coupling, been stabilized.[895,900] Later, these workers found that the tetra-mesityl- and -2,6-dichlorophenylporpholactones also produced the $a_{1u}(\pi)$ radical state, but again weakly ferromagnetically coupled.[902] In fact, no model complexes have been created which reproduce the HRP- or CPO-type EPR and Mössbauer spectra that are mainly weakly or strongly antiferromagnetically coupled.[874–880]

The $a_{2u}(\pi)$ strongly ferromagnetically-coupled radical complexes have rhombic EPR spectra at 10 K (g-values of 4.47, 3.50, 1.98 for the TMP case, 4.26, 3.68 and 1.990 for the 2,6-dichlorophenylporphyrin case), and Mössbauer spectra indicative of stronger coupling between the Fe^{IV}=O and porphyrin π-radical electrons ($J_0 \sim$ 38–43 cm^{-1}), while the porpholactones, with their $a_{1u}(\pi)$ radical states, have "axial" EPR spectra at 10 K, which were nevertheless analyzed as being rhombic (g-values of 3.48, 3.85, 1.99 for the tetramesitylporpholactone and 3.16, 3.64, 1.99 for the tetra-2,6-dichlorophenylporpholactone), and weaker ferromagnetic coupling between the Fe^{IV}=O and porphyrin π-anion radical electrons $[Fe^{IV}{=}O\ P^{-\bullet}]^+$ ($J_0 \sim 11$–17 cm^{-1}).[902] Fujii and coworkers obtained similar results for these two radical states.[895] Thus, the differences in the coupling of the ferromagnetically-coupled radicals are subtle, although they produce quite different EPR spectra, as shown in Figure 74.

In all but one case,[896,903] "hindered" or "protected" porphyrins, such as tetramesitylporphyrin (TMP),[332,892,893] 2, 7,12,17-tetramethyl -3, 8,13,18- tetramesitylporphyrin (TMTMP),[894,895,900] or tetra-(2,6-difluorophenyl)porphyrin ($(2,6\text{-}F_2)_4$TPP) or (F_8TPP))[903] were used for these model studies. In the case of the TMP

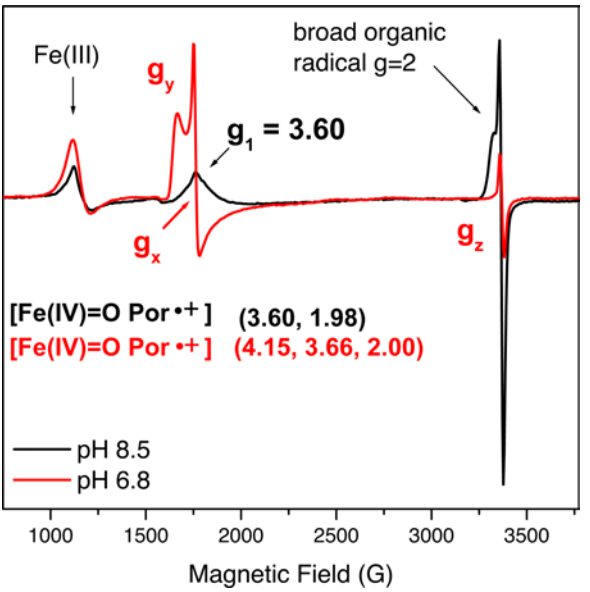

Figure 74. EPR spectrum of the [Fe^{IV}=O $Por^{-\bullet}$] Compound I species formed upon reaction of nitrophorin 2 with 5-fold excess peroxyacetic acid. The rhombic signal with effective g-values of (4.15, 3.66, 2.0) consistent with a strong ferromagnetic coupling is observed at lower pH (6.0 here), while a change to weak ferromagnetic coupling is observed at higher pH values (8.5 here). The Compound I spectrum at pH 6.0 is very similar to that observed for the [Fe^{IV}=O $Por^{-\bullet}$] intermediate formed by ascorbate peroxidase and the ferryl (TMTMP) model complex of Ayougou *et al.*[900] and Fujii *et al.*[895] (see Figure 27 in Ref. 883). The radical signal at g = 2 that contributes to the Compound I spectrum of NP2 obtained at pH 8.5 is consistent with that of a protein-based radical formed as a subsequent intermediate,[905] similar to the cases observed in catalase-peroxidases.[883–888]

complexes, it was found that the porphyrin π-radical is of the a_{2u} type, since large π spin density is detected at the *meso*-phenyl-H and $-CH_3$ positions, as well as a smaller amount of π spin delocalization at the β-pyrrole positions,[128,893] as summarized in Table 15. However, the TMTMP complex has an unpaired electron in the a_{1u} orbital, since the very large pyrrole-CH_3 paramagnetic shift indicates large spin delocalization to the pyrrole positions.[128,895,900] The pyrrole-CH_3 resonance at 132 ppm and the *meso*-H resonance at +54 ppm are shifted to +111 ppm and −1 ppm, respectively, upon binding imidazole.[895] In comparison, pyrrole-CH_3 and *meso*-H shifts for the ferryl complex of protohemin are 4 and 16 ppm, respectively.[857]

Use of *meso*-tetra-2,6-substituted phenyl porphyrins having chloro or nitro substituents produces iron(IV) porphyrin radical states that have more a_{1u} radical character (mixed into the largely a_{2u}-type radical) than is observed for other tetraphenyl-type porphyrins: Using tetrakis-5,10,15,20-(2,6-dichlorophenyl)porphyrin, 5-(2-chloro-6-nitrophenyl), 10,15,20-tris(2,6-dichlorophenyl)porphyrin,

5-(2,6-dinitrophenyl), 10,15,20-tris(2,6-dichlorophenyl)porphyrin as compared to TMP and 2-iodo TMP, pyrrole-H shifts of −61; −54 to −56; −51 to −55; −28; and −24 to −27 ppm, respectively, are observed at −65 °C.[900] In contrast, the fully-a_{1u} radical state of the porpholactones show pyrrole-H shifts of −5 to −20 ppm for the tetramesityl complex and −40 to −60 for the 2,6-dichlorophenyl complex, with the phenyl *meta*-H resonances mirroring this difference in reverse (+20 to +35 ppm for the tetramesityl complex and +10 to +15 ppm for the 2,6-dichlorophenyl complex).[902] Despite the differences in chemical shifts for these two complexes, the low temperature EPR spectra show both of them to be $a_{1u}(\pi)$ radicals.

Goff and coworkers prepared a 6-coordinate, oxo, fluoro complex, [(TPP)Fe=O(F)], by addition of *m*-chloroperbenzoic acid to $[(TPP)FeF_2]^{-\bullet}$ in dichloromethane, or by reaction of the μ-oxo dimer diradical, $[((TPP^{-\bullet})Fe)_2O(ClO_4)_2]$, with excess $Bu_4NF\bullet 3H_2O$ in CD_2Cl_2. This complex has very small pyrrole-D shifts and large, alternating signs for the phenyl-H,[361] which indicate a radical of a_{2u} type. This species has EPR signals at g = 4.2, 3.9 and 3.5 at 5 K, but not higher, which suggests an overall S = 3/2 species composed of S = 1 iron(IV) and the S = 1/2 porphyrin radical.[361] This is presumably the valence isomer of the iron(V) porphyrin species obtained from the fluorinated TPP derivative,[903] discussed in Section IV.A.14.

Nitrophorin 2 also reacts with H_2O_2[904] or peroxyacetic acid to give EPR spectra similar to these, with the rhombic signal seen at pH = 5.5–6.8 and the axial signal at pH 7.7–8.6,[905] as shown in Figure 74, g-values of 4.03, 3.80, and 2.00, and 3.8, ~2.0, respectively. The rhombic spectrum is believed to arise from stabilization of the $a_{2u}(\pi)$ radical state by strong ruffling of the heme, which is relaxed by loss of H-bonds at high pH, and becomes an $a_{1u}(\pi)$ radical state.[905] In fact, it may be that the difference between the EPR spectra of the model heme systems is that the *meso*-substituted models encourage ruffling, which stabilizes the $a_{2u}(\pi)$ radical state, while the β-pyrrole-substituted models prevent ruffling, which stabilizes the $a_{1u}(\pi)$ radical state. As in the KatGs, the ferryl porphyrin π-radical electron can be transferred to protein side chains, in this case only to tyrosines.[905]

Nanthakumar and Goff's nonferryl iron(IV) porphyrin radical or iron(V) complex, probably $[((2,6\text{-}F_2)_4TPP)FeCl](ClO_4)_2$,[896,903] which is produced by two-electron electrochemical oxidation of $[((2,6\text{-}F_2)_4TPP)FeCl]$ in dichloromethane, has reversed phenyl-H shifts (+30.5 and −2.0 ppm for *m*-H and *p*-H, respectively) from those of the one-electron reduced iron(III) porphyrin radical (−3.5, −4.5 (*m*-H) and +16.0 ppm (*p*-H)) discussed in Section IV.A.11, and the pyrrole-H signal has moved from +85.5 ppm to −5 ppm upon oxidation from the iron(III) to the iron(IV) porphyrin radical. Although this pyrrole-H shift is similar to those observed for ferryl porphyrin radicals, Table 15, solution characterization of the two-electron oxidized product of $[((2,6\text{-}F_2)_4TPP)FeCl]$ provides no evidence of an oxo ligand.[896]

The chloroiron (III) corrole π-radicals discussed in Section IV.A.11.e[840] can be oxidized by one electron to create an antiferromagnetically coupled iron(IV) corrole π-cation radical.[906] The magnetic moment of $[(Et_8Corr)Fe(Ph)]^+$ is 1.78 μ_B at 293 K, and the EPR spectra of this phenyl complex, as well as the chloro complex, are indicative of an overall S = 1/2 system (g = 2.17, 2.04, 2.01 and 2.12, 2.07, 2.02, respectivly).[906] These species have not been characterized by NMR spectroscopy.

14. *Iron(V) Porphyrins*

The single report of a possible Fe(V) porphyrin is that of Nanthakumar and Goff,[896,903] in which they used highly electronegative fluorine substituents on the phenyl rings and the strong oxidizing agent, m-chloroperbenzoic acid, to produce a red complex with Soret band at 430 nm and visible band at 550 nm, similar to those of $(P)Fe^{IV}$=O complexes,[897] but with different NMR and EPR spectra. The pyrrole-D signal was observed at +1.3 ppm at 210 K. The EPR spectrum at moderate temperatures (g = 4.38, 3.11 and 2.70, plus a g = 2 radical signal from decomposition products) is believed to be indicative of a S = 3/2 species,[903] rather than a S = 1 iron(IV)/S = 1/2 porphyrin radical species, which is expected to be EPR silent above ~5 K.[903] However, a recent study of related halogenated high-valent iron porphyrins using tetrakis-5,10,15,20-(2,6-dichlorophenyl)porphyrin, 5-(2-chloro-6-nitrophenyl), 10,15,20-tris(2,6-dichlorophenyl)porphyrin, 5-(2,6-dinitrophenyl), 10,15,20-tris(2,6-dichlorophenyl)porphyrin and others, mentioned in the previous section, yield somewhat different rhombic EPR spectra at 10 K (g-values of 4.26, 3.68 and 1.99), pyrrole-H shifts of −61 to −51 ppm at −65 °C, and Mössbauer and resonance Raman spectra indicative of iron(IV) π-cation radicals.[900] The researchers comment that the Mössbauer data are inconsistent with formulation of these complexes as high-spin iron(V).[900] However, the large difference in the chemical shift of the pyrrole-H reported by Nanthakumar and Goff[896,903] and by Jayaraj *et al.*[900] raises the question as to whether the same species was detected in the two studies. Thus, perhaps the possibility of the existence of an Fe(V) porphyrin should be retained — but with a question mark.

B. Ruthenium and Osmium Porphyrins

Unlike the extensive chemistry and NMR spectroscopy of Fe^{I}–Fe^{IV}=O π-cation radicals discussed in Section IV, the reported NMR studies of porphyrin complexes of the heavier elements of the iron group involve mainly diamagnetic compounds. Fairly recent examples include the oligomeric ruthenium(II) porphyrin complexes of mono-(2- or 4-pyridyl)-tri-tolyl- or tri-(4-*t*-butylphenyl)porphyrin,[907] a number of complexes formed by scission of the Ru–Ru bond of

dimeric Ru^{II} complexes[908] or reductive cleavage of that bond,[909] complexes of (TPP)Ru^{III} with NO and anions,[910] osmium(II) porphyrin ylides,[911] oligomeric osmium(II) porphyrin complexes of mono-(3- or 4-pyridyl)-triphenylporphyrin[912] and dioxoruthenium(VI) porphyrins.[913]

Dimeric metal–metal bonded ruthenium(II) complexes of OEP, TPP and TTP, prepared by vacuum pyrolysis of the corresponding [(P)Ru$(Py)_2$] monomeric complexes, have been studied by NMR spectroscopy.[914] These dimeric ruthenium(II) porphyrins are paramagnetic and have a formal Ru=Ru double bond, with an overall d-electron configuration $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$. The NMR spectra of the TPP and OEP complexes at 30 °C are shown in Figure 75, where it can be seen that the unusually high resolution (for a paramagnetic complex) of the resonances, including all spin–spin splittings, is helpful in assigning them. The negative chemical shift of the pyrrole-H resonance of the TPP complex and the positive chemical shifts of the $-CH_2$ resonances of the OEP complex, as well as the near-diamagnetic shift of the *meso*-H of the latter complex,[914] are all diagnostic of unpaired electrons in the d_π orbitals of the two metals, which is totally consistent with the d-electron configuration. The Os_2 and RuOs analogs also have this electron configuration.[915] However, the d^4–d^6 dimeric mixed metal MoRu,[916,917] WOs,[916] WRu,[918] and

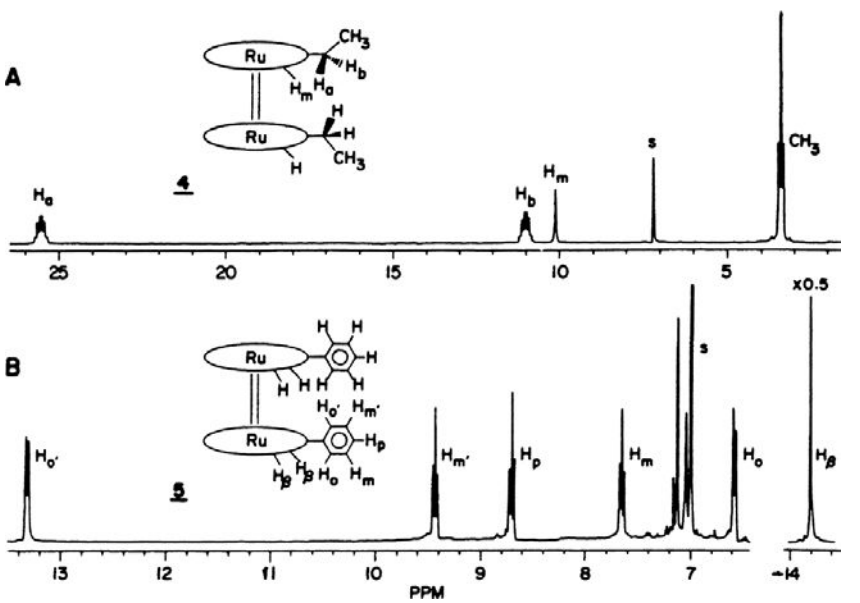

Figure 75. 100 MHz ^1H NMR spectra of $[(P)Ru^{II})]_2$. A: $[(OEP)Ru]_2$ in oxygen-free benzene-d_6. B: $[(TPP)Ru]_2$ in oxygen-free toluene-d_8. Reprinted from Collman, J. P.; Barnes, C. E.; Collins, T. J.; Brothers, P. J. *J. Am. Chem. Soc.* **1981**, *103*, 7030–7032, with permission from the American Chemical Society.

MoOs[918] complexes have the δ^* and π^* orbitals reversed in energy, as is evidenced by the fact that they are paramagnetic.

C. Cobalt Porphyrins

Cobalt porphyrins do not occur naturally, but the related vitamin B_{12} corrins (also called cobalamins) are important in a number of carbon skeleton rearrangements, methyl group transfers and reduction of amino and hydroxyl groups to the hydrocarbon level.[919] In these reactions, cobalt(I), cobalt(II) and cobalt(III) were implicated in the various enzymatic transition states. X-ray crystallographic structure determinations of methionine synthase[920] and methylmalonyl CoA mutase[921] were very informative concerning the binding of the cobalamin to its protein and the possible mechanism of action of the enzyme. In addition, cobalt(II)-reconstituted hemoglobins and myoglobins were extensively investigated in an attempt to elucidate further information concerning quaternary structural interconversions,[922] geometry of the metal–O–O bond,[923–926] and the rate of rotation of bound O_2 by EPR lineshape analysis techniques.[927]

Just one report of NMR investigations of cobalt(II)-reconstituted hemoglobins or myoglobins has appeared, and that one shows an extremely broad peak at +26 or +29 ppm, depending on whether the cobalt(II) is in the α or the β chains of the hemoglobin molecule.[928] These resonances are believed to be due to the *meso*-H of the protoporphyrin IX-cobalt(II). Several broad peaks are also observed in the −5 to −10 ppm region.[928] The breadth of these signals is probably a result of the decreased g-anisotropy of 5-coordinate cobalt(II) porphyrins (as compared to the 4-coordinate complexes), which decreases the paramagnetic shifts of these species. This point will be discussed further in the next section.

1. *Low-Spin Cobalt(II) Porphyrins*

a. *Observed shifts and the pseudocontact interaction*

Table 16 lists the typical paramagnetic shifts for several natural and synthetic cobalt(II) porphyrins. As pointed out previously,[2,4,233] all shifts are to lower shielding. Because the electronic ground state of low-spin cobalt(II) is $^2A_1$ ($d_{z^2}{}^1$), and because the d_{z^2} orbital interacts only very weakly with the σ system of the porphyrin ligand, the majority of the paramagnetic shift at all positions is a result of the pseudocontact interaction. The pseudocontact shifts can be caluclated by use of the factoring method outlined in Section III.B.2 indicates that the majority of the paramagnetic shift is pseudocontact, with small contact shifts at the *meso* (+4 ppm) and pyrrole (−2.4, H; −1.6 ppm, CH_2, at 35 °C) positions.[2,4,233]

Table 16. Chemical shifts of cobalt(II) porphyrins.[a,b]

Porphyrin	Proton position	δ_{iso}, ppm	δ_{dip},[c] ppm	δ_{con}, ppm	Ref.
TTP[d]	Pyrrole-H	7.0[e]	9.4	–2.4	233
	o-H (CH_3)	5.0[e] (2.68,1.29, 1.97, –0.35)[f]	5.0	~0	
	m-H	2.15[e]	2.3	~0	
	p-H (CH_3)	2.03[e] (1.45)[g]	2.05 (1.52)	~0 (~0)	
OEP[d,h]	Pyrrole-CH_2 (CH_3)	4.73 (4.05)	5.2	~ –1.6	233
	meso-H	19.0	15.0	4.0	
EP	Pyrrole-CH_3	4.73			931
	Pyrrole-CH_2 (CH_3)	4.66 (3.92)			
	meso-H	17.57			
MPDME	Pyrrole-CH_3	4.35			931
	Pyrrole-CH_2 (CH_3)	4.4 (3.67)			
	meso-H	16.62

Pseudocontact shifts calculated from Eq. 9 by use of g-values, obtained from low-temperature EPR measurements of polycrystalline samples of cobalt(II) porphyrins[238] are in approximate agreement with those calculated by the factoring method (Eq. 23) at room temperature, but deviate at low temperatures because of solvation of the axial positions of the cobalt(II) porphyrin at lower temperatures. Furthermore, the EPR spectra of cobalt(II) porphyrins in solution are very sensitive to solvation of the axial positions,[929] and do not allow calculation of the pseudocontact shifts observed at room temperature.

The g-values of a number of cobalt(II) porphyrins have been reported previously[238,929] and discussed with respect to their effect on the g-anisotropy that gives rise to the pseudocontact interaction ($g_\parallel^2 - g_\perp^2$, Eq. 9).[2,4] Four-coordinate, polycrystalline cobalt(II) porphyrins have very large differences between $g_\perp$ and $g_\parallel$, with values of 3.25–3.29 and 1.83–1.79, respectively, such that $g_\parallel^2 - g_\perp^2$ is of the order of –7.3 to –7.6, while in toluene solution the g-values are 2.85–2.93 and 1.97–1.95 and this anisotropy decreases to –4.1 to –4.8; in $CHCl_3/CH_2Cl_2$ the g-values are 2.38 and 1.97 and it decreases to –1.78. In the presence of a Lewis base, the g-values

more closely approach 2, with $g_\perp = 2.32$ and $g_\parallel = 2.03$ for the NMeIm complex in toluene, and the value of $g_\parallel^2 - g_\perp^2$ shrinks to −1.2 or even smaller.[2,4] Thus, the observed paramagnetic shifts of [(TPP)Co^{II}] of +7 ppm (pyrrole-H) and [(OEP)Co^{II}] of +19 ppm (*meso*-H) at 35 °C in $CDCl_3$ (at which temperature there is very little solvation of the axial positions of the cobalt(II)) are expected to shrink to 1.2 and 2.5 ppm, respectively, if the mono-(NMeIm) complex is formed, or even more, if the g-anisotropy calculated by the factoring method of Section III.B.2 (−8.2) is used. These very small paramagnetic shifts are not very useful for NMR investigations of cobalt(II) porphyrins or cobalt-substituted heme proteins, and only in one case have such resonances have been reported for a protein.[928] Furthermore, since linewidths are dominated by the pseudocontact interaction, which in this case is more complex than Eq. 19 because of the magnetic anisotropy of low-spin cobalt(II), the proton resonances were postulated to become broader as the magnetic anisotropy becomes smaller.[2,4] However, according to Sternlicht's expression for the nuclear relaxation rate for complexes possessing magnetic anisotropy[105] (Section II.B.2.c, Eq. 21), resonances of protons that are in the plane of the porphyrin should be sharpened according to the ratio of $[\langle g \rangle^2 + g_\perp^2]$, or to about 5/9 their value for 5- as compared to 4-coordinate low-spin cobalt(II) porphyrins. No good test of this relationship has been reported.

The complete dominance of the pseudocontact interaction suggested early that cobalt(II) porphyrins might be used as "shift reagents," to determine stereochemistry of molecules with which they associate.[930,931] This has been reported by Uemori and Kuyno for some "jellyfish" type porphyrins having bridging alkyl groups across two opposite *meso* positions of a "picket fence"-type 4-coordinate cobalt(II) porphyrin.[932] The phenyl-H shifts vary linearly with their geometric factors, which suggests that their shifts are mainly pseudocontact in nature. Ironically, although the use of cobalt(II) porphyrins as shift reagents has not occurred for axial ligand complexes (largely because of the reduced magnetic anisotropy that occurs when ligands are bound to the axial positions of cobalt(II)), certain diamagnetic cobalt(III) porphyrins have been proposed as "chiral shift reagents," based on ring-current shifts of coordinated amine ligands.[933]

b. *Oxidation of cobalt(II) porphyrins to produce π-radical dimers*

Cobalt(II) porphyrins can undergo one-electron oxidation from either the cobalt d or porphyrin π orbitals depending on the choice of porphyrin and reaction media. Oxidation of (OEP)Co^{II} in the presence of ligands such as H_2O and CO produces diamagnetic 5- and 6-coordinate complexes of (OEP)Co^{III},[934–939] while in the absence of additional ligands to coordinate the Co^{III}, the oxidation occurs from a porphyrin π molecular orbital to produce a π-radical complex $[(OEP^{-\bullet})Co^{II}]^+$.[934–937]

The paramagnetic monomer (S = 1) interconverts to a diamagnetic dimer, $[(OEP)Co^{II}]_2^{2+}$. The bonding in the dimer is believed to involve both porphyrin π–π bonding, probably similar to that in the vanadyl porphyrin π-cation radical dimer,[123] and in addition, weak Co^{II}–Co^{II} ($3d_{z^2}$–$3d_{z^2}$) bonding, weaker than that observed in $[(OEP)Rh^{II}]_2^{2+}$ discussed in Section IV.D.

c. *Low-spin cobalt(II) oxaporphyrins and porphodimethenes*

As mentioned earlier, in the coupled oxidation of $[(OEP)Fe^{II}(Py)_2]$, the first product is $[(OEPO)Fe^{II}(Py)_2]$, where OEPO is the monoanion of octaethyl-5-hydroxoporphyrin, also called octaethyloxophlorin, Structure **8**. Further oxidation of this complex produces a mixture of the iron(II) complex of octaethyl-5-oxaporphyrin, Structure **9**, $[(OEOP)Fe^{II}(Py)_2]$, also known as octaethylverdoheme, and $[(OEB)Fe^{III}(Py)_2]$, where OEB is the trianion of octaethylbilindione, the hydrolysis product of verdoheme. Since the Co^{II} complexes of both of the final products are more stable than the Fe^{II} complexes, the cobalt(II) oxoporphyrin complex, $[(OEOP)Co^{II}]PF_6$ was investigated by ^1H NMR and shown to have chemical shifts and linewidths consistent with a low-spin cobalt(II) complex.[939] The magnetic moment of the complex is 1.9 μ_B, in solution at 25 °C,[376,377] which confirms the S = 1/2 state. Two *meso*-H resonances are observed at +30 and +21 ppm (intensities 2:1, respectively), three $-CH_2$ resonances at +8, +4 and −2 ppm (intensities 4:4:8, respectively), and two $-CH_3$ resonances at +5 and +2 ppm (intensities 12:12, respectively).[940]

The other product of coupled oxidation of $[(OEP)Fe^{II}(Py)_2]$, mentioned above, is octaethylbilindione, H_3OEB, from which the iron has been lost. (H_3OEB is the diketone formed when the formyl carbon of Structure 11 is removed by oxidation.) Balch and coworkers have studied the effect that complexation of H_3OEB by metal ions has on the redox properties of the resulting complexes. While the iron complex is important in the coupled oxidation process, which occurs upon treatment of this complex with dioxygen in pyridine solution in the presence of a reducing agent,[220,941] it is unstable with respect to loss of iron.[942] However, the cobalt complex, Co(OEB), is stable to both metal ion dissociation and toward dioxygen.[943] The Co(OEB) complex consists of a cobalt ion with approximately planar coordination that is surrounded by four pyrrole nitrogen atoms of the helical ligand. The ^1H NMR spectrum has marked temperature dependent changes.[940] These changes are most prominent in the *meso*-H resonances and indicate that there is thermal population of a low-lying paramagnetic state. This behavior may result from low-spin/high-spin equilibrium for Co^{III}, or from thermal equilibrium between $[(OEB^{3-})Co^{III}]$ (S = 0) and $[(OEB^{2-\bullet})Co^{II})]$, the oxidized ligand radical dianion, or from temperature dependent coupling of ligand and metal spins in $[(OEB^{\bullet})Co^{II})]$.[940] Spectral data indicate that ((OEB)Co] reversibly coordinates pyridine ligands.

The four-membered electron transfer series involving $[Co(OEB)]^n$ with n = +1, 0, −1, −2 has been studied electrochemically and by oxidation with I_2.[942] All complexes are monomeric, and all but Co(OEB) appear to contain Co^{II}. The ^1H NMR spectrum of the 1-electron-oxidized species, $[Co^{II}(OEBOx)]I_3$, shows eight methylene resonances with chemical shifts that range from +16 to −11 ppm, four methyl resonances at 5.55, 3.73, 0.49 and 0.20 ppm, and two *meso*-H resonances, at −20 (2) and +12.62 (1) ppm, which, by the multiplicity of signals observed, suggests that the I_3^- ion is only loosely bound.[942]

Coordination of cobalt(II) with octaethylformylbiliverdin, Structure **11**, formed by coupled oxidation of cobalt(II) octaethylporphyrin, followed by dissociation of the cobalt, produces a complex whose NMR spectrum is consistent with a low-spin cobalt(II) complex of this formylbiliverdin.[944] *Meso*-H and *meso*-formyl resonances are observed at +34, +26, +11 and +3 ppm, and CH_2 resonances range from +19 to −12 ppm. Six CH_3 resonances, two of double intensity, are also observed between +8 and −2 ppm.[944] The pattern of shifts is similar to that of the symmetrical [(OEP)Co] complex, except for the wide spread of the *meso* shifts. The resonances are considerably sharper than those of [(OEP)Co], however, and excellent COSY spectra have been obtained. The EPR spectrum of the OEFB complex in toluene solution in the presence of pyridine yields a spectrum similar to that of [(OEP)Co] bound to one pyridine molecule,[238] with g-values of 2.465, 2.181, 2.001, except that it is rhombic rather than axial. Molecular oxygen readily binds to this complex, to produce the typical Co–O_2 EPR signal.[944]

d. *High-spin cobalt(II) N-alkylporphyrins and alkoxy adducts of oxaporphyrins*

Most cobalt(II) porphyrins are low-spin (S = 1/2) and have rather broad ^1H resonances with relatively small shifts that are largely pseudocontact in origin,[2,4] but the ^1H NMR spectra of the chlorocobalt(II) N-methylporphyrin complexes of TPP and OEP, shown in Figure 25, are those of high-spin cobalt(II) centers (S = 3/2), and are quite a bit sharper.[230] The lower symmetry of the N-methylporphyrin ligand creates many more resonances for each complex. The Curie plots for these resonances are linear but do not extrapolate to the diamagnetic region for the pyrrole-H or N–CH_3. The phenyl-H, however, exhibit paramagnetic shifts as expected if they are mainly pseudocontact in origin,[230] and the pyrrole substituent shifts are indicative of mainly σ delocalization, as expected. The N,N′-vinylene-linked cobalt(II) porphyrins prepared by addition of free-base porphyrins to a C_2H_2 complex of cobalt(III) octaethylporphyrin, followed by oxidative rearrangement and addition of cobalt(II) or other metal to the free-base N-vinylporphyrin have been

reported.[945] The patterns of *meso*-H and β-CH_2 shifts are similar to those of the simple N-alkylporphyrin complexes of $Co^{II}Cl$.[230] When the planar macrocycle octaethyloxaporphyrincobalt(II), discussed in the previous section, is opened by alkoxide addition, helical complexes are formed. These complexes have much sharper resonances, with larger chemical shifts,[946] than the (OEPO)Co^{II} precursor.[940] For the ethoxy product, *meso*-H resonances are observed at about +70 and +55 ppm, and porphyrin β-CH_2 resonances from +40 to about 0 ppm, with the ethoxy $-CH_2$ resonance at −20 ppm, while for the methoxy product all shifts are increased somewhat.[946] These large chemical shifts are not consistent with low-spin cobalt(II), but rather are similar to the chemical shifts of the cobalt(II) N-alkylporphyrins discussed in the previous paragraph. Indeed, the chemical shifts for the two types of cobalt(II) complexes are similar.

2. *High-Spin Cobalt(II) Complexes of a Weak-Field Porphyrin Ligand*

The cobalt(II) complexes of β-pyrrole-fluoro substituted TPP, (F_8TPP)Co^{II}, and perfluorinated TPP, (F_{28}TPP)Co^{II}, are not pure low-spin cobalt(II) complexes, but rather, have varying degrees of low-spin/high-spin character.[947] For the latter complex, the magnetic moment (Evans method, 25 °C, $CDCl_3$)[376,377] is 2.15 μ_B and the β-pyrrole-F shift is −124.8 ppm (as compared to −145.4 ppm for the Zn(II) complex), while the mono-pyridine complex displays a higher magnetic moment of 2.82 μ_B and a β-pyrrole-F shift of −104.6 ppm. Formation of the 6-coordinate complex, in pyridine-d_5 as solvent, created a nearly pure high-spin cobalt(II) center, with a magnetic moment of 3.82 μ_B and a β-pyrrole-F shift of −20.5 ppm, similar to that observed for the bis-(THF) complex (−1.6 ppm). The most positive shift observed for these complexes was the bis-(N-methylimidazole) complex shift, +141.1 ppm.[947] The more positive the β-pyrrole-F shift, the more fully populated the $d_{x^2-y^2}$ orbital is believed to be. Of the two possible S = 3/2 ground states, $^4A_{2g}$, $(d_\pi)^4(d_{xy})^1(d_{z^2})^1(d_{x^2-y^2})^1$, and ^4E_g, $(d_{xy})^2(d_\pi)^3(d_{z^2})^1(d_{x^2-y^2})^1$, the latter is believed to be the ground state of these complexes because of the similarity of the bis-(pyridine) and −(THF) shifts.[947] Neither the EPR spectrum nor the temperature dependence of the ^{19}F NMR shifts have been reported.

3. *Alkylcobalt(III) Porphyrins: Agostic Interactions or Paramagnetic Excited States?*

X-ray crystallography and ^1H and ^{13}C NMR spectroscopy have been used to study apparantly diamagnetic alkylcobalt(III) porphyrins.[948] Porphyrins studied included OEP, TTP, OEC and OEiBC, while alkyl groups included methyl, ethyl, propyl and butyl. Agostic interactions between the β-protons and the metal had previously

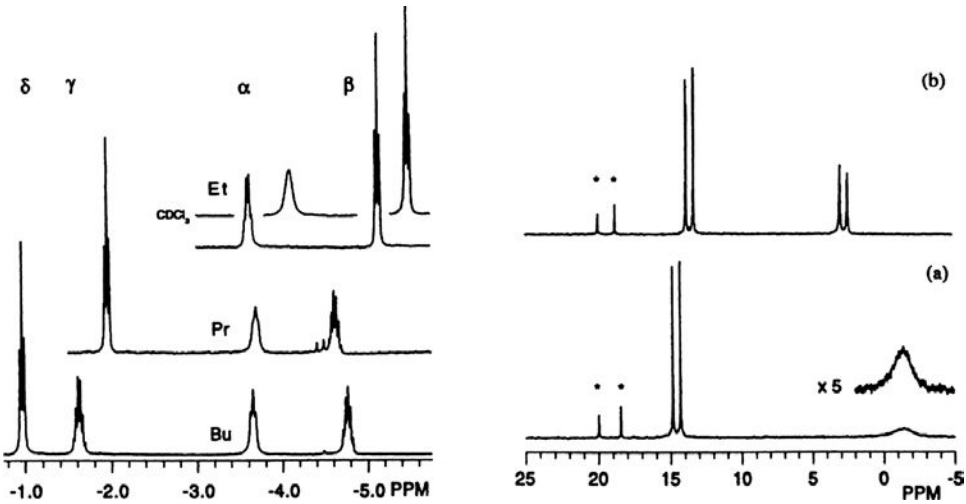

Figure 76. Left: 270 MHz ^{1}H NMR spectra of the axial alkyl groups of [(OEP)Co^{III}(R)] in C_6D_6. Right: 67.9 MHz ^{13}C NMR spectra of the high-shielding region of [(OEP)Co($^{13}C_2H_5$)] in C_6D_6 (a) and in C_5D_5N (b). The inset in spectrum (a) is a fivefold expansion of the α-carbon peak. Peaks indicated with asterisks are the natural abundance CH_3 and CH_2 peaks of OEP. Reprinted from Cao, Y.; Petersen, J. L.; Stolzenberg, A. M. *Inorg. Chim. Acta* **1997**, *263*, 139–148, with permission from Elsevier Publishing Company.

been suggested to explain the broad, ^{1}H resonances of the β-protons of the alkyl group that are shifted to higher shielding,[949] as shown in Figure 76, left. (This shift of the β-protons to higher shielding relative to the α-H is inconsistent with the expectations of ring-current shifts of diamagnetic aromatic compounds.) The three-dimensional structure of the OEP-ethyl complex, [(OEP)Co(Et)], has been determined, and shows no evidence of agostic interactions in the solid state. Furthermore, the ^{13}C resonances of carbons bound to cobalt are very broad and have unusual shifts to higher shielding (Figure 76, right) that are probably better explained by the effects of the quadrupolar ^{59}Co nucleus and to paramagnetic contact shifts that arise from thermal population of an excited state.[948] Organocobalt-mediated radical polymerization of acrylic acid in water has been studied using a water-soluble Co^{II} porphyrin, tetra(3,5-disulfonatomesityl)porphyrin. Low polydispersity, high molecular weight poly(acrylic acid) (PAA) was formed rapidly by the aqueous polymerization of acrylic acid initiated by an azo radical source (V-70) in the presence of this Co^{II} porphyrin. The pyrrole-H resonance of paramagnetic (TMPS)Co^{II} disappears during the induction period of this reaction.[950] Exchange of organic radicals between solution and organo-cobalt complexes was experimentally observed and the reaction pathway was probed through DFT calculations.

Cyanoisopropyl radicals from AIBN (2,2′-azobisisobutyronitrile) enter solutions of cobalt(II) tetramesitylporphyrin ((TMP)$Co^{II\bullet}$) and vinyl acetate (VAc) in benzene and react to produce transient hydride (TMP)Co–H and radicals ($\bullet CH(OAc)CH_2C(CH_3)_2CN$) that proceed on to form organo-cobalt complexes (TMP)Co-$CH(OAc)CH_3$ and (TMP)Co–$CH(OAc)C(CH_3)_2CN$, respectively.[951] Rate constants for near-degenerate exchange of radicals in solution with organo-cobalt complexes are deduced from ^1H NMR studies and kinetic modeling. Associative radical interchange of the latent radical groups in organo-cobalt porphyrin complexes with freely diffusing radicals in solution that is observed in this system provides a pathway for mediation of living radical polymerization of vinyl acetate.[951–953]

4. *A Cobalt(III) Porphyrin π-Cation Radical*

Anodic oxidation of [(OEP)Co^{II}] in the presence of a carbon monoxide atmosphere creates the [(OEP)$Co^{III}(CO)]^+$ π-cation radical complex, whereas in the presence of a dinitrogen atmosphere, a [$(OEP^{-\bullet})Co^{II}]^+$ π-cation radical.[954] The two complexes were characterized by IR spectroscopy; NMR spectra of these species have not been reported. While the NMR spectrum of this species has not been reported, it is probably diamagnetic. The two-electron oxidized complex in the absence of CO yields a species formulated as [$(OEP^{-\bullet})Co^{III}]^{2+}$ $2Br^-$, which exhibited a methylene proton signal at +23 ppm with a halfwidth of 900 Hz, and a broad *meso*-H signal at −81 ppm (linewidth not given, spectrum not shown). At 275 K the latter signal had a paramagnetic shift of −91 ppm, which corresponds to an electron density at the *meso*-C of 0.054 (Eq. 5). This is considerably larger than that at the *meso*-C of the isoelectronic [(OEP)Ru(CO)]$^+$ (0.027), and is probably more indicative of the limiting shift of an $a_{2u}(\pi)$ cation radical-based unpaired electron in a porphyrin macrocycle, although as mentioned in Section IV.B, the EPR spectrum of [$(OEP^{-\bullet})Mg]^+$ yields a splitting constant of 1.48 G, which translates to an electron density at the *meso*-C of 0.066 (Eq. 5), or a contact shift of −107 ppm.

D. Rhodium Porphyrins

The majority of rhodium porphyrins reported to date are diamagnetic dimers.[955] However, if the more sterically bulky tetramesitylporphyrin is used instead, stable monomeric complexes are formed.[956,957] These complexes have NMR spectra and EPR spectra typical of a low-spin d^7 metal with a d_{z^2} unpaired electron. The g-values of the 4-coordinate [(TMP)Rh^{II}] in toluene glass are $g_\perp = 2.65$ and $g_\parallel = 1.915$,[956] similar to those of 4-coordinate cobalt(II) porphyrins.[238] The proton NMR shifts of the porphyrin protons in C_6D_6 at 296 K are +18.3 ppm (pyrrole-H), +3.35 ppm (*o*-CH_3), +8.87 ppm (*m*-H) and +3.51 (*p*-CH_3).[956] The pyrrole-H shift is slightly larger

than that of [(TPP)Co] (+15.5 ppm at 35 °C),[233] which indicates slightly larger pseudocontact shifts, probably, for the rhodium(II) porphyrin. A study of the reactivity of the (TMP)Rh^{II} complex, also described as (TMP)Rh•, with O_2 gave rise to formation of a monomeric O_2 complex, which could also form a peroxo-bridged dimer with another (TMP)Rh•. O_2 could also react with (TMP)Rh-H to yield (TMP)RhOOH.[958] All species were characterized by ^{1}H NMR spectroscopy.

Rh^{III} water-soluble tetra(*p*-sulfonatophenyl)porphyrin has been used to study the reactions of olefins in water to form β-hydroxyalkyl complexes,[959] and the tetrakis(3,5-disulfonatomesityl)porphyrin complex of Rh^{III} has been used to study the reaction with H_2, CO and olefins in water to form formyl and alkyl complexes.[960] Although most detectable species were diamagnetic Rh^{III} complexes, both Rh^{I} and Rh^{II} intermediates were implicated.

Paramagnetic Rh^{II} complexes, Rh(OEP)(PEt_3) and Rh(TPP)(PEt_3), result from addition of PEt_3 to the corresponding metallohydrides, Rh(Por)H, under rigorously anaerobic and anhydrous conditions.[961] According to low-temperature EPR studies ($g_\perp = 2.018$, $g_\parallel = 1.982$ for the mono-PEt_3 complex, $g_\perp = 2.021$, $g_\parallel = 1.973$ for the bis-PEt_3 complex), the HOMO of both complexes is said to be mainly porphyrin based, and not the metal-based $d\sigma^*_{Rh-P}(d_{z^2})$ bond, as reported earlier by Wayland *et al.*[956] However, these g-values are too far from 2.003 and 2.002 to be porphyrin-based radicals, yet they are much closer to these values than that for the Rh(TMP)(PEt_3) (2.116, 2.004, respectively). The ^{1}H NMR resonances for the pyrrole-CH_2 and $-CH_3$ are at 10.2 and −0.7 ppm, respectively. However, the phosphine ligand resonances are said to have a chemical shift of +21 ppm (broad) for all 15 H,[961] which is not what one would expect for CH_2 and CH_3 protons of PEt_3. In the presence of dioxygen the O_2 adduct is formed, which has EPR spectra ($g_\parallel = 2.002$, $g_\perp = 1.982$)[961] similar to those of the Co-O_2 adduct;[238] in both of these complexes the unpaired electron is mainly on O_2 (superoxide ion complex of the M^{III} porphyrinate).

Tris-(mesityl),mono-(*p*-hydroxyphenyl)porphyrin has been used to construct an $-O-(CH_2)_6-O-$bridged porphyrin dimer that, following insertion of rhodium(II), reacts with CO ($P_{CO} = 0.3–0.9$ atm) at room temperature to form the Rh–CO–CO–Rh bridged dimer, which has eight unique pyrrole-H doublets in the 8.18–8.86 ppm region of the ^{1}H NMR spectrum.[962] This presumably indicates that the –C(O)–C(O)– unit binds in such a way as to make the protons of the two rings inequivalent. It would be interesting to investigate the COSY and NOESY spectra of this complex, in order to determine which pyrrole-H are in the same pyrrole ring and which pyrrole-H are in adjacent pyrrole rings, in order to determine the three-dimensional structure of this complex. Warming the sample over the temperature range 300–350 K causes broadening of the resonances, indicating homolytic cleavage of the C–C bond. The activation parameters for this homolytic

cleavage are $\Delta H^{\ddagger} = 88 \pm 4$ kJ/mol and $\Delta S^{\ddagger} = 54 \pm 13$ J/K.mol. The rhodium(II) dimer also reacts with ethylene and 1,3-butadiene to produce the Rh–C_n–Rh bridged complexes, and with CO and H_2O, EtOH, H_2 or CH_4 to produce the H-Rh, Rh-formyl, (EtOC(O))Rh, Rh-formyl, formyl-Rh,Rh-formyl and formyl-Rh,Rh-acetyl organometallic complexes, respectively, all of which have been characterized by ^1H and ^{13}C NMR spectroscopy.[962]

The same diporphyrin ligand system, and one with a more rigid m-xylylene spacer were used to study the dimethyl complex, which has the nondecoupled Rh-$^{13}CH_3$ ^1H signal at −5.29 ppm ($J_{CH} = -141$ Hz) and the ^{13}C signal as a quartet of doublets at −13.58 ppm ($J_{CH} = -141$ Hz, $J_{C103Rh} = -29$ Hz).[963] The dirhodium(II) derivatives were generated by photolysis of the dimethyl complexes, and are stable bimetalloradicals because of the ligand steric demands prohibit Rh^{II}–Rh^{II} bonding.[963] EPR spectra of the dirhodium(II) derivatives ($g_\perp = 2.64$, $g_\parallel = 1.90$), their 5-coordinate triphenylphosphine adducts ($g_\perp = 2.17$, $A_\perp$ (^{31}P) = 756 MHz, $g_\parallel = 2.00$ $A_\parallel$ (^{31}P) = 1016 MHz, $A_\parallel$ (^{103}Rh) = 61 MHz) , and their O_2 adducts ($g_1 = 2.080$, A_1(^{31}P) = 50.9 MHz, $g_2 = 2.005$, A_2(^{31}P) = 50.5 MHz, $g_3 = 1.996$, A_3(^{31}P) = 50.3 MHz) are reported. The ^1H resonance for the pyrrole-H of the 4-coordinate Rh^{II} porphyrin was at +19 ppm at ambient temperature, and the temperature dependence of that resonance extrapolated to 7.53 ppm, which is only about 1.5 ppm from its diamagnetic position;[963] i.e., the complex follows the Curie law quite well. The kinetic advantage of bimetalloradical complexes for substrate reactions that have two metal-centered radicals in the transition state was demonstrated by reactions of dihydrogen with dirhodium(II) bimetalloradical complexes: The ^{103}Rh-H doublet at −40.03 ppm clearly showed that addition of a small amount of H_2 first formed a species in which both Rh centers in the same few dimers were hydrogenated, but over the period of nearly a month it converted to the overall most stable species, in which twice the number of dimers had one RhH and one 4-coordinate Rh^{II} center in each dimer.[963] Methanol reacts with the ligand-free Rh^{II} complex exclusively by C–H bond cleavage to form Rh-CH_2OH and Rh-H centers, and very slowly went on to form H_2 and two Rh–CH_2OH centers in each molecule.[964] This work was further extended to investigate the strength of the C–H bonds in a series of substrates CH_3R (R = H, CH_3, OH, C_6H_5) using the *m*-xylyl diether tethered diporphyrin ligand. Bimolecular substrate reactions involving the intramolecular use of two metalloradical centers and preorganization of the four-centered transition state (M•···X···Y···•M) result in large rate enhancements as compared to termolecular reactions of monoradicals.[965] NMR spectroscopy played an important role in this study.

The Rh–Rh bond dissociation energy of $[(OEP)Rh^{II}]_2$, to give the paramagnetic monomers,

$$[(OEP)Rh]_2 \leftrightarrows 2\ [(OEP)Rh^{\bullet}], \tag{43}$$

has been evaluated using ^{1}H NMR line broadening techniques.[955] At room temperature, all porphyrin resonances are sharp, but as the temperature is raised from 294 to 373 K all resonances broaden. Analysis of the line broadening of the *meso*-H resonance at 9.28 ppm in benzene-d_6 yielded an activation energy E_a +77 ± 3 kJ/mol.[955] Using this value and available data for the bond dissociation energy of H_2 and the reaction of the dimer with H_2:[966]

$$[(OEP)Rh]_2 + H_2 \leftrightarrows 2\ [(OEP)RhH], \tag{44}$$

it was possible to calculate the bond dissociation energy of [(OEP)RhH]

$$[(OEP)RhH] \leftrightarrows [(OEP)Rh^{\bullet}] + H^{\bullet}, \tag{45}$$

as 259 kJ/mol or 61.8 kcal/mol.[955] Using this value, the activation data for the formation of [(OEP)Rh-CHO]:[967]

$$[(OEP)RhH] + CO \leftrightarrows [(OEP)Rh–CHO], \tag{46}$$

and the formyl radical,[968] the bond dissociation energy for the homolytic bond cleavage of [(OEP)Rh–CHO]:

$$[(OEP)Rh–CHO] \leftrightarrows [(OEP)Rh^{\bullet}] + {}^{\bullet}CHO, \tag{47}$$

was calculated to be 243 kJ/mol or 58 kcal/mol.[955] Thus, NMR spectroscopic line-broadening techniques provide a useful method for measuring bond dissociation energies that cannot readily be measured by other methods.

E. Manganese Porphyrins

The manganese(III) porphyrins have been studied for quite some time, probably first for their unusual optical properties, which were interpreted as reflecting extensive manganese-porphyrin π bonding.[969] The complexes are always high-spin d^4, S = 2, and may be 5-coordinate [(P)MnX] or 6-coordinate [(P)MnX(B)], where X is a halide or pseudohalide and B is a Lewis base. Manganese porphyrins have not been shown to exist in or play any role in the functioning of biological systems, but the high-valent states (manganese(V) porphyrins or manganese(IV) porphyrin π-cation radicals) have been shown to be good models of the reactivity of the enzymatically active high-valent states of cytochromes P450, peroxidases, catalases and chloroperoxidase.[970,971]

1. *High-Spin Manganese(II) Porphyrins*

High-spin manganese(II) porphyrin complexes are produced by reduction of manganese(III) porphyrins with zinc amalgam[161] or autoreduction with hydroxide or other OR^- anions.[972] Both 4-coordinate and 5-coordinate (OH^- or OR^- coordinated) complexes can be produced.[161,972] The 4-coordinate complexes have slightly smaller positive pyrrole-H shifts (+34 to +35 ppm at 25 °C)[161,972] than the 5-coordinate complexes (+37 ppm at 25 °C).[161,972] Although these shifts are not nearly as positive as those of high-spin iron(III) porphyrins (Section IV.A.6.a), the spin state of the manganese(II) porphyrins is believed to be high-spin d^5.[972] The binding constants of imidazole, pyridine and DMSO to [(TPP)Mn] have been measured electrochemically in dichloroethane (0.1 M TBAP), and are large, with log K_1 = 4.12, 4.55 and 4.38 log M^{-1}, respectively.[973] The NMR spectra of these 5-coordinate manganese(II) complexes have not been reported. The complex of potassium superoxide with [(TPP)Mn^{II}] shows a pyrrole-D resonance at +32 ppm at 25 °C.[161] The magnetic moment of 5.0 μ_B suggests that the electronic ground state is high-spin manganese(II) coupled antiferromagnetically to the $O_2^{-\bullet}$ axial ligand. This differs from the iron case, where the electron configuration is high-spin iron(III)-O_2^{2-}.[161]

2. *High-Spin Manganese(III) Porphyrins*

The high-spin d^4 electron configuration of [(P)Mn^{III}X] complexes leads to negative shifts for the β-pyrrole-H (−30 ppm in $CDCl_3$ at 35 °C) and positive shifts for the β-pyrrole-CH_2 (+18 ppm),[234] which suggests significant π spin delocalization to the β-pyrrole positions, while *meso*-phenyl resonances are shifted only a small amount in an alternating fashion that suggests a small amount of π spin density at the *meso* positions. [(OEP)Mn^{III}Cl], however, has a *meso*-H shift of +41.4 ppm at 35 °C in $CDCl_3$,[234] which rules out large π spin delocalization from the $3a_{2u}(\pi)$ orbital of the porphyrin ring to the Mn^{III} half-filled d_{z^2} orbital.[156] Thus, the filled $3e(\pi)$ orbitals are utilized for P → Mn π donation. However, this does not account for the large positive shift of the *meso*-H of the OEP complex, which can only be explained in terms of significant σ spin delocalization to the *meso* positions or by a Mn^{II}–$a_{2u}(\pi)$ radical configuration (see below), since the g-anisotropy of high-spin manganese(III) is fairly small.[2,4] EPR spectra of these manganese(III) porphyrins are not detectable at X- or Q-band because the microwave quantum is too small, but have been measured at 226–544 GHz.[974] The zero-field splitting parameters for [(TPP)MnCl], [(DPDME)MnCl] and several tetraazaporphyrin derivatives were found to be in the range D = −2.27 to −2.62 cm^{-1}, with $g_{\|}$ = 1.822 to 2.0.[974] Water-soluble manganese(III) porphyrins have been investigated as possible

water relaxation agents for MRI applications. As expected, porphyrin aggregation decreases the relaxivity of these complexes.[975]

3. *Low-Spin Manganese(III) Porphyrins*

Only three examples of apparant low-spin d^4 (S = 1) manganese(III) porphyrins have been reported: The bis-(cyanide), bis-(imidazolate) and bis-(4-methylimidazolate) complexes. The magnetic moments (Evans method)[376,377] range from 3.0 to 3.7 μ_B,[976] which is higher than the spin-only value of 2.83 μ_B expected for two unpaired electrons, but a T-state system should have considerable spin-orbit coupling with consequent increase in the magnetic moment. The red-brown bis-(cyanide) complexes tend to autoreduce over a period of hours to green high-spin manganese(II) complexes, based on the magnetic moments of the products ($5.8 \pm 0.2\ \mu_B$).[376,377,976] In all of the TPP complexes investigated the β-pyrrole-H resonance is shifted to higher shielding (−14.7, −18.1 and −18.1 ppm, respectively, at 26 °C in DMSO-d_6).[976] These pyrrole-H shifts are indicative of π spin delocalization, probably involving P → Mn π donation from the filled 3e(π) orbitals to the d_{xz},d_{yz} half-filled orbitals of the metal, which thus indicates an electron configuration $(d_{xy})^2(d_{xz},d_{yz})^2$. However, the $[(OEP)Mn(CN)_2]^-$ and $[(Etioporphyrin)Mn(CN)_2]^-$ complexes have very large positive *meso*-H shifts (+34 and +37 ppm, respectively), as shown in Figure 77, which are inconsistent with π delocalization from the metal to the *meso* positions.[976] These large, positive *meso*-H shifts are reminiscent of the iron(III) porphyrin and corrole π-radical spectra discussed in Section IV.A.11.c–v (although with less positive shifts), as well as the Mn corrole spectra discussed in the following Section (IV.E.4) (with very similar shifts). Thus, this author suggests that these "low-spin manganese(III) porphyrins" may actually be intermediate spin (S = 3/2) manganese(II) porphyrin π-radicals, which would be consistent with the observed β-pyrrole shifts of H and CH_2, and would further be consistent with the positive *meso*-H shift if the porphyrin cation electron is antiferromagnetically coupled to the metal electrons. Further study of "low-spin manganese(III) porphyrins," including EPR measurements and the temperature dependence of the NMR spectra, should be carried out in order to obtain a more complete understanding of these complexes.

4. *"Manganese(III) Corrole" at Low Temperatures = Manganese(II) Corrole π-Cation Radical at Ambient Temperatures*

In Section IV.A.10.e it was mentioned that the corrole ring may either stabilize higher oxidation states of metal ions, or may be readily oxidized to the corrole

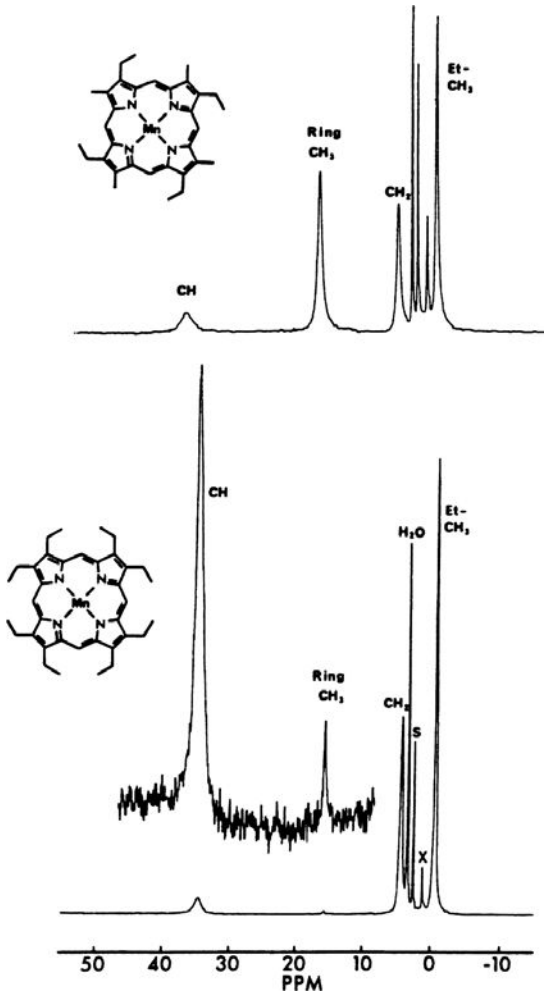

Figure 77. ^{1}H NMR spectra of dicyano complexes of (P)Mn^{III} in DMSO-d_6 at 26 °C (0.005 M manganese porphyrin, solutions saturated with KCN). Bottom: [(OEP)Mn^{III}(CN)$_2$]$^-$; top: [(etioporphyrin)Mn^{III}(CN)$_2$]$^-$. Reprinted from Hansen, A. P.; Goff, H. M. *Inorg. Chem.* **1984**, *23*, 4519–4525, with permission from the American Chemical Society.

π-radical state. Isolation of a putative manganese(III) corrole seemed strange, in that the complex was 4-coordinate.[977] On closer examination, it became clear that in this case the NMR spectra of the 4-coordinate, square planar complex were more consistent with a manganese(II) corrole π-radical electron configuration.[978] The manganese dimethylhexaethylcorrole complex in frozen pyridine solution has an EPR spectrum at 77 K which is characteristic of intermediate-spin manganese(II) (S = 3/2), probably due to the fact that the radical spins on adjacent molecules are paired, as in the low-spin iron(III) π-radical complex of the same

macrocycle, discussed in Section IV.A.10.e. Consistent with this, the X-ray crystal structure shows that the molecular packing of the molecules is such that there is strong overlap of the π systems of the corrole rings to form infinite stacks of molecules.[978] The NMR spectra in pyridine-d_5 of a series of manganese complexes with alkylcorrole isomers (Me_8Corr, 2,18-Me_2Et_6Corr, 3,17-Et_2Me_6Corr, 7,13-Et_2Me_6Corr, 8,12-Et_2Me_6Corr and its 5,15-deuterated analog, 7,13-Me_2Et_6Corr, and 7,8,12,13-Me_4Corr) provide a complete mapping of the spin density in the corrole ring: As in the case of the chloroiron corroles discussed in Section IV.A.11.e, the 5,15- and 10-*meso*-H are at positive chemical shifts (+70.5 and +25 ppm, respectively) because of the antiparallel spin of the corrole π-radical electron, while the 3,17-H and 2,18-H of [(Me_4Corr)Mn] are at very negative chemical shifts (−40 and −123 ppm, respectively)[978] because of large π spin density at those ring positions due to the d_{xz} and d_{yz} unpaired electrons of the S = 3/2 manganese(II) center (while the $3a_{2u}(\pi)$-type orbital, S_{-1}, has small spin density at the β-pyrrole positions, Figure 7). The methyl and methylene proton shifts are positive, confirming the large π spin density at those ring positions due to the d_{xz} and d_{yz} unpaired electrons. Like the 2,18-H, the 2,18-CH_3 and –CH_2 have the largest shifts (+112.4 and +55 ppm, respectively). Next in magnitude are the 8,12-CH_3 and –CH_2 shifts (+64.3 and +35.6 ppm, respectively), followed by the 3,17-CH_3 and –CH_2 shifts (+45.5 and +21.5 ppm, respectively), and finally the 7,13-CH_3 and –CH_2 shifts (+15.8 and ~+8 ppm, respectively).[978] In all cases the CH_3 shifts are very close to twice the size of the –CH_2 shifts, and the pattern of large-small, small-large shifts as one moves away from the directly-bound pyrrole rings is very characteristic of the spin density distribution in the d-A_{-2} orbital, Figure 7. Thus, it appears that the manganese(II) electrons are delocalized by L → Mn π bonding, while the corrole π-radical electron is in the $3a_{2u}(\pi)$-equivalent orbital, S_{-1} (Figure 7). The reason for the much smaller *meso*-H shifts for the Mn complex (+70.5 and +25 ppm (intensities 2:1, respectively)) as compared to the FeCl complex (+175 and +166 ppm (intensities 1:2, respectively)[158]) is at present unclear, but one may guess that it probably has to do either with a difference in the strength of the antiferromagnetic coupling in the two metal complexes or with aggregation to allow partial coupling of the radical spins in these 4-coordinate complexes. Further studies will be required in order to obtain a full explanation of the magnetic interactions in the two metal complexes, both of which are d^5 π-radical centers having metal spin state S = 3/2.

An entirely different situation was found for these complexes at very low temperatures, where high-field and frequency electron paramagnetic resonance (HFEPR) of solid (8,12-diethyl,2,3,7,13,17,18-hexamethylcorrolato)manganese(III) shows that in the solid state they are well described as an S = 2 (high-spin) Mn^{III}

complex of a trianionic ligand, [$Mn^{III}Corr^{3-}$],[979] just as Mn^{III} porphyrins are described as [$Mn^{III}P^{2-}]^{+}$.[980,981] Comparison among the structural data and spin Hamiltonian parameters reported for [$Et_2Me_6CorrMn$], Mn^{III} porphyrins, and a different Mn^{III} corrole, [(tpfc)Mn($OPPh_3$)], previously studied by HFEPR,[982] shows that despite the molecular asymmetry of the corrole macrocycle, the electronic structure of the Mn^{III} ion is roughly axial. However, in corroles, the S = 1 (intermediate-spin) state is much lower in energy than in porphyrins, regardless of axial ligand. HFEPR of [$Et_2Me_6CorrMn$] measured at 4.2 K in pyridine solution shows that the S = 2 [$Mn^{III}Corr^{3-}$] system is maintained, with slight changes in electronic parameters that are likely the consequence of axial pyridine ligand coordination.[979] The present result is the first example of the detection by HFEPR of a Mn^{III} complex *in solution*. Over a period of hours in pyridine solution at ambient temperature, however, the S = 2 Mn^{III} spectrum gradually disappears leaving a signal with g = 2 and ^{55}Mn hyperfine splitting.[979] Analysis of this signal, also observed by conventional EPR, leads to its assignment to a manganese species that could arise from decomposition of the original complex. The low-temperature S = 2 [$Mn^{III}Corr^{3-}$] state is in contrast to that at room temperature, which is described as a S = 1 system deriving from antiferromagnetic coupling between an S = 3/2 Mn^{II} ion and a corrole-centered radical cation: [$Mn^{II}Corr^{2-\bullet}$],[978] as discussed above. The authors state in the abstract that "This temperature-dependent valence state isomerization has been observed for other metallotetrapyrroles."[979] However, to determine whether this is in fact what is happening, it would be worthwhile to study the temperature dependence of the NMR spectrum, in, say toluene-d_8 down to at least –90 °C, to determine whether evidence can be obtained for or against the valence isomerization.

"Manganese(III) octaethylcorrole" in d_8-toluene has rather different chemical shifts, with *meso*-H at +93 and +68 ppm (intensities 2:1, respectively) and $-CH_2$ resonances at +72, +40, +19 and +4.3 ppm.[983] The very positive *meso*-H shifts are still characteristic of a manganese(II) macrocycle π-cation radical formulation, but probably with somewhat stronger antiferromagnetic coupling in this case.

5. *Manganese(III) Porphyrin π-Radicals and Their Transformation to Dichloromanganese(IV) Porphyrins*

[(TMP)$Mn^{III}Cl$] can be chemically oxidized with $Fe(ClO_4)_3$, which leads to the porphyrin-oxidized red product [(pyrrole-d_8-$TMP^{-\bullet}$)$Mn^{III}(ClO_4)_2$], which has its pyrrole-D signal at –48 ppm at room temperature.[984] Magnetic susceptibility measurements and EPR spectroscopy show that the total spin of the complex changes from S = 5/2 at high temperatures (300 K) to S = 3/2 at low temperatures

(100 K).[972] Ligand exchange of the perchlorato ligands to chloride anions is accompanied by a change of the oxidation site from porphyrin to metal, resulting in green [(pyrrole-d_8-TMP)$Mn^{IV}(Cl)_2$], which has its pyrrole-D signal at −38 ppm at room temperature, an EPR spectrum with $g_\perp = 4$ and $g_\parallel = 2$ and a magnetic moment of 3.7 μ_B in solution[376,377] and 3.6 μ_B in the solid state, indicating a spin state S = 3/2. This high-valent metal complex can effect chlorine atom transfer to olefins and natural substrates of chloroperoxidases.[984] The related dimethoxy complex, [(TPP)$Mn^{IV}(OCH_3)_2$], has a somewhat higher magnetic moment (3.9 μ_B) in the solid state and solution.[376,377,985] The EPR spectra of this complex and the related bis-(azide) and bis-(isocyanate) complexes are highly anisotropic, with g-values of 5.43, 2.4, 1.6 (methoxy), similar values for the azide complex, and 5.96, 3.92, 2.01 for the bis-(isocyanate).[986]

6. *Oxomanganese(IV) Porphyrins*

Addition of *m*-chloroperbenzoic acid to [(TMP)MnCl] under basic conditions yields the red complex [(TMP)Mn=O], which has been characterized by optical, infrared, EPR and NMR spectroscopy, as well as mass spectrometry and chemical reaction with β-methylstyrene.[229] Use of pyrrole-deuterated TMP resulted in a pyrrole-D signal at −32 ppm in CD_2Cl_2 at −40 °C of about 2.4 kHz in width, as shown above in Figure 24, which is indicative of π spin delocalization. The EPR spectrum shows g-values of 4 and 2, consistent with an S = 3/2 center. The observed shift of the pyrrole-D of this d^3 [(P)Mn=O] complex[229] is considerably larger than those of the d^3 [(P)CrCl] complexes, discussed in Section IV.H.3.

F. Nickel Porphyrins

Several nickel(II) porphyrins have been used as diamagnetic reference compounds for the investigation of paramagnetic metalloporphyrins, as well as a T-state model in mixed-metal hemoglobins and a model for the nickel macrocyclic complex known as Factor F430 that is the active site of methyl coenzyme M reductase, a methane-forming enzyme. In all of these cases, nickel(II) is diamagnetic. However, there are a number of paramagnetic nickel porphyrins that have been investigated by NMR spectroscopy. The first report of the study of a paramagnetic nickel(II) porphyrin by NMR spectroscopy was that of Abraham and Swinton,[987] who studied the binding of piperidine to (MP)Ni^{II}. They concluded that a 5-coordinate complex was formed, although it was later shown by optical methods that the corresponding TPP complexes are 6-coordinate.[988] A study of the pyrrolidine complexes by UVvisible and resonance Raman spectroscopy and molecular simulations measured the stepwise binding constants (K_1 = 1.1 M^{-1}, K_2 = 3.8 M^{-1} in

CH_2Cl_2),[989] and suggest that there are several nonplanar porphyrin ring conformations (domed, saddled, ruffled) that can occur for the 5-coordinate complex. No mention was made of the likely spin state of each of these possible conformations, although the implication of the discussion was that the 5-coordinate complex is paramagnetic.[989]

The best way of insuring that nickel(II) will have a coordination number greater than four, and thus be paramagnetic, is to create positive charge(s) on the porphyrin ring. Such is the case for both N-alkyl- or N-arylporphyrins as well as the thia-, selena- or carbaporphyrins. In all of these cases, an anion is bound to the nickel(II), which is thereby forced to be 5-coordinate. Latos-Grażyński and coworkers have synthesized and investigated a number of modified macrocycles, where one of the porphyrin nitrogens is replaced by another donor group. These include O, S, Se, NO, N–CH_3 and C. In each case, the modified macrocycle carries an overall charge of −1, so an anion is always bound to one of the axial positions of the metal. Furthermore, since the hybridization of the unique heteroatom is different than that of the "aromatic" nitrogens of the porphyrin, there is always a distortion in the bond angle of the metal-heteroatom bond that distorts the macrocycle from planarity. The first of these studies involved the preparation of the chloronickel(II) complexes of *N*-methyltetraphenyl porphyrin and *N*-methyloctaethylporphyrin.[230] For the N-MeTPP complex, the three types of pyrrole-H from unmodified pyrrole rings are found at +68.2, +72.6 (adjacent pyrrole rings) and +33.7 ppm (opposite pyrrole ring) (in $CDCl_3$ at −60 °C), while the N-methyl pyrrole ring pyrrole-H is found at −9.8 ppm. Pseudocontact shifts of +6.7 to +7.7 ppm, which arise from a zero-field splitting (Eq. 10) were calculated for the pyrrole-H resonances using Eq. 22, which indicates that the majority of the observed shifts are due to the contact interaction. The large positive contact shifts observed at the β-pyrrole positions of the unmodified pyrrole rings are consistent with population of the $d_{x^2-y^2}$ orbital, while the negative contact shifts of the N-methyl pyrrole β-H suggests some π spin density in that pyrrole ring. Multiple phenyl-H resonances are found in the +12.7 to +2.4 ppm range. The N–CH_3 signal is found at +177.8 ppm.[230] Geometric factors for the N-methylporphyrin complexes of $Ni^{II}Cl$ were also reported.[230]

For [(N-MeOEP)NiCl] the pattern of observed shifts is consistent with the conclusions reached above: –CH_2 resonances are observed at +39.0, +34.6, +23.6, +18.8, +16.4, +13.9, +11.7 and +3.0 ppm, while *meso*-H resonances are observed at −15.2 and −20.1 ppm in $CDCl_3$ at −60 °C, and the N–CH_3 resonance is observed at +190.2 ppm. The negative shift of the *meso*-H was explained in terms of spin-orbit mixing of the d_{z^2} and $d_{x^2-y^2}$ unpaired electrons with the d_{xz} and d_{yz} orbitals, which could introduce π spin density at the *meso* positions,[230] as had been suggested earlier.[2] The same explanation could account for the difference in shifts of

the pyrrole-H in the two pyrrole rings adjacent to that carrying the methyl group. However, as pointed out earlier,[4] it seems unlikely that spin-orbit coupling could account for such large differences in contact shift, and therefore another explanation should be found. Thermal population of a $(d_{xy})^2(d_{z^2})^2(d_{x^2-y^2})^2(d_{xz},d_{yz})^2$ excited state, discussed below for the dioxoporphyrin, was suggested not to be an option because of the strict adherence of the shifts to Curie law behavior, Eq. 11.[4] Now, with the explanation of Cheng *et al.*,[156] we can interpret the *meso*-H shifts and the small π spin delocalization to the pyrrole positions as being fully consistent with the 5-coordinate chloronickel(II) center, where overlap of the half-filled d_{z^2} orbital with the $3a_{2u}(\pi)$-like filled orbital of the macrocycle can allow P $\rightarrow$ Fe π donation to the d_{z^2} orbital. The chemical shifts of the porphyrin protons of all modified macrocycle complexes of chloronickel(II) are summarized in Table 17.

Treatment of [(NMeTPP)NiCl] with deuterated aryl Grignard reagents yields the deuterated σ-aryl complexes of nickel(II).[990] At −70 °C in toluene, these complexes have fairly similar (except for the pyrrole-H in the ring opposite the N-methyl) pyrrole-H (+72.6, +52.0, ~ −0.7 ppm) and N-methyl β-H (−21.5 ppm) chemical shifts to those of the starting chloro complex (+75.7, +70.1, +30.3 ppm and −14.2 ppm, respectively), and the phenyl-D resonances are all very large and positive (+568 (*o*), +148 (*m*), +62.8 (*p*) ppm, which indicates mainly σ delocalization to the aryl ring. These patterns are similar to those of the corresponding thiaporphyrin complexes, discussed below.

The nickel(II) thiaporphyrin complex, [(STPP)NiCl], has a similar pattern of pyrrole-H and phenyl-H resonances to that of the N-MeTPP analog. Pyrrole-H resonances were assigned using NOE difference spectral methods, and it was shown that, for the three unmodified pyrrole rings, as one moves away from the thiophene ring the pyrrole-H shifts are +64.6, +32.5 and +30.9 ppm, while the thiophene β-H resonance appears at −29.8 ppm at 298 K in $CDCl_3$,[991] as shown in Figure 78. Replacement of the chloride ion by bromide or iodide decreases the magnitude of the observed shifts of the pyrrole-H and thiophene-H, which is consistent with the expectation that the pseudocontact contribution is dependent on the zero-field splitting created by the particular halide. In DMSO and methanol the chemical shifts of the pyrrole-H are increased (+67.7, +35.9, +56.3 ppm and +68.5, +36.0 and +57.0 ppm, respectively), especially that of the protons in the pyrrole ring opposite the thiophene ring. In the same solvents, the chemical shift of the thiophene β-H become smaller in magnitude (−23.4 and −22.0 ppm, respectively). In $CDCl_3$ with varying amounts of added *n*-butylamine, two species are observed, with pyrrole-H resonances at +63.9, +31.7, +35.6 ppm (1:1 mole ratio) and +64.5, +32.2, +42.0 ppm (1:4 mole ratio), respectively, and thiophene β-H resonances at −26.7 and −25.5 ppm, respectively. Because of the similarity in the shifts of the second *n*-butylamine complex to those observed in DMSO and methanol, it is probable that

Table 17. Chemical shifts of chloronickel(II) modifed porphyrins.

Modifed porphyrin	Solvent	T, °C	Pyrrole-H or $-CH_2$	Modified ring-H or $-CH_2$	Phenyl-H or *meso*-H	Ref.

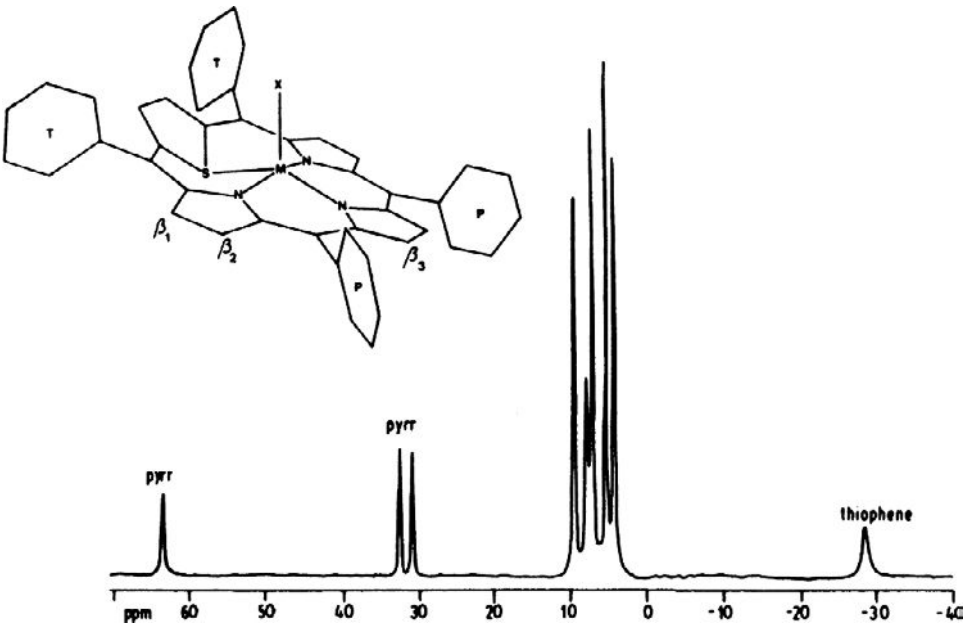

Figure 78. ^{1}H NMR spectrum of [(STPP)NiCl] in $CDCl_3$ at 298 K. Reprinted from Chmielewski, P. J.; Latos-Grażyński, L.; Pacholska, E. *Inorg. Chem.* **1994**, *33*, 1992–1999, with permission from the American Chemical Society.

all three of these are bis-ligand complexes with the halide displaced. Addition of N-methylimidazole also appears to form both mono- and bis-ligand complexes that are in fast exchange with each other and the starting material.[991] Consistent with the importance of a fifth ligand in creating the high-spin state, removal of the halide ion by treatment with $AgClO_4$ yields a diamagnetic thiaporphyrin complex. The chemical shifts of porphyrin protons are summarized in Table 17.

Use of Fenske-Hall calculations to investigate the molecular orbitals of the thiaporphyrin revealed that the extra lone pair on the sulfur creates an extra set of π-symmetry orbitals, where the former $a_{1u}(\pi)$ and this additional π orbital are transformed into two new orbitals, one of which can interact directly with $d_{x^2-y^2}$ when the thiophene ring makes a 30° angle with the plane of the three pyrrole rings.[991] This orbital has extremely large spin density at the sulfur, large π spin density at the β-H of the thiophene ring, and varying spin density at the three unique pyrrole β–H positions, as shown in Figure 79. Thus, this π delocalization, plus the large σ delocalization expected at the pyrrole positions due to population of the $d_{x^2-y^2}$ orbital, account for the pattern of contact shifts observed for the pyrrole-H.[991]

Treatment of [(SDPDTP)NiCl] (SDPDTP = 5,20-diphenyl, 10,15-ditolyl-21-thiaporphyrin) with deuterated aryl Grignard reagents yields the σ-aryl complexes

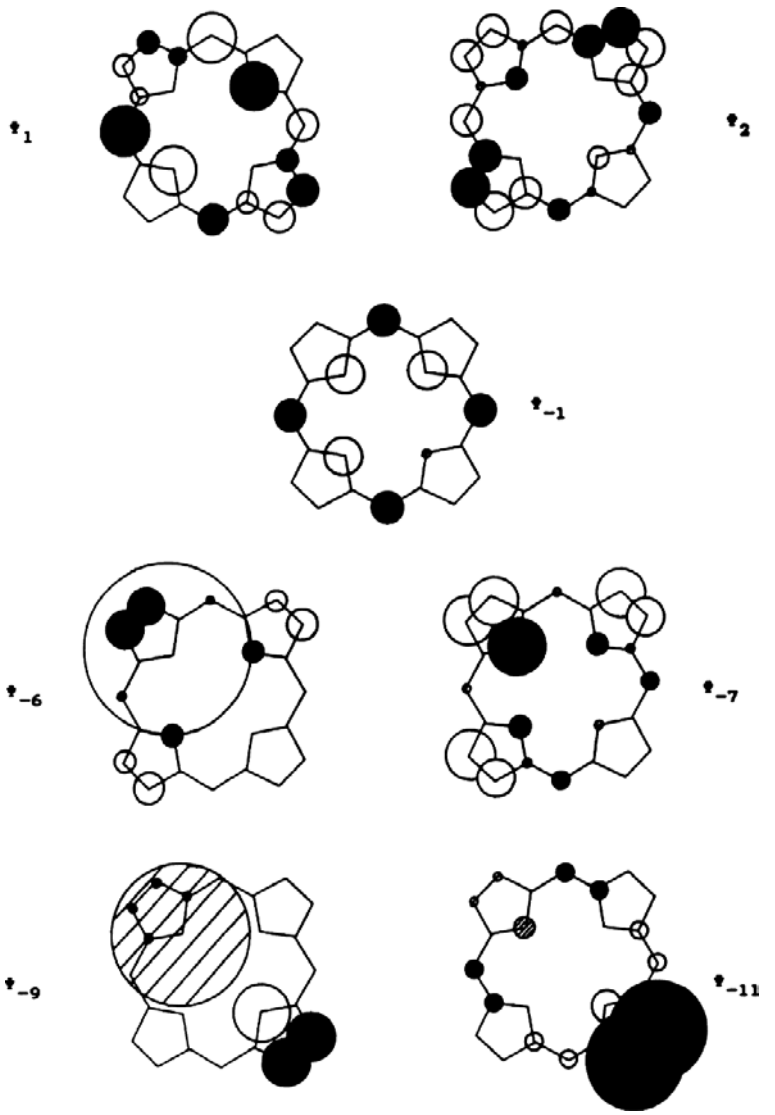

Figure 79. Molecular orbitals of the 21-thiaporphyrin ring, showing the two sulfur π orbitals (cross-hatched circles for φ_{-9} and φ_{-11}, large empty and filled circles for φ_{-6} and φ_{-7}); φ_{-9} can interact in a sigma fashion with the $d_{x}2_{-y}2$ orbital. Reprinted from Lisowski, J.; Latos-Grażyński, L.; Szterenberg, L. *Inorg. Chem.* **1992**, *31*, 1933–1940, with permission from the American Chemical Society.

of nickel(II).[990] At −70 °C in toluene, these complexes have similar (except for the pyrrole-H in the ring opposite the thiophene) pyrrole-H (+87.0, +35.4, ~+2 ppm) and thiophene β-H (−58.0 ppm) chemical shifts to those of the starting chloro complex (+97.6, +46.4, +41.7 ppm and −56.4 ppm, respectively), and the phenyl-D

resonances are all very large and positive (+616 (*o*), +170 (*m*), +76 (*p*) ppm, indicating mainly σ delocalization to the aryl ring.[990] These patterns are similar to those of the corresponding N-MeTPP complexes mentioned above.

Single-electron reduction of [(STPP)NiCl] yielded complexes that could be formulated in terms of the contribution of two canonical forms: nickel(I) thiaporphyrin and nickel(II) thiaporphyrin anion radical.[992] The resonances were assigned by preparation of the deuterated complexes, either [(d_6-STPP)NiCl] or [(d_2-STPP)NiCl]. The three pyrrole-D resonances were found to be at −66.5, +28.8 and +23.7 ppm, while the thiophene-D resonance was at +41 ppm at 298 K in toluene.[992] Addition of a ligand to the axial position of nickel(I) caused a shift of the negative pyrrole-D resonance to higher shielding, to −8.3 ppm for the SO_2 adduct and −43.3 ppm for the $PMePh_2$ complex. The other resonances, if observed, were less affected by the presence of the axial ligand.[992] A combination of σ and π delocalization mechanisms were considered to account for the paramagnetic shift pattern. ^{61}Ni enrichment of [(STPP)Ni] yielded the nickel hyperfine coupling constants for the complex, whose g-values are consistent with a nickel(I) $d_{x^2-y^2}$ unpaired electron ($g_1 = 2.109$, $g_2 = 2.039$, $g_3 = 2.031$).[992]

The corresponding selenaporphyrin complex, [(SeDPDTP)NiCl], where DPDTP = diphenyldi-*p*-tolylporphyrin, has similar pyrrole-H and selenophene β-H chemical shifts (+68.3, +40.2, +17.1 and −38.7 ppm, respectively)[993] which show small shifts on addition of one or two (or more) equivalents of imidazole. In this case the bis-(imidazole) complex is considerably more stable than in the thiaporphyrin case, and thus limiting chemical shifts of the coordinated ligand could be obtained for the N–H, 2-, 4- and 5-H at 298 °C in $CDCl_3$ (+71.0, +55.3, +59.2, +49.6 ppm, respectively). All of these shifts are indicative of a major role of σ delocalization to the axial imidazoles. Addition of an aryl Grignard to this chloride complex produces the corresponding Ni-phenyl complex,[994] which has similar pyrrole-H and selenophene β-H shifts to those of the corresponding 21-thiaporphyrins, except for the pyrrole-H opposite to the selenophene ring. Whereas the thiaporphyrin phenylnickel(II) complex has that pyrrole-H resonance at +2.5 ppm, the corresponding selenophene complex has it at −15 ppm at 203 K in toluene.[994]

The corresponding 21-oxaporphyrin complexes, [(ODPDTP)NiCl] and [(ODPDTP)NiPh] have also been reported.[994] While the chloride complex shows quite similar pyrrole-H chemical shifts (+84.5, +24.8 and +81.6 ppm) to those of the N-MeTPP analog,[230] the furan β-H are observed at +40.1 ppm, rather than at −21.5 ppm as in the N-MeTPP case. For the phenyl complex, the β-H in the pyrrole ring opposite the modified ring have a chemical shift of −13.1 ppm, similar to that observed for the selenophene ring of the corresponding Se-substituted macrocycle, but the furan β-H resonance is again uniquely at a positive chemical shift (+30.0 ppm).[994] The dichloro- and dicyanonickel(II) complexes of

21,23-dioxatetraphenylporphyrin have also been reported and show positive shifts for both pyrrole and furan β-H (+64.1, +41.8 ppm and +36.6, +26.7 ppm, respectively), while the diphenyl complex shows very negative chemical shifts for these two types of macrocyle β-H (−143.1, −31.6 ppm, respectively) at 243 K in toluene-d_8.[995] The authors propose that there is a change in the electron configuration from $(d_{xy})^2(d_{xz},d_{yz})^4(d_{z^2})^1(d_{x^2-y^2})^1$ (as usually observed for high-spin nickel(II)) to $(d_{xy})^2(d_{z^2})^2(d_{x^2-y^2})^2(d_{xz},d_{yz})^2$, where the two unpaired electrons are each in one of the two d_π orbitals. Consistent with this, the phenyl-H resonances appear at +5.5 (*o*) and −4.5 (*m*) ppm.[995] This change in electron configuration seems quite extreme, and it may well be that the normally-expected electron configuration, together with macrocycle to Ni π donation to the half-filled d_{z^2} orbital,[156] even in this 6-coordinate Ni^{II} center, where the metal may be out of the plane of the four nitrogens, represents the actual situation. Warming these diphenylnickel(II) complexes resulted in their decomposition to nickel(I) species that have typical g-values of a d^9 system (2.411, 2.161, 2.049 for the phenyl complex in THF and 2.298, 2.140, 2.093 for the chloride complex). NMR signals could not be observed for these species.[995]

The nickel(II) complex of the "frustrated" porphyrin, 2-aza-5,10,15,20-tetraphenyl-21-carbaporphyrin ($CTPPH_2$) and its C-21-methyl analog have been prepared.[996] The C-21-methyl analog has been characterized structurally and contains a carbon-nickel bond, with the geometry about the carbon being very close to tetrahedral. The complex is diamagnetic. If the 2-N is also methylated, a paramagnetic complex (2-NCH_3-21-CH_3CTPP)NiCl is formed.[996] This complex shows seven separate pyrrole-H resonances when deuterated methyl bromide is used to prepare the di-CD_3 labeled complex.[996] The chemical shifts of pyrrole-protons are summarized in Table 17. Treatment of this dimethyl complex with phenyl Grignard reagents, phenyllithium created the Ni^{II}-σ-phenyl complex, which is high-spin.[997] One-electron reduction with excess PhLi yields [(2-NCH_3-21-CH_3CTPP)Ni^{II}Ph]$^-$, in which the macrocycle has become a π-anion radical. The presence of two paramagnetic centers in this complex produces remarkable variations in spectral patterns, including pyrrole resonances at both low and high shielding (+103.8, +96.7, −25.4, −51.0, −92.2, −114.8 ppm, and sign alternations of the *meso*-phenyl resonances (*ortho* −77.8, −79.3 ppm; *meta* +48.8, +48.0 ppm, *para* −85.7, −86.5 ppm, all at 253 K.[997] Different products are obtained with n-BuLi.

As a variation on the theme of porphyrin macrocycles with different donor atoms to the metal, the *meta*- and *para*-benziporphyrins have been investigated.[998–1000] These are macrocycles where one pyrrole ring has been replaced by either a *meta*- or a *para*-bound benzene ring. The *para*-bound macrocycle does not bind metals, but the *meta*-bound macrocycle, with a CH pointing in the same direction as the N of a typical porphyrin or the CH of the N-confused porphyrin discussed above, does react with Ni^{II} to produce 5-coordinate $Ni^{II}Cl$ complexes that have the 22-H

at about +205 ppm.[998] It appears that the H of the 22-CH can be removed so that the metal can form a diamagnetic 4-coordinate complex with the metal, but that upon HCl addition the complex becomes 5-coordinate and paramagnetic, with an H bound to the 22-carbon.[999]

As another variation on the theme of porphyrin macrocycles with different donor atoms to the metal, the coordinating properties of acetoxy-*meta*-benziporphyrin, (TPBPOAc)H have been investigated for a number of metal ions.[1001] Insertion of Ni, Pd and Fe results in the cleavage of the acetoxy group to yield complexes (TPBPO)M^{II} or $M^{III}X$, but no cleavage if M = Zn or Cd. The TPBPO ligand has one phenolate oxygen which can act as a ligand to the metal. The Pd^{II} and Ni^{II} complexes are 4-coordinate and diamagnetic, while the Fe^{III} complex is high-spin and 5-coordinate. Upon reaction with acetyl chloride the phenolate oxygen is again esterified and the Ni^{II} takes on a distorted 4-coordinate geometry with chloride as the fourth ligand. This complex is paramagnetic, with pyrrole-H resonances at about +65, +55 and +23 ppm.

As a final variation on the theme of porphyrin macrocycles with different donor atoms to the metal, the coordinating properties of the tetraaryl-21-vacataporphyrin (butadieneporphyrin, or annulene-porphyrin hybrid), which contains a vacant site instead of a heteratomic bridge, has been synthesized and its Zn, Cd and Ni complexes investigated.[1002] Two isomers can be made, with the cis-butadiene inside or outside the center of the macrocycle. Both isomers can form complexes with Ni^{II} in which one chloride ion is also bound to the metal. A 6-coordinate bis-imidazole complex can also be made; both are paramagnetic, with resonances extending from the diamagnetic region to about +67 ppm at 298 K.[1002] All of this work has been reviewed recently.[1003]

The EPR spectrum of the one-electron oxidized form of nickel(II) octaethylcorrole has been reported. The spectrum is axial with $g_{\perp} = 2.02$ and $g_{\parallel} = 2.00$,[983] which is suggestive of a π-radical of nickel(II), as proposed previously,[1004] although a g-value of 2.02 is very large for a carbon-centered unpaired electron. Either a d_{xy} unpaired electron for nickel(III) or the dioxygen complex of the d^7 nickel(III) center are also possible.

Electrolysis of 0.5 equivalents of the nickel(II) corrole produced $[(OECorr)Ni]_2^+$, whose EPR spectrum showed similar g-values but was broader than that of the monomeric nickel(III) complex.[983] Neither of these complexes has been characterized by NMR spectroscopy.

G. Lanthanide Porphyrins

The success of lanthanide, Ln^{III}, complexes as "shift reagents" for simplifying second-order NMR spectra of organic compounds with O or N functional groups,[1005,1006]

the extension of "shift reagent" techniques to the determination of the conformation of molecules, including biomolecules, in solution,[1007] and the use of other lanthanide ions as "broadening reagents,"[1008] especially in magnetic resonance imaging (MRI) applications, to increase contrast in images of tissues, has inevitably led to the preparation and investigation of lanthanide and actinide porphyrins. Because the oxidation state of stable lanthanide ions is typically +3, an anionic axial ligand is needed. Because of the higher coordination number preference of lanthanide ions, bidentate anionic ligands such as acylacetonate ($acac^-$) are often bound, or else a diporphyrin-$Ln^{III}H$ or di-Ln^{III}-triporphyrin "triple decker" complex is formed. Yet another means of satisfying the coordination desires of the lanthanide(III) ions is to used the "expanded porphyrin" texaphyrin, Structure **17**, along with two anionic ligands.

Lanthanide(III) porphyrin complexes were reported by Horrocks and coworkers,[1009,1010] for the [(TPP)Ln(acac)] complexes where Ln = Pr (f^2) to Lu (f^{14}). The aryl proton resonance shifts were found to be consistent with a dominant pseudocontact interaction with the metal atom situated significantly out of the porphyrin plane by ~1.6–1.8 Å (fit using the chemical shifts of the aryl protons) for the Yb^{III} and Eu^{III} complexes, respectively. The β-diketonate proton resonances are shifted to higher shielding, while the pyrrole-H resonance is usually shifted to lower shielding.[1010] The resonance shifts of the Yb^{III} complex are linear in 1/T with nonzero intercepts. Several of these complexes serve as "shift reagents" toward heterocyclic amines and alcohols, and it is believed that two of these ligands can bind on the same side as the β-diketonate, due to the large displacement of the metal from the porphyrin plane. The lutetium(III) complex is diamagnetic, and serves as a "ring-current" shift reagent to higher shielding, while ytterbium(III), erbium(III) and thulium(III) yield sizable shifts to lower shielding, terbium(III), dysprosium(III) and holmium(III) yield sizable shifts to higher shielding and praseodymium(III), neodymium(III), samarium(III) and europium(III) yield only small shifts of the "substrate" protons to lower shielding. In all cases, the direction of the shifts of the "substrate" were the same as those of the TPP protons, which suggests that the systems have effective axial symmetry on the NMR time scale, and, on average, the "substrate" occupies the equatorial region, where $(3\cos^2\theta - 1)$ is negative.[1010] Horrocks and Hove reported the preparation and NMR study of water-soluble lanthanide porphyrins based on tetra-*p*-sulfonatophenylporphyrin, $TPPS^{6-}$.[1011] Buchler and coworkers[1012,1013] and Machida and coworkers[1014–1016] reported the synthesis of diporphyrin sandwich compounds of cerium(IV) of the type [$(OEP)_2Ce$], [$(TPP)_2Ce$] (and a number of *p*-substituted derivatives of TPP) and [(TPP)(OEP)Ce]. The diamagnetic "double decker"' metallotetraphenylporphyrin complexes have the pyrrole-H resonance at 8.1–8.3 ppm for the neutrally-charged complexes in $CDCl_3$, and the *o*-H at 9.3–9.4 and 6.2–6.3 ppm for the "outside" and "inside" phenyl protons, and the *m*-H at more variable positions, depending on *p*-phenyl substituent, but again differing by up to

1.2 ppm, with the "inside" *m*-H at higher shielding (smaller chemical shift) than the "outside" *m*-H.[1012] The [$(OEP)_2Ce$] complex has the *meso*-H resonance at 9.11 ppm, the *exo*-CH at 4.20 ppm, the *endo*-CH at 3.86 ppm, and the $-CH_3$ at 1.68 ppm.[1017]

Two cofacial porphyrins, with 1,8-bis[5-(2,8,13,17-tetraethyl-3,7,12,18-tetramethyl)porphyrin]anthracene, DPA^{4-}, and 1,8-bis-[5-(2,8,13,17-tetraethyl-3,7,12,18- tetramethyl) porphyrin]biphenylene, DPB^{4-}, have been synthesized, and their dilutetium(III) complexes prepared.[1018] A crystal structure shows that the lutetium(III) ions are bridged by two hydroxides, and a methanol molecule is also bound to one of the lutetium(III) centers. These complexes are diamagnetic and have all resonances in the −1 to +10 region of the NMR spectrum.

Buchler and coworkers prepared the first di-lanthanide triple-decker molecules,[1017] in which two lanthanide(III) ions are bound to three porphyrins. The diamagnetic La^{III} complex [$(OEP)_3La_2$] has the external OEP resonances at +8.19 ppm (*meso*-H), $-CH_2$ resonances at +3.72 and +3.37 ppm, and $-CH_3$ resonance at +0.95 ppm, and the internal OEP resonances at +8.13 ppm (*meso*-H), $-CH_2$ at +4.09 ppm, and $-CH_3$ at +2.59 ppm, while the paramagnetic Ce^{III} complex has the external OEP resonances at +3.47 ppm (*meso*-H), $-CH_2$ resonances at +0.72 and −0.15 ppm and $-CH_3$ resonance at +2.08 ppm, and the internal OEP resonances at −8.12 ppm (*meso*-H), $-CH_2$ at −5.33 ppm and $-CH_3$ at −5.00 ppm. Thus the paramagnetic shifts of all resonances except the external $-CH_3$ are indicative of the mainly pseudocontact nature of the shifts.

A series of lanthanide complexes of texaphyrin, Structure **17**, have been synthesized and investigated by NMR spectroscopy.[1019] The complexes studied had the formula [$(Tx)Ln(NO_3)_2$], where Ln = Ce, Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er, Tm and Yb. The ^1H resonances were assigned on the basis of 1D NOE, COSY and ROESY experiments, as well as line width and paramagnetic shift analysis. No reports of lanthanide porphyrin NMR studies have appeared since 1999.

H. Miscellaneous Metalloporphyrins which Have Extremely Broad Lines

1. *Copper(II) and Silver(II) Porphyrins*

As discussed in Section II.B.2.a, the electron configuration d^9 is one for which there are no low-lying excited states to which the ground state is connected by spin-orbit coupling (as is the case of low-spin d^5 and d^7), and thus ions with this electron configurations have long T_{1e}s,[93] well-resolved EPR spectra and poorly-resolved NMR spectra. Both of these metals have the single unpaired electron in the $d_{x^2-y^2}$ orbital, with $g_\parallel = 2.169$, $g_\perp = 2.062$ for [$(EP)Cu^{II}$][1020] and $g_\parallel = 2.104$, $g_\perp = 2.029$ for [$(DPDME)Ag^{II}$].[1021] To our knowledge, no proton NMR spectra (other than those of phenyl ring substituents of TPP derivatives,[2,4,164]) of these metalloporphyrins have been reported to date. Deuterium substitution at the pyrrole positions of

(TPP)Cu^{II}, and *meso* and β-CH_2 of (OEP)Cu^{II} and $-Ag^{II}$ has permitted detection of the β-pyrrole substituent resonances, as shown in Figure 80 for the copper(II) complexes. The extremely broad (1.15 kHz) pyrrole-D resonance of [(d_8-TPP)Cu^{II}][164] suggests that the ^1H resonance could be as broad as 48 kHz! The chemical shift at 25 °C is about +41 ppm, consistent with σ delocalization of the $d_{x^2-y^2}$ unpaired electron, and gives us an estimate of the positive contact shift contribution from a single unpaired electron in the $d_{x^2-y^2}$ orbital for a +2 metal. The *meso*-D and β-pyrrole $-CD_2$ resonances of [(d_{20}-OEP)Cu^{II}] are found at −6.2 ppm and +11.5 ppm, respectively, at 25 °C, while those of [(d_{20}-OEP)Ag^{II}] are found at −15.1 and +17.3 ppm, respectively. The $-CD_2$ resonance is about 103 Hz wide, suggesting that the $-CH_2$ resonance could be up to 4.3 kHz wide. However, in retrospect, the $-CH_2$ resonance of [(OEP)Cu^{II}] was found to be barely detectable, Figure 80, now that it is known where to look, and it is not nearly as broad as predicted by the ratio of 42. The pyrrole-D resonance of [(d_8-TPP)Ag^{II}] could not be detected.[164]

The *meso*-D shift to higher shielding, unlike those of 5-coordinate high-spin iron(III) porphyrins (Section IV.A.6.a) and 6-coordinate high-spin nickel(II) porphyrins (Section IV.F),[156] is counter-intuitive, and may represent polarization of the π-symmetry paired spin by the $d_{x^2-y^2}$ unpaired electron;[164] at least it is fairly small. The copper(II) complex of the thiaporphyrin, (STPP), has been prepared and examined by NMR spectroscopy.[992] The pyrrole-D resonances are observed at +49.9, +38.5 and +29.6 ppm, and the thiophene-H resonance at −9 ppm for the 5-coordinate [(d_6-STPP)CuCl] at 298 K in toluene solution. The phenyl resonances are clustered around 7.5 ppm, and they show the shift pattern typical of π delocalization: *meta*-H to lower shielding, *ortho*- and *para*-H to higher shielding with respect to their diamagnetic resonances.[992]

One-electron oxidation of [(d_8-TPP)Cu^{II}] and [(d_{20}-TPP)Cu^{II}] produces complexes in which the pyrrole-D signal appears at +13.4 ppm and the *o*, *m* and *p*-D resonances are at −4.9, +15.8 and −1.01 ppm, respectively.[164] The pyrrole-D resonance is considerably sharper (~ +220 Hz) than for the parent complex. The alternating pattern of phenyl-D shifts suggests that this complex has an $a_{2u}(\pi)$ unpaired electron. In contrast, study of [(d_{20}-OEP)Cu^{III}]$^+$ and [(d_4-OEP)Cu^{III}]$^+$ showed the β-pyrrole-CH_2 resonance to be at +17.1 ppm and the *meso*-D at −4.1 ppm, which suggested to the authors that in this case the electron has been removed from the $a_{1u}(\pi)$ orbital.[164] It is also possible that, if the complex is 5-coordinate, there may be delocalization from the $a_{2u}(\pi)$ orbital to the half-filled d_{z^2} orbital.[156]

Aggregation of copper(II) porphyrins under various conditions has been investigated in detail by EPR spectroscopy.[1022] The close proximity of the two copper centers in the aggregated forms produces not only a $m_S = \pm 1$ allowed transition in the 3100–3300 G region of the X-band EPR spectrum, but also a $m_S = \pm 2$ "double quantum" spin-forbidden transition at half the magnetic field, near 1500–1600 G.[1022]

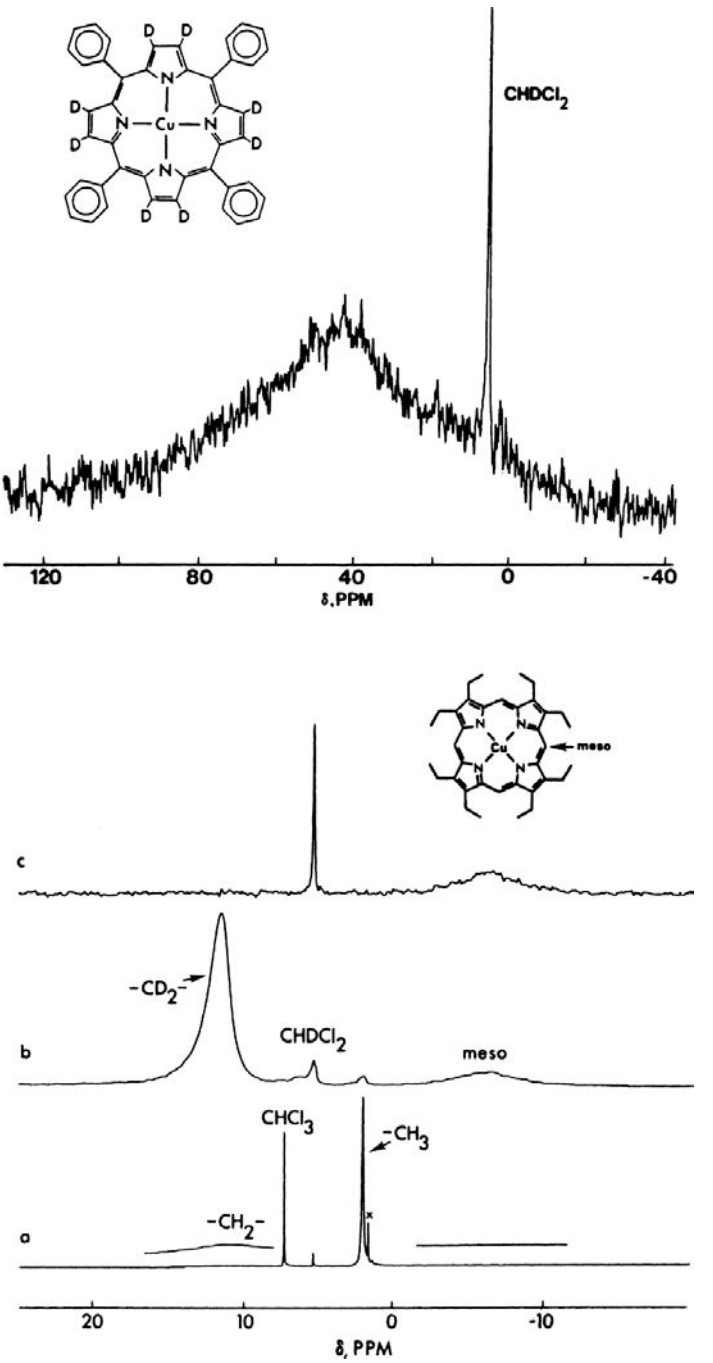

Figure 80. Top: ^{2}H NMR spectrum of [(d_8-TPP)Cu] in CH_2Cl_2 at 25 °C. Bottom: Proton and deuterium NMR spectra of (OEP)Cu: (a) proton NMR spectrum of [(OEP)Cu] in $CDCl_3$; (b) deuterium NMR spectrum of [(d_{20}-OEP)Cu] in CH_2Cl_2; deuterium NMR spectrum of [(d_4-OEP)Cu] in CH_2Cl_2, all recorded at 25 °C. Reprinted from Godziela, G. M.; Goff, H. M. *J. Am. Chem. Soc.* **1986**, *108*, 2237–2243, with permission from the American Chemical Society.

Following that publication, several singly- and doubly-bridged dicopper diporphyrins have been synthesized and studied by EPR spectroscopy to determine the geometry of the dimeric porphyrin.[1023] The distance between the copper atoms in the diporphyrins was determined from the ratio of the intensity of the half-field transitions to the intensity of the allowed transitions and by computer simulation of the spectra. The values obtained by the two methods were in good agreement and ranged from 4.1 to 5.6 Å. The porphyrin planes were parallel within experimental uncertainty. The angle between the interspin vector and the normal to the porphyrin planes (slip angle) was determined by computer simulation of the spectra and values ranged from 20° to 45°. For the majority of the diporphyrins the separation between the porphyrin planes was 3.9 ± 0.1 Å. In an anthracene pillared diporphyrin the interplanar separation was 4.6 Å. The simulations of the spectra indicated that the absolute value of the copper-copper exchange interaction, J, was > 0.3 cm^{-1}.[1023]

2. *Vanadium(IV) Porphyrins*

As is the case for copper(II) and silver(II) porphyrins, vanadyl (VO^{2+}) porphyrins, with a d_{xy}^1 electron configuration also have no low-lying excited states to which the ground state is connected by spin-orbit coupling, and thus ions with this electron configurations have long T_{1e}s,[93] well-resolved EPR spectra and poorly-resolved NMR spectra. Furthermore, unlike copper(II) and silver(II) porphyrins, the g-tensor of vanadyl porphyrins is nearly isotropic.[121,122] Thus extremely small pseudocontact shifts are expected, and in addition, no contact shifts are expected for complexes of this nonruffled metalloporphyrin. The paramagnetic shifts of vanadyl porphyrins are thus expected to be extremely small. Except for several VOTPP entries in Table 32 of Ref. 2, which listed the pyrrole-H and phenyl-H shifts as those expected for diamagnetic porphyrins (Zn(II), Ni(II)), no other reports of proton NMR studies of monomeric vanadyl porphyrins have appeared. However, the preparation and characterization of a π-cation radical derivative of a vanadyl porphyrinate, $[VO(OH_2)(OE\,P^{-\bullet})]SbCl_6$ by chemical oxidation of [VO(OEP)] has been reported, and the formulation has been confirmed by a single-crystal X-ray structure determination.[123] EPR spectra were measured for $[VO(OH_2)(OE\,P^{-\bullet})]SbCl_6$ in the solid (powder) state, in a single crystal, and in fluid and frozen solution. The solution-state EPR spectra of $[VO(OH_2)(OE\,P^{-\bullet})]SbCl_6$ were found to be quite distinct, with vanadium hyperfine lines resolved, and with different spectra in fluid and frozen solution. The solution spectra are identical to those reported earlier by others.[1024–1026] In the solid state, the EPR spectrum of a polycrystalline sample consists of a single broad line with g = 1.99; single-crystal spectra also show vanadium hyperfine-splitting consistent with V–V coupling. The solid-state EPR intensity increases with increasing temperature. $[VO(OH_2)(OE\,P^{-\bullet})]SbCl_6$ was also characterized by a detailed temperature-dependent (6–300 K) magnetic susceptibility study. Satisfactory fits of the temperature-dependent

moments were obtained from a model in which the vanadyl electron is ferromagnetically coupled to the porphyrin π-radical electron ($J_{V\text{-}R} = 63\ cm^{-1}$) and the two radical spins are antiferromagnetically coupled ($J_{R\text{-}R} = -139\ cm^{-1}$). This model also gave a satisfactory prediction of all solid-state EPR properties.[123] The intramolecular ferromagnetic coupling is consistent with the principle of cospatial, orthogonal magnetic orbitals. The intermolecular antiferromagnetic coupling appears to arise from a novel, steplike orientation of pairs of $[VO(OEP^{-\bullet})]^+$ radicals. Unfortunately, no NMR studies of this radical system at ambient temperatures were reported.

3. *Chromium Porphyrins*

Until recently, there was little information about the paramagnetic shifts of chromium(III) porphyrins because of the extreme broadness of the resonances.[2,4,165] However, as discussed in Section II.D.2 and shown in Figure 12, deuterium labeling of several chromium(III) porphyrins has allowed observation of the ^2H resonances of these complexes.[165] The shifts observed for [(d_8-TPP)Cr(OPh-d_5)] at 24 °C are −13.4 ppm (pyrrole-D) and +19, +11.5, +10 ppm (*p*-H, *m*-H, *o*-H, respectively), while the pyrrole-D shift of [(d_8-TPP)CrCl] is −16.7 ppm in THF but −17.5 ppm in $CHCl_3$ and CH_2Cl_2, all at 23–24 °C. Addition of imidazole to a sample in the latter solvent shifts the pyrrole-D to a limiting value of −23 ppm, probably due to formation of a mono-imidazole complex.[165] These shifts are consistent with the expected electron configuration for chromium(III): $(d_{xy})^1(d_{xz})^1(d_{yz})^1$, where the d_{xy} unpaired electron could contribute a maximum of +1–2 ppm shift that will decrease the negative shift expected for the two d_π electrons. (However, the porphyrinate ring of [(TPP)Cr(OPh)(THF)] appears to be planar, with the Cr in the plane of the porphyrin nitrogens,[165] and if the THF remains coordinated in $CHCl_3$ and CH_2Cl_2, then the d_{xy} electron may not provide any delocalization.) Even taking this contribution into account, however, the pyrrole-D shift is not nearly as negative as might have been expected on the basis of the pyrrole-H shifts of low-spin iron(III) porphyrins having the $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration (Figure 19); if the two d_π unpaired electrons each contributed the same as the single d_π unpaired electron of low-spin iron(III), then a chemical shift of about −41 ppm at 25 °C should be expected, assuming no contact contribution from the d_{xy} electron, whereas the observed pyrrole-D shifts range from −13 to −17 ppm for the 5-coordinate complexes. Thus, it appears that at least in this case, two d_π electrons do not lead to significantly greater spin delocalization from the 3e(π) orbitals of the porphyrin ring to the d_π orbitals of chromium(III) than does the one of low-spin iron(III). The temperature dependence of the pyrrole-D resonance of [(d_8-TPP)Cr(OPh)(THF)] in THF solution is strictly Curie in nature, while the intercepts of the phenoxide deuterons deviate somewhat from their predicted diamagnetic shifts in an alternating fashion that suggests some

π spin density is delocalized to the phenoxide axial ligand.[165] In fact, it may be this spin delocalization that decreases the pyrrole-H shift somewhat.

The d^4 chromium(II) porphyrin, [(d_8-TPP)Cr], prepared by one-electron reduction of [(d_8-TPP)CrCl], has a larger negative pyrrole-D shift than any of the chromium(III) complexes mentioned above, –34.9 ppm at 24 °C.[165] The presumed electron configuration is $(d_{xy})^1(d_{xz})^1(d_{yz})^1(d_{z^2})^1$, and the d_{z^2} electron is expected to contribute essentially nothing to the contact shifts, because the Cr^{II} is not expected to be out of the plane of the porphyrin nitrogens.[156] Thus, chromium(II) has a pyrrole-D shift closer to that expected for the chromium(III) analog, and the reason for the difference is not clear. The temperature dependence of the pyrrole-D shift is linear, with an extrapolated shift at infinite temperature of 12 ppm, which suggests only a small contribution from a thermally-accessible excited state.

In the presence of an excess of pyridine, the pyrrole-D resonance shifts to about +12.8 ppm, suggesting a change in electron configuration. A similar shift is observed when imidazole is added.[165] The magnetic moment of the bis-(pyridine) complex of [(d_8-TPP)Cr] is 2.9 μ_B at 23 °C,[376,377] indicating two unpaired electrons.[165] The positive value of the pyrrole-D shift is suggestive of no unpaired electrons in the d_{xz} or d_{yz} orbitals, unless there is an unusually large positive pseudocontact shift for this S = 1 chromium(II) porphyrin that cancels the expected negative contact shift, such as those observed for low-spin d^4 iron porphyrins.[157,832] Additional low-spin chromium(II) porphyrin complexes must be investigated before a complete understanding of the contributions to the paramagnetic shifts can be obtained. The linewidth of the ^{1}H signal of the pyrrole-H is sharp enough[165] that such a study could be done with protonated porphyrin ligands.

An oxochromium(IV) complex has also been investigated. When [(d_8-TPP)CrCl] is reacted with *tert*-butylhydroperoxide at –40 °C, followed by warming, a new ^{2}H signal is observed at +9.2 ppm at 23 °C.[165] However, the hydroperoxide also attacks the porphyrin to produce an isoporphyrin,[165] which makes it difficult to study the diamagnetic d^2 chromium(IV) center in detail. Nevertheless, the fact that the complex is diamagnetic suggests that the electron configuration is $(d_{xy})^2$. This is consistent with the electron configuration of oxovanadium(IV) porphyrins, $(d_{xy})^1$.[121,122] No further reports of NMR studies of chromium porphyrins of any oxidation state have appeared since 1999.

I. Summary of Paramagnetic Shifts and Mechanisms of Spin Delocalization for the Metalloporphyrins

In Table 18 are summarized the magnitudes and directions of contact and pseudocontact shifts for first row transition metal porphyrins, the nature (σ or π) of the contact shifts, and the nature of the pseudocontact contribution for each metal in

Table 18. Summary of spin delocalization patterns of metalloporphyrins of various oxidation and spin states.

each oxidation state and each spin state. As can be seen, for the contact shift, σ spin delocalization to the porphyrin or related macrocycle is seen when there is an unpaired electron in the $d_{x^2-y^2}$ orbital, while π spin delocalization is seen when there is an unpaired electron in the d_{xz} or d_{yz} orbital (or both), or, if the macrocycle is ruffled or saddled, if there is an unpaired electron in the d_{xy} orbital. In every example seen thus far, delocalization of both σ and π spin density occurs by macrocycle to metal electron donation, which leaves a hole or partial hole on the macrocycle, which is readily sensed by the protons (and carbons) of the macrocycle, and it has been estimated that 3% of an unpaired electron in a π orbital of a particular carbon leads to a contact shift of approximately −20 ppm for the proton bound to that carbon. The π-symmetry orbitals most frequently involved in P → M electron delocalization, which give rise to π spin delocalization to the carbons of the macrocycle, are the $3e(\pi)$ orbitals, which have proper symmetry for interaction with the d_{xz} and d_{yz} orbitals of the metal. However, if the macrocycle is ruffled, the $3a_{2u}(\pi)$ orbital has proper symmetry to interact with the d_{xy} orbital (and the $1a_{1u}(\pi)$ orbital has proper symmetry to interact with the $d_{x^2-y^2}$ orbital), while if the macrocycle is saddled, the $3a_{2u}(\pi)$ orbital has proper symmetry to interact with the $d_{x^2-y^2}$ orbital (and the $1a_{1u}(\pi)$ orbital has proper symmetry to interact with the d_{xy} orbital). If the metal is out of the plane of the porphyrin nitrogens (as in a 5-coordinate metalloporphyrin complex), there can be a different means of involving the $3a_{2u}(\pi)$ orbital in spin delocalization, in this case by P → M π donation from the $3a_{2u}(\pi)$ orbital to the half-filled d_{z^2} orbital of the metal (for high-spin d^5, d^6 and d^8); this spin delocalization is prohibited if the complex binds a second axial ligand. A major finding of the past ten years is that there is at this time no evidence for the involvement of the $4e(\pi^*)$ orbitals in spin delocalization for any metalloporphyrin.

V. Acknowledgments

This chapter is dedicated to the memory of Professor Richard Koerner of Pennsylvania State University, whose life ended much too soon, on December 17, 2002, as a result of pneumonia. As an undergraduate in the author's laboratory, Richard did the majority of the work reported in Ref. 419. Richard obtained his Ph.D. at U. C. Davis where he worked with Professor Alan L. Balch on projects referenced in this chapter that involved "deconstructing" the heme ring. He then became a postdoctoral fellow with Professor Richard H. Holm, and went from there to Penn State University in the fall of 2001, where he began his independent career.

The author wishes to thank Dr. Nikolai V. Shokhirev for continually updating and modifying the programs on his website, especially ShiftPatterns, MPorphW and TDFW, so that they are more and more useful to those who wish to analyze the chemical shifts or spin density distributions of metalloporphyrins and related

macrocycles. She also wishes to thank all of her present and former talented coworkers for their positive contributions to the work from this laboratory which is discussed in this chapter, and Mary Sparks, who prepared the structures and tables.

118. MPorphW, an interactive simple Hückel program for Windows, with visualization of the orbitals, their nodal properties and energies is available: http://www.shokhirev.com/nikolai/programs/prgsciedu.html, program MPorphW. The input of this program can be modified to include planar axial ligands, to remove double bonds, atoms, or to change the energy of a

meso-C, to simulate the effect of -OH substitution at a *meso*-C, for example. This program was last updated September 8, **2009**.

460. Baker and Lewis obtained values of 260–270 cm^{-1} for nonheme low-spin Fe(III) complexes (*J. Chem. Soc., Dalton Trans.* **1975**, 598–602). Maltempo has used the value of 300 cm^{-1} for low-spin ferrihemes, while Levin and Brill obtained a value of 350 cm^{-1} for metmyoglobin complexes (*J. Phys. Chem.* **1988**, *92*, 5103–5110). We have used 400 cm^{-1} as the maximum possible value of λ.

30 Heme Acquisition by Hemophores: A Lesson from NMR

Paola Turano

Magnetic Resonance Center (CERM) and Department of Chemistry,
University of Florence, Via Luigi Sacconi 6,
I-50019 Sesto Fiorentino, Italy

List of Abbreviations

Ccm	cytochrome c maturation
CRINEPT	cross-correlated relaxation-enhanced polarization transfer
DPC	dodecyl phosphocholine
HAS	heme acquisition system
HO	heme oxygenase
HSQC	heteronuclear single quantum correlation
LbpA	lactoferrin binding protein A
LbpB	lactoferrin binding protein B
NOESY	nuclear Overhauser effect spectroscopy
PBP	periplasmic binding protein
TbpA	transferrin binding protein A
TbpB	transferrin binding protein B
TROSY	transverse relaxation-optimized spectroscopy

I. Biological Background

Iron is an essential element for virtually all living organisms. It has been reported that the iron content in bacteria is of the order of 10^5–10^6 iron ions per cell.[1] Virtually all living microorganisms require a minimum effective concentration of 10^{-8} M for growth.[2]

Iron ranks fourth in abundance of all elements on the Earth's crust,[3] but its bioavailability is limited. Under aerobic conditions iron(III) is the dominant oxidation state and is characterized by an extremely low solubility (of the order of 10^{-18} M, at pH of 7.4).[4] Iron(II) is more soluble, but available to organisms only in anaerobic environments. In the presence of air, it becomes toxic due to its redox chemistry which leads to the formation of ferric iron and reactive oxygen species.

As a consequence of these considerations, iron in biological systems is found tightly sequestered by high-affinity iron-binding proteins.[5] Bacteria have developed a number of mechanisms to acquire iron, allowing their survival in free iron-poor environments.[1,2,6–8] In Gram-negative bacteria, a number of pathways have been identified which rely (i) on iron ion uptake through siderophores; (ii) on iron ion uptake from transferrin/lactoferrin; (iii) on the use of heme as an iron source through its direct uptake in free form or from heme-binding proteins; and (iv) on the uptake of heme mediated by hemophore proteins. All these processes share common key elements (Figure 1) i.e., an outer membrane receptor, a periplasmic binding protein (PBP), and an inner membrane ATP-binding cassette (ABC) transporter. The transport through the outer membrane receptor requires the action of the TonB system (TonB, ExbB, and ExbD).[8]

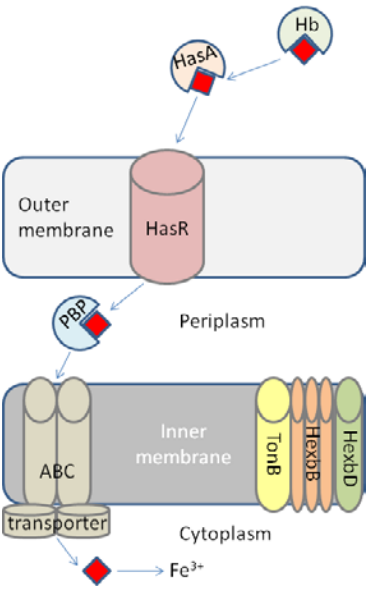

Figure 1. Schematic representation of the key elements of the heme acquisition system in Gram-negative bacteria. The hemophore protein HasA uptakes heme (red diamond) from a host protein (here hemoglobin, Hb) and delivers it to the outer membrane receptor (HasR). The other key components for heme delivery to the cytoplasm and iron abstraction are a periplasmic binding protein (PBP), an inner-membrane ABC transporter, and the TonB system (TonB, ExbB, ExbD). In the cytosol, heme oxygenase or functionally analogous enzymes extract iron(III) from heme.

Siderophores are low molecular weight (MW < 1000 Da) and high affinity ($K_{aff} > 10^{30}$) iron chelators.[9,10] Their biosynthesis is induced by intracellular iron deficiency and they are secreted into the extracellular milieu to scavenge iron. They are able to dissolve insoluble iron(III) species and facilitate its transport into the cell. Siderophores are structurally well characterized and numerous studies are available on the mechanism of the siderophore-mediated iron acquisition system.[11,12]

In vertebrate hosts, only a small amount of iron is extracellular and bound to the glycoproteins transferrin or lactoferrin. In many pathogenic bacteria, such as *Neisseria meningitidis* and *Haemophilus influenza,* extraction of the iron atoms from the host's iron carriers occurs via outer membrane receptors, the TbpB/TbpA and LbpB/LbpA proteins.[13–15] These two-component receptors are constituted by a membrane-anchored binding protein (the B-protein) and an integral membrane protein (the A-protein), specific for transferrin (Tb) and lactoferrin (Lb), respectively.

Nevertheless, in vertebrates, most irons are intracellular, either stored in ferritin or inserted in the protoporphyrin ring of heme-containing proteins, mainly

hemoglobin. Microorganisms can up take the heme either as a free heme (whose concentration in living systems is however very low due to its cytotoxicity) or as heme associated with host hemoproteins (hemoglobin, hemoglobin–haptoglobin, heme-albumin, heme-hemopexin, and myoglobin).[16–18] The uptake relies either on the two-component receptor HpuA/HpuB, an analog of the transferrin/lactoferrin system, which binds hemoglobin, hemoglobin–haptoglobin, and apohaptoglobin, or on the single-component HmbR receptor, specific only for hemoglobin.

The second mechanism that bacteria use to extract iron from heme uses specialized bacterial proteins, termed hemophores.[1,7,19,20] They are extracellularly secreted and acquire heme from the environment, usually extracting it from heme proteins. The hemophore then delivers heme to a specific outer membrane receptor, where the process of heme transport to the cytoplasm initiates and proceeds through the steps common to the other iron-uptake mechanisms described above (Figure 1). The ensemble of proteins involved in the hemophore-dependent process constitutes the heme acquisition systems (HAS). The use of heme as an iron source requires iron abstraction from the heme. This process occurs in the bacterial cytoplasm, where the heme is degraded, through oxidative cleavage, to biliverdin, carbon monoxide, and free iron by the enzyme heme monooxygenase (HO). [21] Non-HO homolog heme degrading enzymes have also been described for some bacteria.[22–25] Very recently two enzymes that promote iron extraction from heme preserving the tetrapyrrole ring intact have been reported.[26]

The focus of this chapter is on the use of NMR to investigate structure and chemistry of some components and key steps of the mechanism of the heme acquisition system in Gram-negative bacteria.

II. Hemophore Protein HasA

A. Heme-Loaded HasA

Under conditions of iron limitation, the Gram-negative bacterium *Serratia marcescens* secretes HasA, a monodomain 19 kDa protein, which acts as a hemophore. This protein was the first hemophore to be discovered and the only one structurally characterized until now. The X-ray crystal structure of the heme loaded form of HasA shows an original $\alpha+\beta$ fold, with a seven-stranded antiparallel β-sheet on one side of the protein and four α-helices on the other side (Figure 2a). Two loops, L1 and L2, connect the α and β faces of the molecule and provide the heme-iron(III) axial ligands, H32 through its Nε2 and Y75 through its Oη. His/Tyr coordination is quite atypical for heme proteins in native states; it has been reported only for the cytochrome c maturation protein (CcmE),[27] and for the oxidized form of the cytochrome cd_1 nitrite reductase.[28] A H-bond between H83 Nε2 and the Y74 Oη was observed in two out of the three crystal structures available

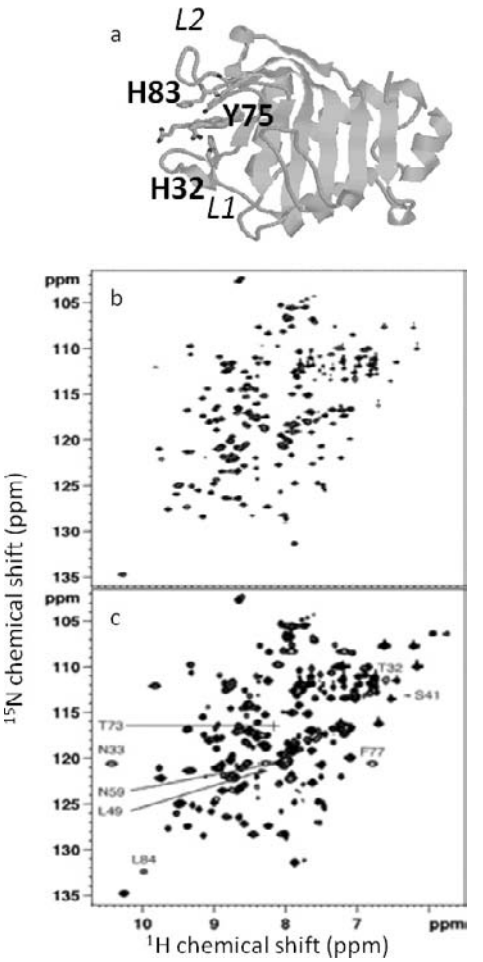

Figure 2. The X-ray crystal structure of holoHasA (PDB ID 1B2V). (a) Loop L1 provides the H32 ligand. Loop L2 bears the Y75 ligand and H83. In this structure an H-bond between Y75 Oη and H83 Nε2 is present. ^{1}H–^{15}N HSQC (b) and paramagnetic tailored ^{1}H–^{15}N HSQC (c) of the holoprotein. A set of peaks (here labeled) due to residues in the proximity of the paramagnetic center is detectable only in the latter experiment. (Panels b and c are adapted from Ref. 33.)

(PDB ID 1B2V at pH 4.6 and PDB ID 1DKO at pH 8.0).[29,30] In the third structure (PDB ID 1DKH at pH 6.5)[30] H83 does not interact with Y75 while it is involved in a hydrogen bond with a water molecule.

In order to learn about the heme-coordination environment in solution and the possible relevance of second coordination sphere interactions on the heme binding properties of HasA, a number of studies have been conducted by NMR.

It is worth mentioning that both X-ray crystallography[29,30] and NMR[31–34] reveal the presence of two orientations, with a relative ratio of the order of 70:30, for the

heme inserted in the hemophore that differ for a rotation of 180° around the α, γ-*meso* axis. This phenomenon, commonly observed in b-type heme proteins,[35–37] results in a doubling of the peaks of the heme resonances, the axial ligands and most of the heme-binding pocket residues. For the sake of clarity, no mention to the presence of the minor species will be made in the remaining of this chapter; all the considerations presented for the major species are assumed to hold equally for the major one as well.

1. *NMR of the Gallium(III) Derivative*

The presence of iron(III) complicates NMR spectral analysis due to the important paramagnetic effects induced by the metal ion on surrounding residues. An initial characterization of HasA in solution was therefore carried out using the gallium(III)-heme derivative as a diamagnetic analog of the holoprotein; gallium(III) and iron(III) have the same charge, similar atomic radius (0.62 Å vs. 0.65 Å) and similar coordination preferences. The backbone assignment of gallium(III)–HasA provided evidence of intact secondary structures with respect to iron(III)–HasA.[32]

$^{1}H–^{15}N$ multiple bond connectivity spectra[38] for the detection of $^{15}N–^{1}H$ correlations via $^{3}J_{NH}$ coupling constants were used to characterize the protonation state of the imidazole ring of His residues in the protein.[39] Patterns of ^{3}J connectivities between non-exchangeable imidazole protons Hδ2 and Hε1 and Nδ1 and Nε2 allowed the identification of all these nuclei for the His residues present in HasA, i.e. H17, H32, H83, H128, H133, and H179. The ^{15}N chemical shifts of the imidazole nitrogens are diagnostic for their protonation state[40–42]: in a fully protonated, positively charged, imidazole ring, both nitrogens resonate on average at 175 ppm; in a neutral imidazole ring, the deprotonated nitrogen typically resonates at about 250 ppm, whereas the protonated nitrogen resonates at about 165 ppm; intermediate chemical shift values are indicative of fast exchange between the two tautomers. Involvement in H bonding affects the above shift values up to 10 ppm: the shift of a nitrogen behaving as an acceptor in a hydrogen bond decreases, whereas that of a nitrogen behaving as a donor increases.

In gallium(III)–HasA, a relatively low chemical shift value was measured for the Nδ1 of H83 (227.3 ppm) and attributed to the involvement of this nitrogen in a hydrogen bond, presumably as an acceptor of the hydroxyl proton Hη of Y75,[39] by analogy with the X-ray data.[29]

2. *NMR of the Iron(III) Derivative*

a. *^{1}H NMR*

Heme methyl chemical shifts in iron(III) provide a signature of the spin state of heme iron.[35] In high-spin iron(III) heme proteins, they resonate in the 60–100 ppm

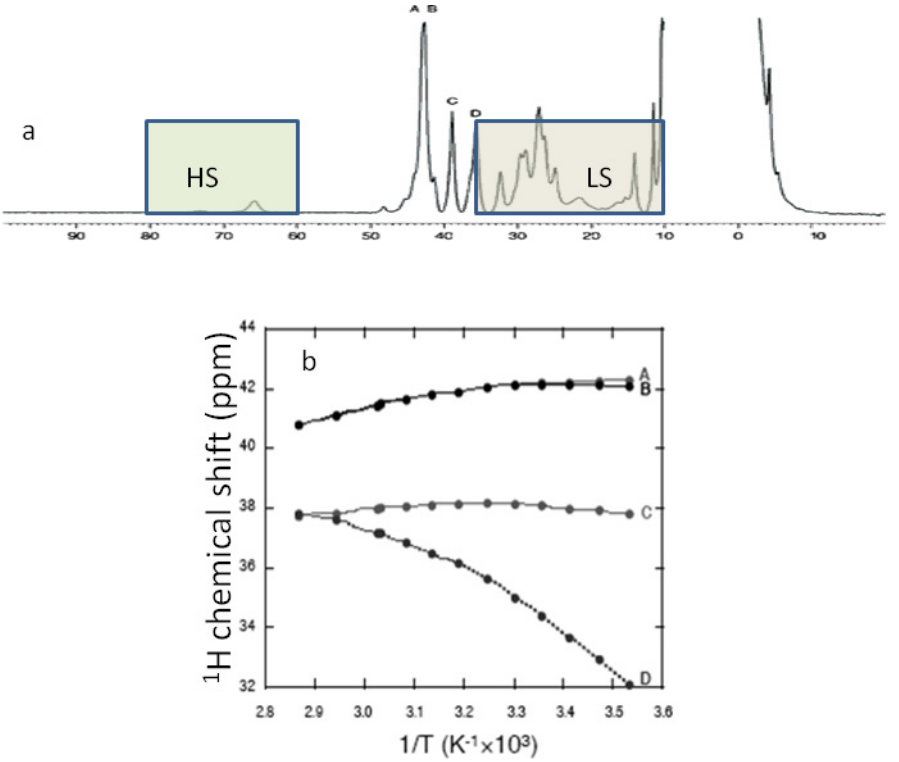

Figure 3. The ^{1}H NMR spectrum of iron(III) heme-loaded HasA recorded at 700 MHz and 303 K (a). The resonances attributed to the heme methyl resonances are labeled A–D. Typical ranges for the chemical shift of heme methyls in high-spin and low-spin iron(III) heme proteins are indicated by the semitransparent boxes. The temperature dependence of the chemical shift for heme methyl resonances does not follow the Curie behavior (b). (Adapted from Ref. 33.)

range. In low-spin iron(III) heme proteins their chemical shifts range between 5 and 35 ppm. In HasA, the heme methyl resonances have chemical shift values intermediate between those expected for a purely S = 5/2 heme iron(III) and those for a purely S = 1/2 heme iron(III),[33] being observed at 42.7 (two overlapping signals at 303 K), 38.9, and 35.7 ppm (Figure 3a). At a field of 16.4 T, heme methyl T_1 values are 8–9 ms, and line widths of the order of 400 Hz. Similar chemical shift and T_1 values have been reported for heme proteins undergoing high-spin/low-spin equilibria, which are fast on the chemical shift NMR time scale.[43,44] The non-linear temperature dependence of the heme methyl chemical shift values (Figure 3b) further supports the nonpure spin nature of heme–iron(III) in HasA.

The relatively low chemical shift (about 70 ppm) for the exchangeable resonance of Hδ1 H32, its large line width (about 1000 Hz) and the short T_1 value (< 2 ms)

are consistent with literature data on intermediate spin state systems.[45] As typical for nonpurely low-spin heme proteins,[35] the Hδ1 of the bound His is the only signal of an axial ligand detectable in the ^{1}H NMR spectra.

b. *Heteronuclear detection*

The sensitivity of NMR experiments depends critically on the type of nucleus that is detected during acquisition, with a $\gamma^{3/2}$ dependence, where γ is the gyromagnetic ratio of the detected nucleus. This translates into a factor of eight in sensitivity at advantage of ^{1}H-detected experiments over ^{13}C-detected experiments, and into a factor of 31 over ^{15}N-detected experiments. Consequently, virtually all modern biomolecular NMR experiments detect protons during acquisition.[46] The sensitivity of the NMR experiment is also dependent on the nature of the excited nucleus, being directly proportional to its γ value. During the last decade, hardware developments, in particular the advent of cryoprobes, have sensibly increased the sensitivity of the NMR experiments. Therefore, while the relative sensitivity of proton detection and heteronuclear detection remains that predicted by theory, heteronuclear-detected NMR experiments can now be brought into a sensitivity range that makes them feasible even for biomolecular applications.

Development of special probes optimized for ^{13}C sensitivity has given a particular impulse to ^{13}C-NMR with respect to ^{15}N-NMR. While 1D ^{15}N-detected experiments on proteins are nowadays possible, they still suffer from very low sensitivity. By contrast, a number of ^{13}C NMR experiments aimed at sequential and side chain assignments in proteins have been developed that exploit the heteronuclear backbone ^{13}C′–^{15}N and ^{15}N–Cα scalar couplings, as well as the large homonuclear carbon–carbon scalar couplings (30–70 Hz) for coherence transfer.[47–57]

This protonless NMR approach has been proposed as particularly useful in systems characterized by short relaxation times.[58–63] The large proton gyromagnetic ratio that is responsible for the high sensitivity of ^{1}H-NMR experiments also causes large dipole–dipole interactions that lead to short relaxation times and may broaden lines beyond detection with increasing molecular mass or in the presence of paramagnetic centers. In this context, heteronuclei, which are characterized by smaller gyromagnetic ratios, may represent probes with better performances.

By taking advantage of the new NMR tools available for the investigation of fast relaxing biomolecules, a better understanding of the coordination environment and electronic structure of the iron(III)–heme loaded HasA was obtained.

i. ^{13}C NMR

^{13}C-NMR permits researchers to learn about the axial coordination of heme iron in holoHasA.[33] Standard ^{1}H–^{15}N HSQC (Figure 2b) experiments provided peaks for

the NH backbone of all residues but the N-terminal one and 15 amino acids located close to the paramagnetic center (they are amino acids 32–34, 41, 42, 50, 60, 74–78, 83–85). With paramagnetic tailored ^{1}H–^{15}N HSQC experiments, which used fast repetition rates and short INEPT delays, the eight peaks corresponding to residues T33, N34, S42, L50, T60, T74, F78, and L85 could be retrieved (Figure 2c); but resonances for H32, N41, Y75, T76, L77, H83, and T84 remained undetectable. ^{13}C-direct detection experiments, in particular ^{13}C–^{13}C COSY and the CACO spectra, provided the assignment of all protein residues beside the two axial ligands H32 and Y75, and L76. Signals of H83 could be detected only in paramagnetic tailored ^{13}C-spectra (Figure 4).

Although ^{13}C experiments are much more robust for paramagnetic systems than the standard assignment strategy based on ^{1}H-detected experiments, the heme axial ligands could only be detected in 1D ^{13}C experiments. The monodimensional ^{13}C spectrum of holoHasA shows well-resolved peaks that are heavily hyperfine shifted. Most of them are observed downfield in the 220–770 ppm region and have T_1 values of the order of 1–13 ms, (Figure 5a). The upfield signals at −22 and −32 ppm have

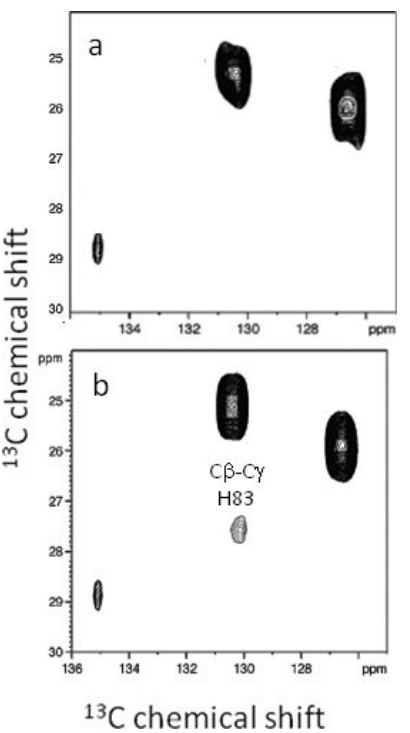

Figure 4. Portion of the ^{13}C–^{13}C COSY spectrum of the holoprotein containing the Cβ–Cγ cross peaks for His residues (a) and its paramagnetic tailored version (b). The Cβ–Cγ correlation for H83 is only detectable in the latter spectrum. (Adapted from Ref. 33.)

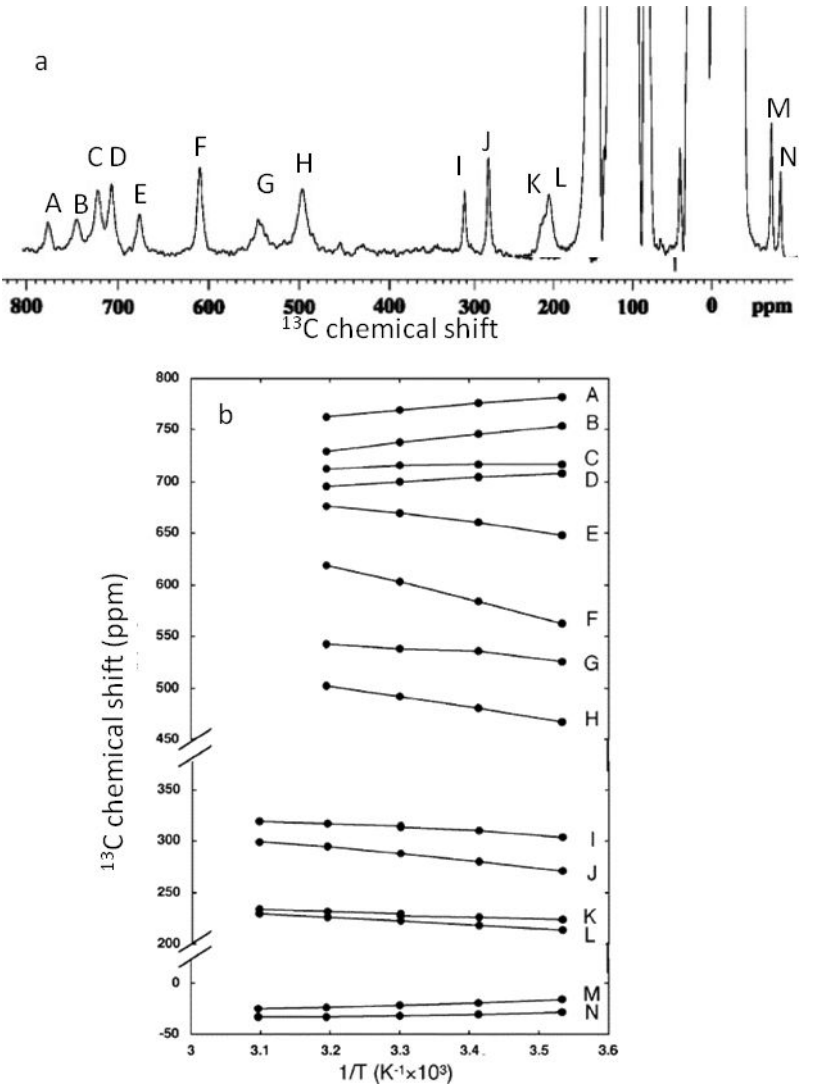

Figure 5. The ^{13}C NMR spectrum of iron(III) heme-loaded HasA recorded at 700 MHz and 303 K (a). The hyperfine-shifted resonances are labeled A–N. Resonances attributed to Y75 have shifts that decrease with temperature, while resonances attributed to H32 have shifts that increase with temperature (b). (Adapted from Ref. 33.)

longer T_1 values (in the 70–90 ms range). The chemical shift, T_1, and line width values of the hyperfine shifted resonances can only be consistent with the hypothesis that they originate from the coordinating residues (the heme was not ^{13}C-enriched and therefore its resonances could not be detected in these spectra). From the comparison of the ^{13}C spectra of the wild type protein and of its Y75A variant,

it was possible to discriminate between Y75 and H32 resonances. The two sets of signals could also be clustered based on their behavior as a function of temperature (Figure 5b). Those attributed to Y75 have shifts that decrease upon increasing temperature, whereas those attributed to H32 have shifts that increase upon increasing temperature. This behavior could be rationalized assuming a temperature-dependent chemical equilibrium between two limit spin states: a low-spin species, S = 1/2, and a high-spin species, S = 5/2, the latter being characterized by substantially larger hyperfine shifts and becoming more populated at higher temperature. In the fully low spin limit species, both H32 and Y75 are strong iron axial ligands; in the purely high spin limit species, Y75 is no longer bound to the heme iron, which becomes five-coordinate. Upon increasing temperature, the shift of H32, which remains invariably coordinated to iron, increases because of the increase in total spin and therefore of the unpaired electron delocalization on its ring. On the contrary, the shifts of Y75 decrease because in the high spin form the Tyr *t* is no more a ligand and therefore its signals do not experience any contact shifts anymore.

In the range of experimentally accessible temperatures, both H32 and Y75 coordinate iron, the latter most probably thanks to the H-bond with H83, which imposes a partial tyrosinate character to Y75 and makes it a better ligand for iron(III).

ii. ^{15}N NMR

Monodimensional ^{15}N-direct detected experiments were used for the identification of the imidazole nitrogen atoms of His residues, with the aim to assign the ^{15}N nuclei of the axial ligand H32 and the key residue H83. A broad signal (70 Hz), with a chemical shift strongly dependent upon temperature (181.2 ppm at 303 K to 193.4 ppm at 317 K) (Figures 6a and 6b) is detectable. This resonance therefore experiences important paramagnetic effects; it is also present in the 1D ^{15}N spectra of the holoH83A mutant (Figure 6c). On this basis, it was assigned to the Nδ1 of H32. The H83 Nε2 was assigned to a relatively sharp resonance present at about 179 ppm at 303 K (Figure 6a); its identification relied on the observation that no corresponding resonance could be detected in the analogous spectrum of the H83A mutant (see Figure 6c and Section II.B). The shift value for the H83 Nε2 resonance in the iron(III) wild-type protein differs by +12.9 ppm with respect to that of the gallium(III) protein. A similar effect is observed for the Cβ of H83, which shows a +7.05 ppm chemical shift variation with respect to the gallium(III) form. Such relatively large observed differences in chemical shift are not explainable in terms of structural differences with respect to the gallium protein, because ^{13}C chemical shifts are very little dependent on the local environment of the nucleus. Furthermore, the observed chemical shift differences cannot be accounted for simply on the basis of pseudocontact shifts that, for the location of these nuclei with respect to the paramagnetic

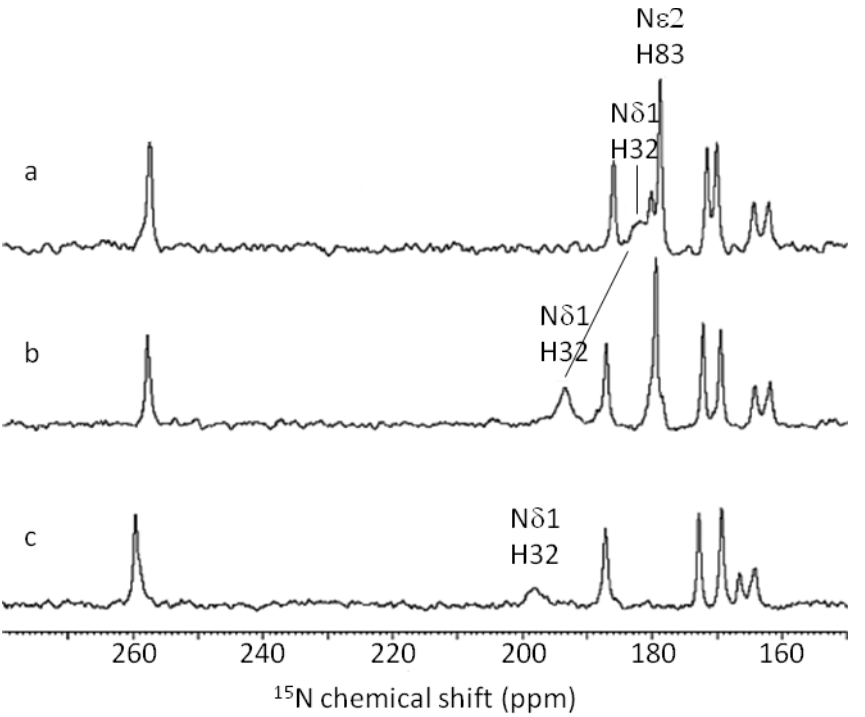

Figure 6. Monodimensional ^{15}N NMR spectra of wild-type holoHasA at 303 K (a); wild-type holoHasA at 317 K (b), and H83A at 317 K (c). All the spectra have been recorded at pH 5.5. (Adapted from Ref. 33.)

center and magnetic axes, were estimated to be < 1 ppm in absolute value. Therefore, contact shift contributions had to be invoked; unpaired spin-density transfer from the ligand to the second coordination sphere nuclei has already been reported, for example, in the case of a tyrosine H-bonded to the cyanide iron ligand in the low-spin iron(III) cyanide adduct of M80A cytochrome *c*.[64,65] The hyperfine shift values observed for the abovementioned H83 nuclei further support the presence of a H-bond between H83 Nδ1 and the iron-ligated Y75 Oη, allowing the delocalization of the iron(III) unpaired spin density onto the imidazole ring of H83. Consistently, the resonance of the Nδ1 of H83 could not be detected, most probably because it is broadened beyond detection by contact shift contributions to its T_2. Of course, the same consideration holds for the Nε2 of H32, which is directly bound to iron(III).

B. The H83A Variant

The hypothesis that H83 in wild-type HasA modulates the strength of the Tyr–iron bond was further confirmed by the characterization of the H83A variant.[34]

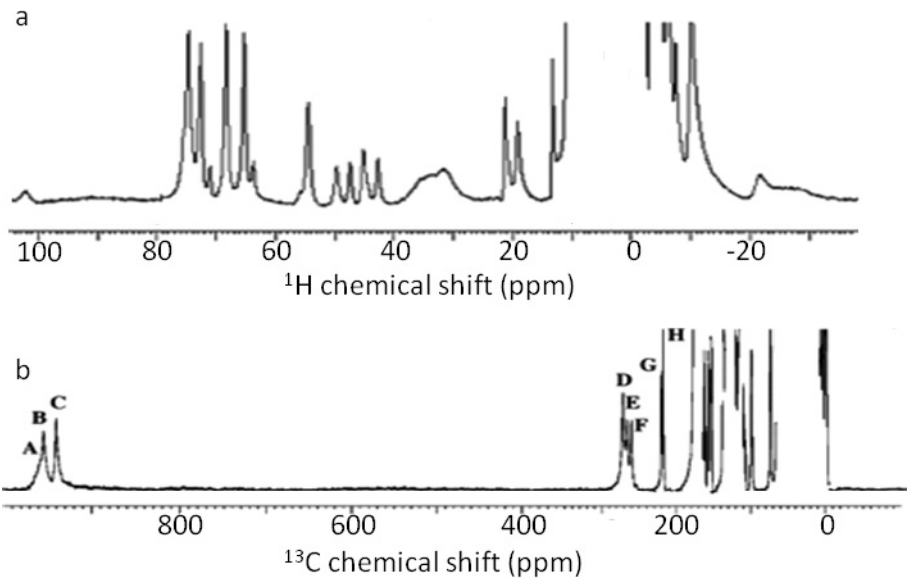

Figure 7. Monodimensional ^{1}H (a) and ^{13}C (b) NMR spectra of H83A recorded at pH values of 5.2 and 5.6, respectively. (Adapted from Ref. 34.)

Replacement of H83 with an alanine causes detachment of the tyrosine ligand, thus giving rise to pentacoordinate, a purely high-spin species that is dominant at neutral pH. The ^{1}H NMR spectrum obtained at 303 K and acidic-neutral pH values for H83A displays heme-methyl resonances between 60 and 80 ppm, and a broad exchangeable resonance at 102.3 ppm, attributed to the Hδ1 of the axial His ligand; resonances with such shifts are typical of high-spin species (Figure 7a).[35] Longitudinal relaxation times are shorter than 1 ms for the four heme methyls and for the H32 Hδ1 and of the order of 4–5 ms for all the other downfield-shifted signals. The hyperfine-shifted resonances exhibit a Curie behavior, consistent with a pure high spin state. The ^{1}H NMR spectrum of holoH83A shows a broad feature at –25 ppm, attributable to *meso* H-peaks. Upfield resonance for *meso* protons are indicative of pentacoordination,[35] a conclusion further supported by resonance Raman, and UV-visible spectroscopy. Monodimensional ^{13}C and ^{15}N NMR spectra also point to the same conclusion (Figures 7b and 76, respectively). In the ^{15}N NMR spectrum the resonance of the Nδ1 of H32 remains as broad as expected for a coordinating residue. In the ^{13}C NMR spectrum the number of hyperfine shifted resonances decreases with respect to the wild type, consistent with the presence of a single axial ligand. The cross peak of Y75 in the ^{13}C–^{13}C COSY spectrum of H83A is detected in the typical Cβ–Cγ region (Figure 8), as expected for a noncoordinating residue. As already observed for the signals of the heme methyls and H32 Hδ1 in the ^{1}H NMR spectrum, the average shift

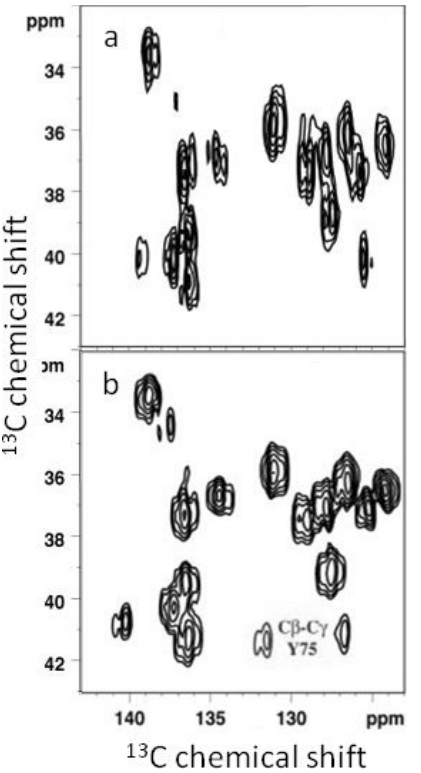

Figure 8. Portion of the ^{13}C–^{13}C COSY spectrum of the holoprotein containing the Cβ–Cγ cross peaks for Tyr residues for wild-type holoHasA (a) and H83A (b). The Cβ–Cγ correlation for Y75 is only detectable in the latter spectrum. (Adapted from Ref. 34.)

of the hyperfine-shifted ^{13}C resonances increases up to 900 ppm, consistently with an increased hyperfine shift contribution due to the change from an intermediate to a high spin state. The chemical shifts of the ^{13}C hyperfine-shifted resonances have a regular Curie dependence, which is normal for a pure spin state.

The ^{1}H NMR spectrum of holoH83A at acidic and neutral pH exhibits unresolved overlapping signals between 20 and 40 ppm (Figure 7a), whose intensity increases with respect to that of the high spin species upon increasing pH. NMR together with a panel of other spectroscopic techniques has established the existence of series of pH-depended equilibria, summarized in Figure 9. It shows that when Y75 is detached from heme binding, the "distal" site of the heme becomes accessible to exogenous ligands. This opening of an access to the heme iron, which does not imply any important conformational change of protein backbone (as deducible from ^{1}H–^{15}N HSQC) has suggested that the protein state found in H83A may represent a possible mechanistic intermediate in the heme transfer reactions involving HasA: the uptake reaction from host hemoproteins and/or the delivery reaction to the membrane receptor HasR.

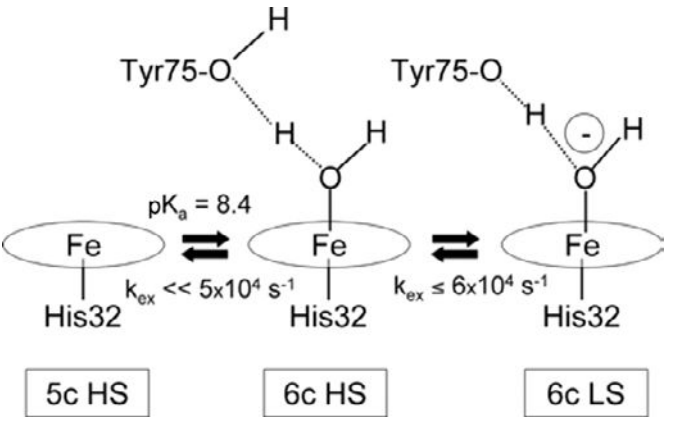

Figure 9. The heme iron spin state and the coordination sphere of holoH83A have been defined over a wide range of pH values. At variance with the wild-type case, variations in iron coordination number and spin state as a function of pH are observed and summarized in this figure. In solution at acidic pH the major form of holoH83A is a high-spin five-coordinate species, having as fifth ligand H32. At increasing pH values, the five-coordinate high-spin species decreases in intensity at the advantage of a high-spin and a low-spin six-coordinate species. The latter is dominant at alkaline pH values. (Adapted from Ref. 34.)

C. Apo HasA

The structure of the apoprotein has been determined by NMR with standard methodology.[66] It shows an intact structure for the α and β portions of the protein. The conformation of loop L2 does not differ much from that of the holoprotein. Notably, the Y75–H83 hydrogen bond is maintained in the apoprotein. In contrast, loop L1 undergoes a major conformational change that gives rise to an "opening" of the structure with respect to the heme-loaded form (Figure 10a). Loop L1 is far more mobile in the apo than in the gallium(III) form of the protein. The ^{1}H–^{15}N HSQC spectrum of the apoprotein (Figure 10b) differs from that of the heme-loaded HasA due to the conformational differences of the unstructured parts of the protein backbone. The conformational rearrangements accompanying heme binding to HasA (Figures 2a and 10a) have led to the description of the hemophore structure as resembling a "fish biting the heme".[29]

III. HasA–HasR Interaction

A. ^{1}H–^{15}N NMR Spectra

The shift patterns of ^{1}H–^{15}N correlations for backbone amides represent a clear signature of the open conformation of apoHasA and of the closed conformation of the heme-loaded HasA, common to both the gallium(III) and the iron(III) derivatives.

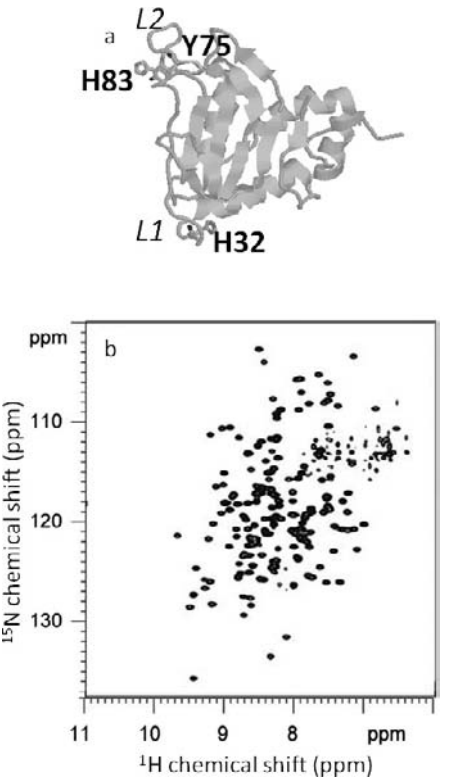

Figure 10. The average NMR solution structure of apoHasA (PDB ID 1YBJ) (a). The two loops, and in particular loop L1, have a different conformation with respect to the holoprotein, where they provide the heme iron axial ligands. $^{1}H–^{15}N$ HSQC of the apoprotein (b). (Panel b is adapted from Ref. 33.)

In addition, the presence of iron(III) in the holoprotein gives rise to hypefine shift contributions for the backbone nuclei in its surroundings and line broadening (even beyond detection) on some of them (Section II.A.2 and Figure 2c). Changes in this NMR signature have been used to monitor the variations occurring upon interaction between HasA and its membrane receptor HasR, in the presence and in the absence of heme.[67]

HasR is a large protein (98 kDa)[68] which could be solubilized in DPC micelles up to a concentration of the order of 300 μM. Both holo and apoHasA form a stable complex with HasR under these experimental conditions. Nevertheless, the low solubility of the system combined with the large total molecular weight of the protein–protein complex embedded in micelles required the use of an *ad hoc* strategy. NMR heavily suffers from molecular size limitations; with increasing molecular mass, the slow molecular tumbling of the complex in solution causes fast

transverse relaxation that broadens signals beyond detection in standard $^{1}H–^{15}N$ HSQC experiments. It is a common practice to alleviate line broadening effects using isotope enrichment with ^{2}H for nonexchangeable hydrogens; this isotope enrichment decreases the magnitude of dipolar interactions provided by the protein frame, thus significantly reducing nuclear spin relaxation rates.[69] For this purpose, ^{2}H (99.7 ± 0.1%),^{15}N-labeled HasA was used in the complex with unlabeled HasR. Even with this optimal isotope-labeling, instead of the conventional NMR HSQC spectra, detection of $^{1}H–^{15}N$ correlations of the low molecular weight component HasA in the supramolecular structure of the complex required the use of CRINEPT-TROSY experiments.[70] Constructive use of cross-correlated relaxation phenomena in transverse relaxation-optimized spectroscopy (TROSY)[71] combined with cross-correlated relaxation-enhanced polarization transfer (CRINEPT)[70,72] provided spectra as those reported in Figure 11a, where most of the resonances of

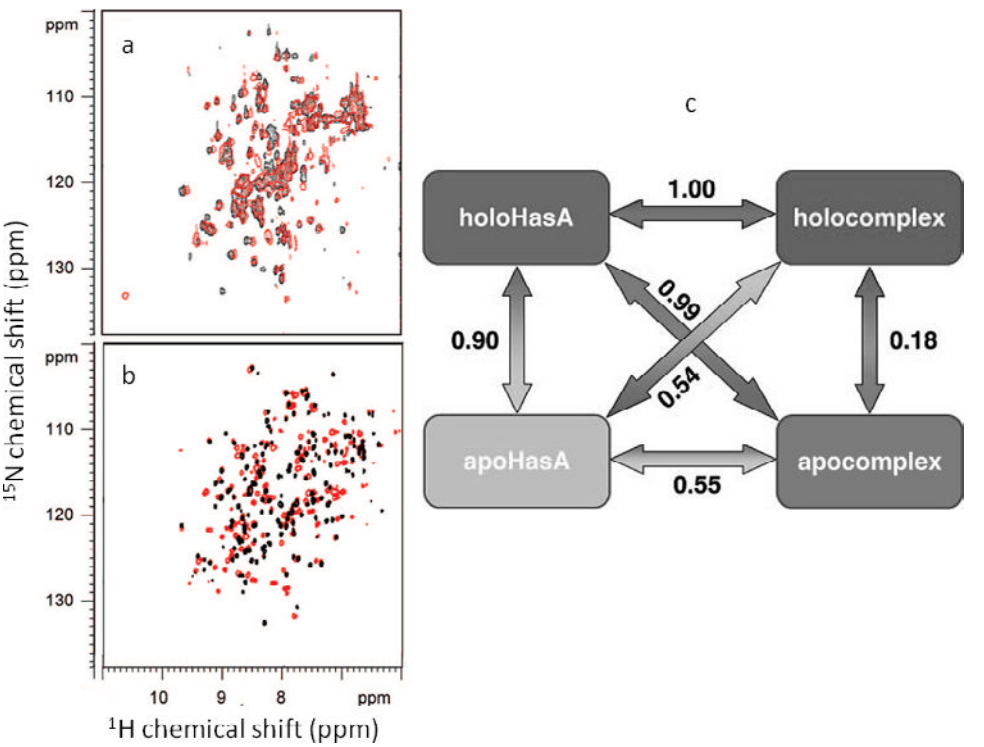

Figure 11. Superimposition of the CRINEPT-TROSY spectra obtained in DPC micelles for apoHasA–HasR (black trace) with holoHasA–HasR (red trace) (a), and apoHasA (black trace) with holoHasA (red trace) (b). Representation of the results obtained from the statistical analysis of the spectral profiles for apoHasA, holoHasA, apoHasA–HasR, and holoHasA–HasR (c). Numbers reported on each arrow are the values of the normalized distance matrix obtained for each pair of spectra. (Adapted from Ref. 67.)

the hemophore protein were still detectable in its complexed forms, although with sensibly increased line widths and consequent reduction in resolution.

1. *Chemical Shift Perturbation Mapping*

Chemical shift perturbation is the most widely used NMR method to map protein interfaces.[73] The interaction with a partner molecule causes environmental changes on the protein interface and, hence, affects the chemical shifts of the nuclei in this area. In addition, if upon interaction there are conformational changes involving the observed protein, they will also be revealed by chemical shift changes. Complex formation between apoHasA and HasR induces a number of chemical shift variations (Figures 11a and 11b, black traces). Two types of signals were useful for analysis of the chemical shift mapping: (1) signals experiencing minimal chemical shift changes (<0.25 ppm), if any, and therefore belonging to regions of apoHasA that are not affected by the presence of the receptor; (2) signals that undoubtedly disappear from their original well-resolved position in the free apoHasA spectrum upon complex formation and are therefore severely affected when binding to the receptor. Residues whose behavior could not be safely defined, mainly because they fall in crowded spectral regions, were unsound for the analysis and were not used to map the interaction. Residues of class 2 are all clustered around the heme binding pocket (Figure 12a) indicating an heavy involvement of L1, L2 and amino acids on strands 2–6 in the interaction surface area. With a similar approach, it was

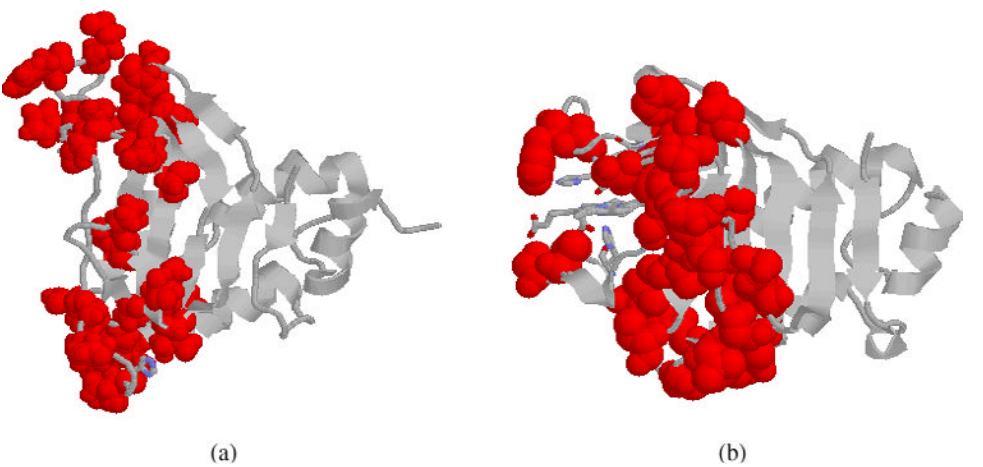

Figure 12. Chemical shift perturbation mapping for apoHasA–HasR (a) and holoHasA–HasR (b). Perturbed residues (red spheres) define the surface contact area on the hemophore upon binding to the receptor. In the holoHasA structure the heme, its axial ligands and H83 are shown as sticks.

possible to map the residues affected upon *complex* formation between holoHasA and HasR; most of the resonances of class 2 in the holoHasA–HasR complex (Figure 12b) coincide with those experiencing chemical shift changes in apoHasA upon binding to HasR. When not coincident, they are located in protein regions found to belong to the interaction area in the apoHasA–HasR complex. Therefore, two important conclusions could be drawn from the chemical shift perturbation mapping: (i) the interaction area was unequivocally identified; (ii) it resulted that the contact surface area between the hemophore and its receptor is independent of the presence of the heme in the complex.

2. *Spectral Profiling*

Identification of the residues at the interface constitutes an important achievement for the structural and mechanistic characterization of the complex; however, the information content embedded in the spectra of Figure 11 is richer. From the simple visual inspection of the spectra of Figures 11a and 11b, it is apparent that differences in the chemical shift signature that characterize free apoHasA and free holoHasA are essentially quenched in their complexes with HasR, This concept could be better rationalized taking advantage of an approach that is used in NMR-based metabolomics, where differences in the metabolic signature of different individuals are quantified in terms of distance matrix without the need of any peak assignment.[74] The obtained results are summarized in Figure 11c, from which it emerges that spectral patterns for the four available protein forms (free apoHasA, free holoHasA, apoHasA in the complex with HasR, and holoHasA in the complex with HasR) carry unique features that are conformation specific. A normalized distance matrix value of 1 is attributed to the most distant pair of spectra, that is the pair holoHasA/holocomplex. The second most distant pair is constituted by the spectra of holoHasA and apoHasA. On the contrary, apoHasA–HasR and holoHasA–HasR spectra are very close (0.18; a value equal to 0 would correspond to spectral identity). Normalized distance matrix values of 0.55 and 0.54 are obtained for apoHasA compared with apocomplex and holocomplex, respectively. In summary, signal patterns are substantially identical for the two complexes, relatively similar for the two pairs apoHasA/apoHasA–HasR and apoHasA/holoHasA–HasR, whereas holoHasA is different from all the others. A clear outcome from this statistical analysis is that three conformations are accessible to HasA in solution: the isolated holoprotein, the isolated apoprotein, and the conformation in the complex. The spectral features for the complex are much closer to those of the isolated apoHasA than those of the isolated holoHasA. Therefore the closed conformation of holoHasA and the paramagnetic effects on its spectra, that is the two factors determining its spectral signature, are not shared with the complex.

While the standard chemical shift mapping perturbation allowed the identification of the interaction area for both apo- and holo-hemophores, the statistical analysis of the spectral fingerprint in terms of distance matrix permitted inference about the differences and similarities in the structure of apoHasA and holoHasA in their isolated forms and in their complex with HasR. In addition, a number of individual conformations accessible to the protein in solution is also defined through the statistical analysis.

B. The Fate of the Heme

Signals of residues on loops L1 and L2 that were undetectable in the holoHasA ^{1}H–^{15}N spectra due to severe paramagnetic line broadening are observed in the holocomplex at shifts typical for apoHasA, strongly suggesting that upon complex formation, the heme group is not located on the hemophore protein anymore, but is transferred to HasR. This important mechanistic hypothesis could have been better supported by the detection of the signals of H32 and Y75 for the holocomplex in diamagnetic ^{13}C–^{13}C spectra (by analogy with the finding for Y75 in the H83A; see Section II.B and Figure 8). Unfortunately, the combination of large molecular weight and relatively low concentration of the complex prevented the detection of aromatic Cβ–Cγ signals with enough resolution and signal-to-noise in complexes.

Given the intrinsic low sensitivity of ^{13}C-direct detected NMR experiments, lack of any detectable hyperfine-shifted resonance in monodimensional spectra for the diluted samples typical of these large and poorly soluble complexes does not constitute a reliable negative proof of the breaking of the heme iron axial bonds.

The definitive proof for the working hypothesis of heme transfer from the hemophore to the receptor upon complex formation came from the X-ray crystal structure of the complex published at the same time as the NMR characterization (Figure 13).[75] In the structure of the ternary complex HasA–HasR–heme, the heme is found to be no longer bound to HasA but axially coordinated to two His residues of HasR (H603 and H189, located on the extracellular face of the receptor) (Figure 13). This implies a transfer of the heme over a distance of about 9 Å. In the same complex, a rotation of the His83 side chain is observed that would reduce the Y75 binding ability and therefore could impair sliding back of the heme to the HasA heme-binding site.

While X-ray crystallography provided a clear evidence of the heme transfer and of the reorientation of H83,[75] the loop containing His32 could not be modeled due to missing electron density (residues 29 to 38) possibly due to multiple conformations or disorder. The NMR spectra,[67] instead, allowed detection of

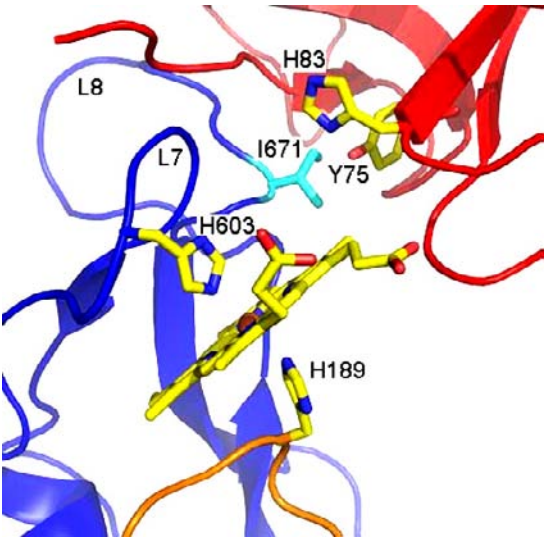

Figure 13. The heme binding site in the X-ray crystal structure of the ternary complex: HasA–HasR–heme. HasA is shown as red ribbon, HasR in blue. Key residues on both proteins are labeled. (Adapted from Ref. 75.)

resonances of this loop, indicating that it has the same arrangement in both complexes and that its conformational features are close to those of the apoprotein. These considerations show the complementarity of the two approaches for the study of complex biomolecular assemblies.

IV. Interaction with Hemoglobin

In *Pseudomonas aeruginosa,* a hemophore named HasAp, which shares 50% identity with *S. marcescens* HasA has been identified.[76] From X-ray crystallography[77] HasAp was found to share with HasA the fold and the axial heme–iron coordination by H32 and Y75. The orientation of the side chain of H83 places its Nδ1 within hydrogen-bond distance from Y75 Oη.

An extensive assignment of the protein backbone NMR resonances was performed with triple resonance experiments on uniformly labeled ^{13}C-, ^{15}N-samples as well as with a number of amino acid selective ^{15}N-enriched samples.[77] The amide backbone identification constituted the starting point for a chemical shift perturbation mapping of the interaction between HasAp and hemoglobin.

In vivo heme internalization through HasR and release of the apo-hemophore requires energy provided by the TonB system.[78,79] *In vitro*, the HasA–HasR interaction gives rise to a stable complex that remains associated even after the heme

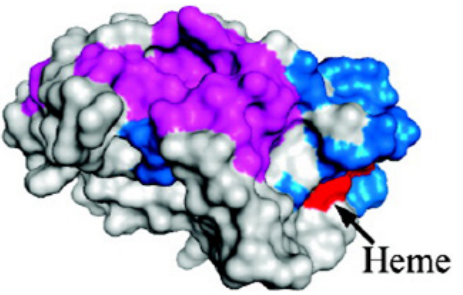

Figure 14. Surface representation of the structure of holo-HasAp where residues whose peaks exhibit chemical shift perturbations upon titration with met-Hb are highlighted in magenta and residues whose resonances disappear upon addition of met-Hb are highlighted in blue. (Adapted from Ref. 77.)

has been transferred from the hemophore to the receptor.[67] This allowed the characterization of the complexes reported in the previous section.

On the contrary, the interaction of apoHasAp and met-Hb gives rise to a rapid transfer of the heme to the hemophore followed by complex dissociation.[77] Therefore, the identification of the possible interaction area between the two partner proteins was studied in a binary system constituted by holoHasAp and met-Hb. Two segregated surface areas on the hemophore have been identified (Figure 14), one where $^{1}H–^{15}N$ connectivities display chemical shift perturbations upon interaction with met-Hb and the other where signals become broadened beyond detection. The former are due to residues mainly located on helix $\alpha 2$ and on the hairpins connecting $\beta 3$ to $\beta 4$ and $\beta 6$ to $\beta 7$. The latter mainly belong to loop L1 and to some portions of loop L2; their behavior has been interpreted in terms of increased conformational dynamics between the open and closed conformations of this loop that gives rise to line broadening beyond detection. A second interpretation of the data is that the loop bearing H32 may represent a second binding area with different affinity for the heme carrier. No attempts to quantify paramagnetic effects of the heme iron(III) in met-Hb on the chemical shifts of the residues of HasAp has been reported. However, it cannot be ruled out as a possible contribution to the observed signal line broadening.

V. Concluding Remarks

In 2000, Bertini and coworkers reviewed the available solution NMR structures of small low-spin heme proteins[80] and showed that the goal of obtaining solution structures for S = 1/2 iron(III) heme proteins as good as those for the diamagnetic iron(II) forms had been reached, mainly thanks to the use of paramagnetism-based

constraints such as pseudocontact shifts[81–84] and residual dipolar couplings.[85,86] During the last decade, structure determination of low-spin ferriheme proteins in solution has become routine.

In the meantime, NMR has gained importance as a structural biology study technique, substantially raising the bar for the size of macromolecules that can be studied. The exploitation of cross-correlated techniques in ^{1}H-detected NMR and the use of ^{13}C-direct detection, in combination with specific sample labeling techniques, represents a very important breakthrough for the detailed analysis of large systems and in particular for large protein–protein assemblies.[62,63,70,87–94] ^{13}C direct detection has also demonstrated its potentiality in reducing the blind zone around paramagnetic centers characterized by $S > 1/2$.[33,34,58,61,95–97]

The present chapter reviews the first application of these strategies to the characterization of the heme uptake: heteronuclear detection experiments proved to be extremely valuable to unravel the first and second coordination sphere effect on the iron electronic structure in HasA[33,34] while cross-correlated ^{1}H–^{15}N NMR provided important structural and mechanistic insights on the protein–protein interactions assisting the heme transfer process.[67]

VI. Acknowledgments

I'm deeply indebted to all the people who have worked with me on HasA characterization: Ivano Bertini and Mario Piccioli at CERM, and Célia Caillet-Saguy, Muriel Delepierre and Anne Lecroisey at Institut Pasteur, who introduced us to the problem and with whom we have established a fruitful and pleasant long-term collaboration.

I. General Introduction

The principal objective of this chapter is to provide an overview of our current understanding of the structure and function of heme-containing peroxidases which belong to the plant and animal peroxidase superfamilies, with an emphasis on recent insights obtained from UV-vis electronic absorption and resonance Raman (RR) studies. In order to highlight the enzymatic mechanism of peroxidases, recent findings from multifrequency electron paramagnetic resonance (EPR) spectroscopy are also discussed. The relatively recently discovered family of bifunctional peroxidases, which are encoded by the *katG* gene in different bacteria, archebacteria and fungi, and which are phylogenetically related to heme peroxidases but are structurally and functionally more complex than the latter, are included.

In general, peroxidases include a very large group of enzymes (with or without heme) that reduce peroxide and oxidize a wide variety of substrates. In particular, heme-containing peroxidases, which almost invariably have the Fe-protoporphyrin IX chromophore (see below), use hydrogen peroxide as the

electron acceptor to catalyze a number of oxidative reactions using various substrates as donors, which are converted into radicals. Peroxidases typically catalyze a reaction of the form

$$\text{ROOR}' + \text{electron donor } (2e^-) + 2H^+ \rightarrow \text{ROH} + \text{R}'\text{OH}$$

Heme peroxidases are found in bacteria, fungi, plants and animals. On the basis of sequence similarity, they can be divided into two superfamilies: one found in bacteria, fungi and plants, and the other in animals.

Plant, fungal and bacterial peroxidases constitute a superfamily which has been divided into three classes, based on sequence alignment and biological origin.[1,2] Animal peroxidases make up a group of homologous proteins which constitute a separate peroxidase superfamily[3] characterized by a markedly different amino acid sequence, overall structure and prosthetic group properties compared to plant, fungal or bacterial peroxidases. Animal peroxidases evolved independently from the plant, fungal and bacterial superfamily and most likely belong to a different gene family. Recently, evolutionary relationships among animal heme peroxidases have been proposed after advanced phylogenetic analysis.[4]

In addition to these two families, a new category of peroxidases has recently been identified, known as the dye-decolorizing peroxidase-type (DyP-type) peroxidase family.[5] Eighty putative members of this family have been included in databases such as PeroxiBase (http://peroxibase.isb-sib.ch) and Pfam.[6] They are not considered members of the plant or animal peroxidase superfamily because of their specific primary and tertiary structures and unique reaction characteristics. Although the characterization of the function and structure of these proteins is still in the early stages, they appear to be bifunctional enzymes with hydrolase or oxygenase activities, in addition to the typical peroxidase activity. A review focusing on the DyP-type peroxidase family has just been published.[7] Furthermore, chloroperoxidase (CPO) and *Pseudomonas aeruginosa* cytochrome c peroxidase do not belong to the two peroxidase superfamilies mentioned above. They are dimeric proteins and each monomer is divided into two domains, both containing a covalently bound *c*-type cytochrome and a Ca^{2+} ion bound between the two domains.[8,9] CPO from *Caldariomyces fumago*[10] differs from plant peroxidases mainly in that the proximal ligand is not a histidine residue but a cysteine thiolate, in common with the cytochrome P450 enzyme. It is also characterized by an unusual distal heme pocket.[11,12] Although its biological role is the chlorination of organic substrates, it also shows peroxidase-, catalase- and p450-type reactions.[13] *P. aeruginosa* cytochrome c peroxidase[8] belongs to the bacterial peroxidases responsible for catalyzing the two-electron reduction of hydrogen peroxide to water, a key function within the cellular detoxification pathway of reactive oxygen

species in microbes.[14] The abovementioned structural differences, particularly with regard to the heme pocket of CPO and *P. aeruginosa* cytochrome *c* peroxidase, have led to their classification as a different family. Hence, they will not be discussed in this chapter.

The availability of three-dimensional structural data for members of the peroxidase superfamilies has increased dramatically in recent years. The new crystal structure data combined with site-directed mutagenesis has allowed the roles of many of the catalytic residues conserved across the three classes of the plant peroxidase superfamily, as well as in the animal superfamily, to be well understood.

A. Resonance Raman Spectroscopy

Spectroscopic techniques have been fundamental to the comprehension of peroxidase function under physiological conditions.[15] In particular, resonance Raman (RR) spectroscopy, which has been widely applied to the study of heme proteins,[16] has made a significant contribution to the understanding of the molecular interactions at the peroxidase active sites. The extreme sensitivity of RR spectroscopy to alterations in the surroundings of the heme, in combination with site-directed mutagenesis and X-ray structural data, has given insight into the influence exerted on protein architecture in the vicinity of the active site by key amino acids and furnished critical information on protein flexibility, functionality and stability.[17,18] Moreover, in recent years, the extensive developments of Raman microscopy have opened up interesting new perspectives. This technique, consisting of an optical microscope coupled to a Raman spectrometer, allows one to collect Raman signals from small regions of a crystal. A schematic view of the experimental setup for Raman microscopy is shown in Figure 1.[19] The comparison of detailed Raman spectra for peroxidases in crystal and solution forms has offered a means of bridging crystallographic and solution studies, providing a powerful synergy with X-ray-crystallographic analysis.

B. Multifrequency Electron Paramagnetic Resonance Spectroscopy

Electron paramagnetic resonance (EPR) is a spectroscopical technique based on the response of paramagnetic molecules (those having unpaired electrons) to an applied external magnetic field. Transition metal ions and organic radicals are naturally occurring paramagnetic molecules, which have crucial roles in catalytic reactions and related electron transfer processes in metalloproteins.[20] Accordingly, EPR spectroscopy has been extensively used to obtain structural and functional information of active sites in metalloproteins.[20] In the case of heme peroxidases, important information on the spin state and coordination number can be obtained from the EPR spectrum of the heme active sites of the resting enzymes.[21]

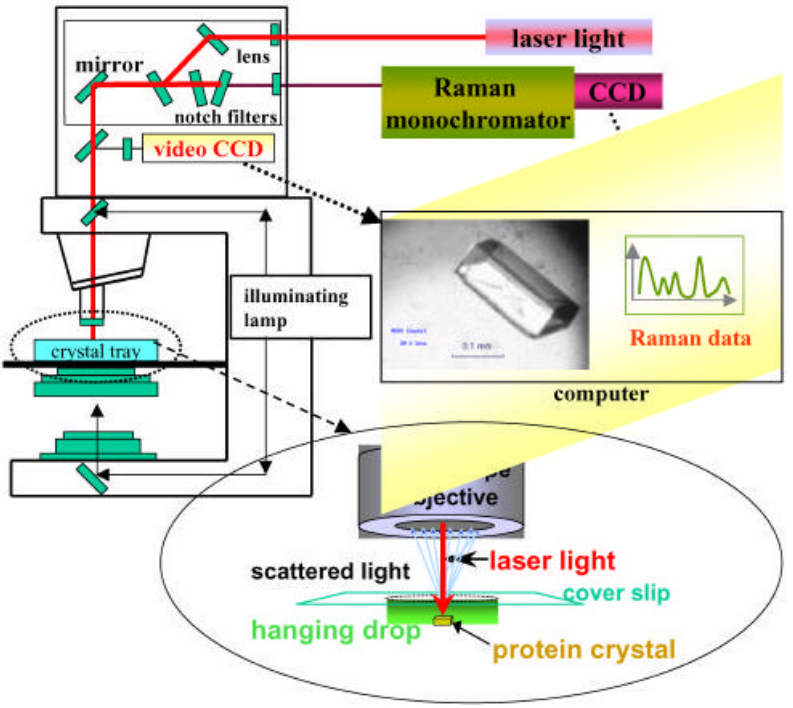

Figure 1. Raman microscope coupled to a laser and spectrometer**.** Crystals are placed with a small amount of mother liquor in a hanging drop under a cover glass, or mounted with a small amount of mother liquor in a capillary tube which is then sealed. The crystal can be viewed via a long focal length objective and a video of a charge-coupled device (CCD) camera for optical imaging. The same objective is used for both the sample excitation and the collection of the back-scattered radiation. The beam focused on the crystal can be viewed on the computer monitor. A magnified view of a protein crystal as observed under the microscope objective is also shown. (Reprinted with permission from Carey, P. R.; Dong, J. *Biochemistry* **2004**, *43*, 8885–8893. © 2004, American Chemical Society.)

Moreover, the intermediates formed during the catalytic cycle of peroxidases, and resulting from changes in the oxidation state of the heme iron and formation of radical species, can be monitored by EPR spectroscopy.[22–24] EPR spectrometers employing continuous wave irradiation at standard frequencies (9 GHz, the so-called X-band) have been widely used for the characterization of the environment of the heme site in peroxidases (reviewed in Ref. 15), since the EPR spectrum obtained from samples in frozen solutions is very sensitive to geometry changes induced by varying the pH (see for example Ref. 25) and/or by the effect of site-directed mutations affecting directly or indirectly the proximal and distal heme sides (see for example Ref. 26). The information obtained from the 9 GHz EPR spectrum is limited, in particular for unequivocal determination of the chemical

nature and magnetic interactions of organic radical intermediates with the heme iron (a good example is given in Ref. 27). The development of EPR spectrometers that use higher microwave frequencies (ranging from 95 to 360 GHz) and the related higher magnetic fields (up to 14 T), as well as the development of the theoretical and experimental aspects related to their application to characterize cofactors in metalloproteins,[28,29] constitute a crucial advancement in the understanding of the putative role of protein-based radicals formed as alternative catalytic intermediates in peroxidases.[30,31] Accordingly, it is only recently that substantial evidence from multifrequency EPR spectroscopy has challenged the view of the heme moiety as the unique site for reaction with substrates via higher valence intermediates, in particular the [Fe(IV)=O $Por^{\bullet+}$] species. As will be discussed in this chapter (see Sections II.F.3 and III.D.2), both peroxidases and catalase–peroxidases can stabilize [Fe(IV)=O $Trp^{\bullet}$] or [Fe(IV)=O $Tyr^{\bullet}$] species with well-defined radical sites that are formed subsequently to the [Fe(IV)=O $Por^{\bullet+}$] intermediate by intramolecular electron transfer. Such radical species can play the role of alternative reactive intermediates in the oxidation of specific substrates.

II. Superfamily of Plant, Fungal and Bacterial Peroxidases

The superfamily of plant, fungal and bacterial peroxidases is divided into three classes of structurally related peroxidases[1] and comprises proteins which are present in a wide variety of living organisms. Comprehensive analyses of the origins of the nonanimal peroxidase superfamily have recently been reported.[32,33] Plants contain two groups of heme peroxidases: intracellular peroxidases of prokaryotic origin (class I) and classical or secretory plant peroxidases (class III). Class I includes cytochrome c peroxidase (CCP), ascorbate peroxidase (APX) and catalase–peroxidases (KatGs), which have recently raised considerable interest. In fact, despite their striking sequence homologies to the members of class I of the plant peroxidase superfamily, they exhibit peroxidase and substantial catalase activities similar to those of monofunctional catalases.

Horseradish peroxidase isoenzyme C (HRPC) is the most extensively studied prototype of class III, but in the last decade many other members of this class have been studied, including horseradish isoenzyme A (HRPA2), barley (BP1), soybean (SBP), peanut (PNP) and *Arabidopsis thaliana* (ATP). In particular, the entire peroxidase gene family of the plant *Arabidopsis thaliana* has recently been fully described.[34,35] The 73 class III peroxidase genes in *Arabidopsis thaliana*, encoding what are predicted to be 71 stable enzymes folded similarly to HRP C, were used for surveying the evolutionary relationships among peroxidases in the plant kingdom.[35]

The remaining group of peroxidases in the plant peroxidase superfamily are of fungal origin (class II) and include well-characterized examples such as *Coprinus cinereus* peroxidase (CIP), *Coprinus macrorhizus* peroxidase (CMP), *Arthromyces ramosus* peroxidase (ARP) and the lignin (LIP) and manganese peroxidases from white-rot fungi (MNP). Since CIP and ARP peroxidases are identical in both their covalent structure and enzymatic properties,[36] we will refer to these peroxidases by the name ARP/CIP, unless differently stated.

Plant peroxidases are involved in a wide range of biological functions, such as defence against stress (class I), metabolism of lignin (classes II and III), developmental processes and defence against environmental changes (class III).[37]

A. Heme Pocket

After the first three-dimensional structure of yeast cytochrome *c* peroxidase (CCP), solved more than two decades ago,[38] in the last 20 years many other three-dimensional structures of native peroxidases with and without substrates have been determined by X-ray crystallography. Seven of these structures have been extensively discussed by Poulos in a chapter devoted to peroxidases in the previous handbook of porphyrins,[13] namely CCP,[38] lignin peroxidase (LIP),[39–41] ARP/CIP,[42,43] manganese peroxidase (MNP),[44] APX,[45] peanut peroxidase (PNP),[46] HRPC[47] and barley peroxidase (BP1).[48] Recently, other structures of native proteins have been obtained, namely those of *Arabidopsis thaliana* A2 (ATPA2)[49,50] and N (ATPN),[51] soybean peroxidase (SBP),[52] and catalase–peroxidase from different origins.[53–57] At present, more than 300 structures can be found in the Protein Data Bank (http://www.rcsb.org/pdb/home/home.do), including native, recombinant, mutated proteins and their complexes with substrates and small ligands.

The X-ray structures clearly show that the overall helix-rich protein fold is conserved. Moreover, although the three classes show less than 20% amino acid sequence identity, all peroxidases contain invariant amino acids in the heme cavity important for catalytic activity, as predicted on the basis of the amino acid alignment.[1] As shown in Figure 2, these conserved residues (distal His, Arg, Asn and proximal His, Asp) are connected by an extended hydrogen-bond network through various water molecules. In particular, on the proximal side of the heme the axial His ligand of the heme iron is hydrogen-bonded to a buried carboxylate group of an Asp residue. Moreover, the catalytic His residue on the distal side is hydrogen-bonded to an Asn residue.

The role played by the key amino acids has been studied by kinetic methods and spectroscopic techniques in a number of peroxidases. Moreover, the application of site-directed mutagenesis to these proteins provided important insight into heme pocket interactions.

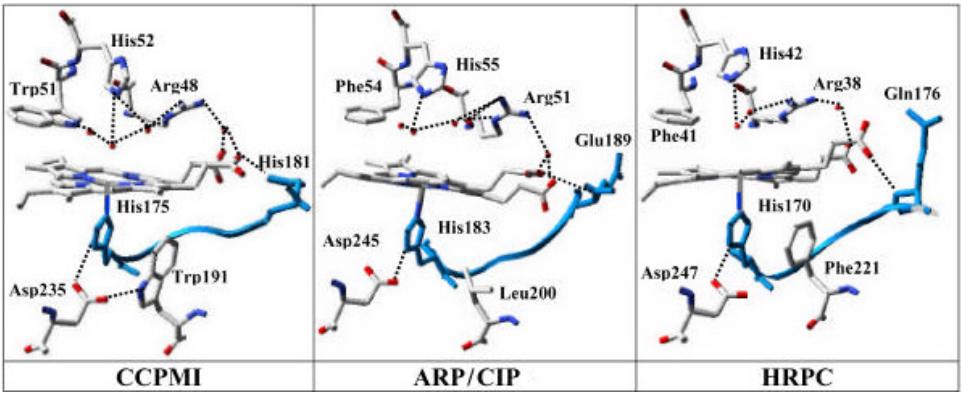

Figure 2. Structural diagram of the heme pocket of recombinant CCP (CCPMI) (PDB 1CCP), ARP/CIP (1GZB) and HRPC (1ATJ). Dotted lines indicate H-bonds. Water molecules are also shown. The loop connecting the proximal Fe-ligand with the residue H-bonded to the heme propionyl is shown in blue. (Reprinted with permission from Smulevich, G.; Feis, A.; Howes, B. D. *Acc. Chem. Res.* **2005**, *38*, 433. © 2005, American Chemical Society.)

The combination of X-ray crystallography and the extensive resonance Raman studies on wild-type (WT) proteins and various site-directed mutants representative of the three classes of the plant superfamily, namely cytochrome *c* peroxidase (class I),[17,58–62] ARP/CIP (class II)[63–66] and HRPC (class III),[18,63.67–69] has allowed the identification of many common characteristics of these enzymes.

1. *Fe(III) Resting State*

In the Fe(III) resting state, the heme iron sixth coordination site is vacant (pentacoordinate, 5c) or bound weakly to water (hexacoordinate, 6c), emphasizing that one coordination site must be free to enable peroxides or other ligands to bind and react with the protein.[17] However, while the resting state of the proteins belonging to either class I or II is mainly 5c high-spin (5cHS), a distinctive characteristic of the class III peroxidases is a pentacoordinate quantum-mechanically mixed-spin (5cQS) state. The QS state reflects a quantum-mechanical admixture of intermediate ($S = 3/2$) and high ($S = 5/2$) spin states, and is very unusual in biological systems. Among the various class III peroxidases so far studied, the proportion of the $S = 3/2$ state increases in the order HRPC < HRPA2 < SBP < BP1.[70–73] Figure 3 compares the high-frequency region resonance Raman spectra of the Fe(III) forms of different representatives of peroxidases belonging to class III. The progressive increase in frequency of the core size marker bands on passing from wt HRP to the F221M HRP mutant reflects an increasing proportion of the intermediate spin species in the QS state.

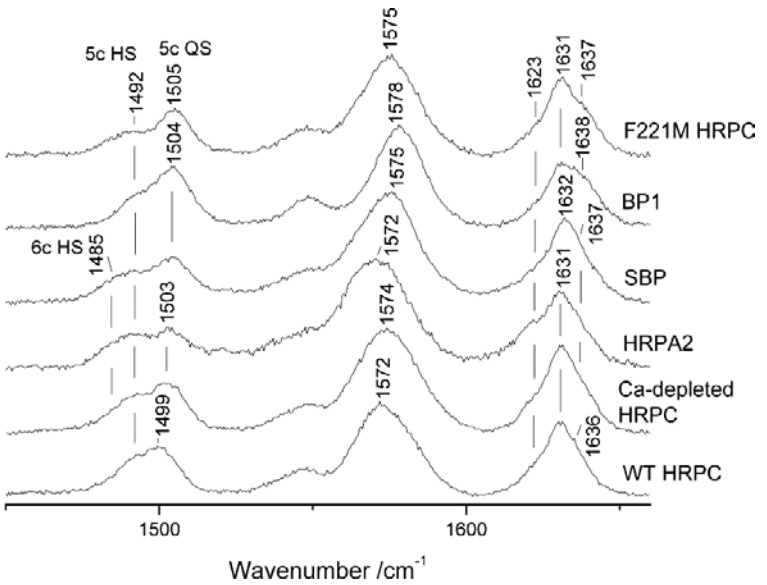

Figure 3. High-frequency region resonance Raman spectra of the Fe(III) forms of different representatives of peroxidases belonging to class III: WT HRPC, soybean peroxidase (SBP), the F221M mutant of HRPC (pH 7.0), HRPA2 (pH 7.3), Ca-depleted HRPC (pH 7.8), barley peroxidase (BP1) (pH 6.5). Excitation wavelength 406.7 nm (WT HRPC, Ca-depleted HRPC, HRPA2, SBP, F221M HRPC) and 413.1 nm (BP1). 5cHS and 6cHS indicate the bands ν_3 due to five- and six-coordinate high spin, respectively, and 5cQS indicates the band from the quantum-mechanically mixed-spin state.

The spectroscopic characteristics of the QS spin state (for both penta- and hexacoordination) have been reviewed previously.[18,74] The 5cQS state is characterized (Figure 4, *left*) by a blue-shifted UV-vis absorption spectrum compared to those of a 5cHS heme, higher frequency of the RR core-size marker bands, which cannot be assigned to either 5cHS or hexacoordinate high-spin (6cHS) hemes but closely resemble those characteristic of hexacoordinate low-spin (6cLS) hemes, and EPR spectra with g_{12} values in the range $4 < g_{12} < 6$, typical only of a QS heme.

The binding of benzohydroxamic acid (BHA) to class II and III peroxidases induces the formation of a 6c state (see below), which in class III peroxidases has been assigned to a quantum-mechanically mixed-spin (6cQS) heme (Figure 4, *right*). The latter is characterized by absorption spectra in which the Soret band sharpens with about a 35% increase of the extinction coefficient and red-shifts about 4 nm with respect to those of a 5cQS state, similar to those of a 6cHS heme, RR core-size marker band frequencies which resemble those of a 5cHS system, and EPR spectra with g_{12} values in the range $4 < g_{12} < 6$.

The structural origin and functional significance of the QS states remain elusive. The most widely suggested origins, a weak axial ligand field[75] or a saddle-shaped

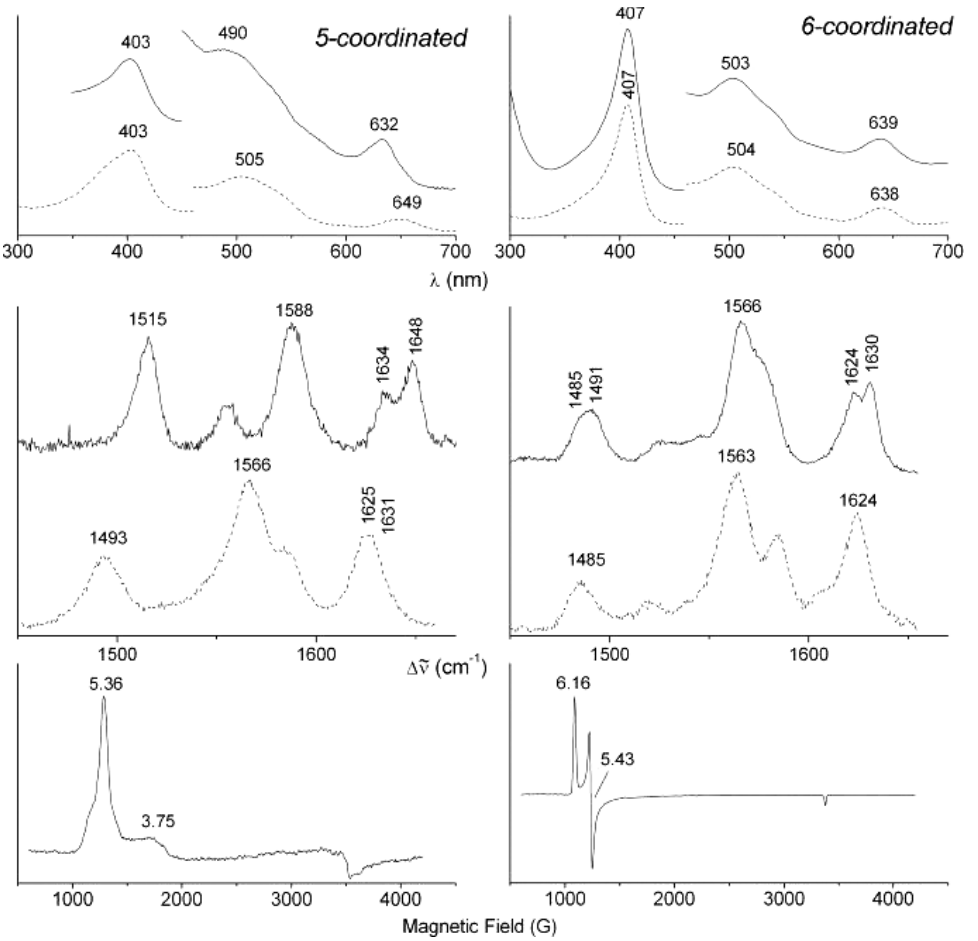

Figure 4. From top to bottom. Absorption, RR and EPR spectra at 10 K (solid line) and room temperature (RT) (dashed line). (Left) barley peroxidase (BP1) at 10 K (5cQS) and ARP/CIP at RT (5cHS); (right) HRPC–BHA at 10 K (6cQS) and CIP/ARP–BHA at RT (6cHS). (Reprinted with permission from Smulevich, G.; Feis, A.; Howes, B. D. *Acc. Chem. Res.* **2005**, *38*, 433. © 2005 American Chemical Society.)

heme deformation,[76] are not sufficient to cause the QS states. However, an analysis of the heme conformation by the normal-coordinate structural decomposition (NSD) method of all the X-ray crystal structures of peroxidases contained in the Protein Data Bank[77] revealed that the peroxidases exhibit a conserved out-of-plane distortion equal to, or larger than, that of the cytochromes. The heme of cytochrome is highly distorted by covalent attachments at the heme periphery. Moreover, the mainly saddled deformation of the peroxidase heme is observed for all of the peroxidase X-ray structures. In addition, contributions from other deformation types

were found, namely ruffling (varying from 0.6 to 0.2 Å) and other small deformation components (doming, waving[53]) usually with a negative sign.[73]

Recently, the out-of-plane modes of horseradish peroxidase (HRP) in different spin, oxidation and ligation states have been measured by RR spectra with (near) Soret excitation.[78] The nonplanar modes of the heme are Raman-inactive for planar macrocycles, but become RR-active in the presence of out-of-plane deformations. A variety of out-of-plane modes such as γ_5, γ_6, γ_7 (A_{2u}), γ_{21} and γ_{22} (E_g), γ_{15} (B_{2u}) and γ_{11} (B_{1u}) have been observed in the Fe(III) 5cHS, QS and 6cLS states as well as in the 5cHS Fe(II) form. The appearance of these bands is clearly indicative of nonplanar deformations. In addition, in the Fe(III) hydroxo-6cLS state observed at alkaline pH,[79] a substantial reduction of the ruffling distortion was found, whereas the doming deformation remained largely unaffected by the change of the iron spin and ligation state.

The spectroscopic characterization of peroxidases has mainly been performed on the proteins in solution. The importance of applying Raman spectroscopy to biomolecular crystals was recognized in the 1970s.[80,81] In the 1980s and 1990s, new technologies permitted the development of Raman microscopy, where an optical microscope is coupled to a Raman spectrometer to collect Raman signals from sample regions as small as a few micrometers. A review of the application of Raman microscopy to proteins has recently been published.[82,83] Pioneering applications of Raman microscopy in cell biology have also been reported.[84,85] More recently a number of nonresonant, resonant or polarized Raman studies have been reported on heme proteins.[60,86–88] In the last 20 years, single-crystal microresonance Raman spectra on heme-containing peroxidases have been obtained on CCP[89] and some of its site-directed mutants,[90] HRP-C,[91] SBP,[52] ATPA2[50] and ARP/CIP.[74,91] Comparison between the spectroscopic data of the protein in solution and crystal forms not only showed that the coordination could be different from that determined by X-ray crystallography, but also revealed the presence of artefacts induced either by the temperature used to acquire the data (see below) or by the chemicals used for crystallization. In fact, the difficulties which are sometimes encountered in crystallizing proteins are often overcome by the addition of salts or hydrophilic compounds to the crystallizing medium that help the crystallization process. However, the chemicals can modify the active site of the protein, since the structural balance that determines the coordination state in a heme protein can be very delicate. In the first application of micro-Raman to peroxidases it was found that, unlike WT CCP, the Trp51Phe CCP mutant showed a dominant 5-c heme population in the single crystal[90,92] whereas in solution the 6-c form was dominant.[58] The different coordination state was mimicked by adding 2-methyl-2,4-pentanediol (MPD) to the solution and was attributed to the dehydrating effect of MPD, which is present during crystallization.[90]

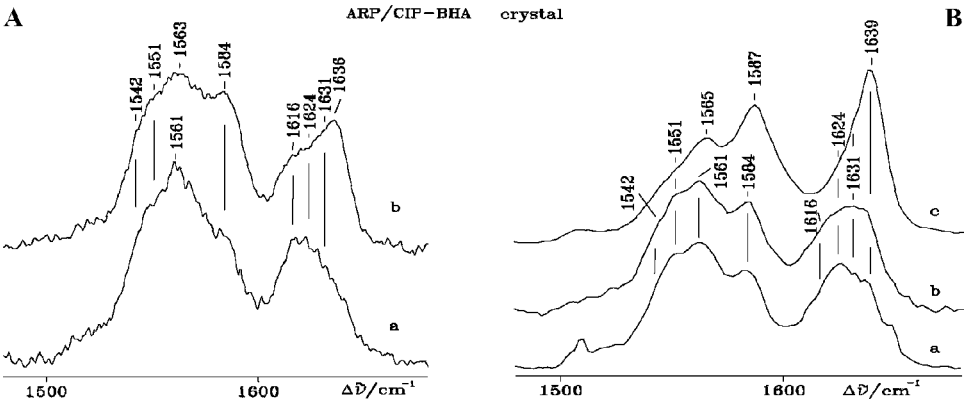

Figure 5. (A) RR spectra of ARP/CIP–BHA as a single crystal soaked in (a) Na_2SO_4 and in (b) $(NH_4)_2SO_4$. (B) RR spectra of ARP/CIP–BHA soaked in $(NH_4)_2SO_4$ taken at different laser power on the crystal surface: (a) 100 μW; (b) 180 μW; (c) 550 μW. (Reprinted with permission from Indiani, C.; Santoni, E.; Becucci, M.; Boffi, A.; Fukuyama, K.; Smulevich, G. *Biochemistry* **2003**, *42*, 14066–14074. ©2003, American Chemical Society.)

Figure 5 shows the RR spectra[93] of ARP/CIP-BHA for 514.5 nm excitation as a single crystal (a) obtained from a soaking solution containing Na_2SO_4 and (b) obtained from a soaking solution containing $(NH_4)_2SO_4$. Although the same experimental conditions were applied, it is evident that the presence of $(NH_4)_2SO_4$ induces the formation of a 6cLS heme, as judged by the intensity increase of the bands at 1584 cm^{-1} (ν_{19}) and at 1636 cm^{-1} (ν_{10}). These findings clearly indicate that the characteristics of the protein crystal depend critically on its preparation and suggest that the micro-Raman technique may offer a sensitive tool for the screening of sample preparation.

The laser power at the sample might also be a factor inducing artefacts. In this particular case, the amount of the 6cLS heme depends on the laser power at the sample surface during the RR experiment. For single crystals of ARP/CIP-BHA soaked in $(NH_4)_2SO_4$, the higher the laser power, the greater the intensity of the bands characteristic of the 6cLS (Figure 5B). A laser power of 550 μW on the crystal gave rise to an almost pure 6cLS heme with core size marker bands at 1551 cm^{-1} (ν_{38}), 1565 cm^{-1} (ν_{11}), 1587 cm^{-1} (ν_{19}), and 1639 cm^{-1} (ν_{10}) (Figure 5B, spectrum c).

Finally, the combined analysis of solution and single-crystal data allows one to obtain also critical information on protein flexibility and the existence of possible alternative conformations, as in the case of recombinant *Arabidopsis* peroxidase, ATPA2.[50] Figure 6 compares the RR spectra of ATP A2 crystals obtained at room temperature with those of the protein solution at different pH values. Different ATPA2 crystals from the same batch of crystals exhibited two slightly different RR spectra. Crystal I (Figure 6c) was identical to the ATP A2 in solution at pH 7.5

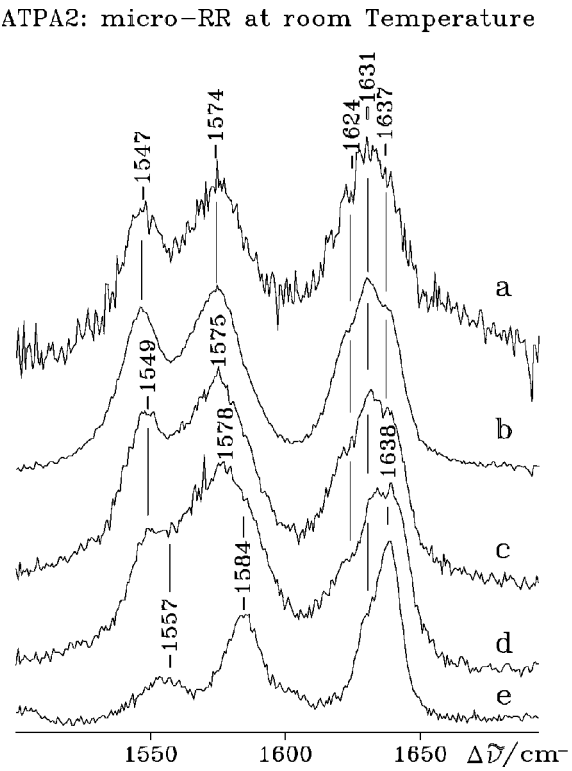

Figure 6. Micro-RR spectra of ATPA2 crystals. (a) ATPA2 dissolved in the crystallization medium at pH 6.6; (b) ATP A2 in bicine buffer at pH 7.5; (c) ATPA2 crystal form I; (d) ATPA2 crystal form II, (e) ATP A2 in glycine buffer at pH 10.6. Experimental conditions: 514.5 nm excitation, 5 cm^{-1} resolution, and 50 μW and 2.1 mW laser power in crystal and solution samples, respectively. The laser beam was moved to a new surface spot of the crystal every 60 s, and the spectra were added to give the total accumulation time. (Reprinted with permission from Nielsen, K. L.; Indiani, C.; Henriksen, A.; Feis, A.; Becucci, M.; Gajhede, M.; Smulevich, G.; Welinder, K. G. *Biochemistry* **2001**, *40*, 11013–11021. © 2001, American Chemical Society.)

(Figure 6b). Crystal II (Figure 6d) exhibited additional weak bands compared to crystal I at 1557 (ν_{11}), 1584 (ν_{19}) and 1638 (ν_{10}) cm^{-1}. They were due to the presence of a small amount of 6cLS heme, as judged by comparison with the spectrum of ATPA2 at pH 10.5 (Figure 6e), which is a pure 6cLS form. The differences observed between crystals I and II were not induced by the crystallization medium, since the spectrum of ATPA2 dissolved in the medium (Figure 6a) gave rise to a spectrum almost identical to that in bicine at pH 7.5. Moreover, the presence of an artefact due to the laser-induced heating of the crystal could be ruled out since no damage was detected on the surface of the crystals after irradiation with the very low power applied, and no spectral changes were observed during the exposure time. The experimental conditions giving rise to the slightly

different crystal spectra are not clear, but crystal II demonstrates that it is possible to induce the formation of a 6cLS heme in ATPA2 even at room temperature, confirming the presence of a flexible distal side.

2. *Extended Network of H-Bonds*

Peroxidases are characterized by the presence of an extended network of H-bonds coupling the distal and proximal sides of the heme, constituted on the distal side by water molecules H-bonded to His and Arg, the heme propionate and the proximal His ligated to the heme iron (Figure 2). As a consequence of the high polarity of the distal cavity and the extended H-bond network involving water molecules and conserved distal and proximal amino acids, the coordination state of peroxidases can be dramatically affected by chemical conditions. The distal arginine and histidine residues have been extensively mutated in the various peroxidases. Resonance Raman spectroscopy clearly indicated that the mutation modifies the heme coordination and perturbs the proximal Fe–imidazole (Fe–Im) bond strength, as a consequence of charge distribution, size, and H-bonding acceptor/donor properties of the substituting amino acid.[18] Therefore, the H-bond network preserves the protein function and keeps intact the coupling between the proximal and distal residues.

Interestingly, the coordination and spin states of the heme in peroxidases are also markedly sensitive to changes of temperature. The importance of low-temperature experiments on proteins is often underestimated, since very low temperatures and the frozen state are nonphysiological and, therefore, are considered to give little useful insight into structure–function relationships. However, from a spectroscopic point of view, low-temperature experiments give rise to narrower spectral bands, allowing one to separate bands which would overlap at room temperature. Moreover, some techniques, such as EPR spectroscopy, must be applied at liquid nitrogen or helium temperatures due to the magnetic relaxation properties of the heme iron. One of the main disadvantages of low-temperature measurements on hemoproteins and, in particular, peroxidases, is their sensitivity to temperature-dependent conformational changes, which may alter the spin and coordination states of the heme iron. The temperature effect on the heme iron has become an important issue over the last decade, with the increased use of synchrotron radiation as an X-ray source, many protein structures have also been solved at liquid nitrogen temperature. In fact, macromolecular crystals commonly suffer rapid radiation damage during room temperature X-ray data collection, and most macromolecular crystal diffraction data are now collected at or near 100 K. The benefits of cryocrystallography include reduced secondary radiation damage and, usually, higher-resolution and better-quality data.[94] Therefore, if the maximum

advantage is to be gained from the comparison of results obtained by various techniques in different temperature ranges, it is important to establish whether any reversible or irreversible changes have been caused by the variation in temperature. Many RR and electronic absorption data have proven that a significant number of peroxidases undergo a temperature-induced transition from a 5c- to a 6cLS heme. Moreover, conformational changes in the heme cavity, including a contraction of the heme core, reorientation of the vinyl group in position 2 of the porphyrin macrocycle, and binding of the distal His to the Fe atom, often occur.[73,95–98] The recent study of plant anionic horseradish peroxidase HRPA2 and the orthologous *Arabidopsis* peroxidase ATPA2, produced recombinantly in *E. coli*, provides an example of how spectroscopy, crystallography and enzyme kinetics can complement each other.[50] It was shown that the location of a water molecule, which might be important for reactivity, could be different at low temperatures and, therefore, not representative of the active state of the protein under physiological conditions. While the crystal structure of ATPA2 at 1.45 Å resolution at 100 K showed a water molecule at 2.1 Å from the heme iron,[49] a distance which could impede activity since the water molecule is expected to be ligated to the heme iron, the X-ray-crystallographic and single-crystal/solution resonance Raman studies at room temperature confirmed that the sixth coordination position of the ATPA2 heme iron is essentially vacant,[50,71] showing a 5c heme iron. In fact, the UV-vis (Figure 7A) and RR (Figure 7B) spectra at room temperature of ATPA2 and HRPA2 are identical and characteristic of a mixture of three species: 5cHS, 6cHS and 5cQS. This last species is predominant at room temperature, as in many other class III peroxidases. Hence, ATPA2 and HRPA2 have the same coordination previously described for other class III plant peroxidases.

When the temperature is lowered at neutral pH, the UV-vis spectra of ATPA2 (Figure 7C)[50] and HRPA2[98] undergo major changes and exhibit isosbestic points at 590, 514 and 465 nm. The spectra are consistent with the presence of two types of 6cLS hemes — a bis-histidyl type and a hydroxyl type — coexisting with the 5cQS species. All the forms are characterized by high RR frequencies, indicating a contraction of the heme core at low temperatures. The changes were reversible and much more pronounced than those seen for SBP,[97] HRPC[95] and BP1,[73] indicating that the A2 type peroxidases have an unusually flexible heme cavity, possibly of importance for the catalytic process.

3. *Vinyl–Protein Interaction*

The heme prosthetic group of peroxidases has two vinyl substituents in positions 2 and 4 (Figure 8) which are conjugated to the porphyrin macrocycle to a different extent, depending on the protein in question. As a consequence, the absorption

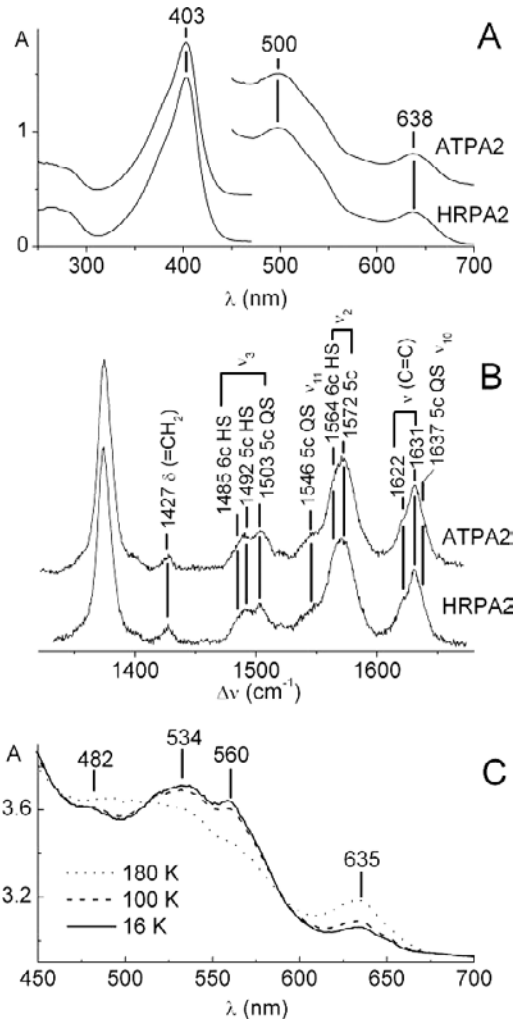

Figure 7. (A) Electronic absorption spectra of Fe(III) ATPA2 and HRPA2, at pH 7.5, in bicine buffer at room temperature. The region between 450 and 700 nm has been expanded eight fold. (B) Corresponding RR spectra obtained with Soret excitation (406.7 nm excitation). (C) Electronic absorption spectra of Fe(III) ATPA2, at pH 7.5, in bicine buffer at 180, 100 and 16 K. maxima of the Fe-protoporphyrin IX prosthetic group are related not only to the coordination/spin state of the heme but also to the degree of conjugation between the heme group and its two vinyl substituents.[18,99] Therefore, the electronic coupling between the vinyl groups and the porphyrin modulates the energy of the π–π^* transitions and furnishes an enhancement mechanism for the vibrational

modes of the vinyls in the RR spectra.[100] The conjugation can induce an upshift of the UV-vis maxima of up to 10 nm, as clearly observed in the electronic absorption spectra of plant peroxidases. In fact, despite their largely invariant coordination and spin state and the close similarity of their RR spectra, the Soret band wavelength varies from 398 nm in BP1[73] to 408 nm in CCP[101] as a consequence of the degree of conjugation between the porphyrin macrocycle and the vinyl substituents.[102]

To rationalize this effect, the absorption and RR spectra of selected mutants and fluoride complexes of various peroxidases have been analyzed in detail in relation to their X-ray structures.[99] The X-ray structures revealed that the vinyl orientation among the various plant peroxidases differs mainly at position 2, as a consequence of different steric hindrances imposed by the protein matrix. The ν(C=C) vinyl stretching frequency was found to be a sensitive probe of the degree of electronic conjugation between vinyl and porphyrin and, hence, the RR vinyl stretching frequencies can vary markedly. As the constraint on the 2-vinyl diminishes, the conjugation between the vinyl and the porphyrin decreases, the 2-vinyl ν(C=C) stretching frequency increases, and a large frequency separation is observed between the two ν(C=C) stretching modes in the RR spectra. When the protein matrix exerts weak or

no constraints on the 2-vinyl group, two distinct ν(C=C) stretching modes are found in the RR spectra. A relationship between the ν(C=C) stretching frequency and the torsion angle, τ, of the 2-vinyl group, involving the relative orientations of vinyl (C_b–C_a) and pyrrole (C_β–C_α) C=C double bond π planes, has been established.[99] The maximum and minimum conjugation between the vinyl group and the porphyrin macrocycle is observed when the vinyl and pyrrole double bond π planes are mutually parallel ($\tau = 140°$) and perpendicular ($\tau = 50°$), respectively. Three limiting vinyl conformations (trans, twist and cis) are sketched in Figure 8.[18] The amino acid that interacts with vinyl 2 is possibly that at position 172 (CCP numbering), which is methionine in CCP, leucine in class II peroxidases and serine in ascorbate peroxidase (APX) and class III peroxidases. The repulsive interaction between the vinyl group and the amino acid is strongest in CCP (class I) and weakens on passing from class II to class III peroxidases and APX (class I). On the basis of the spectroscopic data, amino acid sequence alignment, and the distances between the vinyl Ca and Cb atoms and the surrounding amino acids as determined by the X-ray structures, the role of a variety of interactions, including van der Waals contacts, π–π electron interactions, and C–H–––O H-bonds, has been inferred.[99] The vinyl group orientations appear to depend on the concerted orientations of the distal helix B and proximal helix F axes, controlled by the H-bonds between the distal arginine, a heme propionyl group, and an amino acid on the extended strand adjacent to proximal helix F.

4. *Imidazolate Character of the Proximal Iron Ligand*

The conserved H-bond between the N_δ atom of the imidazole ligand and the carboxylate group of the aspartic side chain, which acts as H-bond acceptor, imparts an imidazolate character to the proximal heme ligand (Figure 9). This effect can be detected by RR spectroscopy, since the imidazolate character induces an increase in the frequency of the ν(Fe–Im) stretching mode (between 230 and 250 cm^{-1}) of the 5c Fe(II) state. Moreover, the polarity of the H-bond results in a downshift of the frequency of the ν(Fe–Im) stretching mode at alkaline pH and upon buffer deuteration due to a weakening of the H-bond interaction, as shown in early work by Kitagawa and coworkers.[103–105]

This pH effect on the ν(Fe–Im) frequency has been observed for all heme peroxidases so far studied (see Table 1). However, within the plant peroxidase superfamily, the RR spectral features of classes I and II noticeably differ from those of class III. In fact, at neutral pH, the peroxidases belonging to the first two classes (Table 1) show a broad band due to the coexistence of two bands at very different frequencies. They have been assigned to two tautomers: in one tautomer the proton resides on the imidazole, while in the other the proton is transferred to the carboxylate (Figure 9). On the contrary, peroxidases of class III at neutral pH

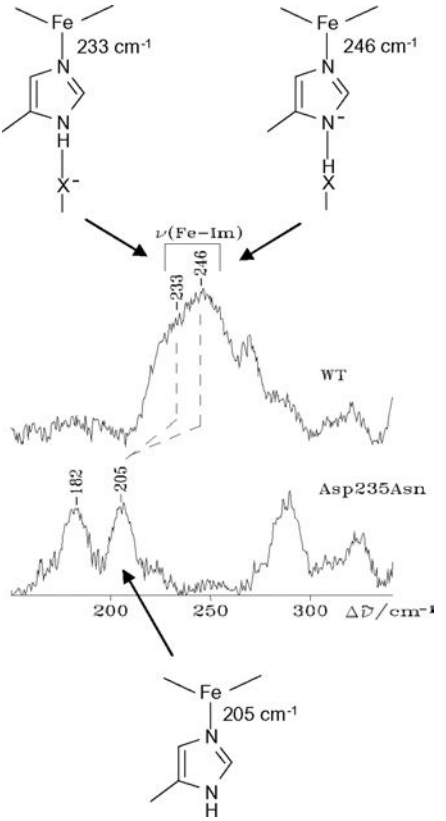

Figure 9. Low-frequency RR spectra of Fe(II) recombinant CCP(MKT) and the Asp235Asn mutant. The broad Fe-His stretching band observed in Fe(II) CCP is composed of two ν(Fe-His) modes, assigned to tautomers of the H-bond between the His175 N_δ proton and the Asp235 carboxylate chain. In one tautomer, the proton resides on the imidazole [ν(Fe-His) = 233 cm^{-1}], while in the other, the proton is transferred to the carboxylate [ν(Fe-His) = 246 cm^{-1}]. Disruption of the H-bond in the mutant lowers the frequency of [ν(Fe-His) to 205 cm^{-1}.[58,62] (Reprinted with permission from Smulevich, G.; Feis, A.; Howes, B. D. *Acc. Chem. Res.* **2005**, *38*, 433. © 2005, American Chemical Society.)

show only one tautomer, their RR spectra being characterized by a sharp band at a relatively high frequency (Table 1). A possible explanation of this behavior might derive from a different geometry of the H-bond between the proximal His and Asp (contained in helix H) residues compared to the members of classes I and II, which inhibits the formation of a double-well potential for the imidazole proton.

The replacement of the Asp carboxylate group with the amide group of an asparagine in ARP/CIP[64] and in CCP[58,62] causes a dramatic frequency lowering (about 40 cm^{-1}) of the ν(Fe–Im) stretch (Figure 9 and Table 1). In addition, the rupture of the His–Asp H-bond interaction upon mutation causes a change in the

Table 1. RR frequencies (cm^{-1}) of the ν(Fe–Im) stretching mode for various heme-containing peroxidases and selected site-directed mutants of the key residues of the heme pocket.

heme coordination and spin states from a 5cHS heme to a 6cLS bis–His heme. Therefore, the His–Asp H-bond interaction not only modulates the Fe–His bond strength but also restrains the Fe from moving into the heme plane and binding a distal water or the distal His.

B. Heme Pocket in Catalase–Peroxidases

In this section we will treat separately catalase–peroxidases (KatGs), since in the last few years they have aroused considerable interest. In fact, despite their striking

sequence homologies to CCP, they are the only members of the plant peroxidase superfamily exhibiting both peroxidase and substantial catalase activities. Many spectroscopic and functional studies have been published. Moreover, four crystal structures of different KatGs have recently become available, namely those from *Haloarcula marismortui*,[53] *Burkholderia pseudomallei*,[54] *Mycobacterium tuberculosis*[56] and *Synechococcus* PCC 7942.[106] They all revealed that the proximal and distal heme pockets contain conserved amino acids at almost identical positions as in other class I peroxidases, such as CCP and APX. In particular, both the proximal triads His/Trp/Asp (His290, Trp341 and Asp402) in *Synechocystis* numbering (which is used here) and the distal His/Arg/Trp (His123, Arg119 and Trp122) together with the H-bond interactions are conserved (Figure 10).

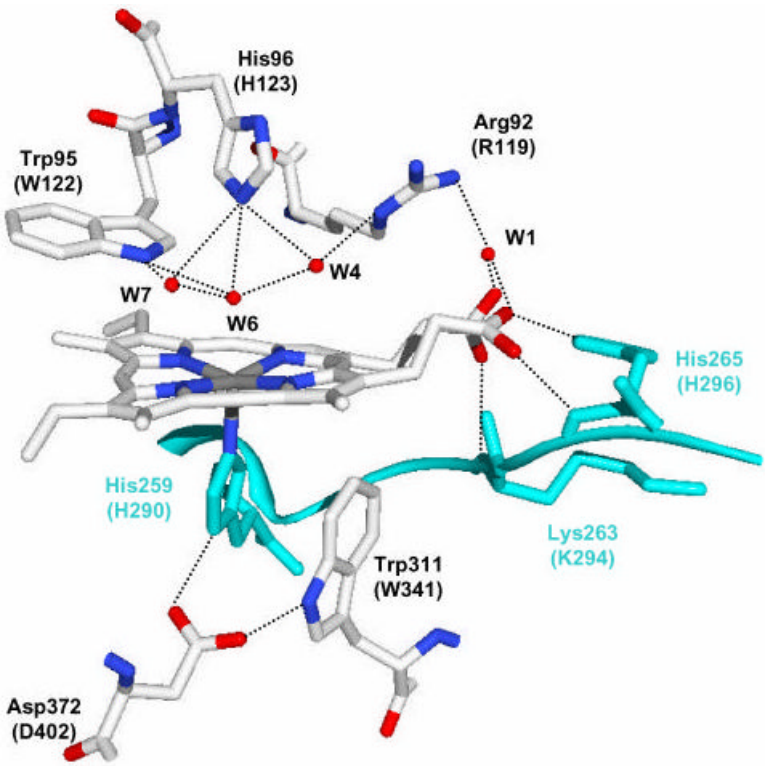

Figure 10. Structural diagram of the extended hydrogen-bond network connecting the distal and proximal sides of the heme pocket of *H. marismortui* KatG. The loop containing the proximal Fe-ligand (His290) and the residues hydrogen-bonded to the heme propionyls is shown in cyan. Smulevich, G.; Jakopitsch, C.; Droghetti, E.; Obinger, C., Probing the structure and bifunctionality of catalase–peroxidase (KatG). © 2006, with permission from Elsevier.)

However, the X-ray structures also revealed features unique to KatG. In the vicinity of the active site, novel covalent bonds between chains of the three considered distal residues, (Trp122, Tyr249 and Met275) (Figure 11) were found. Other specific KatG features are three large loops, two of them (indicated as LL1 and LL2) showing highly conserved sequence patterns.[107] Both LL1 and LL2 constrict the access channel of H_2O_2 to the heme group on the distal side. The LL1 insertion, in particular, is positioned at one edge of the heme between helices D and E, thereby connecting the distal and proximal catalytic domains and controlling the flexibility and character of the bond between the proximal histidine and the Fe(III) iron (Figure 12). In addition to the covalently linked distal Tyr249, LL1 contains other residues highly conserved in all KatGs, namely Ile248, Asn251, Pro252 and Glu253.[108]

Furthermore, Glu253 creates an acidic entrance to the channel characterized by a pronounced funnel shape and a continuum of water molecules (Figure 13). At the narrowest part of the funnel, the highly conserved residues Asp152 and Ser335 control the access to the distal side residues Arg119, His123 and Trp122. Ser335 is situated along the access channel, and probably H-bonded to the carbonyl oxygen atom of the heme propionate group. The side chain carboxyl group of Asp152 points toward the heme pocket at 7.8 Å from the heme iron and is H-bonded to two distal water molecules forming part of an extended H-bond network. The

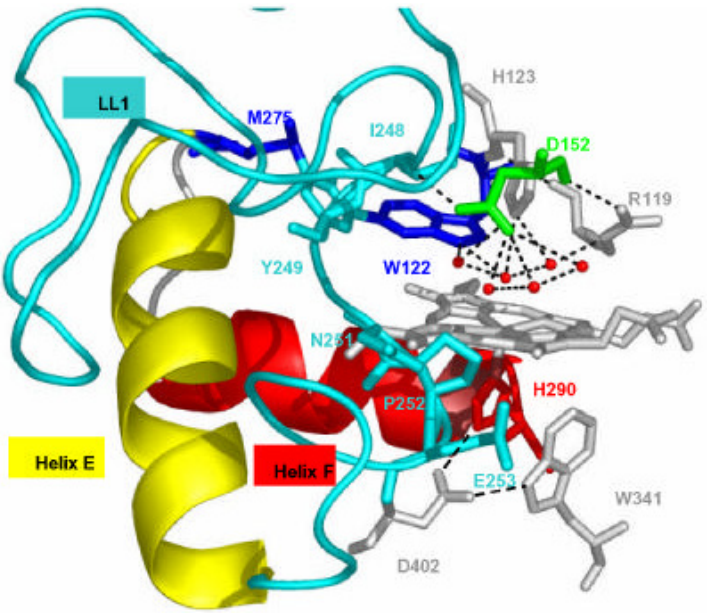

Figure 12. LL1 connecting the distal heme side with helices E (yellow) and F (red). Coordinates are from *H. marismortui* KatG but residue numbering is for *Synechocystis*. Typical peroxidase residues are depicted in gray and the proximal histidine in red. The distal aspartate is shown in green, residues forming the covalent adduct in blue, and residues belonging to LL1 in cyan. Only selected waters (in red) are shown. Dashed lines indicate hydrogen bonds, inferred on the basis of distance criteria. (Reprinted from *J. Inorg. Biochem.* **2006**, *100*, 568–585. presence of this novel Asp residue in the distal heme cavity provides some structural constraints in KatG. In fact, Asp152 is H-bonded to the LL1 residue Ile248 and is adjacent to Asn153, which is conserved in all plant-type peroxidases[1] and H-bonded to the distal His (Figure 11).

Extensive spectroscopic and kinetic studies (see Ref. 109 and references therein) have been performed on WT and selected variants of KatGs from different sources in order to understand how the structural features typical of KatG correlate with its bifunctional activity. Mutagenesis of both proximal and distal side residues of KatG affects selectively the function inhibiting mainly the catalase but not the peroxidase activity. Moreover, marked differences in the structural role of conserved amino acids and H-bond networks in KatG with respect to the other plant peroxidases were found.

RR has been mainly applied to the study of the cyanobacterium *Synechocystis* PCC 6803 (overexpressed in *E. coli*) KatG and selected mutants[108,110–112] and *M. tuberculosis* KatG and selected mutants.[113–118]

1. *KatG from Synechocystis*

The electronic absorption and RR spectra of Fe(III) KatG from *Synechocystis* are characterized by a predominant 5cHS heme with a small amount of both 6cHS and 6cLS hemes (Figure 14).[108]

Upon reduction the protein becomes predominantly 5cHS.[110] At pH 5.7, two ν(Fe–Im) stretching modes have been assigned at 205 and 253 cm^{-1}, the frequency being correlated with the strength of the H-bond between the proximal His and the Asp carboxylate side chain. As for CCP and APX (see Table 1), the band at 205 cm^{-1} corresponds to a species whose proton resides on the imidazole, while the band at 253 cm^{-1} corresponds to a form where the proton is transferred to the carboxylate (Figures 15 and 16). The absence of a decrease in the intensity ratio between the two bands upon changing the pH suggested that the two species are independent as in APX[96] and not in equilibrium as in CCP[58,62] or ARP/CIP.[63]

Based on the results obtained from the characterization of various site-directed mutants, marked differences in the structural role of the conserved amino acids and H-bond networks in KatG with respect to the other plant peroxidases were found. Mutations affecting the proximal His–Asp or Asp–Trp H-bond interactions dramatically alter not only the enzymatic activity[119] but also the coordination and spin states, as observed for other heme peroxidases.[18] In fact, as for the other heme

peroxidases, KatG contains a H-bond network connecting the proximal and the distal sides of the heme pocket (Figure 10). However, unlike the other plant peroxidases, mutation of the proximal key residues alters to differing degrees the heme architecture, weakening the heme binding. Partial loss of the heme, accompanied by the concomitant presence of a 6cLS heme due to the binding of an internal ligand to the heme, was revealed by both RR and electronic absorption.[112] The major role played by the proximal His–Asp H-bond in the stability of the KatG architecture was also directly confirmed by the Fe–Im bond strength, as measured via the RR frequency of the Fe–Im stretching mode. The experiment highlighted that the *v*(Fe–Im) stretching mode frequency is the result of a delicate equilibrium of the H-bonds between the conserved proximal His (His290) and Asp residues (Asp402) and between the Asp residue (Asp402) and the nitrogen atom of the indole group of Trp341. The disruption of the N_{Trp}–O_{Asp} H-bond in the W341F mutant strengthens the Fe–Im bond, resulting in a protein which maintains the spectral and kinetic properties of the WT protein. On the contrary, the combined

effect of the disruption of the Trp–Asp H-bond and absence of the π–π interaction between the His and the aromatic ring, as in the W341A mutant, completely destabilized the protein architecture. Moreover, the RR spectrum of the Fe(II) D402E mutant showed the presence of two different conformers, each characterized by two Fe–Im stretching modes at 202 and 251 cm^{-1}, as the WT enzyme, and at 213 and 237 cm^{-1}. The new conformer is likely a consequence of the novel Glu–His H-bond formed in the mutant (Figure 16), which, therefore, maintains its native HS character and peroxidase activity.[119]

Contrary to expectations, mutation of three distal amino acid side chains, Trp122, Tyr249 and Met275, involved in the two covalent bonds located on the distal side of the heme (Figures 11 and 12) does not significantly affect the Fe–Im bond strength [as judged by the RR ν(Fe–Im) band frequency] or the coordination state (as judged by the core size marker band frequencies), compared to the WT protein. However, unlike the WT protein, the variants show a tendency to lose the heme group. Interestingly, the Trp122Ala and Trp122Phe mutants showed a decreased alkaline transition pKa and, as a consequence, the Fe(III) RR spectra showed the presence of an aquo-6cHS heme and hydroxo-6cLS hemes coexisting with the 5cHS state at neutral pH. Therefore, when the complete crosslink is absent (Tyr249Phe and Trp122Phe or Trp122Ala) or only partially formed (Met275Ile), the heme binding is weakened and the protein is destabilized.[112]

Mutation of the conserved Trp, Arg and His distal residues perturbs the distal Fe coordination state and weakens the proximal Fe–Im bond. This is a consequence of the H-bond network which, via the distal water molecules, Trp, His and Arg residues, connects the distal and proximal sides of the heme pocket, as found for other plant peroxidase members (Figure 10).[18,110] As with the Arg51Asn CIP[65] or Trp51Phe CCP mutants,[58] substitution of the distal Arg with an Asn, or the distal Trp with either Ala or Phe residues,[110] facilitated binding of the distal water molecule to the iron. Similarly, a water molecule also binds the heme iron upon alteration or disruption of the Asn–His H-bond, by replacing the hydrogen-acceptor carboxamide group of the Asn153 residue with an aspartate carboxylate group (N153D) or an aliphatic residue (N153A). In fact, alteration or disruption of the Asn–His H-bond alters the distal His basicity, preventing the distal His from binding the distal water molecule. However, unlike plant peroxidases, distal mutation alters also the stability of the heme architecture. The Arg119Ala mutant was found to be particularly unstable, easily losing the prosthetic group even at neutral pH. The His123Glu variant also loses the heme at neutral pH, probably as a consequence of the nearby negatively charged Asp152 residue, a unique characteristic of KatGs. The study of variants that disrupt the H-bonding between Asp152, which resides in the distal cavity, and Ile248, located on the LL1 chain (Figures 11 and 12), gave important insight into the structural architecture characteristic of

only KatGs. RR data and structural analysis demonstrate the existence of a very rigid and ordered structure resulting from interactions of LL1 residues with both distal and proximal residues and the heme itself. This distal H-bond represents a novel link between the proximal and distal sides of the heme cavity and is important for the stability of the heme pocket and for maintaining the proximal H-bond strength. Substitution of Ile248 by Phe, or Asp152 with Ser, present in CCP, makes KatG spectroscopically and structurally similar to CCP. Mutation increases the 5cHS form at the expense of the aquo-6c species and drastically alters the proximal His–Asp H-bond interaction. Two pH-sensitive bands were found in the RR spectra of the Fe(II) forms at about 237 and 250 cm^{-1} (Figure 16 and Table 1), reminiscent of the 233 and 247 cm^{-1} doublet found in CCP,[62,120] corresponding to tautomeric forms of the H-bond between the His290 and Asp402 carboxylate side chain. These results confirm that perturbation of the Asp152–Ile248 H-bond leads to changes at the proximal heme site which are mediated by LL1 and its connection with helices E and F, with helix F carrying the proximal histidine (Figure 12). Moreover, since these mutations increase the peroxidase activity with a concomitant dramatic reduction of the overall catalase activity, it was suggested that small structural perturbations and disruption of the H-bond networks have only a small impact for compound I formation (see Section II.F), which is common to catalatic and peroxidatic activity, but a defined extended H-bond network is crucial for selectively guiding and binding the (second) peroxide molecule necessary for the catalatic activity.[108]

2. *KatG from Mycobacterium tuberculosis*

KatG from *M. tuberculosis* is important for the virulence of this pathogen because of its role in the removal of peroxide in infected host macrophages.[121–123] Moreover, *M. tuberculosis* KatG is of great interest in the field of tuberculosis research, since it plays a direct role in activation of the prodrug isoniazid, a potent antituberculosis drug which has been in use for more than half a century since its discovery in 1952.[124] The growing worldwide problem of resistance to this drug due to mutations in the katG gene has been addressed in clinical and biochemical studies often focused on the 315 position. The S315T variant has been produced in the laboratory and studied in detail, since this mutation is that most commonly found in isoniazid resistant bacteria.[56,125] As mentioned above, the Ser residue is situated along the substrate access channel, and is probably H-bonded to the carbonyl oxygen atom of the heme propionate group. Recently, an explanation for isoniazid resistance in the S315T mutant was found in the loss of the high-affinity drug-binding site, since the methyl group of the threonine residue restricts the narrow opening at the bottom of a substrate access channel.[125] Nevertheless, the

S315T mutant preserves the enzyme functions, thereby preserving bacterial physiology and virulence.[126]

Recombinant KatG and selected variants from *M. tuberculosis* have been extensively studied by optical and RR spectroscopy, giving apparently discordant results, characterized by variability of the heme spin and coordination states. However, recently the RR examination of Fe(III) KatG from *M. tuberculosis* under a variety of conditions, including the presence of fluoride, chloride or isoniazid, and isolated at different stages during purification in different buffers, allowed the Fe(III) heme structural heterogeneity to be explained, and underlined that it contains a heterogeneous population of heme species that present distinct spectroscopic properties.[115,118] The RR results reveal that a 5c heme form of KatG could be isolated, but that coordination and spin state changes are unavoidable during handling of the enzyme under a variety of conditions, as reported earlier for CCP.[127] Therefore, while the 5c form (HS and QS) predominates in the freshly isolated enzymes, a 6c heme species accumulates in the resting enzyme after purification. This form has been shown to have a unique structure containing weakly associated water on the heme distal side and it is the favored reactant for ligand binding. In particular, the use of resting enzyme samples with different proportions of the 5c and 6c forms, as well as the use of the KatG mutants with replacements at residue 315, which have different tendencies to create the 6c form, allowed the authors to demonstrate that the 6cHS species binds cyanide more rapidly and is the preferred heme state for peroxide binding. In particular, RR provided direct evidence for favored binding of cyanide to the 6c S315T mutant.

Fe(II) KatG from *M. tuberculosis* also shows contrasting results. While two pH-dependent ν(Fe–Im) stretches at 244 and 228 cm^{-1} have been reported,[113] in a more recent report[114] only the 244 cm^{-1} ν(Fe–Im) stretching mode has been observed. The Fe–Im stretching vibration is detected also at 244 cm^{-1} in the Fe(II) forms of the S315T variant.[116] Minimal, if any, perturbation of the distal heme pocket in the S315T mutant has been observed. Instead, the S315T mutation seems to induce small changes in the KatG conformation/dynamics of the ligand access channel, as indicated by CO rebinding kinetics in flash photolysis experiments. Therefore, as noted above, it is suggested that substitution of Ser315 with Thr confers resistance to isoniazid by reducing accessibility to the KatG heme pocket by steric hindrance in the access channel. However, since the actual binding site of isoniazid in KatG and its S315T mutant remains elusive, this model may be relevant only when isoniazid binds inside the heme pocket, and modification of an isoniazid binding site outside the heme pocket by the mutation cannot be ruled out.[116]

The characterization of the *M. tuberculosis* Tyr229Phe and Met255Ile mutants,[115] in agreement with the slight differences noted between the WT protein

from *M. tuberculosis* and that from *Synechocystis* PCC 6803, showed spectroscopic features slightly different from those of the corresponding mutants of *Synechocystis*. The Met255Ile variant has a significantly greater relative population of the 6cHS heme than either WT KatG or the Tyr229Phe mutant. Similar to the corresponding mutants of *Synechocystis* KatG, this latter mutant of *M. tuberculosis* has decreased steady-state catalase activity and enhanced peroxidase activity. In addition, since it shows a significantly reduced affinity for isoniazid,[128] it has been proposed that the Trp–Tyr–Met linkage, absent in the Y229F variant, may be required for establishing the proper geometry of the residues that contribute to the formation of a small-molecule binding site.[54] Moreover, although disruption of the cross-linked adduct in the Y229F mutant does not seem to affect H-bonding in the proximal heme pocket, since the Fe–Im stretching frequency is the same for the Fe(II) Tyr229Phe variant and WT protein,[117] the absence of the covalent linkage perturbs the active site. RR spectra of the Fe(III) Y229F variant are consistent with a significant amount of the 6cLS heme and a more planar heme compared to WT KatG. Moreover, changes in the properties of the CO (see below) and NO vibrations indicate that their binding geometry and their steric and electrostatic interactions with distal residues are modified in the Y229F variant.[117] These observations support the idea that loss of the cross-linked triad by the Y229F mutation causes rearrangement of distal heme pocket residues and perturbs their H-bonding interactions with ligands bound to the heme.[114,116] The authors proposed that the Met–Tyr–Trp cross-linked adduct stabilizes a distal H-bonding network that is disrupted in the Y229F variant due to rearrangement of distal residues. This network includes Ile228, which forms a H-bond with Asp137. In *Synechocystis* KatG, the analogous Asp (Asp152) plays an important role in stabilization of the LL1 loop which is anchored by Tyr229.[53,54,56,107,111,129] Asp137 forms a H-bond with Arg104 which interacts with a water molecule that is H-bonded to the heme propionates.[56] Perturbation of H-bonding to the heme propionates can explain the difference in heme planarity and pH sensitivity between the Y229F variant and WT KatG.[114] Differences in the steric and electrostatic environment of their distal heme pockets are most likely due to rearrangement of distal pocket residues and, to a lesser extent, perturbation of the H-bonding network. Figure 17 shows the proposed H-bonding network. The integrity of the covalent adduct seems crucial for the stability of the LL1 loop, the maintenance of the proposed H-bonding network and, in general, of the heme pocket architecture.

C. Calcium Binding Sites

In addition to the conserved residues, the peroxidases of classes II and III have two calcium binding sites, one distal and one proximal to the heme plane (as shown

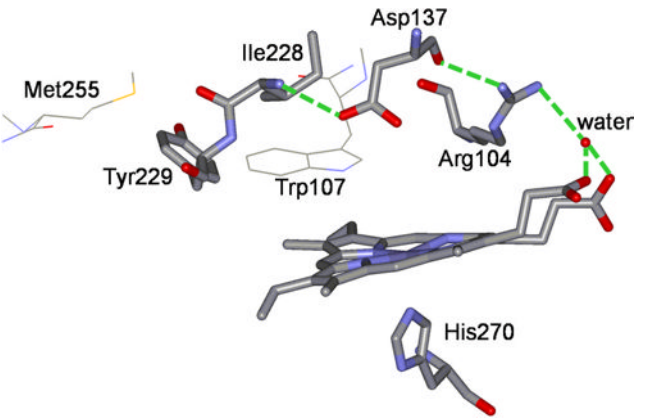

Figure 17. H-bonding network between Tyr229 and heme propionate groups that may be perturbed in the Y229F mutant of KatG from *M. tuberculosis*. The dotted lines indicate the H-bonds with lengths shorter than 3 Å. (Reprinted from *J. Inorg. Biochem.* **2006**, *101*, 422–433. Kapetanaki, S. M.; Zhao, X. B.; Yu, S. W.; Magliozzo, R. S.; Schelvis, J. P. M., Modification of the active site of *Mycobacterium tuberculosis* KatG after disruption of the Met–Tyr–Trp cross-linked adduct. © 2006, with permission from Elsevier.)

for HRPC in Figure 18), which are important for maintaining protein stability and activity.[1,39,44] These features are absent from class I peroxidases. However, APX has a K^+ binding site on the proximal site.[45] As with the effect of Ca^{2+} ion removal from peroxidases of classes II and III (see below), the electronic absorption and MCD spectra of the engineered K-site APX mutant, which has had its potassium cation binding site removed, gave rise to a bis-imidazole ligated heme system. Therefore, it appears that upon removal of the proximal K^+ ion the protein undergoes a conformational change to yield a bis-histidine coordination structure in both the Fe(III) and Fe(II) oxidation states at neutral pH.[130]

Figure 18 shows the local structure in the proximity of the distal and proximal Ca^{2+} ion binding sites of native HRPC.[47] Both Ca^{2+} ion sites are seven-coordinate, with ligands composed of side chain oxygen atoms and carbonyl groups and one water molecule in the case of the distal site. The distal and proximal Ca^{2+} ions are structurally coupled to the active site (His42 and His170, respectively) through an intermediate residue adjacent in sequence (Asp43 and Thr171, respectively). Each of these intermediate residues provides two bonds to the corresponding Ca^{2+} ion; therefore, the loss of either Ca^{2+} ion has considerable potential to perturb the active site structural and catalytic properties.

Although peroxidases of the plant superfamily display primary structure homology, the role of calcium in maintaining the function of the enzyme is different between classes II and III. The class II peroxidases MNP and LIP showed complete loss of activity after calcium release, in contrast to the class III peroxidases

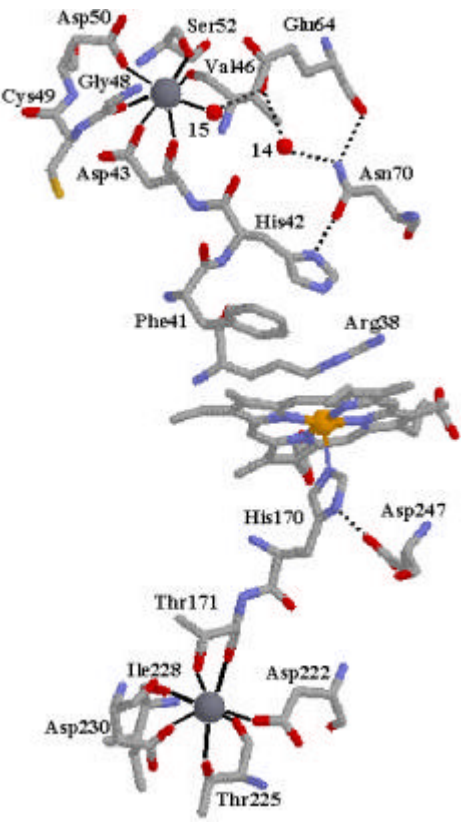

Figure 18. The structural features of the heme pocket of HRPC, showing the distal and proximal Ca^{2+} ion-binding sites, heme group and principal residues. Bonds with the Ca^{2+} ions are shown as continuous lines and hydrogen bonds as dashed lines.

HRPC, HRPA1 and PNP, which retained 40–60% of their activity after calcium release.[131,132] This difference between the two classes of peroxidases was attributed to different locations of intramolecular disulfide bridges.[133] Moreover, spectroscopic and functional studies of many class III peroxidases indicate that one of the two Ca^{2+} ions may play a more important role in maintaining the heme pocket structural characteristics necessary for high catalytic activities.[131,134] Loss of activity, observed under thermal and alkaline inactivation for many classes II and III peroxidases, has been correlated with the loss of one or both calcium ions. Thermal[135] and alkaline[136] inactivation of LIP has been correlated with loss of calcium ions and formation of an inactive bis-histidyl hexacoordinate low-spin (6cLS) heme state. In apparent contrast with alkaline inactivation, which results in the loss of both calcium ions, thermal inactivation causes the loss of only the more weakly bound distal calcium ion. Likewise, thermal inactivation of MNP has been correlated

with loss of a distal calcium ion and formation of an inactive 6cLS state.[133,137] Perturbation of the distal calcium binding site by construction of the site-directed mutant, Asp47Ala, resulted in an enzyme that had properties identical to those of thermally inactivated MNP.[133] ^{1}H-NMR studies on class III peanut peroxidase could not distinguish the structural contributions of each calcium ion. However, it was evident that binding of the two Ca^{2+} ions was required in order not to compromise the structural properties and activity of the enzyme.[138]

Removal of the bound calcium ions from native HRPC results in a considerable decrease in activity and thermal stability.[131,134,139–142] Calcium is required to maintain the structural integrity of the heme in its optimal geometry for catalysis, which is lost upon calcium depletion.[143] Moreover, based on the spectroscopic results obtained upon mutation of the amino acids involved in the H-bonding network around the heme,[144–147] it was concluded that the Ca^{2+} ion on the distal side of the heme plays a determining role. Unlike the abovementioned studies, RR and UV-vis spectra firmly favor the proximal Ca^{2+} ion as the first to be lost.[148] In fact, in the Fe(II) form, the ν(Fe–Im) stretching mode downshifts 27 cm^{-1}, revealing a significant structural perturbation of the proximal cavity near the His ligand. Since the Thr171 residue, adjacent to the proximal His, provides two coordination bonds to the proximal Ca^{2+} ion (Figure 18), it is reasonable to expect that loss of only this Ca^{2+} ion would cause a change in the disposition of the histidine leading to a weakening of the His–Asp hydrogen bond and, therefore, of the heme iron–His170 interaction. The binding properties of the distal cavity are maintained since, as for native HRPC, the Ca^{2+}-depleted enzyme binds benzohydroxamic acid in its Fe(III) state, and CO in its Fe(II) state, suggesting that modification of the distal cavity by Ca^{2+} depletion is not particularly extensive and/or can be easily reversed. However, unlike the native protein, observation of a bis-histidyl LS heme in reduced Ca^{2+}-depleted HRPC indicates that loss of calcium induces some conformational change in the heme pocket. Alteration of the distal side heme structure enables the imidazole group of the distal histidine to bind to the sixth coordination position of the reduced heme iron. In agreement with the loss of the proximal calcium ion is the finding that a similar LS heme is formed in Fe(II) HRPC[69] upon mutation of the proximal Phe221 residue, which is stacked approximately parallel to the proximal histidine ligand. Clearly, alteration of the proximal heme side can be transmitted to the distal cavity, inducing some flexibility in the position of the distal histidine.

Interestingly, the mutation of F190 in MNP (equivalent to F221 of HRPC) by either Ile or Ala has also a marked destabilizing effect on the enzyme,[149] giving rise to a 6cLS bis-histidyl complex.[150] The formation of this complex requires displacement of helix B to enable the distal His46 to coordinate with the heme iron atom. Moreover, it has been suggested that this mutation also results in the loss of

the distal calcium ion.[151] However, the calcium ions of class II fungal peroxidases such as LIP and MNP are more labile than those of class III plant peroxidases.[136] The difference between the lability of the distal calcium in classes II and III peroxidases is due mainly to the disulphide bridge between Cys44 and Cys49, which is unique to the latter.[1] This restricts the flexibility of distal helix B and limits movement of His42 in the distal heme cavity of HRPC.

The role of Ca^{2+} ions has also been addressed by computer simulations. A 500 ps[143,152] and 2 ns[153] molecular dynamics calculation on the native HRP structure and those produced by computer simulation techniques after partial and total Ca^{2+} depletion have been performed. The NSD analysis of the heme group revealed that the deformation of the heme group from D_{4h} symmetry, significant in the native form,[154] upon total Ca^{2+} depletion changed both the in-plane and out-of-plane distortions with a decrease of nonplanarity.[152,154] NSD analysis showed also a lack of coupled dynamics of the heme and protein motion[153] after Ca^{2+} removal. In addition, polarized RR spectroscopy on partially Ca^{2+}-depleted samples[155] suggested more significant structural effects than those previously reported[148] and somewhat different changes in the spin state of the heme. These different results have been attributed to differences in the sample preparation techniques, even if they appear to be similar.

Recently, the native and totally Ca^{2+}-depleted forms of HRPC have been compared by using pH-, pressure-, viscosity- and temperature-dependent UV absorption, CD, H/D exchange-FTIR spectroscopy and by binding of the substrate benzohydroxamic acid. It has been reported that Ca^{2+} depletion does not change the alpha helical content of the protein, but strongly modifies the tertiary structure and dynamics to yield a homogeneously loosened molten globule-like structure. The observed tertiary changes in the heme pocket have been related to changes in the dipole orientation and coordination of a distal water molecule. Deprotonation of distal His42, linked to Asp43 which is coordinated with the distal Ca^{2+}, perturbs an H-bonding network connecting this Ca^{2+} to the heme crevice that involves the distal water.[156] Moreover, unlike the previously observed effects noted after one Ca^{2+} ion depletion,[148] the authors did not observe effects that required involvement of a role for the proximal Ca^{2+}. The significant structural effects on the overall protein structure and also in the heme pocket reported in this study indicate that the binding of the distal Ca^{2+} is of critical importance.

D. Binding Sites for Substrates: Benzohydroxamic and Salicylhydroxamic Acids

The mechanism of substrate binding and catalysis in heme peroxidases has been reviewed previously.[2,157] The application of site-directed mutagenesis enabled

significant progress to be made in understanding the roles of the amino acid residues involved in substrate binding. The combination of X-ray crystallography and Raman spectroscopy has been particularly informative, highlighting the effects of hydroxamic acid binding to peroxidases. In particular, comparison of detailed Raman spectra for complexes in crystal and solution forms provides a means of bridging crystallographic and solution studies.[17]

The binding of nonphysiological substrates, such as aromatic hydroxamic acids, to peroxidases has been extensively investigated with the aim of probing the aromatic donor binding site. In particular, X-ray structures have been solved for the complexes formed between HRPC and benzohydroxamic acid (BHA),[158] and ARP/CIP with both BHA[159] and salicylhydroxamic acid (SHA).[160] The comparison between these structures reveals that the location of the aromatic rings in the active site is similar (Figure 19).

The aromatic ring is located in the distal cavity, nearly parallel to the heme plane. The hydroxamic acid moiety forms H-bonds with the conserved distal His, Arg and Pro55 residues. The additional hydroxyl group of SHA (compared to BHA) does not form H-bonds with any amino acid residue in the heme cavity. In addition, a hydrophobic pocket surrounding the aromatic ring of the substrate was found in HRPC, which is not present in ARP/CIP.[158] The aromatic molecule does not bind directly to the heme iron, but the addition of SHA or BHA to HRPC and ARP/CIP displaces water molecules from the distal cavity, leaving only one molecule of water close to the heme iron. The iron–water distances in the HRPC–BHA, ARP/CIP–BHA and ARP/CIP–SHA complexes were found to be 2.6,[158] 2.7[159] and 2.8 Å,[160] respectively. Considering the rather long Fe–H_2O distance, there have been conflicting interpretations concerning the extent to which BHA affects the binding of the water molecule to the Fe atom. While NMR proton hyperfine shifts indicated that the HRPC–BHA complex was a five-coordinate high-spin (5cHS) species,[70] based on electronic absorption,[161] resonance

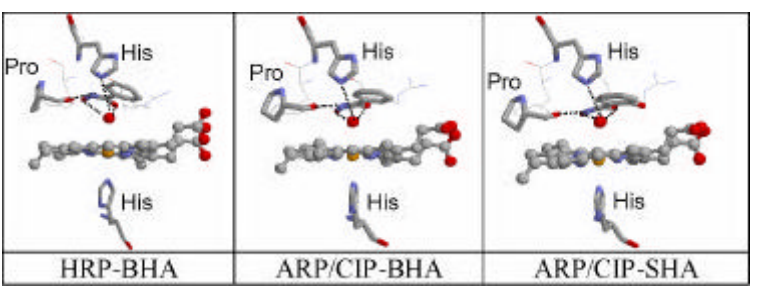

Figure 19. Comparison of the heme pocket of HRPC with BHA,[158] and ARP/CIP with both BHA[159] and SHA.[160]

Raman[67,95,162,163] and EPR,[164] it was concluded that binding of BHA to both HRPC and ARP/CIP[74,91] induces the formation of a six-coordinate high-spin (6cHS) heme. Comparison of the RR spectra of single-crystal and solution samples of the complex demonstrated that this form derives from a water molecule bound to the heme iron.[91,93] However, the solution spectra for HRPC and ARP/CIP complexed with BHA differ in terms of the amount of the 6c form present. This difference was correlated with the small variation observed by X-ray crystallography in the iron–water distance between HRPC–BHA (2.6 Å), ARP/CIP–BHA (2.7 Å) and ARP/CIP–SHA (2.8 Å), which is longer than the usual iron–ligand distance (2.1 Å). The combined analysis of the spectroscopic data and X-ray crystal structures of the ARP/CIP–SHA complex indicates that the Fe–H_2O distance measured by X-ray diffraction is an average resulting from the 5c and 6c species in equilibrium which, however, are directly revealed by RR spectroscopy.[93] Figure 20 compares the RR spectra of solution and single-crystal samples of the ligand-free ARP/CIP and its complexes with SHA and BHA at pH 5.5. It can be seen that there are no substantial differences in the band frequencies between the solution and the crystalline states. The Fe(III) protein at pH 5.5 is a pure 5cHS.[63,93] Upon addition of either BHA or SHA, changes in the frequency and relative intensities of the core size marker bands are observed, clearly indicating the formation of a 6cHS (ν_{11} at 1542, ν_{19} at 1561 and ν_{10} at 1616 cm^{-1}) at the expense of the 5cHS species (ν_{11} at 1551, ν_{19} at 1568, and ν_{10} at 1631 cm^{-1}), which remains in a small amount, as judged by the bands at 1631 cm^{-1} (ν_{10}) and the shoulder at 1551 cm^{-1} (ν_{11}). The ARP/CIP–SHA complex gives rise to spectra characterized by features that are in

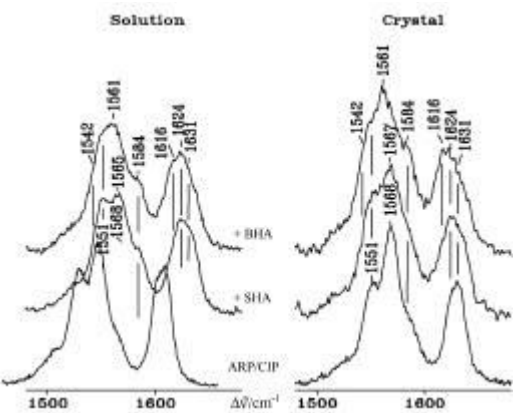

Figure 20. Comparison between solution (left) and single-crystal (right) RR spectra of ARP/CIP–BHA and ARP/CIP–SHA, obtained with the 514.5 nm line of an Ar^+ laser. (Reprinted with permission from Indiani, C.; Santoni, E.; Becucci, M.; Boffi, A.; Fukuyama, K.; Smulevich, G. *Biochemistry* **2003**, *42*, 14066–14074. © 2003 American Chemical Society.)

between those typical of the free and BHA ligated protein, since it contains a higher amount of the 5cHS heme. The RR spectra of the crystals are characterized by a striking enhancement of the inverse-polarized ν_{19} mode at 1568 cm^{-1} (ARP/CIP) 1567 cm^{-1} (ARP/CIP–SHA), and 1561 cm^{-1} (ARP/CIP–BHA), which does not depend on the orientation of the crystal in the laser beam, but is likely the result of a larger ruffled distortion of the heme for the crystalline form of ARP[73] with respect to the protein in solution.

E. Ligand Binding

It is well known that heme pocket proximal and distal amino acid residues control ligand binding in heme proteins. For example, the conserved distal histidine of vertebrate globins has been shown to be important in fine-tuning the ligand affinities via H-bond stabilization involving its N_ε proton.[165,166] In peroxidases, the H-bond stabilization of the incoming ligand by the distal residues is of particular importance, since they have a more polar distal cavity compared to globins. The postulated mechanism of peroxide decomposition relies on the concerted roles played by the proximal histidine together with the distal histidine and arginine residues, through H-bonds and charge stabilization, as originally proposed by Poulos and Kraut.[167] Furthermore, the H-bond between the N_δ proton of the distal His and a conserved Asn residue, and/or the presence of the positively charged guanidinium group of the distal Arg in the proximity of the distal His, depresses its p*K*a to values between 4 and 5,[59] forcing the N_ε of the imidazole ring to act as an H-bond acceptor. Therefore, many studies on peroxidases have been devoted to understanding whether the different cavity characteristics of the globins and peroxidases are also reflected in the binding of other exogenous ligands. Crystal structures of the complexes formed between CCP and CN^-, NO, CO and F^- revealed that significant changes are induced in the distal cavity upon adduct formation. The disposition of the distal Arg and His residues is significantly perturbed, and there is a rearrangement of the water molecules present in the active site.[168] In the case of the CCP–CN complex, all three distal residues, Arg48, Trp51 and His52, can potentially form H-bonds with the N atom of cyanide; the ligand in the CCP–F complex is directly H-bonded to the Trp51 and Arg48 residues, whereas the distal His appears H-bonded to a water molecule, which in turn interacts strongly with the fluoride. The interaction between Arg48 and F^- is possible because the distal Arg undergoes a conformational change that places it within H-bonding distance of F^-. Clearly, the fact that the X-ray structures of both the CCP fluoride complex and the CCP compound I (see Section II.F) show that the distal Arg48 adopts an "in" position, which enables Arg48 to H-bond with the ferryl O and the fluoride ligand,[169] highlights the effectiveness of the fluoride ligand in

probing the distal heme cavity of CCP, CIP and HRPC. The electronic absorption and RR data on a carefully chosen selection of site-directed mutants for these peroxidases allowed diagnostic correlations to be established between spectroscopic parameters, and the number and nature of H-bonding partners in the corresponding fluoride complexes.[65]

Upon fluoride binding, despite the fact that all the peroxidases under investigation showed almost identical RR spectra characteristic of six-coordinate high-spin species, the position of the charge transfer band (CT1) in the electronic absorption spectra varied between 610 and 620 nm. In general, the wavelength of this band depends on the p and π donor capability of the axial ligands[61,64,170] and, therefore, it is a sensitive probe of axial ligand polarity and of its interaction with the distal protein residues. The stronger the H-bond from the ligand to a distal residue, the lower the CT1 wavelength. The opposite effect is observed when the ligand acts as an H-bond acceptor. This trend is illustrated by the effect on the CT1 band of mutation of the distal Trp/Phe residue in CCP and CIP, respectively (Table 2 from Ref. 18). The CT1 wavelength of the fluoride complex of both CCP–F and the Phe54Trp CIP variant is greater than that observed for CIP–F or the Trp51Phe CCP variant. In fact, while in the first case the bound F^- receives H-bonds from the distal Arg, Trp, and a water molecule, in the CCP Trp51Phe mutant and in CIP, the number of H-bonds is reduced from three to two. The loss of Trp, which acts as an H-bond donor, blueshifts the CT1 band.

The combined analysis of the UV-vis and RR data on peroxidases has highlighted that the complex mechanism of stabilization of anionic ligands exerted by the distal amino acids resembles that of compound I formation during peroxidase catalysis, where ligand stabilization by the distal Arg is coupled to protonation of the distal His. Clearly, the mechanism of stabilization of the fluoride ligand exerted by the distal residues is different between myoglobin and peroxidases. In peroxidases, the Arg is the determinant in controlling the ligand binding via a

strong H-bond between the positively charged guanidinium group and the anion. Mutation of Arg to Leu decreases the stability of the complex 900-fold, suggesting that this interaction stabilizes the complex by 4 kcal/mol. The distal His also contributes to the stability of the fluoride complex, presumably by accepting a proton from HF and H-bonding, through a water molecule, to the anion. Mutation of His to Leu decreases the stability of the fluoride complex 30-fold, suggesting that this interaction is much weaker than the interaction with the distal Arg. For Mb, the distal His is solely responsible for stabilization of the exogenous ligand.

On the basis of RR studies, the involvement of the distal residues in the stabilization of the CN^-,[171,172] and OH^- ligands[67,79] has also been proposed. In particular, for the HRP–OH[67] and CIP–OH complexes[65] both the distal Arg and His interact, in a concerted manner, via H-bonds with the ligand. The positive guanidinium group of the distal Arg is strongly H-bonded to the ligand, since upon mutation of the Arg the hydroxyl is not able to bind to the iron atom in both proteins. The distal His plays a secondary role, but is also H-bonded to the bound ligand, giving rise to a 6cLS heme.[65,67] Interestingly, WT CCP does not bind OH^- at alkaline pH. In fact, the alkaline transition induces a conformational change that permits the distal His52 to bind the Fe atom, forming a bis-His 6cLS heme. When this residue is replaced by Leu, the hydroxide ligand instead binds to the Fe atom.[59]

CO binds to the heme iron of peroxidases in the Fe(II) oxidation state. The interactions between the oxygen of the CO and the distal residues are weaker than in the case of fluoride complexes. Therefore, conformational transitions, such as that induced by fluoride in CCP, have not been observed. X-ray structures are available for the CCP–CO and HRPC–CO complexes.[173,174] In the case of HRPC, the angles and distances between the oxygen atom of CO and the side chains of His and Arg indicate a strong H-bond with His42 and a weaker one with Arg38 (Figure 21).[174] For CCP, the distance between the oxygen atom of CO and Arg48 is greater than 3.2 Å and it appears that the ligand interacts with the guanidinium group via an H-bond with a water molecule. Whether or not His52 is H-bonded with CO is less certain. However, His52 is close enough for H-bonding (within 2.8 Å) to CO.

The heme protein adducts with CO are the most frequently studied Fe(II)–ligand complexes, since CO is a sensitive vibrational probe of heme binding sites in proteins. In particular, polar interactions and the formation of H-bonds between the bound CO and the distal residues increase the extent of back-donation from the Fe d_π to the CO π^* orbitals. As a consequence, the Fe–C bond strengthens while the CO bond weakens, thereby increasing the ν(FeC) vibrational frequencies and decreasing the ν(CO) frequencies.[175,176] There is an inverse linear correlation between the ν(FeC) and ν(CO) frequencies which depends on the extent of π back-bonding (Figure 22).

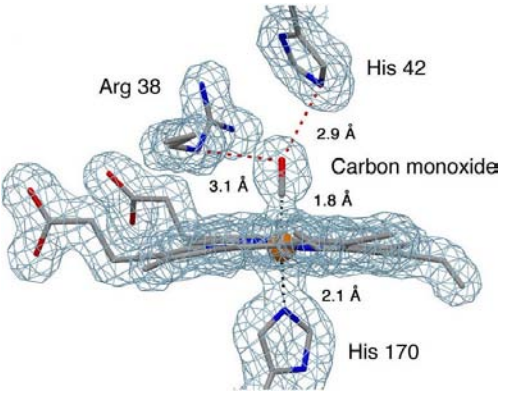

Figure 21. Refined crystal structures, showing the active site of the HRPC–CO complex. (Reprinted with permission from Carlsson, G. H.; Nicholls, P.; Svistunenko, D.; Berglund, G. I.; Hajdu, *J. Biochem.* **2005**, *44*, 635–642. © 2005, American Chemical Society.)

The CO adducts of many members of the plant peroxidase families have been obtained. It is clear from Table 3 that the study of CO–peroxidase complexes has benefited greatly from the availability of site-directed mutants. In fact, comparison between wild-type and mutated proteins has enabled clarification as to which CO–amino-acid interactions are most important.

The main results obtained by vibrational spectroscopy for heme peroxidases can be summarized as follows:

(i) The CO complexes of heme peroxidases differ markedly from those of sterically hindered model CO–porphyrin complexes, being sensitively dependent on interactions between the CO molecule and adjacent amino acids.

(ii) Multiple pH-dependent conformers may be present in the CO complexes of peroxidases. On the basis of distal mutations, it has been demonstrated that the conformers differ in terms of their H-bond interactions between the oxygen of the bound CO and the distal His or Arg.[127,170,177–179] In particular, at neutral pH, while only one form has been found for the CCP–CO complex, HRPC–CO has two different conformers deriving from different protein–CO interactions. The RR and IR results on the CCP–CO complex in solution revealed that the oxygen atom of the bound CO is H-bonded with a distal residue,[120] subsequently identified as the distal Arg.[59] However, this H-bond interaction is weaker than that observed for the HRP–CO form I, characterized by ν(FeC) and ν(CO) at 539 and 1906 cm^{-1}, respectively (Figure 22 and Table 3). This result agrees with the conclusions obtained from the comparative

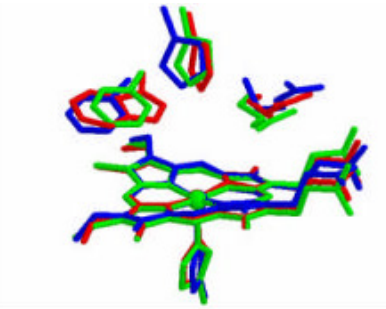
[a]Cationic ascorbate peroxidase isoenzyme II from tea.

study of compound I formation upon mutation of the distal Arg and His in CCP and HRPC. The removal of the positively charged guanidinium group of Arg from the active site is more critical in HRPC than in CCP.[180] In the other conformer of HRPC–CO, form II (characterized by ν(FeC) and ν(CO) at 516 and 1934 cm^{-1}), His42 is the interacting residue. The vibrational frequencies of this latter conformer are very similar to those observed for the ARP/CIP–CO complex[181] (see point iv).

(iii) The H-bonding capability of the distal Arg residue influences the water molecule occupancy of the distal cavity, which orchestrates the H-bond network of the distal cavity and the ability to form stable complexes between anionic ligands and the heme Fe atom. However, it is not essential to stabilize the CO ligand, as in the case of ARP/CIP–CO, demonstrating that Arg51 of ARP/CIP does not interact with the CO molecule directly, but modulates the back-bonding and the CO dissociation rate.[181]

(iv) The capability of CO to form H-bonds with the distal residues clearly depends on their geometrical disposition and the size of the distal cavity. The Fe(II) ARP/CIP–CO complex is characterized by a much more open cavity than the other peroxidases. On the basis of the X-ray structure of the Fe(III) protein[42] (Figure 23), it appears that only the His residue is able to interact with the CO ligand, since the location of the Arg residue precludes its interaction with the CO.



Distances (Å) between the Fe atom and the N atoms of the distal Arg				Residues involved in H-bonds with CO
	N_ε	NH_1	NH_2	
HRPC	4.6	5.8	6.7	His Arg
CCPMI	5.5	7.0	7.7	H_2O Arg
ARP/CIP	6.3	8.0	8.3	His

Figure 23. Comparison between the heme pocket of HRPC,[46] CCPMI[92] and ARP/CIP.[42] The table reports the relative distances between the Fe atom and the N atom of the distal Arg, together with residues involved in the H-bonds with the bound CO, as inferred on the basis of the RR spectra.

By comparing the structures of Fe(III) CCP(MI)[92] and HRPC,[46,47] it can be seen that the terminal nitrogen atom of the distal Arg is located at a shorter distance (about 1 Å) from the heme iron in HRPC than in CCP. This characteristic accounts for the stronger H-bond interaction with CO in HRPC compared to CCP. Moreover, both the distal His and Arg residues in HRPC are involved in H-bond interactions with the coordinated CO. The different geometric dispositions and p*K*a's of the distal residues in the two proteins are considered to be responsible for the different stabilization mechanisms.

F. Catalytic Intermediates

Peroxidases catalyze the oxidation of a wide variety of organic and inorganic substrates at the expense of hydrogen peroxide via the formation of two higher-valence intermediates, commonly named compounds I and II.[157,182] The initial step in the catalytic mechanism is heterolysis of the O–O bond of hydrogen peroxide, resulting in compound I and water. Compound I is two oxidation equivalents higher than the resting form, containing an iron oxoferryl center [Fe(IV)=O] and a porphyrin cation radical ($Por^{\bullet+}$). As will be discussed later, in some peroxidases the

radical can be formed on an amino acid residue (as in the case of CCP, in which the long-lived intermediate known as compound ES consists of a ferryl porphyrin with a radical localized on the Trp191 residue).[30]

Compound I is then reduced back to the resting state by two sequential one-electron oxidations of two substrates, SH, via the intermediate compound II [Fe(IV)=O].

The reaction can be summarized as follows:

$$\text{Resting state Fe(III)} + H_2O_2 \rightarrow \text{Compound I [Fe(IV)=O Por}^{\bullet+}\text{]} + H_2O$$

$$\text{Compound I [Fe(IV)=O Por}^{\bullet+}\text{]} + SH \rightarrow \text{Compound II [Fe(IV)=O]} + S^{\bullet}$$

$$\text{Compound II [Fe(IV)=O)]} + SH \rightarrow \text{Resting state Fe(III)} + S^{\bullet} + H_2O$$

It is of note that, historically, the terms "compound I" and "compound II" have been used to refer to the two reactive intermediates formed in the catalytic cycle of HRP and for which the electronic structures are [Fe(IV)=O Por$^{\bullet+}$] and [Fe(IV)=O], respectively, as shown in the above reaction scheme. They also reflect the idea that only the heme is the catalytically active species. In order to underline the differences observed in the case of CCP, in which the more stable and detectable intermediate has a different electronic structure, [Fe(IV)=O Trp$^{\bullet+}$], the term "compound ES" was given to it. As will be described in the following section, a higher degree of complexity in the reactive intermediates has been elucidated in the past few years, in particular for the bifunctional peroxidases. Hence, the use of the nomenclature — compound I, compound II and compound ES — for these more complex cases can be misleading, and it is preferable to use the actual electronic structure to accurately define the reactive intermediates. In this section, the terms "compound I" and "compound II" are used in the description of the HRP case and ES in the case of CCP, since there is no ambiguity. Furthermore, they reflect the commonly used terminology in the literature. For the more complex and recently characterized cases, the electronic structure will be used.

The conserved distal His and Arg residues, which render the heme cavity of peroxidases much more polar than in the globins, are involved in acid-base catalysis and cleavage of the peroxide O–O bond during the catalytic cycle. The postulated mechanism of peroxide decomposition relies on the concerted roles played by the proximal histidine, the distal histidine and arginine, through H-bonds and charge stabilization, as originally proposed by Poulos and Kraut.[167] In particular, the distal His functions as an acid/base catalyst that assists in the deprotonation of hydrogen peroxide and facilitates its binding to the heme iron, and the distal Arg assists in charge stabilization during the formation of compound I. The proximal His ligand of the heme iron is H-bonded to a conserved Asp residue which imparts an imidazolate

character. The imidazolate character of the proximal heme ligand has been proposed to stabilize the ferryl intermediate due to its electron-donating properties.

On the distal side, the concerted interactions of His and Arg with hydroperoxide bound to the heme have been called "the pull effect", and the increased electron donation of the proximal imidazole ligand is called "the push effect" since it stabilizes the high oxidation state of the iron in compound I, leading to the rapid reaction of peroxidases with hydrogen peroxide.[38]

1. *X-Ray Structures of Intermediates*

In a recent review, the novel high-resolution X-ray structures of resting state CCP[169] and HRP[47] together with those of their reactive intermediates,[183] are compared and extensively discussed.[184] Figure 24 shows the distal (His and Arg) and proximal (His and Asp) key residues in the heme cavities of HRPC and CCP, and the H-bond interactions between these residues and water molecules. In addition, H-bonds between the ferryl-ligated oxygen, the key residues and the closest water molecules are shown for the high-valence intermediates. The proximal heme cavity of CCP contains a Trp residue (Trp191, the site for the radical formation) and a Met residue (Met172), which in HRP are substituted by Phe221 and Ser167, respectively (not shown in the figure).

The higher resolution of the recent crystal structures of Fe(III) CCP and compound ES[169] enables very accurate determination of the changes in heme parameters which occur upon reaction with hydrogen peroxide. In particular:

(iii) In the resting state of CCP a distal water molecule is at 2.33 Å from the iron and is H-bonded to the distal His52. This form corresponds to a predominant 5cHS heme state with a minor 6c aquo form, as observed in the single-crystal RR spectra.[89] Upon passing from the resting Fe(III) state to compound ES, the His–Fe bond distance increases and the iron moves into the porphyrin plane, leading to shorter pyrrole N–Fe bonds. The Fe(IV)–O bond distance is 1.87 Å, more similar to HRP compound II (1.84 Å) than HRP compound I (1.71 Å).

(iv) The distal Arg48 residue, a key residue for the formation of compound ES, in resting state CCP occupies two positions: an "out" position close to the heme propionate and an "in" position close to the heme iron. In compound ES, only the "in" position exists, which enables Arg48 to H-bond with the ferryl O ligand.[169] The "in" position has also been observed in the CCP fluoride complex.[173]

(v) In the resting state, the proximal Met172 residue is also best modeled in terms of two conformations. In compound ES, Met172 occupies the position closer to the proximal His175 ligand. The distance between the Met172 SG atom and His175 varies from 6.4 Å in the resting state position to 4.4 Å in compound ES.

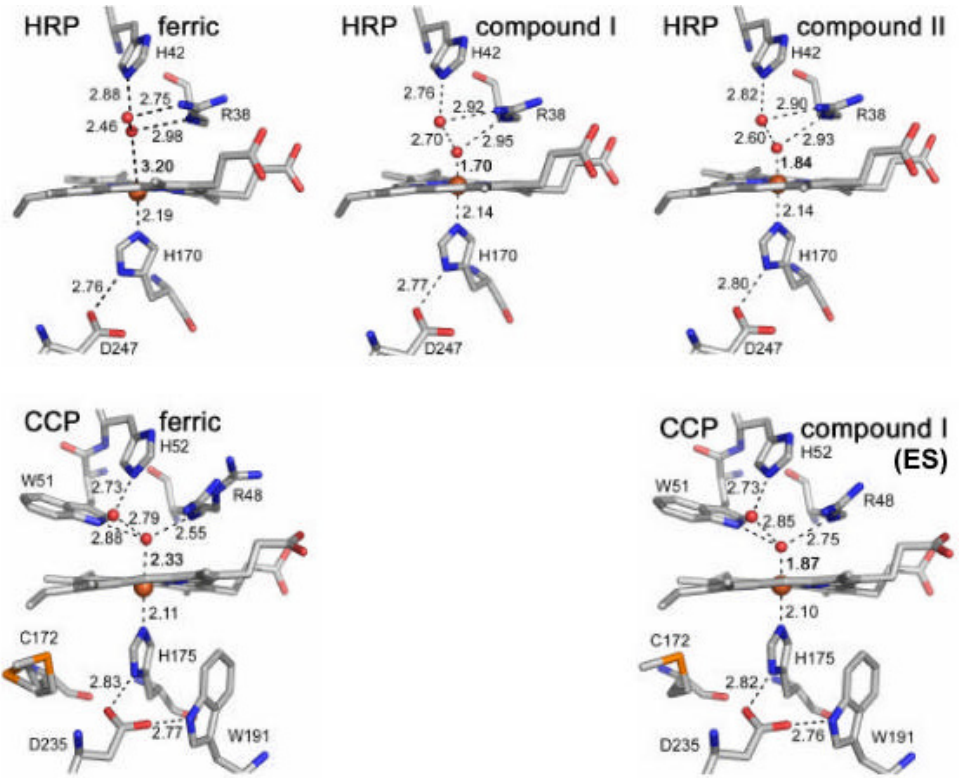


Figure 24. Crystal structure of the heme cavity with key residues of resting state HRP, and CCP, together with their intermediate compounds. Hydrogen bonds based on distance criteria are indicated by dashed lines. Distances are in Å. The following color coding is used: carbon is light gray, oxygen red, nitrogen blue, sulfur dark yellow and iron orange. (A) Fe(III), compounds I and II HRP (1ATJ, 1HCH, 1H55); (B) Fe(III) and compound I (ES) CCP (1ZBY, 1ZBZ).[47,169,183] Since the Fe^{4+}–O distance observed for HRP-II at neutral pH is quite close to 1.87 Å, as found for CCP compound I (ES), this latter has been positioned below HRP compound II, to underline their similarities. (Adapted from *J. Inorg. Biochem.* **2006**, *100*, 460–476. Hersleth, H. P.; Ryde, U.; Rydberg, P.; Gorbitz, C. H.; Andersson, K. K., Crystallographic and spectroscopic studies of peroxide-derived myoglobin compound II and occurrence of protonated Fe-IV-O. © 2006, with permission from Elsevier.)

Finally, a region between residues 193–195 also shows an ordering process upon passing from the Fe(III) state to the compound ES intermediate. The ordering of Met172 and the 193–195 residues region have been suggested to provide electrostatic stabilization of the cationic Trp191 radical.[185]

The crystal structures of the HRP Fe(III) resting state and its compounds I and II are shown in Figure 24A.[47,183] The Fe(III) state has a water molecule in the active site within H-bonding distance to His42, at 3.20 Å from the iron. This leads to a

predominant pentacoordinate state, as confirmed by the RR spectra of the single crystal[91] (Table 4), with the iron being slightly shifted toward the proximal side of the heme plane, giving rise to a saddle-shaped distortion. The same type of distortion is seen in compounds I and II, even if the iron becomes six-coordinated and is positioned in the heme plane. In compounds I and II, the oxygen ligated to the iron is H-bonded to the N_ε of Arg38 and to a (putative leaving) water molecule, which in turn is H-bonded to the $N_{\varepsilon 2}$ of His42 and to NH_1 of the distal Arg38. One-electron reduction from

compound I to compound II does not change the Fe–His170 bond, giving rise only to small changes in the two Arg38 and His42 H-bonding distances. However, compound II differs from compound I as a consequence of the elongation of the Fe–O bond, which is 1.70 Å in compound I and 1.84 Å in compound II. This can be interpreted as a protonation of the oxygen, which would change the Fe–O interaction from a double bond in compound I to a single bond in compound II.

The intermediates of the heme-containing enzymes have been extensively studied for many years by different spectroscopic methods, such as UV/visible, near-IR, CD, EPR, resonance Raman, Mossbauer, ENDOR and MCD (magnetic circular dichroism). In this section the results obtained by multifrequency EPR and RR spectroscopies will be discussed. To illustrate the electronic absorption spectra of peroxidase intermediates, we show in Figure 25 the well-characterized case of HRPC.[186] Compound I (green trace) exhibits the characteristic electronic absorption spectrum of an [Fe(IV)=O Por$^{\bullet+}$] species.[187,188] Restoration of an electron to the porphyrin ring generates the [Fe(IV)=O] species (red trace).[24,189]

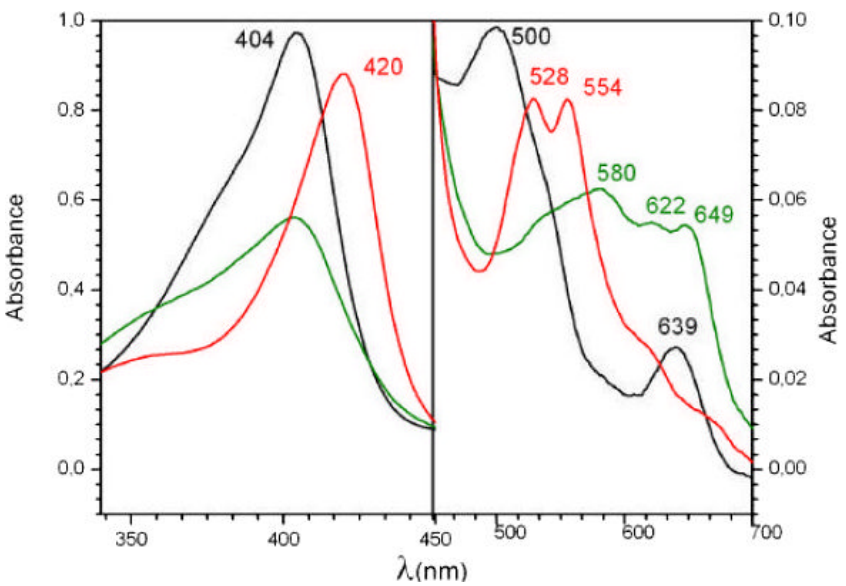

Figure 25. The UV-vis electronic absorption spectra of horseradish peroxidase C in the resting [Fe(III)] state and the catalytic intermediates. The first committed intermediate formed in the catalytic cycle and upon the two-electron reaction of the Fe(III) enzyme (black trace) with hydrogen peroxide is the [Fe(IV)=O Por$^{\bullet+}$] species (green trace), The corresponding 9 GHz EPR spectrum is shown in Figure 27. The 60% hypochromicity of the Soret band (404 nm) and the charge-transfer band at 649 nm are characteristics of the [Fe(IV)=O Por$^{\bullet+}$] species. A clear shift, and narrowing of the Soret band together with the appearance of the α and β bands at 528 and 554 nm, are characteristic of the [Fe(IV)=O] species (red trace) and result from the one-electron reaction of the [Fe(IV)=O Por$^{\bullet+}$] with the substrate.

2. *Resonance Raman Characterization of Intermediates*

In a previous edition of *The Porphyrin Handbook*, Kincaid extensively reported the RR data obtained on the intermediate compounds of peroxidases.[172] Moreover, recently, in a special issue of the *Journal of Inorganic Biochemistry* devoted to high-valent iron intermediates in biology, a number of articles reviewed the RR results obtained on the intermediate compounds of peroxidases.[184,186,190]

In principle, RR spectroscopy is well suited for investigating the intermediates of the peroxidase cycle since the vibrational frequencies of the [Fe(IV)=O] and [Fe(IV)=O Por$^{\bullet+}$] intermediates are different (Figure 26, from Ref. 186). In fact, following the four-orbital model proposed by Gouterman,[191] the formation of a porphyrin π cation radical results from the removal of an electron from either of the two highest-occupied molecular orbitals, a_{1u} and a_{2u}, which are nearly degenerate. Hence, the compound I species which is formed that is of either $^2A_{1u}$ or $^2A_{2u}$ symmetry, is expected to give rise to vibrational frequencies different from those of the nonradical intermediate.[187,188,192–194] Therefore, (i) the identification of the frequencies of the in-plane heme skeletal modes enables the nature of the electronic ground states to be characterized and (ii) the frequency of the ν(Fe(IV)=O) stretching mode, which can be identified via the solvent oxygen exchange since its frequency is ^{18}O-sensitive, should provide information on the characteristics of the intermediate compounds. However, RR spectra for intermediates of the [Fe(IV)=O Por$^{\bullet+}$] type have sometimes been contradictory, due to the weakness of the RR signals from porphyrin π cation radical species, the presence of strong signals due to impurities, and further complications arising from the photolability, which causes the [Fe(IV)=O Por$^{\bullet+}$] signals to appear similar to those of the [Fe(IV)=O] species or other forms.

Table 5 compares the absorption maxima of resting state and oxidized intermediates of several heme-containing peroxidases. Table 6 compares the corresponding RR frequencies for the ν(Fe(IV)=O) stretching modes of the intermediate compounds.

A comparison of these results, together with the structure of the resting states and the intermediate compounds when available, allows a number of conclusions to be drawn:

(i) The [Fe(IV)=O Por$^{\bullet+}$] species exhibits unique and characteristic vibrational spectra, in agreement with the studies of synthetic systems which indicate that its vibrational signatures are different from the nonradical forms. The frequencies and band assignments are given in Table 6.

(ii) The vibrational spectra of the various ferryl intermediates so far detected in peroxidases, namely LIP,[195] ARP/CIP,[196] HRPA and HRPC,[197,198] CCP (compound ES),[199] KatG,[200] are very similar.

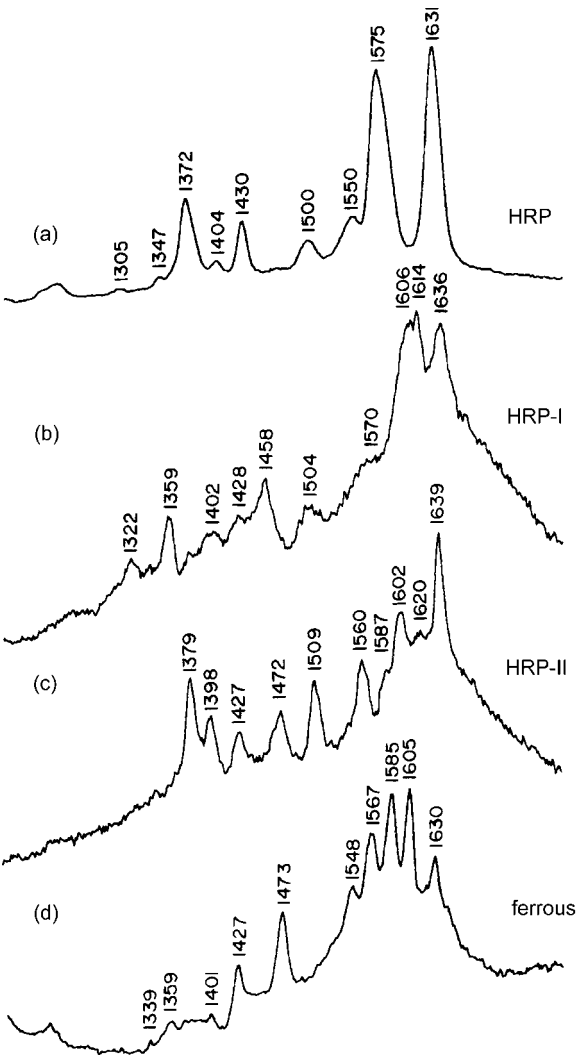

Figure 26. Resonance Raman spectra of: (a) resting horseradish peroxidase; (b) compound I; (c) compound II; (d) Fe(II) horseradish peroxidase; 356.4 nm excitation, pH 6.8. (Reprinted from *J. Inorg. Biochem.* **2006**, *100*, 480–501. Terner, J.; Palaniappan, V.; Gold, A.; Weiss, R.; Fitzgerald, M. M.; Sullivan, A. M.; Hosten, C. M. Resonance Raman spectroscopy of oxo-iron(IV) porphyrin pi-cation radical and oxoiron(IV) hemes in peroxidase intermediates.)

(iii) The ν(Fe=O) mode gives rise to a polarized band (ρ = 1/8) characterized by ^{18}O-sensitivity (see Table 4). The intensity of the metal–oxo vibration is greatly enhanced using Soret excitation between 400 and 450 nm.[186] However, recently a new Raman excitation profile maximum of an oxygen-to-iron charge-transfer transition for the ν(Fe=O) mode at 580 nm was found.[201]

Table 5. Electronic absorption maxima (nm) of the Fe(III) resting state and the intermediate compounds of HRPC, CCP and ARP/CIP.

Protein	Resting state	[Fe(IV)=O Por$^{\bullet+}$]	[Fe(IV)=O] and [Fe(IV)=O Trp$^{\bullet+}$] CCP[a]	Ref.
HRPC	403, 498, 643	400, 525(sh), 577, 622(sh), 651	420, 527, 555	299
CCP	408, 507, 647		418, 530, 560	300, 301
ARP/CIP	405, 504, 645	402, 658	419, 530, 554	302

[a] The Fe(IV)–O distance observed for [Fe(IV)=O] HRP at neutral pH is quite close to 1.87 Å, as found for [Fe(IV)=O Trp$^{\bullet+}$] CCP. Moreover, the electronic absorption of this latter compound is very similar to the [Fe(IV)=O] species of both HRP and ARP/CIP. Therefore, as for Table 6, these compounds are placed in the same column to underline their similarities.

Table 6. Resonance Raman frequencies (cm^{-1}) of the $\nu_{Fe(IV)=O}$ stretching mode observed for the intermediate compounds of HRPA, HRPC, CCP and ARP/CIP. The isotopic shift (in cm^{-1}) observed in $H_2{}^{18}O_2$ is reported in parentheses.

Protein	[Fe(IV)=O Por$^{\bullet+}$]	[Fe(IV)=O] and [Fe(IV)=O Trp$^{\bullet+}$] CCP[a]	Ref.
HRPA		789 (34), pH 11 778 (34), pH 5	211
HRPC	792 (38), pH 7.0 786 (29), pH 4.4	787 (30), pH 11 788 (31), pH 10.6 775 (30), pH 7	186, 189, 201, 208, 211, 303–305
ARP/CIP	781 (37, 50), pH 7.3	787 (38), pH 9.6 788 (39)	196, 201
CCP		753 (28) 767	199, 202

The authors obtained RR spectra of the ferryl intermediates for both HRPC and ARP/CIP excited at 580 and 590 nm, respectively, characterized by spectra of remarkably high quality, similar to those typical of Soret excitation (Tables 4 and 6).

(iv) Unlike the frequency reported for the [Fe(IV)=O Por$^{\bullet+}$] intermediate, the RR frequencies of the ν(Fe(IV)=O) stretching mode observed for the [Fe(IV)=O] intermediate in HRPA, HRPC and ARP/CIP at similar pH values are very similar. We will discuss hereafter the RR frequency in the context of the high-resolution structures of the intermediate compounds of HRPC and CCP. The RR frequencies of the ν(Fe(IV)=O) stretching mode of HRPC and CCP intermediates agree well with their expected structures. Comparing the two intermediates for HRPC at neutral pH, the ν(Fe=O) vibration occurs at 792 cm^{-1}

for the [Fe(IV)=O Por$^{\bullet+}$] intermediate, and 17 cm^{-1} lower (775 cm^{-1}) for the [Fe(IV)=O] state. The crystal structures[183] indicate that a water molecule in the heme distal pocket moves 0.1 Å closer to the ferryl oxygen upon the formation of the [Fe(IV)=O] intermediate. Moreover, the [Fe(IV)=O] intermediate differs from [Fe(IV)=O Por$^{\bullet+}$] due to the elongation of the Fe–O bond, i.e. 1.70 Å vs. 1.84 Å. This can be interpreted as a protonation of the oxygen, which would change the Fe–O interaction from a double bond in the [Fe(IV)=O Por$^{\bullet+}$] intermediate to a single bond in [Fe(IV)=O], in agreement with the RR downshift observed for the ν(Fe=O) band. Therefore, the RR 18 cm^{-1} downshift observed for the ν(Fe(IV)=O) stretching mode of HRP upon conversion to the ferryl species can be attributed to the formation of ferryl oxygen by means of charge transfer and proton transfer, accompanied by an increase in H-bonding strength with a nearby water molecule. The Fe(IV)–O distance observed in the crystallographic structure of HRP in the [Fe(IV)=O] intermediate state at neutral pH is quite close to 1.87 Å, as found for the [Fe(IV)=O Trp$^{\bullet+}$] intermediate from CCP. In the latter case, Poulos and coworkers suggested that this Fe^{4+}–O distance corresponds to a single Fe(IV)–O bond.[169] It is noteworthy that the RR frequency of the ν(Fe=O) band in the CCP ferryl intermediate is even lower than that of the HRP ferryl intermediate (775 cm^{-1}), being observed at 753 cm^{-1} or 767 cm^{-1} in two different reports.[199,202] This is consistent with an increased H-bonding to the ferryl oxygen in CCP, as the oxygen is H-bonded to Arg48 and Trp51, whereas the homologous Phe41 of HRP is unable to form an H-bond. Moreover, the X-ray structure of CCP shows that the guanidinium side chain of Arg48 swings in to make close contact with the ferryl oxygen.

Prior to the determination of the X-ray structure, the Fe(IV)–O distance of HRP compound II was determined by EXAFS. The EXAFS studies on HRP in the 1980s showed two different bond lengths for compound II, 1.64 Å and 1.93 Å, while only a short bond was observed for CCP (1.67 Å) and (Mb 1.69 Å).[203–205] Clearly, the inconsistency between the reported HRP-II Fe–O bond lengths has resulted in considerable confusion. However, a recent study by Gray and coworkers gave only a short Fe–O distance for HRP.[206] Moreover, the Fe–O bond length in HRP-II was found to be pH-sensitive, being 1.90 Å at pH 7 and 1.72 Å at pH 10,[207] suggesting a transition from single bond to double bond. The Raman frequencies of the ν(Fe(IV)=O) group are also pH-sensitive, increasing from 775 cm^{-1} at neutral pH to 789 cm^{-1} at alkaline pH. The pH effects on the ν(Fe(IV)=O) frequency of HRP-II[208–211] and the ν(Fe^{2+}–Im) stretching frequency[103] have been attributed to ionization of the same distal histidine, His42, with a perturbation of the distal H-bonding network by the protonation status of $N_{\epsilon 2}$ and orientation of a bridging distal

water molecule, as suggested by Terner.[186] This interpretation appears to be confirmed by the effect of the mutation of His42 to glutamic acid or glutamine. The ν(Fe(IV)=O) stretch of compound II observed at 775 cm^{-1} in the wild type at neutral pH shifts to 789 cm^{-1} in the mutant, a frequency that compares well with that observed in the wild-type compound II at alkaline pH. This was attributed to lack of an H-bond to the ferryl oxygen due to the absence of the distal His.[146] Therefore, the presence of H-bonding between the oxoferryl iron and distal residues in peroxidases lowers this frequency relative to those of synthetic model compounds.

(v) The ν(Fe(IV)=O) stretch of compound II is also sensitive to deuteration. An upshift of 3 cm^{-1} upon deuteration was observed for the neutral/lower pH ν(Fe=O) frequencies, accompanied by dramatic increases in intensity.[209,211,212] This change has been attributed to a deuterium-induced decrease in the strength of the H-bond between the ferryl oxygen and the protonated Arg38.[186]

Several theoretical and experimental investigations have raised the question of whether the protonated ferryl Fe(IV)–OH species might be a better description than Fe(IV)=O for compounds I and II.[184,190] The protonation status of the ferryl group, as well as the presence of a distal-pocket proton delivery network linked to the oxo ligand, can play an important role in proton-coupled electron transfer during catalysis. In this regard, the presently available experimental data are not in complete agreement. As noted in the foregoing discussion, high-resolution crystal structures of the compound II intermediate of HRPC and the [Fe(IV)=O $Trp^{\bullet+}$] intermediate of CCP indicate that the ferryl oxygen is protonated.[169,183] In both cases precautions were taken to ensure that reduction of the active centers induced by the X-ray radiation did not occur. In the case of CCP compound ES, UV-vis of dissolved crystals and single-crystal EPR at low temperature before and after X-ray exposure were used to characterize the heme state. No reduction was observed.

Particularly elaborate procedures were utilized for the intermediate of HRP, which is more suseptible to photoreduction than CCP, including the use of a multicrystal data collection strategy and monitoring of the electronic absorption spectum of the crystals at 100 K before and after X-ray exposure with a microspectrophotometer. This procedure enabled nearly pure compounds I and II to be studied. An analysis of the available RR data by Terner and coworkers is in accord with a protonated status for the ferryl oxygen. On the basis of a comparison of the ν(Fe(IV)=O) stretching frequencies and oxygen atom solvent exchangeability of many heme proteins at various pHs, they noted that oxygen atom solvent exchangeability is more pronounced at lower pH and the corresponding ν(Fe(IV)=O) stretching frequencies are lower. The authors concluded that this implies that compound II has at least a partial Fe(IV)–OH character, conferred by

strong H-bonding from within the distal pocket, which contributes to the substantial lowering of the *v*(Fe(IV)=O) stretching frequencies of compounds II relative to those of model compounds.[186] As pointed out by Babcock and coworkers, though,[213] it is important to recall in such a discussion that the pH-dependent shift of *v*(Fe(IV)=O) to lower frequency upon protonation of the distal histidine cannot be unambiguously assigned to the H-bond formed with the Fe=O group. Protonation of the distal histidine also strengthens the proximal Fe–N(His) bond through the H-bonding network linking the distal and proximal sides of the heme, which would lead to a lower *v*(Fe(IV)=O) frequency. RR studies of distal-site-directed mutants of HRP have clearly demonstrated that disruption of the H-bonds between distal residues leads to a downshift of the proximal Fe–N(His) stretching frequency.[67] However, it is noteworthy that, at least in the case of HRP, no variation in the proximal Fe-His170 bond is detected upon conversion from compound I to compound II.[183] Behan and Green suggest that the available RR and Mossbauer data are not consistent with a protonated ferryl oxygen.[190] In particular, application of Badger's rule shows good agreement between RR data of Fe–O stretching frequencies and Fe-oxo distances determined by EXAFS measurements. The contrast of these conclusions with respect to that resulting from the crystal structures is proposed to depend on the possibility that, since some reduction of high-valent hemes might occur in the X-ray beam during data collection,[214] the observed Fe–O distance determined by the X-ray structure might be affected by such a reduction. This suggestion appears to be contradicted by a recent work where high-resolution crystal structures of myoglobin in the pH range 5.2–8.7 have been used as models for the peroxide-derived compound II intermediates in heme peroxidases.[215] In this work a combination of X-ray crystallography, microspectrophotometry, RR on both solution and single crystals, and Mössbauer spectroscopy were used to elucidate the structure of Mb compound II. The compound II state of myoglobin in crystals was controlled by single-crystal microspectrophotometry before and after synchrotron data collection. Radiation-induced changes were observed resulting in an unknown unstable intermediate H, which by heating regenerates compound II. Based on the crystallographic and spectroscopic data, the authors suggest that for Mb compound II the observed Fe–O bond length (1.86–1.90 Å) is consistent with that of a single bond, the presence of an Fe(IV) center being indicated by Mössbauer spectroscopy. Since this long Fe–O bond for compound II is also consistent with those measured for compound II of HRP, catalases, and the isoelectric compound ES in CCP, the authors concluded that this finding is probably a general feature of the compound II states and the isoelectric compound ES states in heme proteins. However, recent EPR and ENDOR studies of cryoreduced compound II of various peroxidases and myoglobin[216] suggest that the high-valent iron center of globin and HRP compounds II, as

well as that of CCP compound I (CCP-ES), is $[Fe(IV)=O]^{2+}$ and that its cryoreduction produces $[Fe(IV)–OH]^{+}$. This product is formed presumably because the heme is linked to a distal-pocket hydrogen bonding/proton delivery network through an H-bond to the "oxide" ligand. The data also indicate that Mb and HRP compounds II exist as two major conformational substates.

3. *Multifrequency EPR Spectroscopy: Identification and Reactivity of Intermediates*

EPR spectroscopy has been widely used for elucidating the electronic structure of active sites in heme-containing proteins.[21,217] As mentioned before, specific information on the iron oxidation, spin state and coordination number can be obtained from the low-temperature (4 K) EPR spectrum of the heme iron. Moreover, the intermediates resulting from changes in the oxidation state of the heme iron and formation of radical species can be monitored by EPR spectroscopy. RR and EPR spectroscopies are fairly complementary techniques for the characterization of hemes (see for example Ref. 218). The information inferred from the low-temperature 9 GHz EPR spectrum of peroxidases in their resting (Fe(III)) state is less detailed than that obtained from the RR spectrum (see previous section), although EPR spectroscopy has proven to be important in elucidating long-range interactions of amino acid residues with the heme iron.[26] In the case of reactive intermediates, the distinct EPR spectra (g-tensors) and magnetic properties of the heme iron and radicals involved, as well as the possibility of characterizing the radicals formed as substrate products of the reaction, render the EPR technique particularly advantageous.[219] Heme peroxidases, in particular HRP and CCP, have been extensively and thoroughly characterized by EPR spectroscopy. Comprehensive reviews on the topic are available, and hence only selected aspects will be discussed in this section with the aim of highlighting putative new research directions. A very complete description of the full body of work on HRP and CCP can be found in the book *Heme Peroxidases*, by Dunford.[15]

The 9 GHz EPR spectrum, recorded at 4 K, of the first committed intermediate in the catalytic cycle of HRP that is formed upon reaction of the Fe(III) enzyme with hydrogen peroxide, shows a very broad EPR signal extending over about 2500 G (Figure 27). Such a broad spectrum is hardly detected at temperatures higher than 30 K, due to relaxation broadening.[220] It was necessary to combine 9 GHz EPR and Mössbauer spectroscopies to assign such an abnormal EPR spectrum to that of a porphyrin cation radical magnetically coupled to the ferryl iron, the $[Fe(IV)=O\ Por^{\bullet+}]$ species.[221] The model proposed by Schulz and coworkers to explain the unusually broad EPR spectrum considers that the effective g values of the EPR spectrum depend on the interaction parameter (J), the zero-field splitting

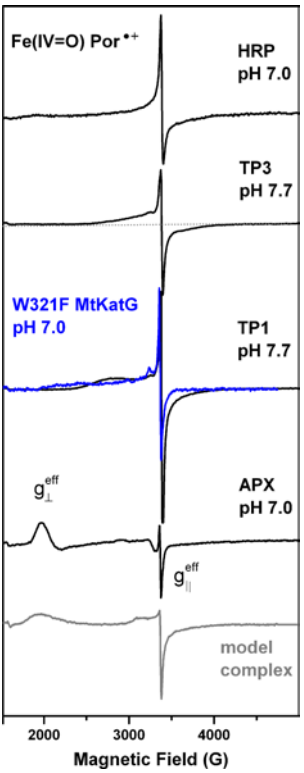

Figure 27. The 9 GHz EPR spectra, recorded at 4 K, of the [Fe(IV)=O Por$^{\bullet+}$] species formed during the reaction of hydrogen peroxide with horseradish peroxidase (HRP), isoforms 1 and 3 of turnip peroxidase (TP1 and TP3), and ascorbate peroxidase (APX). In the case of the W321F variant of *M. tuberculosis* catalase–peroxidase (W321F KatG), it was possible to trap the otherwise short-lived [Fe(IV)=O Por$^{\bullet+}$] intermediate, when incubating the enzyme with five-fold excess of isoniazid prior to the 2s mixing with 15-fold excess of peroxyacetic acid.[31] The [Fe(IV)=O (tmtmp)$^{\bullet+}$] species was obtained upon addition of 10-fold excess of m-cholorobenzoic acid in deuterated methanol to solutions of Fe(III) triflate [Fe(III)Tf(tmtmp)] in methylene chloride or butyronitrile at –78° C.[225] The experimental conditions used for the spectra of HRP, TP1, TP3 and APX are the same as in Ref. 25.

(D) of the oxoferryl iron, and the g values of the interacting species. To a first approximation, when the Zeeman energy is small compared to the zero-field splitting, the effective g-values are given by

$$g_{\|}^{\text{eff}} = g_{\text{rad}},$$

$$g_{\perp}^{\text{eff}} = g_{\text{rad}} + 2\, g_{\perp}^{\text{Fe}}\, (J/D),$$

where g_{rad} is the g value of the isolated porphyrinyl radical (taken as isotropic and approximately equal to 2.0, if considering the resolution of the 9 GHz EPR

spectrum), $g_{\perp}^{Fe}$ represents the g component of the oxoferryl iron ($g_{\perp}^{Fe} = 2.28$ and $g_{\parallel}^{Fe} = 1.94$),[222] and D is the zero-field splitting parameter of the oxoferryl iron. The EPR spectrum of the exchange-coupled species arises from the lowest of the three Kramers doublets, which is well separated in energy from the other two, and can be represented as an effective spin $S^{eff} = 1/2$. A thorough description of the model and its implications was provided by Hoffman and coworkers.[223,224] It is of note that differences in the strength of the exchange-coupling interaction (J) are reflected in the different shapes of the EPR spectra of the [Fe(IV)=O Por$^{\bullet+}$] intermediates in peroxidases, as illustrated in Figure 27. However, in all cases the overall width and temperature dependence of the signals are very similar. Moreover, the estimated values of $J/D = 0.4$, obtained by using the above-mentioned model and the observed effective g values (Figure 27) of the different peroxidases, agree well with a weak ferromagnetic interaction similar to that of the oxoferryl triflate π cation radical obtained from the [Fe(III)Tf(tmtmp)] model complex.[225] The EPR signal observed for the [Fe(IV)=O Por$^{\bullet+}$] intermediate formed upon addition of hydrogen peroxide to the isoforms of turnip peroxidase at basic pH shows a sharp central resonance at $g = 2.0$ with broad asymmetric wings, as in the case of HRP (Figure 27, top). In the cases of ascorbate peroxidase[226] and the turnip isoforms at acidic pHs,[25] the [Fe(IV)=O Por$^{\bullet+}$] intermediate shows an axial signal with the observed $g_{\perp}^{eff}$ between 2.56 and 3.4, and $g_{\parallel}^{eff} = 2.0$ (Figure 27, bottom). The possible correlation of the sign (negative for antiferromagnetic and positive for ferromagnetic) and strength of the exchange interaction with the reactivity of the [Fe(IV)=O Por$^{\bullet+}$] intermediate remains to be explored. In particular, this open question becomes relevant in the light of the remarkable differences observed for the lifetimes of the [Fe(IV)=O Por$^{\bullet+}$] intermediates among different peroxidases, and the possibly correlated propensity to form subsequent protein-based radical intermediates by intramolecular electron transfer, as in the case of isoform 7 of turnip peroxidase at basic pH.[25]

CCP is an interesting example of such a case. The [Fe(IV)=O Por$^{\bullet+}$] intermediate is extremely short-lived, and readily converts to the [Fe(IV)=O Trp$_{191}^{\bullet+}$] species (for a review, see Ref. 15). The electronic absorption spectrum characteristic of the [Fe(IV)=O Por$^{\bullet+}$] species can be detected only when the site for the formation of the Trp radical is removed, i.e. the W191F variant.[227] Even in this case, the transition from the [Fe(IV)=O Por$^{\bullet+}$] to the ferryl species is observed within 8 ms.[227] The mechanism for the selective stabilization of the porphyrin or tryptophanyl radicals is not well understood. As shown in Figure 27, APX forms a relatively stable [Fe(IV)=O Por$^{\bullet+}$] intermediate even though the proximal side Trp, equivalent to Trp191 in CCP (see Figure 2), is conserved. From a comparative study of the active site structure of APX and CCP, including mutations[169] and theoretical calculations,[169,228] it was proposed that the electrostatic environment and redox potentials of the porphyrin or the protein redox cofactors are responsible

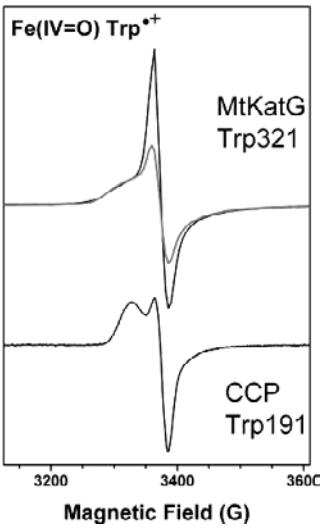

Figure 28. The 9 GHz EPR spectra, recorded at 4 K, of the [Fe(IV)=O Trp$^{\bullet+}$] intermediates formed in *M. tuberculosis* catalase–peroxidase (MtKatG, radical site Trp321) upon reaction with peroxyacetic acid[31] and in cytochrome *c* peroxidase (CCP, radical site Trp191) upon reaction with hydrogen peroxide.[27] The 400 G-broad spectra of the Trp radicals reflect the exchanged-coupling interaction with the ferryl iron. The two narrower (isolated) protein-based radicals (shown in Figure 29) centered at $g \approx 2$, which contributed to the central part of the [Fe(IV)=O $Trp_{321}^{\bullet+}$] spectrum (top, black trace), were not formed when the enzyme was preincubated with the isoniazid substrate prior to the reaction with peroxyacetic acid (top, gray trace).

for the differences in the stabilities of the radicals. The 9 GHz EPR spectrum of CCP upon reaction with hydrogen peroxide (Figure 28) is different from that of HRP, APX and turnip peroxidase isoforms. The axial EPR signal (about 400 G wide) observed at 9 and 35 GHz could be modeled by a weak exchange coupling interaction between a tryptophanyl radical and the oxoferryl moiety,[30] including a distribution in *J* values, with ferro- and antiferromagnetic coupling.[224,229] EPR and ENDOR spectroscopies combined with site-directed mutagenesis studies unequivocally identified the site of the radical formation as Trp 191 (located on the proximal side of the heme cavity of CCP; see Figure 2). In a more recent study, multifrequency (9–285 GHz) EPR spectroscopy and spectral simulations were used to further characterize the [(Fe(IV)=O) Trp$^{\bullet+}$] intermediate in CCP.[27] The tryptophanyl radical, having an exchange coupling interaction with the oxoferryl moiety, could be modeled by a powder pattern spectrum with effective *g* values that depend on the interaction parameters, the zero-field splitting (*D*) of the oxoferryl iron, and the *g* values of the interacting species. The use of multiple frequencies (9, 95, 190 and 285 GHz) to record the EPR spectrum provided more strict constraints on the

spectral simulations. Moreover, by modeling the spin coupling as an anisotropic interaction, instead of as a sum of isotropic exchange terms,[224] it was possible to obtain a representation which was consistent both with the frozen solution and the single-crystal data. In addition, the inherently superior resolution of high-field EPR spectroscopy permitted unequivocal identification of a transient tyrosyl radical formed 60 s after the addition of one equivalent of hydrogen peroxide to the wild-type CCP at 0 °C. The Tyr radical disappeared after 1 h incubation at 0 °C, unlike the long-lived [Fe(IV)=O Trp191$^{\bullet+}$] intermediate. Accordingly, the ambiguities about the "narrow" signal reported previously for CCP[224,230,231] could be clarified by the higher resolution of the *g* values at higher frequencies/higher fields.[27]

Other cases of peroxidases that form a short-lived [Fe(IV)=O Por$^{\bullet+}$] intermediate are LIP[232] and versatile peroxidases.[233] These peroxidases together with MNP are the fungal enzymes playing a key role in the ligninolytic cycle (for a review, see Ref. 15). As in the case of CCP, multifrequency EPR and ENDOR studies have unequivocally identified a Trp radical intermediate in versatile peroxidases,[234] although the site for the radical formation differs from that of CCP. In lignin peroxidase, structural data[235,236] and site-directed mutagenesis studies[232] led to the proposal of a surface Trp residue (Trp171) surrounded by negatively charged residues, as the oxidation site for the substrate veratryl alcohol (VA). No direct evidence from EPR spectroscopy on the formation of Trp171$^{\bullet}$ species, or its reactivity with VA, has been reported to date, a fact tentatively explained by the short-lived nature of the radical.[237] No major differences are observed in the crystal structures of lignin[235] and versatile[238] peroxidases that could explain the remarkably different stability of the Trp$^{\bullet}$ in these two enzymes. Hence, as in the case of CCP and APX, understanding the physicochemical properties that determine the stability and reactivity of the Trp radical intermediate remained an open issue. Recently, an EPR characterization of LIP variants that were designed to modify the microenvironment of the putative Trp$^{\bullet}$ radical site, inequivocally showed that the radical is formed on Trp171 and it is the reactive species with VA.[239]

Catalase–peroxidases constitute yet another case of enzymes in which porphyrin- and protein-based radical intermediates with different stability have been detected. These bifunctional enzymes are homodimeric, each monomer containing two sequence-related domains but only the N-terminal domain binds the heme cofactor.[53,54,56,106] The overall structure of the N-terminal domain has similar topology to that of CCP,[53] yet these enzymes have a catalase-like activity comparable to that of monofunctional catalases, in contrast to monofunctional peroxidases. These unique features of KatGs, together with the fact that KatGs are considered as ancestors of monofunctional peroxidases, render this family of heme enzymes an appealing system in which to investigate the role of alternative electron transfer pathways involving Trp and Tyr as alternative cofactors in the catalytic cycle of peroxidases and catalases. A powerful combination of multifrequency EPR

spectroscopy, isotopic labeling of tryptophan and tyrosine residues, and site-directed mutagenesis has been applied to characterize the chemical nature of the intermediates formed in the peroxidase-like reaction of KatGs from *Synechocystis* PCC6803[26,240] and *Mycobacterium tuberculosis*.[31,241–243] The formation of the [Fe(IV)=O Por$^{\bullet+}$] species and two subsequent protein-based radical intermediates, Trp$^{\bullet}$ and Tyr$^{\bullet}$, was discerned by their distinct EPR spectra.[240] Moreover, Trp106 was shown to be the unique site for the formation of the Trp$^{\bullet}$ despite the high number of Trp residues in *Synechocystis* KatG.[26] Trp106 belongs to a KatG-specific short stretch of residues on the enzyme surface that results in the heme propionates of KatGs being less surface-exposed compared to those of monofunctional peroxidases. Kinetic studies on *Synechocystis* KatG using stopped-flow absorption spectrophotometry showed that an [Fe(IV)=O Por$^{\bullet+}$] intermediate is formed upon reaction with peroxyacetic acid (for a review, see Ref. 109). In the case of *M. tuberculosis* KatG, comparative kinetic studies using stopped-flow electronic absorption spectrophotometry showed that the [Fe(IV)=O Por$^{\bullet+}$] intermediate is shorter-lived than that of *Synechocystis* KatG.[244] Accordingly, the broad EPR spectrum of the [Fe(IV)=O Por$^{\bullet+}$] species in *M. tuberculosis* KatG could not be detected,[31] even when the rapid-mix freeze-quench technique was applied to prepare the EPR samples.[241] Interestingly, the short-lived [Fe(IV)=O Por$^{\bullet+}$] intermediate could be detected when *M. tuberculosis* KatG was incubated with isoniazid prior to the reaction with peroxyacetic acid (see Figure 27, blue trace).[31] The assignment of the chemical nature of the radical intermediates formed in *M. tuberculosis* KatG based on EPR studies is controversial. Magliozzo and coworkers assigned their 9 GHz EPR spectra of MtKatG to a tyrosyl radical species formed on Tyr353, a residue which is not conserved in other KatG enzymes.[242] Later, a revised interpretation of the same 9 GHz EPR data together with the 130 GHz EPR spectrum of the radicals led the same authors to propose the formation of a Trp$^{\bullet}$, as a minority species to Tyr$^{\bullet}$.[243] More recent studies by Ivancich and coworkers, in which multifrequency (9–285 GHz) EPR spectroscopy combined with selective deuterium labeling of Trp and Tyr residues was applied to investigate the intermediates of the wild-type MtKatG and selected Trp variants, concluded that two Trp$^{\bullet}$ radicals are formed.[31] Trp321, the same site as in cytochrome *c* peroxidase, was identified as one of the radical sites in MtKatG.[31] Accordingly, a broad EPR signal was clearly detected in the 9 GHz EPR spectrum of *M. tuberculosis* KatG (Figure 28). Comparison of the exchange-coupled Trp$^{\bullet}$ spectra of *M. tuberculosis* KatG and CCP shows that they have a different line shape (see Figure 28), an effect that is most probably explained by a different distribution of the ferro- and antiferromagnetic components of the exchange coupling of the Trp radical (see above). The narrow signal contributing to the central part of such a spectrum (see Figure 28) was shown to arise from the other, not exchange-coupled Trp$^{\bullet}$

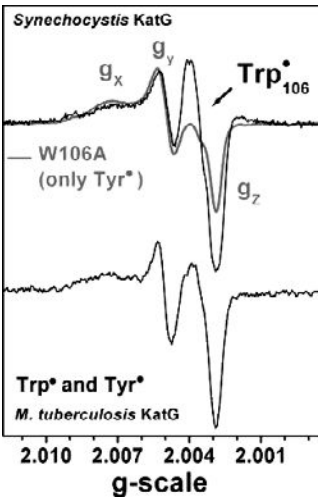

Figure 29. The high-field/high-frequency (10 T, 285 GHz) EPR spectra of the $Trp^{\bullet}$ and $Tyr^{\bullet}$ formed in the wild-type (top, black trace) and W106A variant (top, gray trace) of *Synechocystis* PCC6803 catalase–peroxidase, and wild-type *M. tuberculosis* catalase–peroxidase (bottom, black trace) upon reaction with peroxyacetic acid. The spectra were recorded at 10 K, using a frequency modulation of 30 kHz and a field modulation of 10 G. The (initial) sample concentration was 1 mM and 40 μL volume; a 15-fold excess of peroxyacetic acid was used for the 10 s reaction performed in ice. The site for the radical in *Synechocystis* KatG is Trp106,[26] so only the signal of the $Tyr^{\bullet}$ with g values of $g_x = 2.0064(4)$, $g_y = 2.0040(5)$ and $g_z = 2.0020(8)$ was detected in the W106A variant (top, gray trace).

species by using selective deuteration of Trp and Tyr residues and the higher resolution of g tensors at higher fields/higher frequencies (Figure 29). However, the site for the formation of this (isolated) $Trp^{\bullet}$ is not the same as in *Synechocystis* KatG (see above). The differences observed between the two KatGs with regard to the radical sites reveal that catalase–peroxidases are similar to the monofunctional peroxidases in the stabilization of different radical intermediates.

For a long time, it has been considered that CCP was the exception among heme peroxidases because the stable [Fe(IV)=O $Trp^{\bullet+}$] species is the oxidizing intermediate in the reaction with the substrate cytochrome *c*. Such a reaction was shown to require a well-defined electron transfer pathway[245] between the unique radical site, Trp191, and the binding site for cytochrome *c* on the surface.[185] Nonetheless, CCP uses the short-lived [Fe(IV)=O $Por^{\bullet+}$] intermediate for the oxidation of small molecules such as guaiacol, pyrogallol, aniline and mesidine that can access the δ-meso heme edge through the solvent channel,[246] like in all other peroxidases. A recent crystal structure of CCP that was crystallized with bound isoniazid showed that this aromatic molecule also binds close to the δ-meso heme edge.[247] Recent findings on the specific role of Trp radicals as oxidizing species in

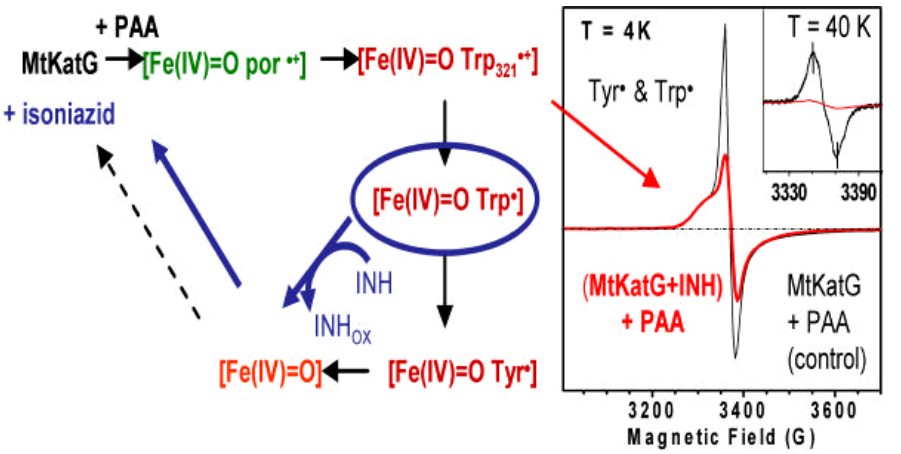

Figure 30. Scheme of the intermediates, detected by multifrequency EPR spectroscopy, in *M. tuberculosis* KatG upon reaction with peroxyacetic acid (PAA). The electronic structure of the intermediates included in the scheme is based on the direct detection and characterization of the corresponding EPR spectra, with the exception of the [Fe(IV)=O] species, which is EPR-silent (integer spin). Yet, it is possible to infer the formation of the missing signal when comparing the Fe(III) conversion and the yield of the detected intermediates. The Trp• not exchange-coupled (circled in blue) was concluded to be the reactive species for the peroxidase-like reaction of MtKatG with isoniazid as a substrate.[31]

the reaction with substrates in other peroxidases and catalase–peroxidases[31,232,236,248] support the hypothesis that, in heme enzymes, specific Trp (or Tyr) residues can either play a role in facilitating electron transfer between redox cofactors[249,250] or act as true intermediates in the peroxidase cycle.[31] The reactivity of *M. tuberculosis* and *Synechocystis* KatGs with isoniazid was also carefully monitored by using EPR spectroscopy in order to identify the intermediate responsible for the oxidation of isoniazid.[31,251] The results show that in *Synechocystis* KatG, the isoniazid substrate can react readily with the [Fe(IV)=O Por•+] species.[251] In contrast, in *M. tuberculosis* KatG the reactive species was shown to be the [Fe(IV)=O Trp•] (Figure 30) formed subsequently to the [Fe(IV)=O Trp_{321}•+] intermediate.[31] These findings indicate that, in both KatGs and monofunctional peroxidases, the observed variability of Trp sites where the subsequent intermediates to the [Fe(IV)=O Por•+] can be stabilized, appears to be correlated with differences in substrate binding sites.

III. Superfamily of Animal Peroxidases

Animal peroxidases are classified in a separate superfamily, which is often indicated as the superfamily of mammalian peroxidases for historical reasons.

The superfamily includes myeloperoxidase (MPO), eosinophil peroxidase (EPO), lactoperoxidase (LPO) and thyroid peroxidase (TPO). Both MPO and EPO are involved in the immune system response. MPO is produced by neutrophil cells and released during phagocytosis, whereas EPO is secreted by eosinophil cells. LPO can be found in milk and other fluids. All of these proteins react with H_2O_2 and form intermediate compounds, which are related to those already discussed in the section describing plant peroxidases. The specific electron donors are small inorganic anions, and particularly chloride, bromide and thiocyanate. The resulting acids, HOCl, HOBr and HOSCN, have a strong antimicrobial activity. The production of these reactive species is considered to be the biological function of MPO, EPO and LPO. Thyroid peroxidase has a different function, being involved in the synthesis of thyroid hormones. Both the chemical properties and the biomedical aspects of animal peroxidases have been reviewed in recent articles.[252–254]

A. Covalent Links and Heme Structure

From the chemical point of view, the most noteworthy structural property of animal peroxidases is the presence of covalently linked heme cofactors. The Fe-protoporhyrin IX tetrapyrrole ring is bound to the protein matrix by chemical bonds at rings A and C. The protein–heme link is the result of posttranslational modifications, the mechanisms of which are currently being clarified.[255]

MPO is a unique case, bearing three covalent bonds (Figure 31): an ester bond at ring C, resulting from oxidation of methyl 5 and esterification to an aspartate side chain (Asp94); a similar ester bond at ring A between methyl 1 and a glutamate residue (Glu242); an unusual sulfonium bond (also at ring A) between the

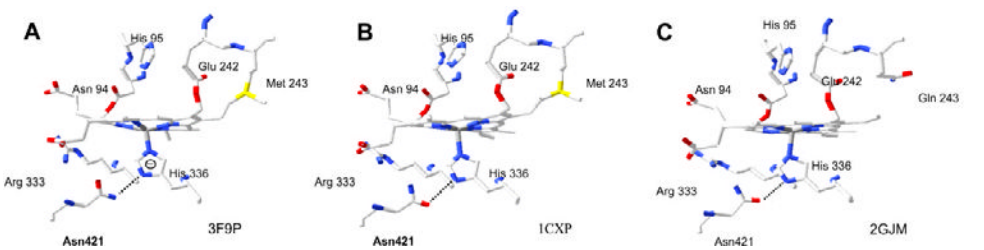

Figure 31. (A) Heme structure and porphyrin–protein linkages in human glycosilated myeloperoxidase according to the coordinate file 3F9P.[261] H-bonding between the NH2 group of Asn 421 and *anionic* His336 has been proposed. Covalent bonding between heme and Glu242 is limited to 20% of the molecules. (B) Heme structure and porphyrin–protein linkages in human myeloperoxidase according to the coordinate file 1CXP.[259] In this structure, Asn421 is H-bonded to *neutral* His336 through its amide carbonyl.[259,269] (C) Structure of the active site[259] of bovine LPO (2GJM).[263] The numbering of the residues follows that of MPO.

b-carbon atom of vinyl 2 and a methionine residue (Met243). Both LPO[256] and EPO[257] have two covalent bonds, namely, ester bonds between methyl 1 and Glu242 (MPO alignment number) and between methyl 5 and Asp 94 (Figure 31).

There are several effects of the covalent links on the heme structure that can be clearly seen by spectroscopy and X-ray crystallography: distortion from planarity, symmetry lowering, and changes in the electronic structure.

B. X-Ray Structures: An Overall View

X-ray structures of MPO have been published for one glycoform of canine[258] and human origin.[259,260] In the X-ray structure of human MPO obtained at −180 °C with 1.8 Å resolution (Figure 31B),[259] the heme tetrapyrrole ring appears to be considerably distorted from planarity, since rings A and C are tilted toward the protein distal side. The iron atom is slightly displaced toward the proximal side (0.2 Å below the line connecting the N atoms of rings B and D), and is coordinated with the proximal His residue (His336) with a bond length Fe–N = 2.19 Å. The imidazole ring of His336 is H-bonded with Asn421, at variance with plant peroxidases where the proximal His is H-bonded with the carboxylate group of an Asp residue (see Figure 2). In all the MPO structures, the distal heme cavity contains not only the His/Arg couple (His95, Arg239), which is common to plant peroxidases, but also a glutamine residue (Gln91). Moreover, a network of water molecules has been localized in the distal cavity. The water molecules are H-bonded with the distal residues, a heme propionate on ring C, and between themselves. One of them lies at 2.9 Å from both His95 nitrogen and the heme iron, which suggests H-bonding to the histidine and weak coordination to the iron.

The very recent crystal structure of a mixture of MPO glycoforms (hMPOm), obtained directly by purification from human leukocytes, exhibits several significant differences compared to previous MPO structures reported in the literature.[261] The variations include heme-to-protein linkages, sites and extent of glycosylation. First of all, X-ray modeling, cross-checked by molecular dynamics simulations, gave new insights into the interaction between proximal His336 and Asn421, strongly suggesting that the imidazole of His336 could be present as imidazolate. Moreover, it was underlined that the His–Asn–Arg interaction is important in the maintenance of both the proximal and the distal heme cavity architecture as well as the catalytic properties of MPO. Upon replacing Asn421 by Asp, a 10 nm blue shift of the Soret band was observed in the UV-vis spectrum, as well as complete loss of the chlorination activity. Another difference with published MPO structures concerns the heme-to-protein bonds in hMPOm. On the basis of the electron density maps, two alternative conformations of the side chain of Glu242 are suggested. In hMPOm the majority of the ester bond with Glu242 is broken, whereas

both the sulfonium ion linkage and the second ester bond are fully present. Therefore, the heme is still considerably distorted, but flatter compared to the other published structures (Figure 31A).

Structures of bovine LPO, both in the resting state and as a complex with SCNO,[262] goat LPO,[256] buffalo LPO (2GJM)[263] and its complex with SCN^-,[264] have recently become available. The heme cofactor in LPO is less distorted than in MPO (Figure 31C), mainly because of the absence of the covalent link with Met at ring A. The Fe–His bond length and the Fe–distal water distance are 2.14 Å and 2.65 Å, respectively.[256] The proximal His is H-bonded with the Asn437 residue, which corresponds to the Asn421 of MPO. A comparison between the structure of the SCN^- complex of (bovine and buffalo) LPO and that of the SCN^- complex of (human) MPO[260] has led to the suggestion that the structural determinant for the substrate specificity of LPO, i.e. preference for the oxidation of SCN^- rather than halides, is the conformation of the loop which extends from Arg418 to Phe431.

C. Resonance Raman and Electronic Absorption Spectroscopies

In a previous edition of *The Porphyrin Handbook*, Kincaid extensively reported the RR data obtained on the various mammalian peroxidases, including the Fe(III) and Fe(II) states, their exogenous ligand adducts and catalytic intermediates.[172] Therefore, in this chapter we focus on the new results obtained in the last decade.

The electronic absorption spectrum of MPO has been known to be anomalous since the first protein preparations became available.[265] The Soret band maximum lies at 428 nm, the α and β bands at 570 and 622 nm, respectively, and the CT1 band at 690 nm. All these maxima are markedly redshifted compared with the wavelengths of both high- and low-spin Fe(III) heme-containing proteins. Clarification of the origin of the red shift could be obtained with the aid of site-directed mutagenesis combined with electronic and RR spectroscopies. This is best illustrated (Figure 32) by the spectral properties of the MPO mutant, where Met243 is substituted with Thr. Mutation of the Met243 residue prevents the formation of the sulfonium heme–protein link.[266–268] In particular, the absorption and magnetic circular dichroism spectra of the M243T mutant and of its CN complexes become similar to those of other heme proteins. Recently, the comparison between the RR spectra of wt MPO and M243T[269] showed that the iron coordination is the same in the two proteins, since the ν_3 core-size marker band frequency indicates a 6cHS heme (the ν_2 marker band frequency is not coincident with that expected for such a spin state, since it is coupled to the stretching mode of the vinyl groups, which are quite different in the two proteins). In spite of the common coordination, the RR intensities are quite different, and in particular: (i) the RR spectrum of MPO shows intense bands due to nontotally symmetric modes,

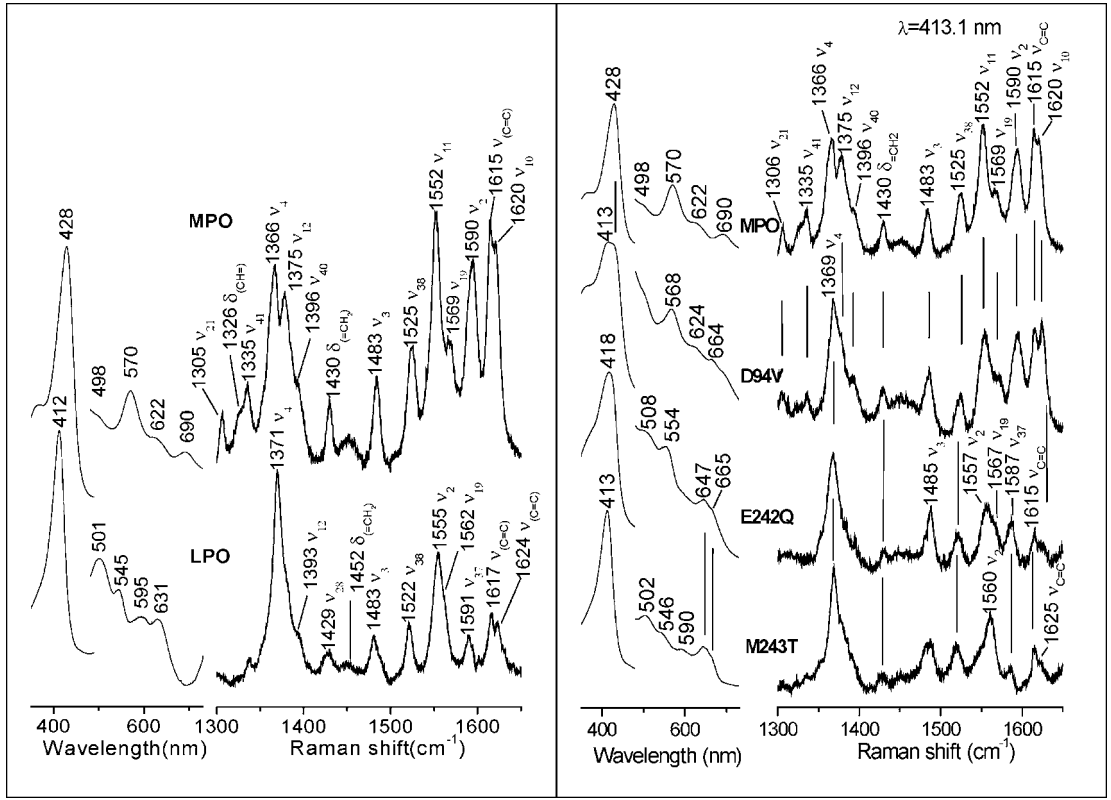

Figure 32. (Left) Electronic absorption and RR spectra of Fe(III) LPO and MPO. The intensity in the visible region is expanded four-fold. The spectra in the Soret region have been shifted along the coordinate axis to allow better visualization. (Right) Electronic absorption and RR spectra in the high-frequency region of Fe(III) MPO and its Asp94Val, Glu242Gln and Met243Thr mutants. (Adapted from: Zederbauer, M.; Furtmueller, P. G.; Brogioni, S.; Jakopitsch, C.; Smulevich, G.; Obinger, C. *Nat. Prod. Rep.* **2007**, *24*, 571–584. Reproduced by permission of The Royal Society of Chemistry.)

e.g. ν_{12}, ν_{11}, ν_{19} and ν_{10}, which suggest that the heme macrocycle symmetry is lowered to C_2, with the C_2 axis perpendicular to the heme plane; (ii) the spectrum of M243T is dominated by totally symmetric modes, indicating a heme with D_{4h} pseudosymmetry. However, the combined analysis of the RR spectra of M243T, Glu242Gln and Asp94Val mutants demonstrates that the heme is distorted to some extent even in the absence of the sulfonium linkage, possibly owing to the residual covalent linkages with Asp and Glu which contribute to the distortion from the planar conformation and the lowered symmetry. In fact, despite the absence of the sulfonium linkage in the Met243 variant, its RR spectra retain some unusual features compared to other heme proteins, such as a remarkable enhancement of several out-of-plane low-frequency modes. Fe(II) MPO maintains the spectroscopic complexity observed for the Fe(III) form. In fact, the electronic absorption spectrum is rather unique, being red-shifted with respect to other heme proteins, with a Soret maximum at 472 nm. Concomitantly, its vibrational spectrum is very complex. Moreover, as for the Fe(III) form, mutation of the D94, E242 and M243 alters the spectroscopic features of the corresponding Fe(II) species, causing a blue-shift of the Soret band with a concomitant reduction in the complexity of the Raman spectra.[266–268,270,271]

Both the absorption spectra[253] and the RR spectra[272] of the resting state of LPO are similar to those of "regular" hexacoordinated heme proteins, e.g. Fe(III) myoglobin (Figure 32).

In contrast with Fe(II)MPO, the Fe(II) state of LPO displays a time-dependent equilibrium between multiple species. The presence of multiple Fe(II)LPO species has been demonstrated by magnetic circular dichroism,[273] and by electronic absorption spectroscopy and ligand-binding kinetics.[274,275] A recent RR spectroscopy study[276] has allowed the characterization of three different forms of Fe(II)LPO on the basis of their ν(Fe–His) stretching frequencies. In particular, the species with absorption maxima at 444, 432 and 425 nm display a ν(Fe–His) band at 254, 221 and 227 cm^{-1}, respectively (Table 7 and Figure 33). The species with the weakest Fe–Im bond [ν(Fe–His) at 221 cm^{-1}] does not appear immediately, but develops with time. An interesting finding is that the M243T and M243V MPO mutants exhibit a similar behaviour, whereas mutations at D94 and E243 yield a single, stable Fe(II) form with a ν(Fe–His) at 243 cm^{-1},[276] similar to the band observed in wt MPO at 246 cm^{-1} (Figure 34).[277] Therefore, only the presence of the sulfonium linkage in MPO prevents the slow conformational change observed for Fe(II)LPO; when it is absent Fe(II) MPO is less stable.

In the low-frequency region both MPO and LPO are characterized by ν(Fe–His) stretching frequencies at markedly high frequencies (248–255 cm^{-1}), with the ν(Fe–His) of LPO being slightly higher than the ν(Fe–His) of MPO.[163,271] This fairly high RR frequency suggests a substantial imidazolate character of the proximal histidine which could not be justified by the X-ray structures since the H-bond acceptor

Table 7. Electronic absorption maxima (nm) and resonance Raman frequencies (cm^{-1}) of the different Fe(II) forms observed for LPO, MPO, and its Met243Thr, Met243Val, Asp94Val and Glu242Gln mutants. From Ref. 276.

MPO	474 nm	246 cm^{-1}				

in animal peroxidases was found to be the amide oxygen of a conserved Asn.[253] At present, the crystal structure of hMPOm together with molecular dynamics simulations support the RR findings which suggest that a neutral proximal histidyl imidazole would have unfavorable H-bonding interactions, whereas a deprotonated His336 would strengthen the Fe–imidazole bond.[261] The authors suggest that in animal peroxidases the NH2 group of the Asn421 (MPO numbering) is oriented toward the unprotonated N_δ of the proximal His, while its carbonyl group interacts with the (positively charged) guanidinium group of Arg333 (Figure 31A).

RR spectroscopy of the CO complex of MPO has not been performed, since MPO is one of the very few examples of heme proteins which cannot bind CO,* contrasting with EPO[274] and LPO.[278]

RR spectroscopy of EPO has been performed both on the isolated enzyme and on eosinophil granulocytes.[279] The analysis of the spectra, which were obtained using a micro-Raman spectrophotometer with excitation wavelengths at 413.1, 514.5 and 660 nm, has demonstrated that the coordination of Fe(III)EPO is the same as that of Fe(III)LPO.

*Very weak CO binding to MPO has been recently demonstrated by differential Fourier transform infrared spectroscopy. (Murphy, E. J.; Marechal, A.; Segal, A. W.; Rich, P. R. *Biochemistry* **2010**, *49*, 2150–2158.)

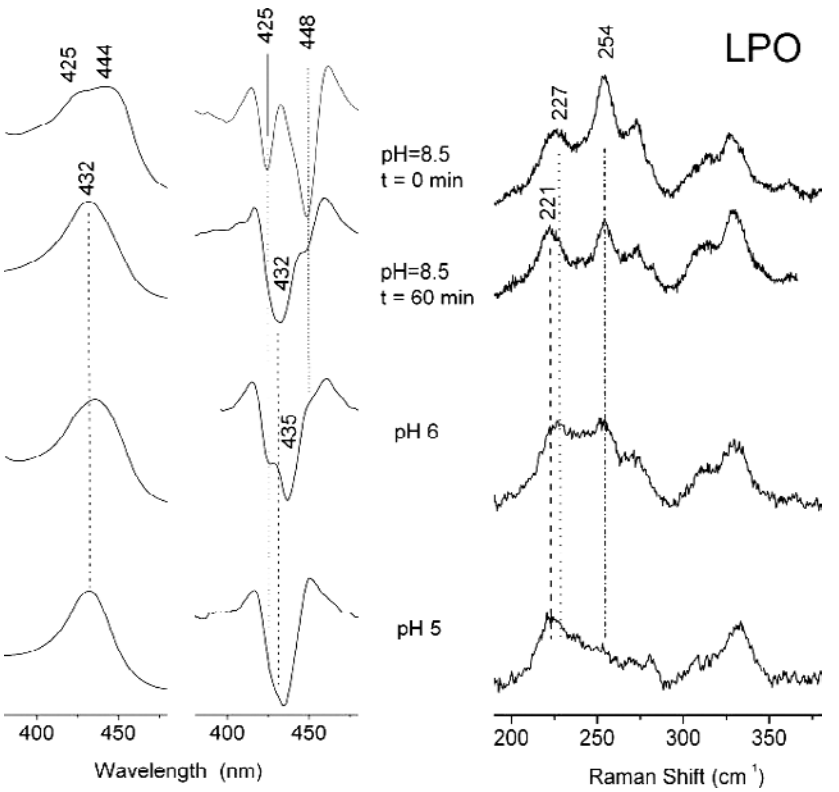

Figure 33. *From left to right*: Absorption, second derivative absorption, and resonance Raman spectra of Fe(II) lactoperoxidase at pH 8.5, 6 and 5. The set of spectra at pH 8.5 demonstrates the slow conformational change occurring in the first hour after sample reduction. The absorption maxima/shoulders for the different species, and the corresponding frequency of the *v*(Fe–Im) stretching bands, are marked.

D. Catalytic Intermediates

1. *Resonance Raman and Electronic Absorption Studies*

The reactive intermediates of animal peroxidases have only been partially characterized by means of RR spectroscopy, due to their instability. No new experiments have been performed recently and the complete set of available data has been already reported in the previous *Handbook* series.[172] The rapid-scan electronic absorption spectra of the reaction of MPO with hydrogen peroxide are shown in Figure 35.[252] The Fe(III) spectrum (bands at 430, 570 and 690 nm) displays significant spectral changes upon addition of a 10-fold excess hydrogen peroxide (hypochromicity of the Soret band and appearance of a charge-transfer band at 625 nm). These variations, observed within 100 ms, were assigned to the

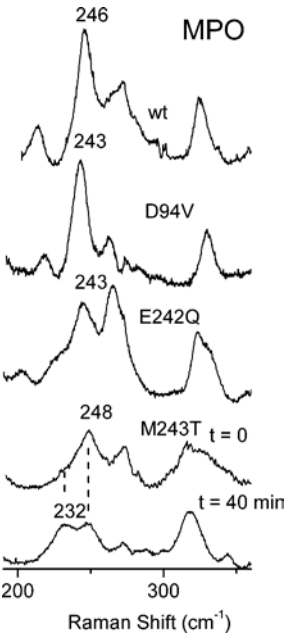

Figure 34. Resonance Raman spectra of Fe(II) myeloperoxidase and of its mutants D94V, E242Q and M243T. In this last mutant, a slow conformational change — similar to the lactoperoxidase case — occurs in the first hour after sample reduction. The frequency of the *ν*(Fe–Im) stretching band is marked.

[Fe(IV)=O Por$^{\bullet+}$] intermediate (compound I). Further spectral changes (shift of the Soret band to 456 nm and increase in intensity of the band at 625 nm) were assigned to the ferryl intermediate (compound II). The spectrum characterized by a Soret band at 453 nm and a CT band at 625 nm was assigned to the oxygen complex, often termed "compound III."

Optical spectroscopy has been performed for MPO in the ferryl oxidation state (compound II)[280] at pH 7.0 and 10.7, giving evidence of two distinct ferryl species at neutral and alkaline pH with a pKa of about 9. The two species are characterized by different electronic absorption spectra. However, the corresponding features in the RR spectra could not be detected. In fact, an isotopic $^{16}O/^{18}O$ shift was present only in the spectra at pH 10.7, which allowed assignment of a band at 782 cm^{-1} to the Fe=O stretching mode.

The RR spectra of the ferryl intermediate (compound II) was reported for LPO at pH 6.8; the intermediate was stable for 2–3 min under laser irradiation. A noteworthy feature is the very low frequency (745 cm^{-1}) of the Fe=O stretching band.[199] Furthermore, the frequency of the Fe–O_2 stretching band (531 cm^{-1}) in compound III is particularly low in LPO.[281]

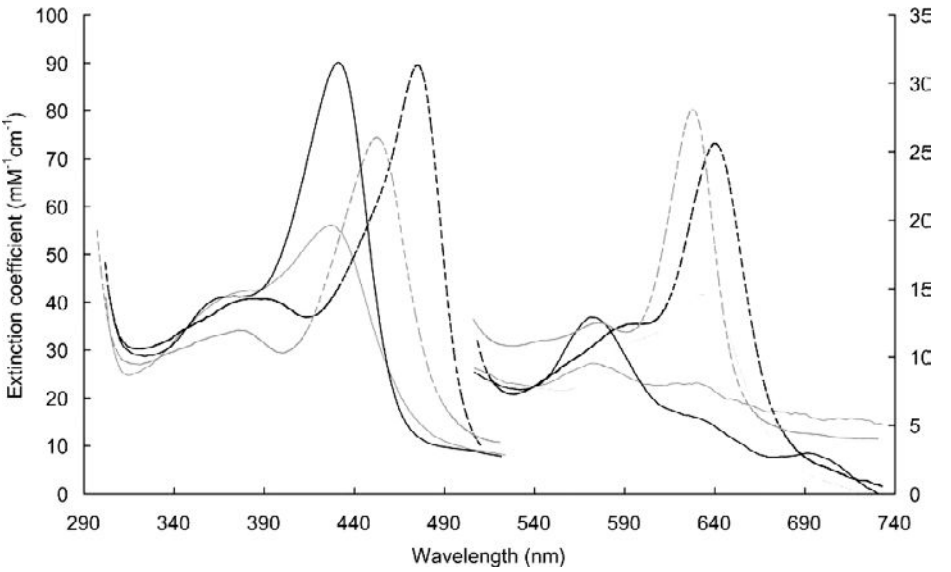

Figure 35. Absorption spectra of redox intermediates of myeloperoxidase at pH 7.0: Fe(III) protein (black and bold), compound I (gray), compound II (black and thin) and compound III (gray dashed line). In addition, Fe(II) MPO is shown (black dashed line). (Reprinted from *Arch. Biochem. Biophys.* **2005**, *445*, 199–213. 2. *Multifrequency EPR Spectroscopy Combined with Stopped-Flow Electronic Absorption Spectrophotometry*

The recently available X-ray crystal structures of bovine (PDB entry 2GJ1) and caprine[256] LPO obtained at 2.34 Å and 2.4 Å resolution, respectively, confirmed the previous proposal of a deeply buried heme site.[282] The channel allowing the access of substrates from the enzyme surface to the distal side of the heme in caprine LPO is cylindrical in shape, with a diameter of approximately 6 Å.[256] The structures of the enzyme complexed with thiocyanate (PDB entry 2IPS), 2-hydroxybenzohydroxamic acid (also known as salicylhydroxamic acid) (PDB entry 2QPK) and acetylsalicylic acid (PDB entry 2QQT) have also been deposited and reveal a substrate binding site on the heme distal side, in close contact with the iron and the distal histidine. Such a binding site is favorable for a heme-edge type of reaction with aromatic (or small) substrates, typical of peroxidases.[158,159] Kinetic studies on the reaction of LPO with hydrogen peroxide[283] and hypochlorous acid[119] led to the conclusion that the [Fe(IV)=O Por$^{\bullet+}$] species was the reactive intermediate. Indirect evidence for the formation of protein-based radical species as isomers of the [Fe(IV)=O Por$^{\bullet+}$] intermediate was reported. In one case, spin-trapping

experiments indicated the formation of one protein radical, and Mass Spectrometry analysis showed that a surface residue, Tyr289, was the cause of the enzyme dimerization, via a dityrosine crosslink.[284] Kinetic studies of the LPO reaction with *p*-substituted phenols showed that the enzyme reactivity was correlated with the redox potential of these substrates.[285] These authors invoked a tyrosyl radical intermediate to explain the very low enzyme reactivity, measured at pH 5 for p-substituted phenols containing an amino group.[285] More recently, multifrequency (9–285 GHz) EPR spectroscopy combined with stopped-flow electronic absorption spectrophotometry was applied in order to directly detect the radical(s) and unequivocally determine their electronic nature and microenvironment, as well as their putative catalytic competence in the reaction of milk LPO with hydrogen peroxide as a function of pH.[219] The use of high frequency/high field (285 GHz/10 T) to record the EPR spectrum provides enhanced resolution of the *g* tensor components (*g* values) of organic radicals, which are unresolved in the EPR spectrum recorded at conventional (9 GHz) frequencies. In particular, Tyr$^\bullet$ and Trp$^\bullet$ can be clearly discerned from their 285 GHz EPR spectrum, based on the higher *g* anisotropy (defined as $\Delta g = g_Z - g_X$) of Tyr radicals (as illustrated in Figure 29). Further information about the microenvironment of the protein-based radical can also be obtained from the 285 GHz EPR spectrum, since the g_x value of tyrosyl radicals is sensitive to the presence of H-bonds or positively charged residues.[218] The high-field EPR spectrum of LPO upon reaction with five-fold excess hydrogen peroxide showed the predominant signal of a Tyr$^\bullet$, with *g* values of g_x = 2.0077(0), g_y = 2.0039(5) and g_z = 2.0020(8) at pH = 8.0, and of g_x = 2.0066(2), g_y = 2.0039(5) and g_z = 2.0020(8) at pH ≤ 7.5 (Figure 36, left panel). The corresponding EPR spectra recorded at 9 GHz showed differences in the (unresolved) proton hyperfine couplings of Tyr$^\bullet$ (Figure 36, central panel) that were consistent with the changes observed at the higher frequency. Taken together, the differences in g_x values (detected in the 285 GHz EPR spectra) and the proton hyperfine couplings (detected in the 9 GHz EPR spectra) were indicative of two chemically different Tyr radicals as a function of pH. Accordingly, a single Tyr with a pH-dependent microenvironment or, alternatively, two Tyr with different microenvironments are consistent with the EPR spectra. Interestingly, the different microenvironment of Tyr$^\bullet$ could be related to the reactivity of the radical (see below), as has been shown in the case of the Tyr_D and Tyr_Z radicals in photosystem II.[286] Another feature revealed by the 285 GHz EPR spectrum of LPO upon reaction with hydrogen peroxide was the additional intensity contributing to the g_y–g_z spectral region of the Tyr$^\bullet$ signal. The narrower signal agreed well with that expected for Trp$^\bullet$, as observed in the cases of *Synechocystis* and *M. tuberculosis* KatGs (see Figure 29). Such a less anisotropic signal was better observed in the HF EPR spectrum of a commercial LPO sample at pH 6.8 (Figure 36, left panel,

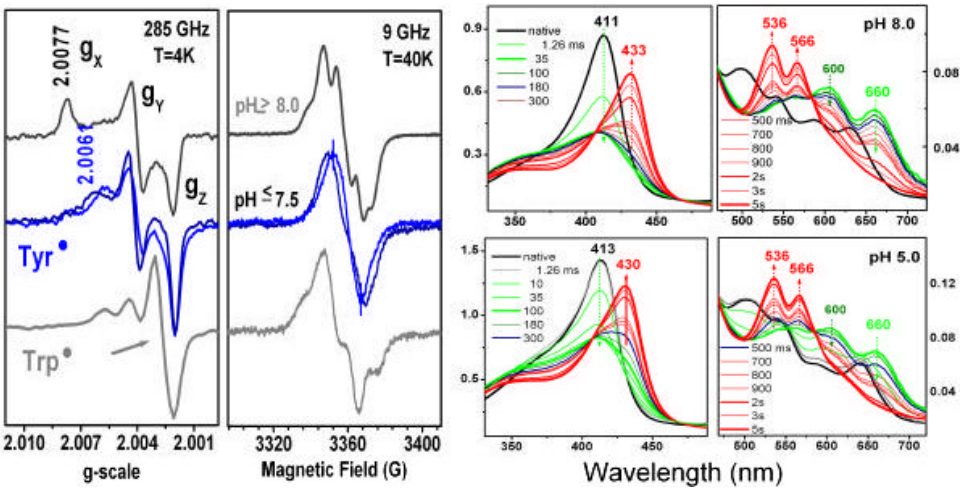

Figure 36. The 285 GHz (left panel) and 9 GHz (central panel) EPR spectra of the Trp• and Tyr• intermediates formed by the reaction of lactoperoxidase with five-fold excess hydrogen peroxide at 0 °C and as a function of pH (4 = pH = 10). For both frequencies, the spectra obtained at pH 8 (left and central panels, top; gray trace) are representative of all spectra obtained for samples at basic pH values (pH = 8), and the spectra at pH 5 (left and central panels, middle; black trace) are representative of those obtained at neutral and acidic pH values (4 = pH = 7.5). The signal with smaller g anisotropy ($\Delta g = g_z - g_x = 0.0014$) and contributing to the g_y–g_z region of the Tyr• spectrum ($\Delta g = g_z - g_x = 0.0044$) recorded at 285 GHz (left panel, top; black trace) was totally consistent with the expected g values of a Trp•, as shown in the case of *Synechocystis* KatG (Figure 29). Such a signal was clearly observed in the commercial lactoperoxidase sample (left panel, bottom; black thin trace) due to the different relative yield of Trp• and Tyr• species. The right panel shows rapid-scan electronic absorption spectra of the reaction of lactoperoxidase with five-fold excess hydrogen peroxide at 5 °C and monitored up to 5 s. The experiments were carried out at pH 8 (top) and pH 5 (bottom). Selected representative spectra are shown. The resting (Fe(III)) enzyme is shown in black, the [Fe(IV)=O Por•+] in green, the transition to the ferryl species in blue and the ferryl intermediate in red. Experimental conditions are described in Ref. 219.

bottom spectrum), for which the 9 GHz EPR spectrum (Figure 36 central panel, bottom spectrum) showed an overall broader signal and different shape, both spectra indicating a higher yield of the Trp• signal (relative to the Tyr• signal) in this sample. The difference in relative yields of the Tyr and Trp radicals may be related to variations in purification steps reflecting different contents of the enzyme isoforms. The absence of the broad signal (2500 G overall width) consistent with the [Fe(IV)=O Por•+] intermediate (see Section II.F.3) in the 9 GHz EPR spectrum of lactoperoxidase was clearly explained by the complementary kinetic information obtained from the rapid-scan electronic absorption spectra of the reaction of LPO with hydrogen peroxide, in conditions (pH and mixing temperature) comparable to those of the EPR experiments (Figure 36, right panel). Accordingly, the

[Fe(IV)=O Por$^{\bullet+}$] intermediate (hypochromicity of the Soret band and shift of the CT band to 660 nm) was shown to be formed within 35 ms at pH 8 and 100 ms at pH 6 (Figure 36, right panel, thick green trace) and the transition to the ferryl-like spectrum (shift of the Soret band to 433 nm and two distinct new CT bands at 536 nm and 566 nm) was achieved within 2 s, which is the mixing time used in the EPR experiments. It is important to note that the electronic absorption spectrum of an [Fe(IV)=O] intermediate as observed in the case of HRP (see Figure 25) is indistinguishable from that of an [Fe(IV)=O Tyr$^{\bullet}$] or [Fe(IV)=O Trp$^{\bullet}$] species, because the bands corresponding to Tyr$^{\bullet}$ (405–410 nm) and Trp$^{\bullet}$ (510–560 nm) are completely masked by the heme bands.[287,288] Information obtained from the EPR spectra and the rapid-scan electronic absorption spectra of the reaction of LPO with hydrogen peroxide unequivocally allowed one to clearly identify the short-lived [Fe(IV)=O Por$^{\bullet+}$], [Fe(IV)=O Trp$^{\bullet}$] and [Fe(IV)=O Tyr$^{\bullet}$] intermediates, and a final [Fe(IV)=O] species (Figure 37).

The combination of EPR and stopped-flow measurements was also used to characterize the reaction of LPO with two types of substrates (small aromatic vs. bulkier organic molecules). Two different mechanisms for substrate oxidation were distinguished in LPO.[219] The [Fe(IV)=O Por$^{\bullet+}$] intermediate was shown to be responsible for the oxidation of *o*-dianisidine, *o*-anisidine, and benzohydroxamic acid via a

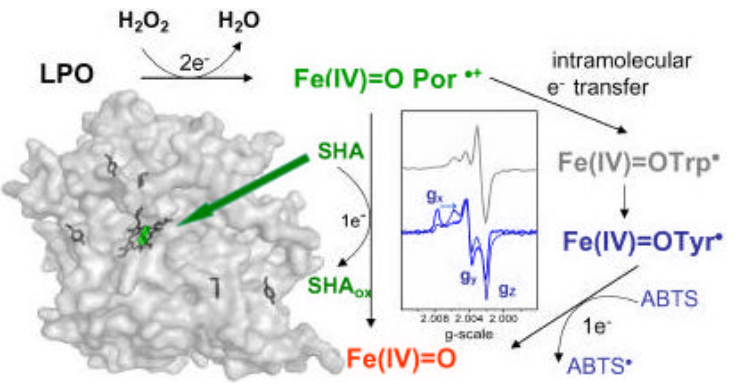

Figure 37. Scheme of the catalytic intermediates, detected by combining multifrequency EPR spectroscopy and stopped-flow electronic absorption spectrophotometry in lactoperoxidase. The global view of the crystal structure of lactoperoxidase, highlighting the five tyrosine residues identified as candidates for the radical site based on the high-field EPR spectroscopy studies, is also shown. Tyr433 and Tyr468 are close to the surface, and Tyr7 and Tyr71 are directly exposed on it; Tyr177 is located deeper in the protein, adjacent to a putative secondary access channel. The deeply buried heme site is partially visible at the end of the narrow access channel. The figure was prepared using the coordinates deposited in the Protein Data Bank (accession code 2GJ1). The [Fe(IV)=O Por$^{\bullet+}$] intermediate was shown to be the reactive species with bezohydroxamic acid (BHA) and small substrates, while the oxidation of ABTS by the [Fe(IV)=O Tyr$^{\bullet}$] intermediate was favored at pH 5.

heme-edge reaction, and of mitoxantrone (1,4-dihydroxy-5,8-bis[2-(2-hydroxyethylamino)ethylamino]-anthracene-9,10-dione) via long-range electron transfer (favored at pH 8), but not involving the [Fe(IV)=O Tyr$^{\bullet}$] intermediate. It is important to note that a very recent paper discussing the crystal structures of milk lactoperoxidase complexes with benzohydroxamic acid concluded that the proximity of the oxygen atom of the hydroxyl group of this substrate to the heme iron (a distance of 3.3 Å) and apparent displacement of water molecules of the heme distal side would block the peroxide binding site and prevent enzymatic action.[289] Such a conclusion is at odds with the stopped-flow measurements, since these experiments clearly demonstrated that the [Fe(IV)=O Por$^{\bullet+}$] intermediate readily reacted with benzohydroxamic acid.[219] Accordingly, care must be taken when concluding about enzymatic reactions based on a static view of the enzyme and the substrates. Interestingly, it was shown that at pH 5 the formation of the [Fe(IV)=O Tyr$^{\bullet}$] intermediate was in competition with the oxidation of mitoxantrone, and that this intermediate was responsible for the efficient reaction with ABTS (2,2′-azino-bis(3-ethylbenzthiazoline-6-sulphonic acid).[219] In conclusion, lactoperoxidase showed similarities to cytochrome *c* peroxidase, lignin peroxidase and catalase–peroxidases with regard to the formation of protein-based radical intermediates as alternative oxidation species for substrates that cannot access the heme site (Figure 37).

IV. Acknowledgments

We thank members of our research groups and coworkers who are responsible for some of the work reviewed in this chapter; their names are listed in the appropriate references.

Contents

Preface

Although the porphyrin and tetrapyrrole research area was regarded as "fully matured" during the 20th century, as evidenced for example by the awarding of numerous Nobel Prizes to its principal researchers, new advances and accomplishments in the field still amaze us as editors. The area continues to blossom and to expand into new areas of science and applications that would probably never have occurred to our 20th century heroes. An earlier *Porphyrin Handbook* assembled the large amount of factual data that had been accumulated during the 20th century. Our new venture, the *Handbook of Porphyrin Science* takes a completely new look at our research area and comprehensively details the contemporary science now appearing in the scientific literature that would indeed have been hard to predict even 10 years ago. In particular, fundamentally new methodologies and potential commercial applications of the beautiful compounds that we all love are exemplified, fully recognizing the subtitle of the series — "with applications to chemistry, physics, materials science, engineering, biology and medicine".

The three of us have complementary expertise in physical chemistry, synthetic and bioorganic chemistry, and in synthetic and mechanistic organometallic chemistry; this has enabled us to cover the whole field of porphyrin science and applications, and to devise comprehensive volume and author content. As of the date of writing, between the three of us, we have published more than 1600 tetrapyrrole research articles, and hold 31 patents related to commercial applications of porphyrin science. So we do know our field, and this has enabled us to assemble a first-rate group of experts who have written comprehensive up-to-date chapters with accuracy and authority; we thank our authors for their cooperation and willingness to go along with our highly ambitious schedule for production of these volumes.

We look forward to comments from our readers, and to suggestions that might enable us to expand our basic interests and scientific coverage even further. Meanwhile, we hope that porphyrin researchers, old, new and of the future, will enjoy reading these volumes just as much as we enjoyed planning and, with the help of World Scientific Publishing Company, producing them from manuscript to published article, in a timely manner.

Karl M. Kadish (Houston, Texas, USA)
Kevin M. Smith (Baton Rouge, Louisiana, USA)

I. Introduction

Heme proteins play important roles in various aspects of biological processes, which include oxygen transport in hemoglobin, oxygen storage in myoglobin, electron transfers in various cytochromes, disproportionation of hydrogen peroxide in catalase, and oxidation of organic substrates in cytochrome P450.[1–3] Figure 1 shows an example of enzymatic reactions, i.e. oxidation of organic substrates catalyzed by cytochrome P450.[4–9] The active site of cytochrome P450 contains a heme, the iron of which is connected to the protein via a thiolate linkage of a cysteinate residue. In the resting state of cytochrome P450, the iron adopts a six-coordinate ferric low-spin state (A), Fe^{III}(S = 1/2), with water as a sixth axial ligand. However, once organic substrate is incorporated into the substrate binding pocket, all the water molecules in the pocket are excluded and consequently the iron adopts the five-coordinate ferric high-spin state (B), Fe^{III}(S = 5/2), with cysteinate as the sole axial ligand. The redox potential increases on going from the six-coordinate low-spin state to the five-coordinate high-spin state, which makes the reduction of iron(III) much easier. As a result, the five-coordinate ferric high-spin state is converted to the five-coordinate ferrous high-spin state (C), Fe^{II}(S = 2), having cysteinate as an axial ligand. Next follows the oxygen-binding step. Thus, the addition of dioxygen to the high-spin ferrous heme leads to the formation of an oxygen-bound diamagnetic species, which is considered to adopt either a six-coordinate ferrous low-spin state with dioxygen (O_2) as the sixth axial ligand (D), Fe^{II}(S = 0), or a six-coordinate ferric low-spin state with superoxide anion radical ($O_2^{\bullet-}$) as the sixth ligand (D′), Fe^{III}(S = 1/2); $O_2^{\bullet-}$ (S = 1/2). In the latter case, the observed diamagnetism could be explained in terms of the strong antiferromagnetic coupling between Fe^{III}(S = 1/2) and S = 1/2 superoxide anion radical. After the second one-electron reduction, the heme adopts a very labile six-coordinate ferric low-spin state, Fe^{III}(S = 1/2), with peroxide (O_2^{2-})(E) or hydroperoxide(F) as the sixth ligand. The latter complex receives a proton and releases a water molecule

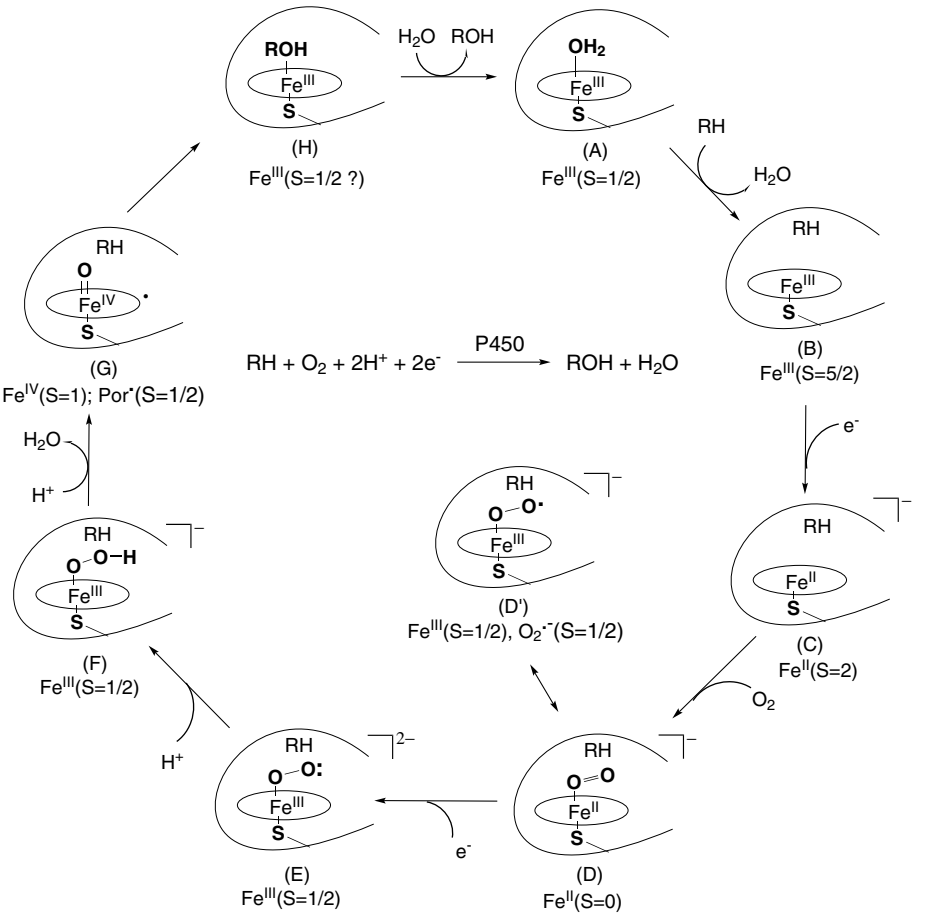

Figure 1. Catalytic mechanism proposed for cytochrome P450. (Adapted from Refs. 4–9.)

to form what is called compound I, a reactive intermediate which is believed to be a six-coordinate low-spin $Fe^{IV} = O$ species with porphyrin cation radical(G), $[(Fe^{IV} = O)(Por^{\cdot})]^{+}$.[10–17] The oxygen is then transferred from the reactive intermediate to the organic substrate to form an alcohol.

As this example shows, the iron porphyrin complexes change their electronic and coordination structures during the enzymatic reaction. Each of the iron porphyrin complexes plays a crucial role in each step of the catalytic cycle by utilizing the physicochemical properties specific to the heme. Thus, it is very important to reveal the detailed physicochemical properties of various iron porphyrin complexes with different electronic and coordination structures. For these purposes, the use of model complexes is quite important because one can characterize them by means of a number of techniques such as UV–vis, IR, CV, NMR, EPR,

resonance Raman, CD, MCD, Mössbauer, SQUID, EXAFS, and X-ray crystallography.[18,19] In addition, these measurements, which are sometimes difficult to perform in proteins, can be done even under extreme conditions Among the techniques mentioned above, ^{1}H and ^{13}C NMR spectroscopy are particularly useful, since they provide detailed information on the electronic structures of the complexes in solution at various temperatures.[20–31] This is because the half-occupied iron 3d orbital interacts with the specific σ and π molecular orbitals of the porphyrin and increases the spin density at the specific carbon and nitrogen atoms of the complex. Consequently, the ^{13}C NMR signals of the carbon atoms with large spin density appear at extremely upfield or downfield positions. Similarly, the ^{1}H NMR signals of the hydrogen atoms directly attached to the carbon atoms with large spin density are observed outside of the so-called diamagnetic region, i.e. 0–10 ppm. Thus, one can determine which 3d orbitals of the iron have unpaired electrons by an analysis of the observed ^{1}H and ^{13}C NMR chemical shifts. In other words, the chemical shift can be an excellent probe for revealing the electronic structure of paramagnetic iron porphyrin complexes.

Through extensive studies using various spectroscopic, magnetic, and structural analyses, it is now clear that the spin states of iron porphyrins are controlled by the nature and number of axial ligands, electronic effects of peripheral substituents, deformation of the porphyrin ring, etc.[25,26,28–35] In the case of low-spin iron(III) porphyrins, while the six-coordinate complexes carrying axial ligands with strong field strength (such as imidazole and cyanide) exhibit a low-spin (S = 1/2) state, the five-coordinate complexes carrying an anionic ligand such as halide and acetate show a high-spin (S = 5/2) state. If the field strengths of anionic ligands are extremely weak, the complexes adopt a rare intermediate-spin (S = 3/2) state.[36] Figure 2 shows three kinds of spin states in iron(III) porphyrins.[30]

Furthermore, each spin state could have a different electron configuration. This is most explicitly exemplified in the low-spin complexes which exhibit either the $(d_{xy})^2(d_{xz}, d_{yz})^3$ or the $(d_{xz}, d_{yz})^4(d_{xy})^1$ electronic ground state, as shown in

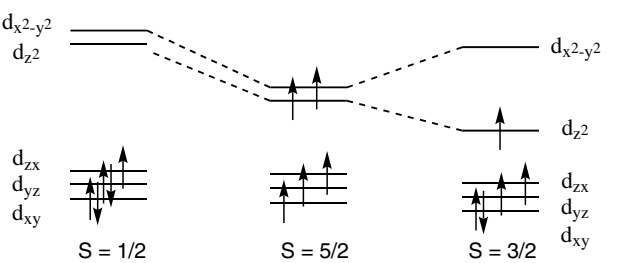

Figure 2. Spin states of iron(III) porphyrins. (Adapted with permission from Ref. 30. Copyright 2006, Elsevier Science.)

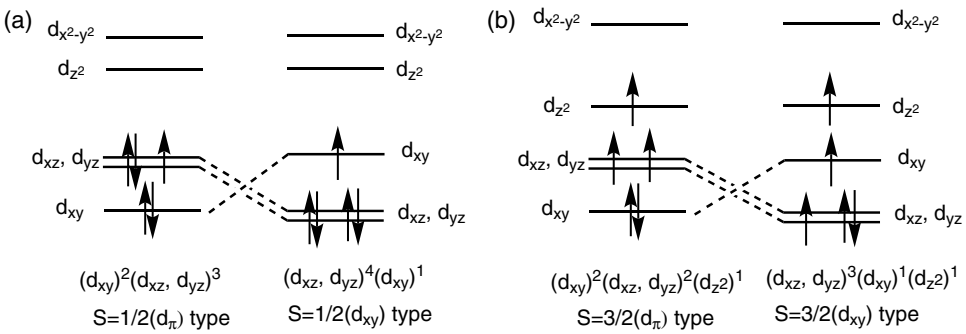

Figure 3. Two types of electronic ground states in (a) low-spin and (b) intermediate-spin iron(III) porphyrins. (Adapted with permission from Ref. 373. Copyright 2003, American Chemical Society.)

Figure 3[25,26,28–31]; they are abbreviated as S = 1/2(d_π) type and S = 1/2(d_{xy}) type, respectively. Similarly, at least two electronic ground states, $(d_{xy})^2(d_{xz}, d_{yz})^2(d_{z^2})^1$ and $(d_{xz}, d_{yz})^3(d_{xy})^1(d_{z^2})^1$, exist even in the intermediate-spin complexes[37]; they are abbreviated as S = 1/2(d_π) type and S = 1/2(d_{xy}) type, respectively. The assignment of the electronic ground states of the specific intermediate-spin complexes such as $[Fe(T^iPrP)(THF)_2]^+$ and $[Fe(OETPP)(THF)_2]^+$ is still a controversial issue.[37–39]

The one-electron oxidation of iron(III) porphyrins should form either an iron(III) porphyrin cation radical or an iron(IV) porphyrin.[26,40] Actually, however, most of the papers reported previously have shown the formation of iron(III) porphyrin cation radicals. These radical species give characteristic ^{1}H NMR spectra, where some of the signals appear at extraordinary upfield or downfield positions due to the presence of an unpaired electron in the porphyrin orbitals.[26,40] The unpaired electron cannot be independent of the paramagnetic iron center. It could interact with the paired and/or unpaired electrons in the iron 3d orbitals. Consequently, the ^{1}H NMR spectra should be affected by the spin states and electron configurations of the iron(III) ions. In other words, the electronic and magnetic structures of iron(III) porphyrin cation radicals could be completely different, depending on the electron configuration of the iron(III) ions. In the case of iron(IV) porphyrins, the iron could adopt the S = 0 and S = 2 spin states, though all the complexes reported to date show the S = 1 spin state.

The two-electron oxidation of iron(III) porphyrins should give either one of the four possible electronic structures, i.e. iron(V) porphyrin, iron(IV) porphyrin cation radical, iron(III) porphyrin dication, or iron(III) porphyrin N-oxide.[11,12] The iron porphyrins with this oxidation state are quite important, since the reactive intermediates that appear transiently in the catalytic cycle of heme proteins such

as catalase, peroxidase, and cytochrome P450 are supposed to adopt these oxidation states.[4–9]

In this review, we will describe the formation and spectroscopic properties of synthetic iron porphyrins with various oxidation states, spin states, electron configurations, and coordination structures. Special emphasis will be placed on the iron porphyrin complexes with unusual electronic and magnetic properties. The synthetic iron porphyrin complexes described in this review are summarized in Scheme 1 together with their abbreviations.

II. NMR and EPR Methods to Determine the Electronic Structures

A. Orbital Interactions

It is very important to understand the iron–porphyrin orbital interactions to reveal the electronic structures of the complexes. Thus, before discussing the electronic structures of various iron porphyrin complexes, the iron–porphyrin orbital interactions will be surveyed. Figure 4 shows the frontier orbitals of a zinc porphyrin with D_{4h} symmetry, calculated by the DFT method.[41] The symmetry presentation of metal and porphyrin orbitals in six-coordinate planar D_{4h} complexes is given in Table 1.[42,43] Among these orbitals, the occupied $3e_g$ and vacant $4e_g$* orbitals can interact with the iron d_π(d_{xz} and d_{yz}) orbitals. If the complex in question has half-occupied d_π orbitals as in the case of low-spin iron(III) complexes with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, the unpaired electron can delocalize to the porphyrin ring by the d_π–$3e_g$ interactions especially to the pyrrole C_β atoms because the $3e_g$ orbitals have a relatively large coefficient at these carbon atoms, as shown in Figure 4.[20,23,26,28–31] In principle, all the frontier orbitals of the porphyrin except for the e_g orbitals are orthogonal to any of the iron 3d orbitals and thus there should be no interaction other than the d_π–$3e_g$ and d_π–$4e_g$* interactions. However, porphyrin rings are flexible and are easily deformed by steric and electronic effects of the peripheral substituents and the axial ligands.[44–51] Typical deformation modes frequently encountered both in synthetic iron porphyrins and in naturally occurring heme proteins are ruffling, saddling, and doming, as given in Figure 5.[50] The ruffling indicates that the *meso* carbon atoms deviate from the mean plane up and down alternately, while the saddling indicates that the β carbon atoms deviate similarly. Doming is typical of five-coordinate iron porphyrin complexes where iron is placed out of the plane defined by the four nitrogen atoms of the pyrrole rings. If the porphyrin ring deforms in a ruffled or saddled fashion in six-coordinate iron porphyrins, some iron–porphyrin orbital interactions can be symmetry allowed, which are originally forbidden in a planar D_{4h} complex. For example, although the

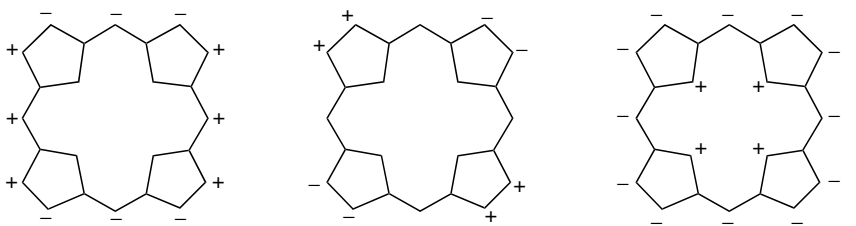

Figure 5. Major deformation modes of porphyrin: (a) ruffled, (b) saddled, and (c) domed deformation. Only the most significant displacements are shown. + indicates displacements above the mean plane and — indicates displacements below the mean plane. (Modified with permission from Senge, M. O. *The Porphyrin Handbook*; Kadish, K. M.; Smith, K. M.; Guilard, R.; Eds.; Academic Press: San Diego, CA, **2000**; Vol. 1, Chapter 6, p. 241.[50])

porphyrin a_{2u} orbital is orthogonal to any of the metal 3d orbitals in a planar D_{4h} complex, it can interact with the iron d_{xy} and $d_{x^2-y^2}$ orbitals if the porphyrin ring deforms in a ruffled or saddled fashion, respectively, as shown in Table 1.[42,43] Similarly, although the a_{1u} orbital is orthogonal to any of the iron 3d orbitals in the planar D_{4h} complex, it can interact with the $d_{x^2-y^2}$ orbital in the ruffled complex and with the d_{xy} orbital in the saddled complex. The symmetry presentation given in Table 1 also indicates that the d_π–$3e_g$ and d_π–$4e_g$* interactions in planar D_{4h} complexes can be maintained even in the deformed complexes since the d_π and e_g orbitals in D_{4h} complexes are signified as e symmetry in ruffled and saddled D_{2d} complexes as well as in domed C_{4v} complexes. Thus, the energy levels of iron 3d orbitals are finely modulated by the degree and mode of porphyrin deformation.

B. NMR Spectroscopy

As mentioned above, a number of techniques have been used to elucidate the electronic structures of iron porphyrin complexes. Among them, ^{1}H and ^{13}C NMR are particularly useful because they provide detailed information on the electronic structures of the complexes in solution at various temperatures.[20,31] In this section, discussion will be confined to the low-spin iron(III) porphyrins and to a description of how NMR spectra are useful for characterization of the two types of electronic ground state, $(d_{xy})^2(d_{xz}, d_{yz})^3$ and $(d_{xz}, d_{yz})^4(d_{xy})^1$, that the low-spin complexes adopt.[25,26,28–31] The NMR characteristics of the complexes with other spin states and oxidation states will be mentioned later.

1. *^{1}H NMR Spectroscopy*

Figure 6 shows the ^{1}H NMR spectra of low-spin $[Fe(T^{n}PrP)(DMAP)_2]^+$(a) and $[Fe(T^{i}PrP)(4\text{-}CNPy)_2]^+$(b) taken in CD_2Cl_2 solution at 213 K.[52] Extensive studies

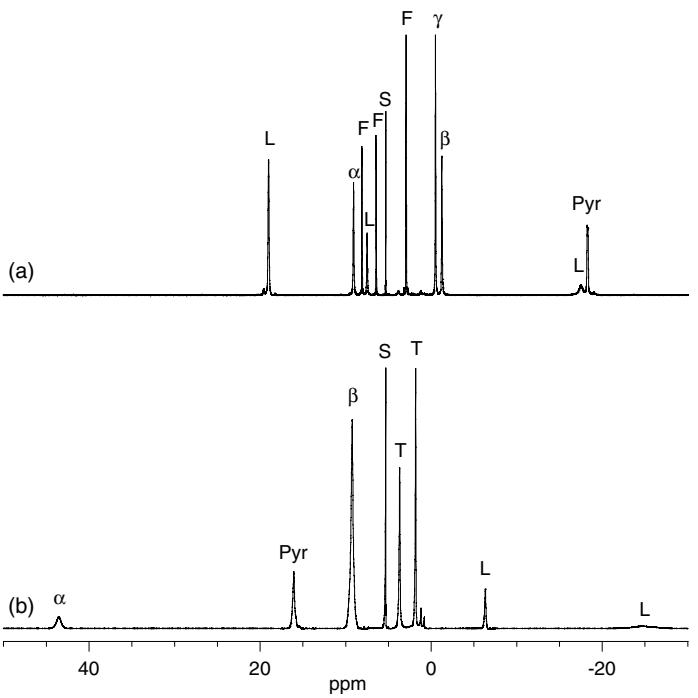

Figure 6. ^{1}H NMR spectra of (a) $[Fe(T^{n}PrP)(DMAP)_2]^+$ and (b) $[Fe(T^{i}PrP)(4\text{-}CNPy)_2]^+$ taken in CD_2Cl_2 solution at 213 K. Signal assignments: pyr shows the pyrrole-H signal; *α*, *β*, and γ indicate the meso alkyl-H signals; F and L are the free and coordinated ligand-H signals; S and T are the solvent and THF signals. (Adapted with permission from Ref. 52. Copyright 2000, American Chemical Society.)

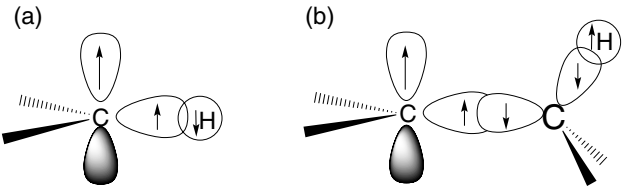

Figure 7. Spin polarization from the π spin on the pyrrole C_β atoms. The effect of π spin density on the carbon atom toward (a) the directly bonded hydrogen atom and (b) the hydrogen atom through two σ-bonds. (Modified from Refs. 28 and 53.)

have revealed that the former adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state while the latter adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state.[52] Thus, the large upfield shift of the pyrrole-H signal, $\delta = -18.5$ ppm, in $[Fe(T^nPrP)(DMAP)_2]^+$ can be explained in terms of the interaction between the half-occupied d_π orbital and the filled $3e_g$ orbital. As mentioned in the previous section, the unpaired electron in the d_π orbital is delocalized to the porphyrin ring especially on the pyrrole C_β atoms since the $3e_g$ orbital has a relatively large coefficient on these carbon atoms (see Figure 4 for the $3e_g$ orbitals). Consequently, the pyrrole-H signal shows a large upfield shift due to the spin polarization mechanism. Figure 7a shows the spin polarization of the pyrrole C–H σ bond caused by the π spin density on the C_β atoms.[28,53] In contrast, the *meso*-CH(α) signal appears at $\delta = 8.0$ ppm, which is rather close to the corresponding signal in the diamagnetic complex. The result is understandable, because the $3e_g$ orbital has zero coefficient on the *meso*-C atoms. Thus, *the large upfield shift of the pyrrole-H signal together with the small isotropic shift of the* meso-*CH(α) signal are the characteristic features of the ^{1}H NMR spectra of low-spin [Fe(TRP)L$_2$]$^+$ with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, where R is the alkyl groups attached to the* meso-*C atoms.*

In the case of $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$, the unpaired electron is in the iron d_{xy} orbital, which is delocalized to the porphyrin ring by the d_{xy}–a_{2u} interaction in the ruffled porphyrin framework. It is understandable that the pyrrole-H signal of this complex appears at $\delta = 16$ ppm, rather close to the pyrrole-H signal, $\delta = 9.4$ ppm, of diamagnetic $[Co(TEtP)(2\text{-}MeIm)_2]^+$,[54] since the a_{2u} orbital has a fairly small coefficient at the C_β atoms. A small downfield shift should be ascribed to the dipolar contribution of the low-spin iron(III) with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. In contrast, the *meso*-CH(α) signal appears at an extremely downfield position, $\delta = 43$ ppm. The large downfield shift is also understandable since the a_{2u} orbital has a large coefficient at the *meso*-C atoms, which induces the large downfield shift to the *meso*-CH(α) signal by the spin polarization mechanism, as shown in Figure 7b. Thus, *the large downfield shift of the meso-CH(α) signal together with the small isotropic shift of the pyrrole-H signal are the characteristic features of*

the ^{1}H NMR spectra of low-spin[Fe(TRP)L$_2$]$^{\pm}$-with the (d_{xz}, d_{yz})^4(d_{xy})^1 ground state.

In low-spin iron(III) porphyrins having aryl groups at the *meso* positions, [Fe(TArP)L$_2$]$^+$, the *meta*-H chemical shift can be a good probe of the electronic ground state. The theoretical background is as follows[55–59]: the observed chemical shift (δ_{obs}) of the *meta*-H signal can be given by Eq. 1, where δ_{iso} is the isotropic shift and δ_{dia} is the chemical shift of the *meta*-H signal in a suitable diamagnetic complex such as [Co(TArP)L$_2$]$^+$.[60,61] The δ_{iso} value, which is the sum of the contact and dipolar shift, δ_{con} and δ_{dip}, respectively, can be expressed by Eq. 2 in the case of the complexes with axial symmetry, where K_{con} and K_{dip} are positive constants, ρ_C^{meta} is the spin density at

$$\delta_{obs} = \delta_{iso} + \delta_{dia}, \tag{1}$$

$$\delta_{iso} = \delta_{con} + \delta_{dip} = \frac{-K_{con}\rho_C^{meta} + K_{dip}(\chi_{\parallel} - \chi_{\perp})(3\cos^2\theta - 1)/r^3}{T}, \tag{2}$$

the *meta*-C atom, θ is the angle between the nucleus(m-H)–metal(Fe) vector and the z axis, and r is the length of this vector. The term $(3\cos^2\theta - 1)/r^3$ is referred to as the axial geometric factor. As mentioned previously, the spin density at the *meso*-C atoms in low-spin (d_{xy})^2 (d_{xz}, d_{yz})^3 type complexes is supposed to be zero. Therefore, both the isotropic shift and the slope of the Curie plots for the *meta*-H should be negative. This is because the ρ_C^{meta} value is nearly zero and the ($g_{\parallel}^2 - g_{\infty}^2$) $(3\cos^2\theta - 1)/r^3$ is negative; the latter term is negative because $g_{\parallel}^2 - g_{\infty}^2$ is positive in the (d_{xy})^2 (d_{xz}, d_{yz})^3 type complexes,[25] while $(3\cos^2\theta - 1)/r^3$ is negative for the *meta*-H. In contrast, the low-spin (d_{xz}, d_{yz})^4(d_{xy})^1 type complexes have a sizable amount of spin density on the *meso*-C atoms due to the interaction between the half-occupied d_{xy} and filled a_{2u} orbitals. The positive spin at the *meso*-C atoms is delocalized to the attached phenyl rings and induces a positive π spin density at the *ortho*- and *para*-C and a negative π spin density at the *meta*-C atoms.[28] Thus, the slope for the contact shift, $-K_{con}\rho_C^{meta}$, should be positive. In addition, the slope for the dipolar shift, ($g_{\parallel}^2 - g_{\infty}^2$) $(3\cos^2\theta - 1)/r^3$, should also be positive because the $g_{\parallel}^2 - g_{\infty}^2$ value is negative in the (d_{xz}, d_{yz})^4(d_{xy})^1 type complexes.[25,53] Consequently, it is expected that the *meta*-H signal appears more downfield than the corresponding signal of the diamagnetic complex and that the slope of its Curie plots is positive. This tendency is clearly seen in the Curie plots of the *meta*-H signals of [Fe(OMTPP)L$_2$]$^{\pm}$. As shown in Figure 8,[62] the Curie slope is negative if L is HIm, CN^-, and DMAP, and positive if L is ^{t}BuNC. Thus, we can conclude that the HIm, CN^-, and DMAP complexes adopt the (d_{xy})^2(d_{xz}, d_{yz})^3 ground state while the ^{t}BuNC complex adopts the (d_{xz}, d_{yz})^4(d_{xy})^1

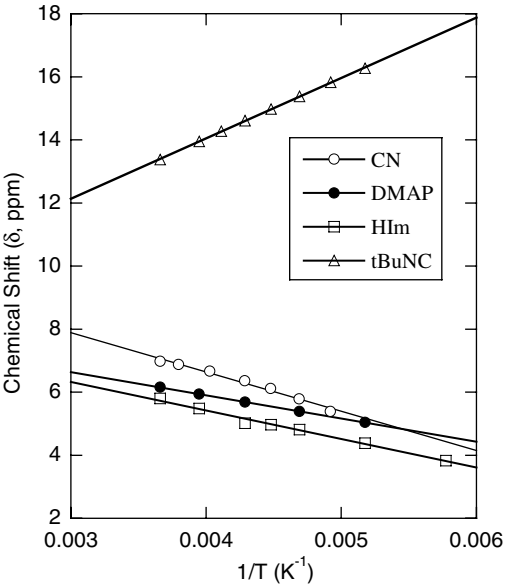

Figure 8. Curie plots of the *meta*-H signals of $[Fe(OMTPP)L_2]^+$, where L is HIm, CN^-, DMAP, and ^{t}BuNC. (Adapted with permission from Ref. 62. Copyright 2003, American Chemical Society.)

ground state. Therefore, *Curie plots of the meta-H signal can predict the electronic ground state of low-spin* $[Fe(TArP)L_2]^{\pm}$.

Walker and coworkers[28] have proposed that the electronic ground state of low-spin iron(III) porphyrins having *meso*-aryl groups such as $[Fe(TPP)L_2]^+$, $[Fe(OETPP)L_2]^+$, and $[Fe(TPC)L_2]^+$ can be determined by the $\delta_m - \delta_p$ and $\delta_m - \delta_o$ values; δ_o, δ_m, and δ_p are the chemical shifts of the *ortho*-, *meta*-, and *para*-phenyl signals, respectively. If $\delta_m - \delta_p$ and $\delta_m - \delta_o$ are both large and positive, then the complex has large amounts of positive spin at the *meso*-C atoms, which in turn indicates that the complex adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. In contrast, if $\delta_m - \delta_p$ and $\delta_m - \delta_o$ are small with $\delta_m - \delta_p$ positive and $\delta_m - \delta_o$ usually negative, then the complex adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state since the *meso*-C atoms have little or no spin density.

2. *^{13}C NMR Spectroscopy*

Figure 9 shows the ^{13}C NMR spectra of (a) $[Fe(T^nPrP)(DMAP)_2]^+$, (b) $[Fe(T^cPrP)(2\text{-MeIm})_2]^+$, and (c) $[Fe(T^iPrP)(4\text{-CNPy})_2]^+$ taken in CD_2Cl_2 solution at 298 K.[52] The chemical shifts of the three kinds of carbon atoms constituting the porphyrin core, i.e. C_{meso}, C_α, and C_β, are quite different among these complexes. In the case

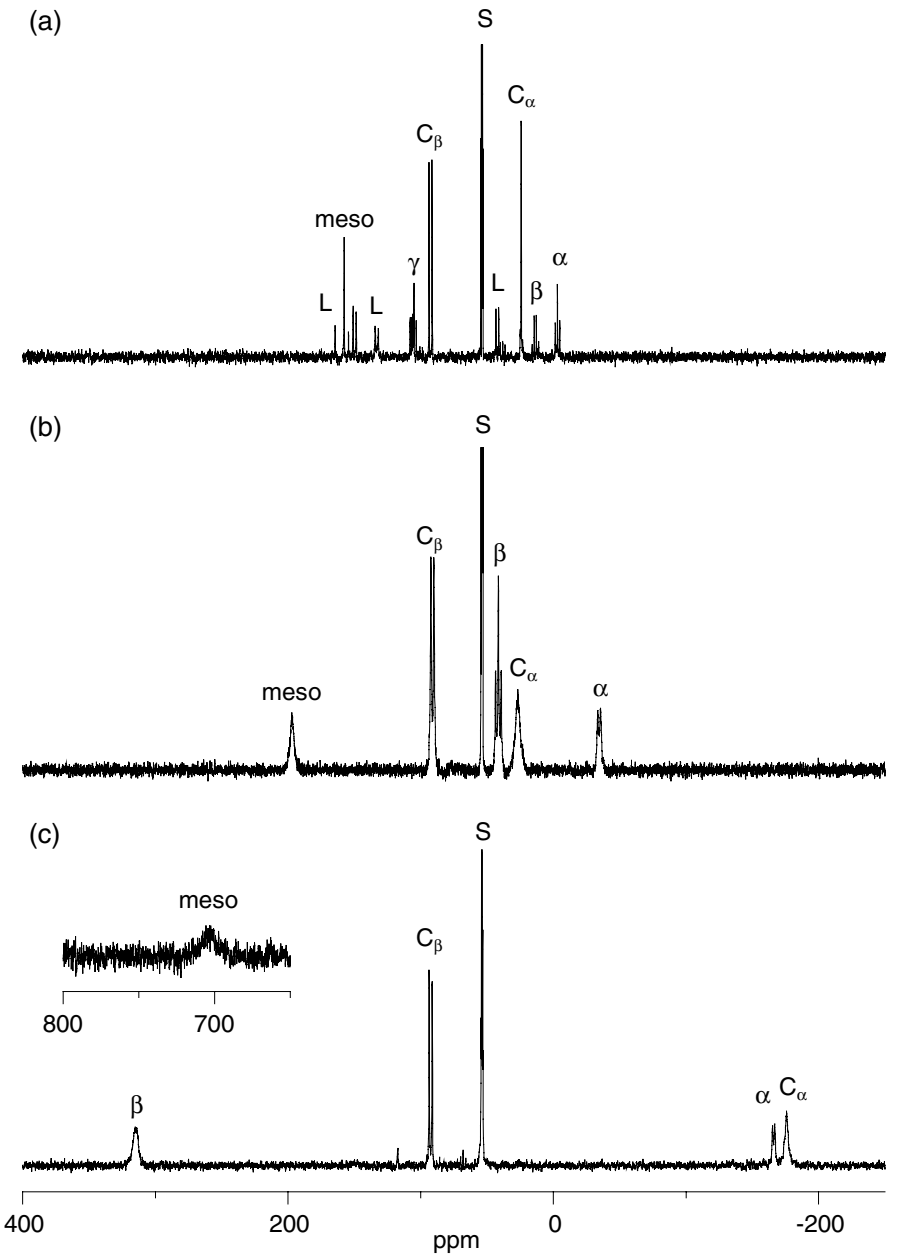

Figure 9. ^{13}C NMR spectra of (a) $[Fe(T^nPrP)(DMAP)_2]^+$, (b) $[Fe(T^cPrP)(2\text{-MeIm})_2]^+$, and (c) $[Fe(T^iPrP)(4\text{-CNPy})_2]^+$ taken in CD_2Cl_2 solution at 298 K. Signal assignment: C_α, C_β, and *meso* are the *α*-, *β*-, and *meso*-carbon atoms, respectively; *α*, *β*, and *γ* are the *α*-, *β*-, and *γ*-carbons of the *meso*-alkyl groups, respectively; and S and L are the signals for the solvent and coordinating ligand, respectively. Both coordinating and free ligand signals are not observable in (b) and (c) at this temperature. (Adapted with permission from Ref. 52. Copyright 2000, American Chemical Society.)

of $[Fe(T^nPrP)(DMAP)_2]^+$, the chemical shifts of these carbon signals are 157.7, 24.3, and 92.6 ppm, respectively, while they are 707, −176, and 92.5 ppm, respectively, in the case of $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$. The large downfield shift of the C_{meso} signal together with the large upfield shift of the *meso*-C_α signal in $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$ is understandable since the *meso*-C atoms have large spin density due to the d_{xy}–a_{2u} interaction in a highly ruffled porphyrin framework. However, a slightly upfield-shifted C_β signal, δ = 73.6 ppm, in the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type $[Fe(T^nPrP)(HIm)_2]^+$ needs to be explained, as the C_β atoms also have relatively large spin density due to the interaction between the half-occupied d_π and fully occupied $3e_g$ orbital. In fact, the large upfield shift of the pyrrole-H signal, δ = −21.5 ppm at 223 K, is a direct indication that the C_β atoms certainly have a considerable amount of spin density.

In the case of ^{13}C NMR spectroscopy, the chemical shift of the specific carbon atom is determined not only by the spin density of the carbon in question but also by the spin density on the neighboring carbon atoms. Thus, the isotropic shift of the carbon signal (δ_{iso}), which is obtained by the subtraction of the corresponding chemical shift of a diamagnetic complex (δ_{dia}) from the observed chemical shift (d_{obs}), is given by Eq. 3,

$$\delta_{iso} = \delta_{obs} - \delta_{dia} = \delta_{con} + \delta_{dip}{}^{MC} + \delta_{dip}{}^{LC}, \tag{3}$$

where δ_{con}, $\delta_{dip}{}^{MC}$, and $\delta_{dip}{}^{LC}$ represent the metal-centered dipolar shift, ligand-centered dipolar shift, and contact shift, respectively.[21,31,55–59] The metal-centered dipolar shift in the complexes with axial symmetry is defined by Eq. 4,

$$\delta_{dip}{}^{MC} = \frac{(1/2\pi)(\chi_{\parallel} - \chi_{\perp})(3\cos^2\theta - 1)}{r^3},^{58} \tag{4}$$

where χ's are molecular susceptibilities, θ is the angle between the nucleus–metal vector and the z axis, r is the length of this vector, and the term $(3\cos^2\theta - 1)/r^3$ is the axial geometric factor. $\delta_{dip}{}^{LC}$ is assumed to be proportional to the π-spin density ρ^π-at the observed carbon atom and is given by Eq. 5,[55–59,63]

$$\delta_{dip}{}^{LC} = -(\chi_{\parallel} - \chi_{\perp})K\rho^\pi, \tag{5}$$

where K is a positive constant. Thus, $\delta_{dip}{}^{LC}$ is negative in the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes while it is positive in the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type complexes, provided that ρ^π is positive.

Carbon contact shifts originate from unpairing of carbon 1s electrons and unpairing of the three carbon sp^2 bonding pairs. Thus, the isotropic shift of

C_{meso}, C_α, C_β, and *meso*-C_α signals can be given by Eqs. 6–9, respectively,[63–66] where the S^C term indicates polarization of the 1s orbital, the $Q^C_{CC'}$ term reflects polarization of the three sp^2 bonds by the π-spin density at the observed carbon atom, and the $Q^C_{C'C}$ term represents polarization of the C–C bond by the π spin densities centered on the neighboring carbon atoms; the S^C, $Q^C_{CC'}$, Q^C_{CH}, and $Q^C_{C'C}$ values are estimated to be −35.5, +40.3, +54.6, and −39.0 MHz, respectively.[63,64] The F^C value is defined as $F^C = 2\pi g\mu_B S(S + 1)/3\gamma_C kT$,[65] where γ_C is the magnetogyric ratio of carbon, k is the Boltzmann constant, and μ_B is the Bohr magneton.

For the C_{meso} signal,

$$\begin{aligned}\delta_{iso}(C_{meso}) &= \delta_{obs} - \delta_{dia} = \delta_{con} + \delta_{dip}{}^{LC} + \delta_{dip}{}^{MC}(C_{meso}) \\ &= [(S^C + 3Q^C_{CC'})\rho^\pi_{meso} + (2Q^C_{C'C})\rho^\pi_\alpha]F^C + (\chi_\perp - \chi_\parallel)K\rho^\pi_{meso} \\ &\quad + \delta_{dip}{}^{MC}(C_{meso}). \end{aligned} \tag{6}$$

For the C_α signal,

$$\begin{aligned}\delta_{iso}(C_\alpha) &= [(S^C + 2Q^C_{CC'} + Q^C_{CN})\rho^\pi_\alpha + (Q^C_{C'C}\rho^\pi_\beta + Q^C_{C'C}\rho^\pi_{meso} + Q^C_{N'C}\rho^\pi_N)]F^C \\ &\quad + (\chi_\perp - \chi_\parallel)K\rho^\pi_\alpha + \delta_{dip}{}^{MC}(C_\alpha). \end{aligned} \tag{7}$$

For the C_β signal,

$$\begin{aligned}\delta_{iso}(C_\beta) &= [(S^C + 2Q^C_{CC'} + Q^C_{CH})\rho^\pi_\beta + (Q^C_{C'C}\rho^\pi_\beta + Q^C_{C'C}\rho^\pi_\alpha)]F^C \\ &\quad + (\chi_\perp - \chi_\parallel)K\rho^\pi_\beta + \delta_{dip}{}^{MC}(C_\beta). \end{aligned} \tag{8}$$

For the *meso*-C_α((alkyl) signal,

$$\delta_{iso}(meso\text{-}C_\alpha) = Q^C_{C'C}\rho^\pi_{meso}F^C + \delta_{dip}{}^{MC}(meso\text{-}C_\alpha). \tag{9}$$

Let us consider the isotropic shifts of the C_{meso} signal in $[Fe(T^nPrP)(HIm)_2]^+$ adopting the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. The major interactions should occur between the d_π and $3e_g$ orbitals. Since the $3e_g$ orbital has zero coefficient at the C_{meso} atoms, we can simplify the isotropic shift of the C_{meso} signal given in Eq. 6 by assuming that $\rho_{meso} = 0$. Thus, Eq. 6 is converted into Eq. 6′:

$$\delta_{iso}(C_{meso}) = (2Q^C_{C'C})\rho^\pi_\alpha F^C + \delta_{dip}{}^{MC}(C_{meso}). \tag{6′}$$

The $\delta_{iso}(C_{meso})$ value must be negative in the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes because both $Q^C_{C'C}$ and $\delta_{dip}{}^{MC}(C_{meso})$ are negative; $\delta_{dip}{}^{MC}(C_{meso})$ given in Eq. 4 is negative because $\chi_\parallel - \chi_\perp$ is positive in the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes while the axial geometric factor $(3\cos^2\theta - 1)/r^3$ is negative for the C_{meso} atoms. In fact, the

C_{meso} signal of this complex is observed at 84.9 ppm at 298 K, which is more upfield by 36.1 ppm than the corresponding signal of diamagnetic Zn(TPP).[67]

As for the isotropic shift of the C_β signal given in Eq. 8, this can be rewritten into Eq. 8′ by using the Q^C and S^C values:

$$\delta_{iso}(C_\beta) = [(60.7\rho^\pi{}_\beta - 39.0\rho^\pi{}_\alpha)]F^C + (\chi_\perp - \chi_\parallel)K\rho^\pi{}_\beta + \delta_{dip}{}^{MC}(C_\beta). \quad (8')$$

Since the $(\chi_\perp - \chi_\parallel)K\rho^\pi{}_\beta$ and $\delta_{dip}{}^{MC}(C_\beta)$ values are negative for the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes, the $\delta_{iso}(C_\beta)$ is not always positive although the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes have relatively large $\rho^\pi{}_\beta$ values. This is the reason why the C_β signal in $[Fe(T^nPrP)(HIm)_2]^+$ is observed at δ = 87.0 ppm at 298 K, which is 45.0 ppm further upfield than the corresponding signal of diamagnetic Zn(TPP).[67]

For the low-spin complexes with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, such as $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$, the unpaired electron in the d_{xy} orbital is delocalized to the porphyrin ring by the d_{xy}–a_{2u} interaction in a ruffled porphyrin framework. Since the a_{2u} orbital has a negligibly small coefficient at the C_α and C_β atoms, the isotropic shift of the C_{meso} signal can be approximated as Eq. 6″ by assuming that $\rho_\alpha = 0$ and $\rho_\beta = 0$:

$$\delta_{iso}(C_{meso}) = (S^C + 3Q^C{}_{CC'})F^C\rho^\pi{}_{meso} + (\chi_\perp - \chi_\parallel)K\,\rho^\pi{}_{meso} + \delta_{dip}{}^{MC}(C_{meso}). \quad (6'')$$

Since the $(S^C + 3Q^C{}_{CC'})$, $(\chi_\perp - \chi_\parallel)K$, and $\delta_{dip}{}^{MC}$ values are all positive for the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type complexes, the C_{meso} signal should appear at a fairly downfield position. If the complex adopts a quite pure $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, the d_{xy} orbital is located far above the d_π orbital. In such a case, the $\rho^\pi{}_{meso}$ value should be quite large, due to the strong d_{xy}–a_{2u} interaction. Consequently, the C_{meso} signal appears at a more downfield position. In fact, the C_{meso} signal is observed at δ = 707 ppm at 298 K in the case of $[Fe(T^nPrP)(4\text{-}CNPy)_2]^+$, which is more downfield by 586 ppm than the corresponding signal of the diamagnetic complex.[52] Therefore, *the chemical shift of the* C_{meso} *signal is an excellent probe not only for determineing the electronic ground state of low-spin iron(III) porphyrins but also for evaluating the purity of the* $(d_{xz}, d_{yz})^4(d_{xy})^1$ *ground state.* Figure 10 shows the correlation of chemical shifts between pyrrole-H and *meso*-C signals in a number of low-spin iron(III) porphyrins taken at 223 K.[68] As revealed in the figure the downfield shift of the *meso*-C signal is proportional to that of the pyrrole-H signal if the chemical shift of the pyrrole-H signal is less than 10 ppm; the correlation coefficient reaches as much as 0.9863. However, once the chemical shift of the pyrrole-H exceeds δ = 10 ppm, the chemical shift of the *meso*-C signal exhibits a steep increase. As a result, there seems to be no correlation in the chemical shifts of these two signals in the complexes where the pyrrole-H signals exceed 10 ppm. In fact, while

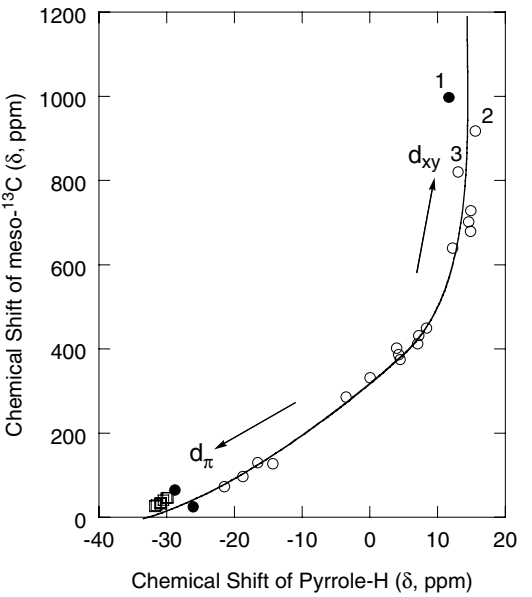

Figure 10. Relation of chemical shifts between pyrrole-H and *meso*-^{13}C nuclei at 223 K obtained from 18 $[Fe(TRP)L_2]^{\pm}$ (*), 3 $[Fe(TPP)L_2]^{\pm}$ (•), and 8 $[Fe(TArP)L_2]^{\pm}$(□). d_{xy} and d_{π} indicate the $(d_{xz}, d_{yz})^4(d_{xy})^1$ and the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, respectively. Numbers in the graph, **1**, **2**, and **3**, indicate the *meso*-C chemical shifts of $[Fe(TPP)(^tBuNC)_2]^+$, $[Fe(T^nPrP)(4\text{-}CNPy)_2]^+$, and $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$, respectively. (Adapted with permission from Ref. 68. Copyright 2003, Royal Society of Chemistry.)

the pyrrole-H chemical shifts of $[Fe(TPP)(^tBuNC)_2]^+$(**1**), $[Fe(T^nPrP)(4\text{-}CNPy)_2]^+$(**2**), and $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$(**3**) are 11.7, 13.0, and 15.6 ppm, the *meso*-C chemical shifts for these complexes are 997, 820, and 918 ppm, respectively. It should be interesting to determine the *meso*-C chemical shifts of $[Fe(T^nPrP)(^tBuNC)_2]^+$ and $[Fe(T^iPrP)(^tBuNC)_2]^+$. However, no reports have been published concerning the observation of the *meso*-C signals in $[Fe(TRP)(^tBuNC)_2]^+$, where R is an alkyl group attached to the *meso*-C atoms. Probably, these signals should appear extremely downfield with very broad bandwidths due to the large spin density on the *meso*-C atoms.

C. EPR Spectroscopy

EPR spectroscopy is also a powerful tool for determining the electronic structure of iron porphyrins.[25,26,28–30,69–71] High-spin complexes exhibit their $g_{\perp}$ and $g_{\parallel}$ signals at *ca*. 6.0 and 2.0, while the intermediate-spin complexes show them at *ca*. 4.0 and 2.0. In the case of low-spin complexes, there are three types of EPR spectra. Complexes that adopt the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state exhibit either rhombic or

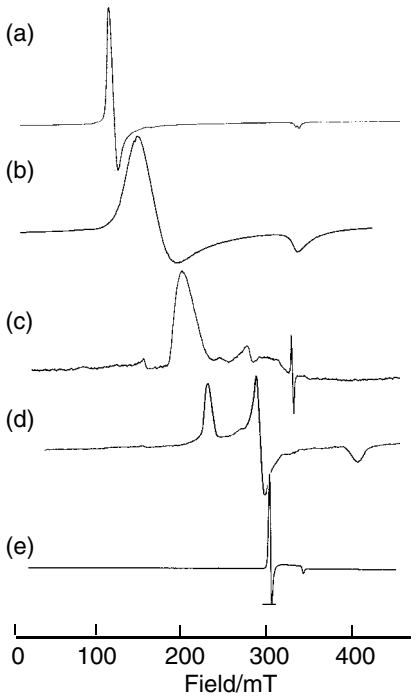

Figure 11. EPR spectra of iron(III) porphyrins with various electronic structure: (a) Fe(T^{i}PrP)F, (b) [Fe(T^{c}PrP)(THF)$_2$]$^+$, (c) [Fe(OETPP)(2-MeIm)$_2$]$^+$, (d) [Fe(OEP)(DMAP)$_2$]$^+$, and (e) [Fe(T^{n}PrP)(^{t}BuNC)$_2$]$^+$ taken in frozen CH_2Cl_2 solution at 4 K. (Adapted from Refs. 81, 82, 83, 84 and 52, respectively.)

large g_{max} type spectra, depending on the orientation of planar axial ligands such as imidazole and pyridine. The complexes with parallel-aligned axial ligands show rhombic type spectra, while those with perpendicularly aligned axial ligands show large g_{max} type spectra.[72–74] Complexes with linear ligands such as cyanide also exhibit large g_{max} type spectra.[75] According to the work of Yatsunyk and coworkers,[76] the spectral type changes from rhombic to large g_{max} type if the dihedral angle between the axial ligand planes exceeds *ca*. 57°. In contrast, the complexes that adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state always exhibit axial type spectra where $g_\perp$ values are smaller than 2.6.[26,28–30,77–79] In Figure 11 are shown the EPR spectra of (a) Fe(TEtPrP)F,[80] (b) [Fe(T^{c}PrP)(THF)$_2$]$^+$,[81] (c) [Fe(OETPP)(2-MeIm)$_2$]$^+$,[82] (d) [Fe(OEP)(DMAP)$_2$]$^+$,[83] and (e) [Fe(T^{c}PrP)(4-CNPy)$_2$]$^+$ taken in frozen CH_2Cl_2 solution at 4 K.[52] These complexes are examples that adopt the (a) high-spin state, (b) intermediate-spin state, (c) low-spin $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state with perpendicularly aligned axial ligands, (d) low-spin $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state with parallel aligned axial ligands, and (e) low-spin $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state.

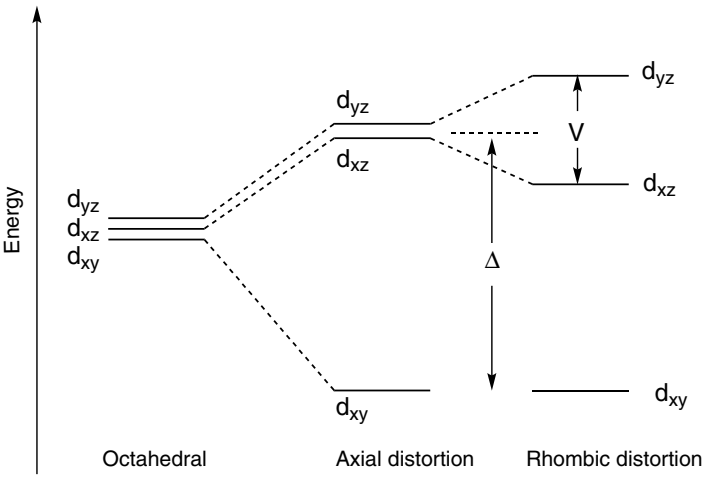

Figure 12. Energy levels of the three t_{2g} orbitals as the symmetry is reduced from being octahedral with axial distortion and rhombic distortion. (Adapted from Ref. 69.)

Once the three *g* values are obtained from the EPR spectra in low-spin iron(III) porphyrins, it is possible to calculate the relative energy levels of the 3d orbitals using Eqs. 10 and 11 developed by Taylor,[71] where V is the energy difference between the d_{xz} and d_{yz} orbitals, Δ is the energy difference between the d_{xy} and the average of the d_{xz} and d_{yz} orbitals, as shown in Figure 12, and λ is the spin–orbit coupling constant. This constant has the value of 460 cm^{-1} for the free ferric ion and a much smaller value in iron(III) porphyrins.

$$\frac{V}{\lambda} = \frac{E_{yz}}{\lambda} - \frac{E_{xz}}{\lambda} = \frac{g_x}{g_z + g_y} + \frac{g_y}{g_z - g_x}, \tag{10}$$

$$\frac{\Delta}{\lambda} = \frac{E_{yz}}{\lambda} - \frac{E_{xy}}{\lambda} - \frac{V}{2\lambda} = \frac{g_x}{g_z + g_y} + \frac{g_z}{g_y - g_x} - \frac{V}{2\lambda}. \tag{11}$$

III. Low-Spin Iron(III) Porphyrins

A. General Considerations

As shown in Figure 3, there are two types of electronic ground state in low-spin iron(III) porphyrin complexes. One is a commonly observed $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state and the other is a less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state.[26,28–30] Studies have revealed that complexes carrying axial ligands with strong σ-donating and weak π-accepting ability, such as imidazole and dimethylaminopyridine (DMAP), adopt

the common $(d_{xy})^2(d_{xz}, d_{yz})^3$ state. In contrast, complexes carrying axial ligands with strong π-accepting ability, such as *tert*-BuNC and 4-CNPy, prefer the less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ state. Walker, Scheidt and others have explained that the d_π orbitals in the latter complexes are stabilized by interaction with the low-lying $\pi*$ orbital of the ligand to the points which are lower than the d_{xy} orbital.[78,79] As a result, the unpaired electron occupies the d_{xy} orbital to form the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Generally speaking, low-spin complexes should exist as an equilibrium mixture of two spin isomers, i.e. electron configurational isomers, as given by Eq. 12.

$$(d_{xy})^2(d_{xz},d_{yz})^3 \underset{\longleftarrow}{\overset{K}{\longrightarrow}} (d_{xz},d_{yz})^4(d_{xy})^1. \tag{12}$$

If the energy difference between two isomers is rather small, two isomers should exist in a comparable ratio. In contrast, if the d_{xy} orbital is located far above the d_π orbitals in the energy diagram, then the isomer with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state should exist exclusively. The spectroscopic properties of the complex, therefore, change depending on the energy difference between the d_{xy} and d_π orbitals.

The rate for interconversion between two electron configurational isomers is generally very fast on the NMR time scale. Therefore, the observed chemical shift for the ^1H and ^{13}C signal is the average of the chemical shifts of two isomers, which is expressed by Eq. 13,

$$\delta_{\text{obs}} = \frac{1}{1+K}\,\delta_{d_\pi} + \frac{K}{1+K}\,\delta d_{xy}. \tag{13}$$

Figure 13 shows the Curie plots of the pyrrole-H signals of a series of low-spin iron(III) porphyrins, $[Fe(T^cPrP)L_2]^{\pm}$, where axial ligands are 4-CNPy, Py, 3-MePy, CN^-, DMAP, and HIm.[52] As shown in the figure, all the complexes except $[Fe(T^cPrP)(CN)_2]^-$ exhibit good linearity although the slopes of the lines are different depending on the axial ligands. The low-spin complexes with the positive slope have the spin isomer with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state as the major component, while those with the negative slope have the spin isomer with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ground state as the major component. The curvature in Curie plots of the pyrrole-H signal in $[Fe(T^cPrP)(CN)_2]^-$ can be explained in terms of the temperature dependence of the equilibrium constant *K* shown in Eq. 12.

In contrast to the case of the NMR spectra, both of the spin isomers could be directly observed by EPR spectroscopy since the rate for interconversion between two isomers shown in Eq. 12 should be slow enough on the EPR time scale at 4.2 K. Figure 14 displays the EPR spectrum of $[Fe(Et\text{-}TPP)(CN)_2]^-$ taken in frozen

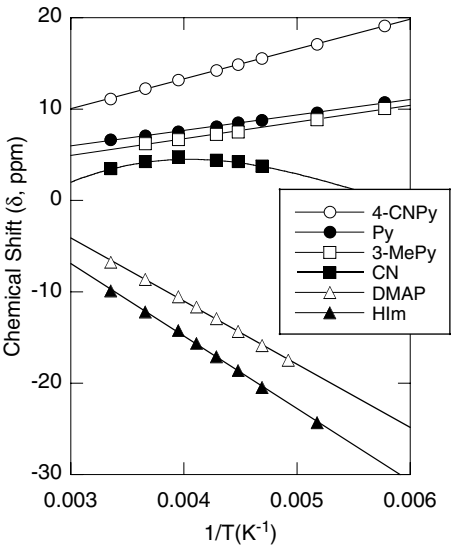

Figure 13. Curie plots of the pyrrole-H signals of a series of $[Fe(T^cPrP)L_2]^+$. (Adapted with permission from Ref. 52. Copyright 2000, American Chemical Society.)

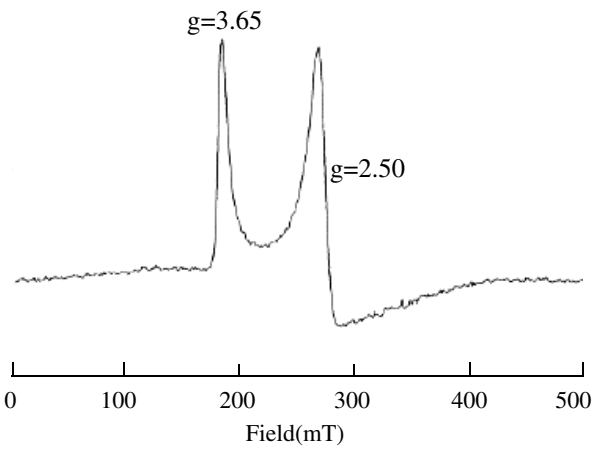

Figure 14. EPR spectrum of $[Fe(Et\text{-}TPP)(CN)_2]^-$ taken in frozen CH_3CN solution at 4.2 K. (Adapted with permission from Ref. 84. Copyright 2002, American Chemical Society.)

acetonitrile solution at 4.2 K, which clearly shows two types of EPR signals: one is a large g_{max} type signal with $g = 3.65$ and the other is an axial signal with $g = 2.50$.[84] Thus, the complex exists as a mixture of two electron configurational isomers at 4.2 K; one adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state while the other adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. If we assume that the equilibrium constant between

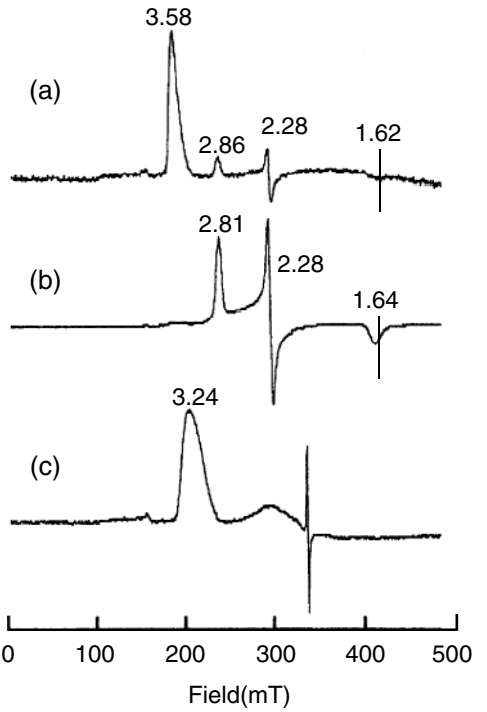

Figure 15. EPR spectra of (a) $[Fe(TMTMP)(DMAP)_2]ClO_4$, (b) $[Fe(OEP)(DMAP)_2]^+$, and (c) $[Fe(OETPP)(DMAP)_2]ClO_4$ taken in frozen CH_2Cl_2 solution at 4.2 K. (Reprinted with permission from Ref. 83. Copyright 2000, Chemical Society of Japan.)

two isomers is *ca*. 10 in favor of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ isomer, the $\Delta G°$ is calculated to be 80 J/mol at 4.2 K. Thus, this phenomenon is observable when the difference in thermodynamic stability of the isomers is fairly small.

The EPR spectrum can differentiate the conformational isomers as well. Figure 15 shows the EPR spectra of (a) $[Fe(TMTMP)(DMAP)_2]ClO_4$, (b) $[Fe(OEP)(DMAP)_2]^+$, and (c) $[Fe(OETPP)(DMAP)_2]ClO_4$ taken in frozen CH_2Cl_2 solution at 4.2 K.[83] As shown in Figure 15(a), $[Fe(TMTMP)(DMAP)_2]^+$ gives two sets of signals, i.e. rhombic type signals at $g = 2.86$, 2.28, and 1.62 and a large g_{max} type signal at $g = 3.58$. The EPR spectrum of the former isomer resembles that of $[Fe(OEP)(DMAP)_2]^+$ shown in Figure 15b, indicating that the axial ligands are aligned parallel above and below the porphyrin ring. In contrast, the EPR spectrum of the other isomer resembles that of $[Fe(OETPP)(DMAP)_2]^+$ shown in Figure 15c, suggesting that the axial ligands are aligned perpendicularly. It is clear from Figure 15a that the perpendicular isomer predominates over the parallel isomer. EPR measurement at various temperatures could yield the thermodynamic

parameters, $\Delta H°$ and $\Delta S°$, which would help us understand the properties of these biologically relevant complexes.

B. Factors Affecting the Electronic Ground States

There are several factors that affect the electronic ground states of low-spin iron(III) porphyrins.[26,30,31] Four major factors that should be considered are (i) number and nature of axial ligands, (ii) electronic effects of peripheral substituents, (iii) deformation of porphyrin rings, and (iv) solvent effects. Among them, the number and nature of axial ligands are the most important factor that affects the electronic ground state of low-spin iron(III) porphyrins. In this section will be described in detail how these factors affect the electronic structure by using various model complexes given in Scheme 1.

1. *Axial Ligands*

Axial ligands can directly affect the energy level of the iron d_{z^2} orbital by σ donation. If the coordination atom of the axial ligand is a part of an aromatic ring such as imidazole or pyridine, then the ligand can also affect the energy levels of the iron d_π orbitals by donating or accepting π electrons. Axial ligands with strong σ-donating and weak π-accepting ability, such as HIm and CN^-, lead to the formation of low-spin complexes with the common $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, while those with low-lying π^* orbitals, such as 4-CNPy and ^{t}BuNC, stabilize complexes with the less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state.[26,30,31] Safo and coworkers[78] have measured the ^{1}H NMR chemical shifts of $[Fe(TMP)L_2]^+$ and correlated them with the pKa(BH^+) values of a wide variety of nitrogen bases (Ls) ranging from pKa 9.7 (DMAP) to 1.1 (4-CNPy). Table 2 lists the chemical shifts (δ_{obs}) and isotropic shifts (δ_{iso}) of *meso*-H and pyrrole-H signals together with the pKa values of the conjugate acids; the isotropic shift is defined by Eq. 1. The data in the table indicate that the magnitude of the *meso*-H isotropic shift increases while that of the pyrrole-H decreases as the axial ligand becomes less basic.[78] The result is interpreted in terms of a smooth change in the electronic ground state from largely $(d_{xy})^2(d_{xz}, d_{yz})^3$ to at least 50% $(d_{xz}, d_{yz})^4(d_{xy})^1$ as the energy level of the ligand π^* orbital decreases. It should be noted that low-spin complexes with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state such as $[Fe(TMP)(DMAP)_2]^+$, have relatively large π spin density on the pyrrole C_β atoms, which induces a large upfield shift of the pyrrole-H signal. In contrast, the low-spin complexes with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, such as $[Fe(TMP)(4\text{-}CNPy)_2]^+$, have fairly small π spin density on the pyrrole C_β atoms, inducing a fairly small upfield shift of the pyrrole-H signal.

Table 2. ^{1}H NMR Chemical Shifts of a Series of $[Fe(TMP)L_2]^+$ at 193 K in CD_2Cl_2.

		δ_{obs}		δ_{iso}	
Ligand	pKa(BH^+)	m-H	Pyrrole-H	m-H	Pyrrole-H
DMAP	9.70	4.85	–30.9	–2.42	–39.5
2-MeIm	7.56	7.77	–20.4	0.5	–29.0
1-MeIm	7.33	5.01	–31.3	–2.26	–39.9

Simonneaux and coworkers[85] have reported that iron(III) porphyrins with phosphonite derivatives, such as $P(OMe)_2Ph$ and $P(OEt)_2Ph$, also exhibit the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, as revealed from the ^{1}H NMR and EPR data. The pyrrole-H signal appears at +2.6 ppm at 293 K for $[Fe(TPP)(P(OEt)_2Ph)]^+$. The EPR spectrum is axial with $g_\perp = 2.36$ and $g_\parallel = 1.91$ for $[Fe(4\text{-Me-TPP})(P(OEt)_2Ph)]^+$.[86] In contrast, the corresponding bis-phosphine complex $[Fe(TPP)(PMe_3)_2]^+$ adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, as indicated by the upfield shift of the pyrrole-H signal, i.e. –19.6 ppm at 303 K.[87] Since the pKa values of the conjugate acids of phosphorus ligands decrease in the order $PMe_3 > PMe_2Ph > P(OMe)_2Ph > P(OMe)_3$,[88] the result can be ascribed to the presence of a low-lying π^* orbital in phosphonite ligands. The $\delta_m - \delta_p$ and $\delta_m - \delta_o$ values for $[Fe(TPP)(PPh(OEt)_2)]^+$ are 6.34 and 4.64 ppm, respectively, while those for $[Fe(TPP)(PMe_3)_2]^+$ are 0.42 and 1.78 ppm, respectively, supporting the above-mentioned assignment of the ground state.

Latos-Grazynski, Marchon, and coworkers[89] have reported the ^{1}H NMR spectra of a series of low-spin iron(III) chiroporphyrins $[Fe(TMCP)L_2]^{\pm}$. Because of the presence of bulky chiral cyclopropyl groups at the *meso* positions, the complexes are projected to be highly ruffled. Thus, the bis-CN complex gives two pyrrole-H signals even at ambient temperature; one is due to the 2-, 3-, 12-, and 13-H and the other is due to the 7-, 8-, 17-, and 18-H. In the case of complexes carrying hindered axial ligands, such as 2-MeIm or 1,2-Me_2Im, two atropisomers, I and II, exist due to hindered rotation about the imidazole-*N* and iron(III) bond.[90–93] Each isomer gives four pyrrole-H signals and two cyclopropyl CH(1′) signals. In Table 3, the axial ligands are arranged in the descending order of the pyrrole-H chemical shifts, which exactly corresponds to the descending order of

Table 3. ^{1}H NMR chemical shifts (CD_2Cl_2, 293 K) of a series of $[Fe(TMCP)L_2]^{\pm}$.

Ligand (L)	Solvent		Pyrrole-H	Pyrrole-H(ave)	*Meso*-CH	*Meso*-CH(ave)

[a]The complex has two atropisomers, I and II, due to the slow rotation of axial ligands around the N–Fe bond. (Source: Ref. 89.)

the isopropyl-CH(1′) chemical shifts. Thus, it is clear that the electronic ground state changes from $(d_{xz}, d_{yz})^4(d_{xy})^1$ to $(d_{xy})^2(d_{xz}, d_{yz})^3$ as the axial ligand varies from CN^- (in CD_3OD) to HIm. The data in Table 3 indicate that the population of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ isomer increases (i) if the CD_2Cl_2 solvent is replaced by CD_3OD in the bis-CN complex and (ii) if a methyl group is introduced into the 2-position of the imidazole. These two aspects will be discussed in Section III.B.3.

The effect of axial ligands on the electronic ground states of low-spin iron(III) porphyrins is most explicitly seen in the *meso*-alkyl-substituted complexes, i.e. $[Fe(TRP)L_2]^{\pm}$.[52] Table 4 lists the ^{1}H and ^{13}C NMR chemical shifts (CD_2Cl_2, 223 K) of a series of $[Fe(T^nPrP)L_2]^{\pm}$, $[Fe(T^cPrP)L_2]^{\pm}$, and $[Fe(T^iPrP)L_2]^{\pm}$. The EPR g values taken in frozen CH_2Cl_2 solution at 4.2 K are also listed. The ligands are arranged in ascending order of the pyrrole-H chemical shifts except for 4-CNPy and ^{t}BuNC; the pyrrole-H signal of the 4-CNPy complex in each series appears slightly more downfield than that of the ^{t}BuNC complex. The ligand arrangement in Table 4 corresponds to the ascending order of the CH(α)-H and *meso*-C and the descending order of the CH(α)-C and C_α chemical shifts. The large downfield shift of the pyrrole-H and *meso*-C signals, which is observed when the axial ligand changes from HIm to ^{t}BuNC, indicates that the electronic ground state changes from nearly pure $(d_{xy})^2(d_{xz}, d_{yz})^3$ in the HIm complex to nearly pure $(d_{xz}, d_{yz})^4(d_{xy})^1$ in the ^{t}BuNC complex in $[Fe(T^nPrP)L_2]^{\pm}$ and $[Fe(T^cPrP)L_2]^{\pm}$.

The situation is a little different, however, in the case of $[Fe(T^iPrP)L_2]^{\pm}$. Even the pyrrole-H signal of the HIm complex is observed considerably downfield, at 0.11 ppm, as compared with the corresponding signals in $[Fe(T^nPrP)(HIm)_2]^+$ and $[Fe(T^cPrP)(HIm)_2]^+$; these are observed at –21.45, and –18.70 ppm, respectively. Similarly, the *meso*-C signal appears considerably downfield, at 331.6 ppm, in $[Fe(T^iPrP)(HIm)_2]^+$ as compared with 73.1 and 97.1 ppm in $[Fe(T^nPrP)(HIm)_2]^+$

[a]Measurement was difficult due to the low solubility. [b]Calculated from $g_x^2 + g_y^2 + g_z^2 = 16$. [c]The electronic ground state was determined at 4.2 K from the EPR spectra. The d_π and d_{xy} represent the $(d_{xy})^2(d_{xz}, d_{yz})^3$ and $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, respectively. [d]Signals were too broad to detect. [e]Data at 298 K. (Source: Refs. 52 and 82.)

and $[Fe(T^cPrP)(HIm)_2]^+$, respectively. The EPR spectrum of $[Fe(T^iPrP)(HIm)_2]^+$ taken at 4.2 K shows a broad signal at $g = 2.55$, which should be classified as axial-type.

These results strongly indicate that $[Fe(T^iPrP)(HIm)_2]^+$ is a unique example that adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state in spite of the coordination of HIm; all of the bis-HIm complexes reported previously adopt the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. The anomaly observed in $[Fe(T^iPrP)(HIm)_2]^+$ can be ascribed to the deformation of the porphyrin ring, which will be discussed in the next section. On the basis of the data listed in Tables 2–4, it is concluded that the population of the $(d_{xz}\ d_{yz})^4(d_{xy})^1$ type isomer increases as the axial ligand changes from HIm to ^{t}BuNC in the order given by Eq. 14:

$$\begin{aligned} &HIm < DMAP,\ 1\text{-}MeIm < 2\text{-}MeIm < 1,2\text{-}Me_2Im < CN^- \\ &< 3\text{-}MePy < Py < 3\text{-}CNPy,\ 4\text{-}CNPy < {}^t\text{BuNC}. \end{aligned} \tag{14}$$

2. *Electronic Effects of Peripheral Substituents*

In addition to the field strengths of axial ligands, the electronic ground state of low-spin iron(III) porphyrins can be influenced by the electronic effect of peripheral substituents. Table 5 lists the ^{1}H and ^{13}C NMR chemical shifts of a series of $[Fe(p\text{-}X\text{-}TPP)(CN)_2]^-$.[94] Figure 16a shows the Hammett plots for the *meso*-C isotropic shifts, where the isotropic shifts are determined in CD_2Cl_2 and CD_3OD solutions separately.[94] In both solvents, the Hammett plot yields a good straight line. While the isotropic shifts are positive, +18.7 to +85.2 ppm, in all the complexes examined in CD_3OD solution they are negative, −24.3 to −43.5 ppm, in CD_2Cl_2 solution. Furthermore, the slope of the line is −69.5 ppm in CD_3OD solution which is more than three times as much as that in CD_2Cl_2 solution. The positive isotropic shifts in CD_3OD solution indicate that the *meso*-C atoms have positive spin density, which in turn indicates that all the complexes given by $[Fe(T(p\text{-}X)PP)(CN)_2]^-$ adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state in CD_3OD solution regardless of the kind of *p*-substituents. The large negative slope observed in CD_3OD solution then indicates that the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state is stabilized as the electron-donating ability of the *p*-substituent increases. In contrast, the negative isotropic shifts together with the insensitive substituent effect suggest that all the complexes adopt the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state in CD_2Cl_2 solution. The isotropic shifts of the C_α signals obtained in CD_2Cl_2 and CD_3OD at 298 K are also plotted against the Hammett σ_p values, and they are shown in Figure 16b. Although the Hammett plots show good linearity in both CD_2Cl_2 and CD_3OD, the slopes are rather small, 7.5 (CD_2Cl_2) and 22.6 (CD_3OD) ppm, as compared with those of the *meso*-C Curie plots. Thus, the isotropic shifts of the C_α signals are less

Table 5. NMR chemical shifts of $[Fe(4\text{-}X\text{-}TPP)(CN)_2]^-$ determined in CD_2Cl_2 and CD_3OD solutions at 298 K: (a) ^1H NMR, (b)^{13}C NMR chemical shifts.

sensitive to the *p*-substituents than those of the *meso*-C signals. As the population of the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type isomer increases, the spin density at the *meso*-C decreases and that at the C_α increases. Thus, the positive and negative slopes in Hammett plots observed for the *meso*-C and pyrrole C_α signals, respectively, indicate that the electron-withdrawing substituents stabilize the $(d_{xy})^2(d_{xz}, d_{yz})^3$ state. The electronic ground state determined by the NMR spectra is supported by the EPR spectra taken in frozen CH_2Cl_2 solution at 4.2 K. These complexes commonly exhibit a strong signal at $g = 3.6$ in CH_2Cl_2 solution, while they commonly exhibit a strong signal at $g = 2.5$ in CH_3OH solution regardless of the kind of *p*-substituents. The results clearly indicate that these complexes adopt the $(d_{xy})^2(d_{xz}, d_{yz})^3$ and $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground states in frozen CH_2Cl_2 and CH_3OH solutions, respectively, at 4.2 K. It should be noted here that the EPR spectra are less sensitive to subtle changes in the electronic ground state as compared with the NMR spectra.

There is another good example showing that the electron-withdrawing *meso* substituents stabilize the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. Compare the spectroscopic data of $[Fe(TPP)(^tBuNC)_2]^+$ with those of $[Fe(F_{20}–TPP)(^tBuNC)_2]^+$.[82] The porphyrin ring in the latter complex should be electron-deficient because of the presence of a strong electron-withdrawing pentafluorophenyl (C_6F_5) group at each *meso* position. In accordance with the general tendency of bis-^{t}BuNC complexes, both $[Fe(TPP)(^tBuNC)_2]^+$ and $[Fe(F_{20}\text{-}TPP)(^tBuNC)_2]^+$ adopt the less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, as revealed by the axial type EPR spectra. However, the $g_\perp$ and $g_\parallel$ values are quite different; they are 2.18 and 1.93 in the former complex, and 2.31 and 1.86 in the latter. Similarly, the pyrrole-H signals of $[Fe(TPP)(^tBuNC)_2]^+$ and $[Fe(F_{20}\text{-}TPP)(^tBuNC)_2]^+$ appear at 11.7 and 5.48 ppm at 223 K, respectively. The results clearly indicate that the d_{xy} orbitals of both complexes are located above the d_π orbitals. However, the energy gaps between the d_{xy} and d_π orbitals are very different; they are calculated to be 9.16 and 5.55λ for $[Fe(TPP)(^tBuNC)_2]^+$ and $[Fe(F_{20}\text{-}TPP)(^tBuNC)_2]^+$, respectively, according to Eqs. 10 and 11.

The examples given above indicate that electron-donating groups at the *meso* positions stabilize the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state while electron-withdrawing groups stabilize the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. The electronic effects of the peripheral substituents are most explicitly observed in saddle-shaped $[Fe(OETArP)L_2]^\pm$ where Ar represents various substituted phenyl groups, such as 4-CH_3O, H, 4-CF_3, and 3,5-$(CF_3)_2$, and the axial ligand (L) is either HIm or ^{t}BuNC.[95] Tables 6 and 7 list the ^{1}H and ^{13}C NMR chemical shifts of these complexes taken in CD_2Cl_2 solution at 298 K together with those of the corresponding diamagnetic zinc complexes, Zn(OETArP).[95] In the ^{1}H NMR spectra of $[Fe(OETArP)(HIm)_2]^+$, most of the signals exhibit no drastic change depending on the *meso* phenyl substituents. In contrast, the ^{1}H and ^{13}C signals in $[Fe(OETArP)(^tBuNC)_2]^+$ exhibit considerable

Table 6. ^{1}H NMR chemical shifts of [Fe(OETArP)(HIm)$_2$]$^+$, [Fe(OETArP)(^{t}BuNC)$_2$]$^+$, and [Zn(OETArP)] taken in CD_2Cl_2 solutions at 298 K.

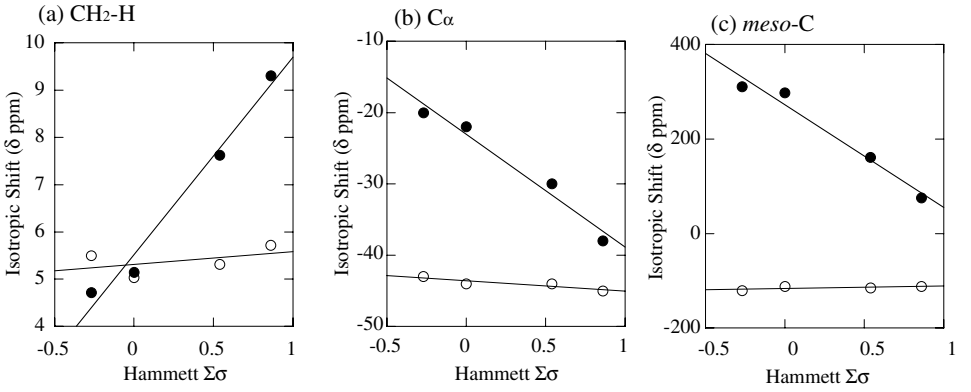

Figure 17. Hammett plots of the ^{1}H and ^{13}C NMR isotropic shifts of $[Fe(OETArP)(HIm)_2]^+$ (○) and $[Fe(OETArP)(^tBuNC)_2]^+$ (●). (a) CH_2-H, (b) C_α, and (c) *meso*-C. (Adapted with permission from Ref. 95. Copyright 2007, American Chemical Society.)

substituent dependence. Figure 17 shows the Hammett plots of some ^{1}H and ^{13}C signals of $[Fe(OETArP)(HIm)_2]^+$ and $[Fe(OETArP)(^tBuNC)_2]^+$.[95] For each signal, the substituent effect on the chemical shifts is considerably larger in $[Fe(OETArP)(^tBuNC)_2]^+$ than in $[Fe(OETArP)(HIm)_2]^+$ The isotropic shift of the CH_2–H signal of $[Fe(OETArP)(^tBuNC)_2]^+$ increases from +4.72 to +9.31 ppm with increase in the Hammett σ value, as shown in Figure 17a.

Correspondingly, the isotropic shift of the C_α signal decreases from −20 to −38 ppm, as shown in Figure 17b. The isotropic shift of the *meso*-C signal exhibits the largest change; it decreases from 311 to 76 ppm, as shown in Figure 17c. Thus, the Hammett plot for the *meso*-C signal shows a large negative slope, −220 ppm, in $[Fe(OETArP)(^tBuNC)_2]^+$ as compared with +5.4 ppm in $[Fe(OETArP)(HIm)_2]^+$. The results suggest that the spin density of the C_β gradually increases while that of the *meso*-C drastically decreases with increase in the Hammett σ value, which in turn indicates that the electronic ground state in $[Fe(OETArP)(^tBuNC)_2]^+$ gradually changes from $(d_{xz}, d_{yz})^4(d_{xy})^1$ to $(d_{xy})^2(d_{xz}, d_{yz})^3$. The change in the electronic ground state is further confirmed by the EPR spectra shown in Figure 18. As expected, $[Fe(OETArP)(HIm)_2]^+$ exhibits either rhombic or large g_{max} type spectra typical of the low-spin $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes. In the case of $[Fe(OETArP)(^tBuNC)_2]^+$, all the complexes except the 3,5-$(CF_3)_2$ complex show axial type spectra characteristic of low-spin complexes with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Only the 3,5-$(CF_3)_2$ complex exhibits a rhombic type spectrum, which unambiguously indicates that this complex adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state in spite of the coordination of ^{t}BuNC. Thus, it is clear on the basis of the NMR and EPR data that the electronic ground state of $[Fe(OETArP)(^tBuNC)_2]^+$ gradually changes

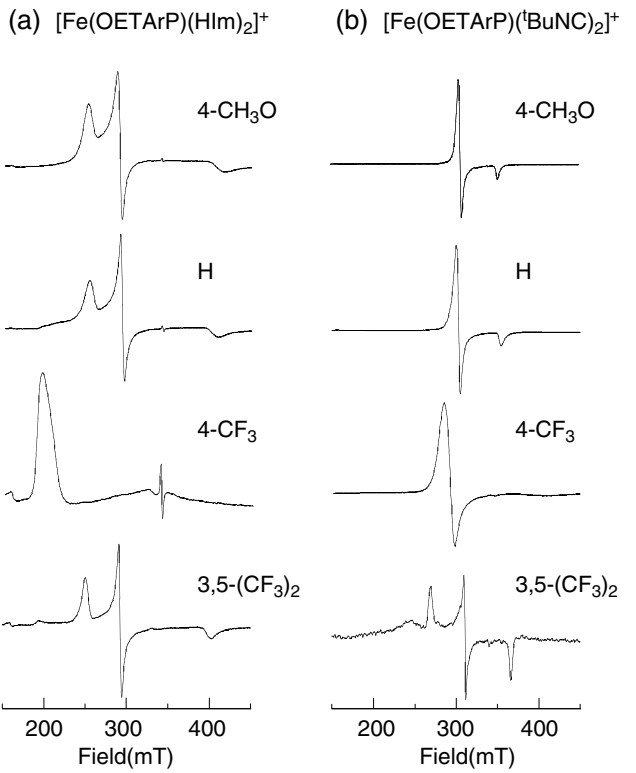

Figure 18. EPR spectra of a series of $[Fe(OETArP)(HIm)_2]^+$ and $[Fe(OETArP)(^tBuNC)_2]^+$ taken in CH_2Cl_2 solutions at 4.2 K. (Adapted with permission from Ref. 95. Copyright 2007, American Chemical Society.)

from nearly pure $(d_{xz}, d_{yz})^4(d_{xy})^1$ to nearly pure $(d_{xy})^2(d_{xz}, d_{yz})^3$ as the *meso*-aryl substituent changes from 4-CH_3O to 3,5-$(CF_3)_2$. Figure 19 shows the relative energy levels of the d_{xy}, d_{yz}, and d_{xz} orbitals of a series of $[Fe(OETArP)(^tBuNC)_2]^+$ obtained on the basis of the EPR *g* values in frozen CH_2Cl_2 solution at 4.2–20 K according to Eqs. 10 and 11. In the figure, the average value of the energy levels of the three d orbitals is fixed at a constant value. The 3,5-$(CF_3)_2$ complex is the first example of a low-spin iron(III) porphyrin that shows the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state in spite of the coordination of ^{t}BuNC.

Electronic effects of peripheral substituents on the electronic ground state can be explained as follows: electron-donating *meso* substituents should destabilize the porphyrin π orbitals, especially the a_{2u} orbital, because this orbital has large coefficients at the *meso* positions. As a result, the interaction between the d_{xy} and a_{2u} orbitals is strengthened since the energy gap separating these two orbitals decreases as shown in Figure 20a, which in turn lifts the d_{xy} orbital above the d_π

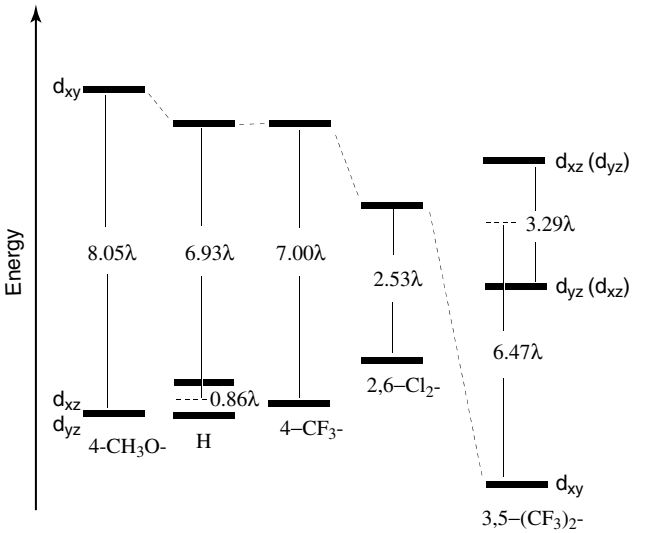

Figure 19. Relative energy levels of the d_{xy}, d_{yz}, and d_{xz} orbitals of a series of [Fe(OETArP)(^{t}BuNC)$_2$]$^+$. (Adapted with permission from Ref. 95. Copyright 2007, American Chemical Society.)

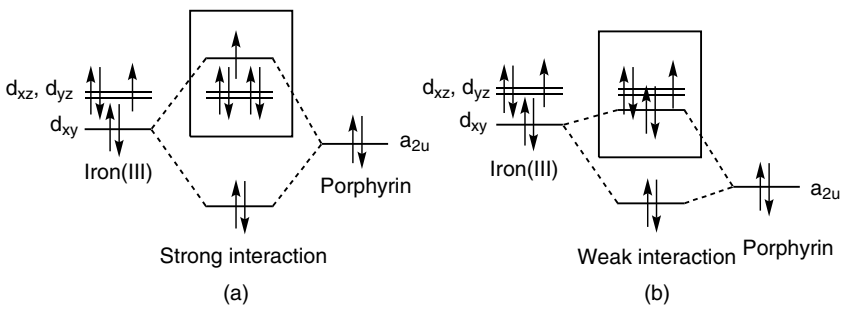

Figure 20. Schematic presentation of the change in energy levels in iron 3d orbitals by the introduction of substituents on the *meso* phenyl ring: (a) electron-donating substituents, (b) electron-withdrawing substituents. (Adapted with permission from Ref. 94. Copyright 2002, Elsevier Science.)

orbitals.[94] In contrast, electron-withdrawing *meso* substituents stabilize the a_{2u} orbital, and weaken the a_{2u}–d_{xy} interaction, as shown in Figure 20b. Consequently, the energy level of the d_{xy} orbital is lowered and thus the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state is stabilized.

It should be noted here that the low-spin complex with the purest ever reported $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state is not the bis-^{t}BuNC complex, but the bis-Py complex with strongly electron-withdrawing heptafluoropropyl (C_3F_7) groups at the *meso* positions, $[Fe(T(C_3F_7)P)(Py)_2]^+$.[96] This complex shows $g_\perp$ and $g_\parallel$ signals at 2.07

and 1.99, respectively. The energy gap (Δ) between the d_{xy} and d_π orbitals reaches as much as -26.4λ, which is much larger than that of $[Fe(T^iPrP)(^tBuNC)_2]^+$ ($g_\perp$ = 2.16, $g_\parallel$ = 1.96; $\Delta/\lambda = -11.3$). At present, it is difficult to explain why this complex adopts the purest $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state despite the presence of strongly electron-withdrawing C_3F_7 groups at the *meso* positions. The highly ruffled structure expected for this complex could strengthen the d_{xy}–a_{2u} interaction and lift the d_{xy} orbital. In addition, the low-lying $4e_g$* orbitals of $T(C_3F_7)P$ could lower the iron d_π orbitals by the d_π–$4e_g$* interactions to stabilize the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Anyway, because of the presence of a highly ruffled structure together with strongly electron-withdrawing *meso* substituents, $[Fe(T(C_3F_7)P)(Py)_2]^+$ should be an interesting complex for further electronic structure investigations. Unfortunately, however, this complex seems to be so unstable that the only spectroscopic data reported are from the EPR spectrum at 4.2 K.

3. *Deformation of the Porphyrin Ring*

Porphyrins are intrinsically planar 18π aromatic macrocycles. However, because the porphyrin ring is not a rigid macrocycle, it can be easily deformed in order to relieve the steric repulsion that occurs between a peripheral substituents and/or between a peripheral substituent and an axial ligand.[44–51] Deformation of the porphyrin ring affects the energy levels of the 3d orbitals of the iron, and in some cases changes the electronic ground state.[52,89,97–101] This is because the ring deformation always shortens the Fe–N bond to destabilize the $d_{x^2-y^2}$ orbital. Even the energy level of the t_{2g} orbitals should be affected by deformation of the porphyrin ring. Although the porphyrin a_{1u} and a_{2u} orbitals are orthogonal to any of the iron 3d orbitals in a planar D_{4h} complex, they can interact with the iron d_{xy} and $d_{x^2-y^2}$ orbitals if the porphyrin ring deforms, as shown in Table 1.[42,43] It has already been described in detail that the porphyrin a_{2u} orbital can interact with the iron d_{xy} orbital if the normally planar complex deforms in a D_{2d} ruffled fashion. It is also well known that the a_{2u} orbital can interact with the $d_{x^2-y^2}$ orbital if the complex deforms in a D_{2d} saddled fashion.[102,103] Similarly, the interaction between a_{1u} and $d_{x^2-y^2}$ orbitals is symmetry-allowed in a ruffled D_{2d} complex, and the interaction between a_{1u} and d_{xy} is symmetry-allowed in a saddled D_{2d} complex, as listed in Table 1.[38,42,43,104]

a. *Ruffled deformation*

Extensive structural and theoretical studies have revealed that the introduction of bulky substituents at the *meso* positions induces the highly ruffled deformation of the porphyrin ring.[105–108] In contrast, the introduction of aryl groups at the *meso*

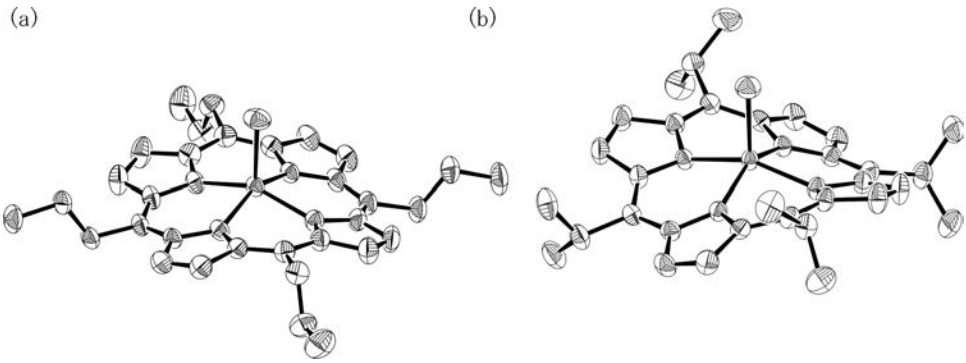

Figure 21. Molecular structure of (a) Fe(T^{n}PrP)Cl and (b) Fe(T^{i}PrP)Cl. (Adapted with permission from (a) Ref. 110, copyright 1999 American Chemical Society, and (b) Ref. 111, copyright 1999 International Union of Crystallography.)

positions does not usually affect porphyrin planarity because of the less bulky nature of the pseudoperpendicular phenyl group as compared with the alkyl group; note that the half-thickness of the benzene ring is 1.85 Å while that of a methyl group is 2.0 Å.[109] As the bulkiness of the *meso*-alkyl group increases, the ruffling of the porphyrin ring increases correspondingly.[105] Figure 21 shows the molecular structures of Fe(T^{n}PrP)Cl and Fe(T^{i}PrP)Cl.[110,111] Obviously, the porphyrin ring of the latter complex is ruffled to a greater extent. Thus, examination of the electronic structure of $[Fe(TRP)(CN)_2]^-$, where R is H, Me, Et, and ^{i}Pr, should reveal the relationship between porphyrin deformation and the electronic structure. Figure 22 shows the ^{1}H NMR spectra of a series of $[Fe(TRP)(CN)_2]^-$ taken in CD_2Cl_2 solution at 298 K.[97] As the *meso*-R changes from H to Me, Et, and then to the ^{i}Pr group, the pyrrole-H signal moves from −17.2 to −1.5, −2.0, and then to +10.0 ppm, suggesting clearly that the electronic ground state changes from $(d_{xy})^2(d_{xz}, d_{yz})^3$ to $(d_{xz}, d_{yz})^4(d_{xy})^1$. The results can best be explained in terms of destabilization of the d_{xy} orbital due to the d_{xy}–a_{2u} interaction, which is strengthened as the ruffling of the porphyrin ring increases on going from the R=H to the R=^{i}Pr complex.

In Table 8 are collected all the spectroscopic data of these complexes, including the ^{1}H NMR chemical shifts, the ^{13}C NMR chemical shifts of the coordinating CN^- ligand, and the EPR *g* values. The crystal field parameters obtained from the EPR *g* values are also listed.[97] Among these data, the chemical shifts of the coordinating CN^- ligand need to be explained. The chemical shift of the cyanide ligand moves downfield on going from the H to Me, Et, and then to the ^{i}Pr complex. Thus, the chemical shifts should reflect the electronic ground state of the complex. Various ferric porphyrin complexes with bis-CN coordination have been examined by ^{13}C NMR.[112–116] Their chemical shifts are in the range of −2000 to −2400 ppm.

In the case of the complexes carrying both cyanide and imidazole ligands, the iron-bound cyanide signal is observed far more upfield: −3500 to −4300 ppm.

Figure 23 shows the correlation of the chemical shifts between the pyrrole-H and CN carbon signals in $[Fe(TRP)(CN)_2]^-$.[97] A fairly good correlation suggests that the change in chemical shifts of the CN carbon signal has the same origin as that of the pyrrole-H signal. In other words, the chemical shifts of the coordinating cyanide are controlled by the electronic ground state of the low-spin iron(III) ion. Cheng and coworkers have carried out DFT calculations for planar $[Fe(TPP)(CN)_2]^-$ and ruffled $[Fe(T^iPrP)(CN)_2]^-$.[117] Figure 24 shows the molecular orbitals involving d_{xy} and d_π obtained by the spin-restricted ADF calculations. In the case of the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type low-spin complexes, the unpaired electron in the d_π orbital should interact with the CN π orbitals to induce positive spin density at the CN carbon atom, as shown in Figure 24b. Consequently, the CN carbon signal is expected to appear at a downfield position. Actually, however, the CN signals in the six-coordinate bis-CN and mixed cyanide–imidazole complexes are observed at extremely upfield positions, i.e. −2000 to −4300 ppm. The upfield shift is ascribed to indirect spin polarization via σ bonding interaction between d_{z^2} and the CN^- lone pair. Thus, the axial CN^- donates more positive spin density to

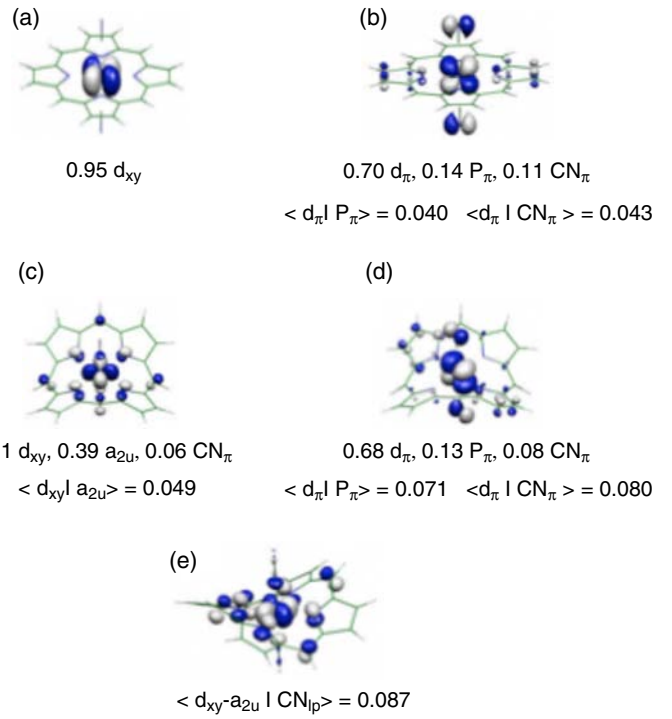

Figure 24. Molecular orbitals based on spin-restricted calculations depict the bonding characteristics of d_{xy} and d_{xz}, d_{yz} for $[FeP(CN)_2]^-$ complexes with planar [(a), (b)] and ruffled [(c), (d)] macrocycle conformation. Bonding interaction between d_{xy} and cyanide lone pairs is depicted in (e), a perspective view of (c). The corresponding major orbital contributions and the effective orbital overlap in space are also shown under each molecular orbital. (Reprinted with permission from Ref. 104. Copyright 2009, Royal Society of Chemistry.)

the vacant d_{z^2} orbital, which results in negative spin density at the CN^- carbon atom. The large upfield shift of the CN^- carbon signals indicates that the spin polarization mechanism predominates over the spin delocalization mechanism.

In the case of the low-spin $(d_{xz}, d_{yz})^4(d_{xy})^1$ type complexes, the CN^- π orbital is orthogonal to the half-occupied iron d_{xy} orbital. Consequently, the negative spin on the CN^- carbon should be much larger in the $(d_{xz}, d_{yz})^4(d_{xy})$ type complexes and induces a much larger upfield shift of the CN^- carbon signal in these complexes. This expectation is, however, against the experimental facts. Thus, there should be some direct spin delocalization mechanism between the half-occupied iron d_{xy} orbital and the axial cyanide. Cheng and coworkers have found that there is an unexpected bonding interaction between iron d_{xy} and cyanide lone pair in ruffled $[Fe(Por)(CN^-)_2]^-$, as shown in Figure 24e.[117] Because of this bonding interaction specific to the ruffled complexes, the spin density of the CN^- carbon in

$[Fe(T^iPrP)(CN^-)_2]^-$ becomes much less negative than for all the other low-spin complexes.

There are several more examples suggesting that the ruffled deformation stabilizes the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Table 9 lists the slopes of the Curie plots of pyrrole-H signals in a series of $[Fe(R_3\text{-TPP})L_2]^+$, where R are H, Me, Et, and ^{i}Pr groups and L are various imidazole ligands.[119] From the data in the table, it is possible to extract the general tendency that the slope increases when both of the following two conditions are satisfied: (i) the *meso*-phenyl group has substituents at the *ortho* positions and (ii) the imidazole ligand has an alky substituent at position 2 of the ring.

Low-spin complexes that satisfy these two conditions should have a ruffled porphyrin ring because of the steric repulsion between the bulky axial ligand and the *ortho* alkyl substituents of the porphyrin. In fact, the X-ray molecular structure of $[Fe(TMP)(1,2\text{-}Me_2Im)_2]^+$ is highly ruffled, in contrast to that of $[Fe(TMP)(1\text{-}MeIm)_2]^+$, as shown in Figure 25.[118,120] The highly ruffled conformation creates mutually perpendicular clefts along the C_{meso}–Fe–C_{meso} axes above and below the porphyrin ring. The planar axial ligands coordinate to the iron(III) along these clefts to minimize their steric repulsion with the porphyrin core. Consequently, the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state is stabilized due to the d_{xy}–a_{2u} interaction which is specific to the ruffled deformation. Similar examples can be seen in *meso*-alkyl-substituted complexes such as $[Fe(TCHP)L_2]^+$ and $[Fe(TMCP)L_2]^+$.[89,121] The pyrrole-H signals of these complexes move downfield by 3.6 (298 K) and 5.7 (223 K) ppm, respectively, as the axial 1-MeIm ligand is replaced by 1,2-Me_2Im. Similarly, the pyrrole-H signal of $[Fe(T^nPrP)(2\text{-}MeIm)_2]^+$ appears more downfield by 13.3 ppm than the corresponding signal of $[Fe(T^nPrP)(HIm)_2]^+$. $[Fe(TMP)(2\text{-}MeBzIm)_2]^+$ is a special case.[122] This complex exhibits the pyrrole-H signal *ca.* 2 ppm

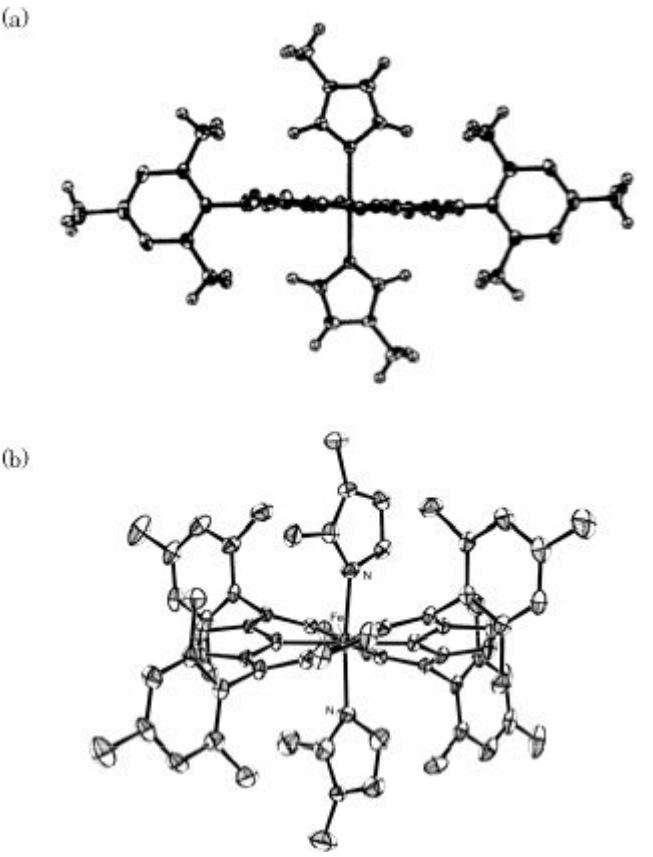

Figure 25. ORTEP diagrams of (a) $[Fe(TMP)(1\text{-}MeIm)_2]^+$ and (b) $[Fe(TMP)(1,2\text{-}Me_2Im)_2]^+$. The thermal ellipsoids enclose 30% probability. Hydrogen atoms are omitted for clarity. at 206 K and the *meso*-C signal at 321 ppm at 221 K. The EPR spectrum exhibits a single band at $g = 2.6$. All these data strongly indicate that the complex adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state because of the highly ruffled structure expected for this complex.[122] On the basis of the data in Tables 3, 4 and 9, it is reasonable to conclude that *the ruffling of the porphyrin ring stabilizes the* $(d_{xz}, d_{yz})^4(d_{xy})^1$ *ground state* if other conditions such as basicity and number of the axial ligands and the electronic effect of peripheral substituents are similar.

b. *Saddled deformation*

Next, the effect of another typical mode of porphyrin deformation, the saddled deformation, on the electronic ground state of the low-spin iron(III) porphyrins is

considered. As mentioned above, low-spin iron(III) complexes with the axial ligands having low-lying π^* orbitals, such as ^{t}BuNC, almost always adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. However, the energy gap between the d_{xy} and d_π orbitals shown as Δ in Figure 12 should be different among bis-^{t}BuNC complexes. Therefore, the effect of the saddled deformation can be evaluated by comparison of the Δ values in a wide variety of $[Fe(Por)(^tBuNC)_2]^+$ complexes. Table 10 lists the EPR *g* values of these complexes taken in frozen CH_2Cl_2 solution at 4.2 K together with the crystal field parameters, Δ and *V*.[82,95] As the data in Table 10 show, the $|\Delta|$ value increases in the order given by Eq. 15:

$$\text{ProtoIXMe}_2, \text{OEP} < \text{OETPP} < \text{TPP}, \text{OMTPP} < T^nPrP, T^cPrP, T^iPrP. \quad (15)$$

It is clear that the OETPP core prefers the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state as compared with the TPP core. However, it is difficult to generalize whether or not this order indicates that the saddled deformation of the porphyrin ring actually stabilizes the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. This is because OETPP has eight electron-donating ethyl groups at the C_β positions as compared with TPP, which should affect the electronic ground state of the low-spin iron(III) complexes. In fact, the substitution of alkyl groups at the pyrrole C_β atoms seems to stabilize the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state since the energy gaps between the d_{xy} and d_π orbitals in OEP and ProtoIXMe$_2$ complexes are much smaller than in OETPP. What is more puzzling is that the energy gap in the OMTPP complex is similar to that of TPP although

OMTPP is known to have a highly saddled structure as in the case of OETPP.[50] In fact, X-ray crystallographic analysis has revealed that $[Fe(OMTPP)(^tBuNC)_2]^+$ has a pure saddled structure.[123] It should be noted, however, that the only bis-^{t}BuNC complex that adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state is $[Fe(OETArP)(^tBuNC)_2]^+$, where aryl (Ar) is the electron-withdrawing 3,5-$(CF_3)_2$Ph group. In contrast, the TPP complex with the strongly electron-withdrawing pentafluorophenyl groups at the *meso* positions, $[Fe(F_{20}\text{-TPP})(^tBuNC)_2]^+$, still maintains the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Thus, it can be said with reservation that *the* $(d_{xy})^2(d_{xz},d_{yz})^3$ *ground state is stabilized to some extent if the porphyrin ring is saddled.*

All the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type complexes in which the molecular structures have been determined by X-ray crystallography exhibit the ruffled structure. However, $[Fe(OMTPP)(^tBuNC)_2]^+$ has a purely saddled porphyrin core in the solid state though it adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state.[123] Therefore, the ruffled geometry is not necessary for the existence of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. However, $[Fe(OMTPP)(^tBuNC)_2]^+$ shows the *meso*-C signal at an extremely downfield position in CD_2Cl_2 solution, i.e. 979 ppm at 223 K, which is quite close to that of $[Fe(TPP)(^tBuNC)_2]^+$, at 997 ppm.[82] The result clearly indicates that the *meso*-C atoms of $[Fe(OMTPP)(^tBuNC)_2]^+$ certainly have large amounts of spin density though the complex shows a purely saddled structure in the solid state. The large downfield shift of the *meso*-C signal could be an indication that the ring conformation in solution is different from that in the solid. There could be an effective spin delocalization mechanism from the $(d_{xz}, d_{yz})^4(d_{xy})^1$ iron(III) to the porphyrin ring even in purely saddled $[Fe(OMTPP)(^tBuNC)_2]^+$. Interestingly, both axial ligands in this complex are tilted in opposite directions.[123] Tilted axial ligand binding seems to be a common characteristic of the bis-^{t}BuNC complexes since the axial ligands in $[Fe(OEP)(^tBuNC)_2]^+$ and $[Fe(TPP)(^tBuNC)_2]^+$ are also tilted; they are tilted in the same direction in these complexes.[74] Obviously, both experimental and theoretical studies are necessary in order to reveal the spin delocalization mechanism in purely saddled $[Fe(OMTPP)(^tBuNC)_2]^+$.

4. *Solvent Effects*

In general, solvent can affect the electronic ground state because it can vary the field strengths of the axial ligands. An example is the *methanol effect* on the electronic ground state of bis-CN complexes. As shown in Tables 3, 5 and 8, addition of methanol greatly stabilizes the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. La Mar and coworkers pointed out many years ago that hydrogen bonding between the coordinated cyanide and solvent molecules decreases σ-donation and increases the π-accepting ability of the cyanide ligand, which lowers the d_{xz} and d_{yz} relative to the d_{xy} orbital, and hence the energy gap Δ shown in Figure 12.[124] Figure 26 shows the

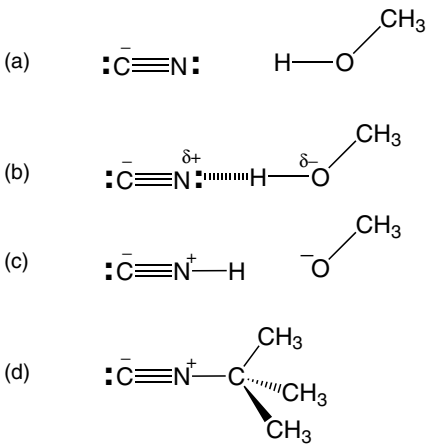

Figure 26. Relationship between cyanide and methanol: (a) no interaction, (b) hydrogen bonding, (c) limiting case of the hydrogen bonding where H^+ is completely transferred to the nitrogen atom, and (d) structural formula of *tert*-butylisocyanide. (Modified with permission from Ref. 84. Copyright 2002, American Chemical Society.)

interaction between cyanide and methanol.[84] The limiting structure of hydrogen bonding, where the proton is completely transferred to the nitrogen atom as given in Figure 26c, has a structural formula similar to ^{t}BuNC given in Figure 26d. Thus, hydrogen bonding should lower the π^* orbital of cyanide, which in turn stabilizes the iron d_π orbitals by d_π–p_{π^*} interactions to the points that are lower than the d_{xy} orbital. Consequently, the d_{xy} orbital has an unpaired electron to adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Bis-CN complexes are suitable for revealing the effect of solvent on the electronic ground state because the energy difference between the d_π and d_{xy} orbital is small. This means that the small perturbation to the coordinated cyanide could change the energy levels of the 3d orbitals of low-spin iron(III) complexes and alter their physicochemical properties. Table 11 lists the ^{13}C NMR chemical shifts of $[Fe(Et_3\text{-TPP})(CN^-)_2]^-$ obtained in various solvents at 253 K, which clearly indicate that the downfield shift of the *meso*-C signal increases in the order given in Eq. 16.[84]

$$\begin{aligned} CCl_4 < C_6D_6,\ C_6D_5CD_3,\ CD_3CN < (CD_3)_2CO,\ &\text{DMSO-}d_6,\ \text{DMF-}d_7 \\ < CD_2Cl_2 < CDCl_3 < CD_3OD. \end{aligned} \tag{16}$$

Examination of the data in Table 11 reveals the following relationships between the *meso*-C chemical shifts at 253 K and solvents: (i) the *meso*-C signal appears fairly downfield, δ = 275 ppm, in a protic solvent such as methanol; (ii) large differences in chemical shifts are observed even among nonpolar

Table 11. ^{13}C NMR chemical shifts of $[Fe(Et_3\text{-}TPP)(CN)_2]^-Bu_4N^+$ determined in various solvents at 253 K.

Solvent	Meso	C_α	C_β	Ipso	o	m	p

CCl_4	79.6	25.6	82.2	119.1	158.2	122.6	140.8

[a]The values are extrapolated from high temperature. (Source: Ref. 84.)

solvents; for example, the chemical shifts in $CDCl_3$ and CD_2Cl_2 are $\delta = 191$ and 172 ppm, respectively, as compared with δ = 80–100 ppm in toluene-d_8 ($C_6D_5CD_3$), benzene-d_6 (C_6D_6), and CCl_4; (iii) the *meso*-C signals appear in a quite narrow range, $\delta = 129 \pm 6$ ppm, in dipolar aprotic solvents, such as DMF-d_7, DMSO-d_6, and acetone-d_6, which are located between those for the two types of nonpolar solvents mentioned above; (iv) the *meso* signal in acetonitrile-d_3 (CD_3CN) appears rather close to that in $C_6D_5CD_3$ or C_6D_6, *ca.* 100 ppm, though CD_3CN is classified as a dipolar aprotic solvent.

As mentioned in Eqs. 6′ and 6″, the isotropic shifts of the *meso*-C signals are positive (downfield shift) in the complexes with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state, while they are negative (upfield shift) in those with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. Figure 27 shows the Curie plots of the *meso*-C signal of $[Fe(Et_3\text{-}TPP)(CN)_2]^-$ taken in various solvents. The chemical shifts of diamagnetic $[Co(Et\text{-}TPP)(CN)_2]^-$ are almost constant, 115.5 ± 0.6 ppm, at 298 K in various solvents. Curie plots of the *meso*-C signal of $[Co(Et\text{-}TPP)(CN)_2]^-$ determined in CD_2Cl_2 solution are also given in Figure 27. This line separates the Curie plots of the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes from those of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type complexes. From the viewpoint of the *meso*-C Curie plots, the solvents can be classified into four types — type A — protic solvents such as CD_3OD; type B — nonpolar solvents such as $CDCl_3$ and CD_2Cl_2; type C — dipolar aprotic solvents such as DMF-d_7, DMSO-d_6, and acetone-d_6; Type D — nonpolar solvents such as toluene-d_8, benzene-d_6, and CCl_4. While the complex adopts the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state in the solvents classified as types A–C, it shows the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state in the solvents classified as type D. Figure 27 also indicates that the $(d_{xz}, d_{yz})^4(d_{xy})^1$ character is the largest in type A solvents, followed by types B and C. It should be noted that

acetonitrile-d_3(CD_3CN) is an exceptional case; the complex exhibits the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state in this solvent, though the solvent is classified as a type C solvent. Table 12 shows the ^{1}H NMR chemical shifts taken in various solvents at 298 K and 253 K. As mentioned, the chemical shifts of the pyrrole-H and *meta*-H

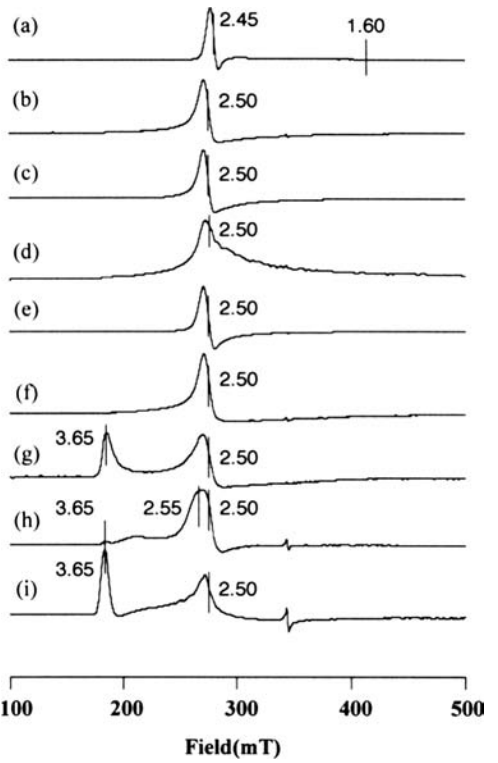

Figure 28. EPR spectra of $[Fe(Et_3\text{-}TPP)(CN)_2]^-Bu_4N^+$ taken in frozen solutions at 4.2 K: (a) CD_3OD, (b) $CDCl_3$, (c) CD_2Cl_2, (d) DMF-d_7, (e) DMSO-d_6, (f) $(CD_3)_2CO$, (g) CD_3CN, (h) $C_6D_5CD_3$, and (i) C_6D_6. (Reprinted with permission from Ref. 84. Copyright 2002, American Chemical Society.)

signals are good probes of the electronic ground state. The order of the chemical shifts of these signals is the same as is given in Eq. 15. Thus, the data listed in Table 12 are totally consistent with those obtained using ^{13}C-NMR spectroscopy.

Figure 28 shows the EPR spectra of complexes taken in various frozen solvents at 4.2 K.[84] While the complex shows only the axial type signals centered at $g = 2.5$ in types A–C solvents, it exhibits both the axial type ($g = 2.5$) and large g_{max} type ($g = 3.7$) signals in type D solvents, indicating that two kinds of electron configurational isomers are present in the frozen solutions. Thus, the EPR results are totally consistent with the NMR results. Again, acetonitrile behaves like type D solvent, though it is classified as type C.

Type A solvents such as methanol are good proton donors in hydrogen bonding with coordinating cyanide, which lowers the π^* orbital of cyanide and stabilizes the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. The effect of hydrogen bonding is more explicitly observed when much stronger proton donors are added, as shown in

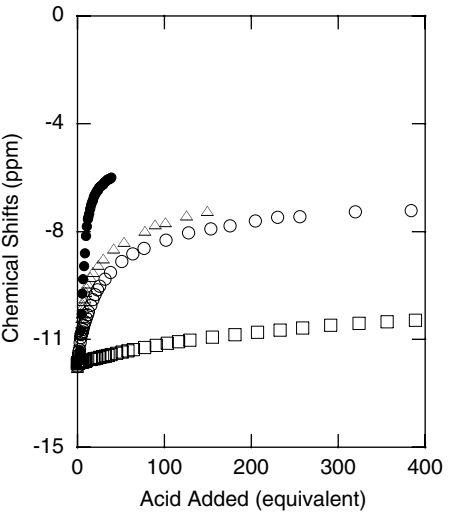

Figure 29. Change in the ^{1}H NMR pyrrole-H shift against the acid added. Each acid was added to a solution containing $[Fe(Et_3\text{-TPP})(CN)_2]^-Bu_4N^+$ and CN^- in 1:2 molar ratios at 298 K: CH_3COOH (●), C_6H_5OH (Δ), CD_3OD (○), and $CDCl_3$ (□). (Adapted with permission from Ref. 84. Copyright 2002, American Chemical Society.)

Figure 29.[84] The downfield shift of the pyrrole-H signal increases as the acidity of the solvents increases, as shown in the following order: $CD_3OD < C_6H_5OH < CH_3COOH$.

As for the type B solvents such as chloroform, they are known to be much stronger proton donors than other compounds having C–H bonds on the basis of C–H···X distances in the crystal.[125–127] Formation of C–H···X hydrogen bonding is also reported for dichloromethane in the crystal.[128] The presence of C–H···X hydrogen bonding has been reported even in solution between chloroform and pyridine or between chloroform and DMSO.[129] Thus, it must be a reasonable assumption to ascribe the stabilization of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state in $CDCl_3$ and CD_2Cl_2 to the weak C–D···N hydrogen bonding between the coordinated cyanide and solvent molecules.[130]

In type C solvents such as DMF and DMSO, the chemical shifts of the *meso*-C and pyrrole-H signals are located between those obtained in the two types of nonpolar solvents, types B and D. On the basis of the NMR results, it is concluded that the energy gap between the d_{xy} and d_π orbitals in type C solvents is less than that in type B solvents, which should be ascribed to the difference in proton donor ability among these solvents. The proton donor ability is estimated by the C–H···X bond distances in the crystal, where X = N, O, or Cl. In fact, X-ray crystallographic studies have revealed that the C–H···X bond distances of acetonitrile,

DMSO, and acetone are longer than those of $CHCl_3$ and CH_2Cl_2, supporting the hypothesis mentioned above.[128] Among the type C solvents examined in this study, CD_3CN differs from the others and resembles the type D solvents. In fact, the chemical shifts of the *meso*-C signals are 96.5 and 99.0 ppm in CD_3CN and $C_6D_5CD_3$, respectively, at 233 K. Similarly, the EPR spectrum in frozen CH_3CN shows both axial and large g_{max} type signals, as in the case of C_6D_6 solutions. Thus, CD_3CN behaves like type D solvents, which could be ascribed to the weak proton donor ability.

C. Low-Spin Complexes with a Rare Electronic Ground State

In the previous sections, the factors that affect the electronic ground state of low-spin iron(III) porphyrins have been described in detail. In general, low-spin complexes carrying imidazole (HIm) as axial ligand adopt the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state while those carrying *tert*-butylisocyanide (^{t}BuNC) adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. In this section, we will describe the reverse cases: bis-HIm and bis-^{t}BuNC complexes that adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ and the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, respectively.[131] Preparation and characterization of such complexes should deepen our understanding of the electronic structures of iron(III) porphyrins as well as heme proteins.

1. *Bis-Imidazole Complexes that Adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ Ground State*

As mentioned in the previous section, low-spin complexes with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state exhibit axial type EPR spectra. However, EPR spectra reflect the electronic structure at the extremely low temperature where the measurement is carried out. For determination of the electronic structure at ambient temperature, ^1H and ^{13}C NMR spectroscopy serve a useful role. Chemical shift data listed in Tables 2–8 suggest that low-spin complexes adopting the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state at ambient temperature satisfy the following three conditions: (i) $\delta > 0$ ppm for the pyrrole-H signal, (ii) $\delta > 200$ ppm for the *meso*-C signal, and (iii) positive Curie slopes for these signals. As for the pyrrole-H chemical shifts, some complexes adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state even if the pyrrole-H signals appear more upfield, i.e. *ca.* −10 ppm, at ambient temperature. There are several bis-HIm complexes reported previously that satisfy the NMR criteria mentioned above. They are highly ruffled $[Fe(T^iPrP)(HIm)_2]^+$ and $[Fe(T^iPrP)(2\text{-}MeIm)_2]^+$.[52,132] At 298 K, the pyrrole-H and *meso*-C chemical shifts are 1.1 and 287 ppm, respectively, for $[Fe(T^iPrP)(HIm)_2]^+$ and 4.9 and 356 ppm, respectively, for $[Fe(T^iPrP)(2\text{-}MeIm)_2]^+$. Curie slopes are all positive for these signals. Thus, it is clear that both of these complexes adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state at ambient temperature

in spite of the coordination of imidazole ligands. The $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground states of these complexes are directly confirmed at 4.2 K by the EPR spectra, since they exhibit g_∞ signals at 2.55 and 2.58.[52,132] Other complexes such as $[Fe(T^cHxP)(HIm)_2]^+$ and $[Fe(T^cHxP)(1,2\text{-}Me_2Im)_2]^+$ also adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state at ambient temperature, since the pyrrole-H chemical shifts are 2.81 and 7.83 ppm, respectively, at 293 K.[121] Stabilization of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state of these complexes is ascribed to the highly ruffled structure of the porphyrin ring, which raises the energy level of the d_{xy} orbital by the a_{2u}–d_{xy} interaction to the point that is higher than the d_π orbitals. As shown in Eq. 12, low-spin complexes exist as an equilibrium mixture of two spin isomers. Thus, the chemical shifts of the pyrrole-H and *meso*-C signals are determined by Eq. 13. The pyrrole-H chemical shifts of 1.1 and 4.9 ppm observed in $[Fe(T^iPrP)(HIm)_2]^+$ and $[Fe(T^iPrP)(2\text{-}MeIm)_2]^+$, respectively, suggest that the population of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ isomer is not exclusively large. There is no doubt that $[Fe(T^tBuP)(HIm)_2]^+$ should give a much purer $(d_{xz}, d_{yz})^4(d_{xy})^1$ type low-spin complex, since the presence of bulky *tert*-butyl groups at the *meso* positions should ruffle the porphyrin ring to the greatest extent. Unfortunately, insertion of iron into $H_2(T^tBuP)$ to form for example $Fe(T^tBuP)Cl$ seems to be difficult, as up to now there has been no report describing the formation of this very interesting complex. Probably, the narrow N_4 cavity expected for this highly ruffled porphyrin ring hampers the iron insertion reaction. However, there are a couple of examples of T^tBuP complexes having paramagnetic metal ions, such as $[Cu(T^tBuP)]$ and $[Mn(T^tBuP)(OAc)]$, which exhibit quite interesting properties caused by the deformed structure.[108,133]

2. *A Bis*-Tert-*Butylisocyanide Complex Adopting the* $(d_{xy})^2(d_{xz}, d_{yz})^3$ *Ground State*

The first example of a bis-^{t}BuNC complex adopting the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state is the iron(III) diazaporphyrin, $[Fe(DAzP)(^tBuNC)_2]^+$.[134] This complex exhibits various unusual spectroscopic characteristics that have never been observed in other bis-^{t}BuNC complexes, such as $[Fe(OEP)(^tBuNC)_2]^+$. Table 13 lists the spectroscopic data of various bis-^{t}BuNC complexes, including $[Fe(DAzP)(^tBuNC)_2]^+$.[134] Figure 30 shows the Curie plots of the α-CH_2 and *meso*-H signals of $[Fe(DAzP)(^tBuNC)_2]^+$ and $[Fe(OEP)(^tBuNC)_2]^+$, which strongly indicate the difference in electronic structure of these complexes.[134] The major spectroscopic differences are as follows: (i) the α-CH_2 signals of $[Fe(DAzP)(^tBuNC)_2]^+$ and $[Fe(OEP)(^tBuNC)_2]^+$ are observed at δ = 17.8 and 7.6 ppm at 298 K, respectively, suggesting that $[Fe(DAzP)(^tBuNC)_2]^+$ has a sizable amount of spin density at the pyrrole C_β atoms; (ii) the *meso*-H signals of $[Fe(DAzP)(^tBuNC)_2]^+$ and $[Fe(OEP)(^tBuNC)_2]^+$ appear at δ = 19.2 and −37.7 ppm, respectively, indicating that the *meso*-C atom

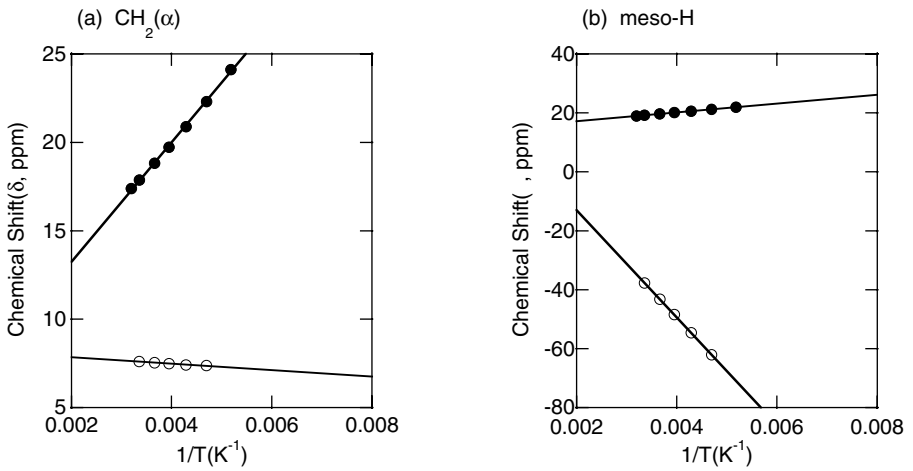

Figure 30. Curie plots of (a) $CH_2(\alpha)$ and (b) *meso*-H signals of $[Fe(DAzP)(^tBuNC)_2]^+$ (●) and $[Fe(OEP)(^tBuNC)_2]^+$ (○). (Adapted with permission from Ref. 134. Copyright 2006, Royal Society of Chemistry.)

of $[Fe(DAzP)(^tBuNC)_2]^+$ has a negative spin while that of $[Fe(OEP)(^tBuNC)_2]^+$ has a large positive spin; (iii) while the *meso*-C signal of $[Fe(DAzP)(^tBuNC)_2]^+$ appears upfield, at $\delta = 21$ ppm at 223 K, that of $[Fe(OEP)(^tBuNC)_2]^+$ appears significantly downfield, at $\delta = 491$ ppm; analysis of the isotropic shifts reveals that the spin densities at the *meso*-C atoms are –0.012 and +0.028 for $[Fe(DAzP)(^tBuNC)_2]^+$ and $[Fe(OEP)(^tBuNC)_2]^+$, respectively; (iv) the EPR spectrum of $[Fe(DAzP)(^tBuNC)_2]^+$ is rhombic while that of $[Fe(DAzP)(DMAP)_2]^+$ is axial. All these results strongly indicate that $[Fe(DAzP)(^tBuNC)_2]^+$ adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state despite the coordination of ^{t}BuNC.

The CN stretching frequency of the coordinating ^{t}BuNC in [Fe(DAzP)(^{t}BuNC)$_2$]$^+$ is 2213 cm^{-1}, which is higher by 13–20 cm^{-1} than the corresponding values for all the other bis-^{t}BuNC complexes as listed in Table 13. The higher frequency indicates stronger σ-bonding and/or weaker π-back-bonding in [Fe(DAzP)(^{t}BuNC)$_2$]$^+$ as compared with other bis-^{t}BuNC complexes.[135] A reasonable explanation is that because of the presence of two electronegative nitrogen atoms at the *meso* positions, the a_{2u}-like orbital in DAzP is stabilized as shown in Figure 20. As a result, the a_{2u}–d_{xy} interaction is weakened, which makes the iron(III) ion electron poor. Consequently, the σ-donation from ^{t}BuNC is strengthened and/or π-back-donation from iron(III) to the axial ligand is weakened, both of which contribute to the higher CN stretching frequency in [Fe(DAzP)(^{t}BuNC)$_2$]$^+$ compared with other bis-^{t}BuNC complexes.

Another interesting finding in Table 13 is the chemical shift of the *tert*-butyl signal. While [Fe(DAzP)(^{t}BuNC)$_2$]$^+$ exhibits its *tert*-butyl signal at 6.6 ppm at 223 K, all the other complexes exhibit the signal further upfield, −1 to −3 ppm. The large difference in chemical shifts can be explained in terms of the difference in dipolar shifts. In the case of coordinating *tert*-butyisocyanide, the major part of the methyl isotropic shift should come from the dipolar shift; the contribution of the contact shift should be negligibly small, since three σ-bonds separate the proton and nitrogen atoms. As shown in Eq. 2, the dipolar shift is given by $K_{dip}[(g_{\parallel}^2 - g_{\infty}^2)(3\cos^2\theta - 1)/r^3]/T$. Since the sign of $g_{\parallel}^2 - g_{\infty}^2$ is positive in the $(d_{xy})^2(d_{xz}, d_{yz})^3$ and negative in the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type low-spin complex, the *tert*-butyl signal should appear downfield and the Curie slope should be positive if the complex adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state; note that the geometric factor $(3\cos^2\theta - 1)/r^3$ is positive for the *tert*-butyl protons. In contrast, the *tert*-butyl signal of the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type complex appears somewhat upfield and the Curie slope should be negative since $(g_{\parallel}^2 - g_{\infty}^2)(3\cos^2\theta - 1)/r^3$ is negative. Thus, the chemical shift and the Curie slope of the *tert*-butyl signal can be good probes for the electronic structure of bis-^{t}BuNC complexes.[134] Figure 31 shows the Curie plots of the methyl signals in 11 kinds of bis-^{t}BuNC complexes.[82,134] It is evident that the methyl signal appears somewhat downfield and the Curie slope is positive only in [Fe(DAzP)(^{t}BuNC)$_2$]$^+$, which clearly indicate that the complex adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state despite the coordination of ^{t}BuNC.

It is interesting to elucidate the electronic structure of the corresponding monoazaporphyrin complex, [Fe(MAzP)(^{t}BuNC)$_2$]$^+$. This complex shows an NMR spectrum similar to that of [Fe(DAzP)(^{t}BuNC)$_2$]$^+$; notably, downfield-shifted $CH_2(\alpha)$, *meso*-H, and *tert*-butyl methyl signals.[136] Furthermore, the EPR spectrum taken in frozen CH_2Cl_2 solution shows three signals at g = 2.84, 2.26, 1.58. These data clearly indicate that the complex adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. Thus, introduction of only one nitrogen atom into a *meso* position of

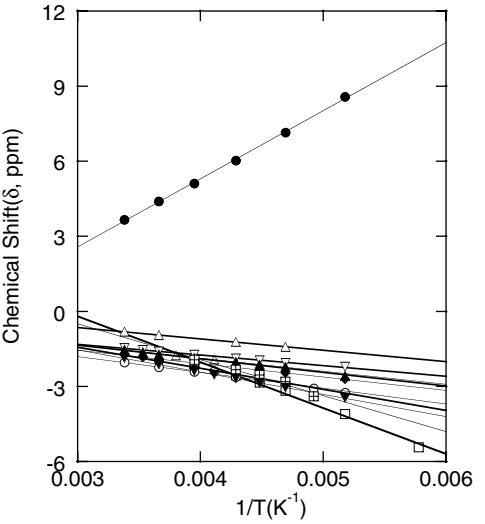

Figure 31. Curie plots of the methyl signals of coordinating ^{t}BuNC in various [Fe(Por)(^{t}BuNC)$_2$]$^+$ complexes. The methyl signal of [Fe(DAzP)(^{t}BuNC)$_2$]$^+$ is given by the symbol ●, the Curie plots of which clearly indicate the positive slope. Other porphyrins are OETPP, OMTPP, OEP, TMeP, TEtP, T^{n}PrP, T^{c}PrP, T^{i}PrP, ProtoIXMe$_2$, and TPP. The Curie plots of these complexes exhibit the negative slopes. (Adapted with permission from Ref. 134. Copyright 2006, Royal Society of Chemistry.)

[Fe(OEP)(^{t}BuNC)$_2$]$^+$ is sufficient to convert the electronic ground state from $(d_{xz}, d_{yz})^4(d_{xy})^1$ to $(d_{xy})^2(d_{xz}, d_{yz})^3$.

IV. Mixed High-Spin and Intermediate-Spin Complexes

A. General Considerations

Five-coordinate iron(III) porphyrin complexes, Fe(Por)X, with anionic axial ligands (X^-) such as chloride and methoxide, usually exhibit the high-spin (S = 5/2) state.[32–35,137–139] This is because the iron(III) ion deviates from the porphyrin plane in these complexes to stabilize the $d_{x^2-y^2}$ orbital. If axial chloride or acetate is replaced by a much weaker anionic ligand such as ClO_4,[140–147] $C(CN)_3$,[148,149] or SbF_6,[149] then the d_{z^2} orbital is stabilized and the $d_{x^2-y^2}$ orbital is destabilized.[32] The destabilization of the $d_{x^2-y^2}$ orbital is ascribed to contraction of the out-of-plane distance of iron.[32] As a result, these complexes are expected to adopt the intermediate-spin (S = 3/2) state. Actually, however, they exhibit not a pure S = 3/2 but a mixed S = 3/2, 5/2 spin state. The mixed S = 3/2, 5/2 spin state has been considered to be a quantum-mechanical admixture caused by spin–orbit coupling between the high-spin and intermediate-spin states, and not a thermal equilibrium

between two spin states.[147,150–153] However, some complexes have also been found that exhibit thermal equilibrium between the S = 3/2 and S = 5/2.[101,154–156] In this section, the spectroscopic properties of mixed S = 3/2 and S = 5/2 complexes will be described, together with the conditions for obtaining an essentially pure intermediate-spin complex.

B. Formation of Pure Intermediate-Spin Complexes

In general, formation of pure intermediate-spin complexes is quite difficult. In order to obtain this state, one has to expand the energy gap between the $d_{x^2-y^2}$ and d_{z^2} orbitals. Stabilization of the d_{z^2} orbital should be attained by coordination of the axial ligand with extremely weak field strength. Destabilization of the $d_{x^2-y^2}$ orbital is possible if an iron porphyrin with short Fe–N bonds is used.

1. *Axial Ligands with Extremely Weak Field Strength*

a. *Magnetochemical series*

^{1}H NMR spectroscopy is a good method for determining the contribution of the S = 3/2 in the mixed S = 3/2, 5/2 spin state.[20–31] This is because the pure high-spin complex exhibits its pyrrole-H signal fairly downfield due to the presence of an unpaired electron in the $d_{x^2-y^2}$ orbital; the unpaired electron in this orbital delocalizes to the pyrrole-H position through σ-bonds and induces a large downfield shift of the pyrrole-H signal. In contrast, the $d_{x^2-y^2}$ orbital is depopulated in the pure S = 3/2 complexes. As mentioned in Section II.B, the S = 1/2 complexes with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state exhibit pyrrole-H signals somewhat upfield due to the interaction between half-occupied d_π and fully occupied $3e_g$ orbitals. The pyrrole-H signals in the S = 3/2 complexes should appear even further upfield because they could have two unpaired electrons in both of the d_π orbitals. In fact, the chemical shift of the pyrrole-H signal in Fe(TPP)$[Ag(Br_6CB_{11}H_6)_2]$, which is considered to adopt an essentially pure intermediate-spin state, reaches –60 ppm.[36,156,157] If the chemical shifts of the pyrrole-H signals of the pure S = 5/2 and pure S = 3/2 complexes are determined to be δ_{high} and δ_{int}, respectively, then the contribution of the S = 3/2 spin state, signified as Int(%), in the analogous complex with the mixed S = 3/2, 5/2 spin state should be given by Eq. 17, where δ_x is the chemical shift of the pyrrole-H signal of the complex in question[80]:

$$\mathrm{Int}(\%) = \left[\frac{\delta_{\mathrm{high}} - \delta_x}{\delta_{\mathrm{high}} - \delta_{\mathrm{int}}} \right] \times 100. \tag{17}$$

It should be noted that Eq. 17 is valid if the chemical shift of the pyrrole-H signal is proportional to the contribution of the S = 3/2 state.

EPR spectroscopy is also a good method for determination of the spin state.[26,28–30,69] High-spin complexes exhibit a $g_\perp$ signal at 6.0, while the intermediate-spin complexes show the signal at 4.0. Depending on the contribution of the S = 3/2 in the mixed S = 5/2 and S = 3/2 complex, the $g_\perp$ value varies in the range between 4.0 and 6.0. Thus, the contribution of the intermediate-spin state, Int(%), is given by Eq. 18[69]:

$$\mathrm{Int}(\%) = \left[\frac{6.0 - g_\perp}{2}\right] \times 100. \tag{18}$$

On the basis of the pyrrole-H chemical shifts and EPR $g_\perp$ values, Reed and Guiset succeeded in ranking the weakness of anionic ligands (X) in five-coordinate Fe(TPP)X complexes, and denoted the hierarchy given in Eq. 19 as the *magnetochemical series*[36,157,158]:

$$\begin{aligned}[\mathrm{Ag(Br_6CB_{11}H_6)_2}]^- &< \mathrm{CB_{11}H_{12}^-} < \mathrm{SbF_6^-} < \mathrm{Co(C_2B_9H_{11})_2^-} < \mathrm{AsF_6^-} < \mathrm{ClO_4^-} \\ &< \mathrm{C(CN)_3^-} < \mathrm{CF_3SO_3^-} < \mathrm{BF_4^-} < \mathrm{ONC(CN)_2^-} < \mathrm{ReO_4^-} \\ &< \mathrm{OTeF_3^-} < \mathrm{I^-} < \mathrm{Br^-} < \mathrm{Cl^-}. \end{aligned} \tag{19}$$

The weakest anionic ligand is determined to be $[\mathrm{Ag(Br_6CB_{11}H_6)_2}]^-$, since the pyrrole-H signal is observed at the most upfield position, i.e. $\delta = -60$ ppm at 298 K. Moreover, Reed and coworkers have reported that $\mathrm{H(CHB_{11}Cl_{11})}$ is the strongest isolable acid presently known, which in turn indicates that $\mathrm{CHB_{11}Cl_{11}^-}$ is the weakest anionic ligand.[159] The magnetochemical series is also applicable to porphyrin isomers such as porphycene. The pyrrole signal of (TPrPc)FeX moves upfield as the axial ligand (X) changes from $\mathrm{PhO^-}$ to $\mathrm{Cl^-}$, $\mathrm{Br^-}$, $\mathrm{I^-}$, and then to $\mathrm{ClO_4^{-\bullet}}$, which corresponds to spin state change from S = 5/2 to S = 3/2.[160]

Six-coordinate iron(III) porphyrin complexes usually show the low-spin state. However, the complex can adopt a rare high-spin state if a neutral ligand has oxygen as the coordinating atom as exemplified by DMSO and DMF.[161–164] Fluoride is unique, because it can bind Fe(TPP)F to form $\mathrm{Fe(TPP)F_2^-}$.[165,166] These complexes commonly exhibit the pyrrole-H signals at extremely downfield positions, i.e. 70–90 ppm at 298 K. As in the case of five-coordinate complexes, the high-spin state is converted into the intermediate-spin state if the field strength of the oxygen ligand is weakened. Table 14 lists the ^{1}H and ^{13}C NMR chemical shifts as well as EPR g values for a series of $[\mathrm{Fe(TPP)L_2}]^+$, where L is an oxygen ligand.[167–169] The pyrrole-H signal moves upfield from 71 to 3 ppm as the axial ligand changes from 4-MePyNO to THF, demonstrating the increase in the S = 3/2 contribution.

Table 14. ^{1}H NMR, ^{13}C NMR, and EPR data of $[Fe(TPP)L_2]^+$.

	^{1}H NMR[a]				^{13}C NMR[a]			EPR[b]

THF	3.1	14.1	10.1	10.3	547	518	60	4.59		2.00
								6.03	5.48	2.00

[a]CD_2Cl_2, 298 K; [b] CH_2Cl_2, 4.2 K. (Source: Ref. 168.)

In Table 14, the axial ligands are arranged in descending order of the pyrrole-H chemical shifts, which therefore corresponds to the magnetochemical series for oxygen ligands given in Eq. 20:

$$\begin{aligned} &\text{THF} < \text{Et}_2\text{NNO} < \text{MeOH} < \text{DMF} < \text{DMSO} < \text{4-ClPyNO} \\ &\quad < \text{PyNO} < \text{3,5-Me}_2\text{PyNO, 4-MePyNO.} \end{aligned} \tag{20}$$

It should be noted that the C_α and C_β signals move upfield as the axial ligand changes from 4-MePyNO to THF. Similarly, the EPR $g_\perp$ value decreases in the same order. The order of the field strengths of some ligands, such as PyNO, substituted PyNOs, and DMSO, are difficult to determine from the data in Table 14 because of the similarity of the chemical shifts; the pyrrole-H and C_α signals are observed in a narrow range, 71.0–67.2 ppm and 1638–1538 ppm, respectively. The magnetochemical series of oxygen ligands given in Eq. 20 is determined on the basis of the pyrrole-H chemical shifts of both planar $[Fe(TPP)L_2]^+$ and ruffled $[Fe(T^iPrP)L_2]^+$, as will be described in detail in Section IV.B.2.a(ii). If the porphyrin is fixed in a series of $[Fe(Por)L_2]^+$, THF should be the best ligand for obtaining a six-coordinate complex where the contribution of the intermediate-spin state is the largest.[167–169]

b. *Four-coordinate iron(III) porphyrin cation*

As the field strength of the anionic axial ligand (X) is weakened in the magnetochemical series given in Eq. 18, the iron(III) ion in five-coordinate Fe(Por)X is brought to the center of the porphyrin ring. Consequently, the $d_{x^2-y^2}$ orbital is

greatly destabilized. In contrast, the Fe-X bond is elongated to stabilize the d_{z^2} orbital. The limiting case is the complex that has no axial ligand [i.e. four-coordinate iron(III) porphyrin cation]. Such a complex has been prepared recently by Suslick and coworkers.[170]

Treatment of Fe[2,6-(OSi^{i}Pr$_3$)$_2$-TPP]Cl with various silver salts AgY (Y = $CB_{11}H_6Br_6^-$, SbF_6^-, ClO_4^-, $CF_3SO_3^-$) yields a series of anion-exchanged complexes Fe[2,6-(OSi^{i}Pr$_3$)$_2$-TPP]Y, where the porphyrin has very bulky 2,6-bis(triisopropylsiloxy)phenyl groups at the *meso* positions. Surprisingly, CD_2Cl_2 solutions of these complexes exhibit pyrrole-H signals at exactly the same position, i.e. −81 ppm at 290 K. The anions examined in this study are very different within the magnetochemical series. In fact, the pyrrole-H chemical shifts of Fe(TPP)Y are −60, −31.5, −13, and 39.3 ppm for $CB_{11}H_6Br_6$, SbF_6, ClO_4, and CF_3SO_3, respectively. Thus, the anomalous result indicates that the complexes are four-coordinate iron(III), where iron(III) adopts the pure intermediate-spin state. In fact, the crystal structure of Fe[2,6-(OSi^{i}Pr$_3$)$_2$-TPP]($CB_{11}H_6Br_6$) confirms the absence of an axial ligand. The average Fe–N bond length is 1.94 ± 0.01 Å, with the iron situated in the porphyrin plane. Because of the bulky 2,6-bis(triisopropylsiloxy)phenyl groups at the *meso* positions, there are cavities above and below the porphyrin ring. The carborane anion ($CB_{11}H_6Br_6^-$) is located outside of the cavity. The solution magnetic moment determined by the Evans method is 4.1 μ_B in CH_2Cl_2 solution between 298 and 190 K, and the SQUID data show no change between 300 and 10 K. EPR spectra show a signal at $g_\perp = 4.2$ in both frozen solution and the crystalline state. The Mössbauer spectra obtained at 6 K show an IS value of 0.33 mm/s, which is typical of intermediate-spin complexes. But the complex shows a very large QS value which reaches 5.16 mm s^{-1}.[171–173] All these data clearly indicate that Fe[2,6-(OSi^{i}Pr$_3$)$_2$-TPP]($CB_{11}H_6Br_6$) is the first example of a four-coordinate iron(III) porphyrin that adopts an essentially pure intermediate-spin state.

As mentioned earlier, the pyrrole-H signal of this complex appears at −81 ppm, which is more upfield by 13–20 cm^{-1} than another essentially pure intermediate-spin Fe(TPP)($CB_{11}H_6Br_6$).[36,157,158] The results suggest that the pyrrole-H chemical shifts are different even among pure intermediate-spin complexes, probably because of the difference of the out-of-plane distance of the iron(III) ion from the N_4 plane. Thus, Eq. 16 should be carefully applied to five-coordinate complexes because the pyrrole-H chemical shifts are determined not only by the contribution of the intermediate-spin state but also by the out-of-plane distance of the iron(III) ion.

2. *Deformation of the Porphyrin Ring*

As mentioned earlier, the destabilization of the $d_{x^2-y^2}$ and stabilization of the d_{z^2} orbital are the necessary conditions for obtaining intermediate-spin complexes.

Since the deformation of the porphyrin ring usually contracts the Fe–N bond length,[32–35] it should raise the energy level of the $d_{x^2-y^2}$ orbital. Consequently, the electronic structure is perturbed by the ring deformation. Since the typical modes for deformation are ruffled and saddled, in this section it will be discussed how such deformation affects the spin state in the mixed S = 5/2 and S = 3/2 spin system.

a. *Ruffled deformation*

i. Five-coordinate complexes

Ruffling of the porphyrin ring affects the energy levels of the iron d orbitals. As mentioned in Sections II.A and II.B, the d_{xy} orbital can interact with the porphyrin a_{2u} orbital in the ruffled porphyrin framework. Consequently, the d_{xy} orbital is lifted in the energy diagram. The $d_{x^2-y^2}$ orbital is also lifted, due to the contraction of the equatorial Fe–N bonds, which is commonly observed in highly ruffled iron(III) porphyrin complexes.[35] Because of the destabilization of the $d_{x^2-y^2}$ orbital, the ruffled complexes tend to adopt the intermediate-spin state. Figure 32 shows the ^{1}H NMR spectra of a series of five-coordinate Fe(TEtPrP)X.[80] The upfield shift of the pyrrole-H signal is clearly seen as the axial ligand changes from Cl^- to I^-, and then to ClO_4^-. Table 15 lists the ^{1}H NMR chemical shifts of Fe(TEtPrP)X and the structurally analogous Fe(T^{i}PrP)X.[80] Figure 33 shows the Curie plots of the

pyrrole-H signals of Fe(TEtPrP)X and Fe(T^{i}PrP)X.[80] The Curie lines are drawn so that they intercept the ordinate axis at the chemical shifts of the corresponding diamagnetic complexes, *ca*. 9.5 ppm. In both Fe(TEtPrP)X and Fe(T^{i}PrP)X, the pyrrole-H signals of the F^- complexes appear in the most downfield position, δ = *ca*. 97 ppm at 298 K, and move further downfield linearly versus 1/*T*. The pyrrole-H signals of the Cl^- complexes show similar temperature dependence. These results suggest that the F^- and Cl^- complexes in both systems are in a pure high-spin state. By contrast, the pyrrole-H signals of the ClO_4^- complexes appear at the most upfield positions, −34 and −31 ppm, and move further upfield almost linearly versus 1/*T*. Thus, the ClO_4^- complexes are considered to be in an essentially pure intermediate-spin state. The pyrrole signals of the Br^- and I^- complexes appear between those of the F^- and ClO_4^- complexes, and their Curie lines exhibit considerable curvature. The results suggest that they are in the mixed S = 3/2 and S = 5/2 spin state and that the contribution of the S = 3/2 increases as the temperature is lowered. Thus, in the ruffled complexes, even the Br^- complexes exhibit considerable contribution of the S = 3/2 state. If we assume that the F^- and ClO_4^- complexes are in the pure S = 5/2 and S = 3/2 spin state, respectively, then the contribution of the S = 3/2, Int(%), can be estimated on the basis of the pyrrole-H chemical shifts by Eq. 17. As mentioned, the Int(%) value determined by Eq. 17 is an approximate value especially in the five-coordinate complexes because the

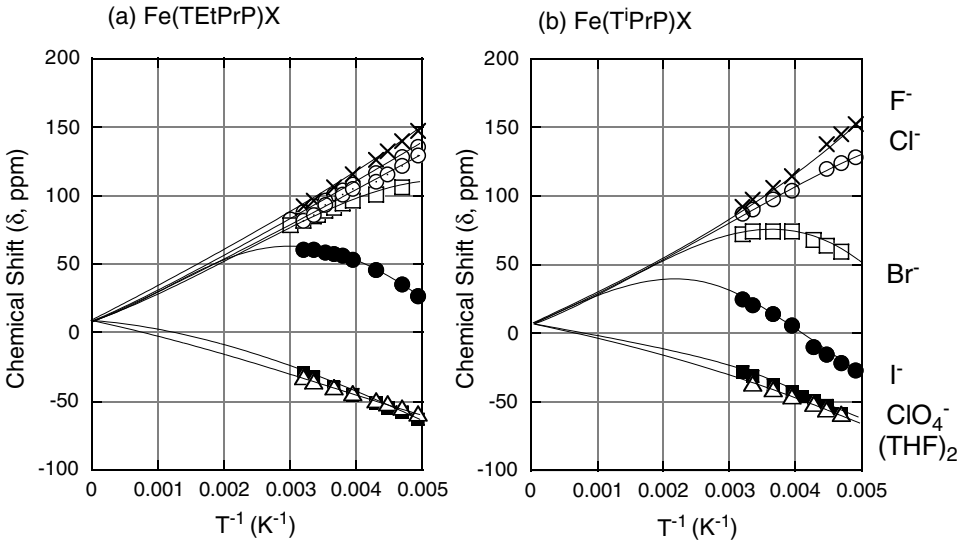

Figure 33. Curie plots of the pyrrole-H signals taken in CD_2Cl_2 solution: X = F (×), Cl (○), Br (□), I (•), ClO_4 (■), and $(THF)_2$ (Δ). Curie plots of [Fe (TEtPrP)I] determined in toluene-d_8 solution is given by ⊙. (Adapted with permission from Ref. 80. Copyright 2004, American Chemical Society.)

chemical shifts of the pyrrole-H signal in the pure high-spin or pure intermediate-spin complexes could change, depending on the out-of-plane distance of the iron(III) ion. The Int(%) values of [Fe(TEtPrP)X] and [Fe(TⁱPrP)X] listed in Table 15 indicate that they are very much dependent on the solvent used. While the Int(%) of [Fe(TEtPrP)I] is 28% at 298 K in CD_2Cl_2 solution, it is only 9% in toluene-d_8 solution at the same temperature.[80]

Figure 34 shows the EPR spectra of [Fe(TEtPrP)X] taken in frozen CH_2Cl_2 solution.[80] The EPR *g* values are listed in Table 15. Once these values are determined, it is possible to estimate the Int(%) values by using Eq. 18. The data in the table suggest that, while the F^-, Cl^-, and Br^- complexes are essentially in the high-spin state, I^- complexes such as [Fe(TEtPrP)I] and [Fe(TⁱPrP)I] are mainly in the intermediate-spin state with Int(%) values of 87% and 91%, respectively. Since the Int(%) values of [Fe(TEtPrP)I] and [Fe(TⁱPrP)I] are estimated by the ^{1}H NMR method to be 28% and 60% at 298 K, respectively, they increase as the temperature is lowered from 298 to 4.2 K. In contrast, the Int(%) values of the Br^- complexes seem to decrease with decreasing temperature.

The data in Table 15 also indicate that the Int(%) of [Fe(TEtPrP)I] varies depending on the conditions.[80] Although the complex exhibits a mixed S = 5/2 and S = 3/2 spin state in CH_2Cl_2 solution, it shows a pure S = 5/2 value both in toluene

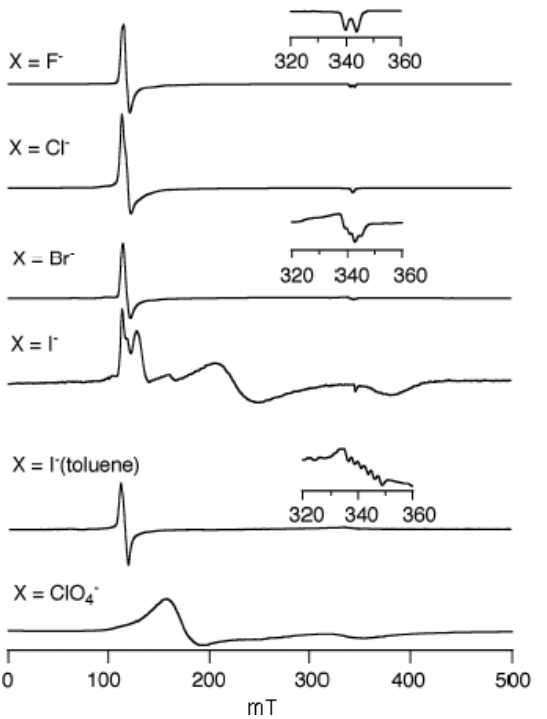

Figure 34. EPR spectra of a series of [Fe(TEtPrP)X] taken in frozen CH_2Cl_2 solution at 4.2 K. (Adapted with permission from Ref. 80. Copyright 2004, American Chemical Society.)

solution and in the solid state; the $g_\perp$ and $g_\parallel$ values are 5.94 and 2.01 in toluene solution and 5.98 and 2.05 (not shown in the table) in the solid state, respectively. The difference in spin states of [Fe(TEtPrP)I] in solution and in the solid state is not a very unusual phenomenon. For example, iodo(etiohemiporphycenato)iron(III) exhibits an S = 3/2 state with a minor contribution of S = 5/2 in solution.[174] The same complex shows, however, a quite pure S = 5/2 spin state in the solid. The difference is ascribed to the extraordinarily labile nature of the iodide ion in iodo(etiohemiporphycenato)iron(III). Thus, the iron is pulled toward the N_4 cavity in solution and, consequently, the complex adopts the intermediate-spin state. In the crystal lattice, however, packing forces could contract the labile Fe–I bond. Thus, the iron is lifted from the N_4 cavity toward the iodide, resulting in the formation of a typical high-spin five-coordinate structure. The difference in spin states of [Fe(TEtPrP)I] in solution and in the solid state could be explained similarly. The labile nature of the spin state mentioned above is one of the characteristics of the five-coordinate iron(III) porphyrin complexes, because similar lability in the spin state has been observed in five-coordinate iron(III) porphyrin complexes in biological systems such as cytochromes c′.[175]

ii. Six-coordinate complexes

Table 16 lists the ^{1}H and ^{13}C NMR chemical shifts, as well as EPR *g* values, of a series of six-coordinate $[Fe(T^{i}PrP)L_2]^+$.[168] The axial ligands are arranged according to the magnetochemical series for oxygen ligands shown in Eq. 18. Comparison of the ^{1}H NMR chemical shifts between $[Fe(TPP)L_2]^+$ and $[Fe(T^{i}PrP)L_2]^+$ listed in Tables 14 and 16, respectively, reveals that each pyrrole-H signal shifts upfield to a different extent on going from planar $[Fe(TPP)L_2]^+$ to ruffled $[Fe(T^{i}PrP)L_2]^+$. These results suggest that *the* S = 3/2 *character increases as the planar TPP is replaced by ruffled* $T^{i}PrP$, as in the case of the five-coordinated complexes. Consequently, the difference in pyrrole-H chemical shifts increases among the 4-MePyNO, PyNO, 4-ClPyNO, and DMSO complexes, which enables a ranking of the field strength for oxygen ligands, as shown in Eq. 20.

The ^{13}C NMR chemical shifts of the C_α and C_β signals correlate well with those of the pyrrole-H chemical shifts, suggesting that these signals can also be good probes of the contribution of the S = 3/2 spin state. In contrast, the chemical shifts of the *meso*-C signals exhibit a poor correlation.

The data in Tables 14 and 16 indicate that the complex with a highly ruffled porphyrin ring and a fairly weak oxygen ligand such as $[Fe(T^{i}PrP)(THF)_2]^+$ shows an essentially pure intermediate-spin state.[98,99,168] Figure 35 displays the molecular structure of (a) $[Fe(T^{i}PrP)(THF)_2]^+$ and (b) $[Fe(TEtP)(THF)_2]^+$.[176,177] The porphyrin ring of the former complex is highly ruffled. The average deviations of the *meso*-C atoms in $[Fe(T^{i}PrP)(THF)_2]^+$ and $[Fe(TEtP)(THF)_2]^+$ are 0.629 and 0.244 Å, respectively, and the average equatorial Fe–N bond lengths are 1.967 and

2.006 Å, respectively. As a result, the former adopts an essentially pure S = 3/2 spin state while the latter shows a mixed S = 5/2 and S = 3/2 spin state.[168,177] The average equatorial Fe–N bond lengths in planar complexes such as $[Fe(OEP)(THF)_2]^+$ and $[Fe(TPP)(THF)_2]^+$ are 1.999 and 2.040 Å, respectively.[178,179] Consequently, these complexes exhibit the mixed S = 5/2 and S = 3/2 spin state.

b. *Saddled deformation*

The saddled deformation of the porphyrin core also affects the energy levels of the 3d orbitals. Although the saddled deformation decreases the overlap between the iron $d_{x^2-y^2}$ orbital and the nitrogen lone pair for geometrical reasons, it should raise the energy level of the $d_{x^2-y^2}$ orbital since the interaction between and a_{2u} orbitals becomes symmetry-allowed in D_{2d} saddled complexes, as shown in Table 1.[42,43] In addition, the interaction should be enhanced because the Fe–N bonds in OETPP complexes are in general much shorter than those of the corresponding TPP complexes. The most explicit example showing the $d_{x^2-y^2}$–a_{2u} interaction is the cation radical, $[Cu(II)(OETPP^{\cdot})]^+$, reported by Fajer *et al.*[102] The complex exhibits sharp ^1H NMR lines, indicative of a diamagnetic species, which is ascribed to strong antiferromagnetic coupling between the half-occupied $d_{x^2-y^2}$ orbital and the half-occupied a_{2u} orbital.[103] Thus, the $d_{x^2-y^2}$ orbital can be destabilized in highly saddled complexes, which increases the contribution of the intermediate-spin state.

i. Five-coordinate complexes

Table 17 shows the ^{1}H NMR and EPR data of a series of five-coordinate Fe(OETPP)X, where X = F^-, Cl^-, Br^-, I^-, and ClO_4^-.[180,181] The Int(%) values estimated at 4.2 K by Eq. 17 clearly indicate that, while the F^- and Cl^- complexes are in the S = 5/2 state with a minor contribution of S = 3/2, the Br^- and I^- complexes adopt the S = 3/2 state with a minor contribution of S = 5/2. The ClO_4^- complex exhibits an essentially pure S = 3/2 spin state. It should be noted that the Int(%) values of ruffled Fe(TEtPrP)Br and Fe(T^{i}PrP)Br are 3% and 4%, respectively, while the Int(%) value is 89% in saddled Fe(OETPP)Br. Thus, *the saddled OETPP core stabilizes the S = 3/2 spin state more effectively than the corresponding ruffled T^{i}PrP core* if the axial ligands are the same. The possibility of the saddled porphyrin ring stabilizing the intermediate-spin state was first proposed by Cheng *et al.* in the discussion of the spin state of Fe(OETPP)Cl.[182] Although the Int(%) of Fe(OETPP)Cl is not as high as proposed,[183] saddled complexes such as Fe(OETPP)I are certainly in a pure intermediate-spin state in spite of the coordination of the halide, ion as Cheng *et al.* pointed out from the theoretical point of view.[183] Figure 36a shows the Mössbauer spectrum of Fe(OETPP)I taken for a microcrystalline sample at 77 K. The IS and QS values are 0.42 and 3.05 mm s^{-1}, respectively. The large QS value indicates that the complex is in the $S = 3/2$ spin state. Figure 36b shows the temperature dependence of the effective magnetic moments measured by SQUID magnetometry. The μ_{eff} values are 3.8–3.9 μ_B over a wide range of temperature, which are quite close to the spin-only value, 3.87 μ_B, expected for the S = 3/2 state. Thus, Fe(OETPP)I adopts a quite pure intermediate-spin state both in solution and in the solid state.[180]

ii. Six-coordinate complexes

The ^{1}H NMR, ^{13}C NMR, and EPR data of a series of six-coordinate $[Fe(OETPP)L_2]^+$ are listed in Table 18.[168] The complexes with weak axial ligands such as THF, MeOH, DMF, and DMSO exhibit $g_\perp$ signals from 4.0 to 4.2, suggesting that the complexes are in an essentially pure intermediate-spin state. These complexes commonly exhibit fairly upfield *meso*-C signals, which should be ascribed to the interaction between the filled a_{2u} and empty $d_{x^2-y^2}$ orbital in saddle-shaped complexes.[42,43] This interaction induces positive spin in the $d_{x^2-y^2}$ orbital, leaving the negative spin in the a_{2u} orbital by the spin polarization mechanism, and shifts the *meso*-carbon signal to an upfield position. In addition, the d_π–$3e_g$ interaction should also contribute to the upfield shift of the *meso*-carbon signals, especially when the complexes adopt the S = 3/2 state with the $(d_{xy})^2(d_{xz}, d_{yz})^2(d_{z^2})^1$ electronic

ground state because of the presence of two unpaired electrons in the d_π orbitals, as shown in Figure 3b.

C. Electronic Ground State in Intermediate-Spin Complexes

In the case of low-spin iron(III) porphyrins, it is now well established that there are two types of electronic ground states, i.e. $(d_{xy})^2(d_{xz}, d_{yz})^3$ and $(d_{xz}, d_{yz})^4(d_{xy})^1$. The complexes adopting the less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state almost always have highly ruffled structures. In contrast, the saddled structure tends to stabilize the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. Therefore, it is expected that even in the intermediate-spin complexes, there should be two different electronic ground states, $(d_{xz}, d_{yz})^3(d_{xy})^1(d_{z^2})^1$ and $(d_{xy})^2(d_{xz}, d_{yz})^2(d_{z^2})^1$ abbreviated as $S = 3/2(d_{xy})$ and $S = 3/2(d_\pi)$, respectively, as shown in Figure 3b. It seems to be quite natural, by analogy with the low-spin complexes, to assume that ruffled intermediate-spin $[Fe(T^iPrP)(THF)_2]^+$ should adopt the $S = 3/2(d_{xy})$ ground state while the saddled intermediate-spin $[Fe(OETPP)(THF)_2]^+$ should adopt the $S = 3/2(d_{xy})$ ground state.[37]

Table 19 lists the ^1H and ^{13}C NMR chemical shifts of ruffled and saddled low-spin and intermediate-spin complexes. The isotropic shifts of these complexes are also listed in bold. As the data in the table indicate, both the ^1H NMR and ^{13}C NMR data are totally different between ruffled and saddled complexes even if the spin state is the same, which in turn indicates that the electronic ground state could be different between ruffled and saddled complexes.[37,98,168] Reed and Guiset reported that $Fe(TPP)(Br_6CB_{11}H_6)$ is a pure intermediate-spin state, as is revealed from the presence of an extremely upfield-shifted pyrrole-H signal, i.e. −62 ppm.[157] In contrast, the pyrrole-H chemical shift is −31 ppm in $Fe(T^iPrP)ClO_4$ although the complex is also proven to be in an essentially pure intermediate-spin state.[37] On the basis of the large difference in pyrrole-H chemical shifts, *ca.* 31 ppm, between these two S = 3/2 complexes, Nakamura and coworkers proposed that highly ruffled intermediate-spin complexes such as $Fe(TEtPrP)ClO_4$ and $[Fe(T^iPrP)(THF)_2]^+$ should adopt the novel $S = 3/2$ (d_{xy}) ground state.[37] This is because the $S = 3/2(d_{xy})$ complexes have only one unpaired electron in the d_π orbitals; the presence of the unpaired electron in the d_π orbital is the major factor contributing to the upfield shift of the pyrrole-H signals. The electronic ground state mentioned above is further supported by the fact that the difference in pyrrole-H chemical shifts between low-spin $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$ and $[Fe(TPP)(HIm)_2]^+$ adopting $S = 1/2(d_{xy})$ and $S = 1/2(d_\pi)$, respectively, is also quite large, *ca.* 30 ppm.[52,82] The large difference can be explained in terms of the number of unpaired electrons in the d_π orbitals; $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$ has no unpaired electron in the d_π orbitals, while $[Fe(TPP)(HIm)_2]^+$ has one. Thus, $[Fe(T^iPrP)(THF)_2]^+$ is expected to be the first example of the intermediate-spin complex adopting the $S = 3/2(d_{xy})$ ground state.

[a]Isotropic shifts are determined on the basis of the chemical shifts of diamagnetic Ni(T^{n}PrP) and Zn(OETPP) and they are given in boldface. [b]Chemical shifts are determined in CD_2Cl_2 at 298 K.

The data in Table 19 indicate, however, that the isotropic shift of the *meso*-C signal of $[Fe(T^iPrP)(THF)_2]^+$ is negative, −8 ppm. Although it is more downfield than the corresponding value, −32 ppm, in $[Fe(T^nPrP)(HIm)_2]^+$ adopting the S = 1/2(d_π) state, it is much more upfield than the corresponding value, 591 ppm, in the $(d_{xz}, d_{yz})^4(d_{xy})^1$ type $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$. The outcome might be the suggestion that $[Fe(T^iPrP)(THF)_2]^+$ exists not as a pure S = 3/2(d_{xy}) complex but as a mixture of S = 3/2(d_{xy}) and S = 3/2(d_π) where S = 3/2(d_π) predominates over S = 3/2(d_{xy}). How can a much purer S = 3/2(d_{xy}) complex be obtained? In the case of low-spin complexes, the pure S = 1/2(d_{xy}) complex is obtained by the combination of a highly ruffled porphyrin and axial ligands with low-lying π^* orbitals. This is because ruffling of the porphyrin core raises the energy level of the d_{xy} orbital by way of the a_{2u}–d_{xy} interaction. Furthermore, axial ligands with low-lying π^* orbitals lower the d_π orbitals via the d_π–p_π^* interaction. Therefore, $[Fe(T^iPrP)(4\text{-}CNPy)_2]^+$ and $[Fe(T^iPrP)(^tBuNC)_2]^+$ are considered to be the purest examples of an S = 1/2(d_{xy}) complex.[52,82]

To obtain a much purer S = 3/2(d_{xy}) complex, it is necessary to use a weak oxygen ligand that has low-lying π^* orbitals. In Table 19 are added the NMR data of one such complex, $[Fe(T^iPrP)(PhCHO)_2]^+$.[184] This complex should adopt a much purer S = 3/2(d_{xy}) state, because benzaldehyde has a low-lying π^* orbital. The intermediate-spin state of this complex has been confirmed on the basis of EPR data; the g_∞ value is 4.1 in frozen CH_2Cl_2 solution at 4.2 K. In fact, the isotropic shift of the *meso*-C signal of $[Fe(T^iPrP)(PhCHO)_2]^+$ appears as high as +88 ppm. The positive and negative isotropic shifts of the *meso*-C and the *meso*-CH_α carbon signals, respectively, strongly indicate that the *meso*-C atoms have sizable amounts of positive spin, which in turn indicates that the d_{xy} orbital is half-occupied.

The S = 3/2(d_π) ground state in $[Fe(OETPP)(THF)_2]^+$ is supported by the isotropic shift of the pyrrole-CH_2 carbon signals. While the isotropic shift of this signal in $[Fe(OETPP)(THF)_2]^+$ is −75 ppm as listed in Table 19, it is only −44 ppm in $[Fe(OETPP)(HIm)_2]^+$. Since the isotropic shift of the pyrrole-CH_2 carbon signal is proportional to the spin density on the C_β atoms, this result indicates that the spin density on the C_β atoms in $[Fe(OETPP)(THF)_2]^+$ is nearly 1.8 times as high as that in $[Fe(OETPP)(HIm)_2]^+$, which in turn indicates that $[Fe(OETPP)(THF)_2]^+$ has two unpaired electrons in the d_π orbitals.[37]

Assignment of the electronic ground state of intermediate-spin complexes such as $[Fe(T^iPrP)(THF)_2]^+$ and $[Fe(OETPP)(THF)_2]^+$ is a good target for theoretical calculations. Cheng and coworkers reported, on the basis of DFT calculations, that $[Fe(T^iPrP)(THF)_2]^+$ and $[Fe(OETPP)(THF)_2]^+$ should adopt the S = 3/2(d_π) and S = 3/2(d_{xy}) states, respectively, which is an opposite assignment of the previously mentioned electronic ground states.[38] In the saddled complex, the calculation

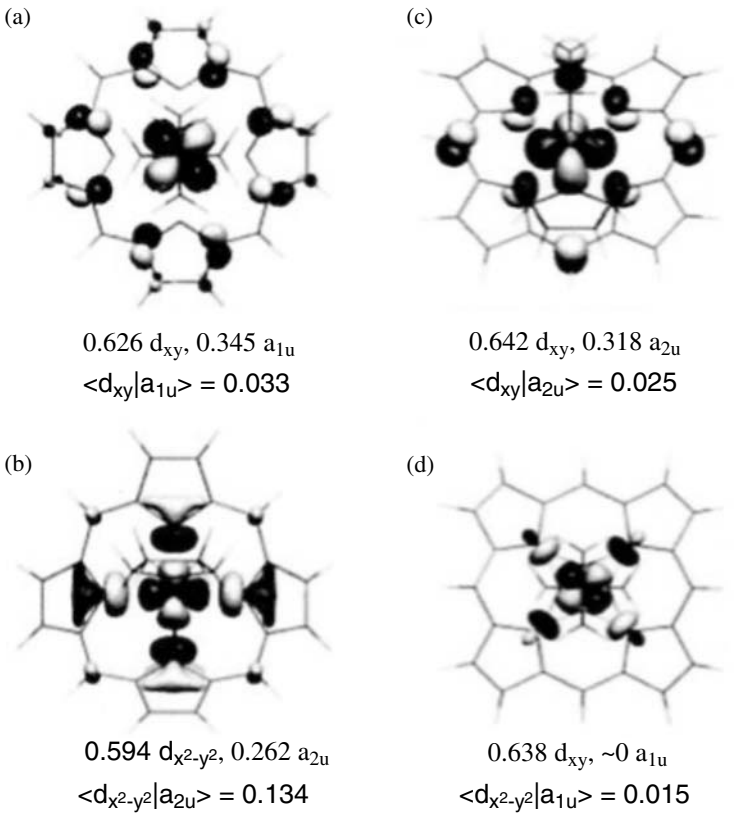

Figure 37. Bonding interactions between (a) d_{xy}–a_{1u}, (b) $d_{x^2-y^2}$–a_{2u} for saddled $[FeP(THF)_2]^+$, and the bonding interactions between (c) d_{xy}–a_{2u} and (d) $d_{x^2-y^2}$–a_{1u} for ruffled $[FeP(THF)_2]^+$. (Adapted with permission from Ref. 38. Copyright 2005, Royal Society of Chemistry.)

reveals the presence of two symmetry-allowed bonding interactions. One is a well-established interaction between a_{2u} and $d_{x^2-y^2}$ orbitals, and the other is the interaction between a_{1u} and d_{xy} orbitals. As shown in Figure 37, the bonding interaction between a_{1u} and d_{xy} orbitals in the saddled complex is unexpectedly strong; it is much stronger than the bonding interaction between a_{2u} and d_{xy} orbitals in a ruffled complex. As a result, the d_{xy} orbital in the saddled complex is lifted above the d_π orbital to form the $S = 3/2(d_{xy})$ electronic ground state. Table 20 shows the net spin population and the nuclear spin populations for each symmetry-distinct atom type for $[Fe(OETPP)(THF)_2]^+$ and $[Fe(T^iPrP)(THF)_2]^+$ with high-spin and two different intermediate-spin states, $S = 3/2(d_{xy})$ and $S = 3/2(d_\pi)$, obtained by spin-unrestricted ADF calculations.[38] As for saddled $[Fe(OETPP)(THF)_2]^+$, the data listed in Table 20 suggest that both $^4A_1$ and ^4E explain correctly the existence of extraordinarily upfield-shifted *meso*-C signals since both have large negative

Table 20. Net spin populations and the [nuclear spin populations] in the order of 10^{-4} on each symmetry-distinct atom type for bis-THF complexes from unrestricted DFT calculations.

net spin populations on the *meso*-C atoms. However, the fact that C_α is more downfield-shifted than the C_β signal in saddled $[Fe(OETPP)(THF)_2]^+$ suggests that ^4E should be the leading contribution to this unusual intermediate-spin state complex.[38] DFT calculations also suggest that the intermediate-spin $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ adopts the S = 3/2 (d_{xy}) rather than the S = 3/2(d_π) ground state.[117] As for ruffled $[Fe(T^iPrP)(THF)_2]^+$, the DFT calculations predict an extraordinarily large downfield shift for the *meso*-C signal if the complex adopts the ^4E, S = 3/2(d_{xy}) ground state. Thus, $[Fe(T^iPrP)(THF)_2]^+$ is concluded to adopt the $^4A_1$, S = 3/2(d_π) electronic ground state.[38]

Ling and Zhang have applied quantum-chemical calculations to predict the Mössbauer and NMR properties of various S = 3/2 iron(III) porphyrins with planar, ruffled, and saddled conformations.[39] The calculations correctly reproduced the Mössbauer QS and IS values as well as the ^1H and ^{13}C NMR chemical shifts. An interesting new observation is the dependence of d_{z^2} ordering on the Fe–N distance; the d_{z^2} orbital is relatively stabilized as the Fe–N_P bond distance decreases. Consequently, the d_{z^2} orbital is usually of the lowest energy due to a weaker interaction along the z-axis as compared to the stronger interactions in the *x*–*y* plane from the shorter Fe–N contact. Thus, the frontier iron MO orderings in S = 3/2 complexes are different from those reported previously if the Fe–N bond distance is less than 1.975 Å. The orbital ordering in ruffled $[Fe(T^iPrP)(THF)_2]^+$ is $d_{x^2-y^2} > d_\pi > d_{xy} > d_{z^2}$, while that in saddled $Fe(OETPP)ClO_4$ is $d_{x^2-y^2} > d_{xy} > d_\pi > d_{z^2}$. In the case of $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ where the Fe–N distance is 1.975 Å, the orbital orderings become $d_{x^2-y^2} > d_{xy} > d_{z^2} > d_\pi$. Presence

or absence of the unpaired electron in the d_{z^2} orbital should affect the chemical shifts of the coordinating ligand. Thus, further systematic NMR experiments focusing on the chemical shifts of axial ligands together with theoretical studies are necessary in order to fully understand the electronic structure of the intermediate-spin complexes.

V. Spin Crossover in Iron(III) Porphyrins

A. General Considerations

The spin crossover phenomenon was first discovered in 1931 for iron(III) tris-dithiocarbamate complexes.[171–173,185–187] Since then many transition metal complexes showing thermal spin crossover phenomena have been found both in the solid state and in solution. Most of the complexes that exhibit the spin crossover phenomenon contain Fe(II), Fe(III), and to a lesser extent Co(II), Co(III), Mn(II), Mn(III), Ni(II), and Mo(II).[185–187] Among them, Fe(II) complexes have been most extensively studied because of their potential uses as electronic and optical switching and memory devices.[188] In the case of iron(III) porphyrins, there are three possible spin states: high-spin (S = 5/2), intermediate-spin (S = 3/2), and low-spin (S = 1/2) states. Thus, there should be three kinds of spin crossover processes; the ones between S = 5/2 and S = 1/2, between S = 3/2 and S = 1/2, and between S = 5/2 and S = 3/2, as shown in Figure 38.[30] The spin crossover process between S = 5/2 and S = 1/2 has been actively studied in six-coordinated complexes since its first observation in metmyoglobin by Beetlestone and George in 1964.[189] Since then ample examples have been reported in hemoproteins such as hemoglobin,[190] cytochrome P450,[191] cytochrome c peroxidase, etc.[192–194] As in the case of hemoproteins, spin crossover phenomena between S = 5/2 and S = 1/2 have been found

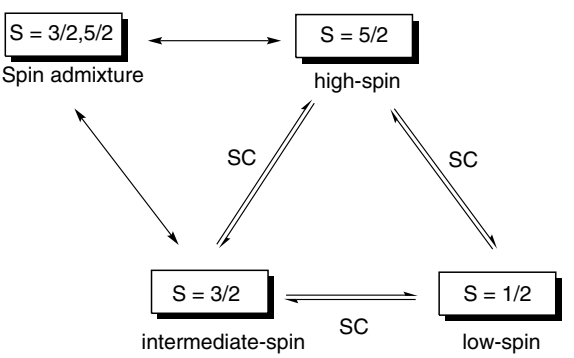

Figure 38. Possible spin crossover(SC) processes between two spin states. (Adapted with permission from Ref. 30. Copyright 2006, Elsevier Science.)

also in synthetic iron(III) porphyrins. Typical examples are azide complexes such as $[Fe(OEP)(3\text{-}ClPy)_2]^+$ and $[Fe(TPP)(N_3)_2]^-$ reported by Scheidt *et al.*,[195,196] and $[Fe(Por)(N_3)(1\text{-}MeIm)]$ reported by Neya *et al.*,[197,198] (Note: Por indicates various porphyrin isomers, such as corrphycene, porphycene, and hemiporphycene.)[199] Each porphyrin isomer has a unique size and shape of the cavity surrounded by the four pyrrole nitrogen atoms. Thus, the electronic and magnetic properties of these complexes are specific.[200–203] In mixed azide and imidazole complexes, $[Fe(Por)(N_3)(1\text{-}MeIm)]$, corrphycene stablizes the high-spin state while porphycene and hemiporphycene stabilize the low-spin state.[198]

On the other hand, the spin crossover between S = 3/2 and S = 1/2 had not been observed in iron porphyrins until recently, although two examples have been reported in iron(III) complexes without a porphyrin ligand. They are $[Fe^{III}(TMC)(NO)](BF_4)_2$ and $[Fe^{III}(L\text{-}N_4Me_2)(S_2C_6H_4)](ClO_4)\oplus 0.5H_2O$,[204,205] where TMC, L-$N_4Me_2$, and $S_2C_6H_4$ are 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane, *N*,*N*′-dimethyl-2,11-diaza[3.3](2,6) pyridinophane, and 1,2-benzendithiolate, respectively. The first example of an iron(III) porphyrin complex to show spin crossover between S = 3/2 and S = 1/2 was observed by Ikeue and coworkers in highly saddled $[Fe(OETPP)L_2]^+$ having a nitrogen base such as Py or 4-CNPy as an axial ligand (L).[100,200]

It has long been considered that the mixed S = 3/2 and S = 5/2 is not a thermal equilibrium between S = 3/2 and S = 5/2 but a quantum mechanical spin admixture caused by spin–orbit coupling between the two spin states.[150,151] In other words, the thermal spin crossover between S = 3/2 and S = 5/2 does not exist in principle. In fact, all the mixed S = 3/2 and S = 5/2 complexes exhibited averaged NMR and EPR signals. However, several examples have been reported that have to be explained in terms of a spin crossover between S = 3/2 and S = 5/2.[101,154–156] Understanding the mechanism for the spin crossover processes is quite important, since they take place in various biological processes.[190–194,206–208] In this section, we will first describe complexes that exhibit the rare spin crossover processes between S = 3/2 and S = 1/2. We will then introduce a couple of new complexes that exhibit the spin crossover between S = 5/2 and S = 3/2.

B. Spin Crossover Between S = 3/2 and S = 1/2

1. *$[Fe(OETPP)L_2]^+$*

Six-coordinate complexes with a nitrogen base such as imidazole or pyridine usually show a low-spin state. As mentioned in the previous section, saddle-shaped complexes tend to stabilize the intermediate-spin state. Examples are [Fe(OETPP)I],[180] $[Fe(OETPP)ClO_4]$,[181] and $[Fe(OETPP)(THF)_2]^+$.[98] As listed in Tables 17 and 18,

Table 21. ^{1}H NMR chemical shifts of $[Fe(OETPP)L_2]^+$ and $[Fe(OMTPP)L_2]^+$ taken in CD_2Cl_2 solution at 298 K and 193 K.

[a]Values are revised from the original ones. [b]Data obtained by the extrapolation from high temperature. (Source: Refs. 62 and 82.)

these complexes adopt an essentially pure intermediate-spin state. It is then expected that even the complexes carrying nitrogen bases with a weak-field ligand should exhibit a quite pure intermediate-spin state if the porphyrin is highly saddled. Table 21 lists the ^{1}H and ^{13}C NMR chemical shifts of $[Fe(OETPP)L_2]^+$ and $[Fe(OMTPP)L_2]^+$, where Ls are nitrogen bases such as DMAP, Py, and 4-CNPy.[62,100] The chemical shifts of $[Fe(OETPP)(THF)_2]^+$ and $[Fe(OETPP)(^tBuNC)_2]^+$,[82,98] which are well characterized as the intermediate-spin and low-spin complexes, respectively, are also listed for comparison. As the axial ligand changes from DMAP to Py, and then to 4-CNPy in Table 21, the CH_2, *o*-H, and *p*-H signals of $[Fe(OETPP)L_2]^+$ exhibit a downfield shift and approach the corresponding signals of $[Fe(OETPP)(THF)_2]^+$. In addition, the large upfield shift of the *meso*-C and the

downfield shift of the C_α signals of $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ resemble those of $[Fe(OETPP)(THF)_2]^+$. These NMR results suggest that the spin state actually changes from S = 1/2 in the DMAP complex to S = 3/2 in the 4-CNPy complex. In fact, the solution magnetic moments of $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ determined by the Evans method in CD_2Cl_2 solution are 4.2 ± 0.1 μ_B at 193–298 K, which is close to the spin-only value expected for the S = 3/2 complexes.[100]

It is interesting to compare the electronic structures of saddled $[Fe(OETPP)L_2]^+$ carrying nitrogen bases with those of the corresponding ruffled $[Fe(T^nPrP)L_2]^+$.[52,62,100] In the case of ruffled $[Fe(T^nPrP)L_2]^+$, all the complexes maintain the low-spin state although the electronic ground state changes from $(d_{xy})^2(d_{xz}, d_{yz})^3$ to $(d_{xz}, d_{yz})^4(d_{xy})^1$ on going from DMAP to Py, and then to 4-CNPy, as shown in Table 4.[52] In the case of saddled $Fe(OETPP)L_2^+$, however, while strong σ-donating and weak π-accepting ligands such as HIm and DMAP give a low-spin complex with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state, weak σ-donating and strong π-accepting ligands such as 4-CNPy form intermediate-spin complexes.[62,100] Thus, in the saddled complexes, *it is the spin state that changes depending on the field strength of the axially coordinating nitrogen ligands.*

The data in Table 21 indicate that the ^1H and ^{13}C signals of $[Fe(OETPP)Py_2]^+$ are located between those of low-spin $[Fe(OETPP)(DMAP)_2]^+$ and intermediate-spin $[Fe(OETPP)(4\text{-}CNPy)_2]^+$. These results suggest that low-spin and intermediate-spin $[Fe(OETPP)Py_2]^+$ coexist as an equilibrium mixture in CD_2Cl_2 solution at 298 K. Figure 39a shows the Curie plots of the CH_2–H signals of $[Fe(OETPP)L_2]^+$,

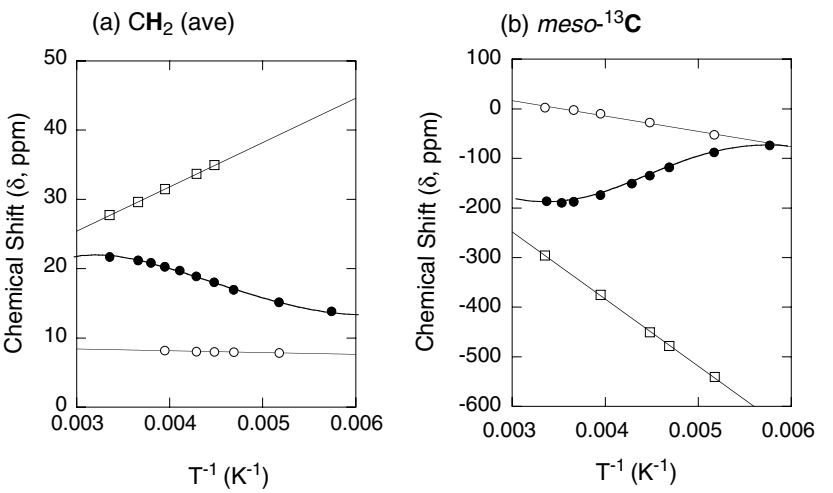

Figure 39. Curie plots of the (a) CH_2 and (b) *meso*-C signals of $[Fe(OETPP)(DMAP)_2]^+$ (★), $[Fe(OETPP)(Py)_2]^+$ (•), and $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ (□). (Adapted with permission from Ref. 100. Copyright 2001, WILEY-VCH Verlag GmbH.)

where Ls are DMAP, Py, and 4-CNPy.[100] While the Curie plots of the DMAP and 4-CNPy complexes give good linearity, the Curie plots of the Py complex exhibit considerable curvature. A similar tendency is observed in the Curie plots of the *meso*-C signals shown in Figure 39b.[100] Although both the CH_2 and *meso*-C signals of the Py complex appear close to the corresponding signals of the 4-CNPy complex at ambient temperature, they approach those of the DMAP complex at lower temperature. The curvature of the Curie lines of $[Fe(OETPP)Py_2]^+$ clearly indicates that spin crossover takes place between S = 3/2 and S = 1/2. In contrast, $[Fe(OETPP)(DMAP)_2]^+$ and $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ maintain the S = 1/2 state and the S = 3/2 spin state, respectively, in the temperature range examined. The equilibrium constant for the spin crossover process (K_{SC}) in CD_2Cl_2 solution is determined at several temperatures on the basis of the *meso*-C chemical shifts according to Eq. 20, where δ_{DMAP}, δ_{Py}, and $\delta_{4\text{-}CNPy}$ are the *meso*-C chemical shifts of the DMAP, Py, and 4-CNPy complexes, respectively:

$$S = \frac{1}{2} \underset{\longleftarrow}{\overset{K_{SC}}{\longrightarrow}} S = \frac{3}{2},$$
$$K_{SC} = \frac{S = \frac{3}{2}}{S = \frac{3}{2}} = \frac{\delta_{DMAP} - \delta_{Py}}{\delta_{Py} - \delta_{4-CNPy}}. \quad (20)$$

The plots of $\log(K_{SC})$ vs. $1/T$ show a good linearity from which the thermodynamic parameters are determined as follows: $\Delta H° = 17$ kJ mol^{-1} and $\Delta S° = 67$ J mol^{-1} K^{-1}. Although the spin crossover process between the S = 1/2 and S = 3/2 states is not unprecedented in iron(III) complexes,[204,205] $[Fe(OETPP)Py_2]^+$ is actually the first example in iron(III) porphyrin complexes.[100] It should be noted here that $[Fe(OETPP)Py_2]^+$ adopts the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state at lower temperatures on the basis of the upfield-shifted *m*-H and *meso*-C signals listed in Table 21.

What are the magnetic properties of these complexes in the solid state? Table 22 lists the Mössbauer parameters of a series of $[Fe(OETPP)L_2]^+$ measured at ambient and liquid nitrogen temperatures.[98] At ambient temperature, the QS value of $Fe(OETPP)(DMAP)_2^+$ is 2.21 mm s^{-1}, which is within the range of the low-spin state. In contrast, the QS value of $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ is quite large, 3.26 mm s^{-1}, and is close to that of $[Fe(OETPP)(THF)_2]^+$, suggesting that this complex adopts the intermediate-spin state. The QS value of $[Fe(OETPP)Py_2]^+$ is 2.76 mm s^{-1}, which is between the QS values of the DMAP and 4-CNPy complexes. Thus, the Py complex exists as a mixture of the S = 3/2 and the S = 1/2 spin states at ambient temperature in the solid. As the temperature is lowered to 80 K, the QS value of the DMAP complex is maintained while that of the Py complex decreases to 2.26 mm s^{-1}. These results indicate that the Py complex adopts predominantly

the low-spin state at 80 K. In the case of the 4-CNPy complex, two doublets (sites A and B) appear below 230 K. Since the IS and QS values for sites A and B are in the range of intermediate-spin and low-spin states, respectively, the complexes with different spin states coexist at low temperature. Thus, a rare spin crossover occurs even in $[Fe(OETPP)(4\text{-}CNPy)_2]^+$ in the solid state. Figure 40 shows the effective magnetic moments (μ_{eff}) measured on microcrystalline samples with a SQUID magnetometer over 2–300 K. The results confirm that the DMAP complex is in the low-spin state while the THF complex is in the pure intermediate-spin state over a wide range of temperatures.[100] Figure 40 also indicates that a major part of the Py complex is in the S = 1/2 state below 150 K, though the population of the S = 3/2 ground state considerably increases above this temperature. Similarly, the 4-CNPy complex is a mixture of the S = 1/2 and S = 3/2 states below 200 K though it exists almost exclusively as the S = 3/2 above 200 K. On the basis of the Mössbauer and SQUID results, it is clear that *not only* $[Fe(OETPP)Py_2]^{\pm}$ *but also* $[Fe(OETPP)(4\text{-}CNPy)_2]^{\pm}$ *exhibits the spin crossover process in the solid state.*

2. $[Fe(OMTPP)L_2]^+$ and $[Fe(TBTXP)L_2]^+$

Figure 41 shows the Curie plots of (a) the CH_3–H and (b) the *meso*-C signals of $[Fe(OMTPP)L_2]^+$, where L is DMAP, Py, 4-CNPy, THF, and ^{t}BuNC.[62] Among

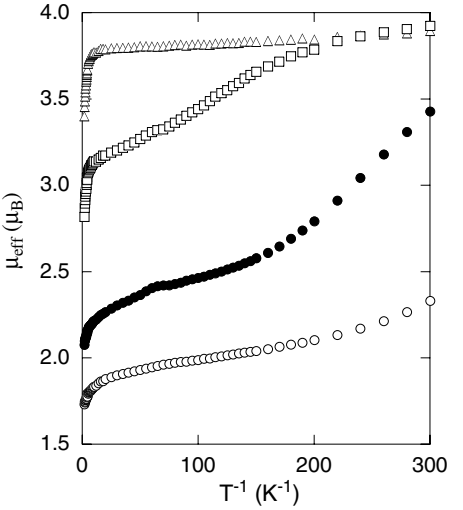

Figure 40. Temperature dependence of the effective magnetic moments of $[Fe(OETPP)L_2]^+$. L = DMAP (○); Py (●); 4-CNPy (□); and THF(Δ). (Adapted with permission from Ref. 100. Copyright 2001, WILEY-VCH Verlag GmbH.)

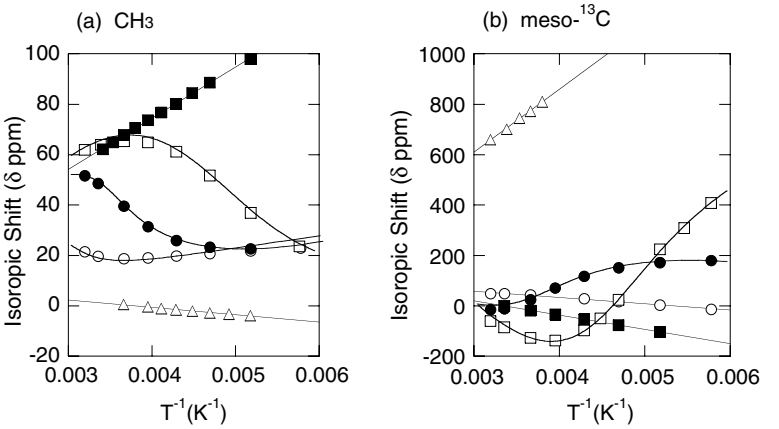

Figure 41. Curie plots of the (a) CH_3–H and (b) *meso*-^{13}C signals of $[Fe(OMTPP)(DMAP)_2]^+$ (○), $[Fe(OMTPP)(Py)_2]^+$ (●), $[Fe(OMTPP)(4\text{-}CNPy)_2]^+$ (□), $[Fe(OMTPP)(THF)_2]^+$ (■), and $[Fe(OMTPP)(^tBuNC)_2]^+$ (Δ). (Adapted with permission from Ref. 62. Copyright 2003, American Chemical Society.)

these complexes, $[Fe(OMTPP)(THF)_2]^+$ shows a good linearity, suggesting that the complex is in a quite pure S = 3/2 spin state. Similarly, the Curie plots of the *meso*-C signals of both $[Fe(OMTPP)(DMAP)_2]^+$ and $[Fe(OMTPP)(^tBuNC)_2]^+$ exhibit good linearity with negative and positive slopes, respectively, suggesting

that the former adopts S = 1/2 with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state while the latter adopts S = 1/2 with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state.[62] In contrast, the Curie plots of $[Fe(OMTPP)Py_2]^+$ and $[Fe(OMTPP)(4\text{-}CNPy)_2]^+$ shown in Figure 41a exhibit a curvature, suggesting that the spin crossover takes place between S = 3/2 and S = 1/2 in both of these complexes. Inspection of the Curie lines for the *meso*-C signals shown in Figure 41b reveals, however, that the magnetic behaviors of $[Fe(OMTPP)L_2]^+$ (L = Py and 4-CNPy) are quite different from those of $[Fe(OETPP)L_2]^+$ (L = Py). As the temperature is lowered, the Curie line of $[Fe(OMTPP)(4\text{-}CNPy)_2]^+$ (□) moves away from that of $[Fe(OMTPP)(DMAP)_2]^+$ (○) and approaches that of $[Fe(OMTPP)(^tBuNC)_2]^+$ (Δ). Similar temperature dependence is observed for $[Fe(OMTPP)Py_2]^+$ (•), though the deviation from the Curie line of $[Fe(OMTPP)(DMAP)_2]^+$ (○) is much smaller. $[Fe(TBTXP)L_2]^+$ exhibits a similar curvature in Curie plots if L is Py or 4-CNPy though the spin crossover phenomenon from S = 3/2 to S = 1/2 starts at higher temperature. These results suggest that the spin crossover pathways of OMTPP and TBTXP complexes are different from those of OETPP complexes. *While the spin state of* $[Fe(OETPP)Py_2]^{\pm}$ *changes from* S = *3/2 to* S = *1/2 with the* $(d_{xy})^2(d_{xz}, d_{yz})^3$ *ground state as the temperature is lowered, that of* $[Fe(OMTPP)(4\text{-}CNPy)_2]^{\pm}$ *and* $[Fe(OMTPP)Py_2]^{\pm}$ *changes from* S = *3/2 to* S = *1/2 with the* $(d_{xz}, d_{yz})^4(d_{xy})^1$ *ground state.*[62]

What are the magnetic properties of $[Fe(OMTPP)L_2]^+$ in the solid state? Table 22 also shows the Mössbauer parameters of the DMAP and Py complexes.[209] The IS values increase from 0.16 to 0.23 mm s^{-1} in $[Fe(OMTPP)(DMAP)_2]^+$ and from 0.19 to 0.25 mm s^{-1} in $[Fe(OMTPP)(Py)_2]^+$ as the temperature is lowered from 290 to 77 K. In contrast, the QS values are almost constant in this temperature range; they are 1.86–1.90 mm s^{-1} for $[Fe(OMTPP)(DMAP)_2]^+$ and 2.13–2.18 mm s^{-1} for $[Fe(OMTPP)Py_2]^+$. Thus, these complexes maintain the low-spin state over a wide range of temperature. The low-spin state assignment of $[Fe(OMTPP)(DMAP)_2]^+$ and $[Fe(OMTPP)Py_2]^+$ is further supported by the effective magnetic moments determined by SQUID magnetometry; they are 2.1–2.8 μ_B in the temperature range of 50–300 K.[209] Thus, the magnetic behavior of $[Fe(OETPP)Py_2]^+$ and of $[Fe(OMTPP)Py_2]^+$ are quite different in the solid. *While* $[Fe(OETPP)Py_2]^{\pm}$ *shows a spin crossover between the S = 3/2 and S = 1/2 spin states,* $[Fe(OMTPP)Py_2]^{\pm}$ *maintains the* S = *1/2 spin state in the solid state.*[209]

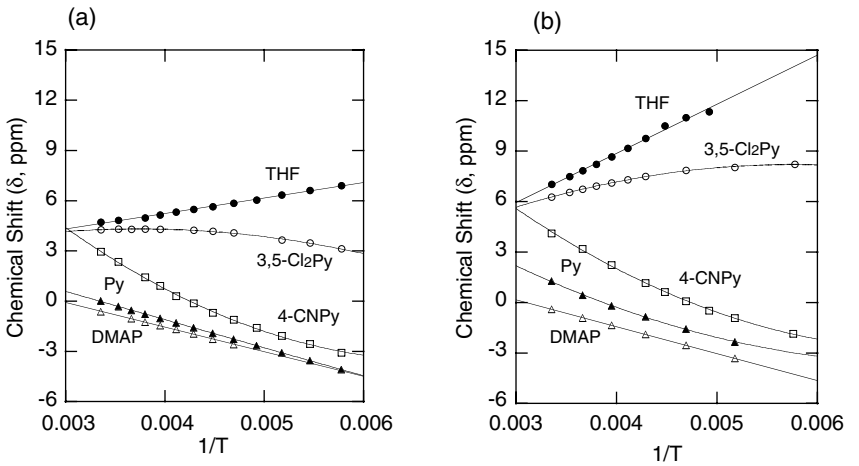

Figure 43. Curie plots of the CH_3 signals in (a) $[Fe(MAzP)L_2]^+$ and (b) $[Fe(OEP)L_2]^+$. (Adapted with permission from Ref. 136. Copyright 2008, American Chemical Society.)

As listed in Table 23a, $[Fe(MAzP)L_2]^{\pm}$ complexes carrying axial ligands with strong field strength such as DMAP, 1-MeIm, and CN^- exhibit their CH_2 signals at downfield positions, 6–8 ppm, and the *meso*-H signals at upfield positions, 1–3 ppm. In addition, all the signals of these complexes show fairly good linearity in the Curie plots. The ^1H NMR characteristics mentioned above suggest that these complexes adopt the low-spin state with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state. The small downfield shifts of the CH_2 signals can be explained in terms of the interaction

between the half-filled iron d_π and the filled $3e_g$-like orbitals of MAzP. The upfield shift of the *meso*-H signals should mainly be caused by the dipolar contribution in the $(d_{xy})^2(d_{xz}, d_{yz})^3$ type complexes.

The CH_2 and *meso*-H signals of $[Fe(MAzP)(4\text{-}CNPy)_2]^+$ and $[Fe(MAzP)(3,5\text{-}Cl_2Py)_2]^+$ appear much further downfield than those of low-spin complexes with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state; the chemical shifts of the CH_2 and *meso*-H signals of the 3,5-Cl_2Py complex reach as far as 32.12 (ave) and 25.22 (ave) ppm, respectively, at 298 K. The large downfield shift of the CH_2 signals at 298 K suggests that these complexes are either in the S = 3/2 spin state with two unpaired electrons in the d_π orbitals or in the S = 5/2 spin state with an unpaired electron in the $d_{x^2-y^2}$ orbital. It is difficult to differentiate the S = 5/2 from the S = 3/2 spin state on the basis of the CH_2 chemical shifts, because they appear downfield in both the S = 3/2 and S = 5/2 complexes. In such a case, the chemical shifts of the β-CH_3 signals and their temperature dependence should be a good probe for determining the spin states since the S = 5/2 complexes exhibit β-CH_3 signals further downfield than the S = 3/2 complexes; the unpaired electron can be delocalized to the CH_3 protons through σ-bonds in the S = 5/2 complexes. The data in Table 23a indicate that the CH_3 signals of the 4-CNPy and 3,5-Cl_2Py complexes appear at 3.83 and 4.27 ppm, respectively. Since the CH_3 signals of high-spin Fe(MAzP)Cl appear at 6.9–7.5 ppm, it is reasonable to conclude that they are mainly in the S = 3/2 state.

As shown in Figures 42a and 43a, the *meso*-H and CH_3 signals of $[Fe(MAzP)(4\text{-}CNPy)_2]^+$ show large upfield shifts as the temperature is lowered and approach those of the low-spin DMAP complex. These result can be explained in terms of spin crossover from the mainly S = 3/2 to the mainly S = 1/2 state. Similar temperature dependence is observed in $[Fe(MAzP)(3,5\text{-}Cl_2Py)_2]^+$, though the degree of the spin crossover is much smaller; the *meso*-H signals still appear far downfield even at 223 K. Thus, the magnetic behaviors of the 4-CNPy and 3,5-Cl_2Py complexes resemble those of $[Fe(OETPP)Py_2]^+$ and $[Fe(OMTPP)Py_2]^+$, since all of these complexes exhibit the spin transition from S = 3/2 to S = 1/2. However, the magnetic behavior of $[Fe(MAzP)Py_2]^+$ is different from that of $[Fe(OETPP)Py_2]^+$ and $[Fe(OMTPP)Py_2]^+$, because it maintains the S = 1/2 spin state even at ambient temperature; the average chemical shift of the CH_2 signals at 298 K is 10.77 ppm, which is not much different from 6.69 ppm for the low-spin DMAP as listed in Table 23a.

Comparison of the electronic structures between $[Fe(MAzP)L_2]^\pm$ and $[Fe(OEP)L_2]^\pm$ should be useful for elucidating the effect of a nitrogen atom at one of the *meso* positions. Figures 42 and 43 suggest that the electronic structure of $[Fe(MAzP)L_2]^\pm$ is surprisingly similar to that of $[Fe(OEP)L_2]^\pm$ if the axial ligand is the same. Close inspection of the data in Table 23 reveals, however, that the

chemical shifts and the temperature dependence of the CH_3 signals are different in the two 3,5-Cl_2Py complexes. While the CH_3 signals in [Fe(MAzP)(3,5-Cl_2Py)$_2$]$^+$ appear at 4.27 ppm on average at 298 K, the corresponding signal in [Fe(OEP)(3,5-Cl_2Py)$_2$]$^+$ is observed much more downfield, at 6.27 ppm. These results indicate that the $d_{x^2-y^2}$ orbital in the OEP complex has a much larger spin population than in the MAzP complex. In other words, the population of the S = 5/2 state increases on going from [Fe(MAzP)(3,5-Cl_2Py)$_2$]$^+$ to [Fe(OEP)(3,5-Cl_2Py)$_2$]$^+$. Furthermore, the Curie plots of the CH_3 signals of these complexes presented in Figure 43 indicate that the averaged CH_3 signal in the MAzP complex shows a small negative slope, while that of the OEP complex exhibits a positive slope. The negative slope of the CH_3 signal in [Fe(MAzP)(3,5-Cl_2Py)$_2$]$^+$ is consistent with spin crossover from mainly S = 3/2 at 298 K to the mixed S = 3/2 and S = 1/2 state at 173 K. In contrast, the positive slope in [Fe(OEP)(3,5-Cl_2Py)$_2$]$^+$ suggests that the contribution of the S = 5/2 spin state is dominant even at 173 K. EPR spectra support this conclusion, because [Fe(MAzP)(3,5-Cl_2Py)$_2$]$^+$ exhibits S = 1/2 while [Fe(OEP)(3,5-Cl_2Py)$_2$]$^+$ shows the mixed S = 3/2 (major) and S = 5/2 (minor) states at 4.2 K; the $g_\perp$ values of these complexes are 3.46 and 4.23, respectively, in frozen CH_2Cl_2 solution.[136] The low-spin state in [Fe(MAzP)(3,5-Cl_2Py)$_2$]$^+$ at 4.2 K can be explained in terms of a destabilization of the $d_{x^2-y^2}$ orbital caused by the smaller N_4 cavity of the MAzP core as compared with the OEP core. An X-ray crystallographic analysis reported by Balch and coworkers has also revealed that the average Fe–N_p bond in Fe(MAzP)Cl is 2.044 Å, which is *ca*. 0.02 Å shorter than that in Fe(OEP)Cl.[210,211]

4. *Structural Consequences of Spin Crossover*

It is interesting to know how the coordination structure and the surrounding lattice of [Fe(OETPP)Py_2]$^+$ change during the spin crossover process in the solid state. Temperature dependence of the crystal and molecular structures of [Fe(OETPP)Py_2]$^+$ and [Fe(OMTPP)Py_2]$^+$ is instructive.[209,212] Figure 44 shows the molecular structures of [Fe(OETPP)Py_2]$^+$ and [Fe(OMTPP)Py_2]$^+$ determined at 298 K, together with the perpendicular displacements of the peripheral atoms from the least-squares plane.[209,212] The maximum deviation among the $C_{20}N_4Fe$ core is observed for one of the pyrrole β carbon atoms, which is 1.31 Å for [Fe(OETPP)Py_2]$^+$ and 1.10 Å for [Fe(OMTPP)Py_2]$^+$. Deviation of the *meso*-carbon from the least-squares plane is at most 0.05 Å in [Fe(OETPP)Py_2]$^+$, while it is as much as 0.19 Å in [Fe(OMTPP)Py_2]$^+$. Thus, the OETPP complex adopts a pure saddled structure while the OMTPP core includes some ruffling. This does not mean that the saddled OMTPP core is generally much easier to ruffle than the corresponding OETPP core. In fact, the structural analysis of [Fe(OMTPP)(^{t}BuNC)$_2$]$^+$ reveals

that the OMTPP core shows a quite pure saddled structure in spite of the coordination of ^{t}BuNC, which usually induces the ruffled deformation of the porphyrin core.[123] Table 24 lists the crystallographic and structural data for $[Fe(OETPP)Py_2]^+$.[212] The axial and equatorial bond lengths given at three different temperatures clearly indicate that most of the bonds contract at lower temperature. The shortening of the axial bonds is much larger than that of the equatorial ones. The average axial and equatorial bonds, Fe–N_{ax} and Fe–N_p, have shown 9.5% and 1.4% contraction, respectively, as the temperature is lowered from 298 to 80 K. The data in Table 24 also demonstrate that the bond contraction between 298 and 180 K is much larger than that between 180 and 80 K; the bond contraction for Fe–N_{ax} is 0.160 and

0.048 Å for each temperature range, respectively, while that for Fe–N_p is 0.031 and < 0.01 Å.[212]

Another notable change in structure is the rotation angle ϕ of the pyridine ligand; ϕ is defined as the dihedral angle between the coordinated pyridine and N_p–Fe–N_{ax} plane. The pyridine ligands are placed almost along the diagonal Np–Fe–Np axes perpendicularly above and below the porphyrin; ϕ values for two ligands are fairly small, 1.1° and 3.6°, at 298 K. The rotation angle increases, however, from 1.1° and 3.6° to 6.3° and 9.7° as the temperature is lowered to 80 K. The increase in the rotation angle can be ascribed to a shortening of the Fe–N_{ax} bond at lower temperatures.

Because of the bond contraction, the steric repulsion between the ligand and pyrrole nitrogen atoms should increase. Thus, the conformation at $\theta = 3.6°$, which is most stable at 298 K, where Fe–N_{ax} is 2.201 Å, is no longer stable at 80 K, where Fe–N_{ax} is 1.993 Å. These results suggest that the rotation of the axial ligand is quite important for minimizing steric repulsion that is caused by bond contraction at lower temperatures. Figure 45 illustrates how the molecule adjusts its structure to maintain the most stable conformation as the temperature is raised or lowered.[212]

The data in Table 24a indicate that the unit cell decreases by 9.3% in volume on going from 298 to 80 K because of packing forces. In this crystal, the *a*, *c*, and *b* axes almost coincide with the N1–N3, N2–N4, and N5–N6 axes, respectively; N1, N2, N3, and N4 are porphyrin nitrogen atoms, while N5 and N6 are pyridine nitrogen atoms. Examination of the crystal data in Table 24 reveals that the lattice contractions along the *a*, *c*, and *b* axes are 1.2%, 1.9%, and 3.3%, respectively, in the temperature range of 298–180 K. Correspondingly, the bond contraction takes

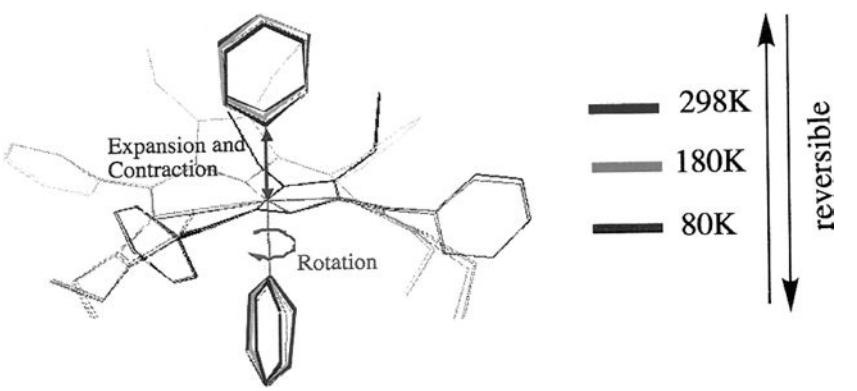

Figure 45. Temperature-dependent structural change in $[Fe(OETPP)Py_2]^+$ at three different temperatures. (Adapted with permission from Ref. 200. Copyright 2002, American Chemical Society.)

place by 1.0%, 2.2%, and 7.3% for Fe1–N1(N3), Fe1–N2(N4), and Fe1–N5(N6), respectively. It should be noted that, as the temperature is lowered from 298 to 180 K, the largest contraction of the unit cell occurs along the *b* axis, which results in the largest contraction of the Fe–N_{ax} bonds. *It is this shortening of the axial bonds that destabilizes the* d_{z^2} *orbital and induces the spin transition from S* = 3/2 *to S* = 1/2.[209]

The phenomenon observed in the crystal seems to be closely connected with the functional tuning process of some heme proteins such as leghemolobin in the dioxygen binding process.[213] Orientation changes of the proximal and distal histidine ligands together with Fe–N bond contraction induce a change in the spin state. In this sense, the crystal of $[Fe(OETPP)Py_2]^+$ may be regarded as a superstructure parallel to a protein matrix in its constraining function.[212]

C. Spin Crossover Between S = 3/2 and S = 5/2

1. *Monoaqua Complexes of Saddled Porphyrins*

In the previous section, it was reported that highly saddled complexes with fairly weak axial ligands such as $[Fe(OETPP)(THF)_2]ClO_4$ and $Fe(OETPP)ClO_4$ adopt a quite pure intermediate-spin state.[98,181] Furthermore, the analogous complexes such as $[Fe(OETPP)(Py)_2]^+$ and $[Fe(OMTPP)(Py)_2]^+$ with much stronger nitrogen bases exhibit a novel spin crossover between S = 3/2 and S = 1/2.[100,209,212] Similar spin crossover has been reported by Rivera and coworkers in the heme metabolism process mediated by human heme oxygenase.[206,207] While the spin crossover between S = 5/2 and S = 1/2 and between S = 3/2 and S = 1/2 have been observed both in heme proteins and in model heme complexes, the spin crossover between S = 5/2 and S = 3/2 has never before been observed.

As previously mentioned, the mixed S = 5/2 and S = 3/2 spin state is considered to be a quantum-mechanical spin admixture caused by spin–orbit coupling between the S = 3/2 and S = 5/2 spin states.[150,151] However, Ohgo and coworkers have found that highly saddled complexes $[Fe(OMTArP)(H_2O)]ClO_4$, where Ar is 3,5-dimethylphenyl (3,5-Me_2Ph) and 3,5-bis(*tert*-butlyl)phenyl (3,5-$^t Bu_2$Ph), exhibit an unprecedented example of spin crossover between the S = 3/2 and S = 5/2 spin states.[101] Figure 46 shows the X-ray molecular structures of these complexes, both of which have highly saddled five-coordinated monoaqua complexes.[101] Table 25 shows geometric parameters of these complexes together with those of some analogous complexes.[101] Short Fe–Np bond lengths together with the small out-of-plane displacement of the iron(III) ion indicate that these complexes are in the intermediate-spin state. Extremely downfield-shifted methyl signals together with downfield-shifted *o*- and *p*-H signals in the ^{1}H NMR spectra

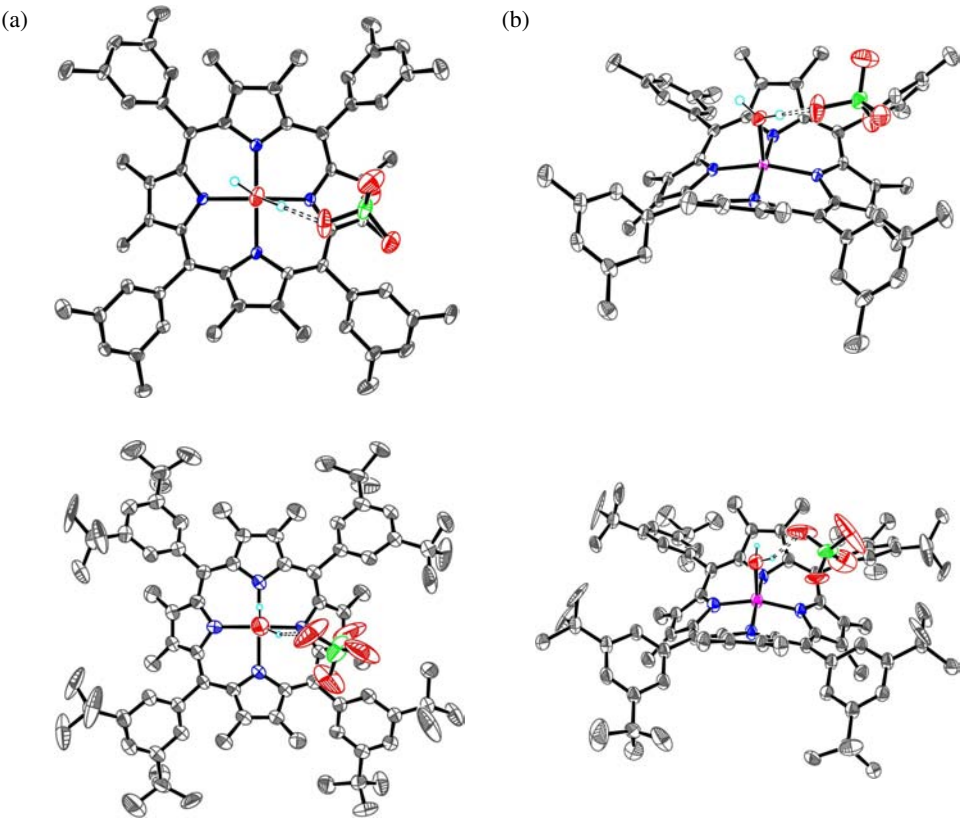

Figure 46. Molecular structures of $[Fe(OETArP)(H_2O)]^+$, where (a) Ar = 3,5-Me_2Ph and (b) Ar = 3,5-^{t}Bu_2Ph. Hydrogen bonds are shown as dotted lines. (Adapted with permission from Ref. 101. Copyright 2006, Royal Chemical Society.)

also support the intermediate-spin state proposal for these complexes; the chemical shifts of the py-CH_3, *o*-H, and *m*-H signals are 60.1, 11.7, and 9.12 ppm, respectively, for the 3,5-Me_2Ph complex, and 60.4, 11.7, and 9.12 ppm, respectively, for the 3,5-^{t}Bu_2Ph complex.

Temperature-dependent EPR spectra taken in frozen CH_2Cl_2 solution are given in Figure 47.[101] As shown in this figure, both complexes exhibit a strong signal at *ca*. 4.0 at 70 K, indicating that they adopt the intermediate-spin state. As the temperature is lowered, the intensity of the signal at 4.0 decreases while that at 6.0 increases. The EPR spectra at 4 K exhibit two types of signal characteristic of the high-spin and intermediate-spin species. The *g* values, determined by computer simulations of the observed spectra, are as follows: (a) 6.10, 5.90, 2.00 (S = 5/2) and 4.20, 3.80, 2.10 (S = 3/2); (b) 6.10, 5.90, 2.00 (S = 5/2); 4.37, 3.77, 1.99 (S = 3/2). When the temperature is further lowered, the intensity of the high-spin

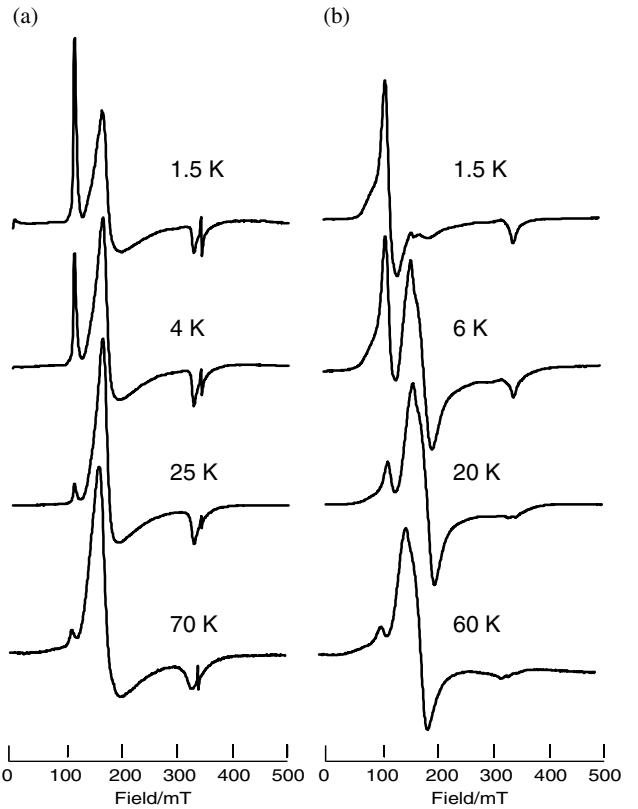

Figure 47. EPR spectra of [Fe(OMTArP)(H_2O)]$^+$ taken in frozen CH_2Cl_2 solution, where (a) Ar = 3,5-Me_2Ph and (b) Ar = 3,5-$^t Bu_2$Ph. (Adapted with permission from Ref. 101. Copyright 2006, Royal Society of Chemistry.)

signal increases, especially in the 3,5-^{t}Bu$_2$Ph complex; this complex exists exclusively as a high-spin complex at 4.2 K. The process is reversible, because the original spectra are completely reproduced when the temperature is raised back to 70 K. The temperature dependence of the EPR spectra could best be explained in terms of the unprecedented spin crossover between S = 5/2 and S = 3/2. The populations of each species are determined by computer simulations of the observed spectra. The van't Hoff plots yield $\Delta H°$ and $\Delta S°$ values corresponding to the equilibrium given in Eq. 21.

$$S = \frac{5}{2} \underset{\longleftarrow}{\overset{K}{\longrightarrow}} S = \frac{3}{2}. \tag{21}$$

The values are 60 J·mol^{-1} and 48·J·mol^{-1}·K^{-1} for the 3,5-Me$_2$Ph, and 100 J·mol^{-1} and 19 J·mol^{-1}·K^{-1} for 3,5-^{t}Bu$_2$Ph complexes, respectively.

2. *Monoazide Complexes*

Neya and coworkers have found that the azide complex of iron(III) porphycene, [Fe(TPrPc)N$_3$], exhibits interesting spectroscopic and magnetic behavior.[154] In the ^{1}H NMR spectra, the pyrrole-H signal appears at 19 ppm at 298 K and shifts to −30 ppm when the temperature is lowered to 200 K. The EPR spectrum is nearly axial with $g_\infty = 5.41$(ave) and $g_\parallel = 2.00$, suggesting that Int(%) = 30% at 5 K. The QS value in the Mössbauer spectrum increases from 2.20 mm s^{-1} at 290 K to 2.68 mm s^{-1} at 77 K, which also supports the S = 3/2 contribution increasing at lower temperature. The effective magnetic moment is 4.80 μ_B at 290 K and decreases to 4.06 μ_B at 50 K. All of these data suggest that the complex is in a mixed S = 5/2 and S = 3/2 spin state. It is very difficult to determine if the complex is in a thermal equilibrium between S = 5/2 and S = 3/2, or in a spin admixture of the two spin states; all the complexes except [Fe(OETArP)(H$_2$O)]$^+$ exhibit averaged NMR, EPR, and Mössbauer signals.[101] Neya and coworkers considered IR spectroscopy to be a good method for observing directly the two spin state isomers expected for [Fe(TPrPc)N$_3$]. This is because the approximate time scale of IR is 10^{-13} s, which is shorter than the time scales of EPR, NMR, and Mössbauer spectroscopy; they are are 10^{-4}–10^{-8}, 10^{-1}–10^{-9}, and 10^{-7} s^{-1}, respectively.[212] Consequently, IR spectroscopy should discriminate the thermal spin-state equilibrium from the quantum-mechanical spin admixture. In fact, the IR spectra given in Figure 48 show two separate absorptions centered at 2049 and 2066 cm^{-1}. They are assigned to the azide stretching band for the S = 3/2 and S = 5/2 spin-state isomers, respectively. Increase of the 2049 cm^{-1} band and concomitant decrease of the 2066 cm^{-1} band with decreasing temperature, accompanied by the 2054 cm^{-1} isosbestic point,

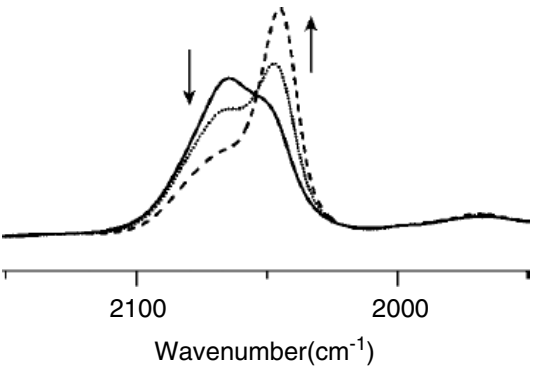

Figure 48. The IR absorption spectra of Fe(T^nPrPc)N_3 in chloroform. Temperature decreases (295, 254, 216 K) as indicated by the arrow. (Adapted with permission from Ref. 154. Copyright 2007, Wiley-VCH Verlag GmbH & Co. KGaA.)

demonstrate that the S = 5/2 and S = 3/2 isomers are in a thermal equilibrium. The IR analysis further reveals that [Fe(T^iPrP)N_3] also exhibits a similar spin crossover between S = 5/2 and S = 3/2.[155] Thus, it seems that spin crossover phenomena are possible between any two of the three spin states in iron(III) porphyrin complexes.[101,154,155]

D. Spin Crossover in Monoimidazole Complexes

Cytochromes c′ are a unique class of heme proteins found in photosynthetic, denitrifying, and nitrogen-fixing bacteria.[215] These proteins are usually found as dimers. In spite of low homology in the amino acid sequences, the overall folding of the monomers is similar. They possess a heme prosthetic group covalently bound to the protein via two thioether linkages that are provided by a conserved Cys–X–Y–Cys–His motif near the C-terminal region.[215–222] The heme iron is five-coordinate with a solvent-exposed histidine residue. Although X-ray crystallographic analyses have revealed the structural similarity among these proteins, the microenvironment around the heme center is slightly different among the proteins. Thus, the solvent-exposed histidine residue can participate in hydrogen bonding with water molecules and/or basic protein residues in a slightly different way among the proteins. These proteins are considered to adopt a unique spin state, a quantum-mechanical admixture of a high-spin (S = 5/2) and an intermediate-spin (S = 3/2) state,[150,151] although some examples have been found showing the thermodynamic equilibrium between S = 5/2 and S = 3/2 spin state isomers, as described in the previous section.[101,154–156] The contribution of the S = 5/2 or 3/2 state changes depending on the bacterial source and the spectroscopic methods

applied for the measurements.[223] In most cases, the oxidized form of iron is predominantly in the S = 5/2 spin state though the contribution of the S = 3/2 state increases in cytochromes c′ isolated from some bacteria, such as C. *vinosum* and *Rb. capsulatus*.[223] To reveal the ambiguous spin state of these proteins, both structural and spectroscopic studies with synthetic monoimidazole complexes are necessary. In fact, the isolation of monoimidazole complexes is quite difficult because of the formation of the corresponding stable bis-adducts.[224–227] The only structurally characterized complex is [Fe(OEP)(2-MeIm)]ClO_4, reported by Scheidt *et al.* in 1985.[228] This complex maintains the S = 5/2 state at least above 60 K. In this section, the spectroscopic, magnetic, and crystallographic properties of monoimidazole complexes such as $[Fe(TMP)L]^+$,[229,230] $[Fe(TMTMP)L]^+$,[231] and $[Fe(OETPP)L]^+$ will be described.[232]

1. *[Fe(TMP)L]⁺ and [Fe(TMTMP)L]⁺*

In principle, it is possible to obtain monoimidazole complexes by the reaction of iron(III) porphyrins with a 1.0 equivalent of the imidazole ligand. In the case of the reaction between Fe(TPP)ClO_4 and 1-MeIm, however, not only [Fe(TPP)(1-MeIm)]$^+$ but also [Fe(TPP)(1-MeIm$_2$)]$^+$ is formed. Furthermore, contamination with water leads to the formation of μ-oxo dimer $[Fe(TPP)]_2O$ according to the reaction mechanism shown in Scheme 2.[229] If a 1.0 equivalent of sterically hindered imidazole such as 1,2-Me_2Im or 2-MeBzIm is added in place of 1-MeIm, then the μ-oxo dimer is formed predominantly, together with a small amount of monoimidazole complex.[229] It is then expected that the addition of a 1.0 equivalent of hindered imidazoles to [Fe(TMP)]ClO_4 could form the corresponding monoimidazole complexes [Fe(TMP)L]ClO_4 as the sole product, since formation of the μ-oxo dimer is prohibited due to the presence of the *o*-methyl groups. In fact, a quite pure monoimidazole complex can be obtained by the addition of a 1.0 equivalent of the hindered ligand.[230] Figure 49 shows the ^{1}H NMR spectrum of (a) [Fe(TMP)]ClO_4 and (b) $[Fe(TMP)(2\text{-MeIm})]^+$ taken in CD_2Cl_2 solution at 298 K.[230] The pyrrole-H signal of $[Fe(TMP)(2\text{-MeIm})]^+$ is observed at 35.1 ppm, suggesting that the complex adopts the mixed high-spin and intermediate-spin state. Because of the five-coordinate structure, two *m*-H signals are observed at 14.3 and 13.2 ppm.

$$Fe(TPP)ClO_4 + H_2O \rightleftharpoons [Fe(TPP)(H_2O)]ClO_4$$

$$[Fe(TPP)(H_2O)]ClO_4 + L \rightleftharpoons Fe(TPP)(OH) + HL^+ClO_4^-$$

$$Fe(TPP)(OH) + Fe(TPP)ClO_4 + L \rightleftharpoons [Fe(TPP)]_2O + HL^+ClO_4^-$$

Scheme 2. Mechanism for the formation of μ-oxo dimmer.

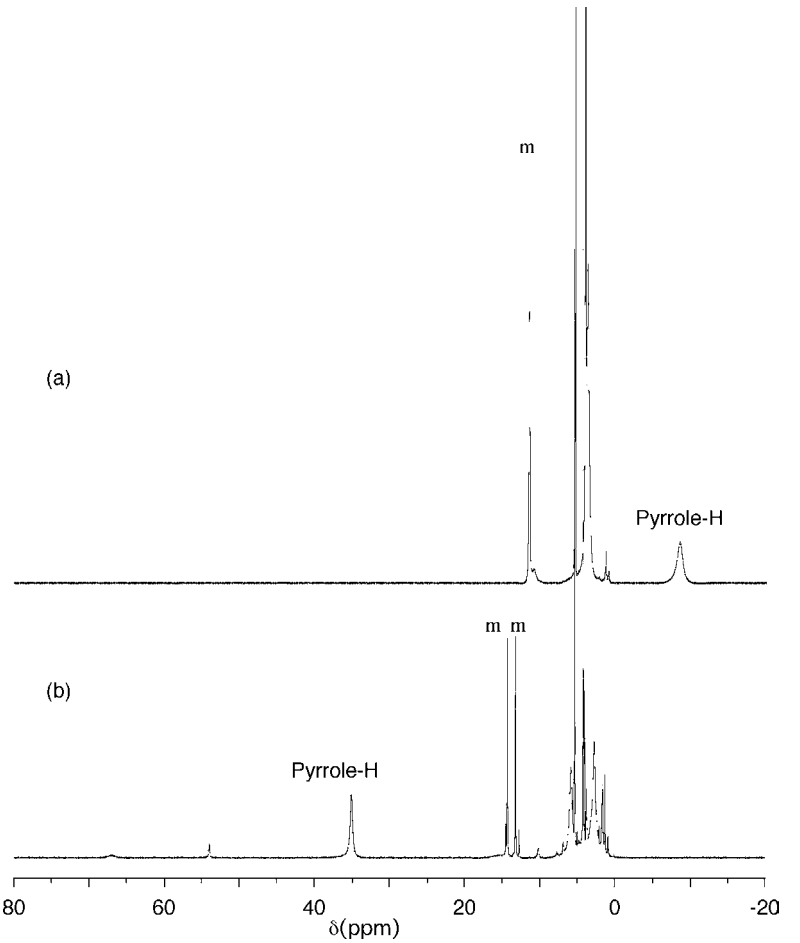

Figure 49. ^{1}H NMR spectra of (a) Fe(TMP)ClO_4 and (b) [Fe(TMP)(2-MeIm)]$^+$ taken in CD_2Cl_2 at 298 K. (Adapted with permission from Ref. 230. Copyright 2002, American Chemical Society.)

Table 26a lists the ^{1}H NMR chemical shifts of a series of [Fe(TMP)L]ClO_4 together with the Int(%) values obtained from Eq. 16, where the chemical shifts of the high-spin and intermediate-spin complexes, δ_{high} and δ_{int}, are considered to be +80 and −60 ppm, respectively.[230] Table 26b shows the ^{1}H NMR chemical shifts of a series of [Fe(TMTMP)L]ClO_4, where the mesityl and methyl groups are attached to the C_β atoms and no substituent is attached to the *meso*-C atoms.[231]

Among the axial ligands listed in Table 26a, there is no doubt that 4,5-Cl_2Im stabilizes the intermediate-spin state most effectively, which should be ascribed to the weaker σ-donating and stronger π-accepting ability as compared with other ligands. In contrast, 2-^{t}BuIm greatly stabilizes the high-spin state; the pyrrole-H signal is observed at 78.4 ppm, which indicates that Int(%) is only 1%. In the case

Table 26. 1H NMR chemical shifts (d, ppm) of (a) $[Fe(TMP)L]ClO_4$[a] and (b) $[Fe(TMTMP)L]ClO_4$[b] determined at 298 K in CD_2Cl_2 solution together with Int(%).

[a]Ref. 230. [b]Ref. 231. [c]Data in parentheses are the chemical shifts at 193 K. [d]Data are obtained by extrapolation from low temperature. [e][Fe(TMP)Cl]. [f]$[Fe(TMP)]ClO_4$.

of $[Fe(TMP)(2\text{-}^t BuIm)]ClO_4$, the distance between the ligand and the porphyrin ring should be the largest among the complexes listed in Table 26a because of the severe steric repulsion between the *tert*-butyl group and the porphyrin core. As a result, the iron(III) ion is pulled toward the imidazole nitrogen, which increases the out-of-plane distance of the iron(III) ion and stabilizes the high-spin state. The out-of-plane distance should decrease as the axial ligand changes from 2-^{t}BuIm to 2-(1-EtPr)Im, and then to 2-RIm (R = Me, Et, ^{i}Pr), resulting in stabilization of the intermediate-spin state of the corresponding complexes. In fact, the Int(%) values of the 2-(1-EtPr)Im and 2-RIm (R = Me, Et, ^{i}Pr) complexes are 19% and 32–35%, respectively.

The data in Table 26a also indicate that the introduction of the 1-Me group to the 2-Rim (R = Et, ^{i}Pr) ligand stabilizes the intermediate-spin state. Thus, the

pyrrole-H chemical shift moves upfield from 4.4 to −23.5 ppm at 193 K as the axial ligand changes from 2-^{i}PrIm to 1-Me-2-^{i}PrIm. A similar upfield shift, from 16.9 to −12.0 ppm, is observed as the axial ligand changes from 2-EtIm to 1-Me-2-EtIm. However, the pyrrole-H signal shows no appreciable change as the axial ligand changes from 1-MeIm to 1,2-Me_2Im. Introduction of the 1-Me group should regulate the conformation of the 2-^{i}Pr and 2-Et substituents in such a way that the Me groups of these substituents face the porphyrin ring. As a result, the tilting angle of the Fe–N_{axial} bond from the heme normal should increase by the introduction of the 1-Me group, which weakens the field strengths of these ligands and stabilizes the intermediate-spin state.

Table 27 lists the ^{13}C NMR chemical shifts where axial ligands are arranged in the same order given in Table 26. The chemical shifts of the C_α and C_β signals correlate well with those of the pyrrole-H chemical shifts. On the basis of the data in Tables 26 and 27, the order of the Int(%) values in the imidazole complexes is given by Eq. 22:[230]

$$\begin{aligned} 2\text{-}^{t}\text{BuIm} << 2\text{-(1-EtPr)Im} < \text{HIm, 5-MeIm, 2-RIm (R = Me, Et, }^{i}\text{Pr)}, \\ 1,2\text{-Me}_2\text{Im} < \text{1-Me-2-RIm (R = Et, }^{i}\text{Pr)} < 4,5\text{-Cl}_2\text{Im}. \end{aligned} \quad (22)$$

It is interesting to discuss how the spin state of a monoimidazole complex is affected by the solvents. While the pyrrole-H signal is observed at 35.0 ppm in

Table 27. ^{13}C NMR chemical shifts (δ, ppm) of some carbon signals in [Fe(TMP)L]ClO_4 determined at 298 K in CD_2Cl_2 solution.

[a][Fe(TMP)Cl]. [b][Fe(TMP)]ClO_4. (Source: Ref. 230.)

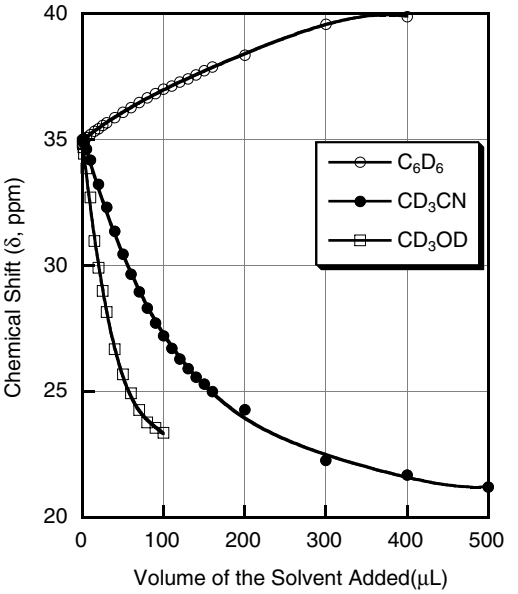

Figure 50. Change in chemical shifts of the pyrrole protons observed by the addition of various amounts of C_6D_6, CD_3CN, or CD_3OD into a CD_2Cl_2 solution of [Fe(TMP)(2-MeIm)]ClO_4 at 25 °C. (Adapted with permission from Ref. 230. Copyright 2002, American Chemical Society.)

CD_2Cl_2 solution, it moves upfield as a polar solvent such as CD_3CN or CD_3OD is added to the CD_2Cl_2 solution of [Fe(TMP)(2-MeIm)]ClO_4; the pyrrole signals reachs 27.2 and 23.4 ppm in CD_2Cl_2 solutions containing 15% CD_3CN and 15% CD_3OD, respectively. In contrast, the pyrrole signal moves downfield, and appears at 37.0 ppm in CD_2Cl_2 solutions containing 15% of nonpolar C_6D_6. Figure 50 shows the change in chemical shifts of the pyrrole signals observed by addition of (a) C_6D_6, (b) CD_3CN, and (c) CD_3OD.[230] The upfield shift of the pyrrole-H signals in polar solvents corresponds to the increase in the intermediate-spin character. This result indicates that the Fe(III)–N_{axial} bond is weakened as the polarity of the solvent increases. In other words, the 2-MeIm ligand behaves as a weaker ligand in a polar solvent than in a less polar solvent. Thus, the Fe(III) ion is pulled toward the center of the N_4 cavity, resulting in an increase in Int(%). In nonpolar solvents such as benzene, the Fe(III)–N_{axial} bond is strengthened, resulting in a decrease in Int(%). In the present study, it has been shown experimentally that the population of the S = 3/2 isomer increases as polar solvents such as methanol and acetonitrile are added. It is expected that the NH of the coordinated imidazole ligand participates in hydrogen bonding with polar solvents such as methanol. If this is the case, the hydrogen bonding would increase the S = 3/2 contribution. In fact, the X-ray crystallographic analysis of *Rb. capsulatus* has shown hydrogen bonding between

the coordinated imidazole(His122) and a water molecule.[219] Correspondingly, the S = 3/2 contribution of cytochrome c′ reached as high as 40%.[223] In contrast, the structural analysis of *R. molischianum* has shown that the coordinated imidazole (His122) is not involved in hydrogen bonding.[233] Therefore, the S = 3/2 contribution decreased to 13% as determined by EPR spectgroscopy;[223] the S = 3/2 contribution was estimated to be 0% by ^{1}H NMR spectroscopy.[234] On the basis of these results, it is proposed that *the hydrogen bonding of solvent molecules to the coordinated histidyl imidazole ligand somewhat weakens the ligand field strength and increases the S* = 3/2 *contribution in the mixed S* = 5/2, 3/2 *spin system.*[230]

2. *[Fe(OETPP)L]$^+$*

In the previous section, spectroscopic studies of the spin state of a wide variety of monoimidazole model complexes, $[Fe(TMP)L]^+$, were described. However, structural studies of these monoimidazole complexes have been hampered because of the difficulty of obtaining good crystals.[225] Ikezaki and coworkers have prepared the saddle-shaped monoimidazole complexes, $[Fe(OETPP)L]ClO_4$, and determined their crystal and molecular structures.[232] In this section, the spectroscopic and magnetic properties of structurally characterized $[Fe(OETPP)L]ClO_4$, where L is Him and 2-MeIm, will be described together with spectroscopic data of the L = 2-MeBzIm complex.

These complexes are prepared by the addition of a 1.0 equivalent of HIm, 2-MeIm, or 2-MeBzIm, respectively, to CH_2Cl_2 solutions of $[Fe(OETPP)(THF)_2]ClO_4$. Figure 51 shows the molecular structure of $[Fe(OETPP)(2\text{-MeIm})]ClO_4$

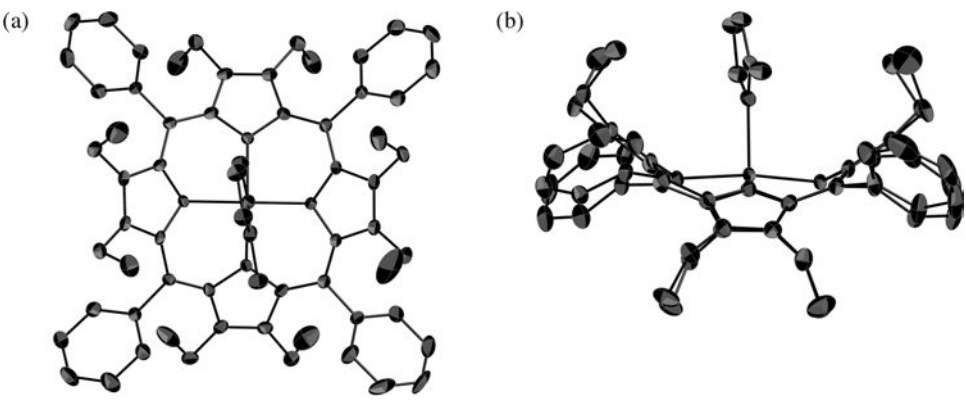

Figure 51. Molecular structure of $[Fe(OETPP)(2\text{-MeIm})]ClO_4$ presented by ORTEP diagrams: (a) viewed from the top and (b) viewed from the side. Thermal ellipsoids are drawn to enclose 50% probability. (Adapted with permission from Ref. 232. Copyright 2009, Wiley-VCH Verlag GmbH & Co. KGaA.)

[a]Spin state.

determined by X-ray crystallography at 120 K. Table 28 lists the structural parameters of these complexes together with those of the analogous five-coordinate complexes. As shown in Figure 51, $[Fe(OETPP)(2\text{-}MeIm)]^+$ exhibits a highly saddled porphyrin core. The average Fe–N_p lengths are 1.969(3) Å, which is quite close to the average Fe–N_p length of S = 3/2 Fe(OETPP)ClO_4, i.e. 1.963(7) Å,[181] and is much shorter than that of S = 5/2 $[Fe(OEP)(2\text{-}MeIm)]^+$, i.e. 2.038(6) Å.[228] In contrast, the Fe–N_{axial} bond length of $[Fe(OETPP)(2\text{-}MeIm)]^+$ is slightly larger than that of $[Fe(OEP)(2\text{-}MeIm)]^+$. The axial 2-MeIm ligand is aligned along the N–Fe–N axis. Deviation of the Fe(III) ion from the 4N mean plane is small, 0.26 Å, which is again quite close to that of Fe(OETPP)ClO_4, 0.25 Å.[181a] The similarity between the structural parameters of $[Fe(OETPP)L]^+$ (L = HIm, 2-MeIm) and those of Fe(OETPP)ClO_4 suggests that the monoimidazole complexes adopt the S = 3/2 form in the solid state at 120 K.

The intermediate-spin state of these complexes can also be verified by Mössbauer spectroscopy. Figure 52 shows the Mössbauer spectra taken for microcrystalline samples in the temperature range of 300–80 K. In both $[Fe(OETPP)(HIm)]^+$ and $[Fe(OETPP)(2\text{-}MeIm)]^+$, the QS values are almost constant, 3.06 ± 0.01 and 3.03 ± 0.01 mm s^{-1}, respectively. Even at 4 K the QS values are nearly the same. On the basis of the X-ray crystallographic and Mössbauer spectroscopic studies, it is concluded that the two kinds of monoimidazole complexes retain the $S = 3/2$ state over a wide range of temperature, i.e. from 4 K to 300 K in the solid state.[232]

Although these complexes adopt the intermediate-spin state in the solid, they could adopt a different spin state in solution, as exemplified for Fe(TEtPrP)I.[80] The spin state in solution can be determined by ^1H NMR, ^{13}C NMR, and EPR spectroscopy.

Table 29 lists the ^1H NMR and ^{13}C NMR chemical shifts determined in CD_2Cl_2 solutions at 298 K. Curie plots of the signals in these complexes exhibit good linearity, suggesting that they maintain a single spin state over the NMR temperature range, i.e. 298–173 K. Negative $\delta(meta)$–$\delta(para)$ values together with the negative

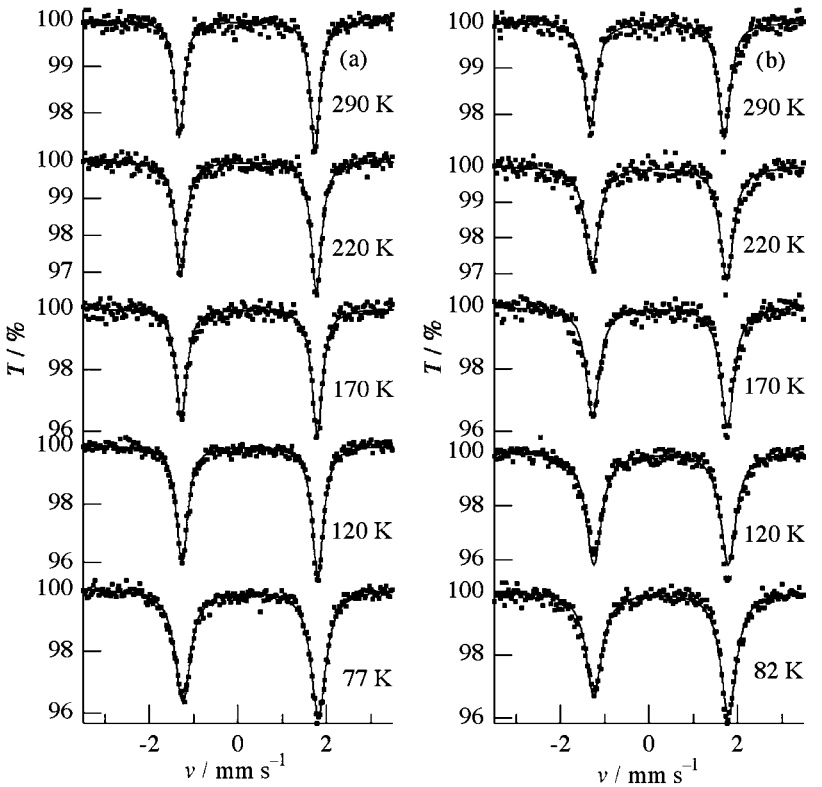

Figure 52. Mössbauer spectra of (a) [Fe(OETPP)(HIm)]$^+$ and (b) [Fe(OETPP)(2-MeIm)]$^+$ taken for the microcrystalline samples. (Adapted with permission from Ref. 232. Copyright 2009, from Wiley-VCH Verlag GmbH & Co.)

Curie slopes of the *m*-H signals indicate that the *meso*-carbon atoms have negative spin, which in turn indicates that these complexes adopt the S = 3/2 state; five-coordinate high-spin Fe(III) porphyrins should have positive spin at the *meso*-carbon atoms and thus give positive $\delta(meta)$–$\delta(para)$ values, as in the case of Fe(OETPP)Cl. The solution magnetic moment of [Fe(OETPP)(2-MeIm)]$^+$ determined by the Evans method is 4.2 μ_B at 298 K and is invariant down to 173 K. This value is close to the spin-only value expected for the S = 3/2 spin state.

^{13}C NMR chemical shifts of these complexes are also listed in Table 29. The C_α and C_β signals appear considerably further upfield than those in high-spin Fe(OETPP)Cl, which can be ascribed to the presence of the vacant $d_{x^2-y^2}$ orbital. Considerable upfield shifts of the *meso* signal, −79, −54, and 11 ppm for the HIm, 2-MeIm, and 2-MeBzIm complexes, respectively**,** satisfy the condition required for the saddle-shaped intermediate-spin complexes. Large upfield shifts are also observed for the CH_2 signals. The average chemical shifts of these signals are

Table 29. ^{1}H and ^{13}C NMR chemical shifts of Fe(OETPP)Cl, Fe(OETPP)ClO_4, and [Fe(OETTPP)L]$^{+}$, where L = HIm, 2-MeIm, and 2-MeBzIm taken in CD_2Cl_2 at 298 K.

[a]Signals at 19.5 and 57.0 ppm correspond to 4H. Other signals correspond to 2H. [b]Signals at −1.0, −0.3, and 1.0 ppm correspond to 6H, 6H, and 12H, respectively. [c]Either C_α or C_β signals. [d]^{1}H NMR: Ref. 182. ^{13}C NMR: Ref. 232.

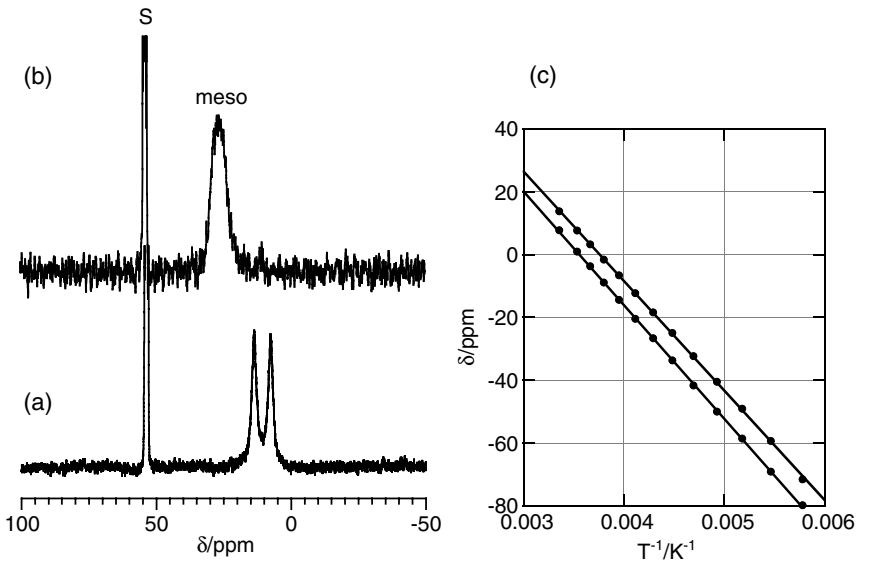

Figure 53. Temperature dependence of the *meso*-C signals in [Fe(OETPP)(2-MeBzIm)]$^+$ at (a) 298 K and (b) 338 K. (c) Curie plots of the *meso*-C signals. (Adapted with permission from Ref. 232. Copyright 2009, Wiley-VCH Verlag GmbH & Co.)

almost constant, –48, –49, and –45 ppm, which are close to the corresponding chemical shift in intermediate-spin Fe(OETPP)ClO_4. Thus, the ^{13}C NMR results also suggest that these complexes are in the S = 3/2 spin state in CD_2Cl_2 solution.

As shown in Figure 53a, the *meso*-C shows two signals at 7.7 and 13.6 ppm at 298 K, suggesting that the ligand rotation about the Fe–N_{axial} bond is slow on the NMR time scale, even at ambient temperature.[90–93,235–239] These signals have broadened and coalesced at 338 K as shown in Figure 53b, from which the activation free energy ($\Delta G^{\neq}$) for rotation is estimated to be 64 kJ mol^{-1}. A similar phenomenon is observed in the 2-MeIm complex at lower temperature; $\Delta G^{\neq}$ is 35 kJ mol^{-1} at 197 K. In contrast, the HIm complex maintains a single *meso*-C signal even at 183 K. The extremely high barrier to rotation in the 2-MeBzIm complex can be ascribed to the fact that the bulky 2-MeBzIm ligand is situated in the cavity created by the saddled porphyrin ring, as is speculated from the molecular structure of the analogous 2-MeIm complex shown in Figure 51b.

Figure 54 shows the EPR spectra of the HIm and 2-MeIm complexes taken in frozen CH_2Cl_2 solution. As shown in Figure 54a, the 2-MeIm complex exhibits a major signal at $g = 5.9$ together with a minor signal at $g = 4.0$, which clearly indicates that the major component adopts the S = 5/2 state at 60 K. As the temperature is further lowered, the signal at $g = 4.0$ decreases in intensity and completely disappears at 4 K. Thus, the [Fe(OETPP)(2-MeIm)]$^+$ complex is in a quite pure

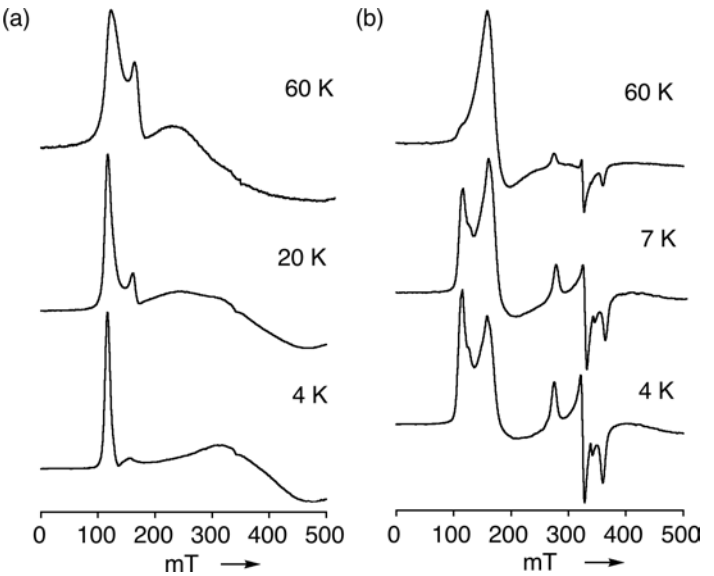

Figure 54. Temperature-dependent EPR spectra of (a) $[Fe(OETPP)(2\text{-MeIm})]^+$ and (b) $[Fe(OETPP)(HIm)]^+$ recorded in CH_2Cl_2 solution. (Adapted with permission from Ref. 232. Copyright 2009, Wiley-VCH Verlag GmbH & Co.)

S = 5/2 state at 4 K. The process is reversible, since the original spectrum is completely reproduced when the temperature is raised back to 60 K. The NMR and EPR spectra can best be explained in terms of spin crossover from the S = 3/2 to the S = 5/2 spin state as the temperature is lowered.

The EPR spectra of the HIm complex shown in Figure 54b are even more unusual. This complex exhibits a major signal at $g = 4.0$ at 60 K though some weak signals are observed at a higher field. As the temperature is lowered, the signal at $g = 4.0$ decreases in intensity while the signals at $g = 6.0$, 2.5, 2.1 increase. At 4 K, the HIm complex exists as a mixture of three species with different spin states: an S = 5/2 species with $g_\perp = 6.0$, an S = 3/2 species with $g_\perp = 4.0$, and an S = 1/2 species with $g = 2.47$, 2.10, 1.55. Formation of the S = 1/2 and S= 5/2 complexes can be ascribed to the disproportionation given by Eq. 23:

$$2[Fe(OETPP)(HIm)]^+ \leftrightarrows [Fe(OETPP)(HIm)_2]^+ + Fe(OETPP)ClO_4. \qquad (23)$$

This possibility is, however, completely ruled out, since $Fe(OETPP)ClO_4$ is well characterized as an essentially pure S = 3/2 complex.[37,180,181] Furthermore, the g values of $[Fe(OETPP)(HIm)_2]ClO_4$ determined under the same conditions are 2.72, 2.37, and 1.64, which are different from those of the S = 1/2 complex observed at 4 K.[82] Thus, it is reasonable to deduce that the S = 5/2 and S = 1/2

complexes are spin isomers and that they exist as an equilibrium mixture with the S = 3/2 complex.

Existence of the three kinds of spin isomers indicates that there are three different structures in [Fe(OETPP)(HIm)]ClO_4 at extremely low temperatures. The spin crossover from the S = 3/2 to the S = 1/2 spin state at lower temperature induces a contraction of the Fe–N(axial) and Fe–N(equatorial) bonds, as in the case of [Fe(OETPP)Py_2]$^+$ listed in Table 24(b).[212] Similar spin crossover is known in the five-coordinate iron(II) porphyrin [Fe(TPP)(CN)]$^-$ reported by Scheidt and coworkers.[234] This complex exhibits a decrease in both the Fe–CN bond length and the out-of-plane distance of the iron(II) ion by 0.23 and 0.28 Å, respectively, as structural consequences of the spin crossover from the S = 2 spin state at 400 K to the S = 0 spin state at 100 K.

In contrast to the spin crossover from the S = 3/2 to the S = 1/2 spin state, spin crossover from the S = 3/2 to the S = 2/5 spin state should increase the out-of-plane displacement of the iron(III) ion toward the axial imidazole ligand as the temperature is lowered. As mentioned in the previous section, the five-coordinate saddle shaped monoaqua complex [Fe(OMTArP)(H_2O)]$^+$ also exhibits spin crossover from S = 3/2 to S = 5/2 at extremely low temperature.[101]

The question arises as to why two kinds of spin crossover processes take place simultaneously only in [Fe(OETPP)(HIm)]$^+$. In the case of [Fe(OETPP)(2-MeIm)]$^+$ and [Fe(OETPP)(2-MeBzIm)]$^+$ carrying hindered imidazole ligands, the approach of the axial ligand toward the porphyrin ring should be hampered due to steric repulsion between the axial ligand and the porphyrin core. A space-filling model of the crystal structure of [Fe(OETPP)(2-MeIm)]$^+$ suggests that a further approach of the ligand toward the porphyrin ring is impossible because of steric repulsion between the ligand methyl and the *meso*-phenyl groups. For this reason, [Fe(OETPP)(2-MeIm)]$^+$ and [Fe(OETPP)(2-MeBzIm)]$^+$ exhibit only one type of spin crossover process, S = 3/2 to S = 5/2, in contrast to the case of [Fe(OETPP)(HIm)]$^+$. Thus, the electronic structure of monoimidazole complexes is quite different from those of other five-coordinate complexes, Fe(Por)X, where X is an anionic ligand such as ClO_4^- or Cl^-.

As is well known, imidazole and alkyl-substituted imidazoles are intrinsically strong-field ligands. In monoimidazole complexes, however, the field strength of imidazole varies drastically due to steric interactions with the porphyrin core and/or peripheral substituents. These steric interactions should influence not only the Fe–N_{axial} bond lengths but also the Fe–N_{axial} tilt angle from the heme normal plane. All of these structural changes affect the field strength of imidazole ligands and result in the formation of a unique complex showing the S = 5/2, S = 3/2, and S = 1/2 spin states as an equilibrium mixture. Figure 55 summarizes the magnetic behavior of [Fe(OETPP)(HIm)]$^+$. These findings cast light on the long-standing mystery of the ambiguous spin state of cytochromes c′.[215]

VI. Oxidized Products of Iron(III) Porphyrin Complexes

A. One-Electron-Oxidized Products

High-valent iron porphyrin complexes have been extensively studied both experimentally and theoretically because they play important roles in the catalytic cycles of a number of heme enzymes.[4–17] One-electron oxidation of iron(III) porphyrins should form either an iron(IV) porphyrin or an iron(III) porphyrin cation radical. However, most publications have reported the formation of iron(III) porphyrin cation radicals. These radical species give characteristic ^{1}H NMR spectra, where some of the signals appear at extraordinary upfield or downfield positions due to the presence of half-occupied porphyrin orbitals.[11,26,40]As mentioned in the previous sections, iron(III) porphyrin complexes can adopt various electronic structures, including the S = 5/2, S = 3/2, and S = 1/2 spin states.[25–35] Some complexes exhibit spin crossover phenomena between two of the three spin states. Furthermore, each spin state can have different electron configurations, as is well exemplified in the low-spin complexes which adopt either the $(d_{xy})^2(d_{xz}, d_{yz})^3$ or the $(d_{xz}, d_{yz})^4(d_{xy})^1$ electronic ground state.[25–31] Similarly, at least two types of electronic ground states exist even in the intermediate-spin complexes, i.e. $(d_{xy})^2(d_{xz}, d_{yz})^2(d_{z^2})^1$ and $(d_{xz}, d_{yz})^3(d_{xy})^1(d_{z^2})^1$.[37–39,104,168,184] The unpaired electron in the porphyrin orbital cannot be independent of the paramagnetic iron center. It can interact with the paired and/or unpaired electrons in the iron 3d orbitals. Consequently, the ^{1}H NMR spectra should be affected by the spin states and electron configurations of the iron(III) ions.[40] In the case of iron(IV) porphyrins, the iron can adopt the S = 0, S = 1, or S = 2 spin state, though no examples have ever been reported for S = 0 and S = 2. The unpaired electrons in the S = 1 complexes can be delocalized to the porphyrin ring by the interactions with the porphyrin π orbitals to give characteristic ^{1}H NMR spectra. For these reasons, ^{1}H NMR spectroscopy has been used as a powerful tool for determining the fine electronic structures of one-electron oxidized products of iron(III) porphyrins. In this section, we will describe the characteristic features of the NMR spectra of one-electron-oxidized products

of iron(III) porphyrins such as iron(III) porphyrin cation radicals and iron(IV) porphyrins. These oxidized products are signified as follows for the anionic ligand X^-; $[Fe^{III}(Por^{\cdot})]^{2+}$, $[Fe^{III}(Por^{\cdot})X]^+$, $[Fe^{III}(Por^{\cdot})X_2]$, $[Fe^{IV}(Por)]^{2+}$, $[Fe^{IV}(Por)X]^+$, and $[Fe^{IV}(Por)X_2]$. The oxidation number is added to avoid confusion.

1. *Iron(III) Porphyrin Cation Radicals*

a. *High-spin iron(III) porphyrin cation radicals*

One-electron oxidation of iron(III) porphyrins was reported by Goff *et al.*[240] These authors electrochemically oxidized a series of [Fe(TPP)X], where X is an anionic ligand such as F^-, Cl^-, Br^-, I^-, or ClO_4^-, and found that the one-electron oxidation potentials are quite insensitive to the axial ligands; the first oxidation potentials are *ca.* 1.1 V for all the complexes examined.[240] Consequently, these oxidized species are characterized as iron(III) porphyrin cation radicals, $[Fe^{III}(TPP^{\bullet})X]^+$, rather than iron(IV) porphyrins, $[Fe^{IV}(TPP)X]^+$. Marchon, Reed, and coworkers chemically oxidized $[Fe^{III}$(4-Me-TPP)Cl] by using the hexachloroantimonate salt of phenoxathiin cation radical $(Phenox^{\bullet})SbCl_6$ and obtained $[Fe^{III}$(4-Me-TPP$^{\cdot}$)Cl$](SbCl_6)$.[241] The X-ray crystal structure of $[Fe^{III}$(4-Me-TPP$^{\bullet}$)Cl$](SbCl_6)$ revealed that the crystal lattice consists of discrete $[Fe^{III}$(4-Me-TPP$^{\bullet}$)Cl$]^+$ and $SbCl_6^-$ ions where the porphyrin core is strongly S_4-saddled.[241] In the chemical oxidation of $[Fe^{III}$(TPP)Cl], the porphyrin cation radical $[Fe^{III}$(TPP$^{\cdot}$)Cl$](ClO_4)$ thus formed exhibits a pyrrole-H signal at 66.1 ppm at 299 K, which indicates that the iron(III) ion maintains the high-spin (S = 5/2) state.[242] The cation radical nature of the porphyrin ring can clearly be seen in the ^{1}H NMR spectra of these complexes. The characteristics in ^{1}H NMR spectra are the chemical shifts of the *meso*-phenyl signals. They are at 37.6, 34.4 ppm for the *o*-H, −12.4 ppm for the *m*-H, and 29.5 ppm for the *p*-H.[242] Observation of two kinds of *o*-H signals is a direct indication that the iron is five-coordinate. The presence of extremely downfield- or upfield-shifted *meso*-phenyl-H signals indicates that the *meso*-carbon atoms have a large amount of spin density, which in turn indicates that the a_{2u} orbital of the porphyrin is half-occupied. As mentioned in the previous section, the unpaired electron at the *meso*-carbon atoms should induce an upfield shift of the *o*- and *p*-H signals and a downfield shift of the *m*-H signals. Thus, the chemical shift pattern of the *meso*-phenyl signals in $[Fe^{III}(TPP^{\bullet})Cl]^+$ suggests that the *meso*-carbon atoms have a sizeable amount of negative spin, which can only be explained in terms of antiferromagnetic coupling between the radical and metal spins.[240,242] In fact, the Mössbauer spectroscopy and magnetic susceptibility studies of the solid sample indicate that the complex shows a strong antiferromagnetic coupling between the S = 5/2 iron(III) ion and the S = 1/2 porphyrin radical to lead to an

overall S = 2 spin state.[241,243,244] [Fe^{III}(TDP)Cl] is similarly oxidized to form [Fe^{III}(TDP$^{\bullet}$)Cl]$^{+}$.[245] The pyrrole-H signal appears at 72 ppm at 217 K. Upfield shifts of the *o*-CH_3 signals at −8.0 and −10.3 ppm in [Fe^{III}(TDP$^{\cdot}$)Cl]$^{+}$ correspond to the downfield shifts of the *o*-H signals in [Fe^{III}(TPP$^{\bullet}$)Cl]$^{+}$, suggesting that [Fe(TPP$^{\cdot}$)Cl]$^{+}$ and [Fe^{III}(TDP$^{\cdot}$)Cl]$^{+}$ adopt the same electronic structure.[245]

While the *meso*-phenyl signals of [Fe^{III}(TPP)Cl] exhibit large isotropic shifts upon one-electron oxidation, the isotropic shift of the *meso*-H signal is reduced in the case of [Fe^{III}(OEP)Cl]; the *meso*-H signal appears at −54 ppm in [Fe^{III}(OEP)Cl], while it appears at −18 ppm in oxidized [Fe^{III}(OEP$^{\bullet}$)Cl]$^{+}$.[242] Similarly, the isotropic shifts of the CH_2 signals are reduced upon one-electron oxidation; the CH_2 signals appear at 43.1 and 39.5 ppm in [Fe^{III}(OEP)Cl], while they are observed at 30.5 and 29.6 ppm in [Fe^{III}(OEP$^{\bullet}$)Cl]$^{+}$. Reduced isotropic shifts in [Fe^{III}(OEP$^{\bullet}$)Cl]$^{+}$ can be explained in terms of electron removal from the a_{1u} orbital; the a_{1u} orbital has a large coefficient at the C_{α} atoms, as shown in Figure 4. Thus, the unpaired electron in the a_{1u} orbital in [Fe^{III}(OEP$^{\bullet}$)Cl]$^{+}$ is delocalized to the C_{α} atoms and should shift the *meso*-H signal to downfield positions. However, the NMR chemical shifts can also be explained in terms of the weak antiferromagnetic coupling of the a_{2u} radical with the metal spins;[26] the a_{2u} orbital can interact with the iron d_{z^2} orbital in five-coordinate C_{4v} complexes, as shown in Table 1. The antiferromagnetic coupling between the iron(III) and a_{2u} radical spins is most explicitly observed in the analogous iron(III) octaethyloxophlorin radical, [Fe^{III}(OEPO$^{\bullet}$)Br].[246] Because of the large negative spin at the *meso*-C atoms, the *meso*-H signals resonate at extremely downfield positions, i.e. 344 and 232 ppm. Table 30 lists the chemical shifts of some iron(III) porphyrin cation radicals together with those of the precursors. These data indicate that complexes carrying aryl groups at the *meso* positions exhibit similar chemical shifts. Thus, these complexes are classified as high-spin iron(III) cation radicals where the a_{2u} radical spin antiferromagnetically couples with metal spins.[149,247,248]

^{13}C NMR spectroscopy is quite useful for determination of the electronic structures of iron(III) porphyrin complexes.[30,31,208] Little is known, however, of the ^{13}C NMR spectra of iron(III) porphyrin radicals although their importance and usefulness as probes of the electronic structure of radical species was pointed out many years ago.[249] This is because some ^{13}C NMR signals in radical species are quite difficult to observe due to their extreme broadness. In fact, the ^{13}C NMR spectrum of [Fe^{III}(TPP$^{\bullet}$)Cl]$^{+}$ exhibits only four signals at 1050, 958, 137, and 8.7 ppm for C_{β}, C_{ipso}, *m*-C, and *p*-C, respectively. No *meso*-C signal is observed even by the use of *meso*-^{13}C (99% ^{13}C)–enriched [Fe^{III}(TPP$^{\bullet}$)Cl]$^{+}$. Hoshino and Nakamura have determined the ^{13}C NMR chemical shifts of [Fe^{III}(TPP$^{\bullet}$)Cl]$^{+}$ by the titration method.[250] As shown in Figure 56, addition of only 0.075 equivalents of [Fe^{III}(TPP$^{\bullet}$)Cl]$^{+}$ to the CD_2Cl_2 solution of [Fe^{III}(TPP)Cl] shifts the *meso*-C signal

Table 30. ^{1}H NMR chemical shifts of (a) high-spin iron(III) porphyrin cation radicals $[Fe^{III}(Por^{\cdot})Cl]^+$ and (b) their parent complexes $[Fe^{III}(Por)Cl]$ taken at ambient temperatures.

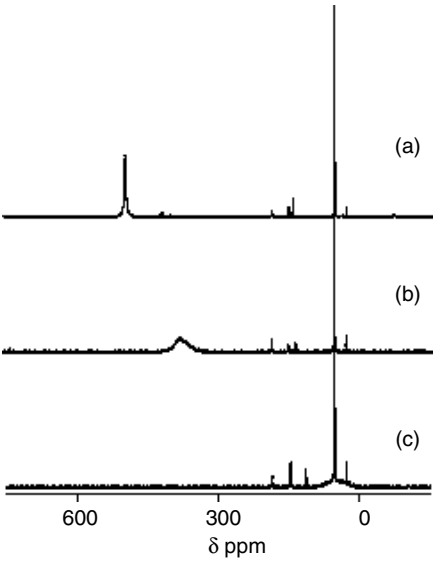

Figure 56. Change in the ^{13}C NMR spectrum of *meso*-^{13}C–enriched [Fe^{III}(TPP)Cl] observed when (a) 0.00, (b) 0.075, and (c) 0.23 equivalents of *meso*-^{13}C–enriched cation radical [Fe(TPP$^{\bullet}$)Cl]$^{+}$ were added in CD_2Cl_2 solution at 298 K. (Adapted with permission from Ref. 250. Copyright 2005, Royal Society of Chemistry.)

from 495 to 376 ppm.[251,252] Furthermore, the half-heigth width ($W_{1/2}$) increases from 306 to 2530 Hz. When 0.23 equivalents of the radical are added, the *meso* signal with $W_{1/2}$ = 3890 Hz appears at 48.0 ppm. The signal is no longer observed after the addition of 0.3 equivalents of the radical. Since the electron exchange between [Fe^{III}(TPP)Cl] and [Fe^{III}(TPP$^{\cdot}$)Cl]$^{+}$ is fast on the ^{13}C NMR time scale, the observed chemical shift δ_{obs} is expressed by Eq. 24 in the presence of x equivalents of the radical, where δ_N and δ_R are the chemical shifts of the carbon atoms in [Fe^{III}(TPP)Cl] and [Fe^{III}(TPP$^{\cdot}$)Cl]$^{+}$, respectively. Plots of δ(obs) against 1/(1 + x) yield a straight line, from which the chemical shifts of *meso*-C, C_α, and *o*-C are determined to be −1910, 2230 and −721 ppm, respectively. Four other signals at 1050, 958, 137, and 8.7 ppm are assigned to C_β, *ipso*-C, *m*-C, and *p*-C, respectively. The ^{13}C NMR chemical shifts of [Fe^{III}(TPP$^{\cdot}$)Cl]$^{+}$ are summarized in Table 31 together with those of some high-spin [Fe^{III}(Por)X]. The large upfield shift of the *meso*-C signal is a direct indication of antiferromagnetic coupling in this species. Because of the large negative spin at the *meso*-C and pyrrole-N atoms, the neighboring C_α signal appears at an extraordinary downfield position, i.e. 2230 ppm.

$$\delta(\text{obs}) = \delta_R + \frac{\delta_N \bar{G} \delta_R}{1 + x}. \tag{24}$$

b. *Mixed high-spin and intermediate-spin iron(III) porphyrin cation radicals*

As mentioned in Section IV, iron(III) complexes carrying weak-field axial ligands adopt the mixed high-spin and intermediate-spin state. What is the electronic structure of the corresponding iron(III) porphyrin cation radicals? Marchon, Reed, and others oxidized $[Fe(TPP)]ClO_4$ by using thianthrene cation radical perchlorate, $(Thian)^{\bullet+}ClO_4^-$, or $Fe(ClO_4)_3$ and obtained the iron(III) porphyrin cation radical $[Fe^{III}(TPP^{\bullet})(ClO_4)_2]$.[241] The X-ray crystal structure of $[Fe^{III}(TPP^{\bullet})(ClO_4)_2]$ reveals that, unlike the highly saddled $[Fe^{III}(TPP^{\bullet})Cl](SbCl_6)$ core, the $[Fe^{III}(TPP^{\bullet})(ClO_4)_2]$ core is nearly planar.[241] The ^1H NMR spectrum shows that the pyrrole-H signal appears at 31.4 ppm, and the *o*-, *m*-, and *p*-H signals appear at −19.3, 34.7, and −12.9 ppm, respectively, at 298 K.[241,246] Thus, the chemical shifts of $[Fe^{III}(TPP^{\bullet})(ClO_4)_2]$ are quite different from those of $[Fe^{III}(TPP^{\bullet})Cl](SbCl_6)$. It should be noted that the signs of chemical shifts of the phenyl protons are reversed; they are 36.0 (ave), −12.3, and 29.5 ppm for the *o*-, *m*,- and *p*-H signals, respectively, in the case of $[Fe^{III}(TPP^{\bullet})Cl](SbCl_6)$.[242] The NMR data suggest that the *meso*-C atoms of $[Fe^{III}(TPP^{\bullet})(ClO_4)_2]$ have a large amount of positive spin, which indicates that there is no appreciable antiferromagnetic coupling in this complex. The result is understandable, because the half-occupied a_{2u} orbital is orthogonal to any of the iron 3d orbitals in the planar D_{4h} complex. The solution magnetic moment of this complex ranges from 4.4 to 5.2 μ_B, depending on samples preparation.[246] The NMR spectrum of analogous $[Fe^{III}(TPP^{\bullet})(SO_3CF_3)_2]$ shows the pyrrole-H signal at 43.9 ppm at 305 K and the *o*-, *m*-, and *p*-H signals at −17.1, 31.3, and −11.3 ppm, respectively, at 309 K. Table 32 lists the chemical shifts of one-electron-oxidized $[Fe^{III}(TPP^{\bullet})X_2]$ together with those of the parent $[Fe^{III}(TPP)X]$ where X is a weak-field anionic ligand such as ClO_4^- or $CF_3SO_3^-$. The data in the table indicate that the pyrrole-H signals in both $[Fe^{III}(TPP^{\bullet})X_2]$ and $[Fe^{III}(TPP)X]$ move upfield as the axial ligand X changes from $CF_3SO_3^-$ to ClO_4^-; note that ClO_4^- is a much weaker ligand than $CF_3SO_3^-$ in the magnetochemical series shown in Eq. 18.[36,157,158] Thus, the pyrrole-H chemical shifts of these complexes are mainly determined by the contribution of the S = 3/2 spin state. It should be noted that the electronic structure of $[Fe^{III}(TPP^{\bullet})(ClO_4)_2]$ in solution seems to be different from that in the solid, because the solid sample of $[Fe^{III}(TPP^{\cdot})(ClO_4)_2]$ exhibits a magnetic moment of 6.5 μ_B, which suggests the presence of ferromagnetic coupling between the radical spin and the high-spin iron(III) spins.[241] As listed in Table 32, the chemical shifts of $[Fe^{III}(TMP^{\cdot})(ClO_4)_2]$ are very sensitive to solvent and temperature.[253] In CD_2Cl_2 solution at 294 K, the ^1H NMR spectrum shows the pyrrole-H signal at 18.7 ppm and the *o*-CH_3, *m*-H, and *p*-CH_3 signals at 20, 55, and 12.5 ppm, respectively. Thus, the complex has large positive spin at the *meso*-C atoms due to the formation of the a_{2u} radical. As the temperature is lowered, the pyrrole-H signal moves

Table 32. ^{1}H NMR chemical shifts of mixed high-spin and intermediate-spin iron(III) porphyrin cation radicals [Fe^{III}(Por·)XY] and their precursors [Fe^{III}(Por)X], where X and Y are weak anionic ligands.[a]

	195	CD_2Cl_2/ CD_3OD[c]	47.9	(4.82)	11.9	(5.96)	253

[a]Data in parentheses are the chemical shifts of the methyl signals. [b]Data at 305 K. [c][Fe^{III}(TMP·)$(ClO_4)_2$] is converted to high-spin [Fe^{III}(TMP•)$(CD_3OD)_2$]$(ClO_4)_2$ in CD_2Cl_2/5% CD_3OD solution. [d]Three signals are observed at 93.1, 102, 108 ppm.

upfield while the *meso*-phenyl signals shift further downfield. At 195 K, the pyrrole-H signal is observed at –22.5 ppm while the *o*-CH_3, *m*-H, and *p*-CH_3 signals appear at 32.2, 90.9, and 19.7 ppm, respectively. The NMR spectral behavior suggests that the interaction between the a_{2u} radical and iron(III) spins is fairly weak and that the spin state of iron(III) changes from the mixed S = 5/2, S = 3/2 at state 294 K to the mainly S = 3/2 state at 195 K. In toluene-d_8 solution, however, the pyrrole-H signal moves downfield from 39.6 ppm at 294 K to 61 ppm at 195 K. This result can be explained in terms of an increase in population of the high-spin state in nonpolar toluene-d_8 solution.[249] Upon addition of methanol-d_4 to the CD_2Cl_2 solution of [Fe(TMP•)$(ClO_4)_2$] at 195 K, the pyrrole-H signal shows a large downfield shift from –22.5 to *ca.* 100 ppm. Thus, [Fe(TMP•)$(ClO_4)_2$] is converted into [Fe(TMP•)$(CD_3OD)_2$]$(ClO_4)_2$, which is in a high-spin state with the a_{2u} porphyrin cation radical. Although both [Fe(TMP•)$(CD_3OD)_2]^{2+}$ and [Fe(TMP•)Cl^+] have high-spin iron(III) ions, the radical spin in the former complex is almost independent of the high-spin iron(III).

c. *Low-spin iron(III) porphyrin cation radicals*

It is possible to obtain six-coordinate low-spin iron(III) porphyrin cation radicals [Fe^{III}(Por•)$L_2]^{2+}$ by addition of neutral axial ligands L to the S = 5/2 or mixed

S = 3/2, S = 5/2 iron(III) porphyrin cation radicals such as $[Fe^{III}(TPP^{\bullet})Cl]^{+}$ and $[Fe^{III}(TMP^{\bullet})(ClO_4)_2]$. Depending on the nature of the axial ligands and the deformation mode of the porphyrin ring, the low-spin iron(III) ions adopt either the $(d_{xy})^2(d_{xz}, d_{yz})^3$ or the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Thus, the interaction of the porphyrin radical with these two types of iron(III) ions should be different.

i. Iron(III) with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ electron configuration

Addition of imidazole to a CD_2Cl_2 solution of $[Fe^{III}(TPP^{\bullet})Cl^{+}]$ at 235 K yields the corresponding bis-HIm complex $[Fe^{III}(TPP^{\bullet})(HIm)_2]^{2+}$.[255] This complex shows the pyrrole-H, *o*-, *m*-, and *p*-H signals at −40.1, −31.7, 30.4, and −22.1 ppm, respectively, at 235 K. The NMR data suggest that the oxidized bis-HIm complexes are best described as low-spin iron (III) porphyrin cation radicals, where the radical spin is in the a_{2u} orbital. The solution magnetic moment for the analogous $[Fe^{III}(4\text{-}OMe\text{-}TPP^{\cdot})(HIm)_2]^{2+}$ is 2.8 ± 0.2 μ_B, suggesting that this spin does not strongly couple with the metal spin. The result is indicative of a planar porphyrin structure where the a_{2u} orbital is orthogonal to any of the iron 3d orbitals. As mentioned in Section III, the pyrrole-H chemical shifts are affected by the electronic ground state of low-spin iron(III). While low-spin complexes with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state exhibit pyrrole-H signals rather upfield due to d_{π}–$3e_g$ interactions, those with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state exhibit them close to their diamagnetic positions, as shown in Tables 2–5. Thus, it is clear that $[Fe^{III}(TPP^{\bullet})(HIm)_2]^{2+}$ adopts the S = 1 $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ ground state.

Addition of imidazole ligands such as 2-MeIm and HIm to a CD_2Cl_2 solution of $[Fe^{III}(TDP^{\bullet})Cl^{+}]$ at 195 K forms $[Fe^{III}(TDP^{\bullet})(2\text{-}MeIm)_2]^{2+}$ and $[Fe^{III}(TDP^{\bullet})(HIm)_2]^{2+}$, respectively.[245] Figure 57 shows the ^1H NMR spectra of (a) $[Fe^{III}(TDP^{\bullet})Cl^{+}]$, (b) $[Fe^{III}(TDP^{\bullet})(2\text{-}MeIm)_2]^{2+}$, and (c) $[Fe^{III}(TDP^{\bullet})(2\text{-}MeIm\text{-}d_6)_2]^{2+}$ taken in CD_2Cl_2 solution at 217 K. As shown in Figure 57b, $[Fe^{III}(TDP^{\bullet})(2\text{-}MeIm)_2]^{2+}$ exhibits four pyrrole-H signals at −45.6, −45.9, −51.7, and −54.7 ppm at 217 K. Similarly, the complex shows four *o*-CH_3 signals at 42.4, 34.0, 8.0, and 6.7 ppm, four *m*-CH_3 signals at 4.7, 3.7, −0.6, and −0.7 ppm, and two *p*-H signals at −1.0 and −2.1 ppm. The number of signals indicates that rotation of the coordinating 2-MeIm is hindered on the ^1H NMR time scale to form a C_2 structure wherein the axial ligands are aligned perpendicularly along the C_{meso}–Fe–C_{meso} axes above and below the porphyrin ring, as in the case of the parent $[Fe^{III}(TDP)(2\text{-}MeIm)_2]^{+}$ complex.[90–93,235–238] Since the large downfield shifts of the *o*-CH_3 signals correspond to the large upfield shift of the *o*-H signal in the analogous $[Fe^{III}(TPP^{\bullet})(HIm)_2]^{2+}$ compound, it is clear that $[Fe^{III}(TDP^{\bullet})(2\text{-}MeIm)_2]^{2+}$ adopts the same electronic structure as $[Fe(TPP^{\bullet})(HIm)_2]^{2+}$, i.e. the S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ ground state. Table 33 lists the chemical shifts of various low-spin

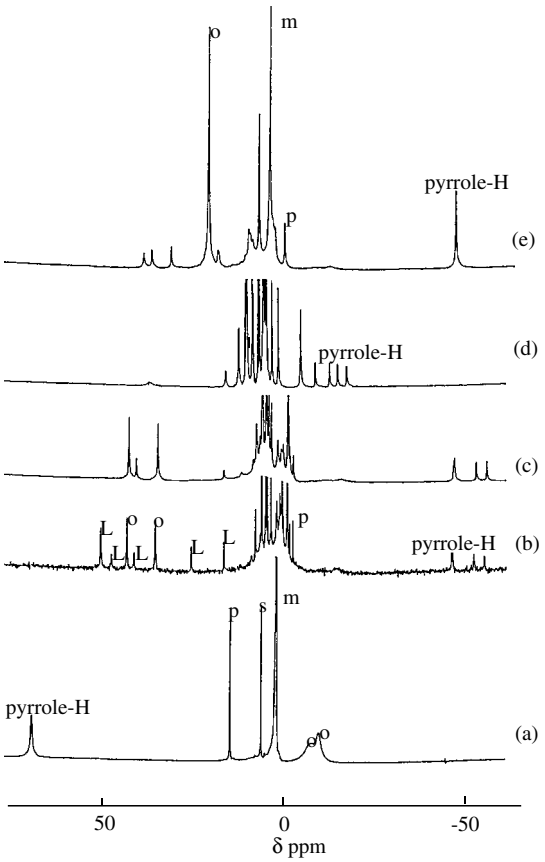

Figure 57. ^{1}H NMR spectra taken in CD_2Cl_2 solution at 217 K: (a) [Fe^{III}(TDP•)Cl], (b) [Fe^{III}(TDP•)(2-MeIm)$_2$]$^{2+}$ obtained by the addition of 4.0 equivalents of 2-MeIm to [Fe^{III}(TDP•)Cl], (c) [Fe^{III}(TDP•)(2-MeIm-d_5)$_2$]^2, (d) [Fe^{III}(TDP)(2-MeIm)$_2$]$^+$ obtained after standing the sample at 298 K for 10 min, and (e) [Fe^{III}(TDP•)(HIm)$_2$]$^{2+}$ obtained by the addition of 4.5 equivalents of HIm to [Fe^{III}(TDP•)Cl]. iron(III) porphyrin cation radicals [Fe^{III}(Por•)L_2]$^{2+}$ together with the parent [Fe(Por)L_2]$^+$, respectively.

ii. Iron(III) with the $(d_{xz}, d_{yz})^4(d_{xy})^1$ electron configuration

As mentioned in Section III, highly ruffled low-spin [Fe(T^iPrP)L_2]$^+$ adopts the less common $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state regardless of the kind of axial ligands.[30,31,52,82] In fact, the pyrrole-H and *meso*-C signals of [Fe(T^iPrP)(HIm)$_2$]$^+$ appear at downfield positions, namely 0.1 and 332 ppm, respectively, at 223 K, which unambiguously

[a]Data in parentheses are the chemical shifts of the methyl signals. [b]Averaged value. [c]Ikezaki, A. *et al.*, unpublished results.

indicates that the complex is in the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state; these are actually the only examples of bis-HIm complexes that adopt the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state. Therefore, it is expected that the one-electron-oxidized product, $[Fe(T^iPrP^{\bullet})(HIm)_2]^{2+}$, should have a $(d_{xz}, d_{yz})^4(d_{xy})^1(a_{2u})^1$ ground state. However, the data in Tables 33b indicate that the pyrrole-H signal appears somewhat upfield, at $\delta =$ −20.4 ppm, as compared with $\delta = 0.1$ ppm in the parent $[Fe(T^iPrP)(HIm)_2]^+$. Thus, the electronic structure of low-spin iron(III) ion switches from $(d_{xz}, d_{yz})^4(d_{xy})^1$ to $(d_{xy})^2(d_{xz}, d_{yz})^3$ as the electron is removed from the porphyrin ring. Since the *meso*-CH(α) signal is observed at a downfield position, 42.4 ppm, the electronic structure of $[Fe(T^iPrP^{\bullet})(HIm)_2]^{2+}$ can be expressed as S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$. These results suggest that the $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ ground state is more stable than the $(d_{xz}, d_{yz})^4(d_{xy})^1(a_{2u})^1$ ground state. This is understandable, because the a_{2u} orbital is stabilized to a great extent by the one-electron oxidation. As a result, the interaction between the d_{xy} and a_{2u} orbitals in $[Fe(T^iPrP^{\cdot})L_2]^{2+}$ is weakened, which stabilizes the d_{xy} orbital to form the complex with the S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ ground state. Figure 58 shows the ^{1}H NMR spectra of (a) $[Fe(TEtP^{\bullet})(HIm)_2]^{2+}$ and (b) $[Fe(T^iPrP^{\bullet})(2\text{-MeIm})_2]^{2+}$.[256] It is clear that the electronic structure of these complexes is also described as S = 1 $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ because of the presence of the upfield-shifted pyrrole-H signal together with the downfield-shifted *meso*-CH_α signals. Close inspection of the data in Table 33 reveals that the pyrrole-H signal in $[Fe(TRP^{\cdot})(HIm)_2]^{2+}$ moves downfield from −36.0 to −20.4 ppm as the *meso* substituent changes from Et to the much bulkier ^{i}Pr group. This result suggests that the population of the $(d_{xz}, d_{yz})^4(d_{xy})^1(a_{2u})^1$ spin isomer increases relative to that of the $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ isomer as the ruffling of the porphyrin ring increases. It should be noted that the $(d_{xz}, d_{yz})^4(d_{xy})^1(a_{2u})^1$ spin isomer should really be expressed as S = 0, $(d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^2$ since the half-occupied d_{xy} orbital is expected to interact antiferromagnetically with the half-occupied a_{2u} orbital in the ruffled porphyrin structure.[43] These results suggest that, in order to obtain $[Fe(Por^{\cdot})L_2]^{2+}$ with the S = 0, $(d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^1$ ground state, the axial ligand should have low-lying π^* orbitals. Needless to say, ^{t}BuNC is the best candidate for obtaining such a complex since almost all the low-spin complexes of porphyrins and porphyrin analogs carrying a ^{t}BuNC ligand exhibit the $(d_{xz}, d_{yz})^4(d_{xy})^1$ ground state; the only examples showing the $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state are the monoazaporphyrin $[Fe(MAzP)(^tBuNC)_2]^+$,[136] the diazaporphyrin $[Fe(DAzP)(^tBuNC)_2]^+$,[134] and the highly saddled $[Fe(OETArP)(^tBuNC)_2]^+$ with electron-withdrawing aryl groups at the *meso* positions.[95]

Ikezaki and coworkers prepared a series of $[Fe(TMP^{\bullet})L_2]^{2+}$ (L = HIm, 4,5-Cl_2Im, and ^{t}BuNC) complexes by addition of axial ligands L to a CD_2Cl_2 solution of $Fe(TMP^{\bullet})(ClO_4)_2$ at 195 K.[257] Figure 59 displays the ^{1}H NMR spectra of these complexes taken at 173 K. As shown in Figure 59a, the pyrrole-H and *m*-H signals

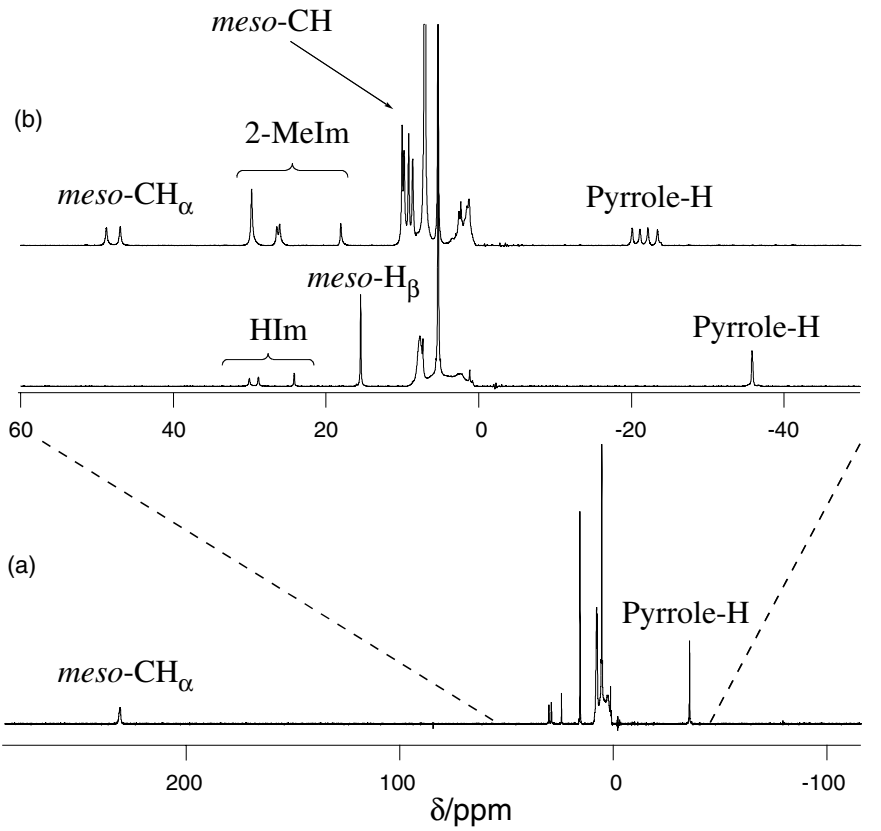

Figure 58. ^{1}H NMR spectra of low-spin iron(III) porphyrin cation radicals taken in CD_2Cl_2 solution at 223 K: (a) $[Fe(TEtP^{\bullet})(HIm)_2]^{2+}$ together with the expanded spectrum, (b) $[Fe(T^iPrP^{\bullet})(2\text{-MeIm})_2]^{2+}$. (Adapted with permission from Ref. 256. Copyright 2003, Royal Society of Chemistry.)

of $[Fe(TMP^{\bullet})(HIm)_2]^{2+}$ are observed at −70.8 and 65.7 ppm, respectively, at 173 K, which clearly indicates that the complex adopts the S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ ground state. If axial HIm is replaced by 4,5–Cl_2Im, the pyrrole-H and *m*-H signals shift to *ca.* −26 and 24 ppm, respectively, as shown in Figure 59b; these signals split into several lines at this temperature due to slow rotation of the 4,5-Cl_2Im ligand.[90–93] Thus, the isotropic shifts are greatly reduced on going from $[Fe(TMP^{\bullet})(HIm)_2]^{2+}$ to $[Fe(TMP^{\bullet})(4,5\text{-}Cl_2Im)_2]^{2+}$. In the case of $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$, all the signals are observed in the so-called diamagnetic region, from 1.7 to 6.8 ppm in this case, as shown in Figure 59c. The effective magnetic moment of this complex is 0.45 μ_B at 173 K and 0.57 μ_B at 223 K. The ^{1}H NMR chemical shifts of both the cation radical $[Fe(TMP^{\bullet})L_2]^{2+}$ and the parent $[Fe(TMP)L_2]^+$ are listed in Tables 33c and 33c′, respectively. In neutral $[Fe(TMP)L_2]^+$, the pyrrole-H signal moves downfield from −16.8 to −9.4, and then to 7.1 ppm at 298 K as the axial

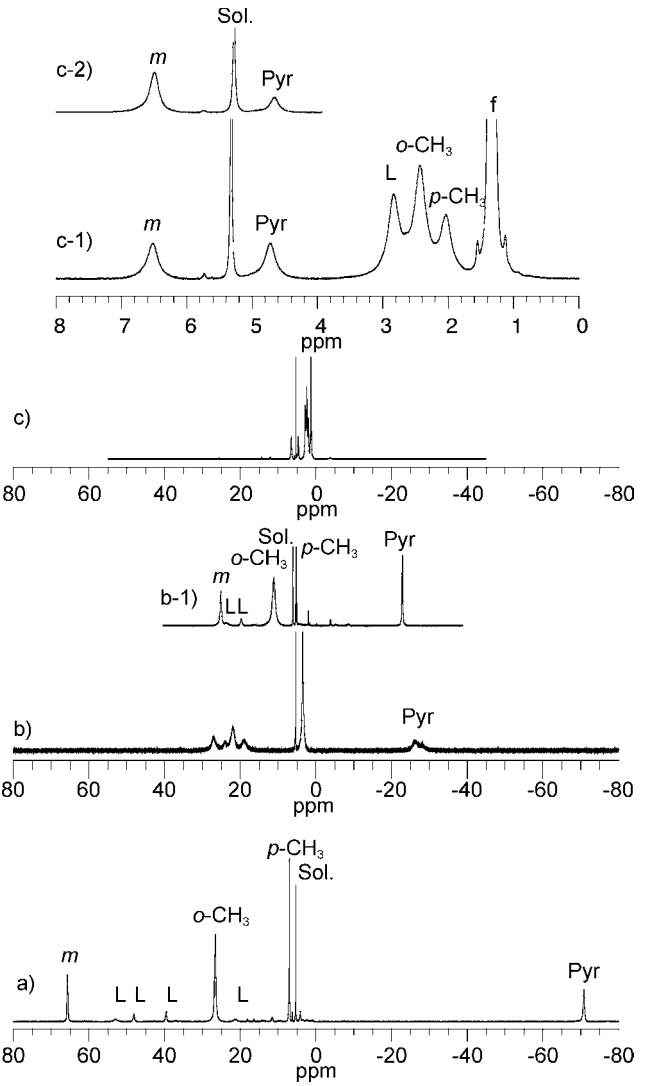

Figure 59. (a) ^{1}H NMR spectrum of $[Fe(TMP^{\bullet})(HIm)_2]^{2+}$ taken in CD_2Cl_2 solution at 173 K. (b) ^{1}H NMR spectrum of $[Fe(TMP^{\bullet})(4,5\text{-}Cl_2Im)_2]^{2+}$ taken in CD_2Cl_2 solution at 173 K. The same sample taken at 253 K is given in inset (b-1). (c) ^{1}H NMR spectrum of $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$ taken in CD_2Cl_2 solution at 173 K. Inset (c-1) shows the 0–8 ppm region and inset (c-2) shows the spectrum obtained from the pyrrole-d_8 complex. (Adapted with permission from Ref. 257. Copyright 2008, Royal Society of Chemistry.)

ligand changes from HIm to 4,5-Cl_2Im, and then to ^{t}BuNC. These results indicate a change in the electronic ground state from $(d_{xy})^2(d_{xz}, d_{yz})^3$ to $(d_{xz}, d_{yz})^4(d_{xy})^1$. A similar tendency is observed in the cation radical $[Fe(TMP^{\bullet})L_2]^{2+}$. The pyrrole-H signal moves downfield from –53.2 to –25.6, and then to 4.6 ppm, which can also be

ascribed to the change in electron configuration of the low-spin iron(III) from $(d_{xy})^2(d_{xz}, d_{yz})^3$ to $(d_{xz}, d_{yz})^4(d_{xy})^1$. The diamagnetic nature of $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$ can then be explained in terms of strong antiferromagnetic coupling between the half-occupied d_{xy} and half-occupied a_{2u} orbitals in a highly ruffled porphyrin framework. Thus, the electronic ground state of $[Fe(TMP^{\bullet})(HIm)_2]^{2+}$ and $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$ should be expressed as S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ and S = 0, $(d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^2$, respectively. The pyrrole-H signal of $[Fe(TMP^{\bullet})(4,5\text{-}Cl_2Im)_2]^{2+}$ is observed just between the pyrrole-H signals of $[Fe(TMP^{\bullet})(HIm)_2]^{2+}$ and $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$, which indicates that $[Fe(TMP^{\bullet})(4,5\text{-}Cl_2Im)_2]^{2+}$ exists as an equilibrium mixture of two kinds of spin isomers as expressed by Eq. 25:

$$S = 1,\ (d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1 \leftrightarrows S = 0,\ (d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^2. \quad (25)$$

The pyrrole-H and *m*-H signals of $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$ are observed to be more upfield by 4.2 and 0.8 ppm than the corresponding signals of diamagnetic $[Co(TMP)(^tBuNC)_2]^+$. Similarly, the *meso*-C signal of $[Fe(TMP^{\bullet})(^tBuNC)_2]^{2+}$ appears at 160 ppm at 173 K, which is more downfield by 42 ppm than is the corresponding signal of diamagnetic $[Co(TMP)(^tBuNC)_2]^+$. Figure 60 shows the Curie plots of the *m*-H and pyrrole-H signals of the three complexes. Clearly, the isotropic shift of each signal decreases as the axial ligand changes from HIm to

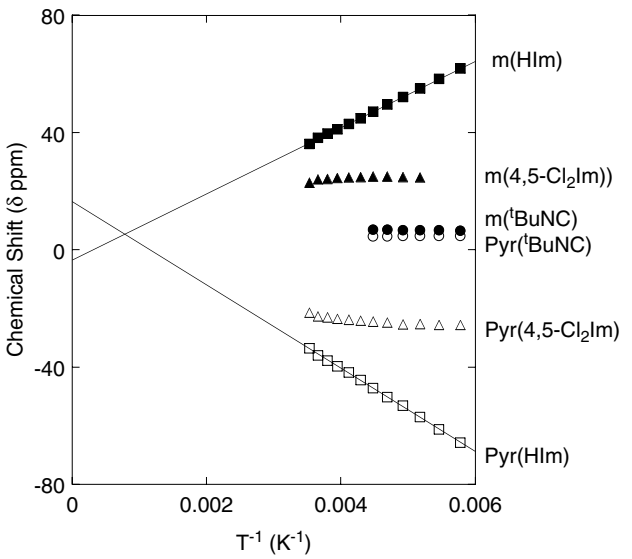

Figure 60. Curie plots of the *m*-H(m) and pyrrole-H(Pyr) chemical shifts of $[Fe(TMP^{\bullet})L_2]^{2+}$. (Adapted with permission from Ref. 257. Copyright 2008, Royal Society of Chemistry.)

4,5-Cl_2Im, and then to ^{t}BuNC. The Curie plot of the *meso*-C signal of $[Fe(TMP^{\bullet})(^t BuNC)_2]^{2+}$ exhibits a small downfield shift at higher temperatures. These results indicate that $[Fe(TMP^{\bullet})(^t BuNC)_2]^{2+}$ exists mainly as the S = 0, $(d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^2$ spin isomer with a small population of the S = 1, $(d_{xy})^2$ $(d_{xz}, d_{yz})^3(a_{2u})^1$spin isomer. The population of the latter isomer increases only slightly at higher temperatures, as is revealed from the temperature dependence of the effective magnetic moments. However, a slight increase in population of the paramagnetic isomer greatly affects the signal width. That should be the reason why the *meso*-C signal disappears as the temperature is raised. As shown in Figure 56, the *meso*-C signal of [Fe(TPP)Cl] broadens to a great extent when 0.075 equivalents of $[Fe(TPP^{\bullet})Cl]^+$ are added.

On the basis of the data described above, low-spin iron(III) porphyrin cation radicals denoted by $[Fe(Por^{\bullet})L_2]^{2+}$ exist in either one of the three possible electronic ground states. They exist (i) predominantly as S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ as in the case of $[Fe(TMP^{\cdot})(HIm)_2]^{2+}$, (ii) predominantly as S = 0, $(d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^2$ as in the case of $[Fe(TMP^{\cdot})(^t BuNC)_2]^{2+}$, and (iii) as an equilibrium mixture of S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^3(a_{2u})^1$ and S = 0, $(d_{xz}, d_{yz})^4(d_{xy}, a_{2u})^2$, as in the case of $[Fe(TMP^{\bullet})(4,5\text{-}Cl_2Im)_2]^{2+}$.[257]

2. *Iron(IV) Porphyrin Complexes*

a. *Iron(IV) porphyrins with an Fe^{IV}=O bond*

Iron(IV) porphyrins are in general quite unstable and difficult to obtain. Most of the iron(IV) complexes reported to date have an Fe^{IV}=O group, since they are more stable than the corresponding iron(IV) complexes without the Fe^{IV}=O bond. Balch, La Mar, and coworkers reported the first example of an Fe^{IV}=O complex [(Fe^{IV}=O)(3-Me-TPP)(1-MeIm)] obtained by addition of 1-MeIm to the peroxo-bridged dimer [(3-Me-TPP)Fe^{III}O–OFe^{III}(3-MeTPP)].[258,259] The iron(IV) oxidation state has been confirmed by the solution magnetic moment, which is $2.9 \pm 0.1\ \mu_B$ at 221 K and is invariant down to 183 K. Furthermore, the Mössbauer spectrum has revealed that the isomer shift of the iron atom is 0.11 mm s^{-1} at 4.2 K, which is characteristic of an iron(IV) complex.[260] In the ^{1}H NMR spectra, all the signals are observed between 5 and 10 ppm. The temperature dependence of the paramagnetic shift of each signal strictly follows the Curie law over a wide temperature range. The complex reacts instantaneously with Fe^{II}(3-Me-TPP) to form quantitatively the μ-oxo dimer [(3-Me-TPP)Fe^{III}]$_2$O. Thus, the electronic structure of [(Fe^{IV}=O)(3-Me-TPP)(1-MeIm)] should be given as S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^2$. Thermal decomposition of the peroxobridged dimer of sterically hindered TMP, [(TMP)Fe^{III}O–OFe^{III}(TMP)], yields the five-coordinate [(Fe^{IV}=O)(TMP)].[261,262]

Similarly, thermal decomposition of the alkylperoxo complex [Fe^{III}(TMP)(OO^{t}Bu)] produces [(Fe^{IV}=O)(TMP)].[263] Although electrochemical and chemical one-electron oxidation of [Fe(Por)Cl] have produced [Fe(Por$^{\bullet}$)Cl]$^+$, as mentioned in the previous section, the same oxidation of [Fe(Por)(OH)] produces [(Fe^{IV}=O)(Por)] if Por has *o*-phenyl substituents that prevent the formation of a μ-oxo dimer.[264–267] Later, Groves *et al.* reported a convenient preparative method for [(Fe^{IV}=O)(TMP)]; namely, ligand metathesis of the iron(III) cation radical, [Fe^{III}(TMP$^{\cdot}$)(ClO_4)$_2$], over moist basic alumina.[268] Although [(Fe^{IV}=O)(TMP)] is unstable in CH_2Cl_2 solution and forms [Fe^{III}(TMP)Cl] within a minute at ambient temperature, it is much more stable in benzene solution.[268] Figure 61 shows the ^{1}H NMR spectrum of [(Fe^{IV}=O)(TMP)] taken in CD_2Cl_2 solution at 195 K together with the UV spectrum taken in benzene solution at room temperature. The ^{1}H NMR chemical shifts of various Fe^{IV}=O complexes are listed in Table 34.[231,253,258,261,268–272] As is revealed from the data in the table, the isotropic shift of each signal in both five- and six-coordinate Fe=O complexes is quite small. Since these complexes adopt the S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^2$ ground state, one can expect that the pyrrole-H signals should appear extremely upfield due to an interaction between half-filled iron d_π and filled porphyrin $3e_g$ orbitals, as in the case of the S = 3/2 iron(III) complexes such as [Fe^{III}(T^{i}PrP)($THF)_2$]$^+$ and [Fe^{III}(TPP)]Ag($Br_6CB_{11}H_6$)$_2$;[98,157] the chemical shift of the pyrrole-H signal reaches as much as −62 ppm in the latter complex at 298 K.

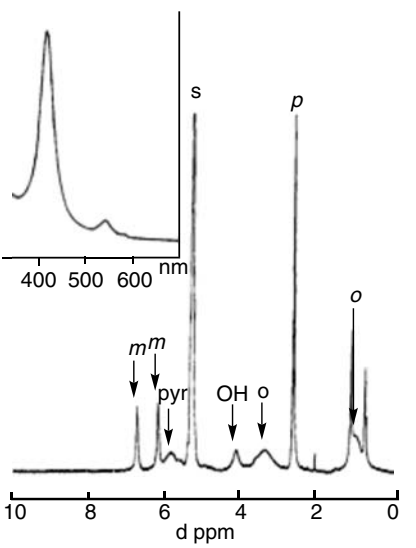

Figure 61. ^{1}H NMR spectrum of (Fe^{IV} = O)(TMP) in CD_2Cl_2 solution at 195 K. The peaks marked *p*, *m*, and *o* are *p*-Me, *m*-H, and *o*-Me. The peak marked OH is due to the *p*-Me of Fe^{III}(TMP)(OH). Inset: UV spectrum in benzene at room temperature. (Adapted with permission from Ref. 268. Copyright 1994, American Chemical Society.)

[a]P and P· indicate porphyrin and porphyrin cation radical, respectively. [b]S = 3/2. [c]S = 1. (Source: Refs. 274, 275.)

Table 35 lists the gross atomic spin populations determined by DFT calculations for various high-valent iron complexes.[274,275] As shown in the table, most of the unpaired electrons in the Fe^{IV}=O complexes are localized on the axial part, i.e. iron and oxygen atoms, and the amount of the total spin density on the porphyrin ring is negligibly small. Thus, the theoretical study explains why the isotropic shifts of the peripheral proton signals in Fe^{IV}=O complexes are negligibly small in spite of the presence of two unpaired electrons in the d_π orbitals.

b. *Iron(IV) porphyrins without an Fe=O bond*

While there are ample examples of iron(IV) complexes with an Fe=O bond, iron(IV) complexes without the Fe=O bond are quite rare. The only example is the bis-methoxo complex, $[Fe(TMP)(OMe)_2]$, which is prepared by the addition of methoxide to the iron(III) porphyrin cation radical, $[Fe^{III}(TMP^{\bullet})(ClO_4)_2]$, as shown in Eq. 26.[253]

$$Fe^{III}(TMP^{\bullet})(ClO_4)_2 + 2MeO^- \leftrightarrows [Fe^{IV}(TMP)(OMe)_2] + 2ClO_4^- \qquad (26)$$

The electronic structure of $[Fe^{IV}(TMP)(OMe)_2]$ has been examined by various spectroscopic methods. Figure 62 shows the ^1H NMR spectrum of this complex taken in $CDCl_3$ at 223 K. The ^1H NMR chemical shifts of this complex are listed in Table 34. The characteristic is that the pyrrole-H signal appears at an extremely upfield position, $\delta = -37.5$ ppm at 195 K, while the other signals such as *o*-CH_3, *m*-H, and *p*-CH_3 are quite close to their diamagnetic positions. The effective magnetic moment, μ_{eff}, is 2.9 ± 0.2 μ_B between 229 and 193 K in CH_2Cl_2 solution. Thus, the complex is best described as an iron(IV) porphyrin with the S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^2$ ground state, which is further verified by the Mössbauer and EXAFS data.[276] Because of the absence of the Fe=O bond, the unpaired electrons

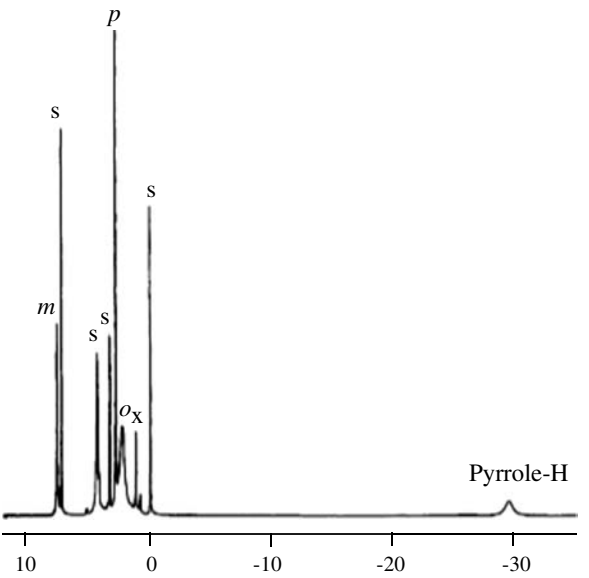

Figure 62. ^{1}H NMR spectra of [Fe^{IV}(TMP)$(OCH_3)_2$] taken in $CDCl_3$ solution at 223 K. (Adapted with permission from Ref. 253. Copyright 1985, American Chemical Society.)

in the d_{xz} and d_{yz} orbitals delocalize to the porphyrin ring by interaction with the filled $3e_g$ orbitals to induce a large upfield shift of the pyrrole-H signal. That is the reason why the ^{1}H NMR spectrum of [(Fe^{IV}=O)(TMP)] shown in Figure 61 is quite different from that of [Fe^{IV}(TMP)$(OCH_3)_2$] shown in Figure 62, although both complexes adopt the S = 1, $(d_{xy})^2(d_{xz}, d_{yz})^2$ ground state. A ^{13}C NMR study further reveals that [Fe^{IV}(TMP)$(OCH_3)_2$] has negligibly small spin density at the *meso*-C atoms because the *meso*-C signal appears at 64.3 ppm, at 213 K; the *meso*-C signal of low-spin [Fe^{III}(T^nPrP)$(HIm)_2$]$^+$ with the $(d_{xy})^2(d_{xz}, d_{yz})^3$ ground state appears at 73.1 ppm as listed in Table 4.[52] [Fe^{IV}(TMP)$(OCH_3)_2$] can be produced together with the two-electron-oxidized product, [(Fe^{IV}=O)($TMP^{\bullet}$)]$^+$, by oxidation of Fe^{III}(TMP)(ClO_4) with iodosylbenzene or dimethyldioxirane in mixed CD_2Cl_2 and CD_3OD solution.[277,278]

It was expected that the addition of strong anionic ligands to a solution of iron(III) porphyrin cation radical would produce an iron(IV) porphyrin as in the case of [Fe^{IV}(TMP)$(OMe)_2$]. Among various anionic ligands, F^- should be a suitable ligand since it is highly ranked in the magnetochemical series proposed by Reed *et al.*[157,158] In fact, the electrochemical oxidation of $Fe^{III}(TPP)F_2^-$ is unique, in the sense that the first oxidation wave is at +0.68 V.[165,166] Since the first oxidation wave for most five-coordinate iron(III) porphyrins is *ca.* +1.1 V, the corresponding wave for [$Fe^{III}(TPP)F_2]^-$ has been suggested to be due to an iron-centered

oxidation to form the iron(IV) species, $[Fe^{IV}(TPP)F_2]$. However, the complex is too unstable to obtain an NMR spectrum. A density functional study has also predicted that one-electron oxidation of $[Fe^{III}(TPP)F_2]^-$ should form the iron(IV) porphyrin, $[Fe^{IV}(Por)F_2]$, rather than the iron(III) porphyrin cation radical.[279] However, *ab initio* CASPT2 calculations by Ghosh and Taylor favor a high-spin porphyrin cation radical as the ground state by a significant energetic margin over an iron(IV) porphyrin.[280,281] Thus, the electronic structure of the one-electron oxidized product of high-spin $[Fe^{III}(TPP)F_2]^-$ is still ambiguous and further experimental studies are necessary.

B. Two-Electron-Oxidized Products of Iron(III) Porphyrins

As shown in Figure 1, a reactive intermediate in the catalytic reaction of cytochrome P450 is considered to be two oxidizing equivalents above the ferric state. There are several kinds of two-electron-oxidized species.[12,285] They are an oxoiron(V) porphyrin $[(Fe^{V}{=}O)(Por)]^+$[11,12,26,282–284]; a six-coordinate iron(V) porphyrin without an $Fe^{V}{=}O$ bond $[Fe^{V}(Por)(X)(Y)]^+$ where X and Y are anionic ligands; an oxoiron(IV) porphyrin cation radical $[(Fe^{IV}{=}O)(Por^{\bullet})]^+$[11,12,26,277,285]; a six-coordinate iron(IV) porphyrin cation radical without an $Fe^{IV}{=}O$ bond $[Fe^{IV}(Por^{\bullet})(X)(Y)]^+$; an iron(III) porphyrin N-oxide[12,285,286,287]; and an iron(III) porphyrin dication.[12,285,288,289] Figure 63 shows some of the two-electron-oxidized-complexes mentioned above.[285]

In the case of naturally occurring heme proteins that are involved in oxidation reactions, the reaction intermediate where the second oxidation equivalent is placed on the iron ligand has been denoted as compound I. The nature of compound I in heme proteins such as peroxidase, catalase, and cytochrome P450 has been considered to be an oxoiron(IV) porphyrin cation radical $[(Fe^{IV}{=}O)(Por^{\bullet})]^+$.[4–17] In this section we will describe the electronic structures of $[(Fe^{IV}{=}O)(Por^{\bullet})]^+$ together with other two-electron-oxidized complexes such as the oxoiron(V) porphyrin $[(Fe^{V}{=}O)(Por)]^+$, the iron(III) porphyrin N-oxide, and the iron(III) porphyrin dication.

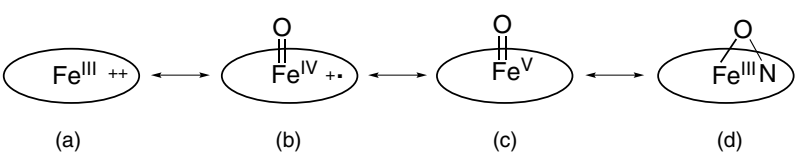

Figure 63. Two-electron-oxidized species of iron(III) porphyrin complexes: (a) Iron(III) porphyrin dication; (b) iron(IV) porphyrin radical cation; (c) iron(V) porphyrin; (d) iron(III) porphyrin N-oxide. (Adapted with permission from Ref. 285. Copyright 2002, Elsevier Science.)

1. *Oxoiron(IV) Porphyrin Cation Radicals*

The first example of an oxoiron(IV) porphyrin cation radical was reported by Groves *et al.* in 1981.[277] These authors examined the oxidation of [Fe(TMP)Cl] with 1.5 equivalents of *m*-CPBA in CD_2Cl_2–CD_3OD-methanol (4:1) solution at 195 K and obtained a green intermediate. The pyrrole-H signal of [Fe(TMP)Cl] at δ 120 ppm disappears and a new signal appears at δ –27 ppm. Figure 64 shows the ^{1}H NMR spectrum of the green intermediate taken at 195 K in CD_2Cl_2-CD_3OD. The *o*-Me signals appear at 26 and 24 ppm, the *m*-H signal at 68 ppm, and the *p*-Me signal is at 11.1 ppm. Thus, the green intermediate has an unpaired electron in the a_{2u} orbital. These chemical shifts are highly temperature dependent and obey the Curie law between 237 and 184 K. The magnetic susceptibility was determined by the Evans method to be 4.2 μ_B, which is slightly larger than the expected value, μ_{eff} = 3.87 μ_B, for an S = 3/2 system. The visible spectrum shows a broad Soret band at 406 nm and another broad band centered at 645 nm. The Mössbauer spectrum derived from ^{57}Fe-enriched [Fe(TMP)Cl] shows a quadrupole doublet centered at 0.05 mm/s (QS = 1.49 mm/s). Treatment of a CH_2Cl_2-CH_3OH solution of the green intermediate with norbornene in the presence of $H_2{}^{18}O$ yields ^{18}O-incorporated norbornene oxide, which clearly indicates the presence of an Fe^{IV}=O unit in the intermediate. Thus, the complex is best expressed as

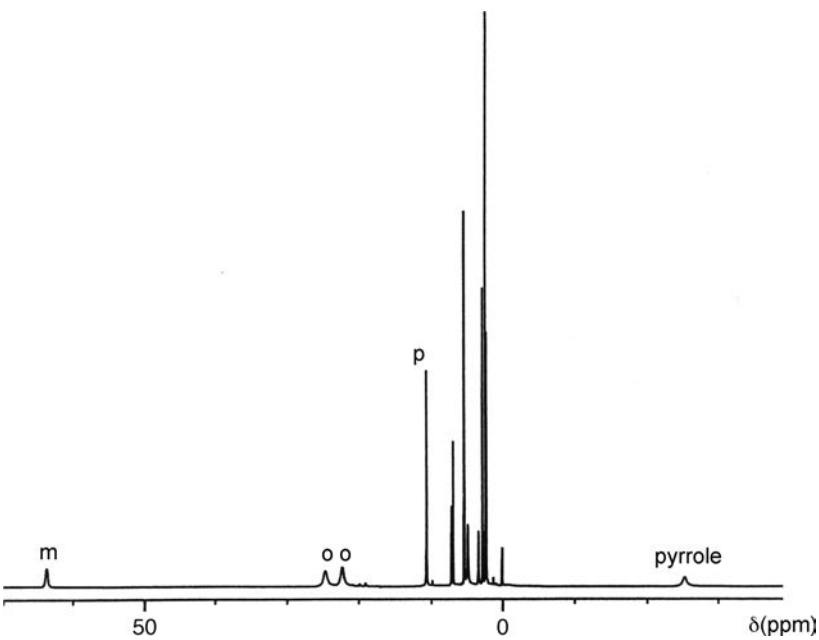

Figure 64. ^{1}H NMR spectrum of [(Fe^{IV}=O)($TMP^{\bullet}$)]$^+$ taken in CD_2Cl_2–CD_3OD at 195 K. (Adapted with permission from Ref. 277. Copyright 1981, American Chemical Society.)

$[(Fe^{IV}{=}O)(TMP^{\bullet})]^+$, a compound I analog of HRP and cytochrome P450. The large downfield shift of the *m*-H signals together with the large upfield shift of the pyrrole-H signals indicate the presence of an a_{2u} radical together with the half-occupied d_π orbital(s). Thus, the electronic structure of $[(Fe^{IV}{=}O)(TMP^{\bullet})]^+$ can be expressed as $(d_{xy})^2(d_{xz},d_{yz})^2(a_{2u})^1$. The EPR spectrum of $[(Fe^{IV}{=}O)(TMP^{\bullet})]^+$ shows signals at 4.47, 3.50, and 1.98, which suggest the presence of ferromagnetic coupling between the iron(IV) ion and the porphyrin cation radical to form the S = 3/2 state.[290,291] Resonance Raman spectroscopy shows a band at 828 cm^{-1} for Fe=O.[292] The EXAFS reveals the Fe=O length to be 1.6 Å, which is close to the Fe=O lengths of compound I and compound II of HRP.[293] In order to investigate the relationship between structure and reactivity of $[(Fe^{IV}{=}O)(Por^{\bullet})]^+$, various oxoiron(IV) porphyrin cation radicals have been prepared using *m*-CPBA or ozone as oxidizing reagents.[227,294–297] In Table 36 are listed the ^{1}H NMR chemical shifts of such complexes.

Fujii found that the pyrrole-H signal in $[(Fe^{IV}{=}O)(TArP^{\bullet})]^+$ shifts upfield from −27.6 to −44.1, −65.5, and then to −72.7 ppm as the *meso*-aryl substituent changes from (2,4,6-Me_3)phenyl to (2-Cl-6-Me)phenyl, (2,6-Cl_2)phenyl, and then to (2,4,6-Cl_3)phenyl.[295] In contrast, the paramagnetic shift of the *m*-H signal decreases with the same change in the *meso*-aryl substituent, as listed in Table 36. These results are interpreted in terms of a mixing of the a_{1u} radical state with the original a_{2u} radical state; note that the a_{2u} orbital is stabilized relative to the a_{1u} orbital by introduction of electronegative substituents at the *meso* position. Thus, in the complex having strongly electron-withdrawing pentafluorophenyl (C_6F_5) groups at the *meso* positions, i.e. $[(Fe^{IV}{=}O)(F_5\text{-}TPP^{\bullet})]^+$, the pyrrole-H signal appears at an extremely upfield position, −96 ppm at 193 K, which indicates that the a_{1u} radical character predominates over the a_{2u} radical character.[295]

Oxo-iron(IV) porphyrin cation radicals with the a_{1u} radical character can also be expected for $[(Fe^{IV}{=}O)(TMTMP^{\bullet})]^+$. TMTMP has four methyl and four mesityl groups at the pyrrole β carbon atoms, as shown in Scheme 1. Thus, it is expected that the electronic structure and reactivity of $[(Fe^{IV}{=}O)(TMTMP^{\cdot})]^+$ should resemble compound I of naturally occurring heme proteins such as HRP and peroxidase. A wide variety of pyrrole-substituted complexes such as $[(Fe^{IV}{=}O)(TMTMP^{\bullet})]^+$ and $[(Fe^{IV}{=}O)(TArP^{\bullet})]^+$ have been prepared.[295] The ^{1}H NMR chemical shifts of these complexes are also listed in Table 36. Extremely large downfield shifts of the pyrrole β-methyl signals suggest that the pyrrole β-carbon atoms have large spin density, which is consistent with formation of the a_{1u} radical. The *meso*-H signals of some complexes appear rather downfield, i.e. 7–55 ppm. These results indicate that the *meso*-carbon atoms have a sizable amount of negative spin density, which is induced by the large positive spin density on the pyrrole α-carbon atoms characteristic of the a_{1u} radical. The EPR spectrum of $[(Fe^{IV}{=}O)(TMTMP^{\bullet})]^+$ shows signals at g = 3.6 and 2.0, which are close to those of compound I of

Micrococcus lysodeikticus catalase and ascorbate peroxidase.[297,298] Thus, compound I of these enzymes should adopt the a_{1u} radical state.[299]

2. *Iron(III) Porphyrin N-Oxides*

A bridged iron porphyrin N-oxide has been suggested as a reactive intermediate in the catalytic cycle of cytochrome P-450 on the basis of the crystal structure of N-bridged iron porphyrin carbenes,[300–306] several metalloporphyrn N-oxides,[307–309] and an N-bridged nitrene.[310] The first iron(III) porphyrin N-oxide, which is isoelectronic with the iron(IV) porphyrin cation radical, was prepared and characterized by Groves and Watanabe.[286] Addition of two equivalents of mCPBA to a toluene solution of [Fe^{III}(TMP)(mCB)] at 273 K yielded a new complex together with bis(3-chlorobenzoyl)peroxide. The UV–vis spectrum of this complex showed a dramatically red-shifted Soret band at 441 nm. The ^{1}H NMR spectrum taken at 223 K showed *m*-H signals at 17.2, 15.0, and 13.8 ppm (relative intensity 1:2:1) and *p*-CH_3 signals at 4.2 and 3.9 ppm. The EPR spectrum showed strong signals at $g = 4.3$. The solution magnetic moment determined by the Evans method is $5.4 \pm 0.1\ \mu_B$ at 248 K in toluene-d_8 solution. The electronic structure of this complex has been assigned as rhombically distorted high-spin iron(III) on the basis of the presence of the downfield-shifted *m*-H signal. Mechanistic studies have revealed that the iron(III) porphyrin N-oxide is formed via homolytic O–O bond cleavage of the coordinated *m*-chlorobenzoylperoxo ligand. At higher concentration or under acidic conditions, the oxo-iron(IV) porphyrin cation radical [(Fe^{IV}=O)($TMP^{\bullet}$)]$^+$ is formed by heterolytic O–O bond cleavage.[287,311]

3. *Iron(III) Porphyrin Dications*

The first well-characterized iron(III) porphyrin dication was reported by Watanabe and coworkers.[288,289] The complex was prepared by the reaction of an iron(III) porphyrin N-oxide, Fe^{III}(TMP N-oxide), with trifluoroacetic acid in toluene at low temperature. The EPR spectrum taken at 77 K shows two signals at 9.5 and 4.25. The intensity of these signals decreases upon warming the solution to afford the EPR silent iron(III) cation radical. The pyrrole-D signal in pyrrole deuterated [Fe^{III}(TMP N-oxide)] appears at 118 ppm at 193 K, which indicates that the complex adopts the ferric high-spin state.

4. *Iron(V) Porphyrins*

Two groups have reported the formation of iron(V) porphyrins. Nanthakumar and Goff oxidized pyrrole deuterated [Fe^{III}(F_2-TPP)F_2]$^-$ with *m*-CPBA in CH_2Cl_2

solution in the presence of excess fluoride ions and obtained a red complex.[282a] The product shows the pyrrole-D signal at 1.3 ppm at 210 K. This signal is observable even at 290 K although it is converted rapidly to the starting $[Fe^{III}(F_2\text{-}TPP)F_2]^-$ complex along with partial decomposition of the porphyrin. The chemical shift of the pyrrole-D signal obeys the Curie law from 220 to 270 K with a *y* intercept at 7.3 ppm. The phenyl proton signals are observed at 9.0 and 15.0 ppm, unlike the case for iron porphyrin cation radical species. The red complex shows a Soret band at 430 nm and a Q band at 550 nm. The EPR spectrum taken at 80 K exhibits three distinct signals at $g = 4.38, 3.11, 2.70$. Its solution magnetic moment at 210 K is $4.1 \pm 0.2\ \mu_B$, which is close to the spin-only value expected for $S = 3/2$. Since an iron(IV) compound with $S = 1$ is expected to be EPR-silent, the red complex appears to be the first example of an iron(V) porphyrin. It should be noted that this complex is observed only in the presence of a large excess of fluoride ligands. Thus, the red complex can be expressed as either $[Fe^V(F_2\text{-}TPP)F_2]^+$ or $[(Fe^V{=}O)(F_2\text{-}TPP)F]$.

Formation of an iron(V) porphyrin was also reported by Morishima *et al.*[283,284] They oxidized $[Fe^{III}(2,6\text{-}Cl_2\text{-}TPP)(OCOAr)]$ with 1.8 equivalents of *p*-nitroperbenzoic acid (*p*-NPBA) in CH_2Cl_2 solution in the presence of nine equivalents of *m*-chlorobenzoic acid at 183 K and obtained the green oxo-iron(IV) porphyrin cation radical $[(Fe^{IV}{=}O)(2,6\text{-}Cl_2\text{-}TPP^{\bullet})]^+$. This green solution turns red upon addition of four equivalents of methanol. The red complex exhibits characteristic UV–vis bands at 418 and 546 nm, which are similar to those of the $Fe^{IV}{=}O$ species, but very different from those of iron(III) porphyrin dications and iron(III) porphyrin N-oxides.[286–289] The pyrrole-D and *meta*-D signals of the deuterated red complex appear at −35.1 and 8.0 ppm, respectively. While the green complex is EPR silent, the red one exhibits EPR signals at 4.33, 3.69, and 1.99 at 4.2 K in frozen CH_2Cl_2 solution. Both green and red complexes are reduced by two equivalents of tetra-n-butylammonium iodide. The red complex reacts with norbornene even at 183 K to form norbornene oxide, though this reactivity is about 10 times less than for the green complex. The solution magnetic susceptibility of the red complex is $4.0 \pm 0.2\ \mu_B$, indicating that the complex has three unpaired electrons. The red complex ισ also obtained by addition of 1.8 equivalents of pentafluoroiodosylbenzene in the presence of 200 equivalents of methanol. Taken all together, the red complex is isoelectronic with the green one $[(Fe^{IV}{=}O)(2,6\text{-}Cl_2\text{-}TPP^{\bullet})]^+$ and is best expressed as an oxo-iron(V) porphyrin $[(Fe^V{=}O)(2,6\text{-}Cl_2\text{-}TPP)]^+$.

The iron(V) porphyrins reported by the two groups are similar in UV–vis and magnetic properties. However, the former complex is relatively stable even at ambient temperature while the latter decomposes at 208 K to the starting high-spin iron(III) complex after several hours. In addition, the ^2H NMR chemical shifts of the deuterated complexes are totally different. While the former complex shows

the pyrrole-D signal at +1.3 ppm at 210 K, the latter complex shows it at −35.1 ppm at 178 K. The difference in chemical shifts of pyrrole-D signals could be explained in terms of the difference in axial ligands. In the case of the former complex, the iron(V) species is obtained only in the presence of a large excess of fluoride ions. Thus, the complex could be expressed as $[Fe^{V}(F_2\text{-TPP})F_2]^+$ rather than $[(Fe^{V}{=}O)(F_2\text{-TPP})F]$. Even in such a case, it is still difficult to explain why two kinds of iron(V) species exhibit such a large difference in pyrrole-D chemical shifts. As mentioned in the previous section, the ^{1}H NMR spectrum of $[(Fe^{IV}{=}O)(TMP)]$ is very different from that of $[Fe^{IV}(TMP)(OMe)_2]$ though both of the complexes adopt the iron(IV) with the $(d_{xy})^2(d_{xz}, d_{yz})^2$ electronic ground state. In this case, the former complex with the Fe^{IV}=O bond shows the pyrrole-H signal close to the diamagnetic position, at 5.85 ppm at 195 K, while the latter complex exhibits it at −37.5 ppm at the same temperature, as shown in Table 34.

Jayaraj *et al.* oxidized similar complexes [Fe(Por)Cl], where Por has strongly electron-withdrawing aryl groups at the *meso* positions, including [Fe(2,6-Cl_2-TPP)Cl]. The ^{1}H NMR, UV–vis, Mössbauer, EPR, and resonance Raman spectra indicated the formation of an oxo-iron(IV) porphyrin radical cation $[(Fe^{IV}{=}O)(Por^{\bullet})]^+$ with an a_{1u} cation radical even in the presence of methanol.[312] On the basis of the spectroscopic data, Jayaraj *et al.* ruled out the possible structural assignment of high-spin iron(V) coordinated to the neutral porphyrin ligand. Dey and Ghosh reported that DFT calculations suggest that the oxo-iron(IV) porphyrin cation radical is more stable than the corresponding oxo-iron(V) complex.[239] However, since the ^{1}H NMR spectra of Nanthakumar and Goff, Morishima *et al.*, and Jayaraj *et al.* are all different, it is impossible to rule out the existence of the iron(V) porphyrins reported by Nanthakumar and Goff as well as by Morishima *et al.* Further experimental and theoretical studies are necessary in order to fully characterize these iron(V) porphyrins.

VII. Acknowledgments

The authors would like to thank all their current and former coworkers and students whose names are given in the references of this chapter. We are especially indebted to Dr. Takahisa Ikeue of Shimane University, Professor Masashi Takahashi of Toho University, and Professor Saburo Neya of Chiba University. Without their cooperation, our contributions to this field would have been much smaller. Work in the authors' laboratories was financially supported by the Research Center for Materials with Integrated Properties in Toho University, a Research Promotion Grant from Toho University Graduate School of Medicine, Sumitomo Foundation, and a Grant-in-Aid for Scientific Research from MEXT, Japan.

33 Optically Active Porphyrin Systems Analyzed by Circular Dichroism

Nagao Kobayashi

Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-8578, Japan

I. Introduction

Circular dichroism (CD) is detected as the difference between the absorption of left and right circularly polarized light when equal amounts of left and right polarized light interact with chiral molecules, i.e. $\Delta A = A_l - A_r$, where A_l and A_r are the absorptions of left and right circularly polarized light respectively.[1–6] Depending on the relative sizes of A_l and A_r, the observed CD can be either positive or negative. Since normal porphyrins (Por) are planar achiral molecules, they do not show CD *per se*. However, when chiral substituents are linked (they are called extrinsically active) or molecules are intrinsically optically active, or when a plurality of Pors have the proper (chiral) mutual orientation, CD is often observed. In this chapter, the fundamental aspects of CD theory which may be required to understand the chapter are first described, and then Por systems analyzed using this spectroscopy are introduced in roughly chronological order. Here, discussion is confined to electronic CD, since Pors are chromophores having absorptions in the near-UV to near-IR regions. Syntheses of some representative optically-active Pors are also introduced, even where the CD spectra are not necessarily well-analyzed. In particular, some systems are interesting from the view point of CD analysis even if their CD spectra are not analyzed or even reported.

II. Fundamentals of Circular Dichroism

A. Phenomenological and Theoretical Basis

Since CD is defined as the difference of absorbance between left and right circularly polarized light, we should first know about electronic absorption spectra. When chromophores are excited by electromagnetic radiation in the form of light, the transition of the electron from the initial to the final orbital is associated with a charge migration or electron cloud redistribution, which leads to an electronic dipole (μ). For each electronic transition, an electronic and a magnetic transition dipole can be defined. If the initial and final states are labeled i and j respectively, a linear charge displacement brings about an electronic transition dipole, μ_{ij}, while an electron rotation produces a magnetic transition moment $\mathbf{m}_{ij}$. The experimental

absorption intensity is obtained by integration of spectra whose abscissa is expressed by a unit proportional to energy, and this is directly related to the oscillator strength $\mathbf{f}_{ij}$ that is proportional to $|\mu_{ij}|^2 + |\mathbf{m}_{ij}|^2$. For symmetry reasons, the electronic dipole term is often much larger (*ca*. five orders of magnitude) than the magnetic dipole, so that if the absorption is strong, it is generally called an electric-dipole allowed transition, and this is the case for almost all aromatic molecules without chirality. In the case of optically active molecules, a magnetic transition moment is also produced, i.e. both μ_{ij} and $\mathbf{m}_{ij}$ have some value. The direction of $\mathbf{m}_{ij}$ is determined using the right hand grip rule. If the second through fifth fingers follow the movement of charge, then the thumb points in the direction of $\mathbf{m}_{ij}$. The CD intensity $\mathbf{R}_{ij}$, called the *rotational strength,* is experimentally obtained from the integral of the CD curves. $\mathbf{R}_{ij}$ is proportional to the scalar product of μ_{ij} and $\mathbf{m}_{ij}$, i. e. $\mathbf{R}_{ij} = \mu_{ij} * \mathbf{m}_{ij}$, and can have both signs. As mentioned above, the intensity of the electronic absorption spectra is roughly proportional to $|\mu_{ij}|^2$ and that of the CD spectra $\mu_{ij} * \mathbf{m}_{ij}$. CD is therefore generally obtained only in the same wavelength region as the electronic absorption spectra. An intense CD is observed only when either μ_{ij} or $\mathbf{m}_{ij}$ is large, so that if the electronic absorption is weak, the CD is also often weak. There is a rule that the integral of the CD over the whole electromagnetic spectrum is zero. Although CD spectra of only one sign are sometimes observed, in such cases the spectra of the counter sign is hidden at shorter wavelengths than the instrumental limit.

B. Porphyrin Chromophores

Porphyrins (Figure 1) have an almost square planar shape, so that metallocomplexes are approximated as chromophores of D_{4h} or D_4 symmetry, while metal-free

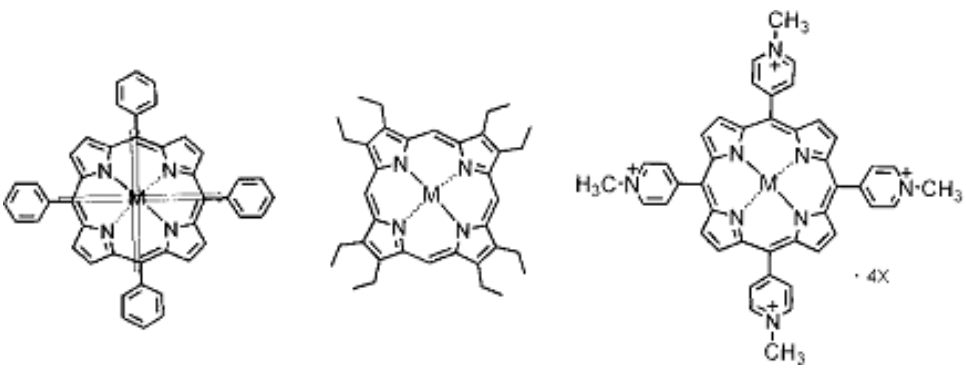

Figure 1. Metalloporphyrin chromophores and degenerate transition dipoles. In the case of *meso*-aryl porphyrins, one dipole is along 5 and 15-positions while another is along 10 and 20-positions.

derivatives have D_{2h} or D_2 symmetry. Depending on the type or position of substituent groups, the symmetry can be lowered further. The porphyrins usually used for chiroptical systems are often 5,10,15,20-tetraphenylporphyrin and its derivatives. When there is no other substituent on the periphery, the lowest two excited states are doubly degenerate and the x- and y-directions are set on the lines connecting the *trans meso–meso* positions, while this can be changed by peripheral substituent groups on the pyrrole ring. For example, in the case of tetraphenylporphyrin, when a carboxyl group is introduced at the para position of one of the four phenyl groups in order to link to the OH groups of natural products, the two orthogonal transition dipoles in the π-plane are still lying along the *trans meso–meso* directions. In the case of chlorins, where one of the four pyrrole rings is reduced, the two axes are aligned along the *trans pyrrole–pyrrole* directions. Chlorophylls have an extra carbocyclic ring between one pyrrole ring and the meso positions, so that in this case, the precise direction of the two dipoles has to be determined by MO calculations. On the other hand, D_{4h} or D_4 symmetric metallophthalocyanines have two degenerate transition dipole moments along the *trans pyrrole–pyrrole* directions.

C. Exciton Coupling

Typical exciton coupling is seen when a plurality of chromophores with electric dipole-allowed transitions interact through space, maintaining independence as a chromophore. Depending on the arrangement or orientation in space, the resultant spectra become different (Figure 2).[7,8] When two (or more) chromophores are in a cofacial arrangement, the absorption spectrum shifts to shorter wavelengths, which is often called an H-aggregate if the constituent chromophores are numerous. Another typical orientation is the almost parallel head-to-tail type which produces a spectrum at longer wavelengths compared to that of the constituent chromophore. If many chromophores are arranged in this fashion, this is called a

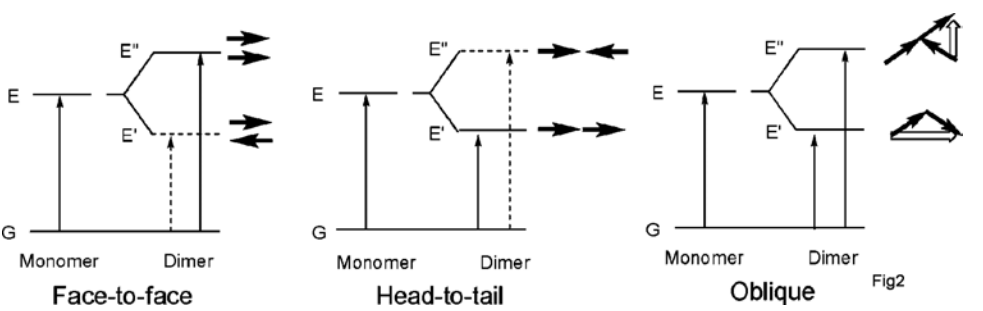

Figure 2. Band splitting of face-to-face, head-to-tail, and oblique dimers.

J-aggregate. A more general type is the case where the chromophores are arranged obliquely in space. Under these conditions, theoretically, two absorption peaks would appear at both a longer and shorter wavelength compared to the absorption peak of the monomer, although depending on the spatial arrangement and distance of the chromophores, two peaks are not always clearly seen. For a theoretical analysis, the use of two identical chromophores and a C_2 or lower symmetry arrangement is particularly important for CD spectroscopy. This exciton coupling method has been widely applied in order to determine the configuration and conformation of natural products and organic compounds. Although not necessarily stated explicitly, there are several important points to consider when using this method. These are: (1) The chromophores must retain independence. If the chromophores are mutually conjugated, this often leads to an incorrect analysis; (2) It is desirable to use chromophores which have intense absorption in the wavelength region where the substrates do not absorb, and (3) It is desirable to use chromophores whose direction of transition moment is established. From these standpoints, *para*-dimethylaminobenzoic acid and 5-*p*-carboxyphenyl-10,15,20-triphenylporphyrin have been widely used as chromophores. The former case has strong absorption ($\varepsilon = ca.$ 28,000–30,000) at *ca.* 310–320 nm, where natural products have almost no absorption. *Para*-dimethylaminobenzoic acid has a permanent dipole along the axis connecting the dimethylamino and carboxyl groups, and the transition moment at the longest wavelength band lies in this direction.[9] In the case of porphyrins, the Soret band lies at a longer wavelength at *ca.* 410–420 nm, and its absorption coefficient reaches[8,9] the order of *ca.* 5 or 6×10^5 so that this chromophore can be used for further analysis of large substrates where dimethylaminobenzoic acid is of limited use.

Figure 3 illustrates an example of the exciton coupling of a 1,2-diol bis(4-substituted benzoate). Here, one would like to know the configuration of the two carbon atoms to which OH groups are linked. The important point to note is that the direction of the transition moment at the longest wavelength (the line connecting the carboxyl C and the para position of the benzene ring) is almost parallel to that of the C–O of C–OH. As shown in Figure 3(b), upon exciton coupling between two benzoate chromophores, the excited state splits into two energy levels, while the ground state remains as a single state. The energy gap of 2V in the excited state is called the *Davydov splitting*. As a result, there are two electronic transitions leading to two absorption bands. If the two transition moments are not coplanar, the magnetic moment generated by the oscillating dipole **1** will be non-orthogonal to dipole **2**. Thus, excitations to the two split energy levels give rise to the CD Cotton effect of mutually opposite signs (Figure 4) which are separated by the energy gap $\Delta\lambda$ (= 2V, Davydov splitting). Summation of the component Cotton effects results in a solid curve having two extrema. The maximum at longer

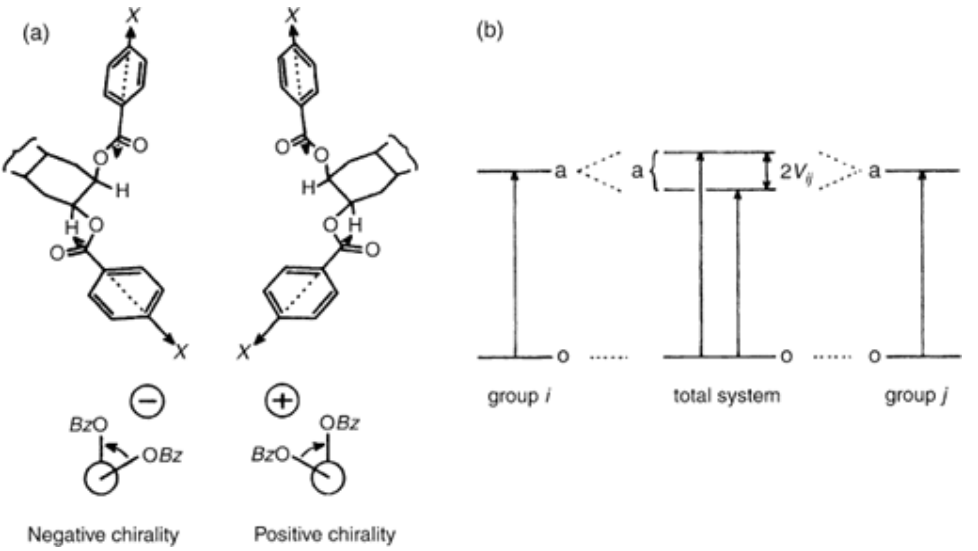

Figure 3. (a) Exciton coupling between two identical chromophores (degenerate system), as exemplified by the system of 1,2-diol bis(4-substituted benzoate); (b) by exciton coupling, the excited states split into two energy levels; the energy gap $2V_{ij}$ is called Davydov splitting (redrawn from Ref. 7).

wavelength is called the first Cotton effect, while that at shorter wavelength is called the second Cotton effect. The amplitude of split Cotton effects is defined as $\Delta\varepsilon_1$–$\Delta\varepsilon_2$, where $\Delta\varepsilon_1$ and $\Delta\varepsilon_2$ are the intensities of the first and second Cotton effects. In the case of UV spectra, summation of two component spectra often leads to a single broadened maximum because in many cases, the energy gap $\Delta\lambda$ is relatively small compared to the bandwidth. Provided the electronic transition dipole moments of the two chromophores constitute a clockwise screw sense (positive exiton chirality), as exemplified by the dibenzoate on the right hand side of Figure 3a, the sign of the first CD Cotton effect (lower energy side) is positive and that of the second Cotton effect (higher energy side) is negative (Figure 4, right). When the two dipole moments make a counter-clockwise screw sense (negative exciton chirality as shown on the left hand side of Figures 3a and 4), the signs of the first and second Cotton effects are negative and positive, respectively. Since the $\Delta\lambda$ is small, the resulting CD spectrum has a bisignate shape with respect to the absorption maximum. The amplitude of a CD spectrum, which is defined as the distance between the peak and trough of a split CD curve is (i) inversely proportional to the square of the interchromophoric distance, (ii) proportional to the absorption coefficient of their chromophores and (iii) dependent on the interchromophoric projection angle with a maximum at approximately 70 degrees and minima at 0 and 180 degrees.[10]

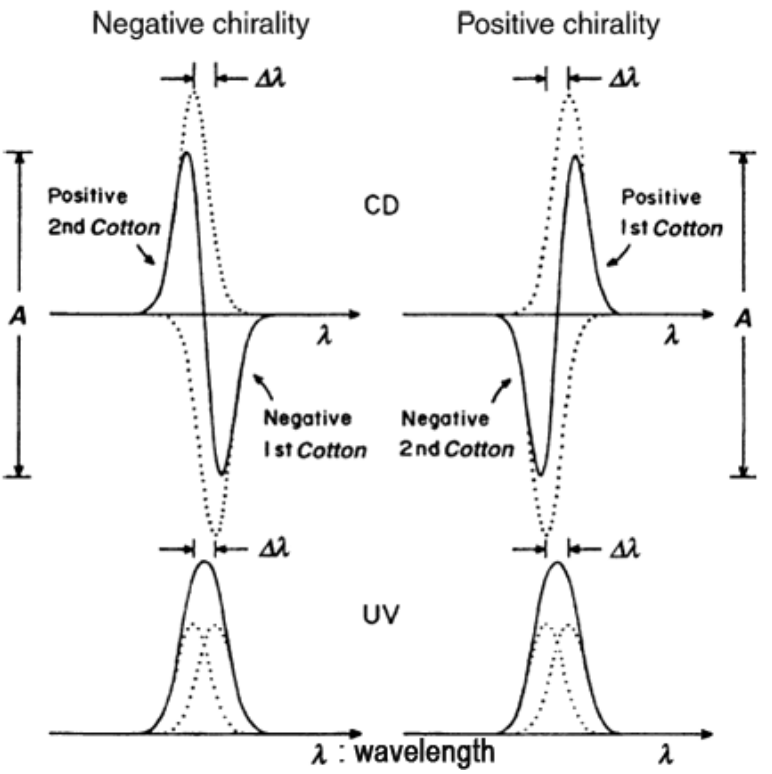

Figure 4. Typical pattern of CD and electronic absorption spectra of exciton coupling system. Summation of two component Cotton effects (dotted line) of opposite signs separated by Davydov splitting ($\Delta\lambda$) yields CD and absorption curves of solid line; positive chirality gives positive first and negative second CD Cotton effects, whereas negative chirality gives negative first and positive second Cotton effects; the amplitude (A) is defined as: $A = \Delta\varepsilon_1 - \Delta\varepsilon_2$ where $\Delta\varepsilon_1$ and $\Delta\varepsilon_2$ are intensities of the first and second Cotton effects. (left) Counter-clockwise and (right) clockwise of two identical exciton coupling chromophores leads to negative (left) and positive (right) chirality (redrawn from Ref. 7).

III. Natural Heme and Synthetic Heme Systems

A. Natural Heme Systems

CD spectra of hemoproteins began to appear at the end of the 1960s, but interpretation of the spectra has rarely been attempted. As an example, Figure 5 shows the spectra of human hemoglobin.[11] Although four hemes are included (in a strict sense, heme means an iron porphyrins found in nature), there is almost no heme–heme interaction, so that these can be regarded as representative monomeric heme spectra. One observes large negative CD troughs at 222 and 208 nm in the 200–250 nm region, which have been assigned to n–π^* and π–π^* transitions in an α-helix, and the helix content can be estimated therefrom. Although several

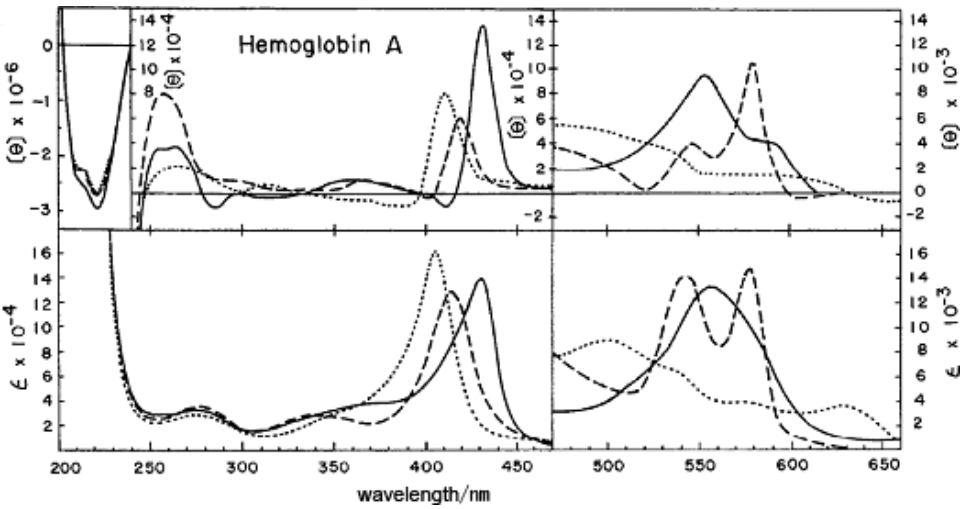

Figure 5. CD and electronic absorption spectra of native human hemoglobin. Oxygenated hemoglobin (broken lines), deoxygenated hemoglobin (solid lines), and methemoglobin (dotted lines) (redrawn from Ref. 11).

methods are reported to estimate the helix content from the negative CD intensity, the estimated helix contents are in good agreement with the data from X-ray analysis for myoglobin, lisozyme, ribonuclease, and chimotripcin.[12] Greenfield and Fasman[12] and others[13,14] further suggested a method from which the content of α-helix, β-sheet structure and random coil structure in unknown samples can be estimated.[12–15] However, the contribution of porphyrin chromophores to the CD in this region is small, so not many porphyrin chemists are interested in CD in this region.[16] The CD of heme in the 250–300 nm region is generally produced by aromatic amino acids.[17] However, only a CD peak at *ca.* 260 nm commonly appears for hemoglobin,[11] myoglobin,[18] and cytochrome *c*,[19] and its intensity varies depending on the spin and oxidation of the central iron. Furthermore, this peak is observed in hemeoctapeptides[20] not containing aromatic amino acids, S–S bonding, or SH groups so that it is believed to be a heme-related CD peak.

The *ca.* 320–650 nm region has been assigned to the porphyrin chromophore. As clearly shown in Figure 5, the shapes of the CD spectra resemble those of the electronic absorption, and the sign is positive except in a small region at shorter wavelengths than the Soret band. Although many hemoproteins show this kind of CD pattern, only larvae cytochrome *b*-563[21] and *b*-555[22] from the housefly, *Musca domestica L.* (Figure 6), cytochrome b2 from bakers' yeast L-lactate dehydrogenase,[23,24] indoleamine-2,3-dioxygenase,[25,26] and lamprey hemoglobin[27] give negative CD troughs corresponding to almost all the absorption peaks. In addition, a

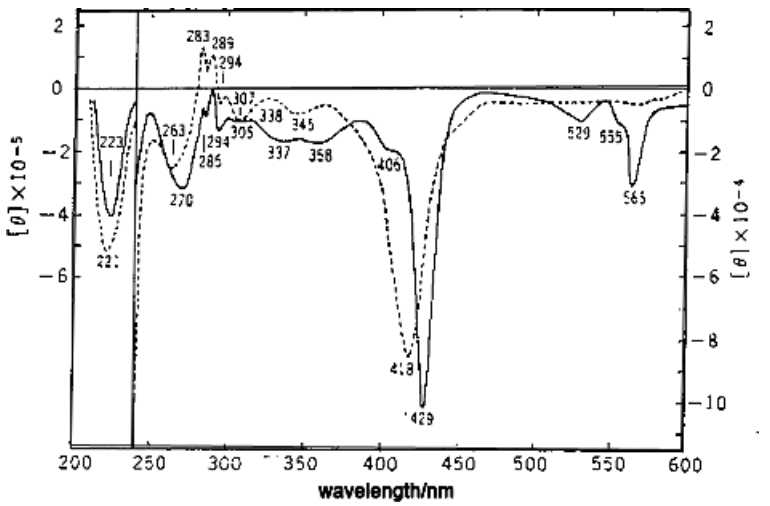

Figure 6. CD spectra of larval ferri- (broken line) and ferrocytochrome *b*-563 (solid line) from *Musca domestica L.* (redrawn from Ref. 21)

dispersion type CD is observed for the Soret band of a cytochrome *c*[28] and human hemoglobin.[27] These differences of CD Cotton effects were once conjectured to reflect the difference of the functions of hemoproteins,[21] but were insufficient to allow generalization. Furthermore, some information or facts had been accumulated on the Soret and visible region CD up to the mid-70s. For example, changing the oxidation state of the heme iron induces CD changes in both the aromatic amino acid (200–250 nm) and porphyrin chromophore (*ca.* 320–650 nm) regions.[29] For this phenomenon, the change of the sixth ligand and the out-of-plane shift of iron from the porphyrin plane were suggested as the origin.[19] No satisfactory explanation was given for the changes in intensity and shape in the visible region CD peaks accompanying a change of the axial ligand. On the other hand, the Soret CD of tetrameric hemoglobin could not be expressed as a summation CD of the constituting four subunits.[30]

Under such circumstances, Hsu and Woody were the first to attempt a theoretical analysis of the CD spectra of hemoproteins whose several structures were analyzed by X-ray spectroscopy.[31] Before calculation, they extracted rotational data from experimental data. The Soret rotational strengths in metmyoglobin and hemoglobin were estimated to be 0.5 and 0.2 Debye–Bohr magnetons (DBM, 1 DBM = 0.9273×10^{-38} cgs unit), respectively. They considered, with respect to the shape, intensity, and sign of the Soret and visible CD spectra of X-ray-analyzed myoglobin and hemoglobin, that the interaction between transitions in heme and the excited states in the globin skeleton and side chains is responsible. On the basis of Kirkwood's theory[32] as extended by Tinoco[33], they then calculated the interaction

between the Soret or Q transition and π–π^* transitions of aromatic amino acids, π–π^* and n–π^* transitions of polypeptides, and σ–σ^* transitions of alkyl groups located in the proximity of the heme, and obtained results which could be rationalized with the experimental data. According to these authors, the sign and intensity of the Soret and Q band CD are determined by interaction between the transitions in heme and the allowed π–π^* transitions of aromatic amino acids. The calculated myoglobin rotational strengths arising from interaction with allowed π–π^* transitions in aromatic side chains are 0.306 (Rx = 1.295, Ry = –0.989), 0.0146, –0.0050, and 0.1619 DBM for the Soret, Q, N, and L band respectively. These are qualitatively in agreement with the experimental results. Here, the Q band rotational strength was positive and about one order of magnitude smaller than that of the Soret band. Among the aromatic residues, His(64,7E), His(97,2FG), Phe(33,14B), Tyr(103,4G) and Tyr(146, 23H) give major contributions. His(64,7E) is the distal histidine that is close to the sixth ligand of the iron. The fifth ligand, His(93,8F), gives only a small effect because its imidazole group sits in a rather symmetrical position with respect to the heme, and the imidazole plane is nearly perpendicular to the heme plane. Because of the closeness of the proximal imidazole and heme, one might expect that the resultant Soret rotational strength would be sensitive to the relative position of these two groups. Accordingly, calculations were carried out with the imidazole plane rotated by 0–90 degrees and tilted by 1–10 degrees with respect to the heme plane. In all cases, the calculated Rx and Ry are almost equal in magnitude and opposite in sign. Hence, the proximal histidine was concluded not to play a major role in induced Cotton effects of the heme proteins.

In a similar manner, calculations for horse hemoglobin show that the α and β chains have contributions to the average rotational strength which are nearly equal in magnitude and opposite in sign (α chain, 0.631 DBM; β chain, –0.634 DBM).[31] Among the aromatic residues in the α chain, His-58, Phe-33, Phe-43, Phe-98, Try-42, Try-140, and Trp-14 make the major contributions to the rotational strength. For the β chain, the major contributions come from His-63, His-69, Phe-42, Phe-41, Phe-71, Phe3-85, Phe-103, Tyr-130, and Trp-15. Again the proximal histidines, His-87 of the α chain and His-92 of the β chain, give only small net contributions to the Soret rotational strength. It was found that,[31] because of the strongly allowed transitions in the far-UV region, tyrosine and tryptophan at a distance of 10–15 Å from the heme group give significant rotational strength to the heme transitions. The calculated Soret rotational strength due to intersubunit interactions was 0.1 DBM, as compared to the experimental 0.23 DBM for human oxyhemoglobin.

In order to estimate the extent of coupling of the heme transitions with transitions in the polypeptide backbone, the 220 nm (n–π^*) and then the 190 nm (π–π^*)

bands of amides (about 120 in all) were considered.[31] The net contribution to the Soret rotational strength from these two types of coupling was negligibly small (0.003 DBM). In calculating the coupling of heme transitions with transitions in the alkyl side chains, 65 side chains in myoglobin were included. The intensity of the σ–σ^* transition in the C–C bond was fairly large, but the induced Soret rotational strength through coupling with these transitions was at most only a few hundredths of a DBM, partly because of the large energy separation between the Soret and σ–σ^* transitions (~280 nm). The total contribution to the myoglobin Soret rotational strength from the σ–σ^* transitions of the 65 alkyl side chains was only 0.04 DBM.

Later, similar results were obtained for the CD band of hemoglobin III from *Chironomus*[34] and cytochome *c* peroxidase from baker's yeast (*Saccharomyces cerevisiae*).[35] A small negative Cotton effect seen at shorter wavelengths in the Soret band of Figure 5 was reproduced by taking the direction of the transition of the Soret band into account (experimental data were reproduced when the two Soret components are polarized towards the bridging methine carbons[31]). When calculations were performed assuming that the vinyl groups at the 2 and 4 positions of protoporphyrin IX were rotated by 45°,[36] the contribution of negative CD was revealed in the Soret band region. In particular, the effect of the two vinyl groups was so marked that the CD sign and intensity produced by interaction between the heme transition and π–π^* transitions of the aromatic amino acids may be canceled when two vinyl groups are rotated in a similar direction.

Figure 7a shows the CD spectrum of a undecapeptide–CO complex purified from horse heart cyctochome *c*.[37] This compound contains only a heme and an eleven amino acid peptide (Val-Glu-Lys-Cys-Ala-Gln-Cys-His-Thr-Val-Glu), and has been considered to be the simplest heme model compound (a heme is linked to two Cys units). With increasing concentration, it aggregates in a head-to-tail fashion, and the intermolecular distances are estimated to be 10 and 13 Å, respectively, when the iron is in trivalent and divalent states (in the case of heme octapeptides where a Val-Glu-Lys unit was removed from heme undecapeptide,[38] they form a card-type aggregate and the interplanar distance is considered to be less than 7 Å[39]). In the spectra, the solid line shows the aggregated state, and can be explained by an exciton coupling interaction. The minus-to-plus pattern of almost similar intensity from longer wavelengths associated with the Soret peak indicates that the molecules are aggregated in a left-handed manner.[1,7] Figure 7b shows the CD spectra of monomeric ferric (solid line) and ferrous hemes (broken line) coordinated by an imidazole molecule as a fifth ligand. Although the spectra are similar in shape to those of Figure 5, theoretical calculations were carried out incorporating various factors,[37] since the intensity was much larger than that seen in Figure 5. The Soret CD intensity was estimated taking into account the

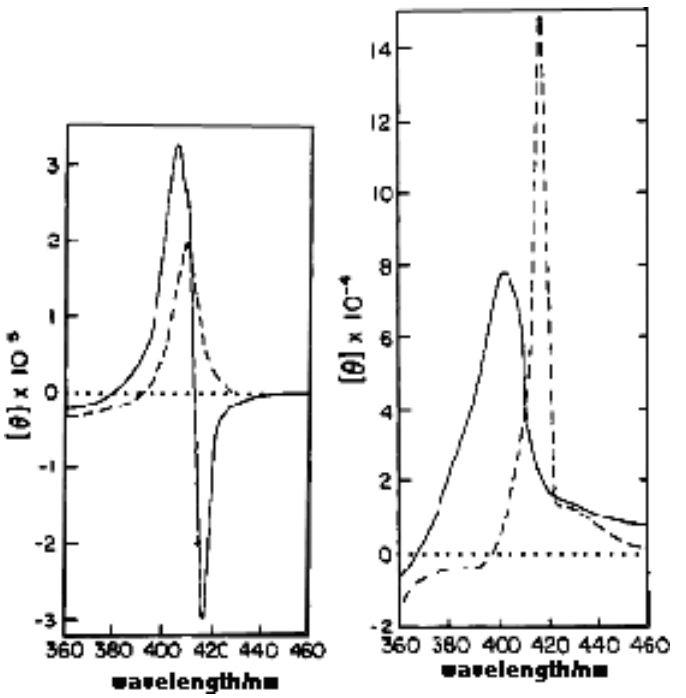

Figure 7. (a) CD spectrum of the CO complex of reduced heme undecapeptide at two different concentrations, 6.2×10^{-3} M (solid line) and 1.5×10^{-6} M (broken line), at pH 7.4. (b) CD spectrum of the heme undecapeptide (concentration = 7.3×10^{-5} M) from equine heart cytochrome *c* in the presence of 0.1 M imidazole in aqueous solution, ferric (solid line, pH 9) and ferrous (broken line, pH 8.4) state (redrawn from Ref. 37).

deformation of the heme plane from the X-ray data,[40] in addition to the π–π^* transition of imidazole, π–π^* and n–π^* of peptides, and polarization of the bonding. As a consequence, it was found that the n–π^* of peptides can be neglected and that the contribution of the π–π^* of imidazole was also small. That is, when imidazole was coordinated as an axial ligand, the intensity did not change whether one or two imidazole molecules were coordinated. The π–π^* transition of peptides and the polarization effect of the sulfur of thioether were found to produce large positive and negative CDs respectively. The polarization effect of the group depended on the models used, and the experimental data could only be reproduced when the symmetry axis was situated approximately along the C=O bond. In addition, it was concluded that the asymmetry of the ligand fields give little contribution.

In recent years, the CD of reconstituted hemoproteins has attracted attention.[41–46] When heme is inserted into apoprotein, the most stable orientation equilibrium is not always attained immediately, sometimes taking a few minutes to several weeks to complete. If the porphyrin is deformed and if the front and back

sides can be discriminated, the process can be followed as a change in the CD spectra. Since the same process can also be monitored by NMR, the ratio of front and back sides can be estimated by comparing the CD and NMR spectra. When naturally occurring hemes are used, the CD spectrum approaches that of natural hemoproteins with elapsing time, but occurs almost instantaneously (milliseconds) in the case where synthetic porphyrins having a plane of symmetry are used.[45,46] The latter case is considered to be produced as a result of the front and back sides being identical.

As an example, Figure 8 (top) shows the Soret CD spectra of native and reconstituted sperm whale myoglobin in the carbonmonoxy form at pH 7.4,[42] and the

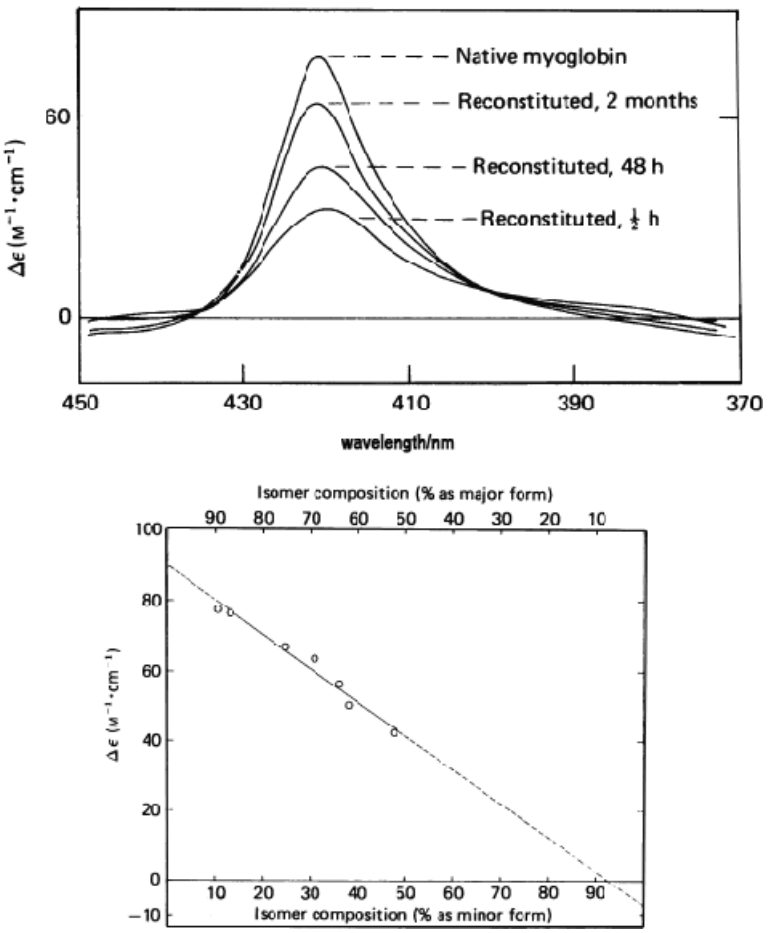

Figure 8. CD spectra of carbomonoxymyoglobin in 0.1 M sodium phosphate buffer (top), and correlation of CD signal with percentage isomer composition (bottom) (redrawn from Refs. 42 and 44).

correlation of CD intensity with isomer composition determined from the ^{1}H NMR spectra (Figure 8b), major and minor refers to native and disordered forms, respectively).[46] By extrapolation of the results in Figure 8 (bottom), the CD intensities of the pure native and pure disordered orientations were predicted, so that using these values, the native orientation in sperm whale myoglobin at equilibrium was found to be predominant (90%) with 10% of the disordered form still persisting.

Reports on the CD spectra of hemoproteins in the near-IR region are very rare. Iron(II) cytochome *c* shows very broad, weak absorptions between 600 and 1000 nm, and the corresponding CD spectra have been reported (Figure 9).[47] In this hemoprotein, the fifth and sixth coordination sites are occupied by methionyl sulfur and histidyl nitrogen. The anisotropy factor (four times the CD intensity divided by the absorption intensity,[48] i.e. 4R/D) is about 0.002, which is larger than those of typical magnetic dipole-forbidden π–π transitions by about one order of magnitude. This relatively much larger anisotropy factor for the near-IR band, compared to the porphyrin π–π transitions, permitted the authors to identify some of the near-IR bands as due to magnetic dipole allowed *d*–*d* transitions. The low absorption intensity compared with the porphyrin π–π transition was also consistent with this conclusion. Both the absorption and CD spectra were simultaneously

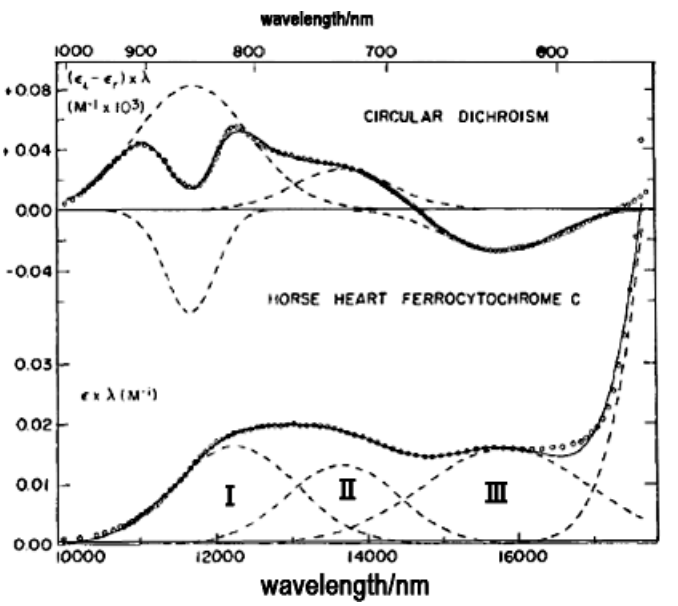

Figure 9. Absorption and CD spectra of horse heart ferrocytochrome *c* with resolution into Gaussian bands using a least-square method. Circles are the experimental points, dashed lines are the Gaussian components, and the solid lines are the Gaussians (the fit) (redrawn from Ref. 47).

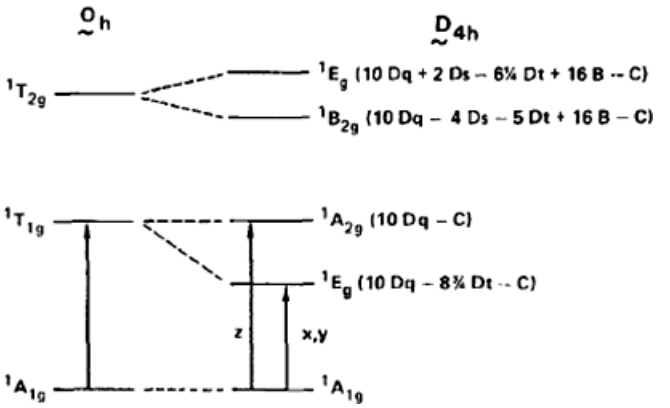

Figure 10. Singlet states of a low-spin d^8 iron in a tetragonal crystal field with first-order energies relative to the ground state. Also indicated are the magnetic dipole allowed transitions from the ground state which are allowed in octahedral symmetry (redrawn from Ref. 47).

fitted on the assumption that the corresponding band has a similar energy and bandwidth. Three components were required in the absorption spectra (bands I to III in order of ascending energy), while two CD components were included associated with band I. These fits were analyzed using the lowest excited singlet states in Figure 10.[49,50] In this *magnetic* dipole radiation field (600–1000 nm), only in-plane polarized *electric* dipole intensity can contribute to the rotational strength of *d–d* transitions, since for a transition to be optically active, *electric and magnetic* transition dipole vectors must be parallel or antiparallel.[1] As shown in Figure 10, the lowest and second lowest ligand–field transitions are polarized along the x, y (in-plane) and z-axes, respectively. The lowest transition can therefore borrow intensity from the nearby intense in-plane polarized, electric dipole-allowed π–π transitions. As a result, the CD intensity in the lowest transition region was expected to be larger than the other region. Indeed, between 900 and 1000 nm, the anisotropy factor was estimated to be 0.013, which is more than 6 times larger than in the other region, so that band I was assigned to $^1A_{1g} \rightarrow {}^1E_g$.[47] The two CD components in this region were then presumed to be the components of the doubly degenerate ^1E_g states.

In Ref. 50, an $^1A_{2u}$ charge-transfer state was predicted by the authors to lie close to ^1E_g. This charge-transfer state arises by promotion of an electron from the top-filled porphyrin π-orbital to an empty iron d_{z2} orbital. Therefore, this transition is polarized normal to the porphyrin plane (z-axis). Taking into account that this CT transition is predicted at 17,000 cm^{-1},[49] either band II (14,400 cm^{-1}, *ca.* 795 nm) or III (15,800 cm^{-1}, *ca.* 633 nm) can be assigned to this CT band. Thus, the use of CD spectroscopy coupled with electronic absorption spectroscopy enabled

the analysis of *d–d* transitions. Although for low-spin iron(II) carboxymyoglobin, the lowest energy *d–d* transitions and z-polarized CT transitions of similar energy were found at 16,000 and 19,000 cm^{-1}, which are higher than the observed 14,400 and 15,800 cm^{-1} for ferrous cytochrome *c*, this was attributed to a weaker ligand-field for the latter. These differences are further attributed to differences in the fifth and sixth ligands, which in carboxymyoglobin are hystidyl nitrogen and carbon monoxide.

The near-IR CD of bovine liver catalase (Figure 11) has also been measured.[51] Native Fe(III) catalase shows a very intense near-IR CD peak at 880 nm with $[\theta] = 30{,}000$ and a shoulder at 970 nm. When an extraneous ligand was added, the magnitude of the CD bands decreased in the order of native > azide > cyanide.[50] Fe(III) catalase is known to have a high-spin character compared with other hemeproteins, since one of the axial ligands is phenolate, different from the imidazole of most hemoproteins.[52] Indeed, the effective Bohr magneton numbers for native catalase and its azide and cyanide analogs are 5.96, 5.86, and 2.63, respectively,[53] indicating that both the native and azide forms are ferric high-spin and

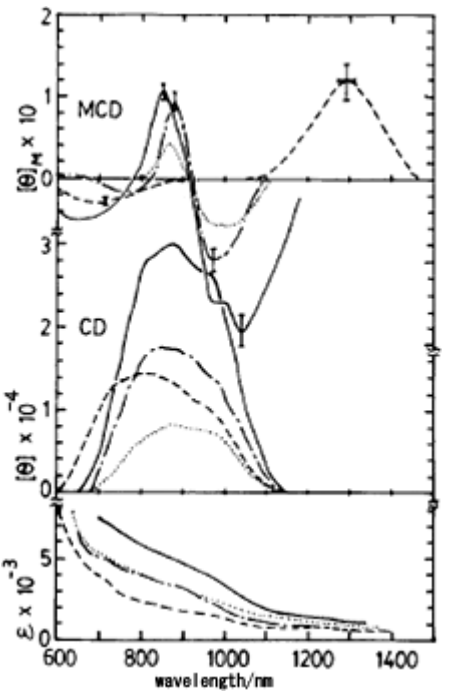

Figure 11. Near-IR MCD, CD and absorption spectra for native Fe(III) bovine liver catalase (solid lines), and its azide (dotted broken lines), cyanide (broken lines), and imidazole (dotted lines) derivatives (redrawn from Ref. 51).

that cyanide is a ferric low-spin compound. MCD spectra in this region showed dispersion type Faraday *A* terms except for cyanide, and at a shorter wavelength than for other ferric hemoproteins. From these spectroscopic results,[54–57] the near-IR band has been assigned to a charge-transfer transition from porphyrin a_{1u}, a_{2u} (π) to iron e_g (dπ) orbitals. However, the reason for the extraordinarily strong CD has not yet been elucidated.

Although high-spin ferrous myoglobin shows positive CD bands at *ca*. 1330, 970, and 760 nm with low anisotropy factors of 0.01, 0.001, and 0.0001, respectively, favoring the assignments as charge-transfer transitions or magnetically forbidden *d–d* transitions, no definitive assignment has yet been performed.[58] However, from the energy of transitions in the CD spectra, the bands at 1330 and 760 nm have been tentatively assigned to a *d–d* and some charge-transfer transition, respectively.

A few reports of the vibrational CD (VCD) spectra for hemoproteins or reconstituted hemoproteins have been reported in the literature.[59–61] VCD spectra of the asymmetric stretch of azide ligated to the heme of a series of evolutionally diverse and site-directed mutant hemoglobin and myoglobin (Mb) were anomalously intense in most cases examined. These papers also demonstrated its intriguing sensitivity to subtle protein-ligand interactions between the azide ligand and distal globin amino acid residues based on the observation of a drastic decrease in the VCD intensity of the azide stretching in a variety of metMb whose distal histidine was replaced by other amino acids. Figure 12 shows the IR and VCD spectra of several myoglobin and hemoglobin species. In the absorption spectra, some species show bands at *ca*. 2044 and 2022 cm^{-1}, the former of which was assigned as derived from the ionically bound high-spin azide form and second as derived from the covalently bound low-spin azide form. Interestingly, the only species which have large anisotropy ratios (-8.0 to -9.5×10^{-4}) showed a negative VCD sign corresponding to the low-spin band.[59] The authors considered several factors in trying to find the origin of the heme-azide VCD spectra. For negative anisotropy values, the electric and magnetic dipole transition moments must orient in roughly opposite directions such that their scalar vector projection on one another is negative, while the magnetic dipole transition moment must be unusually large in relation to the accompanying electric dipole transition moment. As the most likely source of the large circulating electron current for the magnetic dipole transition, the authors further considered the heme-ring with a large number of π-electrons (*ca*. 20). The observed anisotropy values of *ca*. 10^{-3} in the VCD spectrum demonstrate that the lone azide oscillator generates a large magnetic dipole transition moment. Long-range electron flow, the coupling of electric current to the nuclear moment of the azide ligand, a polarizability mechanism and vibronic coupling have all been suggested as possible mechanisms for this.

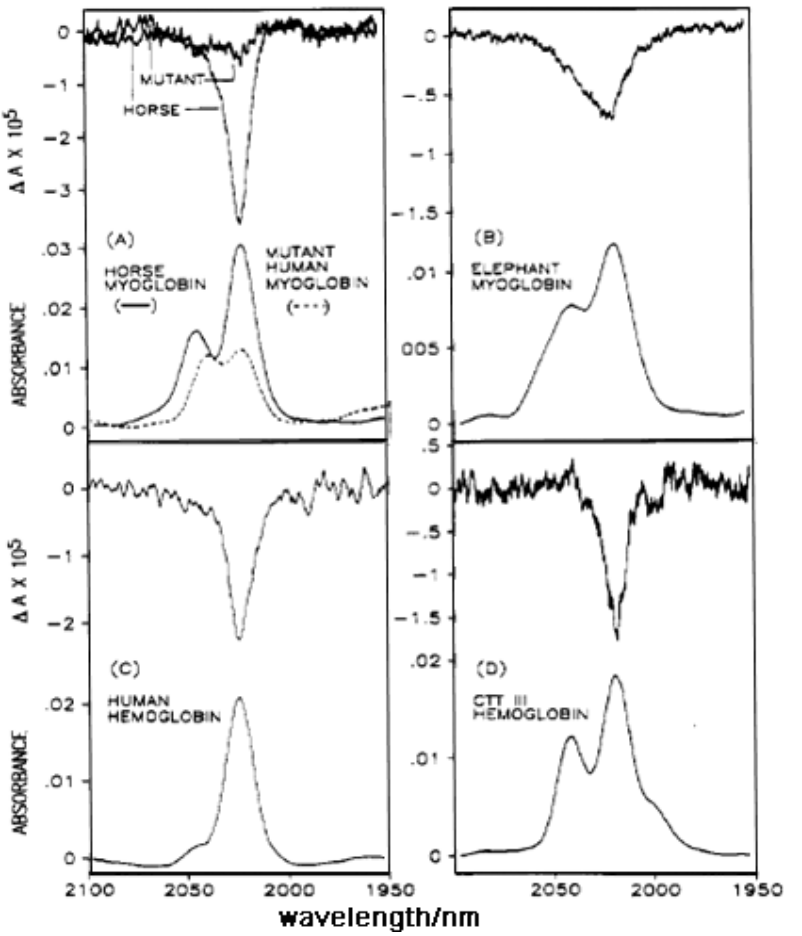

Figure 12. IR absorption and VCD spectra of the following: (A) 11.5 mM horse metMbN_3, and 7.1 mM mutant (Asn E11) human metMbN_3 with 2.7 mM unbound N_3–; (B) 6.0 mM elephant MbN_3; (C) 8.0 mM human HbN_3; (D) 6.0 mM CTT III HbN_3, pH 7 with 0.01M phosphate buffer (redrawn from Ref. 59).

In order to clarify the VCD mechanism of the azide ligand, Teraoka *et al.* then investigated the VCD spectra of metMb with a variety of extraneous ligands (SCN^-, OCN^-, CN^-, and CO), in addition to a reconstituted azidometMb with ironoctaethylporphyrin (FeOEP) (Figure 13a).[60] No VCD band was observed for the reconstituted azidometMb, although the dipole strength was as great as that of native metMb with an iron-protoporphyrin IX and both 2024 (low-spin) and 2042 cm^{-1} (high-spin) absorption bands appeared (Figure 13b). From this observation, it was proposed that the asymmetry of the porphyrin ring may be an important factor for the strong VCD signal. The metMb cyanide complex exhibited an

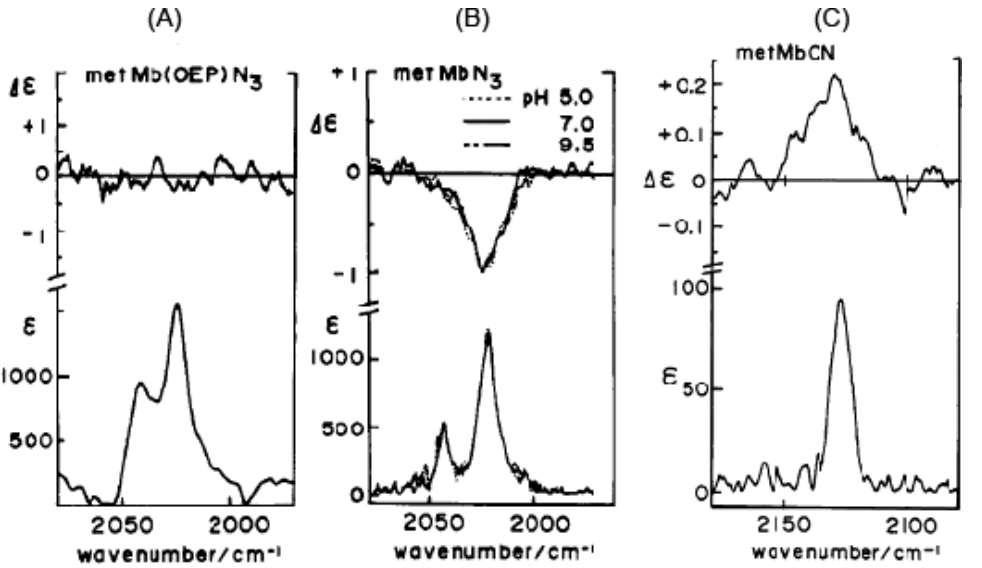

Figure 13. Absorption and VCD spectra of (A) 2.3 mM of metMb(OEP)N_3 reconstituted with iron-octaethylporphyrin at pH 7.0 (B) 2.3 mM metMbN_3 and (C) 13.5 mM (KCN) metMbCN at ph 7.0 (redrawn from Ref. 60).

extraordinarily strong positive VCD band (Figure 13c), i.e. in the opposite sense to the case of the azide complex, corresponding to the CN stretching vibration, while no VCD band was observed for metMb with SCN^-, OCN^-, or CO axial ligands. The anisotropy value of the VCD band of metMb cyanide was 2.8×10^{-3}, which is almost four times stronger than that of metMb azide and opposite in sign. They concluded that the relative orientation of the electric and magnetic dipole moments induced by the stretching of a ligand is approximately parallel for the cyanide but antiparallel for the azide in the ferric low-spin state.

B. Synthetic Heme Systems

In this section, only systems designed to mimic heme systems or systems containing both porphyrin and polypeptides are described. Ikeda and Nezu reported the absorption and CD spectra for aqueous solutions of a water-soluble porphyrin,[62,63] *meso*-tetra(4N-methylpyridinium)porphyrin tosylate (TMpyP tosylate), in the presence of poly(L-glutamic acid) or poly(S-carboxymethyl-L-cystein) at different pH values. At neutral and alkaline pH, where poly(L-glutamic acid) is randomly coiled, essentially no CD was induced in the Soret region over a wide range of [polypeptide]/[TMpyP] ratios. At acidic pH, where poly(L-glutamic acid) is helical, a positive CD band and a negative CD band were induced at 415 and

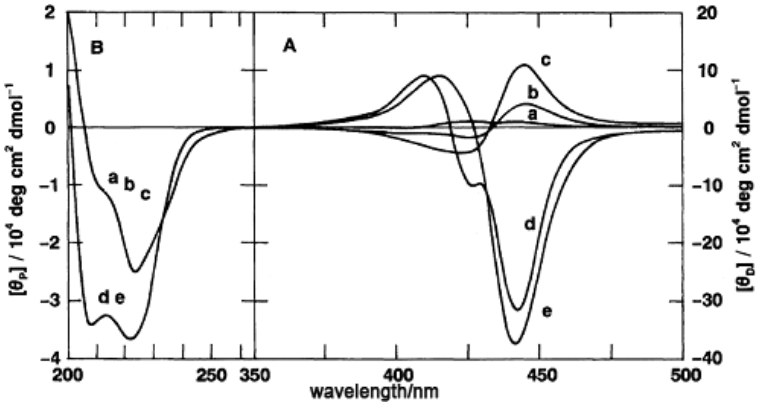

Figure 14. CD spectra of TMpyP mixed with poly(L-glutamic acid) at pH 4.4 (poly(L-glutamic acid) makes α-helix at pH smaller than *ca.* 6). [TMpyP] = 1.00×10^{-5} M, [poly(L-glutamic acid)]/[TMpyP]: a, 1.0; b, 5.0; c, 10.0; d, 50.0 (redrawn from Ref. 63).

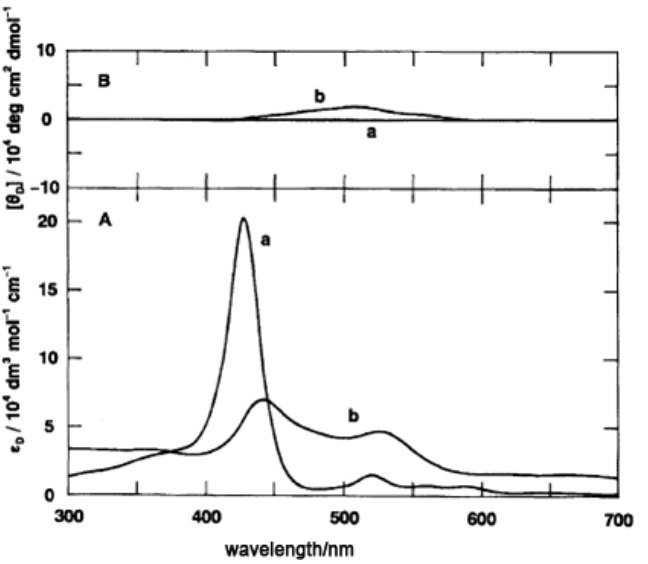

Figure 15. Absorption and CD spectra of TMpyP aqueous solutions in the presence of poly(S-carboxymethyl-L-cyctein) at [poly(S-carboxymehtyl-L-cystein)]/[TMpyP] = 100. [TMpyP] = 1.00×10^{-5} M. a, pH7.41; b, pH 4.49 (redrawn from Ref. 63). Poly(S-carboxymehtyl-L-cystein) exists as random coil and β-sheet structures at pH 7.41 and 4.49, respectively.

442 nm, respectively if the [polypeptide]/[TMpyP] ratio was high, but this induced CD became considerably weaker as the [polypeptide]/[TMpyP] ratio was lowered (Figure 14). In the presence of poly(S-carboxymethyl-L-cyctein), the absorption spectra differ considerably depending on the pH (Figure 15).[63] At neutral and

alkaline pH, where the polypeptide exists as a random coil structure, the absorption spectrum was typically that of normal porhyrins. At pH 5.5, where the polymer exists as a β-sheet structure, the Soret band shifted to longer wavelength and the Q band concomitantly increased. Although no CD was induced when the peptide had a coil structure, a weak and broad CD was induced when the peptide adopted the β-sheet structure, but strangely only in the Q band region. Although the absorption and CD spectral behavior of TMpyP in the presence of polypeptide was thus described phenomonologically, no explanation has been given by way of interpretation.

Fukushima studied the effect of NaCl on the absorption and CD spectra of a system comprising poly(Glu-Val-Lys-Val) (molecular weight, *ca.* 14,000) and diprotonated tetrakis(4-sulphonatophenyl)porphyrin (TPPS) in aqueous solution.[64] Experiments were carried out mainly at pH 4, where poly(Glu-Val-Lys-Val) exists in a β-sheet structure and the central two pyrrole imine nitrogens of TPPS are diprotonated. In the absence of poly(Glu-Val-Lys-Val), diprotonated TPPS shows a Soret band at 434 nm ascribed to monomeric species. As a result of the addition of poly(Glu-Val-Lys-Val) or NaCl, a new peak due to aggregates appears at around 489 nm. Interesting CD behavior was observed when [poly(Glu-Val-Lys-Val)]/[TPPS]= 1:5 (Figure 16), depending on the NaCl concentration. As seen in curves a–c in Figure 16, when the NaCl concentration was typically less than 250 mM, the sign of the CD curve changed from minus to plus in ascending energy corresponding to both the 434 and 489 nm absorption bands, thus suggesting that the

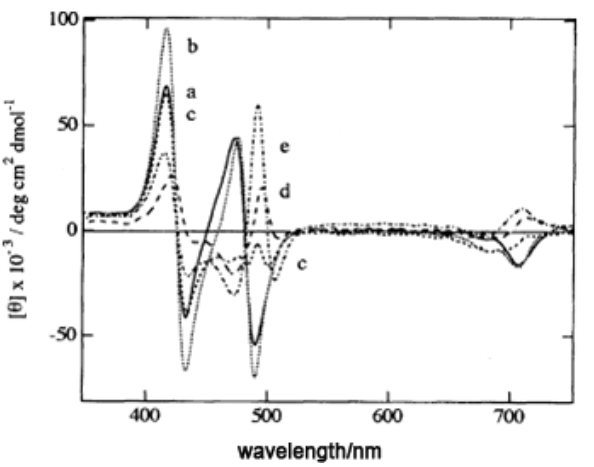

Figure 16. CD spectra of 6.67×10^{-5} M TPPS (5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin) in aqueous solution at pH 4.0 and [poly(Glu-Val-Lys-Val)]/[TPPS]=2 in the presence of poly(Glu-Val-Lys-Val) at different NaCl concentrations. [NaCl]: a, 0 mM; b, 100 mM; c, 250 mM; d, 500; e, 1000 mM (redrawn from Ref. 64).

aggregates adopt an S-chiral conformation. Although a dispersion type CD curve was observed in the 434 nm region where the author assigned a monomeric TPPS Soret band, this was ascribed to two different monomeric species bound consecutively to different sites located on the polypeptide. When the NaCl concentration was increased to 500 and 1000 mM (curves *d* and *e*), the CD sign corresponding to the 489 nm absorption band changed from plus to minus in ascending energy. The author, therefore, concluded that the helicity of the aggregates changed from S to R with increasing NaCl concentration. Since the ellipticity at 217 nm for the polypeptide was unchanged with increase of the NaCl concentration, the above CD change upon increase of NaCl concentration was thought to be unrelated to any polypeptide conformational change. Thus, it was presumed that an increase in the ionic strength induced a chiral conformational transition due to the prevention of electrostatic interaction between TPPS and the polypeptide. By conducting experiments under various conditions, the author claimed that four types of aggregate were obtained. However, it was difficult to carry out quantitative analysis, since the conformation between the porphyrin and polypeptide is unknown.

The CD and absorption spectra of synthetic peptide-sandwiched mesoheme have been reported by several groups. Benson and coworkers prepared compound **1** (Figure 17, top) using iron(III) mesoporphyrin IX,[65] and **2** (Figure 17, middle) using iron(III) mesoporphyrin II.[66] A theoretical analysis of the CD data has not been attempted. However, interestingly, compound **1** showing a negative CD ($[\theta] = -80{,}000$) corresponding to the Soret absorption band in water exhibited reduced intensity with increasing helix content as a result of the addition of the helix-stabilizing cosolvent (1,1,1,3,3,3-hexafluoro-2-propanol) to *ca.* $[\theta] = -15{,}000$.[65] For this phenomenon, they inferred that a greater alignment of the peptide backbone amides alters the average orientation of the transition dipoles of the amides relative to the Bx and By transitions of the heme. In contrast, compound **2** showed a positive CD in helix-stabilizing co-solvent.[66]

Pavone and coworkers[67,68] prepared hemoprotein model compounds containing iron or cobalt 3,7,12,17-tetramethylporphyrin (deuteroporphyrin IX) (Figure 17, bottom). In the case of the cobalt(III) complex, they succeeded in separating two equally abundant Δ and Λ complexes using HPLC.[68] These isomers showed either a negative (Δ isomer) or positive (Λ isomer) CD envelope corresponding to the Soret absorption peaks (Figure 18). Interestingly, the absolute CD intensity was different, i.e. a negative trough of the Δ isomer was about twice as large as the positive peak of the Λ isomer. By using the CD intensity at 222 nm assigned to an α-helix, it was revealed that helix content in the Δ isomer is always larger than that in the Λ isomer under similar conditions.

Sakamoto and coworkers designed and synthesized a series of amphiphilic two α-helix peptides, which bound iron(III) mesoporphyrin IX through a ligation

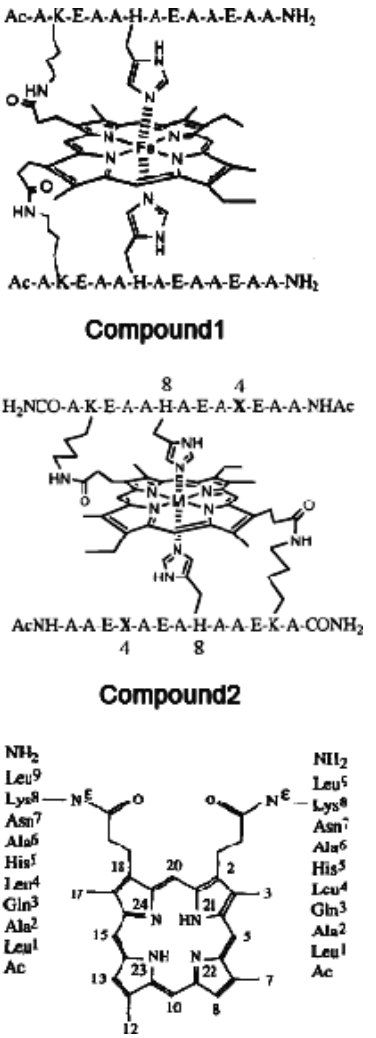

Figure 17. Peptide-sandwiched mesohemes reported by Benson *et al.* (left and middle) and monochrome reported by Pavone *et al.* (right) (redrawn from Refs. 65, 66 and 67). The meaning of A, K, E, H are not explicitly described even in original papers, although they are amino acid residues.

of two histidine (His) residues.[69] These peptides contain 17 amino acid residues. Hydrophobic Phe, Ile, Leu, Val, and Ala residues (Figure 19) were systematically substituted into the peptide structure around the axial ligands in order to explore how hydrophobic and/or steric effects alter the interaction between the peptides and the heme. In Figure 19, eight positions designated by X and Y were substituted. Figure 20 shows the CD spectra in the 190–250 nm region in the absence (broken lines) and presence (solid lines) of the heme. CD curves with an intense

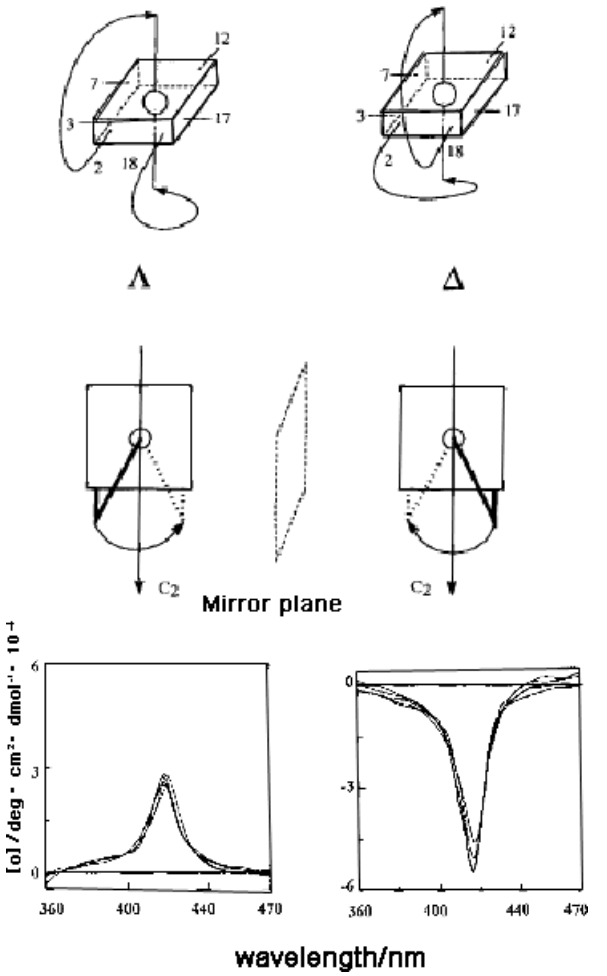

Figure 18. Schematic representation of the Δ and Δ isomer configuration of the cobalt(III) complex of Pavones' mesoheme (Fig. 17, bottom), and their CD spectra in the Soret region at various trifluoroethanol concentration (0–30%) (redrawn from Ref. 68). The fifth and sixth positions are coordinated by histidinyl imidazole.

positive peak at 190 nm and weaker negative troughs at 209 and 222 nm, such as (j) in this figure, indicate that the peptides are forming an α-helix. In many cases (a, b, c, e, f, j, k, and f), the peptide exists as an α-helix, but in the presence of the heme the CD intensity often increased, indicating an increase in the α-helicity. This was attributed to a ligation of the peptides to iron through the His residue. Namely, in acidic pH where the His residue was protonated and therefore the ligation was disabled, this kind of increase was not observed. In cases d, g, h and l of Figure 20, the helix content in some peptides, particularly those containing

(a)

(b)

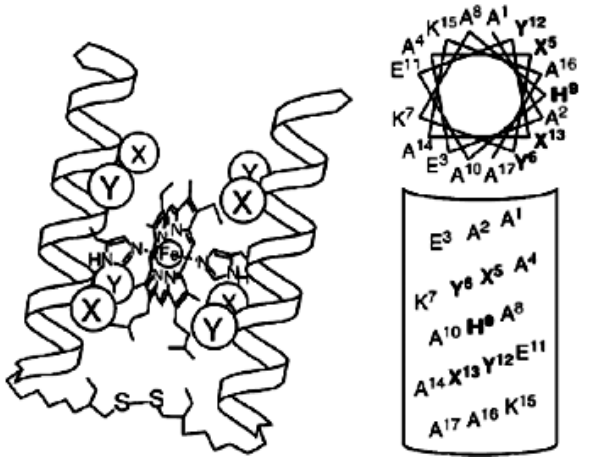

Figure 19. Structure of the designed peptide, H2α17-XY (a) Amino acid sequence of H2α17-XY; (b) Schematic illustration of two-α-helix peptide structure bound to the heme and helix wheel and net drawings of the 17-peptide (redrawn from Ref. 69).

valine, appeared very low in the absence of the heme. However, even in these cases, α-helix was generated by the addition of the heme except for case g (β-sheet structure in both absence and presence of the heme).

Figure 21 shows the CD spectra in the Soret region, which were collected under similar conditions as in Figure 20. The heme bound to the Ile- and Val-containing peptides, except for H2a17-VV, showed a strong induced CD peak in the Soret region, which was split into a negative peak at longer wavelengths and a positive peak at shorter wavelengths (d–f, h, l). The crossover wavelengths were coincident with those of the maximum position of the Soret peak, and the intensities of both positive and negative peaks were almost equal, indicating that the induced Soret CD was derived from exciton coupling with heme-heme interactions.

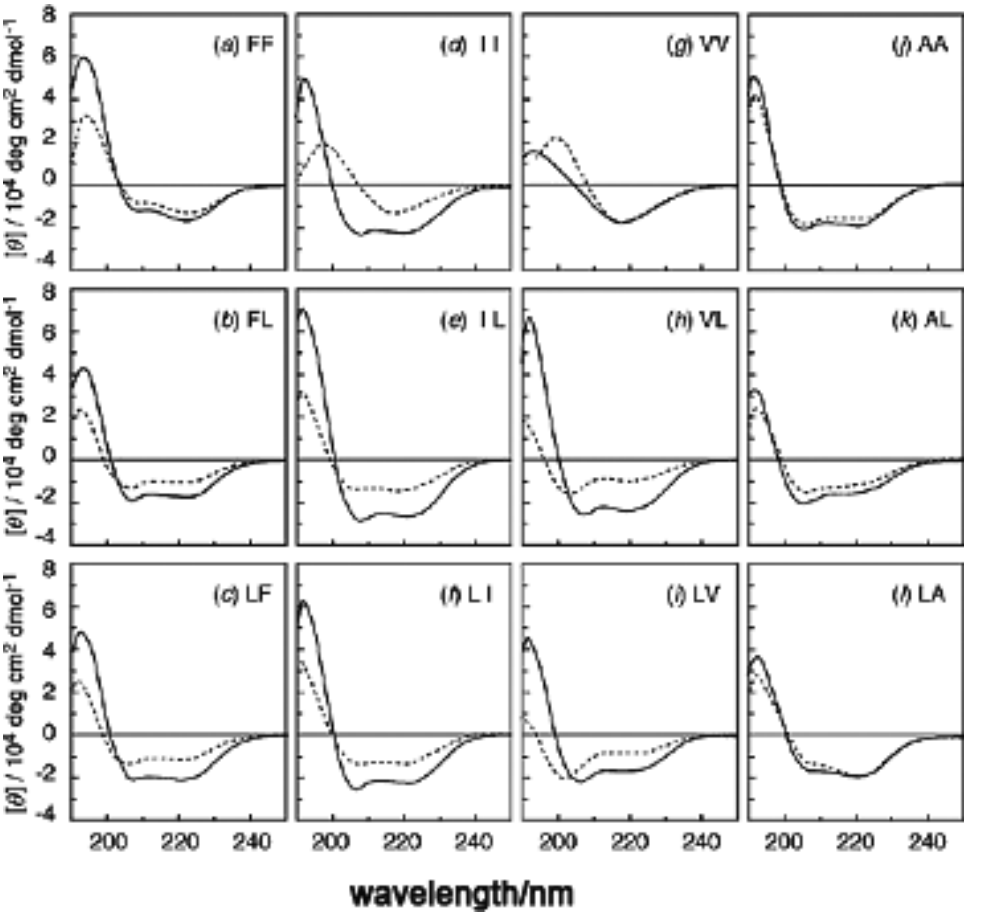

Figure 20. CD spectra of H2α17-FF (a), -FL (b), -LF (c), -II (d), -IL (e), -LI (f), -VV (g), -VL (h), -LV (i), -AA (j), -AL (k), and -LA (l) in the absence (broken lines) and presence (solid lines) of heme (redrawn from Ref. 69).

The split Cotton effect indicated that the heme groups were highly oriented in close positions in the self-assembled peptides. Among the Ile- Val-containing peptides, the most hydrophobic H2a17-IL showed the largest Soret CD peaks. On the other hand, the most hydrophilic H2a17-LV showed the smallest Soret CD peaks. These results were taken to imply that the mutual orientation and distance of heme molecules in the assembled peptides varied depending on the hydrophobicity and/or arrangement of hydrophobic residues around the heme.

The CD spectrum of heme bound to H2a17-FL was characterized by a negative peak at longer wavelengths and a weak positive peak at shorter wavelengths (b). These data suggest that two hemes are left-handed in (d–f, h, l). The CD spectra of the heme in the presence of H2a17-VV, -AA, -AL, and -LA (g, j–l) showed a

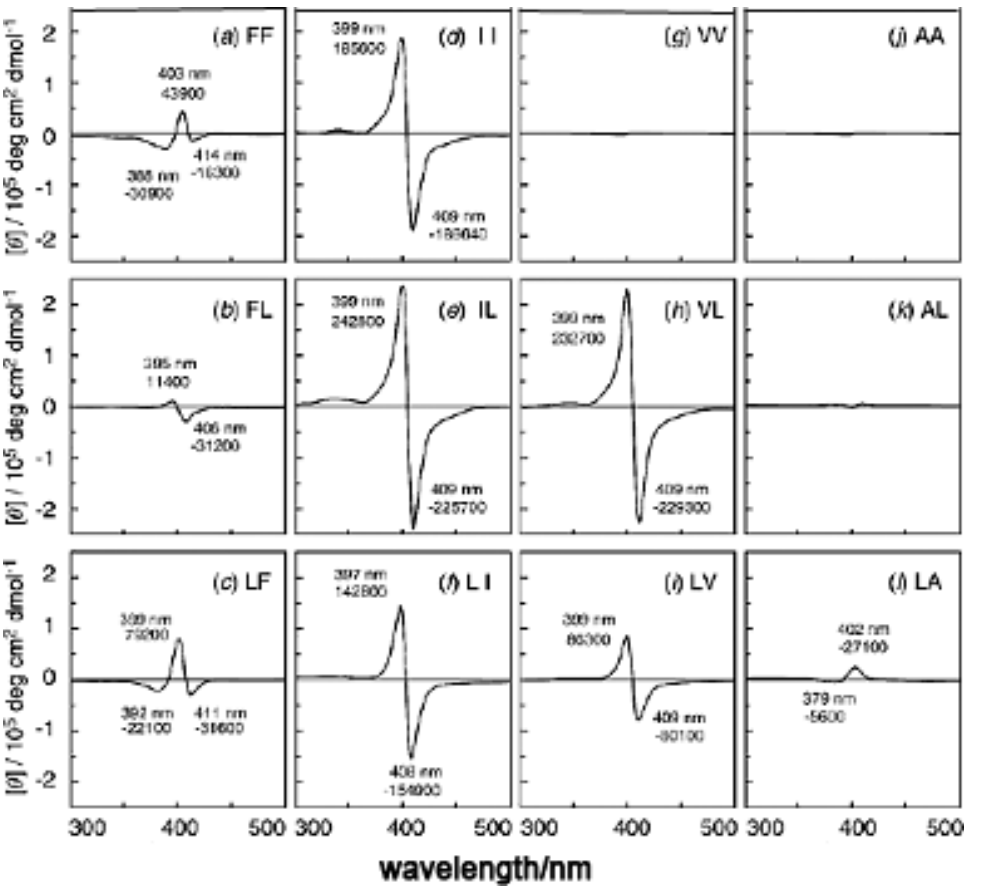

Figure 21. The Soret CD spectra of heme in the presence of H2α17-FF (a), -FL (b), -LF (c), -II (d), -IL (e), -LI (f), -VV (g), -VL (h), -LV (i), -AA (j), -AL (k), and -LA (l) in the absence (broken lines) and presence (solid lines) of heme (redrawn from Ref. 69).

small or no induced CD in the Soret region, suggesting that the peptide could not bind the heme effectively.

IV. Chlorophyll, Bacteriochlorophyll, Chlorin, and Bacteriochlorin Systems

A. Natural Chlorophyll and Bacteriochlorophyll Monomer and Dimer Systems

1. *Chlorophyll* a *and Bacteriochlorophyll* a *and Their Derivatives*

Of the few existing reports on the CD of chlorophylls,[70–73] that by Housser and Sauer is the most detailed.[73] The CD, MCD, and absorption spectra of chlorophyll

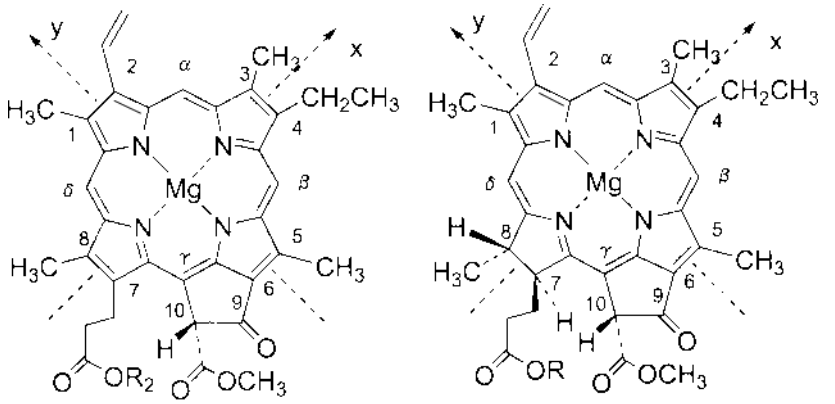

Figure 22. Molecular structures of protochlorophyll *a* and chlorophyll *a,* showing the absolute configuration of the asymmetrically placed ring substituents reported for chlorophyll *a*.

a (Chl *a*), pheophytin *a* (Pheo *a*, the metal-free complex of Chl *a*), pyrochlorophyll *a* (pyroChl *a*, the compound obtained by removal of the C-10 carbomethoxy group from Chl *a*), pyropheophytin *a*, (pyroPheo *a*, the metal-free compound of pyroChl *a*), and as protochlorophyll pigments, photochlorophyll *a* (PChl *a*), and 4-vinylprotochlorophyll *a* (VPChl *a*) were reported together with those of some of their dimers in Ref. 73. (Figure 22 contains the structures of protochlorophyll *a* and Chl *a*[73]). Before their analysis, it was known, as an empirical interpretation, that the effects of alternation in the asymmetry of the substitution at carbon atoms C-10 (in the cyclopentanone ring V) and C-7 and C-8 (of ring IV) are found to be directly related to the signs and amplitudes of the CD bands.[71,72] For example, from their optical activity data, Wolf *et al.*[71] succeeded in confirming that the 10-carbomethoxy group present in methyl pheophorbide *a* is in the *trans* configuration relative to the propionic acid side chain on C-7.

Figure 23 shows the CD, MCD and absorption spectra of Chl *a* and pyroChl *a*, while Figure 24 shows the spectra of Pheo *a* and pyroPheo *a* (note these are metal-free compounds of Chl *a* and pyroChl *a* in Figure 23). Note that in each figure, in the pyro compounds, the 10-carbomethoxy group is eliminated from Chl *a* or Pheo *a*. The optical spectra of PChl *a* (Figure 25) and its demetalated species, protopheophytin *a* (PPheo *a*, Figure 26) are quite different from those of Figures 23 and 24, since the pyrrole ring IV in the proto compounds is unsaturated, which is different from the compounds in Figures 23 and 24 (see Figure 22). Several general observations can be made from an examination of these spectra. In some cases, a strong MCD band is observed to correspond to a weak or non-existent CD band, e.g. the Qx(00) bands of Chl *a* and pyroChl *a* in Figure 23 and of Pheo *a* in

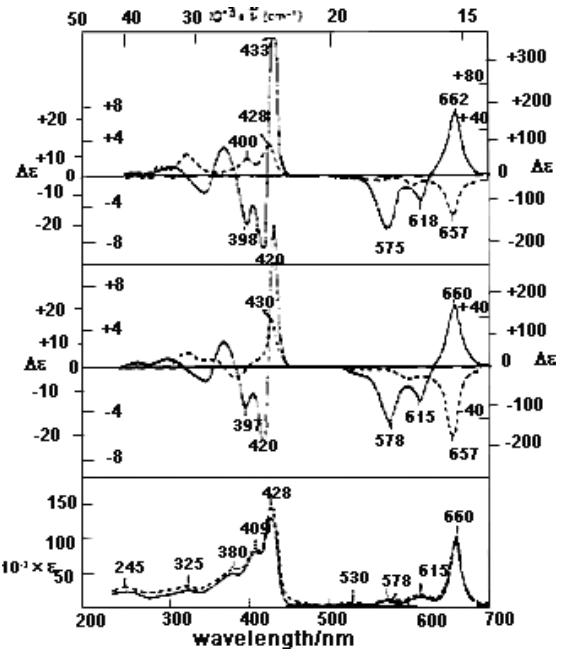

Figure 23. CD (broken lines) and MCD (solid lines) (upper and middle curves) and absorption (lower curve) spectra of Chl *a* and pyroChl *a* in ether. In absorption spectra, solid and broken line are for Chl *a* and pyroChl *a*, respectively (redrawn from Ref. 73).

Figure 24. As seen in Figures 23 and 24, the almost degenerate B bands (Soret bands) are more clearly resolved in the MCD compared to the CD spectra. On the other hand, the longest wavelength component in the Soret region appears in the CD but not in the MCD spectra of PChl *a* (Figure 25) and PPheo *a* (Figure 26). Optical activity data of the chlorophyll *a* and protochlorophyll *a* pigments in ether are summarized in Table 1.[73]

The CD spectra of the group of compounds show some distinct correlations with molecular structure, particularly for the Q band. The relevant data are summarized in Table 2.[73] Since CD is sensitive to slight conformational changes,[1–7,9,10] one has to be aware of the structural differences in the species studied. Chl *a* contains substituents asymmetrically placed at ring carbons C-7, C-8, and C-10. PChl *a* has only the C-10 substituent asymmetry, and pyroChl *a* has only the C-7 and C-8 asymmetries, by virtue of the loss of the C-10 carboxymethyl substituent and its replacement by a proton upon pyrolysis. As seen in Figures 23 and 24, Chl *a* and pyroChl *a* show negative and positive CD corresponding to the Q and Soret bands, respectively, while their metal-free derivatives, Pheo *a* and pyroPheo *a* exhibit positive, negative, and positive CD corresponding to the Qy(00), Qx(00), and Soret bands, respectively. In addition, as is discernible from a comparison

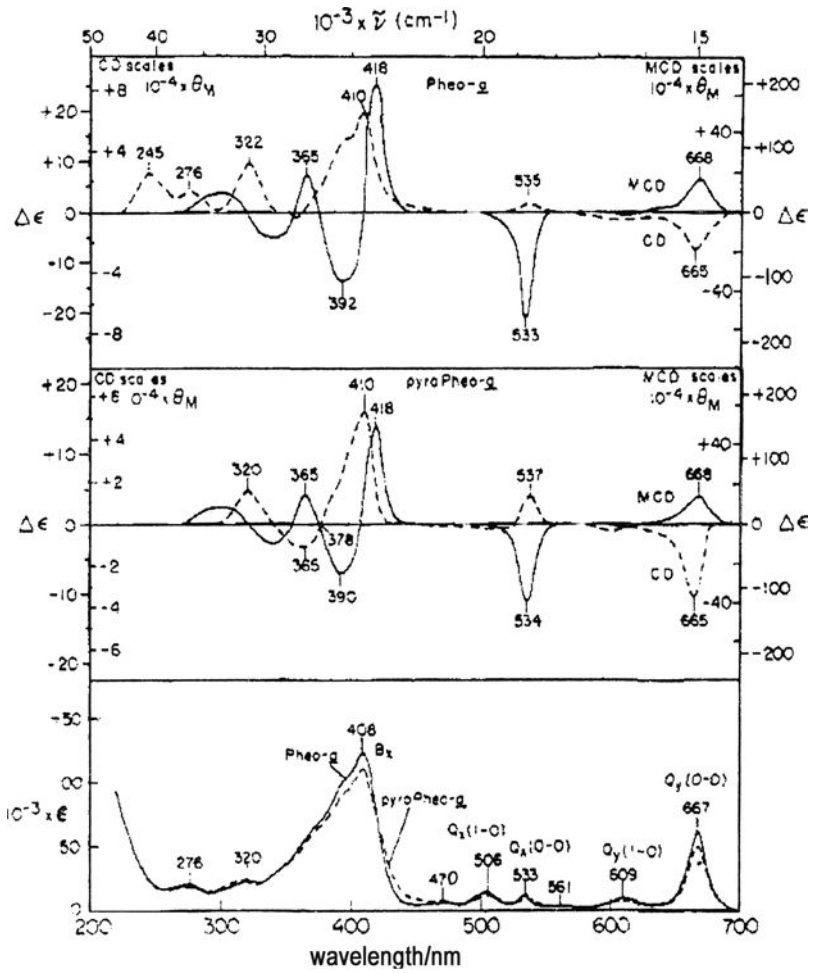

Figure 24. CD (broken lines) and MCD (solid lines) (upper and middle curves) and absorption (lower curve) spectra of Pheo *a* and pyroPheo *a* in ether. In absorption spectra, solid and broken line are for Chl *a* and pyroChl *a*, respectively. These are the metal-free compounds of the compounds in Figure 23 (redrawn from Ref. 73).

between Chl *a* and pyroChl *a* (Figure 23) and between Pheo *a* and pyroPheo *a* (Figure 24), the loss of asymmetry at the C-10 carbon atom commonly produces an increase in the CD intensities of the chlorophyll pigments. From the MCD spectra in Figures 25 and 26, the splitting of the Qy and Qx components is smaller for PChl *a* and PPheo *a* than for the species in Figures 23 and 24, due to the unsaturation of ring IV. Corresponding to the split Q components, the CD sign of PChl *a* (Figure 25) changes from positive to negative in ascending energy, while negative CD was observed for the Q band of Chl *a* and PChl *a* at the longest

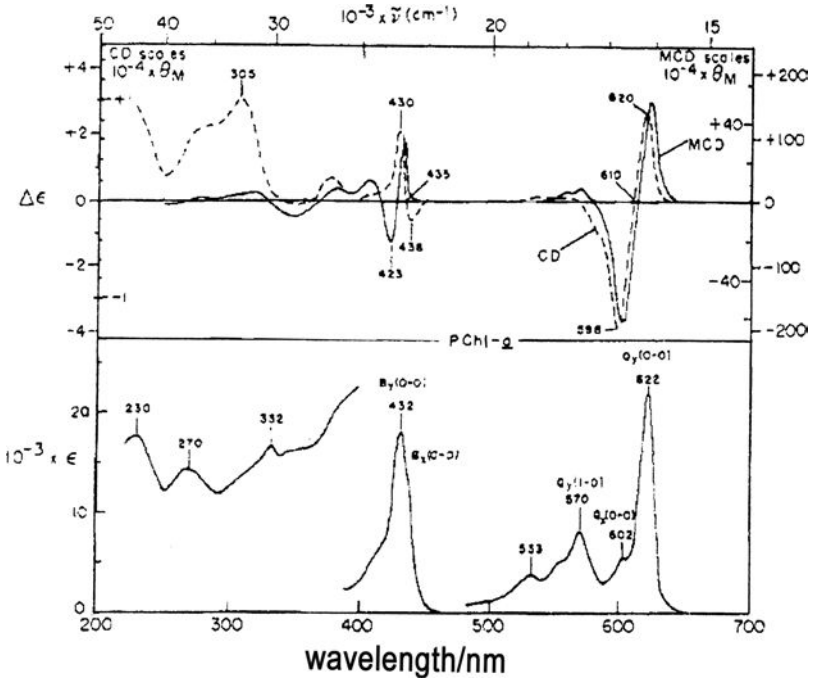

Figure 25. CD (broken line) and MCD (solid line) (upper) and absorption (lower) spectra of PChl *a* in ether. (redrawn from Ref. 73). As seen in Figure 22, in PChl *a,* the pyrrole ring IV is unsaturated different from Chl. a whose ring IV is saturated.

wavelength. An analysis of the behavior for PPheo *a* was more difficult since its CD was much smaller in magnitude (Figure 26). From the MCD sign, which is positive and negative at 640 and 593 nm, respectively, the longest wavelength band was assigned as a Qx component, which is different from other derivatives. A negative CD trough was observed corresponding to the Qx band.

The authors calculated the anisotropy factors using a point dipole to represent the electric transition moments, and compared these with experimentally obtained values (Table 3).[73] Although the calculated values were smaller than the experimental quantities by at least an order of magnitude, the sign was reproduced. It was found that the contribution to the CD of the carboxymethyl substituent at carbon atom C-10 of the cyclopentenone ring V is of an opposite sign compared to the C-7 and C-8 substituents of ring V. For the C-10 substituent, the CD contributions were positive in the y-polarization direction and negative in the x-polarization direction, while the reverse was true for the C-7 and C-8 substituents (x polarization through rings II–IV). It was also suggested that the substituents at C-10 and at C-7 and C-8 are probably the only ones responsible for the visible CD.

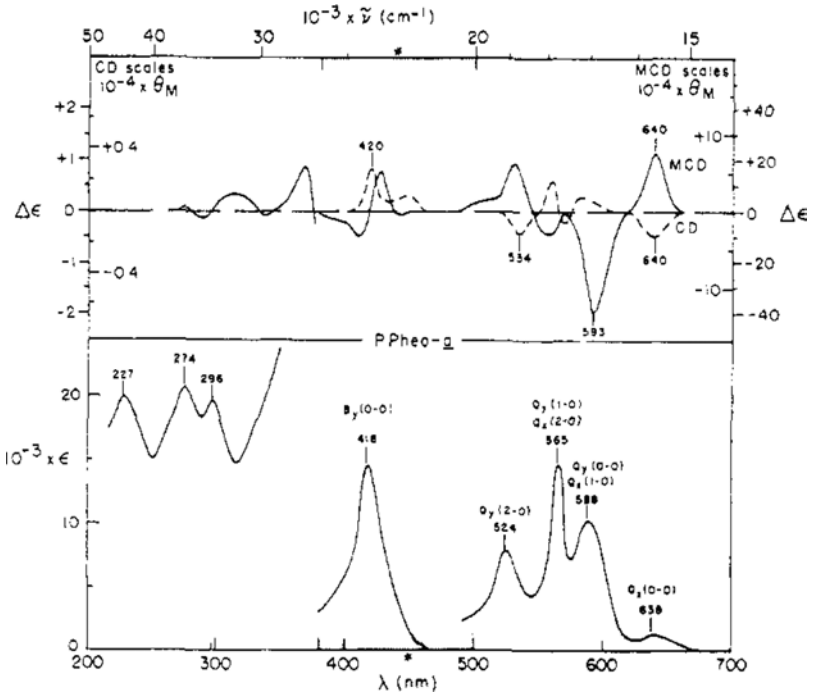

Figure 26. CD (broken line) and MCD (solid line) (upper) and absorption (lower) spectra of PPheo *a* in ether (redrawn from ref. 73). PPheo *a* is the metal-free compound of PChl *a* in Fig. 22.

The formation of aggregates gives rise to important modifications in the absorption and optical activity compared to the corresponding monomers. Figures 27–29 show the spectra of the dimer species in CCl_4. The Chl *a* (Figure 27), pyroChl *a* (Figure 28), and PChl *a* (Figure 29) spectra are characterized by the appearance of split components in the Q and B monomer absorption bands upon formation of the dimers, concomitant with hypochromicity of the dimer absorption compared with the monomer. The Qy bands of Chl *a* and pyroChl *a* clearly show absorption shoulders on the long-wavelength side, and the maxima are shifted slightly to the red. In the Soret region, the bandwidths become larger and the maxima are also shifted slightly to longer wavelength. On the other hand, the Q and B transitions of the aggregated PChl *a* are shifted to shorter wavelength compared to the monomer. The Q transitions for PChl *a* (Figure 29) do not show any clear splitting in the absorption, but the bandwidth is slightly increased. The B transition, however, showed a very distinct separation of components for the aggregate (436 and 455 nm, respectively).

The CD spectra of the dimers provide clear evidence of additional splitting. In the case of Chl *a* and pyroChl *a* (Figures 27 and 28), the Qy bands exhibit positive

CD corresponding to the shoulders in the absorption bands (677 and 680 nm, respectively), cross zero near the absorption peaks (664 and 670 nm), and show negative CD bands on their short wavelength sides (659 and 661 nm). For the B transition, the behavior is reversed, with the negative CD band being on the long wavelength side. In the case of PChl *a*, the longest wavelength component (628 nm) is negative, while it is positive for Chl *a* and for pyroChl *a*. In the region of overlap between the x and y components, the effects add together, which may be the reason for the very intense negative CD band centered at 443.5 nm.

In order to interprete the CD spectra in Figures 23–29, the bands must first be properly assigned. For this, the knowledge of MCD and theoretical treatment of Kirkwood[32] was utilized. Thus, the long wavelength transition was assigned as y-polarized for all compounds except PPheo *a* in Figure 26 (x-polarized). Implicit in the Kirkwood model is the assumption that each of the asymmetric centers acts independently on the transition moments. Accordingly, it was expected that the observed rotational strengths can be accounted for by a summation of the interactions associated with each significant asymmetric site on the porphyrin ring. This was observed quantitatively for the different compounds studied for the Qy transitions of PChl *a*, pyrroChl *a*, and Chl *a*. However, it cannot be tested further for the Qx bands, because the corresponding CD component could not be distinguished. The correspondence of calculation and experiment was insufficient, since the calculated CD intensity was weaker than the experimentally observed intensity by one order.

In the case of strongly interacting dimers, the oscillators associated with corresponding transitions in different molecules couple with each other, leading to a splitting of each of the excited states, and producing CD components associated with each of the new transitions. From previous studies, the spectrum in CCl_4 was

thought to be that of dimers, and in detailed studies by Katz and coworkers, the molecules were proposed to be oriented so that the C-9 carbonyl group of one molecule interacts with the central magnesium of the other.[74] (Note that the so-called Fischer nomenclature was used by Katz and coworkers because the work

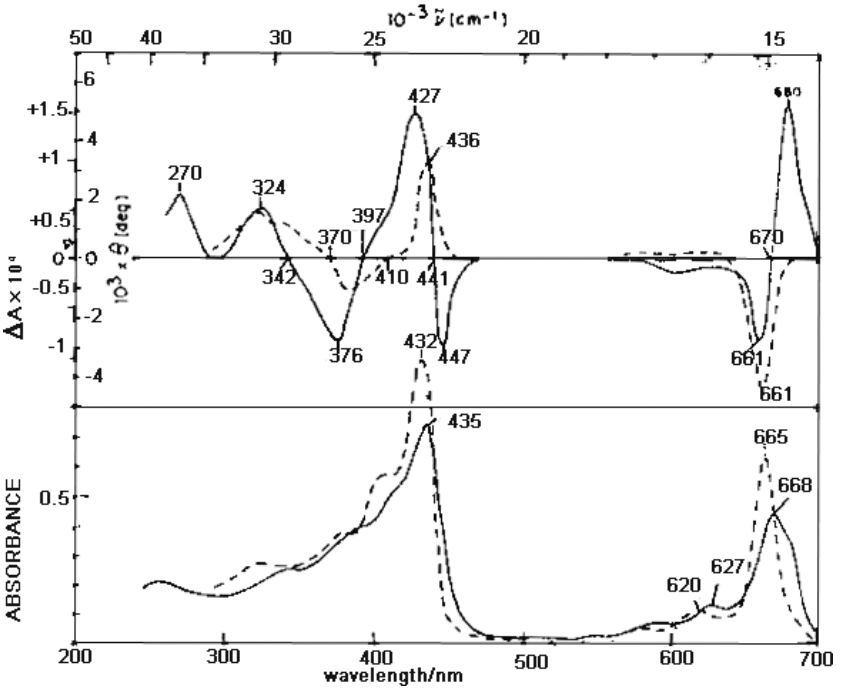

Figure 28. CD and absorption spectra of pyroChl *a* dimer in CCl_4 (redrawn from Ref. 73).

pre-dates adoption of the IUPAC system). Furthermore, the CD data of Katz and coworkers showed that the porphyrin rings do not lie in parallel planes, but that one molecule is inclined with respect to the other. Examination of the short wavelength regions of the dimer spectra for Chl *a* and pyroChl *a* in Figures 27 and 28 shows a very close correspondence between the two, even though the corresponding monomer spectra are quite dissimilar (Figure 23). This was taken as evidence to indicate marked similarities in the dimer structures of Chl *a*, pyroChl *a*, Chl *b* and BChl. The inclusion of pyroChl *a* in this group was significant, in that it does not posses a carboxymethyl substituent on the C-10 carbon, indicating further that the carboxymethyl substituent on C-10 has no significant influence on the formation of the dimer. In the case of PChl *a*, where ring IV is not reduced, the CD spectrum of the aggregated dimer species is quite different (Figure 29). Here, the longest wavelength component of the CD is negative for the aggregated PChl *a* (solid curve) whereas it is positive for each of the other molecules. Thus, it was concluded that PChl *a* has a significantly different dimer structure from that of Chl *a* and the other molecules. The major difference in molecular structure between PChl *a* and the other molecules is that the first C-C bond of the propionic ester substituent at C-7 lies in the porphyrin plane for PChl *a*, but is at an almost

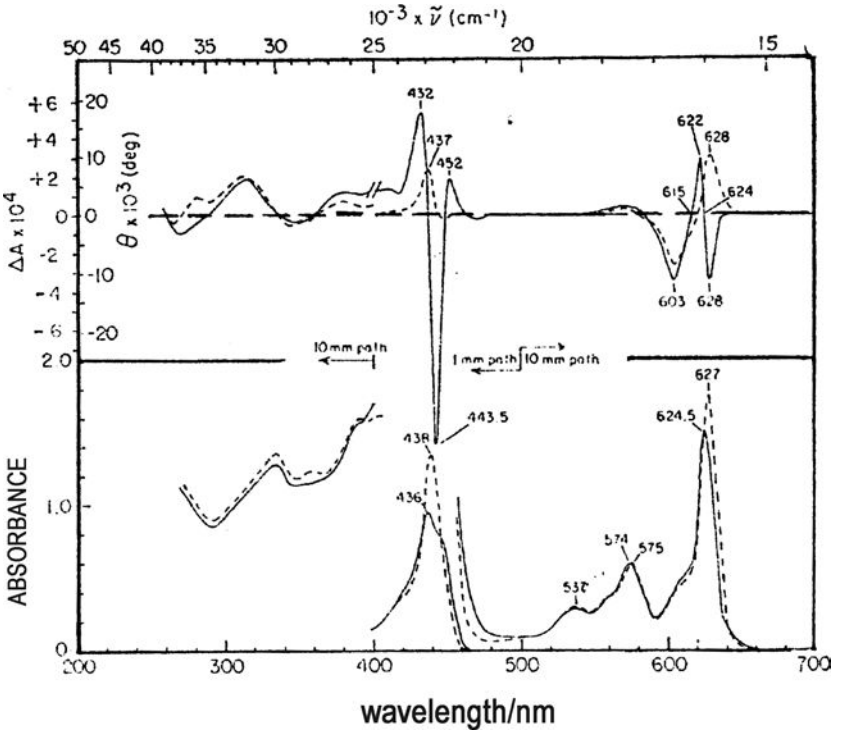

Figure 29. CD and absorption spectra of PChl *a* dimer in CCl_4 (redrawn from Ref. 73).

tetrahedral angle for the others. Since this group is farther from the proposed point of interaction at C-9 than the C-10 carboxymethyl group, the authors could not connect the dimer structure to the CD spectra.

2. *Bacteriochlorophylls* c, d, e *and* g

Although the structures of bacteriochlorophyll (BChl) *c, d, e* and *g* (Figure 30) were established before the end of the 20th century, little is known about their CD spectra.[75–88] BChl *c in vivo* is a mixture of at least five homologs, all of which form aggregates in organic solvents such as CH_2Cl_2, $CHCl_3$, and CCl_4. Various groups have reported absorption and CD spectra under various conditions. However, the spectra are sensitive to changes in both position and intensity from group to group, depending on the pre-treatment, concentration, temperature, and solvent used for the measurements. The spectra of two species which appear reliable from the experimental data are shown here. The first is the spectra of epimerically pure BChl *c*, isolated from *Chlorobium tepidum* (Figure 31),[85] and the other is the spectra of BChl *g* and *g′* from *Heliobacterium chlorum* (Figure 32).[81] The structure of

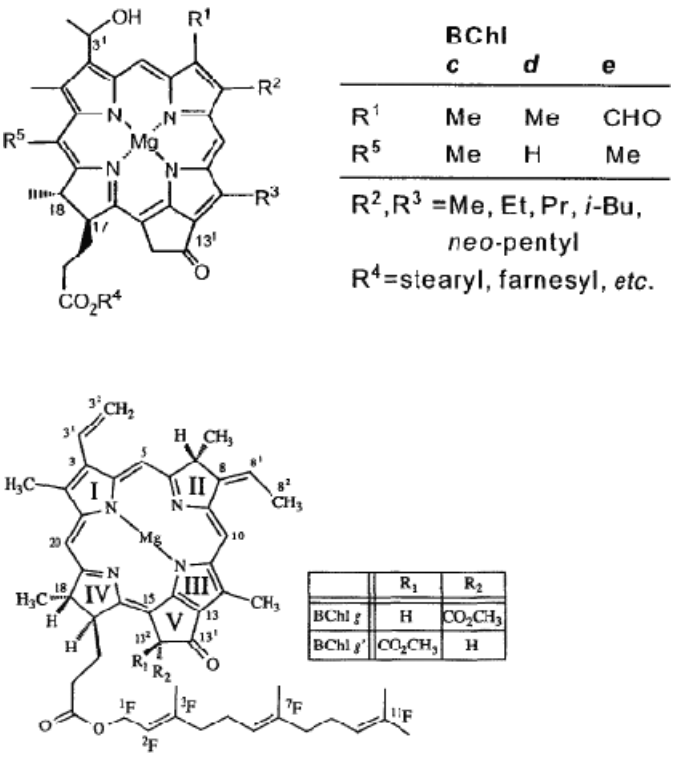

Figure 30. Structures of bacteriochlorophyll *c, d, e* and *g* (redrawn from Refs. 81 and 84).

quite unstable BChl *g* resembles that of BChl *b*, both pigments containing the unusual ethylidene group at ring II (Figure 30). Photoisomerization of BChl *g* at ring II yields Chl *a*, the main chlorophyll of oxygenic photosynthesis. BChl *g′* is the 13^2-epimer of BChl *g*. In the case of BChl *c*, a strong CD peak and trough were observed corresponding to the Q and Soret bands, respectively, while in the case of BChl *g* and *g′*, the CD sign at both the Q and Soret absorption peaks was the same, positive for BChl *g′* and negative for BChl *g*. Although the absorption spectra of BChl *g* and *g′* are very similar, the CD spectra are distinctly different, not only in sign but also in the intensity in the Q region. Attempts to interpret the CD spectra of BChl *c, d, e*, and *g* have not been successful.

3. *Light Harvesting Complex 2 (LH2)*

The photosynthetic antenna of purple bacteria consists of two types of light-harvesting antenna complex, termed complex 1 (LH1, the core antenna complex) surrounding the reaction center, and complex 2 (LH2, a peripheral antenna

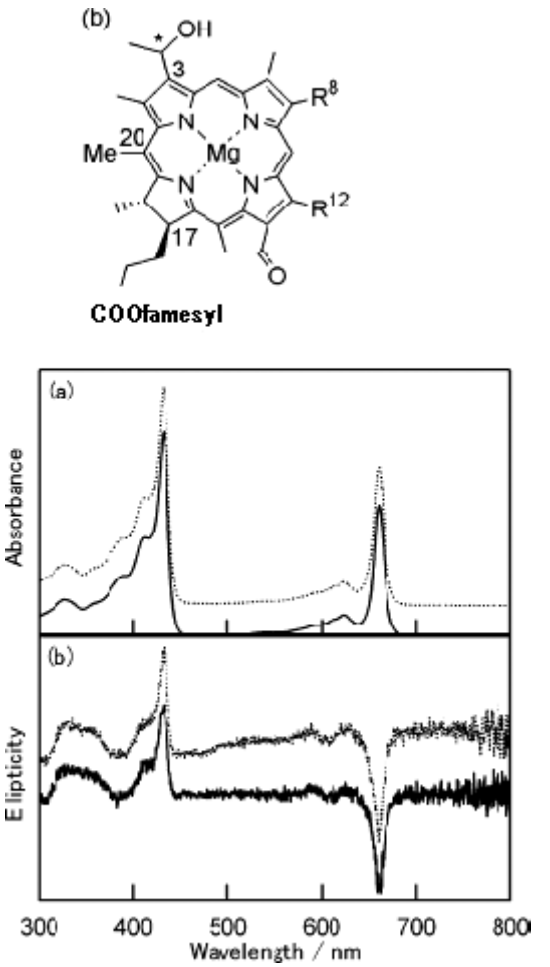

Figure 31. (a) Absorption and (b) CD spectra of synthetic epimerically pure BChl *c* (solid line) and BChl *c* from *Chlorobium tepidum* (doted line) in Et_2O (redrawn from Ref. 85).

complex) positioned away from the reaction center. The crystal structures of bacterial LH2 complexes from two species, *Rhodospirillum (Rs.) molischianum* and *Rhodopseudomonas (Rps.) acidophila* determined in 1995[89] and 1996[90] opened the door to an increasingly detailed understanding of the unusual spectroscopic and dynamic properties of the bacterial antenna complexes. The LH2 from *Rps. acidophila* consists of nine copies of each of two proteins (*a* and *b*), 27 BChl and 18 carotenoid molecules arranged in a ring structure with C9 symmetry. A striking feature is their separation into two parallel rings. The ring of 9 BChl is larger in diameter than the ring of 18 BChl, while the spacing between successive BChl in the ring of 18 is closer, by a factor of two, than the spacing in the ring of 9 BChl

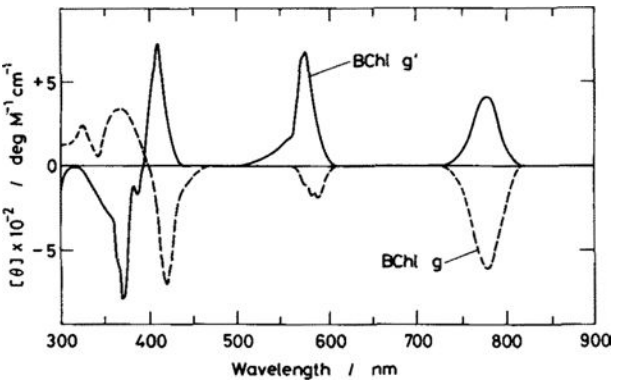

Figure 32. CD spectra of BChl *g* (broken line) and *g′* (solid line) in benzene at room temperature (redrawn from Ref. 81). Although not shown, absorption spectra are very similar except Qx band at around 550–600 nm; the peak of *g′* is sharper.

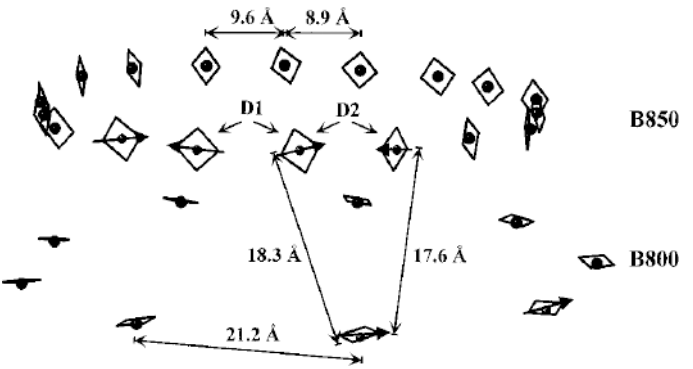

Figure 33. Schematic structure of LH2 from *Rps. acidophila*. The BChl *a* molecules with the central Mg atom are shown. D1 refers to a protomer and D2 refers the dimer between adjacent protomers. The directions of the Qy transition dipole vectors are indicated by vectors. Upper part consists of 18 B850 pigments; below are shown the 9 B800 pigments (redrawn from Ref. 102).

(Figure 33). Thus, the ring of 18 closely-spaced BChl is thought to be responsible for B850 and the ring of 9 widely-spaced BChl for B800.

The absorption spectra of LH2 complexes from different species of purple bacteria features an intense band at 850–860 nm and another band of about half that intensity at *ca*. 800 nm. At shorter wavelengths, there is a single band at *ca*. 590 nm attributable to the Qx band of BChl, while bands in the 400–500 nm region are attributed to carotenoids. The Soret band generally appears around 350–400 nm. The CD spectrum of LH2 exhibits a –/+ pattern in ascending energy, corresponding to the Qy bands at *ca*. 850–860 nm, and a much weaker CD of

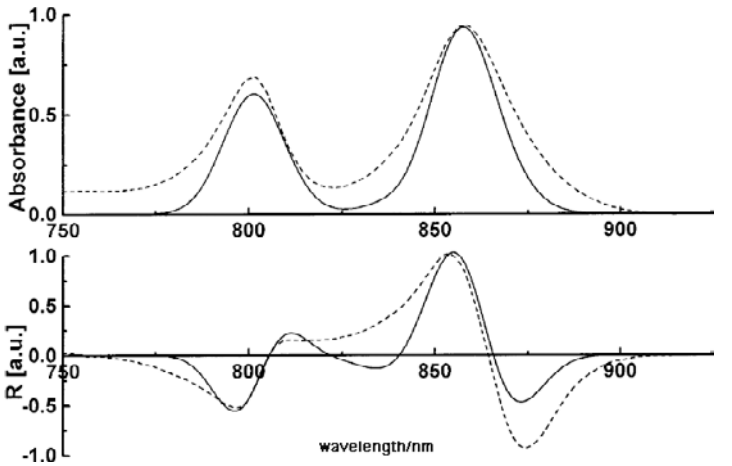

Figure 34. Experimental (dashed lines) and simulated (solid lines) of LH2 antenna of *Rps. acidophila* at room temperature (redrawn from Ref. 102).

negative envelope associated with the *ca*. 800 nm Qy band (Figure 34).[102,104] Linear dichroism studies show that the transition moments of both B800 and B850 lie in the plane of the chromophore membrane (the closely associated BChl in the ring of 18 are arranged in a head-to-head and tail-to-tail fashion around the ring).[106]

Sauer and coworkers[101] were the first to calculate the spectrum of LH2 of *Rps. acidophila* using the X-ray crystal structure.[89] They adopted a point monopole approximation in order to calculate the chromophore-chromophore interactions. The BChl *a* transition energy was first set at 12,500 cm^{-1} corresponding to the absorption wavelength of the B800 ring, where the excitonic interactions are small. By increasing the units of calculation from the protomer (two B850 and one B800), the trimer (one third of the full nonameric complex, with six B850 and three B800), the nonamer (18 B850 and nine B800), they showed that the absorption spectra are essentially additive, to give the spectrum of the complete nonamer. In the case of the protomer, the Q band appeared seemingly as a single peak at *ca*. 12,300 cm^{-1}, while in the trimer, split Q bands appeared at *ca*. 11,900 and 12,000 cm^{-1}, and in the nonamer, finally largely split Q bands were estimated at *ca*. 11,800 and 12,500 cm^{-1}, substantiating that the 850 nm band is essentially produced by excitonic coupling. Finally, to match the experimental spectrum, the transition energies of the B850 molecules were scaled to 12,260 cm^{-1}. In addition, by calculating the set of 18 B850 and the set of nine B800 separately, the authors confirmed that the B800 molecules are sufficiently isolated in LH2, and that the excitonic interaction among molecules in B800 is small. In addition, as seen in Figure 34, although the zero-crossing of the CD spectrum appears at lower energy than the

absorption peak by *ca*. 7 nm. This was explained by the negative rotational strength of the lowest energy state and the positive rotation just above this. Furthermore, because the lowest state has very weak absorption while the state just above it is very strong, the CD zero-crossing is at a lower energy than that of the absorption maximum.

The next higher level of calculation, i.e. an INDO/S calculation, was carried out for B800 (eight pigments) and B850 antenna (16 pigments) of *Rs. molischianum*,[97] which was the largest semi-empirical calculation on bacterial antenna. For calculation of the B850 antenna, the BChl *a* molecule was approximated by a reduced structure containing 44 atoms. The chromophore–chromophore interactions were estimated semi-empirically using the known crystal structure. However, the computed energy levels did not predict the experimental transition energies well.

Linnanto and coworkers then calculated the excitonic spectra of the LH2 antenna complex of *Rps. acidophila* adopting four different approaches.[102] For comparison, the energy levels were first calculated by applying the frequently used dipole-dipole approximation between all the 27 BChl a pigments of a single LH2 complex (case A). In the second level of calculation, the interaction energy between the neighboring B850 BChl *a* molecules was calculated semi-empirically (case B). Here, the values of nearest neighbor interaction matrix elements of the B850 ring were estimated by considering both possible ab–BChl *a* dimers as a supermolecule. By using this method, the special extension of the transition densities and the overlap between the wave functions with nearest neighbor molecules were taken into account. The calculation was further improved (case C) by calculating semiempirically (ZINDO/S) the transition energy of each monomer (B800, B850*a* and B850*b*) with a selected part of the protein. The difference from case B is that the monomer energies were calculated separately instead of using the experimental value of 12,937 cm^{-1} (773 nm).

The transition energies of the B850 BChl *a* monomers were calculated with the histidine residues. The B800 monomer was calculated with the nine nearest amino acids, the part of the phytyl tail of B850 which is in close vicinity of B800, and part of the carotenoid. In this way, the effects of surrounding protein environments were included. The result was then used to recalculate the interaction energy. In the last phase (case D), diagonal and off-diagonal disorder was included in the calculation, in order to account for the inhomogeneous line width of the experimental spectrum. Here, the computation included uncorrected random variation of the values of matrix elements which leads to inhomogeneous broadening of the spectral lines. The transition dipoles were kept fixed, while homogeneous widths of 210 cm^{-1} (B800) and 188 cm^{-1} (B850) were fixed for each transition. The diagonal disorder was 200 cm^{-1} (B800) and 220 cm^{-1} (B850), and the off-diagonal

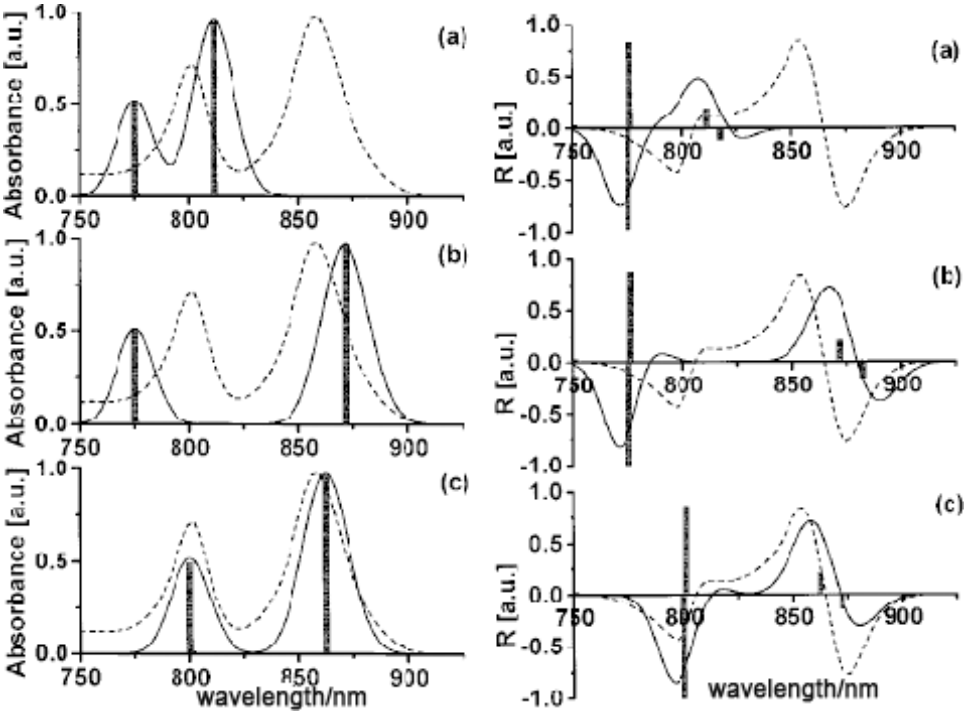

Figure 35. Exciton stick electronic absorption (left) and CD (right) spectra of LH2 complex and simulated spectra with a 350 cm^{-1} Gaussian line width. The experimental spectra at room temperature are shown as dashed lines for comparison. (a), (b) and (c) correspond to cases A, B and C, respectively, in the text (redrawn from Ref. 102).

disorder was 10% of the value of the matrix element. These linewidths were similar to the experimental values.[107–109] The results are clearly shown in Figure 35, together with the experimental spectra (dashed line).

In Case A, the exciton interaction energy between the nearest neighbor BChl *a* of B850 were 346 cm^{-1} (within the protomer) and 249 cm^{-1} (between the protomers). The exciton interaction energies between non-neighboring pigments were of the order of 30–40 cm^{-1}. The absorption intensity was concentrated mainly on four excited states, two of which were red shifted only to 775 nm. The other two states were red shifted to 811 nm, corresponding to a displacement from the Qy transition energy of the monomeric BChl *a* at 773 nm. The energy separation of the two absorption bands was much smaller. Thus, although the calculated values were not accurate, the general shapes of the absorption and CD spectra were in agreement with the experimental results. In case B, the exciton interaction energy between the nearest neighbor BChl *a* of B850 were 771 cm^{-1} (within the protomer) and 712 cm^{-1} (between the protomers), which were twice as large as those in case A.

The calculated absorption intensity was again concentrated mainly on four exciton states, and these four components formed two absorption bands, as in case A. The positions of these absorption bands were at 775 nm corresponding to the B800 transition, and 871 nm associated with B850 transition. The energy separation between the two transitions is about twice as large as is experimentally observed. The CD spectrum consisted of two pairs of lines: one pair centered at around 775 nm with an energy separation of only 17 cm^{-1} and one pair at around 876 nm with an energy separation of 140 cm^{-1}. The sequence of signs of the CD lines was identical with that obtained in case A. In case C, the Qy transition energies of the three monomers were calculated, on the wavelength scale, at 797 (B800), 784 (B850b), and 779 nm (B850a), respectively.

Compared with the Qy transition energy of monomeric BChl *a*, shifts induced by the surroundings of the BChl *a* monomers were −385 (B800), −189 (B850*b*) and −107 (B850*a*) cm^{-1}. The exciton interaction energies between the nearest neighbor BChl *a* of the B850 ring are *ca*. 650 cm^{-1} (within the *a,b*-protomer) and 560 cm^{-1} (between the protomers). The calculated absorption intensity of the whole LH2 complex is again concentrated on four components, and gives rise to two absorption bands at *ca*. 800 and 862 nm (Figure 35 bottom), which are very close to the experimental peaks. The energy separation of these two bands was 910 cm^{-1}, while the energy difference between the low-energy exciton state ^1A and $^{1,2}E_1$ state was 125 cm^{-1}. The CD spectrum consists of two pairs of lines (Figure 35, bottom). One pair is centered at 800 nm with an energy separation of 18 cm^{-1}, and one pair at 867 nm with an energy separation of 125 cm^{-1}. From these results, the authors concluded that the red-shift of the B800 band is to a large extent due to pigment–protein interactions, which is consistent with hole burning data indicating that exciton effects are unimportant for the B800 molecules and therefore, the B800 band.[110] Finally, by introducing diagonal and nondiagonal disorder to the exciton Hamiltonian, the experimental CD and absorption curves were simulated, with the results shown in Figure 34 as solid lines. Good agreement with the experimental spectra was obtained.

B. Synthetic Chlorins, Bacteriochlorins and Their Dimeric and Aggregated Systems

Although the CD spectra of several synthetic chlorin and bacteriochlorin systems have been reported,[111–118] papers which include analysis are very rare. Here, we restrict ourselves to introducing representative spectra of relatively well-defined systems.

Pandy, Kadish, Fukuzumi and coworkers compared the electronic absorption and CD spectra of ring-B reduced chlorins obtained by oxidation of bacteriochlorins

with those of ring-D reduced chlorins (Figures 36 and 37).[117] In these cases, there is a tendency for both the Qy and Soret bands to appear at longer wavelength when the B-ring is reduced (see in particular Figure 37). CD spectra were also reported, and CD peaks and troughs were observed associated with each absorption peak. Interestingly, the CD sign of the ring-B reduced species was opposite to the ring-D reduced species; with respect to the Qy and Soret bands, the B-ring reduced chlorins always gave positive and negative CD signs respectively. Although the authors

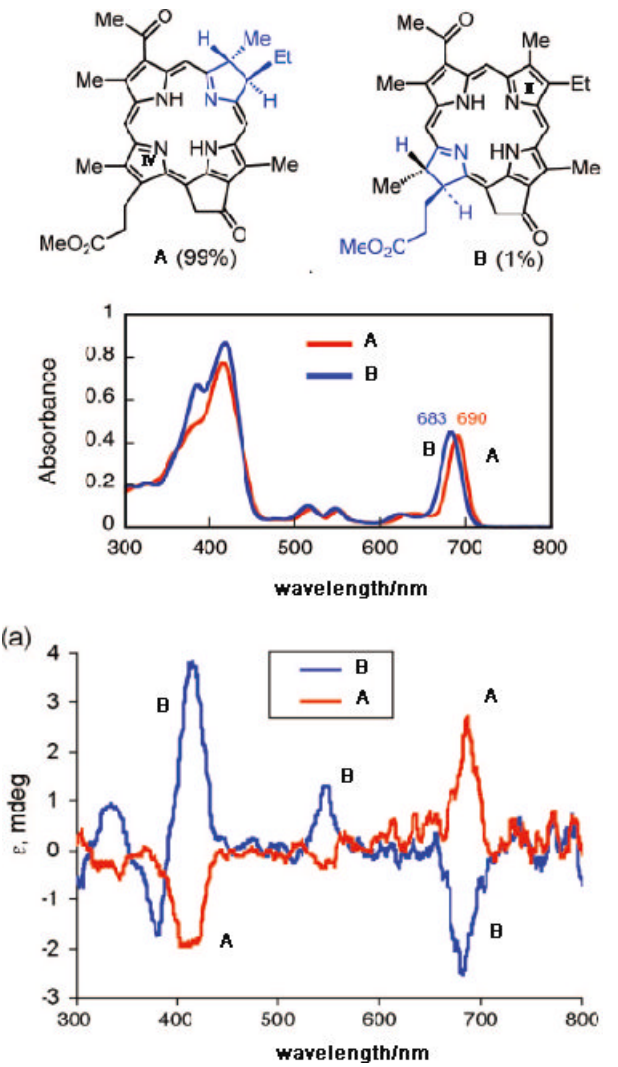

Figure 36. Electronic absorption and CD spectra of ring B or D reduced chlorins containing five-membered rings in CH_2Cl_2 (redrawn from Ref. 117).

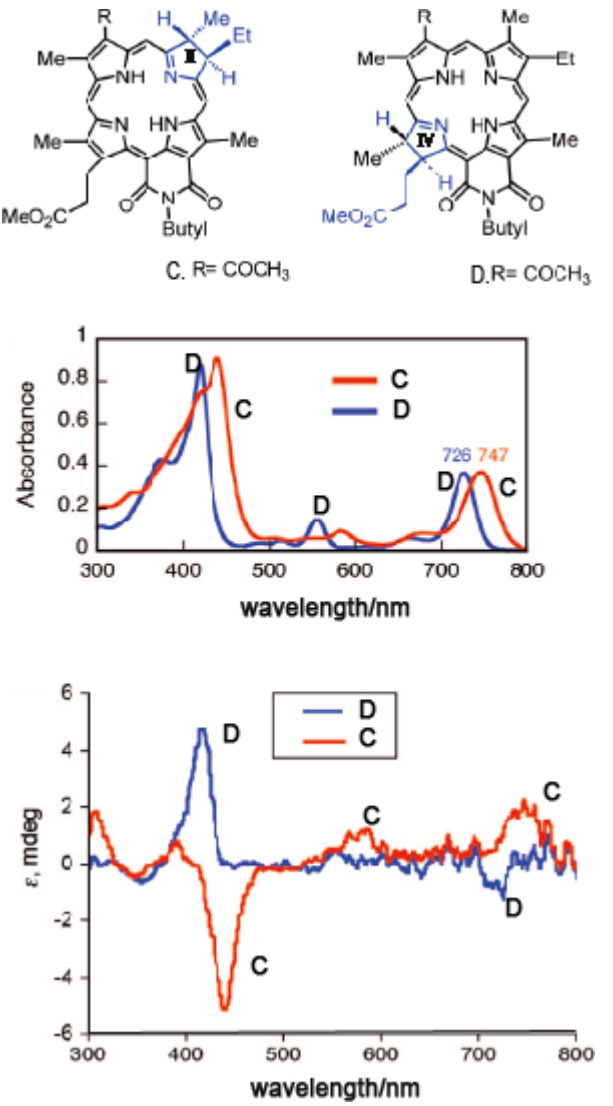

Figure 37. Electronic absorption and CD spectra of ring B or D reduced *N*-butyl-purpurinimide in CH_2Cl_2 (redrawn from Ref. 117).

suggested exciton coupling produced by self-association of the molecules, this interpretation is incorrect, since there are no dispersion type curves associated with absorption peaks, and the intensity is weak so that the spectra are noisy. The spectra shown in Figures 36 and 37 are characteristic of intrinsically active molecules.

Bucks and Boxer reported data of several cofacial chlorophyll-based dimers (Figures 38 and 39).[111] The main structural difference between the compounds in

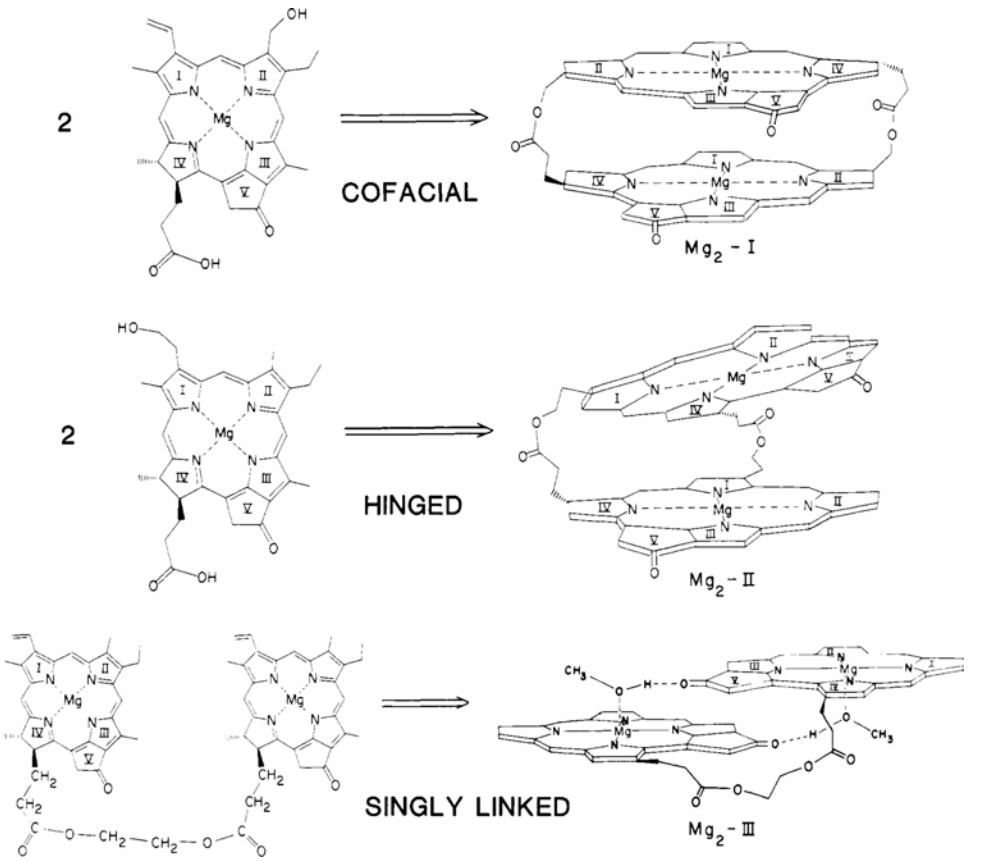

Figure 38. Chemical structures and schematic molecular conformations for the dimers by Bucks and Boxer (redrawn from Ref. 111).

Figures 39 and 40 are that in the former case, five-membered rings are fused while in the latter, six-membered rings are fused. In order to discuss the CD and absorption spectra, an understanding of the conformation is prerequisite. Inspection of a molecular model of the cofacial dimer showed that the macrocycles are parallel, and the angle between the y-axes is about $40 \pm 5°$. The centers might be offset by as much as 3.5 Å, as the rings move closer to maximize their π–π interactions. The structure of the hinged dimer was less well defined because of the considerable flexibility in the connection. For small opening angles of the hinge, the y-axes of the monomers were at approximately 90 degrees to each other. Based on this information, the two components of the cofacial dimer were predicted to be separated by about 700 cm^{-1} (*ca.* 30 nm) with most of the oscillator strength in the higher energy component (8:1, leading to a blue-shift). The rotational strengths of these components should be large, equal and opposite in

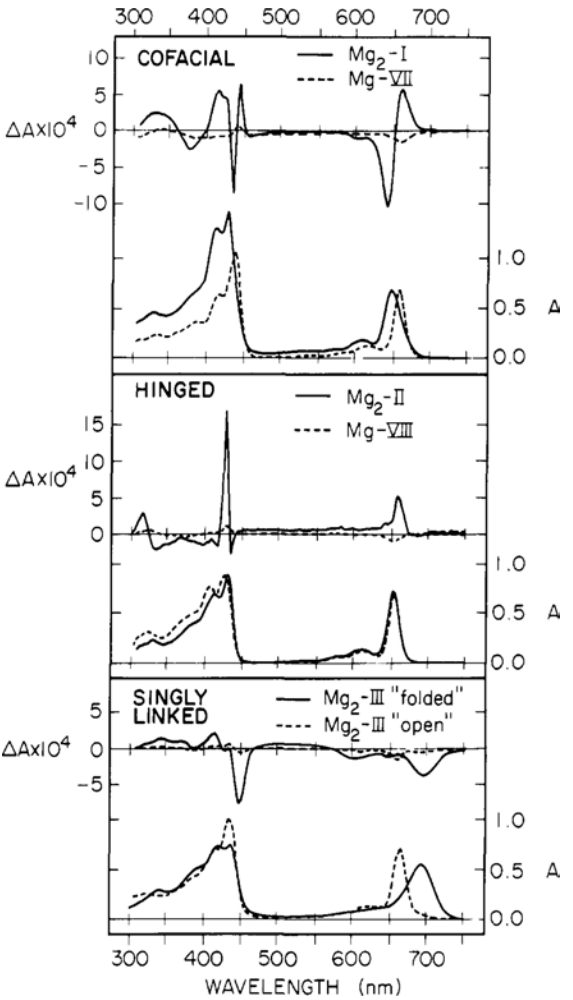

Figure 39. Comparisons of the absorption and CD spectra for the monomers (top and middle, broken lines) and the dimers (top and middle, solid lines) shown in Figure 38. In the bottom, "folded" (solid lines) and "open" (broken lines) forms were obtained by changing the solvent; "folded" was in toluene, and "open" was in toluene:pyridine = 9:1 v/v (redrawn from Ref. 111).

sign, with the band at lower energy positive. In the case of the hinged dimer, the Qy transition should not be split, since the transition moments are perpendicular, and any excitonic components in the CD should cancel out, as is indeed observed (Figure 39, middle). In the singly-linked "folded" dimer, the transition dipole moments are nearly antiparallel, so that nearly all of the oscillator strength is expected to lie in the lower energy component of the split Qy band (leading to a red shift). Although the rotational strength appears to be nearly zero theoretically,

the CD intensity in Figure 39, bottom is not particularly weak, indicating that the dipole coupling effect is still significant.

Kosaka and Tamiaki reported a well-defined cyclic hetero-dyad as a model compound for stacked chlorophylls, together with a linear non-cyclic hetero-dyad (Figure 40).[115] The largest difference of the constituent chlorin units is that one chlorin has a 13-keto carbonyl group while another has no substituent at the 13 position. After NMR analysis and consideration of the total energies obtained by molecular modeling, the cyclic dyad was concluded to take a conformation as shown at the bottom of Figure 40. The Qy absorption maximum of the cyclic dyad and linear dyad appeared at the same wavelength. The Qy and Soret bands of the former were slightly broader in the red and blue regions, respectively, relative to the latter. Intense S-shaped and reversed S-shaped CD signals in the Qy and Soret regions, respectively, of the cyclic dyad demonstrated that the two constituting chlorin units were close enough to give rise to an intramolecular transition dipole-dipole moment interaction. By applying the CD exciton chirality method, the S-shaped signal in the Qy region of the cyclic dyad revealed a "clockwise" rotational orientation of the two Qy transition dipole moments on the N21-N23 axis, which is in accordance with the two electronic transition moments drawn at the bottom of Figure 40 (top view).

Tamiaki and coworkers reported the aggregation of a Zn chlorin.[83] Including previous data,[78] it was known that the central zinc atom, the hydroxyl group at C-3^1 and the keto group at C-13^1 are prerequisites for aggregation. Furthermore, for the aggregation of the Zn chlorin in nonpolar solvents (Figure 41), it was found that the 3^1-hydroxyl oxygen of one chlorin coordinates to the zinc of another as a fifth axial ligand, and that the hydrogen of the ligated hydroxyl binds to the 13^1-carbonyl oxygen of a third molecule. In Figure 41, the spectra drawn as dotted lines are for monomeric species in THF. In this state, the CD is very weak. By adding 1 vol% of hexane, the Qy band shifted to the red, as seen for natural Mg chlorins,[78,118] and an intense dispersion type CD appeared corresponding to the Qy band, indicating the presence of strong exciton coupling due to supramolecular structure formation. As compatible structures, an antiparallel orientation, with head-to-head dimeric building blocks joined by hydrogen bonding and chlorine ring overlapping, has been proposed (Figure 42).

V. Synthetic Porphyrin Monomer Systems

Although several CD spectra of synthetic monomeric porphyrins have been reported, their analysis has been limited. In most cases, only the spectra were reported without explanation. In this section, therefore, only the structures of compounds and their spectra will be presented.

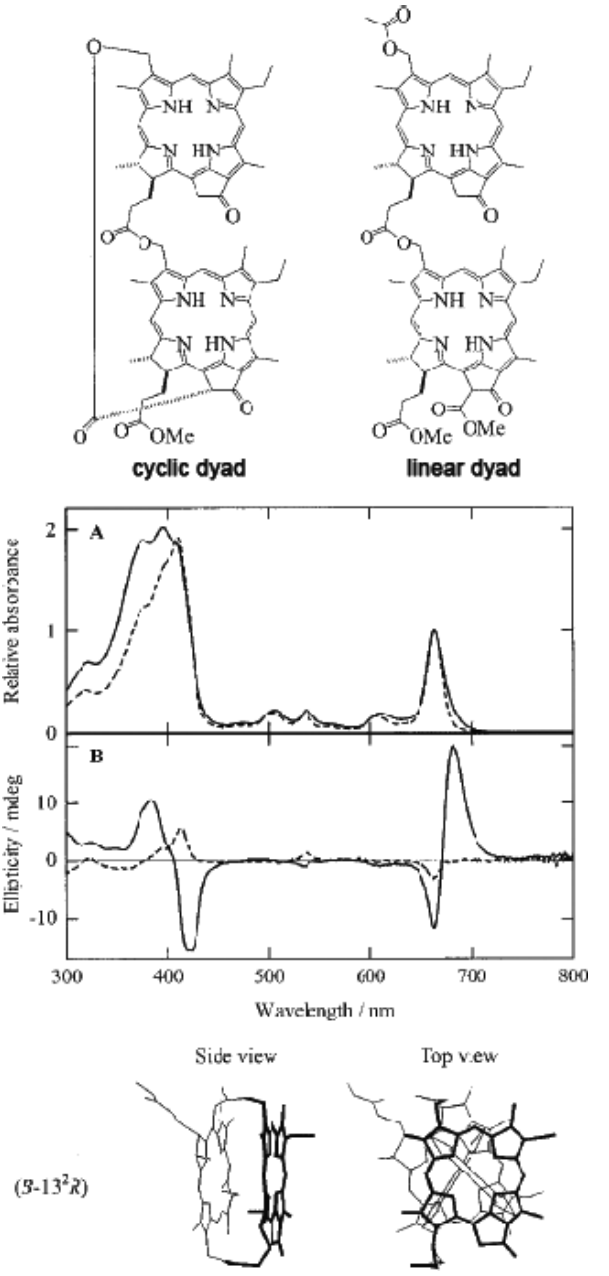

Figure 40. Structures of cyclic (top left) and linear (top right) chlorophyll hetero-dyads and their electronic absorption and CD spectra in CH_2Cl_2. Solid lines are for cyclic dyad. The bottom shows the optimized structure of cyclic dyad, which is consistent with NMR data (redrawn from Ref. 115).

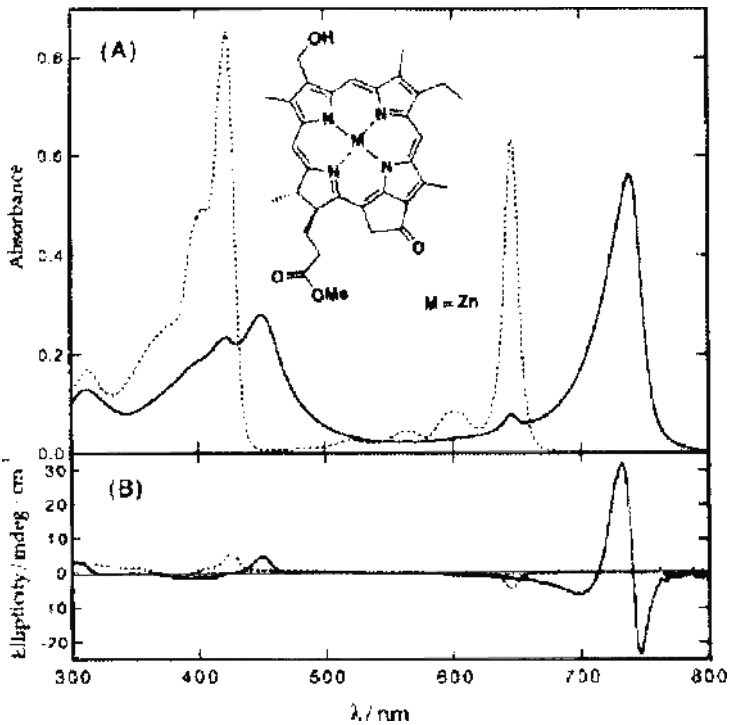

Figure 41. Electronic absorption and CD spectra of a Zn chlorin in THF (solid lines) and THF:hexane (99:1 v/v) (dotted lines) (redrawn from Ref. 83).

Daniell and Bruckner reported the enantiomeric resolution of a ruffled porphyrinoid (Figure 43).[119] As indicated by + and − signs in the structure of this figure, the relative position of the carbon atoms are displaced from the mean plane of the macrocycle. Two enantiomers displayed the Soret and Q bands at 442 and *ca*. 660 nm, and exhibited mirror image CD spectra. The sign at the Soret and Q was opposite for the two enantiomers.

Naruta and coworkers reported four binaphthyl-linked porphyrins and their CD spectra (Figure 44).[120,121] In these cases, S-binaphthyl-linked porphyrins show positive CD in all regions with the R-binaphthyl-linked examples being conversely negative. No explanation was given for these data.

Inoue, Aida and coworkers reported several CD-active porpohyrins[122–127] with one of the simplest examples being shown in Figure 45.[122] In the structure, the ethyl and methyl peripheral substituent groups on the pyrrole rings are oriented in a single-handed manner, so that two structures constitute antipodes depending on whether the RNH group is on this side or the other side of the porphyrin plane. The antipodes showed CD of perfect mirror images in the Soret band region. Pyrrole N-alkylated porphyrins (Figure 46) are conceptually an extension of the

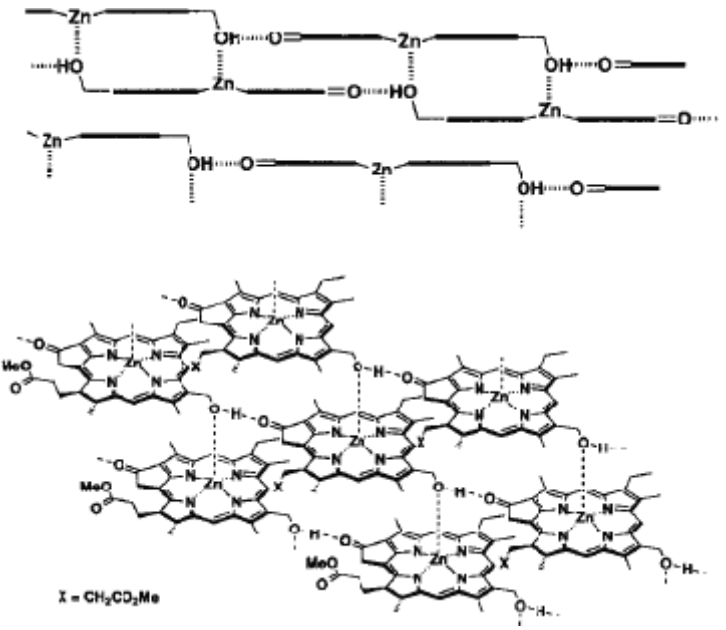

Figure 42. Schematic anti-parallel structures of Zn chlorine aggregates which show spectra drawn in solid lines in Figure 41 (top) and proposed supramolecular (bottom) (redrawn from Ref. 83).

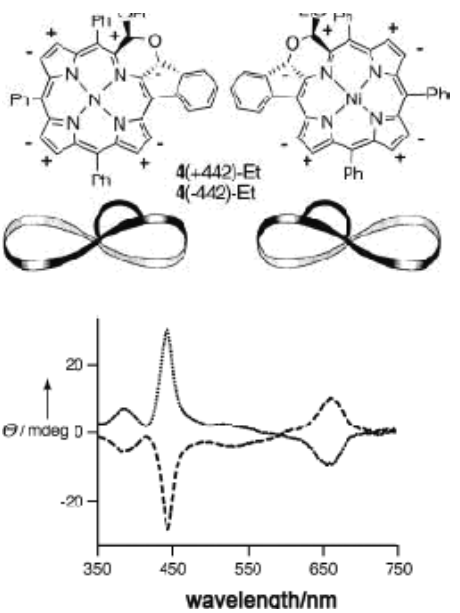

Figure 43. Ruffled porphyrins reported by Daniell and Bruckner, and their CD spectra (redrawn from Ref. 119). The "+" and "–" in the structures indicate the ruffled conformation, that is, the relative position of the carbon atoms with respect to the mean plane of the macrocycle.

compounds in Figure 45.[123] Again, methyl and ethyl groups on the pyrrole β-positions are arranged in a single-handed manner, so that these molecules can be enantiomers depending on whether the alkyl group is protruding upwards or downwards from the porphyrin plane. In their case, however, four chiral porphyrins were obtained, since the authors used optically active R and/or S-alkyl groups. No interpretation of the CD spectra was attempted. Strapped porphyrins, shown in Figure 47 are chiral following resolution using optically active HPLC.[124] Although the correspondence between the CD spectra (sign) and enantiomeric structures were not elucidated, the data give insight into the CD generation mechanism. The spectra exhibited in A and B in Figure 47 contain a benzene ring in the strap. However, as C shows, compounds without a benzene ring in the stap also show an intense CD signal at the Soret band, indicating that a benzene ring in the strap portion is not important for strong CD generation. Since the enantiomers in this figure are intrinsically active compounds which do not contain any chiral

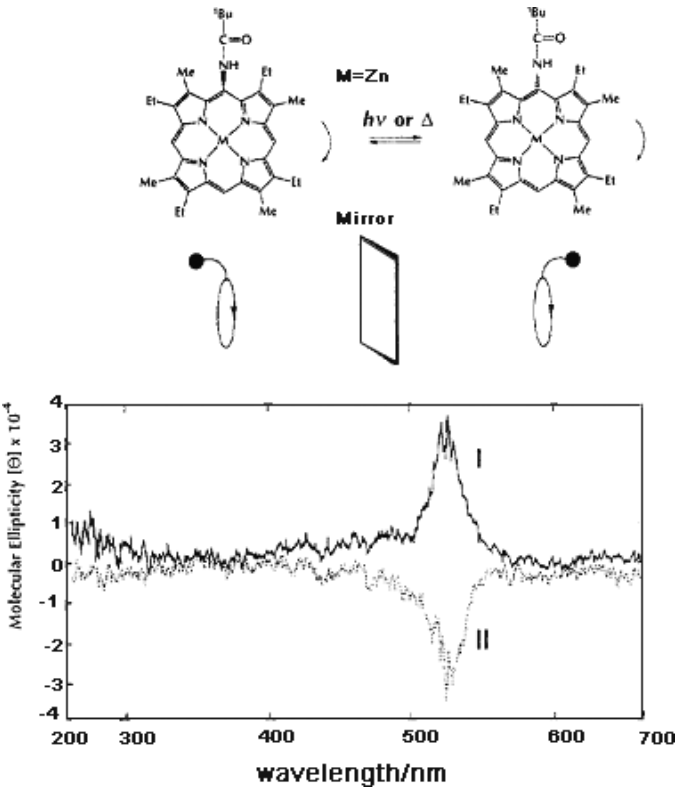

Figure 45. Structures and CD spectra of zinc α-(pivaloylamino)etioporphyrin reported in Ref. 122 (redrawn from Ref. 122). The relationship between the antipodes and CD spectra has not been elucidated.

moiety, the CD can most probably be considered to be generated by interaction of the electronic dipole moment in the amido moiety with that in the porphyrin plane. If optimized structures are obtained, it is now possible to calculate the CD spectra of the compounds in this figure, although this was not possible at the time the paper was published.

The oxophosphorus porphyrins in Figure 48 were also prepared.[125] It was proven beforehand from X-ray data that upon treatment with acid, oxoporphyrins produce the protonated form (cationic hydroxo complex) in which the porphyrin is ruffled and distorted from planarity.[128] The CD spectra of the enantiomers of the ethyl complex in a basic medium (planar oxo form) exhibited mirror-image monosign CD bands in the Soret region with a $[\theta]$ value of approximately 5000 (Figure 48A(a)), while in an acidic medium (ruffled hydroxyl form) the CD intensity was significantly enhanced, to give a $[\theta]$ value of *ca*. 25,000 (Figure 48A (b)). In the case of the phenyl complex, a much clearer pH dependence was observed.

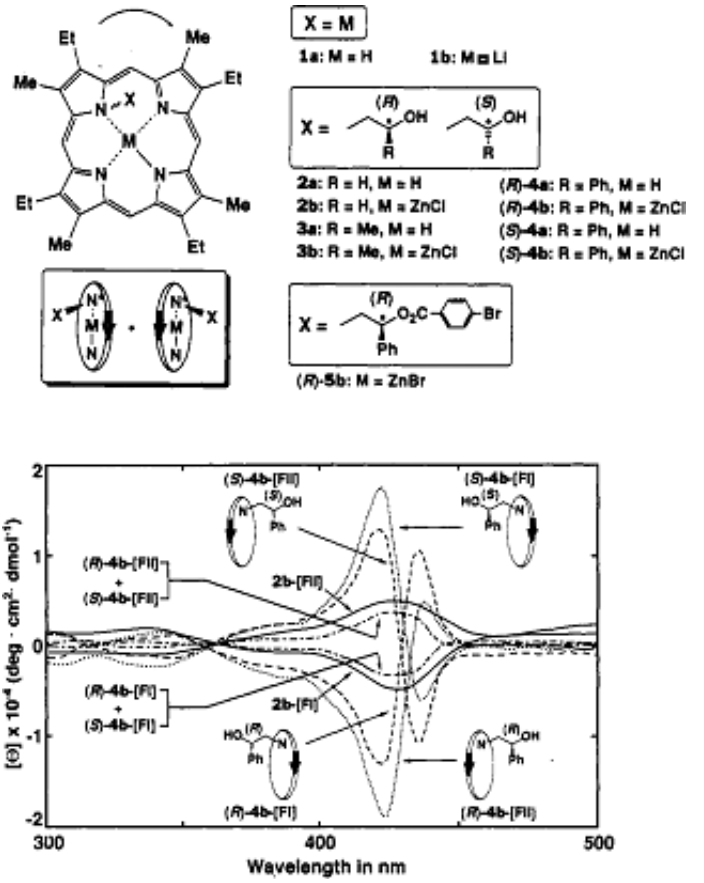

Figure 46. Structures and CD spectra of pyrrole *N*-alkylated porphyrins reported in Ref. 123 (redrawn from Ref. 123).

In basic media (planar oxo form), negative or positive monosignated CD bands were observed, similar to the case of the ethyl complex Figure 48B (a). While in acidic media (ruffled hydroxyl form), the CD showed split Cotton effects (Figure 48B (b)). The authors attributed this difference in the CD profile of the latter compound to an electronic interaction between the porphyrin chromophore and the axial phenyl groups. A D_2-symmetric porphyrin[126] and cobalt porphyrins which have similar structures to those in Figure 46 are also known.[127]

Ogoshi and coworkers reported two types of C_2 symmetric type porphyrin having two chromophores at the opposite positions of a porphyrin moiety (Figure 49).[129,130] In the case of porphyrins containing two naphthyl units, CD spectra were measured in the presence of L or D-amino acids or their esters.[130] In particular, when hydroxyl groups are present in the naphthyl moiety, extraneous amino

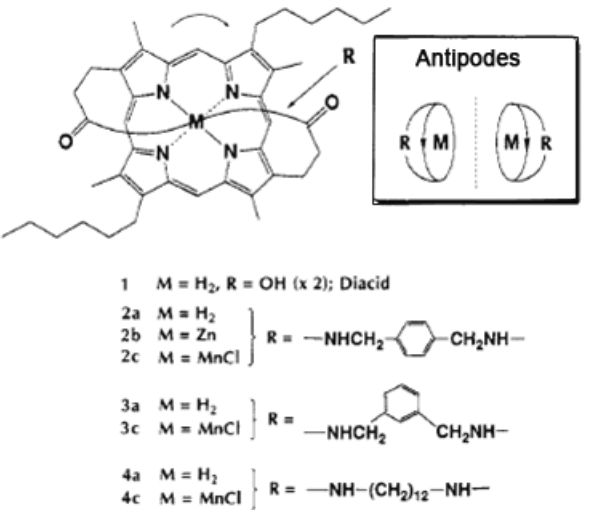

Figure 47. Structures and CD spectra of the antipodes reported in Ref. 124 (redrawn from Ref. 124). The relationship between the antipodes and CD spectra has not been elucidated.

acids fix the mutual special orientation of the naphthyl groups and porphyrin by hydrogen bonding to the OH group and coordinating to the central zinc atom. All of the hydrogen-bonded host-guest complexes exhibited a split Cotton effect; i.e. all complexes with L-aminoacid esters, where the longer wavelength peak of the Soret band was negative and the shorter wavelength peak was positive (Figure 49). However, a single-peak CD was observed if the OH group was changed to OCH_3. For aliphatic amino acid ester-complexes, positive and negative CD envelopes had the same intensity, while for aromatic amino acid esters, the induced CD was not symmetric, and the envelope at longer wavelength was always stronger than that at shorter wavelength. Accordingly, it was concluded that not only hydrogen bonding interactions but also aryl–aryl interactions between the aromatic group of aromatic amino acids and the porphyrin make a contribution to the observed Cotton effects. Since the Soret band consists of two nearly degenerate transitions (Bx and By) in the porphyrin plane, the two being perpendicular to each other, the positive and negative peaks were assigned to the two nearly-degenerate transitions. As possible mechanisms, hydrogen bonding which would fix the orientation of the carbonyl group of the guest amino acid (ester), and consequently the coupling between the magnetic transition dipole moment of the carbonyl group and the electronic transition dipole moment of the porphyrin Soret transitions were considered. A mechanism of coupling between the naphthyl electric transition dipole moment and the two Soret electric transition moments was ruled out, since this mechanism was theoretically found to induce Cotton effects with the same sign in both the Bx and By bands.

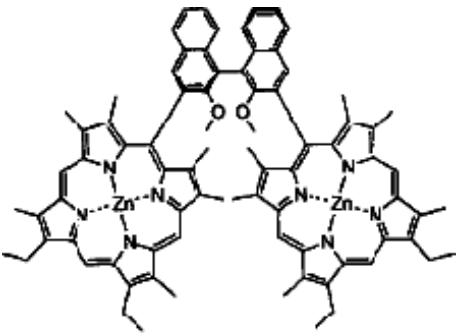
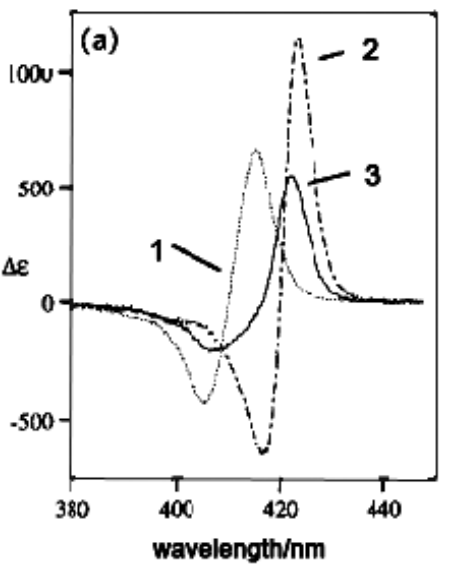
VI. Synthetic Porphyrin Dimer and Oligomer Systems

A. Bis-porphyrin Systems Linked to Optically Active Naphthalene Units

Hayashi and coworkers linked two zinc porphyrins to optically active (S)-binaphthyl, and used this as a ditopic coreceptor for a series of diamines. CD spectra were recorded for varying lengths of alkyl group between the two terminal amino groups, (Figure 50).[131] In the absence of diamines, the diporphyrin showed a plus-to-minus CD pattern as viewed from longer wavelength, corresponding to the Soret band, since (S) binaphthyl is a right-handed conformer. When diamines were





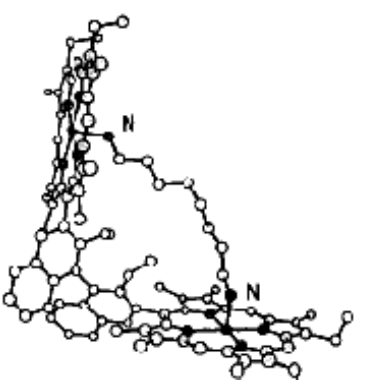


Figure 50. Binaphthayl-linked bis-porphyrin reported by Hayashi *et al*. and its CD spectra in the absence (1) and presence of 1,8-diaminooctane (2) or N-octylamine (3) (modified from Ref. 131).

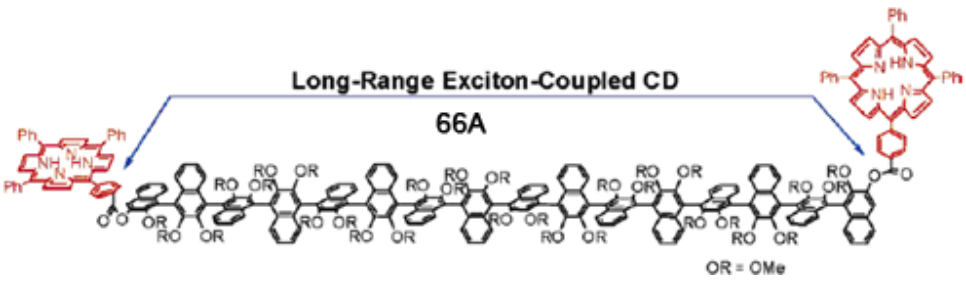

Figure 51. Hexadecanaphthalene that posseses two H_2TPPs (redrawn from Ref. 132).

added to the system, two amino groups coordinate to the zinc ion so that the angle between the two porphyrins changed. When 1,8-diaminooctane was used, the complexation constant was the largest, and the most intense bisignate CD was observed, although it was plus-to-minus in ascending energy. As shown in the proposed structure in Figure 50, the two porphyrins maintain a right-handed helicity in this state.

Tsubaki and coworkers synthesized oligomers of naphthalenes in a right-handed or left-handed manner, and linked tetraphenylporphyrins (H_2TPPs) at the two terminals (Figure 51).[132] By changing the number of naphthalene units, and accordingly the distance between the two porphyrins, they measured long-range exciton-coupled CD. They succeeded in detecting a coupled CD associated with the Soret band of the H_2TPPs separated by *ca.* 66 Å (this is the record to date). However, a rather more intriguing point is the finding of a very clear correlation between chirality and intensity. The authors concluded from the X-ray data of several oligomers and molecular mechanics calculations that the average dihedral angle between the adjacent naphthalene units is *ca.* 89–90 degrees. If this is the case, as shown in Figure 52, when four naphthalene units are linked with only an S-configuration, the two H_2TPPs are orientated in an anticlockwise direction, which leads to a negative exciton-coupled CD spectrum. However, when they are linked through two S- and one R-configuration, the two H_2TPPs are positioned in a clockwise direction, so that a positive split CD is expected. The results are excellent (Figure 53). In this figure, (S)-binaphthalene and (S,R,S)-quaternaphthalane have positively split CD curves, while in the case of (S,S,S)-quaternaphthalene, a negatively coupled CD is exhibited, but the absolute intensity is approximately the same as that of (S,R,S)-quaternaphthalane. With increasing naphthalene units from 4 to 8 and further to 16, the intensity of the observed coupled CD decreased at a ratio of 75:22:6 for the estimated ratio of 4:1:0.25. This is a useful system, since naphthalene units are linked linearly in a straight line and the interdistance of the two porphyrin units can be easily estimated.

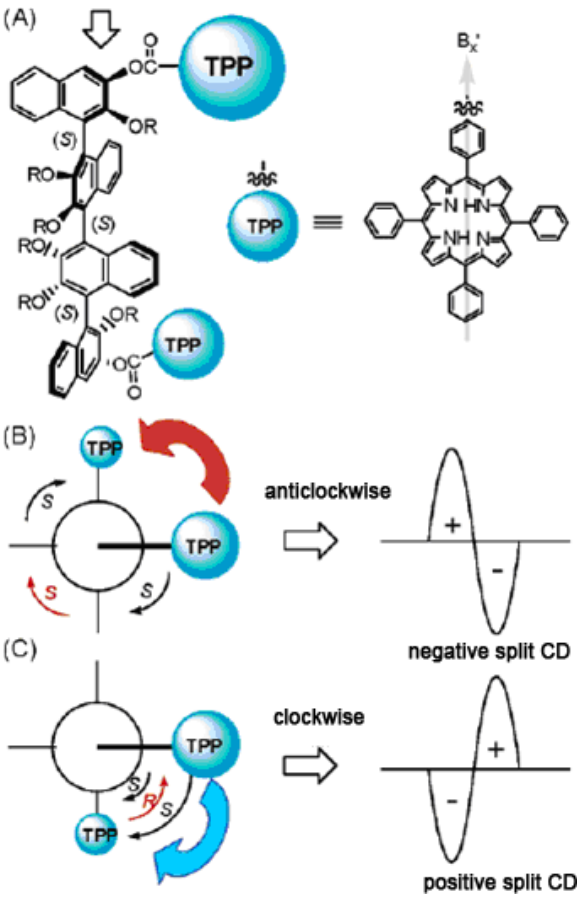

Figure 52. (A) (*S,S,S*)-quaternaphthalene with two H_2TPP units, and presentation of (B) anti-clockwise (*S,S,S*)- and (C) clockwise (*S,R,S*)-quaternaphthalene structures (redrawn from Ref. 132).

B. Dimeric Porphyrin Systems Without Optically Active Substituents

The first optically meso–meso linked porphyrin dimer was reported by Yoshida and Osuka in the year 2000.[133] Soon thereafter, a series of *meso–meso* linked Zn diporphyrins strapped with a dioxymethylene group of various lengths were reported (Figure 54).[134] Shortening the strap length resulted in a gradual decrease of the dihedral angle between the porphyrins and an increasing distortion of the porphyrin ring. The absorption spectrum of relatively unconstrained diporphyrins $\mathbf{S_{10}}$ strapped with a 10-carbon chain exhibits a split Soret band at 414 and 447 nm and a weak Q_{00} and prominent Q_{01} bands, both of which are similar to those of nonstrapped diporphyrin. Shortening the strap length causes systematic changes in the absorption spectra, in which the intensities of the split Soret band decrease, the

Sn

Figure 54. Strapped porphyrins ***Sn*** (redrawn from Ref. 134).

absorption bands at about 400 nm and longer than *ca*. 460 nm increase in intensity, and a prominent one-band feature of a Q-band becomes a distinct two-band feature with concurrent progressive red-shifts of the lowest Q_{00} band. These strapped porphyrins were separated into the optically active enantiomers through a chiral HPLC column. The two isolated enantiomers displayed opposite Cotton effects, as shown in Figure 55. There was no significant Cotton effect in the Q-band region. The CD spectrum of the fast eluting isomer, S10(A) exhibited Cotton effects,

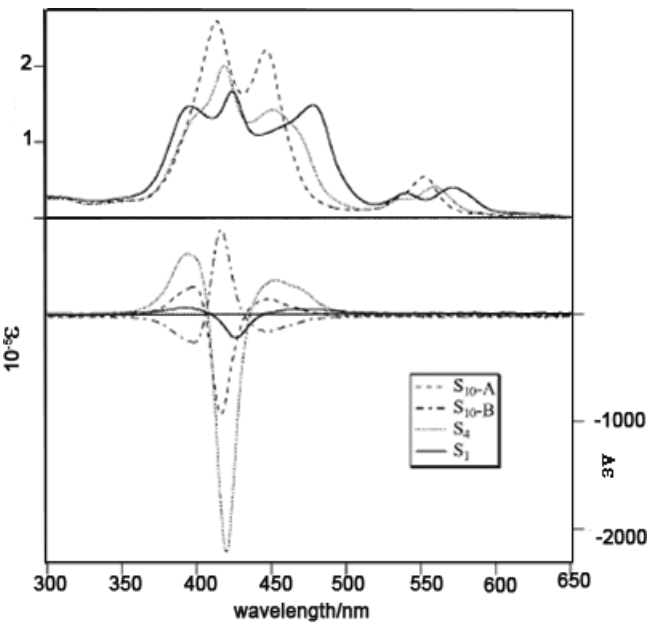

Figure 55. Absorption and CD spectra of several strapped diporphyrins; S_{10}(A), S_{10}(B), S_4(A), and S_2(A) in CH_2Cl_2. A and B means fast and second eluting isomer, respectively (redrawn from Ref. 134).

positive at 446 nm, negative at 416 nm, and positive at 398 nm. These CD spectra were interpreted as a superimposition of two bisignate split Cotton effects with opposite signs. In the case of $\mathbf{S_{10}}$(A), the first Cotton effect at around 430 nm was positive and the second one at around 405 nm was negative, and thus the negative band at 416 nm had the largest intensity. As the strap length was shortened, the first bisignate Cotton effect was red-shifted, while the second one remained at almost the same position. The intensities also changed with the strap length, and the largest intensity was observed for $\mathbf{S_4}$. For oblique diporphyrins, exciton coupling between $\mu_{\perp 1}$ and $\mu_{\perp 2}$ and between $\mu_{//1}$ and $\mu_{//2}$ can explain the three absorption peaks in the absorption spectra, but the CD spectra cannot be explained conceptually. Although not published[135] this kind of CD spectra can be conceptually reproduced if $\mu_{//1}$ and $\mu_{//2}$ are slightly bent.

Bringmann and coworkers reported *meso*-arylated β–β linked diporphyrins and their atropo-enantiomers,[136,137] using Zn, Cu, Ni, and Pd as central metals, or metal-free. Although enantiomers were obtained by repeated resolution using HPLC on a chiral phase, the enantiomeric purity decreased with time, the extent of which varied according to the central metal; after 24 hours, copper and nickel were almost racemic, while zinc was enantiopure. X-ray data revealed that the two nickel porphyrin moieties are largely distorted and have a ruffled conformation,

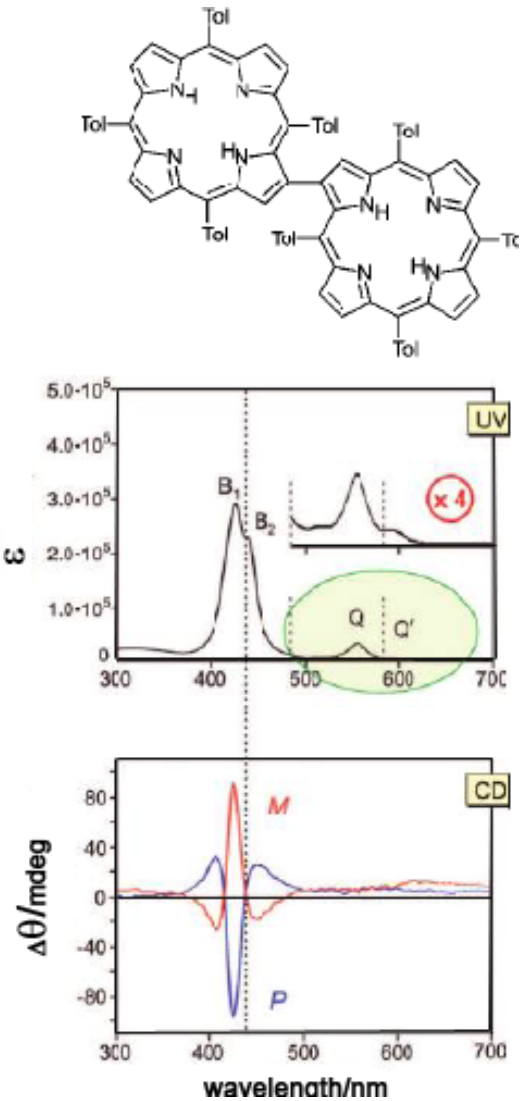

Figure 56. A β–β linked Zn porphyrin dimer and the electronic and CD spectra of their enantiomers (redrawsn from Ref. 137).

while the two zinc porphyrin moieties have a near-planar structure. The CD data were, accordingly, collected for the dizinc porphyrins (Figure 56). Corresponding to the split Soret band, the *P*-enantiomer showed a plus-minus-plus pattern in ascending energy, which is very close or almost identical to the CD pattern observed for the meso–meso linked diporphyrins (Figure 55).[134] The authors did not attempt to explain the spectra either by concept or exciton coupling theory. DFT calculations using a B3LYp/3-21G basis set, however, reproduced a plus-minus-plus CD

pattern for the Soret region of *P*-configurated Zn diporphyrin consistent with experiment.[136]

Matano and coworkers reported the synthesis of *meso*-phenylsulfinyl zinc porphyrins and their self-organization to S-oxo-tethered cofacial dimers.[138] When a hexane:2-propanol (100:1) solution of the above zinc porphyrins were applied to a chiral HPLC, two fractions were obtained in high optical purity. Under conditions where the homodimers and monomer were considered to be present in a 4:1 ratio, the authors measured the CD spectra of these isolated species. The first fraction showed a plus-to-minus pattern in the Soret band region in ascending energy, so that the absolute configuration of this fraction was assigned as *S*. From NMR data, the dimer was considered to be produced through the coordination of an oxygen of S=O to the Zn atoms (Figure 57).

From several *meso–meso*, *meso–β,* and *β–β* linked porphyrin dimers, Osuka and coworkers succeeded in isolating optically active meso–meso and *β–β* doubly linked dimers (Figure 58) whose enantiomers show a mirror-image relationship in their CD spectra.[139] According to the X-ray structure, the two porphyrin rings adopt an almost coplanar, helically twisted conformation, perhaps due to steric repulsion of the hydrogen atoms at the nearest pyrrole *β* protons. Interpretation of the CD spectra was attempted using the exciton chirality method. However, this was an essentially unsuitable system since the constituting porphyrin chromophores were not independent. Indeed, theoretical studies using MCD and TD-DFT calculations later proved that the assignment in Ref. 139 was incorrect; the right-handed dimer showed a mainly positive CD envelope in the Q band region (Figure 59).[140]

Werner, Vogel and coworkers reported the enantiometric separation and determination of the absolute configuration of "figure eight" cyclooctapyrroles (Figure 60).[141] Although this species is not a porphyrin, it is considered to be a porphyrinoid system since two metals can be incorporated utilizing four pyrrole rings each, i.e. the loop-shaped conformation of the macrocycles exhibits two structurally identical, helical N4 cavities. The "figure eight" structure in the solid state was confirmed by X-ray crystallography, and that in the solution by NMR analysis.

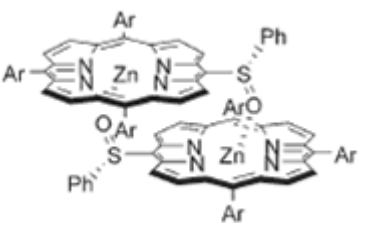

Figure 57. A cofacial dimer of *meso*-phenylsulfinyl zinc porphyrin (redrawn from Ref. 138).

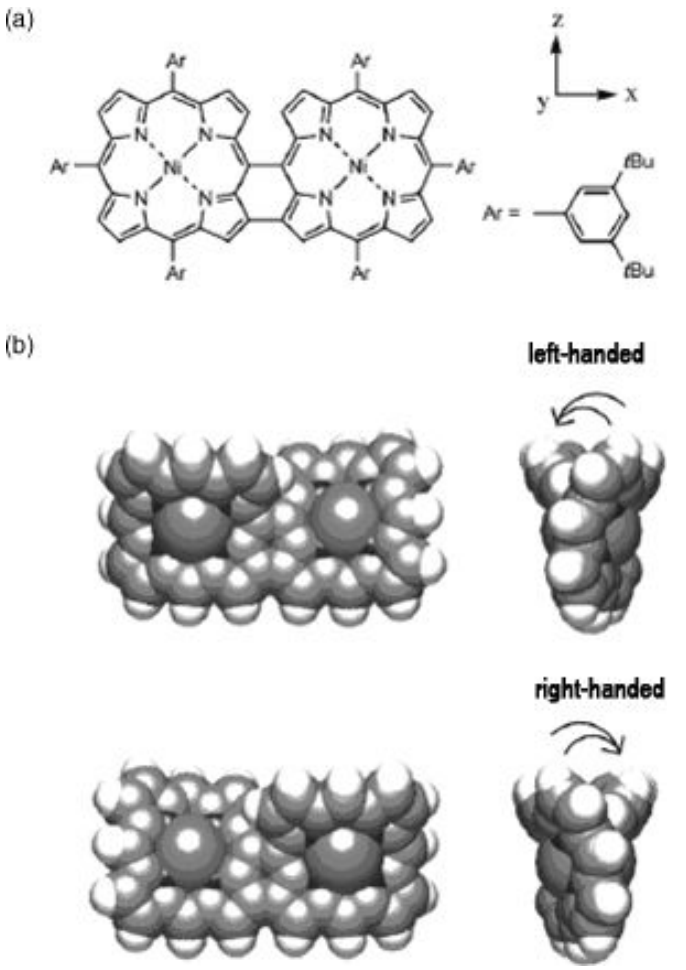

Figure 58. A *meso–meso β–β* doubly linked porphyrin dimer and its left- and right-handed structure (redrawn from Ref. 140).

The four dipyrrin units are almost planar, so that the helical conformation of the two tetrapyrrole substructures is mainly attributable to the torsions of the bipyrrole C–C single bonds (N–C–C′–N′ torsion angle: $\Phi = 30°$). The enantiometric separation was carried out on an HPLC column, and the enantiomers in this figure were optically stable in hexane even at 60 °C. As shown in Figure 60, the (*M,M*) enantiomer (solid line) and (*P,P*) enantiomer (broken line) exhibit exciton-coupled type CD spectra.

Ethane-bridged bis(zinc octaethylporphyrin) complexed with (*R,R*)-1,2-diaminocyclohexane results in a stable 1:1 tweezer complex exclusively as a consequence of its remarkably large association constant ($> 10^7 M^{-1}$).[142] The structure

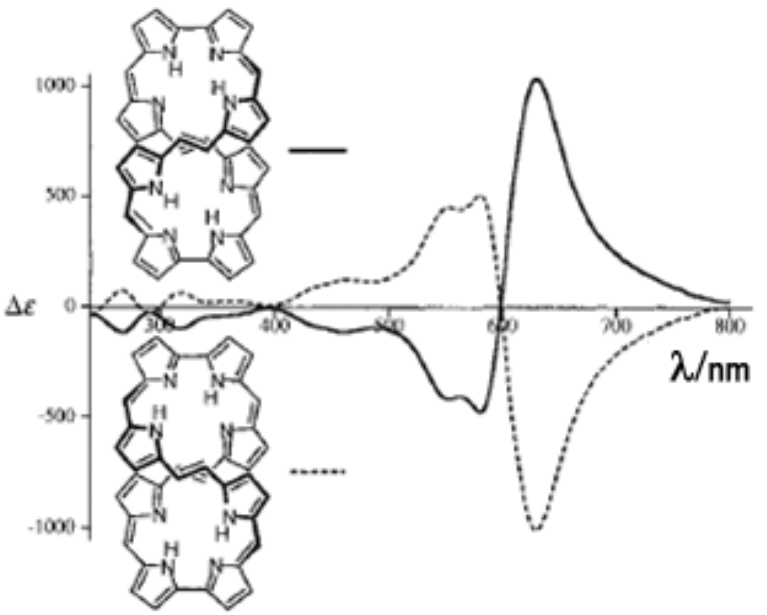

Figure 60. Structures of "figure eight" octapyrrole (*M,M*)- (top) and (*P,P*)- (bottom) enantiomers and their CD spectra (solid and broken lines, respectively) (redrawn from Ref. 141).

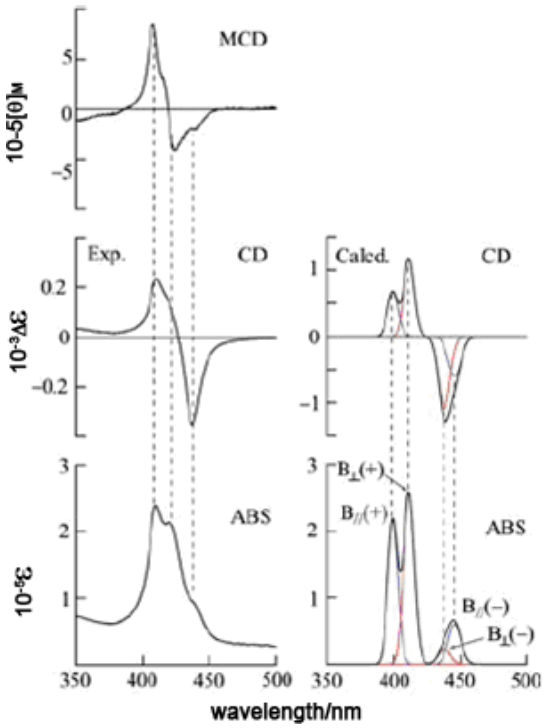

Figure 61. Experimental MCD, CD, and absorption spectra as well as the calculated CD and absorption spectra of the tweezer consisting of ethane-bridged bis(zinc octaethylporphyrin) and (R,R)-1,2-diaminocyclohexane. Each calculated exciton band was described by a single Gaussian curve. The notations plus and minus represent the in-phase and out-of-phase transitions, respectively (redrawn from Ref. 142).

of this chiral tweezer complex was analyzed by X-ray crystallography to have a noncrystallographic pseudo-two fold axis through the centers of the ethano-bridge, and furthermore its electronic and conformational structures in solution were examined by analyzing the CD, MCD, and electronic absorption spectra (Figure 61). In this figure, three well-resolved absorption bands are seen at 410, 419, and 436 nm. The positions of the MCD peaks coincide very closely with these transitions, indicating their nondegenerate character. Importantly, electronic transitions of different polarization exhibit MCD signals of opposite sign, so that it was found accordingly that the two transitions (at 408 and 419 nm) with the same positive CD sign are indeed of different polarization: the higher energy MCD signal (at 408 nm) is positive, while the lower energy MCD signal (at 424 nm) is negative.

To rationalize the experimentally observed spectral data, and taking into account the assignment of the transition polarization, theoretical absorption and

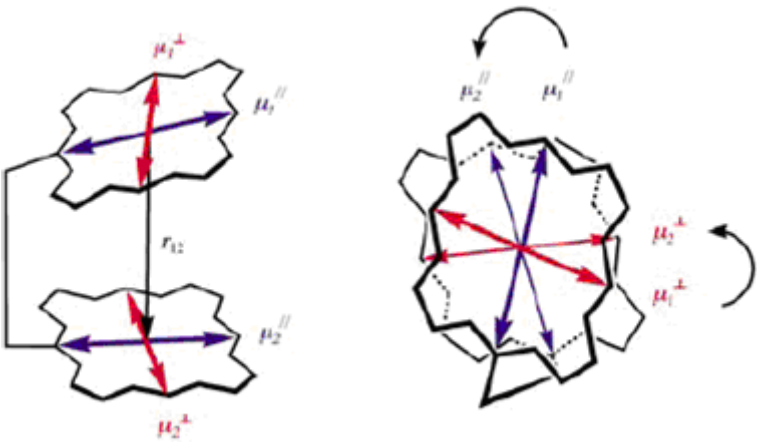

Figure 62. Definition of the direction of the transition dipole moments used in the theoretical analysis. r_{12} is the distance between the centers of gravity of the porphyrin units. The subscripts 1 and 2 are used to distinguish the two chromophores (redrawn from Ref. 142).

CD spectra were calculated using the geometrical parameters obtained from the corresponding crystal structure and the spectral parameters of the corresponding porphyrin monomer on the basis of the Kuhn–Kirkwood coupled-oscillator mechanism.[32,33,143] This tweezer system consists of two identical porphyrin moieties, each having two different transition moments $B_{//}$ and $B_{\perp}$, which have parallel and perpendicular orientations to the ethane bridge, respectively (Figure 62). This arrangement results in two major types of degenerate exciton interaction ($B_{//} - B_{//}$ and $B_{\perp} - B_{\perp}$ couplings), and thus leads to four exciton states. The relative orientation between these two pairs of electronic transition is anticlockwise, which according to the exciton chirarity method[7] predicts the negative chirality that was observed experimentally. The resulting calculated absorption spectrum has three well-resolved bands that are also similar to the experimental results (Figure 61). The face-to-face conformation and short distance between the centers of the interacting electric dipoles ($r_{12} = 6.23$ Å) results in the higher energy $B_{//}(+)$ and $B_{\perp}(+)$ and lower energy $B_{//}(-)$ and $B_{\perp}(-)$ exciton states being well separated. These pairs of states become optically allowed and partially forbidden transitions, respectively, as a consequence of strong exciton interactions that result in the observed absorption profile. Furthermore, the MCD $B_{//}(+)$ and $B_{\perp}(+)$ bands should theoretically be of opposite sign because of their orthogonal polarization, which is in full agreement with the experimental results. A minus-to-plus CD pattern was calculated for the both $B_{//} - B_{//}$ and $B_{\perp} - B_{\perp}$ couplings, and results in one intense negative CD signal at lower energy and two partly resolved, positive CD signals at higher energy. This CD pattern was in good agreement with that observed experimentally.

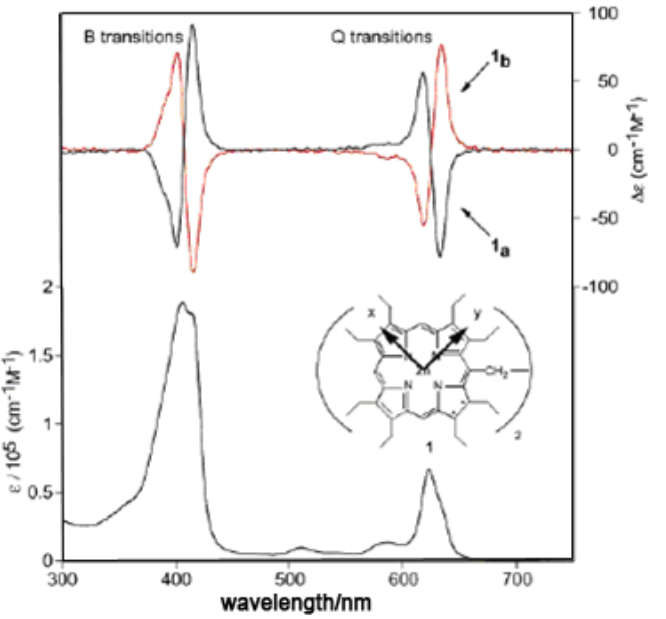

Figure 63. Absorption and CD spectra of two enantiomers ($\mathbf{1}_a$ and $\mathbf{1}_b$) of ethane-bridged bis(zinc octaethylchlorin). $\mathbf{1}_a$ and $\mathbf{1}_b$ are the first and second eluting enantiomers in the HPLC column (redrawn from Ref. 144).

Furthermore, the electronic absorption and CD spectra were nicely reproduced by TD-DFT calculations at the B3LYP/6-31G(d) level.

Ethane-bridged bis(zinc octaethylchlorin) was resolved to yield two enantiomers which exhibit dispersion CD signals in the regions of chlorin B and Q transitions (Figure 63).[146] UV-visible absorption profiles of 1a (first eluting fraction in HPLC column) and 1b (second fraction) are not distinguishable from each other, showing considerable broadening and splitting of the corresponding B and Q bands due to strong excitonic interaction. In the case of the CD spectra, very clear dispersion curves were observed, not only in the B band region but also in the Q band. The positions of the CD peaks and troughs in the B region coincide closely with the maxima of the split B band in the absorption spectrum. The anisotropy factor in the Q band region is more than three times that in the B band region. Furthermore, and importantly, the B and Q signals have opposite CD signs, which is a clear indication of distinct special orientation of the relevant coupling transitions, apparently due to the different polarization along the chlorin x- and y-axes (see Figure 63).

For assignment of the absolute configurations of the two fractions 1a and 1b, the coupling direction of the chlorin's lowest energy Qy electronic transitions is of the utmost importance because of their well-distinguished absorption characteristics.

In particular, the negative sign of the Qy couplet of 1a indicates an anticlockwise orientation of the corresponding transitions, while in the case of 1b, the situation is exactly the opposite. According to X-ray data possessing C_2 symmetry, these bis-chlorins are V-shaped, with the reduced pyrrole rings of two chlorin moieties located at the closest special position to each other. In this geometry, two Qy transitions of the (S,S/S,S)-enantiomer form a clockwise turn that, in accordance with the exciton chirality method, corresponds to positive chirality as determined for 1b. For the (R,R/R,R)-enantiomer the direction of coupling and thus the corresponding chirality sign are opposite, as seen for 1a.

To theoretically confirm this assignment, the CD spectrum of the (R,R/R,R)-enantiomer was calculated using the following approach. Firstly, the spacial geometry of this enantiomer was obtained at the semi-empirical PM3 level using the corresponding crystallographic data as a starting point (interchromophoric distance is 8.16 Å). Under such conditions, a Coulombic rather than electron exchange interaction model is more appropriate to apply for the two chlorin chromophores. In the second step, spectral parameters (exciton energies and transition moments) of the chlorin monomer were obtained from CI calculations at the ZIBDO/S level of zinc 5-methyloctaethylchlorin. The derived absorption spectrum of the monomer consists mainly of four well-distinguished (Qy, Qx, Bx, and By) transitions (Figure 64b), and is typical of chlorin-type chromophores.[73–88] Finally, on the basis of the geometrical and spectral parameters obtained by the point-dipole approximation and the Kuhn-Kirkwood coupled oscillator analysis,[32,33,143] the theoretical electronic absorption and CD spectra of the (R,R/R,R)-enantiomer were calculated (Figure 64a). The calculated spectral features are in good agreement with the experimental spectra of 1a. It is clearly seen that the intensity of the out-of-phase Qy(−) transition is smaller than that of the in-phase Qy(+) transition due to the partially forbidden nature as a result of the V-shaped orientation of these dipoles. A negligibly small CD signal arising from the Qx–Qx coupling is also predicted correctly, since its intensity is proportional to the square of the magnitude of the Qx transition moment. Furthermore, the lower energies of the Qy and Bx transitions, in comparison to the corresponding Qx and By transitions, allow one to attribute the origin of their opposite chirality signs to the different direction of the coupled transitions: i.e., clockwise and anticlockwise for the x and y polarizations, respectively. Thus, this theoretical model nicely reproduces the relative energy levels and intensities of the coupling transitions, particularly the three degenerate Qy–Qy, Qx–Qx, and Bx–Bx couplings. Although there was some overestimation of the CD intensities arising from the By–By coupling, the actual CD signals of the CD By band are expected to be less pronounced due to the smaller excitonic splitting than those of the Bx bands. More importantly, this analysis predicted the negative chirality of the most red-shifted and energetically

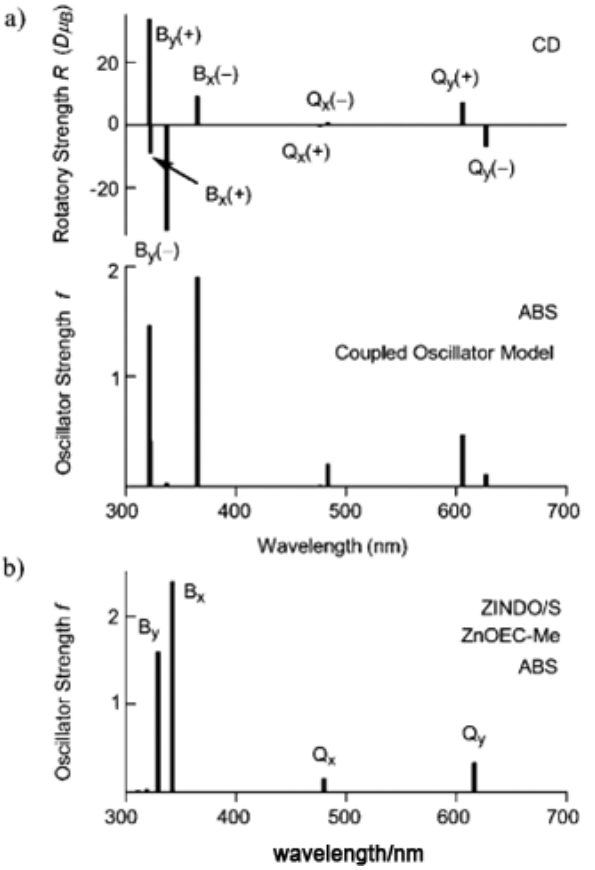

Figure 64. (a) Calculated absorption and CD stick spectra of (*R,R/R,R*)-bis-chlorin drawn in Figure 63 based on the optimized structure. isolated Qy transitions of 1a, thus unambiguously supporting the assigned absolute configuration.

C. Oligomeric Porphyrin Systems

CD spectra of several oligomeric porphyrin systems have been reported. However, since the systems become complex, virtually no anaysis has been carried out. For example, Osuka and coworkers synthesized *meso*-cinchomeronimide-appended *meso–meso*–linked metal (H_2 and Zn) porphyrin dimers (Figure 65) which can exist as mixtures of six atropisomers.[145] These atoropisomers can be separated since the free rotation of the cinchomeronimide group is considerably restricted

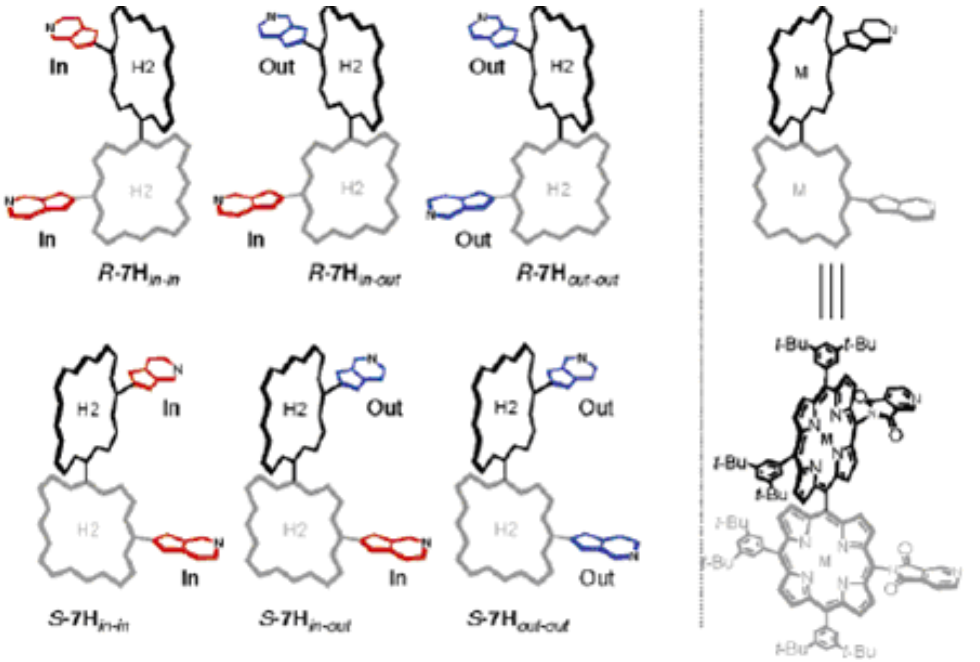

Figure 65. *meso*-Cinchomeronimide appended *meso–meso* linked metal (H_2, Zn) diporphyrin and its six kinds of atropisomers. In the abbreviations, *S* and *R* indicate chirarity, "in" and "out" means whether the nitrogen atoms of cinchomeron moiety is oriented inward and outward, respectively, of the porphyrin plane (redrawn from Ref. 145).

due to the steric hindrance of the two imide-carbonyl groups. Depending on whether the nitrogen atoms of the cinchomeronimide are facing outwards or inwards from the porphyrin plane, these atropisomers are expressed by adding the subscript in–in, in–out, out–out, in addition to handedness (S and R). When the zinc complexes of the separated isomers were dissolved in solution, they exhibited high-fidelity self-sorting assembly, to form discrete cyclic trimers, tetramers, and pentamers with large association constants from $7_{in–in}$, $7_{in–out}$, and $7_{out–out}$, respectively (compound **7** in the paper) (Figure 66). Although the absorption spectra of $R7_{in–in}$, $R7_{in–out}$, and $R7_{out–out}$ (*meso–meso* linked diporphyrin) are practically identical, with two strong Soret peaks at 427 and 465 nm and a Q_{01} band at 574 nm, their self-assembled oligomers showed the CD spectra shown in Figure 67. Although these CD spectra appear to be rationalized by exciton coupling theory, no analysis has been attempted.

Osuka and coworkers reported fairly similar box-type porphyrin enantiomers and their absorption and CD spectra.[146] Although the CD spectra were perfect mirror images of each other (Figure 68), again no explanation was given. Aida and

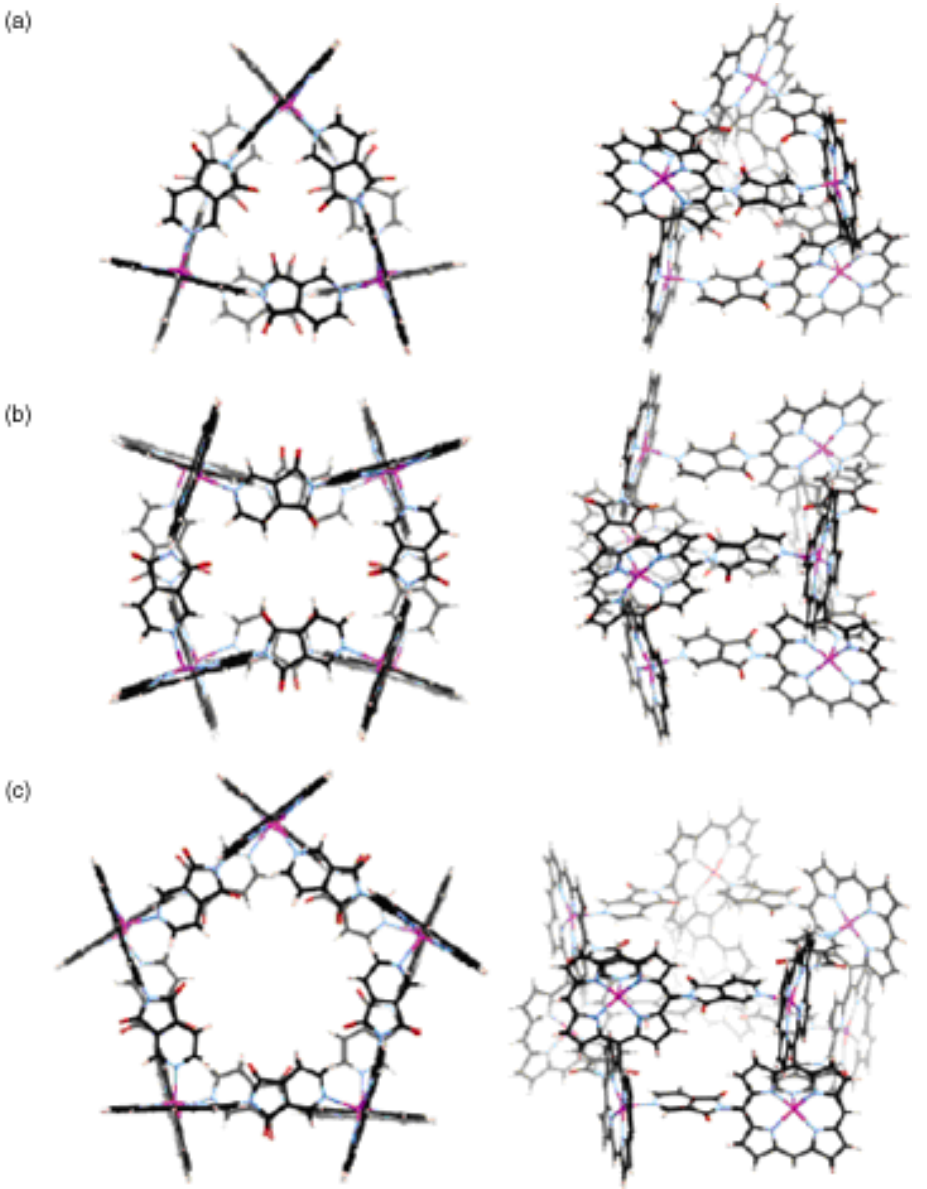

Figure 66. Structures of DFT-calculated (a) (R-$7_{in–in}$)$_3$, (b) (R-$7_{in–out}$)$_4$, and (c) (R-$7_{out–out}$)$_5$. The structure of (c) is very close to that confirmed by X-ray (redrawn from Ref. 145).

coworkers reported box-type porphyrin assemblies having CD spectra very close to those in Figure 68.[147]

Stang and coworkers reported a cyclic tetramer of a 5,15-diphenyl-10,20-dipyridyl metal-free porphyrin connected by four optically active R or S-binaphthyl

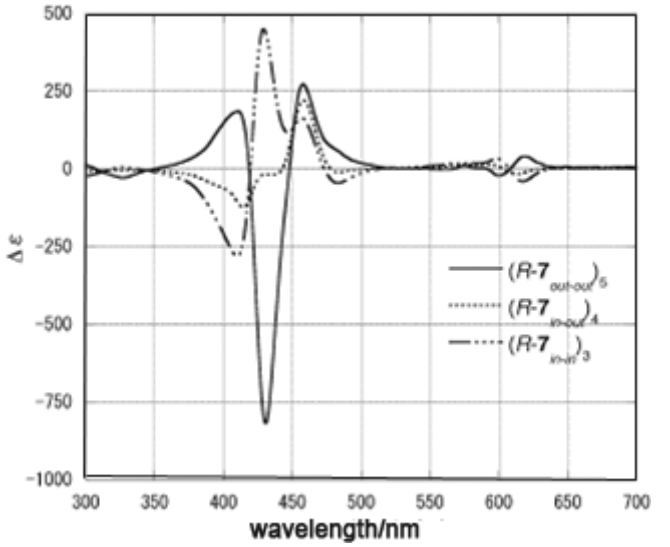

Figure 67. CD spectra of R-7 in $CHCl_3$. Broken dotted, dotted, and solid lines represent the spectra of cyclic trimer, tetramer, and pentamer, respectively in Figure 66 (redrawn from Ref. 145).

(BINAP) units (Figure 69 top) and their electronic absorption and CD spectra (Figure 69 bottom).[148] Although the absorption spectrum is typical of monomeric porphyrin without aggregation, very sharp bisignate CD curves were observed in the Soret band region. The apparent Davydov splitting is 10 nm. The authors suggested three types of coupling interaction: (a) four "adjacent" porphyrin couplings (pairs of porphyrins attached to the same transition metal corner), (b) two "opposing" porphyrin couplings (porphyrins on opposite sides of the macrocycle), and (c) a combination of (a) and (b). Careful examination of the structure revealed that both the "adjacent" and "opposing" pairs of porphyrin chromophores are in the same chiral environment of the BINAP ligands. This was in accord with the signs of the first and the second Cotton effects observed in the CD spectrum for the Soret band of the macrocycle, as well as with the large magnitude of the splitting due to mutual cooperativity. Interestingly, when zinc was inserted into the macrocycle, a bisignate CD was not recorded, but a single peak (when R(+)-BINAP was used) was observed corresponding to the Soret peak. The authors suggested that this is due to the high symmetry (D_{4h}) of the zinc complex. In the case of the metal-free complex, the Bx and By (Soret) transition is separated by about 200–250 cm^{-1} and the direction of transition moment is mutually normal.[149] Thus, when R(+)-BINAP was used as a linkage, the coupling interaction among Bxs may give a negative CD and that among Bys a positive CD. Then, as a result, a

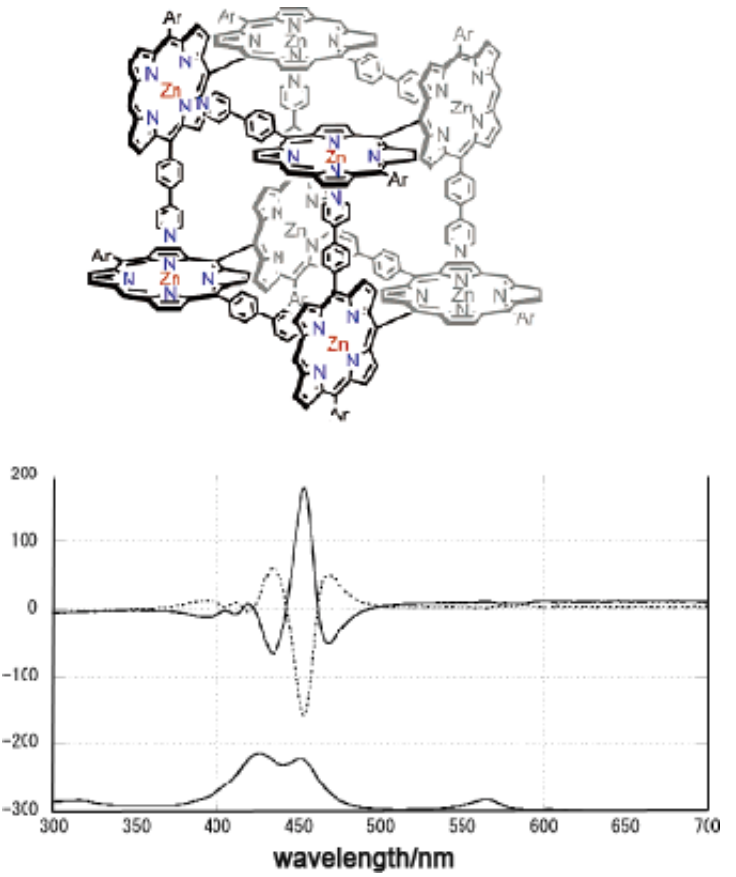

Figure 68. (top) (R)-Isomer structure of tetrameric box type assembly of *meso*-pyridine appended *meso–meso*-linked Zn porphyrin dimer. (bottom) The absorption and CD spectra of the above box type assembly of the Zn porphyrins. CD spectra-isomer relationship is not elucidated, although mirror-like curvatures are recorded (redrawn from Ref. 146).

bisignate CD curve is observed since the energies of Bx and By are very close. Whether this is correct or not has to be judged carefully by considering the optimized structures.

Kimura and coworkers reported (R)- or (S)-BINAP-linked diporphyrins and their CD spectra (Figure 70).[150] Similarly to the abovementioned Stang and coworker's case, metal-free derivatives display bisgnated CD signals in the Soret region. The R-enantiomer exhibited a positive CD sign at 427 nm corresponding to the Soret absorption peak and a negative CD sign at shorter wavelength. When iron was inserted, the bisignate CD signal almost disappeared, and the R-enantiomer showed positive CD in the Soret region, strongly suggesting that the Soret CD is actually induced CD produced by a coupling interaction between the BINAP

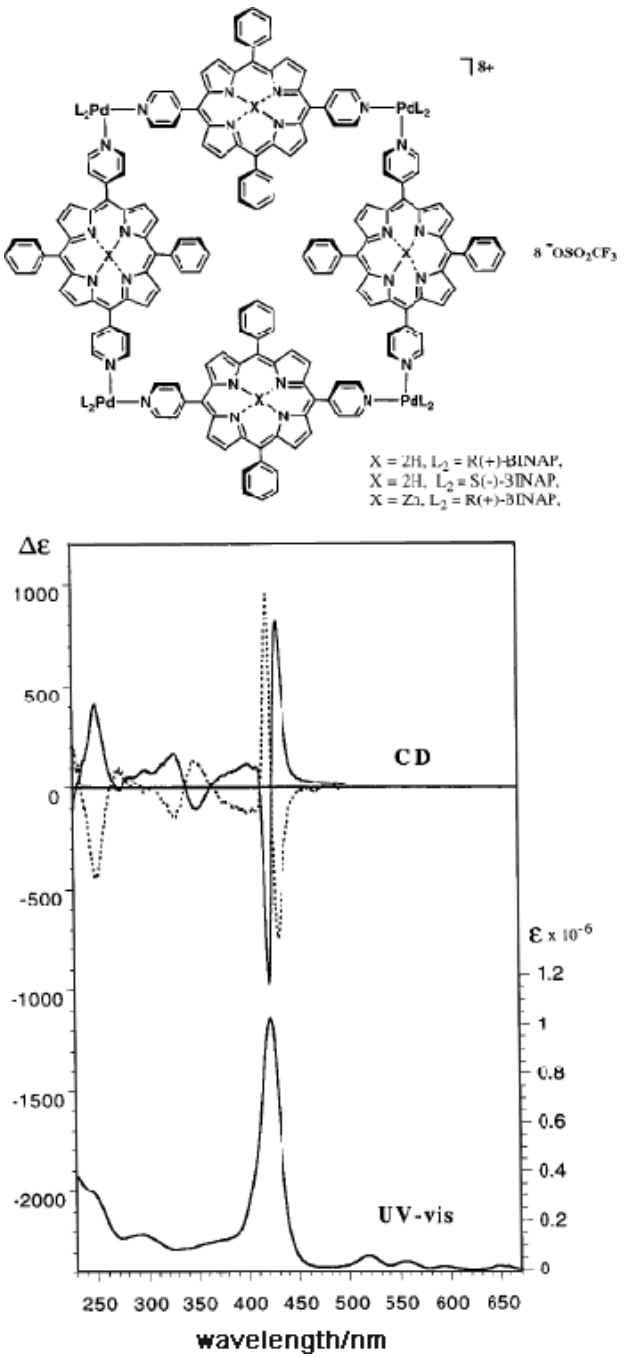

Figure 69. (top) A cyclic tetramer of 5,10-diphenyl-10,20-dipyridyl porphyrin connected by four Pd^{2+} ions. L2 means R(+)- or S(-)-BINAP. X = H_2 or Zn. (bottom) CD and UV-vis spectra of the above tetramer, X = H_2: (solid line) L2 = R(+)-BINAP, (dotted line) L2 = S(–)-BINAP (redrawn from Ref. 148).

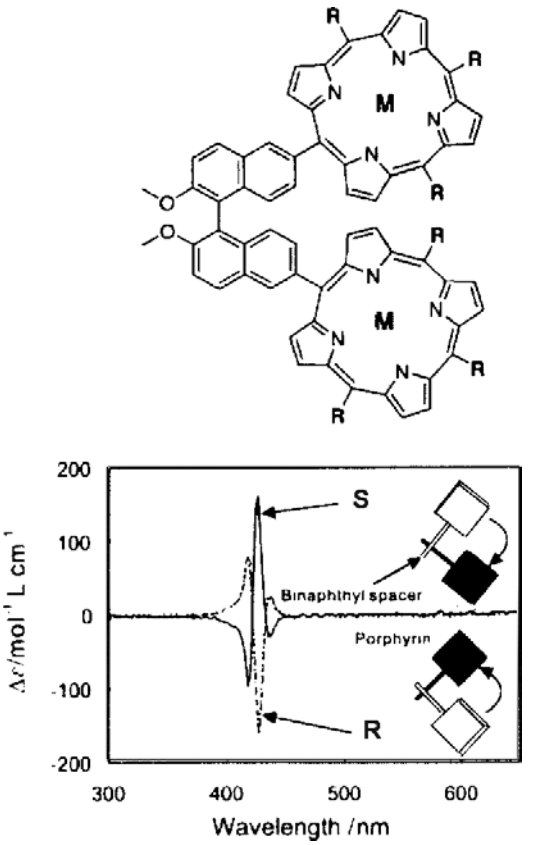

Figure 70. The structure of BINAP-linlked porphyrin dimer by Kimura *et al.* (M = H_2), and their CD spectra. The rotation direction in the inset in the original paper was wrong (here it was fixed) (redrawn from Ref. 150).

chromophore and the porphyrin chromophore.[151] Fe(III) porphyrins generally produce μ-oxo dimers when treated with basic solutions. Kimura and coworkers also treated their iron complexes with aqueous solutions at various pHs, particularly at alkaline pH.[150] Since Fe porphyrins form oligomeric or polymeric μ-oxo complexes intermolecularly, the resulting species began to show bisignate CD curves in the Soret region due to excitonic interaction (Fe–Fe distance is *ca.* 0.38 Å).

Liu, Ji and coworkers reported chiral linear zinc porphyrin arrays constructed from an amino acid-bridged zinc porphyrin dimer and ethylene diamine via self-assembly (Figure 71).[152] Unfortunately, there are several misconceptions in this paper with respect to the interpretation of the electronic absorption and CD spectra. When the positions of the Soret band of zinc porphyrin and amino acid-bridged zinc porphyrins were compared, the band of the

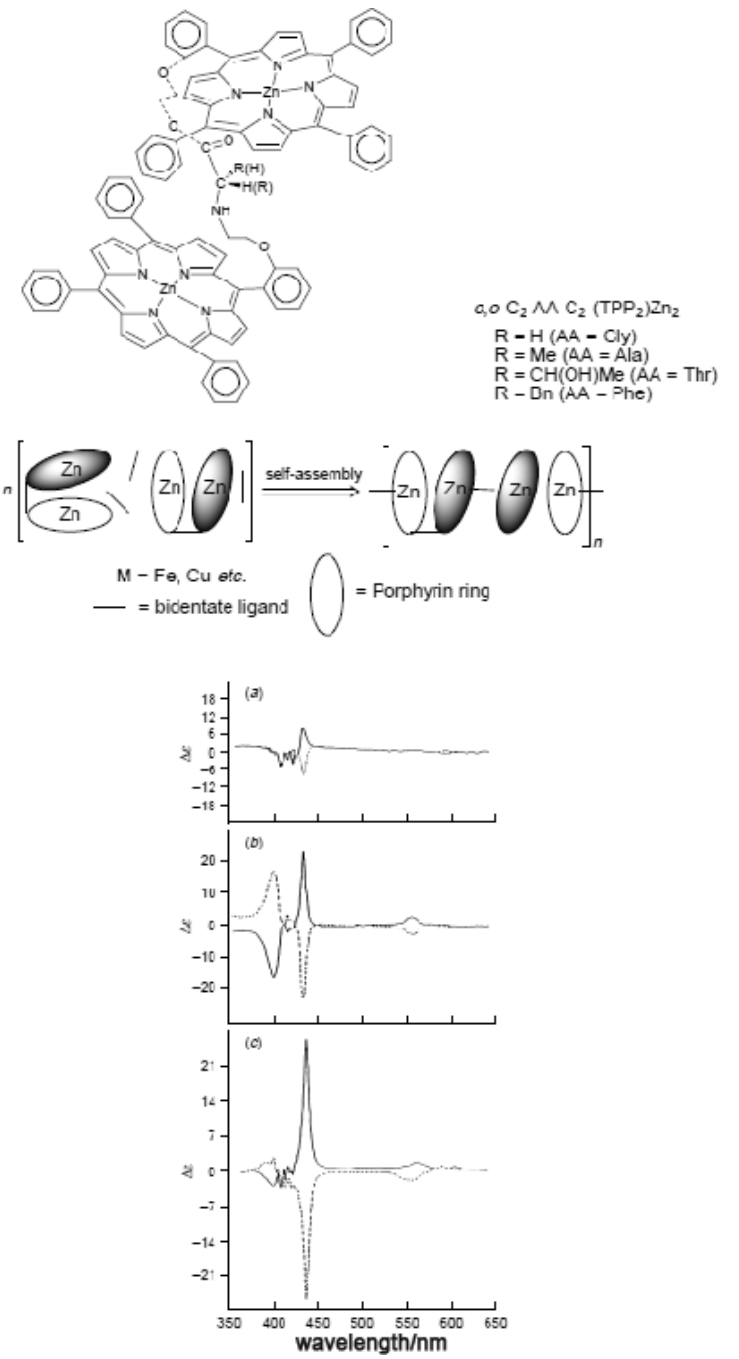

Figure 71. (top) Zn porphyrin dimers bridged by amino acid, (middle) formation of one-dimentional assembly of the zinc porphyrin by the addition of bidentate ligands, and (bottom) CD spectra of some of the Zn dimers in the absence of extraneous ligands (redrawn from Ref. 152).

dimer was at longer wavelength but the difference was always 0–3 nm. The authors concluded that this was due to the formation of a head-to-tail dimer produced by a π–π interaction. Unless there is further clear evidence, such as from NMR, these small values might be considered to be substituent effects or experimental error. The authors insisted that the CD spectra were correlated to chiral π–π stacking of the zinc porphyrins in the dimers even where no bisignate CD curves are seen in Figure 71. Furthermore, it is strange that glycine-bridged dimers show mirror-image CD curves (Figure 71(a)) since there is no L or D-isomer for glycine. Zn porphyrin dimers linked by alanine or threonine showed CD envelopes of either plus or minus in both the Soret and Q band regions. This kind of CD curve can never be explained as being produced by chiral π–π stacking of the zinc porphyrins in the dimers. In the paper, the authors show that the CD curves in Figure 71 are diminished by adding extraneous bidentate ligands. Since zinc porphyrins are generally five-coordinate in the presence of extraneous strong ligands, these data suggest that, in the absence of extraneous bidentate ligands, the amino group and carbonyl oxygen in the bridging moiety coordinate to two zinc ions in the dimer, so that the two porphyrin planes are very close. Accordingly, the CD curves in this figure appear to be produced by interaction of the porphyrin and the amino acid in the bridging moiety. Since the CD envelope changes sign by the use of L- or D-amino acid, this fact also strongly suggests that the CD was induced by the bridging amino acid.

Tamiaki and coworkers reported a similar porphyrin dimer, but with cyclic dipeptides (2,5-piperazinediones) as the linking units, and provided valuable data (Figure 72).[153] A porphyrin monomer with an appended optically active 2,5-piperazinedione gave no CD signal, but a dimer linked by cyclo(L-Tyr-L-Tyr) showed a minus-to-plus CD pattern in ascending energy in the Soret region (left-handed helicity), while a dimer linked by cyclo(D-Tyr-L-Tyr) was CD silent in the same region. These data indicate that the CD was generated by exciton coupling of the two porphyrin chromophores and that the two porphyrins most probably take a C_2 or C_{2v} arrangement in the cyclo(L-Tyr-L-Tyr)-linked dimer.

The CD spectra of water-soluble porphyrins (mostly anionic tetrasulfonate or cationic N-methylpiridinium-4-yl porphyrins) in the presence of D- or L-polyglutamate[154] or poly-L-lysine[155] have been reported. Although the CD spectra show a mirror-image relationship upon changing the coexisting L- or D-amino acid polymer, no detailed analysis was given in these reports, where the porphyrins exist as aggregates.

Sebek and Bour evaluated, with the aid of quantum chemical computations, the magnitudes of the perturbational, dipolar, and direct covalent contributions

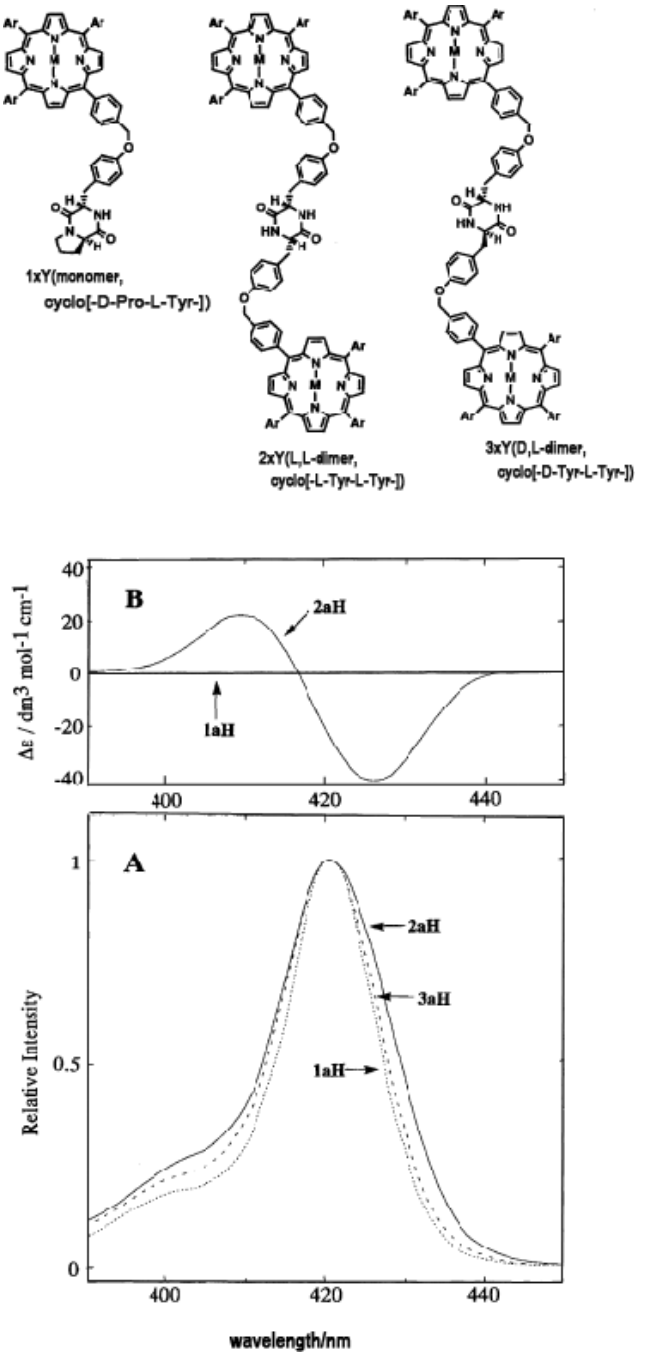

Figure 72. Structures of cyclic dipeptides (2,5-piperazinedione)-appended monopophyrin **1aH**, and cyclic dipeptides (2,5-piperazinedione)-bridged diporphyrin **2aH** and **3aH**. The difference between **2aH** and **3aH** are in the cyclic dipeptide moiety; **2aH** is composed of cyclo(L-Tyr-L-Tyr) while **3aH** consists of cyclo(D-Tyr-L-Tyr) (redrawn from Ref. 153).

to the electronic CD of porphyrin systems.[156] They claimed that TD-DFT, particularly with the hybrid B3LYP functional, are suitable for estimating the electronic excitation energies and spectral intensities. Transition dipole coupling between chirally stacked porphyrins was determined as the most important mechanism contributing to the optical activity. Perturbation models realized by a chirally arranged porphyrin and a point charge provided very small CD signals.

Kim and coworkers discussed the stacking of tetrakis(3-N-methylpyridinium-4-yl)porphyrin on poly[d(A-T)2] (DNA) in terms of electronic absorption, CD, and linear dichroism spectroscopy under different conditions (particularly at various NaCl concentrations).[157] In the investigation of the porphyrin-DNA interactions, a negative CD band in the Soret region has generally been accepted as an intercalated porphyrin, while porphyrin bound at the groove exhibits a positive CD band. A bisignate CD band is pronounced for the stacked porphyrins. In the presence of poly[d(A-$T)_2$], the cationic porphyrins showed bisignate signal changing of plus-to-minus in ascending energy, but this signal changes with time when the NaCl concentration is low. Together with the data of linear dichroism, the authors concluded that the molecular plane of the porphyrin is almost parallel to the DNA base plane under the above conditions. No concrete conclusions were drawn from the CD data in this study.

Aida and coworkers found an interesting phenomenon using their 5,15-bis(4-carboxyphenyl)-10,20-dendronyl zinc porphyrins (Figure 73).[158] As the dendritic moieties, they prepared from first to third generations. When porphyrins containing second generation dendrons at the 10 and 20 positions were dissolved at 5 mM (very concentrated solution) in $CHCl_3$, absorption peaks at 453 and 413 nm were displayed, which were assigned to a J-aggregated species. Similar absorption spectra were obtained when porphyrins contraining third generation dendron were dissolved at 5 mM in benzene. On the other hand, this type of absorption spectrum was not observed for species whose carboxyl groups at 5 and 15 positions were methyl esterified (these showed a single Soret band at *ca*. 423 nm). When the J-aggregated solutions were cast onto glass plates, the authors noticed that the spin-coated films displayed a chirality dominance in the statistical distributions which was dependent on the spinning direction. As seen typically in Figure 73, films spin-coated in a clockwise direction showed a plus-to-minus CD pattern in ascending energy, corresponding to the 453 nm peak, while those films spin-coated in an anticlockwise direction displayed exactly the opposite CD behavior. For this kind of phenomenon to occur, the distance between the porphyrin and dendron units was important: if the distance was too short, the bisignate CD curves were not observed (for details, see Ref. 158).

VII. Application of Porphyrins to Conformational Analysis

A. Determination of the Helicity of Polyisocyanides

Takei and coworkers determined the helicity of helical polyisocyanide using exciton coupling of porphyrins.[159] Chiral polyisocyanide was synthesized 35 years ago, in 1974.[160] Since then, nobody has succeeded in finding a relationship between the helicity and CD sign. Takei prepared poly(aryl isocyanide)s with a polymerization degree of 100, where aryl = alkyloxycarbonylphenyl, and furthermore alkyl = (L)- or (D)-menthyl, (D)-isomenthyl, (D)-neopenthyl, (S)-butyl, and (S)-octyl (Figure 74, compounds **1a**–**1f**). Simultaneously, corresponding

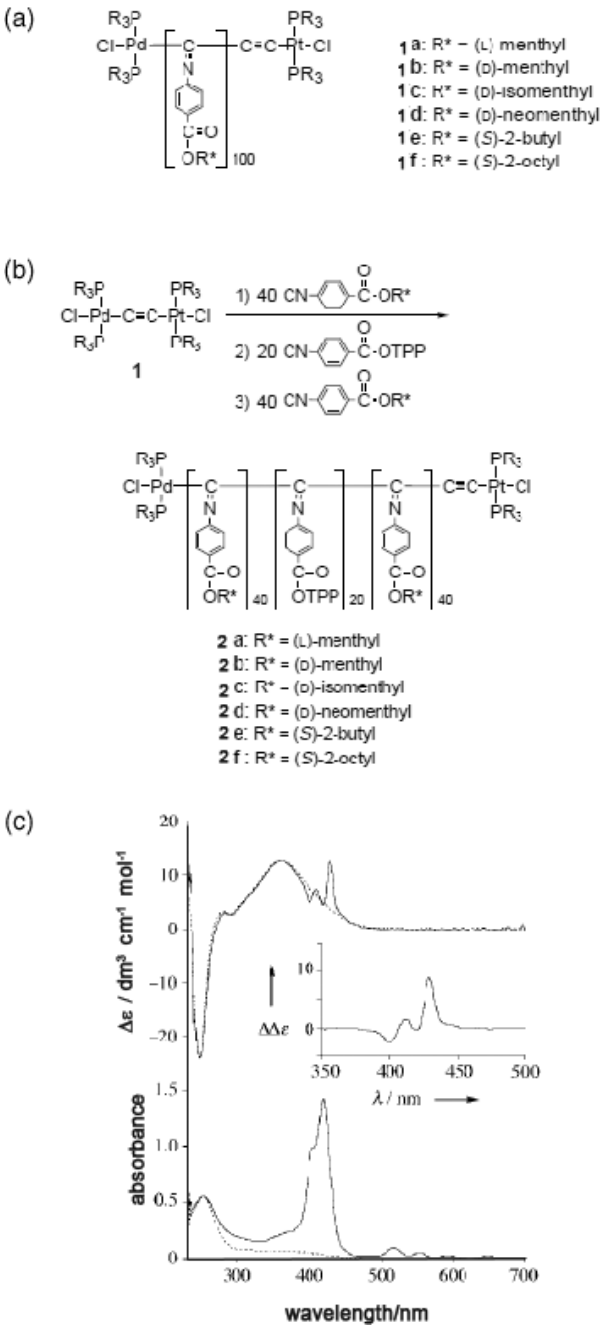

Figure 74. (a) Structures of optically active isocyanide homopolymers, **1a**–**1f** (degree of polymerization (DP) = 100), (b) structures of optically active isocyanide triblock copolymers containing a block with tetraphenylporphyrinyl substituents, **2a**–**2f** (DP = 100), and (c) electronic absorption and CD spectra of **1a** (dotted lines) and **2a** (solid lines). The inset in (c) shows the subtracted CD spectrum: i.e. **2a**–**1a** (redrawn from Ref. 159).

triblock copolymers containing a tetraphenylporphyrin unit as one of two aryl groups were prepared (Figure 74, compounds **2a**–**2f**). As the dotted lines in this figure show, the homopolymer with an (L)-menthyloxycarbonylphenyl group exhibits a very weak broad absorption band between 300 and 500 nm, and a broad positive CD envelope in the same wavelength region. The triblock copolymer showed absorption bands due to the tetraphenylporphyrin moiety; a Soret band in the *ca.* 380–450 nm region and four weak Q peaks in the 500–700 nm region. The CD spectrum is similar in shape to that of the corresponding homopolymer, except in the Soret region, which indicates that the helicity of the homopolymer and the triblock copolymer is the same. Subtraction of the CD spectrum of the homopolymer from that of the triblock copolymer showed a positive-to-negative pattern (positive CD couplet) on going from longer to shorter wavelength (see the inset of (c)) in the Soret region, indicating that the CD spectrum in this region of the copolymer is produced by superimposition of this positive couplet and the broad CD envelope originating from the homopolymer main chain. Then, from the positive-to-negative CD pattern in the Soret region, this copolymer was found to have right-handed helicity. Therefore, the homopolymer poly(aryl isocyanide)s showing a positive CD envelope in the 300–500 nm region was found to be a right-handed polymer. Thus, the CD sign-helicity relationship of the chiral polyisocyanide was elucidated 35 years after its advent. This assignment was opposite to that predicted theoretically, and underlines the importance of experimental evidence.[161] Interestingly, the helicity depended on the configuration (L or D) of the alkyl moiety, being right-handed (P helicity) for (L) and left-handed (M helicity) for (D).

B. Determination of the Absolute Configurations of Natural Products

Nakanishi, Berova, Woody and coworkers applied exciton-coupled CD spectroscopy to determine the absolute configurations of natural products.[162,163] In 1995 and 1996, these authors began using zinc(II) or metal-free 5-(4-carboxyphenyl)-10,15,20-triphenylporphyrins to determine the configuration of steroids and brevetoxin.[162,163] First, with respect to the transition moment directions for the porphyrin Soret band, Woody described in Ref. 163 that we can not expect the porphyrin chromophore to behave like a linear oscillator as previously assumed, instead that it must be treated as a nearly circular oscillator, with nearly degenerate, orthogonal transition moments of approximately the same magnitude. However, in all the cases they examined in which the bis-porphyrin derivative can be compared with bis(*p*-dimethylaminobenzoyl) derivatives, the signs of the Cotton effects were identical that they suggested

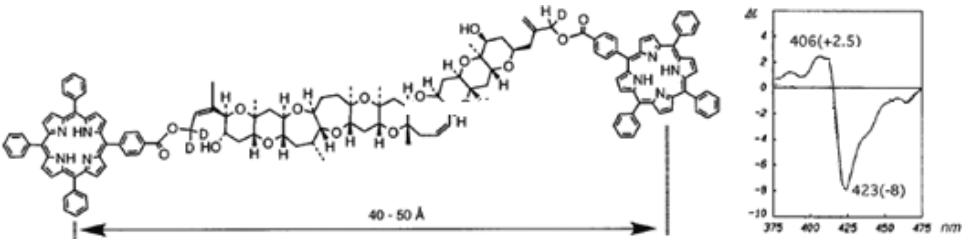

Figure 75. Structure and CD spectra of brevetoxin-bridged porphyrin dimer and its CD spectra in MeOH/water = 4:1 (redrawn from Ref. 163).

that the normal exciton rule for linear oscillators can be used. After all, it was concluded that the effective transition moment can be regarded as being in the 5,15-direction of the porphyrin skeleton. Two porphyrin molecules were linked to steroids and brevetoxin molecules by ester linkages, and utilizing the CD exciton coupling, they determined the absolute configuration. Within the samples examined, all results were consistent with those obtained using bis[*p*-(dimethylamino)benzoates]. There are several merits to using pophyrin chromophores; 1) the absorption coefficient of the Soret band is very large, 2) the position of the Soret band is much longer compared to chromophores found in many natural products, and 3) the polarization direction is known to run along the C-5/C-15 direction.[162] Porphyrins at the termini of dimeric steroids and brevetoxin B exhibited exciton coupling over interchromophoric distances of up to 50 Å (Figure 75).

Several years later, the same authors applied the CD exciton method to gymnocin-B, separated from the red tide species, dinoflagellate *Karenia mikimotoi* at Kushimo, Japan.[164] Gymnocins are a series of cytotoxic marine polycyclic ethers, and in gymnocin-B, two hydroxyl groups are present at C-10 and C-37, separated by *ca*. 20 Å (Figure 76). This exhibited a positive-to-negative sign in ascending energy, showing that two OH groups are in a right-handed configuration.

Since chiral bis-porphyrins are the subject of intense interest as chiral receptors and as probes in the determination of the structure and stereochemistry of natural and synthetic products, Woody and coworkers reconsidered the CD spectra of bis-porphyrins from three classes to provide an improved framework for their interpretation: I, where the porphyrins can adopt a relatively wide range of orientations relative to each other, II, porphyrins having a fixed orientation and III, porphyrins undergoing π-stacking (Figure 77).[165] The calculations primarily utilized the classical polarizability theory of DeVoe (point dipole approximation),[166,167] but were supplemented by a quantum chemical matrix method

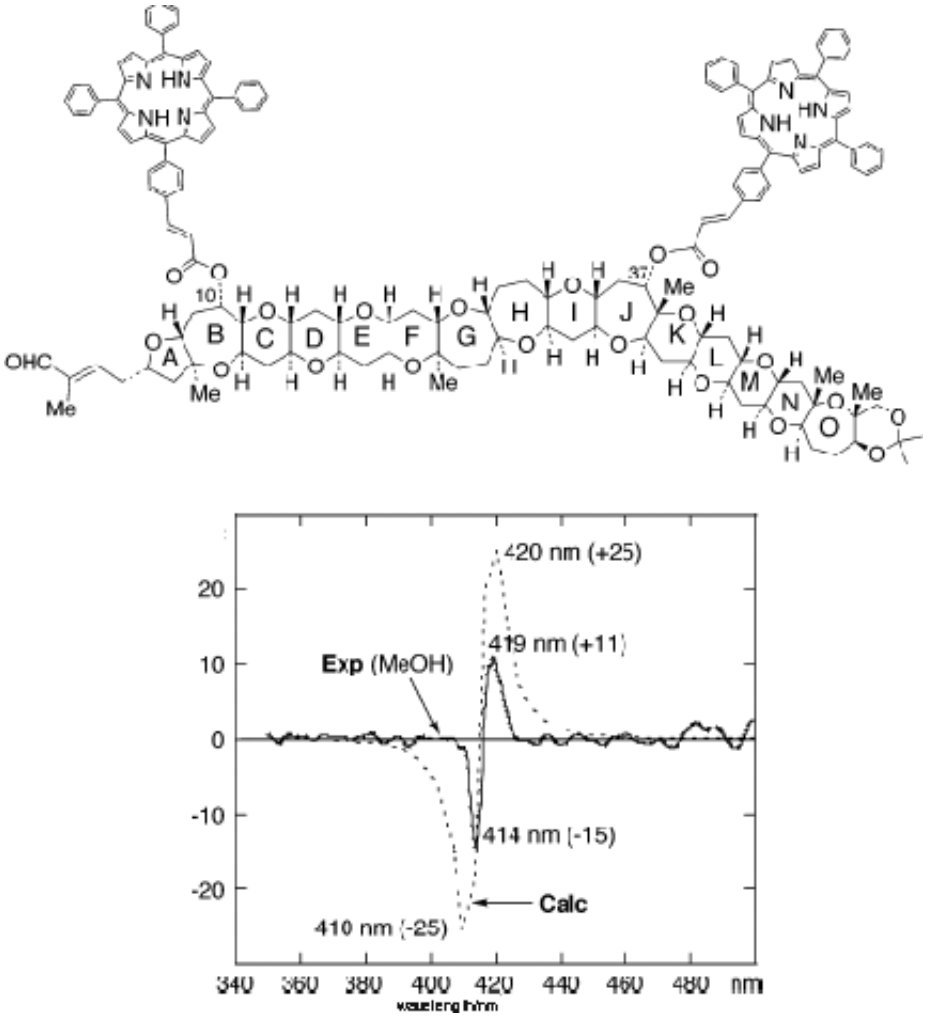

Figure 76. Structure of gymnocin B linked with two tetraphenyl porphyrins at C-10 and C-37 OHs, and its experimental (solid line) and calculated (broken line) CD spectra (redrawn from Ref. 164).

(monopole approximation with the program MATMAC).[168] Class I was represented by three isomers of the diester of 5a-cholestane-3,17-diol with 5-(4′-carboxyphenylporphyrin) (*αβ*, *βα*, *ββ*) (Figure 78). Careful analysis of the torsional degrees of freedom led to two to four minimum-energy conformers for each isomer. The CD spectra in the Soret region were calculated as Boltzmann-weighted averages over the low-energy conformers for each isomer. Three models were used: the effective transition moment model, in which only one of the degenerate Soret components is considered, along the 5–15 direction ($D = 88.3$ D^2);

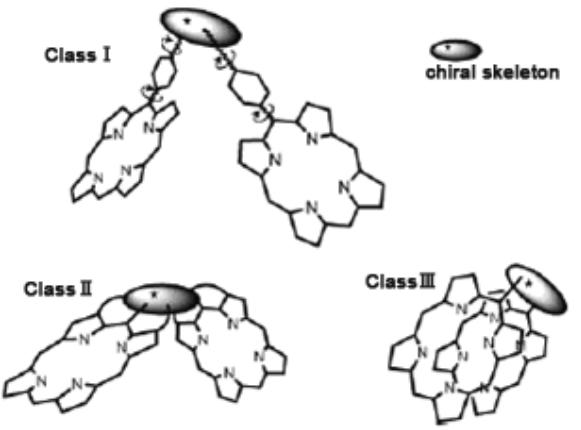

Figure 77. Schematic representations of the three classes of bis-porphyrins. Class I: compounds with unrestricted rotation (about one or more axes). Class II: compounds with two porphyrin rings with fixed special orientation. Class III: compounds with π–π stacked porphyrins (redrawn from Ref. 165).

the circular oscillator model, in which both Soret components are given equal weight ($D = 88.3$ D^2 each); and the hybrid model, in which the 10–20 oscillator is given half the weight ($D = 44.1$ D^2, a value heuristically justified) of the 5–15 oscillator, to mimic the effect of extensive vibrational averaging about the 5–15 direction. All three models predicted Soret exciton couplets with signs in agreement with experiment. Quantitatively, the best results were given by the hybrid and circular oscillator models, validating the widely-used effective transition moment model for qualitative assignments of bis-porphyrin chirality, and thus permitting application of the exciton chirality model. However, simultaneously, it was indicated that for quantitative studies, the circular oscillator or hybrid models should be used. The simplified effective transition moment and hybrid models were justified by the vibrational averaging in class I bis-porphyrins, and it was stressed that they are to be used only with these kinds of system. Two class II bis-porphyrins were also studied by DeVoe method calculations in the circular oscillator model, which yielded good agreement with experiment (Figure 79).[169] For class III bis-porphyrin systems, the calculations gave only qualitative agreement (Figure 80), and limitations in the conformational analysis with the close contacts and dynamic effects in these π-stacked systems precluded quantitative results.

Methods for determination of the absolute configurations of amino acid, amino alcohols, α-hydroxy acids, monoalcohols, primary and secondary monoamines, and α-chiral carboxylic acids by zinc and magnesium porphyrin tweezers were developed mainly by the Nakanishi and Berova and their

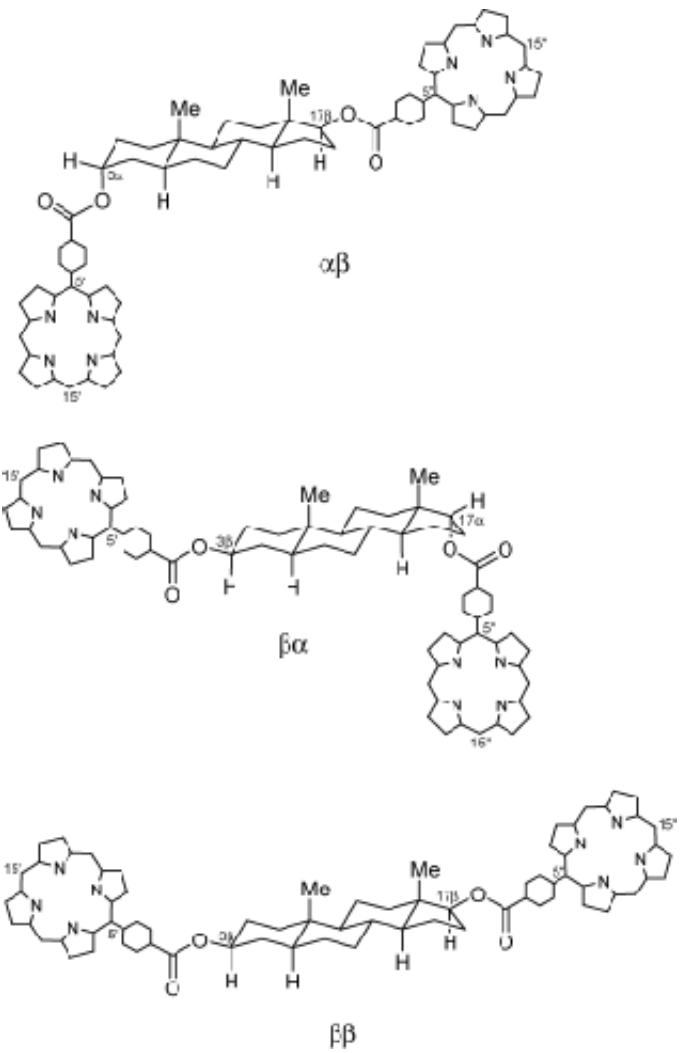

Figure 78. Three isomers ($\alpha\beta$, $\beta\alpha$, $\beta\beta$) of diester of 5α-cholestane-3,17-diol with 5-(4′-carboxyphenyl-10,15,20-triphenylporphyrin (redrawn from Ref. 165).

coworkers over a period of about 10 years from the late 1990s onward.[170–178] The concept is simple (Figure 81). As exemplified in Figure 81, the chiral substrates are linked to the achiral trifunctional bidentate carrier molecule (3-aminopropylamino)acetic acid, and the resultant conjugates are then complexed with dimeric zinc porphyrin hosts, giving rise to 1:1 host/guest sandwiched complexes (primary and secondary amines coordinate to two zinc ions). These complexes exhibit exciton-coupled bisignate CD spectra due to stereo-differentiation, leading to preferred porphyrin helicity. Since the chiral

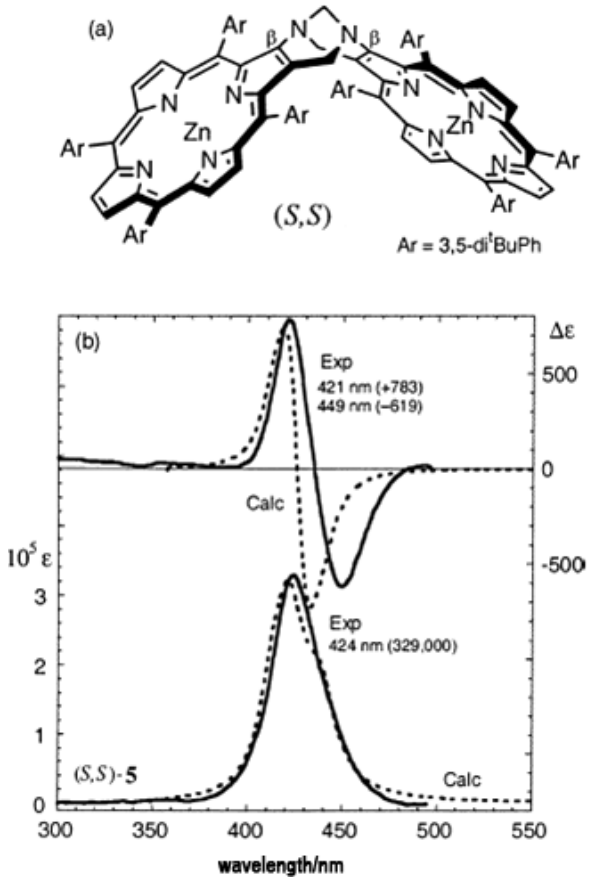

Figure 79. Structure of spactially obliquely fixed diporphyrin and its experimental (solid lines) and calculated (broken lines) electronic absorption and CD spectra (redrawn from Refs. 165 and 169).

sense of twist between the two porphyrins in the complex is dictated by the stereogenic center of the substrate, the sign of the complex determines the absolute configuration at this center. The twist of the porphyrin tweezer in the complex can be predicted from the relative steric sizes of the group flanking the sterogenic center, such that the bulkier group (L) protrudes from the complex sandwich. As an example, the case of (S)-2-(1-hydroxy)ethylnaphthalene (Figure 82) which is shown as a conjugate in Figure 81 can be considered. The schematic representation (Newman projection) depicts the substituent attached to the stereogenic center which leads to the prediction of the CD couplet sign. If the hydroxyl group is placed at the rear, as shown, the clockwise arrangement of L (larger group), M (medium group) and hydrogen results in a positive CD couplet, and *vice versa*. The absolute sense of twist between the porphyrin

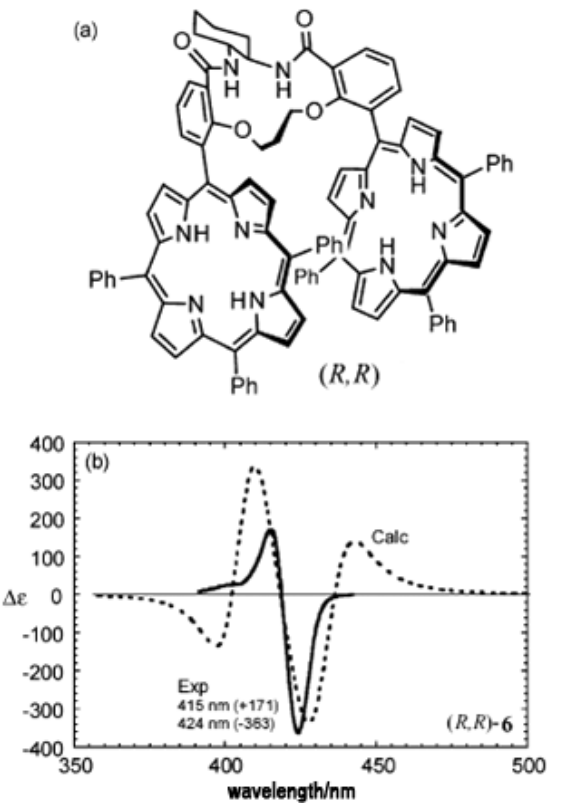

Figure 80. (R,R) ($\alpha\alpha$)-form of diester of 5α-cholestane-3,17-diol with 5-(4′-carboxyphenyl-10,15,20-triphenylporphyrin (redrawn from Ref. 165).

electric transition moments, and hence the sign of the exciton-coupled CD is dependent on whether the P-2 porphyrin of the tweezer coordinates to the secondary amine nitrogen from the direction of the M or L group (Figure 81). The preferred conformer determines the sign of the CD couplet, and hence the observed CD exciton chirality reveals the absolute configuration of the substrate. The assignment of M and L to substituents at the stereogenic center is thus crucial for predicting the sign of the CD couplet. However, at the same time, the authors emphasized that factors other than steric bulk, such as electronic interactions, hydrogen bonding, and rotational degrees of freedom cannot be ignored. The authors discussed L/M based on relative steric factors and electronic factors separately. In Ref. 178, *meso*-tetra(pentafluoro)phenyl zinc porphyrins are used. It is stressed that an electron-withdrawing effect increases the Lewis acidity of the central zinc, thereby facilitating coordination of guest (Lewis base) molecules.

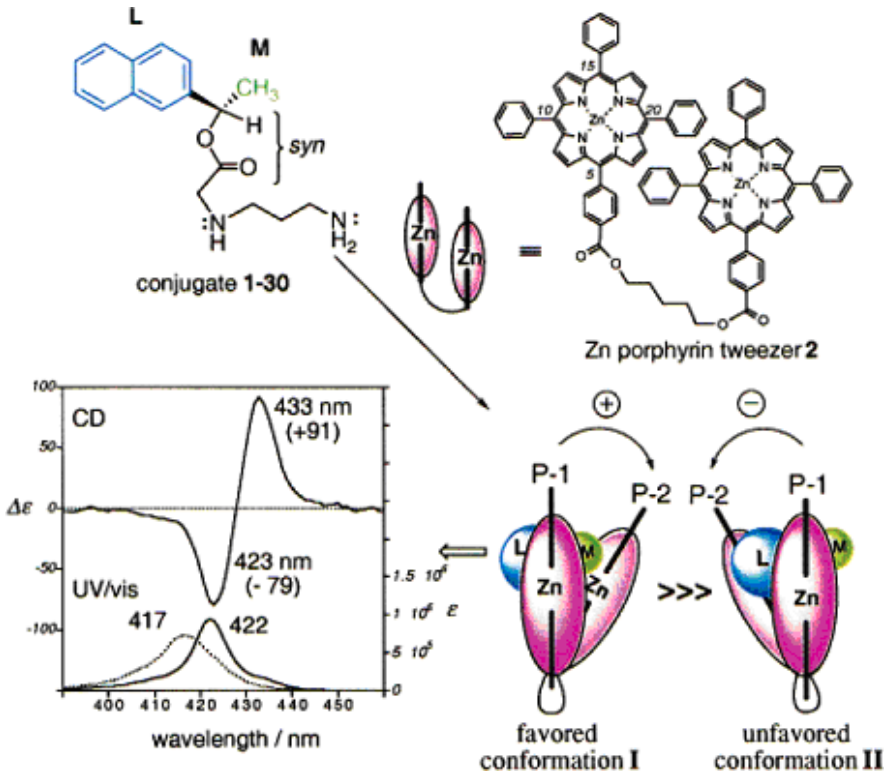

Figure 81. Complex formation between a conjugate and a tweezer leads to two conceivable conformations with opposite sense of twists. The predominant conformation I, the one in which the **L** (larger) group is protruding away from the porphyrin-1/porphyrin-2 sandwich, giving rise to a typical CD couplet representing the sense of twist between the two porphyrins and hence the absolute configuration at the stereogenic center; the broken curve in the absorption spectrum represents the tweezer prior to complexation (redrawn from Ref. 172).

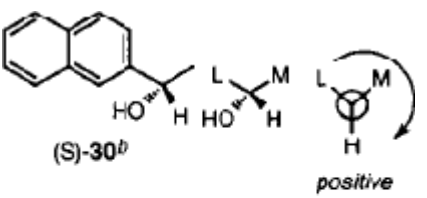

Figure 82. Prediction of CD couplet in the case of (*S*)-2(1-hydroxy)ethylnaphthalene and CD amplitude observed in the experiment. MCH is methylcyclohexane (redrawn from Ref. 172).

VIII. Concluding Remarks

CD spectroscopy is highly sensitive to small conformational changes so great care must be taken in analyzing CD spectra. If X-ray data exist, those coordinates should be used to calculate CD solution spectra, since all conformational analyses reported to date have shown close agreement with the X-ray structures. Some researchers who are unfamiliar with the technique calculate CD spectra based on optimized enantiomeric structures of low symmetry porphyrinic compounds. This should be avoided since near planar porphyrin ligands are often predicted to have deformed low symmetry structures resulting in unrealistic calculated spectra. CD spectral analysis of compounds for which no X-ray data exist must be performed carefully. The most important factors are the distance and angles between the chromophores. If the orientations of the electronic and magnetic transition moments are estimated correctly, the CD sign pattern can often be successfully predicted. Knowledge derived from the assignment of electronic absorption spectra should be used whenever possible. For instance, the use of strong electronic absorption bands can be particularly helpful during CD studies, as described in the context of conformational analyses of natural products. Since many research institutes and universities are now able to provide porphyrinoid researchers with easy access to CD spectrometers, it is important for researchers in the field to fully understand this elegant spectroscopic technique. This can be achieved relatively easily based on a brief study of the theory of circular dichroism and chirality.

34 Photochemical and Photophysical Properties of Metallophthalocyanines

Tebello Nyokong and Edith Antunes

Department of Chemistry, Rhodes University, Grahamstown, 6139, South Africa

List of Abbreviations

AcO	acetate
ADMA	anthracene-9,10-bis-methylmalonate
BSA	bovine serum albumin
BHDC	benzyl-*n*-hexadecyldimethyl ammonium chloride
BTH	2,6,-di-tri-tert-butyl-4-methyl phenol
CEL	cremophore EL
CTAC	cetyltrimethylammonium chloride
CTAB	cetyltrimethylammonium bromide
1-ClNP	1-chloronaphthalene
DABCO	1,4,diazobicyclooctane
DCM	dichloromethane
DMF	dimethylformamide
DMSO	dimethylsulfoxide
DPBF	1,3-diphenylisobenzofuran
EC	ethyl cellulose
HPLC	high performance liquid chromatography
HSA	human serum albumin
ISC	intersystem crossing
LB	langmuir-blodgett
LDH	layered double oxide
MPc	metallophthalocyanine
NPc	naphthalocyanine
PBS	phosphate buffer saline (or solution)
Pc	phthalocyanine
PDT	photodynamic therapy
Py	pyridine
d-py	deuterated pyridine
PVC	polyvinyl chloride
SDS	sodium dodecylsulfate

SOLM	singlet oxygen luminescence method
THF	tetrahydrofuran
TX	triton X-100
Φ_F	fluorescence quantum yield
Φ_Δ	singlet oxygen quantum yield
Φ_P	photodegradation quantum yield
τ_T	triplet lifetime

I. Introduction

Phthalocyanines (Pcs) and metallophthalocyanines (MPcs) have a wide variety of applications due to their diverse chemical, structural, electronic and optical properties.[1–7] As a result of their bright blue, green to violet colors and excellent lightfastness, Pcs are used worldwide as dyes and pigments.[7] MPc complexes, in particular CuPcs, are produced in industry on a large scale (~50,000 tons per year). Phthalocyanines show exceptional thermal and chemical stability, with strong acids only protonating conventional MPc complexes.[8–11]

Pcs have found application in rewritable optical media (CD-RW),[1] as photoconducting materials in laser printers and photocopiers,[1] in nonlinear optics,[12] Langmuir-Blodgett (LB) films,[13] semiconductor devices[2,13] and as electrochemical and chemical sensors.[14,15] They have also attracted much attention in oncology as photosensitizers for malignant tumor treatment in photodynamic therapy (PDT). PDT uses a combination of a photosensitizing drug (e.g. MPcs) and light in the presence of molecular oxygen to obtain a therapeutic effect based on selective cell destruction.[4] For use in photocatalysis (photosensitization), MPc complexes containing non-transition metal ions are employed. High triplet state quantum yields and long triplet lifetimes are required for efficient photosensitization, and these criteria may be fulfilled by the incorporation of diamagnetic metals such as zinc, aluminum or silicon into the phthalocyanine macrocycle. A recent review by Ishii and Kobayashi provided the photophysical (singlet and triplet state parameters) data of a range of substituted and unsubstituted MPc complexes,[16] and fast methods for the direct detection of triplet states such as time-resolved electron paramagnetic resonance were discussed. The present chapter focuses chiefly on main group phthalocyanine complexes with emphasis on their photochemical behavior (singlet oxygen and photostability), in addition to some photophysical studies carried out on these complexes. The effects of phthalocyanine ring substituents on these parameters will also be discussed. The common abbreviations employed in this chapter are listed in front. Table 1 lists the phthalocyanine substituents discussed in this chapter. Figure 1 lists MPc (not included in Table 1) and related complexes which will be used in this chapter.

Table 1. General ring (R_1 to R_4) substituents of phthalocyanines.

R can be any of the ring substituents listed in Table 1a. Each ring substituent is represented by **S** followed by an identification number. A **q** following **S1**, **S2**, **S3** and **S4** refers to the quaternized form of the complex. X_1 and X_2 are general axial ligands; X can be any of the axial ligands in Table 1b. The axial ligands are represented by **L** followed by an identification number.

II. Photochemical and Photophysical Parameters

Photochemical studies include singlet oxygen and photodegradation quantum yields, as well as photocatalysis, while photophysical studies include fluorescence and triplet state quantum yields and lifetimes. Since the fluorescence lifetimes have been extensively reviewed,[16] they will not be included in this chapter. Figure 2 shows a Jablonski diagram representing the photophysical processes following light absorption.

A. Singlet Oxygen Quantum Yields (Φ_Δ)

MPc complexes act as photosensitizers for many reactions, including the degradation of pollutants[17–19] and transformation of alkenes and alkanes.[20] Most notable among the uses of Pcs is their use as photosensitizers in oncology, particularly in

$$\mathrm{MPc} \rightarrow {}^{1}\mathrm{MPc}^{*} \xrightarrow{\mathrm{ISC}} {}^{3}\mathrm{MPc}^{*} \quad (1)$$

$${}^{3}\mathrm{MPc}^{*} + {}^{3}\mathrm{O}_2 \rightarrow {}^{1}\mathrm{O}_2 \quad (2)$$

$${}^{1}\mathrm{O}_2 + \mathrm{Subs} \rightarrow \mathrm{Oxidation\ products} \quad (3)$$

Scheme 1. Type II mechanism.[27,38–45] Here, MPc = metallophthalocyanine, ISC = intersystem crossing, Subs = substrate, ${}^{3}\mathrm{O}_2 = \mathrm{O}_2({}^{3}\Sigma_g)$ and ${}^{1}\mathrm{O}_2 = \mathrm{O}_2({}^{1}\Delta_g)$.

$${}^{3}\mathrm{MPc}^{*} + \mathrm{O}_2 \rightarrow \mathrm{MPc}^{+\bullet} + \mathrm{O}_2{}^{-\bullet} \quad (4)$$

$${}^{3}\mathrm{MPc}^{*} + \mathrm{Subs} \rightarrow \mathrm{MPc}^{-\bullet} + \mathrm{Subs}^{+\bullet} \quad (5)$$

$$\mathrm{MPc}^{-\bullet} + \mathrm{O}_2 \rightarrow \mathrm{MPc} + \mathrm{O}_2{}^{-\bullet} \quad (6)$$

$$\mathrm{O}_2{}^{-\bullet} \xrightarrow{\mathrm{H}^{+}} \mathrm{HO}_2{}^{\bullet} \quad (7)$$

$$\mathrm{HO}_2{}^{\bullet} + \mathrm{Subs{-}H} \rightarrow \mathrm{H}_2\mathrm{O}_2 + \mathrm{Subs}^{\bullet} \quad (8)$$

$$\mathrm{Subs}^{+\bullet}, \mathrm{Subs}^{\bullet}, \mathrm{H}_2\mathrm{O}_2 \rightarrow \mathrm{Oxidation\ Products} \quad (9)$$

Scheme 2. Type I mechanism.[27,40] MPc = metallophthalocyanine, Subs = substrate.

photodynamic therapy (PDT).[4,21–28] ZnPc complexes in particular are well known for their photosensitizing abilities,[29–37] while unmetalated phthalocyanine complexes show very little PDT effect.[28] It is believed that during photosensitization (photocatalysis), the MPc molecule is first excited to the triplet state, and then transfers the energy to ground state oxygen, $\mathrm{O}_2({}^{3}\Sigma_g)$, generating excited state oxygen, $\mathrm{O}_2({}^{1}\Delta_g)$, the chief cytotoxic species, which subsequently oxidizes the substrate. This is the Type II mechanism as shown in Scheme 1.[27,38–45]

Singlet oxygen is generated when oxygen in its triplet state (${}^{3}\mathrm{O}_2$) interacts with a sensitizer (in its triplet state, ${}^{3}\mathrm{MPc}^{*}$).Thus singlet oxygen quantum yields are expected to be comparable to the MPc triplet state quantum yields if quenching of the latter by ground state oxygen is efficient.[39] The excited triplet state of the MPc (${}^{3}\mathrm{MPc}^{*}$) can also interact with ground state molecular oxygen or substrate molecules (Eqs. 4 and 5) generating superoxide (Eqs. 4 and 6) and hydroperoxyl radicals (Eq. 7), which subsequently afford oxidation of the substrate (Eqs. 8 and 9) by a Type I mechanism (Scheme 2).[27,40]

It has been reported that the Type II mechanism is more prevalent[39] in photoinitiated oxidation reactions; thus the magnitude of singlet oxygen quantum yield (Φ_Δ), which expresses the amount of singlet oxygen generated per quanta of light, is often employed as a main criterion in choosing the photosensitizers to be used in photocatalytic reactions. Many factors associated with the sensitizers are responsible for the magnitude of the determined quantum yield of singlet oxygen, including: triplet excited state energy, ability of substituents and solvents to

quench the singlet oxygen, the triplet excited state lifetime and the efficiency of the energy transfer between the triplet excited state of the sensitizer and the ground state of oxygen.

The singlet oxygen quantum yields for the MPc complexes may be conveniently determined using a singlet oxygen quencher such as 1,3-diphenylisobenzofuran (DPBF), or by using the singlet oxygen luminescence method (SOLM). The results using the two methods are comparable.[33] Side reactions are excluded when SOLM is employed. When DPBF is employed in micellar solutions, chain reactions occur as a result of the endoperoxide initially formed, but this problem can be overcome by adding sodium thiosulfate which destroys endoperoxide.[33] DPBF is an efficient $^1O_2$ quencher in organic solvents and its disappearance can be readily monitored by following the decrease in its absorption peak at 416 nm [in dimethylsulfoxide (DMSO), for example], as in Figure 3.[33]

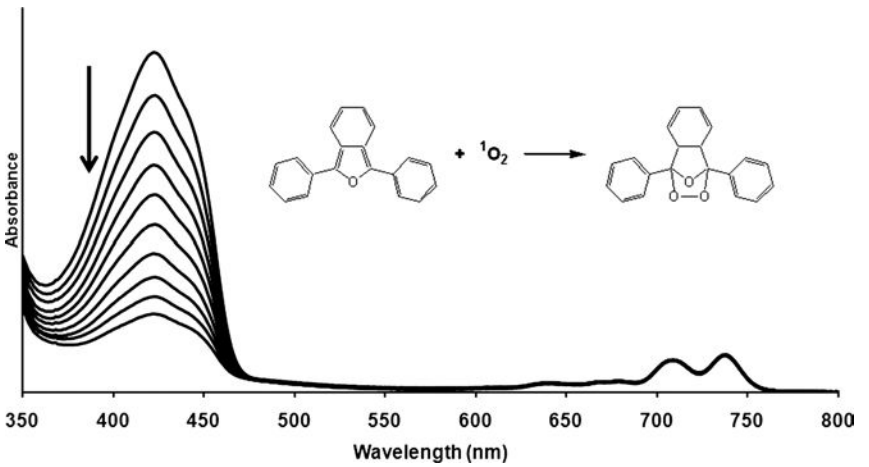

Figure 3. Change in absorption spectra of diphenyl isobenzofuran (DPBF) as singlet oxygen is produced by the phthalocyanine. Inset: Representation of the reaction of singlet oxygen with DPBF.

$$^3O_2 + {}^3MPc^* \xrightarrow{h\nu} {}^1O_2 \quad (10)$$

$$^1O_2 \xrightarrow{k_d} {}^3O_2 \quad \text{Natural decay} \quad (11)$$

$$^1O_2 + DPBF \xrightarrow{k_q} \text{Oxidation products (chemical quenching)} \quad (12)$$

$$^1O_2 + DPBF \xrightarrow{k_{p(DPBF)}} {}^3O_2 + DPBF^* \text{ (physical quenching)} \quad (13)$$

$$^1O_2 + MPc \xrightarrow{k_{p(MPc)}} {}^3O_2 + MPc^* \text{ (physical quenching)} \quad (14)$$

$$^1O_2 + MPc \xrightarrow{k_{q(MPc)}} \text{Chemical reaction (chemical quenching)} \quad (15)$$

Scheme 3. Physical and chemical reactions of DPBF in the presence of $^1O_2$.

Anthracene-9, 10-bis-methylmalonate (ADMA) may be employed as a singlet oxygen quencher in aqueous media by monitoring its disappearance at 380 nm in the presence of singlet oxygen. Scheme 3 shows the fate of $^1O_2$ in the presence of DPBF.

DPBF acts exclusively as a chemical quencher in DMSO and other organic solvents, and thus Eq. 13 may be disregarded. Physical quenching through Eq. 14 may also be ignored since Φ_Δ does not depend on the concentration of the sensitizer (MPc). Furthermore, the reaction rate of the sensitizer with $^1O_2$ according to Eq. 15 is negligible compared to the rate of $^1O_2$ of reaction with DPBF. Thus, only Eqs. 11 and 12 are relevant to the decay of singlet oxygen, and these equations may be used in deriving Eq. 16 for the determination of Φ_Δ employing a standard such as unsubstituted ZnPc[19,35,37]:

$$\Phi_\Delta = \Phi_\Delta^{Std} \frac{W \cdot I_{abs}^{Std}}{W^{Std} \cdot I_{abs}} \tag{16}$$

where Φ_D^{Std} is the singlet oxygen quantum yield for the standard, W and W^{Std} are the DPBF photobleaching rates in the presence of MPc derivatives under investigation and the standard, respectively. I_{abs} and I_{abs}^{Std} are the rates of light absorption by the MPc derivative and standard, respectively. A similar equation may be derived for the use of ADMA as a quencher.

I_{abs} is determined by Eq. 17:

$$I_{abs} \frac{\alpha SI}{N_A} \tag{17}$$

where α is the fraction of light absorbed, S is the cell area irradiated, N_A is Avogadro's constant and I the light intensity.

In the absence of appropriate standards, DPBF (or ADMA) quantum yields (Φ_{DPBF}) are calculated using Eq. 18[33]:

$$\Phi_{DPBF} = \frac{(C_0 - C_t)V}{tI_{abs}} \tag{18}$$

where C_0 and C_t are the respective concentrations of DPBF before and after irradiation, t the irradiation time and V is the volume of the sample. Singlet oxygen quantum yields are then calculated using Eq. 19[33]:

$$\frac{1}{\Phi_{DPBF}} = \frac{1}{\Phi_\Delta} + \frac{1}{\Phi_\Delta} \frac{k_d}{k_a} \frac{1}{[DPBF]} \tag{19}$$

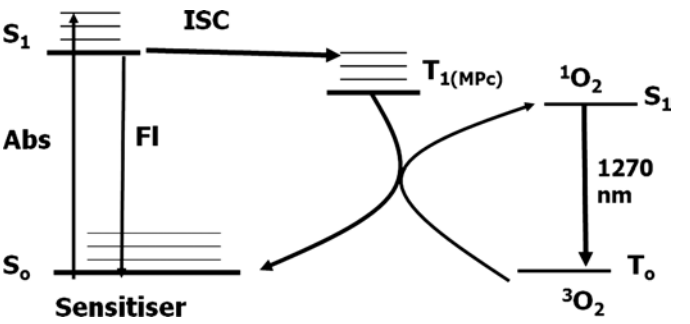

Figure 4. Simplified Jablonski diagram showing the 1270 nm luminescence of singlet oxygen. ISC = intersystem crossing, Fl = fluorescence.

where k_d is the singlet oxygen decay rate constant and k_q the reaction rate constant of DPBF in the presence of singlet oxygen. $1/\Phi_\Delta$ is obtained from the intercept of a plot of $1/\Phi_{DPBF}$ versus 1/[DPBF].

The use of the singlet oxygen luminescence method (SOLM) relies on the luminescence of singlet oxygen at 1270 nm, which is a spin forbidden process (S_1–T_1) (Figure 4), but occurs in an area that is generally free from interference. However, the signal is weak. The dynamic course of $^1O_2$ concentration [$^1O_2$] can be clearly recorded, following Eq. 20 as described theoretically in the literature[38]:

$$[^1O_2] = A\frac{\tau_D}{\tau_T - \tau_D}\left[\exp\left(\frac{-t}{\tau_T}\right) - \exp\left(\frac{-t}{\tau_D}\right)\right] \quad (20)$$

where the τ_D is the lifetime of $^1O_2$, τ_T is the lifetime of MPc at the triplet state, *t* is time in seconds and *A* is a coefficient involved in sensitizer concentration and singlet oxygen quantum yield. The singlet oxygen quantum yield may then be determined by the relative method using a standard such as ZnPc, Eq. 21:

$$\Phi_\Delta = \Phi_\Delta^{Std}\frac{A}{A^{Std}} \quad (21)$$

where Φ_Δ^{Std} is the singlet oxygen quantum yield for the standard, A and A^{std} are the coefficients of the sample and standard, respectively. Standards which are often employed for Φ_Δ are listed in Table 2 in different solvents.[12,27,33,41,42,48]

The equipment employed for the SOLM method is shown in Figure 4, and consists of an ultrasensitive detector such as a Ge detector, combined with a series of filters to minimize background signals. The equipment uses a laser excitation source as shown in Figure 5. A typical signal obtained from the SOLM for singlet oxygen obtained from an MPc complex is shown in Figure 6.

Table 2. Photochemical and photophysical data for complexes commonly used as references for triplet quantum yields (Φ_T), fluorescence quantum yields (Φ_F) and singlet oxygen quantum yields (Φ_Δ).[a]

Complex	Solvent	$\lambda_{Q\ band}$/nm (log ε)	λ_T/nm (log ε)	Φ_T	Φ_F	Φ_Δ	τ_T (μs)	Ref.
ZnPc	Toluene/ 1% py	671.5 (5.25)	490 (4.56)	0.58	0.34	0.54	330	48
ZnPc	DMSO	672 (5.38)		0.50	0.20	0.67	350	41
ZnPc	DMF	670				0.56		33
ZnPc	1-ClNP				0.3			47
ZnPc	Ethanol	670			0.53			33
ZnT*t*BPc	Ethanol	674 (5.20)	490 (4.55)	0.58		0.54	200	12
Li_2Pc	Acetonitrile	665 (5.18)	469 (3.58)	0.60	0.5	0.50	60	50
Chlorophyll *a*	Pyridine					0.59		27
Chlorophyll *a*	Benzene					0.60		27
Chlorophyll *a*	Toluene					0.60		27
Chlorophyll *a*	Ether				0.32			48
Cresyl violet	Methanol					0.54		48
Rhodamine 6G	Ethanol				0.94			46, 49

[a]The following symbols apply to all tables: Φ_F = fluorescence quantum yield (in general the standard used for determination of Φ_F is chlorophyll *a* in ether (Φ_F = 0.32) [49]); Φ_T = triplet quantum yield; Φ_Δ = singlet oxygen quantum yield; τ_T = triplet life time.

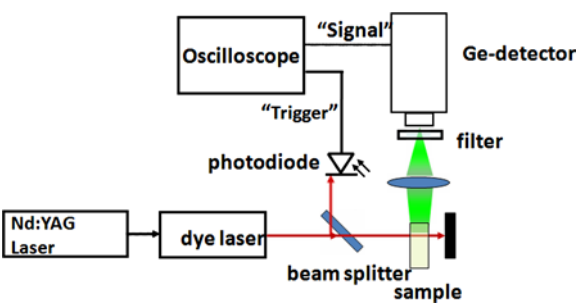

Figure 5. A diagrammatic representation of the singlet oxygen detector system using the singlet oxygen luminescence at 1270 nm.

B. Photodegradation Quantum Yields (Φ_P)

Photostability of MPc complexes is important for their application as photocatalysts (photosensitizers). Photodegradation is the oxidative degradation of a photosensitizer molecule with time into lower molecular weight fragments.[33] Photodegradation generally depends on the structure of the molecule, concentration, solvent and light intensity. It is believed that photodegradation is a $^1O_2$ mediated process, since $^1O_2$ is highly reactive and it can react with macrocyclic metal

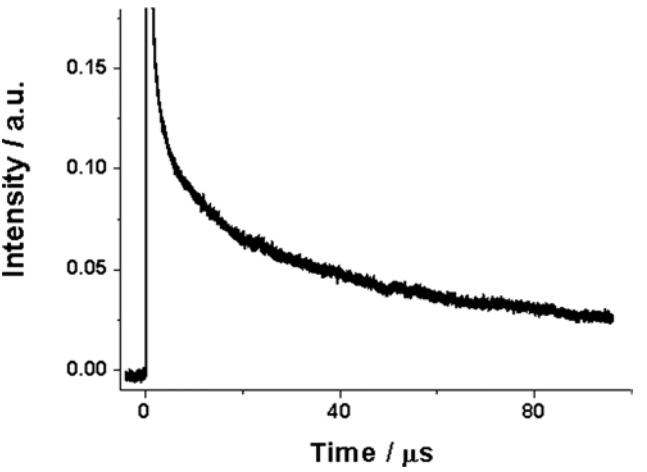

Figure 6. A typical decay curve observed during singlet oxygen determination using its luminescence at 1270 nm.

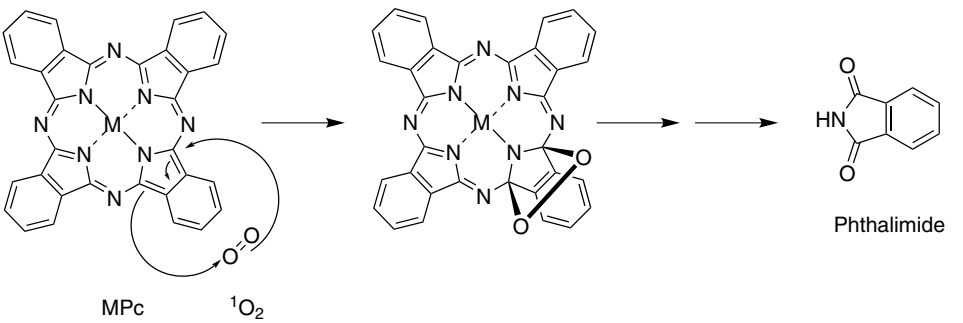

Scheme 4. Photodegradation of phthalocyanine by singlet oxygen. Modified from Ref. 34.

complexes, such as phthalocyanines as shown in Scheme 4.[34] Phthalimide was found to be the photooxidation product following degradation of MPcs.[34] Photodegradation (photobleaching) is characterized by a decrease in the intensity of both the Q- and B-bands, without a shift in maxima or formation of new bands in the visible region. Photobleaching quantum yields (Φ_p) may thus be determined using Eq. 22.[19,33,35,37]

$$\Phi_P = \frac{(C_0 - C_t)VN_A}{I_{abs}St} \tag{22}$$

where C_t and C_0 in mol.l^{-1} are the MPc molar concentrations after and prior to irradiation, respectively, V is the reaction volume, S the irradiated area of the

cell, t the irradiation time, N_A is the Avogadro's number and I_{abs} is defined by Eq. 17.

C. Fluorescence Quantum Yields (Φ_F)

Fluorescence properties of MPcs such as spectral shifts, fluorescence quantum yields and lifetimes are influenced by the presence and nature of the central metal, aggregation, nature of solvent, pH, halogenation, photoinduced electron transfer or electronic energy transfer, amongst other factors. Fluorescence quantum yield (Φ_F) is a measure of the efficiency of the emission process. Fluorescence quantum yields may be determined by the comparative method, using a well-known standard. Equation 23 may be employed,[44–47] using a reference such as chlorophyll *a*:

$$\Phi_F = \Phi_F^{Std} \frac{FA^{Std} n^2}{F^{Std} A (n^{Std})^2} \tag{23}$$

where F and F^{Std} are the areas under the emission curves of the sample and standard, respectively, A and A^{Std} are the absorbances of the sample and standard, respectively, and n and n^{Std} are the refractive indices of the solvents used for sample and standard, respectively. The references often employed for the determination of fluorescence quantum yields (Φ_F) are listed in Table 2.[41,46–50]

D. Triplet State Quantum Yields (Φ_T) and Lifetimes (τ_T)

Population of the triplet state with excited MPc molecules is of importance in visible light driven processes such as photocatalysis (photosensitization), since these excited molecules transfer their energy to ground state oxygen to produce singlet oxygen which is essential in these processes.

Laser flash photolysis gives information about the triplet–triplet absorption and the lifetime of the excited species. The equipment employed is shown diagramatically in Figure 7. The triplet quantum yield (Φ_T) is based on the maximum absorption of the triplet state generated during laser flash photolysis experiments. The triplet state absorption of MPcs is at ~500 nm, a region which is far away from their ground state absorption maximum (Q- band ~700 nm). This provides for easy measurement of the triplet absorption since there is no overlap. Φ_T can be determined using a standard with a known Φ_T, some of the standards are listed in Table 2.[12,41,48,50] The transient absorption due to the triplet state between 450 and 550 nm is accompanied by loss in the absorption in the Soret and Q-band regions due to depletion of the parent compounds (Figure 8). For triplet quantum yield

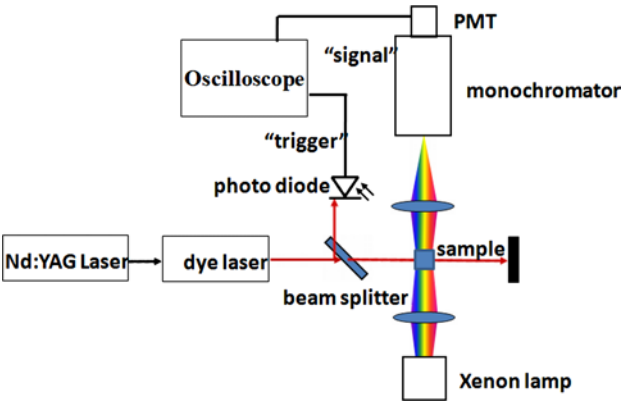

Figure 7. A diagrammatic representation of the laser flash photolysis system used for triplet yields and lifetimes.

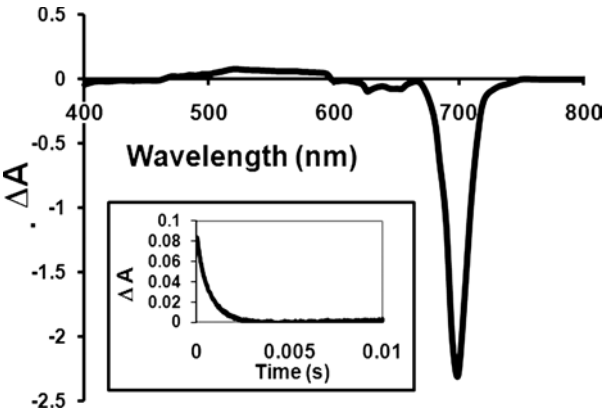

Figure 8. Typical differential absorption spectrum of a metallophthalocyanine (MPc). Inset: Typical triplet decay curve of MPc.

determinations, either the singlet depletion method, Eq. 24,[41,51–54] or triplet absorption method, Eq. 25,[54,55] may be employed:

$$\Phi_T = \Phi_T^{Std} \frac{\Delta A_S \varepsilon_S^{Std}}{\Delta A_S^{Std} \varepsilon_S} \tag{24}$$

$$\Phi_T = \Phi_T^{Std} \frac{\Delta A_T \varepsilon_T^{Std}}{\Delta A_T^{Std} \varepsilon_T} \tag{25}$$

where ΔA_S and ΔA_S^{Std} are the changes in the singlet state absorbance of the MPc derivative and standard (such as ZnPc), respectively. ΔA_T and ΔA_T^{Std} are the

changes in the triplet state absorption of the MPc derivative and the standard, respectively. Φ_T^{Std} is the triplet state quantum yield for the standard. ε_S and ε_S^{Std} are the singlet state extinction coefficients for the MPc derivatives and the standard, respectively. ε_T and ε_T^{Std} are the triplet state extinction coefficients for the MPc derivatives and the standard respectively, and are determined from the molar extinction coefficients of their respective singlet states (ε_S and ε_S^{Std}), the changes in absorbances of the ground singlet states (ΔA_S and ΔA_S^{Std}) and changes in the triplet state absorptions (ΔA_T and ΔA_T^{Std}), according to Eqs. 26 and 27:

$$\varepsilon_T = \varepsilon_S \frac{\Delta A_T}{\Delta A_S} \tag{26}$$

$$\varepsilon_T^{Std} = \varepsilon_S^{Std} \frac{\Delta A_T^{Std}}{\Delta A_S^{Std}} \tag{27}$$

The lifetime of an excited state is the time taken to diminish the population of the molecules in that state to 1/e of its initial concentration. A decay curve (Figure 8 inset) gives the triplet lifetime. The lifetimes of the transients are determined from a software program such as OriginPro 7.5, used in fitting the triplet decay curve. The triplet curve may obey second order kinetics, at high concentrations ($> 1 \times 10^{-4}$ M), due to the triplet–triplet recombination.[56]

III. Water Soluble Phthalocyanine Complexes

For PDT action, it is necessary that the drug be easy to administer via systemic injection into the blood stream. As the blood itself is a water-based system, water solubility then becomes an essential requirement for a PDT drug. Additionally, the drug will have to traverse lipid membranes, meaning that it should also be lipophilic. Water solubility is also essential for use of MPc complexes in the photodegradation of pollutants such as chlorinated phenols under homogeneous conditions. Hence, water soluble Pc complexes will be discussed separately. The most common water-soluble complexes are the sulfonated MPcs.[57,58] Sulfonation[59] by the reaction of MPc complexes with fuming sulfuric acid (containing SO_3) gives a variable mixture of differently sulfonated metallophthalocyanine complexes ($MPc(SO_3^-)_n$, where M = metal ion, n = mixture of 1, 2, 3, or 4 sulfonate groups, which will be represented as $MPc(SO_3)_{mix}$ in this chapter, each containing a variety of positional isomers. Mixed-sulfonated aluminium phthalocyanine [ClAl(III)$Pc(SO_3)_{mix}$], commercially known as Photosens® has been developed as a PDT drug with a fair measure of success.[27] Tetrasulfonated derivatives are generally synthesized by Weber and Busch's method.[60]

Pentasulfonation has been reported in cases where tetrasulfonation was expected.[61]

Tetrapyridinoporphyrazine (Figure 1, complexes **1** and **2**) are phthalocyanines in which the outer benzene rings are replaced with electron-withdrawing pyridine rings.[62] The *N*,*N*′,*N*″,*N*‴-tetramethylated quaternized forms of tetrapyridinoporphyrazines (Figure 1, complexes **1q** and **2q**) are tetrapositively charged and hence water soluble.[62–66] Other positively charged water soluble complexes include quaternized phthalocyanines containing substituents **S1q**, **S2q**, **S3q** or **S4q** which are quaternized forms of **S1**, **S2**, **S3** or **S4**.[67–72] A wide variety of quaternized MPc complexes exist in addition to the ones mentioned above. These include MPc complexes substituted with **S5**,[73] **S6**,[74] **S7**,[75] **S8**,[76] and **S9**.[74] MPcs containing carboxylic acid groups,[77] hence negatively charged, have also been studied. These include MPc complexes substituted with **S10**,[78] **S11**,[78] **S12**,[79] and **S13**.[79] Some cationic phthalocyanines have been found to target vulnerable sites in cells,[80] showing their importance in tumor necrosis and photoinactivation of bacteria.

A. Aggregation Behavior

Aggregation is usually depicted as a coplanar association of rings progressing from monomer to dimer and higher order complexes. Aggregation in MPcs is dependent on the concentration, nature of the solvent, nature of the substituents, complexed metal ions and temperature. In the aggregated state, the electronic structure of the complexed phthalocyanine rings are perturbed, resulting in the alternation of the ground and excited state electronic structures. Water soluble Pc complexes readily form aggregates. Sulfonated MPc complexes often form dimers or higher aggregates in solution.

The relative geometry of the macrocycles determines the spectroscopic behavior of aggregates. According to Kasha's molecular exciton theory,[81] the absorption band of aggregates will be blue-shifted (Figure 9) with respect to the monomer band when the angle between the polarization axes of monomer and the line of molecular center of the aggregate is larger than 54.7°. If the angle is equal to 90°, the molecules are in a face-to-face fashion (the so-called H-type aggregate). On the other hand, when the angle is smaller than the critical angle of 54.7°, the aggregate peak is red-shifted (the so-called J-type aggregate). The cofacial arrangement (common in most Pc aggregates) generally yields the blue-shifted H-aggregates,[82,83] whereas an edge-to-edge arrangement of the J-aggregates is less common. The H aggregates show an absorption band around 630 nm.[82] MPc photosensitizers that form dimers and higher aggregates show a lower photosensitization efficiency.[57,84] Aggregation reduces the lifetimes of the MPc excited state, most probably due to enhanced radiationless excited state dissipation.[83] Therefore, the quantum yields

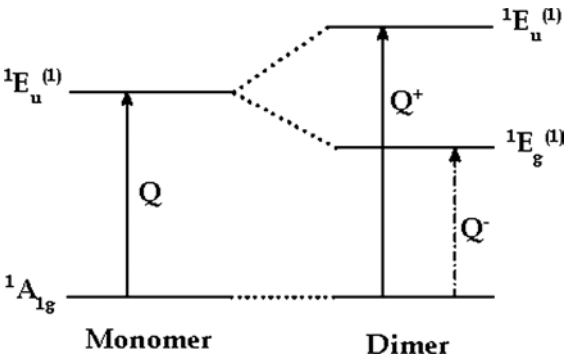

Figure 9. Energy levels showing the transitions involved in aggregated MPc complexes. Modified from Gasyna, Z.; Kobayashi, N.; Stillman, M. J. J. *Chem. Soc. Dalton Trans.* **1989**, 2397–2405, Copyright 1989 Royal Society of Chemistry.

of the excited states and consequently, singlet oxygen generation, are lowered. The degree of sulfonation, isomeric composition and the nature of the central metal ion affect the extent of aggregation. Biological environments support monomerization of phthalocyanines.

1. *Sulfonated Derivatives*

$ClAl(III)Pc(SO_3)_{mix}$, $(OH)_2Si(IV)Pc(SO_3)_{mix}$ and $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ complexes in pH 7.4 buffer show broadening and splitting of the Q-band.[51,53] This behavior is characteristic of the formation of aggregates in sulfophthalocyanines. For these three complexes, addition of a surfactant (Triton X-100) did not bring about any noticeable change in shape and intensity of the spectra, suggesting that these complexes are in a monomeric state. Addition of Triton-X-100 to solutions of $ZnPc(SO_3)_{mix}$ and $(OH)_2Sn(IV)Pc(SO_3)_{mix}$ induced considerable increases in intensity of the low energy band in the visible region, suggesting that the molecules are aggregated and that addition of Triton X-100 breaks up the aggregates.

The degree of aggregation in water increases with lipophilicity,[58] hence the prevalence of the less sulfonated fractions in solution is expected to increase aggregation. High performance liquid chromatography (HPLC) confirmed[53] that $ClAl(III)Pc(SO_3)_{mix}$, $(OH)_2Si(IV)Pc(SO_3)_{mix}$ and $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ had a prevalence of fractions with a higher degree of sulfonation, hence were not aggregated compared with $ZnPc(SO_3)_{mix}$ and $(OH)_2Sn(IV)Pc(SO_3)_{mix}$ complexes which contained less sulfonated fractions and were therefore more aggregated. $ClAl(III)Pc(SO_3)_{mix}$, $(OH)_2Si(IV)Pc(SO_3)_{mix}$ and $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ consisted

mainly (~90%) of tetrasulfonated derivatives, while $ZnPc(SO_3)_{mix}$, and $(OH)_2Sn(IV)Pc(SO_3)_{mix}$ contained approximately the same amounts of the tetra-, tri- and di-sulfonated derivatives.[52] Tetrasubstituted MPc complexes ($MPc(SO_3)_4$) contain positional isomers in a statistical ratio of 1:1:2:4 (for the 2,9,16,23-, 2,10,16,24-, 2,9,17,24- and 2,9,16,24-isomers). The isomers are difficult to separate chromatographically. For a series of $ClAl(III)Pc(SO_3)_n$ complexes, only the di-[85] and tri-sulfonated complexes were essentially monomeric.[42,85]

2. *Carboxylated Derivatives*

The ground state electronic absorption spectra of $(OH)Al(III)Pc(COOH)_8$, $ZnPc(COOH)_8$, $(OH)_2Si(COOH)_8$ and $(OH)_2Ge(IV)Pc(COOH)_8$ in PBS pH 7.4 shows no aggregation, typical of octacarboxysubstituted complexes, whereas tetracarboxylated derivatives ($MPc(COOH)_4$) are aggregated.[19,77,86] The plurality of COOH substituents prevents aggregation. For MPc complexes containing **S12** and **S13** substituents, the former resulted in aggregated MPc complexes, while those containing **S13** were not aggregated due to the bulkiness of the substituent.[79] MPc complexes substituted with **S10** or **S11** were also found to be aggregated.[78]

3. *Quaternized Derivatives*

MPc complexes containing quaternizable groups are constantly reported in the literature.[68–72,74–76,87,88] According to the literature,[64,65] water soluble porphyrazine complexes (complexes **1q** or **2q**; Figure 1) do not form aggregates in aqueous solutions. Positively charged water soluble phthalocyanine complexes containing substituents **S1q**, **S2q**, **S3q** or **S4q** are aggregated in solution.[67–72] For example, ZnPc complexes tetra- or octasubstituted with substituent **S4q** are highly soluble in aqueous media but were aggregated with the monomer band appearing near 700 nm and the band due to aggregates near 640 nm.[72] The presence of the bulky quaternized 2-diethylaminoethanethiol substituent **S4q** at the periphery of the ZnPc does not prevent aggregation of the Pc macrocycles. The addition of a surfactant, Cremophore EL (CEL), to the aqueous solution of these complexes resulted in a decrease in the intensity of the band due to the aggregates, with a concomitant increase in the intensity of the band due to the monomeric species. The disappearance of the peak due to the aggregates was, however, not complete.[72] Addition of Cremophore EL reduced aggregation resulting in increased photoactivity and improved photosensitizing ability for MPcs substituted with **S1q** to **S4q**. Aggregated MPcs are expected to disaggregate and exhibit monomeric behavior in organic solvents, and this was observed

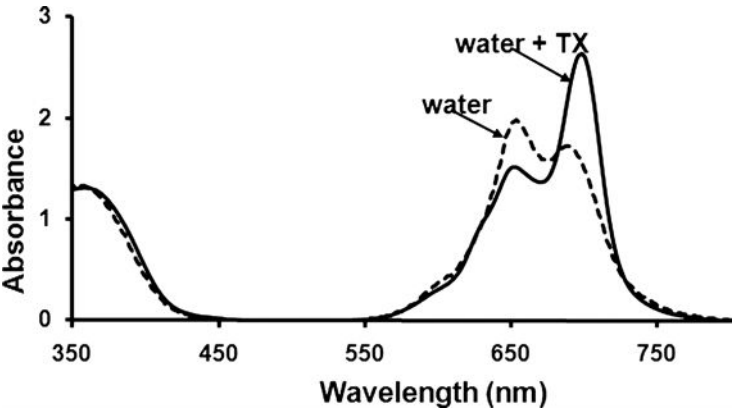

Figure 10. Absorption spectra of In(III)Pc (**S1q** substituent) in water in the presence and absence of Triton X-100 at a concentration of 6.6×10^{-5} mol dm^{-3}. TX = Triton X 100. Reproduced with permission from Ref. 69.

for ZnPc complexes tetra- or octasubstituted with substituent **S4q** in dimethylsulfoxide (DMSO).[72] The presence of trialkylated compounds, due to incomplete quaternization of the outer nitrogen atoms, induces severe aggregation.[87] Water soluble quaternized ZnPc complexes containing **S6**, **S7**, **S8** and **S9** were also found to be aggregated in water.[74–76]

Water soluble ClGa(III)Pc complexes containing **S1q** substituents were not aggregated in water; however their Clln(III)Pc counterparts were aggregated in water.[67,69] It is not clear why the two derivatives show different aggregation behavior. The addition of Triton X-100 to the water solution of the ClIn(III)Pc derivatives resulted in disaggregation, as evidenced by the sharp increase in the intensity of the monomer peak and a decrease in the intensity of the dimer peak (Figure 10).[69] However, the disappearance of the peak due to the aggregate is not complete as judged by the persistence of the peak at 649 nm even after addition of Triton X-100. Water soluble ZnPc complexes containing **S2q** substituents were highly aggregated in water, and the spectra were recorded in a water–pyridine solvent mixture.[70]

B. Fluorescence Spectra and Quantum Yields (Φ_F)

Fluorescence spectral behavior of Pcs has been extensively studied.[16,89–98] Generally in phthalocyanines, the excitation spectra are similar to the absorption spectra and both are mirror images of the fluorescence emission spectra (Figure 11a).[68] However for aggregated MPc complexes, the absorption profile is

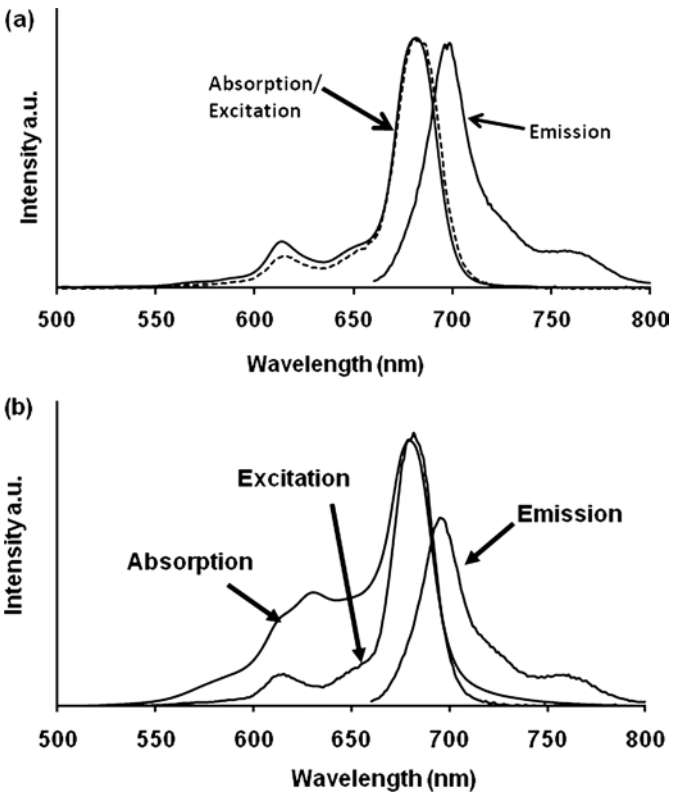

Figure 11. Absorption, excitation and emission spectra of (a) typical MPc (Cl_2Si(IV)Pc tetra substituted on the peripheral position with **S2** substituent) in DMSO. Excitation wavelength = 620 nm. Modified from Ref. 68. (b) A typical aggregated MPc in DMSO. Excitation wavelength = 620 nm. Modified from Ref. 89.

different to that of the fluorescence spectrum, Figure 11b,[89] since aggregates do not fluoresce.

The Φ_F values often increase with increase in the viscosity of the solvent. The relationship between Φ_F and the viscosity (η) of the solvent is given by the Forster-Hoffmann equation (Eq. 28):[99,100]

$$\log \Phi_F = C + x \log \eta. \tag{28}$$

As is the case with other photophysical and photochemical properties of MPc complexes,[101–115] fluorescence behavior is affected by solvent, aggregation and the presence of surfactants or proteins. The fluorescence quantum yield values for water soluble MPc complexes are shown in Table 3. The values are typical of MPc complexes in general, with the exceptions discussed below.

[a]The following symbols apply to all tables: Φ_F = fluorescence quantum yield (in general the standard used for determination of Φ_F is chlorophyll *a* in ether ($\Phi_F = 0.32$)[48]; Φ_T = triplet quantum yield; Φ_Δ = singlet oxygen quantum yield; Φ_P = photodegradation quantum yield; τ_T = triplet life time. Subscripts = average number of sulfo groups per molecule.

1. *Sulfonated Derivatives*

a. *$MPc(SO_3)_{mix}$ complexes*

For $MPc(SO_3)_{mix}$ complexes, which are a mixture of sulfonated MPc complexes, the determined photophysical and photochemical parameters are an average for each mixture. It is important to report these parameters for the mixtures since such mixtures are already in use in PDT for example. For the aggregated $ZnPc(SO_3)_{mix}$ and $(OH)_2Sn(IV)Pc(SO_3)_{mix}$ complexes,[52] it was only the monomer that fluoresced. For the nonaggregated $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ and $(OH)_2Si(IV)Pc(SO_3)_{mix}$, the excitation spectra are different from the absorption spectra, suggesting that not all the components fluoresced. The fluorescence quantum yields were influenced by the heavy atom effect. Comparing the monomeric $MPc(SO_3)_{mix}$ [M = ClAl(III) (Φ_F = 0.44), $(OH)_2Ge$ (Φ_F = 0.30), $(OH)_2Si$ (Φ_F = 0.34)] complexes in phosphate buffer saline (PBS) in Table 3, Φ_F values were lower for complexes with the heavier atoms (e.g. Ge) due to the heavy atom effect.[52] The aggregated $(OH)_2Sn(IV)Pc(SO_3)_{mix}$ (Φ_F = 0.05) and $ZnPc(SO_3)_{mix}$ (Φ_F = 0.16) complexes showed significantly lower Φ_F values in PBS than the nonaggregated complexes in water[52] and the Φ_F values increased when a surfactant such as Triton X-100 was added (see Table 4). The Φ_F values are generally lower (Table 3) for the $MPc(SO_3)_{mix}$ (M = Zn and $(OH)_2Sn(IV)$) complexes in DMSO than in water (with or without Triton X-100) and this was attributed[52] to the presence of the relatively heavier atoms in DMSO, which may tend to favor intersystem crossing rather than fluorescence. However, in general DMSO gives larger Φ_F values compared to water in Table 3, since there is less aggregation in DMSO.

Bovine serum albumin (BSA) decreased the fluorescence quantum yields of the nonaggregated MPc complexes ($ClAl(III)Pc(SO_3)_{mix}$, $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ and $(OH)_2Si(IV)Pc(SO_3)_{mix}$).[52,53] $ClAl(III)Pc(SO_3)_2$ gave higher Φ_F in D_2O compared to water.[95,96]

For $(Cl)_3Ta(V)Pc(SO_3)_{mix}$, the Φ_F values ranging from 0.15 in PBS to 0.22 in DMSO are not as low as would be expected for the complex containing the heavy Ta central metal. However compared to the corresponding $OTi(IV)Pc(SO_3)_{mix}$ (Φ_F = 0.42) in DMSO, the Φ_F value of 0.18 for $(Cl)_3Ta(V)Pc(SO_3)_{mix}$ is low.[113]

b. *Other $MPc(SO_3)_n$ complexes*

Φ_F values either decreased or remained unchanged as the number of sulfonate groups increase for $ZnPc(SO_3)_2$ (Φ_F = 0.16), $ZnPc(SO_3)_3$ (Φ_F = 0.12), $ZnPc(SO_3)_4$ (Φ_F = 0.07) in DMSO.[41,90,91] When comparing $ZnPc(SO_3)_4$ (Φ_F = 0.28) with $ClAl(III)Pc(SO_3)_4$ (Φ_F = 0.56) and $H_2Pc(SO_3)_4$ (Φ_F = 0.60) in DMF, the Zn complex showed a low Φ_F value (Table 3), but was found to be the best

Table 4. Photochemical and photophysical properties of non-water soluble metal phthalocyanines.[a] Refer to Figure 1 and Table 1 for the numbering of the complexes.

[a]The following symbols apply to all tables: Φ_F = fluorescence quantum yield (in general the standard used for determination of Φ_F is chlorophyll a in ether ($\Phi_F = 0.32$) [49]); Φ_T = triplet quantum yield; Φ_Δ = singlet oxygen quantum yield; Φ_P = photodegradation quantum yield; τ_T = triplet life time.

photosensitizer in terms of cell-killing ability.[92] The low Φ_F value for $ZnPc(SO_3)_4$ could be the result of some aggregation even in organic solvents such as DMF in addition to the heavy atom effect of Zn central metal. The value is also low for this complex in a methanol–water mixture ($\Phi_F = 0.14$).[93] Bovine serum albumin quenches the fluorescence of $ClAl(III)Pc(SO_3)_4$ complexes.[94]

2. *Carboxylated Derivatives*

The absorption spectra of $MPc(COOH)_8$ complexes are mirror images of the fluorescence emission spectra as is usually observed for MPc derivatives, due to a lack of aggregation.[77] Φ_F values for the $MPc(COOH)_8$ [M = Al ($\Phi_F = 0.27$), Zn ($\Phi_F = 0.23$), Ge ($\Phi_F = 0.13$), Si ($\Phi_F = 0.24$)] decrease with an increase in the size of the central metal which is consistent with the strength of the spin-orbit coupling induced by the respective central metals based on their relative masses.[77] The fluorescence quantum yields of $(OH)Al(III)Pc(COOH)_4$ complex adsorbed onto silica particles were found to be higher than in solution[111] (Table 3). The unmetalated form of complex **3** (Figure 1) containing **S10** substituents is water soluble but it is highly aggregated in water and methanol, but mainly monomeric in DMSO (with a low $\Phi_F = 0.04$) and chloroform.[97] The fluorescence quantum yield of this complex in water containing a surfactant cetyl trimethylammonium chloride (CTAC) was $\Phi_F = 0.12$, a value typical of MPc complexes.[97] ZnPc complexes containing **S10** or **S11** substituents gave typical values of Φ_F.[54,78] ZnPc substituted with **S13** ($\Phi_F = 0.006$) gave a higher Φ_F value than **S12** ($\Phi_F = 0.0015$) due to presence of bulkier substituents resulting in less aggregation, however these values are low compared to ZnPc complexes in general in Table 3.[79]

3. *Quaternized Derivatives*

a. *Porphyrazine complexes*

As stated above, the presence of triakylated compounds due to incomplete quaternization of the outer nitrogen atoms induces severe aggregation of porphyrazine complexes,[87] resulting in low Φ_F values which were lower in water (containing sodium dodecylsulfate, SDS) compared to toluene for these complexes. The Φ_F value for quaternized Zn porphyrazine derivatives (complex **2q**, R = CH_3) of 0.30 (Table 3) was similar to that of the corresponding unquaternized complex (complex **2**, $\Phi_F = 0.35$) in DMF.[102]

b. *MPc complexes*

Zwitterionic conjugates of ZnPc complexes exhibited Φ_F values in the region of 0.2 to 0.3 in organic solvents.[101] For ZnPc derivatives octasubstituted with **S1q**

groups, the Φ_F values ranged from 0.0038 to 0.0614 in DMSO, pH 7 and methanol,[115] values which are very low for MPc complexes (Table 3). For the corresponding Si(IV) complexes (containing **S1q**), the values ranged from 0.0361 to 0.1146 for the same solvents, hence showing an improvement.[115] When Zn was employed as a central metal for **S2q** ligands[70] there was considerable aggregation, resulting in a disagreement between absorption and emission spectra. However, in a mixture of water and pyridine (50:50) the complex was less aggregated. Addition of organic solvents normally breaks the aggregates, resulting in monomerization and a mirror image relationship between the fluorescence emission and absorption spectra (Figure 11a).[68] For MPc complexes containing the **S4q** substituent and Zn central metal, there was a lack of agreement between absorption and emission spectra due to aggregation.[72] For these complexes, the band centered around 640 nm associated with the dimer, is not seen in the fluorescence excitation spectra since only the monomer fluoresces. In DMSO, the absorption and fluorescence excitation spectra of the complexes were similar and are mirror images of the emission spectrum. Monomerization of the ZnPc (substituted with **S4q**) leads to enhanced fluorescence and this is noticed in the Φ_F value of this complex in the presence of Cremophore EL and in DMSO compared to the value in aqueous media alone. The Φ_F values followed the trend PBS 7.4 < PBS 7.4 + CEL < DMSO for ZnPc complexes containing the **S4q** substituent.[72] Also in DMSO, Φ_F values for ionic complexes (i.e. those containing an **S4q** substituent) were slightly lower than for the nonionic complexes (i.e. those containing an **S4** substituent).[72] Fluorescence quantum yield values of the ZnPc derivative substituted with **S2q** or **S3q** were found to be 0.17 and 0.11 respectively in a pyridine–water (50:50) mixture,[70] values which are within the range of phthalocyanine complexes (Table 3).

The water soluble ClGa(III)Pc complexes containing **S1q** substituents are not aggregated[67] and, as such, the excitation spectra were similar to absorption spectra and both were mirror images of the fluorescence spectra. The proximity of the wavelength of the Q-band absorption and excitation spectral maxima, suggest that the nuclear configurations of the ground and excited states are similar and are not affected by excitation.

The fluorescence quantum yields of ClGa(III)Pc derivatives peripherally or nonperipherally substituted with **S1q** are typical of MPc complexes (Table 3).[67,98] The peripherally substituted complexes showed marginally higher Φ_F values in comparison to the nonperipherally substituted ClGa(III)Pc and ClIn(III)Pc derivatives (Table 3), suggesting less quenching of the excited singlet state by non-peripheral substitution compared to the peripheral substitution.[67,69]

C. Triplet Quantum Yields (Φ_T) and Lifetimes (τ_T)

1. *Sulfonated Derivatives*

a. *$MPc(SO_3)_{mix}$ complexes*

Triplet quantum yields (Φ_T) are influenced both by the heavy atom effect and aggregation for a series of $MPc(SO_3)_{mix}$ complexes.[52] Φ_T values for the aggregated $(OH)_2Sn(IV)Pc(SO_3)_{mix}$ and $ZnPc(SO_3)_{mix}$, complexes improved upon addition of Triton X-100 (Table 3). For the monomeric $ClAl(III)Pc(SO_3)_{mix}$, $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ and $(OH)_2Si(IV)Pc(SO_3)_{mix}$ complexes, the Φ_T values were lower (considering the same solvent) for the smaller atom, due to the heavy atom effect. Comparing $ZnPc(SO_3)_{mix}$ and $ClAl(III)Pc(SO_3)_{mix}$ complexes, a larger Φ_T value was obtained for the former due to the heavy atom effect, considering the same solvent.

It is important to note that the triplet states of MPc complexes are quenched by oxygen,[88] hence deoxygenation is important for the accurate determination of triplet lifetimes. Values of τ_T for $ZnPc(SO_3)_{mix}$ and MPc complexes in general are very low in water compared to when nonaqueous solvents or D_2O are employed.[93,103,104] This was explained in terms of the near IR spectra of the solvents. Figure 12 shows the near IR absorption spectra of three solvents: DMSO, DMF and H_2O, and how these affect the triplet and singlet oxygen lifetimes in solution.[41] The triplet state energy of ZnPc and many of its derivatives in solution is ~1.12 eV,[27] which corresponds to an absorption wavelength of ~1108 nm. The intensity and broadness of the solvent absorption in this wavelength region should

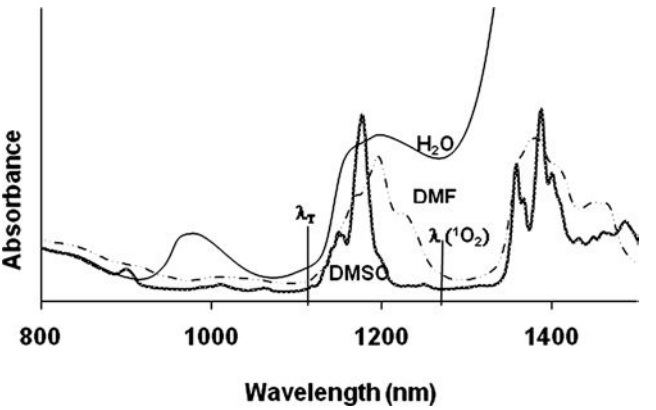

Figure 12. Near IR absorption spectra of some common solvents: DMSO, DMF and water. Reproduced with permission from Ref. 41.

have a considerable effect on the triplet lifetime. H_2O shows a very broad absorption band near 1108 nm, which implies that nonradiative decay and quenching of the sensitizer's triplet state would be more rapid in H_2O than in DMSO or DMF where absorption at 1108 nm is minimal. Thus τ_T values are generally lower in water when compared to DMSO, D_2O or DMF (Table 3). The τ_T values for the $MPc(SO_3)_{mix}$ complexes in DMSO ranged between 120 and 800 μs,[52] the highest value being observed for $ClAl(III)Pc(SO_3)_{mix}$ (800 μs), followed by $(OH)_2Ge(IV)Pc(SO_3)_{mix}$ (760 μs), $(OH)_2Si(IV)Pc(SO_3)_{mix}$ (439 μs), and $ZnPc(SO_3)_{mix}$ (530 μs).

b. *Other $MPc(SO_3)_n$ complexes*

For $ZnPc(SO_3)_4$, the Φ_T value was high in DMSO ($\Phi_T = 0.88$;[41] Table 3). Generally, Φ_T values are higher for $ZnPc(SO_3)_4$ compared to the disubstituted derivatives (Table 3).[108,109] Compared to other substituted ZnPc complexes (such as *tert*-butylphenoxy, methylphenoxy and nitro-substituted ZnPc derivatives), sulfonation of the Pc ring brings about longer triplet lifetimes.[41] The triplet lifetime values for $ZnPc(SO_3)_4$ and $ZnNPc(SO_3)_4$ in the presence of detergents[107] (Table 3), were increased when compared to water alone.[103] There was little effect of the degree of sulfonation on triplet lifetimes,[94,95] when considering the same solvent: compare $ClAl(III)Pc(SO_3)_2$ (τ_T = 520 μs), $ClAl(III)Pc(SO_3)_3$ (τ_T = 490 μs) and $ClAl(III)Pc(SO_3)_4$ (τ_T = 530 μs) in PBS or (τ_T = 1130 μs, 1150 μs and 1140 μs respectively in D_2O in Table 3. Bovine serum albumin (BSA) increases the lifetime of the triplet state of $ClAl(III)Pc(SO_3)_4$ as shown in Table 3.[94] However, association of BSA with ZnPc complexes decreased the triplet quantum yields, suggesting singlet state and/or static triplet quenching of the bound dye by the host protein.[106]

A large τ_T value was obtained for $ClAl(III)Pc(SO_3)_2$ in CD_3OD ($\tau_T = 1440$ μs)[95] compared to $\tau_T = 550$ μs in pH 4 buffer or 775 μs in methanol.[104,108–110] Sulfonated ClGa(III)Pc derivatives show low Φ_T values in methanol,[108] but the triplet state is long lived (τ_T ranging from 300 to 440 μs)[108,109] (See Table 3).

2. *Carboxylated Derivatives*

The variation of Φ_T among the $MPc(COOH)_8$ complexes in aqueous media [Φ_T = 0.0 (Zn), 0.32 (Al), 0.34 (Si) and 0.62 (Ge)] depends on the heavy atom effect which encourages intersystem crossing to the triplet state.[77] The triplet state lifetime values of the $MPc(COOH)_8$ range from 90 μs (M = Si) to 450 μs (M = Al), which is a typical range for many MPc complexes.[77]

For the unmetalated water soluble complex **3** (Figure 1) containing **S10** substituents, Φ_T values were highly solvent dependent, with the highest value being

observed in water containing CTAC ($\Phi_T = 0.56$), followed by DMSO ($\Phi_T = 0.34$), again showing that monomerization increases the photophysical parameters. This complex however, showed very low τ_T values (< 5 μs) in all solvents.[97] For complex **3** (M = Zn and containing **S10** substituent), $\Phi_T = 0.25$ in DMSO for the disubstituted complex, which did not change on tetrasubstitution ($\Phi_T = 0.27$). The lifetime decreased upon moving from the disubstituted to tetrasubstituted complex.[54]

3. *Quaternized Derivatives*

As expected, the presence of CEL gave increased Φ_T values for ZnPc complexes containing the substituent **S4q** compared to the phosphate buffer solution (PBS) alone.[72] An increase in triplet lifetimes (τ_T) in the order, PBS 7.4 < PBS 7.4 + CEL < DMSO were observed with these ZnPc complexes. The lowest τ_T values exhibited in PBS 7.4 are likely due to the fact that the triplet state of MPcs can be quenched by water (Figure 12), in addition to aggregation. The slight increase τ_T values in the presence of CEL may be due to less exposure of the Pc to the aqueous medium as well as a decrease in aggregation. The triplet quantum yields were very low in the presence of HSA for ZnPc tetrasubstituted with **S7** ($\Phi_T < 0.001$) with a reasonable lifetime of $\tau_T = 220$ μs.[75] The Φ_T value increased in the presence of CTAC ($\Phi_T = 0.16$, while the τ_T (= 150 μs) decreased.[75] These values changed in the presence of SDS, i.e. Φ_T increased to 0.59, while τ_T decreased to 140 μs).[75] ZnPc complexes containing other quaternizable substituents such as **S2q** and **S3q** showed typical Φ_T values in the presence of organic solvents (Table 3).

Unsubstituted ClIn(III)Pc and ClIn(III)Pc tetrasubstituted either peripherally or nonperipherally with **S1q** substituents gave shorter lifetimes and correspondingly larger triplet quantum yields (Φ_T) when compared to ZnPc derivatives in general (Table 3), due to the enhanced intersystem crossing induced by the larger In central metal.[69] In DMSO, Φ_T value for the quaternized octasubstituted ClIn(III)Pc containing the substituent **S1q**, ($\Phi_T = 0.68$) is larger than that in water with Triton X-100 ($\Phi_T = 0.59$), which is attributed to increased intermolecular interaction in water compared to that in DMSO.[98] Even in the presence of Triton X-100, some level of aggregation still exists for ClIn(III)Pc complexes containing the substituent **S1q** in water. The Φ_T value for the quaternized ClIn(III)Pc complexes tetrasubstituted with **S1q** substituents at peripheral positions ($\Phi_T = 0.94$, Table 3) was very high in DMSO.

The triplet lifetime values for the ClIn(III)Pc complexes substituted with **S1q** were lower in water when compared to DMSO due to the aggregation in water, and this was also due to absorption by water at the same wavelength as the triplet state of MPc complexes (Figure 12). τ_T values for the quaternized ClIn(III)Pc

complexes (**S1q** substituents, peripheral or nonperipheral, Table 3) were similar to those of the corresponding unquaternized derivatives (**S1** substituents) in DMSO. Addition of Triton X-100 increased the τ_T values in water for these ClIn(III)Pc complexes.

D. Singlet Oxygen Quantum Yields (Φ_Δ)

Energy transfer between the triplet state of photosensitizers and ground state (triplet) molecular oxygen leads to the production of singlet oxygen. Therefore singlet oxygen quantum yield, which is the efficiency of singlet oxygen generation, should depend on the triplet state quantum yield and lifetime, the efficiency of energy transfer, the energy of the triplet state and the ability of the substituents to quench the triplet state among other factors. Thus, the trend in variation of Φ_Δ within an array of photosensitizers should be parallel to the variations in their Φ_T values. Due to the aggregation behavior of MPc complexes, the values of Φ_Δ are expected to increase in the presence of detergents (e.g. Triton X-100), in the same manner as for the Φ_T values.[112]

1. *Sulfonated Derivatives*

a. *$MPc(SO_3)_{mix}$ complexes*

For a range of $MPc(SO_3)_{mix}$ [M = ClAl(III), Zn, $(OH)_2Si(IV)$, $(OH)_2Ge(IV)$] photosensitizers,[52] lower singlet oxygen quantum yields (Φ_Δ) were observed in aqueous solutions (in the absence of detergents) compared to organic solvents or in aqueous media in the presence of detergents (Table 3). The degree of sulfonation has an influence on the production of singlet oxygen. For a series of $ZnPc(SO_3)_{n(mix)}$ (n = an average number of SO_3 groups) complexes (Table 3), Φ_Δ values were almost the same in DMSO, but an increase in Φ_Δ with the value of n is observed in PBS (pH 7.4) in the absence of Triton X-100.[114] The Φ_Δ value is low for the more aggregated $ZnPc(SO_3)_{2.1(mix)}$ ($\Phi_\Delta \leq 0.01$), but high for the mainly monomeric $ZnPc(SO_3)_{3.7(mix)}$ ($\Phi_\Delta = 0.49$) in pH 7.4 buffer (Table 3).[114]

For the unmetalated $H_2Pc(SO_3)_{n(mix)}$, complex, intermolecular hydrogen bonding results in extensive aggregation, with the addition of Triton X-100 leading only to partial monomerization and a low Φ_Δ value (0.02).[114]

b. *Other $MPc(SO_3)_n$ complexes*

In reversed micelles, singlet oxygen quantum yields for the di- and trisubstituted $(OH)Al(III)Pc(SO_3)_n$ complexes were found to be the same as in water, even

though enhanced intersystem crossing was observed in micelles.[42] (OH)Al(III)Pc$(SO_3)_n$ derivatives generally give low Φ_Δ values compared to the corresponding ZnPc derivatives due to the small size of the central Al metal ion compared to Zn.

As observed with ZnPc$(SO_3)_4$, the Φ_Δ value for ZnNPc$(SO_3)_4$ increased in the presence of detergents.[107] However, for ClAl(III)Pc$(SO_3)_4$ (Φ_Δ = 0.20 in DMF and 0.18 in aqueous media) and H_2Pc$(SO_3)_4$ (Φ_Δ = 0.16 in DMF and 0.09 in aqueous media), low singlet oxygen quantum yields (< 0.3) were observed (Table 3).[18,33,35,83,92] The Φ_Δ values for tetrasulfonated MPc complexes were found to increase as follows in DMF: ZnPc$(SO_3)_4$ (Φ_Δ = 0.52) > XGa(III)Pc$(SO_3)_4$ (Φ_Δ = 0.41) > XAl(III)Pc$(SO_3)_4$ (Φ_Δ = 0.2) ~ H_2Pc$(SO_3)_4$ (Φ_Δ = 0.16), (where X represents an anionic axial ligand). In general, Φ_Δ values were higher in DMF than in water or water containing CTAC.[33] MgPc$(SO_3)_2$ gave a low Φ_Δ value in DMSO, most likely due to the large fluorescence expected for small central metals.[114]

2. *Carboxylated Derivatives*

MPc$(COOH)_8$ (M = Al, Zn, Si and Ge) gave low Φ_Δ values even though these complexes are not aggregated. The values increase with the size of the central metal as follows: Al (Φ_Δ = 0.12) < Si (Φ_Δ = 0.22) < Zn (Φ_Δ = 0.32) ≈ Ge (Φ_Δ = 0.31) in aqueous media.[77] When considering the number of carboxyl groups, the Φ_Δ values obtained for ZnPc$(COOH)_8$ (Φ_Δ = 0.48 in DMF) and ZnPc$(COOH)_4$ (Φ_Δ = 0.51 in DMF) were similar (Table 3). For (OH)Al(III)Pc$(COOH)_8$, association via hydrogen bonding occurs, affecting the production of singlet oxygen and hence the photosensitizing ability.[42] Thus, (OH)Al(III)Pc$(COOH)_8$ gave a low Φ_Δ value of 0.12 in DMSO or aqueous media (Table 3).[35,77] For complex **3**, containing Zn as the central metal ion and substituted with **S10**, low Φ_Δ values were obtained for both the tetrasubstituted (Φ_Δ = 0.31) and disubstituted (Φ_Δ = 0.23) complexes.[54] Table 3 shows an even lower Φ_Δ value for complex **4** substituted with **S10**.

3. *Quaternized Derivatives*

a. *Porphyrazine complexes*

For the zinc porphyrazine **2q** complexes substituted with CH_3 or $CH_3COOCH_2CH_3$, singlet oxygen quantum yields were higher in aqueous (SDS) solutions (Table 3) compared to organic solvents.[87] The Φ_Δ value for the quaternized Zn porphyrazine complex (**2q**) of 0.50 (Table 3) was similar to that of the corresponding unquaternized complex (Φ_Δ = 0.56) in DMF (Table 4).[102] For the **1q** complexes containing Ge, Sn and Zn central metals, the Φ_Δ values are very low (< 0.1).

b. *MPc complexes*

Efficient production of singlet oxygen in DMSO was observed with values of S_Δ (= Φ_Δ/Φ_T, which represents the efficiency of quenching of the triplet excited state by singlet oxygen), being near unity for quaternized tetra- or octasubstituted ZnPcs containing the **S4q** substituent.[72] The low Φ_Δ values obtained for these complexes in PBS (Table 3) are consequently due to low Φ_T values, as discussed above. However, a slight improvement is observed in Φ_Δ values in CEL. ZnPc complexes octasubstituted with **S6** or **S9** gave Φ_Δ values which were larger for the former substituent (0.60, 0.62 and 0.65 in methanol, ethanol and water, respectively for **S6**),[74] compared to **S9** which ranged from < 0.05 to 0.45 in the same solvents.[74] For ZnPc tetrasubstituted with **S5** substituents, a Φ_Δ value of 0.6 was obtained in neat water. This was reduced to about 0.32 in phosphate-buffered saline.[73]

As with the ZnPc counterparts, ClAl(III)Pc complexes octasubstituted with **S6** or **S9**, gave Φ_Δ values which were generally larger for **S6** (0.35, 0.35 and 0.38 in methanol, ethanol and water, respectively).[74] The values for **S9** ranged from Φ_Δ < 0.05 to 0.37 in the same solvents.[74] As expected, the Φ_Δ values were larger for ZnPc compared to ClAl(III)Pc due to the heavy atom effect.

Quaternized ClIn(III)Pc complexes (tetrasubstitued with **S1q** substituent at peripheral and nonperipheral positions) showed lower Φ_Δ values (ranging from 0.44 to 0.70; Table 3) when compared to their unquaternarized counterparts (containing **S1**), with Φ_Δ values ranging from 0.65 to 0.86 in various solvents.[69]

In some cases, the Φ_Δ values are low relative to Φ_T for ClIn(III)Pc complexes substituted with **S1q** in Table 3, suggesting inefficient transfer of energy from the triplet state of MPc to triplet state oxygen (and thus the subsequent formation of singlet oxygen). ClIn(III)Pc octasubstituted with **S1q** gave $\Phi_\Delta = 0.66$ in DMSO and $\Phi_\Delta = 0.56$ in water.[98] The lower value in water is ascribed to the quenching of singlet oxygen by water, as demonstrated by the shorter lifetime of singlet oxygen in water (4.2 μs)[116] compared to that in DMSO (30 μs).[117] The Φ_Δ values for ClGa(III)Pc complexes (containing **S1q** substituent) showed that the point of substitution (peripheral or nonperipheral positions) does not affect the Φ_Δ values[67] (Table 3).

E. Photobleaching Quantum Yields (Φ_p)

Observation of the degradation of the molecules under irradiation can be used to study their stability and this is especially important for those molecules intended for use as photocatalysts. The collapse of the absorption spectra without any distortion of the shape (or shifts in wavelength) is generally taken to imply clean photodegradation and is not associated with phototransformation. The

photodegradation (photobleaching) quantum yield (Φ_p) is a measure of the stability of a molecule under photo-irradiation. It is believed that photobleaching is a singlet oxygen-mediated process; hence, its efficiency should depend on the value of Φ_Δ. Thus, oxidative attack of the excited triplet state of MPcs by singlet oxygen brings about photodegradation, since the triplet state is sufficiently long lived to participate in photochemical reactions.

In general, for sulfonated ZnPc derivatives, Φ_p values are of the order of 10^{-5} (Table 3). For a series of $MPc(SO_3)_{mix}$ complexes, photodegradation quantum yield values tend to follow singlet oxygen trends (Table 3).[52,53] Photodegradation quantum yields were found to be high in DMSO for unquaternized peripherally tetra- or octasubstituted ZnPcs containing the **S4** substituent ($\Phi_p = 66 \times 10^{-5}$ in DMSO Table 4) compared to their quaternized counterparts containing the **S4q** substituents ($\Phi_p = 17 \times 10^{-5}$ in DMSO).[72] The lowest values of photodegradation were exhibited in PBS pH 7, for the **S4q** substituent on ZnPc (Table 3),[72] where Φ_Δ values are also low. This confirms that photodegradation is dependent on singlet oxygen.

For quaternized ClIn(III)Pc complexes containing the **S1q** tetrasubstituent at peripheral and nonperipheral positions, the photodegradation quantum yields were almost similar, showing that the point of substitution does not affect stability. For ClIn(III)Pc or ClGa(III)Pc derivatives containing **S1q** as the substituent, the variation of Φ_p follows the same trend as that of Φ_Δ, with Φ_p values being higher in aqueous media compared to DMSO. Hence, the complexes are less stable in the former solvent.[69]

IV. Non-Water Soluble Phthalocyanine Complexes

A. Aggregation Behavior in General

The aggregation tendencies of non-water soluble MPc complexes are attributed to the formation of π–π interactions between adjacent MPc rings. Coordinating solvents may be axially ligated to the central metals in the MPc complexes, thereby preventing columnar aggregation. However the presence of axial or ring substituents is often not sufficient to prevent aggregation. Thus the non-water soluble complexes discussed in this work often show aggregation. CdPc derivatives showed unique aggregation behavior and are therefore discussed in greater detail.[118] The spectrum of CdPc nonperipherally substituted with **S14** is typical of a monomeric species (Figure 13a), whereas that of its peripherally substituted counterpart (with **S14**) tends to be slightly broad in both DMF and DMSO.[118] The spectrum of the latter was quite unusual in DCM or chloroform (Figure 13b), suggesting extensive aggregation. No changes in spectra occurred on addition of the

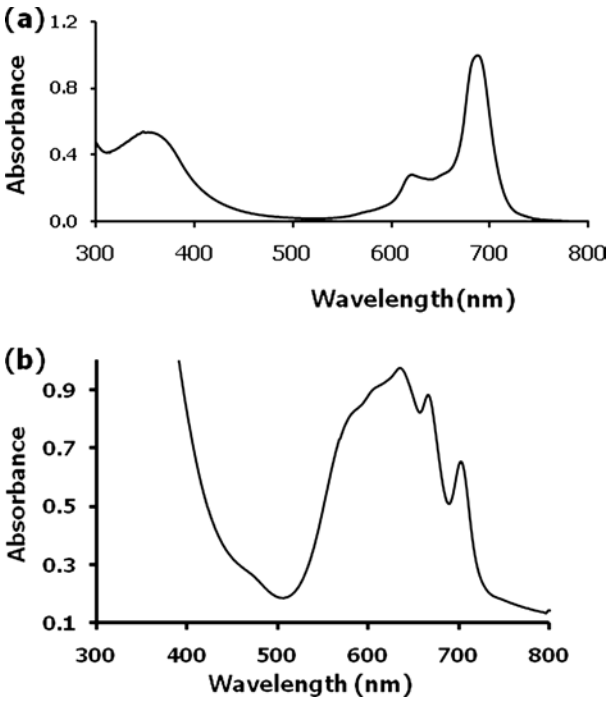

Figure 13. Electronic absorption spectra of CdPc peripherally tetrasubstituted with **S14** ligand in (a) DMSO and (b) DCM. Modified from Ref 118.

surfactant to solutions of CdPc peripherally substituted with **S14**, which is an indication that this complex is in a monomeric state or that the aggregates are too strong to be broken by surfactants. For CdPcs, triple-decker and higher oligomeric complexes have been reported in addition to demetalation.[119–122] The oxidizing and noncoordinating nature of the solvents may also play a role,[123,124] where chlorinated solvents are known to oxidize some MPc complexes.[119,120]

The presence of two sharp bands near 700 nm (Figure 13b) may suggest demetalation. Addition of a metal salt such as zinc acetate to these solutions resulted in the collapse of the two sharp bands confirming that the peaks were due to demetalation. Partial oxidation was also confirmed by addition of reducing agents.[119] Thus in DCM, $CHCl_3$, THF and toluene, CdPc peripherally substituted with **S14** showed partial oxidation and partial demetalation in addition to aggregation.

ZnPc complexes peripherally octasubstituted with **S10**, **S15**, **S16** and **S17** and the octachlorinated ZnPc [$ZnPc(Cl)_8$] complex showed aggregation behavior in organic solvents even at low concentrations ($< 1 \times 10^{-5}$ M).[36] The UV-visible spectrum of ZnPc complexes peripherally octasubstituted with **S18** showed an extra band[8] (the so-called X-band[125]) in nonpolar or less polar solvents such as benzene

and chloroform, but not in solvents of higher polarity such as DMF, acetone and DMSO. The origin of the X band has been explained in terms of the distortion of the Pc ring due to the presence of eight phenyl groups on the peripheral positions of the phthalocyanine ring.[126]

The axially ligated $X_2Si(IV)Pc$ complexes (where X is the negatively charged axial ligand) containing phenoxy groups (**S18**) on the ring showed spectra typical of a monomeric species.[127] For $X_2Si(IV)Pc$ complexes containing axial hydroxyl ligands, aggregation occurs due to hydrogen bonding between the axial hydroxyl groups.[127]

B. Unmetalated, Group 1 and Group 2 Phthalocyanine Complexes

Phthalocyanine complexes are notorious for their lack of solubility in common organic solvents. Unmetalated Pc complexes are generally less soluble compared to their metalated counterparts. Introduction of substituents onto the Pc ring as well as metalation enhances the solubility of these complexes. Thus, as Table 4 shows, there are fewer studies available on unmetalated phthalocyanines.

Unmetalated phthalocyanine complexes substituted with fluorine and terphenyl ligands gave very high fluorescence quantum yields of $\Phi_F = 0.88$.[128] Unsubstituted H_2Pc exhibits a higher Φ_F value ($\Phi_F = 0.55$) in $CHCl_3$ when compared to the complex tetrasubstituted with $OCH_2C(CH_3)_3$ ($\Phi_F = 0.24$) in Table 4.[129,130] Unmetalated phthalocyanines nonperipherally octasubstituted with long chains gave Φ_F values ranging from 0.05 to 0.10 in DCM.[131] On insertion of the Zn central metal, the Φ_F values increased, ranging from 0.13 to 0.17 (Table 4).[131] Unmetalated phthalocyanines octasubstituted with **S19** gave low Φ_F values in DMSO and polyvinyl chloride (PVC), but the values were found to be higher in THF.[132] For this complex, the Φ_F values were generally higher (in THF and ethyl cellulose, EC) than for the corresponding ZnPc derivative (Table 4).[132]

H_2Pc tetrasubstituted with $(CH_2)_2O(CH_2)_2OCH_3$ gave a low singlet oxygen quantum yield (Φ_Δ) of 0.19, but had a long lifetime in toluene (504 μs).[88] A mixture of solutions of anionic 5,10,15,20-sulfonato-phenyl-porphyrin (TSPP) and a positively charged $H_2Pc(SCH_2CH_2N^+(CH_3)_3CH_3SO)_2(NH_2)_2$ complex gave high Φ_Δ values compared to individual components.[129,133] For the phosphorus dendrimers (**S20**) built from an octasubstituted metal free phthalocyanine core, the fluorescence quantum yield increased with an increase in the number of dendrimers.[134] Both Li_2Pc and Li_2NPc complexes gave the same Φ_T and Φ_F values of 0.6 and 0.5 respectively[50] (Table 4), giving $\Phi_T + \Phi_F$ of ~ 1. This suggested that the dominant radiationless decay path was intersystem crossing for these complexes.

There are only a few studies on the photochemical properties of MgPc derivatives. Unsubstituted MgPc was found to give a Φ_F value of 0.76 (Table 4).[135]

C. Group 4 To 11 Phthalocyanine Complexes

For these groups only the OTi(IV)Pc complexes have been relatively intensely studied. OTi(IV)Pc complexes containing the **S14**, **S22-S25**[136–139] substituents at the peripheral and nonperipheral positions have been studied in a variety of solvents. Φ_F values for nonperipherally tetrasubstituted OTi(IV)Pcs are generally lower than that for the corresponding peripherally substituted derivatives (Table 4). The Φ_F values generally increase (or remain the same) for peripherally substituted derivatives, from tetrasubstituted to octasubstituted derivatives. OTi(IV)Pc complexes substituted with polyethylene glycol units gave Φ_F values which ranged from 0.05 to 0.32 (not in Table 4).[140]

Studies on the triplet state properties of OTi(IV)Pc derivatives are few. However, the Φ_T values range from moderate to high, where the highest value of $\Phi_T = 0.85$ was obtained for a OTi(IV)Pc derivative octasubstituted with **S26** in DMSO.[138] The triplet lifetimes are highly dependent on the solvent and substituents present, and the lowest values were obtained for OTi(IV)Pc octasubstituted with **S14** ($\tau_T = 60$ μs) and **S18** ($\tau_T = 40$ μs) in chloronaphthalene.[139] The Φ_Δ values obtained for the OTi(IV)Pc derivatives octasubstituted with substituent **S26** were high, corresponding to high Φ_T values.[138] The Φ_p values for OTi(IV)Pc complexes were within the range typically obtained for MPc complexes, showing stability.

X_2Zr(IV)Pc complexes (where X = Cl, **L1**, **L2** and **L3**), gave very low Φ_F values ranging from 0.006 to 0.016 (Table 4).[141]For PdPc and NiPc complexes containing long chain substituents, low Φ_F values were obtained (<0.01) due to the open-shell nature of the complexes (Table 4).[142]

D. Group 12 Phthalocyanine Complexes

1. *ZnPc Complexes*

a. *Fluorescence quantum yields (Φ_F)*

ZnPc derivatives are the most intensively studied of all MPc complexes photochemically and photophysically, with substituents ranging from **S14** to **S56**.[9,29,41,143–166] Fluorescence quantum yields (Φ_F) for unsubstituted ZnPc is ~ 0.2[41,157] in DMSO and this value is often employed as the reference for Φ_F determinations of other MPc complexes. Φ_F values for unsubstituted ZnPc range from 0.07 to 0.34 in various solvents (Table 4). The values are influenced by the viscosity of the solvent, where lower values are obtained in less viscous solvents.[37] Of the substituted complexes, there are fewer studies on nonperipherally substituted ZnPc derivatives compared to those that are peripherally substituted (Table 4). For ZnPc complexes octasubstituted with **S18** on the peripheral

positions, the fluorescence excitation and emission spectra exhibited two bands. This is associated with the loss of symmetry due to the twisting of the phenyl ring which distorts the molecule.[41]

Fluorescence of aggregated ZnPc complexes such as $ZnPc(NO_2)_4$ and $ZnPc(NH_2)_4$ complexes occurs from the monomeric component,[157] thus the Φ_F values were found to be very low ($\Phi_F < 0.02$; Table 4) for these complexes as expected. Fluorescence quantum yields were not affected by the addition of cyclodextrin,[157] which is known to prevent aggregation in porphyrins.[167] Halogenation of ZnPc derivatives resulted in a decrease in fluorescence quantum yields as expected, due to the heavy atom effect.[30] A decrease in the Φ_F value was observed from ZnPc ($\Phi_F = 0.17$ in acetone) to $ZnPcF_{16}$, ($\Phi_F = 0.04$), followed by an increase for the $ZnPc(C(CF_3)_2F)_8F_8$ complex ($\Phi_F = 0.39$) in acetone[146] (Table 4). This observation is consistent with the notion that aromatic fluorine groups in $ZnPcF_{16}$ are part of the phthalocyanine π system and thus enhance the intersystem crossing. Aliphatic fluorine groups in $ZnPc(C(CF_3)_2F)_8F_8$ are not conjugated with the phthalocyanine π system, resulting in increased fluorescence lifetimes.[146]

The fluorescence quantum yields obtained for ZnPc tetrasubstituted (at peripheral positions) with bulky substituents such as **S46**, **S47**, **S49** or **S54**, are typical of MPc complexes.[78,159,161] ZnPc complexes tetra(α)- or octa(β)-substituted with the **S48** substituent, also a bulky substituent, gave very low fluorescence quantum yields (0.003 and 0.004, respectively) in DMSO, with complete quenching of its fluorescence in aqueous solutions.[160] Low Φ_F values were also obtained for Zn naphthalocyanine (ZnNPc) complexes and this was explained in terms of the fast degradation of these complexes upon photolysis.[41,157] The Φ_F value of ZnPc in the pentamer (β-tetrasubstituted with four **S37** molecules, $\Phi_F = 0.03$ in DMSO; (Table 4), was much smaller than that for ZnPc alone ($\Phi_F = 0.2$), implying that ZnPc fluorescence is quenched in the presence of the porphyrin substituents.[168] The fluorescence spectra of a phthalocyanine–porphyrin complex containing eight units of zinc tetraphenylporphyrin (**S37**) showed extensive energy transfer between the porphyrin and phthalocyanine moieties.[151] The excitation spectra were slightly different from the absorption spectra in terms of Q-band absorption wavelength, suggesting that changes in the nature of the molecules occur upon excitation. Φ_F values upon excitation at the porphyrin Q-band were found to be very small due to energy transfer taking place from the porphyrin units to the phthalocyanine moieity.[151] For the porphyrin–phthalocyanine heterodimer ($ZnTPP\text{-}O\text{-}ZnPc(C(CH_3)_3)_4$), selective excitation of the porphyrin chromophore resulted in a very efficient energy transfer to the phthalocyanine moiety,[169] resulting in very low Φ_F values compared to the individual components. This was also observed for a porphyrin–phthalocyanine hetero dimer linked by a triple bond[170,171] and ZnPc substituted with four tetraphenylporphyrins (**S37**).[168]

Binuclear ZnPc complexes (complex **4**, Figure 1) containing catechol bridges and substituted with **S18**, **S23** and **S42** gave low Φ_F values (Table 4), and this was attributed to a self-quenching process in the binuclear phthalocyanine complexes.[156] Annulated dinuclear (**5**) and trinuclear (**6** and **7**, Figure 1) ZnPc phthalocyanines containing substituent **S55** gave much lower Φ_F values (< 0.03 for **6** and **7** and 0.08 for **5**) compared to the monomeric complex (Φ_F = 0.28), which is in agreement with the reduction in fluorescence lifetime.[164]

b. *Triplet quantum yields (Φ_T) and lifetimes (τ_T)*

The triplet lifetimes of unsubstituted ZnPc in DMSO is relatively long at 350 μs (Table 4). There were no differences in Φ_T (or τ_T) values for ZnPc when compared to the fully deuterated derivative (ZnPc-d_{16})[48] in toluene containing 1% pyridine.

A relatively low τ_T value was reported for ZnPc β-tetrasubstituted with bulky **S23**,[41] τ_T = 160 μs in DMSO, compared to when ZnPc is β-octasubstituted with **S17** or Cl (τ_T = 370 μs) in Table 4. This was explained in terms of the "loose bolt" effect,[41] which accelerates internal conversion. The τ_T values increased with solvent viscosity for β-octasubstituted ZnPc complexes containing **S28** and Cl as substituents (Figure 14).[100]

The triplet lifetimes increased with a decrease in temperature for the ZnPc complexes containing **S32–S36** as substituents.[147] The degree of aggregation decreased for complexes containing bulky substituents, and increased for long alkyl chain substituents.[147] An efficient intersystem crossing was observed for the heterodimer complex consisting of a positively charged porphyrin and a negatively charged phthalocyanine.[172–174]

For ZnPc β-substituted with **S37**, the triplet lifetime decreased compared to the respective monomers. This decrease was dependent on the number of por-

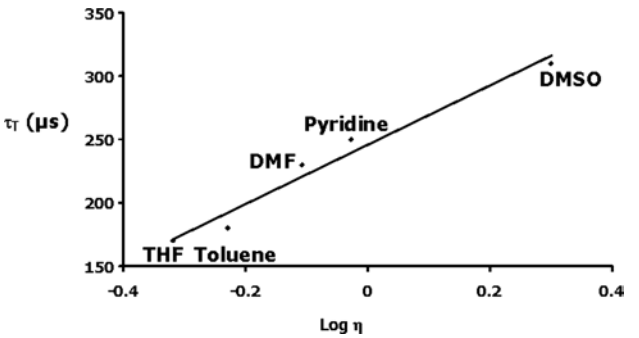

Figure 14. Dependence of ZnPc (**S28** substituent) triplet lifetime on logarithm of solvent viscosities. Reproduced with permission from Ref. 100.

phyrin rings present on the molecules.[168] ZnPc β-tetrasubstituted with **S37** had a triplet lifetime of 230 μs, while the β-octasubstituted derivative gave a τ_T value of 170 μs, in DMSO.[151,168] The triplet quantum yields also decreased with an increase in the number of porphyrin rings: $\Phi_T = 0.12$ for ZnPc (β-tetrasubstituted with **S37**) and 0.04 for ZnPc (β-octasubstituted with **S37**) in DMSO.[151,168] There was a decrease in τ_T values in going from ZnPc ($\tau_T = 77$ μs) to $ZnPcF_{16}$ ($\tau_T < 1$ μs), followed by an increase for the $ZnPc(C(CF_3)_2F)_8F_8$ complex ($\tau_T = 131$ μs) in acetone[146] (Table 4). As discussed above, the differences are explained in terms of changes in the conjugation of the phthalocyanine π system.

Compared with ZnPc ($\tau_T = 350$ μs), the excited states of the complexes **3** and **8** (Figure 1 with τ_T ranging from 90 to 180 μs; See Table 4), were found to be much more short-lived,[54] due to the quenching abilities of naphthalene.[54,148] The binaphthalo complex **8** had a relatively high τ_T (= 150 μs) value (Table 4), which was attributed to its rigid structure. Quantum yields of the triplet state also favor the less aggregated complex **3**, which contains the bulky **S23** substituents.[54] A film of porphyrazine complex **9** was found to have a low τ_T of 26 μs.[155]

c. *Singlet oxygen quantum yields (Φ_Δ)*

In general unsubstituted ZnPc shows higher singlet oxygen quantum yields compared to its substituted derivatives, with a few exceptions such as $ZnPc(SO_3)_{mix}$. For the $ZnPc(NH_2)_4$ complex containing amine functional groups at the β positions, a low Φ_Δ (= 0.11 in DMSO) value was obtained[157] due to the well-known quenching abilities of singlet oxygen by the amino groups, as well as the aggregated nature of this complex. High Φ_Δ values were observed for the monomeric ZnPc peripherally tetrasubstituted with **S23** in DMSO ($\Phi_\Delta = 0.60$)[41,157] and $\Phi_\Delta = 0.58$ in toluene[88] (Table 4). Very high Φ_Δ values were obtained for the monofunctionalized Zn azaphthalocyanines ($\Phi_\Delta = 0.80$) in organic solvents.[175]

For ZnPc complexes β-tetrasubstituted with **S51**, the Φ_Δ values were lower ($\Phi_\Delta = 0.23$ in DMF/water) than for the unsubstituted ZnPc in the same solvent system ($\Phi_\Delta = 56$).[158] The Φ_Δ values increased to $\Phi_\Delta = 0.62$ (for unsubstituted ZnPc) and $\Phi_\Delta = 0.30$ (for **S51** β-tetrasubstituted ZnPc) in benzyl-*n*-hexadecyldimethyl ammonium chloride (BHDC) micelles.[158] For ZnPc complexes β-octasubstituted with **S15–S17**, **S23**, **S41–S43**, aggregation played a significant role in the magnitude of the Φ_Δ values (Table 4).[36] Thus the relatively low Φ_Δ value for **S16** was explained in terms of the aggregated nature of these complexes. ZnPc complexes β-octasubstituted with **S23** gave a larger Φ_Δ value (0.73) in chloroform[36] than in DMSO ($\Phi_\Delta = 0.52$).[176] The $ZnPc(Cl)_8$ complex gave relatively low Φ_Δ values and this is attributed to aggregation.[51] $ZnPc((CH_2)_2O(CH_2)_2OCH_3)_4$ ($\Phi_\Delta = 44$ in toluene) gave a larger Φ_Δ value than the unmetalated $H_2Pc((CH_2)_2O(CH_2)_2OCH_3)_4$

complex with Φ_Δ = 0.19 in toluene (Table 4).[88] Nanoparticles of $ZnPc(C_6C_{13})_7(CH_2)_{11}SH$ complex on gold were found to generate singlet oxygen with higher quantum yields (Φ_Δ = 0.65) compared to their non-nanoparticle form (Φ_Δ = 0.45 Table 4).[153]

A decrease in Φ_Δ values was observed on going from ZnPc (Φ_Δ = 0.17) to $ZnPcF_{16}$ (Φ_Δ = 13) followed by an increase for the $ZnPc(C(CF_3)_2F)_8F_8$ complex (Φ_Δ = 21) in acetone.[146] Axial ligation of ZnPc using cyanide, pyridine and piperidine resulted in a decrease in Φ_Δ. The decrease in Φ_Δ was attributed to the lowering of the triplet energy to a value where energy transfer to ground state oxygen was no longer feasible. ZnPc complexes octasubstituted at the nonperipheral position with two or four **S52** ligands gave very large Φ_Δ values (0.85 and 0.92, respectively).[166] Comparing data obtained for the tetrasubstituted complexes **3** ($R_2 = R_3$) with that for the disubstituted complex **3** (R_3 = H), the latter was observed to have lower Φ_Δ values.[54] The Φ_Δ values for complexes **4** were low compared to the values obtained for monomeric ZnPc and this was attributed to intramolecular coupling of the rings as explained above.[156]

d. *Photodegradation quantum yields (Φ_P)*

ZnPc is stable towards degradation in DMSO[41] compared to some ring substituted derivatives. This was explained in terms of intramolecular vibrations of some ring substituents which quench singlet oxygen as soon as it is formed.[41] The aggregated complexes $ZnPc(NH_2)_4$ and $ZnPc(NO_2)_4$ did not undergo photobleaching, but instead were found to undergo transformation from the aggregated to the monomeric state upon photolysis.[157]

The disubstituted complex **3** (R_3 = H, Figure 1) was found to be generally more stable to photodegradation than the corresponding tetrasubstituted derivative (Complex **3**, $R_3 = R_2$, Table 4). The increase in stability of the former was attributed to the plurality of the bulky substituents which may destabilize the Pc ring in the latter complexes.[54,148]

In general, zinc phthalocyanine complexes β-octasubstituted with the more electron-withdrawing substituted phenoxyl groups (e.g. **S42**) tended to stabilize the phthalocyanine molecule in DMSO in the presence of light.[36] The more electron-donating phenoxyl groups (e.g. **S23** and **S41**) tend to be easily degraded in chloroform,[36] confirming that the photobleaching mechanism involves oxidative degradation of the ring. However in DMSO, ZnPc complexes octasubstituted with **S23** or **S41** were found to be relatively stable[176] (Table 4), through less stable than **S42**. ZnPc complexes octasubstituted with **S15** or **S40** which contain biologically important substituents, i.e. cholesterol and estrone, respectively, were easily degraded in chloroform[36] (Table 4). In THF, ZnPc complexes β-octasubstituted

with **S18** underwent phototransformation rather than photobleaching, resulting in an increase in the low energy band (the X-band), due to the distortion of the ring.[37] $ZnPc(SC_6H_4CH_3)_8$ and $ZnPc(SC_4H_9)_8$ complexes containing thioether substituents were relatively stable ($\Phi_P \sim 6 \times 10^{-5}$; Table 4, with the former showing less stability than the latter, due to the ability of benzene ring to enhance photobleaching.[35,152]

2. *CdPc Complexes*

a. *Fluorescence quantum yields*

The most studied CdPc complexes are those tetrasubstituted with substituents **S2**, **S14**, **S18** and **S23**[118,119,177] at the peripheral and nonperipheral positions. Where there is no aggregation, the absorption spectra are similar to the excitation spectra, and both are mirror images of the emission spectra. The fluorescence excitation and emission spectra of the CdPc containing **S2** were typical of phthalocyanine complexes, with the fluorescence excitation spectrum being a mirror image of the emission spectrum and the latter being similar to the absorption spectra. Hence, no demetalation for this complex upon excitation occurred. However, for CdPc tetrasubstituted with **S14** at the peripheral positions, the excitation spectra show a split in the Q-band in toluene, $CHCl_3$, DCM and THF due to the demetalation discussed above. For this complex, the excitation spectrum was similar to the absorption spectrum of an umetalated derivative, suggesting that the loss of symmetry is due to demetalation upon excitation.[118,119,177]

The fluorescence quantum yields of CdPc derivatives tetrasubstituted with substituents **S18** and **S23** at the nonperipheral positions are generally high in THF and chloroform, compared to MPc complexes in general (Table 4). As discussed above, even though the CdPc derivatives containing **S14** are demetalated in some solvents, it is expected that the heavy atom effect of Cd will still influence the Φ_F values. The Φ_F values for these complexes are typical of MPcs. For CdPc containing **S2** substituents,[118,119] low Φ_F values were obtained for peripheral substitution as expected on the basis of the heavy atom effect of Cd. However, this was not the case for nonperipherally substituted derivatives. Unsubstituted CdPc shows low Φ_F and high Φ_T, as expected for complexes with heavy atoms (Table 4).

b. *Triplet quantum yields and lifetimes*

The Φ_T values for the CdPc derivatives in Table 4 correspond to Φ_F to the extent that, where the values of the latter are low, the former values are high. For CdPc peripherally tetra substituted with **S18**, the sum of Φ_T (0.87) and Φ_F (0.13) was

unity in DMF. This suggests that the dominant radiationless decay path was intersystem crossing for these complexes, as was observed for Li_2Pc and Li_2NPc complexes.[50] The triplet lifetimes for the CdPc derivatives are generally low in Table 4 due to the heavy atom effect.

c. *Photochemistry*

When considering the Φ_Δ values, there is a trend towards lower yields for those phthalocyanines substituted with (benzyloxy)phenoxyl groups (**S14**), particularly at the peripheral positions. This suggests that these groups reduce the ability of the molecules to produce singlet oxygen efficiently, since large Φ_T values were obtained. However, the Φ_Δ values for CdPc containing **S14** at nonperipheral positions were not as low as that for the peripheral substitution (Table 4). The differences could be a result of the change in symmetry upon excitation, as discussed above for the CdPc complexes peripherally substituted with **S14**. Some CdPc complexes containing pyridyloxy substituents (**S2**) underwent phototransformation rather than photodegradation, as indicated by a shift in the Q-band maxima. The phototransformation was ascribed to some distortion of the pyridyloxy-substituted phthalocyanine macrocycle upon exposure to intense light.[118] For CdPc, peripherally substituted with **S14**, no phototransformation or photodegradation was observed in some solvents (toluene, $CHCl_3$, THF and DCM), since no decrease in absorption intensity was observed. The stability of this complex was ascribed to partial oxidation in these solvents.[118] Coordinating solvents such as DMSO are capable of protecting the molecule against oxidative attack, while non-coordinating solvents leave the molecule prone to oxidative attack, giving rise to a high Φ_P yields.

3. *HgPc Complexes*

For HgPc complexes containing an **S2** substituent at the peripheral position, the fluorescence emission spectrum was different from the absorption spectrum in that the former was broad. This suggests the loss of symmetry for the fluorescing molecule, which is most likely due to demetalation as observed for the CdPc complexes above.[119] HgPc complexes containing the **S2** substituent at the peripheral position gave the lowest Φ_F value when compared to the corresponding CdPc and ZnPc derivatives.[119] The order of fluorescence quantum yield values is ZnPc ($\Phi_F = 0.077$) > CdPc ($\Phi_F = 0.013$) > HgPc ($\Phi_F = 0.005$) for these complexes in DMSO. This trend is also observed for the unsubstituted complexes, and is expected due to the spin-orbit coupling induced by the respective central metal ions. In general, the effect of introducing pyridyloxy substituents (**S2**) to peripheral positions on

the HgPc ring is a reduction in Φ_F values (Table 4) when considering the same solvent.[119] The substituents perhaps encourage the deactivation of the excited singlet state via nonradiative means (intersystem crossing and internal conversion) rather than via fluorescence.

As expected, the HgPc complex containing **S2** substituents at peripheral positions has the lowest triplet lifetime when compared to the corresponding ZnPc and CdPc complexes. The order of triplet lifetimes with respect to the central metal ions is Zn(II) (τ_T = 350 μs) > Cd(II) (τ_T = 30 μs) > Hg(II) (τ_T = 20 μs). It is clear from Table 4 that HgPc derivatives give higher Φ_Δ (0.78) and Φ_T (0.89) values than the corresponding ZnPc derivatives (Φ_Δ = 0.46 and Φ_T = 0.80) containing **S2** substituents in DMSO.

E. Group 13 Phthalocyanine Complexes

1. *XAl(III)Pc Complexes*

The studies on non-water soluble XAl(III)Pc complexes (X = negatively charged axial ligand) are limited, since research has focused on water soluble derivatives as indicated above. Given that Al(III) is a small ion, unsubstituted XAl(III)Pc predictably has large Φ_F values ~0.65.[111] Polymer-bound chloroaluminum tricarboxymonoamidephthalocyanine gave a lower Φ_Δ value compared to the unbound (in solution) complex.[178] Singlet oxygen production is restricted on polymers due to decreased lifetimes of the triplet state.[178]

2. *XGa(III)Pc and XIn(III)Pc Complexes*

a. *Fluorescence quantum yields*

The most studied complexes are those that are unsubstituted or those containing **S1**, **S14**, **S18** and **S23** as substituents.[179–189] XGa(III)Pc and XIn(III)Pc complexes are often studied together, so in this work they will also be treated likewise. With a few exceptions, the shapes of the excitation spectra are similar to absorption spectra, both are mirror images of the fluorescent spectra for ClGa(III)Pc complexes. For the tetra(peripheral or nonperipheral)- and octa(peripheral)-substituted ClIn(III)Pc containing **S14** substituents, the shape of the excitation spectra was different to the absorption spectra in that the Q-band of the former showed splitting, unlike the narrow Q-band observed for the latter. This suggests that there are changes in the molecule following excitation, most likely due to loss of symmetry. However, this was not observed for the corresponding ClGa(III)Pc complexes. The difference in the behavior of ClGa(III)Pc and ClIn(III)Pc upon excitation was explained in terms of the larger indium metal that is more displaced from the core

of the phthalocyanine ring. The displacement becomes more pronounced upon excitation, causing a loss of symmetry.

Table 4 shows that the Φ_F values of ClGa(III)Pc complexes are in general typical of MPc complexes. These values are slightly higher for peripherally substituted derivatives compared to the nonperipherally substituted complexes, suggesting less quenching of the excited singlet state by peripheral tetrasubstitution compared to nonperipheral tetrasubstitution. For the ClIn(III)Pc complexes in general, the Φ_F values are very low due to an enhancement in intersystem crossing caused by the presence of the heavier indium atom.

b. *Triplet quantum yields and lifetimes*

For both ClGa(III)Pc and ClIn(III)Pc derivatives, there was a change in spectra following laser irradiation. The spectral changes involved a decrease in the Q-band and an increase in absorption near 590 nm (Figure 15).[188] However, upon exposure of the solution to air, the Q-band increased in intensity and the band around 590 nm decreased, suggesting that this band was due to reduction products of the complexes.[190] The first ring reduction in MPc complexes was characterized by a decrease in the Q-band and the formation of weak bands between 500 and 600 nm.[190] Thus during laser irradiation, the ClGa(III)Pc and ClIn(III)Pc derivatives were partly transformed into an anion (Pc^{-3}) species. The suggested mechanism for the formation of Pc^{-3} in the presence of H donors is shown by Eqs. 29 to 31 (where S–H is an acidic solvent):

$$MPc + h\nu \rightarrow {}^3MPc^* \quad (29)$$

$${}^3MPc^* + S\text{–}H \rightarrow MPc^{\bullet -} + S\text{–}H^{\bullet +} \quad (30)$$

$$MPc^{\bullet -} + O_2 \rightarrow MPc + O_2^{\bullet -} \quad (31)$$

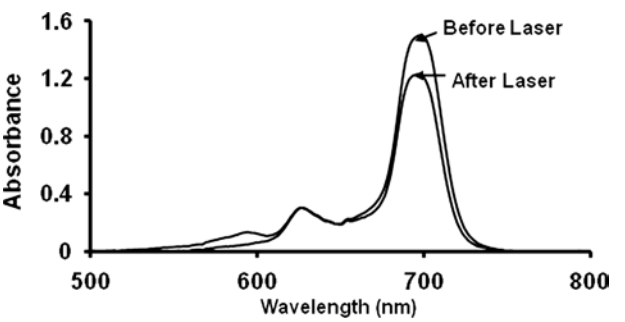

Figure 15. Absorption spectral changes of In(III)Pc tetrasubstituted with **S14** before and after laser irradiation. Reproduced with permission from Ref. 188.

For a series of indium and gallium phthalocyanine monomers as well as bridged dimers, the ClGa(III)Pc complexes were found to have much longer triplet lifetimes compared to the corresponding ClIn(III)Pc complexes, due to the heavy atom effect of In.[173,174]

For complexes **10** and **11** (Figure 1, both naphthalocyanine-based and containing Ga(III) as the central ion), the τ_T values were low in chloroform (ranging from 14 to 21 μs).[181,182] However, for complex **12** (Figure 1, Ga(III) central ion) containing oxygen and **L5** bridges, high τ_T values (357 and 667 μs respectively) in toluene were obtained (Table 4).[183] ClIn(III)Pc complex **12** (Figure 1) containing oxygen ($\tau_T = 42$), **L6** ($\tau_T = 35$) and **L7** ($\tau_T = 22$) bridges gave relatively low τ_T values (Table 4).[183,185,187] The Φ_T values of unsubstituted ClAl(III)Pc, ClGa(III)Pc and ClIn(III)Pc complexes increased with the size of the central metal as follows: ClAl(III) ($\Phi_T = 0.4$) < ClGa(III) ($\Phi_T = 0.7$) < ClIn(III) ($\Phi_T = 0.9$), while the Φ_F values correspondingly decreased (ClAl(III) ($\Phi_F = 0.58$) > ClGa(III) ($\Phi_F = 0.31$) > ClIn(III) ($\Phi_F = 0.031$), in 1-chloronaphthalene due to the heavy atom effect.[189]

In the case of ClGa(III)Pc containing the **S14** substituents, the trend of singlet oxygen quantum yields (in DMSO) was as follows: nonperipherally tetrasubstituted ($\Phi_\Delta = 0.69$) > peripherally tetrasubstituted ($\Phi_\Delta = 0.62$) > peripherally octasubstituted ($\Phi_\Delta = 0.51$). The same trend applied for ClIn(III)Pc derivatives substituted with **S14**, with $\Phi_\Delta = 0.94$, 0.87 and 0.78 respectively. As expected, due to the heavy atom effect ClIn(III)Pc complexes show larger singlet oxygen quantum yields in general (Table 4). The ClGa(III)Pc and ClIn(III)Pc complexes show about the same stability, with Φ_P of the order of 10^{-5} to 10^{-4}.[191] These complexes are however, generally less stable than the corresponding ZnPc derivatives (Table 4).

F. Group 14 and 15 Phthalocyanine Complexes

1. *Photophysics*

a. *X_2Si(IV)Pc complexes*

The axial ligands studied for these complexes range from **L9** to **L28** (Table 4). The most studied complexes are the X_2Si(IV)Pc derivatives.[127,192–196] X_2Si(IV)Pc complexes containing **L12** as the axial ligand (4-*tert*-butylbenzoic acid), giving a rigid conformation, gave a high Φ_F value of 0.62.[195] μ-Oxo Si(IV)Pc complexes containing two, three or four Si(Pc) units showed triplet lifetimes and yields which decreased with an increase in the number of units (Table 4).[196] The change in the nature of axial ligand for Si(IV)Pc complexes has some effect on the fluorescence quantum yields[44,127] (Table 4) ranging from $\Phi_F = 0.02$ to 0.34 for axial ligands OH, Cl, **L13**–**L16** β-octasubstituted with the same ring substituent (**S18**) (Table 4).

β-Octa-chlorinated (Φ_F = 0.73) or brominated (Φ_F = 0.34) Si(IV)Pc complexes containing two poly(ethylene glycol) axial ligands (**L17**) show a larger Φ_F value (in DMF) for the chlorinated complex since bromine encourages intersystem crossing more than chlorine[192] (Table 4), being larger in size.

For unsubstituted X_2Si(IV)Pc complexes containing a series of axial ligands (including phenyl, terphenyl, thienyl and pyrenyl systems), the Φ_F ranged from 0.31 to 0.84 in DCM (values not in Table 4) with the thiophene ligands giving significantly lower Φ_F.[197] It was suggested that the electron-rich thiophene group may quench the excited state by an electron transfer mechanism resulting in a lower value for Φ_F.[197] For unsubstituted Si(IV)Pc complexes containing axial ligands **L10** and **L11**, τ_T values decreased on substitution of one of the axial ligands with a hydroxyl ligand (Table 4).[145]

In the case of the axially ligated X_2Si(IV)Pc complexes containing OH, Cl, **L13–L16** axial ligands and β-octasubstituted with **S18**,[44] triplet state lifetimes vary according to the degree of aggregation, with the aggregated complex (containing OH ligands) showing a shorter lifetime compared to the rest of the complexes in the series (ranging from 194 to 356 μs)[44] in Table 4. For Si(IV)Pc complexes β-octasubstituted with **S18** and containing axial ligands OH, Cl, **L13–L16**, the Φ_T values were low, ranging from 0.29 to 0.43[44] (Table 4).

b. *Other group 14 and 15 phthalocyanine complexes*

The Φ_F values for octasubsubstituted X_2Ge(IV)Pc derivatives are typical of MPc complexes in Table 4. For Cl_2Sn(IV)Pc complexes, Φ_F values are less than 0.01 for tetrasubstituted derivatives due to the size of the Sn central metal ion, but these values increase on octasubstitution (Table 4). The Φ_T values were lower for the $(Cl)_2$Sn(IV)Pc (β-octasubstituted with **S18**, **S40** and **S45**) derivatives compared to the corresponding $(Cl)_2$Ge(IV)Pc derivatives.[45,186] Triplet quantum yields were not affected greatly by changes in axial ligands for X_2Sn(IV)Pc derivatives. The X_2Sn(IV)Pc complex containing estrone (**L9**) as an axial ligand showed very short triplet lifetimes (τ_T = 18 μs), and uncharacteristically low triplet quantum yields (Φ_T = 0.08).[45] The τ_T values were found to be very low for $(Cl)_2$Sn(IV)Pc derivatives in general, ranging from 10 to 32 μs (β-octasubstituted with **S18**, **S40** and **S45**) compared 168 to 340 μs for the corresponding ClGe(IV)Pc complexes (Table 4.)[45]

$[(OH)_2Sb(V)Pc]^+$ complexes showed very low Φ_F values ($\leq$ 0.01) regardless of the axial ligand or peripheral substituent.[198,199] PbPc complexes substituted with **S18** or **S23** gave low Φ_F values due to the presence of the heavy Pb ion. These complexes were demetalated upon excitation, but the effects of the Pb ion (in solution) will still affect the fluorescence behavior.[200,201] This also results in high Φ_T values ranging from 0.70 to 0.88 in Table 4. Phosphorus phthalocyanine

complexes exhibit Φ_F values which are typical of MPc complexes in general, but also show low Φ_T values ($\Phi_T < 0.6$),[202] while high τ_T values were observed for some PPc complexes (Table 4).[202]

2. *Photochemistry*

The Φ_Δ values did not vary much for unsubstituted $(OH)_2$Ge(IV)Pc ($\Phi_\Delta = 0.25$), $(OH)_2$Sn(IV)Pc ($\Phi_\Delta = 0.26$), and $(OH)_2$Si(IV)Pc ($\Phi_\Delta = 0.28$) complexes in DMSO (Table 4).[63] Φ_Δ values for complexes **1** containing Ge(IV), Sn(IV) or Si(IV) as central metals were low, ranging from 0.15 (Sn(IV)), to 0.17 (Ge(IV)) and 0.21 (Si(IV)).[63] When comparing Cl_2Sn(IV)Pc, Cl_2Ge(IV)Pc and Cl_2Si(IV)Pc β-octasubstituted with the same peripheral (**S18**), an increase in Φ_Δ with an increase in the size of the central metal was observed as follows: Si(IV) ($\Phi_\Delta = 0.14$) < Ge(IV) ($\Phi_\Delta = 0.18$) < Sn(IV) ($\Phi_\Delta = 0.22$) in DMSO, due to the heavy atom effect.[45] This effect was also used to explain the higher Φ_Δ value obtained for the Cl_2Ge(IV)Pc complex when the axial chloride ligands are replaced by the iodide ligands.[45,63] For complex Cl_2Sn(IV)Pc containing estrone ligands (**S40**) on the periphery, the Φ_Δ value was similar to when estrone was located axially.[45] For a series of axially substituted Si(IV)Pc derivatives peripherally β-octasubstituted with **S18** and containing axial ligands (OH, Cl, **L13–16**, **L18–28**), the Φ_Δ values varied to some extent with the axial ligand[127] and were generally low, ranging between 0.03 and 0.41 (Table 4).

Photolysis of the less aggregated tetrapyridinoporphyrazine complexes (**1**) containing Sn(IV) or Si(IV) as the central metals in DMSO resulted in degradation accompanied by reduction of the ring. Thus the complexes exhibited a strong tendency towards reductive quenching of the excited states.[63] Attempts to photobleach Ge(IV)Pc complexes containing **S18**, **S40** and **S45** substituents resulted in the reduction of the central Ge(IV) ion to the Ge(II)Pc species,[45] with the Ge(II)Pc compound being stable to photodegradation. However, the corresponding Sn(IV)Pc complexes did not show phototransformation to the Sn(II)Pc species. For the latter complexes, there was evidence of photoreduction of the Pc ring during the photobleaching process with a mechanism similar to Eqs. 29–31.[45]

For Si(IV)Pc complexes containing Cl and **L13–L16** as the axial ligands, attempts to photobleach the Pcs resulted in the well-known axial ligand transformation into a hydroxyl group for all complexes.[44]

V. Photocatalytic Reactions

The use of Pc complexes in oncology as photosensitizers for malignant tumor treatment by photodynamic therapy (PDT) is well-documented and is part of the

current series (see Volume 4). PDT will therefore not be discussed in this chapter, which concentrates on selected photocatalytic reactions of industrial (such as oxidation of alkenes) and environmental importance (such as photodegradation of pollutants). Photodegradation of toxic sulfur compounds, phenols and chlorinated phenols are known to be catalyzed by MPc complexes.[203–231]

Sulfur-containing compounds, such as mercaptans, alkali sulfides, alkali sulfites, and alkali thiosulfates are byproducts of industrial processes and are pollutants in waste and natural waters.[209] The presence of sulfide ions in industrial wastewater (from the oil-processing industry, paper manufacturing, and synthetic fiber production) is of great environmental concern. The complete oxidation of sulfur-containing compounds is an essential solution to environmental problems.

Phenols are widespread in nature and are also produced by normal human metabolism from tyrosines. The bactericidal properties of phenols make them useful in natural defense mechanisms in biological systems. Phenolic compounds may be released into the environment in a number of ways, including during the manufacture of industrial products such as plastics, pharmaceuticals, dyes and pesticides (e.g. pentachlorophenol). Insecticides containing toxic nitrophenols are used in agriculture and tend to persist in the environment.

The oxidation of olefins into useful products is of immense industrial interest. For example, epoxides are useful intermediates obtained on catalytic oxidation of alkenes that are widely used for petrochemicals, fine chemicals and polymers such as oxygen-containing natural products or production of epoxy resins. Use of molecular oxygen as an oxidant for the transformation of alkenes is preferred as it is cheap, environmentally friendly and readily available.[232–234]

Phthalocyanines are employed as sensitizers in the oxidation of chemicals via singlet oxygen since they are able to generate singlet oxygen. Both Type I and II mechanisms may be involved during the photocatalytic degradation or transformation of molecules using MPc complexes. Table 5 summarizes the phenols, sulfur containing compounds and alkenes which are photodegraded by MPc complexes.

A. Sulfur-Containing Compounds

Wöhrle and coworkers developed phthalocyanine complexes for the photocatalysis of sulfur compounds under homogeneous or heterogeneous (impregnated on SiO_2, Al_2O_3, charcoal and TiO_2) conditions.[203] The catalytic and photocatalytic oxidations of sulfide, thiol and phenol derivatives were studied. Heterogeneous photocatalysis resulted in higher activities than homogeneous catalysis. The phthalocyanine and naphthalocyanine complexes studied for photocatalysis included those containing Mg, Al(III), Si(IV) and Zn. Photocatalytic activity of

the oligomers were found to be higher than that of the analogous low molecular weight complexes.[203] 2-Mercaptoethanol, used as an example of a thiol, was photooxidized to the corresponding sulfonic acid.[203]

ZnPc and ClAl(III)Pc are efficient photocatalysts for the oxidation of thiolates or sulfides to sulfonic acids or sulfate. Co-sensitizers involving phthalocyanines $ZnPc(SO_3)_4$ or Ge(IV)Pc (containing substituent **S8**) and CTAC were employed for the photooxidation of 2-mercaptoethanol in aqueous alkaline solutions.[76] Compared to single-component sensitizers, an improvement in the photocatalytic activity is observed in the case of co-sensitization. CTAC reduces aggregation which would otherwise lower photocatalytic activity due to low singlet oxygen quantum yields. $ZnPc(SO_3)_4$ and $ZnPc(COOH)_4$ were studied for the photooxidation of 2-mercapto-ethanol and sodium thiosulfate.[216] In the presence of CTAC, quinoline and ethanol additives, $ZnPc(SO_3)_4$ and $ZnPc(COOH)_4$ were monomerized, resulting in an increase in photocatalytic activity as stated above for CTAC. Monomerization in the presence of quinoline is enhanced due to axial coordination of the base to the central metal atom in the complexes, which impedes the π–π interactions between the phthalocyanine complexes. Increasing solvent viscosity enhances the self-association of the phthalocyanine complexes, lowering photocatalytic activity.[216]

B. Phenols

1. *Phthalocyanine Complexes on Supports*

The homogeneous and heterogeneous photocatalytic oxidation of chlorinated phenols in the presence of oxygen or hydrogen peroxide and MPc complexes has been researched extensively.[215–228] The oxidation products for unsubstituted phenols have been determined to be mainly carbonate and maleic/fumaric acids when using phthalocyanine complexes.[203]

The association of TiO_2 and ZnPc resulted in a small increase (< 6%) in the photodegradation efficiency of phenol over TiO_2 alone. This behavior was expected since the light employed had a maximum absorption at 360 nm, where there is insignificant absorption by ZnPc,[222] showing the need for visible light excitation of the MPc complexes. The photooxidation of phenol was catalyzed by metal-free phthalocyanine (H_2Pc) supported on Al_2O_3 or TiO_2 in the presence of visible light.[223] The rate of phenol photooxidation catalyzed by H_2Pc/TiO_2 was much higher than that obtained for H_2Pc/Al_2O_3. The high photocatalytic activity of the sample is explained by an electron transfer from the conduction band of the excited H_2Pc semiconductor particles to the conduction band of TiO_2 support.[223]

OHAl(III)Pc or ClAl(III)Pc were supported on aminopropyl silica and/or exchange resins and employed for the photocatalytic oxidation of phenol.[221] Resins included IRA 67, IRA 96, Amberlite 200, Amberlite XAD 8, and Dowex. On the whole, the electronic absorption spectra of the grafted photosensitizer were close to its absorption spectra in the homogeneous state. However, the bonding to the support inhibited the photosensitizer, resulting in a loss of the photosensitizing efficiency in some cases. In order to prevent self-quenching or nonaccessibility of the substrate, the amount of the photosensitizer on the support was kept at a low level.[221]

Bentonite was modified with cetyltrimethylammonium bromide (CTMA), then ClAl(III)Pc was inserted successfully into the interlamellar space of CTMA-modified bentonite and employed as a photosensitizer.[226] Under visible light irradiation, the composite catalyst exhibited good photocatalytic activity for degradation of pollutants such as phenol, 4-chlorophenol, 4-nitrophenol, 2,4-dichlorophenol, and 2,4,6-trichlorophenol in an aerated aqueous medium. It was noted, however, that during repeated experiments, the degradation rate of 2,4,6-trichlorophenol was gradually decreased, due to some intermediates formed and sorbed onto the catalyst surface.[226]

(OH)Al(III)Pc$(COOH)_4$ easily adsorbs onto SiO_2, Al_2O_3, and TiO_2 from DMF/aqueous solutions with no desorption. Adsorption of an (OH)Al(III)Pc$(COOH)_4$ onto the TiO_2 surface resulted in a reusable material to perform selective photocatalytic oxidations under visible light irradiation. 4-Chlorophenol was mostly decomposed into CO_2 and chloride ions when an Al(III)Pc$(COOH)_4$/TiO_2 catalyst was employed.[227] Injection of electrons into the semiconductor conduction band from the excited dye leaves a radical cation, initiating the oxidation reactions in these systems. TiO_2 was found to be superior to SiO_2 and Al_2O_3 in terms of the photocatalytic degradation of 4-chlorophenol in the presence of (OH)Al(III)Pc$(COOH)_4$.[227] The products of photodegradation of 4-chlorophenol are CO_2 and Cl^- (Table 5). (OH)Al(III)Pc$(COOH)_4$/TiO_2 was also found to catalyze the photodegradation of 2-chlorophenol, 2,4-dichlorophenol, 2,4,6-trichlorophenol, catechol and others.[227] ZnPc$(COOH)_4$, CuPc$(COOH)_4$ and CoPc$(COOH)_4$ were also found to show photocatalytic activity for the degradation of 4-chlorophenol under visible light.[227] However CuPc$(COOH)_4$ and CoPc$(COOH)_4$ showed low photoactivity, due to their short lifetime in the triplet state.

In another study, TiO_2 sensitized with ZnPc$(COOH)_4$ and CoPc$(COOH)_4$ showed improved photocatalytic activity for the degradation of phenol using visible light.[225] Photodeposition of platinum on MPc$(COOH)_4$/TiO_2 enhanced reaction photoefficiency from ~ < 0.05 (without Pt) to 0.1 (with Pt) in Table 5. The enhanced degradation in the presence of Pt was explained in terms of platinum electron trapping, which is fast enough to compete with electron back transfer,

thereby increasing the probability of interaction with molecular oxygen to form highly reactive oxygen species. The main product of the photooxidation was CO_2.[225]

Hydroxoaluminium tricarboxymonoamide phthalocyanine [(OH)Al(III)Pc-$(COOH)_3(NH_2)$] was adsorbed onto TiO_2 and employed for the photocatalytic degradation (using visible light) of different substrates which included phenol, thiophenol and 4-chlorophenol. The radical cation of the phthalocyanine, produced by electron injection of the dye into the TiO_2 conduction band, was found to be the species responsible for the oxidation of the substrates.[228]

It is known that the most active photocatalysts for the photodegradation of pollutants are phthalocyanines bearing Al, Zn and Si central atoms.[217] FePc is not expected to be effectively activated by the photon flux. However, the photocatalytic activity of FePc (in the presence of hydrogen peroxide) has been reported.[215] FePc adsorbed on silica (FePc/SiO_2) has higher intrinsic activity towards the degradation of phenol in water, than when encapsulated within NaY zeolite (FePc@NaY).[215] While adsorption on silica was reported to be more simple with the solid exhibiting higher photocatalytic activity, FePc/SiO_2 was not found to be suitable in organic media in which iron phthalocyanine may become soluble and/or self-degraded. The preparation of FePc@NaY was more complicated, but permanent immobilization was achieved, rendering a more durable photocatalyst for reuse.[215]

Dioxoiron phthalocyanine tetrasulfonate ($FeO_2Pc(SO_3)_4$) was incorporated inside the space of a layered double oxide hydoxides (LDH).[220] The resulting material exhibited an optical spectrum characteristic of isolated metalated phthalocyanine. Laser flash photolysis of the solid showed the $FeO_2Pc(SO_3)_4$ complex to have a long-lived transient (> 2 ms). The solid is able to act as an effective photocatalyst for the degradation of phenol in aqueous media.

2. *Phthalocyanine Complexes in Solution*

$CuPc(SO_3)_4$ was found to be an effective photocatalyst for the degradation of 4-chlorophenol, 2,4-dichlorophenol and 2,4,6-trichlorophenol in aerated aqueous solutions under visible light ($\lambda > 450$ nm) irradiation.[229] The $CuPc(SO_3)_4$ photosensitizer was found to be stable and could be used repeatedly.[229]

The oxidation of phenol and its chlorinated derivatives (2-chlorophenol, 3-chlorophenol, 4-chlorophenol, 2,6-dichlorophenol and 2,4,6-trichlorophenol) was photocatalyzed by $MPc(SO_3)_n$ (M = OHAl, Zn or $(OH)_2Si$).[218] The chlorinated phenols were transformed at higher rates than phenol with 4-chlorophenol identified as the most reactive molecule with the highest achieved quantum yield of 0.61% at pH 10 (Table 5).[218] The photooxidation of phenol and 2-, 3- and

4-monochlorophenols by irradiation with visible light in aqueous alkaline solutions in the presence of (OH)Al(III)Pc$(SO_3)_4$, (OH)Ga(III)Pc$(SO_3)_4$ and Zn Pc$(SO_3)_4$ as well as oxygen have been reported.[224] The stabilities of the photosensitizers were found to be strongly dependent on the pH and aggregation tendency. The photooxidation products included carbon dioxide and maleic or fumaric acid (Table 5).[224]

Carboxylated polymeric Al and Zn phthalocyanines were also found to be more photocatalytic towards the oxidation of 2-mercaptoethanol than their mononuclear counterparts.[205,206] The photocatalytic activity of the polymer (complex **13**, Figure 1) was also found to be much higher than that for the monomers in the oxidation of phenols.[208] The high photoactivity of the polymers was explained by the presence of intra-molecular triplet–triplet energy transfer between the phthalocyanine macrocycles. The products of the oxidation of phenols in an alkaline medium were the same for both the mono- and polynuclear phthalocyanine complexes that were employed as photocatalysts.[208] Maleic and fumaric acids as well as carbon dioxide were obtained as the final products of the photooxidation.[208] The formation of quinones (Scheme 5) is an intermediate step during the photocatalytic oxidation of phenols at pH 13, before the final destruction of the substrate.[208]

The use of lanthanide diphthalocyanines (complex **14**, Figure 1) as photocatalysts for the degradation (phototransformation) of chlorophenols has been reported.[17] Lutetium diphthalocyanine is an intrinsic semiconductor. Irradiation of catalysts with semiconductor properties such as $NdPc^{2-}$ generates electrons (e^-) and holes (h^+). Once the electrons and holes are produced, the electron scavenging action of molecular oxygen prevents the recombination of the electron–hole pairs. The formation of reactive hydroxyl radicals produced by the reaction between the photogenerated hole, h^+, and OH^- or H_2O is known to be the primary oxidizing agent for the photomineralization of organic pollutants over semiconductor catalysts.

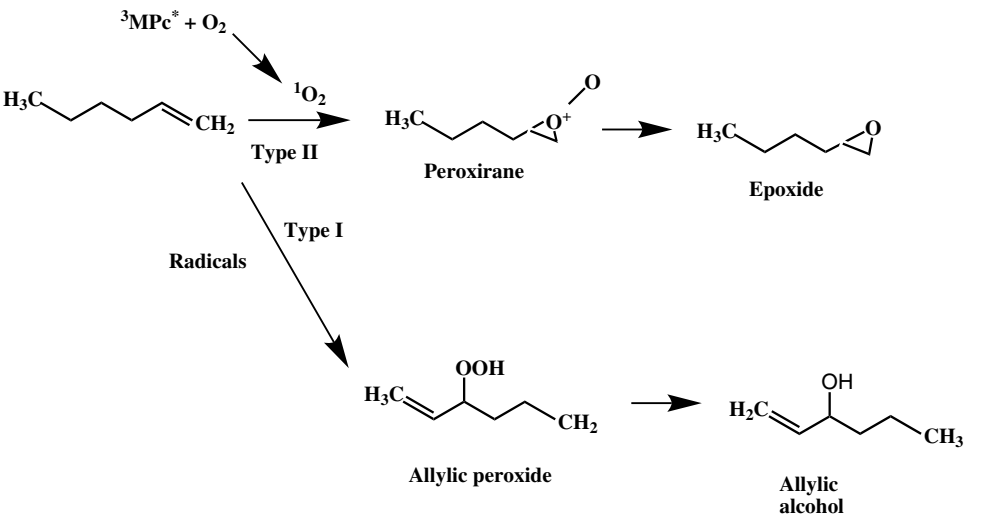
C. Alkanes and Alkenes

Literature on the use of MPcs as alkene and alkane photocatalysts is scanty; therefore, only a few reports are listed in Table 5. The photocatalytic activities of the various OTi(IV)Pc, ClGa(III)Pc and ClIn(III)Pc complexes towards the oxidation of 1-hexene in the presence of oxygen resulted in 2-epoxyhexane as the main product and 1-hexen-3-ol as the minor product.[136,210] In addition, a correlation was observed between the photocatalytic trends and singlet oxygen quantum yields.

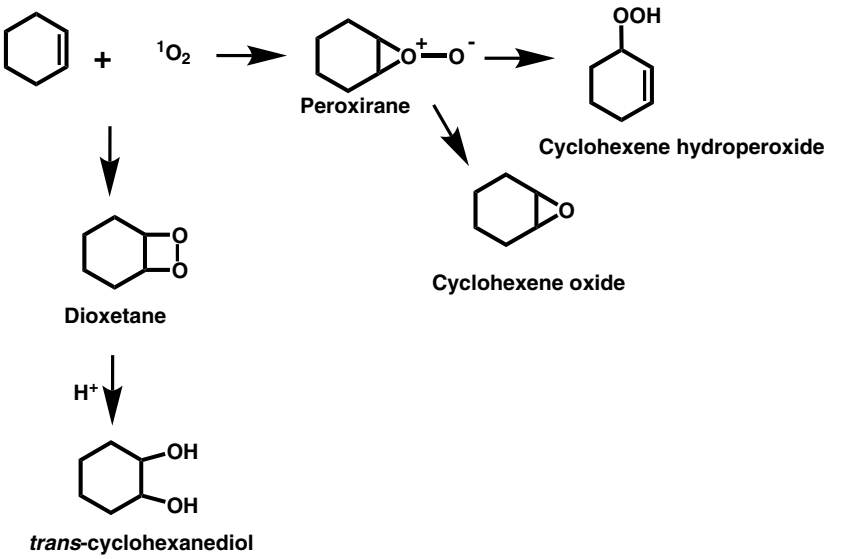
The mechanisms involved (Type I, Scheme 2 or Type II, Scheme 1) in the production of the oxidation products were determined by the use of 1,4-diazabicyclo[2.2.2]octane (DABCO, singlet oxygen quencher) and a radical quencher, 2,6-di-*tert*-butyl-4-methylphenol (BHT). Singlet oxygen was found to be the sole active species in the production of the epoxide, and the radicals were responsible for the formation of the allylic alcohol. Thus, both Type I and Type II mechanisms were involved (Scheme 6). The yields for the products were higher for ClGa(III)Pc and ClIn(III)Pc complexes when compared to OTi(IV)Pc complexes, probably due to larger singlet oxygen quantum yields.[136,211]

ZnPc was employed as a photocatalyst for cyclohexene oxidation, with the following trend in product yield being observed: cyclohexenone > cyclohexene hydroperoxide > cyclohexenol > *trans*-cyclohexane diol > cyclohexene oxide. The suggested mechanism for the formation of the products is shown in Scheme 7.[20]

Excitation of phthalocyanines populates the triplet state, effecting the generation of singlet oxygen which subsequently attacks the Pc complexes, causing



Scheme 6. Proposed mechanism for the formation of the photooxidation products of 1-hexene. Reproduced with permission from Ref. 136.



Scheme 7. Suggested mechanism for the formation of photolysis products of cyclohexene. Modified from Ref. 20.

decomposition of the Pc. Electron-withdrawing substituents have been shown to increase catalyst stability and therefore improve product yields.[20] However, unsubstituted or sulfonated MPc complexes tend to decompose upon photolysis, as judged by the decrease in the intensities of both the Q- and Soret bands, for both red and white light.[20,205] For ZnPc, degradation was found to be more pronounced with white light than with red light.[20] The rate of degradation is also affected by light intensity, with low intensity light giving less degradation as expected.

VI. Conclusions

The triplet state, singlet oxygen, photobleaching and fluorescence quantum yields, as well as triplet lifetimes of MPc complexes are hugely affected by the nature of substituents and by the aggregation behavior of the complexes. Water solubility is essential for PDT action as well as other applications of Pc complexes; thus, many studies have been conducted in water and have concentrated on XAl(III)Pc and ZnPc derivatives. A recurring problem, however, is the aggregation behavior of the conventional water soluble MPcs, such as those tetrasubstituted with carboxylic or sulfonated groups. This review shows that there are some known MPc complexes that are water soluble but not aggregated.

The most important parameter for the application of MPc complexes is the singlet oxygen quantum yield. Many factors are responsible for the magnitude of

the determined quantum yield of singlet oxygen. These include: triplet excited state energy, ability of substituents and solvents to quench the singlet oxygen, the triplet excited state lifetime and the efficiency of the energy transfer between the triplet excited state and ground state oxygen. The triplet quantum yields increase for complexes with heavier central metals due to the heavy atom effect, which inevitably shortens the triplet lifetimes. There is considerable literature on singlet oxygen generation ability of the Zn phthalocyanine complexes, with less attention being paid to the other non-transition metals or metalloids (e.g. Ge(IV), Si (IV), Sn(IV), Ga(III) and In(III)) Pcs. Photodegradation generally depends on the structure of the molecule, concentration, solvent and light intensity.

The photocatalytic degradation of a selection of environmental pollutants and industrially important molecules using MPc complexes is also presented in this chapter. There are still very few reports on the use of MPc complexes as photocatalysts compared to their use as catalysts in the presence of oxidants. This is an area where MPc complexes may be applied with a great deal of success, although MPc complexes that are stable to light, such as halogenated derivatives are necessary.

35 Structure, Spectroscopy, Photophysics, and Tautomerism of Free-Base Porphycenes and Other Porphyrin Isomers

Jacek Waluk

Institute of Physical Chemistry, Polish Academy of Sciences,
Kasprzaka 44, 01-224 Warsaw, Poland

List of Abbreviations

CPMAS	cross-polarization magic angle spinning
DFT	density functional theory
EPR	electron paramagnetic resonance
ENDOR	electron-nuclear double resonance
HB	hydrogen bond
HOMO	highest occupied molecular orbital
LCAO	linear combination of atomic orbitals
LUMO	lowest unoccupied molecular orbital
MCD	magnetic circular dichroism
NMR	nuclear magnetic resonance
OECp	2,3,6,7,11,12,17,18-octaethylcorrphycene
OEIPc	2,3,6,7,13,14,17,18-octaethylisoporphycene
OEHPc	2,3,6,7,12,13,17,18-octaethylhemiporphycene
OEPc	2,3,6,7,12,13,16,17-octaethylporphycene
OEPr	2,3,7,8,12,13,17,18-octaethylporphyrin
PDT	photodynamic therapy
PPP	Pariser–Parr–Pople method
TPP	5,10,15,20-tetraphenylporphyrin
TPPo	2,7,12,17-tetraphenylporphycene

I. Introduction

Nature relies upon porphyrins in many fundamental processes involving living matter and light. In photosynthesis, for instance, chlorophylls and bacteriochlorophylls play several roles, acting as light-harvesting pigments and participating in charge separation and transport. Myoglobin and hemoglobin, the proteins responsible for

oxygen binding, transport, and storage, owe their function to the heme prosthetic group, made up of an iron porphyrin. The same compound can also bind nitric oxide or carbon monoxide. Another heme protein, cytochrome *c*, does not bind oxygen, but owing to its redox properties is an essential component of the electron transport chain. In turn, vitamin B_{12} contains a corrin moiety — a reduced porphyrin-like structure with a Co^{2+} ion. Cobalt–porphyrin-containing enzymes are involved in the biosynthesis of hydrocarbons. In a patent, it was proposed to use cobalt-porphyrin complexes as antiobesity agents.[1] All these facts demonstrate that it is quite appropriate to refer to porphyrins as "pigments of life".[2] One should recall in this context that the green color of leaves, the red color of blood, and various hues of red in meat are due to the porphyrin chromophore. Actually, *πορφυριων* (*porphyrion*) is the Greek word for purple.

An enormous number of applications involving porphyrins have been proposed. The Patent Storm US database returns above 15,000 entries with "porphyrin" as a keyword. The corresponding number from a Scopus patent search is 19,500. Among various possible applications, artificial photosynthetic units or dye-sensitized solar cells are extremely promising for photovoltaics. Porphyrins are widely used in photodynamic therapy (PDT) for cancer treatment, in photodiagnostics, and as catalysts and biomimetic models. The prospects of exploiting porphyrin-based nanostructures for sensing applications have been reviewed.[3]

Designing a porphyrin-based system for a particular purpose requires a desired modification of structural, electronic, or spectral parameters. These can be controlled, albeit to a limited degree, by appropriate substitution. Much larger room for improvement is available if the four pyrrole moieties are connected in a different fashion than is found in porphyrin, while maintaining the general $C_{20}N_4H_{14}$ formula and the π-electron conjugated pathway. The synthesis of porphycene, first reported by Vogel and coworkers in 1986,[4] initiated a new area of research, devoted to constitutional isomers of porphyrin. If the N_4 coordination site is to be preserved, the four pyrrole and four methine units can be reshuffled in eight different ways, as demonstrated in a theoretical paper.[5] Thus, seven "nitrogen-in" constitutional isomers of porphyrin can be envisaged. Of those, four have been synthesized as of now: porphycene (**2**), hemiporphycene[6,7] (**3**), corrphycene[8,9] (**4**), and isoporphycene[10,11] (**5**) (Figure 1). In a more systematic nomenclature, each of these compounds may be called [18]porphyrin-(n_1.n_2.n_3.n_4), where the number in square brackets indicates the number of π electrons in the conjugation path and n_i ($0 \le n_i \le 4$) denotes the number of the methine groups in each bridging unit, starting with the highest value and going toward the next highest one. The parent compound can thus be called [18]porphyrin-(1.1.1.1), and porphycene is [18]porphyrin-(2.0.2.0), whereas the names [18]porphyrin-(2.1.1.0), [18]porphyrin-(2.1.0.1), and [18]porphyrin-(3.0.1.0) correspond to hemiporphycene,

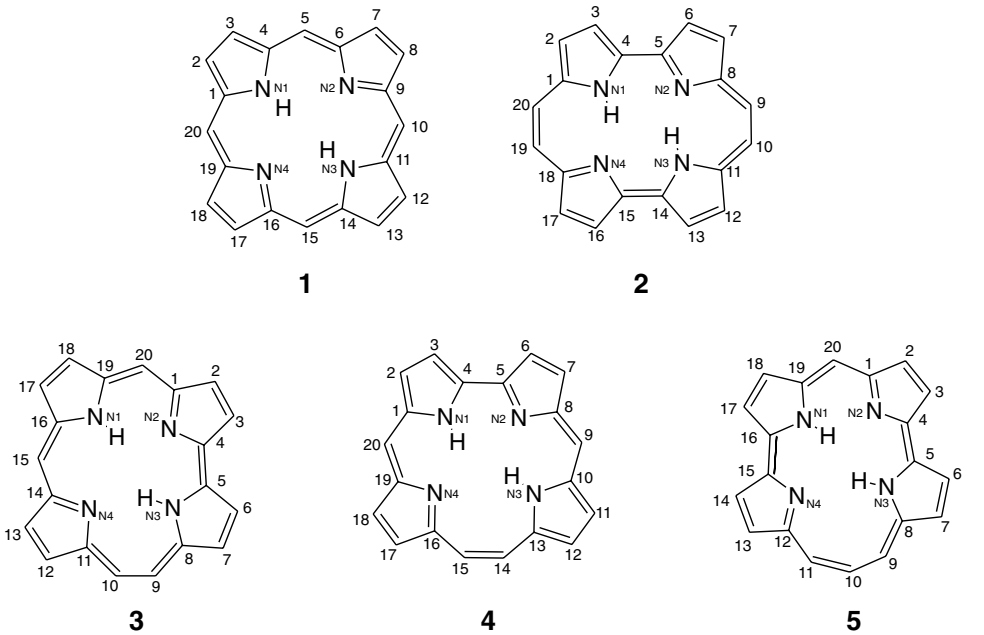

Figure 1. Porphyrin (**1**), porphycene (**2**), hemiporphycene (**3**), corrphycene (**4**), and isoporphycene (**5**). The formulas correspond to the most stable tautomeric form of each isomer (See Table 1).

corrphycene, and isoporphycene, respectively. Interestingly, the chronological order of syntheses of porphyrin isomers correlates with their calculated relative energies (Table 1). One can also see that for porphycene a lower energy is predicted than for porphyrin. This is due to exceptionally strong intramolecular hydrogen bonds in the former. For metal complexes, the energy ordering is reversed, making metalloporphyrins more stable. The highest energies are expected for the three molecules which have not yet been obtained: [18]porphyrin-(2.2.0.0) (**6**), [18]porphyrin-(3.1.0.0) (**7**), and [18]porphyrin-(4.0.0.0) (**8**).

Another type of porphyrin isomer was obtained, initially in the form of *meso* tetraaryl-substituted derivatives, at about the same time as corrphycene and hemiporphycene. In this molecule one of the pyrrole units has its nitrogen atom pointing outward. Accordingly, it has been dubbed inverted[12] or N-confused[13] porphyrin (**9**). These studies were followed by successful syntheses of various core-modified porphyrins, in which the CH unit was replaced by a heteroatom such as O, S, Se, Te.[14,15]

After the initial studies of porphycene, it became obvious that even though the basic properties of the porphyrin chromophore are preserved in the isomer, the quantitative characteristics can be very different. For example, the electronic absorption spectra in the low-energy range are red-shifted and much more intense

Table 1. Calculated relative energies (kcal/mol) of porphyrin isomers. The values correspond to the lowest-energy tautomeric form of each isomer (see formulas **1**–**8**).

	BLYP/6-31G** //3-21G[a]	B3LYP/6-311+G** //6-31G[b]	B3LYP/6-31G**[c]

than those of the parent compound, which suggested that porphycenes may be better phototherapeutic agents than porphyrin. This hypothesis was soon corroborated[16]; the studies of photodynamic properties of porphycenes are now quite intense.[17] A still unexploited area is the use of porphycenes in artificial light-harvesting systems.

While the investigations of corrphycene, hemiporphycene, and, in particular, isoporphycene have been rather limited, this is not the case for porphycene. About 300 derivatives have been described so far. Most of a few hundred porphycene-related patents propose this chromophore as a photosensitizer in PDT. Other patent applications involve, besides synthetic procedures, information storage, and use of porphycenes as optical recording media, in catalysis, fluorescence immunoassays, molecular imaging, tissue marking, and drug delivery tracking.

With regard to fundamental research, porphycenes have become model molecules for studying the mechanisms of intramolecular double hydrogen transfer, both experimentally[18–40] and theoretically.[41–50] Several factors make porphycenes ideal for that purpose. First, the geometry of the two intramolecular hydrogen bonds is well defined and insensitive to the environment. On the other hand, the hydrogen bond (HB) geometry can be significantly modified by peripheral substitution. Depending on the position of a substituent, both strengthening and weakening of the HBs are possible. Moreover, the substitution pattern can be selected in such a way that the symmetric double minimum character is either preserved or destroyed. A low potential energy barrier facilitates tunneling; the consequences can be monitored both in condensed phases and in the regime of isolated molecules. The spectral and photophysical properties of porphycenes, such as absorption and strong emission in the red spectral region, make them readily amenable to various experimental techniques, including those of high spectral and temporal resolution. Finally, the presence of two intramolecular HBs provides an opportunity to study cooperative effects, both in hydrogen bonding and in proton/hydrogen transfer.

Previous reviews of isomeric porphyrins included both free-base and metal derivatives,[51–57] providing detailed information on synthetic aspects and redox properties. The latter have been studied quite intensely,[58–67] whereas the spectroscopic and photophysical properties have been reviewed less frequently.[19,68,69] The applications of porphycenes in phototherapy have been summarized recently.[17] The present work focuses on structural, spectroscopic, photophysical, and tautomeric properties of free-base porphyrin isomers. After discussing the geometries, in particular the inner cavity parameters crucial for the intramolecular HB characteristics, we analyze the electronic structure. A simple molecular orbital approach is described, which enables one to explain and to predict differences in the electronic absorption patterns of different isomers. Next, photophysical

properties are presented. Understanding both spectral and photophysical behavior is a prerequisite for successful applications based on chromophore–light interactions. Finally, the mechanisms of tautomerism are discussed for ground and electronically excited states. Because porphycenes have been studied much more intensely than other isomers, they are the main object of this work. The relevant data for other porphyrin isomers will be reviewed as well, whenever available.

II. Structure

A. Symmetry and Planarity

The mode of reshuffling of pyrrole units determines the symmetry of the ensuing isomer. Parent free-base porphyrin belongs to the D_{2h} group; in metalloporphyrins the symmetry is even higher — D_{4h}. The corresponding symmetries are C_{2h} and D_{2h} for porphycene, and C_s and C_{2v} for corrphycene. Parent porphycene is planar[4]; an essentially planar ring structure has been found also for 2,7,12,17-tetra-*n*-propylporphycene **10**,[70] 9,10,19,20-tetra-*n*-propylporphycene **11**,[71] 9,10,19,20-tetraphenylporphycene **12**,[72] 2,3-dihydroporphycene **13**,[73] and 2,7,12,17-tetraethyl-3,6,13,16-tetramethylporphycene (etioporphycene, **14**).[74] For the last, replacement of the methyl by ethyl groups, leading to 2,3,6,712,13,16,17-octaethylporphycene (OEPc, **15**), introduces a slight twist[74] (Figure 2).

An interesting pattern is obtained through gradual substitution of 2,7,12,17-tetra-*n*-propylporphycene by bromine in the β' positions (3,6,13,16). In the mono-, dibromosubstituted (at positions 3 and 13) and tribromosubstituted (3,6,13) derivatives, **16**–**18** respectively, the macrocycle is reported to be planar, but it becomes

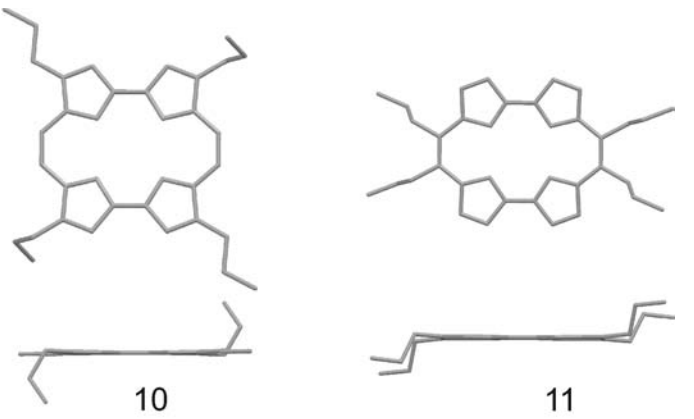

Figure 2. Front and side views of X-ray-determined structures of several free-base porphycene derivatives: **10**,[70] **11**,[71] **12**,[72] **13**,[73] **14**,[74] and **15**.[74] Hydrogen atoms have been omitted for clarity.

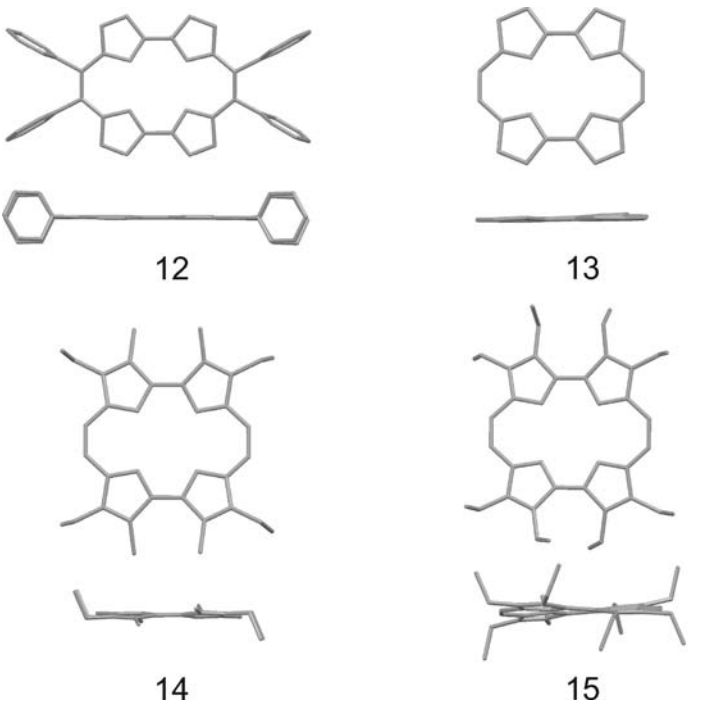

Figure 2. (*Continued*)

distorted in 3,6,13,16-tetrabromo-2,7,12,17-tetra-*n*-propylporphycene **19**.[75] For the last compound, three papers report quite different degrees of distortion.[75–77]

The unsubstituted corrphycene has not yet been obtained. 2,3,6,7,11,12,17,18-Octaethylcorrphycene (OECp, **20**) has a planar macrocyclic ring.[9] An intriguing observation is that in the crystalline phase both protons are located at the adjacent nitrogens belonging to the bipyrrole unit. Such a *cis* tautomeric form (**20a**) is

	R^1	R^2	R^3	R^4

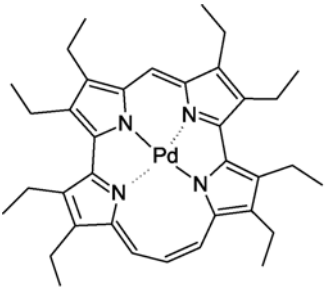
22

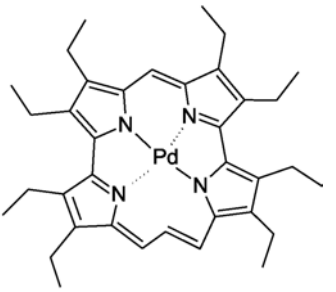
predicted by calculations performed for the parent corrphycene to be less stable than the *trans* structure **20** (see Table 3). The NMR data indicate that the latter predominates in solution. Protonation of two cavity nitrogens leads to a strongly nonplanar structure.[78]

Both free-base and metallohemiporphycenes can have at most C_s symmetry, provided that they are planar. Synthesis of the unsubstituted hemiporphycene has not been reported so far. The crystallographic analysis of free-base 2,3,6,7,12,13,17, 18-octaethylhemiporphycene (OEHPc, **21**)[7] reveals a nearly planar conformation, whereas in nickel,[6,56] zinc,[56] magnesium,[56] and iron[79] complexes the macrocycle is slightly saddle-shaped. An even larger distortion from planarity is observed for 5-iodo-6,11,16-triphenylhemiporphycene **22**.[80]

In isoporphycene, the trimethine moiety can assume *cis* or *trans* conformations. Both isomers were isolated in the form of palladium complexes of octaethylisoporphycene (**23a** and **23b**) and found to be almost planar.[7] However, in the *trans* (*E*) isomer **23b**, the central atom of the C_3 bridge lies 0.44 Å above the molecular plane. As in the cases of hemiporphycene and corrphycene, isoporphycene has not yet been obtained in the parent, unsubstituted form.



23a



23b

The general tendency predicted by calculations for the high-energy isomers **6**–**8** is that they should be essentially planar in the (*Z*) configuration, whereas the (*E*) structures can be somehow distorted from planarity.[41]

The symmetry can be different for different tautomeric forms of a given isomer. The symmetry predictions given above were based on calculations, which revealed that the most stable structure corresponds to a *trans* form, with the protons on the opposite pyrrole rings. The planar (if possible) *cis* tautomers of porphycene, as well as two out of three *cis* forms of corrphycene, isoporphycene, and **8**, should reveal C_{2v} symmetry. On the contrary, the *cis* forms of **6** should exhibit lower symmetry (C_s) than the *trans* ones.

Geometry optimizations performed at the B3LYP/6-31G** level yield planar structures for all the tautomeric forms of porphyrin and corrphycene. In the other isomers some tautomeric forms become nonplanar, most probably due to the repulsion of the inner hydrogens. The nonplanar structure is predicted for one of the *cis* tautomers of porphycene (**2b**, Figure 8), one of the four possible *cis* forms of hemiporphycene (**3e**, Figure 13), and two tautomeric species of isoporphycene (**5b** and **5c**, Figure 10). In **6**, of the two pairs of *trans* and *cis* forms one is planar (**6** and **6b**, Figure 12), while the other is not (**6a** and **6c**). For **7** (in the *Z* configuration), the planar structure is predicted for only two out of six possible tautomers: the *trans* structure **7** and the *cis* form **7c** (Figure 14). Finally, geometry optimization of **8** yields nonplanar geometry for all possible tautomers (Figure 11).

The shape and size of the internal N_4 cavity are crucial for both metal coordination and intramolecular hydrogen bonding properties. The calculated and experimentally determined N–N distances are shown in Table 2. For parents **1** and **2**, the agreement between experimental and computational results is good. It becomes much worse if the predictions based on calculations for the unsubstituted isomers **3**–**5** are confronted with the experimental data for octaethyl derivatives. The reason is the sensitivity of the geometry of the inner cavity to the substituent, as discussed in the following section.

Table 2. N–N distances (pm) of the inner cavity of porphyrin isomers. Calculated using B3LYP/6-31G** for the lowest-energy tautomer of each form. In parentheses are experimental values.

B. Influence of Substituents on the Geometry of the Internal Cavity

The size of the internal N_4 cavity in porphyrin is remarkably stable with regard to four-fold or eight-fold symmetrical substitution by alkyl or aryl groups. This is illustrated in Figure 3, where the N–N distances are compared for parent porphyrin **1**[81–83] and its derivatives: 2,3,7,8,12,13,17,18-octaethyl- (OEPr, **24**),[84] 5,10,15,20-tetra-*n*-propyl- (**25**),[85] and 5,10,15,20-tetraphenyl- (TPP, **26**).[86,87] An analysis of the Cambridge Crystallographic Database, containing above 500 variously substituted free-base porphyrins, revealed that in about 80% of the compounds the N–N distances oscillate around 292 ± 10 pm. On the other hand, it is possible to strongly distort the cavity, making it rectangular, by substitution, by either aryl or alkyl groups at the opposite *meso* positions, as shown in Figure 3 for 5,15-diphenylporphyrin (**27**)[88] and 5,15-di-*n*-butyl-2,3,7,8,12,13,17,18-octaethylporphyrin (**28**).[89]

Structural studies of the alkyl derivatives of porphycene demonstrate that the dimensions of the N_4 core are significantly affected by the substitution pattern. Interestingly, the same substituent, when placed at different positions, can either decrease or increase the N–N distances (Figure 4). Four-fold alkyl substitution at the *meso* positions (9,10,19,20) leads to a more rectangular cavity, as shown in Figure 3 for the tetramethyl-, (**29**) tetra-*n*-propyl- (**11**),[71] and tetraphenyl- (**12**)[72] derivatives. The opposite effect is obtained in β,β'-octaalkylporphycenes, illustrated by the examples of octaethyl- (**15**)[74] and etioporphycene **14**.[74] Finally, in 2,7,12,17-tetraalkyl derivatives, such as tetra-*n*-propyl- (**10**)[70] and tetra-*tert*-butyl- (**30**), the size of the cavity remains similar to that of the parent, unsubstituted

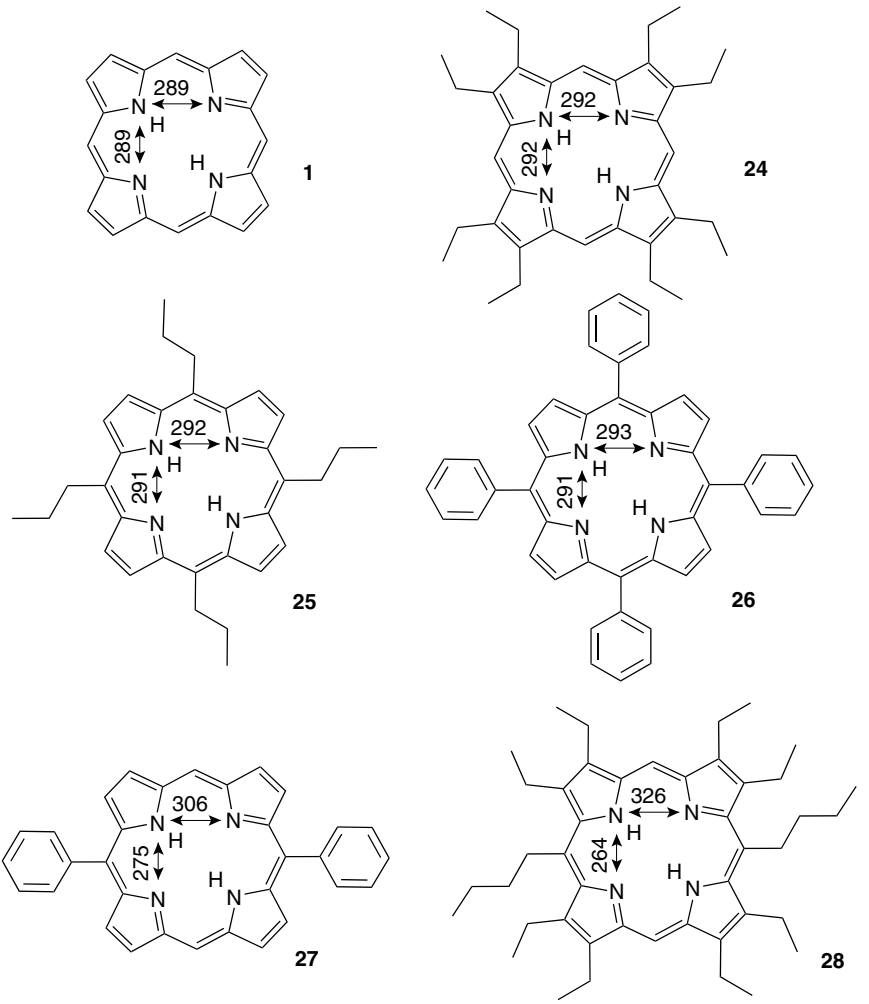

Figure 3. Crystallographically determined internal cavity dimensions (in pm) in differently substituted porphyrins: **1**,[81–83] **24**,[84] **25**,[85] **26**,[86,87] **27**,[88] and **28**.[89]

compound, strongly suggesting that the changes observed for octaalkyl derivatives are mainly due to substituents at the β' positions (3,6,13,16). This conclusion was confirmed by calculations, but has not yet been established experimentally. A strongly distorted structure has been reported for 2,7,12,17-tetraethyl-3,6,13,16-tetrakis(trifluoromethyl)porphycene **31**[90] (Figure 5).

A gradual evolution of the cavity dimensions was observed upon consecutive brominations in β' positions[75] (Figure 6). The first bromine substitution does not noticeably change the geometry of the inner core (see structure **10** in Figure 4). Subsequent introductions of bromine atoms result in the reversal of the short and

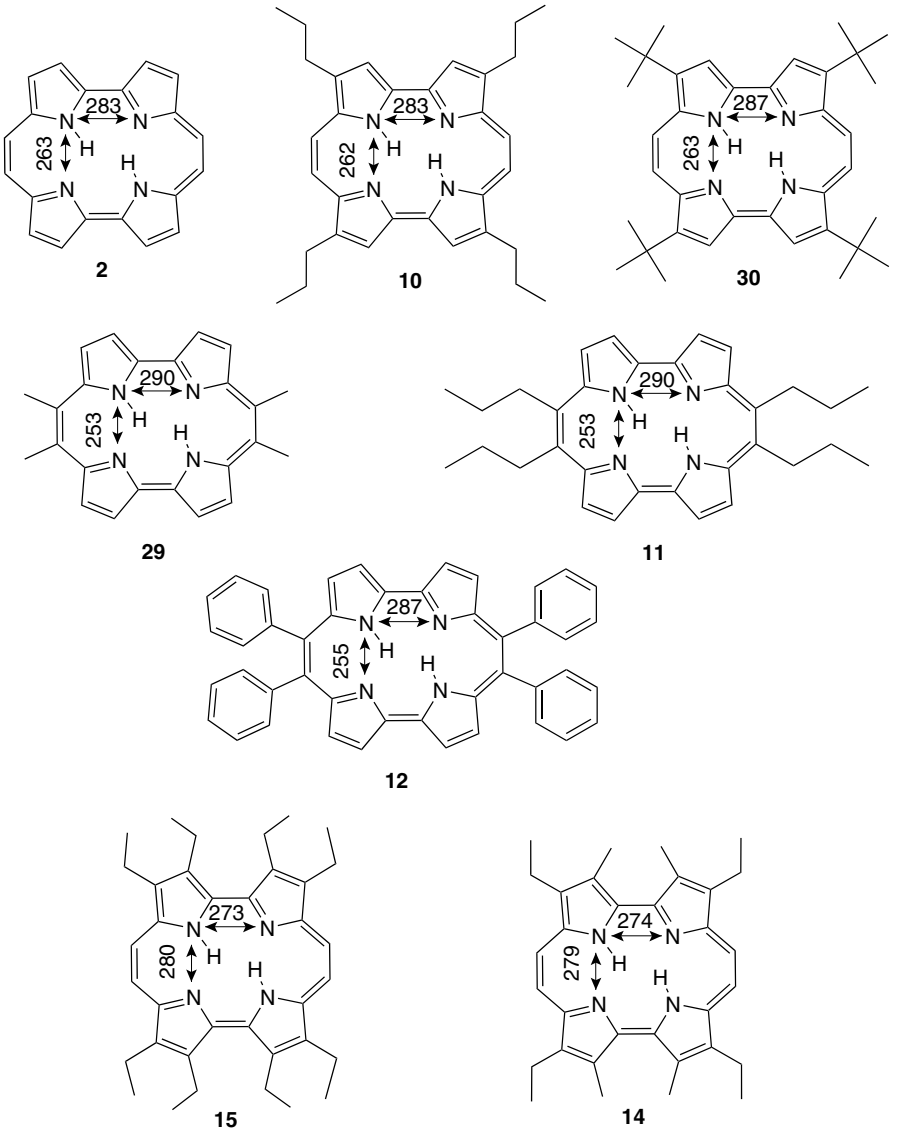

Figure 4. Crystallographically determined internal cavity dimensions (in pm) in differently substituted porphycenes: **2**,[4] **10**,[70] **30**, **29**,[71] **11**,[71] **12**,[72] **15**,[74] and **14**.[74]

long sides of the cavity. In the tetrabromosubstituted derivative **19**, the cavity dimensions are the same as in OEPc **15**.

The position-dependent sensitivity of the porphycene inner core to substitution has a large impact on the strength of two intramolecular hydrogen bonds and on the rate of double hydrogen transfer. As discussed in more detail in Section V,

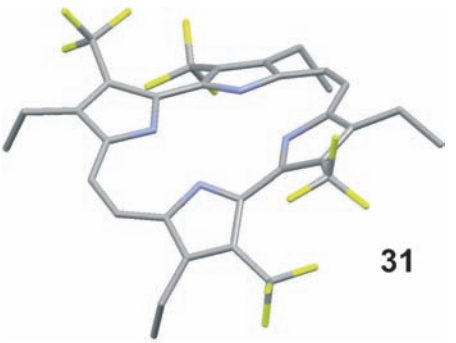

Figure 5. X-ray structure of 2,7,12,17-tetraethyl-3,6,13,16-tetrakis(trifluoro-methyl)porphycene.[90] Hydrogen atoms have been omitted for clarity.

changing the NH···N distance from 2.80 Å in 2,3,6,7,12,13,16,17-octaethylporphycene **15** to 2.53 Å in 9,10,19,20 tetramethylporphycene **29** or tetra-*n*-propylporphycene **19** results in nearly four orders of magnitude larger tautomerization rates in the *meso*-substituted derivatives, in which the smaller NH···N separation

makes the hydrogen bonds much stronger. It is also instructive to note that fourfold *meso* substitution by methyl and *n*-propyl groups leads in both cases to the same changes in the cavity dimensions, which suggests that the electronic rather than steric factors are of primary importance for the geometry modifications.

C. *Cis–Trans* Tautomerism

The two inner protons may be distributed between the four nitrogens in several ways. In the *trans* form, the protons are positioned at the opposite pyrrole rings, whereas the *cis* structures correspond to their location on the adjacent pyrroles. The *trans* tautomers are predicted to be thermodynamically more stable (Table 3); the relative energies presented in Table 1 for the lowest energy structures of each isomer all correspond to such forms. The number of possible nonequivalent *cis*

Table 3. Relative energies (kcal/mol; in parentheses, the values including zero-point energy correction) and dipole moments calculated (B3LYP/6-31G**) for different tautomeric forms of porphyrin isomers. The energies are given with respect to the lowest-energy tautomer of each isomer.

and *trans* forms increases with lowering of molecular symmetry. Thus, one *trans* and one *cis* tautomer are expected for porphyrin. More correctly, two chemically equivalent *trans* (**1′** and **1″**) and four equivalent *cis* tautomers (**1a′**–**1a″″**) exist, described by symmetric double or quadruple minimum potentials (Figure 7). One

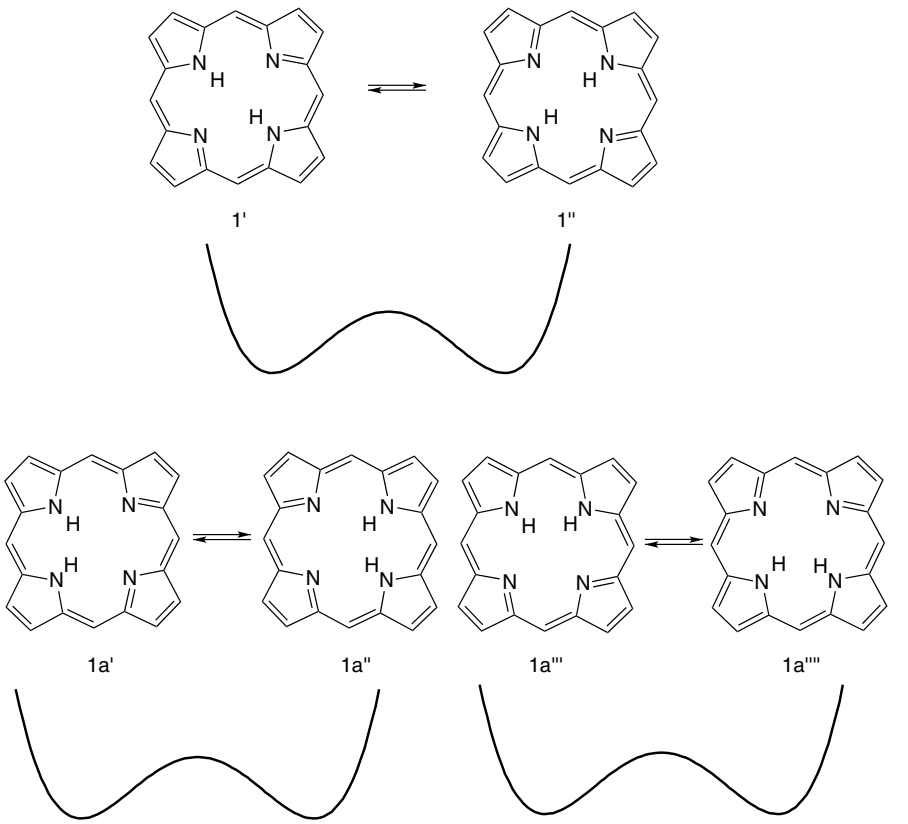

Figure 7. *Trans* (top) and *cis* (bottom) tautomers of porphyrin. Symmetric potential for hydrogen exchange has been schematically indicated.

should note that the four-fold degeneration of the *cis* tautomers does not necessarily imply equal energy barriers for their interconversion. Thus, while the same barrier may be expected for the 1a′–1a″ and 1a‴–1a⁗ transformations, this is not the case for e.g. 1a′–1a‴, if the former process occurs in a concerted fashion. For a conversion such as 1a′–1a‴, a stepwise mechanism is preferable, involving a *trans* form as an intermediate. The interconversion between the equivalent forms, often called a self-exchange process, may be monitored by such techniques as NMR,[18,24,33,37,91–93] or electronic and IR spectroscopy using polarized light.[20,31,32,34–36,94–96] In the regime of an isolated molecule, the two inner protons are delocalized between the four nitrogens, which gives rise to tunneling splittings. These have been observed for porphycene isolated in supersonic jets[22] or helium nanodroplets,[40] and for *meso*-alkylated derivatives in supersonic beams[30] (see Section V).

For porphycene, one pair of equivalent *trans* tautomers and two pairs of equivalent *cis* forms are possible (Figure 8). Corrphycene can exist as a pair of equivalent *trans* structures, but for the *cis* form a symmetric double minimum is

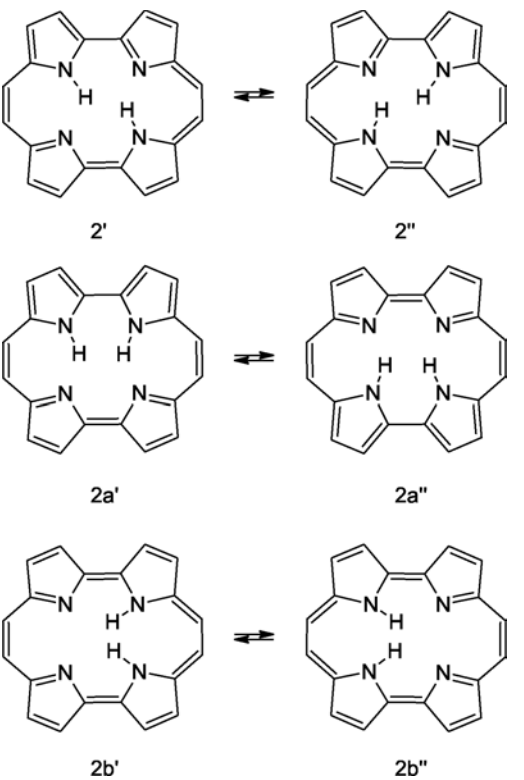

Figure 8. *Trans* and *cis,* pairwise–degenerate tautomers of porphycene.

possible only for one out of three different species (**4c** in Figure 9). The same situation arises for isoporphycene (Figure 10) and [18]porphyrin-(4.0.0.0) **8** (Figure 11). For [18]porphyrin-(2.2.0.0) **6**, two nonequivalent *trans* tautomers and two pairs of degenerate *cis* forms are possible (Figure 12). No degeneracies are expected for hemiporphycene (Figure 13) and [18]porphyrin-(2.2.0.0) **7** (Figure 14). These molecules can assume two *trans* and four *cis* forms, each corresponding to a different energy. Considerations of *E/Z* isomerism and nonplanarity show a

possibility of lifting the degeneracy and/or increasing the number of tautomeric forms.[41,97,98] Moreover, the relative energies of the *E* and *Z* forms may be changed by substitution. This was demonstrated for free-base isoporphycene.[98] DFT calculations show that the *Z* isomer has lower energy than the *E* form in the parent

compound, but in the octaethylderivatives (analogous to **23a** and **23b**) the ordering is reversed.

III. Spectroscopy

A. Electronic Absorption Spectra

Free-base porphyrins reveal a characteristic electronic absorption pattern.[99] In solutions at room temperature, at least four bands of moderate intensity are observed in the region between 660 and 500 nm. The relative intensities of the bands vary for different derivatives. This observation led to empirical classification into three types: etio, rhodo, phyllo.[100] These so-called Q bands are followed by a very strong transition around 400 nm, referred to as a Soret band. Both Q and Soret bands correspond to two π–π^* electronic transitions. In the parent free-base porphyrin, D_{2h} symmetry dictates that the transition moments in both Q and Soret pairs be orthogonal and lie in the molecular plane. The notation Q_x and Q_y was introduced, reflecting the polarization along the NH–HN direction (Q_x) or perpendicular to it (Q_y). In most cases, the Q_x transitions are observed at lower energies than Q_y. A characteristic is a strong vibronic component lying between the origins of Q_x and Q_y bands. Quite often, its intensity is higher than that of the 0–0 transition of Q_x.

In lower symmetry porphyrins, the Q_x/Q_y notation is no longer strictly correct. It can be replaced by using Q_1 and Q_2, where the indices indicate the energetic order. A more general notation, based on the perimeter model,[99,101–107] refers to the Q transitions as L_1 and L_2, whereas the transitions responsible for the Soret band are denoted as B_1 and B_2.

Qualitatively, the same absorption pattern is preserved in porphyrin isomers, although quantitative differences are substantial and vary for different species. The largest changes are observed between porphyrin and porphycene, particularly in the Q region. Comparison between the electronic absorption spectra of porphyrin **1** and porphycene **2** (Figure 15) shows that the Q (L) bands in porphycene are shifted to the red and the Soret (B) transitions to the blue with respect to their locations in porphyrin. Most spectacular is the increase in Q band intensity, by approximately an order of magnitude, and the reversal of the intensity pattern of vibronic structure: the origins of L transitions, weak in **1**, become dominant (L_1) or quite strong (L_2) in **2**. The intensities of the B bands are similar in the two isomers, the higher maximum value of the absorption coefficient in **1** being compensated for by a greater bandwidth in **2**.

The positions of the L and B transitions and their intensities are presented for selected derivatives of **1**–**5** in Tables 4–6. These values demonstrate that porphyrin

and porphycene represent the extreme cases with regard to the L band intensity. This is further exemplified in Figure 16, where the spectra of four octaethyl derivatives of **1**–**4** are compared. As in the case of the unsubstituted isomers, the largest intensity increase in the Q region is observed for OEPc **15**. The octaethylcorrphycene

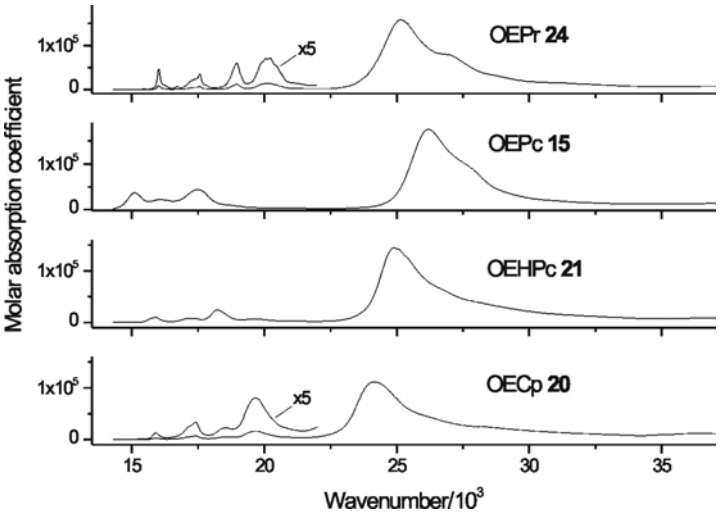

Figure 16. Room temperature absorption spectra for octaethyl derivatives of **1**–**4**, recorded in *n*-hexane solutions.

spectrum resembles that of OEPr **24**, whereas the absorption of OEHPc **21** in the Q region is significantly more intense, but still much less so than in OEPc. This behavior can be readily explained using a perimeter model approach, as presented in Section III.B.

1. *Absorption Spectra of Porphycenes*

The influence of alkyl substitution of porphycene on the electronic absorption spectra is strongly position-dependent, as shown in Figure 17. Very small changes are observed for β-substitution (2,7,12,17). Such an effect could be expected, given that this type of substitution does not lead to considerable geometric alteration. In contrast, adding four alkyl groups in the β' positions (3,6,13,16) induces a significant red shift of both L transitions. The effect is significantly larger for octaethylporphycene **15** than for etioporphycene **14** and 2,7,12,17-tetra-*n*-propyl-3,6,13,16-tetramethylporphycene **32**. This finding suggests that the shift may be related to deviation from planarity, smaller for the two derivatives with methyl substituents. In a series of β'-brominated 2,7,12,17-tetra-*n*-propylporphycenes,[75] planar mono- and dibromoderivatives **16**–**17** reveal small red shifts. In the triply brominated compound **18** both L_1 and L_2 exhibit the same shifts as OEPc **15**, whereas in the tetrabromo derivative **19** the shifts become much larger (see Table 5). The latter is definitely nonplanar, but **18** is not,[75] showing that both nonplanarity and electronic effects may contribute to the shift. This could explain exceptionally large shifts

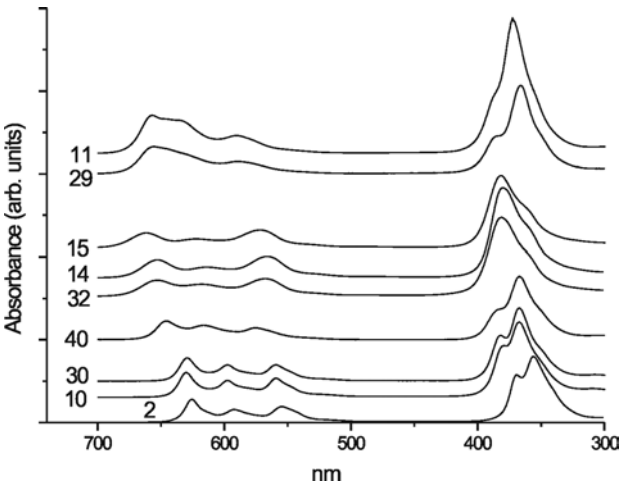

Figure 17. Room temperature absorption spectra in acetonitrile. From bottom to top: porphycene **2**, 2,7,12,17-tetra-*n*-propylporphycene **10**, 2,7,12,17-tetra-*tert*-butylporphycene **30**, 2,7-di-*tert*-butyl-10,19-dimethylporphycene **40**, 2,7,12,17-tetra-*n*-propyl-3,6,13,16-tetramethylporphycene **32**, 2,7,12,17-tetraethyl-3,6,13,16-tetramethylporphycene **14** (etioporphycene), 2,3,6,7,12,13,16,17-octaethylporphycene **15** (OEPc), 9,10,19,20-tetramethylporphycene **29**, 9,10,19,20-tetra-*n*-propylporphycene **11**.

observed for highly nonplanar 2,7,12,17-tetraethyl-3,6,13,16-tetrakis(trifluoromethyl)porphycene **31**.[90] A similar behavior is observed for β'-sulfonated derivatives **33**–**36**.[108] The shifts in the triply sulfonated product **36** are much larger than those observed for singly (**33**) and doubly sulfonated species **34**–**35**. Two sulfonamide derivatives **37**–**38**[109] reveal shifts similar to those of **34** and **35**.

Octaalkyl β,β'-substitution introduces an interesting change in the intensity pattern in the Soret region. As in the parent porphycene and β-substituted derivatives, two features are observed, but with reverse intensities: The lower-energy band, less intense in the parent compound, now becomes dominant.

The red shift of Q bands is also observed for *meso*-substitution (9,10,19,20). In this case, the L_2 transition is stabilized to a larger degree than L_1, which leads to their

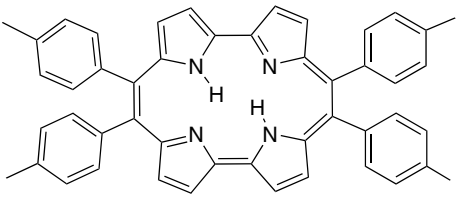
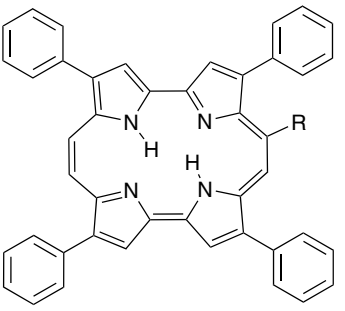
near-degeneracy in 9,10,19,20-tetraalkylporphycenes. The two transitions could be resolved by linear dichroism[110] and MCD[19] measurements. Practically the same spectra are observed for porphycene substituted by four methyl (**29**), ethyl (**39**), and *n*-propyl groups (**11**).[71] In contrast to the behavior of octaalkylporphycenes, the intensity pattern in the Soret region resembles that of parent or β-alkylporphycenes.

An interesting case is provided by unsymmetrically substituted porphycene: 2,7-di-*tert*-butyl-10,19-dimethylporphycene (**40**). For this molecule, the shifts of L_1 and L_2 are similar, and the shape of the spectrum in the low-energy region resembles the parent porphycene much more than those of the *meso*-tetraalkyl-substituted compounds (Figure 17).

The absorption spectra of *meso*-aryl-substituted derivatives resemble those of the alkyl-substituted compounds, as demonstrated by the tetraphenyl (**12**) and tetratolyl (**41**) derivatives.[72] This is in line with similar geometries, in particular practically the



41



R= H **42**; OAc **43**; NO_2 **44**; NH_2 **46**

same inner cavity dimensions. On the other hand, substitution by phenyl at the β positions leads to significant changes in the absorption. 2,7,12,17-Tetraphenylporphycene (TPPo, **42**)[111] shows significant red shifts of both L_1 and L_2 with respect to the parent porphycene (26 and 29 nm, corresponding to 699 and 855 cm^{-1}, respectively). Substitution of **42** by an acetoxy or nitro group in position 9, leading to **43**–**44**,[112] does not alter the spectrum significantly. Similar behavior was observed for 2,7,12,17-tetra-*n*-propylporphycene and its 9-acetoxy derivative **45**.[23] On the other hand, huge shifts of both Q bands are observed for 9-amino-2,7,12,17-tetraphenylporphycene **46**.[112]

Another way to induce strong shifts of both low-energy transitions is the replacement of β' CH groups by nitrogen atoms, leading to imidacene **47**.[113] Further red shifts are observed when this is combined with aryl substitutions in the β positions, as observed for derivatives **48**[114] and **49**.[115] Interestingly, for the last two cases the red shift is accompanied by a significant decrease in the intensity of both transitions. An even larger decrease in intensity is observed for the Soret bands, so that the absorption spectra of **48** look rather atypical, displaying similar intensities in the Q and Soret regions.[114]

In a review of photophysical properties of porphycenes,[68] Braslavsky and coworkers have reported transition energies for the lowest excited singlet state along with the values of the corresponding absorption coefficients for 38 derivatives (**10**, **45**, **50**–**85**). Some of these compounds (**60**, **78**–**79**, **81**, **85**) and three others (**86**–**88**) have been studied earlier by Richert and coworkers as photodynamic antitumor agents.[16] These datasets and the values presented in Tables 4–6 demonstrate remarkable

stability of the intensity of the S_0–S_1 transition and its high oscillator strength compared with porphyrin and other constitutional isomers. The reason for the insensitivity to the type and position of substituents is the "negative-hard" character of the porphycene chromophore, described in Section III.B. On the other hand, the S_0–S_1

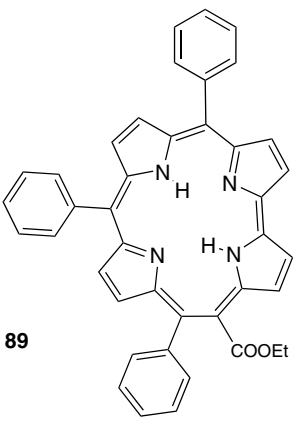
transition energy may be tuned over a large range. These properties make porphycenes very attractive for applications, particularly in photodynamic therapy.

2. *Absorption Spectra of Hemiporphycene, Corrphycene, and Isoporphycene Derivatives*

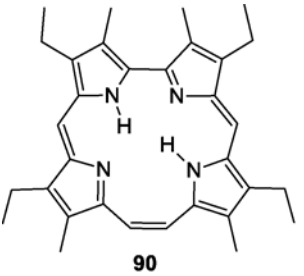
Absorption spectra of free-base hemiporphycene derivatives have been reported in only a few papers.[6,7,116,117] The data available for OEHPc **21**, 5-iodo-6,11,16-triphenylhemiporphycene **22**[80] and 9-carbethoxy-10,15,20-triphenylhemiporphycene **89**[6] (Figure 16 and Table 6) reveal similar spectral patterns for the three compounds. The Q bands are red-shifted with respect to those of octaethylporphyrin, the shift of Q_2 being larger than that of Q_1. Both shifts are significantly smaller than in octaethylporphycene. The spectra in the Soret region are similar to those of octaethylporphyrin. The values of absorption coefficients are similar for OEPr and OEHPc in the Soret region. In the Q region, hemiporphycenes definitely absorb more strongly. Interestingly, the absorption of **89** is about twice as weak as that of **21** for both the Q and Soret band regions.

Temperature dependence studies have shown that the absorption of **21** in 3-methylpentane is due to both possible *trans* tautomers, analogs of **3** and **3a** in Figure 13.[116] The enthalpy of tautomerization was determined to be 0.65 kcal/mol, in agreement with computational predictions (see Table 3).

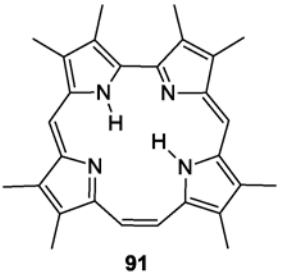
The absorption spectra of octaethylhemicorrphycene **20**,[9,118] etiocorrphycene **90**,[9] 2,3,6,7,11,12,17,18-octamethylcorrphycene **91**,[119] 2,3,6,7,11,18-hexamethyl-12,17-bis-(2-methoxycarbonylethyl)corrphycene **92**,[119] and 2,3,6,7,11,18-hexamethyl-12,17-bis-(2-ethoxycarbonyl)corrphycene **93**[120] are all similar and, of all isomers, the closest to the spectra of porphyrins (Figure 16, Table 6), with regard to both



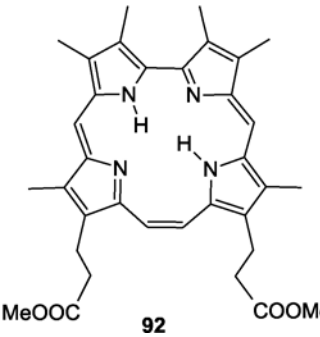
89



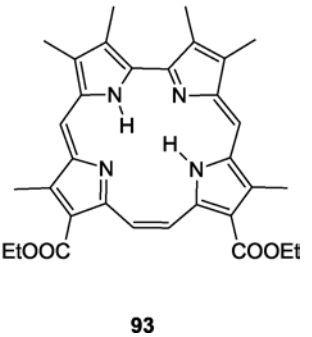
90



91



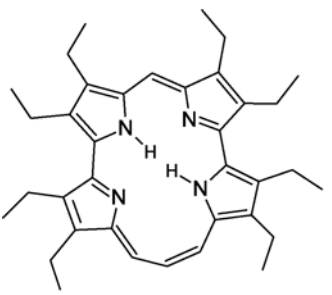
92



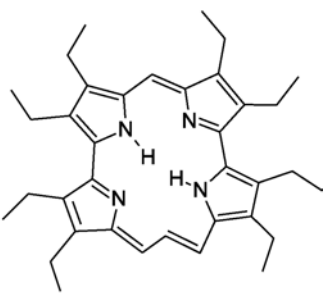
93

spectral positions and intensities. Corrphycene derivatives reveal small and similar red shifts of Q_1, Q_2 and Soret bands with respect to OEPr. The intensities in the Soret region are similar or slightly smaller than in OEPr, whereas those of Q bands are definitely lower. In **90**, the 0–0 transition is very weak, and similar in intensity to that in parent porphyrin. Another similarity is the domination of vibronic peaks over purely electronic 0–0 transition, for both Q_1 and Q_2.

Derivatives of isoporphycene are the least investigated of all the isomers. The data for octaethylisoporphycene (OEIPc, **94**)[10] reveal a spectrum which is strongly red-shifted with respect to that of OEPr. The shifts of both Q bands are similar to those observed for OEPc, but the intensities are definitely smaller, resembling



94a



94b

those in hemiporphycene derivatives. The wavelength maximum of the Soret band exhibits the largest shift among all isomers.

It was demonstrated that the *E* (**94b**) and *Z* (**94a**) forms of OEIPc are both present in 3-methylpentane solutions, the *E* isomers being dominant.[116] Using low-temperature fluorescence spectroscopy, it was possible to obtain excitation spectra of both forms; somewhat surprisingly, they turned out to be very similar.

B. Perimeter Model Applied for the Elucidation of Absorption and Magnetic Circular Dichroism Spectra

The electronic absorption spectra of porphyrins exhibit a great sensitivity to structural perturbations, such as substitution, metal complexation, reduction in one or more rings, or fusion of aromatic rings onto the basic skeleton. Still, it is possible to interpret the spectra of diverse porphyrins on the basis of a simple model, developed by Gouterman and coworkers.[99,121,122] In this approach the Q (L) and Soret (B) transitions are described by taking into account the interactions between the four singly excited electron configurations, obtained by promoting an electron from one of the two highest occupied π molecular orbitals (HOMOs) into one of the lowest unoccupied orbitals (LUMOs).

A closely related methodology, based on a perimeter model, was proposed by Michl[104–107] in order to understand absorption and, in particular, magnetic circular dichroism (MCD) spectra of $4N + 2$ π electron aromatic compounds. The perimeter model has been now successfully applied to several hundred compounds, including many porphyrin derivatives.[107,123–144]

Figure 18 presents the absorption and MCD spectra of the octaethyl derivatives of three porphyrin isomers: OEPc **15**, OEHPc **21**, and OECp **20**. The differences in the MCD pattern are dramatic. For OEPc, the MCD intensity for the Q transitions is higher than in the Soret range. In the hemiporphycene derivative, the intensities are almost equal in the two regions. For OECp, larger intensity is observed for the Soret (B) bands; thus, only in this case does the MCD spectrum follow the pattern of the absorption intensity. The MCD signals of both L bands of OECp are extremely weak for the 0–0 transitions. Finally, their signs are opposite to those observed for porphycene and hemiporphycene derivatives. It should be recalled that the sign of the Faraday *B* term is negative for a positive MCD signal, and positive for a negative MCD signal.

These huge differences can readily be explained by simple considerations based on a perimeter model. Using this approach, the compounds are formally derived from an ideal $C_{20}H_{20}^{++}$ perimeter, by distorting its shape and bridging with two NH and two N^- units (Figure 19). This perturbation shifts the orbital energies of the ideal perimeter by an amount which is dictated by the position of the

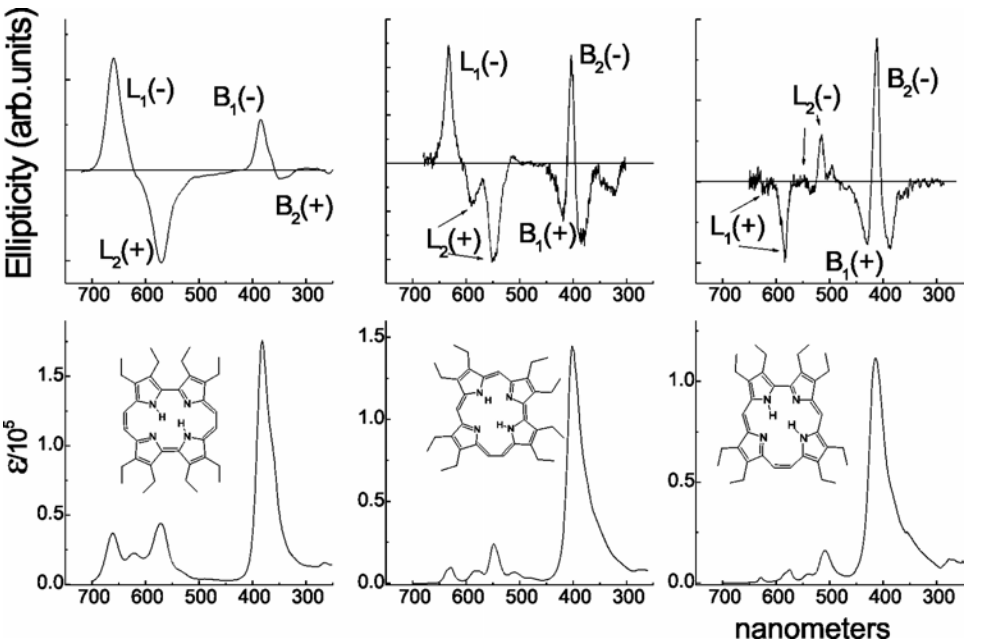


Figure 18. Absorption (bottom) and MCD (top) spectra of OEPc **15** (left), OEHPc **21** (middle), and OECp **20** (right), recorded in aconitrile at 293 K. The location of L and B transitions is indicated, with the sign of a corresponding *B* term.

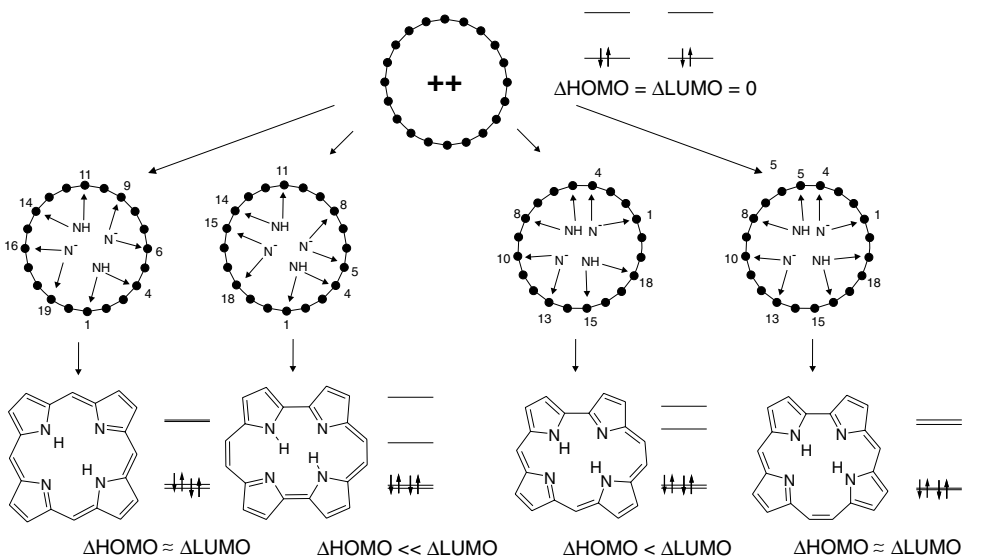

Figure 19. Derivation of porphyrin, porphycene, hemiporphycene, and corrphycene from the $C_{20}H_{20}^{++}$ perimeter, with the resulting HOMO and LUMO splittings.

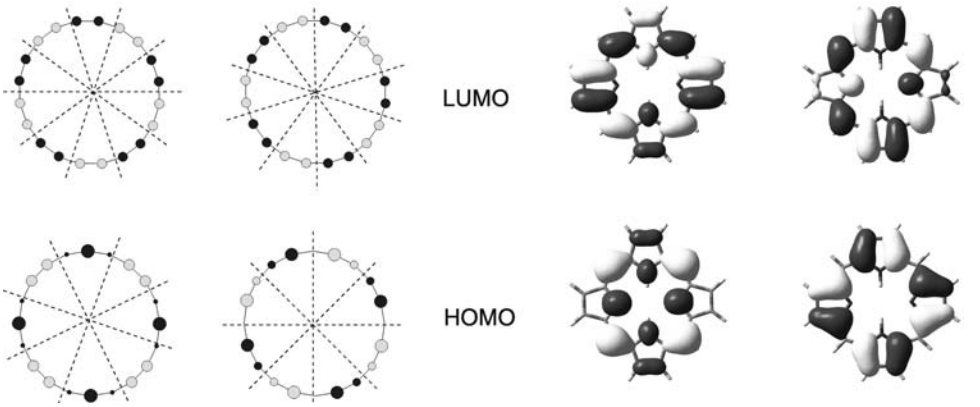

Figure 20. Two highest occupied and two lowest unoccupied orbitals of the unperturbed $C_{20}H_{20}^{++}$ perimeter. Right: The HOMO and LUMO pair calculated for porphyrin.

substituent and the orbital shape. No change in energy is expected if a bridging atom lies in the orbital nodal plane, or if the attachment points lie on nodes. Otherwise, the orbital energy shift should be proportional to the algebraic sum of LCAO coefficients in the bridging positions. It is therefore easy to predict relative orbital energy changes just on the basis of nodal properties. Figure 20 shows the HOMOs and LUMOs of an ideal perimeter compared with the orbitals calculated for porphyrin. The same pattern of nodal planes is evident. The HOMO and LUMO pairs are degenerate in the parent perimeter, but they need not be degenerate after the perimeter has experienced a perturbation leading to a particular molecule. The analysis of the shape of ideal perimeter orbitals, given by symmetry, permits predicting the orbital splittings in porphyrin isomers. In general, HOMOs are less affected than the LUMO pair and no large splitting in the occupied pair is expected (ΔHOMO $\approx$ 0). With regard to LUMOs, they are shifted differently in different isomers. In porphyrin and corrphycene, two bridges raise the energy of one LUMO; the other two bridges, the energy of the other LUMO. Thus no splitting is expected (ΔLUMO $\approx$ 0). On the contrary, in porphycene all four bridges destabilize the energy of one LUMO component, not affecting the other. Hence, a large LUMO splitting is predicted. Hemiporphycene represents an intermediate case, with three bridges interacting with one LUMO component, and only one with the other LUMO. As a result, a moderate LUMO splitting is expected, definitely smaller than for porphycene. The orbital splittings expected for the four isomers are presented in Figure 19.

The values of ΔHOMO and ΔLUMO are the crucial parameters in the perimeter model, since they are contained in the formulas for transition dipole strengths of all four states resulting from the interaction between singly excited

HOMO–LUMO configurations. ΔHOMO and ΔLUMO also enter into the equations for the Faraday terms *A*, *B*, and *C*, which determine the MCD intensity. For free-base porphyrin and isomers, only *B* terms are nonzero. They are expressed by formulas containing two contributions, μ^- and μ^+. The former are practically structure-independent and smaller than the latter, which are very sensitive to molecular structure. Various MCD sign patterns are expected, depending on the value of ΔHOMO and ΔLUMO: a +,–,+,– sequence of *B* term signs of L_1, L_2, B_1, and B_2 transitions is predicted for ΔHOMO > ΔLUMO, whereas the opposite sequence, –,+,–,+, should hold when ΔHOMO < ΔLUMO. Finally, when ΔHOMO = ΔLUMO, a +,+,+,– sequence is expected. However, the equality of ΔHOMO and ΔLUMO may easily be destroyed, even by a weak perturbation. Therefore, the molecules for which ΔHOMO ≈ ΔLUMO have been called "soft" chromophores, indicating that their MCD behavior can be easily changed. In contrast, in molecules for which ΔHOMO > ΔLUMO or ΔHOMO < ΔLUMO the MCD pattern is not easily influenced by perturbation. They have therefore been called "positive-hard" or "negative-hard" chromophores, depending on the sign of ΔHOMO–ΔLUMO.

According to the simple orbital analysis, porphycene, with ΔHOMO << ΔLUMO, should be a strongly negative-hard chromophore, with the negative/positive *B* term MCD pattern for L_1/L_2, not expected to change in different derivatives. Indeed, such a pattern has been observed for all porphycene derivatives studied so far (see Figure 18 as an example), as well as for doubly protonated and doubly deprotonated **2**.[19] The same pattern is expected and observed (Figure 18) for hemiporphycene and its derivatives. On the other hand, corrphycene, similarly to porphyrin, is predicted to be a soft chromophore (ΔHOMO ≈ ΔLUMO). For such a molecule, the MCD signal in the L_1/L_2 region can be extremely weak and dominated by effects not taken into account in the perimeter model, e.g. vibronic interaction. This indeed seems to be the case for OECp. On the other hand, the model predicts strong MCD intensity in the region of B transition, dominated by μ^- terms, with the +,– *B* term sequence for B_1, B_2, exactly as observed (Figure 18). The perimeter model also explains why the MCD intensity falls so drastically in the Soret region upon passing from corrphycene to hemiporphycene and porphycene. The reason is the interplay of μ^- and μ^+ contributions, which are of the opposite signs; the contribution of μ^+ increases with |ΔHOMO–ΔLUMO|, and thus from hemiporphycene to porphycene.

The perimeter model also allows understanding changes in the absorption intensity of the L with respect to the B transitions. The ratio of dipole strengths, D(L)/D(B), should grow, approximately, as $\Delta LUMO^2 - \Delta HOMO^2$. This relation immediately explains the increasing absorption intensity of the Q region in the order porphyrin ≈ corrphycene < hemiporphycene < porphycene. Similar behavior

has been observed for neutral, diprotonated, and doubly deprotonated forms of OEHPc: the prediction, based on theoretical arguments, that D(L)/D(B) should increase in the order dication, neutral molecule, dianion has been confirmed by experiment.[117]

The perimeter model has worked perfectly for hundreds of molecules, including numerous porphyrins. In fact, the predictions regarding the absorption and MCD patterns for all porphyrin isomers were made at the time when only porphycene was available.[5] The MCD experiments for corrphycene[118] and hemiporphycene[117] derivatives, which confirmed the theoretical predictions, were performed a decade later. Table 7 presents a comparison of predictions based on a perimeter model with the results of (i) simple PPP calculations performed in 1990 and (ii) more advanced calculations carried out for the purpose of this work. It is obvious that all the earlier predictions remain valid. The novel calculations improve somewhat the numerical agreement with perimeter model predictions, in particular when reproducing more accurately the soft character of the porphyrin chromophore. The theoretical predictions await experimental verification for four isomers, of which only one (isoporphycene) is available at present.

MCD is a very useful spectroscopic tool for detecting spectral transitions which overlap in the absorption. From the point of view of other applications, such as studies of tautomeric equilibria, solvent effects, etc., the interesting chromophores are those of a soft character, since they are able to respond strongly even to weak perturbations. Of the existing isomers, corrphycene and isoporphycene are obvious choices for such studies. The three isomers which remain to be synthesized should be strongly (**6**, **8**) or moderately (**7**) negative-hard chromophores. They

[a]Ref. 5. [b]In eV.

should thus exhibit strong absorption in the Q region. In the case of **6** and **8**, similarity to porphycene is expected, whereas the spectral properties of isomer **7** should rather resemble those of hemiporphycene.

The validity of the four orbital and perimeter models has been confirmed for other members of the porphyrinoid family: smaragdyrin isomers,[145] tetraphenylsapphyrins,[146] and doubly protonated cyclohexa-, cyclohepta-, and cyclooctapyrroles.[147] It is reassuring that the predictions based on a simple model are confirmed by high-level *ab initio* computational studies. Nakatsuji and coworkers studied the excited state of porphycene, corrphycene, and porphycene using the symmetry-adapted cluster-configuration interaction method (SAC-CI),[148] concluding that "the differences in the Q-band absorptions among the isomers were clearly explained by the four-orbital model." A rare example of a molecule which requires treatment beyond the four-orbital model is rosarin, a nonaromatic hexapyrrolic expanded porphyrin. For a proper description of its molecular structure, six orbitals have to be taken into account: three occupied and three unoccupied.[149]

The perimeter model has been successfully extended to 4N electron[150–154] (and 4N ± 1 electron)[155] systems, opening up new possibilities for understanding spectral characteristics of large and diverse groups of compounds on the basis of a conceptually unifying treatment.

C. Low-Temperature Spectroscopy of Porphycene

In addition to measurements in solutions and glasses, porphycene and some of its derivatives have been investigated in the regime of molecular isolation, in supersonic jets,[22,28,30] nanohelium droplets,[40] or rare gas and nitrogen cryogenic matrices.[23,42,156–160] The jet and droplet studies are discussed in detail in Section V, since they greatly contribute to the understanding of mechanisms of intramolecular double hydrogen tunneling. The matrix isolation experiments allowed information to be obtained on molecular vibrations in the ground and lowest excited electronic states. Malsch and Hohlneicher compared IR, Raman, UV, and site-selective fluorescence and fluorescence excitation spectra recorded for the parent porphycene.[42] They observed that the rule of mutual exclusion was obeyed in the IR and Raman spectra. This suggests that the spectra are due to the *trans* tautomeric forms, because the *cis* tautomers do not have the inversion center. However, in the opinion of the authors this result does not provide a decisive proof, because the spectra calculated for the *cis* form reproduce the experiment equally well, indicating that the geometry and electronic structure of porphycene are not sensitive to tautomerization. Another surprising result was the absence of the NH stretching vibration in the IR spectrum, even though the calculations predicted that the corresponding band should be the most intense of all.

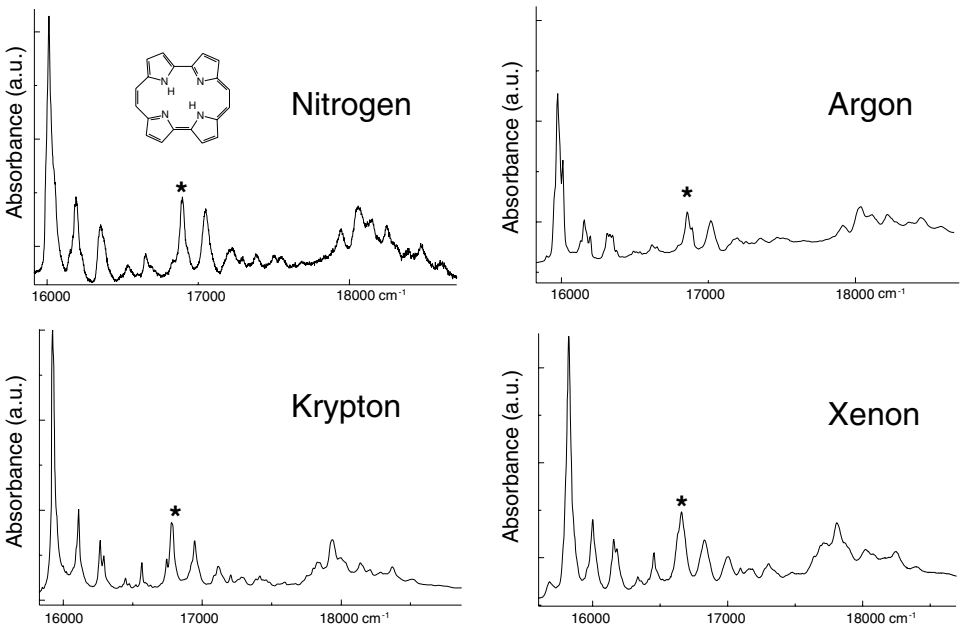

Figure 21. Absorption spectra of porphycene in different matrices at 15 K. The asterisks indicate the origin of the S_1–S_2 transition. (Modified with permission from Ref. 156.)

Comparison of shifts of vibronic bands in different rare gas and nitrogen matrices allowed determination of the electronic origins of the S_0–S_2 transition, normally mixed with the S_0–S_1 vibronic components.[156] The spectra of **2** in four different cryogenic matrices are shown in Figure 21. Comparison with the matrix spectra of parent porphyrin[95] reveals several important differences in the absorption patterns of the two isomers, which could not be so clearly observed in solution: (i) the origins of L_1 and L_2 are much closer to each other in **2** than in **1**; (ii) in contrast to the situation in **1**, where the L_2 transition is much stronger than L_1, the two transitions in **2** are of comparable intensity; actually the transition to the lowest excited singlet state seems to be slightly stronger; (iii) the 0–0 transitions are dominant for both L_1 and L_2 in porphycene, whereas for **1** they are weaker than the vibronic components.

These studies were followed by a series of papers which used molecular dynamics simulation of matrix deposition to analyze the site structure observed in the electronic and IR spectra of porphyrin, porphycene, and tetra-*tert*-butylporphycene embedded in argon and xenon matrices.[161–164] The structure of the main trapping sites has been identified. Interestingly, porphycene occupies the same main site in argon and xenon, whereas for porphyrin the situation is different: the same main site as for porphycene dominates for xenon matrices (Figure 22), but

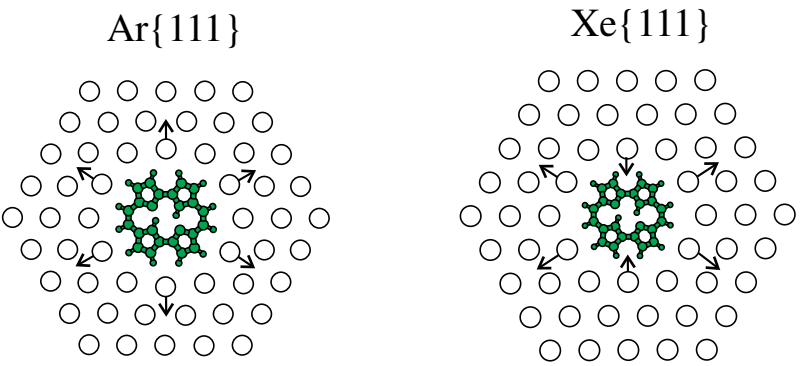

Figure 22. The structure of the main trapping site of porphycene in argon (left) and xenon (right) matrices. (Modified with permission from Ref. 161.)

in argon porphyrin occupies several different substitutional sites. These studies demonstrated that a seemingly minor structural difference in two similar molecules can lead to drastic changes in the absorption pattern of chromophores embedded in cryogenic matrices.

Another conspicuous difference between the electronic spectra of **1** and **2** was the doublet splitting of lines observed for the S_0–S_1 transition in the former, and the absence of splitting in the latter. This was explained by differences in the absolute directions of the transition moments of the two *trans* tautomeric forms with respect to the sides of the hexagonal cavity embedding the molecule. Due to the symmetries of the cavity and the chromophores, for porphycene the interaction of each of the two transition moments with the rare gas atoms forming the cavity should be approximately the same, but this is not the case for porphyrin (Figure 23).

IV. Photophysics

The values of basic photophysical parameters for the parent porphyrin and some derivatives are presented in Table 8. In planar free-base porphyrins the main channel of the S_1 decay is the intersystem crossing to the triplet manifold. Room temperature fluorescence quantum yields are usually of the order of 10% and the fluorescence decays in about 10 ns. The photophysical characteristics drastically change when the macrocycle skeleton becomes nonplanar. This leads to a large decrease in the fluorescence yield and lifetime, as shown in Table 8 by the examples of 5,10,15,20-tetraphenyl-2,3,7,8,12,13,17,18-octamethylporphyrin **95**, 5,10,15,20-tetraphenyl-2,3,7,8,12,13,17,18-octaethylporphyrin **96**, and 2,3,5,7,8,10,12,13,15,-17,18,20-dodecaphenylporphyrin **97**. Interestingly, for these derivatives both internal conversion and intersystem crossing become

faster in the distorted macrocycle.[165] On the contrary, the excited state deactivation is dominated by S_1–S_0 internal conversion in ruffled, nonplanar 5,10,15,20-tetra-*tert*-butylporphyrin **98**.[166]

The values of fluorescence quantum yields and lifetimes, as well as those of triplet yields and the efficiencies of singlet oxygen generation, reported for various porphycenes are presented in Table 9. Based on these values are the radiative and radiationless S_1 depopulation rates, shown in Table 10. Additional extensive data containing the values of quantum yields of fluorescence, triplet formation, and singlet oxygen generation for 38 porphycene derivatives are available in the review by Braslavsky and coworkers.[68] In general, fluorescence quantum yields of free-base porphycenes are higher than in porphyrins. This could be expected on the basis of larger absorption coefficients. The radiative constants determined for different porphycenes from the values of fluorescence quantum yields and decay times are very similar for various derivatives, in analogy with the observation of similar absorption coefficients. This comparison suggests that the geometry of most porphycenes is not significantly changed upon excitation.

As long as the porphycene chromophore remains planar (and for nonaryl substituents), both fluorescence and intersystem crossing contribute to the excited state decay with comparable efficiencies, the yield of triplet formation usually being somewhat higher. One should note that internal conversion to the ground state cannot be neglected either. For instance, in the parent porphycene, the yields of fluorescence, intersystem crossing, and internal conversion are 0.36, 0.42, and 0.22, respectively. Very similar values are obtained for 2,7,12,17-tetrapropyl-derivative **10**. When phenyl groups are substituted at the same position, the respective yields become 0.15, 0.33, and 0.52, demonstrating that now the internal conversion becomes the main decay channel. This process definitely takes over when the chromophore becomes nonplanar, as demonstrated for two dibenzoporphycenes: 2,7,12,17-tetra-*t*-butyl-3,6,13,16-dibenzo[*cde*, *mno*]porphycene **84** and its tetramethyl analog **99**,[157,159] as well as by the huge increase in k_{IC} observed upon passing from mono- and dibrominated porphycenes **16–17** to tri- and tetrabrominated derivatives **18** and **19**.[75] However, the increase in k_{IC} is also observed for tetraazaporphycenes which are probably planar, such as **48** and **49a**. This has been interpreted in terms of the energy gap law, since the S_0–S_1 transition in azaporphycenes is strongly shifted to the red with respect to that of the parent compound **2** (see Table 5).[115]

As expected, substitution by heavy atoms leads to an increase in the triplet formation yields. This is clearly observed for brominated porphycenes **16–19**.[75] A finding which awaits explanation is the large decrease in the radiative rates of the nitro (**44)** and amino (**46)** derivatives of TPPo **42**.[112]
